3,7,11,15-Tetramethylhexadecanoic acid (phytanic acid) pyrrolidide. MS *m/z* (rel. intensity): 365 (M^+, 0.7), no peak at *m/z* 366, 350 (1.6), 322 (0.5), 308 (0.3), 294 (0.5), 280 (0.4), 266 (0.1), 252 (0.7), 238 (0.2), 224 (0.9), 210 (1.0), 196 (0.4), 194 (0.3), 182 (2.5), 180 (20.), 168 (0.9), 166 (0.6), 154 (2.3), 140 (12.3), 126 (4.1), 113 (100), 98 (13.8), 85 (5.4), 72 (12.1), 71 (12.5), 70 (12.3), 57 (10.7), 55 (26.2), 43 (26.2), 41 (12.2), 29 (4.6).

Saturated fatty acids. Two common isoprenoid fatty acids were detected in the total lipids as minor components, namely 4,8,12-trimethyltridecanoic and 3,7,11,15-tetramethylhexadecanoic acid (phytanic acid). They were readily identified from GC and coupled GC/MS data concerning their methyl esters (Table 2). GC/MS data of pyrrolidide derivatives con-

TABLE 2
Equivalent Chain Length (ECL) Values of Selected Branched-Chain Fatty Acids of the Gorgonian *Leptogorgia piccola* (yellow morph)

Fatty acids	ECL (DB-1)	
	Methyl esters	Pyrrolidides[a]
4,8,12-Trimethyl-13:0	14.53	14.32
11-Methyl-14:0	14.63	14.62

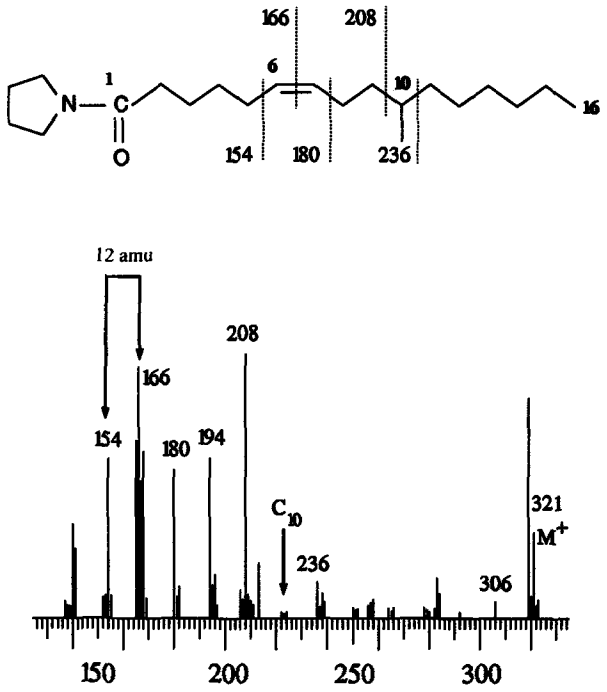

FIG. 2. Partial mass spectrum of 10-methyl-6-hexadecenoic acid pyrrolidide **4** (×7 expanded).

firmed the structures. The mass spectrum of the pyrrolidide of phytanic acid is described in the Results section, which to our knowledge has not been previously reported. Furthermore, the GC behavior of these isoprenoid acid pyrrolidides appeared noteworthy. As shown in Table 2, the phytanic acid pyrrolidide (**13** in Fig. 1) eluted faster than the corresponding methyl ester (ECL of 17.23 and 17.72, respectively), all things being equal.

This effect seems convenient for GC analyses as the phytanic acid methyl ester usually falls in a rather crowded area just before stearic acid methyl ester. 4,8,12-Trimethyltridecanoic acid pyrrolidide presented similar behavior, but to a lesser extent (ECL of 14.32 instead of 14.53 for the methyl ester; Table 2). Another interesting result was the occurrence in only one gorgonian sample (yellow morph harvested in June) of 11-methyltetradecanoic and 13-methylhexadecanoic **7** acids (Table 1), which were readily identified by GC/MS of their pyrrolidides. These unusual fatty acids previously have not been described in gorgonian lipids.

Monoenoic fatty acids. Four interesting unsaturated fatty acids, the first three being monounsaturated, were detected as methyl esters and characterized as pyrrolidide derivatives (**4,5,9,11**). The first acid in question (the methyl ester) showed a molecular ion peak at *m/z* 282, corresponding to a 17:1 acid structure, and an ECL value of 16.35, implying methyl branching. Upon catalytic hydrogenation, the compound was converted into the methyl ester of 10-methylhexadecanoic acid (ECL 16.42) occurring in marine sponges as a natural product, probably of bacterial origin (17,18). The position of the double bonds and the branching were determined from GC/MS data for pyrrolidide derivative **4** (Fig. 2).

The molecular ion peak was present at *m/z* 321, confirming a 17:1 structure. The difference of 12 amu betweeh homologous fragmentation ions at *m/z* 154 (C_5) and *m/z* 166 (C_6) indicated Δ6 unsaturation. A very diminished peak at *m/z* 222 (C_{10}), flanked by an elevated peak at *m/z* 208 (C_9), and an appreciable peak at *m/z* 236 indicated a methyl branch at C-10. Thus, we identified the new 10-methyl-6-hexadecenoic acid, which to our knowledge, has not been reported in any natural source.

The second interesting short-chain fatty acid (the methyl ester) showed a molecular ion peak at *m/z* 282 corresponding to a 17:1 acid structure and an ECL value of 16.46, also implying methyl branching. The GC peak disappeared upon catalytic hydrogenation. This fatty acid was readily identified as the already known, but unusual, 7-methyl-6-hexadecenoic acid (19,20) as its pyrrolidide **5** (molecular ion peak at *m/z* 321) showed a difference of 12 amu between fragmentation ions *m/z* 154 (C_5) and 166 (C_6) (Δ6 unsaturation), and a very low peak at *m/z* 180 (C_7) flanked by two elevated peaks at *m/z* 166 and 194 (C_8) (7-methyl branch).

The third fatty acid (the methyl ester) showed a very low ECL value of 16.82 for a molecular ion peak at *m/z* 296, indicating a 18:1 acid structure. These data clearly suggested methyl branching. The peak corresponding to this methyl ester disappeared upon catalytic hydrogenation. The corresponding pyrrolidide derivative **9** showed a molecular ion peak at *m/z* 335, confirming the 18:1 acid structure (Fig. 3). Δ6 Unsaturation was proved by a difference of 12 amu between homologous fragmentation ions at *m/z* 154 and 166. A diminished peak at *m/z* 180 (C_7), flanked by an intense peak at *m/z* 166 (C_6), and an appreciable peak at *m/z* 194 (C_8), indicated a methyl branch at C-7. A second methyl branch occurred at C-9 position as the expected peak at *m/z* 222 (C_{10} fragment but C-9 position) appeared with a very low relative intensity between two elevated peaks at *m/z* 208 (C_9 fragment but C-8 position) and *m/z* 236 (C_{11} fragment but C-10 position). Thus, we identified the 7,9-dimethyl-6-hexadecenoic acid, not yet reported in nature.

Dienoic fatty acids. The fourth short-chain fatty acid in question showed an ECL value of 17.06 (methyl ester) with a

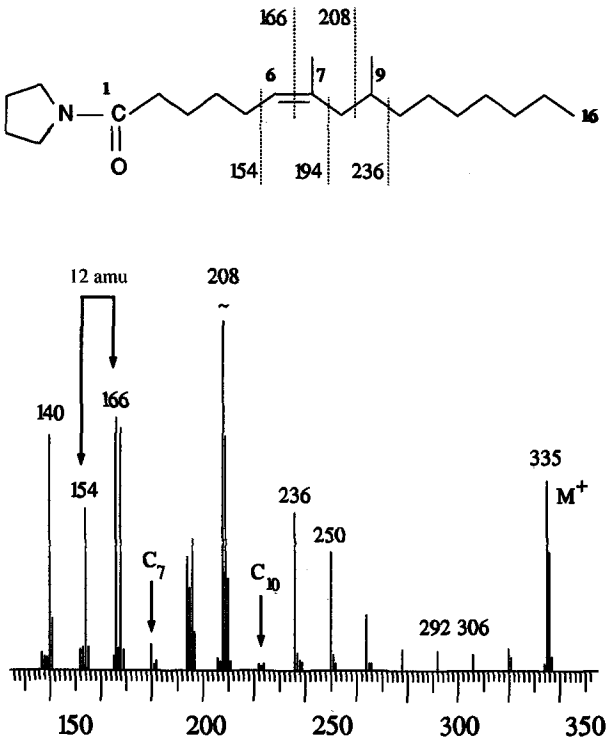

FIG. 3. Partial mass spectrum of 7,9-dimethyl-6-hexadecenoic acid pyrrolidide **9** (×6 expanded).

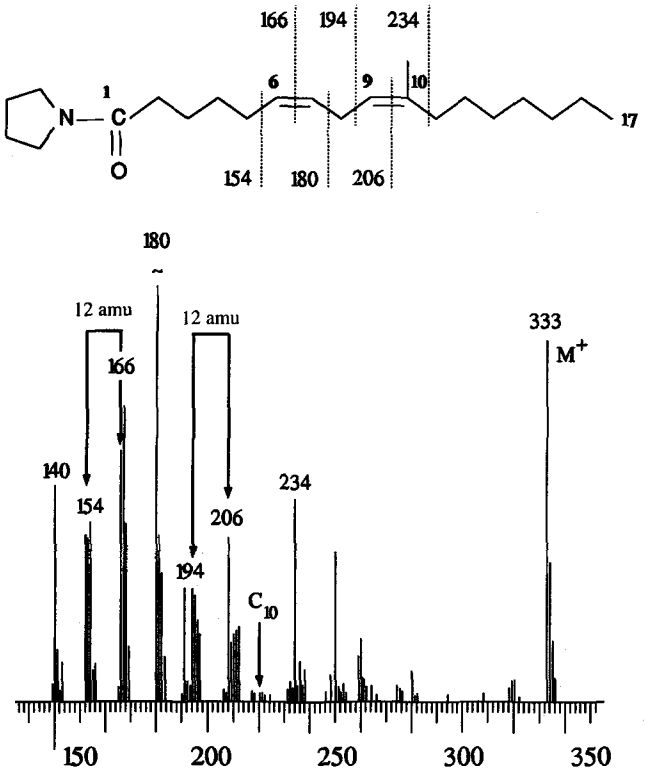

FIG. 4. Partial mass spectrum of 10-methyl-6,9-heptadecadienoic acid pyrrolidide **11** (×20 expanded).

molecular ion peak at *m/z* 294 compatible with a methyl branched 18:2 acid structure. Upon catalytic hydrogenation, it was converted into a branched saturated methyl ester (M^+ 298). The mass spectrum of pyrrolidide **11** (Fig. 4) showed a molecular ion peak at *m/z* 333, confirming the 18:2 acid structure.

Differences of 12 amu between fragmentation ions at *m/z* 154 and 166 and *m/z* 194 and 206 indicated Δ6 and Δ9 unsaturations, respectively, and the presence of a methyl branch at C-10 was indicated by a low peak at *m/z* 220 (C_{10}), flanked by two elevated peaks at *m/z* 206 (C_9) and 234 (C_{11}). Thus, another new fatty acid, namely 10-methyl-6,9-17:2, was identified. Furthermore, we readily identified the straight-chain 6,9-heptadecadienoic acid because its pyrrolidide displayed a molecular ion peak at *m/z* 319 and key fragmentation ions at *m/z* 154 and 166 and *m/z* 194 and 206.

PUFAs. Gas chromatograms of FAME showed several unusual peaks, especially in lipids from colder water specimens, showing relatively high molecular ions. For example, a major component had an ECL value of 25.40 on Carbowax-20M and 22.90 on OV-1 (22.95 on DB-1). Upon catalytic hydrogenation, it was converted to the lignoceric acid methyl ester (24:0), which indicated that there was no branching. The MS of the methyl ester showed a molecular ion peak at *m/z* 372, suggesting a 24:5 fatty acid structure. This 24:5 structure was confirmed by MS of the pyrrolidide derivative as previously described (7). Its MS showed a molecular ion peak at *m/z* 411 (24:5) and differences of 12 amu between the following homologous fragments: *m/z* 154 and 166 (Δ6), *m/z* 194 and 206 (Δ9), *m/z* 234 and 246 (Δ12), *m/z* 274 and 286 (Δ15), *m/z* 314 and 326 (Δ18). These key fragments indicated a methylene-interrupted polyenoic fatty acid, namely 6,9,12,15,18-24:5. Similarly, 9,12,15,18,21-24:5 and 6,9,12,15,18,21-24:6 were detected in all samples.

In FTIR spectra, all unsaturated FAMEs exhibited absorptions near 3010 cm^{-1} and 700 cm^{-1}, but no absorption near 960 cm^{-1}, that characterized only a (*Z*)-configuration (21).

Fatty aldehydes, long-chain dimethyl acetals. During GC analyses of the crude FAME mixtures, we observed several unexpected peaks in all samples, in ratios up to 10% depending on the samples studied, relative to the crude total mixture arising from the transmethylation reaction of the total lipids. GC/MS studies showed that these peaks corresponded to fatty aldehydes and dimethyl acetals with even and odd carbon numbers ranging from 14 to 20. The major components were thus octadecanal and its dimethyl acetal. As examples, all the MS of dimethyl acetals displayed the fragmentation ion at *m/z* 75 as the base peak. Other significant ions corresponded to the $(M - 31)^+$ ions, i.e., *m/z* 283 for octadecanal dimethyl acetal. Such fatty aldehydes indicated the presence of plasmalogens (1-*O*-alkyl-1-enyl-2-acyl lipids).

DISCUSSION

The fatty acid composition of the gorgonian specimens collected during the same period was generally quite similar

(Table 1). The saturated fatty acid content of warmer water specimens was about twice that of colder water specimens. Fatty acids that are usually bacterially derived, such as *iso* and *anteiso* branched acids, were only present at low percentages, despite the fact that gorgonians are filter-feeding organisms.

An interesting result of our study was the identification of four closely related branched, unsaturated fatty acids, three of which proved to be new compounds. All of these acids contained Δ6 unsaturations, also encountered in some straight-chain monoenoic acids (Table 1), mainly 6-hexadecenoic acid. The rare 7-methyl-6-hexadecenoic acid occurring in easily-measured proportions of the total fatty acid mixtures was previously found in sponges (19,20) and in whales (22). Furthermore, an isomer of this compound was the newly described 10-methyl-6-hexadecenoic acid that eluted just prior to 7-methyl-6-hexadecenoic acid on GC. Two theories have been proposed regarding the biosynthetic origin of such branched, unsaturated fatty acids. First, it was proposed that the introduction of the double bond in 7-methyl-8-hexadecenoic acid could occur after chain-elongation and introduction of the methyl branch (23). Another theory implies that the insertion of a methylene group across a preexisting ethylenic bond and a subsequent rearrangement probably involved bacterial systems (16). This second theory is supported by the fact that 7-methyl-7-hexadecenoic and 7,8-dimethyl-7-hexadecenoic acids are found together at high levels in certain fish oils (16). In this respect, the 7-methyl-7-hexadecenoic acid occurring in the jellyfish *Physalia physalis* is thought to originate from 7-hexadecenoic acid (24), which is also present in this organism. Such branched, monoenoic fatty acids may be biosynthetic intermediates to cyclopropane fatty acids from the corresponding monoenoic acid, with *S*-adenosylmethionine donating the methyl branch (24). In our gorgonians, the co-occurrence of the isomeric 7-methyl-6-hexadecenoic and 10-methyl-6-hexadecenoic acids, together with the straight-chain 6-hexadecenoic acid, also seems to corroborate the second theory as the latter acid is a precursor. If so, 10-methyl-6-hexadecenoic acid should arise from a dienoic fatty acid such as 6,9-hexadecadienoic acid, even though this acid, was not detected in the fatty acid mixtures. This possibility would involve a subsequent reduction step. Nevertheless, it cannot be excluded that 10-methyl-6-hexadecenoic acid could arise from 10-methyl-hexadecanoic acid, a relatively usual fatty acid of bacterial origin (17,25), because gorgonians possess ample Δ6 desaturase activity. However, no traces of corresponding 7-methyl- and 10-methylhexadecanoic acids were detected in the gorgonians.

In the same way, hypothetical pathways may also be suggested for the other related new fatty acids, namely 7,9-dimethyl-6-hexadecenoic and 10-methyl-6,9-heptadecadienoic. These compounds also possess Δ6 unsaturation and a methyl branch at either the C-7 or C-10 position as common features. As suggested above, a second unsaturation (Δ9) could exist. Thus, a methylene group could be inserted to yield, for example, 7,9-dimethyl-6-hexadecenoic acid after rearrangement to a 9-methyl branch and reduction, despite the absence of 6,9-hexadecadienoic acid in the mixture. The fact that we identified 7,9-dimethyl-6-heptadecenoic acid instead of the expected 7,10-dimethyl-6-hexadecenoic acid emphasizes the interest of determining the mode of biosynthesis of these new branched fatty acids. In contrast, 6,9-heptadecadienoic acid was present and perhaps a precursor in the biosynthesis of 10-methyl-6,9-heptadecadienoic acid, implying a unique 10-methyl branching. According to these speculations, the most plausible biosynthetic pathway would involve methylene insertion across double bonds. However, further biosynthetic experiments need to be performed to establish this with certainty.

Even taking into consideration possible differences due to the different extraction methods used, it is noteworthy that a low percentage of lipids, but a high level of PUFA, was observed during the cool season, whereas a high percentage of lipids, but a low level of PUFA, was observed for gorgonians collected in warmer waters. Such a low percentage of lipids was also reported for a Caribbean gorgonian harvested in December and extracted by the Bligh and Dyer method (6). Increased lipid content is often reflected by increases in TGs and wax esters. Thus, a high level of wax esters could account for the decrease of PUFA content (5,6). Furthermore, the possibility of lipid autoxidation may not be excluded, which would imply loss of PUFA (6). The influence of environmental temperature seems the most plausible explanation. Temperature is known to be one of the major environmental changes to which marine organisms are subjected. It is generally reported that increases in the highly unsaturated fatty acids of marine organisms occur in colder waters (26,27). This is assumed to be a way of adapting to the environment, in that temperature-dependent changes in lipids influence the thermal flexibility of cell membranes, ensuring correct physicochemical properties (28). As an exception, arachidonic acid was present at high levels in all the specimens studied here. This was probably correlated with the fact that arachidonic acid is known primarily as a component of polar lipids.

Dietary input or a symbiotic origin may also account for the variations in PUFA levels. Cnidarians are hosts for photosynthetic Zooxanthellae, especially in shallow waters (5). Dinoflagellate endosymbionts are widely distributed among marine invertebrates, and their lipids are characterized by high PUFA concentrations (29). In a previous study, we reported the fatty acid compositions of five *Palythoa* (Zoantharia) from the Senegalese coast and their associated organisms (10). Four of them harvested in shallow waters were associated with Zooxanthellae, whereas *Palythoa senegambiensis*, which lives at depths of 12 to 20 meters, was devoid of endosymbiotic Zooxanthellae. In fact, at 30 meters depth on average, light is insufficient to sustain photosynthetic processes because of the constant turbidity of the ocean. This observation was also documented in our recent work showing that 23,24-dimethylcholesta-5,22-dien-3β-ol, a gorgosterol precursor specific to Zooxanthellae, was present only in shallow

water *Cinachyrella* sponges, whereas the corresponding deep-water specimens did not possess this sterol (30). Thus, PUFA would not seem to originate from symbiotic Zooxanthellae.

An interesting result was the identification at high levels of the 6,9,12,15,18,-24:5 and quite rare 6,9,12,15,18,21-24:6 fatty acids in gorgonian specimens from colder waters. These fatty acids have only been reported at similar levels in two gorgonians (7) and in some other Cnidarians, such as Pennatularia and Alcyonaria (7). The 6,9,12,15,18,21-24:6 fatty acid was previously found in Crinoidea and Ophiuroidea (31). These tetracosapolyenoic fatty acids probably arise from arachidonic and icosapentaenoic acids, although further experiments are required to clarify this point. According to preliminary investigations (Mirallès, J., and Galonnier, R., unpublished results), high proportions of tetracosapolyenoic acids would seem characteristic of the total lipids of gorgonians collected in colder waters. To further elucidate this point, studies are currently underway in our laboratory to investigate a wide range of available gorgonians.

The Rare Caribbean Sponge *Leucosolenia canariensis:* Phospholipid Fatty Acids and Sterols

Néstor M. Carballeira* and Fathi Shalabi

Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico 00931-3346

ABSTRACT: The phospholipid fatty acid composition of the Calcarean sponge *Leucosolenia canariensis* was studied, and no $\Delta^{5,9}$ fatty acids were detected. These results are in contrast to the phospholipids from sponges belonging to the class Demospongiae where Δ5,9 fatty acids are predominant. Odd branched-chain fatty acids between 17 and 19 carbons accounted for 26% of the total fatty acids of *L. canariensis*, while straight-chain fatty acids between 16 and 22 carbons accounted for 61% of the total fatty acid composition. The sterol composition of *L. canariensis* is also reported, and only $\Delta^{5,7,22}$ sterols were observed.

Lipids 30, 467–470 (1995).

Fatty acids and sterols from marine sponges are metabolites of particular interest for the unusual array of new structures that have been isolated (1). In particular, the class Demospongiae has been recognized as having very long-chain fatty acids (typically between 26 and 30 carbons) with a characteristic $\Delta^{5,9}$ diunsaturation pattern (2). However, little is known about the specific chemical structures of fatty acids of lipids of the Calcarea. In the only study of Calcarea, Bergquist *et al.* (3) analyzed the lipids of the genus *Clathrina* and *Leucettusa* (subclass Calcinea), and *Sycon* (subclass Calcarea). This study revealed that the only difference in fatty acid profiles between the Demospongiae and Calcarea were the smaller percentages of C_{24}–C_{30} acids and fewer unsaturated fatty acids in the class Calcarea. The species *Leucettusa lancifer* was atypical within the Calcarea in that the fatty acid chain lengths were no greater than 22 carbons (3). However, no specific chemical structures for these fatty acids were reported. Moreover, the order Leucosolenida has not been studied for fatty acid composition.

The sterol composition of the Calcarea has also been studied, indicating that they do contain small amounts of sterols, the Δ^5 sterols between C_{27}–C_{29} carbons being predominant in these sponges (4). The sterol composition of the Calcarea compares favorably to the class Demospongiae (5). However, there are no reports of the sterol composition of the order Leucosolenida within the Calcarea. One reason might be that the Leucosolenid sponges are difficult to find and/or collect.

In our ongoing research of the fatty acid composition of Caribbean sponges, we were fortunate to find the rare Calcarean sponge *Leucosolenia canariensis* (genus Leucosolenia, order Leucosolenida, subclass Calcaronea). The phospholipid fatty acid distribution and the sterol composition of *L. canariensis* have not been studied before and are, therefore, presented herein.

MATERIALS AND METHODS

Instrumentation. Gas chromatography (GC) spectra were recorded on a Hewlett-Packard 5890A gas chromatograph (Palo Alto, CA) equipped with a flame-ionization detector and a DB-1 (J&W Scientific, Folsom, CA) nonpolar fused silica capillary column (30 m × 0.25 mm i.d.) containing dimethylpolysiloxane (carrier gas He). Electron ionization/mass spectrometry (MS) data was collected in a 5972A MS ChemStation operated at 70 eV (Hewlett-Packard) and equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) crosslinked with 5%-phenyl methylpolysiloxane. The temperature program was as follows: 130°C for 2 min, then increased at 3°C/min to 270°C and maintained for 40 min. ^{1}H nuclear magnetic resonance (NMR) spectra were recorded on a General Electric GN-300 (300 MHz) (Broker Instruments, Billerica, MA) spectrometer in $CDCl_3$. Preparative high-performance liquid chromatography (HPLC) was carried out on a Waters Associates HPLC system (M 510 pump, Waters 410 differential refractometer; Milford, MA), using an Altex Ultrasphere ODS-2 column (25 cm × 10 mm i.d.; Berkeley, CA) and methanol as solvent.

Sampling and lipid analyses. Leucosolenia canariensis was collected north of Puerto Rico, at a depth of 10 m. The sponge (*ca.* 100 g) was washed in seawater, carefully cleaned of all nonsponge debris, and cut into small pieces. Immediate extraction after collection with 200 mL of chloroform/methanol (1:1, vol/vol) yielded the total lipids (100 mg). The neutral lipids, glycolipids, and phospholipids (60 mg) were separated

by column chromatography on silica gel (60–200 mesh) using the procedure of Privett *et al.* (6). The phospholipid classes were fractionated by preparative thin-layer chromatography (TLC) using Silica gel 60 and $CHCl_3/CH_3OH/NH_4OH$ (65:35:5, by vol) as solvent, affording mainly phosphatidylethanolamine, phosphatidylserine, and phosphatidylcholine. The fatty acyl components of these phospholipids were obtained as their methyl esters by reaction with methanolic hydrogen chloride (7) followed by silica gel chromatography with hexane/diethyl ether (9:1, vol/vol) as eluent.

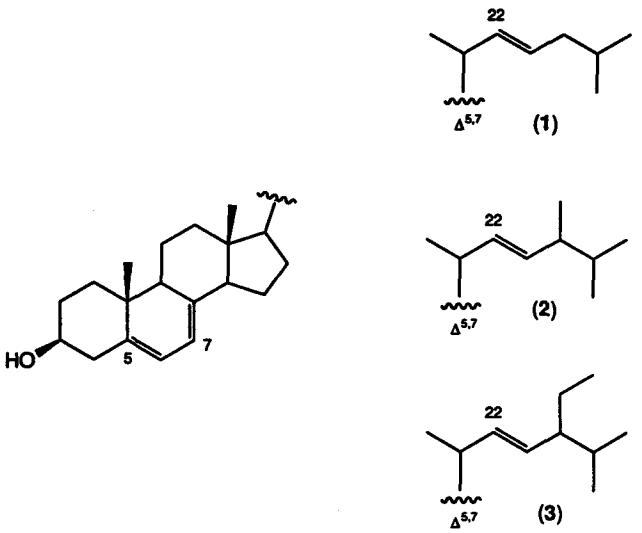
Hydrogenations were carried out in 10 mL of absolute methanol and catalytic amounts of platinum oxide (PtO_2). The double-bond positions of the mono- and dienoic fatty acids were determined by preparing the corresponding dimethyl disulfide derivatives by dissolving the esters or dimethyl acetals (2 mg) in dimethyldisulfide (0.2 mL) and adding a solution (0.05 mL) of I_2 in Et_2O (60 mg/mL), heating the solution at 50°C for 24 h, followed by the standard work-up (8). Spectral data for the dimethyldisulfide adducts of the unsaturated aldehydes were as follows: 10,11-*bis*(methylthio)nonadecanal. MS *m/z* (relative intensity) 374 (M^+, 3), 201($C_{11}H_{21}SO^+$, 27),173 ($C_{10}H_{21}S^+$, 100), 157 (5), 135 (9), 124 (4), 121 (2), 109 (8), 107 (7), 97 (10), 95 (26), 93 (12), 87 (24), 83 (40), 81 (31), 79 (15), 74 (13). 10,11-*bis*(methylthio)Heneicosanal. MS *m/z* (relative intensity) 402 (M^+, 2), 202 (13), 201($C_{11}H_{21}SO^+$ and $C_{12}H_{25}S^+$, 88), 200 (10), 174 (4), 157 (3), 143 (3), 135 (10), 123 (4), 113(7), 111 (8), 109 (10), 107 (9), 101 (5), 97 (30), 95 (33), 93 (16), 91 (8), 87 (31), 85 (11),83 (43), 81 (39), 79 (20), 74 (16), 71 (18).

For the isolation of the sterol mixture, the previously isolated neutral lipids were chromatographed on a silica gel column [ether/hexane (1:1, vol/vol) as eluant] to provide the sterol mixture. The sterol mixture was recrystallized from both CH_3OH and CH_3CN (Carballeira, N.M., unpublished data). The individual sterols were fractionated by HPLC on an Altex ODS-2 column and then run on GC to confirm purity.

RESULTS AND DISCUSSION

The phospholipid fatty acid composition of *L. canariensis* is presented in Table 1. In contrast to the class Demospongiae, no Δ5,9 fatty acids were observed in this Calcarean sponge. The longest fatty acids in the phospholipids of the sponge were the polyunsaturated fatty acids 4,7,10,13,16,19-docosahexaenoic acid (22:6) and 7,10,13,16-docosatetraenoic acid (22:4).The principal fatty acids in *L. canariensis* were hexadecanoic acid (16:0) and octadecanoic acid (18:0), which together accounted for 23% of the total fatty acid composition of this sponge. Branched-chain fatty acids were the predominant classes in *L. canariensis,* with odd-chain fatty acids accounting for 26% of the total fatty acid composition and even-chain branched fatty acids for 12%. In this regard, the *iso/anteiso* pair of nonadecanoic acids were in considerable abundance. *Leucosolenia canariensis* also presented the related n-7 monounsaturated fatty acids 9-hexadecenoic acid and 11-octadecenoic acid (Table 1). The double-bond positions were unambiguously determined from the mass spectra of the corresponding dimethyldisulfide adducts (8).

TABLE 1
Fatty Acids and Aldehydes from *Leucosolenia canariensis*



Compounds	Abundance (wt%)
Fatty acids	
Tetradecanoic (14:0)	7.6
4,8,12-Trimethyltridecanoic (16:0)	3.5
13-Methyltetradecanoic (15:0)	3.5
Pentadecanoic (15:0)	1.7
9-Hexadecenoic (16:1)	0.7
11-Hexadecenoic (16:1)	0.2
Hexadecanoic (16:0)	13.5
15-Methylhexadecanoic (*i*-17:0)	4.7
14-Methylhexadecanoic (*ai*-17:0)	1.4
Heptadecanoic (17:0)	2.0
16-Methylheptadecanoic (*i*-18:0)	8.4
9-Octadecenoic (18:1)	0.1
11-Octadecenoic (18:1)	6.1
Octadecanoic (18:0)	9.8
17-Methyloctadecanoic (*i*-19:0)	6.1
16-Methyloctadecanoic (*ai*-19:0)	9.8
Nonadecanoic (19:0)	9.6
13-Eicosenoic (20:1)	0.5
15-Eicosenoic (20:1)	0.1
Eicosanoic (20:0)	1.9
4,7,10,13,16,19-Docosahexaenoic (22:6)	1.0
7,10,13,16-Docosatetraenoic (22:4)	5.9
Aldehydes	
Heptadecanal (17:0)	1.2
Octadecanal (18:0)	0.1
10-Nonadecenal (19:1)	0.5
10-Heneicosenal (21:1)	0.1

Dimethyl acetals of aldehydes were also present in the methyl ester mixture from the sponge. The dimethylacetal derivatives of the saturated aldehydes heptadecanal and octadecanal exhibited a base peak at *m/z* 75 and $[M - 31]^+$ ions at *m/z* 269 and at *m/z* 283, respectively. The previously unrecognized 10-nonadecenal (19:1) and 10-heneicosenal (21:1), which predominated in phosphatidylethanolamine, were also identified in *L. canariensis*. Their dimethyl acetals probably accompanied the methyl esters as "artifacts" in the transesterification. The dimethyl acetal derivatives of both aldehydes exhibited a base peak at *m/z* 75 and $[M - 31]^+$ ions at *m/z* 295 and at *m/z* 323, respectively. The double-bond position in the chains was determined by dimethyldisulfide derivatization of small amounts of free aldehydes accompanying the methyl esters and dimethyl acetals. For example, 10-nonadecenal afforded, upon reaction with dimethyldisulfide and iodine in diethyl ether, the 10,11-*bis*(methylthio)nonadecanal. The electron impact mass spectrum of the latter derivative displayed predominant fragments at *m/z* 201 $[C_{11}H_{21}SO]^+$ and at *m/z* 173 $[C_{10}H_{21}S]^+$, resulting from preferential cleavage between C-10 and C-11, and this indicates a double bond at C-10. The 10-heneicosenal (21:1) was characterized in a similar way.

The 10,11-*bis*(methylthio)heneicosanal provided major fragments with the same mass at *m/z* 201$[C_{11}H_{21}SO]^+$ and at *m/z* 201 $[C_{12}H_{25}S]^+$, which also indicates a double bond at C-10. However, in this particular case, a single ion peak was observed for both fragments at *m/z* 201.

The sterol composition of *L. canariensis* was also carefully studied and is presented in Table 2. The ^{1}H NMR spectrum of the sterol mixture presented signals characteristic of a $\Delta^{5,7}$ nucleus (9). For example, the C18 and C19 methyl groups were observed at 0.63 and 0.94 ppm, respectively, as well as the two characteristic ring-olefinic signals deshielded to δ 5.38 and 5.58 ppm, corresponding to the $\Delta^{5,7}$ protons.

The HPLC chromatogram of the sterol mixture presented only three main peaks (Scheme 1). The first peak (27% of the total sterol composition) was characterized as cholest-5,7,22-trien-3ß-ol (**1**).The mass spectrum of **1** displayed a $[M]^+$ at 382 and fragments at *m/z* 271 $[C_{19}H_{27}O]^+$ (loss of side chain) and at *m/z* 253 $[C_{19}H_{25}]^+$ (loss of side chain and water) corresponding to an unsaturated side chain characteristic of sterols with the $\Delta^{5,7}$ nucleus (9). The double bond at C22 was confirmed from the existence of an ion at *m/z* 323 (loss of the terminal isopropyl group and water). The second HPLC peak (34% of the total mixture) was identified as 24-methylcholest-5,7,22-trien-3ß-ol (**2**). Diagnostic fragments for **2** also occurred at *m/z* 396 $[M]^+$, *m/z* 378 (loss of water), *m/z* 363 (loss of methyl and water), *m/z* 337 (loss of the terminal isopropyl group and water), and at *m/z* 253 (loss of side chain and water). The C28 methyl signal appeared as a doublet at δ 0.91 ppm. Finally, the third HPLC peak (38% of the total mixture) contained a sterol with $[M]^+$ at 410. This was shown to be 24-ethylcholest-5,7,22-trien-3ß-ol (**3**) by comparison of its mass spectrum with the literature (9). The mass spectrum of **3** presented fragments at *m/z* 392 (loss of water), *m/z* 377 (loss of methyl and water), *m/z* 351(loss of the terminal isopropyl group and water), and at *m/z* 253 (loss of side chain and water).The C29 methyl group appeared on ^{1}H NMR as a triplet at 0.84 ppm, confirming the presence of a methyl group at C-24 (9).

SCHEME 1

TABLE 2
Sterols from *Leucosolenia canariensis*

Sterols	Abundance (wt%)
Cholest-5,7,22-trien-3ß-ol (**1**)	28
24-Methyl-5,7,22-trien-3ß-ol (**2**)	34
24-Ethylcholest-5,7,22-trien-3ß-ol (**3**)	38

Our study of the phospholipid fatty acid composition of *L. canariensis* is important for several reasons. First, we have shown that *L. canariensis* does not have any Δ5,9 fatty acids. This is an interesting observation that could have taxonomic relevance when we compare this Calcarean sponge to other sponges from the class Demospongiae, a class where most of the sponges do have Δ5,9 fatty acids in their phospholipids. A second interesting observation can be made as to the relative fatty acid chain lengths of sponges within the Calcarea. A comparison of the fatty acid profile of *L. canariensis* with that reported for other Calcarean sponges reveals that it compares favorably to that of the Leucettida sponge *Leucettusa lancifer*, a sponge previously analyzed by Bergquist *et al.* (3). Both sponges had fatty acids with chain lengths up to only 22 carbons. Other Calcarean sponges from the order Clathrinida and Sycettida do show predominantly fatty acids with very long chain lengths up to 26 carbons. Although this comparison of the two sponges is not strictly correct, i.e., they were analyzed under different conditions, our results seem to imply that the order Leucosolenida is closer to the order Leucettida, but farther away from the orders Clathrinida and Sycettida.

The sterol composition of *L. canariensis* also supports the different chemical composition of the Leucosolenida as compared to the Clathrinida and Sycettida (4). *Leucosolenia canariensis* had only $\Delta^{5,7,22}$ sterols, while the other Calcarean sponges have been reported to have mainly Δ^5 sterols (4). Unfortunately, we could not find any reports on the sterol composition of *Leucettusa lancifer*.

The last interesting observation in *L. canariensis* is the report of the aldehydes 10-nonadecenal and 10-heneicosenal, probable "artifacts" of transesterification. Work is in progress in our laboratory elucidating the origin of these unusual lipids in marine sponges.

ACKNOWLEDGMENTS

We thank Dr. Vance Vicente for the collection and classification of the sponge. We thank the Puerto Rico (EPSCoR) Tropical Marine Biotechnology Center for financial support as well as the National Science Foundation MRCE program. This work was also supported by the National Institutes of Health (NIH-MBRS Program) under Grant No. S06 GM08102-20.

Dietary Manipulation of Long-Chain Polyunsaturated Fatty Acids in the Retina and Brain of Guinea Pigs

Harrison S. Weisinger[a], Algis J. Vingrys[a] and Andrew J. Sinclair[b,*]

[a]Department of Optometry, University of Melbourne, Parkville, 3052, Victoria, Australia and
[b]Department of Food Science, Royal Melbourne Institute of Technology, Melbourne, 3000, Victoria, Australia

ABSTRACT: High levels of n-6 docosapentaenoic acid (22:5n-6) have been reported in the retina of guinea pigs fed commercially-prepared grain-based rations (commercial diet). In rats and monkeys, high levels of 22:5n-6 are an indicator of n-3 polyunsaturated fatty acid (PUFA) deficiency. We have examined the fatty acid composition of the retina and brain in guinea pigs fed a commercial diet or one of three semi-purified diets containing three different levels of n-3 PUFA. The diets comprised a diet deficient in n-3 PUFA (semi-purified diet containing safflower oil), two diets containing α-linolenic acid (standard commercial laboratory diet and semi-purified diet containing canola oil), and a diet containing α-linolenic acid, eicosapentaenoic acid, and docosahexaenoic acid (DHA) (semi-purified diet containing canola oil, safflower oil, and fish oil). Two groups of guinea pigs were given the diets from day 1 to 4 wk or day 1 to 8 wk, when they were sacrificed and the retinal tissues were extracted and analyzed for PUFA content by gas–liquid chromatography. Fatty acid analyses of the retinal phospholipids of the four-week-old animals revealed that the group fed DHA (from the fish oil) had the highest level of DHA (32%), compared with values of 19 and 13% for the groups fed canola oil diet and commercial diet, respectively, and 2% for the group fed the diet deficient in n-3 PUFA. The levels of 22:5n-6 in the retinal lipids were inversely related to the DHA values, being 0.6, 6.6, 11.4, and 20.6 for the fish oil, canola oil, commercial diet, and safflower oil diet groups, respectively. The long-chain PUFA profiles in the brain phospholipids of the four-week-old group were similar to those from the retina. The retinal PUFA values for the eight-week-old animals were similar to the four-week-old group. The safflower oil diet induced a greater deficit of DHA in retinal lipids than has been reported in rats and monkeys fed similar diets. The guinea pigs fed the commercial diet had retinal and brain PUFA patterns similar to that produced by n-3 PUFA-deficient diets in rats and monkeys. Guinea pigs fed the canola oil diet had significantly greater retinal DHA levels than those fed the commercial diet, but lower than those fed fish oil. The data suggest that the guinea pig has a reduced capacity for DHA synthesis from α-linolenic acid as compared with other mammals. Supplementation of guinea pig diets with fish oil produced high retinal and brain DHA levels and prevented the accumulation of 22:5n-6.
Lipids 30, 471–473 (1995).

Docosahexaenoic acid (DHA) (22:6n-3) is the major polyunsaturated fatty acid (PUFA) in brain grey matter and retina of most mammalian species (1–3). Animals fed n-3 PUFA-deficient diets develop low levels of DHA in the brain and retina and an increase in n-6 docosapentaenoic acid (22:5n-6) (3–6). High levels of 22:5n-6 and low levels of 22:6n-3 in tissue phospholipids are considered to be a biochemical marker of n-3 PUFA deficiency (3–6). Such fatty acid changes are associated with abnormal electroretinograms in rats and monkeys (3–6), and alterations in enzyme activities in neural tissue (4). In 1986, Leat *et al.* (7) reported that commercial diet-fed guinea pigs contained a high level of 22:5n-6 and a relatively low level of DHA in the retinal lipids, suggesting that the commercial diet used was deficient in α-linolenic acid. The guinea pig commercial diet contained linoleic and α-linolenic acid as the only dietary PUFA. The finding that the control guinea pigs showed biochemical evidence of reduced DHA levels might explain why Leat *et al.* (7) were not able to detect electroretinogram differences between the control guinea pigs and those fed a semi-purified diet containing linoleic acid as the only PUFA (n-3-deficient diet).

The purpose of this study was to establish whether guinea pigs fed semi-purified diets containing α-linolenic acid and/or DHA could prevent the accumulation of docosapentaenoic acid (22:5n-6) in retinal and brain tissue.

MATERIALS AND METHODS

Animals and diets. Sixteen commercial diet-fed female guinea pigs (in groups of four) were weaned onto a guinea pig commercial diet (Barrastock Guinea Pig Food; Barrastock, Melbourne, Australia), or one of three semi-purified diets

*To whom correspondence should be addressed at the Department of Food Science, Royal Melbourne Institute of Technology, GPO Box 2476V, Melbourne, 3001, Victoria, Australia.

Abbreviations: DHA, docosahexaenoic acid (22:6n-3); PUFA, polyunsaturated fatty acids.

Copyright © 1995 by AOCS Press

based on those described by Leat *et al.* (7). The diets contained (g/kg) casein 300, sucrose 100, glucose 70, starch 200, solkafloc 100, oil 100, kaolin 30, L-arginine 3, DL-methionine 2, mineral mix 68, and vitamin pre-mix 27. All diets were supplemented with 10 g fresh carrots daily, and water containing ascorbic acid (400 mg/L) was freely available. Details of the vitamin premix and mineral mix are given in Leat *et al.* (7). The guinea pig commercial diet contained 14 g/kg linoleic acid, 1.6 g/kg α-linolenic acid, and no long-chain PUFA. The semi-purified diets were identical, except for the added oils. The n-3-deficient diet contained safflower oil as the sole source of fat (71 g/kg linoleic acid, <0.7 g/kg α-linolenic acid), the second diet contained canola oil which provided linoleic acid and α-linolenic acid as the only PUFA (20 g/kg linoleic acid, 8 g/kg α-linolenic acid), and the third diet contained a mixture of safflower oil, canola oil, and fish oil, thus providing eicosapentaenoic acid (4.5 g/kg) and DHA (2.6 g/kg) as well as linoleic acid (30.5 g/kg) and α-linolenic acid (3.8 g/kg). The fish oil was supplied in gelatin-coated powder form (Dry n-3®; DanoChemo, Ballerup, Norway). Guinea pig dams were reared on these diets to four months of age, at which time they were joined with commercial diet-fed males. Six offspring from each diet group were sacrificed at 28 ± 2 d, and a further 12 animals from each of the four diets were sacrificed at 56 ± 4 d. The young guinea pigs consumed solid food from about seven days of age. There were an equal number of animals of each sex in each diet group. The animals were sacrificed following intraperitoneal injection of sodium pentabarbitone (100 mg/kg body weight) (Boehringer Ingelheim, Artarmon, NSW, Australia). The retinas were removed within 2 min, washed in ice-cold phosphate-buffered saline, blotted dry, and immediately placed in chloroform/methanol (2:1, vol/vol) in glass Teflon-lined screw-capped tubes. The brains were also removed (from the young group) within 2 min, halved down the mid-line, diced, and also immediately placed into chloroform/methanol solution.

Lipid analyses. Lipids were extracted from the retinas and brain tissue using chloroform/methanol, and the phospholipids were separated from the neutral lipids by thin layer-chromatography (8). The methyl esters of the phospholipid fatty acids were formed by a saponification step using KOH followed by transesterification in BF_3 in methanol (8), and the fatty acid methyl esters were separated by capillary gas–liquid chromatography using a 50 m × 0.32 mm (i.d.) fused silica bonded-phase column (BPX70; SGE, Melbourne, Australia). The column oven was programmed from 125°C for 3 min to 220°C at 8°C/min with helium as carrier gas at a flow rate of 43 cm/s. Fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters, and the results were calculated using response factors derived from chromatographing standards of known composition (Nu-Chek-Prep, Elysian, MN).

Statistical analysis. A single factor analysis of variance considered the effect of diet on retinal fatty acid content between the four groups. Post-hoc comparisons were performed using a Bonferroni/Dunn procedure. The *a priori* alpha level for both tests was 0.05.

RESULTS AND DISCUSSION

The retinal phospholipid fatty acid patterns are shown in Table 1. The four- and eight-week-old animals fed the safflower oil diet showed very low tissue levels of DHA (<3%) and substantial elevations in the 22:5n-6 levels (>21%): DHA/22:5n-6 ratios of <0.12. The commercial diet-fed animals had approximately the same levels of 22:5n-6 as DHA in their retinal lipids. The canola oil-fed animals had significantly higher levels of DHA than 22:5n-6 (ratio ≥2.9). The four- and eight-week-old fish oil-fed group had the highest levels of DHA, with DHA/22:5n-6 ratios of ≥54. The 22:5n-6 comprised less than 1% of the phospholipid fatty acids in the fish oil-fed group by comparison with values of 20% in the safflower group. The data for the brain for the four-week-old animals were similar to the retina, with the DHA/22:5n-6 ratios being 0.1, 0.9, 1.5, and 24 for the safflower, chow, canola, and fish oil diet groups, respectively.

[a]Mean ± standard deviation, n = 6 for four-week-old, n = 12 for eight-week-old animals; PUFA, polyunsaturated fatty acids.
[b,c]Significantly different from commercial diet fed values: [b]$P < 0.01$, [c]$P < 0.001$.
[d]Less than 0.1%.

These data show that guinea pigs raised on a diet containing α-linolenic acid (canola oil-based diet or the commercial guinea pig diet) have lower retinal and brain DHA levels relative to those fed fish oil. Furthermore, the group fed the safflower oil diet had very low DHA levels (<3% of the total fatty acids of retinal phospholipids). In rats and monkeys fed similar diets deficient in n-3 PUFA, the retinal DHA values do not fall below 40% of the value obtained by feeding control diets containing α-linolenic acid (soybean oil) (3–6). In the group fed the commercial guinea pig diet, the retinal and brain DHA/22:5n-6 ratios would be considered typical of tissue PUFA patterns induced by feeding n-3 PUFA-deficient diets in other species (rats and monkeys) (3–6,9).

It has been reported that rabbits fed chow diets have similar retinal PUFA profiles to those reported here for the guinea pigs fed the commercial diet (10). In rabbits fed rabbit chow containing linoleic and α-linolenic acid as the only dietary PUFA, the retinal tissue had approximately equal levels of 22:5n-6 and DHA up to nine weeks of age, and the high levels of 22:5n-6 were suppressed by the inclusion of fish oil in the diet (10). It was also noted that the retinal DHA/22:5n-6 ratio increased substantially in adult animals fed these diets from weaning. We have not examined the DHA/22:5n-6 ratios in adult guinea pigs.

The four diets used in this experiment contained four different levels of n-3 PUFA. As the level of dietary n-3 PUFA increased, the DHA levels in the retina and brain increased and the 22:5n-6 decreased. There was almost a complete absence of 22:5n-6 in the group fed fish oil, which suggests that DHA is a strong inhibitor of 22:5n-6 synthesis. An explanation as to why the guinea pigs fed α-linolenic acid do not have the same retinal DHA levels as those fed DHA would be that the guinea pig has a reduced capacity to synthesize long-chain PUFA from α-linolenic acid, relative to the rat and the rhesus monkey. Such a possibility is consistent with the finding of Willis (11) in which he reported that the guinea pig had a substantially lower Δ5 desaturase activity as compared with the rat. This is also supported by data showing a fourfold higher proportion of 20- and 22-carbon PUFA in the liver phospholipid fatty acids from rats fed canola oil diets as compared with guinea pigs fed canola oil diets (Sinclair, A.J., unpublished observations). The question of whether high levels of 22:5n-6 in the guinea pig retina are species-specific or associated with a functional deficit is presently being investigated in our laboratory.

Names of journals must be abbreviated according to *Chemical Abstracts Service Source Index* (CASSI), published by Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210. These abbreviations are identical to those used in *Chemical Abstracts. These abbreviations are to be used exclusively.*

If it is necessary to refer to "unpublished data," "personal communication," "manuscript in preparation" or papers "submitted for publication," such citations should not be listed as references, but are to appear in the text, e.g., (Turner, E.H., and Smith, D.E., unpublished data). Authors must obtain written permission to cite the unpublished work of others, and copies of such correspondence must accompany the manuscript. Avoid the use of *et al.* in referring to authors: list all names.

NOTE: *Lipids* is now italicizing all mathematical variables. This may not have been clear in January 1995 "Guide to Authors."

AVAILABILITY OF FISH OIL TEST MATERIALS

The Fish Oil Test Materials Program is a cooperative effort of the National Institutes of Health (NIH) and the National Oceanic and Atmospheric Administration/Department of Commerce (NOAA/DOC). This program provides a long-term, consistent supply of quality-assured/quality-controlled test materials to researchers that facilitates the evaluation of ω-3 fatty acids in health and disease.

Current test materials available, in both capsules and bulk, include: (i) vacuum deodorized menhaden oil; (ii) ethyl esters of olive, corn, and safflower oils; (iii) commercial preparations of corn, olive, and safflower oil; (iv) n-3 ethyl ester concentrates; (v) EPA ethyl ester; and (vi) DHA ethyl ester.

To qualify to receive the fish oil test materials from the Program, the researcher must fill out an application. The applicant must: (i) have peer-reviewed research indicating the need for the requested materials, and (ii) submit a cor-

(continued on next page)

rectly completed application form and a signed waiver of liability. *The awarded materials are provided free of charge (researchers will pay shipping costs).*

Investigators may obtain further information and an application form from Fish Oil Test Materials Program, NIAAA, National Institutes of Health, 12501 Washington Ave., Flow Building, Room 2, Rockville, MD 20852 (Phone: Beth Aurecchia, 301-443-9643; Fax: 301-594-0035).

Determination of Lysine Modification Product ε-*N*-Pyrrolylnorleucine in Hydrolyzed Proteins and Trout Muscle Microsomes by Micellar Electrokinetic Capillary Chromatography

Rosario Zamora*, José L. Navarro and Francisco J. Hidalgo

Instituto de la Grasa, Consejo Superior de Investigaciones Científicas, Sevilla, Spain

ABSTRACT: ε-*N*-Pyrrolylnorleucine (Pnl) is a product of the reaction between the lipid peroxidation product 4,5(*E*)-epoxy-2(*E*)-heptenal (EH) and the ε-amino group of lysine. Because Pnl might also be produced in proteins, a specific method to determine this compound in protein hydrolysates has been developed. Homoarginine, added as the internal standard, and Pnl are derivatized with diethyl ethoxymethylenemalonate and analyzed by micellar electrokinetic capillary chromatography. The method also analyzes lysine and arginine, and these analyses were useful in determining losses of these amino acids after treatment with EH. The lowest concentration of Pnl detected with acceptable reproducibility is 5 nmol/mL, and the coefficient of variation was determined from four standard curves assayed on separate days. Detector response was linear for samples containing 1.6 to 74 nmol/mL of Pnl. The assay was applied in investigations of Pnl production in bovine serum albumin (BSA) and trout muscle microsomes treated with EH. When BSA was incubated overnight with 30 mM EH, 76% of lysine residues were modified, and a part of these residues were detected as Pnl (12%). Pnl formation was also detected when trout muscle microsomes were incubated for three hours with 1 or 10 mM EH. These results show that Pnl is produced *in vitro* in proteins treated with the lipid peroxidation product EH, and suggest that Pnl might also be constituent of *in vivo* damaged proteins by their reaction with oxidized lipids.

Lipids 30, 477–483 (1995).

Lipid peroxidation seems to be a consequence of *in vivo* oxidative stress, and has been implicated as a deleterious factor in a variety of diseases, including carcinogenesis, mutagenesis, aging, and atherosclerosis (1–3). Although the mode of action is not clear, the production of reactive carbonyl compounds and their subsequent reactions with cellular nucleophiles may be one of the mechanisms (4,5). These reactive carbonyl compounds are strong electrophiles and are capable of reacting rapidly with nucleophiles, including amino acids and proteins. The actual carbonyl compounds involved in such reactions with cellular nucleophiles are not yet well known (6), which is due at least in part to a lack of satisfactory analytical methods to study these reactive carbonyl compounds or their reaction products.

Previous work from this laboratory has shown that the lipid peroxidation product 4,5(*E*)-epoxy-2(*E*)-heptenal (EH) can react with amines, amino acids, and proteins to produce brown-colored and fluorescent products (7,8). The first step in this complex polymerization reaction is the formation of both 1-substituted-2-(1′-hydroxyalkyl)pyrroles and 1-substituted-pyrroles. Pyrroles with such structures have been isolated and characterized in the reaction between EH and butylamine, glycine methyl ester and lysine (9,10). 1-Substituted-2-(1′-hydroxyalkyl)pyrroles can later polymerize to produce brown macromolecules with fluorescent lipofuscin-like characteristics (9). In contrast, 1-substituted-pyrroles seem to be final products in these reactions, and their presence in proteins might be related to damage of proteins as a consequence of its reaction with oxidized lipids.

The objective of this study was to develop an analytical procedure for the isolation and quantitation of the interaction product ε-*N*-pyrrolylnorleucine (Pnl) [This compound was previously named 1-(5′-amino-5′-carboxypentyl)pyrrole (see Ref. 10). ε-*N*-Pyrrolylnorleucine is preferred here because it better reflects the amino acid character. As an abbreviation, a three-letter code has been chosen.] (Fig. 1A). Pnl is the 1-substituted-pyrrole produced in the reaction between EH and the ε-amino group of lysine (10), and might be produced in the presence of proteins. Determination of Pnl may be a satisfactory analytical tool for studying protein damage due to oxidative stress.

EXPERIMENTAL PROCEDURES

EH was prepared from 2(*E*),4(*E*)-heptadienal as described by Swoboda and Peers (11). 2(*E*),4(*E*)-Heptadienal, L-lysine

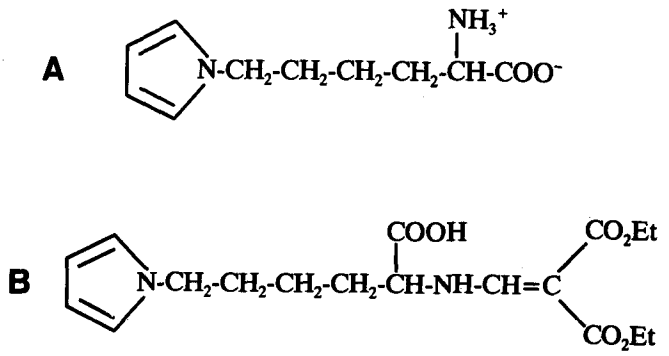

FIG. 1. Chemical structures of ε-*N*-pyrrolylnorleucine (A) and its *N*-[2,2-*bis*(ethoxycarbonyl)vinyl] derivative (B).

monohydrochloride, 3-chloroperoxybenzoic acid, and diethyl ethoxymethylenemalonate (DEEMM) were purchased from Aldrich Chemical (Milwaukee, WI). All other chemicals used were analytical-grade and were purchased from reliable commercial sources. ^{1}H and ^{13}C Nuclear magnetic resonance (NMR) spectra at 300 and 75.4 MHz, respectively, were determined on a Bruker AC-300P (Karlsruhe, Germany), with sodium 3-(trimethylsilyl)-1-propanesulfonate as internal standard. Two-dimensional NMR was used for the assignment of ^{13}C NMR spectra. Mass spectra (MS) were obtained in an AEI-MS-30SB-VG mass spectrometer (VG Analytical, Manchester, United Kingdom).

Synthesis of Pnl. Pnl was prepared by a slight modification of a previously described procedure (10). Briefly, an emulsion of EH (0.5 mmol) in 4 mL of 0.3 M sodium borate, pH 9.0, was treated with lysine (1 mmol) and stirred overnight at 37°C. The reaction mixture was fractionated by semipreparative high-performance liquid chromatography (HPLC) on a Spherisorb ODS2 C18 column (25 × 1 cm) and eluted with 5% acetonitrile in deionized water at 40°C. The HPLC system consisted of a 126 Programmable Delivery Module and a 168 Diode Array Detector Module (Beckman, Fullerton, CA). Data acquisition and processing were effected with software System Gold 7.1 version (Beckman). The flow rate was 5 mL/min with detection by absorbance at 250 nm. A loop of 500 µL was used in all the experiments. Under these conditions, Pnl eluted at 9.5 min. After 10 min, the column was cleaned with acetonitrile and equilibrated for 10 min with the solvent before the next injection. Pnl was collected in successive injections, and combined. Solutions were gassed with nitrogen to remove acetonitrile, and freeze-dried to obtain chromatographically pure Pnl.

Derivatization of Pnl and other amino acids with DEEMM. The free amino groups in Pnl and other amino acids obtained in protein hydrolysates were protected by using DEEMM, which facilitated separation and detection. The derivatization reaction was carried out by modification of a previously described procedure (12), as follows: a mixture of standard amino acids, or a neutralized protein hydrolysate (50 µL containing approximately 0.5 mg of the pool of amino acids), was dissolved in 1 M sodium borate buffer (pH 9.0) (3 mL) containing 0.02% of sodium azide, then mixed with 100 µL of internal standard (IS) solution (homoarginine in deionized water, 1 mg/mL), and finally treated with 5 µL of DEEMM. The reaction mixture was stirred at 50°C for 60 min to completely derivatize proline, the less reactive amino acid for this reaction (12).

Detection of Pnl in amino acid mixtures. Two different techniques (HPLC and capillary electrophoresis) were used for detection and quantitation of Pnl, and other amino acids, in amino acid mixtures. The HPLC system (Waters, Milford, MA) consisted of a Model 600E multi-solvent delivery system, a Wisp Model 712 automatic injector, and a Model 484 ultraviolet (UV)-visible detector. Pnl was derivatized and separated on a 300 × 3.9 mm i.d. reversed-phase column (Nova-Pack C18, 4 µm; Waters) using a previously described gradient for amino acid analysis (13). The capillary electrophoresis system consisted of a Beckman 2100 P/ACE unit equipped with a UV detector. (The P/ACE unit was linked to a 386/33 computer loaded with System Gold Software for data collection and handling.) The capillary consisted of 50 cm in length uncoated silica tubing with 75 µm internal diameter and a detector aperture window of 100 × 200 µm. The sample was introduced into the capillary by pressure injection for 2.0 s. Micellar electrokinetic capillary chromatography (MECC) was carried out at 30 kV and 30°C in 100 mM sodium borate buffer, pH 8.4, containing 100 mM SDS. Electrophoretic profiles were monitored by UV absorption at 280 nm. After repetitive runs, a decrease in the resolution of the capillaries was sometimes observed and the capillary was regenerated by washing with 15% Extran solution (Merck, Darmstadt, Germany) for 10 min at 35°C, and then with water for another 10 min.

Stability of Pnl during hydrolysis. Both acid and basic hydrolyses were tested to obtain the best Pnl recovery in protein hydrolysates. Acid hydrolysis was carried out by dissolving Pnl in 6 M hydrochloric acid, gassing the solutions with nitrogen, and sealing in hydrolysis tubes under nitrogen. Samples were incubated in an oven at 120°C for 18 h. Analogous treatment was used for alkaline hydrolysis, with 2 M sodium hydroxide instead of 6 M hydrochloric acid.

Quantitation. Standard plots of peak are ratio of Pnl, arginine, and lysine, to the IS vs. their concentrations were run on a daily basis. Linear least squares regression was performed to determine the slope, y-intercept, and correlation coefficient of the best fit line. Amino acid concentrations in unknown samples were calculated using results of the regression analysis.

Precision of the method and determination of the lower limit of quantitation. Precision and accuracy of the assay were determined by analyzing the back-calculated sample concentrations and regression parameters from four standard curves of Pnl, arginine, and lysine prepared and analyzed on separate days. Coefficients of variation of mean-predicted concentration for independently assayed standard mixtures pro-

vided the measure of precision. The lower limit of quantitation was defined as the minimum concentration of amino acid that can be analyzed with a coefficient of variation not exceeding 15%.

Determination of Pnl in protein hydrolysates. Bovine serum albumin (BSA, 10 mg) was dissolved in 1 mL of 50 mM sodium phosphate buffer pH 7.0 (or sodium borate buffer pH 9.0) and treated with EH (4 mg). The mixture was allowed to react for 24 h at 37°C. Fifty microliters of the browned protein solution were then mixed with 800 µL of 2 M NaOH and hydrolyzed by heating under nitrogen for 18 h at 120°C. The resulting solution was neutralized with hydrochloric acid, filtered, and derivatized with DEEMM. Twenty-five microliters of protected amino acids were diluted with 125 µL of water and submitted to MECC as previously described.

Determination of Pnl in trout muscle microsomes incubated with EH. Muscle microsomes from freshly killed rainbow trout (*Salmo gairdnerii*) were prepared by differential centrifugation using a modification of the procedure described by McDonald *et al.* (14). Trout muscle was homogenized in 4 vol of cold Krebs-Ringer phosphate buffer (KRPB), pH 7.4 (15), using an Omni 2000 blender (Omni Int'l, Waterbury, CT) at the maximum speed for 20 s. Fish homogenate was then centrifuged at 22,000 × *g* and 4°C for 30 min to remove mitochondria and fractions heavier than mitochondria. The post-mitochondrial supernatant was collected and centrifuged at 105,000 × *g* and 4°C for 60 min. The microsomal pellet was collected and washed twice by suspending the microsomes in cold KRPB (pH 7.4) and by ultracentrifugation under the same conditions. Washed microsomes were dispersed in KRPB, and protein concentration, measured according to Bradford method (16), was adjusted to 3.0 mg/mL for experiments.

Six hundred and seventy microliters of the microsomal preparation were diluted with 3 mL of KRPB and incubated at 37°C for 3 h in the presence, or not (control), of 1 and 10 mM EH. At the end of the incubation period, samples were centrifuged at 105,000 × *g* and 4°C for 60 min. The microsomal pellet was collected and washed with water. Washed incubated microsomes were dispersed in water (1.8 mL), treated with 0.9 mL of 6 M NaOH, and hydrolyzed by heating under nitrogen for 18 h at 120°C. The resulting solution was neutralized with hydrochloric acid, filtered, and derivatized with DEEMM. Twenty-five microliters of protected amino acids were diluted with 125 µL of water and submitted to MECC as previously described.

RESULTS

Preparation and derivatization of Pnl. Pnl is one of the products of the reaction between EH and lysine. The method developed in this study for its isolation shortens the time previously described by cleaning the column after eluting Pnl. Pnl was obtained chromatographically pure, and its ^{1}H and ^{13}C NMR and MS confirmed the proposed structure (10).

The derivatization reaction with DEEMM is quick and clean, producing the corresponding *N*-[2,2-*bis*(ethoxycarbonyl)vinyl] derivative (Fig. 1B). This derivative provided a high absorptivity for easy detection at 280 nm (12). Its HPLC (data not shown) and MECC profiles exhibited one peak for Pnl, which could be used for its separation and quantification only in MECC. Figure 2A shows the electropherogram obtained when derivatized Pnl was submitted to MECC. Peak 5 at 4.20 min corresponded to Pnl. The IS (peak 9) appeared at 6.41 min. The peak in the high-performance liquid chromatogram overlapped with that of lysine and could not be separated from it.

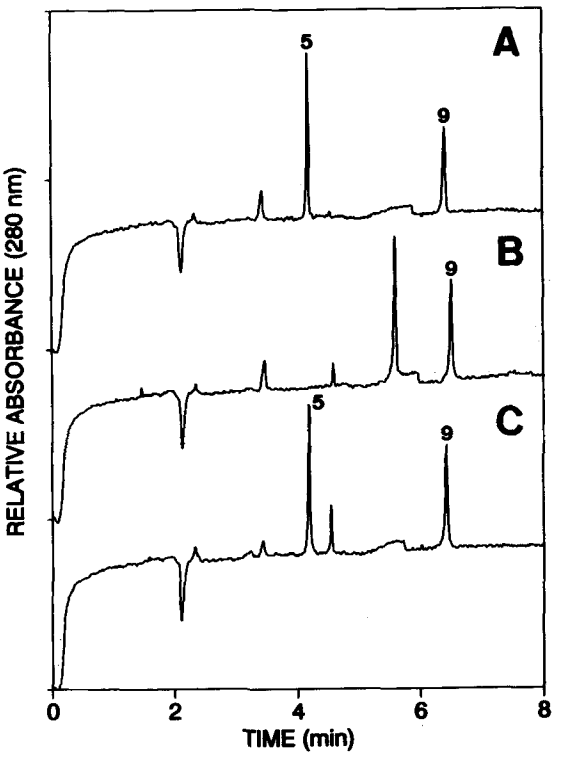

FIG. 2. Effect of hydrolysis on ε-N-pyrrolylnorleucine (Pnl, Peak 5). A, Pnl before hydrolysis. B, Pnl after acid hydrolysis. C, Pnl after basic hydrolysis. Peak 9 is internal standard, homoarginine.

Stability of Pnl during hydrolysis. Because Pnl might be produced in proteins by reaction of the ε-amino group of lysine residue with the lipid peroxidation product EH, the method for its detection and quantification should include the hydrolysis of the protein as a first step. Figure 2 shows electropherograms of derivatized Pnl before hydrolysis (A), after acid hydrolysis (B), and after basic hydrolysis (C). As indicated in Figure 2B, the peak due to Pnl disappeared after acid hydrolysis. The pyrrole ring in Pnl is apparently very sensitive to acid condition, but is resistant to basic hydrolysis (Fig. 2C). For this reason, only basic hydrolysis was used in the rest of this study. Some attempts to recover Pnl from proteins by enzymatic hydrolysis were also tested, but they were not satisfactory.

Detection of Pnl in amino acid mixtures. Twenty-two common amino acids and Pnl were hydrolyzed and analyzed by MECC. For the determination of Pnl, mixtures of amino acids

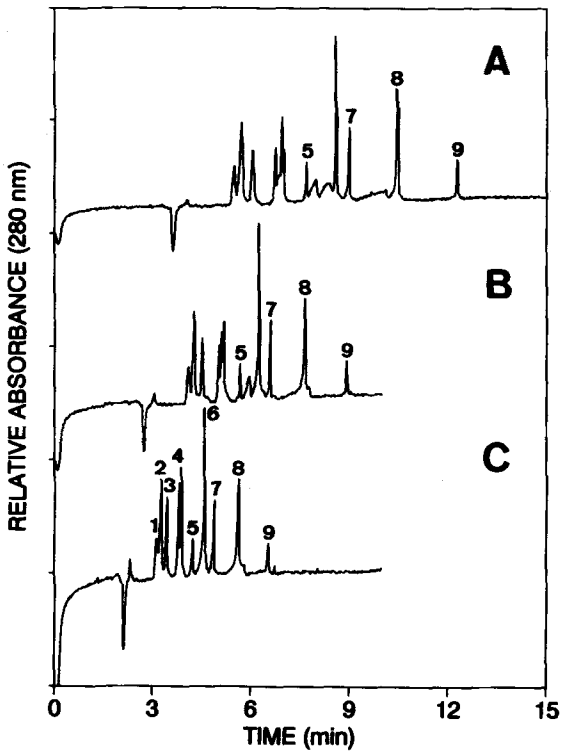

FIG. 3. Effect of voltage on peak resolution of ε-*N*-pyrrolylnorleucine (Peak 5). A, 20 kV; B, 25 kV; C, 30 kV.

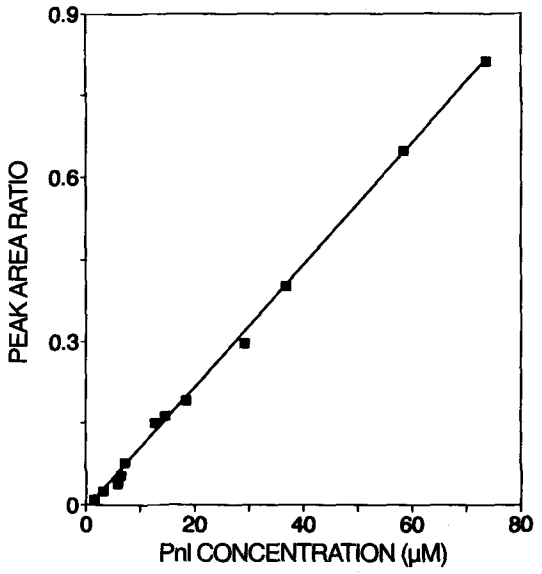

FIG. 4. Standard curve of ε-*N*-pyrrolylnorleucine obtained by using twelve standard mixtures independently prepared and assayed on four different days.

were used to optimize electrophoretic conditions. Figure 3 shows the influence of the voltage on the separation of the peak corresponding to Pnl (peak 5). A voltage of 30 kV produced the best and most rapid separation of Pnl (Fig. 3C). Also, a concentration of 100 mM SDS was required for the best separation. Assignment of the peaks in the electrophoretic pattern in Figure 3C obtained with mixtures of different amino acids were as follows: Peak 1 corresponded to histidine, serine, and threonine. Peak 2 corresponded to alanine, aspartic acid, glycine, proline, serine, threonine, and tyrosine. Peak 3 was common for most amino acids: alanine, ammonia, arginine, asparagine, cystine, glutamic acid, glutamine, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, Pnl, proline, serine, threonine, tyrosine, and valine. Peak 4 corresponded to cysteine, cystine, isoleucine, leucine, phenylalanine, and tryptophan. Peak 5 corresponded to Pnl. Peak 6 appeared as one or two components depending on the amino acid composition of the protein mixture (for example, two peaks were observed with a hydrolysate of BSA, Fig. 5A). This peak (or two peaks) corresponded to ammonia, arginine, asparagine, aspartic acid, cysteine, cystine, glutamic acid, glutamine, threonine and tryptophan. Peak 7 corresponded to arginine. Peak 8 corresponded to lysine. Peak 9 corresponded to the IS homoarginine. Therefore, Peak 5 (Pnl), Peak 7 (Arg), Peak 8 (Lys), and Peak 9 (homoarginine) were the only peaks that corresponded to single amino acids and could be used for quantification.

Assay validation. Figure 4 shows a typical calibration curve of Pnl in basic hydrolysates of amino acids. For twelve standard mixtures, ranging from 1.59 to 73.7 nmol/mL, the Pnl (and also arginine and lysine) to IS electrophoretic peak area ratio was directly proportional to amino acid concentration. Values of the slope, y-intercept, and correlation coefficient of the calibration curves obtained for the three amino acids are shown in Table 1. Coefficients of variation for the mean predicted Pnl concentration of each standard mixture were equal or less than 15% from 5.84 to 73.7 μM (Table 2). Pnl was readily detected in samples at a concentration below 5.84 μM; however, the variability in peak response was considered unacceptable, and a concentration of 5.84 μM was considered the practical lower limit of quantitation. Relative recoveries of Pnl ranged from 90 to 108% within the 6–74 μM range (Table 2).

Determination of Pnl in BSA incubated in the presence of EH. BSA was incubated with 30 mM EH for 24 h, and then subsequently hydrolyzed, derivatized, and analyzed by MECC. Figure 5 shows the electropherograms obtained with starting BSA (A), BSA/EH mixture incubated at pH 7.0 (B), and BSA/EH mixture incubated at pH 9.0 (C). The incubation of BSA with EH produced Pnl (Peak 5), and this corresponded to a decrease in the peak area of lysine (Peak 8). Reaction of EH with the ε-amino group of lysine produces, in addition to Pnl, 1-(5′-amino-5′-carboxypentyl)-2-(1″-hydroxypropyl)pyrrole and macromolecular fluorescent substances by polymerization of this latter compound (10). The alkaline hydrolysis of 1-(5′-amino-5′-carboxypentyl)-2-(1″-hydroxypropyl)pyrrole yielded a decomposition product that appeared under Peak 6 (data not shown). Possibly for this reason, electropherograms 5B and 5C also showed a change in Peak 6. At higher pH, the BSA/EH reaction mixture produced more Pnl, which also corresponded to a decrease in the peak area of lysine, suggesting that Pnl formation was favored at basic pH. Analogous results were obtained when the EH/lysine reaction mixture

TABLE 1
Calibration Curves Obtained for Pnl, Arginine (Arg), and Lysine (Lys), Using Twelve Standard Mixtures[a]

Amino acid	Slope	y-Intercept	Correlation coefficient
Pnl	0.0112	−0.012	0.999
Arg	0.0397	−0.102	0.994
Lys	0.0466	−0.028	0.992

[a]Standard mixtures were independently prepared and assayed on four different days. Values used for calibration curves were the mean of these four measurements; Pnl, ε-N-pyrrolylnorleucine, 1-(5'-amino-5'-carboxypentyl)pyrrole.

TABLE 2
Relative Recovery and Reproducibility of the Analytical Method for the Quantitation of Pnl Using MECC[a]

Amount added (nmol/mL)	Mean amount found (nmol/mL)	Relative recovery (%)	Coefficient of variation (%)
1.59	1.84	116	35
3.19	3.28	103	25
5.84	5.26	90	15
6.38	5.83	91	15
7.37	7.93	108	13
12.8	13.8	108	11
14.6	15.6	107	13
18.4	18.0	98	12
29.2	27.6	94	6
36.8	36.7	100	7
58.4	58.9	101	7
73.7	75.1	102	8

[a]The number of replicates was four for each amount added. Relative recoveries and coefficients of variation were calculated for the whole process, including hydrolysis and derivatization. MECC, micellar electrokinetic capillary chromatography. See Table 1 for other abbreviation.

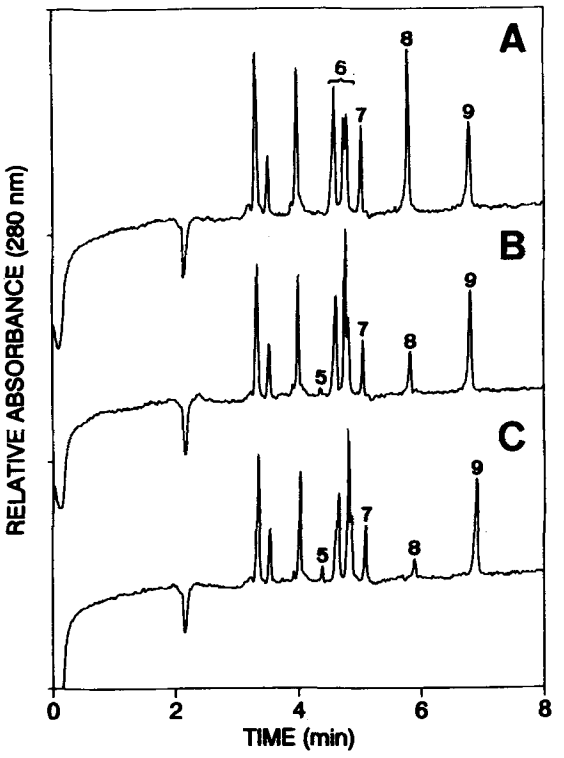

FIG. 5. Electropherograms obtained for amino acid analysis after basic hydrolysis and derivatization of nonincubated bovine serum albumin (A), bovine serum albumin incubated overnight with 4,5(*E*)-epoxy-2(*E*)-heptenal at pH 7.0 (B), and bovine serum albumin incubated overnight with 4,5(*E*)-epoxy-2(E)-heptenal at pH 9.0 (C). ε-*N*-Pyrrolylnorleucine is Peak 5.

without derivatization was fractionated by analytical HPLC (17).

Table 3 shows the Pnl, arginine, and lysine concentrations in hydrolyzed BSA and BSA incubated with EH at pH 7.0. After 24 h incubation, 76% of lysine residues were modified, and approximately 12% of lysine residues were detected as Pnl. The other 64% of modified lysine residues are in part responsible for the changes in Peak 6 (Fig. 5B). A decrease of 34% of arginine residues was also observed by MECC.

For comparison purposes, the loss of amino acids in BSA incubated with EH at pH 7.0 was also determined by HPLC, using a previously described gradient (13) after acid hydrolysis (Table 4). Amino acid composition determined in this way showed some differences in respect to the data found by MECC. First, a smaller decrease in arginine concentration was observed, suggesting that arginine may react with EH to produce a complex or derivative stable to basic hydrolysis but it is partly reversible by acid hydrolysis. In addition, a lower decrease in lysine was also observed that may be due to both a lysine release during acid hydrolysis of some of the lysine/EH products, and the appearance of other derivatives (like Pnl) with the same retention as lysine. Finally, an important decrease in histidine was also observed by HPLC. This could not be corroborated by MECC because histidine appears in Peak 1 and Peak 3, and its concentration may be masked by other amino acids.

TABLE 3
Determination of Pnl, Arg, and Lys in BSA and BSA Incubated with EH at pH 7.0[a]

Amino acid	BSA	BSA/EH	Difference (%)
Pnl	—	1.03 ± 0.06	—
Arg	3.33 ± 0.12	2.20 ± 0.18	−34
Lys	8.39 ± 0.37	2.01 ± 0.23	−76

[a]Values are expressed in μmol of amino acid/mL incubation mixture and represent the mean ± *SD* of four incubation mixtures. Amino acid analysis was determined by MECC after basic hydrolysis and derivatization with diethyl ethoxymethylenemalonate; BSA, bovine serum albumin; EH, 4,5(*E*)-epoxy-2(*E*)-heptenal. See Tables 1 and 2 for other abbreviation.

Determination of Pnl in trout muscle microsomes incubated with EH. Trout muscle microsomes were incubated with 1 or 10 mM EH for 3 h at 37°C, and then subsequently hydrolyzed, derivatized, and analyzed by MECC. Figure 6 shows the electropherograms obtained with control microsomes (A), microsomes incubated with 1 mM EH (B), and microsomes incubated with 10 mM EH (C). Analogously to BSA, the incubation of microsomes with EH produced Pnl (Peak 5), and this corresponded to a decrease in the peak area of lysine. Table 5 shows the Pnl, arginine, and lysine concen-

TABLE 4
Amino Acid Composition of BSA and BSA Incubated with EH at pH 7.0[a]

Amino acid	BSA	BSA/EH	Difference (%)
Aspartic acid	7.48	7.63	+2
Glutamic acid	11.57	11.34	−2
Serine	4.21	4.29	+2
Histidine	2.65	1.88	−29
Glycine	2.45	2.46	0
Threonine	5.11	5.21	+2
Arginine	3.53	2.97	−16
Alanine	6.88	6.90	0
Proline	4.02	3.78	−6
Tyrosine	2.84	2.73	−4
Valine	5.26	5.31	+1
Methionine	0.64	0.65	+2
Cystine	2.55	2.60	+2
Isoleucine	2.18	2.19	0
Leucine	9.10	9.28	+2
Phenylalanine	4.16	4.12	−1
Lysine	8.84	4.86	−45

[a]Values are expressed in μmol of amino acid/mL incubation mixture and represent the mean of two independent incubation mixtures. Amino acid analysis was determined by high-performance liquid chromatography. See Table 3 for other abbreviations.

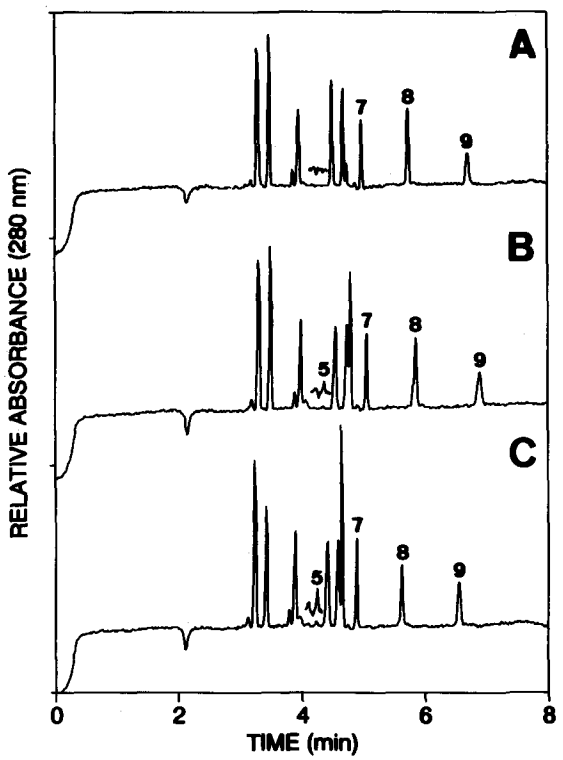

FIG. 6. Electropherograms obtained for amino acid analysis after basic hydrolysis and derivatization of untreated trout microsomes (A), trout microsomes incubated for 3 h with 1 mM 4,5(*E*)-epoxy-2(*E*)-heptenal (B), and trout microsomes incubated for 3 h with 10 mM 4,5(*E*)-epoxy-2(*E*)-heptenal (C). ε-*N*-Pyrrolylnorleucine is Peak 5.

trations determined by MECC. After 3-h incubation in the presence of 1 mM EH, 20% of lysine residues in microsomal proteins were modified and approximately 6% of lysine residues were detected as Pnl. These percentages increased when the incubation was carried out in the presence of a higher concentration of EH. Thus, after 3-h incubation, 34% of lysine residues in microsomal proteins were modified and approximately 11% of lysine residues were detected as Pnl. Analogously to BSA, some changes were also observed in Peak 6 (Fig. 6). However, no changes in arginine residue were observed.

TABLE 5
Determination of Pnl, Arg, and Lys in Trout Muscle Microsomes Incubated for 3 h at 37°C in the Presence, or Not (control), of 1 and 10 mM EH[a]

Amino acid	Control	1 mM EH	10 mM EH
Pnl	—	6.1 ± 2.3	10.3 ± 1.4
Arg	65.3 ± 3.7	64.5 ± 1.3	67.5 ± 1.8
Lys	69.3 ± 3.9	55.8 ± 1.2	45.6 ± 3.1

[a]Values are expressed in ng of amino acid/μg of protein, and represent the mean ± SD of five experiments. Amino acid analysis was determined by MECC after basic hydrolysis and derivatization with diethyl ethoxymethylenemalonate. See Tables 1, 2, and 3 for abbreviations.

DISCUSSION

Analogously to its reaction with lysine (10), the results obtained in this study show that EH reacts with protein amino groups, producing a decrease in the basic amino acids recovered after acid or basic hydrolysis. A part of lysine residues were transformed into Pnl, a new amino acid that was previously characterized in the reaction between EH and lysine (10). This study proposes a method to determine this amino acid that can be applied to proteins damaged by their reaction with oxidized lipids. The method is based on the basic hydrolysis of the protein and derivatization of the resulting amino acids with DEEMM. This analysis by capillary electrophoresis takes only 8 min, and Pnl can be easily detected and quantified.

The method has been applied to the study of the *in vitro* damage suffered by trout muscle microsomes and BSA incubated for different times and in the presence of several concentrations of EH. The results obtained show that the decrease in lysine recovered after basic hydrolysis depended on the concentration of EH and the incubation time. Thus incubation of trout muscle microsomes for 3 h at 37°C in the presence of 1 mM EH decreased by 20% the lysine resides recovered after basic hydrolysis, and this loss increased to 34% when the reaction was carried out in the presence of 10 mM EH. The proportion of lysine residues that were transformed into Pnl was constant at the two concentrations assayed. About 30% of these modified lysine residues were detected as Pnl. Part of the other 70% might have been converted, in a first step, into 1-(5′-amino-5′-carboxypentyl)-2-(1″-hydroxypropyl)pyrrole, and, lately, into the macromolecular fluorescent substances derived from polymerization of this latter compound (9,10).

When the study was carried out with BSA using 30 mM EH and 24-h incubation, the percentage of modified lysine residues increased to 76%. However, the percentage of these

residues that was detected as Pnl decreased to 16%, suggesting that very high concentrations of EH or very long incubation times, favored reactions other than Pnl formation. These results are in agreement with previous studies on EH/lysine reaction mechanism (17).

Differently to lysine, arginine residues recovered after basic hydrolysis were unmodified in the treatments assayed with muscle microsomes, but not when the reaction was carried out with BSA, suggesting that modification of this amino acid is more difficult than modification of lysine, and higher incubation times or higher concentrations of EH are needed.

In spite of the importance given to the problem of *in vivo* oxidative stress, which has been related to the development of several chronic and acute diseases, no absolute and definitive index has yet been discovered (18). This is probably due to the complexity of the problem. It involves many different processes and it is very difficult to find only one biomarker that is related to all these processes. One approximation to this problem may be the measurement of one of the products from one of the processes involved, and to try to demonstrate that a change in this measurement is related to a change in the overall oxidative stress, or with the development of the related diseases. Thus, for example, the measurement of volatile pentane or ethane has been proposed, among others (19,20).

The results obtained in this study propose a method to determine an amino acid that may be produced during oxidative stress. It is based on Pnl, an amino acid that has been shown to be produced in BSA and trout microsomes when free amino groups of their lysine residues react with the lipid peroxidation product EH, and, therefore, their formation might be related to the conditions that produce lipid peroxidation. Additional studies are needed to detect the presence of Pnl in *in vivo* oxidatively-modified proteins, and to establish a relationship, if any, between Pnl concentration and oxidative stress.

ABSTRACT: The effects of natural mixed diets on lipid peroxidation were investigated in humans. In the first study, 59 subjects were fed a rapeseed oil-based diet rich in monounsaturated fatty acids (MUFA) and a sunflower oil-based diet rich in polyunsaturated fatty acids (PUFA) in a cross-over manner for three and a half weeks. The lipid peroxidation products in plasma were determined by measuring conjugated dienes and malondialdehyde (MDA). In a second study, plasma thiobarbituric acid reactive substances (TBARS), lipid hydroperoxides, and the susceptibility of very low density lipoprotein + low-density lipoprotein (LDL) to *in vitro* oxidation were measured from subjects fed similar MUFA and PUFA diets for six week diets. No significant differences in plasma MDA or conjugated diene concentrations were found after the rapeseed oil diet or the sunflower oil diet in Study 1. In the second study, a small but significant decrease ($P < 0.05$) in both lipid hydroperoxides and TBARS was observed in the LDL fraction after the sunflower oil diet. The *in vitro* oxidation gave opposite results, showing increased oxidation after the sunflower oil diet. Despite a high intake of α-tocopherol during the oil periods, no increase in plasma α-tocopherol was noticed in either study. The results suggest that moderate changes in the fatty acid composition in the Western-type diet may be adequate to affect lipoprotein susceptibility to oxidation *in vitro*, but there is considerable disparity with some indices of *in vivo* lipid peroxidation.
Lipids 30, 485–492 (1995).

Increased lipid peroxidation is thought to be involved in a wide variety of clinical diseases and toxicological conditions, including atherosclerosis, diabetes mellitus, cancer, rheumatoid arthritis, and toxicity induced by certain metals, drugs, and pesticides (for review, see Ref. 1). Recently, evidence suggesting lipid peroxidation in human plasma lipoproteins *in vivo* has been presented (2). The composition of cellular membranes and also lipoprotein fatty acids reflects the type of dietary fat (3), and it is frequently assumed that there is a relationship between dietary fat type and tissue susceptibility to lipid peroxidation initiated by oxidative stress. Oxidative stress and subsequent lipid peroxidation *in vivo* may partly depend on the balance between prooxidants (some metals) and antioxidants [vitamin E, ß-carotene, ascorbate, glutathione peroxidase (GHSPx)(4)] in tissues. In animal studies, lipid peroxidation has been shown to differ when the type of dietary fat was changed (5). The amount of lipid peroxidation is largely dependent on the amount of antioxidants, especially vitamin E, in the diet (6–8).

It is not yet established whether dietary fatty acids affect lipid peroxidation in humans consuming an ordinary Western-type diet. In a recent study of 37 men, plasma thiobarbituric acid reactive substances (TBARS) decreased in those on a diet with a higher content of polyunsaturated fatty acids (PUFA) as compared to those on a low-fat diet with lesser amounts of PUFA (9). Generation of conjugated dienes in low-density lipoprotein (LDL) *in vitro*, however, was significantly depressed after consuming a high oleic acid diet as compared to a high linoleic acid diet (10,11). Also, linoleic acid supplementation in humans has led to an increased susceptibility of LDL to *in vitro* oxidation (11,12).

In the present paper, we describe two studies on humans attempting to examine dietary effects on lipid peroxidation. First, we examined the effects of mixed diets of highly different fatty acid composition on plasma lipid peroxidation products and plasma glutathione concentration in healthy men and women in a strictly controlled cross-over design. In the second study, the amounts of TBARS and lipid hydroperoxides

in plasma lipoprotein fractions, and the susceptibility of very low density lipoprotein (VLDL) + LDL to *in vitro*-induced oxidation, were measured after high linoleic or oleic acid diets in 6–7 healthy men.

METHODS

Both studies were approved by the Human Ethical Committee of the Faculty of Forestry and Agriculture at the University of Helsinki (Helsinki, Finland).

Subjects and design of Study 1. Fifty-nine (30 female, 29 male) healthy, normotensive, nonsmoking volunteers entered the first study after giving informed consent. The participants were mainly university students and employees (average age 30 yr, range 18–60 yr) having a normal body mass index of 22.3 ± 2.5 kg/m^2 (mean ± SD). The participants continued their normal activities during the study period.

A detailed description of the study design has been reported (13). The study was performed over three consecutive periods: during the first 14 d, subjects were given a milk fat-based (saturated fat) diet, after which 30 subjects were given a sunflower oil-based (PUFA) diet for 24 d and then a low erucic acid rapeseed oil-based [monounsaturated fatty acids (MUFA)] diet for 24 d. The other 29 subjects had the sunflower oil and the rapeseed oil diets for 24 d each in reverse order. The subjects were aware that they were being given milk fat diet during the first 14 d, but they were unable to determine the order of the oil diets.

The experimental diets contained mixed solid foods customary in the Finnish diet covering about 90% of the energy intake per day. In addition to the food supplied, the subjects were allowed to choose 10% of their daily energy intake from foods free of fat and cholesterol (candies, fruit, beer, etc.). The subjects recorded these foods in their diaries. The diets were planned to have the same energy, total fat, cholesterol, and nutrient content throughout the dietary periods. The differences between the diets were solely in their fatty acid composition (Table 1). The figures are based on chemical analyses of the daily collected duplicate portions in addition to the calculated contribution from the freely chosen foods. The test oils were included in the diets in special margarines, bread, salad dressing, ice cream, buns, pies, cakes, and pancakes. The food for each subject was weighed according to energy intake and adjusted to maintain the actual body weight of the subject throughout the study. The subjects ate lunch at the University premises on working days. Foods for the rest of the day and next morning and for weekends were packed and given to the subjects on Fridays.

Subjects and design of Study 2. In the second study, 13 healthy normotensive, nonsmoking, male volunteers (average age 29 yr, range 21–36 yr) were divided into two groups after giving their informed consent. Seven subjects were fed a high oleic acid rapeseed oil diet, and six subjects a high linoleic acid sunflowerseed oil diet for six weeks in a parallel manner. Approximately 50 g of test oil/day as margarine, salad dressing, cooking oil, oil-enriched bread, cakes, and cookies baked using the test fats were included in normal mixed diets. Fatty fish and fish oil were excluded from the diets. Dietary records were kept by the subjects before the study for three days and for seven days during the six-week study period. The nutrient composition (Table 2) is based on the calculated composition of the diets. The percentage of energy (en%) obtained from MUFA and PUFA in the rapeseed and sunflowerseed oil diets were 18.3 and 9.0, and 12.1 and 15.6, respectively, and the amount of saturated fatty acids was practically the same (12.5 and 12.0 en%). The subjects were asked to continue their normal activities during the study period. Dietary compliance was checked with food records, food disappearance inventory, and plasma fatty acids.

Blood sampling. In the first study, blood was taken from overnight fasted subjects into EDTA (0.1 mL/10 mL; 3.8 mmol/L) by venipuncture once during the last week of each period (baseline milk fat diet, rapeseed oil diet, and sunflower oil diet). The blood samples were centrifuged at 1000 × *g* for 10 min, and plasma was separated within 1 h after venipuncture. Aliquots of the samples with butylated hydroxytoluene (BHT; 1 mmol/L) were quickly frozen to −70°C.

During the second study, blood was taken twice, before

[a]HABSO, habitual diet before sunflower oil diet; SO, sunflower oil diet; HABRO, habitual diet before rapeseed oil diet; RO, rapeseed oil diet; en%, percent of energy. Other abbreviations as in Table 1.
[b]The ratio between polyunsaturated fatty acids and saturated fatty acids.

and at the end of the six-week oil supplementation, into EDTA (0.1 mL/10 mL; 3.8 mmol/L). Plasma was separated as described previously, and the samples were kept at 4°C until the lipoprotein fractions were separated. Separation of different lipoprotein fractions was carried out within 48 h of the venipuncture.

Measurement of plasma malondialdehyde (MDA). MDA was analyzed spectrophotometrically in protein-free plasma and by high-performance liquid chromatography (HPLC) with fluorometric detection in plasma lipid fractions.

Spectrophotometric detection of MDA. The spectrophotometric detection of MDA was based on determination of MDA as a thiobarbituric acid (TBA)–MDA adduct after protein precipitation (14). Two mL of TBA-solution (0.67% glacial acetic acid/water, 50:50, vol/vol), 0.28 mL of BHT (1.0 mM final concentration), and 0.07 mL $FeCl_3$ (0.25 mM final concentration) were added to clear supernatant (0.5 mL), and the samples were heated for 60 min at 100°C, cooled, and centrifuged at 25°C 12000 × *g* for 15 min. MDA was detected at 532 nm. MDA-*bis*-(diethylacetal) standards (from 0.49 to 3.95 μmol/L) were prepared daily.

HPLC–fluorometric detection of MDA. Plasma samples with lipid extraction and HPLC separation of the TBA–MDA adduct were analyzed with a slight modification from the method of Wade and van Rij (15). MDA-*bis*-(diethylacetal) (Merck, Schuchardt, Germany) was used as a standard instead of 1,1,3,3-tetraethoxypropane. The standards (0.49, 0.99, 1.98, and 2.97 μmol MDA/L) were prepared daily. All the samples from each subject were analyzed on the same day with an internal standard (serum pool) to eliminate within-series variation.

After hexane/isopropanol (2:3, vol/vol; 5.0 mL) extraction, plasma samples were centrifuged (200 × *g* for 15 min), and 2.5 mL of the supernatant was separated and dried under nitrogen using a 30°C waterbath. Triton X-100 (10%; 0.1 mL), acetic acid (50%; 0.5 mL), TBA (0.67% in glacial acetic acid/water, 50:50, 1.0 mL), BHT (0.1 M; 50 μL), and $FeCl_3$ (0.01 M; 50 μL) were added in this order to the dried samples. The final concentrations of $FeCl_3$ and BHT were 0.25 and 1.0 mM, respectively. $FeCl_3$ was used to stimulate the degradation of all lipid hydroperoxides to MDA (15). BHT was added just before the iron to prevent the peroxidation of intact fatty acids. The samples were heated at 100°C for 60 min, cooled and, after addition of 2 mL of 2% NaCl, the TBA–MDA adduct was extracted to 1.5 mL of *n*-buthanol (BuOH). Samples were centrifuged (5 min 200 × *g*), and fluorometric detection of TBA–MDA complex was made on the BuOH supernatant (excitation 515 nm/emission 553 nm). The chromatographic column used was a self-made RP18 Lichrosorb 9333 (150 mm; 5 μm particle diameter), and the mobile phase was MeOH/acetic acid 50 mM/L (80:20), pH 5 (flow rate 0, 75 mL/min).

Measurement of conjugated dienes. Conjugated dienes were measured spectrophotometrically from plasma. After lipid extraction with hexane/isopropanol (3:4, vol/vol), the samples were centrifuged for 10 min at 200 × *g* and the absorbance was measured at 235 nm. The final concentration of conjugated dienes was calculated using the molar absorbance for conjugated dienes (27,000 $M^{-1}cm^{-1}$) (8).

Total GSH measurement. GSH was measured using the method of Saville (16) and modified by Heinonen and Vainio (17). Briefly, plasma (0.1 mL) was mixed with 0.2 mL of 10 mM *bis*(3-carboxy-4-nitrophenyl)disulfide and centrifuged for 6 min at 2000 × *g*. Oxidized GSSG and reduced NADPH were added to the supernatant, and the absorbance was measured at 412 nm.

Separation of lipoprotein fractions. Lipoprotein fractions were separated in the second study by gel permeation chro-

matography using an application (18) from the general scheme (19) with one ultracentrifugation step (50.4 Ti rotor, Beckman XL-90; Beckman Instruments, Palo Alto, CA) and gel chromatography on modified agarose columns. The total lipoproteins were prepared by adding solid potassium bromide to 6 mL of plasma to obtain the required density of 1.22 g/mL (20) and centrifuging the sample in Beckman polyallomer tubes for 23 h at 218,000 × *g* and 10°C. The removed lipoprotein fraction was concentrated at +4°C (Centricon miniconcentrators; Amicon, Danvers, MA), with a cut-off at 10^5 daltons. The filtered samples (0.2 μm) were injected into the gel chromatographic column. A fast protein liquid chromatographic system at +10°C was used. Samples were introduced *via* a P-1 peristaltic pump and an MV-7 motor valve (Pharmacia, Uppsala, Sweden) with a 500 μL loop. Two Superose 6 (Pharmacia) columns were used in series for the separation of the lipoprotein fractions. The mobile phase consisted of sodium phosphate buffer with 1 mM EDTA and 0.02% NaN_3 (pH 7.2). The elution of lipoproteins was monitored at 280 nm.

The TBARS in lipoprotein fractions were measured fluorometrically (21) directly on 1 mL of sample mixed with 600 μL of 40% trichloroacetic acid and 1 mL of 0.8% TBA without any sample pretreatment. The method was calibrated using 1,1,3,3-tetraethoxypropane as a standard. The protein content of the lipoprotein fractions was measured as described previously (18).

Tri-iodide test for the determination of lipid hydroperoxides. Lipoprotein fraction lipid hydroperoxides were measured spectrophotometrically at 365 nm (22,23). Two hundred μL of 3% acetic acid and 50 μL of 1 mmol/L I_2 solution were added to a 300 μL aliquot of the lipoprotein sample (adjusted to 0.025 mg protein/mL), and the mixture was incubated for 10 min at room temperature. A color reagent (500 μL, CHOD-iodide, Cat. no. 14106; Merck, Darmstadt, Germany) was added, and after 1 h of incubation at room temperature the reaction was stopped by adding 200 μL of 7% Nonidet P40 (BDH, Poole, England). Hydrogen peroxide (50 μmol/L) was used as a standard in every run, together with samples. A sample blank was prepared for every sample by adding Nonidet P40 to the reaction mixture before the color reagent.

Copper-induced oxidation of the VLDL + LDL fraction. Combined VLDL and LDL were isolated by ultracentrifugation in a Beckman XL-90 ultracentrifuge for 23 h at 4°C in a potassium bromide gradient containing 0.2 mmol/L of EDTA. The top layer from the tube (<1.063 g/mL density) was collected with a pipette and assayed immediately. EDTA and other salts were removed from the VLDL + LDL fraction by using PD-10 columns (Pharmacia). VLDL + LDL was diluted to 1.5 mL with phosphate-buffered saline (PBS; 0.16 M sodium chloride, 0.01 M sodium phosphate, pH 7.4), poured into the column and eluted with PBS. The first 0.8 mL was discarded, and the next 1.6 mL was collected. VLDL + LDL was diluted with oxygen-saturated PBS to a protein concentration of 0.05 mg/mL. The reaction was started by adding 33.5 μL of 0.1 mM $CuCl_2$ to 2 mL of diluted VLDL + LDL fraction and followed at 37°C by a temperature-controlled spectrophotometer with an enzyme kinetic data system (Hitachi U-2000; Hitachi, Tokyo, Japan) for 3 h. The measurement wavelength was 234 nm. Maximum oxidation velocity (V_{max}), the time from the start of the reaction to the steepest slope (lag time), the maximum absorbance of oxidation, and the time for maximum absorbance was computed from the reaction curve.

Statistical analysis. Statistical analysis of the data from the spectrophotometric TBA method with protein precipitation (Study 1) was based on the model of univariate analysis of variance taking repeated measurements into account (2 × 2 cross-over trial)(24,25). The factors studied were carry-over effect (any possible carry-over effect from one oil diet to another), period effect, and treatment effect. No evidence was found to suggest a carry-over effect between the diet treatment sequences. The data from the HPLC–fluorometric TBA method and from the conjugated dienes was analyzed using Student's *t*-test for paired data, comparing the different dietary periods. The effects of age and sex were also studied using Student's *t*-test for paired data and one-tailed analysis of variance. The results of *in vitro*-induced oxidation, TBARS, and lipid hydroperoxides were tested with the unpaired Wilcoxon Signed Rank test (Study 2). A carry-over effect between the diet treatment sequences was found when analyzing the GSH data, and the data for the two groups could not be combined.

RESULTS

The first study was strictly controlled, and therefore it was possible to obtain a great difference in the fatty acid composition of the diets in three periods (Table 1). In the baseline milk fat period, nearly 19 en% was from saturated fatty acids and only 3.2 en% from linoleic acid. During the two oil periods, less than 13 en% originated from the saturates. During the sunflower oil period, 13.3 en% was covered by polyunsaturates and 10.2 en% by monounsaturates. The respective figures in the rapeseed oil period were 7.6 and 16.2 en%. The analyzed nutritional values from duplicate portion analysis came very close to the calculated values (95–98% for total fat in the three diets, 92–95% for saturated fat, 95–98% for MUFA, 95–99% for PUFA, and 73–81% for cholesterol). Dietary compliance was evaluated by monitoring the ratio of oleic (18:1n-9) to linoleic (18:2n-6) acid in the plasma phospholipids. The mean ratio was 0.49 ± 0.07 at the end of the saturated baseline diet and was reduced to 0.27 ± 0.04 during the sunflower oil diet ($P < 0.001$) and increased to 0.56 ± 0.07 during the rapeseed oil diet ($P < 0.01$). No significant differences between the oil periods were found in the plasma concentrations of either MDA or conjugated dienes. After the monounsaturated rapeseed oil period, the plasma level of spectrophotometrically detected MDA was lower than the amount of MDA in the baseline milk fat period ($P < 0.01$, Table 3). Vitamin E intake was very high (27.2 mg/d according to duplicate portion analysis) when the subjects were on

TABLE 3
Mean (SD) Plasma Lipid Peroxidation [malondialdehyde (MDA) and conjugated dienes] and GSH Levels in the First Study

	Baseline diet milk fat	Sunflower oil diet	Rapeseed oil diet
MDA μmol/L, method 1[a]	1.13 (0.41) n = 19	1.11 (0.39) n = 28	1.11 (0.30) n = 28
MDA μmol/L, method 2[a]	7.52 (3.66) n = 53	7.25 (2.94) n = 53	6.29 (3.05) n = 57[b]
Conjugated dienes μmol/L	5.21 (1.69) n = 17	6.03 (2.70) n = 12	4.79 (2.43) n = 24
Glutathione μmol/L, group 1	1.49 (0.23) n = 30	1.49 (0.26) n = 30	
Glutathione μmol/L, group 2	1.79 (0.32) n = 28		1.65 (0.34) n = 28[c]

[b]Significant difference between baseline diet and rapeseed oil diet: $P = 0.007$.
[c]Significant difference between baseline diet and rapeseed oil diet: $P = 0.01$.

the sunflower oil diet and the intake was also well above recommendations during the rapeseed oil diet (Table 1). Plasma α-tocopherol increased from 4.8 to 6.35 mg/L during the rapeseed oil diet, but no significant changes were observed during the sunflower oil diet (after milk fat diet vs. after sunflower oil diet; 6.4 ± 1.5 vs. 6.9 ± 1.6 mg/L). When taking the initial concentrations into account, the difference between the diets was not significant. The ratio of plasma α-tocopherol/LDL was also calculated, and a significant increase was observed after both diets (milk fat vs. PUFA diet; 4.7 ± 1.0 vs. 6.0 ± 2.0, $P < 0.05$; milk fat vs. MUFA diet; 4.8 ± 1.5 vs. 7.0 ± 1.6, $P < 0.001$).

GSH results could be analyzed only for the first dietary treatment period (half of the subjects), because of a carry-over effect found (Table 3). Sunflower oil diet (1.49 ± 0.26 μmol/L) had no effect on GSH values as compared to baseline milk fat diet (1.49 ± 0.23 μmol/L, group 1), whereas the initially higher baseline values (1.79 ± 0.32 μmol/L) of group 2 were significantly decreased by the rapeseed oil diet (1.65 ± 0.34 μmol/L, $P < 0.05$).

Considerable differences between the intakes of MUFA and PUFA were achieved in the second study (Table 2). Several methods were used to check the compliance of the subjects. The nutrient intake from food records showed at group level that the experimental fats and foods had been used. In accordance with the food record data, the food disappearance inventory reflected an 85% compliance to the test food intake on average. Also, the proportion of α-linolenic acid in plasma cholesterol esters increased from 0.9 to 1.2% by the rapeseed oil diet and decreased from 0.9 to 0.4% by the sunflower oil diet ($P < 0.001$ at the end of the test periods), all showing a good compliance to the diets.

The amounts of TBARS and lipid hydroperoxides were measured in VLDL, intermediate-density lipoprotein, LDL, and high-density lipoprotein fractions. Small but significant differences between the treatments ($P < 0.05$) were found

TABLE 4

only in the LDL fraction (Table 4). The change in the production of lipid hydroperoxides was −412 ± 291 μmol/g for the sunflower oil period and −131 ± 170 μmol/g for the rapeseed oil period. The respective figures for plasma TBARS were −0.25 ± 0.46 μmol/g and 0.04 ± 0.10 μmol/g. The *in vitro* Cu^{2+}-induced oxidation of VLDL + LDL gave very different results. The lag time and time to maximum oxidation decreased during the sunflower oil diet and increased during the rapeseed oil diet. The differences for the changes between diets were significant ($P < 0.01$ for lag time and $P < 0.05$ for time to maximum oxidation). The oxidation velocity increased during the sunflower oil diet and slightly decreased during the rapeseed oil diet ($P = 0.032$ for significance between diets). The maximum absorbance in Cu^{2+}-induced oxidation did not change significantly during either diet. There were no significant differences in plasma concentrations of α-tocopherol between the polyunsaturated (baseline vs. intervention; 8.58 ± 3.24 vs. 7.89 ± 1.00 mg/L) and monounsaturated (8.79 ± 1.33 vs. 7.67 ± 1.01 mg/L) study groups. No changes were observed in the plasma α-tocopherol/LDL ratio after the MUFA diet (baseline vs. intervention; 8.7 ± 0.8 vs. 10.7 ± 4.0, $P = 0.230$) or the PUFA diet (baseline vs. intervention; 6.8 ± 2.5 vs. 7.1 ± 1.7, $P = 0.831$).

DISCUSSION

The purpose of our controlled diet study was to evaluate the effects of PUFA and MUFA diets on plasma lipid peroxidation levels, when consumed in amounts practical for mixed diets. The very different fatty acid composition of the oil diets had, however, no marked effects on the indicators of lipid peroxidation used in the first study. In the rapeseed oil diet group, however, less MDA was present when measured by the spectrophotometric method. The aim of our second study was to find out if these types of diets have any special effect on the *in vitro*-induced oxidation of LDL or on the levels of TBARS or lipid hydroperoxides in lipoprotein fractions. The results of lipoprotein oxidation resistance, TBARS, and lipid hydroperoxides are rather controversial. TBARS and lipid hydroperoxides measured by the tri-iodide test from lipoprotein fractions indicate that dietary PUFA do not increase the content of oxidation products in plasma lipoproteins. On the contrary, the results from Cu^{2+}-induced oxidation resulted in three of four parameters that the PUFA diet significantly decreased the oxidation resistance of lipoproteins.

There are only two strictly controlled human studies where normal foods have been used as components of experimental diets. In a study from Israel, a PUFA diet induced a significantly higher tendency toward plasma lipid peroxidation (as ascertained by more TBARS formed) compared with a MUFA diet (26). However, moderate amounts of PUFA (7.9 en%) decreased plasma TBARS as compared to a low-fat diet with a low content of polyunsaturates (3.2 en%) in free-living Finnish men (9). The TBARS results of our second experiment are in line with the latter results and also with those obtained from healthy subjects showing a negative correlation between serum MDA concentration and the lipoprotein linoleic acid content (27). It is known, however, that plasma MDA is largely generated by platelet aggregation during *ex vivo* clot formation, and so is unlikely to reflect lipid peroxidation *in vivo* (28).

In several recent studies, the effects of different fatty acids on the *in vitro* oxidation of LDL have been studied. Either liquid diets or oil supplements have been used as sources of the fatty acids under investigation, so these diets cannot be referred to as diets of normal, healthy, free-living humans. No difference in the susceptibility to oxidation has been found between fish oil (1 g n-3 fatty acids/day) and corn oil supplemented diets (29) or after a diet rich in *trans* fatty acids (7 en%)(30). Our results from Study 2 are in line with two other studies where oleate-rich diets (28.7 and 16.8 en% monounsaturated as compared to 12.1–18.3 en% in our study) have decreased and linoleate-rich diets (50.9 and 12.2 en% of PUFA as compared to 9.0–15.6 en% in our study) have increased the *in vitro* oxidability of LDL measured as in the production of conjugated dienes (3,11).

It is widely assumed that LDL particles rich in PUFA should be more readily oxidized than those with less unsaturated fatty acids. *In vivo* antioxidant availability may be an even more important factor than substrate in the potential oxidation of PUFA (11). As shown in Table 1, the intake of vitamin E increased considerably with the intake of PUFA. The ratio of vitamin E/PUFA intake, however, was actually fairly constant within diets (1.8–2.2 in Study 1 and 2.0–3.2 in Study 2). No change in plasma α-tocopherol content was noticed after the diets in either study, indicating higher endogenous consumption of vitamin E during the high vitamin E sunflower oil diets. Some animal (7,11) and human (31,32) experiments using high PUFA fish oils with different amounts of vitamin E support this assumption. In line with this, the urinary excretion of MDA decreased when a high level of antioxidants (vitamin E and C, BHT) was fed to rats (33). A significant increase in the ratio α-tocopherol/LDL was observed after both diets in Study 1, but not in Study 2. This may be partly explained by a higher interindividual variation in dietary and plasma α-tocopherol in Study 2, due to a less strict study design. The decrease in LDL cholesterol was also higher in Study 1 (on average 22%) than in Study 2 (on average 18%).

As the substrate for GSHPx, reduced GSH effectively protects tissues and cellular constituents from the damaging effects of hydroperoxides formed during normal metabolism. Decreased plasma and tissue GSH concentrations or increased GSHPx concentrations have been associated with cell damage (34), depressed immunity (35), lipid peroxidation (36), and the progression of aging (37). Although the decrease in plasma GSH following the monounsaturated rapeseed oil diet in our first experiment was quite small, it may indicate increased GSH consumption and elevated oxidative stress. It is worth emphasizing that the initial GSH level was clearly higher in group 2 (having rapeseed oil diet) when compared to group 1 (having sunflower oil in their diet), and in spite of a significant decrease during the rapeseed oil period the

plasma GSH level did not reach the level found in the sunflower oil group.

The other purpose of our studies was to compare different methods for measuring lipid peroxidation. It seems that the amount of lipid peroxidation in human blood plasma and lipoproteins varies greatly depending on the method used (Table 3). The highly different results obtained with different methods can partly be attributed to the fact that lipid peroxidation was measured in different phases of the chain reaction. Conjugated dienes are formed during the rearrangement of double bonds in fatty acids after hydrogen atom abstraction by a free radical. Conjugated dienes are therefore formed when peroxidation begins. However, only fatty acids with three or more double bonds produce MDA as an end product. The sensitivity of these methods is obviously not the reason for not detecting any differences in lipid peroxidation, as the detection limit of these methods is picomoles per liter, e.g., 8.3 pmol for the fluorometric method (38).

Plasma MDA (1.11–1.13 μmol/L) was easily detected with the HPLC–fluorometric method as it was the only compound at the wavelengths used. The results were also quite consistent with the latest results from other studies (14,38). Interestingly, in this study the HPLC method gave slightly, but not significantly, lower mean plasma MDA concentrations for men than for women (data not shown), contrary to results obtained by Knight *et al.* (39). This may be partly explained by slightly, but not significantly lower serum total and LDL cholesterol of men in this study. Knight *et al.* (39) also observed that the plasma concentration of MDA rose with age. In this study, the women were slightly older than the men (32.8 ± 14.1 vs. 27.9 ± 9.0 yr). There was no correlation between age and plasma MDA in different dietary periods (r = –0.096–0.253). A weak correlation (r = 0.275) between age and the concentration of conjugated dienes in human serum has been found by Fink *et al.* (40).

The protein-free plasma samples with spectrophotometric detection gave 6–7 times higher MDA values (6.3–7.9 μmol/L) than those obtained with fluorometric detection. The reproducibility of the spectrophotometric method, which was quite poor [coefficient of variation (CV) was 18% and day-to-day variation 8.7%], may partly explain the unexpected result obtained between habitual milk fat diet and rapeseed oil diet obtained with this method (Table 3). Various other compounds react with TBA and/or MDA, and the varying concentrations of these compounds or varying degrees of *ex vivo* artifact were obviously the reason for the variance found in the results. The Fe^{3+} concentration of samples markedly affects the results and the amount of MDA in samples by stimulating the peroxidation and degradation of lipids and lipid hydroperoxides. Fe^{3+} is normally bound in the body, but conditions in which the bound Fe^{3+} is released may, however, occur in healthy humans as a result of normal metabolism in exercising muscles or hypoxic tissues when the pH falls under 6 (1). The Fe^{3+} concentration may therefore vary from subject to subject. This was, however, taken into account by adding a sufficiently high amount of Fe^{3+} (14).

The concentration of conjugated dienes, 4.79–6.03 μmol/L, fell within the results obtained with the two other methods. The precision of this method was quite good, CV being only 2.1%. The measurement of conjugated dienes is a simple and quick method and suitable for routine analysis. However, methods for the determination of conjugated dienes do not discriminate between those arising from lipid peroxidation and those from dietary sources, e.g., cow's milk, lard, and pork fat (41). Therefore, dietary conjugated dienes may raise plasma concentrations during the milk fat diet. Despite this, a tendency for the highest concentration of conjugated dienes was found after the sunflower oil period, which is in accordance with the theory that diene conjugation in humans is associated mainly with the metabolism of linoleic acid (42). Plasma conjugated dienes have been measured in only a few human studies. Fink *et al.* (40) studied healthy controls and patients with various diseases. Using an HPLC-based method for determining the main diene conjugated derivative of linoleic acid [18:2(9,11)], the molar concentration in healthy humans was 18.3 ± 5.8 μmol/L in men and 23.6 ± 6.9 μmol/L in women. The concentration for healthy subjects is, however, 3–4 times higher than we observed, possibly due to methodological differences or higher mean age of subjects.

The day-to-day CV for the determination of TBARS from lipoprotein fractions was 7.8% (n = 6). Although the CV for lipid hydroperoxides by tri-iodide test was worse (15.6%), both methods gave the same significance between sunflower oil and rapeseed oil groups (Table 4). The lipoprotein fractions for the analysis of TBARS, lipid hydroperoxides, and *in vitro* oxidation were separated within 48 h after sampling, and the fractions were stored frozen. Both samples (before and after diet) of a subject were analyzed in the same batch after the study in order to reduce the variation of the results.

In conclusion, the discrepancy between the results with different methods in Study 2 (TBARS, lipid hydroperoxides, *in vitro* oxidation) shows very clearly the methodological difficulties of lipid peroxidation measurements and their extrapolation to the *in vivo* situation. The measurement of plasma TBARS has been widely criticized and partly replaced by the method of *in vitro* oxidation of LDL, but information obtained by the latter method is of uncertain relevance to atherogenesis. Our results using the latter method agree well with those from other supplementation studies with similar fatty acid contents. These results also suggest that moderate changes in mixed diets may be adequate to affect the susceptibility of lipoproteins to oxidation. Further work will be needed, however, to establish whether any relationship exists between a tendency to chemical oxidation *in vitro* and disease processes associated with *in vivo* lipid peroxidation.

ACKNOWLEDGMENTS

We thank Marina Heinonen, D.Sc., for analyzing diet samples for vitamin A and E. The work was supported by grants from the Academy of Finland, the Finnish Cultural Foundation, the Food Research

Foundation, the Sigrid Juselius Foundation, the Ministry of Agriculture and Forestry, and the Yrjö Jahnsson Foundation. The test fats and some of the foods were kindly supplied by the Finnish food industry.

9-*cis* β-Carotene in Human Plasma and Blood Cells After Ingestion of β-Carotene

Hiroshi Tamai*, Takao Morinobu, Takuji Murata, Mitsuhiro Manago and Makoto Mino

Department of Pediatrics, Osaka Medical College, Takatsuki, Osaka 569, Japan

ABSTRACT: For 44 wk, thirty male volunteers were given daily either 60 mg of synthesized all-*trans* β-carotene, a naturally-occurring β-carotene derived from *Dunaliella bardawil*, or a placebo. Basal levels of 9-*cis* β-carotene in plasma, platelets, and mononuclear cells were 10, 20, and 25% of those of the all-*trans* form, respectively. The plasma levels reached a maximum after two weeks of administration and plateaued thereafter in the subjects who took the β-carotene preparations. The all-*trans* β-carotene level in the subjects given the synthesized all-*trans* form was almost twice that for the *Dunaliella* preparation. The plasma 9-*cis* level was found to be higher in the all-*trans* β-carotene group than in the *Dunaliella* group, despite no intake of the 9-*cis* form in the all-*trans* group and the higher intake of the 9-*cis* form in the *Dunaliella* group. This finding suggests that isomerization of the all-*trans* form to the 9-*cis* form may occur in the body either during or after absorption.
Lipids 30, 493–498 (1995).

Naturally-occurring carotenoids have recently attracted much attention, due to extensive epidemiological evidence and intervention studies which indicate their potential usefulness in cancer prevention (1,2). However, little is known about the metabolism of β-carotene, the most potent precursor of vitamin A, contained in significant amounts in fruit and vegetables. The halotolerant alga *Dunaliella bardawil* and the closely related species *D. salina* have the unique capacity to accumulate naturally-occurring β-carotenes intracellularly, especially all-*trans* β-carotene and 9-*cis* β-carotene. With respect to bioavailability of the naturally-occurring β-carotenes, a few investigations have shown that all-*trans* β-carotene is predominant in human plasma (3–5), whereas only a small amount of the geometrical isomers of all-*trans* β-carotene is found, even if a large amount of β-carotene isomer derived from alga has been taken orally (6-8). Little is known about the absorption of 9-*cis* β-carotene, which is the second most predominant form contained in the alga. It is not clear whether the 9-*cis* isomer is converted to the other stereoisomers during ingestion and absorption, or whether it is directly stored in specific tissues, but not in plasma. In this paper, we investigate changes in stereoisomers of β-carotene in plasma and in blood cells of healthy human subjects after ingesting either naturally-occurring β-carotene derived from *D. bardawil* or a synthesized all-*trans* β-carotene preparation.

MATERIALS AND METHODS

Subjects and β-carotene intake. Thirty male volunteers, aged 20–25 years old, were given either 60 mg of a synthesized all-*trans* β-carotene (kindly provided by Nippon Roche K.K., Tokyo, Japan), 60 mg of a naturally-occurring β-carotene derived from *D. bardawil* (Nikken Sohonsha Corporation, Gifu, Japan), or an identical placebo. The preparations were taken orally every morning immediately after breakfast for 44 wk. None of the subjects took any other vitamin supplements or medications before or during the study. The study was performed in a single blind manner. The study protocol was approved by the ethics committee of the hospital, and informed consent was obtained from the subjects themselves.

Blood collection. Blood was collected with EDTA–Na_2 after an overnight fast. The blood samples were centrifuged at 900 rpm for 10 min at room temperature to obtain platelet-rich plasma in the top layer and white blood cells containing red blood cells (RBC) in the bottom layer. The top layer was centrifuged again at 3000 rpm for 10 min to sediment the platelets, which were suspended in a sterile plastic tube with 10 mL of 0.9% NaCl and washed three times with 10 mL of 0.9% NaCl (2 × 5 min and 1 × 10 min). After the final washing, the platelet pellet was resuspended in 2.5 mL of 0.9% NaCl and sonicated for 1 min at 20 kc with a Handy Sonic (Ultrasonic Disruptor UD-201; Tomy Co. Ltd., Tokyo, Japan). RBC and mononuclear cells (MN) were separated by density-gradient centrifugation using a "Lymphoprep®" (Nycomed Pharma AS, Oslo, Norway). Three milliliters of the RBC–MN suspension were slowly placed on the 1.5 mL layer of the medium, and then centrifuged at 1,200 rpm for 30 min at 10°C. Thus, the MN layer was separated from the RBC layer. The RBC pellet was washed three times with 0.9% NaCl (2 × 5 min and 1 × 10 min), and after the final washing the cells were resuspended in an equivalent volume of 0.9% NaCl. The hematocrit of the RBC suspension was also measured for a final correction. The tubes containing MN were filled with 10 mL of 0.9% NaCl and centrifuged at 10°C for

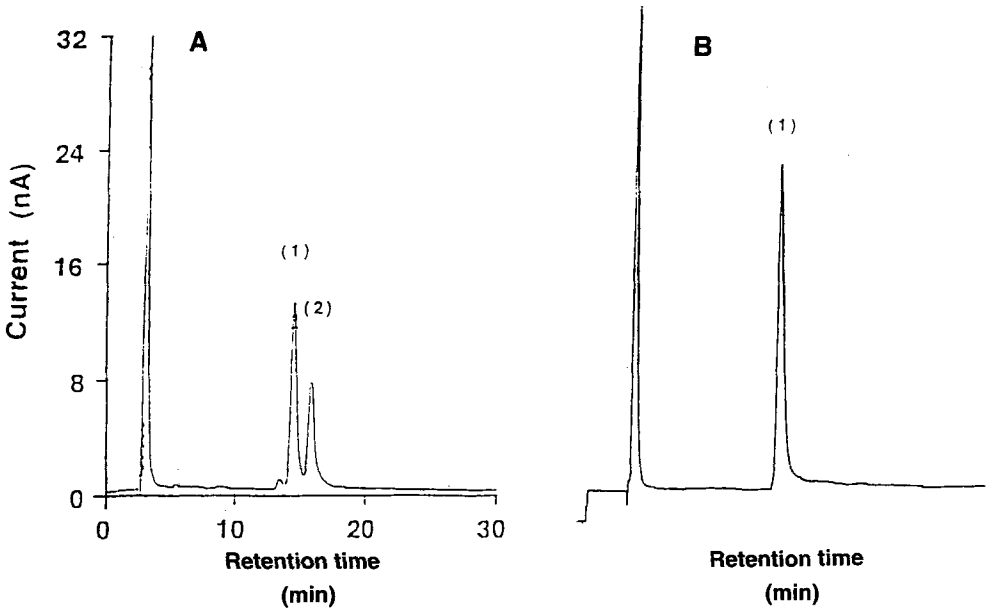

FIG. 1. Chromatograms of extracts from the *Dunaliella* preparation and the synthesized all-*trans* β-carotene. Equal amounts of all-*trans* and 9-*cis* β-carotenes were found in the *Dunaliella bardawil* extract. A, the *D. bardawil* extract; B, the synthesized all-*trans* β-carotene; C, the authentic standards. (1) all-*trans* β-carotene; (2) 9-*cis* β-carotene.

15 min at 1,000 rpm. To remove small amounts of RBC contaminated in the layer, the MN pellet was then washed for 40 s with 2 mL of hypotonic 0.2% NaCl solution, to which 2 mL of 1.6% NaCl was added after 40 s. After refilling the tubes with 10 mL of 0.9% NaCl, centrifugation and decantation at 1,000 rpm for 15 min at 10°C were repeated twice. After the final washing, the pellets were suspended in 2.5 mL of 0.9% NaCl, and the cells were counted with a leukocyte counter (Sysmex Platelet Counter, PL-110; Kobe, Japan). Then, the plasma, platelets, MN, and RBC were assayed for β-carotene in this study.

Analysis of β-carotene and retinol. Determination of β-carotene has been reported previously (9). Briefly, 1 mL of ethanol containing 0.015% butylated hydroxytoluene was added to 0.2 mL of plasma or 0.4 mL of a cell suspension followed by vigorous shaking under nitrogen gas. Five mL of 0.9% NaCl was added to this mixture, which was then centrifuged at 3,000 rpm for 10 min, and 4 mL of the hexane layer was evaporated under a stream of nitrogen. The residue was dissolved in 50 μL of ethanol; a 20 μL aliquot was injected into the high-performance liquid chromatography (HPLC) column for determination of β-carotene, and the 20 μL aliquot from the plasma extract sample was injected into the other HPLC column for retinol determination. The HPLC equipment for β-carotene was an IRICA Σ 871 (IRICA Co. Ltd., Kyoto, Japan) with a Vydac (Hesperia, CA) reverse-phase C_{18} column (Cat. No. 201TP54; 250 × 4.6 mm), and the detector was an IRICA Σ 875 amperometric detector. The standard eluent was methanol/acetonitrile (95:5, vol/vol), including 50 mM $NaClO_4$, and the flow rate was 1 mL/min. Authentic all-*trans* and 9-*cis* β-carotenes were provided by Nippon Roche K.K., and were dissolved in methanol to produce the standard. The concentration of the authentic β-carotene standard was spectrophotometrically determined using an absorption coefficient $E^{1\%}_{1\,cm} = 2620$ at 450 nm for all-*trans* form and $E^{1\%}_{1\,cm} = 2290$ at 446 nm for 9-*cis* form by a Hitachi U-2000 spectrophotometer (10) (Hitachi Co. Ltd., Tokyo, Japan). The HPLC for retinol measurement was a Shimadzu LC-5A (Shimadzu Co. Ltd., Kyoto, Japan) with an IRICA

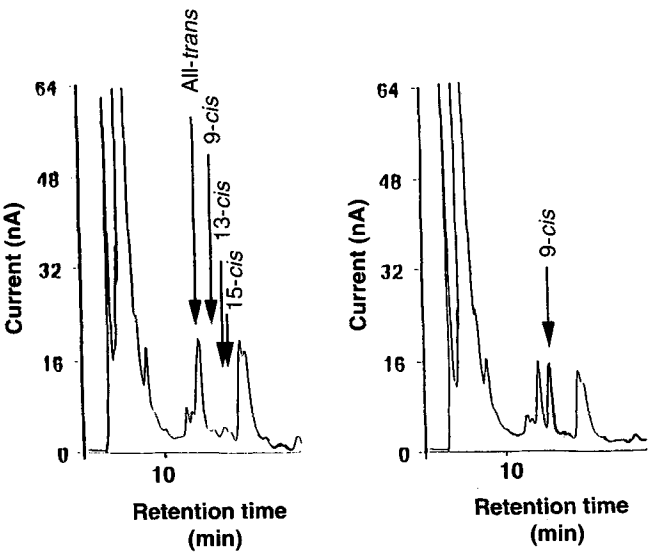

FIG. 2. Chromatograms of extracts from human plasma. Left panel shows clear separation of all-*trans*, 9-*cis*, 13-*cis*, and 15-*cis* β-carotene. Right panel shows the chromatogram added by the authentic 9-*cis* β-carotene. Pure 9-*cis* β-carotene coincided with the presumed 9-*cis* β-carotene. All-*trans*, all-*trans* β-carotene; 9-*cis*, 9-*cis* β-carotene; 13-*cis*, 13-*cis* β-carotene; 15-*cis*, 15-*cis* β-carotene.

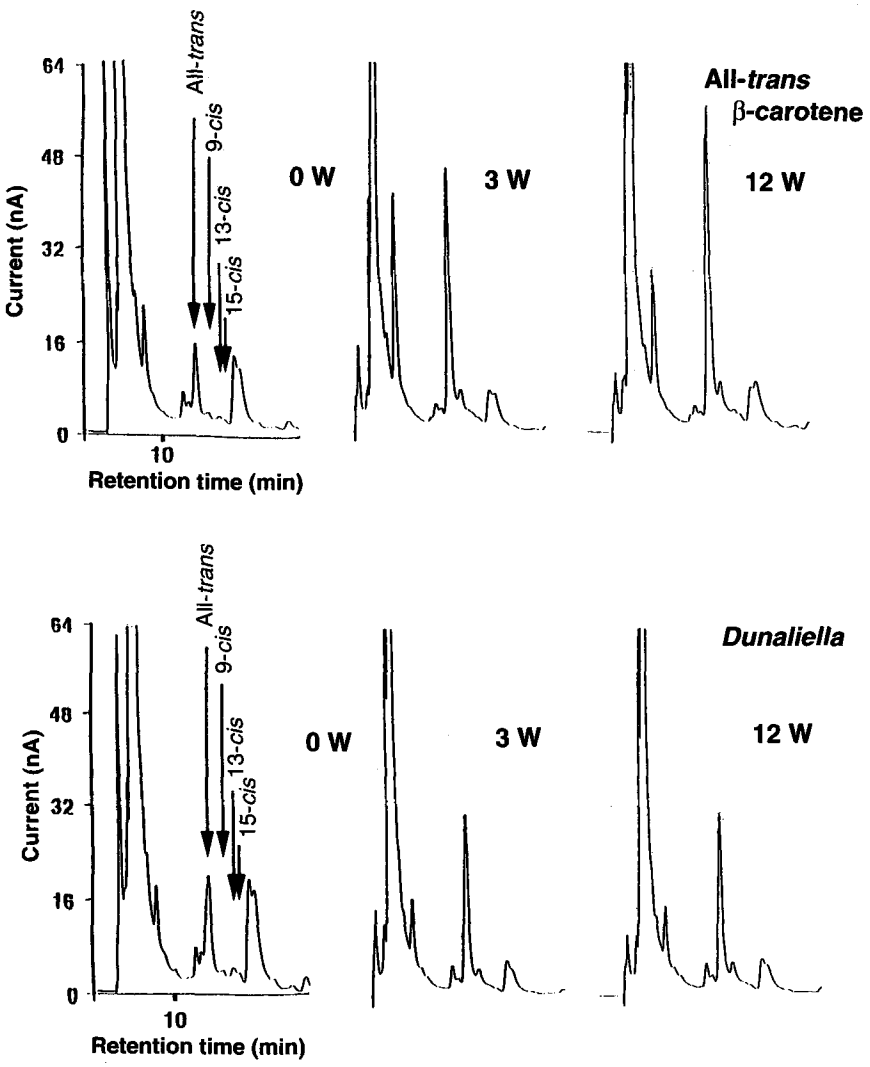

FIG. 3. Typical high-performance liquid chromatography tracings of plasma extracts before and after ingestion of the synthesized β-carotene preparation and the *Dunaliella* preparation. All-*trans*, all-*trans* β-carotene; 9-*cis*, 9-*cis* β-carotene; 13-*cis*, 13-*cis* β-carotene; 15-*cis*, 15-*cis* β-carotene.

RP-18 (4 × 250 mm) column. The detector was a Shimadzu RF-550 fluorescencephotometer (ex: 340 nm, em: 460 nm). The eluent was ethanol/water (95:5, vol/vol), and the flow rate was 0.7 mL/min.

Statistical analysis. All results are expressed as mean ± SE. Statistical significance was assessed at $P < 0.05$ by a repeated measures analysis of variance.

RESULTS

Analysis of administered preparations. Figure 1 shows chromatograms of extracts from two preparations of β-carotene mixture, the naturally-occurring and the synthesized forms, as described in the Materials and Methods section. The naturally-occurring β-carotene derived from *D. bardawil* is approximately 50% all-*trans* β-carotene and 50% 9-*cis* β-carotene, with a very small amount of α-carotene. The synthesized preparation contains only all-*trans* β-carotene, and there were no detectable α-carotene and *cis*-forms. This indicated that no isomerization occurred during sample processing. Figure 2 shows the chromatograms of the plasma extract. The pure additional 9-*cis* β-carotene coeluted with the presumed 9-*cis* β-carotene.

Changes in plasma β-carotene levels after administration of the preparations. Typical chromatograms of plasma extracts before and after carotene administration are shown in Figure 3. The peaks of 13- and 15-*cis* β-carotene were detected after the 9-*cis* form peaked. The basal plasma level of each *cis*-form was found to be only about 10% of the all-*trans* form. In this study, only the all-*trans* and 9-*cis* forms were examined, because administered β-carotenes included predominantly the all-*trans* form and the 9-*cis* form, with much less 13- or 15-*cis* form. The plasma levels reached a maximum after two weeks of administration and plateaued there-

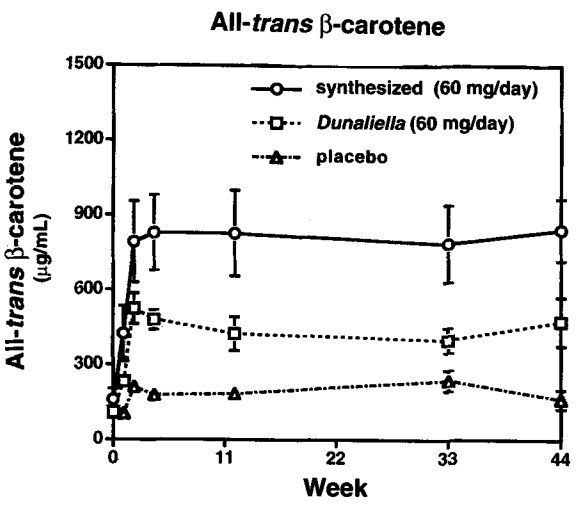

FIG. 4. Changes in plasma levels of all-*trans* and 9-*cis* β-carotenes by administration of the *Dunaliella* preparation, the synthesized β-carotene preparation, or a placebo.

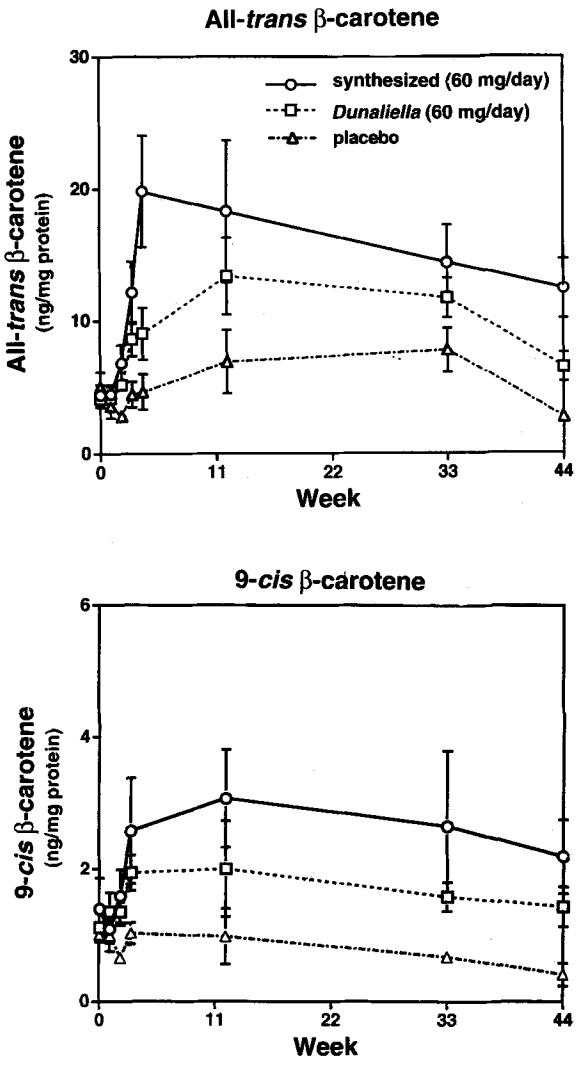

FIG. 5. Changes in platelet content of all-*trans* and 9-*cis* β-carotenes by administration of the *Dunaliella* preparation, the synthesized β-carotene preparation, or a placebo.

after in the subjects who took the β-carotene preparations, and the plasma level in the placebo group showed only seasonal variation (Fig. 4). The all-*trans* β-carotene level in the subjects given the synthesized all-*trans* β-carotene was almost twice that for the *Dunaliella* preparation, indicating that the elevation of plasma level corresponded to the content of the all-*trans* form of both preparations. The plasma level of the 9-*cis* form did not show the same pattern as for the all-*trans* form, because a higher plasma 9-*cis* level was found in the all-*trans* β-carotene group than in the *Dunaliella* group, despite no intake of the *cis*-form in the all-*trans* group and a higher intake of the 9-*cis* form in the *Dunaliella* group.

Changes in β-carotene isomer level in platelets and MN. The ratio of 9-*cis* to all-*trans* in platelets (20%) and MN (25%) was higher than that in the plasma at basal levels before administration. As shown in Figures 5 and 6, all-*trans* β-carotene was also dose-dependently elevated in platelets and MN of the two β-carotene groups. With respect to RBC β-carotenes, the basal level was low and no remarkable changes were observed during and after administration (data not shown). With respect to 9-*cis* β-carotene levels in platelets and in MN, the elevation after administration was marked both for the all-*trans* and *Dunaliella* groups after administration, as compared with the placebo group. Changes in the ratio of 9-*cis* to all-*trans* in platelets and MN in the all-*trans* group were similar to those in the *Dunaliella* group after administration, indicating that increased 9-*cis* levels occurred even in the cells of the all-*trans* group, despite the fact that no *cis*-form existed in the all-*trans* preparation.

Changes in plasma retinol levels after administration with β-carotene preparations. Throughout the experimental periods (Fig. 7), the plasma retinol level did not change in the groups with β-carotenes as compared with the placebo group.

DISCUSSION

Recently, Stahl *et al.* (4) investigated the β-carotene isomers in human serum and tissues and reported that 9-*cis* β-carotene

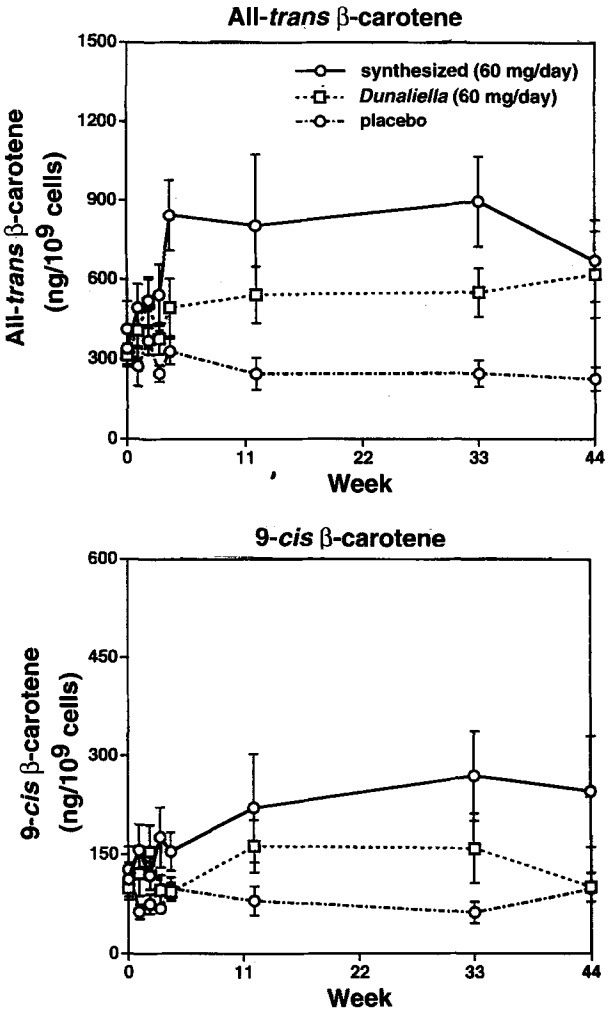

FIG. 6. Changes in mononuclear cell content of all-*trans* and 9-*cis* β-carotenes by administration of the *Dunaliella* preparation, the synthesized β-carotene preparation, or a placebo.

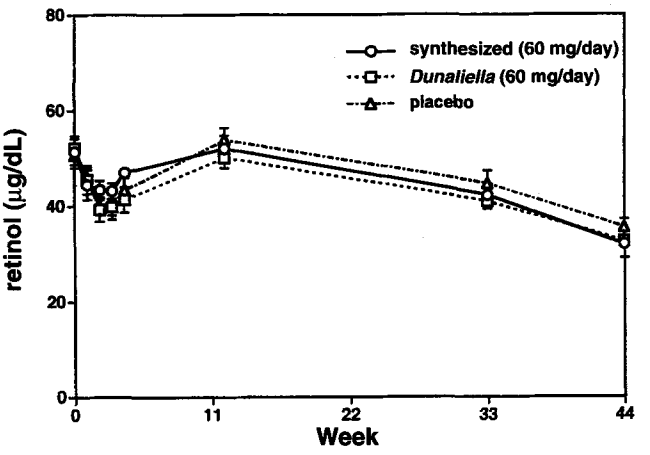

FIG 7. Changes in plasma retinol by administration of the *Dunaliella* preparation, the synthesized β-carotene preparation, or a placebo.

is not detectable in serum although it is present in tissues, especially in liver. They have proposed that the 13-*cis* form, rather than the 9-*cis* form, is the dominant *cis*-isomer in humans. Similar findings were observed in other studies (11,12). Under our HPLC conditions, the 9-*cis* form is detected in plasma, and shows a similar peak to the 13- and 15-*cis* forms. In this study, only changes in the level of the all-*trans* form and 9-*cis* form were detected, because the administered preparation from *D. bardawil* included all-*trans* and 9-*cis*, but much less 13- and 15-*cis* β-carotene and α-carotene. Stahl *et al.* (7) found that the all-*trans* form predominates serum and tissues, and presumed that this is either due to preferential absorption of the all-*trans* form, rapid distribution of the 9-*cis* form into the tissues, or isomerase activity converting the 9-*cis* to the all-*trans* form. With respect to the basal level, a relatively higher ratio of 9-*cis* form to all-*trans* form in the platelets and MN was observed, as compared to that in plasma. This may indicate the accumulation of 9-*cis* in the cells. In addition, after administration with both β-carotene preparations, the elevated plasma and cellular all-*trans* levels depended on the administered dose of the all-*trans* form, while the levels in the 9-*cis* form did not. Different biokinetics may be operative in the body for these isomers. If the cellular level of β-carotene isomers reflects the tissue content, it may be that isomerization of the all-*trans* form to the 9-*cis* form occurs *in vivo*, because a higher level of the 9-*cis* form was observed in MN and platelets after administration with only the synthesized all-*trans* β-carotene, and the level was comparable to that of the *Dunaliella* preparation, which contained a relatively large amount of 9-*cis* isomer.

These findings suggest that 9-*cis* isomer may not be absorbed through the intestine, probably because of specific discrimination mechanism for geometrical isomers. However, it is unlikely that 9-*cis* isomer is absorbed, but very rapidly distributed, into tissues or that isomerase produces all-*trans* β-carotene from the 9-*cis* form. The likely explanation is that isomerization of all-*trans* to 9-*cis* occurs in the body either during or after absorption. The latter hypothesis comes from our finding that, in plasma and blood cells, the 9-*cis* level rose even after the administration of the synthesized all-*trans* form, while changes in the all-*trans* level after administration were quite dose-dependent. To confirm this hypothesis, administration of the purified 9-*cis* isomer needs to be investigated.

ACKNOWLEDGMENTS

We gratefully thank Nikken Sohonsha Corporation (Gifu, Japan) and Nippon Roche K.K. (Tokyo, Japan) for their financial support. We also thank Dr. H. Takenaka (MicroAlgae Corporation, Gifu, Japan) for his useful comments.

Sesamin (a compound from sesame oil) Increases Tocopherol Levels in Rats Fed *ad libitum*

Afaf Kamal-Eldin*, Dan Pettersson and Lars-Åke Appelqvist

Department of Food Science, Swedish University of Agricultural Sciences, 750 07 Uppsala, Sweden

ABSTRACT: Six groups of rats were fed diets low, but adequate, in α-tocopherol but high in γ-tocopherol. The six diets differed only in their contents (0, 0.25, 0.5, 1.0, 2.0, and 4.0 g/kg, respectively) of sesamin, a lignan from sesame oil. After four weeks of *ad libitum* feeding, the rats were sacrificed and the concentrations of α- and γ-tocopherols were measured in the plasma, livers, and lungs. Sesamin-feeding increased γ-tocopherol and γ-/α-tocopherol ratios in the plasma ($P < 0.05$), liver ($P < 0.001$), and lungs ($P < 0.001$). The increase was non-significant for α-tocopherol. Thus, sesamin appears to spare γ-tocopherol in rat plasma and tissues, and this effect persists in the presence of α-tocopherol, a known competitor to γ-tocopherol. This suggests that the bioavailability of γ-tocopherol is enhanced in phenol-containing diets as compared with purified diets.

Lipids 30, 499–505 (1995).

Sesame seed (*Sesamum indicum*, Linn., Pedaliaceae) is known for its high nutritional value, and for having high oil (*ca.* 50%) and protein (20–25%) content (1). Sesame oil is characterized by a very high oxidative stability compared with other vegetable oils (2,3). The oil is composed of *ca.* 98% glycerides and 1.5–2% unsaponifiables (4,5). The fatty acid composition of sesame oil is palmitic (7–12%), stearic (3.5–6%), oleic (35–50%), and linoleic acid (35–50%) (4,6,7). Two lignan-type compounds, sesamin and sesamolin, are the major constituents of sesame oil unsaponifiables (5,8). Sesamol (a sesamolin derivative) can be present in sesame seeds and/or oils in very small amounts. Other lignans and sesamol are also present in sesame seeds and/or oils in very small amounts as aglycones, but are present in considerable amounts in the seeds as glucosides (9–14). The structures of all sesame seed lignans are shown in Figure 1, and their systematic names and levels in sesame seeds are presented in Table 1. Crude sesame oil also contains *ca.* 500–700 mg tocopherols per kg, which are about 97% γ-tocopherol (γ-T) (5).

Sesame seed lignans were reported to be responsible for many unique chemical and physiological properties of sesame oil (2,9,15–21). It is of special interest to note that they have antioxidant and antimutagenic properties (9,22). Sesamin has no antioxidant activity in itself, but it is possible that its metabolites can act as antioxidants *in vivo*. Recently, Yamashita *et al.* (23) suggested that certain antioxidants in sesame, other than tocopherols, suppressed senescence in mice. Sesamin also caused a significant increase in γ-T levels in the plasma and liver of rats (24). In their experiment, Yamashita *et al.* (24) studied the effect of addition of sesame seed, sesamin, and sesaminol (a transformation compound from sesamolin in refined sesame oil) to rat diets containing

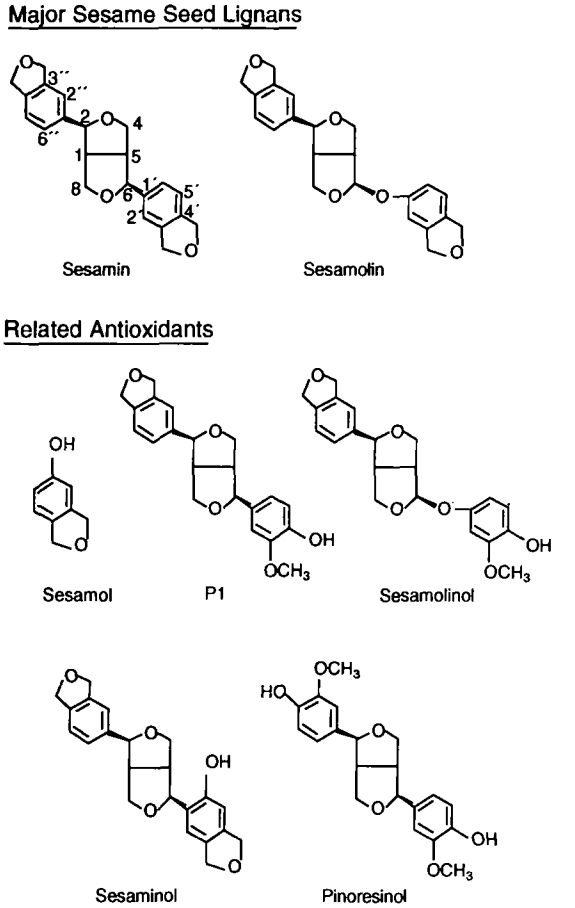

FIG. 1. The chemical structures of sesamin and related compounds in sesame seeds.

TABLE 1
Trivial and Systematic Names and Levels[a] of Lignans and Lignan Glucosides in Sesame Seeds (*Sesamum indicum*, Linn.)

Trivial names	Systematic names	Weight % in seed	Reference number
Lignans			
Sesamin	2,6-*bis*-(3,4-methylenedioxy phenyl)-*cis*-3,7-dioxabicyclo-[3.3.0]-octane	0.2–0.5	9
Sesamolin	2-(3,4-methylenedioxy phenoxy)-6-(3,4-methylenedioxy phenyl)-*cis*-3,7-dioxabicyclo-[3.3.0]-octane	0.2–0.3	9
Sesamol	3,4-methylenedioxy phenol	0.0004	10
P1	2-(3-methoxy-4-hydroxy phenyl)-6-(3,4-methylenedioxy phenyl)-*cis*-3,7-dioxabicyclo-[3.3.0]-octane	0.002	11
Sesamolinol (P2)	2-(3-methoxy-4-hydroxy phenoxy)-6-(3,4-methylenedioxy phenyl)-*cis*-3,7-dioxabicyclo[3.3.0]-octane	0.006	11
Sesaminol (P3)	2-(3,4-methylenedioxy-6-hydroxy phenyl)-6-(3,4-methylenedioxy phenyl)-*cis*-3,7-dioxabicyclo [3.3.0]-octane	0.002	11
Pinoresinol	2,6-*bis*-(3-methoxy-4-hydroxy phenyl)-*cis*-3,7-dioxabicyclo[3.3.0]-octane	—	12
Lignan glucosides		total *ca.* 1%	12
—	Sesaminol 2′-O-ß-D-glucopyranoside	—	13
—	Sesaminol 2′-O-ß-D-glucopyranosyl(1→2)-ß-D-glucopyranoside	—	13
—	Sesaminol 2′-O-ß-D-glucopyranosyl(1→2)-O-[β-D-glucopyranosyl(1→6)]-ß-D-glucopyranoside	—	13
KP1	Pinoresinol 4′-O-ß-D-glucopyranosyl(1→6)-ß-D-glucopyranoside	—	12
KP2	Pinoresinol 4′-O-ß-D-glucopyranosyl(1→2)-ß-D-glucopyranoside	—	12
KP3	Pinoresinol 4′-O-ß-D-glucopyranosyl(1→2)-O-[ß-D-glucopyranosyl(1→6)]-ß-D-glucopyranoside	—	14

[a]The levels of total lignans and lignan glucosides in sesame seeds can range from 1–1.5%.

practically no α-tocopherol (α-T) but being rich in γ-T. It has been reported that γ-T can be present in plasma at fairly high concentrations in cases of α-T deficiency (25,26). On the other hand, with increased intake, α-T displaces γ-T in serum (27,28) as well as in red blood cells, platelets, and lymphocytes (29).

As mixed diets for humans and animals generally contain both α-T and γ-T as major dietary tocopherols, we considered it relevant to study the effects of dietary sesamin on the retention of γ-T in the rat in the presence of low, but adequate, levels of α-T (30).

MATERIALS AND METHODS

Chemicals and reagents. Sesamin, DL–γ-T and groundnut oil were gifts from Takemoto Oil & Fat Co., Ltd. (Gamagori Aichi, Japan), F. Hoffmann-La Roche (Basel, Switzerland), and from Aarhus Olie (Aarhus, Denmark), respectively. The authentic α- and γ-T used as external standards in high-performance liquid chromatography (HPLC) analyses were purchased from Merck (Darmstadt, Germany). All other chemicals and reagents were of analytical grade and were used without further purification.

Animals, diets, and study design. Thirty-six male, 25-day-old Sprague-Dawley rats (B & K Universal, Sollentuna, Sweden) weighing on average 70 g, were used. The rats were housed individually in wire-bottom cages in a room kept at 25°C and 50% relative humidity. A 12-h light (07:00–19:00)/dark (19:00–07:00) cycle was used. Six groups, of six rats each, were fed the various experimental diets (Table 2). Groundnut oil (containing 13 mg of endogenous α-T and 10 mg of endogenous γ-T per 100 g and fortified with additional γ-T, 40 mg/100 g) was added, at a level of 100 g/kg diet, as a source of energy, essential fatty acids, and vitamin E. Thus, the vitamin E content of the six diets was 13 mg/kg α-T and 50 mg/kg γ-T. Sesamin was the only variable in the diets and was present in diets 1–6 at levels of 0.0, 0.25, 0.50, 1.0, 2.0, and 4.0 g/ kg, respectively. The rats were allowed free access to tap water and were fed experimental diets *ad libitum* for four weeks. Feed was given daily (13:00), and feed wastage was determined at the same time. The rats were weighed every week and the tissues were weighed at sacrifice. This

TABLE 2
Composition of the Basal Experimental Diet[a]

Ingredient	g/kg
Maize starch	570
Casein, vitamin free	200
Groundnut oil[b]	100
Cellulose powder	40
Mineral and trace element premix[c]	40
Sucrose	40
Vitamin premix[d]	10

[a]On dry weight basis, seamin was added to the six diets at levels of 0, 0.25, 0.50, 1.0, 2.0, and 4.0 g/kg diet, respectively.
[b]The groundnut oil had the following fatty acid composition, based on gas chromatographic analysis of the fatty acid methyl esters: 16:0 (12.7%), 18:0 (2.4%), 18:1 (51.3%), 18:2 (31.4%), 20:0 (1.0%), and 20:1 (1.2%). The oil contained (mg/100 g): α-tocopherol (α-T; 13), α-tocotrienol (0.1), ß-tocopherol (0.4), γ-tocopherol (γ-T; 10) and δ-tocopherol (δ-T; 0.6). The oil was supplemented with additional γ-T (40 mg/100 g). Thus, each diet contained 13 and 50 mg/kg of α-T and γ-T, respectively.
[c]The composition of mineral and trace element premix (g/kg) was: Ca, 220; P, 58; Mg, 5; Na, 79; I, 0.065; Se, 0.010; Fe, 2; Co, 0.020; Cu, 0.600; Mn, 2.50; Zn, 3.00.
[d]The composition of the vitamin premix (g/kg) was: vitamin A (retinol), 0.5835; vitamin B_1, 2.57; vitamin B_2, 1.09; vitamin B_6, 1.93; vitamin B_{12}, 0.0028; vitamin C, 0.800; vitamin D_3 (cholecalciferol), 0.0106; pantothenic acid, 3.90; vitamin K_3, 0.430; choline chloride, 188.2; biotin, 0.030; ß-carotene, 0.02; folic acid, 0.27; myo-inositol, 206.4; and nicotinic acid, 8.15.

study was approved by the Ethical Committee for animal experiments of the Uppsala region.

Blood and tissue collections. Rats were deprived of feed for 24 h before sacrifice. Rats were anaesthetized by an intraperitoneal injection of sodium pentobarbital, blood was withdrawn from *vena cava,* and rats were killed by exsanguination. Blood was collected in tubes containing EDTA as anticoagulant, and plasma was isolated following centrifugation (3000 rpm, 4°C, 10 min). The plasma was stored at −20°C until analyzed for tocopherol concentration. The livers and lungs were quickly removed, weighed, immersed in isopropanol (10 mL), and stored at −20°C until analyzed.

Chemical analysis. The tocopherols were extracted from 500 μL portions of the plasma in glass tubes. Ethanol (500 μL) was added to each tube, and the lipids were extracted twice with 2 mL of *n*-hexane after shaking and centrifugation. The lipid extracts were dried over anhydrous sodium sulfate, centrifuged (4000 rpm, 5 min), quantitatively transferred to other tubes, flushed with nitrogen, and sealed and stored at −20°C until analyzed by HPLC within the same or next day. Before HPLC analyses, the hexane extracts were dried under nitrogen and redissolved in 200 μL of hexane.

The livers and lungs were extracted in hexane/isopropanol (3:2, vol/vol) according to Hara and Radin (31) using an Ultra-Turrax homogenizer (Janke and Kunkel GmbH & Co. KG, Breisgau, Germany). Briefly, the livers were homogenized in 100 mL hexane/isopropanol (3:2, vol/vol) and centrifuged at 3000 rpm for 10 min. The lipid extracts were decanted, the tissue was rehomogenized in 50 mL hexane/isopropanol (3:2, vol/vol), and extracts pooled. The extracts were washed twice with aqueous sodium sulfate, and the salt solution was then washed twice with hexane/isopropanol (7:2, vol/vol) (31). The lipid extracts were concentrated under vacuum and transferred to glass tubes containing anhydrous sodium sulfate. The tubes were centrifuged (4000 rpm, 5 min), and the lipid extracts were quantitatively transferred to other tubes. The hexane/isopropanol was evaporated to dryness under nitrogen because α-T has a higher oxidation rate in protic polar solvents. The extracts were then dissolved in hexane, flushed with nitrogen, and sealed and stored at −20°C until analyzed by HPLC within 1–2 d. The solvent was completely evaporated under nitrogen, and the residue was reconstituted in *n*-hexane directly before HPLC analyses.

The tocopherol levels in the plasma and tissues were quantified by HPLC analysis on a Hibar pre-packed LiChrosorb NH_2 column (25 cm × 4 mm i.d., particle size 5 μm; E. Merck). The mobile phase was *n*-heptane/methyl-tertiary butyl ether/tetrahydrofuran/methanol (79:20:1:0.1, by vol) at a flow rate of 1.0 mL/min. The HPLC system consisted of a Merck-Hitachi HPLC L-6200A Intelligent pump, a 20 μL injection loop, and a Merck F-1050 Fluorescence spectrophotometer. The peaks were detected at an excitation wavelength of 295 nm and an emission wavelength of 320 nm, and were recorded using an HP 3396A integrator (Hewlett Packard, Avondale, PA). The tocopherol peaks were identified and quantified against authentic tocopherols used as external standards.

Statistical analysis. Statistical analyses were performed by using the Statistical Analysis System (32). Linear regression analyses of tocopherol concentrations (Y) against sesamin level (X) were done by using the regression procedure (PROC REG) and analysis of variance by using the general linear model with level of sesamin as the only main effect.

RESULTS

The relationships between the sesamin levels in the diets and the α- and γ-T concentrations in the plasma, livers, and lungs of the experimental rats are shown in Figure 2. Positive regression slopes were obtained for both α- and γ-T, showing an increasing effect with increasing sesamin levels in the diets.

For γ-T, the following regression equation was obtained for the plasma: GTL (γ-T level) = 0.270 + 0.214 SL (sesamin level), with a correlation coefficient (r) of 0.60. The intercept (0.270) shows γ-T level (μmole/L plasma) in the control group, and the slope (0.214) shows the rate of increase in γ-T level with increasing sesamin level (SL, g/kg diet) in the experimental groups. The regression equations for γ-T in the liver and lungs were: GTL = 2.913 + 2.072 SL (r = 0.839) and GTL = 1.898 + 2.663 SL (r = 0.86), respectively. The regression analysis procedure showed significant correlations between SL and GTL in plasma ($P < 0.005$), liver ($P < 0.001$), and lungs ($P < 0.001$). On the other hand, the relationships between the sesamin level in the diet (SL) and α-T levels in the plasma, liver, and lungs were not statistically significant (Fig. 2).

The effects of increasing sesamin concentration on the means of α-T, γ-T, and α-T + γ-T levels and on the ratios of γ-T/α-T in the plasma and tissues of experimental rats were assessed by analysis of variance (Table 3). Plasma γ-T concentrations generally increased from 0.06 to 1.07 μmol/L, whereas α-T concentrations varied between 3.06 and 4.79 mmol/L. The concentration of γ-T in the plasma was significantly increased ($P < 0.05$) by sesamin level, whereas the increase in α-T concentration was not statistically significant. The sesamin feeding did not change total body weights nor weights of livers and lungs of experimental rats. In the livers, γ-T increased from 2.12 to 11.03 nmol/g fresh weight ($P < 0.001$) as a result of increasing dietary sesamin. Although α-T concentrations were not significantly changed, they varied between 16.96 and 27.03 nmol/g fresh weight. Similar results were obtained in the lungs, where γ-T concentrations increased from 1.55 to 13.07 nmol/g fresh weight ($P < 0.001$) and α-T concentrations did not change significantly.

DISCUSSION

In this study, the rat diets were rich in γ-T and contained an adequate level of α-T, as judged from the results of Hakkarinen *et al.* (30). The minimum vitamin E requirement for rat survival was reported as 7 mg DL-α-tocopherylacetate per kg

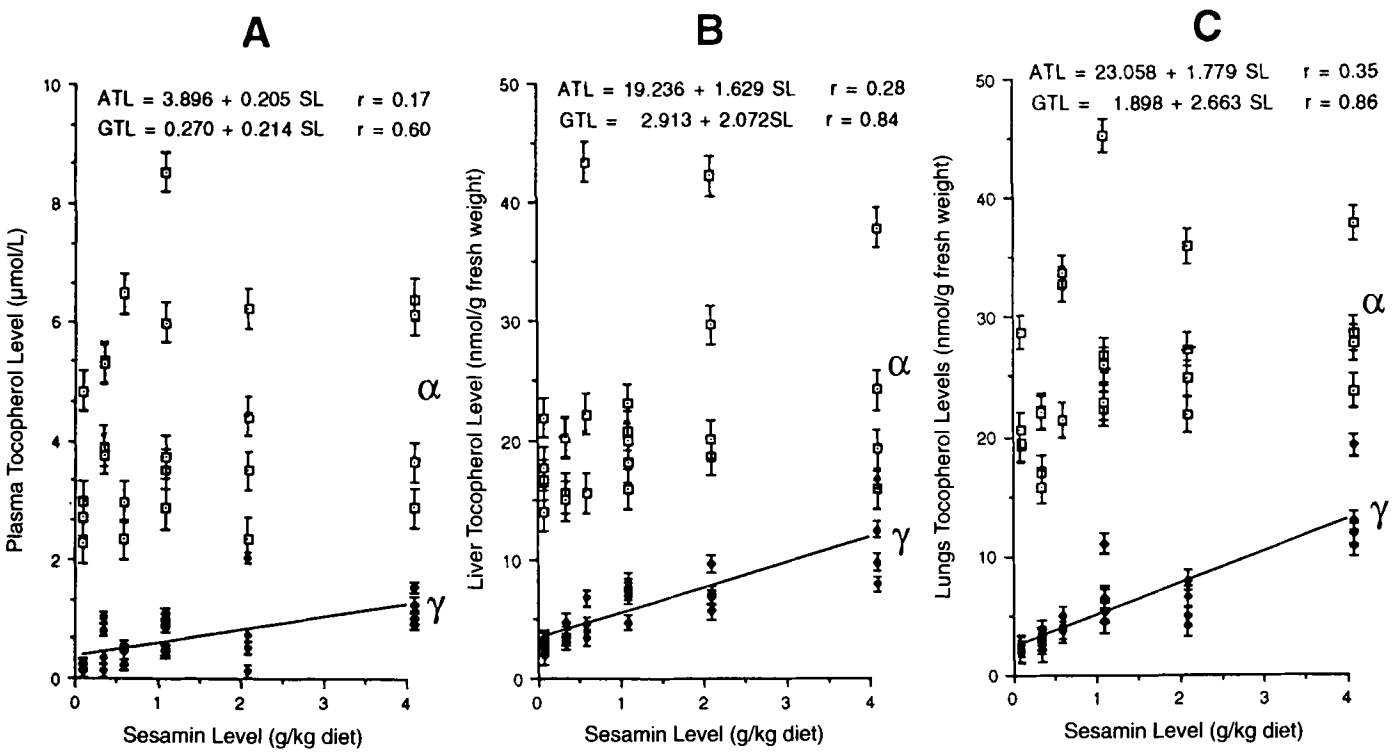

FIG. 2. Linear relationships between α- and γ-tocopherol levels (ATL and GTL, respectively) in rat plasma (A), liver (B), and lungs (C), and sesamin level (SL) in the diet (g/kg). The points show the tocopherol levels for 3–5 rats per sesamin level (group); r denotes the correlation coefficients: the correlations were nonsignificant in the case of α-Tocopherol (α), but significant in the case of γ-tocopherol (γ) (plasma, $P < 0.005$; liver and lungs, $P < 0.001$).

feed when the selenium content of the diet is 6.6 μg/kg and the vitamin E/polyunsaturated fatty acid ratio is 0.45 (30). This experimental approach was introduced to explore if the presence of the adequate α-T levels will mask the reported effect of sesamin on γ-T retention (24). The experiment was designed so that sesamin content was the only differing variable in the experimental diets. Groundnut oil was chosen because of its resemblance to sesame oil in fatty acid composition and for the fact that it contains only α-T and γ-T as major tocopherols (Refs. 4, 6, Table 2).

[a]Levels of α- and γ-tocopherols measured by HPLC relative to external standards. Values represent means ± SEM (n = 3–5). The composition of the diets is as in Table 2.

^{b,c,d,e}Values within each row not sharing a common superscript letter are statistically different at $P < 0.05$. N.S., not significant.

In the United States, the daily dietary supply of γ-T is approximately twice that of α-T (33,34). Earlier studies showed that the biological activity of γ-T is only about 10–35% of that of α-T (26–28,35,36). Hence, α-T is recognized as the most important natural lipophilic antioxidant in biological systems (36–39). Both isomers (α-T and γ-T) are absorbed to the same extent from the gastrointestinal tract (25,35,40–43), but γ-T is cleared from the tissues at a considerably faster rate than α-T (44,45). Upon feeding equal amounts of the two isomers, both tocopherols were found to increase similarly in the plasma up to 12 h. After 24 h, the level of γ-T decreased drastically, while that of α-T remained almost unchanged (41,43,46). The latter is preferentially bound to the cellular membranes of the liver and to the transporting proteins, while γ-T is excreted through bile without combining with the transporting protein (26,41,43,47). Comparative studies in humans using deuterium-labeled γ-T also showed that there is no discrimination between γ-T and α-T during absorption and secretion in the chylomicrons, but subsequently there is a preferential enrichment of the very low density lipoprotein with α-T (48). All animal studies on relative tocopherol bioavailabilities were conducted using purified diets which contained no antioxidants other than the tocopherols. To date, there is no knowledge about the relative bioavailabilities of the different tocopherols in mixed diets containing other antioxidants, such as plant phenols (49).

Our results are in agreement with previous findings that sesamin-feeding increases γ-T levels in rat plasma and in liver (24). Moreover, we have demonstrated that the effect persists even in the presence of α-T, which is a known competitor to γ-T expression (27–29). In addition, we observed that sesamin induced almost equal increases in the α-T levels in rat plasma, liver, and lungs, although these increases were not statistically significant, perhaps due to the large within-group variation in the levels of this tocol in the plasma and tissues.

The sparing effect of sesamin on vitamin E may explain the observation that some antioxidants, other than tocopherols, in sesame suppressed senescence in mice (23). The resulting increase in total vitamin E bioavailability may also explain some interesting early observations. Tobin (15) reported that daily injection of sesame oil to adrenalectomized female rats increased the number of successful pregnancies, prolonged the survival time of those animals having a successful gestation, and increased their ability to rear young. This effect might have been related to high vitamin E bioavailability as vitamin E is well known to increase fertility in vitamin E-deficient rodents and other animals (50,51). Chou and Marlatt (16) found that sesame oil produced better carotene utilization (a factor of 1.84) than did soybean (1.00) and peanut oils (0.68) when fed to rats. At that time, the effect was surprising as the sesame oil meal contained 11.5 mg tocopherols/kg diet and the soybean oil meal had 27.5 mg /kg. Sesamol was also mentioned to counteract fish oil toxicity to chicks in a similar manner to the antioxidants α-T and x,x′-diphenyl-p-phenyl-enediamine (17).

There is but one report on the absorption of sesamin in rats, where only 0.15% of the fed sesamin was recovered in the lymph during 24 h, suggesting limited absorption (20). Around 15–19% was excreted in the feces in rats fed a purified diet and *ca.* 34% in rats fed a nonpurified diet. The mechanism by which sesamin acts is unknown, but at least two possibilities exist. The mechanism may involve synergistic interaction with γ-T (a regeneration mechanism) in a similar way to other antioxidant synergists, like ascorbic acid. Another possibility is that sesamin may compete with γ-T in its oxidation and/or clearance. Lignans having the methylenedioxyphenyl (1,3-benzodioxole) function are known inhibitors of the mixed function oxidases associated with the endoplasmatic reticulum of the microsomes (52). Many mixed function oxidases are active in the metabolism of lipids, steroids, and in the compounds foreign to the metabolic network (53). Thus, sesamin and related compounds may be regarded as xenobiotic substances by the mixed function oxidases, and their further metabolism may competitively inhibit the activity of these enzymes toward the lipids, sterols, tocopherols, etc.

The sparing of α- and γ-T by sesamin may be of nutritional and physiological significance. A hamburger with a sesame bun, rather common in urban western diets, adds *ca.* 10 mg sesamin to the diet. The metabolism of sesamin in the rat was reported to occur, through the mixed function oxidase enzymes, *via* oxidation of the methylene dioxy function, resulting in a 1,2-diphenol (51), which is expected to have antioxidant properties, at least *in vitro*. Human diets are rich in antioxidant phenols, which may have comparable effects to that of sesamin (49). As sesamin feeding caused a high relative increase in γ-T in rats, we postulate that the bioavailability of γ-T may have been underestimated in the previous studies performed using purified diets (26–28,35,36). The metabolic interaction(s) of γ-T with other food or feed constituents with an antioxidant function needs to be studied further.

ACKNOWLEDGMENTS

We thank Dr. R.V. Cooney (Cancer Research Center, University of Hawaii, Honolulu, HI) for discussions on γ-T and sesame oil during a sabbatical stay (LÅA) at University of Hawaii and for critical reading of the manuscript; Prof. J. Hakkarainen (Department of Clinical Nutrition, this University) for discussions in the preparation for this experiment; Lotta Wall (from this department) for technical assistance; Takemoto Oil & Fat Co., Ltd. (Gamagori Aichi, Japan) and F. Hoffmann-La Roche (Basel, Switzerland) for the sesamin and DL-γ-tocopherol gifts, respectively; and Aarhus Olie (Aarhus, Denmark) for the gift of groundnut oil. The International Science Program in Chemical Sciences (IPICS, Uppsala University) is thanked for extended support to A. Kamal-Eldin.

[a]Department of Pediatrics, Division of Neonatology, University of Wisconsin, Madison, Wisconsin 53792 and [b]Department of Pathology, Northwestern University, Chicago, Illinois 60611

ABSTRACT: The level of annexin I, a 36 kDa calcium-dependent phospholipid-binding protein (36 kDa PLBP) in the reproductive organs of young, mature, and pregnant rabbits was determined immunologically with antibodies raised against purified rabbit lung annexin I. In the cytosolic fractions of the ovary, fallopian tube, uterus, and placenta, annexin I was the only major immunoreactive protein. The reproductive organs appeared to have higher annexin I levels than most nonreproductive organ tissues, except the lung and the spleen which were also rich in annexin I. A small amount of annexin I and a nearly equal amount of its hydrolytic product, a 33 kDa polypeptide, were detected in the amniotic fluid between 21 and 27 days gestation. Structural similarity of annexin I in the reproductive organs and in the lung was suggested by their identical isoelectric point values. Annexin I in the ovary of adult rabbits was 70% higher than that in the respective organ of immature rabbits. The uterus of pregnant rabbits had about 84% higher annexin I contents than that of the nonpregnant rabbits. The placenta had more annexin I per mg cytosolic protein than either the ovary or the uterus during pregnancy. The high concentration of annexin I in the reproductive organs may reflect specific functions of these organs in the reproductive years and during the reproductive cycle.

Lipids 30, 507-511 (1995).

Annexins are a group of calcium-dependent phospholipid-binding proteins (PLBPs) that may play a role in signal transduction, membrane fusion, exocytosis, anti-inflammation, and anti-coagulation (1–6). More than eight annexins have been found in various tissues (7–10). The wide distribution of these proteins suggests that each of them may have a specific role in different tissues and cells. Recently, we observed changes in the levels of annexin I, a 36 kDa calcium-dependent PLBP, during growth of the fetal rabbit lung, corresponding to the development of lung surfactant in the alveolar epithelial type II cells (11). Kaetzel and co-workers (12) demonstrated an increased expression of three other annexins called calcimedins 35α, 35β, and 35γ (corresponding to annexins III, IV, and V, respectively) in the rat ovary and uterus during labor. Myatt and co-workers (13,14) detected annexin I in the human amnion and suggested that this protein might regulate prostaglandin production at childbirth. These observations raised the possibility that annexins may play a role in the development of the reproductive organs and during a reproductive cycle. Aside from possibly being a regulator of prostaglandin production (4,5) that increased greatly in the reproductive organs at birth of a newborn, little is known about annexin I with respect to its role in sexual maturity and pregnancy. As an initial step toward understanding the role of annexin I in reproduction, we determined the levels of annexin I in the reproductive organs of young and mature female rabbits, as well as at different stages of pregnancy, with a polyclonal antibody specific to the rabbit lung annexin I. For comparison, we also used the antibody to determine annexin I in some of the nonreproductive tissues to illustrate the tissue specificity of annexin I expression.

MATERIALS AND METHODS

Animals and preparation of tissue samples. Female New Zealand white rabbits, nonpregnant with different ages or pregnant with known gestational ages, were purchased from Bakkom's Rabbitry (Vroqua, WI). The animals were anesthetized with an intravenous injection of sodium pentobarbital/heparin (20 mg/1000 units per kg body weight). For the pregnant rabbits, tracheotomy was performed, and the lung was ventilated with a respirator. Cesarean section was performed to expose the uterus. Amniotic fluid in each amniotic sac was withdrawn. Fetuses were removed for other studies (11). Following the removal of fetuses, portions of the placenta and uterus were collected from each amniotic sac in a total of 10 g for each tissue. Then, the lung of the doe was lavaged with 20 mL of 0.9% NaCl saline three times through the trachea. After lavage, the lung was ventilated and the chest opened. The lung was perfused with saline through the pulmonary artery and removed. The ovaries, fallopian tubes, and other organ tissues to be studied were removed from the carcass. Organ tissues of the nonpregnant rabbits were collected by similar procedures.

Tissues of the same organ from two pregnant rabbits with the same gestational age or from two nonpregnant rabbits were pooled, washed with saline, and homogenized in two volumes of 0.01 M Tris-HCl, pH 7.4, containing 0.33 M sucrose using a tissue homogenizer (PCU Polytron; Drehzahlreglar, Kinematica, Switzerland). The homogenate was centrifuged at 10,000 × *g* for 10 min. The supernatant was further centrifuged at 100,000 × *g* for 60 min. The cytosolic fraction or the 100,000 × *g* supernatant was saved and stored at −20°C before use. The amniotic fluid was centrifuged at 200 × *g* for 5 min to remove debris, and the supernatant was reduced to about 1 mL using an ultrafiltration apparatus with an UM10 membrane and a Centricon™-10 (Amicon, Inc., Beaverly, MA). All sample preparations were carried out at 4°C or on ice. The amount of total proteins in each sample was determined using the Lowry method as described previously (11).

Western blotting, isoelectric focusing (IEF), and enzyme-linked immunosorbent assay (ELISA). Proteins in each sample were qualitatively analyzed by Western blotting and IEF, and quantitatively determined by ELISA using guinea pig antiserum raised against rabbit lung annexin I as previously described (11). The addition up to 80 ng of external annexin I into the samples of ovary and uterus showed a 76.3 ± 4.9% (n = 4) recovery. The ELISA results shown in this paper were expressed as μg annexin I/mg total sample protein from direct measurement without correction of the recovery. Annexins in the cytosolic proteins of the rabbit tissues also were immunoblotted against the mouse monoclonal antibodies to human annexins I, II, IV, and VI (Zymed Laboratories, Inc., San Francisco, CA) and the polyclonal antibodies to annexins I, II, III, IV, and V (kindly provided by Dr. Blake Pepinsky, Biogen, Cambridge, MA). The human fibroblast lysate proteins (Zymed Laboratories) were used as the positive control for the monoclonal antibodies. Human annexins I, III, IV, V, and bovine annexin II (kindly provided by Dr. Pepinsky) were used as positive control for the polyclonal anti-annexins antibodies as detailed elsewhere (11).

RESULTS

Annexins in reproductive organs. A 36 kDa PLBP was the only major cytosolic protein in the female rabbit reproductive organs that was immunorecognized by the guinea pig anti-rabbit lung annexin I antiserum (Fig. 1). Based on the same amounts of cytosolic proteins, the placenta, uterus, ovary, and fallopian tube appeared to have higher annexin I levels than most nonreproductive organ tissues, except the lung and the spleen (Fig. 1). The preimmunized serum of the same guinea pig prior to immunization was negative to the rabbit proteins. The 36 kDa protein in the uterus, ovary, fallopian tubes, and placenta had the same isoelectric point value as the lung annexin I (pI 6.0) (Fig. 2). The multiple bands of annexin I shown on the IEF gel probably resulted from charge modifications (11).

Monoclonal and polyclonal antibodies to human annexin I also reacted with the 36 kDa protein. Only in the uterus and placenta did a protein weakly react to monoclonal antibodies to annexin II. Anti-annexins III, IV, and V polyclonal antibodies, and anti-annexin IV and VI monoclonal antibodies did not react with any protein in the cytosolic fraction of the tissues we examined (data not shown). The 36 kDa protein, the annexin I, was by far the most prominent annexin in the female rabbit reproductive organs.

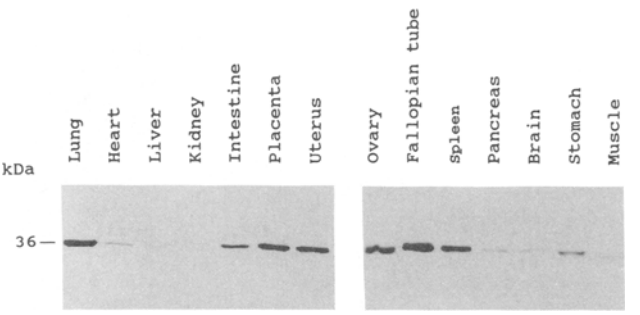

FIG. 1. Western blot of proteins in the cytosolic fraction of female rabbit reproductive organs against the anti-rabbit lung annexin I, a 36 kDa calcium-dependent phospholipid-binding protein, polyclonal antibody in comparison with proteins in nonreproductive tissues. Each sample applied to SDS polyacrylamide gel (7 × 8 cm) contained 10 μg cytosolic protein. Samples containing 200 μg proteins analyzed by 16 × 18 cm SDS gel yielded similar results. The amount of each reference phospholipid-binding protein purified from rabbit lung was 0.25 μg.

Pregnancy-related variation in annexin I in reproductive organs. The amount of annexin I in the ovary of 10-day- and 3-month-old nonpregnant rabbits was 56% lower than that in the ovary of the 5-month-old rabbits, 86% less than the 3-year-old rabbits, and 74% lower than the pregnant rabbits (Table 1). The New Zealand albino female rabbits reach maturity about five months after birth. Although age-related difference in annexin I in the uterus was not as obvious as in the ovary, the uterus of pregnant rabbits contained nearly twice

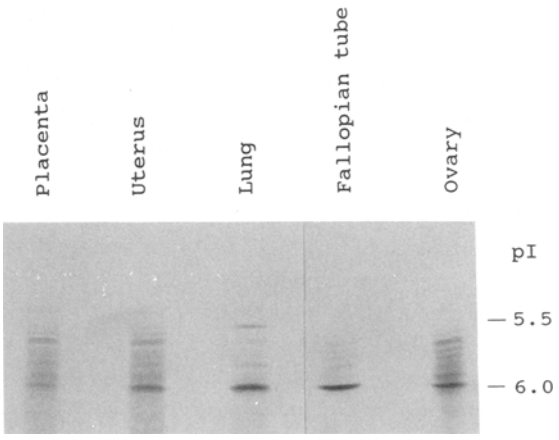

FIG. 2. Isoelectric focusing (IEF) and Western blot of cytosolic proteins (10 μg) in the female rabbit reproductive organs and the lung. The IEF agarose gel was 10 × 12.5 cm with a pH gradient of 3–10. IEF values of all specimens were identical.

TABLE 1
Annexin I Content in the Cytosolic Fractions of the Ovary, Uterus, and Placenta of Rabbits[a]

Age	Annexin I content (μg/mg protein)		
	Ovary	Uterus	Placenta
Nonpregnant rabbits			
10 d	5.6 ± 0.65	3.9 ± 0.25	—
3 mon	5.9 ± 0.34	3.1 ± 0.22	—
5 mon	9.0 ± 0.91	3.2 ± 0.06	—
3 yr	10.6 ± 0.20	4.2 ± 0.26	—
Pregnant rabbits (days of gestation)			
21	9.8 ± 0.78	5.6 ± 0.18	10.9 ± 0.31
26	10.8 ± 0.15	6.7 ± 0.36	15.8 ± 0.56
30	9.0 ± 0.63	8.0 ± 0.26	11.1 ± 0.89
31	10.2 ± 0.53	6.2 ± 0.06	10.1 ± 0.53

[a]The content of a 36 kDa calcium-dependent phospholipid-binding protein (annexin I) was determined by enzyme-linked immunosorbent assay as described in the text. The results are means ± SD of three tests.

the PLBP than that of nonpregnant rabbits (Table 1). The placenta contained higher annexin I than the ovary and the uterus, but the level remained relatively unchanged during pregnancy (Table 1).

Apparent hydrolysis and gestation-related increase in annexin I in amniotic fluid. Annexin I and its hydrolytic product, a 33 kDa protein, were detectable in amniotic fluid as early as at 21 days gestation (Fig. 3). However, on a per mg total protein basis, the amount of annexin in the amniotic fluid was less than that in the reproductive organs. Unlike in other organs where negligible breakdown products of annexin I could be detected, the amounts of annexin I and 33 kDa protein were about the same in the amniotic fluid, with an increase in quantity for both with advanced gestation. The volume of the amniotic fluid in the amniotic sac beyond the 27th gestational day was too small to be collected.

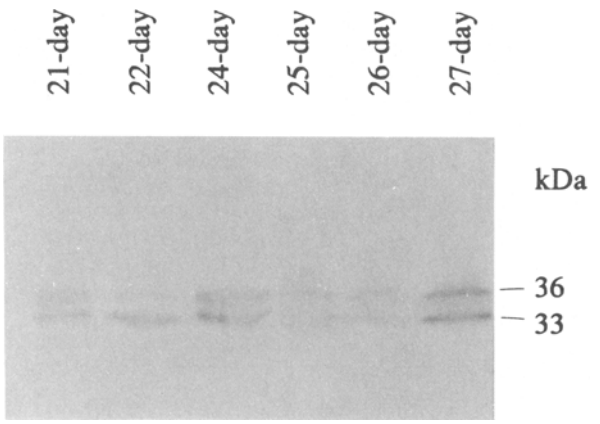

FIG. 3. Western blot of amniotic fluid against anti-rabbit lung annexin I antiserum. Each sample applied to sodium dodecyl sulfate gel (16 × 18 cm) contained 200 μg protein. Lanes of 21-day to 27-day represent gestational ages. Nearly equal amounts of annexin I (36 kDa) and its hydrolytic product (33 kDa) were present in the amniotic fluid, and the quantity of both annexin I and the breakdown product increased with increasing gestational days.

DISCUSSION

The polyclonal antibodies raised against a rabbit lung 36 kDa PLBP (15), previously identified as annexin I (11,16), together with monoclonal and polyclonal antibodies to other annexins, were employed to probe the expression and levels of annexins in the female rabbit reproductive organs, and in relation to maturity and pregnancy. With the polyclonal antibodies to rabbit lung annexin I, a rich presence of a 36 kDa protein was detected in the cytosolic fraction of all reproductive organs. The protein was also immunorecognized by monoclonal and polyclonal antibodies to human annexin I. There is little doubt that the immunoreacted 36 kDa protein in the reproductive organs is annexin I.

Annexin I was practically the sole annexin in the cytosolic fraction of the organs we examined, with a weak presence of annexin II in the uterus and placenta. Earlier, several investigators demonstrated multiple annexin proteins in a given tissue such as the lung and placenta (10,17,18). The absence of many of those annexins in our samples probably is related to the fact that the fractions used in our studies were prepared in mild buffer solutions. It is possible that other annexins associated with cellular membranes remained bound. In studies where multiple annexins were detected, the tissue was often treated harshly with buffers containing large quantities of detergents, chelating agents, and/or calcium ions.

The most interesting findings of the present study are the age- and pregnancy-related changes in annexin I levels in reproductive organs of the female rabbit. Annexin I in the ovary of immature rabbits was about one-half of that in the ovary of mature animals. Since annexin I is alleged to be involved in secretion and exocytosis, its increased levels may be needed to fulfill certain activities demanded by specific physiologic functions of the mature ovary, such functions may include ovualtion and hormone production. Similarly, annexin I in the uterus of pregnant rabbits was nearly twice as high as that of nonpregnant rabbits. It should not be difficult to imagine that activities normally carried out by uterine cells would be augmented and new activities assumed as the uterine wall is implanted with growing fetuses.

On a per mg protein basis, the placenta contained greater amounts of annexin I than other reproductive organs. The placenta is probably the most metabolically active tissue in sustaining a pregnancy, once fertilized eggs are implanted in the uterine wall and the fetuses are growing. The high annexin contents may simply reflect a heightened metabolic state of the tissue.

Annexin I in the amniotic fluid may be derived from multiple sources. It could be released from placental tissue as the protein is richly present in the placenta. Although cDNA does not predict a hydrophobic signal peptide on annexin molecules, the concept that annexin can be secreted has been suggested by Pepinsky *et al.* (19). Recent findings of Christmas

et al. (20) that annexin I is secreted by human prostate cells, probably *via* a previous unrecognized pathway, lend support to that notion. Conversely, annexin I in the amniotic fluid could originate from fetal tissue such as the lung. It has been shown that fetal lung surfactant components can appear in the amniotic fluid (21). This, together with our findings of the presence of annexin I in fetal rabbit lung and in the lung lavage fluid (11,22), suggests the possible release of annexin I from fetal lung into amniotic fluid. It is interesting to note that amniotic fluid had a relative high content of the 33 kDa protein. In the reproductive organs, as well as in fetal lung (11), the 33 kDa protein was barely or not detectable. The positive immunoreactivity of this protein to antibodies raised against annexin I is highly suggestive that the 33 kDa protein is a hydrolytic product of annexin I. It has been reported that annexin I can be subjected to limited proteolytic hydrolysis at the N-terminus to yield a 34 kDa peptide which can be recognized by the anti-annexin I polyclonal antibodies (23). If so, one must assume the presence of an annexin I hydrolytic enzyme in the amniotic fluid whose concentration would be considerably higher than in the organs. The pathophysiologic significance of the presence of the enzyme, and the function, if any, of the hydrolytic product remain to be delineated.

In conclusion, we have demonstrated a rich presence of annexin I in the reproductive organs of female rabbits, and the level of this protein increased in relation to maturity and/or pregnancy. Expression of annexins has been shown as a function of cellular growth state (24), and appears to be developmentally regulated in lymphocyte differentiation (25). Our finding of high concentrations of annexin I in the reproductive organs, and an increased level of this protein in mature animals and during pregnancy, is consistent with notion that this protein may play a regulatory role in the reproductive system of the female rabbit. The fact that annexin I is widely distriubuted in the reproductive organs may underscore particular activities (e.g., secretion and hormone production) common to these organs.

ACKNOWLEDGMENTS

This study was supported by the pulmonary SCOR grant 1P50 HL46478 and grant HL38744 from the National Institutes of Health. We are grateful to Dr. R. Blake Pepinsky of Biogen, Cambridge, MA, for kindly providing the annexins and anti-annexin antibodies.

Inhibition of Cardiolipin Biosynthesis in the Hypoxic Rat Heart

Philip Cheng and Grant M. Hatch*

Departments of Internal Medicine and Biochemistry and Molecular Biology, University of Manitoba, Winnipeg, Manitoba, R3E 3J7 Canada

ABSTRACT: Cardiolipin is the principal polyglycerophospholipid in the heart. The effect of hypoxia on cardiolipin biosynthesis was investigated in isolated rat hearts perfused in the Langendorff mode. Hearts were pulsed-labeled for 60 min with 0.1 mM [1,(3)-^{3}H]glycerol in Krebs Henseleit buffer saturated with either 95% O_2/5% CO_2 (control) or 95% N_2/5% CO_2 (hypoxic). Radioactivity incorporated into phosphatidylglycerol and cardiolipin were reduced 88% ($P < .05$) and 79% ($P < .05$), respectively, in hypoxic hearts compared to controls. In other experiments, hearts were pulse-labeled for 15 min with 1.4 mM [^{32}P]P_i in Krebs Henseleit buffer saturated with 95% O_2/5% CO_2 and subsequently perfused for 60 min under control or hypoxic conditions. The radioactivity incorporated into CDP–1,2-diacyl-*sn*-glycerol, phosphatidylglycerol, and cardiolipin were reduced 61% ($P < .05$), 71% ($P < .05$), and 70% ($P < .05$), respectively, in the hypoxic hearts compared to controls, indicating a decreased formation of CDP–1,2-diacyl-*sn*-glycerol in the hypoxic heart. The activities of the enzymes involved in cardiolipin biosynthesis and the cardiac pool sizes of cardiolipin, phosphatidylglycerol, and CDP–1,2-diacyl-1,2-diacyl-*sn*-glycerol were unaltered between hypoxic and control hearts. In contrast, cardiac adenosine-5′-triphosphate and CPT levels were decreased 94% ($P < .05$) and 92% ($P < .05$), respectively, in hypoxic hearts compared to controls. We postulate that the biosynthesis of the cardiac polyglycerophospholipid cardiolipin may be inhibited by a decreased adenosine-5′-triphosphate and cytidine-5′-triphosphate level in the heart.

Lipids 30, 513–519 (1995).

Polyglycerophospholipids are a special class of glycerolipids which include cardiolipin (CL), phosphatidylglycerol (PG), and *bis*(monoacylglycero)phosphate (1,2). Polyglycerophospholipids are widely distributed in nature and are found in plants, microorganisms, and animals (1). In the rat heart, PG was shown to comprise approximately 1.5% of the total phospholipid phosphorus mass whereas *bis*(monoacylglycero)-phosphate was not detected (3,4). CL is the principal polyglycerophospholipid in the heart muscle ranging from 9.0% in humans to 14.7% in rats of the total lipid phosphorus mass (1,3,4). CL is predominantly found within the inner leaflet of the inner mitochondrial membrane (5). CL aids in the association and function of mitochondrial membrane enzymes (6). Such enzymes include creatine kinase (7), cytochrome c oxidase (8), and the phosphate carrier (9). In addition, CL is essential for the proper functioning of the electron transport chain (10). Hence CL is a multifunctional phospholipid essential for cellular oxidative phosphorylation.

Mammalian mitochondria contain enzymes for the *de novo* synthesis of CL (11). In the rat heart, CL is synthesized *via* the CDP–1,2-diacyl-*sn*-glycerol (CDP–DG) pathway (3). The first step of the reaction is the conversion of phosphatidic acid (PA) to CDP–DG which requires CTP as substrate and is catalyzed by the enzyme CTP:PA cytidylyltransferase (12). The subsequent steps of PG biosynthesis involves the condensation of glycerol-3-phosphate with CDP–DG to form phosphatidylglycerolphosphate (PGP) *via* the action of PGP synthase and PGP phosphatase which rapidly dephosphorylates PGP to PG (12). Finally PG is converted to CL by a condensation reaction with CDP–DG catalyzed by CL synthase (13).

At present, the regulatory mechanisms that govern CL biosynthesis remain largely unknown, and regulation of these mechanisms in mammalian heart has received little attention. Myocardium derives most of its energy from mitochondrial oxidative phosphorylation under normal physiological conditions (14). When available oxygen is limited, as in the case of myocardial hypoxia, high-energy phosphate stores decline (15). The effect of a reduction in cardiac high-energy stores on CL biosynthesis in mammalian heart was unknown. Thus, the purpose of this study was to determine the effect of hypoxia on CL biosynthesis in the isolated perfused rat heart. In this study, we demonstrate that CL biosynthesis is decreased when the heart is perfused under hypoxic conditions.

MATERIALS AND METHODS

Materials. [1,(3)-^{3}H]Glycerol, [^{32}P]P_i, and [U-^{14}C]glycerol-3-phosphate were obtained from Amersham (Oakville, Ontario, Canada). Thin-layer plates (silica gel 60, 0.25 mm thickness) and Ecolite™ scintillation cocktail were obtained from CanLab Division of Baxter Co. (Winnipeg, Manitoba, Canada). All other biochemical reagents were of analytical grade and were obtained from either Fisher Scientific (Ed-

monton, Alberta, Canada); Sigma Chemical Co. (St. Louis, MO); or CanLab Division of Baxter Co. Male Sprague-Dawley rats (100–220 g) were used for all the experiments.

Perfusion of isolated rat hearts in the Langendorff mode with [1,(3)-^{3}H]glycerol or [^{32}P]P_i. Male Sprague-Dawley rats were sacrificed by decapitation. The heart was quickly removed and cannulated *via* the aorta using a modified syringe needle (18 gauge). Then 5 mL of Krebs Henseleit buffer (KHB) (16) was injected through the coronary circulation with a 5-cc syringe to remove the remaining blood. Immediately after, the heart was placed on the perfusion apparatus (Fig. 1) and perfused in the Langendorff mode (17) with 12.5 mL KHB containing 0.1 mM [1,(3)-^{3}H]glycerol (2.5 μCi/mL) for 60 min in continuous pulse-labeling experiments. The concentration of glycerol (0.1 mM) used throughout this experiment was representative of the physiological plasma concentration in rats (18). The perfusate was saturated either with 95% O_2/5% CO_2 (control) or 95% N_2/5% CO_2 (hypoxic). The pO_2 of the O_2 saturated buffer was 69.6 ± 2.0 kPa, while the pO_2 for the N_2 saturated buffer was 2.9 ± 0.7 kPa (19). In the pulse-chase experiments, the heart was perfused for 15 min with KHB containing 1.4 mM [^{32}P]P_i (67 μCi/mL) under control condition and subsequently chased with KHB (1.4 mM P_i) for another 60 min under either control or hypoxic conditions.

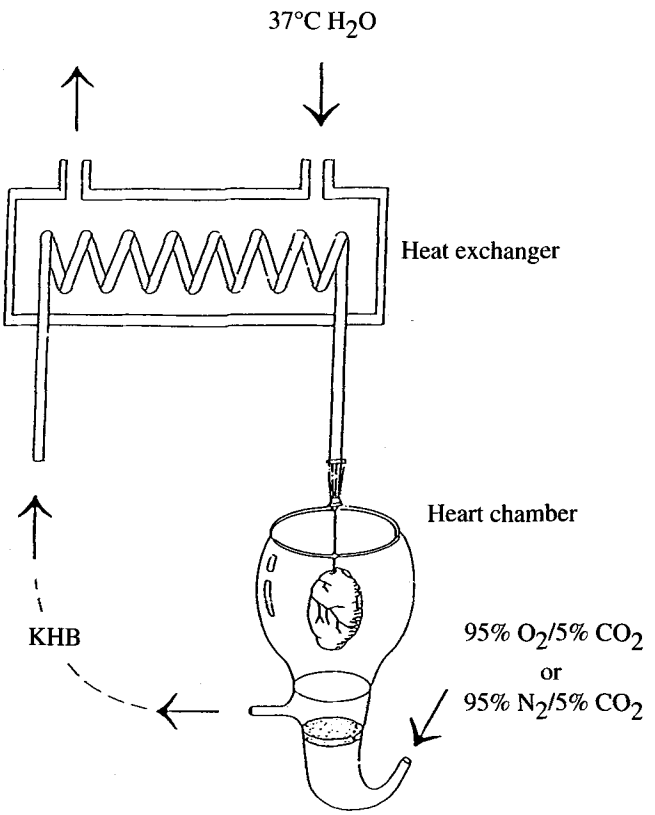

FIG. 1. Retrograde perfusion apparatus. Krebs Henseleit buffer (KHB) flows through a heat exchanger, is warmed to 37°C, and subsequently flows into the heart *via* the aorta in a retrograde manner. The buffer is collected in the heart chamber and recirculated. The pool of buffer in the heart chamber is saturated with either 95% oxygen/5% carbon dioxide (control) or 95% nitrogen/5% carbon dioxide (hypoxic).

Extraction and isolation of radioactive phospholipids. Subsequent to perfusion, 10 mL of air was injected into the heart to remove perfusate that remained in the coronary circulation, and the heart was blotted dry. The heart was weighed (typically 0.30–0.50 g) and homogenized by a 20 s burst of a Polytron® Homogenizer (Kinematika, Lucerne, Switzerland) in 5 mL of chloroform/methanol (2:1, vol/vol). Tissue left on the homogenizer probe was removed by homogenization with another 5 mL of chloroform/methanol (2:1, vol/vol). The two 5-mL homogenates were combined and centrifuged at full speed for 10 min in a bench-top centrifuge (Model TJ-6; Beckman Instruments, Mississauga, Ontario, Canada) to pellet debris. After centrifugation, the homogenate was decanted into a 16 × 125 mm screw-cap tube. Addition of 5 mL of 0.73% NaCl to the homogenate resulted in the formation of organic and aqueous phases. The tube was vortexed and centrifuged at full speed for 10 min in a bench-top centrifuge, causing a biphasic separation. The upper aqueous phase was removed by aspiration, and the remaining organic layer was further washed with 5 mL of theoretical upper phase (chloroform/methanol/0.9% NaCl, 3:48:47, by vol). The tube was vortexed and centrifuged as described above. The resulting upper aqueous phase and interphase were removed, and the remaining organic phase was dried down under a stream of N_2 gas. The dried organic lipid sample was resuspended in 100 μL chloroform/methanol (2:1, vol/vol). Thin-layer chromatography plates treated with 0.4 M boric acid were used to resolve individual phospholipid species (4). Before application of the lipid sample, the thin-layer plate was heat activated for one hour at 145°C. The thin-layer plate was allowed to cool; then 25 μL of the resuspended lipid sample was placed on the plate. The thin-layer plate was subjected to a two-dimensional separation. In the first dimension, the plate was developed in a solvent system containing chloroform/methanol/NH_4OH/water (70:30:2:3, by vol). The second dimension, at 90° to the first separation, was performed in a solvent system containing chloroform/methanol/water (65:35:5, by vol). The thin-layer plate was allowed to dry overnight, and the separated phospholipids were visualized by exposing the plate to iodine vapor. Corresponding radioactive phospholipids of interest were removed and placed in 6-mL scintillation vials. Radioactivity of [^{32}P] and [^{3}H] incorporated phospholipids were determined immediately and 48 h, respectively, after the addition of 5 mL of the Ecolite scintillation cocktail. The radioactivity was determined in a Beckman Model LS 3801 liquid scintillation counter. CDP–DG was resolved by a separation system containing chloroform/methanol/acetic acid/water (50:24:4:8, by vol) (20). A 10-μL sample of the organic phase was placed on a thin-layer plate with 25 μL of 2 mM CDP–DG standard. The CDP–DG band was identified by exposing the thin-layer plate to iodine vapor, and the corresponding silica gel was removed and placed into a 6-mL scintillation vial and radioactivity determined as described above.

Determination of CL, PG, and CDP–DG pool sizes. In phospholipid mass determination experiments, 35 μL of the organic phase was placed on borate-treated thin-layer plates and developed in the two-dimensional chromatography system described above (4). Silica gel corresponding to the phospholipids was identified by exposure to iodine vapor and were removed from the plate and placed in 13 × 100-mm test tubes. The phosphorus content of the phospholipid was determined *via* the method of Rouser *et al.* (21). The separation of CDP–DG from a 15 μL aliquot of the organic phase, without standard CDP–DG, was performed as described above (20). The phosphorus content was determined as described above and confirmed by the more sensitive malachite green phosphorus determination method (22).

Preparation of subcellular fractions. Crude mitochondrial fractions were prepared for assay of enzyme activities of the following enzymes: CTP:PA cytidylyltransferase, PGP synthase, PGP phosphatase, and CL synthase. The animal was sacrificed by decapitation, and the heart was quickly removed and perfused with KHB saturated with either 95% O_2/5% CO_2 or 95% N_2/5% CO_2 for 60 min as previously described. Subsequent to perfusion, a 10% homogenate was prepared by homogenizing the heart (Polytron® 20-s burst) in homogenizing buffer containing 5 mM Tris-HCl, 0.25 M sucrose, 0.145 M NaCl, pH 7.4. For CL synthase assays, the heart was homogenized in 10 mM Tris-HCl, 0.25 M sucrose, 2 mM EDTA, pH 7.4. The homogenate was then centrifuged for 10 min at 1,000 × *g* (Sorvall RC-5 Superspeed refrigerated centrifuge with SS-34 rotor; Dupont, Mississauga, Ontario, Canada). The resulting pellet was discarded, and the supernatant was centrifuged at 12,000 × *g* for 15 min. The resulting pellet was resuspended in homogenizing buffer (0.5–1.0 mL) using a Dounce tissue grinder (15 hand strokes) and was designated the mitochondrial fraction. A 5-μL aliquot of the crude mitochondrial fraction was taken to determine the protein concentration.

Assay of enzyme activities involved in CL biosynthesis. Enzyme activities were determined in the mitochondrial fraction prepared from the rat hearts after 60 min of perfusion under control or hypoxic conditions. CTP:PA cytidylyltransferase was assayed by determining the conversion of [5-^{3}H]CTP to [5-^{3}H]CDP–DG (3). Test tubes (16 × 100 mm) treated with dimethyldichlorosilane 2% in 1,1,1-trichloroethane were dried overnight at 142°C and were used as the reaction tubes. The reaction mixture contained 50 mM Tris-maleate, pH 6.5, 10 mM [5-^{3}H]CTP (specific activity, 5,739 dpm/nmol), 0.1 mg of mitochondrial protein, 0.5 mM PA dissolved in 0.15 M Triton X-100. Homogenizing buffer was added to yield a final volume of 90 μL. The reaction was initiated by the addition of 10 μL of 0.2 M $MgCl_2 \cdot 6H_2O$. The mixture was incubated at 30°C for 5 min, and the reaction was terminated by the addition of 0.5 mL of 0.1 M HCl in methanol. To the mixture was added 1 mL of chloroform and 1.5 mL of 1.0 M $MgCl_2$. The suspension was vortexed, and the mixture was centrifuged at full speed for 10 min in a bench-top centrifuge. The aqueous phase was removed by suction, and 500 μL of the organic phase was placed in a 6-mL scintillation vial. The organic phase in the vial was evaporated to dryness at 60°C in a water bath. Then 5 mL of scintillation cocktail was added to the vial and the radioactivity determined.

PGP synthase activity was assayed by determining the conversion of [U-^{14}C]glycerol-3-phosphate to phosphatidyl[U-^{14}C]glycerol-3-phosphate (23). The reaction mixture contained 50 mM Tris-HCl, pH 7.0, 10 mM ß-mercaptoethanol (prepared fresh), 0.5 mM [U-^{14}C]glycerol-3-phosphate (specific activity, 11,794 dpm/nmol), 2 mM CDP–DG (dipalmitoyl) dissolved 10 mM Triton X-100, and 50–100 μg of mitochondrial protein to a final volume of 90 μL. The reaction mixture was initiated by the addition of 10 μL of 0.15 M $MgCl_2 \cdot 6H_2O$. The mixture then was incubated at 30°C for 10 min. Next, 0.5 mL of 0.1 M HCl in methanol was added to terminate the reaction. To the mixture was added 1 mL of chloroform and 1.5 mL of 1 M $MgCl_2$. Radioactivity in the organic fraction was determined as described for CTP:PA cytidylyltransferase.

PGP phosphatase activity was assayed by determining the conversion of phosphatidyl[U-^{14}C]glycerol-3-phosphate to phosphatidyl[U-^{14}C]glycerol (24). The reaction mixture contained 50 mM Tris-maleate, pH 6.5, 10 mM β-mercaptoethanol, 0.5 μM phosphatidyl[^{14}C]glycerol-3-phosphate (specific activity, 15,000 dpm/nmol), and 0.1 μg of mitochondrial protein to a final volume of 90 μL. The reaction mixture was incubated at 37°C for 5 min and was terminated by addition of 2 mL of chloroform/methanol/HCL (100:100:0.6, by vol). This was followed by the addition of 1 mL of chloroform and 1.5 mL of 0.73% NaCl to cause biphasic separation. The tube was vortexed and centrifuged at full speed for 10 min in a bench-top centrifuge. The resulting aqueous phase was removed, and the organic phase was dried under N_2 gas. The residue was resuspended in 25 μL of chloroform/methanol (2:1, vol/vol), and 20 μL was placed onto a 0.5 N oxalate-treated thin-layer plate (25). Oxalate plates were prepared by immersing the thin-layer plate in a solution of 0.5 N oxalic acid, and they were dried overnight before use. This treatment is to ensure clear separation of PGP and PG in the thin-layer plate. Standard PG (3 μL) was placed on the thin-layer plate with the sample. The solvent system used for development of the thin-layer plate contained chloroform/methanol/HCl (87:13:0.2, by vol). Iodine vapor was used to visualize the separated phospholipids. The silica gel representing PG was removed and the radioactivity determined.

CL synthase activity was assayed by determining the conversion of phosphatidyl[U-^{14}C]glycerol to [^{14}C]CL (26). The reaction mixture contained 0.3 mM EDTA dissolved in 45 mM Tris-HCl, pH 8.5, 50 μM CDP–DG, 8 μM phosphatidyl[U-^{14}C]glycerol (specific activity, 45,000 dpm/nmol), and 0.1 mg of mitochondrial protein to a final volume of 90 μL. The reaction was initiated by the addition of 5 mM $CoCl_2 \cdot H_2O$ and incubated at 37°C for 120 min. The reaction was terminated by the addition of 3 mL of chloroform/methanol (2:1, vol/vol). This mixture was then decanted into a screw-cap tube (16 × 125 mm), and 1 mL of chloroform followed

by 1 mL of water were added and immediately mixed. The mixture was centrifuged at full speed in a bench-top centrifuge for 10 min. The upper aqueous phase was removed by suction, and the organic phase was evaporated to dryness under N_2 gas. The residue lipid sample was resuspended in 25 μL of chloroform/methanol (2:1, vol/vol), and 20 μL was placed onto a 0.5 N oxalate-treated thin-layer plate. Standard PG (3 μL) and CL (2 μL) were placed on the thin-layer plate with the sample. The same solvent system used for isolation of PG in the PGP phosphatase assay was employed. Iodine vapor was used to visualize the separated phospholipids, and silica gel representing CL was removed and the radioactivity was determined.

Determination of ATP and CTP level. Subsequent to perfusion under either control or hypoxic conditions, the heart was weighed and homogenized in 5 mL chloroform/methanol (2:1, vol/vol). Tissue left on the homogenizer probe was removed by another 5 mL of chloroform/methanol. The two 5-mL homogenates were combined and centrifuged at full speed for 10 min in a bench-top centrifuge to pellet debris. After centrifugation, the homogenate was decanted into a 16 × 125-mm screw-cap tube. Addition of 3 mL of water to the homogenate resulted in the formation of organic and aqueous phases. The tube was vortexed and centrifuged at full speed for 10 min in a bench-top centrifuge. The resulting upper aqueous phase was collected in a 16 × 125 mm test tube. The organic phase was washed twice with 3 mL of water and the aqueous phase pooled. The pooled aqueous phase was dried down under air (24–48 h), and the residue was resuspended in 200 μL of water. The sample was diluted either 20 times (for ATP determination) or 5 times (for CTP determination) with tetrabutylammonium (TBA) buffer. TBA buffer contained 0.03 M KH_2PO_4, 0.02 M TBA phosphate in 19% acetonitrile, pH adjusted to 2.65 using H_3PO_4. Next, 20 μL of the diluted sample was injected into an Ultrasphere-ODS C_{18} reversed-phase high-performance liquid chromatography column for the detection of either ATP or CTP. In an isocratic system, TBA was used to elute nucleotide from the column. The flow rate was set at 2 mL/min and 1.2 mL/min for ATP and CTP, respectively. Nucleotides were detected by an ISCO® UA-5 Absorbance/Fluorescence Detector (Beckman Instruments). The numerical data was generated by a Beckman 450 Data System/Controller.

Other analytical procedures. Protein concentration was determined by the method of Bradford (27). Student's *t*-test was used for the determination of statistical significance. The level of significance was defined as $P < 0.05$.

RESULTS

Effect of hypoxia on CL biosynthesis. To determine if the biosynthesis of CL was effected by hypoxia, rat hearts were perfused in the Langendorff mode with 0.1 mM [1,(3)-^{3}H]glycerol (2.5 μCi/mL) for 60 min in a continuous pulse-labeling experiment under control or hypoxic conditions and the radioactivity incorporation into PG and CL in the organic fraction was determined. Total radioactivity incorporated into the heart was $6.1 \pm 0.7 \times 10^6$ dpm/g heart in the control hearts and $6.4 \pm 0.2 \times 10^6$ dpm/g heart in the hypoxic hearts. Radioactivity incorporated into the organic fraction was reduced 78% ($P < .05$) from $1.8 \pm 0.5 \times 10^6$ dpm/g heart in control hearts to $0.4 \pm 0.1 \times 10^6$ dpm/g heart in the hypoxic hearts. Radioactivity incorporated into CL and PG were significantly reduced, 79% ($P < .05$) and 88% ($P < .05$), respectively, in the hypoxic hearts compared to controls (Fig. 2). Thus, hypoxia caused an apparent reduction in biosynthesis of PG and CL. A problem with continuous pulse-labeling experiments is that changes in the radioactivity incorporated into metabolites may be due to isotope dilution or altered uptake of radioactive precursors (28). Therefore, a pulse-chase protocol was designed to circumvent this problem. Rat hearts were pulse-labeled for 15 min with 1.4 mM [^{32}P]P_i (67 μCi/mL) in 95% O_2-saturated KHB and subsequently the radioactivity was chased with nonradioactive KHB (1.4 mM) for 60 min under control or hypoxic conditions. The radioactivity in both control and hypoxic hearts was $3.1 \pm 0.5 \times 10^6$ dpm/g heart at the beginning of the chase. The radioactivity incorporated into CDP–DG, PG, and CL were determined at time 0 and 60 min of the chase. Radioactivity incorporated into CDP–DG, PG, and CL was increased with the time of perfusion in both

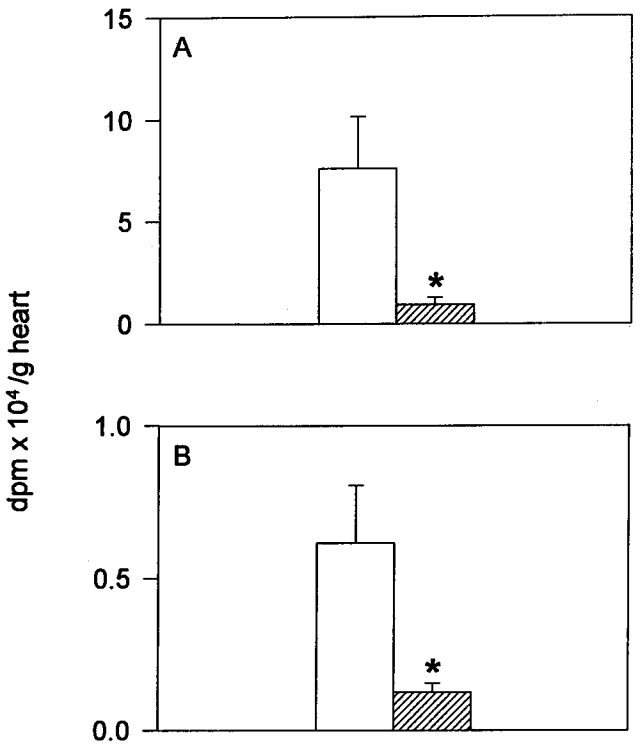

FIG. 2. Radioactivity incorporated into cardiolipin (CL) and phosphatidylglycerol (PG) in hearts perfused with 0.1 mM [1,(3)-^{3}H]glycerol. Rat hearts were perfused for 60 min with Krebs Henseleit buffer containing 0.1 mM [1,(3)-^{3}H]glycerol under control (open columns) or hypoxic (hatched columns) conditions. The hearts were homogenized, and PG and CL were isolated by thin-layer chromatography and the radioactivity associated with PG (A) and CL (B) determined. Vertical bars represent the mean ± SD of at least three hearts (*$P < .05$).

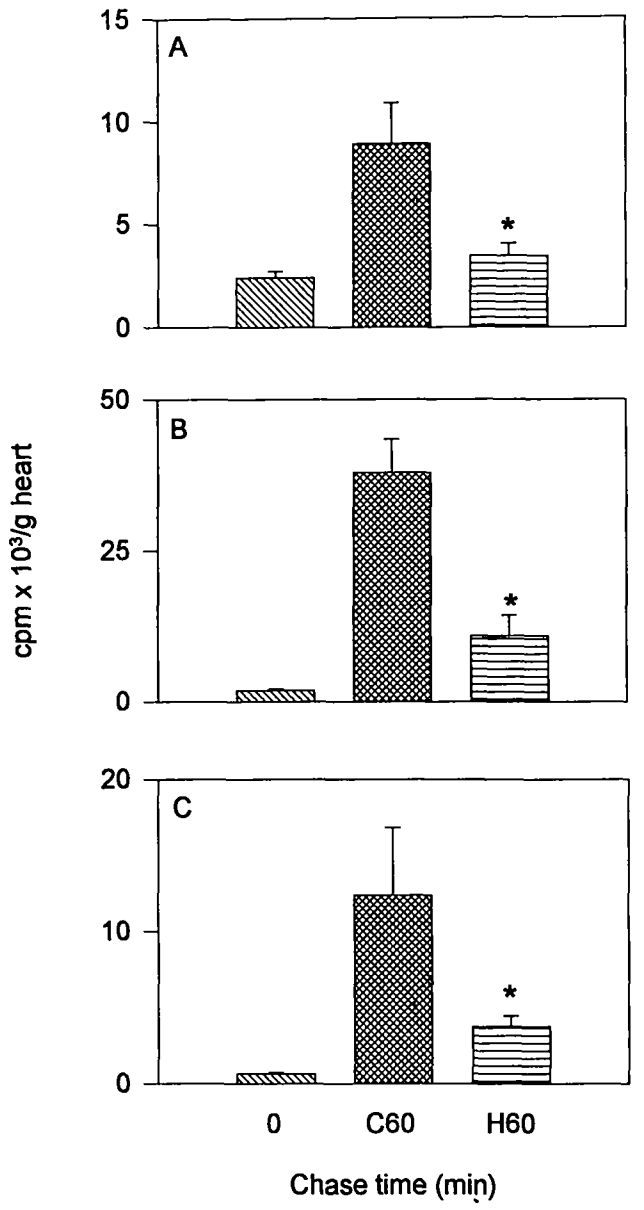

FIG. 3. Pulse-chase experiment of 1.4 mM [^{32}P]P_i incorporated into CDP-1,2-diacyl-*sn*-glycerol (CDP–DG), PG, and CL. Rat hearts were pulsed for 15 min with KHB containing 1.4 mM [^{32}P]P_i under control conditions (0). Subsequently, the hearts were perfused for 60 min with Krebs Henseleit buffer under control (C60) or hypoxic (H60) conditions. The hearts were homogenized subsequent to perfusion, and various phospholipids were isolated by thin-layer chromatography. The radioactivity associated with (A) CDP–DG, (B) PG, and (C) CL was determined. Vertical bars represent the mean ± SD of three hearts (*$P < .05$). See Figure 2 for abbreviations.

control and hypoxic hearts (Fig. 3). In contrast, radioactivity incorporated into CDP–DG, PG, and CL was decreased 61% ($P < .05$), 71% ($P < .05$), and 70% ($P < .05$), respectively, in hypoxic hearts compared to controls (Fig. 3). These experiments suggested that a reduction in the formation of new CDP–DG, PG, and CL occurred in the hypoxic heart.

Effect of hypoxia on the pool size of CL, PG, and CDP–DG. To determine if hypoxia affected CL mass, rat hearts were perfused under control or hypoxic conditions for 60 min. Subsequently, the phospholipids were extracted after 60 min of perfusion and the phospholipid phosphorus determined. As seen in Figure 4, there were no significant changes in the pool sizes of CL, PG, and CDP–DG between hypoxic hearts and controls. The phosphorus mass of other phospholipids were determined from the heart extract and were unaltered. PA, phosphatidylinositol, phosphatidylethanolamine, phosphatidylcholine, phosphatidylserine, sphingomyelin, and lysophosphatidylcholine content were 38 ± 24, 1,077 ± 103, 6,858 ± 138, 7,946 ± 958, 655 ± 72, 177 ± 31, and 144 ± 19 nmol/g, respectively, of heart in control hearts and were unchanged after perfusion under hypoxic conditions. Thus, the

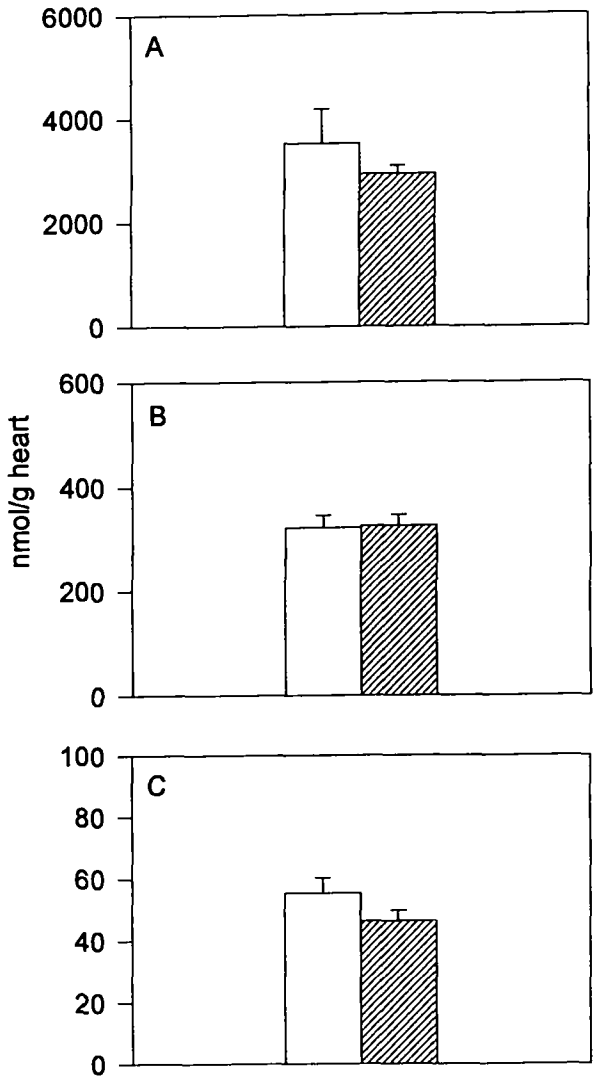

FIG. 4. Pool size of CL, PG, and CDP–DG in control and hypoxic hearts. Hearts were perfused for 60 min with KHB under control (open columns) or hypoxic (hatched columns) conditions. The hearts were homogenized subsequent to perfusion and phospholipids were isolated by thin-layer chromatography. The pool sizes were determined for: (A) CL, (B) PG, (C) CDP–DG. The vertical bars represent the mean ± SD of at least three hearts.

TABLE 1
***In vitro* Enzyme Activities Involved in Cardiolipin Biosynthesis[a]**

Enzyme	Activity (pmol/min per mg of protein) Control	Hypoxic
CTP:PA cytidylyltransferase	33.1 ± 6.5 (3)	33.5 ± 9.7 (3)
PGP synthase	72.6 ± 9.7 (3)	71.7 ± 13.5 (3)
CL synthase	1.0 ± 0.7 (4)	1.1 ± 0.5 (3)
PGP phosphatase	0.70 ± 0.05 (3)[b]	0.72 ± 0.13 (3)[b]

[a]Rat hearts were perfused for 60 min with Krebs Henseleit buffer under either control or hypoxic conditions. Subsequent to perfusion, the hearts were homogenized, and the activities of the enzymes involved in cardiolipin (CL) biosynthesis were determined in isolated mitochondrial fractions prepared from the homogenate. The enzymes were assayed under optimal conditions. Values represent the mean ± SD (number of hearts). PGP, phosphatidylglycerolphosphate; PA, phosphatidic acid.
[b]nmol/min per mg of protein.

reduction of radioactivity in CL in the hypoxic heart was not caused by a change in the pool size of CL or its precursors.

Effect of hypoxia on the in vitro *enzyme activities involved in CL biosynthesis.* The decrease in radioactivity observed in CL could be due to a change in the activity of one of the enzymes involved in CL biosynthesis. Thus, the specific activities of the enzymes involved in CL biosynthesis from control and hypoxic hearts were determined. Hearts were perfused for 60 min under control or hypoxic conditions. Subsequent to perfusion, the hearts were homogenized, and the mitochondrial fraction was prepared by differential centrifugation. CTP:PA cytidylyltransferase, PGP synthase, PGP phosphatase, and CL synthase were assayed in the isolated mitochondrial fractions. Enzyme activities between the control and hypoxic hearts were unaltered (Table 1). Thus, the reduction of radioactivity in CL in the hypoxic heart was not caused by a change in the activity of the enzymes involved in CL biosynthesis.

Effect of hypoxia on ATP and CTP level of the heart. In the CDP–DG pathway, CTP is a cofactor required for the conversion of PA to CDP–DG. Since the continuous-pulse and pulse-chase labeling studies indicated a possible decreased formation of new CDP–DG, the levels of cardiac ATP and CTP were determined in the hearts perfused for 60 min under control or hypoxic conditions. It was found that in the hypoxic hearts, ATP and CTP levels were significantly decreased 94 and 92%, respectively, when compared to controls (Table 2). Thus, the large reduction of cardiac CTP may have been responsible for the decreased formation of CDP–DG in the hypoxic hearts and the resulting decrease in radioactivity incorporated into CL.

TABLE 2
ATP and CTP Concentration in Control and Hypoxic Hearts[a]

	ATP	CTP
	(nmol/ g heart)	
Control	633 ± 110 (3)	5.25 ± 0.85 (3)
Hypoxic	39 ± 8 (3)[b]	0.41 ± 0.06 (3)[b]

[a]Rat hearts were perfused for 60 min with Krebs Henseleit buffer saturated with either control or hypoxic conditions. Subsequent to perfusion ATP and CTP levels were quantified by C_{18} reverse-phase high-performance liquid chromatography. Values represent the mean ± SD (number of hearts).

DISCUSSION

The purpose of this study was to determine if hypoxia affected CL biosynthesis in the heart. In order to examine this hypothesis, we perfused hearts in the Langendorff mode with radioactive glycerol or P_i under control or hypoxic conditions. Langendorff perfusion is a highly reproducible, stable method which is especially useful in metabolic labeling studies (29). In the continuous pulse-labeling studies, we observed an apparent reduction in the biosynthesis of new PG and CL. In addition, the pulse-chase studies indicated that the radioactivity incorporated into CDP–DG, PG, and CL was reduced in the hypoxic hearts compared to controls at 60 min of perfusion. Thus, perfusion of the heart under hypoxic conditions inhibits CL biosynthesis.

The level of cardiac ATP and CTP was reduced by perfusing the isolated rat heart under hypoxic conditions consistent with that of hamster hearts perfused under similar conditions (19). Indeed, following a 60-min perfusion under hypoxic conditions, we observed a 94% decrease in the cardiac ATP level compared to controls. ATP is required for the amination reaction in CTP production (30); therefore, loss of ATP would consequently reduce the biosynthesis of CTP. We observed a corresponding reduction of 92% in the cardiac CTP level in hypoxic hearts compared to controls.

The mechanism of the reduction of CL biosynthesis under hypoxic conditions was investigated. Our results indicated that the activities of the enzymes of the CDP–DG pathway were unaltered between the hypoxic and control hearts. This is in contrast to previous studies on PC biosynthesis in the hamster heart (19,31). In those studies, CTP:phosphocholine cytidylyltransferase activity was increased as a compensatory mechanism for the reduction in cardiac CTP level. The results of the present study suggest that there may not be such a compensatory mechanism for reduced CL biosynthesis caused by lowered cardiac CTP.

ATP is required to convert glycerol to glycerol-3-phosphate, and oxygen is required for oxidative phosphorylation and the conversion of [^{32}P]Pi to [^{32}P]ATP. Thus, the reduction in labeling of PG and CL in the [^{32}P]Pi perfused hearts was not surprising. Depletion of cardiac ATP and, hence, CTP might also result in a decreased formation of new CDP–DG, producing less available radioactive CDP–DG to form CL. Indeed, this was observed in the pulse-chase studies. Despite the drastic reduction in the ATP and CTP level of the heart, the pool sizes of CDP–DG, PG, and CL in the hypoxic hearts were unchanged compared to controls. One possible explanation for this is that a large decrease of phospholipid mass would simply be incompatible with the viability of the heart. Alternatively, the total phospholipid pool may eventually decrease but was not detectable after 60 min of perfusion under

hypoxic conditions. Perhaps an alteration in phospholipid mass would be apparent if the hypoxic treatment was prolonged. However perfusion for periods beyond 60 min under hypoxic conditions causes irreversible damage to the heart (19).

Previous studies have set a precedent for the regulation of CL biosynthesis under conditions of altered mitochondrial oxidative metabolism. For example, thyroid hormone treatment of rats increased the oxidative activity of heart mitochondria and increased the CL content in these hearts 51% (32). In rat liver, CL synthase activity was increased 52% in rats treated with thyroxine (33). Such an increase in CL synthase activity has offered a plausible mechanism for the increased CL observed in the tissues of thyroid hormone-treated animals. The above studies are in contrast to our study utilizing acute hypoxia, since thyroid-induced increased oxidative activity appears to be associated with increased CL biosynthesis. The observed reduction in cardiac PG and CL biosynthesis in hearts perfused under hypoxic conditions is interesting in light of the observation that ultraviolet A radiation inhibits PG and CL biosynthesis in N.C.T.C. 2544 human keratinocytes (34) and decreased ATP levels have been observed in lymphocytes exposed to a ultraviolet A radiation (35).

In summary, we have utilized an intact isolated rat heart to study the effect of hypoxia on CL biosynthesis. We have shown that perfusion of the heart under hypoxic conditions will result in the reduction of newly synthesized CL. The results provide strong evidence to support that the biosynthesis of CL is governed by the ATP and CTP level of the heart.

Absorption of Triglycerides with Defined or Random Structure by Rats with Biliary and Pancreatic Diversion[1]

Michael Søberg Christensen[a,b,*], Anette Müllertz[c] and Carl-Erik Høy[a,b]

[a]Department of Biochemistry and Nutrition and [b]Center for Food Research, Technical University of Denmark, DK-2800 Lyngby, Denmark, and [c]Novo Nordisk A/S, DK-2880 Bagsvaerd, Denmark

ABSTRACT: Fat absorption may be compromised by pancreatic or bile insufficiency, resulting in low uptake of essential fatty acid and energy. Using a rat model of malabsorption, we examined the absorption of defined triglycerides with medium-chain fatty acids (MCFA) in the *sn*-1,3 positions and essential fatty acids in the *sn*-2 position (MLM) compared to other fats. The thoracic duct was cannulated for collection of lymph, and the common bile and pancreatic duct was cannulated to divert both the pancreatic juice and bile. The rats were given a single bolus of triglyceride as a taurocholate emulsion. Fat absorption was measured from collected lymph samples. The triglycerides administered were a defined triglyceride, MLM [mainly (8:0/10:0)-(18:2n-6)-(8:0/10:0)], a similar triglyceride subjected to chemical randomization, a mixture of medium-chain triglycerides and soybean oil, and soybean oil, respectively. The first three triglycerides had approximately 36 wt% linoleic acid (18:2n-6) content. Administration of defined triglyceride was followed by significantly higher lymphatic level (wt%) of 18:2n-6 ($P < 0.01$) as well as a relative enhancement in mol% of 18:2n-6 ($P < 0.05$) compared to the other triglycerides. Lymphatic absorption of MCFA was similar in the three first groups but not as efficient as for long-chain fatty acids. Our results indicate that defined triglycerides thus may provide a means to increase absorption of essential fatty acids in fat malabsorption, such as that seen in cystic fibrosis, or for pre-term infants.
Lipids 30, 521–526 (1995).

In the digestion of triglycerides (TG), lingual, gastric, and pancreatic lipases participate, of which under normal circumstances the pancreatic lipase is predominant. In certain patients, fat malabsorption may occur due to reduced or absent activity of pancreatic lipase, for instance, in cystic fibrosis in which the pancreatic duct may be occluded or in the pre-term infant with immature pancreas (1,2). In the treatment of cystic fibrosis, two strategies have been followed: (i) addition to the diet of major doses of protected hydrolytic enzymes (1); or (ii) addition to the diet of medium-chain triglycerides (MCT), which can be hydrolyzed very rapidly by lingual or gastric lipase, but do not contain essential fatty acids (EFA) (3). In order to include EFA in these TG, chemical interesterification of soybean oil and MCT has been used to produce TG which contain both MCFA and EFA, but with two-thirds of the EFA esterified in the *sn*-1,3 positions in contrast to normal fats (4,5). Since the lingual and gastric lipases are *sn*-3 specific and preferentially hydrolyze MCFA, these interesterified TG may not be optimal. By lipase-catalyzed *sn*-1,3 specific interesterification, it is, however, possible to produce TG in which EFA are maintained in the *sn*-2 position and MCFA are introduced into the *sn*-1,3 positions of the TG molecule.

In the present experiment, we used a rat model of pancreatic insufficiency and examined the absorption of various fats. We introduced a cannula into the thoracic lymph duct for collection of lymph containing the absorbed fat released as chylomicrons and a cannula into the common bile and pancreatic duct to divert bile and pancreatic juice from the intestine. We examined the absorption of four different fats: (i) A triglyceride with defined structure containing 18:2n-6 in the *sn*-2 position and MCFA in the *sn*-1,3 positions; (ii) a fat with similar fatty acid profile but random distribution of the fatty acids in the TG molecule as the presently used structured TG; (iii) A mixture of MCT and soybean oil; and (iv) soybean oil.

Our experiment demonstrates that in this model the best absorption of EFA is obtained from TG with defined structure.

MATERIALS AND METHODS

Animals. Male Wistar rats (Møllegaarden Breeding Laboratory, Ll. Skensved, Denmark) weighing 200–250 g, which had been raised on formula stock diet were fasted overnight (16 h) prior to surgery and then randomly divided into four groups.

Dietary fats. Defined TG with medium-chain, long-chain, medium-chain fatty acids (MLM), randomized MLM, a mixture of MCT and soybean oil, or soybean oil were used as bolus fat. The defined MLM and the randomized MLM were produced by Novo Nordisk A/S (Bagsvaerd, Denmark). The fatty acid composition and the structure of these oils (Table 1) were determined. Fatty acid profile was determined by

gas–liquid chromatography (GLC). Fatty acid methyl esters were prepared with sodium methoxide (6). The fatty acid methyl esters were analyzed by GLC using a Hewlett-Packard 5890, series II (Waldbronn, Germany) chromatograph with a fused-silica capillary column (SP™-2380, 30 m × 0.32 mm i.d.; Supelco, Inc., Bellefonte, PA). Initial oven temperature was 70°C for 5 min followed by temperature programming at a rate of 15°C/min until 140°C, which was maintained for 2 min, and hereafter 3.5°C/min until 200°C. The final temperature was maintained for 18 min. Injection was on-column, and the carrier gas was helium at an initial flow rate of 2 mL/min. The fatty acid methyl esters were identified by GLC of authentic standards. TG structure was determined by regiospecific Grignard degradation followed by analysis of the 2-monoglycerides (7).

Fat emulsions were prepared by sonicating 0.5 mL fat with 0.5 mL of taurocholate (20 mM) plus 5 mg choline for 10 s (M.S.E. 150 watt Ultrasonic Disintegrator; M.S.E. Inc., Crawley, England. Settings: power: medium, Amplitude: 3). The emulsion was cooled with ice water during this procedure.

Surgical procedure. The experiments were approved by The Danish National Committee for Animal Experiments. Each animal was anesthetized with pentobarbital (8 mg/100 g body weight, i.p.), and after tracheostomy, the abdominal cavity was opened. A feeding tube was introduced orally about 2 cm into the stomach and secured with a ligature. The common bile and pancreatic duct was exposed close to the duodenum. A polyethylene catheter, 0.28 mm i.d. and 0.61 mm o.d., was inserted into the duct toward the liver and secured. The free end of the catheter was exteriorized. *Ductus thoracicus* was cannulated according to a modified procedure of Bollman *et al.* (8): The aorta was separated from the lymphatics cranially for the *cisterna chyli*. Approximately 0.8–1 cm of the duct was freed of connective tissue and two ligatures placed around the duct at a distance of 5 mm. The duct was partially transected and a U-shaped polyethylene catheter, 0.58 mm i.d. and 0.96 mm o.d., with a short bevel and prefilled with heparin (5000 i.U./mL), was inserted into the duct. The catheter was secured and exteriorized from the abdomen. The viscera was replaced *in situ* and the wound was closed. The rats were maintained at 25°C in anesthesia throughout the experiment.

Administration of oil emulsion and collection of lymph. After the surgery, the oil emulsion was administered intragastrically through the feeding tube followed by 1 mL of physiological saline, and the saline infusion was continued at a rate of 2 mL/h. The lymph was collected in tared tubes at 0°C containing 50 μL of a 10% (wt) solution of sodium EDTA. The collection of lymph commenced the moment the oil emulsion was administered and was pooled in 30-min fractions in the first 4 h and 60 min fractions in the following 4 h. The lymph samples were frozen immediately and kept at −20°C until further processing.

Lipid analysis. Fifty μL were taken from each fraction, and after addition of internal standard (methylpentadecanoate), the total lipid fraction was extracted according to Folch *et al.* (9). The solvent was evaporated under nitrogen, and the lipids resolved in 1 mL hexane. The fatty acid profile was determined as previously described for the dietary oils.

Data analysis. The data represent mean ± SEM. Two-way analysis of variance with the factors time and oil was used to test for significant differences between fatty acid wt% profiles. Student's *t*-test was used to test for significant variations in the total recovery and enhancement in mol% between groups. The absorption patterns were examined by fitting the best cubic polynomials to the means of the accumulated lymphatic transport.

RESULTS

The lymphatic absorption of various oils was examined in anesthetized rats subjected to cannulations of the thoracic duct and the common bile and pancreatic duct. Each sample

taken at a given time represented the total lymph collected between the previous collection and the designated time. The lymph flow was approximately 0.5 mL/h in all four groups.

The content of 18:2n-6 (wt%) in the lymph increased rapidly from the initial level of approximately 26% following administration of the oils and plateaued after 2 h (Fig. 1). The content was significantly higher ($P < 0.01$) after administration of defined MLM compared with the other oils. The plateau level of 18:2n-6 (wt%) in the lymph was 45.1 ± 1.6 (last sample) after administration of defined MLM, which was higher than the content of 18:2n-6 in the defined MLM administered (37.8%). After administration of randomized MLM or a mixture of MCT and soybean oil, the lymph contents plateaued at 40.7 ± 3.5 and 34.8 ± 2.4, respectively, which was approximately the same levels of 18:2n-6 as the contents of the administered oils. After administration of soybean oil, the content of 18:2n-6 increased from 26.7 ± 0.9 to 39.7 ± 2.2, which was much lower than in the soybean oil (53 wt% 18:2n-6).

As some MCFA were transported through the lymphatics, the wt% was converted to mol%, due to differences in molecular weight. The enhancement in mol% of 18:2n-6 (Fig. 2) was significantly greater following administration of defined MLM compared to the other sources ($P < 0.05$). For this calculation of the enhancement in mol%, the data for the 180–480-min period was pooled under the assumption that a steady state had been reached.

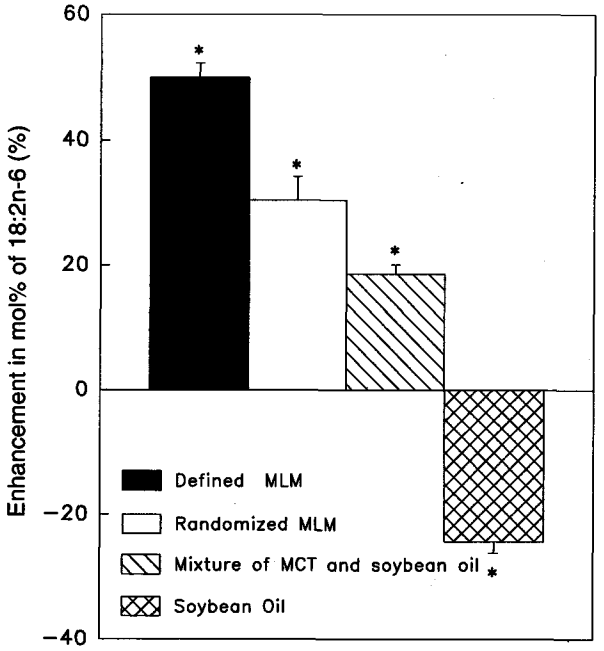

FIG. 2. The enhancement in mol% of 18:2n-6 in lymph total lipid fraction relative to the oil administered. The values represent mean ± SEM of the pooled data within each group from 180–480 min calculated as: [(mol% 18:2n-6 in the lymph/mol% 18:2n-6 in the oil) × 100 − 100]. Defined MLM, n = 39; randomized MLM, n = 42; mixture of MCT and soybean oil, n = 35; soybean oil, n = 28. *Significant differences at $P < 0.05$. See Figure 1 for abbreviations.

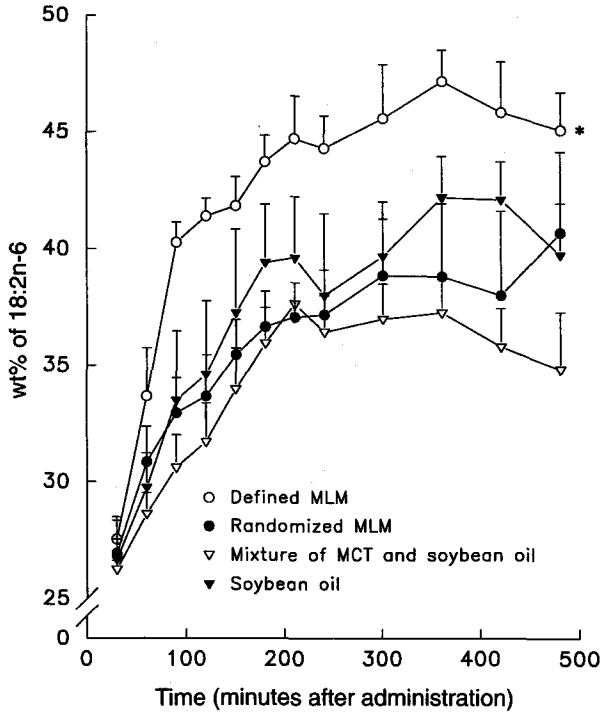

FIG. 1. Appearance of 18:2n-6 (wt%) in the lymph after administration of either defined triglycerides with medium-chain, long-chain, medium-chain fatty acids (MLM) (n = 6), randomized MLM (n = 6), mixture of medium-chain triglycerides (MCT) and soybean oil (n = 5), or soybean oil (n = 4). Values are expressed as mean ± SEM. *Significantly different from the three other groups at $P < 0.01$ by two-way analysis of variance.

The total recovery (percentages) of 18:2n-6 in the thoracic lymph was greater following administration of defined MLM compared to the three other types of TG which gave similar recoveries (Table 2).

TABLE 2
Recovery (% of administered amount of fatty acid)

	Fatty acid			
Administered fat	8:0	10:0	18:2n-6[a]	18:3n-3[b]
Structured MLM (n = 6)	0.8 ± 0.2	1.6 ± 0.4	9.9 ± 1.7	8.9 ± 1.9
Randomized MLM (n = 6)	0.7 ± 0.1	1.1 ± 0.2	5.7 ± 1.7	4.4 ± 1.0
MCT and soybean oil (n = 5)	1.3 ± 0.5	4.6 ± 1.6	6.6 ± 1.6	5.1 ± 1.6
Soybean oil (n = 4)	ND[c]	ND	3.7 ± 1.3	2.8 ± 1.3

[a]Significance level: for comparisons of 18:2n-6, $P = 0.07$ for structured MLM vs. randomized MLM; $P = 0.20$ for structured MLM vs. MCT and soybean oil; $P = 0.03$ for structured MLM vs. soybean oil.
[b]For comparisons of 18:3n-3, $P = 0.06$ for structured MLM vs. randomized MLM; $P = 0.17$ for structured MLM vs. MCT and soybean oil; $P = 0.05$ for structured MLM vs. soybean oil.
[c]ND, not detected. Data are expressed as mean ± SEM. *Student's t-test* was used to test for significant differences between the dietary groups. See Table 1 for abbreviations.

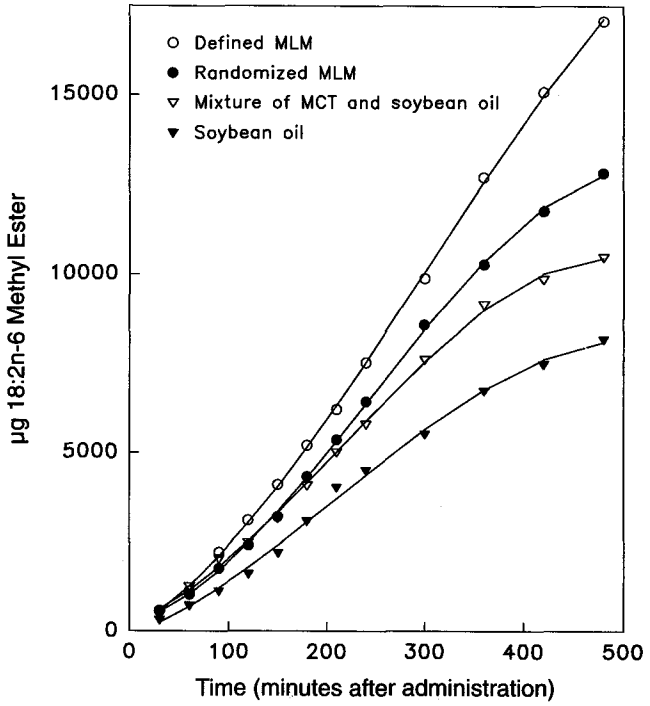

FIG. 3. The amount (μg) of 18:2n-6 transported through the lymphatics accumulated over the experimental period after administration of defined MLM (n = 6), randomized MLM (n = 6), mixture of MCT and soybean oil (n = 5), and soybean oil (n = 4). The curves indicate the best fitted cubic polynomials through the actual means (symbols). See Figure 1 for abbreviations.

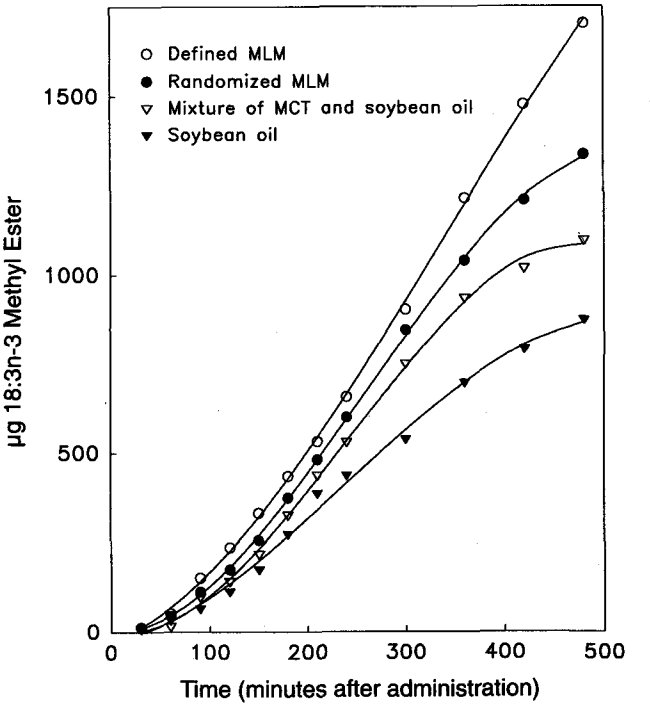

FIG. 4. The amount (μg) of 18:3n-3 transported through the lymphatics accumulated over the experimental period after administration of defined MLM (n = 6), randomized MLM (n = 6), mixture of MCT and soybean oil (n = 5), and soybean oil (n = 4). The curves indicate the best fitted cubic polynomials through the actual means (symbols). See Figure 1 for abbreviations.

The absorptions of 18:2n-6 and 18:3n-3 into the thoracic lymph as estimated from the amount (μg) accumulated in the lymph over the 8-h collection period are shown in Figures 3 and 4. The amount absorbed over the 8-h period was greater, and there seemed to be a progressive tendency beyond the 8-h for the increased absorption of both 18:2n-6 and 18:3n-3 from defined MLM compared to the other oils. This was evident from comparison of the slopes of the curves at the end of the experimental period: The absorption continued for defined MLM throughout the experimental period, whereas the slopes for the other three groups declined.

MCFA were also transported by the thoracic lymph duct but not as efficiently as long-chain fatty acid (LCFA) as seen by a relatively lower content of MCFA in the lymph lipids compared to the administered oils. The lymphatic transport of 10:0 was relatively higher compared to 8:0. The lymphatic levels of MCFA (maximal wt%) observed within the experimental period for 8:0 were 3.6 ± 0.8, 4.9 ± 0.9, 4.1 ± 1.3, not detected; and for 10:0, 7.8 ± 1.7, 9.0 ± 1.2, 6.9 ± 2.1, not detected, in defined MLM, random MLM, mixture of MCT and soybean oil, and soybean oil, respectively. There were no significant differences in the total lymphatic transport of MCFA between the three groups.

DISCUSSION

In this experiment, we examined the effect of TG structure and fatty acid profile on the intestinal absorption of linoleic acid. The study was performed in a rat model of pancreatic insufficiency, since obvious future applications of defined TG are in cases of malabsorption (10–12). The common bile and pancreatic duct was cannulated close to the entrance of the duodenum, and both the bile and the pancreatic juice were diverted. The absorption of fatty acids was monitored by collection of the total thoracic duct lymph which drains the chylomicrons secreted by the intestine.

In this model of pancreas insufficiency, the fatty acid absorption profiles demonstrated that EFA was better absorbed from defined TG compared to randomized TG, mixture of soybean oil and MCT, or soybean oil, although the last of these had a considerably higher content of 18:2n-6. The more efficient absorption of 18:2n-6 and 18:3n-3 from defined MLM is also evident from the accumulated 8-h absorptions. The absorption of EFA from defined MLM continued at a constant rate throughout the observed period, whereas the rate of absorption from the other fats declined toward the end of the experiment.

We administered the test emulsions intragastrically in order to reflect the hydrolysis due to the action of preduodenal lipases which are important in fat absorption during pancreatic insufficiency (1). In the rat, this lipase activity is mainly lingual, whereas gastric lipase is prominent in humans (2). In the present experiment, the esophageal secretion was obstructed, which previously was demonstrated to decrease intragastric hydrolysis of ingested fat by 90% (13). A normal

level of preduodenal lipases, irrespective of the origin, might result in a more significant difference in the absorption of defined MLM than observed in this experiment since these lipases favor degradation of TG with MCFA esterified in the *sn*-1,3 positions.

We did not monitor the portal vein transport of fatty acids. To determine the total absorption, this transport pathway should be taken into account, especially for MCFA but also for absorption of LCFA (14–16). It is well-established that the transport of MCFA by the portal vein is higher compared to LCFA in agreement with the present findings. However, the lymphatic transport of 10:0 was considerably greater compared to 8:0, especially when the content in the administered oil is taken into consideration. The major absorption pathway for 18:2n-6 is by the lymphatic system, irrespective of the experimental conditions considered (14), although the portal absorption becomes significant for low infusions (0.3–3 μmol/h) of 18:2n-6 (17). In the present experiment, the luminal load of 18:2n-6 was approximately a thousandfold higher and the average lymphatic output of 18:2n-6 was 60–70 μmol/h, demonstrating that the luminal load was adequate to make the lymphatic absorption the main pathway.

Endogenous fatty acids in the lymph predominantly originate from the bile (18) which was diverted in the present experiment. During lipid absorption, mucosal uptake of plasma free fatty acids and incorporation into intestinal TG is increased (19), but the dietary fatty acids are the major fatty acids of the lymph (20). The lymphatic transport of fat is reduced in bile-diverted rats as fat accumulates inside the enterocytes primarily due to the lack of biliary phosphatidylcholine (21,22). Previously, addition of choline has been demonstrated to have a similar influence on the fat transport, as adding egg yolk lecithin, and normalized the transport to the level of sham-operated rats (21). The fat absorption in our experiment was reduced fivefold compared to rats without common duct cannulation (23), indicating that a state of malabsorption had been established. Valdivieso and Schwabe (24,25) examined the influence of both pancreatic juice and bile on the absorption of trioctanoin and observed a 2.5–3-fold reduction after bile diversion and a 5–7-fold reduction after pancreatic atrophy in agreement with Bézard and Bugaut (26).

We observed lower lymphatic flow compared to experiments with unanesthetized rats (27), probably due to the influence of the anesthesia which in dogs has been demonstrated to reduce the lymph flow by 50% (28). Saline was infused at a rate of 2 mL/h, and bile and pancreatic juice were diverted at a rate of approximately 1 mL/h. The total absorption of fat was probably affected by the low lymph flow, but it should not influence the relative absorptions among parallel groups given different fats as the lymph flows were similar for all groups.

In a previous paper, Ikeda *et al.* (29) described the thoracic lymph absorption of 18:2n-6, 8:0, and 10:0 from various defined TG in rats with normal pancreatic lipase and bile secretion. They found higher absorption of 18:2n-6 from 8:0/18:2/8:0 than from 18:2/8:0/18:2 or from 18:2/18:2/18:2, and higher levels in the lymph of 8:0 and 10:0 when these fatty acids were located in the *sn*-2 position of the TG. However, they did not compare the absorption of fatty acids from TG with similar fatty acid profiles by defined or random structure. Our experiments demonstrate that when rats were fed TG with similar fatty acid profiles, the 18:2n-6 was better absorbed from a defined TG with 18:2n-6 in the *sn*-2 position. Furthermore, in our experiments we used defined TG and randomized TG, which were produced from soybean oil and MCT. Our experiment thus confirms the findings of Ikeda *et al.* (29) and extends them to include a state of reduced bile and pancreatic lipase levels and, furthermore, demonstrate the potential use of defined TG produced from commercially available fats.

We found that linoleic acid was considerably better absorbed from defined MLM than from soybean oil, in agreement with previous experiments by Jandacek *et al.* (30). They used rats with irrigated intestinal loop as a model for pancreatic insufficiency and demonstrated that 18:2n-6 was better absorbed from 8:0/18:2/8:0 than from 18:1/18:2/18:1. They did not, however, compare TG with similar fatty acid profiles and different structures. The relatively low content (wt%) of 18:2n-6 in the lymph observed after administration of soybean oil most likely reflects that soybean oil is absorbed less readily than oils containing MCFA either due to the emulsification properties or substrate specificities of the lipases in the gastrointestinal tract.

Jensen *et al.* (31) have demonstrated that TG with random structure based on MCT and fish oil are well absorbed into the lymph in dogs. They agreed with our results that the MCFA were well-absorbed from interesterified fats and from mixtures of MCT and polyunsaturated fat, but they detected no difference in absorption of polyunsaturated fatty acids. Recently, we have demonstrated in rats that defined TG with decanoic acid esterified in the *sn*-1,3 positions and n-3 polyunsaturated fatty acids in the *sn*-2 position were more readily absorbed compared to randomized TG with similar fatty acid composition (32) in agreement with the present findings in bile and pancreatic insufficient rats. Guillot *et al.* (33) also demonstrated lymphatic uptake of 8:0 and 10:0 in pancreatic-deficient pigs given a continuous duodenal infusion of MCT, indicating that these fatty acids are absorbed and that a considerable part will be released to the lymph.

Randomly esterified TG containing MCFA and 18:2n-6, which are frequently described in literature as structured lipids, are suitable sources of EFA and nonglucose energy for cystic fibrosis patients (5). Our study indicates that defined TG with MCFA in the *sn*-1,3 positions may be an even better fat source. This may result from the esterification of MCFA in the *sn*-1,3 positions since both the lipases in the gastrointestinal tract and preduodenal lipases are *sn*-1,3 specific and preferentially hydrolyze MCFA, resulting in rapid absorption of MCFA as free fatty acids and polyunsaturated fatty acids as 2-monoglyceride.

It has been hypothesized that MCT may be absorbed directly across the intestinal wall (34,35). The molecular

weights of structured MLM and the MCT used by Chow *et al.* (35) are similar to those in the present study, and, therefore, a contribution of structured TG taken up as such, or perhaps diglycerides, cannot be excluded.

Patients with cystic fibrosis may suffer from fat malabsorption caused by impaired secretion of pancreatic lipase (36). This may result in altered EFA status and in extreme cases may initiate EFA deficiency (37,38). Attempts to correct the EFA abnormalities using intravenous (39,40) or oral (41,42) administration of several types of lipid supplementation have been inconclusive.

In prolonged treatment, enteral administration of lipid supplementations must be preferred over intravenous administration. Defined MLM provides EFA as well as energy and should be considered as a possible dietary fat in the future treatment of malabsorption.

Sources of Triacylglycerol Accumulation in Livers of Rats Fed a Cholesterol-Supplemented Diet

Chuan-Hsiu Liu[a], Ming-ta Huang[b] and Po-Chao Huang[c,*]

[a]Department of Biochemistry, China Medical College, Taichung, [b]Department of Biochemistry, Chang Gung College of Medicine and Technology, Tao-yuan and [c]Department of Biochemistry, College of Medicine, National Taiwan University, Taipei, Taiwan

ABSTRACT: The source of free fatty acids (FFA) and the pathways contributing to the accumulation of neutral fats in livers of rats fed a cholesterol-enriched diet were investigated in this report. Supplementation with 1% cholesterol in the diet for four weeks resulted in hepatomegaly in the rats. The contents of cholesterol and triacylglycerols (TG) per gram liver measured in rats fasted overnight increased by 48 mg (~tenfold) and 66 mg (~fourfold), respectively. The activities of glycerophosphate acyltransferase and diacylglycerol acyltransferase, the two key enzymes for TG synthesis in liver microsomes, were found to increase by 23 and 19%, respectively, in the cholesterol-fed rats. The secretion of plasma TG present predominantly in very low density lipoprotein was found to decrease by ~30%. The incorporation of tritium from tritiated water in liver FFA increased by twofold in rats fed the cholesterol-supplemented diet, whereas the activity of CPT I in liver mitochondria decreased by 23%. The uptake of plasma FFA *in vivo* in livers of fasted rats maintained on the cholesterol-supplemented diet decreased by 60%. Our data thus indicate that the excess TG accumulated in livers of rats fed the cholesterol-enriched diet resulted from increased synthesis and decreased secretion of TG. To meet the demand of fatty acids for this purpose, *de novo* lipogenesis increased, whereas β-oxidation decreased. Although difference in the uptake of extrahepatic FFA may be discounted, a difference in the uptake of chylomicron remnants between the control and cholesterol-fed rats may not be ruled out.
Lipids 30, 527–531 (1995).

We have previously found that rats fed diets enriched in cholesterol often developed moderate to severe fatty livers (1,2). Cholesterol and triacylglycerols (TG) were found to accumulate in the liver (1,2). It has been suggested that the etiology of the fatty liver is related to essential fatty acid (EFA) deficiency (3), as linoleic acid was shown to be a preferred substrate for the esterification of cholesterol (4). EFA deficiency may impair the synthesis and function of phospholipids (PL) in the liver. Consequently, the ability to assemble and secrete very low density lipoprotein particles (VLDL) may be impaired. Recent reports by Fungwe *et al.* (5–7), however, showed that cholesterol-induced fatty liver was not necessarily related to EFA deficiency. Supplementing the cholesterol diets with a large quantity of corn oil (5–20%), a vegetable oil rich in linoleic acid, failed to prevent the accumulation of excess TG in the liver (6). Furthermore, the secretion of VLDL from the perfused liver was shown not to decrease, but rather to increase, in rats fed cholesterol-supplemented diets (7).

TG accumulation in the liver may be caused by increased synthesis of TG in the liver and/or decreased secretion of TG from the liver (5). The availability of free fatty acids (FFA) in the hepatocytes may be increased through an increase in *de novo* synthesis (7), an increase in uptake from extra-hepatic sources (6), and/or a decrease in β-oxidation (6). In this report, the roles of these metabolic pathways in contributing to cholesterol-induced fatty liver were characterized.

MATERIALS AND METHODS

Chemicals. L-[2-^{3}H]Glycerol 3-phosphate, disodium (10.6 Ci/mmol), [1-^{14}C]palmitoyl CoA (60 mCi/mmol), and tritiated water (1 Ci/mL) were purchased from Du Pont/New England Nuclear (Boston, MA). L-[methyl-^{3}H]Carnitine hydrochloride (74 Ci/mmol) was purchased from Amersham Corp (Arlington Heights, IL). Enzyme kits for the determination of cholesterol, TG, and FFA were purchased from Boehringer Mannheim (Mannheim, Germany). The kit for the determination of PL was purchased from bioMerieux Co. (Marcy-l'Etoile, France). Triton WR-1339 was purchased from Sigma Chemical Co. (St. Louis, MO). All other chemicals and reagents were of analytical grade.

Animals and diets. Male Wistar rats (190–210 g) were housed in a room with a 12 h light–dark cycle (light period: 7 a.m. to 7 p.m.). The animals were divided into two groups—one was fed a cholesterol-supplemented diet (1%) and the other the control diet for four weeks. The compositions of the control and cholesterol-supplemented diets are shown in Table 1. Lard and soybean oil were proportioned in the diets to yield a polyunsaturated/saturated fatty acid ratio of 1. De-

[a]AIN 76 vitamin and mineral mixtures.

pending on the protocol, the rats were either fed or fasted overnight at the time of the experiment. For rats fasted overnight, the food was removed at 5 p.m. and the experiment started at ~9 a.m. on the next day. The animals were allowed free access to drinking water at any time prior to the experiment.

Lipid analyses. Rats fasted overnight were sacrificed by decapitation. Blood was collected in tubes containing EDTA (1 mg/mL). Livers were excised and placed in ice-cold saline. The weight of the liver was determined after blotting dry. The livers were minced. Total lipids in the liver were isolated by the method of Folch *et al.* (8). The concentrations of cholesterol, PL, and TG were determined by the methods of Abell *et al.* (9), Stewart (10), and Soloni (11), respectively. Plasma was separated from blood cells by centrifugation. Plasma FFA were measured enzymatically (12).

Enzyme assays. Liver mitochondria were isolated from fed rats according to Harper and Saggerson (13). The microsomal fraction of liver homogenates was isolated according to Erickson *et al.* (14). The activity of mitochondrial CPT I was assayed by measuring the formation of [^{3}H] palmitoylcarnitine from [^{3}H] carnitine and palmitoyl CoA according to Saggerson *et al.* (15). The activity of microsomal diacylglycerol acyltransferase (DGAT) was measured by following the formation of [^{14}C] TG from [^{14}C] palmitoyl CoA and diacylglycerol according to Coleman and Bell (16). The microsomal activity of glycerol acyltransferase (GAT) was assayed by following the formation of [^{3}H]1-acylglycerol 3-phosphate from [^{3}H]glycerol 3-phosphate and palmitoyl CoA as described by Aarsaether *et al.* (17). Protein was determined by the method of Lowry *et al.* (18).

De novo synthesis of FFA. Fed rats were injected with 30 mCi [^{3}H]H_2O intraperitoneally one hour before sacrifice. *De novo* synthesis of FFA was measured according to Venkatesan *et al.* (19). Briefly, lipids were extracted from the liver and separated on thin-layer chromatography plates (Silica gel G) using a solvent system consisting of *n*-hexane, diethyl ether, and formic acid (80:20:2). Lipid fractions were visualized in an iodine chamber. FFA fractions were identified and scraped off the thin-layer chromatography plates. Radioactivity in FFA was determined in a Beckman (Palo Alto, CA) LS-250 β-counter.

TG secretion. A 20% solution of Triton WR-1339 was intravenously injected (50 mg/100 g body weight) to inhibit lipolysis of TG in the rats in the fasted state (20). The rats were sacrificed two hours after the injection as described by Swift *et al.* (21). Blood plasma was collected and VLDLs ($d < 1.006$ g/mL) were isolated by ultracentrifugation. Cholesterol, PL, and TG in VLDL, as well as in the unfractionated plasma, were measured by methods described previously.

Hepatic uptake of FFA. The uptake of plasma FFA in the liver *in vivo* was measured by an arteriovenous technique as described by Huang *et al.* (22). The animals were anesthetized with an intraperitoneal injection of ketamine (100 mg/kg). Polyethylene cannulas (PE 10) were implanted in the aortas, portal veins, and hepatic vein (22). While the animals were being anesthetized, blood samples were taken sequentially from the hepatic veins, portal veins, and aortas through the implanted cannula into 1 c.c. tuberculin syringes previously rinsed with 5% EDTA. Hepatic uptake of FFA was determined by subtracting the concentration of FFA in the hepatic vein from that calculated for the hepatic influx (22). Hepatic influx concentration of FFA ($[FFA]_{inf}$) was calculated from the sum of the concentrations of FFA in the aorta ($[FFA]_a$), substituting for the hepatic artery, and the portal vein ($[FFA]_p$) multiplied by their respective fractional contributions of blood supply to the liver (i.e., $[FFA]_{inf} = 0.3 \times [FFA]_a + 0.7 \times [FFA]_p$). The fractional contributions of blood supply to the liver from the portal vein and the hepatic artery were previously determined to be 0.7 and 0.3, respectively (23). The purity of blood taken from the hepatic vein, free from vena caval contamination, was determined by the $p0_2$ method according to Huang (24).

Statistical analyses. Data were expressed as means ± SD. Statistical significance between data from rats fed the control and cholesterol-supplemented diets was determined by Student's *t*-test. A P value less than 0.05 was considered statistically significant.

RESULTS

Body and liver weight. Feed efficiency of the control and the cholesterol-supplemented diets was about the same. The gain in body weight was not significantly different between the two groups for a period of up to four weeks. Liver weight was, however, significantly increased in the group fed the high-cholesterol diet (12.4 ± 1.0 g vs. 8.4 ± 1.1 g in the control). Consequently, liver-to-body weight ratio increased in this group of rats.

Liver lipids. The content of cholesterol in the fasted state increased from ~5 mg/g liver in the control to ~53 mg/g liver in the cholesterol-fed rats (Table 2), and the content of TG increased from ~25 mg/g liver to ~90 mg/g liver (Table 2). The increases of cholesterol and TG in the liver were approximately ten- and fourfold, respectively, in the cholesterol-fed rats as compared to the controls. PL, on the other hand, de-

TABLE 2
The Contents of Cholesterol, Triacylglycerols, and Phospholipids in Livers of Rats That Had Been Fed Control or Cholesterol-Supplemented Diets for Four Weeks[a]

Diet	Cholesterol (mg/g liver)	Triacylglycerols (mg/g liver)	Phospholipids (mg/g liver)
Control	4.8 ± 0.5	24.5 ± 6.2	31.7 ± 2.3
Cholesterol	53.1 ± 7.8[b]	90.3 ± 16.9[b]	26.9 ± 2.3[b]

[a]Data are means ± SD of six experiments for both groups, which were fasted overnight prior to sacrifice.
[b]$P < 0.05$, vs. control.

creased (13%) on a per gram liver basis in the cholesterol-fed rats, as compared to the controls (Table 2). On the whole liver basis, cholesterol feeding increased the content of cholesterol in the liver by 14.6-fold, TGs by 5.1-fold, and PLs by 1.3-fold.

TG synthesis. The activities of the two key enzymes involved in TG synthesis, GAT and DGAT, were measured in liver microsomes isolated from rats fed the control and the cholesterol-supplemented diets in the fed state. The activity of GAT, which catalyzes the first esterification step of TG synthesis, increased 23% in the cholesterol-fed rats (Table 3). The activity of DGAT, which catalyzes the conversion of diacylglycerols to TG, increased by 19% in the cholesterol-fed rats, as compared to the controls (Table 3).

β-Oxidation of FFA. The activity of CPT I in isolated mitochondria, the rate-limiting enzyme for β-oxidation, was found to decrease significantly by 23% in the fed state in rats fed the cholesterol-supplemented diet, as compared to the controls (Table 3).

De novo *synthesis of FFA.* The incorporation of tritiated water injected intraperitoneally in fatty acids in the liver was 6,544 ± 1,480 dpm/h/g in the control and 13,240 ± 2,663 dpm/h/g in the cholesterol-fed rats. The rate of *de novo* synthesis of FFA thus increased by twofold in the cholesterol-fed rats as compared to the controls.

Hepatic secretion of lipids. Total and VLDL lipid secretion were measured in the fasted state. Triton WR-1339 was injected intravenously to block the activity of lipoprotein lipase. The contents of lipids in the unfractionated plasma and in VLDL before and after two hours of injection are shown, respectively, in Tables 4 and 5. No significant difference in

TABLE 4
Total Triacylglycerols, Cholesterol, and Phospholipids in Plasma Before and After Injection of Triton WR-1339 in Rats That Had Been Fed Control or Cholesterol-Supplemented Diet for Four Weeks[a]

Diet	Control	Cholesterol-fed
Triacylglycerols		
Before	104.7 ± 39.0	80.5 ±17.4
After	785.1 ± 86.9	574.8 ± 88.8[b]
Cholesterol		
Before	82.5 ± 10.5	85.5 ± 10.5
After	156.6 ± 17.2	345.2 ± 24.2[b]
Phospholipids		
Before	126.5 ± 13.0	105.6 ± 6.2[b]
After	91.7 ± 12.9	182.5 ± 23.4[b]

[a]Data are means ± SD. Units are mg/dL. Rats from each dietary group were divided into two groups for the experiments—after fasting overnight, one was sacrificed before, and the other two hours after intravenous injection of Triton WR-1339 (50 mg/100 g body weight). Numbers of experiments for both the control and cholesterol-fed rats were six before the injection, and eight after the injection.
[b]$P < 0.05$, vs. control.

TG concentration was found between VLDL and the unfractionated plasma before the injection of Triton in the two groups. After the injection, plasma TG, found to be associated predominantly with VLDL, increased approximately sevenfold in both groups of rats. The rate of increase in plasma TG concentration in the cholesterol-fed rats was, however, ~40% less than that in the controls. VLDL cholesterol was 13% of the total in the plasma in the control and 29% in the cholesterol-fed rats before the injection of Triton. The proportion of plasma cholesterol in VLDL increased to 60% in the cholesterol-fed and 72% in the control rats after the injection of Triton. The increases in the concentration of cholesterol were 1.9–4.0-fold in the plasma and 8.2–11-fold in VLDL after the injection of Triton. VLDL–PL as a percentage of total plasma PL was ~15% in the two groups before

Before	78.0 ± 32.1	58.0 ±14.0
After	774.5 ± 86.9	550.0 ± 85.3[b]
Cholesterol		
Before	10.9 ± 4.1	25.2 ± 9.4[b]
After	112.2 ±18.5	207.5 ± 3.3[b]
Phospholipids		
Before	16.4 ± 6.4	18.2 ± 5.5
After	112.4 ± 9.5	139.6 ± 11.1[b]

[a]Data are means ± SD. Units are mg/dL. Rats from each dietary group were divided into two groups for the experiments—after fasting overnight, one was sacrificed before, and the other two hours after intravenous injection of Triton WR-1339 (50 mg/100 g body weight). Numbers of experiments for both the control and cholesterol-fed rats were six before the injection, and eight after the injection.
[b]$P < 0.05$, vs. control.

the injection. After the injection, the concentration was not changed in the control, but was increased 73% in the cholesterol-fed rats. VLDL–PL as a percentage of the total in the plasma was increased to 75% in the cholesterol-fed rats and 100% in the control rats after the injection of Triton.

Hepatic gradients of FFA. The uptake of extra-hepatic FFA in the liver was measured by arteriovenous difference technique in intact rats (22). In the fasted state, the concentration of FFA in the aorta was 0.74 ± 0.17 mM (n = 5) in rats fed the cholesterol-supplemented diet and 0.96 ± 0.19 mM (n = 4) in rats fed the control diet. The difference between the two was not statistically significant. The arteriovenous gradient of FFA across the liver in the control rats was, however, 100% greater than that found in the cholesterol-fed rats (0.78 ± 0.37 vs. 0.39 ± 0.18 mM). This indicates that the uptake of plasma FFA in the liver was 50% less in rats fed the cholesterol-supplemented diet than the controls in the fasted state, assuming that hepatic blood flow was not significantly different between the two groups.

DISCUSSION

In this study, we showed that supplementation of 1% cholesterol in the diet for four weeks stimulated the synthesis and accumulation of TG in the liver. Because the polyunsaturated/saturated fatty acid ratio of the dietary fat was set to be 1, following the dietary guideline of the National Science Council (Washington, D.C.), the supply of the polyunsaturated fatty acids to the rats was deemed sufficient. The incidence of the fatty liver was thus not a result of a deficiency in EFA (3,4) or a result of impaired PL synthesis (3,4), as was suggested by the diminished PL content in rats fed the cholesterol-supplemented diet on the basis of per gram tissue weight (Table 2). On the basis of the whole liver, PL content in the cholesterol-fed rats was found to increase by 30%. Furthermore, the secretion of PL in VLDL was found to increase in rats fed the cholesterol-supplemented diet.

The amounts of TG and cholesterol accumulated in the liver in the current study were three- to fivefold greater than those reported by Fungwe *et al.* (6). These discrepancies may be attributed to differences in the dietary regimen in the two studies and the duration during which the animals were maintained on the diets. Fat content in our diet was 10% rather than 5% as in the study of Fungwe *et al.* (6). Cholesterol contents in the diets in our study and that of Fungwe *et al.* (6) were 1 and 0.5%, respectively. The animals in our study were fed the diet for four weeks, while those of Fungwe *et al.* (6) were fed for one week. According to Fungwe *et al.* (6), changing dietary fat content alone from 5 to 15% can result in a threefold increase in liver TG and a twofold increase in liver cholesteryl esters.

While Fungwe *et al.* (5) showed that the secretion of VLDL-TG increased in the isolated perfused liver, we found that *in vivo* the secretion of TG by the liver determined in the plasma or VLDL decreased in rats fed the cholesterol-supplemented diet, as compared to the controls. Plasma TG was found predominantly in VLDL both before and after the injection of the inhibitor for lipoprotein lipase, Triton WR 1339, in either the control or cholesterol-fed rats (Tables 4 and 5). Very little TG was found to be associated with lipoproteins other than VLDL.

In contrast, the concentration of cholesterol increased 3.5-fold in the plasma and 1.8-fold in VLDL in the cholesterol-fed rats, as compared to the controls (Tables 4 and 5). The majority of the cholesterol in the plasma was found to be present in lipoproteins other than VLDL before the injection of Triton WR 1339. After the injection, the percentage of cholesterol in VLDL increased. A significant proportion of plasma cholesterol remained in lipoprotein fractions other than VLDL. The rate of accumulation of cholesterol in non-VLDL lipoproteins was greater in the cholesterol-fed rats than in the controls, suggesting that the turnover of cholesterol and cholesteryl esters in non-VLDL lipoproteins was increased in the cholesterol-fed rats.

Like cholesterol, the secretion of PL also increased in the cholesterol-fed rats (Tables 4 and 5). Blockade of the activity of lipoprotein lipase resulted in no additional PL secretion in the control, but about 73% more PL in the cholesterol-fed rats. The percentage of plasma PL in VLDL increased in both groups of rats following the injection of Triton. Before the injection of Triton WR 1339, only a small fraction of plasma PL was found to be associated with VLDL. After the injection, almost all of the PL in the control and 75% in the cholesterol-fed rats was found in VLDL. Thus, it seems that inhibition of lipoprotein lipase could result in the redistribution of PL in the lipoproteins.

No attempt was made to differentiate the unesterified and esterified forms of cholesterol in this study. Given the magnitude of the increase in total cholesterol in VLDL (85%), both forms of cholesterol can be expected to increase. Fungwe *et al.* (5) showed that the increase in plasma cholesterol can be found mainly in the esterified rather than the unesterified fraction of cholesterol. Because the increases in the amounts of surface lipids (PL and cholesterol) in the cholesterol-fed rats were small (~10%), VLDL from this group of rats and that from the control rats were not expected to be different in size. Both TG and cholesteryl esters are located in the core of VLDL particles. Constrained by particle size, excess secretion of cholesteryl esters may result in less space for TG to be incorporated in VLDL (25). This has been demonstrated in *in vitro* experiment. When isolated hepatocytes were incubated in a medium enriched in cholesterol, the secretion of cholesteryl esters increased and TG decreased in VLDL (26).

The other question to be addressed in this report is the source of FFA for TG synthesis in the liver. We found that *de novo* synthesis of FFA increased, and the degradation of FFA in the liver decreased in rats fed the cholesterol-supplemented diet, in agreement with the findings of Fungwe *et al.* (5–7). In contrast to the experiment of Fungwe *et al.* (6), hepatic uptake of FFA was measured *in vivo* instead of *in vitro* in the isolated perfused liver (6). Whereas the uptake of plasma FFA in the isolated perfused liver was not affected by

dietary cholesterol (6), the uptake *in vivo* as indicated by the arteriovenous gradient of FFA across the liver decreased by 60%. Both studies nevertheless ruled out plasma FFA as a source for excess TG synthesis in the liver. It appears that the *de novo* synthesized FFA may be sufficient to account for the TG accumulated in the liver in the cholesterol-fed rats. As the supply of cholesterol is abundant, it is not necessary to maintain 3-hydroxy-3-methylglutaryl–CoA reductase in an active state. More acetyl CoA may be available for lipogenesis (7). To prevent futile cycling between lipogenesis and FFA oxidation, the activity of mitochondrial CPT I diminished (6).

Another source of extrahepatic FFA for TG accumulation in cholesterol-fed rats is cholesteryl esters contained in the hydrophobic cores of apolipoprotein C-depleted VLDL and chylomicron remnants (27). Cholesteryl esters in these lipoprotein particles can be transferred preferentially to the liver through interactions at the cell surface between these particles, hepatic lipase, and low-density lipoprotein receptor before the irreversible uptake of the lipoprotein particles themselves (27,28). The half-life of cholesteryl esters in the liver is short (~15 min) (27). Fatty acids released through the hydrolysis of cholesteryl esters in the liver were found to be incorporated in glycerolipids (27). The exact role for this pathway in TG accumulation in the cholesterol-fed rats was not determined in this report.

The increases in the activities of GAT and DGAT in livers of the cholesterol-fed rats may be secondary to the increase in fatty acid synthesis. The increases in DGAT activity and TG synthesis in primary culture of hepatocytes were found to be associated with an increase in the availability of FFA in the medium (29). Our data from the arteriovenous studies, however, indicate that newly synthesized FFA is more effective than plasma FFA in serving as the substrate for TG synthesis in the liver. The effectiveness of endogenous FFA in promoting TG synthesis has also been shown by Fungwe *et al.* (6). These investigators found that although the incorporation of [^{14}C] oleate in TG increased in the isolated perfused liver, the uptake of [1-^{14}C] oleate was not significantly altered in the cholesterol-fed rats.

In conclusion, our results support the roles of increased lipogenesis, decreased oxidation of fatty acids and decreased secretion of VLDL as causes for the accumulation of TG in the liver in the cholesterol-fed rats. Of the two extra-hepatic sources of fatty acids, albumin-bound FFA may be discounted for the difference in TG accumulation in the livers between the control and cholesterol-fed rats. A difference in the uptake of esterified fatty acids in chylomicron remnants, however, remains a possibility.

ABSTRACT: We investigated the relationship between dietary highly hydrogenated soybean oil (HSO) and cholesterol transport in rats. In the first study, to examine the effects on cholesterol transport of different concentrations of HSO in dietary oil, rats were given one of the three diets containing 0, 25, or 50% HSO in dietary oil with cholesterol (5 g/kg diet) or a diet without HSO and cholesterol for 22 d. Feeding the high concentration of HSO prevented the increase in plasma total cholesterol, hepatic total lipids, and cholesterol and the decrease in high-density lipoprotein-cholesterol, which were caused by dietary cholesterol. Moreover, HSO increased the fecal excretion, fecal lipids, and steroids in a dose-dependent manner. In the second study, to examine the effects on cholesterol transport of redistribution of stearic acid in the triacylglycerol species contained in HSO, rats were given one of the six diets containing HSO (distearoylmonoacylglycerol and tristearoylglycerol)-rich, monostearoylglycerol-rich, or palmitic acid-rich oil with/without cholesterol (5 g/kg diet), for 30 d. Whereas the accumulation of cholesterol in the body was reduced, cholesterol excretion was enhanced effectively in rats given the HSO-rich diet compared with rats given the monostearoylglycerol-rich diet. These results suggested that not only the high concentration of stearic acid but also its uneven distribution in HSO–triacylglycerol contributed to the reduction in intestinal cholesterol absorption in rats.

Lipids 30, 533–539 (1995).

Epidemiological studies have shown that plasma cholesterol affects the development of arteriosclerosis. Keys *et al.* (1) and Hegsted *et al.* (2) have shown that the fatty acid composition in dietary fat affected the concentration of plasma cholesterol. Their reports confirmed that the effect of saturated fatty acids on plasma cholesterol is altered by their chain length. To reduce the risk of coronary heart disease, several official recommendations have suggested a reduction of saturated fatty acid and cholesterol intake. However, among the saturated fatty acids, stearic acid is not hypercholesterolemic (3–6). Michel *et al.* (7) and Apgar *et al.* (8) have reported the poor absorption of this fatty acid from cocoa butter. Grigor and Dunkley (9) have also reported the low absorptivity of stearic acid from an investigation of the origin of this fatty acid in feces. Considering these reports and others (10,11), dietary stearic acid might prevent cholesterol absorption by promoting cholesterol excretion as dietary fiber does. However, there are some conflicting reports about stearic acid absorption (4,12), which have demonstrated that it is not so difficult to absorb, despite its high melting point. Therefore, the controversy has remained regarding the digestibility of stearic acid, which might be affected by its distribution in triacylglycerols.

During post-absorption, Bonanome and Grundy (4) have shown that stearic acid is rapidly desaturated to oleic acid, which may have indicated a neutral or slightly hypocholesterolemic effect. They suggested that this reaction might be a regulatory mechanism of the stearic acid effect on plasma cholesterol level.

In highly hydrogenated vegetable oils, most of C-18 unsaturated fatty acids have been converted to stearic acid. A large amount of stearic acid unevenly distributed in hydrogenated oils might have different nutritional effects compared with a similar amount of this fatty acid distributed uniformly in natural fats or interesterified hydrogenated oils. One of these effects, for example, might be interference with absorption of other dietary components. Therefore, we investigated whether highly hydrogenated soybean oil (HSO) influences the absorption and transport of dietary cholesterol in rats.

MATERIALS AND METHODS

Animal experiments. Male Wistar rats (Japan SLC Inc., Hamamatsu, Japan) were used throughout the experiments. Animals weighing about 80 g were housed in cages with a

wire-screen floor and were fed with a commercial, nonpurified diet (Clea Japan, Inc., Tokyo, Japan) for 5 d before the experiment. Room temperature was maintained at 22–24°C with a 12-h cycle of light (1300–0100) and dark (0100–1300). In Experiment 1, pre-feeding rats were divided into four groups of six animals each and were given the experimental diets for 22 d. In Experiment 2, after pre-feeding, rats were divided into six groups of six animals each and were given the experimental diets for 30 d. Animals were provided food and water *ad libitum* in both experiments. Feces collected for 48 h just before fasting were lyophilized and frozen at −70°C until assay. At the end of the experimental period, after fasting overnight, the rats were anesthetized with diethyl ether and sacrificed between 0700–0800. Blood was collected from the abdominal aorta, using a plastic syringe containing heparin, for plasma cholesterol analysis. Immediately after the livers were removed, weighed, and cooled on ice, they were frozen at −70°C until assay. All aspects of the animal experiment were approved by the Animal Policy and Welfare Committee in our Institute.

Diets in Experiment 1. The composition of the basal diet and the fatty acids in the dietary fats are shown in Tables 1 and 2. Soybean oil was the control dietary fat. Experimental dietary fats were prepared by replacing 25 or 50% of the soybean oil with HSO, which was a gift from Ueda Oils & Fats Manufacturing Co. (Kobe, Japan). These fats were named HSO25 and HSO50, respectively. To prepare diets containing cholesterol, i.e., the control diet, the cholesterol-containing control diet, the HSO25-Chl diet (where Chl = cholesterol), and the HSO50-Chl diet, cholesterol and sodium–cholate were added to each diet to final concentrations of 0.5 and 0.05%, respectively.

TABLE 1
Composition of Experimental Diets

Diet (g/kg diet)	Cholesterol-containing	Cholesterol-free
Milk casein	200	200
α-Corn starch	240.5	245.5

[a]In Experiment 1, fats applied to each experimental diet were as follows: soybean oil in the control diet, highly hydrogenated soybean oil (HSO)/soybean oil (1:3) in the HSO25-Chl diet and HSO/soybean oil (1:1) in the HSO50-Chl diet. The fatty acid composition of each fat is shown in Table 2. The HSO25-Chl diet and HSO50-Chl diet were supplemented with cholesterol as well as the cholesterol-containing control diet. In Experiment 2, applied fats were prepared by mixing in some oils to modulate the fatty acid composition comparably. The proportion of oils and the fatty acid composition of each fat is shown in Table 3. Milk casein, α-corn starch, cellulose powder, mineral mix, and vitamin mix were purchased from the Oriental Yeast Co. (Tokyo, Japan); Chl, cholesterol.

TABLE 2
Fatty Acid Composition in Dietary Fats/Oil Applied on Experiment 1[a]

	Control (%)	HSO25-Chl (%)	HSO50-Chl (%)
16:0	10.6	8.5	6.8
18:0	3.8	25.0	46.8
18:1	23.9	18.5	13.1
18:2	53.2	41.0	28.0
18:3	7.5	5.6	4.0
20:0	0.5	0.7	0.7
22:0	0.6	0.7	0.6
Total saturated	15.5	34.9	54.9

[a]Soybean oil was used as the control oil. HSO25 and HSO50 were prepared by mixing soybean oil and HSO at the ratio of 3:1 and 1:1, respectively. HSO was a gift from Ueda Oil Co.(Kobe, Japan). Soybean oil was obtained from a local market. The fatty acid composition was determined by gas–liquid chromatography as detailed in the text. The melting point of HSO was 65.7°C and the iodine value was 1. See Table 1 for abbreviations.

Diets in Experiment 2. The composition of the experimental basal diet was the same as that discussed for Experiment 1 except for fat composition. As shown in Table 3, the fatty acid composition of three dietary fats was adjusted to nearly the same amount. The triacylglycerol profile of HSO analyzed by the procedure described by Litchfield (13) consisted of tristearoylglycerol 57% and distearoylmonoacylglycerol 43%. HSO-rich fat (Fat-B) was prepared by mixing HSO, olive oil, and safflower oil at the ratio of 4.5:5:0.5, respectively. Monostearoylglycerol-rich fat (Fat-C) was prepared by mixing monostearoylglycerol (the grade as the food additive), olive oil, and safflower oil at the ratio of 5:6:1, respectively, to balance the fatty acid composition with Fat-B. The distribution of stearic acid among the acylglycerols was uneven in Fat-B, whereas it was uniform in Fat-C. Because our pre-experiment showed similar results for lipid transport in rats fed stearic

TABLE 3
Fatty Acid Composition, Melting Point, and Iodine Value in Dietary Fats Applied on Experiment 2[a]

	Fat-A (%)	Fat-B (%)	Fat-C (%)
16:0	52.6	10.1	16.1
18:0	4.8	44.8	38.6
18:1	32.1	36.4	37.0
18:2	7.3	6.0	4.9

Iodine value	42.9	48.6	42.5

[a]Fat-A (dietary fat in which most of the stearic acid was replaced by palmitic acid) was prepared by mixing palm stearin and palm oil (9:1). Fat-B (HSO-rich fat) was prepared with HSO, olive oil, and safflower oil in the ratio 4.5:5:0.5, respectively. Fat-C (monostearoylglycerol-rich fat) contained monoglyceride, olive oil, and safflower oil at the ratio 5:6:1, respectively. In monoglyceride, 72% of component fatty acid was stearic acid and most of the rest was palmitic acid. See Table 1 for abbreviation.

acid-rich interesterified fat and those fed monoacylglycerol-rich fat (data not shown), in this experiment, we adopted monoacylglycerol-rich fat for its easy availability. Another dietary fat (Fat-A), in which most of the stearic acid was replaced by palmitic acid, was prepared by mixing palm stearin (the solid fraction of palm oil, mostly palmitate) and palm oil at the ratio of 9:1 and was used as the comparative fat to examine the stearic acid effects. Palm stearin and palm oil were gifts from Fuji Oil Co. (Osaka, Japan).

Analysis. Blood was centrifuged for 10 min at 1,600 × *g* to obtain plasma. Total cholesterol and high-density lipoprotein (HDL)-cholesterol in plasma were measured using commercially available kits (Cholesterol C-test and HDL-cholesterol C-test; Wako Pure Chemical Industries, Ltd., Osaka, Japan). Liver lipid was extracted by the method of Folch *et al.* (14) and determined gravimetrically. Fecal lipid was extracted by the modified method of Folch *et al.* (14) using an extraction with warm chloroform–methanol solution. In detail, lipid in the freeze-dried feces was extracted by warm Folch solution containing a small amount of water (60°C, 1 h). Reduced to dryness under a N_2 stream, the residue was dissolved in 25 mL petroleum ether over anhydrous Na_2SO_4. Twenty mL of petroleum ether phase was transferred to a tared container, evaporated by N_2 spray and oven-dried (100°C, 1 h). Total lipid was determined gravimetrically. After mild saponification of the lipids, liver cholesterol was extracted and determined by the method of Grundy *et al.* (15). Fecal steroids were extracted by the method of Yamanaka *et al.* (16). Fecal neutral steroids were assayed by the procedure of Grundy *et al.* (15). The concentration of fecal total acidic steroids was assayed by the method of Forman *et al.* (17). The dietary fats and the lipid extracts from feces were methylated at 100°C for 3 h by 5% HCl–methanol. The fatty acid composition of the methylated extracts was measured by a slightly modified procedure of Kawai and Nakayama (18). The triacylglycerol profile in HSO was determined as described by Monsma and Ney (19).

Statistical analysis. Differences among dietary treated groups were assessed by analysis of variance and Duncan's multiple-range test (20). Group means were considered to be significantly different at $P < 0.05$ as determined by the protected least significant difference technique.

RESULT

We investigated the effects of HSO by means of two studies using rats. In Experiment 1, the effects of various concentrations of HSO in the diets with cholesterol on the growth, the cholesterol concentrations of plasma and liver, and the levels of fecal steroids were studied. In Experiment 2, the effects of the distribution of stearic acid in dietary fats, in which each fatty acid was balanced well, on lipid transport in rats were examined.

Experiment 1. As shown in Table 4, the average daily consumption was greater, although body weight gain was lower, among rats fed the HSO50-Chl diet than those on the other diets. Dietary cholesterol did not affect body weight gain and food intake, but it increased liver weight. The effects of dietary HSO and cholesterol on plasma cholesterol, and liver lipid and cholesterol are also shown in Table 4.

Plasma total cholesterol concentration with the control-Chl and HSO25-Chl diets was about 2.5-fold greater than control without cholesterol, whereas it was only 45% greater than control with the HSO50-Chl diet.

The concentration of HDL-cholesterol in rats fed with the HSO50-Chl diet was 74% of that in rats fed with the control diet. However, in rats on the control-Chl or HSO25-Chl diet, it was only 45–56% of that in rats on the control diet. Liver lipid accumulation was about three times greater in rats on the control-Chl and HSO25-Chl diets than in those on the control diet without cholesterol. On the other hand, the accumulation of lipid in the liver induced by dietary cholesterol was only about 75% that of lipid in rats on the HSO50-Chl

TABLE 4
Effect of Highly Hydrogenated, Dietary Soybean Oil with Cholesterol on Body Weight Gain, Food Intake, Relative Liver Weight, Liver Lipids, Liver Cholesterol, Fecal Dry Weight, Fecal Neutral and Acidic Steroids[a]

	Control	Control-Chl	HSO25-Chl	HSO50-Chl
Body wt gain (g/22 d)	97.9 ± 1.57[a]	95.0 ± 5.39[a]	101.0 ± 3.41[a]	80.8 ± 3.99[b]
Food intake (g/22 d)	297 ± 16.0[a]	323 ± 6.8[a]	324 ± 4.1[a]	349 ± 7.8[b]
Relative liver wt (g/100 g b.w.)	3.1 ± 0.11[a]	4.3 ± 0.15[b]	4.2 ± 0.15[b]	4.0 ± 0.16[b]
Total-Chl (mg/dl)	42 ± 4.3[a]	105 ± 6.3[b]	107 ± 6.1[b]	61 ± 4.3[c]

Liver lipids (%)	9.6 ± 0.35[a]	29.3 ± 2.36[b]	27.1 ± 2.41[b]	21.3 ± 1.22[c]
Liver Chl (mg/liver/100 g b.w.)	12.5 ± 1.22[a]	44.1 ± 5.11[b]	40.3 ± 3.91[b]	29.1 ± 1.25[c]
Fecal dry wt (g/day/100 g b.w.)	0.36 ± 0.02[a]	0.41 ± 0.03[a]	0.54 ± 0.03[b]	0.79 ± 0.03[c]
Fecal lipid (%)	4.2 ± 0.92[a]	3.9 ± 0.63[a]	11.3 ± 1.81[b]	32.1 ± 4.54[c]
Fecal cholesterol (mg/day/100 g b.w.)	1.0 ± 0.06[a]	8.7 ± 0.23[b]	14.1 ± 0.83[c]	18.0 ± 0.88[d]
Fecal coprostanol (mg/day/100 g b.w.)	0.8 ± 0.03[a]	2.5 ± 0.26[b]	N.D.	N.D.
Fecal acidic steroids (mg/day/100 g b.w.)	3.75 ± 0.15[a]	7.7 ± 0.46[b]	8.1 ± 0.62[b,c]	8.9 ± 0.55[c]

[a]Each value shows the mean ± SEM of six rats. Values in the same line without common superscript letters denote significant difference ($P < 0.05$). N.D. in the coprostanol line means a value under 0.1 mg/day/100 g body weight (b.w.); HDL, high-density lipoprotein; see Table 1 for other abbreviation. See Table 2 for HSO25 and HSO50 definitions.

diet. The concentration of hepatic cholesterol was 3.2–3.5-fold greater with the control-Chl and HSO25-Chl diets than control, whereas that with the HSO50-Chl diet was only 2.3-fold greater than control.

Table 4 also describes the effects of dietary HSO and cholesterol on the fecal dry weight (g/day/100 g body weight) and the concentration of lipids and steroids in the feces. Fecal dry weight increased with the increased proportion of HSO in the diet. Thus, the feces from animals on the HSO50-Chl diet were twice as heavy as those from rats on the control diet. Accompanying the increase in fecal weight, a marked greater amount of fecal lipids was excreted by rats fed with the HSO50-Chl diet in comparison with those fed with the other diets. Dietary cholesterol appeared not to affect either fecal weight or the concentration of fecal lipids. Excretion of fecal neutral steroids (cholesterol and coprostanol) with the HSO50-Chl diet was twice that with the control-Chl diet. Coprostanol, a metabolite of cholesterol produced in the intestine, was one of the main components in fecal neutral steroids of animals on the control diet. However, this compound was undetectable in feces from animals fed with the diet containing HSO.

Experiment 2. Table 5 shows that feeding Fat-B suppressed body weight gain and promoted food intake, but did not change the relative liver weight compared with Fat-A and Fat-C. Cholesterol supplement did not affect body weight gain or food intake with any dietary fat, but it resulted in a 20% average increase in liver weight. Total plasma cholesterol in rats on the Fat-B diets was significantly less than that on the other diets. Total plasma cholesterol in animals given the Fat-C diet was slightly lower than that on the Fat-A diet, though not significantly. HDL-cholesterol level remained the same among rats on these three diets without supplementary cholesterol. However, the reduction of HDL-cholesterol observed in rats with the Fat-A + Chl and Fat-C + Chl diets was somewhat attenuated in rats with the Fat-B + Chl diet. The amount of liver total lipids in rats fed with the Fat-B diet was significantly less than that with the Fat-A and Fat-C diets, in the absence of added cholesterol. Cholesterol supplement to the Fat-A diet increased the total liver lipids, but this effect was significantly less than that seen on the other two cholesterol-supplemented diets. Liver cholesterol level was similar among rats with these three diets without added dietary cholesterol. The increase in liver cholesterol by dietary cholesterol was greatest in rats given the Fat-A + Chl diet and lowest in rats given the Fat-B + Chl diet. Fecal dry weight was greater in rats on the Fat-B diet than in those on the Fat-A and Fat-C diets, whether or not cholesterol was supplemented. Rats fed with the Fat-B diet excreted greater fecal lipid compared to rats fed the Fat-C or Fat-A diet. The amounts of fecal neutral steroids (cholesterol and coprostanol) were similar among rats fed with the three cholesterol-free diets. However, in cholesterol-containing diets, Fat-B + Chl resulted in a 5-fold increase in neutral steroid excretion compared with a 3.6-fold increase for rats fed Fat-C + Chl ($P < 0.05$). In rats on the Fat-B diet, almost all the fecal neutral steroids consisted of cholesterol, which was different from the pattern of fecal neutral steroids in rats on the other diets, whether cholesterol was supplemented or not. The concentration of fecal acidic steroids was lower on the Fat-A + Chl diet compared with those on the other two diets supplemented with cholesterol. Fatty acid absorption was calculated from the difference between the ingested and excreted amounts of each fatty acid (Table 6). On the Fat-B diet, about 70 and 80% stearic and palmitic acids were absorbed, respectively, regardless of cholesterol supplementation, whereas over 90% of other fatty acids were absorbed. Cholesterol absorption was the lowest in animals given the Fat-B + Chl diet and the highest in those on the Fat-A + Chl diet (Table 6).

DISCUSSION

This study showed that replacing more than 50% of dietary fat by HSO attenuated the rise in plasma cholesterol associated with cholesterol feeding and the HDL-cholesterol reduc-

Cholesterol		63.1 ± 0.31[a]		52.1 ± 0.31[b]		59.2 ± 0.34[c]

[a]Each value shows the mean ± SEM of six rats. Values in the same line without common superscript letters denote a significant difference ($P < 0.05$). N.D. in the coprostanol line means a value under 0.1 mg/day/100 g b.w. The apparent absorptivities were estimated as the difference between the ingested and excreted amounts of each fatty acid or cholesterol. See Tables 1 and 4 for abbreviations and Table 3 for Fat-A, Fat-B, and Fat-C definitions.

tion induced in rats fed with supplementary cholesterol. The HSO-rich diet also prevented the hepatic lipid and cholesterol accumulation caused by dietary cholesterol in rats. Moreover, the HSO-rich diet increased the fecal mass, fecal lipids, and fecal neutral steroids. There are at least three possible explanations for the alteration of cholesterol transport and metabolism in rats fed with an HSO-rich diet.

The first is based upon the indigestibility and low absorptivity of tristearoylglycerol, the primary component of HSO. Fifty-seven percent of the triacylglycerol composition of HSO was tristearoylglycerol, which is considered to be partially or totally indigestible (21) and not absorbed (12). This low intake of tristearoylglycerol could not be attributed only to its high melting point, because monostearoylglycerol, having a similar or rather higher melting point, is almost completely absorbed. Some other properties, including impaired micelle formation and low susceptibility to lipase, might contribute to poor digestibility of tristearoylglycerol. Regardless, we estimated the absorptivity of stearic acid on the HSO50 diet at 70%. Therefore, the HSO-rich diet could be considered as a low-fat diet. As a low-fat diet improves the lipid profile (22,23), this property of HSO would have significant influence.

The second possibility, which is probably related to the first and may be more relevent, is that HSO, especially the tristearoylglycerol component, would prevent the absorption of dietary cholesterol by a dietary fiber-like action. This possibility is supported by the decreases in body weight gain, plasma cholesterol level and liver cholesterol and by the increases in fecal weight and fecal neutral steroids (Table 4) on the HSO-rich diet compared with those on the control diet, regardless of cholesterol supplementation.

Sugano and his colleagues (24,25) reported several different observations in contrast to our results. They showed that plasma total- and HDL-cholesterol were comparable among four saturated fatty acid-rich diets, including one which was stearic acid-rich, in rats (24) and in hamsters (25). They also showed that there were no differences in body weight gain, food intake, relative liver weight, and fecal weight among animals fed with the experimental diets. The discrepancies between their results and ours are probably due to the different distribution of stearic acid in the dietary triacylglycerols. We used a simple mixture of hydrogenated soybean and natural vegetable oils. This fat contained a higher proportion of tristearoylglycerol than the stearic acid-rich fat used by Imaizumi *et al.* (25), which was prepared by the interesterification of hydrogenated and natural oils.

As described above, the poor absorptivity of tristearoylglycerol might impair intestinal cholesterol absorption. Generally speaking, water-soluble dietary fiber is much more effective than water-insoluble dietary fiber in suppressing plasma cholesterol (26,27). Although HSO is poorly absorbed and has characteristics of water-insoluble dietary fiber, it influences cholesterol transport significantly, like water-soluble dietary fiber. Mechanisms by which soluble dietary fiber reduces plasma cholesterol include suppression of intra-intestinal mobility of cholesterol, reduction of absorptivity by sequestering cholesterol, and the suppression of micelle formation. The mechanism of the dietary fiber-like effect of HSO, probably mainly due to tristearoylglycerol, on cholesterol absorption should be evaluated.

Another possible mechanism for the altered cholesterol transport is the action of post-absorbed stearic acid. In the HSO used in this experiment, 43% of triacylglycerol molecular species consisted of distearoylmonoacylglycerol which is reported to be easily absorbed by the intestine (12). In this study, we found that a significant amount of stearic acid was absorbed (Table 6) especially if fecal stearic acid was considered to be supplemented by a slough of intestinal cells (28), or by intestinal hydrogenation of C-18 unsaturated fatty acid by enterobacteria (9).

Stearic acid has a neutral or hypocholesterolemic effect, which is different from that of other saturated fatty acids (3–6). Bonanome and Grundy (4) have suggested that stearic acid is rapidly desaturated to oleic acid, which seems to be a desirable fatty acid for prevention of arteriosclerosis in humans. Woollett *et al.* (29) have shown that stearic acid did not suppress the rate of receptor-dependent low-density lipoprotein removal from the plasma and/or did not increase the low-density lipoprotein-cholesterol production rate in contrast to other saturated fatty acids in hamsters. Recently, Tholstrup *et al.* (30) reported that fats high in stearic acid may favorably affect the balance between blood coagulation and fibrinolysis in humans, which would induce a less thrombogenic

state by a significant decrease in the level of factor VIIc coagulant activity. Abe *et al.* (24) have reported that stearic acid-rich fat reduced platelet aggregation by ADP and the aortic production of prostacyclin in rats. Thus, stearic acid may contribute to the prevention of arteriosclerosis, but the detailed mechanisms remain controversial.

The ingestion of the HSO-rich diet altered the molecular species of neutral steroids in feces; coprostanol, one of the main neutral steroids in feces from rats on the control diet, was undetectable. As coprostanol is produced by some species of enterobacteria including *Eubacterium* (31), the HSO-rich diet may possibly alter the enterobacteria spectrum. In this study, we did not assay molecular species of acidic steroids in feces, and therefore cannot evaluate the effect of the HSO-rich diets on the enterobacteria spectrum. However, alteration of the enterobacteria spectrum might reduce the quantity of some carcinogenic substances, including sterols and secondary bile acids in the intestine.

In conclusion, dietary HSO reduced the expected increase in plasma and liver cholesterol associated with feeding cholesterol in cholic acid-fed rats. More than half of the stearic acid contained in HSO was tristearoylglycerol, which might play an important role in these effects. However, this triacylglycerol has not been used as a dietary component because of its physical properties and texture. Nevertheless, if food technology overcomes these problems, tristearoylglycerol could contribute to the maintenance of health.

Changes in Ether-Linked Phospholipids in Rat Kidney by Dietary α-Linolenic Acid *in vivo*

Jin H. Park, Eek J. Park, Kye S. Kim and Young K. Yeo*

Lipid Chemistry Laboratory, Kyungpook National University, Taegu, 702-701 Korea

ABSTRACT: We investigated the effects of perilla oil containing a high level of α-linolenic acid on *in vivo* phospholipid metabolism, particularly three subclasses of choline glycerophospholipids (CGP) and ethanolamine glycerophospholipids (EGP), in rat kidney. After three weeks of feeding, a significantly lower proportion (by 35%) of the alkylacyl subclass of CGP was found in the perilla oil, as compared to corn oil-fed animals. The alkylacyl species of EGP was also higher in the perilla oil than in the corn oil-fed animals. These alterations were accompanied by a remarkably lower proportion of arachidonic acid and a higher level of eicosapentaenoic acid (EPA) in all six subclasses of CGP and EGP in the perilla oil-fed animals. The levels of linoleic acid were even higher in the diacyl subclasses of CGP and EGP in the perilla oil group, suggesting that desaturase and elongase enzymes prefer n-3 to n-6 fatty acids as substrates for diacyl species. These data are useful in defining the effects of α-linolenic acid on the biosynthesis of renal phospholipids and on the replacement of n-6 with n-3 fatty acids in the six CGP and EGP subclasses.

Lipids 30, 541-546 (1995).

In previous studies, we demonstrated that the biosynthesis of ether-linked forms (1-*O*-alk-1′-enyl-2-acyl and 1-*O*-alkyl-2-acyl subclasses) of choline glycerophospholipids (CGP) in rat kidney *in vivo* was remarkably changed by dietary fish oil enriched in eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) (1,2). Platelet activating factor (PAF, 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) biosynthesis was markedly reduced in renal tissue in rat by increased intake of fish oil *in vitro* and *ex vivo* (3,4). In addition, very high levels of EPA and DHA accumulated in the ether phospholipids, particularly the ethanolamine plasmalogens, during fish oil consumption, compared to the diacyl phospholipids (5,6). Large proportions of DHA acyl groups were also associated with the ethanolamine plasmalogens when a microsomal membrane fraction isolated from the P388D1 cell was supplemented with n-3 fatty acids (7). It is of interest that ether-containing phospholipids have been proportionally changed by dietary fatty acids although their specific metabolic functions have not been well-elucidated.

α-Linolenic acid, as an n-3 fatty acid, has an effect similar to EPA in terms of *ex vivo* platelet aggregation (8,9) and reduction of serum cholesterol (10). It has also been suggested to prevent thrombosis and myocardial infarction (11), suppress of prostaglandin synthesis (12–14), and alleviate hypertension, although these properties are controversial (15). Perilla oil, which is traditionally a very popular edible oil in oriental countries, contains a high level of α-linolenic acid, up to 65% of the total fatty acids. However, little attention has been devoted thus far to the effects of perilla oil on lipid metabolism in animal tissues.

The purpose of the present work was to evaluate the influence of dietary perilla oil enriched in α-linolenic acid on phospholipid metabolism in rat kidney *in vivo* with emphasis on changes in the ether-linked phospholipids in the CGP and ethanolamine glycerophospholipids (EGP). The distribution of fatty acids in the six CGP and EGP subclasses was also observed.

MATERIALS AND METHODS

Animals and diets. Fourteen female Fischer-344 weaned rats (Korea Chemical Research Institute, Taejeon, Korea), average body weight 35 g, were fed for three weeks *ad libitum* a diet containing either corn oil enriched in linoleic acid (18:2n-6) or perilla oil containing a high level of α-linolenic acid (Table 1). The fatty acid compositions of the corn oil (CO) and perilla oil (PO) diets are shown in Table 2.

Isolation of kidney. The animals were anesthetized with methoxyflurane (Pitman-Moore Ltd., Mississauga, Ontario, Canada). The kidneys from each rat were rapidly removed, decapsulated, perfused with 0.9% saline solution, and weighed. The tissues were homogenized in chloroform/methanol (2:1, vol/vol) using a Polytron homogenizer to obtain total lipid extracts (16).

Lipid analyses. The lipid extracts were separated into various phospholipid classes using thin-layer chromatography (TLC) on precoated silica gel 60 plates (E. Merck, Darmstadt, Germany) developed with chloroform/methanol/acetic acid/water

(50:37.5:3.5:2, by vol) as a solvent system (17). The phospholipid bands were viewed under ultraviolet light after spraying with 2′,7′-dichlorofluorescein solution (Sigma Chemical, St. Louis, MO) and exposing to ammonia vapor.

In order to separate the 1-*O*-alk-1′-enyl-2-acyl (alkenylacyl), 1-*O*-alkyl-2-acyl (alkylacyl), and 1,2-diacyl (diacyl) CGP and EGP subclasses, the CGP and EGP fractions were incubated with phospholipase C by the method of Bernett *et al.* (18). The resulting diacylglycerols were then acetylated with acetic anhydride and pyridine, and the products were separated by TLC using the developing solvent of petroleum ether/diethyl ether/acetic acid (90:10:1, by vol) followed by a second development in toluene (6). The bands corresponding to the six CGP and EGP subclasses were scraped from the TLC plates and transmethylated with 6% methanolic sulfuric acid in the presence of known amounts of monopentadecanoin (Nu-Chek-Prep, Elysian, MN) as an internal standard to quantitate the acyl chains. The fatty acid methyl esters from the alkenylacyl species were separated from the aldehyde derivatives by TLC using toluene as a solvent. The fatty acid compositions of the various phospholipid classes were analyzed with a Shimadzu GC14A gas chromatograph (Shimadzu Co., Tokyo, Japan) equipped with a DB-225 megabore column (Chromatographic Specialties, Brockville, Ontario, Canada). The flow rate of the nitrogen as a carrier gas was 36 mL/min, and the oven temperature was 210°C isothermal. The molar amounts of total methyl esters derived from the diacyl subclasses were divided by two to compare them quantitatively to the ether lipid subclasses because the acyl groups from the diacyl subclasses are derived from the *sn*-1 and *sn*-2 positions, whereas the acyl groups from the two ether phospholipids represent only the *sn*-2 position. The results were analyzed by a one-way analysis of variance for comparison of the CO and PO groups and expressed as mol%.

RESULTS AND DISCUSSION

There was no significant difference ($P > 0.05$) in body or kidney weights of CO– or PO–fed rats after three weeks of feeding (Table 3). The renal phospholipid composition was very similar for both groups (Table 4). The relative proportions of the six subclasses of renal CGP and EGP in rat are given in Tables 5 and 6, respectively. A significantly lower proportion of alkenylacyl- and alkylacyl-*sn*-glycero-3-phosphocholine (alkenylacyl- and alkylacyl-GPC), relative to diacyl-GPC, was found with dietary perilla oil compared to corn oil (Table 5). The alkenylacyl- and alkylacyl-GPC were remarkably lowered by 65 and 25% in the PO group. The distribution of the alkenylacyl- and alkylacyl-GPC subclasses differed significantly between the two groups, in agreement with the previous reports (1,2) using fish oil. It is of interest that the lower level of alkylacyl-GPC *in vivo* as a precursor of PAF may result in lowering PAF biosynthesis, which is similar to *in vitro* experiments reported by Yeo, Philbrick, and Holub (3). By contrast, the two ether-linked EGP phospholipid subclasses were higher in the PO group by 64 and 57%, respectively, though they are not significantly different (Table 6). The importance of these changes cannot be evaluated until the functions of the ether-linked phospholipids are elucidated in greater detail.

The compositions of the fatty acyl moieties in the three CGP subclasses are provided in Tables 7, 8, and 9. The major unsaturated fatty acyl chain in all three CGP subclasses from the CO group was arachidonic acid, which was 8.8, 5.6, and 10.4 mol% alkenylacyl-, alkylacyl-, and diacyl-GPC, respec-

tively. High levels of arachidonic acid in phospholipids relative to neutral lipids were also reported in other studies (1,19,20,21) when linoleic acid was fed to animals. Animals consuming PO showed remarkably lower levels of the n-6 fatty acids compared to CO animals in all three subclasses of CGP. The proportion of linoleic acid in PO–fed animals was lowered by 69.4% in alkenylacyl-GPC, but was slightly higher in alkylacyl- and diacyl-GPC. It seems that the linoleic acid in the PO group originated mainly from maternal nutrition than from the diet. The different distributions of linoleic acid between dietary PO and fish oil reflect that the affinity of linoleic acid to phospholipids is higher with PO. Much higher levels of α-linolenic acid were shown in the alkenylacyl- and diacyl-GPC subclasses of the PO group, as expected; however, only trace amounts of α-linolenic acid were found in the alkylacyl-GPC of both groups. Arachidonic acid was significantly different between CO and PO group only in diacyl-GPC subclass. All three subclasses of CGP showed much higher levels of EPA in the PO group, with 12, 3, and 27 times higher proportion of alkenylacyl-, alkylacyl-, and diacyl-GPC, respectively. Levels of docosapentaenoic acid (DPA) and DHA were found to be higher in alkenylacyl-GPC than in alkylacyl- or diacyl-GPC in the PO group. Markedly higher levels of the n-3 polyunsaturated fatty acids, such as α-linolenic acid, EPA, and DHA, were exhibited in all CGP classes of the perilla oil group. By contrast, DPA and DHA contributed less to the high levels of n-3 fatty acids in all CGP classes (particularly in alkenylacyl-GPC). The total n-6/n-3 fatty acid ratios for the CO group were 9.3, 1.4, and 11.3 for

[a,b,c,d]See Table 9 for description.

alkenylacyl-, alkylacyl, and diacyl-GPC, respectively. For the PO group, the respective ratios were 0.5, 0.8, and 1.9 for alkenylacyl-, alkylacyl-, and diacyl-GPC. Generally, overall differences in acyl chain compositions of the three subclasses of kidney EGP for the corn oil vs. perilla oil groups indicated trends similar to those found for CGP, although the two diets produced moderate differences in the individual phospholipid subclasses (Tables 10, 11, and 12). The levels of linoleic acid were lower in the alkenylacyl- and alkylacyl-GPE of the PO-fed animals, slightly higher in the diacyl species. Levels of α-linolenic acid were considerably higher in all three subclasses of EGP for the PO group; the CO group had only trace amounts. Levels of arachidonic acid were lowered by 43.4, 21.9, and 58.3% in alkenylacyl-, alkylacyl-, and diacyl-*sn*-glycero-3-phosphoethanol-amine (GPE), respectively, of the PO group. Levels of arachidonic acid with PO feeding were substantially lower in diacyl-GPE subclass, as shown for CGP. A higher proportion of arachidonic acid in the CO group reflected the conversion of linoleic acid to arachidonic acid by enzymic reaction. EPA provided the greatest contribution to the higher levels of n-3 fatty acids in all three subclasses of EGP (8.0 in alkenylacyl-, 12.9 in alkylacyl-, and 7.2 mol% in

diacyl-GPE), which indicated a high conversion rate of α-linolenic acid to EPA by Δ6 and Δ5 desaturase. The proportions of DPA and DHA were 3.6 and 2.7 times higher in alkenylacyl-GPE, 6.9 and 3.3 times higher in alkylacyl-GPE, and 5.3 and 1.5 times higher in diacyl-GPE in the PO–fed animals. All of the n-6 and n-3 fatty acids exhibited pronounced differences between the two dietary groups, whereas only small differences were found in the 16:0, 18:0, and 18:1 acyl chains. The ratios of n-6/n-3 fatty acids in the three subclasses of EGP were around 10 times different between the two dietary groups. The ratios were 14.6 and 1.1 in alkenylacyl-, 4.9 and 0.8 in alkylacyl-, and 17.0 and 1.6 in diacyl–GPE of the CO– vs. PO–fed animals.

This study indicates that ingestion of α-linolenic acid-enriched PO is associated with a reduced proportion of alkylacyl-GPC in rat kidney. The results may bear relevance to previous reports (2–4) on the potential for dietary fish oil to suppress the biosynthesis of PAF. Because the metabolism of the ether-linked phospholipids, particularly alkylacyl-GPC, is closely related to PAF generation and degradation, it is possible that dietary PO may affect PAF levels and metabolism *via* effects on the turnover of the alkylacyl species of CGP. The specific biochemical mechanisms involved in the biosynthesis and turnover of the alkylacyl species of CGP, including those processes specifically documented in the kidney (22–26) and polymornuclear leukocytes (27) that are altered by dietary oil ingestion, remains to be elucidated, although the reactions involved in the turnover of the ether-linked phospholipids in animal tissues have been examined in some detail (22,28–33).

In addition, this study shows that an effect of the PO feeding was a reduced availability of a precursor for the synthesis of the arachidonic acid-derived eicosanoids. The reduction of alkylacyl-GPC synthesis by the replacement of arachidonic acid with α-linolenic acid may also be a potential benefit by reducing the pathophysiological effects of PAF which are mediated by the generation of eicosanoids. The relative availabilities of various n-6 and n-3 fatty acids and their esterified forms, enzyme selectivities, and competition for enzyme binding can regulate their utilization by various *de novo* biosynthetic, deacylation/reacylation, and transacylation reactions leading to CGP and EGP formation in kidney. In general, the diacyl subclasses of CGP and EGP, as major contributors to kidney phospholipids in the PO–fed rats, showed lower amounts of linoleic, arachidonic, adrenic acid, and 22:5n-6, and higher levels of α-linolenic acid, EPA, DPA, and DHA. The fatty acid distribution after dietary α-linolenic acid was somewhat different from that after dietary fish oil, even though both increase n-3 fatty acids. This finding is generally in agreement with the reported replacement of the n-6 by the n-3 fatty acids in kidney tissues of rodents fed fish oil-based diets (34,36) and suggests that the n-3 fatty acids compete with the n-6 fatty acids for the desaturation enzymes; however, both Δ6 and Δ4 desaturases prefer n-3 to n-6 fatty acids as substrates (37). The extent to which dietary PO influences flux through these pathways at the level of substrate selectivity (n-6 vs. n-3 substrates) and enzyme activity or regulation thereof remains to be studied. Further work will be required to determine the effects of replacement of the n-6 by the n-3 fatty acids in the biosynthesis of eicosanoids and PAF as well as the possible effects of these biochemical changes on renal physiology.

ACKNOWLEDGMENTS

This study was supported by a research grant from the Korea Ministry of Education and Woobang Company, Taegu, Korea. We thank Dr. Lloyd A. Horrocks for reviewing the manuscript.

Inhibition of Gonadotropin-Stimulated Ovarian Steroid Production by Polyunsaturated Fatty Acids in Teleost Fish

François Mercure and Glen Van Der Kraak*

Department of Zoology, University of Guelph, Guelph, Ontario N1G 2W1 Canada

ABSTRACT: The effects of the polyunsaturated fatty acids (PUFAs)—eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and arachidonic acid (AA)—on *in vitro* steroid production by full-grown prematurational ovarian follicles from goldfish and rainbow trout were investigated. EPA and DHA inhibited gonadotropin-stimulated testosterone production in a dose-related manner, but AA was inhibitory only at the highest dose tested (400 μM). AA alone stimulated testosterone production by increasing cAMP production, but the effects of other PUFAs alone were marginal. The inhibitory actions by PUFAs were not restricted to long-chain PUFAs, as linoleic and linolenic acids had similar actions in the goldfish. The inhibitory action of EPA on testosterone production was reversible upon removal of the PUFA from medium. Testosterone production stimulated by the addition of the cAMP analogues, dibutyryl cAMP, and 8-bromo cAMP, was attenuated by PUFAs, suggesting that they act at a site distal to cAMP formation. A post-cAMP site regulating cholesterol availability may be involved as testosterone production induced by addition of 25OH-cholesterol was not affected by the PUFAs in either fish species. Together, these findings underscore the importance of lipids in ovarian physiology and suggest that PUFAs may participate in the regulation of ovarian steroidogenesis in teleost fish.
Lipids 30, 547–554 (1995).

Environmental influences on long-chain polyunsaturated fatty acids' (PUFAs) composition and metabolism in fish have been considered by many (1–4). However, even though lipid composition in fish is seasonal and may be related to reproductive status (5), little is known of how PUFAs affect ovarian physiology. In freshwater fish, arachidonic acid (AA) (20:4n-6) is usually the most abundant tetraenoic fatty acid, eicosapentaenoic acid (EPA) (C20:5n-3) is often the predominant pentaenoic acid, and docosahexaenoic acid (DHA) (C22:6n-3) is, without exception, the main hexaenoic acid (5). The physiological significance of AA as an eicosanoid precursor and in signal transduction is well established (6–9), as is the importance of eicosanoids, such as prostaglandins, as regulators of ovarian physiology in fish and in many vertebrates (10). However, the roles of EPA and DHA in fish and in mammals remain relatively unclear, even though they are the focus of much research in human health (11,12).

In reproduction, lipids are most often considered from an energetic point of view, and their possible involvement in other physiological processes are often overlooked. Selective lipid depletion has been observed in spawning salmonids (13), and selective PUFA utilization has been reported during gonadal development of salmonids and goldfish (14–16). AA, EPA, and DHA were preferentially released from arctic char ovarian follicles in the presence of melittin, a phospholipase A_2 activator (Geritts, M., Van Der Kraak, G., and Ballantyne, J., unpublished data), and from goldfish testicular fragments upon stimulation with a protein kinase C activator and a calcium ionophore (17). AA, *via* its conversion to eicosanoids, stimulates testosterone production in goldfish ovaries (18), and also in testes (19). By comparison, EPA and DHA inhibit gonadotropin-stimulated testosterone production by goldfish testis (17). PUFAs also modulate gonadal steroidogenesis in avian and in mammalian species (20–25).

This study examines the effects of unesterified long-chain PUFAs including AA, EPA, and DHA on goldfish and rainbow trout ovarian steroidogenesis *in vitro*. Testosterone production was used as an index of steroidogenic activity, as it is a major steroid secreted by full-grown, prematurational ovarian follicles of teleost fish (26,27).

MATERIALS AND METHODS

Fish. Goldfish (*Carassius auratus*), common or comet varieties, were purchased from Grassyfork Fisheries Co. (Martinsville, IN). Fish were held in 1.2-m diameter tanks with flow-through water at 15–18°C under a constant photoperiod (14 light/10 dark). Fish were fed a commercial trout diet once daily to satiation. Prespawning female rainbow trout (*Oncorhynchus mykiss*) were obtained from the Alma Aquaculture Research Station (Alma, Ontario, Canada). Trout were held at the University of Guelph for a period no longer than a week, at 8–11°C.

Ovarian follicle incubations. The follicle incubations followed the general methods described by Van Der Kraak and Chang (18). Fish were sacrificed by spinal transection, and ovaries were immediately placed in a modified Cortland's medium consisting of (g/L): NaCl, 7.25; KCl, 0.38; $CaCl_2 \cdot 2H_2O$, 0.23; $NaH_2PO_4 \cdot H_2O$, 0.41; $MgCl_2 \cdot 6H_2O$, 0.20; $MgSO_4 \cdot 7H_2O$, 0.23; $NaHCO_3$, 1.0; bovine serum albumin, 1.0; glucose, 1.0; and streptomycin sulfate, 0.1; pH 7.6. Each experiment used full-grown, prematurational follicles from a single fish. Due to the asynchronous development of goldfish follicles, full-grown follicles (0.9–1.1 mm in diameter) were manually sorted from the smaller vitellogenic follicles using a Pasteur pipette before placing them in polystyrene (24-well) tissue culture plates (Falcon 3047; Toronto, Ontario, Canada) containing incubation medium. Each treatment consisted of four replicate incubations of 20 follicles for goldfish or 10 full-grown follicles (4–6 mm in diameter) for rainbow trout. Immediately prior to the addition of test chemicals and/or hormones, the medium was replaced with fresh medium. Goldfish follicles incubations routinely included the phosphodiesterase inhibitor 3isobutyl-1-methylxanthine (IBMX) at 1 mM to ensure detectable basal steroid levels and to facilitate measurement of cAMP. IBMX was not added to trout follicle incubations, as basal levels were often higher in this species. Treatment chemicals and hormones were added from concentrated stocks and diluted to working concentrations in the incubation medium. Final incubation volume was 1 mL. Fresh aliquots of fatty acids were opened immediately prior to each experiment to ensure their integrity. Incubations were in air at 18°C in the dark. Incubation periods were routinely for 18 h or as indicated in the figure legends. Following incubation, 0.8 mL of medium was removed from each well and placed in separate borosilicate test tubes to be stored at –20°C for subsequent radioimmunoassay. Media collected for cAMP measurement was boiled immediately for 15 min to destroy phosphodiesterase activity prior to freezing.

The protocols for the testosterone and cAMP assays were described by Van Der Kraak and Chang (18), and by Van Der Kraak (28), respectively. Medium from each replicate was assayed in duplicate.

Chemicals and hormones. Unesterified free fatty acids, human chorionic gonadotropin (hCG), forskolin, IBMX, dibutyryl cAMP (dbcAMP), 8-bromo cAMP, and 25-hydroxycholesterol (25-OH Chol) were obtained from Sigma Chemical Co. (St. Louis, MO). Partially purified salmon gonadotropin (SG-G100) was a gift from Dr. E.M. Donaldson (Department of Fisheries and Oceans, West Vancouver, British Columbia, Canada). hCG, SG-G100, IBMX, and dbcAMP were dissolved directly in incubation medium; and forskolin, free fatty acids, and 25-OH Chol were dissolved in absolute ethanol. 8-Bromo cAMP was solubilized in dimethyl sulfoxide (DMSO). The final volume of ethanol never exceeded 1.0% of final incubation volume, and this concentration has no effect on basal or gonadotropin-stimulated testosterone production (18). Similarly, DMSO at final concentration of 0.5% had no effect on steroid production (data not shown).

Statistical analysis. Following logarithmic transformation (Log_{10}), differences between means were assessed by one-way analysis of variance and by Duncan's Multiple Range test. A P value of ≤ 0.05 was considered significant. Values reported in all figures represent the mean ± SEM of four replicate incubations, and representations lacking error bars indicate a smaller error than the symbol depicting the mean. Data presented are representative of at least two experiments yielding similar results.

RESULTS

Effects of PUFAs on steroidogenesis. Experiments were conducted to test the effects of graded dosages of PUFAs (6.25–400 µM) on ovarian steroidogenesis of goldfish and rainbow trout. Consistent with earlier studies, hCG caused a marked increase in testosterone production by goldfish prematurational follicles (Fig. 1). Addition of EPA and DHA caused similar inhibitions of hCG-stimulated testosterone production, with the effects being significant at the higher doses (100–400 µM). AA was also inhibitory, but only at the highest dose tested. AA alone stimulated testosterone production in a dose-dependent manner with maximum stimulation achieved at 100 µM. EPA and DHA caused marginal increase in testosterone production at the higher dosages. In the trout, DHA inhibited SG-G100-stimulated testosterone production in a dose-related manner, but the inhibition by AA was significant only at the highest dose (Fig. 2). AA at 6.25 µM, but not at higher dosages, stimulated testosterone production.

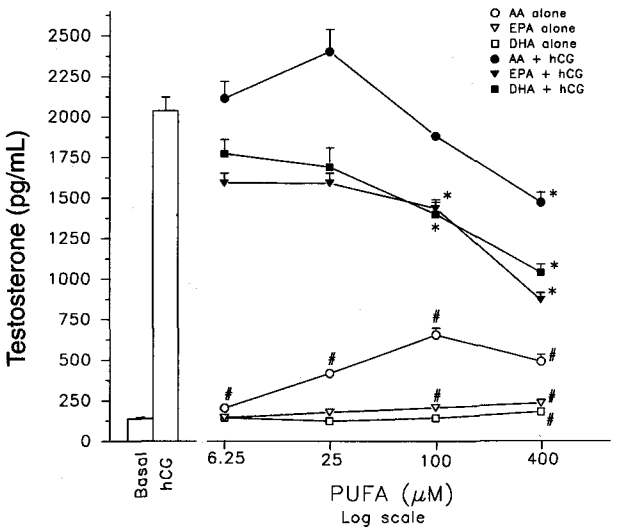

FIG. 1. Effects of graded dosages of arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) on basal- and on human chorionic gonadotropin (hCG)-stimulated (10 IU) testosterone production by goldfish full-grown ovarian follicles incubated for 18 h at 18°C. Values represent the mean ± SEM of four replicate incubations. * Indicates a significant difference from hCG alone, and # indicates a significant difference from basal level.

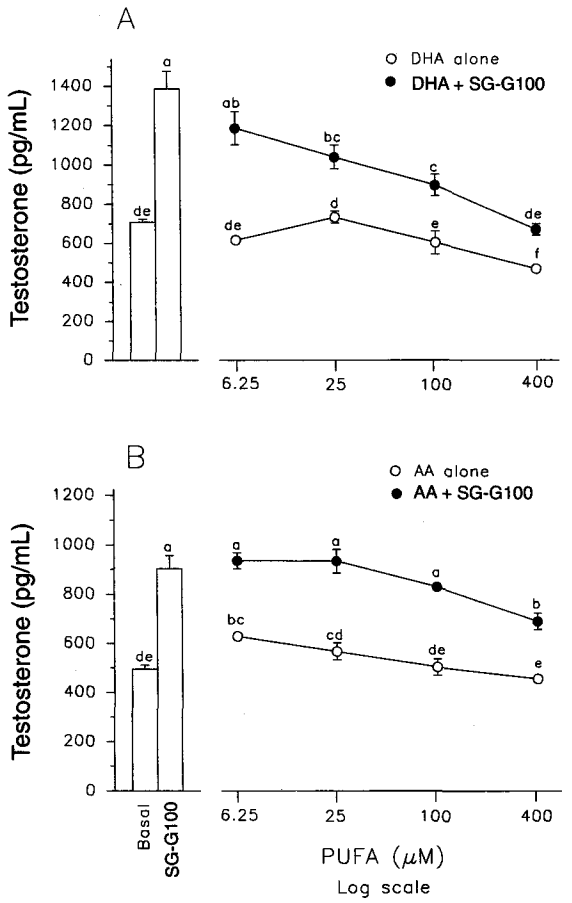

FIG. 2. Effects of graded dosages of DHA (A) and AA (B) on basal- and on partially purified salmon gonadotropin (SG-G100) (1 μg/mL) stimulated testosterone production by rainbow trout full-grown ovarian follicles incubated for 18 h at 18°C. Values represent the mean ± SEM of four replicate incubations. Means with different letters are significantly different. Abbreviations as in Figure 1.

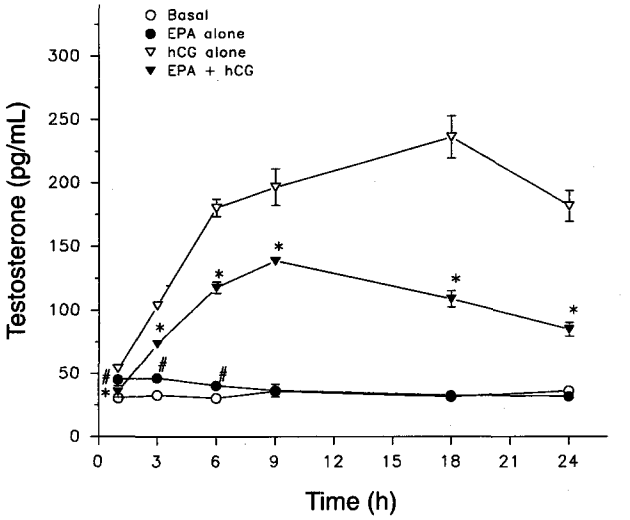

FIG. 3. Time course response of EPA (400 μM) effects on basal- and hCG-stimulated (10 IU) testosterone production by goldfish full-grown ovarian follicles incubated at 18°C. Values represent the mean ± SEM of four replicate incubations. * Indicates a significant inhibition by EPA from hCG alone, and # indicates a significant difference from basal level at each time interval. Abbreviations as in Figure 1.

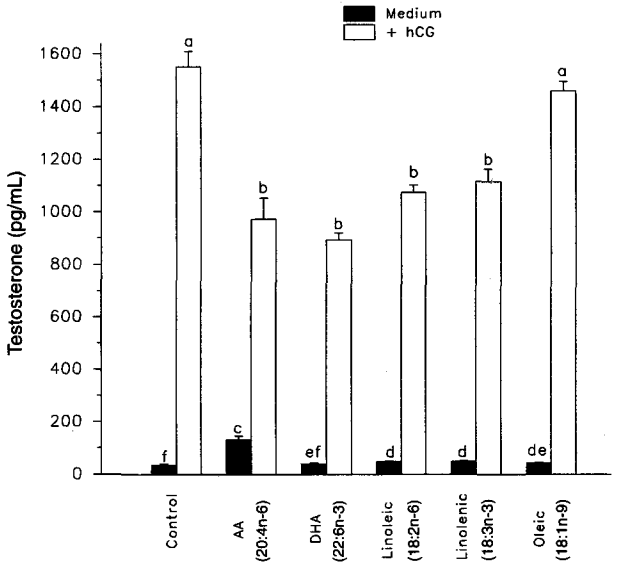

FIG. 4. Effects of AA, EPA, linoleic acid, linolenic acid, and oleic acid at 400 μM on basal- and on hCG-stimulated (10 IU) testosterone production by goldfish full-grown ovarian follicles incubated for 18 h at 18°C. Values represent the mean ± SEM of four replicate incubations. Means with different letters are significantly different. Abbreviations as in Figure 1.

EPA was found to have rapid effects in time course experiments with goldfish follicles (Fig. 3). EPA attenuated hCG actions, but increased basal testosterone production after the first hour on its own. Maximal stimulation by hCG was found after 18 h, where inhibition by EPA was also greatest. The initial stimulation of testosterone production by EPA alone subsequently disappeared after six hours of incubation.

Experiments were conducted to test the specificity of the effects found with the long-chain PUFAs. In addition to AA and DHA, linoleic, and linolenic acids at 400 μM attenuated hCG-stimulated testosterone production by goldfish ovarian follicles, although oleic acid had no significant effect (Fig. 4). Basally, AA, linoleic, linolenic, and oleic acids had stimulatory effects, with AA being most effective.

Effects of PUFA removal. Given that relatively high dosages of fatty acids were routinely used to inhibit gonadotropin-stimulated testosterone production, experiments were conducted with goldfish to establish whether the decrease in steroidogenesis was due to effects on follicular viability. The approach was to conduct an initial 15-h incubation testing the actions of graded dosages of EPA and, following removal of EPA by washing several times with fresh medium, to measure the follicular response to hCG during a subsequent 15-h incubation. Media were removed and frozen until assayed for testosterone after each 15-h incubation. In initial in-

cubation, follicles responded with the typical stimulation by hCG, and EPA attenuated hCG actions (Fig. 5A). In the subsequent incubation, basal testosterone production was maintained: 63 and 64 pg/mL in initial and in subsequent incubations, respectively. However, the overall responsiveness of follicles to hCG was much less than in initial incubation (Fig 5B). Most importantly, the follicles initially exposed to hCG alone and hCG in combination with EPA were equally responsive during a second incubation with hCG. These data demonstrate that although responsiveness of follicles to hCG was affected after 15 h of incubation, the inhibition by EPA was reversible.

Sites of inhibition. Because gonadotropin stimulates steroid production *via* cAMP, the effects of PUFAs on cAMP and testosterone production were assessed in goldfish. As expected, addition of hCG increased accumulation of cAMP in the media (Fig. 6). Addition of EPA (100 and 400 μM) inhibited hCG-stimulated cAMP production (Fig. 6A). EPA alone caused a slight but significant dose-related accumulation of cAMP in the media, but this effect did not match the effect on testosterone production, as EPA at 100 μM was inhibitory, whereas EPA at 400 μM was stimulatory. AA alone increased cAMP levels in a dose-related manner which corresponded with an increase in testosterone production (Fig. 6B). However, AA potentiated hCG-stimulated cAMP production but did not affect testosterone production. Relatively low levels of testosterone were produced in these experiments compared to previous results, due to the shorter (4-h) incubation period used for cAMP assessment.

Phosphodiesterase activity is an important intracellular regulatory site controlling cAMP levels. Because the phosphodiesterase inhibitor IBMX was necessary to detect cAMP levels, and because it was routinely added to all goldfish follicle incubations, it was important to test whether IBMX affected the actions of the PUFAs. IBMX at dosages of 0.1 and 1.0 mM led to a modest increase in basal testosterone production, but markedly enhanced the stimulatory actions of hCG (Fig. 7). More importantly, EPA attenuated hCG-stimulated testosterone production both in the presence or absence of IBMX.

A series of experiments were conducted to test whether PUFAs may act at other sites post-cAMP formation. The

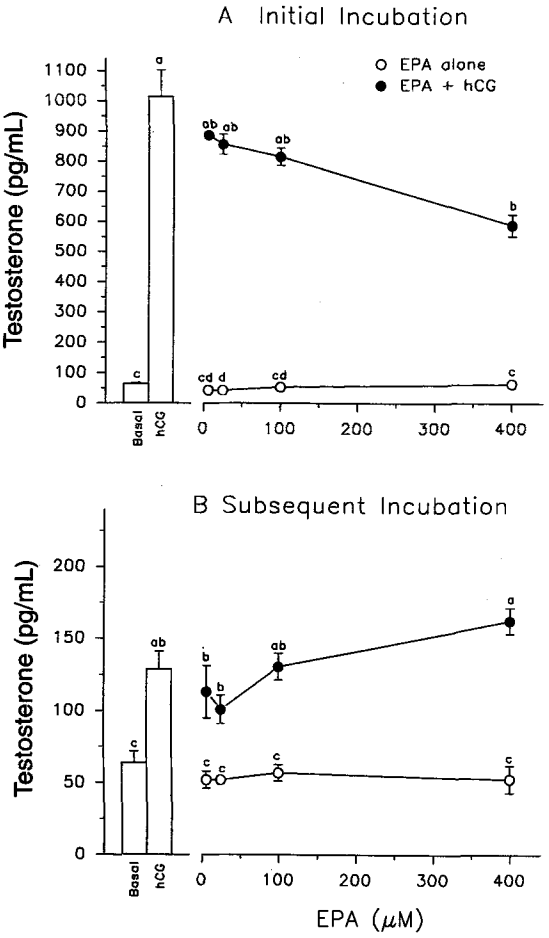

FIG. 5. Assessment of follicular responsiveness to hCG following the removal of EPA. Effects of graded dosages of EPA on basal- and hCG-stimulated testosterone production by goldfish full-grown ovarian follicles after a 15-h initial incubation at 18°C (A). Basal- and hCG-stimulated testosterone production of the same follicles during a subsequent 15-h incubation after removal of EPA and in fresh medium with and without hCG (B). Values represent the mean ± SEM of four replicate incubations. Means with different letters are significantly different. Abbreviations as in Figure 1.

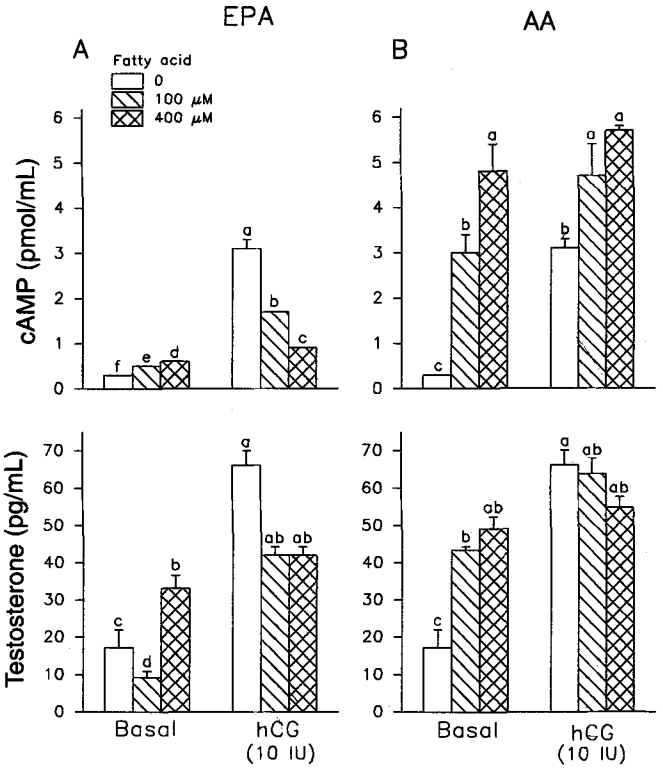

FIG. 6. Effects of EPA (A) and AA (B) on basal- and hCG-stimulated cAMP and testosterone production by goldfish full-grown ovarian follicles incubated for 4 h at 18°C. Values represent the mean ± SEM of four replicate incubations. Means with different letters are significantly different. Abbreviations as in Figure 1.

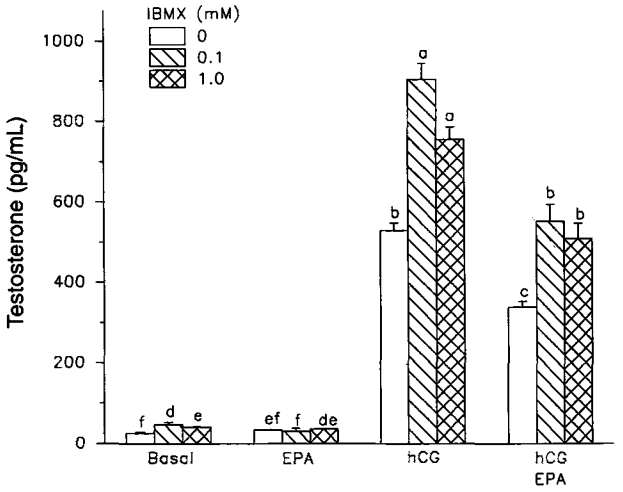

FIG. 7. Dosage effects of 3-isobutyl-1-methylxanthine (IBMX) on basal- and hCG-stimulated (10 IU) testosterone production by goldfish full-grown ovarian follicles incubated for 18 h at 18°C with and without EPA (400 μM). Values represent the mean ± SEM of four replicate incubations. Means with different subscripts are significantly different. Abbreviations as in Figure 1.

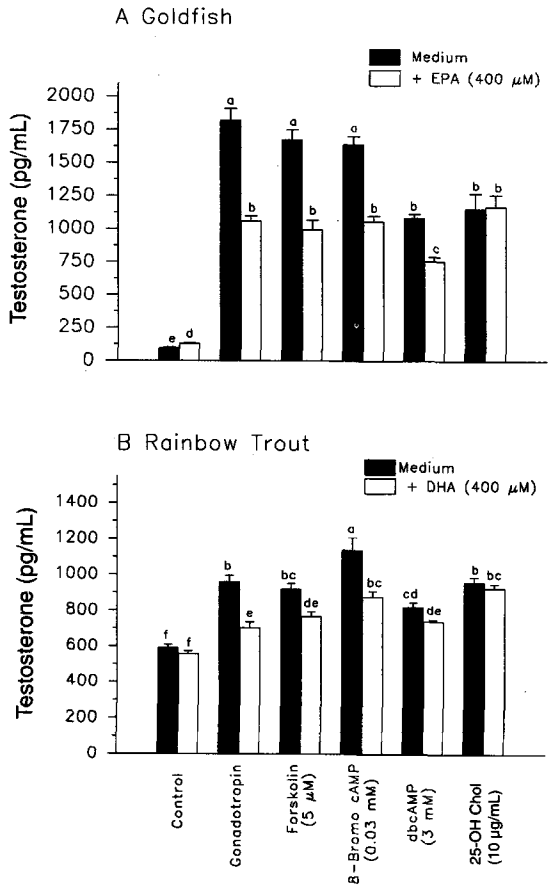

FIG. 8. Effects of polyunsaturated fatty acids on hCG (SG-G100 for trout), forskolin, 8-Bromo cAMP, dibutyryl cAMP (dbcAMP), and 25-OH Cholesterol (25-OH chol) stimulated testosterone production by goldfish (A) and rainbow trout (B) full-grown ovarian follicles incubated for 18 h at 18°C. Values represent the mean ± SEM of four replicate incubations. Means with different letters are significantly different. Abbreviations as in Figures 1 and 2.

stimulatory actions of hCG and forskolin, a direct activator of adenylate cyclase, on testosterone production were inhibited by EPA in the goldfish (Fig. 8A). Testosterone production induced by two cAMP analogues, 8-Bromo cAMP and dbcAMP, which mimic the actions of cAMP, were also inhibited by EPA, indicating an effect distal to cAMP formation. When follicular testosterone production was stimulated by addition of the steroidogenic substrate 25-OH Chol, EPA was without effect. In the rainbow trout, SG-G100, forskolin, and 8-Bromo cAMP actions on testosterone production were inhibited by the addition of DHA (Fig. 8B). However, it is not clear why DHA did not block the dbcAMP-induced increase in testosterone production in the trout. As with the goldfish, the stimulatory effect of 25-OH Chol was not affected by DHA.

DISCUSSION

These studies demonstrate differential actions of PUFAs on basal and on gonadotropin-stimulated steroid production in goldfish and in rainbow trout ovarian follicles. In both species, PUFAs inhibit the stimulatory action of gonadotropin at a site distal to cAMP formation which may regulate cholesterol supply to the steroidogenic pathway. AA alone stimulated testosterone production by increasing cAMP production, but the effects of other PUFAs alone were marginal. These studies support the contention that unesterified long-chain PUFAs, including AA, EPA, and DHA, participate in the regulation of ovarian steroidgenesis in teleosts.

Gonadotropin stimulation of steroidogenesis in teleosts involves the cAMP signal transduction pathway (28–31), and studies with mammals have established that cAMP plays a role in regulating the synthesis, storage, and transport of cholesterol in steroidogenic tissues (32–36). EPA inhibited gonadotropin actions on steroid production by blocking cAMP formation. Given that the phosphodiesterase inhibitor IBMX was added to the incubation medium, the effect of EPA was on cAMP formation rather than on its degradation. However, AA at high dosage inhibited gonadotropin-stimulated testosterone production in spite of its potentiation on cAMP levels, suggesting a second site of action distal to cAMP. This was confirmed in studies showing that PUFAs also inhibited testosterone production stimulated by addition of cAMP analogues. This distal site must affect substrate availability to the steroidogenic enzymes as the PUFAs did not inhibit testosterone production stimulated by 25-OH Chol. It is becoming evident that regulation of substrate availability may be central in controlling gonadal steroidogenesis, as the inhibitory actions of other messengers, such as growth factors and cytokines, on steroid production were also reversible upon addition of exogenous cholesterol (37–39).

As with previous studies with goldfish ovarian follicles (18,28), there was variation in the basal, and gonadotropin-stimulated testosterone production. Although several factors, such as follicular maturity, may affect responsiveness to gonadotropin and steroid production during the preovulatory pe-

riod, PUFAs consistently inhibited gonadotropin-stimulated steroid production. Similarly to vitellogenic goldfish follicles, AA, EPA, and DHA attenuated hCG-stimulated testosterone and 17ß-estradiol production (McFarlane, W., Mercure, F., and Van Der Kraak, G., unpublished).

Because PUFAs can inhibit gonadotropin-stimulated testosterone production independently of their effects on cAMP formation or follicular maturity, intracellular mechanisms other than the cAMP signal transduction pathway may be involved. Several other transduction pathways participate in the regulation of ovarian function in mammals (40,41) and in teleost species (28,42–46). Stimulation of the lipid and calcium dependent phosphoinositol (PI) transduction pathway, with a tumor promoting phorbol ester (phorbol 12-myristate 13-acetate, PMA) and calcium ionophore A23187, was inhibitory to testosterone production in goldfish ovarian follicles (18,45). PMA is known to activate protein kinase C (PKC) (47,48), and in mammalian species PUFAs directly modulate PKC activity (23,24). Therefore, the inhibitory action of PUFAs on testosterone production in teleosts could be mediated by PKC activation. However, in goldfish testicular tissue, in which PUFAs inhibited hCG-stimulated testosterone production, PUFAs failed to activate PKC, suggesting some differences between mammals and fish (49). In chicken ovarian tissue, AA, which also inhibited gonadotropin-stimulated steroid production, failed to activate PKC (21,22). The inhibitory action of AA in hen ovarian granulosa cells appeared to be calcium-dependent (22). The inhibition of steroidogenesis in mouse testicular Leydig cells by nonesterified fatty acids occurs at a step prior to the conversion of cholesterol which was also found to be calcium-dependent (20). Thus, it is plausible that the inhibitory action of PUFAs in fish ovaries may be mediated by a calcium-dependent mechanism. In earlier studies, high dosages of A23187, which would elevate intracellular calcium levels, inhibited gonadotropin-stimulated testosterone production by goldfish prematurational ovarian follicles (28,43).

Since the inhibition of gonadotropin-stimulated testosterone production by PUFAs was not specific to any fatty acid and was found in both species studied, it is unlikely that specific metabolites are responsible for the inhibition. Thus, the inhibitory effect could have been the consequence of some shift in lipid and cholesterol metabolism induced by the PUFAs. Cholesterol metabolism is intimately linked with lipid absorption, transport, and metabolism; and in poikilotherms such as fish, regulation of lipid uptake, membrane integrity, and metabolic pathways must be integrated (50). Recent findings suggest that PUFAs act in a hormone-like manner to regulate the expression of peroxisomal enzymes involved in the metabolism of cholesterol and of long-chain PUFAs (51–56). Peroxisome proliferators are chemicals which induce peroxisomal enzymes by disrupting lipid metabolism, resulting in a fatty acid overload responsible for the induction (57–59). Given the relatively high doses tested and the nonspecificity of the PUFA inhibitory action in this study, it is possible that PUFAs inhibit by way of peroxisomal induction. Preliminary results have shown that recognized peroxisome proliferators inhibit ovarian steroid production of goldfish follicles (Mercure, F., and Van Der Kraak, G., unpublished). Thus, the fatty acid overload model proposed by Lock *et al.* (57), whereby PUFAs induce metabolic changes, warrants more attention in the present experimental model.

The paradoxical effects of AA on basal- and gonadotropin-stimulated testosterone production may relate to differential effects of AA and its metabolites. The finding that AA alone stimulates ovarian steroid production in goldfish and trout was consistent with previous studies showing that the actions of AA were dependent on its conversion to cyclooxygenase metabolites in goldfish ovaries (18) and testes (19), and that prostaglandins stimulate testosterone production *via* cAMP in goldfish testis (19) and in ovaries (Mercure, F., and Van Der Kraak, G., unpublished). However, there were differences in the sensitivity to AA alone between goldfish and trout. Given that temperature affects membrane lipid composition (1–4) and eicosanoid production in the goldfish (Mercure, F., and Van Der Kraak, G., unpublished), important differences may exist with respect to PUFA conversion to eicosanoids in goldfish and trout, which are warm and cold water species, respectively. Although EPA and DHA also affect basal steroid production, these data should be interpreted with caution, as stimulation was modest and not always statistically significant.

We were concerned that the high dose of fatty acids routinely used in this study caused cytotoxicity resulting in lower steroid production. This study demonstrated that PUFAs even at the highest dose did not affect follicular viability, as the inhibition was reversible upon removal of the PUFAs. However, it is unclear why the overall follicular responsiveness to hCG was greatly reduced after 15 h of incubation, and over time. It is likely that the overall follicular steroidogenic capacity diminishes with time under the incubation conditions used. Expression of steroidogenic enzymes, and thus their activity, was found to decline with time in similar incubations of rainbow trout and medaka ovarian follicles (Tanaka, M. and Nagahama, Y., personal communication). Nevertheless, this study demonstrates that PUFAs do not irreversibly affect steroidogenesis, which is consistent with the findings of others. Meikle *et al.* (20) reported, using trypan blue exclusion and chromium-51 release tests, that unesterified fatty acid concentrations up to 2,900 μM had no effect on membrane integrity and cell viability of mouse Leydig cells. Further, they demonstrated that the inhibition by nonesterified fatty acids, such as oleic and linoleic, was reversible upon removal of the fatty acids.

Although the high doses of PUFAs added were not lethal to the cells, the physiological significance of such doses must be addressed. The levels of nonesterified plasma fatty acids in fish are often much higher than in mammals, and large concentrations of nonesterified PUFAs have been reported in the gonads of some fish (5). Plasma levels ranging between 1,200 and 18,500 μM of total nonesterified fatty acids have been measured for several fish species (60), which is significantly

higher than the experimental dosages tested in the present study. As a result, the dosages tested may be regarded as physiological in fish. Due to the hydrophobicity of the fatty acids, dosages in excess of 400 μM could not be tested under the conditions used.

In summary, PUFAs have been found to inhibit gonadotropin-stimulated steroidogenesis in a cold and a warm water fish species. PUFAs have varying effects on cAMP formation, but apparently act in a similar manner at a site distal to cAMP to inhibit testosterone production. Their inhibitory actions were reversible. Intracellular transduction mechanisms other than the cAMP signal transduction pathway, possibly a calcium-dependent mechanism, may mediate the action of the PUFAs. Finally, PUFAs may induce changes in cellular metabolism with consequences on steroidogenic activity. These results implicate PUFAs as putative regulators of ovarian function in teleost fish.

ACKNOWLEDGMENTS

This work was supported by Operating Grant U0554 from the Natural Sciences and Engineering Research Council of Canada to G.V.D.K. The rainbow trout used in this study were donated by the Alma Aquaculture Research Station of the University of Guelph and the Ontario Ministry of Agriculture and Food. The antisera for testosterone and cAMP were generously donated by Dr. R.J. Etches (University of Guelph) and Dr. J.P. Chang (University of Alberta), respectively. SG-G100 was generously provided by Dr. E.M. Donaldson (Department of Fisheries and Oceans, West Vancouver, British Columbia, Canada).

Occurrence of 22:3n-9 and 22:4n-9 in the Lipids of the Topminnow *(Poeciliopsis lucida)* Hepatic Tumor Cell Line, PLHC-1

Douglas R. Tocher*, James R. Dick and John R. Sargent

NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland

ABSTRACT: The lipids of the hepatic tumor cell line, PLHC-1, from the topminnow *(Poeciliopsis lucida),* were found to contain considerable amounts of a range of n-9 polyunsaturated fatty acids despite culture in serum containing significant amounts of essential fatty acids. The structural identity of all the n-9 polyunsaturated fatty acids was confirmed by gas chromatography/mass spectrometry. Of particular interest, PLHC-1 cell total lipid contained 1.9% of 22:3n-9 and 3.3% of 22:4n-9. As the culture medium contained virtually no n-9 polyunsaturated fatty acids, these fatty acids are all formed by the PLHC-1 cells, presumably from 18:1n-9. The 22:3n-9 and 22:4n-9 are presumably formed by processes of elongation and "Δ4" desaturation of Mead acid, 20:3n-9, present at over 11% in fatty acids of total lipid. Both 22:3n-9 and 22:4n-9 were primarily located in phosphatidylserine (4.1 and 8.5%, respectively) and, to a lesser extent, in phosphatidylethanolamine (2.2 and 6.5%, respectively), in common with the C_{22} derivatives of the n-3 and n-6 series, whereas 20:3n-9 was preferentially located in phosphatidylinositol (31.2%). The results establish that long-chain polyunsaturated fatty acids of the n-9 series can be formed in vertebrate tissue other than in conditions of classical essential fatty acid deficiency.

Lipids 30, 555–565 (1995).

Animals, including fish, lack the Δ12 and Δ15 fatty acyl desaturase enzymes required for the production of 18:2n-6 and 18:3n-3 from 18:1n-9 and, hence, have an essential dietary requirement for these polyunsaturated fatty acids (PUFA) (1,2). In general, animals have the ability to desaturate and elongate the C_{18} essential fatty acids (EFA) to longer-chain, more unsaturated derivatives such as 20:4n-6, generally the major PUFA in terrestrial mammals (3), or 20:5n-3 and 22:6n-3, generally the major PUFA in fish (4–6). In EFA deficiency, animals synthesize n-9 PUFA derived from 18:1n-9 which, under normal conditions, is a process suppressed by the presence of n-3 and n-6 PUFA (7–9). The normal end-product of the metabolism of 18:1n-9 *via* the desaturase/elongase pathways is Mead acid (10), 20:3n-9, which accumulates in mammals in the place of 20:4n-6 (11). Mead acid also accumulates in salmonids and other freshwater fish placed on EFA-deficient diets (12,13). There is no evidence for any significant metabolism of Mead acid to longer-chain, more unsaturated fatty acids in EFA-deficient animals (11,14).

Cell culture media are normally devoid of any fatty acids so that cells in culture generally derive all their lipid and fatty acids from the lipid contained in the serum supplement. Sera are lipid-rich, and fetal calf serum (FCS), the predominant serum supplement in use, is relatively rich in PUFA (15,16). For mammalian cells, FCS provides a sufficient amount and balance of n-6 and n-3 PUFA. In contrast, although the total amount of PUFA is adequate, fish cells grown in FCS display lower percentages of n-3 PUFA and are enriched in n-6 PUFA in comparison with fish tissues (15). Most fish cell lines grown in FCS contain only small amounts of n-9 PUFA, generally 20:3n-9 (15).

In the present paper, we report on a fish cell line, PLHC-1 (17), derived from hepatocarcinoma tissue from the topminnow (*Poeciliopsis lucida*), which, under standard, routine culture conditions in medium containing 10% FCS, contained considerable amounts of n-9 PUFA and, in particular, significant amounts of 22:3n-9 and 22:4n-9.

MATERIALS AND METHODS

Cell lines and media. The cell line, PLHC-1, was initially cultured in 1985 *via* trypsinization of a differentiated hepatocellular tumor from the topminnow (*P. lucida*) (17). The cells are epithelial but retain some of the characteristic morphology of primary liver hepatocytes. The cells used in the present study had been subcultured for 90–100 passages. The PLHC-1 cells were maintained in CO_2-Independent Medium (a proprietary product obtained from Gibco BRL, Life Technologies Ltd., Paisley, Scotland) supplemented with 2 mM glutamine, antibiotics (50 I.U. mL^{-1} penicillin and 50 mg · mL^{-1} streptomycin), and 10% FCS. The cells used in

the present study were a gift from Dr. L.E. Hightower (Department of Molecular and Cell Biology, University of Connecticut, Storrs, CT).

Incubation conditions. Cells were cultured at 30°C in sealed plastic tissue culture flasks (Greiner Laboritechnik Ltd., Dursley, United Kingdom). For routine cultivation of the cells for provision of experimental material, cells were cultured in 75-cm^2 flasks and were subcultured within 24 h of reaching confluence. For lipid analyses, cells were subcultured into 175-cm^2 flasks at a seeding density of 1×10^5 cells · cm^{-2}. For each sample for full lipid analyses, 4×175 cm^2 flasks were seeded, and this experiment was repeated three times to obtain the replicates. Therefore, all results are means ± SD of three such experiments.

Lipid extraction. The medium was aspirated, and the cultures were washed twice with 20 mL of ice-cold Hanks' balanced salt solution (HBSS) without calcium and magnesium. Cells were harvested by trypsinization with 0.05% trypsin/0.5 mM EDTA, washed with 5 mL ice-cold HBSS containing 1% fatty acid-free bovine serum albumin (BSA) and counted as described in Tocher *et al.* (18). Total lipid was determined gravimetrically after extraction with chloroform/methanol (2:1, vol/vol) essentially by the method of Folch *et al.* (19) as described in detail previously (15). All solvents contained 0.01% butylated hydroxytoluene (BHT) as antioxidant.

Lipid class analysis. Lipid classes were separated by one-dimensional, double-development high-performance thin-layer chromatography using methyl acetate/propan-2-ol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) and hexane/diethyl ether/acetic acid (85:15:1.5, by vol) as developing solvents as described previously (20). Lipid classes were quantified by charring (21), followed by calibrated scanning densitometry using a Shimadzu CS-9000 dual wavelength flying spot scanner and DR-2 recorder (Tokyo, Japan) (22).

Separation of glycerophospholipid and neutral lipid classes. Samples of total lipid (3–4 mg) were applied in 4-cm streaks to a thin-layer chromatography plate, and the polar lipid classes were separated using methyl acetate/propan-2-ol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) as developing solvent (23). Lipid classes were visualized under ultraviolet after spraying with 2,7-dichlorofluorescein. Individual glycerophospholipid classes were scraped into stoppered test tubes and transmethylated directly on the silica after addition of 1 mL toluene and 2.5 mL 1% sulfuric acid in methanol, and fatty acid methyl esters (FAME) prepared as described below. Total neutral lipid classes which run at the solvent front in the above solvent system were scraped and eluted from the silica using chloroform/methanol (2:1, vol/vol) before transmethylation, as described below.

Fatty acid analyses. FAME were prepared from total lipid and individual lipid classes by acid-catalyzed transmethylation at 50°C for 16 h (see Ref. 24) and were extracted and purified as described previously (20). Methyl esters were analyzed in a Carlo Erba Vega GC6000 gas chromatograph (Carlo Erba Instrumentazone, Milan, Italy) equipped with a CP Wax 51 fused silica capillary column (50 m × 0.32 mm i.d.; Chrompack U.K. Ltd., London, England), with on-column injection using hydrogen as carrier gas and a biphasic thermal gradient from 50 to 225°C. Routinely, FAME were identified by comparison with known standards and a well-characterized fish oil and by reference to published data as described previously (20), and were quantified using a Carlo Erba DP800 data processor. All solvents contained 0.01% BHT as an antioxidant.

Gas chromatography/mass spectrometry (GC/MS). The identities of fatty acids were confirmed by subjecting the methyl or picolinyl esters (25) to GC/MS using a Carlo Erba 8000 gas chromatograph coupled to an MD800 mass spectrometer (Fisons Instruments, Crawley, United Kingdom) (see Ref. 26). Methyl esters were analyzed using chemical ionization (CI) using methane as reagent gas, and picolinyl esters were analyzed using the electron ionization (EI) mode at 70 eV. The gas chromatograph was equipped with a fused silica capillary column (15 m × 0.25 mm i.d.) coated with DB 5MS (J&W Scientific, Folsom, CA) and used helium as carrier gas. Samples were applied using on-column injection with the oven temperature programmed to rise from 50 to 260°C.

Materials. HBSS, glutamine, antibiotics, FCS, trypan blue, trypsin/EDTA, fatty acid-free BSA, and BHT were obtained from Sigma Chemical Co. Ltd. (Dorset, United Kingdom). Thin-layer chromatography (20- × 20-cm × 0.25-mm) and high-performance thin-layer chromatography (10- × 10-cm × 0.15-mm) plates precoated with silica gel 60 (without fluorescent indicator) were purchased from Merck (Darmstadt, Germany). All solvents were high-performance liquid chromatography-grade and were from Rathburn Chemicals (Peebleshire, United Kingdom).

RESULTS

Lipid content and lipid class composition. PLHC-1 cells contained almost 21 μg of total lipid per million cells (Table 1). Polar lipid classes predominated, accounting for 81.5% of the total lipid, with phosphatidylcholine (PC) and phosphatidylethanolamine (PE) together amounting to almost 54% of the total lipid, with approximately 8% each of phosphatidylserine (PS), phosphatidylinositol (PI), and sphingomyelin (Table 1). Cholesterol was the major neutral lipid at about 13% with the storage lipids, triacylglycerol and steryl ester, accounting for less than 5 and 1% of the total lipid, respectively (Table 1).

Fatty acid composition of total lipid. The fatty acid composition of the total lipid was characterized by approximately equal proportions of saturated, monounsaturated, and PUFA (Table 2). The total for saturated fatty acids was mainly due to 16:0 and 18:0 and the monounsaturated fatty acids were predominantly 18:1n-9 (Table 2). Total n-3 and n-6 PUFA were both present at about 5% of the total fatty acids with 22:6n-3 (3.8%) and 20:4n-6 (3.0%) being the main components, respectively (Table 2). However, the predominant

[a]Results are means ± SD (n = 3). PUFA, polyunsaturated fatty acids; n.d., none detected.

PUFA in PLHC-1 cells was 20:3n-9, which accounted for over 11% of total fatty acids with total n-9 PUFA amounting to 21.5% of the total fatty acids (Table 2). PLHC-1 cells also contained 3.7% 18:2n-9, but of most interest was the presence of 1.9% 22:3n-9 and 3.3% 22:4n-9 (Table 2). Culture of the cells in lipid-free medium increased the percentage of total n-9 PUFA to 25.1 ± 0.7%, with 20:2n-9 and 22:3n-9 increased 3-fold and 1.5-fold, respectively, all increases being significant (data not shown). The percentages of 18:2n-9 and 20:3n-9 were slightly, but not significantly, increased, but the percentage of 22:4n-9 decreased in lipid-free culture.

Identification of 22:4n-9 by GC/MS. Figure 1 shows the analytical gas chromatogram of PLHC-1 total lipid FAME with the positions of the major and unusual (putative n-9 PUFA) fatty acids marked. The n-9 PUFA were all subjected to GC/MS in order to positively identify their structure. The GC trace from the GC/MS for PLHC-1 cell total lipid FAME shows C_{22} PUFA as a cluster of peaks between positions 3259 and 3356 (Fig. 2A). CI+ was used to generate molecular (base) ions to determine molecular weights. Peak 3283 gave a molecular (base) ion of molecular weight 347 corresponding to 22:4 (Fig. 2B). CI also established (data not shown) that peaks 3259 and 3356 in Figure 2A were 22:6 and 22:3, respectively. The shoulder on the front of 3259 was 22:5, and the two peaks between 3283 and 3356 were, in elution order, further 22:4 and 22:5 fatty acids.

To identify the double-bond positions of the various C_{22} PUFA, picolinyl esters were prepared and subjected to GC/MS (Fig. 3A) (25). Peak 3751 in the picolinyl trace corresponded to peak 3283 in the FAME trace. EI analysis of peak 3751 showed a mass ion of 423 *m/z*, and fragments at 394, 380, 366, 352, 338, 324, 310, 296, and then 284 *m/z* (Fig. 3B). This pattern with an initial interval of 29 for the first main fragment (15 for the terminal methyl plus 14 for the first methylene) followed by intervals of 14 (methylenes) is characteristic of the fragmentation of picolinyl esters of fatty acids (see Refs. 25,26). The interval of 26 (14 + 12) between 310 and 284 denotes the position of the first double bond, indicating that this fatty acid is n-9. Therefore peak 3751was confirmed as 22:4n-9. The EI spectra of peaks 2785 and 3894 are shown in Figure 4A and B, respectively. Peak 2785 showed a fragmentation pattern with a mass ion of 397 *m/z* and peaks at 368, 354, 340, 326, 312, 298, 284, 270, and 258 (Fig. 4A). Peak 2785 was known to be 20:3n-9, and this pat-

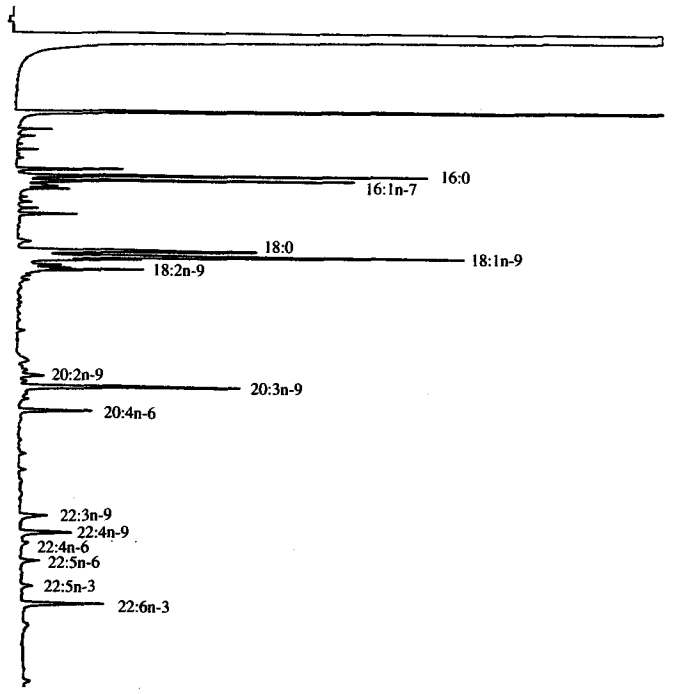

FIG. 1. Capillary gas chromatograph of fatty acid methyl esters (FAME) prepared from total lipid from PLHC-1 cells cultured at 30°C in medium containing 10% fetal calf serum. Lipid was extracted, FAME prepared, and gas chromatography performed as described in the Materials and Methods section.

tern with the 26 (14 +12) interval between 284 and 258 confirmed its structure as n-9. Peak 3894 was known from the CI analysis to be 22:3, and the EI fragmentation pattern of the picolinyl ester with mass ion of 425 *m/z* and fragments at 396, 382, 368, 354, 340, 326, 312, 298, and then 286 *m/z* confirmed its structure as n-9 (Fig. 4B).

Fatty acid compositions of glycerophospholipids and neutral lipid in PLHC-1 cells. The fatty acid compositions of the major phosphoglycerides showed that all the C_{22} PUFA were found in the greatest percentages in PS with 22:3n-9 and 22:4n-9 accounting for 4.1 and 8.5% of total fatty acids in PS, respectively (Table 3). However, the highest percentage (35.4%) of total n-9 PUFA was found in PI due to a highly selective localization of 20:3n-9 which made up over 31% of total PI fatty acids (Table 3). The highest percentage of arachidonic acid (20:4n-6) was also found in PI. The major non-PUFA in PS and PI was 18:0, accounting for some 39 and 34% of their total fatty acids, respectively.

Total neutral lipids had the lowest levels of PUFA, with over 81% of total fatty acids being saturated or monounsaturated, predominantly 18:1n-9, 16:0, and 16:1(n-7) (Table 3). A very similar composition to that of total neutral lipids was found in PC which was also characterized by having the highest percentage (5.7%) of 18:2n-9 (Table 3). PE had the lowest percentage of saturated fatty acids, intermediate levels of monounsaturated fatty acids, n-9 and n-3 PUFA, but had the highest percentage of total n-6 PUFA due to the specific localization of 20:3n-6 (5.5%) (Table 3).

DISCUSSION

The present paper reports on the presence of 22:3n-9 and 22:4n-9 in a cultured hepatoma cell line from a fish, the topminnow (*P. lucida*). The unequivocal characterization of these two unusual PUFA was made by GC/MS of picolinyl esters of the fatty acids. The resolution of picolinyl esters by the GC was not as high as with FAME, and this resulted in very close elution of the picolinyl esters of 22:4n-9 and 22:6n-3. However, culture of the PLHC-1 cells in lipid-free medium resulted in the almost complete loss from the cells of the n-3 and n-6 C_{22} PUFA including 22:6n-3 (data not shown). This resulted in a much simpler GC trace in the region of the C_{22} PUFA so that the 22:4n-9 peak (peak 3751 in Fig. 3A) was >99% 22:4n-9. Therefore, culture in lipid-free conditions facilitated positive identification of the n-9 PUFA by GC/MS. However, the data shown here establish positive identification of the n-9 PUFA in PLHC-1 cells under routine culture conditions, i.e., in medium containing serum. Culture of the cells in lipid-free medium also suggested that oleate in the medium was not the primary source of the n-9 PUFA in the PLHC-1 cells as total n-9 PUFA were increased in lipid-free culture.

Under normal culture conditions, in the presence of 10% FCS, the 22:3n-9 and 22:4n-9 were present at a combined level of over 5% of the total fatty acids. Neither of these PUFA is present in FCS. Indeed PUFA of the n-9 series are virtually absent in FCS, with only 0.6% of 20:2n-9 found in the batch of FCS used in these experiments. Thus, the 22:3n-9 and 22:4n-9 are the result of endogenous metabolism of 18:1n-9 in the PLHC-1 cells. It is probable that they arise *via* elongation of 20:3n-9 followed by a "Δ4 desaturation" in a situation paralleling the formation of 22:4n-6/22:5n-6 and 22:5n-3/22:6n-3. Studies have shown that 20:3n-9 can be a substrate for the fatty acid chain elongation system of mammalian liver endoplasmic reticulum and at a rate similar to that for the elongation of 20:4n-6 (27). Banerjee and Rosenthal (28) found that, in human skin fibroblasts in culture, the rate of elongation of 20:3n-9 to 22:3n-9 was intermediate between the rates of elongation of 20:5n-3 (which was faster) and 20:4n-6 (slower). This is different to the situation with most desaturases where the rank order for relative rates of activity is n-3 > n-6 > n-9 (14,29). However, there is nothing known about the desaturation of 22:3n-9 to 22:4n-9. Recently, Sprecher and co-workers (30–32) have characterized a pathway for the desaturation of 22:5n-3 to 22:6n-3 in rat liver independent of a Δ4 desaturase activity. This pathway involves microsomal elongation of 22:5n-3 to 24:5n-3 followed by microsomal desaturation to 24:6n-3 *via* a Δ6 desaturase activity and finally partial β-oxidation, probably peroxisomal, to yield 22:6n-3 (30). In the present study with the columns used in the GC/MS, it would have been possible to detect the presence of very small amounts of C_{24} PUFA. However, if any C_{24} PUFA was present in the PLHC-1 cells, it was below detection limit. Therefore, the pathway for the formation of 22:4n-9 in PLHC-1 cells is not known.

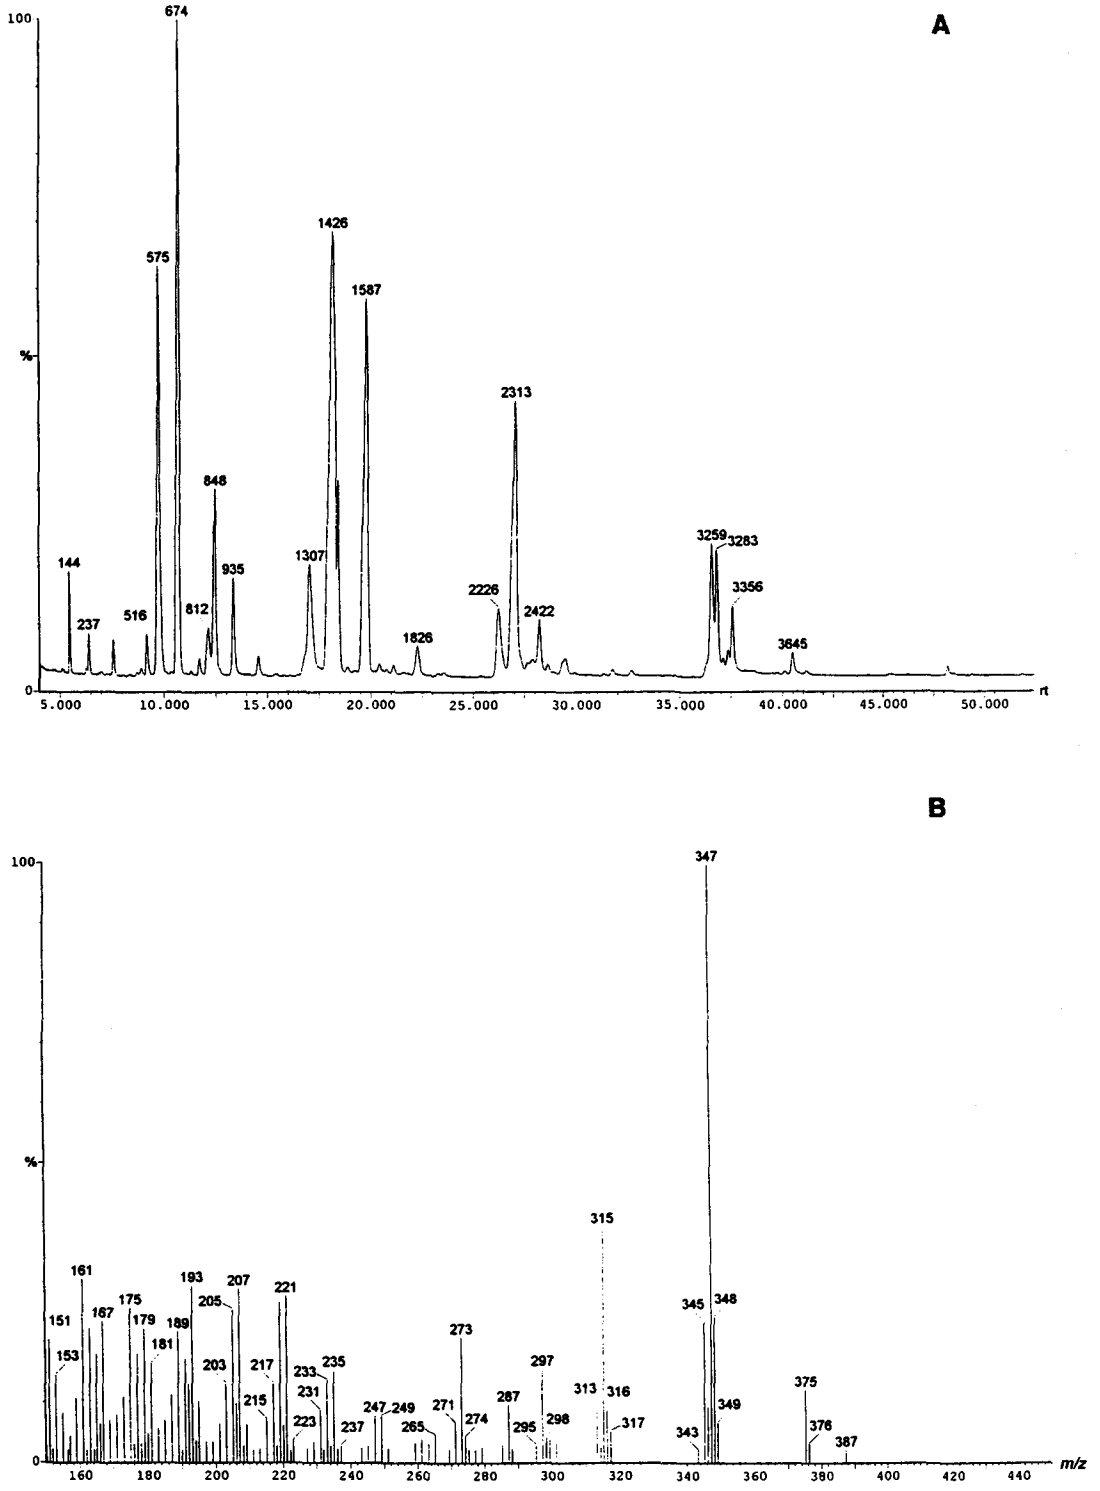

FIG. 2. Capillary gas chromatography of total lipid fatty acid methyl esters from PLHC-1 cells (A) and the chemical ionization mass spectrum of 22:4n-9 (peak 3283) (B). Cell culture conditions and gas chromatography/mass spectrometry procedures as described in the Materials and Methods section; rt, retention time.

Neither of these very long-chain metabolites of 20:3n-9 has been commonly found in animal tissues where Mead acid has long been regarded as the end product of the metabolism of 18:1n-9 *via* the classical elongation/desaturation pathways (7,8). Furthermore, the metabolism of 18:1n-9 by the desaturase/elongase pathway and the production of Mead acid generally only occurs in conditions of EFA deficiency (7,8,11). For instance, in rats fed for 5 mon on an EFA-deficient diet (hydrogenated coconut oil), 20:3n-9 accumulated in erythrocytes in the place of 20:4n-6, and only very small amounts of two minor fatty acids that behaved chromatographically similar to 22:3n-9 and 22:4n-9 were found (11). An EFA-defi-

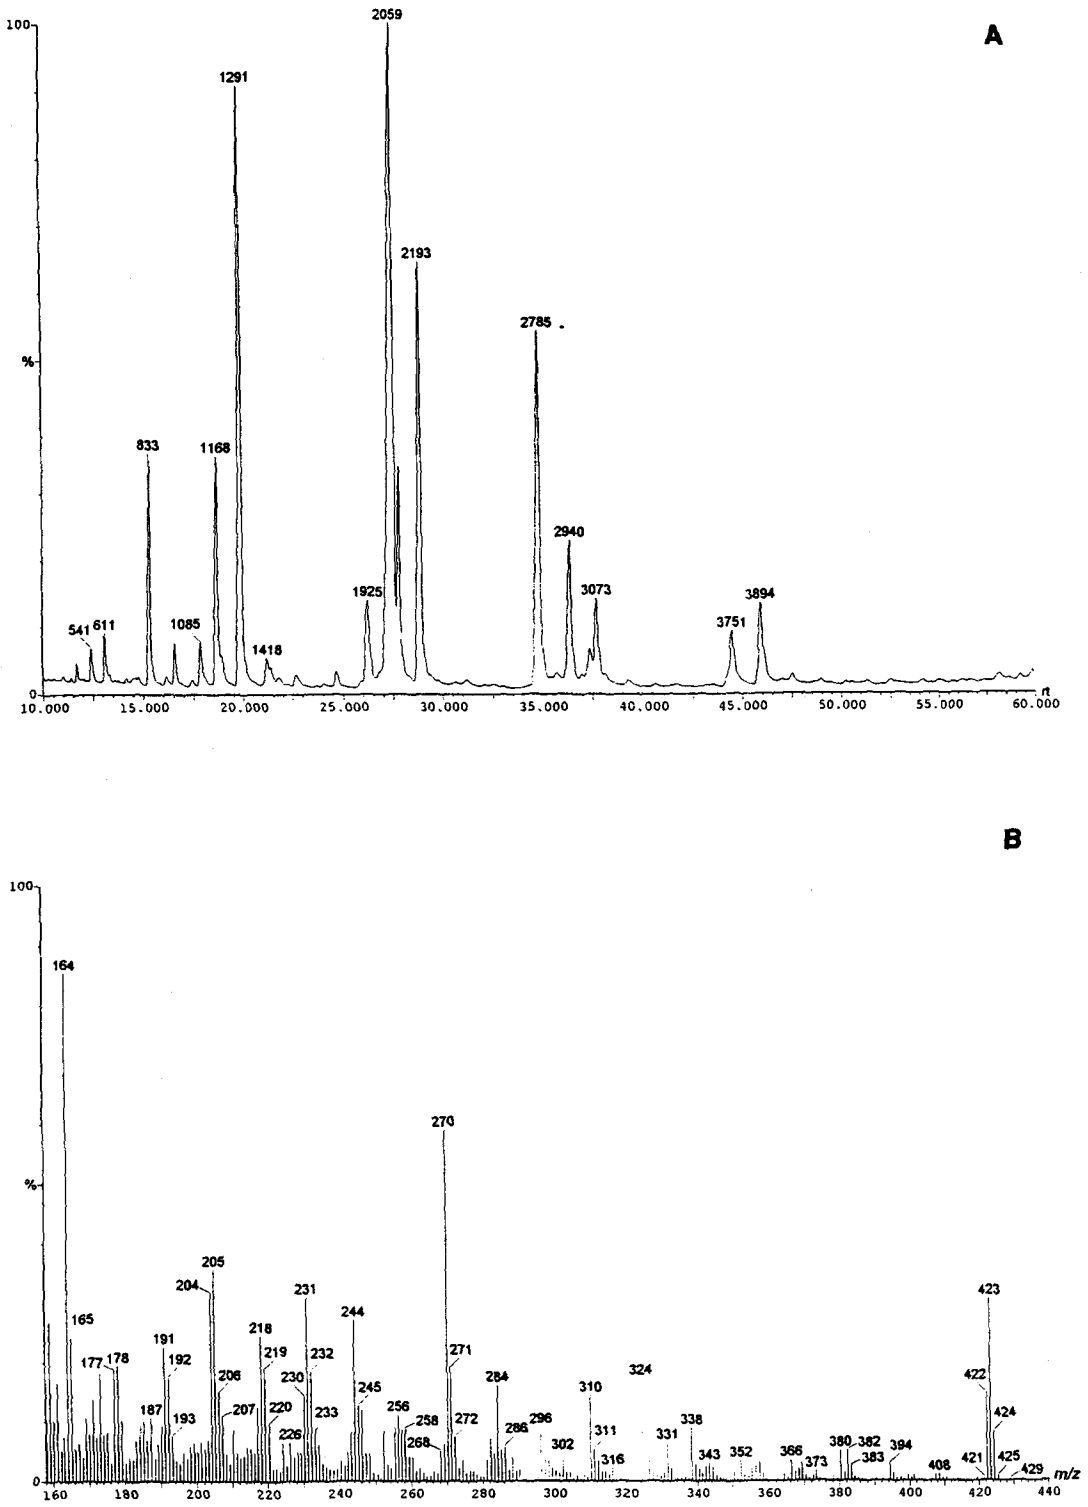

FIG. 3. Capillary gas chromatography of picolinyl esters of total lipid fatty acids from PLHC-1 cells (A) and electron ionization (70 eV) mass spectrum of 22:4n-9 (peak 3751) (B). Cell culture conditions and gas chromatography/mass spectrometry procedures as described in the Materials and Methods section; rt, retention time.

ciency-like profile of fatty acids, with increased 20:3n-9, has been observed in human skin fibroblasts when cultured at low density in culture medium containing low levels (0.4%) of FCS (33–35). No 22:4n-9 was detected in the human skin fibroblasts, but the cells were interesting in that they also produced measurable 22:3n-9 as well as 20:3n-9 under these low-lipid conditions (33–35).

However, although they contain substantial amounts of 20:3n-9, it is not likely that the PLHC-1 cells are in a state of EFA-deficiency. FCS delivers substantial amounts of EFA

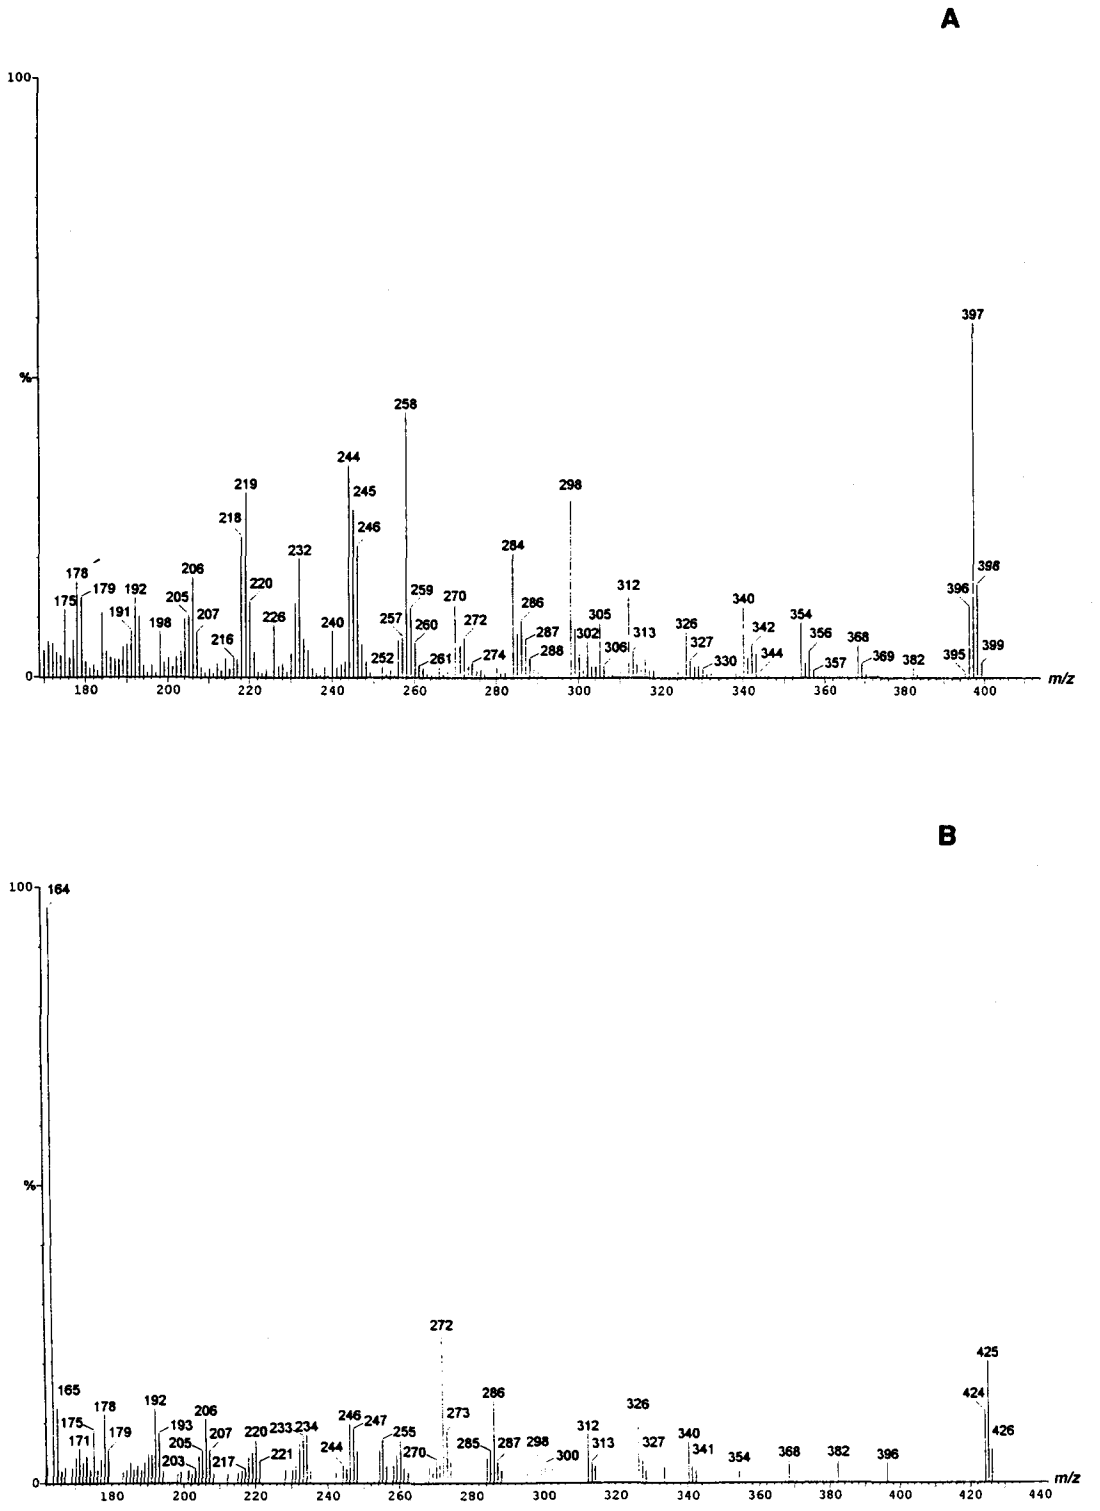

FIG. 4. Electron ionization (70 eV) mass spectra of 20:3n-9 (peak 2785 in Fig. 3A) (A) and 22:3n-9 (peak 3894 in Fig. 3A) (B). Cell culture conditions and gas chromatography/mass spectrometry procedures as described in the Materials and Methods section.

(2.8% 18:2) and, especially, significant amounts of C_{20} and C_{22} PUFA of the n-3 (3.7% 22:5 and 5.2% 22:6) and n-6 series (6.1% 20:4). In quantitative terms, the batch of FCS used contained approximately 4 mg of total lipid per mL of serum. Based on the lipid and fatty acid composition of the serum, approximately 50% (2 mg) of the serum was total fatty acid, a quarter of which was total PUFA. Therefore, the serum contained about 500 μg of PUFA/mL, and so the medium contained 50 μg of PUFA/mL. At confluence, PLHC-1 cells were present at 0.5×10^6 cells/cm^2 (representing about 5 μg of total

Total unidentified	2.6 ± 0.1	1.0 ± 1.2	2.8 ± 0.3	2.2 ± 0.3	4.8 ± 1.2

[a]Results are means ± SD (n = 3); n.d., not detected; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; TN, total neutral lipids.
[b]Predominantly n-7 isomer.

fatty acid), and medium was present at 267 μL/cm^2 (representing about 200 and 13.5 μg of total fatty acid and PUFA, respectively). Therefore, the medium contained a great excess of fatty acids including PUFA, over the amount of total fatty acids as determined at confluence. Although the precise rates of turnover and consumption of fatty acids by PLHC-1 cells were not determined, it appears unlikely that the medium is deficient in EFA and highly likely that there is sufficient n-6 and n-3 PUFA to satisfy general cell requirements for PUFA. Biochemically, there would appear to be more than enough long-chain n-3 and n-6 PUFA available to effectively inhibit the metabolism of 18:1n-9 *via* the desaturation/elongation pathway (9), but this does not happen in the PLHC-1 cells. Therefore, the production of 22:3n-9 and 22:4n-9 in PLHC-1 cells may be indicative of unusual metabolism which is perhaps a specific feature of PLHC-1 cells.

Some mammalian cell lines have also been shown to contain detectable n-9 PUFA in the absence of EFA-deficiency conditions. The presence of 20:3n-9 has been reported at levels of up to 4% of total fatty acids in total lipid from MDCK cells grown in 10% newborn calf serum (36), total phospholipids from THP-1 cells grown in 10% FCS (37), and lipids from rat liver epithelial cells and primary hepatocytes cultured in 10% FCS (38). Mead acid also accumulated in total phospholipids in confluent cultures of 3T3 cells grown in 10% FCS (39). No C_{22} n-9 PUFA were detected in the cell

lipid in any of these studies. Therefore, PLHC-1 cells were unusual both in the amount of n-9 PUFA produced (>21% of total fatty acids) and the fact that a substantial amount (>5% of total fatty acids) of it was the elongated and desaturated derivatives of 20:3n-9, 22:3, and 22:4.

However, the presence of 22:4n-9 in PLHC-1 cells is not entirely unique as it has some similarity to rat sperm where very long-chain n-9 PUFA have been shown to be formed as a part of normal metabolism (40,41). Mammalian sperm characteristically contains high percentages of C_{22} PUFA, generally 22:5n-6 and 22:6n-3 (42,43), but rat sperm is unique in also containing significant amounts of 22:3n-9 and 22:4n-9 (41). The levels of 22:3n-9 and, especially, 22:4n-9 increased during maturation of the sperm, indicating ongoing metabolism of the n-9 PUFA (41). The rats in that study were healthy, well-fed, and maintained on EFA-sufficient diets, leading the authors to conclude that long-chain n-9 PUFA can be normal, physiological components of certain cells (40). Interestingly, small percentages of 24:4n-9 and 24:5n-9 were also found in the rat sperm, as was 20:3n-9 (40,41).

It is not known if the situation in PLHC-1 cells is analogous to the situation described above in rat sperm. For instance, it is not known if hepatic lipids from normal, well-fed EFA-sufficient topminnows contain long-chain n-9 PUFA. Furthermore, it is not known whether hepatocarcinoma tissue from the topminnow, similar to the tissue that the PLHC-1 cell line was derived from, normally contains n-9 PUFA. Therefore, it is not known if the tissue origin, i.e., a tumor, of the PLHC-1 cell line is related to the unusual fatty acid metabolism found in the cell line. This is an area that requires investigation as it could be of considerable interest if lipid and fatty acid metabolism were altered in tumor cells *in vivo*.

All the fish cell lines we have studied to date produced some n-9 PUFA when grown in 10% FCS (16,44–47). RTG-2 cells, a rainbow trout line, contained as much as 8% total n-9 PUFA, over half of which was 20:2n-9 and turbot (TF) cells produced nearly 14% n-9 PUFA, almost all of which was 18:2n-9 (44). However, none of the other fish cell lines we have studied produced C_{22} n-9 PUFA or as much 20:3n-9 as the PLHC-1 cells used in the present study. The TF cells are known to lack or have very low Δ5 desaturase activity, and RTG-2 cells appear to express a low level of Δ4 desaturation (48). Therefore, it would appear that PLHC-1 cells exhibit a wider range of desaturation activities than the other fish cell lines studied to date.

In the present study, 22:3n-9 and 22:4n-9 showed a very characteristic pattern of distribution among the major phospholipid classes, being particularly concentrated in PS as were all the other C_{22} PUFA. In contrast, the 22:3n-9 and 22:4n-9 of rat sperm were more specifically located in the plasmenylcholine fraction with only very small amounts found in the PS fraction (40,41). The overall fatty acyl distribution in the major phospholipids of PLHC-1 cells, with high 16:0 and lower PUFA in PC, high 18:0 and C_{22} PUFA in PS, high 18:0 and C_{20} PUFA in PI, and generally intermediate levels of saturated and monounsaturated fatty acids and PUFA in PE was similar to the distributions found in other fish cell lines (45–47,49). The very high level of 20:3n-9 in PI in PLHC-1 cells was interesting, especially when combined with the highly specific localization of 20:3n-6 in PE, which was a little surprising. However, in rainbow trout gonad and chum salmon heart cells, 20:2n-9 and 20:3n-9 were also found primarily in PI, although in those studies 20:3n-9 could not be resolved from 20:2n-6 (45,49). In Atlantic salmon and TF cells, which do not produce much 20:3n-9, 20:2n-9 was found in the highest percentages in PI (46,47). However, whereas 20:3n-6 was found primarily in PI in chum salmon heart, rainbow trout gonad, and TF cell lines, it was located to a greater extent in PE than PI in Atlantic salmon cells (45–47,49). Overall therefore, the phospholipid class distribution of PUFA in PLHC-1 cells very clearly showed the apparent association between individual phospholipid classes and specific intermediates/products of the desaturation/elongation pathways that has been reported and discussed previously (46). Specifically PI is associated with the immediate products of Δ5 desaturase, and PS is associated with the elongated and further desaturated derivatives of the immediate Δ5 desaturase products.

In conclusion, the lipids of the hepatic tumor cell line, PLHC-1, from the topminnow (*P. lucida*), contain considerable amounts of long-chain n-9 PUFA, including 22:3n-9 and 22:4n-9, despite culture in serum containing sufficient EFA. The results indicate that long-chain PUFA of the n-9 series can be formed in vertebrate tissue other than in conditions of classical EFA deficiency.

ACKNOWLEDGMENT

The authors gratefully thank Dr. L.E. Hightower for supplying the PLHC-1 cells.

ABSTRACT: *Caenorhabditis elegans* was cultured in semi-defined medium containing yeast extract, soy peptone, glucose, hemoglobin, Tween 80, and sitosterol. Monoglycosylceramides were chromatographically purified from nematode extracts. Their structures were elucidated with mass spectrometry, nuclear magnetic resonance spectroscopy, and analysis of methanolysis products of the parent cerebrosides. The glycosylceramides were unusual in that the only long-chain sphingoid base detected was an *iso*-branched compound with a C-4 double bond (i.e., 15-methyl-2-aminohexadec-4-en-1,3-diol). Glucose was the only sugar moiety detected. The fatty acids consisted of a series of primarily straight-chain, saturated, 2-hydroxylated C_{20}–C_{26} acids; some *iso*-branched analogs also occurred. The sphingomyelins of *C. elegans* were also hydrolyzed, and the same *iso*-branched C_{17} compound was the only sphingoid base detected. This is the first structural analysis of a nematode glycosphingolipid and the first report of an organism in which the long-chain sphingoid bases are entirely *iso*-branched.
Lipids 30, 567–573 (1995).

Glycosphingolipids are ubiquitous components of animal cell membranes, where they possess a remarkable diversity of functions (1). Some of these roles are structural, such as providing increased rigidity to membranes or serving as anchors for cellular proteins (1,2). In recent years, intensive research has focused upon the roles of glycosphingolipids as antigenic determinants, mediators of recognition events, and precursors for lipid second messengers involved in signal transduction pathways (3).

Although many nematodes are important parasites of animals and plants, structural analysis of glycosphingolipids from nematodes has not been reported. The lack of direct knowledge of nematode glycosphingolipids is surprising, given that the surfaces of some animal–parasitic nematodes contain glycolipid (4) and that glycoconjugates on the nematode surface are suspected to be involved in chemoreception (5), recognition, and other aspects of host–parasite interaction between parasitic nematodes and their hosts (4,6–8). The only analytical investigations of nematode glycosphingolipids have been thin-layer chromatography (TLC) characterizations (9–14).

During recent years, our research has focused on nematode steroid biochemistry, including the possible existence of ecdysteroids (insect molting hormones) in nematodes (15). In such investigations of a plant–parasitic nematode *(Meloidogyne incognita)*, we detected large amounts of material that migrated during TLC identically to ecdysone (16). Because identification of this material was difficult and because quantities of nematodes were insufficient for unequivalent structural elucidation, we examined the microbivorous nematode *Caenorhabditis elegans* to determine if it contained similar material. Unlike parasitic nematodes, this species is readily propagated in the laboratory and has become an organism of choice for developmental biologists (17). In this report, we describe the structural elucidation of the unknown lipid from *C. elegans* as a series of cerebrosides (i.e., monoglycosylceramides) with a rather unusual long-chain sphingoid base.

MATERIALS AND METHODS

Culture methods. Caenorhabditis elegans strain N2 was propagated at 22°C in a semi-defined aqueous medium containing 30 mg/mL yeast extract (Difco Laboratories, Detroit, MI), 30 mg/mL soy peptone (Sigma Chemical Co., St. Louis, MO), 10 mg/mL glucose (Sigma), 0.5 mg/mL hemoglobin (Sigma), 10 µg/mL sitosterol [98.5% purity by gas–liquid chromatography (GLC); remaining sterol was campesterol], 0.5 mg/mL Tween 80 (Sigma), and 0.2 µL/mL silicone Antifoam C emulsion (Sigma). Yeast extract, glucose, and hemoglobin were extracted with organic solvents to remove endogenous lipid contaminants (18). Nematodes were propagated axenically in

acrated 3-L cultures in 4-L side-arm flasks, and mixed life stages were isolated and lyophilized (5.1–5.9 g dry weight per harvest) as described previously (18).

Cerebroside extraction and purification. Although lipids from lyophilized nematodes were initially isolated by extraction with $CHCl_3$/methanol (MeOH) (2:1) (19), in most cases nematodes were extracted three times with hexane/isopropanol (3:2) (20). No additional cerebrosides (i.e., the unknown lipid from *C. elegans*) were detected by TLC or HPLC (high-performance liquid chromatography) when the nematode pellet remaining after the hexane/isopropanol extraction was extracted with $CHCl_3$/MeOH (2:1), although some sphingomyelin was detected. The lipids (*ca.* 1,200 mg) were fractionated on a 19-mm i.d. column containing 17.6 g silica (Kieselgel 60, 70–230 mesh; E. Merck, Darmstadt, Germany) previously deactivated with 15% H_2O; compounds were eluted with 400 mL $CHCl_3$, 250 mL each of $CHCl_3$/acetone (3:1, 2:1, 1:2, and 1:3), 250 mL acetone, and 250 mL MeOH. The unknown material emerged in the $CHCl_3$/acetone 1:2 and 1:3 fractions, as indicated by TLC on high-performance silica gel H plates (Merck) developed with $CHCl_3$/ethanol (EtOH) (70:30). (All EtOH used in this investigation contained 5% H_2O.) Further purification was obtained on a 15-mm i.d. column containing 13.0 g of nondeactivated silica; compounds were eluted with 100-mL fractions of 0, 5, 10, 15, 20, and 40% EtOH in $CHCl_3$ and MeOH. The unknown emerged in the 15% EtOH fraction.

Individual cerebrosides were separated from each other by reversed-phase HPLC with a Spectra Physics (San Jose, CA) model SP8700XR solvent delivery system pumping 2.0% water in MeOH through a Shandon (Runcorn, United Kingdom) C_{18} column (ODS-Hypersil, 25 cm × 4.6 mm i.d., 5 µm particles) at a flow rate of 1.0 mL/min at 30°C. Absorbance at 214 nm was monitored with a Waters (Milford, MA) model 441 detector. Quantification was obtained with a Shimadzu (Columbia, MD) C-R3A recording integrator.

Spectroscopic methods. The most abundant cerebroside was analyzed by electron impact (EI) and chemical ionization (CI) mass spectrometry (MS) and nuclear magnetic resonance spectroscopy (NMR). Mass spectra were obtained with a Finnigan model 4510 instrument (Finnigan MAT, San Jose, CA) connected to an Incos data system; ammonia and methane CI spectra were produced as described (21). Fourier transform ^1H NMR spectra in C_5D_5N were recorded on a Bruker 400-MHz instrument (Bruker Analytische Messtechnik GmbH, Rheinstetten, Germany) with tetramethylsilane as a reference. An NMR spectrum was also obtained for an authentic compound purified by HPLC from a mixture of galactocerebrosides (Sigma); the purified standard was *N*-2′-hydroxyoctadecanoyl-1-*O*-β-D-galactopyranosyl-4(*E*)-sphingenine. Some cerebroside derivatives (subsequently described) were analyzed by gas chromatography/mass spectrometry (GC/MS) with a 15-m × 0.32-mm J&W (Folsom, CA) DB-1 fused silica capillary column (0.25 µm film).

Methanolysis. Both the cerebroside mixture (i.e., before HPLC) and individual, HPLC-purified cerebrosides were methanolyzed in 3 mL of a solution of concentrated HCl/H_2O/MeOH (43:47:410) at 70°C for 18 h (22). Fatty acid methyl esters (FAMEs) were extracted from the reaction mixture four times with 3 mL hexane; the lower phase was cooled, adjusted to pH 10 with 4.0 M KOH, and extracted with an equal volume of diethyl ether five times to thoroughly remove the long-chain sphingoid bases (LCBs). The aqueous layer, containing methyl glycosides, was dried in a rotary evaporator and stored in MeOH until analysis.

FAME analysis. The combined hexane extracts of the methanolyzate were dried with a rotary evaporator and applied to a silica Sep-Pak previously conditioned with 5 mL $CHCl_3$ and 10 mL hexane; elutions were with 5 mL hexane, 5 mL hexane/diethyl ether (97.5:2.5) (eluate contained FAMEs), 7 mL hexane/ether (9:1) (hydroxylated FAMEs), 5 mL ether, and 5 mL MeOH. Methyl esters were analyzed by GLC in a Varian (Palo Alto, CA) model 3700 gas chromatograph fitted with a J&W on-column injector, a flame-ionization detector, and a 15.0-m × 0.25-mm J&W DB-1 capillary column. The column temperature was held at 130°C for 1 min after injection and then was increased at 15°C/min to a final temperature of 150–255°C, depending upon the chain length and degree of hydroxylation of the particular compounds. Peaks were quantified with a Shimadzu C-R1B recording integrator. Tentative identifications were confirmed by GC/MS.

LCB analysis. The ether extract of the methanolyzate was applied to a silica Sep-Pak (Waters) previously conditioned with 5 mL MeOH and 10 mL $CHCl_3$. Compounds were eluted from the Sep-Pak with 5 mL $CHCl_3$, 7 mL $CHCl_3$/EtOH (9:1), 5 mL $CHCl_3$/EtOH (4:1), 7 mL $CHCl_3$/EtOH (3:2) (containing LCBs), 5 mL $CHCl_3$/EtOH (2:3), and 5 mL MeOH. The purified LCBs were *N*-acetylated in 240 µL MeOH and 60 µL acetic anhydride under nitrogen overnight at room temperature. After removal of the solvents with a stream of nitrogen, the *N*-acetyl LCBs were purified on a silica Sep-Pak conditioned with 10 mL $CHCl_3$ and eluted with 5-mL fractions of 0, 2, 5, 10, 40, and 100% MeOH in $CHCl_3$. The *N*-acetyl LCBs (in the 5% MeOH fraction) were preparatively purified by HPLC in the same system as the parent cerebrosides, except that a mobile phase of 20% H_2O in MeOH was used. For determination of double-bond position, the major peak was subjected to periodate/permanganate oxidation (23). The resulting free fatty acids were methylated at 60°C under nitrogen overnight in 4 mL of MeOH/benzene (3:1) containing 100 µL H_2SO_4. The methyl esters were then extracted by solvent partition with five transfers of hexane across two tubes containing equal volumes of countersaturated MeOH/water (7:3), purified by the Sep-Pak scheme as in the FAME analysis section, and identified by GLC and GC/MS.

In addition, the purified LCBs were *N,O,O*-triacetylated in pyridine/acetic anhydride (1:1) under nitrogen overnight at room temperature. After removal of the solvents under a stream of nitrogen, the triacetates were purified on a silica Sep-Pak identically to the *N*-acetyl LCBs. The LCB triacetates emerged in the 2% MeOH fraction and were analyzed

by GLC similarly to the FAMEs, except the final column temperature was 240°C.

Methyl glycoside analysis. Following the ether partition, the remaining aqueous phase of the methanolyzate was applied to a C_{18} Sep-Pak previously conditioned with 5.0-mL portions of MeOH, water, MeOH, and water. The methyl glycosides were eluted with 10 mL water; 5 mL MeOH was used to strip the Sep-Pak of any apolar material. The methyl glycosides were separated from the KCl acquired during the methanolysis procedure by elution with 100 mL water through a 15-mm i.d. column containing 10.0 g Bio-Rad (Richmond, CA) AG 501-X8(D) mixed bed resin (24). Water was removed with a rotary evaporator, trimethylsilyl (TMS) derivatives of the methyl glycosides were prepared with 100 µL hexamethyldisilazane/trimethylchlorosilane/pyridine (2:1:10) (TriSil; Pierce, Rockford, IL) (25), and the TMS ethers were analyzed by GLC on the DB-1 column as mentioned previously, with a final column temperature of 160°C.

TLC. All chromatographic fractionations and derivatizations were monitored on Silica Gel 60 high-performance plates (Merck) with an appropriate solvent: $CHCl_3$/95% EtOH (7:3) (cerebrosides); $CHCl_3$/MeOH/water (65:25:4) (sphingomyelin and other phospholipids); hexane/diethyl ether/acetic acid (70:30:1) (fatty acids and methyl esters); or $CHCl_3$/MeOH/10 M aqueous ammonia (66:30:4) (LCBs and methyl glycosides), 90:10:0.2 (*N*-acetyl LCBs), or 95:5:0.2 (LCB triacetates). Compounds were detected by heating plates sprayed with 50% H_2SO_4 at 120°C.

Sphingomyelin analysis. For comparative purposes, the long-chain bases from sphingomyelins and cerebrosides of *C. elegans* were compared. Only *C. elegans* extracted with hexane/isopropanol was used; however, TLC indicated that sphingomyelins occurred in the $CHCl_3$/MeOH extraction of the nematode pellet remaining after hexane/isopropanol extraction. Therefore, this $CHCl_3$/MeOH extract was applied to a silica column similar to that used with the original hexane/isopropanol extract, and the combined methanolic eluates were considered to be the crude sphingomyelin fraction, which contained several other phospholipids. This material was then applied to a DEAE-cellulose column (8.66 g in a 19-mm i.d. column) prepared and eluted by the procedure of Rouser *et al.* (26). The sphingomyelins and choline phosphoglycerides, which emerged together from the DEAE-cellulose column, were then separated by preparative TLC on Silica Gel 60 chromatoplates pre-developed with the solvent used for fractionation, i.e., $CHCl_3$/MeOH/water 65:25:4. Compounds were extracted from the silica gel with $CHCl_3$/MeOH (2:1) and then hydrolyzed identically to the cerebrosides.

Cerebroside content of medium. Ingredients for 100 mL medium were dissolved in 75 mL water, and 175 mL MeOH was added. Putative cerebrosides were isolated by extraction with two 250-mL portions of hexane. The pooled hexane extracts were fractionated on a silica Sep-Pak conditioned with 5 mL $CHCl_3$; lipids were eluted with 5-mL portions of 0, 5, 10, and 30% EtOH in $CHCl_3$ and MeOH. Putative cerebrosides in the 30% EtOH fraction were analyzed with the same HPLC system used for the *C. elegans* cerebrosides.

Analytical standards. Cerebroside, ceramide, phospholipid, sphingosine (4-sphingenine), and methyl glycoside standards were from Sigma; *iso-* and *anteiso*-FAME standards were from Matreya (Pleasant Gap, PA); and ecdysone was from Simes Pharmaceuticals (Milan, Italy). Hydroxylated FAME standards were prepared from a methylated mixture of fatty acids [Humko (Memphis, TN) Hystrene 9022] by oxygenation of the lithium diisopropylamide-generated dianions (27).

RESULTS

The 15% ethanolic eluate of the silica column contained TLC-homogeneous material which migrated slightly faster than authentic ecdysone. (After the unknown had been partially characterized, it was found to migrate between bovine brain galactosylceramides containing hydroxylated and nonhydroxylated fatty acids.) Reversed-phase HPLC of this material produced over a dozen distinct peaks (Fig. 1).

NH_3 CI/MS of the major HPLC peak (Fig. 1, peak 6) [*m/z* (relative intensity): 803 ($M + NH_4$, 100), 786 ($M + H$, 21), 768 ($M + H - H_2O$, 17)] indicated that the molecular weight of the unknown was 785. A weak ion at *m/z* 641 ($M + NH_4 - 162$) suggested loss of a hexose moiety. Presence of a base peak at 804 in $^{15}NH_3$ CI/MS confirmed that the peak at 803 in the NH_3 spectrum had only one adducted nitrogen atom.

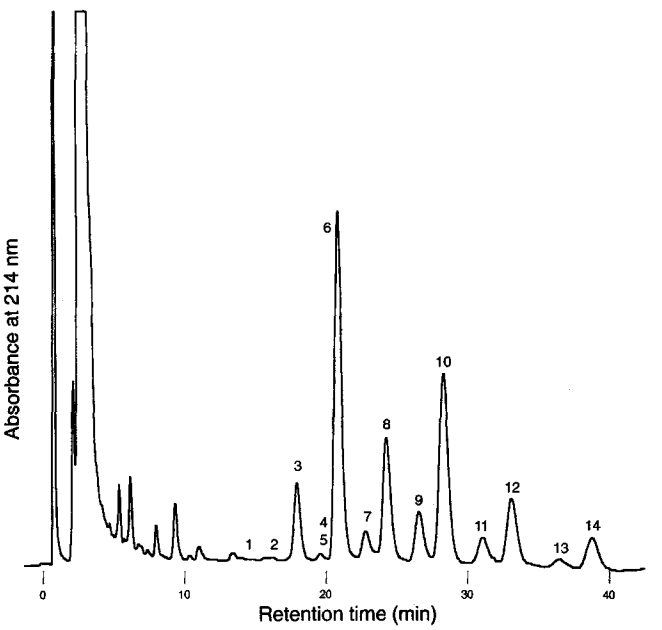

FIG. 1. High-performance liquid chromatography chromatogram of glucosylceramides of *Caenorhabditis elegans*. Glucosylceramides were fractionated on a Shandon (Runcorn, United Kingdom) ODS-Hypersil C_{18} column (25 cm × 4.6 mm i.d., 5 µm particles) with 1.0 mL/min of 2.0% H_2O in methanol at 30°C. Absorbance at 214 nm was monitored with a Waters (Milford, MA) model 441 detector.

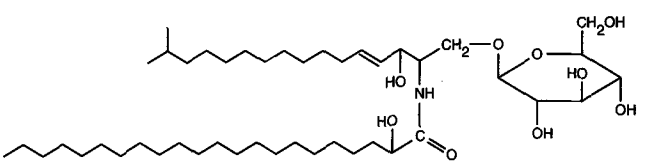
Methane CI/MS data [814 (M + C_2H_5, 14), 786 (M + H) 100, 768 (M + H – H_2O, 23), 624 (M + H – 162, 14)] was consistent with the NH_3 data. Finally, the ND_3 CI/MS [814 (100), 794 (18), 774 (14)] indicated the presence of seven exchangeable hydrogen atoms on the parent molecule.

Attempted methylation of the major HPLC-purified component with diazomethane failed to alter the TLC migration of the compound, indicating the lack of a carboxylic acid functional group. Attempted weak acid hydrolysis of the unknown yielded several products. TLC revealed that an apolar product moved identically to a 2-hydroxy FAME standard (methyl 2-hydroxydocos-13-enoate) and that a highly polar, suspected hexose-like product moved identically to an α-methyl galactoside standard. The TLC results, the number of exchangeable hydrogens, and the odd molecular weight of the parent compound indicated the possibility of a glycosphingolipid; therefore, a methanolysis procedure suitable for glycosphingolipids was employed. This methanolysis yielded three products of greatly different polarities, as judged by TLC. The most apolar of these products (i.e., from the hexane extraction of the reaction mixture) yielded MS data from NH_3 CI/MS [405 (M + $(NH_3)_2H$, 13), 388 (M + NH_4, 100)] and ND_3 CI/MS [413 (12), 393 (100)] indicating that the product had a molecular weight of 370 and one exchangeable hydrogen. The EI/MS data [370 (M^+, 25), 352 (M–H_2O, 1), 338 (M – CH_3OH, 3), 311 (M – CH_3COO), 292 (M – $HCOOCH_3$ – H_2O, 6), 57 (C_4H_9, 100)] and GLC retention time were identical with those from a 2-hydroxydocosanoic acid methyl ester standard.



The compound purified from the ether extraction of the methanolyzate of the major HPLC fraction had a molecular weight of 285, as indicated by CI/MS data obtained with NH_3 [303, (M + NH_4, 100), 286 (M + H, 67)] and CH_4 [286 (M + H, 100), 268 (M + H – H_2O, 42)]. EI/MS data revealed little structural information, except for a loss of CH_2OH to produce a weakly abundant (2% relative to the base peak at *m/z* 60) ion at *m/z* 254. Because TLC indicated co-migration with sphing-4-enine, a C-17 sphingoid structure was suspected. The *gem*-dimethyl obtained in the NMR spectrum of the parent cerebroside and the lack of such a dimethyl in the fatty acid moiety of the molecule suggested an *iso*-branched structure for the sphingoid base. Following *N*-acetylation of the sphingoid base, HPLC purification of the *N*-acetyl LCB, permanganate/periodate oxidation of the *N*-acetyl LCB and methylation of the oxidation products, a single peak was obtained in GLC that migrated identically to an *iso*-13:0 FAME. This established that the sphingoid base was indeed an *iso*-17:1 compound, i.e., 15-methyl-2-aminohexadec-4-en-1,3-diol.

The molecular weight of the product obtained from the aqueous phase of the extracted methanolyzate was 194 with 4 exchangeable hydrogens, based on CI/MS data obtained with NH_3 [229 (M + $(NH_3)_2H$, 100), 212 (M + NH_4, 68)], $^{15}NH_3$ [231 (100), 213 (79)], and ND_3 [240 (100), 220 (43)]. Following trimethylsilylation of the material, GLC detected two peaks with retention times identical to those of TMS ethers of α- and β-methyl glucosides in a 2.2:1 ratio. The EI/MS of the peaks were identical to those of TMS ethers of α- or β-methyl glucoside, galactoside, or mannoside, all of which were differentiated poorly by MS, but resolved excellently by GLC; GLC revealed a 76:24 mixture of α- and β-methyl glucoside TMS ethers.

The results obtained from ^1H NMR analysis were consistent with those obtained from analysis of the hydrolysis products. The most striking feature of the NMR spectrum of the major, HPLC-purified compound was a strong doublet at δ0.651 ppm (6H, J = 6.68 Hz), indicative of *gem*-dimethyl moiety in the compound. This doublet was absent in the spectrum of the reference cerebroside. A broad peak at δ1.04 ppm occurred in the methylene region. A septet (J = 6.66 Hz) centered at δ1.27 ppm represented the single tertiary hydrogen between the *gem*-dimethyls. Other features of the NMR spectrum included singlets at δ1.50 and δ1.60 ppm (also present in the NMR of the standard), representing the hydrogens at C-3 of the 2-hydroxydocosanoic acid moiety (28), a quartet (identical to that in the standard) at δ1.86 (J = 7.28 Hz) from the C-6 hydrogens on the sphingoid base (28,29), a sugar region (δ3.4–5.8 ppm) greatly different from the galactosylceramide (GalCer) standard, two double doublets at δ5.69 and δ5.76 ppm (J = 15.36 Hz), representing the two vinylic hydrogens and indicative of an *E*-double bond (28,29), and a doublet at δ7.49 ppm (J =5.16 Hz), representing the amino hydrogen (30). Unfortunately, although the reference GalCer contained a well-defined doublet at δ4.01 ppm (J = 6.8 ppm) indicative of a β-configuration at C-1 of the galactose (28), the region from δ4.16–4.28 [where a doublet (J = 7–9 Hz) would be indicative of a β-conformation at C-1 of the glucose moiety (29–31)] consisted of a pentet at δ4.17 ppm. This multiplet, plus the lack of the expected doublet for an α-conformation at δ4.86 ppm (J = 3.4 Hz) (29–31) indicates that the GluCer (Scheme 1) from *C. elegans* likely has the β-conformation.

After the material had been conclusively identified as a series of glucosylceramides, the HPLC-purified material was quantified by ultraviolet absorbance. Because a source for GluCer standards containing hydroxylated fatty acids could not be located, the basis for quantification was the average absorbance during HPLC for the fatty acid-hydroxylated, bovine brain galactocerebrosides, and the nonhydroxylated, human (Gaucher's) spleen glucocerebrosides. Quantification indicated that the glucosylceramides comprised 0.17% of the dry weight of the nematodes.

After hydrolysis of the most abundant compounds, the material in each remaining HPLC peak was hydrolyzed. In each case, the methyl glycosides were identified with GLC of the TMS ethers as methyl glucosides, the sphingoid base was

13	*iso*-26:0	26.87	1.6
14	26:0	27.25	3.5

[a]The sugar and sphingosine moieties of all glycosylceramides were determined as glucose and 15-methyl-2-aminohexadec-4-en-1,3-diol with procedures described in the Materials and Methods section.
[b]Peaks refer to the chromatogram depicted in Figure 1.
[c]Fatty acids were identified by gas chromatography/mass spectrometry of the methanolysis products of the HPLC-purified peaks. The equivalent chain lengths (ECLs) of the fatty acid methyl esters, all of which were 2-hydroxylated, were obtained on a J&W (Folsom, CA) DB-1 capillary column and were calculated with respect to nonhydroxylated fatty acid methyl ester standards. Fatty acids are represented by a binumeric system in which the first number refers to the chain length and the second number refers to the number of double bonds.

identified by GLC of the LCB triacetates as 15-methyl-2-aminohexadec-4-en-1,3-diol, and the fatty acids were identified by GC/MS as the compounds shown in Table 1. Although hydroxylated *iso*-fatty acid standards were unavailable, comparison of GLC results of authentic nonhydroxylated *n*-, *iso*-, and *anteiso*-FAME standards indicated that the *iso* and *anteiso* compounds (which did achieve baseline separation) emerged 0.36 and 0.29 units, respectively, before the *n*-isomers. Because the methyl esters of the hydroxylated, branched fatty acids from *C. elegans* had equivalent chain lengths 0.36 or 0.37 units lower than the corresponding hydroxylated *n*-FAMEs, we concluded that the branched methyl esters were *iso*.

Sphingomyelin LCB. Acid hydrolysis of sphingomyelin from *C. elegans* yielded a single peak in the ether extract of the hydrolysis products. The purified *N*-acetyl and triacetyl derivatives of this compound co-migrated during HPLC and GLC, respectively, with the respective *N*-acetyl LCB and triacetate of the sphingoid base isolated from the cerebrosides of *C. elegans*. Therefore, the sphingoid base in the sphingomyelin from *C. elegans* was also concluded to be 15-methyl-2-aminohexadec-4(*E*)-en-1,3-diol.

Cerebroside content of medium. Most of the material in the $CHCl_3$/EtOH (7:3) Sep-Pak fraction generated from 100 mL medium ingredients emerged near the solvent front during HPLC, well in advance of the cerebroside elution volume. The polar nature of this fraction undoubtedly resulted from its cruder purification relative to the cerebrosides from *C. elegans*. Three small peaks (containing 5.9 μg total) were detected in the cerebroside region; however, their retention times did not correspond to any of the retention times for the cerebrosides from *C. elegans*. Because of the minuscule amounts of this material and lack of correlation of its retention times with those of the major cerebrosides of *C. elegans*, we considered identification of this material to be beyond the scope of this investigation.

DISCUSSION

The identification of the unknown material from *C. elegans* as a mixture of cerebrosides containing a homologous series of fatty acids was interesting from several perspectives. Perhaps the most remarkable structural feature was the detection of 15-methyl-2-aminohexadec-4(*E*)-en-1,3-diol as the only sphingoid base. Branched LCBs do occur in other organisms, including mammals, bacteria, protozoa, mollusks, starfish, and a sponge (32–36). Rarely, however, have such isomers been reported as the predominant sphingoid bases; the only other reported occurrence to our knowledge is in the sponge *Halichondria japonica*, in which an *anteiso*-, trihydroxy, saturated C_{19} compound is the major (70%) sphingoid base. The lack of detectable amounts of sphingoid bases other than an *iso*-compound seems unique to *C. elegans* at this point.

The homogeneity of both the sugar and sphingoid base compositions was unexpected. The cerebrosides of most organisms, including most other species of invertebrates examined to date, contain both GluGer and GalCer (37–39). The presence of hydroxylated C_{22} and C_{24} fatty acids is a common feature of many mammalian and invertebrate cerebrosides (37,38). Although *iso*-fatty acids are not necessarily typical of cerebrosides, the glycerolipids of *C. elegans* (40) and some other nematodes (41,42) do contain substantial quantities of shorter (C_{15-18}) *iso*-fatty acids. A notable feature was the presence of only a minute amount of unsaturation, in contrast to the large degree of unsaturation in the glycerolipids of *C. elegans* (40).

Failure to detect cerebrosides in the medium used for propagation of *C. elegans* indicates that the nematodes could biosynthesize cerebrosides from simpler precursors. Although complex glycosphingolipids (such as lactosylceramide or gangliosides) could exist in the medium components and be degraded by *C. elegans*, this possibility seems unlikely because of the branched structure of the nematode LCB and detection of only straight-chain LCBs in GlcCer from soybean (43) and in glycosphingolipids from yeast (44), the latter which contain phosphoinositol as the polar head group.

Although the glycosphingolipids of cestodes and trematodes have been the subject of recent research interest (38,39,45–48), this is the first report of the detailed structural analysis of a nematode glycosphingolipid other than by TLC (9–14). Interestingly, GluCer occurred in much lower concentration than GalCer in adults of the bovine parasite *Onchocerca gibsoni* (9), and in the only TLC study in which cerebrosides with different sugars were spotted on TLC chro-

matoplates. In our research, a faintly visible spot did appear near a hydroxylated GalCer standard when *C. elegans* polar lipids from another silica column fraction were spotted; therefore, *C. elegans* may contain some other hexosylceramide, but in a much lesser quantity than GluCer.

Although sphingosine and sphinganine have been characterized radiochemically in a TLC investigation of *Ascaridia galli* (49), our report is the first chemical analysis of the sphingoid base from nematode sphingomyelin. Interestingly, the only detected sphingoid base from *C. elegans* sphingomyelin is the same compound as was present in the glycosylceramides, i.e., 15-methyl-2-aminohexadec-4(*E*)-en-1,3-diol. The branched structure of the *C. elegans* sphingoid base warrants structural determination of the sphingoid bases of other nematodes to determine if this peculiarity is common to the phylum.

The large amount of the glucocerebroside in *C. elegans* could indicate that the compound has a structural role in stabilizing cellular membranes (50). Because of the growing realization that various parts of the glycosphingolipid molecule (e.g., sphingosine, ceramide) are released and can have important roles as cellular messengers (3), a similar role for such compounds in nematodes or in the interactions of nematodes with their hosts is likely. A possible involvement of glycosphingolipids in host–parasite relationships and a potential for such compounds to be targets for potentially antinematodal compounds have been proposed (9). Scott *et al.* (4) found a 6,000–10,000 Da surface-associated glycolipid in *Dirofilaria immitis* that may be associated with evasion of the host immune system or may be involved in peptide anchoring. Although the compound from *D. immitis* may not be a glycosphingolipid, the importance of recognition events in host–parasite relationships of both animal– and plant–parasitic nematodes indicates that structural elucidation of glycosphingolipids more complex than the rather simple molecules described herein should indeed prove interesting.

ACKNOWLEDGMENTS

We thank Patricia Oakley and Dawn Harrison for skilled technical assistance. The *Caenorhabditis elegans* N2 isolate used in this investigation was originally supplied by the Caenorhabditis Genetics Center, which is supported by the National Institutes of Health.

Effects of Dietary Oil Related to the Toxic Oil Syndrome on the Lipids of Guinea Pig Liver Microsomes

E. de la Casa, N. Pérez-González, C. Sánchez-Bernal and M. Llanillo*

Departamento de Bioquímica y Biología Molecular, Universidad de Salamanca, Edificio Departamental, 37007 Salamanca, Spain

ABSTRACT: The potential effects of oil specimens related to cases of toxic oil syndrome (TOS) on the liver microsomal lipid composition from guinea pigs were investigated. For four weeks, animals were fed diets supplemented with either "case oil" (oil related to cases of TOS) or "control oil" (oil unrelated to cases of TOS), either previously heated or not. Results were compared with those from guinea pigs fed the same diet with no oil. The administration of case oil produced changes in liver microsomal lipid composition. Statistically significant differences were also found between heated case and heated control oils. The cholesterol/phospholipid molar ratios and the major phospholipid class distribution were unaffected under these diet conditions. However, increases in the relative contents of linoleic and arachidonic acids and, simultaneously, a reduction in palmitic and palmitoleic acid levels were observed by diet effects. Heated oil administration decreased the saturated/unsaturated ratios in all cases. Our data suggest that changes observed in the fatty acid composition are attributable to the free fatty acid contents of administered oils. The toxic constituents of case oil seem to be able to alter the liver microsomal lipid composition.

Lipids 30, 575–579 (1995).

"Toxic oil syndrome" (TOS) is an illness that appeared in Spain in May 1981, as a massive epidemic affecting thousands of people (1). The disease has been epidemiologically linked to the ingestion of cooking oil containing rapeseed oil denatured with 2% of aniline (2,3). Although the acute and chronic phases of TOS have been well defined (1,4), the causal agent in the oil has not yet been identified (4,5). Fatty acyl anilides have been proposed as the main toxic agents in the aniline-denatured rapeseed oil that causes TOS (2,3). More recently, several authors have reported evidence pointing to the existence in humans of an association between increased risk of illness and the presence of aniline and anilide contaminants (4,6). Clinical or biological evidence of liver injury has been documented in many patients hospitalized with acute manifestations of TOS (7,8). It is also well established that the oxidative metabolism of drugs and xenobiotics, taking place in liver endoplasmic reticulum, depends on the tissue fatty acid composition and on dietary fat (9,10), and that the microsomal phospholipid composition can be altered by dietary lipid treatments (11–13).

The present study was designed to obtain information about the potential effects of an oil related to cases of TOS on the fatty acid profile of total lipids, as well as on cholesterol and phospholipid levels in liver microsomes from guinea pigs.

MATERIALS AND METHODS

Oil samples. The oil samples for the experiments were provided by the FIS (Fondo de Investigación Sanitaria, Ministerio de Sanidad y Consumo, Madrid, Spain). As indicated by the supplier, samples were coded as "case oil" (specimens from families whose clinical histories met a strict case definition of TOS) and "control oil" (oils from families who did not have TOS) (6). Aliquots of each oil sample heated at 190°C for 30 min are being referred to as "heated oils."

Animals and treatment schemes. Male guinea pigs of the New Zealand strain (Charles River, Lyon, France) weighing 250–400 g were randomly divided into five groups of eight animals each and were fed a basal guinea pig diet (COBAYO 114; PANLAB S.L., Barcelona, Spain) consisting of: protein (18.3%); fats (2.7%); cellulose (11.9%); ashes (8.3%); starch (21.3%); calcium (1.1%); phosphorus (0.6%); sodium (0.25%); moisture (9.9%); lysine (0.95%); methionine (0.3%); vitamin E (24.3%); vitamin A (15 000 I.U./kg diet); and vitamin D (2 000 I.U./kg diet). Animals had free access to food and water. Four groups of animals were fed the same basal diet supplemented with 2 mL/kg body weight/day of case oil or control oil delivered by an esophageal tube over a period of four weeks. One group, referred to as the control group, was kept pair-fed with the other four groups, but received no oil. The treatment groups were: Group 1, consisting of animals fed nonheated control oil; Group 2, consisting of animals fed heated control oil; Group 3, consisting of animals fed nonheated case oil; and Group 4, consisting of animals fed heated case oil.

Preparation of liver microsomal fraction. After fasting, guinea pigs were killed 24 h after the treatments were com-

pleted. Liver specimens were rapidly removed after blood had been drawn from the abdominal aorta, with the animals under anesthesia. The livers were then carefully washed with 0.9% NaCl, weighed, and stored at –80°C until use. Microsomes were obtained as reported by Lake (14) using precooled homogenization Buffer I, containing 50 mM Tris-HCl, 0.154 mM KCl, 1 mM EDTA, pH 7.4. The microsomal pellets were resuspended in Buffer I, their protein contents determined by the method of Lowry *et al.* (15) using bovine serum albumin as the standard, and were stored at –80°C under N_2 until use.

Lipid extraction and lipid class determinations. Total lipids from microsomes were extracted according to the method of Bligh and Dyer (16). The chloroform layers containing the lipids were washed with a 0.73% NaCl solution and evaporated to complete dryness. The final lipid residues were determined gravimetrically and stored under nitrogen at –20°C until analysis.

Total cholesterol of the lipid extracts was evaluated as reported by Kates (17), using free cholesterol as standard. Total phospholipid contents were determined according to Rouser *et al.* (18) by measuring lipid phosphorus after $HClO_4$ treatment. Phospholipid classes were fractionated by two-dimensional thin-layer chromatography on silica gel 60G plates (10 × 20 cm, 0.25 mm layer; Merck, Barcelona, Spain) and identified as reported by Sánchez-Yagüe and Llanillo (19). Phospholipid classes were determined by measuring lipid phosphorus (18).

Fatty acid analysis. Aliquots of lipid extracts from each sample were transmethylated using BF_3/methanol reagent (Supelco, Barcelona, Spain) according to Metcalfe *et al.* (20). The fatty acid methyl esters obtained from the total lipid extracts were analyzed with a Konik-3000 gas chromatograph (Konik, Barcelona, Spain) equipped with a fused silica capillary column Supelcowax 10 (Supelco), 30 m × 0.53 mm, with 1.0-nm film thickness, and a flame-ionization detector. Hydrogen was the carrier gas. The oven was programmed at 190°C for 7 min, then heated from 190–230°C at 2°C/min, and finally held isothermally at 230°C for 13 min. Peaks were identified by comparison of their retention times with those of known fatty acid methyl ester standards (Supelco). Peak areas were measured with an electronic integrator (Konik).

Statistical analysis. Results were treated statistically by analysis of variance. The Scheffé test was used for comparisons among groups. P values ≤0.01 were considered significant.

RESULTS AND DISCUSSION

The compositions of fatty acids and of other constituents of the oil specimens used in the present study have been described by Kilbourne *et al.* (6). The case oil contained relatively high levels of aniline and fatty acid anilides. Linoleic acid was the main fatty acid component in the control oil, whereas linoleic acid was lower in the case oil.

Table 1 shows the microsomal levels of total lipids (μg/mg protein), cholesterol (nmol/mg protein), total phospholipids (nmol/mg protein), and the cholesterol/phospholipid molar ratios measured. There were increases in each lipid class in

TABLE 1
Lipid Composition of Liver Microsomes from Guinea Pigs Fed Either Case or Control Oil[a]

Lipid classes	Control (no oil)	Control oil		Case oil	
		Nonheated	Heated	Nonheated	Heated
Total lipids (μg/mg protein)	70 ± 10[b]	129 ± 10[b,c]	81 ± 13[b]	189 ± 12[c]	194 ± 22[c]
Cholesterol (C) (nmol/mg protein)	24 ± 4[b]	37 ± 5[b,c]	23 ± 6[b]	51 ± 4[c]	51 ± 5[c]
Total phospholipids (PL) (nmol/mg prot.)	71 ± 8[b]	143 ± 12[b,c]	92 ± 15[b]	204 ± 17[c]	224 ± 26[c]
PL classes (% of total)					
Phosphatidylcholine	50.3 ± 0.4	53.1 ± 0.9	52.2 ± 1.2	51.6 ± 0.3	51.3 ± 0.4

Sphingomyelin	2.5 ± 0.3	2.1 ± 0.2	1.8 ± 0.3	2.7 ± 0.2	1.7 ± 0.3
Lysophosphatidylethanolamine	0.7 ± 0.2	0.8 ± 0.2	0.9 ± 0.2	0.6 ± 0.1	0.8 ± 0.3
C/PL ratio	0.26 ± 0.01	0.23 ± 0.01	0.20 ± 0.02	0.25 ± 0.01	0.23 ± 0.01

[a]Values are means ± SE for eight animals per dietary group. Total lipids were determined gravimetrically. Proteins, lipid phosphorus, and cholesterol were assayed calorimetrically (see Materials and Methods section). The phospholipid contents were calculated by lipid phosphorus determination. Phospholipid class values are given as percentages of total lipid phosphorus in each sample. Comparisons between control and control oil indicate the diet effect and between control oil and case oil indicate the case oil effect.

[b,c]By rows, values with different superscripts are significantly different at $P < 0.01$.

animals fed case oil as compared to the animals fed no oil and those fed the control oil. Statistically significant differences were found between heated case and heated control oils. The cholesterol/phospholipid molar ratio in the liver microsomal fraction was about 0.26. This is in agreement with the values found in the endoplasmic reticulum of rats (21). The phospholipid composition is also given in Table 1. It can be seen that the percentages of the major phospholipids were not affected by the dietary oils, consistent with other reports (22,23). The major phospholipid classes were phosphatidylcholine (50–53%), phosphatidylethanolamine (28–32%), and phosphatidylserine plus phosphatidylinositol (9–13%), representing 92% of the total. Other phospholipids were present at less than 3.5%. This profile is in accordance with that described by Diagne *et al.* (24) in guinea pig liver.

Table 2 shows the relative fatty acid composition of liver microsomal lipids in the control guinea pigs (fed no oil) and in the guinea pigs fed test oils. Linoleic (18:2n-6), palmitic (16:0), stearic (18:0), and oleic (18:1n-9) acids were the predominant fatty acids in all groups, representing about 91% of the total. Other fatty acids were present at percentages below 3.5%.

Microsomal lipids from guinea pigs fed a standard diet supplemented with nonheated control oil showed several changes in fatty acid composition, the most striking being a significant increase in the relative stearic (55.5%), linoleic (21%), and arachidonic (117%) acid levels, with a concomitant decrease in the percentages of palmitic (43%), palmitoleic (16:1n-7, 65%), oleic (39%), and α-linolenic (70%) acids. These results are in general agreement with those of other studies in which increased levels of n-6 polyunsaturated fatty acids were found in the tissues of animals fed corn (9,10,12), soybean (11), and sunflower (11,25–28) oils. Diets rich in linoleic acid typically result in its large uptake and an increase in the contents of n-6 fatty acid in phospholipids from different tissues.

The fatty acid profile from the animals fed nonheated case oil displayed a behavior similar to that observed in the animals fed with nonheated control oil. Thus, the changes should be attributed exclusively to the dietary oil.

Ingestion of heated control oils, which have the lowest content of linoleic acid, induced changes in the fatty acid composition of microsomal lipids similar to those induced by nonheated control oil diets. However, the 18:1/18:0 ratio reached values higher than those obtained in animals fed nonheated oil. Similarly, the administration of heated case oil produced the highest increase in the 18:1/18:0 ratio. These results are in a good agreement with those found in rat liver microsomes from animals fed heated oils (29).

In conclusion, our data demonstrate that the administration of dietary case oil produces changes in the liver microsomal lipid composition, which may be attributable to the pres-

TABLE 2
Comparative Studies of Fatty Acid Composition of Lipid Microsomes from Liver Guinea Pigs After Administration of Control and Case Oils[a]

Major fatty acids	Control (no oil)	Control oil		Case oil

SFA/UFA	0.86 ± 0.04	0.85 ± 0.04[d]	0.71 ± 0.03[d,e]	0.89 ± 0.03[d]	0.62 ± 0.01[e]
Unsaturation index[f]	97.6 ± 1.6	109.8 ± 4.0	112.8 ± 3.2	100.3 ± 2.0	111.6 ± 2.7

[a]Values are means ± SE for eight animals per dietary group. Fatty acids contributing less than 0.5% are omitted: 15:0, 18:4, 19:0, 20:0, 20:1, 21:0, 22:5, and 22:6 + 24:0. Unknown fatty acid methyl esters represent about 0.5–0.7% of the total. SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; UFA, unsaturated fatty acids.

[b,c]By rows, values with different superscripts are significantly different at $P < 0.01$, for comparisons between control and control oil (diet effects).

[d,e]By rows, values with different superscripts are significantly different at $P < 0.01$, for comparisons between control oil and case oil (case oil effects).

[f]The unsaturation index was calculated as the sum of percentages by weight of each fatty acid times the number of olefinic bonds.

ence of aniline and fatty acid anilides in the samples. The failure to detect additional effects could be due to an insufficient quantity of TOS agent administered, as suggested by Kilbourne *et al.* (6). However, it could also be due to a clearance of the TOS agent by detoxifying enzyme systems, because it is well known that dietary and nutritional factors are able to modulate such enzyme systems (30). In fact, there is evidence that diets containing high levels of linoleic acid, such as corn oil, increase the mixed function oxidase activity and cytochrome P_{450} in rat liver (31).

CHANGE OF REFERENCE STYLE FOR *LIPIDS*

References should be used to quote published work as well as papers accepted for publication ("in press"). References are quoted in the text in numerical order (arabic numerals, in parentheses). **Titles of journal articles and chapter titles in multi-author books are to be included immediately preceding the name of journal or book.** When consecutive citations refer to the same journal, the source abbreviation should be given in each case (Avoid "*Ibid.*"). Each reference should refer only to one source. References are to be typed double-spaced on a separate page following the acknowledgments.

Literature citations *must* conform to the following format:

For reference to journal articles:

• 1. Turner, E.M., Miller, E., and Smith, D.E. (1975) Temperature and Diet Effects on Trout, *J. Biol. Chem. 250,* 108–115.

For reference to books:

1. Turner, E.H., and Smith, D.E. (1964) *Enzymes,* 2nd edn., pp. 565–567, Academic Press, New York.

For reference to multi-author books:

• 1. Turner, E.H. (1967) Temperature and Diet Effects on Trout, in *Comprehensive Biochemistry* (Florkin, E.M., and Stotz, E.M., eds.) Vol. 28, pp. 23–65, Elsevier, Amsterdam.

For reference to theses:

Manuscripts accepted for publication should be listed as:

• 1. Turner, E.H., Temperature and Diet Effects on Trout, *J. Biol. Chem.*, in press.

Names of journals must be abbreviated according to *Chemical Abstracts Service Source Index* (CASSI), published by Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210. These abbreviations are identical to those used in *Chemical Abstracts. These abbreviations are to be used exclusively.*

If it is necessary to refer to "unpublished data," "personal communication," "manuscript in preparation" or papers "submitted for publication," such citations should not be listed as references, but are to appear in the text, e.g., (Turner, E.H., and Smith, D.E., unpublished data). Authors must obtain written permission to cite the unpublished work of others, and copies of such correspondence must accompany the manuscript. Avoid the use of *et al.* in referring to authors: list all names.

NOTE: *Lipids* is now italicizing all mathematical variables. This may not have been clear in January 1995 "Guide to Authors."

AVAILABILITY OF FISH OIL TEST MATERIALS

The Fish Oil Test Materials Program is a cooperative effort of the National Institutes of Health (NIH) and the National Oceanic and Atmospheric Administration/Department of Commerce (NOAA/DOC). This program provides a long-term, consistent supply of quality-assured/quality-controlled test materials to researchers that facilitates the evaluation of ω-3 fatty acids in health and disease.

Current test materials available, in both capsules and bulk, include: (i) vacuum deodorized menhaden oil; (ii) ethyl esters of olive, corn, and safflower oils; (iii) commercial preparations of corn, olive, and safflower oil; (iv) n-3 ethyl ester concentrates; (v) EPA ethyl ester; and (vi) DHA ethyl ester.

To qualify to receive the fish oil test materials from the Program, the researcher must fill out an application. The applicant must: (i) have peer-reviewed research indicating the need for the requested materials, and (ii) submit a cor-

(continued on next page)

rectly completed application form and a signed waiver of liability. *The awarded materials are provided free of charge (researchers will pay shipping costs).*

Investigators may obtain further information and an application form from Fish Oil Test Materials Program, NIAAA, National Institutes of Health, 12501 Washington Ave., Flow Building, Room 2, Rockville, MD 20852 (Phone: Beth Aurecchia, 301-443-9643; Fax: 301-594-0035).

Structure and Biosynthesis of Novel Conjugated Polyene Fatty Acids from the Marine Green Alga *Anadyomene stellata*

Marina V. Mikhailova[a], Debra L. Bemis[a], Mitchell L. Wise[b], William H. Gerwick[b], James N. Norris[c] and Robert S. Jacobs[a,*]

[a]Marine Science Institute, University of California, Santa Barbara, California 93106, [b]College of Pharmacy and Department of Biochemistry and Biophysics, Oregon State University, Corvallis, Oregon 97331, and [c]Department of Botany, National Museum of Natural History, Smithsonian Institution, Washington, DC 20560

ABSTRACT: Novel polyunsaturated fatty acids with four conjugated double bonds were found in extracts of the green macroalga, *Anadyomene stellata*. The isolation of five of these with different chain lengths and varying degrees of unsaturation—16:5, 18:4, 20:5, 20:6, and 22:7—was accomplished by organic extraction followed by a combination of vacuum and high-performance liquid chromatography. One of these that was a novel substance (22:7) was characterized as 4*Z*,7*Z*,9*E*,11*E*,13*Z*,16*Z*,19*Z*-docosaheptaenoic acid and assigned the trivial name stellaheptaenoic acid. The structure of this new compound, isolated as its methyl ester derivative, was deduced from detailed nuclear magnetic resonance, gas chromatography/mass spectrometry (GC/MS), and other spectroscopic methods. Incubation of a chloroplast preparation, isolated from a crude algal homogenate by differential centrifugation, with six unsaturated fatty acids (palmitoleic, 6*Z*,9*Z*,12*Z*,15*Z*-octadecatetraenoic acid, arachidonic acid, eicosapentaenoic acid, 7*Z*,10*Z*,13*Z*,16*Z*-docosatetraenoic acid, and 4*Z*,7*Z*,10*Z*,13*Z*,16*Z*,19*Z*-docosahexaenoic acid) resulted in substantially increased synthesis of unique tetraene compounds as detected by ultraviolet spectrophotometry and tentatively identified by GC/MS.

Lipids 30, 583–589 (1995).

Despite the many differences between marine and terrestrial organisms at the cellular and biochemical level, the application of a comparative approach has proven to be successful in the elucidation of many shared physiological and biochemical processes in these classes of life forms (1). The oxidation of polyunsaturated fatty acids (PUFAs), such as arachidonic acid (AA), to biologically active compounds is one such process. The capacity to utilize this fatty acid and produce metabolites with structures similar to prostaglandins and leukotrienes, mediators of inflammation among other functions, has been found in such marine organisms as coralline red algae (Corallinales) and tunicates (Urochordata) (2–6). The biological functions of these enzymatic cascades and resulting metabolites, along with the evolutionary implications of such similarities, are the focus of our interests.

Additionally, compounds derived from some sponges (Porifera) and soft corals (Anthozoa: Gorgonacea) have been found to inhibit the signaling cascade involved in inflammation in mammalian models. A few examples include fuscoside, scalaradial, and manoalide, which were isolated from the gorgonian, *Eunicea fusca*, a sponge from the genus *Cacospongia*, and another sponge, *Luffariella variabilis*, respectively (7–12). Thus, not only do marine invertebrates and algae provide us with unique models to study fatty acid metabolism and other biochemical pathways, but they provide us with new molecular probes with which to study the process of inflammation in mammalian systems.

Oxylipins (13), oxidative metabolites of AA and its homologues, are found in four kingdoms, Eubacteria, Protista, Plantae, and Animalia, suggesting that they possess important physiological roles. Among the marine algal macrophytes, various chain length PUFAs and resulting oxylipins have been found in all of the major multicellular groups (Rhodophyta, Phaeophyceae, and Chlorophyta) (4,6). Cyanobacteria, on the other hand, appear to metabolize shorter chain fatty acids of 14 to 18 carbon atoms in length (4,6,14).

The ability of marine algae to produce PUFAs, particularly 20- and 22-carbon ω3 fatty acids, has long been recognized (15). In addition, enzyme(s) have been found that are capable of producing eicosanoids *via* oxidation of 20-carbon PUFAs. The biochemical pathways involved have been considered to some extent in marine red algae (4,6); however, little work has been done with marine green algae. Furthermore, the physiological significance of the metabolites produced in these groups of algae, as well as many other organisms, is largely

unknown. It has been a frequent observation that some marine algae possess enzyme systems capable of metabolizing 20-carbon PUFAs as well as 18- and 22-carbon PUFAs, resulting in the production of diverse chain length oxylipins. However, in most cases the substrate preference and specific functions of the enzyme cascade(s) involved are still to be determined.

In 1991 we undertook a study of selected red and green marine algae to determine the relative capacity of various organisms to metabolize AA (Bober, M.A., Norris, J.N., Williams, A.B., and Jacobs, R.S., submitted for publication). Among the 27 benthic marine algal species collected off the central Atlantic coast of Florida and in the Florida Keys, we detected high levels of AA metabolic activity in a green algal species, *Anadyomene stellata.* This alga is frequently found in shallow marine habitats exposed to high herbivory, yet does not appear to be preyed upon. This observation has lead to suggestions that it is a fairly unpalatable species among the family Anadyomenaceae (16,17).

Several characteristics of *A. stellata* made it an attractive species in which to study PUFA metabolism, the biological roles of its metabolites, and their possible pharmaceutical applications. These include the relative ease of collection of this alga, and though patchy in distribution, it is often abundant where found. This species is found from low intertidal to the shallow subtidal regions in subtropical to tropical waters of the Western Atlantic and Mediterranean (18). *Anadyomene stellata* is often found growing sympatrically with *A. saldanhae*. It is distinguished from the latter by the characteristics of the branching pattern of the veins and cells of their unistratose blades, as seen under a dissection microscope. Furthermore, the uniserate veins and cells between the veins are large and easily visible under a light microscope, rendering them accessible for observation and experimentation both *in vivo* and *in vitro.*

MATERIALS AND METHODS

Algae. Anadyomene stellata (Wulfen) C. Agardh (Anadyomenaceae, Cladophorales) was collected in 0.3 to 2.0 meters of water off the north coast of Long Key, Florida (April and September 1994), cleaned of infauna, epizooa, and epiphytes, damp dried, immediately frozen in liquid nitrogen, and transported to California on dry ice, and stored at –77°C. Taxonomic voucher specimens of the species studied are deposited in the Algal Collection, U.S. National Herbarium, National Museum of Natural History, Smithsonian Institution (Washington, D.C.). Field work was conducted at the Keys Marine Laboratory, Long Key, and laboratory work at the Smithsonian Marine Station at Link Port (Fort Pierce, FL) and the University of California (Santa Barbara, CA).

Materials. Polyvinylpolypyrrolidone (PVPP), phenylmethylsulfonyl fluoride (PMSF), DL-dithiothreitol (DTT), EDTA, and deuterated benzene were obtained from Sigma Chemical Co. (St. Louis, MO). Palmitoleic, 6Z,9Z,12Z,15Z-octadecatetraenoic acid, AA, eicosapentaenoic acid (EPA), 7Z,10Z,13Z,16Z-docosatetraenoic acid, and 4Z,7Z,10Z,13Z,16Z,19Z-docosahexaenoic acid were also obtained from Sigma Chemical Co. High-performance liquid chromatography (HPLC) grade organic solvents and thin-layer chromatography (TLC) grade silica gel were obtained from Fisher Scientific (Pittsburgh, PA) or by fresh distillation. Diazald (*N*-methyl-*N*-nitroso-*p*-toluenesulfonamide) was obtained from Aldrich Chemical Co. (Milwaukee, WI), and Miracloth from Calbiochem (La Jolla, CA).

Lipid preparation. Portions of approximately 100 g of frozen algal thalli were ground in liquid nitrogen. The coarse powder was added to chloroform/methanol (2:1) and homogenized at 0°C with a Tekmar (Cincinnati, OH) homogenizer. The homogenate was then filtered through a Buchner funnel fitted with Whatman (Clifton, NJ) filter paper #1. For further purification, distilled water was added to the mixture along with 1 M NaCl in a 1:10 final volume. The water phase was discarded, and the organic phase dried with anhydrous Na_2SO_4, filtered, and reduced *in vacuo*. The dry sample was resuspended in 1 mL hexane and methylated with diazomethane (19).

Preparation of chloroplast fraction. Chloroplasts were obtained from 25 g of frozen algal specimens by the following procedure. Thalli of thawed algae were first ground with a mortar and pestle using a small amount of purified silica to aid in the grinding process and then suspended in 40 mL of 0.1 M potassium phosphate buffer (pH 7.4) containing 5 mM EDTA, 5 mM DTT, and 1 mM PMSF. The mixture was filtered through one layer of Miracloth and centrifuged for 1 min at 400 × *g* (Beckman TJ-6; Beckman, Fullerton, CA) with 3% wt/vol PVPP. The supernatant was filtered through a layer of Miracloth and centrifuged for 5 min at 1000 × *g*. This chloroplast-enriched pellet was resuspended in 0.1 M potassium phosphate buffer, pH 7.4, to a concentration of 60 µg/mL as determined by the methods of Bradford (20), and then used for incubations with fatty acid substrates.

Incubation with fatty acid substrates and extraction of products. Six unsaturated fatty acids not containing conjugated double bonds (palmitoleic, 6Z,9Z,12Z,15Z-octadecatetraenoic acid, AA, EPA, 7Z,10Z,13Z,16Z-docosatetraenoic acid, and 4Z,7Z,10Z,13Z,16Z,19Z-docosahexaenoic acid) were used as substrates for incubation with the chloroplast fraction. Incubations were prepared in triplicate by adding a fatty acid substrate dissolved in EtOH to a 500 µL aliquot of the chloroplast fraction (200 µM final concentration). The incubations were mixed continuously for 3 h at room temperature (*ca.* 22°C). Following the incubation period, the lipids were extracted in 3 mL of hexane, and dried to completion under nitrogen. Ultraviolet (UV) spectrophotometric analysis of the samples was conducted following reconstitution in a small volume of hexane. Controls, with no substrate added, were treated as described above.

Chromatographic and instrumental methods. Methyl esters were chromatographed over TLC grade silica gel under vacuum with increasing percentages of ethyl acetate (EtOAc) in hexane. After separation, the fractions were scanned in the UV range with an IBM (Danbury, CT) 9430 UV-VIS scan-

ning spectrophotometer or on a Hewlett-Packard (Palo Alto, CA) 8452A diode array spectrophotometer. TLC of 1 μL of this extract (0.2% of total) was conducted on Whatman TLC plates (silica gel 60 A) in a solvent system of either hexane/diethyl ether/acetic acid (85:15:1, by vol) or EtOAc/hexane (2:98, vol/vol). Further purification of methyl esters was achieved by both reverse- and straight-phase HPLC using either a Hitachi (Mountain View, CA) 4200 instrument or a Waters (Milford, MA) M-6000A pump with a Waters Lambda Max 480 UV detector. Reverse-phase HPLC was performed over Partisil 5 ODS-3 (250 × 4.6 mm) (Whatman) with a gradient of acetonitrile/tetrahydrofuran/water (9:5:11) (15) (solvent A) and methanol (solvent B) as follows: 0 min 100% A; 10 min 99% A and 1% B; 20 min 95% A and 5% B; 45 min 90% A and 10% B. Detection was at 328 nm with a flow rate of 3 mL/min. Straight-phase HPLC was conducted on two 4 mm × 30 cm Alltech (Deerfield, IL) 10 μ silica columns connected in series. An isocratic solvent system of EtOAc/hexane (1:99, vol/vol) was used with a 3 mL/min flow rate and 328 nm detection.

Gas chromatography/mass spectrometry (GC/MS) of derived natural products from *A. stellata* was performed with a Hewlett-Packard Model 5890 Series II gas chromatograph and an HP5971A quadrapole mass selective detector interfaced with a Hewlett-Packard Chemstation using G1034B software for data analysis. An 11.5 meter Ultra 1 (100% dimethylpolysiloxane) capillary column was used in the splitless injection mode. Injector temperature was 250°C, and oven temperature was 100°C with a 10°C/min temperature ramp to a final temperature 240°C (detector temperature 280°C). Helium was used as the carrier at 11 psi. GC/MS of samples from incubation experiments was performed on a modified HP 5985B GC/MS instrument. Samples were loaded onto a solvent-free GC injector (dropping needle type; Ray Allen Associates, Boulder, CO) connected to a bonded phase fused silica capillary column (DB-1, 15 m, 0.26 mm i.d., film thickness 0.25 μM; J&W Scientific, Folsom, CA). Injector temperature was 250°C, and oven temperature was set at 80°C for 1 min with a 7°C/min temperature ramp up to a final temperature of 300°C. Helium was used as the carrier gas. Nuclear magnetic resonance (NMR) experiments were conducted on either Bruker ACP 300 MHz or AM 400 MHz instruments.

RESULTS AND DISCUSSION

Isolation of tetraene compounds from A. stellata. The UV-spectrum of the lipid fraction of the algae in hexane with absorption maxima at 294, 306, and 322 nm (Fig. 1) indicates the presence of conjugated tetraene structures (21). However, preliminary observations of the crude extract by UV spectrophotometry suggested that these compounds were chemically unstable. Hence, the crude lipid extract was methylated with diazomethane which improved the stability and chromatographic characteristics of these compounds. These derivatives were stable at −77°C under nitrogen for one month with no detectable decomposition by TLC. For further purification, the methyl esters were separated by vacuum liquid chromatography using mixtures of EtOAc and hexane from 0 to 100% EtOAc. With the use of UV spectrophotometry, compounds with tetraene structures were detected in the third fraction eluting with EtOAc/hexane (1:99, vol/vol). This fraction was dried and its components separated with straight-phase HPLC. Compounds showing significant adsorption at 328 nm eluted in three fractions centered at 42, 48, and 54 mL. These fractions were collected, reduced *in vacuo*, and analyzed by GC/MS and NMR.

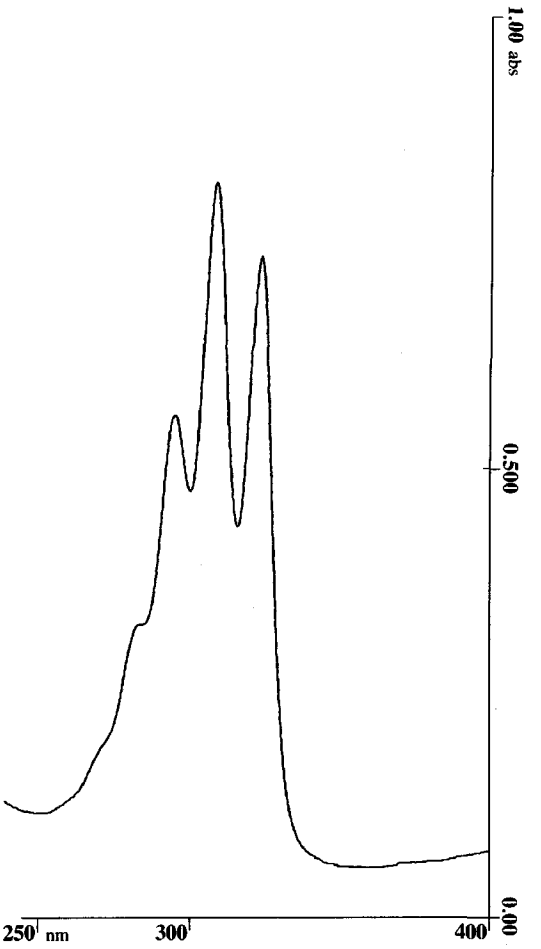

FIG. 1. Ultraviolet spectrophotometric scan of organic extract of *Anadyomene stellata*.

GC/MS and NMR analyses of methylated tetraenes. The three HPLC fractions (Fig. 2) showing significant UV absorption at 328 nm all had UV spectra with maxima at 294, 306, and 322 nm, characteristic of conjugated tetraenes. The fraction eluting at 54 mL showed (Fig. 3) a single major peak by GC/MS, derivative **2**, with an $M^+ = 340$, corresponding to a molecular formula of $C_{23}H_{32}0_2$ [LR EIMS *m/z* (rel. intensity) obs.[M^+] *m/z* 340 (6), 260 (18), 232 (30), 171 (10), 157 (21), 145 (27), 131 (83), 117 (83), 105 (63), 91 (100), 79 (57), 67 (30)]. Assuming an $\varepsilon \cong 72{,}000\ M^{-1}cm^{-1}$ (9) for the UV maxima at 306 nm, 0.53 mg of derivative **2** was isolated in this process (Scheme 1—structural formulas for conjugated tetraene metabolites and derivatives discussed in text). The

FIG. 2. High-performance liquid chromatography-straight phase chromatogram of fraction 3 eluted in 1% ethyl acetate in hexane by vacuum liquid chromatography: peaks 1 and 3—mixture of methyl ester derivatives having molecular ions *m/z* 260, 290, 314, 316; peak 2—methyl bosseopentaenoate, molecular ion *m/z* 316; and peak 4—methyl ester derivative having molecular ion *m/z* 340.

infrared spectrum for **2** showed the following: (neat) 3015, 2959, 2926, 2874, 1740, 1717, 1457, 1436, 1251, 1196, 1163, 995, 955, 668 cm^{-1}. The ^1H NMR (300 MHz) in d_6-benzene showed the following (shifts relative to solvent peak at 7.15 ppm): δ 0.90 (3H, *t*, *J* = 7.51 Hz, H-22), 1.99 (2H, *m*, H-21), 2.11 (2H, *t*, *J* = 7.45 Hz, H-2), 2.30 (2H, *dt*, *J* = 7.3,7.3 Hz, H-3), 2.81 (2H, *dd*, *J* = 5.0, 5.0 Hz, H-18), 2.92 (4H, *m*, H-6,15), 3.32 (3H, *s*, OMe), 5.31–5.44, (8H, *m*, H-4,5,7,14,16,17,19,20), 6.10 (2H, *m*, H-8,13), 6.24 (2H, *m*,

SCHEME 1

H-10,11), 6.55 (2H, *m*, H-9,12). A ^{13}C distortionless enhancement by polarization transfer experiment (100 MHz) showed the following [shifts relative to solvent at 128.00 ppm, assignments based on model compounds (1,2)]: δ14.44 (C-22; CH_3), 20.89 (C-21; CH_2), 23.09 (C-3; CH_2), 25.92 (CH_2), 26.51 (CH_2), 26.61 (C-18,15,6; CH_2's), 33.94 (C-2, CH_2), 51.98 ($-OCH_3$), 127.33 (C-9; CH), 128.49, (C-8; CH), 128.52 (C-12; CH), 128.54 (C-4; CH), 128.69 (C-7; CH), 128.98 (C-5; CH), 129.19 (C-13; CH), 129.50 (C-19; CH), 129.51 (C-17; CH), 130.37 (C-16;CH), 130.41 (C-20, CH), 132.18 (C-14; CH), 133.84 (C-10; CH), 133.86 (C-11; CH). Resolution of the low field signals was accomplished by Guassian multiplication of the DEPT spectrum from 126 to 136 ppm. A heteronuclear multiple bond coherence experiment showed long range coupling from H_2-2 and the OMe protons to a quaternary carbon (carbonyl) at approximately δ173 ppm and also confirmed assignments of C-3 and C-21.

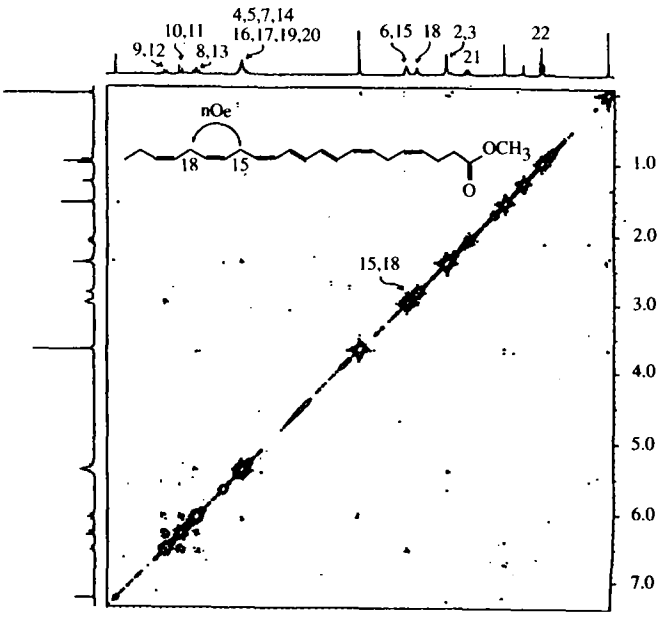
From these data, it was clear that there were fourteen olefinic methines, six aliphatic methylenes, two methyl groups, and one carbonyl carbon. Three of the methylenes were bisallylic groups as indicated by their chemical shifts, one at δ2.81 and two at δ2.92. A ^1H-^1H chemical shift correlation spectroscopy (COSY) experiment demonstrated coupling from the C2-methylene at δ2.11 through the aliphatic protons at δ2.30 ppm to the C4 olefinic proton at approximately δ5.3–5.4. Similarly, coupling from the terminal methyl at δ0.90 through the methylene protons at δ1.99 to the cluster of olefinic protons at δ5.3–5.4 established that portion of the molecule. The relative positions in the conjugated tetraene functionality of the six low-field proton signals at δ6.10, δ6.24, and δ6.55 (2H each) were assigned by comparison with methyl bosseopentaenoate **5** (22), and were consistent with the COSY data obtained for **2** (Scheme 1). The large cluster of signals at δ5.3–5.4 represented the protons in the three isolated olefinic groups as well as the first and last protons in the conjugated system. The ^1H-^1H COSY experiment also showed a long range coupling from the H3 protons to a bisallylic signal at δ2.92 as well as a long-range coupling between the δ2.92 signal and a low-field olefinic proton at

δ6.10. A long-range ^{1}H-^{1}H COSY experiment optimized for 1 Hz convincingly showed coupling from the ω2 protons (δ1.99) to the bisallylic signal at δ2.81. This was confirmed by decoupling the signal at δ2.81 and observing a distinct sharpening of the ω2 signal. These data eliminated the possibility of the conjugated system starting at C4 or C13, leaving only two possible regioisomers for the natural product fatty acid; i.e., 4,7,9,11,13,16,19 docosaheptaenoic acid (**1**), or 4,7,10,12,14,16,19 docosaheptaenoic acid (**3**).

Resolution of these two possibilities was accomplished by two-dimensional nuclear Overhauser enhancement spectroscopy (NOESY) in $CDCl_3$. This experiment revealed a distinct nuclear Overhauser effect between the bisallylic proton signals at δ2.82 and δ2.97 (Fig. 4). In this solvent, identification of the δ2.08 signal as H21 and the δ2.82 signal as H18 was accomplished by selectively irradiating the δ2.08 signal and observing a distinct sharpening of the proton signal at δ2.82, resulting from the loss of homoallylic coupling, and the collapse of the methyl triplet (H_3-22 at δ0.98). Having established that the δ2.82 signal corresponded to H18, the nOe results could only be accounted for by structure **2**.

The relative stereochemistry of the seven olefinic groups (4Z,7Z,9E,11E,13Z,16Z,19Z) is based on the high degree of comparability between the low-field region of the ^{1}H NMR spectrum (22), the ^{13}C NMR spectrum (23,24), and the UV/Vis spectrum (25) for this compound with that of methyl bosseapentaenoic acid (BPA) (**5**). Other possible olefin configurations do not seem likely, given the symmetry of the tetraene system as observed by NMR and the precedence of *Z,E,E,Z* configurations in naturally occurring conjugated tetraenes (24,26).

The HPLC fraction eluting at 42 mL also showed only one major peak by GC/MS with a M^+ *m/z* = 316, corresponding to a molecular formula $C_{21}H_{32}O_2$ [LR EIMS *m/z* (rel. intensity) obs. [M^+] *m/z* 316 (56), 245 (9), 201 (14), 147 (11), 145 (18), 143 (13), 131 (52), 117, (73), 105 (52), 91 (100), 79 (44), 67 (30, 55 (13); ^{1}H NMR (300 MHz, d_6-benzene, shifts relative to the solvent peak at 7.15 ppm) δ 0.86 (3H, *t*, *J* = 7.4 Hz, H-20), 1.23 (4H, *m*, H-18,19), 1.31 (2H, *m*, H-17), 1.58 (2H, *tt*, *J* = 7.4,7.4 Hz, H-3), 1.96 (2H, *bdt*, *J* = 7.3, 7.3 Hz, H-4), 2.09 (2H, *t*, *J* = 7.4 Hz, H-2), 2.13 (2H, *dt*, *J* = 7.6, 7.6 Hz, H-16), 2.88 (2H, *bdd*, *J* = 7.4, 7.4 Hz, H-7), 3.32 (3H, *s*, OMe), 5.27 (1H, *dtt*, *J* = 8.3, 8.3, 1.5 Hz, H-5), 5.36–5.47, (3H, *m*, H-6,8,15), 6.09 (1H, *dd*, *J* = 11.0, 11.0 Hz, H-9), 6.14 (1H, *dd*, *J* = 11.0, 11.0 Hz, H-14), 6.25 (1H, *m*, H-12), 6.31 (1H, *m*, H-11), 6.56 (2H, *dd*, *J* = 11.4,13.7 Hz, H-10,13]. [These coupling constants are slightly different than those described in Burgess *et al.* (22). We believe these to be the correct values.] The proton spectrum of this compound was essentially identical to that of BPA (22). However, to confirm its identity as methyl 5*Z*,8*Z*,10*E*,12*E*,14*Z*-eicosapentaenoate (**5**) as opposed to methyl 5*Z*,7*E*,9*E*,11*Z*,14*Z*-eicosapentaenoate, two additional proton decoupling experiments were performed. First, irradiation of the signal at δ1.96 (H_2-4) collapsed the signals at δ1.58 (H_2-3) and δ5.27 (H-5). In turn, irradiation at δ1.58 collapsed the signals at δ1.96 and δ2.09. These results clearly demonstrated that the unsaturation pattern in this isolate of **5** was 5*Z*,8*Z*,10*E*,12*E*,14*Z*, as previously assigned for BPA (**6**).



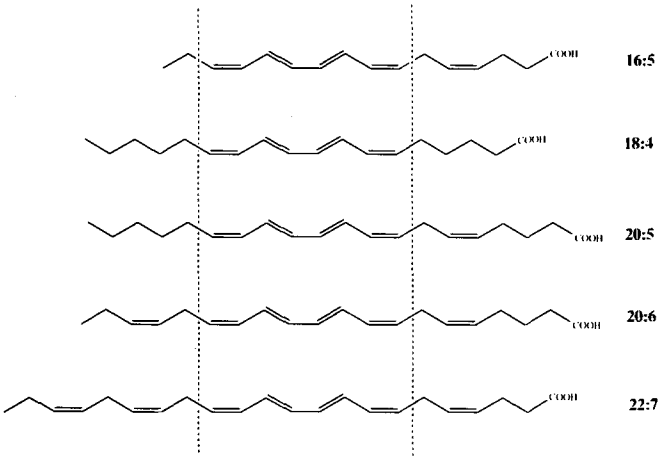


FIG. 4. ^{1}H-^{1}H Nuclear Overhauser enhancement correlation spectroscopy of methyl 4*Z*,7*Z*,9*E*,11*E*,13*Z*,16*Z*,19*Z*-docosaheptaenoate (**2**).

The HPLC peak eluting at 48 mL contained a mixture of four compounds as determined by GC/MS having molecular ions at *m/z* 260, 290, 314, and 316. These ions are consistent with the methyl esters of C16:5 (11.3 min), C18:4 (13.3 min), C20:5 (14.8 min), and C20:6 (15.2 min). Better separation of these fatty acid methyl esters (FAMEs) was achieved by reverse-phase HPLC. Compounds showing significant adsorption at 328 nm eluted in five fractions centered at 118, 192, 197, 222, and 229 mL; these were separated, reduced under vacuum, and analyzed by GC/MS. The fraction eluting at 118 mL showed a single major peak with M^+ 260 corresponding to the methyl ester of 16:5, fraction 192 mL-M^+ 314-C20:6; 197 mL-M^+ 290-C18:4; 222 mL-M^+ 340-C22:7 and 229 mL-M^+ 316-C20:5. While three of these FAMEs, C16:5, C18:4, and C20:6, have not yet been purified to a degree sufficient for rigorous molecular analysis, their structures are tentatively presented here as 16:5Δ4,7,9,11,13, 18:4Δ6,8,10,12, and 20:6Δ5,8,10,12,14,17 (Scheme 2—structures of conjugated tetraene metabolites were aligned so as to show the relationship of the tetraene functionality to the carboxyl terminus. Presumably, this is established as a result of substrate recognition and binding characteristics of the producing enzyme). The structures of the methyl esters of the other two compounds, stellaheptaenoic acid (22:7, 4*Z*,7*Z*,9*E*,11*E*,13*Z*,16*Z*,19*Z*-docosaheptaenoate) and BPA (20:5, 5*Z*,8*Z*,10*E*,12*E*,14*Z*-EPA), were rigorously established (Scheme 1; **2** and **5**).

Analysis of chloroplast incubations by UV spectrophotometry. UV spectrophotometry was utilized to determine the presence of tetraene structures following incubations of

SCHEME 2

chloroplast fractions with PUFA precursors (final concentration of 200 μM). UV scans of the extracts resulting from the incubations were characteristic of tetraene structures with absorption maxima at 294, 306, and 322 nm. Additionally, marked increases in these signals were found in samples incubated with the fatty acid substrates. The largest increases were found in the samples incubated with 6Z,9Z,12Z,15Z-octadecatetraenoic acid which showed a nearly 18-fold increase in absorbance of the 306 nm peak above control. Assays containing AA, EPA, 7Z,10Z,13Z,16Z-docosatetraenoic acid, and 4Z,7Z,10Z,13Z,16Z,19Z-docosahexaenoic acid all had similar levels of tetraene compounds present following incubation. The increase in absorbance of the 306 nm peak for each of these samples was 9.2-, 10.8-, 6.6-, and 8.4-fold above control levels, respectively. The samples incubated with palmitoleic acid showed the smallest increase in absorbance of the 306 nm peak (2.6-fold). These relative differences in absorbance were not quantitated further because precise extinction coefficients are not known in the mixture of products. Samples in which the chloroplast fraction was boiled prior to incubation with AA showed no increase in the magnitude of the tetraene signal, suggesting that tetraene formation is dependent on an enzymatic process (data not shown).

*Analysis of chloroplast incubations by GC/MS.*The fatty acids present in samples incubated with 6,9,12,15-octadecatetraenoic acid were determined by GC/MS of the corresponding methyl ester derivatives to be 16:5, 18:4, 20:5, and 20:6. Which of these represent conjugated tetraenes as unmetabolized PUFAs was not determined by this methodology. In the case of application of AA, only fatty acids with 20 carbons were found, 20:5 and 20:6. In contrast, 16:5, 18:4, 20:5, and 20:6 were detected in the assays with EPA added. Five fatty acids, 16:5, 18:4, 20:5, 20:6, and 22:7, were found in the samples in which 4Z,7Z,10Z,13Z,16Z,19Z-docosahexanoic and 7Z,10Z,13Z,16Z-docosatetraenoic fatty acids were used as substrates. In contrast, 20:6, presumably BPA, was the only fatty acid detected in incubations prepared with exogenous palmitoleic acid.

Our tentative interpretation of these results is that the various exogenously applied fatty acids, or metabolites produced from them, are each eliciting the release of specific profiles of fatty acids from complex lipid species which then potentially feed into this tetraene biosynthetic pathway. These complex lipids may be the galactolipids which are found in abundance in chloroplast membranes. Further work is underway to clarify this apparently complex regulation of the flow of fatty acids into this biochemical pathway, as well as other aspects of the biosynthesis of these novel metabolites.

This study demonstrates the capacity of at least six PUFAs, in either free or complexed form, to serve as substrates for the production of novel tetraene structures *via* an oxidative enzymatic pathway present in *A. stellata.* As suggested by Scheme 2, it appears that the enzyme system introduces the conjugated tetraene at a position recognized in relationship to the carboxyl terminus. Recently, mechanistic features of conjugated tetraene biosynthesis were studied in an unrelated red marine alga, *Lithothamnion corallioides* (Corallinales), using cell free methodology (26). If similar fatty acid oxidase systems are in operation in these taxonomically divergent algal phyla, then this biosynthetic pathway must be of considerable biochemical and physiological significance to have survived evolutionary pressures. We believe *A. stellata* to be a useful model for the analysis of the cellular and molecular mechanisms underlying the biosynthetic pathway of these highly reactive fatty acids.

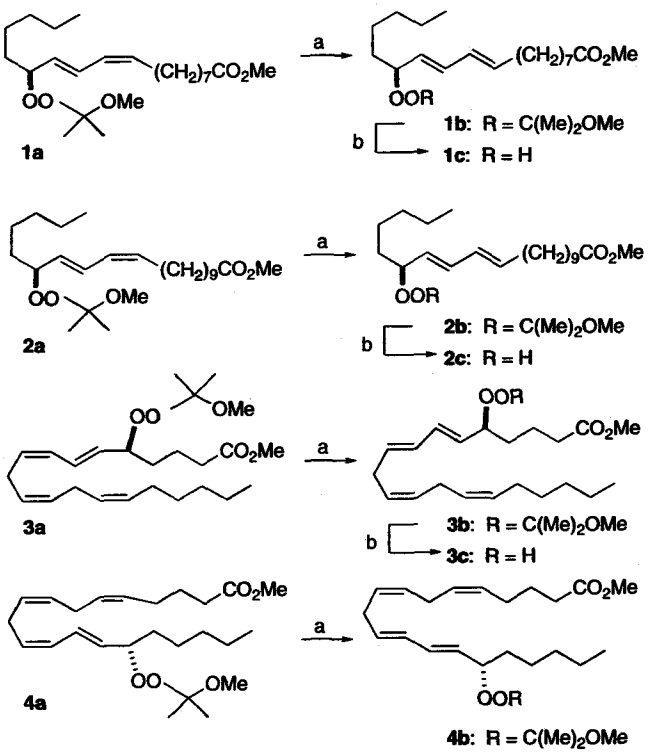
Synthesis of *E,E*-Diene Hydroperoxides *via* Photoisomerization of Protected Hydroperoxides

P.H. Dussault*, I.Q. Lee and C.T. Eary



Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska 68588-0304

ABSTRACT: A general approach to *E,E*-diene hydroperoxides is described based upon photoisomerization of readily available *Z,E*-diene monoperoxyketals. Protection of a *Z,E*-diene hydroperoxide as the 2-methoxypropyl peroxyketal is followed by iodine-mediated photoisomerization to produce a mixture enriched in the *E,E* isomer. After chromatographic purification, deprotection of the peroxyketal with mild acid furnishes the *E,E*-diene hydroperoxide.

Lipids 30, 591–594 (1995).

As part of a research program concerned with peroxide synthesis, we became aware of the challenges associated with the synthesis of *E,E*-diene hydroperoxides. Most methods for the construction of diene hydroperoxides, including enzymatic dioxygenation of 1,4-dienes, olefination of γ-peroxy-α,ß-unsaturated aldehydes, or reaction of 1,4-dienes with singlet oxygen, favor production of the *Z,E*-isomers (1–3). Radical autoxidation of 1,4-dienes does produce *E,E*-diene hydroperoxides, but in poor yield and as a mixture of regioisomers (4). The only general method for synthesis of *E,E*-diene hydroperoxides involves silver-mediated addition of hydrogen peroxide to vinylcyclopropanes (5). Given the ready availability of both natural and unnatural *E,Z*-diene hydroperoxides, a method for their conversion to the *E,E*-isomers would represent a useful addition to the existing methodology. We report herein the iodine-catalyzed isomerization of protected *Z,E*-diene hydroperoxides to the *E,E*-isomers [Scheme 1; where a, I_2, CH_2Cl_2, hv; b, $HOAC/H_2O$ (90:10)].

Although radical isomerization has been applied to unsaturated fats and derived alcohols (6,7), extension of this methodology would seem to be ruled out by the reactivity of the hydroperoxide moiety. However, recent reports have demonstrated that conversion of hydroperoxides into monoperoxyketals, a transformation first reported more than forty years ago, imparts greatly increased stability toward a variety of common synthetic protocols (3,8–11). As shown in Scheme 1, we have found that temporary protection of readily available *E,Z*-diene hydroperoxides as their monoperoxyketals allows for chemoselective isomerization of the diene in the presence of the peroxide group.

SCHEME 1

MATERIALS AND METHODS

Reagents. The methyl esters of 13(*S*)-hydroperoxy-9*Z*,11*E*-octadecadienoic acid [13(*S*)-HPOD], 15(*S*)-hydroperoxy-5*Z*,8*Z*,11*Z*,13*E*-eicosatetraenoic acid [15(*S*)-HPETE], and 15-hydroperoxy-11*Z*,13*E*-eicosadienoate were prepared according to published procedures (12–14). The monoperoxyketal of 5(*S*)-hydroperoxy-6*E*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid [5(*S*)-HPETE] methyl ester was prepared through total synthesis (3). Halogenated solvents (CH_2Cl_2, $CHCl_3$, and CCl_4) were filtered through a short column of neutral alumina before use. A description of standard protocols for spectral characterization has been reported (3,8).

Ketalization. Peroxyketals were prepared in >90% yield from the reaction of hydroperoxides and 2-methoxypropene in CH_2Cl_2 in the presence of catalytic pyridinium *p*-toluenesulfonate according to a published procedure (8).

Isomerization. I_2 (0.01 equivalent from a 0.1 M stock solution in CCl_4) was added to a stirred 0.3 M solution of the perketal in CH_2Cl_2 or $CHCl_3$. The reaction was stirred for 4–8 h on a bench top under ambient fluorescent lighting (160 W fixture) from a distance of approximately six feet. The concentrated reaction was directly subjected to flash chromatography on silica gel; elution with ethyl acetate (EA)/hexane afforded 70–80% of the diene peroxyketals as an approximately 80:20 *EE/EZ* mixture.

Deprotection. A 0.1 M solution of the diene peroxyketal in HOAc/H_2O (90:10) was stirred for 2 h and then extracted with hexane containing a trace of butylated hydroxytoluene. The hexane layer was washed with water and dried over sodium sulfate. The crude hydroperoxide obtained after concentration was directly subjected to flash chromatography on silica gel; elution with EA/hexane afforded >80% yields of the diene hydroperoxide as a colorless oil. Residual *E,Z*-diene was typically removed at this stage by semi-preparative (25 × 2 cm column) normal-phase high-performance liquid chromatography (NP–HPLC).

Spectral data. Methyl 13(*S*)-[(1-methoxy-1-methylethyl)-dioxy]-9*Z*,11*E*-octadecadienoate (**1a**): R_f = 0.4 in 10% EA/hexane; ^{1}H nuclear magnetic resonance (NMR) (300 MHz) δ 6.45 (*dd*, 1H, *J* = 15.3, 11.3), 5.97 (*t*, 1H, *J* = 10.9), 5.59 (*dd*, 1H, *J* = 15.3, 7.6), 5.42 (*dt*, 1H, *J* = 10.8, 7.7), 4.38 (*q*, 1H, *J* = 7.3), 3.64 (*s*, 3H), 3.27 (*s*, 3H), 2.28 (*t*, 2H, *J* = 7.7), 2.15 (*q*, 2H, *J* = 8.1), 1.6–1.2 (24H), 0.86 (*t*, 3H, *J* = 6.85).

Methyl 13(*S*)-[(1-methoxy-1-methylethyl)dioxy]-9*E*,11*E*-octadecadienoate (**1b**): R_f = 0.4 in 10% EA/hex; ^{1}H NMR (300 MHz) δ 6.16 (*dd*, 1H, *J* = 15.3, 10.5), 6.02 (*dd*, 1H, *J* = 15.0, 10.5), 5.69 (*dt*, 1H, *J* = 14.8, 7.4), 5.50 (*dd*, 1H, *J* = 15.0, 8.1), 4.34 (*q*, 1H, *J* = 7.6), 3.65 (*s*, 3H), 3.28 (*s*, 3H), 2.29 (*t*, 2H, *J* = 7.6), 2.05 (*q*, 2H, *J* = 6.9) 1.62–1.28 (24H), 0.86 (*t*, 3H, *J* = 6.7)

Methyl 13(*S*)-hydroperoxy-9*E*,11*E*-octadecadienoate (**1c**): Following deprotection of **1b**, the mixture of hydroperoxides was purified by NP–HPLC (0.25% ethanol/hexane) to afford spectroscopically pure *E,E*-diene as a colorless oil: R_f = 0.3 in 10% EA/hexane; ^{1}H NMR (300 MHz) δ 7.72 (*s*, 1H) 6.26 (*dd*, 1H, *J* = 15.3, 10.5), 6.04 (*dd*, 1H, *J* = 15.0, 10.5), 5.75 (*dt*, 1H, *J* = 14.5, 7.5), 5.36 (*dd*, 1H, *J* = 15.1, 8.5), 4.38 (*q*, 1H, *J* = 8.1), 3.65 (*s*, 3H), 2.29 (*t*, 2H, *J* = 7.6), 2.07 (*q*, 2H, *J* = 6.9) 1.63–1.25 (18H), 0.86 (*t*, 3H, *J* = 6.7); ^{13}C NMR (125 MHz) δ 137.1, 135.8, 130.0, 129.7, 87.4, 52.1, 34.7, 33.2, 32.4, 29.7, 29.5, 25.6, 25.5, 23.1, 14.6.

Methyl 13(*S*)-hydroxy-9*E*,11*E*-octadecadienoate (**1d**): Methyl ester **1c** (38.7 mg, 0.12 mmol) was dissolved in 3 mL of EA with triphenylphosphine (32.5 mg, 0.12 mmol) and stirred at 25°C for 40 min. The solution was concentrated to dryness and directly subjected to flash chromatography (10% EA/hexane) to afford 31.2 mg (85%) of the hydroxy methyl ester: R_f = 0.1 in 10% EA/hexane; [α]D = +7.23 (c = 0.16, CH_2Cl_2); ^{1}H NMR (500 MHz) δ 6.16 (*dd*, 1H, *J* = 14.9, 10.1), 6.0 (*dd* 1H, *J* = 15.3, 10.5), 5.67 (*dt*, 1H, *J* = 14.5, 6.9), 5.56 (*dd*, 1H, *J* = 15.3, 7.3), 4.1 (*m*, 1H, *J* = 7.3), 3.65 (*s*, 3H), 2.29 (*t*, 2H, *J* = 7.7), 2.04 (*q*, 2H, *J* = 6.9), 1.6–1.25 (18H), 0.87 (*t*, 3H, *J* = 6.9); ^{13}C NMR (125 MHz) δ 135.9, 134.4, 131.5, 130.2, 73.5, 52.0, 37.9, 34.7, 33.2, 32.4, 29.8, 29.7, 29.6, 25.7, 25.5, 23.2, 14.6.

13-(*S*)-Hydroxy-9*E*,11*E*-octadecadienoic acid (**1e**): Methyl ester **1d** (29.7 mg, 0.096 mmol) and K_2CO_3 (132 mg, 0.96 mmol) were dissolved in MeOH/H_2O (4:1) (1.42 mL) and stirred at room temperature for 72 h. The mixture was diluted with 2 mL of H_2O, acidified with 5% HCl, and extracted with 20% EA/hexane. The organic extracts were combined, washed with water, and dried/filtered over $MgSO_4$/Celite. The organic layer was concentrated and directly subjugated to flash chromatography in 225:15:1 hexane/EtOH/HOAc to afford 24.8 mg (85%) of the hydroxy acid: R_f = 0.4 in 225:25:1 hexane/EtOH/HOAc; [α]D = +5.4 (c = 0.8, $CHCl_3$); ^{1}H NMR (500 MHz) δ 6.17 (*dd*, 1H, *J* = 15.0, 10.3), 6.02 (*dd*, 1H, *J* = 15.0, 10.5), 5.70 (*dt*, 1H, *J* = 14.6, 7.1), 5.57 (*dd*, 1H, *J* = 15.0, 7.2), 4.11 (*q*, 1H, *J* = 6.5), 2.35 (*t*, 2H, *J* = 7.3), 2.07 (*q*, 2H, *J* = 7.3, 6.9), 1.64–1.25 (18H), 0.89 (*t*, 3H, *J* = 6.9); ^{13}C NMR (125 MHz) δ 136.0, 134.3, 131.6, 130.2, 73.6, 37.9, 33.2, 32.4, 30.3, 29.7, 29.6, 29.5, 25.8, 23.2, 14.7.

Methyl 15(*S*)-[(1-methoxy-1-methylethyl)dioxy]-11*Z*,13*E*-eicosadienoate (**2a**): R_f = 0.6 in 10% EA/hexane; ^{1}H NMR (300 MHz) δ 6.46 (*dd*, 1H, *J* = 15.3, 11.3), 5.97 (*t*, 1H, *J* = 11.3, 10.9), 5.59 (*dd*, 1H, *J* = 15.3, 8.1), 5.4 (*dt*, 1H, *J* = 10.9, 7.7), 4.4 (*dd*, 1H, *J* = 6.9, 7.3), 3.64 (*s*, 3H), 3.27 (*s*, 3H), 2.28 (*t*, 2H, *J* = 7.7), 2.16 (*dd*, 2H, *J* = 7.3, 6.1), 1.62–1.28 (28H), 0.86 (*t*, 3H, *J* = 7.1).

Methyl 15(*S*)-[(1-methoxy-1-methylethyl)dioxy]-11*E*,13*E*-eicosadienoate (**2b**): R_f = 0.6 in 10% EA/hexane; ^{1}H NMR (300 MHz) δ 6.16 (*dd*, 1H, *J* = 15.3, 10.5), 6.02 (*dd*, 1H, *J* = 15.0, 10.5), 5.69 (*dt*, 1H, *J* = 14.8, 7.4), 5.5 (*dd*, 1H, *J* = 15.1, 8.1), 4.38 (*dd*, 1H), 3.65 (*s*, 3H), 3.28 (*s*, 3H), 2.29 (*t*, 2H, *J* = 7.6), 2.05 (*q*, 2H *J* = 6.9), 1.62–1.28 (28H), 0.86 (*t*, 3H, *J* = 6.7).

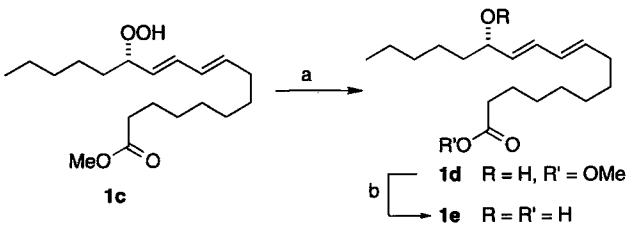
Methyl 15(*S*)-hydroperoxy-11*E*,13*E*-eicosadienoate(**2c**): The diene was purified by NP–HPLC (7% EA/hexane). R_f = 0.4 in 10% EA/hexane; ^{1}H NMR (300 MHz) δ 7.72 (*s*, 1H), 6.26 (*dd*, 1H, *J* = 15.3, 10.5), 6.04 (*dd*, 1H, *J* = 15.0, 10.5), 5.75 (*dt*, 1H, *J* = 14.5, 7.5), 5.36 (*dd*, 1H, *J* = 15.1, 8.5), 4.38 (*q*, 1H, *J* = 8.1), 3.65 (*s*, 3H), 2.29 (*t*, 2H, *J* = 7.6), 2.07 (*q*, 2H *J* = 6.9), 1.63–1.25 (22H), 0.86 (*t*, 3H, *J* = 6.7).

Methyl 5(*S*)-[(1-methoxy-1-methylethyl)dioxy]-6*E*,8*Z*,11*Z*,14*Z*-eicosatetraenoate (**3a**): R_f = 0.6 in 20% EA/hexane. ^{1}H NMR (300 MHz) δ 6.51 (*dd*, 1H, *J* = 15.3, 11.2), 5.98 (*t*, 1H, *J* = 10.9), 5.61 (*dd*, 1H, *J* = 15.3, 8.0), 5.36 (5H), 4.36 (*q*, 1H, *J* = 7.6), 3.64 (*s*, 3H), 3.26 (*s*, 3H), 2.94 (*t*, 2H, *J* = 6.2), 2.79 (*t*, 2H, *J* = 6.0), 2.32 (*t*, 2H, *J* = 7.2), 2.03 (*q*, 2H, *J* = 6.9), 1.69 (2H), 1.55–1.25 (14H), 0.86 (*t*, 3H *J* = 6.8); ^{13}C NMR (75 MHz) δ 173.7, 132.7, 130.6, 130.5, 128.9, 128.0, 127.9, 127.4, 127.3, 104.6, 84.0, 51.4, 49.2, 33.8, 32.5, 31.5, 29.3, 27.2, 26.1, 25.6, 23.0, 22.7, 22.5, 20.9, 14.0; high-resolution

mass spectrometry (HRMS) calculated for $C_{25}H_{42}O_5Li$ (M + Li) 429.3192, found: 429.3210.

Methyl 5(*S*)-[(1-methoxy-1-methylethyl)dioxy]6*E*,8*E*,11*Z*, 14*Z*-eicosatetraenoate (**3b**): The isomerized 5(*S*)-HPETE peroxyketal was purified by NP–HPLC (7% EA/hexane) to afford the spectroscopically pure 6*E*,8*E*,11*Z*,14*Z*-isomer (30 mg, 72%) as a colorless oil: R_f = 0.6 in 20% EA/hexane; $[\alpha]_D$ = -22.2 (c = 0.36); ^{1}H NMR (300 MHz) δ 6.19 (*dd*, 1H, *J* = 15.3, 10.4), 6.07 (*dd*, 1H, *J* = 15.0), 5.68 (*dt*, 1H, *J* = 15.0, 7.6), 5.52 (*dd*, 1H, *J* = 15.0, 8.1), 5.40 (4H), 4.36 (*q*, 1H, *J* = 7.6), 3.65 (*s*, 3H), 3.27 (*s*, 3H), 2.85 (*t*, 2H, *J* = 6.2), 2.78 (*t*, 2H, *J* = 6), 2.32 (*t*, 2H, *J* = 7.2), 2.03 (*q*, 2H, *J* = 6.9), 1.69 (2H), 1.58 (*s*, 6H); 1.35–1.25 (8H), 0.86 (*t*, 3H, *J* = 6.8); ^{13}C NMR (75 MHz) δ 173.8, 133.3, 133.2, 130.5, 130.4, 129.8, 129.4, 127.4, 126.6, 104.6, 84.1, 51.5, 49.3, 33.9, 32.5, 31.5, 30.4, 27.3, 27.2, 25.6, 23.0, 22.8, 22.5, 20.9, 14.0.

Methyl 5(*S*)-hydroperoxy-6*E*,8*E*,11*Z*,14*Z*-eicosatetraenoate (**3c**): R_f = 0.4 in 20% EA/hexane; ^{1}H NMR (300 MHz) δ 7.94 (*s*, 1H), 6.28 (*dd*, 1H, *J* = 15.3, 10.5), 6.04 (*t*, 1H, *J* = 15.0), 5.74 (*dt*, 1H, *J* = 15.0, 7.6), 5.52 (*dd*, 1H, *J* = 15.0, 8.1), 5.40 (4H), 4.42 (*q*, 1H, *J* = 7.6), 3.66 (*s*, 3H), 2.85 (*t*, 2H, *J* = 6.2), 2.78 (*t*, 2H, *J* = 6.2), 2.32 (*t*, 2H, *J* = 6.8), 2.04 (*q*, 2H, *J* = 6.8), 1.76–1.28 (10H), 0.88 (*t*, 3H, *J* = 6.8, Me).



Methyl 15(*S*)-[(1-methoxy-1-methylethyl)dioxy]-5*Z*,8*Z*,11*Z*, 13*E*-eicosatetraenoate (**4a**): R_f = 0.5 in 10% EA/hexane; ^{1}H NMR (300 MHz) δ 6.50 (*dd*, 1H, *J* = 15.3, 10.9), 6.00 (apparent triplet, 1H, *J* = 10.7), 5.64 (*dd*, 1H, *J* = 15.1, 8.0), 5.37 (*m*, 5H), 4.40 (*q*, 1H, *J* = 7.6), 3.66 (*s*, 3H), 3.28 (*s*, 3H), 2.95 (*t*, 2H, *J* = 6), 2.79 (*t*, 2H, *J* = 5.5), 2.30 (*t*, 2H, *J* = 7.6), 2.10 (*qt*, 2H, *J* = 7), 1.69 (*quintet*, 2H, *J* = 7.4), 1.46–1.25 (14H), 0.87 (*t*, 3H, *J* = 6.5); ^{13}C NMR (75 MHz) δ 174.1, 133.6, 130.1, 129.0, 128.7, 128.6, 128.2, 127.6, 127.5, 104.6, 84.7, 51.5, 49.2, 33.4, 33.0, 31.7, 26.5, 26.1, 25.6, 25.1, 24.7, 23.0, 22.8, 22.5, 14.1; high-resolution mass spectrometry calcd. for $C_{25}H_{42}O_5Li$ (M + Li) 429.3193, found 429.3207.

Methyl 15(*S*)-[(1-methoxy-1-methylethyl)dioxy]-5*Z*,8*Z*,11*E*, 13*E*-eicosatetraenoate (**4b**) was purified by NP–HPLC (7% EA/hexane): R_f = 0.6 in 20% EA/hexane; ^{1}H NMR (300 MHz) δ 6.19 (*dd*, 1H, *J* = 15.0, 10.4), 6.07 (*dd*, 1H, *J* = 14.8, 10.5), 5.68 (*dt*, 1H, *J* = 14.6, 6.4), 5.56 (*dd*, 1H, *J* = 15.0, 8.1), 5.40 (4H, olefinic), 4.34 (*q*, 1H, *J* = 7.6), 3.65 (*s*, 3H), 3.27 (*s*, 3H), 2.85 (*t*, 2H, *J* = 5.6), 2.78 (*t*, 2H, *J* = 6.2), 2.31 (*t*, 2H), 2.08 (*q*, 2H, *J* = 6.7), 1.69 (*quintet*, 2H, *J* = 7.4), 1.57–1.21 (14H), 0.86 (*t*, 3H, *J* = 6.8).

RESULTS AND DISCUSSION

This strategy was initially investigated with a monoperoxyketal (**1a**) ultimately derived from lipoxygenase-mediated dioxygenation of linoleic acid. No isomerization occurred upon either addition of 0.5 equivalent of diphenyldisulfide or brief photolysis with a Pyrex-filtered (λ ≥ 320 nm), medium-pressure Hg lamp, and photolysis of a deoxygenated diene/disulfide mixture led to simultaneous isomerization and decomposition. The apparent incompatibility between the monoperoxyketal and the intermediate thiyl radical led us to investigate the use of a milder catalyst. Addition of 1 mol% of I_2 to a $CHCl_3$ or CH_2Cl_2 solution of the perketal under fluorescent room lights led to diene equilibration. Prolonged reaction times or use of a more powerful light source resulted in elimination to a dienone. No reaction was observed in the dark. NMR analysis revealed an equilibrium mixture comprising approximately 80:20 mixture of the 9*E*,11*E*/9*E*,11*Z* isomers of monoperoxyketal **1b**. Acidic deprotection afforded a mixture of 9*E*,11*E*- and 9*Z*,11*E*-diene hydroperoxides. Similar results were observed for the isomerization of an eicosadienoate monoperoxyketal (**2a**).

HPLC purification of the mixture of hydroperoxides derived from **1b** afforded optically active 9*E*,11*E*-13-HPOD methyl ester (**1c**), which was converted to the enantiomer of coriolic acid as shown in Scheme 2 (15) [where a, PPh_3, EtOAc (85%); b, K_2CO_3, $MeOH/H_2O$ (85%)]. Comparison of the optical rotations indicate the enantiomeric excess of **1e**, and therefore **1c**, to be >90%; clearly, the isomerization does not affect the hydroperoxide-bearing carbon.

SCHEME 2

We next attempted application of this methodology to polyene hydroperoxides, substrates containing both conjugated and nonconjugated diene units. The monoperoxyketal of 5(*S*)-HPETE methyl ester (**3a**) underwent selective isomerization of the 6,8-diene to afford *E*,*E*-monoperoxyketal **3b**, which was deprotected to furnish the 8*E*-isomer of 5(*S*)-HPETE methyl ester (**3c**). Similarly, the monoperoxyketal of 15(*S*)-HPETE methyl ester (**4a**) underwent selective isomerization of the 11,13-diene to produce the 11*E* isomer **4b**. The lack of change in the ^{1}H NMR signals for the isolated *bis*allylic methylene groups (C_{13} in **3b** or C_7 in **4b**) verified the lack of isomerization at the nonconjugated diene subunits.

In summary, the reversible masking of diene hydroperoxides as their methoxypropyl peroxyketals is found to allow for chemoselective isomerization of the conjugated diene to produce *E*,*E*-diene hydroperoxides.

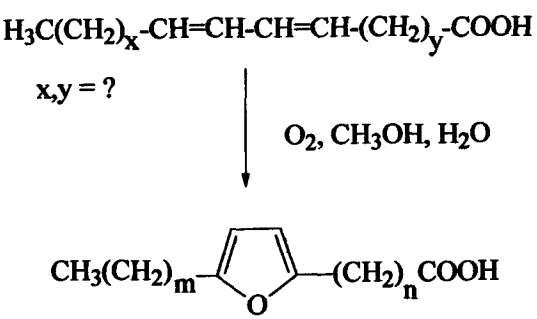
U.S. Food and Drug Administration, Center for Food Safety and Applied Nutrition, Washington, DC 20204

ABSTRACT: The objective of this study was to identify oxidation products of conjugated linoleic acid (CLA), a series of octadecadienoic acids with conjugated double bonds, which have been reported to have antioxidant and anticarcinogenic properties. Reference materials of CLA were oxidized in different concentrations of water/methanol; for example, 0.5 g octadecadienoic acid was dissolved in 50 mL methanol, and 100 mL water was added; this suspension was heated at 50°C and continuously aerated. Aliquots of 5 mL were taken over time, extracted with ether, treated with diazomethane and examined by gas chromatography/mass spectrometry and/or gas chromatography with flame-ionization detection. Products identified included the following furan fatty acids (FFAs): 8,11-epoxy-8,10-octadecadienoic; 9,12-epoxy-9,11-octadecadienoic; 10,13-epoxy-10,12-octadecadienoic; and 11,14-epoxy-11,13-octadecadienoic. Conjugated dienes should be considered as a possible source of FFAs, and CLA may have products common to furans in their overall oxidative scheme.



Lipids 30, 595–598 (1995).

"Conjugated linoleic acid" (CLA) is a term used to describe a group of octadecadienoic acids which contain two conjugated double bonds. Interest in CLA has been growing as a result of recently reported antioxidant (1) and anticarcinogenic (1–3) properties of these compounds.

It is not apparent from the structure of CLA isomers how these compounds could be effective antioxidants. CLA does not have a tautomeric form nor does it seem to have the functional group necessary to chelate metal ions. The oxidation products of conjugated fatty acids have been studied much less than their methylene-interrupted counterparts (4).

Previous oxidation studies of conjugated acids do not indicate that hydroxylation occurs to the extent that significant stable products are formed (4). The work described here attempted to characterize oxidation products of CLA by oxidizing a commercially obtained reference, nominally 9,11-octadecadienoic acid, a mixture of *cis* and *trans* isomers of an octadecadienoic acid.

Initial attempts to oxidize CLA in a methanol solution were unsuccessful; the soluble CLA was remarkably stable, e.g., there were no detectable products after days of attempted oxidation at 45°C. When enough water was added to produce a suspension, oxidation commenced. The oxidation then proceeded at a controlled and reproducible rate. Four furan fatty acids (FFAs), 8,11-epoxy-8,10-octadecadienoic ($F_{8,11}$); 9,12-epoxy-9,11-octadecadienoic ($F_{9,12}$); 10,13-epoxy-10,12-octadecadienoic ($F_{10,13}$); and 11,14-epoxy-11,13-octadecadienoic ($F_{11,14}$), as shown in Scheme 1, were identified by gas chromatography/mass spectrometry (GC/MS) and GC/matrix isolation (MI)/Fourier transform–infrared spectroscopy (FT–IR) when methylated ether extracts of an oxidized, commercially obtained CLA reference were examined by GC.

The compound $F_{9,12}$ has been found in *Exocarpus cupressiformis* as a plant lipid (5), and its oxidation and that of $F_{10,13}$ have been studied (6,7). FFAs with alkyl ring substitution have been found in latex (8), fish (9,10), plants (11), and bovine liver (12). The origin (13) and biological function (14,15) of their occurrence are active areas of current research. Although many compounds may result from the oxidation of FFAs (6) and undoubtedly other oxidation products of CLA, this work presents analytical data related only to the identification of the FFAs shown in Scheme 1.

MATERIALS AND METHODS

Diazomethane was prepared from Diazald (*N*-methyl-*N*-nitroso-*p*-toluenesulfonamide) according to Technical Information Bulletin No. AL-180, Aldrich Chemical Company (Milwaukee, WI). CLA, 9,11-octadecadienoic acid (manufacturer's assay: *c*-9,*t*-11/*t*-9,*c*-11 41%; *t*-10,*c*-12 44%; *c*-10,*c*-12 9.5%; *t*-9,*t*-11/*t*-10,*t*-12 1.3%; *c*-9,*c*-11 1%; *c*-9,*c*-12 0.7%) and other fatty acids and methyl esters were obtained from Nu-Chek-Prep, Inc. (Elysian, MN). CLA produced from alkali isomerization of safflower oil (assay: palmitic/oleic/stearic 30%; linoleic 0.5%; *c*-9,*t*-11-$C_{18:2}$/*t*-9,*c*-11-$C_{18:2}$ 29%; *t*-10,*c*-12-$C_{18:2}$ 32%; *c*-9,*c*-11-$C_{18:2}$ 2.4%; *c*-10,*c*-12-$C_{18:2}$ 2.7%; *t*-9,*t*-11-$C_{18:2}$/*t*-10,*t*-12-$C_{18:2}$ 4.8%) was obtained from Sou F. Chin (Food Research Institute, University of Wisconsin, Madison, WI). Organic solvents were redistilled-from-glass. Water was distilled and deionized. Cylinder air was breathing quality. Methyl $F_{9,12}$ was synthesized by a previously published procedure (16).

CLA oxidation. Stearic acid ($C_{18:0}$) or heptadecanoic acid ($C_{17:0}$) was sometimes used as the internal reference for the oxidations described below. CLA acids were exposed to varying amounts of air, water, and methanol. Several oxidations were performed similarly, with the following minor variations: *Oxidation 1* (OX_1): Fixed quantities of 75 mg CLA and 3.38 mg $C_{17:0}$ were dissolved in 1 mL methanol in test tubes; 0.0, 0.1, 0.2, 0.5, 1.0, or 2 mL water was added and the individual tubes, which contained air, were sealed and immersed in an oil bath and held at 45°C for 46 h. *Oxidation 2* (OX_2): 0.5 g CLA was dissolved in 50 mL methanol in a 250-mL Erlenmeyer flask with a stirring bar and air flowing through a pipette under the liquid surface at 100–200 mL/min. Then 100 mL water was added, and the suspension was heated on a stirrer-hot plate at temperatures varying from 48 to 69°C. The heat was turned off after 7.5 h, but restored 16 h later. Methanol/water (1:2) was added as needed to maintain a volume between 100 and 150 mL. Aliquots (5 mL) were taken hourly and examined after methylation. *Oxidation 3* (OX_3): Fixed quantities (e.g., 44.2 mg CLA and 3.22 mg $C_{18:0}$) were dissolved in 2 mL methanol in test tubes; a micro stirring bar and 4 mL water were added to each tube. The tubes were placed in an oil bath on a stirrer-hot plate and held at 40°C. Tubes were continuously stirred and aerated (2–5 mL/min). Methanol/water (1:2) was added as needed to maintain a volume between 4 and 6 mL. Individual tubes were removed from the oil bath at different times and examined after methylation.

Methylation procedure. To each aliquot in a test tube were added 5 mL saturated NaCl/water and 5 mL ethyl ether. The tube was vortexed for 30–60 s. The ether portion was dried over Na_2SO_4; 1 mL diazomethane in ether solution was carefully and slowly added to the dried ether portion. After 20 min, 1–2 drops of acetic acid were added to react with the remaining diazomethane. The solution was injected into the gas chromatograph without further cleanup.

Instrumentation. For GC, a Hewlett-Packard 5890A instrument was used under the following conditions: column, 50 m × 0.25 mm i.d. CP Sil 88 capillary (Chrompack, Raritan, NJ); helium carrier gas; flame-ionization detector (FID); temperatures, injector 220°C, detector 280°C, column 75°C for 2 min, then raised 20°C/min to 185°C and held for 33 min, then raised at 4°C/min to 225°C. Samples were run in both split and splitless modes.

Low-resolution electron ionization (EI) GC/MS analyses were obtained with a Hewlett-Packard 5890 series II gas chromatograph coupled to a Fissons VG (Wytheshawe, United Kingdom) Autospec Q mass spectrometer and OPUS 2000 data system. The GC/MS system used version 1.6C software.

The same capillary GC column was used to obtain FID data and GC/MS data. Adjusting the capillary GC column head pressure to 10 psi gave chromatography results comparable to the GC/FID data. The GC/MS conditions were as follows: splitless injection with helium sweep restored 1 min after injection; injector and transfer lines 250°C; oven 75°C for 2 min after injection, then 20°C/min to 185°C, hold 185°C 15 min, 4°C/min to 225°C, hold 225°C 5 min.

The mass spectrometer was tuned to a resolution of 1000 (5% valley) by observing *m/z* 305 in the EI mass spectrum of perfluorokerosene (PFK). The mass scale was calibrated with PFK for magnet scans from 440 to 44 daltons at 1 s per decade. Filament emission was 200 μA at 70 eV. Ion source temperature was 250°C. A TSQ-46 instrument was used for direct probe MS/MS by a procedure that has been described (17).

A Mattson Instruments Model Sirius 100 FT-IR spectrometer equipped with an MI Cryolect interface operated at 10 K under vacuum was used with GC to obtain IR spectra. This system, which was used with a CP-Sil-88 capillary column, has been described in detail (18).

The supercritical fluid chromatography (SFC)/FT–IR system has been previously described in detail (19). Spectra were obtained by using a 25% cyanopropylsiloxane column, 100 μm i.d., with the following density (CO_2) gradient: 0.18 g/mL, hold for 20 min, then from 0.18 to 0.80 g/mL at 0.02 g/mL/min, hold for 5 min. Test solutions were injected from the OX_2 experiment without prior methylation.

RESULTS AND DISCUSSION

The oxidized CLA was treated with diazomethane to obtain methyl esters prior to GC analysis. In initial experiments, it was observed that CLA was very stable in methanol solutions

and the experiment OX_1 was performed to determine if the addition of water would speed up oxidation. No FFAs or other volatile compounds were detected when methanol or 10% water/methanol was used as the solvent. The amounts of FFA produced with increasing percentages of water are as follows: 1.9 mg FFA with 20% water; 2.8 mg FFA with 33% water; 3.0 mg FFA with 50% water; and 2.3 mg FFA with 67% water. It was observed that the better the suspension of CLA acid was, the greater the yield of FFAs.

The chromatogram in Figure 1 shows the FFAs produced after 26.5 h of oxidation by the OX_1 procedure. The major components eluting before CLA include aldehydes, methylated short-chain fatty acids and aldehyde-acids. The FFA esters were identified by mass spectrometry. The general scheme for identifying FFA methyl esters has been reported (20). The molecular ion, *m/z* 308, and the furanyl ring with 0, 1, or 2 methylene groups, *m/z* 67, 81, and 95, respectively, are characteristic of the fatty acid methyl esters (FAMEs) of all the FFAs shown in Scheme 1. The ions characteristic of the specific furan isomers, $[M^+\text{-}(CH_2)_{n-1}CO_2CH_3]$ and $[M^+\text{-}(CH_2)_{m-1}CH_3]$, respectively, and their intensities in parentheses are as follows: $F_{8,11}$, *m/z* 179(100), *m/z* 223(20); $F_{9,12}$, *m/z* 165(100), *m/z* 237(18); $F_{10,13}$, *m/z* 151(100), *m/z* 251(18); and $F_{11,14}$, *m/z* 137(100), *m/z* 265(14). The identity of the FFA methyl ester $F_{9,12}$ was confirmed by comparison of its GC retention time and mass spectrum with those of a synthesized reference material (16).

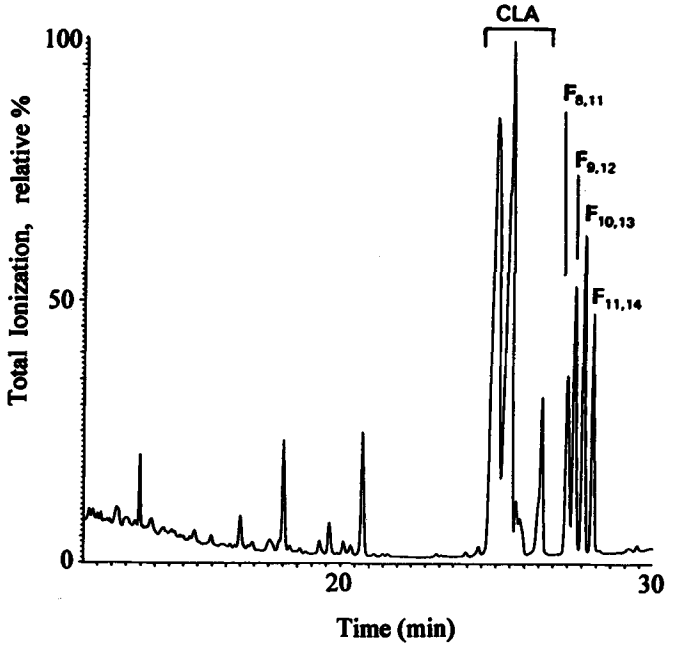

FIG. 1. Chromatogram with total ion mass spectrometry detection after 26.5 h of oxidation of conjugated linoleic acid (CLA) isomers by the Oxidation 2 method (details in Materials and Methods section). Retention regions where methyl esters of CLA and furan fatty acids elute are indicated; earlier responses are due to aldehydes and short-chain fatty acid methyl esters (FAMEs) and aldehyde-acid FAMEs. Methyl esters of $F_{8,11}$, 8,11-epoxy-8,10-octadecadienoic acid; $F_{9,12}$, 9,12-epoxy-9,11-octadecadienoic acid; $F_{10,13}$, 10,13-epoxy-10,12-octadecadienoic acid; $F_{11,14}$, 11,14-epoxy-11,13-octadecadienoic acid.

GC/MI/FT–IR spectra were similar for the CLA oxidation products and the synthesized $F_{9,12}$. The frequencies (4 cm^{-1} resolution) characteristic of the furan that we observed were assigned as follows: 3111, 3031, and 3000 cm^{-1} for =C–H stretch; 1574 cm^{-1} for C=C stretch; 1013 cm^{-1} for C–O stretch; and 780 cm^{-1} for =C–H out-of-plane bend.

The increase in FFA and the decrease in CLA concentration with time (OX_3) are shown in Figure 2. At 46 h, the total of the furan FAMEs amounted to 3.2% of the starting amount of CLA used in this experiment. It is clear from the plot (Fig. 2) that the majority of the mass balance is not accounted for by formation of furans and loss of CLA alone. A plausible explanation, which we intend to investigate, is that under these oxidative conditions the furans are less stable than the CLA isomers from which they may arise. Aldehydes and esters of short- and medium-chain fatty acids and aldehyde-acids may account for a majority of the remaining unaccounted mass, but no effort was made to recover them from the oxidation mixtures.

The CLA produced from alkali isomerization of safflower oil, when oxidized (OX_2), produced only $F_{9,12}$ and $F_{10,13}$. The compositions of the two CLA reference materials that we oxidized differ in the distribution of octadecadienoic acid *cis/trans* isomers. Both reference materials were produced by alkali isomerization of the linoleic fatty acid moiety. The Nu-Chek-Prep assay was performed for only one lot and may not necessarily represent the actual isomeric distribution in the test portion that we examined. It is possible that the FFAs produced may be better indicators of the original CLA composition; hence, in Scheme 1, m = x and n = y. At this time, we do not know how the furans are formed, and the results of these experiments should not be freely extrapolated to other matrices containing CLA.

Researchers have previously shown that FFAs may arise from precursor compounds (e.g., methyl-9,12-dioxo-stearate) when the precursor is injected into a gas chromatograph (10).

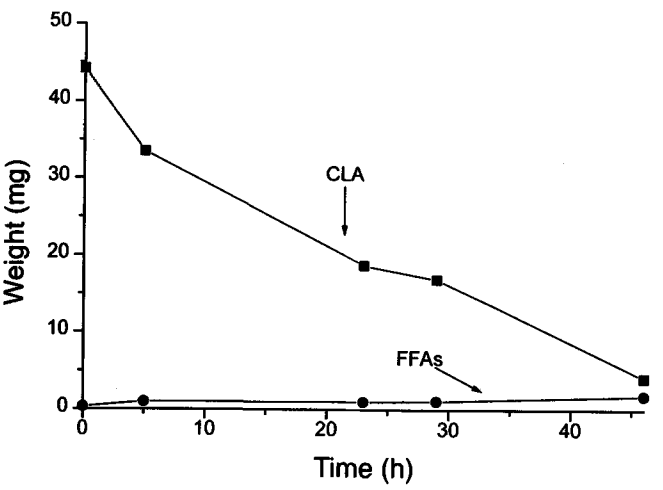

FIG. 2. Abundance of conjugated linoleic acid (CLA) and furan fatty acid (FFA) methyl esters as a function of oxidation time at 40°C, Oxidation 3 method (details in Materials and Methods section); weight is based on stearic acid, which was included in the oxidation.

Furans are also known to arise as a result of dehydration of endoperoxides (21). We do not know the extent to which such precursors may be present in the CLA oxidation mixtures; however, the presence of the furans in methylated and unmethylated CLA oxidation mixtures was confirmed. The presence of furan acids in the unmethylated OX_2 mixture was confirmed by SFC/FT–IR; the major bands expected for the furan acids were observed, and the –C=C– stretch at 1574 cm^{-1} was especially characteristic. The methyl esters of the four FFAs shown in Figure 1 were also confirmed to be present in the methylated, oxidized mixture by direct probe MS/MS. The ions *m/z* 137, 151, 165, and 179 were determined to be daughter ions of the *m/z* 308 methyl FFA parent ion.

It turns out that the same reaction products described in the above experiments are produced by merely exposing neat CLA or CLA methyl esters to ambient air. The greatly improved stability of CLA in solution may be related to its antioxidant properties, i.e., it will readily react, when solvated, only with oxidants that are more reactive than those found in ambient air. The formation of FFAs from conjugated diene systems is known to occur when singlet oxygen is used as a reactant (21). It was surprising that FFAs were produced in the experiments described here, because singlet oxygen was not deliberately introduced into any of the systems described. Oxidation products of conjugated dienes should be considered as a source of FFAs in biological systems.

Experiments are ongoing to establish the mass balance in the described oxidations, and to determine the relationship of the FFAs produced to the specific isomers of octadecadienoic acid used as starting materials.

Reinvestigation of the Antioxidant Properties of Conjugated Linoleic Acid

Jeroen J.M. van den Berg[a,*], Nancy E. Cook[a] and Diane L. Tribble[b]

[a]Children's Hospital Oakland Research Institute, Oakland, California 94609 and [b]Department of Molecular and Nuclear Medicine, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT: Despite repeated suggestions that antioxidant activity of conjugated linoleic acid (CLA), a collective of conjugated dienoic isomers of linoleic acid, underlies its reported anticarcinogenic and antiatherosclerotic effects, the antioxidant properties of CLA remain ill-defined. Therefore, this study was undertaken to gain more insight into the mechanism of potential CLA antioxidant activity. It was tested whether CLA could protect membranes composed of 1-palmitoyl-2-linoleoyl phosphatidylcholine (PLPC) from oxidative modification under conditions of metal ion-dependent or -independent oxidative stress. Progress of oxidation was determined by direct spectrophotometric measurement of conjugated diene formation and by gas chromatographic/mass spectrometric analysis of fatty acids. The oxidative susceptibility of CLA was higher than that of linoleic acid, and comparable to arachidonic acid. When oxidation of PLPC (1.0 mM) was initiated using the lipid-soluble 2,2′-azo*bis*(2,4-dimethylvaleronitrile) or the water-soluble 2,2′-azo*bis*(2-amidinopropane) hydrochloride, the radical scavengers vitamin E and butylated hydroxytoluene (BHT) at 0.75 μM efficiently inhibited PLPC oxidation, as evident from a clear lag phase. In contrast, 0.75 μM CLA did not have any significant effect on PLPC oxidation. Inhibition of PLPC oxidation by higher concentrations of CLA appeared due to competition, not to an antioxidant effect. When oxidation of PLPC was initiated by hydrogen peroxide/Fe^{2+} (500 μM/0.05–20 μM), both vitamin E (1 μM) and ethylene glycol-*bis*(aminoethyl ether) tetraacetic acid (50 μM) efficiently inhibited PLPC oxidation. However, CLA (1–50 μM) did not show a clear protective effect under any of the conditions tested. We conclude that CLA, under these test conditions, does not act as an efficient radical scavenger in any way comparable to vitamin E or BHT. CLA also does not appear to be converted into a metal chelator under metal-ion dependent oxidative stress, as had previously been suggested. On the basis of our observations, a role for CLA as an antioxidant does not seem plausible.

Lipids 30, 599–605 (1995).

"Conjugated linoleic acid" (CLA) is a collective term to describe positional and geometric isomers of linoleic acid (9,12-*cis,cis*-octadecadienoic acid, LA) with conjugated double bonds at carbon atoms 10 and 12 or 9 and 11, and with all possible *cis* and *trans* combinations. Although conjugation of double bonds occurs as part of free radical-mediated oxidation of LA, CLA is a true isomer of LA, in that it does not possess an additional oxygen. Low concentrations of CLA can be found in human blood and tissues (1–6). Its presence may be accounted for *via* two possible pathways. First, CLA may be produced *in vivo* from free radical-mediated oxidation of LA (1,6). Hydrogen abstraction by a free radical species and subsequent diene conjugation produces an LA lipid radical with conjugated diene structure. In the presence of protein, the LA radical may react with protein instead of molecular oxygen, giving rise to a CLA molecule and a protein radical. Second, CLA in human tissues may be derived from dietary sources, as certain foodstuffs, such as fried ground beef and dairy products, have been shown to contain significant amounts of CLA (7–10).

There is a large and growing body of evidence indicating that free radicals and radical-mediated oxidation processes play a role in many pathological conditions, including cancer and atherosclerosis. Thus, considerable effort is invested in the search for natural and synthetic antioxidants that may help prevent or treat these disease states. CLA has been identified as a potent anticarcinogen in a number of model systems (8,11–16), and antioxidant activity has been offered as a possible explanation for its anticarcinogenic effect (11,13,17). Moreover, it also has been suggested that antioxidant properties of CLA may be involved in the observed reduction in atherosclerosis in CLA-fed rabbits (18). However, the information available to date suggests antioxidant activity of CLA is not unambiguous. One study reported that CLA acted as an antioxidant more powerful than α-tocopherol and comparable to butylated hydroxytoluene (BHT) (11). This study, however, was performed using free fatty acids in a phosphate buffer/ethanol mixture (60:40, vol/vol), which is obviously very dissimilar to biological systems. Another study reported antioxidant activity of CLA in rats *in vivo* (13). Unfortunately, the only measure of oxidative damage employed was the thiobarbituric acid-reactive substances assay, a method

known to be indirect and not specific. In addition, CLA antioxidant activity in this study was observed in mammary gland tissue, but not in liver. Also, CLA antioxidant activity was independent of its concentration, and tenfold lower concentrations of vitamin E and butylated hydroxyanisole had a more pronounced effect.

It thus appears that insufficient experimental evidence has been accumulated to substantiate the descriptions of CLA as an *in vitro* and *in vivo* antioxidant. In view of the purported importance of antioxidant activity of CLA in its reported anticarcinogenic and antiatherogenic effects, we considered it essential to reinvestigate CLA's antioxidant potential using defined model systems and more precise analytical methodology. The present studies were undertaken to assess the antioxidant potential of CLA in a model system with phospholipid membranes composed of 1-palmitoyl-2-linoleoyl phosphatidylcholine (PLPC). These membranes were subjected to various types of metal ion-dependent, as well as metal ion-independent oxidative stress, and the effect of CLA was compared with that of vitamin E, BHT, and EGTA.

MATERIALS AND METHODS

Chemicals. 1-Palmitoyl-2-oleoyl phosphatidylcholine (POPC) and PLPC were obtained from Avanti Polar Lipids (Alabaster, AL). 2,2′-Azo*bis*(2,4-dimethylvaleronitrile) (AMVN) and 2,2′-azo*bis*(2-amidinopropane) hydrochloride (AAPH) were from Polysciences (Warrington, PA). BHT and dl-α-tocopherol were purchased from Sigma (St. Louis, MO). Hydrogen peroxide, ferrous ammonium sulfate, and cupric sulfate were obtained from Fisher (San Francisco, CA). CLA was a kind gift of Dr. J. Scimeca at Kraft General Foods (Glenview, IL). CLA was a mixture of isomers with the following composition: 9,11 *(cis,trans)* and 9,11 *(trans,cis)* CLA, 42.2%; 10,12 *(trans,cis)* CLA, 44.2%; 9,11 *(cis,cis)* CLA, 2.2%; 10,12 *(cis,cis)* CLA, 1.4%; 9,11 *(trans,trans)* and 10,12 *(trans,trans)* CLA, 2.3%; 9,12 *(cis,cis)* LA, 4.3%; unidentified, 3.4%. Pure 9,11 *(trans,trans)* CLA and margaric acid (17:0) were obtained from Matreya (Pleasant Gap, PA). CLA stock solutions were made up in ethanol and stored under argon at −20°C. To check the CLA concentration, an absorption spectrum was recorded from 200–300 nm after appropriate dilution, and the CLA concentration was calculated using an average molar extinction coefficient of 27,500 for the absorption maximum at 230–234 nm. All solvents used were of high-performance liquid chromatography grade, and chemicals used were of the highest purity available.

Oxidation of LA and CLA in air. For separate incubations of LA and CLA, a dichloromethane/methanol (1:1) solution containing 0.5 mg LA plus 0.7 mg margaric acid (17:0), or 0.5 mg CLA (mixed isomers) plus 0.7 mg 17:0, was dried down in a roundbottom flask on a rotary evaporator. For incubation of a mixture of LA and CLA together, the solution contained 0.25 mg LA, 0.25 mg CLA, and 0.7 mg 17:0. The dried lipid film in the flask was exposed to air at room temperature. At certain time points, the lipid was dissolved in 2 mL methanol, and duplicate 50-μL samples were taken for gas chromatography/mass spectrometry (GC/MS) analysis of fatty acids. The remaining incubation mixture in the flask was dried down again and further exposed to air. To the sample, 100 μL 0.1 mM BHT was added to stop the oxidation. The methanol was evaporated under nitrogen, and fatty acids were derivatized to the corresponding trimethylsilyl esters by adding 50 μL acetonitrile, 100 μL *bis*(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane (Pierce, Rockford, IL), and incubating at 50°C for 20 min. GC/MS analysis was then performed on a Hewlett-Packard (Palo Alto, CA) 5890 Gas Chromatograph coupled to a Hewlett-Packard 5971 Mass Selective Detector under analytical conditions as described before (19) with the exception of a slightly modified temperature program. The initial oven temperature of 50°C was retained for 2 min after injection, then increased to 160°C at a rate of 30°C/min, and subsequently increased to 320°C at a rate of 4°C/min. Loss of LA and CLA due to oxidation was calculated relative to 17:0 (nonoxidizable internal standard).

Metal-independent oxidation of PLPC membranes and effect of antioxidants. The antioxidant activities of CLA, vitamin E (α-tocopherol), and BHT were tested using unsaturated phospholipid model membranes (PLPC vesicles) that were exposed to a steady flux of oxyradicals generated in the lipid phase (AMVN) or in the water phase (AAPH). Unilamellar PLPC vesicles were produced by the ethanol-injection technique (20) as follows. PLPC (2.0 μmol), the appropriate amounts of CLA (mixed isomers), dl-α-tocopherol, or BHT, and AMVN (1.0 μmol) were mixed from stock solutions before each experiment, dried down under nitrogen, and redissolved in a total volume of 70 μL ethanol. This was injected into 2 mL of buffer (10 mM Tris, 150 mM NaCl, pH 7.4, containing 25 μM EGTA) at 40°C in a quartz cuvette with magnetic stirring. When AAPH was used as oxidant, it was not included in the lipid mixture in ethanol, but added to the vesicle suspension from a fresh and cold stock solution in buffer. After 2 min equilibration, the absorbance at 233 nm was zeroed using the complete mixture as its own reference, and absorbance was subsequently monitored in time using a Milton-Roy (Rochester, NY) Spectronic 3000 diode array spectrophotometer. Measurement of absorbance at 233 nm is a direct and sensitive indicator of conjugated diene formation due to oxidation of PLPC substrate, and is frequently used to monitor lipoprotein and model membrane oxidation (21–23). Under the present conditions, an absorbance reading at 233 nm of 0.1 translates into a conjugated diene concentration of approximately 4 μM (using $\varepsilon = 25{,}000\ M^{-1}cm^{-1}$), or an extent of bulk lipid oxidation (1 mM PLPC) of only 0.4%. In some control experiments, POPC vesicles were used instead of PLPC. When fatty acid analysis was called for, samples were taken and processed as described below.

Metal-dependent oxidation of PLPC membranes and effect of antioxidants. PLPC vesicles were prepared by ethanol injection as above. The buffer used in these experiments was 0.5 M sodium phosphate, pH 8.0, and incubations were carried out in glass tubes at room temperature. Hydrogen perox-

ide and Fe^{2+} (ferrous ammonium sulfate) were added from fresh stock solutions at the indicated time points. Samples were taken at specific time points for measurement of 233 nm absorbance (formation of conjugated dienes) using buffer as a blank, and for fatty acid analysis as described below.

Sample processing for fatty acid analysis. At chosen time points during the oxidation of PLPC or POPC vesicles, duplicate 200 µL samples were taken for GC/MS analysis of fatty acids. To stop oxidation, 10 nmol BHT was added to the samples, and 17:0 plus 9,11*(trans,trans)* CLA, a CLA isomer that is virtually absent in the CLA isomer mixture used to test antioxidant activity, were added as internal standards. Samples were processed on ice as much as possible. After adding 1.7 mL deionized water and 100 µL 80 mM HCl, samples were vortex-mixed and extracted three times with 2 mL ethyl acetate. The combined extracts were dried down in a screw-capped tube under nitrogen. In order to prepare fatty acid methyl esters, 200 µL dichloromethane and 800 µL anhydrous methanolic HCl (2 M) was added, the tubes were sealed under nitrogen and left at room temperature for 18 h. Although methylation of fatty acids with methanolic HCl can be achieved much more rapidly when heating the sample (e.g., 85°C for 1 h), we found that the combination of acid and heat results in changes in the CLA isomer distribution pattern, as also found by others (Dr. E.A. Decker, private communication). Methylation with methanolic HCl at room temperature was found to preserve the isomer distribution of the CLA isomer mixture and to esterify free fatty acids as well as glyceride-bound fatty acids.

Finally, 1 mL of water was added to the samples, and fatty acid methyl esters were extracted three times with 2 mL hexane. The pooled hexane extracts were dried down to approximately 100 µL and analyzed by GC/MS as described above. In order to accurately quantify the very small amounts of CLA present in some samples, the mass spectrometer was operated in selected ion monitoring mode, and the molecular ion at *m/z* 294 was used to quantify CLA.

RESULTS AND DISCUSSION

To test whether CLA may act as an antioxidant, two possible antioxidant modes of action for CLA were considered. Our experiments addressed (i) whether CLA could act as a radical scavenging antioxidant, such as vitamin E, or (ii) whether CLA is converted into an antioxidant metal chelator, such as EGTA, under oxidative stress. Oxidative modification of CLA into a metal chelator that subsequently stops radical generation has been suggested to explain the potent antioxidant activity of CLA observed in a previous study (11). For either mode of action, it is important for CLA to be substantially more reactive toward radicals than the substrate it is to protect. Obviously, a radical scavenger should be able to act as a radical sink in order to protect the substrate from radical attack. Likewise, the putative metal chelator formed upon oxidation of CLA should be formed rapidly, before extensive oxidative damage to the substrate has occurred. In view of the proposed relationship between oxidative modification of low-density lipoproteins (LDL) and atherogenesis, we used LA as oxidizable substrate in our experiments, either as free acid or esterified in phospholipid. LA is a major polyunsaturated fatty acid in many tissues, and the major oxidizable fatty acid in LDL.

To assess the oxidative susceptibility of CLA relative to LA, each fatty acid individually [in the presence of margaric acid (17:0) as a nonoxidizable internal standard] was exposed to air. The progress in oxidation was measured by GC analysis of fatty acids after sampling and derivatization as described in the Materials and Methods section. Figure 1A shows that CLA

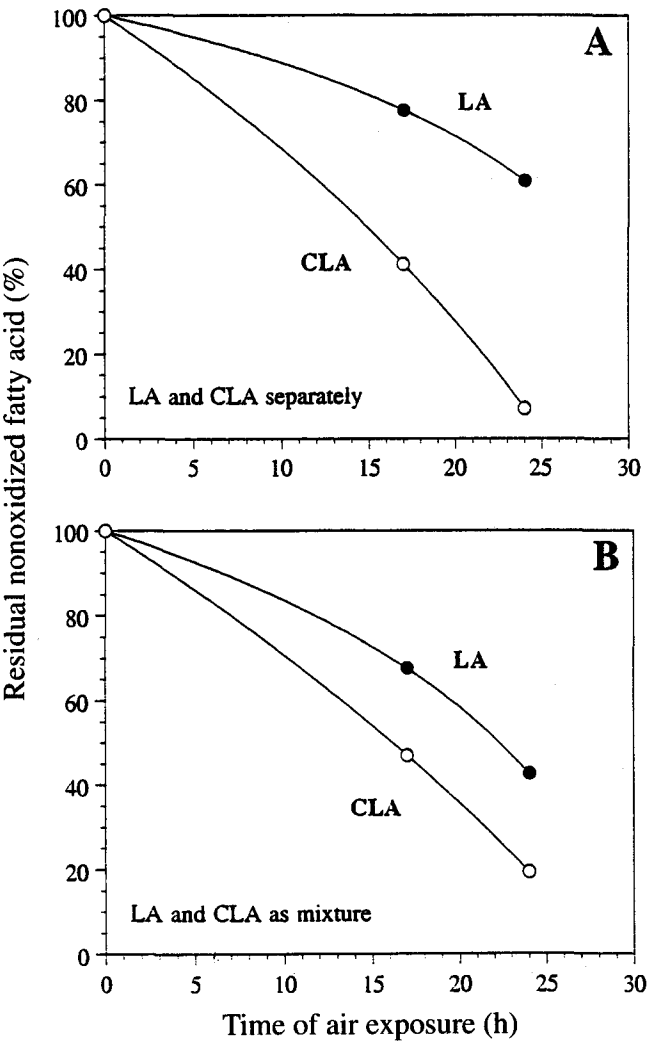

FIG. 1. Oxidation of linoleic acid (LA) (●) and conjugated linoleic acid (CLA) (○) in air when incubated separately (A) and together (B). Lipid in organic solution was dried down in a roundbottom flask on a rotary evaporator and subsequently exposed to air at room temperature. Samples were taken at various time points and the extent of fatty acid substrate loss due to oxidation was determined by gas chromatography/mass spectrometry using 17:0 as a nonoxidizable internal standard. Data points are the mean of duplicate samples. The data spread for each point was within the size of the symbol. The CLA results represent the combined values for individual isomers present in the isomer mixture. Oxidation rates for individual CLA isomers were found to be virtually identical.

was indeed oxidized considerably faster than LA when incubated separately. When exposing a mixture of CLA, LA, and 17:0 to air (Fig. 1B), the order of oxidative susceptibilities was the same, but there was a significant difference. Compared with the separate CLA and LA incubations, the oxidation rate of LA in the CLA/LA mixture had increased, whereas the oxidation rate of CLA had decreased. Additional experiments in which a mixture of LA, CLA, and arachidonic acid (20:4) was present as oxidizable substrate revealed that the oxidative susceptibility of CLA is similar to that of 20:4 (results not shown). Thus, it would appear that, although CLA is more susceptible to oxidation than LA, the difference in oxidative susceptibility between CLA and LA is insufficiently large for CLA to be an efficient antioxidant. In fact, the data in Figure 1B suggest that CLA may even act as a prooxidant, at least under these nonphysiological conditions.

These data are in disagreement with previous reports suggesting that air oxidation of CLA proceeds more slowly than air oxidation of LA (8,11). In those studies, however, a peroxide oxidation product was measured to follow the course of the reaction. As the double bonds in CLA and LA have a different configuration, oxidation of these two fatty acids may proceed *via* different mechanisms and/or give different oxidation products. Assaying for a particular oxidation product instead of measuring the remaining nonoxidized substrate thus may give a misleading picture of the oxidation process. Furthermore, one would expect on theoretical grounds that a conjugated double bond system is more susceptible to radical attack than a nonconjugated double-bond system. We have shown this for the oxidative susceptibility of parinaric acid (18:4), which contains four conjugated double bonds, compared with 20:4, which contains four nonconjugated double-bonds (24).

In a more direct measure of antioxidant potential, PLPC membranes were exposed to oxidative stress, and a spectrophotometric assay of diene conjugation was used to assess the effects of incorporated CLA, α-tocopherol, and BHT. Because CLA itself already contains a conjugated diene structure that can potentially interfere with this measurement, control experiments were performed to assess the behavior of the conjugated double bonds of CLA under AMVN- or AAPH-induced oxidative stress. To that end, vesicles composed of POPC (1.0 mM) plus 0.5 mM AMVN were prepared by ethanol injection (see Materials and Methods section). As the oleoyl chain in POPC contains only one double bond, it cannot form a conjugated diene upon oxidation. Figure 2 shows that a very slight decrease in absorbance occurred over the course of 1 h, probably as a result of the decomposition of AMVN. POPC vesicles containing 25 μM CLA show an elevated initial absorbance at 233 nm of approximately 0.6, which is caused by the conjugated diene structure of CLA. After 1 h of AMVN-induced oxidative stress, fatty acid analysis by GC/MS indicated that approximately 35% of the CLA was lost due to oxidation. No significant change in absorbance was observed during that time, indicating that CLA retains its conjugated diene structure upon oxidation in this

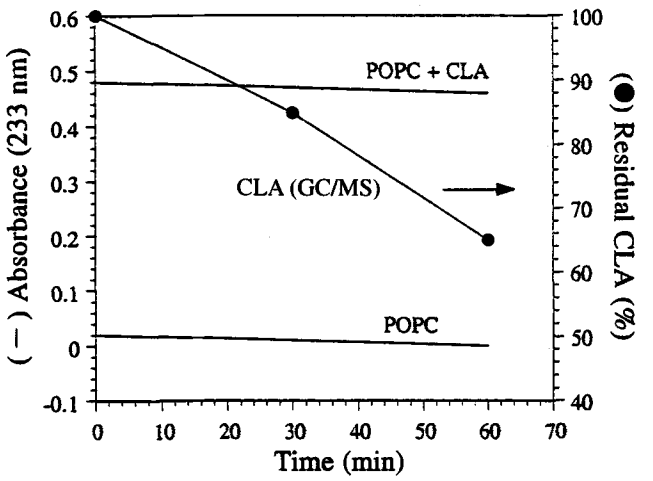

FIG. 2. CLA retains diene conjugation upon 2,2′-azo*bis*(2,4-dimethylvaleronitrile (AMVN)-mediated oxidation. Solid lines: continuous monitoring of absorbance at 233 nm. 1-Palmitoyl-2-oleoyl phosphatidylcholine (POPC): control experiment where the absorbance at 233 nm of 1 mM POPC membranes plus 0.5 mM AMVN was monitored in time. POPC + CLA: 1 mM POPC membranes containing 25 μM CLA (mixed isomers) plus 0.5 mM AMVN. (●) Residual nonoxidized CLA determined by gas chromatography/mass spectrometry (GC/MS) analysis of samples taken from the incubation of 1 mM POPC membranes containing 25 μM CLA plus 0.5 mM AMVN. POPC vesicles were prepared by injection of an ethanolic solution containing the appropriate lipid mixture into Tris buffer, pH 7.4. GC/MS data points represent the mean of duplicate determinations. Other abbreviation as in Figure 1.

system. Therefore, the 233 nm absorbance measurements in the PLPC experiments reflect PLPC oxidation, and CLA oxidation or decomposition of AMVN does not interfere with the measurement, to any significant degree.

Oxidation of PLPC vesicles by AMVN-derived radicals resulted in a steady increase in 233 nm absorbance in time; a representative experiment is shown in Figure 3. GC/MS analysis of fatty acids in sample lipid extracts after reduction with sodium borohydride, alkaline methylation, and trimethyl silyl derivatization (25) indicated that the increased absorbance at 233 nm was caused by an isomeric mixture of LA hydroperoxides with the hydroperoxy moiety either in the 9-position (10,12-diene) or in the 13-position (9,11-diene) (results not shown). In the presence of 0.75 μM α-tocopherol, the formation of conjugated dienes was almost completely suppressed during a lag phase, then gradually increased (presumably after α-tocopherol had been consumed). BHT (0.75 μM) appeared more effective than vitamin E in suppressing PLPC oxidation. In contrast, 0.75 μM CLA in the PLPC vesicles did not result in a lag phase in PLPC oxidation. PLPC oxidation after 1 h of oxidative stress in the presence of 0.75 μM CLA was only marginally lower than without CLA. These results indicate that α-tocopherol and BHT are excellent radical-scavenging antioxidants, and that CLA is not effective at all in that respect.

Increasing the concentration of α-tocopherol or BHT present in the vesicles resulted in a proportional increase in the duration of the lag phase in PLPC oxidation (not shown). As

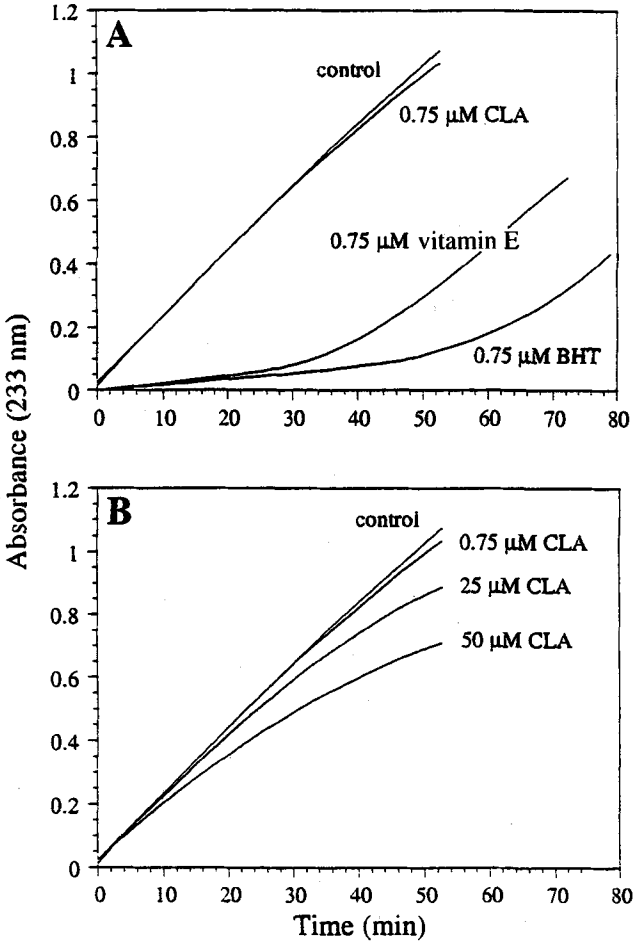

FIG. 3. Effect of CLA, vitamin E, and butylated hydroxytoluene (BHT) on AMVN-mediated oxidation of 1-palmitoyl-2-linoleoyl phosphatidylcholine (PLPC) membranes. (A) Comparative effect of 0.75 μM of CLA (mixed isomers), vitamin E (dl-α-tocopherol), and BHT on PLPC oxidation as monitored by conjugated diene formation. (B) Effect of increasing CLA concentrations on PLPC oxidation. PLPC vesicles (1 mM) were prepared by injection of an ethanolic solution containing the appropriate amounts of PLPC, antioxidant, and AMVN into Tris buffer, pH 7.4. In each experiment, the aborbance at 233 nm was zeroed using the complete mixture as its own reference after allowing 2 min for equilibration. Other abbreviations as in Figures 1 and 2.

shown in Figure 3B, increased concentrations of CLA did proportionally reduce the rate of PLPC oxidation, but a lag phase was not observed at any concentration. GC/MS analysis of fatty acids confirmed that the observed reduction in PLPC oxidation at higher CLA concentrations was due to CLA increasingly competing with LA for available radicals, an effect similar to what could be achieved by adding 20:4 instead of CLA. This would not qualify as a true antioxidant effect unless CLA lipid radicals are not reactive (which they do appear to be, see Fig. 1B), or a specific detoxification mechanism exists for CLA radicals (which is entirely speculative at this point). Generating radicals in the water phase instead of in the lipid phase by using AAPH instead of AMVN yielded very similar results (not shown) and led to the same conclusions as described above.

Subsequent experiments addressed whether CLA could be converted into an antioxidant when exposing PLPC membranes to metal ion-dependent oxidative stress. Figure 4 shows a representative experiment in which oxidative stress was produced by hydrogen peroxide (0.5 mM) plus Fe^{2+} (20 μM). Vitamin E (1 μM) in the vesicle membranes was able to temporarily suppress PLPC oxidation, and 50 μM EGTA prevented lipid oxidation altogether. CLA, however, did not appear to have a protective effect at either 1, 10 (Fig. 4A,B), or 50 μM (not shown). GC/MS data confirmed that CLA was oxidized faster than LA (Fig. 4C), but following the same oxidation pattern as LA. As oxidation of PLPC did not stop or slow down considerably upon oxidation of CLA, apparently CLA was not converted into an antioxidant under these conditions. Many additional experiments were performed in which the reaction conditions were varied. Substituting Tris buffer for phosphate buffer resulted in overall faster oxidation, but did not affect the basic results. Other changes involved variation of the Fe^{2+} concentration from 0.1–20 μM, using Cu^{2+} (0.05–10 μM) instead of Fe^{2+}, using tert-butyl hydroperoxide instead of hydrogen peroxide, and varying CLA concentrations from 1–10 μM. No unequivocal antioxidant effect of CLA could be demonstrated under any of these test conditions, whereas vitamin E and EGTA always exhibited strong antioxidant activity. Therefore, the combination of a peroxide plus transition metal ions, which is a frequent choice of oxidant in model studies and probably a relevant combination *in vivo*, apparently did not give rise to the formation of a potent antioxidant as a result of oxidation of CLA.

In overview, we have not been able to show any clear antioxidant properties of CLA under a variety of experimental conditions. The primary reason why CLA was ineffective appears to be that CLA is insufficiently reactive toward radicals for it to either act as a radical scavenger comparable to vitamin E, or to be rapidly converted into an antioxidant compound as previously proposed (11). The fatty acid oxidation kinetics observed in the present study indicate that CLA behaves similarly to other polyunsaturated fatty acids under oxidative stress. We did not make a detailed study of reaction products formed but, in terms of oxidative susceptibility, CLA was moderately more susceptible than LA, and comparable to 20:4. In a physiological setting, this would mean that, during conversion of CLA into the putative antioxidant chelator (a multi-step process!), significant oxidative damage to LA chains of membrane lipids would likely occur, with even more extensive degradation of arachidonoyl and higher unsaturated fatty acyl chains that are present in biological tissues, including LDL. By the time antioxidant activity of CLA started to have an effect, it would probably be too late.

On a philosophical note, it may even be argued that sequestering transition metal within the lipid phase, as could result from chelation of metal by a CLA oxidation product, could have the opposite of a protective effect. Iron delocalization has been proposed to contribute to increased oxidative stress in a number of pathological conditions, among which sickle cell anemia is a prominent example (26). There-

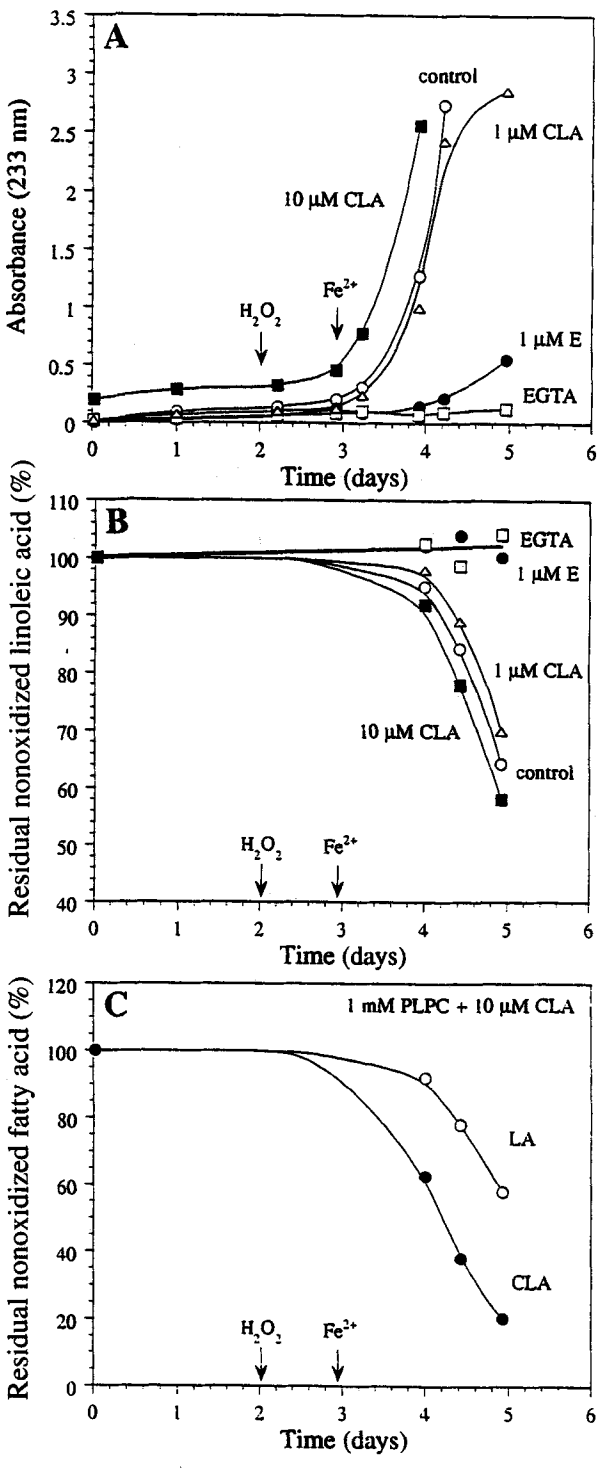

FIG. 4. Effect of CLA, vitamin E, and EGTA on oxidation of PLPC membranes initiated by H_2O_2/Fe^{2+}. (A) Formation of conjugated dienes. (B) Loss of LA as determined by GC/MS analysis of fatty acids in samples taken from the incubation mixture. PLPC vesicles: prepared by ethanol injection of the appropriate lipid mixture in 0.5 M phosphate buffer, pH 8.0. PLPC final concentration was 1.0 mM with 1.0 or 10 μM CLA (mixed isomers) or 1 μM vitamin E where indicated. EGTA (50 μM) was added to buffer before preparation of vesicles. Mixtures were incubated in glass tubes at room temperature. H_2O_2 (500 μM) and Fe^{2+} (20 μM) were added as indicated. (C) Comparison of oxidation of LA and CLA in experiment with 10 μM CLA in 1 mM PLPC vesicles. GC/MS data points represent mean of duplicate determinations. Other abbreviations as in Figures 1 and 3.

fore, unless the metal ion is chelated in a way that also makes it redox-inactive, the binding of metal ion by a CLA oxidation product could potentially be more harmful than protective.

Previously, CLA antioxidant activity had been observed in mammary gland, but not liver tissue of the rat (13). That study employed the widely used, but error-prone thiobarbituric acid-reactive substances assay. Also, CLA antioxidant activity was significant, but not impressive, and did not appear to be concentration-dependent, whereas its anticarcinogenic activity was. The most potent CLA antioxidant activity was observed in the fatty acid model system described in the Introduction section (11), which contained 40% ethanol. Questions may arise with regard to the validity of the observations in that study, since the only assay for assessing oxidation used in those studies also showed CLA to be much less susceptible to oxidation than LA. We have shown here that CLA is in fact more susceptible to oxidation than LA, which confirms the theoretical expectation. Nevertheless, the observation that CLA exhibits antioxidant activity in the buffer/ethanol mixture may have been valid, but the more relevant test conditions employed by us did not demonstrate any antioxidant properties of CLA.

Summarizing, our results clearly indicate that in model membranes CLA does not function as an effective antioxidant or antioxidant precursor.

ACKNOWLEDGMENTS

Studies on the Mechanism of the Ursodeoxycholic Acid-Induced Increase in Hepatic Low-Density Lipoprotein Binding

Bernard Bouscarel[a,*], Susan Ceryak[a], Sander J. Robins[b] and Hans Fromm[a]

ABSTRACT: Previously, we have shown, in golden Syrian hamsters, that chronic feeding of ursodeoxycholic acid (UDCA), in contrast to that of its 7α-epimer, chenodeoxycholic acid (CDCA), produced a significant increment in hepatic low-density lipoprotein (LDL) uptake, despite similar suppression of bile acid synthesis by both bile acids. Evidence for a direct effect of this bile acid on hepatic LDL metabolism was shown *in vitro*, with isolated hamster hepatocytes, suggesting that this effect was unique to UDCA and specific for receptor-mediated LDL catabolism. The aim of the present study was to define the cellular mechanism(s) associated with this phenomenon, using male golden Syrian hamsters. Regardless of chronic exposure of the liver to either UDCA or CDCA, acute incubation with UDCA consistently resulted in an increase of LDL binding to isolated hepatocytes by 15 to 40%. Furthermore, chronic treatment with either UDCA or CDCA did not result in alterations in lipoprotein particle composition. Likewise, incubation of hepatocytes with UDCA was not associated with a change of the membrane lipid composition. In isolated liver membrane fractions, UDCA increased both the maximum number of LDL binding sites and the affinity constant for LDL by around 35%, suggesting an interaction of UDCA with the LDL receptor, at the plasma membrane level, independent of an effect on receptor cycling. The results of the studies support a role for UDCA in the recruitment of cryptic LDL receptors from a cellular membrane pool, possibly due to the unique localization of UDCA in the plasma membrane lipid bilayer.

Lipids 30, 607–617 (1995).

The low-density lipoprotein (LDL) receptor plays a central role in the regulation of cholesterol homeostasis (1–3). In a number of species, including the hamster, most of receptor-mediated clearance of LDL occurs in the liver (4,5) by rapid internalization of the complex formed by the binding of the apolipoprotein-B_{100}-containing particle to the LDL receptor (6–8). Once in the cell, the LDL particle is delivered to lysosomes, where it is degraded to cholesterol and amino acids, while the LDL receptor generally is cycled back to the membrane (9,10).

The activity of the LDL receptor has been shown to be tightly regulated. Hepatic LDL receptor synthesis and cycling can be markedly suppressed either by dietary cholesterol (3,11,12) or by triglycerides (TGs) ingested together with cholesterol (13,14). Conversely, administration of either cholesterol synthesis inhibitors or bile acid-binding resins increases the number of LDL receptors by increasing the cellular cholesterol demand (15–19). The consequent changes in cellular cholesterol pools modulate the production of LDL receptor mRNA and the synthesis of the LDL receptor (15, 16,20). This indirect adaptive process is slow and requires hours or days.

There is also evidence that LDL receptor activity can be directly regulated independently of the mRNA level. LDL binding to both the human fibroblast and hepatoma cell LDL receptor is altered in the presence of unesterified fatty acids (21,22), as well as ketoconazole (17), an antifungal agent, due to their respective effects on either the plasma membrane lipid composition, or on the LDL receptor conformation. Furthermore, glucagon has also been shown to rapidly increase hepatic LDL receptor activity, possibly by affecting intracellular LDL receptor processing or recycling (23).

Finally, the composition of the LDL particle itself may affect its rate of receptor-mediated catabolism. Denser, smaller LDL subfractions of normal subjects, which were characterized by a higher percentage of protein, as well as a larger cholesterol/TG ratio, exhibited an increased receptor-mediated uptake in cultured fibroblasts when compared to their less dense, larger counterparts (24). In contrast, the receptor-mediated catabolism of LDL, that was isolated from hypertriglyceridemic subjects, was decreased in fibroblasts. This decreased affinity of these LDL particles for the fibroblast LDL receptor was attributed to a TG-induced alteration in the

tertiary structure of the apolipoprotein, independent of the LDL receptor binding domain (25).

We have previously shown *in vivo*, in the golden Syrian hamster, that chronic feeding of ursodeoxycholic acid (UDCA), in contrast to that of its 7α-epimer, chenodeoxycholic acid (CDCA), evoked a significant increment in hepatic LDL uptake, in spite of both a 55–71% enrichment of the bile acid pool with CDCA and a marked suppression of bile acid synthesis (26). We also have documented this increase of LDL receptor-dependent LDL uptake and degradation *in vitro*, upon acute exposure to UDCA, in hepatocytes isolated from chow-fed hamsters (27). This direct effect of UDCA, which is time- and concentration-dependent, did not occur with either CDCA or lithocholic acid (LCA), and was not associated with a toxic effect of the bile acid.

The present investigation was undertaken in order to elucidate the mechanism of both the short-term (direct) and long-term effect of UDCA on the LDL receptor. The direct effect of UDCA on hepatic LDL binding was studied following chronic exposure to UDCA and CDCA, respectively. The plasma lipoprotein composition was also determined following bile acid feeding, in order to investigate the possibility of LDL particle alteration. Furthermore, to explore the membrane-related effect of UDCA as a mechanism by which UDCA directly enhances hepatic LDL binding, the LDL binding to isolated liver membranes was studied, and the plasma membrane lipid composition was determined in the presence and absence of UDCA.

MATERIALS AND METHODS

Materials. $Na^{125}I$ (specific activity 16–20 mCi/μg) was purchased from Amersham Corporation (Arlington Heights, IL). Gelatin and bovine serum albumin (fraction V) were purchased from Sigma (St. Louis, MO). UDCA was supplied by Tokyo Tanabe Co. (Tokyo, Japan), CDCA by Dr. Falk GmbH and Co. (Freiburg, Germany). UDCA and CDCA were 98–99% pure, as judged by gas–liquid chromatography. All other chemicals used were of analytical or high-performance liquid chromatography grade available from commercial sources.

Animals. Unless otherwise indicated, hamsters were maintained on a standard chow diet. For chronic bile acid treatment studies, three groups of male golden Syrian hamsters (115–130 g body weight; Harlan Sprague Dawley, Indianapolis, IN), consisting of eight animals per group, were fed a standard rodent chow diet (Ralston Purina Co., St. Louis, MO) for four weeks. One group received the diet alone (control), the second received, in addition, 0.1% UDCA, and the third, 0.1% CDCA. There were no differences among the treatment groups as far as food intake and weight gain were concerned. Mean food intake was 7.5 g/animal/day, while mean body weight ranged from 133.1–133.6 g following treatment. Both bile acids were well tolerated by the animals, and the livers appeared macroscopically normal after four weeks of bile acid feeding. Previously we have reported that light microscopic examination of the livers of hamsters fed the same bile acid-supplemented diets showed normal findings (26).

Hepatocyte isolation. Hepatocytes were isolated from male Golden Syrian hamsters by the collagenase perfusion technique of Exton (28), as previously described (27). The cells were suspended at a concentration of approximately 40–50 mg wet wt/mL of Krebs-Henseleit bicarbonate buffer, containing 118 mM NaCl, 5 mM KCl, 2.5 mM $CaCl_2$, 1.2 mM KH_2PO_4, 1.2 mM $MgSO_4$, 25 mM $NaHCO_3$, and 1.5% gelatin, pH 7.4. Prior to each experiment, hepatocytes were incubated for 20–30 min at 37°C under constant agitation and gassing, in order for the cells to reach a steady-state (27).

Separation of plasma lipoprotein fractions. Blood was collected from healthy human subjects, as well as from both bile acid-treated and untreated hamsters, into EDTA-containing vacuum collection tubes. The plasma was separated by centrifugation at 300 × *g* for 40 min at 4°C. Plasma lipoproteins were separated by density gradient ultracentrifugation as previously described (26,27), according to the method of Redgrave *et al.* (29). Layers were aspirated from the centrifuge tubes at the following density ranges, in order to assess the lipoprotein composition following bile acid feeding: <1.007 g/mL, very low density lipoprotein (VLDL); 1.007–1.019 g/mL, intermediate-density lipoprotein (IDL); 1.020–1.064 g/mL, LDL; 1.065–1.210 g/mL, high-density lipoprotein (HDL); >1.210 g/mL, albumin-rich, lipoprotein-free fraction. The LDL that was used in the study of LDL binding to hamster hepatocytes and isolated liver membrane fractions, respectively, was isolated at a density range of 1.020–1.060 g/mL, and was further purified and concentrated following adjustment to a density of 1.063 g/mL, and recentrifugation (27).

Determination of lipoprotein composition. The total protein concentration of the different lipoprotein fractions was determined by the method of Bradford (30), using the Bio-Rad® protein assay (Bio-Rad Laboratories, Richmond, CA). Enzymatic assays were used to measure cholesterol and TG (BioDynamics; Boehringer Mannheim, Indianapolis, IN), as well as choline-containing phospholipid (PL) (Nippon Shoji Kaisha Ltd., Higashi-Ko, Osaka, Japan) concentrations.

The apoprotein composition of the different lipoprotein fractions was assessed by SDS–polyacrylamide gel electrophoresis (PAGE) according to the method of Irwin *et al.* (31), followed by silver staining (32). The relative intensity of the respective apoprotein bands was determined densitometrically with a Hoeffer GS300 scanning densitometer (Hoeffer Scientific Instruments, San Francisco, CA). The electrophoretic mobility of the individual lipoprotein fractions on thin agarose gels was determined using the method of Elevitch *et al.* (33), followed by staining with Fat Red 7B (Analytical Chemists, Inc., Palo Alto, CA)(34).

Biliary bile acid composition. In order to confirm the enrichment of the respective bile acid pool by either UDCA or CDCA in the hamsters receiving the bile acid-supplemented diets, the relative bile acid composition was determined by gas–liquid chromatography in gallbladder bile as previously described (26,35).

LDL radiolabelling. Native hamster LDL isolated from untreated animals was labelled with [^{125}I]sodium iodide to a specific radioactivity of 80–200 cpm/ng of protein as previously described (27) using the iodine monochloride technique (36) as modified for lipoproteins (37), and was dialyzed overnight against 0.15 M NaCl, 0.01 M Tris, 0.001 M NaN_3, pH 7.4. ^{125}I-labelled LDL was filtered through a 0.45 μm cellulose nitrate membrane filter (Millipore Corp., Bedford, MA), and used within four days.

Hepatocellular ^{125}I-LDL binding. For a period of three consecutive days, all studies of the acute effect of UDCA on hepatic LDL binding were performed using hepatocytes isolated from one animal of a given chronic treatment group, using the same [^{125}I]LDL preparation. The order of animals studied from each chronic treatment group was varied for each set of experiments.

The binding experiments were performed as previously described (27). Following five washes with ice-cold bicarbonate buffer, the hepatocytes (150–250 mg protein/mL) were incubated at 4°C with increasing concentrations of ^{125}I-labelled hamster LDL (1–90 μg protein/mL) in the presence and the absence of 700 μM UDCA. Previous studies have shown that, at this concentration, UDCA is not toxic to the cell (27,38). After one hour, the cell-associated radioactivity was measured in a Beckman model 4000 gamma-radiation counter (Beckman Instruments, Fullerton, CA). Nonspecific binding was determined by incubating the cells under the same conditions as described, but with an excess of native human LDL (1–2 mg/mL) (27). Specific binding was determined by subtracting nonspecific binding from total binding. Saturation binding curves were derived by plotting the amount of ^{125}I-labelled hamster LDL specifically bound per mg of cell protein on the y axis against the concentration of unbound LDL on the x axis. The maximum number of binding sites (B_{max}, ng/mg protein) and the dissociation constant (K_D, μg LDL protein/mL) were calculated from the saturation curves, as previously described (27).

Liver membrane isolation. Livers obtained from male Golden Syrian hamsters were homogenized with 150 mM NaCl, 1 mM $CaCl_2$, 20 mM Tris-HCL, pH 7.5 using a Dounce homogenizer as previously described (39). Liver membranes were prepared by the method of Kovanen *et al.* (40). All isolation and preparative procedures were carried out at 4°C. The homogenates were centrifuged at 500 × *g* for 5 min. The supernatant was then centrifuged at 8,000 × *g* for 15 min, and the 8,000 × *g* supernatant was centrifuged at 100,000 × *g* for 60 min using a Beckman 70.1 Ti fixed-angle rotor. The resulting pellet was resuspended in the same buffer and recentrifuged at 100,000 × *g* for 60 min. The final pellet was used either immediately, or quickly frozen in liquid N_2, stored at –70°C, and used within two weeks.

Binding of ^{125}I-LDL to isolated liver membrane preparations. Membrane pellets were resuspended in 50 mM NaCl, 1 mM $CaCl_2$, 20 mM Tris-HCl, pH 7.5 and sonicated for 20 s, using a Sonifier Cell Disrupter (Branson Sonic Power Co., Plainview, NY). The binding of LDL to liver membranes was essentially carried out as described by Kovanen *et al.* (40), in a total volume of 80 μL 100 mM NaCl, 0.5 mM $CaCl_2$, 50 mM Tris-HCL, pH 7.5, containing 20 mg/mL bovine serum albumin. Liver membranes (100 μg protein/mL) were incubated with 1–100 μg protein/mL [^{125}I]-labelled hamster LDL for 60 min at 22°C in the presence and absence of 700 μM UDCA. Binding was rapid, and equilibrium was reached in less than 20 min and remained stable for at least one hour. The nonspecific binding was determined under the same conditions but in the presence of an excess of unlabeled human LDL (1–2 mg/mL). Saturation binding curves were derived, and the data were analyzed according to the method of Scatchard (41) by linear and nonlinear curve fitting, using the EBDA/LIGAND program (Elsevier-BIOSOFT®, Cambridge, United Kingdom), as modified for microcomputers (42). The B_{max} (ng/mg protein) and K_D (μg LDL protein/mL) were calculated from the equation of the regression line.

Assessment of release of cellular lipids into media. Isolated hepatocytes were incubated for either 10 or 120 min at 37°C in bicarbonate buffer containing 1.5% gelatin, and in the presence and absence of 700 μM UDCA. At the end of these incubation periods, the incubation buffer was collected and the cells were washed and centrifuged at 50 × *g* for 3 min at 4°C. Total lipids were extracted from the incubation medium as well from the cells by adding 3.75 mL $CHCl_3$/methanol, 1:2 (vol/vol), for each mL of aqueous suspension according to the method of Bligh and Dyer (43). Lipid extracts were kept under nitrogen in glass tubes to prevent oxidative degradation. PC molecular species and cholesterol amounts were determined by previously published methods (44,45), using several different high-performance liquid chromatography procedures to separate these lipids. Quantitation was performed by integration of peak areas in conjunction with internal standards. Total PL was quantitated by phosphorus measurement (46).

Statistical analysis. The paired *t*-test was used to compare the acute effect of UDCA treatment with that of the respective controls. An analysis of variance was used to compare the differences in the measured parameters as a result of bile acid feeding.

RESULTS

Effect of acute UDCA treatment on specific [^{125}I]-labelled hamster LDL binding at 4°C to hepatocytes isolated from chronic UDCA- or CDCA-fed hamsters. The specific binding of increasing concentrations (1–90 μg protein/mL) of [^{125}I]hamster LDL to hepatocytes isolated from animals fed either a standard chow diet or a 0.1% UDCA- or CDCA-supplemented diet for four weeks was studied at 4°C, in the presence and absence of 700 μM UDCA. Nonspecific binding, which was measured in the presence of an excess of native human LDL, represented 30–40% of the total binding, and was not affected by either acute or chronic bile acid treatment. Saturation of specific binding occurred at LDL concentrations of 30–50 μg/mL. The apparent binding constants, B_{max}, are

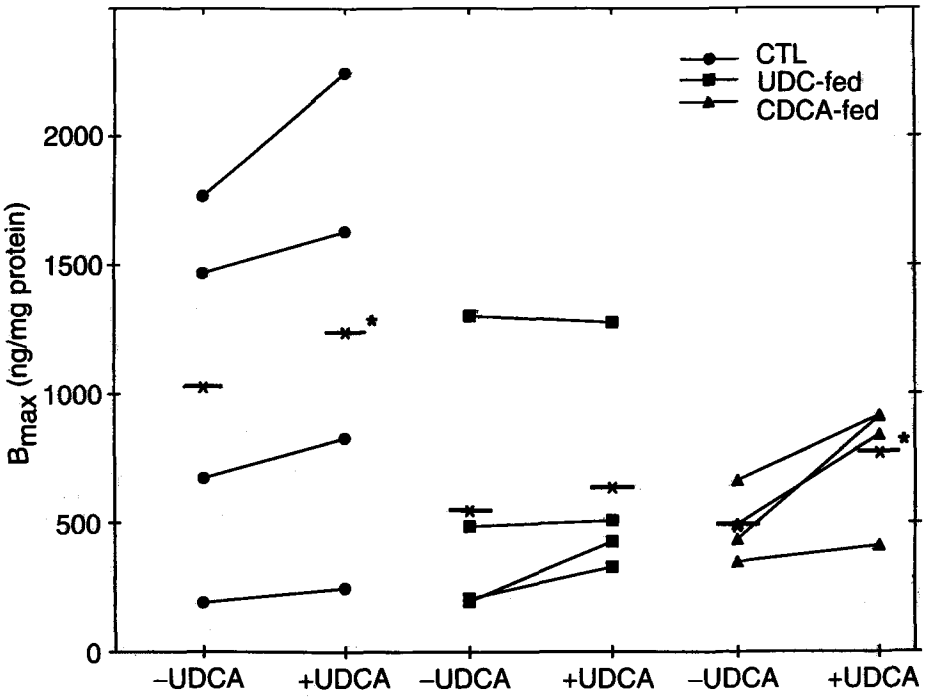

FIG. 1. Effect of acute treatment with ursodeoxycholic acid (UDCA) on the binding of [^{125}I]hamster low-density lipoprotein (LDL) to hepatocytes isolated from hamsters following chronic feeding of either a normal diet, or a normal diet supplemented with either UDCA or chenodeoxycholic acid (CDCA). For each experiment, hepatocytes were isolated from one hamster of each treatment group on three consecutive days, following four weeks of feeding either a normal chow diet alone (control, CTL), or the same diet supplemented with either 0.1% UDCA (UDCA-fed) or CDCA (CDCA-fed). Hepatocytes (150–200 μg protein/mL) were incubated at 4°C for 60 min with 1–90 μg/mL of [^{125}I]hamster LDL protein, and specific LDL binding was determined both in the absence (–UDCA) and presence of 700 μM UDCA (+UDCA). The unbound [^{125}I]hamster LDL was separated from the bound by rapid centrifugation of the cells (2000 × *g* for 2 min) and by washing them three times with ice-cold incubation buffer. Nonspecific binding, which was determined in a parallel set of experiments by incubating the cells under the same conditions with an excess of unlabelled native human LDL (1–2 mg/mL), was subtracted from the total binding. The respective apparent binding constant, B_{max}, was derived from analysis of the saturation curves. Horizontal bars represent the means of four experiments. *Significantly different from respective control incubation, $P < 0.05$.

shown in Figure 1, and were derived from analysis of the respective saturation curves.

As shown previously (27), when hepatocytes isolated from hamsters fed a standard chow diet were incubated with 700 μM UDCA, the maximum LDL binding (B_{max}) significantly increased by approximately 20%, from a control value of 1024 ± 361 to 1238 ± 439 ng/mg protein (Fig. 1).

The apparent decrease in LDL binding as a result of UDCA feeding was not statistically significant (Fig. 1). Furthermore, the B_{max} of 547 ± 261 ng/mg protein, determined in hepatocytes isolated from UDCA-fed animals, was not significantly altered after incubation of the cells with 700 μM UDCA (634 ± 218 ng/mg protein).

The tendency for the four-week treatment with CDCA to attenuate the maximum LDL bound to the hepatocytes was not significant, compared to the respective control-fed animals. However, the B_{max} value of 769 ± 241 ng/mg protein, after the acute exposure to 700 μM UDCA, was significantly higher than that of 483 ± 134 ng/mg protein in the control experiment (Fig. 1).

The K_D values were not significantly altered by either acute incubation with 700 μM UDCA, or by bile acid feeding, and ranged from 14.6 to 25.9 μg LDL protein/mL, under control conditions, and from 12.4 to 26.6 μg LDL protein/mL following one hour incubation with 700 μM UDCA (data not shown).

Effect of chronic UDCA and CDCA treatment on hamster plasma lipoprotein composition. Previously it has been shown that the relative abundance of components of the LDL particle could affect its receptor-mediated catabolism (24,25). To determine whether or not chronic feeding of UDCA or CDCA could alter the lipoprotein composition, and thus offer a possible mechanism for their observed effects on hepatic LDL uptake *in vivo* (26), the plasma lipoprotein composition was analyzed in hamsters after four weeks of feeding UDCA, CDCA, or the control diet.

The relative molar percent composition of protein, cholesterol, PL, and TG in the LDL- and HDL-containing fractions are shown in Tables 1 and 2, respectively. Neither the UDCA nor CDCA feeding resulted in any significant modification of

TABLE 1
Biliary Bile Acid Composition in Hamsters Following Chronic Bile Acid Feeding[a]

Treatment	LCA (%)	DCA (%)	CDCA (%)	UDCA (%)	CA (%)	Other[b] (%)
Control	1.2 ± 0.3	9.3 ± 1.4	28.7 ± 2.6	1.0 ± 0.1	54.0 ± 3.7	5.6 ± 2.0
UDCA	3.4 ± 0.4	3.9 ± 0.6*	49.4 ± 1.7*	20.6 ± 1.2*	16.8 ± 1.6*	6.0 ± 0.6
CDCA	2.9 ± 0.4	2.5 ± 0.1*	74.1 ± 2.2*	n.d.	13.4 ± 1.9*	7.0 ± 1.3

[a]Relative bile acid composition was determined by gas–liquid chromatography in gallbladder bile obtained from hamsters following four weeks of feeding either a normal chow diet alone (control), or the same diet supplemented with either 0.1% urosdeoxycholic acid (UDCA) or 0.1% chenodeoxycholic acid (CDCA). Results are the means ± SEM of determinations in four animals of each treatment group. *Significantly different in comparison to control-fed animals, $P < 0.05$. TABLE 2
Relative Plasma LDL Composition Following Chronic Administration of the UDCA- and the CDCA-Supplemented Diets[a]

	% Composition by weight			
Treatment	Protein	Cholesterol	Choline-containing phospholipid	Triglyceride
Control	11.2 ± 1.8	23.9 ± 3.1	49.2 ± 2.2	15.7 ± 1.0
UDCA	15.0 ± 3.3	24.4 ± 3.1	40.3 ± 5.6	16.6 ± 1.4
CDCA	11.8 ± 4.9	34.1 ± 5.2	38.5 ± 4.0	15.5 ± 1.9

[a]Low-density lipoprotein (LDL) were isolated by density gradient ultracentrifugation from plasma obtained from hamsters following four weeks of feeding either a normal chow diet alone (control), or the same diet supplemented with either 0.1% UDCA or 0.1% CDCA. Relative plasma lipoprotein protein, cholesterol, phospholipid, and triglyceride composition was determined by colorimetric methods. Results are the means ± SEM of determinations in four animals of each treatment group. See Table 1 for other abbreviations.

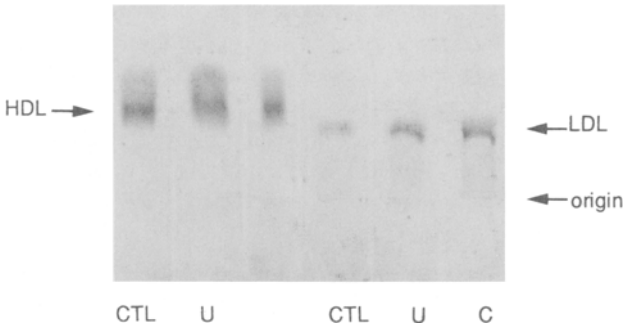

FIG. 2. Agarose gel electrophoretic mobility of LDL and high-density lipoprotein (HDL) fractions isolated from plasma obtained from hamsters following chronic feeding of UDCA and CDCA, respectively. LDL and HDL were isolated by density gradient ultracentrifugation from plasma obtained from hamsters following four weeks of feeding either a normal chow diet alone (control, CTL), or the same diet supplemented with 0.1% UDCA (U) and CDCA (C), respectively. Following electrophoresis on thin agarose gels, the lipoproteins were visualized by lipid staining with a solution of Fat Red 7B (Analytical Chemists, Inc., Palo Alto, CA). See Figure 1 for other abbreviations.

the plasma lipoprotein composition as far as total protein, cholesterol, PL, or TG was concerned. However, there was an increase, although statistically not significant, in the relative proportion of LDL cholesterol from 23.9 ± 3.1% in the controls to 34.1 ± 5.2% in the CDCA-fed animals. Furthermore, no effect of bile acid feeding was observed in the relative composition of VLDL- or IDL-containing fractions (data not shown).

The absence of alterations in the protein composition was further confirmed by SDS–PAGE of the delipidated lipoprotein fractions. This revealed no apparent differences in either the protein composition or mobility in the three experimental groups. Apolipoprotein B_{100} comprised 95.5 ± 4.5, 93.8 ± 6.2, and 93.5 ± 6.5% of the LDL proteins in LDL isolated from control, UDCA-, and CDCA-fed animals, respectively. The variable presence of proteins at an apparent M_r of 36 kDa (3–4%) and 25 kDa (1–2%) probably represented contamination of apolipoprotein E and AI, respectively, from the HDL fraction. HDL isolated from the control, UDCA-, and CDCA-treated hamsters was characterized by a respective apolipoprotein AI component representing 94.8 ± 2.4, 95.6 ± 1.4, and 95.7 ± 0.3% of the total proteins. Protein bands were also detected at an apparent M_r of 64 kDa (<1%), 48 kDa (1–2%), 36 kDa (2–3%), 13 kDa (<1%), and 12 kDa (<1%), corresponding to the respective molecular weights for albumin, and apolipoproteins AIV, E, and Cs.

In addition, the apparent electrophoretic mobility of the lipoprotein fractions on agarose gels also was not altered by bile acid feeding. As shown in Figure 2, similar β and α migration patterns were obtained with the respective LDL and HDL fractions isolated from the plasma of animals following chronic bile acid treatment.

Effect of chronic UDCA and CDCA treatment on hamster biliary bile acid composition. As shown in Table 3, the

TABLE 3
Relative Plasma High-Density Lipoprotein Composition Following Chronic Administration of the UDCA- and the CDCA-Supplemented Diets[a]

Treatment	Protein	Cholesterol	Choline-containing phospholipid	Triglyceride
Control	40.5 ± 2.6	16.4 ± 0.7	40.1 ± 2.6	2.9 ± 0.6
UDCA	42.2 ± 1.4	16.5 ± 0.8	36.2 ± 1.6	5.1 ± 1.3
CDCA	41.5 ± 1.4	19.2 ± 2.7	35.4 ± 2.0	3.8 ± 0.6

[a]For experimental details and abbreviations, see legends of Tables 1 and 2.

CDCA content in bile increased significantly during chronic treatment with both CDCA and UDCA, as has been previously observed in this model, due to the intestinal biotransformation of UDCA to CDCA (26,47). While significantly increased compared to control and CDCA-treated animals, the 20.6% enrichment of bile in UDCA in the UDCA-treated animals was considerably less than that observed in humans under comparable conditions (48). The relative percentages of biliary deoxycholic and cholic acids decreased significantly due to the relative enrichment in both the respective fed bile acid, and its metabolites.

Effect of UDCA on specific ^{125}I-labelled LDL binding to membranes isolated from hamster liver. From our previous studies (27), we concluded that the effect of UDCA was specific to the LDL receptor, since it was abolished following proteolytic degradation of the LDL receptor. One hypothesis proposed was that UDCA may uncover, or make accessible, LDL receptors, which are sequestered in the plasma membrane. Therefore, the effect of 700 μM UDCA on the binding of LDL was determined using isolated liver membrane fractions. Nonspecific binding increased linearly with LDL concentration, and represented 25–35% of the total LDL binding. The results of the specific binding studies are shown in Table 4. Scatchard analysis of the saturation curve showed that UDCA increased the B_{max} by 32% (Fig. 3 and Table 4). This UDCA-induced increase in LDL binding is similar to that previously observed in isolated hamster hepatocytes (27). However, in contrast to observations in intact hepatocytes, UDCA caused a significant decrease in the binding affinity by 37% (Table 4). The Hill coefficient was around 0.98 in

TABLE 4
Effect of UDCA on LDL Receptor Number and Affinity in Hepatic Membrane Fractions[a]

	K_D (μg LDL protein/mL)	B_{max} (ng/mg of protein)
–UDCA	67.4 ± 7.4	1338 ± 210
+UDCA	92.3 ± 13.9*	1763 ± 251**

[a]The binding of increasing concentrations (1–100 μg protein/mL) of [^{125}I]hamster LDL to isolated hamster liver membrane fractions (100 μg protein/mL) was measured at 22°C in the presence and absence of 700 μM UDCA, in a total volume of 80 μL. Nonspecific binding was determined by incubating the membrane fractions under the same conditions but in the presence of an excess of native human LDL (1–2 mg/mL). The unbound LDL was separated from the bound by centrifugation at 100,000 × *g* for 5 min. The apparent binding constants were determined by Scatchard analysis of the saturation binding curves, as represented in Figure 3. The results are the mean ± SEM of five different experiments. *$P < 0.05$; **$P < 0.02$—significantly different in the presence of UDCA. B_{max}, maximum number of binding sites; K_D, affinity constant. See Table 1 for other abbreviations.

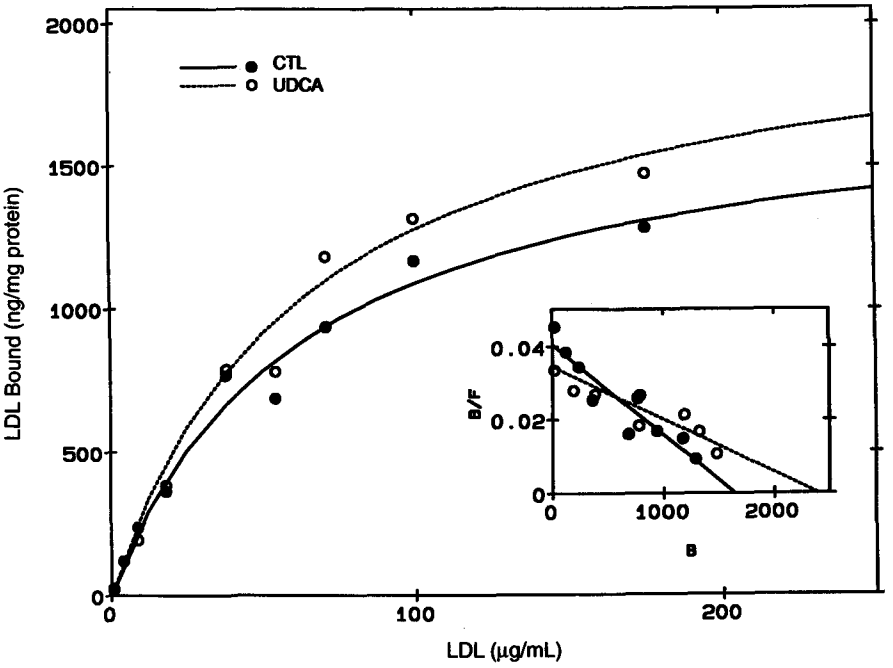

FIG. 3. Effect of UDCA on the binding of [^{125}I]hamster LDL to membranes isolated from hamster liver. For experimental details, see legend of Table 4, and the Materials and Methods section. Hamster liver membrane vesicles were incubated at 22°C with increasing concentrations (1–100 μg protein/mL) of [^{125}I]hamster LDL, in the presence and absence of UDCA. The data were analyzed according to the method of Scatchard by linear and nonlinear curve fitting, using the EBDA/LIGAND program (Elsevier-BIOSOFT®, Cambridge, United Kingdom), as modified for microcomputers. The saturation curve and Scatchard plot (inset) of the specific LDL binding is representative of five experiments. In this experiment, the Hill coefficient was 0.960 and 0.971, respectively, in the presence and absence of UDCA, suggesting the presence of a single homogenous population of LDL binding sites, while the corresponding coefficient of correlation was –0.903 and –0.933. See Figure 1 for abbreviations. B/F, bond/free.

[a]The cell-associated lipids (Cells) and the lipids released into the incubation media (Media) were extracted into chloroform/methanol (1:2, vol/vol) and measured as indicated in Materials and Methods, following incubation of isolated hamster hepatocytes at 37°C for 10 and 120 min, respectively, in the presence and absence of 700 μM UDCA. The results represent one determination. PL, total phospholipids; PC, phosphatidylcholine; FC, free cholesterol. See Table 1 for other abbreviation.
[b]A 1 mL cell suspension contains approximately 45 mg/mL cells, and 1 mg of cells contains 0.13 ± 0.009 mg protein.

both the absence and presence of UDCA, suggesting the presence of a single homogeneous population of binding sites.

The possibility was considered that perfusion of the liver with collagenase, as it is performed for the isolation of hepatocytes, could decrease the reactivity of the LDL receptors. UDCA may counteract the collagenase effect by stabilizing the plasma membrane, with consequent normalization of LDL binding. To assess the possibility of a damaging effect of collagenase, the binding of 70 μg/mL LDL was measured using liver membranes incubated without or with 0.4 mg/mL collagenase for 60 min at 4°C. The concentration of collagenase selected corresponded to five times the concentration used in the liver perfusion. The LDL specifically bound (1210.8 ± 32.7 ng/mg protein, n = 3), was not significantly changed after incubation of the membranes with collagenase (1279.5 ± 30.2 ng/mg protein, n = 3).

Effect of UDCA on hepatocellular lipid composition. As amphipathic molecules, bile acids are known to have detergent action. Therefore, one of the possible mechanisms by which UDCA could induce this increment in hepatic LDL binding and uptake is to alter the plasma membrane lipid composition, and, consequently, affect the conformation of the LDL receptor in the membrane lipid bilayer. Therefore, the hepatocellular lipid composition following 10 and 120 min incubation of the hepatocytes at 37°C was determined in the presence and absence of 700 μM UDCA (Table 5). The cellular concentrations of total PL, total PC, and free cholesterol (FC) in the 10-min control incubation were approximately 1.8, 0.8, and 0.2 mM, respectively. The corresponding values in the UDCA incubation were almost identical. Similar observations were made in the 120-min incubation experiments, which showed no differences in the cellular lipid concentrations between the control and UDCA incubations.

Incubation with UDCA also did not induce any changes in the release of cellular lipids into the incubation media at either 10 or 120 min (Table 5). However, in both the control and UDCA incubations the total PL concentration in the media was 0.09 and 0.09 mM, respectively, at 10 min and 0.18 and 0.17 mM at 120 min. The respective values for the total PC concentration were 0.04 and 0.04 mM, at 10 min, and 0.08 and 0.08 mM, at 120 min. FC showed barely an increase from 10 to 120 min of incubation, i.e., from 0.02 and 0.02 mM, respectively, to 0.03 and 0.03 mM.

When the PC content was expressed as % of phospholipids or when the ratio FC/PC was calculated, there was no change during the 120-min cell incubation at 37°C either in the presence or absence of UDCA (Table 5). Furthermore, when the different PC molecular species were determined in cells and in incubation buffer, the relative fatty acid composition of PC was not altered in the period of incubation, during which the effect of UDCA was studied (Table 6).

DISCUSSION

The results of the present studies are in keeping with previous reports of the UDCA-induced enhancement of hepatic LDL catabolism (26,27). Regardless of chronic exposure of the liver to either UDCA or CDCA, acute incubation with UDCA for one hour consistently increased the B_{max} for LDL binding to isolated hamster hepatocytes, without altering the binding affinity.

Malavolti *et al.* (26) observed that the unique UDCA-induced enhancement of hepatic LDL uptake *in vivo* occurred in spite of suppression of bile acid synthesis. The extensive biotransformation of UDCA to CDCA in the hamster was thought to have been the probable cause for the observed suppression of bile acid synthesis, since, in contrast to UCDA, CDCA is a potent inhibitor of bile acid synthesis (49,50). Because chronic suppression of bile acid synthesis has been associated with LDL receptor downregulation (51), a direct effect of UDCA was postulated to account for the increment in hepatic LDL uptake *in vivo*. Indeed, a direct effect of this bile acid on hepatocellular LDL metabolism was later demonstrated *in vitro* (27). The results of the present study confirm the existence of a direct effect of UDCA *in vivo*. The tendency for chronic feeding of either UDCA or CDCA to decrease specific LDL binding to isolated hepatocytes could be due to the downregulation of LDL receptor synthesis by a

[b]Molecular species were not separated.

CDCA-induced suppression of bile acid synthesis (52,53), resulting from the increase in the relative percentage of CDCA in bile, in both CDCA- and UDCA-fed hamsters. However, this explanation seems insufficient, in the case of UDCA feeding, which *in vivo*, increased LDL-receptor-dependent LDL uptake (26). A more important factor is probably the extensive washing of the cells during hepatocyte isolation which would remove UDCA from the plasma membrane (27), and thus eliminate any direct effect of this chronically fed bile acid on the LDL receptor. However, as shown in the current study, acute exposure, which would occur with each passage of UDCA through the liver, enhances hepatic LDL binding.

Previous studies from this laboratory (27), as well as the findings in the present study, indicate that the increase of cell-associated LDL by UDCA was not related to a detergent or toxic effect of this bile acid on the membrane. A two-hour incubation with 700 μM UDCA had no significant effect on either the lipid composition of the hepatocytes or the release of cellular lipids into the medium, indicating that the effect of UDCA on hepatic LDL binding is not due to an alteration in the membrane lipid composition. These results are supported by those of several studies, which showed that, up to very high concentrations, UDCA is not only nontoxic, but also shows evidence for preventing the cytotoxicity induced by other bile acids, such as CDCA and lithocholic acid (54–56).

Rudling and Angelin (23) have shown that the LDL binding activity of hepatic LDL receptors was stimulated three hours after acute glucagon administration in rats. However, the absence of upregulation of the LDL receptor activity at the transcriptional level, in spite of an increase in the LDL receptor number, prompted these authors to conclude that the effect was due to either a glucagon-induced decrease in LDL receptor recycling time, or a modification in the intracellular fate of the LDL receptor. In our previous studies, the UDCA-induced stimulation of LDL was found to occur within a time period during which a UDCA-induced effect on LDL receptor cycling could occur (27). However, in the present study, the ability of UDCA to increase the maximum LDL binding to isolated liver membranes provides evidence for an initial action of this bile acid at the plasma membrane level in the absence of an effect on LDL receptor processing or cycling.

The LDL receptor binding affinity in liver membranes was two- to fourfold lower than that observed in isolated hepatocytes. This may be due to the absence, in membrane vesicle preparations, of the structural support of cytoskeletal elements which may serve to anchor the LDL receptor in the intact cells, thus maintaining a certain binding conformation. The observation that the effect of UDCA on LDL binding to liver membranes is accompanied by a UDCA-induced decrease in LDL receptor binding affinity further supports the idea that the bile acid may be interacting with the receptor. Indeed, if UDCA were interacting with the LDL receptor in the cell membrane, as is our hypothesis, such an association should undoubtedly alter the affinity of this membrane-spanning receptor for its ligand, in an isolated membrane preparation, in which cytoskeletal anchors are absent.

It has also been suggested that the use of collagenase in the isolation of hepatocytes may alter receptor-dependent LDL binding (57). The results of the current studies suggest that, at the concentration used, collagenase treatment of isolated liver membranes did not significantly affect the LDL binding characteristics nor did it decrease the number of LDL receptors present at the membrane level.

Changes in the size and relative TG concentration of the LDL particle itself have been shown to affect its receptor-dependent catabolism (24,25). However, we have previously shown that the effect of UDCA was not due to either an acute alteration of the LDL particle or a change in nonspecific LDL

binding (27). Likewise, it was shown in the present study that neither UDCA nor CDCA feeding for four weeks significantly altered the relative protein, cholesterol, PL, and TG composition of the LDL particle. Lipid transfer activity among lipoprotein fractions has been shown to be present in hamster plasma (58); however, the relative composition of the HDL fraction was also not affected by bile acid feeding for four weeks, thus excluding any indirect effects of bile acids on LDL particle composition through lipid transfer.

With the use of electrophoretic methods to ascertain any effects on apoproteins, no apparent changes in either the electrophoretic mobility of the LDL and HDL particles on agarose gels, or their apoprotein composition on SDS–PAGE, were observed. Therefore, it can be assumed that neither the protein nor the PL content of the lipoprotein coat is affected by UDCA, since the respective relative charge of the LDL and HDL particles, as assessed by agarose gel electrophoresis, was not changed after chronic treatment with this bile acid. Furthermore, since all LDL used in this study was isolated at a density of 1.020–1.060, a difference in the size of the LDL particles was not a factor in the observed effect of UDCA on LDL binding. Similarly, since the relative protein and lipid concentrations of the LDL particles were not affected by chronic feeding of UDCA, the density of the lipoprotein particle should not be altered by this bile acid. Therefore, it can be concluded that the stimulatory effect of UDCA on hepatocellular LDL binding is not due to modification of the lipoprotein particle.

The observed effect of UDCA on LDL binding can occur in the absence of an effect on either LDL receptor transcriptional regulation, LDL receptor recycling, LDL particle composition or membrane lipid composition or release. It was previously postulated that the mechanism of action of UDCA may be to uncover, or recruit a latent pool of LDL receptors on the cell membrane (27). As proposed by Triggle (59), cryptic receptors may act as modulators of cell sensitivity to external stimuli. The speculation that UDCA probably uncovers receptors present at the membrane level, which normally may not be able to bind the LDL particle, is supported by the observations in the present studies. UDCA may either induce conformational allosteric changes leading to exposure of latent binding sites or make receptors, which are sequestered in the plasma membrane, accessible.

The mechanism of action by which UDCA may recruit cryptic LDL receptors could be related to its unique localization in the plasma membrane. Güldütuna *et al.* (54) have postulated that UDCA and its conjugates localize to specific regions in the membrane lipid bilayer, resulting in an increased membrane stabilization. In the present studies, only unconjugated UDCA was used; however, in previous studies (27) we have demonstrated that the only bile acids able to directly enhance LDL metabolism were UDCA and its taurine (T) and glycine (G) conjugates. UDCA, TUDCA, and GUDCA were all able to increase LDL binding by around 30%. However, GUDCA was significantly slower than UDCA and TUDCA in eliciting this effect. Moreover, similar effects have been observed with UDCA and TUDCA on hepatocellular calcium mobilization and phosphorylase a activation, although GUDCA did not mimic their effect (38). Therefore, while the taurine conjugate of UDCA appears to mimic the action of the free bile acid, the slower effect of GUDCA on hepatic LDL binding and uptake (even though equal in magnitude), may indeed be due to a differential localization of the bile acid in the plasma membrane bilayer. Collectively, these potential membrane stabilization mechanisms may be responsible for the observed effects of UDCA and its conjugates on hepatic LDL binding. It is easy to imagine how the integration of these bile acids into the plasma membrane lipid bilayer could affect the function of certain integral membrane proteins, such as the LDL receptor.

In conclusion, the present studies have focused on direct and novel mechanisms of LDL receptor regulation by bile acids which, in spite of their potential importance, have hitherto received little attention. The results of the present study support previous studies which showed that UDCA directly increases receptor-dependent LDL metabolism in isolated hamster hepatocytes. The effect of UDCA is not due to its effect on either the LDL particle, or the membrane lipid composition, and, as such, is not due to a detergent effect of the bile acid. Since UDCA has been shown to localize to certain regions in the plasma membrane lipid bilayer, its action on LDL binding and uptake may be to uncover a cryptic pool of LDL receptors in the plasma membrane, and make them accessible for binding.

ACKNOWLEDGMENTS

The authors are grateful to Dr. M.M. Cassidy, Department of Physiology, The George Washington University, for helpful discussions. The authors thank Ken Kim, Marie Maralit, Kathleen Caslow, and Joan Fasulo for their assistance in the studies with isolated hepatocyte preparations, and Dr. V. Hu and Dr. L. Gallo, Department of Biochemistry and Molecular Biology, The George Washington University, for allowing the use of their equipment. The studies were supported, in part, by grants from the American Heart Association Nation's Capital Affiliate (B.B.) and the General Medical Research Service of the Veterans Administration (S.J.R.). S.C. was a recipient of an American Liver Foundation Student Research Fellowship, and an American Heart Association Postdoctoral Fellowship (Nation's Capital Affiliate). Portions of this manuscript work were derived from a dissertation presented by S.C. to the Columbian College and Graduate School of Arts and Sciences of The George Washington University.

Carbohydrate Type and Amount Alter Intravascular Processing and Catabolism of Plasma Lipoproteins in Guinea Pigs

Maria Luz Fernandez*, A. Karin Conde, Laura R. Ruiz, Carlos Montano, John Ebner and Donald J. McNamara

Department of Nutritional Sciences and Interdisciplinary Nutritional Sciences Program, University of Arizona, Tucson, Arizona 85721

ABSTRACT: To test the effects of exchanging dietary complex and simple carbohydrate for fat calories on lipoprotein metabolism, guinea pigs were fed two different fat/carbohydrate ratios: 2.5:58% (w/w) or 25:29% (w/w) with either sucrose or starch as the carbohydrate source. Animals fed high-fat had higher plasma low-density lipoprotein (LDL) and hepatic cholesterol concentrations than animals fed low-fat diets ($P < 0.01$). The cholesteryl ester content per particle was higher, and the number of triacylglycerol (TAG) molecules was lower in very low density lipoprotein (VLDL) and LDL from animals fed high-fat diets. Intake of high-fat/sucrose resulted in higher plasma LDL concentrations than intake of high-fat/starch, and animals fed low-fat/starch had the highest plasma TAG concentrations associated with VLDL particles containing more TAG molecules, as well as a TAG-enriched LDL. The activity of plasma lecithin cholesteryl:acyl transferase (LCAT) was highest in animals fed high-fat/sucrose, and heart lipoprotein lipase (LPL) activity was higher in animals fed high-fat diets. Hepatic apoprotein B/E (apo B/E) receptor number (B_{max}) was increased 21% with low-fat diets ($P < 0.01$). These results suggest that the hypercholesterolemia induced by high-fat and by sucrose intake are associated with a higher plasma LCAT activity which results in a cholesteryl ester-enriched VLDL which, by the action of LPL, might be more readily converted to LDL through the delipidation cascade leading to downregulation of hepatic apo B/E receptors. The hypertriglyceridemia associated with low-fat intake may result from increased production of VLDL TAG, which would explain the increased TAG content and the higher TAG/CE ratio of VLDL from animals fed the low-fat/starch diet.
Lipids 30, 619–626 (1995).

High-carbohydrate, low-fat diets have been shown to decrease plasma low-density lipoprotein (LDL) concentrations (1); however, they can also increase plasma triacylglycerol (TAG) and decrease high-density lipoprotein (HDL) concentrations (2,3), resulting in a plasma lipid profile associated with increased risk for cardiovascular disease (1). For example, diets containing 55–60% of calories derived from carbohydrates have been shown to increase plasma TAG levels in hyperlipidemic and noninsulin-dependent diabetes mellitus patients (4,5). Other studies have shown that, compared to a high-fat diet (43% calories from carbohydrates), intake of a low-fat diet (60% carbohydrate calories) results in a lowering of plasma HDL cholesterol levels independent of the type of dietary fatty acids (6,7). In these studies, an increase in plasma TAG was only observed when patients were fed simple sugars in a liquid formula (6). Studies in normolipidemic subjects have shown a progressive increase in plasma TAG levels as sucrose intake was increased (8). It has also been demonstrated that the metabolic effects of high carbohydrate diets related to increased plasma TAG concentrations can be attenuated if dietary sucrose is not increased in parallel (9).

Animal studies have been contradictory regarding the plasma lipid response to dietary carbohydrates. Although simple carbohydrates have been consistently shown to increase plasma TAG concentrations in normal and in Zucker rats (10–12), studies in cynomolgus monkeys showed no effect on plasma TAG levels with consumption of 49 vs. 76.5% of calories derived from sucrose or starch (13,14).

The effects of exchanging carbohydrate calories with fat have been studied in guinea pigs (15). Increasing dietary fat resulted in higher plasma LDL concentrations, which could be explained, in part, by increases in hepatic cholesterol concentrations and decreases in hepatic apoprotein B/E (apo B/E) (LDL) receptor number (B_{max}) (15). Studies in the guinea pig have also demonstrated that a high sucrose intake raises plasma TAG compared to starch, and while TAG secretion rates were not modified by the type of carbohydrate (16), the higher plasma TAG could be explained by increased apo B secretion rates in animals fed the simple carbohydrate.

Although interactions between the type and amount of dietary carbohydrates have been previously addressed (9), the present studies were undertaken to differentiate carbohydrate type/amount specific effects on the mechanisms which deter-

mine plasma lipid levels. The guinea pig was used as the animal model for this investigation, based on its plasma lipoprotein profile (high LDL/HDL ratio); distribution of hepatic cholesterol pools, activities of plasma lecithin cholesteryl:acyl transferase (LCAT) and cholesteryl ester transfer protein (CETP) and of tissue lipoprotein lipase (LPL), which are involved in the intravascular processing of lipoproteins; and the documented responses to dietary treatments, which are similar to humans (15–17).

MATERIALS AND METHODS

Materials. Reagents were obtained from the following sources—cholesterol and TAG enzymatic assay kits, cholesterol oxidase, and cholesterol esterase from Boehringer-Mannheim (Indianapolis, IN), free cholesterol and phospholipid enzymatic assay kits from Waco Pure Chemical Industries, Ltd. (Osaka, Japan), ^{121}I-Na from Amersham (Clearbrook, IL), halothane from Halocarbon (Hackensack, NJ), and quickseal ultracentrifugation tubes from Beckman Instruments (Palo Alto, CA).

Animals. Male Hartley guinea pigs (Sprague Dawley; Sasco, Omaha, NE) weighing between 300–400 g were randomly assigned to one of four experimental diets for four weeks to achieve a metabolic steady state prior to analysis of the metabolic variables. Animals were kept in a light-cycled room, fed *ad libitum* and gradually adapted to the experimental diets by mixing regular chow and increasing portions of experimental diets in a six-day period. At the end of the four-week experimental period, animals were fasted overnight, anesthetized with halothane vapors, and exsanguinated by cardiac puncture. Animals from the four dietary groups consumed equal amounts of diet, and there were no significant differences in the rates of weight gain or final weights between groups. Animal experiments were conducted in accordance with U.S. Public Health Service and U.S. Department of Agriculture guidelines, and experimental protocols were approved by the University of Arizona Institutional Animal Care and Use Committee.

[a]Fat mix: palm oil/butter fat (1:1).
[b]Carbohydrate either sucrose or corn starch.
[c]Compositions of vitamins and minerals mixtures have been previously reported (Ref. 16).

Diets. Diets were prepared and pelleted by Research Diets, Inc. (New Brunswick, NJ). Two levels of dietary fat were used—2.5 and 25% (w/w) corresponding to 6.9 and 53% of total calories with levels of carbohydrate at either 59.3 or 26.2% (w/w) equivalent to 70.6 and 24.4% of total calories (Table 1). The dietary carbohydrate was either sucrose or starch. The fat source was a mix of palm oil/butter fat (1:1), with the following fatty acid composition: myristic, 6.8%; palmitic, 33.6%; oleic, 32%; and linoleic, 7.8% (4:3:1 polyunsaturated/monounsaturated/saturated fat ratio). The amounts of fiber, protein, vitamins, and minerals were adjusted to an identical caloric density so that animals consumed similar amounts of nonfat, noncarbohydrate nutrients to assure that any observed changes were attributable to the amount and type of carbohydrate in the diet. The diets contained 0.04% cholesterol which, for the guinea pig, is the physiological equivalent (i.e., absorbed cholesterol relative to endogenous cholesterol synthesis) of 300 mg/d for humans (17).

Lipoprotein isolation. Plasma samples were obtained from guinea pigs under halothane vapor by cardiac puncture; EDTA was used as an anticoagulant (1 mg/mL), and aprotinin (0.5 mg/mL), phenylmethylsulfonylfluoride (0.1 mg/mL), and sodium azide (0.1 mg/mL) were added to minimize changes in lipoprotein composition during isolation. Plasma lipoproteins were isolated by sequential ultracentrifugation with the following densities: very low density lipoprotein (VLDL) (d = 1.006 g/mL) and LDL (d = 1.019–1.09 g/mL) as previously described (14,15). Plasma cholesterol and TAG were determined by enzymatic assays and HDL cholesterol by measuring cholesterol in the supernatant after precipitation of apo B lipoproteins with dextran sulfate–$MgCl_2$ (18).

Chemical determinations. Plasma total and lipoprotein cholesterol concentrations and plasma TAG were measured using enzymatic kits and a microtiter plate reader (15). Hepatic total and free cholesterol and TAG were determined according to Carr *et al.* (19) after extraction of hepatic lipids with chloroform/methanol (2:1).

VLDL and LDL compositions were determined by measuring lipid components (total and free cholesterol, TAG, phospholipids) and protein by a modified Lowry procedure (20). Based on LDL composition and molecular weight of components (412,000 Da for guinea pig apo B) (21), LDL diameters were calculated according to Van Heek and Zilversmit (22). Apo B in VLDL was selectively precipitated with isopropanol (23), and based on one apo B per molecule, the number of molecules of the lipid components were calculated.

LPL assay. Heart tissue was isolated from guinea pigs, and LPL activities assayed in the supernatant following homogenization of 1 g tissue in buffer (0.025 mol ammonia, 5 mmol

EDTA, 8 mg Triton X-100/mL, 0.4 mg SDS/mL, 5 IU heparin/mL, 10 μg leupeptin/mL, 1 μg pepstatin/mL, 25 IU trasylol/mL) and centrifuged at 10,000 × *g* for 20 min at 4°C. The homogenate was incubated with [^{3}H]triolein (50×10^6 dpm) for 30 min at 25°C in a water bath, and reactions were stopped by addition of 3.25 mL methanol/chloroform/heptane (1.41:1.24:1). The methanol/water upper phase was removed, and free fatty acid radioactivity determined in a scintillation counter. Results are expressed as nmol of fatty acid released per min per gram tissue at 25°C.

LCAT assay. Freshly isolated plasma samples were incubated at 0°C (control) or 37°C (experimental) for 6 h. Plasma free cholesterol concentrations were determined in control and in incubated samples by enzymatic methods using a microtiter plate reader (19). This method measures the physiological plasma LCAT activity from the decrease in the mass of endogenous free cholesterol in incubated plasma samples. LCAT activity was expressed as the molar cholesterol esterification rate (μmol decrease in unesterified cholesterol/h-mL plasma). The conditions for plasma LCAT activity have been standardized for guinea pig (15).

LDL binding assays. Pooled samples of guinea pig LDL were radioiodinated with ^{125}I by the iodine monochloride method (24) to give a specific activity between 120–300 cpm/ng. Hepatic membranes isolated as previously described (15) from animals fed the homologous diet were incubated with the radiolabeled LDL over a concentration range of 10 to 80 μg/mL in the presence or absence of 1 mg/mL of unlabeled human LDL, an effective competitor at 37°C (25). After incubation, membranes were pelleted and counted. K_d and B_{max} were determined from Woolf plots (26).

Statistical analysis. One-way analysis of variance (ANOVA) was used to determine significant differences in plasma total and lipoprotein cholesterol and TAG concentrations, LDL and VLDL compositions, hepatic free and esterified cholesterol, plasma LCAT, heart LPL and LDL binding to hepatic membranes in animals from the four dietary groups, and the Newman-Keules post-hoc was used to identify differences in means after ANOVA (INSTAT, San Diego, CA). Two-way ANOVA was used to detect differences due to the type of carbohydrate or dietary fat amount (or percentage of dietary carbohydrate). Because animals fed low- and high-fat diets had significantly different weight gains, weight gain was used as a covariate in all determined measurements. Linear regression was used to identify significant correlations between variables.

RESULTS

Carbohydrate type and fat amount effects on plasma lipoprotein levels and composition. There were no significant differences in body weight gain in animals fed the four dietary groups as indicated by one-way ANOVA; however, animals fed high-fat diets gained more weight per day than animals fed low-fat diets (Table 2). For this reason, weight gain was used as a covariate to determine whether differences in measured parameters were affected by differences in weight gain of animals fed low- and high-fat diets.

[a]Values represent mean ± SD for n = 6 determinations. Values in the same column with different superscripts are significantly different as determined by analysis of variance (ANOVA) and Newman–Keules post-hoc test ($P < 0.01$). N.S., not significant.

Plasma cholesterol levels were higher in animals fed high-fat diets ($P < 0.0001$), and there was a carbohydrate effect as animals fed the high-fat/sucrose diet had higher plasma cholesterol concentrations than animals fed high-fat/starch (Table 2). Plasma TAG levels were higher in animals fed low-fat compared to high-fat diets ($P < 0.05$), and the most pronounced increase in plasma TAG was observed in animals fed the high-starch diet (Table 2).

Plasma VLDL cholesterol concentrations were higher in animals fed the high-starch diet (Table 3), which correlates with the higher plasma TAG levels observed in this group (Table 2). Plasma VLDL cholesterol levels of animals fed high-fat/sucrose were not significantly different from any of the three dietary groups (Table 3). Plasma LDL cholesterol concentrations followed an identical trend with plasma total cholesterol; high-fat diets increased plasma LDL levels with

Interaction	N.S.	N.S.	N.S.	N.S.	$P = 0.03$

[a]Values represent mean ± SD for n = 6 determinations. Values in the same column with different superscripts are significantly different as determined by one-way ANOVA and the Newman–Keules post-hoc test ($P < 0.01$). Abbreviations as in Tables 2 and 3.

the high-fat/sucrose diet having the most pronounced effect (Table 3). No significant differences were observed in plasma HDL cholesterol concentrations, although there was a trend for lower concentrations in animals fed low-fat diets (Table 3).

VLDL composition was significantly modified by diet and the lipid content changed accordingly (Fig. 1). Animals fed low-fat diets exhibited larger VLDL particles containing more TAG and phospholipids than VLDL from animals fed high-fat diets (Fig. 1). The type of carbohydrate also influenced VLDL composition as animals fed sucrose had a higher cholesteryl ester content per VLDL than animals fed starch diets.

Plasma LDL size and composition were also affected by carbohydrate type and amount. Based on a single apo B per LDL, the TAG, phospholipid, free cholesterol, and cholesteryl ester molecules per particle were calculated to provide information on the composition of LDL. The purity of LDL isolated from the four dietary groups was verified by SDS–PAGE (data not shown), and only apo B was present. Cholesteryl ester content was highest in animals fed the high-fat/sucrose diet and lowest in LDL from the low-fat/starch group (Table 4). High-fat and sucrose intake resulted in a higher concentration of cholesteryl ester in LDL, as indicated by two-way ANOVA (Table 4). The TAG content of LDL was lower in animals fed high-fat diets, and a carbohydrate effect was evident as TAG content was highest in animals fed low-fat/starch, resulting in an LDL particle with higher TAG content and larger diameter than is usually found for LDL (27) (Table 4). The number of phospholipid molecules was not modified by carbohydrate type or amount, whereas carbohydrate type altered the free cholesterol content of LDL with increased values for LDL from animals fed the low-fat/starch diet. The high percentage of TAG in LDL from animals fed low-fat/starch resulted in the largest LDL particle as judged from the calculated diameters (Table 4). The higher TAG mass of LDL from the low-fat/starch group and the higher cholesteryl ester content of LDL from animals in the high-fat/sucrose group in part account for the larger diameters of these particles compared to LDL from the high-fat/starch group (Table 4).

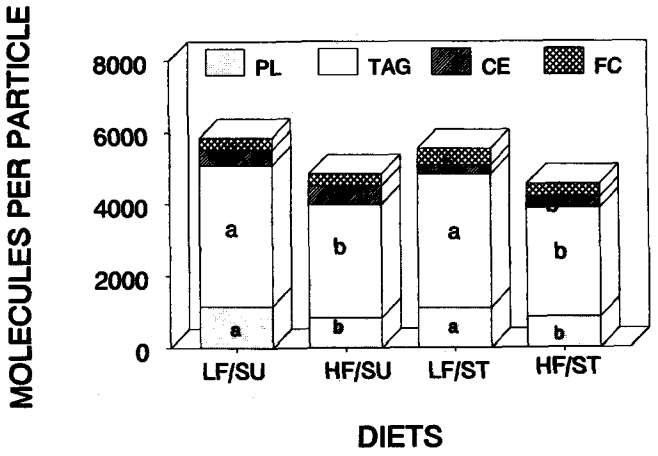

FIG. 1. Phospholipid (PL), triacylglycerol (TAG), free cholesterol (FC), and cholesteryl ester (CE) content of very low density lipoprotein particles from guinea pigs fed low-fat/sucrose (LF/SU), high-fat/sucrose (HF/SU), low-fat/starch (LF/ST), and high-fat/starch (HF/ST). The numbers of TAG and PL molecules were significantly higher in animals fed low-fat diets ($P < 0.01$), while the number of CE molecules was higher in animals fed sucrose diets ($P < 0.01$). Each bar represents the mean ± SD of n = 6 determinations.

Carbohydrate type and fat amount effects on plasma LCAT and heart LPL. Plasma LCAT activity was higher in guinea pigs fed high-fat diets, and the highest activity was found in animals fed high-fat/sucrose (Table 5). Plasma LCAT activity and VLDL cholesteryl ester content (percent) exhibited a positive correlation (Fig. 2) ($r = 0.99$, $P < 0.01$) as well as plasma LCAT and cholesteryl ester in LDL ($r = 0.97$, $P < 0.01$, data not shown), suggesting that as cholesterol is being esterified in HDL, it is rapidly transported to the apo B-containing lipoproteins, presumably by the action of CETP.

Although adipose tissue was isolated from the test animals, LPL activity could not be measured, due to the extremely low enzyme activity in fasted guinea pigs (28). LPL in the heart is

not decreased by fasting and was found to be elevated in animals fed high-fat diets as compared to the low-fat groups ($P < 0.05$), which could, in part, explain the presence of smaller, TAG reduced plasma VLDL in animals fed the high-fat diets (Table 5).

Dietary carbohydrate type and fat amount effects on hepatic lipids and hepatic LDL receptor. Hepatic free cholesterol concentrations were significantly altered by the amount of dietary fat. Animals fed high-fat diets, especially with sucrose, had higher levels of hepatic free cholesterol than animals fed low-fat diets (Table 6). Hepatic esterified cholesterol levels were also significantly affected by the type of carbohydrate. Animals fed starch had higher concentrations of esterified cholesterol in the liver than animals fed sucrose diets ($P < 0.05$). Hepatic TAG concentrations were not affected by dietary carbohydrate type or amount (Table 6).

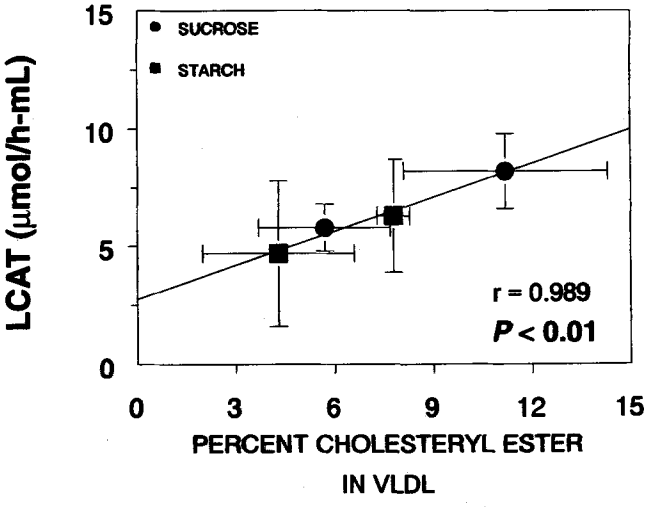

FIG. 2. Correlation between plasma lecithin cholesteryl:acyl transferase (LCAT) activity (μmol/h-mL) and percent cholesteryl ester in very low density lipoprotein (VLDL) from animals fed low-fat/starch, low-fat/sucrose, high-fat/starch, and high-fat/sucrose diets. Each point represents the mean ± SD of n = 6 determinations.

Hepatic LDL receptor B_{max} values were higher in animals fed low-fat diets, and no differences due to carbohydrate type were found (Table 7). LDL receptor affinity (K_d) was not modified by the amount of fat or the carbohydrate type (Table 7).

DISCUSSION

These studies demonstrate that, in addition to modifications in hepatic LDL receptor number, the amount of fat and type of carbohydrate in the diet affect several parameters of plasma lipoprotein production, remodeling, and catabolism which influence the concentration of plasma lipids, the composition of lipoproteins, and their potential atherogenicity.

While high-fat diets increased the plasma concentration of atherogenic LDL, intake of the low-fat diets resulted in higher concentrations of plasma TAG, a profile also associated with increased risk for cardiovascular disease. In addition, interactive effects on certain parameters of lipoprotein metabolism were observed between the type of dietary carbohydrates and the amount of dietary fat. The combination of sucrose with

high-fat intake elicited the highest plasma cholesterol levels, whereas low-fat and starch intake resulted in the highest plasma TAG concentrations. The hypertriglyceridemic effect of starch was unexpected and differs from some studies in humans (6) and in rats (29); however, other studies have found no differences in plasma TAG with intake of high-starch vs. high-sucrose diets (13,14,30). In our previous study in guinea pigs, we observed higher concentrations of plasma TAG with intake of 59% of calories from sucrose compared to starch (16). In the present study, starch contributed 70.6% of the caloric intake and was given with a highly saturated fat which, in combination, could alter the activities of various enzymes involved in lipoprotein processing, resulting in the observed pattern of responses.

Effects of dietary carbohydrates with high-fat diets. Dietary treatments significantly affected the composition of VLDL and LDL and the activity of plasma LCAT, modifications related to plasma lipoprotein remodeling in the intravascular compartment and possibly associated with plasma lipid levels and atherogenic potential. Similar to our observations, studies in rats and monkeys (10,13) have shown increases in plasma cholesterol with intake of sucrose compared to feeding a starch-based diet. Because intake of sucrose and starch at the same level of dietary fat had similar effects on hepatic LDL receptor B_{max} values, it is postulated that the interactive effects of high-fat diets with sucrose on plasma lipoprotein remodeling accounts for the higher plasma LDL levels observed in this group of animals. Studies in cynomolgus monkeys have shown that sucrose, when compared to starch intake, increases plasma LCAT and CETP and hepatic lipase (HL) activities, and that these increases are related to effects on TAG metabolism and lipoprotein interconversion processes (31). In the present study, we observed higher LCAT activity and the higher concentration of cholesteryl ester in VLDL and LDL, which suggest increased CETP activity in animals fed high-fat/sucrose; however, this would need to be measured directly to confirm this hypothesis.

Cholesteryl ester-enriched VLDL have been shown to be more readily converted to intermediate-density lipoprotein with increased conversion to LDL through the delipidation cascade (32). In addition, studies in African green monkeys have shown that cholesterol-enriched VLDL (induced by feeding a high-cholesterol diet) are readily converted to LDL, contributing to the higher plasma LDL concentrations and atherosclerosis observed in these animals (33). Based on these studies, one can speculate that these cholesteryl ester-enriched VLDL generated by high-fat/sucrose intake are more readily converted to LDL and partly account for the higher plasma LDL levels in sucrose-fed vs. starch-fed guinea pigs, given that the number of hepatic LDL receptors was not altered by the type of dietary carbohydrate. In addition, nascent VLDL from cholesterol-fed guinea pigs has been shown to have a higher concentration of cholesteryl ester than nascent VLDL from animals fed low-cholesterol diets, which appears related to the higher hepatic cholesterol concentrations (34). Because animals fed the high-fat/sucrose diet had a higher concentration of hepatic cholesterol, the increased number of cholesteryl ester molecules per VLDL from sucrose-fed animals could be explained by the increased availability of hepatic cholesterol for incorporation into nascent VLDL (34).

Effects of dietary carbohydrate with low-fat diets. With intake of both high-carbohydrate diets, significant increases in plasma TAG were observed, although the effect was more pronounced in animals fed the high-starch diets. In addition, the starch-fed guinea pigs had a large LDL with unusual compositional characteristics, indicating that the intravascular conversion of VLDL to LDL is affected by the type of dietary carbohydrate. Guinea pigs are known to have high tissue LPL activity (35), which is one reason this animal model does not develop hypertriglyceridemia under most dietary conditions; however, HL activity is low. In the present study, both low-fat groups (starch and sucrose) had similar VLDL compositions, a large particle containing a high number of TAG molecules and more phospholipids, as has been observed in rats fed high-carbohydrate diets (36). The only difference in VLDL composition between sucrose and starch diets was a higher cholesteryl ester content for the low-fat/sucrose fed guinea pigs. However, LDL composition was substantially altered by the type of carbohydrate in animals fed the low-fat diets. LPL is the key enzyme in the hydrolysis of TAG derived from VLDL and chylomicrons, whereas HL hydrolyzes phospholipids of remnant particles (VLDL remnant) and HDL (37). Guinea pigs fed starch diets had higher concentrations of hepatic cholesteryl ester than did animals fed sucrose diets. It has been demonstrated in the Zucker rat that mRNA levels of HL are suppressed by high levels of cholesteryl ester in the liver (38) with a strong association between low HL activity and high concentrations of hepatic cholesteryl ester (38). It is possible that guinea pigs fed the starch diet had a greater suppression of HL than animals fed high sucrose due to the expanded pools of hepatic cholesteryl ester, and this, in combination with the low activity of HL in guinea pigs, resulted in a TAG-enriched LDL. The relevance of this particle to atherosclerosis deserves further attention as it is not known whether these changes in composition would alter the permeability of this LDL particle across the arterial wall or make it more susceptible to oxidation. Studies by Rudel *et al.* (39) have correlated cholesteryl ester content and LDL size with coronary artery atherosclerosis in African green monkeys and found that larger cholesteryl ester-enriched LDLs derived from animals fed saturated fat are more atherogenic than smaller LDL from monkeys fed polyunsaturated fats. Similarly, LDL from pigs with genetic hypercholesterolemia have a higher concentration of cholesteryl ester, and lower TAG content than LDL derived from normal pigs (40). Because in the present study LDL from animals fed low-fat/starch contained a high proportion of TAG and less cholesteryl ester than LDL from the other dietary groups, it is not possible at this point to compare this large TAG-enriched particle with the atherogenic large cholesteryl ester-enriched LDL observed in monkeys and in mutant pigs (39,40).

From these studies we conclude that the amount of dietary fat and the type of dietary carbohydrate elicit divergent responses in terms of plasma lipid and lipoprotein profiles and the potential atherogenicity of the evolved lipoprotein patterns deserves further consideration. Suppression of hepatic LDL receptors apparently makes a major contribution to the elevated plasma LDL observed with high-fat intake, whereas the higher plasma TAG concentrations and the larger VLDL particles resulting from high-carbohydrate intake could be due to an increase in TAG secretion from the liver (41) or a decrease in TAG removal from plasma (42). The interactive effects of the type of carbohydrate with the amount of fat also resulted in specific alterations in hepatic cholesterol distribution and the intravascular processing of lipoproteins. For example, the cholesteryl ester-enriched VLDL obtained from animals fed high-fat/sucrose is probably readily converted to LDL, thus increasing plasma LDL concentrations, and animals fed low-fat/starch exhibited a large TAG enriched LDL, whose metabolic significance and relationship to atherosclerosis is not known at present. The results from these studies also indicate that not only are fat calories relevant in terms of the plasma lipid profile and potential atherogenicity of lipoproteins, but the type of carbohydrate replacing the fat is also a major determinant of the potential cardiovascular disease risk. What is also evident is that with a high-fat diet, the type of carbohydrate contributes to the degree of fat-induced hyperlipidemia.

Effect of Peroxyl Radicals on Lecithin/Cholesterol Acyltransferase Activity in Human Plasma

Chen Chen and George Loo*

Department of Food, Nutrition and Food Service Management, School of Human Environmental Sciences, The University of North Carolina at Greensboro,Greensboro, North Carolina 27412-5001

ABSTRACT: The objective of this study was to determine whether subjecting human plasma to oxidant stress reduces the activity of lecithin/cholesterol acyltransferase (LCAT, EC 2.3.1.43). Plasma was incubated for 4 h with 2.25–45 mM of 2,2′-azo*bis*(2-amidinopropane)HCl (AAPH), a source of peroxyl radicals. A time- and concentration-dependent reduction of LCAT activity occurred, relative to control samples incubated in the absence of AAPH. Reduction of LCAT activity was disproportionate to elevation of thiobarbituric acid-reactive substances (TBARS) in the plasma. Added ascorbate was able to significantly prevent reduction of LCAT activity, but this effect was unrelated to blockage of TBARS formation by the antioxidant. The results suggest that LCAT activity can be down-modulated by oxidant stress, but not necessarily by lipid peroxidation.
Lipids 30, 627–631 (1995).

By modifying lipoproteins, oxidant stress may be implicated in the development of atherosclerosis (1). As low-density lipoprotein (LDL) is oxidatively modified, constituent polyunsaturated fatty acids undergo lipid peroxidation. Oxidized LDL particles are metabolized by macrophages, resulting in accumulation of cellular cholesterol. Transformation of macrophages into foam cells is an early event in the onset of atherogenesis. The impact of oxidative modification of high-density lipoprotein (HDL) is less clear. Since the bulk of lipid hydroperoxides in human plasma is believed to be carried by HDL (2), oxidation of HDL might be relevant to atherogenesis. The function of HDL may be impeded after oxidative modification. For example, oxidized HDL has a reduced capacity to promote cholesterol efflux from macrophage/foam cells (3,4).

On the other hand, HDL oxidation may adversely affect activity of the enzyme, lecithin/cholesterol acyltransferase (LCAT, EC 2.3.1.43). Plasma LCAT is typically associated with HDL and is believed to play a pivotal role in facilitating HDL-mediated removal of cholesterol from peripheral tissue sites (5). Isolated HDL activates purified LCAT, but this ability is decreased after copper-induced oxidation of HDL (6). Few studies are available concerning the effect of oxidant stress on LCAT and cholesterol esterification. The purpose of the present study was to determine if the activity of LCAT is reduced in human blood plasma exposed to a high concentration of peroxyl radicals. We also determined whether the antioxidant, ascorbate, is able to prevent the effects of peroxyl radicals on LCAT activity.

EXPERIMENTAL PROCEDURES

Chemicals. [4-^{14}C]Cholesterol (51.40 mCi or 1.9 GBq/mmol) was purchased from New England Nuclear (Boston, MA). The hydrophilic prooxidant, 2,2′-azo*bis*(2-amidinopropane)HCl (AAPH), was obtained from Polysciences, Inc. (Warrington, PA). All other reagents were obtained from either Fisher Scientific Co. (Norcross, GA) or Sigma Chemical Co. (St. Louis, MO).

Human blood plasma. Blood was obtained by venipuncture from normal human adults using heparinized Vacutainer tubes. After centrifugation of the blood at 1,500 × *g* for 30 min at 4°C, plasma was recovered and pooled for use in the experiments.

Treatment of human blood plasma with AAPH and assay of LCAT. As detailed below, AAPH dissolved in 0.2 M sodium phosphate buffer, pH 7.4, was added to plasma while its LCAT activity was being simultaneously assayed. LCAT activity was measured using a slight modification of the method adapted by Wallentin and Vikrot (7) from the original procedure of Stokke and Norum (8). Twenty μL of 10 mM Ellman's reagent were added to test tubes containing 50 μL of plasma and 20–40 μL of 10 mM phosphate-buffered saline. The tubes were incubated for 30 min in a shaking water bath at 37°C to allow for temporary inactivation of LCAT. Then, 30 μL of [4-^{14}C]cholesterol/albumin emulsion (265,000 dpm) were added to the tubes, followed by AAPH or both AAPH and ascorbate. After 4 h of additional incubation to allow for equilibration of radiolabel, the reaction catalyzed by LCAT was initiated by addition of 20 μL of 0.1 M β-mercaptoethanol to the tubes. After 30 min, the reaction was terminated and lipids were extracted by addition of 3.4 mL of chloroform/methanol (2:1, vol/vol). Cholesteryl esters were sepa-

Copyright © 1995 by AOCS Press

rated from unesterified cholesterol by silica gel thin-layer chromatography using chloroform/methanol/glacial acetic acid/water (25:15:4:2, by vol) as the solvent system. After chromatography, iodine vapor was used to detect lipids, and appropriate spots were marked. The iodine was then allowed to completely evaporate, and spots were scraped off directly into liquid scintillation vials. After addition of 10 mL of ScintiVerse I (Fisher), radioactivity was measured in a Beckman LS 6000SE scintillation spectrometer (Fullerton, CA). In all of our work, LCAT measurements typically produce intraexperiment coefficient of variation of less than 5% and interexperiment coefficient of variation of less than 10%.

Determination of lipid peroxidation after treatment of plasma with AAPH. AAPH or both AAPH and ascorbate were added to 50–100 μL of plasma to give a total volume of 150–300 μL, depending on the experiment. Tubes were incubated at 37°C for 4.5 h. Levels of thiobarbituric acid-reactive substances (TBARS) were measured spectrophotometrically (9). Post-incubation tubes and also tubes containing 1,1,3,3-tetramethoxypropane standards (0–4.0 nmoles) received 1 mL of 20% trichloroacetic acid containing 2.15 mM EDTA. Then, 1 mL of 1% thiobarbituric acid was added. After mixing and allowing color development for 20 min in a boiling water bath, tubes were allowed to cool and were then centrifuged at 1,500 × *g* for 15 min. Absorbance of the supernatant was measured at 532 nm.

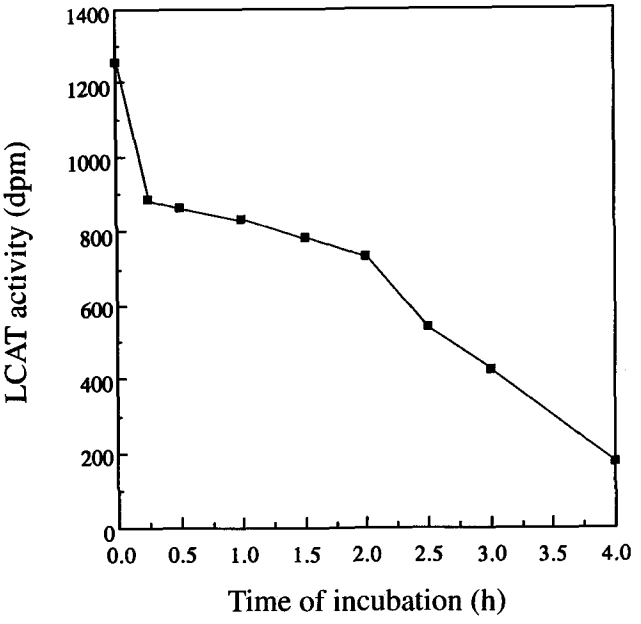

FIG. 1. Time course for the effect of 2,2′-azo*bis*(2-amidinopropane)HCl (AAPH) on the activity of lecithin/cholesterol acyltransferase (LCAT) in human blood plasma. Conditions were as in Figure 2 except that during equilibration of radiolabel, AAPH was added at various time intervals to give a final concentration of 33 mM. Counterpart control tubes received buffer alone at the beginning of the 4-h equilibration period. LCAT activity is expressed as amount of radioactivity detected in the cholesteryl ester fraction, and values are the average of two determinations.

RESULTS

Figure 1 shows the change of LCAT activity while incubating plasma with 33 mM AAPH for 4 h. With just 15 min of incubation with AAPH, there was a striking 30% reduction of LCAT activity in the plasma. Afterwards, the rate at which LCAT activity was lost remained relatively constant for up to 2 h. During this time interval of 1.75 h, only an additional 12% reduction of LCAT activity occurred. Thereafter, the rate at which LCAT activity was lost increased noticeably. At the end of 4 h after initiating the incubation, LCAT activity was reduced to 14% of control plasma samples.

As shown in Figure 2, incubation of human blood plasma with AAPH at 37°C for 4 h prior to initiating the enzyme-catalyzed reaction resulted in a concentration-dependent reduction of LCAT activity. The inhibitory effect of AAPH was small in the lower concentration range of 2.25–9 mM with only 3–13% reduction of LCAT activity. However, our preliminary data indicate that incubation of plasma at these lower AAPH concentrations for a longer period of time, instead of 4 h, produces a more appreciable reduction of LCAT activity. At the highest concentration of AAPH tested (45 mM), there was a 61% decrease in LCAT activity relative to control.

Reduction of LCAT activity in plasma incubated with AAPH was also accompanied by an increase in the levels of TBARS (Fig. 2), indicating that AAPH induced lipid peroxidation in the plasma. However, reduction of LCAT activity was only partially related to extent of lipid peroxidation. The only concentrations of AAPH that were able to produce linear increases in TBARS levels were 2.25–18 mM. These lower concentrations of AAPH also produced proportional reductions of LCAT activity. In contrast, no additional increases in TBARS levels were produced up to an AAPH concentration of 45 mM. Yet, these higher concentrations of AAPH still produced additional reduction of LCAT activity. Thus, between 18–45 mM AAPH, reduction of LCAT activity was unrelated to the extent of lipid peroxidation.

Since reduction of LCAT activity in plasma incubated with AAPH seemed to be related to lipid peroxidation at least over a certain time/concentration range, experiments were performed to evaluate the efficacy of added ascorbate to prevent both lipid peroxidation and reduction of LCAT activity. It should be noted that ascorbate concentrations that are indicated exclude the ascorbate found endogenously in normal human plasma which was not measured. However, Zannoni *et al.* (10) have reported a mean adult plasma ascorbate level of 0.071 mM, with a range of 0.012–0.121 mM. As shown in Figure 3, the presence of added ascorbate at relatively high concentrations during incubation of plasma with 30 mM AAPH was able to inhibit formation of TBARS in a concentration-dependent manner. Ascorbate added at a concentration of 8 mM was able to essentially block AAPH-induced TBARS formation under these conditions, whereas 0.5 and 1 mM ascorbate produced 21 and 46% reductions in TBARS formation, respectively. However, this concentration range of added ascorbate is much higher than would be found under physiological conditions. Therefore, the capacity of added

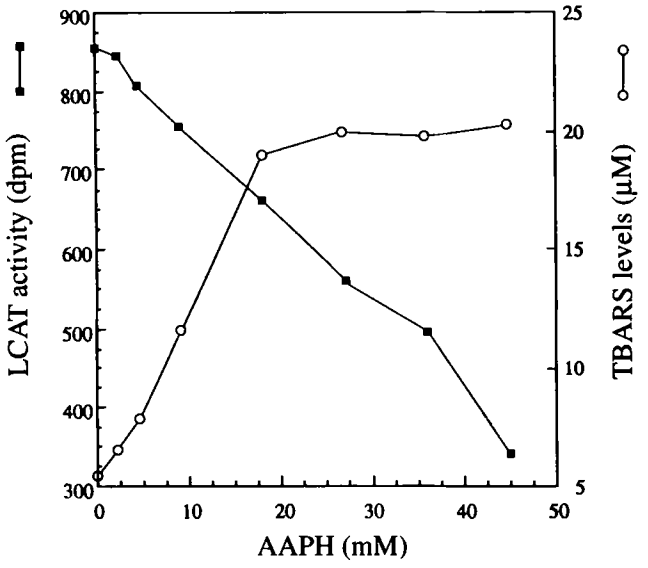

FIG. 2. Effect of 2,2'-azo*bis*(2-amidinopropane)HCl (AAPH) on the activity of lecithin/cholesterol acyltransferase (LCAT) and levels of thiobarbituric acid-reactive substances (TBARS) in human blood plasma. To test tubes containing 50 μL of plasma and 40 μL phosphate-buffered saline were added 20 μL of 10 mM Ellman's reagent. Tubes were incubated for 30 min at 37°C. Then, 30 μL of [4-^{14}C]cholesterol/albumin emulsion were added to the tubes, followed by 10 μL of AAPH to give the designated concentrations of AAPH. After 4 h of additional incubation, the reaction catalyzed by LCAT was initiated by addition of 20 μL of 0.1 M β-mercaptoethanol. LCAT activity is expressed as amount of radioactivity detected in the cholesteryl ester fraction, and values are the average of two determinations. TBARS assay was performed on other samples. To test tubes containing 100 μL of plasma and 160 μL of phosphate-buffered saline were added AAPH to give a total volume of 300 μL. Tubes were incubated at 37°C for 4.5 h, and levels of TBARS were determined as described in the Experimental Procedures section. Values represent the average of quadruplicate determinations.

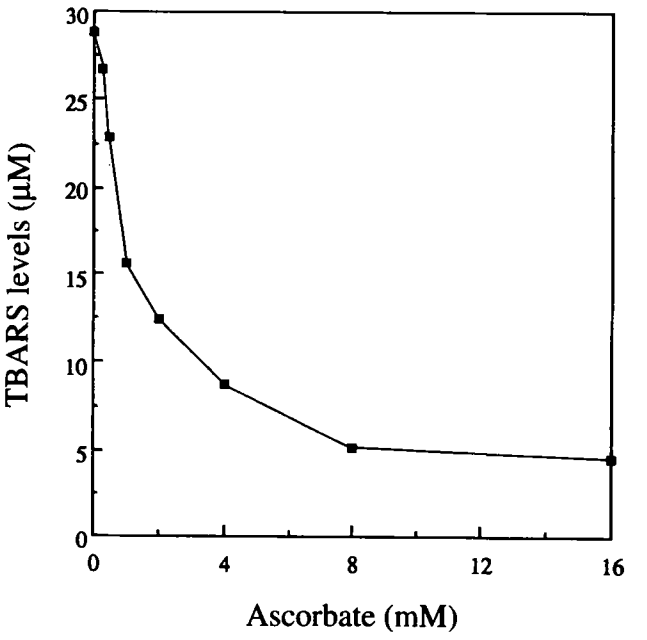

FIG. 3. Effect of added ascorbate on the levels of thiobarbituric acid-reactive substances (TBARS) in human blood plasma treated with 2,2'-azo*bis*(2-amidinopropane)HCl (AAPH). To tubes containing 50 μL of plasma and 60 μL of phosphate-buffered saline were added ascorbate to give the designated final concentrations. AAPH concentration was 30 mM. Tubes were incubated at 37°C for 4.5 h, and levels of TBARS were determined as described in the Experimental Procedures section. Values represent the average of quadruplicate determinations. The TBARS level in untreated control samples was 4.12 μM.

ascorbate to block AAPH-induced reduction of LCAT activity was tested at lower concentrations of the antioxidant.

Added ascorbate in the concentration range of 0.030–0.960 mM was able to partially prevent reduction of LCAT activity in plasma incubated with 30 mM AAPH to induce lipid peroxidation (Fig. 4). The protective effect of added ascorbate was concentration-dependent up to 0.480 mM. In the absence of added ascorbate, a 72% decrease in LCAT activity was found. However, the presence of 0.030, 0.060, 0.120, 0.240, and 0.480 mM added ascorbate allowed only 67, 58, 42, 34, and 28% decreases in LCAT activity, respectively. Higher levels of added ascorbate up to 2 mM (data not shown) were unable to block AAPH-induced reduction of LCAT activity to any greater extent than did 0.48 mM.

DISCUSSION

AAPH was used to induce oxidant stress in plasma. When incubated at 37°C, this thermally labile compound generates peroxyl radicals at a constant rate (11), and a time-dependent reduction of LCAT activity occurred (Fig. 1). A sharp de-

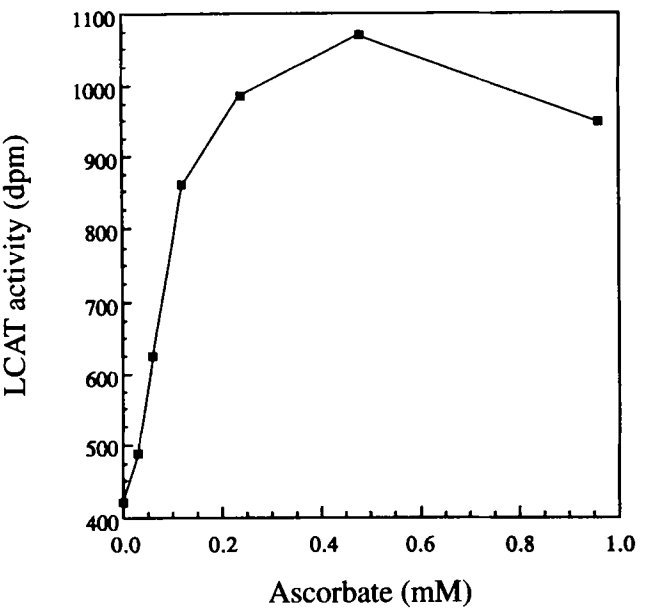

FIG. 4. Effect of added ascorbate on loss of lecithin/cholesterol acyltransferase (LCAT) activity in human blood plasma caused by 2,2'-azo*bis*(2-amidinopropane)HCl (AAPH). Conditions were as in Figure 3 except that at the start of equilibration of radiolabel during the LCAT assay, ascorbate was added to give the designated final concentrations. LCAT activity is expressed as amount of radioactivity detected in the cholesteryl ester fraction, and values are the average of two determinations. The control sample yielded 1495 dpm.

crease (30%) in LCAT activity was observed at the end of 15 min. This striking effect of AAPH might reflect rapid oxidative depletion of the β-mercaptoethanol that was added to initiate the enzyme reaction. On the other hand, it could be related to depletion of ascorbate and protein thiols which happens early when plasma is incubated with AAPH (12,13). Only slight additional reduction of LCAT activity was seen over the next 1.75 h. During this lag phase, other hydrophilic antioxidants such as bilirubin and urate might be depleted by AAPH-derived peroxyl radicals (12,13). Thereafter, however, LCAT activity decreased at a relatively faster rate. This might occur as α-tocopherol is simultaneously depleted after oxidation of all hydrophilic antioxidants (12,13).

Results in Figure 1 are consistent with recent work by McCall *et al.* (14). They observed a similar inhibition profile of LCAT activity when plasma was exposed to another form of oxidant stress, gas-phase cigarette smoke. A sharp decrease (56%) in LCAT activity occurred at the end of 1 h, followed by a lag phase of 2 h, and then noticeable resumption in the rate of decrease in LCAT activity for the next 3 h. Rapid depletion of endogenous plasma ascorbate occurred at the end of 1 h, parallelling the sharp reduction in LCAT activity. However, they also reported that addition of ascorbate at 85 μM concentration did not prevent reduction of LCAT activity. In contrast, reduced GSH significantly protected against cigarette smoke-induced inhibition of LCAT, suggesting that GSH preserved free functional sulfhydryl groups at the active site of LCAT.

Reduction of LCAT activity in AAPH-treated plasma did not appear to correlate closely with lipid peroxidation (Fig. 2). No inverse relationship can be established between reduction of LCAT activity and TBARS formation (Fig. 2). Ascorbate was able to prevent AAPH-induced lipid peroxidation (Fig. 3), as previously demonstrated (13), and also, to a large degree, the reduction of LCAT activity (Fig. 4) but the concentration-dependencies of these effects were not similar. Ascorbate at a concentration of 0.25 mM had little impact in preventing AAPH-induced formation of TBARS (Fig. 3), yet concentrations of ascorbate under 0.25 mM were able to prevent appreciable reduction of LCAT activity (Fig. 4). Lipid peroxidation can occur once the endogenous ascorbate in plasma has been depleted (12,13), but the capacity of ascorbate to protect against reduction of LCAT activity may not be due to its ability to block lipid peroxidation. More likely, ascorbate directly neutralizes AAPH-derived peroxyl radicals.

These above results suggest that LCAT activity can be down-modulated by oxidant stress, but not necessarily by lipid peroxidation. McCall and co-workers (14) have reached a similar conclusion, suggesting that greatest reduction of LCAT activity in plasma treated with cigarette smoke seems to precede lipid peroxidation. The mechanism by which AAPH causes reduction in LCAT activity remains to be elucidated. It is possible that peroxyl radicals generated from AAPH may directly attack LCAT, causing protein structural alteration. Reduction of LCAT activity might be the result of oxidation of cysteinyl free sulfhydryl groups at the active site of the enzyme. Recent studies by Frei *et al.* (12,13) have revealed that incubating human plasma, which had undergone prior gel filtration to remove endogenous ascorbate, with 50 mM AAPH leads to rapid depletion of protein thiols before the onset of lipid peroxidation. Over half the protein thiols in plasma were oxidized in less than 60 min of incubation. Added ascorbate (100 μM) was unable to prevent near complete depletion of protein thiols at the end of 180 min of incubation. Between 40 and 120 min, however, this concentration of ascorbate had a marginal but noticeable effect in retarding the rate of oxidation of protein thiols. It was not made known if higher concentrations of ascorbate could totally block AAPH-induced oxidation of protein thiols in plasma. It was suggested that protein thiols undergo autoxidation in scavenging AAPH-derived peroxyl radicals and that ascorbate cannot effectively negate this autoxidative process. Hence, in our study this could explain why added ascorbate was unable to completely prevent AAPH-induced loss of LCAT activity.

An additional explanation of the effect of AAPH may be that the peroxyl radicals produced from it may attack apolipoprotein A-I, which is a known activator of LCAT (15). This would reduce availability of intact protein cofactor to activate LCAT and decrease enzyme activity. Oxidative modification of HDL by cupric ions results in structural damage to apolipoprotein A-I and also in a modified HDL species less capable of promoting cholesterol efflux from macrophage-derived foam cells (3,4).

In conclusion, additional work is needed to uncover the mechanism by which oxidant stress reduces LCAT activity. However, it seems that reduction of LCAT activity in plasma subjected to AAPH-induced oxidant stress does not correlate directly with lipid peroxidation. Thus, the relationship between oxidant stress, reduction of plasma LCAT activity, and increased atherogenesis is in need of further study.

Kinetic Analysis of Cardiolipin Synthase: A Membrane Enzyme with Two Glycerophospholipid Substrates

Michael Schlame[a,b], Ming Zhao[a], Diego Rua[a], Dipak Haldar[b] and Miriam L. Greenberg[a,*]

[a]Department of Biological Sciences, Wayne State University, Detroit, Michigan 48202 and [b]Department of Biological Sciences, St. John's University, Jamaica, New York 11439

ABSTRACT: Mitochondrial cardiolipin synthase catalyzes the transfer of a phosphatidyl moiety from phosphatidyl-CMP (PtdCMP) to phosphatidylglycerol (PtdGro) in the presence of specific divalent cations. The synthase was solubilized from *Saccharomyces cerevisiae* mitochondria and purified about 300-fold. The partially purified enzyme was part of a medium-size, mixed micelle which had to bind to a foreign substrate/detergent micelle before catalysis could occur. The kinetics of cardiolipin synthase were studied by changing the molar fraction of substrate in the micelles. The enzyme obeyed Michaelis-Menten kinetics in relation to PtdCMP with a K_m of 0.03 mol%. PtdGro caused sigmoidal kinetics with a low apparent affinity. It is speculated that it was involved in docking the enzyme to the substrate/detergent micelle. Cardiolipin synthase did not catalyze isotope exchange between [^{14}C]CMP and PtdCMP, virtually excluding a ping-pong catalytic mechanism. Mg^{2+} stimulated the activity by increasing the turnover number rather than the substrate affinity, a mechanism which was also found for the Co^{2+}-activation of rat liver cardiolipin synthase. It is concluded that a direct association of the metal ion and the enzyme forms the active cardiolipin synthase which has a very high affinity for PtdCMP and a lower affinity for PtdGro.
Lipids 30, 633–640 (1995).

Cardiolipin is an essential phospholipid of mitochondria and some bacteria (1). It has a dimeric structure in which two phosphatidyl moieties are linked by a glycerol bridge; thus, its synthesis requires two phospholipid molecules as precursors. There is a eukaryotic and a prokaryotic reaction for cardiolipin biosynthesis, the former being a phosphatidyl transfer from phosphatidyl-CMP (CDP-diacylglycerol) (PtdCMP) to phosphatidylglycerol (PtdGro) (2–4), the latter being a phosphatidyl transfer between two PtdGro's (1). Cardiolipin formation in eukaryotes is dependent on the presence of divalent metal cations, such as Mg^{2+}, Mn^{2+}, or Co^{2+} (3–5), and is inhibited by Ba^{2+}, Ca^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, and Zn^{2+} (5), as well as the polyvalent cation ruthenium red (6). Cardiolipin synthases from individual organisms have different cation specificities, showing highest activity with either Co^{2+} (mammals, *Neurospora crassa*) or Mg^{2+} (yeast, higher plants, molluscs), respectively (4). It is not known which cation is the authentic activator of cardiolipin biosynthesis *in vivo*, although Mg^{2+} is a likely candidate because it was effective in all organisms studied (3–5) and it is sufficiently concentrated in the cell. Cardiolipin synthase was purified from rat liver to characterize its properties, in particular the high sensitivity to its lipid environment (7).

In as much as both substrates of cardiolipin synthase are glycerophospholipids, which are insoluble in water, the kinetics of this enzyme are of particular significance. Extensive studies of the kinetic behavior in nonsoluble lipid aggregates have been performed for several enzymes which use a single lipid substrate, such as phospholipase A_2 (8,9), diacylglycerol kinase (10), or glycerol-3-phosphate acyltransferase (11). Recently, such experiments have been extended to the yeast enzymes PtdCMP synthase (12), phosphatidylserine synthase, phosphatidylinositol synthase (13), and phosphatidylinositol 4-kinase (14). Micellar detergent/phospholipid mixtures were used in the kinetic studies since they provided the enzymes with a well-dispersed substrate at a defined lipid/water interface. Because it has two lipid substrates instead of one, cardiolipin synthase adds an additional dimension to the problem of interfacial kinetics. To study its properties in a micellar system, yeast cardiolipin synthase was solubilized by Triton X-100 (Pierce Chemical Company, Rockford, IL) and partially purified. The major goal of this work was to compare the function of the two substrate phospholipids and to elucidate the role of the divalent cation in the catalytic process.

EXPERIMENTAL PROCEDURES

Materials. Phenylmethylsulfonylfluoride (PMSF), leupeptin, and aprotinin were obtained from Boehringer (Mannheim, Germany). *N*-ethylmaleimide and pepstatin A were from Sigma (St. Louis, MO). Blue Sepharose CL-6B, Q-Sepharose Fast Flow, S-Sepharose Fast Flow, and the Superose 12 column (HR 10:30) were obtained from Pharmacia (Uppsala, Sweden). Precoated silica gel 60 plates were from Merck (Darmstadt, Germany), and DE-52 anion exchange resin was

from Whatman BioSystems Ltd. (Maidstone, United Kingdom). PtdGro (derived from egg yolk phosphatidylcholine) was obtained from Sigma and Triton X-100 was from Pierce Chemical Company. 1,2-Dimyristoyl-*sn*-[U-^{14}C]glycero-3-diphospho-5′-cytidine ([^{14}C]PtdCMP) was synthesized exactly as described (15). Its specific radioactivity was 88 dpm/pmol. 1,2-Dimyristoyl-*sn*-[2-^{3}H]glycero-3-phospho-5′-cytidine ([^{3}H]PtdCMP) was synthesized from [2-^{3}H]glycerol by the following procedure: (i) enzymatic phosphorylation to *sn*-glycero-3 phosphate by glycerokinase (16), (ii) chemical acylation to dimyristoylphosphatidic acid (15), and (iii) enzymatic conversion to PtdCMP by incubation with CTP and membranes of the PtdCMP synthase overproducing *Escherichia coli* strain DH1-pCD100 (3). The specific radioactivity of the [^{3}H]PtdCMP was 1070 dpm/pmol. [5-^{3}H]Cytidine-5′-monophosphate ([^{3}H]CMP) was obtained by acid hydrolysis of [5-^{3}H]cytidine-5′-triphosphate. A 50 mM solution of the nucleoside triphosphate was incubated for 8 h in 0.1 M Tris (pH 6) at 90°C. The degree of hydrolysis was monitored by thin-layer chromatography on silica gel G plates developed with 1-butanol/acetone/acetic acid/1.6% ammonia (45:15:10:30). The specific radioactivity of [^{3}H]CMP was 4.4 dpm/pmol.

Partial purification of cardiolipin synthase from yeast. The wild-type *Saccharomyces cerevisiae* strain D273-10B (*met6* MATa) was grown to mid-logarithmic phase at 30°C in a medium containing 1% (wt/vol) yeast extract, 2% (wt/vol) peptone, and 2% (wt/vol) glucose. The harvested cells were stored at −80°C and rethawed for the enzyme preparation which was performed in a cold room (4°C). The cell paste (100 g wet weight) was washed with water and then suspended in 400 mL of medium containing 50 mM Tris (pH 7.5), 20% (vol/vol) glycerol, 0.5 mM PMSF, and 4 mM NaF. The cells were disrupted by homogenization with prechilled glass beads in a Biospec (Bartlesville, OK) Products Bead Beater. The homogenate was spun at 1000 × *g* for 5 min to remove glass beads and unbroken cells, and the supernatant was spun at 17,500 × *g* for 10 min to pellet crude mitochondria. The mitochondria were resuspended in 100 mL isolation medium, containing 50 mM Tris (pH 7.5), 0.3 M sucrose, 1 mM EDTA, and 0.5 mM PMSF, and centrifuged at 2000 × *g* for 5 min. Mitochondria remained in the supernatant from which they were pelleted by centrifugation at 17,500 × *g* for 15 min. The final mitochondrial pellet was resuspended in a small volume of isolation medium and then diluted by 100 mL of 5 mM phosphate buffer (pH 7.5) containing 0.25 mM EDTA, 0.25 mM EGTA, 0.5 mM PMSF, 0.1 mM *N*-ethylmaleimide, 1 mg/L pepstatin A, 1 mg/L leupeptin, and 2 mg/L aprotinin. This suspension was gently stirred for 20 min in order to swell the mitochondria. After that, the pH was adjusted to 8.5 with several drops of a 1 M Tris solution and solid KSCN (potassium thiocyanate; General Chemical Co., New York, NY), a chaotropic salt, was added to a final concentration of 1M. Stirring was continued for 30 min, and the suspension was sonicated for 1 min using a Model W140 Sonifier Cell Disruptor (Ultrasonics, Inc., Plainview, NY) set at 70% of maximal power output. The KSCN-extracted mitochondrial membranes were pelleted by ultracentrifugation (100,000 × *g*; 1 h) and resuspended in about 4 mL of medium which contained 30 mM Tris (pH 7.5; 4°C), 20% (vol/vol) glycerol, 0.5 mM EDTA, and 0.5 mM EGTA. The protein concentration of the membranes was adjusted to 10 g/L, Triton X-100 was added to a final concentration of 2% (wt/vol), and solid KCl was added to a final concentration of 0.05 M. The suspension was incubated for 30 min after which it was homogenized in a Dounce tissue grinder (Wheaton Dounce Tissue Grinders, Millville, NJ). Nonsolubilized membranes were spun down at 25,000 × *g* for 15 min and the supernatant was used for further preparations. During solubilization and all chromatographic procedures, the following cocktail of protease inhibitors was present: 0.5 mM PMSF, 0.1 mM *N*-ethylmaleimide, 1 mg/L pepstatin A, 1 mg/L leupeptin, and 2 mg/L aprotinin. All inhibitors were freshly added to the solvents prior to use. The Triton-extract was consecutively passed through a DEAE-anion exchange column (DE-52), a Cibacron Blue 3G-A column (Blue Sepharose CL-6B), and a Q-Sepharose Fast Flow anion exchange column. The pass-through fraction was collected at each step. The columns were equilibrated with a medium containing 30 mM Tris (pH 7.5; 4°C), 20% (vol/vol) glycerol, 0.5 mM EDTA, 0.5 mM EGTA, and 0.5% Triton X-100. Their bed volume was 60% of the volume of the Triton-extract. The pass-through fraction of the Q-Sepharose column was loaded on a S-Sepharose Fast Flow cation exchange column which had the same bed volume as the applied fraction and which was equilibrated in the same medium as described above. After loading the sample, the column was washed with one bed volume of equilibration medium. Subsequently, the enzyme was eluted by equilibration medium containing 1 M KCl. One milliliter fractions were collected and assayed for cardiolipin synthase activity. The peak fractions were pooled, concentrated, and applied on a Superose 12 HR 10:30 gel filtration column equilibrated with a medium containing 30 mM Tris (pH 7.5; 4°C), 20% (vol/vol) glycerol, 0.5 mM EDTA, 0.5 mM EGTA, 0.2% (wt/vol) Triton X-100, and 1 M KCl. Fractions of 0.8 mL were collected and assayed for activity. The two peak fractions were pooled and used for the kinetic studies. The enzyme preparation did not contain detectable levels of phospholipid contamination (determined in the dried, ashed lipid extract by colorimetric measurement of the phosphomolybdate complex).

Isolation and permeabilization of rat liver mitochondria. Rat liver mitochondria were prepared by a standard differential centrifugation procedure at a temperature of 0–4°C. Sprague-Dawley rats were starved overnight and decapitated, and the liver was homogenized in 0.25 M sucrose containing 20 mM Tris (pH 7.4) and 0.5 mM EDTA. The homogenate was spun at 600 × *g* for 5 min, the supernatant was removed and spun at 6,000 × *g* for 4 min. The pellet was resuspended in the same buffer and centrifuged at 15,000 × *g* for 90 s. After an additional resuspension/centrifugation cycle, the pellet was homogenized in the isolation medium and stored at −20°C. Before the experiments, the mitochondrial suspension was rethawed and adjusted to a protein concentration of 25

g/L, followed by a 30-min preincubation with 1 mM *N*-ethylmaleimide and 4 mM Triton X-100 at 0°C.

Assay of cardiolipin synthesis. Cardiolipin synthase activity was assayed at 37°C by incubating the enzyme with radiolabeled PtdCMP and unlabeled PtdGro in a total volume of 0.11 mL (15). The phospholipids were added individually from 10-fold concentrated stock solutions which were prepared by sonication of the lipids in water. The reaction medium contained 50 mM Tris (pH 9.0), 0.25 mM EGTA, and Triton X-100. All ingredients were allowed to equilibrate for 5 min before the reaction was started by addition of a metal cation (either Mg^{2+} or Co^{2+}). The reaction was stopped by addition of 2 mL methanol. Extraction of lipids, chromatographic isolation of labeled cardiolipin, and scintillation counting were performed exactly as described previously (15). Specific assay conditions were as follows: To measure the enzyme in the purification procedure, samples were incubated for 1 h in the presence of 3.4 μM [^{14}C]PtdCMP, 1 mM PtdGro, 10 mM $MgCl_2$, and 0.8 mM Triton X-100. For the kinetic analysis of the partially purified yeast enzyme, 4 μg of protein were incubated for 40 min in the presence of various concentrations of radiolabeled PtdCMP, PtdGro, $MgCl_2$, and Triton X-100. The amount of Triton, which was added with the enzyme, was taken into consideration. [^{3}H]PtdCMP (1070 dpm/pmol) was used when working at low PtdCMP concentrations, and [^{14}C]PtdCMP (88 dpm/pmol) was used when higher concentrations (>1 μM) were required. Cardiolipin synthase activity in rat liver mitochondria was assayed for 1 h in the presence of 0.25 mg protein. Further details are given in the legends. Cardiolipin formation was linear with respect to time over the indicated incubation periods.

^{31}P nuclear magnetic resonance (NMR) spectroscopy. ^{31}P NMR measurements of PtdGro/Triton X-100 mixtures were performed under incubation conditions similar to those in the cardiolipin synthase assay. The medium contained 50 mM Tris (pH 9.0, 37°C), 0.25 mM EGTA, 10 mM $MgCl_2$, and 173 mM KCl. KCl was added because it was present in all cardiolipin synthase assays as a contaminant of the enzyme preparation. The total concentration of PtdGro plus Triton X-100 was 16.5 mM and different ratios of PtdGro/Triton X-100 were adjusted. The samples were placed in 10-mm probes and maintained at 37°C during aquisition of the NMR spectra. The spectra were obtained by averaging 400 scans recorded with a GN-300 NMR (300 MHz) (General Electric, Fremont, CA). The tip angle was 60°, the aquisition time was 0.54 s, the relaxation delay was 0.2 s, and the sweep window was 7518 Hz.

Other methods. The protein concentration was determined by the method of Lowry *et al.* (17). Nonlinear regression analysis was performed with the program Sigmaplot 4.0 (Jandel Scientific, San Rafael, CA) which uses the Marquardt-Levenberg algorithm.

RESULTS

Micellar properties of partially purified cardiolipin synthase from yeast. Cardiolipin synthase was solubilized by Triton X-100 from yeast mitochondrial membranes and partially purified as shown in Table 1. The specific activity of the final enzyme preparation suggested a purification of about 300-fold. Partially purified cardiolipin synthase was associated with Triton, as indicated by the following facts: (i) Relatively high concentrations of Triton X-100 were required to solubilize the enzyme, whereas the chaotropic salt KSCN was unable to release it from the membranes; and (ii) Decrease of Triton X-100 below its critical micellar concentration led to aggregation and irreversible inactivation of the enzyme (data not shown).

The size of a mixed protein/detergent micelle depends on the molecular mass of the protein and on the number of detergent binding sites on its surface. We determined the size of the enzyme/Triton complex by fast-pressure liquid chromatography gel filtration on a Superose 12 HR 10:30 column and compared it to the size of pure Triton X-100 micelles (Fig. 1). The size distribution of the cardiolipin synthase activity was virtually identical to that of pure Triton micelles with aggregation numbers 100 to 155 (18). Calibration of the gel filtration column showed that the apparent molecular mass of the cardiolipin synthase–Triton complex was about 70 kDa. Thus, the enzyme protein must be smaller than 70 kDa and the number of Triton molecules bound to the enzyme must be lower than 100.

Basic kinetic features of yeast cardiolipin synthase in a micellar system. The rate of cardiolipin formation was measured in a mixed micellar system containing Triton X-100, PtdCMP, and PtdGro. In this system, the total lipid concentration (LIPID) is defined as the sum of the bulk concentrations of Triton, PtdCMP, and PtdGro, while the molar ratio of the substrates is defined as [PtdCMP]/LIPID, and [PtdGro]/LIPID, respectively. As shown in Figure 2A, a proportional increase of the bulk concentrations of PtdGro and Triton X-100 resulted in a decrease in the reaction rate. Since the enzyme activity was not inhibited by Triton X-100 up to a concentration of 3 mM (3), detergent inactivation could be excluded as a possible cause. A more plausible explanation for the decreasing rate was the drop of the PtdCMP molar ratio resulting from the addition of PtdGro and detergent. This im-

[a]The specific activities are average values (+ SEM) of three enzyme preparations; KSCN, a chaotropic salt; Q-Sepharose, S-Sepharose, and Seperose 12 (Pharmacia, Uppsala, Sweden); Triton extract (Pierce Chemical Company, Rockford, IL).

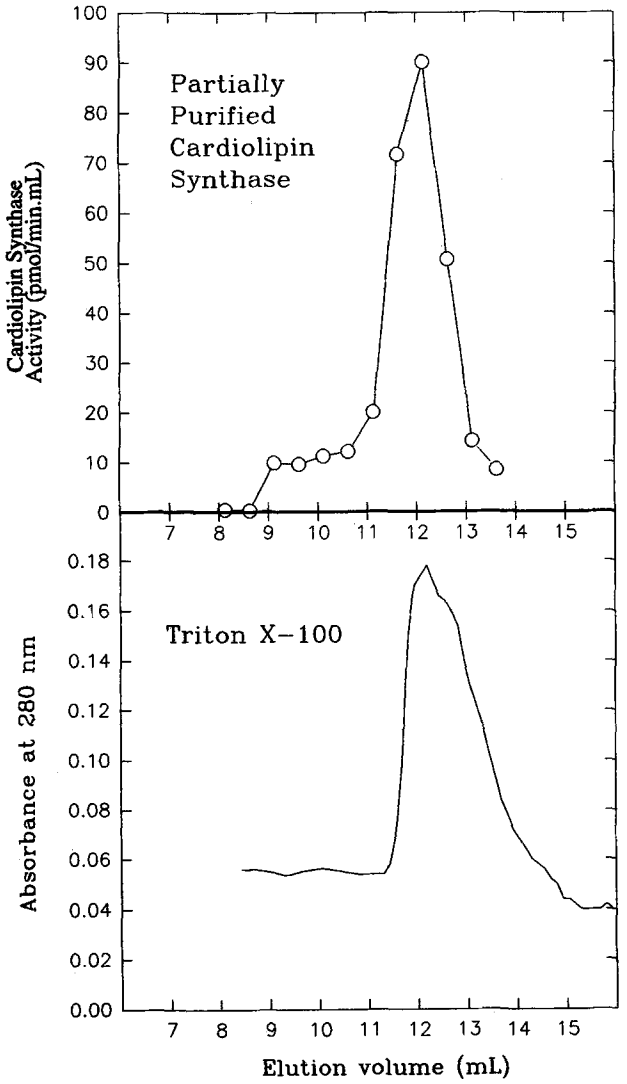

FIG. 1. Size-exclusion chromatography of partially purified cardiolipin synthase and Triton X-100 (Pierce Chemical Company, Rockford, IL) micelles. Upper panel: An aliquot of partially purified cardiolipin synthase was chromatographed on a Superose 12 HR 10:30 FPLC column (Pharmacia, Uppsala, Sweden). The column was equilibrated in 20% (vol/vol) glycerol, 0.03 M Tris (pH 7.5, 4°C), 0.2% (wt/vol) Triton X-100, 1 M KCl, 0.5 mM EDTA, and 0.5 mM EGTA, and it was run at a flow rate of 0.25 mL/min. Fractions of 0.5 mL were collected, and 25 µL aliquots were withdrawn for the determination of cardiolipin synthase activity. Lower panel: A sample of 1% (wt/vol) Triton X-100 was chromatographed under exactly the same conditions, and the elution of Triton was monitored spectrophotometrically at 280 nm.

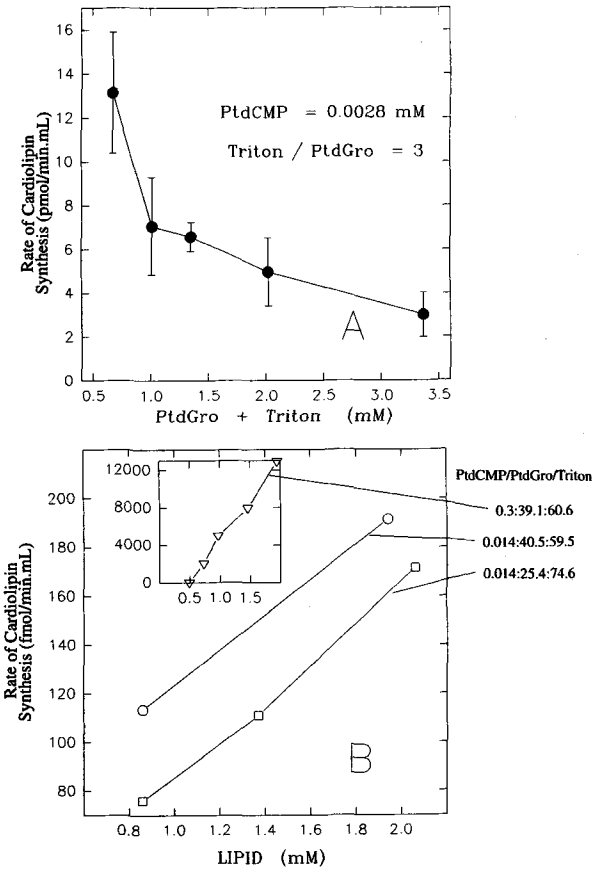

FIG. 2. Rate of cardiolipin synthesis at different micellar compositions. A: Dependence of the reaction rate on the concentration of phosphatidylglycerol (PtdGro) plus Triton X-100 at a fixed PtdGro/Triton ratio. The velocity of partially purified yeast cardiolipin synthase was measured in the presence of 2.8 µM phosphatidyl-CMP (CDP-diacylglycerol) (PtdCMP) and 10 mM Mg^{2+}. The absolute concentration of Triton and PtdGro was varied while maintaining a Triton/PtdGro ratio of 3. The data are mean values with standard error of mean (n = 3). B: Dependence of the reaction rate on the total lipid concentration at a constant molar ratio of lipids. The velocity of partially purified yeast cardiolipin synthase was measured at the indicated ratio of PtdCMP/PtdGro/Triton. The total concentration of lipids (LIPID = PtdCMP + PtdGro + Triton) was varied. The concentration of Mg^{2+} was 10 mM. The data are mean values of two experiments. Ranges were lower than 13%. See Figure 1 for company source.

plies that PtdCMP was presented to the enzyme as a PtdCMP/PtdGro/Triton aggregate and that it was the molar ratio of PtdCMP in this aggregate, rather than its bulk concentration that determined the rate of cardiolipin formation. When the total lipid concentration was increased while keeping the lipid ratio constant, the rate of cardiolipin formation increased as well (Fig. 2B). This experiment was repeated for different lipid ratios, demonstrating a dependence on that ratio at constant total lipid concentration: The rate was slightly higher in the presence of 40.5 mol% PtdGro than in the presence of 25.4 mol% PtdGro, and it increased about 50-fold when the PtdCMP ratio was enhanced from 0.014 to 0.3 mol% (Fig. 2B). In conclusion, the reaction rate was dependent on both the total lipid concentration and the molar ratios of the two substrates.

Kinetic dependence of yeast cardiolipin synthase on the molar fraction of PtdGro. The rate of cardiolipin formation was measured at constant total lipid concentration and changing molar fractions of PtdGro. The kinetics showed a sigmoidal behavior with an estimated Hill coefficient of 3.3 (Fig. 3). Substrate saturation was reached between 40 and 50 mol% of PtdGro; however, further increase of the PtdGro level led to strong inhibition of the cardiolipin formation. In the presence of low concentrations of cardiolipin, the sig-

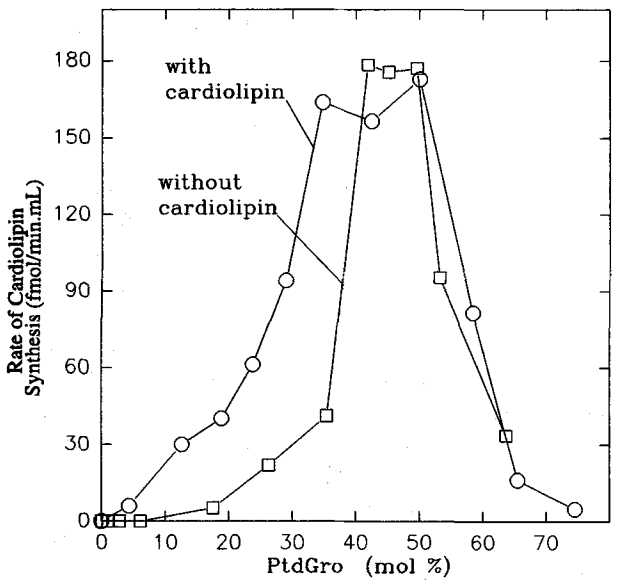

FIG. 3. Dependence of the reaction rate on the molar ratio of PtdGro in the presence and absence of cardiolipin. The velocity of partialy purified yeast cardiolipin synthase was measured at constant total lipid concentration [total lipid concentration (LIPID) = 1.7 mM] in the absence (□) and presence (○) of 3.2 mol% cardiolipin. The molar ratio of PtdGro was increased at expense of Triton X-100. For the calculation of the micellar PtdGro/LIPID ratio, the critical micellar concentration of Triton X-100 (0.25 mM) was subtracted from the total lipid concentration. The molar ratio of PtdCMP was 0.016 mol% and the concentration of Mg^{2+} was 10 mM. The data are mean values of two experiments. Ranges were lower than 28%. See Figure 2 for other abbreviations and company source.

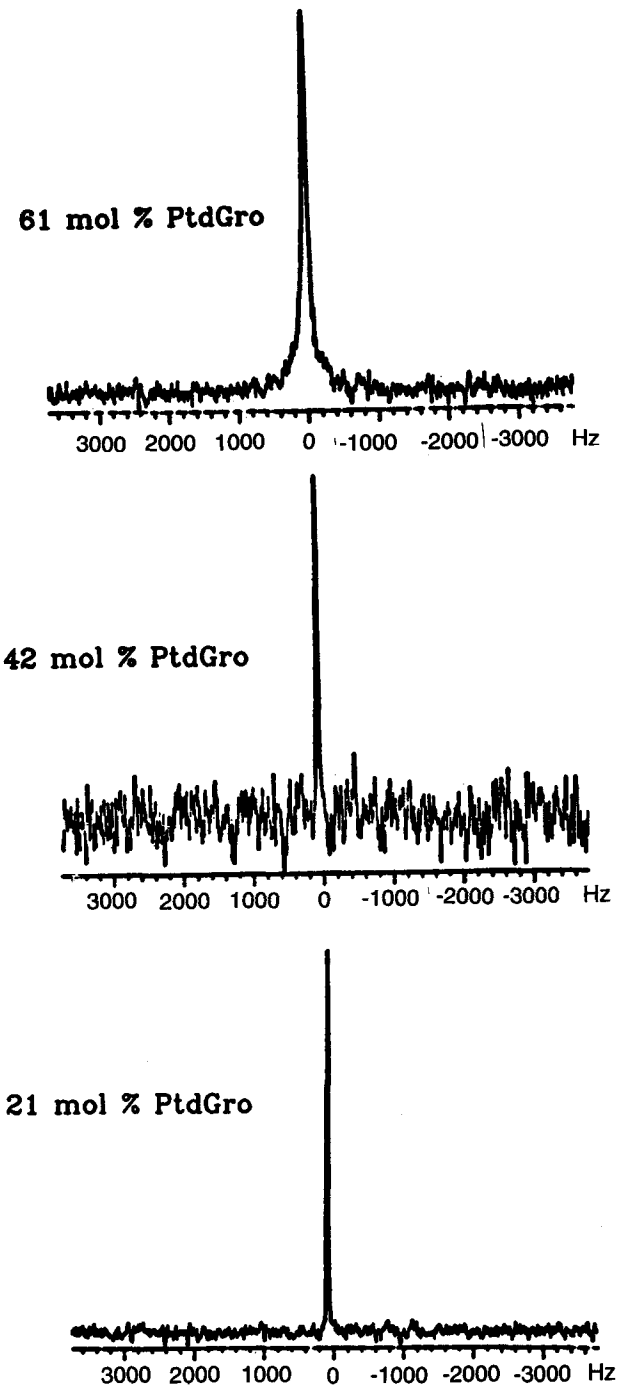

FIG. 4. ^{31}P nuclear magnetic resonance (NMR) spectra of different PtdGro/Triton X-100 mixtures. PtdGro and Triton X-100 were incubated in a medium similar to the cardiolipin synthase assay mixture. The total lipid concentration (LIPID = PtdGro + Triton) was 16.5 mM. ^{31}P NMR spectra were recorded for three different molar fractions of PtdGro. The improvement of the signal to noise ratio at higher PtdGro levels was partly offset by an increase of the sample viscosity. See Figure 2 for other abbreviations and company source.

moidal part of the curve was shifted toward lower PtdGro concentrations; thus, cardiolipin increased the apparent affinity of cardiolipin synthase for PtdGro. At the same time, it decreased the sigmoidality as reflected by a drop of the Hill coefficient from 3.3 to 1.5. In contrast, the neutral phospholipids phosphatidylcholine and phosphatidylethanolamine had no stimulating effect on cardiolipin formation (data not shown). Since the ratio of PtdGro to Triton X-100 was varied significantly in the kinetic experiment, it was important to have some information about the physical state of the lipids. To this end, we measured ^{31}P NMR spectra of PtdGro/Triton X-100 mixtures at the same ionic strength, pH, and Mg^{2+} concentration as in the assay system. The NMR sensitivity made it necessary to use higher absolute lipid concentrations than in the enzyme assay, but comparable lipid ratios were used (PtdCMP was omitted because it cannot affect the physical state due to its very low abundance). Figure 4 shows that, regardless of the PtdGro ratio (21, 42, and 61 mol%), a single, isotropical ^{31}P peak was found in all NMR spectra. This strongly suggested a micellar state since phase changes toward more lamellar structures were expected to result in the appearance of either asymmetrical NMR line shapes or two-component spectra (19). The NMR data were in line with a similar study on phosphatidylcholine/Triton X-100 mixtures, in which a purely isotropic state was preserved up to a lipid/detergent ratio of 1 (19). However, one must remember that ^{31}P NMR reports phase transitions only and is not susceptible to more subtle changes of the micellar structure.

Effect of Mg^{2+} on yeast cardiolipin synthase. The Mg^{2+} dependence of the purified yeast cardiolipin synthase is

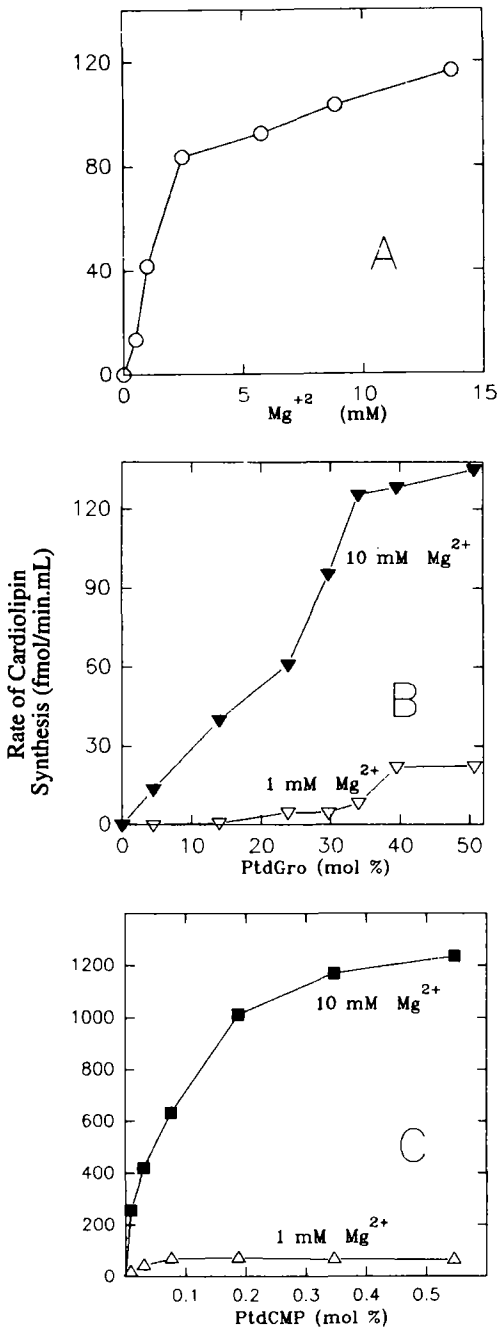

FIG. 5. The effect of Mg^{2+} on yeast cardiolipin synthase. A: The velocity of partially purified yeast cardiolipin synthesis was measured at different Mg^{2+} concentrations in the presence of 0.17 μM PtdCMP, 0.57 mM PtdGro, 1.0 mM Triton X-100, and 0.05 mM cardiolipin. B: The PtdGro dependence of cardiolipin synthesis was measured at low and high Mg^{2+} concentration. LIPID = 1.72 mM; PtdCMP = 0.17 μM; cardiolipin = 0.05 mM. The concentration of PtdGro was increased at expense of Triton X-100. For the calculation of the micellar PtdGro/LIPID ratio, the critical micellar concentration of Triton X-100 (0.25 mM) was subtracted from the total lipid concentration. C: The PtdCMP dependence of cardiolipin synthesis was measured at low and high Mg^{2+} concentration. LIPID = 1.72 mM; PtdGro = 0.46 mM; cardiolipin = 0.05 mM. For the calculation of the micellar PtdCMP/LIPID ratio, the critical micellar concentration of Triton X-100 (0.25 mM) was subtracted from the total lipid concentration. All data are average values of three experiments. Standard errors were lower than 29% of the respective mean values. See Figures 2 and 3 for abbreviations. See Figure 2 for company source.

shown in Figure 5A. The Mg^{2+} concentration required for half-maximal activity was 1.7 ± 0.7 mM as estimated by nonlinear fitting of the hyperbolic saturation curve. To investigate the Mg^{2+} effect in more detail, the substrate dependence of cardiolipin synthase was measured at optimal and suboptimal Mg^{2+} concentrations (Fig. 5B,C). Mg^{2+} affected both the PtdGro and the PtdCMP kinetics by increasing the maximal enzyme activity. However, there was no significant effect on the PtdCMP substrate affinity: The two K_m values for PtdCMP, each estimated by nonlinear regression analysis of 18 kinetic points, were 0.02 ± 0.01 and 0.03 ± 0.01 mol% in the presence of 1 and 10 mM Mg^{2+}, respectively. On the other hand, the apparent affinity to PtdGro was slightly higher at the higher Mg^{2+} concentration (Fig. 5B). It is important to note that, in contrast to PtdGro, the rate dependence on PtdCMP followed hyperbolic saturation kinetics (Fig. 5C). Thus, it was possible to estimate the apparent K_m value of PtdCMP but not that of PtdGro.

Measurement of isotope exchange between CMP and PtdCMP. PtdCMP contains an anhydride bond which is cleaved during the reaction with PtdGro. Thus, cardiolipin synthesis could potentially involve binding of PtdCMP as the first substrate followed by its conversion to a high-energy enzyme ~ Ptd intermediate and free CMP (ping-pong mechanism). If this were the case, cardiolipin synthase would catalyze isotope exchange between CMP and PtdCMP. To test this hypothesis, we measured the ^3H transfer from [^{3}H]CMP to PtdCMP in the presence of partially purified yeast cardiolipin synthase. The data of Table 2 show unequivocally that there was no enzyme-catalyzed exchange reaction between CMP and PtdCMP, even under conditions where the labeled substrate was in 30-fold excess over the unlabeled one. Addition of PtdGro to the reaction mixture did not stimulate the exchange reaction.

Effect of Co^{2+} on cardiolipin synthase in rat liver mitochondria. Co^{2+} is the most efficient cation for the activation

TABLE 2
Yeast Cardiolipin Synthase Does Not Catalyze an Exchange Reaction Between [^{3}H]CMP and PtdCMP[a]

	Recovery of [^{3}H]PtdCMP (pmol)		
Metabolites	25 min	75 min	180 min
300 nmol [^{3}H]CMP (10 nmol PtdCMP)	−1 ± 6	−3 ± 9	+5 ± 5
300 nmol [^{3}H]CMP (10 nmol PtdCMP + 30 nmol PtdGro)	−11 ± 6	+3 ± 2	+1 ± 3

[a]The indicated metabolites were dissolved in a total volume of 0.12 mL reaction buffer containing 50 mM Tris (pH 9.0), 0.25 mM EGTA, 1.3 mM Triton X-100, 10 mM $MgCl_2$, and 11 μg partially purified cardiolipin synthase. Samples were incubated at 37°C for 0, 25, 75, or 180 min. The incubation was stopped by lipid extraction followed by chromatographic isolation of phosphatidyl-CMP (CDP-diacylglycerol) (PtdCMP) on precoated silica gel 60 plates using the solvent chloroform/methanol/water/30% ammonia (70:38:2:8). The recovery of [^{3}H]PtdCMP was calculated from the radioactivity found in the PtdCMP fraction after subtracting the blank value (0 min incubation). Data are means (± SEM) of three experiments. See Table 1 for company source; PtdGro, phosphatidylglycerol.

of rat liver cardiolipin synthase (4,5), reaching saturation at about 5 mM (5,7). To characterize the effect of Co^{2+}, apparent kinetic parameters were determined at high (5 mM) and low (0.5 mM) Co^{2+} concentration in rat liver mitochondria. The kinetic curves obtained were hyperbolic, and kinetic parameters were derived by nonlinear fitting (Sigmaplot 4.0) of at least 8 data points for each parameter respectively. Co^{2+} activated cardiolipin formation by increasing the maximal enzyme activity from 2.9 ± 0.1 pmol/min/mg protein (at low Co^{2+}) to 4.1 ± 0.6 pmol/min/mg protein (at high Co^{2+}). The apparent K_m for PtdGro decreased from 61 ± 9 μM (at low Co^{2+}) to 32 ± 18 μM (at high Co^{2+}), while the apparent K_m for PtdCMP was not affected (2.4 ± 1.0 μM and 2.9 ± 1.6 μM at low and high Co^{2+}, respectively). Thus, the Co^{2+} effect on the liver enzyme was similar to that of Mg^{2+} on the yeast enzyme. This was true despite the differences in assay conditions between whole mitochondria (rat enzyme) and mixed micelles (yeast enzyme).

DISCUSSION

Cardiolipin synthase is a membrane-bound enzyme which uses two phospholipids as substrate. The enzyme was solubilized by Triton X-100, partially purified, and then used for kinetic experiments. In theory, there are three ways in which the solubilized cardiolipin synthase could interact with the substrate lipids: (i) The enzyme could react with soluble substrate monomers, (ii) the enzyme could react with substrate molecules associated with its own lipid/detergent anulus, and (iii) the enzyme could bind to a Triton/phospholipid micelle and react with substrates from this "foreign" micelle. In case (i), the reaction rate is expected to obey Michaelis-Menten kinetics with respect to the bulk concentrations of substrates. In case (ii), the rate should depend on the relative number of substrate molecules in the lipid/detergent anulus of the enzyme. Provided that the intermicellar lipid exchange is much faster than the reaction rate [Intermicellar phospholipid exchange may occur by both monomer diffusion and transient micelle collision. The rate constants of these processes were estimated for phosphatidylcholine/taurocholate mixed micelles (21,22). The data suggest that intermicellar lipid exchange is faster by several orders of magnitude than the maximal rate of cardiolipin formation measured ($2 \cdot 10^{-10}$ M^{-1} s^{-1}). Although the taurocholate/phosphatidylcholine system is different from the PtdCMP/PtdGro/Triton mixture, micellar exchange rates are expected to have the same order of magnitude.], this number is expected to be proportional to the molar fraction of substrates in the lipids [(PtdCMP)/LIPID and (PtdGro)/LIPID]. Case (iii) is analogous to a kinetic model developed for venom phospholipase A_2 (8,9). It predicts that the reaction rate depends on both the concentration of micelles (total lipid concentration) and the molar ratio of substrates in the micelles. This is what we found in the kinetic experiments with partially purified cardiolipin synthase (Figs. 2,3,5). Thus, it seems that cardiolipin synthase must first associate with the PtdCMP/PtdGro/Triton micelles before it can catalyze the formation of cardiolipin. However, it remains unknown whether the association between the enzyme/Triton micelle and the phospholipid/Triton micelle is achieved by surface attachment or by micelle fusion.

Most kinetic experiments were done at constant total lipid concentration and variable molar proportions of the lipid components. The rationale of that approach was to keep the overall surface area of the micelles approximately constant while changing the surface concentration of individual lipids (8). The fact that cardiolipin synthase requires high molar fractions of PtdGro, in order to be active, makes this assumption somewhat problematic, since structural changes of the micelle are likely to occur as PtdGro content increases from 0 to 70 mol%. The same does not apply to PtdCMP whose molar proportion was never above 0.5 mol%. Thus, at the present stage, there are several interpretations possible for the curves in Figure 3. For instance, the sigmoidal part of the PtdGro dependence may indicate that cardiolipin synthase interacts with more than one PtdGro molecule at a time. In addition to being a substrate, PtdGro may be an enzyme activator or may facilitate enzyme binding to the micelle. However, the fact that cardiolipin formation decreased when the PtdGro ratio was over 50 mol% is most likely due to changes of the micellar structure. While the NMR data do not suggest the formation of a lamellar-type phase (Fig. 4), other structural changes within the micellar phase cannot be excluded by NMR spectroscopy. In any case, PtdGro was crucial in forming the specific microenvironment of the enzyme. Cardiolipin, but not the neutral lipids phosphatidylcholine and phosphatidylethanolamine, was able to shift the PtdGro dependence toward lower concentrations (Fig. 3), suggesting that cardiolipin synthase was susceptible to both PtdGro and cardiolipin (and perhaps other acidic phospholipids).

Since a ping-pong catalytic mechanism seems to be very unlikely for cardiolipin synthase (Table 2), the enzyme is expected to form a ternary complex with the two substrate phospholipids. However, the kinetic data showed that the two phospholipids have different functional properties. PtdCMP shows hyperbolic kinetics with an extremely low K_m value (Fig. 5); thus, it behaves like a regular substrate with very high binding affinity. PtdGro, on the other hand, is not only a substrate but is also involved in establishing the proper environment for the enzyme (see above). As few as 2–3 molecules of PtdCMP in 10,000 lipid molecules are required for half-maximal activity of cardiolipin synthase while the equivalent PtdGro level is several hundredfold higher. Mitochondria contain PtdGro as a minor phospholipid, accounting for 1 to 10% of lipid phosphorus (22). The mitochondrial content of PtdCMP is usually below the detectable level, which provides a potential reason for the high PtdCMP affinity.

Divalent metal cations are specific cofactors of cardiolipin formation (3–5). In theory, these ions may either bind to the anionic substrates, forming lipid-metal complexes, or to the enzyme protein. If one of the authentic substrate species was, in fact, a metal complex, the K_m value of that substrate should depend on the metal ion concentration. We measured the sub-

strate affinities of cardiolipin synthases from yeast and rat liver at optimal and suboptimal concentrations of Mg^{2+} and Co^{2+}, respectively, and we found no differences in the PtdCMP affinity and only small differences in the PtdGro affinity. Instead, both metal ions had a significant effect on the maximal velocity; thus, it seems that divalent metal ions bind to the enzyme directly and become part of the catalytic site and/or induce a more active protein conformation. Therefore, the cation specificity of cardiolipin synthesis in different eukaryotes (4) reflects intrinsic properties of the respective enzymes rather than differences in the mitochondrial membrane composition.

Synergistic Induction of Phospholipid Metabolism by Granulocyte-Macrophage Colony Stimulating Factor and Steel Factor in Human Growth Factor-Dependent Cell Line, M07e

C. Mantel*, Z. Luo and H.E. Broxmeyer

ABSTRACT: Steel factor (SLF), the ligand for the c-kit proto-oncogene tyrosine kinase receptor, synergizes with several hematopoietic growth factors to produce greatly enhanced proliferation of normal human hematopoietic progenitor cells as well as that of the human growth factor-dependent myeloid cell line, M07e. The mechanisms of this phenomenon remain unknown. In an attempt to understand the cellular processes relevant to this phenomenon, we examined the effects of SLF and granulocyte-macrophage colony-stimulating factor (GM–CSF) on induced lipid metabolism in M07e cells. We find that both GM–CSF and SLF induced increased phosphatidylcholine (PC) turnover rates (biosynthesis and degradation) as measured by increased [^{3}H]-choline labelling, with SLF being more potent than GM–CSF after 6 h of stimulation, but equipotent at 24 h of stimulation. The labelling of aqueous intermediates of PC metabolism was also increased by cytokine stimulation, most notably phosphocholine. Simultaneous stimulation with GM–CSF plus SLF resulted in a true synergistic induction of PC, lysoPC, and phosphocholine labelling. GM–CSF and SLF each induced asymmetric labelling of various phospholipid classes as measured by incorporation of different [^{3}H]-fatty acids. [^{3}H]-myristic acid labelling of phosphatidylserine was most prominently induced (approximately 12-fold). Cytosolic choline kinase activity was also upregulated more than twofold over control by SLF, which might contribute to the increased phosphocholine labelling. These effects may have relevance to the intracellular mechanisms of the synergistic proliferative stimulation of SLF plus GM–CSF on M07e cells.

Lipids 30, 641–647 (1995).

In recent years the study of phospholipid metabolism has achieved a new aspect of interest due mainly to the findings of the roles that phospholipids (PLs) play in cellular signal transduction. The hydrolytic cleavage of phosphatidylinositol (PI), phosphatidylcholine (PC), and sphingomyelin (SPH) by various phospholipases has been strongly implicated in a number of cell surface receptor mediated signal transduction processes (1–3). More recently, the biosynthesis of PC, the major eukaryotic membrane PL, has been shown to be closely coordinated with events in the cell cycle (4) that can be regulated by extracellular hormones, including the cytokines that regulate blood cell production. One of these cytokines is granulocyte-macrophage colony-stimulating factor (GM–CSF). It regulates the proliferation and differentiation of hematopoietic progenitor cells leading to the eventual generation of myeloid blood cells (i.e., granulocytes, monocytes) (5,6). The GM–CSF receptor is a heterodimeric transmembrane protein that contains no known intrinsic catalytic activity, but its activation results in rapid tyrosine and serine/threonine phosphorylation of many proteins (7,8), the activation of PI hydrolysis by phospholipase C (9), and the activation of transcription factors (10) ultimately culminating in mitosis in established myeloid cell lines.

Another cytokine is steel factor (SLF), the ligand for the proto-oncogene encoded c-kit receptor protein. The SLF-receptor is a homodimeric transmembrane protein with intrinsic tyrosine kinase activity (11), the activation of which results in signals, some of which are the same, and some different from those of the GM–CSF receptor (7,8,12) in the growth factor-dependent human myeloid cell line M07e. Simultaneous stimulation of this cell line with GM–CSF and SLF results in an interesting phenomenon known as synergistic proliferation (i.e., greater-than-additive effect) (7,8,12). This phenomenon has not yet been adequately explained by modulation of receptor number or affinity, or by effects on signal transduction events such as tyrosine phosphorylation. However, we have previously reported a relationship of immediate early gene transcription (10), as well as choline-lipid metabolism (13), to synergistic stimulation in M07e cells. In the latter study (13) we found that GM–CSF and SLF upregulated PC biosynthesis and degradation (i.e., turnover) and that co-stimulation with both cytokines resulted in a much greater effect, which was temporally associated with synergistic cell proliferation. Since GM–CSF and SLF both are known to activate phospholipases

as part of their signal transduction pathways, we had proposed that the cooperative increase in choline–lipid metabolism may be relevant to synergistic growth signals. We also suggested that these cytokines might upregulate the activity of choline kinase, one of the enzymes of PC biosynthetic pathways in M07e cells (13). This was based on the observation of the accumulation of label in the phosphocholine pool while label decreased in the choline pool.

This line of investigation has now been extended by analyzing lipid metabolism at different time points after stimulation and by examining effects of these two cytokines on different lipid classes labelled with different fatty acids (FAs). The results demonstrate that a bona fide synergistic response to GM–CSF plus SLF in PC turnover occurs in M07e cells, and that growth-factor induced PL metabolism in M07e cells is PL class- and species-specific. Additionally, choline kinase activity is increased by these cytokines.

METHODS AND MATERIALS

Materials. M07e cells are a cell line originally isolated from a patient with acute megakaryocytic leukemia, which is dependent for growth on stimulation by cytokines such as GM–CSF, interleukin-3, and SLF (14). Their growth characteristics, and conditions for "factor-starvation," have been previously characterized (7,14). Culture conditions were exactly as described elsewhere (14). Purified recombinant human (rhu) SLF and rhu GM–CSF were gifts from Dr. D.E. Williams (Immunex Corp., Seattle, WA). Silica Gel 60A thin-layer chromatography plates were from Whatman International (Maidstone, England). [^{3}H]-choline, [^{3}H]-myristic acid (MA), and [^{3}H]-arachidonic acid (AA) were from Amersham Corp. (Arlington Heights, IL). Lipid standards and all other reagents were from Sigma Chemical Co. (St. Louis, MO). Protein was determined using the Bio-Rad Protein Assay (Bio-Rad Laboratories, Hercules, CA).

Labelling of cells and analysis of labelled cellular lipids. Cell labelling and choline lipid separation and analysis were done as previously described (13). For some experiments, cells were labelled in a similar fashion, except with [^{3}H]-MA or [^{3}H]-AA (1 μCi/mL). The separation of [^{3}H]-FA labelled cellular PL classes was done by two-dimensional thin-layer chromatography as described previously (15). PL spots were visualized and quantitated as above for [^{3}H]-choline labelled lipids.

Cell-free choline kinase (CK) assay. The *in vitro* CK activity of whole cell cytosolic homogenates was measured essentially as described by others (16), except [^{3}H]-choline was used instead of [^{14}C]-choline, and the reaction was terminated by adding 3 mL of chloroform/methanol (1:2, vol/vol). Extraction and separation of phosphocholine was done the same as for cellular lipids (described previously). The cell-free cytosolic homogenate was prepared as previously described (15). CK activity is expressed as phosphocholine associated cpm synthesized per minute per mg of homogenate protein (cpm/min/mg).

RESULTS

Effects of GM–CSF and SLF on choline-lipid labelling. Factor starved-M07e cells were stimulated for various times with GM–CSF, SLF, or GM–CSF plus SLF, pulse-labelled with [^{3}H]-choline and the lipids extracted. Figure 1A shows the effects of these cytokines on [^{3}H]-choline accumulation into choline-lipids in M07e cells. Both cytokines induced an increase in labelling of PC, lysoPC (LPC), and SPH with the combination of GM–CSF plus SLF being the most effective (except in SPH labelling). SPH labelling stimulated by the combination of GM–CSF plus SLF for six hours was no more effective than SLF alone. A statistically significant effect of the combination of GM–CSF plus SLF on PC labelling could be observed after ten minutes of stimulation (plus one hour labelling), while effects on LPC and SPH required longer stimulation times before statistical significance was observed.

Ten minutes after stimulation with the growth factors, there was a slight decrease in CDP-choline labelling and a concomitant slight increase in choline pool labelling after SLF stimulation, and no significant change in phosphocholine labelling (Fig. 1B). After one hour of stimulation with GM–CSF or GM–CSF plus SLF, the CDP-choline labelling level was lower than control (unstimulated), and choline pool labelling fell significantly when stimulated with SLF or SLF plus GM–CSF. After six hours of stimulation with GM–CSF plus SLF, choline pool labelling continued to be lower while phosphocholine and CDP-choline labelling was increased by stimulation with GM–CSF or SLF alone and was increased additively when stimulated with GM–CSF plus SLF. There was a considerable increase in the rate of [^{3}H]-choline accumulation into choline lipids and intermediates between 1 and 6 h (Fig. 1). In general, SLF was a more potent inducer of choline lipid metabolism than GM–CSF, but simultaneous stimulation with both cytokines was the most potent inducer.

The effects of 24 h of growth-factor stimulation were also examined (Fig. 2). However, the 24-h experiments were treated separately. We have previously demonstrated that the viability of growth-factor starved M07e cells did not change during the previous 6 h stimulation time irrespective of the stimulant (13). But after 24 h, the viability of the medium control cultures fell to approximately 60%. The viable cell density was adjusted to 1×10^6 cells/mL for all experiments, but because of this difference, the 24-h effects could not be directly compared to the 6-h (or earlier) data, and are thus shown separately. After 24 h of stimulation, SLF was equipotent to GM–CSF in inducing choline-lipid labelling. There was a true synergistic response to stimulation with the combination of SLF plus GM–CSF in PC, LPC, and phosphocholine labelling, but not in choline and CDP-choline labelling, which had no significant difference from control when stimulated with the single cytokine, but was increased slightly by stimulation with the combination of GM–CSF plus SLF. SPH labelling was increased additively with the combination of GM–CSF plus SLF.

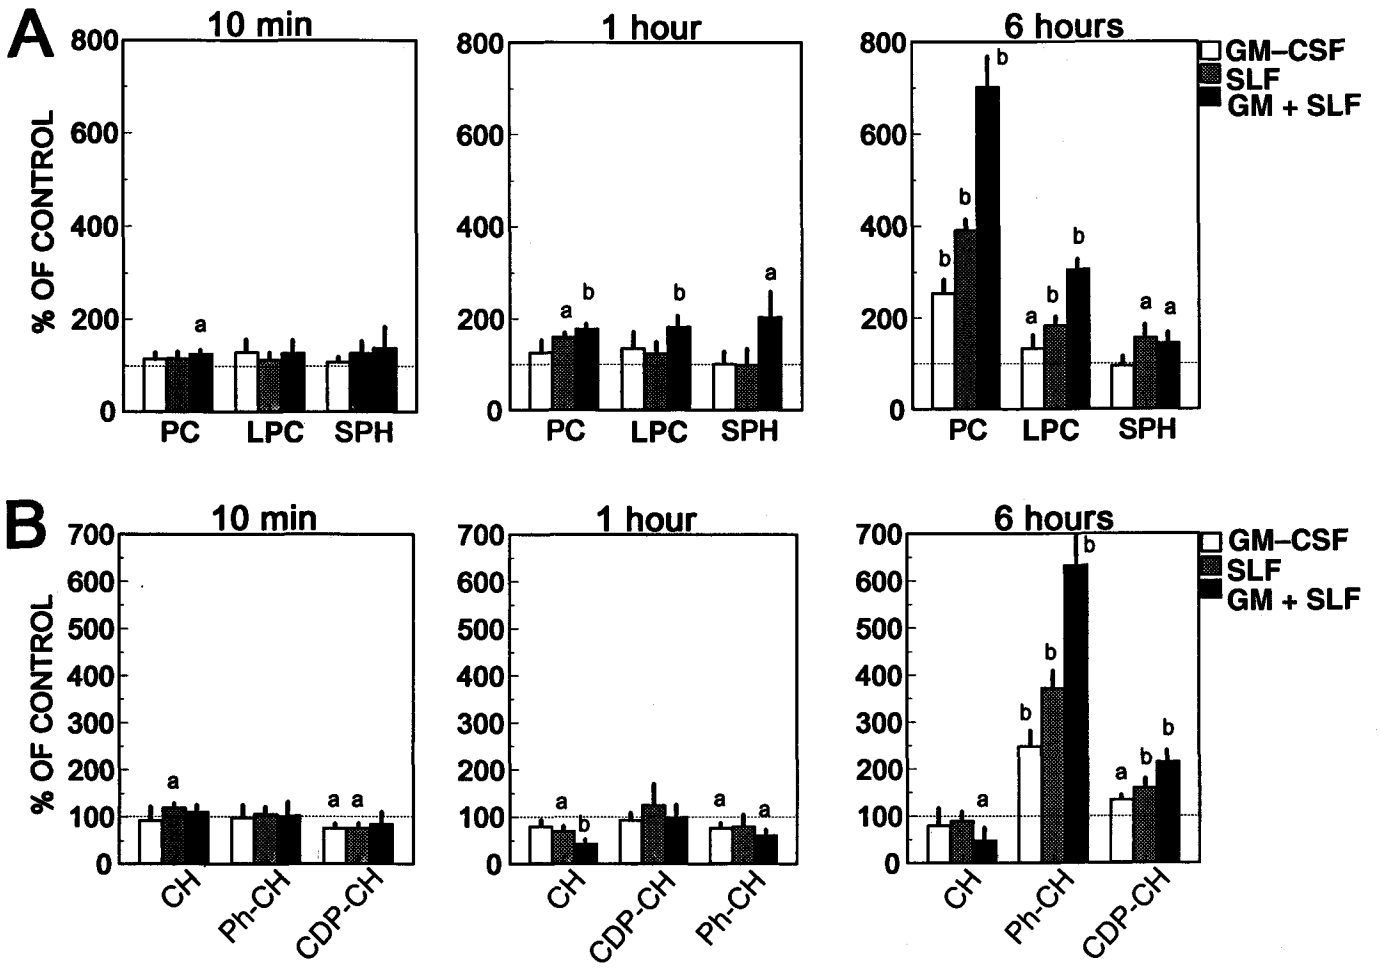

FIG. 1. Effect of cytokines on [^{3}H]-choline accumulation into M07e cellular choline–lipids and precursors. Factor starved-M07e cells were stimulated with granulocyte-macrophage colony-stimulating factor (GM–CSF), steel factor (SLF), or GM–CSF plus SLF for the indicated times, and cellular choline–lipids and aqueous intermediates were labelled with [^{3}H]-choline according to the Methods and Materials section. The cells were then harvested by centrifugation and the lipids extracted and separated by thin-layer chromatography. Spots corresponding to the indicated choline–lipid (A) or intermediates (B) were scraped and counted. Results are expressed as percent of control cpm (± SEM) of radioactivity recovered per spot per 1×10^7 cells. Statistical analysis compared to control: a = $P < 0.05$; b = $P < 0.001$; n = 3 experiments with triplicate determinations. Control cpm for phosphatidylcholine (PC), lysoPC (LPC), and sphingomyelin (SPH) was 2055, 107, and 55, respectively. Control cpm for choline (CH), phosphocholine (Ph-CH), and CDP-choline (CDP-CH) was 603, 6341, and 132, respectively.

Effects of GM–CSF and SLF on PL labelling by FAs. The pattern of FA labelling of different PL classes in unstimulated M07e cells is shown in Table 1. PC, PI, phosphatidic acid (PA), and phosphatidylethanolamine accumulated the most [^{3}H]-AA, followed by LPC, phosphatidylserine (PS), diacylglycerol (DAG), and SPH. PC also accumulated the most [^{3}H]-MA, followed by phosphatidylethanolamine and PA. SPH, LPC, PI, PS, and DAG accumulated the least MA.

The effects of growth-factor stimulation of FA labelling are shown in Table 2. GM–CSF and SLF had similar effects in inducing increased accumulation of [^{3}H]-FAs into different PL classes. However, this effect was enhanced in cells that were simultaneously stimulated with GM–CSF plus SLF. In some cases there was an additive or greater-than-additive effect when cells were stimulated with GM–CSF plus SLF. All PL classes studied showed growth-factor induced increases in [^{3}H]-MA accumulation with SLF being generally more potent in this effect than GM–CSF. PS labelling showed the greatest response (~12-fold increase), and PC showed the least (~ 2-fold). In contrast, only PA and DAG consistently had significantly enhanced accumulation of [^{3}H]-AA, which was induced only when SLF was present. Also, there was no further enhancement of this effect when stimulation was done with GM–CSF plus SLF.

With respect to the AA/MA ratio, only a slight change in relative magnitude between the different PL classes occurred after growth factor stimulation, but in general, GM–CSF and/or SLF reduced the AA/MA ratio in all PL classes studied, with PS displaying the greatest effect (8% of unstimulated control).

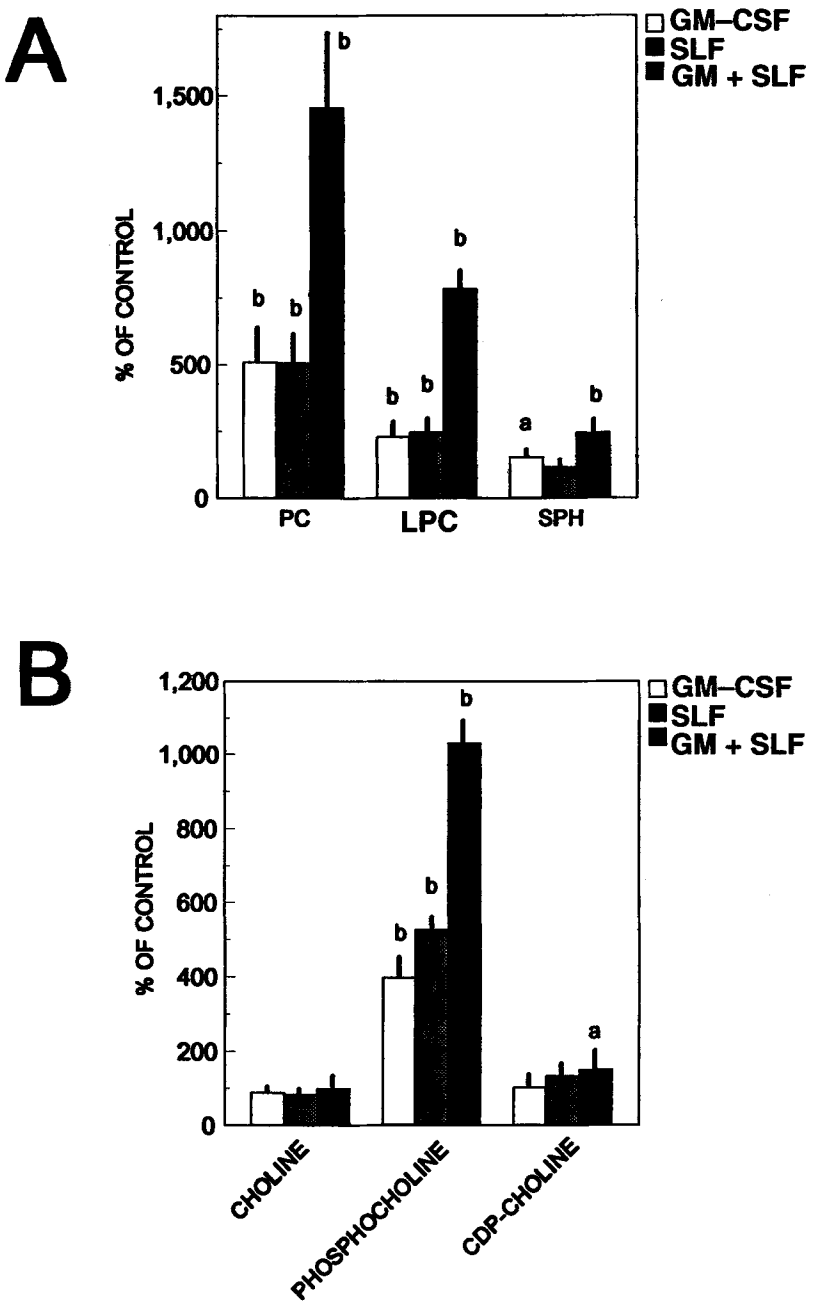

FIG. 2. Effect of cytokine stimulation for 24 h on [^{3}H]-choline accumulation into M07e cellular choline-lipids and precursors. Factor starved-M07e cells were treated, labelled, harvested, and analyzed exactly as in Figure 1, except that cells were stimulated with cytokines for 24 h. Statistical analysis and significance were the same as Figure 1. Control cpm for PC, LPC, and SPH (A) was 505, 51, and 41, respectively and for choline, phosphocholine, and CDP-choline (B) was 335, 1372, and 72, respectively. Abbreviations as in Figure 1.

Effects of GM–CSF and SLF on cytosolic CK activity. We previously proposed that GM–CSF and SLF upregulate CK activity in M07e cells (13). This was based on the observation that phosphocholine labelling increased and choline pool labelling decreased after GM–CSF and/or SLF treatment for six hours. Therefore we examined the effects of GM–CSF and/or SLF stimulation on cytosolic CK activity (Fig. 3). CK activity increased in a time-dependent fashion, with SLF being more effective than GM–CSF in this effect. Ten minutes after stimulation with GM–CSF plus SLF, there was a significant decrease in CK activity compared to control, but this increased to 251 ± 38% of control after six hours of stimulation with GM–CSF plus SLF. Although SLF alone was more potent in this effect than GM–CSF alone, the combination of GM–CSF plus SLF was no more potent than SLF alone, indicating that stimulated CK activity was not synergistically increased by the combination of GM–CSF plus SLF.

TABLE 1
Unstimulated [3H]-Fatty Acid Labelling of Selected Factor Starved-M07e Cellular Lipids[a]

	CPM/Spot × 1000	
	Arachidonic acid	Myristic acid
Phosphatidylcholine	239 ± 62	84.0 ± 9.3
Sphingomyelin	0.82 ± 0.10	2.3 ± 0.3
Lysophosphatidylcholine	17.6 ± 1.6	2.7 ± 0.16
Phosphatidylethanolamine	169 ± 19	15.5 ± 1.9
Phosphatidylserine	2.6 ± 0.7	1 ± 0.28
Phosphatidic acid	183 ± 13	8.9 ± 0.44
Phosphatidylinositol	194 ± 23	1.4 ± 0.11
Diacylglycerol	1 ± 0.05	0.5 ± 0.1

[a]Factor starved-M07e cells were labelled with either [^{3}H]-arachidonic acid or [^{3}H]-myristic acid according to the Methods and Materials section. Cellular lipids were extracted, separated by two-dimensional thin-layer chromatography, and spots corresponding to the indicated lipids were scraped and counted. Results are expressed as cpm/spot (from 1 × 10^7 cells) ± SEM from two experiments each done in triplicate.

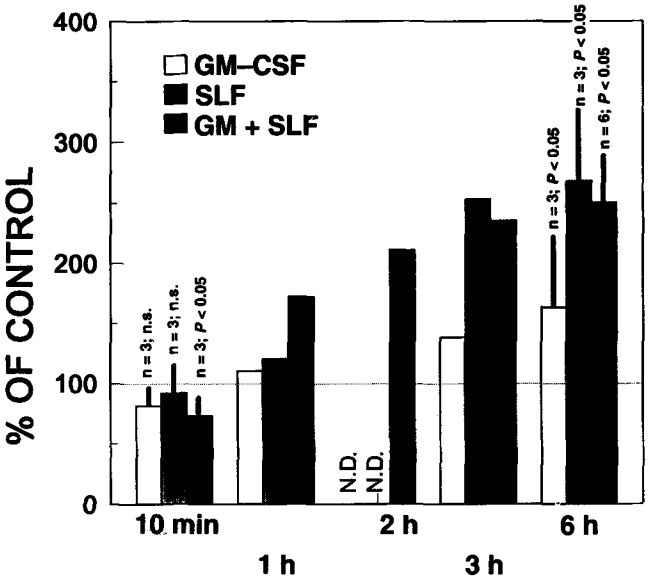

FIG. 3. Effect of cytokines on factor starved-M07e cytosolic choline kinase activity. Factor starved-M07e cells were stimulated for the indicated times, the cells harvested, cytosol prepared, and choline kinase assayed according to the Methods and Materials section. Results were expressed as percent of control activity. The number of experiments (with triplicate determinations; n, the statistical significance (*P*), and SEM bars are shown where appropriate. Other results are the means of a single experiment with triplicate determinations. N.D. = not done. Unstimulated control values for 10 min, 1, 2, 3, and 6 h were 8397 ± 660, 1432, 1539, 1257, and 1416 ± 142 cpm/min/mg cytosolic protein, respectively.

DISCUSSION

It is clear from this study and from our previous study (13) that GM–CSF and SLF upregulate choline lipid metabolism in M07e cells. Simultaneous stimulation with saturating concentrations of both GM–CSF and SLF results in a true synergistic stimulation of [^{3}H]-choline flux through the PC biosynthetic and degradative pathways (i.e., turnover). Because both of these cytokines are known to use second messenger molecules which can be derived from PC (i.e., DAG) (9,17) as part of their signalling mechanism, this induced synergistic PC turnover may have relevance to synergistic signalling mechanisms, and this suggests that a PC hydrolytic cycle (18) may be part of the synergistic proliferative response of M07e cells to these two cytokines. Even though some significant effects could be seen after 10 min of stimulation time, a large increase in the effects of GM–CSF and/or SLF on PC metabolism occurred between one and six hours, suggesting that these effects may be considered "delayed" response elements (19). Support for this notion comes from the delayed (one hour) increase in CK activity. Further experiments are required to determine the mechanism of upregulation of CK activity (i.e., transcriptional regulation-vs.-post-transcriptional modification regulation). It is also noteworthy that the increase in CK activity stimulated by the combination of GM–CSF plus SLF was no more than SLF alone (i.e., not synergistic or even additive). Yet at six hours of stimulation, the increased phosphocholine labelling was at least additive,

[a]Factor starved-M07e cells were stimulated with cytokines as described in the Methods and Materials section and the cells labelled, extracted, separated, and analyzed as in Table 1. Results are expressed as fold increase over control cpm/spot (Table 1). The results from two experiments are shown separated by a slash (/). For clarity, only those results that were statistically significant ($P < 0.05$) are shown. Other results (n.s.) were not statistically significant ($P > 0.05$). SEMs are not shown for clarity, but did not exceed the percentages of those shown for the control (Table 1). GM–CSF, granulocyte-macrophage colony-stimulating factor; SLF, steel factor.

suggesting that the proportion of label in the phosphocholine pool which was contributed by the hydrolytic component of the synergistic turnover rate (i.e., PLC) at six hours may be more significant than the contribution by the biosynthetic component. It therefore seems unlikely that CK upregulation is solely responsible for the observed synergistic increase in phosphocholine labelling.

Saturating amounts of SLF were, in general, a more potent inducer of FA labelling of various PL classes than saturating amounts of GM–CSF. This is interesting because SLF is a much weaker single mitogen than GM–CSF in M07e cells (7,14). Therefore the upregulation of PC metabolism by SLF is not just simply due to upregulation of the general metabolic state of the cell in lieu of mitosis. However, it is interesting that after 24 h of stimulation, GM–CSF and SLF were equipotent in induction of PC and LPC labelling. PC metabolism has been demonstrated to be closely correlated to cell-cycle events (4). As SLF has been recently suggested to be a "competence factor" (20) or a "survival factor" (21), whereas GM–CSF appears to be a more complete mitogen [competence and progression (20)], it is possible that the difference in relative potency of GM–CSF and SLF at different times after stimulation may reflect the differences of these cytokines in regulating the cell-cycle status of M07e cells, resulting in different ratios of biosynthesis and degradation of PC. Even after 24 h of stimulation, SLF was still more effective in stimulating phosphocholine labelling. This is noteworthy because phosphocholine has been suggested as a potential second messenger-like molecule which appears to be related to other competence factors, such as platelet-derived growth factor (22).

The level of GM–CSF-induced labelling of PC with [^{3}H]-choline was approximately the same as the induced level of [^{3}H]-MA labelling. SLF and SLF plus GM–CSF (synergistic) induced labelling with [^{3}H]-choline (~7-fold increase) could not be accounted for by either [^{3}H]-AA or [^{3}H]-MA labelling (~2-fold increase). Therefore, other species of PC also must be involved in GM–CSF and/or SLF-induced synergistic upregulation of PC metabolism. Alternatively, the mechanism of introduction of FAs and choline into PC may be independently regulated, and there may be differential activation of these pathways. SLF, but not GM–CSF, also was able to stimulate the incorporation of AA into only two PLs, PA and DAG. This may significantly contribute to the differential effects of these two cytokines, especially as phospholipase D has already been implicated in SLF signal transduction. Phospholipase D catalyzes the degradation of PC to PA, and PA is a precursor to DAG.

GM–CSF and SLF both induced a asymmetric patterns of FA labelling of various PL classes (i.e., AA vs. MA labelling). This differential activation of metabolism of different PL species may have relevance to the generation of different species of lipid second messenger molecules (i.e., DAGs). Different lipid second messengers have already been suggested as differentially activating different isoforms of PKC (23). Further work is required to determine which species of PC are involved in GM–CSF and/or SLF stimulated PC turnover and the relevance of this to the generation of different species of second messenger molecules which could contribute to the diversity of effects of different cytokines.

Both GM–CSF- and SLF induced asymmetric FA labelling of PS; GM–CSF plus SLF induced at least an additive or cooperative effect on PS labelling by [^{3}H]-MA. Of all the PL classes studied, PS labelling was most affected by these cytokines, with an approximately 12-fold increase in [^{3}H]-MA labelling. The AA/MA ratio was also reduced to only 8% of the unstimulated control. As PS is usually found to be one of the least abundant components of eukaryotic cell membranes and because it displays extreme leaflet asymmetry (24), this effect of GM–CSF plus SLF may be of significance in the signalling process. This is especially interesting in view of the finding of the potential requirement of PS in the membrane binding, translocation, and activation of protein kinase-C (PKC) (25). Therefore, the cooperative effect of GM–CSF plus SLF on upregulation of PS metabolism also may have relevance to signal transduction mechanisms involving PKC as well as other inducible enzyme activities [such as Raf-1 kinase (26)] that are translocated to various membrane surfaces *via* PS. Further work is required to determine which species are involved in cytokine-induced PS metabolism and whether this phenomenon plays a role in induced membrane translocation and cytokine activation of PKC, Raf-1, or other signalling molecules.

ABSTRACT: Levels of serum lipids and lipoproteins, and the fatty acid composition of plasma phospholipids, were measured in two genetically comparable, but widely separated, populations. The 1975 mortality rates for ischemic heart disease were significantly higher in one of these populations, the Manitoban residents of pure Icelandic descent, than in the other, a rural population from Northeastern Iceland. Two study populations, Icelanders and Icelandic–Canadians, were drawn from these larger populations. The study populations were matched for age and sex and divided into three age groups, 20–39, 40–59, and 60–69 years. In comparison to the Icelandic–Canadians, the Icelanders exhibited significantly higher levels of total cholesterol, low-density lipoprotein cholesterol, and high-density lipoprotein cholesterol, but lower triglyceride levels. Their plasma phospholipids contained significantly lower levels of saturated fatty acids (SFA), monounsaturated fatty acids, and n-6 polyunsaturated fatty acids (PUFA); but their n-3 PUFA levels were three times as high. It was additionally found that fatty acid composition of plasma phospholipids differed among Icelanders of different ages. SFA levels were significantly lower, and n-6 PUFA levels significantly higher, in the 20–39 year group than in the 60–69 year group, possibly due to different dietary fat consumption patterns between generations. No corresponding age-related difference in the fatty acid composition of plasma phospholipids was found in the Icelandic–Canadian study population. As the Icelandic and Icelandic–Canadian groups are assumed to be genetically similar, the biochemical differences between them are evidently due to environmental, probably dietary, differences. The findings indicate that n-3 PUFA may be cardioprotective in the context of an otherwise atherogenic diet. *Lipids 30,* 649–655 (1995).

This investigation is part of a larger, and on-going, comparative study, begun in 1979, of cardiovascular risk factors in two genetically comparable, but geographically and culturally separate populations, one Icelandic and the other Icelandic–Canadian (1,2).

Abbreviations: BMI, body mass index; CVD, cardiovascular disease; HDL, high-density lipoproteins; LDL, low-density lipoproteins; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids.

By the late 19th century, Icelanders had lived in virtual isolation from the rest of the world for 1,000 years, and the population of Iceland was thus unusually homogeneous. In the period between 1870 and 1914, some 18,000 Icelanders, about 20% of the national population in that period, migrated to North America. Because of meticulous record-keeping, the names, professions, and ages of these emigrants, the farms from which they came, the ships they traveled with, and the places in North America where they settled are known (3,4). Many of these Icelanders migrated from Fljótsdalshérad, a rural district in Northeastern Iceland, to the Interlake District, just north of Winnipeg, Manitoba; and hundreds of individuals currently living there are pure descendants of the Icelandic immigrants from Fljótsdalshérad. A large number of these purely-descended Icelandic–Canadians have been identified through genealogical records (5,6) and questionnaires. Individuals living in Fljótsdalshérad were invited to participate in the study if their families had been living in Fljótsdalshérad for at least three generations (1). The environmental homogeneity within the sample was increased by selecting those who live in the same district as their parents and grandparents did. There is every reason to suppose that these two study populations thus identified are highly comparable genetically. This presumed genetic comparability has been confirmed by anthropomorphic studies (1,7). The existence of these two genetically comparable populations living in wide separation from one another and in quite dissimilar surroundings provides an exceptional opportunity for comparative studies aimed at distinguishing environmental from hereditary influences, for example on the prevalence of ischemic heart disease.

In 1975, crude mortality rates for ischemic heart disease were significantly higher in the Icelandic–Canadian communities of Manitoba than in Iceland, for both females and males (1,8). Because the explanation for this difference is evidently not genetic, environmental factors—dietary factors in particular—are indicated. Indeed, the traditional Icelandic diet differs considerably from the normal diet of Icelandic–Canadians. As an effect of diet, it is the lipid profile which is thought to have the most to do with the risk of cardiovascular disease (CVD). The present study investigates serum levels of total choles-

terol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglycerides, and plasma phospholipid fatty acids of two genetically similar study populations; these profiles exhibit significant differences. We attempt to link the study parameters with CVD risk.

MATERIALS AND METHODS

Subjects. Two study populations were constructed, one consisting of 119 subjects (60 females and 59 males) drawn from the rural district of Fljótsdalshérad, in Northeastern Iceland, and a second consisting of 119 subjects (59 females and 60 males) drawn from a previously-identified pool of residents of the Interlake District of Manitoba who are pure descendants of immigrants from Fljótsdalshérad (1,2). The Icelandic study population was constructed first; five-year cohorts of persons aged 20–69 years, each cohort containing approximately six females and six males, were selected. The Icelandic–Canadian study population was then constructed by selecting matching cohorts. The two resulting study populations were thus well matched with respect to age and sex, down to the level of the five-year cohorts. For the purpose of analysis in the present study, the two populations were divided into three age groups—20.0–39.9, 40.0–59.9, and 60.0–69.9 years (Table 1).

Overnight fasting blood samples were collected by venipuncture into Vacutainer® tubes (Sarstedt, Nünbrecht, Germany) containing EDTA for fatty acid determinations and no anticoagulant for determinations of lipids and lipoproteins. Plasma or serum was prepared immediately, frozen, and flown in cold packs to the Heart Preventive Clinic (Reykjavík, Iceland), where it was stored at –22°C until analyzed.

Analysis of lipids and lipoproteins. Total serum cholesterol was determined on a Cobas Mira (Roche Diagnostic Systems, Hoffmann-la Roche Ltd., Basel, Switzerland) automatic analyzer by an enzymatic colorimetric method as described by Allain *et al.* (9) and Trinder (10). Serum triglyceride was determined on the Cobas Mira by an enzymatic colorimetric method as described by Fossati and Prencipe (11) and McGowan *et al.* (12). Serum HDL cholesterol was determined on the Cobas Mira according to the method of Burstein *et al.* (13) and Lopes-Virella *et al.* (14). The concentration of LDL cholesterol was calculated as follows:

$$[\text{LDL cholesterol}] = [\text{total cholesterol}] - ([\text{HDL cholesterol}] + [\text{triglyceride}] \times 0.37) \quad [1]$$

Commercial control sera were used for internal quality control, and external quality control was performed by the World Health Organization Lipid Reference Centre in Prague.

Analysis of phospholipid fatty acids. Plasma lipids were extracted with chloroform/methanol (2:1, vol/vol) by the method of Sperry and Brand (15) as modified by Nelson (16). The antioxidant butylated hydroxytoluene was added to the extraction medium at 5 mg/100 mL. Phospholipids were separated on thin-layer plates (Adsorbosil H; Alltech, Deerfield, IL) and developed in a solvent system consisting of petroleum ether/diethylether/acetic acid (80:20:1, by vol). The phospholipid fatty acids were methylated by the method of Morrison and Smith (17) using 14% boron trichloride/methanol (Sigma

[a]Values are mean ± SEM of n determinations, where n represents the number individuals in each age group. Sex distribution among the age groups is shown in parentheses (F = female, M = male).
[b]Significance calculated by two-way analysis of variance, NS = not significant; G = group of all Icelanders (n = 119) or group of all Icelandic–Canadians (n = 119), A = age.
[c]Represents age period in years, and mean age is given in parentheses.
[d]$P < 0.02$, compared to the youngest and middle age groups, Scheffe post-hoc test.
[e]$P < 0.01$; [f]$P < 0.02$, compared to the youngest age groups, Scheffe post-hoc test.

Chemical Co., St. Louis, MO). The methyl esters were analyzed using a gas chromatograph (Hewlett-Packard 5890A; Hewlett-Packard, Palo Alto, CA) equipped with a capillary column, 25 m × 0.2 mm i.d., coated with a 0.25 μm film of 5% diphenyl- and 95% dimethyl polysiloxane. The gas chromatograph was programmed to have an initial oven temperature of 160°C rising in three increments to 235°C. The carrier gas was hydrogen at a flow rate of 1 mL/min. The fatty acid methyl ester peaks were identified and calibrated against those of commercial standards (Sigma Chemical Co.; Applied Science Division, Milton Roy Company, State College, PA).

All measurements in the comparative studies of Icelanders and Icelandic–Canadians have been carried out by the same personnel, using the same techniques and equipment, and the chemical analyses have been performed in the same laboratory.

Statistical analysis. The influence of environment (Fljótsdalshérad vs. Interlake District) and age on serum lipids, lipoproteins, and fatty acid composition of plasma phospholipids in all subjects studied was examined by two-way analysis of variance using SYSTAT (18) general linear model procedures. To determine the significant difference in level of lipids, lipoproteins, and phospholipid fatty acids between the age groups within each population, one-way analysis of variance was used, followed by application of Scheffe post-hoc test. Pearson's correlation coefficient was used to measure the correlation between age and the percentage of fatty acids in plasma phospholipids. Differences were considered significant at $P < 0.05$.

RESULTS

The study parameters for persons of different ages in the two populations are shown in the tables and the figure. There were no significant differences in body weight and body mass index between the two study populations (Table 1). The body mass index of the oldest age group of Icelandic–Canadians was significantly higher than that of the youngest age group. The Icelandic study population exhibited significantly lower triglyceride levels and significantly higher levels of total cholesterol, LDL cholesterol, and HDL cholesterol than the Icelandic–Canadian study population (Table 1).

Age-related differences between total cholesterol and LDL cholesterol levels were found among the Icelanders. Within this population the oldest age group exhibited significantly higher total cholesterol and LDL cholesterol levels than the youngest and middle groups. The middle group contained significantly higher levels of total cholesterol and LDL cholesterol than the youngest group. No significant age-related differences in lipid levels were found among the Icelandic–Canadians.

Sex-related differences between lipid levels were found in both study populations (data not shown). Triglyceride levels were significantly higher in males than in females; 1.41 ± 0.15% vs. 1.00 ± 0.06% ($P = 0.046$), in the Icelanders, and 1.74 ± 0.11% vs. 1.26 ± 0.06% ($P = 0.009$), in the Icelandic–Canadians. Within the Icelandic study population, total cholesterol levels were significantly lower in males than in females, 5.9 ± 0.1% vs. 6.3 ± 0.2% ($P = 0.039$). HDL cholesterol levels were also significantly lower in males than in females; 1.17 ± 0.04% vs. 1.43 ± 0.04% ($P < 0.0005$) in Icelanders, and 0.90 ± 0.03% vs. 1.04 ± 0.04% ($P = 0.004$) in Icelandic–Canadians.

The two study populations differed markedly in the fatty acid composition of plasma phospholipids (Table 2). Seven out of the eleven fatty acids analyzed differed significantly between the two populations. The levels of 20:5n-3 and 22:6n-3 were three times higher in Icelanders than in Icelandic–Canadians, in all age groups (2.20 ± 0.09 and 4.30 ± 0.11% vs. 0.72 ± 0.03 and 1.38 ± 0.06%, respectively). There were no significant differences in the n-6 polyunsaturated fatty acids (PUFAs), 20:3n-6 and 20:4n-6, and in the saturated fatty acids, 14:0 and 18:0. The interaction between group and age was significant in six fatty acids (Table 2).

Age-related differences between fatty acid levels in plasma phospholipids were found within both study populations. In the Icelandic study population, the level of 14:0 was significantly lower, and the levels of 18:2n-6 and 20:4n-6 were significantly higher in the youngest age group than in the middle and oldest age groups. The plasma phospholipids of the youngest age group of Icelandic–Canadians contained significantly lower levels of 20:5n-3 than the middle and oldest age groups.

In both study populations, significant sex-related differences between fatty acid levels in plasma phospholipids were found only in saturated fatty acids (SFAs) (data not shown). SFA levels were significantly higher in females than in males, 46.6 ± 0.37% vs. 43.3 ± 0.47% ($P = 0.002$) in Icelanders and 49.0 ± 0.33% vs. 46.9 ± 0.36% ($P < 0.005$) in Icelandic–Canadians.

Figure 1 shows the relationship between age and levels of SFA (A), n-6 PUFA (B) and n-3 PUFA (C) in plasma phospholipids of Icelanders and Icelandic–Canadians of both sexes. In Icelanders, SFA levels were positively correlated ($r = 0.528$, $P < 0.0005$), and n-6 PUFA levels correlated negatively ($r = -0.573$, $P < 0.0005$) with age. A small positive correlation between n-3 PUFA levels and age in Icelanders was observed ($r = 0.273$, NS). No relationship was found between age and levels of SFA ($r = 0.042$, NS), n-6 PUFA ($r = -0.051$, NS), and n-3 PUFA ($r = 0.231$, NS) in the plasma phospholipids of Icelandic–Canadians.

DISCUSSION

Mortality from coronary heart disease is relatively low among Icelanders, even though they exhibit a lipid profile which is normally considered atherogenic. It is recognized that many chronic forms of CVD have long development periods, and total serum cholesterol level has been thought to play a central role in development of atherosclerosis. Hypercholesterolemia in childhood is one of the factors that may affect the development of CHD with aging (19,20). Icelandic

[a]Data are expressed as relative weight percent of total fatty acids. Each value represents the mean ± SEM of n determinations, where n represents the number of individuals in each age group. Sex distribution among the age groups is shown in Table 1. SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.
[b]Represents age period in years and mean age is given in parentheses.
[c]Significance calculated by two-way analysis of variance, NS = not significant, G = group of all Icelanders (n = 119) or group of all Icelandic–Canadians (n = 119), A = age.
[d]$P < 0.05$; [e]$P < 0.01$, compared to the middle and oldest age groups, Scheffe post-hoc test.
[f]$P < 0.02$, compared to the youngest and middle age groups, Scheffe post-hoc test.
[g]$P < 0.05$, compared to the youngest age groups, Scheffe post-hoc test.

youngsters, ages 6–19, exhibit one of the highest levels of total serum cholesterol yet reported, 5.31 ± 0.86 mM (mean ± SD) (4). However, mortality from CVD is relatively low among Icelanders, which indicates that mean total cholesterol levels fail to reflect cardiovascular risk in a population and are a poor predictor of individual risk (4).

In the face of this conundrum, it is worth noting that Icelanders hold the European record in fish consumption (73 g/day/person), and the use of cod liver oil as a daily food supplement is widespread (21). Consumption of fish and fish oil rich in the n-3 PUFA, 20:5n-3, and 22:6n-3, has been shown to have a beneficial effect on plasma lipid profiles, thereby reducing the risk of CVD (22–27). The effects of fish oil consumption on the levels of total serum cholesterol and LDL cholesterol are less clear (28,29). Some studies have indicated that consumption of fish containing moderate amounts of n-3 PUFA may cause a deleterious rise in LDL cholesterol levels in normotriglyceridemic males, whereas other studies have found no change (30,31). The relatively high levels of LDL cholesterol exhibited by the Icelandic study population lend support to the argument that the consumption of fish and fish oil increases LDL cholesterol (Table 1).

Low levels of serum triglycerides in humans have been observed to correlate with consumption of fish and fish oil (29). The high Icelandic consumption of these foods may thus explain why serum triglyceride levels were significantly lower in the Icelandic study population than in the Icelandic–Canadian population (Table 1).

It has been maintained that relatively high plasma phospholipid levels of 20:5n-3 and 22:6n-3 are strictly related to diet (32–34). The relatively high levels of plasma phospholipid n-3 PUFA observed in the Icelandic study population may thus be taken to reflect the dietary intake of these two n-3 PUFA found in fish and fish oil, whereas the 30% lower levels of n-3 PUFA observed in the Icelandic–Canadians evidently reflect low dietary levels of n-3 PUFA in the ordinary Canadian diet (Table 2).

Mean levels of plasma phospholipid 20:4n-6, the precursor of the thrombogenic and vasospastic thromboxane A_2, have been shown to be twice as high in Canadians and in Americans (32,33) as in Nordic populations (35–37). It has been suggested that relatively low levels of plasma phospholipid 20:4n-6 may be genetically controlled and independent of diet (33). In the present study, no significant difference was observed in plasma phospholipid 20:4n-6 levels between the two genetically similar study populations, which is consistent with this suggestion (Table 2).

It is generally supposed that the prevalence of CVD correlates positively with the proportion of dietary energy supplied by saturated fatty acids and negatively with the proportion of

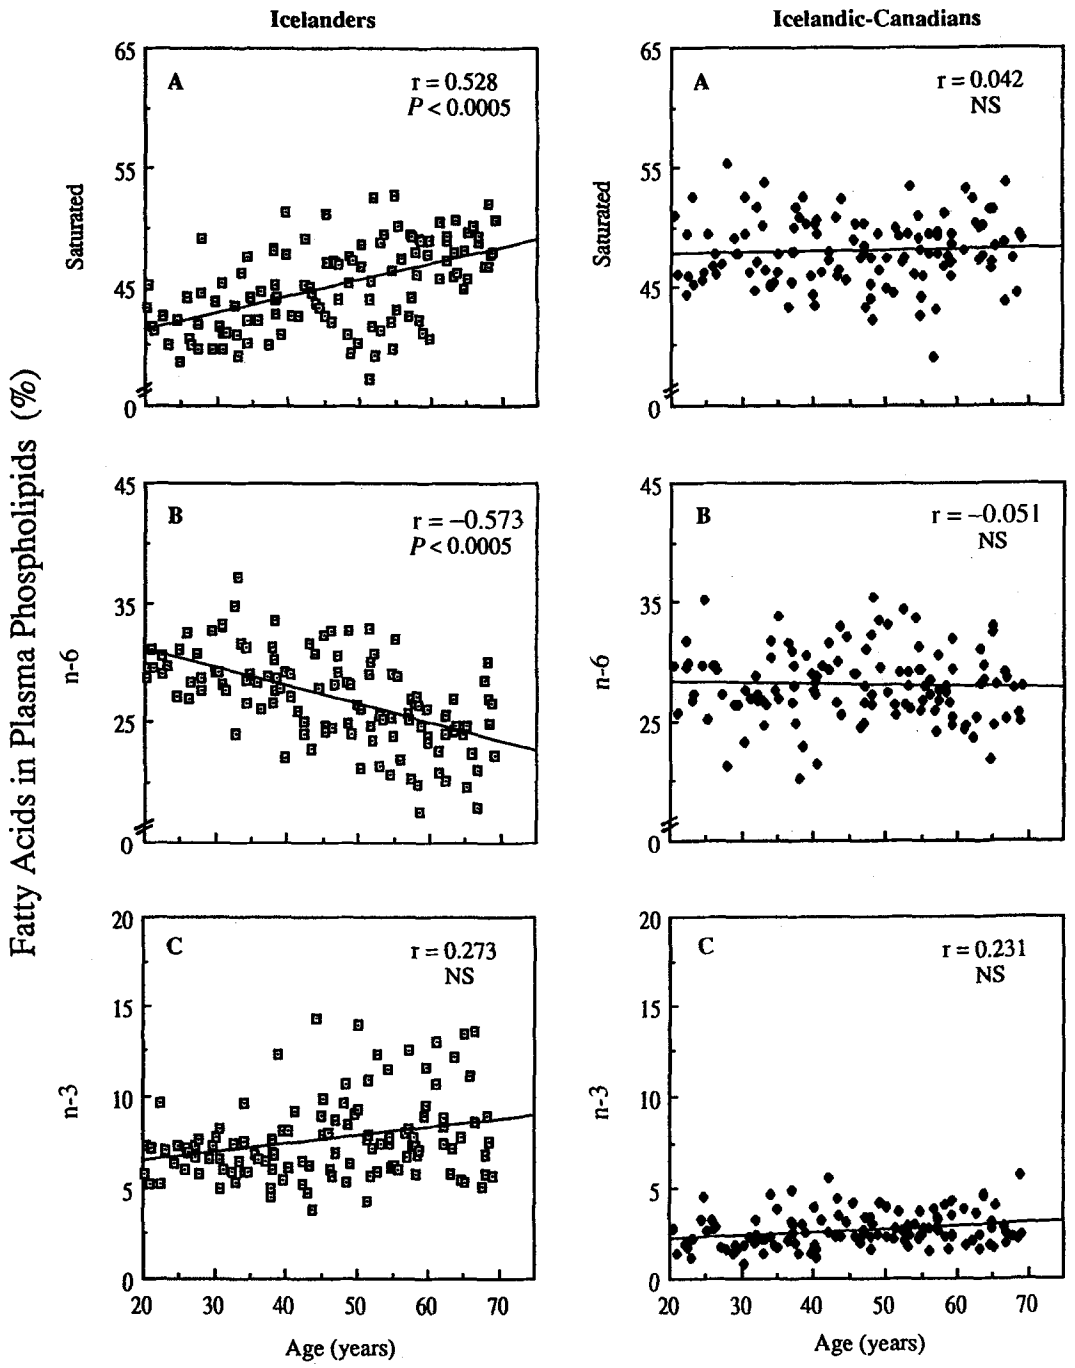

FIG. 1. Relationship between age and percentage of saturated fatty acids (A), n-6 polyunsaturated fatty acids (PUFAs) (B), and n-3 PUFA (C) of plasma phospholipids in Icelanders (left) and Icelandic–Canadians (right). Each point represents an individual subject. Saturated, sum % (14:0 + 16:0 + 18:0); n-6 PUFA, sum % (18:2 + 20:3 + 20:4) n-6; n-3 PUFA, sum % (20:5 + 22:5 + 22:6) n-3. NS, not significant.

dietary n-6 PUFA (38). In Iceland, fat contributes 41% of total dietary energy, with the contribution of saturated fat amounting to 20% (21). However, the contribution of total dietary fat energy in Canada is 38% and saturated fat is estimated to 13% (39). Until the late 1970s, the traditional Icelandic diet consisted of local products, i.e., fish, lamb, and dairy products rich in cholesterol and saturated fat (40). Grains, fruits, and vegetables, which were generally imported and expensive, contributed less to the Icelandic diet. In the Icelandic study population, plasma phospholipid SFA levels were found to increase with age, while in the Icelandic–Canadian population, no age-related difference was observed (Table 2 and Fig. 1). Canadian–Icelanders of all ages exhibited SFA levels of plasma phospholipids similar to those observed in Icelanders 60 years of age and older. Since the late 1970s, a public health campaign in Iceland has advocated the reduction of

fatty meats and dairy fats in the diet and the increased consumption of vegetable oils and grains. The lower levels of SFA and n-3 PUFA, and higher levels of n-6 PUFA observed in plasma phospholipids of younger Icelanders (Table 2 and Fig. 1) probably reflect the effects of this campaign (4). Older persons in Fljótsdalshérad who tend to eat the traditional Icelandic high-fat diet and consume cod liver oil exhibit higher levels of SFA and n-3 PUFA and lower levels of n-6 PUFA in plasma phospholipids than do younger Icelanders (Table 2 and Fig. 1). The study indicates that the dietary habits of Icelandic–Canadians are rather stable, as no age-related differences in SFA, n-6 PUFA, or n-3 PUFA of plasma phospholipids were observed (Table 2 and Fig. 1). That such age-related differences in plasma phospholipid fatty acids in the Icelanders are due to changes in dietary patterns rather than effects of aging as such is supported by the work of Holman *et al.* (32).

Of interest in this connection is that lamb, which is a major element in the traditional Icelandic high-fat diet, contains more n-3 PUFA than has been generally realized. Due to short and often hard summers in Iceland, it is customary to supplement the ewes' diet with fish meal, herring, or fish oil during breeding season and prior to the lambing season in the spring. The maternal dietary n-3 PUFA are incorporated into the lean muscle phospholipids of the lamb meat, which in lambs from Fljótsdalshérad contains 7% of n-3 PUFA (unpublished data from our laboratory).

Serum triglyceride level, now recognized as an independent risk factor for CVD (41), is increasing rapidly in Icelanders (42). A 10-year follow-up study (1980–1990) on a subgroup of the population in Fljótsdalshérad (ages 20–60 years) revealed that the cardiovascular risk attributable to triglyceride levels and atherogenic indices have increased markedly (43), evidently reflecting changes in dietary fat intake.

It is generally agreed that n-3 PUFA play an essential role in human growth and development throughout life and are a necessary part of the diet (44). They may be instrumental in preventing the development of CVD (45). The present study supports the idea that n-3 PUFA, such as Icelanders obtain through their consumption of fish, fish oil, and Icelandic lamb, can afford protection from atherosclerotic disease, even in the face of a diet that in other respects may be counted as atherogenic (46).

ACKNOWLEDGMENTS

This study was supported by grants from the University of Iceland Research Foundation and the Icelandic Council of Science. Thanks to Mikael M. Karlsson for valuable help with the manuscript.

Dietary Fatty Acids, Membrane Transport, and Oxidative Sensitivity in Human Erythrocytes

David E. Mills[a,b,*], Mahadev Murthy[c] and William R. Galey[b]

[a]Scientific Laboratory Division, New Mexico Department of Health, Albuquerque, New Mexico 87196-4700, [b]Department of Physiology, University of New Mexico School of Medicine, Albuquerque, New Mexico 87131 and [c]Department of Foods and Nutriton, University of Manitoba, Winnipeg, Manitoba R3E 0V9, Canada

ABSTRACT: This study examined effects of dietary n-3 fatty acids on age-related changes in erythrocyte anion transport and susceptibility to oxidation. Blood was drawn from healthy adult volunteers before and after six weeks' supplementation (nine/group) with 4.0 g/day of safflower oil (containing 2.9 g n-6 fatty acids) or fish oil (containing 1.2 g long-chain n-3 fatty acids). Following density separation of young and old erythrocytes, membrane anion transport and cell membrane lipid composition were measured. Oxidative damage was measured in erythrocyte ghosts exposed to a free radical generator. Fish oil significantly increased 16:0 and 20:5n-3 in ghosts of both young and old cells, and 22:5n-3 and 22:6n-3 in old cells alone. Safflower oil increased 16:0, 18:0, 18:1n-9, and 22:5n-6 in ghosts of young cells only. The age-dependent increase in membrane anion transport ($P < 0.01$) was decreased by dietary fish oil supplementation, but not by safflower oil supplementation. Safflower oil and fish oil increased the susceptibility of both young and old erythrocytes to oxidative damage by free radical generation ($P < 0.001$).

Lipids 30, 657–663 (1995).

The aging of the circulating erythrocyte is associated with numerous structural and functional changes, including altered membrane fatty acid composition (1–6), solute transport (7), antigen expression (8,9), decreased deformability, and increased fragility (10,11). These changes may interfere with the ability of the senescent erythrocyte to deliver oxygen to peripheral tissues, or to contribute to its removal from the circulation (7,8).

It is well established that the types of polyunsaturated fatty acids consumed in the diet can influence erythrocyte membrane phospholipid composition and function in humans (12–20). Studies examining the effects of dietary supplementation with 20 and 22 carbon n-3 fatty acids, such as those found in fish oils (20:5n-3 and 22:6n-3), have generally observed an increase in membrane n-3/n-6 ratio, a decrease in whole blood viscosity, and an increase in membrane deformability in human erythrocytes (2–10). Furthermore, we recently reported that dietary supplementation with fish oil reversed the age-related decrease in the *in vitro* filterability of old circulating erythrocytes in humans, restoring it to the level of young cells (21). These changes were accompanied by an increased incorporation of long-chain n-3 fatty acids into the membrane lipids of both young and old erythrocytes.

While these data suggest a possible role for dietary n-3 fatty acids in reversing age-related changes in erythrocyte function, more information concerning their effect on age-related membrane function, e.g., transport properties, would be useful. In addition, it would be of interest to determine whether the increased levels of long-chain, highly unsaturated fatty acids in the erythrocyte membrane make it more susceptible to damage from oxidative stressors.

The purpose of the present study was to investigate the effects of dietary supplementation with long-chain n-3 fatty acids (fish oil), as compared with n-6 fatty acids [safflower oil (SAF)], on erythrocyte membrane anion transport, and susceptibility to oxidative damage of young and old erythrocytes, separated by density centrifugation, in humans.

MATERIALS AND METHODS

Subjects. Healthy adult volunteers were recruited from the University of Waterloo (Ontario, Canada) student population. After the elimination of smokers, individuals taking medication or oral contraceptives, and those currently under medical treatment, 18 subjects (9 males and 9 females, 21–41 yr, mean 27 yr) were enrolled in the study.

Protocol. All participants were randomized within gender into one of two treatment groups in which their normal diet was supplemented with 4.0 g/day of either SAF, high in 18:2n-6 (4 males and 5 females) or fish oil, high in 20:5n-3 and 22:6n-3 (5 males and 4 females), in the form of 0.5-mL gelatin capsules, for a six-week period (unpublished pilot studies in our laboratory have shown that membrane phospholipid fatty acid changes occur within this time frame). Both fatty acid supplements, whose compositions are shown in Table 1, also contained 26 mg α-tocopherol acetate/g oil (30 IU/g) to protect against oxidation. The intervention was

n-6	72.3	4.3
n-3	0.4	33.7

conducted under double-blind conditions. Prior to and immediately following the dietary supplementation period, a 60-mL blood sample was drawn into heparinized tubes from an antecubital vein, after an overnight fast, for analysis of lipid composition, anion transport, and sensitivity to oxidative damage of the erythrocyte membranes of young and old circulating erythrocytes. In addition, both prior to and following the dietary supplementation period, all subjects completed a food frequency survey (the dietary portion of the Health Habits and History Questionnaire, National Cancer Institute, National Institutes of Health, Bethesda, MD) in order to (i) evaluate the dietary fat intake of the subjects in the two treatment groups and to (ii) determine any significant shifts in dietary fat consumption that might have occurred during the dietary supplementation period.

Preparation and age separation of erythrocytes. After removing the plasma and buffy coat, packed erythrocytes were washed twice with 0.05 M phosphate-buffered saline (pH 7.4). Cells were separated by age according to the method of Murphy (22). In this procedure, 12 mL aliquots of packed cells, adjusted to a hematocrit of 85–90%, were centrifuged for 60 min at 27,000 × *g* in a fixed angle rotor at 27°C. After discarding the supernatant, the top (least dense) and bottom (most dense) 2.1 mL (~20%) of erythrocytes, i.e., the youngest and the oldest, were aspirated from each tube. Of these fractions, 0.1 mL were drawn off for measurement of erythrocyte number (23) and wet and dry weight in order to calculate erythrocyte water content. The remaining 2.0 mL of each erythrocyte fraction were taken for preparation of erythrocyte ghosts, according to the method of Steck (24) and used for measurements of fatty acid composition and oxidative sensitivity.

Measurement of anion transport. Membrane anion transport was determined in young and old erythrocytes according to the method of Zanner and Galey (7). Briefly, 1.0 mL of erythrocytes were diluted to a hematocrit of 25% and incubated with 3 mL buffer (80 mEq/l NaCl, 5 mEq/l KCl, 10 mEq/l Na_2SO_4, 5 mEq/l Na-Hepes, 5 mM glucose, and 100 mM sucrose, adjusted to pH 7.4) containing 10 μCi/mol $^{35}SO_4$ at 37°C for 2.5 h. The incubate was then centrifuged at 6,000 × *g* for 10 min, the buffer removed, and the packed cells washed twice. The labeled, packed erythrocytes were reconstituted to 5% hematocrit in buffer and incubated in a shaking water bath at 37°C for 2 h. At 10-min intervals, samples of 1 mL were drawn, centrifuged (Eppendorf microfuge; Eppendorf, Madison, WI) for 15 s, and 0.1 mL of the supernatant was added to 5.0 mL scintillation cocktail and counted in a liquid scintillation counter (LS1801; Beckman Instruments, Fullerton, CA). The rate coefficient of $^{35}SO_4$ efflux (SO_4^{2-}-Cl^- exchange), k, was calculated by linear regression analysis of the plot of $\ln(1-a_t/a_\infty)$ vs. time, where a_t and a_∞ indicate the extracellular radioactivity at sampling time t, and equilibrium, respectively. The negative of the slope of this plot is equal to the rate coefficient of the SO_4 efflux (7).

Measurement of oxidative sensitivity. A superoxide generating system was developed by adding 1 mL of erythrocyte ghost suspension, containing 5 mg protein, to 200 μmol xanthine (Sigma, St. Louis, MO) and 0.2 U xanthine oxidase (Sigma) in a total reaction volume of 1.5 mL. This mixture was incubated at 37°C for 24 h, at which time 1.5 mL trichloroacetic acid (15%) was added. The mixture was then centrifuged at 1,500 × *g* for 10 min and the supernatant removed. One mL thiobarbituric acid (0.67%) was added to the supernatant, which was heated for 25 min in a boiling water bath to develop the color. The production of thiobarbituric acid-reactive substances (TBARS), primarily malondialdehyde (MDA), was measured using a spectrophotometer (Shimadzu, Tokyo, Japan) at 532 nm. TBARS were determined from a standard curve prepared from a TBA–MDA conjugate of known concentration.

Lipid analysis of erythrocyte ghosts. Fatty acid composition of the total ghost lipid fraction was determined by gas–liquid chromatography. Lipids were extracted from 0.4 mL ghost suspension with chloroform/methanol, as previously described (25). Following the addition of an internal standard (10 μg 17:0; Nu-Chek-Prep, Elysian Fields, MN), samples were transmethylated with methanolic sulfuric acid (6%) at 90°C for 2 h. Fatty acid methyl esters were then analyzed on a Perkin Elmer (Norwalk, CT) gas chromatograph (model 8420) equipped with a flame-ionization detector and a 30 m capillary column (Supelcowax 10; Supelco Ltd., Oakville, Ontario, Canada). A temperature ramped program was used, as previously described (25). Phospholipid content of ghost membranes was estimated from inorganic phosphorus content (P_i). Thirty μL ghost suspension were digested with 1.2 mL perchloric acid over 4 h at 90°C, and then 1.5 mL ammonium molybdate (2.5%) and 0.2 mL Fiske-Subbarow reagent were added and the mixture heated in a boiling water bath for 7 min. The resulting color was read at 830 nm and compared with a standard curve generated using KH_2PO_4. The P_i was then multiplied by 25 to estimate the phospholipid content of the ghosts.

Statistics. Data comparing dietary intake patterns were analyzed using a two-way analysis of variance (treatment × time) on repeated measures. Data comparing membrane lipid

and phospholipid composition, cell water content, membrane anion exchange, and TBARS production were analyzed using a three-way analysis of variance (treatment × time × cell age) on repeated measures. Where a significance of $P < 0.05$ was achieved, specific comparisons were then made using Tukey's highly significant differences test.

RESULTS

One male subject from the fish oil intervention group did not complete the protocol for reasons unrelated to the study, leaving a sample size of 8 (4 males and 4 females) in the fish oil group. The dietary fat intake of both experimental groups prior to and following dietary intervention (not including the supplements) is shown in Table 2. All values represent mean ± SEM. Neither treatment nor time significantly affected the estimated daily intake of total, saturated, or monounsaturated fat, 18:2n-6 or dietary polyunsaturated fat/saturated fat ratio.

Red cell membrane fatty acid composition. The total membrane fatty acid compositions of density separated (young and old) erythrocyte ghosts prior to and following six weeks' dietary supplementation with either SAF or fish oil are shown in Table 3. There were no age-related differences in the fatty acid composition of ghosts from young vs. old cells, with the exception of an increase in 14:0 ($P < 0.05$) in the ghosts from old cells of the SAF group. Dietary supplementation with SAF increased the content of 16:0, 18:0, 18:1n-9, and 22:5n-6 ($P < 0.05$) of ghosts from young cells and decreased the content of 14:0 ($P < 0.05$) from ghosts of old cells. It also tended to increase the n-6 fatty acids, although this did not attain statistical significance ($P < 0.07$). Supplementation with fish oil increased the content of 16:0 ($P < 0.05$) and 20:5n-3 ($P < 0.01$) of ghosts from young cells. It also increased the content of 16:0, 20:5n-3, 22:5n-3 ($P < 0.01$), and 22:6n-3 ($P < 0.05$) and decreased the content of 18:3n-3 ($P < 0.05$) from the ghosts from old cells. Consistent with this was an increase in the n-3 fatty acids in fish oil-supplemented groups ($P < 0.05$). The double-bond index (DBI) of erythrocyte ghosts was not significantly altered by dietary supplementation. Supplementation with fish oil significantly increased the n-3/n-6 ratio vs. pre-supplementation values ($P < 0.01$).

Membrane phospholipid content. The calculated phospholipid contents of young and old erythrocyte ghosts prior to and following dietary supplementation with SAF or fish oil are shown in Figure 1. Prior to dietary intervention, there were no significant differences in phospholipid content

[a]Separated by density, prior to and following six weeks' dietary supplementation with either safflower or fish oil. DBI = double-bond index. Values represent X ± SEM. *$P < 0.05$ vs. pre-diet; **$P < 0.01$ vs. pre-diet; †$P < 0.05$ vs. young cells.

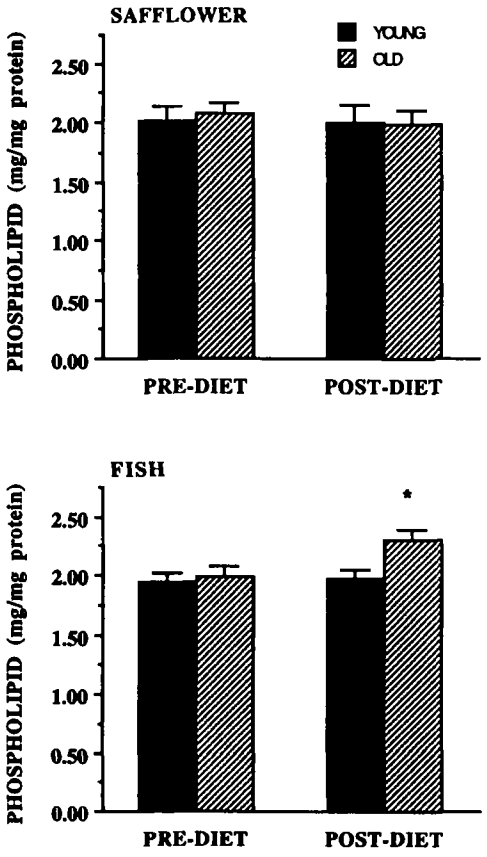

FIG. 1. Calculated phospholipid content (μg/mg protein) of young and old erythrocytes prior to and following six weeks' dietary supplementation with 4.0 g/day safflower oil or fish oil. All values represent X ± SEM. $^*P < 0.05$ vs. young cells.

(mg/mg protein) of either young or old ghosts in either dietary supplementation group. While supplementation with SAF had no effect on phospholipid content in either young or old ghosts, supplementation with fish oil significantly increased the phospholipid content of old ghosts vs. pre-treatment ($P < 0.05$). The phospholipid content of young ghosts, however, was unaffected by fish oil supplementation.

Water content. The water contents of young and old erythrocytes, separated by density centrifugation, prior to and following dietary supplementation with SAF or fish oil are shown in Figure 2. The water content of old erythrocytes (l/kg solids) was significantly lower than that of young erythrocytes ($P < 0.001$) and was unaffected by either dietary fatty acids or time.

Anion exchange rate constant. The rate constant, *k*, of SO_4^{2-} efflux from young and old erythrocytes, prior to and following dietary treatment with n-6 and n-3 fatty acids, is shown in Figure 3. Prior to dietary intervention, the efflux rate constant in both treatment groups was significantly higher in the old cells than in the young cells ($P < 0.01$). This age-related difference was approximately 10.6 and 12.7% in the SAF and fish oil groups, respectively. Following six weeks of dietary supplementation with SAF, there was no change in the efflux constant in either the young or old cells from the pre-treatment

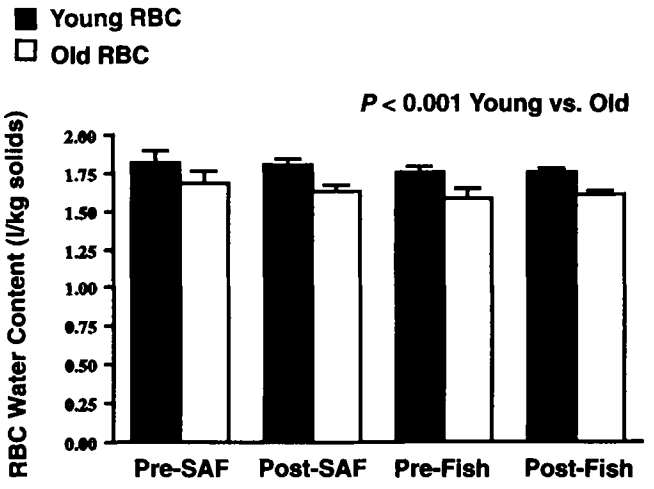

FIG. 2. Erythrocyte water content (1/kg solids) in young and old cells before and after dietary supplementation, as in Figure 1. RBC, red blood cells; SAF, safflower oil.

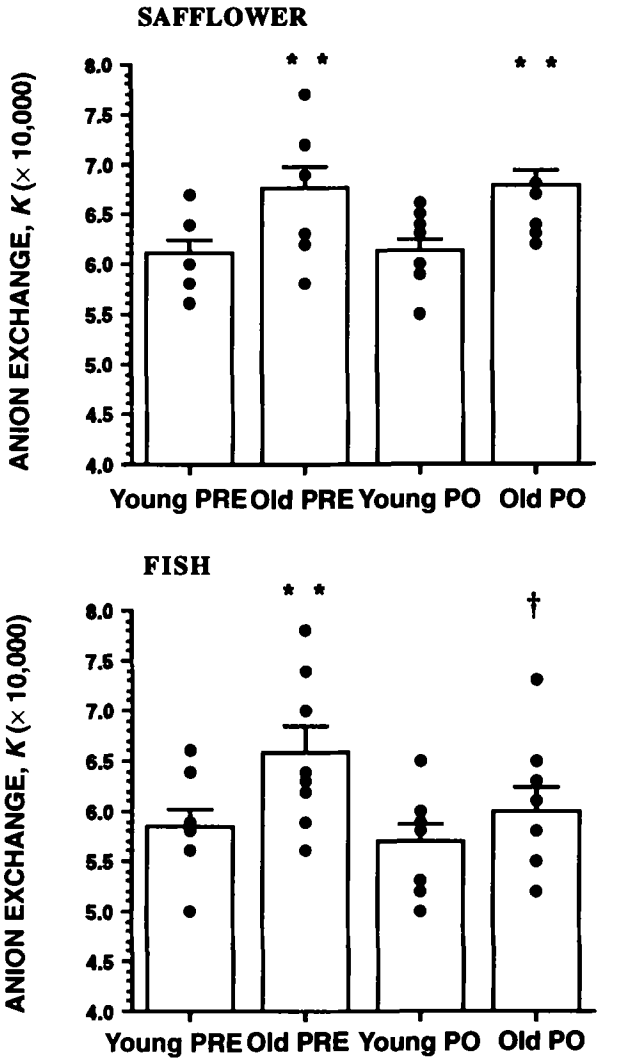

FIG. 3. Anion exchange rate constant, *k*, of young and old erythrocytes prior to (PRE) and following (PO) dietary supplementation, as in Figure 1. $^{**}P < 0.01$ vs. young cells. $^{\dagger}P < 0.05$ vs. pre-diet.

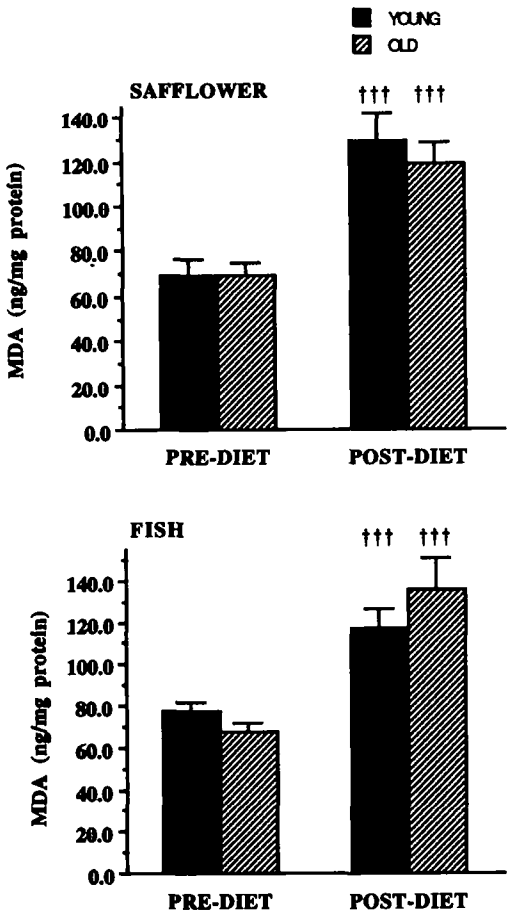

FIG. 4. Thiobarbituric acid-reactive substances production [malondialdehyde (MDA)] in young and old erythrocytes prior to and following dietary supplementation, as in Figure 1. $P < 0.001$ vs. pre-diet.

values, and the k in the old cells was significantly higher than in the young cells ($P < 0.01$). Following fish oil supplementation, however, the efflux constant of the old cells was significantly reduced from the pre-treatment value ($P < 0.02$), so that the efflux constants of the young and old cells were not significantly different from each other. There was no change in the k of the young erythrocytes vs. pre-treatment.

Oxidative sensitivity. The TBARS production in young and old erythrocyte ghosts prior to and following dietary supplementation with SAF and fish oil is shown in Figure 4. Prior to dietary intervention, there were no differences in TBARS production (ng/mg protein) in response to a superoxide generator between young and old erythrocyte ghosts in either treatment group. Following dietary supplementation with either SAF or fish oil, TBARS production was significantly higher in both young and old ghosts ($P < 0.001$) vs. pre-supplementation. However, TBARS production was influenced by neither the erythrocyte age nor the type of dietary fat (SAF or fish oil) used.

DISCUSSION

Cell age-related changes in erythrocyte phospholipid fatty acid composition have been reported by several investigators, although the exact nature of these changes varies among the reports (1–6,26,27). As erythrocyte membrane fatty acids are known to exchange with those in plasma phospholipids over a relatively short period of time (8–12 d) (4), it has been suggested that the differences among studies might be due, in part, to variations in the pattern and quantity of dietary fat intake over the course of the study (4). In the present study, fatty acid composition of erythrocyte ghost total lipids did not exhibit consistent age-related differences, although a decrease in the n-3/n-6 ratio in old cells vs. young cells was observed, as in our previous report (21). The absence of age-related differences in specific fatty acids in the present study may be due in part to (i) the use of the total lipid extract of the erythrocyte ghost in the present study vs. the erythrocyte phospholipid fraction for fatty acid analysis as in previous studies and (ii) the reporting of absolute levels of fatty acids in the present study vs. the reporting of relative levels (percentage of total fatty acids) in previous work.

Dietary supplementation with SAF decreased the n-3/n-6 ratio in old cells and decreased the DBI of both young and old cells. It also led to increased 22:4n-6 in young cells. The decrease in n-6 previously reported following SAF supplementation (21) was not observed in this study. Supplementation with fish oil increased long-chain n-3 fatty acid levels in both young and old cells, as previously reported, and increased the n-3/n-6 ratio of old cells.

Differences among the present study and our previous study with respect to erythrocyte lipid responses to dietary SAF administration may be related to methodological differences between the studies. In the earlier study, dietary supplementation was carried out over 12 wk in contrast to the 6 wk in this study. The question of possible shifts in dietary intake patterns during the study was addressed by the administration of a food frequency questionnaire pre- and post-dietary supplementation. This survey indicated that, aside from the experimental supplement, no significant changes in the intake of total calories, total, saturated, or monounsaturated fat, or linoleic acid occurred in any of the experimental groups during the study. This measure, not used in previous studies of age-related changes in erythrocyte lipids, suggests that the present findings were not attributable to uncontrolled dietary alterations.

The use of centrifugation techniques to separate young and old erythrocytes for comparison prior to and after dietary intervention makes the assumption that the dietary intervention does not alter the relative densities of the young and old cell populations. The validity of this assumption is critical to properly interpreting this and previous studies. Unfortunately, there have been no published investigations that address this issue. Nevertheless, we believe this assumption is valid because in our previous study, supplementation with SAF did not significantly affect several density-dependent cell membrane characteristics normally associated with cell aging, including relative filtration time, anion exchange constants, and water content. Density separation demonstrated the age-re-

lated characteristics similarly in both unsupplemented and safflower-supplemented subjects. Fish oil supplementation differentially affected the measured parameters, suggesting that supplementation *per se* did not alter the relationship.

We have previously reported increases in cell deformability and membrane lipid composition of old erythrocytes following fish oil supplementation. The present data demonstrate a fish oil-related abolition of the age-related increase in erythrocyte membrane anion transport. Together, these reports suggest that the functional changes brought about in the erythrocyte membrane by dietary long chain n-3 fatty acids are quite broad, and may represent a general alteration of the physiology of the aging cell. Whether or not these changes also result in the alteration of the oxygen delivery capability of the old cell or its survival time in the circulation, however, remains to be tested. Furthermore, it also would be of interest to determine whether or not dietary n-3 fatty acids alter other primary aging phenomena, such the expression of senescent cell antigen (8).

While the described changes brought about by dietary fish oil in the aging erythrocyte at first appear to be beneficial, the addition of highly unsaturated fatty acids, such as 20:5n-3 and 22:6n-3 to the erythrocyte membrane, might also increase the burden on cellular antioxidant defense mechanisms and lead to exaggerated oxidative damage. In the present study, both SAF and fish oil supplementation significantly and similarly increased TBARS production by erythrocyte ghosts during *in vitro* incubation with a free radical generator vs. pre-dietary controls. TBARS production was independent of cell age, supplement fatty acid composition, and post-intervention DBI of erythrocyte ghosts. This indicates that fish oil is no more deleterious in this regard than the SAF. Why fish oil, with its greater degree of unsaturation, is not associated with a greater degree of oxidative damage is not clear. It is possible that above a certain dietary fat level, the amount of dietary fat is more critical than the particular type of fat. Alternatively, the consumption of the highly unsaturated fish oil has been shown to lead to a compensatory increase in cellular antioxidant defenses (28), although this is not always observed (29). It is also possible that the *in vitro* reaction produced oxidative products other than MDA, e.g., lipid peroxides, which are not detectable with the TBARS method. Perhaps the most interesting aspect of the latter experiment was that the supplemental dietary 18:2n-6 (~29% above regular diet) had such a powerful effect on the oxidative susceptibility of the erythrocyte.

The current findings lend further support to the concept that dietary supplementation with sources of long-chain n-3 fatty acid sources selectively attenuate a number of age-related membrane changes seen in the aging human erythrocyte. These changes occur in the apparent absence of an increased susceptibility of the membrane lipids to oxidative damage. The potential benefits of these dietary-induced changes on erythrocyte function *in vivo* remain to be seen.

ACKNOWLEDGMENTS

This work was conducted with the support of grants-in-aid from the Heart and Stroke Foundation of Ontario and the Natural Sciences and Engineering Research Council of Canada to D. Mills and M. Murthy, and from the American Heart Association (GNM-04-90) to W.R. Galey. The authors would like to thank the Efamol Research Institute, Kentville, Nova Scotia, for donating the fish oil (Polepa) and safflower oil for the study.

Separation of γ- and α-Linolenic Acid Containing Triacylglycerols by Capillary Supercritical Fluid Chromatography

Pekka Manninen*, Päivi Laakso and Heikki Kallio

Department of Biochemistry and Food Chemistry, University of Turku, 20500 Turku, Finland

ABSTRACT: The separation of γ- and α-linolenic acid containing triacylglycerols with an identical acyl carbon number and degree of unsaturation was obtained on capillary supercritical fluid chromatography using a 25% cyanopropyl–75% methylpolysiloxane stationary phase. The resolution of 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol and 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol was 1.35 on a 10 m × 50 μm i.d. column, whereas the resolution was enhanced to 1.66 by combining two 10-meter columns in series. The difference in the position of double bonds in one linolenic acid residue of triacylglycerols resulted in two series of peaks in the separation of alpine currant *(Ribes alpinum)* and black currant *(R. nigrum)* seed oils. The use of the 10-meter column was found to be appropriate for the screening of the triacylglycerol profile in both seed oils studied.
Lipids 30, 665–671 (1995).

Edible oils containing γ-linolenic acid, 18:3n-6, are of physiological and nutritional importance. It has been considered that γ-linolenic acid should be regarded as an n-6 essential fatty acid having a notable role in health and disease, as recently reviewed by Horrobin (1). The most important functions of the n-6 essential fatty acids are related to the modulation of membrane structure and the formation of eicosanoids (1). The occurrence, as well as the physical and chemical properties of γ-linolenic acid, are well reviewed by Gunstone (2).

Of the several seed oils containing γ-linolenic acid known today (3), evening primrose (*Oenothera biennis*) oil and borage oil (*Borago officinalis*) are the most well-known. Such oils also have value as commercial products and are consequently under study. Usually the amount of γ-linolenic acid is measured by analyzing the fatty acid composition of the corresponding oil by gas chromatography, as their methyl esters. However, more detailed data of the triacylglycerol composition of edible oils is needed, e.g., to evaluate their nutritional importance and to improve their technological properties.

Using gas chromatography, it has not been possible to separate triacylglycerols with an identical acyl carbon number (ACN) and degree of unsaturation containing either γ- or α-linolenic acid, as reported by Řezanka and Mareš (4). Some articles have been published in which high-performance liquid chromatography (HPLC) has been applied to the separation of triacylglycerols containing γ-linolenic acid residue (5–9). These studies are mostly concerning evening primrose oil and borage oil, in which triacylglycerol compositions were analyzed by silver-ion or reversed-phase HPLC (5,6). However, these oils contain none or very small amounts of α-linolenic acid. Similar separation of triacylglycerols containing γ-linolenic acid also has been reported from the seeds of *Anemone* species by reversed-phase HPLC (7). Perrin *et al.* (8) separated triacylglycerols in black currant seed oil having identical ACNs and degree of unsaturation, containing γ- and α-linolenic acid, with good resolution using two reversed-phase columns in series. Recently, Aitzetmüller and Grönheim (9) produced a similar separation using a 25-cm reversed-phase column for *Primula florindae* and *Ribes nigrum.* Due to the dual nature of the separation mechanism on reversed-phase HPLC, using silver-ion HPLC to separate triacylglycerols according to the degree of unsaturation only has been recommended (5). Furthermore, it may be advantageous to use a combination of silver-ion and reversed-phase HPLC for the analysis of γ-linolenic acid oils.

Supercritical fluid chromatography (SFC) with a packed capillary column impregnated with silver nitrate has been applied to the separation of triacylglycerols in borage oil (10). This technique was able to produce partial separation of γ-linolenoyl-linoleoyl-palmitoyl-glycerol and α-linolenoyl-linoleoyl-palmitoyl-glycerol triacylglycerols. However, no articles of similar separations with open-tubular capillary columns have been published, although capillary SFC has been shown to be able to separate free fatty acids according to the degree of unsaturation (11).

In addition, fatty acids also can be separated as methyl esters by capillary SFC, as shown in this study. Triacylglycerols have been separated according to the ACN and the degree of unsaturation by capillary SFC by using a 25% cyanopropyl–75% methylpolysiloxane stationary phase, and the general elution behavior of triacylglycerols on this particular column has been discussed in more detail in a concurrent pub-

lication (Manninen, P., Laakso, P., and Kallio, H., unpublished data). In this study, a column with the same stationary phase was used to separate triacylglycerols containing α- and γ-linolenic acid residues. The separation was studied on both 10- and 20-meter columns. The method was applied for the analysis of alpine currant and black currant seed oils.

EXPERIMENTAL PROCEDURES

Materials. The reference compounds 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol (*sn*-18:1n-9-18:3n-6-18:1n-9) and 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol (*sn*-18:1n-9-18:3n-3-18:1n-9) (custom synthesized by Larodan, Malmö, Sweden) were diluted in *n*-hexane (Rathburn Chemical Ltd., Walkerburn, Scotland) to a concentration of approximately 0.5 mg mL^{-1}, and 1 mg of the mixture of trilinoleoyl-glycerol (18:2n-6-18:2n-6-18:2n-6), dilinoleoyl-γ-linolenoyl-glycerol (18:2n-6-18:2n-6-18:3n-6), and linoleoyl-di-γ-linolenoyl-glycerol (18:2n-6-18:3n-6-18:3n-6) (kindly donated by Dr. David Horrobin of Scotia Pharmaceuticals, Guilford, England) was diluted in 1 mL of dichloromethane (Merck, Darmstadt, Germany) for SFC analysis. Alpine currant (*Ribes alpinum)* seed oil and sea buckthorn (*Hippophaë rhamnoides*) seed oil were extracted with supercritical carbon dioxide at Flavex (Rehlingen, Germany) using production scale plant, and black currant (*R. nigrum)* seed oil was isolated by extraction using methanol/chloroform (1:2, vol/vol). The oils were stored under nitrogen below 0°C, and diluted 1:23 by volume in dichloromethane before chromatography. The fatty acid methyl esters were prepared by sodium methoxide catalyzed transesterification of 40 mg of alpine currant and sea buckthorn seed oils (12). The unpurified fatty acid methyl esters were diluted in 0.7 mL dichloromethane before SFC.

Methods. SFC was obtained on a Lee Scientific Series 600 supercritical fluid chromatograph (Lee Scientific, Dionex, Salt Lake City, UT) equipped with a flame-ionization detector and a pneumatically and electrically-controlled Valco switching valve with an internal loop volume of 1.0 μL. The flame-ionization detector was held at the temperature of 340°C, and nitrogen was used as a make-up gas. Frit restrictors (30 cm × 50 μm i.d.; Lee Scientific, Dionex) were connected at the split outlet and to the end of the analytical column. Sample introduction was performed by a combined timed and dynamic split technique. The columns used were: 10 m × 50 μm i.d. SB-Octyl-50 (50% octyl–50% methylpolysiloxane; Lee Scientific, Dionex) with a film thickness of 0.25 μm, and two 10 m × 50 μm i.d. SB-Cyanopropyl-25 (25% cyanopropyl–75% methylpolysiloxane; Lee Scientific, Dionex) with a film thickness of 0.25 μm. A 1/16" zero dead volume butt connector (SGE, Austin, TX) was used to combine two columns in series. SFC-grade CO_2 (Scott Specialty Gases, Plumsteadville, PA) was used as the carrier fluid. The column flow rate of CO_2 was 0.37 mL min^{-1} with the columns of 10 meters and 0.17 mL min^{-1} with the combination of the two 10-meter columns, as measured with propane at a column temperature of 140°C and CO_2 density of 0.140 g mL^{-1}. Chromatography on the 10-meter columns was performed at the constant temperature of 140°C using a linear density ramp from 0.140 g mL^{-1} at a rate of 0.005 g mL^{-1} min^{-1}, unless otherwise mentioned. With the combination of the two 10-meter columns, the linear density ramp used was from 0.150 g mL^{-1} using a 0.004 g mL^{-1} min^{-1} programming rate. Mass spectrometric analyses were obtained on a Finnigan MAT (San Jose, CA) TSQ-700 triple quadrupole mass spectrometer using a direct exposure probe for sample introduction. Ammonia negative-ion chemical ionization with an ammonia pressure of 8500 mtorr and a temperature of 200°C was used to produce the mass spectra of triacylglycerols (13).

RESULTS AND DISCUSSION

The main components in both alpine currant and black currant seed oils, according to the ACN group separation on a nonpolar stationary phase, were triacylglycerols containing 54 acyl carbons (Fig. 1). In addition, the composition of triacylglycerols obtained on mass spectrometry (MS) analysis was very similar, with only minor differences, in both oils (Table 1). The amount of γ-linolenic acid in alpine currant and black currant seed oils studied were 11.5 and 14.7% in weight, respectively, as measured by methyl esters *via* gas

[a]The proportions of triacylglycerols are calculated according to the ^{13}C-corrected intensities of $[M - H]^-$ ions.
[b]Four replicates.
[c]The combined proportion of components corresponding to less than 0.3% of the total.

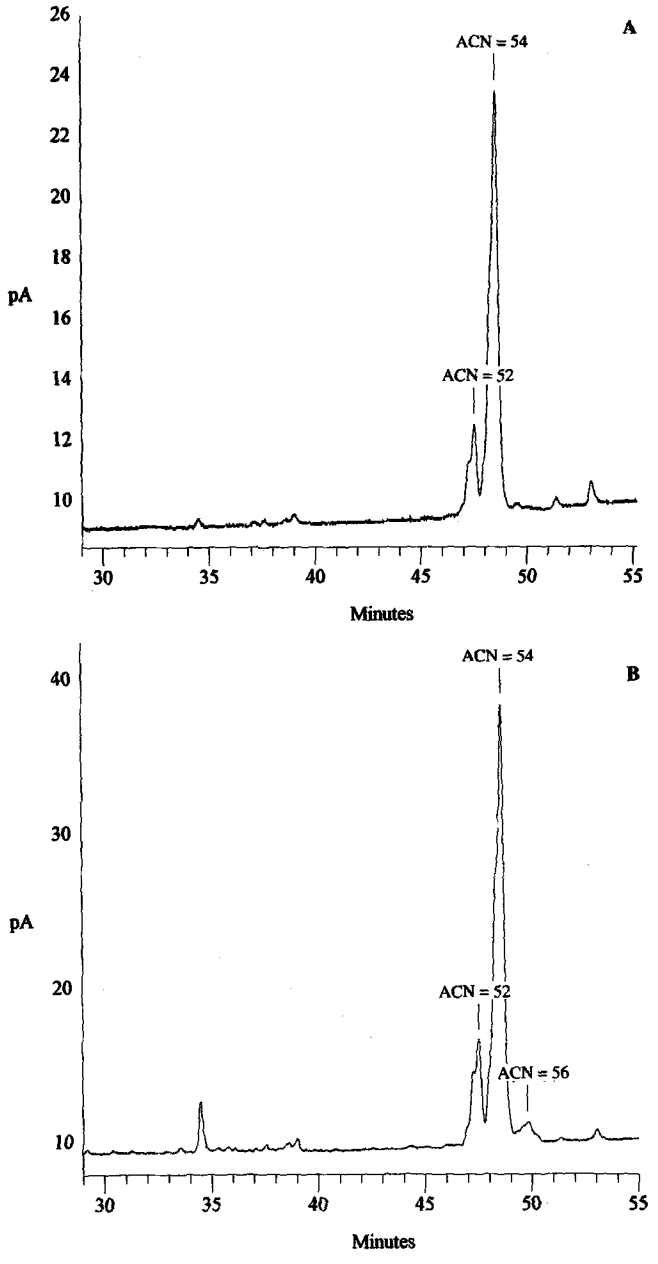

FIG. 1. Separation of alpine currant and black currant seed oils on an SB-Octyl-50 column (Lee Scientific, Dionex, Salt Lake City, UT): (A) alpine currant seed oil, and (B) black currant seed oil. Loop open time 0.7 s. ACN, acyl carbon number.

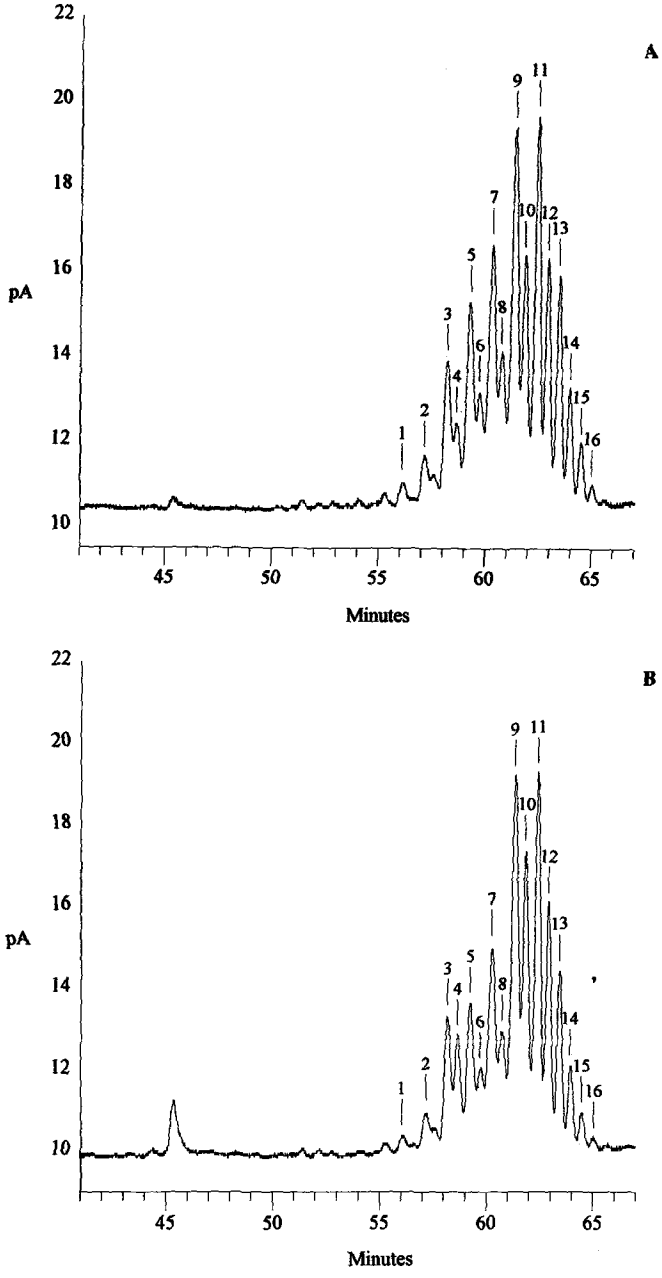

FIG. 2. Separation of triacylglycerols on an SB-Cyanopropyl-25 column (10 m × 50 μm i.d.; Lee Scientific, Dionex): (A) alpine currant seed oil, and (B) black currant seed oil. For peak identification see Table 2. See Figure 1 for company's location.

chromatography. The content of α-linolenic acid was found to be 18.3% by weight in alpine currant seed oil and 14.6% by weight in black currant seed oil fatty acids.

The separation of alpine currant and black currant seed oils on an SB-Cyanopropyl-25 column resulted in two series of prominent peaks (Fig. 2). This chromatographic resolution was not observed in the earlier study of sea buckthorn pulp and seed oil, and cloudberry seed oil (Manninen, P., Laakso, P., and Kallio, H., unpublished data). Such oils do not contain any γ-linolenic acid. The difference in the retention of triacylglycerols containing γ-linolenic acid from those containing α-linolenic acid or no 18:3 fatty acid residues could explain the additional series of triacylglycerol peaks in alpine currant and black currant seed oils. In addition, both alpine currant seed oil and black currant seed oil contained a small amount of stearidonic acid, 18:4n-3, which also could have influenced the resultant separation.

The retention behavior of triacylglycerols containing either γ- or α-linolenic acid could be predicted to some extent by studying the elution pattern of their fatty acid methyl esters. Triacylglycerols do not contain any free carboxylic acid group; therefore, it was more reasonable to study methyl ester derivatives than free fatty acids. The methyl esters of fatty acids of sea buckthorn oil were used to confirm the elution

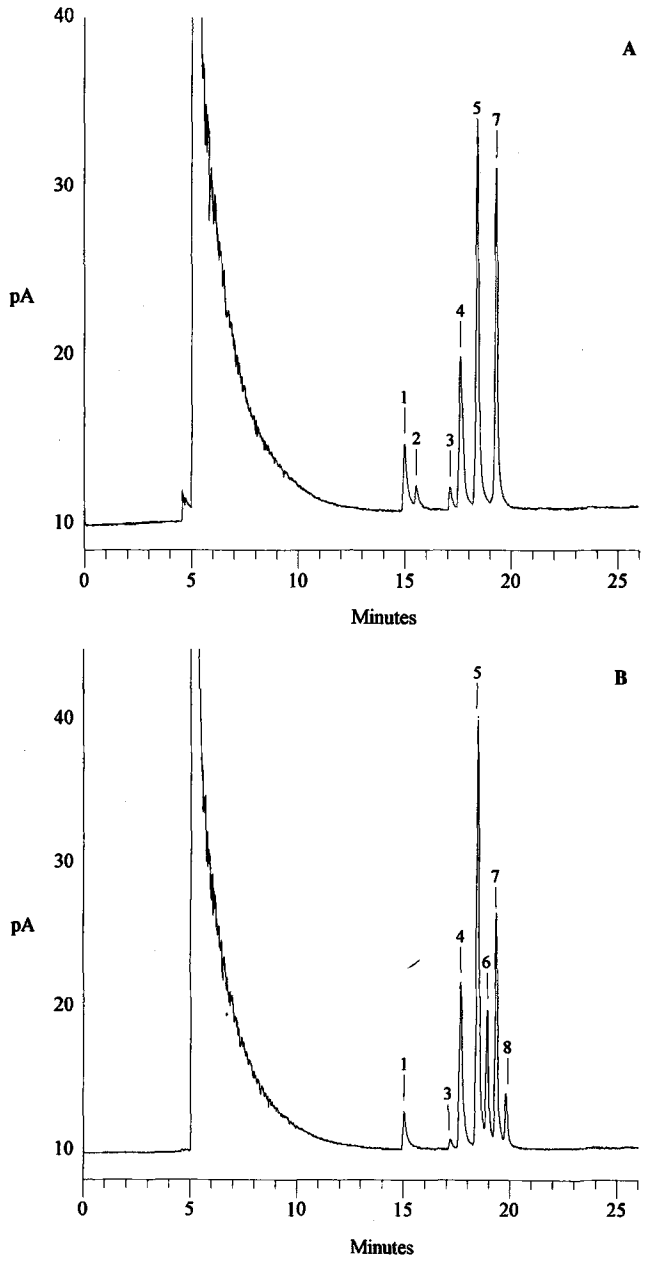

FIG. 3. Separation of fatty acid methyl esters on an SB-Cyanopropyl-25 column (10 m × 50 μm i.d.; Lee Scientific, Dionex): (A) sea buckthorn seed oil and (B) alpine currant seed oil. Chromatographic conditions: linear density ramp from 0.16 g mL^{-1} with 0.010 g $mL^{-1}min^{-1}$. Peak identification: 1 = 16:0, 2 = 16:1n-7, 3 = 18:0, 4 = 18:1n-9, 5 = 18:2n-6, 6 = 18:3n-6, 7 = 18:3n-3, and 8 = 18:4n-3. See Figure 1 for company's location.

order of the fatty acid methyl esters of alpine currant seed oil (Fig. 3). The retention of the fatty acid methyl esters increased with the increasing number of double bonds. In addition, the methyl ester of γ-linolenic acid eluted before that of α-linolenic acid, which indicates that the closer the double bonds are positioned to the ester group, the weaker their interaction between the stationary phase. Therefore, it was reasonable to assume that triacylglycerols with identical ACN and degree of unsaturation, containing either γ- or α-linolenic acid residues, could have slightly different retention.

A two-component mixture containing *sn*-18:1n-9-18:3n-6-18:1n-9 and *sn*-18:1n-9-18:3n-3-18:1n-9 was used to confirm this assumption (Fig. 4A). The component containing the γ-isomer of linolenic acid eluted before that containing the α-isomer, with a resolution of 1.35. The elution behavior was similar to that observed with fatty acid methyl esters. A three-component mixture containing 18:2n-6-18:2n-6-18:2n-6, 18:2n-6-18:2n-6-18:3n-6, and 18:2n-6-18:3n-6-18:3n-6 was separated with the resolutions (R) of $R_{3,4} = 1.12$ and $R_{4,5} = 1.46$ (Fig. 4B). *sn*-18:1n-9-18:3n-6-18:1n-9 and *sn*-18:1n-9-18:3n-3-18:1n-9 were spiked in alpine currant seed oil to confirm the elution order of triacylglycerols with identical ACN and degree of unsaturation having either one γ-linolenic acid or α-linolenic acid moiety. Spiking a real sample with the three-component mixture revealed that triacylglycerols containing two γ-linolenic acid moieties co-eluted with triacylglycerols having identical ACN and one less double bond without any γ-linolenic acid; for example, 54:7 with two γ-linolenic acid moieties co-eluted with 54:6 with only α-isomer of linolenic acid or with no linolenic acid moieties. The difference in the resolution of triacylglycerols containing two α-linolenic acid residues and those with one α- and one γ-linolenic acid was expected to be similar to that of triacylglycerols containing either one α- or one γ-linolenic acid moiety.

The separations were also tested with a longer column (Figs. 4C and 4D). Two 10-meter columns were combined *via* a zero dead volume SGE butt connector, because 20 m × 50 μm i.d. SB-Cyanopropyl-25 columns were, unfortunately, no longer available. The resolution of 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol and 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol was enhanced to 1.66 (Fig. 4C). Similarly, the resolution of the three component mixture increased to $R_{3,4} = 1.67$ and $R_{4,5} = 1.46$ (Fig. 4D).

The analysis of alpine currant and black currant seed oils on a 20-meter column improved the separation of the early eluted peaks (Fig. 5). Although the resolution was enhanced and chromatographic conditions further optimized, very similar proportions of the peaks were obtained with both lengths of the column (Table 2). The repeatability of the proportions of triacylglycerols was good in both cases. However, the repeatability in retention times was not satisfactory using the 20-meter column. It would be appropriate to use the 10-meter column for screening the triacylglycerol profile of both oils studied, even though the two peaks could not be effectively integrated using the 10-meter column.

The proportion of the peaks of triacylglycerols containing one γ-linolenic acid was 35.0% in alpine currant seed oil, which was in agreement with the proportion of γ-isomer of linolenic acid (38.6%). In black currant seed oil, the proportion of corresponding peaks was 37.7%, whereas the proportion of γ-isomer of the linolenic acid was 50.1%. Both alpine currant seed oil and black currant seed oil also contained stearidonic acid, 18:4n-3, 4.4 and 3.2% by weight, respectively. The effect of stearidonic acid to the retention of tria-

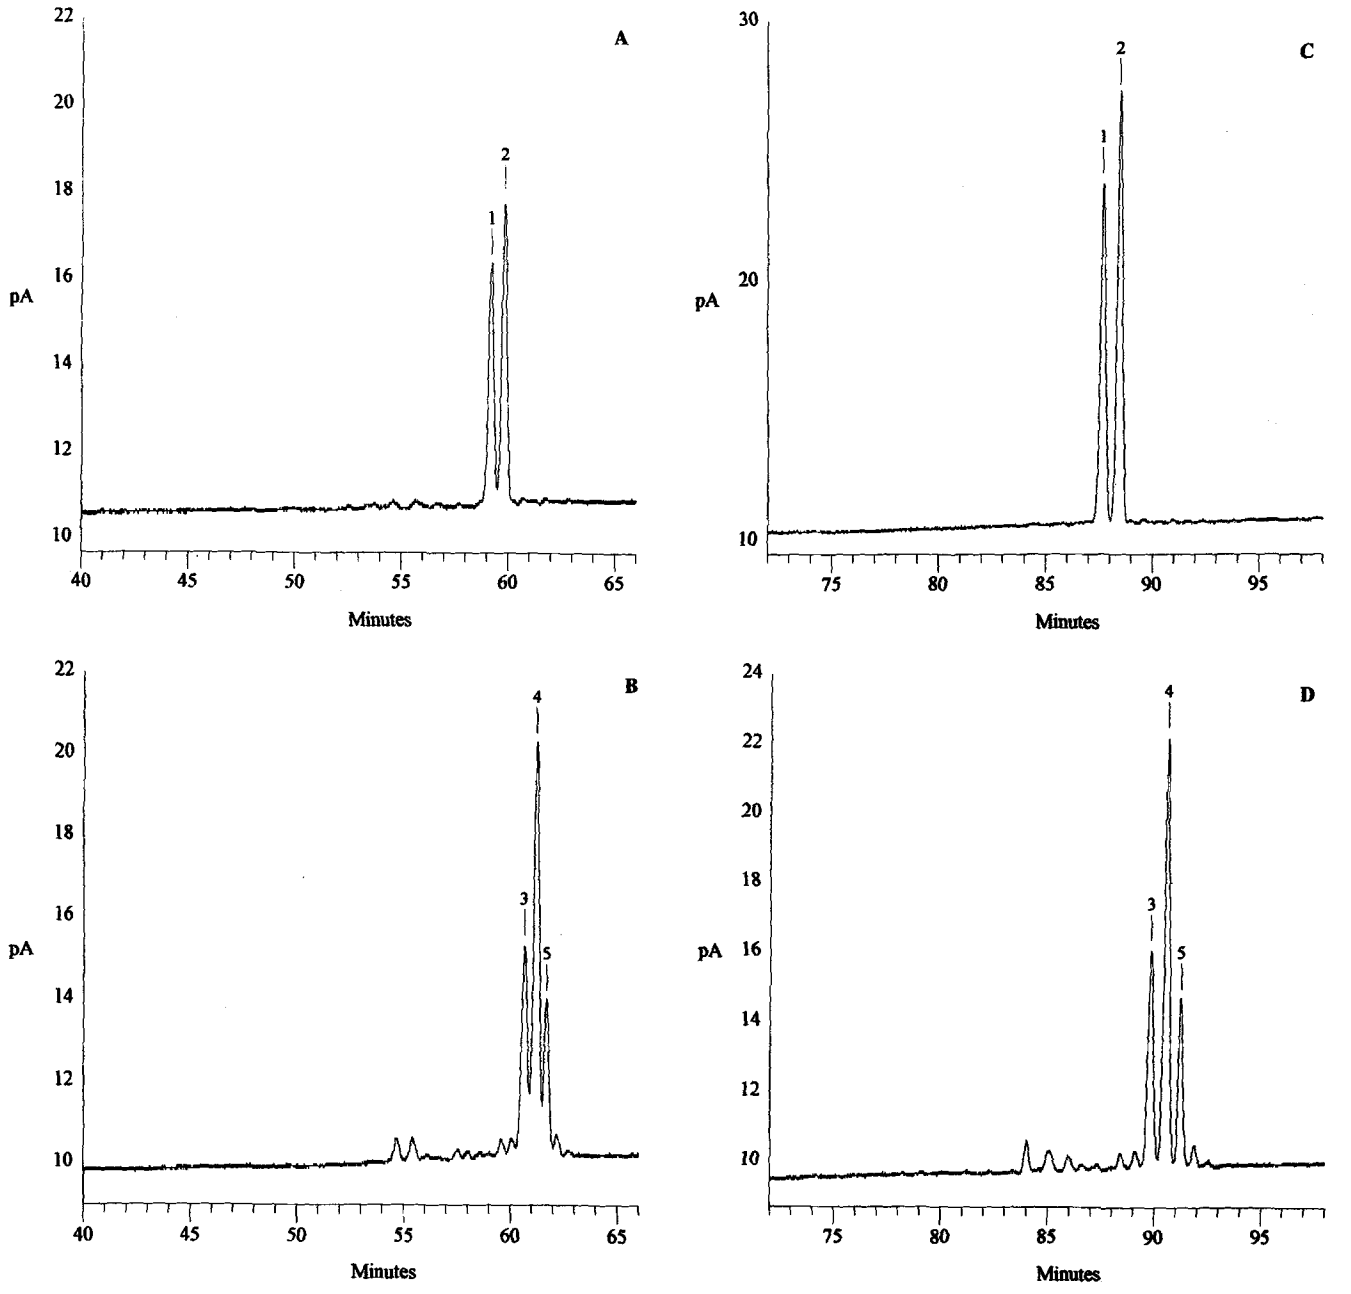

FIG. 4. The separation of reference mixtures of triacylglycerols on an SB-Cyanopropyl-25 column (Lee Scientific, Dionex): (A) a two-component mixture on 10 m x 50 μm i.d. column, (B) a three-component mixture on 10 m x 50 μm i.d. column, (C) a two-component mixture on 20 m x 50 μm i.d. column, and (D) a three-component mixture on 20 m x 50 μm i.d. column. Peak identification: 1-sn-18:1n-9-18:3n-6-18:1n-9, 2 = sn-18:1n-9-18:3n-3-18:1n-9, 3 = 18:2n-6-18:2n-6-18:2n-6, 4 = 18:2n-6-18:2n-6-18:3n-6, and 5 = 18:2n-6-18:3n-6-18:3n-6. See Figure 1 for company's location.

cylglycerols could not be examined during this study because of the lack of reference compounds. However, the difference between the proportion of triacylglycerols containing γ-linolenic acid in black currant seed oil expected and that actually observed (according to the proportion of γ-isomer of the linolenic acid) could not be explained by the amount of stearidonic acid alone, because it was too low. However, the greater difference in proportion indicates that black currant seed oil may contain triacylglycerols having two γ-linolenic acid residues. The presence of such triacylglycerols in black currant seed oil has been reported by Perrin *et al.* (8) and Aitzetmüller and Grönheim (9).

The most abundant triacylglycerols in alpine currant and black currant seed oils based on the MS analysis were 54:5, 54:6, 54:7, and 54:8. The distribution of triacylglycerols containing one γ-linolenic acid residue was quite similar in both oils studied. Among isomeric triacylglycerols (equal number of acyl carbons and double bonds), the proportion of triacylglycerols containing one γ-linolenic acid residue increased with increasing degree of unsaturation. However, one notable

exception to this trend was found in black currant seed oil, in which the proportion of the peak representing triacylglycerols 54:4 and 52:5 was nearly twice as high as the corresponding peak in the alpine currant seed oil.

The described method gives a new tool for achieving more information of the composition of triacylglycerols in the seed oils containing γ-linolenic acid. However, a method yielding more detailed separation is needed. Fractionation of triacylglycerols according to the number of acyl carbons before SFC on a 25% cyanopropyl–75% methylpolysiloxane stationary phase would be advantageous to enhance chromatographic resolution. The analysis and identification of co-eluting components having different ACNs could also be improved by combining SFC with MS. Nevertheless, chromatographic separation of triacylglycerols containing α- and γ-linolenic acid residues is important, because double-bond positional isomers of linolenic acid cannot be distinguished by MS without fractionation of the sample.

Lymphatic Fatty Acids from Rats Fed Human Milk and Formula Supplemented with Fish Oil

Richard M. Clark* and Li She

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

ABSTRACT: Absorption of long-chain polyunsaturated fatty acids from human milk and formula supplemented with fish oil was studied to determine if the distribution route into lymphatic triacylglycerol (TAG) and phospholipid (PL) varies with the dietary source. Rats were intraduodenally infused with human milk or formula containing graded amounts of fish oil (0, 0.5, or 1.0 g/100 mL), and the mesenteric lymph was collected. Arachidonic acid (20:4n-6) levels in lymphatic TAG and PL were highest from animals fed human milk. In the animals infused with formula containing fish oil, as the amount of eicosapentaenoic acid (EPA, 20:5n-3) infused increased, there was essentially an equal increase in EPA associated with both lymphatic TAG and PL. Animals intraduodenally infused with human milk or formula without fish oil had only minor levels (less than 1%) of EPA in the lymph. In the fish oil-treated animals, as the amount of docosahexaenoic acid (DHA, 22:6n-3) infused increased, there was a 16-fold increase in DHA associated with lymphatic TAG, but only a 3-fold increase in DHA associated with lymphatic PL. The highest level of DHA in rats infused with human milk was observed in lymphatic PL. Hence, fish oil can be added to formula as a source of long-chain polyunsaturated fatty acids, but the distribution of fatty acids into lymphatic TAG and PL is not the same as that observed with human milk.
Lipids 30, 673–676 (1995).

The rapidly growing neonate uses lipid from human milk for varied functions. Some of these functions include using it as an energy source, for the synthesis of membranes, and for the production of eicosanoids. To meet these varied needs, milk lipid contains a wide range of fatty acids, many of which are not found in infant formulas. The long-chain polyunsaturated fatty acids (LCPUFA) contained in human milk, but not in formulas, particularly arachidonic acid (AA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3), are of special interest because they are required by the neonate in the formation of neural and retinal tissue (1). Although AA and DHA can be synthesized from linoleic acid and α-linolenic acid, the neonate may not have the capacity to synthesize the amounts needed for normal development (2,3). Fish oils have been suggested as a possible source of LCPUFA for supplementation of infant formulas. Unfortunately, supplementation with fish oil has been reported to negatively affect infant growth and psychomotor development (4–6). It is thought that the much greater amounts of eicosapentaenoic acid (EPA, 20:5n-3) in fish oil, compared to human milk, may have adversely affected AA utilization by the infant (7). Because of the competition between n-6 and n-3 families of LCPUFA, further study is needed before appropriate recommendations can be made regarding LCPUFA supplementation of infant formulas.

The metabolic fate of a fatty acid is partially determined by its incorporation into different lipid classes of intestinal lipoproteins (8). The purpose of this study was to compare the distribution of fatty acids, particularly AA, EPA, and DHA, in lymphatic triacylglycerols (TAGs) and phospholipids (PLs) from rats fed human milk and infant formula containing corn oil supplemented with graded amounts of fish oil.

MATERIALS AND METHODS

Animals and surgical procedure. Male Holtzman albino rats obtained from Harlan Sprague Dawley (Indianapolis, IN) were used in this study. At the time of surgery, the rats weighed 300–375 g and were consuming a standard laboratory diet—Purina Rodent Chow 5001 (Purina Mills, St. Louis, MO)—and water *ad libitum.*

The major mesenteric lymph duct was cannulated as described by Warshaw (9). Surgery was performed under methoxyflurane–pentobarbital anesthesia. A right subcostal incision was made and a heparin-filled vinyl tube (medical grade, 0.50 mm i.d., 0.80 mm o.d.; Dural Plastics and Engineering, Dural, Australia) was threaded approximately 2 mm into the lymph duct. The cannula was secured using methylcyanoacrylate adhesive. A feeding tube was placed in the duodenum by passing Micro-renathane tubing (MRE 040; Braintree Scientific, Braintree, MA) in a caudal direction through a small gastric puncture and secured with methylcyanoacrylate adhesive. The abdominal wall was closed by suturing.

Immediately following surgery, the rats were placed in a warm, dark environment and allowed to recover for approximately 36 h. The rats had access to water and received a glu-

cose/electrolyte solution (Pedialyte; Ross Laboratories, Columbus, OH) at 2.0 mL/h during the recovery period *via* the duodenal feeding tube.

Infusates. The liquid diets used in this study were human milk, infant formula, infant formula plus 0.5% fish oil (0.5 g/100 mL) and infant formula plus 1.0% fish oil (1.0 g/100 mL). The human milk was donated by a woman during her eighth month of lactation. The infant formula contained corn oil (Nutramigen; Mead Johnson, Evansville, IN). Fish oil concentrate (Consumer Value Stores, Melville Corp., Woonsocket, RI) was emulsified (Branson Sonifier, Model 185; Branson Sonic Power, Danbury, CT) in the formula at room temperature and a setting of "4" for 15 s, repeated four times.

Following their recovery, seven rats per diet were infused (2.0 mL/h) for 12 h through the feeding tube. After infusing the diet for 6 h, lymph was collected during the next 6 h of infusion. During the collection period lymph flow averaged 2.6 mL/h. The lymph was then stored at −70°C until analyzed.

Lipid analyses. Total lipid was extracted from aliquots of each diet and lymph collection by a modified Folch procedure (10). The nonpolar and polar lipid (total PLs) were separated on a column containing Unisil (Clarkson Chemical Co., Williamsport, PA). The TAG in the lymph was isolated from other neutral lipid on silica gel G thin-layer chromatographic plates developed with hexane/diethyl ether/glacial acetic acid (90:30:2, by vol).

Fatty acids associated with TAG and total PL were transmethylated in methanol/hexane (4:1, vol/vol) in the presence of acetyl chloride (11), and fatty acid methyl esters were separated by gas–liquid chromatography on a Supelcowax 10 fused silica capillary column (30 m, 0.53 mm i.d.; Supelco, Bellefonte, PA).

Statistical analyses. Statistical analyses were performed by one-way analysis of variance. Comparisons between individual diets were made using Student's *t*-test for unpaired variates.

TABLE 1
Fatty Acid Composition of Liquid Diets

	Formula[a]	Formula plus 0.5% fish oil[b]	Formula plus 1.0% fish oil[b]	Human milk
Total fatty acid (mg/mL)	23	28	33	32
Fatty acid (wt%)				
14:0	—[c]	2.0	3.1	6.3
16:0	11.1	12.0	12.3	24.2

[a]Formula was Nutramigen (Mead Johnson, Evansville, IN) containing corn oil.
[b]Fish oil concentrate (Consumer Value Stores, Melville Corp., Woonsocket, RI): 0.5% fish oil was 0.5 g/100 mL formula. 1.0% fish oil was 1.0 g/100 mL formula.
[c]Not detected (less than 0.05 wt%).

RESULTS

The fatty acid compositions of the diets are shown in Table 1, and fatty acids in the lymph are shown in Table 2. The fatty acids in lymphatic TAG closely reflect the fatty acid composition of the diet, whereas PL was moderately affected.

The saturated fatty acid (14:0, 16:0, and 18:0) levels associated with lymphatic TAG in rats fed human milk were approximately twofold higher than those in the TAG from formula-fed rats. The saturated fatty acids were relatively constant in lymphatic PL and were not significantly influenced by diet. The monoenoic fatty acid (16:1 and 18:1) levels also were higher in the diet and lymph of the rats fed human milk compared to the animals fed formula. AA level was highest in the lymph of animals fed human milk.

[e]Fish oil.

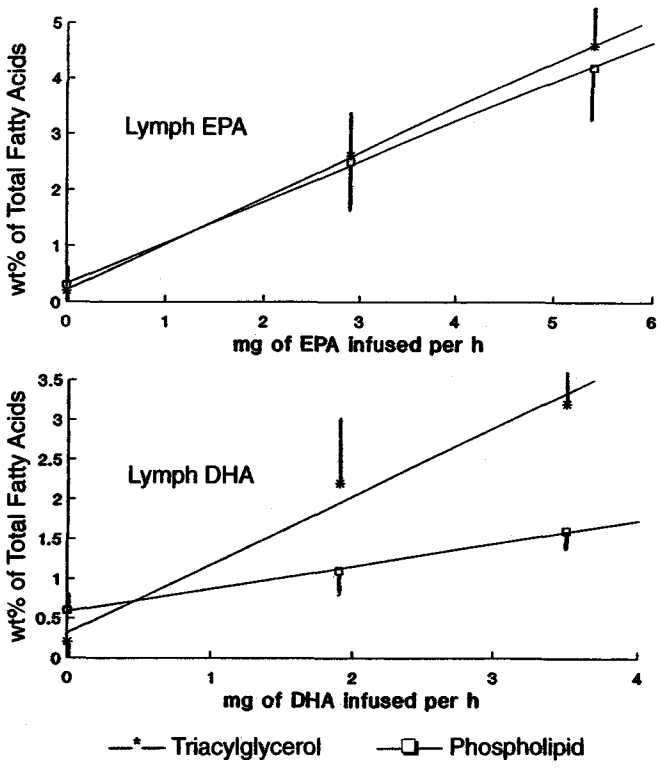

FIG. 1. Relationship between intraduodenal infusion of eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) and their distributions in lymphatic triacylglycerol and phospholipid. Each point is the average of seven observations ± SD.

The major difference among diets was the EPA associated with feeding fish oil. EPA was less than 1% of the fatty acids in the lymph from rats fed human milk and formula without fish oil and more than 4% in the lymph from rats fed formula supplemented with 1% fish oil. The proportion of EPA in the lymph was dose-dependent on the fish oil infused. In Figure 1, the proportions of EPA in lymphatic TAG and PL from rats fed formula with graded levels of fish oil are shown. As the amount of EPA infused increased, there was essentially an equal increase in EPA associated with both lymphatic TAG and PL.

DHA increased in the lymph with the amount of fish oil infused. However, as shown in Figure 1, DHA did not appear to be incorporated equally into TAG and PL in the lymph. As the amount of DHA intraduodenally infused increased, there was a 16-fold increase in DHA associated with lymphatic TAG, but only a 3-fold increase in DHA associated with lymphatic PL. In the human milk-fed animals, the lymphatic PL had a higher proportion of DHA than did lymphatic TAG. DHA was absorbed from both human milk and formula supplemented with fish oil, but its distribution route into lymphatic TAG and PL varied with the dietary source.

DISCUSSION

It has been proposed that LCPUFA be added to infant formulas, particularly those designed for low-birth-weight infants. Fish oil has been suggested as one source of LCPUFA. However, there are concerns about the use of fish oil, which include the bioavailability of LCPUFA from fish oil, and the EPA competitive inhibition of AA metabolism.

Reports on the bioavailability of LCPUFA from fish oils have not been consistent. Decreased absorption of EPA and DHA from fish oil compared to absorption of fatty acids from other oils has been reported in rats (12) and in humans (13), and other experiments have suggested more complete absorption (14–16). These differences may be due to experimental approach or previous diet. Rats previously fed fish oil had a greater apparent absorption of EPA and DHA from a test dose of fish oil than those fed corn oil (16). The well established resistance of fish oil to hydrolysis by pancreatic lipase is probably not physiologically important and not a factor affecting bioavailability (17).

In the present study, the proportion of EPA and DHA in the lymph from animals fed fish oil is only about 50% of that observed in the original diet (Table 1 vs. Table 2). This is in agreement with a similar study, which observed 55% less EPA and DHA as a proportion of total fatty acids in the lymph compared to the fatty acid composition of the fish oil fed (15). Although bioavailability may be a factor in the lower proportions of LCPUFA in the lymph, the present study was not designed to measure this. The actual quantities of fatty acids were not measured, and the length of time lymph was collected would not have been sufficient to recover all of the LCPUFA infused (16).

Figure 1 shows that DHA from fish oil was not incorporated equally into lymphatic TAG and PL. This difference in distribution of DHA in lymphatic PL compared to TAG may be explained by the structure of TAG in the fish oil supplement, positional specificity of pancreatic lipase, and the pathways for lipid synthesis in the enterocyte. Based on recent analyses of TAG from different fish oil supplements, DHA has been reported enriched in the *sn*-2 (15) or *sn*-2,3 position (13,18), whereas EPA was randomly distributed or enriched in the *sn*-3 position (13,15,18). Pancreatic lipase is known to hydrolyze fatty acids from the primary (*sn*-1,3) positions of menhaden oil (19). As a result of pancreatic lipase specificity, the *sn*-2 monoacylglycerol in the intestinal lumen of rats fed fish oil is enriched with DHA compared to the free fatty acids liberated from the glycerol (19). These products of lipid digestion are absorbed into the enterocyte where *sn*-2 monoacylglycerol enriched with DHA and two molecules of fatty acyl CoA form lymphatic TAG *via* the *sn*-2 monoacylglycerol pathway. The PL in lymph, mainly phosphatidylcholine, is synthesized in the enterocyte by acylation of lysophosphatidylcholine. Therefore, DHA in lymphatic TAG originates from the DHA-enriched *sn*-2 monoacylglycerol, while DHA associated with lymphatic PL originates from the less enriched DHA free fatty acid pool. Because EPA is not enriched in the *sn*-2 position of fish oil (13,15,18), it appears equally incorporated in lymphatic TAG and PL.

The second concern with adding fish oil to formulas was that the EPA in fish oil may negatively affect AA status. AA

in lymphatic PL was greatest in animals fed human milk and significantly ($P < 0.05$) less in animals fed formula with 1% fish oil. A similar trend ($P < 0.10$) was observed with lymphatic TAG (Table 2). The EPA/AA ratio also should be considered as it is a better index of AA status than AA alone (20). The EPA/AA ratio was 15-fold higher in lymphatic TAG and 8-fold higher in lymphatic PL from animals fed 1% fish oil formula compared to those fed human milk. This increase in EPA/AA ratio could suppress AA metabolism and potentially cause undesirable side effects such as increased risk of bleeding, altered immune function, and decreased neonatal growth and development (4–7).

In summary, fish oil can be added to formula to increase total DHA in lymph comparable to amounts seen with human milk. However, the distribution of DHA between lipid classes in the lymph is different. Lymphatic PL is most enriched with DHA in animals fed human milk, while in fish oil-supplemented animals lymphatic TAG accumulates DHA to a greater degree than PL. This difference may affect the metabolic fate of DHA as the fatty acids bound to lymphatic TAG are metabolized differently than those bound to the PL fraction of chylomicrons. Fish oil supplementation also increases the EPA/AA ratio 8- to 16-fold in lymphatic PL and TAG. Based on the EPA/AA ratio in lymph, adding fish oil to formula would have a negative effect on AA status.

ABSTRACT: The fatty acid composition of the tunicate *Botryllus schlosseri* and of two bacterial strains found within the tunicate, namely *Vibrio parahaemolyticus* and of an associated but previously unreported gram positive cocci were studied. The polyunsaturated fatty acids 6,9,12-octadecatrienoic acid, 5,8,11,14,17-eicosapentaenoic acid, and 4,7,10,13,16,19-docosahexaenoic acid were particularly abundant in *B. schlosseri* and were not detected in the two bacterial strains found in the tunicate. The *iso/anteiso* pair, 13-methyltetradecanoic acid and 12-methyltetradecanoic acid, were the principal fatty acids in the gram positive cocci, and the 9- and 11-hexadecenoic acids were particularly abundant in *V. parahaemolyticus*. The diunsaturated fatty acid 9,12-octadecadienoic acid was also shown to be present in *V. parahaemolyticus*. The fatty acid composition of a third bacterial strain, characterized as either a *Pseudomonas* or an *Alteromonas species*, and shown to be present only in the sea water from the Black Sea and not in *B. schlosseri*, is also reported. This is the first investigation on fatty acids from Black Sea bacteria.

Lipids 30, 677–679 (1995).

There are only a few investigations on the lipid composition of tunicates. Probably, the most comprehensive study has been reported by Kostetsky and collaborators (1,2), where the fatty acid composition of phosphatidylethanolamines and phosphatidylcholines from *Botryllus tuberatus* and *Botryloides eligulatum* were reported. The main fatty acids in these phospholipids were identified as 16:0, 18:2ω6, 20:4ω6, 20:5ω3, and 22:6ω3. However, some of the double-bond positions in the monoenoic fatty acids from these tunicates were not determined. Moreover, there is no known report on the bacterial composition of tunicates. A careful study of the fatty acid composition of the different bacteria present in the tunicate could reveal which fatty acids originate from the bacteria and which arise from tunicate cells. For example, it is known that cultures of *Shewanella putrefaciens* strain ACAM 342, grown aerobically and anaerobically at 15 and 25°C, produce the polyunsaturated fatty acids 18:2ω3, 18:3ω3, and 20:5ω3 (3). Some of the latter fatty acids, such as 20:5ω3, are also known to be present in tunicates. *Shewanella putrefaciens* is a common facultative anaerobe from the Black Sea, and reduces thiosulfate, sulfite, and elemental sulfur to sulfide (4).

In the present study, we report the fatty acid composition of the colonial tunicate *Botryllus schlosseri* and two associated bacteria from the Black Sea. To the best of our knowledge, there are no reports on the fatty acid composition of *B. schlosseri*. It was also of interest to determine if a bacteria such as *S. putrefaciens* was present in *B. schlosseri*. Are the polyunsaturated fatty acids in tunicates produced by bacterial symbionts? Which fatty acids are produced by bacterial associates and which are produced by the tunicate? These are the questions that we answer in the present study.

MATERIALS AND METHODS

Sample. The tunicate was collected September 10, 1993, near Ravda (South Black Sea coast of Bulgaria) at 20 m from the beach and at a depth of 2–3 m. Water samples were also collected from the same place.

Bacterial isolation. The bacteria were obtained from both *B. schlosseri* and sea water from the collection sites. *Botryllus schlosseri* was cut into small pieces and ground in a porcelain mortar. The homogenates obtained were diluted in standard nutrient broth with a final salt concentration of 1.6% (equal to the concentration of salts in the Black Sea). The following dilutions were used: 10^{-1} (0.1 mL water or homogenate + 0.9 mL broth), 10^{-2}, 10^{-3}, and 10^{-4}. From every dilution, 0.1 mL were taken and inoculated into two Petri dishes containing standard nutrient agar with a final concentration of NaCl 1.6%. After incubation at 37°C for 24 h, we

established the morphology of the material obtained. We transferred each strain to a separate flask and cultivated them in the standard nutrient broth with aeration at 37°C for 24 h. The bacterial biomass obtained from every strain was separated by centrifugation of the cultured liquid (6000 r.p.m. for 20 min) and the lipids were extracted as described by Christie *et al.* (5).

Bacterial identification. Characterization of the bacteria was done by standard biochemical tests modified for marine bacteria (6–8). The API 20E system (Analytab Products, Plainview, NY) was also used for the marine isolates. The three samples were identified as *Pseudomonas–Alteromonas* (OB-1), gram positive cocci (OB-2), and *Vibrio parahaemolyticus* (OB-3).

Fatty acid isolation. The lipids from *B. schlosseri* and from the three bacterial strains were extracted with chloroform/methanol (2:1, vol/vol) and saponified, the nonsaponifiables were removed, and the acids were methylated with methanol containing 1% sulfuric acid (5).

Instrumentation. Gas chromatography (GC) spectra were recorded on a Hewlett-Packard (Palo Alto, CA) 5890A gas chromatograph equipped with a flame-ionization detector and a nonpolar fused silica capillary column (30 m × 0.25 mm i.d.) containing DB-1 (carrier gas He). GC/mass spectrometry (GC/MS) data was collected at 70 eV in a Hewlett-Packard 5972A MS ChemStation equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS), similar, but crosslinked with 5% phenyl methylpolysiloxane. The temperature program for both GC and GC/MS analyses was as follows: 130°C for 2 min, then increased at 3°C/min to 270°C and maintained for 40 min.

Derivatives. Hydrogenations were carried out in 10 mL of absolute methanol and catalytic amounts of platinum oxide (PtO_2). The double-bond positions of the mono- and dienoic fatty acids were determined by preparing the corresponding dimethyl disulfide derivatives by dissolving the esters (2 mg) in dimethyldisulfide (0.2 mL), adding a solution (0.05 mL) of I_2 in Et_2O (60 mg/mL), and heating the solution at 50°C for 24 h, followed by the standard work-up (9,10).

RESULTS AND DISCUSSION

In the present study, the total fatty acids from the tunicate *B. schlosseri* were analyzed together with three bacterial strains from the sea water, two of which were found in the tunicate. The fatty acid profile of *B. schlosseri* is presented in Table 1. Saturated normal-chain fatty acids accounted for almost 40% of the total fatty acid composition of *B. schlosseri*, hexadecanoic acid (21%) and octadecanoic acid (6%) being the most prominent fatty acids in the mixture. Saturated branched-chain fatty acids accounted for only 4.3% of the total composition, the *iso/anteiso* 15:0 and 17:0 acids being the most abundant. As expected, the polyunsaturated fatty acids 20:5ω3 and 22:6ω3 were the main fatty acids in the tunicate, accounting for 26% of the total composition. The common marine fatty acids 20:4ω3 and 22:5ω3 were not found in *B. schlosseri*. Similar results were observed by Kostetsky and co-workers in *B. tuberatus* and in *Botrylloides eligulatum* (1,2). The most important dienoic fatty acids characterized in *B. schlosseri* were 9,12-octadecadienoic acid (18:2), 5,11-

TABLE 1
The Fatty Acid Composition (wt% of the total) from the Tunicate *Botryllus schlosseri* and the Three Associated Bacterial Strains

Fatty acid	Abundance (wt %)

Tetracosanoic (24:0)	0.3	—	0.2	0.1

[a]The OB-1 bacteria was identified as a *Pseudomonas–Alteromonas*. It was only detected in the sea water and not in the tunicate.
[b]The OB-2 bacteria was identified as a gram positive cocci. It was detected in both the tunicate and in the sea water.
[c]The OB-3 bacteria was identified as *Vibrio parahaemolyticus*. It was also detected in both the tunicate and in the sea water.

eicosadienoic acid (20:2), and 7,15-docosadienoic acid (22:2). The double-bond positions in these dienoic fatty acids were determined by GC/MS analysis on the corresponding dimethyl disulfide derivatives prepared and analyzed as previously described (10).

Two bacterial strains, designated as OB–2 and OB–3, were isolated from *B. schlosseri* and a third, OB–1, only detected in the sea water where the tunicate was collected, was also isolated. The strain OB-2, a new bacteria, could only be identified as a gram positive cocci since the biochemical characteristics did not match those of any known bacteria. The fatty acid profile of OB-2 is also presented in Table 1. The most important fatty acids in OB-2 were the 13-methyltetradecanoic (*i*-15:0) and the 12-methyltetradecanoic (*ai*-15:0), which accounted for 74% of the total fatty acid composition of this gram positive cocci. These fatty acids were characterized by GC/MS, GC retention times, and GC co-injection with authentic standards. Therefore, OB-2 seems to be responsible for most of the *isolanteiso* 15:0 fatty acids found in the tunicate.

The second bacterial strain present in the tunicate, namely OB-3, was characterized as *V. parahaemolyticus* as described in the Materials and Methods section. *Vibrio parahaemolyticus* showed the more common even-chain fatty acids. The key fatty acids in *V. parahaemolyticus* were 9-hexadecenoic acid (16:1), hexadecanoic acid (16:0), 11-octadecenoic acid (18:1), and octadecanoic acid (18:0), which together accounted for 76% of the total fatty acids of *V. parahaemolyticus*. Therefore, *V. parahaemolyticus* seems to be the major supplier of even-chain ω7 fatty acids for *B. schlosseri*. Moreover, *V. parahaemolyticus* was the only bacterial strain tested in this study to produce 11-hexadecenoic acid (16:1) and 14-methylhexadecanoic acid (*ai*-17:0). It is also of interest to note that the 9,12-octadecadienoic acid of bacterial origin was present in both OB-2 and OB-3, and these bacteria are likely to be the suppliers of this fatty acid for *B. schlosseri*. Are bacteria the source of the 9,12-octadecadienoic acid in marine invertebrates? More research has to be done on other marine invertebrates to answer this question, but this seems to be a very likely possibility.

A third bacterial strain, namely OB-1, could only be characterized as a *Pseudomonas–Alteromonas*. The biochemistry did not match that of any known bacteria. This strain was only found in the sea water where the tunicate was collected and not in *B. schlosseri*. Therefore, this seems to be a bacterium typical for the collection period and place in the Black Sea. Aerobic marine bacteria of the genera *Alteromonas*, *Pseudomonas*, and *Shewanella* have often been confused, due to phenotypic similarities (11). Therefore, because these marine bacteria share similar physiological and biochemical characteristics, more comprehensive tests, such as rRNA–DNA hybridization studies, must be carried out in order to fully characterize this bacterium (11). It is very likely that OB-1 will be closer to the *Alteromonas* as many *Pseudomonas* species have been found to contain cyclopropane and 2-hydroxy fatty acids (12). Such acids were not found in OB-1. The most abundant fatty acids in OB-1 were 13-methyltetradecanoic acid (*i*-15:0), 9-hexadecenoic acid (16:1), hexadecanoic acid (16:0), and 9-octadecenoic acid (18:1).

The results presented in this work are of interest because they clearly define which fatty acids in *B. schlosseri* are of bacterial origin and which are from the tunicate itself. From our results, it can be concluded that the more highly polyunsaturated fatty acids in *B. schlosseri*, namely 18:3ω6, 20:4ω6, 20:5ω3, 22:6ω3, and 22:5ω6, are not of bacterial origin. Although true symbiosis is difficult to assess in marine organisms, it is very likely that the bacteria found in *B. schlosseri*, the source of most of the short-chain saturated and monounsaturated fatty acids in the tunicate, are in symbiosis with the tunicate. Work is in progress toward the elucidation of the origin of unusual fatty acids in marine invertebrates.

Gas Chromatography/Tandem Mass Spectrometry as an Analytical Tool for the Identification of Fatty Acids

F. Couderc*

Institut de Biologie Cellulaire et Génétique du CNRS, 31062 Toulouse Cedex, France

ABSTRACT: Structures of fatty acids present at very low quantities in mycobacteria are difficult to determine. A commonly used strategy is to introduce heteroatoms into functional groups by chemical means before subjecting them to gas chromatography/tandem mass spectrometry (GC/MS/MS) analysis. Routinely used methods give very low abundance diagnostic ions leading to ambiguities in structural conclusions. GC/MS/MS associated with electron capture ionization of pentafluorobenzyl esters was used to study very complex mixtures of fatty acids from *Mycobacterium fallax* and *M. aurum*. The charge–remote fragmentation of fatty acid carboxylate anions was used for structure determination at the nanogram level of a large number of unsaturated, branched, and cyclopropane-containing fatty acids. Some of them have not been observed previously in these Mycobacteria. On the basis of these studies, biosynthetic pathways of unsaturated, branched, and cyclopropane-containing fatty acid are proposed.

Lipids 30, 691-699 (1995).

Mycobacteria synthesize considerable quantities of a wide variety of fatty acids (1). In *Mycobacterium phlei*, for example, more than 40 different fatty acids, from C_{12} to C_{36}, have been detected by gas chromatography/mass spectrometry (GC/MS) (2). Although it is not difficult to characterize the saturated fatty acids by GC/MS by electron ionization (EI), the location of double bonds, cyclopropane rings, or branched points is more difficult. On EI, it is possible for double bonds and cyclopropane rings to migrate, making their spectra difficult to interpret (3,4).

A widely used strategy is to introduce heteroatoms into these functional groups by chemical means before subjecting them to GC/MS analysis (5–9). The fragmentation pattern is markedly influenced by the presence of these heteroatoms, and the position of the ring structures and double bonds can be deduced from the characteristic EI spectra. The various methods, however, give very low abundance diagnostic ions, leading to ambiguities in structural conclusions (7,9).

It was shown that using collision activated dissociation/(CAD) mass analyzed ion kinetic energy spectra (MIKES) of aliphatic ions containing a strongly localized charge provides an easy and accurate method for analysis of fatty acids (charge-remote fragmentation). In particular, monounsaturated (10), α,β-unsaturated (11), polyunsaturated (12,13), methyl branched (14), methylene branched (15,16), cyclopropyl (17), cyclopentyl, and cyclohexyl (18) rings are easily detected and located.

Some years ago, we developed a new method that allows straightforward structural determination of fatty acids coming from very complex mixtures (19–21). Direct analysis of $(M - H)^-$ of fatty acids desorbed by fast atom bombardment and collisionally activated negative ion tandem mass spectrometry (MS/MS) was unsuccessful because many isomeric ions were present (19). Thus a chromatographic separation (as GC) was necessary. As we proposed earlier (19–21), the present paper describes a GC/MS/MS investigation of the fatty acids mixture from *M. fallax* and *M. aurum* by using charge–remote fragmentation process of collisionally activated carboxylate anions generated in the gas phase by electron capture of fatty acid pentafluorobenzyl esters (PFBE).

MATERIALS AND METHODS

Bacteria and growth conditions. Strains were obtained from the Collection of the Institut Pasteur (CIP) (Paris, France) and from the American Type Culture Collection (ATCC) (Rockville, MD). The CIP 8139 strain of *M. fallax* and ATCC 10437 of *M. aurum* were grown under agitation in 2-L Erlenmeyer flasks containing 500 mL of Middelbrook medium 7H9 (Difco, Detroit, MI), supplemented with 0.5% casitone (Difco) and 1% glucose (22). *Mycobacterium fallax* was cultivated at 30°C and *M. aurum* at 37°C. The bacteria were collected by centrifugation at the end of the exponential growth period. *Mycobacterium fallax* was also cultivated by using [*methyl*-$^2H_3$]L-methionine containing medium [500 mL Middelbrook medium 7H9 supplemented with 0.468% (wt/vol) casitone, 0.032% (wt/vol) [*methyl*-$^2H_3$]L-methionine (99% $^2H_3$-enrichment) (Aldrich, Steinheim, Germany) and 1% (wt/vol) glucose].

Isolation of nonhydroxylated fatty acid fractions. The cells were extracted by using a mixture of chloroform/methanol (2:1, vol/vol), and the dry extract was saponified in 1 mL of a 0.2 M solution of potassium hydroxide in a mixture ethanol/benzene/water (5:1:1, by vol) which was heated under reflux for 12 h at 85°C. Fatty acids were precipitated by a solution of sulfuric acid (0.2 M in water), extracted with diethyl ether and washed several times with water, then evaporated to dryness. Fatty acids were methylated with diazomethane in diethyl ether and chromatographed on an open, neutralized silicic acid column (CC7; Mallinckrodt Inc., St. Louis, MO) by using a gravity flow gradient of diethyl ether in hexane, adjusted by hand. The nonhydroxylated methylated fractions were pooled and analyzed by capillary GC.

Separation of saturated and unsaturated fatty acid methyl esters was achieved by silver nitrate (Sigma, St. Louis, MO) silicic chromatographic column as described by De Vries (23).

PFBE derivatization. Fatty acid methyl ester mixtures (0.5 mg) corresponding to each saturated and unsaturated fraction were saponified in 1 mL of 0.2 M KOH in water/methanol solution (1:1, vol/vol) at 80°C for 2 h. The PFBE derivatives of the mixture of liberated fatty acids were formed by treatment of 0.1–0.5 mg of each sample with pentafluorobenzyl bromide (2 μL) (Sigma) and diisopropyl methyl amine (2 μL) (Fluka, Buchs, Switzerland) in 60 μL of a mixture of dry methanol/acetonitrile (1:5, vol/vol). After 1 h at ambient temperature, the mixture was evaporated, dissolved in hexane (1 mL), and an aliquot analyzed by capillary GC.

GC experiments, GC/MS, and GC/MS/MS analysis. The gas chromatograph (Serie 30; Girdel, Dijon, France) was fitted with a solid injector (solvent split injection mode) and a fused silica capillary column (30 m × 0.32 mm i.d.) coated with nonpolar dimethyl silicon phase (OV1, 0.3-mm thickness; SGE, Ringwood, Victoria, Australia). The carrier gas was helium. The temperature program was 140–290°C at 2°C/min; the detector was a flame-ionization detector. The temperature of the injector was 240°C and, for the detector, 280°C.

GC/MS and GC/MS/MS analyses of PFBE were performed with a reverse geometry ZAB HS instrument (VG Analytical, Manchester, United Kingdom). It was fitted with a high-pressure ion source, and coupled with a capillary gas chromatograph (DANI 3800; Dani, Monza, Italy). The GC conditions were as described previously.

The electron capture ionization mode (identical to chemical ionization conditions) was obtained by using methane as moderator gas and a 50-eV electron beam. The pressure of methane was adjusted in order to have the maximum current of ion *m/z* 281 of electron capture ionization on 5 ng of pentafluorobenzyloleate (no pressure measurement in the ion source is available on the ZAB–HS instrument). The VG 2035 data system was used for acquisition and data processing.

For GC/MS/MS experiments, we have used the collision cell located between the magnet and the electrostatic analyzer. The pressure of helium was adjusted in order to reduce the main beam to approximately 50% of its original value. The MIKES were acquired in the continuum mode at a speed of 5000 $eV.s^{-1}$ from 7850 eV (0.98 E_0) to 400 eV (0.05 E_0) (E_0 is the value of the electric field transmitting the main beam). A 1.7-s cycle rate was obtained by using interscan delay of 0.2 s.

RESULTS AND DISCUSSION

Description of the method. Jensen *et al.* (12) have found that the decomposition of aliphatic ions containing a strongly localized electric charge (closed-shell ions) proceeds *via* a thermal-like mechanism with no participation of the charge (Scheme 1).

The mechanism involves a 1,4 loss of H_2 to give terminally unsaturated fatty acid carboxylates and 1-alkenes. In this process, double bonds do not migrate before fragmentation. Such a mechanism was found to operate in the CAD spectra of fatty acid carboxylates (10,12,14,16,17; for reviews see Refs. 24,25). Thus, the CAD spectra of the $(M - H)^-$ ion from saturated-chain fatty acids exhibit an envelope of regularly spaced signals at 14-mass-units intervals, owing to parallel cleavages of each C–C bond and simultaneous ejection of alkenes and hydrogen. When the aliphatic chain contains a double bond, allylic cleavages prevail, whereas cleavages of the double and vinylic bonds induce only weak signals. Thus, a "diagnostic" pattern of two intense signals separated by three weak ones indicates the presence of a double bond and allows its location by simply counting the number of signals between the main beam (the molecular ion mass) and the first weaker signal of the "dip," representing the three low-abundance ions. This gives the number of methylene groups between the methyl terminal and the double bond (10). A methylene branch is detected and located by the same phenomenon as double bonds, but there is a nearly complete absence of the middle single peak in a "dip" representing the three low-abundance ions (15,16). A methyl branch is detected and located by the absence of a single signal in the envelope (14).

Because the free fatty acids generally have less desirable chromatographic properties than their esters, we have gener-

SCHEME 2

ated gas-phase carboxylate anions from electron capture ionization of PFBE, according to Scheme 2 (19–21).

The chromatographic separation of such derivatives is possible for most positional isomers of monounsaturated, methyl branched, and cyclopropane-containing fatty acids, provided a good capillary column is used. The mass spectra are very simple, as carboxylate ions are the only ones produced. Carboxylate ions are formed in high yields by this ionization method (19–21). Because the collision activated processes of anions produce competing reactions of electron detachment (26,27) and ionic fragmentations (28), the intensity of the CAD spectra are generally weak. Nevertheless, the very high abundance of carboxylate anions obtained with electron capture ionization of PFBE allows their CAD/MIKE analysis to be performed by very fast kinetic-energy scans, in a reverse-geometry, double-focussing mass spectrometer.

A preliminary analysis of the fatty acids PFBE was carried out by conventional GC/MS. These experiments established the retention times of the various constituents and the masses of the corresponding carboxylate anions.

During the recording of GC/MS/MS analysis, just before the arrival of the chromatography peak, the magnetic field was adjusted to the value required for transmission of the carboxylate anion. Then, all spectra obtained by electric-field scanning were stored in the data system and transformed further into mass spectra. In the last part of the procedure, the whole acquired data were further converted into mass spectra by computer software. Thus, for each precursor ion of the same mass, we have obtained a reconstructed total (fragments plus parent) ion current chromatogram (GC/MS/MS chromatogram) and CAD spectra corresponding to the different chromatographic peaks of isomers. All of the GC/MS/MS chromatogram of each *m/z* value of precursor ion and CAD spectra obtained from these different precursor ion masses give the complete GC/MS/MS analysis.

Analysis of the fatty acids fractions of M. aurum *and* M. fallax. Fatty acid structures were easily determined with about 1.2 μg of fatty acid mixture. Saturated, unsaturated, odd, and even number fatty acids of *M. aurum* and *M. fallax* are described in Table 1. Three injections of each sample of PFBE fatty acid in GC/MS/MS were needed to make complete GC/MS/MS studies and to identify all the kinds of fatty acids.

The unsaturated fraction of *M. fallax* shows 12 major fatty acids, which represent about 98% of all the components of the fatty acid mixture (result estimated from gas chromatogram, not shown). Two percent of this mixture is composed of the 15 minor fatty acids reported in Table 1. We conclude that a mean of 1.6 nanograms (1200 ng × 0.02/15) of each PFBE fatty acid are needed for structural determination by GC/MS/MS.

Identification of three enzymatic C*-methylation processes in* M. fallax. Fatty acids of *M. fallax* were briefly reported by Levy-Frébault *et al.* (22). GC/MS/MS allows an exhaustive structural determination of these fatty acids.

Some years ago, it was shown that enzymatic C-alkylation process of isolated double bonds of unsaturated fatty acid is often observed in mycobacteria (29). Different reaction schemes were proposed in which different intermediate structures of fatty acids were described. These structures were very

[a]Δ indicates the position of double bond; *i, iso* type; a, *anteiso* type; n, linear type; R^j, methyl branched on carbon j; ΔR^j, methylene branched on carbon number j; $R^{i,j}$, two methyl branched on carbon number i and j; $C^{i,j}$, cyclopropyl ring between carbon number *i* and j; Δ4, 8, 12, 16, tetraunsaturated on position 4, 8, 12, 16; Δ4, 8, 12, 16, 20, pentaunsaturated on position 4, 8, 12, 16, 20; ΔiR^j, unsaturated on position *i* and branched in position *j*; ND, nondetected. The major component in each series is bold, the second major component is underlined.

difficult to identify, and some of these fatty acids were never observed. We have focused our attention on the C_{18} and C_{19} saturated and unsaturated fatty acids from *M. fallax*, because there are implications for double-bond enzymatic methylation processes.

Figures 1–3 show the GC/MS/MS data of anion of *m/z* 297 (19:0) from the saturated fraction, another of *m/z* 295 (19:1) from the unsaturated fraction, and another of *m/z* 281 (18:1) from the unsaturated fraction. The top chromatogram in each figure represents the reconstructed total ion current profile from the fragments of each precursor ion. The subsequent spectra correspond to the CAD/MIKE spectra of the precursor ion at different GC retention times.

There are two principal components yielding anion of *m/z* 297 (Fig. 1A). The CAD spectra on the rising and falling sides of the main component 1B are all identical and show a dip of one signal at *m/z* 169, indicating a methyl branch on C_{10} carbon atom (Fig. 1B); it is assigned as 10-methyl-octadecanoic acid (tuberculostearic acid). Peak 1C of the GC/MS/MS chromatogram shows a small amount of a linear nonadecanoic acid (Fig. 1C).

The data for the anion *m/z* 295 (Fig. 2A) are more complex; there are approximately six fatty acids: Figure 2B (spectrum of peak *2B*) shows a dip of four weak signals between ions *m/z* 171 and 239, separated from the main beam by four intense signals. This was previously identified as a 11-methyl-12-octadecenoic acid (30). Figure 2C (spectrum of peak *2C*) is a 10-methyleneoctadecanoic acid (dip of three consecutive weak signals between ions *m/z* 141 and 197, extremely weak signal at *m/z* 155). Figure 2D, 2E, and 2F (spectra of peak *2C, 2D,* and *2E*) show, respectively, Δ9 (dip of three consecutive weak signals between ions *m/z* 127 and 183), Δ10 (dip of three consecutive weak signals between ions *m/z* 141 and 197), Δ11 (dip of three consecutive weak signals between ions *m/z* 155 and 211), nonadecenoic acid. Figure 2G (spectrum of peak *2G*) can be used to characterize clearly a 11,12-*C*-methylideneoctadecanoic acid (lactobacillic acid). Ions a, b, c, d, e, f, and g are diagnostic of a cyclopropyl ring, and ion c specifies its location at ω7 position (17).

The GC/MS/MS chromatogram of mass *m/z* 281 (18:1) (Fig. 3A) shows three GC peaks, which were identified as Δ9, Δ11-, and Δ13-octadecenoic acid (3B, 3C, 3D, spectrum of peaks *3B, 3C,* and *3D,* respectively).

These results identify three coexisting methylation processes in *M. fallax*. First, oleic acid is methylated into 10-methylene octadecanoic acid, followed by double-bond reduction to tuberculostearic acid. This mechanism was called the "CD_2 mechanism" some years ago, because two deuterium atoms were found on tuberculostearic acid when bacteria were cultivated on [*methyl*-$^2H_3$]L-methionine-containing medium (29,31–34, for a review see Ref. 35).

There are also two methylation processes of vaccenic acid: one gives lactobacillic acid (29,31–34) and the other produces 11-methyl-12-octadecenoic acid (37). Such methylation processes give two deuterium atoms in lactobacillic acid and three deuterium atoms in 11-methyl-12-octadecenoic acid, respectively, when bacteria are cultivated on [*methyl*-$^2H_3$]L-methionine-containing medium. This last process has been called the "CD_3 mechanism" (33–35,38).

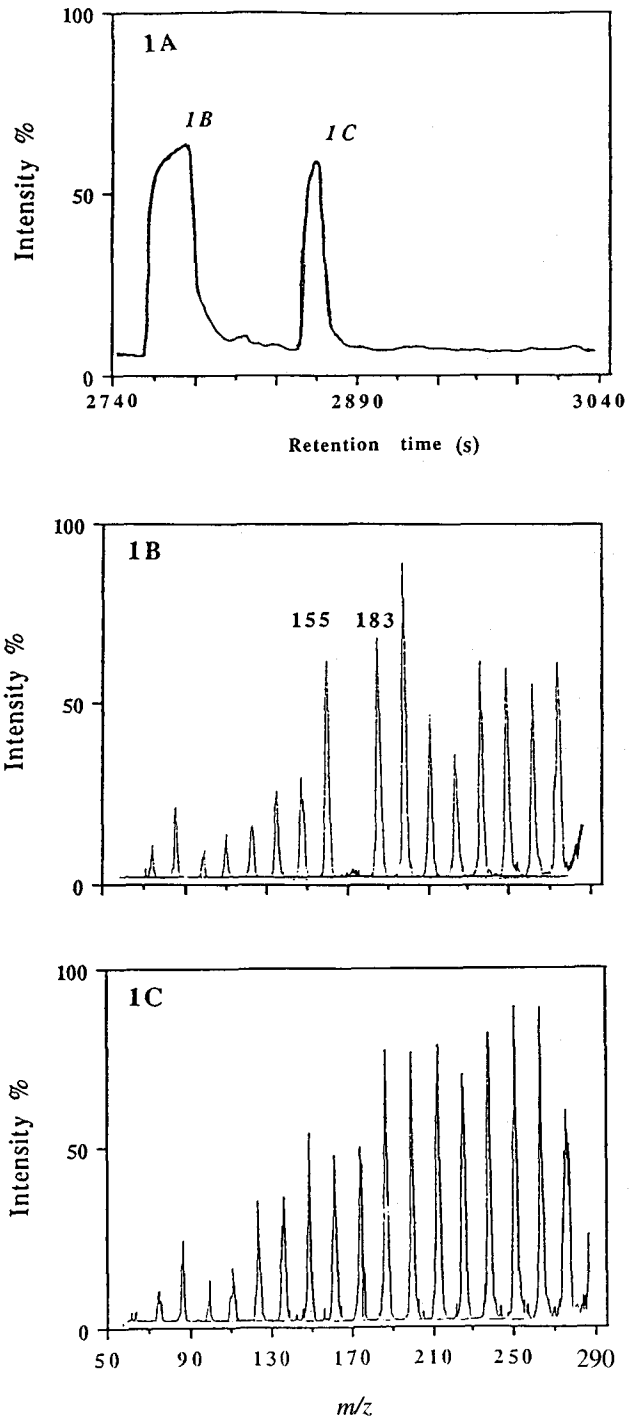

FIG. 1. Gas chromatography/tandem mass spectrometry analysis of saturated acids from *Mycobacterium fallax* (CIP 8139): nonadecanoic acid. A is the reconstructed chromatogram of anions of *m/z* 297. B and C are collision activated dissociation/mass-analyzed ion kinetic energy (CAD/MIKE) spectra of the two components labelled *1B* and *1C*, B, 10-methyloctadecanoic acid, C, *n*-nonadecanoic acid.

Table 2 gives the number of deuterium atoms found in branched fatty acids of *M. fallax* cultivated on [*methyl*-$^2H_3$]L-

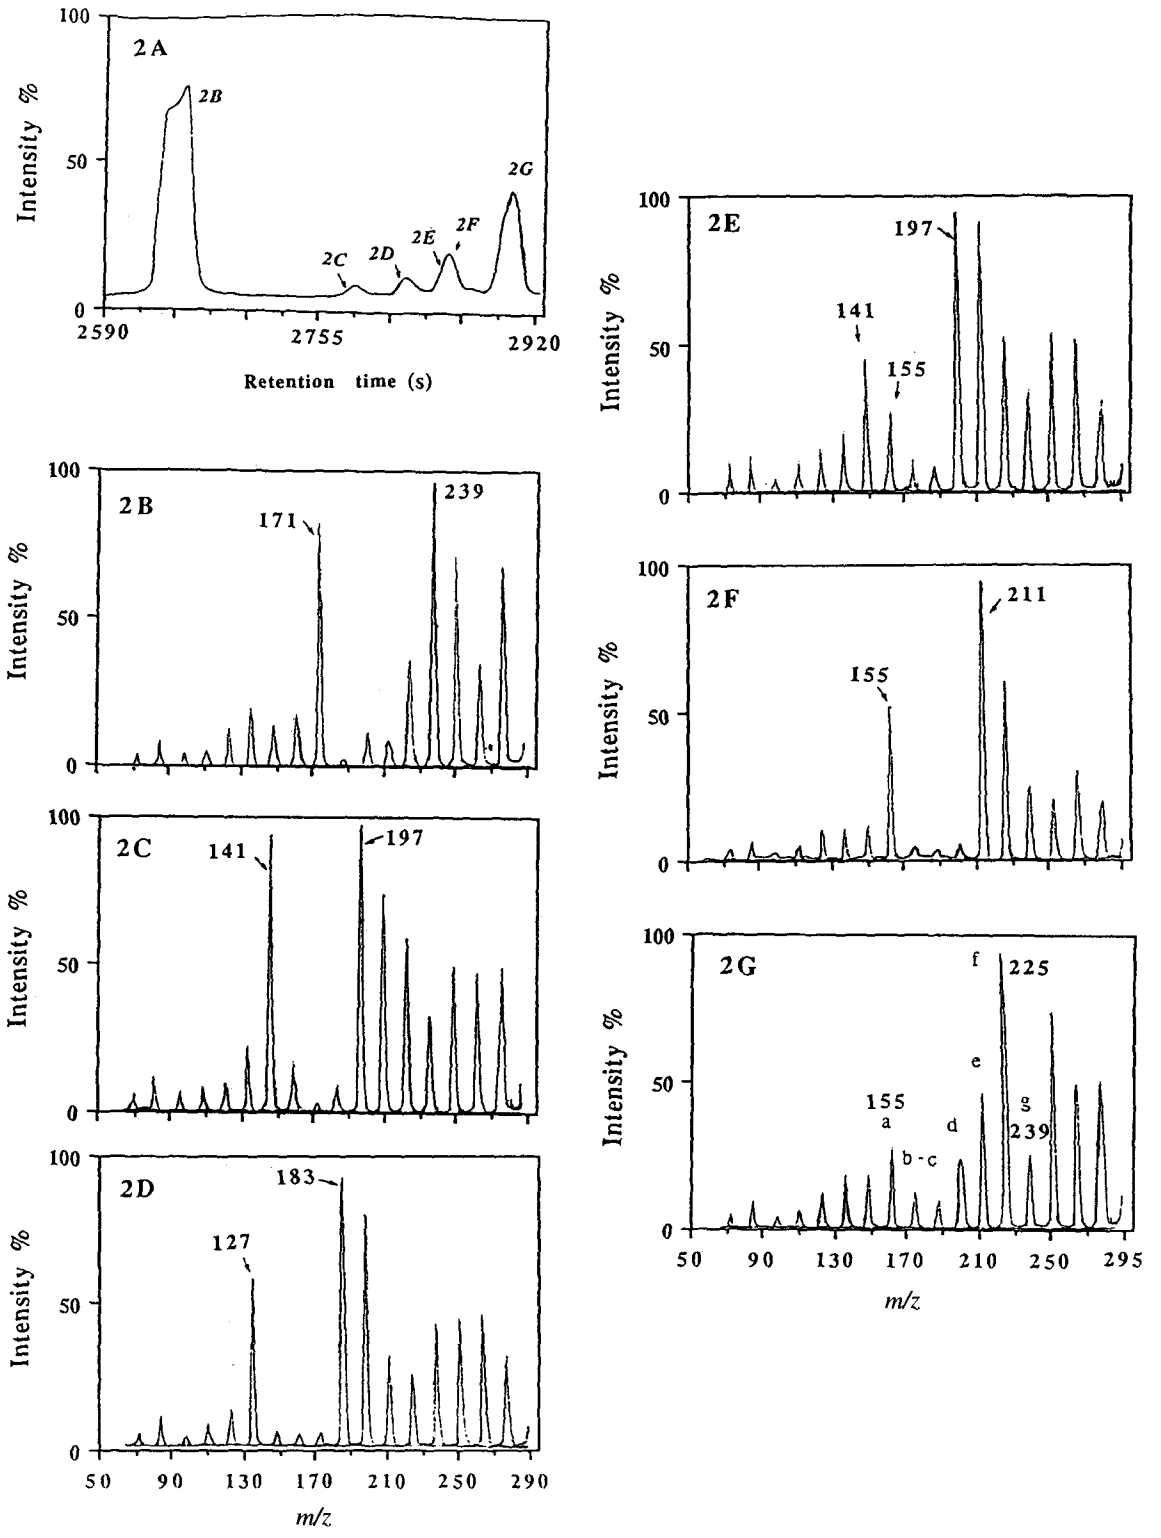

FIG. 2. Gas chromatography/tandem mass spectrometry (MS/MS) analysis of monounsaturated acid from *Mycobacterium fallax* (CIP 8139): nonadecenoic acid. A is the reconstructed chromatogram from MS/MS analysis of anion of *m/z* 295 ions. B–G: CAD/MIKE spectra of the components labelled *2B-2G*: 2B, 11-methyl-12-octadecenoic acid; 2C, 10-methyleneoctadecanoic acid; 2D, 9-nonadecenoic acid; 2E, 10-nonadecenoic acid, the abnormal high intensity of ion *m/z* 155 is due to the major ion of the following poorly separated fatty acid 2F; 2F, 11-nonadecenoic acid; and 2G, lactobacillic acid [ions noted a, b, c, d, e, f, and g are diagnostic ions of a cyclopropyl ring (Ref. 17)]. The mean quantity of each fatty acid is estimated to 1.6 ng. Abbreviations as in Figure 1.

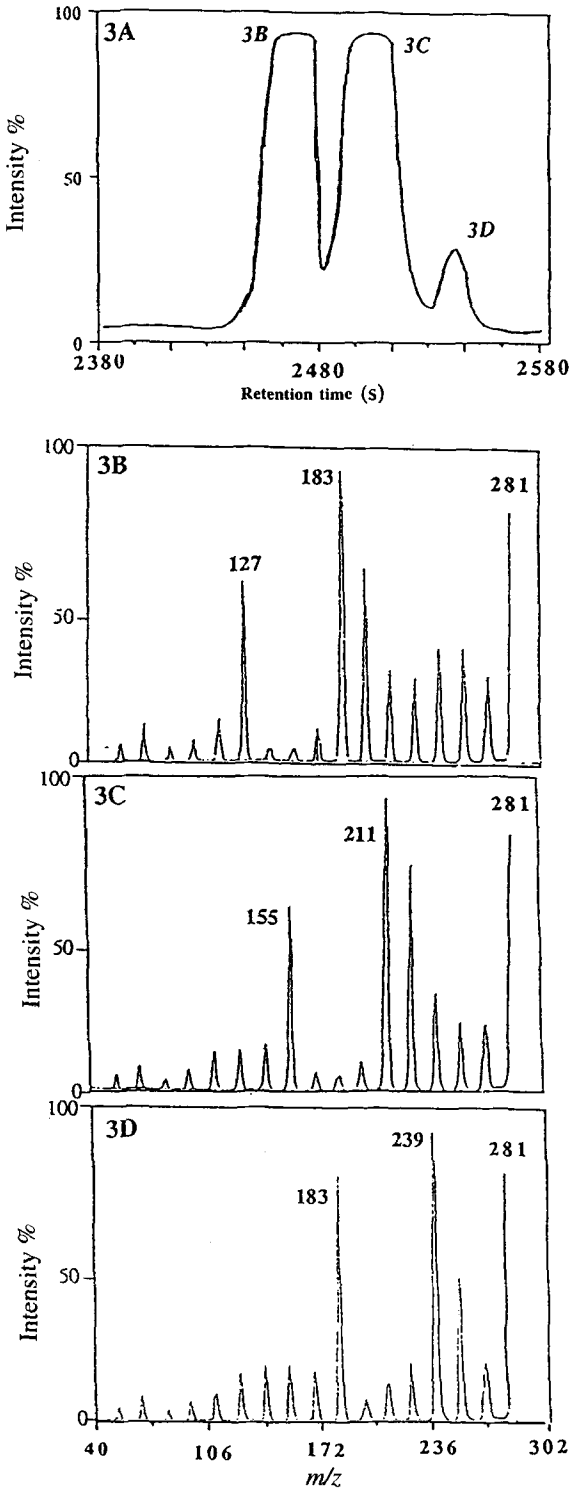

FIG. 3. Gas chromatography/MS/MS analysis of monounsaturated acids from *Mycobacterium fallax* (CIP 8139): octadecenoic acids. A is the reconstructed chromatogram of anions of *m/z* 281. 3B–3D, CAD/MIKE spectra of the three components, labelled *3B-3C*: 3B, 9-octadecenoic; 3C, 11-octadecenoic; and 3D, 13-octadecenoic. Abbreviations as in Figure 1.

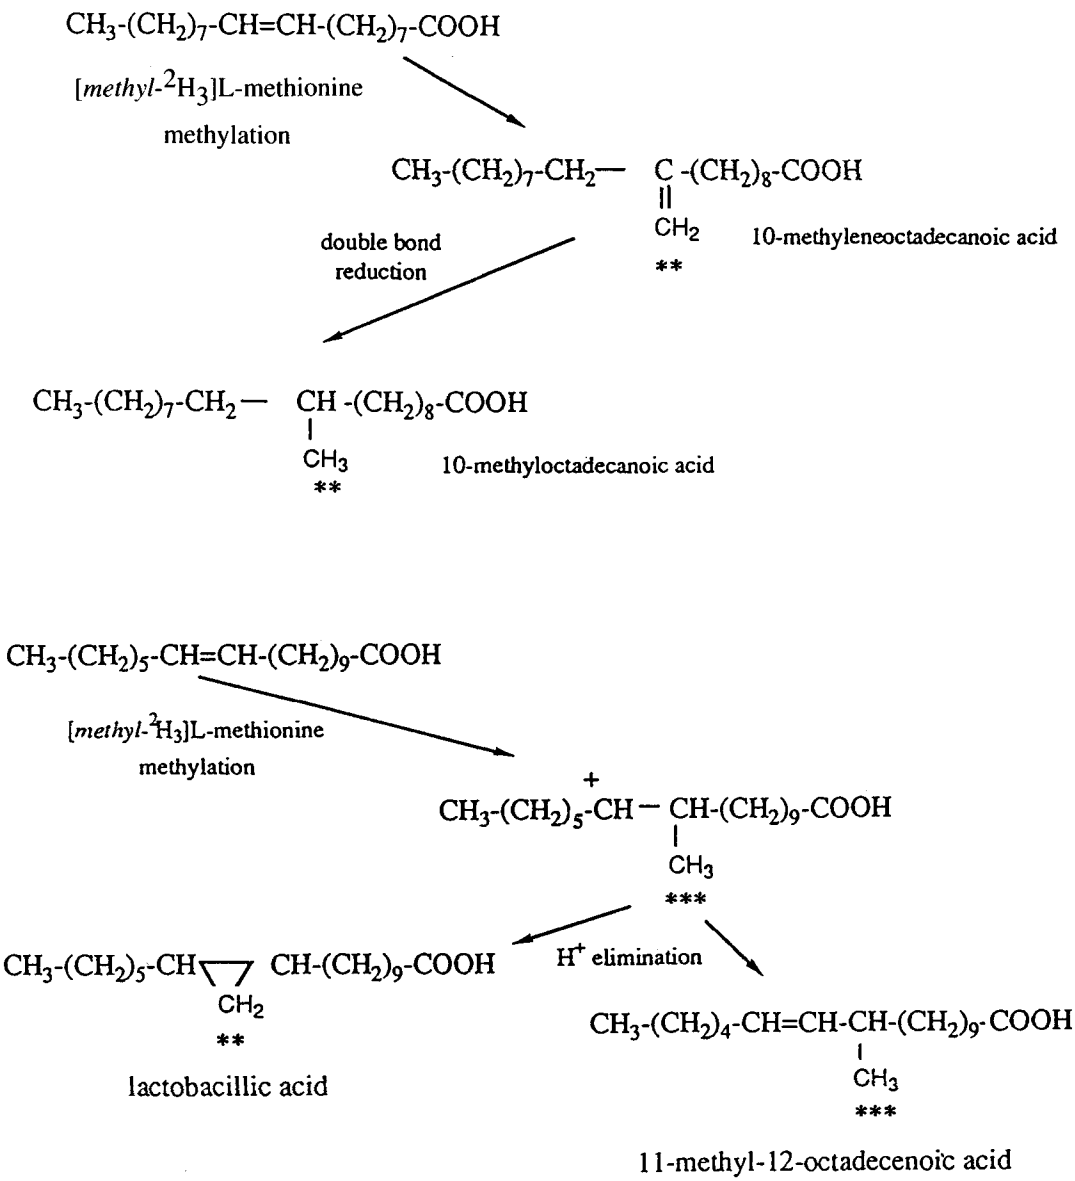
methionine-containing medium, confirming the three methylation processes already described. The two deuterium atoms in 10-methyleneoctadecanoic acid and in tuberculostearic acid confirm the methylation process of oleic acid ("CD_2 mechanism"). Three deuterium atoms in 11-methyl-12-octadecenoic acid and two deuterium atoms in lactobacillic acid ("CD_3 mechanism") suggest two different and independent methylation processes for vaccenic acid. These are summarized in Scheme 3 (where ** indicates two deuterium atoms in fatty acid coming from Mycobacterium grown on [*methyl*-$^2H_3$]L-methionine-containing medium; and *** indicates three deuterium atoms in fatty acid coming from Mycobacterium grown on [*methyl*-$^2H_3$]L-methionine-containing medium).

TABLE 2
Number of Deuterium Atoms in Deuterated Fatty Acids from *Mycobacterium fallax* (Collection of the Institut Pasteur 8139) Grown on [*methyl*-$^2H_3$]L-Methionine-Containing Medium[a]



Fatty acid	Mass of labeled carboxylate ion (amu)	Mass of nonlabeled carboxylate ion (amu)	Number of D atoms in labeled fatty acid
11, 12-*C*-Methylidene octadecanoic	297	295	2
11-Methyl-12-octadecenoic	298	295	3
10-Methyl octadecanoic	299	297	2
10-Methylene octadecanoic	297	295	2

[a]These fatty acids are implicated in C methylation processes of oleic and vaccenic acids by methionine.

To my knowledge, this is the first report of the co-existence of these three C methylation processes on oleic and vaccenic acids in Gram-positive bacteria (38,39).

"Phleic acids" in M. aurum *fatty acids mixture. Mycobacterium aurum* fatty acids were described earlier (40,41), and contain many methyl branched fatty acids. We also identified two polyunsaturated fatty acids [phleic acids (42)]. CAD/MIKE spectra of the ion of *m/z* 525 (36:5) (Fig. 4, spectrum A) shows five dips of three weak signals between ions of *m/z* 58 to 111, 111 to 165, 165 to 219, 219 to 273, and 273 to 327, indicating a Δ4,8,12,16,20 36:5 fatty acid. The CAD/MIKE spectrum of the ion of *m/z* 471 (Fig. 4, spectrum B) indicates a Δ4,8,12,16 32:4 fatty acid. These polyunsaturated acids were previously described in *M. phlei* (43) and *M. smegmatis* (44).

Accurate analysis of fatty acid complex mixtures can be achieved by MS/MS of their carboxylate derivatives. The analysis can be obtained on very small quantities, down to nanogram levels. The instrumentation is relatively accessible because double-focussing sector reverse-geometry mass spectrometers are now commonplace. The experiments also can be done by linked scanning on a forward-geometry instrument, but only with difficulty on triple-quadruple tandem mass spectrometers (27). This technique is, therefore, a valuable addition to the tools of studying fatty acid biosynthetic pathways, the chemical taxonomy of bacterial strains, and all other fatty acid structural determination.

Peroxisomes in Mice Fed a Diet Supplemented with Low Doses of Fish Oil

C. Van den Branden[a,*], D. De Craemer[a], M. Pauwels[a] and J. Vamecq[b]

ABSTRACT: The influence of low dietary doses (0.1 and 0.8% w/w) of a commercial fish oil preparation on peroxisomes in normal mice was studied and compared to the known strong inductive effects of high (10%) fish oil diets. Low fish oil doses were chosen to supply the mice with a concentration of docosahexaenoic acid, which was beneficial to patients with a peroxisomal disease. Peroxisomes were evaluated by cytochemical, morphometric, and enzymological techniques. The 0.1% fish oil diet had no effect on peroxisomes in liver, heart, and kidney even after prolonged treatment. The 0.8% diet did not change the peroxisomal number nor the catalase (EC 1.11.1.6) activity in the liver. Hepatic peroxisomal β-oxidation, however, was increased by 50% after 14 d. This was accompanied by reduced peroxisomal size. The 0.8% diet also caused a small increase (+25%) in myocardial catalase activity. No effect was observed in kidneys. Our results indicate that in mice a low (<0.8%) dietary fish oil dose has no or only a slight effect on hepatic peroxisomal β-oxidation. This may be of particular interest to patients with a peroxisomal fatty acid β-oxidation defect and who display a severe deficiency of docosahexaenoic acid—diets supplemented with low fish oil doses will improve the docosahexaenoic acid level without adding a strong load to the disturbed fatty acid metabolism.

Lipids 30, 701–705 (1995).

Peroxisomes are cell organelles with multiple functions (1). Their importance was revealed when Goldfischer *et al.* (2) reported their absence in the liver and the kidneys of patients with Zellweger's syndrome. A number of other diseases also could be related to the absence of peroxisomes or to a deficiency of one or more peroxisomal enzymes (3). Today there is no established therapy for these diseases. Therapeutic approaches range from dietary treatment to organ transplantation (4).

Recently it was found that patients with several peroxisomal disorders show depletion of docosahexaenoic acid (DHA) in brain, retina, liver, kidney, and erythrocytes (5,6). DHA ethyl ester has been added to the diet of two children diagnosed with neonatal adrenoleukodystrophy (NALD). In both patients, biochemical changes were observed (normalization of erythrocyte n-3 polyunsaturated fatty acids and increase in the 18:0 molecular species of plasmalogens); in one patient, a one-year administration resulted in significantly decreased 24:1n-9/22:0 and 26:1n-9/22:0 ratios and clear neurologic and electrophysiologic improvement (7,8). For this reason, Martinez *et al.* (8) suggested a dietary treatment with DHA ethyl ester to all patients with lowered blood levels of DHA. This suggestion was supported by Roels *et al.* (9).

In a study on the influence of a commercial fish oil preparation containing 20% DHA and 30% EPA (eicosapentaenoic acid) on peroxisomal enzymes and morphology, we concluded that a 10% (w/w) fish oil diet had a strong stimulatory effect on peroxisomal metabolism in mouse liver and myocardium (10,11). The final concentration of DHA present in this diet was 2% and corresponds to a daily intake of 3.5 g/kg body weight of the mice. This is high when compared to the daily oral dose of 250 mg DHA ethyl ester administered to the children with NALD (8). Two low doses of Bęromegan (a gift from FHER, Boehringer Ingelheim, Germany) were chosen in order to supply the mice with DHA concentrations comparable to those clinically tested. The aim of this study was to investigate the possible effects of these low doses of Beromegan on peroxisomes in liver, heart, and kidneys of healthy mice and to compare them to the findings previously obtained after treatment with a 10% fish oil diet (10,11).

MATERIALS AND METHODS

Adult male NMRI mice (35–40 g) were randomly assigned into groups of at least five animals. They were fed a standard laboratory meal (A04; UAR, Epinay, France) supplemented with 0.1% Beromegan for 3, 21, and 100 d or with 0.8% Beromegan for 3 and 14 d. Beromegan is a fish (salmon) oil extract mainly containing polyunsaturated fatty acids. The composition of the standard laboratory meal and of Beromegan is given in Table 1. The dietary doses were chosen to approximate the daily oral dose of 250 mg DHA ethyl ester administered in a clinical setting to the two children with NALD (8). We considered the body surface area as reference point to convert doses from human to mice (12), and calculated that a dose of 250 mg/d given to a child weighing a maximum 20 kg corresponds to a daily intake of 104 mg/kg body

weight in the mouse. The intake of DHA by the mice on a diet with 0.1 or 0.8% Beromegan was 35 mg/kg/d and 280 mg/kg/d, respectively, being ± one-third and three-fold, respectively, of the clinical dose. In comparison, the 10% Beromegan diet used in previous studies (10,11) corresponds to a daily uptake of 3500 mg DHA/kg body weight of the mice. The time control groups received the A04 meal only. All animals had free access to food and water.

Peroxisomal fatty acyl–CoA oxidase (EC 1.3.99.3) activity in liver (first- and rate-limiting step of the peroxisomal β-oxidation) was studied using the method of Vamecq (13), the cyanide-insensitive fatty acyl–CoA oxidation in liver (third step of the peroxisomal β-oxidation) was measured as described by Lazarow and de Duve (14), and catalase (EC 1.11.1.6) activity was assayed in homogenates of liver, heart, and kidney according to Baudhuin (15) and Van den Branden *et al.* (16).

Histological analysis (after diaminobenzidine staining for catalase) and morphometry of hepatic peroxisomes were performed as previously described (17). All results are given as the mean ± SEM. For statistical analysis, the Mann–Whitney test was used (18). Significance was obtained when $P < 0.05$.

RESULTS

The fish oil diet was well accepted by the mice. At the end of the experiment, body weight of Beromegan-treated animals was similar to the weight of control animals. No hepatomegaly was observed. Liver, heart, and kidney weights expressed as percentages of body weight were not changed. The time control groups showed no differences in peroxisomal β-oxidation capacity, catalase activity, or morphometric parameters and, therefore, were pooled into one control group.

The biochemical data, as well as enzymological data obtained in a previous experiment using a 10% fish oil diet are included in Table 2 to facilitate observation of dose- and time-related changes. Even a prolonged treatment of 100 d with 0.1% fish oil failed to induce peroxisomal β-oxidation. In animals fed a diet supplemented with 0.8% Beromegan for 14 d, peroxisomal β-oxidation was significantly increased (± ×1.5). Previous experiments revealed a four-to-fivefold increase of peroxisomal β-oxidation capacity in mice fed a diet supplemented with a high dose (10%) of Beromegan after only three days of treatment (Table 2) (10,11).

Hepatic catalase activity was not changed in mice fed the diets supplemented with 0.1 or 0.8% fish oil. Even after 100 d of 0.1% Beromegan administration, catalase activity was similar to values in control animals (Table 2). Renal catalase activity was also unchanged by the fish oil diets (results not shown). Myocardial catalase activity was significantly increased only in mice fed the 0.8% Beromegan diet—when compared to controls (1.26 ± 0.07 U_B/g), catalase activity was 1.60 ± 0.06 U_B/g and 1.55 ± 0.12 U_B/g after 3 and 14 d of treatment, respectively ($P < 0.05$).

Light microscopic study of diaminobenzidine-stained liver, heart, and kidney sections did not reveal differences in number, size, and staining intensity of the peroxisomes between control and Beromegan-fed animals. Apparently, the increase in myocardial catalase activity in animals fed the

0.8% Beromegan diet was too small to be noticed by visual evaluation of catalase stained myocardial sections.

Ultrastructural investigation of the liver sections of fish oil-fed mice failed to reveal differences in electron density of the peroxisomal matrix (catalase reaction product) in size or in number of peroxisomes when compared to control liver sections. Peroxisomal shape strongly varied in all control and treated mouse livers. Morphometric analysis (Table 3) demonstrated a decreased peroxisomal size in 0.8% fish oil-fed mice after 14 d. This was not observed in mice fed the 0.1% Beromegan diet, not even in the animals fed this diet for 100 d. No differences in volume density, numerical density, or surface density were found with either diet.

Myocardial peroxisomes contained a reticular matrix in both control and in fish oil-fed mice. The electron density of the peroxisomal matrix showed no differences between the experimental groups and the control animals. The organelles were strongly dispersed and sparse. By visual evaluation, size, shape, and number were unchanged.

DISCUSSION

We recently showed that a high fish oil diet containing 10% Beromegan induces a strong (up to eightfold) increase in peroxisomal β-oxidation capacity and a twofold increase in catalase activity and peroxisomal number in the liver (Table 2) (10). In the present study, we found a moderate (up to 1.7-fold) increase in peroxisomal β-oxidation capacity and a reduction of the peroxisomal size in the liver of mice fed a 0.8% fish oil diet, while a lower dose (0.1%) of fish oil did not influence the investigated peroxisomal parameters. These findings indicate that more and stronger peroxisomal changes are observed with increasing dietary fish oil concentrations. The duration of dietary treatment is also an important factor—the increase in peroxisomal β-oxidation capacity provoked by the 10% fish oil diet was already evident after three days (10,11), the 0.8% fish oil diet induced only a moderate increase after 14 d, and the 0.1% fish oil diet failed to affect peroxisomal β-oxidation after up to 100 d of treatment.

To our knowledge, papers reporting on peroxisomal characteristics in animals fed a diet supplemented with concentrations of fish oil as low as in our present experiments are not available. A significant increase in the activities of catalase and peroxisomal fatty acyl–CoA oxidase was found in the liver of rats fed diets with different n-3/n-6 fatty acid ratios (ranging between 0.12 and 10) (19). However, the total amount of fatty acids in each diet was 10% (w/w) (19,20), and this is considerably higher than in the present experiments. In our experiments, the animals fed the 0.8% fish oil diet had a daily intake of 280 mg DHA/kg body weight and 420 mg EPA/kg body weight; the daily ingestion of all polyunsaturated fatty acids amounted to ±800 mg/kg body weight. Demoz *et al.* (21) demonstrated an increase of hepatic peroxisomal acyl–CoA oxidase and catalase activities of 50 and 30%, respectively, after daily administration of 1000 mg ethyl–EPA/kg body weight to mice for 10 d. In rats, the same daily intake of ethyl–EPA for three months had a similar effect on both peroxisomal enzymes (22). Ethyl-DHA, administered in a daily dose of 1000 mg/kg body weight for three months to rats, induced the fatty acyl–CoA oxidase and catalase activities in the liver (+64 and +18%, respectively) (22). In addition, peroxisomal β-oxidation and fatty acyl–CoA oxidase activity were significantly increased in the peroxisome-enriched fraction of the liver of rats on a daily intake of 1000 mg ethyl–EPA or ethyl–DHA/kg body weight for 10 d (23). In our experiments, the lower dose of n-3 polyunsaturated fatty acids in the 0.8% fish oil diet, as well as the use of mice instead of rats as experimental animals, may account for the slightly weaker induction of the peroxisomal β-oxidation capacity and the normal catalase activity (Table 2) when compared to the findings of Demoz *et al.* (21,22) and Willumsen *et al.* (23). In this respect, we assume that the increased production of H_2O_2 by peroxisomal fatty acyl–CoA breakdown in response to the 0.8% Beromegan diet is not sufficiently high to require an increased activity of catalase in order to avoid cell damage.

It is often noticed that a strong induction of the peroxisomal β-oxidation capacity is not accompanied by as strong an increase in catalase activity. In fact, it represents a constant finding in male rodents after treatment with one of the so-called peroxisome proliferators (24). From our present and previous experiments, we calculated the ratio of induction of peroxisomal β-oxidation to catalase (Table 4). The imbalance between the induction of a peroxisomal H_2O_2-generating metabolic pathway (fatty acid β-oxidation) and catalase, the most important H_2O_2-metabolizing peroxisomal enzyme, created by a dietary treatment of 10% fish oil, mimics the effect of a peroxisome proliferator. The resulting increase in peroxisomal H_2O_2-pool may be detrimental to cellular function and DNA, and is believed to be the underlying mechanism of the

[a]Statistically significant.

induction of hepatic neoplasia in rodents treated with peroxisome proliferators (25,26). However, the effective concentration of any peroxisome proliferator to obtain this metabolic imbalance is far below the fish oil dose needed. In addition, peroxisome proliferators also induce specific changes in peroxisomal morphology in the liver of susceptible animals (male rodents)—an increase in size and number, sometimes resulting in a 20-fold increase of total peroxisomal volume (27). In contrast, the 10% Beromegan diet induced a doubling of the peroxisomal volume density and did not change the mean size of the organelles (10). These differences in effective dose and peroxisomal effects may be a result of different influences on other enzyme activities. A stimulation of peroxisomal metabolism in the liver in conditions other than a treatment with peroxisome proliferators is often accompanied by an increase in number and a reduction in size of the peroxisomes (10). In the liver of mice fed the 0.8% Beromegan diet, a significant reduction in size was found when the numerical density was [not significantly ($P = 0.16$)] increased with 27%. In addition, the lowest tested dose did not provoke peroxisomal fatty acid oxidation alterations or changes in peroxisomal size and number.

No changes in catalase activity or in intensity of the catalase staining of the peroxisomes were observed in the kidney with either diet. This is in line with the findings previously made in mice fed a 10% fish oil diet (10,11).

Catalase activity was not changed in mice myocardium on the 0.1% fish oil diet; it was slightly but significantly increased in mice fed the 0.8% fish oil diet, and this after three days. Catalase activity was more pronounced in mice fed a 10% fish oil diet (10). This indicates that myocardial response is dose-dependent. Increased catalase activity may point to an increased production of H_2O_2. Diets supplemented with partially hydrogenated marine oils or with soybean oils provoked an increase in catalase activity, together with an increase in the H_2O_2-generating peroxisomal fatty acid β-oxidation (28). Myocardial and hepatic response to Beromegan are different with respect to catalase induction. The effect of drugs and dietary fatty acids on peroxisomal metabolism in myocardium can be very different from what is found in liver (29,30).

Our results indicate that a dietary supplementation of low doses of DHA and EPA has little effect on the hepatic peroxisomal compartment in healthy mice. Only the 0.8% Beromegan diet induces an adaptation of the peroxisomal morphology, permitting a more efficient metabolism, as is reflected in a significant increase in β-oxidation activity. A 50% increase of peroxisomal β-oxidation can be considered as only a minor change when compared to the effects of the high-fat diets (10) or peroxisome proliferators (24). Though we cannot extrapolate mouse results to peroxisomal patients, we would like to make the following reflection—patients with Zellweger's syndrome, pseudo-Zellweger's syndrome, and typical or atypical NALD suffer from a defective peroxisomal fatty acid β-oxidation (4) and reveal a severe deficiency of DHA (6,8). The administration of low doses of fish oil [comparable with the 0.1% (w/w) dose we tested] most probably will not cause an additional load to the already disturbed hepatic peroxisomal fatty acid β-oxidation metabolism in these patients; on the other hand, recent evidence (8) has shown that peroxisomal patients will benefit from the supply of DHA to correct for the DHA deficiency in brain, retina, and in several other organs. Efforts to induce peroxisomes in patients with Zellweger's syndrome were not successful (31). DHA treatment is especially recommended for patients with a peroxisomal biogenesis defect (8,9). The fact that the DHA doses which give clinical improvement are low enough not to be a burden for β-oxidation can be considered an advantage.

Enteral Feeding a Structured Lipid Emulsion Containing Fish Oil Prevents the Fatty Liver of Sepsis

Susan Lanza-Jacoby*, Hope Phetteplace and Robert Tripp

Department of Surgery, Jefferson Medical College, Philadelphia, Pennsylvania 19107

ABSTRACT: Fish oils (FO) have been shown to reduce plasma triglycerides (TG). In this study we evaluated whether enteral feeding with a structured lipid emulsion (SLE) containing FO and medium-chain triglycerides (MCT) would prevent the hypertriglyceridemia and fatty infiltration of the liver that develops during sepsis. For five days, male Lewis rats (275–300 g) were fed intragastrically a nutritionally complete diet containing a SLE or a similar diet with a soybean oil emulsion (SOE) in place of the SLE. On the fifth day, sepsis was induced by intravenously injecting 8×10^7 live *Escherichia coli* colonies/100 g b.w.; 24 h later the control SLE, septic SLE, control SOE, and septic SOE rats were sacrificed. Diet, but not treatment, had a significant effect on serum TG and free fatty acids (FFA). Feeding the SLE reduced the plasma FFA of the control and septic rats by more than 50% in comparison to both control and septic rats fed the SOE. Soleus muscle activity of lipoprotein lipase from the septic SLE rats was 44% higher than the control SLE rats. Soleus muscle from the septic SLE rats also had a twofold greater activity of lipoprotein lipase than the septic SOE rats. TG did not accumulate in the livers of the septic rats fed SLE when compared to the control SLE rats and the rats fed the SOE. Livers from the septic rats fed the SLE had a third of the TG that were present in the livers from the septic rats fed the SOE. The rate of incorporation of [^{14}C]oleate into liver lipids was significantly lower in septic rats fed SLE than in those fed the SOE. TG esterification was 70% lower in the septic rats fed SLE rather than the SOE. Our findings suggest that the SLE with FO and MCT has a role in the prevention of the sepsis-associated fatty liver by reducing the biosynthesis of liver TG.

Lipids 30, 707-712 (1995).

Gram-negative sepsis produces liver injury and dysfunction, which results in alterations in lipid metabolism, leading to the accumulation of liver lipids. Maintaining normal liver function is essential in preventing liver failure and improving survival rates (1,2). Fatty infiltration of the liver developed in both fasted and fed septic rats and was associated with an increase in lipid synthesis (3,4). Lipids accumulated in freshly isolated hepatocytes from septic rats because the synthesis of *de novo* fatty acids and the synthesis of triglycerides (TG) were increased, while secretion rates remain unaltered (5). Earlier studies with *Diplococcus pneumoniae* infection in rabbits (6) and *Streptococcus pneumoniae* infection in rats (7) have also noted that the synthesis of liver lipids was increased.

Numerous studies have shown that fish oils (FO) (ω3 fatty acids) have hypolipidemic effects in normolipidemic subjects (8,9) and in patients with hyperlipidemia (10). The primary lipid-lowering effect of FOs has been attributed to a reduction in TG production by the liver (11–14), which may result from an inhibition of *de novo* fatty acid synthesis (11,15,16), an increase in hepatic fatty acid oxidation (17), a reduction in adipose tissue lipolysis (18), and/or a subsequent decrease in TG synthesis (19,20). There is also the possibility that FOs may contribute to the TG-lowering effect by increasing the removal of circulating TG by stimulating lipoprotein lipase (LPL) activity (21,22).

In a previous study, we reported that septic rats who were adapted to an FO diet for two weeks prior to inducing sepsis and then fasted overnight did not develop fatty liver compared with septic rats adapted to a corn oil diet (23). Total parenteral nutrition with a 10% lipid emulsion with FOs rather than with safflower oil has been shown to improve survival in septic guinea pigs (24). These findings suggested that FOs may have a role in ameliorating the disturbances in lipid metabolism associated with gram-negative sepsis. Lipid emulsions of soybean or safflower oil, which contain long-chain fatty acids (LCFA) of the n-6 series, are routinely used in parenteral and enteral nutritional formulas as part of the treatment for septic and critically ill patients. However, the use of these conventional lipid emulsions with LCFA has been associated with increased prostaglandin production, acute respiratory distress syndrome, reticuloendothelial system blockade, and hepatic steatosis (25). For these reasons, the conventional lipid emulsions may not be appropriate for the septic or hypermetabolic patient.

Lipid emulsions containing both LCFA and medium-chain fatty acids (MCFA) were developed to provide the essential fatty acid requirement and a source of immediate energy. Medium-chain triglycerides (MCT) offer an advantage in that they are cleared and oxidized rapidly. Developing structured lipids provided another advantage of the ability to design TG with mixtures of fatty acids suitable for a specific metabolic

need. Recently Teo *et al.* (26) showed that a structured lipid emulsion (SLE) with FO and MCT was more effective than safflower oil emulsion in reducing protein catabolism associated with burn injury in rats. These investigators also have demonstrated that this SLE abated the development of lactic acidosis in endotoxin-treated guinea pigs (27). Accordingly, this study was designed to evaluate whether feeding SLE containing FO and MCT during the septic episode would alter the development of hypertriglyceridemia and fatty liver. To understand the mechanism for the diet effect, the isolated perfused liver was used to evaluate the production and secretion of TG, and the activity of LPL was measured in adipose tissue and soleus muscle to assess the role of these tissues in the removal of TG.

METHODS

Animals. Male Lewis rats (Harlen Sprague-Dawley, Walkerville, MD) weighing between 275–300 g were used in all experiments. The rats were housed in temperature and humidity controlled rooms on a 12 h light–dark (0600–1800 h) schedule. All the rats were allowed free access to a standard rat diet (Purina Rat Chow #5000; Ralston-Purina, St. Louis, MO) for one week prior to the start of the experiment.

Experimental protocol. Two groups of rats were prepared for surgical placement of the intragastric catheter as described in our previous papers (4,5). Rats were infused with 0.09% NaCl at a rate of 0.5 mL/h and allowed free access to the rat diet for the first 24 h after surgical placement of the catheter. On the second day, one group of rats was infused with a liquid diet (Table 1) consisting of a soybean oil emulsion (SOE) (Intralipid; Baxter, Deerfield, IL), and a second group of rats was infused with the same diet, except that the SOE was replaced with an SLE containing 50% MCT, 40% menhaden oil, and 10% canola oil. These diets were as described previously and provided 21% of the calories as fat (4). On the fifth day of feeding, half the rats in each group were made septic by intravenously injecting 8×10^7 live *Escherichia coli*/100 g body weight. Control rats were injected with 0.09% NaCl. Twenty-four hours later the rats were anesthetized by administering ketamine HCl containing acepromazine (Ketaset; Bristal Laboratories, Syracuse, NY) at a dose of 100 mg/kg body weight. Blood, soleus muscle, and adipose tissue were retained for analysis of serum TG, cholesterol (CH), free fatty acids (FFA), liver TG, total CH, and total phospholipids, and activities of LPL in the soleus muscle and epididymal fat pads, as described in a previous report (4). A 120-min isolated *in situ* recirculating liver perfusion was performed on five to six rats in each group (SOE control, SOE septic, SLE control, and SLE septic). The perfusate was collected at 60 and 120 min and analyzed for incorporation of [1-^{14}C]oleic acid into TG, total CH, and total phospholipids. At the end of the 120 min, livers were removed for measuring the incorporation of [1-^{14}C]oleic acid into liver TG, total CH, and total phospholipids. Livers were then frozen at −80°C for subsequent measurement of TG, CH, and phospholipid phosphorus.

TABLE 1
Composition of Liquid Diets

Nutrient	Soybean oil (per L)	Fish oil/MCT structured lipid (per L)
Amino acids (g)	27.2	27.2
50% Dextrose (g)	250	250
Soybean oil emulsion (mL) (Intralipid)[a]	130	—
Structured lipid (mL) Fish oil/MCT	—	130
Electrolytes[b] (g)	11.6	11.6
Trace elements[c] (mg)	12.74	12.74
Vitamins, M.V. 1–12 (mL)	3.0	3.0

[a]Intralipid from Baxter (Deerfield, IL). MCT, medium-chain triglyceride.
[b]Electrolytes in g/L: 5.2 sodium chloride, 1.9 potassium acetate, 1.1 potassium phosphate, 2.2 calcium gluconate, and 1.2 magnesium sulfate.
[c]Trace elements in mg/L: 9.24 zinc chloride, 2.32 cupric chloride, 7.75 manganese sulfate, and 0.1 chromic chloride; M.V., multi-vitamin infusion.

Liver perfusion. The isolated *in situ* liver perfusion was performed according to the method of Exton (28), which we described in a previous paper (29). The perfusate volume of ≈150 mL of Krebs-Ringers bicarbonate buffer (pH 7.4) containing 0.1% glucose (Sigma, St. Louis, MO), 2% (vol/vol) minimum essential medium amino acid solution (50×) without glutamine (Gibco, Grand Island, NY), 1% (vol/vol) of 200 mM L-glutamine (100×) (Gibco), 3% bovine serum albumin (Sigma), and 30% hematocrit using fresh human erythrocytes was passed through a silastic tube and reoxygenated with 95:5 oxygen/carbon dioxide (30).

The liver was washed by perfusing for 20 min at a rate of 11 mL/min with 100 mL of perfusate before the label was added. This perfusate was removed, and the liver was perfused for 120 min with fresh medium containing 20 μCi of 1-^{14}C]oleic acid (50 mCi/mmol) complexed with albumin (fatty acid/albumin ratio, 9:9); the initial concentration was 0.4 mmol. During the initial perfusion and after the first and second hour of perfusion, bile flow and the concentrations of lactate and pyruvate (Sigma kits No. 826 UV and No. 726 UV) were measured. The lactate/pyruvate ratio was used as an estimate of liver viability (31). At the end of the perfusion, the livers were perfused with cold (4°C) 0.9% NaCl for 3 min; perfusate and liver tissue were extracted with chloroform/methanol (2:1, vol/vol) (32) for analysis of lipids and radioactivity. Separation of lipid by thin-layer chromatography and measurement of the incorporation was described previously (4).

Analysis of tissue LPL activities. Total LPL activity in epididymal fat was measured in deoxycholate extracts. Soleus muscle was prepared for analysis of LPL activity by homogenizing in NH_3–HCl (pH 8.1) using a Polytron (Brinkman Instruments, Westbury, NY) with a PT probe at maximum speed for 2 min at 0°C. The extracts were diluted 1:7 in detergent-free buffer, and 150 μL was mixed with 150 μL of glycerol-stabilized triolein substrate emulsion as described by Nilsson-Ehle and Schotz (33). The extracts were then incubated for

2 h at 37°C. Activity is expressed as μmoles FFA/gram wet weight/hour.

Statistical analysis. The data were evaluated by two-way analysis of variance with testing of the interaction of diet and *E. coli* treatment, then testing of hypothesis of diet and treatment as main effects. Specific comparison of group means was made when F values were significant for diet or treatment using the Bonferroni correction for the *t*-test. Analysis was conducted using Systat (Systat Inc., Evanston, IL).

RESULTS

Effect of SLE on serum lipids. The diet had a significant effect on serum TG and FFA (Fig. 1). Serum TG and FFA concentrations were reduced significantly in rats fed the SLE as compared to rats fed the SOE. The serum FFA of the rats fed the SLE were 50% lower than that of the rats receiving the SOE. There was no significant *E. coli* treatment effect with serum TG, CH, or FFA. The significance of F values was as follows: for TG: diet effect, $P \leq 0.05$; treatment effect, nonsignificant; diet × treatment, nonsignificant; for FFA: diet effect, $P \leq 0.000$; treatment effect, nonsignificant; diet × treatment, nonsignificant; for CH: diet effect, nonsignificant; treatment effect, nonsignificant; diet × treatment, nonsignificant.

Effect of SLE on LPL activities. To evaluate the ability of fat tissue and skeletal muscle to utilize TG, the activities of LPL were measured in the epididymal fat pads and soleus muscle. Sepsis had a significant effect on LPL activities in the epididymal fat, but the diet had no effect (Fig. 2). There was a significant diet and *E. coli* treatment effect on LPL activity in the soleus muscle. The decrease in LPL activities in the adipose tissue was evident in the septic rats fed the SOE or the SLE. Feeding the SLE rather than the SOE increased LPL activities significantly (threefold) in the soleus muscle from the septic rats (septic-SLE = 64.1 ± 7.5 μmoles FFA/g; septic-SOE = 20.1 ± 1.6 μmoles FFA/g), and by 49% in the soleus muscle from the control rats (control-SLE = 43.8 ± 4.6. μmoles FFA/g; control-SOE = 29.3 ± 2.3 μmoles FFA/g). LPL activity was depressed in septic rats fed the SOE in comparison to the control rats fed the SOE. In contrast, the SLE led to a 46% elevation of LPL activity in soleus muscle of the septic compared to the control rats. The significance of F values was as follows: for the epididymal fat pad: diet effect, nonsignificant; treatment effect, $P \leq 0.001$, diet × treatment, nonsignificant; for soleus muscle: diet effect, $P \leq 0.05$; treatment effect, ≤ 0.001; diet × treatment, nonsignificant.

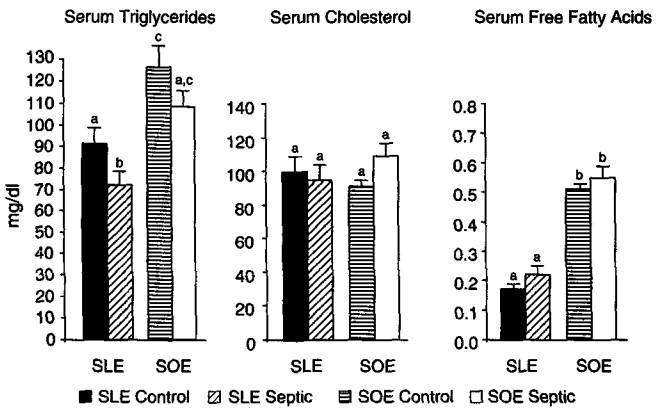

FIG. 1. Concentration of serum triglycerides, cholesterol, and free fatty acids in control and in septic rats fed a structured lipid emulsion (SLE) or a soybean oil emulsion (SOE). Bars represent ± SEM for six rats per group. Values having different superscripts (a,b,c) are significantly different $P \leq 0.05$ by 2 × 2 analysis of variance and Bonferroni correction of *t*-test.

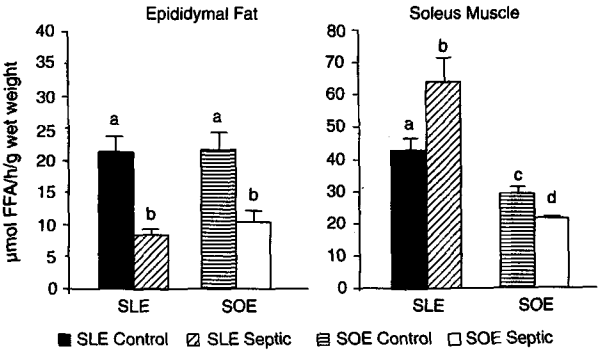

FIG. 2. Lipoprotein lipase activity in the epididymal fat pad and soleus muscle of control and septic rats fed diets containing an SLE or SOE; FFA, free fatty acids. See legend to Figure 1 for details and other abbreviations.

Effect of SLE on the sepsis-induced fatty infiltration of the liver. Table 2 presents the values for the concentrations of TG, total CH, and total phospholipid in the post-perfused livers. Feeding the SLE reduced the TG and total phospholipid contents significantly in livers from both control and septic rats. The livers from the septic rats fed the SOE retained 82% more TG than the livers of the SOE control rats. Feeding the SLE rather the SOE to the septic rats produced a 70% decrease in the content of liver TG.

Effect of SLE on TG production and secretion. The incorporation of [1-^{14}C]oleic acid into liver TG, total CH, and total phospholipids is illustrated in Figure 3. There was a significant diet effect for TG, CH, and total phospholipids. In addi-

TABLE 2

Diet × treatment effect	0.000	NS	NS

[a]Values are means ± SEM of 5–6 rats per group. SLE, structured lipid emulsion; C, control; S, septic; SOE, soybean oil emulsion.
[b–d]Different superscripts are significantly different from each other by 2 × 2 analysis of variance and Bonferroni correction of *t*-test. NS, nonsignificant.

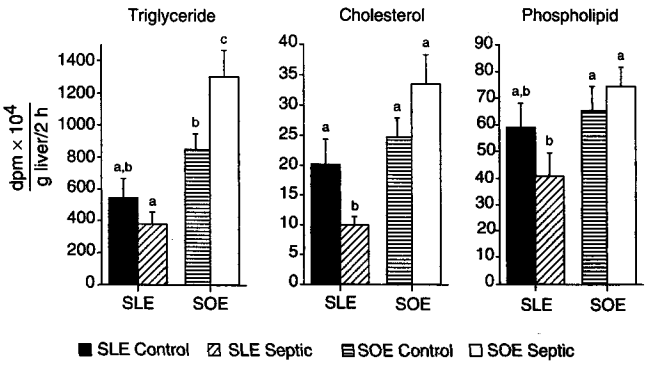

FIG. 3. Rates of incorporation of [1-^{14}C]oleic acid into liver triglycerides, cholesterol, and phospholipids. Livers from control and septic rats fed intragastrically liquid diets with an SLE containing menhaden oil, medium-chain triglycerides, and canola oil or an SOE were perfused as described in the Methods section. See Figure 1 for details and abbreviations.

tion to the reduction in liver TG, TG esterification was also reduced by 71% when septic rats were fed the SLE rather than the SOE. Comparing the control and septic rats fed the SLE, septic rats exhibited a trend toward lower TG and phospholipid esterification, whereas there was a significant reduction in total CH esterification in the livers from the septic rats. Septic rats fed the SOE had a 53% higher rate of TG esterification than that found in the livers from the SOE control rats. The significance of F values was as follows: for TG: diet effect, $P \leq 0.005$; treatment effect, nonsignificant; diet × treatment, nonsignificant; for CH: diet effect, $P \leq 0.000$; treatment effect, nonsignificant; diet × treatment, nonsignificant; for phospholipid: diet effect, $P \leq 0.05$; treatment effect, nonsignificant; diet × treatment, nonsignificant.

The secretion of newly esterified ^{14}C-labeled TG, total CH, and total phospholipids are shown in Figure 4. There was no significant diet or *E. coli* treatment effect for TG or for CH. Total phospholipid secretion was less for the rats fed the SLE rather than for those fed the SOE. The significance of the F values was as follows: for TG: diet effect, nonsignificant; treatment effect, nonsignificant; diet × treatment, nonsignificant; for CH: diet effect, nonsignificant; treatment effect, nonsignificant; diet × treatment, nonsignificant; for phospholipid: diet effect, $P \leq 0.05$; treatment effect, nonsignificant; diet × treatment, nonsignificant.

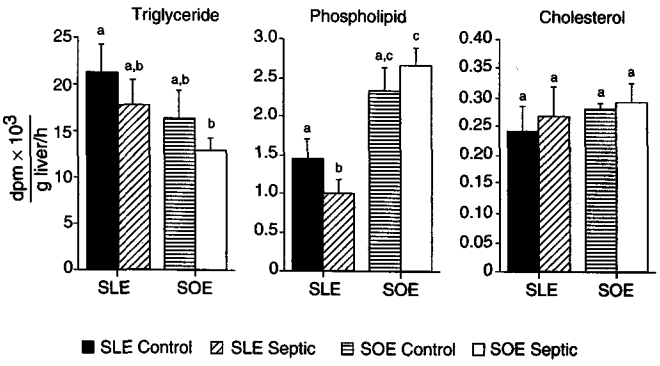

FIG. 4. Rates of incorporation of [1-^{14}C]oleic acid into perfusate triglycerides, cholesterol, and phospholipids. Livers from control and septic rats fed liquid diets with an SLE containing menhaden oil, medium-chain triglycerides, and canola oil or an SOE were perfused as described in the Methods section. See Figure 1 for details and abbreviations.

DISCUSSION

In this study we have shown that an enteral diet containing an SLE with FO and MCT will prevent the development of fatty liver that occurs with sepsis. Lipids accumulate in the liver when there is a disturbance in the balance between synthesis and secretion. Feeding this SLE to the septic rats was associated with a reduction in the synthesis of TG, CH, and phospholipid. Secretion rates were not significantly altered by the diet. The prevention of fatty liver observed with the SLE appears to be due to the decrease in TG synthesis, as the liver content of TG and the incorporation of ^{14}C oleate into TG were both decreased to a similar extent when the septic rats were fed the SLE rather than the SOE. Suppression of TG synthesis and secretion by FOs has been demonstrated in perfused rat livers (11,19,20), cultured rat hepatocytes (13,14), and in HepG2 cells (34). These reports have indicated that the primary mechanism for reduced TG secretion is due to a decrease in TG synthesis. Yet, a recent report by Lang and Davis (35) suggested that decreased secretion may be the primary factor, as they found that TG synthesis was increased in cultured hepatocytes while secretion of TG and apoprotein B were impaired. Otto *et al.* (36) proposed that TG accumulate in the liver when FOs are fed with high-fat diets (30% of calories), but not with lower fat diets (12 and 21% of calories). The *in vitro* experiments conducted by Lang and Davis (35) contained a high concentration of eicosapentaenoic acid or docosahexaenoic acid (1 mM fatty acid). Other reports of *in vivo* studies have also shown that TG was not altered (37) or reduced (11,14,16,36,38) when low- or medium-fat FO diets were fed. In contrast, when high-fat FO diets were fed to rats (39,40), the reduction in plasma lipids was accompanied by a retention in liver TG. The diet used in this study contributed 21% of the calories as fat, which may explain why TG were not retained in the liver. The capacity of the liver to secrete TG may be saturated when there is an excessive supply of exogenous FFA, whereas with low-fat or medium-fat diets, the rate of TG synthesis is the limiting factor for secretion.

The SLE also contained MCT, which are preferentially oxidized rather than esterified into lipids, and are not retained by the liver. There is question as to whether the lipid-lowering effects observed with the SLE are due to the presence of menhaden oil or to MCT. However, one study has shown that lipids accumulated in the livers of septic rats fed either a lipid emulsion with long-chain triglycerides (LCT) or a mixture of LCT and MCT (41). These findings suggest that MCT may not have a role in the prevention of fatty liver observed with the septic rats fed the SLE.

A reduction in availability of FFA in the livers of the SLE-fed rats also may explain the decrease in TG synthesis and, subsequently, the prevention of fatty liver. Serum FFA concentrations were lower in the rats fed the SLE than in the rats fed the SOE, which would lead to a reduced influx of FFA into the liver. Feeding FOs has been shown to reduce blood concentrations of FFA in humans (42), and in rats fed either low- or high-fat diets (14,22). The mechanism for the FO-lowering effect on blood FFA is not fully understood. Parrish *et al.* (18) and Rustan *et al.* (43) have shown that basal lipolysis was lower in epididymal fat from FO-fed rats than in lard-fed rats. Increased activity of LPL in soleus muscle from rats fed the SLE suggests that more fatty acids could be removed from the circulation. An increase in the oxidation of fatty acids by the liver also may reduce fatty acid availability for TG biosynthesis. Studies have shown that mitochondrial and peroxisomal fatty acid oxidation is stimulated in FO-supplemented rats (17,37). The decrease in *de novo* lipogenesis, as was observed by Wong *et al.* (11) and Topping *et al.* (16), also may contribute to the reduced availability of fatty acids for TG biosynthesis.

The hypotriglyceridemic effect of FOs has been demonstrated in animals fed a solid diet (11,14,16,36–40). We also observed a reduction in serum TG with the rats fed the SLE vs. SOE, which may be the result of the higher soleus muscle LPL activity in the rats fed the SLE. Previously we showed that feeding septic rats with the SOE abolished the hypertriglyceridemia of fasted septic rats (4). Our present findings indicate that an SLE with FO and MCT produces similar effects.

Other investigators have shown that skeletal muscle LPL activity was stimulated by feeding FO at 22 and 30% of the calories (21,22), and with prefeeding 10% FO by weight of diet (21% of the calories) then fasting (23). These findings are consistent with our observed increase in the soleus muscle LPL activity in control and in septic rats fed the SLE. The MCFA in the SLE also may influence the clearance of TG. *In vitro* lipid emulsions with MCT are hydrolyzed faster by rat diaphragm LPL than are lipid emulsions with LCFA (44). Yet, *in vitro*, LPL hydrolyzed SLE with MCFA and LCFA slower than physical mixtures of MCT and LCT. The activity of adipose LPL was not altered by feeding the SLE, which was similar to those previously reported (21,36,40).

In this study, we have shown that feeding during the septic episode with SLE containing FO and MCT will prevent the development of fatty liver that occurs when septic rats are fed an SOE. One mechanism for this effect appears to be associated with a reduction in esterification of fatty acids, which could be attributed to a decreased supply of fatty acids presented to the liver. The reduction in serum fatty acids may be related to the increase in skeletal muscle LPL activity. The mechanism for the diet effect on liver and skeletal muscle requires further study. These findings point out that structured lipids with FO and MCT may have an important role in the nutritional support of the septic host.

ACKNOWLEDGMENTS

The authors wish to thank Drs. Vigen K. Babayan and George L. Blackburn for their gift of the structured lipid emulsions. This study was supported by Grant No. GM31828 to S.L.J. from the National Institute of General Medical Sciences

Effect of Tumor Necrosis Factor-α on Triglyceride and Phospholipid Content and Fatty Acid Composition of Liver and Carcass in Rats

Nilima Raina, Junichi Matsui, Stephen C. Cunnane and Khursheed N. Jeejeebhoy*

Departments of Medicine and Nutritional Sciences, University of Toronto, Toronto, Ontario M5S 1A8, Canada

ABSTRACT: We have previously shown that a continuous infusion of tumor necrosis factor-α (TNF-α) in rats results in an increase in plasma triglyceride (TG), liver protein and DNA, and at the same time a reduction in muscle protein. However, there is no information on the associated effects of TNF-α on liver and muscle lipids. The present study, therefore, determined the effect of TNF-α on the TG and phospholipid (PL) content and their fatty acid composition, in the liver and carcass of rats and correlated with the plasma levels of insulin, corticosterone, and catecholamaines. Total parenteral nutrition that met the daily nutrient requirements was continuously infused for 10 d through a central vein catheter in two groups of rats, one receiving infused TNF-α (100 μg/kg/d) and a control group. Hepatic TG and PL, expressed either as mg/g dry weight or total organ content, were significantly increased in the TNF-α-infused group compared with controls. Livers of TNF-α infused rats contained significantly less saturated and monounsaturated fatty acids and significantly more polyunsaturated fatty acids (PUFA) of the ω3 and ω6 series than controls. The carcass, on the other hand, contained significantly more monounsaturated and significantly less polyunsaturated fatty acids of the ω6 series than controls. There were no changes in corticosterone level. Although plasma glucose levels were comparable between control and TNF-α infused rats, the latter had a marked increase in insulin levels, demonstrating insulin resistance. In addition TNF-α infused rats had raised norepinephrine levels. The fall in carcass and rise in liver TG and PL are consistent with the presence of insulin resistance and raised norepinephrine levels. However, the increase in PUFA content of the liver, especially the increase in 20:4ω6 levels in liver PL and TG, is likely to be the effect of TNF-α and suggests increased activity of Δ5-desaturase.

Lipids 30, 713–718 (1995).

Sepsis is associated with hypertriglyceridemia (1), which could be primarily due to either an increase in hepatic lipid synthesis (2) or a decrease in lipoprotein lipase (3,4). The disturbance of the host lipid metabolism is thought to be mediated by cytokines (5). The cytokine, tumor necrosis factor-α (TNF-α), is derived from macrophages and has been implicated in the pathogenesis of cachexia as well as derangement of host lipid metabolism (6). A previous study (7) from our laboratory showed that total parenteral nutrition (TPN), providing 14% of total energy by long-chain triglycerides (LCT) as Intralipid 20% (Pharmacia Inc., Mississauga, Ontario, Canada), increased visceral (including liver) protein and DNA content together with wasting of the carcass, despite the same weight gain in control and TNF-α-treated animals. These findings suggested a preferential accumulation of visceral protein at the expense of carcass protein. Raised serum triglyceride (TG) levels in TNF-α-infused rats were also observed by us (7) and others (8–10). However, the effect of TNF-α on the lipid content of carcass and liver in rats receiving TPN has not been reported previously. In addition, these changes have not been related to concomitant changes in hormones which could, in turn, influence lipid metabolism.

We used our previously described rat model (11) to investigate the effect of continuous TNF-α infusion on the total lipids and fatty acid content of both carcass and liver. Two group of rats, TNF-α-infused and controls, were given the same amount of nutrients by TPN and the TG and phospholipid (PL) content of carcass and liver (expressed as mg/g dry weight and total organ content), and their fatty acid composition in carcass and liver (expressed as wt% of total) was determined.

MATERIALS AND METHODS

Animals and treatments. Fourteen male Wistar rats weighing 200–220 g were divided into two groups and housed in individual cages. The animals were kept at an environmental temperature of 22°C in a 12-h light/dark controlled room. They were fed Purina rodent chow (5001) *ad libitum* for a week. Under general anesthesia (sodium pentobarbital: 50 mg/kg i.p.), a silicone catheter was advanced through the internal jugular vein and positioned in the superior vena cava. The catheter was tunneled through the back of the rat and was encircled by a protective wire spring secured to the rat by a stainless-steel button (Insect Labs, Horsham, PA), as described previously (12,13). The rats were individually housed for 6 d post-operatively and given food and water *ad libitum.* Pre-infusion procedure included the keeping of 60-cm long

catheters patent, by injecting 0.25 mL of heparinized saline (heparin sodium, 10 U/mL) daily at 11:30 a.m. No heparin was given during the actual infusion study. (This protocol was approved by the University of Toronto Animal Care Policies and Guidelines.)

Recombinant human TNF-α, with an endotoxin content of <25 ng lipopolysaccharide/mg TNF-α, was used. The TNF-α was diluted according to the manufacturer's instructions and was stored in 2-mL aliquots, each containing 25 μg of TNF-α, and was kept frozen at −70°C until used. Each aliquot was thawed just before use and was infused intravenously over 24 h in a rat.

The composition of the TPN solution is shown in Table 1. The nutrients met the recommended requirements for rats, and the infused volume was adjusted to 60 mL/d per rat. The amino acid mixture used was Travasol (Baxter, Mississauga, Ontario, Canada). The infused fat was Intralipid 20% (Pharmacia Inc.) containing LCT, which provided 14% of total energy intake (Table 2). Carbohydrate was added to the infusate as 50% dextrose. Vitamins (Multi-1000 containing per 10 mL; vitamin C, 1000 mg; vitamin A, 10,000 I.U.; vitamin D, 1000 I.U.; vitamin E as dl-alpha tocopheryl acetate, 10 I.U.; thiamine as hydrochloride, 45 mg; riboflavin as sodium phosphate, 10 mg; niacinamide, 100 mg; pyridoxine as hydrochloride, 12 mg; d-pantothenic acid as d-panthenol, 26 mg; and benzyl alcohol, 9 mg) and trace elements were also added, in amounts sufficient to meet the daily requirements of the rats.

18:2ω6	54.3
18:3ω3	7.2

[a]From Pharmacia Inc., Mississauga, Ontario, Canada.

Rats in the control group (n = 7) received a continuous infusion of TPN at the rate of 2.5 mL/h, resulting in the infusion of 60 mL containing 79.4 kcal/24 h (Table 1). The TNF-α-infused group (n = 7) received TPN at the same rate as controls. In addition to TPN, they also received a continuous infusion of TNF-α at the rate of 25 μg/d. The TNF-α was added to the TPN solution, and both were infused together through the same syringe. During the study, the animals were housed individually in metabolic cages, and both catheter and spring were connected to a swivel, allowing them to move freely. The TPN solution was administered continuously for 10 d, at a constant rate, using a Harvard infusion pump (Pump 22; Harvard Apparatus, Wellesly, MA). New TPN solution was mixed aseptically daily in a laminar air flow hood.

Liver and carcass analysis. After completing the 10 d of infusion, the rats were anesthetized with sodium pentobarbital and were killed by exsanguination. The blood was drawn into a heparinized syringe. Plasma was separated and stored at −70°C until biochemical determinations were made. The liver was removed and weighed. The carcass was also weighed. Both liver and carcass were homogenized. An aliquot of each was lyophilized and the dry weight determined. The lipids were extracted as given below and the extracts stored in chloroform under nitrogen at −70°C until further analysis.

Total lipids and fatty acid profiles. Total lipids in liver and carcass were extracted using chloroform/methanol in the ratio of 2:1 (vol/vol) (14), and the extracts were freed from nonlipid material by washing with normal saline. The lipid extracts were then separated by thin-layer chromatography. The plates were developed with hexane/diethyl ether/acetic acid (80:20:2, by vol) to separate TG and PL. The bands were made visible by spraying with 0.02% dichlorofluorescein in methanol and marking the areas under ultraviolet light. The silica from the marked areas was scraped off into glass tubes with Teflon-lined caps.

Methyl esters of the TG and PL fatty acids were prepared by hydrolysis with 2 mL of 14% boron trifluoride in methanol at 90°C for 30 min (15). Although 30 min hydrolysis yields 80.97% recovery of sphingomyelins as against 100% at 90 min hydrolysis (Raina, N., and Jeejeebhoy, K.N., unpublished data), nevertheless, it is not likely to influence the results, be-

cause sphingomyelins, as percentage of total phospholipid, contribute to only 4.2% in rat's liver and 2.7% in rat's skeletal muscle (16).

Fatty acid methyl esters were analyzed on a gas–liquid chromatograph (Hewlett-Packard 5890A; Mississauga, Ontario, Canada) equipped with a fused silica capillary column (Durabond 225/30 mm × 0.2 mm i.d.; Brockville, Ontario, Canada) and a flame-ionization detector (FID). A temperature gradient increasing from 150 to 220°C over 20 min was used. The output of the FID was quantified and recorded on chromatograms (3393 Hewlett-Packard integrator). The total TG and PL were quantitated from peak areas of fatty acids. The peak areas were then referred to areas of the known amounts of 17:0 internal standards derived from added triheptadecanoin and diheptadecanoyl phosphatidylethanolamine. Individual fatty acid compositions of TG and PL in a sample were calculated by multiplying the percentage peak areas of each fatty acid by the concentrations of total TG and PL in that sample. The total values were expressed as concentration (mg/g dry weight) as total organ content. The individual values was expressed as wt% of total lipid.

Statistical methods. The data, presented as mean values ± standard errors of the means, were compared using the Student's unpaired *t*-test. The differences were considered significant at $P < 0.05$.

RESULTS

Liver composition. The liver of TNF-α-infused rats, both as mg/g dry wt and total organ content, contained significantly more TG and PL than controls (Table 3).

[a]The fresh liver weights of control and tumor necrosis factor-α (TNF-α)-treated rats were 12 ± 0.6 and 24 ± 2 g, respectively; TG, triglycerides; PL, phospholipids.
[b]The fresh carcass weights of control and TNF-α-treated rats were 231 ± 5 and 226 ± 4 g, respectively.
[c]$P < 0.05$, indicates significant difference between the TNF-α and the control group. NS, Not significant.
[d]Values are given as mean ± SEM.

Among liver PL fatty acids, only 18:0 was significantly reduced and 22:4ω6 was significantly increased (Table 4). However, the total hepatic PL in TNF-α-infused rats contained significantly less saturated and more polyunsaturates of the ω6 series than did controls.

The liver TG fatty acid composition showed reduction in 16:0 and 18:1ω9 and increases in 18:2ω6, 20:4ω6, 22:4ω6, 22:5ω6, 18:3ω3, 22:5ω6, 22:5ω3, and 22:6ω3 (Table 5). The

increased TG in the liver contained significantly less saturated and monounsaturated fatty acids but more polyunsaturated fatty acids (PUFA) of the ω3 and ω6 series.

Carcass composition. The TG and PL content of the carcass of TNF-α-infused rats, calculated either as mg/g dry wt or total organ content, were not significantly different from controls (Table 3).

Among carcass PL fatty acids, 16:0 and 16:1ω7 were significantly reduced, and 20:3ω6 and 20:4ω6 were significantly increased (Table 4). However, the total carcass PL in TNF-α-infused rats contained significantly less monounsaturates and more polyunsaturates of the ω3 series than did controls.

The carcass TG fatty acid composition was only changed by a significant reduction in 18:2ω6 (Table 5). The total TG in the carcass contained significantly more monounsaturated fatty acids but significantly less PUFA of the ω6 series than did controls.

Arachidonic acid and linoleic acid in the carcass and liver of control and TNF-α-treated rats. Total arachidonic acid content in the liver of control rats was 29.6 mg and in the TNF-α-treated rats was 86.8 mg (Table 6). Therefore, there was a net gain of 57.2 mg arachidonic acid content in the liver, and, by similar calculations, there was a net loss of 43.5 mg arachidonic acid content from the carcass of the TNF-α treated rats. A reverse trend in the linoleic acid content was also seen: a net gain of 93.9 mg in the liver with a loss of 1100 mg from the carcass in the TNF-α-treated rats (Table 6).

Plasma glucose, insulin, and catecholamines. Plasma insulin and norepinephrine levels were significantly higher in the TNF-α-infused group as compared with the controls (Table 7). Plasma epinephrine, glucose, and corticosterone

levels were not significantly different between the control and the TNF-α-infused rats.

DISCUSSION

Infusion of TNF-α reproduces some of the metabolic effects of sepsis and injury (10). Among these effects are an increase in circulating TG levels due to reduced lipoprotein lipase activity (17–19), but the effect of TNF-α on carcass and liver lipid composition in animals has not been studied in detail. The infusion of TNF-α results in anorexia and reduced food intake. Therefore changes in tissue lipid profiles observed in animals infused with TNF-α will be confounded by the changes in nutrient intake. In order to avoid the effects of reduced nutrient intake, we used a model in which nutrient intake was kept constant in control and TNF-α infused animals, by giving TPN in quantities sufficient to maintain normal growth (7). In other studies where animals received TNF-α by bolus injection, shock occurred with attendant circulatory changes, and these animals had elevated levels of corticosteroid hormones. We have avoided these additional confounding factors in our model by a continuous infusion of TNF-α which, while resulting in marked metabolic and body compositional changes (7,11), did not result in shock and measured corticosterone levels, an index of stress, were comparable to controls (Table 7). Therefore, in this study the changes observed took place in the fed steady-state kept comparable in control and TNF-α infused animals.

In a previous study (7), we showed that when the nutritional status was kept constant by the administration of TPN, there were reciprocal changes in carcass and visceral protein, with the carcass losing and the viscera gaining protein. The present study, therefore, was undertaken to determine the effect of TNF-α on total lipids and fatty acid composition of TG and PL in the liver and the carcass of rats. The two groups of rats (TNF-α and control) received continuously the same amount of nutrients by TPN, in which the lipids infused provided only 14% of total calories.

Liver composition of saturated, ω9, ω6, and ω3 fatty acids in our control rats (Tables 4 and 5) is comparable to those published by Innis (20) in rats receiving TPN with the same lipid source as in this study. Comparable data for the carcass have not been published, to the best of our knowledge.

The TNF-α-infused rats had markedly increased insulin levels (500%) over controls, but plasma glucose levels were similar; therefore, these rats were very resistant to insulin action. The insulin resistance is likely to be due to suppression of the insulin-mediated phosphorylation of the glucose receptor by TNF-α (21). Insulin resistance and the increased norepinephrine levels will increase lipolysis, resulting in increased output of free fatty acids from the carcass. As explained below, the increased free fatty output from the carcass could supply fatty acids necessary for increased accumulation of liver TG and PL (17 and 43% per gram dry weight, respectively) in TNF-α-infused rats.

Although the PL and TG content of the carcass did not significantly change with the infusion of TNF-α, there was a mean loss of 4% in the proportion of ω6 fatty acids in carcass TG. Since the ω6 PUFA of carcass TG fell from 32% of 17 g to 28% of 15 g (Tables 3 and 5) in the TNF-α-infused animal, this change would amount to a loss from carcass of about 1240 mg of ω6 fatty acids. The corresponding gain in the liver of ω6 fatty acids in TG was from 35% of 117 mg to 48% of 200 mg, which is about 55 mg and, by the same calculation, 101 mg in PL. It is clear that the loss in carcass was of a magnitude which could easily supply the gain in liver. The total arachidonic acid and linoleic acid content (Table 6) showed a net gain in the liver with a net loss from the carcass in the TNF-α-treated rats. However, the gain of total liver 18:2ω6 was not in proportion to the loss of total carcass 18:2ω6. Despite the fatty acids' mobilization from carcass to liver, it is apparent that the loss from the carcass exceeds such a transfer, raising the possibility of selective oxidation of PUFA in the carcass or in the liver to supply the increased energy needs induced by the hypermetabolic state induced by TNF-α infusion.

The TNF-α-infused rats had increased liver PL levels with increased content of unsaturated fatty acids. These changes are likely to be due to the insulin-resistant state caused by TNF-α infusion. In streptozotocin-induced diabetes, it was shown acyl-CoA:1-acylglycerol 3-phosphate acyltransferase and acyl-CoA:1-acylglycerol 3-phosphorylcholine acyltransferase were both markedly increased associated with decreased mitochondrial phospholipase A_2 activity and lysophospholipase activity (22). These changes will result in increased PL synthesis. Since both acyl-CoA:1-acylglycerol 3-phosphate acyltransferase and acyl-CoA:1-acylglycerol 3-phosphorylcholine acyltransferase have increased activity toward unsaturated acyl-CoA donors, the PL synthesized will be rich in unsaturated fatty acids.

The abovementioned effects due to insulin resistance cannot however explain the marked increase 20:4ω6 (90%), 22:4ω6 (300%) levels in liver TG with only a 31% increase in 18:2ω6 levels (Table 5). Similarly, there was a significant increase in 20:4ω6 (28%), 22:4ω6 (250%) in liver PL with no change in 18:2ω6 levels (Table 4). These observations suggest an increase in the activity of Δ5-desaturase, which is contrary to the expected change with insulin resistance. In insulin-resistant subjects, increased insulin levels as seen in TNF-α-infused animals, reduced arachidonic acid and longer chain PUFA levels (23), and increased Δ5-desaturase activity (24,25). Therefore, the increased desaturase activity is likely to be a specific effect of TNF-α. In this context, it is of interest that adipocytes lacking the ability to synthesize arachidonic acid are resistant to the cytotoxic effect of TNF-α (26), indicating that inducing desaturase activity may be essential to the cellular effect of TNF-α.

Finally, increased TG synthesis in the liver may also contribute to hypertriglyceridemia observed by us (7) and others (8–10). Hence, the hypertriglyceridemia seen in sepsis may not be due only to reduced lipoprotein lipase. In addition, the shift of PUFA to the liver may provide substrate in that

organ for the production of inflammatory mediators (27) and may contribute to abnormal liver function, which we have observed in TNF-α-infused animals in an earlier communication (7). Further studies need to be done to resolve these issues.

ACKNOWLEDGMENTS

This work was supported by MRC of Canada grant MT-12238 and in part by a grant from Mead Johnson (Bristol-Myers Squibb Company, Evansville, IN). Recombinant human TNF-α, with an endotoxin content of <25 ng lipopolysaccharide/mg TNF-α, was a gift of the Chiron Corporation (Emeryville, CA).

Phospholipid Molecular Species Composition of Developing Fetal Guinea Pig Brain

Graham C. Burdge* and Anthony D. Postle

Child Health, University of Southampton, Southampton SO16 6YD, United Kingdom

ABSTRACT: Adequate accumulation of polyunsaturated essential fatty acids, in particular docosahexaenoic acid (22:6n-3), into membrane phospholipids is critical for optimal fetal brain development. This process is maximal during the period of rapid neurite outgrowth, neuritogenesis, which precedes the major growth phase, myelination. There is no information about differential changes during gestation to individual brain phospholipid molecular species which contain 22:6n-3. Such details of brain development would be concealed by total fatty acid analysis of isolated phospholipid classes. We have detailed phosphatidylcholine (PC) and phosphatidylethanolamine (PE) molecular species compositions in developing fetal guinea pig brain. Total brain PC concentration increased substantially between 40 and 68 (term) d of gestation, corresponding to myelination, while PE increased in a biphasic manner between 25–35 d, which was coincident with onset of neuritogenesis, and 40–68 d. Fetal brain development was accompanied by complex changes in the concentration of individual phospholipid molecular species. During early gestation (25–40 d) 22:6n-3 was enriched in both PC and PE *sn*-1 16:0 molecular species. However, between 40 d and term there was no further increase in brain PC 22:6n-3 content, while brain PE was significantly enriched in both PE18:1/22:6 and PE18:0/22:6. We hypothesize that accumulation of 22:6n-3 into *sn*-1 18:1 and 18:0 species represents establishment of a 22:6n-3-containing membrane PE pool which may be turned over more slowly than *sn*-1 16:0 species. Identification of specific changes in membrane phospholipids which are associated with defined events in brain development may provide a basis for assigning functional roles to individual molecular species.

Lipids 30, 719–724 (1995).

Optimal brain function is dependent upon adequate accumulation of polyunsaturated essential fatty acids (PUFA), in particular docosahexaenoic acid (22:6n-3), into neural membrane phosphatidylethanolamine (PE) (1). The period of maximal 22:6n-3 accumulation is associated with rapid neurite formation and outgrowth (neuritogenesis) which precedes the major brain growth phase (2). Prenatal deprivation of 22:6n-3 supply to developing brain, due to maternal dietary manipulation, has been demonstrated in several species, including the monkey (3), rat (4), and guinea pig (4). Specific effects of such deficit in 22:6n-3 assimilation upon subsequent brain function have not been demonstrated in these animals. However, there is strong circumstantial evidence which suggests inadequate 22:6n-3 accumulation into human fetal brain may have permanent developmental and functional consequences. Preterm human infants who were fed milk formula showed a substantial deficit in IQ at eight years of age compared to controls (5). One possible explanation is that this milk formula did not contain pre-formed 22:6n-3, resulting in a deficit in 22:6n-3 assimilation into infant brain, while infants who were fed breast milk received adequate 22:6n-3 to support brain development. In addition, there is some evidence which suggests that inadequate accumulation of 22:6n-3, due to maintenance of term infants on milk formula which lacked 22:6n-3, may lead to persistence of moderate neurological abnormalities at nine years of age (6).

The period of maximal 22:6n-3 accumulation and neurite formation in developing fetal brain differs between animal species. In human brain development, incorporation of 22:6n-3 into PE starts at about 16 wk of gestation and continues into early postnatal life (7,8), corresponding to the prolonged period of neurite formation. Assimilation of 22:6n-3 into fetal guinea-pig brain is also initiated early in gestation, between 25 and 35 d of gestation, and is largely complete at term (68 d) (9). This process precedes and overlaps neuritogenesis (10). Accumulation of 22:6n-3 into developing rat brain and neurite formation, however, are both largely confined to the first two weeks after birth (11).

Despite the importance of 22:6n-3 in fetal brain development, detailed temporal analysis of 22:6n-3 accumulation into brain phospholipids during gestation has not been addressed. Analyses of phospholipid total fatty acid composition has been reported for fetal human (7), fetal guinea pig (9), and neonatal and adult rat (11) brains. However, such measurements provide no information about the distribution of fatty acids between different brain membrane phospholipid molecular species. Measurement of fatty acid concentration, expressed as a fraction of total phospholipid fatty acids, may conceal specific effects upon individual molecular species which may be important in overall membrane function.

Molecular species compositions of brain phospholipid have been previously reported for adult human (12), adult rat (13), and neonatal monkey (3). However, although these studies have provided detailed information about brain composition, limited numbers of subjects have been used in each case. To our knowledge, there has been no report of molecular species analysis of fetal brain tissue at different stages of development. In the present study, we have determined the composition and concentration of intact phospholipid molecular species of developing fetal guinea pig brain. The results of this study show that increasing gestational age is accompanied by differential enrichments in specific phosphatidylcholine (PC) and PE molecular species.

MATERIALS AND METHODS

Materials. High-performance liquid chromatography (HPLC) grade methanol was obtained from Rathburn Ltd. (Walkerburn, Scotland). Chloroform and choline chloride were purchased from Merck Ltd. (Poole, Dorset, United Kingdom). *Rhizopus arrhizus* lipase (E.C. 3.1.1.3) was from Boehringer Mannhein (Lewes, Sussex, United Kingdom). All other reagents were obtained from Sigma (Poole, Dorset, United Kingdom).

Animal procedures. Outbred virgin adult female guinea pigs were fed maintenance diet (FD1; Special Diets Services, Witham, Essex, United Kingdom) *ad libitum* both before mating and throughout pregnancy. This diet contained 3.4% (wt/wt) fat, which was composed of 22.2% saturated fatty acids, 30.9% monounsaturated fatty acids, 22.7% linolenic acid (18:2n-6), 16.3% α-linolenic acid (18:3n-3), and 7.9% PUFA, mainly arachidonic acid (20:4n-6), expressed relative to total esterified fatty acids.

At gestational ages 25, 35, 40, and 68 (term) d, fetal guinea pigs (n = 6 fetuses/gestation age) were delivered by Caesarian section as described previously (14). Fetal brains were removed, weighed, and frozen in liquid nitrogen. Fetal brain tissue was stored at –20°C.

HPLC analysis of phospholipid molecular species. Fetal brain tissue (100 mg) was homogenized in 0.9% (wt/vol) NaCl using an Ultra-Turrax homogenizer (Janke and Kunkel, Staufen, Germany). Fifty nmoles each of PC14:0/14:0 and PE14:0/14:0 were added as internal standards. Lipids were extracted with chloroform/methanol (15), and phospholipid classes purified on disposable aminopropyl BondElut cartridges (16) (Jones Chromatography, Hengoed, Mid Glamorgan, United Kingdom).

The primary aim of this study was to detail developmental changes in patterns of fetal brain phospholipid molecular species composition at several time points in gestation. In order to be able to analyze a reasonable number of samples, we chose not to separate diacyl from alkyl/acyl and alkenyl/acyl species. While this approach resulted in a number of species being co-eluted, useful information about patterns of molecular species changes in developing fetal brain was obtained. Samples were analyzed by a random protocol to avoid any artifactual time-dependent trend in the results. In addition, the mean variation derived from the whole analytical procedure in the concentration of each molecular species was estimated to be about 20%. PC and PE molecular species were resolved by reverse-phase HPLC on a 25 cm × 4.6 mm APEX I 3μ ODS column (Jones Chromatography), thermostatically maintained at 50°C using a mobile phase of methanol/water (930:70, vol/vol), containing 40 mM choline chloride at a flow rate of 0.8 mL min^{-1}. PE18:1 alkenyl and acyl/18:1 co-eluted with PE18:0/22:6 using this solvent system. These molecular species were resolved by analysis of each sample on the same reverse-phase column maintained at 20°C using a mobile phase of methanol/water (975:25, vol/vol) containing 40 mM choline chloride at a flow rate of 1.0 mL min^{-1}. Mass of eluted molecular species was determined by post-column derivatization with 1,6-diphenyl-1,3,5-hexatriene and fluorescence detection (17). Routine confirmation of phospholipid composition of eluted peaks was provided by on-line determination of ultraviolet absorbance at 205 nm, before the post-column formation of the fluorescence derivative (9). Absorbance at 205 nm was a function both of concentration and of degree of acyl unsaturation of the individual molecular species. The ratio of this integrated absorbance response to phospholipid mass, determined from the fluorescence response, was a constant for each individual molecular species determined by degree of acyl unsaturation. In addition to this method for the validation of species compositions during routine analysis, more detailed assignment of species identities was provided by additional analysis of representative samples. Fatty acid composition of eluted peaks from the reverse-phase HPLC resolutions of PC and PE species was determined by hydrolysis and methylation with BF_3 and analysis by gas chromatography. The *sn*-1 alkenyl *sn*-2 acyl molecular species were identified by susceptibility to hydrolysis with HCl (18). Total PE extracts were resuspended in 500 μL chloroform. HCl was added to a final concentration of 0.4M, and samples were incubated with continuous stirring for 2 min at room temperature. Chloroform and methanol were then added to a final ratio of 1:1, and phase separation was achieved by the addition of isotonic saline and water. The chloroform phase was aspirated and dried under N_2 at 40°C. The *sn*-1 alkyl *sn*-2 acyl species were identified by resistance to hydrolysis with *R. arrhizus* lipase following hydrolysis with HCl (19). PE samples were resuspended in phosphate buffered saline (pH 7.4) (100 μL) by vortexing. The 1000U *R. arrhizus* lipase were added, and the mixture incubated for 2 h at 37°C. The reaction was stopped by addition of chloroform/methanol (1:1, vol/vol) followed by saline and water. The chloroform phase was collected and dried under N_2.

Statistical analysis. Statistical analysis was carried out using the Kruskal Wallis test for multiple comparisons of variables.

RESULTS

Fetal brain growth. Measurement of fetal guinea-pig brain weight showed that between 25 and 40 d of gestation, which

[a]Results of high-performance liquid chromatography analysis of phosphatidylcholine molecular species compositions in fetal guinea-pig brain expressed as mean ± SD; n = 6 fetuses/gestational age.
[b–d]Results significantly ($P < 0.05$) different from 25, 35, and 40 d of gestation, respectively. The wet weights of fetal brains were 1.0 ± 0.1 g, day 25; 1.4 ± 0.4 g, day 35; 1.0 ± 0.4 g, day 40, and 2.5 ± 0.6 g[b–d], day 68.

corresponds to the onset of neurite formation (8), there was no significant change in brain mass (Table 1). The increase in brain mass during the major growth phase, between 40 and 68 d of gestation (Table 1), has been previously shown to be related to deposition of myelin (2).

Fetal brain PC composition. Brain total PC concentration (nmoles/g), which indicates amount of cell membrane, increased 1.4-fold between 35 and 40 d and by a further 1.4-fold between 40 and 68 d (Table 1). However, PC mass per brain, which reflects brain growth, did not change significantly between 25 and 40 days of gestation, but increased 3.4-fold between day 40 (13.1 ± 1.1 μmoles/brain) and day 68 (45.2 ± 1.8 μmoles/brain).

Analysis of individual molecular species showed that increasing gestational age was accompanied by complex, specific modifications to brain membrane composition. Eleven PC molecular species were consistently identified which accounted for >92% molecular species present (Table 1, Fig. 1). At all gestation ages, PC16:0/16:0 and PC16:0/18:1 were the major components (Table 1). PC16:0/22:6 and PC18:0/20:4 concentration increased 2.0- and 2.9-fold, respectively, between gestational ages day 25 and day 35 (Table 1). However, due to statistically nonsignificant decreases in other molecular species, there was no change in total PC concentration (nmoles/g) between 25 and 35 d of gestation (Table 1). PC16:0/22:6 and PC18:0/20:4 concentrations also increased 2.3- and 2.4-fold, respectively, between day 35 and day 40. This was accompanied by increased PC18:0/22:6 (2.4-fold) and PC16:0/18:0 (2.6-fold) concentration (Table 1). The concentration of all PC molecular species identified increased between 40 d of gestation and term (68 d), with the exception of PC16:0/16:1, which decreased 1.4-fold (Table 1). The increment in concentration (nmoles/g) for the majority of PC molecular species was the same as the overall increase in PC concentration. However, between day 40 and day 68, the concentration of PC18:0/18:2 and PC18:0/18:1 increased 4.0- and 3.1-fold, respectively, indicating specific enrichment in these molecular species (Table 1).

Fetal brain PE composition. Fetal brain total PE concentration (nmoles/g) increased 1.7-fold between gestational ages day 25 and day 35, and 3.1-fold between day 40 and term (68 d) (Table 2), whereas there was no significant change in PC concentration during this period (Table 1). Total PE concentration per brain increased 2.4-fold between day 25 (3.1 ± 0.6 μmoles/brain) and 35 d of gestation (7.3 ± 0.9 μmoles/brain), and 7.6-fold between day 40 (5.7 ± 1.4

[a]Results of high-performance liquid chromatography (HPLC) analysis of phosphatidylethanolamine (PE) molecular species compositions in fetal guinea-pig brain expressed as mean ± SD; n = 6 fetuses/gestational age. "A" indicates peaks containing a significant amount of *sn*-1 alkyl *sn*-2 acyl PE molecular species. "P" indicates peaks containing a significant amount of *sn*-1 alkenyl *sn*-2 acyl PE molecular species.

[b–d]Results significantly ($P < 0.05$) different from 25, 35, and 40 d of gestation, respectively.

[e]PE16:0/22:6 + PE18:1/18:1A,P appear as a single peak (6) in Figure 2. PE16:0/22:6 and PE18:1/18:1 A,P were separated by HPLC on an ODS 3 μ APEX I column (Jones Chromatography, Hengoed, Mid Glamorgan, United Kingdom) maintained at 20°C, and the mass of each molecular species was determined as described in the Materials and Methods section.

μmoles/brain) and term (43.2 ± 1.4 μmoles/brain). The difference in PE content per brain between day 35 and day 40 was not significant.

In contrast to fetal brain PC, the corresponding PE fraction was composed primarily of molecular species containing PUFA and included species with *sn*-1 acyl, *sn*-1 alkyl-, and *sn*-1 alkenyl-linked fatty acids (Table 2). Eleven molecular species were consistently resolved which accounted for >97% of total PE (Table 2, Fig. 2) and included an unusually high proportion of *sn*-1 alkyl *sn*-2 acyl species (Table 2, Fig. 2B). The increase in brain PE concentration between day 25 and day 35 was accounted for by increased PE16:0/22:6 (2.4-fold), PE 16:0 alkyl/22:6 (2.3-fold), and PE18:0/20:4 (3.5-fold) (Table 2). However, between day 35 and day 40, there were specific increases in PE18:0/22:6 (1.6-fold) and PE18:1 alkenyl/18:1 (1.4-fold) (Table 2). The concentrations of all fetal brain PE molecular species identified increased between 40 d of gestation and term, with the exception of PE16:0/18:0 (Table 2). The increments in PE16:0/22:6 (2.5-fold), PE16:0/20:4 (1.9-fold), PE 16:0 alkyl/22:6 (2.6-fold), PE18:0/20:4 (2.2-fold), PE18:0 alkyl/22:6 (1.6-fold), and PE18:0 alkenyl/22:6 + PE18:0 alkenyl/20:4 (2.6) (Table 2) concentration were all less than that of total brain PE (3.1-fold). However, the increase in PE18:1/22:6 (4.1-fold), PE16:0 alkenyl/20:4 (6.2-fold), PE18:0/22:6 (5.8-fold), and PE18:0 alkenyl/18:1 (7.0-fold) (Table 2) concentration were greater than that of total PE, indicating that these molecular species were enriched in fetal guinea pig brain between day 40 and term.

DISCUSSION

The results of this study show, for the first time, that growth and development of fetal guinea pig brain is associated with specific changes in the concentration of individual PC and PE molecular species. Fetal guinea pig brain PC was composed mainly of saturated and monounsaturated molecular species while the corresponding PE fraction contained primarily *sn*-2 22:6n-3 and 20:4n-6 species. The molecular species distribution of term fetal guinea pig brain PC and PE was strikingly similar, but not identical, to neonatal and adult rat brain PC and PE (13,20), neonatal monkey brain PE (3), and adult human brain (12) composition. This is in marked contrast to rat (19) and guinea pig (7) liver, which differ substantially in phospholipid composition. The similarity of brain phospholipids between these animal species suggests evolutionary convergence and conservation of molecular species composition. In addition, these results suggest that optimal membrane phospholipid molecular species composition is of critical importance to brain function and is maintained largely independent of diet.

In agreement with previous studies (7–11), the present data shows that enrichment of developing brain phospholipids in PUFA occurred during neuritogenesis which precedes the onset of the major brain growth phase, myelination. Increased concentrations of saturated fatty acids were associated primarily with myelination. Measurement of total PE showed a biphasic increase in concentration, the initial increase being associated with the period of maximal neuritogenesis

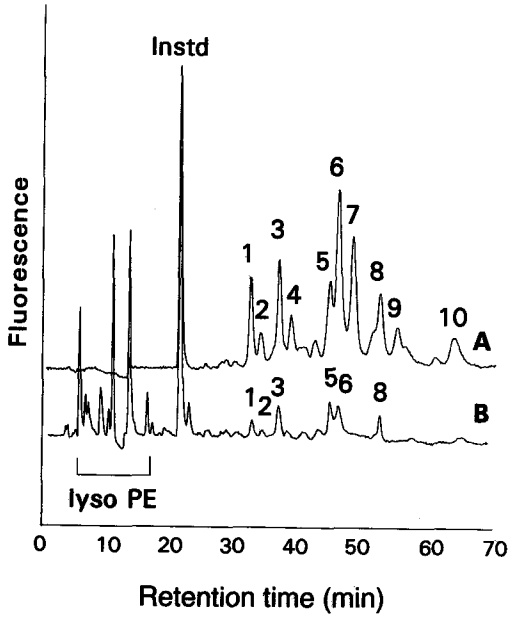

FIG. 2. High-performance liquid chromatography chromatogram of term fetal guinea pig brain phosphatidylethanolamine (PE) molecular species. Numbers correspond to peaks identified in Table 2. A. Intact PE molecular species. B. PE molecular species which were resistant to both digestion with *Rhizopus* lipase and HCl hydrolysis and which were, therefore, *sn*-1 alkyl, *sn*-2 acyl species. Since the PE14:0/14:0 internal standard would have been hydrolyzed by this treatment, it was added after hydrolysis was complete and thus could not be used to correct for losses in recovery. Therefore, PE14:0/14:0 was used to identify peaks according to the retention time relative to this standard. See Figure 1 for other abbreviation.

(d25–d35) while the second phase corresponded with increased total brain mass (d40–d68). Significant increase in PC concentration was restricted to late gestation (d40–d68) and was associated with the period of maximal myelin deposition.

Adequate accumulation of 22:6n-3 and 20:4n-6 is critical for optimal fetal brain growth. Our previous analyses of fetal guinea pig brain PC and PE fatty acid content, expressed as a fraction of total PC or PE fatty acids, showed that 22:6n-3 and 20:4n-6 accumulation into both phospholipid classes was maximal between 25 and 35 d of gestation (9). However, analysis of fetal guinea pig brain PC and PE molecular species showed that increasing gestational age was accompanied by complex changes in the content of individual species, which were not indicated by the previous measurement of total fatty acids (9). For instance, the increased incorporation of 22:6n-3 into brain PC between 25 and 35 d of gestation was primarily into PC16:0/22:6, while 20:4n-6 was accumulated as PC18:0/20:4. Also, the major phase of brain growth and myelination between 40 d of gestation and term was associated with specific enrichment of PC16:0/18:2, PC18:0/18:2, and PC18:0/18:1.

Initial incorporation of 22:6n-3 during the period which corresponded to maximal neurite formation, between 25 and 35 d of gestation (10), was into both PE16:0/22:6 and PE16:0 alkyl/22:6, while accumulation of 22:6n-3 into fetal brain between 35 and 40 d of gestation was primarily into PE18:0/22:6. However, during the major brain growth phase, between 40 d of gestation and term, fetal brain PE was enriched in PE18:1/22:6 and PE18:0/22:6. The *sn*-1 16:0 PE molecular species in both adult rat (21,22) and neonatal guinea pig (14) liver has been shown to be turned over more rapidly than *sn*-1 18:0 PE species. It is, therefore, possible that accumulation of 22:6n-3 into PE16:0/22:6 during neuritogenesis may represent incorporation into molecular species which are turned over rapidly. However, in late gestation when the majority of neurite formation is complete, accumulation of 22:6n-3 into *sn*-1 18:1 and 18:0 PE molecular species may be associated with establishment of a more stable membrane phospholipid pool which is relatively resistant to depletion of PUFA.

It is possible that the contents of more saturated phospholipid species were regulated to compensate for membrane fluidizing effects of increased amounts of unsaturated species. For instance, between 25 and 68 d of gestation, PC16:0/16:0 concentration increased twofold, while that of PE18:1 alkenyl/18:1 increased sevenfold. It is important to recognize, that calculated on a fractional basis, the percentage content of PC16:0/16:0 did not change, while that of PC18:1 alkenyl/18:1 only increased 1.7-fold. This comparison emphasizes that, for future determinations of biological function of individual molecular species of phospholipids, both absolute and fractional concentrations will have to be considered.

The present data shows that fetal guinea pig brain development is accompanied by complex changes in the biologically relevant membrane phospholipid components, which were not detected by analysis of phospholipid fatty acids. These analyses provide an overall pattern of developmental changes in brain phospholipid molecular species composition. Detailed studies on modifications to the molecular species content of developing brain require separation of phospholipid subclasses and are only practical in a relatively limited number of samples. While assignment of specific functions to particular molecular species is not generally possible at present, identification of specific changes in the content of specific species at defined points in development may provide a basis for defining the role of individual membrane phospholipid components. In this context, one useful application of the analytical technique described in this report for the resolution of intact phospholipid species will be to investigate synthesis and turnover of brain phospholipid molecular species from incorporation of radiolabelled precursors.

ABSTRACT: Blubbers of four ringed seal subspecies from Lake Saimaa, Lake Ladoga, the Baltic Sea, and Spitsbergen were analyzed for very long chain polyunsaturated fatty acids (VLCPUFA; $>C_{22}$) using gas–liquid chromatography and gas chromatography/mass spectrometry. The VLCPUFA of the blubber oils were mainly n-3 polyunsaturated fatty acids—23:5n-3, 24:3n-3, 24:4n-3, 24:5n-3, 24:6n-3, 26:5n-3, 26:6n-3, and 28:7n-3. The largest VLCPUFA components in all populations were 24:5n-3 (0.1–0.2 wt% of total fatty acids) and 24:6n-3 (0.1%), but 24:4n-3 (0.1%) was also prominent in the Baltic specimens. The blubber oils of the freshwater species contained considerably more 24:4n-6 and 24:5n-6 than the blubbers of the marine species. The differences among the VLCPUFA in these subspecies appear to be mainly due to different dietary VLCPUFA.

Lipids 30, 725–731 (1995).

Very long chain polyunsaturated fatty acids (VLCPUFA; $>C_{22}$) have been detected in aquatic invertebrates (1–4) and in fish (5–7), but no reports on VLCPUFA in marine mammals have been published. Seals deposit large amounts of polyunsaturated fatty acids (PUFA), mainly 22:6n-3, 20:5n-3, and 22:5n-3 (8–10) in their depot fats (blubbers). In addition, the blubbers of freshwater seals are known to contain considerable amounts of n-6 PUFA—20:4n-6, 22:4n-6, and 22:5n-6 (Ref. 10; Käkelä, R., unpublished results). Undoubtedly, diet is the major source of PUFA in seal depots, but it was not known if the VLCPUFA of the diet are incorporated into the blubber in the same way as the shorter chain PUFA. Among the latter, the 22:5n-3 in depot fats of seals and other marine mammals attracts attention, as it is at least one-half of the 22:6n-3 and sometimes equal to it (11), whereas in fish the proportion is normally one-tenth of 22:6n-3. It was felt that the VLCPUFA intermediates could reflect this difference and be of some help in assessing the origin of the VLCPUFA.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; PUFA, polyunsaturated fatty acids; VLCPUFA, very long chain polyunsaturated fatty acids.

The biosynthesis of 22:6n-3 and 22:5n-6 has recently been reevaluated (12,13). In rats, 20:5n-3 (in liver) and 20:4n-6 (in seminiferous tubules) are first elongated to 24:5n-3 and 24:4n-6, respectively, then Δ6-desaturated to 24:6n-3 and 24:5n-6 and, finally, chain-shortened to 22:6n-3 and 22:5n-6, respectively. Whether this could also occur in the tissues of marine mammals was not known. Alternatively, the levels and composition of the VLCPUFA of the seals could simply resemble those of their diet. Freshwater fish are known to contain large amounts of n-6 PUFA compared to marine fish (14–18). Accordingly, we have compared the VLCPUFA in the blubber oils of ringed seals from freshwater, brackish water, and ocean populations.

MATERIALS AND METHODS

Blubber samples. The blubbers of the ringed seals from Lake Saimaa (eastern Finland), Lake Ladoga (western Russia), the Bothnian Bay of the Baltic Sea, and Spitsbergen (the Arctic Ocean) were collected as described in Table 1. The blubber samples were stored and transferred frozen, except for those of four individuals from Lake Ladoga. These samples were sent to Joensuu in formalin. Blubber samples cut from the middle of the original sample blocks were homogenized and extracted with hexane using a mechanical blender. After alkali saponification of the recovered oils, the unsaponifiables were removed with diethyl ether, and the fatty acids were liberated with dilute H_2SO_4. The fatty acids were taken up in hexane, and their purity was improved by a thin-layer chromatography clean-up step.

Fractionation, hydrogenation, and methylation of the fatty acids. For qualitative studies, parts of the fatty acid samples were fractionated by urea complexing (19). The free fatty acids were dissolved in an ethanolic solution of urea by refluxing. Fractions were collected during two stages of cooling and filtration, first at room temperature and then in an ice bath. After addition of water and acidification, the fatty acids of nonurea-complexing fractions were extracted into hexane (19). However, only the original fatty acid samples were used for quantitation.

To detect the proportions of the fatty acids of different chain lengths, samples of total fatty acids, and the nonurea-complexing fractions from urea complexation were hydrogenated. Fatty acids (5 mg) in methanol (30 mL) were stirred with platinum oxide catalyst (1 mg) under hydrogen for one hour. The solution was filtered and the filtrate was concentrated in a nitrogen stream. The hydrogenated fatty acids were recovered in hexane, washed with water, and concentrated under nitrogen.

Before gas–liquid chromatographic analysis, the free fatty acids were converted to methyl esters by heating at 100°C with 7% BF_3 in methanol plus hexane as cosolvent, in glass tubes with Teflon-lined caps for one hour under nitrogen. The esters were extracted into hexane, and the extract was dried and concentrated.

Gas–liquid chromatography. The fatty acid methyl esters were analyzed with a Perkin-Elmer 8420 gas chromatograph (Norwalk, CT) with flame-ionization detection on an Omegawax-320 capillary column (30 m × 0.32 mm i.d., film thickness 0.25 μm; Supelco Inc., Bellefonte, PA). Helium carrier gas was set at 12 psig. The injector and detector temperatures were 250 and 270°C, respectively. Both temperature-programmed (180°C/8 min, 3°C/min, 230°C to end) and isothermal (210 and 245°C) analyses were conducted. The peak areas were recorded on a Perkin-Elmer GP–100 graphic printer. The areas of the PUFA present in sufficiently large amounts were converted to weight percent using theoretical correction factors (20). The good reproducibility of the VLCPUFA analysis and the small deviations of that data from the whole blubber analyses showed that, in spite of small percentages, the accuracy of the quantitation was not significantly reduced.

Gas chromatography/mass spectrometry (GC/MS). The primary identifications of VLCPUFA were made using conventional techniques—the linear log plot procedures based on retention time (21), the occurrence of the components in different urea-complexing fractions, and chain-length studies after hydrogenation. The identifications were confirmed by electron impact MS [Hewlett Packard 5971 mass selective detector on a Hewlett Packard 5890 A gas chromatograph (Avondale, PA) equipped with an OV-1 methyl silicone capillary column (20 m × 0.32 mm i.d., film thickness 0.25 μm), isothermal and temperature programmed runs] after the method of Fellenberg *et al.* (22). These authors have discovered that the intensity of the fragment *m/z* 108 clearly exceeds that of the *m/z* 150 for n-3 PUFA, but *m/z* 150 is more considerable for n-6 PUFA.

Statistics. The fatty acid data (% w/w) were analyzed by one-way analyses of variance, and the means were compared by the Newman Keuls test (Statgraphics 5.0 software; STSC, Inc.). Prior to this analysis, the fatty acid percentages were normalized through arcsine-transformation (23).

RESULTS

The VLCPUFA in the blubber oils (hexane extract) of the ringed seals were mainly n-3 PUFA (Table 2). In GC/MS they produced intense fragments *m/z* 79 and 91, and the fragment *m/z* 108 was considerable, whereas *m/z* 150 was almost absent. The most important VLCPUFA in each subspecies were 24:5n-3 (0.10–0.24 wt%) and 24:6n-3 (0.06–0.13%), the ringed seal of Lake Ladoga having the highest amounts. The blubbers of the Lake Ladoga (Fig. 1) and Spitsbergen seals contained an amount of 24:5n-3 that was twice as high as 24:6n-3, but in the Lake Saimaa and the Baltic specimens these acids were almost equal. In the Baltic ringed seal, 24:4n-3 (0.11%) was also prominent, thus differing from the other subspecies (Fig. 2). The levels of 24:3n-3 and 23:5n-3 were low (0.02% or less) in each subspecies (Figs. 1 and 2), and traces of 25:5n-3 were also seen in some Baltic samples when examined by GC/MS.

Two hexacosapolyenoic acids, 26:5n-3 and 26:6n-3, were found (Fig. 2). The percentages for the ringed seals from Lake Ladoga and the Baltic were 0.02–0.04%, but the Lake Saimaa and Spitsbergen seals had even lower amounts (0.01% or less). No unambiguous interdependence between the n-3 ho-

mologues from eicosapolyenoic to hexacosapolyenoic fatty acids was found in the comparison of the subspecies (Table 2). The possible octacosapolyenoic homologues of 26:5n-3 and 26:6n-3 were too small to be detected. However, 28:7n-3 was found (Fig. 2). Although the lipids from the other subspecies contained 0.02–0.05% of 28:7n-3, only trace amounts of this fatty acid were observed in the gas–liquid chromatography analyses of lipids from seals of Lake Saimaa.

The blubbers of the freshwater seals contained two n-6 VLCPUFA, 24:4n-6 and 24:5n-6, both subspecies having approximately 0.02% (Table 2, Fig. 1). These fatty acids were present in negligible proportions in the marine ringed seals. Thus, the contents of 24:4n-6 and 24:5n-6 clearly reflected those of the shorter chain homologues in the blubbers of the seals. The identification of n-6 VLCPUFA was based on retention times and occurrence in fractionated samples, despite their coincidence (24) with much larger n-3 VLCPUFA on the OV-1 column used in GC/MS. Unfortunately, the accuracy of the quantitation of 24:4n-6 was diminished by a plasticizer, dioctyl (di-2-ethylhexyl) phthalate (25), eluting just before it and causing inaccuracies in the integration of the peak area.

The analyses of the hydrogenated fatty acids gave the proportions of the different chain lengths in the fatty acids of the blubbers (Table 3, Fig. 3). The results for fatty acids $>C_{20}$ paralleled those of the PUFA of the unhydrogenated samples, but gave a little larger total for each chain length. When the amounts of 24:1n-9 and 24:0 were added to the sum of tetracosapolyenoic acids, the agreement with hydrogenated 24:0 was satisfactory. In addition, traces of 26:0, 26:1, 28:0, and 28:1 could be seen in the chromatograms of the nonhydrogenated fatty acids, and these contributed to the sums of hexacosanoic and octacosanoic acids. However, these fatty acids failed to totally account for the differences observed, suggesting that there were probably several trace polyunsaturated components that could not be detected individually.

DISCUSSION

Although the VLCPUFA found in the blubbers of the ringed seal subspecies studied were qualitatively the same, clear differences in the abundance of several VLCPUFA were detected (Table 2). The Baltic ringed seal had high proportions of 24:4n-3 and 28:7n-3 compared to other subspecies, and 24:5n-3 was particularly high in the Lake Ladoga specimens. As anticipated, the blubbers of the freshwater seals contained more n-6 VLCPUFA than those of the marine individuals. The proportion of total VLCPUFA in the blubbers also varied; the ringed seal of Lake Ladoga had the largest amount (0.58%), followed by the Baltic (0.44%), Lake Saimaa

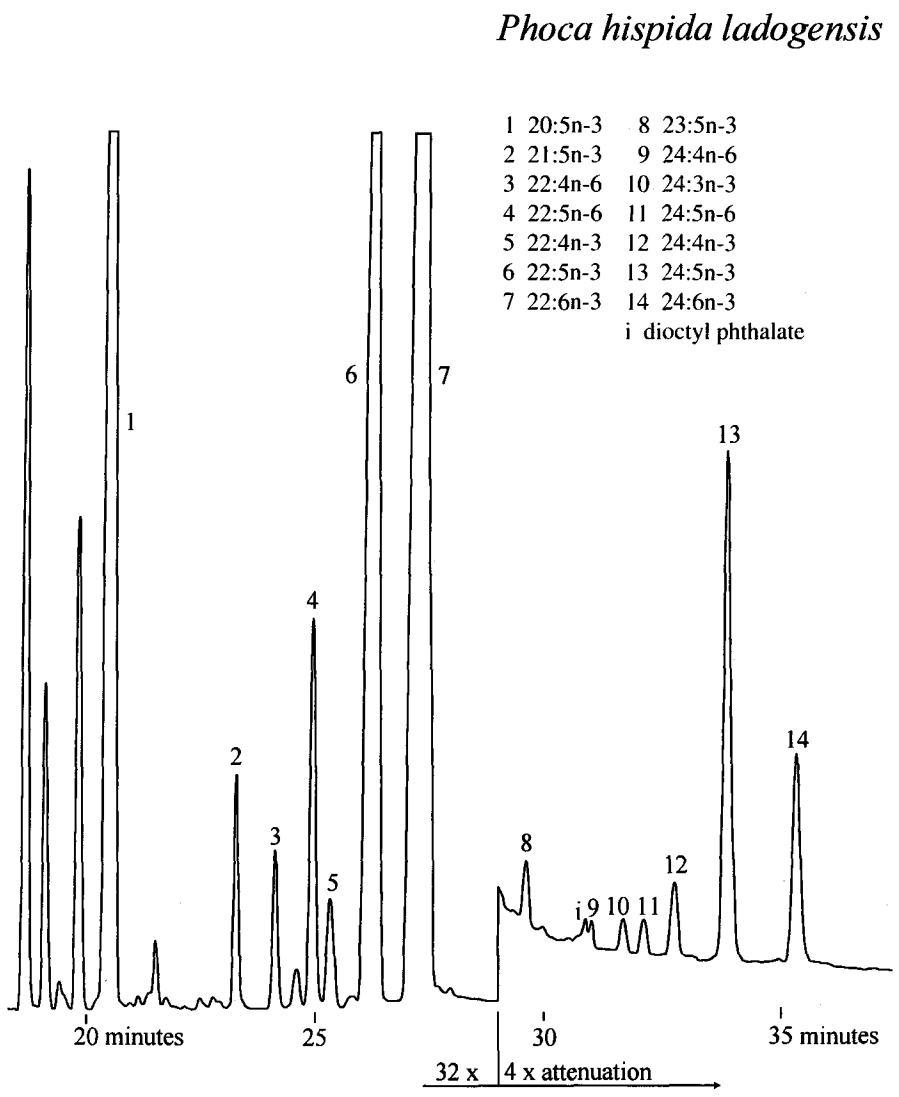

FIG. 1. Partial gas–liquid chromatogram of the total fatty acids from the blubber of the ringed seal of Lake Ladoga showing the area of C_{22-24} PUFA (180°C/8 min, 3°C/min, 230°C to end, Omegawax-320 capillary column; Supelco, Bellefonte, PA).

(0.29%), and Spitsbergen (0.25%) seals. These differences seem to be too large to be due to metabolic divergence only and suggest a dietary explanation.

It is known that the fatty acid composition of seal blubber reflects the dietary fatty acids to a great extent. Especially, the freshwater and marine seals have very different compositions, the former having more of the n-6 PUFA that are abundant in freshwater fish (14–18), and less 20:1n-9 and 22:1n-11 derived from copepoda (10,26). The n-6 PUFA contents of freshwater fish are almost five times those of marine fish, a ratio also found in the long-chain PUFA and VLCPUFA of blubbers from lacustrine and marine seals (Table 2). As far as we know, freshwater fish have not been analyzed for VLCPUFA, and analyses of marine fish for these fatty acids are few. The Baltic herring (*Clupea harengus membras*), an important prey species for the Baltic ringed seal, has been found to contain VLCPUFA of 24–32 carbons in the chain, but the percentages of the total fatty acids have been reported only for 24:4n-3, 24:5n-3, 24:6n-3, 26:5n-3, 26:6n-3, and 28:7n-6 (5). The compositions of the VLCPUFA in the total flesh lipids of the Baltic herring and the ringed seal blubber differ in two ways (Table 4). First, the levels of VLCPUFA in the blubber oils were only one-tenth or less of the herring lipid levels. Second, the 28:7 of the ringed seal was identified to be a n-3 isomer and that of the herring is reported as a n-6 isomer (5). Řezanka (6,27) has used herring (*C. harengus*, unknown origin) as a source of VLCPUFA and, although reporting 28:7n-3 as the main isomer, he also found 28:7n-6 (Table 4). Recently Ota *et al.* (7) found as much as 8 mol% of 24:6n-3 in the flesh triglycerides of flathead flounders from the Sea of Japan.

Could endogenous metabolism (from shorter chain PUFA obtained in the diet) produce VLCPUFA in the seal tissues? Voss *et al.* (28) and Aveldaño *et al.* (13) have shown that

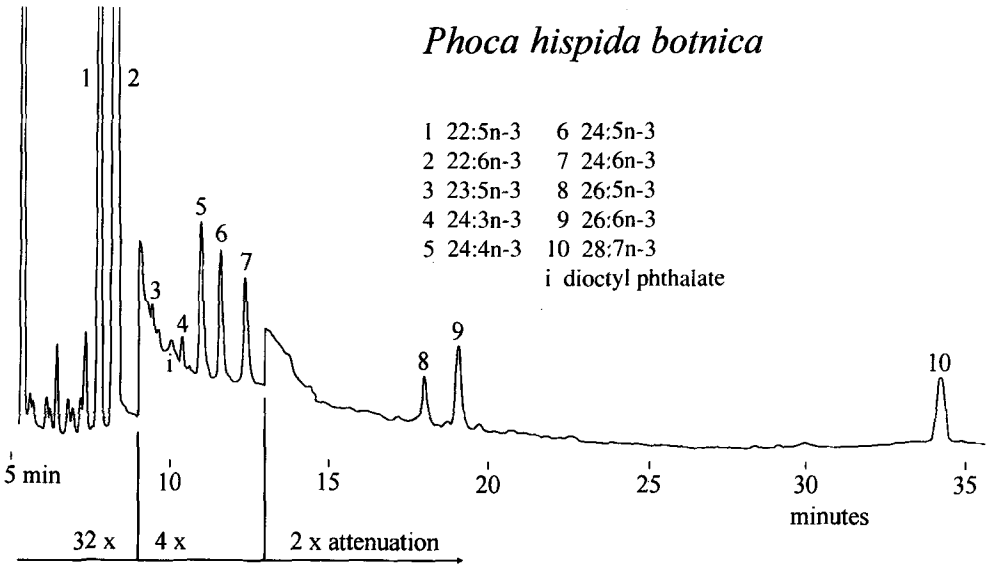

FIG. 2. Partial gas–liquid chromatogram of the total fatty acids from the blubber of the Baltic ringed seal (isothermal 245°C, Omegawax-320 capillary column; Supelco, Bellefonte, PA).

24:5n-3, 24:6n-3, 24:4n-6, and 24:5n-6 are intermediates in the metabolism of 22:6n-3 and 22:5n-6 in the rat, but radiolabel experiments are needed to find out if, or on what scale, these processes occur in seal liver or blubber. Whatever the organisms in which the VLCPUFA of the ringed seal blubbers have been biosynthesized, the biochemistry of these fatty acids seems to follow the pathways proposed in the rat studies. Theoretically, all the VLCPUFA of the ringed seal blubbers could be produced by chain elongation, β- and α-oxidation, Δ5-desaturase and Δ6-desaturase. Even the 28:7n-3 could be seen as being derived from the Δ5-desaturation and subsequent elongation of 26:6n-3.

The occurrence of odd-chain VLCPUFA, 23:5n-3, and trace 25:5n-3 suggest either elongation of 21:5n-3 or α-oxidation. Aveldaño *et al.* (13) have proposed that α-oxidation is an important mechanism in the shortening of fatty acids and that this produces odd-chain PUFA as metabolic intermediates. However, 21:5n-3 was first identified in seal oils (29), where it is more obvious than in fish oils. Possibly the retroconversion of VLCPUFA by β-oxidation is not totally specific, and α-oxidation takes place instead.

Although our knowledge of the biochemistry of PUFA and VLCPUFA has recently expanded, the biological importance of VLCPUFA is not yet understood (30). VLCPUFA have been detected in large amounts in mammalian spermatozoa/testes (1,31–33), brain (34,35), and retina (36–39), which suggests essentiality for at least some specific membrane functions. The tissues known to be rich in VLCPUFA in terrestrial mammals, and also worth analyzing, are those of diving mammals. These obtain large amounts of PUFA from their diets and have special requirements in sensory physiology.

Cucumber Cotyledon Lipoxygenase Oxygenizes Trilinolein at the Lipid/Water Interface

K. Matsui* and T. Kajiwara

Department of Biological Chemistry, Faculty of Agriculture, Yamaguchi University, Yamaguchi 753, Japan

ABSTRACT: The reactivity of cucumber cotyledon lipoxygenase with trilinolein was examined. The activity of the enzyme against linoleic acid rapidly decreased with increasing pH of the assay solution, and essentially no activity could be detected above pH 8.5. The rapid decrease in activity was not the result of an inactiveness of the enzyme at alkaline pH, because with trilinolein, the enzyme showed a broad pH-activity profile, and substantial activity could be detected even at pH 9.0. Rather, the decrease in activity was due to the dissociation of the linoleic acid emulsion into acid-soap aggregates and/or the monomeric form, depending on the ionization of the terminal carboxylic group. This suggests that cucumber cotyledon lipoxygenase acts only on an insoluble substrate at the lipid/water interface but not on a soluble one. High-performance liquid chromatography analyses of the products formed from trilinolein revealed that the enzyme inserted oxygen into the acyl moiety of trilinolein without hydrolysis of the ester bonds. Preincubation of the enzyme with triolein emulsions effectively abolished its activity against trilinolein added afterward. Furthermore, the enzyme was adsorbed on the trilinolein or triolein emulsion droplets in an essentially irreversible manner. A reaction velocity curve of the enzyme with trilinolein showed saturation kinetics. This is thought to be due to a regional substrate deficiency as the reaction proceeds. These lines of evidence indicate that the enzyme, once bound to the lipid/water interface, is unable to break free and bind to other emulsions.

Lipids 30, 733–738 (1995).

Lipoxygenases are enzymes containing a nonheme iron that use molecular oxygen in the oxygenation of a fatty acid having a 1Z,4Z-pentadiene system. The enzyme is ubiquitously distributed in animals and plants. In both animal and plant cells, lipoxygenases are involved in the formation of biologically active substances (1,2). It has been proposed that the formation of these compounds is controlled by the liberation of precursor fatty acids from membrane lipids *via* phospholipase- or lipolytic acyl hydrolase-catalyzed reactions (1,2). Thus, in general, lipoxygenases are thought to act on free fatty acids.

In the cucumber cotyledon, as well as in the cotyledons of other fatty seed plants, lipoxygenase is rapidly formed after germination, and then degrades after the cotyledons have acquired photosynthetic capacity (3,4). The developmental change in the lipoxygenase activity is highly correlated with that of seed storage fats, which are catabolized into sugars *via* gluconeogenesis (5). Thus, the involvement of lipoxygenase activity in the mobilization of fat stored in lipid bodies of seeds has been proposed (3,6). Nonetheless, free fatty acids are not so abundant during seed germination, and the actual reaction catalyzed by lipoxygenases *in vivo* has not yet been elucidated. It is well known that some soybean lipoxygenase isoforms having optimum pHs at neutral and weakly acidic regions act on triacylglycerols (6–8). If this is also the case with cucumber cotyledon lipoxygenase, it would give a new insight into the still-unknown physiological role of the enzyme in cotyledons. Thus, we examined whether a common triacylglycerol is a substrate for cucumber cotyledon lipoxygenase. In this report, the reactivity and kinetics of cucumber cotyledon lipoxygenase with trilinolein are described.

MATERIALS AND METHODS

Chemicals. Trilinolein, linoleic acid, and triolein (99% pure) were purchased from Sigma (St. Louis, MO). Gum arabic and Tween 20 were from Wako Pure Chemicals (Osaka, Japan). All other reagents were chemical grade. Stock solutions of trilinolein and triolein emulsions (25 mM) were prepared either with 50 mg/mL gum arabic (9) or 2 mg/mL Tween 20 after sonication at the highest power with a tip-type sonicator (model UR-150P; Tomy Co., Tokyo, Japan) for 30 s under a nitrogen atmosphere. The stock substrate solution was immediately frozen and kept at –20°C until use. For each assay, the substrate solution was frozen and thawed only once. Linoleic acid (50 mM) was dispersed with 2 mg/mL Tween 20 with sonication as described above and immediately frozen and kept at –20°C until use (4). In the case of linoleic acid/Tween 20, the stock solution was again sonicated just prior to use.

Enzyme and enzyme assays. Cucumber cotyledon lipoxygenase was purified from six-day-old light-grown cucumber cotyledons essentially as described (10). The purified lipoxygenase was apparently free of contaminants (see Fig. 5). The enzyme used in this study had a specific activity of more than

2.0 μkat/mg protein, when assayed with trilinolein/gum arabic emulsions in 0.1 M Tris–Cl, pH 8.5. Although two forms of the lipoxygenases can be purified, only the 96 kDa form was used because it was thought to be an intact enzyme (10). Lipase activity was not detected in the lipoxygenase preparation when trilinolein or triolein was used as a substrate under the assay conditions described (9). Protein content was estimated according to Bradford (11) with bovine serum albumin as a standard.

The lipoxygenase assay was performed with an oxygen electrode (YSI 5331; Yellow Springs Instrument, Yellow Springs, OH) at 25°C (4). In a typical assay, 33.3 μL of 25 mM trilinolein/gum arabic solution was added to 0.1 M Tris–Cl, pH 8.5 (final volume was 1900 μL, and final concentrations of trilinolein and gum arabic were 0.439 mM and 0.877 mg/mL, respectively). With the linoleic acid/Tween 20 system, 50 μL of the stock solution was added, resulting in final concentrations of linoleic acid and Tween 20 of 1.32 mM and 52.6 μg/mL, respectively. After incubation of the solution for 1 min, the enzyme (114 ng; final concentration, 1.75 nM) was added to start the reaction. Although the reaction velocity curves with trilinolein and linoleic acid were considerably different (see Fig. 3A), the maximum activities that appeared within 5 min after addition of the enzyme were used to calculate the activity. Spectrophotometric analysis of the products was performed with a Shimadzu (Kyoto, Japan) UV–160A after extraction with ether. To estimate the effect of triolein on the activity, lipoxygenase (712 nM) was incubated with a given concentration of triolein/gum arabic emulsions in 0.05 M Tris–Cl, pH 8.5 at 25°C for 20 s, and a portion of the solution was used for the assay with trilinolein/gum arabic (final concentration of the enzyme was 1.5 nM).

High-performance liquid chromatography (HPLC) analysis. Trilinolein/gum arabic emulsions (0.438 mM and 0.877 mg/mL, respectively) were oxygenized with 1.5 nM lipoxygenase in 0.1 M Tris–Cl, pH 8.5 at 25°C for 8 min. The products were extracted from the reaction mixture (1.0 mL) with 2 mL of ether. After evaporation of the ether with a nitrogen flow, the residue was dissolved with 100 μL of methanol. A portion (10 μL) of the solution was separated with a Wakosil 5C18 column (Wako Pure Chemicals, 4 × 250 mm) attached to a Shimadzu HPLC pump LC-10A with 1-butanol/methanol (10:90, vol/vol) at a flow rate of 1.0 mL/min (12). Detection was performed with a photodiode array detector, Shimadzu SPD-M10A. HPLC analysis of the hydroperoxides of free fatty acids was performed with a Zorbax SIL (Dupont-Shimadzu, 4.6 mm × 250 mm) after reduction of the hydroperoxides with triphenylphosphine and methylation with ethereal diazomethane (13). Elution was carried out with *n*-hexane/*iso*-propanol (99:1, vol/vol) at a flow rate of 1 mL/min.

Differential centrifugation. The amount of the lipoxygenase bound to emulsion droplets was estimated after separation of the lipid phase with centrifugation. Cucumber cotyledon lipoxygenase (5.7 μg) was incubated with 12.5 mM of trilinolein or triolein emulsions dispersed with 25 mg/mL gum arabic in 0.1 M Tris–Cl, pH 8.5 (total volume, 200 μL) for 20 min on ice. It was then diluted to 3 mL with the same buffer, and was immediately centrifuged at 30,000 rpm for 20 min in a Hitachi (Tokyo, Japan) RPS-56T swing rotor at 4°C (14). The buffer layer was recovered from the bottom of the centrifugation tube. The remaining top lipid layer (300 μL) was thoroughly vortexed and collected. Recovery of the lipid from the respective phases was estimated from the turbidity which was determined from the absorption at 600 nm. A part of each solution (18.8 μL) was mixed with 14.3 μL of SDS–sample buffer, and then applied to SDS–polyacrylamide gel electrophoresis as in Reference 15. The protein bands were visualized by silver-staining with a Silver Staining Kit (Wako Pure Chemicals).

RESULTS

pH-activity curve. The reactivity of cucumber cotyledon lipoxygenase against triacylglycerol was estimated with trilinolein, which is the most abundant triacylglycerol species in dry cucumber seeds. The pH-activity profile of the lipoxygenase against trilinolein dispersed with gum arabic was compared with that against linoleic acid dispersed with Tween 20 (Fig. 1). When the linoleic acid/Tween 20 system was used as a substrate, high activities of cucumber cotyledon lipoxygenase were observed in the acidic pH region as reported previously (16). The activity rapidly decreased with increasing pH value of the buffer from 7.0 to 8.0. Essentially no activity was detected at or over pH 8.5. On the other hand, the lipoxygenase showed a relatively broad pH-activity profile with trilinolein/gum arabic. A substantial activity could be observed even at pH 9.0. This indicates that the low or absent activity of the lipoxygenase against linoleic acid/Tween 20 at alkaline pH was not due to the inactivity of the enzyme but to changes

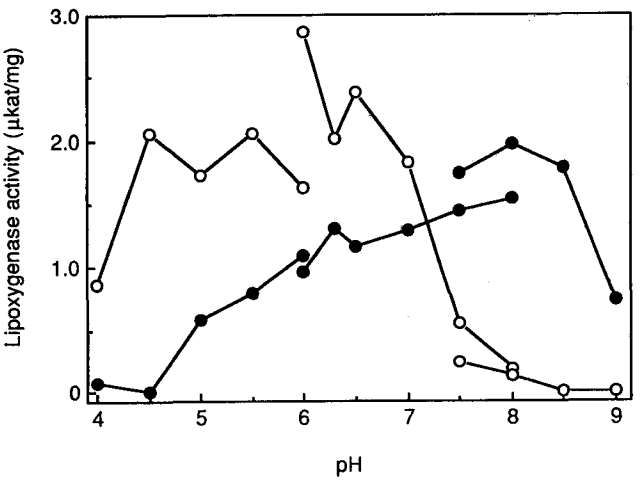

FIG. 1. The pH-activity profiles of cucumber cotyledon lipoxygenase with trilinolein emulsified with gum arabic (●) and with linoleic acid dispersed with Tween 20 (Wako Pure Chemicals, Osaka, Japan)(○). Buffers used were 0.1 M sodium acetate for pH 4.0 to 6.0, 0.1 M sodium phosphate for pH 6.0 to 8.0, and 0.1 M Tris–Cl for pH 7.5 to 9.0.

in the physical state of the substrate in the solution. Almost the same pH-activity profile was obtained when trilinolein was emulsified with Tween 20 (not shown). Bild *et al.* (17) reported the pKa of linoleic acid as about 7.9. Thus, an ionization of the terminal carboxyl group into its carboxylate anion form occurs above pH 7.0. Thus, an emulsion of linoleic acid should dissociate into acid–soap aggregates and/or into the monomeric form (18) as the buffer pH increases. In this respect, it is noteworthy that the pH-activity profile from pH 7.0 to 9.0 highly resembles the acid titration curve of sodium linoleate (17). On the contrary, the physical state of the emulsions of trilinolein should be little affected by the buffer pH because it has no ionizable group. These observations suggest that cucumber cotyledon lipoxygenase cannot act on a soluble substrate but only on an insoluble substrate at the water/lipid interface.

During the reaction of the lipoxygenase with trilinolein/gum arabic, the hydrolysis of the ester bond was not detected when the amounts of liberated fatty acid or its hydroperoxy derivatives were determined using the 1,5-diphenylcarbazide method (9). Spectrophotometric analysis revealed that during the reaction, a peak having a λ_{max} of 234 nm, which is typical of conjugated diene hydroperoxy groups, increased. Formation of the hydroperoxide of a free fatty acid could not be detected by analyzing the products formed from trilinolein with the straight-phase HPLC system. On the other hand, as shown in Figure 2, three peaks appeared in a chromatogram obtained with the reversed HPLC system, which was developed for separation of hydroperoxides of trilinolein (12). All three peaks showed spectra having a λ_{max} at 234 nm. Comparison of the elution profiles with published profiles (12), together with the spectra, allowed us to tentatively assign the peaks to tris-, bis-, and monohydroperoxide of trilinolein (in the elution order). These results suggest that oxygen is introduced into the acyl group of the triacylglycerol without hydrolysis.

Reaction velocity curves. Reaction velocity curves of the oxygenase reaction against linoleic acid/Tween 20 and trilinolein/gum arabic were completely different from each other (Fig. 3A). The enzyme oxygenized linoleic acid after a lag time with a progressively increasing reaction rate. The reaction velocity curve was similar at each pH tested and was not affected by the type of emulsifier used. This reaction velocity curve is typical of those reported for most lipoxygenases (19). The origin of this rate increase is explained with the two-step model for lipoxygenase catalysis (20). A lag time of 10–30 s was also observed with trilinolein, but, unlike the lag time ob-

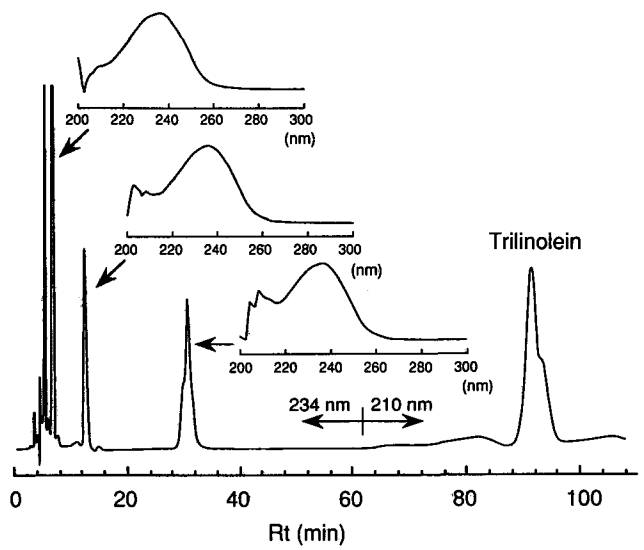

FIG. 2. A reversed-phase high-performance liquid chromatography analysis of the products formed from trilinolein with cucumber cotyledon lipoxygenase. Before 62 min, the eluate was monitored at 234 nm to detect the conjugated diene hydroperoxides. After that time, it was monitored at 210 nm to detect the ester bonds. Absorption spectra of newly appeared peaks (arrows) are also shown. Rt, retention time.

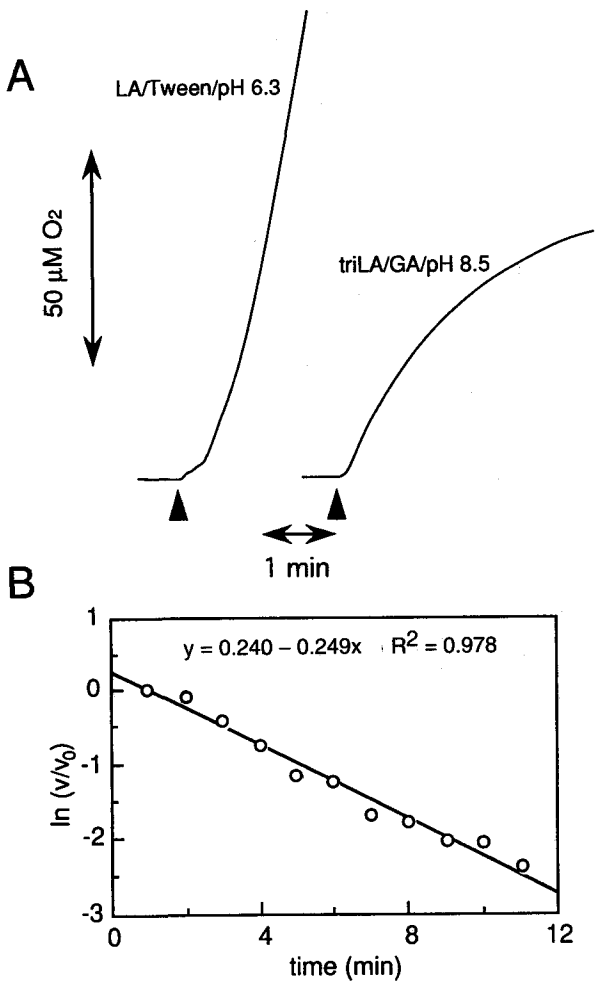

FIG. 3. Reaction velocity curves of cucumber cotyledon lipoxygenase. A: The curves of the lipoxygenase reactions were obtained polarographically with trilinolein (triLA)/gum arabic (GA) and linoleic acid(LA)/Tween 20. The times of enzyme addition are shown with arrowheads. B: Semi-log plot of the activity relative to the initial highest activity vs. time. The reaction rate with triLA/GA was traced every 60 s, and the natural logarithms of the rates at a given time relative to the initial highest rate are plotted. The regression curve does not intersect the zero point on the y-axis because the maximum activity was always observed after 10 to 30 s of the lag time. See Figure 1 for Company source.

served with linoleic acid, little reaction occurred during this period. After the lag time, the reaction rate rapidly increased and immediately reached its highest value. As the reaction proceeded, the rate slowly decreased, and finally the reaction almost ceased when only a fraction of the total available substrate was oxygenized. Such a reaction velocity curve is typical of Michaelis-Menten kinetics where the Michaelis constant is much larger than the concentration of a substrate, although the origin of the lag phase is not clear. Addition of fresh enzyme restarted the reaction with almost the same initial velocity. Thus, strong product inhibition should not be the reason for the cessation of the reaction. On the contrary, addition of trilinolein after the cessation of the reaction caused no change in the course of the reaction.

The decrease in the reaction rate at each point of time apparently obeyed the first-order kinetic law (Fig. 3B). The first-order exponential constant was independent of the initial concentrations of both the substrate and the enzyme as long as the trilinolein/enzyme ratio was kept between 300 and 2500. When a different concentration of the enzyme was used, the reaction began with the maximum velocity proportional to the amount of the enzyme added, and ceased after an amount of oxygen proportional to the initial amount of enzyme was consumed.

Adsorption on emulsions. Further evidence for determining whether cucumber cotyledon lipoxygenase catalyzes its reaction with trilinolein after the enzyme is adsorbed on emulsions could be obtained with triolein. Triolein is thought to form emulsions of almost the same physical properties as trilinolein but it is not a substrate of the lipoxygenase. When cucumber cotyledon lipoxygenase was preincubated with triolein/gum arabic emulsions, the activity was lost depending on the concentration of triolein (Fig. 4). The decrease in the activity observed here could be attributed to an essentially irreversible adsorption of the enzyme on the triolein emulsions. Because the adsorption process was completed within as little as 10 s, we could not follow the adsorption kinetics. From an extrapolation of the semi-log plot of the initial region of the inactivation curve, it can be calculated that one molecule of the lipoxygenase binds to approximately 4200 molecules of triolein (Fig. 4, inset).

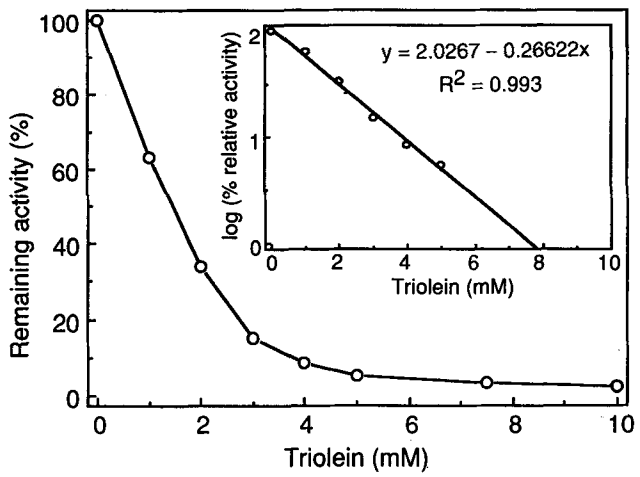

FIG. 4. Effect of preincubation of the enzyme with various concentrations of triolein/gum arabic emulsions on enzyme activity. The lipoxygenase was incubated with a given concentration of triolein/gum arabic, and a portion of the solution was used for the assay with trilinolein/gum arabic. The activity of the enzyme preincubated without triolein was 3.28 μkat/mg protein (designated as 100% in this figure). inset: Semi-log plot of the relative remaining activity. Only data obtained with a low concentration of triolein and which satisfactorily regressed to a straight line are shown.

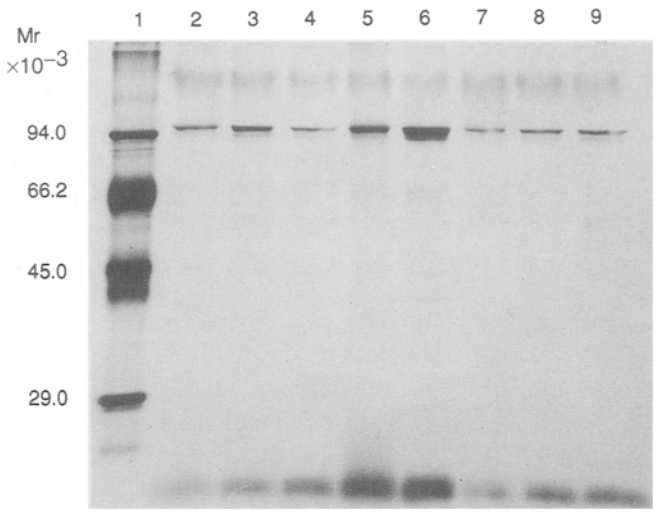

FIG. 5. Binding of cucumber cotyledon lipoxygenase to emulsion droplets. Lipoxygenase was incubated with an emulsion of trilinolein (lanes 2, 5, and 7) or triolein (lanes 3, 6, and 8). For a control, the lipoxygenase was incubated with the gum arabic solution without lipids (lanes 4 and 9). The preparations were then centrifuged, and the bottom buffer layer (lanes 7–9) and the top lipid layer (lanes 5 and 6) were separated. Lane 1, molecular mass standard; lanes 2–4, the solutions before centrifugation.

Binding of lipoxygenase to emulsion droplets. The emulsions were incubated with the enzyme, and then they were concentrated by floating with centrifugation. The turbidity assay indicated that trilinolein and triolein were concentrated 6.85- and 6.91-fold, respectively, in the top lipid phase, while they were diluted 4- and 3.2-fold, respectively, in the bottom buffer phase. The amounts of lipoxygenase recovered from the two phases were analyzed with SDS–polyacrylamide gel electrophoresis followed by silver-staining (Fig. 5). It is obvious that the enzyme was concentrated in the lipid phase and that the degrees of concentration were almost the same as those of the lipids. These results clearly indicate that almost all of the available lipoxygenase adsorbed onto the lipid emulsion droplets in an irreversible manner. Unexpectedly, the total recovery of the enzyme was much less with trilinolein emulsions than with triolein emulsions. The reason for such a low yield is presently unclear.

DISCUSSION

In both animal and plant cells, lipoxygenases are involved in the formation of various species of biologically active sub-

stances (1–3). It has been proposed that the formation of these compounds is controlled by the liberation of the precursor fatty acids from membrane lipids *via* phospholipase- or lipolytic acyl hydrolase-catalyzed reactions (21). Thus, lipoxygenases are thought to act essentially on free fatty acids. On the other hand, some lipoxygenase isoforms in soybean seeds are reported to act on an acyl moiety in glycerolipids (6–8). Furthermore, soybean lipoxygenase-1, which has a peculiar optimum pH, i.e., 9.0 to 10.0, has been reported to stereospecifically oxygenize an acyl moiety in phospholipids (22), although the catalysis required a specific bile salt–phospholipid complex instead of a monomer phospholipid (23). Reticulocyte lipoxygenase is also known to oxygenize biological membranes (24), and thus, involvement of lipoxygenase activity in the maturational breakdown of mitochondria during red cell maturation has been suggested (25). In this study, we demonstrated that cucumber cotyledon lipoxygenase oxygenizes trilinolein efficiently. Several lines of evidence indicated that the lipoxygenase acts only on a substrate at the lipid/water interface, and does not act on a substrate existing as a solute in an aqueous solution. The reaction velocity curve of the oxygenation on trilinolein was highly distinctive. Because the enzyme binds essentially irreversibly to the emulsions of trilinolein and, as a result, cannot jump from one emulsion droplet to another to sample the excess droplets, the cessation of the reaction can be attributed to the local depletion of substrates in the enzyme-containing emulsion droplets. Compared with trilinolein, the hydroperoxide derivatives of trilinolein are more hydrophilic and, thus, should remain on the surface of the emulsion. This is thought to be the reason why the local concentration of substrate that is accessible to cucumber cotyledon lipoxygenase became limited as the reaction proceeded. From these observations, it can be concluded that cucumber cotyledon lipoxygenase oxygenizes trilinolein at the lipid/water interface with the following sequence: the lipoxygenase (i) recognizes the interface, (ii) is irreversibly adsorbed on the surface, and (iii) oxygenizes one of the linoleates esterified to the glycerol moiety. Jain and Gelb (26) have developed the enzyme kinetics for the so-called scooting mode for several enzymes that act on lipids at the lipid/water interface. Although a precise definition of the properties of the substrate emulsions used in this study is needed, the catalysis by cucumber cotyledon lipoxygenase of trilinolein also may be assessed by scooting mode kinetics. Although there is no report on the scooting mode of action of any lipoxygenases, it should be noticed that most plant lipoxygenases investigated so far have optimum pH values at around 5.5–6.5 (2,3). At such pH values, linoleic and linolenic acids are thought to form aggregates under the assay conditions usually used. Thus, it is reasonable to expect that such plant lipoxygenases also act, at least preferentially, on substrates at the interface.

The observations described here raise two important questions about this enzyme. One, a biochemical question, is how the lipoxygenase differentiates a substrate at the lipid/water interface from one dissolved in aqueous solution. The enzyme cannot act on the monomeric form of linoleic acid but can act on the aggregated form. In order to facilitate such differentiation, the enzyme activity must be latent until it binds to the interface. Upon binding to the interface, the enzyme would be activated, probably by undergoing a structural change. Such a regulation of an enzyme activity after interfacial binding is known to occur with several kinds of enzymes, including human lipoprotein lipase (27), pig pancreatic phospholipase A_2 (28), human pancreatic lipase (29), and others. Although the precise tertiary structure of cucumber cotyledon lipoxygenase has not been reported, that of soybean lipoxygenase-1 has been reported (30). It is interesting that the tertiary structure of the N-terminal domain forms a β barrel similar to that of the COOH-terminal portion of human pancreatic lipase (29). Such an adsorption-mediated activation mechanism, if present in cucumber cotyledon lipoxygenase, might be more complicated than these other examples, because in the case of lipoxygenase, product activation that accompanies oxidation of the enzyme from the Fe(II) form to the Fe(III) form (20) should be taken into consideration.

The second question is whether the enzyme's activity on triacylglycerol has any physiological significance. Developmental changes in cucumber cotyledon lipoxygenase activity after germination of the seeds showed a high correlation with the degradation rate of seed storage fats (3,4). Thus, it is expected that the enzyme's activity on triacylglycerol has significance in the mobilization of the carbon and in the production of energy from stored fats. In fact, a lipid body in cucumber cells is reported to bind lipoxygenase on its surface (31). Nonetheless, it has been widely accepted that the stored fats are degraded sequentially by lipase hydrolysis, β-oxidation, and gluconeogenesis (5). Recently, it has been reported that a lipid hydroperoxide is a better substrate than unoxidized lipid for a plant phospholipase (32). Thus, it is expected that oxygenation of triacylglycerols in lipid bodies by cucumber cotyledon lipoxygenase might be a trigger for hydrolysis. In order to test this hypothesis, properties of cucumber cotyledon lipase have to be examined in detail.

ABSTRACT: Using the spectrofluorimetric method described by Wittenauer *et al.* [Wittenauer, L.A., Shirai, K., Jackson, R.L., and Johnson, J.D. (1984) *Biochem. Biophys. Res. Commun. 118,* 894–901] for phospholipase A_2 (PLA_2) measurement, we have detected a phospholipase activity in Ailsa Craig and in mutant *rin* tomatoes at their normal harvest time (mature green stage). This activity in Ailsa Craig tomatoes increased at the beginning of fruit ripening (green–orange stage) and then decreased slowly. The decrease in activity, however, was greater when ripening occurred after tomato picking at normal harvest time than when ripening occurred on tomato plants. This phospholipase activity was always higher in *rin* tomatoes than in normal ones. Thin-layer chromatography of compounds obtained after incubation of tomato extract demonstrated a decrease in the substrate 1-acyl-2-{6[(7-nitro-2,1,3, benzoxadiazol-4-yl)amino]-caproyl}-*sn*-glycero-3-phosphocholine (C_6-NBD-PC), and an increase in one product (NBD-aminohexanoic acid), but failed to detect the second product (1-acyl-*sn*-glycero-3-phosphocholine). We, therefore, developed a new one-step method for separation and quantification of a mixture of phospholipids and other lipids, using straight-phase–high-performance liquid chromatography with light-scattering detection. This method detected another fatty acid-releasing activity in enzyme extract from green–orange tomatoes. This lipolytic enzyme (or family of enzymes) slowly produced free fatty acids when 1-oleoyl-*sn*-glycero-3-phosphocholine was added as substrate. The production of fatty acids was stoichiometric and more rapid when 1-oleoyl-*sn*-glycero-3-phosphate and 1-oleoyl-*sn*-glycerol were used as substrates. On the other hand, the same tomato extract was unable to hydrolyze 1,2-dioleoyl-*sn*-glycero-3-phosphate and 1,2-dioleoyl-*sn*-glycerol. Crude tomato extract exhibited lipid acyl hydrolase activity according to the definition of Galliard [Galliard, T. (1979) in *Advances in the Biochemistry and Physiology of Plant Lipids* (Appelqvist, L.A., and Liljenberg, C. eds.) pp. 121–132, Elsevier, Amsterdam]. But in order to demonstrate whether tomato extract contains PLA_2 activity and/or lysophospholipase activity, further work on purified tomato extract will be necessary.
Lipids 30, 739–746 (1995).

Decrease in phospholipid content usually characterizes the onset of senescence in a wide range of plant tissues (1). In tomato fruits, Güçlü *et al.* (2) have shown that the level of total phospholipids increases during ripening and then decreases drastically.

Phospholipases are enzymes which generally catalyze the hydrolysis of phospholipids, and are classified according to the bond cleaved. Thus phospholipase A_1 (PLA_1; EC 3.1.1.3), which was not described until now in higher plants, and phospholipase A_2 (PLA_2; EC 3.1.1.4), catalyze the hydrolysis of the *sn*-1 or *sn*-2 position fatty acyl ester bond of phosphoglycerides. Lysophospholipase (EC 3.1.1.5) cleaves the single fatty acid ester bond of a lysophospholipid. In contrast to animal and microbial phospholipases, which seem to be quite specific for phospholipid substrate, no such property has been clearly demonstrated in plants (3–5), where a lipid acyl hydrolase has often been described. This enzyme most rapidly catalyzes hydrolysis at the *sn*-1 and *sn*-2 positions of the fatty acyl ester bond of phospholipids, lysophospholipids, and monoacylglycerols (4). Two other phospholipases have been described: phospholipase C (PLC; EC 3.1.4.3), which cleaves the *sn*-3 phosphodiester bond of a diacylglycerophospholipid on the glycerol side, and phospholipase D (PLD; EC 3.1.4.4), which catalyzes hydrolysis of the same bond between the phosphatidic acid and the base represented by choline, ethanolamine, glycerol, or inositol. The products obtained after hydrolysis with these enzymes are free fatty acids, lysophospholipids, diacylglycerol, and/or phosphatidic acid.

Among the enzymes responsible for lipid deterioration, lipoxygenases (LOX) peroxidize unsaturated fatty acids. Droillard *et al.* (6) have shown that LOX levels increase during tomato ripening and then decrease after the green–orange stage of maturation. They also demonstrated that free fatty

acids were better substrates for LOX than fatty acids esterified in phospholipids. In ripening tomato fruits, we studied PLA_2, which is able to release free fatty acids, the substrate for LOX activity. In ripening tomato fruits, phosphatidylcholine is the most important class among phospholipids and contains five different fatty acids: palmitic acid, stearic acid, oleic acid, linoleic acid, and linolenic acid, whose percentages vary during ripening (2). For our study of phospholipid hydrolysis in tomato fruits, we chose 1,2-dioleoyl-*sn*-glycero-3-phosphocholine as substrate in order to avoid LOX oxidation of the released free fatty acids.

PLA_2 has been widely studied in the animal kingdom, especially secreted PLA_2 from venoms and pancreas, because of their high activity. But the activities of intracellular and membrane-bound PLA_2 are very low. Two kinds of sensitive assays are therefore currently used. The most common assay involves the use of a phospholipid with a ^{14}C-labeled fatty acid in the *sn*-2 position, but this method is time-consuming and requires the use of expensive radiolabeled lipids. Because of the high sensitivity of fluorescence, Wittenauer *et al.* (7) used a fluorescent phospholipid, 1-acyl-2-{6[(7-nitro-1,2,3,benzoxadiazol-4-yl)amino]-caproyl}-*sn*-glycero-3-phosphocholine (C_6-NBD-PC), as substrate. This method is rapid and does not require any lipid extraction. It appears to be especially useful for applications, such as monitoring PLA_2 activity during maturation of tomato fruits.

As pointed out by Wittenauer *et al.* (7), Hendrickson *et al.* (8), and Moreau (9), this method is not really specific because of other phospholipases which hydrolyze C_6-NBD-PC with fluorescence enhancement. When the enzymatic extract is likely to contain different phospholipase activities or unknown activities, it is therefore also necessary to analyze the products after hydrolysis of the substrate. Consequently, we have devised a method which uses straight-phase high-performance liquid chromatography (SP–HPLC) with evaporative light-scattering detection to identify and quantify substrate and products after hydrolysis of phospholipids by tomato extract.

MATERIALS AND METHODS

Plant material. Tomato (*Lycopersicon esculentum* Mill. cv. Ailsa Craig and mutant *rin*) plants were grown in a heated greenhouse under natural light. The various stages of ripeness [mature green stage (G), green–orange (GO), orange (O), and red (R)] were determined by measurement of tomato fruit coloration with a Minolta C 100 chromameter (Minolta France S.A., Colombes, France). Mutant green ("G") fruits were harvested when the normal fruits had reached the mature green (G) stage. Since mutant *rin* tomatoes were unable to ripen, the last stage "R" was chosen at the time when the normal fruits became red.

In order to compare natural ripening on tomato plants and post-harvest ripening, mature green tomatoes (normal and mutant) were harvested and kept at 20°C. The various stages of ripeness (GO, O, and R) were determined by tomato coloration.

Reagents. C_6-NBD-PC was obtained from Avanti Polar Lipids (Alabaster, AL). 1-Palmitoyl-2-(1^{14}C)-palmitoyl-*sn*-glycero-3-phosphocholine was obtained from Amersham France (Les Ulis, France). Porcine pancreatic PLA_2 (600 units/mg protein), NBD-aminohexanoic acid and usual lipids were obtained from Sigma (St. Louis, MO). All solvents (HPLC grade) were obtained from Prolabo (Paris, France).

Preparation of tomato extracts. Three tomatoes were peeled, and fresh pericarp tissue was extracted in cold acetone (–20°C). The lipid-free powder was suspended in 100 mM HEPES buffer (pH 7.5) and leupeptin. After homogenization, filtration, and centrifugation, the supernatant was brought to 50% saturation in ammonium sulfate. The pellet was resuspensed in 100 mM HEPES buffer (pH 7.5) and desalted on a PD-10 column (Pharmacia, Uppsala, Sweden). Of the initial activity, 70% was recovered. All extraction procedures were carried out at 4°C. Ammonium sulfate precipitate could be stored at –20°C for more than five days with a very small decrease in activity.

PLA_2 assays. 1. Spectrofluorimetric assays. These were carried out essentially as described by Wittenauer *et al.* (7). The ethanolic solution of C_6-NBD-PC was injected into the thermostated fluorimetric cuvette in 50 mM HEPES buffer pH 7.1 or in 30 mM HEPES–Tris buffer pH 8.5 (5 μM of C_6-NBD-PC in a final volume of 2 mL). The emission spectrum was checked on this mixture. After a 3-min preincubation, the assay was initiated by adding 10–50 μL of tomato extract. The relative fluorescence was monitored continuously (for 10 min) with constant stirring using an Alphascan System from PTI (excitation 466 nm, emission 552 nm; Photon Technology International, Inc., South Brunswick, NJ). No relative fluorescence was found with a heat-deactivated tomato extract.

2. Radiochemical assays. These were carried out essentially as described by Palmgren *et al.* (10) and Vignon *et al.* (11), with some modifications. 1,2-diacyl-*sn*-glycero-3-phosphocholine, type X-E, from egg yolk, was dissolved in ethanol and homogenized with labeled 1-palmitoyl-2-(1^{14}C)-palmitoyl-*sn*-glycero-3-phosphocholine. Aliquots containing about 0.02 μCi were transferred into test tubes and the solvent removed. Sodium deoxycholate, $CaCl_2$, and 30 mM HEPES–Tris pH 8.5 were added before tomato extract addition and incubated at 37°C. After 10 min, the reaction was stopped, the released free fatty acids extracted, and their radioactivity was counted. PLA_2 activity was calculated from the amount of labeled fatty acid produced, with one unit defined as 1 μmol of ^{14}C-palmitoyl acid released per minute.

Analysis of hydrolytic products by thin-layer chromatography (TLC). This analysis was carried out essentially as described by Wittenauer *et al.* (7). The reaction mixture containing 5 μM of C_6-NBD-PC, 30 mM HEPES–Tris buffer, pH 8.5, 10 mM of $CaCl_2$ was injected with dialyzed PLA_2 from porcine pancreas (3.66 μg/mL of reaction mixture) or with tomato fruit extract (400 μL/mL of reaction mixture). The incubation was performed at 37°C, with magnetic stirring, for 1 h. Aliquots were taken out after 30 and 60 min and vigorously shaken in a methanol/chloroform/heptane

mixture (1.42:1.25:1, by vol). Each phase—phase a (aqueous) and phase o (organic)—was spotted on silica gel plates. The plates were developed in a solvent system of chloroform/methanol/water (65:25:4, by vol). C_6-NBD-PC and NBD-aminohexanoic acid were detected with an ultraviolet (UV) lamp. The other phospholipid and lipid spots were examined under UV light after being sprayed with Primulin (Sigma).

Characterization and quantification of 1,2-dioleoyl-sn-glycero-3-phosphocholine and hydrolytic products by HPLC. 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (50 µL of chloroform solution—20 mg per mL) was placed in a test tube, and the solvent was evaporated under nitrogen. One mL of 30 mM HEPES–Tris buffer (pH 8.5) containing 0.3% deoxycholate was added to the dried lipid and vortexed vigorously.

The reaction mixture (final volume: 1 mL) containing 400 µL of tomato extract, 10 mM $CaCl_2$, 150 µM heptadecanoic acid, i.e., internal standard, and 100 µL of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine emulsion in 30 mM HEPES–Tris buffer (pH 8.5) was incubated at 37°C with magnetic stirring.

At various time intervals, 0.2 mL of assay mixture was removed, and lipids were extracted from the different samples according to the procedure of Bligh and Dyer (12). The chloroform layer (0.5 mL) was dried under a nitrogen stream, and the dried sample was resolubilized in 0.2 mL of chloroform; 20 µL of the solution was analyzed by SP–HPLC.

SP–HPLC was carried out with an Ultrasphere silica (5 µm) column (250 x 4.6 mm, Beckman, Fullerton, CA). Two mobile phases were prepared: phase A, chloroform/methanol/ammonia (84:15.5:0.5, by vol) and phase B, chloroform/methanol/water/ammonia (60:34:5.5:0.5, by vol). The column was equilibrated with 100% phase A. The flow rate of the eluent was kept constant at 1 mL/min at room temperature. The solvent program was: 13 min 0% phase B, 6 min 0–100% phase B, 12 min 100% phase B. The effluent was monitored using an evaporative light-scattering detector/DDL 21 (Cunow, Cergy Pontoise, France) with a nebulization temperature of 50°C and a carrier gas (air) pressure of 1.8 bar.

Gas chromatography. Lipids were extracted with Dole's reagent (propanol/heptane/1 N H_2SO_4; 4:1:0.1, by vol) before methylation according to Metcalfe *et al.* (13). For quantitative determination, a known amount of heptadecanoic acid was added as an internal standard. The methylated fatty acid esters were analyzed on a Girdel (Suresnes, France) type 30 gas chromatograph, using a Carbowax column 0.32 mm in diameter and 25 m long. The carrier gas was helium, the column temperature 165°C, the detector temperature 250°C, and the injection temperature 230°C.

RESULTS

Measurement of phospholipase activity in ripening tomato fruits by spectrofluorimetric assay. The activity increased between stages G and GO and then decreased when the fruits were submitted to ripening on tomato plants or post-harvest ripening (Fig. 1). Activities measured in post-harvest tomatoes were always slightly lower than those in fruits ripened on tomato plants, but the variability from one harvest to another was higher when the fruits were post-harvest ripened.

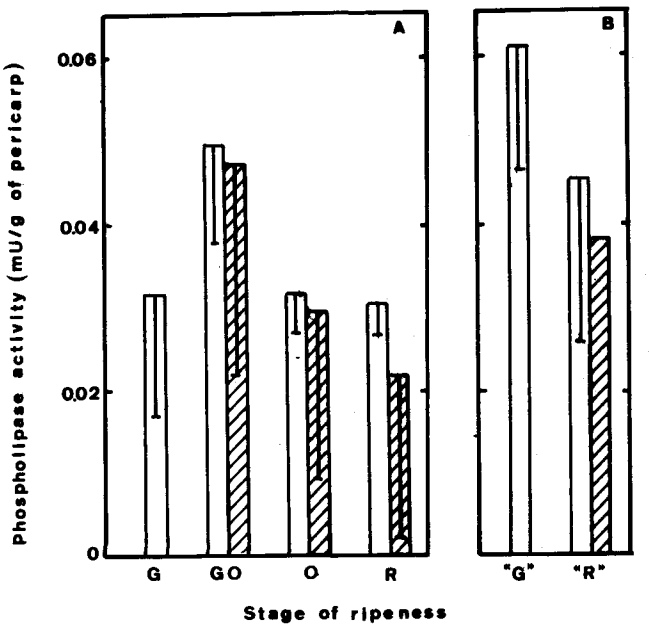

FIG. 1. Phospholipase activity, measured by spectrofluorimetry in normal (A) and in mutant fruits (B), allowed to ripen on tomato plants (white bar) or after harvest at green stages and keeping at 20°C (striped bar). The values are the average with standard deviation of three tomato harvests; G, green; GO, green–orange; O, orange; R, red; "G," mutant green; "R," mutant fruits chosen at the time when the normal fruit becomes red.

The activity in mutant green ("G") fruits was very high in comparison with the normal green (G) tomatoes. In the mutant *rin* fruits, phospholipase activity decreased more when the fruits were post-harvest ripened at 20°C than when they were kept on tomato plants. Surprisingly, activity was higher in mutant *rin* tomatoes, which were unable to ripen, than in ripening normal fruits.

In order to characterize this phospholipase activity, all further assays use extracts from normal tomatoes harvested at the GO stage.

Optimization of spectrofluorimetric assays. The activity of a tomato fruit extract in a fluorimetric cuvette measured by relative fluorescence was multiplied by about 2.5 when the temperature was increased from 25 to 37°C and the pH from 7.1 to 8.5 (Table 1). The activity of a solution of porcine pancreatic PLA_2 increased noticeably at 37°C and pH 8.5 when 10 mM $CaCl_2$ was added. The addition of 0.03% sodium deoxycholate enhanced this increase (results not shown). With tomato extract, this increase was not observed either with $CaCl_2$ or with sodium deoxycholate and $CaCl_2$. In order to determine the true nature of the phospholipase activity revealed by the spectrofluorimetric method, we analyzed the products of the incubation reaction of C_6-NBD-PC with tomato extract.

Study of the products obtained during spectrofluorimetric assays. The products obtained after incubation of C_6-NBD-

[a]From tomato fruits determined by spectrofluorimetric assay. The results are expressed by variation of relative fluorescence for 1000 s. Experimental conditions as described in the Materials and Methods section.

PC with PLA_2 or tomato extract were analyzed by TLC. When C_6-NBD-PC was incubated with porcine pancreatic PLA_2, the intensity of the spot which corresponds to C_6-NBD-PC in the organic phase (Fig. 2B) decreased with time. In the aqueous phase, two spots appeared, one near the solvent front corresponding to NBD-aminohexanoic acid (compare with Fig. 2A, line 6), and the second near the starting line corresponding to 1-oleoyl-*sn*-glycero-3-phosphocholine (compare with Fig. 2A, line 2).

When C_6-NBD-PC was incubated with tomato extract, the decrease in C_6-NBD-PC was observed as the increase in NBD-aminohexanoic acid (Fig. 2C). However, instead of a spot of 1-oleoyl-*sn*-glycero-3-phosphocholine, two unidentified spots appeared in the aqueous phase and one in the organic phase. This result could square with the presence in the tomato extract of a family of enzyme able to hydrolyze different moieties of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine. We therefore developed an SP–HPLC method for one-step separation of a mixture of phospholipids and other lipids.

*SP–HPLC determination of the products of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine hydrolysis by porcine pancreatic PLA_2.* Incubation of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine with porcine pancreatic PLA_2 gave, within 35 min and after extraction of lipids, a typical profile as shown in Figure 3. The substrate, i.e., 1,2-dioleoyl-*sn*-glycero-3-phosphocholine, and both products, i.e., oleic acid and 1-oleoyl-*sn*-glycero-3-phosphocholine, were separated in one step.

In order to confirm the identity and quantify the peaks, standard solutions of heptadecanoic acid, oleic acid, 1-oleoyl-*sn*-glycero-3-phosphocholine, and 1,2-dioleoyl-*sn*-glycero-3-phosphocholine were injected into the chromatographic system.

The concentrations of the different compounds found in the reaction mixture containing 1,2-dioleoyl-*sn*-glycero-3-phosphocholine and porcine pancreatic PLA_2 were determined by SP–HPLC using the calibration curves (Fig. 4). An excellent stoichiometry between the digested 1,2-dioleoyl-*sn*-glycero-3-phosphocholine and both products of hydrolysis by PLA_2 was obtained for high concentrations (>100 μM) of oleic acid and 1-oleoyl-*sn*-glycero-3-phosphocholine produced (Fig. 5). For lower concentrations, oleic acid and 1-oleoyl-*sn*-glycero-3-phosphocholine are probably undervalued because of the lower sensitivity of our method for these products. The validity of values obtained by SP–HPLC for oleic acid was checked using gas chromatography. In the reaction mixture containing 1,2-dioleoyl-*sn*-glycero-3-phosphocholine and PLA_2, two aliquots were taken, one for SP–HPLC determination, which was extracted according to the procedure of Bligh and Dyer (12), and one for gas–liquid chromatography, which was extracted with Dole's reagent before methylation. The values obtained were the same (results not shown). For SP–HPLC, the detection limit of oleic acid was 170 ng, i.e., 30 μM. The coefficient of variation, for 8 injections of 150 μM of heptanoic acid, i.e., internal standard, was about 8%. Gas chromatography was found to be about 10-fold more sensitive than SP–HPLC and the coefficient of variation was about 3%.

*SP–HPLC determination of the products of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine hydrolysis by tomato extract.*

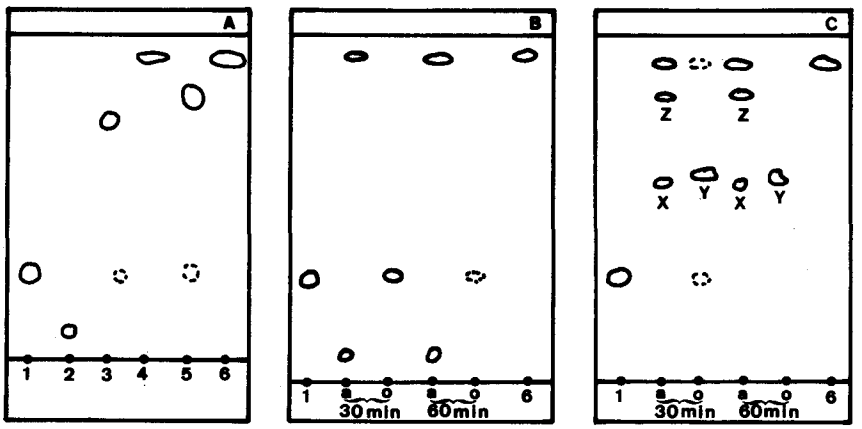

FIG. 2. Thin–layer chromatogram on silica gel plates. Standards in MeOH (A). Separation of 1-acyl-2-{6[(7-nitro-2,1,3,benzoxadiazol-4-yl)amino]-caproyl}-*sn*-glycero-3-phosphocholine (C_6-NBD-PC) hydrolysis products after 30 and 60 min of incubation with porcine pancreatic phospholipase A_2 (B) and tomato extract (C), a = aqueous phase; o = organic phase. 1 = C_6-NBD-PC; 2 = 1-oleoyl-*sn*-glycero-3-phosphocholine; 3 = 1,2-dioleoyl-*sn*-glycero-3-phosphate; 4 = 1-oleoyl-*sn*-glycerol; 5 = 1-oleoyl-*sn*-glycero-3-phosphate; 6 = NBD-aminohexanoic acid; x,y,z = unknown products.

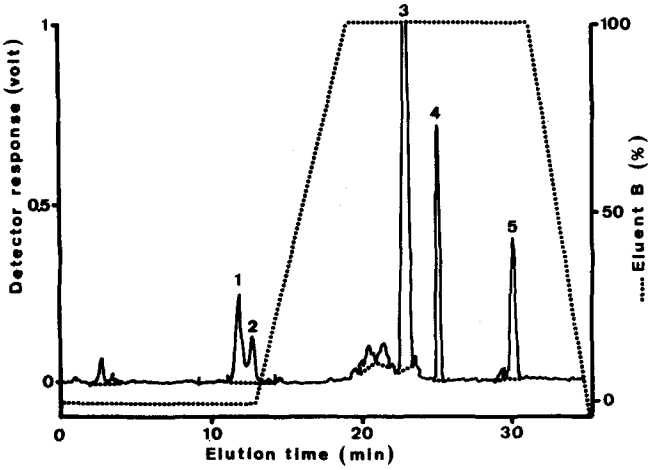

FIG. 3. Typical straight-phase high-performance liquid chromatography separation of lipids after incubation of porcine pancreatic phospholipase A_2 (PLA_2) with 254 μM 1,2-dioleoyl-*sn*-glycero-3-phosphocholine. Assay was performed with 10 mM $CaCl_2$, 0.03% deoxycholate in 30 mM HEPES–Tris buffer, pH 8.5, and 2.5 μg PLA_2 (final volume: 3 mL) at 37°C. Elution conditions are described in the Materials and Methods section. Peaks: 1 = oleic acid; 2 = heptadecanoic acid; 3 = deoxycholate; 4 = 1,2-dioleoyl-*sn*-glycero-3-phosphocholine; 5 = 1-oleoyl-*sn*-glycero-3-phosphocholine.

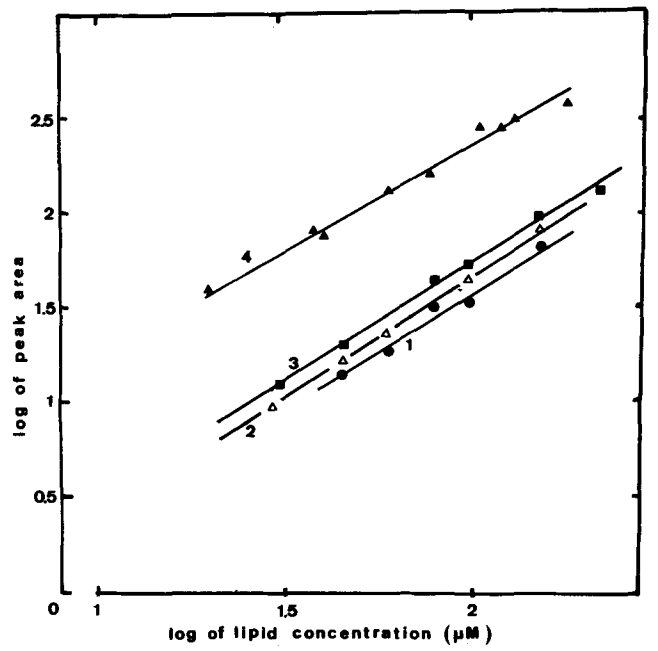

FIG. 4. Calibration curves, according to Stolyhwo *et al.* (Ref. 27), log/log plot of detector response (peak area) against concentration of lipid injected (μM). 1 (●) heptadecanoic acid, 2 (△) oleic acid, 3 (■) 1-oleoyl-*sn*-glycero-3-phosphocholine, 4 (▲) 1,2-dioleoyl-*sn*-glycero-3-phosphocholine. Stock solutions of fatty acids were in ethanol and phospholipids were emulsified in 30 mM HEPES–Tris buffer, pH 8.5, with 0.03% deoxycholate. These solutions were diluted to different concentrations in 30 mM HEPES–Tris buffer, pH 8.5, and lipids were extracted before straight-phase high-performance liquid chromatography analysis.

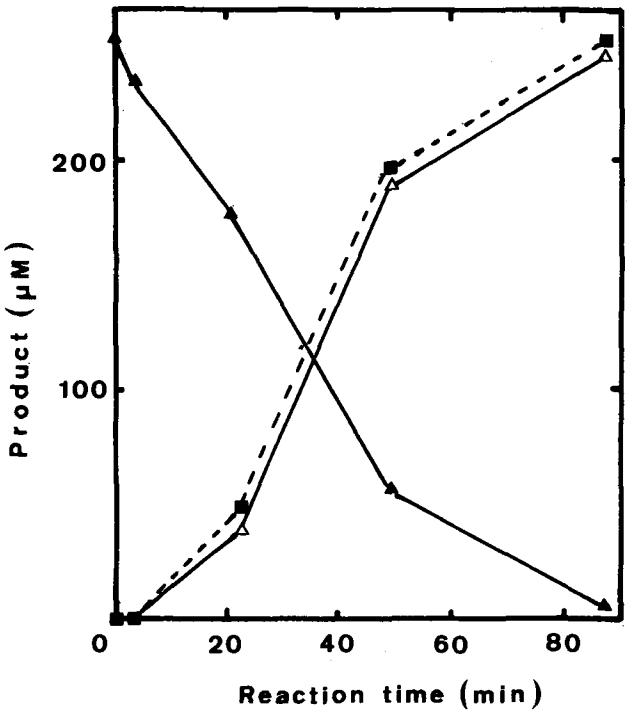

FIG. 5. Straight-phase high-performance liquid chromatography determination of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine hydrolysis, oleic acid, and 1-oleoyl-*sn*-glycero-3-phosphocholine release during incubation with porcine pancreatic PLA_2 at 37°C. Incubation conditions as in Figure 3. (▲) 1,2-dioleoyl-*sn*-glycero-3-phosphocholine; (△) oleic acid; (■) 1-oleoyl-*sn*-glycero-3-phosphocholine. See Figure 3 for abbreviation.

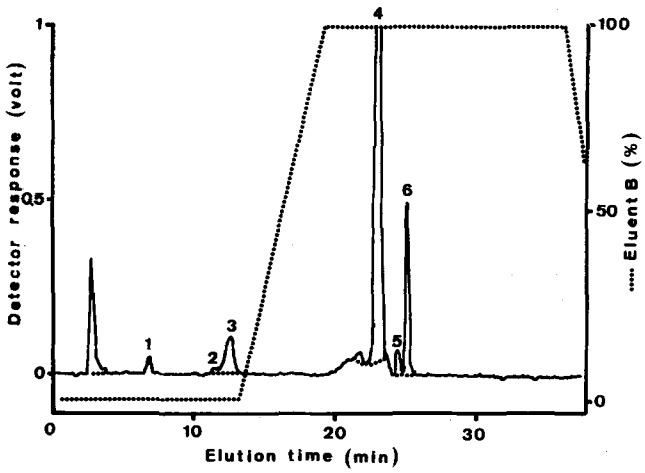

FIG. 6. Typical straight-phase high-performance liquid chromatography separation of lipids after incubation of tomato extract with 127 μM 1,2-dioleoyl-*sn*-glycero-3-phosphocholine. Assay was performed with 10 mM $CaCl_2$, 0.03% deoxycholate in 3 mM HEPES–Tris, pH 8.5, and 1.2 mL of tomato extract (final volume: 3 mL) at 37°C. Elution conditions are described in the Materials and Methods section. Peaks: 1 = unknown; 2 = oleic acid; 3 = heptadecanoic acid; 4 = deoxycholate; 5 = 1,2-dioleoyl-*sn*-glycero-3-phosphate; 6 = 1,2-dioleoyl-*sn*-glycero-3-phosphocholine.

Incubation of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine with tomato extract gave within 110 min, and after an extraction of lipids, a typical profile as shown in Figure 6. The substrate decreased progressively with time, but only a small amount of oleic acid appeared and no 1-oleoyl-*sn*-glycero-3-phosphocholine (Fig. 7). Some 1,2-dioleoyl-*sn*-glycero-3-phosphate

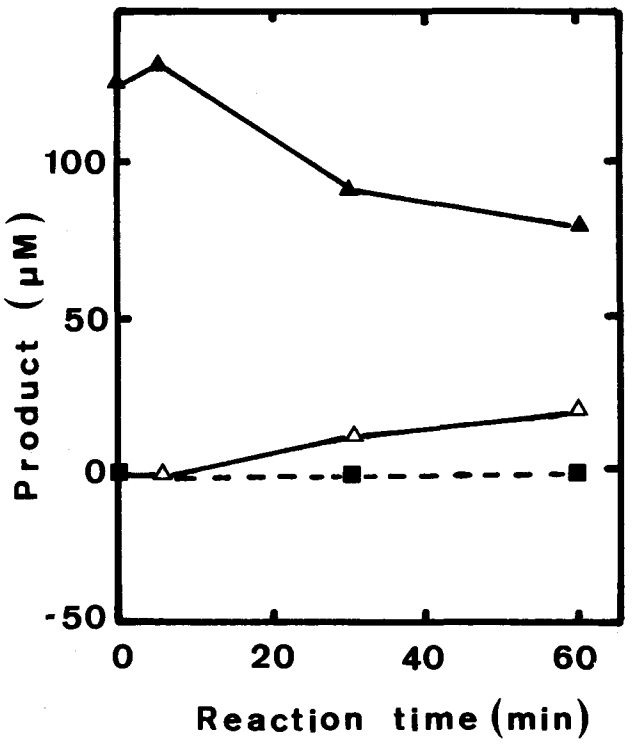

FIG. 7. Straight-phase high-performance liquid chromatography determination of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine hydrolysis and oleic acid release during incubation with tomato extract at 37°C. Incubation conditions as in Figure 6. (▲) 1,2-dioleoyl-*sn*-glycero-3-phosphocholine; (△) oleic acid; (■) 1-oleoyl-*sn*-glycero-3-phosphocholine.

TABLE 2
Comparison of Three Methods of Measurement of Phospholipase A_2 (PLA_2) Activity[a]

	Tomato extract	Porcine pancreatic PLA_2
SP–HPLC[b]	$1.7\ 10^{-4}$	1.14
Radioactivity	$1.9\ 10^{-4}$	0.95
Spectrofluorimetry	$2.6\ 10^{-4}$[c]	0.06

[a]Results are expressed in µmole of fatty acid released/min/mg protein. Experimental conditions as described in the Materials and Methods section.
[b]Straight-phase high-performance liquid chromatography.
[c]Measurement without addition of $CaCl_2$ in the reaction mixture.

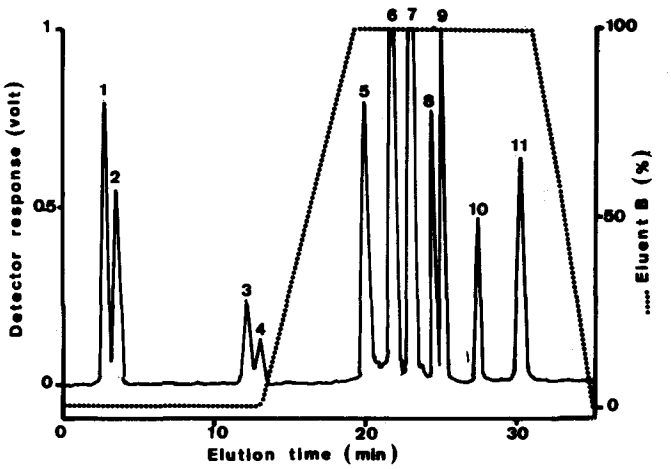

FIG. 8. Elution profile of standard lipids by straight-phase high-performance liquid chromatography (SP–HPLC). Elution conditions are described in the Materials and Methods section. Peaks: 1 = 1,2,3-trioleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, 1,3-dioleoyl-*sn*-glycerol, and oleic acid oleoyl ester; 2 = 1-oleoyl-*sn*-glycerol, 3 = oleic acid; 4 = heptadecanoic acid; 5 = 1,2-dioleoyl-*sn*-glycero-3-[phospho-*rac*-(1-glycerol)]; 6 = diphosphatidylglycerol; 7 = deoxycholate; 8 = 1,2-dioleoyl-*sn*-glycero-3-phosphate ; 9 = 1,2-dioleoyl-*sn*-glycero-3-phosphocholine; 10 = 1-oleoyl-*sn*-glycero-3-phosphate; 11 = 1-oleoyl-*sn*-glycero-3-phosphocholine. Stock solutions of glycerides and fatty acids were in ethanol and phospholipids were emulsified as in Figure 4. After dilution in 30 mM HEPES–Tris buffer, pH 8.5, lipids were extracted before SP–HPLC analysis.

also appeared (see Fig. 6, peak 5), as did an unknown product more apolar than oleic acid (see Fig. 6, peak 1). The level of 1,2-dioleoyl-*sn*-glycero-3-phosphate found by SP–HPLC was very low (peak area <20) and did not significantly change, or slightly increased, with incubation time, depending on the experiments.

Because of the unexplained low level of oleic acid liberated in comparison with the substrate consumed we checked the SP–HPLC method by the radiochemical assay, which is a currently used method. Expressed in µmole of fatty acid released/min/mg protein, the values obtained with tomato extract were approximately the same whether the measurements of phospholipase activity were made by SP–HPLC, spectrofluorimetry, or radioactivity (Table 2). Using porcine pancreatic PLA_2, results were approximately the same for SP–HPLC and radioactivity, but not for spectrofluorimetry. Moreau (9) reported that the rate of hydrolysis of NBD-phospholipids by porcine pancreatic PLA_2 is several hundredfold lower than the rates of hydrolysis of the natural phospholipids used for radiochemical and SP–HPLC methods.

In order to determine the nature of the unknown product, eight apolar lipids were dissolved in ethanol, introduced into the reaction mixture without enzyme, extracted in chloroform, and analyzed by SP–HPLC (Fig. 8). None of these apolar lipids had the retention time of the unknown product.

Substrate specificity of tomato extract. Six polar lipids were checked in order to determine retention time of potential substrates or products of phospholipases or lipases that could be present in the tomato extract. These standards were solubilized as 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (see the Materials and Methods section), introduced into the reaction mixture without enzyme, extracted by the procedure of Bligh and Dyer (12), and analyzed by SP–HPLC (Fig. 8). All these phospholipids were correctly separated.

The loss of 1-oleoyl-*sn*-glycero-3-phosphocholine when 1,2-dioleoyl-*sn*-glycero-3-phosphocholine was incubated with tomato extract could be due to hydrolysis of 1-oleoyl-*sn*-glycero-3-phosphocholine by tomato extract.

Like 1,2-dioleoyl-*sn*-glycero-3-phosphocholine, 1-oleoyl-*sn*-glycero-3-phosphocholine was a substrate for tomato extract, but, as with 1,2-dioleoyl-*sn*-glycero-3-phosphocholine, the oleic acid concentration was lower than the 1-oleoyl-*sn*-glycero-3-phosphocholine consumed (Table 3). The unknown product did not appear when 1-oleoyl-*sn*-glycero-3-phospho-

TABLE 3
Hydrolytic Activity of Tomato Extract on Different Substrates Determined by SP–HPLC Assay[a]

	PC (μM)	LysoPC (μM)	LysoPA (μM)	MAG (μM)	DAG (μM)	PA (μM)
Substrate initial concentration	127	192	229	280	160	142
Consumed substrate in 30 min	34	52	229	280	0	0
Oleic acid concentration after 30 min	12	27	229	280	0	0

[a]PC = 1,2-dioleoyl-*sn*-glycero-3-phosphocholine; LysoPC = 1-oleoyl-*sn*-glycero-3-phosphocholine; LysoPA = 1-oleoyl-*sn*-glycero-3-phosphate; MAG = 1-oleoyl-*sn*-glycerol; DAG = 1,2-dioleoyl-*sn*-glycerol; PA = 1,2-dioleoyl-*sn*-glycero-3-phosphate; SP–HPLC = straight-phase high-performance liquid chromatography. Experimental conditions as described in the Materials and Methods section.

choline was used as substrate even if the level of oleic acid was lower than the substrate consumed. There was therefore no correlation between loss of oleic acid and the presence of the unknown product. According to Reynolds *et al.* (14), PLA_2 may have lysophospholipase activity. This could explain the loss of 1-oleoyl-*sn*-glycero-3-phosphocholine after incubation of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine with tomato extract, but would require that the concentration of oleic acid be twice as high as the concentration of consumed substrate, which was not the case.

Tomato extract also was able to hydrolyze 1-oleoyl-*sn*-glycero-3-phosphate and 1-oleoyl-*sn*-glycerol and, in these cases, the reaction was stoichiometric (Table 3). However, tomato extract did not accept as substrate 1,2-dioleoyl-*sn*-glycero-3-phosphate and 1,2-dioleoyl-*sn*-glycerol.

DISCUSSION

Methods based on measurement of the release of labeled (even by a fluorescent or a radioactive probe) *sn*-2 fatty acid failed to confirm that the tomato extract contained PLA_2. The release of the labeled *sn*-2 fatty acid could be accompanied by release of the *sn*-1 fatty acid without detection of this cleavage by the radioactive or the spectrofluorimetric assay. Moreover, in the spectrofluorimetric assay using C_6-NBD-PC, the fluorescence increased even when PLC released 1-acyl-2-{6[(7-nitro-2,1,3, benzoxadiazol-4-yl) amino]-caproyl}-*sn*-glycerol, after cleavage of the *sn*-3 bond (9). It is necessary to quantitate the release of 1-acyl-*sn*-glycero-3-phospholipid and free fatty acid and the decrease in substrate in order to check the stoichiometry. Nevertheless, the C_6-NBD-PC technique, which was described by Wittenauer *et al.* (7), is sensitive and useful for enzymatic activity measurements because the assay is continuous, and does not require either lipid extraction or chromatographic separations.

The variations in phospholipase activity in the fruits, which were ripened on tomato plants, could be compared to the variation in activity in ripened "cherry tomatoes" (2) and to LOX activities measured in ripened Ailsa Craig tomatoes (6). The GO stage is characterized by peaks in total phospholipids and LOX activity. LOX is known to be most active with free fatty acids as substrate, but it is also capable of specific oxygenation of fatty acids esterified in phospholipids (6,15). On the other hand, Sevanian and Kim (16) have shown that PLA_2 preferentially removes oxidized fatty acid from membrane phospholipids. On the basis of these findings, Van Kuijk *et al.* (17) proposed that a new role for PLA_2 was protection of membranes from oxidized phospholipids. After PLA_2 action on peroxidized phospholipids, the lysophospholipid produced could presumably be reacylated with a long-chain fatty acid CoA to complete the membrane, and the peroxidized fatty acid released would be reduced by the glutathione peroxidase. This suggested role of PLA_2 is in agreement with our finding that in the mutant *rin* tomato, which is unable to ripen, phospholipase activity was higher than in normal fruits.

Leshem (18) reported that in higher plants PLA_2 activity is stimulated by Ca^{2+}, whereas Hasson and Laties (19) found that lipolytic acyl hydrolase activities do not require Ca^{2+}. The phospholipase activity of tomato extract measured by spectrofluorimetry is not stimulated by 10 mM $CaCl_2$, whereas the activity of porcine pancreatic PLA_2 is strongly stimulated. The analysis of products from C_6-NBD-PC incubation with tomato extract revealed the liberation of an *sn*-2 marked fatty acid. But the absence of the correspondent 1-oleoyl-*sn*-glycero-3-phosphocholine indicates that the extract contain a mixture of phospholipases responsible for phospholipid degradation. This method cannot enable both the detection of the liberation of the fatty acid in position *sn*-1 and NBD-aminohexanoic acid. So we cannot conclude that tomato extract contains any PLA_2-type activity.

We have devised a new, one-step SP–HPLC method of separation of the products of incubation of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine with porcine pancreatic PLA_2 which simultaneously quantitates the decrease in substrate and the increase in free fatty acid and 1-oleoyl-*sn*-glycero-3-phosphocholine. With this commercial enzymatic solution, it is possible to very rapidly characterize the nature of the enzyme and to check the values obtained with the spectrofluorimetric methods. Using our SP–HPLC technique, we have shown that the crude tomato extract contained some lipolytic enzymes able to hydrolyze stoichiometrically, 1-oleoyl-*sn*-glycero-3-phosphate and 1-oleoyl-*sn*-glycerol. This extract also was able to hydrolyze 1,2-dioleoyl-*sn*-glycero-3-phosphocholine and 1-oleoyl-*sn*-glycero-3-phosphocholine, but in these cases, the oleic acid increase was less marked than the decrease in the substrates. In the presence of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine, no 1-oleoyl-*sn*-glycero-3-phosphocholine was detectable, but an apolar product appeared as well as a small quantity of 1,2-dioleoyl-*sn*-glycero-3-phosphate in the reaction mixture.

The low level of oleic acid obtained after incubation of 1,2-dioleyl-*sn*-glycero-3-phosphocholine with tomato extract is difficult to understand. Oleic acid is not a substrate for LOX (20), so the idea of its oxidation by lipoxygenases can-

not be entertained. Other oxidations are able to transform oleic acid into epoxystearic acid, but the retention time of epoxystearic acid, measured by SP–HPLC assay, was the same as that of oleic acid. When commercial oleic acid was added to tomato extract and 1,2-dioleyl-*sn*-glycero-3-phosphocholine in the reaction mixture, no change in oleic acid was seen after one hour of incubation; there was no special activity in the tomato extract responsible for the loss of oleic acid after incubation with this substrate.

It is possible to conclude that the crude tomato extract contained phospholipase activity, as demonstrated by Vrbova *et al.* (21), and also lipolytic acyl hydrolase activity according to the definition given by Galliard (4). This author considers that deacylation of phospholipids in higher plants is catalyzed by a lipid acyl hydrolase of wide substrate specificity. A wide range of lipids is hydrolyzed: lysophospholipids and monoacylglycerols are deacylated most rapidly; phospholipids, galactolipids are also hydrolyzed, but triacylglycerols ("lipase" substrate) are not attacked.

Higher plant PLA_2 is scarcely documented. In potato, a putative PLA_2 was found, using the spectrofluorimetric method described by Wittenauer *et al.* (7), in leaves by Moreau (22), and in tubers by Kawakita *et al.* (23). The enzymatic activity was low in the membrane fraction in comparison with that found in the supernatant fraction. In potato tubers and leaves, only the soluble enzyme was shown to be Ca^{2+}-dependent. Gross *et al.* (24) and Cho and Boss (25) used the spectrofluorimetric method to determine PLA_2 activity in carrot cell cultures. Scherer and André (26) measured PLA_2 activity in the microsomal fraction of cultured soybean cells by the accumulation of radioactive 1-acyl-*sn*-glycero-3-phosphocholine hydrolyzed from radioactive 1,2-diacyl-*sn*-glycero-3-phosphocholine in membranes prelabeled with ^{14}C-choline *in vivo*. This result, obtained by a specific method, suggests there is true PLA_2 activity in higher plants and encourages us to search in the future for PLA_2 activity in purified enzymatic extract of tomato fruits.

ABSTRACT: Substrate specificity of the acyltransferase activity of the lipase (EC 3.1.1.3) from *Candida parapsilosis* CBS 604 was studied in aqueous media. The specificity toward both acid and alcohol parts of a large number of acylglycerols and aliphatic esters was investigated. This lipase showed a high activity in the presence of esters with long-chain fatty acids and particularly unsaturated fatty acids with a *cis*-Δ9 double bond. It was observed that the activity profile depended not only on the alcohol part of the acyl ester, but also on the temperature of the reactant medium. The best lipid substrates had their melting point between −40 to +20°C, 14 to 18 carbon atoms in the acyl group and 1 to 4 carbon atoms in the alkyl group. The enzyme, defined as an acyltransferase in a previous paper, showed a high affinity for primary and secondary alcohols with a short carbon chain (1 to 5 carbon atoms) as acyl acceptors. The influence of free alcohols in the reactant medium on the hydrolysis and alcoholysis activities of the enzyme is discussed. Two phenomena seem to be involved, depending on the alcohol: competition with water for the acyltransfer reaction and lipid substrate dilution when the alcohol places at the oil/water interface.
Lipids 30, 747–754 (1995).

Lipases (EC 3.1.1.3) are characterized by their ability to catalyze the rapid hydrolysis of ester bonds at the interface between an insoluble substrate phase (triacylglycerols) and an aqueous phase in which the enzyme is dissolved. Lipases are sometimes able to operate in poorly hydrated organic media in which lipids are soluble. Under such conditions, numerous lipases catalyze reactions such as alcoholysis, transesterification, and synthesis of esters of fatty acid (FA). This process has many advantages over conventional chemical catalysis for the production of peculiar esters. In particular, the reaction is performed under mild conditions which prevent the polymerization of polyunsaturated FA (1). Besides, reactions catalyzed by lipases are often highly specific. As lipases react in a heterogeneous system, the substrate specificity may depend not only on the chemical structure of substrate molecules but also on the physical properties of the emulsion. The numerous reports on the specificity of lipases generally focus on the influence of the chemical structure (notably FA chain length and unsaturation and FA location in the glycerides) and of the chiral properties of the substrates, but do not take into consideration their physical properties. Nevertheless, it has been shown that the surface pressure of substrate monolayers is a factor affecting the rate of hydrolysis catalyzed by pancreatic lipase (2). It has also been found that the activity spectrum of the lipase from *Chromobacterium viscosum* varies with the reactant medium temperature (3).

In recent publications, we have shown and described the acyltransfer activity of the lipase from *Candida parapsilosis* in aqueous media (4,5). In the presence of methanol in the aqueous phase, methyl esters were produced by alcoholysis of triacylglycerols, and, under optimal conditions, hydrolysis of the substrates and the products was almost completely inhibited. Hydrolysis was not reversible under the reaction conditions used. The present paper describes the substrate specificity of this lipase in aqueous media. We have studied the importance of the nature of both acid and alcohol parts of the substrates with attention to their physicochemical properties.

MATERIALS AND METHODS

Organism. The strain used was *C. parapsilosis* (Ashford, Langeron, and Talice), CBS 604, obtained from the Centraalbureau voor Schimmelcultures, Yeast division (Delft, Holland).

Culture techniques. All cultures were performed in Erlenmeyer flasks filled to 10% of their volume, incubated at 28°C, and shaken at 80 oscillations min^{-1} (amplitude 7 cm). The basal medium was medium G (6) adjusted to pH 6.5 with a 50 mM NaH_2PO_4/Na_2HPO_4 phosphate buffer. The carbon source was rapeseed oil (0.5% wt/vol) sterilized by autoclaving at 120°C for 20 min.

Enzyme extract and substrates preparation. The culture was defatted three times with hexane (vol/vol) at the end of the exponential phase. The cells were then harvested by centrifugation (7000 × *g*, 15 min). The supernatant contained the enzyme, which was then purified according to Riaublanc *et al.* (7). The lipid substrates were emulsified (5% wt/vol) in an aqueous poly(vinyl alcohol) solution (2% wt/vol) by sonication as described by Biehn and Ernsberger (8).

Analytical techniques: (i) Gas chromatography (GC). Short-chain FA and long-chain FA methyl esters were sepa-

rated using a fused apolar capillary column coated with DB23 (30 m × 0.25 mm i.d., film thickness 0.25 μm; J&W Scientific, Folsom, CA). Temperatures of the injector and of the flame-ionization detector were 200 and 250°C, respectively. For short-chain FA, the column oven was kept at 80°C for 1 min then heated up to 120°C (1°C · min^{-1}), while for long-chain FA methyl esters the column oven was kept at 140°C for 1 min then heated up to 200°C following a temperature gradient of 2.5°C min^{-1}.

(ii) High-performance liquid chromatography (HPLC). The column used was a Spherisorb ODS2 (250 × 4.6 mm, particule size 5 μm; Alltech Associates, Inc., Deerfield, IL) thermostated at 30°C. Absorbance was read at 210 nm. The solvent was acetonitrile/acetone (1:1, vol/vol). The flow rate was maintained at 0.8 mL/min for 6 min, then increased from 0.8 to 2 mL/min in 4 min, maintained at 2 mL/min for 22 min, and finally decreased to 0.8 mL/min in 4 min.

(iii) Thin-layer chromatography (TLC). Migration was carried out on silica 60G (20 × 10 cm × 0.25 mm; Merck, Darmstadt, Germany) using a hexane/diethyl ether/acetic acid mixture (70:30:1, by vol). The plates were dried and sprayed with a copper acetate/orthophosphoric acid mixture (1:1, vol/vol) before charring at 180°C for 10 min to visualize the sample bands.

(iv) Melting point determination. Melting points were determined using a Mettler FP5 apparatus, equipped with an FP51 cell (Mettler instrumente AG, Zürich, Switzerland).

Enzyme assays: (i) Standard reaction conditions. An emulsion of lipid substrate (200 μL) was added to 2 mL of a 50 mM NaH_2PO_4/Na_2HPO_4 phosphate buffer, pH 6.5, containing the purified enzyme (0.16 U) and the alcohol of interest at various concentrations. The reaction was carried out at 45°C for 15 min and was stopped by the addition of an ethanol/acetone/sulfuric acid (50:50:0.1, by vol) mixture. Long-chain acids or esters were extracted with hexane. Acetic, butyric, and propionic acids and methyl esters were determined in the aqueous phase. One enzyme unit (U) is the quantity of enzyme that releases 1 μmol FA from rapeseed oil in one minute in the standard conditions, in the absence of alcohol. Each experiment was done at least in triplicate and the results were expressed as the mean of three determinations. The highest error on mean was 15%.

(ii) Analysis of the products. Determination of total long-chain free FA was performed according to Van Autryve *et al.* (9). Short-chain free FA were quantified by GC. When required, long-chain free FA were first separated from the other components of the reaction medium by TLC, scraped off the plate, and then methylated. One mL of 12.5% boron trifluoride in methanol was added to the FA in a sealed ampule. This solution was heated to 100°C for 2 min in a water bath. The FA methyl esters were then extracted with hexane after the addition of 1 mL of water. Methyl esters, dissolved in acetone, were analyzed by HPLC.

Reagents. The esters studied (>99% pure) were purchased from Sigma Chemical Co. (St. Louis, MO) or Nu-Chek-Prep, Inc. (Elysian, MN). All other reagents were at least of analytical grade.

RESULTS

The bioconversion of rapeseed oil in the presence of the lipase from *C. parapsilosis* and 2.2 M methanol was followed for 8 h in the standard reaction conditions. The FA of the triacylglycerols of rapeseed oil were converted into methyl esters (53%) and free FA (11.5%). These products were separated by TLC, and their FA composition determined (Table 1). Relative frequencies of the main FA were different in oil, in the methyl esters formed by alcoholysis, and in the free FA released by the residual hydrolysis reaction. Noticeably, palmitic and stearic acids were concentrated in the free FA and almost totally absent in methyl esters. This preliminary experiment indicated that hydrolysis and methanolysis do not apparently show the same selectivity. A deeper study of the substrate specificity of the enzyme was thus undertaken.

Acyl donor specificity. Hydrolysis of various monoesters was performed under the standard conditions. The respective melting points of the substrates tested are given with the results in Table 2. Results are expressed relatively to the rate of hydrolysis of rapeseed oil (0.16 μmol free FA released in one minute in the presence of 0.16 U). The melting point data will be discussed later.

The enzyme displayed a large activity spectrum, including esters of short carbon chain alcohols, nitrophenol, sorbitol, and fatty alcohols. Methyl ester hydrolysis rates showed important variations with the nature of the acyl group. Esters of long-chain FA (more 12 carbon atoms) were the favored substrates. Monounsaturated methyl esters with a *cis*-Δ9 double bond were more rapidly hydrolyzed than both their *cis*-Δ6 and *cis*-Δ11 isomers and their saturated counterpart.

Figure 1 displays activity vs. FA chain-length profiles for aliphatic methyl esters. The graph shows a clear preference for long-chain FA with 14 to 18 carbon atoms. The profile was the same for *cis*-Δ9 monounsaturated and saturated FA, whereas monounsaturated esters were hydrolyzed at a higher rate. On the other hand, the rate of hydrolysis of oleic and lauric esters of aliphatic alcohols decreased with increasing length of the alcohol chain (Fig. 2).

Hydrolysis and methanolysis of homogeneous acylglycerols were then studied. Methanol concentration was 2.2 M, when present. The bioconversion of rapeseed oil, catalyzed by 0.16 U of the enzyme and corresponding to a relative activity of 100%, released 0.16 μmol free FA in one minute in

TABLE 1
Fatty Acid Composition of Free Fatty Acids and Methyl Esters Formed by Bioconversion of Rapeseed Oil in the Presence of 2.2 M Methanol[a]

Major fatty acids in rapeseed oil (94% of total free fatty acids)	Initial rapeseed oil substrate (%)	Methyl esters (%)	Free fatty acids (%)
Oleic acid	61.0	69.0	39.5
Linoleic and linolenic acids	32.0	31.0	7.5
Palmitic acid	6.0	1.0	42.0
Stearic acid	2.0	0.0	11.0

the absence of methanol and 0.18 μmol methyl esters in the presence of 2.2 M methanol (Table 3). A number of triacylglycerols were not or very slowly hydrolyzed. Among them were those containing saturated, Δ6-unsaturated, or *trans*-unsaturated acyl groups. Water-soluble tributyrin was also unreactive. Trilinolenin was the best substrate. It is interesting to observe that trilinolein was hydrolyzed at a higher rate than rapeseed oil, whereas it was methanolyzed at a much lower rate. This confirms the differences of selectivity of hydrolysis and methanolysis suggested by the bioconversion of rapeseed oil in the presence of methanol. It is also noticeable that, while 1,3-diolein and 1,2-diolein were hydrolyzed at the same rate, methanolysis of 1,2-diolein was more than two times as slow. This last observation is consistent with the description of the functioning of this enzyme that we have recently published (5), i.e., a 1(3)-regioselectivity—not a strict regiospecificity—of the enzyme, which is masked in the absence of a free alcohol, like methanol, due to a high rate of acyltransfer between acylglycerols; when methanol is present in the reactant medium, it competes with the free hydroxyl groups of the acylglycerols for the acyltransfer reaction, thus revealing the true regioselectivity of the enzyme.

A comparison of the hydrolysis of methyl esters and homogeneous triacylglycerols containing the same acyl groups showed differences in the activity spectrum according to the esterified alcohol (Tables 2 and 3). Saturated palmitic and stearic acid methyl esters were relatively well hydrolyzed (about half the reference activity) contrary to the corresponding triacylglycerols, which were not transformed. More curiously, hydrolysis rates of the esters of oleic, linoleic, and α-linolenic acids increased with the number of double bonds

when the alcohol part was glycerol, whereas it decreased when the esterified alcohol was methanol.

In another experiment, we have studied the hydrolysis and the methanolysis of triacylglycerols containing two palmitic and one oleic acyl groups, the latter being either on the position 1(3)- or 2- of the glycerol molecule. The results, reported in Table 4, show that: (i) 1,2-dipalmitoyl-3-oleoylglycerol is a much better substrate of the enzyme than the other positional isomer for both reactions; (ii) 1,3-dipalmitoyl-2-oleoylglycerol is a much better substrate for hydrolysis than methanolysis. More free palmitic acid than palmitic acid methyl ester was formed from this substrate. As saturated FAs are generally located on positions 1 and 3 of triacylglycerols of vegetable oils, this result explains the accumulation of free palmitic acid during the bioconversion of rapeseed oil in the presence of methanol; (iii) the location of the FA on the glycerol molecule influences both the rate of the reaction and the FA composition of the products formed.

Acyl acceptor specificity. Alcoholysis of triolein in the presence of increasing aliphatic alcohol (ranging from methanol to butanol) concentrations was analyzed in a previous work (5) in order to understand the functioning of the lipase from *C. parapsilosis* in terms of regioselectivity. In the present study, the determination of the influence of the nature and the concentration of the acyl acceptor was extended to pentanol and branched alcohols; in order to simplify the analysis of the reactant medium, the acyl donors used were oleic acid ethyl ester and triolein.

Figure 3 shows the influence of increasing alcohol concentrations on the rate of hydrolysis of oleic acid ethyl ester. The alcohols studied were of various classes, chain length (one to five carbon atoms), and some of them were branched. The intensity of the inhibition depended on the alcohol tested. For a similar concentration, inhibition by primary alcohols increased with their carbon chain length [Fig. 3 (A and B)]. For a similar carbon chain length and a similar concentration, primary alcohols were more inhibiting than secondary alcohols [Fig. 3 (C and D)]. For a similar number of carbon atoms, branched chain alcohols reduced less hydrolysis than their aliphatic counterparts (Fig. 3E). Similar results were obtained using triolein or rapeseed oil as lipid substrate, the only difference being that their hydrolysis was less inhibited than oleic acid ethyl ester hydrolysis.

The esters formed were determined by HPLC. The alcohol concentrations giving the highest quantity of esters (optimal concentration) from oleic acid ethyl ester and triolein are given in Table 5. At these concentrations, hydrolysis was strongly inhibited. For higher concentrations, both hydrolysis and alcoholysis were inhibited. Esters formed with all the alcohols tested except for tertiary butanol. The absence of affinity toward tertiary alcohols seems to be general among lipases (12,13). Although the optimal alcohol concentration decreased significantly with increasing carbon chain length of the alcohol in both cases, comparable amounts of esters formed from oleic acid ethyl ester and alcohols from methanol to butanol at the optimum, whereas methanol appeared to be the privileged substrate when the acyl donor was triolein. The amount of esters formed thus depended on the nature of both the acyl acceptor (alcohol) and the acyl donor (oleic acid ethyl ester or triolein). It is to be noted that tertiary butanol, even though not a substrate of the enzyme for the al-

TABLE 4
Hydrolysis and Methanolysis of Positional Isomers of Heterogeneous Triacylglycerols

coholysis reaction, was an inhibitor of both the hydrolysis and the methanolysis reactions (Table 6). Inhibition of both reactions was of the same level for each tertiary butanol concentration tested, indicating an inhibition of the overall acyltransfer activity.

Influence of temperature. It is well known that in the temperature range compatible with lipase activity, physical properties of lipids are very versatile and are dramatically influenced by parameters like the conformation and the location of double bonds, or the nature and the position of acyl groups

on the acylglycerols. As the susbtrate specificity of the enzyme was difficult to interpret, we wanted to check whether the physical properties of the substrates (particularly their melting point) were as important for the activity as was their chemical structure. This study was focused on hydrolysis reaction because of the numerous substrates available (Tables 2 and 3). In a general manner, the substrates with a melting point higher than 40°C were very slowly hydrolyzed. The melting point of the preferential substrates was contained between −40 and +20°C.

As temperature influences the physical properties of lipids, its effect on the hydrolysis rate of several saturated (Fig. 4A) and monounsaturated (Fig. 4B) methyl esters was examined. The results showed that whereas palmitic and palmitoleic methyl esters were the best substrates at 35 and 45°C, the activity spectrum tended to be shifted toward shorter chain FA with increasing temperatures. Hydrolysis rates of lauric, myristic, and myristoleic methyl esters increased with temperature contrary to the longer chain esters, for which hydrolysis activity was maximal at 45°C. The rate of hydrolysis of myristoleic acid methyl ester was more than doubled between 35 and 55°C, while it was reduced by one third and more than a half for palmitoleic and oleic acid methyl esters, respectively. The activity spectrum of the lipase thus varied with the temperature of the reactant medium.

DISCUSSION

The influence of the nature of the fatty acyl and alcohol parts of various esters on the hydrolysis and alcoholysis reactions, catalyzed in aqueous medium by the acyltransferase from *C. parapsilosis*, was investigated. The influence of alcohols likely to be acyl acceptors in the alcoholysis reaction was also studied. Complex results were obtained concerning the FA selectivity of the enzyme, depending on the esterified alcohol, the location of the FA on the glycerol molecule in the case of triacylglycerols, and the reaction conditions. Nevertheless, we showed that long-chain *cis*-Δ9 unsaturated FA esterified with short-chain alcohols were good acyl donor substrates and that short chain alcohols were good acyl acceptors.

Physical properties of the acylglycerols are very dependent on the esterified FA. For example, triacylglycerols of long-chain saturated and *trans*-unsaturated FA are solid at the temperature of the assay. The low activity of the enzyme on these substrates is thus likely to be largely due to their physical state. As emphasized by Jensen *et al.* (14), the melting point has a major influence on substrate emulsifiability. A slow rate of hydrolysis of solid triacylglycerols is a general feature of microbial lipases (15).

Temperature was shown to influence the activity spectrum of the enzyme. This also had been described in the case of a lipase from *Chr. viscosum* (3). However, the activity spectrum of the lipase from *Chr. viscosum* was shifted toward long-

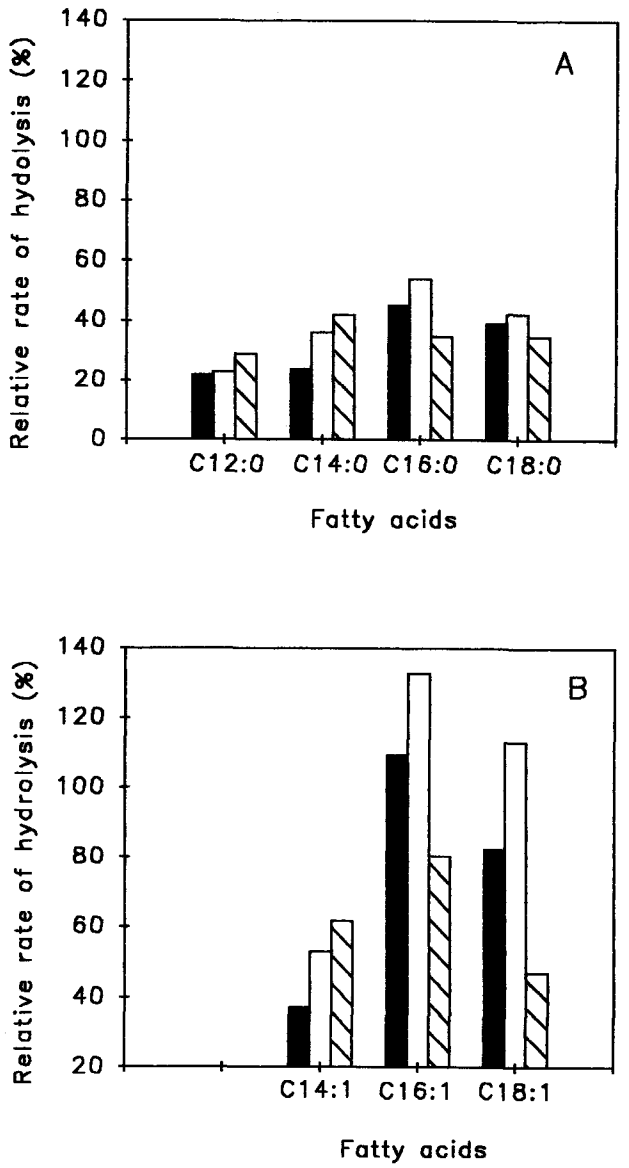

FIG. 4. Effect of the reactant temperature on the activity profile. Results are expressed as percentages of the reference activity determined in the standard conditions on rapeseed oil. 4A: Saturated methyl esters (■) 35°C, (□) 45°C, (striped bar) 55°C; B: *cis*-Δ9 monounsaturated methyl esters (■) 35°C, (□) 45°C, (striped bar) 55°C.

chain (i.e., more than 16 carbon atoms) FA when the temperature increased, whereas medium-chain (12 and 14 carbon atoms) FA were favored in the presence of the lipase from *C. parapsilosis*. A raise in the temperature of the reactant medium, by lowering the viscosity of the lipids (especially when these are saturated), will favorably modify their emulsion state. This was the explanation suggested in the case of the lipase from *Chr. viscosum*. Other phenomenons certainly superimpose in the case of the lipase of *C. parapsilosis*, as suggested by the fact that hydrolysis of palmitic and stearic esters was slower at temperatures which enhanced hydrolysis of lauric and myristic acid esters. Conformation changes of the enzyme may be involved. According to the concept of "induced fit" (16), only some substrates could release the energy required for the change in the conformation of lipases to forms which would be much more efficient catalysts. Substrates which are too small or possess too few double bonds would not be able to release enough energy. In such cases, the changes in conformation would be incomplete and optimal activity could not be achieved. A part of the energy required for the desired conformational change could be brought by thermal agitation. The state of the emulsion, and thus the quality of the interface between the enzyme and its lipid substrates, is also very dependent on the physicochemical conditions of the reactant medium and on the properties (rheology, solubility, hydrophobicity) of the substrates.

The interpretation of the influence of acyl acceptor alcohols is also complex because these compounds are not only substrates of the alcoholysis reaction but also have solvent properties which are physicochemical factors influencing the activity. They solubilize lipids and might change the lipase conformation by favoring the location of the hydrophobic groups of amino acids at the periphery of the proteins (17). The inhibition of hydrolysis by alcohols also involves several phenomena. Primary and secondary alcohols have been shown to compete with water for the acyltransfer reaction, thus inhibiting hydrolysis, in the case of the lipase of *C. parapsilosis* in aqueous medium. For alcohol concentrations higher than the optima given in Table 5, an overall inhibition effect of both hydrolysis and alcoholysis was observed. Moreover, an inhibition of the mass transfer of the lipid substrate at the reactant interface (interfacial inhibition) also has been described for various aliphatic alcohols used with pancreatic lipase (18); alcohols tend to be located at the interface, thus preventing the lipid substrate from accessing to the active area. In this case, the reaction rate was thus reduced by substrate dilution and not by competition. The inhibition effect was total when the alcohol occupied the interfacial area completely. As in our study, the less hydrophilic alcohols, i.e., the longest carbon chain alcohols, were shown to be the strongest inhibitors of hydrolysis by the pancreatic lipase.

The interfacial inhibition by alcohols certainly adds to the competition between alcohols and water in the case of the lipase from *C. parapsilosis*. Water/alcohol competition inhibits hydrolysis in favor of alcoholysis, whereas both reactions are reduced by interfacial inhibition. In the case of the short chain, very water-soluble, methanol, interfacial inhibition is negligible and competition with water is probably the main effect. In the case of longer chain alcohols, which are much less hydrophilic, the interfacial inhibition rapidly becomes the main effect with increasing alcohol concentrations. In the case of tertiary butanol, which was not a substrate of the enzyme for the alcoholysis reaction but inhibited the overall acyltransferase activity, interfacial inhibition seems to be the only effect.

The effects of substrates on the catalytic activities of the lipase of *C. parapsilosis* in aqueous medium are thus difficult to interpret in strict terms of affinity or specificity. Nevertheless, the enzyme has been shown to be able to catalyze the hy-

drolysis and the alcoholysis of a large spectrum of esters in the presence of various alcohols.

Octadecatrienoic Acids as the Substrates for the Key Enzymes in Glycerolipid Biosynthesis and Fatty Acid Oxidation in Rat Liver

Takashi Ide[a,*], Masakazu Murata[a] and Michihiro Sugano[b]

[a]Laboratory of Nutrition Biochemistry, National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Tsukuba 305 and [b]Laboratory of Food Science, Kyushu University School of Agriculture, Fukuoka 812, Japan

ABSTRACT: The activities of key enzymes in glycerolipid biosynthesis and fatty acid oxidation were compared using CoA esters of naturally occurring positional isomers of octadecatrienoic acids (18:3) as the substrates. The trienoic acids employed were 9,12,15-18:3 (α-18:3), 6,9,12-18:3 (γ-18:3), and 5,9,12-18:3 (pinolenic acid which is a fatty acid contained in pine seed oil, po-18:3). The activities of microsomal glycerol 3-phosphate acyltransferase obtained with various 18:3 were only slightly lower than or comparable with those obtained with palmitic (16:0), oleic (18:1), and linoleic (18:2) acids. Mitochondrial glycerol 3-phosphate acyltransferase was exclusively specific for saturated fatty acyl-CoA. The activities of microsomal diacylglycerol acyltransferase measured with various polyunsaturated fatty acyl-CoAs were significantly lower than those obtained with 16:0- and 18:1-CoAs. Among the polyunsaturated fatty acids, γ-18:3 gave the distinctly low activity. The V_{max} values of the mitochondrial carnitine palmitoyltransferase I were significantly higher with α-18:3 and po-18:3 but not γ-18:3, than with 16:0 and 18:2, while the apparent K_m values were the same irrespective of the types of acyl-CoA used except for the distinctly low value obtained with γ-18:3. The response to an inhibitor of the acyltransferase reaction, malonyl-CoA, was appreciably exaggerated with 18:2, α-18:3, and po-18:3 more than with 16:0 and 18:1. However, the response with γ-18:3 was the same as with 16:0. Thus, some of glycerolipid biosynthesis and fatty acid oxidation enzymes could discriminate not only the differences in the degree of unsaturation of fatty acids but also the positional distribution of double bond among the naturally occurring 18:3 acids.
Lipids 30, 755–762 (1995).

It has been demonstrated that the dietary fats containing octadecatrienoic acids, such as α-linolenic and γ-linolenic acids, exert various physiological activities in experimental animals and humans (1–6). It is probable that these polyunsaturated fatty acids exert their specific functions through the modification of prostanoid synthesis (1,6). However, they are not only metabolized by the enzymes in prostanoid biosynthesis but also are handled by those involved in glycerolipid biosynthesis and fatty acid oxidation. Thus, it is important to clarify the efficacies of these trienoic acids as substrates of the enzymes in the fatty acid esterification and oxidation pathways in order to understand their metabolic fates in the organisms. Available data suggested that some of the enzymes in these metabolic pathways in rat liver can discriminate the degree of unsaturation of fatty acid substrates. The activities of the mitochondrial glycerol 3-phosphate acyltransferase (EC 2.3.1.15) using oleoyl- and linoleoyl-CoAs as the substrates were distinctly lower than that obtained with palmitoyl-CoA (7–9). In contrast, the activity of microsomal glycerol 3-phosphate acyltransferase measured with palmitoyl-CoA has been demonstrated to be indistinguishable from that obtained with oleoyl-CoA (7–10) or linoleoyl-CoA (7). Rustan *et al.* (11) reported that microsomal diacylglycerol acyltransferase (EC 2.3.1.20) activity measured with eicosapentenoyl-CoA was considerably lower than that measured with oleoyl-CoA. However, various naturally occurring octadecatrienoic acids have not been tested as the substrates for these enzymes. With regard to the rate of oxidation of octadecatrienoic acids, Clouet *et al.* (12) reported that α-linolenic acid is oxidized at a rate greater than those observable with linoleic and oleic acids in isolated liver mitochondria. Gavino and Gavino (13) have reported that activity of mitochondrial carnitine palmitoyltransferase I (EC 2.3.1.21) measured with α-linolenoyl-CoA is higher than those measured with various fatty acyl-CoA substrates differing in the degree of unsaturation. As carnitine palmitoyltransferase I is an enzyme which regulates the rate of transport of fatty acids across the mitochondrial membrane (14), the substrate specificity of this enzyme accounts for the differences in the rates of oxidation in isolated mitochondria of fatty acids with differences in the degree of unsaturation (12,13). However, it is unknown whether octadecatrienoic acids, other than α-linolenic acid, with differences in the position of the double bonds, behave similarly as substrates for this enzyme. In these contexts, we currently measured the activities of glycerol 3-phosphate acyltransferase, diacylglycerol acyltransferase, and carnitine palmitoyltransferase I using three types of naturally occurring positional iso-

mers of octadecatrienoic acids, α-linolenic, γ-linolenic and pinolenic (5,9,12-octadecatrienoic) acids, as the substrates. Pinolenic acid is rare in nature except for its presence in pine oil, and it appears not to interfere with the metabolism of linoleic acid to arachidonic acid in contrast to α-linolenic acid (15). Thus, it would be of interest to examine whether the enzymes in fatty acid esterification and oxidation distinguish these fatty acids.

MATERIALS AND METHODS

Materials. Hexadecanoic (16:0), 9-octadecenoic (18:1), and 9,12-octadecadienoic acids (18:2) were purchased from Wako Pure Chemicals (Osaka, Japan). 9,12,15-Octadecatrienoic acid (α-18:3) was obtained from Nakarai Tesk Co. (Tokyo, Japan). 6,9,12-Octadecatrienoic acid (γ-18:3) was the product of Funakoshi Chemicals Co. (Tokyo, Japan). Purities of these fatty acids as estimated by gas–liquid chromatography were greater than 98%. 5,9,12-Octadecatrienoic acid (pinolenic acid, po-18:3), which is contained in considerable amounts (14.5% of total fatty acids) in pine oil (seeds oil from *Pinus koraiensis*) (16), was purified as the methyl ester by silver-ion chromatography using commercially available solid-phase extraction column (Mega Bond Elut™ SCX; Analytical International, Cambridge, United Kingdom) as described by Christie (17). The purity of po-18:3 thus obtained was 90.0%. The major contaminants were 18:1 (1.8%), 18:2 (3.8%), and an unidentified fatty acid (2.5%). Various fatty acids were converted to the corresponding CoA esters by the method of Kawaguchi *et al.* (18) and used as the substrates for the enzymes in glycerolipid biosynthesis and fatty acid oxidation. 1,2-Dioleoylglycerophosphorylcholine and 1,2-[1-^{14}C]-dioleoylglycerophophorylcholine were purchased from Avant Polar-Lipids Laboratories (Alabaster, AL) and Amersham International (Bucks, United Kingdom), respectively. 1,2-[1-^{14}C]-Dioleoylglycerol, used as a tracer to determine the activities of rat liver microsomal diacylglycerol acyltransferase activity, was prepared by phospholipase C treatment of [^{14}C]-labeled 1,2-dioleoylglycerophosphorylcholine and purified as described previously (19). L-[methyl-^{3}H]Carnitine chloride was purchased from Amersham International. L-[U-^{14}C]Glycerol 3-phosphate (disodium salt) was the product of New England Nuclear (Boston MA). Malonyl-CoA was the product of Sigma Co. (St. Louis, MO).

Enzyme assays. Male Sprague Dawley rats, weighing 250–350 g (Charles River Japan, Kanagawa, Japan), and maintained on commercial laboratory chow, were used throughout the present study. Rats were killed by withdrawal of blood from abdominal aorta under ether anesthesia, and livers were quickly excised. A portion of the liver (approximately 3 g) was homogenized in 7 vol of 0.25 M sucrose and centrifuged at 500 × *g* for 10 min. The supernatant was recentrifuged at 9000 × *g* for 10 min to isolate mitochondria. Mitochondria were washed twice with 0.25 M sucrose containing 10 mM Tris and 1 mM EDTA (pH 7.2) and finally suspended in the same buffer or 0.25 M sucrose containing 10 mM HEPES and 1 mM EDTA (pH 7.2) for the analyses of carnitine palmitoyltransferase I (EC 2.3.1.21) and glycerol 3-phosphate acyltransferase (EC 2.3.1.15), respectively. Microsomes were isolated from 9000 × *g* supernatant by the method of Kamath and Narayan (20). The microsomes were washed once with 0.25 M sucrose to ensure the removal of cytosols and suspended in 0.25 M sucrose containing 10 mM HEPES and 1 mM EDTA (pH 7.2). Microsomal glycerol 3-phosphate acyltransferase activity was assayed using [^{14}C(U)]glycerol 3-phosphate as an acyl acceptor and various kinds of acyl-CoAs as the acyl donors according to the method of Coleman and Haynes (21) as described previously (22,23). The incubation mixture (0.2 mL) contained 4 mM $MgCl_2$, 0.4 mg bovine serum albumin (fatty acid-free), 8 mM potassium fluoride, 10–150 μM fatty acyl-CoAs, 300 μM [U-^{14}C]glycerol 3-phosphate (5000 dpm/nmol), and 55–75 μg microsomal protein in 75 mM Tris–HCl buffer (pH 7.4). Reactions were started by adding microsomes and were incubated at 37°C for 6 min. The activity of mitochondrial glycerol 3-phosphate acyltransferase activity was assayed in the presence of 1 mM 5,5′-dithio*bis* (2-nitrobenzoic acid) using 200–300 μg mitochondrial protein. It has been reported that 5,5′-dithio*bis* (2-nitrobenzoic acid) at this concentration totally inhibits microsomal, but not mitochondrial, glycerol 3-phosphate acyltransferase activity (7). The other ingredients were the same as those used for the assay of microsomal enzyme. Mitochondria were preincubated at 37°C in the mixture containing 1 mM 5,5′-dithio*bis* (2-nitrobenzoic acid) but devoid of acyl-CoA and glycerol 3-phosphate for 2 min, and the enzyme reactions were started by adding these substrates. Microsomal diacylglycerol acyltransferase activity (EC 2.3.1.20) was determined according to the method of Rustan *et al.* (11). The assay mixture (0.5 mL) contained 8 mM $MgCl_2$, 0.5 mg bovine serum albumin (fatty acid-free), 5–60 μM various acyl-CoAs, 125 μM 1,2-dioleoylglycerol dispersed in ethanol (final concentration was 10%, vol/vol), and microsomes in 175 mM Tris–HCl buffer (pH 7.8). It has been reported that 1,2-dioleoylglycerol, among the various molecular species of diacylglycerol substrates, gave the highest enzyme activity (19,24) and is commonly used as the substrate to measure the activity of this enzyme (11,21,25). The amounts of microsomes employed and the enzyme reaction time were 15–20 μg protein and 3 min, respectively. Triacylglycerols formed were extracted and separated by thin-layer chromatography using a solvent system of petroleum ether/diethyl ether/acetic acid (82:18:1, by vol) and visualized with iodine vapor. The triacylglycerol fraction was scraped off and the radioactivity was counted by a liquid scintillation counter. Carnitine palmitoyltransferase I activity was determined using freshly isolated mitochondria as an enzyme source according as the method of Bremer *et al.* (26). The assay mixture (1.0 mL) contained 82 mM sucrose, 70 mM KCl, 35 mM imidazole, 35 mM HEPES, 1 mM reduced glutathione, 2 mM KCN, 4 mg bovine serum albumin (fatty acid-free), 0.5 mM L-[methyl-^{3}H] carnitine (2220 dpm/nmol), 10–200 μM various acyl-CoAs, and mitochondria (150–250 μg protein). The pH of the

mixture was 7.0. The enzyme reaction was initiated by adding mitochondria and incubated at 30°C for 5 min. The reaction was terminated by adding 2 mL of 6% perchloric acid. After standing at least for 15 min in ice bath, the mixture was centrifuged at 2000 × *g* for 10 min. The precipitate was washed once with 2 mL of 6% perchloric acid and dissolved with 1.6 mL of water. The acylcarnitine was then extracted with 1 mL of butanol, and 0.7 mL of the butanol layer was assayed for the radioactivity by liquid scintillation counting (26). Protein was determined according to the method of Lowry *et al.* (27) using bovine serum albumin as a standard.

Statistical analysis. Data were analyzed by one-way analysis of variance, and significant differences of means were inspected by Duncan's multiple range test (28) at the level of $P < 0.05$. The statistical analyses were performed on a program developed by us using Microsoft Excel (Microsoft Corp., Redmond, WA) for the Macintosh.

RESULTS

Figure 1 and Table 1 show the activities of microsomal glycerol 3-phosphate acyltransferase using CoA esters of various fatty acids with different degree of unsaturation and positional distribution of double bonds as the substrates. The activities of the enzyme progressively increased as the concentrations of various acyl-CoAs increased up to 75–100 μM, and above these concentrations the activities decreased (Fig. 1). Table 1 summarizes the activities of the enzyme mea-

sured with various acyl-CoA substrates at the concentration of 75 μM using six to seven different enzyme preparations from different rats. A significant difference was detected only between the activity measured with 16:0-CoA and that measured with po-18:3-CoA. As we did not measure the activity of any mitochondrial marker enzyme in our microsomal preparations, the activities of microsomal glycerol 3-phosphate acyltransferase were assayed in the presence of 5,5-dithio*bis* (2-nitrobenzoic acid). The activities obtained were less than 0.5% of those obtained in the absence of the inhibitor, and no statistical differences were detected regardless of the types of acyl-CoA substrates employed (data not shown). This observation indicates that contamination with mitochondria of the microsomal preparation was minimal in the present study. Virtually no activity was detected in the absence of acyl-CoA substrates.

When increasing concentrations of 16:0-CoA (5–150 μM) were employed as the acyl-donor, the activities of mitochondrial glycerol 3-phosphate acyltransferase depicted a peak at the substrate concentration of 50 μM and gradually decreased above this concentration (data not shown). The average value of the activity obtained with 50 μM 16:0-CoA using six mitochondrial preparations from different rats was 230 ± 29 pmol/min per mg protein. The activities observable with various unsaturated fatty acyl-CoAs at a concentration of 50 μM were extremely low (less than 18 pmol/min per mg protein), and it was difficult to obtain reliable values using the method employed herein.

Figure 2 shows the activities of microsomal diacylglycerol acyltransferase measured with varying concentrations of acyl-CoA substrates. The concentrations of various acyl-CoAs which gave the maximal activities were 30–40 μM. Apparently, the activities obtained with γ-18:3-CoA at the various concentrations were lower than those obtained with the other acyl-CoAs. Table 2 summarizes the enzyme activities mea-

sured in the presence of various acyl-CoA substrates at the concentration of 30 μM using six to eight microsomal preparations obtained from different rats. The activities observed with polyunsaturated fatty acyl-CoAs were lower than those obtained with 16:0- and 18:1-CoAs. It was again demonstrated that γ-18:3-CoA gave the lowest activity among the various polyunsaturated fatty acyl-CoAs tested.

Figure 3 shows the activity of mitochondrial carnitine palmitoyltransferase I measured with varying concentrations of acyl-CoA substrates. Apparently, α-18:3- and po-18:3-CoAs gave enzyme activities considerably higher than those obtained with 16:0- and 18:2-CoAs at the various concentrations tested. The kinetic behavior of the enzyme using γ-18:3-CoA as a substrate was considerably different from those using other octadecatrienoyl-CoAs. The enzyme activities in the presence of a low concentration (10 μM) of γ-18:3-CoA were the same as those obtained using other octadecatrienoyl-CoAs, but the activities obtained at the concentrations higher than 50 μM were apparently lower. As the contours of changes in the enzyme activities using varying concentrations of different acyl-CoAs were found to be well-fitted with the Michaelis-Menten kinetics, V_{max} and apparent K_m values of the enzyme reaction were calculated and are summarized in Table 3. This table also presents the enzyme activities using various acyl-CoAs at the concentration of 50 μM in the absence and presence of 0.5 and 3 μM malonyl-CoA, an inhibitor of the enzyme reaction (14,29–31). The acyl-CoA concentration of 50 μM did not necessarily saturate the enzyme reaction. However, it was chosen for the comparative purpose because this concentration has been commonly employed in a number of reports for the assay of this enzyme using 16:0- or 18:1-CoA substrates (26, 29–31). V_{max}, but not K_m, values for α-18:3- and po-18:3-CoAs were significantly higher than those observable for 16:0- and 18:2-CoAs. In contrast, the V_{max} value for γ-18:3-CoA was the lowest among those observed for various acyl-CoAs tested. The apparent K_m values of the enzyme reaction were approximately the same irrespective of the types of fatty acyl-CoAs tested, except for the distinctly low value obtained with γ-18:3-CoA. The activities obtained using various acyl-CoA substrates at the concentration of 50 μM reflected the observed kinetic differences for the enzyme reaction. Thus, the activities using octadecatrienoyl-CoAs, except for γ-18:3-CoA, were significantly higher than those obtained with saturated, monounsaturated, and diunsaturated species. As expected, malonyl-CoA at the concentrations of 0.5 and 3 μM severely reduced the activities of carnitine palmitoyltransferase I irrespective of the types of acyl-CoAs used as the substrate. However, the extent of the reduction by malonyl-CoA of the enzyme reaction was apparently dependent on the type of acyl-CoA substrate. Thus, the sensitivities to this inhibitor obtained with 18:2-, α-18:3-, and po-18:3-CoAs were appreciably exaggerated compared to those obtained with 16:0- and 18:1-CoAs. The response obtained with γ-18:3-CoA was unique among

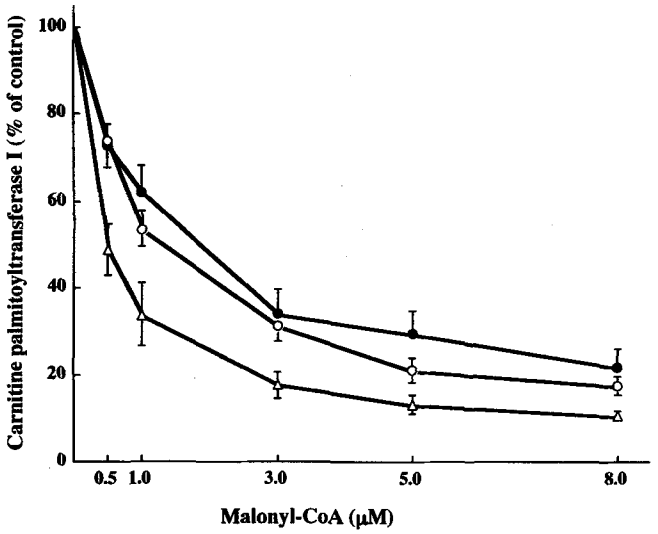

FIG. 4. Activities of mitochondrial carnitine palmitoyltransferase I in rat liver obtained in the presence of varying concentrations of malonyl-CoA. Values are means ± SE of five to six mitochondrial preparations obtained from different rats. Percentages of the value obtained in the absence of malonyl-CoA using 50 μM of 16:0- (○), 18:2- (△), and γ-18:3-CoA (●) as the substrates are presented.

the various acyl-CoAs of polyunsaturated species, and the sensitivity to malonyl-CoA was the same as those obtained with 16:0- and 18:1-CoAs. The data presented in Figure 4 confirmed this observation. Thus, the extent of the reduction in the presence of varying concentrations of malonyl-CoA using 16:0- and γ-18:3-CoAs in relation to 18:2-CoA were appreciably attenuated.

DISCUSSION

This study demonstrated that some of the key enzymes in fatty acid esterification and oxidation pathways of rat liver can discriminate not only the various octadecatrienoic acids from other fatty acids differing in the degree of unsaturation, but also the individual trienoic acids examined.

Substrate specificity of glycerol 3-phosphate acyltransferase. Previous studies have demonstrated that the activities of microsomal glycerol 3-phosphate acyltransferase obtained with 16:0-, 18:1-, and 18:2-CoAs were indistinguishable from each other (7–10). Although the activities of this enzyme tended to decrease with an increase in the degree of unsaturation of acyl-CoA substrates employed in the present study, this enzyme apparently showed a broad specificity toward the various acyl-CoAs with differences in the degree of unsaturation and the position of the double bonds. Marked selectivity of mitochondrial glycerol 3-phosphate acyltransferase toward saturated fatty acyl-CoA compared to 18:1- and 18:2-CoAs (7–9) was confirmed in the present study. In addition, we expanded the observation that various octadecatrienoyl-CoAs were not effective as the substrates for mitochondrial glycerol 3-phosphate acyltransferase. Thus, along with the observations made by others (7–10), it is suggested that the microsomal, but not mitochondrial, glycerol 3-phosphate acyltransferase is rather incapable of discriminating the differences in the degree of unsaturation and positional distribution of double bonds in acyl moieties of the substrate.

Substrate specificity of diacylglycerol acyltransferase. Coleman and Bell (24) showed that the activity of microsomal diacylglycerol acyltransferase was dependent on the chain length of saturated fatty acyl-CoAs. However, the efficacies of acyl-CoA substrates differing in the degree of unsaturation as the substrates of this enzyme have not been the subjects for the extensive studies. Our present observation using various unsaturated fatty acyl-CoAs with 18 carbon chain length clearly demonstrated that this enzyme can discriminate the degree of unsaturation of fatty acyl-CoAs. As the activity measured with γ-18:3-CoA was distinctly lower than that observed with α-18:3- and po-18:3-CoAs, this enzyme apparently discriminated the difference in the positional distribution of double bonds as well.

Substrate specificity of carnitine palmitoyltransferase I. Consistent with a previous finding (13), the activity of carnitine palmitoyltransferase I measured with α-18:3 was higher than those obtained with 16:0, 18:1, and 18:2. Also, the activity measured with po-18:3, but not γ-18:3, was comparable

with that obtained with α-18:3. Thus, this enzyme apparently discriminated not only the degree of unsaturation but also the positional distribution of double bonds of fatty acyl-CoA substrates.

Malonyl-CoA-mediated inhibition of carnitine palmitoyltransferase I represents a mechanism by which mitochondrial oxidation of long-chain fatty acids is regulated (14). The sensitivity of the enzyme to this inhibitor has been demonstrated to be influenced by the nutritional and physiological state of animals (14). In addition, a variety of *in vitro* conditions can modulate the sensitivity of this enzyme to malonyl-CoA (29–31). The present study for the first time presents evidence that the type of acyl-CoA used as the substrate is a factor to modify *in vitro* the response of the enzyme to malonyl-CoA. Our data also suggested that the component(s) which regulate the sensitivity to malonyl-CoA discriminate not only the degree of unsaturation but also the positional distribution of double bonds of acyl-CoA substrates.

The present observation indicated that at least diacylglycerol acyltransferase and carnitine palmitoyltransferase I among the various enzymes in glycerolipid biosynthesis and fatty acid oxidation can discriminate the various positional isomers of octadecatrienoic acids from saturated, monounsaturated, and diunsaturated fatty acids. Moreover, the responses of these enzymes to these octadecatrienoic acid substrates were modified by the differences in the positional distribution of double bonds in the acyl-moieties. Although the physiological significance of the present observation remains to be clarified, several studies indicated that at least the rates of oxidation *in vivo* of octadecatrienoic acids are different from other fatty acids differing in the degree of unsaturation. Bandyopadhyay *et al.* (32) compared the fate of [1-^{14}C]-labeled 18:2 and α-18:3 *in vivo* in the liver of cat fish. They demonstrated that saturated fatty acids were preferentially labeled in the liver when the octadecatrienoic acid was a tracer, indicating that the rate of β-oxidation to [^{14}C]acetyl-CoA was higher than with 18:2. Leyton *et al.* (33) reported that the rate of the oxidation *in vivo* of orally administered [1-^{14}C]-labeled various unsaturated fatty acids, as estimated by radioactivities recovered in carbon dioxide during a 24-h period, was in the order of 18:1 = α-18:3 > 18:2 > γ-18:3 > dihomo-γ-18:3 = 20:4 in the rat. The result of this study may be compatible with our observation that mitochondrial carnitine palmitoyltransferase I can discriminate not only the degree of unsaturation but also the positional distribution of double bonds in the acyl moieties. However, a recent report (34) indicated that [1-^{14}C]-labeled 18:1, 18:2, and α-18:3 are oxidized at similar rates in the rat given a purified 15% fat diet containing equal amounts of 18:1, 18:2, and α-18:3 (23.2, 22.7, and 23.0%, respectively). In the present study, we demonstrated that the response to malonyl-CoA of carnitine palmitoyltransferase I is dependent on the types of fatty acids used as the substrates. Thus, it is supposed that the relative rates of the oxidation of fatty acids are influenced by the nutritional and physiological states which modify the malonyl-CoA concentration in the tissues. Thus, differences in the tissue malonyl-CoA concentrations may account for the discrepancy in the rates of oxidation *in vivo* of polyunsaturated fatty acids between rats fed commercial (33) and purified diets (34).

Fatty acyl-CoA is an amphiphilic molecule and forms monomer solutions only at a low concentration. At the concentrations above the critical micelle concentration, it forms micelles. Available data suggested that critical micelle concentrations of fatty acyl-CoAs decrease as the carbon number increases. On the other hand, the presence of a double bond increases the critical micelle concentration (35–37). However, the concentrations of various acyl-CoAs as monomers or in micelles in our complex system for the assays of respective enzymes containing enzyme protein, albumin, and various ingredients remain to be defined. Also, the information regarding the differences in the position of double bonds which affect the critical micelle concentrations of polyunsaturated fatty acyl-CoAs has been lacking. The possibility that the differences in the specificities of the enzymes for acyl-CoA substrates observed in the present study represent the features of some irregularities in the physical behaviors of various acyl-CoA substrates (35,37), rather than those of enzymes, may not be disregarded. Further studies may be required to clarify this point.

Inhibition of Neutral Cholesteryl Ester Hydrolase by the Glycolytic Enzyme Enolase. Is This a Secondary Function of Enolase?

John H. Shand and David W. West*

Hannah Research Institute, Ayr, KA6 5HL, Scotland, United Kingdom

ABSTRACT: There is an accumulation of the glycolytic enzyme enolase and of cholesteryl esters in macrophages that have been converted into "foam" cells. In this study, we questioned whether enolase could be involved in this accumulation of cholesteryl esters by inhibiting the activity of neutral cholesteryl ester hydrolases. Enolase from both yeast and rabbit muscle were incubated with three different cholesteryl ester hydrolases and were shown to inhibit the hydrolysis of cholesteryl esters. Inhibition was dependent on the concentration of enolase and appeared to occur through binding of the enolase to the cholesteryl ester. Nevertheless, the yeast and rabbit muscle enolases differed in their efficiency of inhibition and in their mechanism of action. Purification of commercial enolase preparations by gel-filtration yielded single proteins with the same inhibitory activities as the originals, indicating that the inhibition was not due to the presence of an impurity. Partially purified αα- and γγ-isoforms of the enzyme from rat brain also appear to have inhibitory effects on cholesteryl ester hydrolysis. Negative control of the hydrolytic phase of the cholesterol/cholesteryl ester cycle may be a secondary function of enolases which correlates with the accumulation of cholesteryl esters in a number of neuro-degenerative and demyelinating diseases.
Lipids 30, 763–770 (1995).

Cholesterol is a molecule critical to the structural and functional integrity of all mammalian cells, and the levels of the free sterol are tightly regulated. Excess cholesterol is esterified with fatty acyl–CoA derivatives in a reaction catalyzed by acyl CoA–cholesterol acyltransferase (1–3), whereas free sterol is released from these cholesteryl ester stores by hydrolysis catalyzed by a neutral cholesterol ester hydrolase (CEH). Thus, a continuous cycle of esterification and hydrolysis exists within the cell (4,5).

Many disease states are characterized by accumulations of cholesteryl esters, the classic case being atherosclerosis, in which macrophages accumulate large amounts of cholesteryl esters to form the "foam" cells which are found in atherosclerotic lesions (5–8). This accumulation has been postulated to arise from an increased intake of cholesterol (5), but, as there is a continual cycle of esterification and hydrolysis, a number of other factors may also affect this process. These could include alteration in the activity of the CEH, and we have recently demonstrated that a number of cells, including hepatocytes (9) and macrophages (10), contain a cytosolic protein inhibitor of this enzyme. The inhibitor activity could be altered by physiological, hormonal, and nutritional manipulation (9,11). In particular, we demonstrated that under conditions that favored the conversion of macrophages into "foam" cells, the activity of this inhibitor was increased (10).

More recently, Tabas and co-workers have shown that when macrophages were converted into "foam" cells by incubation with acetylated low-density lipoproteins (12), the expression of a number of cellular proteins was altered. Two proteins were observed to be increased in amount and one of these, which showed a 458% increase, was shown to have structural homology with the α-isoform of the glycolytic enzyme enolase and to be immunoprecipitated by antiserum specific for α-enolase. Although this form of α-enolase did not appear to have enolase activity and no function was ascribed to it, the similarity between our results with macrophages and those reported by Bottalico *et al.* (12) raised the possibility that the increased inhibitory activity observed in our experiments may have been caused by the increased enolase protein. This hypothesis was given support by the fact that, during attempts to purify the cytosolic inhibitor from rat liver, it became apparent that its behavior, on anion exchange chromatography, showed a strong resemblance to that exhibited by the isoforms of enolase (13,14).

We have therefore investigated the effect of both mammalian and yeast enolases on cholesteryl ester hydrolysis by two different mammalian and one yeast CEH. Our results indicate that the enolase molecule has the ability to bind cholesteryl esters and, in doing so, to inhibit their hydrolysis by the CEH. Binding occurred even in the presence of an excess of bovine serum albumin (BSA) or cytosolic proteins, suggesting that this inhibition could also occur *in vivo*.

MATERIALS AND METHODS

Baker's yeast enolase was purchased from Sigma Chemical Co. (Poole, Dorset, United Kingdom) and the *Candida cylindracea* CEH (EC 3.1.1.13) from BCL (Lewes, Sussex, United Kingdom). Rabbit muscle enolase (EC 4.2.1.11) was purchased from three sources: ICN (High Wycombe, Bucks, United Kingdom), as well as from Sigma and BCL. Cholesteryl [1-^{14}C]oleate was purchased from Amersham (Little Chalfont, Bucks, United Kingdom), and cholesteryl [9,10-^{3}H]-oleate was prepared as previously described (9). Other biochemicals were obtained from Sigma or BCL. Purified bovine adipose tissue hormone-sensitive lipase (HSL) was kindly supplied by Professor S.J. Yeaman (University of Newcastle, Newcastle-Upon-Tyne, United Kingdom).

Tissue fractionation. Microsomes were prepared from the mid-lactating mammary glands of female Wistar rats and from the livers of male Wistar rats, as described previously (9). An acetone–diethyl ether powder was also prepared from the rat liver cytosolic fraction (9).

Preparation of rat brain enolases. Rat brains were homogenized in 15 mM Tris-acetate buffer (pH 6.5) containing 5 mM $MgSO_4$ and 0.1 mM EDTA. The homogenate was centrifuged and treated with Macro-prep CM (Biorad, Hemel Hempstead, Herts, United Kingdom) and ammonium sulfate exactly as described by Suzuki *et al.* (15). The 40–80% ammonium sulfate fraction was passed through Sephadex G-15 (Pharmacia, Uppsala, Sweden) and applied to a column of Macro-prep Q (Biorad) equilibrated in homogenization buffer. The nonretained material was collected (αα-enolase), and further enolase fractions were obtained by washing the column with homogenization buffer containing first 100 mM NaCl (αγ-enolase) and then 220 mM NaCl (γγ-enolase).

Purification of commercial enolase preparations. Rabbit muscle enolase, supplied as a suspension in ammonium sulfate, was centrifuged (10,000 × *g*, 10 min) and the pellet dissolved in 50 mM 2-(*N*-morpholino)-ethanesulfonic acid, 50 mM TRIS buffer, pH 7.2, containing 1 mM EDTA. Baker's yeast enolase was dissolved directly in the same buffer. Both enolase preparations were routinely passed through a small column (2 mL) of Sephadex-G15 (Pharmacia), equilibrated with the same buffer before use. In addition, for some experiments, both enolases were further purified by fast-performance liquid chromatography (FPLC) on a Superose-12 gel-filtration column (Pharmacia) equilibrated in the same buffer. Purity was analyzed by SDS–polyacrylamide gel electrophoresis (PAGE) using both the discontinuous buffer systems of Laemmli (16) and of Amory *et al.* (17), as well as the continuous system of Fairbanks *et al.* (18).

Assay of enzyme activities. CEH activity was assayed (total volume 0.2 mL) using either mammary gland microsomal membranes (100 μg), liver microsomal membranes (50 μg), *C. cylindracea* CEH (25 ng), or HSL (160 ng) in an assay buffer consisting of 50 mM MES, 50 mM TRIS/HCl buffer, pH 7.2, and 0.5 mM EDTA. Fatty acid-free BSA (200 μg) and enolase (0.004–3.6 nmol) were added to the assay mixture, and the reaction was initiated by the injection of an ethanolic solution of cholesteryl [9,10(n)-^{3}H]oleate (20 nmol, 200,000 dpm, 10 μL). Where indicated in the text, the reaction was also initiated by the addition of the mammary gland microsomal membranes, suspended in a solution of BSA, to the incubation tubes containing assay buffer, enolase, and substrate. After 20 min at 37°C, the reaction was terminated and the extent of hydrolysis of the substrate determined as previously described (9). Assays were performed in triplicate, and appropriate controls, without microsomes, were incubated concurrently to correct for background. Enolase activity was measured at 30°C using the coupled assay as described previously (15).

Assay of cholesteryl oleate binding. Enolase (0–1.5 nmol) was preincubated for 10 min at 37°C in the assay buffer, with and without BSA (200 μg), before binding was initiated, by the addition of an ethanolic solution of either cholesteryl [9,10-^{3}H]oleate (20 nmol, 290,000 dpm) or cholesteryl [1-^{14}C]oleate (20 nmol, 103,000 dpm) to give a final volume of 0.2 mL. After a further 10 min at 37°C, the reaction was either terminated immediately, by cooling the mixture in ice for 5 min or, where indicated, BSA (200 μg) was added and incubation continued for a further 10 min prior to termination. The reaction mixture was then centrifuged (15,000 × *g*, 25 min), and duplicate aliquots of the supernatant counted to determine the amount of cholesteryl oleate remaining in solution. Assays were performed in triplicate.

Protein determination. Protein was determined by the method of Bradford (19) using BSA as a standard.

RESULTS

The CEH activity present in the mammary gland microsomes was inhibited when assayed in the presence of rabbit muscle enolase (predominantly the ßß-isoform of the enzyme) (Fig. 1A). Consistent results were obtained only when low molecular weight material was removed from the enolase preparation by passage of the protein through Sephadex-G15. Inhibition was dependent on the concentration of rabbit muscle enolase, but total inhibition of hydrolytic activity was not achieved. Linear regression analysis of the first portion of the graph indicated that 50% inhibition of the CEH activity required 0.56 nmol of muscle enolase (assuming M_r of 45,000). A purified sample of HSL, which has immunological identity with the mammary gland CEH (20), was similarly inhibited (0.76 nmol of muscle enolase gave 50% inhibition).

The CEH activity in liver microsomes (50 μg), which has been shown to be due to a different enzyme from HSL (21,22), was more sensitive to inhibition by the muscle enolase, in as much as 50% inhibition required only 0.33 nmol of the enolase (Fig. 1A). The CEH from *C. cylindracea* was relatively insensitive, 50% inhibition required 5.09 nmol of the enolase (Fig. 1A). Whereas the assay was normally initiated by the addition of substrate to a mixture of enolase, BSA and the mammary microsomal CEH, when rabbit muscle enolase was preincubated with the cholesteryl ester for 10 min, prior to the addition of BSA and the mammary gland microsomal

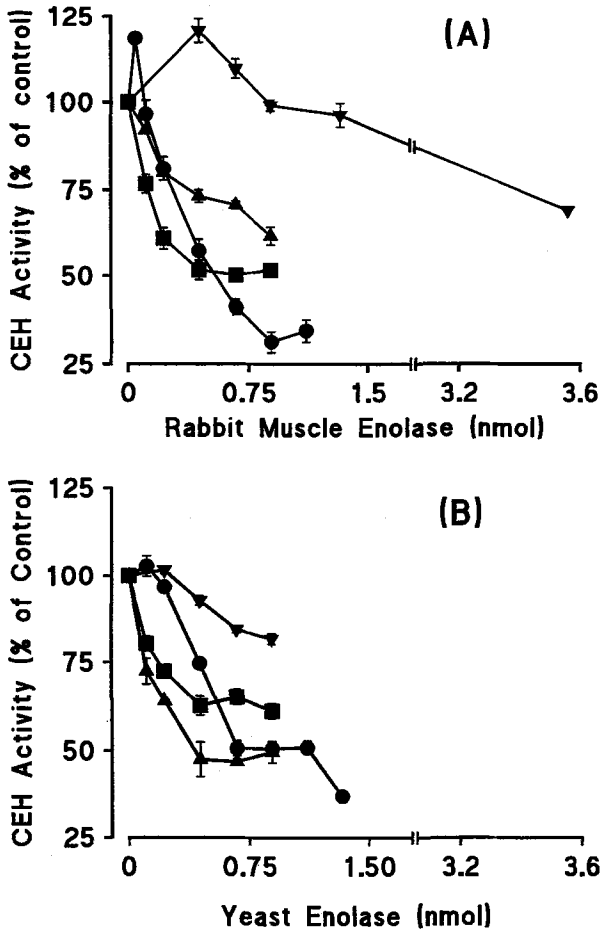

FIG. 1. Variation of the inhibition of neutral cholesteryl ester hydrolases (CEH) with the concentration of (A) rabbit muscle enolase and (B) yeast enolase. Mammary microsomes (100 μg, ▲), liver microsomes (50 μg, ■), hormone-sensitive lipase (HSL) (●), and esterase from *Candida cylindracea* (▼) were assayed for CEH activity in the presence of varying amounts of either rabbit muscle enolase or yeast enolase. Reaction was initiated by the addition of an ethanolic solution of cholesteryl [^{3}H]oleate as indicated in the Materials and Methods section. The control (100%) values for HSL and *C. cylindracea* were 0.384 and 2.95 μmol/min/mg, respectively, and for the microsomes from mammary gland and liver 459.2 ± 7.9 and 76.5 ± 5.6 pmol cholesteryl oleate hydrolyzed per min/mg of protein, respectively. The results are typical of a number of experiments and are the means ± SEM for triplicate measurements in each instance.

CEH, 50% inhibition of hydrolytic activity was achieved with only 10.9 pmol of the enolase. (Fig. 2).

Inhibition by yeast enolase showed a different pattern of sensitivity (Fig. 1B). The mammary gland microsomal CEH required 0.21 nmol of the yeast enolase to produce 50% inhibition, whereas the liver microsomal enzyme required 0.39 nmol. The *C. cylindracea* CEH required 1.51 nmol for 50% inhibition, and HSL required 0.59 nmol for the same effect.

The activity of the mammary microsomal CEH against triolein was also inhibited by yeast and rabbit muscle enolase (40.5 ± 3.3 and 46.4 ± 1.8% inhibition, respectively, with 0.81 nmol of enolase), whereas the activity of the purified HSL

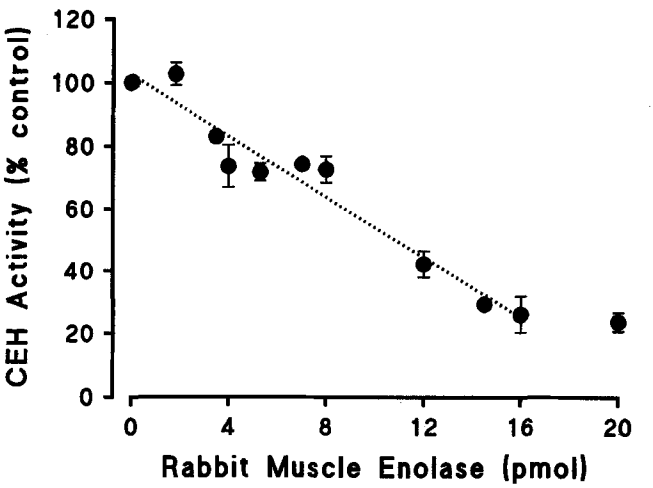

FIG. 2. Variation of the inhibition of cholesteryl ester hydrolysis by rabbit muscle enolase: effect of preincubating enolase and the cholesteryl ester. Rabbit muscle enolase (0–20 pmol) was preincubated for 10 min with the cholesteryl [9,10-^{3}H]oleate (20 nmol) before the reaction was initiated by the addition of a suspension of mammary gland microsomes (100 μg) in a solution of bovine serum albumin (see the Materials and Methods section). The results are means ± SEM for triplicate assays from two experiments. Abbreviation as in Figure 1.

against the water-soluble substrate *p*-nitrophenyl-butyrate was not affected by either enolase (results not shown).

Both enolase preparations were further purified by FPLC using a Superose-12 gel-filtration column. In each instance, the protein in the peak fraction, which had both enolase and inhibitory activity, showed only a single band when analyzed by PAGE in three different buffer systems (Figs. 3 and 4). Consistent with greater than 99% purity of the initial preparations, there was no change in either catalytic or inhibitory specific activity in these FPLC-purified fractions (results not shown). Nevertheless, the enolase catalytic activity was unrelated to the inhibitory activity, as the inclusion of 5 mM KF and 5 mM potassium phosphate completely inhibited enolase activity, whereas inhibitory activity due to 0.65 nmol of rab-

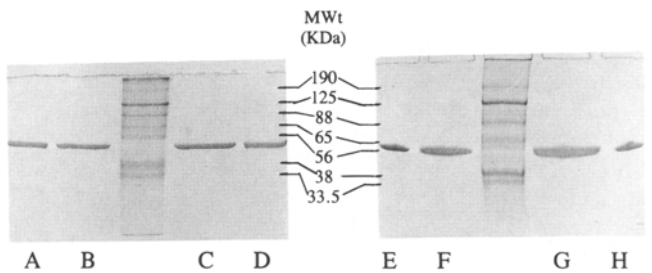

FIG. 3. SDS–polyacrylamide gel electrophoresis analysis of yeast and rabbit muscle enolase after purification by fast-performance liquid chromatography (FPLC) gel-filtration. Lanes A–D were performed on 10% discontinuous Laemmli gels (Ref. 16) and lanes E–H were performed on continuous 5.6% gels with the buffer system of Fairbanks *et al.* (Ref. 18). Each lane contained 5 μg protein and the gels were stained with Coomassie blue. Yeast enolase (i) before FPLC, lanes A and E, (ii) after FPLC, lanes B and F. Rabbit muscle enolase (iii) before FPLC, lanes D and H, (iv) after FPLC, lanes C and G.

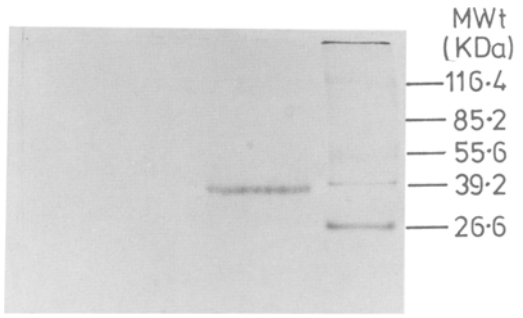

FIG. 4. Electrophoretic analysis of rabbit muscle enolase after FPLC gel-filtration. Electrophoresis was performed on discontinuous 10% acrylamide gels using the cationic detergent, tetradecyl trimethyl ammonium bromide, and the buffer system of Amory *et al.* (Ref. 17) at pH 2.0. The gel was stained with Coomassie blue after extensive washing to remove the detergent. Abbreviation as in Figure 3.

bit muscle enolase was reduced only 36% (from 31.8 ± 1.6 to 20.2 ± 4.4%) by 25 mM KF and 25 mM potassium phosphate. Moreover, the enolase catalytic activity was unaffected by HSL (results not shown).

Three peaks of enolase catalytic activity were obtained from the rat brain preparation, corresponding to the isoforms αα-, αγ-, and γγ- (15), and these coincided with three peaks of inhibitor activity (Fig. 5). The ratio of inhibition to enolase activity was, nevertheless, different in the three peak fractions, with the column fraction containing the αα-enolase (fraction 19) having the highest ratio and the fraction containing γγ-enolase (fraction 60) having the lowest (Table 1). The fraction containing the αγ-isoenzyme (fraction 40) was intermediate between these two extremes. This is consistent with the report that the α-isoenzyme of enolase was markedly increased in cholesterol-loaded macrophages (12).

Binding experiments. Although the bulk of the cholesteryl oleate was pelleted by centrifugation (Table 2), inclusion of BSA allowed retention of a greater proportion of the substrate in the supernatant (Table 2). Inclusion of an acetone–diethyl ether powder, prepared from the cytosolic fraction of rat liver, also increased retention in the supernatant, whereas the presence of either yeast or rabbit muscle enolase (0.56 nmol) increased the amount of cholesteryl ester that was pelleted, despite the fact that both are soluble proteins (Table 2). Neither the protein in the hepatic cytosolic fraction nor BSA (3.03 nmol), whether present in the initial incubation or added later, were able to prevent the precipitation of the cholesteryl ester by rabbit muscle enolase (Table 2). In contrast, the binding of cholesteryl oleate to the yeast enolase was much weaker, and BSA (3.03 nmol) effectively competed with this enolase, resulting in a greater amount being retained in the supernatant. Varying the amount of BSA present in the initial incubation indicated that the presence of even small amounts of BSA competed effectively with the yeast enolase (Fig. 6).

Although binding of cholesteryl oleate to rabbit muscle enolase varied with the concentration of the enolase, there were differences in the response depending on the presence of BSA (Table 2, Fig. 7). When BSA (3.03 nmol) was initially absent from the incubation, only a small amount of enolase

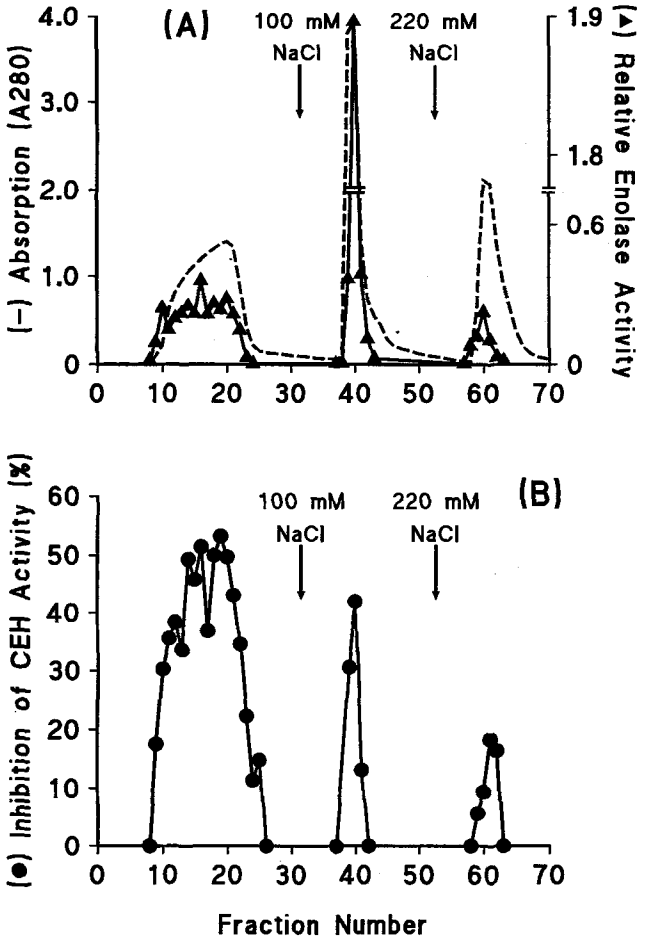

FIG. 5. Separation of enolase isoenzymes of rat brain by chromatography on Macro-prep Q. The column (2.5 × 5 cm) was initially eluted with homogenization buffer (15 mM TRIS–acetate, pH 6.5 containing 5 mM $MgSO_4$ and 0.1 mM EDTA), and this was changed to homogenization buffer containing either 100 mM NaCl or 220 mM NaCl at the points shown. Enolase activity (A) and CEH inhibitory activity (B) were determined as given in the Materials and Methods section. Abbreviation as in Figure 1.

TABLE 1
Relationship Between Inhibition of Neutral Cholesteryl Ester Hydrolase (CEH) and Enolase Activity for the Peak Fractions from the Macro-prep Q Column[a]

Fraction number	Protein (mg/mL)	Protein causing 25% inhibition of CEH (Xμg)	Equivalent enolase activity (nmol/min/Xμg)	Ratio (% inhibition/enolase activity)
19	1.34	20.3	14.6	1:1.712
40	4.06	30.5	104.3	1:0.239
60	2.31	687.6	362.9	1:0.069

[a]The three peak fractions, containing the different isoforms of enolase (fraction 19 = αα-isoform, fraction 40 = αγ-isoform, fraction 60 = γγ-isoform), from the Macro-prep Q column were assayed, in triplicate, for enolase activity and for inhibitory activity (against the mammary microsomal CEH). The amount of protein required to achieve 25% inhibition of enzyme activity was measured and the enolase activity equivalent to that amount of protein then calculated. From this data, the ratio of inhibition to enolase activity was determined.

TABLE 2
The Influence of Various Additions on the Retention of Cholesteryl Oleate in the Supernatant of Aqueous Media by Yeast and Rabbit Muscle Enolase[a]

Preincubation conditions	Second addition	Cholesteryl oleate in supernatant (nmol)
No additions	Cholesteryl oleate	2.22 ± 0.17
BSA	Cholesteryl oleate	16.74 ± 0.51
R.M. enolase	Cholesteryl oleate	0.40 ± 0.17
Yeast enolase	Cholesteryl oleate	0.28 ± 0.04
R.M. enolase + BSA	Cholesteryl oleate	1.1 ± 0.34
Yeast enolase + BSA	Cholesteryl oleate	16.28 ± 1.29
R.M. enolase + cholesteryl oleate	BSA	0.18 ± 0.06
Yeast enolase + cholesteryl oleate	BSA	0.19 ± 0.00
Acetone powder	Cholesteryl oleate	4.28 ± 0.15[b]
Acetone powder + enolase	Cholesteryl oleate	0.60 ± 0.10[b]

[a]The solutions contained various combinations of yeast and rabbit muscle (R.M.) enolase (0.55 nmol), bovine serum albumin (BSA) (3.03 nmol), and an acetone–diethyl ether powder obtained from rat liver cytosol (52.8 μg) in 50 mM 2-(*N*-morpholino)ethanesulfonic acid, 50 mM TRIS, 0.5 mM EDTA buffer, pH 7.2. Cholesteryl [1-^{14}C]oleate (20 nmol, 108,000 dpm) was added as an ethanolic solution. The mixtures were preincubated at 37°C for 10 min before the second addition was made. Incubation was continued for a further 10 min before the tubes were cooled in an ice bath for 5 min prior to centrifugation (15,000 × *g*, 25 min). Duplicate aliquots of the supernatants were counted to determine the radioactivity remaining therein. The results shown are means ± SEM from at least triplicate assays.
[b]Determined using cholesteryl [9,10-^{3}H]oleate (20 nmol, 290,000 dpm).

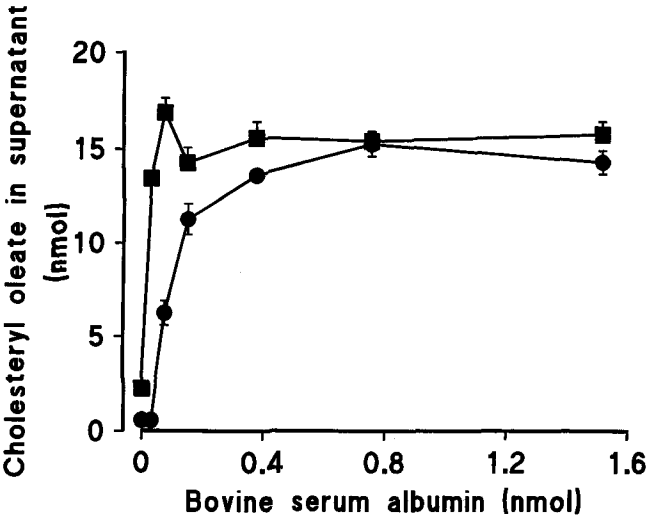

FIG. 6. Competition between yeast enolase and bovine serum albumin (BSA) for binding of cholesteryl oleate. Varying amounts of BSA were incubated at 37°C in 50 mM 2-(*N*-morpholino)ethanesulfonic acid, 50 mM TRIS buffer, pH 7.2 (total volume 190 μL) initially in the absence (■) or the presence (●) of yeast enolase (0.56 nmol). After 10 min, an ethanolic solution (10 μL) of cholesteryl [1-^{14}C]oleate (20 nmol, 103,000 dpm) was added to the tubes, which were incubated for a further 10 min. The tubes were then cooled in ice (5 min) and centrifuged (15000 × *g*, 25 min) before duplicate aliquots of the supernatant were counted to determine the amount of cholesteryl ester remaining therein. The results are the means ± SEM for triplicate assays.

(16 pmol) was required to achieve precipitation of the bulk of the ester (Fig. 7A), and there was a good correlation (r = 0.86) between binding and inhibition of CEH activity (Fig. 8A). When the initial incubation was performed in the presence of BSA (3.03 nmol), much less of the cholesteryl ester was precipitated. Low enolase concentrations caused a slight increase in the amount of cholesteryl oleate retained in the supernatant, but precipitation of the substrate predominated at higher enolase concentrations (Fig. 7B). Due to this change from solubility to precipitation, the correlation between binding and inhibition (r = 0.66) was poorer (Fig. 8B).

These binding experiments thus suggested that the two enolases caused the inhibition by different mechanisms. This was confirmed by Lineweaver-Burk plots (Fig. 9), which indicated that the yeast enolase showed a "competitive" form of inhibition, whereas the plot exhibited by the muscle enolase was characteristic of an "uncompetitive," form of inhibition (23). Kinetic differences between mammalian and yeast enolases have been reported previously (24).

DISCUSSION

The results presented here indicate that, under the assay conditions used, the glycolytic enzyme enolase inhibited the hydrolysis of cholesteryl esters catalyzed by a number of different CEHs. The pattern of inhibition shown by the rabbit muscle enolase was comparable with the inhibition produced by the cytosolic fraction from rat liver (9), in terms of both the sensitivity of the different hydrolases to inhibition and the fact that total inhibition could not be obtained. Moreover, as with the hepatic inhibitory protein, the efficiency of inhibition was very dependent on the mode of initiation of the reaction.

This property was exhibited by rabbit muscle enolase, purchased from a number of different suppliers, as well as by the yeast enolase. This not only indicates that it is a feature of the enolase molecule but also diminishes the possibility that the inhibitory activity was due to an impurity co-purified with the enzyme. The results of PAGE–SDS analysis on three different systems, indicating the purity of the enzyme following gel-filtration by FPLC, also confirms that the inhibition was due to the enolase molecule (Figs. 3 and 4).

The binding experiments indicate that, although cholesteryl oleate is insoluble in aqueous media, binding to soluble proteins allows more of the ester to be retained in solution. Although this occurred with BSA and with the inhibitory material in the cytosolic fraction of rat liver (Table 2; Ref. 9), the binding of both yeast and rabbit muscle enolase caused aggregation and increased precipitation of the sterol ester (Fig. 7, Table 2). This is clearly a strong reaction with the rabbit muscle enolase as 16 pmol of the enzyme protein was able to cause aggregation of more than 4 nmol of the ester even when BSA (3 nmol) was added later as a competing protein (Fig. 7B). In contrast, the binding between the cholesteryl ester and yeast enolase was much weaker because as little as 0.35 nmol of BSA effectively prevented 0.56 nmol of the enolase from causing precipitation of the cholesteryl ester

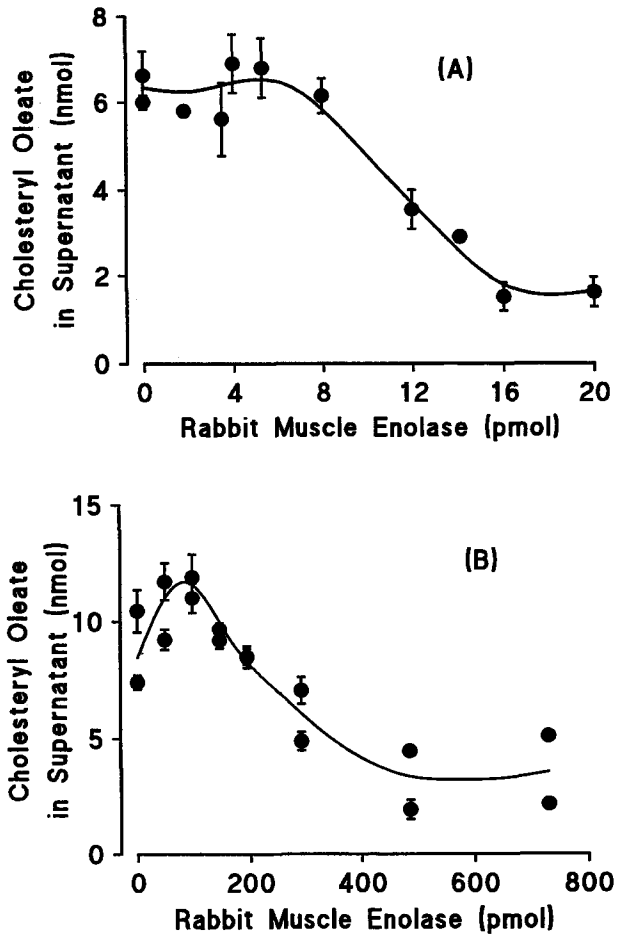

FIG. 7. Binding of cholesteryl ester to rabbit muscle enolase. Varying amounts of rabbit muscle enolase were incubated at 37°C in 50 mM 2-(*N*-morpholino)ethanesulfonic acid, 50 mM TRIS buffer, pH 7.2, with cholesteryl [9,10-^{3}H]oleate (20 nmol, 250,000 dpm) either initially in the absence (A) or the presence (B) of BSA (3 nmol). After 10 min, an equivalent amount of BSA was added to the first tubes (final volume 200 μL), and both sets of tubes were incubated for another 10 min. The tubes were then cooled in ice (5 min) and centrifuged (15,000 × *g*, 25 min) before duplicate aliquots of the supernatant were counted to determine the amount of cholesteryl ester remaining therein. The results are the means ± SEM for triplicate assays from two separate experiments in each instance. Abbreviation as in Figure 6.

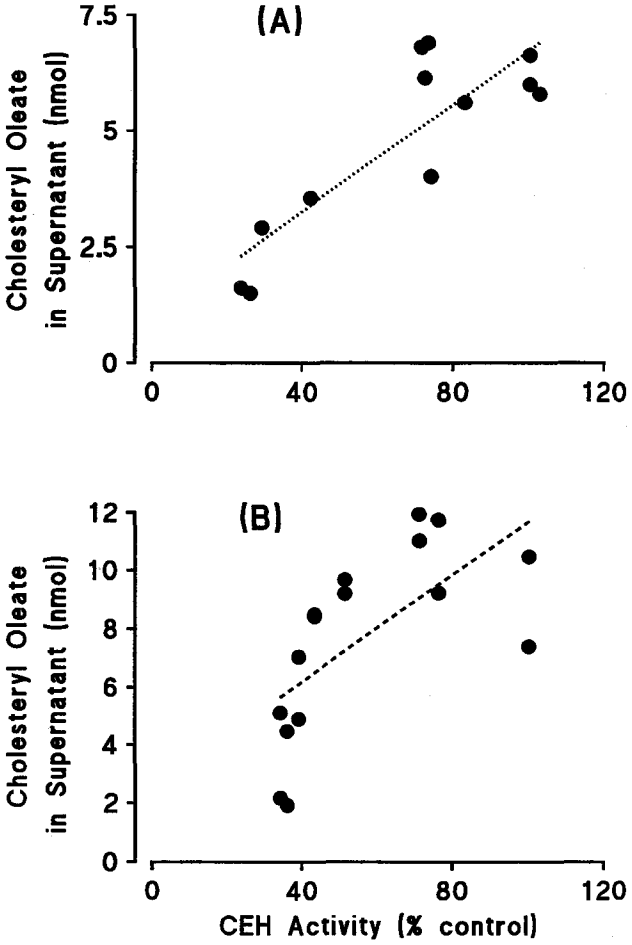

FIG. 8. Scatter diagram relating the binding of cholesteryl oleate and the inhibition of cholesteryl ester hydrolysis produced by rabbit muscle enolase in the initial absence (A), and presence (B) of BSA. The means for triplicate assays from two separate experiments are plotted. Linear regression analysis of the results in (A) gave y = 0.058(x) + 0.921, r = 0.86, and in (B) gave y = 0.92(x) + 2.52, r = 0.66. Abbreviations as in Figures 1 and 6.

(Fig. 6). Aggregation of the cholesteryl ester by the rabbit muscle enolase also occurred in the presence of an excess of liver cytosolic protein, suggesting that binding between the enolase and the cholesteryl ester could also occur in the cytosol *in vivo*.

Although the mechanism for the inhibition of CEH activity is presently unknown, the binding studies suggest that at least part of the process involves an interaction between substrate and enolase, which serves to protect the substrate from the hydrolytic activity of the enzyme. This interpretation is supported both by the binding experiments and by the inability of the enolases to inhibit the hydrolysis of the water-soluble *p*-nitrophenylbutyrate by HSL. Moreover, both the binding experiments and the Lineweaver-Burk plots indicate that there are differences in the mechanism of binding between the substrate and the two enolases, which is further influenced by the addition of other components to the mixture. This then could provide an explanation for the differential sensitivity of the various hydrolases to enolase inhibition. In particular, the liver and mammary gland microsomes are multicomponent systems which could influence the binding in a multitude of ways. The differential binding properties could also reflect the fact that, on average, there is only a 62% sequence identity between yeast and mammalian enolases (25).

The interest in this inhibitory property arises from the observation by Tabas and co-workers (12) that, when macrophages were loaded with cholesteryl esters and converted into "foam" cells, an isoform of α-enolase was increased 4–5-fold. However, cholesterol-loaded macrophages did not exhibit an increase in enolase glycolytic activity, implying that the increased form of α-enolase was not catalytically active, and thus might have some other function. Enolase is known to undergo interactions with other macromolecules and to have secondary functions in some cells (25). The

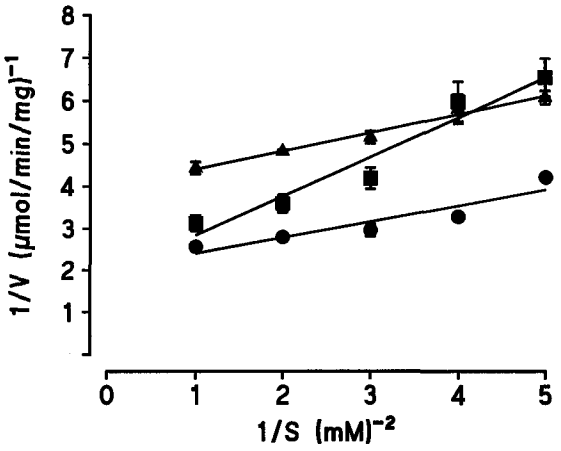

FIG. 9. Influence of yeast and rabbit muscle enolases on cholesteryl ester hydrolysis by hormone-sensitive lipase. Lineweaver-Burk plots of cholesteryl oleate hydrolysis by hormone-sensitive lipase at different substrate concentrations in the absence (●) or presence of either (■) yeast enolase (0.18 nmol) or (▲) rabbit muscle enolase (0.67 nmol).

results presented here suggest that such a secondary function in macrophages could be inhibition and, hence, control of CEH activity.

The observation that enolase acts to inhibit CEHs may also have far-reaching implications beyond the field of atherosclerosis. This glycolytic enzyme is particularly abundant and can constitute around 1% of soluble cell protein, notably in brain tissue (26). This may be relevant to some neuro-degenerative diseases in which increases in enolase activity have been correlated with increases in cholesteryl ester content. Thus, increases in α- and γ-isoenzymes of enolase, as well as accumulations of cholesteryl esters, have been detected in the brain tissue of sufferers of multiple sclerosis and Wallerian degeneration (27–30). The concentration of enolase is also increased in brain tissue of sufferers of transmissible spongiform encephalopathies, e.g., scrapie-affected mice and patients infected with Creuzfeldt Jacob's disease. Moreover, recent research has confirmed an increase in cholesteryl esters in such tissue (31). It is thus particularly interesting that partially purified enolase preparations from rat brain tissue exhibited these inhibitory properties.

In addition, cholesterol metabolism is altered in tumor cell proliferation, and increases in γ-enolase have been used as a diagnostic indicator in a number of cancerous conditions of neuroendocrine origin, particularly in small cell lung cancer (32,33). Thus, there is considerable evidence correlating cholesteryl ester accumulation with an increase in enolase protein, and the results presented here could provide an explanation for that correlation.

It has been speculated that the heterogeneity exhibited by enolases may confer some selective advantage upon the organism. Control of cholesteryl ester hydrolysis may be one such advantage, which may provide a new target for the treatment of those diseases in which cholesterol metabolism is altered.

Inhibition of Cholesterol Esterification in Macrophages and Vascular Smooth Muscle Foam Cells: Evaluation of E5324, an Acyl–CoA Cholesterol Acyltransferase Inhibitor

Andrew C. Nicholson, Kenneth B. Pomerantz, Tohru Fujimori and David P. Hajjar*

Departments of Pathology and Biochemistry, Cornell University Medical College, New York, New York 10021

ABSTRACT: Cholesteryl esters (CE) comprise the principal lipid class that accumulates within macrophages and smooth muscle cells of the atherosclerotic lesion. Acyl–CoA cholesterol acyltransferase (ACAT) is the major enzyme responsible for esterification of intracellular cholesterol. We evaluated the ability of E5324 (*n*-butyl-*N'*-[-2-[3-(5-ethyl-4-phenyl-1H-imidazol-1-yl)propoxy]-6-methyl-phenyl]urea), a novel, orally absorbable ACAT inhibitor, to inhibit esterification of fatty acids to cholesterol and CE accumulation in macrophages and in smooth muscle cells. E5324 significantly inhibited cholesterol esterification in rat aortic smooth muscle cells and in macrophages. In addition, E5324 reduced the cellular mass of CE, the significant measure of the efficacy of drugs designed to modulate cholesterol metabolism. E5324 treatment of macrophages exposed to acetylated low-density lipoprotein reduced CE mass by 97%, and treatment of lipid-loaded smooth muscle cells reduced CE mass by 29%. Although free cholesterol increased approximately twofold, this free cholesterol would presumably be accessible to the membrane for efflux *in vivo* (reverse cholesterol transport). These results demonstrate that E5324 can inhibit cholesterol esterification and CE mass in atherosclerotic foam cells, derived from either macrophages or arterial smooth muscle cells.

Lipids 30, 771–774 (1995).

Atherosclerosis and its associated pathological processes (coronary heart disease, peripheral vascular disease, and stroke) are major causes of morbidity and mortality in industrialized nations. Epidemiological studies have established a link between serum cholesterol levels and the development of atherosclerosis, and have demonstrated that lowering serum cholesterol levels reduces the risk of coronary heart disease. The level of serum cholesterol is determined by the absorption of dietary cholesterol, endogenous synthesis of cholesterol, and excretion of cholesterol into the bile. Each of these areas represents a site for potential therapeutic intervention to lower total serum cholesterol. Cholestyramine, a resin which combines with bile acids in the intestine, has been used successfully to prevent reabsorption of cholesterol and enhance its excretion. Inhibitors of hydroxymethylglutaryl–CoA reductase reduce endogenous synthesis of cholesterol and are widely used clinically.

Inhibition of acyl–CoA cholesterol acyltransferase (ACAT) is also a potential site of modulation of cholesterol and cholesteryl ester (CE) accumulation in atherosclerosis (1). ACAT is a microsomal enzyme which catalyzes the intracellular esterification of cholesterol to a free fatty acid, resulting in the formation of CE, the principal storage form of cholesterol (2). ACAT activity is increased within atherosclerotic lesions in animals with experimental atherosclerosis (3–5). ACAT inhibitors could have beneficial effects in treating or preventing atherosclerosis by reducing absorption of dietary cholesterol or inhibiting production of lipoproteins by the liver. ACAT inhibitors could also inhibit the accumulation of CE within macrophages and smooth muscle cells of the atheroma, facilitating the efflux of cholesterol and inhibiting the progression of atherosclerosis.

A novel ACAT inhibitor, E5324, was discovered after an intensive screening program (6,7), and was reported to have an inhibitory effect on ACAT activity in microsomes from various tissues, as well as in cultured cell homogenates (8). It also had anti-atherosclerotic activity in a rabbit model of atherosclerosis (9). We evaluated the effects of E5324 on the inhibition cholesterol esterification and on accumulation of cholesterol and CE in vascular smooth muscle cells and macrophages, the two cell types which accumulate CE and become the characteristic foam cells of the atherosclerotic lesion (10,11). We also evaluated the effects of E5324 on the two major enzymes in smooth muscle cells responsible for CE hydrolysis—lysosomal (acid) CE hydrolase and cytoplasmic (neutral) CE hydrolase. Lastly, the ability of E5324 to alter cholesterol and CE mass was evaluated in smooth muscle cells exposed to cationized low-density lipoprotein (LDL), an *in vitro* model of smooth muscle cell foam cell development.

EXPERIMENTAL PROCEDURES

Materials. E5324 (*n*-butyl-*N'*-[-2-[3-(5-ethyl-4-phenyl-1H-imidazol-1-yl)propoxy]-6-methyl-phenyl]urea) was a generous gift from the Tsukuba Research Laboratories of Eisai Co. Ltd. (Ibaraki, Japan). Human plasma LDL (d = 1.019–1.063

*To whom correspondence should be addressed at Dept. of Pathology, Cornell University Medical College, 1300 York Ave., New York, NY 10021.

Abbreviations: ACAT, acyl–CoA cholesterol acyltransferase; ACEH, acid cholesteryl ester hydrolase; CE, cholesteryl ester; LDL, low-density lipoprotein; NCEH, neutral cholesteryl ester hydrolase; PBS, phosphate-buffered saline.

Copyright © 1995 by AOCS Press

g/mL) was isolated by ultracentrifugation (12). The LDL was dialyzed against HEPES-buffered saline with EDTA, sterilized by filtration through a 0.22 μm filter, and stored under nitrogen gas at 4°C. Acetylation of LDL was described by Goldstein *et al.* (13). Cationized LDL was made by the method of Basu *et al.* (14,15).

Cholesterol esterification assay. Esterification of cholesterol was measured as described by Brown *et al.* (16). Substrate (LDL or acetylated LDL) was added with [^{14}C]-oleate (final conc. 0.1 mM oleate, 0.02 mM albumin). Cellular lipids were extracted into hexane/isopropanol (3:2) and spotted on thin-layer chromatography plates (Silica Gel 60; Analtech, Newark, DE). Areas corresponding to CE were scraped and counted in a Beckman scintillation counter (Beckman Instruments, Fullerton, CA).

Acid cholesteryl ester hydrolase (ACEH) and neutral cholesteryl ester hydrolase (NCEH) assays. ACEH (17) and NCEH (18) activity of cell homogenates were performed as previously described.

Cells and cell lines. J774 macrophages, a murine macrophage cell line, were obtained from American Type Culture Collection (ATCC, Rockville, MD). They were subpassaged in RPMI 1640 with 10% fetal bovine serum. Smooth muscle cells were propagated from explants of rat thoracic aorta in Medium 199 (Gibco BRL; Life Technologies Inc., Gathersburg, MD) containing glutamine, penicillin/streptomycin, Fungizone (Flow Laboratories, Inc., Mclean, VA), and 10% fetal bovine serum.

Cholesterol and CE mass. Cholesterol and CE mass were quantified by gas–liquid chromatography. Lipids were extracted as described by Brown *et al.* (16). The cell lipid extract was divided into two portions. The first was analyzed directly for determination of free cholesterol and the second was hydrolyzed using methanolic potassium hydroxide, followed by re-extraction into hexane and gas–chromatographic analysis for measurement of total cholesterol. The sterols were separated using a Hewlett-Packard (Palo Alto, CA) 5880A gas chromatograph on a six-foot OV-17 WHP column (Supelco, Bellefonte, PA), at a nitrogen flow rate of 40 mL/min, using a thermal gradient program starting at 260°C and raised 1°C/min to a final temperature of 275°C (19). The quantity of cholesterol (and CE) was determined by proportional area computation of mass/peak ratios toward known amounts of added β-sitosterol. Results were normalized to cellular protein levels measured by the method of Lowry *et al.* (20).

Statistical analysis. Values are expressed as mean ± SEM. Significance of the mean values were determined by the Student's *t*-test ($P < 0.05$).

RESULTS

We first examined the dose response relationship of E5324 to inhibit cholesterol esterification in smooth muscle cells. E5324 significantly inhibited cholesterol esterification at concentrations of 1 μM (30% reduction) and 10 μM (67% reduction) (Fig. 1). E5324 (10 μM) also inhibited esterification in macrophages by 73% (Fig. 2). As E5324 significantly inhibited cholesterol esterification in macrophages, we next evaluated whether E-5324 could alter cholesterol or CE mass in macrophages incubated with acetylated LDL, a scavenger receptor ligand. Incubation of macrophages with acetylated LDL, but not native LDL, results in significant accumulation of CE (13). Treatment of macrophages exposed to acetylated LDL with E5324 significantly reduced CE mass (by 93% relative to macrophages exposed to acetylated LDL alone) (Fig. 3). Free cholesterol increased approximately twofold. E5324 had no significant effects on ACEH or NCEH activities.

Because foam cells of smooth muscle origin are a prominent component of the atherosclerotic lesion, we utilized an *in vitro* model of smooth muscle foam cells. Smooth muscle cells were incubated with cationized LDL to evaluate the potential modulatory effect of E-5324 on cholesterol and CE mass in smooth muscle foam cells. This charge-modified LDL is internalized in a nonreceptor mediated manner by bulk phase endocytosis, resulting in marked CE accumulation (19,21). Incubation with native LDL or acetylated LDL will not result in lipid loading of smooth muscle cells. Treatment of CE-enriched smooth muscle cells with E5324 significantly

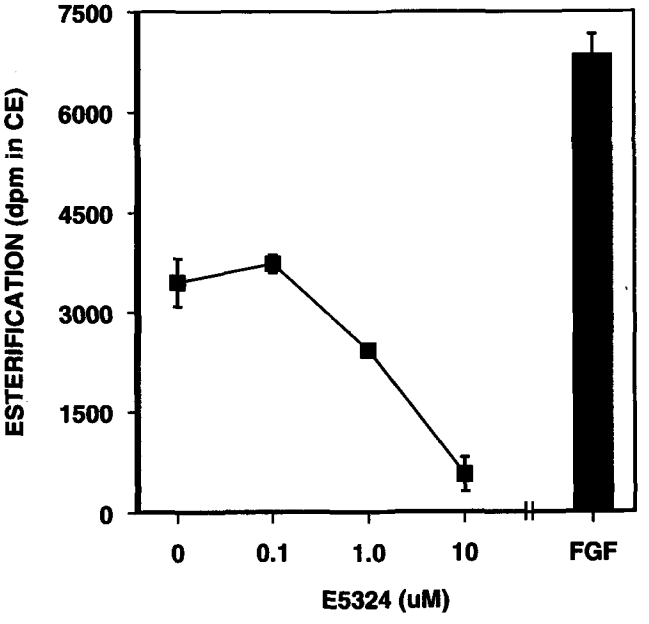

FIG. 1. Dose response of E5324 (Tsukuba Research Laboratories of Esai Co. Ltd., Ibaraki, Japan) on cholesterol esterification by rat aortic smooth muscle cells. Rat aortic smooth muscle cells were grown to confluence and incubated overnight in serum-free medium. Basic FGF (1 ng/mL) was added to one group as positive control. After 19 h, the cells (except for the bFGF-treated cells) were washed in phosphate-buffered saline and incubated for 5 h with media containing 0, 0.1 μM, 1.0 μM, and 10.0 μM E-5324, 50 μg/mL of LDL (cholesterol substrate), and [^{14}C]-oleate (final conc. 0.1 mM oleate, 0.02 mM albumin). Cellular lipids were separated in thin-layer chromatography and counted in a Beckman scintillation counter (Beckman Instruments, Fullerton, CA). The data represent the mean of three wells ± SEM. CE, cholesteryl ester; bFGF, basic fibroblast growth facter.

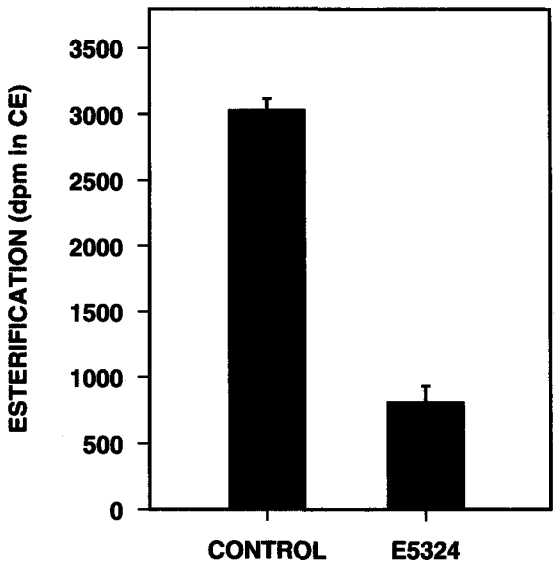

FIG. 2. Effect of E5324 on cholesterol esterification in macrophages. J774 macrophages, a murine macrophage cell line, were grown to confluence in RPMI 1640 with 10% fetal bovine serum in six-well plates. Incubation times are as described in Figure 1. Extraction of lipids and thin-layer chromatography procedures were as described in the Experimental Procedures section, with 10 μM E5324 utilized in the experimental group. The data represent the mean ± SEM of three wells. Abbreviation as in Figure 1, as well as company source.

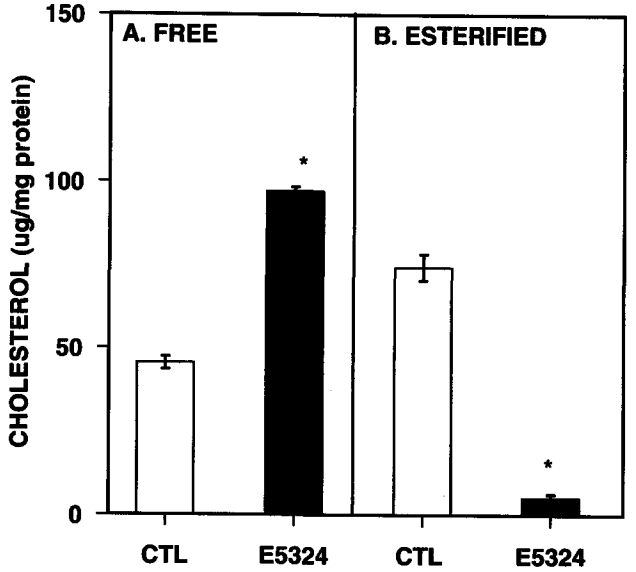

FIG. 3. Effect of E5324 on cholesterol and CE mass in macrophages. J774 macrophages were grown to confluence in 25 cm^2 flasks in RPMI with 10% fetal bovine serum. The media was changed to serum-free RPMI with 100 μg/mL acetylated low-density lipoprotein ± 10 μM E5324. The cells were incubated for 24 h prior to washing at 4°C three times with phosphate-buffered saline (PBS) with albumin and three times with PBS alone, and extraction of lipids in hexane/isopropanol (3:2). β-Sitosterol (30 μg) was added to each flask as internal standard. The cells were solubilized in 1 mL 0.2% NaOH for protein determination. The data represent the mean ± SEM of four flasks. *, $P < 0.05$ vs. control (CTL). See Figure 1 for company source.

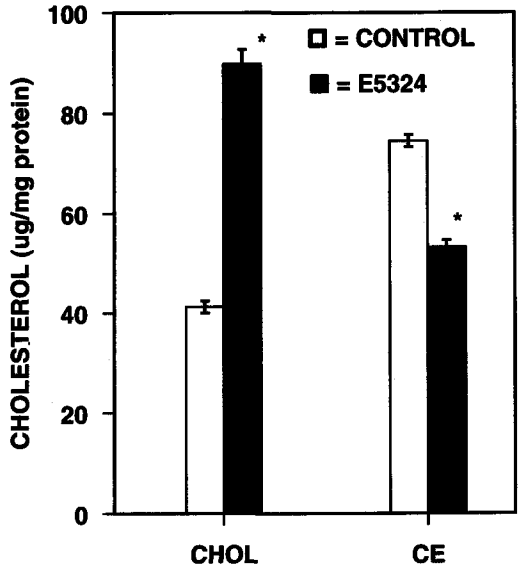

FIG. 4. Effect of E5324 on cholesterol (CHOL) and cholesteryl ester (CE) mass in smooth muscle cell foam cells. Rat aortic smooth muscle cells were exposed to cationized low-density lipoprotein (50 μg/mL) for 24 h in media with 5% fetal bovine serum. After loading, the media was changed and flasks were divided into two groups in triplicate; serum-free media alone and serum-free media with 10 μM E5324. The cells were incubated for 24 h prior to washing and extraction of lipids. β-Sitosterol (30 μg) was added to each flask as internal standard. The cells were solubilized in 0.2% NaOH for protein determination. Cholesterol and CE mass were quantified by gas–liquid chromatography. The data represent the mean ± SEM of three flasks. *, $P < 0.05$ vs. control. See Figure 1 for company source.

reduced CE mass (by 29%). Free cholesterol increased approximately 2.2-fold (Fig. 4).

DISCUSSION

Previous reports have shown that E5324, when administered concurrently with a high-cholesterol diet in rabbits, will prevent increases in plasma lipids and atherosclerotic plaque development (9). Furthermore, in pre-established hypercholesterolemic rabbits, E5324 can also lower plasma lipid levels, reduce plaque thickness, and reduce cholesterol accumulation within atherosclerotic plaques. E5324 also suppressed the accumulation of CEs in arterial lesions independently of its plasma cholesterol lowering effect (9). As these studies implied that E5324 has a direct effect on cells residing within the arterial wall, the current studies were undertaken to determine if E5324 altered cholesterol esterification *in vitro* in smooth muscle cells and macrophages, the progenitor cells for atherosclerotic foam cells.

E5324 significantly inhibited cholesterol esterification in aortic smooth muscle cells and macrophages. In addition, E5324 reduced the cellular mass of CE, a measure of the efficacy of drugs designed to modulate atherosclerotic lesion development. E5324 treatment of macrophages exposed to acetylated LDL reduced CE mass by 93%. Treatment of

"lipid-loaded" smooth muscle cells with E5324 reduced CE mass by 29%. Although free cholesterol increased approximately twofold in both macrophages and in smooth muscle cells, this free cholesterol would, presumably, be accessible to the membrane for efflux (reverse cholesterol transport) *in vivo*.

ACAT inhibitors have been studied for more than ten years, and a diverse set of compounds have been shown to be efficacious in lowering serum cholesterol levels in animal models of hypercholesterolemia. ACAT inhibitors also can decrease atherosclerotic lesion size and cholesterol accumulation in cholesterol-fed animals, but it is unclear if these effects are the indirect result of reduced serum cholesterol levels or a direct result of ACAT inhibition with macrophages and smooth muscle cells within the lesion. In addition to E5324 (9), one other ACAT inhibitor, CI-976, has been shown to inhibit CE accumulation within atherosclerotic arteries independent of lipid-lowering effects (22).

In summary, our data demonstrate that E5324 is effective in inhibiting cholesterol esterification in vascular smooth muscle cells and in macrophages. An important point is that E5324 also has the capacity to inhibit esterification and CE mass in smooth muscle foam cells which are already lipid-laden. These results are particularly significant as previous experments have shown that ACAT inhibitors can inhibit esterification only during the process of lipid loading.

Tissue-Selective Inhibition of Sterol Synthesis in Mice by Pravastatin Sodium After a Single or Repeated Oral Administrations

Teiichiro Koga*, Takashi Kikuchi, Atsuhiro Miyazaki and Hiroyuki Koike

Pharmacology and Molecular Biology Research Laboratories, Sankyo, Co., Ltd., Tokyo 140, Japan

ABSTRACT: Pravastatin, an inhibitor of 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase, exhibits liver-selectivity in inhibiting sterol synthesis, when administered as a single oral dose to mice or rats, whereas lovastatin and simvastatin do not. This may be due to the fact that pravastatin is distributed intracellularly, to a large extent, in the liver and extracellularly in nonhepatic tissues. In the present study, we examined whether the difference in liver-selectivity among these three HMG–CoA reductase inhibitors observed in single-dose studies was preserved after repeated oral administrations of drugs to mice. *De novo* sterol synthesis in different tissues of mice was examined *in vivo* three hours after the last dose of drug by measuring incorporation of intraperitoneally injected [^{14}C]acetate into total sterols. Pravastatin administered orally for 11 consecutive days at 5 and 10 mg/kg exhibited a greater liver-selectivity than lovastatin and simvastatin: sterol synthesis was inhibited more than 60% in the liver by all three drugs, whereas that in nonhepatic tissues was inhibited less than 10% by pravastatin and more than 30% by lovastatin and simvastatinin in most of the nonhepatic tissues examined. Pravastatin administered orally for 11 consecutive days at 10 mg/kg caused more selective inhibition of sterol synthesis in liver *ex vivo* than two other inhibitors at the same dose. Pravastatin inhibited *de novo* sterol synthesis from [^{14}C]acetate into sterol fraction in the liver slices *in vitro*, but minimally in those of the spleen and testis, whereas lovastatin and simvastatin inhibited in those of all three tissues. Since the drug concentrations determined in the same tissue samples of the liver, spleen, and testis were almost comparable among the three drugs, it was suggested that the cellular distribution profiles of pravastatin observed in a single-dose study were preserved in the multiple-dose study. We conclude that the difference in tissue-selectivity between pravastatin and the other two inhibitors to inhibit sterol synthesis in mice is maintained, regardless of the duration of administration.
Lipids 30, 775-779 (1995).

Pravastatin administered as the sodium salt (1–3) is a potent and specific hydrophilic inhibitor of 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase, a key enzyme of sterol synthesis (4). It has been shown that pravastatin exhibits hepatocyte-selective inhibition of sterol synthesis (3,5,6), which is due to the selective uptake of this agent by hepatocytes through the carrier-mediated pathway (7). The drug also exhibited liver-selective inhibition of sterol synthesis when orally administered to mice or rats (3,5,6). Our recent study has demonstrated (6) that, after oral administration to rats, pravastatin is distributed mostly in the intracellular space in the liver and in the extracellular spaces in nonhepatic tissues. These cellular distribution profiles of pravastatin seem to underlie the liver-selective inhibition of sterol synthesis.

In contrast to pravastatin, lovastatin, and simvastatin administered in their lactone forms are hydrophobic HMG–CoA reductase inhibitors, and they do not show tissue-selectivity (3,5,6). Lovastatin and simvastatin were taken up by nonhepatic tissue-derived cells, such as fibroblasts, spleen cells as well as hepatocytes, and inhibited sterol synthesis in these cells (3,5). These drugs also inhibited sterol synthesis both in the liver and nonhepatic tissues when orally administered to mice or rats (3,5,6).

These earlier studies (3,5,6), however, were *in vitro* ones or acute ones in which the inhibitors were administered only once. There have been no reports documenting tissue-selectivity of HMG–CoA reductase inhibitors in intact animals after repeated oral administrations, although hypolipidemic drugs are typically used on a long-term basis.

In the present study, we examined whether the liver-selectivity observed in single oral administration experiments in mice is also apparent in long-term experiments, and whether the cellular distribution profiles of pravastatin observed in single oral administration experiments (6) are preserved after repeated oral administrations.

MATERIALS AND METHODS

Materials and animals. [1-^{14}C]Sodium acetate (1.977 GBq/mmol) was obtained from New England Nuclear Co. (Amersham International, Amersham, United Kingdom). Pravastatin (acid form), lovastatin (lactone form), and simvastatin (lactone form) were prepared as previously described (6). Pravastatin was dissolved in 1% Tween 80 aqueous solution (NACALAI TESQUE, Inc., Kyoto, Japan). Lovastatin and simvastatin were suspended in the same solution. Male C57BL/6 mice, eight weeks old (Charles River, Kanagawa, Japan) were used for the experiment.

Determination of sterol synthesis. Sterol synthesis in different tissues of mice *in vivo* was examined by measuring

incorporation of [^{14}C]acetate into digitonin-precipitable [^{14}C]sterols as described previously (5). [^{14}C]Acetate (20 μCi/mouse) was intraperitoneally injected into mice two hours after the last drug administration. One hour later, tissues were excised for measurement of sterol synthesis. To establish a dose-response relationship of inhibition of *de novo* sterol synthesis in the liver, each drug was orally administered once to mice in various doses from 0.03–30 mg/kg, and sterol synthesis in the liver was measured as described above.

Tissue selectivity of HMG–CoA reductase inhibitors after a single oral administration to mice. In order to confirm our previous results (5), we orally administered HMG–CoA reductase inhibitors once to mice at 20 mg/kg, and sterol synthesis inhibition in different tissues of mice was measured as described above. Tissues from four mice were pooled for measurement of sterol synthesis. Sterol synthesis in lens was measured *in vitro* as described previously (5).

Tissue selectivity of HMG–CoA reductase inhibitors after repeated oral administrations to mice. Each drug was orally administered to mice at doses of 5 and 10 mg/kg for 11 consecutive days. Sterol synthesis inhibition in different tissues of mice were measured as described above. Sterol synthesis in lens was measured *in vitro* as described previously (5). Tissues from four mice were pooled for measurement of sterol synthesis.

Determination of sterol synthesis in tissue slices. Pravastatin, lovastatin, and simvastatin were orally administered to mice at 10 mg/kg for 11 consecutive days. Two hours after the last dosing, mice were killed by decapitation, and the liver, spleen, and testis were excised and sliced. Tissues from five mice were pooled for measurement of sterol synthesis. Sterol synthesis in the tissue slices was monitored for two hours using the incorporation of radioactivity from 1 mM [^{14}C]acetate into digitonin-precipitable sterols as described previously (6). The measurement of radioactivity was carried out in duplicate.

Determination of active drug concentration in tissues. After tissue slices were prepared for measurement of sterol synthesis, the active drug concentrations in the remainder of the tissues were determined based on our previous report (6). In brief, the active drugs were extracted from the tissue homogenate with methanol and assayed for inhibition of rat liver HMG–CoA reductase (6). The bioactivity was related to concentrations of the original drug by comparison with concentration-inhibition curves constructed beforehand with known concentrations of the inhibitors.

Determination of serum total cholesterol. Blood samples collected when the mice were sacrificed were left for 30 min at room temperature, and serum was obtained by centrifugation at 2,150 × *g* for 10 min at 4°C. The levels of serum total cholesterol were determined enzymatically using Hitachi type 736 automatic analyzer (Tokyo, Japan).

RESULTS

Inhibition of sterol synthesis in the liver. We examined dose-response relationship of inhibition of *de novo* sterol synthesis in the liver three hours after a single oral administration of HMG–CoA reductase inhibitors, and determined ED_{50} values, drug doses required for 50% inhibition of sterol synthesis in the liver: They were (mean ± SEM, n = 3) 0.6 ± 0.01, 0.56 ± 0.09, and 0.74 ± 0.10 mg/kg for pravastatin, lovastatin, and simvastatin, respectively.

Typical dose-response curves in sterol synthesis inhibition in the liver after a single oral dose of each drug are shown in Figure 1, where 20 mg/kg is a minimum dose at which each drug equally exhibits almost maximal inhibition (more than 80%) of sterol synthesis in the liver. In single oral administration experiments, we compared tissue-selectivity of these three drugs at 20 mg/kg in inhibiting sterol synthesis in different tissues of mice. On the other hand, sterol synthesis inhibition in the liver was less than 80% at doses of 5 and 10 mg/kg. In the long-term experiments, we chose these doses, lower than that in single oral administration experiments, so that chronic effects were not masked by the acute effect of the last dose of drugs.

Tissue selectivity of HMG–CoA reductase inhibitors after a single oral administration to mice. Administration of a single oral dose of pravastatin at 20 mg/kg inhibited sterol synthesis in the liver three hours later by more than 80% (Table 1). This agent, however, inhibited sterol synthesis at this time point by less than 20% in the kidney, spleen, heart, cerebrum, diaphragm, lens, and in the steroid hormone-producing tissues, such as the adrenal and testis (Table 1). On the other hand, lovastatin and simvastatin inhibited sterol synthesis significantly in the nonhepatic tissues, as well as in the liver. These results agreed well with our previous observations (5) that pravastatin, but not lovastatin and simvastatin, was liver-selective in inhibiting sterol synthesis in mice after a single oral dose.

Tissue selectivity of HMG–CoA reductase inhibitors after repeated oral administrations to mice. Inhibition of sterol

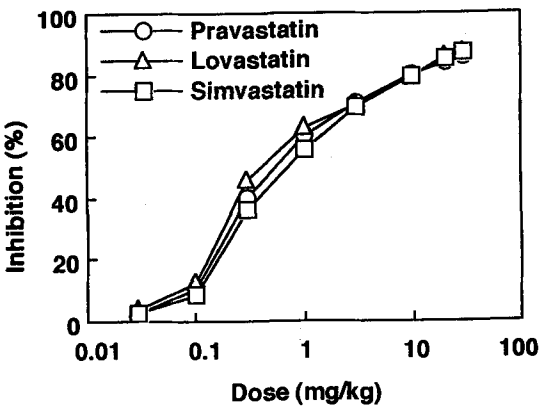

FIG. 1. Dose response curves of inhibition of *de novo* sterol synthesis in the liver. Each drug was orally administered to mice at 0.03–30 mg/kg. Two hours later, [^{14}C]acetate was intraperitoneally injected into mice. One hour after [^{14}C]acetate injection, mice were killed by decapitation, the liver was excised, and sterol synthesis was measured as described in the text. Each point represents the mean from four mice.

TABLE 1
Inhibition of *de novo* Sterol Synthesis in Different Tissues After a Single Oral Dose of Pravastatin, Lovastatin, and Simvastatin in Mice[a]

	(dpm/100 mg tissue)			
	Control	Pravastatin	Lovastatin	Simvastatin
Liver	1278 ± 192	242 ± 38[c] (81.1)	174 ± 31[c] (86.4)	179 ± 33[c] (86.0)
Adrenal	308 ± 30	274 ± 24 (11.0)	223 ± 22[b] (27.6)	173 ± 18[c] (43.8)
Kidney	409 ± 29	328 ± 24[b] (19.8)	187 ± 12[c] (54.2)	225 ± 25[c] (44.9)
Spleen	696 ± 35	617 ± 42 (11.4)	339 ± 12[c] (51.3)	353 ± 18[c] (49.3)
Testis	1055 ± 198	1018 ± 320 (3.5)	377 ± 56[b] (64.3)	261 ± 48[c] (75.3)
Heart	253 ± 23	228 ± 27 (9.9)	182 ± 15[b] (28.1)	185 ± 14[b] (26.9)
Cerebrum	161 ± 8	147 ± 9 (8.7)	135 ± 6[b] (16.1)	115 ± 8[c] (28.3)
Diaphragm	49 ± 8	48 ± 4 (2.0)	22 ± 3[c] (55.1)	23 ± 3[c] (52.0)
Lens	287 ± 32	265 ± 21 (7.7)	183 ± 12[c] (36.2)	188 ± 13[c] (34.5)

[a]Each drug was orally administered to mice at a dose of 20 mg/kg. Two hours later, [^{14}C]acetate was intraperitoneally injected into mice. One hour after [^{14}C]acetate injection, mice were killed by decapitation, and tissues were excised. Tissues from four mice were pooled, and sterol synthesis was measured as described in the text. Values are mean ± SEM (n = 5). Inhibition as percentage of control is shown in parentheses. [b]$P < 0.05$. [c]$P < 0.01$ by Duncan's test.

synthesis in different tissues of mice after repeated oral administrations of HMG–CoA reductase inhibitors at 5 and 10 mg/kg for 11 consecutive days is summarized in Table 2. All three drugs inhibited sterol synthesis by more than 60% in the liver. On the other hand, pravastatin did not inhibit sterol synthesis in nonhepatic tissues even at 10 mg/kg, whereas lovastatin and simvastatin inhibited sterol synthesis by more than 20% at 5 mg/kg and more than 30% at 10 mg/kg in most of the nonhepatic tissues.

Active drug concentrations and inhibition of sterol synthesis in the liver, spleen, and testis. The active drug concentrations and inhibition of sterol synthesis were measured in the liver, spleen, and testis that were excised two hours after the last oral administrations of pravastatin, lovastatin, and simvastatin to mice at a dose of 10 mg/kg for 11 consecutive days. All three drugs were present in higher concentrations in the liver than in the spleen and testis (Table 3). The active drug concentrations of all three drugs were almost identical in the liver (Table 3), where all three drugs inhibited sterol synthesis to a similar degree (Table 4) as they did in the *in vivo* study (Table 2). The active drug concentrations of pravastatin were also comparable to those of lovastatin and simvastatin in the spleen and testis (Table 3), where lovastatin and simvastatin inhibited sterol synthesis, but pravastatin did not (Table 4). These data suggest that pravastatin is liver-selective regarding sterol synthesis inhibition.

Body weight, serum cholesterol, and transaminase levels. Serum total cholesterol levels were not changed with an 11-

Testis	7262 ± 490	7442 ± 332 (−2.5)	3803 ± 500[c] (47.6)	2454 ± 406[c] (66.2)

[a]Each drug was orally administered to mice at 10 mg/kg for 11 consecutive days. Two hours after the last drug administration of pravastatin, lovastatin, and simvastatin, mice were killed by decapitation, and the liver, spleen, and testis were excised and sliced. Tissues from five mice were pooled for measurement of sterol synthesis. Sterol synthesis in the slices was measured as described in the text. Assay was carried out in duplicate. Values are mean ± SEM (n = 4). Inhibition as percentage of control is shown in parentheses. [b]$P < 0.05$. [c]$P < 0.01$ by Duncan's test.

TABLE 5
Changes in Serum Total Cholesterol[a]

	Total cholesterol (mg/dL)
Control	86.0 ± 1.8
Pravastatin (10 mg/kg)	85.5 ± 3.0
Lovastatin (10 mg/kg)	84.0 ± 1.4
Simvastatin (10 mg/kg)	82.0 ± 1.0

[a]Each drug was orally administered to mice at 10 mg/kg for 11 consecutive days. Two hours after the last drug administration of pravastatin, lovastatin, and simvastatin, mice were killed by decapitation, blood was collected, and serum was obtained by centrifugation. The levels of serum total cholesterol were determined enzymatically as described in the text. Values are mean ± SEM (n = 4).

day treatment of HMG–CoA reductase inhibitors (Table 5). There were no differences in body weight gain or serum transaminase levels between the control and drug treatment groups after an 11-day treatment with HMG–CoA reductase inhibitors (data not shown).

DISCUSSION

In the present study, we examined if the hepatic selectivity of pravastatin for HMG–CoA reductase inhibition observed in single oral administration experiments *in vivo* was maintained in long-term experiments. We first confirmed the previous results (3,5,6) that after a single oral administration, pravastatin showed greater liver-selectivity in inhibiting sterol synthesis than lovastatin and simvastatin (Table 1). We then examined tissue-selectivity after repeated oral administration of HMG–CoA reductase inhibitors, and we concluded that the difference in liver-selectivity among these three inhibitors observed in a single-dose study was preserved after repeated oral administrations (Tables 2 and 4).

In long-term experiments, the doses used were 5 and 10 mg/kg. We chose these two doses for the following reasons. First, we chose doses which produced less than 80% inhibition of sterol synthesis in the liver (Fig. 1) to minimize the likelihood that chronic effects would be masked by the acute effect of the last dose of drug. We also chose doses at which drugs similarly reduce serum cholesterol. None of these HMG–CoA reductase inhibitors, however, decreased serum cholesterol in our mice (Table 5), and it is known (8) that HMG–CoA reductase inhibitors do not reduce serum cholesterol in rodents. Since inhibition of HMG–CoA reductase in the liver is thought to cause the reduction of serum cholesterol (9–11), we chose doses producing almost the same inhibition of sterol synthesis in the liver instead. In experimental animals, the doses at which HMG–CoA reductase inhibitors decrease serum cholesterol are more than 3 mg/kg when drugs are administered once a day for more than seven days (Koga, T., unpublished data): in dogs, more than 3 mg/kg; in rabbits and common marmosets, more than 5 mg/kg; in cynomolgus monkeys, more than 20 mg/kg. We therefore chose doses more than 3 mg/kg. Since the efficacy of simvastatin was reported to be nearly two times greater than that of pravastatin or lovastatin, we selected two doses, 5 and 10 mg/kg.

Because these reasons, we administered 5 or 10 mg/kg HMG–CoA reductase inhibitors in long-term experiments. Although these doses were higher than those administered to humans (approximately 0.2–0.6 mg/kg), we think that they do not appear to have been toxic to mice because there were no changes of body weight gain and the levels of serum transaminases between the control and drug treatment groups (data not shown). Since these doses were less than those in single oral administration experiments, the inhibition of sterol synthesis in the liver after repeated administrations was somewhat less than that after a single oral administration. Nevertheless, the liver selective inhibition of sterol synthesis with pravastatin and the lack of such selectivity with the other two inhibitors were apparent (Tables 2 and 4).

Conflicting results have been reported with regard to tissue selectivity of HMG–CoA reductase inhibitors (3,5–7,12). Based on inhibition of sterol synthesis in cells *in vitro* (3,5–7), in rat tissue slices (3,6), and in mice *in vivo* (5), we have reported that pravastatin is more liver-selective than lovastatin or simvastatin. These results were confirmed in the present study (Tables 1, 2, and 4). On the other hand, based on the distribution of drugs in the liver relative to nonhepatic tissues, Germershausen *et al.* (12) have concluded that lovastatin and

simvastatin are more liver-selective than pravastatin. In our recent study (6), we resolved this discrepancy. Namely, because pravastatin is distributed in the intracellular space in the liver and remained in the extracellular space in nonhepatic tissues after oral administration to rats, this drug inhibited sterol synthesis more strongly in the liver than in other tissues.

In order to examine whether the cellular distribution profiles of pravastatin in different tissues were maintained after repeated oral dosings, we administered pravastatin, lovastatin, and simvastatin to mice at 10 mg/kg for 11 consecutive days and determined the relationship between active drug concentrations and sterol synthesis inhibition in the liver, spleen, and testis. The levels of active drug concentrations of three HMG–CoA reductase inhibitors were almost comparable in each tissue, and those in the liver were higher than those in the spleen and testis, as we have previously reported in rats (6). On the other hand, pravastatin was liver-selective in inhibiting sterol synthesis, but lovastatin and simvastatin were not. Together with the results of our previous report (6), these results suggest that pravastatin permeated the cell membrane in the liver, but not in nonhepatic tissues, whereas lovastatin and simvastatin penetrated inside the cells in all these tissues. We conclude that the distribution of pravastatin inside hepatocytes and outside the cells in nonhepatic tissues suggested by single dose studies may also be present after repeated oral administrations.

Lovastatin and simvastatin, but not pravastatin, inhibited sterol synthesis in the diaphragm, lens, and cerebrum after a single or repeated oral administrations. Mosley *et al.* (13) also demonstrated that lovastatin, but not pravastatin, inhibited sterol synthesis in rat lens after a single oral dose. Myopathy (14–16) and insomnia (17–19) have been reported for lovastatin and simvastatin, but have not yet been reported for pravastatin. Significant inhibition of sterol synthesis in nonhepatic tissues by these two inhibitors, but not by pravastatin, may have clinical relevance for a number of effects.

ACKNOWLEDGMENTS

ABSTRACT: The objective was to determine whether rats could synthesize longer chain polyunsaturates from hexadecadienoate (16:2n-6) and hexadecatrienoate (16:3n-3). Rats were gavaged with uniformly ^{13}C-labelled hexadecadienoate or hexadecatrienoate, euthanized 24 h later, and total lipids were extracted from liver and carcass. Gas chromatography/combustion/isotope ratio mass spectrometry was used to measure ^{13}C levels in individual liver, carcass, and whole body fatty acids. ^{13}C Enrichment was present in desaturated and chain-elongated polyunsaturates, including linoleate, arachidonate, α-linolenate, and docosahexaenoate at 12–13% of the dose of tracer given. ^{13}C Enrichment from hexadecatrienoate was highest in carcass and liver α-linolenate, representing 3.5 and 17.9% of the total α-linolenate pool, respectively. For linoleate, arachidonate, or docosahexaenoate, the contribution of ^{13}C did not exceed 0.2% of the total body pool. Green leafy vegetables common in the human diet were shown to contain up to 1.2% of total fatty acids as hexadecadienoate and 11.6% as hexadecatrienoate. Hence, humans consuming green vegetables probably synthesize a small proportion of their total body content of linoleate and α-linolenate.

Lipids 30, 781–783 (1995).

Linoleate (18:2n-6) and α-linolenate (18:3n-3) are widely accepted as being essential nutrients in the diets of mammals. Although plants and mammals can insert methylene-interrupted double bonds at the C_{9-10} position to synthesize oleate (18:1n-9) from stearate (18:0), only plants can desaturate 18:1n-9 at the C_{12-13} and C_{15-16} positions to form 18:2n-6 and 18:3n-3, respectively. Once the unsaturated bond is at the C_{9-10} and C_{12-13} positions, mammals can desaturate and chain elongate 18:2n-6 and 18:3n-3 to longer chain polyunsaturate fatty acids (PUFA).

Thirty years ago it was shown that 18:2n-6 and n-6 longer chain PUFA could be synthesized in rats from shorter chain n-6 PUFA, including tetradecadienoate (14:2n-6) and hexadecadienoate (16:2n-6), but not from the 10 or 12 carbon analogues (1). Hexadecatrienoate (16:3n-3) also can be converted to n-3 long-chain PUFA (2). These important observations suggest that 18:2n-6 and 18:3n-3 may not be essential in the mammalian diet if the 14- or 16-carbon precursors are consumed, but they have not, to our knowledge, been confirmed. However, several species of edible plants and marine algae contain 16:2n-6 and 16:3n-3, so it is possible that humans, especially vegetarians, can use dietary 16:2n-6 and 16:3n-3 to synthesize some 18:2n-6 and 18:3n-3.

METHODS

The marine unicellular microalgae—*Chlorella vulgaris*—was grown in a closed photobioreactor system in which $^{13}CO_2$ was the sole exogenous source of carbon. Over a period of 21 d, the microalgae uniformly incorporated ^{13}C into the entire biomass at levels exceeding 98%. The total fatty acids (composition in Table 1) of the uniformly (U)-^{13}C-labelled microalgae then were extracted and separated to purify the 16:2n-6 and 16:3n-3 by low temperature crystallization, urea adduction, and preparative high-performance liquid chromatography. These procedures yielded [U-^{13}C]-16:2n-6 and [U-^{13}C]-16:3n-3 at 96% purity. Twenty mg of [U-^{13}C]-16:2n-6 or 16:3n-3 methyl ester was suspended in 200 μL olive oil and gavaged into 200 g Sprague-Dawley rats ($n = 4$ per group; Charles River Canada, St. Constant, Quebec,

Canada). The rats were euthanized 24 h later under a CO_2 atmosphere, and the livers were removed for analysis. The remaining carcass was analyzed so that whole body fatty acid and ^{13}C content could be determined.

Liver and carcass total lipids were extracted into chloroform/methanol (2:1), saponified, and weighed. The fatty acids were methylated using 14% boron–trifluoride in methanol. Fatty acid methyl esters were separated by capillary gas chromatography (GC), and the liver and carcass fatty acid profiles were determined relative to the retention times of standard reference mixtures. ^{13}C Enrichment in the fatty acid methyl esters was determined by GC/combustion/isotope ratio mass spectrometry (GC/C/IRMS) (3). The ^{13}C enrichment in 18:2n-6 isotopomers of an aliquot of the liver fatty acid mixture was determined using a mass selective GC/MS equipped with an electron impact detector (Hewlett-Packard, Palo Alto, CA).

To determine possible sources of 16:2n-6 and 16:3n-3 in human diets, the fatty acid profiles of the lipids of several common edible green vegetables were determined by capillary GC and GC/MS following the same lipid extraction procedures as for rat liver lipids.

RESULTS AND DISCUSSION

Twenty-four hours after dosing with [U-^{13}C] 16:2n-6, rat liver total lipids contained ^{13}C in several n-6 PUFA, including 18:2n-6, dihomo-γ-linolenate (20:3n-6), and arachidonate (20:4n-6) in the range of 1.40 to 1.52 atom%. After dosing with [U-^{13}C]-16:3n-3, liver 18:3n-3, eicosapentaenoate (20:5n-3), and docosahexaenoate (22:6n-3) contained ^{13}C ranging from 1.32 to 3.48 atom%. Carcass enrichments were generally lower than those in liver (Fig. 1). Dosing with ^{13}C-16:2n-6 did not statistically affect ^{13}C levels in n-3 PUFA, and *vice versa* for ^{13}C-16:3n-3. No significant ^{13}C enrichment was observed in saturates or monounsaturates in rat liver after either [U-^{13}C]-16:2n-6 or 16:3n-3, indicating that, within the study period (24 h), there was little recycling of ^{13}C into lipids synthesized *de novo* (data not shown).

To determine the percentage of tracer recovered in body lipids and the change in body content of PUFA induced by the tracers, absolute amounts of the main PUFA and their ^{13}C enrichments were calculated from the atom percent data and the quantitative content of total fatty acids in the liver and carcass of both undosed control rats and those given the tracers. The percentage increase in the carcass pool of PUFA after dosing with the ^{13}C-16:2n-6 or 16:3n-3 ranged from below detection limits for 22:6n-3 to 3.45% for 18:3n-3; in liver these values ranged from 0.13% for 16:2n-6 itself to 17.9% for 18:3n-3 (Tables 2 and 3). Liver and carcass data were combined to give whole body values for both the increase in PUFA and the retention of the tracer. The percent change in whole body content of PUFA induced by the tracers ranged from 0.05% for 22:6n-3 to 3.54% for 18:3n-3; these changes accounted for 12–13% of the tracer given.

The actual amount (mg) of ^{13}C-16:2n-6 incorporated into 18:2n-6 was the same as for ^{13}C-16:3n-3 incorporation into

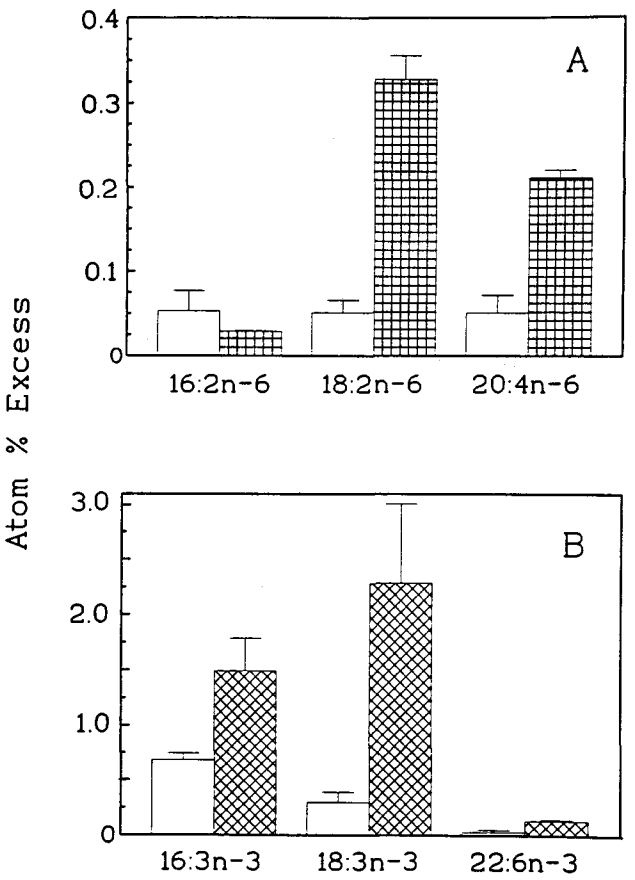

FIG. 1. ^{13}C atom% excess in carcass (open bar) and liver (bars with straight lines, bar with diagonal lines) of rats given an oral dose of 20 mg of [U-^{13}C]-16:2n-6 (A), or [U-^{13}C]-16:3n-3 (B) 24 h earlier.

18:3n-3 (about 2.3 mg each). However, because the whole body pool of 18:2n-6 was twenty times larger than that of 18:3n-3, the increase in the whole body 18:2n-6 caused by the tracer was only 0.18% compared to 3.54% for 18:3n-3 (Tables 2 and 3). Calculated by GC/MS, the change in 18:2n-6 caused by the mass + 16 isotopomer of 18:2n-6, which would have been derived *via* synthesis from [U-^{13}C] 16:2n-6, was approximately 0.4% of the total 18:2n-6 isotopomers in rat liver (data not shown). This value broadly agrees with the calculation of absolute change in 18:2n-6 determined by GC and GC/C/IRMS. The ^{13}C enrichment data suggest that, given an equal dose of 16:2n-6 or 16:3n-3 and an approximately equal body content of 16:2n-6 and 16:3n-3, equal amounts (mg) of ^{13}C-labelled 18:3n-3 and 18:2n-6 are accumulated in rat liver and carcass, but the relative effect on the 18:2n-6 pool is much less due to a 20-fold dilution (Tables 2 and 3).

These results confirm earlier reports that rats are capable of chain-elongating 16:2n-6 to 18:2n-6 and n-6 longer chain PUFA (1), and chain-elongating 16:3n-3 to 18:3n-3 and n-3 longer chain PUFA (2). To our knowledge, the present study reports the first direct comparison of the two 16 carbon precursors in rats already consuming an adequate amount of 18:2n-6 and 18:3n-3; some of the previous work on this topic has involved rats deficient in 18:2n-6 (1), which enhances de-

saturase activity and may therefore increase the conversion of 16:2n-6 to n-6 longer chain PUFA. We also used stable isotope methodology in this study, which is applicable to addressing the same question in humans.

Because the amount of 16:2n-6 and 16:3n-3 in several common edible green plants is up to 1.2 and 11.8%, respectively (Table 1), we infer that humans probably synthesize some of the 18:2n-6 and 18:3n-3 present in the body. The extent that the whole body content of 18:2n-6 or 18:3n-3 is synthesized vs. consumed must vary partly as a function of the ratio of 16:2n-6/18:2n-6 and 16:3n-3/18:3n-3 in the overall diet. In the few green plants analyzed, total 16:2n-6 was highest in broccoli leaves at 13.0% of the 18:2n-6 content. Also in broccoli, 16:3n-3 was 3.8% of the content of 18:3n-3 in the buds and 25.6% of the 18:3n-3 in broccoli leaves (Table 1); 16:3n-3 is also present in spinach (4). Hence, some common edible green vegetables may contribute appreciable amounts of 16:3n-3 to the human diet.

In true vegetarians (vegans), green plants would be an important source of 18:3n-3, but 18:2n-6 is found in a wider range of seeds, pulses, and legumes. If the green plants we analyzed here for 16:2n-6 and 16:3n-3 are representative of those most commonly found in the human diet, and if rats and humans metabolize hexadecadienoate and hexadecatrienoate at a similar rate, about 3–4% of the body's 18:3n-3, but <1% of its 18:2n-6, could be synthesized from their respective 16 carbon precursors. Rats actually appear to synthesize more 22:6n-3/g 18:3n-3 consumed than humans, and the human consumption of 16:3n-3 likely would not exceed 10% of 18:3n-3 intake, even in vegetarians (Table 1). Thus, it seems probable that 18:3n-3 synthesis from 16:3n-3 would account for <1% of the whole body pool, whereas for 18:2n-6, it would probably be <0.1%. From these estimates, there seems to be no doubt that 18:2n-6 and 18:3n-3 remain functionally essential in the human diet even though, extrapolating from the present data obtained in rats, humans can probably synthesize them by chain-elongation.

Antioxidant Stoichiometry and the Oxidative Fate of Vitamin E in Peroxyl Radical Scavenging Reactions

Daniel C. Liebler* and Jeanne A. Burr

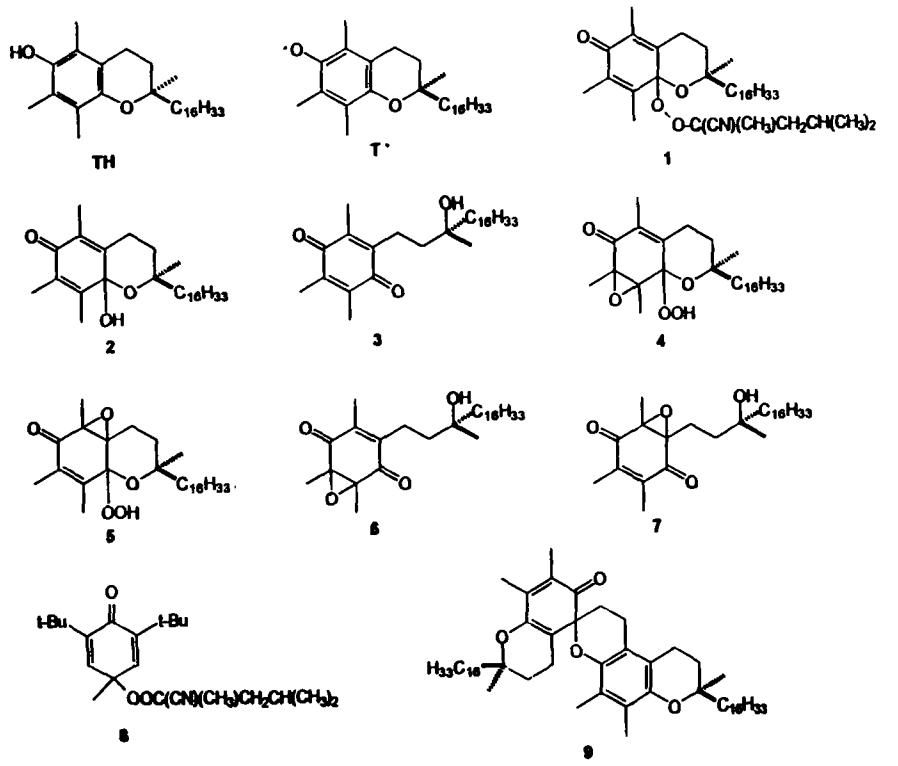
Department of Pharmacology and Toxicology and Southwest Environmental Health Sciences Center, College of Pharmacy, University of Arizona, Tucson, Arizona 85721

ABSTRACT: Oxidation of *R,R,R*-α-tocopherol (vitamin E; TH) by peroxyl radicals generated from the azo initiator azo*bis*(2,4-dimethylvaleronitrile) in acetonitrile, hexane, or in phospholipid liposomes yields 8a-(alkyldioxy)tocopherone adducts, 8a-(hydroxy)tocopherone, and their hydrolysis product α-tocopherolquinone. TH oxidation also yields 4a,5-epoxy- and 7,8-epoxy-8a-(hydroperoxy)tocopherones and their respective hydrolysis products 2,3-epoxy-α-tocopherolquinone and 5,6-epoxy-α-tocopherolquinone. Previous work indicates that the distribution of TH oxidation products varies with reaction environment. We investigated the dependence of antioxidant stoichiometry on TH oxidation product distribution for reactions in hexane, acetonitrile, and in phosphatidylcholine liposomes. Yields of 8a-substituted tocopherones were highest in hexane and lowest in phosphatidylcholine liposomes. In contrast, yields of epoxide products were highest in the liposome system and lowest in hexane. Yields of α-tocopherolquinone were similar in all three systems. Antioxidant stoichiometry, measured by the inhibited autoxidation method, was approximately 2.0 peroxyl radicals trapped per TH consumed in acetonitrile and in liposomes. In hexane, a slightly larger stoichiometric factor of approximately 2.5 was measured. This may, in part, reflect the generation of more reactive alkoxyl radicals in hexane. The reaction environment thus markedly affects the balance between competing TH oxidation pathways but produces comparatively little effect on antioxidant stoichiometry. These results imply that competing reaction pathways contribute similarly to the antioxidant chemistry of TH.

Lipids 30, 789–793 (1995).

α-Tocopherol [vitamin E; 2′*R*,4′*R*,8′*R*-α-tocopherol (*R,R,R*-α-tocopherol) (TH)] is thought to protect tissues by scavenging lipid peroxyl radicals that would otherwise damage biological membranes and other lipid-containing structures (1–3). TH reacts readily with peroxyl radicals to yield a hydroperoxide and the resonance-stabilized α-tocopheroxyl radical (T˙). Further reactions of T˙ yield two groups of nonradical products (4–9). The first consists of 8a-substituted tocopherones, which result either from peroxyl radical addition at C-8a to form 8a-(alkyldioxy)tocopherones (**1**, Scheme 1) (4,6,7,10) or from electron transfer followed by hydrolysis to yield 8a-(hydroxy)tocopherones **2** (9,11,12). Products **1** and **2** hydrolyze and rearrange to form α-tocopherolquinone **3** (13). Both **1** and **2** arise from two-electron oxidations of TH compatible with the previously reported stoichiometry of two peroxyl radicals trapped for each TH oxidized (4,14,15).

The second product group consists of epoxytocopherones **4/5** and their hydrolysis products 2,3-epoxy-α-tocopherolquinone **6** and 5,6-epoxy-α-tocopherolquinone **7** (7,16). The mechanism of TH oxidation to epoxides **4/5** is not known. However, formation of epoxides **4/5** represents a four-electron oxidation of TH and involves the introduction of oxygen as a hydroperoxide moiety at C-8a, possibly *via* an intermediate peroxyl radical (5,7). These considerations prompted us to hypothesize that epoxide formation represented an autoxidation pathway, in which TH is oxidized without consuming peroxyl radicals (7). If so, epoxide formation would reduce the antioxidant stoichiometric factor *n* for TH to values less than two. This is particularly important in view of the considerable variation of epoxide yield with the polarity of the reaction medium. We have reported previously that epoxide yield is highest in polar solvents and in lipid bilayers (16,17). Here we have measured both TH antioxidant stoichiometry and the distribution of TH oxidation products in three different model oxidation systems. The results indicate that TH antioxidant stoichiometry does not vary significantly with epoxide yield and suggests that different TH reaction pathways contribute similarly to radical scavenging by TH.



EXPERIMENTAL PROCEDURES

Chemicals and instrumentation. TH (99%) was a gift from Henkel Corporation (La Grange, IL). 2,6-Di-*tert*-butyl-4-methylphenol (BHT) and *N,N′*-diphenyl-1,4-phenylenediamine (DPPD) were purchased from Aldrich (Milwaukee, WI). DPPD was recrystallized twice from ethanol. Azo*bis*-(2,4-dimethylvaleronitrile) (AMVN) was from Polysciences, Inc. (Warrington, PA). Methyl linoleate was from Nu-Chek-Prep (Elysian, MN). L-α-Phosphatidylcholine (from soybean) was from Sigma (St. Louis, MO). [^{14}C]-TH was synthesized

as described previously (7,18). Gas chromatography/mass spectrometry (GC/MS) analyses were done on a Fisons-VG MD-800 instrument (Fisons Instruments, Beverly, MA) by electron ionization at 70 eV.

Antioxidant stoichiometry measurements. Antioxidant stoichiometric factors *n* were measured by a modification of the method of Boozer *et al.* (19). The accumulation of lipid conjugated dienes, rather than the consumption of oxygen, was used to monitor oxidation of the lipid substrate and its inhibition by antioxidants. For homogeneous solution oxidations, methyl linoleate, antioxidant (BHT or DPPD), and AMVN were dissolved in solvent preheated to 50°C to start the reaction. Reactions in hexane or acetonitrile contained 200 μmol methyl linoleate, 400 nmol antioxidant, and 20 μmol AMVN in a volume of 3 mL. Phosphatidylcholine liposomes contained 50 μmol soybean phosphatidylcholine, 10 μmol AMVN, and 50 nmol antioxidant in a volume of 10 mL. Liposomes were prepared by evaporating stock solutions of all components together under N_2 and then suspending the lipid residue in 50 mM Tris HCl, pH 7.0 preheated to 50°C and then dispersing the mixture in a bath sonicator for 30 s. Incorporation of TH into the liposomes was approximately 100%, as liquid scintillation counting of washes from flasks used to prepare [^{14}C]-TH-containing liposomes (see below) contained only background levels of radioactivity. To monitor substrate autoxidation, 50 μL samples were removed periodically from the reaction mixture, diluted with 1 mL acetonitrile (or 1 mL methanol for liposomal samples), and the absorbance of the sample at 235 nm was measured. Plots of conjugated diene absorbance vs. time were used to determine τ. For each system, 3–6 runs with the antioxidant standard (BHT or DPPD) were done, and an R_i value was calculated. Then 3–6 additional runs were done in which TH was substituted for the antioxidant standard and an *n* value was calculated from Equation 1 (see the Results and Discussion section).

Analysis of [^{14}C]-TH oxidation products. Oxidations contained [^{14}C]-TH (approximately 0.01 μCi) instead of unlabeled TH and all reagent concentrations, and volumes were one-tenth those described above. At the end of the induction period τ for each system, the reaction mixture was prepared for high-performance liquid chromatography (HPLC) analysis as follows. For the acetonitrile system, the entire reaction mixture was injected directly onto the column. For the hexane system, the reaction mixture was evaporated under N_2 and then redissolved in 0.3 mL acetonitrile for HPLC analysis. For the liposome system, one volume of ethanol was added, and the mixture was then extracted three times with two volumes of hexane. The hexane extracts were evaporated under N_2 and then redissolved in 0.3 mL acetonitrile for HPLC analysis. HPLC analyses were done with a Spherisorb ODS-2, 5 μm, 4.6 × 250 mm analytical column (Alltech, Deerfield, IL) eluted with methanol/1N sodium acetate, pH 4.25 (93:7, vol/vol), at a flow rate of 1.5 mL min^{-1}. Fractions (0.8 min) were collected and assayed for radioactivity by liquid scintillation counting. HPLC elution of TH and products **1–7** corresponded to that observed for authentic standards.

Identities of quinone **3** and epoxyquinones **6/7** were further confirmed by GC/MS analysis. Compounds **3** and **6/7**

were converted to trimethylsilyl ethers by treatment with N,O-(*bis*trimethylsilyl)trifluoroacetamide/dimethylformamide (1:1, vol/vol) containing 10% trimethylchlorosilane at room temperature for one hour. Compounds then were analyzed by GC/MS on a DB-5 30 m × 0.25 mm column (J&W Scientific, Folsom, CA) by on-column injection at 150°C. The column was then programmed to 280°C at 15°C min^{-1} and held at that temperature for 10 min. Mass spectra were recorded in the electron ionization mode at 70 eV. Compound **3**: *m/z* 518 ($M^{+\cdot}$, not observed), 430 (44%), 341 (13), 293 (25), 239 (8), 205 (9), 165 (100); compound **6**: *m/z* 534 ($M^{+\cdot}$, not observed), 430 (5%), 341 (41), 309 (100), 267 (61), 209 (14), 165 (15), 137 (19); compound **7**: *m/z* 534 ($M^{+\cdot}$, not observed), 430 (5%), 341 (59), 309 (100), 211 (66), 165 (17), 143 (73).

RESULTS AND DISCUSSION

To assess how changes in TH oxidation product distribution affected the antioxidant stoichiometry for TH, we measured both the antioxidant stoichiometry and the product distribution in hexane, in acetonitrile, and in phospholipid liposomes. Previous studies with the TH model compound 2,2,5,7,8-pentamethylchroman-6-ol indicated that product distributions changed dramatically with increasing polarity of the reaction environment (17). The stoichiometry of radical trapping was measured by the kinetic method originally described by Boozer *et al.* (19) and employed by other investigators to measure the rate constants and stoichiometry for peroxyl radical trapping by TH in solutions (15,20), in sodium dodecyl sulfate micelles (14), and in lipid bilayers (21,22). The stoichiometric factor for peroxyl radical trapping, *n*, is calculated from Equation 1

$$n = R_i\tau/[\mathrm{ArOH}] \quad [1]$$

where R_i is the rate of chain initiation, [ArOH] is the concentration of the antioxidant, and τ is the length of induction period, during which substrate autoxidation is suppressed by the inhibitor. The azo compound AMVN was used to generate peroxyl radicals at a constant rate in each system. The oxidizable substrates used were methyl linoleate (in hexane and acetonitrile) and linoleoyl and linolenoyl acyl chains in the soybean phosphatidylcholine liposomes. Substrate oxidation was monitored by spectrophotometric measurement of conjugated diene accumulation.

To ensure the validity of estimates of R_i obtained with this method, we used two different standard antioxidants, BHT and DPPD. HPLC analyses of reactions in which DPPD was oxidized by AMVN in acetonitrile indicated that *N,N'*-diphenylbenzoquinonimine was the sole detectable product, as was previously reported (19) (data not shown). Likewise, analysis of BHT products formed by oxidation with AMVN in acetonitrile indicated that cyclohexadienone-peroxyl radical adduct **8**, which is analogous to that previously reported from oxidations with azo*bis*(isobutyronitrile) (23), was the predominant product (data not shown). These considerations support the validity of assigning an antioxidant stoichiometric factor *n* of 2 for these antioxidant standards.

BHT and DPPD were used as antioxidant standards to determine R_i values for autoxidations initiated at 50°C by AMVN-derived peroxyl radicals in hexane or acetonitrile solutions containing methyl linoleate as the autoxidation substrate or in soybean phosphatidylcholine liposomes (Table 1). Plots of conjugated diene accumulation vs. time for oxidations of TH in acetonitrile and phosphatidylcholine liposomes are depicted in Figure 1. Sharp breaks in the oxidation curves permitted reproducible estimates of τ (Table 1). The R_i values then were used to estimate stoichiometric factor *n* for TH in each system (Table 1). Values for *n* determined in both acetonitrile and in liposomes were 2.0, within experimental error, which is consistent with previous reports (4,14,15).

The *n* values determined in hexane averaged approximately 2.5 (Table 1), which is slightly greater than would be expected. The reason for the greater *n* value in hexane is not clear. This result may be due to the apparently increased propensity of azo compounds to generate alkoxyl radicals in nonpolar solvents (17,23). Alkoxyl radicals appear to increase the yields of dimer products from TH, and the dimers may

TABLE 1
Antioxidant Kinetic Parameters, Oxidation Product Yields, and *n* Values for Antioxidant Reactions of TH in Hexane, Acetonitrile, and Phosphatidylcholine Liposomes

Reaction medium	Antioxidant standard[a]	τ_{std} (min)	R_i (mM min^{-1})	τ_{TH} (min)	*n*, TH	Product yield (%) 1	3	Epoxides

[a]Incubations in hexane and acetonitrile contained 0.133 mM antioxidant, except for incubations with 2,6-di-*tert*-butyl-4-methylphenol (BHT) in hexane, which contained 0.125 mM BHT. Incubations in phosphatidylcholine liposomes contained 0.005 mM antioxidant.
[b]Numbers of determinations are given in parentheses; R_i, rate of chain initiation; τ, length of induction period; *n*, the stoichiometric factor for peroxyl radical trapping.
[c]Separate estimates of lag time τ for 2'*R*,4'*R*,8'*R*-α-tocopherol (*R,R,R*-α-tocopherol) (TH) for oxidations in acetonitrile reflect the use of different lots of methyl linoleate in oxidations standardized with BHT and *N,N'*-diphenyl-1,4-phenylenediamine (DPPD).

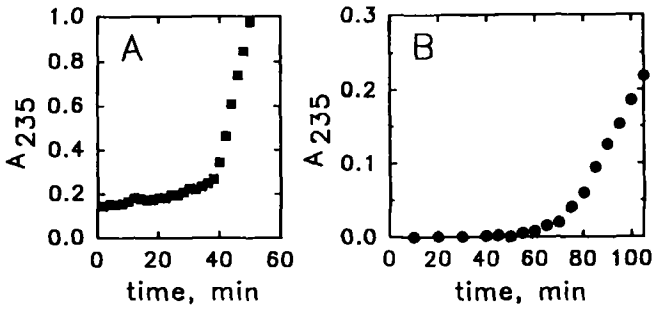

FIG. 1. A) Inhibited autoxidation at 50°C of 66.7 mM methyl linoleate initiated by 6.7 mM azo*bis*(2,4-dimethylvaleronitrile) (AMVN) in acetonitrile containing 0.133 mM 2′*R*,4′*R*,8′*R*-α-tocopherol (*R*,*R*,*R*-α-tocopherol) (TH). B) Inhibited autoxidation at 50°C of phosphatidylcholine liposomes (25 mM in 50 mM Tris HCl, pH 7.0) containing 20 mol% AMVN and 0.1 mol% TH. Autoxidation was monitored in both experiments by measurement of conjugated diene absorbance at 235 nm.

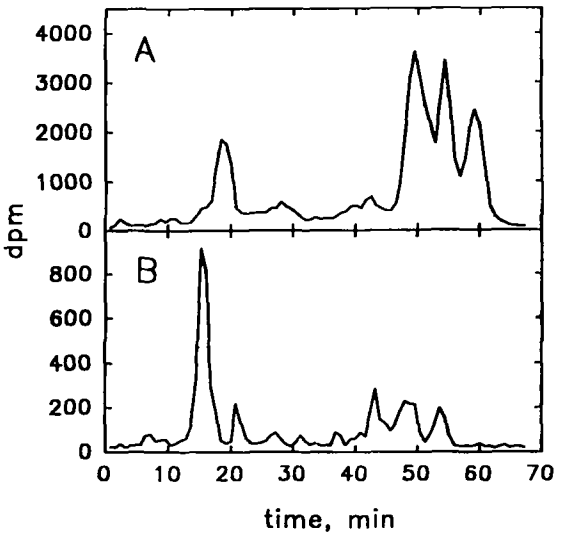

FIG. 2. Reverse-phase high-performance liquid chromatography analyses of products formed from AMVN-initiated oxidation of [^{14}C]-TH in hexane (panel A) and in phosphatidylcholine liposomes (panel B). Epoxides **4**/**5** and their epoxyquinone hydrolysis products **6**/**7** elute between 15–20 min, α-tocopherolquinone **3** elutes at 21 min, and four diastereomers of 8a-(alkyldioxy)tocopherone **1** elute between 40–60 min. See Figure 1 for abbreviations.

themselves trap radicals. However, the yield of dimers in our oxidations in hexane was apparently small (see below). Alkoxyl radicals are considerably more reactive that peroxyl radicals and also may be trapped by other TH oxidation products formed in this system.

Product distribution from TH oxidation was measured in incubations where [^{14}C]-TH was substituted for unlabeled TH. At the time corresponding to the end of the induction period for each system, the run was terminated and residual [^{14}C]-TH and oxidation products were extracted and analyzed by reversed-phase HPLC. Figure 2 depicts HPLC separations of oxidation products formed from [^{14}C]-TH in hexane and in phosphatidylcholine liposomes. Product yields are listed in Table 1. As we had observed previously (16,17), TH product distribution is markedly affected by the reaction medium. In hexane, epoxides are minor products, whereas in liposomes, epoxides account for nearly half of the products. In the acetonitrile and liposome systems, virtually all of the product radioactivity eluted under the chromatographic conditions employed. However, TH spiro dimer **10** was formed during oxidations in hexane, but was not eluted from the HPLC column by the methanol/water mobile phase employed. Parallel analyses with a methanol/ethyl acetate (1:1, vol/vol) mobile phase indicated that the dimer was produced in approximately 5% yield.

These results demonstrate that the antioxidant stoichiometry for TH in peroxyl radical trapping reactions is largely independent of the overall distribution of TH oxidation products. Our earlier speculation (7) that oxidation to epoxides is an autoxidation reaction is probably incorrect. Our present results clearly indicate that increased epoxide formation does not significantly affect antioxidant stoichiometry. Although the mechanism by which the epoxides are formed remains unknown, these data strongly suggest that oxidation of TH to either epoxide **4** or to epoxide **5** results in a net consumption of two peroxyl radicals. Epoxide products **4**–**7**, along with tocopherones **1**–**2** and α-tocopherolquinone **3**, all may serve as biochemical markers for the occurrence of TH antioxidant chemistry in biological membranes. Further investigation of these products as markers for antioxidant function in living tissues are in progress in our laboratory.

ABSTRACT: The interaction of human recombinant sterol carrier protein-2 (SCP-2) with sterols was examined. Two independent ligand binding methods, Lipidex 1000 binding of [^{3}H]cholesterol and a fluorescent dehydroergosterol binding assay, were used to determine the affinity of SCP-2 for sterols. Binding analysis indicated SCP-2 bound [^{3}H]cholesterol and dehydroergosterol with a K_d of 0.3 and 1.7 μM, respectively, and suggested the presence of a single binding site. Phase fluorometry and circular dichroism were used to characterize the SCP-2 sterol binding site. Alterations in dehydroergosterol lifetime, SCP-2 tryptophan lifetime, and SCP-2 tryptophan quenching by acrylamide upon cholesterol binding demonstrated a shielding of the SCP-2 tryptophan from the aqueous solvent by bound sterol. Differential polarized phase fluorometry revealed decreased SCP-2 tryptophan rotational correlation time upon cholesterol binding. Circular dichroism of SCP-2 indicated that cholesterol elicited a small decrease in SCP-2 alpha helical content. The data suggest that SCP-2 binds sterols with affinity consistent with a lipid transfer protein that may act either as an aqueous carrier or at a membrane surface to enhance sterol desorption.
Lipids 30, 795–803 (1995).

Sterol carrier protein-2 (SCP-2), also referred to as nonspecific lipid transfer protein, is one of several lipid binding proteins that are believed to be involved in intracellular cholesterol trafficking (1,2), steroid hormone biosynthesis (3), and bile acid synthesis (4). SCP-2 dramatically stimulates enzymatic reactions involving cholesterol esterification and steroid synthesis *in vitro* (1,2,4). These reactions include the *in vitro* microsomal conversion of intermediates between lanosterol and cholesterol (5), microsomal synthesis of cholesterol esters by acyl CoA–cholesterol acyl transferase (ACAT) (6), and conversion of mitochondrial cholesterol to steroid hormones (3,7). The role of SCP-2 in transferring cholesterol in intact cells was first demonstrated by transient co-expression of human SCP-2 cDNA with expression vectors for cholesterol side-chain cleavage enzyme and adrenodoxin in COS-7 cells. Expression of human SCP-2 resulted in a severalfold enhancement of progestin synthesis as compared to expression of the endogenous steroidogenic enzyme system alone (8).

The precise mechanism by which SCP-2 enhances these reactions of sterol metabolism is not known. The effect of SCP-2 on these reactions does not appear to be due to direct interaction of SCP-2 with the respective enzymes. At least four mechanisms have been proposed where SCP-2 may increase delivery of sterol to the site of reaction—aqueous carrier (2,9,10); tertiary complex formation between SCP-2, the donor, and the acceptor (11); direct membrane effect to enhance sterol desorption from the donor membrane (1); and membrane fusion (1,12). Although SCP-2 mediated membrane fusion has definitively been discounted (12), resolution of the remaining mechanism(s) remains.

The main objective of this study is to elucidate and characterize a potential cholesterol binding site in SCP-2. This is a significant question as SCP-2 purified from liver does not contain any bound cholesterol or other lipid (12,13). It is not known whether bound cholesterol is lost upon purification of SCP-2 or whether SCP-2 does not have a cholesterol binding site. The demonstration of such a site would be consistent with either the aqueous carrier mechanism, as well as a direct membrane effect mechanism whereby SCP-2 binds cholesterol in the membrane and increases its desorption from the membrane.

MATERIALS AND METHODS

Materials. Phosphatidyl-L-serine (PS) and 1-palmitoyl-2-oleoyl phosphatidylcholine (PC) were obtained from Avanti Polar Lipids, Inc. (Birmingham, AL). Dehydroergosterol ($\Delta^{5,7,9(11),22}$-ergostatetraen-3β-ol) was synthesized and its purity checked by high-performance liquid chromatography (HPLC) as previously described (14). Cholesterol (Sigma Chemical Co., St. Louis, MO) was recrystallized and its purity established by HPLC (14).

Recombinant human SCP-2 was isolated as described previously (15). Protein was by Bradford assay (Bio-Rad Laboratories, Richmond, CA) with bovine albumin as standard. All other chemicals were reagent grade or better.

Fluorescent sterol binding assay. The binding affinity of SCP-2 for dehydroergosterol was determined. Dehydroergosterol (0.2–2.0 μM) was added from a concentrated ethanolic stock solution to a sample of SCP-2 (0.6 or 1.0 μM) in 10 mM K_2HPO_4 (pH 7.4) at 24°C. The sample was continuously stirred and the final concentration of ethanol was ≤1.6%. Relative fluorescence intensity was measured upon reaching equilibrium (5 min). The sample was excited at 324 nm using an ISS PC1 photon counting spectrofluorimeter with a 450 watt xenon-arc lamp (I.S.S. Inc., Champaign, IL). Fluorescence emission was measured through a GG-375 sharp cut-off filter (Janos Technology Inc., Townshend, VT). Fluorescence from ligand-only controls were subtracted from those where protein was present to give ΔF. The data from three experiments, each with an n of 2 or 3, were plotted and fit with a simple rectangular hyperbola binding isotherm:

$$\Delta F = F_{max}[L]/(K_d + [L]) \quad [1]$$

where F_{max} is the maximum specific fluorescence enhancement determined from increasing protein added to a fixed, low concentration of ligand and plotted as a simple hyperbolic fit. $[L]$ is the concentration of free dehydroergosterol determined from a plot of increasing ligand added to a fixed concentration of protein. The concentration of free dehydroergosterol is calculated by subtracting the ΔF from the F_{max}. The K_d is defined as the value on the X axis at 50% of F_{max}.

Radiolabeled cholesterol binding assay. The binding of [1,2-^{3}H(N)]cholesterol (specific activity, 50.6 Ci/mmol; New England Nuclear, Boston, MA) to human recombinant SCP-2 was measured by the Lipidex-1000 assay (16) optimized for measuring sterol binding to SCP-2: The assays were carried out in polypropylene tubes with 0.4 mL 10 mM potassium phosphate, pH 7.4, buffer. SCP-2 was 0.4 μM and cholesterol was 0.04 to 1.2 μM (0.95% final ethanol concentration). SCP-2 was added to the assay tubes with mixing, and incubations were carried out at 37°C for 15 min, followed by cooling on ice for 10 min. Unbound cholesterol was removed by addition of 0.5 mL of a continuously-stirred Lipidex-1000 suspension, 50% vol/vol, in phosphate buffer. After a 10-min incubation on ice, with vortexing at 0, 5, and 10 min, the samples were centrifuged at 12,000 × *g* for 3 min. A 0.5-mL aliquot was removed and scintillation counted in an LS 7000 Scintillation Counter (Beckman Instruments Inc., Fullerton, CA). The data were plotted as a Scatchard plot with (*r*/[free cholesterol]) as the Y axis and ([bound/total sterol]) as the X axis. The concentration of bound cholesterol is derived from the % of bound value. The parameter *r* equals [bound sterol/total SCP-2]. The slope = $-1/K_d$ and the B_{max} is indicated by the X intercept.

Fluorescence lifetime determination. Samples consisted of 5 μM SCP-2 in previously described buffer (17) with or without 2 μM cholesterol. Fluorescence lifetime of dehydroergosterol was determined as described earlier (18,19). Self-quenching artifacts were avoided by diluting dehydroergosterol 1:10 with cholesterol. Light scatter was eliminated with a 375 nm emission cutoff filter (Janos Technology). SCP-2 tryptophan fluorescence lifetime was obtained with the same instrumentation, except that excitation at 305 nm was from an Innova 306 Argon Ion laser (Coherent Inc., Palo Alto, CA) with deep ultraviolet multiline optics. A 300-nm rejection filter (Andover Corp., Salem, NH) was used to block the 275 nm output line from the laser. Light scatter was reduced with UV34 (Schott Glass Technologies Inc., Duryea, PA) and U340 (Hoya Optics Inc., Fremont, CA) emission band pass filters. Fluorescence lifetime data were analyzed as described earlier (19,20). The reduced X^2 parameter was utilized to evaluate the "quality of fit" to the applied lifetime model. The data were fit to one, two, and three component lifetime models. A two-component fit (Table 1) was optimal and provided the lowest chi-square values and random residuals. Tryptophan differential polarized phase studies were performed as described earlier (21), except that excitation was with the argon ion laser.

Circular dichroic (CD) spectra. CD spectra of samples in 1-mm circular cuvettes were recorded at room temperature with a J-500A Spectropolarimeter (JASCO, Easton, MD) at human recombinant SCP-2 concentrations of 82 and 190 μg/mL. The CD spectrum of air was subtracted from the CD spectrum of the sample after each scan. The scan rate was 2 nm/min, the time constant was 8 s, and the slit width was 2 nm. Data were collected at 0.04-nm intervals and averaged over a 0.2-nm interval. The instrument was calibrated with a

TABLE 1
Dehydroergosterol Fluorescence Lifetime upon Interaction with SCP-2[a]

SCP-2 (μM)	τ1 (ns)	α1	τ2 (ns)	α2
0	0.73 ± 0.16	0.42 ± 0.03	3.14 ± 0.20	0.58 ± 0.03
5	0.80 ± 0.08	0.61 ± 0.02[d]	3.51 ± 0.16[b]	0.39 ± 0.02[d]
10	0.83 ± 0.01	0.73 ± 0.03[d,e]	3.80 ± 0.06[b,c]	0.27 ± 0.03[d,e]

[a]Samples consisting of dehydroergosterol (0.2 μM) and cholesterol (1.8 μM) were excited at 325 nm, and the lifetime of dehydroergosterol was determined using phase and modulation and analyzed by linear least squares analysis. τ1, τ2 represent the lifetime component ± SEM (n = 3), and α1, α2 represent the mole fraction ± SEM (n = 3) attributed to each lifetime. Samples were analyzed to obtain a minimal $\chi 2$.

[c]$P \leq 0.05$ vs. 5 μM human recombinant SPC-2 using unpaired Student's *t*-test.
[d]$P \leq 0.005$ vs. control using unpaired Student's *t*-test.
[e]$P \leq 0.005$ vs. 5 μM human recombinant SCP-2 using unpaired Student's *t*-test.

0.6% solution of ammonium camphor sulfonate ($[\Theta]_{290.5}$ = 7910 deg cm^2/dmol; JASCO, Inc., Easton, MD). Calculations of secondary structure were made essentially as described previously (22), with constrained parameters and the reference data of Chen *et al.* (23) and Bolotina *et al.* (24) on data to 195 nm.

Steady-state fluorescence. Emission spectra and acrylamide quenching experiments were conducted at the University of Illinois, Laboratory for Fluorescence Dynamics (Urbana, IL), with a PC1 photon counting fluorometer (ISS Inc.). Samples were excited at 295 nm using a (300W) Xe-arc lamp. Emission spectra of 5 μM human recombinant SCP-2 were obtained alone or with either 2 μM cholesterol or 2 μM dehydroergosterol present. The emission spectra of distilled water, 2 μM cholesterol, and 2 μM dehydroergosterol were obtained for background subtraction. Absorbance was below 0.15 in all cases to avoid the inner filter effect. Light scatter was minimized by use of dilute solutions and through use of appropriate cutoff filters as described earlier.

SCP-2 tryptophan quenching experiments were conducted by addition of increasing amounts of acrylamide to 5 μM human recombinant SCP-2, either with or without 20 μM cholesterol. The corrected fluorescence intensities were analyzed using the Stern-Volmer equation as modified by Lehrer (25). The modified equation is valid for systems containing two populations of tryptophan: accessible and inaccessible to the quencher. A plot of $F_0/\Delta F$ vs. 1/[acrylamide] gives a y-intercept of $1/f_a$ and a slope equal to $1/f_aK$, where F_0 is the intensity in the absence of acrylamide, ΔF is the change in intensity at each point from F_0, f_a is the fraction of tryptophan accessible to the acrylamide, and K is the Stern-Volmer constant of the accessible tryptophan.

Fluorescent sterol exchange assay. Small unilamellar vesicles (SUV) were prepared as described earlier (19,20,26) with two modifications. First, donor SUV (PC/PS/dehydroergosterol, 55:10:35 mol%) and acceptor SUV (PC/PS/cholesterol, 55:10:35 mol%) were sonicated for 4 min until optical clarity was attained. Phospholipid was measured according to Ames (27). Second, the buffer (10 mM PIPES/0.02% NaN_3, pH 7.4) was prefiltered with a 0.20 μm filter (Millipore, Bedford, MA). The exchange of dehydroergosterol between donor and acceptor membranes was monitored at 22°C in the absence and presence of SCP-2 as described previously by this laboratory (19,20,28).

ACAT. Microsome isolation and ACAT assay were performed as previously described (29), except that preincubation was for 15 min and the incubation was for 10 min. Liposomes and SCP-2, when included, were added to the preincubation system.

RESULTS

Sterol binding to human recombinant SCP-2. Because purified SCP-2 does not contain bound ligands and as SCP-2 transfers both sterols and phospholipids, sterol binding assays without potential competing phospholipid ligands were used to examine binding to SCP-2. Because dehydroergosterol as aqueous monomers has very low quantum yield, observed fluorescence was due to micellar dehydroergosterol. Upon titration of SCP-2 with dehydroergosterol, the fluorescence intensity due to bound dehydroergosterol (corrected for intensity of dehydroergosterol blanks) increased (Fig. 1). Scatchard analysis of the data gave a K_d of 1.7 ± 0.7 μM (n = 7) and a B_{max} of 0.9 mole/mole, which would suggest a single dehydroergosterol binding site.

To eliminate the possibility that the observed binding of dehydroergosterol by SCP-2 might not be the same as cholesterol, a Lipidex-1000 radioligand binding assay, originally developed for fatty acid binding to fatty acid binding proteins, was modified to examine binding of [^{3}H]cholesterol to SCP-2. As shown in Figure 2, Scatchard analysis of [^{3}H]cholesterol binding to SCP-2 yielded a K_d = 0.31 ± 0.05 μM (n = 3).

Effect of SCP-2 on dehydroergosterol lifetime. Fluorescence lifetime analysis of a dehydroergosterol with or without SCP-2 was used to determine if the sterol interacted with SCP-2. In the absence of SCP-2, dehydroergosterol had a short lifetime component at 0.73 ns and a longer lifetime component at 3.14 ns (Table 1). Dehydroergosterol monomers in aqueous solution have extremely low quantum yield and were not detected. The shorter lifetime component represents dehydroergosterol in a more nonpolar environment while the longer lifetime component represents dehydroergosterol more aqueous exposed within the aqueous dehy-

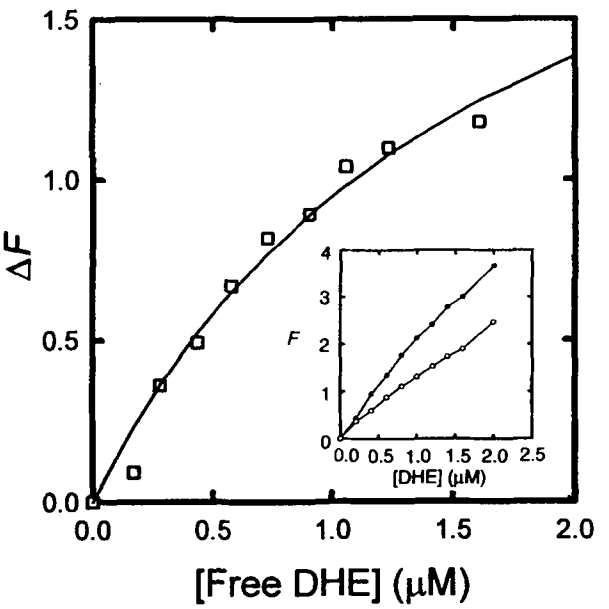

FIG. 1. Dehydroergosterol (DHE) binding by human recombinant sterol carrier protein-2 (SCP-2). Data points represent the specific fluorescence enhancement as DHE by human SCP-2 (1.0 μM) and have been corrected for background fluorescence due to DHE alone. The curve is a theoretical fit to a single binding site isotherm using the equation $\Delta F = F_{max}[L]/(K_d + [L])$. In this particular experiment, the predicted F_{max} is 3.0 units, giving a K_d of 2.0 μM. The standard error was 0.56 and had a dependency of 0.987. In the inset, the fluorescence enhancement of DHE alone (○) and DHE plus SCP-2 (●) are plotted. The difference is ΔF.

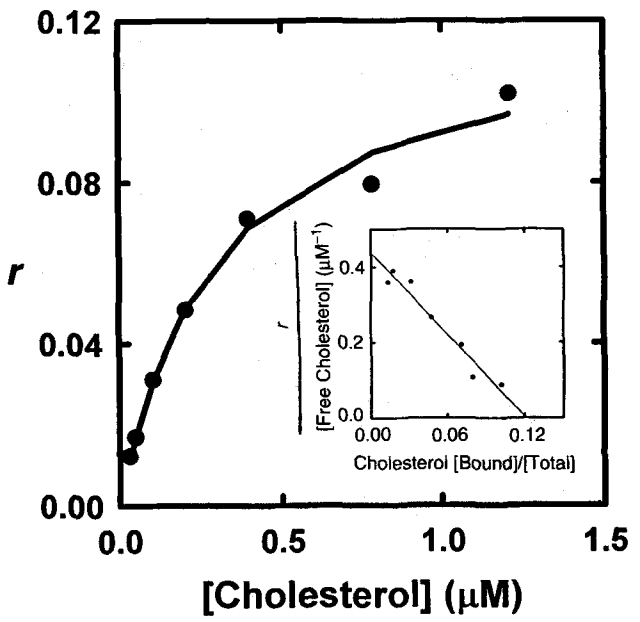

FIG. 2. Binding of radiolabeled cholesterol to human recombinant SCP-2. The parameter *r* equals [bound sterol/total SCP-2]. A plot of *r* vs. cholesterol concentration shows increasing binding of cholesterol by human recombinant SCP-2. The inset shows a Scatchard plot of *r*/[free cholesterol] μM^{-1} vs. [bound/total] cholesterol. Values represent the average of two assays each with an n = 2. Abbreviation as in Figure 1.

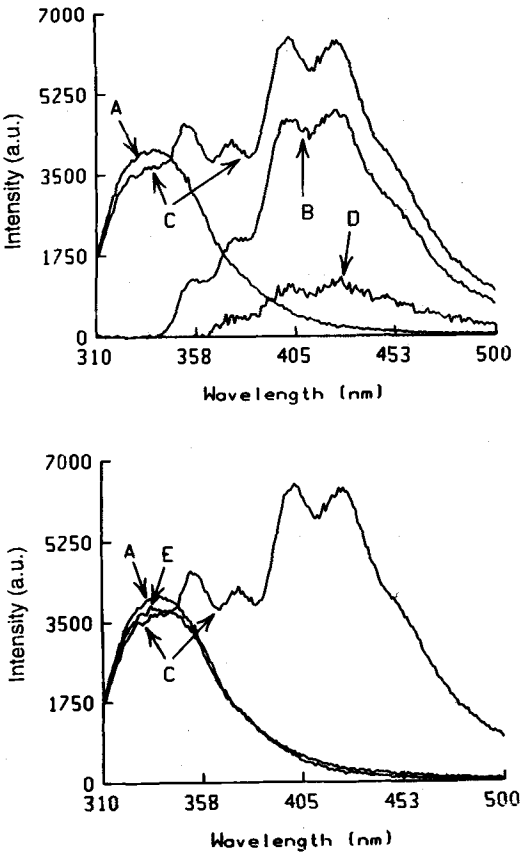

FIG. 3. Fluorescence emission spectra of human SCP-2 samples with or without either cholesterol or dehydroergosterol. Spectra were obtained as described in the Materials and Methods section with excitation at 295 nm. The top panel shows spectra obtained in the presence of dehydroergosterol. Line A is human SCP-2, B is dehydroergosterol, C is human SCP-2 plus dehydroergosterol, and D is line C minus lines A and B. The bottom panel shows line A, which is human SCP-2, line E is human SCP-2 plus cholesterol, and line C is human SCP-2 plus dehydroergosterol. Abbreviation as in Figure 1.

droergosterol micelles. The mole fraction of dehydroergosterol represented by each of the micellar components was 0.42 and 0.58, respectively (Table 1). Addition of human recombinant SCP-2 altered the fractional contributions of the two lifetime components of dehydroergosterol. In the presence of human recombinant SCP-2, almost twofold more dehydroergosterol (0.73 mole fraction) became localized within a nonpolar environment. Concomitantly, the second lifetime component increased significantly by 0.66 ns in the presence of 10 μM human recombinant SCP-2 (Table 1).

Second, human recombinant SCP-2 contains a single tryptophan. Tryptophan emission (Fig. 3, top panel, curve A) overlaps with dehydroergosterol excitation (not shown). If the two molecules have an optimal orientation factor, good overlap of emission of SCP-2 tryptophan, and dehydroergosterol absorbance and are in close proximity within the sterol binding site of human recombinant SCP-2, Forster nonradiative energy transfer occurs from tryptophan donor to dehydroergosterol acceptor. The emission spectra of dehydroergosterol, human recombinant SCP-2 alone, and human recombinant SCP-2 in the presence of dehydroergosterol were obtained with excitation of the single SCP-2 tryptophan at 295 nm. Because of the broad excitation spectrum of dehydroergosterol (Fig. 3, line B), there was also excitation of dehydroergosterol at the tryptophan excitation wavelength. It was not possible to excite tryptophan in the complete absence of exciting dehydroergosterol. However, the excitation of dehydroergosterol at 295 is considerably less than that of tryptophan. The emission spectrum of SCP-2 in the presence of dehydroergosterol was examined for alterations consistent with energy transfer from the tryptophan residue of human recombinant SCP-2 to dehydroergosterol. The top panel of Figure 3 shows emission scans for samples containing dehydroergosterol. All scans were background subtracted using distilled water as the blank. When human recombinant SCP-2 was incubated with dehydroergosterol, fluorescence intensity of dehydroergosterol near 400 nm increased (Fig. 3, top panel, line C) compared to dehydroergosterol without human recombinant SCP-2 (Fig. 3, top panel, line B). Concomitantly, in the presence of dehydroergosterol, the fluorescence intensity of SCP-2 tryptophan near 331 nm decreased (Fig. 3, top panel, line C) compared to SCP-2 alone (Fig. 3, top panel, line A). Subtraction of the human recombinant SCP-2 and dehydroergosterol spectra from line C indicated that the increased intensity that occurred was greater than can be explained by simple overlap of their emission spectra (Fig. 3, top panel, line D). Furthermore, the increase in sensitized emission of dehydroergosterol was accompanied by a concomitant decrease in tryptophan emission intensity for human recombinant SCP-2 tryptophan near 331 nm in the presence of dehydroergosterol (Fig. 3, top panel,

curve C vs. A). These results are consistent either with energy transfer, a conformational change in the human recombinant SCP-2 upon sterol binding, or an alteration of the tryptophan environment upon human recombinant SCP-2 tryptophan binding sterol. The latter could occur if the tryptophan were exposed to some aqueous solvent in a binding pocket of the apoprotein and shielded in the holoprotein when the hydrophobic sterol occupies the binding pocket. These three possibilities were examined in the following experiments.

Comparison of energy transfer and conformational changes in human recombinant SCP-2 upon ligand binding. To prove that the decreased SCP-2 tryptophan fluorescence intensity in the presence of dehydroergosterol (Fig. 3, top panel, curve C vs. A) was due to energy transfer, it is necessary to show the absence of any changes in tryptophan emission spectrum upon addition of a nonfluorescent sterol, cholesterol. However, cholesterol quantitatively affected the tryptophan emission spectrum similarly (Fig. 3, bottom panel, curve A vs. E), to dehydroergosterol (Fig. 3, top panel, curve C vs. A). Because cholesterol is nonfluorescent and does not absorb significantly in the region of tryptophan emission, energy transfer was considered unlikely. Thus, energy transfer from tryptophan to dehydroergosterol can be eliminated as a possible explanation. However, the lack of energy transfer does not preclude the possibility that the tryptophan and dehydroergosterol are still in close proximity. Lack of energy transfer could be due to an unfavorable orientation of the tryptophan rather than the tryptophan being located distant from the dehydroergosterol.

Acrylamide quench of tryptophan fluorescence. The effect of sterol binding on the exposure of SCP-2 tryptophan to the aqueous environment was examined with the water-soluble quencher acrylamide. The tryptophan residue of human recombinant SCP-2, with or without cholesterol present, was excited at 295 nm while increasing amounts of acrylamide were added. Changes in tryptophan fluorescence emission intensity at 331 nm were shown as modified Stern-Volmer plots (Fig. 4). The quenching plots of tryptophan in human recombinant holo-SCP-2 were linear, indicating the presence of a single type of tryptophan residues. The low modified Stern-Volmer quenching constant in the absence of cholesterol (modified K_{SV} = 4.19 M) indicated poor accessibility of this tryptophan residue to the water-soluble acrylamide. A small shift toward the baseline (decreased slope) was observed in the presence of cholesterol. This indicated that the tryptophan was even less accessible to quenching by acrylamide when cholesterol was bound to human recombinant SCP-2. This is further illustrated by the modified K_{SV} values for the quenching. The addition of cholesterol decreased the modified K_{SV} value from 4.19 M to 2.22 M, consistent with decreased quenching upon cholesterol binding. This would suggest a shielding of SCP-2 tryptophan by bound sterol and/or a modest conformational change occurring in the human SCP-2 protein upon cholesterol binding.

Effect of cholesterol on human recombinant SCP-2 tryptophan fluorescence lifetime. Based on these changes in tryptophan accessibility to quenching acrylamide, it is predicted that the tryptophan lifetime also should be altered if a conformational change occurred in the SCP-2. Human recombinant SCP-2 tryptophan fluorescence lifetime was examined in the presence and absence of cholesterol. The SCP-2 tryptophan emission was best resolved into two components near 2.34 and 0.53 ns (Table 2). The mole fractions attributed to these components were 0.33 and 0.67, respectively. Upon addition of 2 μM cholesterol, there was a significant 0.51 ns increase in the lifetime of the long lifetime component ($P \leq 0.05$). There was no significant redistribution of the mole fractions associated with each lifetime component. The increase in tryptophan lifetime upon binding of sterol suggested that the SCP-2 altered its conformation slightly to orient the tryptophan in a more nonpolar environment.

Differential polarized phase fluorimetry of human recombinant SCP-2 tryptophan best fit two rotational correlation components (32.2 and 2.8 ns) describing an ellipsoidal shape. Furthermore, upon addition of cholesterol, there was a de-

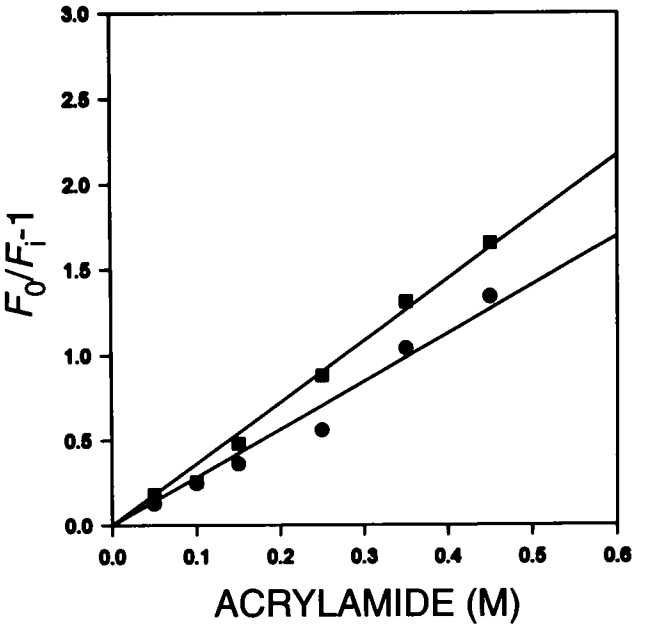

FIG. 4. Acrylamide quench experiments of human SCP-2 with or without cholesterol. Experiments were performed as described in the Materials and Methods section. The open circles (○) represent human SCP-2 and the closed circles (●) represent human SCP-2 plus cholesterol. Abbreviation as in Figure 1.

TABLE 2
Effects of Cholesterol on SCP-2 Tryptophan Fluorescence Lifetime Emission[a]

Cholesterol (μM)	τ1 (ns)	α1	τ2 (ns)	α2
0	2.34 ± 0.15	0.33 ± 0.05	0.53 ± 0.05	0.67 ± 0.05
2	2.85 ± 0.13[b]	0.26 ± 0.07	0.63 ± 0.02	0.74 ± 0.03

[a]Samples of human recombinant SCP-2 (5 μM) with or without cholesterol were excited at 295 nm, and the lifetime of tryptophan emission was determined using phase and modulation and analyzed by linear least squares analysis. Data were handled in a similar manner as explained in the Materials and Methods section and Table 1. Abbreviations as in Table 1.
[b]$P \leq 0.05$ using unpaired Student's *t*-test (n = 6).

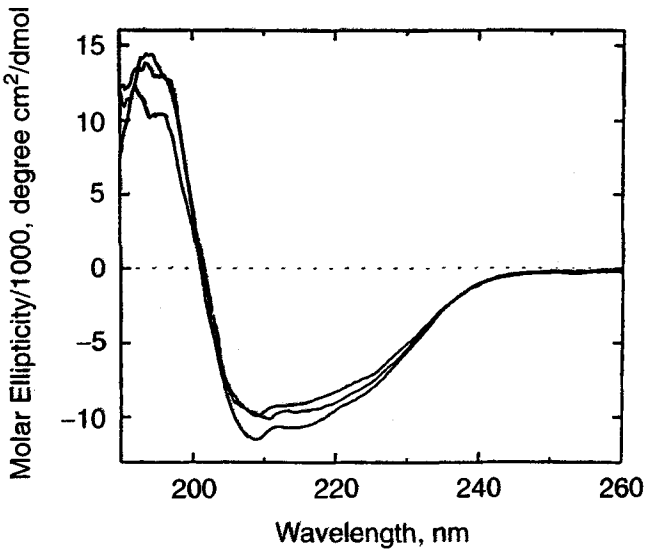

FIG. 5. Effect of cholesterol on dehydroergosterol on circular dichroism spectra of human SCP-2. Spectra were obtained for 6 μM human SCP-2 in a 20 mM phosphate buffer at pH 7.4 in the absence and presence of either 2 μM cholesterol or 2 μM dehydroergosterol. The spectra are ordered at 210 nm from bottom to top: no additions, plus dehydroergosterol, plus cholesterol.

crease in the rotational correlation time for both the long and the short axes, to 21.4 and 2.1 ns, respectively. This was consistent with a conformational change in human recombinant SCP-2 upon interaction with sterol.

CD studies of the conformational properties of human recombinant SCP-2. The effect of sterol binding on human SCP-2 conformation was examined directly through CD. In the far ultraviolet without added ligands, the CD spectra of human SCP-2 (Fig. 5) displayed minima at 208 and 222 nm, consistent with substantial α-helical content. Analysis of the spectrum revealed 31 ± 1% α-helix (Table 3) in the absence of ligands. Analysis of CD spectra by the methods of either Chen *et al.* or Bolotina *et al.* (see Materials and Methods section) both yielded virtually identical values for α-helical content of human SCP-2, 31 ± 1 vs. 30.5 ± 0.5, respectively. Decreasing the concentration of protein in solution did not alter the shape of the spectrum or the fitted secondary structural parameters. A twofold decrease in human recombinant SCP-2 altered the α-helical % content of human recombinant SCP-2 less than 1%. Thus, the SCP-2 was not aggregated, and small differences in protein content could not account for the 3–3.5% decreased α-helical content of human recombinant SCP-2 upon addition of cholesterol (Table 3).

Functional activity of human recombinant SCP-2. Although this data suggested that sterols bind to human recombinant SCP-2, such binding alone does not signify that the protein is actually involved in sterol transfer activity. Therefore, two assays were performed to show functional activity for the recombinant SCP-2.

First, the effect of human SCP-2 on sterol transfer between SUV, was examined using a fluorescence polarization assay which we recently developed (19,20,28,30). The spontaneous exchange kinetics of dehydroergosterol in model membranes were resolved into two exchangeable domains with half times near 18.7 and 185 min. The mole fraction of the exchangeable and nonexchangeable domains was 0.04, 0.83, and 0.13. Human recombinant SCP-2 (1.1 μM) stimulated intermembrane sterol transfer by dramatically decreasing the half times of exchange from 18.7 to 1.1 and from 185 to 98 min, respectively. Concomitantly, the mole fraction of the rapidly exchangable domain increased from 0.04 to 0.68, the slowly exchangable domain decreased from 0.83 to 0.32, and the nonexchangable domain was eliminated.

Second, the ability of human recombinant SCP-2 to enhance cholesterol esterification *in vitro* was determined. The human recombinant SCP-2 increased the formation of cholesterol ester from 145 ± 16 in the absence of SCP-2 to 452 ± 22 in the presence of 10 μg SCP-2 as described in the Materials and Methods section. This stimulation was similar to that noted with native rat liver SCP-2 (15).

DISCUSSION

Both ligand binding and spectroscopic data suggest that SCP-2 interacts with the fluorescent sterol, dehydroergosterol, and cholesterol. The low intrinsic solubility of sterols in aqueous buffer has complicated demonstration of cholesterol binding to SCP-2, and potential binding assays are at the limit of applicability. These assays use micellar substrates and contain significant amounts of solvents. Nevertheless, two such assays were used to examine the possibility of sterol binding to SCP-2.

First, a fluorescence assay using dehydroergosterol was developed to demonstrate binding of a sterol to the human re-

TABLE 3
Analysis of Circular Dichroism Spectra of Human Sterol Carrier Protein-2 with and without Cholesterol

combinant SCP-2. Although a high degree of unspecific fluorescence of dehydroergosterol in the absence of SCP-2 was observed, this type of assay has the advantage of not requiring separation of bound from free ligand. As demonstrated by fluorescence intensity, dehydroergosterol bound to human recombinant SCP-2 with 1:1 stoichiometry and K_d of 1.7 μM.

Second, although dehydroergosterol is an excellent fluorescent analogue whose structure and many other properties mimic those of cholesterol more closely than other known cholesterol probe molecules (reviewed in Ref. 9), it is still possible that the affinity of SCP-2 for dehydroergosterol does not reflect that of cholesterol. Therefore, a Lipidex 1000 assay with [^{3}H]cholesterol was used to confirm this observation. In order to optimize conditions for cholesterol binding, the assay was modified to contain about tenfold higher Lipidex 1000 resin than used for fatty acid binding. [^{3}H]Cholesterol was bound by human recombinant SCP-2 with K_d of 0.3 μM. It was not possible to accurately obtain a B_{max} with the Lipidex 1000 assay due to the very low solubility of cholesterol (20 nM critical micellar concentration), which precluded saturation of the human recombinant SCP-2 cholesterol binding site prior to precipitation of large cholesterol aggregates. The finding that human recombinant SCP-2 bound [^{3}H]cholesterol suggests that its binding of dehydroergosterol was not just a unique feature of the fluorescent sterol. However, SCP-2 did appear to bind cholesterol about sevenfold more tightly than dehydroergosterol, perhaps due to assay difference.

Several sets of spectroscopic results were consistent with a close molecular interaction of sterol with SCP-2 rather than nonspecific absorption of SCP-2 to micellar sterol. Firstly, dehydroergosterol lifetime analysis showed two components—a short lifetime component near 0.73 associated with a nonpolar microenvironment, and a longer lifetime component associated with a more aqueous exposed environment in the dehydroergosterol micelle. Two similar lifetimes and microenvironments were observed for dehydroergosterol in membranes (18). SCP-2 did not alter either lifetime in the dehydroergosterol micelle; it did increase the fraction of shorter lifetime component in hydrophobic environment. This suggests that the hydrophobicity of the SCP-2 dehydroergosterol binding site is similar to that within the nonpolar region of the dehydroergosterol micelle. Second, tryptophan emission decreased upon interaction with sterols. Acrylamide quenching and tryptophan lifetime studies further suggested that this decrease was not due to energy transfer but to shielding of SCP-2 tryptophan by bound sterol. Third, both rotational correlation time and CD studies indicated that SCP-2 undergoes a modest conformational change upon interaction with sterol.

The finding that human recombinant SCP-2 binds sterols addresses a significant unresolved issue. Although it is generally agreed that SCP-2 enhances sterol transfer between membranes, the issue of whether SCP-2 actually binds cholesterol is unclear. This is an important point as SCP-2 purified from liver does not contain bound sterol (12,13). The discrepancy appears to result from the substrate form and/or assay used. When sterol is the only potential ligand in the assay system, binding of sterol to SCP-2 is observed. For example, light scatter studies showed that native rat liver SCP-2 binds dehydroergosterol with 1:1 stoichiometry and 1.4–1.7 μM K_d (21). The Lipidex-1000 assay was used to show that chicken liver SCP-2 (also called nonspecific lipid transfer protein, nsLTP) bound [^{3}H]cholesterol (31). Although it might be argued that presentation of the sterol substrate in micellar form (21,31) is nonphysiological, other studies with adrenal neutral lipid droplets, a physiological substrate form (4,13), are also consistent with cholesterol binding to SCP-2 (32). Adrenal lipid droplets contain primarily neutral lipid (81% cholesteryl ester, 10% triglyceride, 3% cholesterol, and 6% phospholipid) (13). The adrenal lipid droplets were incubated with SCP-2, the subnatant fraction was reisolated, and mass of bound ligand was determined (4). SCP-2 bound cholesterol (but not triglyceride, cholesteryl esters, or phospholipids) with 1:1 stoichiometry. Finally, although the sterol binding observed is not a unique property of SCP-2, it is not an aspecific protein effect. For example, another cytosolic lipid transfer protein, the liver fatty acid binding protein, also binds dehydroergosterol and [^{3}H]cholesterol (18). However, the closely related cytosolic intestinal cytosolic fatty acid binding protein does not bind either dehydroergosterol or [^{3}H]cholesterol (18). Consistent with this, chicken liver nsLTP, but not chicken liver fatty acid binding protein, binds [^{3}H]cholesterol (31). In summary, these types of studies suggest that SCP-2 can bind sterol.

In contrast to these studies with a single potential binding substrate, one study under conditions where the sterol is incorporated into model membranes reported phospholipid, but not sterol, binding to SCP-2 (17). However, both phospholipids and dehydroergosterol were transferred between model membranes by the nsLTP (17). This is in contrast to another study which concluded that SCP-2 bound and transferred cholesterol, but not phospholipid, between natural donors and acceptors (13). In any case, the model membrane assay for dehydroergosterol and fluorescent phosphoplipid binding to nsLTP has several limitations. First, the model membranes had multiple potential ligands (phosphatidylcholine, pyrene-labeled phosphatidylcholine, trinitrophenyl-phosphatidylethanolamine) in addition to dehydroergosterol. SCP-2 binds phospholipids (17,32–34). If the phospholipids and sterols compete for the same binding site on SCP-2, then in this very complicated system (four competing substrates) the relative affinity of SCP-2 for the different phospholipids vs. sterol will determine the degree of respective ligand loading in the SCP-2. Second, the model membrane assay was complicated by the use of multiple quenching molecules (17). Not only was trinitrophenyl-phosphatidylethanolamine used to quench dehydroergosterol emission in the donor membrane, but the dehydroergosterol concentration used (10–50 mole%) was self-quenching. Previous work from our laboratory showed that the dehydroergosterol is self-quenched in model membranes containing more than 6 mole% dehydroergosterol (26). As a consequence, it was reported that dehydroergosterol transfer increased 13-fold and did not compete with the pyrene-labeled phospholipid when dehydroergosterol content

of the donor model membranes was increased from 10–50 mole%. In contrast, through use of a different dehydroergosterol transfer assay (with only a single quenching process), our laboratory showed that the half-times of dehydroergosterol transfer in phosphatidylcholine vesicles containing 10 and 35 mole% (20), as well as 50 mole% (35), did not differ significantly. These data were consistent with those wherein a standard assay with [^{3}H]cholesterol in model membranes was used and no difference in cholesterol transfer half-time between 10 and 35 mole% cholesterol was observed (20). Third, the lack of dehydroergosterol binding from neutral model membrane vesicles does not represent a physiological membrane situation. Biological membranes contain significant amounts of negatively charged phospholipids. SCP-2 binds negatively charged phospholipids up to 13-fold better (17) and low amounts of anionic phospholipids (e.g., 10 mole%) enhance the ability of SCP-2 to transfer sterol between membranes up to several orders of magnitude (9,20,28,30,36). Fourth, in the aforementioned study (17), negatively charged phospholipids were present in the pyrene-phospholipid-SCP-2 binding assay, but not in the dehydroergosterol-SCP-2 binding assay. Thus, the relative binding ability of SCP-2 for phospholipid and cholesterol was not examined under equivalent conditions. Consequently, the SCP-2 did not have equivalent access to sterol and phospholipid ligands in the donor membrane. Fifth, the use of phospholipid model membranes presents SCP-2 with multiple, potentially competing, ligand sites (membrane and SCP-2). Not only will the affinity of the SCP-2 for the respective phospholipids and sterol determine extent of binding, but the affinity of the membrane itself for the respective phospholipids and sterol will complicate demonstration of the binding of sterol to SCP-2. Sixth, the use of pyrene-labeled lipids to mimic the behavior of native lipids is subject to intrinsic structural differences between the probe and the native molecule. For example, pyrene labeled sterol analogues had 4.4-fold faster exchange rates than did radiolabeled cholesterol (37). In contrast, dehydroergosterol is a naturally-occurring fluorophore (9), replaces up to 90% of endogenous sterol in cultured cells without altering cell functions and lipid composition (9), and transfers with half-times not significantly different from those of [^{3}H]cholesterol (20).

In addition to demonstrating binding of sterols to human recombinant SCP-2, the present investigation reports some of the characteristics of such a binding site. The data suggest that SCP-2 binds sterols and that sterol binding shields the SCP-2 tryptophan from the aqueous medium. In addition, lifetime, rotational correlation time and CD studies further suggest that the SCP-2 undergoes a modest conformational change upon cholesterol binding. The finding that cholesterol significantly increased the human recombinant SCP-2 % of α-helical content by 3–3.5% is consistent with a report that phospholipid binding to wheat nsLTP increases the % of α-helical content by 8% (38). The suggestion, based on rotational relaxation time, that SCP-2 is ellipsoidal, is consistent with nuclear magnetic resonance (NMR) data on the structure of human recombinant SCP-2 (39). Although NMR structure of the human recombinant apo-SCP-2 (39) and the wheat apo-lipid transfer protein (40) have been reported, they did not address the lipid binding site. However, a site directional mutagenic approach (41) showed that amino acid residues between 100 and 104 are essential to human recombinant SCP-2 sterol transfer activity. Thus, a putative sterol binding site at the carboxyl terminal of SCP-2 may be far removed from the amino terminal amphipathic basic helix thought to be the membrane binding domain (39,40,42). Indeed, comparison to the NMR-based three-dimensional structure of human recombinant SCP-2 indicates that these residues (strand 5 of the beta sheet) appear to be located at the opposite face of and near one end of the SCP-2 molecule at a distance removed from the amphipathic-helical, basic amino terminal (39). A more precise determination from the NMR data is not possible pending NMR or X-ray crystallographic data on cholesterol-containing holo-SCP-2.

In conclusion, the results presented here and by others are consistent with at least two possible mechanisms whereby SCP-2 may enhance sterol transfer between membranes. In both cases, SCP-2 interacts with the membrane, binds sterol, and a sterol-SCP-2 complex desorbs from the membrane. Then either (i) the desorbed sterol-SCP-2 complex is transient and quickly releases sterol into the aqueous medium, or (ii) the SCP-2 acts as an aqueous carrier between donor and acceptor membranes. Both possibilities would require the presence of a sterol binding site in the protein and formation of a soluble, even if transient, lipid SCP-2 complex. In the case of the desorption model, the binding site may be weak and not easily detected. The half-time of the sterol bound to the SCP-2 could be extremely short. The latter would account for the very low saturation of the binding site observed when phospholipid membranes are the source of sterol (17). Recently, kinetic evidence of fluorescent phospholipid transfer by bovine liver nsLTP is consistent with the formation of a soluble lipid-nsLTP complex being the key step in nsLTP-mediated phospholipid transfer (43). Additional evidence shows that SCP-2 does not act as an aqueous carrier (44), but instead binds to membranes and acts to enhance sterol desorption. An SCP-2 sterol binding site is required for this process (44).

Molecular Species of Sphingomyelin in Sphingomyelinase-Sensitive and Sphingomyelinase-Resistant Pools of HL-60 Cells

Veronica Fitzgerald, Merle L. Blank and Fred Snyder*

Medical Sciences Division, Oak Ridge Associated Universities, Oak Ridge, Tennessee 37831-0117

ABSTRACT: This study of sphingomyelin molecular species in undifferentiated and differentiated (granulocytic form) HL-60 cells demonstrated only minor differences in the distribution of species between the sphingomyelinase-sensitive and sphingomyelinase-resistant pools of sphingomyelin in these cells. The two most prominent species of sphingosine present in both the undifferentiated and differentiated cells were those containing 16:0 (slightly higher in the sphingomyelinase-resistant membranes) and 24:1 *N*-acyl moieties. Cell differentiation exerted little effect on the distribution of molecular species of sphingomyelin between the sphingomyelinase-sensitive and sphingomyelinase-resistant pools in HL-60 cells, although the levels of *N*-palmitoyl sphinganine were significantly lower and the *N*-nervonoyl sphingosine higher in both pools from the differentiated cells. Our results indicate the same species of sphingomyelin, available at both the outer layer of the plasma membrane and inner layer of the plasma membrane (plus intracellular membranes) of HL-60 cells, serve as precursors for generation of the ceramides that participate in signal transduction processes initiated by cell activation.

Lipids 30, 805–809 (1995).

Recent research has indicated that sphingomyelin, in addition to being a structural component of cellular membranes, is involved in signal transduction processes through the generation of ceramides by the action of a sphingomyelinase (1–10). Several investigators have utilized HL-60 cells as the biological system for their studies (1–4,9,10). Yet as far as we are aware, the molecular species of sphingomyelin in HL-60 cells have not been analyzed. Determination of molecular species of sphingomyelin would seem to take on greater importance after a recent report suggesting that a specific "signalling" pool of sphingomyelin is resistant to treatment with sphingomyelinase (11) in HL-60 cells. The question then arises as to whether this precursor pool of sphingomyelin may consist of different types of molecular species than present in the more inert pool of sphingomyelin associated with the outer portion of the plasma membrane. We therefore investigated the possibility of whether a specific distribution of sphingomyelin molecular species in the membranes of HL-60 cells could contribute to the difference in biological activity associated with the sphingomyelinase-sensitive and sphingomyelinase-resistant pools of sphingomyelin in these cells.

MATERIALS AND METHODS

Cell culture. Human leukemic cells (HL-60; purchased from the American Type Culture Collection, Rockville, MD) were grown in RPMI 1640 media containing 10% heat inactivated fetal calf serum, 100 units of penicillin per mL, 100 μg of streptomycin per mL, 2 mM L-glutamine, and 20 mM HEPES buffer. Cells were maintained in a humidified, 5% CO_2 atmosphere at 37°C. Stock cultures were usually diluted 1:4 with fresh media when they reached a cell density of 1.5×10^6 cells/mL. Cells to be treated with sphingomyelinase were isolated from stock cultures by centrifugation at $200 \times g$ for 15 min and washed twice with Dulbecco's phosphate buffered saline (PBS) with the same centrifugation between washes. The washed cells were resuspended in the same media (0.4×10^6 cells/mL) used for stock cultures except the fetal calf serum was replaced with insulin (10 μg/mL), transferrin (10 μg/mL), sodium selenite (100 μg/mL), and fatty acid free bovine serum albumin (0.1% wt/vol). Cells were then incubated in the serum-free media for 48 h, pelleted, washed once with PBS, resuspended in serum-free media (1.6×10^6 cells/mL), and incubated 2 h before adding 0.1 unit of sphingomyelinase (*Staphlococcus aureus*) per mL of media (11). An identical volume of the sphingomyelinase vehicle (0.25 M phosphate buffer pH 7.4 in glycerol/water, 1:1) was added to control cultures. After 20 min in the presence of the sphingomyelinase at 37°C, the cells were pelleted by centrifugation at $600 \times g$ for 10 min and the cellular lipids extracted (12). These procedures are nearly identical to those used previously by others to hydrolyze the sphingomyelin in the outer layer of the plasma membrane of HL-60 cells (9,11). A similar approach also has been used to study the asymmetric distribution of sphingomyelin molecular species in human ery-

throcyte membranes (13). The validity of using sphingomyelinase to determine the external and internal amounts of sphingomyelin also has been demonstrated recently on hepatocytes (14).

Some HL-60 cells were also differentiated into granulocytic type cells by adding dimethyl sulfoxide to the media (15) six days prior to the sphingomyelinase treatment. The average extent of cellular differentiation was 77.7 ± 5.5% (mean ± SE) as measured by the intracellular reduction of nitro blue tetrazolium (16).

Determination of sphingomyelin hydrolysis by sphingomyelinase. Phospholipids from sphingomyelinase-treated cells and vehicle-treated control cells were separated by thin-layer chromatography (TLC) on plates coated with silica gel H that were developed in chloroform/methanol/glacial acetic acid/water (50:25:8:4, by vol). The developed plates were sprayed with sulfuric acid, charred by heating, and the amount of phosphorus in each phospholipid class was measured (17). The percentage decrease in sphingomyelin between the controls and sphingomyelinase-treated cells was taken as the percent of sphingomyelin that had been hydrolyzed.

Preparation of benzoate derivatives. Cellular lipid extracts were divided in half, and one portion was benzoylated using benzoic anhydride and dimethylaminopyridine as previously described for diradylglycerols (18). Ceramide dibenzoates, representing the sphingomyelin that was originally associated with the outer leaflet of the plasma membrane (11), were isolated from these reaction products by preparative TLC on silica gel G plates developed in hexane/diethyl ether (1:1, vol/vol). The developed plates were sprayed with a solution of 0.05% 2,7-dichlorofluorescein in 50% ethanol and viewed under ultraviolet (UV) light to locate the ceramide dibenzoate band (R_f ~ 0.3) which was extracted (12). Sphingomyelinase-resistant sphingomyelin was isolated from the second half of the total lipid extract by TLC on silica gel H plates developed in chloroform/methanol/glacial acetic acid/water (25:15:4:3, by vol). Developed plates were exposed to ammonia fumes for ~ 3 min and then sprayed with 0.05% 2,7-dichlorofluorescein in absolute ethanol to locate the sphingomyelin band under UV light. The sphingomyelin was extracted from the silica gel by the method of Bligh and Dyer (12) and subjected to phospholipase C hydrolysis (19,20) to remove the phosphocholine group. Total products from this phospholipase C hydrolysis were benzoylated and the ceramide dibenzoates isolated by TLC as described earlier.

Analysis of ceramide dibenzoates by high-performance liquid chromatography (HPLC). The identical dual pump HPLC system (Beckman Instruments, Berkeley, CA) previously used for separation of diradylglycerolbenzoate molecular species (20) was used to separate the molecular species of the dibenzoate derivatives of ceramides. A mobile phase of acetonitrile/isopropanol (3:2, vol/vol) at a flow rate of 1 mL per min and a detector set at 230 nm was used for the ceramide dibenzoate analyses.

A ceramide dibenzoate standard was prepared from beef brain ceramides (Sigma Chemical Co., St. Louis, MO) and purified by TLC as described in a previous section. The purified dibenzoate derivative had a molar absorptivity of 2.62 x 10^4 at 230 nm, which would be the expected value for a dibenzoate derivative (20). According to earlier work, treatment of ceramides with benzoic anhydride leads to *O*-benzoylation but not to *N*-benzoylation (21). The components of 13 different HPLC peaks from the beef brain ceramide dibenzoates were collected and treated with HCl–methanol at 70°C for 18 h to produce the free sphingoid bases and methyl esters (22). These products were benzoylated (18,20), and the resulting mixture of methyl esters and benzoate derivatives of the sphingoid bases was separated by TLC on silica gel G plates developed in hexane/diethyl ether (1:1, vol/vol). The developed plates were sprayed with 0.05% 2,7-dichlorofluorescein in 50% ethanol, viewed under UV light to locate the benzoylated sphingoid bases (R_f ~ 0.3) and methyl esters (R_f ~ 0.7), which were then extracted (12) from the silica gel. Addition of 2–3 drops of ammonium hydroxide during this extraction results in almost no contamination of dichlorofluorescein in the lower chloroform layer. The methyl esters were then analyzed by gas–liquid chromatography (GLC), and the sphingoid benzoates were separated by HPLC. An elution solvent of acetonitrile:isopropanol (4:1, vol/vol) at a flow rate of 1 mL per min through a 250 mm x 4.6 mm column packed with 5 μM Ultrasphere-ODS (Beckman Instruments) caused the sphingosine tribenzoate to be eluted at 7.9 min and sphinganine tribenzoate at 9.4 min. On the basis of graphical plots of log retention time vs. chain length the sphingosine (purchased from Sigma Chemicals) contained small amounts of 16:1 and 20:1 (<10%) bases in addition to the expected 18:1 sphingosine base. These analyses permitted identification of 13 major peaks in the beef brain ceramide benzoate standard (tentative identification of other minor peaks were extrapolated through the linear relationship that exists between log retention time and chain lengths). The composition of the beef brain ceramide benzoates was similar to that reported previously using slightly different methodology (23).

Identification of sphingomyelin molecular species in samples from HL-60 cells was based primarily on comparison of HPLC retention times of the ceramide dibenzoate derivatives between the samples and the standard prepared from beef brain. In addition, four of the larger separated ceramide dibenzoate fractions from undifferentiated HL-60 cells were also collected from the HPLC separation and subjected to the analysis of *N*-acyl and sphingoid base groups as described for the beef brain ceramides.

RESULTS AND DISCUSSION

Although HL-60 cells do contain low amounts of ceramide (1,2), it was calculated from information on the amounts of sphingomyelin in HL-60 cells (24) that sphingomyelin levels are about five times higher than the ceramide contents. Therefore, the small amount of free ceramides present in HL-60 cells would not likely cause a problem in interpreting our results. Also, based on the fact that no sphingosine and very lit-

tle sphingomyelin (2.8% in 12 h) was produced by HL-60 cells labeled with [^{3}H]acetylsphingosine (2), any changes in the distribution of ceramide species caused by further metabolism of ceramides during the sphingomyelinase treatment would appear to be minimal.

The extent of sphingomyelin hydrolysis by treatment of HL-60 cells with sphingomyelinase for 20 min was 56%; this accessible pool is considered to be on the outside surface of the cells. The nanomoles of sphingomyelin per 10^7 cells were 10.32 and 4.52 before and after treatment, respectively. Our results agree well with the previously reported amount of sphingomyelinase-accessible sphingomyelin (60%) present in the outer leaflet of the plasma membranes from HL-60 cells (11) using a slightly different analytical technique. TLC analysis of lipids extracted from the media of HL-60 cells after treatment with sphingomyelinase revealed only barely detectable amounts of ceramides, indicating that the ceramide portion of the sphingomyelin molecule remained associated with the outer plasma membrane after sphingomyelinase treatment. The distribution of molecular species in ceramides obtained by either sphingomyelinase or phospholipase C treatment of total sphingomyelin isolated from undifferentiated HL-60 cells was identical (data not shown). Thus, there was no change in the molecular species distribution that could be ascribed to a difference in selectivity between sphingomyelinase and phospholipase C treatments.

An example of the HPLC separation of ceramide dibenzoates, prepared by phospholipase C hydrolysis and benzoylation of the sphingomyelin that remained after treatment of HL-60 cells with sphingomyelinase, is shown in Figure 1. The largest component (peak A), identified as the dibenzoate of *N*-palmitoyl sphingosine, makes up about 50 mole% of the total species. The molecular species eluting with peak E contains nervonic acid and was the next most abundant (~16 mole %) component of the sphingomyelin in HL-60 cells. Identification of peaks A, B, E, and G were verified to contain at least 90% of the indicated molecular species by GLC analysis of their *N*-acyl groups (as methyl esters) and HPLC separation of the benzoate derivatives of the sphingoid bases as described in the Materials and Methods section. Identification of other peaks is based solely on their retention times from HPLC.

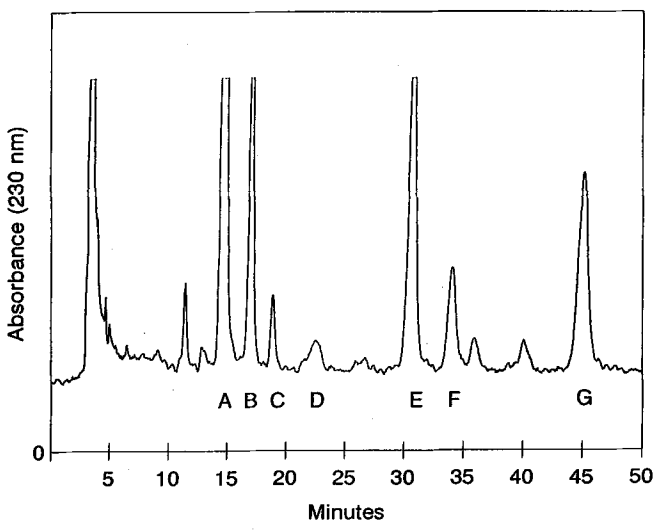

FIG. 1. High-performance liquid chromatography tracing of ceramide dibenzoate derivatives prepared as described in the Materials and Methods section from the sphingomyelin located on the outer membrane surface (sphingomyelinase-sensitive) of undifferentiated HL-60 cells. Full-scale absorbance at 230 nm for this chromatogram was 0.013 O.D. units. See Tables 1 and 2 for identification of the molecular species associated with letters located below the peaks.

Table 1 shows the distribution of molecular species of sphingomyelin that were sensitive (outside) or resistant (inside) to sphingomyelinase treatment of undifferentiated HL-60 cells. Small but statistically significant differences in percentages between the sphingomyelinase-sensitive (outside) and sphingomyelinase-insensitive (inside) sphingomyelin of undifferentiated HL-60 cells were seen in molecular species eluting with benzoate derivatives of *N*-palmitoyl (higher on the inside) and *N*-lignoceroyl sphingosine (higher on the outside, Table 1). However, we did not observe the extensive asymmetric distribution of sphingomyelin molecular species in HL-60 cells that is present in human erythrocyte membranes (13). Except for a small difference in the amount of the *N*-palmitoyl sphinganine species, the differentiated HL-60 cells did not show a pronounced difference in distribution of sphingomyelin molecular species between the sphingomyelinase-sensitive and sphingomyelinase-resistant membrane pools (Table 2). However, the amount of *N*-palmitoyl sphinganine was significantly lower ($P < 0.02$), and the level of *N*-nervonoyl sphingosine was significantly higher ($P < 0.02$) in differentiated cells than was found in the sphingomyelin from both sphingomyelinase-sensitive and sphingomyelinase-resistant pools of sphingomyelin from undifferentiated cells. These data indicate that, although differentia-

TABLE 1
Distribution of Sphingomyelin Species Between the Sphingomyelinase-Sensitive and Sphingomyelinase-Resistant Pools in Membranes of Undifferentiated HL-60 Cells[a]

Peak	*N*-acyl group	Inside (mole percent)	Outside (mole percent)
A	16:0	54.0 ± 1.4	47.5 ± 1.6[b]

F	22:0	3.4 ± 0.2	3.6 ± 0.2
G	24:0	6.0 ± 0.7	4.8 ± 0.4

[a]Values are the average mole percent ± standard error. Other species also were present but none at levels above 2.5 mol%. Determinations of statistically significant differences in the distribution of species between the undifferentiated and differentiated cells were based on Student's *t*-test for paired variables ([b]$P < 0.05$ and [d]$P < 0.001$). High-performance liquid chromatography retention times correspond to those of ceramide dibenzoate species for the indicated *N*-acyl groups connected to a sphingosine base.
[c]The 16:0 *N*-acyl group for this fraction is linked to a sphinganine base.

tion of HL-60 cells to their granulocytic form does not alter the amount of cellular sphingomyelin (25), the molecular species are indeed modified by treatment with dimethyl sulfoxide.

Statistically significant differences also were observed in some molecular species of the total sphingomyelin between undifferentiated and differentiated HL-60 cells (Table 3) that served as controls (cells not treated with sphingomyelinase). In these controls, the sphingomyelin species containing the *N*-palmitoyl sphinganine base and *N*-stearoyl sphingosine base were significantly higher in the undifferentiated cells, and the sphingomyelin containing the *N*-nervonyl sphingosine base was significantly lower; no significant differences were seen in any of the other molecular species of sphingomyelin analyzed in these cells (Table 3).

There is not enough difference in the distribution of sphingomyelin molecular species between the outer leaflet of the HL-60 plasma membrane and the sphingomyelinase-resistant pool of sphingomyelin to suggest that a particular sphingomyelin species could be involved in the sphingomyelin cycle associated with the signalling events described recently (11). Our experiments, while not precluding this possibility, do demonstrate that if specific molecular species of intracellular sphingomyelin are involved in cell signalling events, then essentially the same species are available for selection on the metabolically active internal cellular membranes (11) as are present on the outer surface of the membrane leaflet.

We believe the techniques for analyses of molecular species of sphingomyelin described in this report will be very useful in future studies designed to establish the functional role of sphingomyelin in cells. Moreover, our data provide baseline information about the various molecular species of sphingomyelin in HL-60 cells, a cell line that has proven to be a useful model system in a variety of studies dealing with cell signalling phenomena.

ACKNOWLEDGMENTS

The authors express their sincere appreciation to Shirley L. Poston for her excellent assistance in the preparation of this manuscript. This work was supported by the Office of Energy Research, U.S. Department of Energy (Contract No. DE-AC05-760R00033).

Lipid Changes in HL-60 Cells on Differentiation into Macrophages by Treatment with a Phorbol Ester

Ray Manning[a], Anna Fallani[b] and Salvatore Ruggieri[b,*]

[a]Department of Biological Sciences, University of Durham, Durham DH1 3LE, England, and [b]Istituto di Patologia Generale dell'Università degli Studi di Firenze, Viale Morgagni 50, 50134 Firenze, Italy

ABSTRACT: We studied changes in lipid composition of human promyelocytic leukemia cells (HL-60) on differentiation to the macrophage/monocytic lineage by treatment with the phorbol ester, 12-O-tetradecanoyl-phorbol-13-acetate. Differentiation was accompanied by: (i) a decrease in the level of phospholipids; (ii) a greater amount of triacylglycerols; (iii) an increase in 1-alk-1'-enyl-2-acyl- and 1-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamine and a decrease in 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; and (iv) an increase in the level of arachidonic acid in ethanolamine phospholipids. The increased levels of ether-linked lipids and of arachidonic acid in ethanolamine phospholipids are consistent with an enhanced biosynthesis of platelet-activating factor and eicosanoids, which are particularly important in the macrophage function.
Lipids 30, 811–815 (1995).

In spite of the great deal of information on the lipid structure of mammalian cells, our knowledge of the biological roles of the various lipid components is still limited. In fact, there are only few examples of cell functions related to specific lipid molecules. Cell permeability is known to be controlled by cholesterol levels (1,2) and the fatty acid profile of membrane phospholipids (3), and the activity of several membrane-associated enzymes is dependent on specific phospholipid classes (4,5) and molecular species (6–11). Moreover, receptor activities (12,13), agglutinability by lectins (14,15), and cellular adhesiveness (16) were shown to be influenced by specific fatty acids and phospholipid molecular species. Furthermore, a surfactant activity has been attributed to lung dipalmitoyl phosphatidylcholine (17). Most of this information has been derived from studies based on dietary manipulations (6,10,13, 18,19), treatment with lipases (4,11,20), or incorporation of exogenous lipids into cell membranes (5,9,15,21,22).

An alternative approach to the investigation of the biological role of lipids is to study the lipid changes which occur in different types of cells during differentiation. The rationale for this approach is that a characteristic lipid pattern acquired during differentiation may reflect the appearence of specific cellular functions. Suitable experimental models for this particular approach are represented by transformed cells which differentiate in response to specific treatments, such as Friend erythroleukemia cells (23), myeloid leukemia cells (24), and HL-60 promyelocytic leukemia cells (25). HL-60 cells are a particularly useful model in this type of experiment as these cells can differentiate into either mature granulocytes (25) or macrophages (26), the functions of which are partly dependent on production of biologically-active lipids. Indeed, differentiation of HL-60 into macrophages was associated with an increased synthesis of platelet-activating factor (PAF) (27) and leukotriene (LT) B_4 (LTB_4) (28), whereas differentiation into granulocytes was accompanied by an enhanced generation of LTC_4, LTD_4 as well as LTB_4 (28).

In the present study, we investigated whether the differentiation of HL-60 cells into macrophages, caused by treatment with 12-O-tetradecanoyl-phorbol-13-acetate (TPA), was associated with changes in the lipid structure which might reflect the metabolic and functional characteristics typical of the mature macrophage. Some aspects of lipid composition of HL-60 cells differentiated into macrophages (29,30) and granulocytes (31–33) have been previously described.

MATERIALS AND METHODS

Cells and culture conditions. HL-60 cells supplied by the American Type Culture Collection (Rockville, MD) were kindly donated by Menarini Laboratorios (Barcelona, Spain). HL-60 cells were grown at 37°C in a humidified 5% CO_2 atmosphere in RPMI 1640 medium supplemented with 5% (vol/vol) heat-inactivated fetal calf serum (FCS) (Boehringer, Mannheim, Germany) and 2 mM L-glutamine, without antibiotics. Cells were subcultivated by seeding 5×10^5 cells/mL in Falcon tissue culture flasks (Becton Dickinson Labware, Bedford, MA) and were harvested after six days. At this time, cultures showed a density of 1×10^6 cells/mL.

Differentiation of HL-60 cells by TPA. HL-60 cells were suspended at 1×10^6 cells/mL in the growth medium containing 0.1 μM TPA (Sigma Chemical Co., St. Louis, MO), and

were seeded into 100-mm Falcon plastic dishes. The TPA concentration used in this study (0.1 μM) was observed to induce the highest number of adherent cells (65–70% of cells in the culture) without affecting cell viability. The final concentration of dimethyl sulfoxide (DMSO) used to solubilize TPA did not exceed 0.02% (vol/vol) in growth medium, a concentration that was not found to affect the differentiation of HL-60 cells (26). After a 24-h incubation at 37°C, growth medium was decanted, and the remaining adherent cells were gently washed with 10 mL of phosphate-buffered saline (PBS) at 37°C, and then harvested with a rubber policeman scraper. Cells were counted by an automatic cell counter (ZBI; Coulter Electronics, Luton, Beds., England), and viability was determined by the Trypan Blue exclusion test. Cells suspended in cold PBS supplemented with 10% (vol/vol) FCS at pH 7.4 were smeared onto glass slides and cytocentrifuged at 500 rpm for 5 min (Haereus-Minifuge GL, Osterode, Germany). Slides were stained with a Giemsa solution and used to assess the morphology of macrophage-like differentiated cells. Macrophage features included disappearence of azurophilic granules, a marked adherence to plastic with prominent pseudopodia and adherence of cells to each other. Differentiation into monocyte/macrophage lineage was also assessed by appearance of α-naphthylacetate esterase activity (34). Suspensions of adherent TPA-treated HL-60 cells were also tested for CD11b and CD11c markers, characteristic of monocytic/macro-phagic differentiation, using monoclonal antibodies (Becton Dickinson, Mountain View, CA) in an indirect immunofluorescence procedure. The expression of CD11b and CD11c markers was ten times higher in TPA-treated adherent HL-60 cells than in undifferentiated HL-60 cells (results not shown). Flow-cytometric analysis was performed on a FACS machine (Fluorescent Activated Cell Sorter; Becton Dickinson).

Lipid analysis. TPA-differentiated HL-60 cells were suspended in PBS and washed three times with PBS, and then extracted with 19 vol of chloroform/methanol (2:1, vol/vol) following the procedure of Folch *et al.* (35). This procedure also was used to extract lipids from undifferentiated HL-60 cells after they were freed from growth medium by centrifugation and resuspension in PBS.

Neutral lipids and phospholipids (PL) were fractionated into individual classes as reported previously (36). Triacylglycerols (TG) were determined by the quantitative gas–liquid chromatography (GLC) of their fatty acid methyl esters with an arachidic acid internal standard. Cholesterol was measured in total lipid extracts by quantitative GLC after saponification with 0.3 N methanolic NaOH in the presence of a coprostanol internal standard. Total PL and individual PL classes were measured by the ammonium–ferrothiocyanate procedure (37), using a 2:1 mixture of choline PL (CP) and ethanolamine PL (EP) (Sigma Co.) as a standard. EP and CP were submitted to ether-linked lipid analysis following the procedure of Su and Schmidt (38). By using this procedure, alk-1′-enyl-linked lipids are converted into alkyl-substituted dioxanes, and alkyl-linked lipids are converted into alkylglycerols by hydrogenolysis with sodium *bis*-(2-methoxy ethoxy)-aluminum hydride in toluene (Eastman Kodak Company Co., Rochester, NY). Alkyl-substituted dioxanes and alkylglycerols were separated by thin-layer chromatography (TLC) on silica gel H in the solvent system hexane/diethyl ether (40:60, vol/vol), and then measured by quantitative GLC using dimethoxytetradecane and pentadecylglycerol, respectively, as internal standards.

GLC analyses. Methyl ester derivatives of fatty acids from TG, EP, CP, and phosphatidylinositol + phosphatidylserine (PI + PS) were obtained by heating the samples at 80°C for 12 h in a solution of 5% (vol/vol) H_2SO_4 in methanol/benzene (25:1, vol/vol). Fatty acid methyl esters were extracted into hexane, concentrated under a stream of nitrogen and then analyzed isothermally at 185°C on six-foot glass columns packed with EGSS-X on Gas-Chrom P 100-200 mesh (Supelco, Bellefonte, PA). Fatty acid methyl esters were identified by their retention times relative to those of standard mixtures (Supelco). Alkyl-substituted dioxanes and isopropylidene derivatives of alkylglycerols (39) were analyzed at 195°C on six-foot glass columns packed with EGSS-X on Gas-Chrom P 100–200 mesh. Cholesterol was analyzed at 265°C on a six-foot glass column packed with 3% OV 17 on 80–100 mesh Supelcoport (Supelco). Columns were mounted in a Perkin-Elmer gas chromatograph model 3920 (Perkin-Elmer, Norwalk, CT) equipped with flame-ionization detectors. Peak areas were calculated by using a Perkin-Elmer Sigma 10 integrator.

Statistical analysis. Statistical significance of the differences between differentiated and undifferentiated HL-60 cells was determined by Student's *t*-test.

RESULTS AND DISCUSSION

The amounts of total PL, cholesterol, and TG in undifferentiated HL-60 cells are shown in Table 1, and are similar to those found for other transformed cell types (40–42). Differentiation of HL-60 cells into macrophages by TPA was accompanied by a decrease in total PL. This change was also found in HL-60 cells differentiated into granulocytes by DMSO (32) or retinoic acid (33). Moreover, TPA-induced differentiation was accompanied by an increase of TG, a change also reported by Cabot *et al.* (29). An increase of TG content was also reported by Naito *et al.* (32) in HL-60 cells differentiated into granulocytes by retinoic acid.

TPA-induced differentiation was characterized by a significant decrease in CP content, a change also found in HL-60 cells differentiated into granulocytes by retinoic acid (32) or DMSO (33) (Table 2).

Both EP and CP of undifferentiated HL-60 cells contain appreciable amounts of ether-linked subclasses with a prevalence of 1-alk-1′-enyl-2-acyl molecular species in EP (i.e., ethanolamine plasmalogens), and of 1-alkyl-2-acyl molecular species in CP (Table 3). Differentiation of HL-60 cells into macrophages was accompanied by a marked increase of 1-alk-1′-enyl-2-acyl- and 1-alkyl-2-acyl-*sn*-glycero-3-phospho-

TABLE 1
Changes of Lipid Composition in HL-60 Cells Differentiated into Macrophages by TPA[a]

Lipid class	HL-60 cells	TPA-treated cells
Total phospholipids	183.0 ± 14.9	153.0 ± 7.9[b]
Total cholesterol	45.0 ± 2.2	37.0 ± 6.3
Triacylglycerols	6.0 ± 0.3	10.0 ± 0.4[c]
Cholesterol/phospholipid molar ratio	0.251 ± 0.01	0.272 ± 0.01

TABLE 2
Changes of Phospholipid Composition in HL-60 Cells Differentiated by TPA[a]

Phospholipid class[b]	HL-60 cells	TPA-treated cells
CP	104.0 ± 1.5 (56.8)	83.2 ± 1.3 (54.4)[c]
EP	48.3 ± 1.8 (26.4)	41.2 ± 2.8 (26.9)
PI + PS	14.3 ± 0.4 (7.8)	14.1 ± 0.3 (9.2)
SP	13.0 ± 1.4 (7.1)	11.6 ± 0.8 (7.6)
DPG	2.9 ± 0.6 (1.6)	2.6 ± 0.3 (1.7)
PA	0.5 ± 0.0 (0.3)	0.3 ± 0.0 (0.2)

[a]Values are expressed as nmol/10^7 cells and represent the mean value ± SEM of three separate experiments. Numbers in parentheses are percentages of total phospholipids.
[b]CP, choline phospholipids; EP, ethanolamine phospholipids; PI + PS, phosphatidylinositol + phosphatidylserine; SP, sphingomyelin; DPG, diphosphatidylglycerol; PA, phosphatidic acid; other abbreviation as in Table 1.
[c]$P < 0.05$.

ethanolamine, and a decrease of 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine. A similar increase in the 1-alk-1′-enyl-2-acyl-subclass of EP was observed on differentiation of HL-60 cells into granulocytes (31–33). On the other hand, the increase of 1-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamine found in our HL-60 cells differentiated into macrophages is in contrast with the decrease of the same subclass reported by Suga *et al.* (33) for HL-60 cells differentiated into granulocytes, a discrepancy possibly related to the different pattern of differentiation in HL-60 cells treated with TPA or DMSO. It is worth noting that the levels of ethanolamine plasmalogens found in HL-60 cells on differentiation into macrophages approximated those reported for peritoneal and alveolar macrophages (44–47). An increase in the level of ethanolamine plasmalogens was also found following DMSO-induced differentiation of N1E-115 neuroblastoma cells (48). Moreover, maturation of human central nervous system was accompanied by an increase of ethanolamine plasmalogens in myelin (49).

As shown in Table 4, 16:0 was the major alk-1′-enyl chain, with smaller amounts of 18:0 and 18:1 alk-1′-enyl chains, in the alk-1′-enyl-acyl subclasses of both EP and CP in undifferentiated HL-60 cells. Similarly, 16:0 was found to be the major alkyl chain in the alkyl-acyl subclass of CP, whereas in the alkyl-acyl subclass of EP there were equivalent levels of 16:0 and 18:0 alkyl chains, and smaller, but substantial, levels of 16:1 and 18:1 alkyl chains. TPA-induced differentiation of HL-60 cells was not accompanied by any significant changes of alk-1′-enyl and alkyl chain compositions of ether-linked EP and CP subclasses.

In undifferentiated HL-60 cells, the fatty acid profiles of EP, CP, and PI + PS were characterized by a high level of oleic acid (18:1n-9) and low percentages of linoleic (18:2n-6), arachidonic (20:4n-6), and 22:polyunsaturated fatty acids (Table 5). These characteristics in fatty acid profiles are similar to those reported for other types of malignant cells (36,41,42,50,51). Differentiation of HL-60 cells into macrophages was accompanied by a significant decrease of palmitoleic (16:0n-9) in CP, but there was no change in the level of oleic acid in the various PL classes. Moreover, the level of arachidonic acid in EP of differentiated HL-60 cells was twice as high as that observed in undifferentiated cells, and reached a value very close to that reported for human alveolar macrophages (52). In contrast, Cabot and Welsh (30) reported no difference in arachidonic acid level of the total PL in HL-60 cells differentiated into macrophages. A marked increase in the level of arachidonic acid also was found in individual PL classes of HL-60 cells on differentiation into granulocytes (32), as well as in EP of N1E-115 neuroblastoma cells induced to differentiate by DMSO treatment (48). The increase in the proportion of arachidonic acid in EP of our HL-60 cells differentiated into macrophages corresponds to the rise of the ethanolamine plasmalogen level in these cells. Similarly, arachidonic acid is mainly present in the alk-1′-enyl-acyl subclass of EP in resident alveolar macrophages (45), thioglycollate-elicited peritoneal macrophages (47,53), human neutrophils (54,55), and HL-60 cells following differentiation into granulocytes (32).

In conclusion, differentiation of HL-60 cells into macrophage-like cells, caused by TPA treatment, was associated with an increase in the level of ethanolamine plasmalogens and an enrichment of EP in arachidonic acid. It is difficult to ascertain the biological relevance of this change in the macrophagic differentiation of HL-60 cells, due to our poor knowledge of the physiological function of ethanolamine plasmalogens (56). However, the recent observation that the characteristic vinyl-ether linkage of ethanolamine plasmalogens protects animal cell membranes from certain oxidative stresses (57) points to the possibility that elevated levels of this lipid may permit macrophages to scavenge reactive oxygen species produced during macrophage activation. Moreover, the high level of ethanolamine plasmalogens in HL-60 cells on differentiation into macrophages may reflect a requirement for these particular phospholipid molecules in the generation of bioactive lipids, including PAF and eicosanoids, which are important in macrophage function (55,58–60). Indeed, ethanolamine plasmalogens are the major source of arachidonic acid precursor for eicosanoid production in granulocytes (55,61). This release of arachidonic acid generates 1-alk-1′-enyl-2-lyso-*sn*-glycero-3-phosphoethanolamine, which acts as an acceptor of arachidonic acid released from 1-alkyl-2-acyl-*sn*-

TABLE 3
Changes of 1-Alk-1′-Enyl-2-Acyl, 1-Alkyl-2-Acyl, and 1,2-Diacyl Subclasses of EP and CP in HL-60 Cells Differentiated into Macrophages by TPA[a]

	EP		CP	
Subclasses	HL-60 cells	TPA-treated cells	HL-60 cells	TPA-treated cells
1-Alk-1′-enyl-2-acyl	35.4 ± 1.6	62.6 ± 1.5[b]	6.0 ± 1.0	7.7 ± 0.4
1-Alkyl-2-acyl	3.2 ± 0.4	6.7 ± 0.3[c]	14.8 ± 1.3	10.6 ± 0.8[d]
1,2-Diacyl	61.4 ± 1.2	30.4 ± 1.2[d]	79.2 ± 1.8	81.6 ± 1.2

[a]Values were calculated as described by Fallani *et al.* (Ref. 43), and are expressed as percentages of total EP and CP in each cell type. They are expressed as a mean value ± SEM for three separate experiments. Abbreviations as in Tables 1 and 2.

glycero-3-phosphocholine during the transacylation reaction, which is a critical event in PAF biosynthesis (58–60). Ethanolamine plasmalogens also can be converted into an ethanolamine plasmalogen analog of PAF, as has been reported by Snyder *et al.* (60) in HL-60 cells following differentiation into granulocytes.

ACKNOWLEDGMENTS

This work has been supported by grants from the Consiglio Nazionale delle Ricerche (Special Project: ACRO), from the Associazione Italiana della Ricerca sul Cancro (AIRC), and from Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST, 40–60%). We thank Prof. A. Fonnesu, Chairman of the Institute of General Pathology, University of Florence, for his interest in this study. We also gratefully acknowledge the generous help received by Dr. Valeria Santini, of Department of Hematology, University of Florence, for the assay of the differentiation markers. We express our deepest gratitude to Dr. Nuria Suesa, of the Menarini Laboratorios (Barcelona, Spain), for providing the HL-60 cells used in this study.

Pathogenesis of Oleic Acid-Induced Lung Injury in the Rat: Distribution of Oleic Acid During Injury and Early Endothelial Cell Changes

Greg Beilman*

Departments of Surgery and Internal Medicine, University of Kansas School of Medicine-Wichita, Wichita, Kansas 67214

ABSTRACT: Oleic acid-induced lung injury, a well-described laboratory model for acute pulmonary injury in the rat and other species, causes morphologic and cellular changes similar to human adult respiratory distress syndrome (ARDS). Experiments were performed to test the hypothesis that the initial event of oleic acid lung injury is damage of the pulmonary vascular endothelium by oleic acid, with subsequent pulmonary damage and inflammation. Oleic acid levels were followed in the lung and other tissues by measuring accumulation of ^{14}C-oleic acid; the direct effects of oleic acid and other fatty acids on rat endothelial cells, alveolar type II cells, and hepatocytes in culture were determined. Lung tissue from treated rats was also examined by light and electron microscopy for evidence of endothelial cell damage. At 30 min after injury, oleic acid reached high concentrations in lung tissue as demonstrated by presence of radiolabel (3.24×10^{-6} moles per gram of tissue), with counts in the lung nearly an order of magnitude greater than in any other organ measured. Oleic acid was present in the lung mostly as free fatty acid (85%), and was also present in the alveolar fluid supernatants, rather than being cell-associated (1.7×10^{-7} moles vs. 1.1×10^{-8} moles at 30 min). Oleic acid was toxic to endothelial cells after one minute of exposure at concentrations of 5×10^{-4} M and above. Electron microscopy showed endothelial cell changes as early as 10 min after induction of injury *in vivo*, including the presence of endothelial cell blebbing. The results of these studies suggest that the initial event in oleic acid lung injury is damage to the pulmonary vascular endothelial cell.
Lipids 30, 817–823 (1995).

Adult respiratory distress syndrome (ARDS) afflicts 150,000 patients yearly in the United States, with a mortality rate of over 50%. This rate has not improved since ARDS was first described in 1967 despite the use of positive-pressure ventilation and other therapies (1). The predisposing conditions associated with ARDS are quite diverse, ranging from endotoxic shock to cardiopulmonary bypass. A variety of inflammatory mediators have been investigated in both human ARDS and animal models of acute lung injury, but blocking the effects of any one of these mediators has met with only limited success and no improvement in outcome. This suggests that ARDS is likely to be the final result of several different pathways of pulmonary injury.

Oleic acid (OA), an 18-carbon unsaturated fatty acid, causes morphologic and cellular changes similar to human ARDS when given intravenously (2–6), as recently reviewed (7). It is possible that this injury is similar to that caused in humans by fat embolus, pancreatitis, and possibly narcotic overdose; however, there are scant data on the initial events that occur during acute lung injury from OA. It seems unlikely that complement plays a significant role in OA lung injury, since levels of complement have not been noted to change during its early stages, and depletion of the third component of complement by cobra venom toxin failed to abrogate the injury (2). Similarly, depletion of platelets has failed to significantly affect the course of this form of lung injury (2,8). Although depletion of neutrophils in one set of experiments resulted in decreased permeability of the lung in rats after OA lung injury, such depletion did not lead to differences in histology or bronchoalveolar lavage (BAL) findings (9). Oxygen radicals have been found to be important in the etiology of certain types of pulmonary injury (10–12), but several studies examining oxygen radicals in OA lung injury have argued against a role of this mediator (9,13,14). This suggests that there is an early component of OA lung injury not related to any of the above factors.

The hypothesis that the initial event of OA lung injury is damage of the pulmonary vascular endothelium by OA with subsequent pulmonary damage and inflammation was tested by several approaches. OA levels were measured in the lung and other body tissues after ^{14}C-OA injection to determine relative concentrations of OA in free and esterified forms during early lung injury. The cytotoxic effects of OA and other fatty acids at different concentrations and time intervals were determined with rat endothelial cells and other cells *in vitro*. Tissue samples of lung from rats treated with OA were examined for evidence of endothelial cell damage by electron microscopy.

EXPERIMENTAL PROCEDURES

Animals. Male Sprague-Dawley rats, free of respiratory disease and weighing 250–350 g, were used in this study (Sasco Labs, Omaha, NE). All rats were fed and watered *ad libitum* and housed in microisolator cages. All protocols were approved by the Animal Use Committees of the University of Kansas School of Medicine–Wichita and Veterans Affairs Medical Center–Wichita.

Reagents. Hanks' balanced salt solution (HBSS), phosphate-buffered saline (PBS), and RPMI-1640 were obtained from JRH Bioscience (Lenexa, KS). ^{14}C-labeled OA was obtained from New England Nuclear (Boston, MA). Oleic, linolenic, γ-linolenic, linolenaidic, 14-*cis*-eicosenoic, and arachidonic acids and bovine serum albumin were obtained from Sigma (St. Louis, MO).

Cell culture and harvesting. Endothelial cells were isolated from rat pulmonary arteries using the methods of Habliston *et al.* (15) and were grown in complete media consisting of RPMI-1640 with 10% fetal bovine serum (FBS) (Hyclone Laboratories, Logan, UT), 10% Nu-Serum (Collaborative Research, Cambridge, MA), heparin 20 μg/mL (Fisher, St. Louis, MO), and retinal-derived growth factor (20 μL/mL) (16). Cells were identified as endothelial by morphology and by the ability to take up DiI-ac-LDL, low-density lipoprotein labeled with the fluorescent probe, DiI (Biomedical Technologies Inc., Stoughton, MA). Cells were passaged with trypsin onto gelatin-coated plates. Cells at passages 6–12 were used for this series of experiments.

Rat hepatocytes were obtained using collagenase harvesting as previously described (17) and plated onto 96-well plates coated with bovine dermal collagen (Celtrix, Santa Clara, CA) at a concentration of 4×10^4 cells/well. Cells were used 48–72 h after harvest.

Rat alveolar type II cells (ATII) were harvested using the methods of Dobbs *et al.* (18). ATII morphology was confirmed with electron microscopy and Papinicolou stain demonstrating >90% ATII cells. These cells were plated on 96-well plates at 4×10^4 cells/well and were allowed to adhere for 48 h prior to use.

Induction of lung injury. Lung injury was induced under ketamine anesthesia as previously described (2). Rats under ketamine anesthesia received OA suspended in a solution of bovine serum albumin dissolved in PBS (1 mg/mL) given *via* femoral vein cut down. For experiments using radiolabeled OA, 10 uCi of ^{14}C-labeled OA were added to the dose received by each animal. The total dose of exogenous OA administered per animal was 8.5×10^{-5} moles.

Animal protocol. Rats were sacrificed at 30 min, 2 h, 4 h, and 12 h (n = 3 for each group) after the administration of OA. Animals were anesthetized; then liver, spleen, and kidneys were removed, and blood was drawn into heparinized syringes. BAL was performed using five aliquots of HBSS at 4°C (10 cc/aliquot). The chest cavity was then opened, and lungs, thymus, and heart were removed. The brain was removed after opening the cranium. Urine was aspirated from the bladder at the time of sacrifice. Blood and BAL fluids were centrifuged, and supernatants and cell pellets were stored separately. All samples were weighed and stored at −70°C until assayed.

Measurement of OA levels. A small sample (100–200 mg) was taken from each organ, weighed, homogenized, and then dissolved in Scintigest tissue solubilizer (Fisher) (1.5 mL/100 mg tissue) and water (200 μL/100 mg tissue). This mixture was then placed in scintillation cocktail (Scintiverse, Fisher). Constant volumes of BAL fluid, cells, plasma, and red blood cell pellet were added to scintillation cocktail. Samples were read on a scintillation counter with window set for ^{14}C. Quenching was evaluated for each tissue by adding a known amount of ^{14}C OA to organs prepared from an uninjected animal in the same fashion as noted above. With the exception of the red blood cell prep (necessitating a dilution of 1:4000), no significant quenching was noted.

Data were collected as cpm. By determining the number of cpm in each organ [(total organ weight/weight of counted sample) × cpm of sample] and by dividing this number by the total cpm injected into the animal, the distribution of counts in each organ at each time interval was determined. An approximation of the concentration of exogenous OA in selected instances was determined by multiplying this percentage by the total number of moles injected in each animal (8.53×10^{-5} moles). This calculation does not take into account endogenous sources of OA.

In order to determine the lipid distribution of the radiolabel, tissue from the lung, liver, kidney, and blood from a rat at each time period was extracted with chloroform/methanol and was dried. This extract was diluted with chloroform and spotted onto thin-layer chromatography plates and run using petroleum ether/diethyl ether/glacial acetic acid solvent (80:20:1). Ultraviolet light was used to identify cholesterol ester, triglyceride, free fatty acid, and phospholipid bands which were scraped into vials with scintillation cocktail and counted. The band remaining at the origin was assumed to be the phospholipid fraction. This technique does not measure potential radiolabeled water-soluble components that may be present at the later time intervals.

In vitro *experiments.* Endothelial cells were plated on 96-well tissue culture plates and were allowed to grow to confluence. Solubilized OA was prepared by dissolving OA (10 μL) in 150 μL ethanol and by adding 750 μL of distilled water to this solution. NaOH (1N) was added in a dropwise fashion until OA was completely solubilized (13). Other fatty acids were prepared in the same fashion. Dilutions of these solutions in complete media were filter-sterilized. Diluent without fatty acids was not noted to exhibit cytotoxicity at concentrations used in these experiments. In the first series of experiments, the time course of OA cytotoxicity was evaluated. OA, at a concentration of 5×10^{-4}M and 10^{-3}M in complete media, was added to endothelial cells, grown to confluence and OA-induced cytotoxicity was measured at intervals using the 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) assay to assess viable cells (19). In this assay,

viable cells convert MTT to an insoluble formazan product, which is measured by determining the absorbance of each sample at 560 nm after solubilizing the formazan product in isopropanol.

In another experiment, the dose response of OA was assessed. Dilutions of OA in complete media were added to endothelial cells and incubated for 4 h at 37°C. Control wells contained either media alone or 3M guanidine HCl (Sigma). MTT assay was then performed to determine cytotoxicity. These experiments were repeated four times to ensure consistency. The percentage of cytotoxicity for each concentration of OA was calculated using the formula:

$$\% \text{ cytotoxicity} = 1 - \left[\frac{A_{\text{experimental}} - A_{\text{guanHCl}}}{A_{\text{media}} - A_{\text{guanHCl}}}\right] \times 100 \qquad [1]$$

where $A_{\text{experimental}}$ equals the absorbance at 560 nm of cells treated with OA, A_{guanHCl} equals the absorbance at 560 nm of cells treated with guanidine HCl, and A_{media} equals the absorbance at 560 nm of cells treated with media. These experiments were then repeated with linolenic, γ-linolenic, linolenaidic, 14-*cis*-eicosenoic, and arachidonic acids, using different concentrations of serum with OA. The effects of OA were compared in different rat primary cell cultures. Rat endothelial cells, hepatocytes, and ATII cells were treated for 4 h with OA at various concentrations, followed by MTT assay to assess cytotoxicity.

Electron microscopy. Rats with OA lung injury were sacrificed at 10 min, 30 min, and 1, 2, 4, and 8 h after induction of injury. A control animal injected with carrier solution only was sacrificed as well. The lungs were immediately removed, and tissue was diced into small sections. Biopsies of lung tissue for electron microscopy were taken from areas bordering on grossly hemorrhagic areas of the lungs and were fixed in cold 3% phosphate-buffered glutaraldehyde. The tissue was post-fixed in 2% phosphate buffered OsO_4 (20), dehydrated in graded ethanol, and was embedded in Epon/Araldite (21). Blocks were thick sectioned (2–3 microns; LKB microtome, Bromma, Sweden) and were stained with paragon (22) for orientation. Ultra-thin sections (50–60 nm) were stained with uranyl acetate and lead citrate (23,24). Thin sections were examined, and electron photomicrographs were taken, using a Philips 201 transmission electron microscope (Einthoven, Holland).

Additional tissue specimens were fixed in formaldehyde and were stained with hematoxylin and eosin for routine light microscopy.

Statistical analysis. Means and standard deviations were determined for data, and appropriate data points were compared using Student's unpaired *t*-test with Bonferroni's adjustment for multiple comparisons.

RESULTS

Counts were highest in the lungs 30 min after induction of lung injury. If the assumption is made that most OA is not initially metabolized, this yields a concentration of exogenous OA of 3.24×10^{-6} moles per gram of tissue. These counts are nearly an order of magnitude greater than in any other organ (Table 1). This trend did not reach significance because of small group numbers. Counts were also present in BAL fluid of rats after experimental lung injury, primarily in the BAL supernatants, rather than cell-associated ($4.2 \pm 1.9 \times 10^4$ cpm vs. $3 \pm 3 \times 10^3$ cpm at 30 min). There was only a 22% decrease in counts over the 12-h period of the experiment. Counts were found in other organs in varying amounts, with the highest levels (after the lung) in the heart and liver (Table 1). The approximate half-life of counts, presumably from OA, in the lung parenchyma, was 2½ to 3 h by extrapolation.

TABLE 1
Radiolabel in Various Tissue Compartments[a]

Compartment	Thirty minutes	Two hours	Four hours	Twelve hours
Lung	806 ± 467	297 ± 149	276 ± 138	102 ± 21
Heart	161 ± 99	57 ± 21	34 ± 11	15 ± 3
Liver	159 ± 83	89 ± 23	55 ± 13	25 ± 2
Kidney	53 ± 18	42 ± 11	45 ± 15	28 ± 2
Plasma	34 ± 6	16 ± 5	13 ± 3	34 ± 25
Spleen	32 ± 4	34 ± 11	34 ± 11	21 ± 2
Thymus	23 ± 11	25 ± 8	34 ± 15	23 ± 2
Urine	21 ± 3	49 ± 44	34 ± 11	14 ± 2
Brain	7 ± 4	7 ± 2	8 ± 3	7 ± 1
BAL fluid	42 ± 19	42 ± 13	30 ± 11	33 ± 5
BAL cells	3 ± 3	2 ± 1	3 ± 2	15 ± 1

[a]Data are presented as mean ± SD from three animals at each time period. Data are expressed as cpm per gram of tissue ($\times 10^3$), except for bronchoalveolar lavage (BAL) fluid and cells where data are expressed as cpm $\times$ 10^3 in total collected specimen. The cpm per gram of tissue are increased in pulmonary tissues as compared with other compartments with $P < 0.1$ (Student's unpaired *t*-test).

At 30 min after lung injury, 85% of radioactivity was noted to be associated with the free fatty acid fraction of extracted lipids (Fig. 1). This percentage decreased in a time-dependent manner over the next 12 h to 28%, while the phospholipid

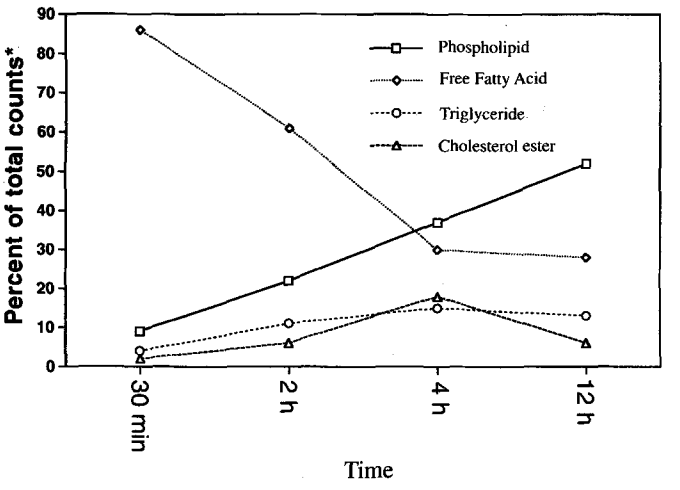

FIG. 1. Percent of total cpm of each fatty acid fraction separated by thin-layer chromatography from rat lungs 30 min, 2 h, 4 h, and 12 h after oleic acid lung injury. *Total cpm at each time point in the fatty acid fraction of the lung were: 30 min, 5142; 2 h, 2134; 4 h, 1252; and 12 h, 3529.

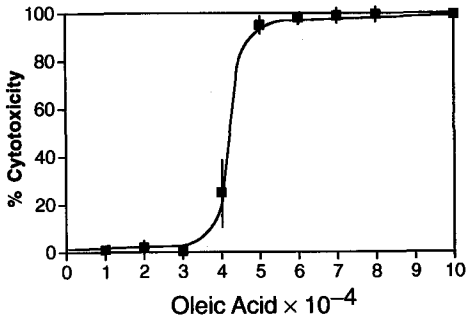

FIG. 2. Toxicity of oleic acid on endothelial cell subcultures. Cell viability was determined with 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide assay after 4 h of culture with oleic acid at varied concentrations (37°C, 5% CO_2). Error bars denote standard deviation.

fraction increased over this time period. In the liver and the kidney, the greatest proportion of radiolabel was in the triglyceride fraction at 30 min (40 and 80%, respectively), with the phospholipid fraction again increasing over the 12 h (39 and 33%, respectively).

OA was found to be toxic to rat pulmonary endothelial cells in culture above levels of 6×10^{-4} M (6×10^{-7} moles/mL) when cultured for 4 h. The LD_{50} of OA on endothelial cells after 4 h in culture was approximately 5×10^{-4} M (Fig. 2). There was also significant cytotoxicity to endothelial cells almost immediately upon exposure (59% cytotoxicity at 1 min of exposure at levels of 10^{-3} M). Cytotoxicity increased linearly over time at OA concentrations of 10^{-3} M and 5×10^{-4} M to 90 and 83%, respectively, for cells exposed to OA for 4 h (Fig. 3). This toxicity was found to be significantly decreased with increasing concentrations of serum, with a 4-h exposure of 4×10^{-4} M OA causing 78% cytotoxicity in the presence of 1% FBS, and no toxicity in the presence of 20% FBS (Fig. 4). Different cell types exhibited variable sensitivity to OA as well, with hepatocytes demonstrating no toxicity with concentrations up to 2×10^{-3} M and ATII cells having sensitivity similar to endothelial cells (data not shown). The sensitivity of endothelial cells to a number of fatty acids was tested (Fig. 5). Endothelial cells were most sensitive to γ-linolenic acid (18:3n-6) and least sensitive to arachidonic acid (20:4n-6).

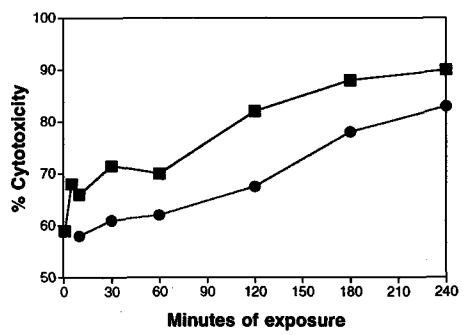

FIG. 3. Time course of cytotoxicity of oleic acid on endothelial cell subcultures. Endothelial cells were cultured in the presence of oleic acid (squares: 10^{-3}M, circles: 5×10^{-4}M) and cytotoxicity determined with 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide assay.

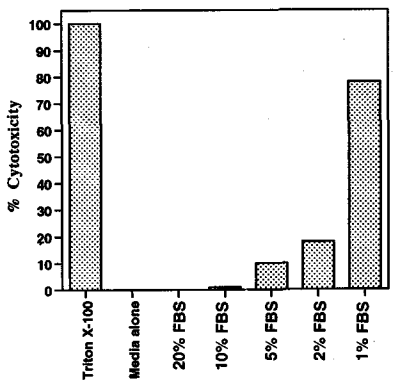

FIG. 4. Serum concentration and endothelial cell injury. Endothelial cells were cultured for 4 h in the presence of oleic acid (5×10^{-4} M) (Triton X-100; Sigma, St. Louis, MO) and different concentrations of fetal bovine serum (FBS). 3-[4,5-Dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide assay performed to determine cytotoxicity. Experiment performed in triplicate with representative experiment shown.

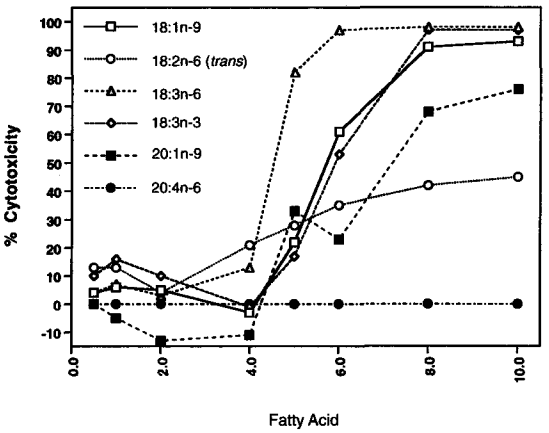

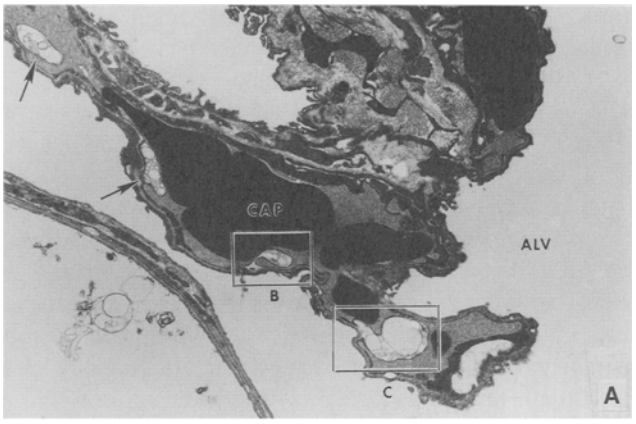

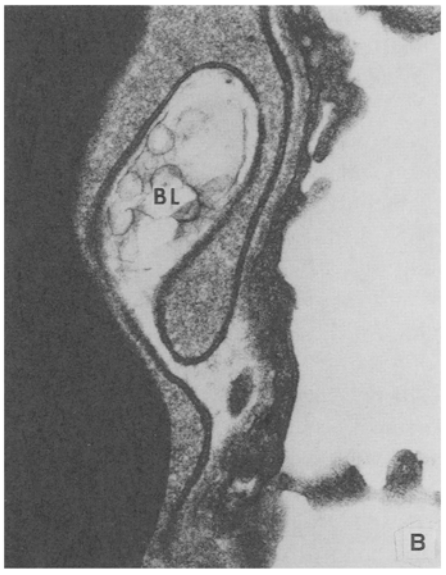

FIG. 5. Cytotoxic effects of different fatty acids on endothelial cells. Endothelial cells were stimulated for 4 h on 96-well plates with various concentrations of fatty acids followed by 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide assay. Experiment performed in triplicate with representative experiment shown.

Gross examination of lungs at the time of sacrifice revealed a patchy distribution of hemorrhagic areas involving the surfaces of both lungs. Light microscopy confirmed this patchy distribution, showing a lipoid necrosis with hemorrhage in the areas of gross involvement, even as early as 10 min after injection of OA.

Electron microscopy performed on grossly unaffected lung tissue from rats with experimental OA lung injury demonstrate definite endothelial cell changes as early as 10 min after induction of injury. These changes are similar to those of endothelial cell blebbing (Fig. 6). Blebbing, a separation of the endothelial membrane from the underlying basement membrane, is a finding strongly suggestive of endothelial cell injury (22). At 10 and 30 min post-injury, the alveolar epithelium was relatively spared in areas examined. Also noted at 10 min post-injury were red cells surrounding amorphous ma-

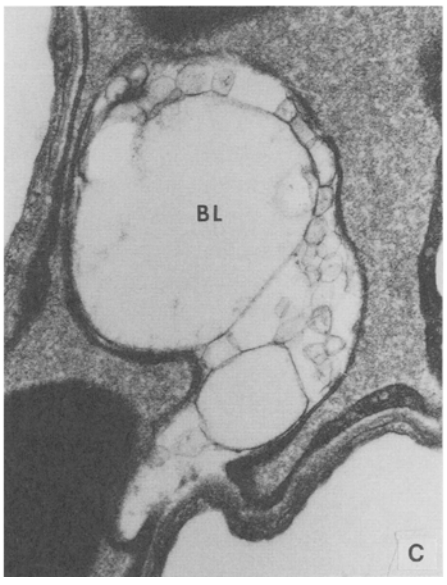

FIG. 6. Transmission electron microscopy of rat lung 10 min after injection of oleic acid. Lung sections were stained with uranyl acetate and lead citrate: A—section including pulmonary capillary (magnification X: 1,600), demonstrating changes consistent with endothelial blebbing. Alveolar space (ALV), capillary space (CAP)—arrows indicate areas suspicious for endothelial blebbing, as seen in areas outlined in A. Higher magnifications seen in B (X: 7,300) and C (X: 9,100) illustrate continuity with the endothelial membrane; BL, bleb.

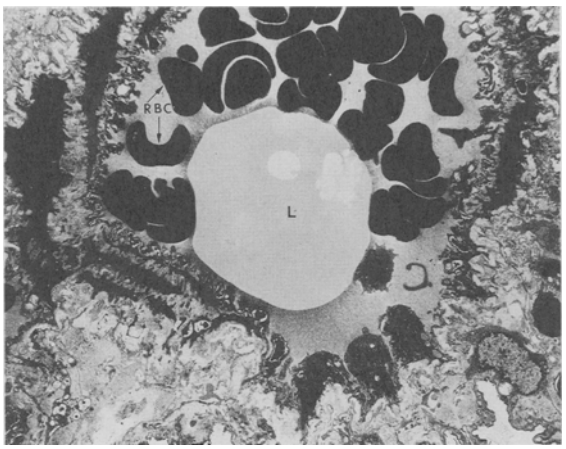

FIG. 7. Transmission electron microscopy of rat lung 10 min after injection of oleic acid, stained with uranyl acetate and lead citrate. Section through small vessel showing red blood cells (RBC, arrows) surrounding material having the appearance of lipid (L), possibly an oleic acid droplet (magnification X: 700).

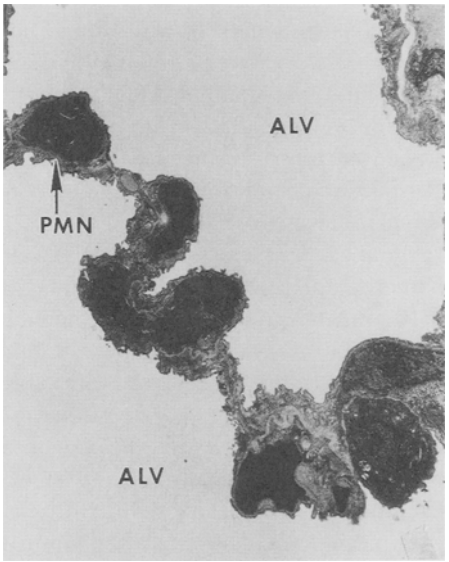

FIG. 8. Transmission electron microscopy of rat lung one hour after injection of oleic acid, stained with uranyl acetate and lead citrate. Polymorphonuclear cell (PMN, arrow) is noted in the capillary of the intraalveolar septa (magnification X: 700); ALV, alveolar space.

terial in a small vessel, possibly an OA globule (Fig. 7). At one-hour post injury, neutrophil adherence to vascular endothelium was noted (Fig. 8).

DISCUSSION

Although OA has been used extensively as a model of acute lung injury, no measurements of its distribution and concentration within the various organs during such injury have been reported. The results of measurements in this series of experiments demonstrate high concentrations of radiolabel, probably representing OA present in the lung early in lung injury.

OA in this study was toxic to endothelial cells *in vitro* at concentrations an order of magnitude less than those measured *in vivo* during experimental lung injury. This toxicity was observed as early as one minute after addition of OA to cell cultures. These findings suggest that at least one component of this form of lung injury is direct toxicity of OA to pulmonary cells. Since the endothelial cell is the first cell in the pulmonary parenchyma exposed to intravascular OA, it is likely the cell that is initially damaged.

This conclusion raises the question of the effects of OA on endothelial cells of other vascular beds. It is possible that a significant amount of OA is removed in the pulmonary vascular bed since this is the first capillary bed to be exposed after intravenous injection. This argument is supported by both the prolonged presence of radioactivity in BAL fluid in this model and the high percentage of radiolabeled free fatty acid in extracts early in lung injury. In the current experiments, the liver and kidneys contained levels of OA approximately one order of magnitude less than those found in the lung, but at levels demonstrated to be toxic *in vitro* to endothelial cells. This may not be the case in these organs *in vivo*, since a greater proportion of the oleate is found in the form of triglycerides. Hepatocytes in these *in vitro* experiments were also markedly more resistant to OA injury than both endothelial and alveolar epithelial cells. It is probable that the lung is the organ most affected by toxic effects of OA since it is the first vascular bed exposed after injection, with consequently higher tissue levels and possibly more sensitive cell types.

Ultrastructural changes in endothelial cells were identified in electron micrographs demonstrating blebbing of endothelial cells at 10 min after injury. Such endothelial blebbing in other systems has been a consistent finding of pulmonary endothelial injury (25). Similar findings have also been noted in baboon and porcine models of OA lung injury (26,27) One possible explanation for the toxicity of OA to endothelial cells is an overloading of the endothelial cell mechanisms of clearance of albumin-bound fatty acids. Both *in situ* and *in vivo*, oleic or palmitic acids bound to albumin were more rapidly taken up by endothelial cells and more rapidly transported to the albuminal surface than was albumin alone (28). It is possible that endothelial cell damage is caused by an overload of this normal mechanism for transportation of fatty acids to metabolizing cells.

Other authors have noted an injury to both pulmonary alveolar epithelial cells and endothelial cells in grossly affected areas 24 h after OA lung injury (2,29). It is obvious from the gross and microscopic appearance of the lung 10 min after injury in this study that there is disruption of the alveolar and capillary membranes in multiple hemorrhagic areas. However, electron microscopy of seemingly spared areas adjacent to the grossly involved ones demonstrates signs of selective endothelial injury with relative sparing of epithelial cells.

It is not surprising that OA exerts at least part of its effects through damage to endothelial cells, and there is evidence that this may be relevant to the etiology of several types of lung injury. Aberrations of fatty acid metabolism are seen in trauma, sepsis, pancreatitis, and fat embolism which can lead to increases in OA levels in the bloodstream. Since OA is toxic to endothelial cells at moderate concentrations, the ARDS frequently seen in such patients may be mediated in part by increased concentrations of OA.

There are several mechanisms whereby OA synthesis in the organism may be induced. During starvation or fatty acid depletion, the usual elongation and desaturation pathways producing long-chain ω6 fatty acids instead synthesize ω9 fatty acids from endogenous sources (30). In a related study on trauma patients given fat-free parenteral nutrition, OA levels in venous blood increased twofold within four weeks of injury and were significantly increased over those levels found in healthy volunteers (31).

OA metabolism is altered during experimental sepsis as well. Fuortes and co-workers (32) measured OA levels in pulmonary arterial blood of septic dogs and found that levels of OA had approximately doubled within 72 h of the onset of sepsis. These levels were comparable to those found to be toxic to endothelial cells *in vitro*; however, an exact correlation is not possible due to the difference between *in vitro* and *in vivo* conditions. The effects of tumor necrosis factor-α (TNF-α) on fatty acid metabolism and lipoprotein lipase may be responsible for these changes. TNF-α inhibits transcription of lipoprotein lipase and fatty acid synthetase in the adipocyte. The presence of TNF-α also results in an increase in hormone-sensitive lipase activity. The net effect of these changes is a reduction of stored fat and an increase in circulating triglycerides. It is plausible that such changes would result in increased OA levels during the cytokine response to endotoxemia and sepsis. Baughman and co-workers (33) measured relative concentrations of OA and other fatty acids in BAL fluid from patients with ARDS. In this study, there was a greater proportion of OA in the group of patients with ARDS as compared with the normal control group, arguing for a shift to favor production of OA.

In summary, the data presented in this study demonstrated radioactive counts consistent with levels of OA in the lung of 1×10^{-3} M 30 min after injection, mostly in the form of free fatty acid. This concentration was demonstrated to be toxic to endothelial cells *in vitro*, and damage to endothelial cells *in vivo* was further demonstrated by electron microscopy as early as 10 min after injection. These findings support the hypothesis that one of the initial events in OA lung injury is direct damage of the pulmonary vascular endothelium by OA. It is possible that OA, through endogenous production during periods of stress such as endotoxemia and trauma, may be a mediator of pulmonary injury during these events. Further studies are needed to investigate the role of OA in other forms of acute lung injury.

[a]Unité de Nutrition Cellulaire et Métabolique, Université de Bourgogne, 21004 Dijon, France, [b]Station de Recherches sur la Qualité des Aliments de l'Homme, Unité de Nutrition Lipidique, Institut National de la Recherche Agronomique, 21034 Dijon, France and [c]Laboratoire de Nutrition et Sécurité Alimentaire, Institut National de la Recherche Agronomique, 78352 Jouy en Josas, France

ABSTRACT: The effect of very low levels of dietary long-chain n-3 fatty acids on Δ6 desaturation of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), and on Δ5 desaturation of dihomo-γ-linolenic acid (20:3n-6), in liver microsomes and its influence on tissue fatty acids were examined in obese and lean Zucker rats and in Wistar rats. Animals fed for 12 wk a balanced diet containing *ca.* 200 mg of long-chain polyunsaturated n-3 fatty acids per 100 g of diet were compared to those fed the same amount of α-linolenic acid. Low amounts of long-chain n-3 fatty acids greatly inhibited Δ6 desaturation of 18:2n-6 and Δ5 desaturation of 20:3n-6, while Δ6 desaturation of 18:3n-3 was not inhibited in Zucker rats and was even stimulated in Wistar rats. Inhibition of the biosynthesis of long-chain n-6 fatty acids was reflected in a decrease in arachidonic acid (20:4n-6) content of serum lipids when fasting, and also in the phospholipid fatty acids of liver microsomes. On the contrary, heart and kidney phospholipids did not develop any decrease in 20:4n-6 during fish oil ingestion. Docosahexaenoic acid (22:6n-3), present in the dietary fish oil, was increased in serum lipids and in liver microsome, heart, and kidney phospholipids.
Lipids 30, 825–832 (1995).

The health benefits of fish oils (FO) have been extensively investigated due to observations that the incidence of coronary heart disease is low among populations that consume large amounts of fish (1). Since the active constituents of FO are likely to be the long-chain n-3 fatty acids, eicosapentaenoic (20:5n-3, EPA) and docosahexaenoic (22:6n-3, DHA) acids, research has been focused on how n-3 fatty acids modify several key risk factors for coronary heart disease. These fatty acids have been shown to lower blood pressure (2), exert antithrombotic effects, protect against ventricular arrhythmias, and modify several atherogenic processes (3). In addition, EPA and DHA reduce fasting and postprandial plasma triglycerides and very low density lipoprotein (VLDL) levels in healthy and hyperlipidemic subjects (4–6), and the arachidonic acid content in cellular and lipoprotein phospholipids (PL) is decreased as it is replaced by EPA and DHA (5).

Mechanisms by which long-chain n-3 fatty acids lower plasma triglycerides have been widely studied in animal models. In humans, hypertriglyceridemia is commonly associated with obesity, so the obese hypertriglyceridemic Zucker rat constitutes a good model since these rats are overweight mainly due to hyperphagia (7), as commonly observed in humans. Hyperphagia in the obese Zucker rats evokes a high level of lipogenesis in liver (8,9), while mitochondrial fatty acid oxidation is decreased (10), giving rise to high VLDL-triglyceride secretion. Increase in Δ9 desaturation activity in liver (11,12) stimulates VLDL secretion, as it has been reported in cultured hepatocytes (13,14). When compared to its lean littermate, the obese Zucker rat presents a decreased arachidonic acid (20:4n-6) content in PL from serum, platelets, liver, heart, and kidneys (15–17), consistent with the decreased biosynthesis of arachidonic acid by Δ6 and Δ5 desaturations demonstrated in liver microsomes (16). This decrease is not compensated for by an increase in DHA (22:6n-3). However, the arachidonic acid content can be slightly augmented if the diet is rich in linoleic acid (18:2n-6) (12). When obese Zucker rats are fed a diet containing FO, hypertriglyceridemia decreases, while the activity of enzymes involved in lipogenesis decreases (18,19) and fatty acid oxidation increases (19,20).

No study has yet addressed the influence of long-chain n-3 fatty acids on the biosynthesis of arachidonic acid by Δ6 and Δ5 desaturation in the obese Zucker rat. In other phenotypes, these acids added to the diet have been reported to decrease the

20:4n-6 content in tissue lipids (21,22). This question is important since in the obese Zucker rat, Δ6 and Δ5 desaturations are lower than in its lean control (16), and dietary long-chain n-3 fatty acids are likely to augment this defect. Accordingly, this study was undertaken to evaluate the influence of dietary long-chain n-3 fatty acids, in comparison with α-linolenic acid, in the obese Zucker rat. Comparisons were also made with the obese rats' lean littermates and with the commonly used Wistar rat. Additionally, tissue lipids were analyzed to see whether the presumed modifications in desaturation rates *in vivo* were reflected in their polyunsaturated fatty acid content. The low level of dietary n-3 fatty acids used in this study corresponds to what can be encountered in human diet.

MATERIALS AND METHODS

Chemicals. [1-^{14}C] Linoleic acid (50 mCi/mmol, 99% radiochemically pure), [1-^{14}C] α-linolenic acid (56 mCi/mmol, 98% pure), and [1-^{14}C] dihomo-γ-linolenic acid (47 mCi/mmol, 99% pure) were purchased from the Radiochemical Centre (Amersham, Buckinghamshire, United Kingdom). Each substrate was diluted in ethanol with the corresponding unlabeled fatty acid to a specific activity of 10 mCi/mmol. Unlabeled fatty acids, coenzymes, and biochemicals were purchased from Sigma Chemical Co. (St. Louis, MO). All other chemicals of analytical grade were purchased from Sigma and Merck (Darmstadt, Germany).

Animals and diets. Three phenotypes of five-week-old male rats, Wistar, obese Zucker (fa/fa), and lean Zucker (Fa/-), were provided by INRA (Jouy en Josas, France). They were fed *ad libitum* for seven weeks a semisynthetic control diet (CO), containing [g/kg]: sucrose [218], maize starch [440], casein [220], cellulose [20], vitamin mixture [10.4], salt mixture [40], methionine [1.6], and a control oil mixture [50] (rapeseed oil 52%, sunflower oil 20%, and hydrogenated palm oil 30%, by weight). After this control diet, animals of each phenotype were randomly divided into two groups of n = 6 animals and fed for 12 wk on different diets. The first group of animals continued to receive the control diet (CO) and the second group was fed a fish oil-supplemented diet (FO) containing (wt%): salmon oil [15], sunflower oil [35], and hydrogenated palm oil [50]. The daily food intake was adjusted to 20 g per rat to prevent hyperphagia of obese Zucker rats. In the conditions, each rat ingested the same amount of long-chain n-3 fatty acids. As shown in Table 1, the two dietary oils contained the same amount of n-6 (linoleic acid) and n-3 fatty acids in a ratio close to 6:1. In the FO diet, 95% of the n-3 fatty acids were of longer chain (principally EPA and DHA) than α-linolenic acid. The latter was the only n-3 fatty acid of the control diet.

After an overnight fast following the dietary period, all the rats were killed by exsanguination between 0700 and 0800 hours to avoid any circadian variation in the desaturation activities (23). Blood from aorta was collected in a tube. Liver, heart, and kidneys were withdrawn, blotted on filter paper, and weighed.

[a]The composition of fatty acids is expressed as weight percentage of total fatty acids in the oil mixture added to the three diets. For 100 g of diet, 18:2n-6 and the n-3 fatty acids represented about 1250 and 210 mg, respectively.
[b]CO: mixture [wt%] of rapeseed oil [50], sunflower oil [20], hydrogenated palm oil [30].
[c]FO: mixture [wt%] of salmon oil [15], sunflower oil [35], hydrogenated palm oil [50].
[d]SFA, saturated fatty acids.
[e]MUFA, monounsaturated fatty acids.

Desaturation assays. Liver microsomes were prepared at 4°C as previously reported (24). Briefly, about 3.5 g of liver were homogenized in a Potter-Elvehjem tube in 6 vol of 0.25 M sucrose and 0.05 M phosphate buffer (pH 7.4). The supernatant of the homogenate centrifugation at 13,000 × *g* for 20 min was recentrifuged at 105,000 × *g* for 60 min. The microsomal fraction was obtained by resuspending the second centrifugation pellet in 0.4 mL of supernatant and 0.8 mL of 0.05 M phosphate buffer (pH 7.4). The protein content of microsomes was measured according to Layne (25).

Microsomal suspensions containing 5 mg of protein were incubated in open flasks containing a high level of substrate solubilized in ethanol: 120 nmol (57 μM) of [1-^{14}C] linoleic acid, 120 nmol (57 μM) of [1-^{14}C] α-linolenic acid and 80 nmol (38 μM) of [1-^{14}C] dihomo-γ-linolenic acid. Incubations were carried out in a shaking water bath for 20 min in a total volume of 2.1 mL of incubation medium containing [mM]: phosphate buffer (pH 7.4) [72], $MgCl_2$ [4.8], CoA [0.5], ATP [3.6], and NADPH [1.2]. Incubations were stopped by adding 15 mL of chloroform–methanol (2:1, vol/vol) according to Folch *et al.* (26). After methylation of fatty acids by methanol–BF_3 (27), the conversion of the three labeled substrates into their Δ6 and Δ5 desaturation products (γ-linolenic, stearidonic, and arachidonic acid, respectively) was determined after separation by reversed-phase high-performance liquid chromatography (28). Radioactivity was measured using a

1900 TR Tri-Carb (Packard, Rungis, France). Counting efficiency was estimated by comparison with radioactive standards to be at least 95% and generally more.

Lipid analysis. Lipids from serum and liver microsomes were extracted by 15 vol of dimethoxymethane–methanol (4:1, vol/vol) (29). Those from heart and kidneys were extracted according to Folch *et al.* (26). Microsomal PL were separated by thin-layer chromatography (30). The other PL were separated by silicic acid column chromatography using Sep-Pak cartridges (31).

After addition of heptadecanoic acid (17:0), the fatty acid methyl esters were prepared by transmethylation using methanol–BF_3 (27). They were analyzed by gas–liquid chromatography. Those from serum lipids and microsomal PL were analyzed using a Becker-Packard Model 417 Gas Chromatograph equipped with a laboratory-made 30 m × 0.3 mm i.d. glass capillary column coated with Carbowax 20M (Applied Science Labs, State College, PA). Analyses were carried out at a constant temperature of 180°C with a nitrogen flow rate of 3 mL/min. The Ros injector and the flame-ionization detector were maintained at 220°C. Areas were measured by means of an ICAP 10 calculator-recorder (LTT, Paris, France). The detector response was checked with standard mixture of methyl esters (Nu-Chek-Prep, Elysian, MN), and results were expressed as mol%.

Fatty acid methyl esters from heart and kidney PL were analyzed on a Hewlett-Packard 5890 Series II Chromatograph (Palo Alto, CA), equipped with a split/splitless injector and a flame-ionization detector, both maintained at 250°C. A fused silica column (50 m × 0.25 mm i.d.) coated with DB-Wax (J&W Scientific, Folsom, CA) was used with helium as carrier gas. The oven temperature was programmed from 60 to 190°C at 20°C/min. Quantitative analysis was performed using a Chromjet integrator (Spectra Physics, Les Ulis, France) coupled to a computer equipped with a Labnet Software (Spectra Physics), and results were expressed as wt%.

Statistics. Desaturase activities and fatty acid compositions were means ± SD for n = 6 animals. After analysis of variance using Duncan's multiple-range test, means were compared in the six groups according to the least significant difference and classified according to decreasing order. Values assigned a different superscript letter were significantly different at $P < 0.05$.

RESULTS

Body weight, liver weight, and microsomal protein. As shown in Table 2, the body weight, before the nutritional experiment, of the obese Zucker rats, fed *ad libitum* was higher (+27%) than the body weights of either their lean littermates or of the Wistar rats, the latter two being equal. When fed the same amount of control diet (CO) per day (20 g), the obese Zucker and Wistar rats gained the same amount of weight (*ca.* 110 g for 12 wk of diet). The weight increase of lean Zucker rats was somewhat less. When expressed as percentage of body weight, weight gain was lower in the obese rats because of higher initial body weight. Feeding the FO diet did not modify the increase of body weight in any of the groups. The liver weight of obese rats fed the control diet was about twofold higher than in the other two groups of rats. It was also higher when expressed as percentage of body weight. In the FO diet, the obese rats had a lower liver weight, contrary to the other rats. In the control diet, the liver microsomal protein content of obese rats was slightly higher when compared to that of their lean controls. Eating the FO diet increased the protein content in the obese Zucker rats (+11%), but not in the lean rats. Liver microsomal protein content of the Wistar rats was increased (+25%) when polyunsaturated n-3 fatty acids (FO) were substituted for α-linolenic acid (CO).

Activity of desaturation in liver. Figure 1 illustrates the activity of Δ6 desaturation of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) and the activity of Δ5 desaturation

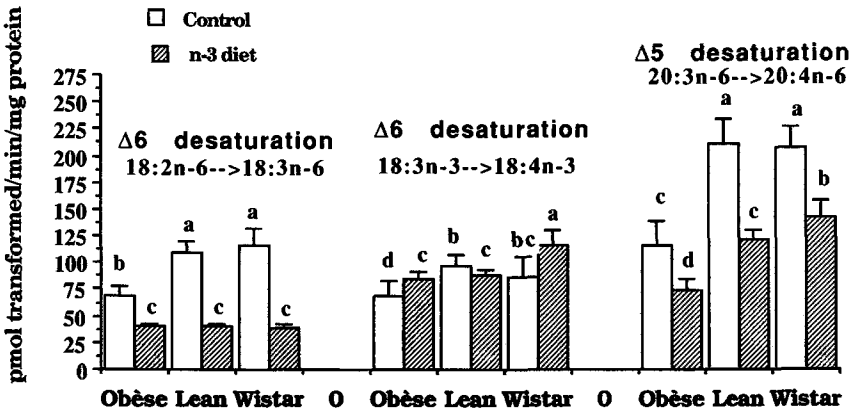

FIG. 1. Δ6- and Δ5-Desaturase activities in liver microsomes from obese, lean Zucker, and Wistar rats fed the control oil (open bars) or the fish oil (hatched bars) diet. Results were means ± SD for n = 6 animals in each group. After analysis of variance, means were compared in each desaturation. Means assigned different superscript letters were significantly different ($P < 0.05$).

of dihomo-γ-linolenic acid (20:3n-6) measured in liver microsomes of the three groups of rats fed CO or FO diets. In rats fed the control diet, the activity of 18:2n-6 Δ6 desaturation was lower in obese rats than in the other phenotypes (–40%). The activities were the same after feeding FO to the three types of rats, showing that the inhibition by FO was higher in Wistar and lean Zucker rats than in obese Zucker rats.

Δ6 Desaturation of 18:3n-3 was as active as desaturation of 18:2n-6 in obese Zucker rats fed the CO, whereas it was less active in the other two types of rats. As observed with Δ6 desaturation of 18:2n-6, the activity of Δ6 desaturation of 18:3n-3 was higher in the lean Zucker rat and in the Wistar rat than in the obese Zucker rat. The FO diet increased the 18:3n-3 desaturation activity in obese Zucker rats and to a somewhat greater degree in Wistar rats, contrary to what was observed with 18:2n-6. Δ6 Desaturation of 18:3n-3 was slightly decreased by FO feeding in lean Zucker rats.

Activity of Δ5 desaturation of 20:3n-6 was higher than the other two desaturations in the three groups of rats fed the CO. The FO diet decreased Δ5 desaturation, approximately in the same proportion in the three groups of rats, but less than the decrease in Δ6 desaturation of 18:2n-6.

If the liver weight and the liver microsomal protein content were taken into account to calculate the capacity of whole liver to desaturate (nmol of substrate converted/minute/whole liver), results showed that, with regard to the three desaturations studied, the capacity of liver to desaturate was higher in obese Zucker rats than in lean rats, contrary to what was observed when only considering the desaturase activity on a per mg protein basis. The reason is that in obese rats the liver weight and the liver microsomal protein content were higher than in lean rats.

Liver microsomal PL fatty acids. As shown in Table 3, some differences can be observed between the three types of rats fed the same control diet. When compared to its lean littermate, the obese Zucker rats had a lower percentage of n-6 fatty acids in their liver microsomal PL, 18:2n-6 being more affected than 20:4n-6; 22:6n-3 was not different. The PL fatty acid composition in Wistar rats was very close to that observed in lean Zucker rats.

The influence of FO diet was pronounced in obese Zucker rats, resulting in a decreased proportion of arachidonic acid (–20%) with a parallel increase in linoleic acid (+72%) and in dihomo-γ-linolenic acid (+75%), and an increase in DHA (+31%). As a consequence, the 20:4n-6/18:2n-6 and 20:4n-6/20:3n-6 ratios were sharply decreased by the FO diet. On the contrary, there was no effect of this diet on the monounsaturated fatty acids.

In lean Zucker rats, the same differences as in their obese littermates were observed in the proportion of n-6 and n-3 fatty acids, except that the proportion of linoleic acid was not increased, so that the 20:4n-6/18:2n-6 ratio was decreased less than in the obese rats. Results in Wistar rats were very close to those obtained in lean Zucker rats.

Serum lipid fatty acids. In obese and lean Zucker rats fed the CO diet, the differences in serum total fatty acids were very small, as can be seen in Table 4. Stearic, linoleic, and α-linolenic acid percentages were only slightly lower in obese rats. Wistar rats exhibited some differences from lean Zucker rats. Linoleic acid was higher in Wistar rats, whereas arachidonic acid and DHA were somewhat lower.

In obese Zucker rats, the FO diet did not significantly modify the arachidonic acid content, although there was a tendency to decrease. However, the 20:4n-6/18:2n-6 and 20:4n-6/20:3n-6 ratios were slightly decreased. Linolenic acid was only present in trace amounts while 22:6n-3 was higher than in the control diet group.

In lean Zucker rats, the percentage of arachidonic acid was significantly decreased by the fish oil diet so that the 20:4n-6/18:2n-6 and 20:4n-6/20:3n-6 ratios were more strikingly decreased than in the obese rats. The 22:6n-3 content was increased. The same was observed in Wistar rats, except that decrease in 20:4n-6 was not significant, similar to the findings in the obese Zucker rats.

Heart and kidney PL in Zucker rats. The PL content of heart lipids in obese and lean rats was the same whatever the diet, that is 21.8 mg/g wet weight on average. Table 5 shows that in obese rats, the FO diet did not modify the 20:4n-6 content of PL, whereas the 22:6n-3 content was increased. In lean rats, the 20:4n-6 content was neither modified while the 22:6n-3 content tended to increase on the influence of FO diet, but the difference with the CO diet was not significant. In these rats, contrary to what was observed in obese rats, the 18:2n-6 content was increased with the FO diet.

The PL content of kidney lipids in obese and lean rats was the same whatever the diet, that is 24.7 mg/g wet weight on average. Table 5 shows that in obese rats, the FO diet increased the 18:2n-6, the 20:4n-6, and the 22:6n-3 content of kidney PL. In lean rats, the 20:4n-6 content was not modified, while 18:2n-6 and 22:6n-3 were increased as in obese rats.

DISCUSSION

In this study, all the rats received the same amount of diet per day, so that the hyperphagic obese Zucker rats were food-restricted. The weight gain during the 12 wk of CO diet was the same, for obese Zucker rats and Wistar rats. Thus both groups of rats had the same food efficiency. Hyperinsulinemia that greatly stimulates lipogenesis in obese rats fed *ad libitum* (32) may not exist in food-restricted rats.

[a]Results are expressed as means ± SD. They were compared in each phenotype between CO and FO diet rats and classified in decreasing order. Means assigned different superscript letters were significantly different ($P < 0.05$). Abbreviations as in Table 1.
[b]Also containing 20:2, 22:4, and 22:5n-6.
[c]Also containing 18:3, 20:5, and 22:5n-3.

When FO replaced CO in the rats' diet, the weight gain was not modified. The absence of effect in the obese rats is not in agreement with results reported by Jen *et al.* (18) in the same type of rats receiving 30 g EPA + DHA/kg diet and by Cunnane *et al.* (33) in the obese ob/ob mice. These authors observed a decreased weight gain when cod liver oil was present in the diet (100 g/kg diet). The reason may be that in our experiments, FO was added to the diet in a very low amount, about 200 mg of n-3 fatty acids per 100 g of diet. Moreover, our obese rats were food-restricted, and not fed *ad libitum* as in the cited authors' experiments.

Despite the low amount of dietary FO, the obese rats eating this diet had significantly lower liver weight, contrary to what was observed in lean Zucker and Wistar rats. This effect was probably due, in part, to a decrease in triglyceride content as observed elsewhere (20) since FO is known to strongly inhibit lipogenesis (34). In contrast, the dietary FO increased the liver microsomal protein content in obese Zucker and in Wistar rats.

With regard to liver desaturation activity, the activity of the three desaturations studied was lower in a per mg protein basis in obese Zucker rats than in lean rats fed the control diet. However, when the total liver microsomal protein was taken into account, the reverse was true, because of higher liver weight and higher amount of microsomal protein per g of liver in the obese rats. Thus, the obese rat liver possessed a higher capacity to desaturate fatty acids than livers of the lean phenotype. This confirms previous results (15), but does not explain why the lipids in several tissues contain less arachidonic acid in obese Zucker rats than in their lean controls (16). The desaturation capacity measured *in vitro* may not be totally expressed *in vivo* because of an unfavorable hormonal environment in the latter case.

The presence of FO in the diet highly decreased Δ6 and Δ5 desaturation of n-6 fatty acids in the three types of rats, in agreement with results obtained by Christiansen *et al.* (35) in Wistar rats, by Garg *et al.* (36,37) in Sprague-Dawley rats and by Grønn *et al.* (38) in isolated rat hepatocytes. We observed this effect with only about 0.75% of salmon oil in the diet. The presence of long-chain n-3 fatty acids in FO is responsible for this effect, since the total n-3 fatty acid content was the same in the control diet, but as 18:3n-3 in the latter.

Surprisingly, the presence of long-chain n-3 fatty acids in the diet did not inhibit Δ6 desaturation of 18:3n-3, despite the fact that this reaction was not needed since longer chain n-3 fatty acids were provided by the diet. This effect is contrary to that observed by Christiansen *et al.* (35) in Wistar rat also fed FO. The differential effect of dietary FO on Δ6 desaturation of 18-carbon n-3 and n-6 fatty acids would support the existence of two different desaturation enzymes or two different forms of the same enzyme.

The mechanism by which dietary long-chain n-3 fatty acids inhibit *in vitro* desaturation of n-6 fatty acids is not established in this work. One possibility may be that they depressed *in vivo* the synthesis of the desaturation enzymes in the same manner as they depressed the synthesis of the enzymes involved in lipogenesis (34). However, the presence of trace amount of free 20:5n-3 or 22:6n-3 in the isolated microsomes used for the desaturation assays may exert an allosteric product inhibition. Only experiments using specific antibodies to measure the actual amount of desaturase in microsomes and/or specific probes to measure the amount of desaturase mRNA synthesized could answer this question.

In fasting animals, serum lipids principally originate from liver, and the activity of liver Δ6 and Δ5 desaturations of n-6

fatty acids is likely to be reflected in serum lipid fatty acid composition. Indeed, the 20:4n-6 content of serum lipids in this work was generally lower after the FO diet, although not significantly in obese rats. On the contrary, there was a higher percentage of 22:6n-3, likely of dietary origin.

Since Δ6 desaturation capacity is limited in heart and kidneys (39), these organs are highly dependent on plasma lipids for n-6 and n-3 long-chain fatty acids needed for membrane PL biosynthesis. However, the analyses of heart and kidney PL fatty acids did not show any decrease in 20:4n-6 content in obese and lean Zucker rats fed the FO diet. The 20:4n-6 content was even higher in kidney PL of the obese rats. Perhaps these organs augment their uptake rate of arachidonic acid to fulfill their specific requirement in this acid, in order to maintain the physical properties of the membranes or to preserve a readily available pool of eicosanoid precursor fatty acids. On the contrary, the 22:6n-3 content was increased in PL from rats fed the FO diet. There are at least two explanations for this effect; this acid represents 39% of the dietary n-3 fatty acids, and the liver capacity to desaturate 18:3n-3 was not inhibited by FO feeding, and even increased in Wistar rats.

In contrast to heart and kidney, inhibition of Δ6 and Δ5 desaturation of n-6 fatty acids in liver microsomes was reflected in their PL fatty acid profile. In rats fed FO, the 20:4n-6 percentage was much lower than in controls. The percentage of 20:3n-6, the precursor of 20:4n-6 in the Δ5 desaturation reaction, was increased in Zucker rats, probably reflecting the sharp decrease of *in vitro* Δ5 desaturation in these animals. This effect was absent in the Wistar rats in which Δ5 desaturation inhibition was less pronounced. This shows that a good correlation between tissue fatty acid composition and desaturase activity is not always observed, as already pointed out by others (40).

Microsomal PL fatty acids closely reflected the decrease in desaturation capacity, because the desaturation products probably were rapidly incorporated into PL, as demonstrated for Δ5 desaturation *in vitro* (24). This could modify the physical and biological properties of the endoplasmic membrane and of the proteins of the desaturation systems anchored in this membrane. On the other hand, the 22:6n-3 content was increased and the total n-6 + n-3 fatty acids was not modified at all after FO feeding. This likely indicates important regulatory mechanisms to maintain an optimal membrane composition and function.

Thyroid Hormone Is Required for Dietary Fish Oil to Induce Hypersecretion of Biliary Cholesterol in the Rat

William F. Prigge*, Scott R. Ketover and Roger L. Gebhard

Department of Medicine, VA Medical Center, Minneapolis, Minnesota 55417
and University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT: In the rat, both fish oil diet and thyroid hormone replacement are reported to augment bile cholesterol secretion out of proportion to bile flow or secretion of other bile lipids. We sought common mechanisms for these effects and evaluated the role of phospholipid fatty acid composition in the process. Methimazole-treated hypothyroid rats were fed low-fat chow or chow supplemented with 10% corn oil or fish oil, and were studied before and after thyroid hormone treatment. Serum, hepatic, and bile lipids were measured, phospholipid fatty acid composition determined, and hepatic 3-hydroxy-3-methylglutaryl CoA reductase activity assayed. Fish oil diet stimulated cholesterol secretion into bile only after thyroid hormone was given, and this action was synergistic with that of thyroid hormone. Reduced serum cholesterol in fish oil-treated rats was associated with increased biliary cholesterol secretion and diminished hepatic cholesterol content. This suggests that augmented biliary cholesterol secretion may contribute to the fish oil-induced reduction of serum cholesterol. No definite relationship between hepatic or biliary phospholipid fatty acid composition and biliary secretion was apparent, although high bile cholesterol secretion was associated with a low percentage of hepatic and bile phospholipid linoleic acid.
Lipids 30, 833–838 (1995).

Dietary fish oil, with ω3 fatty acids which can be incorporated into phospholipids, potentiates biliary cholesterol secretion in the rat (1–4). Rats fed 9–10% fish oil for two to four weeks secreted more cholesterol into bile than did rats fed other lipids. Secretion increased by 50% in bile sampled acutely (2,4), by 200–300% during 24-h bile sampling (1), and by 400% in chronic bile fistula rats (3). Bile acid secretion was less affected and phospholipid secretion increased only modestly, producing saturated bile in the fish oil-fed rats (3). The facilitated cholesterol secretion was increased by bile acid infusion (3). This effect appears to be species-dependent, as dietary fish oil did not increase biliary sterol secretion in the hamster, prairie dog, or green monkey (5–7). Fish oil feeding is reported to reduce cholesterol saturation index in bile of green monkeys and humans (7,8).

Dietary fish oil also lowered blood cholesterol levels in the rats given fish oil diet (FO) (1–4). It has been suggested that augmented biliary cholesterol secretion might be responsible for the fall in lipoprotein cholesterol (1,4). Alternatively, the decreased very low density lipoprotein (VLDL) secretion which is reported during FO (9,10) might increase hepatic cholesterol available for biliary secretion in the reciprocal manner suggested by Stone and Evans (11). However, FO also lowers serum cholesterol in green monkeys and in humans without reported hypersecretion of biliary cholesterol (7,12–14).

Thyroid hormone treatment also is reported to augment biliary lipid secretion (cholesterol > phospholipid > bile acids) by hypothyroid rats (15–17). Thyroid hormone enhanced bile cholesterol secretion and hepatic cholesterol synthesis without altering hepatic cholesterol content (15,18). Fatty acid composition of rat liver microsomal and mitochondrial phospholipids, particularly arachidonic acid content, is reported to be affected by thyroid hormone status (19–21). Fatty acid desaturase and elongase enzymes convert linoleic to arachidonic acid (22). Activity of these enzymes are sensitive to hormonal and nutritional status, and differ among species (19,20,22). The current experiments evaluate whether thyroid hormone is required for dietary fish oil to produce biliary lipid hypersecretion in the rat. It also addresses whether fatty acid composition might be involved in the hypersecretion of bile cholesterol.

MATERIALS AND METHODS

Male Sprague-Dawley rats weighing 125–150 g were separated into three diet groups—one fed a stock diet of Ralston Purina (St. Louis, MO) ground rodent chow with 4.5% fat by weight (low-fat diet, LF), and two groups fed chow supplemented with either 10% (w/w) corn oil (corn oil diet, CO) or FO (13.2% fat by weight). CO was obtained from Procter & Gamble (Cincinnati, OH), and FO came from Southeast Fisheries Center (Charleston, SC). LF contained 12.8% calories as fat, and CO and FO had 32% calories as fat. Because cho-

lesterol content of chow was 18 mg/100 g and the fish oil contained 22 mg/10 g, FO contained 36 mg cholesterol/100 g (0.1 mg/kcal). LF and CO were supplemented to 0.1 mg cholesterol/kcal (LF contained 32 mg/100 g). Animals were housed in a light-reversed room (dark 0700–1900 h; light 1900–0700 h), fed diets for three weeks, and concurrently made hypothyroid by methimazole 0.025% in the drinking water (15).

Forty-eight hours prior to study, half the animals in each group received 200 μg triiodothyronine (T3) per 100 g body weight intraperitoneally, and the remainder received vehicle only (15). The T3 dose is sufficient to saturate nuclear T3 receptors and to maintain 90% occupancy for 54 h (23). Smaller groups of animals also were studied 24 and 72 h after T3 treatment.

At time of study, animals were weighed, anesthetized with Metafane, and their common bile ducts cannulated with PE-10 tubing. At 1100 h (four hours into the dark period), bile was collected by gravity drainage into tared tubes for two hours and weighed. Additional groups of animals had bile collections fractionated into two consecutive one-hour periods. The liver was then removed, weighed, and a one-gram sample homogenized in 11 mL of 0.25M sucrose. Aliquots of whole homogenate were frozen for analysis, and the remainder used to prepare microsomes (15). Animals were killed by exsanguination and serum was saved. Total activity of 3-hydroxy-3-methylglutaryl CoA (HMG–CoA) reductase was assayed in microsomes as previously described (15). Protein was measured by the method of Lowry *et al.* (24). Total bile acids were measured by the procedure of Talalay (25). Bile acids were determined by chromatographic separation of methyl acetate derivatives, by the method of Duane *et al.* (26). Bile phosphatidylcholine and cholesterol were measured as previously described (16).

Total and unesterified cholesterol were extracted from tissue homogenates and serum as previously described (15). Cholesterol was quantitated by gas–liquid chromatography. Liver and microsomal total phospholipids were separated from neutral lipids for fatty acid methyl ester determination as previously described (18). Hepatic lecithin also was separated from total phospholipids by thin-layer chromatography in a chloroform/methanol/28% NH_4OH (65:25:5) system for fatty acid analysis.

Statistics. Values shown are mean ± SD for n = 3–11 animals. Data were analyzed by two-factor analysis of variance (ANOVA). When the ANOVA was significant ($P < 0.05$), means were compared by Student's *t*-test.

RESULTS

Table 1 shows relative fatty acid composition of the three diets. The predominant fatty acids in CO diet were 18:2ω6 and 18:1ω9; and 14:0, 16:0, 16:1ω7, 20:5ω3, and 22:6ω3 were increased in FO.

Table 2 shows measured parameters in each diet group, both before and 48 h after T3. At time of study, animal weights averaged 214 g and did not differ between diets. T3-treated animals had slightly smaller livers, significant for the CO and FO groups. Serum cholesterol was significantly higher for hypothyroid CO animals. Serum cholesterol fell significantly, by 22–28 mg/dl, for all diet groups after T3 treatment. Lowest post-T3 cholesterol levels occurred in FO diet animals. ANOVA showed no main effect of diet on hepatic HMG–CoA reductase activity. T3, however, did have a main effect [$F_{(1,50)} = 56.788$, $P = 0.0001$]. T3 increased activity 4–7-fold in all groups, reaching similar levels.

22:6ω3	0.25	0.21	2.36[a]

[a]Diet fatty acids found to be particularily enriched by addition of the fats chosen.

Bile flow and bile lipids also are shown in Table 2. No diet-specific effects on bile flow were seen. In contrast, ANOVA showed a main effect of T3 on bile flow, which increased significantly 48 h after T3 in LF and FO animals. ANOVA also showed a main effect of both T3 [$F_{(1,45)} = 43.609$, $P = 0.0001$] and diet [$F_{(2,45)} = 4.668$, $P = 0.0144$] on bile cholesterol secretion, and an interaction between T3 and diet [$F_{(2,45)} = 4.589$, $P < 0.0154$]. No diet-specific differences in bile cholesterol secretion were seen for hypothyroid animals, but bile cholesterol secretion increased markedly after T3 for all diets. Furthermore, T3-treated FO animals secreted significantly more cholesterol into bile than did the other diet groups. After T3, bile phospholipid secretion also increased significantly and similarly for all diet groups, whereas bile acid secretion increased significantly only in FO animals. No main effect of diet was seen for phospholipid or bile acid secretion.

To assure that marked bile acid depletion did not influence results during the bile collection period, additional animals in all study groups had bile collected for two consecutive one-hour periods. Bile from the second hour of drainage showed a uniform 24% reduction in bile acid secretion and 16% reductions in cholesterol and lecithin secretion, compared to the first hour. However, all bile lipid relationships in Table 2 were seen for both intervals.

To assure that the time course of T3 response was consistent for all diets, additional animals were studied at 24 and 72 h after T3. Maximal bile lipid secretion occurred 48 h after T3 in all groups, as previously observed (15,17). For all diets, bile lipid secretion 24 h after T3 was modestly increased from the hypothyroid state, and secretion 72 h after T3 was modestly reduced from 48 h, probably due to falling T3 receptor

[a]Values are means ± SD. HMG, 3-hydroxy-3-methylglutaryl. Significance is at least $P < 0.05$ for: [b]difference between hypothyroid vs. T3 treated; [c]different from other diet groups of comparable T3 status;[d]FO vs. CO of comparable T3 status.

occupancy. FO animals had the highest cholesterol secretion at all time points.

Individual bile acid (not shown) were not influenced by diet but showed modest changes after T3. Hypothyroid rat bile averaged 72% cholate, 15% deoxycholate, 8% muricholate, and 4% chenodeoxycholate. After T3 treatment, deoxycholate decreased to 9% ($P < 0.05$). Chenodeoxycholate rose and cholate fell after T3, but not significantly.

Finally, total and free cholesterol in whole liver homogenate and liver microsomes are shown in Table 2. Whole liver cholesterol content was greater in hypothyroid animals on the high-fat diets. After T3, hepatic cholesterol rose in LF animals, but fell significantly in FO animals. Total microsomal cholesterol of hypothyroid rats was similar on all diets, but increased significantly for CO and decreased for FO after T3. Free cholesterol represented 88–90% of whole liver and microsomal cholesterol in LF animals and 76–84% of total cholesterol in CO and FO animals, both before and after T3. Total cholesterol content, therefore, reflected both free and ester cholesterol.

Individual phospholipid species were not determined in these studies, but Table 3 shows major fatty acids in total phospholipids of whole liver homogenates and bile. The influence of FO diet is apparent, with a high percent ω3 fatty acids, and low percent 18:2ω6 and 20:4ω6. CO produced a high percent of 18:2ω6 and 20:4ω6 in total phospholipids. The ratio of saturated fatty acids to mono- and unsaturated fatty acids differed, with CO animals having the lowest proportion of saturates. This is expected, as fish oil contains a high proportion of saturated fatty acids. After T3 treatment, total phospholipid 20:4ω6 increased and 18:2ω6 decreased for all diets. This is likely a result of increased chain elongation and desaturase enzyme activities (22). T3 had no consistent effect on the ratio of phospholipid saturates to unsaturates.

Total phospholipid fatty acids in liver microsomes are not shown, but were similar to results for whole homogenate. Serum phospholipid fatty acids had less 20:4ω6 and more 16:0 than liver, but showed similar diet and T3-related changes in composition (not shown).

Fatty acid composition of hepatic phosphatidylcholine was also determined (not shown). Phosphatidylcholine had a modestly larger component of 16:0 and a smaller component of 20:4ω6. Compositional changes accompanying diet or T3 were less prominent than, but similar to, those shown for total phospholipids. Total phospholipid fatty acid compositions were chosen for display in Table 3, in order to maximally indicate the results of changes in dietary fat content and T3-induced fatty acid synthesis.

Bile phospholipids showed the expected predominance of 16:0 and 18:2ω6 fatty acids. The two fat diets caused small, but significant, changes in composition. CO increased 18:2ω6 and 20:4ω6, and FO increased ω3 fatty acids. T3 tended to increase 20:4ω6 and reduce 18:2ω6 fractions, but changes were significant only for the CO diet.

DISCUSSION

Under most conditions, bile acid secretion rate determines bile flow and the linked secretion rates of biliary cholesterol and phospholipid (27–29). Euthyroid rats fed fish oil fatty acids, alone or with ω6 fatty acids, increase bile cholesterol secretion to a greater extent than bile flow or secretion of other bile lipids (1–3). Thyroid hormone also stimulates bile cholesterol secretion in rats, out of proportion to bile flow or

[a]Values are means ± SD. Abbreviations as in Table 2. Significance is at least $P < 0.05$ for: [b]difference between hypothyroid vs. T3 treated; [c]different from other diet groups of comparable T3 status; [d]CO vs. FO of comparable T3 status; [e]FO vs. LF of comparable T3 status.

other bile lipids (15–17). The present study tested whether T3 is required for dietary ω3 fatty acids to increase bile cholesterol secretion.

For hypothyroid rats, FO had no effect on bile lipids or bile flow when compared to LF or to a diet with equivalent amounts of CO. T3 supplementation augmented bile cholesterol secretion out of proportion to bile flow or secretion of other bile lipids in all groups, but to a much greater extent (7-fold) in FO rats than in LF or CO animals (3–4-fold). This augmentation of cholesterol secretion by FO occurred in spite of the fact that bile flow and bile acid secretion were similar for the three diets after T3. Thus, T3 was necessary for FO to stimulate bile cholesterol secretion, whereas FO had a synergistic effect on T3-induced secretion. The cholesterol hypersecretion of FO was most apparent in comparison to LF, where bile flow and secretion of phospholipids and bile acids were identical.

Dietary cholesterol is not considered to have a major influence on biliary cholesterol secretion (28,30). Because dietary cholesterol was similar for all diet groups in this study, it was not the cause of bile cholesterol hypersecretion in T3-treated FO rats. Newly synthesized cholesterol also is not felt to be a major component of biliary cholesterol secretion (28,31). In this study, hepatic HMG–CoA reductase activity was markedly stimulated by T3 treatment in all diet groups. However, synthesis cannot account for bile cholesterol hypersecretion in T3-treated FO rats, as reductase activity was identical for all diets after T3.

Both FO and T3 are known to affect serum, as well as biliary, cholesterol. Neither basal serum cholesterol level nor the quantitative reduction in blood cholesterol appeared to be sufficient to account for the twofold greater cholesterol secretion of FO rats. However, induced biliary cholesterol secretion may have produced the very low serum cholesterol levels of FO rats after T3. An alternative linkage between biliary and serum cholesterol involves decreased hepatic VLDL production during feeding of FO (9,10). Reduction in the amount of cholesterol leaving the liver *via* VLDL might then result in more hepatic cholesterol available for biliary secretion (11).

We have previously observed that T3-induced cholesterol secretion into bile did not result in reduced hepatic cholesterol content (15). This was also the case for LF and CO animals. However, the marked hypersecretion of bile cholesterol seen in T3-treated FO rats was accompanied by a significant fall in both total hepatic and microsomal cholesterol content (microsomal cholesterol increased after T3 in LF and CO rats). Thus, a primary effect of FO may have been to facilitate biliary cholesterol secretion, leading to hepatic depletion and reduced blood cholesterol. If FO caused biliary cholesterol hypersecretion solely by impairing VLDL output, hepatic cholesterol content might have been expected to increase or to remain constant.

Lecithin fatty acid species, especially 20:4ω6, have been speculated to participate in bile cholesterol distribution and cholesterol gallstone formation (6,32,33). Although dietary fatty acids altered liver and bile phospholipids modestly in this study, a relationship between fatty acid composition and bile lipid secretion was not seen. T3 increased 20:4ω6 in liver, and to a lesser extent in bile. However, FO rats had the highest biliary cholesterol secretion and the lowest 20:4ω6 levels. ω3 Fatty acid content did not correlate with cholesterol secretion either, nor did content of ω3 plus 20:4ω6. Low levels of 18:2ω6, after FO and/or T3, were associated with greater cholesterol secretion. It is possible that phospholipids containing

this fatty acid may have an inverse relationship to cholesterol secretion into bile. However, compositional changes in 18:2ω6 were small, and significant differences were seen only in liver tissue.

Bile acid species did not appear to be a factor in the FO effect. No main effect of diet on bile acids was found, either before or after T3 treatment. Hypothyroid rats did have more deoxycholate in bile than did T3-treated rats, as previously reported for humans (34). This may result from intestinal stasis and increased bacterial conversion of cholate in the hypothyroid state. We also observed an increased ratio of chenodeoxycholate/cholate after T3, consistent with human studies (34).

In summary, we confirm that rats fed FO develop biliary cholesterol hypersecretion out of proportion to bile flow or secretion of other bile lipids. The action appears to involve a thyroid hormone-dependent biliary secretion mechanism. Further studies will be required to determine whether small, diet-related changes in bile or cell membrane phospholipid fatty acid species are involved in the effect.

Laboratory of Animal Nutrition, School of Agriculture, Nagoya University, Nagoya 464-01, Japan

ABSTRACT: The effects of cholestyramine, a bile acid binding polymer, on the lipid and energy metabolism of chicks given dietary medium-chain triacylglycerol (MCT) or long-chain triacylglycerol (LCT) were investigated. Chicks (from 8 to 17 days of age) were fed diets containing MCT or LCT at 200 g oil/kg diet with or without 2% cholestyramine under equalized feeding conditions. An adjusted LCT diet was formulated in order to supply another group with daily nutrients and dietary metabolizable energy (ME) equal to MCT groups, except for corn starch. ME intakes of chicks given MCT or LCT diets were reduced by cholestyramine; consequently, fat and energy retention was reduced, though the reduction was more drastic in chicks fed LCT. This was caused by a change in amounts of the fecal excretion of fat and bile acids. Cholestyramine enhanced the excretion of octanoic acid (8:0) in the feces, which suggests that bile acids are needed for 8:0 absorption. Cholestyramine affects the utilization of dietary MCT and LCT by lowering fat and energy retention in chicks. However, the effect of cholestyramine on MCT utilization was smaller than its effect on utilization of LCT.

Lipids 30, 839–845 (1995).

Medium-chain fatty acids (MCFA) can be better utilized by chicks than can long-chain fatty acids (LCFA) (1). Under *ad libitum* feeding conditions, however, medium-chain triacylglycerol (MCT) reduces food intake in chicks (2). Variations in bile acid content in the intestinal lumen may have a considerable influence on metabolic properties of the intestine. Cholestyramine (CSTY), a bile acid binding polymer, binds bile acids in the intestinal lumen and enhances their excretion, but also has other effects. In rats, CSTY increased food intake without affecting body weight change (3). It also was reported that CSTY altered the active and the passive transport properties of the intestine (4). Thomson and Keelan (4) showed that in rats, CSTY altered the jejunal uptake of fatty acid according to carbon chain length. Although Rubin *et al.* (5) have shown that MCT and long-chain triacylglycerol (LCT) were not different in their effects on bile acid secretion and excretion in rats, the effect of these triacylglycerols on bile acid secretion in chicks is not known. In chicks, the jejunum is the major site of fat absorption (6), but it was reported that MCFA were well absorbed in the absence of bile acids (7). It may be, then, that CSTY may not affect the lipid and energy metabolism in chicks fed MCT. This study, therefore, aims to investigate the effect of CSTY on the lipid and energy metabolism of chicks fed an MCT diet compared to a LCT diet under equalized (in both food amount and energy value) feeding conditions. Moreover, the effect of MCT or LCT infusion on the cystic bile flow in chicks was also studied.

Abbreviations: CSTY, cholestyramine; LCFA, long-chain fatty acids; LCT, long-chain triacylglycerol; MCFA, medium-chain fatty acids; MCT, medium-chain triacylglycerol; ME, metabolizable energy; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids.

MATERIALS AND METHODS

Effects of CSTY on lipid metabolism of chicks fed MCT or LCT diet under controlled feeding conditions. One-day-old single-comb white leghorn male chicks (Hattori Yokei, Nagoya, Japan) were fed a commercial starter diet consisting of 21.5% crude protein and 12.1 kJ/g metabolizable energy (ME) (Marubeni Shiryo Ltd., Tokyo, Japan) for seven days. On day 8, the chicks were individually weighed after overnight food deprivation and were divided into seven groups of five chicks each. The mean body weights per group were as uniform as possible. The chicks in the seventh group were killed by cervical dislocation and were used to determine base values. The remaining six groups were individually housed in stainless-steel metabolism cages, and were fed experimental diets from day 8 to 17.

Table 1 shows the composition of experimental CSTY-free diets. The experimental diets were formulated to meet the requirement of nutrients in growing chicks (8). Oil level was set at 200 g/kg diet, corn oil was used as the LCT source, and glyceryl tricaprylate (Coconado RK®; donated by Kao Corporation, Wakayama, Japan) was used as the MCT source. Corn oil was added to the MCT diet to meet the requirement for linoleic acid (18:2n-6). Glycine was added to the diets to complement the amount of glycine contained in isolated soybean protein necessary for the growth of chicks. MCT or LCT diet was offered in which one group was fed with CSTY-free diet, and one group received 2% CSTY. Questran® (contains 44.4 % CSTY; Bristol-Myers K.K., Tokyo, Japan) was included in the diet, replacing an equal amount of corn starch. Other constituents of Questran include about 42% glucose.

TABLE 2
Daily Food Intake of Chicks Fed Diets Containing Medium- (MCT) or Long-Chain Triacylglycerol (LCT), or Adjusted LCT Diet With or Without 2% Cholestyramine for Ten Days

	Food intake (g)	
Days	MCT or LCT	Adjusted LCT
1	5	4.60
2	6	5.50
3	7	6.43
4	8	7.35
5	9	8.27
6	11	10.11
7	12	11.03
8	13	11.95
9	14	12.87
10	15	13.79
Accumulated consumption	100	91.90

Questran was added at 45 g/kg diet to supply 2% CSTY to MCT or LCT diet. Calculated ME values of CSTY-free diets were 15.9 and 17.2 kJ/g for MCT and LCT diets, respectively. ME of LCT was taken to be 36.5 kJ/g (9), and MCT source was 30.7 kJ/g (2). The diet was given at 100 g/bird • 10 d, which has been observed to be consumable by MCT group in a previous experiment (Mabayo, R.T., Furuse, M., and Okumura, J., unpublished data). The ME value, however, was lower in MCT diet, so an adjusted LCT diet was included in the study in which the ME was 17.3 kJ/g and was given at 91.9 g/bird • 10 d. The composition of the adjusted LCT diet was recalculated in order to provide the amount of daily nutrients equal to the groups given MCT diet. The amount of corn starch was reduced to adjust the amount of protein, vitamins, and minerals (feeding schedule is shown in Table 2). The birds in MCT diet and adjusted LCT diet had equal daily ME intake.

The chicks were killed by decapitation on day 18. The carcass was minced, frozen in liquid nitrogen, reminced and dried at 55°C for 48 h. Nitrogen in the diets and carcasses were determined by the Kjeldahl procedure, and protein was calculated as N × 6.25, where N = nitrogen. The fat of the carcasses was extracted overnight (about 16 h) with diethyl ether using a Soxhlet apparatus and measured gravimetrically. Gains in protein, fat, and energy over the experimental period were determined by subtracting values for the initial body composition from the final experimental ones. Energy content of the chick was calculated using the values 39.1 and 23.7 kJ/g for fat and protein in the body, respectively (10). Droppings were collected during the last three days to determine the N-corrected ME values of the diets (11). An automatic bomb calorimeter (Shimadzu CA-4; Shimadzu Co., Kyoto, Japan) was used to determine the gross energy content of the diets and droppings.

Total fecal bile acids were extracted by the method of Malchow-Møller *et al.* (12), and were measured enzymatically by a Total Bile Acid Test® (Wako Pure Chemical Industries, Osaka, Japan). Fecal samples were weighed and treated with 1 mL 1N HCl, and total fat was extracted by diethyl ether. Total fecal fat was measured gravimetrically by using an aliquot of the lipid extract. The remaining lipid extract was filtered, dried under a gentle stream of N gas, and the residual lipids were redissolved in 2.8% sodium methoxide to obtain the fatty acid methyl esters. The solution was incubated at 45°C for 2 h and extracted three times with 2 mL hexane. An aliquot of hexane was used for determining the fatty acid composition. The fatty acid methyl esters were analyzed on a gas chromatograph (GC-14A; Shimadzu Co.) fitted with a 25 m × 0.25 mm i.d. PEG-20M capillary column (Gasukuro Kogyo Inc., Tokyo, Japan). The chromatograph was equipped with a data system (CR-4A; Shimadzu Co.) to calculate fatty acid composition.

Effect of MCT or LCT infusion on the cystic bile flow of chicks. Single-comb white leghorn male chicks (approximately three weeks old) were selected for the measurement of diverted bile flow in this experiment. The birds were anesthetized with urethane (1.5 g/kg B.W. i.p.), and the right ventral side of the abdominal cavity was opened to expose the gall bladder and duodenum. The proximal duodenum, just below the antrum, was ligated to prevent acid entrance to the intestine. The cystic duct was cannulated with polythene tubing, and the hepatic bile duct was ligated. The cystic duct cannula was passed out of the abdominal cavity, and bile flow was measured at 10-min intervals. The basal rate of flow was established at least three hours, in which the values were discarded, prior to the administration of 1 mL MCT or LCT, which was given by slow infusion into the proximal duodenum. Results were expressed as peak percentage of basal rates, using the values at 10 min before each infusion as basal.

Statistical analysis. One-way analysis of variance was applied in Experiment 1, and Duncan's multiple range test was used to assess the significance between means. In Experiment 2, statistical significance of responses was analyzed using paired *t*-test, and the overall means between treatments was determined by *t*-test. All of the data analyses were done using a commercially available statistical package (13).

[c–g]Means having different letters in a row are significantly different at $P < 0.05$.
[h]Efficiency of energy utilization = energy retention/ME intake.
[i]Heat loss = ME intake – energy retention.
[j]One missing value.

RESULTS

Effects of cholestyramine on lipid metabolism of chicks fed MCT or LCT diet under controlled feeding conditions. Table 3 shows body weight gain of chicks fed diets containing MCT or LCT with or without CSTY under equalized feeding conditions. Body weight of chicks fed the diet containing MCT were not affected by CSTY, whereas there was a negative effect in chicks fed LCT with CSTY. In the adjusted LCT diet, body weight gain was not significantly decreased by CSTY. The body weight gain in adjusted LCT diet was significantly lower than in LCT diet without CSTY.

Table 3 also shows body composition and protein and energy retention, ME value, and ME intake of chicks fed diets containing MCT or LCT with or without CSTY under equalized feeding conditions. Chicks given the LCT diet had the lowest body protein among treatments, although it was not significantly different from the adjusted LCT diet group. Body protein was not affected by the addition of CSTY in MCT or adjusted LCT diet, but was significantly increased in the LCT diet chicks. There was no significant difference in body protein retention among treatments without CSTY. Protein retention in the MCT diet was significantly higher than in the adjusted LCT diet when CSTY was given. There was no significant difference in the efficiency of protein utilization among treatments (data not shown). Body fat in chicks fell in all treatment groups with the addition of CSTY to the diets. Body fat was significantly higher in LCT diets without CSTY than in the MCT groups. Body fat was significantly lower in chicks on the adjusted LCT diet than on the LCT diet. The adjusted LCT group had significantly higher body fat and fat retention (Fig. 1) than the MCT group, in spite of equal ME intakes. In all treatments, fat retention significantly decreased with the addition of CSTY to the diet. Among the groups not given CSTY, the values were significantly higher in the adjusted LCT and LCT diets than in the MCT diet, as shown in Figure 1.

Table 3 also shows that energy retention was significantly decreased by the addition of CSTY in all treatment groups. Among diet groups without CSTY, energy retention was highest on the LCT diet. Chicks given LCT diets without CSTY had significantly higher energy retention than chicks given MCT diets. ME values significantly decreased with the addition of 2% CSTY to all diets. The ME value in the LCT diet group not receiving CSTY was significantly higher than in the MCT diet group. There was no significant difference between MCT and adjusted LCT diets without CSTY. ME intakes significantly decreased with the addition of 2% CSTY to all diets. Chicks given the LCT diet had significantly higher ME intake than those given the MCT or adjusted LCT diets without CSTY. The efficiency of energy utilization was sig-

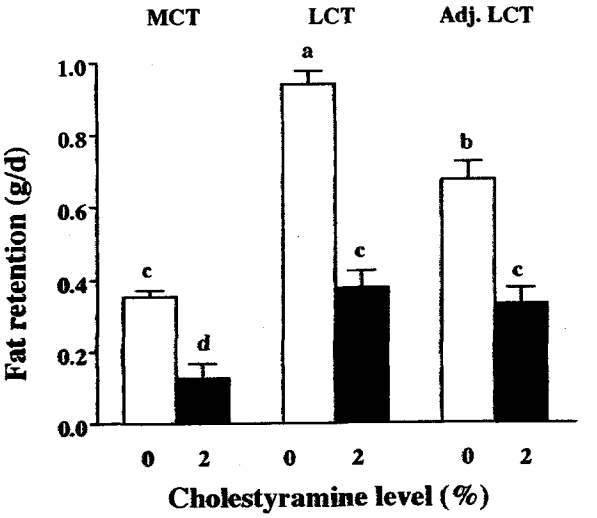

FIG. 1. Fat retention of chicks fed medium-chain triacylglycerol (MCT), long-chain triacylglycerol (LCT), or adjusted long-chain triacylglycerol (Adj. LCT) diets with or without 2% cholestyramine under equalized feeding conditions for 10 d. Values are means ± SEM of five birds. MCT with cholestyramine had one missing value. Different letters are significantly different at $P < 0.05$.

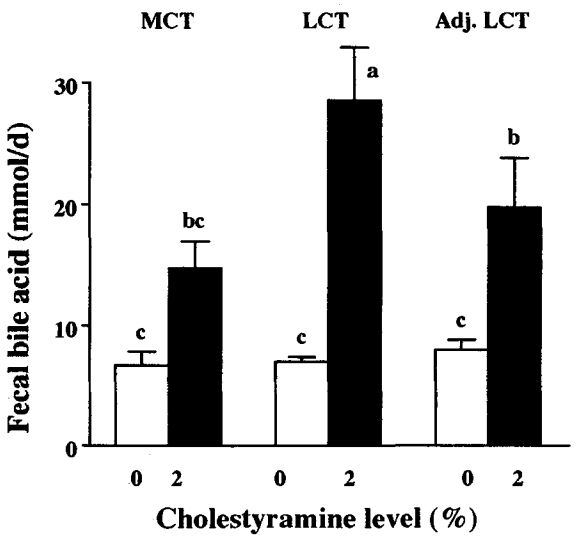

FIG. 2. Fecal bile acids of chicks fed MCT, LCT, or Adj. LCT diets with or without 2% cholestyramine under equalized feeding conditions for 10 d. Values are means ± SEM of five birds. MCT with cholestyramine had one missing value. Different superscript letters are significantly different at $P < 0.05$. Abbreviations as in Figure 1.

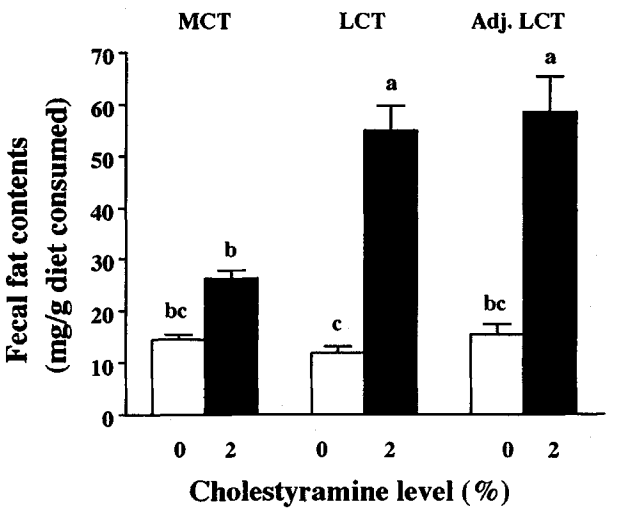

FIG. 3. Fecal fat of chicks fed MCT, LCT or Adj. LCT diets with or without 2% cholestyramine under equalized feeding conditions for 10 d. Values are means ± SEM of 5 birds. MCT with cholestyramine had one missing value. Different superscript letters are significantly different at $P < 0.05$. Abbreviations as in Figure 1.

nificantly higher in both LCT diets without CSTY than with the rest of the treatments. Heat loss was significantly higher in chicks eating the MCT diet than in those eating the adjusted LCT diet. Heat loss was reduced by CSTY in the LCT group, but was not altered by CSTY in the MCT and adjusted LCT groups.

Total fecal bile acids and fecal fat content of chicks fed diets containing MCT or LCT with or without CSTY under equalized feeding conditions are shown in Figures 2 and 3, respectively. The addition of CSTY increased fecal bile acids in all treatments, but was significantly higher in chicks fed LCT with CSTY than in those given MCT diet with CSTY. Total fecal fat content was significantly increased by the addition of CSTY in all treatment groups. In both diets containing LCT, however, the increase was about threefold, whereas with dietary MCT the increase was only about 1.5-fold (Fig. 3).

The fecal fatty acid composition of chicks fed diets con-

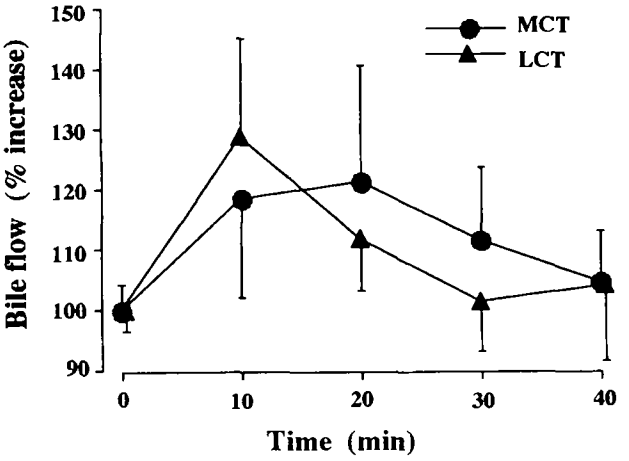

FIG. 4. Bile flow (% increase) in the cannulated cystic duct of about three-week-old single-comb white leghorn male chicks measured at 10-min intervals after duodenal infusion of MCT or LCT. Basal rate of flow was established for three hours before oil infusion in which the values were discarded. The value at 10 min before infusion was considered as basal (time 0). Values represent means ± SEM for seven chicks. No significant difference was observed between treatments. Abbreviations as in Figure 1.

taining MCT or LCT with or without CSTY under equalized feeding conditions is shown in Table 4. The values shown are total fecal of fatty acids during the last three days of the experiment. Excretion of octanoic acid (8:0) in chicks fed MCT was significantly increased by the addition of CSTY. The excretion of lauric acid (12:0) was also significantly increased in the same group. In chicks given the LCT and adjusted LCT diets, the excretion of all fatty acids listed, except for palmitoleic acid (16:1n-7) and linoleic acid (18:2n-6), was significantly increased by CSTY, including saturated and monounsaturated fatty acids. However, although the values for 18:2n-6 in the LCT with CSTY groups were increased, great variations from the means showed that significant difference was not obtained

Effect of MCT or LCT infusion on the cystic bile flow of chicks. Figure 4 shows the bile flow of chicks measured at 10-min intervals after duodenal infusion of MCT or LCT. Bile flow showed a tendency to increase at 10 min after injection of MCT or LCT. No significant difference was observed between treatments or over time.

DISCUSSION

The metabolism of dietary fat is influenced by the amount of food and energy intake, as well as by luminal bile acids. In this study, the effects of CSTY, a bile acid binding polymer, on the lipid and energy metabolism of chicks given dietary MCT or LCT, were investigated under equalized feeding conditions. LCT groups were given food amount, energy value, and CSTY level equal to MCT groups. Nutrient requirements for protein, vitamins, and minerals were adequately supplied to meet the chicks' needs. Dietary fat content, however, was very high so that the protein/energy ratio was decreased. The results presented here should be accounted for by the amount and type of dietary fat included in the diet.

CSTY is an anion exchange polymer which irreversibly binds intraluminal bile acids, as well as other components of normal luminal micelles, including phospholipid, monoacylglycerol, fatty acid, and cholesterol (14). In the present study, the dietary levels of CSTY and triacylglycerol used were 2 and 20%, respectively. Body weight gain was reduced by CSTY in chicks fed LCT, but was not altered in those fed diets with MCT. At the same level of dietary triacylglycerol, CSTY evidently affected the digestive process of chicks given LCT diet, but not MCT diet. Even at the same ME intake, lower body weight gain was attained by chicks given the adjusted LCT diet compared to those given the MCT diet when CSTY was added. Different factors discussed below may explain this finding.

Under free-feeding conditions, an increasing level of dietary MCT led to decreased fat retention as food intake was decreased (2). In the equalized feeding experiment, MCT also decreased fat retention compared to LCT. MCFA are metabolized faster in the liver and are oxidized completely (15), whereas LCFA are deposited in the tissues, resulting in increased energy retention. CSTY decreased body fat and fat retention of chicks either fed the MCT or LCT diets; consequently, energy retention was decreased. However, the drastic decrease of fat and energy retention in chicks fed the LCT diet with CSTY were great factors to consider in the reduced body weight gain. CSTY binds bile acids, decreases fatty acid absorption, and thus decreases the availability of dietary fatty acids for deposition in the body. MCFA were well absorbed by chicks in the absence of bile acids (7). It also was shown by Clark and Holt (16) that maximal steady-state absorption of MCT by rats was the same after total bile diversion as it was before. However, fat retention in chicks given the MCT diet decreased as CSTY was added. Micelle formation may not be necessary for the solubilization of MCFA if the dietary concentration is low, but bile acids may be important when the MCT concentration in the diet is high, as shown by the increased fecal fat and fecal octanoic acid (8:0) concentration (Table 4) in the MCT diet with added CSTY.

Fecal fat was increased by the addition of CSTY in the MCT diet, but it was not as drastic as in chicks given the LCT diet. The calculated ME value of the LCT diet was higher than that of the MCT diet. Furuse *et al.* (2) have shown that ME of the MCT source used in this study was lower than that of LCT (9). The addition of CSTY decreased ME values of all the diets due to incomplete solubilization of dietary fat. Thus, ME intakes also were decreased. The chicks given the MCT diet had higher heat loss than those given the adjusted LCT diet. Intravenous infusion of MCT emulsion increased energy expenditure in rats (17) and in humans (18). This factor also may be responsible for the higher heat loss in chicks fed the MCT diet compared to those fed the adjusted LCT diet, despite the same energy intake (Table 3). The chicks given the LCT diet with CSTY had a lower heat loss with reduced ME intake, which may sug-

gest that they saved more of the available energy from the LCT diet for storage.

In another experiment, bile flow was measured after cystic duct cannulation in chicks to evaluate the effect of MCT or LCT on the rate of bile flow. Diverted bile flow from the cystic duct was not significantly different between MCT or LCT administration (Fig. 4). Bile acid secretion in this experiment was not different, just as Rubin *et al.* (5) have demonstrated that lipid infusion of MCT or LCT did not affect bile flow and bile acid secretion in rats. Bile acid excreted in chicks given MCT diet with CSTY was lower than in those given diets containing LCT, and the reason for this is not understood.

The concentration of fecal fatty acids in the fecal fat (Table 4) may clarify the effect of bile acid binding by CSTY, according to the length of fatty acid carbon chain. It is shown in this study that CSTY did not enhance bile acid excretion as much during MCT feeding as during LCT feeding, but the reduced excretion of bile acids in the feces enhanced the excretion of 8:0 from chicks given MCT diet. This result raises questions in regard to the absorption mechanism of this fatty acid, as the excretion increase implies that bile acids may be needed for its absorption in large amounts. There were reports that 8:0 can be absorbed in the absence of bile acids (7,19); however, we have shown that 8:0 was excreted in the feces in a dose-dependent manner as dietary 8:0 increased (20). Decanoic acid (10:0), myristic acid (14:0), and palmitic acid (16:0) excreted by chicks given the MCT diet could be from endogenous sources. The excretion of these fatty acids increased when CSTY was added into either of the diets containing LCT, which could be due to their presence in the diet and lack of complete emulsification in the lumen. Corn oil, which was used as the LCT source, contained about 27% oleic acid (18:1n-9) and about 58% linoleic acid (18:2n-6). The concentrations of 18:1n-9 and 18:2n-6 in the fecal fat may suggest differences in absorption between these two fatty acids. The addition of CSTY did not markedly alter the absorption of 18:2n-6, which may indicate either that the micellar phase is insignificant for the absorption of this fatty acid when the bile acid concentration is low, or that CSTY is selective in binding fatty acids in the micellar phase. Linoleic acid has distinctive transport mechanisms, such as intestinal absorption through simple passive diffusion, as has been demonstrated in different species (21–23). Other LCFA, including 18:1n-9, were increasingly excreted when bound bile acids were excreted as fewer micelles were formed and fatty acids were less solubilized into micelles, which resulted in reduced fatty acid absorption.

In summary, it was concluded that CSTY alters the lipid and energy metabolism of chicks fed either MCT or LCT, as fat and energy retention of chicks was lowered, perhaps by prevention of micelle formation and bile acid reabsorption. However, the effect of CSTY on MCT utilization was less striking than its effect on that of LCT.

Resistant Starch Is More Effective Than Cholestyramine as a Lipid-Lowering Agent in the Rat

Hassan Younes*, Marie-Anne Levrat, Christian Demigné and Christian Rémésy

Laboratoire des Maladies Métaboliques, INRA de Clermont-Ferrand/Theix, 63122 St-Genès-Champanelle, France

ABSTRACT: Amylase-resistant starch (RS) represents a substrate for the bacterial flora of the colon, and the question arises as whether RS shares with soluble fibers common mechanisms for their lipid-lowering effects. It is uncertain whether a cholesterol-lowering effect depends basically on an enhanced rate of steroid excretion or whether colonic fermentations also play a role in this effect. In the present study, the effect of RS (25% raw potato starch), of a steroid sequestrant (0.8% cholestyramine), or both were compared on bile acid excretion and lipid metabolism in rats fed semipurified diets. RS diets led to a marked rise in cecal size and the cecal pool of short-chain fatty acids (SCFA), as well as SCFA absorption; cholestyramine did not noticeably affect cecal fermentation. Whereas cholestyramine was particularly effective at enhancing bile acid excretion, RS was more effective in lowering plasma cholesterol (–32%) and triglycerides (–29%). The activity of 3-hydroxy-3-methylglutaryl–CoA reductase was increased fivefold by cholestyramine and twofold by RS. This induction in rats fed RS diets was concomittant to a depressed fatty acid synthase activity. In rats fed the RS diet, there was a lower concentration of cholesterol in all lipoprotein fractions, especially the (d = 1.040 – 1.080) fraction high-density lipoprotein (HDL_1), while those fed cholestyramine had only a significant reduction of HDL_1 cholesterol. In contrast to cholestyramine, RS also depressed the concentration of triglycerides in the triglyceride-rich lipoprotein fraction. There was no noticeable synergy between the effects of RS and cholestyramine when both were present in the diet. This suggests that the cholesterol-lowering effect of RS is not limited to its capacity to enhance bile acids excretion. The difference between RS and cholestyramine could relate to the capacity of fermentation end-products to counteract the upregulation of cholesterol and bile acid biosynthesis. Thus, in the absence of fermentation in the large intestine, a high rate of bile acids excretion is not always sufficient to elicit a cholesterol-lowering effect.

Lipids 30, 847–853 (1995).

The possibility of lowering plasma cholesterol by interfering with the absorption of cholesterol or bile acids has been extensively investigated using either compounds of natural origin [e.g., gel-forming fibers, resistant starch (RS), phytosterols, and saponins] or synthetic sequesterants such as cholestyramine (for review, see Ref. 1). Starch is generally the major constituent of the human diet and has long been regarded as almost entirely digested in the upper part of the digestive tract. In fact, some starches contain a significant proportion of amylase-RS and, in humans, RS may represent a susbtantial part of the polysaccharides entering the colon (2–4). These substrates are broken down by the colonic microflora, essentially to short-chain fatty acid (SCFA), which allows the recovery of a part of the chemical energy of RS by the host.

A cholesterol-lowering effect of potato starch (which is partly resistant in its native form) has been reported in rodents (5–8). Furthermore, it has been shown that amylomaize starch is very efficient at depressing plasma cholesterol in obese or in lean rats (9). In humans, a high amylose starch intake has been found to lower plasma cholesterol and triglycerides concentrations, compared to a diet rich in amylopectin starch (10); furthermore, it has been reported that a high amount of cornstarch in the diet also may reduce fat accretion (11).

The cholesterol-lowering effect of fermentable fiber may be explained by various mechanisms: (i) inhibition of diffusion of cholesterol and bile acids at the microvillous boundary layer, (ii) steroid-binding capacities in the small intestine, (iii) impairment of the passive reabsorption in the large intestine by insolubilization of bile acids (by acidification of luminal pH, microbial dehydroxylation to less polar metabolites, or entrapping on various insoluble structures), and (iv) metabolic effects, especially on hepatic lipid metabolism.

The question arises as to whether RS share with soluble fibers some common mechanisms for their lipid-lowering effects. There is little doubt that RS has a low gel-forming capacity, compared with certain soluble fibers (12), but it has been shown recently that RS has a capacity to form inclusion complexes with bile acids (due to a helix structure) (13). It is still debated as to whether a cholesterol-lowering effect depends basically on an enhanced rate of steroid excretion, and whether colonic fermentations play a role in this effect. The present study, therefore, compared the effect of RS (raw potato starch) with that of cholestyramine (a steroid sequesterant) on bile acid excretion and lipid metabolism in rats fed semipurified diets. Using diets containing both compounds, it also was examined whether these two agents had complementary antagonistic effects on plasma cholesterol.

MATERIALS AND METHODS

Animals and diets. Forty male Wistar rats (IFFA-CREDO, l'Arbresle, France) weighing about 160 g were used. The animals were housed two per cage (wire-bottomed to limit coprophagy) and fed a semipurified moistened powder diet that contained the following (by dry weight): 15% casein (L. François, Saint-Maur, France), 5% peanut oil (CIO, Genay, France), 6% mineral mixture (UAR, Villemoisson/Orge, France), and 1% vitamin mixture (UAR). In the control diet, the carbohydrate supply was wheat starch (73%). In the experimental groups, a part of wheat starch was replaced by 25% raw potato starch (L. François) or by 0.8% cholestyramine (Sigma, St. Louis, MO) or by mixture of both. The rats were maintained in temperature-controlled rooms (22°C) with the dark period from 2000 to 0800 h. The daily food consumption and body weight were recorded every three days during the first week, then daily during the last week. Feces were collected and weighed over four consecutive 24-h periods for studies on bile acids and neutral sterol excretion. Animals were maintained and handled according to the recommendations of the Institutional Ethic Commitee (Clermont-Ferrand University, St. Gene's-Champanelle, France).

Sampling procedures. Rats were sampled just after the dark period, at a time when cecal fermentations are still very active (between 0800 and 0900 h). After anesthesia (40 mg/kg of sodium pentobarbital), rats were maintained on a warming plate at 37°C. An abdominal incision was made, and blood was withdrawn from the portal vein and then from the abdominal aorta. The blood was placed in microfuge tubes containing heparin and centrifuged at 10,000 × *g* for 2 min. Plasma samples were kept at 4°C for lipid and lipoprotein analysis. A portion of liver was freezed-clamped and stored at −80°C for the measurement of fatty acid synthase (FAS) activity. For microsome preparation, two grams of liver were quickly homogenized in 4 mL of an ice-cold buffer 1 (50 mmol/L Tris-hydrochloride, 250 mmol/L sucrose, 50 mmol/L EDTA, 2 mmol/L dithiothreitol, and 2 µmol/L leupeptin, pH 7.2) with a Potter-Elvejhem homogeneizer (Braun, Melsungen, Germany) at moderate speed. The homogenate was first centrifuged at 10,000 × *g* for 15 min at 4°C; the resulting supernatant was then centrifuged at 100,000 × *g* for 60 min at 4°C. Pellets were resuspended in 2 mL of chilled buffer 1. The centrifugation procedure was repeated, and the resulting pellets homogenized in 1 mL of buffer 2 (100 mmol/L sucrose, 50 mmol/L KCL, 40 mmol/L K phosphate, 30 mmol/L EDTA, 1 mmol/L dithiothreitol, pH 7.2). The microsomal preparation was stored at −80°C until measurement of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase activity. The protein content of the microsomes was determined using the Pierce BCA reagent kit (Interchim, Montluçon, France).

After blood sampling, the cecum with its contents was removed and weighed. Duplicate samples were collected into 2 mL microfuge tubes that were immediately stored at −20°C. Supernatants of the digestive contents were obtained by centrifuging the microfuge tubes at 20,000 × *g* for 10 min at 4°C.

Analytical procedures. SCFA were measured by gas–liquid chromatography, after ethanolic extraction of plasma samples (14) and on aliquots of supernatants (8,000 × *g*, 5 min) of cecal contents. Bile acid analyses were performed on cecal supernatants (soluble) or after extraction. Bile acids were extracted from untreated cecal samples (total) or feces by 10 vol of ethanolic KOH (0.5M), after dispersion with a Polytron homogeneizer (Luzern, Switzerland), then heating at 80°C for one hour. For the determination of soluble bile acids, 6 vol of ethanol were added to the cecal supernatants to clarify the medium. Bile acids were measured on the supernatant (8,000 × *g*, 5 min) of the ethanolic extracts, using the reaction catalyzed by 3 α-hydroxysteroid dehydrogenase (EC 1.1.1.50; Sigma) (15).

Plasma lipoproteins were separated by density gradient ultracentrifugation (16), using pooled samples. After centrifugation in a TST 41.14 swinging-bucket rotor at 100,000 × *g* for 36 h at 15°C, the gradient was divided into 24 × 500 µL fractions and kept at 4°C for lipid analysis. Triglycerides (Biotrol, Paris, France) and total cholesterol (BioMérieux, Charbonnières-les-Bains, France) were determined in plasma and lipoprotein fractions by enzymatic procedures. The activity of HMG–CoA reductase was measured on liver microsomal fractions as described by Wilce and Kroone (17). Labelled mevalonolactone was separated from unreacted HMG–CoA by column chromatography using AG1-X8 resin (200–400 mesh, formate form; BioRad, Paris, France). Specific radioactivity of the enzyme was expressed in pmoles of [3-^{14}C]HMG–CoA transformed in [^{14}C]mevalonolactone per minute per milligram of microsomal protein, after correcting for recovery of [^{3}H]mevalonolactone from the column. The activity of FAS was determined according to the method described by Hsu *et al.* (18) on cytosolic extracts, and expressed in nmoles of [2-^{14}C]malonyl CoA incorporated into fatty acids per minute per gram of liver.

Statistical analysis. Values are given as the means ± SEM, and, where appropriate, significance of difference between mean values was determined by analysis of variance (ANOVA) coupled with the Student-Newman-Keuls multirange test. Values of $P < 0.05$ were considered significant.

RESULTS

Effects of diets on animals and their digestive tracts. Cholestyramine in the diet had no influence on food intake and body weight gain (Table 1). Feeding diets containing 25% raw potato starch (about 18% of effectively RS) elicited a significantly higher food intake, but the final body weight was not significantly different from that of rats fed the control diet. Whatever the diets, the small intestine and liver weights were not significantly affected. In rats fed the RS diets, the large intestine (colon + cecum) was larger (+70%) than in rats fed the control diet; furthermore, there was a small but significant enlargement of the small intestine in rats fed the cholestyramine diet (+20%), compared to controls. Replacement of wheat starch by RS caused a significant drop (−14%) in the

weight of perirenal fat, while cholestyramine alone had no significant effect.

Cecal fermentation and SCFA absorption. As shown in Table 2, the total cecal weight (cecal content + cecal wall) was significantly heavier in rats adapted to the RS (about 4-fold) or cholestyramine diets (about 1.5-fold). The cecal pH was about 7.2 in rats fed diets containing digestible starch; it was markedly acidic in rats fed RS diets (5.35 and 5.60), but there was no noticeable effect of cholestyramine on this parameter. RS diets led to a marked rise in total SCFA concentration in the cecum (from 90 to about 150 mM). In parallel, the cecal pool of SCFA was considerably elevated in rats fed the RS diets (acetate 8-fold, propionate and butyrate 10-fold). It must be noted that there was a trend toward greater quantities of butyrate in the caecum in rats fed diets containing cholestyramine.

The portal vein concentrations of SCFA were grossly proportional to the cecal SCFA pool. Table 3 shows that the portal concentration of SCFA was 6- to 8-fold higher in rats fed the RS diets than in rats fed the digestible starch diet. It must be noted that propionate absorption was particularly enhanced (8-fold) with diets containing a high amount of RS, compared to the control diet.

The arterial concentration of acetate was strongly increased in rats fed RS diets (from less than 0.2 to about 0.5 mM). No detectable concentration of butyrate or propionate was found in rats fed the control or cholestyramine diets. However, in rats fed RS diets, significant amounts of propionate were present in aortic blood (about 0.05 mM), suggesting that a small percentage of absorbed propionate escaped hepatic uptake.

Effects of RS and cholestyramine on cecal bile acids and their fecal excretion. As shown in Table 4, the cecal bile acids concentration was about 5 mM in control conditions, 40% being in soluble form. Cholestyramine led to a marked accumulation of bile acids in the cecum (about 12 mM) which were almost entirely (98%) under an insoluble bound form. In rats fed the RS diet, the cecal concentration and solubility of bile acids were markedly reduced compared to control conditions. In the group fed the RS/cholestyramine diet, the cecal bile acid concentration also was low, and the concentration of soluble bile acids was particularly low (0.15 mM). The total pool of bile acids in the cecum was increased almost 4-fold by cholestyramine and less than 2-fold by RS. Cholestyramine had a dramatic effect on bile acid excretion (+300% enhanced), whereas RS was much less effective (+70%). In rats adapted to the RS/cholestyramine diet, the fecal excretion of

bile acids was slightly lower (63 μmoles/day) than with cholestyramine alone (79 μmoles/day).

Effects of RS and cholestyramine on plasma lipids, lipoprotein profile, and on liver activities of HMG–CoA reductase and fatty acid synthase. As shown in Figure 1, rats fed a RS diet had a significantly lower plasma cholesterol (–32%) and triglyceride (–29%) concentration than control rats or rats fed the cholestyramine diet. These effects were more accentuated in rats adapted to a RS/cholestyramine diet (–40% and –34% for cholesterol and triglycerides, respectively). The liver cholesterol and triglyceride contents were unaffected by all the experimental diets. Analysis of the plasma lipoprotein profile (Fig. 2) shows that the cholesterol-

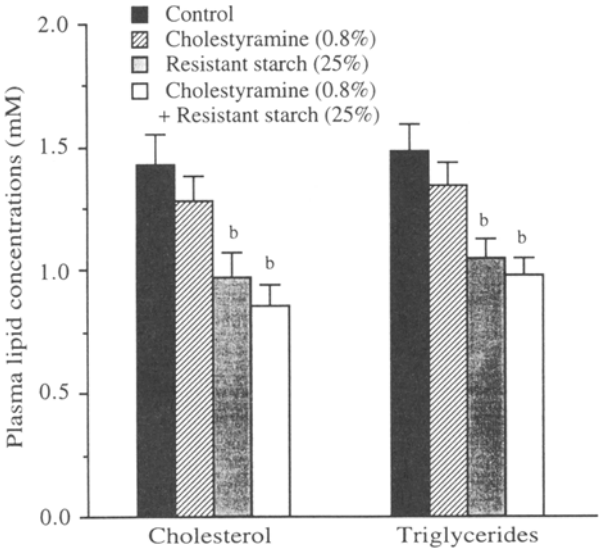

FIG. 1. Effects of replacement of digestible starch by resistant starch and/or cholestyramine on plasma cholesterol and triglycerides concentrations. Values not sharing a common letter are significantly different ($P < 0.05$).

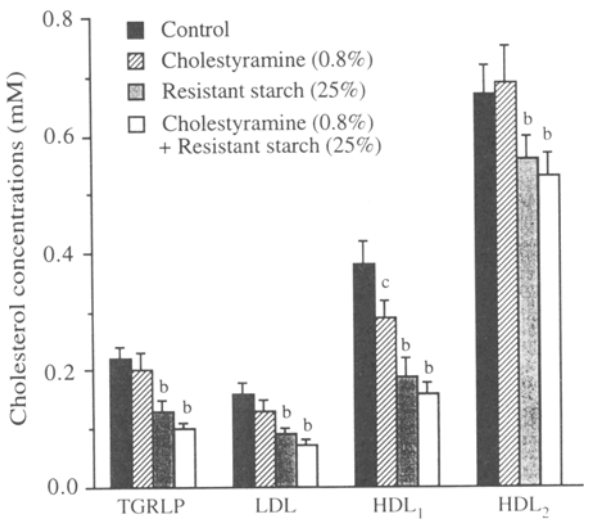

FIG. 2. Effects of replacement of digestible starch by resistant starch and/or cholestyramine on cholesterol concentration in the various lipoprotein fractions. Each value is a mean ± SEM of a triplicate analysis of a pool of ten plasmas. The triglyceride-rich lipoprotein (TGRLP) corresponded to fractions with a density lower than 1.006 kg/L. The low-density lipoprotein (LDL), high-density lipoprotein (HDL_1), and HDL_2 corresponded to fractions within a density range of 1.006–1.040, 1.040–1.080, and 1.080–1.16 kg/L, respectively. Values not sharing a common letter are significantly different ($P < 0.05$).

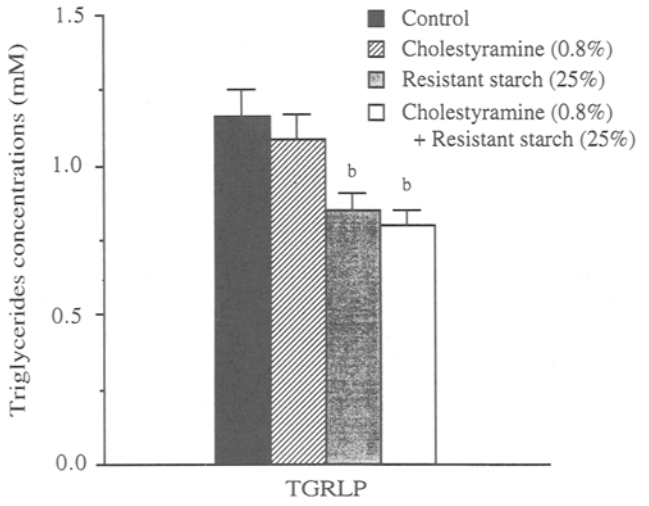

FIG. 3. Effects of replacement of digestible starch by resistant starch and/or cholestyramine on the concentration of triglycerides in the TGRLP fractions. Each value is a mean ± SEM of a triplicate analysis of a pool of ten plasmas. The TGRLP corresponded to fractions with a density lower than 1.006 kg/L. Values not sharing a common letter are significantly different ($P < 0.05$). See Figure 2 for abbreviation.

lowering effect of RS corresponded to depressed concentrations of cholesterol in all lipoprotein fractions, especially in the fraction with a density ranging from 1.040 to 1.080 [namely high-density lipoprotein (HDL_1)]. It must be noted that, with the cholestyramine diet, there was a significant decrease of cholesterol in HDL_1, which could reflect an enhanced uptake of apoE-containing particles by the liver *via* the apoB/E receptor. The concentration of triglycerides in triglyceride-rich lipoprotein (TGRLP) fractions was significantly depressed by RS (–28%) (Fig. 3). On the other hand, as shown in Table 5, the activity of HMG–CoA reductase (rate-limiting enzyme of cholesterol synthesis) was markedly increased with cholestyramine in the diet (5-fold) as well as, to a lesser extent, by RS (about 2-fold). Furthermore, the activity of FAS was negatively affected in rats fed the RS diets, especially in those fed the RS/cholestyramine diet (–30%).

DISCUSSION

It is noteworthy that RS feeding elicits a lipid-lowering effect without affecting the body weight. However, it appears that fat accumulation was slightly reduced, as shown for perirenal fat. This reduction may result from an alteration of the energetic fuels available for liver metabolism, namely a partial substitution of glucose by SCFA. Furthermore, the time course of nutrient absorption is very different when glucose is absorbed from the small intestine from digestible starch breakdown, or when SCFA are progressively produced from fermentable substrates RS, and absorbed in the large intestine. The metabolic impact of absorbed glucose is different from that of SCFA: only a small percentage of glucose is removed and utilized by the liver (19), whereas SCFA are mostly taken up by the liver and play a minor role in extrasplanchnic metabolism. This is accompanied by marked differences in the basal values and the daily fluctuations of plasma insulin (19).

RS fermentation led to a considerable increase in cecal weight (total as well as emptied), a general feature of fermentable carbohydrates in rats (6), and this is accompanied by histological changes in cecal mucosa, such as an elevated crypt height and cell number per crypt (20). The possible effects of RS on the colonic mucosa in humans are still poorly documented, but an accelerated transit rate has been reported for various fermentable carbohydrates and this tends to limit the reabsorption of bile acids (21). The microbial breakdown of RS in the large intestine may promote fermentation resulting in a large proportion of butyric acid (22), especially with a human microflora (23). However, this depends on the type of starch and associated microflora: in the present conditions (pH ≈ 5.5) in rats, high-propionic acid fermentations were rather observed with diets rich in raw potato starch. With a higher percentage of potato starch in the diet (40%), high butyric acid fermentations have been actually observed (24). It is noteworthy that cholestyramine in the diet enhanced the cecal pool of butyric acid (with an effect on the cecal concentration in rats fed a cholestyramine/RS diet). A drastic depletion of soluble bile acids in the cecum might influence the microflora and promote butyric acid production, but these changes in butyrate availability probably would have a minor role on lipid metabolism.

Previous investigations have shown that an elevated excretion of bile acids was necessary to obtain a significant cholesterol-lowering effect with fermentable fibers (25). RS can

actually increase the fecal excretion of bile acids and neutral sterols (7,13). The primary effect of RS is probably in the ileum since the cecal bile acids pool is enhanced, which reflects the extent of bile acid diversion from ileal reabsorption. Abadie *et al.* (13) have shown a comparable effect between β-cyclodextrin and potato starch. However, the effect of cyclodextrin is favored by its ring structure which is more effective than the helical structures formed by the glucose units of amylose and amylopectin (13). In this investigation, RS exhibited a better affinity for the dihydroxy bile acids than for cholic acid, in contrast to the relative affinities seen with cholestyramine.

In the cecum, bile acids are extensively deconjugated and converted to secondary bile acids by bacterial 7α-dehydroxylation (26). A passive absorption of bile acids takes place in the large intestine, but the fact that their fecal excretion is enhanced indicates that colonic absorption fails to compensate for a reduced absorption in the small intestine. Secondary bile acid absorption is likely to be depressed, because of (i) inhibition of 7-α dehydroxylase activity at acidic pH, (ii) depressed bile acid solubility due to acidic conditions. Acidic pH may also favor bile salt precipitation as insoluble calcium salts (27). Even a low concentration of cholestyramine in the diet increased bile acid output from the ileum and inhibited their passive absorption in the colon because of their insolubility (28); as a result, the fecal bile acids excretion was markedly elevated. Although RS enhanced bile acid excretion less efficiently than did cholestyramine, a marked reduction of plasma cholesterol was seen only with RS diets. Thus, this result shows that a high rate of bile acids excretion is not always sufficient to lower plasma cholesterol. In contrast, such an effect with cholestyramine has only been reported with high-fat diets supplemented with cholesterol, which could reflect some adsorption of cholesterol on the resin due to hydrophobic interaction with its apolar core (29).

In growing male rats fed on a low-fat diet, plasma cholesterol is relatively low; nevertheless, RS feeding led to a 30% lowering of plasma cholesterol. Using another type of RS, amylomaize starch, Mathé *et al.* (9) also have found a 30% reduction of plasma cholesterol but in rats (lean Zucker) with a higher basal cholesterol (about 3 mM). Morand *et al.* (19) and De Deckere *et al.* (11) have reported a marginal cholesterol-lowering effect of amylomaize starch, which suggests that potato starch might have specific effects on lipid metabolism. The effect of RS on serum cholesterol concentrations may reflect an accelerated fecal excretion of steroids (7,13) or an effect of SCFA themselves on lipid metabolism (30–32). The putative role of SCFA (chiefly propionate) on the activities of key enzymes of cholesterol metabolism is still disputed. This has been examined using various approaches: supplementation of the diet with propionate (33), intracecal infusion of propionate (34), or in isolated hepatocytes (32,35). These investigations have not always been conclusive, but it remains conceivable that propionate impairs the utilization of major lipogenic precursors (acetate, lactate) by liver cells (36,37).

In response to the elevated excretion of bile acids in rats fed RS diets, there was an induction of liver HMG–CoA reductase activity. The question arises as to whether a high availability of SCFA limits the induction of HMG–CoA reductase. Conceivably, a relatively low insulinemia in rats fed RS diets also could be a factor which limits HMG–CoA reductase induction (38). Furthermore, it appears that liver metabolism was not oriented toward lipogenesis since a low activity of FAS was observed, in accordance with previous data (39). FAS activity was not affected by cholestyramine, suggesting that this compound is very effective to accelerate cholesterogenesis but not fatty acid synthesis, as previously shown (40). Accordingly, the low percentage of cholestyramine used in this experiment failed to significantly affect plasma triglycerides, whereas induction of HMG–CoA reductase was probably sufficient to maintain the plasma cholesterol level.

With the present low-fat diets, RS was effective to lower plasma cholesterol and triglycerides. Nevertheless, a hypotriglyceridemic effect has not been systematically observed with RS (9,19); in fact, the rate of triglyceride uptake by peripheral tissues is closely dependent on the insulin status. In the present experiments, the triglyceride concentration in TGRLP was markedly depressed by the RS diet, in accordance with results obtained by Mathé *et al.* (9). The cholesterol-lowering effect of RS could be connected to a depressed secretion of very low density lipoprotein triglyceride, in keeping with the lower activity of FAS in the liver, as well as that of other enzymes involved in fatty acid synthesis (33).

In contrast to humans, most of the plasma cholesterol in rats is associated with HDL; this fraction is heterogeneous and has been separated into two major subclasses compositionally distinct with regard to the apoE content, lipid and protein composition, and particle size (41,42). RS was effective to depress cholesterol in all the liproprotein fractions, especially in HDL_1. A lowering of this apoE-containing fraction could be explained by its accelerated removal (*via* the liver apo B/E receptor) and/or its reduced formation. The first hypothesis is consistent with a high degree of HMG–CoA induction since a coordinate regulation of HMG–CoA reductase and of the apoB/E receptor have been shown at the transcriptional level (43). However, other studies have proposed that hepatic sterol synthesis and receptor-mediated uptake of low-density lipoprotein particles could be independently regulated in rats (44), thus accounting for the moderate lowering of HDL_1 cholesterol in the presence of highly induced HMG–CoA reductase in rats fed cholestyramine alone. The decrease in HDL_1 also could be explained by a reduced rate of formation, corresponding to a depressed availability of the surface components of TGRLP (45). Low levels of TGRLP were actually observed, which supports the above hypothesis. When both RS and cholestyramine were present in the diet, there was no noticeable synergism between both compounds, which suggests that the cholesterol- lowering effect of RS is not limited by its capacity to enhance bile acids excretion.

In conclusion, this study indicates that RS have hypolipidemic effects which are comparable to those of the most ef-

fective fibers. Diets containing fermentable complex carbohydrates, such as RS, are generally well-tolerated in humans although some cases of intolerance have been reported (46). Cholestyramine therapy also may be associated with troublesome side effects; thus, it remains to assess in clinical trials in which conditions RS may be used in humans, alone or in combination with cholestyramine. The lipid-lowering effects of RS were seen despite its having less effect on bile acid excretion than does cholestyramine, and the role of digestive fermentation in altering hepatic cholesterol metabolism should be reevaluated. Further study should, therefore,be made of the use of RS in the treatment of hyperlipidemia, particularly in hypertriglyceridemic subjects or those with type II diabetes.

Departments of Surgery, Beth Israel Medical Center, New York, New York, and the Albert Einstein College of Medicine, The Bronx, New York

ABSTRACT: The effects of β-muricholic acid and hyocholic acid on cholesterol cholelithiasis were examined in two animal models. The following experiments were carried out: A) In a gallstone prevention study, prairie dogs were fed the lithogenic diet with or without 0.1% β-muricholic or 0.1% hyocholic acid for eight weeks. B) In a second prevention study, hamsters were fed the lithogenic diet with or without 0.1% β-muricholic acid or 0.1% hyocholic acid for six weeks. C) In a gallstone dissolution study, hamsters were fed the lithogenic diet for six weeks to induce stones; stone dissolution was examined during administration of a cholesterol-free purified diet with or without 0.1% β-muricholic acid or 0.1% hyocholic acid. In the prevention study in prairie dogs (A), both bile acids failed to prevent stone formation, the cholesterol saturation index of bile was 0.89 in the lithogenic controls, remained unchanged with hyocholic acid and increased to 1.52 in the β-muricholic acid group. In the prevention study in hamsters (B), β-muricholic acid completely inhibited the cholesterol cholelithiasis (0% stone incidence); the cholesterol saturation index of bile was 1.78 (compared to lithogenic controls, 1.37). Hyocholic acid reduced stone incidence to 16% with a cholesterol saturation index of 0.98. In the dissolution study in hamsters (C), preexisting cholesterol gallstones were not dissolved by either hydrophilic bile acid after feeding these bile acids for an additional six weeks; at the end of the experiment, the cholesterol saturation indices were below unity. These studies suggest that, in the hamster animal model, hydrophilic bile acids may be useful for the prevention of gallstones but not dissolution of preestablished cholesterol gallstones.

Lipids 30, 855–861 (1995).

The administration of exogenous bile acids to modify the natural bile acid pool and dissolve cholesterol gallstones has been in use for some 20 yr (1–4). So far this has been one of the most successful nonsurgical treatments of cholesterol cholelithiasis. Chenodeoxycholic acid and ursodeoxycholic acid were the bile acids used either alone or in combination to dissolve cholesterol stones (5–7). The mode of action of these compounds is quite different: chenodeoxycholic acid, a hydrophobic bile acid, dissolves cholesterol stones by transporting cholesterol into mixed micelles (8,9), while ursodeoxycholic acid, a hydrophilic bile acid, can dissolve cholesterol gallstones *via* (i) transfer of cholesterol from stone to micelle or (ii) formation of multilamellar vesicles, rich in cholesterol and phospholipid but low in bile acid (8,9). Ursodeoxycholic acid is safe but its use has two disadvantages: (i) enrichment of the biliary bile acid pool usually does not exceed 50% (7,8) and (ii) the intestinal bacteria can transform ursodeoxycholic acid (as well as chenodeoxycholic acid) to a hepatotoxic bile acid, lithocholic acid (10,11).

It would be desirable to use cholelitholytic bile acids which cannot be metabolized to a hepatotoxic compound. Potential candidates are bile acids substituted with a hydroxy group at carbons 3 and 6. We have previously examined the cholelitholytic properties of such compounds including hyodeoxycholic acid (3α,6α-dihydroxy-5β-cholanoic acid) and murideoxycholic acid (3α,6β-dihydroxy-5β-cholanoic acid). These compounds were very successful in preventing cholesterol gallstones (12,13). The effectiveness of trihydroxy bile acids in the treatment of cholesterol cholelithiasis remained relatively unexplored. Two compounds of interest are β-muricholic acid (3α,6β,7β-trihydroxy-5β-cholanoic acid) and hyocholic acid (3α,6α,7α-trihydroxy-5β-cholanoic acid). The trihydroxy bile acid, β-muricholic acid, was not 7-dehydroxylated by intestinal microorganisms, suggesting that it might be useful in humans in lower doses than those of the cholelitholytic bile acids currently in use (14–16). Our laboratory has studied the metabolism of β-muricholic acid in hamsters; we found that this bile acid was extracted by the liver after intravenous injection and secreted into the bile quantitatively, either as the free acid or conjugated with glycine and taurine (17). *In vitro* studies have demonstrated that β-muricholic acid can dissolve cholesterol gallstones *via* formation of a liquid crystalline mesophase (14). A second trihydroxy bile acid, hyocholic acid, was examined *in vivo* using the mouse model of cholesterol cholelithiasis; this bile acid prevented and dissolved cholesterol crystals (18). The present study examined

the efficacy of β-muricholic acid and hyocholic acid for prevention of cholesterol gallstones in hamsters and prairie dogs. These trihydroxy hydrophilic bile acids were also tested for gallstone dissolution in the hamster model.

MATERIALS AND METHODS

Bile acids. β-Muricholic acid (3α,6β,7β-trihydroxy-5β-cholanoic acid) was a gift of the Roussel UCLAF Society (Paris, France) and had been synthesized by established methods (19–21). Hyocholic acid (3α,6α,7α-trihydroxy-5β-cholanoic acid) was obtained from Canada Packers (Toronto, Canada). Each bile acid was found to be greater than 98% pure by gas–liquid chromatographic (GLC) analyses of the trimethylsilyl ether methyl esters. 5α-Cholestane was obtained from Alltech (Deerfield, IL) and was used as internal standard for the GLC analyses of cholesterol in liver, plasma, and bile. 3α,7α-Dihydroxy-12-keto-5β-cholanoate was used as an internal standard for quantitation of the biliary bile acids.

Animals. Twenty-seven prairie dogs (*Cynomys ludovicianus*) were obtained from R-Z00 (Neshkoro, WI). The animals weighed between 800–880 g and were quarantined upon arrival for a period of two weeks; during this period, animals were given chow and water *ad libitum*. The animals were divided into three groups and fed the following diets for eight weeks: group 1 (10 animals), lithogenic diet (LD); group 2 (10 animals), LD + 0.1% hyocholic acid; group 3 (7 animals), LD + 0.1% β-muricholic acid. The diets were color-coded for identification during each feeding period. The components of the purified diet (PD) were 43.7% corn starch, 20.0% casein, 14.6% dyetrose (soluble starch), 10.0% fiber (cellulose), 5.0% salt mix (modified U.S.P. XIV salt mix, no. 200951), 4.0% butterfat, 2.0% corn oil, 0.5% vitamin mix (no. 300000), 0.2% choline chloride. The purified LD contained 0.3% cholesterol (added at the expense of corn starch). The bile acids also were added at the expense of corn starch. All diets were prepared by Dyets, Inc. (Bethlehem, PA). The food was weighed every two days to determine the daily food intake.

Male golden Syrian hamsters (*Mesocricetus auratus*) weighing between 50–70 g were purchased from Sasco Inc. (Omaha, NE). Hamsters from this supplier readily developed cholesterol gallstones when fed our LD (13). Animals were quarantined for one week; they were fed Purina Chow and water *ad libitum*. Two experiments were carried out as follows: Prevention—fifty-five hamsters were divided into three groups and fed the following diets for six weeks: group 4 (20 animals), LD; group 5 (19 animals), LD + 0.1% hyocholic acid; group 6 (16 animals), LD + 0.1% β-muricholic acid. The composition of the LD was identical to the one described above for the prairie dog.

In the dissolution study, 72 hamsters weighing between 60-80 g were fed the LD for six weeks. Fifteen animals were sacrificed to determine stone incidence (group 7a). The remaining animals were divided into three groups and fed purified regression diets (LD without cholesterol) as follows: group 7b (28 animals), PD; group 7c (14 animals), PD + 0.1% hyocholic acid; group 7d (15 animals), PD + 0.1% β-muricholic acid. All regression diets were fed for six additional weeks (total experimental period = 12 wk).

Hamsters and prairie dogs were fasted for 24 h prior to sacrifice to ensure that the gallbladders contained adequate quantities of bile for chemical analyses. Prairie dogs were anesthetized with 100–200 mg and hamsters with 20 mg of ketamine hydrochloride (Bristol Labs, Syracuse, NY). Blood was obtained *via* cardiac puncture for determination of plasma cholesterol. The abdominal cavity was exposed, and the gallbladder was examined visually for the presence of cholesterol stones. These usually could usually be observed through the gallbladder wall. Bile was removed using a Hamilton syringe; a drop of bile was immediately examined for the presence of cholesterol crystals using an Olympus MCHAP microscope (Olympus Corp., Lake Success, NY) equipped with polarization optics. Gallstones were crushed and analyzed for cholesterol and other components by Fourier transform infrared spectrometry using a Perkin Elmer 1710 spectrometer (Perkin Elmer, Norwalk, CT). The diameter of the stones usually ranged from 1 to 5 mm.

Analytical procedures for plasma, liver, and bile. Bile (hamster, 3 μL; prairie dog, 50 μL) from each animal was immediately centrifuged at 3000 × *g* for 30 min and aliquots were taken for analyses of the biliary lipids (22). Biliary bile acids, cholesterol, and phospholipids were analyzed using procedures described earlier (12,13). Bile acids were analyzed by GLC as the methyl ester acetates. Cholesterol in liver and plasma was determined from portions of these tissues obtained at sacrifice; quantitation of cholesterol was carried out after preparation of the trimethylsilyl ether derivative using 5α-cholestane as an internal standard. The cholesterol saturation index (SI), lithogenic index (LI) was calculated as described earlier (23,24). The calculation of the CSIs using the hydrophilic bile acid correction was made according to Carey (24). This correction applies only to total lipid concentrations between 5.0 to 15 g/dL. These corrections were made for β-muricholic acid and hyocholic acid using data for ursodeoxycholic acid (the only hydrophilic bile acid for which these equations were available).

Statistical methods and data analyses. The data are reported as mean ± SD. The differences in gallstone incidence between groups were calculated using Fisher's exact test (25). Statistical significance of other values was calculated by analyses of variance to determine the F statistic. When the F statistic was significant ($P < 0.05$), Student's *t*-test was applied to the data to determine the level of significance.

RESULTS

Hamster and prairie dog models of cholesterol cholelithiasis were examined to determine whether hydrophilic trihydroxy bile acids could prevent cholesterol gallstones. In these studies, hamsters averaged 50 g in weight, and prairie dogs averaged between 800–841 g. The hamster model also was employed to test the efficacy of hydrophilic bile acids for disso-

lution of preestablished cholesterol gallstones; hamsters averaged 72 g at the start of the induction phase (week 0) and 109–119 g at the start of the dissolution phase (week 7). All animals remained healthy and gained weight normally throughout the feeding periods. The total liver weights for either hamsters or prairie dogs fed hyocholic acid (Table 1) were slightly lower than those of the other groups.

The incidence of gallstones and crystals was determined at sacrifice (Table 2). Prevention of cholesterol stones was different in the two models. In prairie dogs (groups 1–3), gallstone prevention was not observed with either hydrophilic bile acid. In the Sasco hamster, the incidence of cholesterol stones and crystals was significantly reduced by either hyocholic acid or β-muricholic acid (16 and 0%, group 5 vs. group 6) compared to the LD (90%, group 4). The hamster model also was tested for dissolution of stones using the same hydrophilic bile acids after stones had formed. In phase 1 of this study (group 7a), cholesterol stones were present in 93% of the animals after six weeks. The diet was changed to one containing the identical components of the LD but without cholesterol—PD; this diet was used to facilitate the dissolution of established stones by bile acids. The bile acids were incorporated into the PD as follows: hyocholic acid, 0.1%, group 7c; β-muricholic acid, 0.1%, group 7d. Dissolution of established gallstones was not observed after administration of these diets for six weeks. Stone incidence in all groups ranged from 78–93%.

Table 3 summarizes the cholesterol levels in liver, plasma, and bile. In the prairie dog, both hydrophilic bile acids significantly reduced the cholesterol levels in liver and plasma compared to the LD (group 1, $P < 0.01$). Biliary cholesterol was reduced by β-muricholic acid (1.91 mg/mL) and hyocholic acid (2.91 mg/mL), but these differences were not statistically significant from the controls. In the hamster stone prevention study (groups 4–6), both hydrophilic bile acids significantly reduced liver and plasma cholesterol compared to the LD; hyocholic acid reduced the amount of biliary cholesterol (from 5.3 to 3.9 mg/mL), but this decrease was not significant. β-Muricholic acid did not reduce biliary cholesterol levels even though it completely abolished cholesterol gallstone formation. The gallstone dissolution study was carried out in two phases: induction (group 7a) and regression (groups 7b–7d). Hamsters fed the regression diets + bile acid for a period of six weeks had significantly lower levels of cholesterol in liver and plasma. Biliary cholesterol levels were reduced with 0.1% hyocholic acid in the diet (0.6 mg/mL) but not with β-muricholic acid (1.6 mg/mL). These changes in biliary cholesterol occurred in the absence of cholesterol gallstone dissolution (Table 2).

The biliary lipid composition is summarized in Table 4. In the prairie dog (groups 1–3), the mole% cholesterol in bile ranged from 2.2 (group 2, LD + hyocholic acid) to 5.8 (group 3, LD + β-muricholic acid); the incidence of cholesterol gallstones was similar in all groups. Total lipids (g/dL) were highest in prairie dogs fed LD + hyocholic acid (18.7 g/dL); this group had the lowest CSI (0.76). The highest CSI (1.52) was observed in prairie dogs given 0.1% β-muricholic acid; this group had the greatest incidence of gallstones. In the hamster stone prevention study, stone incidence correlated inversely with the CSI; animals in group 6 had the highest CSI (1.78), but gallstone incidence was 0%. Hamsters in the dissolution study had significant reductions in mole% cholesterol and CSI at the end of twelve weeks (group 7c, 0.5, and 0.11, respectively). These changes occurred in the absence of stone dissolution. Total biliary lipids were 12.2 g/dL in hamsters given the PD + hyocholic acid. This was significantly higher than in animals fed PD or PD + β-muricholic acid (6.4 and 6.3 g/dL, respectively). The CSIs for animals fed the hydrophilic bile acids also were calculated using the ursodeoxycholic acid correction described by Carey (24); these calculations could only be carried out when the total lipid concentration was between 5–15 g/dL. The CSI increased in all cases

TABLE 1
Weight, Food Intake, and Liver Weights of Animals[a]

Group/diet	Number of animals	Initial weight (g)	Final weight (g)	Liver weight (g)	Food intake (g/d)
Prairie dog—prevention

where the correction was applied. Presumably, the modified CSI for prairie dogs fed 0.1% hyocholic acid also would be above 1.0 if the bile acid correction were applicable.

The biliary bile acid composition is summarized in Table 5. Feeding hyocholic acid to prairie dogs resulted in a significant enrichment of this bile acid (11.9%) and its metabolite (murideoxycholic acid, 22.7%) in bile. Feeding hyocholic acid to the hamster resulted in a much smaller enrichment of this bile acid in bile (prevention study, group 5, 0.7%; dissolution study, group 7c, 3.6%). A significant portion of the hyocholic acid was 7-dehydroxylated to hyodeoxycholic acid (Sigma, St. Louis, MO) (prevention study, group 5, 46.8%; dissolution study, group 7c, 52.6%). Administration of β-muricholic acid (a bile acid not normally detected in prairie dog or hamster bile) resulted in an increase in the amount of this bile acid in all groups (group 3, 38.8%; group 6, 16.4%, and group 7d, 17.7%).

DISCUSSION

Interest in medical therapies of cholesterol cholelithiasis has recently been overshadowed by the development of laparoscopic cholecystectomy (26). Nevertheless, prevention of stone development and/or stone recurrence by pharmacologic or dietary means remains an important goal. Long-term bile acid therapy has been suggested to attain this objective, but this presents problems of cost and poor compliance. If cheaper, longer-acting bile acids should become available, ad-

ministration of such compounds for stone prevention might eventually be feasible.

Hydrophilic bile acids solubilize cholesterol in liquid crystals rather than in micelles, thus permitting bile to become supersaturated with cholesterol without the rapid formation of cholesterol monohydrate crystals (27–29). The present studies examined the cholelitholytic properties of two hydrophilic trihydroxy bile acids (hyocholic acid and β-muricholic acid), in two animal models. We studied (i) cholesterol gallstone prevention in the prairie dog and the hamster and (ii) dissolution of established gallstones in the hamster. Previous work had shown that other hydrophilic bile acids, hyodeoxycholic acid, and murideoxycholic acid prevented cholesterol stones in the prairie dog and in the hamster (12,13). Hyodeoxycholic acid was only marginally successful in dissolving cholesterol gallstones in the prairie dog (11). Cholesterol stones dissolved in the presence of supersaturated bile, suggesting that cholesterol was solubilized in liquid crystalline vesicles (27–30). Hyodeoxycholic acid is not useful in humans because it is glucuronidated and lost from the enterohepatic circulation *via* urinary excretion (15). Murideoxycholic acid likewise must be used with great caution because in the presence of cholesterol stones it precipitates as the insoluble calcium/sodium salt (31).

There is some prior evidence that hyocholic and β-muricholic acids may be potentially useful as litholytic agents. Hyocholic acid dissolved cholesterol gallstones in a mouse model of cholesterol cholelithiasis; the stones dissolved almost completely with the addition of 0.1 or 0.3% hyocholic acid to a standard pellet diet (18). The mouse model is probably less suitable to study the preventive effects of hydrophilic bile acids since stone induction requires large amounts of dietary cholesterol (1.0%) plus cholic acid (0.5%) (32,33). The presence of cholic acid confounds the interpretation of results produced by added hydrophilic bile acids. β-Muricholic acid dissolved cholesterol gallstones *in vitro* at physiological concentrations *via* the formation of multilamellar liquid crystals (14).

The effectiveness of the hydrophilic bile acids for stone prevention was different in our two animal models. In the Sasco hamster, both hyocholic acid and β-muricholic acid prevented the formation of cholesterol gallstones, while in the prairie dog they were ineffective. This result is difficult to understand in terms of the observed liver and plasma cholesterol concentrations; both hydrophilic bile acids significantly reduced the accumulation of the exogenous cholesterol in liver and plasma. Hydrophilic bile acids were reported to reduce cholesterol absorption from the gut because they were poor

micelle formers (34). A previous study in hamsters using another hydrophilic bile acid (3α,6β-dihydroxy-6α-methyl-5β-cholanoic acid) indicated that gallstones can be completely prevented (0/11) even though biliary bile acid enrichment was quite low (enrichment of fed bile acid = 4.1%) (13). It thus appears that the percentage of enrichment of the administered bile acid does not necessarily correlate with gallstone prevention.

In a previous study in the prairie dog, the hydrophilic bile acid, hyodeoxycholic acid, prevented cholesterol cholelithiasis (12). We anticipated that β-muricholic acid and hyocholic acid would behave similarly in this model. However, this may not have taken place because the amounts (mg/mL) of 3,6-dihydroxy, hydrophilic bile acids were not sufficiently elevated with either hyocholic acid (hyodeoxycholic acid + murideoxycholic acid = 51%) and with β-muricholic acid (hyodeoxycholic acid + murideoxycholic acid = 41.6%) (12). The present study is not strictly comparable to previous work with 6-hydroxy bile acids in the prairie dog (12). In the earlier experiments, the LD was prepared with soy protein and contained no butterfat. The diet used in the present study was identical for prairie dogs and hamsters and contained butterfat and casein (in place of soy protein). It seems possible that the butterfat/casein diet provided an enhanced lithogenic stimulus which reduced the cholelitholytic effect of the exogenous bile acids.

Dissolution of preestablished cholesterol gallstones was studied in the hamster. Spontaneous dissolution did not occur in six weeks when a cholesterol-free, PD was substituted for the LD. Addition of 0.1% of the hydrophilic bile acids, hyocholic acid, or β-muricholic acid to the diet did not induce dissolution. In all of the regression groups (7b–d), the LIs of bile were less than unity with the greatest decrease observed in hamsters fed hyocholic acid. The failure of the cholesterol stones to dissolve in the presence of unsaturated bile was unexpected. A combination of longer regression times (twelve weeks) plus administration of increased doses of bile acid might give better results, but this was not attempted in the present study because of the limited amounts of bile acids available. Presumably, the stones did not dissolve because the rate of equilibration between the biliary cholesterol monohydrate crystals and the desaturated bile was too slow. Other factors which might also be involved include gallbladder motility, mucin production, and nucleating proteins.

In conclusion, it was demonstrated that certain hydrophilic bile acids, namely hyocholic acid and β-muricholic acid, prevent gallstones in the hamster model, but not in the prairie dog model of cholesterol cholelithiasis. Dissolution of established cholesterol stones was not achieved in the hamster model.

ABSTRACT: Conjugated bile acid hydrolase (CBAH) refers to a class of enzymes which catalyze the cleavage of the amino acid moieties from conjugated bile acids. These enzymes are significant because of their role in providing substrates for further microbial metabolism in the gastrointestinal tract. They also are used in research laboratories for the deconjugation of bile acids prior to structural analyses. A continuous spectrophotometric assay for CBAH activity was developed using a conjugate of cholic acid and the chromophore, 5-amino-2-nitro-benzoic acid. The free chromophore is detected by virtue of its absorbance at 410 nm. The CBAH from *Clostridium perfringens* displayed a K_m for this substrate of 120 μM. These results demonstrate that this new compound functions as an effective substrate of the enzyme and forms the basis for a convenient and rapid method to monitor CBAH activity.
Lipids 30, 863–867 (1995).

Mammalian bile acids are C-24 steroid carboxylic acid molecules which are synthesized in the liver as free bile acids (FBAs) and then conjugated to either glycine or taurine *via* an amide bond. These conjugated bile acids (CBAs) are then released into the small intestine where they act primarily as emulsifiers of dietary lipid. Several genera of intestinal bacteria produce conjugated bile acid hydrolases (CBAHs) which cleave the amino acid moieties from CBAs. The resulting FBAs are less efficiently recycled by the enterohepatic circulation (1,2) and may be converted by further microbial action into potentially toxic bile acids (3,4). Because of the role CBAH plays in the metabolism of native and therapeutic bile acids in the body (5–8), our laboratory is pursuing biochemical studies of the CBAH reaction.

The CBAHs are a heterogenous group of enzymes having varied requirements for their CBA substrates. CBAHs from various bacterial sources have been shown to differ in their preferences for the amino acid moiety as well as for the hydroxyl group orientations on the steroid nucleus (9–13). The substrate specificity of the CBAH from *Clostridium perfringens* has been investigated by Batta *et al.* (14) and by Huijghebaert and Hofmann (15). The latter studies demonstrated that, although the rates and extent of hydrolysis varied according to the length of the side chain, the presence or absence of a negative charge, and steric hindrance around the amide bond, most substrates tested were hydrolyzed to some degree. Maeda *et al.* (16) used a conjugate of ursodeoxycholic acid and para-aminobenzoic acid to detect bacterial growth in the intestine. Initial experiments demonstrated that all individual bacterial strains tested which were capable of deconjugating glycocholic acid could also hydrolyze this synthetic conjugate. A notable exception to this general nonspecificity is the observation that amino acid conjugates of bile acids with longer side chains, such as those found in lower vertebrates and in humans with metabolic disorders, were not hydrolyzed by commercially available *C. perfringens* CBAH (17). For studies requiring the characterization of these longer side-chain bile acids, many of which are destroyed by alkaline hydrolysis, it would be advantageous to identify and make available CBAHs capable of hydrolyzing these conjugates.

One of the difficulties in performing screening and enzymatic studies with CBAH is that the current assay methods are time-consuming, all relying on end point (discontinuous) type assays. These assays are primarily based on the measurement of released free amino groups, most commonly by reaction of a deproteinated aliquot of the enzymatic reaction mix with either ninhydrin (12) or trinitrobenzenesulfonic acid (TNBS) (9). One potential problem with these amine reactive agents is the nonspecific nature of the reaction, prohibiting or complicating measurements in buffers containing amines and, in the case of TNBS, sulfhydryl groups. Yet another method uses radiolabelled substrate to detect activity (18). In addition to also being a discontinuous assay, this method is often impractical because of the limited number of radiolabelled CBAs available.

The CBAHs from *Lactobacillus plantarum* (19) and *C. perfringens* (20) have recently been cloned and sequenced and are homologous to a *Bacillus sphaericus* penicillin-V amidase (PVA) (21). The PVAs are industrially important enzymes, which, like the CBAHs, catalyze the hydrolysis of the amide bond of its substrate, in this case penicillin-V. In an ef-

fort to facilitate the detection and measurement of the PVA reaction, Kerr (22) recently reported the successful use of a conjugate of phenoxyacetic acid and 5-amino-2-nitro-benzoic acid (ANBA) in a spectrophotometric assay for PVA activity. This suggested to us that a substrate consisting of a conjugate of ANBA with a bile acid might similarly be used to measure the CBAH reaction. This report describes the synthesis of a conjugate of cholic acid (CA) and ANBA and a demonstration of its use in a continuous spectrophotometric assay to monitor CBAH activity.

EXPERIMENTAL PROCEDURES

Chemicals and enzymes. Clostridium perfringens CBAH (cholylglycine hydrolase), carboxypeptidase A, carboxypeptidase B, pancreatin, proteinase K, pronase E, and CA were purchased from Sigma Chemical Company (St. Louis, MO). Trypsin (TPCK-treated) was from Worthington Biochemical Corp. (Freehold, NJ). CA was filtered through celite/charcoal and recrystallized from ethanol–water until pure as judged by thin-layer chromatography (TLC). ANBA was purchased from TCI America (Portland, OR) and was recrystallized once from water before use. Ethylchloroformate and tri-*n*-butyl amine were purchased from Aldrich Chemical Company (Milwaukee, WI). Bulk chemicals and organic solvents were either purchased from Aldrich or from Fisher Chemical Company (Raleigh, NC) and were laboratory-grade. Machery-Nagel 0.25 mm thickness, silica gel-G TLC plates with ultraviolet (UV) indicator, were purchased from Alltech Associates, Incorporated (Deerfield, IL).

Analytical. Infrared spectra were determined as potassium bromide disks on a Perkin-Elmer 1605 infrared spectrophotometer (Perkin-Elmer Corp., Norwalk, CT). Absorbances are given as reciprocal centimeters (cm^{-1}). Proton nuclear magnetic resonance spectra were determined on a Varian-Gemini 200 MHz NMR spectrophotometer (Varian Analytical Instruments, Fernando, CA). Chemical shifts are given as parts per million (ppm) relative to tetramethylsilane, which was used as an internal standard.

Synthesis of CA–ANBA. The CA conjugate of ANBA was synthesized using a modification of the procedure used by Maeda *et al.* (16) to synthesize the para-aminobenzoic acid conjugate of ursodeoxycholic acid.

In a 50-mL round bottom flask equipped with a thermometer and a magnetic stirring bar, 0.82 g (2 mmol) CA was dissolved in 6 mL dioxane containing 0.48 mL (2 mmol) tri-*n*-butylamine. This solution was chilled to 8°C, and 0.20 mL (2.1 mmol) ethylchloroformate was added. The mixture was stirred at the same temperature for 15 min, and 0.37 g (2 mmol) ANBA in 2.0 mL 1 M NaOH was added to the vigorously stirring solution. After 20 min, the reaction was stopped by adding 40 mL deionized water, and the solution was acidified with 2 M HCl. The mixture was transferred to a 500-mL separatory funnel and extracted three times with 60-mL portions of ethyl acetate. The organic phases were pooled, washed with deionized water until neutral, dried over sodium sulfate, and evaporated under reduced pressure to yield a deep amber residue. CA–ANBA was separated from unreacted CA and free ANBA by dry column chromatography, using a nylon tube packed with silica gel (63–200 μM; 55 cm × 2.54 cm; Alltech) and developed with chloroform/methanol/acetic acid (8:1:1, by vol). After visualization under UV light, the region containing CA–ANBA was cut out of the column, eluted from the silica gel with 100% methanol, and the methanol evaporated to leave 200 mg light-tan powder. This material was dissolved in a small volume of ethyl acetate and washed once with 0.1 N HCl and several times with water. The organic layer was then evaporated under reduced pressure. This material was then used for melting point determinations, TLC analyses and kinetic studies. The structure of CA–ANBA is shown in Figure 1. Yield 26%. m.p. = 161–164°C. Infrared, cm^{-1}: 3327 (OH), 1703 (C=O, *CO*OH), 1697 (C=O, *CO*NH), 1550/1517, (NO_2). Proton nuclear magnetic resonance spectra (d_6-DMSO): 10.56 (*s*, 1H, COO*H*), 7.95 (*m*, 3H, aromatic), 4.35 (*bs*, 1H, CHO*H*-12), 4.15 (*d*, 1H, CHO*H*-7), 3.82 (*s*, 1H, C*H*OH-12), 3.62 (*s*, 1H, C*H*OH-7), 3.35 (*m*, 1H, C*H*OH-3), 3.18 (*s*, 1H, N*H*), 0.99 (*d*, $J = 5.6$ Hz, 3H, Me-21), 0.81 (*s*, 3H, Me-19), 0.60 (*s*, 3H, Me-18).

The purity of the CA–ANBA preparation was determined *via* TLC using the same solvent system as for the dry column

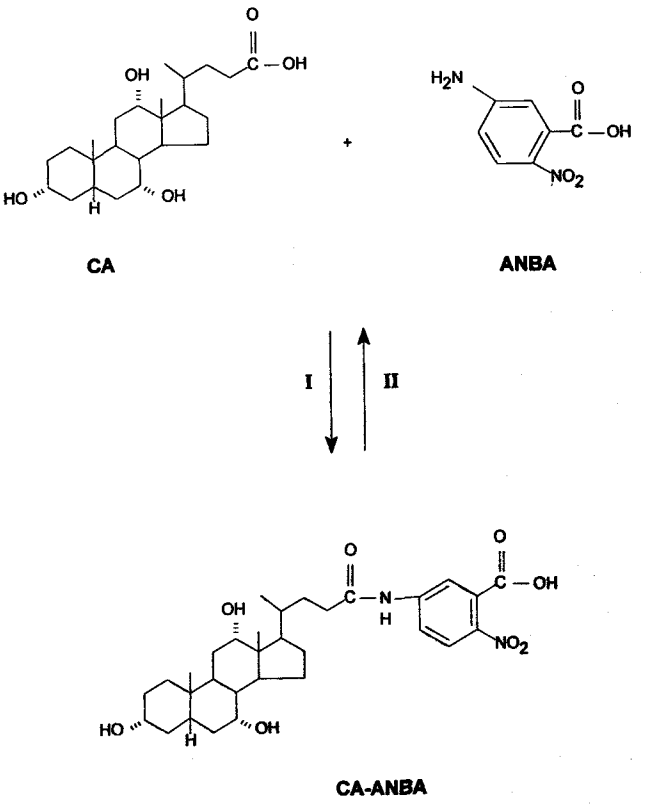

FIG. 1. Chemical synthesis and enzymatic hydrolysis of CA–ANBA. Pathway I, cholic acid (CA) and 5-amino-2-nitro-benzoic acid (ANBA) are conjugated *via* an amide bond in a reaction containing ethylchloroformate and tri-*n*-butlyamine in dioxane. Pathway II, hydrolysis of the product, CA–ANBA, by the enzyme, conjugated bile acid hydrolase.

chromatography. Free ANBA and its conjugate appeared as dark spots under short-wave UV light. CA and CA–ANBA were further visualized by spraying the plates with a 4% ethanolic solution of phosphomolybdic acid, then heating at 110°C for 10 min.

Spectrophotometric studies. All spectrophotometric assays were performed at 37°C on a Beckman DU-65 spectrophotometer (Beckman Instruments, Inc., Fullerton, CA) equipped with a thermojacketted cuvette apparatus. Stock cholylglycine hydrolase was prepared according to the manufacturers instructions, to a concentration of 1000 units/mL (based on Sigma assay). Ninhydrin-based assays were performed according to the Sigma procedure. A unit of enzyme is defined by its rate of hydrolysis of glycocholic acid, since that amount hydrolyzes 1 μmol of glycocholic acid in 5 min at 37°C, pH 5.6. For the continuous assay, a stock solution of CA–ANBA (10 mM; theoretical molecular weight = 572.70) was prepared in 25 mM potassium phosphate buffer, pH 6.0. All reactions were carried out in 1 mL polystyrene cuvettes and contained, in a final volume of 1 mL: 5 μmol sodium phosphate, pH 5.6; 1 μmol EDTA; 1 μmol 2-mercaptoethanol; 0.5 μmol CA–ANBA; and enzyme. Reactions were initiated by the addition of enzyme to final concentrations ranging from 1.0 to 10.0 U per mL. The progress of these reactions was followed for 10 min at 410 nm. From these experiments, a concentration of 5 U/mL CBAH was chosen for subsequent kinetic studies. The initial velocity of hydrolysis of CA–ANBA at 10, 25, 50, 100, 200, 500, 750, and 1000 μM was measured. K_m values were calculated from these data.

The stability of stock solutions of CA–ANBA was assessed by incubating aliquots of the 10 mM CA–ANBA stock solution (prepared as described above and filter sterilized through a 0.2 μM filter) at 25°C under either light (fluorescent room lighting) or dark conditions and by monitoring the absorbance daily at 410 nm. The sensitivity of CA–ANBA to hydrolysis by other enzymes was assessed by monitoring the absorbance of solutions of CA–ANBA (0.5 mM) in 20 mM sodium phosphate, 150 mM sodium chloride, pH 7.0 containing either of the following enzymes at the indicated concentrations: carboxypeptidase A 15 U/mL), carboxypeptidase B (15 U/mL), pancreatin (1 mg/mL), trypsin (200 U/mL), pronase E (15 units/mL), and proteinase K (20 U/mL).

RESULTS AND DISCUSSION

Synthesis. The synthesis of CA–ANBA was accomplished by using a procedure initially used to synthesize glycine or taurine CBAs (16,23). The crude material obtained after acidification and extraction of the reaction mixture was found to have several unknown products of varying polarity. These were removed along with the unreacted ANBA and CA remaining in the mixture by dry column chromatography. The TLC R_f values for CA, free ANBA, and CA–ANBA were 0.33, 0.52, and 0.16, respectively. There was no contamination of the final product with either CA or free ANBA. Although we did not attempt to further optimize yields, it is possible that they could be improved by first protecting the bile acid hydroxy groups by formylation prior to reaction with ethylchloroformate.

Spectral properties. UV scans of CA–ANBA and ANBA showed maximum absorbances of 312 and 387 nm, respectively, with full resolution of the conjugate peak from the free ANBA peak at 410 nm. At this wavelength, the extinction coefficient of ANBA is 7180 M^{-1}. This extinction coefficient is of a magnitude sufficient to allow CBAH assay sensitivity similar to that of the ninhydrin- or TNBS-based assays. The trinitrophenyl derivatives of amino acids (amino acid–TNBS product) have extinction coefficients of approximately 20,000 M^{-1} (24), while the product of the ninhydrin reaction, diketohydrindylidenediketohydrindamine, has an extinction coefficient in its pure form of 22,000 M^{-1} (25). However, for ninhydrin-based assays, the color yield varies with reaction conditions and buffer composition. The typical standard curve for an amino acid such as glycine in the assay used by our laboratory correlates to an extinction coefficient of approximately 9,000 M^{-1} (26).

Enzyme kinetics. The rate of hydrolysis of 500 μM CA–ANBA by varying amounts of CBAH was followed for a period of 10 min (Fig. 2). The initial rate of hydrolysis of CA–ANBA to free ANBA increased linearly (r = 0.999) with increasing amounts of CBAH (Fig. 2, inset). When corrected for the time factor of the standard unit definition (1 unit hydrolyzes 1 μmol glycocholic acid in 5 min), the observed rate of absorbance change per unit of enzyme was 0.089 (5 min)$^{-1}$ U^{-1}, which corresponds to an ANBA formation rate of 12.5 nmol (5 min)$^{-1}$ U^{-1}. Thus, the relative velocity for hydrolysis of CA–ANBA was approximately 80-fold lower than that for hydrolysis of glycocholic acid.

Changing the substrate concentration with the amount of CBAH held constant provided rate measurements which

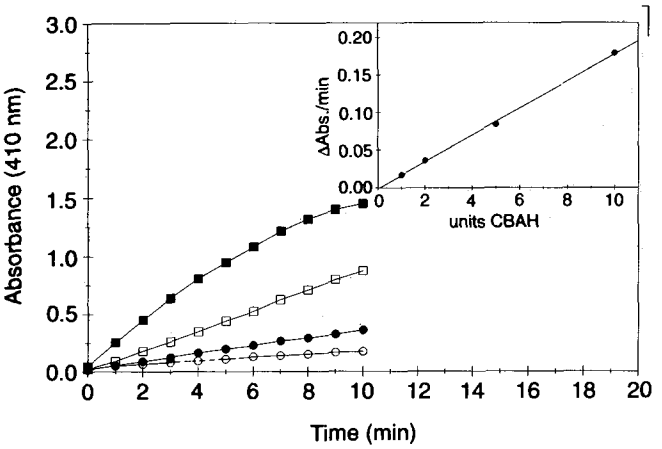

FIG. 2. Time course of hydrolysis of CA–ANBA. In a final reaction volume of 1 mL, CA–ANBA (500 μM) was incubated with increasing amounts of conjugated bile acid hydrolase (CBAH) as follows: 1 U/mL (○); 2 U/mL (●); 5 U/mL (□); and 10 U/mL (■). Inset: Regression analysis of the change in absorbance (Abs.) vs. units CBAH, calculated from the initial velocities of the hydrolysis of CA–ANBA. See Figure 1 for other abbreviations.

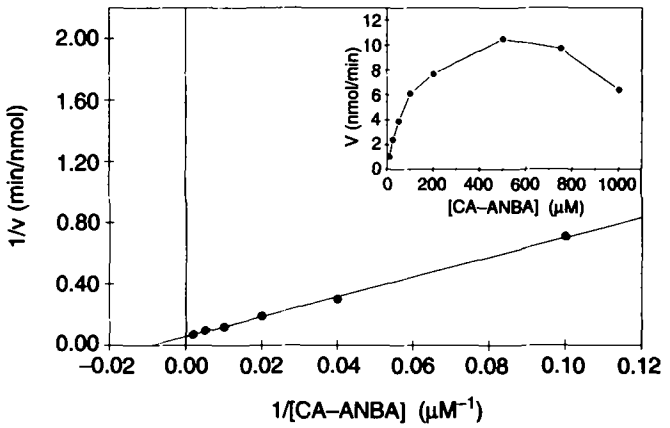

FIG. 3. Kinetic analysis of the hydrolysis of CA–ANBA by CBAH. Lineweaver-Burk plot using the data from 10–500 μM CA–ANBA. K_m = 120 μM. Inset: Michaelis-Menten plot of increasing velocity with constant CBAH concentration and 10, 25, 50, 100, 200, 500, 750, and 1000 μM CA–ANBA. Substrate inhibition occurs above 500 μM. See Figures 1 and 2 for abbreviations.

could be fitted to a classical Michaelis-Menten curve, with saturation of the enzyme and inhibition observed above 500 μM CA–ANBA (Fig. 3, inset). Double-reciprocal plots of the data (10–500 μM) yielded a straight line (r = 0.999) and a K_m value of 120 μM (Fig. 3). Previously reported K_m values of *C. perfringens* CBAHs for glycocholic acid range from 0.5 (9) to 8.0 mM (12). A visual comparison of reaction mixes at time zero and after the course of the reaction showed a distinct yellow color in the completed reaction, whereas the zero time point mixes appeared clear. Thus, this assay also can be used as a basic for a qualitative assessment of the presence of CBAH activity.

Stability to other enzymes and spontaneous hydrolysis. Neither carboxypeptidase A, carboxypeptidase B, crude pancreatin, trypsin, pronase E, nor proteinase K were active in hydrolyzing the amide bond of CA–ANBA. The chromogenic compound therefore appears to be similar to a normal CBA in its resistance to degradation by common proteolytic enzymes (15,27).

Spectrophotometric monitoring of CA–ANBA stock solutions over time indicated that they were relatively stable, showing less than 0.2% decomposition after two weeks under either light or dark storage conditions. Extrapolations from the data obtained over the two-week period indicated that the half life of buffered 10 mM solutions of CA–ANBA was greater than five years.

SUMMARY

The current methods of measuring CBAH activity are time-consuming, requiring a multiple-step procedure to detect the product. During the course of these experiments, it was shown that CA–ANBA was recognized with high affinity as a substrate for the *C. perfringens* CBAH. While the relative hydrolysis rate of CA–ANBA was 80-fold lower than that for glycocholic acid, the reaction produced an easily detectable product even at low concentrations of enzyme and substrate. CBAs are capable of deconjugating CBA substrates conjugated with a variety of moieties, even though with different degrees of efficiency. The results of Maeda *et al.* (16), which demonstrated that intestinal bacteria with CBAH activity could hydrolyze *p*-aminobenzoic acid conjugates of bile acids as well as natural CBA substrates, imply that the structurally related ANBA conjugates also may be generally susceptible to cleavage by these CBAHs. If this proves to be the case, conjugates of ANBA with CA, as well as other bile acids, will be useful substrates for studying the enzymology of CBAHs from a wide variety of bacterial sources. Since the free ANBA product absorbs in the visible region and thus can be monitored visually, the CA–ANBA conjugates reported here may also be useful as a rapid screening tool for the detection of microorganisms possessing CBA deconjugating activity. Kinetic and inhibitor studies can be performed by following CA–ANBA hydrolysis in the presence of natural bile acids or potential inhibitors. In this manner, relative affinities of various compounds for the CBAH can quickly be determined by virtue of their potential to compete with CA–ANBA for CBAH binding. Finally, the conjugation of bile acids or related molecules with ANBA may be generally applicable to the identification and characterization of hydrolases with altered substrate specificities.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Edson Rocha and Ho Young Kang for their helpful discussions and comments and Drs. Richard Marks and Art Rodriguez for valuable advice and critical review of the manuscript.

ABSTRACT: The study of triglyceride (TG) metabolism using stable isotope tracers would be facilitated by being able to detect low ^{13}C enrichment. To meet this goal, we developed a gas chromatography/isotope ratio-mass spectrometry technique to measure the enrichment of palmitate in nonesterified fatty acids (NEFA) and TG as its methyl derivative. This method allows accurate and reproducible measurements of enrichment as low as 0.009 mole percent excess (MPE), in a range between 0–0.65 MPE. The usefulness of this method is shown by two studies of lipid metabolism in human beings. First, we studied the metabolic fate of an oral TG load labeled with [1,1,1-$^{13}C_3$]tripalmitin. Labeled palmitate appeared concurrently in plasma NEFA and TG, and four hours after the load, the labeling was higher in NEFA than in TG (MPE NEFA: 1.53 ± 0.31 vs. MPE TG: 0.78 ± 0.06, $P < 0.05$). In a second study, the hepatic reesterification of NEFA was estimated by measuring the appearance of infused [1-^{13}C]palmitate in circulating TG. The estimated contribution of plasma NEFA to circulating TG increased to a maximum of 22%. Thus, gas chromatography/isotope ratio-mass spectrometry appears to be a useful tool for future studies of lipid metabolism in humans.
Lipids 30, 869–873 (1995).

Stable isotope tracers are being increasingly used for studies of lipid metabolism in humans (1,2). Measurements of the isotopic enrichment (IE) of plasma lipids are generally performed using gas chromatography/mass spectrometry/selected ion monitoring techniques (GC/MS/SIM). However, relatively high IE levels (1 mol%) are required to achieve accurate and reproducible measurements with GC/MS/SIM (1). Moreover, the study of some specific aspects of lipid metabolism requires the detection of low IE, because of the occurrence of an important dilution of the label during the metabolic process. This is the case for the determination of the metabolic fate of orally ingested triglycerides (TG) or the contribution of hepatic reesterification of plasma nonesterified fatty acids (NEFA) to TG secretion. The metabolic fate of ingested lipids has been studied with the vitamin A fat-loading test (3). This method allows investigators to study the metabolism of exogenous TG-rich lipoproteins, but not to trace the fate of the exogenous fatty acids themselves. Some studies have used a fat load labeled with radioactive tracers (4,5), but studies with stable isotopes require the ability to detect low IE in the fatty acids of the various circulating lipids. The contribution of the hepatic reesterification of NEFA to TG secretion has been addressed in one study using ^{14}C labeled fatty acids (6). To perform such studies with ^{13}C labeled fatty acids infusion, low IE should be measured in TG. Thus, to carry out these investigations and to avoid the use of an excessive amount of tracers, there is a need for a method that allows an accurate determination of low IE.

The development of a gas chromatography/isotope ratio-mass spectrometer (GC/IR-MS) (7,8) provides an attractive alternative to GC/MS/SIM. This technique has been shown to allow accurate determination of low IE levels in various metabolites such as glucose (8), lactate (9), and urea (10). Recently, using U ^{13}C labeled tracers in one human subject, Goodman and Brenna (11) were able to follow the appearance of orally ingested stearic acid in various lipoproteins fractions. Metges *et al.* (12) compared the enrichment of TG after ingestion of [1-^{13}C] or [8-^{13}C] triolein, and Brossard *et al.* (13) studied the compartmental metabolism of orally administered ^{13}C labeled docosahexaenoic acid in rats.

We report here that GC/IR-MS allows the determination of very low ^{13}C IE of fatty acids, using [1,1,1-$^{13}C_3$]tripalmitin or [1-^{13}C]palmitate as tracers. To demonstrate the usefulness of this method for *in vivo* human studies, two applications have been developed: (i) the metabolic fate of a triglyceride oral load labeled with [1,1,1-$^{13}C_3$]tripalmitin was investigated by the appearance of labeled palmitate in circulating NEFA and TG; and (ii) the hepatic reesterification of intravenously infused [1-^{13}C] palmitate was estimated from the appearance of labeled palmitate in TG.

MATERIALS AND METHODS

Material. [1,1,1-$^{13}C_3$]tripalmitin (99 atom% ^{13}C) and [1-^{13}C]palmitic acid (99 atom%,^{13} C) were purchased from Eurisotop (Saint Aubin, France). Chemical and isotopic purity were confirmed by GC/MS analysis. Pure, nonlabeled palmitate was obtained from Sigma (St. Louis, MO). Thin-layer chromatography (TLC) was performed on 60 G silica gel plates (Merck, Darmstadt, Germany). All solvents were from Merck. Boron trifluoride methanol (Sigma) was used for fatty acid methyl ester preparations.

Preparation of tracers. The addition of [1,1,1-$^{13}C_3$] tripalmitin to the sunflower oil was realized at 60°C in order to solubilize the tripalmitin, and the mixture was carefully homogenized. An aliquot of the labeled oil was collected to verify its enrichment.

[1-^{13}C]Palmitate was bound to human serum albumin (Mérieux, Lyon, France) as previously described (1). All infusates were checked for pyrogen by Limulus test before administration, and were infused through a 0.22 µm Millipore filter (Millipore, Bedford, MA).

Subjects. The appearance of [1-^{13}C]palmitate in circulating NEFA and TG, after the ingestion of a TG load labeled with [1,1,1-$^{13}C_3$]tripalmitin, was evaluated in six healthy subjects (five women and one man), aged 21–29 yr (mean 24 yr) with a body mass index (BMI) ranging from 19 to 24 (mean 21) kg/m^2.

During [1-^{13}C]palmitate infusion, the reesterification of NEFA was determined in four other subjects: three men and a woman aged 22–30 yr, mean 26 yr with a BMI ranging from 20 to 22 (mean 21) kg/m^2.

All subjects gave their written consent to the study after being informed of its nature, purpose, and possible risks. The experimental protocols were approved by the local ethics committee.

Experimental protocols. All tests were performed in the post absorptive state.

Appearance of [1-^{13}C]palmitate in circulating NEFA and TG after the ingestion of a TG load labeled with [1,1,1-$^{13}C_3$]-tripalmitin. On the morning of the test, an in-dwelling, nonheparinized catheter was placed into one forearm vein for blood sampling. After 30 min of bed rest and the collection of three basal samples, 30 g of sunflower oil enriched with 300 mg of [1,1,1-$^{13}C_3$]tripalmitin were ingested during five minutes. Blood was collected in tubes maintained at 4°C at 10, 20, and 30 min, and then every 30 min until 480 min.

Reesterification of NEFA in circulating TG. On the morning of the test, in-dwelling catheters were placed into a vein of one forearm, for [1-^{13}C]palmitate infusion, and in a vein in the opposite, for blood sampling. To obtain arterialized blood samples, this last catheter was placed in a retrograde manner and kept at 60°C in a warming blanket. Albumin bound [1-^{13}C]palmitate was infused at the rate of 0.04 µmol/kg/min after a bolus of 0.4 µmol/kg. This infusion lasted for 150 min. Blood samples were collected at 120 and 150 min in tubes kept at 4°C.

All blood samples were immediately centrifuged after collection, and plasma was stored at −20°C until the determination of metabolites, insulin concentrations, and IE of palmitate in circulating NEFA and TG.

Analytical procedures. Plasma glucose (14), NEFA (15), and TG (16) concentrations were measured by enzymatic methods. Plasma insulin was measured by radioimmunoassay (17). Total lipids were extracted from plasma according to Folch *et al.* (18) using methanol/chloroform (1:2, vol/vol). NEFA (R_f 0.22) and TG (R_f 0.5) were separated by TLC on 60 G silica gel plates using hexane/diethyl ether/acetic acid (80:20:1 by vol) as mobile phase (19). NEFA and TG were scraped off the plate and then treated with heptane/methanol (1:1, vol/vol) and 14% boron trifluoride in methanol at 100°C for 30 min for fatty acid methyl ester preparation (20).

GC/IR-MS analysis. Analyses were performed using an isotope ratio mass spectrometer (SIRA 12; VG Isogas, Middlewitch, United Kingdom) interfaced with a gas chromatograph (5890A; Hewlett-Packard, Evry, France) equipped with a Ross injector (230°C) and a capillary column (OV-1701, 0.25 mm i.d. × 25 m; Chrompack, Bridgewater, NJ). Oven temperature was maintained at 180°C for 3 min and then raised at 20°C/min to 230°C, where it was maintained for 5 min. Helium was used as carrier gas (injector inlet pressure, 13 psi). The gas chromatograph effluent was diverted to a flame-ionization detector until the elution of methyl palmitate. It was then switched inside a catalytic furnace (0.5-mm) filled with CuO and maintained at 800°C. The effluent of the furnace containing CO_2 and H_2O, flowing in the continuous helium flux, was driven into a water trap maintained at −100°C before its ionization by electron impact in the source of the IR-MS. Description of the GC/IR-MS has been given previously (8). Ions at *m/z* 44, 45, and 46 were continuously recorded until the return of the 44 signal to baseline value. Before and after the CO_2 peak arising from methyl palmitate, a standard CO_2 of known enrichment, calibrated vs. the international standard Pee Dee Belemnite (PDB), was automatically introduced into the spectrometer.

Calculations. The $^{13}C/^{12}C$ ratio of the sample and of the reference were used to calculate the ∂ per 1000 value (∂‰ ^{13}C) of the sample using the following formula:

$$\partial^{13}C‰ = \frac{(^{13}C/^{12}C)\text{sample} - (^{13}C/^{12}C)\text{ reference}}{(^{13}C/^{12}C)\text{ reference}} \times 1000 \quad [1]$$

where the reference is the international standard PDB.

The measured ∂‰ ^{13}C was transformed to ^{13}C atom % (AP) using the following formula:

$$AP = \frac{R \times [(0.001\ \partial^{13}Cs‰) + 1]}{1 + [R \times ((0.001\ \partial^{13}Cs‰) + 1)]} \times 100 \quad [2]$$

where R is the $^{13}C/^{12}C$ ratio of the international standard PDB

(R = 0.0112372) and ∂‰ ^{13}Cs, the ∂‰ ^{13}C value of the sample. The calculated AP of the palmitate in the labeled oil and in the plasma NEFA and TG were transformed into atom % excess (APE) using the following formula:

$$APE = APs - APb \quad [3]$$

where APs is the AP of the sample and APb is the AP of the plasma palmitate in the basal state.

^{13}C Enrichment of palmitate can be calculated from the measured ∂‰ either using a standard curve or the APE formula. However, it has to be taken into account that ∂ ^{13}C values measured on derivatized compounds are different from those of the respective underivatized molecules, and that there is only one ^{13}C carbon atom per molecule. The APE measured (APE m) could be thus converted to mole % excess (MPE) according to Khalfallah *et al.* (9): MPE = 17 APE (17 = number of carbon atoms of the derivatized molecule).

During the TG load study, the proportion of palmitate from exogenous origin found in circulating TG was determined at each time point as:

$$(MPE\ pp/MPE\ ip) \times 100 \quad [4]$$

where MPE pp is the MPE of palmitate in circulating plasma TG and MPE ip is the MPE of palmitate in the ingested triglycerides.

During the infusion of [1-^{13}C]palmitate, the percentage enrichment in TG relative to NEFA was determined after the measurement of the appearance of [1-^{13}C]palmitate in TG as:

$$= (MPE\ TG/MPE\ NEFA) \times 100 \quad [5]$$

where MPE TG is the value of the MPE of palmitate in plasma TG and MPE NEFA is the value of MPE of palmitate in plasma NEFA.

Palmitate flux was determined using steady-state equation:

$$F = (I/MR) - I \quad [6]$$

where *I* is the palmitate infusion rate (μmol/kg/min) and MR the molar ratio between ^{13}C palmitate and natural palmitate in plasma NEFA (mean value between 120 and 150 min).

Results are expressed as mean ± SEM. Comparisons were realized using the paired *t*-test or the nonparametric U test of Mann-Whitney when necessary.

RESULTS

In vitro *validation.* Natural ^{13}C abundance was measured on pure, commercially available methyl palmitate and on palmitate purified from plasma samples. Analyses were performed on 100–300 ng of methyl palmitate that gave a signal of similar intensity to the CO_2 standard. The sensitivity of the method allows one to utilize blood samples of small volume, as the treatment of 500 μL of blood permits 30 injections or more.

∂^{13}C‰ values were −28.4 ± 0.1 for pure methyl palmitate (Sigma) and −25.4 ± 0.4 and −25.8 ± 0.3 (NS) for methyl palmitate in human plasma NEFA and TG, respectively (mean of 12 samples) ($P < 0.001$ for methyl palmitate in NEFA or TG vs. methyl palmitate from Sigma). Interassay variation of ∂ ^{13}C‰ values obtained on pure methyl palmitate was tested by three daily injections over two weeks, and was 0.7% (∂^{13}C‰ mean ± SD −28.62 ± 0.20). The intraassay variability tested on ten successive injections was 0.5% (∂ ^{13}C‰ mean ± SD −28.59 ± 0.14).

Figure 1 shows a representative standard curve of [1-^{13}C]-palmitate diluted in natural palmitate (Sigma) obtained by GC/IR-MS analysis. The standard curve was linear from 0 to 0.65 MPE of [1-^{13}C]palmitate (r = 0.999, $P < 0.00001$) (Fig. 2A), including the part with low enrichment values (Fig. 1) (r = 0.999, $P < 0.00001$). With this technique, differences of 0.5 ∂ ^{13}C‰ = 0.009 MPE of [1-^{13}C]palmitate could be observed ($P < 0.005$, mean of three injections). No carryover of the high ^{13}C enrichment into low MPE samples was observed.

A strong correlation between MPE calculated from the above formula and MPE st deduced from the standard curve: $MPE_{st} = 1.01\ MPE_{th} + 0.009$ (r = 0.9999, $P < 0.0001$) was observed. Calculation of MPE gives results similar to those obtained using the standard curve, and thus, results could be expressed in MPE and the daily standard curve analysis avoided.

In vivo *studies. Appearance of [1-^{13}C]palmitate in circulating TG and NEFA after ingestion of a [1,1,1-$^{13}C_3$]tripalmitin labeled oil.* Figure 2 shows the evolution of TG and NEFA concentrations and the appearance of [1-^{13}C]palmitate in plasma TG and NEFA after the ingestion of [1,1,1-$^{13}C_3$]-tripalmitin labeled oil. Plasma TG concentration did not increase during the study, but a trend to an increase of NEFA concentration was observed six hours after the labeled TG load (Fig. 2A). No significant increase in insulinemia was observed (data not shown). [1-^{13}C]Palmitate appeared in plasma

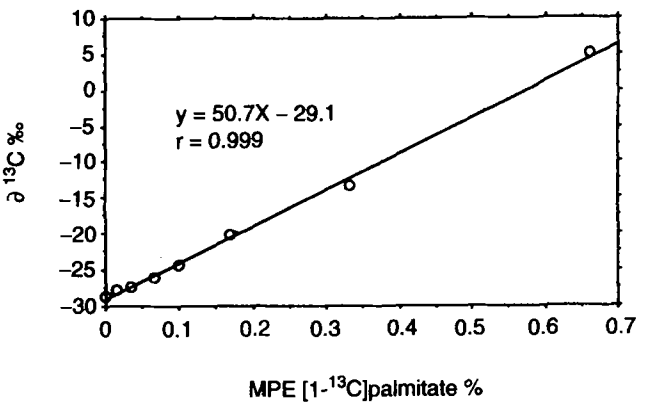

FIG. 1. A representative standard curve obtained by gas chromatography/isotope ratio-mass spectrometry. Palmitate was enriched with 0–0.65% mole percent excess (MPE) [1-^{13}C]palmitate. The measured ^{13}C enrichment is expressed as ∂ ^{13}C‰, referring to an international standard (Pee Dee Belemnite). Each point represents the mean of three analyses.

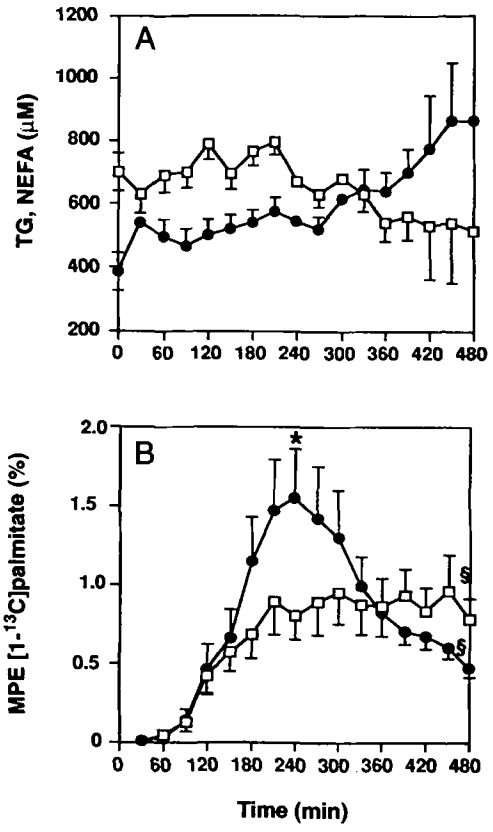

FIG. 2. Evolution of triglyceride (TG) and nonesterified fatty acid (NEFA) concentration (**A**) and of the appearance of [1-^{13}C] palmitate in plasma TG and NEFA (**B**) after the ingestion of a [1,1,1-$^{13}C_3$]tripalmitin labeled oil. ●, Indicates the NEFA, □ indicates the TG. Results are shown as the mean ± SEM. [1-^{13}C]Palmitate enrichment in TG were compared to [1-^{13}C]palmitate enrichment in NEFA, $^*P < 0.05$. [1-^{13}C]palmitate enrichment in TG and NEFA were compared to basal value. Other abbreviation as in Figure 1.

TG at 90 min, and the MPE of [1-^{13}C]palmitate in TG increased and reached a plateau after four hours. At the end of the study, MPE of [1-^{13}C]palmitate in TG remained significantly higher than baseline values ($P < 0.0001$) (Fig 2B). [1-^{13}C]Palmitate appeared in plasma NEFA initially following a similar kinetic to that in TG. Maximal values were obtained at 240 min, and at that time MPE of [1-^{13}C]palmitate was significantly higher in NEFA than in TG (MPE NEFA: 1.53 ± 0.3 vs. MPE TG: 0.78 ± 0.06, $P < 0.05$). Thereafter, it decreased to reach similar values to those of TG. Eight hours after the labeled load, the MPE of [1-^{13}C]palmitate in NEFA remained significantly higher than baseline values ($P < 0.0001$).

The value of each oil aliquot measured after derivatization was 12.6 ± 1.9 MPE. These values were not significantly different from the theoretical ones—the palmitate content of the sunflower oil was 7% (weight), thus the molar ratio of the load was 0.3/(30 × 7) = 14.3%. This demonstrates that a correct mixing of the labeled load was obtained.

The proportion of exogenous palmitate in circulating TG was maximal between four and five hours and was 0.4 ± 0.2, 3.1 ± 0.8, 5.4 ± 1.3, 7.4 ± 1.7, 7.0 ± 1.7, 6.7 ± 1.9, 5.5 ± 1.4, and 6.1 ± 1.4% at 1, 2, 3, 4, 5, 6, 7, and 8, respectively.

TABLE 1
Estimated Contribution from Nonesterified Fatty Acid (%) to Palmitate of Total Triglyceride

Time (min)	Subjects 1	2	3	4	Means ± SEM

[a] $P < 0.001$.

Reesterification of NEFA during the infusion of [1-^{13}C]-palmitate. A constant ^{13}C palmitate enrichment of 1.6 ± 0.2 MPE was observed in NEFA after 120 min of [1-^{13}C]palmitate infusion. The NEFA turnover rate could be determined using steady-state equations and was 2.4 ± 0.2 μmol/kg/min.

In contrast, ^{13}C palmitate enrichment increased in plasma TG between 120 and 150 min from 0.23 ± 0.07 MPE to 0.37 ± 0.07 MPE ($P < 0.001$). Table 1 shows the individual values of the estimated contribution of palmitate from NEFA to palmitate of circulating total TG. This estimated reesterification increased from 13.9 ± 3.6 to 22.6 ± 2.6% between 120 and 150 min ($P < 0.001$).

DISCUSSION

An increase in the number of studies using stable isotopes has accompanied a growing interest in lipid metabolism. However, these investigations still are limited by the lack of accuracy in the measurement of low ^{13}C IE. We describe here, for the first time, a method using GC/IR-MS for the measurement of ^{13}C IE of palmitate. We demonstrate that this method is sensitive and reproducible as enrichments as low as 0.009 MPE of [1-^{13}C]palmitate could be detected and good inter- (0.7%) and intraassay variability (0.5%) are achieved. These characteristics are similar to those reported with the use of GC/IR-MS for measuring ^{13}C IE of glucose (8) or lactate (9). The validity of this method is further shown by the linearity of the results on a large range of enrichments, the concordance of measures of enrichments (12.6 MPE) in the labeled TG load with theoretical values, and by the similarity of palmitate turnover rate determined with this method, to those obtained in other studies using GC/MS (1). For many years we have used GC/MS measurements for the determination of palmitate turnover (1,21,22). The values obtained in healthy subjects were between 1.8 and 2.5 μmol/kg/min. Thus the value of 2.4 μmol/kg/min found in the present study using GC/IR-MS measurements was in agreement with the previous data.

In this study, we were able to estimate the metabolic fate of an oral TG load following the ingestion of [1,1,1-$^{13}C_3$]tripalmitin labeled oil. Significant labeling appeared concurrently both in TG and in NEFA. These findings agree with previous data from Havel and Frederickson (4), where ^{14}C palmitate was given to dogs, and significant radioactivity was

found in NEFA. They also agree with Roust and Jensen (5), who gave ^{14}C oleate to obese subjects and followed the appearance of exogenous oleate in NEFA. Our data are also in agreement with those of Griffiths *et al.* (21), demonstrating that the profile of plasma NEFA changed after a high-fat meal, consistent with the entry of meal-derived fatty acids into the plasma NEFA pool. These labeled NEFA could have come either from a direct release in portal circulation of fatty acids coming from the ingested TG or from an intravascular release of NEFA after the hydrolysis of TG-chylomicron by lipoprotein lipase. In contrast, it is widely accepted that the portal route is the main route for short-acid fatty acid chain (19), and that NEFA released by the lipoprotein lipase are taken up by tissues (20). To clarify the origin of the labeled NEFA, other studies using this GC/IR-MS method are required, including measurements of the labeling in TG chylomicrons.

In the second part of this study, we measured the appearance of infused [1-^{13}C]palmitate in circulating TG in order to estimate the hepatic reesterification of NEFA. The appearance of labeled palmitate in TG allowed us to estimate the conversion of NEFA into TG through the hepatic reesterification process. To our knowledge, few reports have addressed this question. In 1970, using [1-^{14}C]palmitate and hepatic venous sampling in healthy subjects, Havel and colleagues (6) have shown that similar specific activity was obtained in hepatic venous NEFA and arterial VLDL TG–fatty acids. These results differ from our data as they did not show more than 22% of TG coming from NEFA. However, the experimental conditions were different because, in our study, sampling was performed in peripheral arterialized blood and not in hepatic venous blood. Moreover, the contribution of NEFA to circulating TG increased from 120 to 150 min in our study; thus our experimental design might have been too short to reach the plateau. Further studies using GC/IR-MS are therefore required to better characterize the hepatic reesterification of NEFA in physiological and pathological states.

In conclusion, our report emphasizes the advantage of GC/IR-MS analysis for the study of palmitate metabolism in humans. Methods using [1-^{13}C]palmitate and [1-1-1-$^{13}C_3$]tripalmitin as tracers could be easily extended to other tracers:—[^{13}C]oleate, [^{13}C]linoleate—and should rapidly become a useful tool for lipid metabolism studies.

Microscale Synthesis of Phosphatidyl-[^{3}H]choline from 1,2-Diacylglycerol. Assessment of Isomerization by Reversed-Phase High-Performance Liquid Chromatography

Maurice Bugaut*, Joseph Gresti and Jerôme Gagniarre

Unité de Nutrition Cellulaire et Métabolique, Faculté des Sciences Mirande, Université de Bourgogne, 21004 Dijon, Cedex, France

ABSTRACT: The synthesis of *rac*-1-palmitoyl-2-oleoylglycero-3-phospho-[^{3}H]choline of high specific activity was carried out on a microscale by making 7 μmol of *rac*-1-palmitoyl-2-oleoylglycerol react first with an equimolar amount of $POCl_3$ and then of [^{3}H]choline. After purification by thin-layer chromatography and normal-phase high-performance liquid chromatography (HPLC), the yield of the synthesis of [^{3}H]phosphatidylcholine (120 μCi/μmol) was 22%. *rac*-1-Palmitoyl-2-oleoylglycerol was purified before use by reversed-phase HPLC under conditions which were nonisomerizing and allowed the separation of 1,2- and 1,3-isomers of diacylglycerol. Ethanol, but not benzene, was shown to cause isomerization of long-chain diacylglycerol and, therefore, was not used for drying the substrate before reaction. A rapid and complete separation of 1,2- and 1,3-isomers of long-chain phosphatidylcholine was obtained by reversed-phase HPLC using 20 mM choline chloride in methanol/acetonitrile/water (50:50:1, by vol) isocratically as the mobile phase. Under these conditions, analysis of the synthetized *rac*-1-palmitoyl-2-oleoylglycero-3-phospho-[^{3}H]choline showed a total absence of 1,3-isomer.

Lipids 30, 875–881 (1995).

Synthesis of phosphatidylcholine from diacylglycerol and choline was initially described by Baer and Kindler (1). A reactive intermediate, diacylglycerophosphooxychloride, is obtained by action of phosphorus oxychloride ($POCl_3$) on diacylglycerol in a mixture of anhydrous chloroform and pyridine. Addition of dry choline chloride leads to the formation of diacylglycerochlorophosphocholine, which is converted to phosphatidylcholine in the presence of water. The advantage of this method is the commercial availability of choline salt and of an array of various diacylglycerols in unlabeled and labeled form. The synthesis on a smaller scale (from 1–10 mg instead of 2.5 g diacylglycerol) was described by Myher and Kuksis (2). However, the large excess of choline chloride, used to compensate for the low solubility of dry powdered choline chloride in the solvent mixture, did not allow the synthesis of phosphatidyl-[^{3}H]choline with the high specific activity sometimes required for biochemical studies. The aim of the present study is to improve the microsynthesis of phosphatidylcholine with as little dilution of the starting [^{3}H]-choline chloride label as possible, while still keeping a satisfactory yield. Furthermore, isomerization of the substrate diacyl-*sn*-glycerol before its conversion into phosphatidylcholine was observed during drying, purification, and storage. The extent of this isomerization was investigated by analyzing diacyl-*sn*-glycerols by high-performance liquid chromatography (HPLC) under nonisomerizing conditions. An HPLC method also was developed for analysis and purification of the synthesized phosphatidylcholine. In this paper, the experimental conditions for the microsynthesis of phosphatidylcholine and resolution by reversed-phase HPLC of the 1,2- and 1,3-isomers of diacylglycerol and phosphatidylcholine are described. Also reported are results related to the extent of isomerization of diacyl-*sn*-glycerols under different experimental conditions.

MATERIALS AND METHODS

Samples and reagents. rac-1-Palmitoyl-2-oleoylglycerol and 1,3-dipalmitoylglycero-2-phosphocholine were purchased from Serdary Research Laboratories (London, Ontario, Canada). *sn*-1,2-Dioleoylglycerol, *sn*-1,2-dipalmitoylglycerol, dioleoylglycerol (*ca.* 89% 1,3-isomer), and *sn*-1,2-dipalmitoylglycero-3-phosphocholine were obtained from Sigma-Chimie (La Verpillière, France). [^{3}H-*Methyl*]choline chloride (85 mCi/μmol) was obtained from Commissariat à l'Energie Atomique (Saclay, France). Pyridine (0.01% water), $POCl_3$, and choline chloride were purchased from Merck (Darmstadt, Germany). Choline chloride was solubilized into ethanol and dried under vacuum before use. Anhydrous toluene, *(S)*-(+)-1-(1-naphthyl)ethyl isocyanate, and 4-pyrrolidinopyridine were obtained from Aldrich-Chimie (Strasbourg, France). Chloroform (SDS, Peypin, France) contained 0.4% ethanol and 0.015% water. When used for synthesis of

phosphatidylcholine, chloroform was washed twice with distilled water and then allowed to dry over dry $CaCl_2$ for 12 h and then over dry Na_2SO_4 for an additional 12 h. Washed and dried chloroform and pyridine were distilled just before use while being shielded from moisture. All other solvents were of analytical reagent grade or HPLC analysis grade.

Purification of diacylglycerols. The sample of *rac*-1-palmitoyl-2-oleoylglycerol was purified by reversed-phase HPLC as described later (see Fig. 1B). The purity of the collected racemate was approximately 99% when checked by HPLC under the same conditions (see Fig. 1B, 2), and the fatty acid analysis showed 50.3% palmitate and 49.7% oleate. The proportions of the *sn*-1,2 and *sn*-2,3 enantiomers were 50.2 and 49.8%, respectively, when the racemate was analyzed by HPLC on a silica column in the form of chiral derivatives.

Pure 1,3-dioleoylglycerol was prepared by reversed-phase HPLC just before use from a sample of dioleoylglycerol containing 11% X-1,2-isomer and 89% 1,3-isomer. The acetonitrile/acetone solution collected was evaporated to complete dryness at 20°C for about 10 min. When the 1,3-dioleoylglycerol was analyzed by HPLC at this point, its purity was better than 99%. The samples of *sn*-1,2-dioleoylglycerol and *sn*-1,2-dipalmitoylglycerol contained less than 1% 1,3-isomer when analyzed by reversed-phase HPLC and, therefore, were not purified before experiments.

Microsynthesis of phosphatidylcholine. Choline chloride (8.2 μmol in 58 μL ethanol) was placed in a Reacti-Vial (Pierce Eurochemie, Rotterdam, Holland) reaction vial of 1.0 mL inner volume (tube A) and dried under nitrogen at 40°C. [^{3}H]Choline chloride (1 mCi in 1.0 mL of ethanol) was successively added and evaporated to dryness under nitrogen. Drying was improved by using first ethanol and, then, pyridine. A Reacti-Vial magnetic stirring bar (Pierce) and 100 μL pyridine were added, and the tube was closed with a Teflon-lined screw cap and connected *via* a dry $CaCl_2$ cartridge to a vacuum pump with a needle through the septum. Tube A was maintained under vacuum at 40°C for 12 h.

rac-1-Palmitoyl-2-oleoylglycerol was purified by reversed-phase HPLC just before use, and the solution collected corresponding to 4.3 mg (7.2 μmol) of diacylglycerol was transferred into another similar Reacti-Vial tube (tube B). The solvents were evaporated to dryness under nitrogen at 40°C, and drying was completed twice using benzene. A chilled mixture (100 μL) of chloroform/pyridine/$POCl_3$ (5.5:0.5:0.041, by vol), corresponding to 7.4 μmol $POCl_3$, was added with a syringe. Tube B was closed under nitrogen and allowed to stand for 1.5 h at 0°C and then for 1 h at room temperature. The solution was then quantitatively transferred into tube A through the septum with a needle-fitted syringe. The needle connected to the vacuum pump was withdrawn, and the two holes in the septum were closed with fast-drying glue. The mixture was stirred for 48 h at 30 ± 2°C. The reaction was stopped by adding 10 μL water and stirring for 0.5 h. The products were extracted according to Arvidson (3). The organic extract was passed through a small Na_2SO_4 column, dried under nitrogen, and stored in toluene/methanol (50:50, vol/vol) at –20°C.

The labeled phosphatidylcholine was first purified by thin-layer chromatography (TLC) using silica gel H (Merck) and chloroform/methanol/acetic acid/water (75:45:12:6, by vol) as the solvent mixture (4). The labeled phosphatidylcholine was extracted from the silica gel using chloroform/methanol/water/acetic acid (50:39:10:1, by vol). The suspension was allowed to stand for 2 h at room temperature before filtration through glass wool. The solution was then treated following Arvidson's procedure (3). The labeled phosphatidylcholine also was purified by normal-phase HPLC just before use to remove possible traces of lysophosphatidylcholine. About 1.4 mg of labeled phosphatidylcholine in 150 μL chloroform/methanol (1:1, vol/vol) was injected into a 40 cm × 4.5 mm i.d. column packed with 5 μm Lichrosorb Si60 particules (Merck). The phosphatidylcholine was isocratically eluted with acetonitrile/methanol/water (72:18:10, by vol) as the mobile phase at the rate of 2.5 mL/min, using a Varian model 5000 apparatus (Varian Associates, Sunnyvale, CA) equipped with an ultraviolet detector adjusted at 206 nm.

Nonradioactive choline chloride and *sn*-1,2-dipalmitoylglycerol were used during the microsynthesis attempts to preserve substrates. The reaction products were fractionated by TLC according to Myher and Kuksis (2). Phosphatidylcholine was extracted from the silica gel as described earlier, and chloroform/methanol (90:10, vol/vol) was used for extraction of diacylglycerol. The yield of synthesis was determined from quantitative fatty acid analyses of the diacylglycerol and phosphatidylcholine by gas chromatography.

Separation of 1,2- and 1,3-isomers of diacylglycerol and phosphatidylcholine by reversed-phase HPLC. 1,2- and 1,3-Diacylglycerols were separated on a 25 cm × 4 mm i.d. Lichrocart column packed with 4 μm Lichrospher 100RP-18 particles (Merck) and protected by a Lichrosorb RP-18 precolumn using acetonitrile/acetone (55:45, vol/vol) as the eluting mixture at a flow rate of 1.1 mL/min under isocratic conditions. The column was connected to a Waters model 6000A solvent delivery system (Waters, Milford, MA) equipped with a Waters model R401 differential refractometer. Diacylglycerol (200–500 μg) in acetone (approximately 30 μL) was injected at room temperature. Each isomer was identified by analysis of each collected HPLC peak by TLC on 5 wt% borate-impregnated silica gel G (Merck) with chloroform/acetone (95:5, vol/vol) as the developing solvent (5). Reference long-chain diacylglycerols (R_f 0.48 and 0.61 for 1,2- and 1,3-isomers, respectively) were used for comparison. Peak areas were measured during HPLC analyses using an Enica 21 (Delsi Instruments, Suresnes, France) integrator-calculator.

1,2- and 1,3-Phosphatidylcholines were separated by reversed-phase HPLC using 20 mM choline chloride in methanol/acetonitrile/water (50:5:1, by vol) as the mobile phase at a flow rate of 1.3 mL/min. Phosphatidylcholine was dissolved in methanol/acetonitrile (10:1, vol/vol) before injection. Other experimental conditions were similar to those used for separation of 1,2- and 1,3-diacylglycerols.

HPLC resolution of sn-*1,2- and* sn-*2,3-diacylglycerols as chiral derivatives.* Diacyl-*sn*-glycerols were derivatized in the form of (*S*)-(+)-1-(1-naphthyl)ethyl urethanes and were separated by HPLC on a silica column as described by Laakso and Christie (6). Diacylglycerol (300 µg in 300 µL toluene) was reacted with (*S*)-(+)-1-(1-naphthyl)ethyl isocyanate (10 µL) in the presence of 4-pyrrolidinopyridine (approximately 10 µmol) overnight at 50°C. The products were dissolved in 2 mL hexane/diethyl ether (1:1, vol/vol) and washed twice with 2 mL 2N HCl and three times with water. After evaporating solvents under nitrogen, the derivatives were dissolved in diethyl ether and purified on a 25 mm × 10 mm i.d. Sep-pak silica cartridge (Millipore, St. Quentin en Yvelines, France). HPLC separation was carried out using a Waters Model 625 LC System together with a Waters Model 486 ultraviolet detector adjusted at 280 nm, and a Shimadzu Model C-R5A integrator. The diacylglycerol derivatives were eluted on a 40 cm × 4.5 mm i.d. column packed with 5 µm Lichrosorb Si60 particles (Merck) with hexane/2-propanol (99.5:0.5, vol/vol) at a flow rate of 1.2 mL/min. Chromatographic peaks were identified using derivatives of standard diacyl-*sn*-glycerols.

Isomerization of sn-*1,2- and 1,3-dioleoylglycerols.* Isomerization of *sn*-1,2- and 1,3-dioleoylglycerols was studied under several experimental conditions. Under standard conditions, *sn*-1,2-dioleoylglycerol (300 µg) stored in acetone (20 µg/µL) was dried under nitrogen and immediately redissolved in 0.5 mL of the solvent studied (see Table 2 later in paper). The solution was evaporated to dryness under a strong stream of nitrogen at 40°C for 4 min and was maintained in dry form under these conditions for different lengths of time (from 0 to 3 h). The dioleoylglycerol then was dissolved in acetone and analyzed by reversed-phase HPLC to determine the proportion of the newly-formed 1,3-isomer. In some experiments, before drying, *sn*-1,2-dioleoylglycerol remained in contact with the solvent at room temperature (20 ± 2°C) for 15 h. In other experiments, after drying, *sn*-1,2-dioleoylglycerol was stored under vacuum at 20°C for 15 h before being redissolved in acetone for HPLC analysis.

Gas chromatography. Lipids were converted into fatty acid methyl esters using BF_3 according to Slover and Lanza (7), and then were analyzed on a laboratory-made 30 m × 0.4 mm i.d. glass column coated with 20M Carbowax (Applied Science Laboratories, State College, PA), using methyl heptadecanoate as internal standard. The carrier gas was nitrogen at a flow rate of 2.5 mL/min, and the temperature was maintained at 195°C. The column was connected to a Packard model 417 chromatograph (Packard, Downers Grove, IL) equipped with a Ross injector and linked to an Enica-21 integrator-calculator (Delsi Instruments, Suresnes, France).

Radioactivity counting. Radioactivity in lipid samples was measured using Permafluor III scintillation liquid (Packard) and a Packard model Tri-Carb 300C scintillation counter. Unlabeled total lipids of liver were first added to the samples of phospholipid to solubilize phosphatidylcholine in the scintillation liquid. After evaporation of organic solvents, 0.2 mL methanol followed by 7 mL Permafluor III were added. The mixture was stirred and allowed to stand for 2 h before counting. Picofluor 15 scintillation liquid (Packard) was used for measuring radioactivity in aqueous samples.

RESULTS AND DISCUSSION

Synthesis of rac-*1-palmitoyl-2-oleoylglycero-3-phospho-[^{3}H]choline.* Under the experimental conditions described in the Materials and Methods section, 26% of the ^{3}H radioactivity was found in the organic phase when the synthesis products were extracted according to Arvidson (3). After resolution of the lipophylic products by TLC, 86.6% of the extracted tritium was in the phosphatidylcholine fraction, corresponding to a yield of 22.5% when calculated from the initial radioactivity. This means that 1.84 µmol [^{3}H]choline chloride was converted into the same amount of phosphatidyl-[^{3}H]choline, corresponding to a yield of 25.5% when calculated from the starting amount of *rac*-1-palmitoyl-2-oleoylglycerol (7.2 µmol). When phosphatidyl-[^{3}H]choline was thereafter purified by HPLC on a Lichrosorb Si60 column, 85% of the ^{3}H radioactivity was recovered in the phosphatidylcholine fraction. In the present study, the yield was therefore not much lower than what we obtained (30%) under other conditions when starting from 65 µmol *rac*-1-lauroyl-2-oleoylglycerol and 72 µmol [^{3}H]choline chloride (8).

Improvements in the microsynthesis of phosphatidylcholine. When the starting amount of diacylglycerol was as low as 2 mg and the synthesis was carried out based on the procedure of Baer and Kindler (1), and as modified by Myher and Kuksis (2), about a 1% yield was obtained. Water, even in trace amounts, eliminates the reactive chlorine groups of the intermediary product. In the initial procedure (1,2), choline chloride, which is a hygroscopic compound, was dissolved in ethanol and dried under nitrogen. When an additional drying step using pyridine was performed without changes in the other conditions, the synthesis yield increased to 22.7%. The yield reached 24.7% when tube A was connected to a vacuum pump through a device which evaporates solvents to complete dryness and re-introduces air dried on $CaCl_2$ into the vial just before synthesis.

The low solubility of choline chloride in a mixture of chloroform/pyridine also can affect the yield. The ratio of chloroform to pyridine was changed without modifying the $POCl_3$ concentration. When the ratio was 3:3, 5:1, 5.5:0.5, and 5.8:0.2 (vol/vol), the yield was equal to 1.5, 14.2, 25.1, and 13.1%, respectively, after 24 h, although choline chloride is known to be soluble in pyridine, but not in chloroform. Choline chloride did not seem to be completely dissolved in the mixture of chloroform/pyridine (5.5:0.5, vol/vol) after 24 h, but the reaction mixture became clear after 48 h. The latter time was therefore chosen to stop the reaction. When the reaction time was extended to 96 h, no change in the yield was observed, showing that no degradation of the synthesized phosphatidylcholine occurred in the vial during this period. The yield was improved when decreasing the total volume of the reaction medium from 0.65 mL to 100 µL, when always

adding the same amount of $POCl_3$ (7.4 μmol), but was independent of the inner volume (in the range of 1–10 mL) of the reaction vial.

*Resolution of diacyl-*sn*-glycerols by HPLC.* In this study, a good separation method for intact long-chain 1,2- and 1,3-diacylglycerols using reversed-phase HPLC was established. Figure 1A shows that *sn*-1,2- and 1,3-dioleoylglycerols were completely separated under isocratic conditions with acetonitrile/acetone (55:45, vol/vol) as the mobile phase. The 1,3-isomer was eluted before the *sn*-1,2-isomer, as also observed by Kondoh and Takano (9) on an octadecylsilyl column. These authors separated 1,2- and 1,3-distearoylglycerol by a method which requires ethanol/acetonitrile/water as the eluting mixture (potentially isomerizing, see previously), nonisocratic elution conditions, and a longer elution time (40 min). Separation of both isomers appears to be easier on a nonbonded silica column (10–15) than on a reversed-phase column (9,16). However, a mixture of diacylglycerols is not resolved by normal-phase HPLC according to the nature of the constituent acyl chains. Figure 1B shows that during the purification of *rac*-1-palmitoyl-2-oleoylglycerol on a reversed-phase column, the 1,3-isomer (10.3%) and 1,2-isomer (82.5%) were clearly separated from contaminating longer-chain diacylglycerols (7.2%) containing stearate (0.5% of total fatty acids). Figure 2 shows that a rapid and complete separation by normal silica-phase HPLC of the 1,3-, *sn*-1,2- and *sn*-2,3-isomers of dioleoyl-*sn*-glycerol as their urethane derivatives was achieved under conditions similar to those described by Laakso and Christie (6).

Isomerization of sn*-1,2-diacylglycerol in ethanol and other solvents assessed by HPLC.* Isomerization of diacyl-

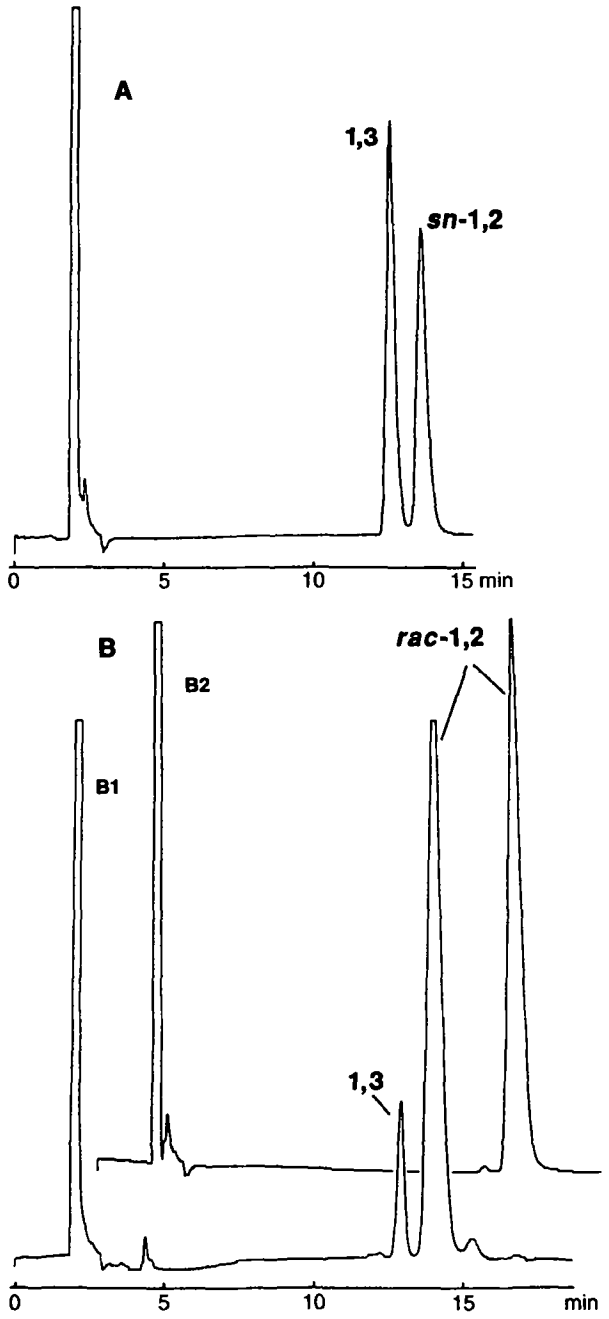

FIG. 1. Separation of the 1,2- and 1,3-isomers of synthetic diacylglycerols by reversed-phase high-performance liquid chromatography (HPLC) (conditions as in the text). A, Chromatogram of a mixture of pure *sn*-1,2- and 1,3-dioleoylglycerols (approximately 200 μg each). B, Chromatograms of *rac*-1-palmitoyl-2-oleoylglycerol before purification (1) and after purification (2) by reversed-phase HPLC.

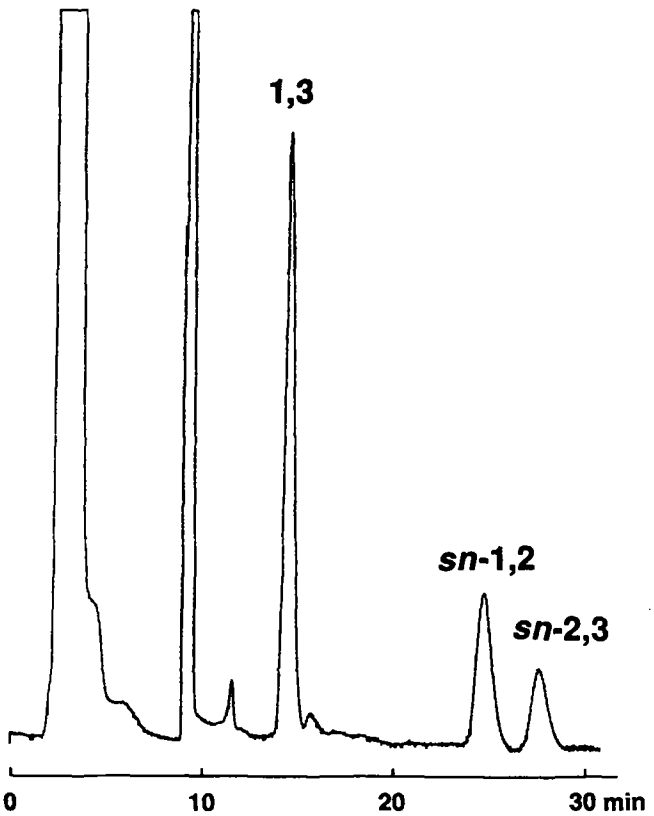

FIG. 2. High-performance liquid chromatography resolution of dioleoyl-*sn*-glycerols in the form of chiral urethane derivatives. Pure *sn*-1,2-dioleoylglycerol (300 μg) in 0.5 ml ethanol was dried under nitrogen at 40°C, maintained dry in this way for 3 h, and then redissolved in 300 μL toluene for derivatization with (*S*)-(+)-1-(1-naphthyl)ethyl isocyanate. Urethanes (100 μg in 50 μL 1,2-dichloroethane) were injected into a silica column (other conditions as in the text.)

glycerol is a reversible process (i.e., *sn*-1,2-, 1,3-, and *sn*-2,3-isomers), leading to an equilibrium mixture of 1,3- and X-1,2-isomers. Similar to that of monoacylglycerols (17,18), the isomerization of 1,2-diacylglycerol into its more thermodynamically stable 1,3-isomer is subject to general acid or base catalysis (19–22). This isomerization also is sensitive to certain reagents, including water (23,24), and may occur in crystalline state (25). In this study, effects of ethanol on isomerization of *sn*-1,2-dioleoylglycerol was examined first under the standard conditions described in the Materials and Methods section. The results obtained from 50 independent assays pointed out that the proportions of 1,3-isomer measured at times between 4 and 15 min were very scattered (from 1 to 67%). However, isomerization was complete within 20 min (*ca.* 65% 1,3-isomer) (Table 1). This result agrees with the fact that in long-chain diacylglycerols at equilibrium the ratio of the 1,2- to the 1,3-isomer is about 40:60 (20). In separate experiments, the dioleoyl-*sn*-glycerols were analyzed as chiral urethane derivatives under conditions known not to cause isomerization (6,26). Table 1 shows that the proportion (24%) of the *sn*-1,2-enantiomer remained higher than that (14%) of the newly-formed *sn*-2,3-enantiomer, even after a long period of drying (24 h).

Isomerization may start during evaporation of the dioleoylglycerol solution, or later when the dioleoylglycerol remains in dry form under nitrogen. Table 2 shows that the proportion (31.6%) of 1,3-isomer arising after a 15-min drying period was not significantly ($P > 0.10$) increased by storage under vacuum at room temperature overnight (46.9%). When *sn*-1,2-dioleoylglycerol was kept in ethanol at room temperature overnight before drying, no significant change in the results was observed (Table 2). Furthermore, 300 μg *sn*-1,2-dioleoylglycerol in 50 μL ethanol was maintained at 40°C for different lengths of time (from 0 to 3 h), and then was injected directly into the HPLC column. The proportion of 1,3-isomer (7.9 ± 14.1% as the average ± SD of 25 determinations) did not appear to depend on the length of contact of the diacylglycerol with ethanol. The results were not modified when *sn*-

Benzene			0.9 ± 1.3 (0.0–2.9)	1.2 ± 0.6 (0.4–1.9)

[a]Proportions of the 1,3-isomer determined by reversed-phase high-performance liquid chromatography. Average (mol%) ± SD of five or more observations with the extreme values in parentheses.
[b]As described in the Materials and Methods section.
[c]One value.
[d]*sn*-1,2-Dioleoylglycerol was dissolved in 5 mL chloroform/methanol (90:10, vol/vol) before drying.
[e]The solution was dried using nitrogen saturated with water vapor.
[f]The tube was maintained under nitrogen until complete evaporation (>15 min).

1,2-dioleoylglycerol was purified beforehand by HPLC under nonisomerizing conditions to remove any trace of 1,3-isomer.

The suggestion that isomerization may arise at the moment when ethanol is nearly completely evaporated, inducing a momentary, high concentration of metals and other residues present in traces in ethanol, was investigated indirectly with different concentrations of *sn*-1,2-dioleoylglycerol ranging from 100 µg to 1.5 mg in 0.5 mL ethanol. After evaporation to complete dryness under nitrogen at 40°C for about 4 min, HPLC analyses were immediately performed. The proportion of the formed 1,3-isomer decreased significantly ($P < 0.05$) from 57.8 ± 8.6% (44.2–65.5% being the range of five determinations) to 30.5 ± 28.0% (1.2–66.5%) when the concentration of *sn*-1,2-dioleoylglycerol increased from 0.2 to 3.0 mg/mL. Moreover, experiments with ethanol purchased from Prolabo (Paris, France), Carlo Erba (Milan, Italy), and SDS led to similar results. Involvement of the solvents used for HPLC analyses, i.e., acetone and acetonitrile, in the isomerization described here can be ruled out (Table 2).

Results in Table 2 show that benzene is more reliable than ethanol in removing water traces in samples of *sn*-1,2-diacylglycerol. By contrast, some isomerization was observed when *sn*-1,2-dioleoylglycerol in acetonitrile/acetone was dried down, and then was maintained in dry form for 3–15 h. The purity of the nitrogen used for drying was questioned because traces of water could have been present. However, the isomerization rate did not change even when nitrogen saturated with water vapor (Table 2) or dried through a $CaCl_2$ cartridge was used. The potential role of water on the isomerization of *sn*-1,2-dioleoylglycerol was investigated further because water had been used as part of the mobile phase in reversed-phase HPLC (9), and has been demonstrated to provoke some isomerization (23,24). Table 2 shows that under all the experimental conditions studied, significant ($P < 0.05$) isomerization occurred when 20% water was added to the mixture of acetonitrile/acetone. By contrast, addition of 20% water to ethanol tended to significantly restrict isomerization when the solution of *sn*-1,2-dioleoylglycerol was stored overnight before drying ($P < 0.05$) or maintained dry under nitrogen for 3 h ($P < 0.001$), in comparison with samples of *sn*-1,2-dioleoylglycerol in ethanol alone (Table 2). Table 2 also indicates that precautions have to be taken to avoid isomerization when chloroform/methanol mixtures are used to extract diacylglycerol from silica gel after TLC and are then evaporated to dryness.

Isomerization of 1,3-dioleoylglycerol. When 1,3-dioleoylglycerol was purified by reversed-phase HPLC, the collected acetonitrile/acetone solution was evaporated cautiously under nitrogen at 20°C for 10 min, which caused no isomerization. However, evaporating the solution at 40°C for 15 min was sufficient to cause some isomerization (4.3 ± 2.5% X-1,2-isomer, 0.5–7.4% as the extreme values). The 1,3-isomer therefore appeared to be more sensitive to isomerization than the *sn*-1,2-isomer under similar conditions. When a solution of pure 1,3-dioleoylglycerol (300 µg) in 0.5 mL ethanol was dried under nitrogen at 40°C for 15 min, the proportion of formed X-1,2-isomer reached 26.0 ± 10.2% (8.5–36.6%). By contrast, Ikeda *et al.* (22) observed no isomerization of 1,3-dilauroylglycerol when the material was held at 80°C for 50 h in ethanol.

Resolution of 1,2- and 1,3-isomers of phosphatidylcholine by reversed-phase HPLC. sn-1,2-Dipalmitoylglycero-3-phosphocholine and 1,3-dipalmitoylglycero-2-phosphocholine were completely separated by reversed-phase HPLC under isocratic conditions at 17°C within a relatively short time (23 min) (Fig. 3A). The chromatogram in Figure 3B recorded during the analysis of labeled *rac*-1-palmitoyl-2-oleoylglyc-

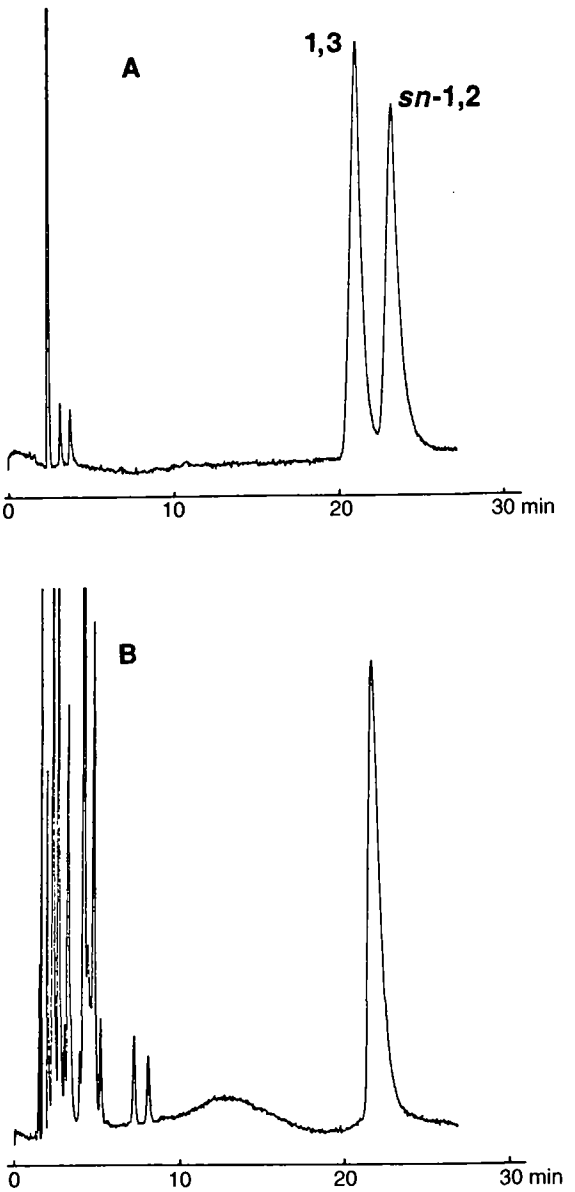

FIG. 3. Separation of synthetic 1,2- and 1,3-phosphatidylcholines by reversed-phase high-performance liquid chromatography (conditions as in the text). A, Chromatogram of a mixture of pure *sn*-1,2-dipalmitoylglycero-3-phosphocholine and 1,3-dipalmitoylglycero-2-phosphocholine (approximately 200 µg each). B, Chromatogram of the *rac*-1-palmitoyl-2-oleoylglycero-3-phospho-[^{3}H]choline synthesized as described in the Materials and Methods section.

ero-3-phospho-[^{3}H]choline displays a total absence of 1,3-isomer, which indicates that no isomerization occurred during the synthesis of the phosphatidylcholine. This result agrees with our previous finding (8) that less than 1% of *rac*-1,2-diacylglycero-3-phosphocholine, synthesized in a similar way, was resistant to phospholipases C and D.

In conclusion, the microscale synthesis of phosphatidylcholine from diacylglycerol and [^{3}H]choline chloride in the presence of $POCl_3$ has been improved to obtain a satisfactory yield and a high specific activity. The reversed-phase HPLC methods adapted here are useful and convenient tools for the control of isomeric purity of the lipid substrate (diacylglycerol) and product (phosphatidylcholine), as well as for their purification.

Preparation and Characterization of Glucosylated Aminoglycerophospholipids

A. Ravandi, A. Kuksis*, L. Marai and J.J. Myher

Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, Toronto, Ontario M5G 1L6, Canada

ABSTRACT: Natural aminophospholipids were isolated from egg yolk and from human red blood cells. Glucosylated ethanolamine and serine phosphatides were prepared by exposing synthetic and natural aminophospholipids to glucose for 3–18 h at pH 7.4. The glucosylation products were resolved from parent phospholipids by normal-phase high-performance liquid chromatography and were identified by on-line mass spectrometry with an electrospray interface. The soft ionization method allowed us to detect the glucosylation products as molecular ions of the Schiff bases. The Schiff bases could be stabilized by sodium cyanoborohydride reduction. The molecular species of the ethanolamine and serine phosphatides reacted in proportion to their molar concentration in the mixtures. The yields of the glucosylation products varied with time of reaction and the concentration of glucose in the medium. At 50 mM glucose and 0.6 mg/mL phosphatidylethanolamine, 20% of the aminophospholipid was glycated in 18 h at 37°C.
Lipids 30, 885–891 (1995).

Advanced glycosylation is believed to be a major pathway for the post-translational modification of tissue proteins, which begins with the nonenzymatic addition of sugars (such as glucose) to the primary amino groups of proteins (1,2). Although the nonenzymatic glycation of the primary amino groups of proteins has been extensively investigated, little attention has been given to phospholipid glycation reactions. The presence of reactive primary amino groups in phosphatidylethanolamine (PE) and phosphatidylserine (PS) has prompted the hypothesis (3) that glucose might react with lipids to initiate advanced glycosylation. However, glycated aminophospholipids have not been specifically isolated from any of the sources.

In this study we have prepared the glucosylation products of PE and PS, which are Schiff bases formed by nonenzymatic attachment of glucose to the amino moiety of the aminophospholipid, and have characterized them by high-performance liquid chromatography (HPLC) and on-line mass spectrometry (MS) with electrospray ionization (ESI).

EXPERIMENTAL PROCEDURES

Materials. D-Glucose was obtained from BDH Chemicals (Toronto, Ontario). Synthetic *sn*-1,2-dipalmitoylglycero-3-phosphoethanolamine and bovine brain *sn*-1,2-dipalmitoylglycero-3-phosphoserine were purchased from Sigma Chemical Co. (St. Louis, MO). Egg yolk PE was isolated in the laboratory from chloroform/methanol (2:1, vol/vol) extracts of egg yolk by thin-layer chromatography (TLC) on Silica gel H (Merck, Darmstadt, Germany) using chloroform/methanol/acetic acid/water (75:35:12:6, by vol) as developing solvent (4). Human red blood cell phospholipids were extracted as described by Rose and Oaklander (5). Red cell PE and PS were isolated by TLC with chloroform/methanol/ammonia (30%) (65:35:7, by vol) as the solvent (6). The phospholipids were recovered from the silica gel by extraction with the developing solvent.

Glucosylation of aminophospholipids. Two mg of either PE or PS was dissolved in 1 mL methanol. Two mL of the glucosylation solution, which consisted of different concentrations of glucose (5–100 mM, in 0.1M phosphate buffer, pH 7.4) was added to this solution. The test tubes were intermittently sonicated for 30 min at room temperature to produce lipid emulsions. These emulsions were incubated on a mechanical shaker in the dark at 37°C for periods of 3–18 h. After incubation, the lipid-soluble material was separated from unreacted glucose by extraction with 2 mL chloroform/methanol (2:1, vol/vol). The tubes were centrifuged for 10 min and the organic phase was collected. The extraction was repeated two more times and the extracts were combined, blown down under nitrogen, and redissolved in chloroform/methanol (2:1, vol/vol) (Scheme 1). The glucosylations were performed several times at each glucose level and at each time interval.

Isolation of glucosylated aminophospholipids. The glucosylated and nonglucosylated lipids (1 mg) were resolved by TLC (20 × 20 cm plates, 250 micron thick layer of Silica gel H) using chloroform/methanol/ammonia (30%) (65:35:7, by vol). The resolved lipids were located by spraying the TLC

SCHEME 1

plate with 2,7-dichlorofluorescein and viewing it under ultraviolet light. Both glucosylated and nonglucosylated lipids were recovered by scraping the gel from the fluorescent areas and extracting it with the developing solvent. After solvent evaporation, the residues were dissolved in chloroform or methanol.

$NaCNBH_4$ reduction. The glycated PE species were reduced by adding freshly prepared $NaCNBH_4$ in methanol (final concentration 70 mM). The sample was incubated at 4°C for 1 h. The product was washed three times with water to remove excess reagent.

Gas–liquid chromatography analysis of fatty acid methyl esters. Fatty acid methyl esters were prepared from aliquots of each sample resolved on the TLC plates by scraping the gel from the appropriate areas into 6% H_2SO_4 in methanol and heating at 80°C for 2 h. After the reaction, the methyl esters were extracted twice with hexane. The solvents were blown down under nitrogen and the samples redissolved in hexane. The fatty acids were analyzed on a polar capillary column (SP 2380, 15 m × 0.32 mm i.d., Supelco, Mississauga, Ontario, Canada) installed in a Hewlett-Packard (Palo Alto, CA) Model 5880 gas chromatograph equipped with a hydrogen flame-ionization detector (7). Hydrogen was the carrier gas at 3 psi.

HPLC of phospholipids. Normal-phase HPLC separations of phospholipids were performed on Spherisorb 3 micron columns (100 mm × 4.6 mm i.d.; Alltech Associates, Deerfield, IL) installed into a Hewlett-Packard Model 1050 Liquid Chromatograph connected to an evaporative light scattering detector (ELSD) (Model ELSD II; Varex, Rockville, MD). The column was eluted a linear gradient of 100% solvent A (chloroform/methanol/30% ammonium hydroxide, 80:19.5:0.5, by vol) to 100% Solvent B (chloroform/methanol/water/30% ammonium hydroxide, 60:34:5.5:0.5, by vol) in 14 min, then at 100% B for 10 min (8). The flow rate was set at 1 mL/min.

Liquid chromatography (LC)/MS of phospholipids. Normal-phase LC/MS was performed by admitting the entire HPLC column effluent into a Hewlett-Packard Model 5988B quadrupole mass spectrometer equipped with a nebulizer-assisted ESI interface (HP 59987A). Negative ESI spectra were taken in the mass range 400–1100. The capillary exit voltage was set at 150 volts, with the electron multiplier at 1795 volts. Selected ion spectra were retrieved from the total ion spectra by computer. The masses given in the tables and figures are the actual masses of the ($[M - H]^-$) ions. The nominal masses are one unit lower.

The molecular species of the various glycerophospholipids were identified on the basis of the molecular mass provided by MS, the knowledge of the fatty acid composition of the aminophospholipid classes, and the relative HPLC retention time (more saturated species migrating ahead of the unsaturated species) of the phospholipids.

Figure 1 shows that on normal-phase TLC the glucosylated phospholipids migrate more slowly than the corresponding nonglucosylated derivatives, and that there is an effective resolution of the glucosylated aminophospholipids from other common phospholipids. The R_f values of PE and PS were 0.69 and 0.21, and 0.46 and 0.09 of glucosylated PE and glucosylated PS, respectively. Transmethylation of the TLC bands showed identical fatty acid composition for the corresponding precursor and product molecules.

Figure 2 shows the normal-phase HPLC separation of glucosylated PE relative to PE and other red blood cell phospholipids. The glucosylated PE is eluted later than nonglucosylated PE. Furthermore, the glucosylated PE is seen to overlap in part with phosphatidylcholine. Similarly, glucosylated PS was eluted later than nonglucosylated PS, both being eluted after the glucosylated PE (discussed later). The peaks were detected by ELSD, and their identity was confirmed by on-line MS.

Figure 3 shows that the yield of the glucosylated product depends on the concentration of the glucose in the incubation medium. Detectable glucosylation was seen at 5 mM, which corresponds to the glucose level in healthy subjects (9). The 50-mM glucose yielded 15–20% glucosylation in 18 h. In-

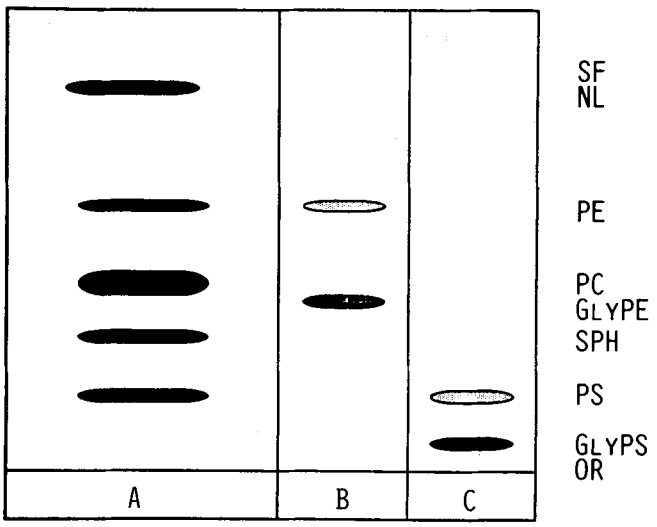

FIG. 1. Thin-layer chromatography of common phospholipids before and after glucosylation with 50 mM glucose. A, reference phospholipids; B, glucosylated phosphatidylethanolamine (PE); C, glucosylated phosphatidylserine (PS); SF, solvent front; NL, neutral lipid; PC, phosphatidylcholine; SPH, sphingomyelin; GLYPE, glucosylated PE; GLYPS, glucosylated PS; OR, origin. Solvent: chloroform/methanol/ammonia (30%) (65:35:7, by vol); detection: 2,7-dichlorofluorescein.

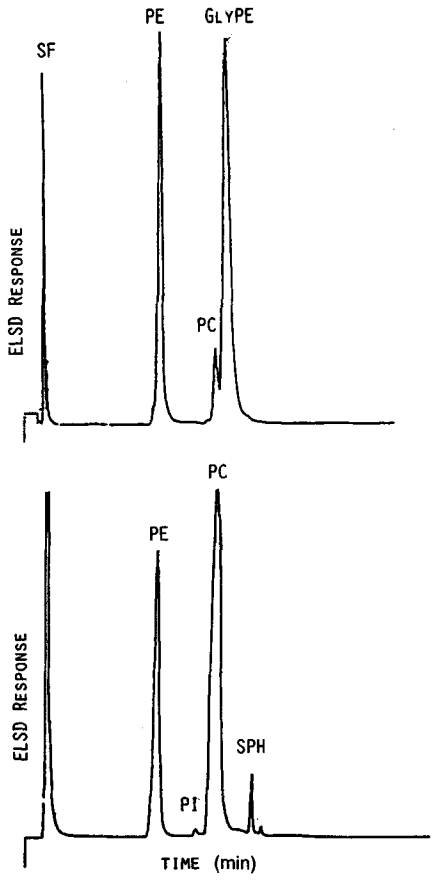

FIG. 2. Normal-phase high-performance liquid chromatography of glucosylated and nonglucosylated phospholipids. A, partially glucosylated egg yolk PE; B, nonglucosylated red blood cell phospholipids. Solvent: linear gradient of 100% Solvent A to 100% Solvent B in 14 min, then Solvent B for 10 min. Solvent A: chloroform/methanol/30% ammonium hydroxide (80:19.5:0.5, by vol); Solvent B, chloroform/methanol/water/30% ammonium hydroxide (60:34:5.5:0.5, by vol). Detection: evaporative light-scattering detection (ELSD). Abbreviations as in Figure 1; PI, phosphatidylinositol. PS and PC overlap in this solvent system.

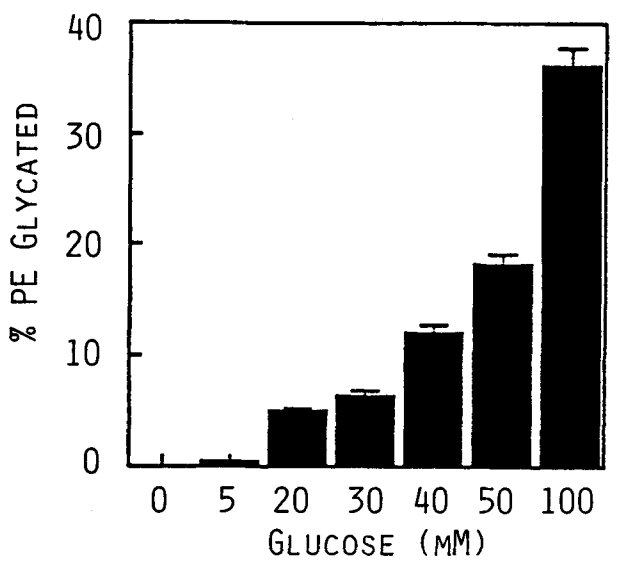

FIG. 3. Formation of glucosylated PE during an overnight (18 h) incubation (37°C, pH 7.4) with various concentrations of glucose. The glucosylated and nonglucosylated PE were quantitated by normal-phase high-performance liquid chromatography with ELSD. Abbreviations as in Figures 1 and 2.

creasing the glucose concentration to 100 μM doubled the yield of the Schiff base, and further increases in glucose led to additional glucosylation of the PE. The small SD values show that the glucosylation is reproducible. Similar results were obtained with PS.

Figure 4 shows the total negative ion current profile and full spectra as obtained by LC/ESI/MS for the dipalmitoyl species of PE after glucosylation and $NaCNBH_4$ reduction and the dipalmitoyl species of PS after glucosylation. In each instance, the symmetrical ion current profiles are accompanied by single $[M - H]^-$ ions of the correct mass. Following reduction, the glucosylated compounds were stable to acid and showed an increase in the *m/z* value of 2 amu, indicating a saturation of the original Schiff base structure. There was a slight increase in the retention time of the reduced, in comparison to the nonreduced, glucosylation products.

Figure 5 shows the total ion current profile obtained by normal-phase LC/MS for a mixture of nonglucosylated and glucosylated (18 h) egg yolk PE, along with the electrospray spectra averaged over the peaks of the two types of PE molecules. The egg yolk PE was incubated with 25 mM glucose. The major ions for the nonglucosylated PE are *m/z* 715 (16:0–18:2), *m/z* 717 (16:0–18:1), *m/z* 739 (16:0–20:4), *m/z* 743 (18:0–18:2 and 18:1–18:1), *m/z* 767 (18:0–20:4), and *m/z* 793 (18:0–22:5), corresponding to the major diacyl species in the original egg yolk PE (10). There are also minor ions corresponding to alkenylacyl species, e.g., *m/z* 775 (18:0–22:6), *m/z* 777 (18:0–22:5), and *m/z* 779 (18:0–22:4). The major molecular ions for the glycated PE are *m/z* 877 (16:0–18:2), *m/z* 879 (16:0–18:1), *m/z* 901 (16:0–20:4), *m/z* 905 (18:0–18:2 and 18:1–18:1), *m/z* 907 (18:0–18:1), and *m/z* 929 (18:0–20:4). It appears that the oligoenoic species of PE are glucosylated as readily as the polyunsaturated and the alkenylacyl species.

Figure 6 shows the normal-phase LC/MS profile of human red blood cell phospholipids following incubation with 50 mM glucose (18 h), along with the mass spectra averaged over the glucosylated and nonglucosylated PE and PS subclasses. The total ion current profile of nonglucosylated PS shows two peaks, because the more unsaturated species migrate slightly faster than the more saturated species. This difference is not apparent following glucosylation when they overlap. About 50% of each phospholipid class was glucosylated. The PE showed glucosylation of both the diacyl and the alkenylacyl species. The molecular species of the PE and PS were glucosylated roughly in proportion to their mole percentages in the phospholipid classes in the human red blood cell. The major component in both nonglucosylated PE (*m/z* 751) and in glucosylated PE (*m/z* 913) was the alkenylacyl (18:0–20:4) species. The major component in both nongluco-

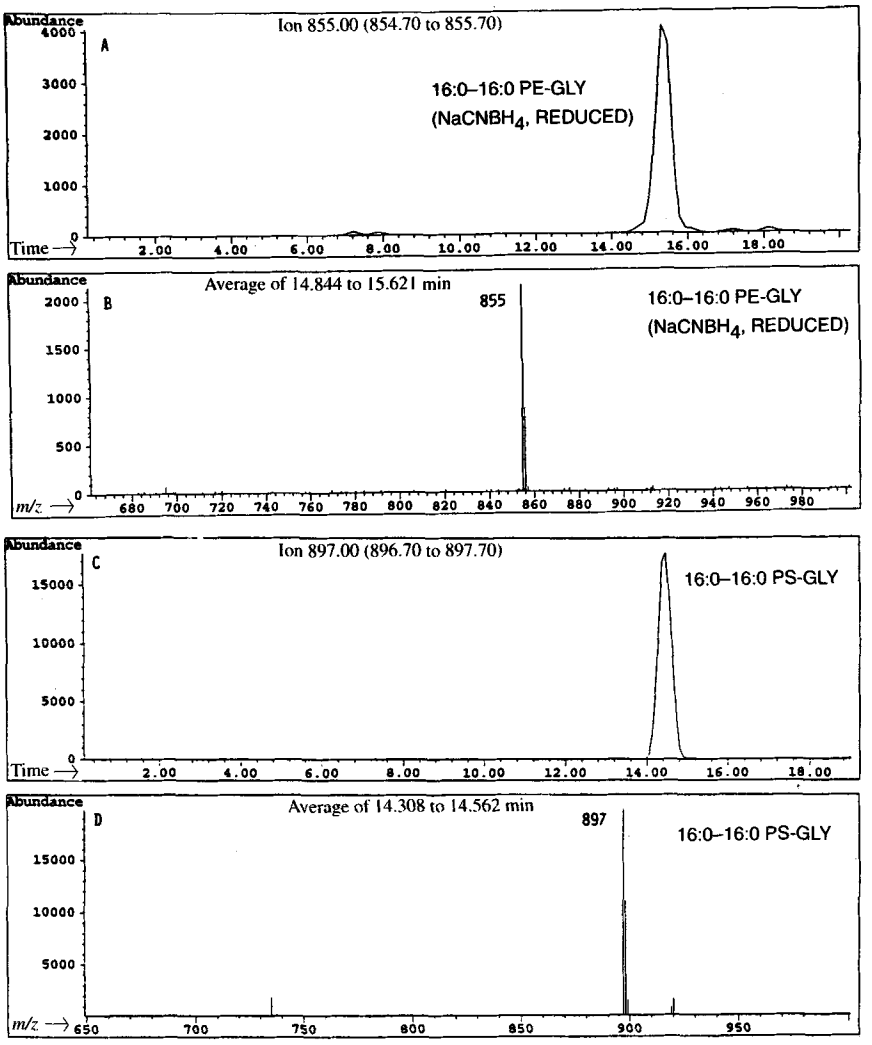

FIG. 4. Normal-phase liquid chromatography/mass spectrometry (MS) with electrospray ionization of glucosylated and $NaCNBH_4$-reduced dipalmitoyl aminophospholipids. Selected ion plot (A) and full spectrum (B) of glucosylated and reduced PE; selected ion plot (C) and full spectrum (D) of glucosylated PS. sylated PS (*m/z* 811) and in glucosylated PS (*m/z* 973) was the diacyl (18:0–20:4) species. Table 1 lists the $[M - H]^-$ values, identities, and the relative proportions of the major molecular species in the glucosylated and nonglucosylated portions of the aminophospholipids. The proportions of the major molecular species within the glucosylated and nonglucosylated forms of each aminophospholipid class were calculated from the $[M - H]^-$ ion (corrected for M + 1 and M + 2, where necessary) intensity and are given as percent of total. These proportions agreed closely with the known composition of the major species of egg yolk and red blood cell PE and PS (11). The proportions of glucosylated and nonglucosylated forms of each aminophospholipid were determined by normal-phase HPLC with ELSD. The ESI intensity differed significantly among the different phospholipid classes and between the glucosylated and nonglucosylated PE and PS, and required appropriate correction during quantitation in either positive or negative ion mode.

DISCUSSION

Although glucose is the least reactive of the common monosaccharides in Schiff base formation (12), it has been suggested that it might react with aminophospholipids and play a role in production of age pigments. The products of the reaction, however, have not been isolated. Previous attempts had not proven successful in the isolation of glycated PE from phospholipid-containing membranes (9). The earlier failure to isolate glycated PE may have been due to the easy dissociation of the Schiff base in the presence of mild acid, which is frequently employed in lipid extraction and TLC of phospholipids. We have not determined the exact time course of acid hydrolysis of glucosylated aminophospholipids. However, we have repeatedly observed the decomposition of the glucosylation products during extraction and chromatography (HPLC and TLC) with solvents containing small amounts of acetic, trifluoroacetic, or phosphoric acid. In contrast, these solvent

systems allowed effective extraction and chromatography of the cyanoborohydride reduction products of the glucosylated aminophospholipids. In the present study, we noted that alkaline solvent systems were best suited for the recovery of the glucosylated aminophospholipids from *in vitro* incubations.

The effect of pH was investigated only over a limited range, keeping close to physiological conditions. This was done in order to approximate the nonenzymatic *in vivo* formation of Schiff bases between the aldehyde form of glucose and the aminophospholipids, and to avoid subsequent transformations. More alkaline conditions (pH > 7.4) were not used because of potential hydrolysis of the lipid ester bonds during prolonged incubation. The alkaline HPLC solvent system and the soft ESI allowed us to demonstrate the glucosylation of both PE and PS in the presence of glucose concentrations found in severe diabetes and hyperglycemia. Such glucose concentrations have been shown to cause membrane damage and cell death of cultured pericytes, endothelial cells, kidney cells, retinal rods, and red blood cells (13–16). Incubation of intact red blood cells with increasing concentrations of glucose under isotonic conditions and pH 7.4 led to glucosylation of largely PE, which we hope to describe in greater detail elsewhere, along with the *in vivo* glucosylation of red blood cell aminophospholipids (A. Ravandi and A. Kuksis, unpublished results). In other unpublished studies, we have demonstrated that glucosylation of PE and PS results in increased accumulation of lipid ester hydroperoxides and core aldehydes in the aminophospholipids. It is not known whether this is due to increased susceptibility of the glucosylated aminophospholipids to peroxidation or to an interference of the glucosylated base structure with the removal of the hydroperoxy fatty acids from the phospholipid molecules by phospholipases A_2. Phospholipase A_2 is believed to be involved in cleavage of oxidized fatty acids as part of oxidation damage repair mechanism in cell membranes (17,18). The availability of the glucosylated standards along with well-defined working conditions for the isolation of these structures should allow an assessment of the natural distribution of the glucosylated aminophospholipids in normal and in pathological tissues. Comparable ESI spectra of nonglucosylated aminophospholipids recently have been reported (19,20).

Structural Importance of the *cis*-5 Ethylenic Bond in the Endogenous Desaturation Product of Dietary Elaidic Acid, *cis*-5,*trans*-9 18:2 Acid, for the Acylation of Rat Mitochondria Phosphatidylinositol

Robert L. Wolff

I.S.T.A.B., Laboratoire de Lipochimie Alimentaire, Université Bordeaux 1, Talence, France

ABSTRACT: When rats were fed elaidic (*trans*-9 18:1) acid at a high load in diets that were otherwise marginally or almost completely deficient in linoleic (*cis*-9,*cis*-12 18:2) acid, elaidic acid was desaturated to *cis*-5,*trans*-9 18:2 acid. This polymethylene-interrupted acid was then incorporated into most phospholipids from rat mitochondria, cardiolipin being an exception. Its level of esterification in phospholipids followed the increasing order: phosphatidylethanolamine < phosphatidylcholine < phosphatidylinositol (PI). The content of *cis*-5,*trans*-9 18:2 acid decreased in organs in the order liver > kidney > heart. The levels of *cis*-5,*trans*-9 18:2 acid increased in mitochondria phospholipids as the level of linoleic acid was lowered in the diet. In liver mitochondria PI, it reached 16% of total fatty acids. After hydrolysis of liver mitochondria PI with *Naja naja* phospholipase A_2, we observed that elaidic acid was essentially esterified to position 1 at the expense of saturated acids, whereas *cis*-5,*trans*-9 18:2 acid was exclusively esterified to position 2, along with 20:3n-9 and 20:4n-6 acids. As a consequence, the sums of saturated and *trans*-9 18:1 acids on the one hand, and of 20:3n-9, 20:4n-6, and *cis*-5,*trans*-9 18:2 acids on the other hand, remained fairly constant in liver mitochondria PI (*ca.* 55 and 30%, respectively). Because *trans*-9 18:1 and *cis*-5,*trans*-9 18:2 acids differ only by the *cis*-5 ethylenic bond, which is also present in 20:3n-9 and 20:4n-6 acids, this distribution pattern indicates that the *cis*-5 double bond, rather than any other ethylenic bond, may be of major structural importance for channeling fatty acids to position 2 of PI.

Lipids 30, 893–898 (1995).

Little is known about the specificity of acylases that ensure the homeostasis of membrane phospholipid fatty acids *in vivo*. There are at least three types of acylases—acyl-CoA acyltransferase, CoA-dependent, and CoA-independent transacylases. To our knowledge, few data have been published on the structural parameters of fatty acids that are recognized by such phospholipid acylating enzymes. For example, it has been suggested that acylases which are specific for the 1(1″) positions of cardiolipin (CL) esterify only fatty acids having at least one *cis*-9 double bond, with no other *cis* double bonds between this position and the carboxylic group (1). In the case of highly polyunsaturated fatty acids such as 20:4n-6 (all *cis*-5,8,11,14 20:4) or 22:6n-3 (all *cis*-4,7,10,13,16,19 22:6) acids, the question that arises is: Which parts of the molecules, which double bonds, are specifically identified by acylases?

The problem seems to be somewhat simplified in phosphatidylinositol (PI), because this phospholipid essentially contains 20:4n-6 acid as a polyunsaturated fatty acid, with practically no 22:6n-3 acid. The situation in this particular case is thus limited to establishing which part of the arachidonic acid molecule is specifically identified by PI-acylating enzymes. It is clear that the *cis*-14 double bond is not essential, because 20:4n-6 acid is easily replaced by 20:3n-9 (all *cis*-5,8,11 20:3) acid, which is devoid of this bond, when the precursor of 20:4n-6 acid, linoleic acid, is depleted in the diet and, therefore, in the cell. Moreover, it was recently shown that 20:4n-6 acid could also be replaced in PI by the rare all *cis*-5,11,14 20:3 acid (2). As this acid lacks the *cis*-8 double bond, it can be deduced that this bond is not essential for the recognition by PI-specific acylating enzymes. So, there remain two double bonds, the *cis*-5 and the *cis*-11, that may be of some structural importance for the specificity of PI-acylating enzymes. Because PI contains only trace amounts of *cis*-11 18:1 (*cis*-vaccenic) acid, we hypothesized that the *cis*-5 double bond might be of major importance. However, to decide which of these double bonds is significant, it is necessary to test fatty acids with isolated *cis*-5 or *cis*-11 double bonds.

Fatty acids containing an isolated *cis*-5 double bond exist, but they are not easily available in sufficient quantities for dietary experiments. For example, pine seed oil contains *cis*-5,*cis*-9,*cis*-12 18:3 acid (3), whereas meadowfoam seed oil is rich in *cis*-5 20:1 acid (4). In the present study, we took advantage of a surprising property of elaidic (*trans*-9 18:1) acid —it can be desaturated to *cis*-5,*trans*-9 18:2 acid either *in vitro* or *in vivo* in the rat, provided the diet is either marginally or completely deficient in linoleic acid (5,6). mon polymethylene-interrupted acid contains an isolated *cis*-5 double bond, and because the *trans*-9 double bond is sterically similar to a single bond (see the Discussion section), the *cis*-5,*trans*-9 18:2 acid is geometrically equivalent to a *cis*-5 18:1 acid. Consequently, we fed rats diets rich in elaidic acid and poor in linoleic acid, and followed the metabolic fate of the endogenously synthesized *cis*-5,*trans*-9 18:2 acid. For this purpose, we analyzed the fatty acids of all individual phospholipids from mitochondria of different rat organs (liver, kidneys, heart), with particular attention to PI. This quantitatively minor phospholipid represents only 3–8% (on a phosphorus basis) of total mitochondria phospholipids, depending on the organ.

MATERIALS AND METHODS

Animals and diets. Three groups of 12 weanling male Wistar rats (mean weight: 45 ± 2 g; 21-day-old) were raised for one month on a basic fat-free diet (UAR, Villemoisson-sur-Orge, France) supplemented with 10% (w/w) of a synthetic triglyceride (trielaidin) mixed with a variable amount of soybean oil (in order to provide a small percentage of linoleic and α-linolenic acids). The fatty acid compositions of the fat supplements are summarized in Table 1. The elaidic acid content was kept almost constant (from 64.5 to 69.0%), whereas that of linoleic acid varied from 0.3 to 7.1% of total fatty acids. In addition to these three groups of rats, ten weaned rats and six young adult rats (*ca.* 150 g) that were reared on a standard complete diet were also used in the present study.

Preparation of mitochondria. At the end of the feeding periods, the rats were decapitated and their liver, kidneys, and heart were excised. The organs were washed with ice-cold buffer (10 mM Tris, 0.25 M sucrose, 2 mM EDTA, pH 7.2), cut into small pieces, pooled, and rinsed with the buffer. Eight volumes of the buffer were added (Bioblock Scientific, Strasbourg, France) and the mixture was homogenized in a Potter homogenizer. For hearts only, type VIII protease from *Bacillus subtilis* (0.8 mg protease/g of heart tissue; Sigma Chemical Company, St. Louis, MO) was added to the homogenate. Mitochondria were then prepared by successive centrifugations (7) and were finally resuspended in a minimum volume of buffer containing 0.25 M sucrose and 10 mM Tris (pH 7.2). All operations were conducted at 4°C.

18:3n-3	0.7	0.1	<0.1
Others	1.1	0.9	2.1

Extraction of lipids. Seven volumes of methanol were added to the mitochondria suspensions, followed by 14 vol of chloroform. The suspensions were stirred for 30 min at room temperature and filtered on a paper filter into a rotary evaporator flask. Solvents were evaporated under reduced pressure, and lipids were dissolved in pure chloroform. The chloroform solution of lipids was transferred and filtered in a tube. Chloroform was evaporated under a stream of N_2, and lipids were dissolved in chloroform/methanol (2:1, vol/vol). After washing according to the procedure of Folch *et al.* (8), the lower layer was filtered and the solvents were evaporated. Lipids were stored at −20°C in chloroform/methanol (2:1, vol/vol) under N_2 in the presence of 0.02% 2,6-di-*tert*-butyl-4-methylphenol as an antioxidant.

Phospholipid isolation. Phospholipids were separated by thin-layer chromatography (TLC) on 0.3-mm thick silica gel H (Kieselgel H 60; Merck, Darmstadt, Germany) laboratory-coated plates using the solvent mixture chloroform/methanol/water (65:25:4, by vol). Phospholipid bands [phosphatidylcholine (PC) plus PI (PC–PI); phosphatidylethanolamine (PE); CL] were visualized under ultraviolet light after lightly spraying the plates with a 0.2% (wt/vol) solution of 2′,7′-dichlorofluorescein (DCF) in 96% ethanol. The bands containing PE and CL were scraped off and transferred into Teflon-lined screw-capped tubes for transmethylation of their fatty acids. The gel band containing PC–PI was transferred into a centrifuge tube, wetted with a few drops of distilled water, and the phospholipids were extracted twice with chloroform/methanol (2:1, vol/vol). The solvent was evaporated under a stream of N_2 at 30°C and the residue dissolved in chloroform/methanol (2:1, vol/vol). This solution was washed with 0.2 vol of a 0.8% KCl aqueous solution, and several times with portions of Folch upper phase (7) until no fluorescence due to the DCF could be detected under ultraviolet light. The solvent was evaporated, and the phospholipids were dissolved in a small volume of chloroform for further processing.

The preceding extract of mixed PC and PI was fractionated a second time by TLC with the solvent mixture butanol/acetic acid/water (40:20:20, by vol). After evaporation of the solvents from the plates with a stream of N_2, phospholipids were detected, and the gel was scraped off and transferred into Teflon-lined screw-capped tubes for transmethylation. In one instance, PI was eluted from the silica gel and purified as described previously for further hydrolysis with phospholipase A_2.

Hydrolysis of PI with phospholipase A_2. Hydrolysis of the ester bonds at position 2 of *sn*-glycerol of PI from liver mitochondria (purified as described previously) with phospholipase A_2 from *Naja naja* venom (Sigma Chemical Company) was performed according to a previously published method (9). The hydrolysis appeared to be complete after an incubation period of 2 h. LysoPI was separated from the free fatty acids from position 2 by TLC on silica gel H-coated plates developed with chloroform/methanol/water (65:25:4, by vol). After visualization of the bands, the gel was scraped off and

transferred into Teflon-lined screw-capped tubes for methyl ester preparation.

Fatty acid methyl ester (FAME) preparation and analysis. FAME from PC, PI, PE, and CL were prepared essentially according to Morrison and Smith (10). A methanolic solution (1–1.5 mL) of BF_3 (12%, wt/vol; Fluka, Buchs, Switzerland) was added to individual phospholipids in the presence of silica gel, and methylation was performed at 90°C for 30 min. FAME were analyzed by gas–liquid chromatography (GLC) using Varian (Palo Alto, CA) 1400 and 940 chromatographs equipped with flame-ionization detectors. Analyses were carried out with 300 x 0.32 cm or 600 x 0.32 cm stainless-steel columns packed, respectively, with 7% BDS (stationery phase; Supelco France, Saint-Gormain-en-Laye, France) on 100–120 mesh gas-chrom Q, at 185°C, or 15% OV-275 (stationary phase; Supelco France) on 80–100 mesh chromosorb P-DMCS, at 215°C. Peaks were identified by comparison of their retention times relative to those of commercially-available standards. Peak identification was supported by GLC analysis of FAME after fractionation by TLC on layers of silica gel H containing 5% silver nitrate (by weight). These plates were developed twice with hexane/diethyl ether/acetic acid (94:4:2, by vol) (11). FAME prepared from *Taxus baccata* L. seed oil, which contains *cis*-5,*cis*-9 18:2 acid (12), were used as a secondary standard on the BDS column for the location of the polymethylene-interrupted diene *cis*-5,*trans*-9 18:2 acid. Peak areas and percentages were calculated by a Shimadzu ICR-1B integrator (Shimadzu, Tokyo, Japan).

RESULTS

After a one-month feeding period on the elaidic acid-rich diets, the *cis*-5,*trans*-9 18:2 acid was esterified to PI, PC, and PE (except in PE from heart mitochondria of rats fed diet A), but practically not in CL (Fig. 1). This occurred in all three organs (liver, kidneys, and heart). Independently of the organ or the level of linoleic acid in the diet, the highest percentages of *cis*-5,*trans*-9 18:2 acid were observed in PI, followed by PC and then by PE. As the content of linoleic acid was lowered in the diet, the rate of incorporation of *cis*-5,*trans*-9 18:2 acid increased in mitochondria PI, PC, and PE from the three organs. A maximum value of 16% was reached in PI from liver mitochondria of rats fed the diet with the minimum amount of linoleic acid (0.3%; diet C). For each of the three phospholipids, the percentage of *cis*-5,*trans*-9 18:2 acid decreased with the organ in the order: liver > kidneys > heart (Fig. 1). Following hydrolysis by phospholipase A_2 of PI from liver mitochondria of rats fed the diet with the lowest amount of linoleic acid (diet C), we observed that the *cis*-5,*trans*-9 18:2 acid was exclusively located at the 2-position, together with 20:3n-9 and 20:4n-6 acids (Fig. 2). On the other hand, elaidic acid was essentially only esterified to position 1 together with saturated acids, mainly stearic acid. We also found an unknown fatty acid in a small amount at position 2 of PI (X in Fig. 2). From its behavior during GLC, this acid should have 20 carbon atoms. It migrated along with *cis*-5,*trans*-9 18:2 acid upon Ag–TLC fractionation, which sug-

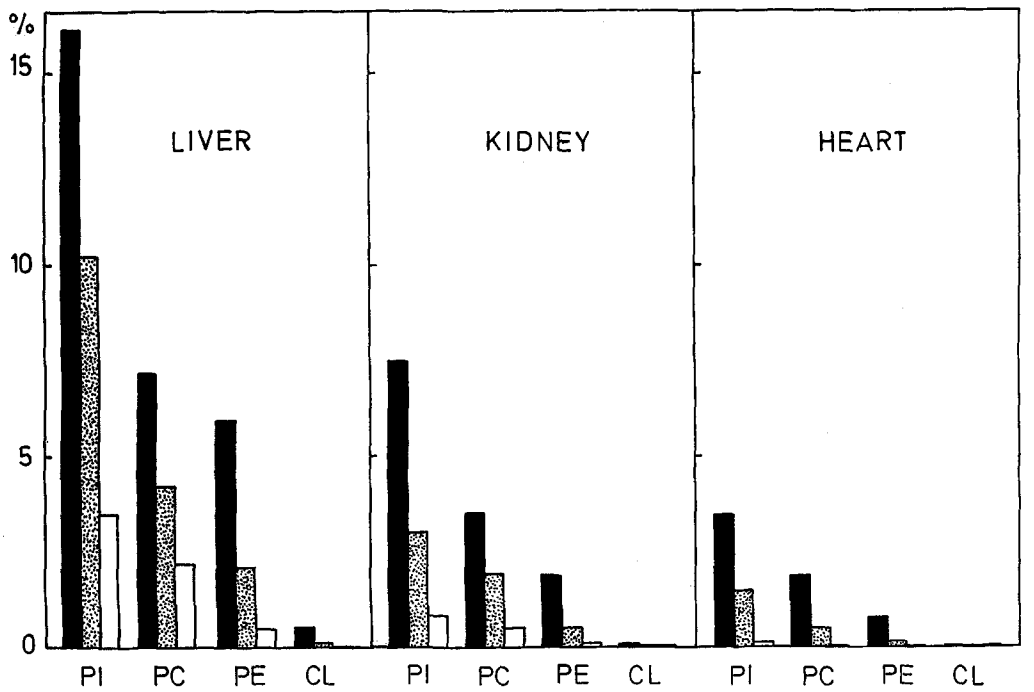

FIG. 1. Levels of *cis*-5,*trans*-9 18:2 acid in phospholipids of mitochondria from different organs of rats fed diets containing an almost constant percentage of elaidic acid (*ca.* 67% of total fatty acids in the fat supplement) with decreasing levels of linoleic acid after a one-month feeding period. Solid bars: 0.3% of linoleic acid (diet C); dotted bars, 2.4% (diet B); open bars, 7.1% (diet A). Results are expressed as weight percentages of *cis*-5,*trans*-9 18:2 acid relative to total fatty acids in a given phospholipid and are the means of at least two analyses. PI, phosphatidylinositol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; CL, cardiolipin.

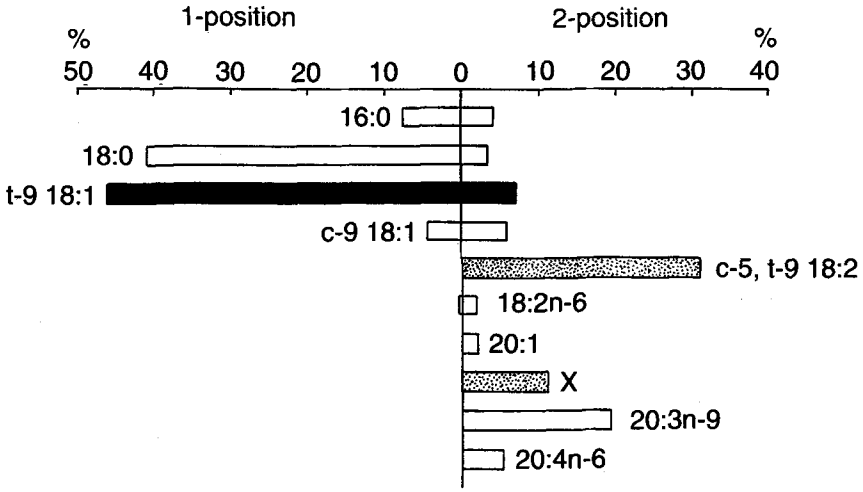

FIG. 2. Distribution of fatty acids between the 1- and 2-positions of phosphatidylinositol purified from liver mitochondria of rats fed for one month a diet containing 10% of fat, of which 68 and 0.3% were elaidic and linoleic acids respectively, (diet C). Results are expressed as weight percentages of fatty acids esterified to each position. X, unknown fatty acid. c, *cis*; t, *trans*.

gests that the two acids have analogous structural features. As this unknown acid was absent from liver PI of rats fed a fat-free diet, devoid of elaidic acid (results not shown), we can hypothesize that X was derived from elaidic acid. When comparing the fatty acid compositions of liver PI from rats fed the three experimental diets with those of liver PI from weaning or young adult rats reared on a complete standard diet, one can establish that the sums of saturated and elaidic acids on the one hand, and of *cis*-5,*trans*-9 18:2 acid (plus the unknown acid), 20:3n-9 and 20:4n-6 acids on the other hand, did not vary much (*ca.* 55 and 30%, respectively) (Fig. 3). In two instances (diets A and B), we followed the time-course evolution of fatty acids in liver mitochondria PI (Fig. 4). Although elaidic acid reached its maximum value after only one week in both cases, the increase of *cis*-5,*trans*-9 18:2 acid was much slower and almost paralleled that of 20:3n-9 acid for the replacement of 20:4n-6 acid. The behavior of the unknown acid followed that of *cis*-5,*trans*-9 18:2 acid. The rate of incorporation of *cis*-5,*trans*-9 18:2 acid increased as the level of linoleic acid in the diet was lowered.

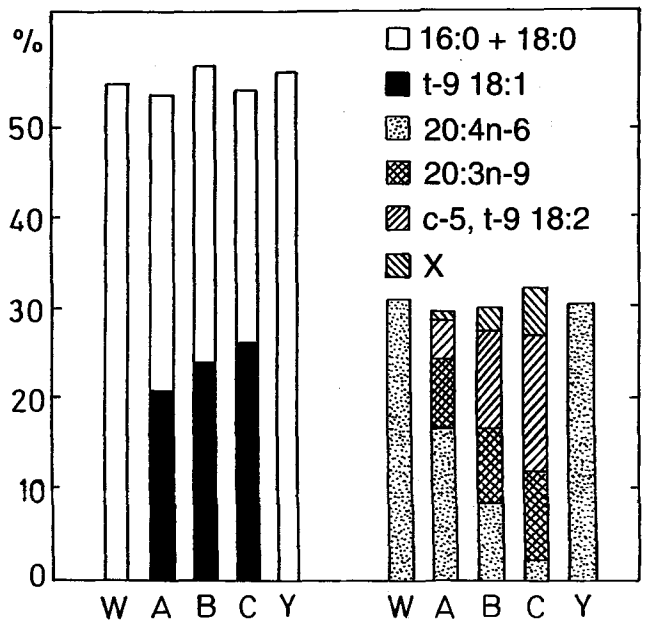

FIG. 3. Fatty acid distributions (main components) in phosphatidylinositol of liver mitochondria from rats fed for one month diets containing 10% of fat containing *ca.* 67% elaidic acid and a variable amount of linoleic acid (see Table 1 for the detailed fatty acid compositions of the diets). Data for weaning rats (W) and young adult rats fed a standard complete diet (Y) are also included. X, unknown fatty acid. c, *cis*; t, *trans*; A, B, C, diets A, B, and C.

DISCUSSION

From the phospholipase A_2 experiment, it is clear that the presence of the *cis*-5 ethylenic bond in *cis*-5,*trans*-9 18:2 acid is fundamental for channeling this acid to the 2-position of PI. Elaidic acid, which lacks this double bond, was essentially only esterified at the 1-position, where it replaced saturated acids. This confirms our previous results, which showed that elaidic acid should be considered as geometrically equivalent to a saturated fatty acid, at least for the esterification of phospholipids. It replaced saturated alkyl chains in PI, PC, and PE (13) and saturated alkenyl chains (after its reduction to the corresponding alcohol) in plasmalogens (14,15). On the other hand, it was hardly incorporated at all in CL (16), which is naturally almost devoid of saturated acids (1,17). The fact that a *trans* double bond should be considered as geometrically equivalent to a single bond is not limited to the *trans*-9 double bond in elaidic acid. For example, *trans*-5,*cis*-9,*cis*-12 18:3 and *cis*-9,*cis*-12,*trans*-15 18:3 acids were mainly incorporated in CL (2,18), which otherwise has a particular affin-

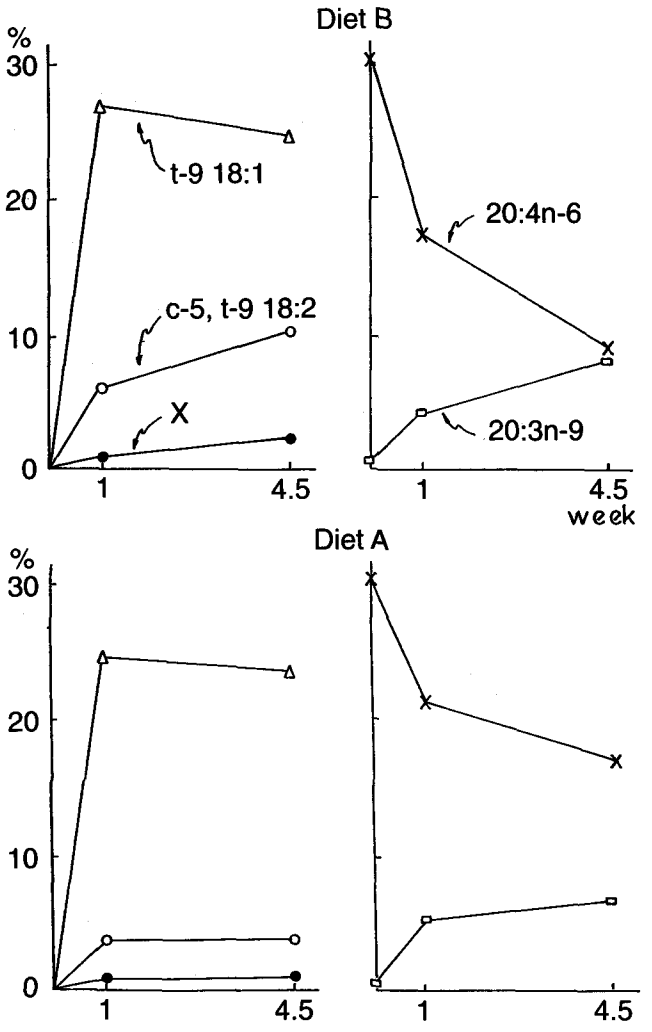

FIG. 4. Time-course evolution of some fatty acids in phosphatidylinositol from liver mitochondria of rats fed diets containing 10% of fat, in which elaidic and linoleic acids accounted for 69.0 and 2.4%, respectively (diet B), or 64.5 and 7.1%, respectively (diet A). X, unknown fatty acid; c, *cis*; t, *trans*.

ity for *cis*-9,*cis*-12 18:2 acid (14). In these two cases, the *trans*-5 and *trans*-15 double bonds were apparently perceived like single bonds by CL-acylating enzymes. The *trans*-5,*cis*-9,*cis*-12 18:3 and *cis*-9,*cis*-12,*trans*-15 18:3 acids thus behaved like *cis*-9,*cis*-12 18:2 acid and were preferentially channeled to CL. In an unpublished experiment, we observed that *cis*-5,*cis*-8,*cis*-11,*trans*-14 20:4 acid, which is endogenously derived from dietary *cis*-9,*trans*-12 18:2 acid (19,20), was incorporated mainly into liver PI, suggesting that the *trans*-14 20:4n-6 acid behaves like 20:3n-9 acid and consequently, that the *trans*-14 double bond is also equivalent to a single bond. This last observation also supports the conclusion that a *cis*-14 double bond is not necessary for a fatty acid to be esterified in PI.

The introduction of a *cis*-5 ethylenic bond in elaidic acid considerably modifies its properties. It is not handled by acylating enzymes like a saturated acid, but like a *cis*-unsaturated acid with a high affinity for PI and, more precisely, for its 2-position. Among phospholipids, PI contains the highest level of 20:4n-6 acid when 18:2n-6 acid is not limited in the diet as in a complete standard diet (*ca.* 30% of total fatty acids, or even more). On the other hand, 20:4n-6 acid is very low in CL. The 20:4n-6 acid contents in PC and PE are intermediate between these two extremes. So, it is tempting to hypothesize that *cis*-5,*trans*-9 18:2 acid follows the same route as 20:4n-6 acid for acylation into phospholipids. It is not incorporated in CL, and it reaches its maximum value in PI with intermediate levels in PC and PE. This hypothesis is supported by the kinetics of incorporation of *cis*-5,*trans*-9 18:2 acid into liver mitochondria PI (Fig. 4). The esterification of elaidic acid is very rapid, the maximum being reached in only one week, or perhaps less. Due to the shortness of this period, it appears that saturated acids in PI are quickly exchanged through deacylation–reacylation with elaidic acid rather than incorporated in *de novo*-synthesized molecules. On the other hand, the incorporation of *cis*-5,*trans*-9 18:2 acid in position 2 of PI was comparatively rather slow. There are at least two possible explanations for this phenomenon. First, the turn-over rate of 20:4n-6 acid might be slower than that of saturated acids in PI. Consequently, and because the precursor of 20:4n-6 acid was low in the diet, one may speculate that *cis*-5,*trans*-9 18:2 acid was mainly incorporated in *de novo*-synthesized PI molecules, in lieu of 20:4n-6 acid, which was depleted in the intracellular fatty acid pool, rather than exchanged with this acid. One may also hypothesize that the desaturation of elaidic acid by the Δ5 desaturase was a slow process, and that the accumulation of *cis*-5,*trans*-9 18:2 acid in the intracellular fatty acid pool was also slow and progressive. Moreover, *cis*-5,*trans*-9 18:2 acid might compete with 20:3n-9 acid, which is derived from oleic (*cis*-9 18:1) acid, for the replacement of 20:4n-6 acid in PI. Such conclusions cannot be drawn from the study of PC and PE fatty acids, because there is a concomitant decrease of both 20:4n-6 and 22:6n-3 acids in these phospholipids (results not shown).

Results obtained in the present study support the view that an acylase (or a group of enzymes involved in acylation) specific for PI exists that is also specific for fatty acids containing a *cis*-5 double bond. The 20:4n-6, 20:3n-9, all *cis*-5,11,14 20:3 and *cis*-5,*trans*-9 18:2 acids all share in common this double bond and present a higher affinity for PI than for any other phospholipid. We observed that the level of *cis*-5 double bond-containing fatty acids remains fairly constant in PI (Fig. 3). Because these acids are esterified to the 2-position of PI, this would imply that about 60% of PI molecules are substrate of the *cis*-5 double bond-specific acylating enzymes. The fatty acid profile in this population should thus only depend on the availability of the different *cis*-5 double bond-containing fatty acids in the intracellular fatty acid pool. Under conditions where linoleic acid is not limiting, 20:4n-6 acid is the main *cis*-5 double bond-containing acid in this pool. According to the concept developed in this study, it is probably recognized by the specific acylase through its *cis*-5

double bond, which thus appears to be the minimum structural requirement for this recognition.

ACKNOWLEDGMENTS

This study was performed in Prof. B. Entressangles's laboratory, and Dr. N.A. Combe provided skillful technical assistance. Trielaidin was a kind gift from the Astra-Calvé company.

A Temperature-Sensitive Strain of *Histoplasma capsulatum* Has an Altered Δ^9-Fatty Acid Desaturase Gene

[a]International Institute of Genetics and Biophysics, CNR, 80125 Naples, Italy and [b]Washington University, School of Medicine, Department of Internal Medicine, Division of Infectious Diseases, St. Louis, Missouri 63110-1093

ABSTRACT: We have isolated and characterized the Δ^9-desaturase gene (*Ole1*), which codes for a key enzyme involved in regulating membrane fluidity in animal cells and microorganisms, from two strains of *Histoplasma capsulatum*, one that is temperature-tolerant (G217B) and the other temperature-susceptible (Downs). These pathogenic fungi are dimorphic in that they undergo a morphologic transition from the mycelial to yeast-like form when the temperature of incubation is switched from 25 to 37°C or when they infect a susceptible host. The coding sequences of the two genes, both containing an intron of 93 nucleotides, are virtually identical and analogous to the Δ^9-desaturase gene of *Saccharomyces cerevisiae* and those of the rat, mouse and human. *Ole1* transcription of the thermotolerant G217B and thermosensitive Downs strains is similar in yeast phase cells and during the temperature shift down from 34, 37, or 40 to 25°C (yeast-to-mycelia transition). Nevertheless, the Δ^9-desaturase gene is transcriptionally inactive in mycelia of G217B at 25°C while it is actively transcribed in the Downs strain at the same temperature. These results are in agreement with the finding that membranes of the Downs strain have a higher level of oleic acid. The differential expression of Δ^9-desaturase genes is discussed in relationship to differences in thermosensitivity in the fungal isolates and in regulating the level of expression of heat shock genes.

Lipids 30, 899–906 (1995).

The physical properties of lipids and the dynamic nature of membranes have important effects on the functions of many membrane-associated proteins. Homeoviscous adaptation, a common feature of all organisms that adapt to different temperature regimes, is generally accomplished by incorporation of different types of fatty acids into the membrane during phospholipid synthesis or by regulation of the degree of unsaturation of the fatty acids itself (1–3). By modifying the transition temperature of membrane phospholipids, homeoviscous adaptation of the membrane maintains a given fluid environment for enzyme function at any physiological temperature. To determine whether a correlation exists between membrane fluidity and adaptation to sudden and rapid changes in temperature shifts up, the heat shock response (4), we began a study on the regulation of genes responsible for unsaturation of fatty acids in two strains of *Histoplasma capsulatum*, a dimorphic fungal pathogen of humans, that have different temperature optima of heat shock gene transcription (5,6).

As a saprobic fungus in nature, *H. capsulatum* grows in a multicellular filamentous form, but when it infects a susceptible host it becomes a unicellular yeast (7). Under laboratory conditions, the transition between the multicellular and unicellular phases can be reversibly induced by shifting the temperature between 25°C (mycelia) and 37°C (yeast). The mycelial-to-yeast-like conversion is of particular interest since it is triggered by an increase in the temperature of incubation, and conversion to the yeast morphology is necessary for virulence (8,9). The capacity to grow in different morphological forms implies that the organism is capable of adapting to different living conditions by expressing phase-specific genes whose products are critical for the survival and colonization of a given environment (10). Several biochemical and molecular events related to the process of temperature adaptation, that occur during the mycelial-to-yeast phase transition, have been studied (5,10–12). Heat shock proteins are among those products that have been best characterized (13). Heat shock genes are induced very early during infection and play a critical role in adaptation to the new environment (10). Recently, we have shown that the capacity to induce a stress response (transcription of heat shock genes) is influenced by the fatty acids composition of cell membranes (14; Carratù, L., Franceschelli, S., Pardini, C.L., Kobayashi, G.S., Horvath, I., Vigh, L., and Maresca, B., manuscript in preparation). Furthermore, the ratio of saturated/unsaturated fatty acids determines the appropriate membrane fluidity at a given temperature and environment (1). We have shown that the temperature-susceptible avirulent Downs strain, altered in its saturated/unsaturated fatty acids ratio, has a different optimal temperature of heat shock gene expression, i.e., 34°C, compared to 37°C in the temperature-tolerant virulent strains such as G217B (5,6) and a different biochemical pattern during the mycelium-to-yeast conversion (10,12).

It is well known that the physical state of the bilayer of biological membranes is a function of lipid composition and

that temperature acclimation causes changes in levels of acyl unsaturation. In the case of temperature shifts down, the introduction of additional unsaturated bonds disrupts the close packing of adjacent lipid chains to compensate for the ordering effects of cold (15,16). The mechanisms that control lipid biosynthesis are not yet clear but unquestionably involve changes in the activity of desaturases and acyltransferases. We postulated that the membrane is a primary target in the biological perception of temperature during rapid temperature changes and proposed that saturated/unsaturated fatty acids ratio and lipoprotein membrane complexes are involved in the perception of temperature changes and that under conditions of heat shock, disturbance of membrane physical state causes transduction of a signal that induces transcription of heat shock genes.

In animal and fungal cells, unsaturated fatty acids are formed by fatty acid desaturases which are lipophilic microsomal enzymes (17). The Δ^9-desaturase gene product is the major enzyme for converting saturated into unsaturated fatty acids and is responsible for the introduction of the first double bond between carbon 9 and 10 of palmitoyl (16:0) or stearoyl (18:0)-CoA to form palmitoleic (16:1) or oleic (18:1) acid (18). In an attempt to elucidate the genetic basis of the difference in fatty acid composition (membrane fluidity) in different isolates of *H. capsulatum* and the mechanisms that regulate heat shock gene expression, we began a molecular analysis of the structure and transcriptional regulation of the gene coding for Δ^9-desaturase, a key enzyme responsible for unsaturated fatty acids formation.

Desaturases are responsible for regulating the appropriate level of desaturation in membrane lipids and are supposed to be key enzymes in modulating membrane fluidity (1,16). Δ^9-Desaturase genes have been cloned from *Saccharomyces cerevisiae* (19), rat (20), mouse (21,22), and humans (23). In this paper we report the cloning, the physical structure, and the transcriptional analysis of the Δ^9-desaturase gene from two strains of *H. capsulatum*. The two genes have been isolated from the genomic library of the virulent, temperature-tolerant G217B strain (normal level of heat shock gene expression) and from a library of the temperature-susceptible, avirulent Downs strain (reduced level of heat shock gene expression). We show that in the latter strain the Δ^9-desaturase gene is actively expressed in mycelia at 25°C while in the temperature-tolerant G217B strain no mRNA was detectable. The transcriptional data are in agreement with the analysis of fatty acids profile that showed the presence of a lower level of saturated fatty acids in mycelia of the Downs strain. Preliminary sequence analyses support the hypothesis that the Downs putative promoter is altered while the two coding regions are virtually identical. These data are discussed in relationship to the role of this enzyme in regulating membrane fluidity and in setting the threshold of the temperature at which heat shock transcription occurs.

MATERIALS AND METHODS

Organisms and preparation of cells for isolation of nucleic acids. Growth conditions and isolation of DNA from the temperature-susceptible avirulent Downs (ATCC38904; American Type Culture Collection, Rockville, MD) and the temperature-tolerant virulent G217B (ATCC26034) strains of *H. capsulatum* have been described previously (5). Total RNA was extracted from the mycelial phase of Downs grown at 25°C and from mycelia that had been incubated at a temperature of 34 or 37°C for 1, 3, 6, or 24 h after the temperature shift. Total RNA was also isolated from mycelia of strain G217B incubated at 25°C and from cells switched either 37 or 40°C for 1, 3, 6, and 24 h after the temperature shift. A 1.5-mL aliquot of the cells was centrifuged and resuspended in 470 µL of lysis buffer containing 100 mM sodium acetate pH 5.3 and 1 mM $MgCl_2$. Cell lysis was obtained in the presence of 5 µL of diethyl pyrocarbonate by adding 25 µL of 20% SDS. Nucleic acids were extracted with 1 vol of the mixture [(by vol phenol/chloroform/isoamyl alcohol (25:24:1)] preequilibrated at 65°C. The mixture was vortexed in the presence of approximately 200 µL of glass beads, allowed to settle, and then centrifuged. The aqueous phase was extracted three times with the above mixture at 65°C and once with $CHCl_3$/isoamyl alcohol (24:1) at room temperature. RNA was precipitated with 0.3 M sodium acetate, pH 5.3, and 3 vol of 95% ethanol at −20°C overnight.

Molecular cloning. The Δ^9-desaturase gene was cloned by polymerase chain reaction (PCR) amplification of genomic DNA of the G217B strain using two synthetic, degenerated oligo-deoxynucleotides corresponding to two conserved regions of the cloned genes (*S. cerevisiae* and rat). The two sequences 5′-ACNGCNGGNTAYCAYMGNYTNTGG-3′ and 5′-TTYTTNARRTCRTANGCNARNCC-3′ correspond to the amino acid sequences TAGYHRLW and GLAYDLKK. The amplified fragment of 651 nt was cloned in pUC18, sequenced, and used to screen two genomic libraries of G217B (λDASH) and Downs (λGT11) strains. The positive clones were analyzed, and the *Xba*I-containing gene fragments were subcloned in pUC18. Appropriate subclones were generated to sequence the entire genes and their flanking regions, using the dideoxynucleotide chain termination method (24). Both strands were sequenced. In some cases, appropriate oligo-deoxynucleotides were synthesized for sequencing particularly unclear regions. All the standard procedures and manipulations were according to Sambrook *et al.* (25). The enzymes were used according to the manufacturers' indications.

Transcription start site analysis by primer extension. An antisense oligonucleotide (5′-TCTGTGATATGAACCTTC-3′) was synthesized spanning from nucleotide +105 to +122 relative to the putative initiation translation site ATG. Five ng of the oligomer were 5′ end-labeled with [γ^{32}P]ATP (specific activity 3,000 Ci/mmole; Amersham Co., Chicago, IL) using 5 units of T4 polynucleotide kinase (BRL, Middlesex, United Kingdom). A mixture containing the oligomer and 10 or 30 µg of total RNA extracted from yeast cells grown at 37°C of strain G217 was denatured at 93°C for 2 min in avian myeloblastosis virus (AMV) reverse transcriptase buffer (0.5 M Tris-HCl, pH 8.3, 60 mM $MgCl_2$, 0.1 M DTT, 0.1 M NaCl) and then frozen in a dry ice/ethanol bath for 2 min. The solu-

tions were slowly thawed on ice. Primer extension reaction was carried out at 42°C for 30 min with 200 µM of a mixture containing the four cold nucleotides and 2 units of AMV reverse transcriptase (Boehringer, Mannheim, Germany). Samples were separated on a 6% polyacrylamide sequencing gel containing 7 M urea. After electrophoresis, gels were transferred to 3 MM Whatman paper, dried, and autoradiographed at −70°C.

Northern blot analysis. Fifteen µg of total RNA was precipitated in ethanol and resuspended in 1 × 3-(*N*-morpholino) propanesulfonic acid (MOPS) [1 × MOPS is 20 mM MOPS, 10 mM sodium acetate pH 5.3, and 1 mM EDTA], 50% formamide, 2.2 M formaldehyde, and heated 10 min at 65°C. Samples were separated by electrophoresis on 1% denaturing agarose gel in 1 × running buffer (1 × MOPS). RNA was then transferred onto nylon membranes in 20 × saline-sodium citrate (SSC) (Boehringer) and fixed by ultraviolet (UV) crosslinking. Filters were then hybridized using 10^7 cpm of [^{32}P]-probe DNA in 5 × SSC, 5 × Denhardt's, 50% formamide at 42°C overnight. The probe was labeled by multipriming to a specific activity of 10^9 cpm/µg, and filters were washed under high stringency conditions at 65°C for 40 min.

Total RNA was determined spectrophotometrically and by scanning an ethidium bromide gel containing the same amount of total RNA which were used for the Northern blot. The ethidium bromide gel was photographed, and rRNA bands were analyzed by the computer program Image 1.47 using a macro specifically designed to quantify gel bands. In addition, the filter, after hybridization, was stained 5 min in 5% acetic acid and 5 min in 0.04% methylene blue in 0.5 M sodium acetate followed by washing with water (not shown). The intensity of rRNA bands were further checked by the software program to make sure that the RNA loaded on the gel was uniformly transferred to filter. Filters that were hybridized with *cdc2* also have been hybridized with a fragment of *Hc* 18S rRNA gene to ensure that same amount of RNA was on filters (not shown). The exposed film was scanned and intensity of bands measured by the Image software (National Institutes of Health, Bethesda, MD).

RESULTS

Cloning of Δ9-fatty acid desaturase gene of thermotolerant G217B strain. Genomic DNA was amplified by PCR with two synthetic degenerated oligonucleotides corresponding to two conserved regions of cloned Δ^9-desaturase genes. The 651-nt fragment obtained by PCR amplification was first sequenced and then used as a probe to isolate the entire *Ole1* gene and its flanking sequences from a genomic λDASH (Stratagene Cloning systems, La Jolla, CA) library of strain G217B. About 10^5 recombinant phages were screened by hybridization with the PCR probe under stringent conditions. One of seven positive clones found was further subcloned in pUC18 vector and analyzed. The entire nucleotide sequence of G217B strain of *H. capsulatum Ole1* gene has been determined (GenBank accession number X85962, Heidelberg). Sequence analysis of the translated fragments revealed that the G217B *Ole1* gene contains a single open reading frame (ORF) starting from the first ATG of 1431-nt that is interrupted by one intron of 93 nt. The presence of the intron that, like other fungal introns, resembles those present in all eukaryotic mRNA having the acceptor and donor conserved consensus sequences following the GT/AG rule for 5′ and 3′ splice site (26), was confirmed by sequencing a cDNA clone with appropriate oligonucleotides on both sides of the intron.

Cloning of Δ^9-desaturase gene of thermosensitive Downs strain. Since strains of *H. capsulatum* exist exhibiting different temperatures of thermotolerance that correlate with optimum of heat shock gene transcription and level of virulence (5,8,10,12), we cloned the Δ^9-desaturase gene from a λGT11 genomic library of the thermosensitive Downs strain using as a probe the PCR product described above. One of the five positive phages were subcloned in pUC18 vector and analyzed (GenBank accession number X85963, Heidelberg), and one of them containing a 4 kb insert was sequenced. The coding sequence (476 aa) contained only seven amino acid substitutions compared to the coding sequence of *H. capsulatum* G217B strain.

The Downs strain contains an intron of 93 nt in the same location as that cloned from G217B. Both ORF code for a protein of approximately 53,700 Da. A screening against a representative protein sequence data base (PIRProtein, release 36) showed a significant similarity to Δ^9-desaturase proteins of *S. cerevisiae* (72% similarity, 49% aa identity), rat (55.3 and 31.5%, respectively), mouse (56 and 34%, respectively), and human (57 and 34%, respectively, human gene has only been partially cloned). Comparisons were done using the GCG sequence analysis program *Gap*. Long stretches of highly conserved amino acids are present, as between aa 270 and 298 of *H. capsulatum* and aa 330 and 358 of *S. cerevisiae* with 25 out 28 identical aa, demonstrating that our cloned sequences coincide with a Δ^9-desaturase gene (Fig. 1). The most conserved amino acid is histidine with 18 out 22 residues perfectly aligned (27,28). Arginine residues of the rat liver enzyme have been previously identified as being involved in substrate binding (29). It is interesting to note that arginine residues are also highly conserved in *H. capsulatum Ole1* genes. Furthermore, it has been shown that both the rat liver and the *S. cerevisiae* enzyme have striking similarities in hydropathic characteristics (27,28). Both proteins have been shown to contain two regions of 50 aa containing long stretches of hydrophobic residues forming loops that have been proposed to be responsible for the anchoring of the protein in the endoplasmic reticulum (27). These hydrophobic regions are in identical position in the aligned *S. cerevisiae* and rat proteins (27). Figure 1 shows that the *Ole1* predicted proteins of *H. capsulatum* contain similar stretches of amino acids located in the same position confirming the presence of transmembrane loop regions.

Transcription start point analysis by 5′ end extension. The location of the putative 5′ end of *Ole1* mRNA was mapped by primer extension experiments for the G217B strain. A 17-

FIG. 1. Comparative analysis of the amino acid sequences of Δ^9-desaturase gene products of *Histoplasma capsulatum* (*H.C.*), *Saccharomyces cerevisiae* (*S.C.*), rat, mouse (mus), and humans (hum). Boxes indicate the highly conserved histidine residues. Lower-case letters indicate residues that are not identical to those in the *H.C.* protein.

nt antisense oligodeoxynucleotide (5′-TCTGTGATATGAACCTTC-3′) was synthesized spanning from nt +105 to +122 relative to the putative start codon ATG and annealed to total RNA extracted from yeast cells grown at 37°C. The result in Figure 2 demonstrates the presence of one major extended molecule of 253 nt. This experiment defines an untranslated 5′ region of 131 nt from the putative translation start codon. Previously, we also found two untranslated regions of 163 and 186 nt in the *hsp82* gene (7) and one of 218 nt in the *cdc2* gene of *H. capsulatum* (30). Search of TATA-like consensus sequence upstream of the transcription start point did not identify any consensus in both sequences.

Analysis of Ole1 expression. We previously showed that the two strains of *H. capsulatum* contain differences in the membrane saturated/unsaturated fatty acid ratio (Carratù, L., Franceschelli, S., Pardini, C.L., Kobayashi, G.S., Horvath, I., Vigh, L., and Maresca, B., manuscript in preparation). Assuming there are no differences in the coding sequences of the two cloned *Ole1* genes, we have investigated transcription of *Ole1* gene in both strains. Northern experiments were performed using total RNA extracted from cells growing at 25°C and then shifted up to 34, 37, and 40°C and from these temperatures to 25°C. Figure 3 shows hybridization of total RNA extracted from G217B mycelia (Fig. 3A) at various times after the shift from 25 to 37°C and from 37 to 25°C. *Ole1* gene expression is poorly detectable in cells growing at 25°C and, when shifted at 37°C, expression can be measurable 6 h from temperature shift. In yeast cells growing at 37°C, the gene is actively transcribed at this temperature, and as expected (31,32), expression was enhanced after shift down to 25°C. When the mycelium-to-yeast phase transition was accomplished at the upper temperature range for this strain (40°C), a similar pattern of expression was observed (Fig. 3B). However, cells required more than 24 h to restore transcription at 40°C, and, after the shift to 25°C, the gene was more rapidly switched off. On the other hand, while transcription of *Ole1* gene in the thermosensitive Downs strain is similar to that of G217B, a striking difference was measurable in mycelia grown at 25°C. Figure 3C shows that *Ole1* gene is actively transcribed at 25°C and switched off when

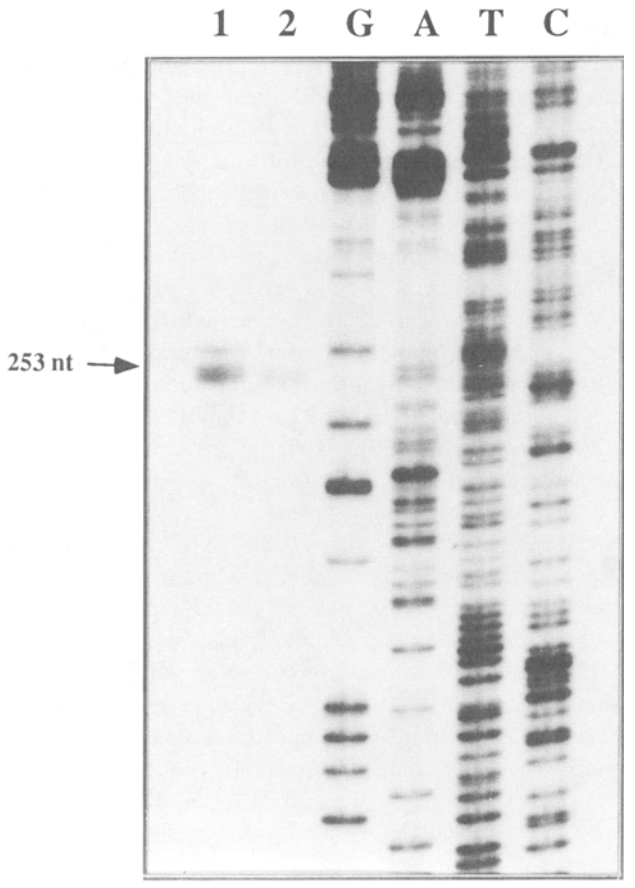

FIG. 2. Location of the 5′ end of *Histoplasma capsulatum* Δ^9-desaturase mRNA by primer extension. An antisense oligonucleotide (5′-TCTGT-GATATGAACCTTC-3′) was synthesized spanning from nucleotide +105 to +122 relative to the putative initiation translation site ATG. Five ng of the oligomer were 5′ end-labeled with [γ^{32}P]ATP. Lane 1: 30 µg total RNA; Lane 2: 15 µg total RNA. Lanes marked G to C are the sequence ladder of DNA of known sequence. Samples were separated on a 6% polyacrylamide sequencing gel containing 7 M urea.

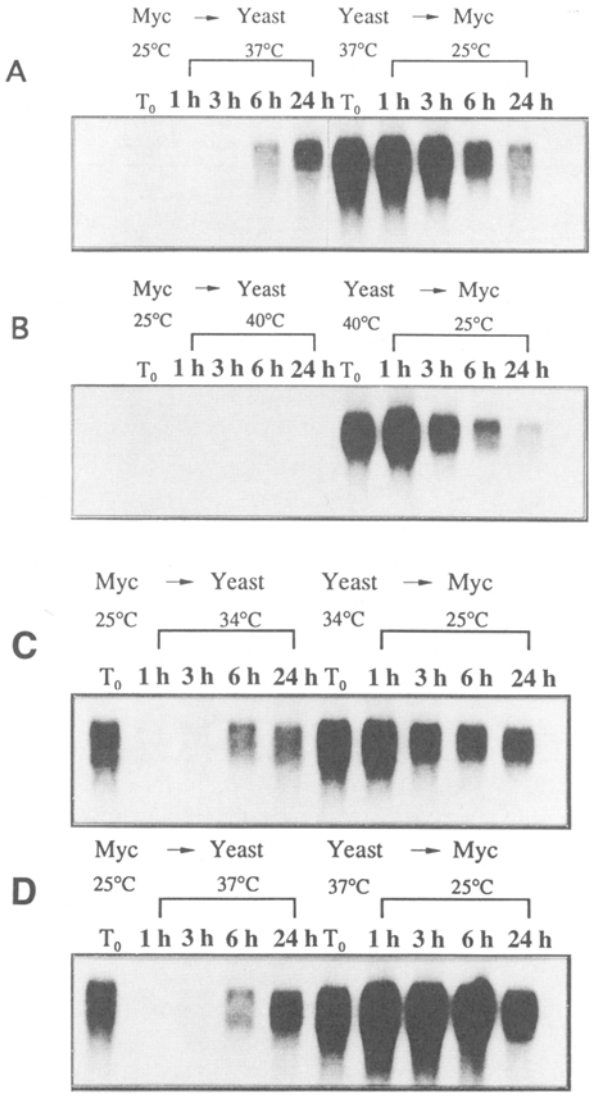

FIG. 3. Northern blot of total RNA purified of *Histoplasma capsulatum* Δ^9-desaturase gene in G217B and Downs. A: Shows hybridization of RNA purified from mycelia (Myc) cells grown at 25°C and from mycelia 1, 3, 6, and 24 h after the shift to 37°C and from yeast grown at 37°C and 1, 3, 6, and 24 h after shift to 25°C. B: Shows an identical experiment, but 40°C was used rather than 37°C. C: Shows hybridization of RNA purified from mycelia cells grown at 25°C and from mycelia 1, 3, 6, and 24 h after the shift to 34°C and from yeast grown at 34°C and 1, 3, 6, and 24 h after shift to 25°C. D: Shows an identical experiment, but 37°C was used rather than 34°C. Fifteen µg of total RNA were loaded for each sample.

temperature was raised either to 34 (Fig. 3C) or 37°C (Fig. 3D), the latter being the upper temperature range for this strain (8). Figure 4 shows a time-course experiment of the effect of temperature shift 25 to 37°C in both strains showing that *Ole1* gene is turned off within 30 min from temperature shift up. These experiments clearly indicate that the *Ole1* gene transcription is altered in the Downs strain.

Thus far, we have sequenced about 900 nt upstream to the ATG of both *Ole1* sequences (data not shown). A preliminary analysis of these sequences shows that while a high conservation in this region has been retained in these genes, major differences have been found in a specific region (data not shown). Though no conclusions can be drawn from these observations at the present time, it is reasonable to speculate that the difference in transcriptional regulation between the two *Ole1* genes may lie in this region of low nucleotide identity.

DISCUSSION

Recently, we demonstrated that, in the two strains of *H. capsulatum* that differ in their optimal temperature of heat shock mRNA induction, it is possible to modulate transcription of these genes by exogenous addition of fatty acids (14). In the temperature-susceptible Downs strain exposure of mycelia to saturated fatty acids at 25°C induced a strong increase in heat shock gene transcription when cells were shifted to 37°C. On

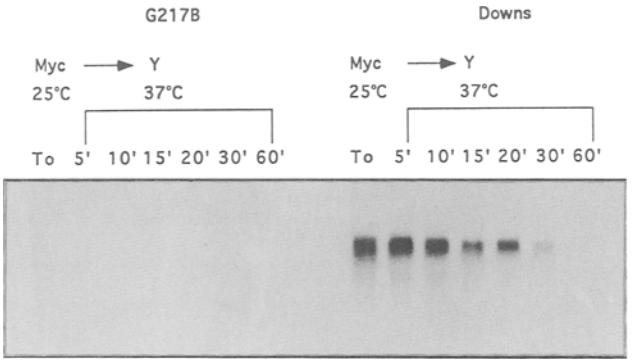

FIG. 4. Time course of the expression of of *Histoplasma capsulatum* Δ^9-desaturase gene in G217B and Downs strains after a temperature shift from 25 to 37°C.

the other hand, in the temperature-tolerant G217B strain addition of unsaturated fatty acids to mycelia drastically reduced heat shock gene transcription when cells were shifted to 37°C. We further observed that the Downs strain has a higher unsaturated fatty acid content, particularly oleic acid; on the other hand, the membrane of the G217B strain has a lower unsaturated fatty acids content and is less fluid (Carratù, L., Franceschelli, S., Pardini, C.L., Kobayashi, G.S., Horvath, I., Vigh, L., and Maresca, B., manuscript in preparation). Thus, these studies suggest that the level of saturation of membrane fatty acids may be involved in the perception of sudden temperature changes (heat shock).

We cloned the Δ^9-desaturase gene by PCR amplification of genomic DNA using two synthetic, degenerated oligo-deoxynucleotides corresponding to two conserved regions of the cloned genes from both the temperature-sensitive Downs and from the temperature-tolerant G217B strains. The 651 nt amplified fragment was cloned in pUC18, and, after sequencing to confirm that it corresponded to a Δ^9-fatty acid desaturase gene, was used to screen two genomic libraries of G217B (λDASH) and Downs (λGT11) strains. The positive clones were analyzed, and the *Xba*I-containing gene fragments were subcloned in pUC18. Appropriate subclones were generated to sequence the entire genes and their flanking regions. In contrast to the *S. cerevisiae Ole1* gene that lacks introns (27), the *H. capsulatum Ole1* gene of both strains contains an ORF starting from the first ATG of a single 1431-nt ORF interrupted by one intron, of 93 nt. Like other fungal introns, the 93 nt sequence resembles those present in all eukaryotic mRNA having the acceptor and donor conserved consensus sequences following the GT/AG rule for 5′ and 3′ splice site (26), which was confirmed by sequencing a cDNA clone with appropriate oligonucleotides on both sides of the intron. Screening against a representative protein sequence data base showed a good degree of homology to *S. cerevisiae* (476 aa, in contrast to 510 aa for the *Ole1* protein of *S. cerevisiae*). The two coding sequences cloned from both strains of *H. capsulatum* are virtually identical with only seven amino acid differences between the two sequences.

Both ORF code for a protein of approximately 53,700 Da (57,400 in *S. cerevisiae*). A screening against a representative protein sequence data base (PIRProtein), using the GCG sequence analysis program *Gap*, showed a significant similarity to *S. cerevisiae* (72% similarity, 49% aa identity), rat (55.3 and 31.5%, respectively), mouse (56 and 34%, respectively), and human (57 and 34%, respectively). The human gene, however, has only been partially cloned (23). Long stretches of highly conserved amino acids, as between aa 270 and 298 of *H. capsulatum* and aa 330 and 358 of *S. cerevisiae* with 25 out 28 identical aa, were identified, demonstrating that our cloned sequences coincide with a Δ^9-desaturase gene. More recently it has been shown that the most conserved amino acid is histidine with 18 out of 22 residues perfectly aligned (28). Furthermore, 8 histidine residues are essential in membrane-associated stearoyl-CoA desaturases, and the relative positions of these residues are conserved in alkane hydroxylases and xylane monoxygenases (28). All of the 8 most conserved His residues that have been shown by mutations (His→Ala) in the rat Δ^9-desaturase gene to be necessary for growth in a minimal medium without unsaturated fatty acids (28) are present in the *Histoplasma Ole1* gene. These His residues have been suggested to have an essential catalytic function. These authors have identified three regions of primary sequence containing conserved His residues. These sequences defined as HX_4H, HX_2HH, and HX_2HH are all present in both *H. capsulatum* Δ^9-desaturase proteins. Though the importance of His in these sequences has not been elucidated, it is interesting to note that a consensus containing these three sets of sequences is present only in 21 of all proteins sequenced, and 18 are fatty acid desaturases, including the Δ^9-desaturase of *H. capsulatum*.

Arginine residues of the rat liver enzyme have been previously identified as being involved in substrate binding (29). We also found that arginine residues in the *H. capsulatum Ole1* genes are highly conserved. Furthermore, previously it has been shown that both the rat liver and the *S. cerevisiae* enzyme have striking similarities in hydropathic characteristics (27). Both proteins contain two regions of 50 aa containing long stretches of hydrophobic residues forming loops that have been proposed to be responsible for the anchoring of the protein in the endoplasmic reticulum (27). These hydrophobic regions are in identical position in the aligned *S. cerevisiae* and rat proteins (27). Figure 1 shows that the *H. capsulatum Ole1* predicted proteins containing such stretches are located in the same position, and confirm the presence of such transmembrane loop regions.

We have determined the transcriptional start site of *Ole1* gene by primer extension demonstrating the presence of one major extended molecule defining an untranslated 5′ region of 131 nt from the translation start codon. Similarly, short 5′ untranslated regions were detected in *hsp82* (5) and *cdc2* (30) genes of *H. capsulatum*.

The *Ole1* gene was transcribed in mycelia of Downs strain grown at 25°C while a shift to 37°C caused an abrupt cessation of expression which lasted at least 3 h and resumed 24 h

after the temperature shift. On the contrary, when mRNA purified from G217B strain was probed, no transcription was detectable in mycelia at 25°C nor in the first 3 h of the temperature shift to 37°C. When yeast cells growing at 37°C were incubated at 25°C, there was a burst in transcription 1 h after temperatures shift down and then transcription resumed at normal rate both in Downs and G217B strain. When a time course experiment was performed in Downs mycelia shifted from 25 to 37°C, it was shown that within 30 min after temperature change *Ole1* gene transcription was turned off (Fig. 4). These transcriptional analyses are in agreement with the differences in saturated fatty acids we found in the two strains. In fact, the lower amount of saturated fatty acids measured in the Downs strain can be explained by the differences in transcriptional regulation of the *Ole1* gene.

It is interesting to note that the *Ole1* gene of *H. capsulatum* is highly expressed in yeast cells of both Downs (at 34 and 37°C) and G217B (37 and 40°C) strains before the shift down to 25°C. The burst in transcription lasted up to 6 h in both strains to decrease but was still present after 24 h of the shift down (yeast-to-mycelium morphologic transition). However, the amount of mRNA present in Downs strain was much higher (Fig. 3). Cells fully transform in 3 to 4 d in the case of G217B while 6–7 d are required for the more temperature-sensitive Downs (8). In the case of the G217B strain, fully transformed cells growing as mycelia at 25°C do not express *Ole1* while Downs cells maintain a high level of expression. We also detected *Ole1* mRNA transcription in mycelia grown at 25°C and then switched to 34 or 37°C in the case of Downs and to 37°C in the case of G217B between 6 and 24 h after temperature shift up. To our knowledge, this is first evidence describing transcriptional induction of a Δ^9-desaturase gene as a result of temperature increase, though it occurs after 6 h after the temperature shift. Nevertheless, we can not exclude that the induction of the desaturase is a result of morphogenesis rather than a consequence of the temperature change. *Histoplasma capsulatum* is a dimorphic fungus, and as other parasites, it adapts to the new conditions present in the host, such as higher temperature, changes in redox potential and pH, different nutrients, etc. It is reasonable to postulate that, among other changes, also a different membrane lipid composition is part of the adaptive process that leads to the morphologic mycelium-to-yeast transition. In addition, morphogenesis comprises a heat shock phenomenon (rapid temperature shift up from 25 to 37°C) that involves induction of a specific set of genes (heat shock genes) that in cohort with others permit adaptation to the new temperature. Our data suggest that the Δ^9-desaturase gene may be involved in the adaptation to a higher temperature during morphogenesis and in the process of reorganization of the membrane of the yeast form.

In summary, we have shown that the Downs strain of *H. capsulatum*, which is altered in its saturated/unsaturated fatty acids ratio, nonvirulent and temperature-susceptible has a different optimal temperature of expression of heat shock gene. Expression studies of cloned *hsp70* (6) and *hsp82* (5) genes revealed that 34°C is the temperature of maximal heat shock mRNA transcription in this strain, while in virulent strains, such as G217B, maximal induction of heat shock gene expression occurs at 37°C. Our results indicate that the cell membrane is a primary target in the biological perception of temperature during rapid temperature changes and propose that saturated/unsaturated fatty acids ratio and lipoprotein membrane complexes are involved in the perception of temperature changes and that under heat shock conditions disturbance of the physical state of the membrane causes transduction of a signal that induces transcription of heat shock genes.

Intestinal and Liver Fatty Acid Binding Proteins Differentially Affect Fatty Acid Uptake and Esterification in L-Cells

Daniel R. Prows[1], Eric J. Murphy and Friedhelm Schroeder*

Department of Physiology and Pharmacology, Texas A&M University, College Station, Texas 77843-4466

ABSTRACT: Differential effects of intestinal (I-FABP) or liver (L-FABP) fatty acid binding proteins on fatty acid uptake and esterification were examined using transfected mouse L-cell fibroblasts. L-FABP, but not I-FABP, expression increased the initial rate and extent of *cis*-parinaric acid uptake by 50 and 29%, respectively, compared to control cells. I-FABP and L-FABP expression preferentially increased [^{3}H]-oleic acid incorporation into triacylglycerols by 5.5-fold and 3.8-fold, respectively. While both L-FABP and I-FABP increased esterification of [^{3}H]-oleic acid into ethanolamine glycerophospholipids, these proteins had opposite effect on esterification into choline glycerophospholipids. These data show for the first time that distinct FABP differentially affect both fatty acid uptake and intracellular esterification.

Lipids 30, 907–910 (1995).

Intestinal fatty acid binding protein (I-FABP) and liver fatty acid binding protein (L-FABP) are homologous proteins produced by intestinal absorptive columnar epithelial cells (enterocytes). L-FABP is also expressed at high levels in hepatocytes (1,2). I-FABP is a 131-residue, 15.1 kDa, cytosolic protein that noncovalently binds one mole of long-chain (C_{16}–C_{20}) saturated or unsaturated fatty acid with K_d values between 1–4 μM (3,4). L-FABP is a 127-residue, 14.3 kDa, cytosolic protein that binds two moles of saturated or unsaturated fatty acid or one mole each of fatty acid and sterol (3,5). The K_d values for saturated and unsaturated fatty acids are between 1.4–2.6 μM (3). Studies *in vitro* show that FABPs stimulate fatty acid uptake, act as intracellular fatty acid carriers, and affect lipid synthetic enzyme activities (3,5–8). FABPs binds numerous hydrophobic ligands including cholesterol (5), hydroperoxy- and hydroxy-arachidonic acid metabolites (9), heme (10), prostaglandin E_1 (11), and acyl-CoA (8). However, the physiological function of FABPs in intact cells is not known. Experiments presented here utilized an identical transfected cell model system (L-cells) expressing either I-FABP or L-FABP. Parallel studies using separate cell lines give insight into their plausible distinct roles in intracellular fatty acid trafficking and esterification.

MATERIALS AND METHODS

Cells. Mouse L-cell fibroblasts (aprt$^-$, tk$^-$) expressing L-FABP were obtained as stated earlier (12). The aprt$^-$, tk$^-$ expressing I-FABP were prepared in the same manner. Briefly, cells were transfected with the cDNA for rat I-FABP by the calcium phosphate-DNA precipitation method (13), using the modification of Wigler *et al.* (14). Expression of I-FABP or L-FABP was determined by quantitative Western blot immunoassay using the respective antisera (12). High expression clones, in which the respective proteins represented 0.35–0.4% cytosolic proteins, were isolated and compared to control and mock-transfected control L-cells.

Cis-*parinaric acid assay. Cis*-parinaric acid (9,11,13,15 *cis, trans, trans, cis*-octadecatetraenoic acid; (Molecular Probes, Eugene, OR) in aqueous buffer is nonfluorescent, but fluorescence intensity increases upon association with a hydrophobic environment. Both L-FABP and I-FABP bind *cis*-parinaric acid very well, as measured by increased fluorescence intensity (3). Fluorescent *cis*-parinaric acid uptake studies were performed on cell suspensions at a final concentration of 1.5×10^5 cells/mL phosphate buffered saline in a total volume of 2 mL. Cells were continuously stirred at 37°C with a Bel-Art cell spinbar (Fisher Scientific, Pittsburgh, PA) in the sample compartment of a photon counting fluorimeter (ISS Instruments, Champaign, IL). *Cis*-parinaric acid (1.8 μM) was added with a Hamilton syringe (Reno, NV).

[^{3}*H*]*-oleic acid incorporation assay.* Cells were washed with phosphate buffered saline and incubated for 30 min at 37°C with serum-free medium containing [^{3}H]-oleic acid diluted with cold oleic acid to a final specific activity of 1 μCi/nmol and a concentration of 1.8 μM. Cellular lipids were extracted, resolved, and quantitated as described earlier (15–17).

Statistics. Statistical analysis was done using one-way analysis of variance combined with the Tukey-Kramer multiple comparisons test (InStat, GraphPad Software, San Diego, CA) or the Student's *t*-test.

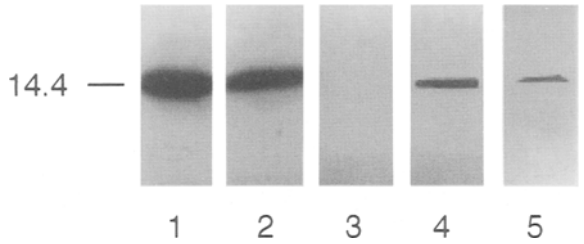

FIG. 1. Western blot showing intestinal fatty acid (I-FABP) and liver fatty acid protein (L-FABP) expression in transfected L-cell fibroblast. Lane 1 is I-FABP standard, and lane 2 shows I-FABP expression in total cell homogenate from transfected I-FABP expressing cells. Lane 3 is representative of total cell homogenate from nontransfected L-cells reacted with α-I-FABP. Lane 4 is L-FABP standard, and lane 5 shows L-FABP expression in total cell homogenate from transfected L-FABP expressing cells.

TABLE 1
***Cis*-Parinaric Acid Uptake Rates and Maximal Fluorescence**

Cell line	Initial rates (fluorescence units/s)	Maximal fluorescence (fluorescence units)
Control cells	220 ± 7.0 (12)	5534 ± 91 (12)
Mock-transfected cells	225 ± 8.7 (10)	5763 ± 82 (10)
High-I-FABP cells	222 ± 7.6 (18)	5897 ± 184 (17)
High L-FABP cells	337 ± 4.7[b] (6)	7128 ± 89[b] (6)

[a]*Cis*-parinaric acid uptake in control cells, mock-transfected control cells, high intestinal fatty acid binding proteins (I-FABP), and high liver fatty acid binding protein (L-FABP) expressing cells was determined as described in the Materials and Methods section. Initial rates are reported as the slope of the uptake curves (fluorescence vs. time) for the initial 10 s after fatty acid addition and mixing. Maximal fluorescence, which represents extent of total uptake, is given in relative fluorescence. Values are the mean ± SEM, with n = 6–18.

[b]$P < 0.001$ from all other cell lines.

RESULTS

Both I-FABP and L-FABP expressing cells had measurable cytosolic levels of their respective proteins (Fig. 1). L-FABP accounted for 0.40% of the total cytosolic protein in L-FABP expressing cells. I-FABP accounted for 0.35% of the total cytosolic protein in I-FABP expressing cells.

Cis-parinaric acid uptake into control, I-FABP expressing, and L-FABP expressing cells was linear for approximately the first 30 s and reached a plateau after approximately 1 min that was maintained for the duration of the assay (Fig. 2). *Cis*-parinaric acid uptake rates were significantly ($P < 0.001$) increased by 50% in L-FABP expressing cells compared to control or I-FABP expressing cells (Table 1). Maximal fluorescence indicates the extent of *cis*-parinaric acid uptake. L-FABP significantly ($P < 0.001$) increased the extent of *cis*-parinaric acid uptake by 29 and 21% compared to control and I-FABP expressing cells, respectively (Table 1). No significant differences in *cis*-parinaric acid uptake or maximal fluorescence were found between the two control cell lines or the high I-FABP expressing clones.

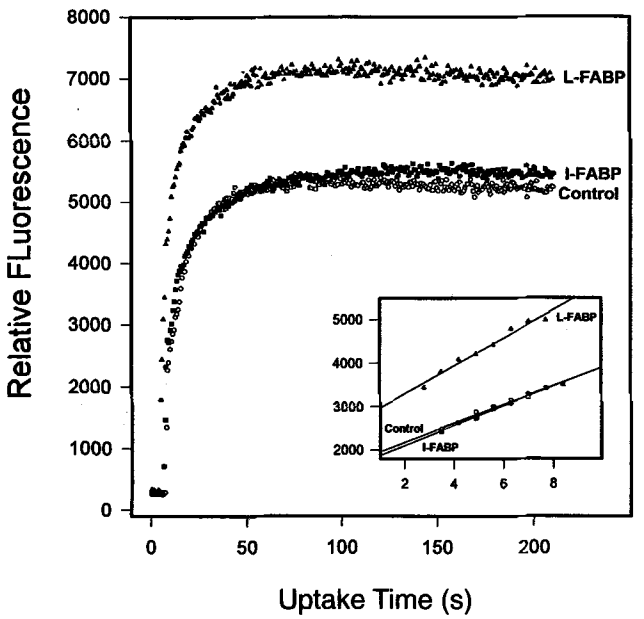

FIG. 2. *Cis*-parinaric acid uptake vs. time curves. *Cis*-parinaric acid (1.8 μM) was added to a continuously stirred cell suspensions (2 mL) in quartz cuvettes at 37°C. Increase in fluorescence over time represents binding and internalization of the fatty acid. Each curve is a representative assay with n = 6–18. Differences (SEM) between runs within the same cell line were always <10%. Inset represents initial readings following *cis*-parinaric acid addition. Initial uptake rates for the various cell lines were determined from the slope of the regression line for the initial readings. See Figure 1 for abbreviations.

Following [^{3}H]-oleic acid incorporation for 30 min, the esterified neutral and phospholipids were separated by high-performance liquid chromatography into individual lipid classes and the radiolabel distribution was determined (Table 2). No significant differences for any lipid classes were observed between the L-cells and the mock-transfected cells. These two groups were subsequently combined and referred to as control cells. No significant differences in nonesterified fatty acid proportions were found between any cell lines tested. In high I-FABP expressing cells, cholesteryl esters, triacylglycerols, and ethanolamine glycerophospholipids had significantly more [^{3}H]-oleic acid incorporated than control cells. However, the distribution of [^{3}H]-oleic acid into choline glycerophospholipids was significantly decreased in high I-FABP expressing cells compared to control cells. For high L-FABP expressing cells, [^{3}H]-oleic acid distribution into triacylglycerols, ethanolamine- and choline glycerophospholipids was significantly increased compared to control cells, while [^{3}H]-oleic acid distribution into cholesteryl esters was decreased. The total [^{3}H]-oleic acid incorporation was not significantly different between high I-FABP expressing cells and control cells; however, the total [^{3}H]-oleic acid incorporation by the L-FABP expressing cells was increased by 45% over control cells (data not shown).

Cis-parinaric acid was only slightly esterified in L-FABP expressing cells over a 30-min incubation period (Fig. 3). After 30 min, less than 3% of the total *cis*-parinaric acid was esterified, with the vast majority of this amount found in the choline- and ethanolamine glycerophospholipids. *Cis*-pari-

TABLE 2
Percent Distribution of [^{3}H]-Oleic Acid in Neutral and Phospholipid Fractions[a]

Lipid species	% Total distribution (dpm/plate)		
	Control cells	High I-FABP	High L-FABP
Nonesterified fatty acids	9.5 ± 0.7	11.5 ± 1.7	10.0 ± 1.0
Cholesteryl esters	9.6 ± 1.1	13.3 ± 1.3[b]	2.7 ± 0.8[c]
Triacylglycerols	2.9 ± 0.3	16.3 ± 3.3[c]	10.9 ± 1.3[c]
Ethanolamine glycerophospholipids	7.1 ± 0.7	10.7 ± 0.3[b]	9.5 ± 0.2[b]
Choline glycerophospholipids	54.6 ± 1.5	39.6 ± 3.1[c]	59.1 ± 0.8[b]
Others	16.3	8.6	7.8

[a]The cells were incubated with [^{3}H]-oleic acid for 30 min and prepared as described in the Materials and Methods section. Listed are the nonesterified fatty acids and the major esterified neutral lipids and phospholipids. "Others" represents the sum total of mono- and diacylglycerols, lysophosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, sphingomyelin, lysophosphatidylcholine, and phosphatidylinositol-4-phosphate. Data represent means ± SEM with n = 3–5. See Table 1 for abbreviations.
[b]$P < 0.05$ from control cells.
[c]$P < 0.001$ from control cells.

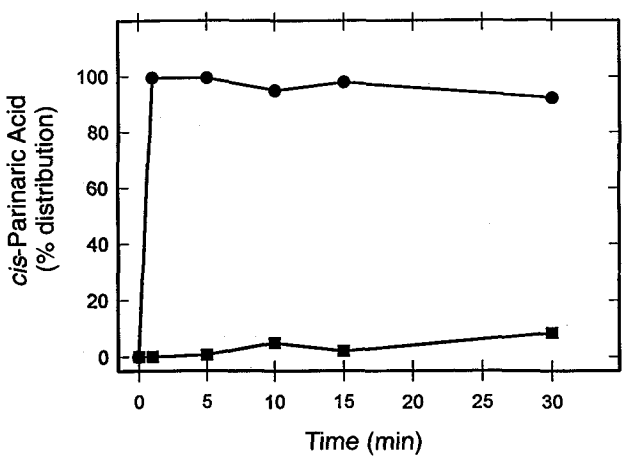

FIG. 3. The percent distribution of *cis*-parinaric acid in L-FABP expressing L-cells. The circles represent total cellular free *cis*-parinaric acid as determined by high-performance liquid chromatography (HPLC). The squares represent *cis*-parinaric acid esterified into phospholipids as determined by HPLC. Data points are the average values from two separate cell culture plates at each time point. Abbreviation as in Figure 1.

naric acid was marginally esterified into triglycerides, with this amount representing less than 0.1% of the total *cis*-parinaric acid taken up. Hence, over 97% of the *cis*-parinaric acid taken up by the cell remains in the free fatty acid pool.

To better illustrate the differential effects of I-FABP and L-FABP on fatty acid trafficking and esterification, the esterified [^{3}H]-oleic acid phospholipid/neutral lipid ratio was calculated for control, I-FABP, and L-FABP expressing cells. This ratio was 3.7 ± 0.4 for control cells, 1.7 ± 0.3 for I-FABP expressing cells, and 5.4 ± 0.5 for L-FABP expressing cells. I-FABP expressing cells had a 220 and 320% decrease in this ratio compared to control cells and L-FABP expressing cells, respectively. In contrast, L-FABP expressing cells had a 44% increase in the phospholipid/neutral lipid ester ratio over control cells.

DISCUSSION

The data presented herein show for the first time that different FABP do not exert the same effect on fatty acid uptake. L-cell fatty acid uptake was resolved from intracellular esterification through the use of the poorly esterified *cis*-parinaric acid. *Cis*-parinaric acid is a naturally-occurring octadecatetraenoic (*cis-trans-trans-cis*) fatty acid that resembles oleic acid in structure and is nonfluorescent in aqueous medium but fluoresces strongly when bound to FABP (3). Because *cis*-parinaric acid is only slightly esterified in L-cells (<3% in 30 min), a fluorescent increase closely represents fatty acid uptake in the absence of appreciable esterification. L-FABP expressing cells had a 53% increase in the initial *cis*-parinaric acid uptake rate and 29% increase in the extent of *cis*-parinaric acid uptake. In contrast, I-FABP had no effect. This indicates that L-FABP expression, but not I-FABP expression, increased the fatty acid flux into the cell.

The bulk of this fluorescent increase stimulated by L-FABP can be accounted for by *cis*-parinaric acid insertion into cellular membranes; although *cis*-parinaric acid bound to the L-FABP could account for some of this increased fluorescence. In assays *in vitro*, L-FABP has a 3.4-fold higher fluorescence yield than I-FABP in the presence of saturating *cis*-parinaric acid levels (3). However, this difference *in vitro* cannot be extrapolated to an intact cell system because the fatty acid can partition into an abundance of membrane relative to the FABP levels.

L-FABP and I-FABP expression differentially affected intracellular [^{3}H]-oleic acid esterification. By determining fatty acid incorporation into specific lipid classes, differences in exogenous fatty acids trafficking by the two proteins were resolved. Cells expressing L-FABP preferentially incorporated [^{3}H]-oleic acid into phospholipids, primarily choline- and ethanolamine glycerophospholipids, rather than esterified neutral lipids (Table 2). In contrast, I-FABP expressing L-cells showed a significant increase in [^{3}H]-oleic acid incorporation into the neutral lipid fraction with a significant decrease

in esterification into the phospholipid fraction. I-FABP expression stimulated a larger increase of [^{3}H]-oleic acid into triacylglycerols and total esterified neutral lipids compared to L-FABP expressing or control cells. Therefore, L-FABP appears to direct newly acquired fatty acids into phospholipids, whereas I-FABP preferentially directs new fatty acids into esterified neutral lipids. The effect of L-FABP may represent increased phospholipid synthesis as seen *in vitro* (8).

Our results support the hypothesis that the two FABP present in the intestine have different roles in fatty acid uptake and metabolism. L-FABP increases fatty acid uptake and targets this fatty acid for esterification into phospholipids, while I-FABP does not increase fatty acid uptake, but does preferentially stimulate esterification into triacylglycerides. The mechanisms by which these differential effects occur are unknown, but may represent the ability of these proteins to stimulate specific synthetic pathways.

ACKNOWLEDGMENTS

The helpful suggestions of Sean Myers-Payne during the preparation of this manuscript were very much appreciated. This work was supported in part by the USPHS National Institutes of Health grant DK41402.

Effects of Bile Salts on Rat Hepatic Acyl CoA:Cholesterol Acyltransferase

Sandra K. Erickson[a,*] and Paul E.A. Van Zuiden[b]

[a]Department of Medicine, University of California, San Francisco and Department of Veterans Affairs Medical Center, San Francisco, California and [b]Department of Medicine, Brown University and Veterans Administration Medical Center, Providence, Rhode Island

ABSTRACT: Acyl CoA:cholesterol acyltransferase (EC2.3.1.26, ACAT), responsible for intracellular esterification of cholesterol, may play an important role in cholesterol trafficking within the cell, and thus, in maintenance of cellular cholesterol homeostasis. Bile acids are potential regulators of cholesterol trafficking in the liver. Therefore, the effect of bile salts on hepatic ACAT activity was studied in the perfused rat liver. ACAT activity was increased after liver perfusion with either taurocholate or taurochenodeoxycholate. However, addition of these bile salts at physiological concentrations *in vitro* had little effect on microsomal ACAT activity. The increase in hepatic ACAT activity due to perfusion with bile salts was accompanied by reduced accumulation of very low density lipoprotein cholesterol in the perfusate, but there was no effect on 3-hydroxy-3-methylglutaryl–CoA reductase activity. Hepatic ACAT activity was decreased after bile diversion for four hours in the intact animal. This treatment had no statistically significant effect on 3-hydroxy-3-methylglutaryl–CoA reductase activity. These data suggest that bile salts induce changes in hepatic compartmentation and traffic of cholesterol within the hepatocyte accompanied by response of ACAT activity to maintain cellular cholesterol homeostasis.

Lipids 30, 911–915 (1995).

The liver is a key organ for the maintenance of whole body cholesterol homeostasis. It plays an important role in regulating both plasma lipoprotein and biliary lipid metabolism. Maintenance of cholesterol homeostasis within the liver involves a complex interplay among cellular and extracellular factors. The major routes of egress of cholesterol and its metabolites from the liver are in lipoproteins and the bile. These two pathways appear to be regulated interdependently; i.e., perturbations in one can lead to changes in the other (1–6). Based on previous work (7–10), the enzyme acyl CoA: cholesterol acyltransferase (EC2.3.1.26, ACAT) responsible for intracellular sterol esterification could play a pivotal role in the direction of cholesterol movement within the hepatocyte, specifically, into the biliary or lipoprotein secretory pathways or into a cholesterol ester (CE) storage compartment. Thus, factors which affect biliary lipid metabolism, such as bile salts, might be expected to affect hepatic ACAT activity, lipoprotein cholesterol secretion, and cholesterol storage.

Feeding bile salts increases hepatic ACAT activity (11,12); however, such a treatment can alter the amounts of cholesterol reaching the liver; thus, the direct effects of bile salts on hepatic ACAT activity are unknown. The perfused rat liver model was utilized to study the effects of short-term administration of the bile salts, taurocholate and taurochenodeoxycholate, on ACAT activity. These effects were compared with the known response of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase, a rate-limiting enzyme of cholesterol synthesis, to this treatment. Further, the effect of bile salts on the net accumulation of very low density lipoprotein (VLDL) cholesterol and triglyceride accumulation in the perfusate was determined. The influence of loss of bile salts on hepatic ACAT and HMG–CoA reductase activities was evaluated in the intact animal after 4-h bile diversion.

EXPERIMENTAL PROCEDURES

Animals. Male, Sprague-Dawley rats, 180–200 g (Simonsen, Gilroy, CA; or Bantin and Kingman, Newark, CA) were housed under normal illumination (lights on 6 a.m.; lights off 6 p.m.). They were allowed free access to food and water at all times. All protocols were approved by animal welfare committees at Stanford University or at the VA Medical Centers (San Francisco, CA, and Providence, RI).

Liver perfusion. Livers were perfused *in situ* as described previously (13) by the method of Mortimore (14) using a silastic lung as described by Hamilton *et al.* (15). Prior to perfusion, a small liver lobe was removed for assay of preperfusion enzyme values. After establishment of perfusion, 16 μmoles Na taurocholate/100 g rat/h or 23 μmoles Na taurochenodeoxycholate/100 g rat/h were added to the perfusate as described previously by Cooper (16). The bile salts were from Sigma (St. Louis, MO). The perfusate also contained 3% bovine serum albumin (Cohn fraction V; Sigma). No gross deleterious effects on the liver were observed as assessed by liver color, ability to extract 0_2, and absence of perfusate loss.

Control rats received an equal volume of vehicle. The perfusate was allowed to recirculate for two hours after which time the perfusate was collected and the livers washed with iced saline. Liver microsomes were prepared (17) and assayed for ACAT (11) and HMG–CoA reductase (17). Perfusate VLDL was isolated by centrifugation at d = 1.019 and assayed for cholesterol and triglyceride as described previously (13).

Bile diversion. Bile was diverted in intact animals by cannulation of the common bile duct and drainage of the bile into a tube. The animals were placed in restraining cages and allowed free access to water. Control animals were sham operated and also placed in restraining cages and allowed free access to water. Bile was collected over 4-h and analyzed as described previously (18). The animals were anesthetized and their livers removed after the 4 h bile diversion and microsomes prepared and assayed for reductase and ACAT as above.

In vitro *effects of bile salts.* Liver microsomes were prepared (17) from untreated rats. Na cholate, Na chenodeoxycholate, Na taurocholate, or Na taurochenodeoxycholate was added to the assay tubes over the concentration range 10^{-9}–10^{-3}M and ACAT activity assayed as above.

Statistical Methods. Student's *t*-test was used to assess significance of group differences after correlation for multiple comparisons.

RESULTS AND DISCUSSION

Hepatic ACAT activity was increased within 2 h after addition to the perfusate of either taurocholate or taurochenodeoxycholate compared with the control perfusions or with the preperfusion values (Table 1). The increase in ACAT activity after bile salt perfusion was unlikely to reflect a change in increased cholesterol availability due to increased *de novo* cholesterol synthesis in as much as Liersch *et al.* (19) reported that *de novo* synthesis of cholesterol was unaffected by perfusion of bile salts. In the present work, perfusion with bile salts had no statistically significant effect on the activity of HMG–CoA reductase, a rate-limiting enzyme for cholesterol synthesis (Table 1), confirming previous observations by Cooper (16), and further supporting the hypothesis that bile salt perfusion had not altered *de novo* synthesized cholesterol available to ACAT.

The increases in ACAT activity were not accompanied by increased recovery of esterified cholesterol in VLDL (Fig. 1). Net accumulation of perfusate VLDL cholesterol and triglyceride was decreased after perfusion with either bile salt. This observation is consistent with that reported by Del Pozo and Barth (20) who observed decreased VLDL secretion by isolated rat hepatocytes exposed to bile salts. The ratio of free to esterified cholesterol in VLDL was unchanged by bile salt perfusion; free cholesterol was about 70% of the total in all samples. Thus, increased CE formation by ACAT induced by bile salt perfusion did not lead to net increase in VLDL CE accumulation in the perfusate.

Although the total amounts of cholesterol recovered in the liver after perfusion in the presence or absence of bile salts were similar [2.34 ± 0.23 mg/g liver (control) vs. 2.38 ± 0.17 mg/g liver (cholate) vs. 2.55 ± 0.08 mg/g liver (chenodeoxycholate), not statistically significantly different, n = 3–4 animals in each group], the proportion as CE increased from about 2.5% in the livers after the control perfusions to approximately 16% (range 8–28%) in the livers after perfusion with either bile salt. Similar observations were reported by Cooper (16). Thus, the increase in ACAT activity coupled with decreased secretion of VLDL cholesterol resulted in increased CE storage in the liver after bile salt perfusion.

Little is known about the effects of bile salt perfusion on VLDL metabolism. In addition to possible effects on secretion, the observed decrease in perfusate VLDL cholesterol and triglyceride accumulation might be due to effects on uptake of VLDL or its remnants by the liver. However, this seems unlikely, since Spady *et al.* (21) found that infusion of bile salts into normal rats for eight hours had no effect on hepatic low density lipoprotein receptor-dependent transport or on cholesterol synthesis. Thus, in the rat, short-term liver perfusion with bile salts would seem unlikely to have induced a change in low density lipoprotein receptor-dependent uptake of newly secreted VLDL.

TABLE 1
Effect of Perfusion with Bile Salts on Hepatic ACAT and HMG–CoA Reductase Activities[a]

Perfusion	ACAT (nmole CE/min/mg prot)	% Increase from preperfusion value	HMG–CoA reductase (nmol MVA/min/mg prot)	% Increase from preperfusion value
Control (11)	0.11 ± 0.01[b]	1 ± 7	0.28 ± 0.04[b]	75 ± 20
+ Cholate (11)	0.17 ± 0.02[c]	57 ± 8[d]	0.46 ± 0.10	119 ± 23
+ Chenodeoxycholate (10)	0.16 ± 0.02[c]	50 ± 9[d]	0.32 ± 0.05	88 ± 20

[a]Rat livers were perfused *in situ* as described in the Experimental Procedures section after removal of a small liver lobe for assay. Liver microsomes were then prepared and assayed as described. The numbers in parentheses are the numbers of animals. All values are ± SEM.

[b]Average preperfusion value for acyl CoA:cholesterol acyltransferase (ACAT) was nmole cholesterol ester (CE)/min/mg protein (prot); the average preperfusion value for 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase was 0.18 ± 0.04 nmoles mevalonate (MVA)/min/mg protein.

[c]Statistically significantly different from control activity after perfusion at $P < 0.01$.

[d]Statistically significantly different from control % increase after perfusion at $P < 0.001$.

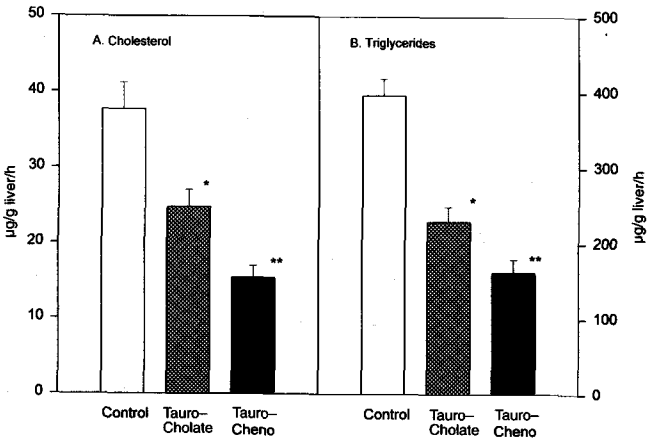

FIG. 1. Effect of taurocholate and taurochenodeoxycholate on net accumulation of very low density lipoprotein cholesterol and triglyceride in rat liver perfusate. Rat livers were isolated and perfused with and without bile salts as described in the Experimental Procedures section. After 2 h, the perfusate was collected and very low density lipoprotein isolated and analyzed as described. The values are the means ± SD. The number of animals is in parentheses. *Different from control at $P < 0.01$; **Different from control at $P < 0.001$. Control (11): open box; + taurocholate (11): hatched box; + taurochenodeoxycholate (10): closed box.

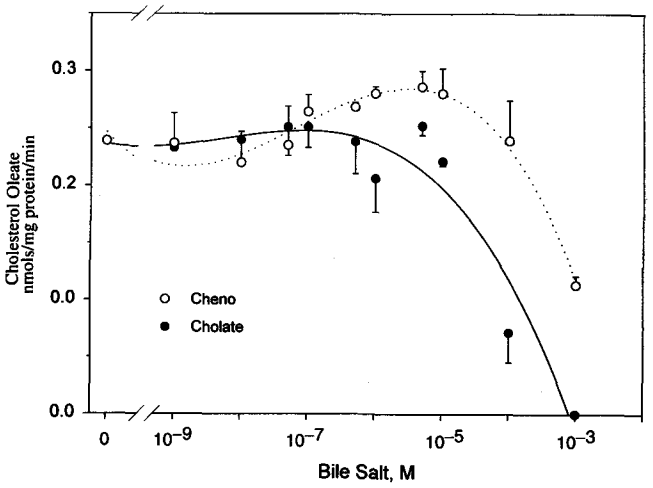

FIG. 2. *In vitro* effects of cholate and chenodeoxycholate on rat liver microsomal acyl CoA:cholesterol acyltransferase activity. The points represent the means ± SD of values obtained using three different preparations of microsomes. Each preparation was assayed in triplicate. Only the values of 10^{-3}M for cholate and 10^{-4} and 10^{-3}M for chenodeoxycholate were statistically significantly different from the values obtained in the absence of bile salt. Cholate, -○-; chenodeoxycholate, -●-.

Administration of bile salts results in increased excretion of cholesterol and phospholipids into the bile (22). Therefore, another explanation for the decreased recovery of VLDL cholesterol and triglyceride induced by bile salt perfusion is that free cholesterol and phospholipid were diverted from the assembly of lipoprotein particles to a pool(s) destined for biliary secretion. Support for this view is provided by the findings of Nervi *et al.* (23) who reported a reciprocal relationship between VLDL cholesterol secretion and the coupling ratio of cholesterol to bile salts in bile.

Because bile salt perfusion increased ACAT activity, it was hypothesized that acute depletion of bile salts might have the opposite effect. However, the short-term effects of bile diversion have not been reported. Longer term studies in intact rats fed cholestyramine, a bile acid-binding resin, revealed that ACAT activity was unchanged (11) or decreased (24), whereas HMG–CoA reductase activity was increased. After acute (4 h) bile diversion in the intact animal, hepatic ACAT activity was decreased about 40% (Table 2). Little change was observed in HMG–CoA reductase activity (Table 2), suggesting that cholesterol was preferentially removed from an ACAT substrate pool which had no regulatory effect on reductase activity.

In order to address the issue of whether bile salts had a direct impact on ACAT activity, their effects were examined in liver microsomes *in vitro*. The physiological range of bile salt concentrations in the normal liver has been estimated to be in the range 0.05–0.3 mM (25,26), reaching a level of 1 mM in cholestasis. No significant changes in ACAT activity were observed over the range 10^{-9}–10^{-5}M for either Na cholate or Na chenodeoxycholate (Fig. 2); however, at concentrations above 10^{-5}M, the activity was inhibited. Similar results were

TABLE 2
Effect of Acute (4 h) Bile Diversion on Rat Hepatic ACAT and HMG–CoA Reductase Activities[a]

Animal	ACAT (nmoles CE/min/mg prot)	HMG–CoA reductase (nmoles MVA/min/mg prot)
Control (3)	0.12 ± 0.01	0.63 ± 0.07
Bile-diverted (3)	0.06 ± 0.02[b]	0.68 ± 0.07

[a]Animals were bile-diverted by cannulation of the common bile duct and placed in restraining cages. Bile was collected. Bile flow was 0.071 ± 0.011 mg/h/g liver, and bile acids were 2.05 ± 0.66 µmoles/h/g liver; cholesterol, 0.029 ± 0.003 µmoles/h/g liver; and phospholipids, 0.15 ± 0.02 µmoles/h/g liver. Control animals were sham operated and also placed in restraining cages. Liver microsomes were prepared 4 h after bile diversion or sham operation and assayed as described in the Experimental Procedures section. The values represent the means ± SE. The number of animals is in parentheses. See Table 1 for abbreviations.

[b]Statistically significantly different from control at $P < 0.05$.

observed with the Na-tauro conjugates, except that significant inhibition was observed only at concentrations above 10^{-3}M (data not shown). Thus, it seems unlikely that bile salts in the physiological concentration range were acting directly on the enzyme or its endogenous membrane cholesterol substrate pool to alter activity *in vivo*, since ACAT activity was increased rather than inhibited after perfusion with bile salts. Reports of bile salt compartmentation in rat liver cells further suggest that bile salts are not acting directly on ACAT in the intact cell. *In vivo*, bile salts in rat liver cells appear to be concentrated in the Golgi apparatus (27), the nuclei (28), and the plasma membrane (29), whereas ACAT activity is localized to the endoplasmic reticulum, with enrichment in the rough fraction (11,30).

Based on the data presented above, we hypothesize that short-term alteration in bile salt traffic also alters the hepatic compartmentation and movement of cholesterol, and that ACAT activity responds rapidly to these changes to maintain cellular cholesterol homeostasis.

ACKNOWLEDGMENTS

We thank Steven Lear for technical assistance and Maggie Cho for typing the manuscript. This work was supported by NIH grant DK38553 and the Department of Veterans Affairs. The Effects of Simvastatin and Cholestyramine, Alone and in Combination, on Hepatic Cholesterol Metabolism in the Male Rat

John H. Shand and David W. West*

Hannah Research Institute, Ayr, KA6 5HL, United Kingdom

ABSTRACT: The influence of dietary simvastatin, cholestyramine, and the combination of simvastatin plus cholestyramine on hepatic cholesterol metabolism has been investigated in male rats. Recovery from the effects of the drugs was also investigated by refeeding normal chow for 24 h. Both drugs, alone and in combination, increased 3-hydroxy-3-methylglutaryl-CoA (HMG–CoA) reductase activity *in vitro*, but activity returned toward control values, after drug withdrawal. Acyl-CoA:cholesterol acyltransferase (ACAT) was significantly reduced ($P < 0.001$) by simvastatin (–75%), cholestyramine (–71%), and by the drug combination (–81%), due both to a decrease in microsomal cholesterol and to nonsubstrate-dependent modulation of enzyme activity. Refeeding control diet increased ACAT activity but not to control levels. The enhanced activity arose partly from higher microsomal cholesterol and partly from increases in total enzyme activity. Cytosolic neutral cholesteryl ester hydrolase (CEH) activity was substantially elevated by simvastatin (3-fold) and by the drug combination (6-fold), whereas the effect of cholestyramine was smaller (1.5-fold). Normal chow for 24 h only partially returned cytosolic CEH activity to control values. Microsomal CEH activity was increased by simvastatin, alone and in combination with cholestyramine (1.4 to 1.7-fold), and was also enhanced, in the cholestyramine-treated animals, following drug withdrawal. Removal of simvastatin did not allow recovery of this enzyme activity, while withdrawal of the drug combination led to values 29% below controls. The results indicate that in the rat, simvastatin and cholestyramine alter both ACAT and CEH activity, as well as inhibiting HMG–CoA reductase activity.

Lipids 30, 917–926 (1995).

The maintenance of cholesterol balance in the intact liver involves the regulation of several pathways of cholesterol influx and efflux, including the uptake of chylomicron and very low density lipoprotein (VLDL) remnants, the secretion of cholesterol and bile acids into bile, and the synthesis and secretion of lipoproteins as well as storage as cholesteryl esters (CEs) (1). In addition, the liver is critically involved in the maintenance of whole-body sterol balance, since net cholesterol excretion occurs almost exclusively through the hepatobiliary tract.

In most species, inhibition of the rate-determining step in hepatic *de novo* cholesterol synthesis, the reductive cleavage of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) to mevalonate, catalyzed by HMG–CoA reductase, leads to an increase in low density lipoprotein (LDL) receptor numbers and a consequent decrease in plasma LDL cholesterol (2,3). Hence, drug-induced inhibition of HMG–CoA reductase activity is one of the major strategies for dealing with hypercholesterolemia in patients (4–6). Among the drugs that have been clinically approved for this purpose are the statins, lovastatin, simvastatin, and pravastatin, which are specific competitive inhibitors of the enzyme (3–5). However, it is becoming apparent that the mechanism of action of these HMG–CoA reductase inhibitors is more complex than simply the inhibition of cholesterol synthesis, with consequent up-regulation of LDL receptors and increased catabolism of LDL and other apo-B-containing lipoproteins (6). In particular, evidence has been accumulating that one effect of these drugs is to stimulate the induction of HMG–CoA reductase in the cell to restore cholesterol synthesis (7,8).

However, cells do not accumulate large quantities of this compound, and cholesterol, excess to the immediate requirement of the cell, is deposited in the form of cytoplasmic lipid droplets containing insoluble cholesterol–fatty acid esters. These are formed from long-chain acyl-CoA derivatives and cholesterol in a reaction catalyzed by acyl CoA:cholesterol acyltransferase (ACAT, EC 2.3.1.26) (9). These esters are not inert but can be rehydrolyzed to release the cholesterol for cellular use. Thus, the regulation of hepatic CE metabolism is mediated, in part, by the balance between this esterification by ACAT and hydrolysis of the resultant CEs, by a neutral cholesteryl ester hydrolase (CEH, EC 3.1.1.13) (10,11). Nevertheless, it has been suggested that ACAT plays the major role in this regulation, by providing a defense against excess free cholesterol accumulation (12) with CEH, which includes both cytosolic (soluble) and membrane-associated fractions (11,13) playing only a passive role, and having no importance in maintaining free cholesteryl levels in the hepatocyte (12).

Although the mechanisms controlling the activity of these two opposing enzymes are unknown at present, recent evidence has suggested that the statins have major effects on ACAT activity. In the cells of the intestinal wall, ACAT has been implicated in the process of cholesterol absorption from the gut (14–16), and Ishida *et al.* (17,18) found that simvastatin increased fecal excretion of sterol in rabbits fed cholesterol, but not in rabbits fed on normal chow. Kam *et al.* (19) found similar results when the ACAT inhibitor 58-035 (Sandoz, Inc., East Hanover, NJ) was used to inhibit the enzyme activity in human intestinal CaCo-2 cells (supplied by Drs. E. Schaefer and J. Ordovas, Tufts University School of Medicine, NJ). Since cholesterol feeding increases the ACAT levels in intestinal cells, it was postulated that simvastatin was inhibiting the activity of this enzyme.

In a study of VLDL–lipid secretion in perfused livers of rats given lovastatin, Khan *et al.* (20) found that, while hepatic concentrations of free cholesterol were unaltered, the CE content was markedly reduced along with VLDL–lipid production. Lovastatin was also found to inhibit ACAT in, and to decrease the basal secretion of, newly synthesized CE and triacylglycerols (TAG) from Caco-2 cells (21). These authors postulated that this effect of lovastatin on lipid secretion was due to its inhibition of ACAT. They suggested, furthermore, that the results of Kahn *et al.* (20) also could be explained on the basis that lovastatin was regulating CE content and VLDL secretion by its inhibition of ACAT activity and not by its effect on newly synthesized cholesterol, as suggested by Reimann *et al.* (22). Further supporting evidence was provided by Kasim *et al.* (23) who found that lovastatin-treated obese Zucker rats also showed a decline in VLDL secretion and CE content with no change in free cholesterol. Since the substrate of ACAT was freely available, they again raised the possibility that lovastatin may suppress the activity of ACAT.

In contrast, recent investigations have shown that ACAT activity in human liver (24) and in mononuclear leucocyte microsomes (25) was not inhibited by pravastatin, whereas it was increased in diabetic patients following simvastatin treatment (26). Furthermore, Ishida *et al.* (27) demonstrated that simvastatin had a direct inhibitory effect on ACAT in isolated intestinal microsomes although the parent lactone form of the drug rather than the open β-hydroxy form was inhibitory in this system. In contrast, the free hydroxy acid, which is rapidly formed in the liver and in the plasma of rats, is the inhibitor of HMG–CoA reductase in tissues.

Thus, there is controversy concerning the effect of this drug on ACAT, and although simvastatin is reported to have reduced hepatic ACAT in cholesterol-fed rabbits in a preliminary experiment (18), there appears to have been no systematic investigation of the inhibition of hepatic ACAT by the statins.

Cholestyramine is a second type of drug that is used to control plasma cholesterol and LDL levels. This resin sequesters bile acids in the gut, preventing their recirculation to the liver (28,29), one consequence of which is increased diversion of free cholesterol in the liver toward bile acid synthesis. The liver compensates by producing more cholesterol, *via* induction of HMG–CoA reductase (30–32), which then tends to blunt the effectiveness of this agent in reducing plasma cholesterol. Because of this effect, cholestyramine often has been combined with the inhibitors of HMG–CoA reductase in treatment of hypercholesterolemia.

We therefore fed both simvastatin and cholestyramine, alone and in combination, to male rats and investigated the effect of the drugs on a number of parameters of hepatic cholesterol metabolism. Since removal of simvastatin leads to a rapid reversal of the induction of HMG–CoA reductase (33), we also investigated the effect of refeeding these animals with control diet for a short period.

The results indicate that, while these drug treatments influence HMG–CoA reductase activity as expected, they also reduce hepatic ACAT activity and at the same time induce a compensatory increase in the activity of the neutral CEHs in the cell. Refeeding the rats with control diet for 24 h returns HMG–CoA reductase to control levels, but the changes in ACAT and CEH activity require a longer period to overcome the effects of the drugs. These variations in the activities of the cholesterol metabolizing enzymes have major effects on the balance between cholesterol and CE in the cell and plasma.

MATERIALS AND METHODS

Materials. [9,10(n)-^{3}H]Oleic acid (370 GBq/mmol), [1-^{14}C]-oleic acid (2 Gbq/mmol), cholesteryl [1-^{14}C] oleate (2 Gbq/mmol), and DL-3-hydroxy-3-methyl[3-^{14}C]glutaric acid (2 Gbq/mmol) were all obtained from Amersham (Little Chalfont, United Kingdom). RS-[5-^{3}H]Mevalonolactone (750 Gbq/mmol) was purchased from DuPont (Stevenage, United Kingdom). Cholesteryl [9,10(n)-^{3}H]oleate, [9,10(n)-^{3}H]-oleoyl CoA, and 3-hydroxy-3-methyl[3-^{14}C]glutaryl-CoA were synthesized as described previously (34–36). Dithiothreitol was purchased from Calbiochem (Nottingham, United Kingdom). All other biochemicals were from Sigma (Poole, United Kingdom).

Animals and diets. Male Wistar rats, weighing about 120–140 g at the start of the experiment, were kept on a constant light/dark cycle (lights on 0800–2000 h) and were fed for five days on a crushed CRM(X) breeding diet (Special Diet Services, Manea, Cambridgeshire, United Kingdom) containing 2.4% (w/w) fat and less than 0.01% (w/w) cholesterol. Rats were split into groups and for five days were fed either the control diet, or that same diet supplemented with cholestyramine (2%), simvastatin (0.1%), or a combination of cholestyramine (2%) and simvastatin (0.1%). At the end of the five-day period, the controls and one-half of the drug-treated rats were killed while the remainder of the treated rats were returned to the control diet for 24 h before they were killed. Simvastatin was incorporated by mixing an acetone solution with the crushed diet then allowing the solvent to evaporate for at least 48 h. The control diet was treated in the same way but with acetone alone, and cholestyramine resin was mixed dry into this treated control diet. The rats were fed

at 0830 at the rate of 30 g per rat per day and were weighed at daily intervals. At the end of the experimental period, the animals were killed by cervical dislocation at 0930, i.e., 25 h after their last feed, and the livers were excised, weighed, and frozen in liquid nitrogen. Blood samples were centrifuged immediately (10,000 × *g*) in heparinized tubes and the clear plasmas stored at −20°C.

Tissue processing. Livers were homogenized as described previously (34,37) in 4 vol of ice-cold buffer consisting of 50 mM 2-(*N*-morpholino)ethanesulfonic acid, 50 mM *tris*(hydroxymethyl)-aminomethane (TRIS)/HCl buffer, pH 7.2, containing 1 mM ethylenediaminetetraacetic acid, 1 mM ethyleneglycol-*bis*(2-aminoethyl)tetraacetic acid, 1 mM dithiothreitol, and proteinase inhibitors (1 μg/mL each of pepstatin A, leupeptin, and antipain). Microsomal and cytosolic fractions were then prepared according to the method of Shand *et al.* (34,37) and stored in aliquots at −80° C.

Enzyme assays. The activity of ACAT was assayed in microsomes (150 μg protein) by measuring the rate of conversion of [9,10(n)-^{3}H]oleoyl CoA to cholesteryl [9,10(n)-^{3}H]-oleate as previously described using endogenous cholesterol as the other substrate (35). In addition, parallel assays were performed in the presence of exogenous cholesterol (200 μg/mL) added as a suspension of liposomes, prepared as described by Batzri and Korn (38), using cholesterol and phosphatidylcholine in a molar ratio of 1:2. All assays were preincubated for 30 min before addition of the oleoyl CoA substrate, and incubation time was limited to 5 min to ensure linearity. Cholesteryl [1-^{14}C]oleate was used as an internal standard to correct for recovery.

The activity of neutral CEH was measured, essentially according to Shand and West (34), using 50 μg of either microsomal or cytosolic protein in a total volume of 200 μL. The reaction was initiated by the addition of an ethanolic solution of cholesteryl [9,10(n)-^{3}H]oleate (20 nmol, 1×10^6 dpm) and terminated after 45 min. [1-^{14}C]Oleic acid was then added as a recovery standard, and the rate of hydrolysis of the substrate was measured by estimation of the released [9,10(n)-^{3}H]oleic acid.

The 'total' activity of HMG–CoA reductase was determined using 100 μg of microsomal protein in a final volume of 150 μL according to the method described by Shand and West (36). The reaction was initiated by addition of 3-hydroxy-3-methyl[3-^{14}C]glutaryl-CoA (22 nmol, 2×10^5 dpm) and terminated after 15 min at 37°C by addition of concentrated HCl (10 μL). A recovery standard of RS-[5-^{3}H]mevalonolactone (30 μmol, 1.5×10^4 dpm) was added and the reaction product separated by thin-layer chromatography.

Assay of the neutral CEH inhibitor protein. The liver cytosols were assayed for inhibitory activity against rat mammary gland microsomal neutral CEH essentially as described previously (34) using 30–40 μg of cytosolic protein. The quantity of cytosolic protein required to produce 50% inhibition of the neutral CEH was then calculated. Controls, without mammary gland microsomes, were incubated at the same time to allow correction for the activity of cytosolic neutral CEH.

Estimation of cholesterol and CEs. Lipids, extracted (39) from the liver homogenates and microsomal suspensions, were redissolved in ethanol while those extracted from plasma lipids were resuspended, by sonication, in buffer containing 50 mM TRIS, pH 7.9, 100 mM KCl, 20 mM KF, and 0.05% (wt/vol) Triton X-100. Total and free cholesterol were then assayed by the fluorometric method of Gamble *et al.* (40) and esterified cholesterol estimated by the difference.

Estimation of TAG. TAG were estimated directly in the liver homogenates and in the aqueous suspensions of the extracted plasma lipids by a modification of the method of McGowan *et al.* (41) using assay kit number 339-10 as supplied by Sigma.

Protein and DNA measurements. Protein concentrations were assayed by the dye-binding method of Bradford (42) and DNA as described by Labarca and Paigen (43).

RESULTS

Diet-induced effects of cholestyramine. Animals fed the cholestyramine diet gained the same weight as controls but exhibited a small (12%) reduction in liver weight. This diet led to a significant increase in liver TAG, whether expressed on a cellular (i.e., related to DNA concentration) or a total liver basis (+23% and +33% respectively, Table 1). CE levels were unaffected whereas cholesterol levels were reduced (−9%, $P < 0.01$) in cellular terms (Table 1). Drug withdrawal led to increases in all of these parameters within 24 h. In contrast, the diet containing cholestyramine had little effect on plasma lipid levels although drug withdrawal led to a 32% drop in plasma cholesterol levels (Table 2).

HMG–CoA reductase activity was increased (1.6-fold) by the cholestyramine treatment (Table 4), as were both microsomal (Table 4) and cytosolic (Table 3) CEH activities, although the increases were much less than was observed with the simvastatin treatment (1.1- and 1.5-fold, respectively, Fig. 1) correlating with a significant decrease (−27%, $P < 0.01$) in the activity of the cytosolic inhibitor of CEH (Table 3). Refeeding normal diet returned HMG–CoA reductase, cytosolic CEH, and inhibitor activity toward normal values but increased the microsomal CEH still further (to 200% of controls). A significant reduction in ACAT activity (−71%, $P < 0.001$, Table 4) was also observed in cholestyramine-treated animals, and this also was observed when the assay was repeated in the presence of exogenously supplied cholesterol. Following drug withdrawal, ACAT activity was significantly raised both when measured with endogenous cholesterol (+54%, $P < 0.001$) and with saturating cholesterol concentrations (+18%, $P < 0.05$), but not sufficiently to return it to the control value. The evidence from the scatter diagram relating ACAT activity to microsomal cholesterol content (Fig. 2) suggests that this enhancement was not due to an increase in the level of microsomal cholesterol.

Diet-induced effects of simvastatin. Animals treated with simvastatin gained considerably less weight during the period of the experiment, and this was reflected in a significant re-

TABLE 1
The Effect of Treatment with Simvastatin and Cholestyramine, Alone and in Combination, on Liver Lipid Levels[a]

	Triacylglycerol		Cholesterol (C)		Cholesteryl esters (CE)		Ratio
Treatment	mg/mg DNA	mg/total liver	μg/mg DNA	mg/total liver	μg/mg DNA	mg/total liver	CE/C in total liver
Control (10)	1.9 ± 0.1	80.9 ± 5.2	315.6 ± 8.5	13.9 ± 0.5	200.2 ± 7.1	8.9 ± 0.5	0.63 ± 0.03

Cholestyramine + 24-h control diet (6)	2.6 ± 0.1[d]	111.7 ± 3.4	371.3 ± 7.6[d]	16.1 ± 0.9	266.0 ± 5.8[d]	11.5 ± 0.6[c]	0.72 ± 0.02
Simvastatin (6)	1.9 ± 0.1	70.7 ± 5.0	211.7 ± 15.3[d]	7.7 ± 0.5[d]	152.6 ± 7.0[d]	5.4 ± 0.2[d]	0.73 ± 0.03
Simvastatin + 24-h control diet (6)	2.1 ± 0.1	88.4 ± 2.9	246.3 ± 11.3[d]	10.0 ± 0.5[c,e]	199.4 ± 8.2[e]	8.1 ± 0.3	0.81 ± 0.03[c]
Simvastatin + cholestyramine (10)	2.0 ± 0.6	86.5 ± 3.8	318.3 ± 7.7	13.6 ± 0.6	220.9 ± 11.3	9.5 ± 0.7	0.68 ± 0.03
Simvastatin + cholestyramine + 24-h control diet (10)	2.0 ± 0.5	97.8 ± 4.1[b]	338.4 ± 5.0[b]	16.1 ± 0.6[b,e]	354.7 ± 13.5[d,f]	16.7 ± 0.4[d]	1.05 ± 0.03[d,f]

[a]Liver triacylglycerol levels were determined directly in the tissue homogenates, whereas liver cholesterol and cholesteryl esters were measured by means of a fluorometric assay in lipid extracts, dissolved in ethanol, as described in the Materials and Methods section. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values (*b,c,d*) and between treatments and treatments plus 24 h on control diet (*e,f*) were determined using Student's *t*-test. $^{b}P < 0.05$. $^{c,e}P < 0.01$. $^{d,f}P < 0.001$.

duction (7.1 ± 0.1 g to 5.8 ± 0.2 g) in their liver weights. They regained much of their lost body and liver weight after refeeding normal diet. The drug had little effect on the levels of TAG in the plasma (Table 2) and the liver (Table 1), but significantly reduced the cholesterol and the CE content of both plasma and liver, as well as that measured in the microsomal fraction of the liver (Table 5). Drug withdrawal allowed the microsomal and the plasma levels of both lipids to return to normal, whereas hepatic free cholesterol levels remained depressed. HMG–CoA reductase activity was markedly increased by simvastatin treatment (Table 4) as was CEH activity, both microsomal (Table 4) and cytosolic (Table 3). The proportionate increase for the cytosolic CEH was, nevertheless, greater than that for the microsomal CEH (3.0- and 1.7-fold respectively, Fig. 1). In contrast, the activity of the inhibitor of CEH was unaffected (Table 3), whereas ACAT activity, measured both in the presence of endogenous and exogenous cholesterol, was dramatically reduced (–75%, Table 4). Feeding normal chow for 24 h allowed the activity of HMG–CoA reductase to decline toward control values but did not cause any further alteration in the elevated activities of the two CEHs. ACAT activity measured under conditions of saturating cholesterol was unaltered following drug withdrawal, whereas it was increased in the presence of endogenous cholesterol. The scatter diagram (Fig. 2) indicates that this stimulation in ACAT was solely due to increased availability of substrate.

Diet-induced effects of cholestyramine plus simvastatin. The livers, obtained from the animals fed these combined drugs,

Cholestyramine + 24-h control diet (6)	14.9 ± 2.7	13.5 ± 2.3	51.3 ± 4.9	18.7 ± 1.7	31.9 ± 5.7	28.7 ± 4.8
Simvastatin (6)	52.4 ± 2.8^{d}	32.7 ± 2.4^{d}	44.3 ± 1.9	11.0 ± 0.7^{c}	95.2 ± 6.6^{d}	59.2 ± 5.0^{d}
Simvastatin + 24-h control diet (6)	39.7 ± 1.9^{d,e}	28.6 ± 1.9^{d}	46.5 ± 3.7	11.7 ± 2.4	76.4 ± 6.3^{d}	55.8 ± 6.1^{d}
Simvastatin + cholestyramine (8)	77.4 ± 4.3^{d}	61.0 ± 4.2^{d}	37.8 ± 1.6^{c}	12.1 ± 0.8^{c}	124.9 ± 6.8^{d}	98.6 ± 6.2^{d}
Simvastatin + cholestyramine + 24-h control diet (8)	42.0 ± 2.4^{d,f}	44.8 ± 1.4^{d}	45.5 ± 2.2	19.3 ± 0.6^{b}	79.2 ± 7.2^{d}	83.5 ± 4.9^{d}

[a]Cytosolic neutral cholesteryl ester hydrolase (CEH) activity was determined using 50 µg of cytosolic protein incubated with cholesteryl [9,10-^{3}H]oleate for 45 min. The CEH inhibitor protein was assayed by determination of the CEH activity in rat mammary gland microsomes (100 µg protein) in the absence and presence of 30–50 µg of cytosolic protein. The activity in whole liver is expressed as 50% inhibitory units where one unit is the amount (µg) required to inhibit the mammary microsomal CEH by 50%. From an estimate of the percentage inhibition of the CEH activity due to 50 µg, the "true" cytosolic CEH activities could be recalculated to allow for the effect of the inhibitory protein. The results are the means ± SEM for the number of animals given in parentheses. Significant differences from control values (*b,c,d*) and between treatments and treatments plus 24 h on control diet (*e,f*) were determined using Student's *t*-test. $^{b}P < 0.05$. $^{c,e}P < 0.01$. $^{d,f}P < 0.001$.

weighed 25% less than either controls or animals similarly treated but refed control diet for 24 h after drug withdrawal. Plasma TAG were reduced by the cholestyramine plus simvastatin treatment (–40%, Table 2), whereas hepatic TAG were unaltered (Table 1). Refeeding normal diet for 24 h did not restore plasma TAG to normal levels but did lead to a significant increase (+21%, $P < 0.05$) in the levels of hepatic TAG.

Hepatic free cholesterol levels were unaffected by this drug combination (Table 1) while cholesterol levels in the plasma (Table 2) and in the microsomes (Table 5) reacted in opposition, being increased in the plasma (+41%) but reduced in the microsomes (–16%). CE levels in the plasma and in the whole liver were not significantly affected by this treatment, whereas the microsomal content of esterified cholesterol was
