ABSTRACT: The popularity of polyunsaturated oils used in food applications and preparation continues to appreciate as a result of positive health claims. With polyunsaturated oils inherently more susceptible to oxidative and thermal degradation, the formation of new fatty acid species increases considerably. The presence of one species known as cyclic fatty acid monomers (CFAM) has been detected as a component of many oils subjected to various thermal processes including deep-fat frying. The effect of CFAM on metabolic processes has not been fully characterized. In this study, confluent porcine aortic endothelial cells incorporated CFAM into their polar and nonpolar lipid fractions following a 48-h exposure to 31 and 62 ppm CFAM in the culture medium. Subsequently, the influence of CFAM incorporation on various membrane-dependent physical properties and biochemical processes was investigated. CFAM decreased the lipid packing order of the membrane bilayer core but did not alter the lipid packing order of lipid chain segments at or near the lipid–water interface of the membrane. CFAM led to significant reductions in Ca^{2+} ATPase activity and monolayer integrity while eliciting a significant increase of prostacyclin synthesis and secretion.

Lipids 32, 925–933 (1997).

During the past two decades, a great deal of progress has been made toward defining the role of dietary fats in the pathogenesis of certain Western diseases. For numerous such conditions including cardiovascular disease and certain cancers, the type and amount of dietary fat have been implicated as positive risk factors (1–4). Several basic pathogenic mechanisms associated with these diseases often can be characterized by altered cell function including aberrant biochemical processes resulting from physical changes at the phospholipid membrane level (5,6). The influence of dietary lipids becomes significant in membrane-dependent properties owing to the importance of fatty acids in membrane phospholipid structure.

In particular, the pathogenesis of vascular disease suggests that dietary fatty acids play an important role especially owing to their influence on the function of the vascular endothelium. Incorporation of polyunsaturated fatty acids (PUFA) into cultured endothelial cells has been shown recently to promote disruption of normal endothelial cell functions (7–9) which would appear to contradict the current hypothesis that PUFA minimize the incidence of atherosclerotic episodes. Furthermore, the inherent instability of PUFA to oxidative and thermal stress can lead to the formation of a host of potential lipid degradation and oxidation products, caused by *in vivo* processes and/or dietary consumption, which subsequently may be presented to endothelial cells .

A popular source of ingested lipid breakdown products is the consumption of deep-fat fried foods. In the case of vegetable oils used in deep-fat frying processes, the formation of lipid oxidation products can be substantial even though a majority of vegetable oils are modified for increased stability by reducing the degree of unsaturation using catalytic hydrogenation. The formation of these partially degraded lipid products can be attributed to the exposure of the frying medium to water (from food), oxygen, metals (from food or equipment), and the high temperature of the frying process (10,11). Various lipid breakdown products have been identified in frying fats and oils derived from both animal and vegetable sources (12,13) and are absorbed by the fried food (14–16). If a frying medium has been abused and overused, accumulation of lipid breakdown products can be significant (17,18).

Cyclic fatty acid monomers (CFAM) are a class of lipid oxidation products generated especially in heated vegetable oils (19–21). A ring structure is formed within the same fatty acyl chain to create a CFAM molecule [Scheme 1 where *x*

Abbreviations: BSA, bovine serum albumin; CFAM, cyclic fatty acid monomer; DPH-PA, 1,6-diphenyl-1,3,5-hexatriene propionic acid; FAME, fatty acid methyl esters; FBS, fetal bovine serum; PUFA, polyunsaturated fatty acids; TMA-DPH, 1-[4-(trimethylamino)phenyl]-6-phenyl-1,3,5-hexatriene.

represents number of methylene groups determined by the formula: CN (carbon number) − *m* − *n* − 9] as a result of a new covalent linkage between two nonadjacent carbon atoms. Because of their unique structure, the physical characterization of CFAM has been under investigation since their identification in heated oils and only recently have novel analytical techniques been applied to definitively confirm the structure of CFAM (22–24).

The metabolic and physiologic effects of fatty acids and lipid oxidation products in tissue culture systems have been reported in the literature (25–29). While CFAM from heated linseed oil have specific effects on the electrophysiological function of cultured rat myocardiocytes (30), the focus of this study was to examine the influence of CFAM derived from heated linseed oil on various physical and biochemical cellular parameters of cultured endothelial cells using measurements of membrane lipid packing order, membrane integrity/permeability, prostacyclin synthesis, and ATPase activity.

EXPERIMENTAL PROCEDURES

Preparation and isolation of CFAM. Linseed oil (Cargill, Riverside, ND) was heated at 275°C under nitrogen for 12 h as described previously (21). The protocol for the isolation and purification of CFAM includes saponification of the heated linseed oil, esterification of fatty acids, separation of fatty acid methyl esters (FAME) from polar compounds using silicic acid column chromatography, and isolation of CFAM methyl esters by urea fractionation of the nonpolar FAME fraction (21,31). The urea fractionation step was conducted twice using a 3:1 ratio (w/w) of urea to FAME.

Preparation of primary endothelial cell culture. Endothelial cells were isolated from a 6- to 8-inch section of the descending aortas of freshly slaughtered 5- to 8-mon-old pigs. Two- to three-inch segments of aortas were meticulously trimmed of fat and serosa, branch points ligated, rinsed with modified Hank's buffered salts solution, and then filled with 0.1% collagenase solution (ICN Biomedicals, Costa Mesa, CA). Following incubation for 30 min at 37°C, the enzyme/cell solution was decanted then centrifuged at 200 × *g* for 5 min. The pellet was resuspended in Medium 199 (M-199) containing 10% fetal bovine serum, 100 μg/mL heparin, and 100 μg/mL streptomycin. The cell suspension was plated on 60-mm culture dishes and incubated at 37°C in a humidified 5% CO_2 atmosphere.

After 12 h, the medium was changed to remove any nonadherent material, and the adherent cells were viewed under an inverted microscope equipped with Hoffman modulation. The cells had a cobblestone morphology typical of cultured endothelial cells. The cells were allowed to grow to confluence then were passaged at a dilution factor of 1:3. Further characterization of the endothelial monolayer was performed using factor VIII histochemical staining [1° antibody-goat antihuman factor VIII (ICN Biomedicals); 2° antibody-rabbit antigoat labeled with fluoroscein isothiocyanate (Cappel Labs, Cochransville, PA)], and diI-acetylated low density lipoprotein (Biomedical Technologies Inc., Boston, MA). The fluorescence staining techniques revealed the cultures to be essentially pure endothelial cells. Beginning at passage 4, cells were frozen in the M-199 growth medium containing 10% dimethylsulfoxide; then they were stored in liquid nitrogen until use.

Treatment of endothelial cells with medium containing CFAM. The culture medium containing CFAM was prepared by adding the sodium soaps of CFAM to M-199 containing fatty acid free bovine serum albumin (BSA) (Fraction V; ICN Biomedicals) at a molar ratio of 6:1, respectively. The fatty acid-free BSA was slowly dissolved in M-199 at 37°C under constant stirring. The sodium soaps were prepared by the addition of 6 N NaOH to CFAM (free fatty acid form) dissolved in hexane. The solution was dried under nitrogen then redissolved in warm water. The sodium soaps were added dropwise followed by mild stirring for 3–4 h at 37°C. The CFAM–BSA solution was sterilized by passage through a 0.2-μm cellulose acetate filter under vacuum. This solution was used as stock for dilution with M-199 to the desired levels of CFAM in the medium. Two concentrations of CFAM at 31 and 62 parts per million (ppm) were selected which corresponded to 112 and 224 μM, respectively. These concentrations fall within the spectrum of fatty acid supplementation levels in cell culture systems previously described in the literature (7,8,38,40,41).

Isolation of total cellular lipids and separation of nonpolar and polar fractions. Following incubation with CFAM for 48 h, a total lipid extract was isolated from freshly homogenized endothelial cells using the method described by Folch *et al.* (32) and stored at −80°C until further use. The total cellular lipid extract was separated into nonpolar and polar fractions using silica gel solid phase extraction (33). The extraction was confirmed by silica gel thin-layer chromatography using a mobile phase of hexane/diethyl ether/methanol/acetic acid (90:20:5:2, by vol) and visualized by the application of concentrated sulfuric acid/water (1:1, vol/vol) containing 0.05% potassium dichromate followed by heating at 120°C for 10–15 min.

Determination of phospholipid classes using high-performance liquid chromatography. The relative percentage of the major phospholipid classes present in the polar lipid fraction was determined by high-performance liquid chromatography using the method developed by Christie (34). The separation of phospholipid classes was achieved using a modified tertiary gradient mobile phase system with a Spherisorb silica-3 column (Alltech, Deerfield, IL), and the separated phospholipid components were detected using an evaporative light-scattering detector (Varex, Rockville, MD).

Determination of cholesterol and fatty acid composition using gas–liquid chromatography (GLC). The cholesterol content in the nonpolar lipid fraction was quantitated by GLC analysis using stigmasterol as an internal standard wtih an HP-5 column (Hewlett-Packard, Avondale, PA) installed in an HP 5890 Series II Plus GC (Hewlett-Packard).

The fatty acid composition of the nonpolar and polar lipid fractions as well as M-199 containing 5% fetal calf serum was determined by GLC of native and completely hydrogenated FAME (35). FAME mixtures were subjected to GLC analysis using a CP-Sil 88 column (Chromapack, Raritan, NJ) installed in an HP 5890 Series II GC (Hewlett-Packard).

Hydrogenation. CFAM methyl esters and cellular FAME were catalytically hydrogenated over platinum oxide using a microhydrogenator (Supelco, Inc., Bellefonte, PA) (20). Briefly, 100–150 mg CFAM was added to a thick-walled glass reaction tube, then diluted in 20 mL anhydrous methanol. Platinum oxide (10–15 mg) was added under constant stirring. The reaction chamber was evacuated then pressurized with 10 psi hydrogen. After 30 min, the reaction mixture was filtered through a 25-mm filter disk containing a polytetrafluoroethylene membrane with a pore size of 0.2 μm. The methanol was evaporated in a warm water bath under a stream of nitrogen.

Measurement of CFAM cytotoxicity. Endothelial cells were grown to confluence then exposed to CFAM-containing media for 48 h. The cell number was determined using a hemocytometer, and viablility was assessed by trypan blue dye exclusion.

Measurement of membrane lipid packing order. The measurement of membrane lipid packing order of cultured endothelial cells was accomplished using methods adapted from Block *et al*. (36) and Sheridan and Block (37). Dislodged endothelial cells (1×10^6 cells) were suspended in M-199 with 10% FBS, centrifuged, decanted, diluted in 0.3 mL of ice-cold 50 mM phosphate buffer containing 0.15 M potassium chloride at pH 7.4 (phosphate buffer), and stored on ice until preparation for the membrane polarization determination. The cell suspension was warmed to room temperature and an equal volume of 10 μM 1,6-diphenyl-1,3,5-hexatriene propionic acid (DPH–PA) or 20 μM DPH working solutions in phosphate buffer was added to the cell suspension. Following mixing, the cell-fluorescence probe reaction mixtures were allowed to incubate in the dark for 20 min at room temperature. The cell–probe mixture was centrifuged and rediluted in 1 mL phosphate buffer warmed to 37°C. The cell suspension was placed in a quartz cuvette containing 1 mL of phosphate buffer at 37°C. The anisotropy was determined at 37°C using an ISS spectrofluorometer (ISS, Bellefonte, PA) configured in the L-format. The excitation and emission wavelengths were 366 and 430 nm, respectively, for DPH–PA, 365 and 428 nm, respectively, for 1-[4-(trimethylamino)phenyl]-6-phenyl-1,3,5-hexatriene (TMA–DPH), and 362 and 430 nm, respectively, for DPH. A cell suspension prepared without the fluorescence probes was used to correct for background fluorescence. The use of cutoff filters was employed to minimize the effects of light scattering.

Measurement of monolayer integrity. Monolayer integrity was assessed by measuring albumin transfer across a confluent endothelial cell monolayer as described by Henning *et al*. (38). Endothelial cells were seeded at confluence density (1.25×10^5 cells/cm^2) on Cellagen 24-well plate inserts (ICN Biomedicals). The cells were incubated for 8 h to ensure that the cells adhered to the Cellagen inserts then observed for monolayer confluence by microscopic examination. The cells were treated with CFAM media for 48 h. Following the removal of media from the insert (upper) and well (lower) chambers, the concentration of BSA in the media from the lower chamber was detected by measuring the absorbance at 630 nm following reaction with bromocresol green.

Measurement of calcium ATPase activity. Calcium ATPase activity in cultured endothelial cells was assayed using the procedure of Henning *et al*. (8). Briefly, dislodged endothelial cells ($2–3 \times 10^6$ cells) were suspended in M-199 with 10% FBS, centrifuged, decanted, and diluted with 0.25 mL of ice-cold 0.1 M Tris buffer at pH 7.4 and placed on ice. The cell suspension was subjected to ultrasonic homogenization for 15 s in an ice bath. Calcium ATPase activity was assayed following the addition of 50 μL cell homogenate to the following reaction mixture: 500 μL of 0.1 M Tris buffer, pH 7.4; 50 μL of 0.1 M $CaCl_2$; 50 μL of 0.01M ATP. The sample was incubated for 15 min at 37°C, and the reaction was stopped by adding 0.5 mL of cold trichloroacetic acid and the inorganic phosphorus content was determined (39). Total protein was determined by a protein assay kit (Pierce, Rockford, IL).

Measurement of prostacyclin synthesis. Confluent monolayers of endothelial cells in 24-well plates were treated with medium containing CFAM–BSA or BSA alone. Indomethacin (5 μM), a cyclooxygenase inhibitor, was employed to inhibit prostacyclin synthesis, and this incubation served as a positive control. At various times, the medium was removed and was frozen at −20°C until analysis for prostacyclin. The prostacyclin content was determined by measuring the amount of 6-keto-$PGF_{1\alpha}$, its stable metabolite, using an enzyme immunoassay (Amersham, Chicago Heights, IL).

Prior to performing the enzyme immunoassay, media aliquots were subjected to solid-phase extraction. This purification step was employed to isolate a fraction containing 6-prostaglandin $F_{1\alpha}$ free from nonesterified fatty acids which may interfere with the immunoassay determination of prostaglandins (40). Following acidification to pH 3 with 6 N hydrochloric acid, the samples were applied to solid-phase extraction columns containing C_2 packing. The prostaglandin fraction was eluted from the column with 5 mL of methyl formate after washing with 5 mL of methanol, 10% ethanol in water, then hexane, respectively.

Statistical analysis. The influence of CFAM treatment on the mean responses for the various biological parameters was tested for statistical significance using one-way analysis of variance. For each endpoint, the treatment means were compared in pairs using the Student's *t* test. Statistical probability of $P < 0.05$ was considered significant.

RESULTS

Cytotoxicity and membrane lipid composition. The cytotoxicity of CFAM was determined in cultured endothelial cells. As measured by the exclusion of trypan blue dye, viability of

confluent endothelial cells was not significantly changed following treatment with BSA or CFAM–BSA media during the 48-h incubation interval.

The amount of material from the nonpolar and polar fractions of endothelial cell total lipid extracts was determined along with total cholesterol, enabling the ratios of cholesterol-to-phospholipid, cholesterol-to-protein, and phospholipid-to-protein to be calculated (Table 1). Additionally, the distribution of the major phospholipid classes isolated in the polar lipid fraction was determined (Table 1). The treatment of endothelial cells with CFAM–BSA did not cause significant change in the amount of total, nonpolar or polar lipid fractions, the distribution of phospholipid classes, or the cholesterol-to-phospholipid ratio. However, the ratio of phospholipid-to-protein decreased in cells treated with 62 ppm CFAM–BSA.

The incorporation of CFAM did not result in a substantial change of the relative amounts of unsaturated and saturated fatty acids. Using the ratio of total-unsaturated-to-total-saturated fatty acids, values of 1.6, 1.7, and 1.6 were determined for the control, 31 ppm CFAM–BSA, and 62 ppm CFAM–BSA groups, respectively. Upon CFAM–BSA supplementation, cultured endothelial cells incorporated CFAM into membrane phospholipids as well as neutral lipids. The fatty acid composition of the membrane and neutral lipids from endothelial cells revealed that the relative amount of CFAM within the membrane phospholipids from treatment with 31 and 62 ppm CFAM–BSA reached 3.2 and 4.3%, respectively (Table 2). CFAM containing cyclopentyl rings were preferentially incorporated into both membrane phospholipids and neutral lipids (Table 3). The polar and nonpolar lipid fractions exhibited identical CFAM GLC peak patterns to the pure fraction of hydrogenated CFAM (not shown).

Membrane lipid packing order. The steady-state anistropy (r) of DPH (Fig. 1) was found to decrease significantly in cul-

[a]Values represent mean (± SD) for a single determination using two samples per treatment group. H_2 represents hydrogenated. n.d. represents not detected. FBS, fetal bovine serum. See Table 1 for other abbreviations.

TABLE 3
CFAM Identified Following Hydrogenation of Lipid Fractions of Cultured Porcine Aortic Endothelial Cells

	Relative proportions of the major CFAM types[a] (% of total CFAM)					
	1	2	3	4	5	6
H_2 CFAM fraction	17.6	22.8	7.6	22.6	6.9	22.5
Polar lipid fraction	24.6	36.3	10.4	14.1	7.3	7.3
Nonpolar lipid fraction	35.4	38.0	—	16.1	6.3	4.1

[a]Numbers correspond to hydrogenated linseed oil CFAM structures. The structures are: 1 and 3, methyl 9-(2′-butylcyclopentyl)nonanoate; 2 and 5, methyl 10-(2′-propylcyclopentyl)decanoate; 4 and 6, methyl 9-(2′-propylcyclohexyl)nonanoate. Values represent single determinations. See Table 1 for abbreviations.

tured endothelial cells following the exposure to CFAM–BSA at both treatment levels compared to BSA controls ($P < 0.05$). The decrease was more significant by treatment with 62 ppm CFAM–BSA than 31 ppm ($P < 0.05$). Since lipid packing order is directly related to *r*, the lipid packing order of the hydrophobic core region decreased as a result of CFAM incorporation into endothelial cell membrane lipids as measured by DPH. This perturbation in order of the bilayer core was not reflected in lipid chain segments at or near the lipid–water interface of the membrane bilayer as shown by the lack of change in the *r* of DPH–PA (Fig. 2) and TMA–DPH (Fig. 3).

Presence of intracellular triglycerides. The presence of intracellular triglycerides using Nile red dye visualization was observed in cultured endothelial cells following incubation with 0, 31, and 62 ppm CFAM–BSA media for 48 h (Fig. 4). The location of intracellular lipid in the 0 ppm CFAM–BSA and BSA controls remained primarily around the nuclei of endothelial cells. Treatment with CFAM–BSA appeared to cause the formation of intercellular lipid droplets, but a loss of lipid around the nuclei of endothelial cells was observed (Fig. 4).

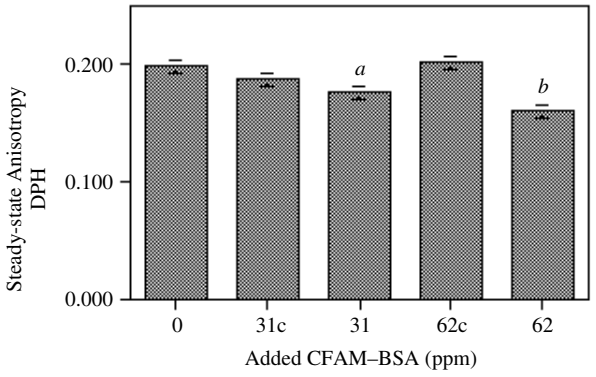

FIG. 1. Steady-state anisotropy (*r*) of 1,6-diphenyl-1,3,5-hexatriene (DPH) in confluent endothelial cells following exposure to media containing cyclic fatty acid monomer–bovine serum albumin (CFAM–BSA) for 48 h. Values represent mean ± SEM for triplicate determinations using three samples per treatment group; c indicates media containing an equivalent level of fatty acid-free BSA in the corresponding CFAM–BSA media; *a* indicates 31 ppm CFAM–BSA treatment group significantly different from 31c and 0 ppm CFAM–BSA treatment groups ($P < 0.05$); *b* indicates 62 ppm CFAM–BSA treatment group significantly different from 62c, 0 ppm, and 31 ppm CFAM–BSA treatment groups ($P < 0.05$).

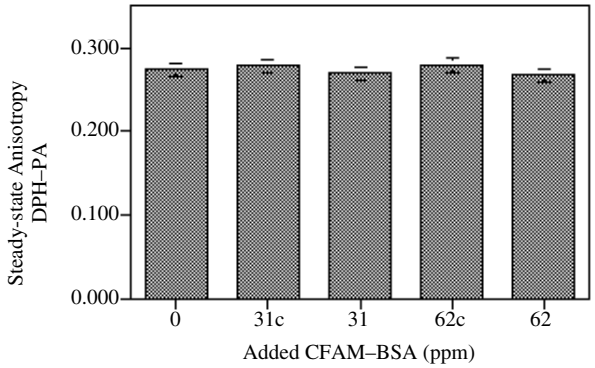

FIG. 2. Steady-state anisotropy (*r*) of DPH–propionic acid (PA) in confluent endothelial cells following exposure to media containing CFAM–BSA for 48 h. Values represent mean ± SEM using three samples per treatment group; c indicates media containing an equivalent level of fatty acid-free BSA as contained in the corresponding CFAM–BSA media. See Figure 1 for other abbreviations.

Monolayer integrity. Exposure to CFAM–BSA resulted in an increase of albumin movement across cultured endothelial cell monolayers (Fig. 5). Both levels of CFAM–BSA caused a significant increase in albumin movement vs. the 0 ppm CFAM–BSA and BSA control treatments ($P < 0.05$) with the influence of 62 ppm CFAM–BSA being more pronounced than 31 ppm ($P < 0.05$).

Calcium ATPase function. The activity of calcium ATPase decreased significantly ($P < 0.05$) in cultured endothelial cells treated with CFAM–BSA compared to the respective BSA controls (Fig. 6). The magnitude of the decreased ATPase activity corresponded to an increase in the level of CFAM–BSA in the media.

Prostacyclin synthesis. The production of 6-keto-prostaglandin $F_{1\alpha}$ was determined in cultured porcine aortic endothelial cells as a function of the incubation time and media concentration of CFAM–BSA (Table 4). The presence of CFAM–BSA in the media caused a significant increase in the production of prostacyclin compared to BSA alone. The production of prostacyclin was inhibited significantly owing to

Values represent mean ± SEM using three samples per treatment group; c indicates media containing an equivalent level of fatty acid-free BSA as contained in the corresponding CFAM–BSA media; *a* indicates 31 ppm CFAM–BSA treatment group significantly different from 31c and 0 ppm CFAM–BSA treatment groups ($P < 0.05$); *b* indicates 62 ppm CFAM–BSA treatment group significantly different from 62c, 0 ppm, and 31 ppm CFAM–BSA treatment groups ($P < 0.05$). See Figure 1 for abbreviations.

DISCUSSION

The incorporation of CFAM into cellular membranes led to changes in several of the biochemical and physical parameters measured in confluent cultured endothelial cells. The uptake of cyclopentyl ring-containing CFAM was favored over cyclohexyl ring-containing CFAM in both the polar and nonpolar lipid fractions. This preferential uptake was observed in cells treated with both 32 and 61 ppm CFAM–BSA for 48 h. A similar trend has been described for the uptake of CFAM in cultured rat myocardiocytes (29).

Though not reported, we observed that CFAM–BSA and the BSA control media inhibited the growth and altered the morphology of cultured endothelial cells at both CFAM con-

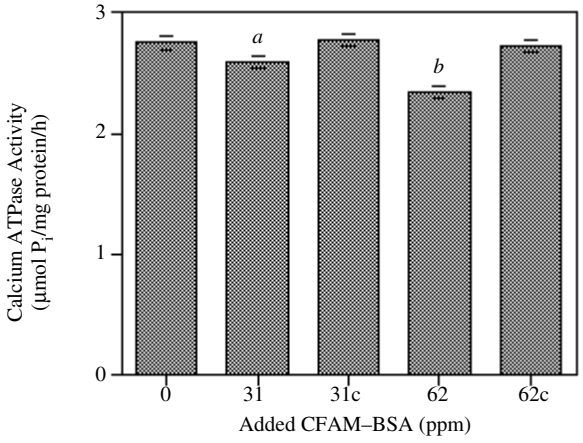

FIG. 6. Calcium ATPase activity of confluent endothelial cells following exposure to media containing CFAM–BSA for 48 h. Values represent mean ± SEM using three samples per treatment group; c indicates media containing an equivalent level of fatty acid-free BSA in the corresponding CFAM–BSA media; *a* indicates 31 ppm CFAM–BSA treatment group significantly different from 31c and 0 ppm CFAM–BSA treatment groups ($P < 0.05$); *b* indicates 62 ppm CFAM–BSA treatment group significantly different from 62c, 0 ppm, and 31 ppm CFAM–BSA treatment groups ($P < 0.05$). See Figure 1 for abbreviations.

TABLE 4
CFAM–BSA Time- and Concentration-Induced Release of 6-Keto Prostaglandin $F_{1\alpha}$ from Confluent Cultured Porcine Aortic Endothelial Cells[a]

CFAM–BSA (ppm)	6-Keto Prostaglandin $F_{1\alpha}$ (pg/mL)			
	4 H	8 H	12 H	24 H
0	402	461	531	855
31	308	447	481	796[b]
31c	—	213	417	331[a]
62	318	310[a,c,d]	332[a,d]	539[a,c,d]
62c	—	131	354	120[a]

[a]Values represent mean ± SD using two samples per treatment group. c indicates media containing an equivalent level of fatty acid-free BSA as contained in the corresponding CFAM–BSA media.[a]Treatment group significantly different from 0 ppm CFAM–BSA ($P < 0.05$). [b]31 ppm CFAM–BSA treatment group significantly different from 31c treatment group ($P < 0.05$). [c]62 ppm CFAM–BSA treatment group significantly different from 62c treatment group ($P < 0.05$). [d]62 ppm CFAM–BSA treatment group significantly different from 31 ppm CFAM–BSA treatment group ($P < 0.05$). See Table 1 for abbreviations.

centrations. Inhibition of growth and morphological changes in cultured cells by supplementation with the nonurea-adducting fraction isolated from thermally abused oils have been reported (41). These authors combined the fatty acids from fresh and heated oils with fatty acid-free BSA (1:60 w/w or 4:1 molar ratio) then added the complexed fatty acids–BSA to the media at concentrations of 20, 60, and 100 mg/L (ppm). The fatty acids from fresh oils served as controls for the measurement of cell growth and determination of changes in cell morphology. The use of BSA controls was not reported. It is our contention that BSA should not be used to incorporate fatty acids into media preparations when examining the influence of fatty acids on cell growth and morphology.

The present experimental evidence suggests that CFAM can alter specific physical characteristics of cellular membranes as well as biological processes involved in the maintenance of homeostatic functions in cultured endothelial cells. In examining factors which influence membrane lipid packing order, the lipid parameters which have undergone measurable change are the phospholipid-to-protein ratio and the presence of CFAM in the membrane lipids. The phospholipid-to-protein ratio and membrane lipid packing order have been observed to be directly proportional (42,43). In addition to further increase in membrane CFAM content compared to the 31 ppm CFAM–BSA treatment, the 62 ppm CFAM–BSA treatment caused a decreased cellular phospholipid-to-protein ratio which may contribute to the observed decrease in membrane lipid packing order.

Another factor to be considered in determining lipid packing order is accumulation of intracellular triglycerides. The use of DPH polarization studies in culture systems often has been precluded owing to the formation of excessive amounts of intracellular triglycerides caused by supplementation of exogenous fatty acids. The uptake of DPH by intracellular lipid droplets in intact cells contributes to a marked decrease in the steady-state anistropy of DPH (44) while the *r* of TMA–DPH and DPH–PA is not influenced by accumulation of intracellular lipid droplets (45). Membrane lipid packing order may not be markedly affected by exposure of cultured endothelial cells to CFAM–BSA as suggested by increased intracellular triglycerides caused by CFAM–BSA exposure as visualized with the use of Nile Red dye. However, the amount of lipid isolated in the nonpolar fraction, which is predominantly triglycerides, was not significantly different between cells treated with and without CFAM–BSA.

The observation that calcium ATPase activity was decreased by exposure of cells to CFAM stands in contrast to the influence of linolenic acid which causes an increase in the activity of total ATPase in lymphocytes (46) and calcium ATPase in endothelial cells (8). This may suggest that the ring structure present in CFAM elicits the same effect on ATPase activity observed for cholesterol incorporation into kidney fibroblast membranes (47). Preliminary results suggest that CFAM treatment also causes a decrease in the total ATPase activity.

The effect of CFAM on monolayer integrity of cultured endothelial cells was identical to the influence of linoleic acid in various mixtures of fatty acids including those prepared from selected edible oils (8). Our result suggests that CFAM disrupt the integrity of the monolayer through changes in cell–cell interactions or transcytosis. Incubation with CFAM–BSA may cause morphological changes in cultured endothelial cells leading to disruption of the monolayer. However, phase-contrast microscopy was the only indicator of endothelial cell morphology used for the observation of the endothelial cell monolayer in culture-well inserts.

CFAM caused greater production of prostaglandin I_2 (PGI_2) (prostacyclin) with respect to the BSA controls, suggesting either that the presence of CFAM was counteracting the inhibitory influence of BSA on PGI_2 production or that CFAM were directly stimulating PGI_2 secretion by cultured endothelial cells. In light of the fact that both BSA and CFAM–BSA caused a decreased production of PGI_2 with respect to the 0 ppm CFAM–BSA media, the presence of CFAM may be compensating for the action of BSA.

Despite the fact that CFAM represented only 8% of the total lipids in the culture medium, the incorporation of CFAM from heated linseed oil into the membrane of cultured endothelial cells caused specific changes in several of the parameters examined in this study. This experimental data indicate that CFAM are by no means inert constituents of biological membranes but can exhibit potent physiological effects *in vitro*. In fact, it is possible that the long-term presence of CFAM in diets may influence the susceptibility of the vascular endothelium toward injury and degeneration. However, having so speculated, the presence of CFAM in membrane phospholipids of vascular endothelia has yet to be confirmed *in vivo*. The present results indicate the need for further consideration regarding the potential impact associated with the presence of CFAM in the diet.

ACKNOWLEDGMENTS

The authors thank the Laboratory for Fluoresence Dynamics at the University of Illinois at Urbana-Champaign for the generous use of

their equipment for anisotropy measurements. Special thanks to Chip Hazlett for his advice and assistance in membrane lipid packing order measurements. The authors also thank John P. Jerrell for his technical assistance in gas chromatography of CFAM.

ABSTRACT: The n-3 fatty acids (FA) from marine sources are known to exert antiinflammatory effects on monocyte function. There is still controversy whether n-3 FA may increase the susceptibility to infections. The present study was designed to assess the effect of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) on monocyte phagocytosis and respiratory burst activity. Fifty-eight healthy men were randomized to take a daily supplement of 3.8 g highly purified EPA (n = 20), 3.6 g DHA (n = 19), or corn oil (n = 19) for 7 wk. Mononuclear leukocytes were collected, isolated, and cryopreserved prior to and after dietary supplementation. Paired samples were analyzed in the presence of autologous serum in a crossover design. Monocyte phagocytosis and respiratory burst activity were measured by flow cytometry after ingestion of *Escherichia coli*. Monocytes retained their phagocytic ability and respiratory burst activity after supplementation. No reduction in internalization of bacteria was registered. Dietary n-3 FA and particularly EPA improved bacterial adherence to the monocyte surface. In the crossover experiments, there was an adverse effect of serum enriched with n-3 FA on bacterial adherence. We conclude that monocytes retain their phagocytic potential after supplementation with purified EPA and DHA.
Lipids 32, 935–942 (1997).

Monocytes play an important part in the defense against infections. They act as antigen-presenting cells, as producers of cytokines, and as phagocytes (1). In addition, they have protective functions by ingesting and killing invading microorganisms. Monocytes are particularly involved in chronic infections, such as tuberculosis and malaria, and in viral infections (2–5).

The n-3 fatty acids (FA) have been reported to decrease monocyte and neutrophil chemotaxis (6), decrease leukocyte superoxide generation (7,8), modify eicosanoid production, and decrease cytokine synthesis (9,10). Thus, n-3 FA may influence inflammatory and immune reactions which are involved in the development of disease. Populations who consume diets rich in n-3 FA have low incidence of inflammatory diseases (11), and fish oil enriched with eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) seems beneficial to patients suffering from such disorders (12,13). On the other hand, it has been suggested that polyunsaturated FA may encourage infection *via* attenuated inflammatory response and immunosuppression (14). Fish oil has been reported both to decrease and to improve survival rate of animals after experimentally induced infections (15–17).

Leukocyte phagocytosis is an important part of the host defense against infections, and few studies have examined the effect of n-3 FA on phagocytosis. In human neutrophils, the phagocytic process diminished (18) or remained unchanged (19) following n-3 FA supplementation. Both improved and decreased phagocytic ability have been reported in murine macrophages after dietary supplementation with n-3 FA (20,21).

Experimental studies indicate that EPA and DHA may have specific and partly different actions on cellular functions (22,23). Previous dietary studies have not investigated the effect of n-3 FA on monocyte phagocytosis, but have restricted their focus to neutrophils. We therefore examined the effect of dietary supplementation with highly purified EPA and DHA on monocyte phagocytosis and respiratory burst activity in humans *ex vivo*. Cryopreserved human monocytes isolated before and at the end of the supplementation period were used to avoid methodological variability (24), and the phagocytic properties were assessed with flow cytometry (FCM), allowing accurate measurements of single-cell functions on a large scale.

MATERIALS AND METHODS

Subjects and study design. Two hundred thirty-four healthy, nonsmoking men entered a double-blind parallel group intervention study lasting for 7 wk. Their mean age was 44 ± 5 yr

*To whom correspondence should be addressed.

Abbreviations: AT, acid-treated; CA, cryopreserved cells collected after intervention period; CB, cryopreserved cells collected before intervention period; CO, corn oil; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acids; FCM, flow cytometry; FCS, fetal calf serum; FITC, fluorescein isothiocyanate; MFI, mean fluorescence intensity; SA, serum prepared after supplementation period; SB, serum prepared before supplementation period.

(range 36–56). They did not take any drugs regularly, and consumed a traditional Western diet with less than four dishes of fish per week and did not expect to change their diet or lifestyle during the study period. Their total serum cholesterol was <8 mmol/L, diastolic blood pressure was <95 mm Hg, and systolic blood pressure was <160 mm Hg. The participants were randomly assigned to ingest either 4 g/d of 95% ethyl ester concentrate of EPA (20:5n-3), 4 g/d of 90% ethyl ester concentrate of DHA (22:6n-3), or 4 g/d of corn oil. The oils were given in indistinguishable soft gelatin capsules each containing 1 g oil and 3.0 IU vitamin E as antioxidant. Each person was asked to ingest four capsules a day. Drugs were manufactured by Pronova Biocare A/S (Oslo, Norway). Twenty subjects were randomly selected from each group prior to the intervention period and asked to give additional blood for isolation of mononuclear leukocytes before and after 7 wk of supplementation. Compliance was calculated as the percentage of the prescribed capsules taken. The study was approved by the regional board of research ethics and was performed according to Good Clinical Practice requirements (25). Written informed consent was obtained from all participants.

Serum. Autologous serum was obtained before and after 7 wk of supplementation with n-3 FA and prepared by clotting whole blood in sterile glass tubes for 1 h at room temperature and then centrifuged at 2000 × *g* for 10 min. Serum was frozen in aliquots of 0.5 mL and stored at −70°C.

Preparation of peripheral blood mononuclear cells. The isolation, freezing, and thawing procedures have been described previously (24). After overnight fasting, 120 mL blood was drawn from an antecubital vein into four 50-mL Falcon tubes (Becton Dickinson, Rutherford, NJ) containing EDTA as anticoagulant. Fifteen mL of the sample was mixed with 15 mL glucose-phosphate buffer and layered on top of 15 mL Lymphoprep (Nycomed Pharma, Oslo, Norway) and centrifuged at 301 × *g* for 30 min. The mononuclear cells at the interface were carefully pipetted off, transferred into another Falcon tube, and diluted before a second centrifugation step. The cell pellet was resuspended in 10 mL glucose-phosphate buffer and centrifuged slowly (20 × *g* for 15 min at 4°C) to remove the platelets. Thereafter the mononuclear leukocytes were resuspended and washed twice in RPMI 1640 (Biowhittaker, Walkersville, MD) containing 5% acid-treated (AT) fetal calf serum (FCS).

Freezing procedure. Mononuclear leukocytes suspended in 5% AT-FCS-RPMI were centrifuged, and the pellet was resuspended in precooled RPMI 1640 with 50% AT-FCS. An equal volume of ice-cold RPMI containing 20% dimethyl sulfoxide dried (Merck, Darmstadt, Germany) was added dropwise over 3 min. Aliquots of 1 mL (4×10^6 mononuclear leukocytes) were dispersed into sterile cryo vials (Greiner Labortechnik, Frickenhausen, Germany). The tubes were placed in an isopropylene box at room temperature, then frozen at −70°C for at least 2 h, and stored until further use at −135°C in a Bio-freezer (Queue Cryostar, Queque Systems, Parkenberg, WV).

Thawing procedure. The frozen cells were rapidly thawed with gentle and continuous agitation at 37°C in a water bath. The suspensions were transferred into 50-mL Falcon tubes in droplet form with 9 mL 20% FCS in RPMI 1640. The cells were centrifuged and finally resuspended in 5% heat-inactivated FCS in RPMI 1640. All experiments were performed 2 h after thawing. Mononuclear cell- and differential counts were made prior to and after thawing of the mononuclear leukocytes in a Coulter Counter S-plus STKR (Coulter Electronics, Harpenden, United Kingdom).

Flow cytometry. A Facscan flow cytometer (Becton Dickinson, San Jose, CA) with an excitation wavelength of 488 nm interfaced to a Hewlett-Packard 340 computer (Hewlett-Packard, Tokyo, Japan) was used for cell identification and measurements of monocyte phagocytosis and respiratory burst activity (24). By recording the fluorescence and light scattering of each cell, information relating to cell size and structure was determined. The resulting scattered light signals were given in a numerical scale and fluorescence signals in a logarithmic scale. Fluorescein isothiocyanate (FITC) fluorescence was measured at 530 nm, rhodamine at 500–530 nm, and right-angle light scatter at 488 nm. Calibration of light scattering and fluorescence was conducted daily with Calibrite beads (Becton Dickinson).

Bacteria. Heat-inactivated *Escherichia coli* (serotype O102:K52:H6, hemolysine negative) isolated from blood cultures were labeled with FITC (Sigma Chemical Company, St. Louis, MO). The number of bacteria were adjusted to 1.5×10^5 per sample. Unlabeled bacteria from the same strain were used in the respiratory burst experiments.

Phagocytosis. Opsonization was performed by incubating the bacterial suspension (1.5×10^6) with 0.5% autologous serum for 7.5 min on a rock'n roller at 37°C. Monocytes (5×10^4) were added, giving a bacteria–cell mixture of 250 µL, and after 5 min the reaction was stopped by adding 250 µL ice-cold phosphate buffered saline with 0.05% EDTA. Mononuclear leukocytes were differentiated by FCM along the right angle- and forward light scatter, and gated separately. Anti-CD14 mAb (Immunotech, Marseille, France) was used to identify the monocyte population and to verify correct monocyte gating. The gate was set manually. Nonphagocytes and phagocytes were differentiated by simultaneous measurements of right-angle light scatter and FITC fluorescence by FCM. Phagocytes expressing fluorescence due to attached and/or internalized FITC-labeled bacteria were quantified as the percentage of the monocyte population (10,000 monocytes). The amount of attached and/or internalized bacteria was quantified as mean fluorescence intensity (MFI) (24,26). An FCM fluorescence quenching technique was used to distinquish between attachment and internalization of bacteria by addition of trypan blue to the cell suspensions (27). Extracellular FITC fluorescence representing attached bacteria was quenched, whereas the fluorescence of internalized bacteria remained unchanged.

Respiratory burst activity. Monocytes (5×10^4) in 250 µL RPMI 1640 with 5% FCS were mixed with 100 µL (10

μg/mL) dihydrorhodamine (Molecular Probes, Eugene, OR) and incubated for 15 min at 37°C. Unlabeled bacteria (1.5×10^6) were opsonized with 0.5% autologous serum and internalized as described above. The fluorochrome accumulated in the cells and was oxidized intracellularly to fluorescent rhodamine after stimulation of the respiratory burst by exposure to bacteria. The fluorescence produced was proportional to the amount of generated hydrogen peroxide. Ten thousand monocytes were counted, and MFI of the whole monocyte population was measured by FCM.

Plasma phospholipid FA. FA were measured by extracting total lipids from 500 μL serum according to Folch *et al.* (28) with phosphatidylcholine diheptadecanoyl added as internal standard (P-5014; Sigma Chemical Co.), chloroform/methanol (2:1, vol/vol) as solvent and butylated hydroxytoluene (75 mg/L) as antioxidant. Total phospholipids were separated by solid-phase extraction using NH_2 columns (size 3 cc Analytic Bond Elut LRC; Varian, Harbor City, CA)(29), followed by transmethylation using boron trifluoride, extraction into hexane and evaporation to dryness. The FA methyl esters were dissolved in hexane and analyzed by gas–liquid chromatography (Shimadzu GC-14A; Shimadzu Co., Kyoto, Japan) using a capillary column (CP-Sil 88, length 50 m i.d. 0.25 mm) obtained from Chrompack Inc. (Raritan, NJ). Retention times and response factors for each FA were determined using standards obtained from Nu-Chek- Prep (Elysian, MN). The results were integrated on a Shimadzu C-R4A integrator. The FA concentrations are reported as μmol/L plasma.

Experimental design and statistical analysis. Mononuclear leukocytes were isolated and cryopreserved prior to and at the end of the supplementation period. Cryopreserved cells collected before (CB) and after (CA) the intervention period from the same participant were thawed and examined on the same day. Serum was also prepared before (SB) and after (SA) the supplementation period, allowing cells to be examined in the presence of autologous serum. Samples were analyzed blindly, and cryopreservation of cells allowed all assays for each subject to be run at the same time. The following experimental design was set up: (i) CB + SB, (ii) CA + SA, (iii) CB + SA, and (iv) CA + SB. The effect of supplementation on phagocytic functions in monocytes was assessed by comparing results obtained in these various conditions: (I) (CA + SB) minus (CB + SB); (II) (CA + SA) minus (CB + SA); (III); (CA + SA); minus (CB + SB); (IV) (CA + SB) minus (CB + SA). The experimental conditions were designed to differentiate between effects of intervention on cellular functions and on serum components.

Examination of the frequency distributions revealed normally distributed variables. Change was calculated as the value obtained after intervention minus the value obtained at baseline according to the above scheme for phagocytic variables. One sample *t*-tests were used to evaluate within-group change (condition III). Analysis of variance was used to evaluate overall difference between-groups (F-test). If the F-test was significant, between group comparisons of change were done by contrasting groups in the SAS general linear models procedure (30). Results were considered significant when the two-sided *P*-value was <0.05. Results are expressed as means ± standard deviation.

RESULTS

Table 1 shows that the groups randomized to receive EPA, DHA, or corn oil (CO) were well balanced at baseline. One subject in the DHA group withdrew after 4 d of supplementation due to gastrointestinal discomfort. One person in the CO group withdrew after 4 wk of supplementation due to acute vertigo and vomiting probably not related to the supplementation. Side effects (belching) were mild and transient, fading 1–2 wk after initiation of trial medication. Compliance was similar in all groups (Table 1). Body mass index (kg/m^2) increased in the EPA (0.3 ± 0.4, $P = 0.0027$) and the CO (0.2 ± 0.3, $P = 0.027$) group during supplementation, but the difference between groups was not significant.

Effects on phagocytosis. When all 58 participants were included in the analysis prior to dietary intervention, 15.5 ± 3.6% of the monocytes were associated with bacteria without opsonizing autologous serum. Introduction of serum increased the percentage of monocytes associated with bacteria to 43.6 ± 7.6%, which corresponded to an MFI of 817.7 ± 72.7. Addition of trypan blue, to extinguish the fluorescence

TABLE 1
Characteristics of Participants Receiving Docosahexaenoic Acid (DHA), Eicosapentaenoic Acid (EPA), or Corn Oil (CO)

	DHA	EPA	CO
Number	19	20	19
Age (yr)	42.9 (4.8)	43.9 (4.9)	43.9 (4.8)
BMI[a] (kg/m2)	25.1 (2.2)	24.7 (2.0)	24.6 (2.5)
SBP[b] (mm Hg)	122.3 (8.0)	123.4 (7.9)	122.8 (10.7)
DBP[c] (mm Hg)	76.6 (6.2)	77.5 (6.5)	78.3 (7.7)
Cholesterol (mmol/L)	5.98 (1.08)	5.78 (0.82)	6.08 (1.09)
Triglycerides (mmol/L)	1.38 (0.79)	1.20 (0.55)	1.17 (0.48)
Compliance[d] (%)	91.3 (7.9)	92.2 (5.7)	91.9 (11.0)

[a]BMI = body mass index. [b]SBP = systolic blood pressure. [c]DBP = diastolic blood pressure. [d]Percentage compliance was calculated as the percentage of the prescribed drugs taken. Values are mean (SD).

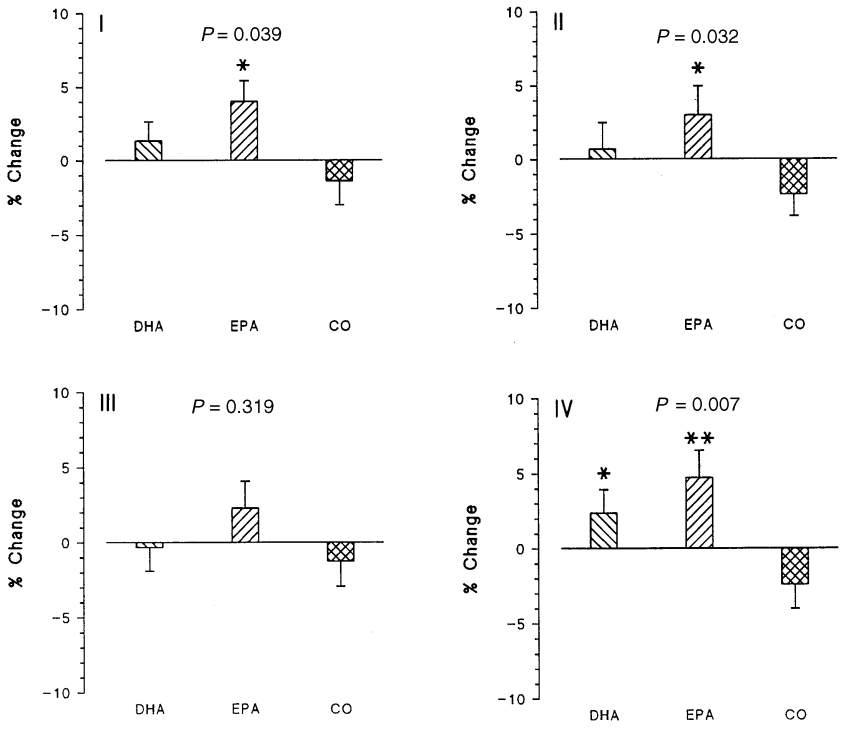

FIG. 1. Percentage change of attached and internalized *Escherichia coli* in monocytes from participants receiving dietary supplementation with purified docosahexaenoic (DHA) ($n = 19$) or eicosapentaenoic (EPA) ($n = 20$) acids, or corn oil (CO) ($n = 19$) for 7 wk. Cryopreserved cells collected before (CB) and after (CA) intervention were examined in the presence of autologous serum collected before (SB) or after (SA) intervention. The effect of supplementation was assessed according to the following model; (I) (CA + SB) minus (CB + SB), (II) (CA + SA) minus (CB + SA), (III) (CA + SA) minus (CB + SB), and (IV) (CA + SB) minus (CB + SA). The *P*-values for the overall F-test are given for each experimental condition. Stars indicate significant difference from CO. * $P < 0.05$ and ** $P < 0.01$. Bars are mean ± SD.

signal from attached and not internalized bacteria, decreased MFI by 50.7 ± 7.2%. Thus, under these experimental conditions, approximately 50% of the associated bacteria were actually internalized.

Phagocytosis of unopsonized bacteria revealed no differences between groups regarding percentage of phagocytosing monocytes nor the amount of associated bacteria (reflected by MFI)(data not shown).

In the presence of autologous serum (Fig. 1 and Table 2), EPA increased the cellular attachment of bacteria in the presence of a constant serum component, which differed significantly from CO (I, $P = 0.01$ and II, $P = 0.03$, respectively), but not from DHA ($P = 0.24$ and $P = 0.36$, respectively). In condition III, which reflects the physiological milieu with cells and serum collected simultaneously, the change in bacterial attachment within the EPA group was diminished, but remained significant ($P = 0.015$). The change did not differ from the other groups. However, when cells collected after intervention were incubated with serum collected before, the enhancement in bacterial attachment was reinforced, and both

TABLE 2
Human Monocyte Phagocytosis of *Escherichia coli* from Participants Receiving Dietary Supplementation with DHA ($n = 19$), EPA ($n = 20$), or CO ($n = 19$) for 7 wk[a]

	DHA		EPA		CO	
	MFI	Attachment (%)	MFI	Attachment (%)	MFI	Attachment (%)
CB + SB	824.3 ± 58.3	49.5 ± 7.4	795.3 ± 80.7	51.3 ± 6.8	834.9 ± 74.4	51.1 ± 7.6
CB + SA	817.6 ± 71.9	49.7 ± 7.4	789.6 ± 72.9	52.1 ± 6.8	845.3 ± 93.7	51.9 ± 8.3
CA + SB	834.4 ± 63.4	53.9 ± 7.5	825.5 ± 77.6	55.2 ± 7.5	820.8 ± 62.8	54.4 ± 7.4
CA + SA	821.1 ± 72.4	55.1 ± 7.8	811.8 ± 86.9	56.2 ± 7.3	822.3 ± 72.2	54.9 ± 6.9

[a]Phagocytosis is expressed as mean fluorescence intensity (MFI) of attached and internalized bacteria and percentage of attached bacteria. Cryopreserved cells collected before (CB) and after (CA) intervention were examined in the presence of autologous serum collected before (SB) or after (SA) intervention. See Table 1 for other abbreviations.

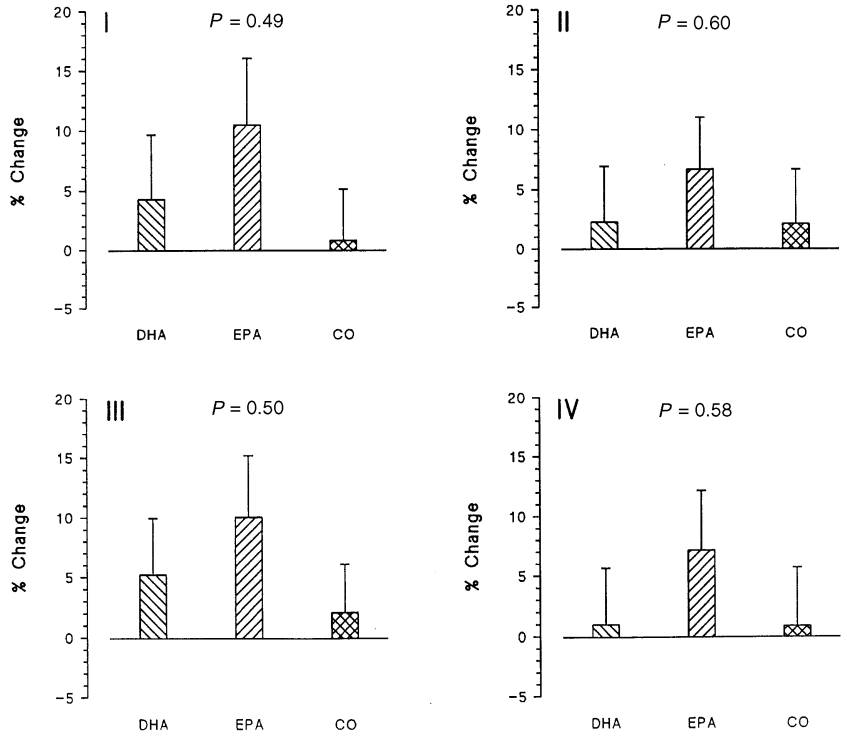

FIG. 2. Percentage change of respiratory burst activity in monocytes exposed to opsonized *E. coli*, from participants receiving dietary supplementation with purified DHA (n = 19) or EPA (n = 20) acids, or CO (n = 19) for 7 wk. Cryopreserved cells collected before (CB) and after (CA) intervention were examined in presence of autologous serum collected before (SB) or after (SA) intervention. The effect of supplementation was assessed according to the following model: (I) (CA + SB) minus (CB + SB), (II) (CA + SA) minus (CB + SA), (III) (CA + SA) minus (CB + SB), and (IV) (CA + SB) minus (CB + SA). The *P*-values for the overall F-test are given for each experimental condition. Bars are mean ± SD. See Figure 1 for other abbreviations.

DHA (P = 0.03) and EPA (P = 0.002) differed significantly from CO. Addition of trypan blue to extinguish the fluorescence signal from attached bacteria abolished all significant changes between the groups described above (data not shown).

Effects on respiratory burst activity. Percentage change of intracellularly generated hydrogen peroxide after exposure to *E. coli* is visualized in the three intervention groups under four experimental conditions (Fig. 2 and Table 3). The generation of hydrogen peroxide tended to be enhanced within the EPA group under all experimental conditions, but the P values for the overall F-tests were not significant under any experimental condition. However, the pattern was similar to what was observed in the phagocytosis experiments with a tendency toward an increase in the EPA and DHA groups compared to CO.

Plasma phospholipid FA concentrations. During intervention there was a small increase in plasma phospholipid saturated FA in the CO group (4%, $P < 0.05$), as compared to no change in the EPA and DHA groups (Table 4). The monounsaturated FA decreased slightly in both the DHA (–15%, $P < 0.01$) and EPA (–9%, not significant) groups. The total amount of plasma phospholipid polyunsaturated FA did not change in the DHA and CO groups, whereas there was a 9% decrease ($P < 0.001$) in the EPA group. This was due to a relatively larger decrease in linoleic (–26%, $P < 0.001$) and

TABLE 3
Respiratory Burst Activity in Human Monocytes Exposed to Opsonized Bacteria[a]

	DHA	EPA	CO
CB + SB	35.7 ± 8.8	32.2 ± 9.1	35.2 ± 10.4
CB + SA	35.9 ± 6.7	34.6 ± 9.4	34.8 ± 9.2
CA + SB	37.1 ± 11.1	33.2 ± 9.4	35.6 ± 11.1
CA + SA	36.3 ± 6.2	34.8 ± 10.5	35.3 ± 8.8

[a]Expressed as mean fluorescence intensity from participants receiving dietary supplementation with purified DHA (n = 19), EPA (n = 20), or CO (n = 19) for 7 wk. Cryopreserved cells collected before (CB) and after (CA) intervention were examined in the presence of autologous serum collected before (SB) or after (SA) intervention. See Table 1 for other abbreviations.

[c]$P < 0.05$; [d]$P < 0.01$; [e]$P < 0.001$; one sample t-test of difference between baseline and 7 wk.

arachidonic acid (−24%, $P < 0.001$) in the EPA group as compared to the DHA group (linoleic acid −6%, not significant; arachidonic acid −17%, $P < 0.01$). In the CO group, plasma phospholipid linoleic acid concentration increased by 6% ($P < 0.01$). During intervention, plasma phospholipid concentration of n-3 FA increased by 60% in the DHA group and by 73% in the EPA group (both $P < 0.001$). In the DHA group, plasma phospholipid DHA and EPA concentrations increased by 87 and 43%, respectively, indicating retroconversion of DHA to EPA, whereas docosapentaenoic acid decreased by 41% ($P < 0.001$). In the EPA group, plasma phospholipid EPA increased by 379% and docosapentaenoic acid by 136% (both $P < 0.001$), whereas DHA decreased by 18% ($P < 0.01$).

DISCUSSION

The n-3 FA from marine sources are reported to modify eicosanoid production and to decrease cytokines and superoxide generation in human studies (7–10). Despite such apparently immunosuppressive actions of n-3 FA, the present study shows that monocytes retain the phagocytic potential and improve their ability to attach bacteria after supplementation with EPA. No reduction in internalization of bacteria was registered. Similar but less prominent changes were observed after supplementation with DHA. The observed changes are caused by altered monocyte function, because bacterial attachment increased in experiments with a constant serum component.

The n-3 FA exert their immunoregulatory effects through modification of the FA composition in membranes of immunocompetent cells. EPA is more effectively incorporated into monocyte membranes than DHA (9,10), and such incorporation occurs within a short period of time, in which there is a direct exchange of phospholipid FA between plasma and cells (31,32). Our data show that EPA is more readily incorporated into plasma phospholipid FA than DHA, which may reflect similar changes in monocyte membrane FA.

Phagocytosis is a rapid, energy-demanding process involving attachment and internalization of the phagocytic particle. Effective engulfment is promoted through complement and immunoglobulin receptors. Whether such opsonin receptor expression is modulated during n-3 FA supplementation is unclear, but decreased expression of adhesion molecules has been reported (21,33). These adhesion molecules are particularly involved in monocyte–endothelium interactions, but are also associated with bacterial adherence to phagocytes. Furthermore, monocytes possess an nonspecific, opsonin-independent pathway for attachment and internalization of bacteria, in which membrane fluidity seems important for the presentation of the synthesized ligand receptors (34). The n-3 FA, and particularly EPA may increase the monocyte membrane fluidity (20,33) and thereby influence the expression of such membrane proteins.

The enhanced bacterial attachment was attenuated in experiments with cells and serum collected simultaneously, but reinforced in the crossover experiments for both EPA and

DHA. Our data therefore indicate that serum enriched with n-3 FA may have an adverse effect on bacterial attachment. Owing to a diluted serum component (10%) and short incubation time of serum with monocytes, it is unlikely that n-3 enriched serum could affect membrane fluidity *in vitro*. However, reactive lipid peroxides generated from blood cells during serum preparation are possibly modified by the n-3 FA supplementation and may thereby affect monocyte behavior. Another possibility is that n-3 FA interfere with serum opsonins such as complement factors and immunoglobulins.

Conflicting data have been reported regarding the influence of unsaturated FA on leukocyte phagocytosis. Few studies are comparable, as both marine and vegetable FA with different degrees of unsaturation and purity have been studied in the presence of various artificial and natural agents. Our data indicate that neither highly purified n-3 FA nor n-6 FA seemed to affect internalization of bacteria. This is consistent with data reported by Knapp and Fitz-Gerald (19), showing that neutrophil phagocytosis was not altered after a daily intake of 10 g/day of EPA for 4 wk. In contrast, Virella *et al.* (18) observed that neutrophil phagocytosis of latex beads was depressed during supplementation with 2.1 g/d of EPA for 6 wk in a single person. In animal studies, both increased and depressed macrophage phagocytosis have been reported after n-3 FA supplementation (20,21). Calder *et al.* (20) concluded that the *in vitro* phagocytic activity increased with increasing degree of unsaturation, except for DHA and EPA which showed lower activity than linoleic (18:2n-6), linolenic (18:3n-3), and arachidonic (20:4n-6) acids. In contrast, Eicher and McVey (21) described depressed *ex vivo* phagocytic activity in fish oil-fed mice during severe salmonella infection. It is difficult to interpret these results, as macrophages are located in tissues for several weeks compared to the short circulation time of monocytes and neutrophils.

Phagocytosis has been reported to be impaired by medium-chain triglycerides, but not in presence of long-chain triglycerides (35). Thus, one might speculate whether the observed changes in bacterial attachment are secondary to reduced serum triglyceride levels. However, *in vivo* studies have not confirmed an inverse association between triglycerides and neutrophil phagocytosis (36,37). In the present study there was no association between changes in serum triglycerides and alterations in bacterial attachment (data not shown).

Respiratory burst activity is an oxygen-dependent process related to adequate NADPH-oxidase and mitochondrial activity and is a consequence of attachment and internalization of bacteria (38). We found no significant differences between the three groups in the intracellular hydrogen peroxide formation. However, a similar pattern as in the phagocytosis experiments was observed with a tendency toward an increased hydrogen peroxide formation in the groups expressing increased bacterial adherance. This is consistent with respiratory burst activity as a graded response related to the number of attached and ingested bacteria (39). Our results are similar to unaltered monocyte and neutrophil chemiluminescence in healthy volunteers, reported by Lammi-Keefe *et al.* (40) and Weiner *et al.* (41). In contrast, Fisher *et al.* (7) observed reduced monocyte (7) and neutrophil (8) chemiluminescence in the presence of latex beads and zymosan. The discrepancies may be due to differences in study design.

The aim of the present study was to investigate whether the known antiinflammatory effects of n-3 FA also involve monocyte phagocytosis. For the first time, the separate effects of EPA and DHA were examined. We observed only minor biological changes in monocyte phagocytic functions, indicating that the engulfment process is not affected during n-3 FA supplementation. Retention of phagocytic properties and even improved bacterial attachment after intake of highly purified EPA and DHA may be of importance for the defense against infections to compensate for the known immunosuppressive actions of n-3 FA.

ABSTRACT: Treatment with β-blockers has been reported to be associated with the development of hypertriglyceridemia. The etiology, even the existence, of this phenomenon is controversial. The purpose of our study was to examine whether the nonselective β-blocker propranolol causes hypertriglyceridemia in the rat and whether its action is mediated by the modulation of lipoprotein lipase (LPL) messenger RNA (mRNA) accumulation or activity. LPL activity was assayed in fresh tissue by incubation with tritiated triglycerides. LPL mRNA was quantified in total RNA by slot-blot analysis using a mouse LPL complementary DNA probe. We have conducted three series of experiments in unanaesthetized rats in order to study the effects of different single doses of propranolol (1.5 to 6 mg i.p.) and different durations of treatment (15 min to 4 wk). We measured triglyceride and cholesterol levels in plasma as well as the LPL activity and mRNA levels in the heart and adipose tissue before and after propranolol administration. In these experiments we did not find any significant decrease in either the activity or the amount of mRNA of lipoprotein lipase nor was there any change in plasma lipids following treatment. Our results lead us to the conclusion that the nonselective β-blocker propranolol affects neither the activity nor the mRNA level of LPL in the rat. *Lipids 32,* 943–947 (1997).

Lipoprotein lipase (LPL) is the enzyme responsible for the metabolism of lipoproteins rich in triglycerides (TG), i.e., chylomicrons and very low density lipoproteins. Located on the surface of the capillary endothelium, it hydrolyzes TG into glycerol and free fatty acids. In many pathophysiological situations where there is decreased LPL activity, e.g., as in diabetes mellitus, obesity, alcoholism and hypothyroidism, there is concomitant hypertriglyceridemia (1). It is also well known that the use of nonselective β-adrenoceptor blocking agents (β-blockers) may be associated with the development of hypertriglyceridemia (2). The mechanism of this phenomenon is as yet unclear. The purpose of our study was to examine the effect of the acute and chronic administration of the nonselective β-blocker propranolol on LPL activity and LPL messenger RNA (mRNA) in the heart and adipose tissue (the two tissues with the highest amount of LPL) in rats.

EXPERIMENTAL PROCEDURES

Chemicals and solutions. [^{3}H]Oleoglycerol (22 mCi/mmol) and Amplify were purchased from Amersham (Arlington Heights, IL). Propranolol, lecithin, triolein, Trasylol, Triton X-100, bovine serum albumin, protein A, EDTA, phenylmethylsulfonylfluoride, HEPES, yeast RNA, β-mercaptoethanol, Krebs-Ringer solution, Leupeptin, and pepstatin were all from Sigma (St. Louis, MO). Heparin sodium salt was from Gibco (Gaithersburg, MD). Zeta-Probe membranes and Tris base were from Biorad (Richmond, CA). GF/B filters were obtained from Whatman (Clifton, NJ). En^{3}hance and Solvable were from Dupont (Wilmington, DE). Human β-actin DNA probe was obtained from Clontech (Palo Alto, CA). Rats were obtained from Harlan (Indianapolis, IN).

Animal procedures. Male Sprague-Dawley rats (approximately 200 g) were maintained under an artificial light–dark cycle of 12 h (lights on at 7:00 a.m.) and were fed rat chow and water *ad libitum*. All animals were studied in the fed state. Propranolol was either administered intraperitoneally (i.p.), with the desired dose suspended in 3 mL of normal saline, or added to the drinking water. Control animals were either injected with 3 mL of normal saline or were given drinking water without propranolol. The rats were sacrificed at various predetermined times after injection. Heart and left epididymal fat pads were excised and frozen immediately in liquid nitrogen. Blood was collected by cardiac puncture for the determination of serum cholesterol and TG.

Serum chemistries. TG and cholesterol levels were determined in serum by using standard Sigma diagnostic kits. Protein was measured by the Coomassie Brilliant Blue method as previously described (3).

LPL assay. LPL activity was assayed using a modification of a previously described technique by Iverius and Östlund-Lindqvist (4). Assays were carried out in a total volume of 500 μL consisting of 300 μL of triacylglycerol emulsion, 75 μL of 0.223 M Tris-HCl (pH 8.5), 25 μL of heat-inactivated (56°C, 30 min) rat serum, and 100 μL of tissue sample. The

reaction was continued at 37°C for 1 h, and 3.25 mL of methanol/chloroform/heptane (1.41:1.25:1.0, by vol) was added to stop the reaction. After vortexing, 1.05 mL of 0.05 M carbonate/borate buffer was added; the reaction mixture was further vortexed and then centrifuged in a benchtop centrifuge at 3,000 × *g* for 15 min. Two mL of the upper aqueous phase were removed, mixed with 4 mL of Aquasol, and radioactivity was measured in a liquid scintillation counter. LPL activity was expressed as nmol of free fatty acids released per mg of protein per hour of incubation.

Extraction of RNA and slot-blot analysis. Isolation of RNA from adipose tissue was performed according to the guanidium–phenol–chloroform method (5), and RNA was quantitated spectrophotometrically. For slot-blot analysis, total RNA was denatured just before blotting. Under our conditions yeast RNA did not show detectable hybridization to the mouse LPL complementary DNA (cDNA). Samples containing approximately 5 µg of total RNA were blotted onto Zeta-Probe membrane using a Minifold II apparatus and fixed by an ultraviolet lamp. A 622 base pair Bam H1 fragment of mouse LPL cDNA (6) was labeled with [^{32}P]dCTP by random oligonucleotide priming. Prehybridization, hybridization, and posthybridization washes were carried out as per the Zeta-Probe protocol. Blots were exposed to film (Kodak XAR-5; Kodak, Ann Arbor, MI) in the presence of two intensifying screens for 20 h at –70°C. Autoradiograms were scanned using a Visage 110 densitometer (BioImage, Kodak). Human β-actin cDNA probe was labeled as described above and used for hybridization.

Statistics. All data are expressed as means ± SEM. Statistical differences were determined by using two-tailed Student's *t*-tests or analysis of variance where appropriate. *P*-values less than 0.05 were considered significant.

RESULTS

We conducted three series of experiments in order to examine the effect of propranolol on LPL activity and LPL mRNA levels in hearts and adipose tissue of rats. In the first series, we studied the effects of a single injection of propranolol at various doses on LPL activity and mRNA. Animals were given i.p. injections of 3 mL of normal saline (controls) or propranolol (1.5 mg to 6 mg/rat, corresponding to 7.5 to 30 mg/kg body weight) and were killed 30 min after injection. TG levels and cholesterol did not increase with any of the doses used (Table 1). Heart LPL activity decreased slightly (about 20%) after the administration of 1.5 and 6 mg of propranolol, but the difference did not reach statistical significance. Adipose tissue LPL activity was decreased by 12, 32, and 33% with doses of propranolol of 1.5, 3, and 6 mg, respectively (nonsignificant). LPL mRNA levels of both heart and adipose tissue (Fig. 1) did not change significantly with any of the doses of propranolol given.

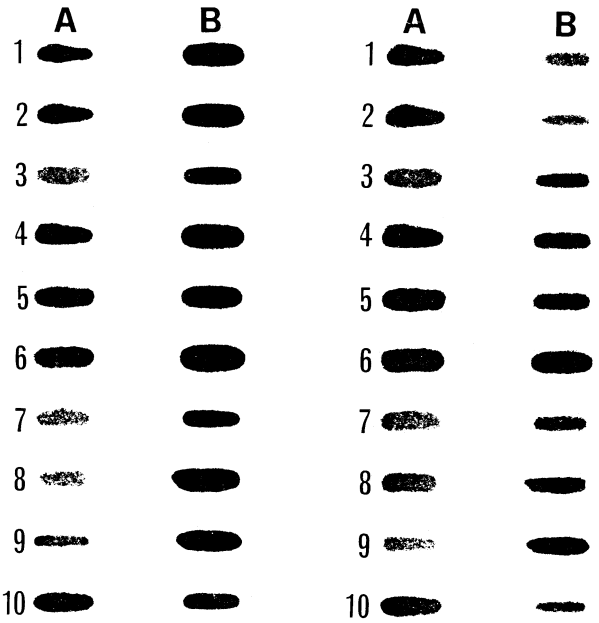

FIG. 1. Autoradiogram of slot-blot analysis of (A) lipoprotein lipase mRNA and (B) β-actin mRNA before (slots #1, 2) and after administration of various doses of propranolol (slots #3, 4 → 1.5 mg; slots 5, 6, 7 → 3 mg; slots 8, 9, 10 → 6 mg); a, adipose tissue and b, heart. 5 µg of total RNA were placed in each slot.

In the second series of experiments, the time course of the effects of propranolol on heart and adipose tissue LPL activities and mRNA was investigated. Animals were given i.p. in-

jections of 3 mg of propranolol and were killed at 15, 30, 60, and 120 min after the injection. TG and cholesterol concentrations remained unchanged (Table 2). The observed fluctuations in the rat heart and adipose tissue LPL activities were not statistically significant. Heart and adipose tissue LPL mRNA did not change significantly at any point during the treatment period.

In the third series of experiments, we studied the effects of chronic propranolol administration on serum TG and cholesterol levels, on LPL activity, and LPL mRNA in rat heart and adipose tissue in order to investigate any possible influence of propranolol on LPL during long-term administration. In two separate experiments, we added propranolol to the drinking water of the rats for 2 and 4 wk, respectively. Each rat received 3 mg/day of propranolol, and the water was renewed every other day. After 2 wk of propranolol administration, there was no statistically significant difference in the TG and cholesterol concentrations (Table 3). Heart LPL activity decreased by 20%, a statistically nonsignificant change and there was no change in the adipose tissue LPL activity. Both heart and adipose tissue LPL mRNA did not change. After 4 wk of propranolol administration, the TG and cholesterol levels did not change significantly (Table 3). Furthermore, there were no statistically significant changes in heart and adipose LPL activities. Heart LPL mRNA increased by 6%, from 0.816 ± 0.03 to 0.864 ± 0.077. Adipose tissue LPL mRNA increased by 7%, from 0.894 ± 0.0193 to 0.9611 ± 0.027. Both changes were not statistically significant.

DISCUSSION

In the present study, we investigated the effects of the nonselective β-blocker propranolol on the expression of the lipoprotein lipase gene. We measured the TG and cholesterol levels in blood, the LPL activity, and the amount of LPL mRNA with and without propranolol administration. There was no significant influence of the drug on any of the parameters determined after single injections of propranolol or during chronic oral administration of the drug for up to 4 wk.

In the literature, there are many contradictory reports on the effects of nonselective β-blockers on blood lipids. Some authors have found that β-blockers are associated with hypertriglyceridemia (2,7–10). Others failed to find such an association (11–13). Most of the aforementioned studies were done in humans with the exception of those of Jansen and Baggen (12) and Dall'Aglio *et al.* (13), which were done in rats.

The effect of nonselective β-blockers on serum cholesterol was also controversial (10,12). Catecholamines were found to decrease the number of LDL receptors and therefore increase the cholesterol levels in blood, since the latter are inversely related to the number of LDL receptors. *In vitro* studies have shown that catecholamines also inhibit cholesterol synthesis in extrahepatic cells through their action on α_2 and β_2 receptors (14). Propranolol therefore could act by suppressing the catecholamine actions (15), but catecholamines themselves do not seem to exert any major influence on lipid metabolism (16). Therefore, it is unlikely that the increase in

TABLE 3
Effects of Chronic Administration of Propranolol (3 mg per day)[a]

	Water only (2 wk)	Propranolol (2 wk)	Water only (4 wk)	Propranolol (4 wk)

plasma catecholamine levels after β-blocker treatment will affect lipid levels.

Contradictory results also were reported in the literature on the effect of β-blockers on LPL activity. Some authors found an increase in the activity of the enzyme (17) while others (11) found a decrease. We could not document any changes in LPL activity after acute or chronic administration, and our results are in agreement with those of other authors (12,18). These contradictory results may be due to the use of different laboratory methods of LPL activity measurements, different tissues in which LPL activity was measured (heart, adipose, serum), use of different β-blockers, as well as variation in doses and duration of treatment. Another factor is that lipoprotein levels as well as LPL activity change during the day and at different seasons. It is also possible that rats and humans respond differently to the administration of β-blockers. Nonetheless most researchers believe that rats are a good model for the study of the effects of the adrenergic system on lipid metabolism (12,13).

In our study, we administered propranolol to rats for up to 4 wk with no significant change in the serum TG levels. This can be due to the fact that, in order for hypertriglyceridemia to develop, an even longer time of treatment is required. Some authors (19) observed an increase in TG levels only after 1 yr of treatment, others (11) after 2 mon and others (8) after 3 mon. There is also the possibility that in order for hypertriglyceridemia to develop there needs to be an underlying lipid abnormality. It has been shown that patients who already had hypertriglyceridemia and were treated with propranolol showed an increased lipemic response to a meal high in fat compared to patients with normal initial TG levels treated with propranolol (20).

Despite the lack of effects of propranolol on serum lipoproteins in the present experiments, an effect on LPL activity or mRNA expression could not be excluded. There is a body of evidence showing that catecholamines affect LPL activity. Stimulation of β-receptors activates LPL (10), so their blockade could result in the opposite effect, i.e., LPL suppression. It also has been shown that factors that increase cAMP (through which catecholamines exert their actions), like β-blockers and the cholera toxin, also increase muscle LPL activity (21). Furthermore it is known that adrenaline decreases LPL synthesis and increases the rate of LPL catabolism in rat adipose tissue (22). Evidence also suggests that adrenaline affects LPL at a posttranslational level, changing the enzyme's secretion and activation (23). It has been observed that adrenaline decreases LPL activity in rat heart and in isolated cardiac myocytes (24). Others have observed that cAMP increases LPL synthesis within 2 h in isolated rat heart cells (25). Furthermore, catecholamines, cAMP and isoproterenol, acting through β-receptors, suppress LPL activity in white adipose tissue of rats *in vitro* (26), in heart and skeletal muscles (27), and in brown adipose tissue (28).

In summary, the results of our study support the conclusion that, under the conditions used, the nonselective β-blocker propranolol does not affect LPL activity and gene expression in the rat.

Effects of Triolein or Oleic Acid on Lymphatic Recovery of Docosahexaenoic Acid Given as Ethyl Ester and Their Intramolecular Distribution in Lymph Triglyceride of Rats

Ikuo Ikeda*, Hiroko Yoshida, and Katsumi Imaizumi

Laboratory of Nutrition Chemistry, Faculty of Agriculture, Kyushu University, Fukuoka 812-81, Japan

ABSTRACT: Effects of oleic acid or triolein on lymphatic recovery of docosahexaenoic acid (DHA) given as an ethyl ester were examined in rats with cannulated thoracic ducts. Lymphatic recovery of ethyl DHA given with oleic acid or triolein was significantly higher than in rats given ethyl DHA alone. DHA distributed almost exclusively at the 1- and 3-position of triglyceride in lymph collected at 0–3 h after the administration, when it was given with oleic acid or triolein. A small part of DHA distributed at the 2-position when ethyl DHA was the sole fatty acid given. Oleic acid given as free acid or triolein with ethyl DHA was a major fatty acid at the 2-position. Intramolecular distribution of DHA and oleic acid in lymph triglyceride was similar when ethyl DHA was given with oleic acid or triolein.

Lipids 32, 949–952 (1997).

It has been reported that docosahexaenoic (DHA) and eicosapentaenoic (EPA) acids in marine oils have beneficial physiological functions in experimental animals and humans (1,2). Different functions between DHA and EPA also have been reported (3). Ethyl esters of DHA and EPA are utilized as a nutritional supplement and a therapeutic. We and other investigators observed that intestinal absorption of DHA and EPA given as ethyl ester was lower than seen in the case of triglyceride or free acid (4–8). The low absorbability of the ethyl esters was ascribed to the low hydrolysis rate by pancreatic lipase (5,9). However, there were observations that when EPA and DHA were given as ethyl ester or as triglyceride to humans, increases of these n-3 polyunsaturated fatty acids in plasma were comparable (10,11).

After incorporation into intestinal cells, almost all fatty acids are synthesized to triglyceride. The intramolecular distribution of EPA and DHA in lymph triglyceride is scanty when these are given as an ethyl ester (12). This information may be important because the difference in intramolecular distribution of EPA and DHA in lymph triglyceride may influence related physiological functions (13,14).

Effects of coexisting free oleic acid or triolein on recovery of DHA given as ethyl ester were examined in this study in rats with cannulated thoracic ducts, and the intramolecular distribution of DHA and oleic acid in chylomicron triglyceride was measured.

MATERIALS AND METHODS

DHA ethyl ester (purity >97%) was kindly provided by Dr. K. Yazawa, Sagami Chemical Research Center, Sagamihara, Kanagawa, Japan. Triolein (purity 99%) and oleic acid (purity 99%) were obtained from Sigma Chemical Co. (St. Louis, MO). Fatty acid-free bovine serum albumin was obtained from Miles Scientific, ICN ImmunoBiologicals (Lisle, IL). Sodium taurocholate (purity >98%) was purchased from Nacalai Tesque Inc. (Kyoto, Japan).

Male Sprague-Dawley rats (Seiwa Experimental Animals, Fukuoka, Japan) weighing 310–330 g were provided *ad libitum* a commercial nonpurified diet (type NMF; Oriental Yeast Co., Tokyo) and tap water for drinking. Thoracic duct was cannulated, and an indwelling catheter was placed in the stomach (4,5). After this surgery, the rats were placed in restraining cages in a warm recovery room. They were given a normal osmotic solution containing 139 mM glucose and 85 mM NaCl as drinking water, which was infused at a rate of 3 mL/h *via* the gastric tube until the end of the experiment. The morning after collection of lymph for 2 h (blank lymph), each animal was given 3 mL of a test emulsion through the gastric tube, and the lymph was collected for 24 h beginning at 10:00 a.m. The 3-mL test emulsion contained 200 mg of sodium taurocholate, 50 mg of fatty acid-free albumin, and either 100 or 200 mg of ethyl DHA, 100 mg of ethyl DHA plus 100 mg of oleic acid, or 100 mg of ethyl DHA plus 100 mg of triolein. Six rats were in each group.

Lymph lipid extracted with 20 vol of chloroform/methanol (2:1, vol/vol) (15) was transmethylated with a BF_3–methanol complex. Fatty acid methyl esters were subjected to gas–liquid chromatography on a 10% Silar 10C (Chromato TEC, Osaka, Japan) column (4,5). Pentadecanoic acid (Aldrich Chemical Co., Milwaukee, WI) was used as an internal stan-

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

dard. The fatty acid recovery rate was calculated by subtracting the fatty acid amount in the blank lymph from that in the lymph collected after the administration of a test emulsion.

Lymph collected at 0–3 h was subjected to determination of the triglyceride structure. After separation of triglyceride by silica gel G thin-layer chromatography developed with petroleum ether/diethyl ether/acetic acid (82:18:1, by vol), triglyceride was extracted with diethyl ether. Intramolecular distribution of triglyceride was analyzed by a Grignard degradation method (14). To triglyceride (about 10 mg) dissolved in 0.6 mL of diethyl ether was added 0.25 mL of 1 M ethylmagnesium bromide in diethyl ether (Aldrich Chemical Co.) under continuous mixing with a magnetic stirrer. After 25 s, 0.25 mL of acetic acid/diethyl ether (1:1, vol/vol) was added to stop the reaction, and 5 mL of 10% boric acid solution was added while mixing. The reaction mixture was extracted using 5 mL of diethyl ether saturated with boric acid. The diethyl ether phase was washed twice with 1 mL of 2% aqueous $NaHCO_3$ and twice with 1 mL water. The solution was dried using a small amount of anhydrous sodium sulfate and nitrogen at room temperature. The lipids were applied to a thin-layer chromatography plate containing 5% boric acid, and the plate was developed with chloroform/acetone (96:4, vol/vol). 2-Monoglyceride and 1,3-diglyceride fractions were transmethylated, and the fatty acid methyl ester was analyzed with gas–liquid chromatography, as described above.

Data are expressed as means ± SEM. Duncan's new multiple-range test was used to determine the exact nature of the difference among the groups (16).

RESULTS

Lymph flow rate was linear, and there was no significant difference among the groups (Fig. 1). The lymph flow rate was sufficient to the extent that lipid absorption was not interfered with (5,17).

Lymphatic recovery of oleic acid is shown in Figure 2. Lymphatic recoveries of oleic acid given as ethyl DHA + oleic acid and ethyl DHA + triolein were quantitative for 24 h (100 ± 4 and 104 ± 2%, respectively), as observed under similar experimental conditions (5,17). When ethyl DHA 100 and 200 mg was given, lymphatic recoveries of DHA for 24 h were 69.9 ± 1.8% and 64.0 ± 3.3%, respectively (Fig. 3), with a significant difference, at $P < 0.05$. The addition of oleic acid or triolein significantly increased the recovery of DHA in lymph compared with findings in groups given ethyl DHA alone. The accelerated recoveries of DHA were mainly observed in lymph at 0–3 h, and the recoveries after 3 to 24 h were comparable among the four groups. The 24-h recoveries of DHA were 84.4 ± 3.0 and 84.8 ± 2.3% in rats given ethyl DHA + oleic acid and ethyl DHA + triolein, respectively. In our previous study done under similar experimental conditions, lymphatic recoveries for 24 h of DHA given as free acid and triglyceride were 82.7 and 78.9%, respectively (5). Therefore, these recovery rates of DHA were thought to be maximal, at least in our setup.

When ethyl DHA was given as a sole fat, DHA was mainly incorporated into the 1- and 3-position of triglyceride in lymph collected at 0–3 h after administration (Table 1). DHA (84%) in lymph triglyceride was located at 1- and 3-position, whereas 16% of DHA was incorporated into the 2-position. The endogenous fatty acids mainly occupied the 2-position. When oleic acid or triolein was simultaneously given with ethyl DHA, DHA was incorporated almost exclusively at the 1- and 3-position (99% of DHA in lymph triglyceride in both groups). In contrast, a major fatty acid in the 2-position was oleic acid; 46 and 49% of oleic acid given as ethyl DHA + oleic acid and ethyl DHA + triolein, respectively, were estimated to be located at the 2-position, and the remaining parts were at the 1- and 3-position. No difference on the intramolecular distribution of DHA and oleic acid was observed between these two groups.

DISCUSSION

Under the coexistence of triolein or oleic acid, lymphatic recoveries of DHA given as ethyl ester increased to a level almost comparable to cases of free fatty acid and triglyceride, as previously reported (5). Hydrolysis products by pancreatic lipase of triglyceride, 2-monoglyceride and free fatty acid, are surface-active and accelerate emulsification of lipids (18). Therefore, it is thought that oleic acid and 2-monoolein increase the accessibility of ethyl DHA to pancreatic lipase and hence increase the rate of hydrolysis. The accelerated recovery of DHA observed in lymph only at 0–3 h (Fig. 3) again suggests that ethyl DHA is rapidly hydrolyzed and absorbed when given with oleic acid or triolein. Although one study did suggest that EPA given as ethyl ester was absorbed at the same rate as administered triglyceride (19), several investigations showed that lymphatic recovery of EPA and DHA, given as ethyl ester, was lower than when given to rats in the triglyceride form (4,5,7). Ethyl ester was given solely in these studies. Therefore, there is the possibility that the rate of hydrolysis of ethyl ester by pancreatic lipase is low under these experimental conditions. In this context, Lawson and Hughes (20) reported that absorption of EPA and DHA from ethyl esters of fish oil fatty acids was increased by coingestion with a high-fat meal compared to low-fat meal in humans. Our results indicate that utilization of ethyl DHA does not reduce the availability as a DHA supplement, if it is ingested with a meal containing dietary fat.

Since the 2-monoglyceride pathway is more active than the phosphatidic acid pathway in intestinal cells (21), there is the possibility that the existence of 2-monoolein formed by hydrolysis of triolein accelerates triglyceride synthesis and secretion into lymph. In our previous study, lymphatic recoveries of DHA and EPA given as free fatty acids were delayed compared with findings when the triglyceride form was given (5). Yang *et al.* (22) also suggested that low absorbability of the ethyl ester may be due to lack of 2-monoglyceride on resynthesis of triglyceride in intestinal cells. However, in the present study oleic acid and triolein had almost the same effect on lymphatic recovery of DHA. Thus, the lack of 2-

monoglyceride is not rate-limiting under these experimental conditions.

Intramolecular distribution of DHA in lymph triglyceride was similar when given with oleic acid or triolein, and DHA was specifically distributed to the 1- and 3-position (Table 1). The result is consistent with the report in which EPA and DHA were mainly distributed at the 1- and 3-position in lymph chylomicron triglycerides of rats given menhaden oil fatty acids as ethyl ester (12). These results suggest that DHA is specifically bound to the 1- and 3-position in triglyceride synthesis *via* the phosphatidic acid pathway. When ethyl DHA was given as a sole fat, a small portion of DHA was incorporated into the 2-position of triglyceride in lymph collected at 0–3 h after administration. Fatty acid absorption and triglyceride synthesis are active in intestinal epithelial cells during this time. There is the possibility that a supply of endogenous fatty acids bound to the 2-position of triglyceride is insufficient during the period when DHA is actively absorbed. Therefore, although DHA has a low specificity at the 2-position, part of DHA might be incorporated into the 2-position. Since little information is available on fatty acid specificity in triglyceride synthesis *via* the phosphatidic acid pathway, more detailed studies are necessary.

We reported that DHA and EPA distributed at the 1- and 3-position of triglyceride were conserved in chylomicron triglyceride and these acids had stronger triglyceride-lowering activity in plasma and liver compared to the case of distribution at the 2-position (14). Although little is known of the influence of fatty acids other than oleic acid on intramolecular distribution of DHA in triglyceride, there is the possibility that DHA given as ethyl ester has physiological functions similar to triglycerides in which EPA and DHA are distributed at the 1-, and 3-position.

The Cholesterol-Lowering Effect of Guar Gum Is Not the Result of a Simple Diversion of Bile Acids Toward Fecal Excretion

Marie-Laure Favier[a,*], Pierre-Etienne Bost[b], Christine Guittard[b], Christian Demigné[a], and Christian Rémésy[a]

[a]Laboratoire des Maladies Métaboliques et Micronutriments, INRA de Clermont-Ferrand/Theix, 63122 Ceyrat, France, and [b]Rhône-Poulenc, 92400 Courbevoie, France

ABSTRACT: The effects of partially hydrolyzed, nonviscous, guar gum (PHGG) on cholesterol metabolism and digestive balance have been compared with those of native guar gum (GUAR) in rats adapted to 0.4% cholesterol diets. Both types of guar gum elicited acidic fermentations in the large intestine, but only GUAR effectively lowered plasma cholesterol ($P < 0.001$), chiefly in the triglyceride-rich lipoprotein fraction. The biliary bile acid excretion was significantly enhanced in rats fed GUAR ($P < 0.05$), as well as the intestinal and cecal bile acid pool ($P < 0.001$). In rats fed GUAR and to a lesser extent in those fed PHGG, the fecal excretion of bile acids and neutral sterol was higher than in controls ($P < 0.01$). The digestive balance (cholesterol intake–steroid excretion) was positive in control rats (+47 μmol/d), whereas it was negative in rats fed GUAR (−20 μmol/d), which could involve a higher rate of endogenous cholesterol synthesis. In rats fed PHGG, the steroid balance remained slightly positive. Liver 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase activity was very low (22 pmol/min/mg protein), owing to cholesterol supplementation, in control rats or in rats fed PHGG, whereas it was markedly higher (+463%) in rats fed GUAR. In conclusion, even if PHGG does alter some parameters of the enterohepatic cycle of cholesterol and bile acids, its effects are not sufficient to elicit a significant cholesterol-lowering effect. The intestinal (ileal or cecal) reabsorption of bile acids was not reduced, but rather increased, by GUAR; nevertheless the intestinal capacities of reabsorption were overwhelmed by the enlargement of the digestive pool of bile acids. In the present model, induction of HMG-CoA reductase probably takes place in the presence of elevated portal bile acid concentrations.

Lipids 32, 953–959 (1997).

Some water-soluble dietary fibers, such as guar gum, have been shown to be hypocholesterolemic in humans or in experimental animals (1,2). Their effectiveness on cholesterolemia has generally been connected to the high viscosity of guar gum. Viscous hydrocolloids may reduce the rate of gastric emptying and the diffusion of nutrients to the mucosa of the small intestine. These mechanisms reduce the absorption of cholesterol, whatever its origin (dietary or endogenous). Steroid sequestrants (cholestyramine or cyclodextrin) are considered as effective as cholesterol-lowering agents (3), but recent investigations suggest that readily fermented substrates, such as resistant starch, may also be very effective in this respect (4). In fact, emphasis has been put on the capacity of fibers to entrap bile acids in the small intestine and to increase their fecal excretion: this should accelerate cholesterol oxidation to bile acids, resulting in a spillover of the body cholesterol pool, due to fecal losses of steroids. It has been proposed that guar gum inhibits the reabsorption of bile acids, especially in the ileum where system(s) of facilitated transport of bile acids are present (5–7). Furthermore, soluble fibers such as guar gum are almost completely fermented by hind-gut microflora to short-chain fatty acids (SCFA), and this process is characterized by an acidification of the cecal content and by a rise in the bacterial mass. These changes are liable to promote bile acid insolubilization and/or trapping of solids, hence a reduced passive reabsorption in the large intestine.

One major drawback of guar gum is its very high viscosity, which alters the acceptability and the palatability of the food in which it is included (8). Thus, attempts have been made to prepare less viscous forms of guar gum, generally by partial enzymatic hydrolysis. However, when guar gum is hydrolyzed with a subsequent reduction of its viscosity, its efficacy may be greatly diminished (9). Yet Ide *et al.* (10) have reported that partially hydrolyzed guar gum may affect biliary bile acid secretion and lead to a cholesterol-lowering effect in rats fed high-fat diets.

The present study was carried out in rats adapted to 0.4% cholesterol diet to compare the lipid-lowering effectiveness of a high-viscosity guar gum (GUAR) or a low-viscosity, partially hydrolyzed guar gum (PHGG) and to examine the impact of these guar gum preparations on bile acid secretion, reabsorption, and excretion and the consequences on the steroid balance in the digestive tract. We also examined whether the hypothe-

sis of an impaired reabsorption of bile acids with diets containing guar gum is valid and whether other processes could play a role in the cholesterol-lowering effect of guar gum.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (IFFA-CREDO, l'Arbresle, France) weighing approximately 150 g were fed for 21 d with semipurified diets distributed as a moistened powder. The control diet contained the following (in g/kg diet): casein (L. François, Paris, France) 150; corn oil 50; cholesterol 4; wheat starch 726; mineral and vitamin mixes (Usine d'Alimentation Rationnelle, Villemoisson/Orge, France) 60 and 10, respectively. The diet of the two experimental groups contained 80 g guar gum/kg diet, at the expense of wheat starch. Guar gum flours were purchased from Meyhall (Kreuzlingen, Switzerland). Two guar gum flours with different molecular weights (MW) and particle sizes were studied: a native guar gum (GUAR; Meyproguar) of high MW ($\approx 2 \cdot 10^6$) and a PHGG (Fiberon) which was produced by β1,4-mannanase (E.C. 3.3.1.78). The hydrolysate of PHGG was then separated, purified, dried, and powdered to produce a product of low MW (≈15,000). The viscosity of PHGG in distilled water was not higher than 10 cP, even at 10% concentration, which is much less viscous than the starting material GUAR, which showed a viscosity of 2800–3400 cP at 1% concentration. Animals were housed two per cage and maintained in temperature-controlled rooms (22°C), with the dark period from 2000 to 0800 h. Rats were maintained and handled according to the recommendations of the Institutional Ethics Commitee (Clermont-Ferrand University). The body weight of rats was recorded every 48 h during the experimental period; food intake and fecal excretion were recorded over three 2-d periods throughout the last 10 d.

Sampling procedures. Rats were killed at the end of dark period, namely at a time at which cecal fermentations are still very active. They were anesthetized with sodium pentobarbital (40 mg/kg) and maintained at 37°C. An abdominal incision was made, and blood (1 mL) was withdrawn from both the portal vein and from the abdominal aorta. For blood flow measurement, bromosulfophthalein in saline (5 mmol/L) was infused at a rate of 50 µL/min into the small afferent vein on the internal curvature of the cecum: dilution of the marker in the vein draining the whole cecum allows determination of the cecal blood flow. The blood of each animal was placed in a plastic tube containing heparin and centrifuged at $10,000 \times g$ for 5 min. After centrifugation, plasma was removed and kept at +4°C for lipid and lipoprotein analysis. After blood sampling, the cecum with contents was removed and weighed, two samples of cecal content were transferred to microcentrifuge tubes and immediately frozen at –20°C.

The small intestine was clamped at the pylorus and the ileal-cecal junction, removed, stripped of mesentery and fat, and weighed. The small intestine was halved to facilitate handling, and the content of each section was emptied into a preweighed tube by finger stripping then frozen at –20°C.

Surgical procedure. In a separate series of anesthetized rats, a mid-line laparotomy was performed and the bile duct exposed and ligated distally. The bile duct was then catheterized with a PE10 polyethylene catheter (Biotrol, Paris, France), and bile was allowed to drain for 30 min and then collected for two 30-min periods into preweighed vials cooled on ice. Bile volume was determined gravimetrically.

Analytical procedures. SCFA concentrations were measured by gas–liquid chromatography (GLC) after ethanolic extraction of plasma samples as described by Rémésy and Demigné (11) and on supernatants ($8,000 \times g$, 5 min at 4°C) of cecal contents. Bile acids analysis was effected either directly on plasma and bile or on extracts from cecal content or small intestine and feces using 10 vol ethanolic KOH (0.5 M); analyses were quantified using the reaction catalyzed by the 3α-hydroxysteroid dehydrogenase (E.C. 1.1.1.50; Sigma, L'isle d'abeau, Chesnes, France). The soluble bile acids levels were determined on supernatants of cecal contents by the enzymatic method described above. Neutral steroids were extracted three times with 1 mL hexane from a 100-µL aliquot of the alkaline ethanolic extract; after addition of 5α-cholestane as an internal standard, the solvent was then evaporated under a stream of N_2 and the residue dissolved in hexane. Portions (0.5 µL) of this extract were injected into a gas chromatograph (Delsi 330, Paris, France) equipped with a 12 m × 0.25 mm i,d. fused-silica capillary column (BP10; SGE, Villeneuve-St-Georges, France) and a flame-ionization detector. Helium was used as a carrier gas, and the sterols were separated isothermally at 260°C. Sterols were calculated from the peak areas relative to the peak area of the internal standard. Triglycerides (Biotrol) and total cholesterol (BioMérieux, Charbonnières-les-Bains, France) were determined in plasma and bile (only cholesterol) by enzymatic procedures.

Plasma lipoproteins were separated on a density gradient by preparative ultracentrifugation (12) in a TST 41.14 swinging-bucket rotor (Kontron, Zürich, Switzerland) at $100,000 \times g$ for 36 h (15°C). Because of the low level of plasma low-density lipoprotein and the partial overlapping of high density lipoprotein 1 (HDL1) and HDL2 fractions in rats, it was considered only two fractions: the fractions of $d < 1.040$ kg/L (chiefly triglyceride-rich lipoprotein, together with some low density lipoprotein) and the fraction of $d > 1.040$ kg/L (HDL). The cholesterol contents of each fraction were determined by the method described above.

Liver triglyceride and cholesterol were extracted and analyzed as described by Mazur *et al*. (13), and a control serum (Biotrol-33 Plus, Biotrol) was treated in parallel to samples and served as a control of accuracy of analysis.

Enzyme activities. Two grams of liver were homogenized in 4 mL of an ice-cold buffer 1 (50 mmol/L, Tris hydrochloride; 250 mmol/L, sucrose; 50 mmol/L, EDTA; 2 mmol/L, dithiothreitol; and 2 µmol/L, leupeptin, pH 7.2) with a Potter-Elvejhem homogenizer (Braun, Melsungen, Germany) at moderate speed. The homogenate was first centrifuged at $10,000 \times g$ (15 min, 4°C); the resulting supernatant was then

centrifuged at 100,000 × *g* (60 min, 4°C). Pellets were resuspended in 2 mL of chilled buffer 1. The centrifugation procedure was repeated and the resulting pellets homogenized in 1 mL of buffer 2 (sucrose, 100 mmol/L; KCL, 50 mmol/L; K phosphate, 40 mmol/L; EDTA, 30 mmol/L; dithiothreitol, 1 mmol/L; pH 7.2). The microsomal preparation was stored at −80°C until measurement of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase activity. The protein content of microsomes was determined using the Pierce BCA reagent kit (Interchim, Montluçon, France). The activity of HMG-CoA reductase (E.C. 1.1.1.34) was determined on microsomal fractions as described by Wilce and Kroone (14). Labeled mevanololactone was separated from unreacted HMG-CoA by column chromatography using AG1-X8 resin (200 to 400 mesh, formate form; BioRad, Paris, France). Specific radioactivity of the enzyme was expressed in picomoles of [3-^{14}C]HMG-CoA transformed in [^{14}C]mevalonolactone per minute per microgram of microsomal protein, after correcting for recovery of [^{3}H]mevalonolactone from the column.

A portion of liver was freezed-clamped and stored at −80°C for the measurement of fatty acid synthase activity and liver lipids. The cytosolic extract was prepared by treating a 100-mg aliquot with 3 mL isotonic phosphate buffer (K phosphate, 143 mM; 2-mercaptoethanol, 5 mM; EDTA, 4 mM; pH 6.8) using a Polytron homogenizer (Kinematica AG, Littau, Switzerland), then centrifuged at 48,000 × *g* (30 min at 4°C). The enzyme activity of fatty acid synthase was determined by an isotopic method: [2-^{14}C] malonyl CoA was used as a tracer (15). Fatty acid synthase activity was expressed in nanomoles of [2-^{14}C]malonyl CoA incorporated into fatty acids per minute per gram of liver.

Calculation and data analysis. The small intestinal and cecal pool was calculated as: concentration (mmol/L) × digestive volume (mL). Cecal bile acids absorption was determined using arteriovenous difference and blood flow measurement ([cecal vein] − [artery]) × cecal blood flow. The apparent neutral sterol absorption was calculated as: cholesterol intake (≈245 µmol/d) − fecal excretion of neutral sterols. The apparent cholesterol digestibility was calculated as: apparent neutral sterol absorption (µmol/d)/cholesterol intake (µmol/d) × 100, and the total steroids retention as: cholesterol intake − (fecal excretion of neutral sterols + fecal excretion of bile acids). Values are given as the means ± SEM and, where appropriate, significance of differences ($P < 0.05$) between mean values was determined by analysis of variance coupled with the Student's Newman-Keuls' Test.

RESULTS

Effects of diets on body weight, cecal development, cecal pH, and cecal fermentations. The data presented in Table 1 show that there were no significant differences in body weight between control rats and rats fed the guar gum diets. The cecum weight was significantly enhanced in rats fed GUAR and PHGG diets (+73% and +65%, respectively), with a parallel increase of cecal wall weight. Diets containing GUAR or PHGG caused an acidification of the cecal content (pH 5.95 and 6.01, respectively, compared to 7.22 for control rats). Rats fed the GUAR or PHGG diets had cecal SCFA concentrations in the range of 140–160 mmol/L, compared to 79 mmol/L for controls. In parallel, the total SCFA pool was significantly enhanced in rats fed the GUAR or PHGG diets (≈+250% compared to controls); furthermore, there was a higher molar proportion of propionate in rats fed PHGG (44%) than in rats fed the GUAR (30%, $P < 0.02$).

Effects of diets on biliary secretion and fecal excretion of acidic and neutral steroids. As shown in Table 2, the biliary flow was higher in rats fed GUAR and PHGG diets than in controls, and the biliary bile acids secretion was significantly enhanced with rats fed GUAR and PHGG diets (+63% and +36%, respectively, $P < 0.05$), whereas there was no effect on biliary cholesterol secretion. As a consequence, the small intestine bile acids content was markedly enhanced with guar gum diets (89 µmol for GUAR and 70 µmol for PHGG, compared to 50 µmol for controls). In rats fed the guar gum diets, the cecal concentration of bile acids was the same as in control rats (in the range of 7.5–10 µmol/g); nevertheless the cecal pool was significantly enhanced (+100% and +41% with GUAR and PHGG diets, respectively, $P < 0.05$). The bile acids solubility was stongly depressed by acidic pH conditions in the cecum (down to 5–7%), independently of the initial viscosity of guar gum. Bile acids reabsorption in the cecum was 13 µmol/h in controls, and it was significantly enhanced only in rats fed GUAR (up to 21 µmol/h, $P < 0.05$). It

Digestive steroids balance			
Apparent neutral sterol absorption[b] (µmol/d)	+77 ± 9[c]	+25 ± 2[a]	+55 ± 5[b]
Apparent cholesterol digestibility[c] (%)	32	10	23
Total steroids balance[d] (µmol/d)	+47	−20	+20

[a]Each value is the mean ± SEM, $n = 10$. Values within a column that are not followed by a common superscript letter are significantly different ($P < 0.05$).
[b]Apparent neutral sterol absorption = cholesterol intake (≈245 µmol/d) − fecal excretion of neutral sterols (coprostanol + cholesterol, in µmol/d).
[c]Apparent cholesterol digestibility = apparent neutral sterol absorption (µmol/d)/cholesterol intake (µmol/d) × 100.
[d]Total steroids retention = cholesterol intake − (fecal excretion of neutral sterols + fecal excretion of bile acids). See Table 1 for abbreviations.

must be noted that this reabsorption represented a very similar percentage of biliary secretion (28–30%) in all diet groups.

The daily fecal weight was markedly increased with GUAR or PHGG (+52% or +65%, respectively). Fecal bile acids excretion was significantly increased only in the GUAR group (+50%) compared to controls ($P < 0.01$). Bile acids fecal excretion represented 2.4 to 2.8% of the biliary bile acids secretion in any conditions. Comparisons between biliary secretion and output from the small intestine (large intestine reabsorption + fecal excretion) afford an estimation of small intestine reabsorption: about 30 µmol/h in controls vs. 49 µmol/h in rats fed GUAR and 40 in those fed PHGG.

In parallel, there was a subtantial excretion of sterols (chiefly as coprostanol) amounting to 165 µmol/d in controls. This excretion was significantly enhanced only in rats fed GUAR, up to 224 µmol/d ($P < 0.01$). In taking into account the daily cholesterol intake (about 245 µmol/d), it appears that the apparent cholesterol absorption was markedly depressed by GUAR (−67%, $P < 0.001$) and to a lesser extent by PHGG (−28%, $P < 0.05$); as a result, the apparent cholesterol digestibility was markedly reduced (10% with GUAR, compared to 32% with the control diet). The total steroids retention was +47 µmol/d in controls; it was lower but still positive in rats fed PHGG, whereas a negative value (−20 µmol/d) was found in rats fed GUAR.

Effects of diets on plasma and liver lipid concentration and hepatic enzyme activities. As shown in Table 3, plasma cholesterol concentration was 2.18 mmol/L in control rats; there was no significant cholesterol-lowering effect of PHGG, whereas GUAR was very effective in this respect (−37%). Plasma triglycerides were significantly depressed by both GUAR and PHGG. In rats fed the control diet (0.4% cholesterol), the major part of plasma cholesterol was found in the $d < 1.040$ kg/L fraction (Fig. 1). GUAR was very effective in lowering cholesterol in this fraction (−71%), in contrast to PHGG which was marginally effective. Cholesterol in the $d > 1.040$ kg/L fraction was not significantly modified by any of the diet conditions.

The cholesterol diet elicited a marked accumulation of cholesterol in the liver, essentially as cholesterol esters in controls; only GUAR was effective in lowering liver cholesterol, especially the cholesterol esters fraction (Table 3). In parallel, the triglycerides accumulation was reduced only by the GUAR diet.

The microsomal activity of HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis, was very low in control conditions (≈20 pmol/min/mg protein), owing to re-

TABLE 3
Effects of Diets on Plasma Lipids Concentration and Liver HMG-CoA Reductase or Fatty Acid Synthase[a]

	Plasma		Liver				
Diets	Cholesterol (mmol/L)	Triglycerides (mmol/L)	Total cholesterol (mg/g·liver)	Free cholesterol (mg/g·liver)	Triglycerides (mg/g·liver)	Microsomal HMG-CoA reductase (pmol/min/mg protein)	Fatty acid synthase (nmol/min/g·liver)
Control (0.4% cholesterol)	2.18 ± 0.12[b]	1.41 ± 0.13[b]	7.17 ± 0.95[b]	2.36 ± 0.28[a]	13.65 ± 1.32[b]	22 ± 4[a]	318 ± 10[c]
8% GUAR (0.4% cholesterol)	1.37 ± 0.07[a]	1.22 ± 0.12[a]	2.75 ± 0.16[a]	1.87 ± 0.11[b]	8.62 ± 1.04[a]	124 ± 23[c]	213 ± 12[a]
8% PHGG (0.4% cholesterol)	1.97 ± 0.17[b]	1.07 ± 0.11[a]	6.57 ± 0.58[b]	2.29 ± 0.25[a]	11.45 ± 1.09[b]	52 ± 8[b]	265 ± 13[b]

[a]Each value is the mean ± SEM, $n = 10$. Values within a column that are not followed by a common superscript letter are significantly different ($P < 0.05$). HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA. See Table 1 for other abbreviations.

pression by dietary cholesterol. This activity remained very low with the PHGG diet, whereas there was a striking induction in rats fed the GUAR diet (up to 124 pmol/min/mg protein). The cytoplasmic activity of fatty acid synthase was significantly depressed in rats fed galactomannans (−33% and −16% for GUAR and PHGG, compared to controls).

DISCUSSION

It is now well established that guar gum is a potent fermentable polysaccharide to lower plasma cholesterol (16,17), but one major drawback of guar gum is its very high viscosity, which alters its acceptability (8). Thus, attempts have been made to prepare less viscous forms of guar gum, generally by partial enzymatic hydrolysis. With the present products, viscosity had little influence on several major parameters of cecal fermentations such as cecal hypertrophy, luminal acidification, or total SCFA concentration. Nevertheless, the fact that PHGG elicited fermentations particularly high in propionic acid suggests that MW may affect the rate of substrate fermentation, hence the SCFA molar ratio.

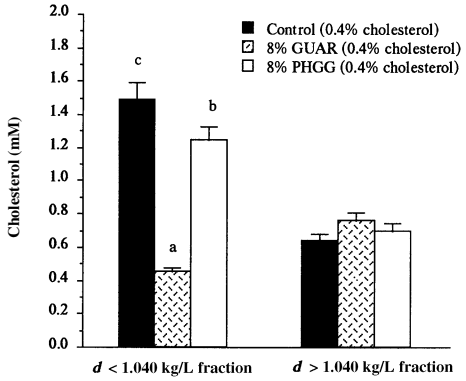

FIG. 1. Changes in concentration of cholesterol (mM) in lipoprotein fractions, in controls rats, and rats adapted to GUAR and PHGG included in 0.4% cholesterol diets. Each value is a mean ± SEM of three pools of rat plasma representing 10 animals per pool. The fractions with a density lower than 1.040 kg/L corresponded chiefly to triglyceride-rich lipoproteins, with a minor contribution of low density lipoprotein. The fractions with a density higher than 1.040 kg/L corresponded essentially to high density lipoprotein. Values not sharing a common letter are significantly different ($P < 0.05$). GUAR, natural guar gum; PHGG, partially hydrolyzed guar gum.

In the present experiment on rats fed 0.4% cholesterol diets, viscous guar gum exerted a strong cholesterol-lowering effect, as previously reported (18,19), whereas this effect is less potent with cholesterol-free diets (20). However, PHGG appears practically devoid of cholesterol-lowering properties in this experiment but displayed a slight but significant triglyceride-lowering effect. In rats fed a cholesterol diet, hypercholesterolemia generally corresponds to a rise in triglyceride-rich lipoprotein cholesterol, HDL cholesterol being practically unchanged (21), and the cholesterol-lowering effect of guar gum affected chiefly the $d < 1.040$ kg/L fraction.

Guar gum is one of the most potent fibers to bind the components of micelles in the small intestine: bile acids, but also phospholipids or cholesterol (6,22). Nevertheless, it is still uncertain whether bile acid availability for dispersion and hydrolysis of lipids is substantially modified. Poksay and Schneeman (23) have reported that, in rats fed guar gum, there is a lowering of bile acids concentration (but the intestinal pool was practically unchanged), whereas Ikegemi *et al.* (24) reported a higher rate of bile acid secretion. The present data show a higher rate of biliary secretion and a larger small intestine pool with GUAR, but it is noteworthy that PHGG also affected these parameters, although less markedly.

The present work suggests that the small intestine reabsorption of bile acids was markedly enhanced in rats fed GUAR (+63%) and to a lesser extent in those fed PHGG (+33%). Yet guar gum has the potential to impair bile acid absorption (5,6,25), but this may be counteracted by opposing factors: enlargement of the small intestine pool and upregulation of ileal transport (26). Nevertheless, even if the ileal reabsorption of bile acids was enhanced in rats fed GUAR, the absorption capacities have probably been overwhelmed since the cecal bile acid pool was dramatically enhanced, as shown for other types of fibers (27). As well as in the small intestine, bile acid reabsorption in the cecum is not sufficient for complete recovery of bile acids escaping ileal reabsorption. Alterations of the physicochemical characteristics of the cecal medium elicited by guar gum fermentation

appear very effective in depressing the solubility of bile acids (from 32% in control conditions down to 5–7% with GUAR or PHGG). Various mechanisms could be invoked: effect of pH itself, elevated availability of Ca, and enlarged bacterial mass, which represents potential binding sites for bile acids (28). However, since the cecal absorption was significantly enhanced with GUAR (and to a lesser extent with PHGG), the consequences of bile acids insolubilization were certainly compensated for by factors such as an accelerated blood flow and an extended surface area of exchange. Whether some other factors could accelerate passive reabsorption itself is still undetermined.

The present experiment indicates that guar gum alters the steroid balance, chiefly by affecting the cholesterol digestibility: with the GUAR diet, compared to control conditions, there was a +59 μmol/d increase in neutral sterol excretion vs. +15 μmol/d for bile acids excretion. Various investigations have established that guar gum is liable to depress cholesterol absorption in the small intestine (19,29), but whether this reflects a direct effect on cholesterol absorption or results from bile acid trapping is still uncertain. As a result, the positive (cholesterol intake–steroid excretion) balance in control rats (+47 μmol/d) was shifted toward negative value (–20 μmol/d) in rats fed GUAR. In rats fed PHGG, this balance was still positive but less than in controls (+20 μmol/d). It appears thus that, in rats adapted to a GUAR diet, there is a concomitant rise in the liver secretion and in the intestinal reabsorption of bile acids, and not merely a diversion of bile acids toward fecal excretion.

PHGG had generally a lesser, but nonnegligible, effect on the various parameters of steroid enterohepatic cycling. Nevertheless, this was not sufficient to shift the steroid balance toward a negative status, required for effective cholesterol-lowering effect.

Cholesterol diets are well known to elicit an accumulation of cholesterol esters and triglycerides in the liver (19,30) and to depress the activity of HMG-CoA reductase drastically (31). It is noteworthy that the cholesterol-lowering effect of GUAR was accompanied by a marked reduction in hepatic cholesterol and the induction of HMG-CoA reductase activity, suggesting that cholesterogenesis could be reactivated by some fibers, as shown by others (32). In the rat, the activity of cholesterol-7α hydroxylase is generally induced by cholesterol feeding, but it may be further induced by steroid sequestrants or gel-forming compounds (3), which is consistent with data on daily bile acids excretion. In rats fed a guar gum diet, this accelerated oxidation of cholesterol toward bile acids apparently leads to an up-regulation of HMG-CoA reductase. It has been proposed that HMG-CoA reductase could be induced in response to a reduced transport of bile acids back to the liver, bile acids being considered as down-regulators of HMG-CoA reductase (33,34). Since bile acid reabsorption is enhanced in rats fed GUAR, this mechanism seems unlikely in the present experiment. Rather, the depletion of liver cholesterol in rats fed GUAR could lead to an up-regulation of the enzyme activity. Inhibition of cholesterol absorption induced by GUAR in the presence of a substantial activity of HMG-CoA reductase appears favorable to normalize plasma cholesterol.

Lipids of Hamster Cheek Pouch Epithelium

Sara Whittle, Donald C. Swartzendruber, Mary Kremer, Christopher A. Squier, and Philip W. Wertz*

Dows Institute, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: The hamster cheek pouch is a much used but incompletely understood experimental model. In particular, the cheek pouch epithelial lipids, which are important for permeability barrier function as well as other aspects of epithelial biology, have not been completely characterized. In the present study, the complete lipid class composition has been determined by thin-layer chromatography in conjunction with photodensitometry. The major lipid classes were phospholipids, free sterols, and ceramides. Minor amounts of monohexosylceramides, sterol esters, fatty acids, and triglycerides were also present. Significant amounts of covalently bound ω-hydroxyceramide was also detected. Transmission electron micrographs reveal extensive, largely paired, lipid bilayers in the intercellular spaces of the stratum corneum.

Lipids 32, 961–964 (1997).

The hamster cheek pouch frequently has been used as a model for studies on oral carcinogenesis (1) and candidiasis (2). From the beginning of 1992 to December 1996, 81 studies have appeared in the MedLine data base that employed the hamster cheek pouch model.

The epithelium in the hamster cheek pouch is a keratinizing epithelium, similar to epidermis or the epithelium from the gingiva and hard palate in the human (3). In these keratinizing epithelia, keratinocytes differentiate to produce a stratum corneum consisting of flat, polygonal cells filled with keratin and surrounded by a lipid matrix (3). The stratum corneum provides a permeability barrier that limits the rate at which materials may penetrate to the underlying tissue. Materials that do traverse the permeability barrier do so by passive diffusion through the intercellular spaces (4–6); therefore, it is the intercellular lipid that determines the quality of the barrier.

In spite of the wide usage of the hamster cheek pouch model and the importance of lipids in epithelial biology and function, the cheek pouch epithelial lipid composition does not appear to have been determined previously. The purpose of the present study was to address this lack of knowledge.

EXPERIMENTAL PROCEDURES

Epithelial lipid extraction and analysis. Four 7-wk-old golden Syrian hamsters were euthanized by asphyxiation with carbon dioxide, and the cheek pouches were excised. Biopsies were fixed for electron microscopy, and the remaining tissue was immersed for 1 min in 65° water, after which the epidermis could be peeled from the underlying tissue. The tissue was dried by lyophilization.

Epithelial lipids were then extracted with chloroform/methanol 2:1, 1:1, and 1:2 for 2 h each at room temperature (7). The extracts from a given sample were combined, dried under nitrogen, and redissolved in 5 mL of chloroform/methanol (2:1, vol/vol). This solution was washed with 1 mL of 2 M KCl to remove nonlipid contaminants (8), and after thorough mixing and centrifugation, the lower phase was transferred to a clean tube and dried under nitrogen.

Lipid class composition was determined by thin-layer chromatography in conjunction with photodensitometry (7,9). Silica gel G plates (Adsorbosil Plus; Alltech Associates, Deerfield, IL) were washed with chloroform/methanol (2:1, vol/vol) activated, and the adsorbent was scored into 6-mm-wide lanes. Samples and standards were applied 2–3 cm from the bottom edge of the plate with 5-μL glass capillaries, and the chromatograms were developed.

In order to resolve phospholipids, monohexosylceramides and ceramides chromatograms were developed to 11 cm with chloroform/methanol/water (40:10:1, by vol), followed by chloroform/methanol/acetic acid (190:9:1, by vol) to 20 cm, followed by hexane/ethyl ether/acetic acid (70:30:1, by vol) to 20 cm. Individual phospholipids were resolved by development with chloroform/methanol/2-propanol/0.25% KCl/triethylamine, 30:9:25:6:18 to 20 cm (10).

To resolve the less polar lipids including cholesterol, fatty acids, triglycerides, and cholesterol esters chromatograms were developed with hexane to 20 cm followed by toluene to 20 cm followed by hexane/ethyl ether/acetic acid (70:30:1, by vol) to 12 cm.

After development, plates were air dried, sprayed with 50% sulfuric acid, and slowly heated to 220°C on an aluminum slab on a hot plate. After charring was complete, chromatograms were scanned with a photodensitometer. Standards used for identification of lipids as well as for quantitation included triolein, cholesterol, cholesterol oleate, phosphatidylethanol-

amine, and sphingomyelin purchased from Sigma Chemical Company (St. Louis, MO). Also, phospholipids, monohexosylceramides, and ceramides from pig epidermis were used. There are no suitable commercially available substitutes for many of these sphingolipids.

Electron microscopy (Ref. 11). Small samples of pouch tissue (approximately 1 mm^3) from each animal were fixed in 2.5% glutaraldehyde buffered in 0.1 M sodium cacodylate. Tissue was then post-fixed for 1 h in either 0.2% ruthenium tetroxide in 0.1 M cacodylate buffer at pH 6.8 or in 1% osmium tetroxide with 1.5% potassium ferrocyanate in 0.1 M cacodylate buffer at pH 6.8. The specimens were then dehydrated in a series of acetone solutions (30, 50, 70, 95, and 100%) before embedding in Spurr's resin. Ultrathin sections were cut and collected on carbon-stabilized Formvar-coated grids (Tousimis, Rockville, MD). Sections were then stained with uranyl acetate and lead citrate prior to examination in a Zeiss EM 10 electron microscope (Carl Zeiss Inc., Chicago, IL).

Covalently bound lipids (Ref. 12). The extracted epithelium was dried *in vacuo*, and each sample was treated with 5 mL of 1 M sodium hydroxide in methanol containing 10% water by volume at 60° for 1 h. After the reaction mixture had cooled to room temperature, 1 mL of 6 M hydrochloric acid and 5 mL of chloroform were added. After thorough agitation, the mixture was filtered through scintered glass. The chloroform phase was separated and dried under a stream of nitrogen. The residue was dissolved in chloroform/methanol (2:1, vol/vol) and analyzed by thin-layer chromatography as described for the free polar lipids.

RESULTS

Table 1 summarizes the lipid class composition of hamster cheek pouch epithelium. The phospholipids include sphingomyelin, phosphatidylcholine, phosphatidylinositol, phosphatidylserine, and phosphatidylethanolamine. The monohexosylceramides and ceramides are similar to the analogous lipids from porcine epidermis and include components with mobilities like acylglucosylceramide and acylceramide in the porcine lipid. The nonpolar lipids from hamster epithelium include free sterol, fatty acid, triglyceride, and sterol esters. In addition to the extractable lipids summarized in Table 1, the hamster epithelium also contains covalently bound lipid matching the ω-hydroxyceramide from porcine stratum corneum and accounting for 0.6 ± 0.2 percentage of the dry weight of the tissue. Smaller amounts of free fatty acids and ω-hydroxy acids are also present.

Figure 1 is a transmission electron micrograph showing the intercellular lipid lamellae in the stratum corneum. It is noteworthy that the lamellae often appear to be paired.

DISCUSSION

Although previous investigators have examined phospholipid and sterol metabolism by hamster oral keratinocytes in cell culture (13–15), the present work is the first complete accounting of the lipid class composition from hamster cheek pouch epithelium. In the previous studies (13–15), the incorporation of ^{14}C-acetate into different lipid classes by basal keratinocytes was measured. Unfortunately, these labeling data cannot be converted into a composition for comparison with the present results. In these earlier studies on lipid synthesis, phospholipids, sterols, fatty acids, triglycerides and sterol esters were detected, and all of these lipid classes also were found in the present study. In contrast, glycosylceramides and ceramides were not detected in the basal keratinocyte cultures, whereas these sphingolipids are abundant in cheek pouch epithelium. The apparent absence of the glycosylceramides and ceramides from basal keratinocytes is in accordance with the concept that basal keratinocytes are relatively undifferentiated cells, while the ceramides and glycosylceramides synthesized as keratinocytes differentiate. Lipid class compositions similar to those found for cheek pouch epithelium have been reported for porcine epidermis and keratinized oral epithelium (7); however, the proportions of the different classes found in cheek pouch epithelium, especially the relatively high proportions of the sphingolipids, are closer to those found in epidermis than porcine oral epithelium.

Likewise, the organization of the intercellular lamellae in the stratum corneum is more reminiscent of that seen in porcine (7), human (16), or murine (11) epidermis than of porcine oral stratum corneum. The keratinizing regions of porcine oral ep-

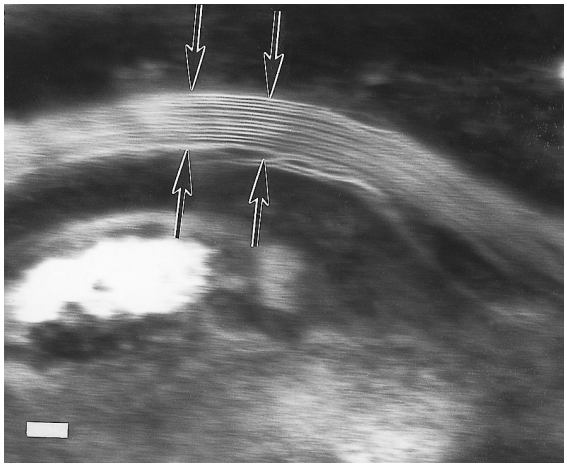

FIG. 1. Transmission electron micrograph of stratum corneum from the hamster cheek pouch. Bar = 50 nm. Note paired bilayers with intervening bands of electron dense material (arrows).

ithelium are adapted for the dissipation of shearing forces associated with mastication, and as such they produce a stratum corneum with many desmosomes. The intercellular spaces between the frequent desmosomes appear to be dilated with a few lamellae at the periphery of the dilation and amorphous material filling most of the interior of the dilation. In contrast, epidermis contains relatively few desmosomes, and the intercellular spaces between the desmosomes in epidermal stratum corneum appear to be more uniform in width and more extensively filled with broad multilamellar sheets.

The transition of membrane structure from the lamellar contents of the membrane coating granules to the broad, multiple lamellae in the stratum corneum in hamster cheek pouch epithelium has been described previously by Hayward (17). The fact that the stratum corneum lamellae appear to be paired can be predicted from Landmann's model for these membrane transitions (18). Based on extensive transmission and freeze fracture electron microscopy, Landmann proposed that the lamellae within the membrane coating granules are actually stacks of flattened lipid vesicles. After extrusion into the intercellular space, the flattened vesicles align and fuse in an edge-to-edge manner to produce paired bilayers.

It has been proposed that in epidermal stratum corneum the covalently bound lipid layer on the outer surface of the corneocyte envelope may serve as a template upon which the flattened vesicles derived from the membrane coating granules can align and fuse to form the extensive broad lamellae that fill most of the intercellular space (19). In keratinized oral epithelia from the porcine hard palate or gingiva, it has been demonstrated that there is no covalently bound lipid, and accordingly, in these tissues there are less extensive and poorly organized intercellular lamellae. The finding of significant levels of covalently bound hydroxyceramide in the present study and the similarity between the intercellular spaces of the cheek pouch stratum corneum and epidermis are in accordance with this proposed role of the covalently bound lipid layer.

It is noteworthy that the intercellular lamellae in hamster cheek pouch stratum corneum can be visualized as well after fixation with osmium tetroxide as with ruthenium tetroxide. This is not the case with epidermal stratum corneum from several different species. With porcine epidermis, for example, the intercellular spaces appear electron lucent without a trace of lamellar structure, following conventional fixation with osmium tetroxide (16). The chemically more reactive ruthenium tetroxide appears to be required to reveal the lamellar organization of the intercellular lipid. This has been shown to be related to the relatively unreactive lipids present in epidermal stratum corneum (16). The present results, as well as one previous study, imply that the lipids in hamster cheek pouch stratum corneum contain more reactive groups than the lipids in epidermal stratum corneum. Future studies will address this point.

Dietary Sandalwood Seed Oil Modifies Fatty Acid Composition of Mouse Adipose Tissue, Brain, and Liver

Yandi Liu and Robert B. Longmore*

School of Pharmacy, Curtin University of Technology, Perth, Western Australia 6001, Australia

ABSTRACT: Sandalwood (*Santalum spicatum*) seed oil, which occurs to about 50% of the weight of the seed kernels, contains 30–35% of total fatty acids (FA) as ximenynic acid (XMYA). This study was designed to obtain basic information on changes in tissue FA composition and on the metabolic fate of XMYA in mice fed a sandalwood seed oil (SWSO)-enriched diet. Female mice were randomly divided into three groups, each receiving different semisynthetic diets containing 5.2% (w/w) fat (standard laboratory diet), 15% canola oil, or 15% SWSO for 8 wk. The effects of SWSO as a dietary fat on the FA composition of adipose tissue, brain, and liver lipids were determined by analyses of FA methyl ester derivatives of extracted total lipid. The FA compositions of the liver and adipose tissue were markedly altered by the dietary fats, and mice fed on a SWSO-enriched diet were found to contain XMYA but only in low concentration (0.3–3%) in these tissues; XMYA was not detected in brain. Oleic acid was suggested to be a principal XMYA biotransformation product. The results were interpreted to suggest that the metabolism of XMYA may involve both biohydrogenation and oxidation reactions.

Lipids 32, 965–969 (1997).

Sandalwood (*Santalum spicatum*) is a small tree or shrub native to the Western Australian arid region. It bears significant numbers of a large fruit, which is a drupe containing a hard-shelled seed which is rich in a drying fixed oil (50–60%, w/w) (1). The kernel of the seed has been part of the traditional Western Australian Aboriginal diet (2) and also has been a minor source of food to people living and working in the bush (3). The food value of the kernel is similar to other commercially available nuts (3).

A distinctive feature of sandalwood seed oil (SWSO) is the presence of conjugated acetylenic fatty acids (FA) with ximenynic acid (XMYA) [30–35% of total FA; *trans*-11-octadecen-9-ynoic acid, 18:2(9a, 11*t*), where "a" indicates the triple-bond position; "*t*" indicates the *trans* configuration of double bond] being the most abundant (1). Stearolic acid [1% of total FA; 9-octadecynoic acid, 18:1(9a)] also occurs naturally (4). The chemistry of conjugated enyne FA is of current interest because of their potential bioactivity as lipoenzyme inhibitors or their involvement in FA metabolism (5–8).

Although kernels of the sandalwood seeds have been eaten in the past without apparent harm, concern has been expressed about the possible long-term toxicity of the acetylenic FA (5–9). The metabolism of XMYA has been previously studied by feeding rats with a diet enriched in quandong (*Santalum acuminatum*) seed oil, which contains XMYA at up to 40–45% of total FA (1,9). Those results indicated that XMYA was incorporated into different tissues only to a minor extent (0.5–5.4%), and it increased hepatic cytochrome P-450 activity (9). Little specific information is currently available about the metabolic fate of XMYA in animals or humans. This study was designed to obtain basic information on quantitative changes in tissue FA composition induced by XMYA and to provide further information on the metabolic utilization of XMYA in mice fed SWSO.

MATERIALS AND METHODS

Diets were formulated and compounded by Glen Forrest Stockfeeders (Perth, Western Australia, Australia). The diets were prepared as 11-mm diameter pellets based upon a sodium caseinate semisynthetic formula with added vitamins and minerals compounded according to the AIN 1993 base formula (10). Canola oil (CO) was purchased from a local supermarket and SWSO was supplied from this study program, following Soxhlet extraction of the mature seed kernels using hexane solvent with complete removal of solvent at reduced pressure using rotary evaporation at 60°C. The diet pellets were stored in closed containers at room temperature. The FA compositions of the diet pellets were determined by gas chromatographic/mass spectral (GC/MS) analysis of the FA methyl esters (FAME).

Animals and diets. Six-week-old female mice, strain ARC, weighing 20 to 30 g, were obtained from the Animal Resources Centre (W.A., Australia) and were given free access to the standard laboratory diet (SLD) for 4 wk. The mice were then randomly divided into three groups, each of 15 mice, and were then ear-punched with unique codes. The mice were

*To whom correspondence should be addressed at the School of Pharmacy, Curtin University of Technology, GPO Box U 1987, Perth, Western Australia 6845, Australia. E-mail: R.Longmore@info.curtin.edu.au.

Abbreviations: AA, arachidonic acid; CO, canola oil; DHA, docosahexaenoic acid; DMOX, dimethyloxazoline; FA, fatty acids; FAME, fatty acid methyl esters; MUFA, monounsaturated fatty acids; SFA, saturated fatty acids; SLD, standard laboratory diet; SWSO, sandalwood seed oil; XMYA, ximenynic acid.

housed in standard lab cages, in a humidity (50 ± 5%), temperature-regulated (21 ± 1°C), light-controlled room which was illuminated daily for a 12-h period. The mice were given free access to feed and water at all times. Consumption of diet pellets was determined on a weekly basis, for a total test feeding period of 8 wk.

One group of mice (control) were fed SLD, another group (high-fat test control) was fed the CO-enriched diet, and the third group was supplied the experimental SWSO-enriched diet. At the end of the 8-wk feeding period, the mice were fasted overnight and killed by cervical dislocation. Adipose tissue, brain and liver were quickly removed, washed with physiological saline, and stored at −20°C in closed, labeled tubes for further analyses. The experimental protocol was reviewed and approved by the Animal Experimentation Ethics Committee of Curtin University (Perth, Australia) (approval number: N44/94).

Lipid analysis. Total lipid was extracted from homogenized organ tissue by the method of Bligh and Dyer (11). The dietary oils and the total lipids of various tissues were converted to FAME by the method of Christie (12). The FAME derivatives were characterized and quantified using gas chromatography (GC) on a Hewlett-Packard (Palo Alto, CA) 5890 Series 11 GC system with HP 5971 mass selective detector. The separation was carried out on a DB 23 capillary column (30 m × 0.25 mm i.d., 0.15 μm; J&W Scientific, Folsom, CA) as reported previously (13).

Statistical analysis. Statistical analysis of results was carried out using one-way analysis of variance and the Scheffe's Test (SPSS; SPSS Inc., Chicago, IL) where appropriate.

RESULTS AND DISCUSSION

The summary composition of the three diets is shown in Table 1. FA analysis of the three diets determined as relative percentage FA content is shown in Table 2. The consumption of the three diets was determined on a weekly basis and found to be SLD: 3.85; CO: 3.00; and SWSO: 2.24 g per mouse per day. Inspection of Table 1 data and the available energy for each diet suggest that the mice consumed 0.056, 0.054, and 0.040 MJ, respectively, available energy per day through the various diets. To a certain extent, the reduced food consumption was balanced by the higher energy content of the diet. At the conclusion of this study, the mice had all shown an increase in body weight which varied according to the diet: SLD: 15.78%; CO: 19.62%; and SWSO: 11.45% body weight increase. Thus, a general effect of feeding the SWSO diet was to decrease food consumption, providing a decrease in available energy intake, and this resulted in the lowest body weight increase over the test period of all three diets. There were no mouse deaths during the feeding experiment.

The mice had initial weights of about 26.5 g and gained weight whether they were fed on SLD or CO or SWSO diets. The decreased growth rates of the SWSO group may be due to one or more of a number of factors such as poor utilization of the diet, a growth-retarding action due to an unbalanced ratio of saturated FA (SFA) to monounsaturated FA (MUFA) in dietary fat, or perhaps a specific action of XMYA as an antifeedant FA. A previous feeding study has shown the optimal ratio of SFA to MUFA in diet fat to be 1:0.7 to 1:0.2, and when the ratio was decreased to 1:1.8, a lower growth rate was observed (14). In this study the ratios of SFA to MUFA were determined to be SLD: 1:0.72; CO: 1:10.86; and SWSO: 1:9.72. Clearly, both of the high-fat CO and SWSO diets are far less than the optimal ratio and may thus be expected to produce a lower growth rate as a consequence. However, it was observed that the CO diet produced the greatest increase in body weight, while the SWSO diet produced the lowest growth rate. No specific essential FA-deficiency symptoms were observed in the SWSO-fed animals, suggesting that XMYA had not exerted an antimetabolic effect or inhibited the uptake of essential FA.

The FA compositions of selected mice tissues were determined.

Adipose tissue. Adipose tissue is considered as a dynamic focal point of lipid metabolism (15). Several reports have provided convincing evidence that the FA profile of adipose tis-

TABLE 1
Percentage Composition of Standard and Test Diet Pellets[a]

sue usually reflects dietary FA composition (16,17). Thus, FA analysis of adipose tissue may provide important information on the uptake and utilization of SWSO, specifically with regard to its FA composition. The effects of SLD, CO, and SWSO dietary fat on adipose tissue FA composition in mice are presented and compared in Table 3.

We have observed that the adipose tissue relative FA composition did not necessarily reflect the dietary FA composition and, indeed, quite profound changes were observed. The relationship between tissue and dietary individual FA profiles has been quantified by calculating the ratio: tissue FA/diet FA, × 100 of specific FA. A strongly positive value in excess of 100 may indicate either enrichment with respect to that FA, evidence of synthesis of one FA from another dietary FA, or differences in intestinal uptake of specific FA. Conversely, a low value, less than 100, may indicate metabolism of the dietary FA and hence its low incorporation into adipose tissue or reduced intestinal uptake of that FA.

It was found that the major SFA of adipose tissue was 16:0, and 18:1n-9 was the predominant MUFA in adipose tissue of all groups. Earlier studies have pointed out that 18:1n-9 is certainly the most widespread FA, representing in many fats more than 30% of the total FA (18).

Mouse consumption of the SLD resulted in decreased SFA components. In contrast, there were marked increases in MUFA such as 16:1n-7 and 18:1n-9, with the appearance of vaccenic acid (18:1n-7) as a minor "new" entity in the adipose tissue. Vaccenic acid is a common FA in laboratory animals, being formed by microorganisms present in the intestine of mice and it may also arise during coprophagy (19).

Mice fed the CO-diet showed a marked increase in 16:0, with slight relative decreases in 18:1n-9, 18:2n-6 and 18:3n-3 compared with their dietary fat supplement composition. Mice fed the experimental SWSO-diet showed a marked relative increase in 16:0, together with a significant relative increase in 18:1n-9 in comparison with the dietary composition. A relative increase was observed in 16:1n-7 level and a marked decrease in 18:3n-3 relative content.

In general, 16:1n-7 occurred only to a low relative content in the dietary fats e.g., 0.7% in SLD, and only traces in CO and SWSO diets. Thus, the large relative increase of this acid in the body fat in all feeding groups was of considerable interest, especially because adipose tissue is the important site for FA biosynthesis. For example, SFA such as 18:0 can be a precursor for conversion into the corresponding monounsaturated form, 18:1n-9 by microsomal Δ9-desaturase enzyme (20,21). Higon *et al.* (21) have demonstrated that such enzymatic reactions may be expressed by the calculated 16:1/16:0 and 18:1/18:0 ratios, and a rise in the numerical value of these ratios would indicate a higher lipogenic activity.

This study demonstrated that the SWSO-fed mice had significantly increased ($P < 0.05$) 16:1/16:0 and 18:1/18:0 ratios, suggesting that XMYA, the major differentiating factor between CO and SWSO diets, may stimulate Δ9-desaturase enzyme activity, an observation which will require further investigation. This finding may be contrasted with the observation that a CO-diet containing *ca*. 71% 18:1n-9 relative FA content did not increase the adipose tissue level of 18:1n-9 but rather maintained it at approximately the same level. In contrast, an earlier study has reported that feeding rats a diet containing high 18:1n-9 resulted in an increased percentage of 18:1n-9 in adipose tissue with a decreased percentage of 16:0 (22).

XMYA constituted 34% of the FA in the SWSO diet, but only about 3% of total FA could be detected in adipose tissue lipids. This is approximately 10% of its content in SWSO diet. This relatively constant relationship, detected in all the adipose tissue samples of rats fed the SWSO diet, may reflect rapid metabolism of XMYA after ingestion, or that XMYA was simply not absorbed.

Subgroups						
16:1/16:0	0.19 ± 0.07[a]		0.12 ± 0.04[a]		0.32 ± 0.07[b]	
18:1/18:0	29.78 ± 7.29[a]		51.35 ± 11.89[b]		118.2 ± 14.29[c]	

[a]Values represent means ± SD of five determinations. Same superscript letters indicate samples which are not significantly different ($P < 0.05$) within a row using the one-way analysis of variance. T/D = tissue FA/dietary FA × 100; n.d. = not detected. See Table 1 for other abbreviations.

Consideration also should be given to the stereochemistry of the XMYA C_{11}-C_{12} double bond which is of a *trans* configuration. In animal studies it has been found that the deposition of *trans* FA in adipose tissue is dependent on its concentration in the dietary fat intake (23). For example, feeding rabbits for 3 wk a diet providing 40% of energy from fat of which 38% was derived from elaidic acid (*trans* 18:1n-9*t*) resulted in the rabbit adipose tissue containing 22% of this *trans* FA (22). In an earlier study (24), it was noted that the amount of 18:0 was higher in adipose tissue in methyl-elaidate-1-^{14}C-fed fat-deficient guinea pigs than those of coconut-oil-fed animals. The pathway leading to the high level of 18:0 was considered to occur by direct biohydrogenation of elaidic acid. XMYA is an example of an unusual *trans* FA which showed insignificant incorporation.

In conclusion, the marked increase in 18:1n-9 content in SWSO-fed mice adipose tissue could be the result of at least two processes: in the first XMYA stimulates the activity of Δ9-desaturase enzyme to convert 18:0 into 18:1n-9, and in the second XMYA could be the substrate for 18:1n-9 biosynthesis *via* a biohydrogenation process. Therefore, the observed high 18:1/18:0 ratio of SWSO-fed mice (118.2 ± 14.29) may have resulted from a mechanism [1], and the higher relative content of 18:1n-9 also would seem to support the role of XMYA as a precursor in another mechanism [2].

$$18{:}0 \xrightarrow[\text{ximenynic acid}]{\text{9–desaturase}} 18{:}1\text{n–}9 \qquad [1]$$

$$18{:}2(9\text{a}, 11t) \xrightarrow{\text{biohydrogenase}} 18{:}1(9c, \text{or } 11t) \qquad [2]$$

Previous workers have indicated that the biohydrogenation of double bonds in nature is only found in ruminant animals and as a reaction in some bacteria, and that "conjugated linoleic acid" (CLA, *cis*-9, *trans*-11-octadecadienoic acid) may be formed by isomerization during hydrogenation of linoleic to stearic acid (25). It may be that biotransformation of XMYA involves an initial step of biohydrogenation of its C9,10-yne bond to form a CLA which is further biohydrogenated to oleic or vaccenic acids.

Stearolic acid, present in SWSO only in low concentration (1%), also was detected in low concentrations (0.8%) in adipose tissue. No evidence has been reported in the literature for biohydrogenation of XMYA to stearolic acid.

Dietary FA content may have a bearing on adipose tissue FA content, but the depositional effect reflects more the actual nature of the FA rather than its general abundance. In this study the adipose tissue FA composition was not a consistent indicator of diet FA content although the content of certain FA in adipose tissue lipid was significantly affected by the dietary intake. It may also be a point of conjecture, but not proven by this study, that an apparent requirement of the animal is to maintain at least a minimal level of 18:1n-9 content, especially in adipose tissue.

Brain. There was no effect on brain FA composition of feeding the different diets, and there was a remarkable degree of similarity between the samples. This may suggest that mouse physiology controls brain lipid FA composition to an exact degree, possibly almost as a protective mechanism for this center of cerebral activity. XMYA was found to be absent from the brain lipid fraction which was in accordance with a recent study (9). The authors suggested that if rats were fed during the critical period of brain development, it could result in the incorporation of XMYA into brain lipids. Other earlier studies have also indicated that the acetylenic FA, crepenynic and stearolic acids, were not incorporated into brain lipids (26).

Liver. The effects of different diets on mouse liver FA composition are shown in Table 4. The liver FA composition of mice fed the SLD almost reflected dietary 16:0, 18:0, and 18:1n-9 levels. The major observed result of the SLD was a relative 50% decrease in the 18:2n-6 level in the liver, accompanied by the appearance of longer chain FA such as arachidonic acid (AA) and docosahexaenoic acid (DHA). Mice fed the CO diet had increased levels of 18:0 and decreases in 18:1n-9 relative content when compared to those on SLD and SWSO diet. The increase in 18:0 did not reflect the original low level in the CO diet. The SWSO-fed mice demonstrated the highest levels of 18:1n-9 in the liver together with a marked increase in the proportion of 18:1(11*t*). The possible reasons for such a relative increase in 18:1n-9 were discussed previously for adipose tissue.

The liver is the important organ for FA oxidation and biosynthesis (25,27), where SFA such as 16:0 and 18:0 can be converted to the corresponding MUFA 16:1n-7 and 18:1n-9 by microsomal Δ9-desaturase enzyme activity (27).

All mice in this study showed evidence of FA elongation and desaturation processes in the liver. Compared with the control SLD, mice fed the CO diet had significantly higher relative levels of AA, suggesting that more active processes of elongation and desaturation of 18:2n-6 may have occurred.

TABLE 4
Relative Percentage Composition of Fatty Acids in Mouse Liver Lipid[a] (g/100 g total FA)

Fatty acid	SLD	CO	SWSO
16:0	31.51 ± 1.33[b]	27.22 ± 2.77[a,b]	24.61 ± 2.00[a]
16:1n-7	2.04 ± 0.71[a]	1.26 ± 0.77[a]	2.14 ± 0.89[a]

Unknown	n.d.	n.d.	0.27 ± 0.13
Subgroups			
DHA/AA	0.42[a]	0.46[a]	2.10[b]

[a]Values respresent means ± SD of five determinations. Same superscript letters indicate samples which are not significantly different ($P < 0.05$) within a row using the one-way analysis of variance; n.d. = not detected. AA, arachidonic acid; DHA, docosahexaenoic acid. See Tables 1 and 2 for other abbreviations.

In contrast, the lower levels of AA of SWSO-fed mice may indicate that XMYA competitively inhibit the conversion of 18:2n-6 to AA. This finding is supported by an earlier study in which rats fed a control diet containing 0.5% of 5,8,11,14-eicosatetraynoic acid showed not only that this acid affected the Δ9-desaturase system but also inhibited the elongation of unsaturated FA (28). However, compared with the control SLD group, mice fed the SWSO diet had higher levels of DHA, which may suggest that while XMYA inhibits the conversion of AA, it promotes the formation of DHA. DHA has the potential to antagonize AA metabolism and hence influence the synthesis of AA-derived inflammatory mediators (29). Therefore, such an effect may have future therapeutic significance to reduce inflammatory responses while promoting the formation of beneficial FA such as DHA.

In conclusion, this study has demonstrated that female mice fed a SWSO-enriched diet showed marked relative increases of 16:0 and 18:1n-9 content in adipose and liver tissues in comparison to SLD and CO-enriched diets. Little change was observed in brain tissue FA relative content. Little XMYA was observed to be incorporated into any of the tissues analyzed, reflecting either a high metabolism of XMYA or simply lack of significant absorption from the intestine. Interpretation of the effects of SWSO on tissue FA relative concentrations suggested the possibility of XMYA undergoing metabolic biohydrogenation (through suitable CLA intermediates) or by stimulation of Δ9-desaturase enzymes. A significant finding was the marked relative increase in liver tissue DHA content with a decrease in the relative content of AA.

The Unusual Occurrence of 14-Methylhexadecanoic Acid in Pinaceae Seed Oils Among Plants

Robert L. Wolff[a],*, William W. Christie[b], and David Coakley[b]

[a]ISTAB, Université Bordeaux 1, Talence, France, and [b]Scottish Crop Research Institute, Invergowrie, Dundee, Scotland

ABSTRACT: 14-Methylhexadecanoic (14-MHD) acid has been identified in a sample of pine seed oil (*Pinus contorta*) by gas–liquid chromatography–mass spectrometry of its picolinyl ester derivative. Its identification (through its equivalent chain length) and its distribution in four conifer families have been checked. It occurred only in Pinaceae, where it was found in 72 species belonging to the genera *Pinus*, *Abies*, *Cedrus*, *Tsuga*, *Pseudotsuga*, *Larix*, and *Picea*, in the range 0.02–1.15%. 14-MHD acid could not be detected in the lipids of Taxaceae (*Taxus baccata*), Cupressaceae (*Juniperus communis*), or Taxodiaceae (*Sciadopytis verticillata*), even after a 10-fold concentration of the saturated acid fraction isolated by argentation thin-layer chromatography. It is concluded that Pinaceae, along with *Ginkgo biloba* seed lipids, are major exceptions in the plant kingdom with regard to 14-MHD acid, which otherwise occurs almost exclusively in lipids of animals and microorganisms. The biosynthesis and metabolic role of 14-MHD acid, which otherwise also occur in wood and leaf lipids, remain unknown.
Lipids 32, 971–973 (1997).

It is generally assumed that methyl-branched saturated fatty acids are characteristic components of animal and microbial lipids, and that they generally do not occur in plant lipids. However, 14-methylhexadecanoic (14-MHD, or *anteiso*-17:0) acid was recently formally identified in *Ginkgo biloba* (maidenhair tree, a Gymnosperm) seed lipids by mass spectrometry (MS) of its picolinyl ester derivative (1). In an earlier study of this material and of other conifer seed lipids, Takagi and Itabashi (2) tentatively identified a 16:2n-6 acid that eluted during gas–liquid chromatography (GLC) on a Silar 5CP capillary column (commercial source not given in Ref. 2) between the 16:1 isomers and 17:0 acid, and which was present in higher amounts in *G. biloba* than in other Gymnosperm species. Because this is the place where 14-MHD acid is expected to elute, one may retrospectively surmise that the 16:2n-6 acid might have been confused with 14-MHD acid. However, this is not certain, because Jamieson and Reid (3) observed and tentatively identified both the 16:2n-6 and 14-MHD acids in the needle lipids of a large collection of conifer species. In addition to these acids, these authors also reported on the presence of *trans*-3-16:1 and 16:3n-3 acids that elute in the same region. 14-MHD acid was also formally identified by its mass spectrum in the sapwood of several North American pines (4).

In two systematic studies of conifer seed lipids, Wolff and Bayard (5) and Wolff *et al.* (6) did not mention any component eluting between the two close-eluting 16:1 isomers and 18:0 acid on a CP-Sil 88 capillary column (Chrompack, Middelburg, The Netherlands). Only recently was it recognized (7,8), through the use of a DB-Wax capillary column (J&W Scientific, Folsom, CA), that there existed an acid that was distinct from the 16:1 isomers and that eluted between them and 17:0 acid. This unknown component coeluted with the second-eluting 16:1 isomer on the CP-Sil 88 capillary column, and it was erroneously reported as a 16:1 acid in earlier publications (5,6). Later, it was observed that the unknown acid migrated along with the saturated acid fraction after silver-ion thin-layer chromatography (Ag-TLC) (7). In addition, it coeluted on both the CP-Sil 88 and the DB-Wax capillary columns with an authentic commercial standard of 14-MHD acid methyl ester (7), and it was then tentatively identified as 14-MHD acid. Although it is absent from Angiosperm lipids, we demonstrate here, by GLC–MS of its picolinyl ester derivative, that the unknown component is actually 14-MHD acid, and that it occurs in the seed oil of numerous conifer species, but exclusively of the Pinaceae family.

EXPERIMENTAL PROCEDURES

Samples. Fatty acid methyl esters (FAME), prepared in duplicate from the seed oil of several conifer species, were available from previous studies by one of us (5–8). The origin of the seeds, the extraction of oils, and the preparation of FAME have been described in detail elsewhere (5–8).

Analytical GLC. FAME were analyzed in a Carlo Erba 4130 chromatograph (Carlo Erba, Milano, Italy) equipped with a DB Wax column (30 m × 0.32 mm i.d., 0.5 μm film; J&W Scientific). The oven temperature was 190°C, and the inlet pressure of the carrier gas (helium) was 140 kPa. The injector (split mode) and the flame-ionization detector were maintained at 250°C. Quantitative data were calculated by an

SP 4290 integrator (Spectra Physics, San Jose, CA). Identification of fatty acids was made as described previously (5,6).

GLC–MS. Methyl esters were hydrolyzed to the free fatty acids (9) before conversion to the picolinyl ester derivatives as described by Balazy and Nies (10). The derivatives were submitted to GLC–MS, with a Hewlett-Packard 5890 Series II plus gas chromatograph (Palo Alto, CA) attached to an HP model 5989 MS apparatus. The latter was used in the electron impact mode at 70 eV with a source temperature of 250˚C. The chromatograph was fitted with on-column injection, and equipped with a capillary column of fused silica coated with BPX-70 (50 m × 0.22 mm i.d., 0.25 µm film; SGE (UK) Ltd., Milton Keynes, United Kingdom). After holding the temperature at 80˚C for 3 min, the column was temperature-programmed at 20˚C/min to 160˚C, then at 2˚C/min to 260˚C, where it was held for 5 min. Helium was the carrier gas.

RESULTS AND DISCUSSION

Identification of 14-MHD. The methyl and picolinyl ester derivatives of the fatty acids were examined by GLC–MS, using a polar BPX-70 column for the separation. The spectrum of the picolinyl ester derivative is shown in Figure 1. The molecular ion is at *m/z* = 361, confirming the molecular weight, but the key diagnostic feature is a gap of 28 amu between *m/z* = 304 and 332. This represents cleavage on either side of the methyl branch point and is typical of cleavage expected of an *anteiso* derivative (11). The mass spectrum of the methyl ester was consistent with this interpretation (9).

Distribution of 14-MHD. As shown in Table 1, 14-MHD acid (identified on chromatograms by its equivalent chain length, 16.68) was present in all Pinaceae species analyzed. It was in the range 0.02–0.23% in *Pinus* species, 0.52–0.57 in *Tsuga* species, 1.15% in *Pseudotsuga menzieseii*, 0.17–0.26% in *Picea* species, 0.42–0.98% in *Cedrus* species, 0.57–0.87% in *Abies* species, and 0.36–0.42% in *Larix* species. Thus it seems that different species inside a given genus show some similarities with regard to their 14-MHD acid level. On the other hand, for species from other conifer families (Taxaceae, Cupressaceae, and Taxodiaceae; results not shown), 14-MHD acid was either absent or at the limit of detection. This was confirmed by GLC analysis after a 10-fold concentration of the saturated acid fractions prepared by Ag-TLC from the seeds of *Taxus baccata*, *Juniperus communis* and *Sciadopytis verticillata*, each of these species being representative of one of the preceding families (results not shown). Not even a trace of 14-MHD acid could be detected in these species, although 17:0 acid was clearly present (results not shown). It should be emphasized that 14-MHD acid was also very low in the needle lipids from these families (0.1–0.4%) as compared to Pinaceae (0.2–4.8%) (3). The reason why 14-MHD acid is present in the leaves and not in the seeds is unexplained.

This study has clearly demonstrated that 14-MHD acid is not limited to animals or microorganisms. It is a common constituent of the needle (3), wood (4), and seed (this study) lipids of Pinaceae. Though the amount of 14-MHD acid was low (most often less than 1%), it was present in the seed lipids from all of the 72 species studied here. However, no other branched-chain component was detected, to the contrary of some conifer leaf lipids where 12-methyltetradecanoic acid has been tentatively identified in trace amounts (3).

The peculiar distribution of 14-MHD acid in conifer seed lipids indicates that the presence of this constituent cannot be attributable to chance. This distribution precludes any possibility of contamination by microorganisms of some seed lots. However, to exclude this possibility definitively, we have purified the triacylglycerols from the crude seed oil of one species (*P. contorta*), and we have prepared FAME therefrom, because it is known that branched acids in microorganisms are esterified to polar lipids. We found that 14-MHD acid was present in triglyceride FAME at the same concentration as that in the original crude oil (result not shown).

Ginkgo biloba is considered to be the most ancient living Gymnosperm fossil on the earth. Based on fossil records, it has existed for *ca.* 200 million years. If one hypothesizes that 14-MHD acid might be an evolutionary marker, then Pinaceae would be phylogenetically closer to *G. biloba* than any other conifer family, which have apparently lost the ability to synthesize 14-MHD acid. However, we are not aware of other dating techniques that could confirm this hypothesis. According to Hierro *et al.* (1), 14-MHD acid accounts for 0.86% of total fatty acids in *G. biloba* seed lipids. Wolff (unpublished data) found independently an even higher value, 1.40%. Takagi and Itabashi (2) found that the acid tentatively identified as 16:2n-6 acid (most probably 14-MHD acid) comprised 0.68% of the neutral lipids, and 1.54% of the polar lipids. Some *Cedrus* and *Abies* species, and *P. menziesii*, have 14-MHD acid contents in this range (Table 1).

ABSTRACT: An unidentified bacterial strain, SCRC-21406, isolated from the intestine of a marine fish, *Glossanodon semifasciatus,* produced docosahexaenoic acid at 23% (mol/mol) [= 28% (w/w)] of total fatty acids in a medium containing 0.5% (wt/vol) peptone and 0.1% (wt/vol) yeast extract at 12°C under atmospheric pressure. The cell yield was 0.43 g/L. The major lipids of the strain were phosphatidylethanolamine and phophatidylglycerol. Docosahexaenoic acid was localized at the *sn*-2 positions of both phospholipids. The amounts of polyunsaturated fatty acids other than docosahexaenoic acid were extremely small [<3% (mol/mol)]. Monounsaturated fatty acids of the *cis*-7, *cis*-9 and *cis*-11 types were detected.
Lipids 32, 975–978 (1997).

Docosahexaenoic acid (22:6n-3; DHA) is an essential nutrient for human health judging from its characteristic localization in the body (1), clinical data (2,3), and its physiological role (4–6). Although DHA concentrates are presently produced from fish oil, DHA-producing algae and fungi have been examined as other sources of DHA for a stable and mass production (7–9). On the other hand, there have been few reports of DHA-producing bacteria isolated from deep-sea fishes (10,11). DHA-producing bacteria seem to be useful for not only DHA production but also gene recombination. However, there has been no report of progress regarding these DHA-producing bacteria. One of the reasons seems to be the need for high pressure and a low temperature during cultivation. Recently, we isolated DHA-producing bacteria, which produce a large amount of DHA under atmospheric pressure, from the intestine of *Glossanodon semifasciatus* caught in the Japan Sea near Toyama Bay. One strain of these DHA-producing bacteria, SCRC-21406, was examined with respect to its lipids and fatty acids, and these results are reported here.

EXPERIMENTAL PROCEDURES

Isolation and cultivation of DHA-producing bacteria. Bacterial strains were isolated from the intestines of many marine fishes caught in the Japan Sea near Toyama Bay. Colonies were purified by streaking onto K28 agar comprising 0.5% (wt/vol) peptone, 0.1% (wt/vol) yeast extract, 50% (vol/vol) artificial seawater, and 1.5% (wt/vol) agar in distilled water. SCRC-21406 was isolated from the intestines of *G. semifasciatus,* which lives at 200–500-m depth, in this manner. SCRC-21406 was cultivated in K28 broth with shaking on a rotary shaker at 12°C under atmospheric pressure. The cells were harvested by centrifugation at 1500 × *g* at 4°C for 15 min and then washed with 50% (vol/vol) artificial seawater.

Analysis of lipids and fatty acids. Lipids were extracted from wet cells according to our previous report (12), and identified by thin-layer chromatography and ^{1}H nuclear magnetic resonance (NMR). Fatty acid methyl esters were prepared from the lipids by heating with 7% methanolic HCl solution at 90°C for 1 h, separated on a reverse-phase thin-layer chromatography plate with acetonitrile/water (28:5, vol/vol), and visualized with iodine. They were then examined by gas–liquid chromatography and gas chromatography–mass spectrometry (12). A fatty acid that was identified as DHA was further analyzed by ^{1}H NMR of its methyl ester and by the infrared spectrum of its pyrrolidide derivative (12). ^{1}H NMR analysis was conducted using the same apparatus and the same method as used for the lipids. The infrared spectrum was recorded with a Jasco model FTIR-5300 (Japan Spectroscopic, Tokyo, Japan) using the thin-layer method.

Analysis of the positional distribution of fatty acids in the lipids was carried out using phospholipase A_2 (12).

RESULTS AND DISCUSSION

While the classification of SCRC-21406 remains to be determined, the strain can be excluded from genus *Vibrio* owing to its insensitivity to a vibriostatic compound (13). Therefore, SCRC-21406 seems to differ from other known DHA-producing bacteria (10,11).

The growth curve for SCRC-21406 in this study is shown in Figure 1. After 24 h, the cells had reached 7.3×10^8 c.f.u./mL. At 37 h, the amounts of dry cells, total lipids, and DHA were 0.43 g, 23.4 mg, and 4.2 mg per liter of culture, respectively.

The lipids of SCRC-21406 consisted of phosphatidyl-

*To whom correspondence should be addressed at Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229, Japan.

Abbreviations: DHA, docosahexaenoic acid; NMR, nuclear magnetic resonance; PE, phosphatidylethanolamine; PG, phosphatidylglycerol.

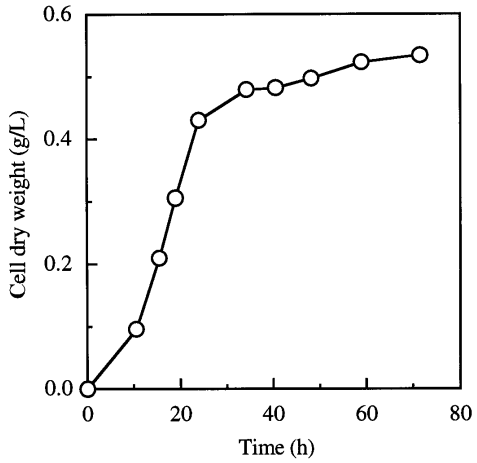

FIG. 1. Growth curve of SCRC-21406 with shaking at 12°C under atmospheric pressure.

ethanolamine (PE) and phosphatidylglycerol (PG) with a mole ratio of 4:1. In the ^{1}H NMR spectrum of the fatty acid methyl ester identified as DHA, the following protons were detected: C*H*$_3$CH$_2$ (0.97 ppm, *t*, 3H), CH$_3$C*H*$_2$ (2.1 ppm, *q*, 2H), C*H*$_2$COOCH$_3$ (2.38 ppm, *m*, 4H), CH=CHC*H*$_2$CH=CH (2.85 ppm, *m*, 10H), COOC*H*$_3$ (3.67 ppm, *s*, 3H), and C*H*=C*H* (5.38 ppm, *m*, 12H). In the mass spectrum of the methyl ester, ions were detected at *m/z* 342 and 311 (Fig. 2). A series of ions at *m/z* 113, 126, 138, 152, 166, 178, 192, 206, 218, 232, 246, 258, 272, 286, 298, 312, 326, 338, 352, 366, and 381 was detected in the mass spectrum of the pyrrolidide derivative (Fig. 3), and their intensities were consistent with those of an authentic sample (data not shown). In the infrared spectrum of the pyrrolidide derivative, since a broad band was detected at 720 cm^{-1} but not over 960–980 cm^{-1} (Fig. 4), the fatty acid has *cis* double bonds but not *trans* ones. These results showed that the fatty acid was *cis*-4, 7, 10, 13, 16, 19-DHA. Other polyunsaturated fatty acids, 18:4n-3, 20:4n-3 and 20:5n-3 (eicosapentaenoic acid), were also identified on the basis of the mass spectra of their pyrrolidide derivatives. Monounsaturated acids, 14:1(*cis*-7), 14:1(*cis*-9), 15:1(*cis*-7), 16:1(*cis*-7), 16:1(*cis*-9), 16:1(*cis*-11), 17:1(*cis*-9), 18:1(*cis*-9), and 18:1(*cis*-11), were identified on the basis of the mass spectra of their trimethylsililoxy derivatives (12). Although the double-bond positions of a 22:5 eluted in front of DHA on gas–liquid chromatography were not determined, it seemed to be of the n-6 type from the relative retention times. The fatty acid compositions of the total lipids, PE, and PG are shown in Table 1. The amounts of polyunsaturated fatty acids other than DHA were extremely small. While the major fatty acid of PE was 16:1(*cis*-9), that of PG was DHA. The positional distributions of the fatty acids in PE and PG are shown in Table 2. In PE and PG, DHA was located at the *sn*-2 position. While 16:1(*cis*-9) was located at the *sn*-2 position in PE, there was more at the *sn*-1 position than at the *sn*-2 position in PG. This indicated that localization at the *sn*-2 position of DHA is more preferential than that of 16:1(*cis*-9). Saturated acids and 16:1(*cis*-7) were localized at the *sn*-1 position in both PE and PG.

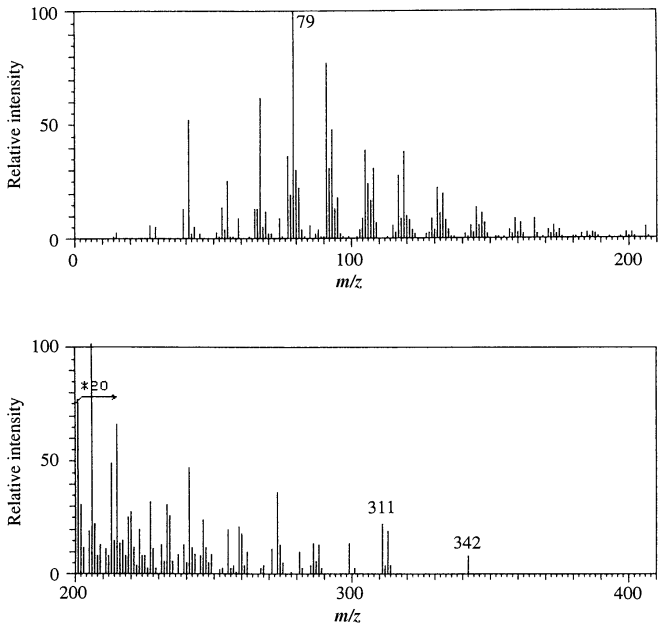

FIG. 2. Mass spectrum of the fatty acid methyl ester identified as docosahexaenoic acid (DHA). The mass spectral analysis was conducted using almost the same method as that described in our previous report (12) except for the column conditions. The column was a capillary one (0.25 m × 25 m) coated with CP-Wax 52 (Chromatopack, Middelburg, The Netherlands). The column temperature was kept at 160°C for the first 1 min, increased to 196°C at 4°C/min, kept for 1 min, increased to 200°C at 4°C/min, kept for 6 min, increased to 232°C at 8°C/min, kept for 3 min, increased to 242°C at 10°C/min, and then maintained for 3 min.

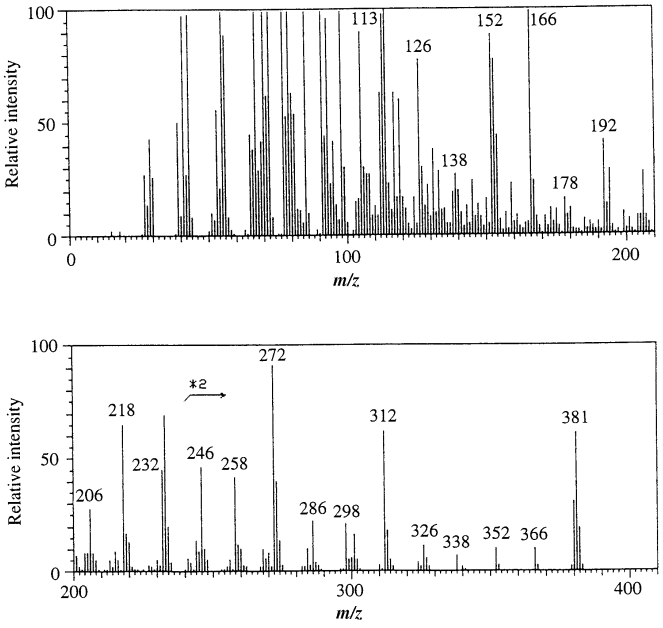

FIG. 3. Mass spectrum of the pyrrolidide derivative identified as DHA. The mass spectral analysis was conducted using the same apparatus and the same conditions as described in our previous report (12). See Figure 2 for abbreviation.

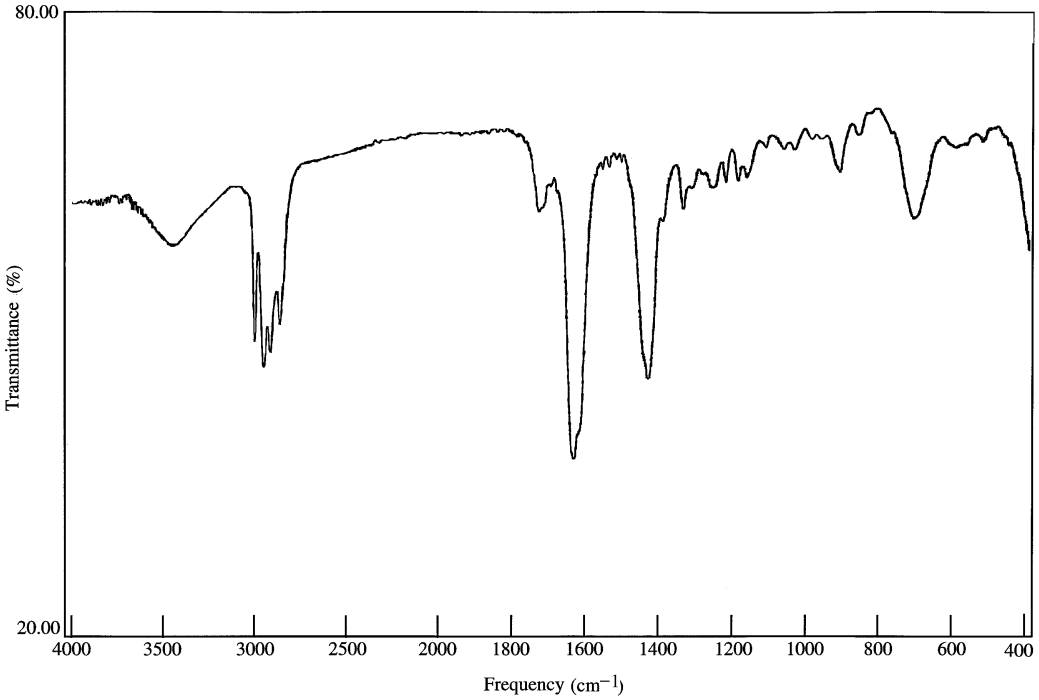

FIG. 4. Infrared spectrum of the pyrrolidide derivative identified as DHA. See Figure 2 for abbreviation.

[d]Branched form. See Table 1 for abbreviations.

It was proposed that DHA contributes the adaptation to a high hydrostatic pressure and a low temperature, in view of growth condition of DHA-producing bacteria isolated heretofore (10). On the other hand, the phase transition temperature of DHA-linked phosphatidylcholine is higher than that of 16:1(*cis*-9)-linked phosphatidylcholine (14,15). Furthermore, one type of deep-sea bacterium does not produce any polyunsaturated fatty acids and adapts to a high hydrostatic pressure with monounsaturated fatty acids (16). Since SCRC-21406 grows at 12°C under atmospheric pressure, DHA seems to be still more unnecessary for this strain with respect to the improvement of membrane fluidity. There is no information on a bacterial synthetic pathway for DHA. It is suggested that the DHA-synthetic pathway for SCRC-21406 is different from that for mammals which involves one turn of the β-oxidation cycle in the peroxisome (17,18). Since the amount of polyunsaturated fatty acids other than DHA is extremely small in SCRC-21406, the pathway also seems to be different from that hypothesized for fungi (19). The production of various monounsaturated fatty acids for double-bond position, such as 16:1(*cis*-7), 16:1(*cis*-9) and 16:1(*cis*-11), is necessary for three different anaerobic pathways with respect to substrate specificity, three different aerobic desaturases with respect to positional specificity, or a combination of them. Information on the synthetic pathway for monounsaturated fatty acid seems to be necessary for elucidation of the DHA synthetic pathway in SCRC-21406. The physiological role of and synthetic pathway for DHA in the strain are interesting subjects.

ABSTRACT: Controlled feeding of linoleic acid (LA) or arachidonic acid (AA) to essential fatty acid-deficient (EFAD) rats was used to define the relationship between dietary AA and the inflammatory response evoked during adjuvant-induced arthritis. Based on energy percentage, EFAD rats were fed AA at the human daily equivalent (1×; 5.5 mg/day) or 10 times that amount (10×; 55 mg/day) or, alternatively, 0.5× of LA (273 mg/day). Feeding of 0.5× LA restored the plasma level of AA to that in chow-fed controls. In contrast, feeding of 1× AA only partially restored the plasma level of AA; 10× AA was required to fully replete AA. In parallel to the degree of repletion of AA in plasma, there were accompanying decreases in the levels of palmitoleic acid, oleic acid, and Mead acid. Compared to rats fed the standard laboratory chow diet (Control), edema in the primary hind footpads was decreased by 87% in EFAD, 71% in EFAD + 1× AA, 45% in EFAD + 10× AA, and 30% in EFAD + 0.5× LA. The decrease in edema in the footpads of EFAD rats was nearly identical to the decrease in edema in the footpads of Control rats dosed with indomethacin. Hind footpad edema correlated with the final AA plasma level and eicosanoid levels extracted from hind footpad tissue, but not with neutrophil infiltration. The data showed that 0.5× LA and 10× AA, but not 1× AA, could quickly replete AA, accompanied by the synthesis of AA-derived eicosanoids and restoration of edema. These results suggest that in humans consumption of the average daily amount of AA without concurrent ingestion of LA would not alleviate an EFAD state.

Lipids 32, 979–988 (1997).

Modifications of dietary fatty acids have been shown to exert antiinflammatory effects in both acute and chronic models of inflammation (reviewed, 1–3). Such dietary modifications have included supplementation with fish oils that are enriched with n-3 polyunsaturated fatty acids (reviewed, 4,5) and induction of an essential fatty acid-deficient (EFAD) state by deprivation of n-6 polyunsaturated fatty acids (reviewed, 6–8). Effects have included the amelioration of glomerulonephritis in a murine model of the human disease, systemic lupus erythematosus (9,10), ulcerative colitis (11,12), nephrotoxic nephritis (13,14), myocardial infarction (15,16), psoriasis (17), microcirculatory manifestations of ischemia–reperfusion injury (18), diabetes (19–21), and rheumatoid arthritis (reviewed, 22). In rheumatoid arthritis and other chronic inflammatory diseases, evidence has been accumulating which indicates that the quantity and quality of fat in the diet can affect the etiological course of chronic inflammatory diseases (reviewed, 23). Populations in Western countries consume a relatively high amount of arachidonic acid (AA) (approx. 200 mg/day) and an even higher amount of its precursor, linoleic acid (LA) (approx. 20 g/day), both of which are essential, polyunsaturated fatty acids of the n-6 series (reviewed, 2). Eicosanoid production and ensuing inflammation have been correlated with the amount of AA consumed in the diet (24–26).

Essential fatty acid deficiency has been used as an extreme dietary means to deplete AA in key lipid pools, resulting in an antiinflammatory effect that, in part, is due to decreased synthesis of proinflammatory eicosanoids (reviewed, 7,8). Notable ramifications are decreased synthesis of prostaglandins and leukotrienes, a decreased number of resident macrophages in tissues, and a decreased influx of neutrophils and macrophages into sites of inflammation (27–29). The correlative factor associated with compromised macrophage or neutrophil function appears to be partial depletion and accompanying unavailability of AA in key lipid pools.

Adjuvant-induced arthritis (AIA) in the rat is a chronic inflammatory disease model that has many facets in common with human rheumatoid arthritis (reviewed, 30). As such, the model has been used for several decades as a predictor of clinical efficacy of antiinflammatory drugs. The disease is initiated by the injection of a mycobacterium/mineral oil suspension (complete Freund's adjuvant) into the hind footpad of Lewis rats. Progression of the disease proceeds quickly. Acute inflammation occurs in the primary footpad within 24 h. After a plateau period, severity increases dramatically between days 12–15, at which time symptoms occur in the noninjected, secondary hind footpad. Maximal severity is

Abbreviations: AA, arachidonic acid; AIA, adjuvant-induced arthritis; bid, twice a day dosing; COX, cyclooxygenase; EFAD, essential fatty acid-deficient; ig, intragastric; INDO, indomethacin; LA, linoleic acid; mpk, milligram per kilogram; MPO, myeloperoxidase; NSAIDs, nonsteroidal antiinflammatory drugs; qd, once a day dosing.

achieved by day 25, while joint deformity occurs by day 35. It is well established that inflammation in AIA is prostaglandin-mediated; nonsteroidal antiinflammatory drugs (NSAIDs) which inhibit cyclooxygenase (COX) activity, notably inducible COX-2 activity, mitigate the inflammatory response, principally owing to inhibition of synthesis of proinflammatory eicosanoids derived from AA (31). The literature is replete with reports on attempts to improve the arthritic index in humans by decreasing the level of AA by dietary means, mainly by fish oil supplementation (reviewed, 22). However, there is a paucity of reports describing the effect that dietary manipulations have on the severity of AIA, especially the effect of dietary AA. Lawrence (32) reported that diets enriched with n-6 polyunsaturated fatty acids exacerbated AIA. Denko (33) reported decreased hind footpad swelling in EFAD rats; edema was restored upon supplemental feeding of corn oil, suggesting a role of n-6 polyunsaturated fatty acids.

The purpose of this study was to examine whether correlations existed in AIA between the level of dietary AA, the ensuing level of plasma AA, and the levels of hind footpad inflammatory markers [i.e., edema, eicosanoids, and myeloperoxidase (MPO) activity]. EFAD rats were utilized because they are severely depleted of both LA and AA. Dietary LA was evaluated along with dietary AA because AA is synthesized from LA *in vivo* by sequential Δ6 desaturation, elongation, and Δ5 desaturation (reviewed, 34). The amount of LA or AA fed to rats was calculated by allometric scaling based on caloric intake from humans to rats, assuming the same intake of fatty acids per kcal per day. Daily feeding of LA (0.5× the human daily equivalent) or AA (1× or 10× the human daily equivalent) to EFAD rats was employed to control repletion of LA and/or AA and to define the relationship between dietary AA and the inflammatory response evoked during AIA. By assuming the validity of allometric scaling based on caloric intake between rodents and humans, the data suggest that, in humans, consumption of the average daily amount of AA would not exacerbate the severity of prostaglandin-mediated inflammation.

MATERIALS AND METHODS

Materials and reagents. Authentic fatty acids and fatty acid methyl esters were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). The vehicle used for oral dosing consisted of 0.5% methylcellulose + 0.025% Tween-20 (polyoxyethylene-sorbital monolaurate), both purchased from Sigma Chemical Co. (St. Louis, MO). The ethyl ester of LA or AA was emulsified in vehicle by sonication and administered orally (0.6 mL/dosing), qd (once a day dosing) (p.m.), starting on day 0 and ending on day 25. Control groups not receiving the fatty acid ethyl esters were gavaged with vehicle only. Indomethacin was purchased from Sigma Chemical Co. and was prepared as a suspension in vehicle by sonication. All solvents and reagents were of analytical grade.

Dietary paradigms and induction of arthritis. Male, Lewis rats were received at 3 wk of age (Harlan Sprague-Dawley, Indianapolis, IN) and were maintained on a a standard rodent diet (Certified Rodent Diet #5002; PMI Feeds Inc., St. Louis, MO), herein referred to as the Control diet, or an EFAD diet (#5803C, low essential fatty acid P.D., Purina Test Diets, Richmond, IN). Water was provided *ad libitum* throughout. The composition of the two diets was as follows:

(i) Control diet (w/w): 55.0% carbohydrates, 20.1% protein, and 4.5% fat (LA, 2.15%; AA, <0.01%). Specific ingredients are ground yellow corn, soybean meal, ground wheat, wheat middlings, fish meal, wheat germ meal, brewer's dried yeast, cane molasses, dried beet pulp, ground oats, alfalfa meal, dried whey, ground soybean hulls, soybean oil, casein, calcium carbonate, dicalcium phosphate, salt, DL-methionine, choline chloride, vitamin A acetate, cholecalciferol, cyanocobalamin, calcium pantothenate, folic acid, riboflavin, thiamine mononitrate, nicotinic acid, pyridoxine hydrochloride, di-alpha tocopheryl acetate, calcium iodate, cobalt carbonate, copper sulfate, manganous oxide, zinc oxide, ferrous carbonate, and zinc sulfate.

(ii) EFAD diet: 21% vitamin-free casein, 69% sucrose, 3% solka floc, 2% PMI vitamin mix, 5% PMI mineral mix #10, 0.15% DL-methionine, and 0.2% choline chloride. Fat, 0.1% (w/w), was composed principally of saturated and monounsaturated fatty acids.

The fatty acid composition of the Control and EFAD diets is shown in Table 1.

Allometric scaling based on caloric intake (percentage energy) was used to calculate the approximate human daily equivalent of LA (545 mg/day) or AA (5.5 mg/day) administered to the rat (Lab Diet™, The Richmond Standard™, *Animal Diet Reference Guide,* PMI Feeds, Inc.) (Table 2).

A state of essential fatty acid deficiency was confirmed by fatty acid composition analysis of plasma; the ratio of Mead acid (20:3n-9)/AA(20:4n-6) was approximately 6 at the end of the study, much higher than the defined minimal value of 0.4 for essential fatty acid deficiency (6). Refer to Scheme 1 for a summary of the testing scheme.

Arthritis was induced on day 0, at which time all of the rats were nearly 13 wk old, having been fed either the Control or EFAD diet for nearly 10 wk. To induce arthritis, the rats were injected with 1 mg of *Mycobacterium butyricum* (Difco Lab-

TABLE 1
Fatty Acid Composition of the Control and EFAD Diets[a]

Fatty acid	Control diet	EFAD diet
16:0	22.8 ± 0.1	40.6 ± 1.3
16:1n-7	4.0 ± 0.1	5.4 ± 0.3
18:0	6.5 ± 0.1	14.3 ± 0.1
18:1n-9	23.6 ± 0.2	36.3 ± 0.9
18:2n-6	35.6 ± 0.1	3.3 ± 0.8
18:3n-3	5.0 ± 0.1	n.d.
20:4n-6	0.2 ± 0.0	n.d.

SCHEME 1

oratories, Inc., Detroit, MI) in 25 μL of mineral oil (Mallinckrodt, Paris, KY) into the right-hind footpad (35). The rats were sacrificed on day 25, at which time the arthritic response was maximal. At the start of the experiment (day 0), the rats were divided into nine groups. Groups 1–7 were injected with mycogen (n = 10/group). The specific manipulations of each group were as follows: (i) Control: Rats were maintained on a control diet throughout. This "chow" diet has been used routinely to evaluate NSAIDs in this model and yields very reproducible results. The rats were gavaged with vehicle [intragastric (ig), bid (twice a day dosing)] from days 0–25. (ii) Acute EFAD: Rats were fed the control diet for 68 d, after which they were switched to an EFAD diet (day 0) until the end of the experiment (day 25). (iii) INDO: Rats were fed the control diet throughout and dosed orally with indomethacin [1 milligram per kilogram (mpk), ig, bid], starting on day 0. Dosing with indomethacin was maintained until the end of the experiment (day 25). (iv) CHRONIC EFAD (referred to as EFAD): Rats at 21 d of age were maintained on the EFAD diet for 68 d prior to the start of the experiment (day 0). Feeding of the EFAD diet was continued until the end of the experiment (day 25). (v) EFAD + 1× AA: Chronic EFAD rats were gavaged (ig, qd) with 1× AA (5.5 mg/day) from day 0 through day 25. (vi) EFAD + 10× AA: Chronic EFAD rats were gavaged (ig, qd) with 10× AA (55 mg/day) from day 0 through day 25. (vii) EFAD + 0.5× LA: Chronic EFAD rats were gavaged (ig, qd) with 0.5× LA (273 mg/day) from day 0 through day 25. This dosing of LA was chosen because in previous experiments it was found that bolus dosing with 1× LA (545 mg/day) led to a 20–30% mortality. The dosing of LA was therefore halved. Groups 8–9 served as control groups, not being injected with mycogen (n = 6/group). (viii) Control/(−) Mycogen. (ix) EFAD/(−)Mycogen. Results from these negative control groups are not reported because they were either baseline (e.g., edema and prostaglandin levels) or were no different than the mycogen-treated groups (e.g., fatty acid composition).

For all groups, the rats were weighed and both right- and left-hind paw volumes were measured twice weekly during the course of the experiment, starting just before injection on day 0. Footpad volume was determined using a model 7150 plethysmometer (Ugo Basile, Camerio-Varese, Italy). On day 25, blood was collected from unfasted rats by retro-orbital puncture for analysis of plasma fatty acids.

Eicosanoid extraction and quantification. On day 25, the rats were euthanized and five of the secondary (left) footpads from each group were injected with 400 μL of sterile saline containing 10 μM indomethacin (15 mM stock solution in ethanol; Sigma Chemical Co.). The footpads were amputated and subjected to centrifugation (5000 × g) to collect the footpad fluid. The fluid extracted was clear, indicating that it was devoid of blood. Furthermore, in order to prevent any possible clotting of the fluid, four drops of a solution of heparin (Na salt, 10,000 U/mL in saline; Sigma Chemical Co.) were placed at the bottom of each centrifuge tube, and the solution was allowed to dry before beginning centrifugation. Eicosanoid levels of prostaglandin E_2 (PGE_2), thromboxane B_2 (TxB_2), 6-keto-$PGF_{1\alpha}$ (6-keto), leukotriene C_4 (LTC_4), and LTB_4 were quantified directly in the hind-footpad fluid by standard ELISA (Caymen Chemical Co., Ann Arbor, MI). Eicosanoid content is expressed on a whole-footpad basis in order to correlate it to footpad edema.

MPO assay. Amputated hind footpads were frozen in liquid nitrogen, and the paws were then pulverized into small pieces. The pieces were homogenized in phosphate buffer and subjected to centrifugation at 35,000 × g for 20 min. The supernatant was discarded, and the homogenization was repeated in the presence of 0.5% hexadecyltrimethylammonium bromide (Sigma Chemical Co.), followed by sonication using

TABLE 2
Allometric Scaling Based on Caloric Intake (energy percentage) Used to Calculate Human Daily Equivalent of Linoleic Acid (LA) or Arachidonic Acid (AA) Given to the Rat

	Actual intake		Extrapolated intake (energy percentage)
	Human[a]	Rat[b]	Rat[c]
LA	20 g/day = 10 mg/kcal/day	290 mg/day = 5.3 mg/kcal/day	545 mg/day
AA	200 mg/day = 0.1 mg/kcal/day	<1.0 mg/day = <0.018 mg/kcal/day	5.5 mg/day

[a]Based on estimated amounts from the literature. Approximations: rat: average body weight: 0.25 kg; Consumption of Control diet—by weight: 13.5 g/day (12–15 g/day); by energy: 54.5 kcal/day (based on 55.0% CHO, 20.1% PRO, 4.5% fat (wt%); gross energy = 4.04 kcal/g). Human: average body weight: 70 kg; caloric consumption: 2000 kcal/day.
[b]Based on amount of LA or AA as stated by the manufacturer, assuming an average of 13.5 g diet consumed per day.
[c]Daily consumption of AA equivalent to that of humans (energy percentage). LA: 10 mg/kcal/day × 54.5 kcal/day = 545 mg/day. AA: 0.1 mg/kcal/day × 54.5 kcal/day = 5.5 mg/day.

a W385 ultrasonic processor (Heat Systems-Ultrasonics, Inc., Farmingdale, NY). The samples were subjected to freeze–thaw three times, followed by sonication and centrifugation. The final assay buffer was a mixture of 16.7 mg *o*-dianisidine HCl (Sigma Chemical Co.) per 10 mL distilled water, 1.6 µL of 30% hydrogen peroxide (Sigma Chemical Co.), and 90 mL of 50 mM phosphate buffer (pH 6.0). Seven µL of sample was added to 200 µL of buffer and then analyzed using an EL 340 Biokinetics Reader (Bio-TEK Instruments, Winooski, VT) (450 nM wavelength). Standard curves were made using MPO purified from human neutrophils (Calbiochem, La Jolla, CA).

Fatty acid composition analysis. Plasma fatty acid composition was determined by gas chromatography using electron capture detection. Twenty µL plasma was spiked with 5 µg heneicosanoic acid (21:0; 0.1 mg/mL stock in hexane) and evaporated to dryness under N_2 gas. Lipids were saponified directly by the addition of 1 mL of 2 N KOH/MeOH (4:1) and incubation of the samples in a 60°C water bath for 1 h. Fatty acids were protonated by the addition of 1 mL 88% formic acid and then extracted into hexane by the addition of 1 mL water + 3 mL hexane followed by thorough mixing. The hexane layer was removed and transferred to a new tube containing a small amount of anhydrous Na_2SO_4 to remove any residual water. The hexane layer was transferred to another new tube and evaported to dryness under N_2 gas. For electron capture detection, the fatty acids were derivatized to pentafluorobenzyl esters by the addition of 10 µL diisopropyl ethylamine (Sigma Chemical Co.) + 20 µL 35% pentafluorobenzylbromide in acetonitrile (Pierce Chemical Co., Rockford, IL) in tightly sealed tubes. The samples were incubated for 15 min in a 50°C water bath, after which the contents were evaporated under N_2 gas. One mL hexane was added, and the samples were washed twice with 1 mL water. The hexane layer was removed and evaporated under N_2 gas. The sample residue was resolubilized in 1 mL hexane and then transferred to a gas chromatographic autosampler vial. Derivatized fatty acids were separated and identified using a Hewlett-Packard model 5880 gas chromatograph (Palo Alto, CA) equipped with a fused-silica capillary column (30 m, 0.32 mm i.d., 0.20 µm film thickness; Supelco, Bellefonte, PA), electron capture detector, and an HP-5880A terminal integrator. Fatty acid pentafluorobenzyl esters were identified by comigration with authentic pentafluorobenzyl ester standards. Results are expressed as relative percentage ± SEM.

Statistical analysis. Primary analysis: The F-test with one-way analysis of variance model was first conducted to test whether the mean endpoint values were identical in the nine groups. If significant ($P = 0.05$), the Dunnett's multiple comparison test was then conducted to compare each group with the Control group ($P = 0.05$). Significant differences are indicated by a "*" (Figs. 1–5). Secondary analysis: If there were significant differences in the means between the EFAD and Control groups in the primary analysis, a secondary analysis was conducted to evaluate the effects of LA or AA fed to EFAD rats. The same methods were used as described for the primary analysis, only EFAD served as the control group. Significant differences are indicated by a "†" (Figs. 2–4).

RESULTS

Effect of diet on weight. The initial weights of the rats in the Chow groups (Fig. 1A) were higher than in the EFAD groups (Fig. 1B). Rats in the Control/(–)Mycogen control group gained weight throughout the experiment. Rats in the Control and Acute EFAD groups lost weight during the course of the experiment, owing to the increasing severity of the arthritis. Rats in the INDO group maintained a relatively constant body weight, owing to mitigation of the arthritis by indomethacin. The weights of the rats fed an EFAD diet remained relatively constant during the experimental period.

Effect of diet on plasma fatty acid content. The fatty acid composition of plasma obtained at day 25, the experimental endpoint, is shown for all the groups in Figure 2 (A–E). Mead acid (20:3n-9), the hallmark fatty acid of essential fatty acid deficiency, is synthesized from oleic acid (18:1n-9) as a compensatory fatty acid for AA when mammals are deprived of

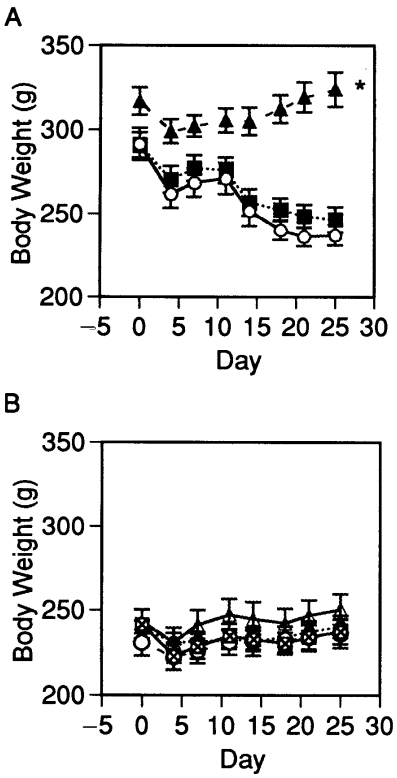

FIG. 1. Body weights of Control (chow groups) (A) or essential fatty acid-deficient (EFAD) (B) groups during the course of adjuvant-induced arthritis. All groups were injected with mycogen on day 0. Body weights (mean ± SEM) were recorded twice weekly for the duration of the experiment. For all groups, $n = 10$, except EFAD + 0.5× LA ($n = 7$). Symbols next to the last data point (day 25) indicate significant differences between the Control (*) or EFAD (†) group ($P < 0.05$). (A) ···■···, Control; —○—, Acute EFAD; -▲--, INDO. (B) ···●···, EFAD; -○--, EFAD + 1× AA; —△—, EFAD + 10× AA; —⊠—, EFAD + 0.5× LA. Abbreviations: INDO, indomethacin; AA, arachidonic acid; LA, linoleic acid.

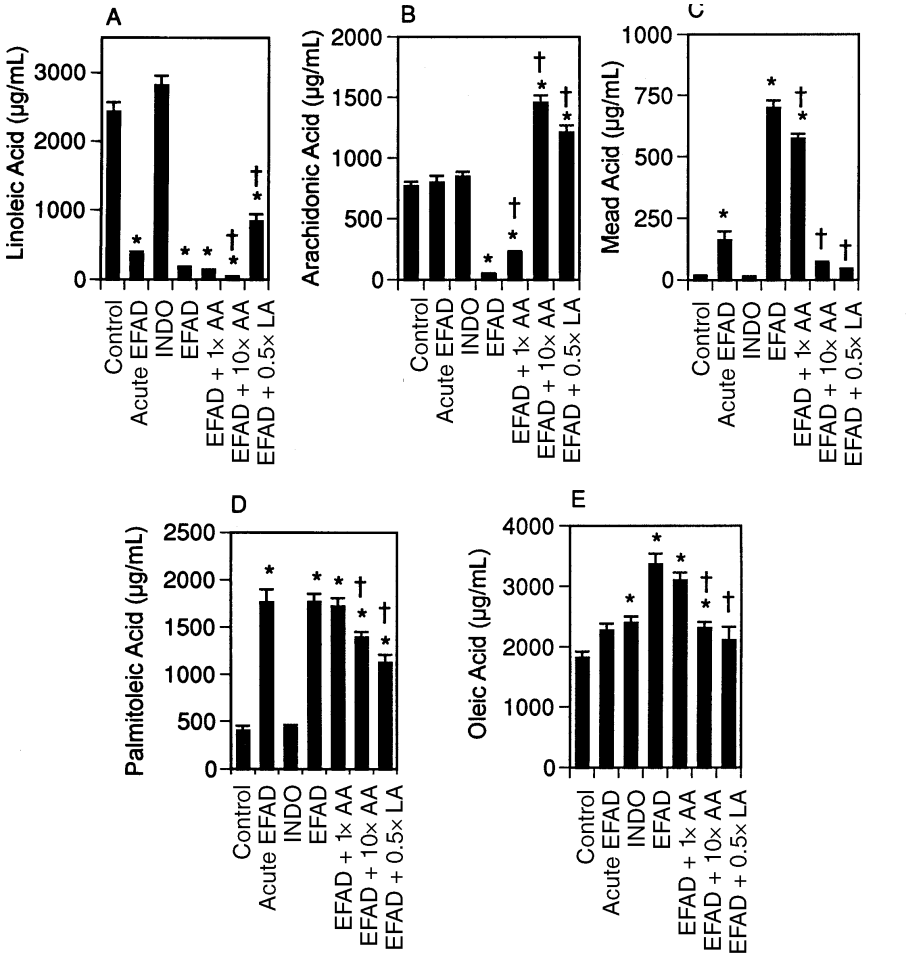

FIG. 2. Plasma fatty acid composition. (A) Linoleic acid (LA) (18:2n-6). (B) Arachidonic acid (AA) (20:4n-6). (C) Mead acid (20:3n-9). (D) Palmitoleic acid (16:1n-7). (E) Oleic acid (18:1n-9). The fatty acid content of plasma was analyzed for each group on day 25, the experimental endpoint. For all groups, $n = 10$, except EFAD + 0.5× LA ($n = 7$). Results are expressed as relative % of total fatty acids (mean ± SEM). Symbols above each bar indicate significant differences between the Control (*) or EFAD (†) group ($P < 0.05$).

n-6 essential fatty acids (reviewed, 6). Palmitoleic (16:1n-7) and oleic acids also accumulate to higher levels in EFAD animals due to induction of the Δ9 desaturase (36).

In the chow-fed groups, the development of arthritis or its mitigation by indomethacin did not cause any alteration in the fatty acid composition; the fatty acid composition remained the same in the Control and INDO groups.

Short-term feeding of the EFAD diet (Acute EFAD) caused changes to occur in some of the fatty acids. LA decreased dramatically (Fig. 2A), whereas AA, the major endproduct of LA metabolism, remained unchanged (Fig. 2B). Mead acid increased (Fig. 2C), as did palmitoleic acid (Fig. 2D) and oleic acid (Fig. 2E).

Chronic feeding of the EFAD diet caused similar changes in fatty acid composition to occur as in Acute EFAD, except that the differences compared to Chow were more extreme; decreases in the n-6 polyunsaturated fatty acids, LA and AA, were compensated for by increases in palmitoleic acid, oleic acid, and Mead acid. The single exception was AA, which was severely depleted in EFAD, but not in Acute EFAD (Fig. 2B). In EFAD rats, the level of AA was only partially restored upon feeding the 1× human daily equivalent of AA (EFAD + 1× AA; Fig. 2B); palmitoleic, oleic, and Mead acids remained relatively high to compensate for the partial depletion of AA. Full repletion of AA occurred only upon feeding the 10× human daily equivalent of AA (EFAD + 10× AA; Fig. 2B); substantive decreases occurred in palmitoleic, oleic, and Mead acids to compensate for the repletion of AA. Feeding the 0.5× human daily equivalent of LA (EFAD + 0.5× LA) gave similar results as did EFAD + 10× AA; there was full repletion of AA and corresponding decreases in the levels of palmitoleic, oleic, and Mead acids. Even though 0.5× LA caused full repletion of AA (Fig. 2B), it caused only partial repletion of LA (Fig. 2A), indicating that LA was quickly metabolized to AA *in vivo*. The saturated fatty acids, stearic (18:0) and palmitic (16:0) acids were unaltered by diet (data not shown).

Effect of diet on hind-footpad edema. The time course of

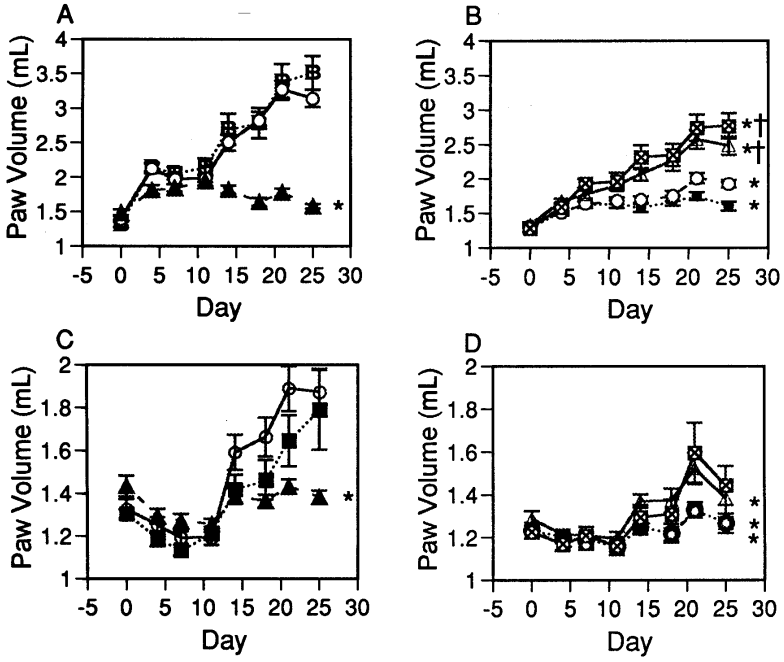

FIG. 3. Time course of mycogen-induced edema in primary and secondary footpads. Mycogen was injected into the right-hind footpads on day 0. Swelling was most apparent in mycogen-injected (primary) footpads, but was also evident in the contralateral, uninjected (secondary) footpads after the second week. For all groups $n = 10$, except EFAD + 0.5× LA ($n = 7$). Results are expressed as paw volume (mL) ± SEM. Symbols next to the last data point (day 25) indicate significant differences between the Control (*) or EFAD (†) group ($P < 0.05$). (A) Control, primary; (B) EFAD, primary; (C) Control, secondary; (D) EFAD, secondary. See Figure 1 for abbreviations. (A) ···■···, Control; —○—, Acute EFAD; -▲-, INDO. (B) ···●···, EFAD; -○-, EFAD + 1× AA; —△—, EFAD + 10× AA; —⊠—, EFAD + 0.5× LA.

mycogen-induced edema is shown for the primary footpads in Figure 3A (Control) and Figure 3B (EFAD) and for the secondary footpads in Figure 3C (Control) and Figure 3D (EFAD). The results were qualitatively the same for the primary and secondary footpads from a given group. The only difference was that the severity of edema was greater in the primary footpads compared to the corresponding secondary footpads. Increases in edema in the primary and secondary footpads in the Control group and mitigation of edema in the INDO group followed the expected progression. Nearly identical increases in edema in the primary and secondary footpads occurred in the Acute EFAD group as in the Control group (Fig. 3A and C), demonstrating that short-term intervention with an EFAD diet was not efficacious. In contrast, edema was mitigated markedly in the chronic EFAD group throughout the time course of the experiment; some initial swelling occurred between days 0–4, after which it plateaued (Fig. 3B and D). On day 25, edema in the EFAD group (Fig. 3B and D) was very similar to that in the INDO group (Fig. 3A and C), demonstrating that EFAD had comparable efficacy as indomethacin. These results are in contrast to the lack of an antiinflammatory response in the Acute EFAD group (Fig. 3A and C). Hence, long-term intervention with an EFAD diet was necessary to evoke an antiinflammatory response.

In the chronic EFAD group, the beneficial effect of EFAD was maintained, even when the rats were dosed with the 1× human daily equivalent of AA (EFAD + 1× AA) (Fig. 3A and B). Compared to the EFAD group, there was perhaps a marginal increase in edema in the EFAD + 1× AA group, but only at the latter time points. In order for dietary AA to evoke a substantial increase in edema, a dosing of the 10× human daily equivalent of AA (EFAD + 10× AA) was necessary (Fig. 3B and D). Significantly, feeding of the 0.5× human daily equivalent of LA was sufficient to increase edema to the same extent as with the 10× human daily equivalent of AA (Fig. 3B and D). It must be kept in mind, however, that the absolute mass of LA at the 0.5× human equivalent (233 mg/day) was still fourfold more than the absolute mass of AA at the 10× human equivalent of AA (57 mg/day). The degree of edema was elevated in animal groups where plasma AA was substantially higher than the EFAD level (i.e., EFAD + 10× AA and EFAD + 0.5× LA).

Effect of diet on hind-footpad eicosanoid levels. The levels of PGE_2, TxB_2, 6-keto-$PGF_{1\alpha}$, and LTC_4 extracted from secondary hind-footpad tissue (Fig. 4A–D) paralleled the level of plasma AA (c.f. Fig. 2B) and the degree of edema (c.f. Fig. 3A–B) in the corresponding Control or EFAD group. LTB_4 was undetectable in any of the control or treatment groups (<20 pg/mL or <2–3 pg/footpad). As predicted from the edema results, eicosanoid levels from the Control and Acute EFAD groups were relatively high. In contrast, the lowest eicosanoid levels were from the INDO and EFAD

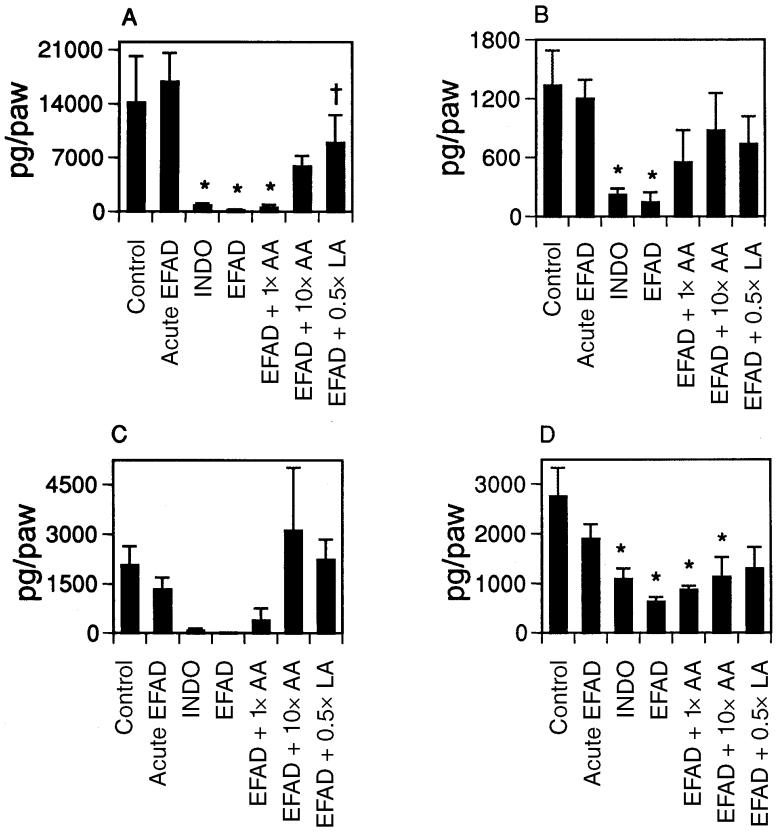

FIG. 4. Eicosanoid levels in hind-footpad extracts. Eicosanoids were quantified by standard ELISA in extracts from secondary hind footpads at day 25, the experimental endpoint. For all groups, $n = 5$, except EFAD + 0.5× LA ($n = 4$). Symbols above each bar indicate significant differences between the Control (*) or EFAD (†) group ($P < 0.05$). (A) PGE_2, (B) TxB_2, (C) 6-keto $PGF_{1\alpha}$, (D) LTC_4. See Figure 1 for abbreviations.

groups. EFAD was just as efficacious in decreasing PGE_2 and 6-keto-$PGF_{1\alpha}$ synthesis as in decreasing edema and was comparable to indomethacin. The antiinflammatory properties of EFAD were also observed in unchallenged rats; there were lower basal levels of PGE_2, TxB_2, and 6-keto-$PGF_{1\alpha}$ in the EFAD/(−)Mycogen group compared to the Control/(−)Mycogen group (data not shown). Dietary supplementation with 1× the human daily equivalent of AA (EFAD + 1× AA) only partially restored eicosanoid levels compared to Control. In order to more fully restore eicosanoid levels, but not to completion, the 10× human daily equivalent of AA (EFAD + 10× AA) or the 0.5× human daily equivalent of LA (EFAD + 0.5× LA) had to be administered.

Effect of diet on neutrophil infiltration. MPO activity, an enzyme marker of neutrophils (37), was quantified in secondary hind-footpad extracts as a measurement of neutrophil infiltration. MPO activity was readily detected and was not greatly affected by diet, even when comparing Control vs. EFAD groups (Fig. 5).

DISCUSSION

AA appears to have a unique preference in mammals compared to other polyunsaturated fatty acids; high-level feeding of AA, but not LA, augmented tissue levels of AA and ensuing eicosanoid production beyond control levels obtained in animals fed a normal chow diet (24,25). The relatively high

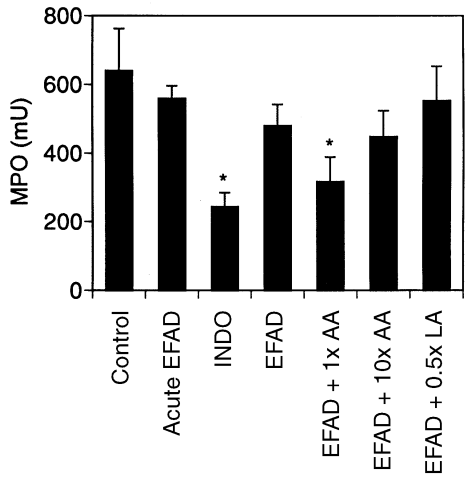

FIG. 5. Myeloperoxidase (MPO) activity in secondary hind-footpad extracts. MPO activity (mU ± SEM) was used as an indicator of neutrophil infiltration at day 25, the experimental endpoint. For all groups, $n = 5$, except EFAD + 0.5× LA ($n = 3$). Symbols above each bar indicate significant differences between the Control (*) or EFAD (†) group ($P < 0.05$).

consumption of n-6 polyunsaturated fatty acids in the Western diet (reviewed, 2), namely, LA (approx. 20 g/day), and, to a much lesser extent, AA (approx. 200 mg/day), raises the possibility that arthritis or other chronic inflammatory diseases could be exacerbated by AA obtained directly in the diet or metabolized *in vivo* from LA. A relatively large clinical effort has attempted to evaluate the role of AA in rheumatoid arthritis, mainly by dietary supplementation with n-3 polyunsaturated fatty acids (20:5n-3 and 22:6n-3) as a means of supplanting existing AA (reviewed, 22). Yet, equivocal results have been obtained in all of these studies, mainly because AA cannot be easily supplanted by 20:5n-3 or 22:6n-3, especially if AA is present in any fish oil-supplemented diet (38,39).

The role of dietary AA in AIA is relevant because proinflammatory eicosanoids derived from AA have been shown to be major contributors of disease severity (31). Essential fatty acid deficiency provides a testable way to evaluate the role of dietary AA in AIA, a rat model of arthritis that mimics many facets of rheumatoid arthritis in humans. Denko (33) showed that EFAD mitigated the severity of arthritis in AIA and that the mitigation was reversed by feeding the animals a corn oil diet. Corn oil is enriched in LA but is totally lacking in AA. Without providing direct evidence, Denko theorized that the LA was metabolized to AA *in vivo* and that proinflammatory eicosanoids derived from AA contributed, in large part, to the inflammatory process. Since EFAD animals are severely depleted of AA, repletion of AA could be titrated precisely by daily feeding of AA. The distribution and metabolism of orally administered AA are similar between EFAD and chow-fed rats (40), lending further validity to the use of the EFAD model as a means to evaluate the effects of dietary AA in AIA. The relevance to the human situation was addressed by feeding rats the daily human equivalent of AA, based on allometric scaling of caloric intake (24). In chronic EFAD rats which were fed either the 1× or 10× human daily equivalent of AA or the 0.5× human daily equivalent of LA, clear correlations were established between the levels of plasma AA (Fig. 2B), hind-footpad edema (Fig. 3B and D), and eicosanoids extracted from edematous hind-footpad tissue (Fig. 4). In contrast, there was no correlation between neutrophil infiltration, as determined by MPO activity, into edematous hind-footpad tissue and the level of plasma AA (Fig. 5). Even though edema and eicosanoid synthesis were markedly decreased in EFAD rats, neutrophil infiltration into secondary hind-footpads occurred unimpeded. This is consistent with data showing that EFAD had no effect on neutrophil infiltration in immune-mediated glomerulonephritis in rats (41).

It was anticipated that acute EFAD would mitigate the severity of arthritis by eliminating AA and its precursor, LA, in the diet. However, acute EFAD did not mitigate edema whatsoever (Fig. 3A and C). Despite the acute EFAD condition, the level of AA remained high in plasma (Fig. 2B) and most likely provided sufficient pools of AA for the synthesis of proinflammatory eicosanoids in hind-footpad tissue (Fig. 4). In contrast to the recalcitrance of AA, rather pronounced changes occurred in other fatty acids during acute EFAD: palmitoleic, oleic, and Mead acids increased, whereas LA decreased. The decrease in LA was striking (Fig. 2A), suggesting that a portion of it was utilized to maintain the level of AA. During the EFAD state, the Δ9 desaturase is induced (36), which would account for the higher levels of palmitoleic, oleic, and Mead acids. These results demonstrated the tenacity with which AA was retained in lipid pools and suggested that long-term curtailment of ingestion of LA or AA might be required to deplete AA sufficiently to manifest an antiinflammatory response. While dietary intervention is probably not feasible, a more acceptable way to decrease AA, besides fish oil supplementation, might be to inhibit Δ6- or Δ5-desaturase activity chronically. Such intervention might result in the antiinflammatory effects associated with EFAD without the accompanying untoward side effects of EFAD (e.g., hair loss, impaired fertility, and psoriatic-type skin) because LA would be present in the diet. Pharmacologic inhibition of the synthesis of AA would allow for LA to be consumed in the diet and, if inhibited at the level of the Δ5-desaturase, for dihomo-γ-linolenic acid (20:3n-6) to serve as the source for PGE_1, thus maintaining gastric and renal function. Also, leukotrienes would not be synthesized from dihomo-γ-linolenic acid because the Δ5 double bond is absent, eliminating another source of proinflammatory mediators. In contrast, no prostaglandins or leukotrienes are synthesized from LA.

The role of dietary AA in modulating the arthritic response in AIA was evaluated by feeding 1× or 10× the human daily equivalent of AA or 0.5× the human daily equivalent of LA to EFAD rats. Since arthritis starts to escalate near day 14, it was reasoned that 2 wk of feeding prior to the arthritic escalation would be sufficient to reach a steady-state level of AA in plasma and inflammatory cells. During the period of maximal arthritic escalation (days 14–25), the AA would then be used as a substrate for the synthesis of proinflammatory eicosanoids. The 1× human daily equivalent of AA was insufficient to restore the plasma level of AA to that of the chow control group (Fig. 2B). In parallel, Mead acid (Fig. 2C), as well as palmitoleic (Fig. 2D) and oleic (Fig. 2E) acids, all products of the Δ9-desaturase, did not decrease in plasma. Based on these results, it was clear why 1× AA was unable to elicit a rebound in edema (Fig. 3) or an increase in eicosanoid production (Fig. 4) in hind footpads. Rather, the 10× human daily equivalent of AA was required to supplant palmitoleic acid (Fig. 2D), oleic acid (Fig. 2E), and, particularly, Mead acid (Fig. 2C) in plasma. Even with full repletion of AA in plasma, there was only a partial rebound in both edema (Fig. 3) and eicosanoid levels in hind footpads (Fig. 4). LA dosed at the 0.5× human daily equivalent was equipotent to 10× AA; AA, synthesized from LA *in vivo* (reviewed, 34), increased to the same level in plasma as in the Control group (Fig. 2B), while palmitoleic (Fig. 2D), oleic (Fig. 2E), and Mead (Fig. 2C) acids decreased. Both edema (Fig. 3) and eicosanoid levels (Fig. 4) rebounded partially in the hind footpads. Even though 0.5× LA resulted in the full repletion of AA in plasma (Fig. 2B), there was only partial repletion of LA in plasma (Fig. 2A). This result, com-

bined with the observation that AA was not depleted during acute EFAD, adds credence to the claim that AA is the most important polyunsaturated fatty acid associated with membrane phospholipids (38).

The combined data suggest strongly that AA obtained directly in the diet or converted from dietary LA by *in vivo* metabolism is an important component of inflammation in AIA; the plasma level of AA (Fig. 2B) correlated with the degree of edema (Fig. 3) and eicosanoid levels extracted from hind footpads (Fig. 4). This would be expected if the progression of AIA depended upon the availability of AA for eicosanoid synthesis. Indeed, prostaglandins derived from AA play a primary role in disease manifestation in AIA (31). Edema and eicosanoid levels were generally highest in the Control and Acute EFAD groups (Figs. 3 and 4). However, the level of plasma AA in those groups was not as high as in the EFAD + 10× AA or EFAD + 0.5× LA groups (Fig. 2B). Thus, while the data indicated that the ready availability of eicosanoid precursor molecules was necessary for disease progression, other factors besides AA, LA, or intermediates between them (i.e., γ-linolenic acid, 18:3n-6, and dihomo-γ-linolenic acid, 20:3n-6) must be involved.

Assuming the validity of allometric scaling based on caloric intake between rodents and humans, the data suggested that in humans the average daily consumption of AA would not exacerbate the severity of prostaglandin-mediated inflammatory diseases. Furthermore, the results suggested that in humans with chronic inflammatory diseases the benefits gained by a low-fat diet would not be compromised by the addition of the average daily amount of AA.

ABSTRACT: We have prepared Schiff base adducts of the core aldehydes of phosphatidylcholine and aminophospholipids, free amino acids, and myoglobin. The Schiff bases of the ethanolamine and serine glycerophospholipids were obtained by reacting *sn*-1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl-glycerophosphocholine (PC-Ald) with a twofold excess of the aminophospholipid in chloroform/methanol 2:1 (vol/vol) for 18 h at room temperature. The Schiff bases of the amino acids and myoglobin were obtained by reacting the aldehyde with an excess of isoleucine, valine, lysine, methyl ester lysine and myoglobin in aqueous methanol for 18 h at room temperature. Prior to isolation, the Schiff bases were reduced with sodium cyanoborohydride in methanol for 30 min at 4°C. The reaction products were characterized by normal-phase high-performance liquid chromatography and on-line mass spectrometry with electrospray ionization. The amino acids and aminophospholipids yielded single adducts. A double adduct was obtained for myoglobin, which theoretically could have accepted up to 23 PC-Ald groups. The yields of the products ranged from 12 to 44% for the aminophospholipids and from 15–57% for the amino acids, while the Schiff base of the myoglobin was estimated at 5% level. The new compounds are used as reference standards for the detection of high molecular weight Schiff bases in lipid extracts of natural products.

Lipids 32, 989–1001 (1997).

The primary products of lipid peroxidation (e.g., hydroperoxides) decompose to form secondary products, which include low and high molecular weight aldehydes (1). The aldehydes may react with cellular components or may be metabolized to inactive tertiary products (alcohols and acids). The low molecular weight bifunctional aldehydes, malonaldehyde and 4-hydroxynonenal, have been extensively investigated for their reactivity with various amines, amino acids and proteins, with which they yield relatively stable covalently bound products. Specifically, malonaldehyde has been shown to undergo 1,4-addition with amino acids to form the eneamines (2), *N*-substituted 3-iminopropenals (3) and *N*,*N*′-disubstituted 1-amino-3-iminopropenes (4). Malonaldehyde also reacts with the amino groups in proteins (4,5) as well as with deoxynucleosides *in vitro* to produce a variety of adducts (6). The early lysine and histidine adduction chemistry of 4-hydroxynonenal has now been elucidated (7,8). It has been shown (7) that a 1:1 Michael adduct predominates in homogeneous aqueous solution and a 1:2 Michael–Schiff base adduct predominates under two-phase aqueous-organic conditions. These findings are in general agreement with recent conclusions regarding the interaction of 4-hydroxynonenal with proteins (9–11). The latter products differ from the amino acid and protein adducts formed with saturated monofunctional lipid ester core aldehydes about to be described. These adducts are more easily reversed than those resulting from the bifunctional aldehydes. Nevertheless, the formation of a Schiff base has been reported between *sn*-1-[9-oxo]nonanyl-2-acetylglycerophosphocholine and bovine thyroglobulin (12), which, following reduction with sodium cyanoborohydride, was suitable for the generation of antibodies that bound specifically to tritiated platelet-activating factor (PAF) and cross-reacted minimally with lyso-PAF, plasmalogens, and other phospholipids. The nature of the amino groups involved in the adduct formation was not established. We have previously identified the lipid ester core aldehydes among the secondary peroxidation products of glycerophospholipids and cholesteryl esters of low density lipoprotein and have noted their partial retention by the apoprotein (13,14). In the following study we have used liquid chromatography/mass spectrometry (LC/MS) with electrospray ionization (ESI) to demonstrate that lipid ester core aldehydes readily form Schiff bases with aminophospholipids, amino acids, and myoglobin, which can be stabilized by reduction with sodium cyanoborohydride before isolation and characterization.

Abbreviations: GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; GPS, glycerophosphoserine; HPLC, high-performance liquid chromatography; LC/ESI/MS, liquid chromatography/electrospray ionization/mass spectrometry; PAF, platelet-activating factor; PC, phosphatidylcholine; PC-ALD, 1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl GPC; PE, phosphatidylethanolamine; PS, phosphatidylserine; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. Egg yolk phosphatidylcholine (PC), phosphatidylethanolamine (PE), sodium cyanoborohydride, horse skeletal muscle apomyoglobin, MW 16,950 (15), and the amino acids (valine, isoleucine, lysine, and lysine methyl ester) were obtained from Sigma Chemical Co. (St. Louis, MO). Since cyanoborohydride is a potential source of HCN, it should be used in a fume hood and acidification avoided. All solvents were of chromatographic purity, while all chemicals were of reagent grade or better quality and were obtained from local suppliers (Caledon Chemicals, Toronto, Canada).

Preparation of aldehydes. The core aldehydes were prepared from egg yolk PC by ozonolysis and triphenylphosphine reduction as previously described (16). The aldehydes were recovered from the reaction mixture with chloroform and were purified by preparative thin-layer chromatography (TLC) on Silica gel H (250 μm thick layer, 20 × 20-cm glass plate) using a phospholipid solvent system made up of chloroform/ethanol/acetic acid/water 75:45:12:6 (by vol) (16). The aldehyde-containing bands were located by spraying the plate with a Schiff base reagent, which gave a purple color (17). The product (5–10 mg from 10–20 mg egg yolk PC) was made up of 70% 1-palmitoyl-2-[9-oxo]nonanoyl and 30% 1-stearoyl-2-[9-oxo]nonanoyl glycerophosphocholine (GPC).

Preparation of reduced Schiff bases of aminophospholipids. Dioleoyl glycerophosphoethanolamine (GPE) (2 mg) and the 1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl GPC (PC-Ald) (1 mg) were dissolved in chloroform/methanol 2:1 and the mixture was kept at room temperature for 1 h. After this time freshly prepared $NaCNBH_3$ in methanol solution was added to a final concentration of 70 mM and the reaction mixture was kept at 4°C for 30 min. At end of reaction, the excess reagent was removed by washing with water. The reduced Schiff base of PE (**I**) was identified by normal-phase LC/ESI/MS as shown below. An identical procedure was used for the preparation and identification of the reduced Schiff base of phosphatidylserine (PS) (**II**). The yields of the Schiff bases were estimated by LC/ESI/MS to range from 30% for the PS adduct to 60% for the PE adduct.

Preparation of reduced Schiff bases of amino acids. The PC-Ald (1 mg) was dissolved in methanol (2 mL), and a twofold molar excess of the amino acid was added as saturated solution in water (2 mL). The reaction mixture was shaken at room temperature for 1 h, and then reduced with $NaCNBH_3$ as described above. The Schiff bases and the residual PC core aldehydes were recovered by extraction with chloroform/methanol 2:1 and were isolated by normal-phase high-performance liquid chromatography (HPLC) and identified by LC/ESI/MS as described below. The yields of the Schiff bases were 15% for lysine (**III**), 30% for isoleucine, 47% for valine (**IV**), and 57% for lysine methyl ester (**V**). Structures **I** to **V** are shown in Scheme 1.

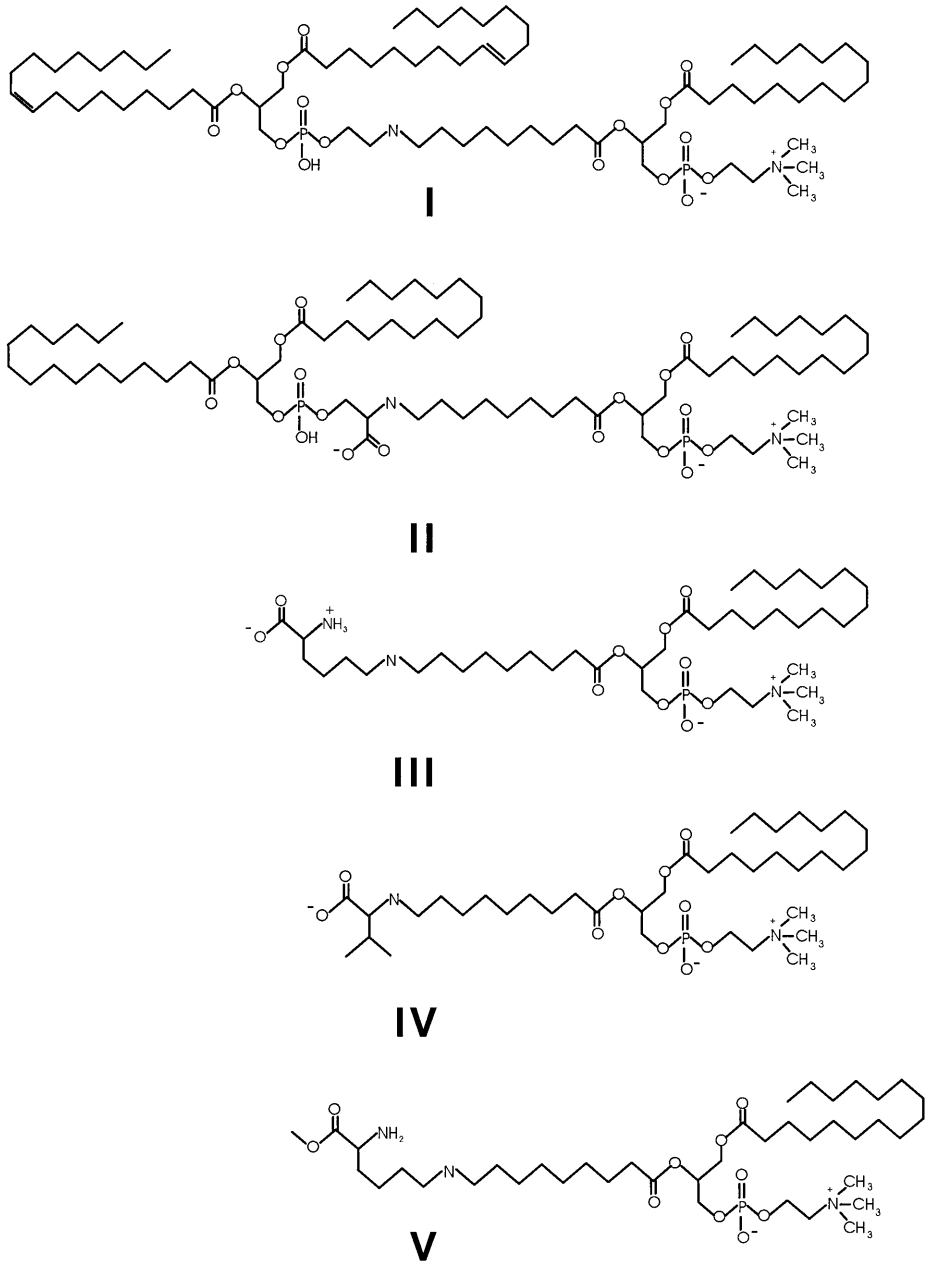
Preparation of reduced Schiff base of the myoglobin . The myoglobin (0.5 mg) was dissolved in distilled water (1 mL). To this solution was added the PC-Ald (2 mg) in ethanol (2 mL) (12) to give an approximate 100:1 ratio of aldehyde to protein. The reaction mixture was kept at room temperature for 1 h. Then $NaCNBH_3$ was added to a final concentration of 70 mM and the mixture kept at 4°C for 30 min. The reaction mixture was dialyzed against distilled water for 24 h with five changes of the solvent in order to remove excess reducing agent. The dialyzed sample was lyophilized and kept at –20°C until further analysis.

HPLC and LC/ESI/MS. Chromatographic analysis of the reduced reaction products of the aminophospholipids or amino acids with PC-Ald were performed on a silica column (Spherisorb, 3 μm, 100 × 4.6 mm i.d., Alltech, Guelph, Ontario) installed in a Hewlett-Packard (Palo Alto, CA) Model 1050 Liquid Chromatograph connected to a Hewlett-Packard Model 5988B quadrupole mass spectrometer equipped with a nebulizer-assisted ESI interface (18). The column was eluted with a linear gradient of 100% A (chloroform/methanol/30% ammonium hydroxide 80:19.5:0.5, by vol) to 100% B (chloroform/methanol/water/30% ammonium hydroxide 60:34:5.5:0.5, by vol) in 14 min, then at 100% B for 10 min (20). Reversed phase LC/ESI/MS was done as described by Kim *et al.* (20). Positive ionization spectra were taken in the *m/z* range 400–1200. Selected-ion mass chromatograms were retrieved from the LC/ESI/MS data. The molecular species of the various Schiff bases were identified from the molecular masses provided by the mass spectrometer, the knowledge of the composition of the reaction mixture, and the relative order of elution (less polar species emerging ahead of more polar species) of the anticipated products from the normal-phase column.

Flow ESI/MS. The Schiff bases of PC-Ald and myoglobin were analyzed by the Hewlett-Packard Model 5988B quadrupole mass spectrometer equipped with the ESI interface using the flow injection mode (19). The lyophilized sample was dissolved in 1 mL methanol/water/acetic acid (50:50:1, by vol), and 50 μL of the sample representing 1.5 nmol protein was injected into the ESI interface at 100 μL/min. Positive ion spectra were taken in the *m/z* range 300–2,000. Similarly the nonreduced Schiff bases of PC-Ald and amino acids were analyzed by flow ESI/MS to indicate that they could be detected as the primary product.

RESULTS

Schiff bases of aminophospholipids. Figure 1 shows the total positive ion current chromatogram (A) of the sodium cyanoborohydride reduced reaction products obtained for dioleoyl GPE along with the reconstructed single-ion chromatograms (B and C) for the $[M + H]^+$ of 16:0-9:0 Ald GPC (*m/z* 1378) and 18:0-9:0 Ald GPC (*m/z* 1406) derivatives, respectively, and the mass spectrum (D) averaged over the entire reduced Schiff base peak (PE + PC Ald). The PE–PC Schiff base is clearly resolved from the unreacted PE and the excess reagent, which has been converted to its hydroxy derivative by the reducing agent, and the small amounts of the azelaoyl GPC and lysoGPC present in the original reagent. On the basis of the peak area proportions, it was estimated



SCHEME 1

that about 40% of the PC-Ald had reacted with the PE. Reconstructed single-ion chromatograms for *m/z* 1378 (B) and 1406 (C), corresponding to $[M + H]^+$ of the reduced Schiff base of the dioleoyl GPE with 16:0-9:0 Ald GPC and 18:0-9:0 Ald GPC, respectively, document coelution of these two products. The mass spectrum averaged over the range of this peak (13.495–14.275 min) shows that the only other high mass ions are due to $[M + Na]^+$ at *m/z* 1400 and 1428, respectively.

Figure 2 shows the fragmentation spectra of the Schiff base of dioleoyl GPE and palmitoyl/[9-oxo]nonanoyl GPC as obtained by increasing the Cap Ex voltage to –300 V in the negative ion mode (A) and to +300 V in the positive ion mode (B). All the major fragment ions detected in the negative and positive ion mode can be assigned to the plausible cleavage products shown in A and B, respectively. The minor ions at *m/z* 125 and *m/z* 86 are due to loss of trimethylamine and phosphoric acid, respectively, from phosphorylcholine (*m/z* 184).

Figure 3 shows the total positive ion current chromatogram (A) of the sodium cyanoborohydride reduced reaction products obtained for dipalmitoyl glycerophosphoserine (GPS) along with the reconstructed single-ion chromatograms (B and C) for 16:0-9:0 Ald GPC (*m/z* 1370) and 18:0-9:0 Ald GPC (*m/z* 1398), respectively, along with the mass spectrum aver-

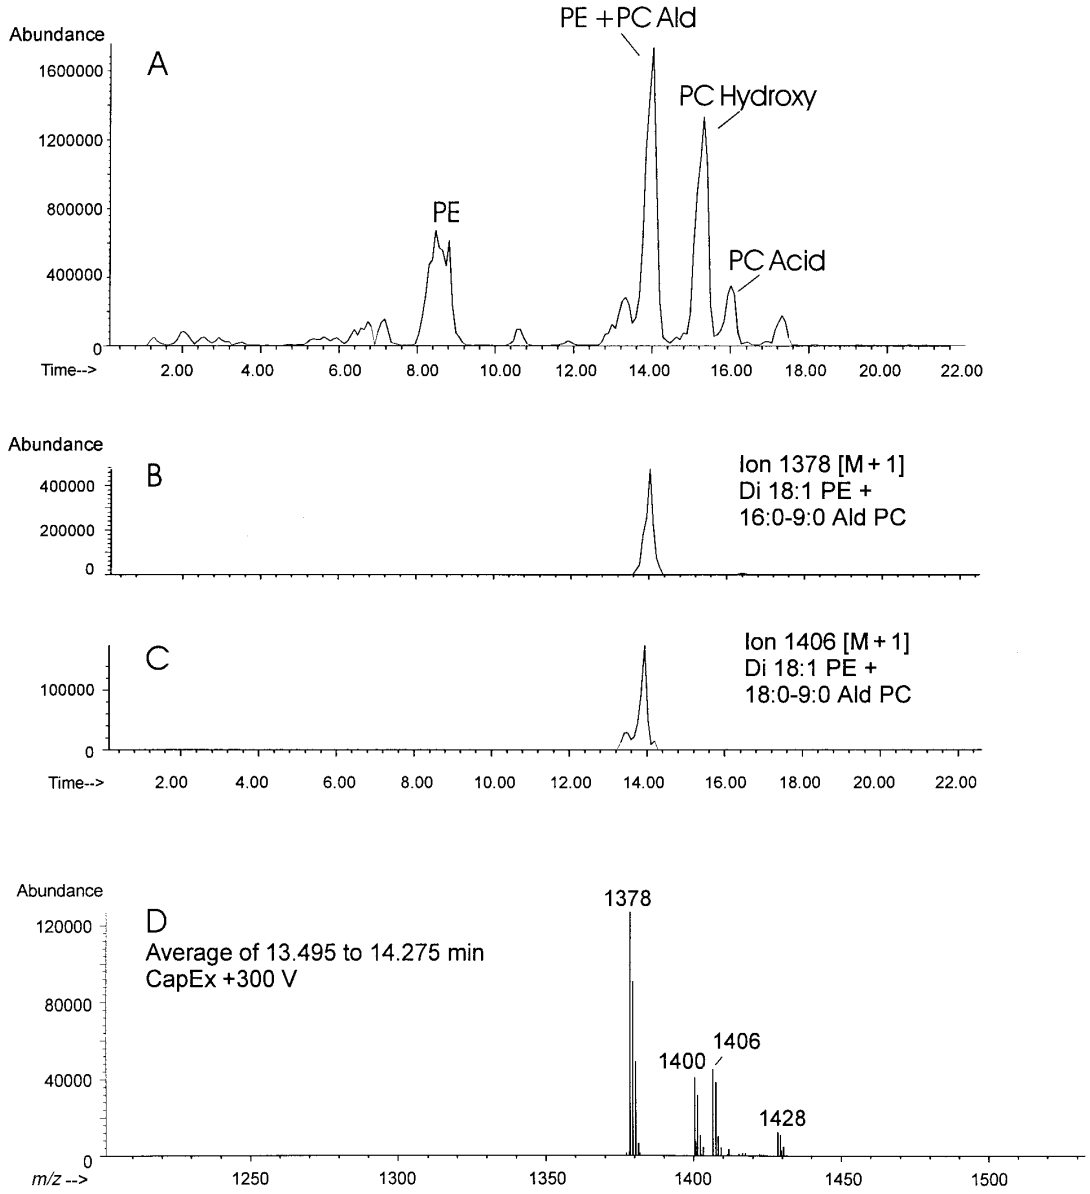


FIG. 1. Normal-phase liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS) of sodium cyanoborohydride-reduced reaction products of dioleoyl glycerophosphoethanolamine (GPE) and 1-palmitoyl(stearoyl)-2-[9-oxo)nonanoyl-*sn*-glycerophosphocholine (GPC). (A), total positive ion current chromatogram; (B) and (C), reconstructed single-ion chromatograms for the 16:0-9:0 Ald GPC (*m/z* 1378) and 16:0-9:0 Ald GPC (*m/z* 1406) derivatives, respectively; (D), total mass spectrum averaged over the entire Schiff base peak in (A). LC/ESI/MS equipment and operating conditions are found in the Materials and Methods section. PE, phosphatidylethanolamine; PC-Ald, phosphatidylcholine core aldehyde; PC Hydroxy, reduction product of PC core aldehyde. Major ions are identified in figure; other ions are described in text.

aged over the entire peak of the Schiff base (D). The reduced PS–PC Schiff base is only partially resolved from the PC 9-hydroxynonanoates [*m/z* 652 and *m/z* 680, not shown in (D)], formed by reduction of the unreacted PC-Ald. The reduced PS–PC Ald Schiff base is preceded by a peak containing a mixture of unidentified PC-Ald condensation products with *m/z* values ranging from 664 to 852. On the basis of the peak area proportions, it was estimated that about 20% of the PC-Ald had reacted with the PS. Reconstructed single-ion chromatograms for the *m/z* 1370 and 1398, corresponding to $[M + H]^+$ of the reduced Schiff base of the dipalmitoyl GPS with 16:0-9:0 Ald GPC and the 18:0-9:0 Ald GPC, respectively, again document coelution of the two products. Only the molecular ions for the PS–PC Ald Schiff bases are seen, with no other ions being detected in the high mass range. Clearly absent are the sodium adducts that were so prominent for the PE–PC Ald Schiff base adducts. The other peaks in Figure 3A were identified as the carboxy (*m/z* 666 and *m/z* 694) and hydroxy (*m/z* 652 and *m/z* 680) derivatives of the 16:0 and 18:0 GPC-Ald. Ionization of the PS–PC Ald Schiff base at Cap Ex of 300 V resulted in fragment ions, which closely resembled the pattern just established for the PE adduct (ion chromatograms not shown).

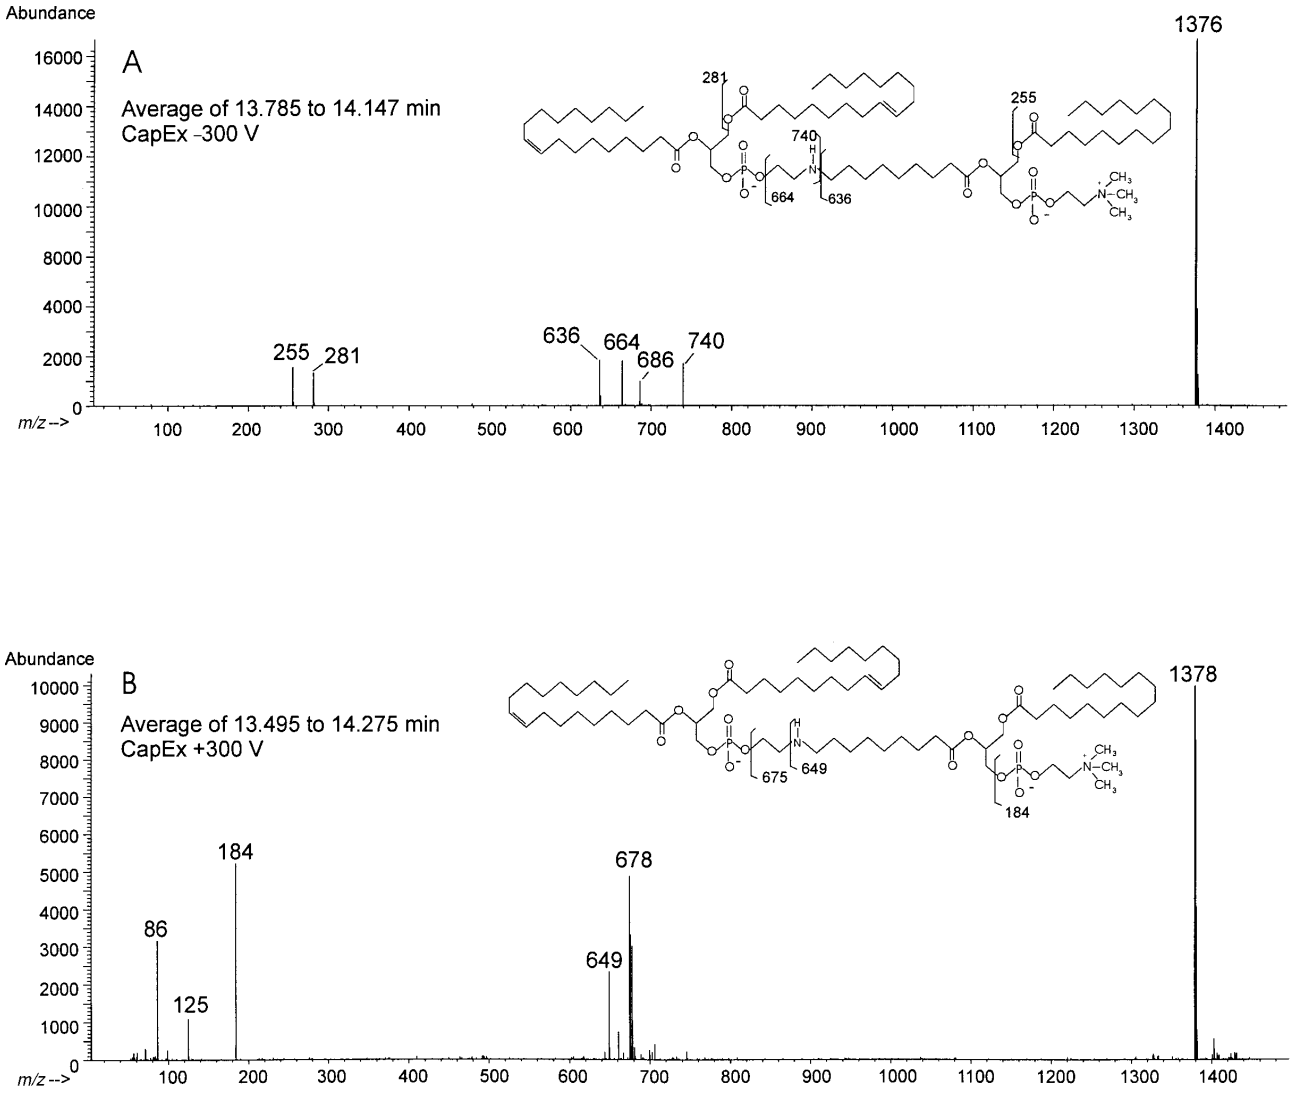

FIG. 2. Normal-phase LC/ESI/MS fragmentation spectra of the reduced Schiff base of dioleoyl GPE and 16:0-9:O Ald GPC at negative Cap Ex voltage of –300 V (A) and of positive Cap Ex voltage of +300 V (B). LC/ESI/MS conditions are as given in Figure 1. The generated ions correspond to the plausible bond cleavages depicted in the sketches accompanying the figures. Other chromatographic and mass spectrometric conditions are as given in the Materials and Methods section. The double bond in the *sn*-1 fatty chains are *cis* and not *trans* as would appear from the artwork. See Figure 1 for abbreviations.

Schiff bases of amino acids. Figure 4 shows the total ion current chromatogram as obtained by reversed-phase LC/ESI/MS for the reduced reaction products of free lysine and 16:0-[9-oxo]nonanoyl GPC (A) and the full mass spectra averaged over the entire peak of the Schiff base (Lys + PC Ald) as obtained by the use of Cap Ex –300 V (B) and Cap Ex +300 V (C), respectively. In both (A) and (B), all the major ions are accounted for by the characteristic fragmentation of the PC moiety indicated in the structural formulae given above. The low molecular weight ion at *m/z* 86 is due to loss of phosphoric acid from phosphocholine, while *m/z* at 71 is due to a cleavage of the α-β carbon bond of bound lysine. The insert in Figure 4A demonstrates that the nonreduced free lysine/PC core aldehyde Schiff base is stable under the conditions of flow injection, yielding the molecular ion (*m/z* 778). The ions at *m/z* 650 and *m/z* 666 are due to the PC acid and aldehyde present in the reaction mixture. It is known that the ε-amino group is more reactive towards Schiff base formation with saturated aldehydes (21).

Figure 5 shows the reconstructed single-ion chromatograms (A and B) corresponding to $[M + H]^+$ ions for the reduced valine-16:0-9:0 Ald GPC (*m/z* 751) and reduced valine-18:0-9:0 Ald GPC (*m/z* 779) adducts, respectively, along with the full mass spectrum (C) averaged over the entire peak of the Schiff base. The mass spectrum shows major ions corresponding to reduced Schiff bases of 16:0-9:0 Ald GPC (*m/z* 751) and of 18:0-9:0 Ald GPC (*m/z* 779) with valine. The ions at *m/z* 773 and *m/z* 801 correspond to the monosodium adducts of the two Schiff bases, respectively.

Figure 6 shows the total positive ion current chromatogram (A) of the reaction mixture of the reduced isoleucine and the

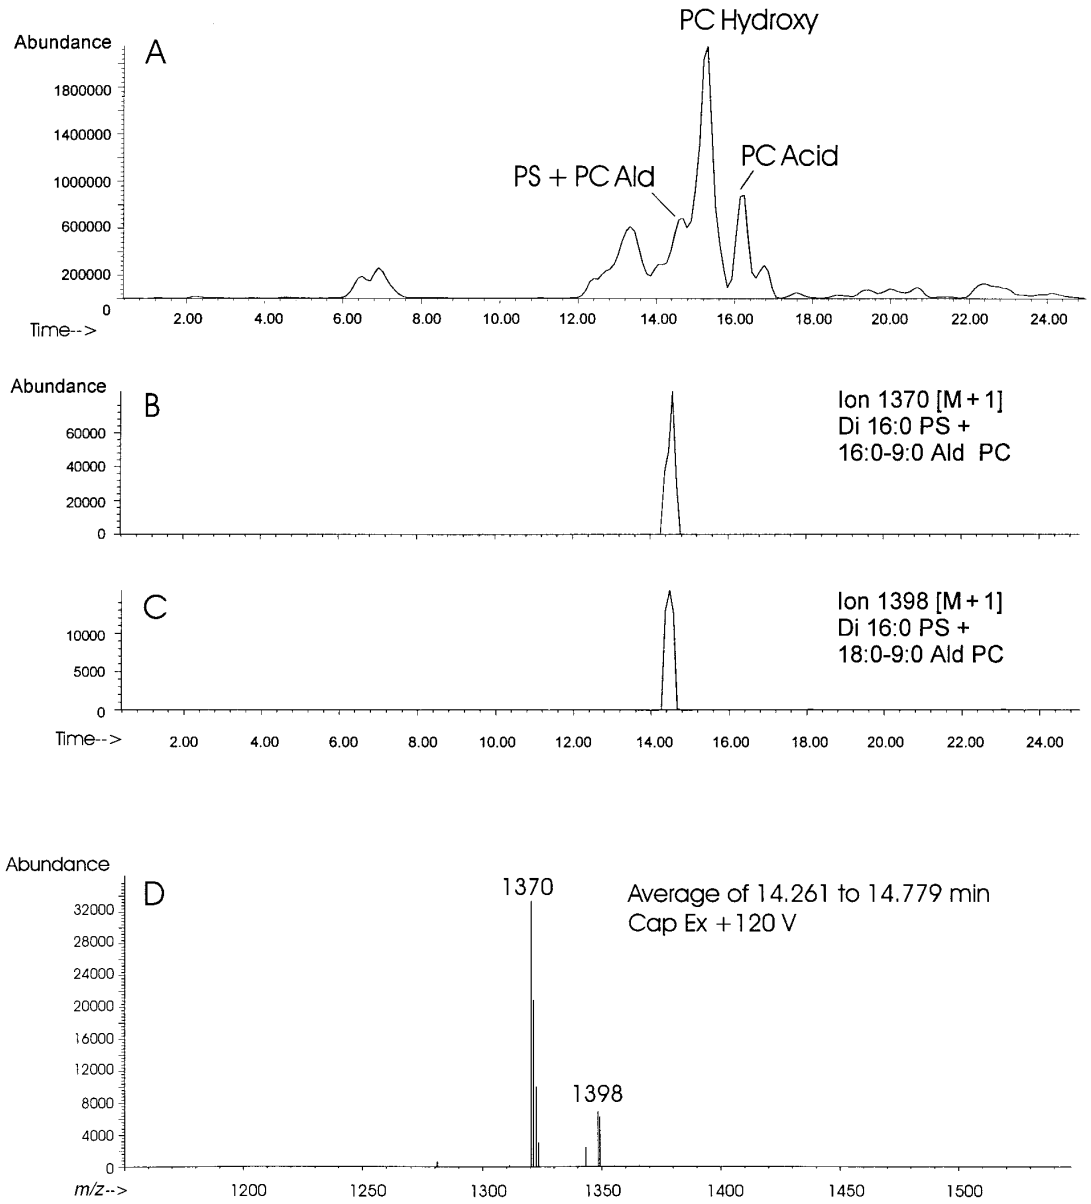

FIG. 3. Normal-phase LC/ESI/MS of sodium cyanoborohydride-reduced reaction products of dipalmitoyl glycerophosphoserine (GPS) and 1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl-*sn*-GPC. (A), total positive ion current chromatogram; (B) and (C), reconstructed single-ion chromatograms for the 16:0-9:0 Ald (*m/z* 1370) and 18:0-9:0 Ald (*m/z* 1398) derivatives, respectively; (D), total mass spectrum averaged over the Schiff base peak in (A). LC/ESI/MS equipment and operating conditions are found in the Materials and Methods section. PS, phosphatidylserine; PC Acid, oxidation product of PC core aldehyde. See Figure 1 for other abbreviations.

PC-Ald along with the reconstructed single-ion chromatograms (B and C) of the isoleucine-16:0-9:0 Ald (*m/z* 765) and isoleucine-18:0-9:0 Ald (*m/z* 793) GPC Schiff base adduct, respectively, with the full mass spectrum (D) averaged over the entire adduct peak (14.464–14.954 min). The mass spectrum of the reduced Schiff base gives major ions corresponding to the adduct of isoleucine and the 16:0-9:0 Ald (*m/z* 765) and the 18:0-9:0 Ald (*m/z* 793) GPC. The ions at *m/z* 787 and *m/z* 815 are due to the monosodium adducts, respectively.

Figure 7 shows the total positive ion current chromatogram (A) of the reaction mixture of the PC-Ald with the methyl ester of lysine along with the single-ion chromatograms (B and C) for the 16:0-9:0 Ald (*m/z* 794) and 18:0-9:0 Ald GPC (*m/z* 822) of the lysine methyl ester Schiff bases, as well as the full mass spectrum (D) averaged over the entire adduct peak. The ions at *m/z* 794 and *m/z* 822 correspond to the reduced Schiff bases of the C_{16} and the C_{18} homologs of the PC-Ald, respectively, while the ions at *m/z* 816 and *m/z* 844 corresponded to the monosodium adducts of the two reduced Schiff bases. The structures of the reduced homologous Schiff bases were confirmed by fragmentation at Cap Ex 300 V.

Schiff bases of myoglobin. Figure 8 shows the flow/

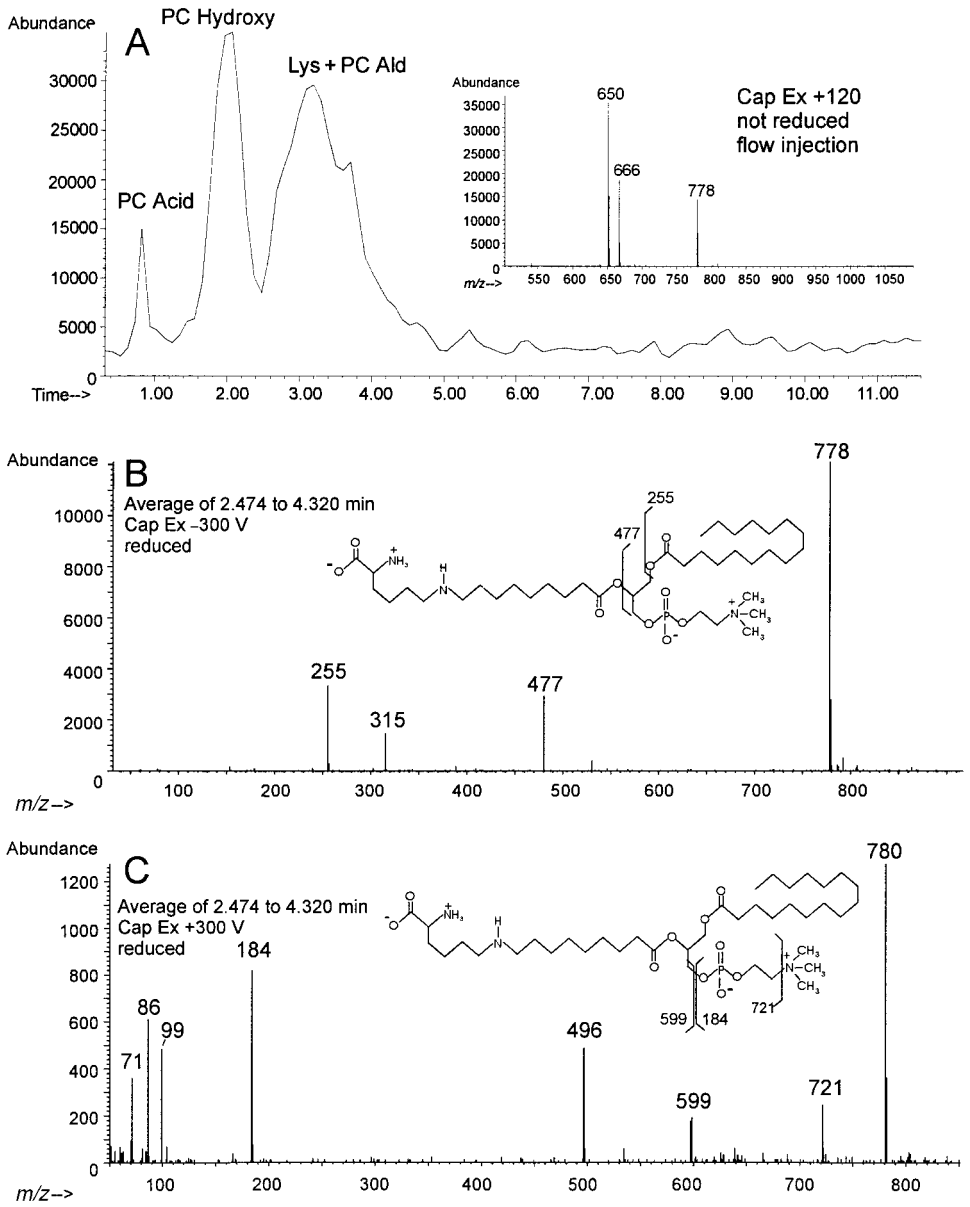

FIG. 4. Reversed phase LC/ESI/MS of the reduced reaction products of free lysine and 16:0/9:0 Ald GPC (A) and fragmentation spectra of the reduced Schiff base of free lysine and 16:0-9:0 Ald PC at negative Cap Ex voltage of –300 V (B) and at positive Cap Ex voltage of +300 V (C). The generated ions correspond to the plausible bond cleavage products depicted in the sketches accompanying the figures. Other ions are as described in text. See Figure 1 for abbreviations.

ESI/MS spectra and the deconvoluted molecular weights of the horse skeletal muscle apomyoglobin (A), its sodium cyanoborohydride reduction product (B), and the product of PC-Ald-apomyoglobin interaction and sodium cyanoborohydride reduction (C). The original apomyoglobin gives a multicharged ion spectrum, which can be deconvoluted to give a MW of 16,948.73. This MW corresponds to the value of 16,950 reported in the literature (17). Following reduction with sodium cyanoborohydride, the apomyoglobin mass spectrum shows two series of multicharged ions, one of which deconvolutes to the original horse skeletal muscle apomyoglobin (major peak) and another one, which deconvolutes to a MW 80 mass units higher (minor peak). The myglobin treated with PC Ald shows the presence of three series of multicharged ions, one corresponding to the original horse skeletal muscle apomyoglobin (MW 16,949.89), a second corresponding to the sodium cyanoborohydride treatment product (MW 17,030.74), and a third corresponding to the reduced PC Ald Schiff base adduct containing two molecules of the 16:0-9:0 Ald (MW 18,218.14). Other incubations gave evidence of the formation of Schiff bases with the mono-16:0-9:0 Ald and mono-18:0-9:0 Ald, and the di-16:0-9:0 Ald and the mixed 16:0-9:0 Ald and 18:0-9:0 Ald adduct. The determination of the actual sites of Schiff base complexing in the apomyoglobin molecules requires further work.

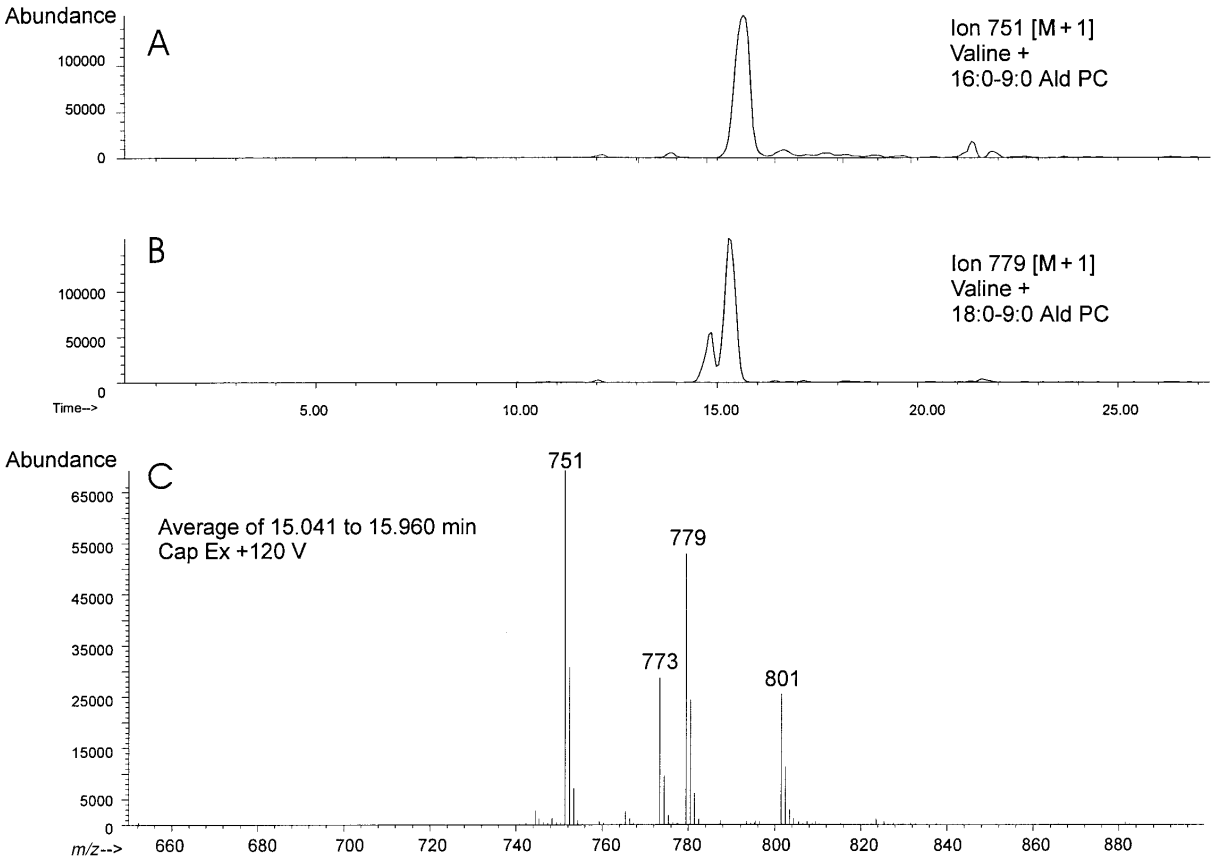

FIG. 5. Normal-phase LC/ESI/MS of sodium cyanoborohydride reduced reaction products of valine and 1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl-*sn*-GPC. (A) and (B), reconstructed single-ion chromatograms for the 16:0-9:0 Ald (*m/z* 751) and 18:0-9:0 Ald (*m/z* 779) derivatives, respectively; (C), total mass spectrum averaged over the entire reduced Schiff base peak. LC/ESI/MS instrumentation and operating conditions are found in the Materials and Methods section. Major ions are identified in figure; other ions are described in text. See Figure 1 for abbreviations.

DISCUSSION

The present study establishes that PC Ald can react with the amino groups of aminophospholipids, amino acids, and polypeptides. Aminophospholipids gave Schiff bases, which could be reduced to yield adducts of characteristic chromatographic and mass spectrometric behavior. There had been no previous demonstration of Schiff base formation between the phospholipid core aldehydes and the amino groups of aminophospholipids. Previous work had shown that the amino groups of the aminophospholipids react with simple aliphatic aldehydes, including malonaldehyde (22), but the exact structure of the products has not been established. Recently, evidence has been obtained for the glucosylation of aminophospholipids (23,24), which represent a type of Schiff base formation. The present study shows that PC Ald also reacts readily with the α-amino group of free amino acids and with the ε-amino group of free and peptide-bound lysine. In a mixed-phase system, the liposomal lipid ester core aldehyde reacts rapidly with the amino compounds to yield a yellow tinge, which deepens with time, resulting in an extensive conversion of the aldehyde into a Schiff's base when incubated with an excess of free amino acid or polypeptide. The Schiff bases could be isolated by TLC and HPLC and could be shown to give molecular ions by flow ESI/MS of concentrated samples in methanol/water solution. This indicated that the Schiff base was the primary reaction product in each instance. Addition of 0.5% ammonia to the HPLC mobile phase resulted in extensive dissociation of the Schiff base and loss of sensitivity of detection. In order to increase the stability of the bases and to permit the use of stronger ionizing solutions, the Schiff bases were reduced with sodium cyanoborohydride. The reduction increased the mass of the Schiff bases by two mass units without any significant effect on their TLC or HPLC migration when compared to the unreduced parent molecules.

Theoretically, free lysine could form Schiff bases either *via* the α- or ε- or both amino groups. Furthermore, the greater reactivity of the primary in comparison to the secondary amino group would suggest that the main product would be the Schiff base of the ε-amino group. This was confirmed by an examination of the Schiff base formed from free lysine and pure 1-palmitoyl 2-[9-oxo]nonanoyl GPC. Both flow injection and reversed-phase LC/ESI/MS with fragmentation of the reduced adduct gave the anticipated ε-amino derivative as the sole or major product. The possibility of for-

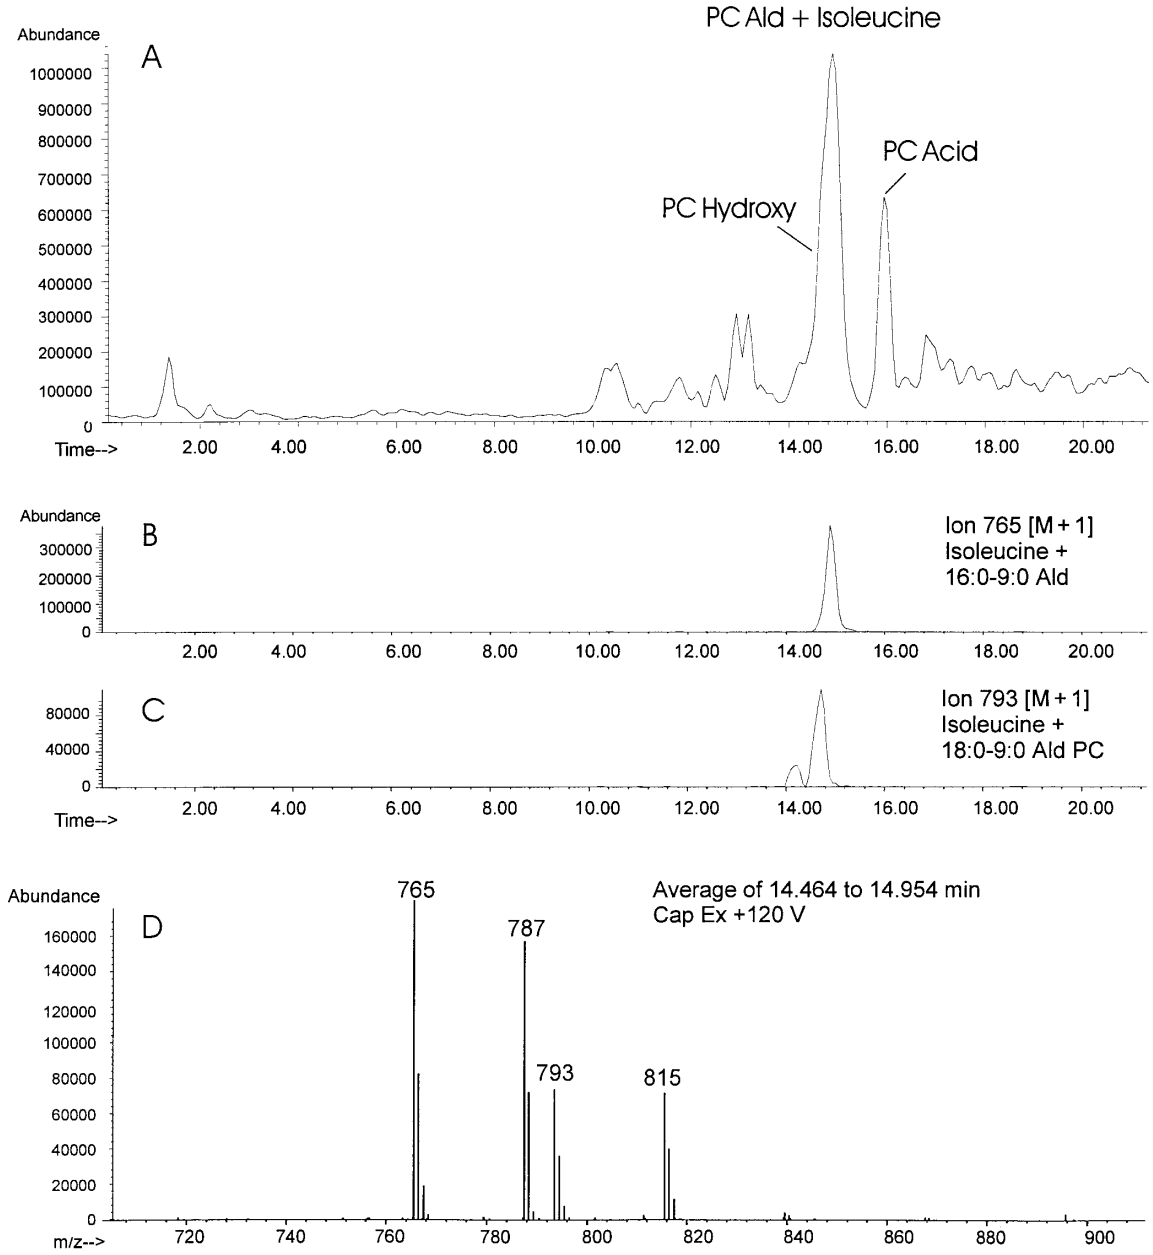

FIG. 6. Normal-phase LC/ESI/MS of sodium cyanoborohydride-reduced reaction products of isoleucine and 1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl-*sn*-GPC. (A), total positive ion current chromatogram; (B) and (C), reconstructed single-ion chromatograms for the 16:0-9:0 Ald (*m/z* 765) and 18:0-9:0 Ald (*m/z* 793) derivatives, respectively; (D), total mass spectrum averaged over the entire reduced Schiff base peak. LC/ESI/MS instrumentation and operating conditions are found in the Materials and Methods section. Major ions are identified in figure; other ions are described in text. See Figure 1 for abbreviations.

mation of an α-amino derivative could not be excluded. The reaction products, if both present, probably would not be separated by the chromatographic methods employed before or after reduction, and would both give the same MW in the mass spectrometer. The matter was not pursued further at this time.

The Schiff bases of the amino acids, including lysine, previously have been prepared using the low MW aldehydes, e.g., malonaldehyde (2-4) and 4-hydroxynonenal (7,8). In these instances, the reaction products are stabilized by secondary reactions, although the structures have not been completely established in all instances. The simple aliphatic aldehydes yield Schiff bases that are more easily dissociated than those of the bifunctional aldehydes and require chemical reduction for stabilization (12,25).

In case of myoglobin, the Schiff base formation would be expected to occur with the N-terminal amino group of glycine and any or all of the ε-amino groups of the internal lysines. Horse skeletal muscle apomyoglobin has a total of 153 amino acid residues with 1 α-amino group and 19 ε-amino groups

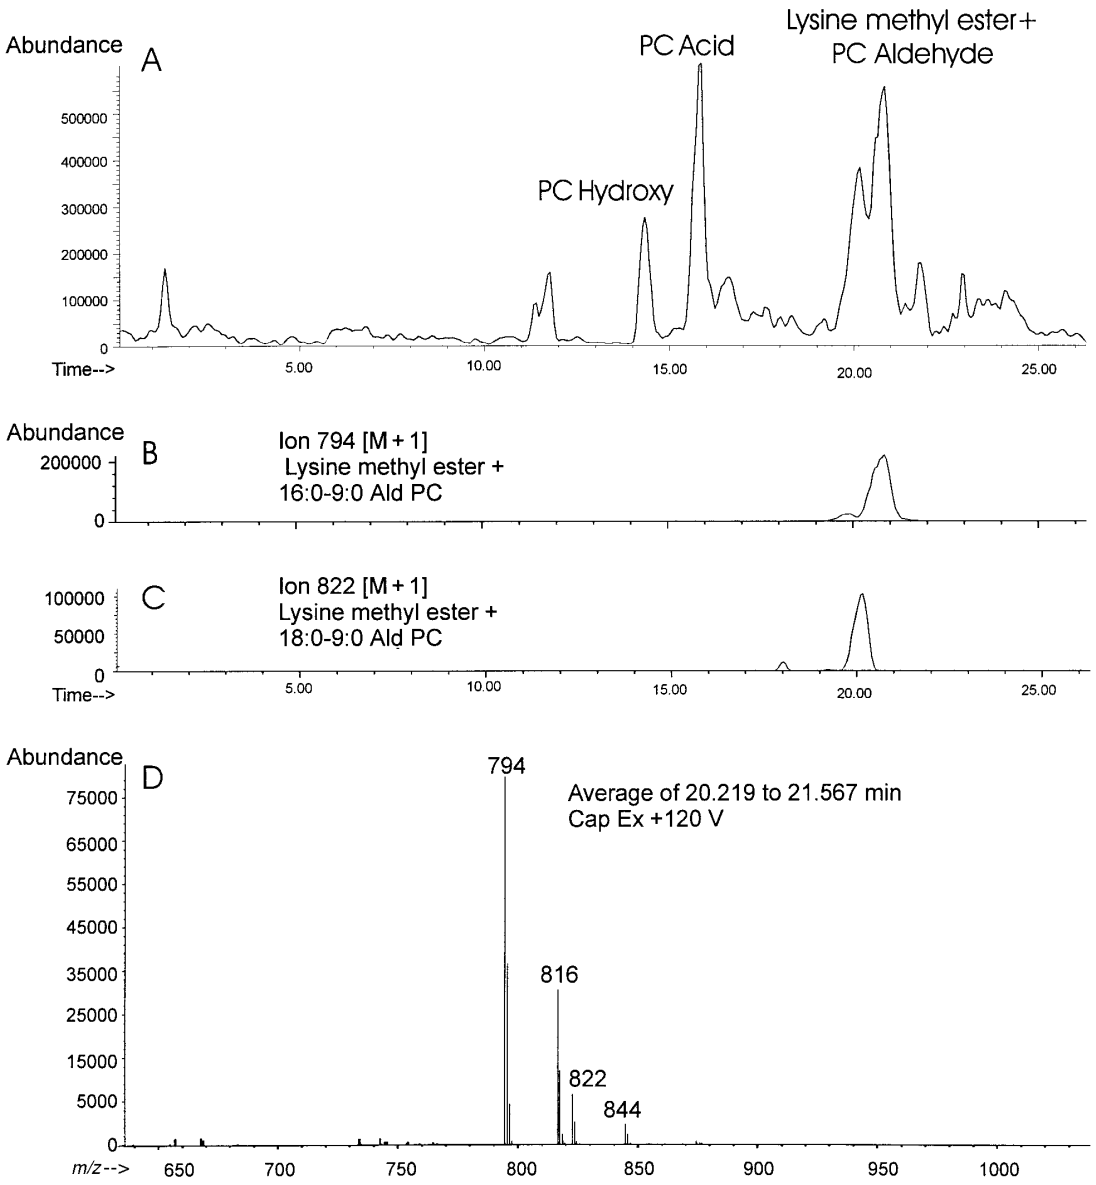

FIG. 7. Normal-phase LC/ESI/MS spectra of sodium cyanoborohydride-reduced reaction products of lysine methyl ester and 1-palmitoyl(stearoyl)-2-[9-oxo]nonanoyl-*sn*-GPC. (A), total positive ion current chromatogram; (B) and (C), reconstructed single-ion chromatograms for the 16:0-9:0 Ald (*m/z* 794) and 18:0-9:0 Ald (*m/z* 822) derivatives, respectively; (D), total mass spectrum averaged over the Schiff base peak. LC/ESI/MS instrumentation and operating conditions are found in the Materials and Methods section. Major ions are identified in figure; other ions are described in text. See Figure 1 for abbreviations.

that can react with carbonyl compounds. In the present experiments, however, only two and no more than four PC Ald appeared to be involved in Schiff base formation with horse skeletal muscle apomyoglobin. It is possible that the apomyoglobin molecule contains two particularly reactive sites susceptible to Schiff base formation, which could explain the presence of only minor amounts of the single Schiff base adduct. The formation of a bis-Schiff base adduct corresponding only to the 1-palmitoyl species is probably due to the predominance of this species (80%) compared to the 1-stearoyl species (20%) in the reaction mixture. The reduced bis-Schiff base adduct of the dipalmitoyl derivative was selected for illustration.

In other studies LC/MS with electrospray has been employed to demonstrate the Schiff base formation between acetone and the ε-amino groups of horse myoglobin lysine (26). The identified protein species contained from 1 to 6 adducts of methyl isobutyl ketone or acetone. In the present experiments, two to four residues of the core aldehyde were bound to horse apomyoglobin. The specific amino acid residues involved in the Schiff base formation were not determined. Since the amino acid sequence of horse myoglobin is known, the exact location of the Schiff base forming lysines could be established in the future by trypsin digestion and reversed-phase LC/ESI/MS of the released peptides, the MW of which

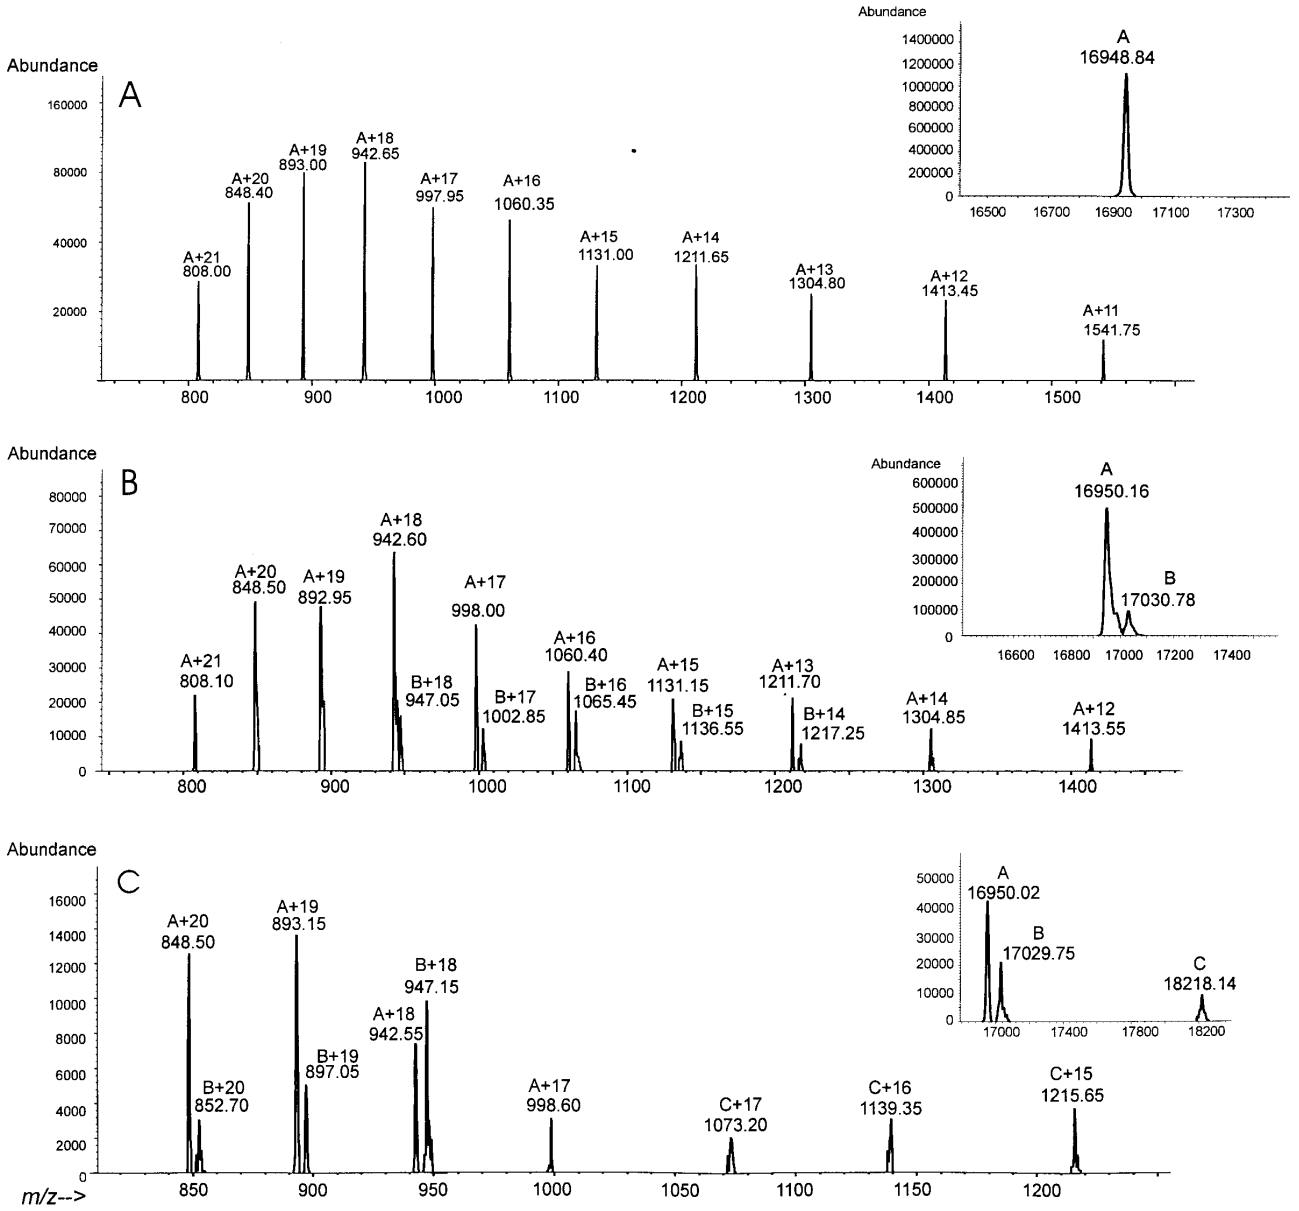

FIG. 8. Flow ESI/MS spectra and the deconvoluted MW of the horse skeletal muscle apomyoglobin (MW 16,948.84) (A), its sodium cyanoborohydride reduction product (MW 17,030.78) (B), and the product of interaction of myoglobin with two 16:0-9:0 Ald GPC (MW 18,218.14) (C). Flow injection ES/MS instrumentation and operating conditions are found in the Materials and Methods section. Major ions and charge distribution are given in figure. See Figure 1 for abbreviations.

could be calculated. The peptides bearing the phospholipid moieties would be expected to be retained much longer on reversed-phase columns than the corresponding peptides without the phospholipid moiety (8).

The previously prepared Schiff base of C_9 core aldehyde of 2-acetylglycerophosphocholine and thyroglobulin (12) was not characterized beyond the demonstration that an antibody could be raised to the reduced adduct to recognize in tissue extracts the PAF, which the C_9 core aldehyde resembles structurally. Uncharacterized have also remained the radioactive complexes formed between apoprotein B and oxidized 2-[1-^{14}C]arachidonoyl PC (27), which must have involved the C_5 core aldehyde, because the malonaldehyde and 4-hydroxynonenal would not be labeled.

The present findings are of interest because the lipid ester core aldehydes like the short-chain aldehydes would be expected to form covalently-bound complexes with proteins. Malonaldehyde and 4-hydroxynonenal-modified lipoproteins have been found entrapped in aortic walls of both humans and animals (28,29), while lysine modification of low density lipoprotein or lipoprotein (a) by 4-hydroxynonenal or malonaldehyde decreases platelet serotonin secretion (30). The generation of reactive aldehyde species next to membrane components possessing active amino groups, which may lead to

Schiff base formation, could lead to membrane damage, loss of enzyme activity, and protein–protein or protein–lipid cross-linking (31). Proteins in the red blood cell membrane show increase in MW, cross-linking, when exposed to lipid-oxidizing conditions (32). The hydrophobicity acquired from complexing with the lipid ester core aldehydes would promote greatly the membrane association of the proteins and contribute to their resistance to proteolytic digestion and *trans*-membrane transport among other effects. Recent work (33) with monoclonal antiphospholipid antibodies has shown that they are directed against epitopes of oxidized phospholipids. A variety of structures that could occur in peroxidized tissues have been suggested, but only a few have been experimentally demonstrated. The present work shows that some of these compounds can be synthesized as well as records the LC/ESI/MS characteristics of these compounds that will be required for the isolation and identification of the Schiff base adducts from natural sources.

Analysis of Oxylipins by High-Performance Liquid Chromatography with Evaporative Light-Scattering Detection and Particle Beam–Mass Spectrometry

Bettina Rehbock, Dietmar Gansser, and Ralf G. Berger*

Institut für Lebensmittelchemie, Universität Hannover, D-30453 Hannover, Germany

ABSTRACT: The metabolism of 13*S*-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid was investigated in a crude enzyme extract from mung bean seedlings (*Phaseolus radiatus* L.). Hydroperoxide-metabolizing activity was mainly due to a hydroperoxide lyase and, to a lesser extent, to an allene oxide synthase and a peroxygenase. Oxylipins originating from hydrolysis and cyclization of the allene oxide synthase product 12,13-epoxy-9*Z*,11,15*Z*-octadecatrienoic acid and from peroxygenase catalysis were identified by high-performance liquid chromatography (HPLC) particle beam–mass spectrometry (PB-MS) and quantified by normal-phase HPLC with an evaporative light-scattering detector (ELSD). An advantage of this methodology was the possibility to avoid extensive derivatization procedures commonly used for the gas chromatographic analysis of oxylipins. Owing to a comparable sample inlet system, the ELSD served an important analytical pilot function for the PB–MS: Qualitatively identical chromatographic patterns were obtained with both detection systems. The HPLC system enabled the separation of methyl 12-oxo-phytodienoate, methyl 11-hydroxy-12-oxo-9*Z*,15*Z*-octadecadienoate, methyl 12-oxo-13-hydroxy-9*Z*,15*Z*-octadecadienoate, methyl 9-hydroxy-12-oxo-10*E*,15*Z*-octadecadienoate, methyl 13-hydroxy-9*Z*,11*E*,15*Z*-octadecatrienoate, methyl 15,16-epoxy-13-hydroxy-9*Z*,11*E*-octadecadienoate, and methyl 13-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoate on a Lichrospher DIOL column within 33 min. Compared with a diode array detector, the ELSD proved to be more sensitive, in the case of methyl 12-oxo-13-hydroxy-9*Z*,15*Z*-octadecadienoate by a factor of about 15. In addition, volatile metabolites were analyzed by capillary gas chromatography. The yield of the hydroperoxide lyase product 2*E*-hexenal was 49%, whereas the sum of oxylipins reached about 15%.

Lipids 32, 1003–1010 (1997).

Plant allene oxide synthases are cytochrome P450 enzymes which convert the 13*S*-hydroperoxides of linoleic or linolenic acid into allene oxides (1). Hamberg (2) was the first to demonstrate the formation of the allene oxide 12,13-epoxy-9*Z*,11-octadecadienoic acid (12,13-EOD) by the incubation of 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13-HPOD) with an allene oxide synthase from corn. Structural elucidation of 12,13-epoxy-9*Z*,11,15*Z*-octadecatrienoic acid (12,13-EOT) derived from 13*S*-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid (13-HPOT) has been reported by Brash and co-workers using an enzyme preparation from flaxseed (3). Allene oxides are extremely unstable metabolites possessing a chemical half-life on the order of 15–33 s at 0°C. In aqueous medium they are spontaneously hydrolyzed into ketol derivatives and cyclopentenone fatty acids (2,3). Hydrolysis of 12,13-EOT leads to the formation of the oxylipins 12-oxo-13-hydroxy-9*Z*,15*Z*-octadecadienoic acid (12,13-α-ketol), 9-hydroxy-12-oxo-10*E*,15*Z*-octadecadienoic acid (9,12-γ-ketol), and racemic *cis*-12-oxo-phytodienoic acid (12-oxo-PDA). Enzymatic cyclization of 12,13-EOT, which can occur in the presence of an allene oxide cyclase, results in the formation of the 9*S*,13*S*-enantiomer of 12-oxo-PDA (4), a precursor of the plant growth hormone jasmonic acid (5).

Analysis of these oxylipins is hampered by at least two factors: first, their structural instability when they are exposed to elevated temperatures (such as under gas chromatographic conditions), and second, the commercial unavailability of reference substances, except for 12-oxo-PDA. In recent literature, several methods have been described to quantify the products generated during allene oxide synthase catalysis. One method employed gas chromatographic analysis after multiple derivatization such as methylation, hydrogenation, and trimethylsilylation (6). For improved analysis of the labile ketol this derivatization procedure was necessary; nevertheless, it is time-consuming, and quantitative derivatization at each step is prerequisite for obtaining accurate data. A second method implied the use of a radiolabeled precursor, namely [1-^{14}C]13-HPOT. The composition of labeled prod-

ucts was estimated either by thin-layer chromatography using a scintillation scanner (4) or by high-performance liquid chromatography (HPLC) equipped with a scintillation detector (7,8). However, subsequent derivatization and gas chromatography–mass spectrometry (GC–MS) analysis of collected peaks or spots are required for identification of the metabolites in both cases. In a third method, allene oxide synthase activity was assayed by the spectrophotometric measurement of the decrease in absorbance at 235 nm (9). This decrease is caused by the degradation of the conjugated diene chromophore in the hydroperoxy fatty acid leading *via* the allene oxide mainly to the α-ketol, which shows no absorbance at this wavelength. A major drawback of this assay is its nonspecificity. It does not differentiate between allene oxide synthase and other hydroperoxide-metabolizing enzymes, e.g., hydroperoxide lyases (reviewed in References 10–12), nor is any information provided about the ratio of the products.

As to the identification of labile compounds, liquid chromatography–mass spectrometry (LC–MS) techniques are of increasing importance. Fast-atom bombardment and negative ion electrospray ionization low-energy tandem mass spectrometry have been used for the analysis of polyhydroxy-substituted eicosanoids (13,14) and unsaturated monohydroxy fatty acids (15). Monohydroxy-epoxy derivatives of arachidonic acid (hepoxilins) as well as mono/polyhydroxy-substituted eicosanoids have been investigated after preparation of an anthryl ester derivative by thermospray ionization mass spectrometry (16).

The present study reports on an alternative method for the analysis of oxylipins which overcomes tedious derivatization procedures commonly used for GC analysis. Quantification and identification of oxylipins were performed using a normal-phase HPLC system coupled to an evaporative light-scattering detector (ELSD) and by LC–MS with a particle beam interface. This analytical system was applied to monitor the product spectrum from the metabolism of 13-HPOT by mung bean seedlings, which has not yet been investigated comprehensively.

MATERIALS AND METHODS

Materials. Mung beans (*Phaseolus radiatus* L.) were obtained from a local market. Linolenic acid (99%) and 2-propanol (HPLC-grade) were purchased from Fluka (Neu-Ulm, Germany). Lipoxygenase (EC 1.13.11.12) from soybean type 1-B (110,600 units/mg solid) and methyl ricinoleate (99%) were from Sigma (Deisenhofen, Germany). *n*-Hexane (HPLC-grade) was from Roth (Karlsruhe, Germany).

Preparation of 13-HPOT. About 150 mg linolenic acid was emulsified in 80 mL 0.1 M K_2HPO_4 buffer pH 9.0 using an ultrasonic bath. The enzymatic dioxygenation was initiated by the addition of 2 mL of a lipoxygenase solution (*ca.* 2–3 mg/mL) to the stirred linolenic acid emulsion. Conversion was allowed to proceed for 20 min at approximately 0°C (ice bath) under continuous bubbling with oxygen. Finally, the reaction mixture was brought to a volume of 100 mL. This procedure resulted in a nearly complete conversion (>95%). The concentration of 13-HPOT was determined spectrophotometrically by measuring the absorbance at 234 nm against a blank containing no linolenic acid. For the calculation a molar extinction coefficient of 25,000 was used (17). Isomeric purity was analyzed after solid-phase extraction (RP-18 cartridges, Macherey & Nagel, Düren, Germany) by normal-phase HPLC (18), which revealed that 13-HPOT was the predominant isomer (>95%). 13-HPOT was always freshly prepared and used without further purification in the subsequent incubation experiments.

Germination of mung bean seeds and plant preparation. Mung bean seeds were soaked in water for 1 h and then placed on moist cotton wool. The seeds were germinated for 12–16 d at room temperature under normal light conditions without additional illumination and irrigated daily. In a typical procedure, 5 g mung bean seedlings were homogenized in 50 mL potassium phosphate–citrate buffer (pH 6.5, 0.1 wt% Triton X-100) with an Ultraturrax (Janke & Kunkel, Staufen i. Br., Germany) for 90 s. The homogenate was centrifuged at 4°C and 6400 × *g* for 20 min and the clear supernatant was used as crude enzyme extract.

Incubation and product isolation. Metabolism of the hydroperoxide was started by the addition of 10 mL of the 13-HPOT solution (about 50 µmol 13-HPOT) to the crude enzyme extract. The slight increase of pH caused by the alkaline precursor solution was immediately corrected with 0.1 M HCl to the desired pH of 6.5. Sealed flasks were incubated for 1 h at room temperature in a circular agitator. A control sample was treated in the same manner except that 10 mL of 0.1 M K_2HPO_4 buffer pH 9.0, instead of the precursor solution, were used. After acidification of the reaction mixture with 0.1 M HCl to pH 4.0, the products were extracted three times with 70 mL pentane/diethyl ether (1:1, vol/vol). The combined organic phases were dried over anhydrous sodium sulfate and brought to 250 mL with the extraction solvent. Subsequently, two methods of concentration were applied, depending on the kind of metabolite to be quantified. To determine volatile compounds, an aliquot (50 mL) was subjected to distillation using a Vigreux column (water bath temperature 40°C), which excluded a loss of volatiles but was relatively time-consuming. After concentration to a final volume of 1–2 mL, an internal standard (methyl nonanoate) was added and the sample was analyzed by GC.

For the analysis of nonvolatile metabolites the remaining extract (200 mL) was concentrated under vacuum at 35°C. The residue obtained after evaporation of the solvent was redissolved in 5 mL of diethyl ether and methylated with diazomethane. Subsequently, the solution was brought to 10 mL, and after suitable dilution with *n*-hexane, subjected to HPLC analysis.

Analysis of volatile compounds by GC. Volatiles were analyzed with a Fisons gas chromatograph GC 8180 (Mainz, Germany) equipped with a cool on-column injector and flame ionization detector. Compounds were separated on a Sato Wax capillary column (30 m × 0.32 mm, 0.45 µm film thick-

ness) from Sato (Mönchengladbach, Germany) with a temperature program from 40°C (held for 2 min) to 220°C at 4°C/min. The temperature of the detector was 270°C. Hydrogen was used as carrier gas at an inlet pressure of 50 kPa.

Analysis of nonvolatile compounds by HPLC–diode array detector (DAD)/ELSD. Analysis was performed with an HPLC apparatus from Jasco (Groβ-Umstadt, Germany), which consisted of a pump PU-980, degasser DG-980-50, gradient unit LG-980-02, DAD MD-910, and an injection valve from Rheodyne (Cotati, CA) with a 20-μL sample loop. An ELSD Sedex 55 from Sedere (Alfortville, France) was connected in series with the DAD.

Methylated oxylipins were separated on a Lichrospher 100 DIOL column (250 × 4 mm, 5 μm) from Merck (Darmstadt, Germany) at a flow rate of 0.4 mL/min. This flow rate was chosen with respect to a transfer of the conditions to the HPLC particle beam–mass spectrometry (PB–MS) system, because the particle beam interface operates best at low flow rates. The compounds were eluted isocratically for 10 min with *n*-hexane/2-propanol (98:2, vol/vol), then a linear increase of the gradient to *n*-hexane/2-propanol (85:15, vol/vol) within the next 25 min was followed by a washing step with *n*-hexane/2-propanol (50:50, vol/vol) for 20 min to elute Triton X-100. Attention had to be paid to the proper composition of the eluent, because slight changes at the beginning [e.g., *n*-hexane/2-propanol (95:5, vol/vol)] caused coelution or even an inversion of the elution order of some peaks. Metabolites were detected with a DAD (210 and 235 nm) as well as with an ELSD. The ELSD operated with compressed air as nebulization gas (2.0 bar) and with an evaporation temperature of 40°C. The gain was set to 8. Because reference substances were not commercially available (or in the case of 12-oxo-PDA for an extremely high price only), the detector was calibrated with methyl ricinoleate (methyl 12-hydroxy-9*Z*-octadecaenoate) and *n*-heptyl jasmonate. *n*-Heptyl jasmonate was prepared from methyl jasmonate (Aldrich, Deisenhofen, Germany) by transesterification with *n*-heptanol and a catalytic amount of H_2SO_4. Preparative thin-layer chromatography on silica plates with pentane/dichloromethane (8:2, vol/vol), R_f = 0.48–0.52, gave pure product (>98%, by GC, ratio *trans/cis* isomer: 95:5).

HPLC PB–MS. Oxylipins were identified by PB–MS. A Hewlett-Packard mass spectrometer 5989A (Palo Alto, CA) equipped with a particle beam interface 59980B was coupled to the HPLC system already described using the same chromatographic conditions. The interface operated with helium as nebulization gas at an inlet pressure of 415 kPa. Temperatures of the desolvation chamber, ion source, and quadrupole were 60, 250, and 100°C, respectively. Electron impact (EI) and chemical ionization (CI) spectra were recorded within a scan range of *m/z* 88–450 at an ionization energy of 70 and 100 eV, respectively. CI was performed with methane as ionization gas. The double-bond configuration of ketol derivatives was not determined explicitly. It was assumed that the stereochemistry of 12,13-EOT hydrolysis products was the same as reported for other plant sources (8,19).

Micropreparative gas chromatography. Methyl 12-oxo-10*E*-dodecenoate was isolated from the methylated organic extract by means of micropreparative gas chromatography and used as reference substance to determine its retention time in the HPLC system. Identity was confirmed by GC–MS analysis.

A MCS Gerstel Series II instrument (Gerstel, Mülheim/Ruhr, Germany) with a Hewlett-Packard 7673 autosampler, a Gerstel KAS-3 cold injection system, a Gerstel PFS fraction collector, and a Gerstel MCS 1.15 control and data acquisition system were employed. An OV 1 capillary column (3 m × 0.53 mm, 2-μm film thickness, Leupold, Fahrenzhausen-Weng, Germany) was connected to a BC CW 20 M capillary column (25 m × 0.53 mm, 1-μm film thickness, Leupold). Conditions were as follows: KAS: 40°C for 20 s, then raised by 10°C/s up to 230°C, there held for 120 s. Oven: 60°C for 4 min, then raised by 4°C/min up to 188°C and, in a second step, by 5°C/min up to 230°C, there held for 15 min. PFS: Supply pipe and distributor 220°C, trap cooling: 0°C. Flame-ionization detector: 250°C. Gases: Carrier gas H_2 at 5.0 mL/min, auxiliary gas H_2 at 1.0 mL/min, counter gas H_2 at 10.0 mL/min. Transfer of methyl 12-oxo-10*E*-dodecenoate from the KAS to the first column was allowed from 20 to 65 s after injection; from the first column to the second column from 29 to 31 min; from the second column to the trap from 35.62 to 36.75 min. The total injection volume was 12 μL per run.

GC–MS analysis. Collected HPLC fractions (methyl esters) were analyzed with and without conversion into methyl oxime and trimethyl silylether derivatives (2). GC–MS analysis was carried out as described elsewhere (20) except that a BC SE-54 capillary column (25 m × 0.32 mm, 0.4-μm film thickness, Leupold) and a split injector (T: 250°C) were used. The oven temperature was programmed from 60 to 270°C at 4°C/min.

RESULTS AND DISCUSSION

GC analysis of oxylipins. During investigations of the metabolism of 13-HPOT by mung bean seedlings we tried to quantify the oxylipins as methyl ester derivatives by GC. In the case of the α-ketol these attempts were not successful. The peak of the ketol was split into a group of peaks, suggesting isomerization of the double bond or decomposition on the capillary column. Such a phenomenon was also observed with 12-oxo-13-hydroxy-9*Z*-octadecenoic acid, the α-ketol arising from 12,13-EOD, when its methyl ester and trimethyl silylether derivative were analyzed (21). The authors pointed out that double-bond isomerization may also be caused by reagent treatment: When the double bond was saturated by hydrogenation prior to trimethylsilylation a single GC peak was obtained. In addition, under our GC conditions 12-oxo-PDA (methyl ester) gave two peaks when a split injector was used, indicating possibly a rearrangement of the *cis*-orientated side chains into the more stable *trans* form.

HPLC-DAD/ELSD analysis of 13-HPOT-derived metabo-

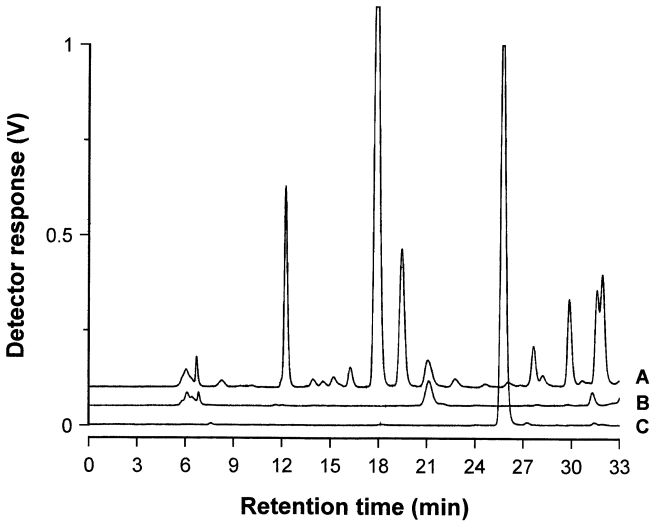

FIG. 1. Metabolism of 13*S*-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid (13-HPOT) by a crude enzyme extract from mung bean seedlings. Products were analyzed by normal-phase high-performance liquid chromatography (HPLC) using a Lichrospher DIOL column (Merck, Darmstadt, Germany) and an evaporative light-scattering detector (ELSD). Trace A: sample (crude enzyme extract plus 13-HPOT); Trace B: control sample (crude enzyme extract without 13-HPOT); Trace C: precursor 13-HPOT. For better presentation of the results an offset of detector response (about 0.1 and 0.05 V) was made for chromatograms A and B.

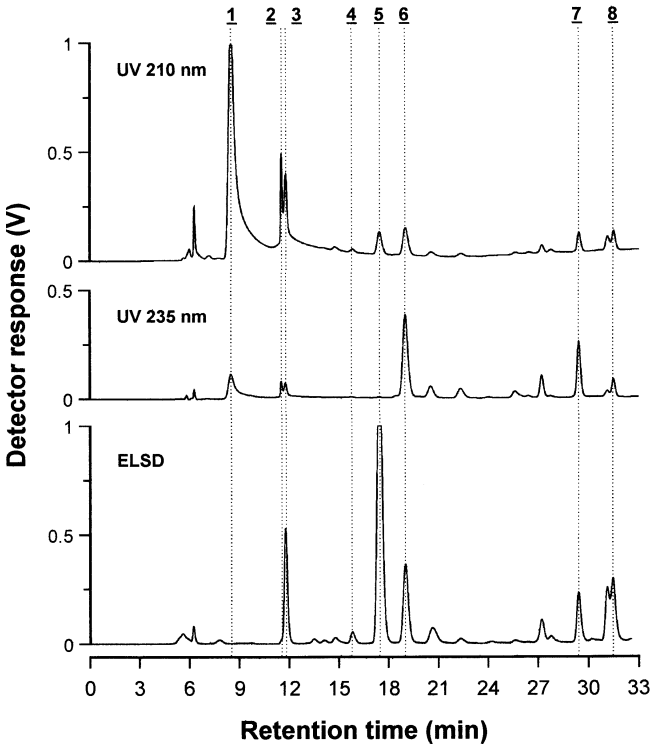

FIG. 2. Representative HPLC chromatograms of 13*S*-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid-derived oxylipins. Metabolites were detected with a diode array detector (DAD) at 210 and 235 nm and with an ELSD connected in series. For better comparability, the ELSD chromatogram, which had a detection time delay of about 0.4 min compared to the DAD, was shifted by this amount toward lower retention times. Peak numbers refer to the identified compounds as described in the text. UV: ultraviolet. See Figure 1 for abbreviations.

lites. A crude enzyme extract from mung bean seedlings was incubated with about 50 µmol 13-HPOT and, after extraction and subsequent methylation, subjected to HPLC analysis. In contrast to a control sample several additional peaks were detected, which could be successfully separated on a diol column (Fig. 1). The gradient elution system was able to resolve 13-HPOT from the products. Metabolites were monitored with a DAD and with an ELSD connected in series (Fig. 2). The wavelength of the DAD was set at 210 nm for the detection of metabolites without a pronounced ultraviolet chromophore and at 235 nm, which represents the absorption maximum of the precursor 13-HPOT (conjugated diene chromophore).

Both detectors differed significantly in their sensitivity for the various compounds (Fig. 2). Compounds **1** and **2**, the predominant peaks in the chromatogram acquired at 210 nm, were not detectable with the ELSD. Conversely, the detector response of the ELSD for compound **5** was about 15 times higher, based on peak area calculations, than the DAD at 210 nm. Such observations are not surprising when one considers the operation principle of an ELSD (22,23). The column effluent is nebulized to form a homogeneous mist of droplets. Subsequently, the aerosol enters a heated tube, where the solvent evaporates leaving a cloud of nonvolatile analyte particles. These particles pass through a light beam, and the scattered light, being proportional to the mass of the analytes, is detected by a photodiode. It follows that analytes, whose differences in volatility compared to the HPLC solvent are too small, cannot be detected with an ELSD or with drastically reduced sensitivity only. Obviously, **1** and **2** were volatile metabolites.

Identification of metabolites. To identify the products, the HPLC system was coupled without any alterations of the chromatographic conditions to a particle beam–mass spectrometer. Principles of LC–PB–MS have been reviewed in detail (24). As the sample inlet system of PB–MS is comparable to the ELSD just described, the ELSD served an important analytical pilot function for the PB–MS: Qualitatively identical chromatographic patterns were obtained with both detection systems. As a result, compounds which were detected with the ELSD were also present in the PB–MS chromatogram (not shown) and vice versa.

Because of their volatility, compounds **1** and **2** were not detectable by PB–MS and could not be identified by this way. Their structure was elucidated by GC–MS after collection of the HPLC effluent at about 9 and 12 min. Retention time and EI mass spectrum of **1** were identical to reference 2*E*-hexenal. GC–MS analysis of the second collected HPLC fraction (compounds **2** and **3**) revealed the presence of two peaks, which were identified as methyl 12-oxo-10*E*-dodecenoic acid (methyl 12-oxo-DDA) and methyl 12-oxo-phytodienoic acid (methyl 12-oxo-PDA). The EI mass spectrum of methyl 12-oxo-DDA

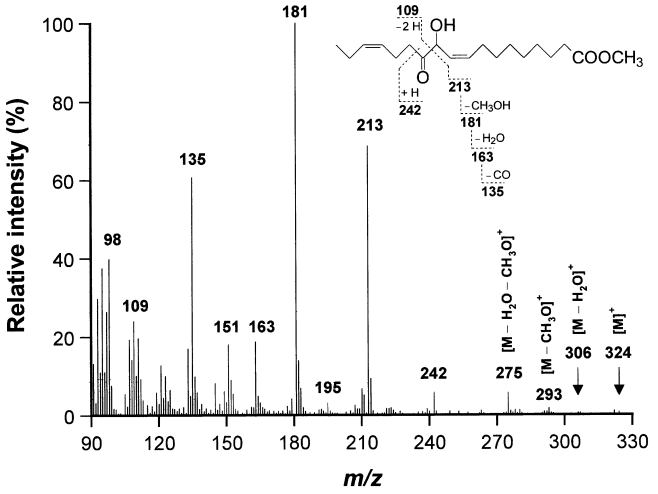

FIG. 3. HPLC particle beam mass spectrum (electron impact) and proposed fragmentation pattern of methyl 11-hydroxy-12-oxo-9*Z*,15*Z*-octadecadienoate. Ionization energy 70 eV. See Figure 1 for abbreviation.

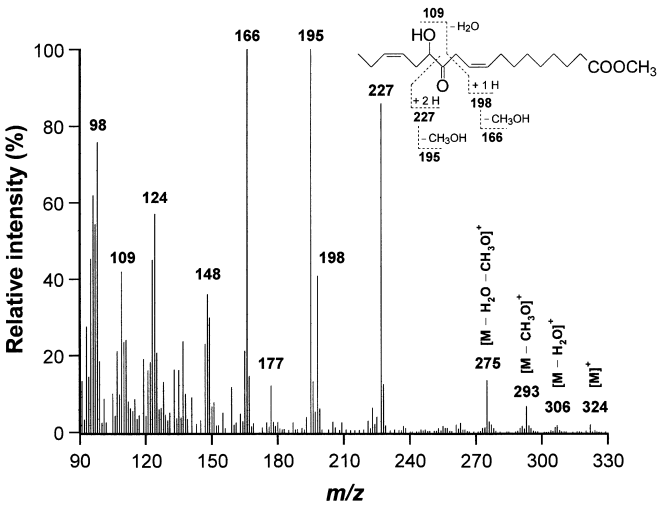

FIG. 4. HPLC particle beam mass spectrum (electron impact) and proposed fragmentation pattern of methyl 12-oxo-13-hydroxy-9*Z*,15*Z*-octadecadienoate. Ionization energy 70 eV. See Figure 1 for abbreviation.

was in agreement with that reported earlier (25). Methyl 12-oxo-PDA furnished an EI mass spectrum consistent with (26).

An exact assignment of these compounds to peak **2** or **3** in Figure 2 was difficult, because both occurred in the same HPLC fraction owing to their similar retention times. Therefore, methyl 12-oxo-DDA was isolated by micropreparative GC and used to determine its HPLC retention time. From this experiment and from cochromatography with the sample, the identity of peak **2** as methyl 12-oxo-DDA was demonstrated unambiguously.

EI and CI mass spectra of compounds **3**–**8** were recorded by PB–MS within a scan range of *m/z* 88–450 (exclusion of ions from the HPLC eluent). In addition, metabolites **4**–**8** were collected from the HPLC effluent and converted into trimethyl silylether derivatives with and without prior preparation of methyl oximes to obtain further proof of the position of keto and/or hydroxyl groups. GC–mass spectra of the derivatives were in agreement with the proposed structures (not all data shown). The CI mass spectrum [*m/z* (ion structure, percentage relative intensity)] of **3**, which was already identified by GC–MS as methyl 12-oxo-PDA, exhibited the expected quasi molecular ion *m/z* 307 ($[M + H]^+$, 100), methane adducts at *m/z* 335 ($[M + C_2H_5]^+$, 18), and 347 ($[M + C_3H_5]^+$, 6), and a peak at *m/z* 275 ($[M + H - CH_3OH]^+$, 17).

Figure 3 presents the EI mass spectrum of **4**. It showed clear similarities to the fragmentation pattern of 11-hydroxy-12-oxo-9*Z*,15*Z*-octadecadienoic acid (11,12-α-ketol) previously reported (8), indicating that **4** might be the methyl ester derivative. The CI mass spectrum consisted of ions at *m/z* 325 ($[M + H]^+$, 100), 307 ($[M + H - H_2O]^+$, 76), 293 ($[M + H - CH_3OH]^+$, 23), and 275 ($[M + H - H_2O - CH_3OH]^+$, 45) and supported the structure of **4** as methyl 11,12-α-ketol.

Metabolite **5** was identified as methyl 12,13-α-ketol. Its EI mass spectrum (Fig. 4) was in agreement with Reference 19. The molecular weight of **5** was confirmed by the CI mass spectrum (Fig. 5) showing an ion at *m/z* 325 ($[M + H]^+$, 19). Methyl 12,13-α-ketol underwent extensive elimination of water to form the most abundant ion at *m/z* 307 ($[M + H - H_2O]^+$, 100).

Compound **6** was characterized as methyl 13*S*-hydroxy-9*Z*,11*E*,15*Z*-octadecatrienoate (methyl 13-HOT). The EI mass spectrum presented peaks at *m/z* 308 ($[M]^+$, 1), 290 ($[M - H_2O]^+$, 7), 277 ($[M - CH_3O]^+$, 3), 239 ($[M - CH_3CH_2CH{=}CHCH_2]^+$, 66), 207 ($[M - CH_3CH_2CH{=}CHCH_2 - CH_3OH]^+$, 100), 189 ($[M - CH_3CH_2CH{=}CHCH_2 - CH_3OH - H_2O]^+$, 20), 171 (35), 147 (44), 95 (41), and 93 (43). The CI mass spectrum of **6** possessed an ion only at *m/z* 291 ($[M - H_2O + H]^+$, 100), due to elimination of water. Methane adducts were at *m/z* 319 ($[M - H_2O + C_2H_5]^+$, 7) and 331 ([M

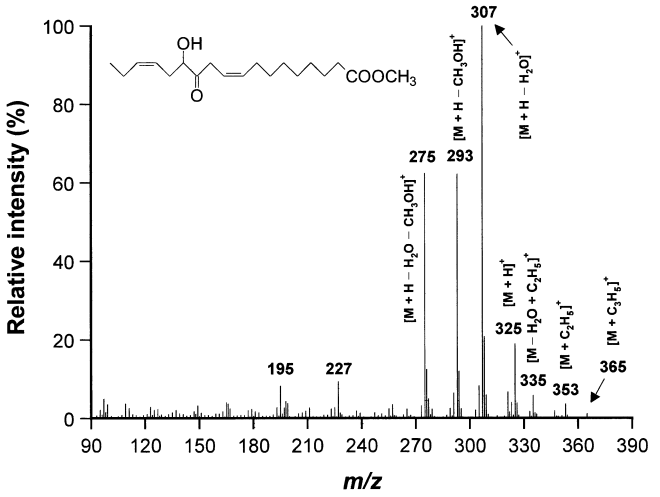

FIG. 5. HPLC particle beam mass spectrum (chemical ionization) and proposed fragmentation pattern of methyl 12-oxo-13-hydroxy-9*Z*,15*Z*-octadecadienoate. Chemical ionization was performed with methane gas as reactant gas. Ionization energy 100 eV. See Figure 1 for abbreviation.

– $H_2O + C_3H_5]^+$, 2).

Metabolite **7** showed fragment ions at *m/z* 324 ($[M]^+$, 2), 306 ($[M - H_2O]^+$, 3), 275 ($[M - CH_3O - H_2O]^+$, 6), 239 ($[HC(OH)CH{=}CHCH{=}CH(CH_2)_7COOCH_3]^+$, 8), 237 (11), 207 ([*m/z* 239 – $CH_3OH]^+$, 27), 189 ([*m/z* 239 – CH_3OH – $H_2O]^+$, 7), 167 ($[M - (CH_2)_7COOCH_3]^+$, 20), 149 ([*m/z* 167 – $H_2O]^+$, 28), 135 (27), 128 (29), 121 (29), 109 (44), and 95 (100), suggesting a methyl 13-hydroxy-9,11-octadecadienoate with an additional oxygen atom. The CI mass spectrum had ions at *m/z* 325 ($[M + H]^+$, 5), 307 ($[M - H_2O + H]^+$, 65), 291 (48), 289 (45), 239 (100), 207 (37). A reliable identification was difficult until **7** was collected from the HPLC effluent and subsequently its trimethyl silylether derivative was prepared. The GC-mass spectrum (EI) obtained was qualitatively consistent with Reference 27. However, the ion intensities differed, because the spectrum published was recorded at an ionization energy of 16 eV only. From these findings **7** most likely represents methyl 13-hydroxy-15,16-epoxy-9*Z*,11*E*-octadecadienoic acid (methyl 15,16-EHOD).

The EI mass spectrum of **8** was similar at higher *m/z* values to the methylated ketols described before, indicating that **8** might also be a methylated ketol. Fragment ions of **8** were at *m/z* 324 (M^+, 2), 306 ($[M - H_2O]^+$, 3), 293 ($[M - CH_3O]^+$,7), 292 ($[M - CH_3OH]^+$, 6), 275 ($[M - CH_3O - H_2O]^+$, 10), 223 (9), 209 (14), 187 ($[HC(OH)(CH_2)_7COOCH_3]^+$, 29), 155 ([*m/z* 187 – $CH_3OH]^+$, 28), 137 ([*m/z* 187 – $CH_3OH - H_2O]^+$, 75), 111 ($[CH_3CH_2CH{=}CH(CH_2)_2CO]^+$, 48), and 95 (100). As mentioned in the introduction, the hydrolysis of the allene oxide 12,13-EOT is regularly accompanied by the formation of a 9,12-γ-ketol. Indeed, diagnostic ions at *m/z* 187 and 137 indicated that a hydroxyl group might be located at C_9. The position of the keto group was tentatively located at C_{12} owing to the ion at *m/z* 111. In CI mass spectrometry the quasi molecular ion of **8** was at *m/z* 325 ($[M + H]^+$, 100). Elimination of water and methanol resulted in peaks at *m/z* 307 ($[M + H - H_2O]^+$, 27), 293 ($[M + H - CH_3OH]^+$, 24), and 275 ($[M + H - H_2O - CH_3OH]^+$, 11). The GC–mass spectrum (EI) of trimethylsilylated **8** exhibited diagnostic ions at *m/z* 259 (hydroxyl group at C_9) and 285 (keto group at C_{12}), supporting the assumption that **8** was methyl 9,12-γ-ketol. Trimethylsilylated methyloxime derivative of **8** was consistent with Reference 28.

In summary, all of these products indicate that mainly three enzymes are involved in the metabolism of 13-HPOT in mung beans, namely, a hydroperoxide lyase, an allene oxide synthase, and a peroxygenase (Scheme 1: In this scheme, POX = peroxygenase; HPL = hydroperoxide lyase; ISO = isomerase; AOS = allene oxide synthase; and AOC = allene oxide cyclase.). 2*E*-Hexenal and 12-oxo-DDA originate from the action of a hydroperoxide lyase, a widely distributed enzyme in plants, on 13-HPOT (10–12). Depending on substrate specificity, hydroperoxide lyases cleave either C_9 or C_{13} hydroperoxides of polyunsaturated fatty acids, which contain a 1*Z*,4*Z*-pentadiene moiety, into C_9/C_6 aldehydes and C_9/C_{12} ω-oxo-acids. By using an extract from mung bean seedlings as an enzyme source, the initial cleavage products 3*Z*-hexenal and 12-oxo-9*Z*-dodecenoic acid were rapidly isomerized into the more stable *trans* isomers (unpublished data).

On account of the generation of 12,13-α-ketol and 9,12-γ-ketol, it is obvious that mung beans contain an allene oxide synthase, whose unstable product (12,13-EOT) undergoes immediate hydrolysis. A pathway for the formation of 11,12-α-ketol, which represents a novel hydrolysis product of 12,13-EOT, and of the other ketols has been proposed (8). 12-Oxo-PDA originates from the cyclization of the allene oxide. Since the enantiomeric composition of 12-oxo-PDA was not determined, it is unknown whether its cyclization occurs enzymatically, catalyzed by an allene oxide cyclase (4), or spon-

TABLE 1
Metabolism of 13-Hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic Acid (13-HPOT) by Mung Bean Seedlings[a]

Peak Number[b]	Metabolite	Amount (μmol)	Conversion rate (%)
1	2*E*-Hexenal	27.25	48.8
2	12-Oxo-10*E*-dodecenoic acid	n.d.	n.d.
3	12-Oxo-phytodienoic acid	2.05	3.7
4	11-Hydroxy-12-oxo-9*Z*,15*Z*-octadecadienoic acid	< 0.40	< 0.7
5	12-Oxo-13-hydroxy-9*Z*,15*Z*-octadecadienoic acid	3.36	6.0
6	13-Hydroxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid	1.22	2.2
7	15,16-Epoxy-13-hydroxy-9*Z*,11*E*-octadecadienoic acid	0.77	1.4
8	9-Hydroxy-12-oxo-10*E*,15*Z*-octadecadienoic acid	0.90	1.6

[a]A crude enzyme extract from mung bean seedlings was incubated with 55.8 μmol 13-HPOT at pH 6.5. Products were extracted with pentane/diethyl ether, methylated, and quantified by high-performance liquid chromatography–evaporative light-scattering detection as described in the Materials and Methods Section. 2*E*-Hexenal was determined by gas chromatographic analysis.
[b]Number of methylated metabolite in Figure 2. n.d.: not determined

taneously leading to the racemate.

A reduction of fatty acid hydroperoxides (13-HPOT, 13-HPOD) to the corresponding alcohols (13-HOT, 13-HOD) can be mediated by a peroxygenase (27) or a hydroperoxide-dependent epoxygenase (29). The terminal oxygen of the hydroperoxide group is transferred by an intermolecular and/or intramolecular mechanism to a substrate (e.g., unsaturated fatty acids, 13-HOT), which serves as oxygen acceptor, yielding hydroxy and concomitantly epoxy or epoxyhydroxy fatty acids (27,29). Indeed, the detection of 15,16-EHOD strongly implies the presence of a peroxygenase in mung beans. In a seed extract of soybean, a formation of 15,16-EHOD has also been reported (30). However, it cannot be excluded that 13-HOT is additionally generated by a nonenzymatic way. Incubation experiments performed in a phosphate–citrate buffer containing 10 mM ascorbic acid (to inhibit polyphenol oxidase) led to a 13-HOT concentration which was 2.8 times higher compared to a buffer without ascorbic acid, whereas the content of 15,16-EHOD was not affected (Rehbock, B., Gansser, D., and Berger, R.G., unpublished data). This suggests that reductants also are able to convert hydroperoxides into the corresponding alcohols.

Quantification of 13-HPOT-derived metabolites. Oxylipins were quantified with the ELSD based on the assumption that structurally similar compounds with nearly identical molecular weight caused the same detector response. Owing to a lack of reference substances, the detector was calibrated with methyl ricinoleate (methyl 12-hydroxy-9*Z*-octadecaenoate) and *n*-heptyl jasmonate. Methyl ricinoleate possesses most of the structural features of the methylated noncyclic oxylipins such as a hydroxyl group, double bond, and equivalent carbon-chain length. Similarly, the content of the cyclopentenoic fatty acid 12-oxo-PDA was calculated according to a calibration curve obtained with *n*-heptyl jasmonate (ratio *trans*/*cis* isomer: 95:5) to consider its cyclic structure. The GC–mass spectrum (EI) of the *trans* isomer [*m/z* (percentage relative intensity)] showed prominent ions at 308 ($[M]^+$, 41%), 290 (9), 261 (14), 240 (8), 210 (6), 193 (8), 192 (7), 191 (6), 164 (10), 163 (11), 151 (100), 150 (27), 83 (50), 57 (38), 55 (43), 43 (38), 41 (66), and of the *cis* isomer at *m/z* 308 ($[M]^+$, 41%), 290 (27), 261 (36), 240 (10), 210 (5), 193 (10), 192 (15), 191 (16), 164 (12), 163 (16), 151 (86), 95 (44), 83 (75), 57 (62), 55 (62), 43 (57), and 41 (100).

Both calibration curves exhibited a small range of linearity; beyond this range the curves became more and more sigmoidal. In the case of methyl ricinoleate, the detector response was linear from 10 to 70 μg/mL (injection volume: 20 μL). The linear regression equation (n = 10 data points), concentration (X) vs. peak area (Y), followed $Y = 4.19 \times 10^5 \times X - 3.78 \times 10^6$ (r = 0.999). In comparison to a calibration curve with methyl 13-HPOT, a nearly identical slope and intercept were achieved (data not shown), supporting the assumption that structurally related compounds possess the same detector response.

The slope and intercept of the curve for *n*-heptyl jasmonate varied markedly from that just described. The linear regression equation (n = 8 data points) was $Y = 2.73 \times 10^5 \times X - 5.41 \times 10^6$ (r = 0.995). Linearity of detector response comprised a range of 20–90 μg/mL (injection volume: 20 μL). Detection limits for *n*-heptyl jasmonate and methyl ricinoleate were at about 100 and 50 ng on column.

Based on these calibration curves the content of oxylipins, which were generated during the incubation of 13-HPOT with a crude enzyme extract from mung bean seedlings, was calculated. Additionally, 2*E*-hexenal was determined by gas chromatographic analysis. Results are summarized in Table 1. The high conversion rate of 13-HPOT into 2*E*-hexenal (48.8%) indicated that mung beans contain a considerable hydroperoxide lyase activity (Rehbock, B., Gansser, D., and Berger, R.G., manuscript in preparation), whereas the amount of oxylipins was relatively low (sum 14.9%). Although 13-HPOT was completely converted (Fig. 1, Trace A, no peak at 25.8 min), there remained a difference of about 36% in the balance. A probable explanation is the formation of one or several other products detectable by neither GC nor HPLC analysis. A control experiment in the absence of plant material revealed that a milky, solvent-insoluble precipitate was formed upon incubation and subsequent extraction of the precursor 13-HPOT. GC and HPLC chromatograms contained only traces of nonidentified products.

In conclusion, the HPLC system described in this study al-

lowed quantification and identification of methylated oxylipins and of the precursor 13-HPOT without additional derivatization. The application of an ELSD for HPLC analysis of oxylipins represented a significant improvement in sensitivity compared to an ultraviolet detector, especially in the case of the 12,13-α-ketol. In combination with the determination of volatile compounds by GC, this method proved to be an efficient tool for investigating the broad product spectrum of fatty acid hydroperoxide metabolism.

ACKNOWLEDGMENTS

The authors are greatly indebted to H.W. Gardner, National Center for Agricultural Utilization Research, Peoria, Illinois, USA, for providing mass spectrometry spectra and to M. Hamberg, Karolinska Institutet, Stockholm, Sweden, for helpful correspondence. This work was supported by the EU project AIR3-CT94-2060 and by the Fonds der Chemischen Industrie, Frankfurt.

Use of an Improved Internal-Standard Method in the Quantitative Sterol Analyses of Phytoplankton and Oysters

Parthasarathi Ghosh[a], Glenn W. Patterson[a,*], and Gary H. Wikfors[b]

[a]Department of Plant Biology, University of Maryland, College Park, Maryland 20742, and [b]NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford, Connecticut 06460

ABSTRACT: Most work reporting the sterol composition of living organisms has not been done quantitatively, although good quantitative data are available for fatty acids and many other cellular components using an internal-standard method that compensates for errors during gas chromatographic analysis. In this paper, we report on the use of 7-stigmastenyl acetate as an internal standard for sterol analysis in two species of phytoplankton and oysters produced with two different diets. This internal-standard method provides an internal standard for this entire process of analysis, not just the gas chromatographic analysis. When analyzing 50-μg samples of cholesterol acetate after hydrolysis and acetylation, about 30% of the sample was lost, resulting in a 30% error using the older external-standard method. Using the internal-standard method, the analysis error was less than 2%. Losses of sterol during analysis apparently are greater with plant and animal samples than with pure sterol standards. This internal-standard method was shown to be extremely useful, especially for samples with less than 500 μg of sterol. Finally, the standard error in sterol analysis is much lower when the internal-standard method is used, allowing statistical distinctions that are not possible otherwise. Use of 7-stigmastenyl acetate as an internal standard offers several advantages over the use of cholestane.

Lipids 32, 1011–1014 (1997).

Sterols are essential compounds for most living organisms, and their main role is as architectural components of membranes, as precursors of hormones, vitamins and bile acids, etc. (1). It is important therefore to quantitate sterols accurately from either plant, microbial, or animal tissues. In the past, total sterols were reported mainly on a weight basis, but after the advent of analysis by gas chromatography (GC), individual sterols were reported mainly as a percentage of total sterol on the recorded chromatogram.

The quantitative relationship between various sterols is important, but data on the quantity of total sterols on a weight or per-cell basis is lacking in most publications. Even when these data are calculated using an external quantitative standard, frequently a large error results because loss of sample during the analytical procedure is not accounted for. With the advent of capillary GC many analyses are performed with sample sizes in the milligram or even microgram ranges. In our laboratory, such analyses sometimes give highly variable quantitative results, with variability increasing with decreasing sample size. The use of cholestane as an internal gas chromatographic standard compensates for some of the error inherent in gas chromatographic analysis, but many potentially greater errors remain unaddressed (from saponification, extraction, purification and derivatization procedures prior to GC).

We have discovered that the quantity of sterols in phytoplankton species greatly affects their effectiveness as oyster food (2). The types and magnitude of variability in analyses of sterols from small samples noted above were not acceptable. Fortunately, this problem was addressed and solved some years ago in fatty acid analysis as follows: A known quantity of a fatty acid known to be absent in the sample is added to the sample as an internal standard prior to extraction and isolation of fatty acids. The amounts of other fatty acids present in the sample are calculated relative to the known quantity of the internal standard. Fatty acids have different response factors on GC depending upon chain length and unsaturation, and this is also taken into account (3). The internal-standard method also has been used for many years in medical analyses for cholesterol, especially for plasma cholesterol analysis (4–6), but it has not been adapted for sterol analysis of plant or animal tissues. The accuracy of sterol analyses from small samples would appear to be improved greatly by using an internal-standard system for the total analysis, not just the gas chromatographic analysis. This paper is an evaluation of an internal-standard method for sterol analyses in small samples.

MATERIALS AND METHODS

The purpose of our internal standard is to sustain losses proportionate to those of the sample during processing and analysis so that mathematical compensation can be made for the losses. The structure of the internal standard therefore should

*To whom correspondence should be addressed.

Abbreviations: GC, gas chromatography; T-ISO, *Isochrysis*; TTM, *Tetraselmis maculata*.

be as near as possible to the sterols being analyzed and yet not interfere with the final gas chromatographic analysis.

Selection and preparation of the internal standard. In our work with phytoplankton and oysters, a great variety of sterols is encountered. In red algae, for instance, many species have only C-27 Δ^5-sterols while green algae may have 27-, 28-, or 29-C sterols with various double-bond systems (7). Although a different standard must be used with some algae, most of them can be analyzed with the acetate of 7-stigmastenol (24-ethyl-5α-cholesten-7-3β-ol) as the internal standard, because it elutes after most sterol acetates on GC. (We use acetate derivatives since they chromatograph better on SPB-1 than free sterols.)

Unfortunately, 7-stigmastenyl acetate is not commercially available; it was obtained for this work by isolation of spinasterol from squash (8) seed. 7-Stigmastenyl acetate was prepared by hydrogenation of the acetate of spinasterol (24-ethyl-5α-cholesta-7,22-dien-3β-ol) over Raney nickel (Aldrich, Milwaukee, WI). Pure spinasteryl acetate (50 mg) in 25 mL ethyl acetate and 1 g Raney nickel (Aldrich) were hydrogenated for 24 h (1 atm, 25°C). Removal of catalyst and evaporation of the solvent yielded a mixture of steryl acetates which were purified by column chromatography over Anasil B (Analabs, Hamden, CT), eluting with 1% ether in hexane followed by recrystallization from methanol. This steryl acetate mixture contained 7-stigmastenyl acetate (93%) and 8(14)-stigmastenyl acetate (7%). It was reported previously that spinasteryl acetate and 7-dehydrostigmasteryl acetate, when hydrogenated by Raney nickel, always gave 8(14)-sterol as the principal product but that the addition of a little triethylamine prevented the formation of 8(14)-sterol (9,10). In these experiments, more than 90% of the hydrogenation product of spinasteryl acetate was 7-stigmastenyl acetate, with or without the addition of triethylamine; with the addition of triethylamine, a small amount of 8(14),22 always formed. In the course of hydrogenation, the 8(14),22 compound was converted to the 8(14) sterol. Pure 7-stigmastenyl acetate was obtained by further column chromatography on Anasil B.

Accuracy of analyses using internal and external standards and effect of sample size. From freshly prepared solutions of cholesteryl acetate and 7-stigmastenyl acetate, 10 samples were prepared to contain 50 µg of each sterol acetate. The solvent was evaporated and the samples were saponified for 1½ h with 1 M KOH in 80% aqueous ethanol at 65°C. Solvent was evaporated to reduce volume by one-half, and a few milliliters of H_2O were added. Sterols were extracted three times into *n*-hexane in a separatory funnel, fractions were combined, evaporated to dryness, dissolved in *n*-hexane, and chromatographed on a Sep-Pak (Waters Associates, Milford, MA) silicic acid cartridge with 2-mL elutions by *n*-hexane, chloroform, diethyl ether, and methanol. Sterols were eluted by diethyl ether and chromatographed as acetates [prepared by dissolving in pyridine/acetic anhydride (1:1) at room temperature overnight] on a Varian 3500 capillary gas chromatograph with an SPI injector and a Varian 4400 integrator (Palo Alto, CA). The injector received the sample at 95°C and was programmed to 300°C at 180° per min. The column was a 0.25 mm × 30 m fused-silica column with a 0.25-µm film of SPB-1. During chromatography, the column was programmed from 150–260°C at 10°C/min and held for 30 min. This experiment was repeated with samples of other quantities to determine how sample size affects percentage recovery.

Sterol analysis in Phaeodactylum *and* Tetraselmis *using the 7-stigmastenyl acetate internal standard.* Phytoplankton samples were from bacteria-free carboy cultures harvested in an N-deficient stationary phase. Freshly prepared 7-stigmastenyl acetate (250 µg) was added to a lyophilized sample of *Phaeodactylum tricornutum* (strain Phaeo) which was then extracted overnight in $CHCl_3/CH_3OH$ (2:1, vol/vol) using a Soxhlet extractor. The extract was divided into five aliquots, and the solvent was evaporated. Saponification, extraction of sterols, and acetylation of sterols and analysis on GC were as described previously except that extraction of sterols from the saponification mixture was better achieved with diethyl ether as compared to hexane.

Oyster analyses using the internal-standard method. Oysters analyzed had been fed a unialgal diet of either *Tetraselmis maculata* (strain TTM) or *Isochrysis* sp. (strain T-ISO) for 12 wk in molluscan rearing chambers at the Milford Laboratory (National Marine Fisheries Service, Milford, CT) (11). The internal standard of 150 µg of 7-stigmastenyl acetate was added to homogenized, fresh oyster tissue and refluxed in $CHCl_3/CH_3OH$ (2:1, vol/vol) for 8 h followed by filtration to remove the tissue (removal of tissue at this point improves the recovery of sterols). Saponification or other treatment of the tissue did not improve recovery. The crude extracts were divided into three aliquots, and the solvent was evaporated for saponification and further sterol isolation as described above.

RESULTS AND DISCUSSION

Cholesteryl acetete (50 µg) was saponified in the presence of the 7-stigmastenyl acetate internal standard, recovered, and reacetylated. This experiment allowed us to determine the accuracy and precision of our analysis with 10 replicates using an external-standard method vs. the internal-standard method. The external-standard method calculates the amount of cholesteryl acetate in the recovered sample by comparing the area of the recovered cholesteryl acetate on GC to the area of a known quantity of cholesteryl acetate. The problem with this method is that it does not account for the sample lost in the saponification–extraction–derivatization procedure. In the internal-standard method, the amount of cholesteryl acetate is calculated by comparing the area of the cholesteryl acetate peak with the area of the internal-standard peak (a known quantity). This method presumes that the relative losses of cholesteryl acetate and the internal standard are the same. When 5α-cholestane is the internal standard (6), the validity of this presumption is questionable since the recovery rate of a hydrocarbon and a sterol from an alkaline aqueous alcohol mixture should not be expected to always be similar.

In the experiments described above, 50-μg samples of cholesteryl acetate were saponified in the presence of 50 μg of the internal standard; then the cholesterol and 7-stigmastenol were recovered and acetylated as described. Data obtained by the internal-standard method had a lower standard error than those obtained by the external-standard method. This is because variable recoveries cause data scatter in the external-standard method while variable recoveries do not affect quantitative values in the internal-standard method. Analysis by the external-standard method shows 35.21 ± 1.37 μg of cholesteryl acetate in our 50-μg sample, while the internal-standard method reports 50.87 ± 0.70 μg.

In this experiment, the value obtained by the internal-standard method (50.87 ± 0.70 μg) is in error from the true value (50 μg) by only 1.8% while the value obtained by the external-standard method (35.21 ± 1.37 μg) is in error by 29.6%. The internal-standard value is more accurate and more precise, with smaller standard error (±0.70 vs. ±1.37). Other sample sizes were used to determine the effect of sample size on recoveries of cholesteryl acetate after saponification. Cholesteryl acetate samples of 500, 250, 100, 50, 25, 10, and 5 μg were saponified, and cholesteryl acetate recoveries were determined. Recoveries in the above series were 91, 87, 76, 69, 50, and 26%, respectively. Clearly, in this range of sample size, percentage losses increase as the sample size decreases, meaning that the external-standard method becomes more and more inaccurate as the sample size decreases below 500 μg.

Lyophilized samples of *P. tricornutum* (Phaeo) and *T. chui* (PLY-429) were extracted, and five aliquots of *Phaeodactylum* and three aliquots of *Tetraselmis* were taken for analysis by the two methods described above. Using the internal-standard method, the sterol composition of *Phaeodactylum* was 283.2 fg/cell (SE 1.1, $n = 5$) compared to 125.2 fg/cell (SE 3.1, $n = 5$) by the external-standard method. In *Tetraselmis* the sterol composition was 192.2 fg/cell (SE 1.8, $n = 3$) by the internal-standard method compared to 83.3 fg/cell (SE 8.5, $n = 3$) by the external-standard method. The amount of sterol recovered from each sample analyzed (as determined by the external-standard method) was 50 μg for *Phaeodactylum* and 83 μg for *Tetraselmis*. In a sample size of 100 μg of cholesteryl acetate (previous section), sample recoveries of about 75% were recorded. The much lower values recorded here by the external-standard method (44.2% from *Phaeodactylum* and 43.8% from *Tetraselmis*) may indicate that sample recoveries from saponified biological samples may be reduced compared to those in pure steryl acetate saponifications because of interference of biological compounds in the efficient extraction of sterols from saponification mixtures. Accordingly, the errors encountered with analyses of biological samples using the external-standard method may be much greater than they were calculated to be using pure cholesteryl acetate.

Extraction of sterols from fresh animal tissue is handled differently from that of dry phytoplankton, but the internal-standard method can be used to advantage here also. Six small individual oysters (each less than 100 mg fresh weight) were analyzed by each of our methods. Three oysters had been grown on a diet of *Isochrysis* (T-ISO), while the other three had been grown on a diet of *T. maculata* (TTM) for 12 wk. These two phytoplankton have very different sterol compositions with T-ISO having brassicasterol as about 99% of its total sterol and cholesterol present in traces (12). By contrast, TTM has 24-methylcholesterol as its major sterol, with much smaller amounts of 24-methylenecholesterol and cholesterol (13). The wild oyster contains nearly 40 sterols (14) with cholesterol, brassicasterol, 24-methylenecholesterol, and several other sterols as major components. The sterols of T-ISO-fed and TTM-fed oysters strongly reflected the sterols of their diet in agreement with the work of Berenberg and Patterson (15). In the oyster samples, the amount of sterol actually recovered using the external-standard method was in the range of 35–75 μg. The external-standard method reports values of 55 and 58% of the internal-standard values for sterol recovery for TTM-fed oysters and T-ISO-fed oysters, respectively. Here again the external-standard method clearly is inferior to the internal-standard method. The discrepancy between the two methods is not so great in the oyster samples as in the phytoplankton, even though the sterol sample is smaller with the oyster. A large lipid fraction (dry weight basis) and potentially more interfering substances in the extraction process in phytoplankton could be an explanation.

It is interesting to note that, in using the internal-standard method, it is possible to say that the total sterol (fresh weight basis) concentration of TTM-fed oysters (1932 μg/g) is greater than that of T-ISO-fed oysters (1777 μg/g). Using the external-standard method with its larger standard error, there are no statistical differences in total sterol concentration in the two sets of oysters (Table 1).

These experiments using the external-standard method and the internal-standard method for estimating the amount of cholesteryl acetate recovered from a saponification mixture show that with a 50 μg sample size the accuracy obtained by the internal-standard method was within 1.8% of the true value, while the error obtained by the external-standard method was 29.6%. The large error in the external-standard method is largely caused by losses of sample during preparation and analysis while the internal-standard method allows us to compensate for those losses. These errors are less with larger and greater with smaller samples with both methods, but the internal-standard method is superior by a wide margain at all levels tested. The advantage of the internal-standard method also is apparent with biological samples where the apparent loss of sample is even greater (with comparable size samples) than with the pure steryl acetate. Finally, the internal-standard method, with its much lower standard error, allows us to make statistical distinctions in sterol compositions of various treatments that we could successfully not do otherwise.

It is important to emphasize that when a steryl acetate such as 7-stigmastenyl acetate is used as an internal standard, it can compensate for errors due to absorption by tissue or glassware, losses due to spillage or air oxidation, or losses encountered in saponification, extraction of sterol from the saponification mixture, or derivatization. Although the traditional in-

[c]μg/g fresh weight. First letter shows results of analysis of variance (ANOVA) comparison ($P = 0.05$) between internal- and external-standard methods. Second letter shows results of ANOVA comparison between oysters fed different algae, using either internal- or external-standard method. A significant difference ($P = 0.02$) in total sterol of oysters fed TTM, as compared to T-ISO, was revealed using the internal-standard method; whereas, there was no significant difference using the external standard.

ternal-standard method was designed to compensate for errors in gas chromatographic analysis, it is obvious that to receive all the benefits of an internal standard listed above, it should (i) be added at the beginning of the analysis, (ii) be structurally similar to the compound being analyzed, and (iii) not interfere with the gas chromatographic analysis.

Although this method appears to be particularly useful for quantitative analysis of sterols from photosynthetic tissue, it should be equally applicable to other biological samples.

REVIEW

High-Resolution Nuclear Magnetic Resonance Spectroscopy —Applications to Fatty Acids and Triacylglycerols

Marcel S.F. Lie Ken Jie* and J. Mustafa

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: During the past two decades, nuclear magnetic resonance spectroscopy (NMR) has played an ever-increasing role in the structural determination of fatty acids, fatty acid derivatives and analogues, and in the analysis of the structures of triacylglycerols including the quantitative analysis of lipid mixtures. This article discusses some of the results obtained through the application of the NMR technique to lipid molecules and reviews the literature. To maintain brevity, this article does not cover the underlying theory of NMR spectroscopy as numerous books devoted to modern NMR spectroscopy have been published.

Lipids 32, 1019–1034 (1997).

Early studies (1–7) of high-resolution ^{1}H nuclear magnetic resonance (NMR) permitted specific structural, kinetic, or equilibrium studies of individual compounds in pure state or in mixtures to be carried out. This technique was first used to determine both the degree of unsaturation in triacylglycerols and the average molecular weight of natural fats (8). Analysis of the positional distribution of fatty acids in triacylglycerols by ^{1}H NMR spectroscopy was performed with the help of shift reagents such as Eu(fod)$_3$, tris-(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato)-europium(III) and Pr(fod)$_3$, tris-(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato)-praseodymium(III) (9–14). These lanthanide shift reagents were Lewis acids with paramagnetic properties, and their action as shift reagents depended entirely on their ability to bind with the molecules as ligands in order to produce large chemical shift changes. Wedmid and Litchfield (10) have identified 2-isovaleroyl and 1,3-isovaleroyl triacylglycerol structures by high-resolution ^{1}H NMR in their studies of isovaleroyl lipids in dolphin, porpoise, and toothed whale fats. Differentiation between unsaturated and isomeric triacylglycerols, such as glycerol 1,3-dipalmitate-2-oleate and glycerol 1,2-dipalmitate-3-oleate, was also feasible by this technique (11,12). Furthermore, positional distribution of linoleate and linolenate chain in triacylglycerols was determined (13). Although this technique could be exploited to reveal structural details of triacylglycerols, the application was limited by the broadening of signals when shift reagents were used and handicapped by the narrow proton magnetic resonance range.

Taking advantage of the development of digital computers, pulse Fourier transform techniques and the availability of superconducting magnets, ^{13}C NMR technique complemented ^{1}H NMR technique in many ways. The natural abundance of ^{13}C (1.1%) in nature was compensated by the low possibility of ^{13}C-^{13}C spin-spin coupling and by broadband heteronuclear decoupling (i.e., elimination of all ^{1}H-^{13}C couplings) which resulted in sharp singlets for all ^{13}C absorptions, permitting small chemical shift differences to be measured. With advanced electronic techniques, it was also possible to run a ^{13}C NMR spectrum under conditions that allow for a quantitative integral, as in the case of ^{1}H NMR. Gated decoupling was used to remove the nuclear overhauser enhancement, and longer pulse delays were used to allow ^{13}C nuclei with long spin-lattice relaxation time to relax completely. These techniques required long experimental time (i.e., >12 h) to obtain a spectrum with suitable signal-to-noise ratio. However, with the use of relaxation reagents, such as tris-(acetylacetonato)-chromium(III) [Cr(acac)$_3$], the total time for collecting a spectrum was shortened to 1–2 h. (Note: relaxation reagents are paramagnetic substances capable of greatly reducing the relaxation times of substrate nuclei without inducing noticeable shifts.) The quantitative applications of ^{13}C NMR spectroscopy on lipid molecules were reviewed by Shoolery (15) with which the iodine values of fats and oils were determined accurately. As a complement to ^{1}H NMR, ^{13}C NMR offered a means of determining the composition of mixtures of fatty acids and lipid molecules in much greater detail. Gunstone published several valuable reviews, which dealt specifically with the use of high-resolution ^{13}C NMR technique in the analysis of lipid mixtures (16–19).

High-resolution ^{1}H NMR spectroscopy has had limited use in fatty acid analysis owing to the small range of chemical shifts covered by protons, which resulted in the small number of signals in the proton spectrum. The splitting patterns of proton signals, however, can provide unique structural properties of lipid molecules under investigation (20). ^{13}C NMR

spectra of fatty acids provided a large number of signals spread over a wide range of chemical shifts, which made the spectrum appear complicated but much more informative. Techniques of correlating signals between ^{1}H and ^{13}C NMR spectra provided two-dimensional correlation spectra (2D COSY), which permitted confirmation of signals. Other techniques, such as INADEQUATE (incredible natural abundance double quantum transfer experiment), HSQC (heteronuclear single quantum correlation), HMQC (heteronuclear multiple quantum correlation) and HMBC (heteronuclear multiple bonds correlation), are some of the latest techniques in NMR spectroscopy from which structural details can be derived in great detail. Many of these NMR experiments can be readily carried out with the latest models of high-field NMR instruments, and such operations have become more and more common in the past 5 yr.

STUDIES OF INDIVIDUAL UNSATURATED FATTY ACIDS AND ESTERS

Olefinic fatty acids. Many long-chain unsaturated fatty acids are claimed to have been "identified" by gas–liquid chromatography. However, in such analyses, it is often presumed that the unsaturated centers of the fatty acids are located at the common position(s) of the alkyl chain, such as the Δ^{9} (oleic acid) and $\Delta^{9,12}$ (linoleic acid) positions. Fatty acids with double bonds in other positions cannot be readily determined from their gas chromatography retention times (21). Application of other analytical techniques, such as chemical oxidation, infrared and ultraviolet spectroscopy and mass spectrometry, are therefore necessary to establish the positions and the configurations of the unsaturated centers in the alkyl chain (22–25).

The high resolving power of ^{13}C NMR spectroscopy allows many of the positional isomers of long-chain fatty acids or esters to be differentiated. For example, in the spectrum of methyl oleate (Fig. 1), the shifts of the olefinic carbon atoms appear at δ_C 129.76 and 130.01 for the C-9 and C-10 carbon atoms, respectively. The terminal methyl carbon shift (C-18) is found at δ_C 14.13, while the carbonyl carbon of the ester function (C-1) gives rise to a signal at δ_C 174.31. The methyl carbon of the ester appears at δ_C 51.46. Four methylene groups are readily identified: δ_C 34.12 (C-2), 24.98 (C-3), 31.94 (C-16), and 22.72 (C-17). The allylic carbon atoms adjacent to the *cis*-double bond are found at δ_C 27.26 and 27.19 (C-8 and C-11). The remaining methylene carbon shifts are more difficult to identify because they are clustered within a small region of the spectrum at about δ_C 29.12–29.80 (often referred to as the "methylene envelope"). In the case of methyl petroselinate, 18:1(6*c*) [where the first number denotes the chain length of the fatty acid, the number after the colon denotes the number of unsaturation, and the number within the parentheses indicates the position of the unsaturation, *c* for *cis*, *t* for *trans,* and *a* for acetylene (Fig. 2)], the

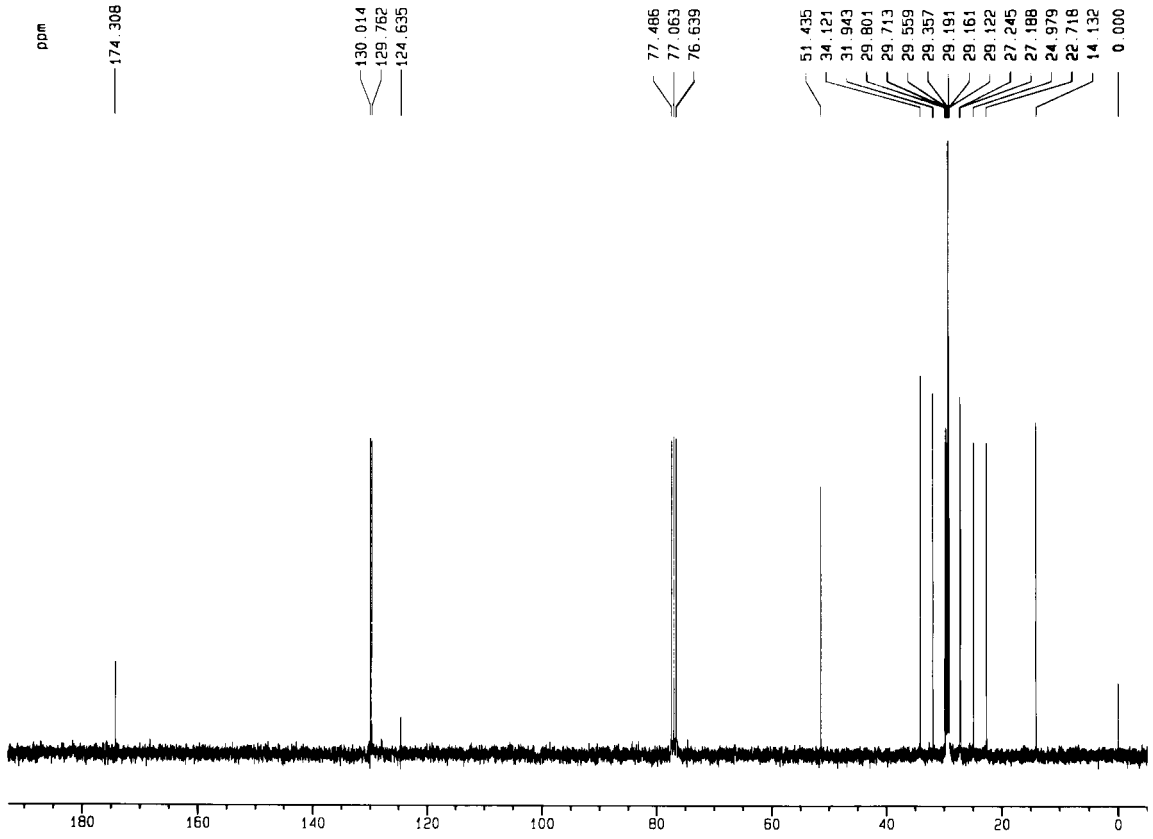

FIG. 1. ^{13}C nuclear magnetic resonance (NMR) spectrum of methyl oleate, 18:1(9*c*); *c, cis.*

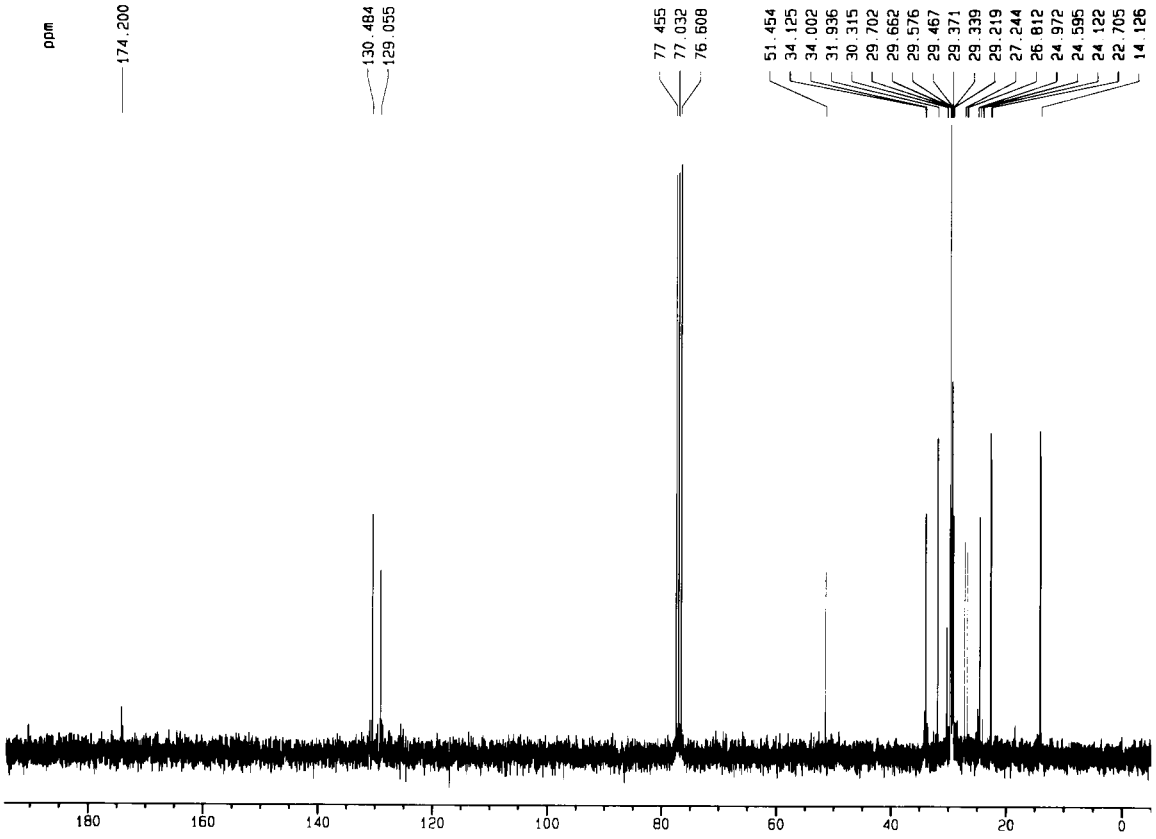

FIG. 2. ^{13}C NMR spectrum of methyl petroselinate, 18:1(6*c*). See Figure 1 for abbreviations.

shifts of the olefinic carbon atoms appear at δ_C 130.48 and 129.06 for the C-6 and C-7, respectively. The difference of these two chemical shift values appears quite constant and is characteristic of the said positional isomer, which allows such data to be used for the location of the position of the olefinic system in the alkyl chain (Δ^6 position in this case). The rest of the signals are similar to those of methyl oleate for the shifts of the corresponding carbon nuclei.

Bus *et al.* (26,27) studied hundreds of fatty acid methyl esters with *cis*- and *trans*-double bonds and triple bonds at various positions and in many different combinations in the alkyl chain. A comprehensive set of chemical shift parameters has been developed for the various substituents. With the aid of these parameters, the chemical shifts of all methyl, methylene, and carbonyl carbon nuclei can be predicted with a high degree of accuracy. A similar approach has been adopted by Gunstone *et al.* (28) in the study of the carbon chemical shifts of more than 90 *cis*- and *trans*-long-chain alkenoic acids. In the case of medium-chain fatty esters, such as the positional isomers of methyl *cis*-undecenoate, the shifts of the olefinic carbon atoms are all fully resolved, and each isomer can be identified by this technique. In the longer chain series, *viz.* methyl octadecenoate isomers (18:1), the olefinic carbon atoms can be marginally resolved as far away as the Δ^{11} position from the carboxylate end. One characteristic feature of the carbon shift data of these positional isomers is that the difference between the shift values of the two olefinic carbon nuclei diminishes gradually with distance of the olefinic system from the carboxylate end. By studying these minute differences, it is possible to define the position of the olefinic bond in the alkyl chain of the fatty acid or ester as illustrated in the case of 18:1(9*c*) and 18:1(6*c*), as discussed above. The effects of the end group on the shifts of the various carbon atoms of the alkyl chain have been interpreted in terms of steric and linear electric field effects by Batchelor *et al.* (29).

In order to predict the position of double bonds in an alkyl chain and to assign the numerous signals arising from the ^{13}C NMR analysis of an unsaturated fatty acid or ester, several authors have given values for the effect that the end groups and the double bond have on the chemical shifts of nearby carbon atoms. By applying the additivity rule, the shifts of each carbon atom of the methylene groups can be estimated by adding or subtracting the parameters, depending on the location of the carbon nucleus from the affecting group(s) (26, 27,30,31). Bus *et al.* (26,27) and Gunstone *et al.* (28) have also reported the carbon chemical shifts of the olefinic carbon atoms of a large number of polyunsaturated fatty esters. The carbon shifts of a few polyunsaturated fatty esters are presented in Table 1.

The assignments of the shifts of the carbon nuclei of such positional isomers of fatty acids or esters by ^{13}C NMR spectroscopy have been possible by the comparative study of complete series of positional isomers, many of which have been obtained by total synthesis. With reference to these car-

bon chemical shift values, the structures of many polyunsaturated fatty acids have been elucidated or confirmed, *inter alia* the presence of 20:4(5*c*,11*c*,14*c*,17*c*) in the seed oil of *Biota orientalis* (32), and 18:4(6*c*,9*c*,12*c*,15*c*) in the seed oil of *Ribes nigrum* (33). The ^{13}C NMR properties of a number of geometric isomers of methylene-interrupted polyolefinic fatty acids have been reported. The spectral properties of 18:2(9*c*,12*t*) and 18:2(9*t*,12*c*) show unique carbon shifts for the two different geometries of the double bonds (34). In these isomers, the shifts of the methylene carbon atoms adjacent to the *cis*-double bond appear characteristically at about δ_C 27.1, while those adjacent to the *trans*-double bond are found at about δ_C 32.5. The shift of the carbon atom of the methylene between the two double bonds of 18:2(9*t*,12*c*) appears at δ_C 30.5.

The carbon shifts of the eight possible geometric isomers of 18:3(9,12,15) have been reported by Rakoff and Emken (35). The spectral properties of 20:3(5*c*,8*c*,14*c*) and 20:3(5*c*,11*c*,14*c*) (36), and 20:5(5*c*,8*c*,11*t*,14*c*,17*c*) and 20:5(5*c*,8*c*,11*t*,14*c*,17*t*) (37) have been studied. The ^{1}H and ^{13}C NMR spectra of six n-3 polyene esters (18:3, 18:4, 20:4, 20:5, 22:5, and 22:6) have been reported and discussed (38). The spectral properties of [1-^{14}C]linoleic acid and arachidonic acid, and some 18:3 isomers were also described (39,40).

We recently reported the synthesis and ^{13}C NMR properties of all four isomers of conjugated linoleic acid esters (41). The chemical shifts for these four isomers are given in Table 2. The assignments of the various signals were accomplished by using a combination of 2D COSY techniques (^{13}C-^{1}H COSY , INADEQUATE, and HMBC correlation experiments). To explain the detailed interpretation of the NMR spectra, the case of 18:2(9*c*,11*t*) was used as an example. The ^{1}H NMR spectrum of 18:2(9*c*,11*t*) showed four distinct signals for the four olefinic protons. These signals appeared as two multiplets (δ_H 5.32 and 5.65) and two triplets (δ_H 5.82, J = 5.4 Hz, 6.24, J = 12.9 Hz), which corresponded to the shifts of the protons of the "outer" (9-*H*, 12-*H*) and "inner" (10-*H*, 11-*H*) positioned olefinic protons of the conjugated diene system, respectively. The large J constant of the triplet at δ_H 6.24 was an indication that this signal arose most probably from one of the protons of the *trans*-double bond (i.e., 11-*H*). The ^{13}C NMR spectrum showed four signals in the olefinic region: δ_C 125.58, 128.71, 129.89, and 134.76. From the ^{13}C-^{1}H NMR COSY correlation spectrum (Fig. 3), it was clear that the triplet at δ_H 6.24 was correlated to the carbon at δ_C 125.58, and the triplet at δ_H 5.82 to the carbon at δ_C 128.71. These correlations therefore determined the shifts of the "inner" carbon atoms (C-10, C-11) at δ_C 128.71 and 125.58. The multiplets at δ_H 5.65 and 5.32 were correlated to the carbon atoms at 129.89 and 134.76, respectively, which determined the shifts of the "outer" positioned carbon atoms (C-9, C-12).

This spectrum also showed a correlation of the allylic carbon atoms (signals at δ_C 27.66 and 32.92) with the proton signals at δ_H 2.0 and 2.1 (multiplets). From the INADEQUATE spectrum (Fig. 4), which showed connections between one carbon nucleus with the adjacent carbon nucleus, the signal at δ_C 134.76 had correlations with two carbon atoms, *viz.* δ_C 125.58 and 32.92. The latter signal was characteristic of the shift of the allylic methylene carbon atom adjacent to a *trans*-double bond, which meant that the signal at δ_C 134.76 arose from the shift of the "outer" carbon of the *trans*-double bond (i.e., C-12). As the signal at δ_C 134.76 was also correlated to δ_C 125.58, this inferred that the latter signal was due to the shift of C-11 (one of the "inner" carbon atoms of the diene

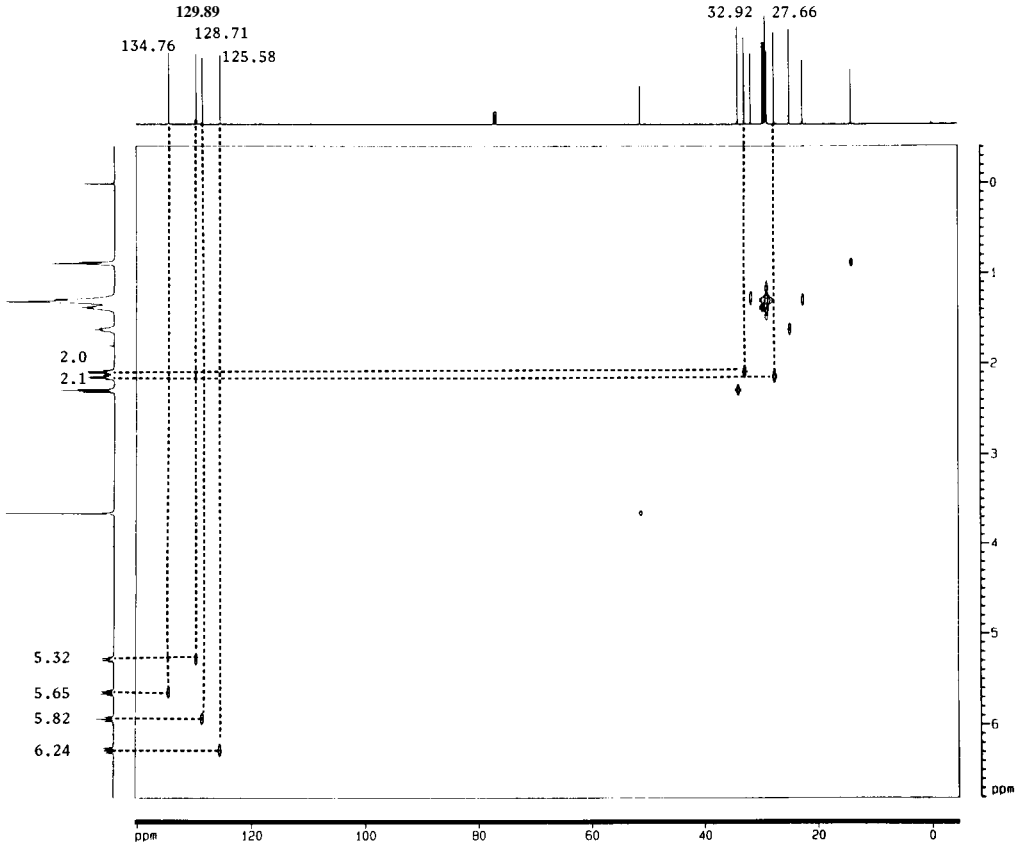

FIG. 3. ^{1}H-^{13}C NMR correlation (COSY) spectrum of 18:2(9*c*,11*t*); *t, trans*. See Figure 1 for other abbreviations.

system). The signal at δ_C 129.89 was correlated to that of δ_C 27.66, the latter being the signal arising from the allylic methylene carbon adjacent to the *cis*-double bond. Thus, the signal at δ_C 129.89 was due to the remaining "outer" signal of the diene system (i.e., C-9). The spectrum further showed a correlation between the signal at δ_C 125.58 (C-11) and that of δ_C 128.71. The latter signal was therefore due to the shift of the C-10 carbon nucleus. From the INADEQUATE spectrum, it was therefore possible to assign unambiguously the four carbon atoms of the *cis,trans*-diene system as: δ_C 129.89 (C-9), 128.71 (C-10), 125.58 (C-11), and 134.76 (C-12). Referring to the ^{13}C-^{1}H COSY spectrum, it is now possible to correlate the signals of the various olefinic carbon atoms with the corresponding proton signals. The proton shifts of the olefinic protons are therefore confirmed as: δ_H 5.32 (9-*H*), 5.65 (12-*H*), 5.82 (10-*H*), and 6.24 (11-*H*). In addition, it is also possible to assign the signals for the 8-*H* and 13-*H* protons as appearing at δ_H 2.1 and 2.0, respectively.

To reconfirm these assignments, the HMBC spectrum was recorded (Fig. 5). This technique shows correlations of nuclei (carbon to carbon or carbon to proton) which are two or three bonds apart. The signal at δ_C 125.58 (C-11) was correlated to the proton signals at δ_H 5.82 (*t*, 10-*H*), 5.32 (*m*, 9-*H*), and also to the signal at 2.0 (*m*, 13-*H*). The signal at δ_C 128.71 (C-10) was correlated to the proton at δ_H 5.65 (*m*, 12-*H*) and to the protons at δ_H 2.1 (*m*, 8-*H*). The signal at δ_C 129.89 (C-9) was correlated (weak signal) to the proton signal at δ_H 6.24 (*t*, 11-*H*). And the signal at δ_C 134.76 (C-12) was correlated to the proton signals at δ_H 5.82 (*t*, 10-*H*) and also to δ_H 2.0 (*m*, 13-*H*). Furthermore, the carbon signal at δ_C 32.92 (13-C) was correlated to the proton signals at δ_H 6.24 (*t*, 11-*H*) and 5.65 (*m*, 12-*H*), while the signal at δ_C 27.66 (C-8) was correlated to δ_H 5.82 (*t*, 10-*H*). These two- or three-bond connections reconfirmed the assignments of the carbon atom of the 9-*cis,*11-*trans*-diene system.

In the structural elucidation of the presence of α- and β-eleostearic acid [18:3(9*c*,11*t*,13*t*) and 18:3(9*t*,11*t*,13*t*), respectively] in the oil from oiticica, *Licania rigida* Benth (Chrysobalanaceae), Bergter and Seidl (42) used a combination of off-resonance decoupling and lanthanide-induced shifts coupled to polarization by a remote keto group to establish the correct order of the conjugated olefinic carbons by ^{13}C NMR spectroscopy. A C_{18} conjugated tetraenoic acid [18:4(8*c*,10*c*,12*c*,14*t*)] and crepenynic acid [18:2(9*c*,12*a*)] are the major fatty acid components in *Ixora chinensis* seed oil. From the ^{13}C NMR spectrum of the oil, the presence of crepenynic acid was confirmed by the signals at δ_C 78.29, 80.05, 125.28, and 131.40 for C-9, C-10, C-12, and C-13, respectively. The structure of the conjugated tetraene fatty acid was elucidated based on the signals for the olefinic carbon atoms (43).

Two new fatty acid metabolites, 20:5(5*c*,7*t*,9*t*,14*c*,17*c*) and

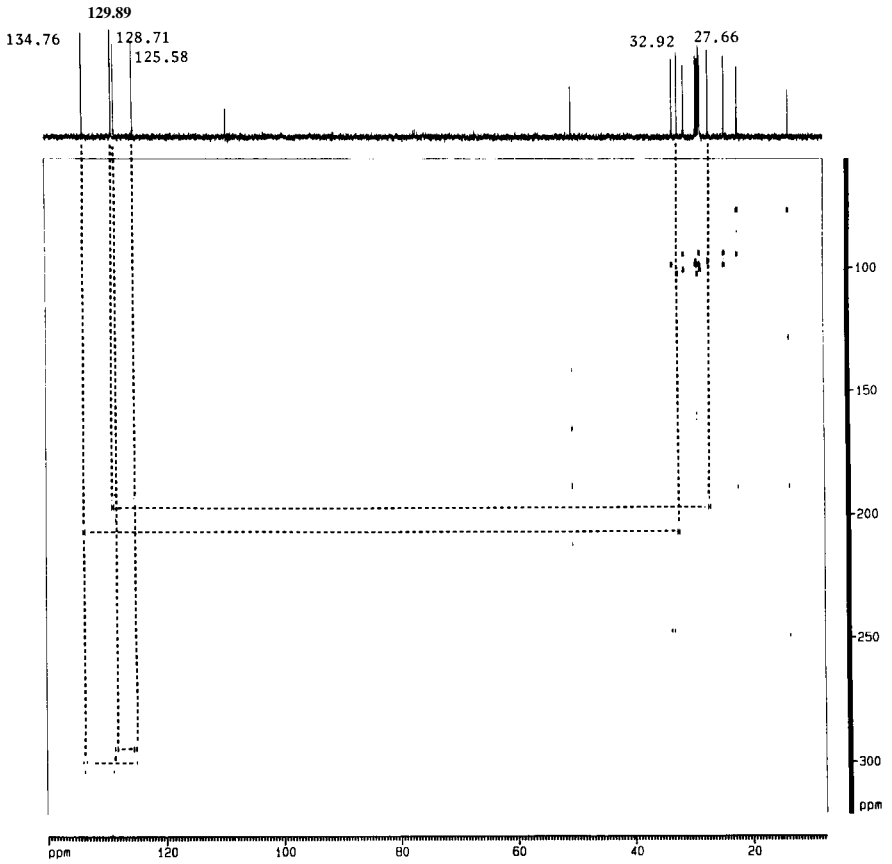

FIG. 4. Incredible natural abundance double quantum transfer experiment spectrum of 18:2(9*c*,11*t*). See Figures 1 and 3 for abbreviations.

20:5(5*t*,7*t*,9*t*,14*c*,17*c*), were isolated from the temperate red marine alga, *Ptilota filicina* (Ceramiales, Rhodophyta). The structures of these compounds were deduced from detailed ^{1}H, ^{13}C NMR, and two-dimensional NMR experiments (44). Aursand and Grasdalen (45) reported the carbon shift of the olefinic carbon atoms of n-3 polyene acids (22:6, 20:5, 18:4, 18:3), while Takagi *et al*. (46) described the shifts of a 24:6 polyunsaturated fatty ester and some 16:3 and 16:4 isomers in fish oils (47).

Acetylenic fatty acids. The ^{13}C NMR spectral analysis of acetylenic fatty acid esters was characterized by the signals at about δ_C 80 for the shifts of the carbon atoms of the acetylenic bond. Similar to the shifts of the olefinic carbon atoms, the effect of the carboxylate group also influenced the shift values of these nuclei, depending on the position of the acetylenic bond in the alkyl chain. The presence of an acetylenic bond in a fatty acid was further characterized by the shifts of the carbon atom of the methylene groups adjacent to the acetylenic bond, which appeared in the upfield region of the spectrum at about δ_C 18 (26,27,30).

The effects of the ester and terminal methyl group on the shifts of the acetylenic carbons allowed all isomers of methyl undecynoate to be differentiated from the shifts of the acetylenic carbon atoms (26). The position of the acetylenic bond in methyl octadecynoates was located as remote as the Δ^{10} position from the carboxylate group by examining the shift position of the acetylenic carbon atoms in the spectrum and from the difference of these shift values (30). The ^{13}C NMR spectral results of dimethylene-interrupted octadecadiynoates (26) and those of the conjugated diacetylenic fatty esters (48) also were reported.

The synthesis of acetylenic fatty acids (e.g., 2-pentadecynoic acid), which are potential inhibitors of the β-oxidation step in the biosynthesis of certain sex pheromones of the Egyptian armyworm *Spodoptera littoralis,* was reported. The position of the acetylenic bond in these fatty acids was readily identified by ^{13}C NMR spectroscopic analysis from the shifts of the acetylenic carbon atoms, which appeared at δ_C 72.5 (C-2) and 92.7 (C-3) for the Δ^2 acetylenic bond (49). The structure of a new polyunsaturated fatty acid, containing an acetylenic bond, was isolated from the thalli of *Riccia fluitans*. The structure of this acid, 18:2(6*a*,9*c*), was established by spectroscopic methods (50).

Deuterated long-chain fatty acids. Specifically deuterated long-chain fatty acids, either as free acids or chemically incorporated in phospholipids, frequently have been used in the investigation of lipid bilayers (membranes) by deuterium NMR (51–53). Many reports have been made on the synthesis of deuterated fatty acids with studies of the ^{13}C NMR properties of such analogs (54–56). Fatty acids which have

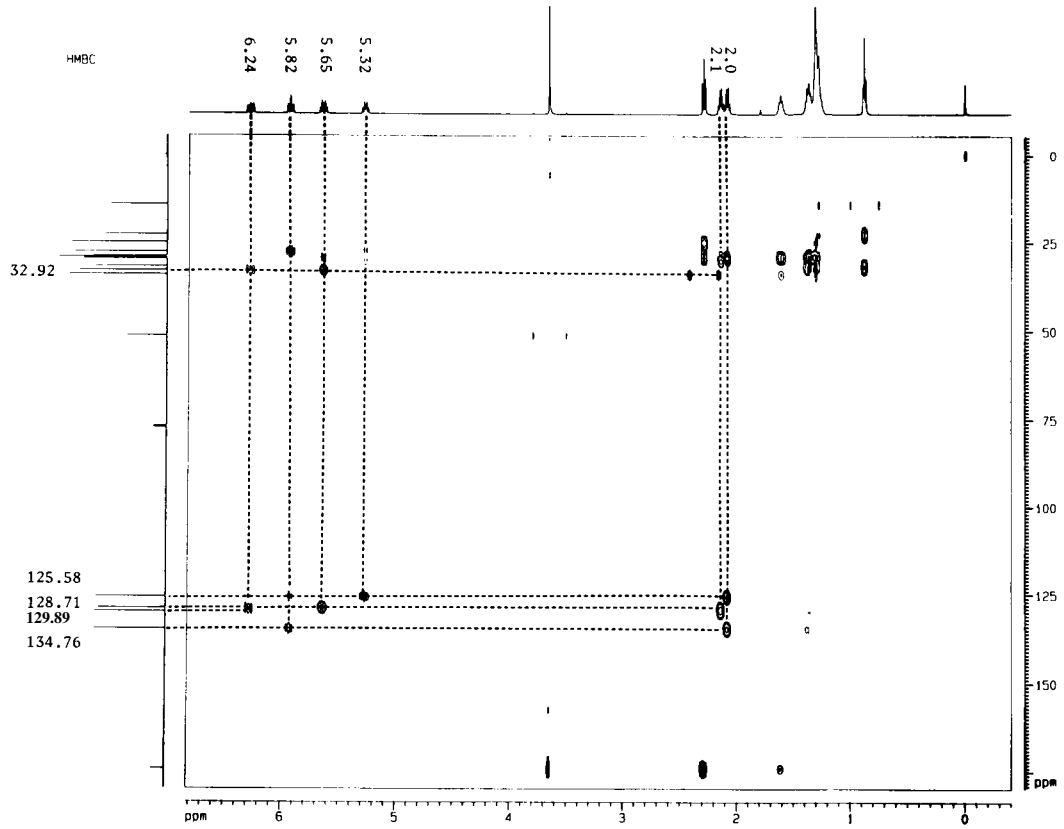

FIG. 5. Heteronuclear multiple bonds correlation spectrum of 18:2(9*c*,11*t*). See Figures 1 and 3 for abbreviations.

two deuterons on a specific carbon atom of the alkyl chain showed two different quadrupole splittings due to the nonequivalence of the deuterons (57,58). Consequently, the covalent attachment of two deuterons to a methylene carbon resulted in loss of signal intensity as a result of an increase in the relaxation time (T_1) and an increase in the line width of the resonance due to ^{13}C-^{2}H coupling (59,60). Signals from the deuterated carbon atoms were therefore absent or very broad, as illustrated in Figure 6 for the spectra of the nondeuterated and deuterated ethyl 8,11,14-eicosatrienoate-19,19,20,20-d_4 (61). The biosynthesis and characterization of a series of deuterated 18:2(6*c*,9*c*) by ^{13}C NMR spectroscopic analysis were carried out using deuterated fatty acids labeled at the C_4, C_5, C_6, C_7, C_8,C_{11}, C_{14}, or C_{18} positions (62). These acids were biosynthesized by supplementing cultures of the protozoan *Tetrahymena* with the corresponding deuterated 18:1(9*c*). The results illustrated the utility of a biological approach for the synthesis of deuterated polyunsaturated fatty acids in yields suitable for ^{2}H NMR studies.

An interesting feature of *gem*-dideuterated fatty acids or esters in the ^{13}C NMR spectral analysis was the deuterium isotope effects of the deuterons on the shift of the adjacent methylene carbon atoms. The average value for the second atom effect was −0.20 (upfield) and for the third atom the effect was −0.05 ppm. Thus the signals for the methylene carbon atoms adjacent to the deuterated methylene were readily identified by comparison to the nondeuterated parent molecule (60). Rakoff also synthesized a number of deuterated polyunsaturated fatty acids, *viz.*18:3(9*c*,12*c*,15*c*)-15,16-d_2, 18:3(9*c*,12*c*,15*c*)-6,6,7,7-d_4 (63), 18:3(6*c*,9*c*,12*c*)-15,15,16,16-d_4 (64), 18:4(6*c*,9*c*,12*c*,15*c*)-12,13,15,16-d_4 (65), and 20:3(11*c*,14*c*,17*c*)-3,3,4,4,8,8,9,9-d_8 (66). The structures and the configurations of these deuterated fatty acid esters were confirmed by ^{13}C NMR and mass spectrometry.

Oxygenated fatty acid esters. Tulloch (60) and his colleague Mazurek (67) have synthesized all positional isomers of hydroxystearic acid and those of ketostearic acid and have studied the ^{13}C NMR spectral properties of these closely related compounds. The presence of the hydroxy function in the alkyl chain of the fatty ester was evident from the shift of the methine carbon atom which was attached to the hydroxy group. The carbon shift of the methine carbon was found in the region of δ_C 71. The shifts of the β- and γ-methylene carbons adjacent to the hydroxy function appeared at about δ_C 37 and 25, respectively. Many of the positional isomers of hydroxystearate were identified by their spectral properties because the position of the signals in the spectrum was also affected by the carboxylate or terminal methyl group, depending on the location of the hydroxy function.

Fatty acids containing a keto function were readily identified by the appearance of a signal in the region of δ_C 210. The shifts of the β- and γ-methylene carbons adjacent to the keto function appeared at about δ_C 42 and 23, respectively (60). Bascetta and Gunstone (68) reported the ^{13}C NMR shifts for

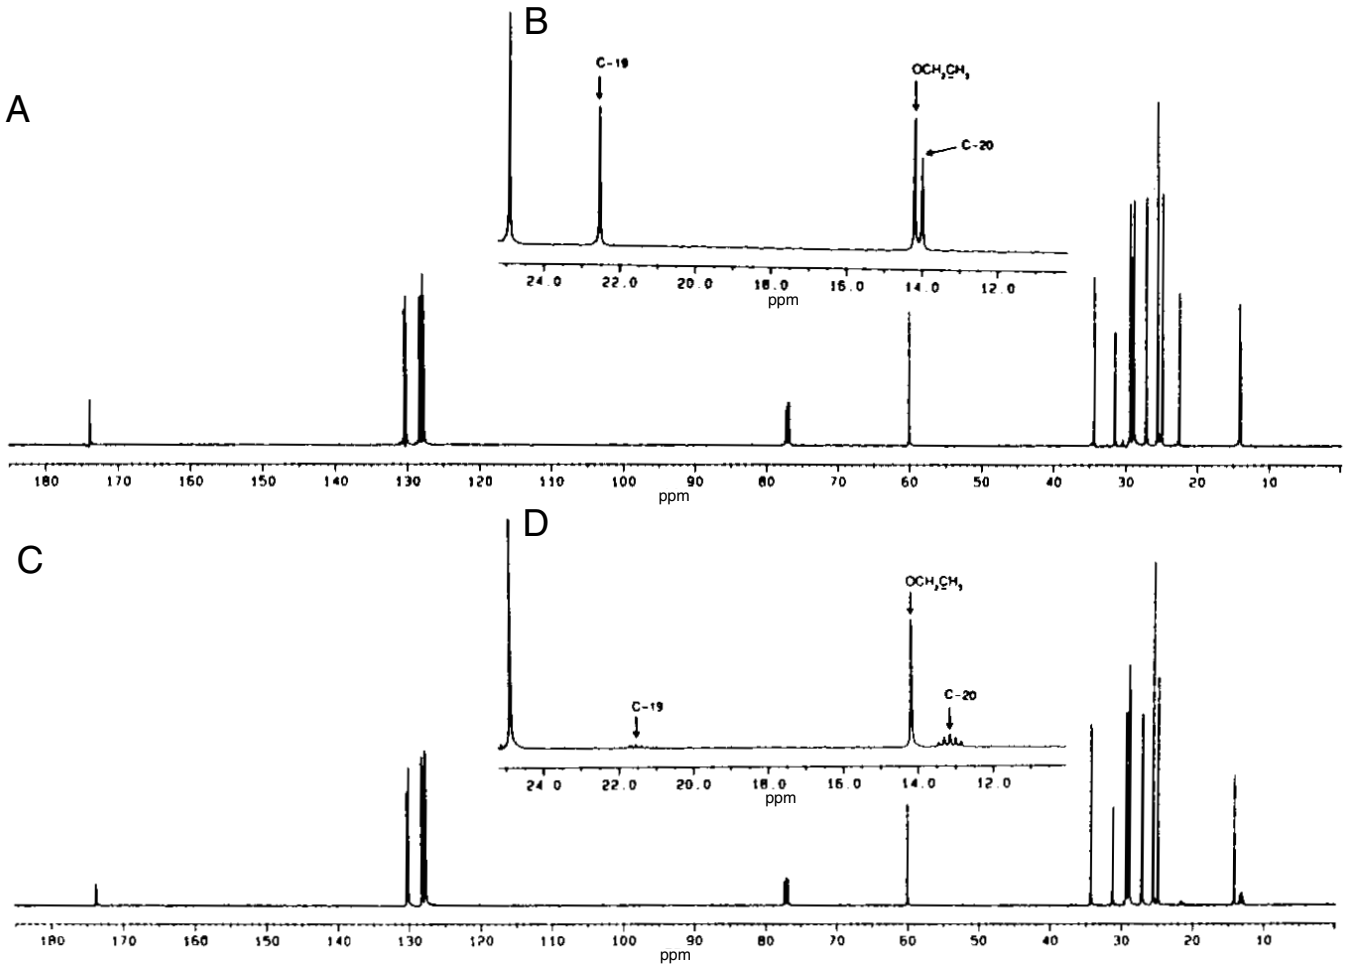

FIG. 6. ^{13}C nuclear magnetic resonance spectra of ethyl 8,11,14-eicosatrienoate: (A) nondeuterated sample, (B) expansion between 10–25 ppm, (C) deuterated sample, (D) expansion between 10–15 ppm (61).

a number of long-chain and cyclic epoxides (*cis* and *trans*, saturated and unsaturated) and of several primary alcohols and hydroperoxides. The influence of each of these functional groups on the chemical shift of nearby carbons was determined and the shift parameters reported.

A survey of the chemical literature shows conflicting assignments of the ^{13}C carbon chemical shifts for the olefinic carbon atoms of homoallylic-substituted unsaturated fatty esters. Methyl ricinoleate [methyl 12-hydroxy-18:1(9*c*)] and methyl isoricinoleate [methyl 9-hydroxy-18:1(12*c*)] are typical examples of such hydroxylated unsaturated fatty esters, which contain a homoallylic and a bis homoallylic hydroxy function in the alkyl chain, respectively. Lie Ken Jie and Cheng (69) recently used a combination of selective irradiation ^1H NMR experiments and 2D COSY (^{13}C-^1H) to determine the carbon chemical shifts of the olefinic carbon atoms. Subsequently, the ^{13}C NMR properties of a series of hydroxy, acetoxy, azido, chloro, and oxo derivatives of unsaturated fatty esters were studied (70).

Several reports have been made on the chemical hydroxylation of unsaturated fatty acids. Knothe *et al*. (71) studied the hydroxylation of oleic acid with selenium dioxide in the presence of *tert*-butylhydroperoxide. The isolated products, *viz*., 8-hydroxy-18:1(9*t*), 11-hydroxy-18:1(9*t*) and 8,11-dihydroxy-18:1(9*t*), were identified by a combination of ^1H- and ^{13}C NMR spectroscopy. Several novel allylic mono- and dihydroxy fatty compounds were synthesized from Δ^5, Δ^7, Δ^8, and Δ^{10} monounsaturated fatty acids with selenium dioxide/*tert*-butylhydroperoxide. The resonance difference of the olefinic carbon atoms was studied by ^{13}C NMR spectroscopy, which allowed the position of the unsaturated center to be located (72,73).

Four unusual hydroxy fatty acids (7-hydroxy-8,14-dimethyl-9-hexadecenoic acid, 7-hydroxy-8,16-dimethyl-9-octadecenoic acid, 7-hydroxy-8,18-dimethyl-9-eicosenoic acid, and 7-hydroxy-8,20-dimethyl-9-docosenoic acid) were identified from fungal species belonging to Ascomycetes and Basidiomycetes by the combination of NMR spectroscopic and mass spectrometric techniques. For example, the ^{13}C NMR result of 7-hydroxy-8,14-dimethyl-9-hexadecenoic acid was reported with the following critical carbon shifts: 72.1 (C-7), 28.5 (C-8), 129.8 (C-9), 129.1 (C-10), 19.8 (Me of C-14), and 22.7 (Me of C-8) (74). Filoboletic acid [8,13-dihydroxy-18:2(9*c*,11*t*)] was isolated as the antiviral principle from a

fungus belonging to the genus *Filoboletus.* The structure was elucidated by a combination of mass spectrometry and advanced techniques in ^{13}C NMR spectroscopy (including 2D COSY, HMQC, and HMBC correlation techniques), which allow the shifts of all carbon atoms to be identified (75). A cytotoxic fatty acid, 11-hydroxy-4-methyl-2,4,6-dodecatrienoic acid, was found in the extract of fermentations of the *Mucor* sp. The structure of this fatty acid was elucidated by the HMBC technique (76).

Studies of triacylglycerols. Most seed oils are composed of triacylglycerols, which contain an array of fatty acids, saturated as well as unsaturated, and distributed among the three positions of the glycerol "backbone." Fat from animals or oils from fish also appear in the form of triacylglycerols. A detailed and systematic study of saturated and unsaturated triacylglycerol molecules was conducted by Lie Ken Jie and colleagues (77–79). The ^{13}C NMR spectrum of a triacylglycerol has two characteristic signals at around δ_C 68.9 and 62.1 for the β- and α-glycerol carbon atoms, respectively. More significantly, in triacylglycerols of type AAA (where all fatty acyl chains are the same), two signals are evident for many of the carbon atoms in the acyl chain, depending on whether the chain is present in the α- (i.e,. at the 1- and 3-positions of the glycerol) or β- (i.e., 2-position of the glycerol) position. Since there are two α-chains and only one β-chain, it is easy to assign the signals on the basis of their relative intensities or sizes. For example, all acyl carbon atoms of α- and β-chains are resolved in the case of glycerol tributyrate (tributyrin), while in glycerol tridodecanoate (trilaurin) seven (*viz.,* C-1 to C-7 of the acyl chains) of the 12 carbon atoms are separated into pairs of signals each (77). The difference between each pair tends to be a constant value, which permits the signal for each of the seven carbon atoms (C-1 to C-7) to be readily identified. The chemical shifts for glycerol tributanoate and glycerol tridodecanoate are given in Table 3.

From these studies of saturated triacylglycerols of type AAA, apparently the small differences between two signals arising from carbon atoms in similar positions in the acyl chain, but not in identical chemical environments, were more reproducible than the observed shifts of the carbon atoms themselves. However, it must be pointed out that the differences in the shift values of similarly positioned carbon atoms in *short* α- and β-acyl chains (for example in the case of triacetin and tributyrin) showed significant deviations from established norms, where the acyl moieties consisted of long-chain fatty acid groups (77). Lie Ken Jie *et al.* (77) also studied the ^{13}C NMR spectra of a number of saturated triacylglycerols of type ABA (where the α-acyl chains comprised the same fatty acid and where the β-acyl chain was a different fatty acid moiety) and those of type AAB. On the whole, it was possible to identify triacylglycerols of type AAA, where the number of carbon atoms in the acyl chain did not exceed 10 carbon atoms. This technique also distinguished the mixed triacylglycerols (type ABA and AAB) from type AAA by evaluating the differences in chemical shift values of the C-1 carbon atoms of these sets of lipid molecules.

[a]See Table 1 for abbreviation.

The ^{13}C NMR properties of a total of 22 synthetic *cis*- and *trans*-olefinic triacylglycerols of type AAA (containing isomeric positional unsaturated fatty acid homolog with the olefinic bond located between Δ^2 and Δ^{12} positions) have been studied (78). The results showed that the shifts of the glyceryl carbon atoms were only significantly affected when the unsaturated center was located at either the Δ^2 or Δ^3 position of the acyl chains. The olefinic carbon atoms in the α- and β-acyl chains were fully resolved except in two cases. From the carbon chemical shift values of the ethylenic carbons and the difference between the shift values of these nuclei in the same acyl chain, determination of most of the positions of the unsaturated center was possible. Using the signal pattern displayed by the olefinic carbon nuclei in the spectra, the positional distribution of short-chain acid moieties in the glycerol "backbone" was determined. Methylene carbon atoms in the α- and β-acyl chain, which were located close to the acyl function, were resolved up to the C-6 carbon atom. It is possible to locate the position of the unsaturated center in the acyl chains as remote as the Δ^{12} position and the positional distribution (α- or β-acyl) of the unsaturated acyl chains on the glycerol "backbone" of these triacylglycerol molecules (78). The carbon chemical shifts of triacylglycerols of type AAA containing *cis*- and *trans*-olefinic acyl groups were reproduced in Tables 4 and 5, respectively.

A large number of triacylglycerols of type AAA containing polyunsaturated (olefinic and acetylenic) acids, including mixed triacylglycerols, also were studied by Lie Ken Jie and Lam (79). From the carbon shift values of the various carbon atoms, confirmation was made of the position and geometry of the unsaturated centers in the acyl chains. Many of the similarly positioned carbon atoms, whether arising from methyl-

[a]See Tables 1 and 4 for abbreviations. [a]Shift values in the α-acyl chains. [b]Shift values in the β-acyl chain. [c]Italic values denote shifts of the ethylenic carbon atoms. [d]Underlined values are obtained from 100.4 MHz spectra. [e]Signal overlapped with other signals.

ene or olefinic carbon nuclei in the α- and β-acyl chains, are resolved to give characteristic pairs of signals. By making use of the differences in shift values for carbon atoms of similarly positioned carbon atoms in the α- and β-acyl chains, the assignment of the chemical shifts of the various nuclei was readily achieved. The nature (type of unsaturation and position of unsaturated centers) and distribution of the various acyl groups on the glycerol "backbone" of these mixed triacylglycerols also were determined by this technique (79).

Using the results from the systematic studies of the ^{13}C NMR properties of saturated and unsaturated triacylglycerols, Lie Ken Jie *et al.* (80,81) have extended their work to the analysis of margarines and natural seed oils. In the analysis of margarines, the technique allowed all major acyl groups (saturated, oleic, linoleic, and linolenic acids) and minor acyl components (different positional isomers of *cis*- and *trans*-long-chain unsaturated fatty acids) to be identified (80). The ^{13}C NMR analysis of the whole oil of *Biota orientalis* seeds confirm the presence of oleate, linoleate, linolenate, and also 20:4(5*c*,11*c*,14*c*,17*c*), and saturated fatty acids in the acyl groups by comparing the observed carbon shifts with previously established shift data for model triacylglycerols. This technique revealed that the saturated and 20:4 fatty acids may be distributed in one or both of the α-acyl positions, whereas oleic, linoleic, and linolenic acids were randomly acylated to the α- and β-acyl positions of the glycerol "backbone." The ^{13}C NMR analysis of carrot seed oil identified the presence of saturated (18:0), 18:1(6*c*), 18:1(9*c*), and 18:2(9*c*,12*c*). The saturated fatty acids were mainly found in the α-acyl positions. Semiquantitative assessment of the signal intensities gave the relative percentage of 18:1(6*c*) as 49.6% of the total fatty acids (81).

Similar differences in the chemical shifts of the various methylene and olefinic carbon atoms of acyl chain of triacylglycerol molecules have been reviewed (18). High-resolution ^{13}C NMR has been used to analyze other natural fats and oils, where the composition of *cis*- and *trans*-double bonds in a mixture of fat was determined (82). This technique also allowed the proportion of saturated, mono-, di-, and polyunsaturated fatty acids in vegetable and fish oils to be estimated (83–86).

The ^{13}C NMR spectra of the saturated and olefinic carbons in palm oil can be used for direct determination of the composition of the fatty acids in mole fractions of the saturated, monoene, and diene acid chains. The method was found to be more informative than the conventional iodine value which is used as a measure of the total unsaturation in the fatty acids (87). The ^{13}C NMR spectral analysis of the carbonyl carbon atoms of the acyl groups of triacylglycerols of palm oil allowed the composition of saturated, oleic, and linoleic acyl groups at the 1,3-position and at the 2-position of the glycerol moiety to be established. The report indicated that, except for the lack of differentiation of the saturated fatty acids, the ^{13}C NMR technique provided the same information as the tedious enzymatic hydrolysis *cum* fatty acid analysis (88). The chemical shift difference of the olefinic carbon atoms in the fatty acid chain of triacylglycerols in palm oil was found to be characteristic of the chain's glycerol position and can therefore be used to identify the glycerol position of an unsaturated fatty acid in the triacylglycerol molecule (89).

cis-Vaccenic acid, 18:1(11*c*), in palm oil was readily detected and identified on the basis of the chemical shift data of the carbonyl and olefinic carbons (90). The seed oil of *Sebastiana brasiliensis* (Euphorbiaceae) contained high levels (39%) of α-parinaric acid, 18:4(9*c*,11*t*,13*t*,15*c*). Complete assignment of the ^{1}H and ^{13}C NMR shifts of α-parinaric acid was carried out by two-dimensional NMR experiments (91). Cherry seed oil, from the Rosaceae family, contains about 10% of α-eleostearic acid, 18:3(9*c*,11*t*,13*t*), which was characterized by ^{1}H- and ^{13}C NMR spectral analysis (92).The seed oil of *Momordica balsamina* contains high levels of punicic acid, 18:3(9*c*,11*t*,13*c*) (50%), and α-eleostearic acid, 18:3(9*c*,11*t*,13*t*) (13%). The structure and the quantities of these conjugated fatty acids in the oil were determined by a combination of gas–liquid chromatographic and ^{13}C NMR analyses (93). Tulloch (94) studied the spectra of seven seed oils (*Punica granatum, Cucurbita palmata, Jacaranda mimosifolia, Centranthus ruber, Catalpa bignonioides, Chilopsis linearis,* and *Calendula officinalis*) and identified six C_{18} isomeric conjugated trienes by this technique.

A study of triacylglycerol species in *Santalum album* (Linn.) seed oil was carried out by comparing the results with synthetic santalbic acid, 18:2(9*a*,11*t*). The distribution of the various fatty acids, including santalbic acid, on the glycerol "backbone" was determined by the results from the ^{13}C NMR spectroscopic analysis (95). Application of the technique to hydrogenated fats led to a semiquantitative estimation of the various 18:1 isomers present (96,97). Mallet *et al.* (98) studied the ^{13}C NMR spectral differences between triolein and tripetroselinin (glycerol tri-6-*cis*-octadecenoate), and applied this method for the determination of petroselinic acid in 10 Umbelliflorae seed oils with success. The distribution of Δ^5 polyene acids, mainly 18:3(5*c*,9*c*,12*c*), in some pine seed oils between the α- and β-acyl positions by ^{13}C NMR was reported. The Δ^5 acids were present only among the α-chains (99,100). The ^{13}C NMR spectra of six seed oils containing petroselinic acid (carrot, celery, parsnip, parsley, caraway, and coriander), of aquilegia oil containing columbinic acid, 18:3(5*t*,9*c*,12*c*), and of meadowfoam oil (*Limnanthes alba*) containing other Δ^5 acids were also reported (101). Using the ^{13}C NMR signals for the C-1 and C-2 carbon atoms, it was possible to determine the proportion of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in the α- and β-acyl positions of triacylglycerols. The results from the analysis of seven fish oils showed that DHA was concentrated in the β-acyl position, but EPA was more randomly distributed between the two positions (86,102).

The fatty acid composition, with emphasis to the n-3 fatty acids, of lipid extracted from the white muscle of Atlantic salmon (*Salmo salar*) was investigated. Complete assignments of the spectra of DHA and EPA were obtained from T_1 measurements and from lanthanide-induced shift studies. The

findings provide a basis for the use of ^{13}C NMR in analyzing fish lipids (45). Quantitative measurements and positional distribution of n-3 fatty acids in other fish lipids also were carried out (103,104).

The positional distribution of fatty acids on the α- or β-acyl of the glycerol backbone was assessed by investigating the carbon chemical shifts of the carbonyl and olefinic nuclei (105–108). As a result, stearic acid, for example, was found mainly distributed to the α-acyl chain of the glycerol molecule in palm and corn oil. Analysis of the positional distribution of fatty acids in butter oil was accomplished by high-resolution ^{13}C NMR method. Pfeffer *et al*. (109) showed that the predominance of butyrate was located at the α-positions of the triacylglycerols of butter oil by this technique.

The resolution of closely related triacylglycerols, such as glycerol 1,2-dilinoleate-3-linolenate (LLLn), glycerol 1,2-dilinolenate-3-linoleate (LnLLn), glycerol 1,3-dilinoleate-2-linolenate (LLnL) and glycerol 1,3-dilinolenate-2-linoleate (LnLLn), was successfully accomplished by ^{13}C NMR analysis (110). The application of ^{13}C NMR to determine the positional distribution of fatty acids on the glycerol backbone in borage and evening primrose oil has been investigated (111). Gunstone (112) studied four oils containing γ-linolenic acid (evening primrose, borage, blackcurrant, and oil of javanicus) where it is shown that the signals for C-1, C-2, and C-3 were used to determine the distribution of γ-linolenic acid between the α- and β-positions for these oils. A comparative study has been carried out for the Grignard deacylation thin-layer chromatography, high-pressure liquid chromatography, and high-resolution ^{13}C NMR for the *sn*-2 positional analysis of triacylglycerols containing γ-linolenic acid. The result showed that there is very good agreement among these methods and that the ^{13}C NMR method proved to be the easiest and most convenient in determining the *sn*-2 position for oil or triacylglycerol samples (113).

Recently the ^{13}C NMR study of cyclopropenoid triacylglycerols was reported. Full ^{13}C NMR shift assignments were made for both the sterculate and malvalate moieties in the seed oil from *Sterculia foetida.* The chain distribution was determined from quantitative NMR measurements (allowing sufficient relaxation delay to prevent saturation to improve the accuracy in integration of the signal intensities) (114). The spectra of *Vernonia galamensis* seed oil and of epoxidized palm super olein, soybean oil, and linseed oil were recorded and interpreted. The carbon shifts of the epoxy carbon atoms appeared at about δ_C 56–57. The epoxide function differed from a double bond in its influence on the chemical shifts of nearby carbon atoms (115).

^{13}C NMR spectroscopy is used in the identification of 1,3-divernoloyl glyceride, which was obtained from enzymatic synthesis from *V. galamensis* seed oil. This method also provided a quantitative approach to study the enzyme-catalyzed transformation (116). The triacylglycerols of *V. galamensis* and *Crepis alpina* seed oils were characterized from the high concentration of vernolic acid (*cis*-12,13-epoxy-*cis*-9-octadecenoic acid) and crepenynic acid (*cis*-9-octadecen-12-ynoic acid). These acids were identified by ^{1}H and ^{13}C NMR spectroscopic analyses (117). ^{13}C NMR spectroscopic analysis was used to determine quantitatively the amount of castor oil in edible and heat-abused oils. The minimal detection limits achieved for qualitative and quantitative analyses were 2.0 and 3.0%, respectively (118).

Gunstone (119) studied mono-, di-, and triacylglycerols, showing a qualitative and semiquantitative estimation of each type of ester from the results of the shifts for the three glycerol carbon atoms and for the C-1 and C-2 nuclei in each acyl chain. ^{13}C NMR analysis of derivatives of monoglycerides was employed to give a quantitative estimation of such esters (120). Further application of the quantitative method was applied to the determination of grades of virgin olive oils by determining the presence and composition of mono-, di-, and triacylglycerols in these oils (121).

There is one area where NMR technique has no rival. This involves the detailed analysis of the oil content of intact oilseeds. Schaefer and Stejskal (122) used this method to select soybeans for producing oil depleted in the less desirable linolenic acid. Other oilseeds such as castor bean, peanut, and radish seeds also have been studied (123–125).

ABSTRACT: Krabbe's disease is an autosomal recessive disease that affects the lysosomal enzyme galactosylceramidase. The storage of one of its substrates, psychosine (β-galactosylsphingosine), is thought to be responsible for the induction of pathological changes. Psychosine has a free amine group which is necessary for the mediation of its toxic effects. In the present study, the physicochemical properties of psychosine were investigated. Nuclear magnetic resonance (NMR) detected pH titration was used to determine that the amine group had a pKa of 7.18 ± 0.05. Pulsed-field gradient NMR spectroscopy was used to determine that the diffusion coefficient of 2.8 mM psychosine in D_2O at pD 4.46 or 7.04 is 1.16 ± 0.02 × 10^{-10} m^2/s or 0.77 ± 0.02 × 10^{-10} m^2/s, respectively. Negative staining electron microscopy (EM) studies of acidic and neutral solutions of psychosine also were performed. At pH 4.5, spherical structures were formed, which were relatively stable between 3, 120, and 216 h following preparation; the diameter ranged from ~14 nm at the earliest time point to ~18 nm at the last time point. The critical micelle concentration (CMC) was 1.26 mM at pH 4.0. At pH 7.1, the structures changed from spherical structures with a diameter of 15–23 nm, at the earliest time point, to a heterogeneous population of structures ranging from spherical structures, with a diameter of only a few nm, to irregularly shaped oblong structures that had one or more dimensions exceeding 100 nm. The NMR and EM data indicate that the deprotonation of the amine group causes psychosine to form aggregates that are unstable, which prevents a determination of the CMC at a neutral pH. These data indicate that molecular interactions of psychosine at the acidic pH of the lysosome, where it is normally digested, are more orderly than those at the pH of the cytoplasm or extracellular space where psychosine goes during disease.

Lipids 32, 1035–1040 (1997).

Psychosine (2-amino-3-hydroxy-4-octadecenyl-beta-D-galactopyranoside or β-galactosylsphingosine) is digested by the lysosomal enzyme galactocerebroside β-galactosidase (galactosylceramidase). In Krabbe's disease, which is an inherited autosomal disorder, this enzyme is defective and the concentration of psychosine increases 10- to 100-fold above normal levels (1,2). The inability of galactosylceramidase to metabolize psychosine led to the hypothesis that psychosine was responsible for inducing pathological changes (3). Several different mechanisms have been postulated to account for its toxic action: (i) psychosine is an inhibitor of protein kinase C (PKC), and inhibition of PKC could initiate pathological events (4); (ii) psychosine causes hemolysis to red blood cells (5), and it causes oligodendrocyte processes, but not the soma, to disintegrate (6); and (iii) psychosine can block mitochondrial enzymes (7–9). Psychosine also has been shown to inhibit cytochrome oxidase molecules facing in either direction in proteoliposomes and submitochondrial particles, suggesting that it can rapidly interact with both sides of a membrane when added externally (10), and it causes an increase in the turbidity of brain homogenates (5).

In Krabbe's disease, psychosine is exposed to environments with a pH of 4.5 or 7.4. In the lysosome, where it is normally digested, the pH is approximately 4.5. In extralysosomal spaces such as the cytoplasm or extracellular milieu, where unmetabolized psychosine goes when it escapes from lysosomes or dying cells, respectively, the pH is approximately 7.4. Psychosine has a free amine functional group which has been shown to be involved with its hemolytic activity (5) and the inhibition of PKC (4). Protonation of this amine group should markedly influence the physicochemical properties of psychosine and, as a result, direct the mechanism of its cytotoxic action.

In the present study, the physicochemical properties of psychosine were examined in acidic and neutral aqueous solutions. Nuclear magnetic resonance (NMR) detected pH titration was employed for the determination of the pKa of the psychosine amine group. In addition, pulsed-field gradient (PFG) NMR spectroscopy and electron microscopy (EM) were used to examine the propensity of psychosine to form

aggregates at neutral and acidic pH. PFG NMR is a well-established method for the investigation of aggregation and micelle formation *in vitro* (11–15). The fundamental protonation and aggregation properties investigated in the present study may have direct bearing on the metabolism of psychosine *in vivo*.

EXPERIMENTAL PROCEDURES

Materials. β-Galactosylsphingosine (psychosine) was obtained from Sigma (St. Louis, MO). D_2O (99.9% *d*, Sigma) was used as the solvent in the NMR studies. Water purified to 18 mΩ resistance was used for the EM measurements. DCl (Cambridge Isotope Laboratories, Andover, MA) and NaOD (Isotec Inc., Miamisburg, OH) were used to adjust the pH of the psychosine solutions. All pH measurements were performed with a Fisher-Scientific (Pittsburgh, PA) Acumet 10 pH meter using a 3-mm Ingold combination microelectrode calibrated with aqueous pH buffers. The pD values reported for solutions analyzed by NMR spectroscopy have been corrected for the isotope effect using the relationship pD = pH meter reading + 0.4 (16).

NMR spectroscopy. The ^{1}H NMR spectra were measured using a Bruker 500 AM spectrometer (Billerica, MA) at temperature of 298 K. One-dimensional NMR spectra were acquired as a function of pD with a 6024 Hz spectral width and 32,764 data points. In most NMR experiments, the HOD resonance was suppressed by application of a selective saturation pulse prior to acquisition. Proton chemical shifts are reported relative to 3-(trimethylsilyl)propionic acid, 2,2,3,3-d_4 sodium salt (Aldrich, Milwaukee, WI) used as an external standard. The proton resonances were assigned using the double-quantum filtered correlated spectroscopy spectrum and by comparison with the reported assignments for psychosine and related galactocerebrosides (17,18).

Diffusion coefficient measurements. Diffusion coefficients were measured by PFG NMR spectroscopy using the bipolar longitudinal eddy-current delay (BPP-LED) pulse sequence (19). In this experiment, an LED Te is used to minimize spectral artifacts resulting from residual eddy currents. In our experiments, a Te of 15 ms was used. The spectra were measured using a Bruker 500 MHz AM spectrometer specially modified to accommodate PFG experiments. Details of the gradient instrumentation have been described previously (20). A 5-mm Bruker inverse probe with an actively shielded z-gradient coil was used. The coil constant was calibrated with β-cyclodextrin which has a diffusion coefficient of 3.2×10^{-10} m^2/s.

In BPP-LED experiments, the attenuation of the NMR resonance depends on gradient strength as shown in Equation 1:

$$I = I_0 \exp [-D(\Delta - \delta/3 - \tau/2)\gamma^2 g^2 \delta^2] \quad [1]$$

where I_0 is the intensity of the resonance in the NMR spectrum in the absence of gradient pulses, γ is the gyromagnetic ratio, Δ is the time period during which diffusion occurs, *g* and δ are the gradient amplitude and duration time, respectively, and *D* is the translational diffusion coefficient. In the BPP-LED experiments, τ is the separation of the bipolar pair of gradient pulses, which were 1.2 or 4 ms. Typically, in each pulsed-field gradient NMR experiment, a series of 15 ^{1}H spectra were collected with the BPP-LED pulse sequence as a function of gradient amplitude. In our experiments, the gradient duration time δ/2 was 1 ms, the gradient amplitude was varied from 0.024 to 0.4 Tm^{-1} and the diffusion delay time, Δ was 0.5 s.

The individual spectra were transferred to a Silicon Graphics (Mountain View, CA) Indigo work station and processed using Felix 2.30 (Molecular Simulations Inc., San Diego, CA). Following Fourier transformation, the series of free induction decays obtained as a function of gradient amplitude were processed using diffusion-ordered spectroscopy, as described previously using computer programs generously provided by Dr. Charles S. Johnson, Jr. (15,21). Diffusion coefficients were extracted using the program SPLMOD (22). The results of our experiments were fit in each case to a single diffusion coefficient.

Critical micellar concentration (CMC). CMC was determined by measuring the visible absorption (404 nm) of a dye with low aqueous solubility, coumarin 503 [(7-ethylamino)-6-methyl-4-(trifluoromethyl)-2H-1-benzopyran] (Exciton, Dayton, OH), as a function of psychosine concentration. The visible absorbance of the dye solution increases dramatically at CMC because of the increased solubility of the dye in the psychosine micelles. CMC is defined by the intersection of the straight line fits of the absorbance data for concentrations below and above CMC.

EM measurements. Solutions of 4.7 and 2.4 mM psychosine were prepared in 18 mΩ H_2O, and the pH was adjusted to 4.5 or 7.1, respectively. A lower concentration of psychosine was used for the pH 7.1 solution due to its propensity to aggregate at this pH. At 3, 120, and 216 h following preparation, the samples were mixed, and one drop of the solution was placed on a FormVar-coated 200-mesh grid (Electron Microscopy Sciences, Fort Washington, PA) for 4 min. The grids were rinsed with 5 drops of 18 mΩ water that had been pH-adjusted to match the original sample. One drop of 0.1% uranyl acetate (Electron Microscopy Sciences) solution was placed on the grid for 45 s, and the excess was removed with filter paper. The grids were allowed to dry for a minimum of 10 min, and then they were viewed and photographed with a JEOL 100CXII transmission electron microscope (Boston, MA) at 80 KV.

Additional EM studies were performed to examine the effects of concentration on the morphology and/or presence of aggregates. At pH 4.5, the concentrations were 4.71, 2.36, 1.18, 0.59 and 0.29 mM, which were examined at 185 h. At pH 7.1, the concentrations were 2.40, 1.20, 0.60, 0.30, 0.15, 0.08, 0.04 and 0.02 mM, which were examined at 205 h. In order to obtain enough material to visualize it at the lower concentrations at pH 7.1, samples were removed from the bottom of the tube without mixing. No visible material was present at pH 4.5 at any of the concentrations prepared.

RESULTS AND DISCUSSION

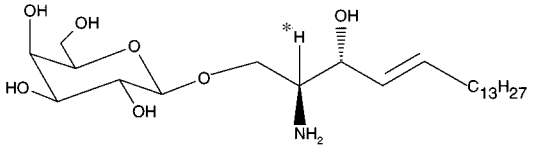
Despite the physiological and pathophysiological significance of pH for the metabolism and toxicity of psychosine (Scheme 1), the physical chemical characterization of this molecule has not received much attention. For example, we were unable to find in the literature a report of the pKa of psychosine. For hydrophobic molecules such as psychosine, a change in protonation state is often accompanied by association to form micelles or vesicles in aqueous solution. Such associative processes can sometimes be detected by a change in chemical shift or by an increase in the NMR line-width resulting from the increased correlation time associated with the aggregates. The ^{1}H NMR spectrum of 2.8 mM psychosine in D_2O solution at pD = 3.45 is shown in Figure 1A. The resonances in this spectrum are relatively sharp. However, a dramatic increase in the resonance line-width is observed as the pD is raised to 6.96 and the protonated amine group of the molecule is partially titrated as illustrated by the spectrum shown in Figure 1B. This increase in line-width probably results from an increase in the average molecular correlation time, suggesting that the neutral form of psychosine forms larger aggregates than the protonated form, a phenomenon common among surfactants and other sphingolipids (23).

The chemical shifts of several of the psychosine ^{1}H NMR resonances are somewhat sensitive to solution pH. However, the most significant pH-dependent change in chemical shift occurs for the proton bound to the same carbon atom as the amine group of psychosine (indicated by an asterisk in the structure drawn in Scheme 1). The resonance due to this proton is marked with an arrow in the spectra shown in Figure 1. In order to calculate the pKa of the amine group, the chemical shift of this proton was measured over a wide pH range as shown by the data points in Figure 2.

Since proton exchange kinetics are generally fast on the NMR time-scale, separate resonances for the amine base and its conjugate acid are not detected. Instead, a single exchange-averaged resonance is detected for this proton that has a chemical shift which is a weighted average of the protonated and deprotonated forms of the molecule. Therefore, in pH regions where a mixture of the protonated and deprotonated species is in equilibrium, the observed chemical shift (δ_{obs}) of the nuclei under examination is given by Equation 2:

$$\delta_{obs} = f_{HA}\,\delta_{HA} + f_{A-}\,\delta_{A-} \qquad [2]$$

where f_{HA} and f_{A-} are the fractional populations and δ_{HA} and δ_{A-} are the chemical shifts of the protonated and deprotonated species. Using Equation 2 and the relationship $f_{HA} + f_{A-} = 1$, the fractional populations can be expressed in terms of δ_{obs}, δ_{HA} and δ_{A-} and directly incorporated into the Henderson-Hasselbalch equation.



SCHEME 1

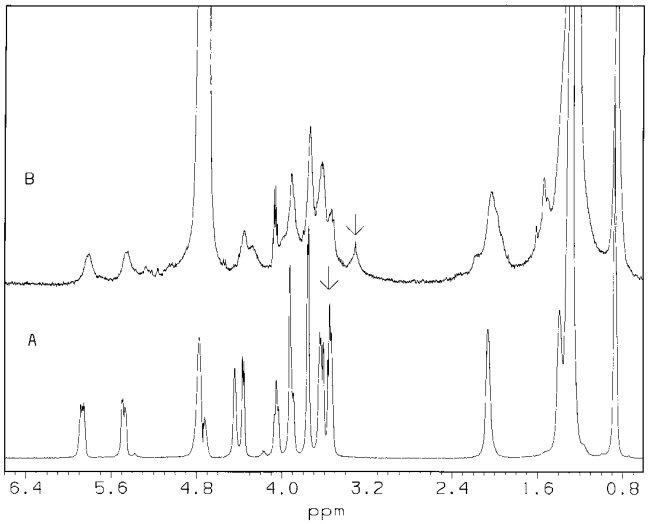


FIG. 1. The ^{1}H nuclear magnetic resonance spectrum of psychosine in D_2O (A) at pD 3.45 and (B) at pD 6.96. The arrows mark the resonance due to the proton indicated by the asterisk in Scheme 1.

A nonlinear least-squares fitting routine was used to calculate the group K_a using the above relationships. The single parameter nonlinear least-squares fit for psychosine in D_2O is shown by the solid line drawn through the data points in Figure 2. The pKa of the protonated amine group of psychosine was calculated as 7.18 ± 0.05 using this method. As described in the subsequent sections, the aggregation of psychosine, especially at higher pH, may introduce some error into the measured pKa. However, the measured pKa is in good agreement with that reported for related molecules such as sphingosine (23).

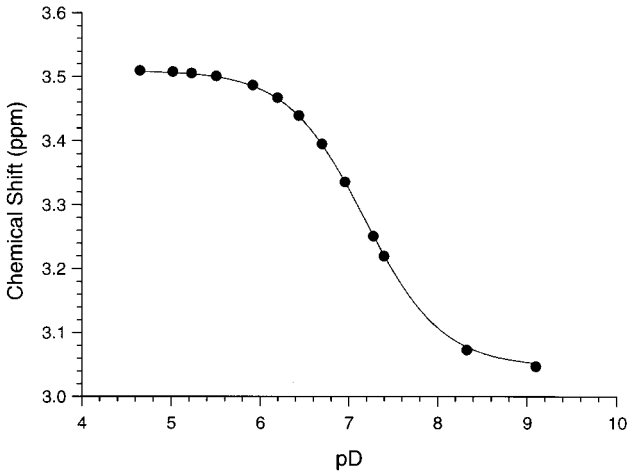

FIG. 2. The pH dependence of the nuclear magnetic resonance chemical shift of the proton adjacent to the psychosine NH group. The solid line drawn through the experimental data is the result of a nonlinear least-squares fit of the monoprotic deprotonation model to the experimental data.

Previous studies that examined the inhibition of PKC (4,6) or mitochondrial enzymes (7–9) by psychosine utilized assay conditions with a pH ranging from 7.4–7.5. Thus, the amine group on psychosine would have been mostly deprotonated (62%) in these assays. Since the free amine group has been shown to be essential for PKC inhibition (4), the charge on the amine group could be essential for the inhibition properties of psychosine. If the protonated state is the active state, then the actual concentration required for inhibition is significantly less than that reported, which represented the total amount of material added to the assays.

NMR diffusion measurements. The association of psychosine to form organized structures, such as micelles, also can be detected by monitoring the translational diffusion coefficient of the molecule in solution. Diffusion coefficients measured with pulsed-field gradient NMR spectroscopy have been employed in the study of a variety of surfactants and phospholipids (14,15,24,25). The diffusion coefficient determined for 2.8 mM psychosine in D_2O solution at pD 4.46 is $1.16 \pm 0.02 \times 10^{-10}$ m^2/s. To evaluate whether association occurs at this concentration even when psychosine is protonated, the diffusion coefficient of a 0.10 mM solution of psychosine was measured at this pD. The diffusion coefficient of psychosine in this dilute solution, $4.06 \pm 0.26 \times 10^{-10}$ m^2/s, probably reflects the diffusion coefficient of the monomer. The higher error obtained in this measurement can be attributed to the lower signal-to-noise ratio of the NMR spectra of the more dilute solution. The diffusion coefficient determined for a pD 7.04 solution of 2.8 mM psychosine, $0.77 \pm 0.02 \times 10^{-10}$ m^2/s, indicates further association of the psychosine as the fraction of the protonated form of the molecule is decreased. The pH dependence of the psychosine diffusion coefficients parallels the increase in line-width observed in the proton NMR spectrum. Although it is not possible to determine the number or shape of psychosine aggregates from the NMR experiments, the good fit of the diffusion results to a single diffusion coefficient in each case suggests fast exchange between the aggregate species.

EM and CMC measurements. The size and shape of psychosine aggregates at 4.7 mM were measured as a function of pH and time. At pH 4.5, spherical aggregates with a diameter of ~14 nm were observed at 3 (Fig. 3A) and 120 h (Fig. 3B). By 216 h, some aggregates increased in size to ~18 nm (Fig. 3C). Solutions at pH 4.5 remained clear for several months following preparation.

Additional studies were performed at 185 h to examine the function of concentration on aggregate formation at pH 4.51. Spherical aggregates were observed at 2.36 and 1.18 mM, but the density of structures was much less in the latter solution. There were no spherical aggregates at 0.59 or 0.29 mM. These findings are in good agreement with the CMC, which was found to be 1.26 mM at pH 4.0.

Increasing the pH to 7.1 dramatically affected the stability of psychosine aggregates at 2.4 mM. At 3 h, a range of spherical structures with a diameter of 15–23 nm was detected (Fig. 3D). At 120 (Fig. 3E) and 216 h (Fig. 3F,3G), a heterogeneous population of structures was observed. Some aggregates were only a few nm in diameter, while other aggregates had a diameter in excess of 100 nm with a spherical or irregular shape. Solutions at pH 7.1 eventually became turbid and remained that way for several months following preparation.

Additional studies were performed at 205 h to examine the function of concentration on aggregate formation at pH 7.15. Pleomorphic structures, which were similar to those structures depicted in Figure 3F and 3G, were observed at the following concentrations: 2.40, 1.20, 0.60, 0.30, 0.15, 0.08, and 0.04 mM. The appearance of the large structures at concentrations of 0.30 mM and lower was generally limited to dense, round structures. Structures were not observed at a concentration of 0.02 mM.

Attempts to determine the CMC at pH 7.0 were unsuccessful with coumarin 503 because a definitive break was not observed in the absorbance data for coumarin 503 as a function of psychosine concentration, although the solubility of the dye did increase concomitantly with the psychosine concentration.

Data from both NMR and EM studies indicate that psychosine forms larger aggregates at a neutral pH compared to an acidic pH, and EM studies indicate that aggregates at a neutral pH form at a lower concentration and increase in size with time. Since the pKa of the free amine group was determined to be 7.18 ± 0.05, the greater propensity to form aggregates at pH 7.1 is likely due to the deprotonation of this amine group. Also, the protonated state of this amine group is likely responsible for the decreased stability of the aggregate structures over time. It is likely that in the protonated state, the amine group is lifted above the hydrophobic layer formed by the carbon chains. This displacement of the amine group could enable the acyl chains to achieve an orderly array that is very stable. The displacement of the amine group also would extend galactose further away from the hydrophobic layer than if the amine were embedded in the hydrophobic region. This greater extension of galactose could be an important component of the enzymatic reaction by galactosylceramidase, which is the lysosomal enzyme that removes the galactose from psychosine. Galactosylceramidase has an optimal pH of 4.2–4.5 (26,27), and 99.8% of psychosine is protonated at pH 4.5. When the amine group is deprotonated, it is probably associated with the hydrophobic aspects of the aggregates. The interaction of the amine group with neighboring hydrophobic regions of adjacent molecules could result in a less orderly packing, which could account for the greater instability of the aggregates at pH 7.1. Although the deprotonated state of sphingosine (psychosine without galactose) enables it to traverse membranes (23), deprotonated psychosine would be less likely to cross membranes due to the galactose moiety.

Previous studies examining the disruption of cellular and mitochondrial membranes by psychosine (5,6,7,28) have performed assays at pH 7.4–7.5. Thus, the amine group on psychosine would mostly be in the deprotonated state in these assays. This finding suggests that the deprotonated state desta-

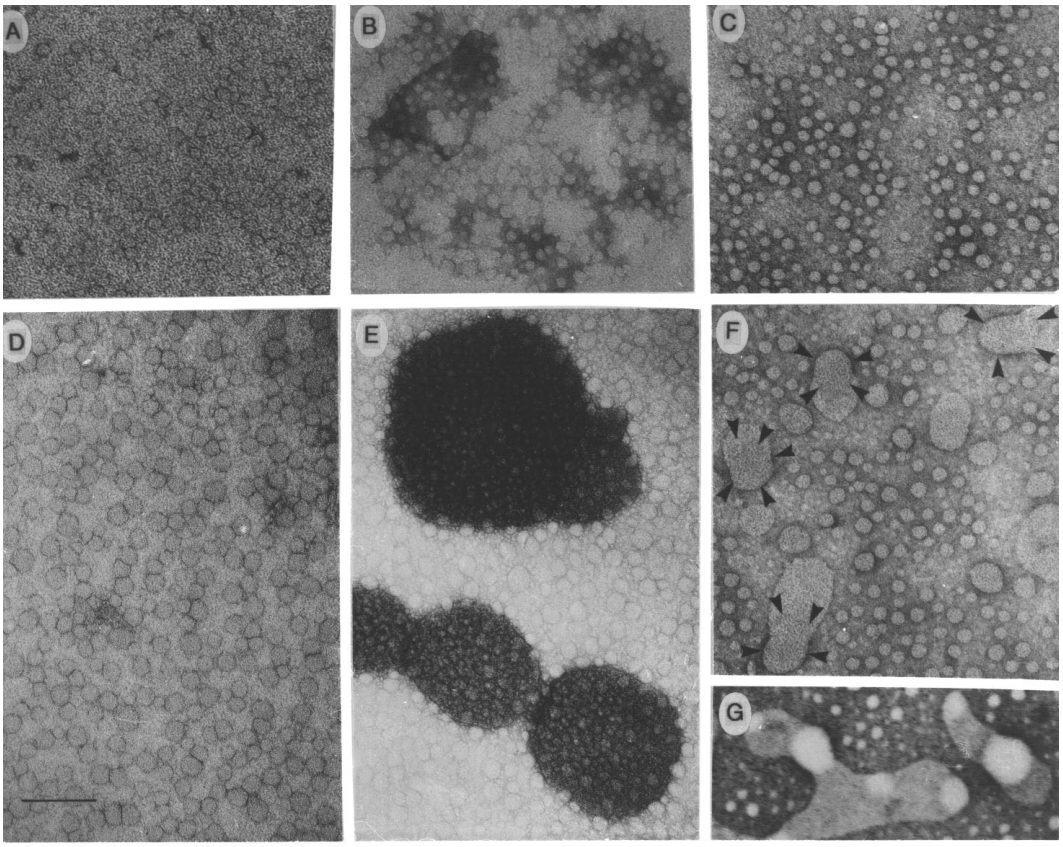

FIG. 3. Psychosine was prepared at pH 4.5 (A–C) or 7.1 (D–G) and processed for negative staining at 3, 120, and 216 h. (A,B) Spherical structures with an approximate diameter of 14 nm were observed in a solution with a pH of 4.5 at 3 h (A) and 120 h (B). Some of the structures had a slightly smaller or larger diameter. (C) Spherical structures with a diameter of ~18 nm or smaller were observed at pH 4.5, 216 h. (D) Spherical structures generally ranging in diameter from 15–23 nm were observed at pH 7.1, 3 h. Some smaller structures also were observed. (E) Two groups of structures were observed at pH 7.1, 120 h—one group had spherical structures with a diameter of ~2–~23 nm, and a second group had large, round structures that could be in excess of 100 nm in diameter. This second group of structures is seen as the intensely stained, large structures. (F,G) Structures ranging in size from a few nm to 100 or more nm were observed at pH 7.1, 216 h. Those structures with a smaller diameter generally had a round appearance, while the larger structures had an oval or irregular oblong shape. Within these larger structures, there was generally a region that had a more dense appearance than the rest of the structure. In F, the dense regions are marked by the arrowheads, and in G they appear as the white structures within the gray oblong structures. Bar = 100 nm.

bilizes and/or disrupts the organization of cellular membranes.

Synthesis and Nuclear Magnetic Resonance Properties of All Geometrical Isomers of Conjugated Linoleic Acids

Marcel S.F. Lie Ken Jie*, Mohammed Khysar Pasha, and Mohammad Shahin Alam

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: Pure geometric isomers of conjugated linoleic acid were prepared from castor oil as the primary starting material. Methyl octadeca-9*Z*,11*E*-dienoate (**2**) and methyl octadeca-9*Z*,11*Z*-dienoate (**4**) were obtained by zinc reduction of methyl santalbate (**1**, methyl octadec-11*E*-en-9-ynoate) and methyl octadec-11*Z*-en-9-ynoate (**3**), respectively, as the key intermediates. Methyl octadeca-9*E*,11*E*-dienoate (**8**) and methyl octadeca-9*E*,11*Z*-dienoate (**9**) were prepared by demesylation of the mesyloxy derivative of methyl ricinelaidate (**6**, methyl 12-hydroxy-octadec-9*E*-enoate). A study of the nuclear magnetic resonance spectral properties was carried out, and the shifts of the olefinic carbon atoms of 18:2(9*Z*,11*E*) (**2**) and 18:2(9*E*,11*Z*) (**9**) were readily identified by a combination of incredible natural abundance double quantum transfer experiment, heteronuclear multiple bond correlation, and ^{1}H-^{13}C correlation spectroscopy correlation techniques. Doubts remain in the absolute identification of the individual olefinic carbon atoms of the 18:2(9*Z*,11*Z*) (**4**) and 18:2(9*E*,11*E*) (**8**), except the fact that the shifts of the "inner" (C-10 and C-11) and "outer" (C-9 and C-12) positioned olefinic carbon atoms of the conjugated diene system are distinguishable.

Lipids 32, 1041–1044 (1997).

There is considerable interest in conjugated linoleic acids (CLA), a mixture of geometric isomers of 18:2(9,11), which show unique biological properties. These fatty acids are recognized as special nutrients that function to regulate energy retention and protein metabolism in animals (1). CLA have been identified as potent anticarcinogens in a number of model systems (2–8). For example, CLA inhibit benzo(α)-pyrene-induced stomach neoplasia in the mouse (3). The antioxidant activity of this group of conjugated unsaturated fatty acids has been offered as a possible explanation for its anticarcinogenic effects (3,5,9). It also has been suggested that the antioxidant properties of CLA cause the reduction of atherosclerosis in CLA-fed rabbits (10). The anticancer properties of CLA may be related to products formed by autoxidation of the substrates. There is speculation that CLA may cyclize to form furan fatty acids, as the autoxidized products of furan fatty acids have been shown to inhibit urease enzyme activities (11).

In order to study the physical and biological properties of each individual geometric isomer of CLA in detail, we report in this paper the synthesis and the nuclear magnetic resonance (NMR) properties of each individual geometric isomer of CLA. Mixtures of the geometric isomers of CLA have been prepared by alkali isomerization of linoleic acid (12,13). CLA isomers were also obtained by the dehydration of methyl ricinoleate on heating *in vacuo* in the presence of $KHSO_4$ (14). Dehydration of ricinelaidic acid at high heat under vacuum formed a polyester, which on pyrolysis afforded the 18:2(9*E*,11*E*) isomer (15). Another method involved the mesylation of methyl ricinoleate, which was followed by base-catalyzed elimination of the mesyloxy function to yield CLA in good yield (16). Many of the abovementioned procedures give rise to mixtures of the conjugated dienoic acids. Our objective in this project was to produce the four geometric isomers of 18:2(9,11) in the pure form and to study their NMR properties.

RESULTS AND DISCUSSION

In planning the synthesis of the individual geometric isomers of CLA, we considered castor oil (a ready source of ricinoleic acid, 12-hydroxy-octadec-9*Z*-enoic acid) as an appropriate starting material. The procedure of Gunstone and Said (16), of demesylation of the mesyloxy derivative of methyl ricinoleate with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), appeared very suitable for the preparation of 18:2(9*Z*,11*E*), as elimination of the mesyloxy group favored the *E*-olefinic bond across the C-11/C-12 carbon atoms of the alkyl chain. However, this approach could not be extended to the production of 18:2(9*Z*,11*Z*) from the same mesyloxy derivative of methyl ricinoleate, as this isomer would constitute a minor component and would be difficult to isolate from the major product [18:2(9*Z*,11*E*)]. To circumvent this problem, methyl santalbate (**1**, methyl octadec-11*E*-en-9-ynoate) and its *Z*-isomer (**3**, methyl octadec-11*Z*-en-9-ynoate) were considered as alternative key intermediates for the synthesis of

Abbreviations: INADEQUATE, incredible natural abundance double quantum transfer experiment; ^{13}C NMR, carbon-13 nuclear magnetic resonance spectroscopy; CLA, conjugated linoleic acid; COSY, correlation spectroscopy; DBU, 1,8-diazabicyclo[5.4.0]undec-7-ene; HMBC, heteronuclear multiple bond correlation; ^{1}H NMR, proton nuclear magnetic resonance; IR, infrared spectroscopy; NMR, nuclear magnetic resonance; UV, ultraviolet spectroscopy.

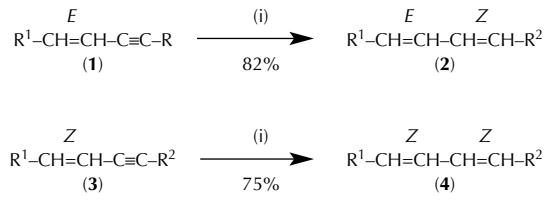
18:2(9*Z*,11*E*) and 18:2(9*Z*,11*Z*), respectively. The procedures for the synthesis of methyl santalbate (**1**) and its *Z*-isomer (**3**) from ricinoleic acid were recently reported (17). Thus, with the olefinic bond in the desired configuration and position in the alkyl chain of the enyne intermediate, zinc reduction (18) of the enyne system would furnish the requisite geometric isomers as presented in Scheme 1.

In this project the results showed that zinc in aqueous *n*-propanol was highly selective in the reduction of the acetylenic bond of the enyne intermediates to the corresponding *Z*-olefinic bond. Any unreacted enyne substrate was readily removed by treatment of the isolated product with mercury(II) sulfate in methanol, which converted the enyne intermediate to the corresponding keto-ene derivative. The latter was then separated by silica column chromatography (19). Thus, by using methyl santalbate (**1**) and its *Z*-isomer (**3**) as intermediates, we were able to obtain 18:2(9*Z*,11*E*) (**2**) and 18:2(9*Z*,11*Z*) (**4**), respectively, in the pure form.

To obtain the 18:2(9*E*,11*E*) and 18:2(9*E*,11*Z*) isomers, the procedure of Gunstone and Said (16) was adopted. Methyl ricinoleate (**5**) was first isomerized (using *p*-toluenesulfinic acid) to methyl ricinelaidate (**6**, methyl 12-hydroxy-octadec-9*E*-enoate). Demesylation of the mesyloxy derivative (**7**) of methyl ricinelaidate with DBU furnished 18:2(9*E*,11*E*) (**8**) in 76% yield and 18:2(9*E*,11*Z*) (**9**) (15%) (Scheme 2). The free acid of 18:2(9*E*,11*E*) (**8**) was readily isolated by crystallization from ethanol. The alcoholic mother liquor contained a high proportion of the 18:2(9*E*,11*Z*) isomer, which was subsequently purified by urea fractionation. This approach allowed the production of pure 18:2(9*E*,11*E*) (**8**) and 18:2(9*E*,11*Z*) (**9**), despite the fact that the latter isomer could be regarded as a side-product rather than a main product.

To assign the chemical shifts of the carbon atoms of the conjugated diene system of each CLA isomer, it was necessary to conduct INADEQUATE (incredible natural abundance double quantum transfer experiment), HMBC (heteronuclear multiple bond correlation), and two-dimensional ^{1}H-^{13}C correlation spectroscopy (COSY) correlation techniques on the carbon signals of the diene system of the *E*,*Z*-isomers. The results of these experiments for the CLA isomers are summarized in Table 1.

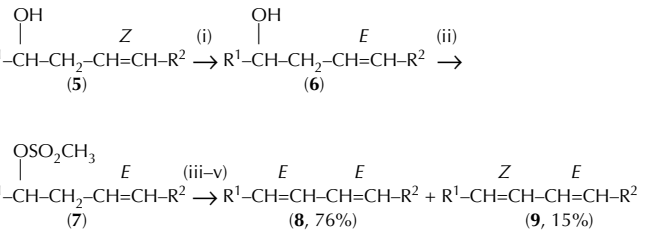
The ^{1}H NMR spectrum of 18:2(9*Z*,11*E*) (**2**) showed four distinct signals for the four olefinic protons. There appeared



R^1 = $CH_3(CH_2)_5$; R^2 = $(CH_2)_7COOCH_3$

Reagents and conditions: (i) zinc, *n*-propanol, reflux, 10 h.

SCHEME 1



R^1 = $CH_3(CH_2)_5$; R^2 = $(CH_2)_7COOCH_3$

Reagents and conditions: (i) *p*-toluenesulfinic acid, dioxane, reflux, 1 h; (ii) methane sulfonyl chloride, triethylamine, dichloromethane; (iii) 1,8-diazabicyclo[5.4.0]undec-7-ene, dimethylsulfoxide, reflux, 12 h; (iv) crystallization from ethanol and urea fractionation of mother liquor; (v) BF_3-methanol, reflux.

SCHEME 2

two multiplets (δ_H 5.32 and 5.65) and two triplets (δ_H 5.82, J = 5.4 Hz and 6.24, J = 12.9 Hz), which correspond to the shifts of the protons of the "outer" (9-*H*, 12-*H*) and "inner" (10-*H*, 11-*H*) olefinic protons of the diene system, respectively. These signals were confirmed by ^{1}H-^{13}C COSY correlation spectral analysis. From the ^{13}C NMR spectrum, the carbon signals of the methylene groups adjacent to the diene system were readily recognized, as the signals of the C-8 carbon atom (adjacent to the *Z*-olefinic bond) appeared at δ_C 27.66, while that of C-13 (adjacent to the *E*-olefinic bond) was found at δ_C 32.92. These results agreed with values reported by Bus *et al.* (20). From the INADEQUATE and HMBC spectra, it was possible to interconnect the signal at δ_C 32.92 to that at δ_C 134.76; δ_C 134.76 to δ_C 125.58; δ_C 125.58 to δ_C 128.71; and δ_C 27.66 to δ_C 129.89, while the latter signal was also

connected to δ_C 128.71. From these connections, it was possible to identify unequivocally the shifts of the diene carbon atoms of 18:2(9*Z*,11*E*) (**2**) as: δ_C 129.89 (C-9), 128.71 (C-10), 125.58 (C-11), and 134.76 (C-12). This result appeared to be contrary to values reported by Bus *et al*. (20), who described their assignments as: δ_C 130.00 (C-9), 125.75 (C-10), 128.90 (C-11), and 134.80 (C-12). However, from the NMR correlation techniques applied, we are of the opinion that the values for the C-10 and C-11 by Bus *et al*. (20) were erroneously assigned.

By using a combination of similar NMR techniques (INADEQUATE, HMBC, and COSY), the assignment of the signals of the various critical carbon atoms of 18:2(9*E*,11*Z*) (**9**) was determined as: δ_C 32.86 (C-8), 134.51 (C-9), 125.72 (C-10), 128.57 (C-11), 130.17 (C-12), and 27.72 (C-13). The ^{1}H NMR spectral analysis showed the signals of the olefinic protons at δ_H 5.30 (*m*, 12-*H*), 5.66 (*t*, *J* = 5.4 Hz, 11-*H*), 5.93 (*m*, 9-*H*) and 6.24 (*t*, *J* = 12.9 Hz, 10-*H*).

The ^{1}H NMR spectrum of 18:2(9*Z*,11*Z*) (**4**) showed a multiplet at δ_H 5.40 for the "outer" positioned protons of the diene system (9-*H*, 12-*H*) and a double doublet at δ_H 6.22 for the "inner" positioned protons (10-*H*, 11-*H*). The presence of a *Z*,*Z*-diene system was clear from signals in the ^{13}C NMR spectrum at δ_C 27.46 and 27.64 corresponding to the C-8 and C-13 carbon atoms, respectively. However, it was not possible to differentiate these two nuclei. A clear connection was established from the INADEQUATE spectrum, which confirmed the link of the signals at δ_C 27.46 and 27.54 to δ_C 131.87 and 132.14. However, it was difficult to assign these signals to individual carbon atoms, except that the olefinic carbon atoms were correlated with the proton signal of the "outer" position protons (C-9, C-12) of the diene system as observed from the ^{1}H-^{13}C COSY correlation spectrum. The two remaining olefinic carbon signals, δ_C 123.58 and 123.72, were correlated to the proton signal of the "inner" positioned protons of the diene system (C-10, C-11). Difficulties therefore remain for the assignment of these closely related olefinic carbon atoms.

The signals of the olefinic protons in 18:2(9*E*,11*E*) (**8**) showed the signals of the "inner" positioned olefinic protons (10-*H*, 11-*H*) in a slightly more upfield position (at δ_H 5.96) than those of the similarly positioned protons of the 18:2(9*Z*,11*Z*) isomer (**4**). The *E*,*E*-diene nature of the conjugated system was evident from the appearance of two signals at δ_C 32.61 and 32.68 for the shifts of the methylene carbon atoms (C-8, C-13) adjacent to the diene system. Similar to the *Z*,*Z*-diene isomer (**4**), it was not possible to differentiate with certainty each of the carbon atoms of the olefinic system of the *E*,*E*-diene isomer (**8**), except that the "inner" and "outer"positioned olefinic carbon atoms appeared at δ_C 130.37 and 130.51 (C-10, C-11) and 132.16 and 132.43 (C-9, C-12), respectively.

From these results we conclude that specific isomers of CLA can be obtained by partial synthesis from castor oil and that the *E*,*Z*-, *Z*,*E*-, *E*,*E*-, and *Z*,*Z*-isomers can be characterized in sufficient detail by a combination of NMR techniques.

EXPERIMENTAL PROCEDURES

Methyl octadec-11*E*-en-9-ynoate (**1**) and octadec-11*Z*-en-9-ynoate (**3**) were prepared from castor oil by the method described elsewhere (17). Infrared (IR) spectra were measured on a Shimadzu model IR-470 spectrophotometer (Shimadzu Corp., Kyoto, Japan) on neat samples placed between NaCl discs. Ultraviolet (UV) spectra were recorded on a Perkin Elmer model Lambda 19 spectrophotometer (Perkin Elmer, Inc., Norwalk, CT), NMR spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) (0.2–0.3 mM) with tetramethylsilane as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from tetramethylsilane ($\delta_{TMS} = 0$).

*Preparation of methyl octadeca-9Z,11E-dienoate (**2**).* A mixture of methyl octadec-11*E*-en-9-ynoate (**1**, 4.9 g, 16.7 mmol), aqueous *n*-propanol (120 mL, 50%, vol/vol), and zinc powder (75 g) was refluxed for 10 h. The cooled reaction mixture was filtered and the filtrate diluted with water (150 mL). The aqueous filtrate was extracted with diethyl ether (2 × 100 mL). The ethereal extract was successively washed with dilute HCl (2 M, 75 mL) then water (50 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated to give methyl octadeca-9*Z*,11*E*-dienoate (**2**, 4.0 g, 82%). IR (cm^{-1}) 2927, 2855, 1743 (C=O, str., ester), 1436, 1171, 982, and 947 (*trans*-unsaturation); UV_{max} 232 nm; ^{1}H NMR(δ_H) 0.88 (*t*, *J* = 6 Hz, 3H, CH_3), 1.25–1.43 (*m*, 18H, CH_2), 2.00–2.10 (*m*, 4H, 8-H_2 and 13-H_2), 2.29 (*t*, *J* = 7 Hz, 2H, 2-H_2), 3.66 (*s*, 3H, COOCH_3), 5.32 (*m*, 1H, 9-*H*), 5.65 (*m*, 1H, 12-*H*), 5.82 (*t*, *J* = 5.4 Hz, 1H, 10-*H*), and 6.24 (*t*, *J* = 12.9 Hz, 1H, 11-*H*).

*Preparation of methyl octadeca-9Z,11Z-dienoate (**4**).* Zinc reduction of methyl octadec-11-*Z*-en-9-ynoate (**3**) in aqueous *n*-propanol was conducted by a similar procedure to that described above. Unreacted substrate (about 14% by gas chromatography analysis) in the isolated product was removed by treating the mixture with mercuric sulfate in anhydrous methanol which allowed hydration of triple bond to give the corresponding keto derivatives (19). Silica gel column chromatographic purification using a mixture of *n*-hexane/diethyl ether, 95:5, vol/vol as eluent gave pure methyl octadeca-9*Z*,11*Z*-dienoate (**4**, 75%). IR (cm^{-1}) 2930, 2856, 1742 (C=O, str. ester), 1435, 1171, and 757; UV_{max} 238 nm, ^{1}H NMR (δ_H) 0.88 (*t*, *J* = 6 Hz, 3H, CH_3), 1.18–1.51 (*m*, 18H, CH_2), 2.15 (*m*, 4H, 8-H_2 and 13-H_2), 2.3 (*t*, *J* = 7 Hz, 2H, 2-H_2), 3.65 (*s*, 3H, COOCH_3), 5.40 (*m*, 2H, 9-*H* and 12-*H*), and 6.22 (*dd*, *J* = 8.1 Hz, 2H, 10-*H* and 11-*H*).

*Preparation of methyl octadeca-9E,11E-dienoate (**8**) and octadeca-9E,11Z-dienoate (**9**).* Methyl 12-mesyloxy-octadec-9*E*-enoate (**7**) was prepared according to the method described earlier (17,21). Methyl 12-mesyloxy-octadeca-9*E*-enoate (**7**, 2.0 g, 5.1 mmol) was refluxed with DBU in dimethylsulfoxide (15 mL) for 12 h. The reaction mixture was passed through a dry column of silica (30 g), and the products were isolated by eluting with a mixture of *n*-hexane/di-

ethyl ether (9:1, vol/vol, 400 mL). The recovered products (1.42 g) were treated with ethanolic KOH (5%, 20 mL) at room temperature for 1 h. Water (50 mL) was added and the aqueous solution acidified with dilute HCl (1 M, 20 mL). The reaction mixture was extracted with diethyl ether (3 × 40 mL). The ethereal extract was washed with water (2 × 20 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated to give a residue (1.3 g). The residue was recrystallized from ethanol (3 × 20 mL) to yield pure octadeca-9*E*,11*E*-dienoic acid (1.0 g, 76%). The latter was esterified to methyl octadeca-9*E*,11*E*-dienoate (**8**) using borontrifluoride methanol complex. IR (cm^{-1}) 1740 (C=O, str. ester) and 988 (C=C, *trans*); UV_{max} 231; ^1H NMR (δ_H) 0.88 (*t*, *J* = 6 Hz, 3H, CH_3), 1.08–1.79 (*m*, 14H, CH_2), 1.61 (*m*, 4H, 7-H_2 and 14-H_2), 2.00–2.07 (*m*, 4H, 8-H_2 and 13-H_2), 2.29 (*t*, *J* = 7 Hz, 2H, 2-H_2), 3.65 (*s*, 3H, $COOCH_3$), and 5.56 (*m*, 2H, 9-*H* and 12-*H*) and 5.96 (*m*, 2H, 10-*H* and 11-*H*).

The mother liquor from the above recrystallization procedure was diluted with water (50 mL) and extracted with diethyl ether (30 mL) and dried over sodium sulfate. The filtrate was evaporated, and the residue (0.23 g) was crystallized with urea (0.7 g) in methanol (5 mL). The mother liquor gave pure methyl octadeca-9*E*,11*Z*-dienoate (**9**, 0.2 g, 15%). IR (cm^{-1}) 2930, 2856, 1742, and 945; UV_{max} 232; ^1H NMR (δ_H) 0.88 (*t*, *J* = 6 Hz, 3H, CH_3), 1.20–1.50 (*m*, 18H, CH_2), 2.00–2.10 (*m*, 4H, 8-H_2, 13-H_2), 2.30 (*t*, *J* = 7 Hz, 2H, 2-H_2), 3.66 (*s*, 3H, $COOCH_3$), 5.30 (*m*, 1H, 12-*H*), 5.66 (*t*, *J* = 5.4 Hz, 1H, 11-*H*), 5.93 (*m*, 1H, 9-*H*), 6.24 (*t*, *J* = 12.9 Hz, 1H, 10-*H*).

ABSTRACT: The growth inhibitory effects of 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OCH_3) and various liposome compositions of ET-18-OCH_3 were compared in a standardized growth inhibition assay utilizing a diverse tumor cell line panel including cell lines expressing multidrug resistance. ET-18-OCH_3 and ELL-12 (4:3:1:2, dioleoylphosphatidylcholine/cholesterol/dioleoylphosphatidylethanolamine–glutaric acid/ET-18-OCH_3), an optimal liposomal ET-18-OCH_3 formulation, inhibited growth in the micromolar range in drug-sensitive and -resistant cells. In general, ET-18-OCH_3–liposomes were about twofold less growth inhibitory than ET-18-OCH_3. However, the known hemolytic effects of ET-18-OCH_3 were greatly reduced, up to 20 or more times, by liposome association. The effects of ET-18-OCH_3 and ELL-12 were compared in intracellular [Ca^{2+}] modulation and DNA fragmentation assays. ET-18-OCH_3 elicited both concentration- and serum-dependent transient and permanent increases in intracellular [Ca^{2+}]. In contrast, ELL-12 did not modulate intracellular [Ca^{2+}]. ET-18-OCH_3 and ELL-12 similarly affected DNA fragmentation, which may be indicative of apoptosis. The results suggest that, although the specific growth inhibitory effects of ET-18-OCH_3 and ELL-12 are similar, associating ET-18-OCH_3 with stable well-characterized liposomes eliminates nonspecific cell membrane-associated lytic effects.

Lipids 32, 1045–1054 (1997).

Alkylphosphocholines, such as the ether lipid 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OCH_3), are antitumor agents that differ from many other cancer therapeutic agents in that they do not interact directly with DNA and are not myelosuppressive in animal models (1,2).

Alkylphosphocholines, including ET-18-OCH_3, have been reported to preferentially accumulate in the plasma membranes of transformed cell lines (3,4) and may modulate membrane-associated signal transduction pathways (5,6). For example, ET-18-OCH_3 directly inhibits two important enzymes involved in intracellular signal transduction, phospholipase C and protein kinase C (7). Furthermore, ET-18-OCH_3 was shown to inhibit transient increases in intracellular Ca^{2+} levels associated with receptor-mediated growth factor and mitogen binding, perhaps by modulating the phosphatidylinositol turnover pathway (8–10). ET-18-OCH_3 has also elicited acute transient intracellular [Ca^{2+}] increases which may be related to inositol triphosphate-induced [Ca^{2+}] transients (11,12). Recent evidence (13) suggests that ET-18-OCH_3 may modulate transcription by inhibiting a nuclear factor kappa B pathway by a protein kinase C-dependent mechanism. ET-18-OCH_3 has also been reported to interfere with cell cycle progression in transformed cells. For example, ET-18-OCH_3 caused an accumulation of BAC1.2F5 cells, a macrophage-like cell line, in G2/M phase (14) and induced DNA fragmentation and morphological changes, indicative of programmed cell death, in both BAC1.2F5 and HL-60, a human leukemia cell line (14,15). These studies suggest that the anticancer effects of ET-18-OCH_3 are mediated by modulation of intracellular signal transduction and/or cell cycle progression.

Although ET-18-OCH_3 has demonstrated antitumor activity in various animal models, only modest clinical activity has been demonstrated, and it has significant clinical toxicities, including hemolysis (1,16). Since the association of several drugs with liposomes has been shown to attenuate nonspecific toxicity *in vivo* (17–19), we thought that association of ET-18-OCH_3 with liposomes would reduce its toxicity and perhaps enhance its delivery to tumors. We have described previously the biophysical characterization of a number of ET-18-OCH_3 liposome formulations (20,21). In this report the growth inhibitory properties, effects on intracellular Ca^{2+} mobilization, and the effects on DNA fragmentation of some of these formulations were compared to those of free ET-18-OCH_3.

MATERIALS AND METHODS

Cell lines. A549, human nonsmall cell lung carcinoma; MCF 7, human breast carcinoma; MCF 7/adr, multidrug-resistant human breast carcinoma; Ovcar 3, human ovarian carcinoma;

Abbreviations: CH, cholesterol; ELL-12, dioleoylphosphatidylcholine/cholesterol/dioleoylphosphatidylethanolamine–glutaric acid, 4:3:1:2; ET-18-OCH_3, 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine; GI_{50}, drug concentration which inhibits cell growth 50%; HI_5, drug concentration required to cause 5% hemolysis; PBS, phosphate-buffered saline without Ca^{2+} and Mg^{2+}; RFU, relative fluorescence units; SRB, sulforhodamine B; TI, therapeutic index.

P388, murine leukemia; and P388/adr, drug-resistant murine leukemia, were obtained from the DCT Tumor Repository (NCI–Frederick Cancer Research Facility, Frederick, MD). Du145, human prostate carcinoma, was obtained from the American Type Culture Collection (Rockville, MD). L1210 and L1210/vmdr, murine leukemias, were a generous gift from Dr. Alan Sartorelli (Yale University School of Medicine, New Haven, CT). The L1210/vmdr subline was L1210 transfected with a vector (pHaMDR1/A) containing the *mdr 1* gene.

ET-18-OCH_3 and ET-18-OCH_3 liposome formulations. The L-isomer of ET-18-OCH_3 was purchased from Calbiochem (La Jolla, CA) or Avanti Polar Lipids, Inc. (Alabaster, AL). The other lipids used for the liposome formulations were all purchased from Avanti Polar Lipids, Inc. ET-18-OCH_3 liposome formulations, listed in Table 1, were prepared using the solvent evaporation method (22). Briefly, ET-18-OCH_3 and other lipids were dissolved in chloroform/methanol (2:1, vol/vol) and mixed in the desired molar lipid ratios of neutral phospholipid/cholesterol/ET-18-OCH_3/glutaric acid-derivatized phospholipid. After thorough mixing, the organic solvent was vacuum-evaporated at 45°C, and the thin dried film was hydrated with Dulbecco's phosphate buffered saline (PBS) without Ca^{2+} or Mg^{2+} (Mediatech, Herndon, VA) for 1 h at room temperature or above the transition temperature for the lipids. The resulting multilamellar preparations were extruded 10 times through 100-nm double-stacked Nucleopore filters using an extruder device (Lipex Biomembranes, Vancouver, British Columbia, Canada). The liposomes were examined by light microscopy to check morphology, and size was determined using a Nicomp Model 370 Submicron Particle Sizer system (Santa Barbara, CA). Liposome size ranged from 96–126 nm. ET-18-OCH_3 and other lipid concentrations in the final preparations were determined using reverse-phase high-performance liquid chromatography using an evaporative light-scattering detector with 4% water in methanol as the mobile phase.

In vitro *growth inhibition.* A sulforhodamine B (SRB) assay was used to determine relative *in vitro* drug sensitivity using the GI_{50} parameter (the concentration of drug which inhibits cell growth 50%). The detailed methodology of the SRB assay is described elsewhere (23,24). Briefly, 96-well microtiter plates were inoculated with 100 µL of the above cell lines at optimal cell densities, 3500–15,000 cells/well, in medium RPMI 1640 with L-glutamine (Mediatech, Herndon, VA) supplemented with 10% fetal bovine serum (Life Technologies, Grand Island, NY) for all cell lines except for Du145 which was cultured in Eagle's minimal essential medium with Earle's salts and L-glutamine (Mediatech) supplemented with 10% fetal bovine serum (Life Technologies). The plates were then incubated for 24 h at 37°C, 100% humidity, and 5% CO_2. Medium (100 µL) was added to designated "time zero" plates which were fixed with 50 µL of 50% trichloroacetic acid (wt/vol) (Sigma, St. Louis, MO) (adherent cells) or 80% trichloroacetic acid (suspension cells) and refrigerated at 4°C for 1 h. The supernatant was then discarded and the plates were rinsed six times with water and air-dried. ET-18-OCH_3 or a liposome formulation of ET-18-OCH_3 was added (100-µL aliquots) to the nonfixed plates at twice the predetermined highest concentration and serially diluted across the plates. Growth control wells received 100 µL of medium. There were triplicate wells on each plate and duplicate plates (six wells) for each drug concentration. The cells were then incubated for 72 h under the above conditions. The treated plates were acid-fixed, rinsed, and dried as above. One hundred microliters of 0.4% SRB (Sigma) in 1% acetic acid (Sigma) was added to the plates and incubated at room temperature for 10 min. Unbound stain was removed by rinsing the plates three times with 1% acetic acid. The plates were air-dried for 24 h. The bound stain was solubilized with 100 µL of 10 mM Tris buffer (Sigma), and the optical density was read spectrophotometrically at 490 nm (Microplate Reader Model 3550-UV; Biorad, Hercules, CA). The raw optical density data were imported into an Excel (Microsoft, Redmond, WA) spreadsheet to determine dose responses. Percentage growth was calculated as follows: $(T - T_0)/(C - T_0) \times 100$ where T = mean optical density of treated wells at a given drug concentration, T_0 = mean optical density of time zero wells, and C = mean optical density of control wells. If $T < T_0$, which indicates that cell death has occurred, then percentage cell death was calculated as $(T - T_0)/(T_0) \times 100$. By varying drug concentration, dose-response curves were generated, and the GI_{50} values were calculated. The GI_{50} values for each experiment were calculated using data obtained from the six wells as described above. The mean GI_{50} values and standard deviations were calculated from the GI_{50} data from each independent experiment. Data obtained using the growth inhibition assay are shown in Tables 1–3 and Figures 1 and 3.

Cell survival assay. Cell survival was determined using a colony-forming assay modified from Fugiwara *et al.* (25). Briefly, T75 culture flasks (Corning Costar, Boston, MA), one for each drug concentration and a growth control, were inoculated with 7.5×10^5 MCF 7 cells (adherent culture) or L1210 cells (suspension culture) in medium (RPMI 1640 with L-glutamine supplemented with 10% fetal bovine serum), and incubated at 37°C, 5% CO_2, and 100% humidity for 24 h (MCF 7) or 6 h (L1210). The supernatant was discarded, and fresh medium containing various concentrations of ET-18-OCH_3 was added to the specified flasks which were incubated at the above conditions for 72 h. In the case of MCF 7, the supernatant from each flask was removed and the cells were rinsed with PBS, and trypsinized using 0.05% trypsin-EDTA (Life Technologies) to dissociate the cell monolayer. The cells were resuspended in the above supernatant so as to include nonadherent (dead or dying) cells in the subsequent cell count. The cell suspension was centrifuged at $180 \times g$, and the cell pellet was resuspended in fresh medium. In the case of L1210, the cell suspension was centrifuged at $180 \times g$, and the cell pellet was resuspended in fresh medium. The cells were counted (Coulter Counter ZM; Coulter Electronics, Inc., Hialeah, FL) and plated in 100-mm plastic petri dishes (500, 200, or 100 cells/plate) (MCF 7) or T75 flasks at 500 cells/flask (L1210).

The petri dishes (or flasks) were incubated 7 to 12 d at the above conditions. In the case of MCF 7, the surviving fraction was determined relative to the mean colony-forming efficiency (number of colonies/the number of cells plated) of the control plates at the different cell densities. The surviving fraction was calculated by dividing the mean colony-forming efficiency of the cells exposed to ET-18-OCH_3 by the control colony-forming efficiency. L1210 survival was determined from number of treated cells as a percentage of controls. The mean surviving cell fraction for each drug concentration was calculated from five duplicate plates or flasks in each experiment. The mean surviving fractions from three individual experiments were averaged and standard deviations were calculated. Data from experiments using the cell survival assay are shown in Figure 2.

Hemolysis assay. Hemolysis was quantitated by measuring hemoglobin release into an isotonic buffer after the addition of ET-18-OCH_3 or liposomal ET-18-OCH_3. Varying concentrations of ET-18-OCH_3 or liposomal ET-18-OCH_3 were incubated with 4% human red blood cell (washed in PBS three times) suspensions in PBS at 37°C for 20 h. The percentage lysis was calculated using lysis after the addition of water as a positive control (100% lysis) and lysis after the addition of PBS as the negative control. After incubation, the samples were centrifuged at 2000 × *g* for 10 min, and the absorbance of the supernatant was measured at 550 nm. Absorbance correlates with hemolysis ($r^2 > 0.9$). ET-18-OCH_3 and the different liposomal formulations were evaluated based on the calculated HI_5 value (the ET-18-OCH_3 concentration required to cause 5% hemolysis). Each formulation was tested in triplicate in each experiment.

Variable drug exposure times (pulse–chase). A549 and MCF 7 cells were used in a modification of the SRB growth inhibition assay to evaluate the effects of ET-18-OCH_3 and liposomal ET-18-OCH_3 at different exposure times. The cell lines were inoculated at 5000 cells/well and incubated for 24 h, as above. "Time zero" plates were fixed, and ET-18-OCH_3 or liposomal ET-18-OCH_3 was added to the rest of the plates. The cells were incubated with the drugs for five different exposure times (1, 4, 8, 24, and 72 h), two plates per exposure time. The posttreatment incubation time totaled 72 h; therefore, the cells exposed for 1, 4, 8, or 24 h were washed twice with fresh medium and incubated 71, 68, 64, or 48 h, respectively. The 72-h time was a continuous exposure. After the posttreatment exposure time, the cells were processed as described for the *in vitro* growth inhibition assay.

Intracellular Ca^{2+} determination. Modulation of intracellular Ca^{2+} was determined utilizing the Ca^{2+} marker Fluo3 (Molecular Probes, Eugene, OR). In order to "load" the Ca^{2+} marker in the cells, the cell-permeable, acetoxy methyl ester derivative of Fluo3, Fluo3AM, was dissolved in a nonionic detergent, 20% Pluronic F-127 (Molecular Probes) in dimethylsulfoxide (J.T. Baker, Phillipsburg, NJ) at 6 mM, then diluted to 6 μM in PBS. The Fluo3AM solution was added to a suspension of L1210 cells. The final concentration of Fluo3AM was 3 μM, and the cell density was either 6×10^5 or 9×10^5 cells/mL. Fluo3AM was incubated with the cells for 30 min at 37°C. Following the 30-min incubation, the cells were centrifuged at 180 × *g*, rinsed with cold PBS, centrifuged, and resuspended in either warm PBS or 10% fetal bovine serum in PBS (pH adjusted to 7.2). The cell suspension was aliquoted into a cuvette, and the relative fluorescence was monitored continuously after the addition of increasing concentrations of ET-18-OCH_3 or a liposomal formulation of ET-18-OCH_3. The Ca^{2+}-associated fluorescence was measured utilizing a photon-counting spectrofluorometer (Photon Technology International, Inc., South Brunswick, NJ) configured for a time-based measurement with the excitation and emission wavelengths set for 470 and 530 nm, respectively (the bandwidth slits were set at 4 nm). Digitonin (Sigma), a nonionic detergent, was added to determine the fluorescence maximum. The fluorescence minimum was calculated at the basal Ca^{2+}-associated fluorescence level when percentage relative fluorescence measurements were compared. EDTA (Sigma) was added to quench fluorescence (fluorescence minimum for $[Ca^{2+}]$ calculation). The $[Ca^{2+}]$ was determined using a method described by Grynkiewicz *et al.* (26). A standard curve was obtained using a calcium calibration buffer kit (Molecular Probes), and from the standard curve, unknown Ca^{2+} concentrations were calculated as: $[Ca^{2+}] = \log_{10}[(F - F_{min})/(F_{max} - F)]$ where F = relative fluorescence units (RFU) of unknown, F_{max} = RFU of sample after the addition of digitonin (50 μM), and F_{min} = RFU of sample after the addition of 50 μM EDTA. In order to differentiate between Ca^{2+} being liberated from intracellular stores or extracellular Ca^{2+}, L1210 cells were assayed with or without the addition of EDTA in the suspension buffer. Ca^{2+} originating from intracellular stores was determined by chelating extracellular Ca^{2+} with EDTA. Total Ca^{2+} originating from both intracellular and extracellular sources was determined without the addition of EDTA.

DNA fragmentation analysis. A modification of the DNA fragmentation analysis described by Gauthier *et al.* (27) was used. L1210 control cells (1×10^6) or cells treated with ET-18-OCH_3 or liposomal ET-18-OCH_3 were washed with PBS and resuspended in 20 μL of lysis buffer [50 mM Tris HCl, pH 8.0, 10 mM EDTA, 0.5% Na laurylsarcosinate containing 1.25 mg/mL proteinase K (Gibco, Grand Island, NY)] and incubated at 50°C for 1 h. Then 10 μL (10.0 mg/mL) of RNase A (Boehringer Mannheim, Indianapolis, IN) was added and incubated at 50°C for 1 h. The reaction was stopped by the addition of 10 μL of loading buffer [10 mM EDTA, pH 8.0, 0.25% bromophenol blue, 0.25% xylene cyanol, 15% Ficoll 400]. The samples were heated at 70°C for 10 min, 10 μL of melted 2% agarose was added, and the whole samples were loaded onto 2% agarose gels. The samples and a marker [100 base pair DNA ladder (Gibco)] were electrophoresed at 50 V for 5–6 h in Tris-borate-EDTA buffer [100 mM Tris, 83 mM boric acid, 1 mM EDTA (pH 8.3)] on a 2% agarose gel. Gels were then stained with 0.5 μg/mL ethidium bromide.

RESULTS

In vitro *growth inhibition by ET-18-OCH$_3$.* A representative dose-response curve for MCF 7 cells treated with ET-18-OCH$_3$ using the SRB assay is shown in Figure 1. There was a twofold difference between the GI_{50} and total growth inhibition (GI_{100}) and a greater than fivefold difference between the GI_{50} and the extrapolated value for 100% cell death (LC_{100}). There were differences in drug sensitivity between cell types. The GI_{50} values for free ET-18-OCH$_3$ for six cell lines investigated were: A549, 6.5 μM; MCF 7, 16.8 μM (Table 1); L1210, 3.9 μM; P388, 5.0 μM (Table 2); Ovcar 3, 6.2 μM; and Du145, 14.0 μM (separate experiments). It is of interest to note that prolonged incubation of MCF 7 cells with ET-18-OCH$_3$ did not select for cells resistant to ET-18-OCH$_3$ or other chemotherapeutic agents. This was shown in experiments where the growth inhibitory effects of ET-18-OCH$_3$, doxorubicin, or 5-fluorouracil were determined against MCF 7 cells before and after the cells were treated for 72 h with 60 μM ET-18-OCH$_3$. The GI_{50} values were 15.2, 0.018, and 4.9 μM before and 13.1, 0.013, and 4.5 μM after treatment with ET-18-OCH$_3$, doxorubicin, and 5-fluorouracil, respectively.

To further characterize the growth inhibitory effects of ET-18-OCH$_3$ on MCF 7 and L1210, we evaluated cells in a cell survival assay (Fig. 2). MCF 7 and L1210 were chosen for this analysis because there was a relatively large (fourfold) difference between their GI_{50} values as described above. Figure 2 shows that greater than 30% MCF 7 cells survived a 72-h treatment with 60 μM ET-18-OCH$_3$ and most cells survived 72 h at the GI_{50} (16.8 μM). In contrast, L1210 cells were much more sensitive to the cytotoxic effects of ET-18-OCH$_3$. Few cells survived at the GI_{50} concentration (3.9 μM), and the surviving fraction was reduced by at least 100-fold at 5 μM. The results with L1210 cells are similar to those reported for BG-1 human ovarian carcinoma cells (25). It can also be seen in Figure 2 that when MCF 7 cells were treated with 7.5 μM ET-18-OCH$_3$ there was a slight increase in the number of colonies ($P < 0.05$, *t*-test) compared to controls, which suggests that at low concentrations ET-18-OCH$_3$ may act as a mitogen in this cell line. Similar results were reported by Lohmeyer and Workman (28) using HT 29 cells. Clearly, however, ET-18-OCH$_3$ functions primarily as a cytostatic rather than a cytotoxic agent against MCF 7 cells at concentrations in the GI_{50} range, whereas the opposite is true for L1210 cells.

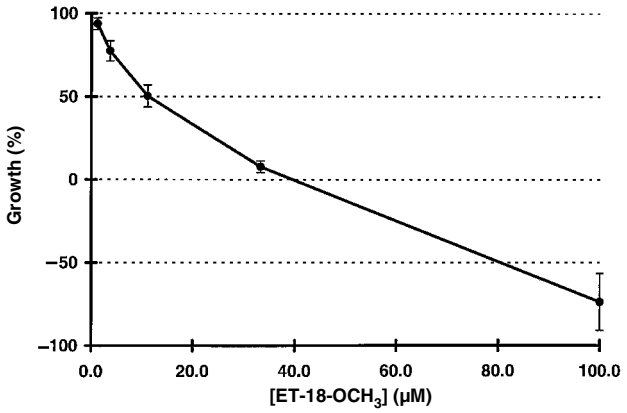

FIG. 1. Dose-response curve of MCF 7 cells after a 72-h exposure at increasing 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine (ET-18-OCH$_3$) concentrations. The curve was generated using the sulforhodamine B assay described in the Materials and Methods section. The means and standard deviations were calculated from three independent experiments.

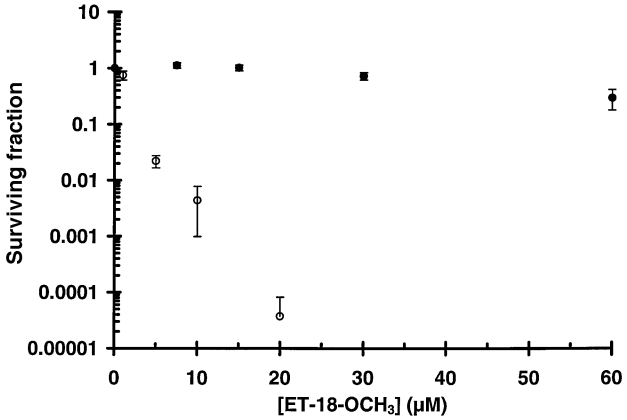

FIG. 2. Survival of MCF 7 (●) and L1210 (○) cells following a 72-h exposure to increasing ET-18-OCH$_3$ concentrations. After drug exposure the cells were washed, plated, and incubated for 7–12 d. Then the number of MCF 7 colonies or L1210 cells was determined as a percentage of the control (untreated) cell or colony number at each drug concentration. The mean fractional cell survival was calculated from three independent experiments. The error bars represent the standard deviations. For abbreviation see Figure 1.

In vitro *growth inhibition and hemolysis by ET-18-OCH$_3$ liposomes.* We have previously shown that ET-18-OCH$_3$ can be stably associated with liposomes, and the stability of the association is composition-dependent, as measured by several parameters, including human red cell lysis (20,21). Table 1 compares the growth inhibitory and hemolytic effects of a number of ET-18-OCH$_3$ liposome compositions. In general, the various ET-18-OCH$_3$ liposomes were 1.5- to 3.0-fold less growth inhibitory than ET-18-OCH$_3$. Growth inhibition was not strongly dependent on liposome composition. Hemolysis by the different formulations was compared using the calculated HI_5 value. As reported previously (20,21), all liposome formulations were less hemolytic than free ET-18-OCH$_3$ (HI_5 = 5.6 μM). For the egg phosphatidylcholine/cholesterol(CH)/dipalmitoylphosphatidylethanolamine–glutaric acid/ET-18-OCH$_3$, egg phosphatidylcholine/CH/1-palmitoyl-2-oleoylphosphatidylethanolamine–glutaric acid/ET-18-OCH$_3$, and distearoylphosphatidylcholine/CH/dipalmitoylphosphatidylethanolamine–glutaric acid/ET-18-OCH$_3$ series of formulations, the higher the mole ratio of ET-18-OCH$_3$, the more hemolytic the formulation. Dioleoylphosphatidylcholine/CH/dioleoylphosphatidylethanolamine–glutaric acid/ET-18-OCH$_3$, 4:3:1:2 (ELL-12) and dioleoylphosphatidylethanolamine/CH/dioleoylphosphatidylethanol-

[a]GI_{50}, the drug concentration that inhibits cell growth 50% after 72-h drug treatment (sulforhodamine B assay).
[b]HI_5, the drug concentration required to cause 5% hemolysis.
[c]If there were three or more experiments, a mean and standard deviation were calculated and the number of experiments is listed in parentheses. If there were fewer than three experiments, the individual GI_{50} values were averaged. If a GI_{50} value is preceded by a > or < symbol, the GI_{50} value fell outside the dose range of that specific experiment and could not be calculated. Abbreviations: n.d., not done; ET-18-OCH_3, 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine; EPC, egg phosphatidylcholine; CH, cholesterol; DPPE-GA, dipalmitoylphosphatidylethanolamine–glutaric acid; POPE-GA, 1-palmitoyl-2-oleoylphosphatidylethanolamine–glutaric acid; DSPC, distearoylphosphatidylcholine; DOPE-GA, dioleoylphosphatidylethanolamine–glutaric acid; DOPC, dioleoylphosphatidylcholine; DPPG, dipalmitoylphosphatidylglycerol.

amine–glutaric acid/ET-18-OCH_3, 4:3:1:2 (ELL-20) were clearly the least hemolytic formulations.

Therapeutic index (TI). An important *in vivo* toxicity of ET-18-OCH_3 is hemolysis (1,29). In order for ET-18-OCH_3 or ET-18-OCH_3-liposomes to be an effective growth inhibitory, anticancer agent, growth inhibition must result at concentrations lower than those that cause hemolysis. A theoretical TI was calculated by dividing the HI_5 by the GI_{50} determined for A549 and MCF 7 cells. Table 3 shows the TI for selected ET-18-OCH_3-liposome preparations. A TI less than one indicates hemolysis should occur at lower concentrations than those required to inhibit tumor cell growth. A TI greater than one suggests cell growth will be inhibited without measurable hemolysis. As Table 3 shows, free ET-18-OCH_3 has a TI less than one and, therefore, growth inhibitory effects would not occur without hemolysis. TI calculated for the liposome preparations were all found to be greater than one. ELL-12 and ELL-20 had a TI greater than eight, suggesting these formulations could achieve growth-inhibitory concentrations without hemolysis. Ahmad *et al.* (30) have shown that ELL-12 is less toxic and has enhanced therapeutic effects compared to ELL-20 *in vivo*, so in the remainder of the experiments described in this report ELL-12 was used as the liposome formulation for comparison with ET-18-OCH_3.

ET-18-OCH_3, ELL-12, and drug resistance. Table 2 illustrates that free ET-18-OCH_3 and ELL-12 were growth inhibitory against several drug-resistant cell lines characterized by P-glycoprotein expression. Multidrug-resistant cell lines were only 1.5–3.0-fold more resistant to free or liposomal ET-18-OCH_3 compared to the parental cell lines. However, the cell lines expressing P-glycoprotein were 100- to 1000-fold more resistant to agents such as doxorubicin, paclitaxel, or colchicine.

TABLE 2
GI_{50} Values of Parent and Resistant Cell Line Pairs Treated with ET-18-OCH_3, ET-18-OCH_3 Liposomes, or Selected Standard Agents

[a]See corresponding footnote in Table 1. For abbreviations see Table 1.
[b]The relative resistance was determined by: GI_{50} (resistant cell line)/GI_{50} (parent cell line).
[c]DOPC/CH/DOPE-GA/ET-18-OCH_3, 4:3:1:2 = ELL-12.

Variable drug exposure times (pulse-chase). In all the previous growth inhibition experiments, the effects of ET-18-OCH_3 and liposomal ET-18-OCH_3 were determined under continuous drug exposure conditions. Figure 3 shows the dose-response curves of MCF 7 cells when exposed to variable ET-18-OCH_3 or ELL-12 concentrations for increasing periods of time. The effects of ET-18-OCH_3 were both time- and concentration-dependent. An ET-18-OCH_3 concentration of 150 μM completely inhibited cell growth after a 1-h exposure and was cytotoxic at longer exposure times. When cells were exposed to 16.7 μM and 5.6 μM ET-18-OCH_3, growth inhibition was not apparent until after 24 h of drug exposure. The effects of ELL-12 were again both time- and concentration-dependent, but the dose-response curves were not as steep for ET-18-OCH_3.

TABLE 3
Theoretical Therapeutic Indices (TI) Based on HI_5 and GI_{50} Values[a]

ET-18-OCH_3 liposome formulation	A549 TI	MCF 7 TI
Free ET-18-OCH_3	0.86	0.33
EPC/CH/POPE-GA/ET-18-OCH_3, 4:3:1:2	2.84	1.06
EPC/CH/DOPE-GA/ET-18-OCH_3, 4:3:1:2	8.86	3.89
DOPC/CH/DOPE-GA/ET-18-OCH_3, 4:3:1:2 (**ELL-12**)	18.25	8.68
DOPE/CH/DOPE-GA/ET-18-OCH_3, 4:3:1:2 (**ELL-20**)	n.d.	18.13

[a]TI is HI_5/GI_{50}. If TI <1, then the GI_{50} cannot be reached without causing hemolysis (HI_5 >5%). When TI >1, there is a "window" for inhibiting tumor cell growth without causing hemolysis (HI_5 <5%). See Table 1 for abbreviations.

Effects of ET-18-OCH_3 or ELL-12 on intracellular Ca^{2+}. The purpose of the Ca^{2+} measurements was to compare the modulation of intracellular [Ca^{2+}] by free ET-18-OCH_3 with that of ELL-12. The important role Ca^{2+} plays in signal transduction is well known, and agents which may perturb signal transduction pathways may be expected to have effects on intracellular Ca^{2+}, as discussed in References 5–7. When the cell plasma membrane is severely damaged, the levels of in-

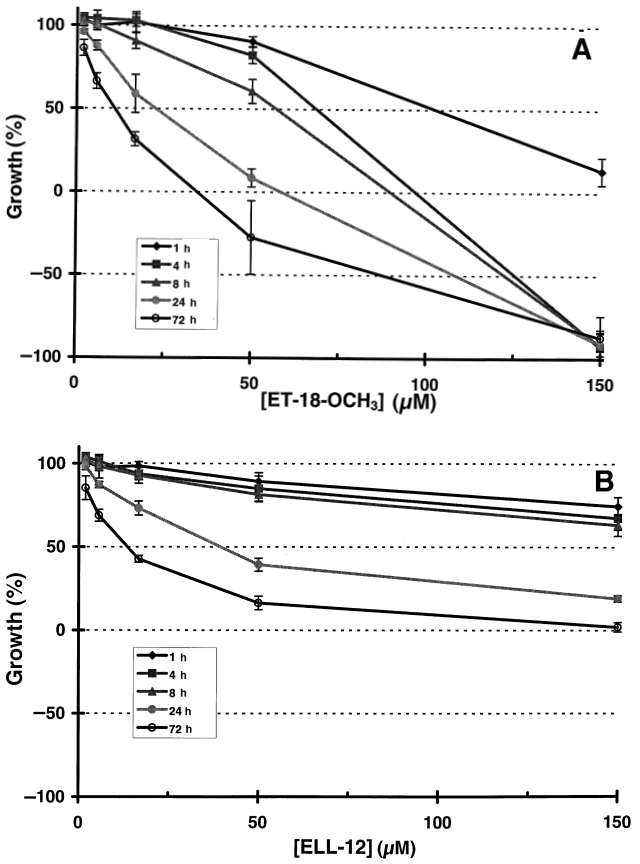

FIG. 3. The effects of free (A) ET-18-OCH_3 or (B) ELL-12 (4:3:1:2 dioleoylphosphatidylcholine/cholesterol/dioleoylphosphatidylethanolamine–glutaric acid/ET-18-OCH_3) on MCF 7 cells treated with increasing drug concentrations for specified periods. After drug exposure, the cells were washed and re-incubated. After a total of 72-h incubation the cells were processed as described in the Materials and Methods section, using the sulforhodamine B assay. Cells were not washed or reincubated for the continuous 72-h exposure. For abbreviation see Figure 1.

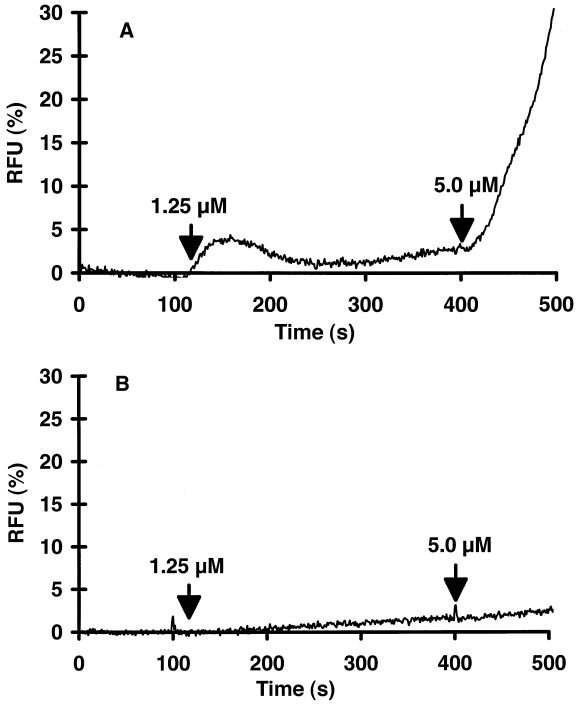

FIG. 4. The effects of ET-18-OCH_3 or ELL-12 on intracellular [Ca^{2+}] in L1210 cells incubated in phosphate-buffered saline without Ca^{2+} and Mg^{2+}. L1210 cells were loaded with the Ca^{2+} marker Fluo3 (Molecular Probes, Eugene, OR) and treated with increasing concentrations of ET-18-OCH_3 or ELL-12. (A) Represents the time-based trace of ET-18-OCH_3, and (B) represents the ELL-12 trace. At 100 s, 1.25 μM ET-18-OCH_3 or ELL-12 (final concentration) was added to the cells. At 400 s, 5 μM ET-18-OCH_3 or ELL-12 (final concentration) was added to the cells. RFU = relative fluorescence units. For other abbreviations see Figures 1 and 3.

tracellular ions, including Ca^{2+}, will change dramatically. However, when plasma membrane damage is sublethal, changes in [Ca^{2+}] are more subtle and may involve release of Ca^{2+} from intracellular sites as well as influx of extracellular Ca^{2+}. We were interested in these changes, as we already had shown (Table 1) that association of ET-18-OCH_3 with liposomes such as ELL-12 abrogated the lytic effects. Figure 4 shows the effects of ET-18-OCH_3 or ELL-12 on intracellular [Ca^{2+}] in L1210 cells suspended in PBS. (L1210 cells were used in these experiments because of their sensitivity to ET-18-OCH_3.) The addition of 1.25 μM free ET-18-OCH_3 caused a transient increase in intracellular [Ca^{2+}] (Fig. 4A), resulting from both intracellular Ca^{2+} liberation from intracellular stores and extracellular [Ca^{2+}] diffusion into the cytoplasm. The total change in intracellular [Ca^{++}], originating from both intracellular and extracellular sources, was 13.0 ± 1.1 nM, whereas the change in intracellular [Ca^{2+}], originating from intracellular sources, was 6.7 ± 3.0 nM. The addition of 5 μM free ET-18-OCH_3 elicited a large permanent increase in intracellular [Ca^{2+}], most likely owing to an influx of external Ca^{2+}. The large increase in [Ca^{2+}] was associated with a substantial decrease in cell viability, approximately 90%, as indicated by trypan blue exclusion. In contrast, the addition of 1.25 μM ET-18-OCH_3 resulted in a less than 10% loss in viability. ELL-12 did not affect intracellular [Ca^{2+}] at either concentration (1.25 or 5 μM) (Fig. 4B). The slow increase observed in percentage RFU was consistent with the increase seen in the negative controls. Even though Fluo3 is reported to be cell impermeable, it appears to leak slowly under these conditions.

Intracellular [Ca^{2+}] was also monitored in the presence of 10% fetal bovine serum which more closely compares with cell growth conditions in the growth inhibition assays. Figure 5A indicates that 5 μM ET-18-OCH_3 or higher was needed in serum to elicit intracellular [Ca^{2+}] transients similar to the transients seen after the addition of 1.25 μM ET-18-OCH_3 in PBS. In contrast, ELL-12 did not elicit measurable [Ca^{2+}] transients in serum, even at the highest concentrations tested (Fig. 5B). Sequential addition of increasing concentrations of ET-18-OCH_3 did not appear to inhibit the modulation of [Ca^{2+}]. The slow increase in fluorescence observed was similar to that in controls. Fluo3 appears to leak more rapidly in 10% serum than in PBS. It is noteworthy that under conditions where both ET-18-OCH_3 and ELL-12 were growth-in-

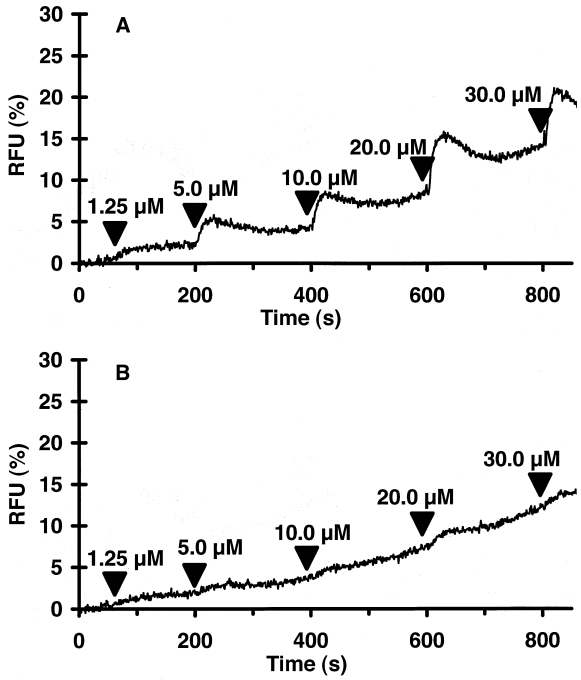

FIG. 5. The effects of ET-18-OCH_3 or ELL-12 on intracellular [Ca^{2+}] in L1210 cells incubated in 10% fetal bovine serum. L1210 cells were loaded with the Ca^{2+} marker Fluo3 and treated with increasing concentrations of ET-18-OCH_3 or ELL-12. (A) Represents the time-based trace of ET-18-OCH_3, and (B) represents the ELL-12 trace. Increasing concentrations of ET-18-OCH_3 or ELL-12 (reported as final concentrations) were added to the cells at the following times: 50 s, 1.25 μM; 200 s, 5 μM; 400 s, 10 μM; 600 s, 20 μM; and 800 s, 30 μM. For abbreviations see Figures 1, 3, and 4.

hibitory against L1210 cells, ET-18-OCH_3 elicited increased [Ca^{2+}] transients whereas ELL-12 had no effect. At all concentrations studied, ET-18-OCH_3 or ELL-12 did not decrease cell viability in serum containing media during the course of the Ca^{2+} experiments.

DNA fragmentation analysis. Figure 6 shows the effects of a 24-h incubation of ET-18-OCH_3 or ELL-12 on DNA fragmentation in L1210 and L1210/vmdr cells. In L1210 cells, DNA was fragmented in a ladder-like pattern, which may indicate programmed cell death (31). DNA ladder formation was detectable after the addition of 1 μM of both ET-18-OCH_3 (Fig. 6A) and ELL-12 (Fig. 6B) and became more evident with the additions of increasing drug concentrations in a dose-dependent manner. In contrast to the effects on L1210 cells, no DNA fragmentation was observed in L1210/vmdr cells after treatment with ET-18-OCH_3 (Fig. 6C) or ELL-12 up to concentrations of 20 μM (data not shown).

DISCUSSION

Although ET-18-OCH_3 has *in vivo* antitumor activity, a major dose-limiting toxicity is hemolysis (30). A number of reports document the advantages of associating chemotherapeutic agents in lipid complexes or liposomes to improve therapeutic efficacy, and such approaches have been productive and well-supported by clinical trials (17–19,32,33). ET-18-OCH_3 was associated with liposomes by Layton *et al.* (34) who showed a nonoptimized liposome formulation retained cytotoxicity and was selectively toxic to a leukemia cell line compared to a "normal" fibroblast cell line, but no investigation of the hemolytic effects of the formulation was described.

In this report we have compared the growth inhibitory and hemolytic effects of free and liposome-associated ET-18-OCH_3. The results indicate that association of ET-18-OCH_3 with liposomes decreased growth inhibition only 1.5–3.0-fold and the inhibitory effects were not strongly dependent on liposome composition. In contrast, hemolysis was highly dependent on liposome composition. When dioleoylphosphatidylcholine or dioleoylphosphatidylethanolamine was the major neutral phospholipid and 30 mol% cholesterol was included as a liposome component, hemolysis was decreased

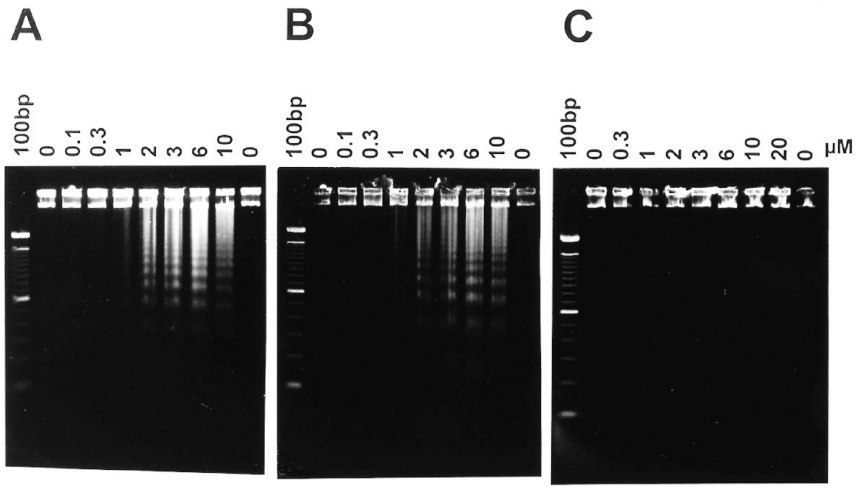

FIG. 6. Photographs of ethidium bromide-stained agarose gels after electrophoresis of DNA isolated from L1210 cells treated with different concentrations (μM) of ET-18-OCH_3 (A) or ELL-12 (B) for 24 h and L1210/vmdr cells treated with increasing concentrations of ET-18-OCH_3 (C) for 24 h. Far left lane in each panel is a 100 base pair (bp) ladder standard.

40 or more times compared to free ET-18-OCH_3. Decreased hemolysis was most likely related to the supramolecular organization of the lipid components where complementary packing in the lipid bilayer (35) provides a stable environment for ET-18-OCH_3, reducing the availability of ET-18-OCH_3 responsible for hemolysis and membrane lytic effects (21). Based on *in vitro* cytotoxicity and hemolysis data, we conclude that free ET-18-OCH_3 cannot be dosed at growth inhibitory concentrations without causing hemolysis, but optimized liposomal formulations can achieve growth inhibitory activity at concentrations 8–20-fold lower than those which cause hemolysis.

The various cell lines used had a 4–5-fold range in GI_{50} values to ET-18-OCH_3, and the relative contributions of cytotoxicity or cytostasis to growth inhibitory effects vary between cell types, as was found for L1210 and MCF7 cells. Different responses to growth inhibitory agents between cell types do not necessarily indicate that the mechanism of action of the agent differs between cell types. It may indicate, for example, that the relative balance of activating or deactivating enzymes varies between cell types. A 4–5-fold difference in drug sensitivity between six widely different cancer lines (human and mouse leukemias and human carcinomas including ovarian/breast/prostate/lung) is not great. However, for all cell types, the GI_{50} values for free ET-18-OCH_3 were paralleled by the GI_{50} values for the liposome formulations. This suggests that in each cell type, ET-18-OCH_3 from the liposome formulation was acting similarly to "free" ET-18-OCH_3. Association of ET-18-OCH_3 with liposomes therefore "protected" cells against acute membrane lytic effects while maintaining growth inhibitory properties. If membrane lysis results from insertion of ET-18-OCH_3 into the plasma membrane, then association of ET-18-OCH_3 with liposomes significantly attenuates these effects.

The different effects of ET-18-OCH_3 and ELL-12 on intracellular [Ca^{2+}] in L1210 cells also suggest that ET-18-OCH_3 and ELL-12 have different membrane-perturbing effects. Free ET-18-OCH_3 elicited both a transient intracellular [Ca^{2+}] increase at 1.25 μM and a permanent increase upon the addition of 5 μM in PBS, whereas ELL-12 did not modulate intracellular [Ca^{2+}] under the same conditions. The transient [Ca^{2+}] increase seen after the addition of 1.25 μM free ET-18-OCH_3 was not associated with a loss of cell viability and was probably due to Ca^{2+} liberation from intracellular sources and influx from the extracellular environment. Others have reported similar results with ET-18-OCH_3 in different cell lines in buffer systems (9,11,12). The permanent increase seen at 5 μM appeared to be associated with a loss of membrane integrity and therefore was not related to possible Ca^{2+}-modulated signal transduction. When changes in intracellular [Ca^{2+}] were determined in media containing 10% fetal bovine serum, free ET-18-OCH_3 also elicited transient [Ca^{2+}] increases, even though at higher concentrations than those required in PBS, but ELL-12 did not cause any changes in [Ca^{2+}] at any concentrations tested. The reduction in the membrane-perturbing effects of free ET-18-OCH_3 in the presence of serum was probably related to the efficient binding of ET-18-OCH_3 to albumin and high-density lipoproteins [Kelley *et al.* (4)]. In contrast to the different membrane effects of ET-18-OCH_3 and ELL-12 on L1210 cells, both affected DNA fragmentation of these cells in a similar concentration- and time-dependent manner, which implies apoptosis as a potential mechanism of action.

The results obtained in the cell lines selected for drug resistance were generally similar to those found for the nonresistant cells and, interestingly, in the sensitive/resistant cell line pairs; L1210, L1210/vmdr; P388, P388/adr; and MCF 7, MCF7/adr; both ET-18-OCH_3 and ELL-12 were equally potent, suggesting that ET-18-OCH_3 is not a substrate for the P-glycoprotein efflux pump. However, an unexpected result was found for the L1210/vmdr cells. Although the growth of these cells was affected by ET-18-OCH_3 and ELL-12 similarly, high drug concentrations did not induce ladder-like DNA fragmentation in L1210/vmdr cells. The differing drug responses may be indicative of multiple growth inhibitory mechanisms.

In conclusion, the results show that both free ET-18-OCH_3 and ELL-12 had similar growth inhibitory effects on cultured cells but, as indicated by the hemolysis and [Ca^{2+}] results, ELL-12 did not have the same direct membrane-perturbing effects as free ET-18-OCH_3. This suggests that in the growth inhibitory concentration range, the specific DNA fragmentation effects of ELL-12 were not a result of direct membrane damage. Thus, ELL-12 differs from ET-18-OCH_3 in that the specific *in vitro* growth inhibitory effects are retained, whereas nonspecific membrane-perturbing effects are reduced.

In Vitro Effect of Garlic Powder Extract on Lipid Content in Normal and Atherosclerotic Human Aortic Cells

Alexander N. Orekhov* and Vladimir V. Tertov

Institute of Experimental Cardiology, Cardiology Research Center, Russian Academy of Medical Sciences, 121552 Moscow, Russia

ABSTRACT: In the present study, the mechanism of the *in vitro* effect of garlic powder extract (GPE) on lipid content of cultured human aortic cells was investigated. The addition of GPE abolished atherogenic blood serum-induced accumulation of free cholesterol, triglycerides, and cholesteryl esters in smooth muscle cells derived from uninvolved (normal) intima. In cells isolated from atherosclerotic plaque, GPE lowered these lipids. GPE inhibited lipid synthesis both in normal and atherosclerotic cells. It inhibited acyl-CoA:cholesterol acyltransferase activity that participates in the cholesteryl ester formation and stimulated cholesteryl ester hydrolase that degrades cholesteryl esters. This may explain the lipid reduction caused by GPE in atherosclerotic cells. GPE inhibited the uptake of modified low density lipoprotein and degradation of lipoprotein-derived cholesteryl esters, thus considerably reducing the intracellular accumulation of cholesteryl esters. This suggests the mechanism responsible for the prevention of lipid accumulation in aortic cells caused by atherogenic blood serum.

Lipids 32, 1055–1060 (1997).

Positive influence of garlic on cardiovascular risk factors has been reported (1,2). Recently we have found that aqueous extract of garlic powder (equivalent to Kwai®, Sapec®; Lichtwer Pharma, Berlin, Germany) possesses direct antiatherogenic-related (preventive) and antiatherosclerotic-related (therapeutic) effects at the arterial cell level *in vitro* (3). In primary culture, garlic powder extract (GPE) taken at the concentration range of 0.01–1 mg/mL inhibited proliferation of smooth muscle cells derived from uninvolved and atherosclerotic human aortic intima (3). In addition, GPE prevented intracellular accumulation of cholesterol caused by atherogenic blood serum of coronary heart disease patients as well as reduced cholesterol content in cells cultured from atherosclerotic plaques (3).

In the present study, we extended investigation of the *in vitro* effect of GPE on lipids of cultured human aortic cells. We have earlier shown that lipid accumulation in these cells is accompanied by stimulation of other cellular manifestation of atherosclerosis, namely, proliferation and extracellular matrix synthesis (4,5). Thus, investigation of GPE action on cellular lipid parameters is closely related to the study of the possible antiatherosclerosis effect of garlic.

MATERIALS AND METHODS

GPE. Aqueous GPE containing 3.58 mmol/L allicin and 0.184 mmol/L ajoene (6) was prepared according to Gebhardt (7). All concentration data are related to the initial amount of garlic powder per extraction volume. The garlic powder used is prepared immediately after harvesting of garlic cloves by careful air-drying. This powder is characterized by a very high content of sulfur-containing components and standardized to an allicin content of 1.3% and a capacity for liberation of allicin of 0.6%.

Cells. Human aortic subendothelial intimal smooth muscle cells were isolated from autopsy material obtained within 2–3 h after sudden death from 40- to 60-year-old men who had died of myocardial infarction. Usually human aorta contained uninvolved (grossly normal) areas and atherosclerotic lesions. Cells were harvested by enzymatic digestion of grossly normal part of aortic intima or atherosclerotic plaque with 0.1% collagenase for 3–4 h and seeded into 24-well culture plates. Cells were cultured for 7 d in Medium 199 containing 10% fetal calf serum (FCS), glutamine, and antibiotics. To identify smooth muscle cells and macrophages in primary cell cultures, cells were stained by immunoperoxidase reaction using monoclonal antibodies HHF-35 interacting with smooth muscle cells and HAM-56 recognizing macrophages (8). Primary cell cultures derived from grossly normal areas contained 87.1 ± 1.3% HHF-35-positive cells and 8.0 ± 1.5% HAM-56-positive cells; cell cultures from atherosclerotic plaques contained 81.0 ± 3.9% HHF-35-positive and 14.7 ± 2.8% HAM-56-positive cells (9). On the seventh day of cultivation, test agents were added, and then intracellular lipids were extracted after 24-h incubation. To induce lipid accumulation in cultured cells, 40% atherogenic serum was added to culture. Pooled atherogenic serum capable of inducing at least a 2-fold increase in total cholesterol level of cultured cells within 24-h incubation was prepared from blood taken from 10 normolipidemic, nondiabetic men with angiographically assessed coronary atherosclerosis. The characteristics of

atherogenic serum were described elsewhere (4,5). Protocols for cell isolation and cultivation as well as technical details of the experiment are presented elsewhere (10).

Lipoproteins. Low density lipoprotein (LDL, P = 1.019–1.063 g/mL) was isolated by sequential ultracentrifugation from blood plasma (0.1% EDTA) of coronary atherosclerosis patient according to Lindgren (11). Native and naturally occurring modified desialylated LDL were separated on lectin-agarose column as described elsewhere (12). After recentrifugation, LDL was labeled with [1,2 (*n*)-^{3}H]cholesteryl linoleate (Amersham International plc, Amersham, United Kingdom): 100 μCi of [^{3}H]cholesteryl linoleate was dissolved in 100 μL dimethylsulfoxide and mixed with 4–7 mg LDL in 2 mL 50 mM Tris-HCl (pH = 7.4) containing 1 M NaCl. LDL preparation was incubated 2 h at 40°C and dialyzed against 2000 vol of phosphate-buffered saline.

LDL metabolism. Normal and atherosclerotic cells were incubated for 24 h with 100 μg/mL of LDL labeled with [^{3}H]cholesteryl linoleate. After incubation, lipids were extracted from cells and culture media according to Hara and Radin (13) and Bligh and Dyer (14), respectively. Neutral lipids were separated by thin-layer chromatography using *n*-hexane/diethyl ether/ acetic acid (75:23:2, by vol) as solvent. Fractions of free and esterified cholesterol were scraped off and radioactivity was measured.

Lipids. Lipids from cells were extracted according to Hara and Radin (13). Neutral lipids were separated by thin-layer chromatography using two solvent systems (i) benzene/diethyl ether/ethanol/acetic acid (50:40:2:0.2, by vol) up to 6 cm from start line and then (ii) *n*-hexane/diethyl ether/acetic acid (90:10:1, by vol) in the same direction. Cholesteryl oleate, triolein, and cholesterol were used as standards. Phospholipids were separated by thin-layer chromatography using methyl acetate/*n*-propanol/chloroform/methanol/0.25% KCl (25:25:25:10:9, by vol) as solvent (15). Lipid content was quantitated by scanning densitometry using a dual-wavelength thin-layer chromato-scanner as described elsewhere (16).

Lipid metabolism. To investigate oleate incorporation into cellular lipids, human intimal cells were incubated during 24 h with 10 μCi/mL [^{14}C]oleate/albumin prepared according to Goldstein *et al.* (17). After incubation, lipids were extracted and separated as described above. Regions corresponding to phospholipids, triglycerides, and cholesteryl esters were scraped off, and radioactivity dissolved in toluene-based scintillation liquid was measured.

Enzyme activities. Freshly isolated normal and atherosclerotic cells were used for assay of enzyme activities. Cells were broken up by sonication (5 s) in 10 mM Tris-HCl, pH 7.0. Sonicates were centrifuged for 20 min at 4000 rpm to remove nuclei and debris.

To measure acyl-CoA:cholesterol acyltransferase (ACAT) activity, homogenate preparations were incubated 20 min with a reaction mixture containing 0.1 μCi [1-^{14}C]oleoyl-CoA (Amersham) in the presence or absence of garlic extract (1 mg/mL). Incubation was stopped by addition of chloroform/methanol (1:2, vol/vol). Cholesteryl esters were separated from other lipids by thin-layer chromatography on silica gel G using *n*-hexane/diethyl ether/acetic acid (75:23:2, by vol) for developing. Regions corresponding to cholesteryl esters were scraped into scintillation vials, and radioactivity was determined.

Cholesteryl ester hydrolase (CEH) activity was measured according to Haley *et al.* (18) using cholesteryl [1-^{14}C]oleate (Amersham) as a substrate.

Statistics. The significance of differences was evaluated using dispersion analysis methods and a BMDP statistical program package (19).

RESULTS

Lipids composition. Smooth muscle cells cultured from grossly normal intima and atherosclerotic plaque differed markedly in their contents of major lipid classes. Phospholipids, free cholesterol, cholesteryl esters, and triglycerides were much higher in atherosclerotic cells as compared to cells derived from normal intima (Table 1). Addition of serum from patients with coronary heart disease to a culture of normal cells induced an intracellular accumulation of all lipid classes except phospholipids. After 24 h of incubation with atherogenic serum, the content of cholesteryl esters increased 3.2-fold and those of triglycerides and free cholesterol 1.7-fold, which amounted to 60–80% of the corresponding lipid contents of cells cultured from atherosclerotic plaques (Table 1).

The addition of GPE abolished serum-induced accumulation of free cholesterol and triglycerides and reduced the accumulation of cholesteryl esters 2.8-fold (Table 1). Besides, in cells isolated from plaque, GPE lowered triglyceride, free cholesterol, and cholesteryl ester levels by 21, 31, and 35%, respectively (Table 1). GPE produced no significant effect on the total phospholipid content of smooth muscle cells cultured from grossly normal intima and atherosclerotic plaque (Table 1). In addition, it did not change the contents of sphingomyelin, phosphatidylcholine, phosphatidylinositol, phosphatidylserine, and phosphatidylethanolamine both in normal and atherosclerotic cells (data not shown).

Lipids and lipoprotein metabolism. Incorporation of [^{14}C]oleate in the lipids of cells cultured from plaque was much greater than that in lipids of normal cells cultured in the presence of atherogenic serum, which may indicate an enhanced synthesis of phospholipids, triglycerides, and cholesteryl esters in atherosclerotic cells (Table 2). GPE decreased [^{14}C]oleate incorporation in the lipids of both normal and atherosclerotic cells.

LDL is the main source of free and esterified cholesterol that accumulates in arterial cells. Arterial smooth muscle cells can bind, internalize, and metabolize LDL. Intracellular metabolism of LDL-derived cholesteryl esters was studied using lipoprotein labeled with [^{3}H]cholesteryl linoleate. The major proportion of LDL-derived cholesteryl esters was degraded to free cholesterol and reappeared in the culture medium (Table 3). A portion of LDL circulating in patients with coro-

TABLE 1
Effect of GPE on Lipid Composition in Human Aortic Intimal Smooth Muscle Cells[a]

	Lipid content (μg/mg cell protein)			
	Phospholipids	Free cholesterol	Triglycerides	Cholesteryl esters
Normal cells				
Control	85.8 ± 3.9	10.5 ± 0.5	7.8 ± 0.7	10.4 ± 0.3
Atherogenic serum	92.3 ± 6.4	17.5 ± 0.7[b]	12.9 ± 0.7[b]	33.1 ± 1.2[b]

Control	136.1 ± 8.3	24.6 ± 1.2	16.0 ± 0.6	56.0 ± 3.3
+ GPE	131.8 ± 8.0	17.0 ± 1.0[b]	12.7 ± 0.7[b]	34.2 ± 1.5[b]

[a]Data represent mean of three determinations ± SEM from three separate experiments. Normal smooth muscle cells derived from grossly uninvolved intima and atherosclerotic cells derived from atherosclerotic plaque cultured in standard conditions with 10% fetal calf serum served as the control. Forty percentage of atherogenic blood serum pooled from patients with coronary atherosclerosis was added to cultured normal cells to induce intracellular lipid accumulation. Garlic powder extract (GPE) was used at concentration 1 mg/mL. Cells with all additives were incubated during 24 h.
[b]Significant difference from the control, $P < 0.05$.
[c]Significant difference from atherogenic serum, $P < 0.05$.

TABLE 2
Effect of GPE on [^{14}C]Oleate Incorporation into Intracellular Lipids[a]

	[^{14}C]Oleate incorporation (dpm/μg cell protein)		
	Phospholipids	Triglycerides	Cholesteryl esters
Normal cells			
Control, atherogenic serum	1922 ± 52	649 ± 22	127 ± 5
Atherogenic serum + GPE	1794 ± 66[b]	570 ± 18[b]	75 ± 5[b]
Atherosclerotic cells			
Control	6887 ± 324	1226 ± 51	274 ± 7
+ GPE	6145 ± 112[b]	795 ± 38[b]	201 ± 12[b]

[a]The cells were incubated with 1 μCi/mL [^{14}C]oleate during 24 h. For other details and abbreviation, see Table 1.

nary atherosclerosis is believed to be modified. In contrast to native LDL of healthy subjects, it induces intracellular accumulation of cholesteryl esters. Uptake and degradation of cholesteryl esters supplied to the cell by modified LDL was considerably greater than that of cholesteryl esters supplied by native LDL (Table 3). GPE reduced the internalization of cholesteryl esters supplied by native and modified LDL by 32 and 56%, respectively (Table 3). As a result, intracellular accumulation of cholesteryl esters caused by native and modified LDL was lowered almost 2- and 4-fold, respectively (Table 3).

Thus, GPE inhibits lipid synthesis both in normal and atherosclerotic cells. In addition, this agent suppresses LDL uptake and intracellular degradation of LDL-derived cholesteryl esters, leading to a decrease in intracellular accumulation of free and esterified cholesterol in arterial smooth muscle cells.

ACAT and CEH activities. The effect of GPE on the enzymes responsible for intracellular metabolism of cholesteryl

TABLE 3
Effect of GPE on the Metabolism of Low Density Lipoprotein-Derived Cholesteryl Esters in Intimal Smooth Muscle Cells[a]

	Intracellular (dpm/μg cell protein)		Extracellular (dpm/μg cell protein)

[a]Smooth muscle cells cultured from uninvolved intima were incubated for 24 h with native and modified (desialylated) low density lipoproteins (LDL) (100 μg/mL) labeled with [^{3}H]cholesteryl linoleate.
[b]Significant effect of GPE (1 mg/mL), $P < 0.05$. For other details and other abbreviation, see Table 1.

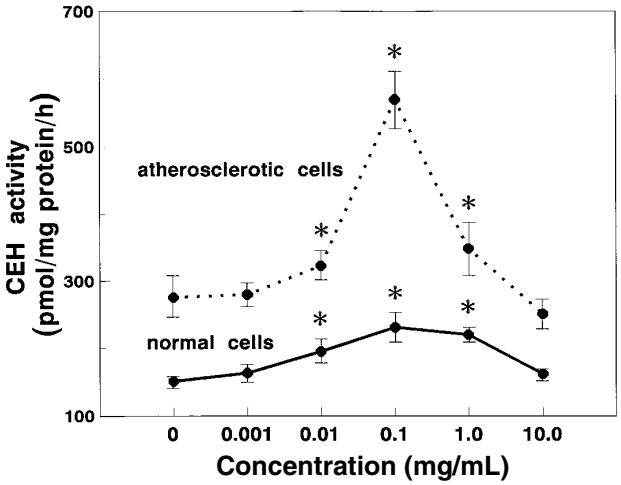

FIG. 1. Effect of garlic powder extract on acyl-CoA:cholesterol acyltransferase (ACAT) activity in aortic smooth muscle cells. Each data point represents the mean of three determinations ± SEM. Significant difference ($P < 0.05$) from the control (0 mg/mL garlic powder extract) is marked by an asterisk.

esters was studied by measuring the activities of ACAT, the enzyme involved in cholesteryl ester formation, and CEH, which hydrolyzes cholesteryl esters, in homogenates of normal and atherosclerotic cells.

The ACAT activity of atherosclerotic cells was 3-fold higher than that of normal cells (Fig. 1). At a concentration of 0.1 mg/mL and greater, GEP significantly decreased the enzyme activity in homogenates prepared from both atherosclerotic and normal cells (Fig. 1).

The CEH activity of atherosclerotic cells was almost 2-fold higher than that of normal cells (Fig. 2). At the concentration range of 0.01–1.0 mg/mL, GPE significantly increased the enzyme activity of both normal and atherosclerotic cells (Fig. 2). The dose dependence of the GPE effect had a bell-shaped pattern. The maximum effect was attained at 0.1 mg/mL GPE; at higher and lower concentrations the effect was less pronounced (Fig. 2).

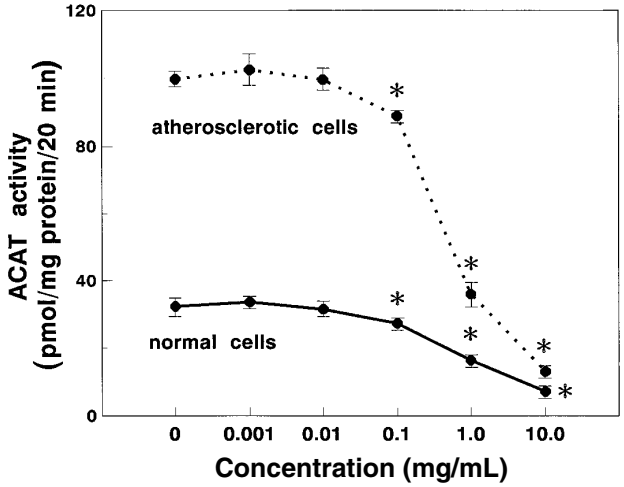

FIG. 2. Effect of garlic powder extract on cholesteryl ester hydrolase (CEH) activity in aortic smooth muscle cells. Details are the same as in the legends to Figure 1.

Thus, GPE inhibits ACAT that participates in the cholesteryl ester formation and stimulates CEH that degrades cholesteryl esters.

DISCUSSION

Garlic has been advocated for various diseases, including heart disease, headache, tumors, infections, and vascular disease. Evidence that garlic reduces cardiosvascular risk factors is accumulating (20). Spontaneous thrombocyte aggregation *in vitro* disappeared, the microcirculation increased, and plasma viscosity, diastolic blood pressure, and blood glucose concentration reportedly decreased as a result of garlic treatment (21). Garlic is also believed to exert beneficial effects on coagulation and serum lipid concentrations. Concentrations of triglycerides and total and LDL cholesterol fell while subjects ingested garlic, and the concentration of high density lipoprotein cholesterol increased (2).

The possibility of a direct influence of garlic on atherosclerosis has been discussed (22–24). Such putative antiatherosclerotic effects of garlic have been attributed to its hypolipidemic activity. Experimental and clinical data have demonstrated that garlic reduces blood cholesterol and LDL levels (2,24). The cholesterol-lowering effect of garlic possibly results from inhibition of hepatic HMG-CoA reductase (7,25).

In contrast to the above-cited studies, we examined not the hypolipidemic but the direct antiatherosclerotic-related and antiatherogenic-related effects of garlic, i.e., the ability of garlic to act directly on the atherosclerotic process in the vessel wall. Primary culture of human aortic cells, enzyme activities of these cells, and aqueous extract of garlic powder were used as a model. To investigate antiatherosclerotic-related effects, we used smooth muscle cells cultured from atherosclerotic plaques of human aorta. To study antiatherogenic-related effects, we imitated atherogenesis in primary cultures of smooth muscle cells derived from grossly uninvolved human aortic intima by adding atherogenic blood serum of patients with angiographically assessed coronary atherosclerosis. GPE decreased triglyceride, cholesteryl ester, and free cholesterol contents of cells cultured from atherosclerotic plaque and prevented atherogenic serum-induced accumulation of these lipids in cells cultured from grossly normal aorta, i.e., elicited direct antiatherosclerotic-related and antiatherogenic-related effects.

Inhibition of triglyceride and cholesteryl ester synthesis in aortic cells can be proposed as a tentative mechanism underlying the ability of GPE to reduce the lipid content of plaque-derived cells overloaded with intracellular fat, a potentially antiatherosclerotic effect. GPE inhibits ACAT and stimulates CEH, thus displaying a direct influence on synthesis and degradation of cholesteryl esters in the cell.

The concentration dependence of GPE stimulatory effect on CEH activity had a bell-shaped pattern, suggesting that

GPE contains agents that both stimulate and inhibit the enzyme activity. On the other hand, similar dose dependence was reported by Siegel *et al.* (6), who have shown that aqueous garlic extract and pure ajoene (a natural garlic product) induced a concentration-dependent hyperpolarization and relaxation in arterial vasculature. At high concentrations of ajoene and garlic extract, the concentration dependence of membrane potential becomes bell-shaped.

We did not examine the effects produced by individual components of GPE. Assuming that these components may exert an antiatherosclerotic effect, we plan to analyze them for such activity in the near future. According to Siegel *et al.* (6), the major components of GPE are allicin (3.58 mmol/L) and ajoene (0.184 mmol/L). Sendl *et al.* (25) have recently demonstrated that garlic extract and individual compounds ajoene, methylajoene, allicin, 2-vinyl-4H-1,3-dithiin, and diallydisulfide inhibited cholesterol synthesis on liver homogenate model.

A potentialy antiatherogenic effect of GPE was studied using cultured cells derived from grossly normal aorta and atherogenic blood serum of patients with coronary atherosclerosis. Previously, we have shown that atherogenic serum induces lipid accumulation in aortic cells which is accompanied by the major atherosclerosis-related manifestations at the cell level: stimulation of cell proliferation and increased extracellular matrix production (4,5). It was found that the modified LDL circulating in the blood of atherosclerotic patients is responsible for serum atherogenicity (4,26). Modification of patients' LDL includes a lower sialic acid content, higher density, smaller particle size, higher negative charge, etc. (27). This modified LDL was employed to induce lipid accumulation in cultured aortic cells. GPE inhibited the uptake of modified LDL and degradation of LDL-derived cholesteryl esters, thus reducing considerably the intracellular accumulation of cholesteryl esters. We believe that this mechanism is responsible for the potentially antiatherogenic effect of GPE on our model system.

ABSTRACT: The fatty acids of milk samples obtained from 51 Hong Kong Chinese and 33 Chongqing Chinese (Si Chuan Province, China) were analyzed by gas–liquid chromatography. Compared with those of published data for Canadian and other Western countries, the Chinese milk from both Hong Kong and Chongqing contained higher levels of longer-chain polyunsaturated fatty acids, particularly docosahexaenoic acid (22:6n-3) and arachidonic acid (20:4n-6). In contrast, the content of *trans* fatty acids in the Chinese milk was lower compared with those for Canadian and other Western countries. Longitudinally, the concentrations of 22:6n-3 and 20:4n-6 gradually decreased when lactation progressed from colostrum (week 1) to mature (week 6). Over the same interval, linoleic acid (18:2n-6) remained unchanged in Chongqing Chinese but significantly increased in Hong Kong Chinese. Unlike 18:2n-6, linolenic acid (18:3n-3) increased in Chongqing Chinese but remained unchanged in Hong Kong Chinese throughout the study. The total milk fat also increased with the duration of lactation. In addition, the milk of Chongqing Chinese had higher total milk fat than that of Hong Kong Chinese and Canadians. The content of erucic acid (22:1n-9) increased with the progression of lactation in Chongqing Chinese, indicating that there was a switch in dietary consumption from fats of animal origin to rapeseed oil when lactation reached week 6. The present study showed that Hong Kong and Chongqing Chinese had a different fatty acid profile in many ways, which largely reflected a different dietary habit and life-style in these two places.
Lipids 32, 1061–1067 (1997).

Human milk is considered the optimal form of nutrition for infants. The importance of n-6 and n-3 longer-chain polyunsaturated fatty acids (LCP) in human milk for normal brain development, especially during early life, has been emphasized in many studies (1–3). Both human milk and infant formula contain precursor essential fatty acids, linoleic acid (18:2n-6), and linolenic acid (18:3n-3). LCP such as arachidonic acid (20:4n-6) and docosahexaenoic acid (22:6n-3, DHA) are, however, naturally present in milk but they are generally absent in current infant formulas. These LCP are important for the structural development of the nervous system and are accumulated in large amounts in the developing brain and retina (4,5). There has been increasing interest in adding these LCP to infant formulas (6–10) because formula-fed preterm infants have lower erythrocyte levels of DHA than breast milk-fed preterm infants (1,2), and because the lower tissue levels of this fatty acid are associated with reduced retinal function (11) and reduced visual acuity of preterm infants (12).

The LCP composition in the tissues of growing infants is largely determined by the LCP content of the milk (1), which in turn partially reflects the fatty acid composition in the maternal diet (13–16). Although the fatty acid composition of milk has been reported in many countries (14–23), there is very limited information on fatty acid composition of milk in Chinese (24). The objective of the present study was therefore to investigate if fatty acid composition of milk in Hong Kong Chinese was significantly different from that in Chongqing Chinese, because the diets in the former are partially westernized and in the latter are still traditional.

MATERIALS AND METHODS

Sample and dietary data collection. Fifty-one and 33 lactating women from Hong Kong and Chongqing (Si Chuan Province, China), respectively, were recruited for this study. All mothers were on their usual diets; no dietary modifications were proposed. Donors were requested to express their milk manually after a feed on the assigned dates. The milk was collected at the first 3 d (colostrum milk) followed by 2, 4, and 6 wk after delivery. Milk (10–15 mL) was sampled each time in a bottle washed previously with deionized water. The milk samples were stored immediately at −20°C.

Dietary information was obtained by self-record on blank sheets over 3 d prior to each milk collection. At the beginning of the study, each subject was requested to record the amount of food and drink she consumed. In brief, the mothers were shown the common measuring kitchen utensils, for examples, standard bowl and tablespoon. They were also requested to record the brand name and size of commercially available products they consumed. The total energy and nutrient intake

Abbreviations: LCP, longer-chain polyunsaturated fatty acids DHA, docosahexaenoic acid.

were computed using a food composition data base, Nutritionist IV (First Databank, San Bruno, CA). The protocol was approved by the Committee of Human Ethics, the Chinese University of Hong Kong, and signed consent was obtained from each milk donor.

Milk lipid extraction. Milk samples were thawed at room temperature (25°C). Fat from a 2-g sample was extracted using 15 vol of $CHCl_3$/MeOH (2:1, vol/vol) containing 1.5 mg/mL triheptadecanoin as an internal standard to quantify total milk fat (13). Another 2-g sample was extracted with the same solvent system but without addition of triheptadecanoin to determine the content of endogenous heptadecanoic acid in milk.

Fatty acid analysis. The milk lipids were converted to fatty acid methyl esters using a mixture of 14% BF_3/MeOH reagent (Sigma Chemical Co., St. Louis, MO) and toluene (1:1, vol/vol) at 90°C for 45 min under nitrogen. Fatty acid methyl esters were analyzed by gas–liquid chromatography using an SP-2560 flexible fused-silica capillary column (100 m × 0.25 mm i.d., 20 μm film thickness; Supelco, Inc., Bellefonte, PA) in a Hewlett-Packard 5890 series II gas chromatograph equipped with a flame-ionization detector (Palo Alto, CA). Column temperature was programmed from 150 to 180°C at a rate of 0.5°C/min, and then to 210°C at a rate of 3°C/min. Injector and detector temperatures were 250 and 300°C, respectively. Hydrogen was used as the carrier gas at a head pressure of 20 psi. The gas chromatographic trace of the fatty acid methyl esters' profile of human milk is shown in Figure 1.

Statistics. Data were expressed as mean ± standard deviation. Analysis of variance followed by Student's *t*-test (two-tailed) where applicable was used for statistical evaluation of significant differences between groups.

TABLE 1
Dietary Intake of Lactating Women in Hong Kong and Chongqing, Sichuan, China[a]

	Hong Kong (n = 51)	Chongqing (n = 33)
Energy (kcal/d)	1809 ± 392	2686 ± 1030[b]
Carbohydrate (g/d)	244 ± 60	199 ± 125[b]
%kcal	54 ± 7	31 ± 15[b]
Protein (g/d)	77 ± 18	196 ± 99[b]
%kcal	17 ± 2	29 ± 7[b]
Fat (g/d)	58 ± 19	117 ± 58[b]
%kcal	28 ± 7	39 ± 9[b]
Food items (g/d)[c]		
Cooked rice	404	590
Eggs	50	340
Chicken	44	220
Pork	29	54
Fish	26	11
Vegetables	75	278
Fruits (apple and orange)	240	0
Milk	228	0
Bread	53	0

[a]Values are mean ± SD. The dietary data (for 3 d) were collected every time before the milk sample was collected.
[b]Means in the same row with different superscripts differ significantly at $P < 0.05$.
[c]No standard deviation could be given because the calculation was made by summing total consumption of each particular food item by all mothers and then dividing by the number of mothers.

RESULTS

The total energy intake between Chongqing and Hong Kong lactating women was significantly different (Table 1). The percentage energy intake from fat and protein was significantly higher in Chongqing than in Hong Kong women while the percentage energy derived from carbohydrate was higher in the latter. Traditionally, Chongqing Chinese stay and eat at home after delivery for at least a month to replenish their nutrient stores. Their dietary fat was usually of animal origin including chicken and pork together with 4–10 eggs/d (Table 1). They consumed no dairy products and fruits. In contrast, Hong Kong Chinese lactating women consumed milk and other dairy products, more fruits, and lesser amounts of vegetables than the Chongqing women (Table 1).

The average fatty acid composition of milk pooled over all stages of lactation in Chongqing and Hong Kong Chinese lactating women is shown in Table 2. For comparison, the data published by us for Canadian women are also shown in Table 2 (13). LCP including 22:6n-3 and 20:4n-6 in the milk of both Hong Kong and Chongqing Chinese were higher than those in the milk from Canadian women and milk from the majority of women from other Western countries. In contrast, the milk from both Hong Kong and Chongqing Chinese had lower contents of *trans* fatty acids than that from women of Canada and other Western countries. However, the total *trans* fatty acids in the milk of Hong Kong Chinese were significantly higher than in that of Chongqing Chinese.

Several differences in the milk fatty acid profiles were observed between Hong Kong Chinese and Chongqing Chinese women (Table 2). The milk in Hong Kong Chinese women contained more n-6 fatty acids, including mainly 18:2n-6. Compared with that of the Chongqing Chinese women, the milk of the Hong Kong Chinese women had less *cis*-monounsaturated fatty acids including 18:1n-9, 16:1n-7, 20:1n-9, and 22:1n-9. Among saturates, 16:0, 18:0, 12:0, and 10:0 were lower while 14:0 was higher in the milk of Hong Kong Chinese women than these in Chongqing Chinese women (Table 2). However, there appeared to be no difference in total n-3 fatty acids between these two places.

As lactation progressed in Chongqing and Hong Kong Chinese women, the milk n-6 LCP decreased although their precursor fatty acid, 18:2n-6, remained unchanged in Chongqing Chinese women or significantly increased in Hong Kong Chinese women (Table 3). These n-6 LCP include 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6 (Table 3). Similarly, the milk n-3 LCP including 22:6n-3 and 22:5n-3 also decreased gradually with the duration of lactation although the precursor fatty acid, 18:3n-3, increased in the milk of Chongqing Chinese women. Among saturated fatty acids, 16:0 and 14:0 progressively decreased in the milk of both Chongqing and Hong Kong Chinese women. In contrast, 18:0 and 12:0 increased in the milk of Hong Kong Chinese women, but they decreased in

Total *trans*	0.22 (0.06)[c]	0.88 (0.61)[b]	7.19 (3.03)[a]
Total milk fat (g/L)	38.1 (17.1)[a]	32.4 (21.9)[b]	31.6 (9.4)[b]

[a]Data are mean (SD). Means in the same row with different superscripts (a–c) differ significantly at $P < 0.01$. Abbreviation: LCP, longer-chain polyunsaturated fatty acids.
[b]Adapted from Reference 13; milk samples were obtained during 3–4 wk of lactation.

that of Chongqing Chinese women (Table 3). With *cis*-monounsaturated fatty acids, 18:1n-9 remained unchanged in the milk of Hong Kong Chinese women, but it increased in that of Chongqing Chinese women (Table 3). In the milk of Chongqing Chinese women, 20:1n-9 and 22:1n-9 increased but they decreased in that of Hong Kong Chinese women.

The total milk fat was determined by the amount of triheptadecanoin added. As can be seen in Table 2, the total milk fat was very similar for Hong Kong Chinese and Canadian women, but it was significantly higher in the milk of Chongqing Chinese women. The total milk fat increased significantly when lactation progressed from colostrum (week 1) to week 6 in both Chongqing and Hong Kong Chinese women.

DISCUSSION

Chongqing and Hong Kong Chinese have different dietary habits and life-styles. Populations in Chongqing have a more

[b]Difference between Chongqing and Hong Kong is significant at $P < 0.01$.

traditional life-style where people have to rely on foods provided by the nearby farms. The general belief is that for the first month postpartum, women have to replenish their body nutrient stores by consuming more eggs, chicken, and pork. Eating more than eight eggs and 200 g chicken meat per day is not uncommon during the first month after delivery. This unique dietary habit leads to a very high intake of protein and fat in Chongqing women. Fruits are considered to be "cold" food and not commonly consumed during the first month. Milk and dairy products are never food items during pregnancy and lactation. In Hong Kong, however, people have a sedentary life-style and the diet is partly westernized. On average, a lactating Hong Kong Chinese woman drinks a glass of milk and eats a slice of bread for breakfast. During pregnancy and lactation, Hong Kong women consume more fruits than Chongqing Chinese women (Table 1). Furthermore, the amounts of rice, eggs, and meat eaten are not as much as for Chongqing Chinese women because of a lower requirement of energy expenditure in physical activity. This dietary habit clearly contrasts to what was observed for Chongqing women (Table 1). As shown in Table 1, the total energy intake in Hong Kong lactating women was only 1809 kcal/d which is consistent with their desire to get back to their prepregnant body shapes by consuming less total energy.

The present study showed that 22:6n-3 and 20:4n-6 levels in Chinese milk were higher than what has been reported in the majority of Western countries (20,21,25–27). The present values were similar to those in Japan (7), Africa (28), and other Asian countries (29). In some cases, the milk content of 22:6n-3 in Chinese women from fishery areas could reach 2.8% of the total milk fat (24). High seafood intake may contribute to the higher n-3 LCP content in human milk from Hong Kong relative to that from Canada and other Western countries. In contrast, the unique dietary characteristic of consuming more than eight eggs per day may contribute to a higher n-3 LCP content in milk from Chongqing lactating women. It is well known that eggs contain a significant amount of 22:6n-3 ranging from 0.9 to 6.6% of total lipids (30). In addition, the intake of chicken and pork would contribute to a higher 20:4n-6 content in milk from Chongqing Chinese women. The 20:4n-6 and 22:6n-3 contents of foods consumed by the women in this study have not been reported to our knowledge. Furthermore, a higher LCP content in the Chinese milk may be due in part to a very low *trans* fatty acid intake in these two places relative to Western countries. It has been suggested that dietary *trans* fatty acids may inhibit chain elongation and desaturation of 18:2n-6 and 18:3n-3 to form 20:4n-6 and 22:6n-3, respectively, in both maternal liver and mammary glands (31). As seen in Table 1, the two precursor fatty acids, 18:2n-6 and 18:3n-3, were similar in the milk of Chongqing Chinese and Canadian women but 22:6n-3 and 20:4n-6 in the former were much higher than in the latter. In contrast, the total *trans* fatty acid content in the Canadian samples was 32-fold higher than that in the Chongqing Chinese samples.

Our results illustrate a marked difference in dietary 20:4n-6 between Hong Kong and Chongqing Chinese lactating women although the milk content of this fatty acid was very similar (Table 2). Eggs and meats are generally a rich source of 20:4n-6. By assuming the fatty acid content of eggs

and meats consumed by the Chinese women is similar to that reported by Mann *et al.* (32), the Chongqing Chinese women would most likely have been consuming very high levels of 20:4n-6 (700–800 mg/d) compared with the Hong Kong Chinese women (120–140 mg/d). Together with observations made by Mantzioris *et al.* (33) and Makrides *et al.* (34), the present results suggest that breast milk 20:4n-6 may not be sensitive to maternal diet. In fact, it has been known that the breast milk 20:4n-6 level in vegan women (no or very little dietary 20:4n-6) is very similar to that of omnivorous women (35). However, it is important to conduct analyses of local foods to establish a reliable local food composition database before this finding can be confirmed.

The fatty acid composition in the milk of Hong Kong and Chongqing Chinese did not remain constant throughout the 6 wk of lactation. The 22:6n-3 and 20:4n-6 levels decreased gradually as lactation progressed from week 1 to week 6. This observation was in agreement of that of Gibson and Kneebone (18), who showed that 22:6n-3 and 20:4n-6 were significantly decreased from colostrum (22:6n-3, 0.64%; 20:4n-6, 0.71%) to mature milk (22:6n-3, 0.32%; 20:4n-6, 0.31%) in Australian lactating women. It was also evident that these fatty acids in mature milk decreased with the duration of lactation (25). However, the results of the present study were in contrast to those of Clark *et al.* (36), who showed that the total fatty acid composition in the milk of 10 lactating women remained constant throughout 16 wk of lactation. In their study, LCP appeared to decrease with time of lactation although a statistical significance was not found probably because the number of the subjects was relatively small compared to that in the present study. It is likely that the change in milk fatty acid composition is largely due to change in maternal diet as lactation progresses (14,36).

Differences in dietary patterns are also reflected by examining the content of individual fatty acids in the milk from Chongqing and Hong Kong. Firstly, 18:2n-6 in the milk from Hong Kong women was higher than that from Chongqing women. This may be due to the higher consumption of eggs and animal fats in the latter and a higher consumption of corn oil in the former during the first month of lactation. Secondly, eicosapentaenoic acid (20:5n-3) was higher in the milk of Hong Kong Chinese women than that of Chongqing Chinese women. This is possibly because Hong Kong lactating women consume more fish and fish soup presumably for inducing milk letdown. Thirdly, erucic acid (22:1n-9) and 18:3n-3 in the milk of Chongqing Chinese women increased as lactation progressed (Table 3). This is attributed to a change in diet from week 4 to week 6 in Chongqing lactating women. After one month of lactation, the Chongqing lactating women switched from a high animal fat diet to a normal diet, the same as the rest of the family. The 22:1n-9 and 18:3n-3 levels were therefore increased in the milk because high-erucic rapeseed oil is one of the major vegetable oils consumed in the Chongqing population.

In summary, the results from the present study are unique because there are few longitudinal and cross-cultural reports available of the fatty acids composition of the milk. The milk fatty acid composition, which reflects that in diets, is different in many ways between Chongqing and Hong Kong Chinese lactating women. Compared with that in the milk of women from Canada or other Western countries, the Chinese milk is characterized by having higher LCP and lower *trans* fatty acids contents. The relative higher *trans* fatty acids contents in the milk of Hong Kong Chinese than Chongqing Chinese may reflect the use of partially hydrogenated vegetable oils and dairy products in Hong Kong.

ACKNOWLEDGMENT

We thank the Hong Kong Research Grant Council for support of this research (CUHK 352/95M).

Comparative Hypocholesterolemic Effects of Six Dietary Oils in Cholesterol-Fed Rats After Long-Term Feeding

Michihiro Fukushima, Takae Matsuda, Kiichiro Yamagishi, and Masuo Nakano*

Department of Bioresource Chemistry, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Hokkaido 080, Japan

ABSTRACT: Rats (8 wk of age) fed a conventional diet were shifted to diets containing 10% *Oenothera biennis* Linn oil (OBLO, linoleic acid + γ-linolenic acid) from a wild plant, evening primrose oil (EPO, linoleic acid + γ-linolenic acid) from a cultivated plant, bio-γ-linolenic acid oil from mold (BIO, palmitic acid + oleic acid + linoleic acid + γ-linolenic acid), safflower oil (linoleic acid), palm oil (PLO, palmitic acid + oleic acid + linoleic acid), or soybean oil (linoleic acid + α-linolenic acid) with 0.5% cholesterol for 13 wk. Though there were no significant differences in the food intake among the groups, the body weight gain of the OBLO group was significantly lower than that of other groups except for the BIO and PLO groups, and that of the EPO and SBO groups were the highest among the groups. The liver weight of the OBLO group was significantly lower than that of other groups, and that of the PLO group was the highest among the groups. The serum total cholesterol and very low density lipoprotein (VLDL) + intermediate density lipoprotein (IDL) + low density lipoprotein (LDL) cholesterol concentrations of the OBLO and EPO groups were consistently lower than those in the other groups. However, those of the BIO group were higher than those in the OBLO and EPO groups. The liver cholesterol concentration of the PLO group was the highest among all groups except for the EPO group. The fecal neutral sterol and bile acid extraction of the BIO group tended to increase compared to the other groups. The results of this study demonstrate that OBLO and EPO inhibit the increasing of serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations in the presence of excess cholesterol in the diet compared with the other dietary oils.
Lipids 32, 1069–1074 (1997).

It is widely accepted that diets rich in linoleic acid (LA, 18:2n-6) reduce plasma cholesterol levels (1,2). There is no doubt that when LA replaces saturated fatty acids in the diet, the major portion of cholesterol lowering occurs in the low density lipoprotein (LDL) fraction (3). However, it also is reported that dietary high-linoleate safflower oil (SFO) is not hypocholesterolemic in aged mice compared with perilla oil and fish oil (n-3 fatty acids) after long-term feeding (4). Although it has been reported that n-3 fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), suppress 3-hydroxy-3-methylglutaryl CoA reductase (5–7) and retard very low density lipoprotein (VLDL) secretion, resulting in decreased LDL (7), the mechanisms involved in the hypocholesterolemic effect of polyunsaturated fats have not been clearly defined.

Fukushima *et al.* (8) reported that *Oenothera biennis* Linn oil (OBLO) containing about 71% LA and 14% γ-linolenic acid (GLA) has a hypocholesterolemic function compared with soybean oil (SBO) containing about 51% LA and 9% α-linolenic acid (ALA), sunflower oil containing about 64% LA, high-oleic safflower oil (SFO) containing about 40% oleic acid and 50% LA, and mixed oil containing about 23% LA and 7% ALA after 6-wk feeding. The purpose of the present study is to investigate the effect of OBLO containing about 14% GLA from a wild plant on the lipid metabolism in rats in comparison with evening primrose oil (EPO) (Efamol) containing about 9% GLA from a cultivated plant, about 23% GLA-enriched bio-γ-linolenic acid from mold (BIO), SFO containing about 75% LA, palm oil (PLO) containing abundant saturated acid, and SBO containing 8% ALA after long-term (13-wk) feeding.

MATERIALS AND METHODS

Animals and diets. Male F344/DuCrj rats (8-wk-old) were purchased from Charles River Japan Inc. (Yokohama, Japan). Thirty-six animals were housed individually in cages in a room with controlled temperature (23 ± 1°C), humidity (60 ± 5%), and light (12-h light/dark cycle). The composition of the experimental diet was as follows (wt%): casein, 20; fat 10; cornstarch, 15; cellulose powder, 5; DL-methionine, 0.3; mineral mixture, 3.5 (AIN-76) (9); vitamin mixture, 1 (AIN-76) (9); choline bitartrate, 0.2; cholesterol, 0.5; sodium cholate, 0.125; and sucrose to 100. OBLO was extracted as described elsewhere (8). EPO, BIO, SFO, PLO, and SBO were purchased from Summit Oil Co. (Chiba, Japan, licensed by

Abbreviations: AA 20:4n-6, arachidonic acid; ALA 18:3n-3, α-linolenic acid; BIO, bio-γ-linolenic acid from mold; DG, diacylglycerol; DHA 22:6n-3, docosahexaenoic acid; EPA 20:5n-3, eicosapentaenoic acid; EPO, evening primrose oil; GLC, gas–liquid chromatography; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; LA 18:2n-6, linoleic acid; LDL, low density lipoprotein; OBLO, *Oenothera biennis* Linn oil; PC, phosphatidylcholine; PLO, palm oil; P/S, polyunsaturated fatty acid/saturated fatty acid; SBO, soybean oil; SFO, safflower oil; TG, triacylglycerol; VLDL, very low density lipoprotein.

Efamol Ltd.), Idemitsu Material Co. (Tokyo, Japan), Hounen Co. (Tokyo, Japan), Asahi Electric Industry Co. (Tokyo Japan), and Fuji Oil Co. (Osaka, Japan), respectively. The lipid class of each oil was as follows: OBLO was composed of 79% triacylglycerol (TG), 6% diacylglycerol (DG), 9% sterol, and other components; EPO was composed of 86% TG, 4% DG, 9% sterol, and other components; BIO was composed of 70% TG, 2% DG, 24% sterol, and other components; SFO was composed of 84% TG, 2% DG, 9% sterol, and other components; PLO was composed of 78% TG, 5% DG, 9% sterol, and other components; and SBO was composed of 80% TG, 1% DG, 13% sterol, and other components. Sitosterol comprised about 77–92% of the sterol concentration in each oil except for BIO, which contained 13% sitosterol and 57% ergosterol in the sterol concentration.

Table 1 shows the fatty acid compositions of the dietary fats. All rats (8-wk-old) were divided into six groups of six animals each. Rats were allowed free access to experimental diets and water for 13 wk. To avoid autooxidation, each diet was stored at −20°C and freshly prepared each day. All animal procedures described conformed to recognized principles (see Ref. 10).

Analytical procedures. Blood samples (2 mL) were collected between 0800 and 1000 h from the jugular veins of fed rats. The samples were taken into tubes without anticoagulant. After the samples stood at room temperature for 2 h, serum was prepared by centrifugation at 1500 × *g* for 20 min. At the end of the experimental period of 13 wk, all fecal excretion during 2 d was collected. Fecal dry weights did not differ among groups. The rats were killed by ether inhalation, and the livers quickly removed, washed with cold saline (9 g NaCl/L), blotted dry on filter paper, and weighed before freezing for storage.

Chemical analysis. Total cholesterol and high density lipoprotein (HDL)-cholesterol concentrations in the serum were determined enzymatically using commercially available reagent kits (assay kits for the TDX system; Abbott Laboratory Co., Irving, TX). The VLDL + intermediate density lipoprotein (IDL) + LDL-cholesterol concentration was calculated as follows: VLDL + IDL + LDL-cholesterol = total cholesterol − HDL-cholesterol.

Total lipids were extracted from serum, liver, and feces by a mixture of chloroform/methanol (2:1, vol/vol) (11). The serum and liver phosphatidylcholine (PC) were separated by two-step single-dimensional thin-layer chromatography on a silica gel plate; the solvents were chloroform/methanol (one-step; 95:5, vol/vol) and chloroform/acetone/methanol/acetic acid/water (two-step; 50:20:15:10:5, by vol). The fatty acids of the PC fraction were esterified in HCl-methanol (5 mL/L) for 2 h at 125°C (12) and analyzed using gas–liquid chromatography (GLC; Shimadzu 14A, Kyoto, Japan) with a 10% DEGS packed column (2 mm × 2.6 m, support shimalite w; Shimadzu) with nitrogen as the carrier gas. Neutral sterols in feces and liver obtained by saponification were acetylated (13) and analyzed by GLC with a DB 17 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA). Acidic sterols in feces were measured by GLC following the method of Grundy *et al*. (14).

Statistical analysis. Data are presented as means and standard deviations. The mean and standard deviation for serum total cholesterol, HDL-cholesterol, and VLDL + IDL + LDL-cholesterol for each time point were calculated. The significance of differences among treatment groups was determined by analysis of variance with Duncan's multiple-range test (SAS Institute, Cary, NC). Results were considered significant at $P < 0.05$.

RESULTS

Feed intake, rat growth, and liver weight. The results are summarized in Table 2. Dietary OBLO and BIO tended to decrease the body-weight gain significantly more than dietary EPO and SBO. The body weight of the dietary SFO group also increased significantly more than in the dietary OBLO group. There were no significant differences in the food intake among the groups. The liver weight in the OBLO group was the lowest of all groups, and that in the BIO group was significantly lower than in the PLO and EPO groups.

Tissue lipid concentration. The serum total, VLDL + IDL + LDL-cholesterol, and HDL-cholesterol concentrations are shown in Table 3. The total and VLDL + IDL + LDL-cholesterol concentrations in the OBLO group were significantly lower than those in the other groups, except for the EPO group, throughout the experimental period. Those in the EPO group were significantly lower than in the PLO and SBO groups throughout the experimental period. Those in the BIO and SBO groups were significantly lower than in the PLO group. Though the HDL-cholesterol concentration in the BIO

SFO	190 ± 5	197 ± 8^{a,b}	1473 ± 42	5.4 ± 0.4^{b,c}
PLO	184 ± 9	186 ± 18^{a,b,c}	1492 ± 139	6.1 ± 0.2^{a}
SBO	187 ± 8	203 ± 22^{a}	1500 ± 124	5.4 ± 0.7^{b,c}

[a]Values are expressed as means ± standard deviations for six rats. Means within the same columns bearing different superscripts are significantly different ($P < 0.05$). OBLO, *Oenothera biennis* Linn oil; EPO, evening primrose oil; BIO, bio-γ-linolenic acid oil; SFO, safflower oil; PLO, palm oil; SBO, soybean oil.

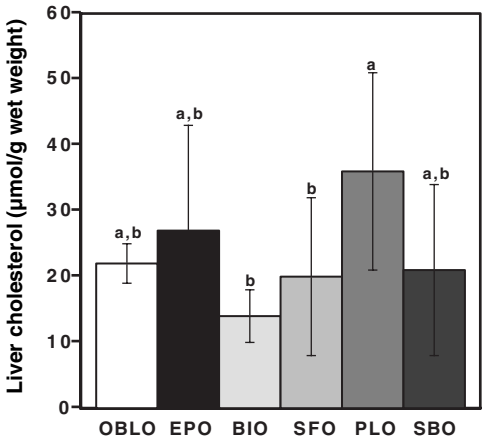

FIG. 1. Liver cholesterol concentration in rats fed dietary fats for 13 wk. Values are means for six rats, with standard deviations indicated by bars. Means values (a,b) were significantly different ($P < 0.05$); OBLO, *Oenothera biennis* Linn oil; EPO, evening primrose oil; BIO, bio-γ-linolenic acid oil; SFO, safflower oil; PLO, palm oil; SBO, soybean oil.

group was significantly higher than that in the other groups at 7 wk, the HDL-cholesterol concentration was significantly lower than in the other groups, except for the OBLO group, at the 13th wk.

Figure 1 illustrates the cholesterol concentrations in the livers of rats at the end of the 13-wk feeding period. Dietary PLO increased the liver cholesterol concentration significantly more than BIO and SFO did.

Fatty acid composition of the tissue. The fatty acid compositions of PC in the serum and liver are shown in Table 4. The level of 18:2n-6 in the serum of the BIO group increased significantly compared with the OBLO, EPO, and SFO groups. The level of 18:3n-6 in the OBLO group was significantly higher than in the other groups. The level of 20:4n-6 in the PLO group was significantly higher than that in the OBLO, EPO, and SBO groups.

The level of 18:2n-6 in the liver of the BIO group decreased significantly in all groups. The level of 18:3n-6 in the BIO group decreased significantly compared with the EPO group. The level of 20:4n-6 in the PLO group was significantly higher than in the other groups, except for the SBO group. The level of 22:6n-3 in the SBO group was significantly higher than in the other groups except for the OBLO group.

Fecal lipid concentration. Table 5 shows the effects of the dietary fat on fecal neutral sterol and bile acid concentrations in rats at the end of the experimental period. The excretion of cholesterol increased in the BIO group, and the excretion of coprostanol in the PLO group was significantly higher than in the OBLO group.

The excretion of chenodeoxycholic acid in the SFO group was highest among the groups, and the excretions of deoxycholic acid and lithocholic acid in the BIO group were significantly higher than those in the other groups. The total bile acid concentrations in the BIO and SFO groups also were significantly higher than in the other groups.

VLDL, very low density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein. See Table 2 for other abbreviations.

DISCUSSION

In a previous study (8), we reported the comparative hypocholesterolemic effects of six vegetable oils in cholesterol-fed rats after 6-wk feeding. The serum total and VLDL + IDL + LDL-cholesterol concentrations of 10 and 20% OBLO groups were consistently lower than those for other oils containing about 9% ALA, 40–64% LA or about 50% oleic acid, and for mixed oil prepared with an n-6/n-3 ratio of 3.5 and polyunsaturated fatty acid/saturated fatty acid (P/S) ratio of

1.0 (8). Ishihara *et al*. (4) also suggested that n-6 fatty acid, LA, had no hypocholesterolemic effect in long-term feeding (120 d). In this long-term feeding experiment (13 wk), the OBLO from a wild plant was compared with EPO from a cultivated plant, BIO from mold, SFO containing about 75% LA, PLO containing about 46% palmitic acid, and SBO containing about 8% ALA and 53% LA.

The body-weight gain was less in the OBLO and BIO groups than in EPO and SBO groups, and the liver weight was less in the OBLO and BIO groups than in the other groups, although food intake was similar among the six groups. The data for body weight in the dietary OBLO group agreed with previous studies (15–17). Takada *et al*. (15) reported that dietary GLA oil reduced body-fat content and facilitated fatty acid β-oxidation in the liver, and the reduction of body weight in this experiment might have been due to those effects.

This study indicated that dietary OBLO with an average level of 212 mg of 18:3n-6/d was more efficient in lowering serum total cholesterol than SFO, PLO, or SBO, which contained abundant LA, saturated fatty acid, and LA + ALA, respectively, without GLA, and that dietary EPO at an average level of 149 mg of 18:3n-6/d also was more efficient than PLO or SBO in long-term feeding. The results for the dietary OBLO and EPO groups agreed with a report on rats fed at levels of about 130 and 177 mg of 18:3n-6/d (18). Ishihara *et al*. (4) reported that increased intake of high-linoleate vegetable oil was not useful for the prevention of hypercholesterolemia-associated diseases; however, dietary oils rich in n-3 fatty

acids might be useful. Although dietary GLA is hypocholesterolemic compared with SBO containing 8% ALA (8), our experiments did not include perilla oil, which contains abundant ALA, and we did not study aged rats. Thus, our results might not agree with results of Ishihara *et al*. (4) because our conditions were different from theirs (4). However, Horrobin and Manku (19) have reported that GLA, the first essential fatty acid metabolite of LA, has cholesterol-lowering action greater than that of the parent molecule, suggesting that LA must be converted to GLA to exert its desirable effects on cholesterol metabolism. They also indicated that the cholesterol-lowering effect of LA is probably not due to LA itself but to that fraction which is converted to GLA and beyond and, in patients with elevated cholesterol levels, the Δ6-desaturase enzyme that converts LA to GLA appears to be functioning inefficiently. Their speculations agreed with our results, and diets containing GLA had a greater hypocholesterolemic effect than diets without GLA.

The cholesterol content in the livers of rats fed the BIO diet was the lowest among the six groups. Consistent with this finding were the data which indicated that total bile acid and cholesterol levels in feces were the highest among the six groups. Dietary BIO at an average level of 365 mg of 18:3n-6/d was shown to be efficient in inhibition against increasing the serum total cholesterol level compared with dietary PLO. The hypocholesterolemic effect depends on the P/S ratio of dietary fats, and Lee *et al*. (20) reported that the P/S ratio (11.1) of SFO was more effective than the P/S ratios (0.2 and 1.8) of PLO and SFO + PLO. Thus, it may be the total amount of polyunsaturates that is important and not one single fatty acid, and the inhibition effect against increasing serum cholesterol concentration of their polyunsaturated oils is not due to increased fecal excretion of neutral and acidic sterols.

The level of 18:3n-6 in the serum and liver PC was detected in OBLO, EPO, and BIO groups. The result shows that dietary GLA affected the amount of 18:3n-6 in serum and liver PC.

The dietary OBLO and EPO could inhibit the increasing of serum VLDL + IDL + LDL-cholesterol concentrations in rats throughout the experimental period compared with the other oils. Grundy and Denke (21), in a review, reported that the n-6 fatty acid replacing saturated acids in the diet reduces the number of LDL particles in circulation, as revealed by a definite fall in LDL-apoB concentrations, inhibits hepatic synthesis of apoB-containing lipoproteins, and increases LDL-receptor activity. The data in this experiment may reflect such mechanisms, because the data for the liver cholesterol concentrations and fecal sterol concentrations in the OBLO and EPO groups alone could not explain the inhibition effects against the increasing of serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations.

In conclusion, the results of this study demonstrate that OBLO from a wild plant and EPO from a cultivated plant inhibit the increasing of serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations as compared with the BIO, SFO, PLO, and SBO in the presence of excess cholesterol in the diet after long-term feeding.

ABSTRACT: In view of the promising future for use of n-3 polyunsaturated fatty acids (PUFA) in the prevention of cancer and cardiovascular diseases, it is necessary to ensure that their consumption does not result in detrimental oxidative effects. The aim of the present work was to test a hypothesis that low doses of eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) do not induce harmful modifications of oxidative cell metabolism, as modifications of membrane fatty acid composition occur. Wistar rats received by gavage oleic acid, EPA, or DHA (360 mg/kg body weight/day) for a period of 1 or 4 wk. Fatty acid composition and α-tocopherol content were determined for plasma, red blood cell (RBC) membranes, and liver, kidney, lung, and heart microsomal membranes. Susceptibility to oxidative stress induced by *tert*-butylhydroperoxide was measured in RBC. EPA treatment increased EPA and docosapentaenoic acid (DPA) content in plasma and in all the membranes studied. DHA treatment mainly increased DHA content. Both treatments decreased arachidonic acid content and n-6/n-3 PUFA ratio in the membranes, without modifying the Unsaturation Index. No changes in tissue α-tocopherol content and in RBC susceptibility to oxidative stress were induced by either EPA or DHA treatment. The data suggest that EPA and DHA treatments can substantially modify membrane fatty acids, without increasing susceptibility to oxidative stress, when administered at low doses. This opens the possibility for use of low doses of n-3 PUFA for chemoprevention without risk of detrimental secondary effects.
Lipids 32, 1075–1083 (1997).

As a part of a recent study of the biological activity of n-3 polyunsaturated fatty acids (PUFA), we found that dietary supplementation with mixtures of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), in human subjects at high risk for colon cancer, suppressed cytokinetic anomalies in the colonic mucosa (1,2). This indicates that these fatty acids may be protective against cancer and supports our earlier observations and those of others in animal models (3–6). In view of the promising future use for n-3 PUFA in the prevention of cancer and cardiovascular diseases (5,7–9), it is necessary to ensure that their consumption does not result in detrimental side effects. The substitution of n-6 PUFA with potentially unstable n-3 PUFA in the membranes may shift fatty acid composition toward a higher degree of unsaturation and enhance membrane susceptibility to lipid peroxidation (10,11). Moreover, increased uptake of PUFA may affect vitamin E status either by impairing the absorption of the antioxidant (12,13) or by causing increased vitamin E consumption in plasma and tissues owing to enhanced lipid peroxidation (14,15).

We reported earlier that treatment of human subjects with n-3 PUFA at low doses and without significant addition of α-tocopherol did not produce any detrimental effect, whereas high doses resulted in harmful modifications of oxidative metabolism, such as an increase of red blood cell (RBC) susceptibility to lipid peroxidation and changes in endogenous tocopherol content and Mg-K-ATPase activity (16,17).

The aim of the present study was to evaluate in a rat model short- and longer-term effects of low dietary administrations of EPA or DHA without significant supplementation of vitamin E on membrane fatty acid composition of a variety of tissues, on RBC susceptibility to lipid peroxidation, and on tissue α-tocopherol content. n-3 Fatty acids were given separately and at doses comparable to the minimum used in our human studies (1,2,16,17).

MATERIALS AND METHODS

Animals. Thirty male Wistar rats (~250 g) were fed a nonpurified commercial diet (Altromin-Rieper, Rieper Company, Bolzano, Italy). The composition of the diet was: (%, w/w) crude protein, 23; fat, 5.5; fiber, 5; mineral, 8; carbohydrate, 58.5; water, 12. The vitamin mixture added to the diet was 2.5 g/kg (vitamin E, 100 mg/kg), and the mineral mixture was

*To whom correspondence should be addressed at Catholic University, Institute of General Pathology, Lgo F. Vito 1, 00168 Rome, Italy.
E-mail: ibipg@rm.unicatt.it.

Abbreviations: DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; OA, oleic acid; PUFA, polyunsaturated fatty acids; RBC, red blood cell; *t*-BOOH, *tert*-butylhydroperoxide.

0.52 g/kg by weight. The diet provided 7.5 g/kg n-6 PUFA as linoleic acid (18:2n-6) and 1.02 g/kg n-3 PUFA as 18:3, 18:4, 20:5 and 22:6 . The dietary n-3/n-6 PUFA ratio was 0.14 and increased to 1.20 after EPA or DHA administration. Food and water were provided *ad libitum*.

The animals were randomly divided into three groups of 10 animals each. One group received oleic acid ethyl ester (OA, control), a second group received EPA-ethyl ester, and a third DHA-ethyl ester. The oils were given by gastric gavage as a single dose of 360 mg/kg body weight/day. The amount of OA (18:1n-9) in the control group was adjusted to equalize caloric intake among the groups. Preliminary experiments comparing OA-treated animals with untreated animals showed that OA treatment did not modify fatty acid composition and α-tocopherol content in plasma and cell membrane fractions.

The dietary dose (360 mg/kg body weight) was chosen to approximate the daily oral dose (2.5 g) that was found to normalize altered cellular proliferation in the colonic mucosa of patients at high risk for colon cancer (1,2). The same dose was found not to produce any adverse effects (16,17). Body surface area was used as the reference for conversion of the human dosage to the rat (18). An n-3 PUFA dose of 2.5 g/d given to patients weighing about 70 kg corresponded to a daily intake of 300 mg/kg body weight in the rat. In the human study, the n-3 PUFA were taken in three daily subdoses to facilitate absorption from the intestine. We increased the dose to 360 mg/kg body weight/d to compensate for reduced absorption when single doses of n-3 PUFA were used in the rat model.

The α-tocopherol amount (3 mg/g) was added to the oils for prevention of autooxidation. Total intake of α-tocopherol was 1.77 mg/d, (1.5 mg/d from the diet plus 0.27 mg/d from oil supplementation). This approximated the intake in earlier human studies (1,2). The α-tocopherol daily intake during the human studies was the sum of the content in the standard Italian diet (13 mg/d) plus the content in oil capsules (0.9–2.7 mg/d) and was similar to the recommended dietary intake (19,20).

The purity of fatty acids was 92 and 90% for EPA and DHA, respectively. Their α-tocopherol content was verified by high-performance liquid chromatography.

Food consumption and body weight gain for the animals were measured twice a week. Five animals from each group were sacrificed after 1 wk of treatment and the remaining five animals after 4 wk. The animal use protocol was approved by the Ministry of Health, Veterinary Service, Rome, Italy.

Sample collection. The animals were decapitated after ether anesthesia, and the blood was collected in heparinized tubes. Plasma was separated by centrifugation at $1000 \times g$ for 10 min at 4°C. RBC were washed three times in buffered isotonic NaCl solution. RBC membranes were prepared as described by Burton *et al.* (21). Liver, kidneys, lungs, and heart were rapidly excised and immediately frozen in liquid N_2 and stored at −80°C prior to processing. Microsomal membranes were prepared from liver, kidneys, heart, and lungs as described by Bartoli *et al.* (22) and protein concentration was measured by the Bradford assay (23).

Analysis of fatty acids. Lipids were extracted from microsomal membranes by the method of Bligh and Dyer (24), using chloroform/methanol (2:1, vol/vol) containing butylated hydroxytoluene (0.01%), and gravimetrically measured (25). Total phospholipids were separated from neutral lipids by thin-layer chromatography using silica gel 60 plates (Merck, Darmstadt, Germany) and toluene/diethyl ether/ethanol 35:3.5:1 (by vol) as a solvent system. Fatty acids in the phospholipid band were transesterified with the use of methanolic-HCl (3 N) (Supelco, Bellefonte, PA) at 70°C for 2 h. After extraction with *n*-hexane, methyl esters were separated and quantified by means of an HRGC 5300 Megaseries gas–liquid chromatograph (Carlo Erba, Milan, Italy) equipped with a 30 m × 0.25 mm capillary column (Supelco, Omegawax 320) using helium as carrier gas. The oven temperature was programmed at 1°C/min from 180 to 220°C. Retention times were identified with standards (Sigma Chemical Co., St. Louis, MO). Peaks corresponding to 16:0, 18:0, 18:1n-9, 18:2n-6, 18:3n-6, 18:3n-3, 20:3n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-3, and 22:6n:3 were detected by the system and their areas measured with a Carlo Erba Megaseries integrator. Unsaturation Index was measured as the sum of the percentages of individual fatty acids × number of double bonds.

Oxidative stress induced by tert-*butylhydroperoxide (t-BOOH) in RBC.* A 5% RBC suspension in phosphate-buffered saline (pH 7.4) was incubated with 0.5 mM *t*-BOOH at 37°C under oxygen for 90 min. At each time point, a sample of 1 mL was taken for analysis of both malondialdehyde formation at 533 nm (26) and K^+ efflux. K^+ efflux was determined by flame emission photometry and expressed as percentage of total efflux evoked by lysis of RBC in distilled water (27).

Vitamin E analysis. α-Tocopherol was extracted in hexane from plasma, RBC membranes, and tissue microsomal membranes using, respectively, 25 µL plasma and a membrane equivalent of 7 mg protein. Samples were dissolved in methanol, and 20 µL aliquots were analyzed by high-performance liquid chromatography fluorescence detection on a Perkin-Elmer (Norwalk, CT) 650-LC fluorescence detector at 295 nm excitation, 340 nm emission. α-Tocopherol, as well as the internal standard, tocol, was eluted with 100% methanol on Alltech (Deerfield, IL) C-183-µm column, as indicated in Reference 28.

Statistical analysis. The results are expressed as means ± SE, and significance was assessed by one-way analysis of variance using Minitab software (Minitab Inc., State College, PA). When significant differences were found, *post hoc* comparisons of means were made using Fisher's test. Differences were considered significant at $P < 0.05$.

RESULTS

Food intake and body weight gain were similar in all groups throughout the 4-wk feeding period. Treatments did not modify the content of total lipids in the tissues, as shown by lipid/protein ratios of 0.20 ± 0.01, 1.16 ± 0.11, 0.77 ± 0.04, 0.65 ± 0.05, 1.07 ± 0.12, and 1.39 ± 0.09 in plasma, RBC,

liver, kidney, heart, and lung membranes, respectively. These ratios did not change throughout short (1 wk) or long (4 wk) periods of treatment.

Tables 1–6 show fatty acid composition for total phospholipids extracted from plasma, RBC membranes, liver, kidney, heart, and lung microsomal membranes isolated from rats treated for 1 and 4 wk with OA, EPA, or DHA.

The content of saturated and monounsaturated fatty acids in plasma, RBC, and tissue membranes was unaffected by dietary supplementation with EPA and DHA. On the other hand, the content of total and individual PUFA changed significantly in rats treated with the two n-3 fatty acids as compared to the control group. Alterations in the PUFA pattern became evident within 7 d of treatment. EPA (20:5n-3) was incorporated to different extents in the tissues studied. Its increase in RBC membranes after 1 wk of EPA treatment was the highest (340%), followed by that observed in heart (218%), lung (157%), liver (107%), plasma (103%), and kid-

ney (87%). After 4 wk of EPA treatment, the level of this fatty acid decreased in plasma and heart membranes (Tables 1 and 5). Nevertheless, EPA was still higher than that observed in the control group. In lung (Table 6) it decreased to the control value, whereas in RBC, liver, and kidney membranes it remained relatively unchanged as compared to that observed after 1 wk (Tables 2–4).

EPA treatment did not modify the DHA content in plasma, RBC, and tissue membranes, whereas it significantly increased docosapentaenoic acid (DPA, 22:5n-3), which is a product of EPA elongation. This effect was exaggerated in heart and liver (259 and 127% increase, respectively). DHA did not modify DPA level in any of the tissues except liver, in which a slight (40%) but significant increase was observed (Table 3).

As observed for EPA, but to a lesser extent, increased incorporation of DHA (22:6n-3) occurred in plasma and tissue membranes following dietary supplementation. The increase in DHA was evident after 1 wk and with the exception of

plasma (Table 1), it was also present after 4 wk of treatment. During DHA supplementation the levels of EPA were elevated in plasma, RBC, liver, and kidney but remained unmodified in heart and lung.

The treatments with EPA or DHA were associated with modifications in n-6 PUFA content. In particular, linoleic acid (18:2n-6) was increased in plasma, heart, liver, and kidney (Tables 3 and 4). Nevertheless the change was significant only in liver and kidney. Similarly, a significant reduction in arachidonic acid (20:4n-6) was observed in plasma, liver, kidney, and heart after both EPA and DHA treatments, while no changes were found in RBC and lung.

Fatty acid modification was associated with a significant decrease in the n-6/n-3 PUFA ratio in plasma and in all the tissues examined from both EPA and DHA groups. On the contrary, the Unsaturation Index of plasma, RBC, and tissue fatty acids was unchanged, presumably because the increase of n-3 PUFA was counteracted by a decrease of n-6 PUFA. A slight but signifi-

cant increase in Unsaturation Index was observed only in heart membranes after 1 wk of DHA treatment (Table 5).

To evaluate whether the changes in fatty acid composition might account for increased susceptibility to lipid peroxidation, we exposed RBC isolated from animals treated with OA, EPA, and DHA for 4 wk to the prooxidant action of *t*-BOOH (Fig. 1A). RBC were incubated in the presence of 1 mM *t*-BOOH at 37°C for 90 min under oxygen. Lipid peroxidation was measured as malondialdehyde release. Neither EPA nor DHA treatments modified malondialdehyde release in RBC with respect to the control group. Under the same experimental conditions, we compared the time course of *t*-BOOH-induced hemolysis, measured as K^+ leakage, in RBC from OA, EPA, and DHA groups (Fig. 1B). *t*-BOOH-induced hemolysis did not differ in RBC isolated from the three groups.

In view of reports that fatty acid supplementation may influence vitamin E status (29), we analyzed the content of this antioxidant in plasma, RBC, and tissues after dietary treatment with OA, EPA, or DHA for 1 and 4 wk. The results are shown in Table 7. The three groups of animals did not differ in plasma, RBC, and tissue α-tocopherol content prior to dietary treatments. The highest level of α-tocopherol was found in lung, followed by heart, liver, RBC, and kidney. EPA did not induce any modification in α-tocopherol level after 1 wk, and a slight but significant decrease in RBC content was observed after 4 wk. DHA increased α-tocopherol content in RBC membranes after 1 wk and decreased it after 4 wk. Moreover, DHA treatment decreased α-tocopherol content in heart membranes after 1 wk and returned it to control values after 4 wk. This suggests a close relation between α-tocopherol content and Unsaturation Index modifications.

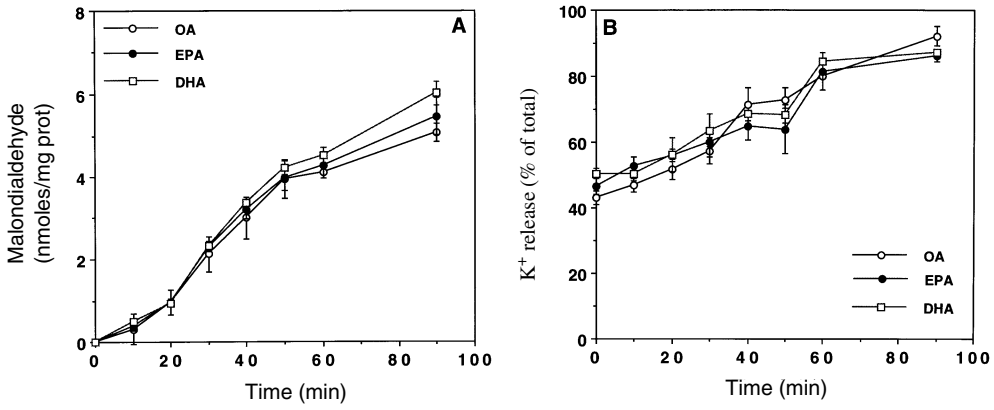

FIG.1. Lipid peroxidation and K^+ release induced by *tert*-butylhydroperoxide (*t*-BOOH) in red blood cells (RBC) isolated from rats treated with oleic acid (OA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) for 4 wk. RBC were incubated at 37°C for 90 min under oxygen in the presence of 0.5 mM *t*-BOOH. Lipid peroxidation (A) was measured as malondialdehyde formation. Intracellular K^+ release (B) was expressed as percentage of total efflux evoked by lysis of RBC in distilled water. Data are means ± SEM of five experiments.

DISCUSSION

The results show that the individual administration of low doses of EPA or DHA to rats does not change total lipid content but significantly modifies fatty acid composition of membrane phospholipids within 1 wk of treatment. The doses of n-3 PUFA in the present study were 2–10 times lower than those used by other authors (30–33) so as to approximate the dietary dose of the mixture of n-3 PUFA consumed in human studies (1,2,16,17). Beneficial effects of equivalent doses in human subjects at high risk for colon cancer (1,2) were not associated with any side effects (16,17). Moreover, the ratio n-3/n-6 PUFA used in the present study (1,2) was in the range (0.5–2) considered optimal for the expression of n-3 PUFA beneficial effects (34–36).

The changes in phospholipid composition in the rat membranes paralleled those observed in plasma and were directly related to the specific supplementation regimen. EPA was incorporated into the membranes, both directly and indirectly, as 22:5n-3 (DPA), its elongation product. This was reminiscent of the DPA accumulation in various tissues that occurs after fish oil administration (37,38). In agreement with our results, it has been reported that administration of purified EPA led to an increased level of DPA (31,32,39,40). This suggests that DPA represents a temporary storage site for surplus EPA, as postulated by Ackman (41).

Conversely, our data show that EPA supplementation did not lead to DHA (22:6n-3) increases in the tissues. This may be explained by an inhibitory effect of EPA on Δ6-desaturase (31,42) that has been postulated to be involved in the synthesis of 22:6n-3 from 22:5n-3 (38).

DHA treatment induced an increase in EPA (20:5n-3) in plasma, RBC, liver, and kidney. This effect was not observed in heart and lung, where DHA is presumably acylated to phospholipids rather than being retroconverted to 20:5n-3. Our data suggest a lowered capacity for retroconversion from 22:6n-3 to 20:5n-3 in tissues. This is in agreement with Gronn *et al.* (32), who reported a limited ability for retroconversion in heart. We reported earlier that retroconversion from 22:6n-3 to 20:5n-3 occurred in colon mucosa and transplanted hepatocarcinoma from rats (3,4).

Our results show increased levels of 20:5n-3 in plasma and in some membranes (lung, heart, and RBC) during EPA treatment. However, this increase was higher after 1 wk than after 4 wk. On the other hand, the increase of DHA observed in plasma and membranes was similar after 1 or 4 wk. Kinetics of incorporation of EPA and DHA in the various tissues probably reflects differences in metabolism and roles of EPA and DHA in biological membranes of specialized cells. For example it is known that DHA is generally present in mammary tissues at higher levels than EPA (43,44), which is consistent with our results. This observation relates to suggestions that DHA has a role in structural stability, whereas EPA is preferentially utilized for energy purposes, e.g., β-oxidation or eicosanoid synthesis (31,45,46).

Many studies with fish oils or purified EPA or DHA show that, as tissues become enriched in n-3 PUFA, they decrease their content in 20:4n-6 (arachidonic acid) and 18:2n-6 (linoleic acid) (31,38,40,47–49). However, in our experimental conditions, EPA or DHA at low concentrations decreased the content of 20:4n-6 in plasma and different tissues (liver, kidney, and heart) while increasing the level of 18:2n-6 in liver and kidney. This is best explained by the low dose used in our study, because with increasing doses of dietary n-3 PUFA, a large decrease of 18:2n-6 content occurs only with the highest doses (50).

The decrease of 20:4n-6 may be explained either by the known inhibition exerted by n-3 PUFA on the formation of 20:4n-6 from 18:2n-6 at the Δ6-desaturation step (51) or by the competition of n-3 PUFA with 20:4n-6 for acylation on the *sn*-2 position of membrane phospholipids (32). The first mechanism is likely to occur in liver, where Δ6-desaturation is a highly active process (48) and 18:2-n-6 levels are increased (Table 3). On the other hand, in heart, where Δ6-desaturation is limited (51) and 18:2n-6 levels do not change, the second mechanism is more plausible.

Although we found changes in plasma, RBC, and tissue membrane fatty acids as a consequence of EPA or DHA treatment, no significant modifications of Unsaturation Index were observed (Table 5). Only heart membranes showed a slight increase in the Unsaturation Index after 1 wk of treatment with DHA.

Our data show that dietary administration with low doses of n-3 PUFA can induce modifications of composition of phospholipid fatty acids without substantially affecting the degree of membrane unsaturation. This observation is consistent with what we found for α-tocopherol content.

α-Tocopherol content was not changed by EPA or DHA treatments. The only exception was heart membranes, where the treatment with DHA for 1 wk decreased the content of α-tocopherol while increasing the Unsaturation Index, suggesting that these two events are closely related. It is generally reported that dietary administration of n-3 PUFA increases lipid susceptibility for peroxidation, which is observed in membranes as an increase in Unsaturation Index and the consequent decrease of α-tocopherol content (52,53). The lack of change in this relationship found in our study suggests that dietary administration of low doses of n-3 PUFA does not modify susceptibility to oxidative stress.

Treatment with EPA and DHA did not modify the Unsaturation Index of RBC membranes. In contrast, α-tocopherol increased after 1 wk of treatment with DHA and decreased after 4 wk of treatment with both EPA and DHA. This confirms our previous data (16) and that of Berlin *et al.* (54) in human subjects. These studies found that short-term treatment with n-3 PUFA increased RBC membrane content of α-tocopherol and long-term treatment decreased it.

The modification of α-tocopherol in RBC could result from the peculiarity of these cells to freely exchange lipids between plasma and the cell membrane or from differential absorption of α-tocopherol induced by n-3 PUFA treatments.

In the present study, the treatments with EPA and DHA, at

the dose used, did not modify lipid peroxidation and hemolysis susceptibility of RBC exposed to an exogenous source of free radicals. Others reported that both parameters changed owing to oxidative stress induced by supplementation with n-3 PUFA (14,52). Our findings suggest that the overall susceptibility to lipid peroxidation of RBC is not increased and that the dose of n-3 PUFA used is an important variable in the induction of detrimental effects.

We conclude that EPA and DHA, administered at low doses and at an appropriate ratio to n-6 PUFA, modify membrane fatty acids in rat tissues without increasing the susceptibility to oxidative stress. This suggests that n-3 PUFA at low doses are appropriate for use in prevention and/or treatment of cardiovascular diseases and cancer, because detrimental secondary effects on cell membranes are unlikely.

ACKNOWLEDGMENTS

The authors thank Hoffmann-La Roche, Ltd., Basel, Switzerland, for the generous provision of purified n-3 PUFA ethyl esters. This study was supported by grants from Italian National Council for Research (CNR PF ACRO n.96.00506.PF39.) and from Italian Ministry for University (MURST 60%). We are grateful to Dr. J.D. Wood for helpful suggestions.

[a]NERC Unit of Aquatic Biochemistry, Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, Scotland, and [b]Hungarian Academy of Sciences, Biological Research Centre, Institute of Biochemistry, H-6701 Szeged, Hungary

ABSTRACT: The molecular species compositions of the main diacyl phosphoglyceride classes and ether-linked subclasses from sperm of three species of fish, sea bass *Dicentrarchus labrax,* Atlantic salmon *Salmo salar* and Chinook salmon *Onchorhynchus tsawytscha,* were determined. The phospholipids from sperm were highly unsaturated, dipolyunsaturated fatty acid (diPUFA) molecular species comprised 64.6 to 71.8% of phosphatidylserine (PS), 10.1 to 17.4% of phosphatidylethanolamine (PE), and 3.3 to 10.1% of phosphatidylcholine (PC). In sea bass sperm, di22:6n-3 phospholipid was the predominant diPUFA molecular species, but in both salmon species 22:5n-3/22:6n-3 was also a major constituent of PS. Phospholipids containing 22:6n-3 dominated in sea bass sperm with 16:0/22:6n-3 as a major component of PC and PE, and 18:0/22:6n-3 of PE and PS in addition to di22:6n-3 in the latter two classes. In contrast, both salmon species contained much more 20:5n-3 and less 22:6n-3 so that saturated/20:5n-3 and monounsaturated/20:5n-3 molecular species were more abundant than the corresponding molecules containing 22:6n-3. Ether-linked lipids comprised 11.3–36.3% of choline and ethanolamine phosphoglycerides in each fish species. Molecular species containing 22:6n-3 were the major components of 1-*O*-alkyl-2-acyl-glycerophosphocholine, especially 16:0a/22:6n-3 in sea bass and 18:1a/22:6n-3 in the two salmon species, while in 1-*O*-alk-1′-enyl-2-acyl-glycerophosphoethanolamine, 16:0a/22:6n-3 was the major component in both salmon and 18:0a/22:6n-3 in sea bass with 18:1a/22:6n-3 abundant in all three species. In Atlantic salmon 1-*O*-alkyl-2-acyl-glycerophosphoethanolamine comprised 24.6% of ethanolamine glycerophospholipids which were predominantly 16:0a/22:6n-3 and 18:1a/22:6n-3. Phosphatidylinositol from sperm was dominated by stearoyl/C_{20} PUFA molecular species, in sea bass overwhelmingly 18:0/20:4n-6, while in both salmon species 18:0/20:4n-6 and 18:0/20:5n-3 were equally abundant. *Lipids 32,* 1085–1091 (1997).

Abbreviations: CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids; GPC, glycero-3-phosphocholine; GPE, glycero-3-phosphoethanolamine; HPTLC, high-performance thin-layer chromatography; MUFA, monounsaturated fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid. Molecular species are abbreviated as follows: e.g., 16:0/22:6 PC is 1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine.

Phospholipids from sperm are rich in polyunsaturated fatty acids (PUFA) and, in most mammals, testes and sperm, together with brain and retina, are the main depositories of docosahexaenoic acid (22:6n-3) (1). PUFA accounted for 65–70% of fatty acids in total phospholipid from bull, boar and ram sperm, and about 40% in rabbit and human sperm (2). However, there is considerable variation between species in which PUFA are predominant. In rabbit, docosapentaenoic acid (22:5, isomer not specified) was the main PUFA with no 22:6n-3, and 22:5 was also abundant in boar sperm (2). In sperm from stallion and rat, 22:5 was also the predominant C_{22} PUFA (3,4), while rooster sperm was much more saturated (3). Ether-linked phosphoglycerides constitute a major part of choline glycerophospholipids (CGP) and ethanolamine glycerophospholipids (EGP) in sperm from mammals (5–7) and fish (8).

Phospholipids from fish tissues, and especially from marine fish, are generally more unsaturated than those from terrestrial mammals, particularly with respect to 20:5n-3 and 22:6n-3 (9,10). However, in a survey of the fatty acid composition of sperm from several species of fish from the Black Sea and freshwater, PUFA levels ranged from 26–55% in phosphatidylcholine (PC) and 26–66% in phosphatidylethanolamine (PE), similar to the levels found in mammals (8). Linoleic acid (18:2n-6) was found to be a major PUFA in fish from the Black Sea (8) which is unusual for marine fish. In farmed rainbow trout, total PUFA made up 33% of fatty acids in PC, 48% in PE and 49% in phosphatidylserine (PS) (11), and although 22:6n-3 was the predominant PUFA, levels of 18:2n-6 and 20:5n-3 were higher than expected for wild fish, reflecting dietary input. In sperm from wild sea bass, PUFA accounted for 35% of PC, 60% of PE and 85% of PS, predominantly 22:6n-3 (12). Farmed broodstock had similar levels of total PUFA and 22:6n-3, but ratios of arachidonic acid to eicosapentaenoic acid were substantially altered, reflecting a dietary input of fish oil rich in 20:5n-3 (12).

The very high amounts of PUFA, and especially 22:6n-3, in sperm suggest that amounts of diPUFA molecular species must be substantial in PE and PS. These unusual phospholipids, which are abundant in retina and to a lesser extent brain (13–16), also may be essential for sperm fertility and

confer protection from cold shock during cryopreservation. In order to gain a better understanding of the membrane structure of sperm, we determined the detailed molecular species composition of sperm phospholipid classes from wild sea bass (*Dicentrarchus labrax*), wild Atlantic salmon (*Salmo salar*), and wild Chinook salmon (*Oncorhynchus tsawytscha*).

MATERIALS AND METHODS

Experimental animals. Milt was obtained from freshly caught wild fish. Sea bass (*Dicentrarchus labrax*) were caught off Castellon, Spain, in February and March in a sea temperature of 15–17°C; Atlantic salmon (*Salmo salar*) were caught in the river Dee in Scotland in November and December in a water temperature of 5–7°C; and Chinook salmon (*Onchorynchus tsawytscha*) were caught off Neath Bay, Washington, USA, in a water temperature of 10°C. Samples were either frozen in liquid nitrogen or immediately mixed with chloroform/methanol (2:1, vol/vol) containing 0.01% (wt/vol) butylated hydroxytoluene, sealed under nitrogen, and stored at −20°C. Milt from three sea bass, three Atlantic salmon, and two Chinook salmon was used in the following experiments.

Chemicals and solvents. Phospholipase C from *Bacillus cereus* was purchased from Boehringer Corporation (London) Ltd. (Lewes, East Sussex, United Kingdom). Oxalyl chloride and anthracene-9-carboxylic acid were supplied by Aldrich Chemical Co. (Gillingham, Dorset, United Kingdom). All other chemicals and biochemicals were purchased from Sigma (Poole, Dorset, United Kingdom), and solvents of high-performance liquid chromatography grade were obtained from Labscan [B.S. & S.(Scotland) Ltd., Edinburgh, United Kingdom)].

Lipid extraction. Total lipid extracts were prepared as described previously (12). For molecular species analysis, equal amounts of total lipid from each fish were pooled for sea bass and Atlantic salmon. The milt from Chinook salmon was already pooled.

Determination of subclasses of CGP and EGP. CGP and EGP (1 mg) were digested with phospholipase C (80 units) in 1 mL 0.1 M borate buffer pH 7.5 and 1 mL diethyl ether for 1½ h under nitrogen at room temperature. Diradylglycerols were extracted and subclasses purified by high-performance thin-layer chromatography (HPTLC) in hexane/diethyl ether (1:1, vol/vol). The plate was sprayed with 0.1% (wt/vol) 2,7-dichlorofluorescein in 97% (vol/vol) methanol containing 0.01% (wt/vol) butylated hydroxytoluene and the bands were visualized under ultraviolet light. The bands were scraped from the thin-layer chromatography plate, 21:0 free fatty acid standard was added, and the mixture methylated for 16 h at 50°C under nitrogen with 2 mL 1% (vol/vol) H_2SO_4 in methanol and 1 mL toluene. Fatty acid methyl esters were extracted and purified as previously described (17) and chromatographed on a Packard 436 gas–liquid chromatograph fitted with a BP20 fused-silica capillary column (50 m × 0.32 mm, SGE) using hydrogen as carrier gas.

Preparation of anthroyl derivatives. Phospholipid classes (CGP, EGP, PS, and PI) were prepared by HPTLC in methyl acetate/chloroform/propan-2-ol/methanol/0.25% aq. KCl 25:25:25:10:9 (by vol). Purified phospholipids (200 µg) were digested with phospholipase C and 9-anthroyl derivatives prepared as described previously (18). For EGP, *N,N*-diisopropylethylamine was added as a proton scavenger to protect the acid-labile alkenyl linkage during the derivatization reaction (19). The 9-anthroyl diradyl derivatives were extracted, purified, and the diacyl, alkylacyl, and alkenylacyl subclasses separated by HPLTC in hexane/toluene/diethyl ether 4.5:4.0:0.3 (by vol).

Molecular species were separated by high-performance liquid chromatography using an Ultrasphere C_{18} column (25 × 0.46 cm, 5 µm particle size) (Beckman Instruments U.K. Ltd., High Wycombe, United Kingdom) and isocratic elution with acetonitrile/propan-2-ol (7:3, vol/vol) at a flow rate of 1.0 mL/min. Methanol/propan-2-ol (4:1, vol/vol) at a flow rate of 1.0 mL/min was employed to separate unresolved peaks. Peaks were detected using a Waters (Watford, United Kingdom) 470 scanning fluorescence detector (excitation 360 nm, emission 460 nm) and quantified with a Shimadzu CR3A recording integrator (Tokyo, Japan). Peaks were identified with reference to standard lipids and samples of known composition (13–15,20).

RESULTS

Ether-linked subclasses were minor components of CGP and EGP from fish sperm (Table 1). 1-*O*-Alk-1′-enyl-2-acyl-GPE comprised 11.3–23.5% of EGP in the three fish species, sea bass sperm containing the lowest proportion. Almost a quarter of EGP from Atlantic salmon sperm was the 1-*O*-alkyl-2-acyl subclass. This was absent in sperm from sea bass. In CGP, 15.5 and 19.2% of 1-*O*-alkyl-2-acyl-glycero-3-phosphocholine (GPC) was present in sea bass and Atlantic salmon, respectively (Table 1).

Molecular species containing 22:6n-3 dominated in PC, PE, and PS from sperm of sea bass (Table 2), with 22:6n-3/22:6n-3 a major component of PE (10.9%) and PS (50.2%), 16:0/22:6n-3 of PC (23.1%) and PE (31.2%), and 18:0/22:6n-3 of PE (13.9%) and PS (14.4%). In PE, 18:1/22:6n-3 was also prominent (8.5%), as was 22:5n-3/22:6n-3 in PS (9.0%). DiPUFA molecular species

TABLE 1
The Subclass Composition of CGP and EGP from Fish Sperm (wt%)[a]

	Subclass (%)		
	Diacyl	Alkylacyl	Alkenylacyl
Sea bass CGP	84.5	15.5	0
Sea bass EGP	88.7	0	11.3
Chinook salmon CGP	n.d.	n.d.	n.d.
Chinook salmon EGP	66.5	0	23.5
Atlantic salmon CGP	80.8	19.2	0
Atlantic salmon EGP	63.7	24.6	11.7

[a]The data were from a pooled sample from five, two, and three fish from sea bass, Chinook salmon, and Atlantic salmon, respectively. n.d. = not determined. CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids.

[a]The data are mean ± range of two determinations on a pooled sample from five fish. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol; PUFA, polyunsaturated fatty acids; MUFA, monounsaturated fatty acids; SFA, saturated fatty acids. The following fatty acids were identified by gas–liquid chromatography: 14:0, 15:0, 16:0, 17:0, 18:0, 16:1n-9 and n-7, 18:1n-9 and n-7, 20:1n-9 and n-7, 16:2, 16:3, 18:2n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-6, 22:5n-3, and 22:6n-3. Molecular species containing minor fatty acids could not be resolved from major species nor could molecular species containing different fatty acid isomers be separated, e.g., 16:0/22:5n-6 from 16:0/22:5n-3. The order of fatty acids does not imply any stereospecificity on the glycerol. A range of 0.0 is <0.05%. — = not detected.

comprised 17.4% of PE and 71.8% of PS (Table 2). Other 22:6n-3-containing molecular species, present at less than 4%, included 20:5n-3/22:6n-3, 20:4n-6/22:6n-3, and 20:1/22:6n-3 (Table 2). Saturated/PUFA species containing 20:5n-3 and 22:5n-3 also made significant contributions to PC and PE. In contrast, phosphatidylinositol (PI) was dominated by 18:0/20:4n-6 (71.5%), with 16:0/20:4n-6 and 18:1/20:4n-6 contributing 3.1 and 3.7%, respectively (Table 2). The second-most abundant molecular species in PI was 18:0/20:5n-3 (6.1%); species containing 22:5n-3 and 22:6n-3 were minor components of PI (Table 2). Over a quarter of the PC existed as molecular species with no PUFA, predominantly 16:0/18:1 (Table 2). Such molecular species were very minor components of the other three diacyl phospholipid classes.

The diacyl phospholipids from Atlantic salmon sperm contained much more 20:5n-3 and much less 22:6n-3 than sperm from sea bass (Table 3). In PC, 16:0/20:5n-3 (16.8%) was slightly more abundant than 16:0/22:6n-3 (14.9%), and 18:1/20:5n-3 and 18:0/20:5n-3 were both more abundant than the corresponding 22:6n-3 species (Table 3), in contrast to sea bass. The largest component of PC was 16:0/18:1 (36.7%). In PE, 16:0/20:5n-3 (21.2%) and 18:1/20:5n-3 (17.5%) were the largest components, closely followed by 16:0/22:6n-3 (15.2%) and 18:1/22:6n-3 (10.2%). The only other molecular species present at over 4% were 18:0/20:5n-3 and 16:0/20:4 n-6. The largest component of diPUFA PE was di22:6n-3, but 20:5n-3/22:6n-3, 20:5n-3/22:5n-3, and 22:5n-3/22:6n-3 were of similar magnitude (Table 3), in contrast to sea bass where di22:6n-3 dominated. DiPUFA species again domi-

[a]Data are mean ± range of two determinations on a pooled sample from three fish. See Table 2 footnote for abbreviations and fatty acid identification information.

nated PS, although the total was lower than in sea bass, and 22:5n-3/22:6n-3 (31.9%) was the largest component followed by di22:6n-3 (24.1%), with 20:5n-3/20:5n-3, 20:5n-3/22:6n-3, and 20:5n-3/22:5n-3 each contributing 1.8–4.2% (Table 3). The only other species present at more than 3% were 18:0/20:5n-3 and 18:0/22:6n-3, both about 10% (Table 2). PI was again dominated by saturated fatty acid (SFA)/PUFA species, with 18:0/20:4n-6 (32.0%) and 18:0/20:5n-3 (31.7%) equally abundant; 16:0/20:4n-6 (8.5%) and 16:0/20:5n-3 (8.1%) were the only other molecular species present at greater than 4%. No diPUFA species were found in PI, and only 0.9% of species containing only SFA or MUFA was present (Table 3).

The molecular species composition of phospholipids from Chinook salmon sperm was generally similar to that of Atlantic salmon with 20:5n-3-containing molecular species being major components (Table 4). In the SFA/PUFA and monounsaturated fatty acids (MUFA)/PUFA categories of PC and PE, 16:0, 18:0 and 18:1 species containing 20:5n-3 were all more abundant than the corresponding species containing 22:6n-3 (Table 4). DiPUFA molecular species comprised a larger proportion of PC, PE, and PS in Chinook than in Atlantic salmon. Although 22:5n-3/22:6n-3 was again abundant in PS (23.8%), di22:6n-3 was the largest component (35.4%) (Table 4). In PI, 18:0/20:5n-3 and 18:0/20:4n-6 were again almost equally abundant (33.4 vs. 30.0%, respectively) but 18:0/22:6n-3 made up 15.3% of PI from Chinook salmon sperm (Table 4).

The differences noted in the molecular speciation of the diacyl phospholipids in the three fish species were also apparent in the ether-linked subclasses. 1-*O*-Alkyl-2-acyl-GPC from sea bass was dominated by 16:0a/22:6n-3 (40.3%), with 18:1a/20:5n-3 the only other molecular species over 10% (Table 5). Molecular species comprised only of SFA or MUFA totaled 3.8% of the sample. The three molecular species containing 20:4n-6 totaled 12.2% in sea bass compared with only 4.0% in Chinook salmon and 1.1% in Atlantic salmon (Table 5). In Chinook salmon sperm, 16:0a/22:6n-3, 18:1a/20:5n-3, 18:1a/22:6n-3, and 16:0a/18:1 1-*O*-alkyl-2-acyl-GPC each comprised 11.6–25.2% of the sample (Table 5). The same four molecular species also dominated the 1-*O*-alkyl-2-acyl-GPC subclass from Atlantic salmon sperm (Table 5). While 16:0a/22:6n-3 and 18:0a/22:6n-3 were less abundant in both salmon species than in sea bass 1-*O*-alkyl-2-acyl-GPC, the converse was the case for 18:1a/22:6n-3, this largely contributing to the increase in the 18:1a/PUFA category of molecular species in Chinook and Atlantic salmon compared to sea bass (Table 5). In 1-*O*-alkyl-2-acyl GPE from sperm of Atlantic salmon, 16:0a/22:6 + 18:1a/22:6 totaled over 59%, and the corresponding 20:5n-3-containing molecular species totaled almost 27% (Table 5). In contrast to 1-*O*-alkyl-2-acyl GPC, 16:0a/18:1 only comprised 0.8% of 1-*O*-alkyl-2-acyl GPE.

In 1-*O*-alk-1′-enyl-2-acyl-GPE, the three main molecular species in sea bass sperm were 18:0a/22:6n-3, 18:1a/22:6n-3 and 16:0a/22:6n-3, which together totaled 75.0% of the sample (Table 6). In the two salmon species 16:0a/22:6n-3 1-*O*-alkenyl-2-acyl-GPE was more prominent than in sea bass while 18:0a/22:6n-3 was much less prominent: *ca.* 2% compared with 33.4% in sea bass. Amounts of 18:1a/22:6n-3 were similar in all three species of fish (Table 6). In contrast 16:0a/20:5n-3 and 18:1a/20:5n-3 were much more abundant in the salmons while 18:0a/20:5n-3 comprised only 1.0% of Chinook salmon alkenylacyl-GPE and was not detected in Atlantic salmon (Table 6). The 18:0a alkenyl chains were much more abundant in sea bass than in either salmon, as were 18:1a/20:4n-6 and 18:1a/22:5n-3. Molecular species containing just SFA or MUFA were very minor constituents of alkenylacyl-GPE in sperm from all three fish (Table 6).

prised 56% of EGP and 70% of CGP in caudal sperm from goat (7), while slightly lower proportions were found in rat and porcine sperm (5,6). Alkylacyl moieties comprised *ca.* 20% of CGP in goat and *ca.* 50% in porcine sperm, and *ca.* 25% of EGP in goat and *ca.* 50% in porcine sperm (6,7). The amounts of alkenylacyl-GPE found in this study were lower than those reported by Drokin (8) in several fish species from the Black Sea (19.7–46.1%) and freshwater (17.2–46.4%). In mammals, the proportion of ether-linked CGP and EGP increases during maturation (5–7), and this could account for the difference. Changes in the phospholipid class composition during sperm maturation have not been investigated in fish, and it is possible that the proportion of ether-linked phospholipids found in this study would have been higher had sperm been collected during natural spawning rather than by stripping. We did not find alkenylacyl-GPC as found by Drokin (8) who did not determine the content of alkylacyl-GPC.

The phospholipids from all three sperm samples were very unsaturated, with almost all molecular species from PE, PS, and PI containing at least one polyunsaturated acyl chain. Only in PC were species containing only SFA and MUFA major components. PS contained by far the largest amount of diPUFA species, with over half the sample di22:6n-3 in sea bass, over a third in Chinook salmon, and a quarter in Atlantic salmon; 22:5n-3/22:6n-3 was also a major component of PS from both salmon species. The specificity for di22:6n-3 in the diPUFA category of PE was again much less marked in the salmon. PI was typically dominated by stearoyl/PUFA species, but there was a marked difference between the sea bass and the two salmon species, sea bass overwhelmingly containing 18:0/20:4n-6, while in the salmon 18:0/20:5n-3 was the largest component and 18:0/22:6n-3 also contributed significantly. Though arachidonic acid is a minor PUFA in many fish species, it is concentrated in PI (21). In retina of trout, and in retina, liver and muscle of cod, 18:0/20:4n-6 was the major molecular species, but in brain of both species 18:0/20:5n-3 was predominant (13,15). Salmon sperm is therefore rather unusual in having so much 18:0/20:5n-3 PI. Few other studies have detemined the molecular species composition of sperm phospholipids. In PC and PE from rat testes, only small amounts (<2%) of diPUFA species (20:4/20:4 and 18:2/20:4) were found, but these two molecular species showed the fastest metabolic turnover (4).

Sea bass have a more southern distribution than either Atlantic or Chinook salmon and are therefore found in warmer waters. It has been proposed that 18:1/22:6n-3 PE is a key molecular species in thermal adaptation of membranes in fish (22–24). It was therefore noteworthy that in this study the MUFA/PUFA category of PE molecular species showed one of the largest differences between sperm from sea bass and sperm from the two salmonids, being more than doubled in the salmonids with a concomitant drop in SFA/PUFA molecular species. However, because of the abundance of 20:5n-3 in the salmonids, most of this increase was due to 18:1/20:5n-3; 18:1/22:6n-3 PE was only slightly elevated in the salmonids compared to the sea bass. These differences

were not apparent in 1-*O*-alk-1′-enyl-2-acyl-GPE. In addition there was little difference in MUFA/PUFA PC in the three fish species.

The plasma membrane of mammalian sperm cells contains regions of nondiffusing lipid resulting from coexistent fluid and gel domains (25). Mammalian sperm encounters some variation in temperature during maturation, and lipid phase transitions may be important for stabilizing the membranes during epididymal storage and during fertilization. It has been suggested that temperature changes might play a role in the mammalian fertilization process by altering membrane phase behavior (26). Sperm from poikilotherms is not exposed to temperature change during fertilization, but in salmonids there will usually be a temperature change during migration of the fish from seawater to fresh water and thus during sperm maturation. It would be interesting to know whether the plasma membrane of sperm from fish has the same lipid organization as sperm from mammals.

The essential role of 22:6n-3 in biomembrane function has attracted considerable attention in recent years, but mainly has been concerned with the role of 22:6n-3 in neural tissue (e.g., 27–29). A deficiency of 22:6n-3 during early development when neural membranes are being formed caused visual and cognitive subperformance in rats, rhesus monkeys, and humans (30–32) and visual impairment in juvenile herring (18). Reconstitution experiments with rhodopsin and phospholipids containing 22:6n-3 have shown that it is a combination of PC, PE, and PS head groups and at least 50% docosahexaenoyl chains that are required to give full activity (see Ref. 33). Molecular modeling studies have suggested that 22:6n-3 has favored conformations (angle-iron or helix) (34,35) which give phospholipids containing this fatty acid unusual packing properties (36). Docosahexaenoic acid also was found to have the smallest volume change with temperature of any fatty acid (35). Sperm are relatively resistant to cold shock (37), and the special properties of 22:6n-3-containing phospholipids could be crucial during cryopreservation as well as being important in thermal adaptation processes in general. Phospholipids with small head groups and two PUFA chains (i.e., di22:6n-3 PE) or polyunsaturated anionic lipids (i.e., PS) give unstable lipid bilayers which revert to reverse hexagonal phases (33). The tendency of such lipids with negative interfacial curvature to form nonlamellar phases is hypothesized to lower the activation energy of the MI-MII transition in rhodopsin (33). Such lipids are also fusogenic (38) and could therefore be important in aiding or promoting fusion between the plasma membrane of eggs and sperm. In guinea pig sperm, anionic-lipid concentrations increased as the membrane became fusionally competent (39). It was found that 18:1/22:6 PE was more effective than other more saturated PE species at lowering the bilayer to hexagonal phase transition, thus enhancing the activity of protein kinase C (40). PE plasmalogens also destabilize the lamellar phase and promote the formation of hexagonal phase, this transition occurring at lower temperatures in 1-*O*-alkenyl-2-acyl GPE than in 1-*O*-alkyl-2-acyl or diacyl GPE (41 and references therein). Perhaps the lower but more constant temperature to which fish sperm are exposed necessitates a smaller proportion of ether-linked phospholipids in order to maintain the lamellar phase found in normal cell membranes.

In humans, sperm density, number of motile sperm, and sperm motility were all correlated with the amount of 22:6n-3 (42), strongly suggesting a role for 22:6n-3 in sperm motility and therefore in fertility. It was especially noteworthy in this study that, in the two salmonids, 22:5n-3 was able to replace 22:6n-3 to a considerable degree in both diPUFA PS and PE. Large amounts of 22:5 were found in sperm from rabbit, boar, rat, stallion and rooster, together with lower amounts of 22:6n-3 (2,3). Therefore, in sperm it appears that 22:5 can substitute functionally for 22:6n-3. This is not the case in neural tissue where neither 22:5n-3 nor 22:5n-6 is able to substitute for 22:6n-3 (18,28). In spite of changes in the relative contributions of 22:6n-3, 22:5n-3 and 20:5n-3 in the different phospholipid classes in the three fish species, considerable constancy in the various categories of molecular species existed within the phospholipid classes, suggesting specific functional requirements at this level of membrane organization. It would be interesting to know whether or not the same pattern of lipid molecular speciation is found in the sperm of homeotherms. As readily available single cells, sperm may be a good experimental system for unraveling the essential roles of C_{22} PUFA in membrane function.

ACKNOWLEDGMENTS

We are very grateful to J. Canales and Dr. J.C. Navarro for collecting milt from sea bass, A.I. Mitchell and J.Webb, SOAEFD, Aberdeen, for collecting milt from Atlantic salmon and Dr. J.E. Halver for collecting milt from Chinook salmon. We thank Prof. J.R. Sargent and Dr. J.C. Navarro for constructive criticism of a draft of this paper.

Lipids and Buoyancy in Southern Ocean Pteropods

Charles F. Phleger[a,*], Peter D. Nichols[b], and Patti Virtue[b]

[a]Department of Biology, San Diego State University, San Diego, California, 92182, and [b]CSIRO Division of Marine Research and Antarctic Co-operative Research Centre, Hobart, Tasmania, 7001, Australia

ABSTRACT: The lipids of *Clione limacina,* a Southern Ocean pteropod (order Gymnosomata), contain 28% diacylglyceryl ether (DAGE) (as percentage of total lipid) whereas the pteropod *Limacina helicina* (order Thecosomata) lacks DAGE. The alkyl glyceryl ether diols (1-*O*-alkyl glycerols, GE) of *Clione* DAGE are dominated by 16:0 (60%) and 15:0 (21%), in contrast with deep-sea shark liver DAGE, which is dominated by 18:1 GE. The fatty acid profiles of *Clione* and *Limacina* are similar (28–32% polyunsaturated, 26–34% monounsaturated) as are the sterols, which include 24-methylenecholesterol, transdehydrocholesterol, cholesterol, and desmosterol. This finding probably reflects the fact that *Limacina* is the major food source for *Clione. Spongiobranchaea australis,* another Southern Ocean pteropod (order Gymnosomata), has 0.9–1.7% DAGE, but has less lipid (3.3–4.8 mg/g lipid, wet weight) than *Clione* (50.8 mg/g lipid, wet weight). We propose a buoyancy role for DAGE in *Clione* since *Limacina* has bubbles for flotation which *Clione* lack; DAGE provides 23% more uplift than triacylglycerol at a concentration of 1.025 g/mL seawater.
Lipids 32, 1093–1100 (1997).

Marine zooplankton maintain buoyancy by diverse strategies including hypotonicity, increased surface area, swimming, gas bubbles, and storage of low-density materials such as lipid (0.86–0.93 g/mL). The most important storage lipids in marine zooplankton are wax esters (WE) and triacylglycerol (TAG) (1). WE may be concentrated in polar and deep ocean copepods, where they are utilized primarily as long-term energy reserves (2). TAG, however, are major short-term energy reserve molecules in most zooplankton. WE have a lower metabolic turnover rate than TAG, and thus may have a more important function in buoyancy than TAG (3). The density of WE (0.86 g/mL at 21°C) is less than TAG (0.93 g/mL at 21°C). Diacylglyceryl ether (DAGE), although not a major lipid in zooplankton, also has a lower metabolic turnover rate than TAG and a lower density (0.89 g/mL at 21°C). DAGE also generates 23% more upthrust than TAG (0.127 g upthrust/g lipid vs. 0.103 g upthrust/g lipid in seawater of 1.025 g/mL density) (4).

Lipid composition is also used to understand and identify food web interactions (5,6). The Southern Ocean has a complex food web including phytoplanktivorous herbivores fed upon by birds, fish, squid, seals, and baleen whales (7). Sterols (ST) and fatty acids are excellent biomarkers for food chain studies (8). The herbivorous Thecosome pteropod *Limacina helicina* is very common in the Southern Ocean, as in other oceans (9). It is fed upon by the carnivorous Gymnosome pteropod, *Clione limacina,* another abundant holoplanktonic Opisthobranch mollusk. *Spongiobranchaea australis* is another highly predaceous Gymnosome pteropod, which also feeds exclusively on a Thecosome pteropod (*Clio pyramidata*).

Limited lipid compositional data are available for these Southern Ocean pteropods. The purpose of this study is to report the use of DAGE as a possible buoyancy lipid in the pteropod *C. limacina,* and to clarify and further understand food web interactions by examining pteropod ST and fatty acids as key biochemical factors.

MATERIALS AND METHODS

Sample description. The pteropods *C. limacina* and *L. helicina* were collected by Isaacs-Kidd midwater trawl from the R/V *Yuzhmorgeologia* on January 23 and 22, l996, respectively. These samples were obtained as part of the Antarctic Marine Life Research Field Study conducted annually in the Elephant Island region of the Antarctic peninsula (10,11). *Clione limacina* was trawled from station A-04 (off Admiralty Bay, King George Island) at 62°14.4´ S and 57°58.5´ W. *Limacina helicina* was trawled from station AB-03 (within Admiralty Bay). In both cases the net was towed to 170 m depth for about 30 min. Pteropods were frozen at –10°C as soon as possible after sorting and counting on board ship. They were then transported frozen by air to the CSIRO Division of Marine Research where they were maintained at –60°C prior to analysis. *Spongiobranchaea australis* was collected by rectangular midwater trawl (to 195 m) from the R/V *Aurora Australis* on Expedition Broke on March 12, l996, from the Adélie coast (within Wilkes land) region of East Antarctica (63°26.27´ S and 138°59.21´ W). They were

frozen in liquid nitrogen immediately and transported frozen to the CSIRO Hobart laboratory for analysis. Individuals of *C. limacina* were pooled for extraction owing to the limited sample size (8–9 individuals weighed 0.25 g wet weight). It was possible to pool 20–25 individuals of *L. helicina* for three extractions owing to a larger sample size. Duplicate analyses of two individuals of the considerably larger *S. australis* were performed.

Lipid extraction. Samples were quantitatively extracted using a modified Bligh and Dyer (12) one-phase methanol/chloroform/water extraction (2:1:0.8, by vol); the sample was extracted overnight and the phases were separated the following day by the addition of chloroform and water (final solvent ratio, 1:1:0.9, by vol, methanol/chloroform/water). The total solvent extract was concentrated (i.e., solvents removed *in vacuo*) using rotary evaporation at 30°C. Lipid class analyses were conducted immediately; for other purposes samples were stored for no more than 3 d in a known volume of chloroform.

Lipids. An aliquot of the total solvent extract was analyzed using an Iatroscan MK V TH10 thin-layer chromatography–flame-ionization detector (TLC–FID) analyzer (Tokyo, Japan) to determine the abundances of individual lipid classes (13). Samples were applied in duplicate or triplicate to silica gel SIII Chromarods (5-μm particle size) using 1 μL disposable micropipets. Chromarods were developed in a glass tank lined with pre-extracted filter paper. The solvent system used for the lipid separation was hexane/diethyl ether/acetic acid (60:17:0.2, by vol), a mobile phase resolving nonpolar compounds such as WE, TAG, free fatty acids (FFA), and ST. A second nonpolar solvent system of hexane/diethyl ether (96:4, vol/vol) was also used to separate hydrocarbons from WE and TAG from diacylglycerol. After development, the chromarods were oven-dried and analyzed immediately to minimize adsorption of atmospheric contaminants. The FID was calibrated for each compound class (phosphatidylcholine, cholesterol, cholesteryl ester, oleic acid, squalene, triolein, and DAGE purified from shark liver oil; 0.1–10 μg range). A laboratory standard of WE was used for peak identification, and steryl ester was used for quantification of WE. Based on the TLC–FID analyses and subsequent analysis of component fatty acids and alcohols by gas chromatography (GC), steryl esters were either absent or only present as trace components. WE and steryl esters coelute in the systems used, but results for combined TLC–FID and GC assays indicated they were either absent or only present as trace components. Peaks were quantified on an IBM-compatible computer using DAPA software (Kalamunda, Western Australia). Iatroscan results are generally reproducible to ±10% (13).

*Fatty acids and 1-*O*-alkyl glycerols (GE).* An aliquot of the total solvent extract was treated with potassium hydroxide in methanol (5% wt/vol) and saponified under nitrogen for 3 h at 80°C. Nonsaponifiable neutral lipids (e.g., glyceryl ether diols and hydrocarbons) were then extracted into hexane/chloroform (4:1 vol/vol, 3 × 1.5 mL) and transferred to sample vials. Following acidification of the remaining aqueous layer using hydrochloric acid (pH = 2), fatty acids were extracted and methylated to produce their corresponding fatty acid methyl esters using methanol/hydrochloric acid/chloroform (10:1:1, by vol; 80°C, 2 h). Products were then extracted into hexane/chloroform (4:1 vol/vol, 3 × 1.5 mL) and stored at −20°C. The nonsaponifiable neutral lipid fractions were treated with *N,O*-bis-(trimethylsilyl)-trifluoroacetamide (50 μL, 60°C, 1 h) to convert ST to their corresponding trimethylsilyl (TMS) ethers.

GC analyses of methyl esters of fatty acids were performed with a Hewlett-Packard 5890A GC (Avondale, PA) equipped with an HP-1 cross-linked methyl silicone fused silica capillary column (50 m × 0.32 mm i.d.), an FID, a split/splitless injector, and an HP 7673A auto sampler. Hydrogen was the carrier gas. Following addition of a methyl tricosanoate internal standard, samples were injected in splitless mode at an oven temperature of 50°C. After 1 min, the oven temperature was raised to 150°C at 30°C/min, then to 250°C at 2°C/min, and finally to 300°C at 5˚C/min. Peaks were quantified with DAPA Scientific Software. Individual components were identified using mass spectral data and by comparing retention time data with those obtained for authentic and laboratory standards. GC results are subject to an error of ±5%.

GC–mass spectrometric (GC–MS) analyses were performed on a Fisons MD 800 GC–mass spectrometer (Manchester, United Kingdom) fitted with an on-column injector. The GC was fitted with a capillary column similar to that described above.

The Iatroscan (TLC–FID) analyzer provides a rapid means of detecting DAGE without any sample treatment and derivatization prior to analysis. To further confirm and elucidate the composition of the DAGE fraction, the process of saponification was used in this study to convert the DAGE to the corresponding GE. The GE are then extracted with other nonsaponifiable neutral lipid material and converted to di-*O*-TMS ether derivatives prior to analysis by GC. GC–MS analysis of the samples readily identified the GE components from their base peak at $m/z = 205$.

Determination of double-bond configuration in fatty acids. Dimethyl disulfide adducts of monounsaturated fatty acids were formed by treating the total fatty acid methyl esters with dimethyl disulfide (14,15). Adducts were then extracted using hexane/chloroform (4:1, vol/vol) and treated with *N,O*-bis-(trimethylsilyl)-trifluoroacetamide to form TMS derivatives prior to GC–MS analysis.

RESULTS

Lipid composition. Clione limacina (order Gymnosomata) has 27.8% DAGE, *S. australis* (order Gymnosomata) has 0.9–1.7% DAGE, and *L. helicina* (order Thecosomata) has only trace amounts of DAGE (Table 1). *Clione limacina* also has over 10 times as much lipid as the other two pteropods (50.8 mg/g, wet weight) (Table 1). The other major lipid classes in *C. limacina* include TAG (22.6%), FFA (23.9%),

[b]Wet weight basis.

and phospholipid (PL) (22.1%) (Table 1). *Spongiobranchaea australis* has 39.5–66.7% TAG, 0.4–0.8% FFA, and 30.0–58.1% PL. ST are present in all pteropods (0.7–6.7%) along with minor amounts of WE (trace–0.8%) (Table 1).

ST. The major ST in *C. limacina* include 24-methylcholesta-5,24(28)*E*-dien-3β-ol (24-methylenecholesterol, 21.5%), cholesta-5,22*E*-dien-3β-ol (*trans*-dehydrocholesterol, 19.0%), 24-methylcholesta-5,22*E*-dien-3β-ol (brassicasterol, 17%), cholesta-5,24*E*-dien-3β-ol (desmosterol, 15.6%), cholest-5-en-3β-ol (cholesterol, 11.6%), and 24-norcholesta-5,22*E*-dien-3β-ol (24-nordehydrocholesterol, 6.5%) (Table 2). The major ST in *L. helicina* are similar to those in *C. limacina* and include 24-methylenecholesterol (22.8–24.1%), *trans*-dehydrocholesterol (14–16.4%), brassicasterol (15.8–16.8%), desmosterol (17.4–19.7%), cholesterol (9.1–9.8%), and 24-nordehydrocholesterol (7–9.1%). The sterol composition of *S. australis* differs from both *C. limacina* and *L. helicina* in that *S. australis* has less 24-methylenecholesterol (12.7–12.9%), more *trans*-dehydrocholesterol (30.9–34.0%), slightly more brassicasterol (l9.0–20.5%), less desmosterol (4.4–4.5%), slightly less cholesterol (7.7–8.6%), and slightly more 24-nordehydrocholesterol (9.7–9.8%) (Table 2). Five minor ST were also detected: cholesta-5,22*Z*-dien-3β-ol (*cis*-dehydrocholesterol, 1.3–3.2%), 24-ethylcholesta-5,22*E*-dien-3β-ol (stigmasterol, 0.4–1.4%), 24-ethylcholest-5-en-3β-ol (24-ethylcholesterol, 0.2–3.2%), 24-ethylcholesta-5,24(28)*Z*-dien-3β-ol (isofucosterol, 0.9–2.9%), and an unidentified C_{30} ST, containing two double bonds (1.0–2.1%) (Table 2). Five stanols were found in minor amounts in the Southern Ocean pteropods. These include 5α-24-norcholest-22*E*-en-3β-ol (24-nordehydrocholestanol, 0.1–0.6%), 5α-cholest-22*E*-en-3β-ol (dehydrocholestanol, 0.1–0.7%), 5α-cholestan-3β-ol (cholestanol, 0.2–2.2%), 24-methyl-5α-cholest-22*E*-en-3β-ol (brassicastanol, 0.2–0.7%), and 24-methyl-5α-cholest-24(28)*E*-en-3β-ol (24-methylenecholestanol, 0.8–0.9%) (Table 2).

GE. The electron ionization-mass spectra of silylated (1-*O*-alkyl-2,3-di-*O*-TMSi) GE showed the following features: a base peak at 205 *m/z*; ions derived from the glycerol-2,3-di-*O*-TMS moiety, namely, *m/z* 103, 117, 130, 133, and 147; M – 90, M – 104, M – 147, and M – 180. The M^+ was generally not observed. The GC–MS analyses confirmed that the ether lipids of the three Southern Ocean pteropods are a mixture of predominantly saturated with lower levels of monounsaturated 1-*O*-alkyl glyceryl ethers. The principal GE of the three pteropod species is 1-hexa-decylglyceryl ether (16:0); 60% for *C. limacina,* 55% for *S. australis,* and 46% for *L. helicina* (Table 3). The GE 1-penta-decylglyceryl ether (15:0) is second in importance in *C. limacina* (21%), whereas hexadec-9-enylglyceryl ether (16:1) is the second-most abundant GE in *S. australis* (l9%), which has only 4% 15:0 GE. *Clione limacina* has less high molecular weight GE (i18:0–20:1 GE summed are 7%), whereas in *S. australis* these GE (i18:0-20:1) are 18% and in *L. helicina* 22% of the total (Table 3). The GE eicosa-9-enylglyceryl ether (20:1) is 8% and 10% in *S. australis* and *L. helicina,* respectively; however in *C. limacina* it is 3% of the total. Also, the GE octadecylglyceryl ether (18:0) is 4% in *S. australis* and *L. helicina* whereas in *C. limacina* it is 1% of the total (Table 3).

Fatty acids. Clione limacina and *L. helicina* both differ substantially from *S. australis* because they have less eicosapentaenoic acid 20:5n-3 (7.2–11.7%) than *S. australis* (21.5–23.3%) 20:5n-3 (Table 4). The sum of the polyunsaturated fatty acids (PUFA) is therefore greater for *S. australis* (46–48%) than for *C. limacina* (26.7%) and *L. helicina* (32.2–42.8%). Docosahexaenoic acid 22:6n-3 is the second-most common PUFA in *S. australis* (18.7–19.1%) and the major PUFA in both *C. limacina* (15.8%) and *L. helicina* (16.3–21.9%). Although levels of 22:5n-3 are generally low, this PUFA is twice as abundant in *L. helicina* (2.6–2.7%) than in *C. limacina* (l.l%) and *S. australis* (1.1–1.4%). The PUFA 20:2n-6 is also more important in *L. helicina* (3.3–3.8%) than *S. australis* (1.1–1.3%), and it was not detected in *C. limacina* (Table 4).

Clione limacina and *L. helicina* also differ substantially from *S. australis* because they have more of the monoene 20:1n-7*c* (11% for *C. limacina,* 17.8–23.1% for *L. helicina*) than *S. australis* (3.7–3.8%) (Table 4). They also have more 20:1n-9*c* (7.7% for *C. limacina* and 3.5–4.6% for *L. helicina*) than *S. australis* (1.7%). The sum of the monounsaturated fatty acids is therefore greater for *C. limacina* (33.4%) and *L. helicina* (26.3–38.8%) than *S. australis* (19.2–19.3%). Despite this, *S. australis* has considerably more 16:1n-7*c* (6.4–6.5%) than *C. limacina* (2.5%) and *L. helicina* (0.6–3.4%). The two isomers of 18:1n-9*c*, and 18:1n-7*c*, together are 8.6% for *C. limacina*, 3.3–10.6% for *L. helicina*, and 5.5–6.4% for *S. australis*.

The principal saturated fatty acids in *C. limacina* and *L. helicina* are palmitic acid (16:0) and stearic acid (18:0) (Table 4). In *C. limacina*, there is 11.8% of 16:0 and 6.6% of 18:0, whereas in *L. helicina* there is 9.8–16.1% of 16:0 and 5.4–16.8% of 18:0. In *S. australis*, the principal saturated fatty acids are 16:0 (17.8–18.2%), 18:0 (3.4–3.8%), and 14:0 (3.7–3.8%). In *C. limacina*, the saturated fatty acids 17:0 (4.8%) and a17:0 (coeluting with 17:1n-8*c*) (8.9%) are also important. Levels of 17:0 and a17:0 in the other pteropods are uniformly low (0.3–2.2%).

DISCUSSION

Occurrence of DAGE in Antarctic zooplankton. The high level of DAGE (28%) in the pteropod *C. limacina* from Antarctic waters (Bransfield Strait) is unusual in marine macrozooplankton (Table 1). Lee (16) reported 19% DAGE in *C. limacina* from Bute Inlet, British Columbia, but the supportive data were unpublished. Published reports on lipid composition of Antarctic invertebrate zooplankton either contain no reference to DAGE or report its presence as less than 1.5%. Hagen (l7) found 1.3% DAGE in *C. limacina* collected from the Antarctische Halbinsel, and DAGE was not reported in pooled samples of *C. limacina* collected from the Weddell Sea in l985. *Limacina helicina* samples had 0–1.5% DAGE (17). From the fatty acid data, it seemed that DAGE constituted 6% in *Clione* specimens (Hagen, W., personal communication). The Thecosome pteropod *Clio pyramidata* had 0.3% DAGE (17). Reinhardt and Van Vleet (5) found TAG, WE, and PL as the major lipid classes in 16 species of Antarctic invertebrate zooplankton, including amphipods, copepods, polychaetes, chaetognaths, cnidarians, tunicates, mysids, and euphausiids as well as mixed plankton. Clarke (l8) found 0.3–1.5% DAGE in the Antarctic isopods *Serolis pagenstecheri* and *S. cornuta*. Fricke *et al.* (l9) found 0.3–0.6% DAGE in Antarctic krill *Euphausia superba*. Hallgren and Stallberg (20) reported less than 1.5% DAGE in benthic invertebrates including marine crayfish, shrimp, and sea mussels (species identifications not given). Some benthic mollusks, such as *Octopus dofleini*, have 5% DAGE (21). The high DAGE percentage in *C. limacina* is accompanied by a

[a]Includes 17:1n-8*c*.
[b]The suffixes *c* and *t* denote *cis* and *trans* geometry, respectively, for monounsaturated fatty acids.
[c]Trace amounts of 18:3n-3 and 20:4n-6 were also present, coeluting with 18:2n-6 and 20:5n-3, respectively. Abbreviation: PUFA, polyunsaturated fatty acids.

high lipid content, 50.8 mg/g wet weight, an order of magnitude greater than in *L. helicina* and *S. australis* (Table 1).

Distribution of DAGE in other marine organisms. DAGE is an abundant component of liver oil of certain shark species (22). Plunket shark (*Centroscymnus plunketi*), Pacific sleeper shark (*Somniosus pacificus*) (23), and the leafscale gulper shark (*Centrophorus squamosus*) (24) have livers rich in DAGE. The liver of many of these sharks is over 50% oil; in some it is over 80% (25). The dogfish, *Squalus acanthias*, has 38–45% DAGE in the liver oil, and the holocephalans *Chimaera barbouri*, *C. ogilbye*, and *Hydrolagus colliei* have more than 50% DAGE in the liver oil (3). *Hydrolagus novaezealandiae* has 66% DAGE in its liver oil (26). Methoxyglyceryl ethers, first isolated from Greenland shark liver lipids, have antibiotic activity and inhibit the growth of tumors in mice (27). DAGE is also an abundant component of

certain deep sea squids. The liver and stomach contents of *Moroteuthis robusta* (giant squid, family Onychoteuthidae) and the liver of Gonatid squids (family Gonatidae, *Berryteuthis magister*, *Gonatopsis makko*, and *G. borealis*) also contain significant amounts of DAGE (28–30).

GE composition. The GE composition of three Southern Ocean pteropods (Table 3) is different from deep-sea sharks and squids. Pteropod GE are dominated by 1-hexadecylglyceryl ether (16:0; 46–60%), whereas the major GE in deep-sea sharks and marine DAGE in general is octadec-9-enylglyceryl ether 18:1n-9*c* (42–62%) (23,31). Although deep-sea squid *M. robusta* has less 18:1n-9*c* GE (24–26%) (30), it is much more than the level of 18:1 GE in pteropods (1–6%, Table 3). In addition, the pteropod *C. limacina* has 21% 1-penta-decylglyceryl ether (15:0 GE) which was generally not reported in deep-sea sharks and is only present at 1–1.4% levels in deep-sea squids. At the present time, the reasons for the high relative proportion of the C_{15} GE are not known. Two isomers of 20:1 GE were also observed (Table 3). This observation is similar to the fatty acid profile where two isomers 20:1n-7*c* and 20:1n-9 were also observed. The similarity in profiles is consistent with a common origin. In *C. limacina* in particular, the GE composition is dominated by lower molecular weight GE than in the deep-sea sharks and squids. The GE of *C. limacina* are also different from *L. helicina* and *S. australis* which are characterized by somewhat higher hexadec-7-enylglyceryl ether (16:1n-7*c*; 9–19%) levels than *C. limacina* (3% 16:1n-7*c*) and higher levels of i18:0–20:1 (summed) (22–18%, respectively) (Table 3).

Two isomers of 20:1 were also observed in the alkyl GE diol fraction of *L. helicina*. The double-bond position was not determined for the GE fractions; however, based on the fatty acid profiles, the two alkyl GE chains are presumed to be the n-7 and n-9 isomers. In comparison, only one main isomer was present in *Clione* and *Spongiobranchaea* with trace levels of a second isomer also present; based on retention time data, the main component was presumed to be the 20:1n-7 isomer. This observation is in contrast to the fatty acid profiles where two isomers (20:1n-7*c* and 20:1n-9*c*) were present in all three animals. In addition for *Clione* and *Spongiobranchaea*, the n-7/n-9 ratio for the fatty acids was generally between 1–2. Although the n-7 20:1 isomer was present at higher relative levels than the n-9 isomer in the fatty acid fraction, the ratio of n-7/n-9 for GE was significantly greater than observed for the fatty acid fractions in both *Clione* and *Spongiobranchaea*. We presently can offer no explanation for these ratio differences between lipid classes (GE from DAGE vs. fatty acids from all lipids) in the proportion of isomers. Kang *et al.* (31) have noted similar ratio differences for DAGE GE and total lipid fatty acids from both shark liver oil rich in DAGE fed to Atlantic salmon and for DAGE and total lipid recovered from the salmon feces.

Comparative lipid compositional features. The PL and ST reported in Table 1 probably include membrane structural PL and membrane ST. The relatively higher amounts of PL in *L. helicina* (34.2–39.4%) vs. *C. limacina* (22.1%) are consistent with their lower lipid (2.4–6.9 mg/g wet weight). The same feature is observed for *S. australis* (3.3–4.8 mg/g wet weight). Also *L. helicina* and *S. australis* have trace or low DAGE (Table 1). The high FFA in *L. helicina* (54.9–59.1%) reflect the time necessary for sorting and counting in a heated zooplankton van prior to freezing. The small body size of *L. helicina* compared with *C. limacina* means that lipase enzyme breakdown of TAG (not detectable in *L. helicina*, Table 1) and/or PL occurred more rapidly than in the larger *C. limacina* (23.9% FFA). We have no explanation for the high PL values in *L. helicina* (Table 1). An alternative explanation might be that the FFA are used as an energy store. The high TAG (39.5–66.7%) in *S. australis* reflect a lack of lipase activity because *S. australis* was sorted and counted in a laboratory aboard the R/V *Aurora Australis* maintained at −1°C. Freezing was also accomplished more rapidly after capture and was in liquid nitrogen. The presence of WE (trace to 0.8%) in all pteropods (Table 1) may mean that these WE were obtained from the food chain. Copepods are rich sources of WE in polar waters (1) and may be the dietary source of WE in pteropods.

The similar ST composition of *C. limacina* and *L. helicina* (Table 2) reflects the feeding selectivity of *C. limacina*, which is believed to feed exclusively on *L. helicina* (9). The ST of *S. australis* differ from *L. helicina* and *C. limacina* (i.e., less 24-methylenecholesterol and more *trans*-dehydrocholesterol, Table 2) because *S. australis* feeds exclusively on certain *Clio* species, such as *C. pyramidata* (17). Both *Limacina* and *Clio* are herbivorous Thecosome pteropods, and their ST are derived from dietary phytoplankton. Desmosterol, for example, in *L. helicina* (17.42–19.68%, Table 3) is probably derived from dealkylation of dietary phytosterols. Desmosterol may also be of some importance in providing cholesterol, since it is an intermediate in cholesterol synthesis. Gastropods can synthesize cholesterol *de novo* (32), but it is a very slow process, as evidenced by the low cholesterol levels in these pteropods (11.6% cholesterol in *C. limacina*, Table 2). Cholesterol was present in only six of 14 diatom species studied by Barrett *et al.* (33). The ST 24-methylenecholesterol (21.5–24.1% in *C. limacina* and *L. helicina*) is the main ST in the diatom *Chaetoceros* (34). Brassicasterol is a major ST in some prymnesiophytes such as *Phaeocystis*, and it is important in *L. helicina* (15.8–16.8%, Table 2). The phytoplankton composition of the Bransfield Strait waters where *C. limacina* and *L. helicina* were collected was characterized by microplanktonic diatoms, such as *Chaetoceros*, *Nitzschia*, and *Rhizoselenia*, as well as 2–5-nm flagellates during l990–l993 (35). *Rhizoselenia setigera* was reported to have 94.2% desmosterol and *Nitzschia closterium* 100% desmosterol (33). The area where *S. australis* was collected is characterized by a different phytoplankton assemblage, which may be reflected in its different ST composition compared to that in the other two pteropods (Table 2).

The similar fatty acid composition of *C. limacina* and *L. helicina* bears out the feeding selectivity already discussed. Despite this, there are differences in the percentage composi-

tion of a17:0/17:1n-8*c* which are unexplained (Table 4). *Spongiobranchaea australis* fatty acids are different from those of *C. limacina* and *L. helicina* in that *S. australis* has over twice as much eicosapentaenoic acid 20:5n-3 (Table 4). This may indicate greater availability of this n-3 PUFA in the phytoplankton grazed by *Clio pyramidata*, the food of *S. australis*. The 20:5n-3 PUFA is found in the diatoms *Chaetoceros calcitrans*, *Skeletonema costatum*, and *Thallassiosira pseudonana*, where it is 4.6–11.1% of the total fatty acids (36). *Clione limacina* and *L. helicina* are enriched in the monoenes 20:1n-7*c* and 20:1n-9*c* in contrast to *S. australis*. This also emphasizes the different sources of food available to these two groups of pteropods.

Potential uses of DAGE. DAGE may be important in the treatment of hematopoiesis and radiation sickness (37,38). Glyceryl ethers are useful as surfactants in cosmetics and ointments, and ratfish liver DAGE are intermediates in the synthesis of alkylacetoglycerophosphocholine, a platelet-activating factor (29,39). Methoxy-glyceryl ethers have been reported in shark liver oil (20) and have antibiotic activity and inhibit the growth of tumors in mice (27). It has been stated that the glyceryl ethers, including those of chimyl or batyl alcohol (or their monounsaturated derivatives), have enormous economic potential because they possess this range of healing activity (40). Shark ether lipids can become a good source of ether-linked lipids, which increase membrane plasmalogen levels in patients suffering from the genetic Zellwegere cerebrohepatorenal syndrome (41). It would be interesting to confirm that the pteropod DAGE also have anticarcinogenic activity, since pteropod culture could be a rapid and renewable source of DAGE. In contrast, the presently utilized deep-sea shark and ratfish may be showing signs of overfishing in selected locations. Harvest of pteropods therefore might be an alternative source of DAGE. *Clione limacina* amounts to 80% of the total Gymnosome population in the north Atlantic Ocean and is so common that it is a food of the Greenland Right whale and some fishes (9). It reaches 50–70 mm in length in cold waters. Further analyses of *C. limacina* and other pteropods from a range of locations are recommended and will be pursued. The economics for harvesting *Clione* presently may appear unattractive. However, culture of this species, including as a possible direct source of DAGE or for use as a source of transgenic material for further application, may have better potential.

A possible buoyancy role for DAGE. A convincing argument for buoyancy regulation as a function for DAGE was made by Malins and Barone (42), who found the concentration ratios of DAGE to TAG to significantly increase in livers of weighted *Squalus acanthias* when compared to an unweighted control group. DAGE gives 23% more lift than TAG in 1.025 g/cc sea water (4). The change was not due to selective mobilization of TAG but involved a net increase in DAGE. Malins and Barone (42) suggested that *S. acanthias* regulates buoyancy by the selective metabolism of DAGE and TAG during vertical migrations, and that this may substitute for the swimbladder in teleost fishes that is not found in sharks.

We propose a buoyancy function for the 28% DAGE found in *C. limacina*. Most lipids are less dense than seawater, and therefore increase the overall buoyancy of aquatic organisms, but their main functions are energy storage and as structural (membrane) components (43). Lee (l), for example, starved *Clione* from Canadian waters for 3 mon and observed a loss of 85% of their lipid (mostly TAG). Significant structural differences between *Clione* and *Limacina*, however, support a buoyancy function. *Limacina* is a Thecosome pteropod, with a calcareous test (shell), but the density of the test is offset by bubbles around it. *Limacina* also has long floppy swimming appendages, like *Clio pyramidata*, another Thecosome (shelled) pteropod (44). These swimming appendages help these pteropods maintain their position in the water column, and the increased surface area slows down sinking. In contrast, both *C. limacina* and *S. australis* are Gymnosome (naked) pteropods, lack bubbles, and have compact, hard bodies, with short, stubby swimming appendages. Both *Clione* and *Spongiobranchaea* have DAGE (28% and 0.9–1.7%, respectively, Table 1), whereas *Limacina* has only trace amounts of DAGE. *Clione* is lipid-rich, whereas *Limacina* is low in lipid (17) (Table 1). Since *S. australis* has both low lipid and low DAGE, it may use an alternative strategy for buoyancy. The Gymnosome pteropods selectively feed on the herbivores *Limacina* and *Clio*, so it is certainly to their advantage to remain at the same level in the water column as their prey. DAGE may give just the added uplift to accomplish the appropriate buoyancy for this selective feeding in *C. limacina*.

ACKNOWLEDGMENTS

This work was supported in part by funding from FRDC. We thank J. Martin and R. Hewitt for the Antarctic Marine Life Research Expedition to the Elephant Island study area and the Australian National Antarctic Research Expedition for collection of samples in East Antarctica. V. Siegal, D. Outram, and V. Loeb gave invaluable help in collection and identification of samples. Thanks to V. Loeb for sharing her insights into pteropod biology. C. Phleger thanks the Department of Biology, San Diego State University, for sabbatical leave time to do research. Professor R.G. Ackman and an anonymus referee provided constructive comments to the manuscript.

Institute for Marine Biosciences, National Research Council of Canada, Halifax, Nova Scotia B3H 3Z1, Canada

ABSTRACT: An extract of the chloromonad *Heterosigma carterae* (Raphidophyceae), cultivated in natural seawater, contained a complex mixture of sulfoquinovosyl diacylglycerols. Palmitoyl (16:0), three isomers of hexadecenoyl (16:1 *cis* Δ9, Δ11, Δ13), and eicosapentenoyl (20:5) were found to be the main fatty acyl substituents. Exact double-bond sites were determined by mass spectrometry analysis of the corresponding nicotinyl derivatives. Four major sulfoquinovosyl diacylglycerol components were partially purified and identified as **1**–**4** by interpretation of their nuclear magnetic resonance and mass spectral data. In addition, complete analysis of the *H. carterae* sulfoquinovosyl diacylglycerols was performed using high-performance liquid chromatography combined with electrospray tandem mass spectrometry.

Lipids 32, 1101–1112 (1997)

Blooms of the microalga *Heterosigma carterae* (formerly *H. akashiwo*) (1) have been implicated in massive fish mortalities at aquaculture sites along the North American Pacific Coast (2) and also in some other regions of the world, particularly Chile (3), Japan (4), New Zealand (5), and Spain (6). Biochemical and biological studies indicated that *H. carterae* produced a toxic substance responsible for the fish deaths (1), and this prompted us to investigate the molecular structures of the sulfoquinovosyl diaclglycerol (SQDG) components produced at high levels by this organism (7,8). SQDG components isolated from other organisms have been shown to exhibit potent antiviral activity, particularly against the human immunodeficiency virus (HIV-1) (9), and also antitumor-promoting activities (10). Furthermore, glycolipids have been implicated in fish mortalities caused by *Chrysochromulina polylepis* (11).

In practice, the isolation of pure SQDG from the complex mixtures usually encountered in nature, which differ only in the length and/or degree of unsaturation of their fatty acyl substituents, is extremely difficult (12). Furthermore, a practical and rapid method for the structural analysis of these substances has been elusive. The goal of the present study was therefore to develop a new method for the structural elucidation of the SQDG produced by *H. carterae*, utilizing liquid chromatography combined with electrospray tandem mass spectrometry (LC/MS/MS). As the structure of the sulfoglycoglycerol moiety is essentially the same for all SQDG isolated and identified to date [i.e., 3-*0*-(6-sulfo-α-D-quinovopyranosyl)-*sn*-glycerol] (13), the objective was to focus on determination of the structures and positional assignments (*sn*-1 or *sn*-2) of the fatty acyl substituents. Nuclear magnetic resonance (NMR) spectroscopy was used to confirm the structure of the sulfoquinovosyl glycerol moiety, and also to firmly establish the structures of purified *H. carterae* SQDG identified using the LC/MS/MS technique.

RESULTS AND DISCUSSION

The SQDG fraction was obtained from the chloroform/methanol extract of *H. carterae* cells using silica gel column chromatography. In order to minimize air oxidation of any polyunsaturated fatty acyl moieties present in the SQDG fraction, the extraction and lipid fractionation were completed within 1 d, and fractions were stored under nitrogen, at –80°C, until further use. Analysis by ^{1}H and ^{13}C NMR spectroscopy and by thin-layer chromatography showed the SQDG fraction to be free of other glycolipids.

Identification of the fatty acyl substituents of H. carterae *SQDG*. A portion of the *H. carterae* SQDG fraction was reacted with boron trifluoride in methanol to liberate the fatty acyl substituents as their methyl ester derivatives, which were analyzed by gas chromatography/mass spectrometry (GC/MS). The major fatty acid methyl esters (FAME) were identified as 14:0, 16:0, 20:5, and three isomers of 16:1 (see Table 1). Minor components were determined to be 15:0, 18:3, and 18:4 (Table 1). By comparison of the GC/MS data with those obtained for FAME standards, the structure of one of the 16:1 isomers was

TABLE 1
Fatty Acid Composition of the SQDG Isolated from *Heterosigma carterae*[a]

Fatty acid	R_t (min)	Amount (%)[b]
14:0 *n*	7.0	6.0
15:0 *n*	7.5	1.4
16:0 *n*	8.2	24.0
16:1 Δ9 *cis*	8.4	7.7
16:1 Δ11 *cis*	8.5	11.8
16:1 Δ13 *cis*	8.6	31.2
18:3 Δ9, Δ12, Δ15 all-*cis*	11.3	2.6
18:4 Δ6, Δ9, Δ12, Δ15	11.6	2.7
20:5 Δ5, Δ8, Δ11, Δ14, Δ17 all-*cis*	14.6	12.7

[a]Abbreviations: SQDG, sulfoquinovosyl diacylglycerol; R_t, retention time.
[b]Amounts were estimated from peak areas in the gas chromatography/mass spectrometry total ion current chromatograms for the fatty acid methyl esters.

determined to be the methyl ester of palmitoleic acid (16:1 *cis*-Δ9), and the 14:0, 16:0, 18:3, and 20:5 FAME were identified as the methyl esters of myristic, palmitic, linolenic (*cis*-Δ9, Δ12, Δ15), and eicosapentaenoic (*cis*-Δ5, Δ8, Δ11, Δ14, Δ17) acids, respectively. The position and stereochemistry of the carbon-carbon double bonds present in the remaining two 16:1, and the 18:4 FAME could not be determined by comparison of the GC/MS data with available standards. [After this work was completed, it came to our attention that the 18:4 (all-*cis* Δ6, Δ9, Δ12, Δ15) FAME is now available from Sigma Chemical Company (St. Louis, MO).]

To determine the position of the double bonds in the unidentified 16:1 and 18:4 SQDG fatty acyl groups and to confirm the assignments previously made using FAME standards analyzed by GC/MS, a portion of the *H. carterae* SQDG fraction was reacted with lithium aluminum hydride to liberate the fatty acyl moieties as the corresponding alcohols. The alcohols were then converted to their nicotinate derivatives, and the resulting mixture was analyzed by GC/MS. Interpretation of the mass spectra of the nicotinate derivatives (discussed shortly) allowed assignment and confirmation of all the carbon-carbon double-bond sites (Table 1). The two unknown SQDG hexadecenoyl moieties were identified as 11-hexadecenoyl (16:1 Δ11) and as 13-hexadecenoyl (16:1 Δ13) (7), and the 18:4 SQDG fatty acyl group was determined to be 18:4 (Δ6, Δ9, Δ12, Δ15). Additionally, the 15:0 fatty acyl substituent was found only as the saturated species.

Previous investigations have reported the use of picolinyl ester derivatives of fatty acids (FA) in order to establish the carbon-carbon double-bond positions (14–18). However, the use of picolinyl ester or nicotinate derivatives for determination of double-bond positions in SQDG fatty acyl moieties has not yet been described. For SQDG, three steps would be required for preparation of the picolinyl esters: (i) cleavage of the SQDG to liberate the FA, (ii) formation of the FA chloride using thionyl chloride, and (iii) esterification with pyridylcarbinol. Steps i and ii involve harsh conditions for polyunsaturated FA prone to air oxidation, although a modification has recently been described for step ii (17,18). The overall reaction procedure described here for the formation of the nicotinate derivatives from the SQDG fatty acyl substituents proceeds in good yield with minimal side reactions, and only two steps are required. The preparation of nicotinate derivatives of long-chain alcohols and their analysis by electron impact mass spectrometry (EI/MS) was previously described by Vetter and Meister (19) and by Harvey (16). However, in contrast to a previous report (16), we have found that the formation of the nicotinate derivatives from long-chain alcohols is highly reproducible when using nicotinyl chloride directly as the reactant in anhydrous pyridine.

To determine the extent of decomposition of the polyunsaturated fatty acyl moieties, the synthesis of the nicotinate derivatives from the SQDG fatty acyl groups was monitored by ^{1}H NMR spectroscopy. A comparison was made between the NMR spectra of the initial SQDG mixture and those of both the long-chain alcohol intermediates and nicotinate products. It was found that there is a stable ratio between the integrals for the protons resonating at *ca.* δ 5.3 ppm (olefinic protons), *ca.* δ 2.8 ppm (doubly allylic methylene protons characteristic of polyunsaturated FA), and the signals in the range between δ 0.7 and δ 2.0 ppm (protons of the aliphatic methylene and terminal methyl groups). This result indicated that the polyunsaturated SQDG fatty acyl moieties were not degraded to a detectable amount more than were the saturated fatty acyl groups, an important objective of this study.

The EI mass spectra of the nicotinate derivatives of the saturated 14:0, 15:0, and 16:0 SQDG fatty acyl moieties show a regular series of fragment ions down to *m/z* 178, resulting from charge-site remote radical-induced cleavage along the hydrocarbon chain. Figure 1 (A and B) shows the EI mass spectra of the nicotinate derivatives of two of the three isomeric SQDG hexadecenoyl (16:1) acyl groups. These two background-subtracted mass spectra (as well as that for the 16:1 Δ9 isomer, not shown) were taken from a single GC/MS experiment, at the crests of GC peaks eluting within a 30-s period. Each 16:1 nicotinate derivative exhibited a molecular ion at *m/z* 345, but the series of fragment ions between *m/z* 345 and *m/z* 178 showed marked differences, in terms of both the *m/z* values and the relative intensities of the fragment ions observed. As described by Vetter and Meister (19), a minimum in the relative intensities of the fragment ions for the nicotinate derivatives of monounsaturated fatty alcohols denotes the position of the double bond. Straightforward interpretation of the mass spectra of the nicotinate derivatives allowed assignment of two of the 16:1 SQDG fatty acyl groups as being 11-hexadecenoyl (Fig. 1A) and 9-hexadecenoyl (not shown). The latter assignment is also consistent with a comparison of the GC retention time of the corresponding FAME (determined in a GC/MS experiment) to that of a 16:1 Δ9 standard. The assignment of the final 16:1 SQDG fatty acyl moiety as 13-hexadecenoyl was not possible by simple interpretation of the mass spectrum of its nicotinate derivative (Fig. 1B). In fact, the mass spectral data could easily be misinterpreted as arising from the nicotinate derivative of a 12-hexadecenoyl moiety. However, we have studied the *H. carterae* SQDG 13-hexadecenoyl moiety in detail (7) and

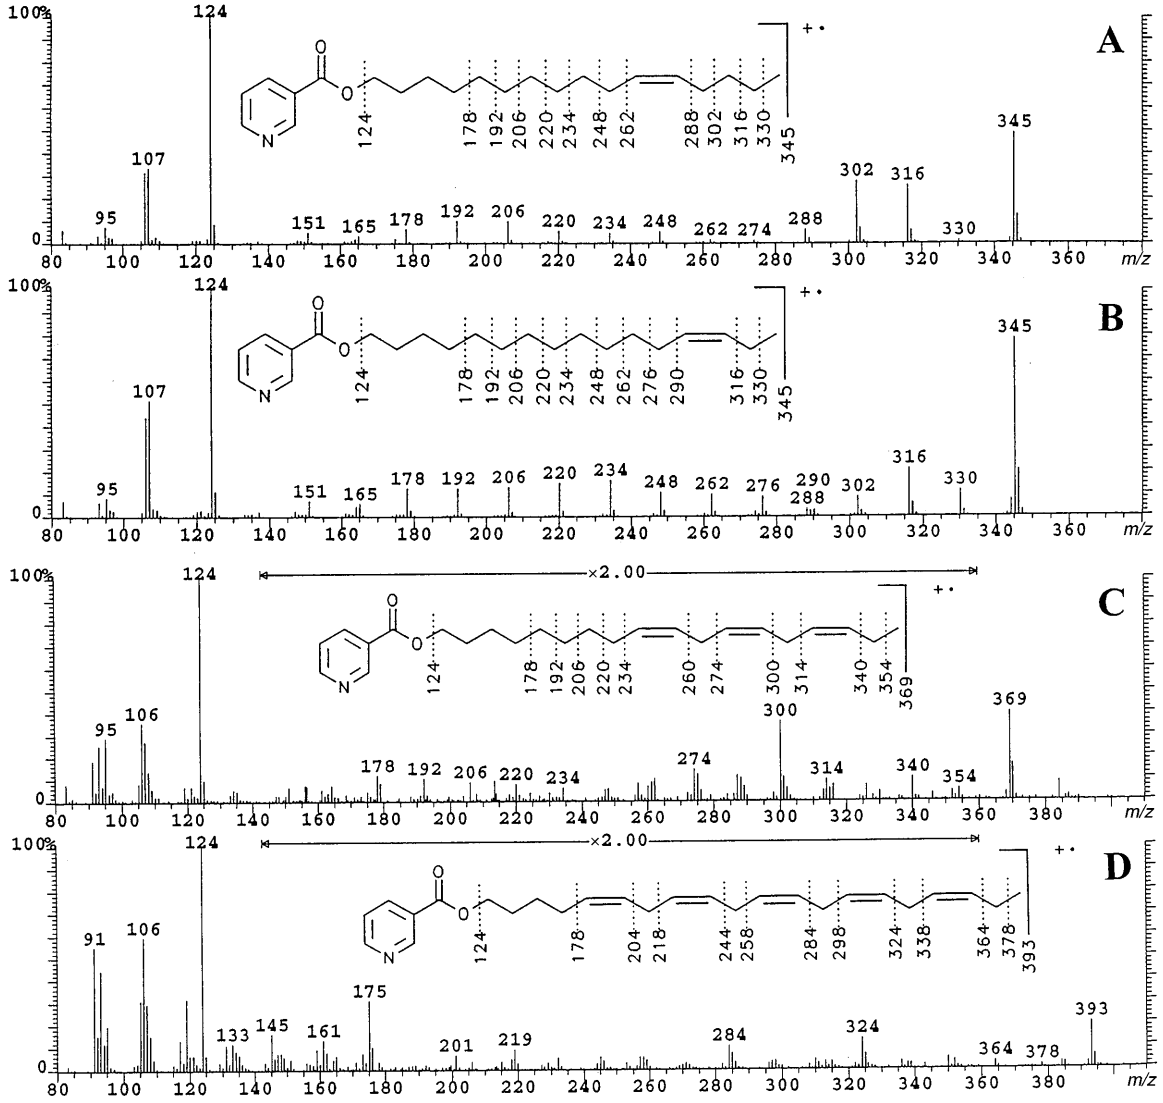

FIG. 1. The gas chromatography/electron impact mass spectra of the nicotinate derivatives of the polyunsaturated sulfoquinovosyl diacylglycerol fatty acyl moieties. A) 16:1 Δ11, B) 16:1 Δ13, C) 18:3 Δ9, Δ12, Δ15, D) 20:5 Δ5, Δ8, Δ11, Δ14, Δ17.

have shown that its nicotinate derivative gives unexpectedly high relative intensities for the fragment ions observed at *m/z* 316 and 302, as is seen in Figure 1B, which is consistent with the observed fragmentation of the picolinyl ester of the homologous 15-octadecenoyl compound (18). These results were in contrast to previous investigations of the total FA-fraction of *H. carterae*, where FAME were used exclusively for structural elucidation of the FA residues (20).

Figure 1 (C and D) shows the EI mass spectra of the nicotinate derivatives of the polyunsaturated *H. carterae* SQDG fatty acyl groups. The signal-to-noise ratio evident in these spectra is much lower than that achievable with more abundant components or with standards, although such a result may be realistic for many minor polyunsaturated components of interest. Furthermore, fragmentations arising from the charge-site remote radical-induced cleavage are seen to be much less intense and increasingly ambiguous with increasing degree of unsaturation. Additionally, the polyunsaturated nicotinate derivatives eluted at higher column temperatures than the saturated or monounsaturated derivatives so that a higher level of background ions was observed. This background noise may not be completely eliminated by background subtraction (e.g., *m/z* 384 in Fig. 1C). The assignments of the 18:3 and 20:5 polyunsaturated SQDG fatty acyl moieties obtained by GC/MS of the FAME were confirmed by the EI mass spectra of their nicotinate derivatives (Fig. 1C and 1D, respectively). The spectrum of the 18:3 nicotinate shows fragmentation similar to that observed by Harvey (15) for the picolinyl ester derivative of *cis* Δ9, Δ12, Δ15-octadecatrienoic acid. In the present case, the dominant signal at *m/z* 300 (Fig. 1C) can be explained by the loss of an allylic radical. The corresponding ion for 18:4 is seen at *m/z* 298 while that for 20:5 is at *m/z* 324 (Fig. 1D), consistent with the assigned structures. However, for 18:4 the signal-to-noise ratio

is too low to allow confirmation by the presence of the expected fragment ions at *m/z* 178 and 192 that the additional unsaturation is indeed located at C-6. It can be seen from Figure 1 that, for the nicotinate derivatives of saturated and monounsaturated fatty alcohols, an ion containing a C-4 chain at *m/z* 178 is generally observed. It was found that for derivatives of polyunsaturated SQDG fatty acyl moieties an ion at *m/z* 178 is seen in the case of 18:3 but is weak for 18:4 and 20:5, consistent with the presence of the proximal double bond at C-5 or C-6.

To assign the configuration of the carbon-carbon double bonds in the 11- and 13-hexadecenoyl SQDG fatty acyl substituents, the purified (7) methyl ester derivatives were examined by ^{1}H NMR spectroscopy. For the methyl ester derivative of the 13-hexadecenoyl substituent, decoupling by irradiation of the allylic methylene protons at δ 2.05 ppm collapsed the multiplet resonating at δ 5.32 ppm to a doublet of doublets with a coupling constant of 10.8 Hz, allowing assignment of the *cis* (*Z*) configuration (21) for the carbon-carbon double bond (Table 2). In the same experiment, the triplet resonance at 0.95 ppm, assigned to the terminal methyl group, collapsed to a singlet. This result proved that the carbon-carbon double bond was in the n-3 (Δ13) position (7). By using the same decoupling technique, the methyl ester derivative of the 11-hexadecenoyl substituent also gave a doublet of doublets for the olefinic protons, with a coupling constant of 10.9 Hz. Thus, the configuration of the double bond in the 11-hexadecenoyl substituent was also assigned as *cis* (*Z*).

The purified methyl ester derivative of the 9-hexadecenoyl substituent was found to be in the *cis* (*Z*) configuration based on GC/MS comparison with an authentic standard. This derivative gave, upon irradiation at 2.05 ppm, a singlet resonance at 5.34 ppm for the two olefinic protons. NMR examination of *cis* and *trans* isomers of the methyl esters of four Δ9 monounsaturated FA standards performed under the same decoupling conditions as described above showed that the *cis* isomers gave a singlet resonance at 5.34 ppm for the olefinic protons, whereas for the *trans* isomers the singlet was observed at 5.38 ppm (Table 2). This result confirmed that the 9-hexadecenoyl fatty acyl substituent was the *cis* (*Z*) isomer.

^{13}C NMR analysis of the methyl ester derivatives of the isolated 9-, 11-, and 13-hexadecenoyl moieties also supported the stereochemical assignments (Table 3). For the *cis* and *trans* standards of 16:1 Δ9, significant differences were observed for both the chemical shifts of the olefinic carbons (*cis*: 130.8 and 130.9 ppm; *trans*: 131.5 and 131.6 ppm) and for the corresponding signals of the adjacent methylene carbons (*cis*: 28.1 and 28.2 ppm; *trans* 33.7 and 33.8 ppm). The ^{13}C NMR chemical shifts assigned to the allylic methylene carbons in both the 16:1 Δ11 and 16:1 Δ13 fatty acyl substituents (Table 3) supported the *cis* stereochemical assignment for the double bonds and are in good agreement with published data (22–24).

Investigation of the intact SQDG from H. carterae *by LC/MS and LC/MS/MS*. With the analysis of the fatty acyl substituents completed, the next step was to examine the intact *H. carterae* SQDG in order to locate the acyl substituents on the sulfoquinovosyl glycerol backbone. Figure 2 shows the flow injection electrospray mass spectrum of the *H. carterae* SQDG in the negative-ion mode. The peaks at *m/z* 837, 813, 791, and 763, which represent singly deprotonated molecules $[M - H]^-$, are the most prominent. On the basis of tandem mass spectrometry (MS/MS) experiments, these ions could be tentatively assigned as SQDG with the following fatty acyl pairings (as described in the following discussion); 20:5/16:1 and/or 18:3/18:3 (*m/z* 837); 18:3/16:1 (*m/z* 813); 16:0/16:1 (*m/z* 791); and 14:0/16:1 (*m/z* 763). On the basis of the fragmentation patterns in their MS/MS spectra, the peaks at *m/z* 823 and *m/z* 869 in Figure 2 were determined to represent peroxidized forms of the two most abundant SQDG (see Table 4) having the 16:0/16:1 and 20:5/16:1 fatty acyl pairings, respectively.

Although it was possible to analyze the major *H. carterae* SQDG by flow-injection MS/MS without chromatographic separation, it was necessary to use LC/MS and LC/MS/MS

methods to resolve isomeric and closely related components as well as some minor SQDG components found in this fraction. A separation method employing a basic mobile phase and an alkali-resistant octadecylsilyl stationary phase provided the best separation of the *H. carterae* SQDG (Fig. 3). As demonstrated by the extracted ion chromatograms (Fig. 4) taken from the LC/MS total ion chromatogram shown in Figure 3, closely related SQDG could be adequately resolved.

Analysis of the MS data showed that the two major peaks in Figure 4B corresponded to two SQDG differing by two mass units. The peak at 22.9 min corresponds to an SQDG of mass 766 ($[M - H]^-$ *m/z* 765, 16:0/14:0 fatty acyl pair), whereas the peak at 20.4 min corresponds to the second isotope peak (i.e., two mass units higher than the nominal mass) of the SQDG of nominal mass 764 ($[M - H]^-$ *m/z* 763, 14:0/16:1 fatty acyl pair, see Fig. 4A). This second isotope peak arises owing to the natural abundance of ^{13}C and ^{34}S resulting in an ion at *m/z* 765 for the 14:0/16:1 fatty acyl pair at 17% abundance relative to the all ^{12}C and ^{32}S ion at *m/z* 763. Similarly, the peaks at 25.1 and 28.3 min in Figure 4F correspond to SQDG of mass 792 ($[M - H]^-$ *m/z* 791, 16:0/16:1 fatty acyl pair) and 794 ($[M - H]^-$ *m/z* 793, 16:0/16:0 fatty acyl pair), and the peaks at 20.2 and 20.9 min in Figure 4I correspond to SQDG of mass 838 ($[M - H]^-$ *m/z* 837, 20:5/16:1 fatty acyl pair) and 840 ($[M - H]^-$ *m/z* 839, 20:5/16:0 fatty acyl pair). In each of these cases, the SQDG components differing by two mass units were nearly baseline resolved, and MS/MS experiments could be performed without interferences due to ^{13}C and ^{34}S isotopic variants of a related SQDG of similar mass (see Table 4 for a complete summary of the LC/MS/MS results).

The MS/MS spectrum of the major SQDG (16:0/16:1 fatty acyl pairing) found in the *H. carterae* cell extract, taken from an LC/MS/MS run, is shown in Figure 5. The observed fragmentation pattern is significantly different from that previously observed by fast atom bombardment ionization-MS/MS of SQDG (25). Of particular note is the absence of fragment ions resulting from cleavages along the fatty acyl chains which only arise at higher collision energies than are accessible on the triple quadrupole mass spectrometer used for this experiment. Also, in contrast to the earlier fast atom bombardment ionization-MS/MS results, the most abundant high

[b]SQDG in smaller amounts (e.g., pairings with the 18:4 fatty acid). Abbreviations: FA, fatty acid; LC/MS, liquid chromatography/mass spectrometry; LC/MS/MS, combined liquid chromatography/tandem mass spectrometry. For other abbreviations see Table 1.

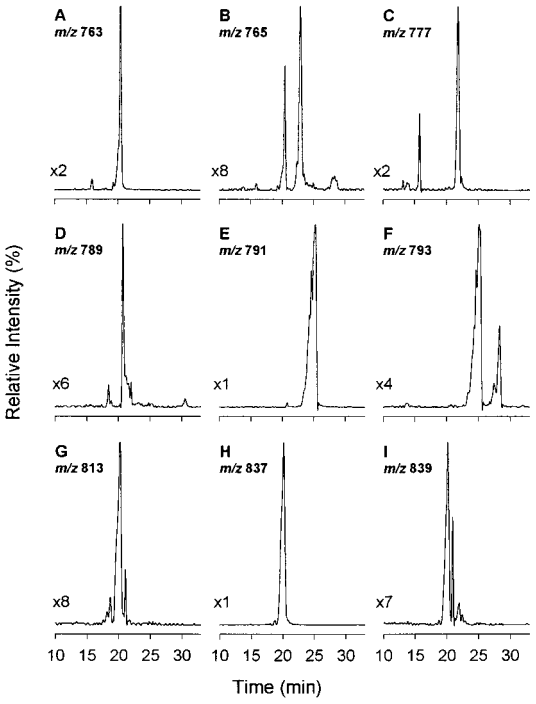

FIG. 4. Extracted ion chromatograms reconstructed from the full-scan liquid chromatography/mass spectrometry data shown in Figure 3 for the *Heterosigma carterae* sulfoquinovosyl diacylglycerols.

mass fragment ions (at *m/z* 537 and *m/z* 535) can be rationalized as arising from a fragmentation involving loss of one acyl substituent from the molecular ion ($[M - H - C_{16}H_{30}0_2]^-$ and $[M - H - C_{16}H_{32}0_2]^-$) and corresponding to fragment ions **b** and **e** shown in Scheme 1. In this Scheme, the fragmentation of SQDG under MS/MS conditions is shown. The fragments **b–e** may be used for determination of the FA substitution. Fragment ions at *m/z* 553 and *m/z* 555 arising from the loss of a ketene analog ($[M - H - R_1C{=}0]^-$ and $[M - H - R_2C{=}0]^-$ (25), ions **c** and **d** in Scheme 1) are of very low intensity in the LC/MS/MS spectrum. Peaks assigned as the fragment ions corresponding to the free FA ($[C_{16}H_{31}0_2]^-$ and $[C_{16}H_{29}0_2]^-$ are clearly visible at *m/z* 255 and *m/z* 253. Other peaks appearing in Figure 5 could be readily assigned to fragment ions **f–o** which can be considered characteristic for the substance class of SQDG under MS/MS conditions, independent of their FA substitution pattern (Scheme 2) (25).

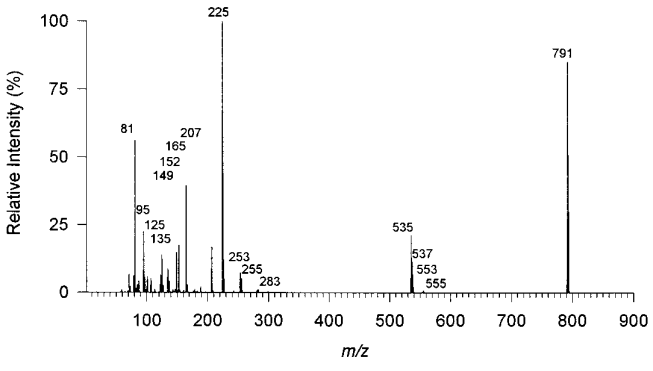

FIG. 5. Tandem mass spectrum of the $[M - H]^-$ ion of the major sulfoquinovosyl diacylglycerol (16:0/16:1 fatty acyl pairing) found in the *Heterosigma carterae* cell extract, taken from a combined chromatography/tandem mass spectrometry run.

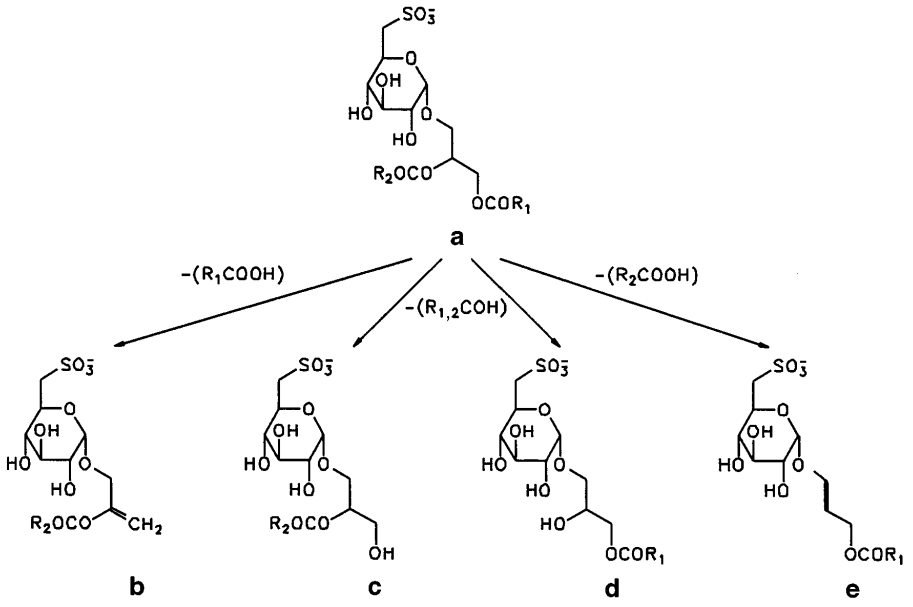
Extensive interpretation of the LC/MS/MS data allowed complete assignment of the SQDG produced by *H. carterae* (Table 4). The positional assignments of the fatty acyl moieties listed in Table 4 were made on the basis of the relative intensities of the $[M - H - R_{sn\text{-}1}CO_2H]^-$ and $[M - H - R_{sn\text{-}2}CO_2H]^-$ fragment ions in the MS/MS spectrum of each SQDG. These assignments were supported by the positional assignments for the SQDG components with the 16:0/16:1 and 20:5/16:1 fatty acyl pairings as determined by interpretation of the NMR spectra and regioselective enzymatic hydrolysis (see below). It was found that, in general, the relative intensity of the fragment ion resulting from loss of the *sn*-1 fatty acyl moiety ($[M - H - R_{sn\text{-}1}CO_2H]^-$, *m/z* 535 in Figure 5) is significantly higher than the relative intensity of the fragment ion resulting from loss of the *sn*-2 fatty acyl group ($[M - H - R_{sn\text{-}2}CO_2H]^-$, *m/z* 537 in Figure 5). The only exception to this rule appears to be when a highly polyunsaturated fatty acyl group is attached to the *sn*-2 position. In this case, only a small difference in the relative intensity of the two fragment ions occurs.

NMR analyses of SQDG fractions. To obtain SQDG components for structural analysis by NMR spectroscopy and for regioselective enzymatic cleavage of the *sn*-1 fatty acyl moiety, the SQDG mixture from *H. carterae* was separated by preparative LC. The fractions containing a mixture of three SQDG components having the 16:0/16:1 fatty acyl pairing (compounds **1**, **2**, and **3**), and the fraction containing mainly the SQDG with the 20:5/16:1 fatty acyl pair (substance **4**), were subjected to NMR analysis. The ^1H and ^{13}C NMR spectra of both fractions exhibited nearly identical chemical shifts for resonances assigned to the sulfoquinovosyl-glycerol moieties. The NMR assignments for the fraction containing the mixture of SQDG with the 16:0/16:1 fatty acyl pairing are listed in Tables 5 and 6, and were made on the basis of interpretation of one- and two-dimensional [(including ^1H-^1H correlated spectroscopy (COSY), total correlated spectroscopy (TOCSY), nuclear Overhauser enhancement spectroscopy, heteronuclear multiple quantum correlation (HMQC), and heteronuclear multiple bond correlation (HMBC)] NMR spectra. Where comparison was possible, the resonances observed for the sulfoquinovosyl-glycerol moieties are in excellent agreement with literature values (26).

The positional distribution of the fatty acyl groups in the mixture of SQDG having the 16:0/16:1 fatty acyl pairing was determined by two different methods, *viz.*, NMR spectroscopy and regioselective cleavage of the acyl group at the *sn*-1 position. By using 3:1 (vol/vol) CD_3OD/C_6D_6 as the solvent for NMR examination of the mixture of compounds **1**, **2**, and **3**, the resonance at 5.44 ppm, assigned to the proton at the *sn*-2 position of the glycerol moiety, could be resolved from the resonances attributed to the olefinic protons in the



SCHEME 1

16:1 acyl substituents. In the HMBC spectrum of the mixture, a correlation was observed between the proton resonance at 5.44 ppm and the carbon resonating at δ 174.96 ppm, thus allowing assignment of the latter resonance to the carbonyl carbon of the fatty acyl group attached to the *sn*-2 position. The methylene protons resonating at 2.32–2.35 ppm showed a correlation in the HMBC spectrum to the same carbonyl carbon (δ 174.96), thereby allowing assignment of these protons as the methylene protons on the carbon adjacent to the carbonyl carbon in the fatty acyl group attached at the *sn*-2 position. Similarly, correlations from the resonances at 4.28 ppm and at 2.26–2.27 ppm to the carbonyl carbon at 175.11 ppm proved the assignment of these resonances to the *sn*-1 position and its associated FA. The TOCSY spectrum of the mixture revealed that the protons resonating at 2.02 ppm (assigned to the allylic protons in the 16:1 fatty acyl groups; see Table 6) belonged to the same spin systems as those resonating at 2.32–2.35 ppm, a result which allowed assignment of

all three 16:1 fatty acyl groups exclusively to the *sn*-2 position.

Enzymatic cleavage of SQDG and analyses of the resulting sulfoquinovosyl monoacylglycerol (SQMG). To confirm this assignment, the 16:0 fatty acyl moiety at the *sn*-1 position of the mixture was regioselectively hydrolyzed using lipase from the fungus *Rhizopus arrhizus* (7,26). Negative ion liquid secondary ion mass spectrometry (LSIMS) analysis of the resulting SQMG gave an $[M - H]^-$ ion at *m/z* 553, clearly indicating that the remaining fatty acyl group was 16:1. However, NMR analysis of this SQMG (including ^1H-^1H COSY, HMBC, and HMQC spectra, see Table 7) revealed a mixture of compounds **5**, **6**, and **7** which have the remaining 16:1 fatty acyl moiety attached to the *sn*-1 position. This is clearly seen from the 4.16 ppm chemical shift of the methine proton attached to the *sn*-2 position, and the chemical shifts of 4.16 and 4.27 ppm observed for the methylene protons attached to the *sn*-1 position. The location of the 16:1 fatty acyl moiety

at the *sn*-1 rather than the expected *sn*-2 position can be explained by an acyl migration favored by proton-donating solvents (28,29) since in this experiment, the SQMG had been purified using a C_{18} derivatized silica gel column followed by preparative LC, involving the use of triethylamine and water.

The enzymatic hydrolysis experiment was then repeated using an alternatve purification procedure in which, following hydrolysis, proteins and salts were precipitated by alcohols. The NMR spectra of the SQMG products were then run directly after filtration of the alcoholic solution. Using this alternative purification procedure, the product was determined to be an SQMG mixture composed of compounds **8**, **9**, and **10** (selected NMR assignments are listed in Table 7). In contrast to the NMR data for the SQMG containing **5**, **6** and **7**, the methine proton attached to the *sn*-2 position now resonated at 5.08 ppm and the signals assigned to the two *sn*-1 methylene protons had identical chemical shifts at 3.72 ppm. The isolation of either the *sn*-1 or *sn*-2 acylated product, depending on purification conditions, demonstrates the importance of conducting regioselective enzymatic cleavage and subsequent workup under carefully controlled conditions in order to obtain the expected *sn*-2 monoacylated product.

The *sn*-1 selective enzymatic cleavage followed by negative-ion LSIMS analysis was also applied to different SQDG fractions containing 14:0/16:1, 16:0/14:0, 18:3/16:1, and 20:5/16:0 FA pairings to yield an $[M - H]^-$ for the corresponding SQMG at *m/z* 553 (loss of 14:0 FA), *m/z* 527 (loss of 16:0 FA), *m/z* 553 (loss of 18:3 FA), and *m/z* 555 (loss of 20:5 FA), respectively. These results are in full accordance with the positional assignments obtained by the LC/MS/MS experiments described earlier (see Table 4).

To confirm the structure of the sulfoglycoglycerol moiety, the mixture of **5**, **6,** and **7** was hydrolyzed under acid conditions to give the deacylated product **11**. The ^{1}H and ^{13}C NMR data for **11** (Table 7) are in excellent agreement with those reported for 3-*0*-(6-sulfo-α-D-quinovopyranosyl)-*sn*-glycerol (26,30). These data, together with comparison of the NMR data of the intact SQDG discussed earlier, support the relative stereochemistry of the sulfoglycoglycerol moiety as shown in Scheme 3. Although the data presented here do not exclude the possibility that the *H. carterae* SQDG sulfoglycoglycerol moiety actually has the opposite absolute configuration to that presented in structure **11**, it is unlikely that *H. carterae* would be the only organism to produce such a sulfoquinovosyl glycerol.

In conclusion, it has been shown that *H. carterae* contains numerous SQDG, all with the same sulfoquinovosyl-glycerol backbone substituted by various saturated, monounsaturated, and polyunsaturated FA. The most abundant SQDG contain the fatty acids 16:0, 16:1, and 20:5. Isolation of the individual SQDG was deemed impractical, so an LC/MS/MS system for their separation and identification was developed to elucidate their profile in extracts of *H. carterae*. The positional assignments of the fatty acyl moieties on the sulfoquinovosyl glycerol backbone could be made on the basis of the relative intensity of the $[M - H - R_{sn\text{-}1}CO_2H]^-$ and $[M - H - R_{sn\text{-}2}CO_2H]^-$ fragment ions in the LC/MS/MS spectra. The locations of carbon-carbon double bonds on the fatty acyl chains was determined from the GC/EI mass spectra of their nicotinyl derivatives. For monounsaturated fatty acyl chains, the configurations of these double bonds were determined by NMR analyses of the corresponding FAME. The combined results obtained from the different analytical techniques allowed an almost complete determination of the SQDG in *H. carterae.*

MATERIALS AND METHODS

All solvents were analytical grade, and purchased either from Baker (Phillipsburg, NJ), BDH (Toronto, Canada), or Sigma (St. Louis, MO). Distilled or Milli-Q-grade water was used for chromatography.

Extraction and isolation of SQDG. Hetersigma carterae (isolate 102R) was obtained from the Notheast Pacific Culture Collection, University of British Columbia, Vancouver, British Columbia, Canada. The cultures were grown in f/2

SCHEME 3

seawater medium (31) at 22°C on a 16:8 h light/dark cycle under an irradiance of 80 mmol-photons $m^{-2}s^{-1}$ provided by 40-W cool-white fluorescent lamps. Wet cell material (160 g) was extracted into MeOH/$CHCl_3$ (7:3, vol/vol), yielding a total of 850 mg of SQDG after silica gel column chromatography, as described in Reference 7. A portion of this crude SQDG fraction was further fractionated on a Nova-Pak C_{18} LC column (7.8 mm i.d. × 300 mm; Waters Ltd., Milford, MA) using a linear gradient (7).

sn-*1 Regioselective enzymatic cleavage of the SQDG.* The enzymatic digestion is based on a procedure described in Reference 27 and is described in detail in Reference 7. Lipase type XI from *Rhizopus arrhizus* (Sigma) was used. Approximately 5 mg of each SQDG-fraction was incubated in Tris buffer (pH 7.4) at 37°C for 15 min. The reaction was stopped by adding isopropanol (15 mL), and the solvent was evaporated under reduced pressure. The residue was loaded onto a flash column (8 mm i.d.) packed with 2.7 g of C_{18} derivatized silica gel (Baker) and eluted with 20 mL water, 5 mL of a mixture of triethylamine, acetonitrile and water (1:1:8, to convert acidic compounds into their corresponding salts), 20 mL water, and finally 40 mL MeOH. The MeOH fraction was analyzed by mass spectrometry (LSIMS). For NMR experiments, this fraction was further purified by LC using a Nova-Pak C_{18} column (4.5 × 300 mm) with an isocratic solvent system containing MeOH/water (9:1), a Waters 510 pump combined with a Waters refractive index detector RI 410, and a flow rate of 1.2 mL/min. In this way 1 mg of SQMG was obtained (R_t 3.8 min), liberated FA eluted at R_t 12.8 min and a small amount of undigested SQDG eluted at R_t 20.9 min. Note that this procedure resulted in a migration of the *sn*-2 fatty acyl moiety onto the *sn*-1 position after enzymatic digestion.

The alternative procedure, adopted to yield **8**–**10**, was to stop the enzymatic reaction with isopropanol (20 mL), then evaporate the solvent under reduced pressure. The residue was dissolved in 2 mL MeOH and transferred to a clean vial, and the solvent evaporated by a stream of dry nitrogen. The residue was dissolved in 1 mL MeOH and filtered (0.5 μm filter cartridge). NMR analysis of the protein-free filtrate was then performed on the same day.

Formation of FAME. Twenty mg of the purified SQDG fraction was dissolved in 2 mL 0.5 M NaOH/MeOH and equilibrated for 30 min at room temperature. A 2-mL aliquot of BF_3 in MeOH (20%) was added, and after 30 min the volume was reduced to 0.5 mL by a stream of nitrogen. Saturated aqueous NaCl solution (20 mL) was added and the mixture extracted three times with 20 mL *n*-hexane each. The hexane layers were combined and volume reduced to 25 mL under reduced pressure. The hexane fraction was washed with 20 mL H_2O, dried over Na_2SO_4 for about 10 min, and solvent was evaporated under reduced pressure to yield 2.6 mg of a colorless oil which was analyzed by GC/MS.

MS. LSIMS and GC/MS experiments were performed using a VG ZAB-EQ mass spectrometer (Micromass Ltd., Manchester, United Kingdom) coupled to a Hewlett-Packard Series II gas chromatograph with on-column injector (Palo Alto, CA). For LSIMS experiments, a 20 keV beam of Cs^+ ions and a triethanolamine matrix were used. MS/MS experiments were performed in the first field-free region by a linked scan at constant B/E. Ar was used as collision gas at a pressure which attenuated the ion beam by 50% and at a collision energy of 8 keV. EI experiments were performed at an ion source temperature of 200°C and an ionizing electron energy of 70 eV. For further details see Reference 7.

LC/MS/MS experiments were performed using a Hewlett-Packard 1090 HPLC system combined with a PE-SCIEX API III+ triple quadrupole mass spectrometer (Concord, ON,

Canada) operated in negative ion ionspray mode. A Zorbax SB C_{18} LC column (0.21 × 15 cm) was used at a flow rate of 0.2 mL min^{-1}. The optimal LC separation was achieved using 0.03% NH_4OH in H_2O and CH_3CN as solvents in linear gradients such that their respective percentages were 70:30 initially; 50:50 at 10 min; 20:80 at 30 min; 0:100 at 35 min; and 70:30 at 45 min.

NMR spectroscopy. NMR spectra at 20°C were recorded on a Bruker AMX-500 spectrometer (Bruker Analytik, Karlsruhe, Germany) at 500.13 MHz (^1H), 125.7 MHz (^{13}C), using 5-mm sample tubes (Wilmad Glass, Buena, NJ; model 535pp) and standard Bruker pulse sequences. Solvents CD_3OD or 3:1 CD_3OD/C_6D_6 were used as noted in the text or tables. Chemical shifts were referred to CHD_2OD at 3.30 ppm (^1H), or $^{13}CD_3OD$ at 49.0 ppm (^{13}C).

Acquisition conditions, one-dimensional spectra: (^1H) spectral width (SW) 4098 Hz, acquisition time (AQ) 4.0 s, 66° pulse, delay after acquisition (D1) 2 s, decoupling field where used *ca.* 250 Hz; (^{13}C) SW 33,333 Hz, AQ 0.98 s, 40° pulses, Waltz decoupling of ^1H, D1 0.1 s. Spectra were processed with zero filling after exponential weighting (line broadening 0.2 Hz for ^1H, 0.5 Hz for ^{13}C) or resolution enhancement by Lorentz-Gauss multiplication. Couplings of some protons were obtained by simulation.

Two-dimensional spectra (^1H TOCSY and double-quantum filtered COSY): SW 3676 Hz, AQ 0.07 s, D1 2.0 s, 512 × 512 increments, TOCSY spin lock for 160 ms at field strength 8 kHz, processed with zero filling and apodization by 90° shifted sine-bell squared in both dimensions; ($^1H/^{13}C$ HMQC and HMBC) ^1H SW 3676 Hz, ^{13}C SW 16,600 or 22,726 Hz, AQ 0.07 s, D1 1.5 s, 512 × 1024 increments, zero filling both dimensions, apodization as above for HMQC, unshifted sine-bell squared in both dimensions for HMBC. Delay for HMBC 60 ms and 90 ms.

Isolated compounds. 1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-2′-*O*-(hexadeca-9- enoyl)-3′-*O*-hexadecanoyl-*sn*-glycerol, **1**; 1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-2′-*O*-(hexadeca-11-enoyl)-3′-*O*-hexadecanoyl-*sn*-glycerol, **2**; 1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-2′-*O*-(hexadeca-13-enoyl)-3′-*O*-hexadecanoyl-*sn*-glycerol, **3**; total yield 100 mg; NMR data, see Tables 5 and 6; MS see Table 4 and References 7, 25.

1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-2′-*O*-(hexadeca-13-enoyl)-3′-*O*-(eicosapenta-5,8,11,14,17-enoyl)-*sn*-glycerol, **4**; 69.2 mg. ^1H NMR data of the eicosapentaenoic acid moiety: δ 2.25 (2H, *t*; H at C_2), δ 1.60 (2H, *m*; H at C_3), δ 2.02 (4H, *m*; H at C_4, C_{19}), δ 5.36 (10H, *m*; olefinic protons), δ 2.80 (8H, *m*; H at C_7, C_{10}, C_{13}, C_{16}), δ 0.96 (3H, *t*, J = 7.6 Hz; H at C_{20}). All other shifts are identical with those given in Table 5. The signal at δ 4.49 (^1H at C_3') is slightly downfield-shifted (δ 4.50). ^{13}C NMR data: methyl groups: δ 15.0, δ 15.1; methylene groups: δ 21.7–δ 35.4; olefinic carbons: δ 128.3–δ 133.0 ($CDCl_3/C_6D_6$, 3:1); all other values are identical with those given in Table 5. MS data: see Table 4.

1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-3′-*O*-hexadecaenoyl-*sn*-glycerols, **5**–**7**; yield after high-performance liquid chromatography separation *ca.* 1 mg. Enzymatic cleavage and purification are described in Reference 7. NMR data: see Table 7. MS data are given in Reference 7.

1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-2′-*O*-hexadecaenoyl-*sn*-glycerol, **8**–**10**; yield *ca.* 5 mg. NMR data, see Table 7; $[M - H]^-$ at *m/z* 553.4; fragmentation series identical with **4**–**7**.

1′-*O*-(6-desoxy-6-sulfo-α-D-glucopyranosyl)-*sn*-glycerol, **11**; yield 3.6 mg. Acid-catalyzed hydrolysis: 15 mg of the SQDG (16:1/16:0) were dissolved in 5 mL absolute MeOH and a few drops of trifluoroacetic acid were added. Compound **11** was purified by LC as described in Reference 7. NMR data are given in Table 7; further analytical data: see References 26 and 30.

ACKNOWLEDGMENTS

We gratefully acknowledge Ping Seto for obtaining the NMR spectra and Dr. Robert K. Boyd and Dr. Archie McCulloch for reviewing the manuscript. This is NRCC publication number 39767.

ABSTRACT: We have standardized simple but sensitive enzyme-linked immunoassays to understand a relationship between intracellular levels and secretion rates of apoB. The assays were based on commercially available antibodies and were specific to human apoB. A monoclonal antibody, 1D1, was immobilized on microtiter wells and incubated with different amounts of low density lipoproteins to obtain a standard curve. Conditioned media were added to other wells in parallel, and the amount of apoB was quantitated from a linear regression curve. To standardize conditions for the measurement of intracellular apoB, cells were homogenized and solubilized with different concentrations of taurocholate. We found that 0.5% taurocholate was sufficient to solubilize all the apoB in HepG2, Caco-2, and McA-RH7777 cells. Next, a standard curve was prepared in the presence of taurocholate and used to determine intracellular levels of apoB in different cell lines. The intracellular levels (pmol/mg cell protein) and the rates of secretion (pmol/mg/h) of apoB100 were positively correlated (r^2= 0.81, P = 0.0009) in HepG2 cells. Furthermore, a positive correlation (r^2= 0.88, $P < 0.0001$) was found between intracellular and secreted apoB42 in stably transfected McA-RH7777 cells. In contrast, no correlation was observed for human apoB28 and apoB18 in stably transfected cells that were secreted either partially associated or completely unassociated with lipoproteins. These studies indicated that the rate of secretion of lipid-associated apoB, but not the lipid-free apoB, was tightly controlled.
Lipids 32, 1113–1118 (1997).

Apolipoprotein B (apoB) is an essential protein constituent for the assembly of triglyceride-rich lipoproteins by the liver and intestine. The size and flotation properties of lipoproteins have been related to the length of apoB. The apoB polypeptides smaller than 23% are secreted as lipid-poor proteins (1,2). As the length of the apoB polypeptide increases, the size of lipoprotein particles increases but the flotation density decreases (1–5). The apoB mRNA levels do not change by various dietary and metabolic conditions that affect plasma apoB levels. Plasma apoB levels are altered by affecting the translational and posttranslational events during lipoprotein biosynthesis. For example, apoB100 synthesis is decreased in streptozotocin-treated diabetic rats (6), insulin-treated rats and HepG2 cells (7,8), cyclosporin-treated HepG2 cells (9), and in cells transfected with human recombinant apoB48 cDNA (10). Different lipids modulate intracellular degradation and secretion of apoB [for reviews, (11–15)]. Fatty acids modulate the secretion of apoB100 in hepatoma cell lines by altering the rates of intracellular degradation (16–18). To determine a relationship between intracellular levels of apoB and rates of secretion of apoB-containing lipoproteins, we standardized methods to measure intracellular and secreted apoB.

MATERIALS AND METHODS

Materials. Cell culture media were from Bio-Whittaker (Walkersville, MD). Fetal bovine (FBS) and horse serums were obtained from BioFluids (Rockville, MD), and Life Technologies, Inc. (Gaithersburg, MD), respectively. A monoclonal antibody, 1D1, was purchased from Dr. Yves Marcel of the Ottawa Heart Institute, Canada. Polyclonal sheep antihuman apolipoprotein (apoB) (#726494) antibodies were obtained from Boehringer Mannheim (Indianapolis, IN). Alkaline phosphatase-labeled antisheep IgG (#56991) was from Cappel (Durham, NC). Neomycin analog G418 was from Gibco/BRL (Gaithersburg, MD). Taurocholic acid (#T4009) was from Sigma Chemical Co. (St. Louis, MO). Microtiter plates (#1424586) were from Dynatech Laboratories Inc. (Alexandria, VA).

Low density lipoproteins (LDL). LDL (d = 1.02–1.06 g/L), prepared from fresh human plasma by sequential ultracentrifugation, were obtained from the core laboratory of the Department of Biochemistry and analyzed by agarose gel electrophoresis (Beckman, Brea, CA), gel filtration chromatography, and amino acid analysis. To study the gel elution profile, it was applied on a Superose-6 HR 10/30 column (Pharmacia, Uppsala, Sweden) at a flow rate of 0.25 mL/min. The elu-

Abbreviations: Apo, apolipoprotein; BSA, bovine serum albumin; ELISA, enzyme-linked immunoassay; FBS, fetal bovine serum; LDL, low density lipoproteins; MEM, minimum essential medium; PBS, phosphate buffered saline; PBS-Tween, PBS containing 0.05% Tween-20.

tion of proteins was continuously monitored by measuring absorbance at 280 nm. LDL were further analyzed by amino acid analysis by the Wistar Protein Microchemistry Facility, Wistar Institute (Philadelphia, PA). For this purpose, 2 μg of LDL were hydrolyzed with 6 N HCl, 1% phenol for 1 h at 160°C, followed by manual phenylthiocarbamyl derivatization and high-performance liquid chromatography separation as described by Ebert (19).

Cells. HepG2, Caco-2 and McA-RH7777 cells were obtained from American Type Culture Collection (Rockville, MD) and cultured in minimal essential medium (MEM) containing 10% FBS, MEM containing 20% FBS, and Dulbecco's modified MEM containing 10% FBS and 10% horse serum, respectively. McA-RH7777 cells (1,10,20) stably transfected with vectors expressing different truncated human apoB cDNA were kindly provided by Dr. Zemin Yao of the Ottawa Heart Institute, Canada. These cells were cultured in Dulbecco's modified MEM containing 10% FBS, 10% horse serum, and 200 μg/mL of G418. All media contained 1% antibiotic-antimycotic cocktail (Gibco/BRL).

Quantification of secreted and intracellular human apoB by enzyme-linked immunoassay (ELISA). Microtiter wells were coated (2 h, room temperatures) with a monoclonal antibody, 1D1, [100 μl, 1:1000 dilution in phosphate buffered saline (PBS), pH 7.4], washed (3×) with PBS containing 0.05% Tween 20 (PBS-Tween). Conditioned media or various concentrations of human LDL in PBS-Tween were added to each well in triplicate and incubated for 2 h. The wells were washed (3×) with PBS-Tween, incubated (1 h) with sheep antihuman apoB polyclonal antibodies (1:2000 dilution in PBS-Tween), washed (3×) with PBS-Tween, and incubated with purified rabbit anti-sheep IgG labeled with alkaline phosphatase (1:1000 dilution, 1 h). The anti-sheep IgG increased the sensitivity of detection. Finally, the wells were washed twice with PBS-Tween, PBS, and 10 mM ethanolamine, 0.5 mM $MgCl_2$, pH 9.5, and incubated with 100 μL of *p*-nitrophenyl phosphate (1 mg/mL in 10 mM ethanolamine, 0.5 mM $MgCl_2$, pH 9.5) for various times. The absorbance at 405 nm was determined using a Microplate Reader (Dynatech Labs, Chantilly, VA). To determine intracellular apoB levels, cells were washed with PBS, scraped, pelleted by centrifugation, resuspended in PBS, and homogenized (30–60 s, setting 3, 4°C). An aliquot of the cell homogenate was saved for protein determinations, and the rest was solubilized with 0.5% (wt/vol) taurocholate in PBS by rotating samples overnight at 4°C. The solubilized mixture was centrifuged (12000 rpm, 4°C, 5 min), and supernatant was used for apoB determinations. Standard curves were prepared using indicated amounts of taurocholate.

Other measurements. Proteins were determined using the Coomassie Plus reagent (Pierce Chemical Co., Rockford, IL) with bovine serum albumin (BSA) as a standard. The statistical and linear regression analyses were performed using Prism2 (Graphpad, San Diego, CA).

RESULTS AND DISCUSSION

Characterization and measurement of human LDL. Human plasma LDL were used as a standard in developing ELISA assays for apoB. Lipoproteins were characterized to ensure their purity. The purified LDL migrated as a single band during agarose gel electrophoresis and eluted as a single peak during Superose-6 column chromatography (data not shown). The expected and observed amino acid compositions were similar (data not shown), indicating that the purified LDL mainly contained apoB100. Next, we evaluated the use of Coomassie Plus reagent in the measurement of apoB since amino acid analysis is not expected to be practical in every laboratory. The LDL protein measured by amino acid analysis was higher by 12.5% in two different determinations compared to that obtained by Coomassie Plus reagent. These studies suggested that Coomassie Plus reagent can be used to quantify apoB.

Quantitation of secreted apoB. The sandwich ELISA technique developed (10) to quantify secreted apoB was based on a monoclonal antibody, 1D1, that recognizes an epitope in the *N*-terminus (amino acids 474–539) of human apoB (21,22). The monoclonal antibody recognizes all subclasses of very low density lipoprotein and LDL, and delipidated apoB with similar association constant of 10^{-9} M (23–25). Because of these properties, it has been used to detect various apoB polypeptides (1,10) and was selected for the development of an ELISA. We observed that the detection of LDL was linear up to 100 ng and reached a saturation at 340 ng of LDL (data not shown). Routinely, 1 to 10 ng of LDL were used to generate standard curves. The standard curves were subjected to linear regression analyses; the r^2 value in various experiments ranged between 0.92 and 0.99. Sensitivity of the assays could be increased by using 200 μL of media instead of the usual 100 μL during all steps, and using lower amounts of human LDL (0.5–5 ng of protein/well) for standard curves coupled with increased time for color development. The assay is specific to human apoB because 1D1 is specific to human apoB (21,22) and does not recognize rat, bovine, or horse apoB. Furthermore, human apoB determinations were not affected by the presence of FBS, horse serum, or BSA in the medium. This procedure has been used to measure apoB levels in plasma and various lipoprotein fractions (data not shown). The method described here is more sensitive, does not require affinity purification of antibodies, and is rapid compared to a recently described ELISA method for apoB detection (26). Hahn *et al.* (26) evaluated the use of monoclonal antibodies as capture antibodies and found that they were less effective than affinity-purified polyclonal antibodies. A possible reason for the poor efficiency may be that the monoclonal antibodies used in their studies recognized only lipid-associated apoB, and the recognition was modulated by the amounts of lipids present in lipoprotein particles (23,25). In our studies, we selected a monoclonal antibody, 1D1, that recognizes lipid-free and lipid-associated apoB with equal affinity (23–25).

Measurement of intracellular apoB. To develop a method for the quantitation of intracellular apoB, we evaluated different detergents for their use in ELISA. Deoxycholate (1%) and sodium dodecyl sulfate (1%) inhibited the detection of apoB by ELISA, whereas Triton X-100 (1%) and taurocholate had no significant effect (data not shown). We concentrated on

sodium taurocholate because it had been used for the measurement of microsomal apoB (27). Furthermore it has a high critical micellar concentration, does not induce protein denaturation, and has been used for the solubilization of membrane enzymes (28). First, we determined the feasibility of using taurocholate for measuring apoB in LDL. For this purpose, ELISA was performed in the presence of different concentrations of taurocholate (data not shown). At low concentrations (0.25%, wt/vol), taurocholate did not affect the slope of the curve compared to control (Table 1). However, at higher concentrations, taurocholate decreased the slope, suggesting the requirement of a standard curve for each taurocholate concentration. What is more important, the linearity of the assay was not affected by the presence of taurocholate. The *P* values after a two-tail test were <0.0001. Thus, apoB could be reliably measured in the presence of taurocholate.

Second, conditions were optimized to find out the maximum amount of taurocholate required for the detection of intracellular apoB in HepG2 and differentiated Caco-2 cells (Fig. 1). No apoB could be detected in cellular homogenate in the absence of taurocholate, indicating that the majority of the intracellular apoB was not accessible to antibodies under these conditions. Increasing concentrations of taurocholate resulted in increased detection of intracellular apoB. For HepG2 cells, 0.1% taurocholate was sufficient for the maximum solubilization of intracellular apoB (Fig. 1A), whereas for differentiated Caco-2 cells 0.3 to 0.4% taurocholate yielded maximum detection (Fig. 1B). In subsequent experiments, 0.5% taurocholate was used to ensure complete solubilization.

Third, we determined the feasibility of using taurocholate to quantify human apoB in McA-RH7777 cells stably transfected with various truncated forms of apoB (1,10). To determine the effect of taurocholate on the measurement of human apoB in McA-RH7777 cell homogenate, known amounts of LDL were added to washed cell monolayers of nontransfected cells. Cells were homogenized, solubilized, and used to detect human apoB. The recovery of added apoB using 0.5% taurocholate was 87%. These studies indicated that taurocholate could be used to solubilize intracellular or added apoB in various cells and to quantitate it by ELISA.

TABLE 1
Statistical Parameters for the Standard Curves Generated to Study the Effect of Different Concentrations of Taurocholate on Apolipoprotein B (apoB) Determinations[a]

Taurocholate (wt/vol)	Slope	Y intercept	r^2	Sy.x
0%	0.063 ± 0.003	0.080 ± 0.026	0.987	0.038
0.25%	0.066 ± 0.002	0.016 ± 0.018	0.994	0.027
0.50%	0.048 ± 0.002	0.027 ± 0.017	0.990	0.025
0.75%	0.053 ± 0.001	0.006 ± 0.005	0.999	0.008

[a]Microtiter wells were coated in triplicate with monoclonal antibody, 1D1 (purchased from Dr. Yves Marcel of the Ottawa Heart Institute, Canada), and incubated with different amounts of low density lipoprotein in the presence or absence of various concentrations of taurocholate (Sigma Chemical Co., St. Louis, MO). Subsequent steps for the determination of apoB (Boehringer Mannheim, Indianapolis, IN) were as described in the Materials and Methods section. The lines were subjected to linear regression analyses. Statistical parameters of the curves are summarized. r^2, coefficient of determinations; Sy.x, standard deviation of residuals from the line.

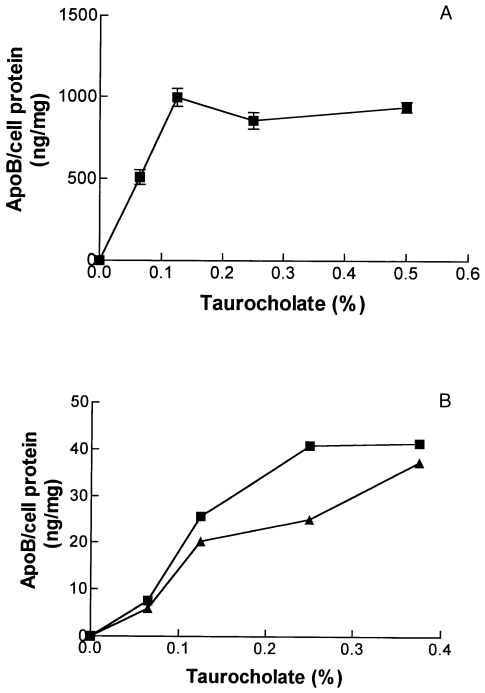

FIG. 1. Effect of different concentrations of taurocholate on the solubilization of intracellular apolipoprotein B (apoB). (A) HepG2 cells were plated in three flasks and used after they reached confluency. Means ± standard deviations of triplicate determinations are presented. (B) Caco-2 cells were plated in two flasks and allowed to differentiate for 21 d. These cells secreted 0.02–0.06 pmol of apoB/mg/h. Cells from these flasks were used to determine intracellular apoB levels. The data from both flasks are presented. To determine intracellular apoB, cells were scraped in phosphate buffered saline, homogenized, and distributed in different aliquots. The aliquots were incubated overnight at 4°C with indicated concentrations of taurocholate, centrifuged (12000 rpm, 5 min, 4°C), and the supernatant was used for enzyme-linked immunoassay. Different standard curves were prepared with indicated concentrations of taurocholate, and intracellular apoB levels were determined.

Intracellular levels and secretion rates of apoB polypeptides in different cell lines. We then used these techniques to quantitate intracellular levels and secretion rates of apoB in HepG2 cells at steady state (Table 2). The intracellular levels (0.43 ± 0.08 pmol apoB/mg cell proteins) of apoB found in the present study were similar to those reported by Hahn *et al.* (26) but were significantly higher than those reported by Byrne *et al.* (29). The lower values in the later studies may be due to the use of a detergent that might not have solubilized all the intracellular apoB. In contrast, the secretion rates (0.11 ± 0.01 pmol/mg/h) observed in the present study are similar to those of Byrne *et al.* (29) but significantly different from those of Hahn *et al.* (26). In the later studies, secretion rates were studied in the first 6 h after a media change and thus may not represent steady-state rates. The higher rates observed in that study also suggest that media changes may stimulate secretion of apoB; however, no attempts were made to study this phenomenon. In addition, we found that the apoB secreted per hour was a small fraction (0.2) of the intracellular levels.

Subsequently, attempts were made to quantitate C-terminally truncated apoB polypeptides. Since we used human

LDL as a standard, the number of molecules calculated for truncated apoB polypeptides was probably an underestimation. In the present assays, the capture of the apoB polypeptides by monoclonal antibodies, 1D1, was on molar basis, but the detection using polyclonal antibodies was not. The epitopes for the polyclonal antibodies are expected to be present throughout the apoB100, and they are expected to be absent to various degrees in truncated polypeptides. Thus, values for intracellular and secreted amounts for the same polypeptide are comparable, but quantitative comparisons between different polypeptides are not valid.

Next, we studied the rate of secretion of different C-terminally truncated apoB polypeptides in stably transfected McA-RH7777 cells (Table 2). In contrast to Hep G2 cells, the fraction of apoB polypeptides secreted by McA-RH7777 cells was higher (0.31 to 0.39), indicating that McA-RH7777 cells secreted shorter peptides more efficiently than the secretion of apoB100 by HepG2 cells. This probably was not due to more efficient secretion of shorter peptides because Parhofer *et al.* (30) have observed that the secretion rates of truncated polypeptides decrease with decrease in length. The most likely explanation is that these two cell lines process apoB polypeptides differently during intracellular transport.

Correlations between intracellular steady-state levels of apoB and rate of secretion of lipid-associated apoB. Until now significant information concerning the role of intracellular degradation and secretion of apoB from different cell lines has been obtained using metabolic labeling involving pulse-chase analysis (1,16,17,31). However, the relationship between intracellular apoB levels and rates of secretion is not known. We observed a strong correlation between intracellular and secreted apoB100 in HepG2 cells with an r^2 value of 0.81, and the slope of the curve was significantly ($P = 0.0009$) different from zero (Fig. 2A). Similar observations have been

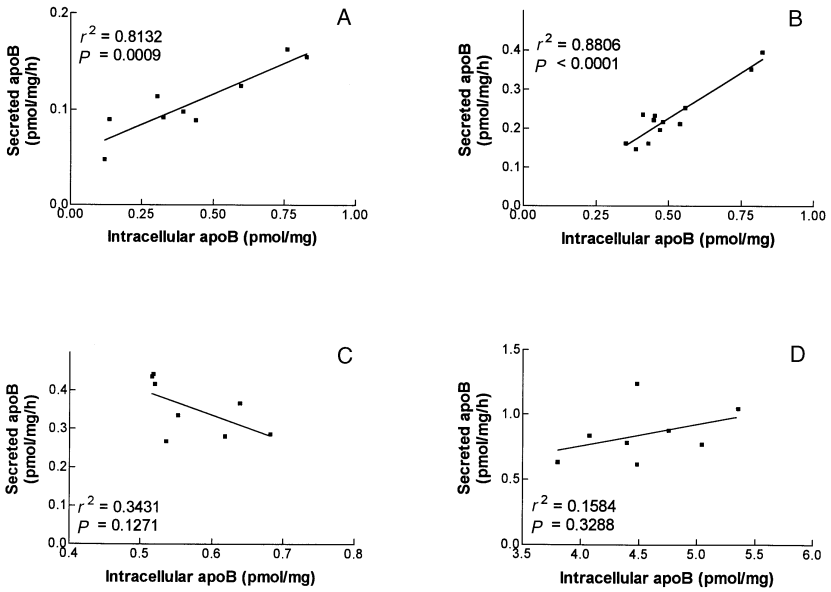

FIG. 2. Correlation between intracellular levels and secretion rates of apoB in cultured cells. Cells were plated in different flasks. At different times, apoB was measured in cells and media. The intracellular levels of apoB were plotted against secreted apoB and subjected to linear regression analysis. (A) HepG2 cells and media were obtained from nine different flasks. McA-RH7777 cells stably transfected with human recombinant (B) apoB 42, (C) apoB 28, and (D) apoB18 were plated in 12, 8, and 8 flasks, respectively. Flasks were harvested at different times of incubation and the amount of human apoB was determined in cells and media. See Figure 1 for abbreviation.

made before (29). Next, we studied the relationship between the lengths of apoB and their secretion rates. The secretion of apoB42, which is secreted as a lipoprotein particle, was significantly correlated ($r^2 = 0.88$) with intracellular levels (Fig. 2B). In contrast, no significant correlation between intracellular levels and secretion rates was observed for apoB28 and apoB18 (Fig. 2C and 2D); these polypeptides are secreted partially or completely in lipid-free forms (1–3). These data suggest that the rate of secretion of lipidated apoB may be more tightly controlled than apoB polypeptides secreted unassociated with lipids. It is tempting to speculate that cells may sense their environment and control the biosynthesis of apoB-containing lipoproteins.

In summary, we have standardized conditions to quantify secreted and intracellular apoB100 and its various truncated forms. We observed that the rates of secretion of lipidated apoB polypeptides are positively correlated with their intracellular levels. It remains to be determined whether such a correlation exists for other apolipoproteins secreted associated with lipids. Furthermore, mechanisms involved in determining the correlations should be explored.

Oxidation Reactions of Acetylenic Fatty Esters with Selenium Dioxide/*tert*-Butyl Hydroperoxide

Marcel S.F. Lie Ken Jie*, Mohammed Khysar Pasha, and Mohammad Shahin Alam

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: Reaction of methyl undec-10-ynoate (**1**) with selenium dioxide/*tert*-butyl hydroperoxide (TBHP) in aqueous dioxane gave methyl 9-oxo-undec-10-ynoate (**2**, 9%) and 9-hydroxy-undec-10-ynoate (**3**, 60%), while methyl octadec-9-ynoate (**4**) yielded mixtures of positional isomers of mono-keto (*viz.* methyl 8-oxo- and 11-oxo-octadec-9-ynoate, **5**, 5%), hydroxy-keto (*viz.* methyl 8-hydroxy-11-oxo- and 11-hydroxy-8-oxo-octadec-9-ynoate, **6**, 10%), and dihydroxy (*viz.* methyl 8,11-dihydroxy-octadec-9-ynoate, **7**, 24%) derivatives. Similar treatment of a conjugated diacetylenic fatty ester (methyl octadeca-6,8-diynoate, **8**) furnished a mixture of methyl 5-oxo- and 10-oxo-octadeca-6,8-diynoate (**9**, 12%) and a complex mixture of very polar products. Reaction of methyl octadec-11*E*-en-9-ynoate (methyl santalbate) (**10**) with selenium dioxide/TBHP in aqueous dioxane gave exclusively a mixture of regiospecific products, *viz.* methyl 8-oxo-octadec-11(*E*)*Z*-en-9-ynoate (**11**, 6%) and methyl 8-hydroxy-octadec-11*E*-en-9-ynoate (**12**, 70%). The structures of the various products were determined by a combination of spectroscopic and mass spectral analyses.

Lipids 32, 1119–1123 (1997).

Selenium dioxide is commonly used to oxidize the α-methylene carbon atoms adjacent to a double bond to form allylic hydroxy derivatives (1). One serious complication of this reaction is the difficulty of removing the colloidal reduced forms of selenium after the reaction. To circumvent this technical obstacle, an improved hydroxylation method has been developed by Umbreit and Sharpless (2) where *tert*-butyl hydroperoxide (TBHP) is used as a re-oxidant in combination with selenium dioxide. This modified procedure has been successfully applied to the allylic hydroxylation of many olefinic compounds including unsaturated olefinic fatty esters (3–6). For example, in the reaction of methyl oleate with selenium dioxide and TBHP, a mixture of methyl 8- and 11-hydroxy-octadec-9*Z*-enoate and methyl 8,11-dihydroxy-octadec-9*Z*-enoate is obtained (4). In such hydroxylation reactions, allylseleninic acid has been identified as an intermediate species (7–9). Aldehydes, ketones, and carboxylic esters also can be subjected to α-oxidation by selenium dioxide (10). Allylic rearrangement reactions often are found to accompany this type of reaction, and *cis* double bonds tend to isomerize to the *trans* configuration (1,2). While allylic hydroxylation reactions involving olefinic compounds have been extensively documented in the chemical literature, comparatively little is reported on the oxidation of acetylenic fatty acids by selenium dioxide/TBHP. Chabaud and Sharpless (11) have shown that oxidation of acetylenes by this procedure yields α,α´-dioxygenated derivatives.

Our continued interest in the oxidation of unsaturated fatty acids has led us to study the chemical effects of selenium dioxide/TBHP on unsaturated fatty acid substrates containing either a terminal acetylenic, an internal acetylenic, a conjugated diacetylenic, or a conjugated olefinic-acetylenic (enyne) system.

MATERIALS AND METHODS

Thin-layer chromatography was performed on microscope glass plates coated with silica gel G (*ca.* 0.1-mm thick) and a mixture of *n*-hexane/diethyl ether (4:1, vol/vol) as the developer. Components on the microplates were viewed by exposing them to iodine vapor. Column chromatographic separation was accomplished using silica gel (Merck Art. 7730, type 60, 70–230 mesh; Darmstadt, Germany) as the adsorbent using gradient elution with mixtures of *n*-hexane/diethyl ether as the eluent. Infrared (IR) spectra were measured on a Shimadzu model IR-470 spectrophotometer (Shimadzu Corp., Kyoto, Japan) on neat samples placed between NaCl discs. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform (CDCl3) (0.2–0.3 mM) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS (δ_{TMS} = 0 ppm). Low- and high-resolution mass spectra were recorded on a Finnigan Mat 95 mass spectrometer (Finnigan Mat Corp., San Jose, CA). The following acetylenic fatty esters were prepared by methods described elsewhere: methyl undec-10-ynoate (**1**) (12), methyl octadec-9-ynoate (**4**) (13), and methyl octadeca-6,8-diynoate (**8**) (14). Methyl octadec-11*E*-en-9-ynoate (**10**) was isolated from *San-*

talum album (Linn.) seed oil (15). Selenium dioxide and 1,4-dioxane were obtained from Aldrich Chemical Company (St. Louis, MO). TBHP (80% solution in di-*tert*-butylperoxide) was purchased from Merck.

General reaction of acetylenic esters with selenium dioxide/TBHP as exemplified by the reaction with methyl undec-10-ynoate (1). A mixture of selenium dioxide (0.57 g, 5.1 mmol), TBHP (2 cm^3), 1,4-dioxane (18 cm^3), and water (2 cm^3) was stirred at room temperature for 30 min. Methyl undec-10-ynoate (**1**, 1.0 g, 5.1 mmol) was added, and the reaction mixture was heated at 85°C for 3 h. Water (60 cm^3) was added, and the reaction mixture was extracted with diethyl ether (3 × 30 cm^3). The ethereal extract was washed with water (20 cm^3) and dried over anhydrous sodium sulfate. The filtrate was evaporated, and the residue was separated by silica gel (60 g) column chromatography by gradient elution using mixtures of *n*-hexane/diethyl ether (100:0, vol/vol, 200 cm^3; 95:5, vol/vol, 200 cm^3; 90:10, vol/vol, 200 cm^3; 80:20, vol/vol, 600 cm^3; 70:30, vol/vol, 600 cm^3; 50:50, vol/vol, 600 cm^3) into two fractions (*viz.* compounds **2** and **3**). The structure of compound **2** (methyl 9-oxo-undec-10-ynoate) (0.1 g, 9%) was determined from the following physical data: R_f = 0.7 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 3250 (C-H str., C≡C-H), 2100 (C≡C, str.), 1735 (C=O, str., ester), 1680 (C=O, str., oxo), and 1430; ^{1}H NMR (δ_H) 1.2–1.7 (*m*, 10H, CH_2), 2.28 (*t*, 2H, 2-*H*), 2.58 (*t*, 2H, 8-*H*), 3.22 (*s*, 1H, 11-*H*), and 3.67 (*s*, 3H, COOCH_3); ^{13}C NMR (δ_C) 23.65 (C-7), 24.83 (C-3), 28.67–28.91 (3C, CH_2), 34.02 (C-2), 45.38 (C-8), 51.48 (COOCH_3), 78.37 (C-11), 81.45 (C-10), 174.23 (C-1), and 187.48 (C-9); and the structure of compound **3** (methyl 9-hydroxy-undec-10-ynoate) (0.65 g, 60%) was determined from the following physical data: R_f = 0.3 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 3450 (O-H, str.), 3300 (C-H, str., C≡C-H), 2350 (C≡C, str.), 1740 (C=O, str., ester) and 1440; ^{1}H NMR (δ_H) 1.3–1.7 (*m*, 12H, CH_2), 2.31 (*t*, 2H, 2-*H*), 2.46 (*s*, 1H, 11-*H*), 2.99 (*s*, broad, O-*H*), 3.67 (*s*, 3H, COOCH_3) and 4.36 (*t*, 1H, 9-*H*); ^{13}C NMR (δ_C) 24.88 (C-7), 24.96 (C-3), 28.99–29.10 (3C, *C*H2), 34.07 (C-2), 37.56 (C-8), 51.56 (COO*C*H_3), 62.02 (C-9), 72.62 (C-11), 85.25 (C-10), and 174.52 (C-1).

Reaction of methyl octadec-9-ynoate (**4**) with selenium dioxide/TBHP at 85°C for 20 h furnished methyl 8-oxo and 11-oxo-octadec-9-ynoate (**5**, 52 mg, 5%), as determined by the following physical data: R_f = 0.7 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 2150 (C≡C, str.) , 1740 (C=O, str., ester) and 1680 (C=O, str., oxo); ^{1}H NMR (δ_H) 0.88 (*t*, 3H, CH_3), 1.2–1.5 (*m*, 14H, CH_2), 1.6–1.9 (*m*, 6H, CH_2), 2.31 (*t*, 2H, 2-*H*), 2.36 (*t*, 2H, -CH_2-C≡C-), 2.50 (*t*, 2H, -C≡C-CO-CH_2-) and 3.66 (*s*, 3H, COOCH_3); ^{13}C NMR (δ_C) 14.10 (C-18), 18.91/18.95 (-C≡C-*C*H_2-), 22.61/22.65 (C-17), 23.92/24.18, 24.73/24.79 (-C≡C-CO-CH$_2$-*C*H_2-), 24.86/24.90 (C-3), 28.88–29.13 (6C, *C*H_2), 31.66/31.81 (C-16), 33.96/34.01 (C-2), 45.40/45.55 (-C≡C-CO-*C*H_2-), 51.45 (COO*C*H_3), 80.91/80.98 (-*C*≡C-CO-), 94.03/94.38 (-C≡*C*-CO-), 174.12/174.16 (C-1), and 188.28/188.53 (-C≡C-*C*O-); methyl 8-hydroxy-11-oxo- and 11-hydroxy-8-oxo-octadec-9-ynoate (**6**, 0.11 g, 10%), as determined from the following physical data: R_f = 0.2 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 3450 (O-H, str.), 2900 (C-H, str.), 1740 (C=O, str., ester), and 1675 (C=O, str., oxo); ^{1}H NMR (δ_H) 0.88 (*t*, 3H, CH_3), 1.2–1.7 (*m*, 20H, CH_2), 1.8 (*s*, *br*, O-*H*), 2.31 (*t*, 3H, 2-*H*), 2.56 (*t*, 2H, -C≡C-CO-CH_2-), 3.67 (*s*, 3H, COOCH_3), and 4.52 (*t*, 1H, -C≡C-C*H*OH-); ^{13}C NMR (δ_C) 14.07 (C-18), 22.60/22.64 (C-17), 23.72/23.96 (-C≡C-CHOH-CH$_2$-*C*H_2-), 24.63/24.74 (-C≡C-CO-CH$_2$-*C*H_2-), 24.83/25.06 (C-3), 28.46–29.71 (4C, *C*H_2), 31.65/31.76 (C-16), 33.94/34.01 (C-2), 36.89/36.99 (-C≡C-CHOH-*C*H2-), 45.23/45.44 (-C≡C-CO-*C*H_2-), 51.53/51.57 (COO*C*H_3), 62.12/62.19 (-C≡C-*C*HOH-), 83.46/92.64 (-*C*≡C-) 174.14 (C-1), and 187.91 (-C≡C-*C*O-); and one fraction containing pure methyl 8,11-dihydroxy-octadec-9-ynoate (**7**, 0.27 g, 24%) as determined from the following physical data: R_f = 0.1 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 3400 (O-H, str.), 1740 (C=O, str., ester) and 1460; ^{1}H NMR (δ_H) 0.88 (*t*, 3H, CH_3), 1.2–1.7 (*m*, 22H, CH_2), 2.31 (*t*, 2H, 2-*H*), 2.5 (*s*, *br*, O-*H*), 3.67 (*s*, 3H, COOCH_3), and 4.39 (*t*, 2H, -C≡C-C*H*OH-); ^{13}C NMR (δ_C) 14.10 (C-18), 22.59 (C-17), 24.77 (-C≡C-CHOH-CH$_2$-*C*H_2-), 24.88 (C-3), 28.79–29.23 (4C, *C*H_2), 31.81 (C-16), 34.03 (C-2), 37.57/37.76 (-C≡C-CHOH-*C*H_2-), 51.54 (COO*C*H_3), 62.34/62.40 (-C≡C-*C*HOH-), 85.81/86.04 (-*C*≡*C*-), and 174.40 (C-1).

Reaction of methyl octadeca-6,8-diynoate (**8**) with selenium dioxide/TBHP at 85°C for 20 h furnished a mixture of methyl 5-oxo- and 10-oxo-octadeca-6,8-diynoate (**9**, 0.13 g, 12%) as determined from the following physical data: R_f = 0.6 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 1740 (C=O, str., ester) and 1675 (C=O, str., oxo) ; ^{1}H NMR (δ_H) 0.88 (*t*, 3H, CH_3), 1.2–1.9 (*m*, 14H, CH_2), 2.3–2.5 (*m*, 6H, CH_2), 2.55, and 2.65 (*t*, 2H, -C≡C-C≡C-CO-CH_2-) and 3.68 (*t*, 3H, COOCH_3); 13C NMR (δ_C) 14.42 (C-18), 19.74/19.97 (-C≡C-C≡C-CH$_2$-), 22.99 (C-17), 24.30 (-C≡C-C≡C-CO-CH$_2$-*C*H_2-), 24.31/24.35 (C-3), 27.51–29.72 (5C, *C*H_2), 32.11/32.17 (C-16), 33.04/33.67 (C-2), 44.67/45.83 (-C≡C-CO-*C*H_2-), 51.93 (COO*C*H_3), 64.08/64.56 (-C≡C-*C*≡C-CO-), 72.31/ 72.73 (-C≡*C*-C≡C-CO-), 76.14/76.87 (-*C*≡C-C≡C-CO-), 89.96/91.39 (-C≡C-C≡*C*-CO-), 173.57/173.89 (C-1) and 186.35/187.63 (-C≡C-C≡C-*C*O-).

Reaction of methyl octadec-11*E*-en-9-ynoate (**10**) with selenium dioxide/TBHP at 75°C for 20 h gave two fractions: *viz.* methyl 8-oxo-octadec-11(*E*)*Z*-en-9-ynoate (**11**, 60 mg, 6%) as determined from the following physical properties: R_f = 0.6 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 2200 (C≡C, str.), 1740 (C=O, str. ester), 1670 (C=O, str. oxo), 1460 and 1420; ^{1}H NMR (δ_H) 0.89 (*t*, 3H, CH_3), 1.2–1.7 (*m*, 16H, CH_2), 2.19 (*dt*, *J* = 6.5 Hz, 2H, 13-*H*), 2.30 (*t*, 2H, 2-*H*), 2.56 (*t*, 2H, 7-*H*), 3.66 (*s*, 3H, COOCH_3), 5.63 (*d*, 1H, 11-*H*) and 6.28/6.47 (*m*, 1H, 12-*H*); ^{13}C NMR (δ_C) 14.07 (C-18), 22.57 (C-17), 23.95 (C-6),

24.73 (C-3), 28.23–29.03 (4C, CH_2), 31.01/31.50 (C-13), 31.60 (C-16), 33.94/34.05 (C-2), 45.24/45.40 (C-7), 51.43 ($COOCH_3$), 87.01/87.86 (C-9), 90.20/92.06 (C-10), 107.04/107.55 (C-11), 151.34/152.72 (C-12), 174.09 (C-1), and 187.87/187.97 (C-8); high-resolution mass spectrum: M^+ found 306.2195 (calc. for $C_{19}H_{30}O_3$, 306.2189), low-resolution mass spectral result [*m/z* (relative intensity)]: 275 (9.3), 221 (10.5), 217 (7.9), 178 (18.1), 172 (9.8), 171 (100), 164 (20.8), 163 (76.3), 149 (21.9), 139 (24.8), 135 (12.6), 121 (17.5), 111 (18.4), 107 (20.3), 105 (10.3), 95 (12.6), 94 (22.4), 93 (20.5), 91 (17.4), 83 (12.5), 81 (13.4), 79 (37.4), 77 (14.5), 73 (17.1), 69 (16.0) and 67 (12.1); and methyl 8-hydroxy-octadec-11*E*-en-9-ynoate (**12**, 0.74 g, 70%, 90% pure by NMR) as determined from the following physical data: R_f = 0.3 (using a mixture of *n*-hexane/diethyl ether, 4:1, vol/vol, as developer); IR (cm^{-1}) 3450 (O-H, str.), 1740 (C=O, str., ester), 1460 and 1440; ^1H NMR (δ_H) 0.88 (*t*, 3H, CH_3), 1.2–1.8 (*m*, 18H, CH_2), 2.08 (*dt*, *J* = 6.7 Hz, 2H, 13-*H*), 2.31 (*t*, 3H, 2-*H*), 2.40 (*s*, *br.*, O-H), 3.66 (*s*, 3H, $COOCH_3$), 4.48 (*t*, 1H, C*H*OH-), 5.48 (*d*, 1H, 11-*H*), and 6.16 (*m*, 1H, 12-*H*); ^{13}C NMR (δ_C) 14.10 (C-18), 22.60 (C-17), 24.86 (C-3), 25.02 (C-6), 28.65–29.03 (4C, CH_2), 31.66 (C-13), 31.79 (C-16), 34.06 (C-2), 37.82 (C-7), 51.51 ($COOCH_3$), 62.76 (C-8), 83.61 (C-10), 88.62 (C-9), 108.85 (C-11), 145.41 (C-12), and 174.34 (C-1).

RESULTS AND DISCUSSION

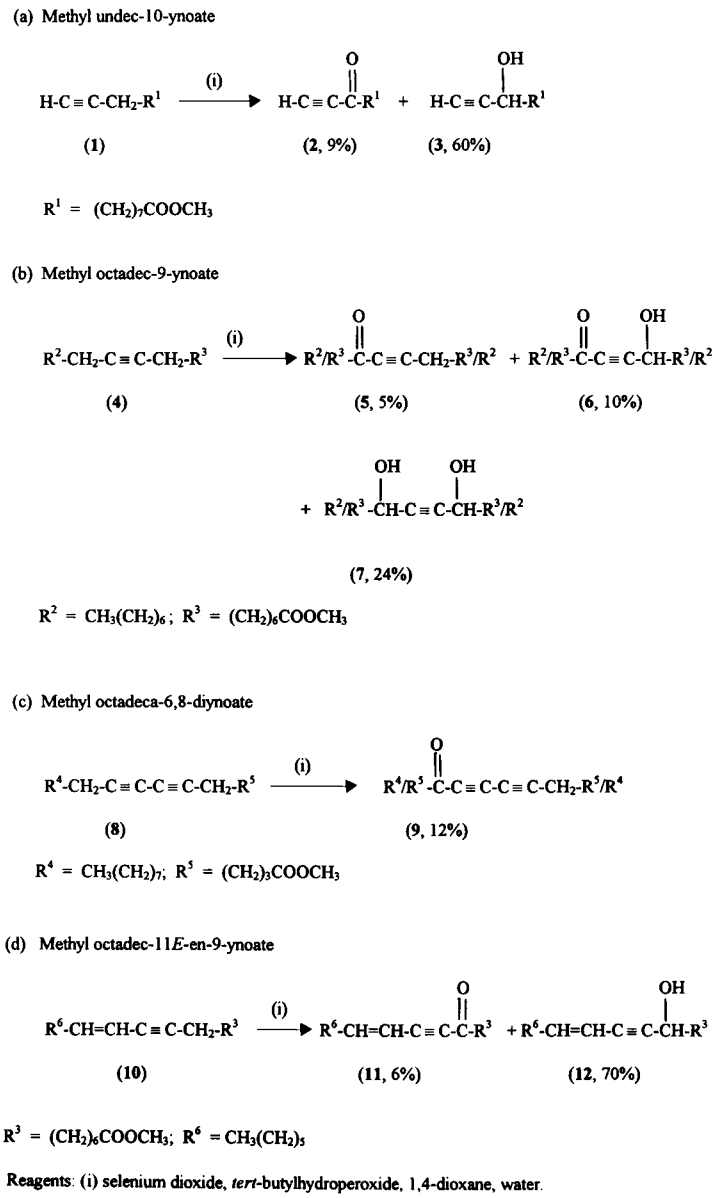
Selenium dioxide hydroxylation reactions of olefins are normally conducted in dichloromethane as the solvent (4). However, when methyl undec-10-ynoate (**1**) was stirred with SeO_2/TBHP in dichloromethane for 48 h as recommended, a complex mixture of products consisting of unreacted substrate, hydroxylated, and other polar oxygenated products was obtained. The polar products could not be separated into individual components by silica gel chromatography. A possible reason for obtaining such an intractable mixture of polar compounds is the absence of water in the system, which may cause attack of the unsaturated system in addition to propargylic hydroxylation of the methylene group adjacent to the acetylenic bond. In order to obtain a cleaner reaction product from such a reaction, various organic solvents or mixtures of solvents were tried. A mixture of dioxane and water (9:1, vol/vol) was found to offer the best reaction condition. Hydroxylation reactions were thus carried out in aqueous dioxane with methyl undec-10-ynoate (**1**), methyl octadec-9-ynoate (**4**), methyl octadeca-6,8-diynoate (**8**), and methyl santalbate (methyl octadec-11*E*-en-9-ynoate, **10**) as presented in Scheme 1.

Reaction of methyl undec-10-ynoate (**1**) with SeO_2/TBHP in aqueous dioxane gave two products. The less polar product was identified as methyl 9-oxo-undec-10-ynoate (**2**, 9%) from the IR absorption bands at 3250, 2100 (terminal acetylenic system), 1680 (C=O, oxo) cm^{-1} and confirmed by the shift of the acetylenic proton at δ_H 3.22 (*s*, 1H, -C≡C-*H*) and the following carbon shifts δ_C: 81.45 (C-10), 78.37 (C-11), 187.48 (C-9), 45.38 (C-8), and 23.65 (C-7). The shifts of the C-11 carbon atom were further confirmed by two-dimensional ^1H-^{13}C COSY correlation NMR spectroscopic technique. The polar and major fraction was found to be the hydroxylated product, methyl 9-hydroxy-undec-10-ynoate (**3**, 60%) as characterized by the IR absorption bands at 3450 (O-H), 3300 (-C≡C-H), 2350 (C≡C) cm^{-1} and supported by the shifts of the protons at δ_H 2.46 (*s*, 1H, -C≡C-*H*) and 2.99 (*s*, *br*, 1H, O-*H*) and carbon shifts at δ_C 72.62 (C-11), 85.25 (C-10), 62.02 (C-9), 37.56 (C-8), and 24.88 (C-7) ppm. The appearance of compound **2** in the reaction product showed that hydroxy-acetylenic ester **3** was further oxidized by SeO_2/TBHP.

Treatment of methyl octadec-9-ynoate (**4**) with SeO_2/TBHP under similar experimental conditions gave, on careful silica gel column chromatographic separation, three fractions containing mixtures of positional isomers of oxygenated acetylenic fatty esters: *viz.* methyl 8-oxo- and 11-oxo-octadec-9-ynoate (**5**, 5%), methyl 8-hydroxy-11-oxo- and 11-hydroxy-8-oxo-octadec-9-ynoate (**6**, 10%) and a fraction of pure dihydroxy-acetylenic fatty ester (methyl 8,11-dihydroxy-octadec-9-ynoate, **7**, 24%). The presence of two positional isomers in the isolated fractions (namely, compounds **5** and **6**) was apparent from the ^{13}C NMR spectra of these products, which showed twin signals (about 1:1 ratio in signal intensity) for some of the critical carbon signals.

The presence of a conjugated oxo-acetylenic system in compound **5** was evident from the IR absorption bands at 1680 (C=O) and 2150 (C≡C) cm^{-1} and was confirmed by the shifts of the following carbon atoms: δ_C 94.03/94.38 (-C≡*C*-CO-), 80.91/80.98 (-*C*≡C-CO-), 188.28/188.53 (-C≡C-*C*O-), 45.40/45.55 (-C≡C-CO-CH_2-), 18.91/18.95 (CH_2 -C≡C-CO-). The structures of the positional isomers of the hydroxy-keto derivatives **6** were identified by the absorption bands for the O-H (3450 cm^{-1}) and C=O (keto, 1675 cm^{-1}) vibrations in the IR spectrum and confirmed by ^1H NMR analysis: δ_H 4.52 [*t*, 1H, -CO-C≡C-C*H*(OH)-] and from the ^{13}C NMR analysis: δ_C 187.91 [-*C*O-C≡C-CH(OH)-], 83.46/92.64 [-CO-*C*≡*C*-CH(OH)-] and 62.12/62.19 [-CO-C≡C-*C*H(OH)-]. The ^{13}C NMR spectral analysis of the dihydroxy-acetylenic derivative **7** gave a "clean" spectrum with characteristic shifts at δ_C 85.81/86.04 for the shifts of the acetylenic carbon atoms [-(OH)CH-*C*≡*C*-CH(OH)-] and signals at δ_C 62.34/62.40 for the hydroxy-bearing methine carbon atoms [-(OH)-*C*H-C≡C-*C*H(OH)-]. Signals corresponding to the shifts of the methylene carbon atoms adjacent to the acetylenic bond were absent, which confirmed that these α-methylene groups were hydroxylated.

When methyl octadeca-6,8-diynoate (**8**) was reacted with SeO_2/TBHP in aqueous dioxane, a very complex mixture of polar oxidized derivative was obtained, which appeared as a continuous streak on a thin-layer chromatographic plate upon analysis. Separation of the reaction products by silica gel column chromatography permitted only a nonpolar fraction to be purified. This fraction comprised a mixture of methyl 5- and 10-oxo-octadeca-6,8-diynoate (**9**, 12%). These positional isomers gave a characteristic absorption band at 1675 cm^{-1}



SCHEME 1

for the C=O stretching vibration. The conjugated oxo-diacetylenic system (-CO-C≡C-C≡C-) was identified from the data of the ^{13}C NMR spectrum: δ_C 186.35/187.63 (-*C*O-C≡C-C≡C-) and by the four pairs of carbon signals at δ_C 64.08/64.56, 72.31/72.73, 76.14/76.87, and 89.96/91.39 due to the shifts of the diacetylenic carbon atoms. While no hydroxy-diacetylenic ester derivatives could be separated from the products of this reaction, the identification of compound **9** as a mixture of oxo-diacetylenic ester derivatives implied that the corresponding hydroxy-diacetylenic ester derivatives must have been initially formed during the reaction between the diacetylenic substrate and SeO_2/TBHP. Attempts to separate the complex polar fractions of this reaction as acetoxy derivatives by chromatography were unsuccessful.

Reaction of methyl santalbate (methyl octadec-11*E*-en-9-ynoate, **10**), which contains a conjugated enyne system in the alkyl chain, with SeO_2/TBHP in aqueous dioxane furnished a mixture of methyl 8-oxo-octadec-11(*E*)*Z*-en-9-ynoate (**11**, 6%) and methyl 8-hydroxy-octadec-11*E*-en-9-ynoate (**12**, 70%, 90% pure by NMR). Hydroxylation of methyl santalbate appeared to be regiospecific with the hydroxylation taking place only at the methylene carbon adjacent to the acetylenic bond to give a propargylic system. No product corresponding to an allylic hydroxy derivative, i.e., hydroxylation at the methylene carbon adjacent to the olefinic bond, was found. Compound **11** was characterized by the absorption bands at 1670 and 2200 cm^{-1} (α-oxo-acetylenes) and from the ^{13}C NMR spectral analysis: δ_C 31.01/31.50 (C-13), 45.24/45.40 (C-7), 87.01 /87.86 (C-9), 90.20/92.06 (C-10), 107.04/107.55 (C-11), 151.34/152.72 (C-12), and 187.87/187.97 (C-8). The presence of a signal at δ_C 31.01/31.58 due to the shift of the C-13 carbon atom indicated

that hydroxylation had not taken place at the α-methylene adjacent to the olefinic bond. This fact was also supported by the absence of a signal at δ_C 18-19 (shift region for a methylene carbon adjacent to an acetylenic bond). The high-resolution mass spectral analysis of compound **11** gave a molecular ion M^+ = 306.2195, which agreed closely with the calculated molecular mass (calc. 306.2189). From the low-resolution mass spectrum, the base peak at *m/z* 171 (100% intensity) and the ion fragment at *m/z* 163 (76.3% intensity) identified the position of the oxo function at the C-8 position of the alkyl chain. These peaks resulted from the α-cleavage of the C-C bonds adjacent to the C=O function.

The structure of compound **12** (methyl 8-hydroxy-octadec-11*E*-en-9-ynoate) was established on the basis of the following spectral data. The IR spectrum of this compound showed a broad and strong band at 3450 cm^{-1} for the stretching vibration of the hydroxy function. The ^1H NMR spectrum showed double triplet (J = 6.7 Hz) δ_H 2.08 due to the shifts of the allylic protons (13-*H* , -C*H*$_2$-CH=CH-C≡C-), and a triplet at δ_H 4.48 was due to the shift of the methine proton (8-*H*) bearing the hydroxy group. The doublet and multiplet at δ_H 5.48 and 6.16 were the result of the shifts of the 11-*H* and 12-*H* protons, respectively. The ^{13}C NMR spectrum of compound **12** showed a signal at δ_C 62.76 for the methine carbon atom of the *C*HOH system. The appearance of a signal for the C-13 carbon atom (δ_C 31.66) indicated that hydroxylation had not taken place at the α-methylene adjacent to the olefinic bond. This fact was also supported by the absence of a signal at δ_C 18-19 region for the shift of a methylene carbon atom adjacent to the acetylenic bond of the enyne system of methyl santalbate (17). A possible explanation for the regiospecific hydroxylation of the enyne system at the methylene adjacent to the triple bond is likely due to the stronger electron withdrawing property of the acetylenic bond (sp^1 character of the acetylenic carbon atoms) than that of the olefinic bond, which permits propargylic hydroxylation to proceed faster than the allylic hydroxylation. Also, the spectra and gas chromatographic analysis of the unreacted material obtained after the oxidation reaction revealed the presence of *Z*-isomer which suggests the isomerization of *E*-double bond of 1,3-enyne system to its *Z*-analog during the treatment with selenium dioxide. This observation is unprecedented and the isomerization of the double bond from the *E*- to the *Z*-double bond of the enyne system may be due to the catalytic effect of selenium metal generated from the hydroxylation process.

It can be concluded from these results that hydroxylation of methylene groups adjacent to an acetylenic bond was achieved when the acetylenic fatty ester substrates were reacted with SeO_2/TBHP in aqueous dioxane. Some of the hydroxy groups in these derivatives were also oxidized to the corresponding oxo functions. However, in the case of a conjugated olefin-acetylenic (enyne) system, the hydroxylation reaction was regiospecific with hydroxylation taking place at the methylene carbon atom adjacent to the acetylenic bond only. Thus, α-hydroxylation of methyl santalbate with SeO_2/TBHP gave exclusively methyl 8-hydroxy-octadec-11*E*-en-9-ynoate in 70% yield and 6% of the corresponding oxo derivative.

ARTICLE

The Effect of Dietary Docosahexaenoic Acid on Platelet Function, Platelet Fatty Acid Composition, and Blood Coagulation in Humans

G.J. Nelson[a], P.S. Schmidt[a,]*, G.L. Bartolini[a], D.S. Kelley[a], and David Kyle[b]

[a]Western Human Nutrition Research Center, ARS, USDA, San Francisco, California 94129, and [b]Martek Corporation, Columbia, Maryland 21045

ABSTRACT: The effect of dietary docosahexaenoic acid (DHA) in the absence of eicosapentaenoic acid (EPA) has been studied infrequently in humans under controlled conditions. This 120-d study followed healthy, adult male volunteers who lived in the metabolic research unit (MRU) of the Western Human Nutrition Research Center for the entire study. The basal (low-DHA) diet consisted of natural foods (30 en% fat, 15 en% protein, and 55 en% carbohydrate), containing <50 mg/d of DHA, and met the recommended daily intake for all essential nutrients. The high-DHA (intervention) diet was similar except that 6 g/d of DHA in the form of a triglyceride containing 40% DHA replaced an equal amount of safflower oil in the basal diet. The subjects (ages 20 to 39) were within −10 to +20% of ideal body weight, nonsmoking, and not allowed alcohol in the MRU. Their exercise level was constant, and their body weights were maintained within 2% of entry level. They were initially fed the low-DHA diet for 30 d. On day 31, six subjects (intervention, group A) were placed on the high-DHA diet; the other four subjects (controls, group B) remained on the low-DHA diet. Platelet aggregation in platelet-rich plasma was determined using ADP, collagen, and arachidonic acid. No statistical differences could be detected between the amount of agonist required to produce 50% aggregation of platelet-rich plasma before and after the subjects consumed the high-DHA diet. The prothrombin time, activated partial thromboplastin time, and the antithrombin-III levels in the subjects were determined, and, again, there were no statistically significant differences in these three parameters when their values were compared before and after the subjects consumed the high-DHA diet. In addition, the *in vivo* bleeding times did not show any significant difference before and after the subjects consumed the high-DHA diet (9.4 ± 3.1 min before and 8.0 ± 3.4 min after). Platelets from the volunteers exhibited more than a threefold increase in their DHA content from 1.54 ± 0.16 to 5.48 ± 1.21 (wt%) during the DHA feeding period. The EPA content of the subjects' platelets increased from 0.34 ± 0.12 to 2.67 ± 0.91 (wt%) during the high-DHA diet despite the absence of EPA in the subjects' diets. The results from this study on blood clotting parameters and *in vitro* platelet aggregation suggest that adding 6 g/d of dietary DHA for 90 d to a typical Western diet containing less than 50 mg/d of DHA produces no observable physiological changes in blood coagulation, platelet function, or thrombotic tendencies in healthy, adult males.

Lipids 32, 1129–1136 (1997).

Since the reports of Bang and Dyerberg (1–3) in the 1970s concerning the health and diets of indigenous Greenland natives, there has been intense interest in the health effects of dietary n-3 polyunsaturated fatty acids, particularly those with 20- and 22-carbon chain lengths and five or more double bonds. Bang and Dyerberg's observations immediately prompted human feeding studies (4–7) with marine oils. It was found that long-chain polyunsaturated n-3 fatty acids decrease plasma triacylglyceride levels (8,9) and caused a prolongation in bleeding times and a decrease in platelet aggregation to various agonists *in vitro* (10–12). Almost all the initial experimental feedings studies (5,6,8–12) used marine oils containing various proportions of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). It was often assumed that EPA was the physiologically active fatty acid in the oil that altered the metabolic pathways and hemostatic parameters measured in these experiments. For several years there has been controversy about the physiological consequences of dietary DHA contained in marine oils (13). Investigators using EPA concentrates were able to show that EPA alone would lower plasma triglycerides and prolong bleeding times (14–16). There was less interest in DHA, and no convenient source of purified DHA was available in sufficient quantity to use in human feeding studies.

Von Schacky and Weber (16) in 1985, using either purified EPA or DHA, reported that both compounds reduced platelet aggregation *in vitro*. They concluded that DHA is an important factor in the reduction of *in vitro* platelet aggregation when fish oils are consumed by humans. Still, this was a short-term study (6 d) with only seven volunteers, who consumed EPA and DHA as ethyl esters rather than triglycerides.

The physiological effects of dietary DHA are complicated, because as shown by several investigators (16–18), DHA is retroconverted to EPA *in vivo* by the "Sprecher shunt" (19, 20). Thus, even if one feeds only DHA to human volunteers, it is difficult to determine whether observed physiological changes are due to DHA or to EPA produced by retroconversion of dietary DHA. Still, we felt that it was important to test whether DHA in longer-term human feeding studies had the same physiological effects as reported for EPA or fish oils containing both EPA and DHA, particularly if the DHA could be fed in the form of a triglyceride.

Recently a purified triacylglycerol oil, produced by a selected algal strain, containing 40% DHA and no EPA has become available in sufficient quantities to conduct human feeding studies (DHASCO™; Martek Biosciences Corp., Columbia, MD). This study was designed to determine if the physiological and biochemical changes reported in humans consuming marine oils containing both EPA and DHA or EPA alone can be reproduced by a diet containing only DHA. This paper reports the results of this study on platelet function *in vitro*, bleeding times, coagulation factors, and platelet fatty acid composition from a human feeding study in which a group of normal healthy volunteers consumed a diet containing 6 g/d of DHA and no EPA for 90 d after a 30-d stabilization period during which they consumed a diet containing less than 50 mg/d DHA.

STUDY DESIGN

The study was designed as a longitudinal, single-blind feeding study in which 12 healthy volunteers lived in the metabolic research unit (MRU) of the Western Human Nutrition Research Center for 120 d. All subjects were fed a stabilization diet (low-DHA) for 30 d after they entered the MRU. On day 31 of the study, 8 of the subjects, designated Group A, were switched to a diet (high-DHA) containing 6 g/d of DHA (from 15 g of DHASCO™ oil). The remaining 4 subjects, designated Group B, continued to consume the low-DHA diet, which contained less than 50 mg/d of DHA. Two subjects dropped out of the study, both from Group A. The subjects were discharged from the MRU on day 120 of the study. Figure 1 shows a schematic plan of the study design and the times of the blood draws.

The protocol for this study was approved by the Institutional Review Boards of the University of California at Davis and the USDA, Houston, TX. The subjects were fed the low-DHA diet, containing about 30% of calories as fat for 30 d, then divided into two groups. Group A (n = 6) was switched to a high-DHA diet containing 6 g/d of DHA (15 g/d of DHASCO™ oil). They remained on this diet for 90 d. Group B (n = 4) continued on the low-DHA diet.

At the beginning of the study, each participant's caloric intake was estimated and the caloric content of the meals calculated to maintain current body weight. As the estimates were subject to error, the participants were weighed every day and the caloric value of their meals adjusted occasionally, if necessary, to maintain their weight within the limits of the study, i.e., ±2% of their weight upon entry into the study. Thus, the average weights of the participants did not vary significantly during the 120 d of the study. If all the intakes for each volunteer were averaged during the entire study, the mean energy intake was approximately 2800 Kcal/d.

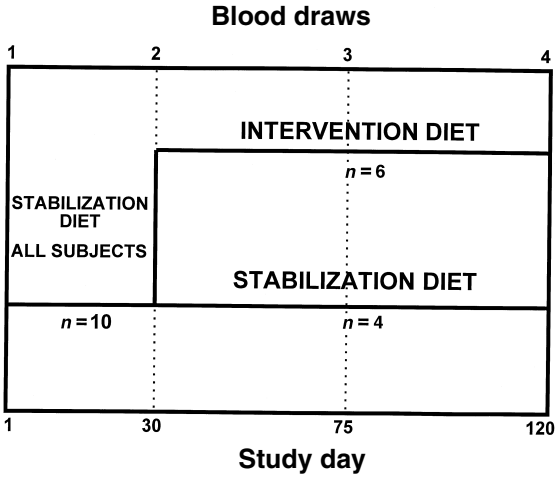

FIG. 1. Schematic plan of the design for this feeding study showing the days of the blood draws and dietary periods. Note that the values were compared for the intervention group (A) after 30 d on the stabilization diet to that obtained after 90 d on the intervention diet.

Diets. Except for DHA supplement in the form of the DHASCO™ oil and a vitamin E supplement, the diets consisted of natural foods. The macronutrient composition of the diets is given in Table 1. (A complete description of the diets, listing all the major and minor nutrients, is available upon request.) A 5-d menu cycle was used throughout the study.

Proximate analysis was made on five individual diet composite samples taken from each menu once during the study for both the stabilization and intervention diets. The results for the five composite samples were averaged to find the actual composition of the diets. No alcohol was included in these diets. The nutrient composition of the diets was calculated from a computerized nutrient data bank using the data from USDA Handbook 8 (21) and adjusted to provide at least the recommended daily intake for known essential nutrients (22). A supplement of 20 mg/d of d-α-tocopherol [Vitamin E (obtained from Bronson Pharmaceutical, St. Louis, MO), 100-mg capsules given every 5 d] was included in the diet to ensure adequate antioxidant levels in the volunteers during the study.

Table 2 gives the measured fatty acid composition of both diets. Inspection of Table 2 indicates that all the major fatty acids were very similar except that the level of DHA was elevated in the high-DHA diet and the level of linoleic acid was reduced.

MATERIALS AND METHODS

The fatty acid composition of the DHASCO™ oil is given in Table 3. The oil also contained 0.025% α-tocopherol and 0.025% ascorbyl palmitate. The oil was kept under nitrogen and at −20°C until it was needed for food preparation. Open bottles were flushed with N_2 before they were resealed and returned to the refrigerator. Since the DHA was fed in a cold yogurt cocktail once daily, it is unlikely that any oxidative degradation took place between the time when the food was prepared and it was eaten. The control group also consumed a yogurt cocktail containing safflower oil once daily.

Subjects. The physical characteristics of the subjects on entry into the study (Study Day 0) are given in Table 4. Initially 12 volunteers were included in the study, but two were unable to complete the protocol; both were from intervention Group A. Thus, at the end of the study, Group A had six volunteers and the control, Group B, had four. See the section on statistical analyses below for information on the analyses of the data from the two groups.

Measurements. Blood was drawn according to the schedule shown in Figure 1 between 7:00 and 8:00 a.m. after an overnight fast. It was drawn into vacutainers with appropriate anticoagulants using a Teflon catheter (Angiocath; Deseret Medical, Sandy, UT) for fatty acid analysis or into syringes containing 1 mL of citrate solution for platelet aggregation studies (23). Platelet-rich plasma (PRP) was prepared by low-speed centrifugation for 10 min at 100 × g. Platelet-poor plasma was prepared by respinning the blood after removal of the PRP for 15 min at 400 × g (24).

Platelet aggregation. Solutions of the aggregating agents were prepared as recommended by Chrono-log Corp. (Havertown, PA) as follows: ADP, 1 μM/μL; collagen, 0.5 μg/mL; arachidonic acid, 0.05 μM/μL. The *in vitro* aggregation characteristics of the subjects' platelets were measured in a Chrono-log Model 560 dual channel aggregometer. An aggre-

Age: Yr (mean ± SD)	33.1 ± 4.8	33.3 ± 6.1
Weight: kg (mean ± SD)	78.6 ± 11.0	74.7 ± 8.4
Body mass index: kg/M^2 (mean ± SD)	23.7 ± 2.0	23.1 ± 2.3
Blood pressure: systolic (mean ± SD)	128.0 ± 17.4	118.8 ± 7.5
Blood pressure: diastolic (mean ± SD)	75.5 ± 7.6	69.3 ± 7.6
Bleeding times: min (mean ± SD)	7.6 ± 2.8	6.4 ± 1.2

[a]Sex, all male; smokers, none.

gation testing methodology description has been published elsewhere (24). The threshold for aggregation was determined when the amount of a particular reagent produced at least 50% of maximum aggregation within 15 min of its addition to the PRP. PRP preparations were all adjusted to 300,000 platelets/mm^3. All aggregation tests were performed within 4 h of the initial blood draw.

Platelet counts. Platelet counts were determined with an electronic particle counter, a Baker-Serono Model 9000 Differential Cell Counter (Allentown, PA) electronic particle counter and cytometer using the manufacturer's recommended procedures (Operations Manual, System 9000 Differential Cell Counter, Baker-Serono Diagnostics, Inc., Allentown, PA, 1988, Manual No. DS-014A) (25).

Bleeding times. Bleeding times were measured on the left or right proximal forearm of each subject using a 1-mm deep by 1-cm long incision using a Simplate II bleeding time device (Organon Teknika, Durham, NC). A wipe of the incision was made every 30 s. Time was measured with a hand-held stopwatch (24).

Clotting factors. Prothrombin time (PT) and the activated partial thromboplastin times (APTT) were measured by the methods described by Houghie (24). Briefly, platelet poor plasma was prepared as described elsewhere (24), and the PT and APTT were measured using the Bio/Data Corporation Model MCA 110 instrument (Bio/Data Corporation, Hatboro, PA) with Organon Teknika coagulation reagents.

Lipid extraction and fatty acid analysis. Platelets were extracted by the procedures described by Nelson (27,28) using chloroform/methanol (2:1, vol/vol). Samples were then transmethylated with methanolic HCl (7%, w/w) by the procedures described elsewhere (29,30). When the total lipid extract was transmethylated, the impurities, extracted into the hexane phase after termination of the reaction, were removed by thin-layer chromatography as described by Nelson (28). Because the amount of material available from human platelets for fatty acid analysis was limited, fatty acid methyl esters were obtained by direct transmethylation of the intact tissue without prior solvent extraction as described in an earlier publication (31). The conditions of the capillary gas–liquid chromatography have been described elsewhere (29). The gas–liquid chromatographic column was a 30-m by 0.25-mm fused-quartz column coated with SP-2340 purchased from Supelco, Inc. (Bellefonte, PA). The gas–liquid chromatographic data were processed with Hewlett-Packard ChemStation software (Palo Alto, CA) running on an IBM-compatible desktop computer.

Statistical analysis. The clotting data and aggregation data were analyzed using the paired *t*-test with $n = 6$ for the intervention group (A) or $n = 4$ for the control group (B), or analysis of variance with repeated measures. The subjects acted as their own controls; statistically significant differences were determined by comparing values of the various parameters on study days 30 (baseline) and 120 (end of study). Because the small number of subjects in the control made the chances of detecting significant changes in that group unlikely, no statistical comparisons were made between the control group and the intervention group. The control group was included to detect temporal drift while the volunteers were confined to the MRU. The fatty acid data were analyzed with a single-tailed t-test. All the statistical analyses were performed with the PC SAS data system, version 6.11, obtained under license from the SAS Institute PC-SAS (SAS PC Manual; SAS Institute, Chapel Hill, NC, 1993).

RESULTS

In this study very few physiological changes in the blood clotting systems, platelet function, or the platelet fatty acid composition were detected in subjects who consumed DHA at the level of 6 g/d for 90 d. The average bleeding times for the six subjects after consuming the high-DHA diet for 90 d were 8.00 ± 3.36 min compared to a baseline value of 9.36 ± 3.06 min on study day 30 (they had consumed the low-DHA diet for 30 d). Thus, in these six subjects the bleeding time was actually less after consuming DHA, but the difference between these values did not reach statistical significance ($P = 0.06$). Bleeding time values for the four control subjects were 5.88 ± 0.25 min at 30 d and 6.38 ± 1.89 min at 120 d. Red blood cell counts, hemoglobin levels, and the average hematocrit did not change significantly in either group during the study. Blood pressure, which was measured daily in all volunteers, did not change significantly from the baseline values in either the intervention or control groups throughout the study.

Table 5 lists the platelet aggregation *in vitro* and the platelet counts determined after 90 d on high-DHA diets and 30 d on the low-DHA diet for the 10 subjects in this study. The platelet counts are the actual platelet numbers in whole blood of the volunteers, not the adjusted values used for the aggregation tests. Again, there were no statistically significant changes in either the aggregation values or the platelet

[a]Values reported as mean ± standard deviation. For abbreviation see Table 1.

counts when the results from the two diets are compared. Table 6 lists some values for the soluble blood coagulation parameters for these subjects before and after they consumed the high-DHA diet. Neither the PT nor APTT values were different after the subjects had consumed either diet, although the antithrombin-III was slightly lower after they had consumed the DHA diet; the difference did not reach statistical significance.

Figure 2 compares the total fatty acid composition of the whole platelets after the subjects consumed the high-DHA diet for 90 d with the composition after 30 d on the low-DHA. The DHA, linoleic acid, oleic acid, arachidonic acid, EPA, and docosapentaenoic acid content of the platelets showed statistically significant changes ($P < 0.05$) between the two diets. DHA appeared to replace arachidonic acid, with some reduction of oleic and linoleic acids also. EPA increased markedly in the volunteers' platelets despite the fact that they consumed none of this compound. Presumably the EPA was produced by retroconversion of DHA. This is normalized weight percentage data, and if the percentage of one or more fatty acids increases then, obviously, one or more fatty acids must decrease. The four control subjects did not show any significant changes between days 30 and 120 while they were consuming the low-DHA diet.

DISCUSSION

Epidemiological studies (32–34) have consistently found an inverse relationship between intake of fish or marine food and cardiovascular disease. Most investigators have made the assumption that it is the presence of n-3 polyunsaturated fatty acids in marine organisms that provides the beneficial effects (4–10). Furthermore, feeding studies with marine oils or pu-

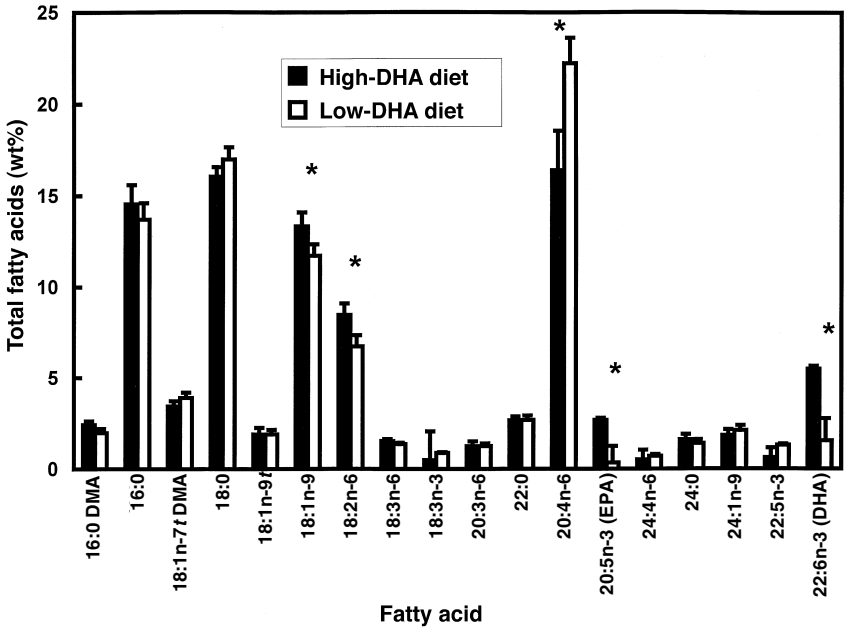

FIG. 2. The total fatty acid composition of the platelets after the consumption of the low-DHA (docosahexaenoic acid) and high-DHA diets by the intervention group in this study. The control group is not shown, but there were no differences among the various fatty acids compared after 30 d and 120 d on the stabilization diet. Individual fatty acids are designated by carbon chain length, number of double bonds in the molecule, and the position of the first double bond from the methylene end of the molecule. The asterisks designate fatty acids that are significantly different between the two diet periods with *P* values of less than 0.05. The vertical lines define one standard deviation from the means for the six subjects in the intervention group. Only fatty acids present in amounts greater than 0.5% of the total fatty acids are displayed in this figure. Abbreviations: DMA, dimethyl acetal; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

rified n-3 fatty acids tend to support this assumption (12, 14–16). Marine oils, containing various proportions of DHA and EPA when added to human diets, tend to reduce platelet aggregation and increase bleeding times (10–12,35). In this study, DHA in the absence of EPA was fed to human volunteers. Dietary DHA did not have significant effects on the major hemostatic parameters such as bleeding time or platelet aggregation, at least, not when consumed at 6 g/d for 90 d. Also, the soluble clotting factors as measured by the PT, the APTT, and antithrombin-III (considered a measure of the *in vivo* thrombotic tendency) were unchanged in the volunteers who consumed 6 g/d of DHA.

These findings are contrary to the report of von Schacky and Weber (16), who found that DHA caused a significant reduction in platelet aggregation in six subjects who consumed ethyl docosahexaenoate for 6 d. The retroconversion of DHA to EPA as reported by von Schacky and Weber (16) and others (3,36) was also observed. Perhaps there is a compensatory adaptation to the higher levels of DHA in the circulation when DHA is fed for a longer period. Thus, von Shacky and Weber (16) may have measured a transitory change in platelet function that the experimental design in our study would not detect. Also, Sanders and Hinds (37) observed an increase in the lag time for collagen-induced platelet aggregation when fish oil was consumed. No similar lag time was found in this study when DHA was the only n-3 fatty acid in the diet.

It should be noted, however, that EPA appears in the blood and tissues in levels equivalent to that obtained when EPA is fed to subjects in marine oils or seafoods (16,18,36) when DHA is fed in the absence of EPA. Conquer and Holub (36) recently demonstrated that dietary DHA, free of EPA, was retroconverted to EPA at a rate of 9.4%. In an accompanying paper (38) we report that dietary DHA does lower plasma triglyceride levels similarly to fish oils and purified EPA preparation. As the plasma EPA levels in these volunteers rose significantly, EPA could still be the physiologically active agent that caused the triglyceride lowering.

Nevertheless, dietary DHA in this study did not cause the changes in hemostatic physiological parameters attributed to fish oils or EPA. Indeed, even at 6 g/d, a level that is about 100 times the typical intake of DHA in the United States (39), it appears to have no short-term adverse consequences. In another aspect of this reported elsewhere (40), it was observed that dietary DHA does inhibit the production of thromboxane, but this inhibition is less than that observed when EPA is fed to humans. Furthermore, dietary DHA does not suppress prostacyclin production while dietary EPA does (40).

The retroconversion of DHA to EPA observed in this work and in studies by other investigators (16,18,36) raises interesting questions regarding these findings that dietary DHA has little effect on the hemostatic parameter in normal human males. The levels of EPA found in the circulation of the volunteers in this study are equivalent to the levels reported by other investigators (37) in studies in which significant changes in several hemostatic parameters, such as bleeding times and *in vitro* platelet function, were detected. In an earlier study from this laboratory, feeding salmon for 50 d caused a slight change in platelet aggregation in response to ADP. Of course, salmon does contain both EPA and DHA, although more DHA than EPA. These paradoxical findings are difficult to explain, as is the finding of von Schacky and Weber (16), that DHA was more effective than EPA in reducing platelet aggregation. EPA synthesized by retroconversion may be compartmentalized and unable to interact with appropriate trigger mechanisms. This is possible but not likely. Another explanation is that our experiment was too short to detect the effects described by others, although the feeding period in this study was longer than many of the studies in the literature (16,37,41) but less than others (42–44). Also, it should be noted that there are a number of reports (45–47) of studies that did not find changes in hemostatic function after fish oil supplementation. However, as platelet aggregation tests are notoriously variable, and the number of subjects in this study was small, it may be that the power of the study was too small to detect changes, although this is unlikely because of the high dosage, 6 g/d of DHA, fed in this study.

Von Schacky and Weber (16) did not find any changes in the platelet fatty acid composition after supplementation with DHA for 6 d. In contrast Conquer and Holub (36), after feeding 1.6 g/d of DHA for 42 d, reported marked changes in the platelet total fatty acids quite similar to those reported here. Apparently little exchange of fatty acids between platelets and plasma occurs *in vivo*. Thus, changes in platelet fatty acid composition caused by changes in dietary fatty acid intake are probably produced by incorporation of fatty acids into the megakaryocytes in the bone marrow during the platelet formation and maturation process. In this study even more DHA was incorporated into the volunteers' platelets than observed by Conquer and Holub (36) presumably owing to the higher dosage fed to the volunteers.

It is difficult to correlate changes in platelet fatty acid composition with platelet functions or *in vitro* aggregation. In an earlier study done here (35), the consumption of a salmon diet caused a modest change in the EPA and DHA levels in the volunteers' platelets, and these changes for both EPA and DHA were less than those found when 6 g/d of DHA were fed. Yet the salmon diet caused a small decrease in platelet aggregation by ADP, a phenomenon not detected here. A complete explanation of these observations must await further studies, feeding purified DHA or EPA and combinations of both.

The findings reported here and elsewhere (5,7–9,15,36) suggest that in short-term human feeding studies, there are few adverse effects from markedly increased levels of DHA in the diet. Tracer studies (48,49) show that very little α-linolenic acid is converted to DHA in human adults; thus, dietary DHA may be helpful in replacing tissue stores of DHA without the need to convert precursor fatty acids to DHA. However, it would be prudent to increase the daily intake of antioxidant vitamins if significant quantities of highly unsaturated fatty acids are added to the diet in light of the current concern over oxidized low-density lipoproteins (50,51), free

radical damage to cells (52,53), and the free-radical theory of aging (54).

ACKNOWLEDGMENTS

The authors wish to acknowledge the help of the staff at our Center. We are especially indebted to the MRU staff, without whose help this study could not have been conducted, including the nursing staff who drew the blood and the dietetics staff who prepared the food. We also thank Dr. Paloma Benito for her reading and suggestions of this paper.

ABSTRACT: Normal, healthy male volunteers ($n = 6$) were fed diets [high docosahexaenoic acid-DHA] containing 6 g/d of DHA for 90 d. The stabilization (low-DHA) diet contained less than 50 mg/d of DHA. A control group ($n = 4$) remained on the low-DHA diet for the duration of the study (120 d). Blood samples were drawn on study days 30 (end of the stabilization period), 75 (midpoint of the intervention period), and 120 (end of the intervention period). Adipose tissue (AT) samples were taken on days 30 and 120. The plasma cholesterol (C), low density lipoprotein (LDL)-C and apolipoproteins (apo) [AI, B, and lipoprotein (a)] were unchanged after 90 d, but the triglycerides (TAG) were reduced from a mean value of 76.67 ± 24.32 to 63.83 ± 16.99 mg/dL ($n = 6$, $P < 0.007$ using a paired *t*-test) and the high density lipoprotein (HDL)-C increased from 34.83 ± 4.38 mg/dL to 37.83 ± 3.32 mg/dL ($n = 6$, $P < 0.017$ using a paired *t*-test). The control group showed no significant reduction in plasma TAG levels. Apo-E, however, showed a marked increase in the volunteers' plasma after 90 d on the high-DHA diet, from 7.06 ± 4.47 mg/dL on study day 30 to 12.01 ± 4.96 mg/dL on study day 120 ($P < 0.002$ using a paired *t*-test). The control subjects showed no significant change in the apo-E in their plasma (8.46 ± 2.90 on day 30 vs. 8.59 ± 2.97 on day 120). The weight percentage of plasma DHA rose from 1.83 ± 0.22 to 8.12 ± 0.76 after 90 d on the high-DHA diet. Although these volunteers were eating a diet free of eicosapentaenoic acid (EPA), plasma EPA levels rose from 0.38 ± 0.05 to 3.39 ± 0.52 (wt%) after consuming the high-DHA diet. The fatty acid composition of plasma lipid fractions—cholesterol esters, TAG, and phospholipid—showed marked similarity in the enrichment of DHA, about 10%, after the subjects consumed the high-DHA diet. The DHA content of these plasma lipid fractions varied from less than 1% (TAG) to 3.5% (phospholipids) at baseline, study day 30. EPA also increased in all plasma lipid fractions after the subjects consumed the high-DHA diet. There were no changes in the plasma DHA or EPA levels in the control group. Consumption of DHA also caused an increase in AT levels of DHA, from 0.10 ± 0.02 to 0.31 ± 0.07 (wt%) ($n = 6$, $P < 0.001$ using a paired *t*-test), but the amount of EPA in their AT did not change. Thus, dietary DHA will lower plasma TAG without EPA, and DHA is retroconverted to EPA in significant amounts. Dietary DHA appears to enhance apo-E synthesis in the liver. It appears that DHA can be a safe and perhaps beneficial supplement to human diets.

Lipids 32, 1137–1146 (1997).

Dietary marine oils may have beneficial roles in the prevention of cardiovascular disease (1–3) and other diseases (4). These oils contain a high content of long-chain n-3 polyunsaturated fatty acids, mainly eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). Fish oils and purified EPA are powerful antihypertriglyceridemic agents (5,6) and may now be the agents of choice in the treatment of uncomplicated hypertriglyceridemia (7). However, it is not known if dietary DHA without EPA has the same antihypertriglyceridemic properties as EPA or fish oil. Although there are many studies in the scientific literature in which fish (8–11), fish oil supplements (12–16), or purified EPA (16–18) have been fed to human volunteers, there are only a few reports in which investigators have fed only DHA without EPA (19,20).

DHA is a normal constituent of the human diet (21) if one is not a vegan, and is found in most cells and tissues in significant amounts (22). DHA appears to have a major role in human physiology, particular in the development of the nervous system and in normal vision (23). *In vivo* DHA can be retroconverted to EPA (19,24). Recently, considerable interest in the metabolism and physiological function of dietary DHA has developed (25–27). Also, as plasma lipids and lipoprotein (Lp), and perhaps the circulating fatty acids associated with plasma lipids, are predictors of cardiovascular risk, it seems important to learn if dietary DHA has independent effects on blood lipids and lipid metabolism in general. In view of the lack of controlled human-feeding studies and the unresolved question about the physiological effects of dietary DHA coupled with the commercial availability of a natural triglyceride (TAG) containing about 40% DHA, we conducted a human-feeding study with DHA in a metabolic research unit (MRU). Normal human volunteers were chosen

Abbreviations: AA, Arachidonic acid; apo, apolipoprotein; AT, adipose tissue; C, cholesterol; DHA, docosahexaenoic acid; DPA, docosapentaenoic; EPA, eicosapentaenoic acid; FA, fatty acid; FFA, free fatty acids; HDL, high density lipoprotein; LDL, low density lipoprotein; Lp, lipoprotein; MRU, metabolic research unit; RBC, red blood cells; TAG, triglycerides.

to avoid confounding by lipid abnormalities and to obtain baseline data. The dose of DHA was based on the maximum amount consumed by volunteers in earlier studies. The detailed protocol and design of the study have been described in a previous paper (28).

This paper reports the effects on several lipid parameters of supplementing a natural food diet (containing <50 mg/d DHA) with 6 g/d of DHA as a TAG. The supplementation period was 90 d. Results from analyses of blood lipid levels, fatty acid (FA) composition of the plasma, red cells and adipose tissue (AT), Lp cholesterol levels, and selected apolipoprotein (apo) levels are presented.

STUDY DESIGN

The design was a single-blind, feeding study in which 12 healthy volunteers lived in the MRU of the Western Human Nutrition Research Center for 120 d. All subjects were fed a stabilization diet (low-DHA), about 30% of calories from fat, for 30 d after they entered the MRU. On day 31 of the study, eight of the subjects, designated Group A, were switched to a diet containing 6 g/d of DHA (from 15 g of DHASCO® oil; Martek Biosciences Corporation, Columbia, MD). The remaining four subjects, designated Group B, continued to consume the low-DHA diet that contained less than 50 mg of DHA. The subjects were discharged from the MRU on day 120 of the study. For further details see the previous paper (28).

Subjects. The physical characteristics of the subjects and the recruitment process were described in the previous paper (28). The Institutional Review Boards of the University of California at Davis and the U.S. Department of Agriculture approved the protocol for this study. Initially, 12 volunteers were included in the study, but two subjects, both from group A, were unable to complete the protocol.

During confinement, blood was drawn on study days 2, 30, 75, and 120. AT samples were taken on study days 30 and 120. Although we analyzed the various parameters under study on all volunteers on these study days, values from samples obtained on days 30 and 120 were used for statistical analysis.

MATERIALS AND METHODS

A description of the oil (DHASCO®) and its FA composition is given in the previous paper (28). The oil was kept under nitrogen and at −20°C until it was needed for the food preparation. Open bottles were flushed with N_2 before they were resealed and returned to the freezer. As the DHA was fed in a cold yogurt cocktail, it is unlikely that any oxidative degradation took place between the time the food was prepared and when volunteers ate it.

Diets. The nutrient composition of the diets was calculated from a computerized nutrient data bank using the data from *USDA Handbook* (29) and adjusted to provide at least the RDA for known essential nutrients (30). A detailed description of the diets is given in the previous paper (28). A complete description of the diets, listing all the major and minor nutrients, is available upon request.

Measurements. Blood was drawn according to the schedule described above between 7:00 and 8:00 A.M. after an overnight fast. It was drawn into vacutainers with appropriate anticoagulants (either citric acid, 1% solution, or EDTA depending on the subsequent use of the sample) using a Teflon catheter (Angiocath; Deseret Medical, Sandy, UT) for FA analysis. Red cells for FA analysis were prepared from the residue by resuspending the cells in 10 mL of phosphate buffered saline and recentrifuging the cells at $400 \times g$ for 15 min three times. The supernate was discarded. The red cells were frozen at −70°C until extraction of the lipids. AT biopsy samples were taken from the buttocks using a hypodermic syringe equipped with 13 gauge stainless-steel needle (28). The samples (10 to 50 mg) were immediately transferred to cold (0°C) isotonic saline, then placed in a −70°C freezer within an hour and stored until further processing.

AT FA analyses. The FA analyses of the AT samples were done by procedures published previously (31). Briefly, the tissue was extracted with $CHCl_3$/MeOH (2:1, vol/vol), the extract transmethylated with methanolic HCl (7%), the methyl ester extracted with hexane, and the FA analyzed by gas–liquid chromatography as mentioned below.

Lipid extraction and FA analysis. Plasma and red cell samples were extracted by the procedures described by Nelson (32,33) using chloroform/methanol (2:1, vol/vol). Samples were then transmethylated with methanolic HCl (7%, w/w) by the procedures described previously (34,35). When the total lipid extract was transmethylated, the impurities, extracted into the hexane phase after termination of the reaction, were removed by thin-layer chromatography as described elsewhere (33). The conditions of the capillary GLC have been described previously (34). Briefly, the column was a 30-m × 0.025-mm fused quartz column coated with SP-2340 (Supelco, Inc., Bellefonte, PA). The GLC data were processed with a Hewlett-Packard ChemStation software (Palo Alto, CA) running on an IBM compatible desktop computer.

Apo analysis. The apo AI (36) and B (37) were analyzed using commercial kits (Sigma Diagnostics, St. Louis, MO). The apo E (38) and Lp(a) (39) were determined using commercial ELISA kits (Perlimmune, Inc., Rockville, MD).

Plasma lipid analyses: triglyceride (TAG) and cholesterol determinations. Plasma cholesterol, TAG, high density lipoprotein (HDL)-cholesterol, and low density lipoprotein (LDL)-cholesterol were analyzed in a Cobas-Faras centrifugal analyzer (Hoffman-La Roche, Nutley, NJ) using automated enzymatic methods as described by McGowan *et al.* (40) and Allain *et al.* (41).

Statistical analysis. The lipid, Lp, and apo data were analyzed using the paired *t*-test with $n = 6$ for the intervention group (A) or $n = 4$ for the control group (B) or analysis of variance with repeated measures. The subjects acted as their own controls; statistically significant differences were determined by comparing values of the various parameters on study days 30 (baseline) and 120 (end of study). No statisti-

cal comparisons were made between the control group and the intervention group due to the small size of the groups. The control group was included to detect temporal drift while the volunteers were confined to the MRU. The fatty acid data were analyzed with a single tailed *t*-test. All the statistical analyses were performed with the PC SAS data system, version 6.11, obtained under license from the SAS Institute, PC-SAS, (*SAS PC Manual*, SAS Institute, Chapel Hill, NC, 1993).

RESULTS

Blood lipids. The blood lipid values of the volunteers on entry to the study for both the control and intervention groups are given in Table 1. Table 2 lists the blood lipid values at study days 30 (baseline) and 120 (end of intervention) for both groups. The addition of 6 g/d of DHA to a natural-food diet for 90 d did not affect the total plasma cholesterol value or the LDL-cholesterol (C) value in these volunteers (See Table 2); however, the plasma TAG levels decreased significantly ($P < 0.004$, using a paired *t*-test). The HDL-C value rose 3 mg/dL and was significant at $P < 0.02$. The control group's TAG, LDL-C, and HDL-C values were unchanged after the group had consumed the low-DHA diet for 90 d. There was a slight decrease in the control group's plasma total cholesterol value, $P < 0.03$, that can be attributed to the low-cholesterol, low-fat diet given to them during this study.

TABLE 1
Blood Lipid Values of Subjects on Entry into the Docosahexaenoic Acid Feeding Study[a]

	Control group[b] (mg/dl)	Intervention group[c] (mg/dl)
Total cholesterol	188.0 ± 60.1	186.8 ± 25.3
LDL-cholesterol	121.7 ± 32.9	129.2 ± 17.2
HDL-cholesterol	46.3 ± 9.4	37.7 ± 8.1
Triacylglycerols	102.3 ± 83.6	99.5 ± 40.1

[a]Mean values ± SD.
[b]$n = 4$.
[c]$n = 6$; LDL, low density lipoprotein; HDL, high density lipoprotein.

Apoproteins. The plasma values for apo-A1, apo-B, and Lp(a) showed very little change (see Table 3) before and after the volunteers consumed the high-DHA diet. Although apo-A1 level decreased about 7 mg/dL and the Lp(a) decreased about 4 mg/dL, these changes were not statistically significant (Table 2); however, the Lp(a) levels rose significantly in the control group ($P < 0.01$), perhaps attributable to the low cholesterol, low-fat diet given the volunteers, although this may have been a statistical quirk due to the small number of volunteers in the control group. Apo-E, however, showed a marked increase in its plasma concentration after the subject had consumed the high-DHA diet, from 7.06 ± 4.47 mg/dL on study day 30 to 12.01 ± 4.96 mg/dL on study day 120 ($P < 0.002$ using a paired *t*-test). The control subject showed no significant change in their apo-E content in their plasma (8.46 ± 2.90 on day 30 vs. 8.59 ± 2.97 on day 120).

Plasma fatty acids. Significant changes in the total plasma FA composition in all subjects in the intervention group were observed, with a fourfold increase in the total plasma DHA level and a similar increase in the plasma EPA level after the consumption of the high-DHA diet by the volunteers. (Fig. 1). In the control group there were no significant changes in the FA composition of the subjects' tissues during the 90 d when they consumed the low-DHA diet (data not shown). In the intervention group, a reduction in the plasma oleic acid, linoleic and arachidonic acid (AA) contents was noted. None of the other plasma FA levels changed significantly. The changes in the FA composition of the individual lipid classes showed few differences from the pattern found in the total plasma FA composition. On study day 30 (low-DHA diet) the volunteers' plasma TAG contained little DHA, about 0.6%. This increased to almost 10% on the high-DHA diet (Fig. 2). Also, the EPA levels went from less than 0.3 to 1.7% in these volunteers after 90 d on the high-DHA diet. Most of the increases were compensated by a decrease in the oleic and linoleic acid contents of the TAG. The changes in the DHA and EPA levels in the cholesterol esters (Fig. 3) were similar to those observed in TAG, although the main reduction was in the palmitic acid content while the oleic and linoleic acid contents were largely unchanged. No other FA showed sig-

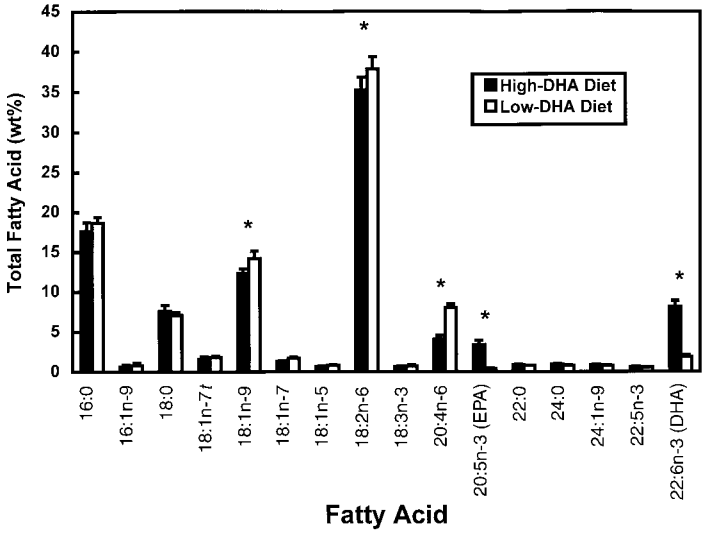

FIG. 1. The mean ($n = 6$) values for the major fatty acids in the subjects' plasma after the subjects in the intervention group had been on the low-docosahexaenoic acid (DHA) (30 d) or high-DHA diet (90 d). The asterisks indicate fatty acid values that differed significantly by at least $P < 0.05$ between the two dietary periods. The vertical lines define one standard deviation from the means for the six subjects in this study. Fatty acids are designated by chain length, number of double bonds in the molecule, and the position of the first double bond from the methylene end of the molecule. A "*t*" at the end of the notation is an abbreviation for a *trans* fatty acid. EPA, eicosapentaenoic acid.

nificant changes in the cholesterol ester fraction. The phospholipid fraction's FA composition underwent similar changes with a marked increase in DHA and EPA contents after the subjects consumed the high-DHA diet (Fig. 4). The DHA level rose from 3.1 to 10.1%, and the EPA content rose from 0.6 to 3.8%. In the phospholipid fraction, however, the AA content dropped noticeably, from 9.2 to 5.6 %, while most of the other major FA showed little change.

Adipose tissue. The total FA composition of the AT is shown in Figure 5. Table 4 lists the DHA and EPA content in the AT. The volunteers' AT contained very little DHA (<0.15%) before consumption of the high-DHA diet; the DHA content of the AT underwent a threefold increase after the volunteers consumed the high-DHA diet for 90 d. The EPA level in the AT did not change significantly during the feeding period, although it should be noted that it was approximately five times the DHA level at baseline.

Red blood cells (RBC). Figure 6 shows the FA composition of the RBC before and after dietary supplementation with DHA. DHA supplementation appeared to increase the level of palmitic, stearic, and DHA and lower the level of linoleic acid and AA in the red cell.

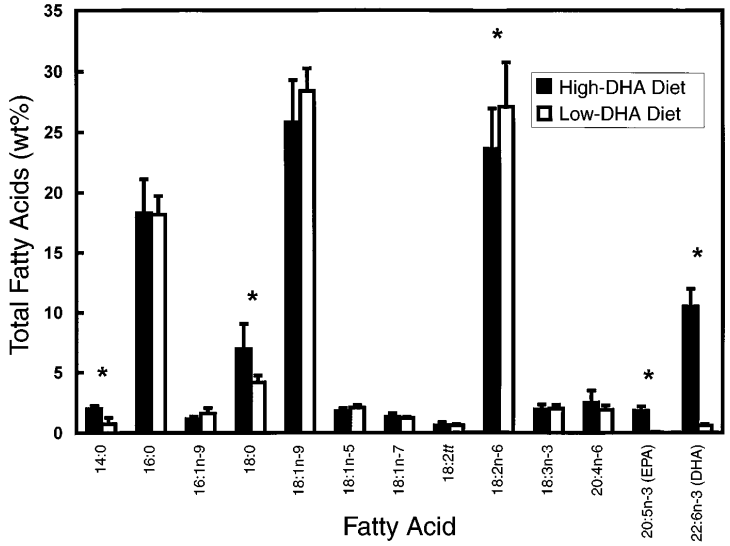

FIG. 2. The mean (n = 6) values for the major fatty acids in the subjects' plasma triglyceride fraction after the subjects in the intervention group had been on the low-DHA (30 d) or high-DHA diet (90 d). The asterisks indicate fatty acid values that differed significantly by at least $P < 0.05$ between the two dietary periods. The vertical lines define one standard deviation from the means for the six subjects. Fatty acid abbreviations are described in the caption to Figure 1.

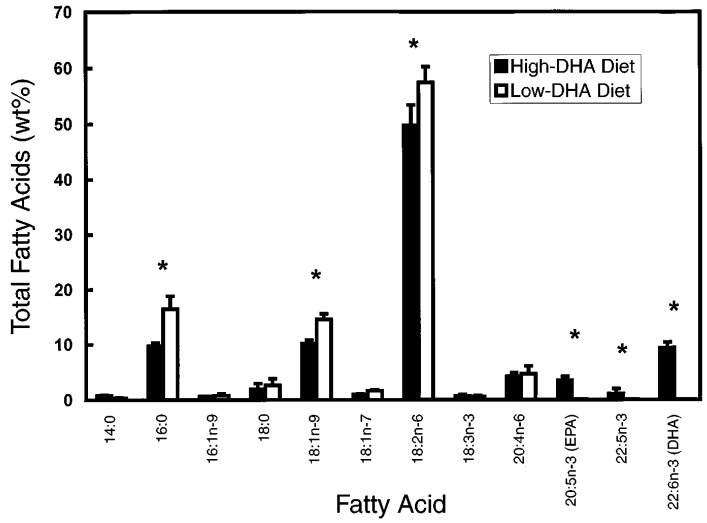

FIG. 3. The mean (n = 6) values for the major fatty acids in the subjects' plasma cholesterol ester fraction after the subjects in the intervention group had been on the low-DHA (30 d) or high-DHA diet (90 d). The asterisks indicate fatty acid values that differed significantly by at least $P < 0.05$ between the two dietary periods. The vertical lines define one standard deviation from the means for the six subjects. Fatty acid abbreviations are described in the caption to Figure 1.

DISCUSSION

When the DHA in the diet was increased for 90 d from less than 50 mg/d to 6 g/d in an isocaloric substitution for linoleic acid, there was a marked decrease in the plasma TAG level without a corresponding change in the plasma cholesterol level. In this diet, about 2% of calories were polyunsaturated n-3 fatty acids (DHA) while the linoleic acid content of the diet was reduced by an equal amount while holding the saturated and monounsaturated fat content of the diet constant. The Lp patterns did show a reduction in the very low density lipoprotein and a rise in the HDL fractions without a change in the LDL fraction. The individuals studied in this work were all healthy, normolipidemic subjects (28), and achieving lipid

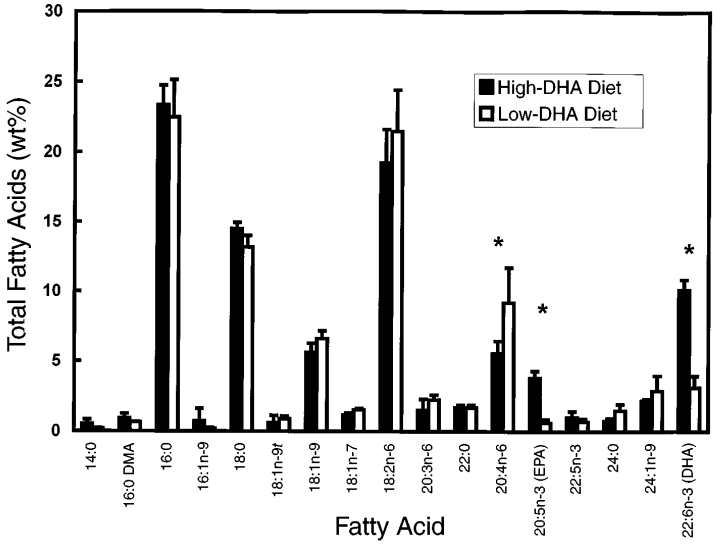

FIG. 4. The mean (n = 6) values for the major fatty acids in the subjects' plasma phospholipid fraction after the subjects in the intervention group had been on the low-DHA (30 d) or high-DHA diet (90 d). The asterisks indicate fatty acid values that differed significantly by at least $P <$ 0.05 between the two dietary periods. The vertical lines define one standard deviation from the means for the six subjects. Fatty acid abbreviations are described in the caption to Figure 1.

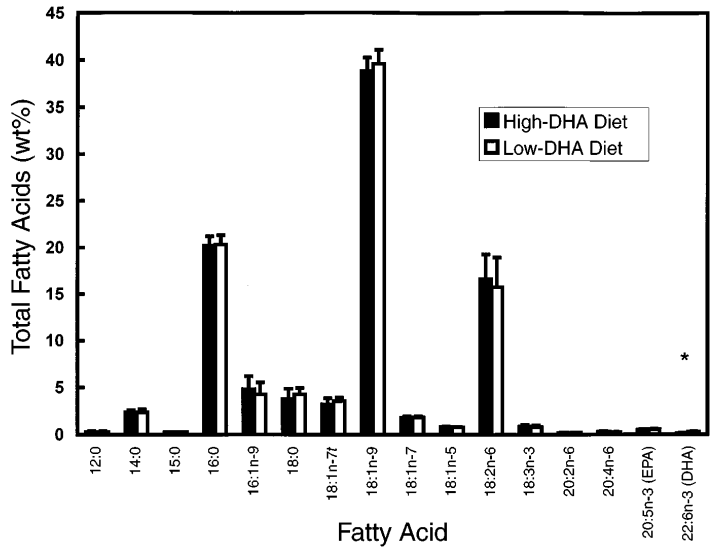

FIG. 5. The mean values for the major fatty acids in the subjects' adipose tissue after the subjects in the intervention group had been on the low-DHA (30 d) or high-DHA diet (90 d). The vertical lines define one standard deviation from the means for the six subjects. Fatty acid abbreviations are described in the caption to Figure 1.

reductions in normolipidemic persons is more difficult than in hyperlipemic subjects (42,43). Thus, increasing the DHA content of the diet in hypertriglyceridemic individuals may cause a more marked reduction in plasma TAG levels than observed here. Also, the polyunsaturated/saturated ratio was constant in this study at about 1:1. Hayes and Khosla (44,45) have suggested that plasma lipid levels show little alteration with changes in the amount of FA in the diet if the linoleic acid content of the diet is above 7%, as it was in this study.

Perhaps the most distinctive change in the plasma Lp observed after DHA feeding was the marked increase in the apo-E content. To our knowledge, this increase in plasma apo-E content after feeding n-3 FA to people has not been reported previously. Although several studies (46–48) have shown that feeding of n-3 FA, particularly EPA, decreased apo-B secretion from the liver, though not necessarily a decrease in plasma apo-B concentrations (49), apo-E was usually not measured in these studies (46–49). Other investigators have

TABLE 4
DHA and Eicosapentaenoic Acid Contents of Adipose Tissue After High-DHA or Low-DHA Diets[a]

[a]Total fatty acids (wt%).

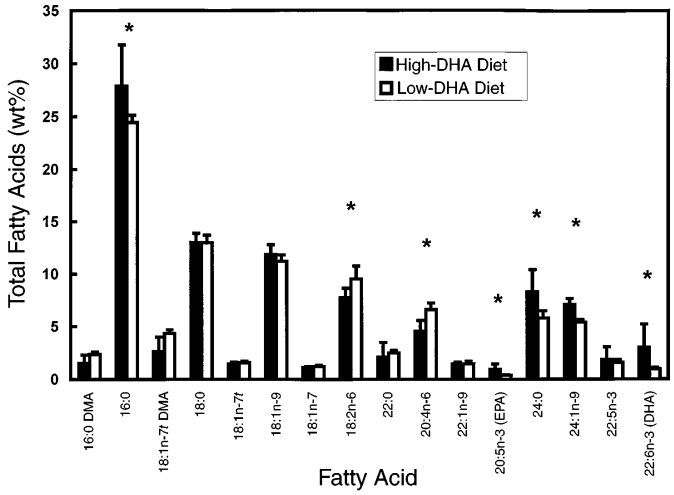

FIG. 6. The mean (n = 6) values for the major fatty acids in the subjects' red blood cells after the subjects in the intervention group had been on the low-DHA (30 d) or high-DHA diet (90 d). The asterisks indicate fatty acid values that differed significantly by at least $P < 0.05$ between the two dietary periods. The vertical lines define one standard deviation from the means for the six subjects. Fatty acid abbreviations are described in the caption to Figure 1.

reported a decrease in Lp(a) after n-3 FA feeding (50,51). In this study the Lp(a) levels did decrease slightly, but the decrease was not statistically significant perhaps because the number of volunteers was too few. The slight decrease in the total cholesterol and Lp(a) levels in the control group may have been caused by the low-fat, high n-6 diet fed to these volunteers although the number of individuals (4) in the control group was small with a commensurately greater chance of a false positive result.

A 6 g/d increase in dietary DHA has significant effects on the FA profile of the plasma. Normally, the plasma FA profile reflects the dietary FA profile (44,52,53). The observations reported from this study regarding the plasma FA composition of individuals consuming DHA without dietary EPA agree well with the recent report of Conquer and Holub (20) in which they reported their data as mol% rather than wt%. They fed volunteers 1.6 g/d of DHASCO® compared with 6 g/d used here; however, the increase in total plasma DHA content was quite similar, from 2.2 mol% at day zero to 7.6 mol% after 42 d on the supplement. Conquer and Holub (20) also found that the EPA levels in their subjects rose from 0.73 mol to 1.16 mol% after the volunteers consumed DHA for 42 d. In an earlier study von Schacky and Weber (19) reported that in volunteers fed 6 g/d of ethyl DHA for 6 d, plasma phospholipid DHA levels doubled. These authors also found a significant increase in the EPA content of the plasma phospholipids, presumably due to retroconversion of DHA in their volunteers. Thus, increased dietary DHA causes a rapid increase in plasma DHA, but it is apparent from the data of von Schacky and Weber (19) that retroconversion of DHA to EPA occurs within 6 d. In this study, no samples were taken in that period although there is no reason to assume that retroconversion was any slower here. Apparently, other body FA pools of DHA turn over much more slowly than the plasma FA pool (28).

In a typical, fasting normolipidemic individual, there is a pool of 15 g of plasma FA in the circulation based on a typical plasma total lipid level of 5 mg/dL and a 6-L blood volume. If one calculated the increase in the percentage of DHA found in the plasma in this study (from about 2 to 10%), much less than one day's dietary intake of DHA appears in the plasma (6 g/d fed vs. 2.5 g in the plasma pool). Even taking into account how much DHA is retroconverted to EPA and that found in the AT, only 3 to 3.5 g of the daily intake of DHA can be accounted for in the plasma of the volunteers

studied here. This observation suggests that an appreciable amount of DHA is retained in the liver and oxidized as rapidly as it is absorbed, which is consistent with observations on the disappearance of dietary α-linolenic and stearic acids (52,54). In contrast to this observation for n-3 FA, the situation with n-6 FA may be different. When 1.5 g/d of AA was fed to normal volunteers, most of it appeared in the plasma AA pool (55). Of course, the amount of AA fed in that study was only one-fourth the amount of DHA fed in this study.

The level of DHA in AT has been suggested as a convenient marker for habitual fish consumption by Marckmann *et al.* (56). In their report (56), the AT DHA levels, based on wt% of total FA, were almost identical to those reported here, 0.1% for 0 g/d of fish consumption to 0.3% for 70 g/d day of fish consumption. The EPA-to-DHA ratio in individuals who do not eat fish or fish products is about 5, and in fish-consuming individuals it drops to 1.6. Although the volunteers' plasma EPA content increased about 10 times, the AT EPA content in these volunteers did not change significantly during the study.

It should be noted, however, that the phospholipids were not separated from the TAG in the AT samples. FA from TAG make up about 98% of the total fatty acids in AT. Thus, the results given here represent primarily the TAG FA composition. As the phospholipids of AT have a different metabolic pathway from TAG, incorporation of DHA into the phospholipids of AT may have been different also although the data of Phinney and colleagues (31,57) and Nelson *et al.* (55) do not suggest that there are major differences between the incorporation of various FA in AT phospholipids and TAG.

Data from Phinney and colleagues (31,57) show that weight loss alone can alter the FA composition of AT. This suggests that release of fat from the AT during caloric deficiency is selective although there is no known mechanism to explain such a process. In individuals not consuming large amounts of DHA, its presence in AT is very low. Here a marked increase in the DHA level in the plasma TAG was observed while the increase in the level in DHA in the AT was much less. Of course, these subjects were in caloric balance, and their weight loss or gain was restricted to less than 2% of their body weight at entry into the study (28). Hence, little new fat was deposited in their AT. Apparently, only 400 mg of the total of 540 g of DHA consumed by the volunteers in this study was incorporated into their AT, based on the difference between the percentage of DHA in the AT at beginning and end of the intervention period. Thus, we can speculate that (i), the increased dietary DHA is rapidly metabolized to other compounds, hence not available for incorporation into AT, or (ii), that the turnover of FA in the AT is so slow in subjects with constant weight that a 90-d period is not long enough to equilibrate the AT. The data from Marckmann *et al.* (56) would suggest that this latter hypothesis is not the explanation as their subject did not have higher levels of DHA than those in this study even after 8 months on a high marine-oil diet. Hence, the former hypothesis is more likely.

The life span of RBCs is approximately 120 d in humans. These red cell FA composition data presented here represent a nonequilibrium state; hence, they are difficult to interpret. It is interesting, however, to note that the increase in the DHA level was small, but the decrease in the linoleic acid level in the red cells was much larger. The decrease in linoleic acid was compensated by increases in the palmitic and stearic acids levels rather than the DHA level in the red cells of these subjects. There is no readily apparent explanation for these changes. One can speculate, however, that increased dietary DHA interferes with incorporation of linoleic acid into RBC. The RBC then compensate by incorporating *in vivo* synthesized palmitic and stearic acids into their phospholipid in place of linoleic acid.

The intake of linoleic acid was reduced in the high-DHA diet by about 7 g/d compared to the low-DHA diet. It is possible that some of the effects observed in this study were due to the reduction of linoleic acid rather than the increase in DHA. This is unlikely, however, as the subjects were still receiving more than 20 g/d of linoleic acid on the high-DHA diet, an amount well above any known requirement for linoleic acid, and an amount that would flood the FA metabolic pathways. The low-DHA diet contained less than 50 mg of DHA per day and the high-DHA diet had 6 g/d. This is an increase of more than 120 times; certainly this dietary change is more likely to produce metabolic effects than a 20% reduction in the daily linoleic acid intake. Still, additional research is needed to resolve this issue definitely.

In conclusion, this study indicates that dietary DHA fed at 6 g/d lowers plasma TAG but does not affect cholesterol levels significantly. Dietary DHA at this level does markedly raise the DHA levels in the plasma. Also, dietary DHA is incorporated into AT but only in small amounts, about 0.1% of the total amount consumed during 90 d. The turnover of RBC is 120 d so equilibrium would not be obtained in a 90-d study, and changes in the FA composition of RBC may still occur when DHA is fed for longer periods. Still, the results from this study show that dietary DHA fed at 6.0 g/d for 90 d is well tolerated and does not cause any grastrointestinal side effects. In fact, dietary DHA may be beneficial in altering the individual's cardiovascular disease risk profile with respect to blood lipids and Lp that are risk factors for cardiovascular disease, but this remains to be established by longer-term studies.

Addendum. After this work was submitted, Vidgren *et al.* (58) published a report of a feeding study with human volunteers who consumed either fish (0.67 g/d DHA), fish oil (0.95 g/d DHA), or an algal oil rich in DHA (1.68 g/d) without any EPA. These authors reported the FA composition of the various plasma lipid fractions (TAG, cholesterol esters, and phospholipids), platelets, and RBC in a 14-wk, free-living study in which the diet was uncontrolled. Their results were similar to those reported here except that they reported increases in the DHA content in the various lipid fractions that were less than those found in this work presumably because the amount of DHA fed was about three times less per day (1.68 vs. 6.0 g/d) than the amount used in this study. The major difference between our results and those of Vidgren *et al.* (58) was that at 6 g/d of DHA incorporation of DHA into the plasma lipid

classes were about equal at 10% (wt%) of the total FA while Vidgren (56) found preferential incorporation DHA into the TAG and phospholipid fractions and little incorporation of DHA into cholesterol esters fraction. Thus, incorporation of dietary FA into particular plasma lipid fractions may be dependent on the amount in the diet.

ACKNOWLEDGMENTS

The authors wish to acknowledge the help of the staff at the Western Human Nutrition Research Center. We are especially indebted to the MRU staff, without whose help this study could not have been conducted, including the nursing staff who drew the blood and the dietetics staff who prepared the food. We also wish to thank the bioanalytical laboratory staff who did the plasma cholesterol, TAG, and Lp analyses, and Dr. Paloma Benito for her careful reading and suggestions for improvement of this paper.

Pancreatic Bile Salt-Dependent Lipase Activity in Serum of Normolipidemic Patients

Nathalie Caillol, Eric Pasqualini, Eric Mas, Anne Valette, Alain Verine, and Dominique Lombardo*

INSERM U-260, 13385 Marseille Cedex 5, France

ABSTRACT: Bile salt-dependent lipase (BSDL, E.C. 3.1.1.-) is a digestive enzyme secreted by the pancreatic acinar cell. Once in the duodenum, the enzyme, upon activation by primary bile salts, hydrolyzes dietary lipid esters such as cholesteryl esters and lipid-soluble vitamin esters. This enzyme is partially transferred from the duodenum or pancreas to the circulation where it has been postulated to exert a systemic action on atheroma-generating oxidized-low density lipoprotein (LDL). In the present study, sera from 40 healthy normolipidemic volunteers were used to investigate the possible linkage between circulating BSDL, lipids, and lipoproteins. We showed, firstly, that pancreatic-like BSDL activity can be detected in these serums. Secondly, BSDL activity increased significantly with the level of LDL-cholesterol and was also positively linked to the serum concentration of Apo B100 and Apo A-I. Thirdly, we also established that BSDL was associated with LDL, in part by a specific interaction with Apo B100, while no interaction was found with Apo A-I. No linkage with other recorded parameters (triglycerides, phospholipids, and high density lipoprotein-cholesterol) was detected. Because an increase in LDL-cholesterol represents an important risk factor for atheroma, the concomitant increase in BSDL, which can metabolize atherogenic LDL, suggests for the first time that this circulating enzyme may exert a positive effect against atherosclerosis.

Lipids 32, 1147–1153 (1997).

Pancreatic bile salt-dependent lipase (BSDL), also referred to as carboxyl ester lipase or bile salt-dependent cholesterol ester hydrolase, is a 100 kDa enzyme which hydrolyzes cholesteryl and lipid-soluble vitamin esters, triglycerides, and (lyso)phospholipids (1,2). Except for the latter substrates, bile salts are a prerequisite for hydrolysis (3). Although the enzyme was secreted into the duodenum where it exerted its digestive function, BSDL has been shown to transit throughout the enterocyte (4). As a consequence, BSDL is found in the blood plasma of humans (5) where lipoproteins are possible targets for the enzyme. Nevertheless, BSDL activity in serum cannot be measured on cholesteryl esters or triglycerides, owing partly to the competitive effect of circulating lipoproteins (6). It has effectively been shown that BSDL has the capability to hydrolyze low density lipoprotein (LDL)-cholesteryl esters in the presence of a concentration of bile salts achievable in plasma (7,8). Of physiological importance is the fact that BSDL reduces the atherogenicity of oxidized LDL by decreasing its lysophospholipid content (9). Evidence has accumulated to suggest that oxidized LDL is a key component in endothelial injury (10). Once formed by the endothelium, oxidized LDL may directly injure the vascular tissue and induce migration of monocytes and T lymphocytes in the intima (11). Oxidized LDL is enriched in lysophosphatidylcholine, which acts as a chemoattractant that recruits monocytes to the subintimal space (12). Once monocytes enter the subendothelial space, oxidized LDL may participate in the activation of monocytes into macrophages. These latter cells internalize LDL through scavenger receptors (13) and can oxidize LDL through several pathways (14). During this process, fatty acids undergo peroxidation which, in turn, yields a variety of reactive molecules, which can become covalently crosslinked to the apolipoprotein (Apo) B100 moiety of LDL particles. This could further exacerbate the atherogenic process. As a result, antioxidants such as probucol and vitamin E have been suggested as a means of preventing atherosclerotic lesions. Given the role attributed to lysophosphatidylcholine in the promotion of atherosclerosis, it has been proposed that BSDL could serve as a protective factor against the deleterious effects of oxidized LDL observed in atherosclerosis (9). Consequently, the aim of this study was twofold: (i) an attempt to accurately record BSDL activity in serum, and (ii) an investigation of whether the activity of circulating BSDL was linked to lipids and/or Apo present in serum.

EXPERIMENTAL PROCEDURES

Patients. Sera from 40 patients (27 women, 13 men, age range of 21–85 years) were used in this study. None had liver or pancreatic disease or was undergoing insulin treatment nor was taking corticosteroids, oral contraceptives or lipid-lowering agents. All were normoalbuminemic (>540 μmol/L). Blood (citrated) samples were drawn at 9:00 a.m. after an

Abbreviations: Apo, Apolipoprotein; BSDL, bile salt-dependent lipase (E.C. 3.1.1.-); DFP, diisopropyl fluorophosphate; HDL, high density lipoproteins; LDL, low density lipoproteins; LPL, lipoprotein-lipase; VLDL, very low density lipoproteins.

overnight fast while subjects had rested for at least 20 min. The study protocol was approved by our Ethics Committee, and informed consent was obtained from all subjects.

Immunoprecipitation. Polyclonal antibodies (*pAb L64*) specific for human pancreatic BSDL were obtained, purified, and, when required, immobilized on agarose beads as described previously (15). Twenty µL of a suspension of immobilized *pAb L64* (corresponding to 100 µg of antibodies) was added (assays) to 100 µL of serum sample and incubated for 4 h at 25°C under agitation. Beads were then pelleted by centrifugation at 10,000 × *g* for 20 min. The esterolytic activity was recorded in the supernatant. Controls were performed under the same conditions, omitting immobilized antibodies. Under these conditions, the difference in activity between control and assay was representative of the BSDL activity in serum.

Enzyme assay. Esterolytic activity of serum samples was spectrophotometrically determined using 4-nitrophenyl hexanoate as substrate (16) at 404 nm in a thermostated cell at 30°C. The substrate was dissolved in 0.2 M Tris/HCl, pH 7.4 buffer containing NaCl (150 mM). Assays were performed in the absence or presence of sodium taurocholate (4 mM) as activator of BSDL. Under these conditions, the difference of measured activity was representative of the bile salt-activated esterolytic activity present in serum samples. Diisopropyl fluorophosphate (DFP)-inhibited esterolytic activity of serum was obtained after sample incubation (1 h at 25°C) in the presence of 4 mM DFP (stock solution 1 M in dry isopropyl alcohol) or of vector alone. Then the esterolytic activity of serum was recorded in the presence of bile salts as described before. The difference in activity before and after DFP treatment represents the DFP-inhibited esterolytic activity. Unless otherwise stated, DFP-inhibited esterolytic activity represents the activity of BSDL (see below).

Polyacrylamide gel electrophoresis (PAGE) and Western blotting. PAGE in the presence of sodium dodecyl sulfate (SDS-PAGE) was performed according to Laemmli (17). Replicas of SDS-PAGE on nitrocellulose membranes were obtained after electrotransfer. These replicas were then treated as previously described (18) using *pAb L64* as the primary antibody. Alternatively, SDS-PAGE was stained with Coomassie blue R250 (Fluka, Buchs, Switzerland).

Apo preparation. Human plasma was adjusted to a density of 1.210 g/cm^3 with solid KBr then centrifuged in a SW 40 rotor (Beckman Instruments, Palo Alto, CA) at 100,000 × *g* for 24 h at 4°C. The supernatant containing mixed very low density lipoprotein (VLDL), LDL, and HDL was again centrifuged under the same conditions and finally dialyzed for 24 h against a 10 mM Tris/HCL buffer pH 7.4 (154 mM, NaCl; 1 mM EDTA; and 0.01% NaN_3). VLDL, LDL, and HDL were isolated by ultracentrifugation on a KBr density gradient according to Chapman *et al.* (19), after chylomicrons had been removed by preliminary centrifugation at 10,000 × *g* for 30 min at 4°C. Apo B100 and Apo A-I were then isolated, respectively, from LDL and HDL preparations as described by Karlin *et al*. (20). Their integrity was analyzed by SDS-PAGE and Western-blot using specific antibodies to Apo B100 and Apo A-I from Sigma Diagnostics (St. Louis, MO).

Apo immobilization. Human Apo B100 and Apo A-I were linked to Sepharose (Pharmacia, Uppsala, Sweden) using epoxy-activated Sepharose 6B (Pharmacia) according to the manufacturer's protocol. Under the conditions used, more than 80% of the Apo was coupled to Sepharose beads. Excess reactive groups, after immobilization of Apo B100 or Apo A-I (or all reactive groups of the control gel), were blocked with 1 M ethanolamine. In a typical experiment, 2.0 mg of pure Apo A-I (i.e., 70 nmoles) or 7.4 mg of Apo B100 (i.e., 15 nmoles) were coupled to 1 g of epoxy-activated Sepharose 6B gel. After exhaustive washings, gels were stored at 4°C in 0.1 M sodium bicarbonate buffer, pH 8.0 (0.5 M NaCl).

BSDL iodination. BSDL was purified from human pancreatic juice as previously described (3); then 10 µg of the pure protein was iodinated with ^{125}I-Na by the chloramine-T method. The radiolabeled BSDL (8 mCi/mg protein) was chromatographed on a Sepharose 6B column (1 × 60 cm), equilibrated, and eluted with 10 mM sodium phosphate buffer (pH 7.4) before use. During the iodination process, no BSDL degradation could have occurred because radiolabeled BSDL comigrates with the native BSDL on the Sepharose 6B column, and more than 87% of radiolabeled BSDL was precipitable with trichloroacetic acid. Stored at 4°C, this preparation remained stable for at least one month.

Binding of BSDL to lipoproteins. Isolated lipoproteins (500 µL; concentration adjusted to the initial plasma concentration) were incubated for 15 min at 37°C in the presence of 400 ng of ^{125}I-BSDL (4 pmoles, 600 ± 35 cpm/ng of BSDL) in 10 mM Tris/HCl buffer pH 7.4 (containing 154 mM NaCl, 1 mM EDTA, and 0.01% NaN_3). At the end of the incubation period, the mixture was chromatographed on a fast protein liquid chromatography-Superose 6 column (Pharmacia) (2 × 60 cm) eluted (0.5 mL/min) with the dialysis buffer. Radioactivity and optical density at 280 nm were monitored in each fraction. A blank experiment was performed by gel filtration under the same conditions of 400 ng of ^{125}I-BSDL added to 20 µg of pure BSDL (40 µg/mL) as a vector.

Interaction between BSDL and Apo. Sepharose-immobilized Apo beads were equilibrated and suspended in 10 mM Tris/HCl buffer pH 7.4 (1 mM EDTA; 0.15 M NaCl), adjusted to the same final amount of gel corresponding to 1 nmole of Sepharose-immobilized Apo B100 or to 5 nmoles of Sepharose-immobilized Apo A-I and pelleted. Immobilized-Apo were finally suspended in 1 mL of buffer and supplemented with approximately 1 pmole of ^{125}I-BSDL and with increasing amounts (from 0 up to 0.50 nmole) of unlabeled BSDL. Tubes were then incubated overnight at 4°C under gentle agitation. The tubes were quickly centrifuged on a benchtop centrifuge, gel pellets were washed several times with the incubation buffer, and the remaining radioactivity of the pellet suspended in counting liquid was recorded. Corrections for nonspecific binding were performed by using adequate amounts of control gel and treated under the same conditions.

Other procedures. Serum concentrations of phospholipids, triacylglycerol, cholesterol, and glucose were measured in duplicate by enzymatic methods (Boehringer Mannheim, Ger-

many; BioMérieux, Charbonnières-les-Bains, France; Roche Diagnostic Systems, Neuilly, France; and Sigma Diagnostics). Apo A-I and Apo B100 were evaluated by turbidimetric methods using specific antiserum to Apo (Turbiquant kit from Behring, Marbur, Germany). HDL-cholesterol was determined after precipitation of LDL and VLDL by phosphotungstic acid in the presence of magnesium ions (HDL-cholesterol kit from BioMérieux). The supernatant, obtained after centrifugation, contained the HDL from which the cholesterol was determined as above. LDL-cholesterol was assayed as described above after specific precipitation of LDL using polycyclic anionic surfactant (LDL-cholesterol kit from BioMérieux).

Statistical analysis. Results were expressed as means ± SD. The significance of differences was examined using Student's *t*-test. Regression lines were calculated by the least-squares method from individual data. Statistical comparisons between regression lines were performed by analysis of covariance. Probability values of $P < 0.01$ were considered significant. Because of serum volume needs to perform this study, not all determinations were done on each serum sample. Consequently, we provided the number of samples, *n*, used for statistical analysis along with the *P* value and the linear regression factor, *r*.

RESULTS

BSDL in serum. First we attempted to find a specific assay for BSDL activity in serum. For this purpose, the activity of BSDL present in serum of normolipidemic patients was estimated by an *in vitro* assay using 4-nitrophenyl hexanoate as substrate. Under our conditions, the difference in activity recorded in the presence or absence of bile salt represents the bile salt-activated esterolytic activity in serum. In another assay, serum samples were either mock-treated or treated with DFP (a potent inhibitor of BSDL) for 1 h at room temperature. At the end of incubation, the esterolytic activity was recorded. The difference in these activities represents the DFP-inhibited esterolytic activity of the serums. The bile salt-activated and DFP-inhibited esterolytic activities, determined on 10 different samples, gave similar results; 0.11 ± 0.05 and 0.12 ± 0.04 U/mL, respectively. These values, which correspond to 27 ± 6% of the total esterolytic activity present in serum, corroborate with the amount of esterolytic activity on 4-nitrophenyl hexanoate (0.11 ± 0.05 U/mL) which can be specifically precipitated by polyclonal antibodies directed against BSDL. The esterolytic activity of serum which was inhibited by DFP appeared similar to that activated by sodium taurocholate and to that specifically precipitated by antibodies specific for BSDL. Consequently, this esterolytic activity was representative of the activity of BSDL present in serum. Examination of the concentration of BSDL, as determined by an enzyme-linked immunosorbent assay technique (5), present in normolipidemic patients demonstrates that it did not differ with sex (males: 4.1 ± 2.8 ng/mL; females: 3.3 ± 2.0 ng/mL). As a consequence, the BSDL activity present in serum did not vary with sex (males: 0.11 ± 0.04 U/mL, females: 0.12 ± 0.03 U/mL). In addition, the relationship between BSDL activity and age was not detectable in the male or female population.

Relationship between BSDL activity and lipids in serum. The initial experiments above demonstrated that BSDL activity can be detected in healthy normolipidemic volunteers. Since this enzyme is potentially important for lipid metabolism (9), we investigated the possible relationship between the activity of BSDL and lipids present in serum sample. For this purpose, the activity of BSDL was tentatively correlated to triglyceride, phospholipid, and total cholesterol concentrations in serum. As shown in Figure 1, no correlation was found between BSDL activity and triglyceride ($n = 28$, $P > 0.05$, $y = 1.05 - 1.37x$, $r = 0.17$, see Fig. 1A). Although a highly significant relationship ($n = 39$, $P < 0.001$, $y = 1.04 + 6.09x$, $r = 0.54$) with a positive slope was detected with total cholesterol present in serum samples (Fig. 1A), no significant relationship was found with phospholipids ($n = 28$, $P \approx 0.05$, $y = 6.76\ 10^{-2} + 0.13x$, $r = 0.36$, Fig. 1B). The relationship between BSDL activity and total cholesterol leads us to resolve

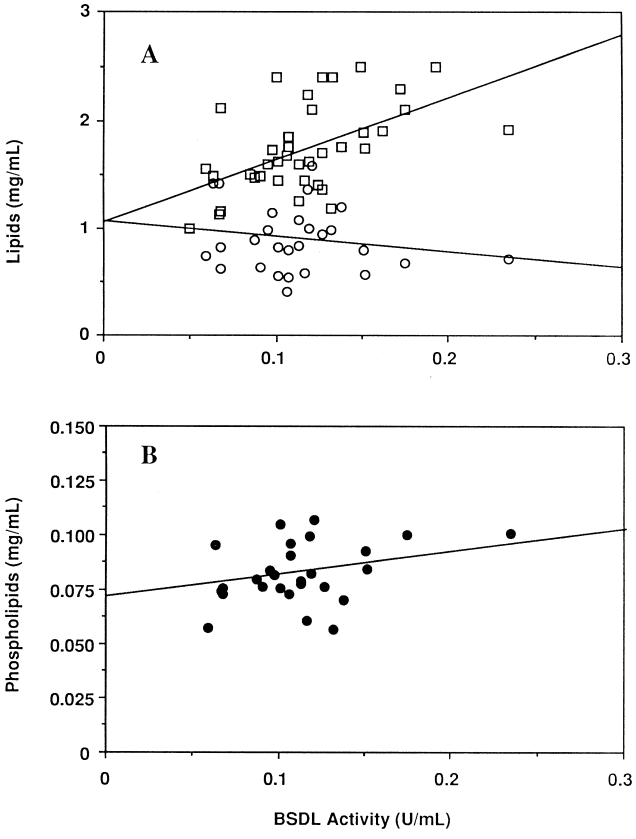

FIG. 1. Relationship between bile salt-dependent lipase (BSDL) activity and lipid concentrations in serum. (A) Total cholesterol (□), triglycerides (○) and (B) phospholipids (●) were determined by adequate methods. The BSDL activity was expressed as the diisopropyl fluorophosphate-inhibited esterolytic activity using 4-nitrophenyl hexanoate as substrate.

whether BSDL activity was linked to either LDL- or HDL-cholesterol. A significant relationship ($n = 35$, $P < 0.01$, $y = 0.51 + 5.50x$, $r = 0.51$) with a positive slope was found between BSDL activity and LDL-cholesterol while no relationship was detected between BSDL activity and HDL-cholesterol ($n = 35$, $P > 0.05$, $y = 0.44 + 0.26x$, $r = 0.09$, Fig. 2). It is worthwhile noting that neither triglycerides, phospholipids, nor total cholesterol present in sera increased significantly with patient age; nevertheless, a poorly significant increase was observed with LDL-cholesterol ($n = 28$, $P < 0.05$, $y = 0.67 + 5.70\ 10^{-3}x$, $r = 0.42$). None of these lipid concentrations was linked to the sex of our donor population.

Relationship between BSDL activity and Apo in serum. We went further in this study in examining possible relationships between BSDL activity and Apo present in serum as suggested by the relationship between BSDL activity and LDL-cholesterol. Eventual linkages between Apo A-I and Apo B100 with sex and age were investigated. Concerning sex, no significant difference was found with Apo A-I concentration (males: 1.32 ± 0.52 mg/mL; females: 1.40 ± 0.32 mg/mL) or Apo B100 concentration (males: 0.98 ± 0.29 mg/mL; females: 0.94 ± 0.34 mg/mL). Also, no relationship was detected between age and Apo A-I concentration. Nevertheless, Apo B100 increased a little with age ($n = 28$, $P < 0.05$, $y = 0.71 + 3.55\ 10^{-3}x$, $r = 0.38$). We next attempted to relate BSDL activity to Apo A-I and Apo B100 concentrations. A significant relationship associated with a positive slope was found between BSDL activity and Apo B100 ($n = 40$, $P < 0.01$, $y = 0.39 + 4.71x$, $r = 0.44$, Fig. 3) or Apo A-I ($n = 40$, $P < 0.01$, $y = 0.82 + 4.89x$, $r = 0.44$).

Binding of BSDL to LDL. In previous publications, we showed that BSDL activity on cholesteryl esters and triglycerides was inhibited by LDL but not by lipoprotein-depleted plasma (6). We also showed that BSDL was able to degrade

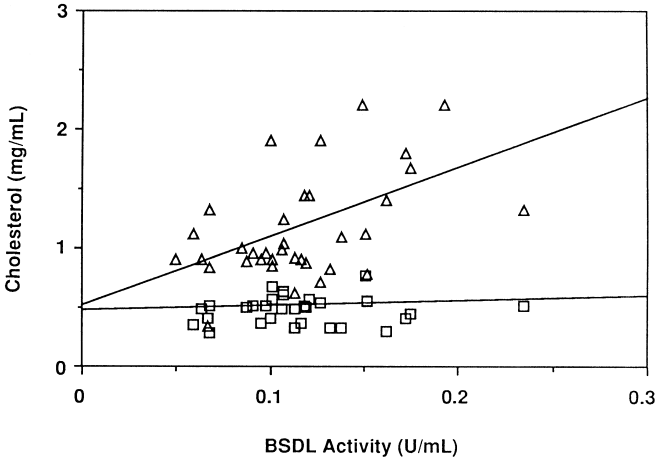

FIG. 2. Relationship between BSDL activity and lipoprotein cholesterol. High density lipoprotein (□) and low density lipoprotein (△) were isolated by specific precipitation and their total cholesterol content determined by enzymatic methods. The BSDL activity was evaluated as described in the legend of Figure 1. See Figure 1 for other abbreviation.

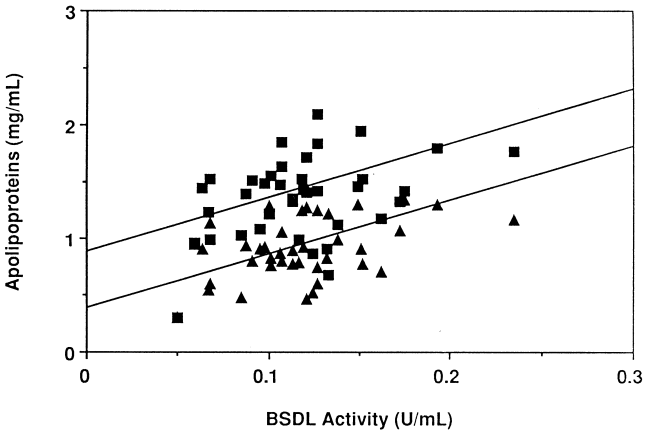

FIG. 3. Relationship between BSDL activity and apolipoprotein (Apo) level. Apolipoprotein levels were evaluated by the turbidity method using specific antibodies to Apo A-I (■) or Apo B100 (▲). BSDL activity was measured as described above in the legend of Figure 1. See Figure 1 for other abbreviation.

oxidized LDL (9). In light of the results presented above, these data suggested that BSDL may have a specific interaction with LDL. To detect such an interaction, ^{125}I-BSDL (4 pmoles) was incubated with a preparation of lipoproteins, including VLDL, LDL and HDL, and chromatographed by FPLC on a Superose 6 column. Under the conditions used, approximately 70% of the ^{125}I-BSDL was coeluted with LDL while 20% was associated with VLDL. Only a minute amount of ^{125}I-BSDL was detected in HDL-containing fractions (not shown). These data indicated that BSDL may be specifically associated with LDL. Nevertheless, this may indicate that BSDL recognizes LDL as a potential substrate.

Interaction between BSDL and Apo B100. In another series of independent experiments, Apo B100 and Apo A-I, isolated from human LDL and HDL, were analyzed on SDS-PAGE and Western-blotting using *pAb L64* antibodies specific for human pancreatic BSDL as primary antibodies. As shown in Figure 4A, BSDL could be detected in Apo B100, but not in Apo A-I preparations. This result, which was reproduced with preparations of Apo originating from many different normolipidemic sera, suggests that BSDL in serum is associated with Apo B100 but not Apo A-I. In addition, we determined whether BSDL was capable of a direct interaction with Apo. For this purpose, ^{125}I-labeled BSDL (≈ 50,000 cpm, approximately 1 pmole) was incubated with 1 nmole of Sepharose-immobilized Apo B100 or 5 nmoles of Sepharose-immobilized Apo A-I. After an overnight incubation and an exhaustive washing of beads and correction for nonspecific binding to control agarose beads, more than 82% of the loaded radioactivity remained associated with Sepharose-immobilized Apo B100 while no radioactivity was bound to Sepharose-immobilized Apo A-I beads. The ^{125}I-BSDL bound to Sepharose-immobilized Apo B100 could have been displaced by increasing amounts of unlabeled BSDL (Fig. 4B) which supports the specificity of the interaction. The

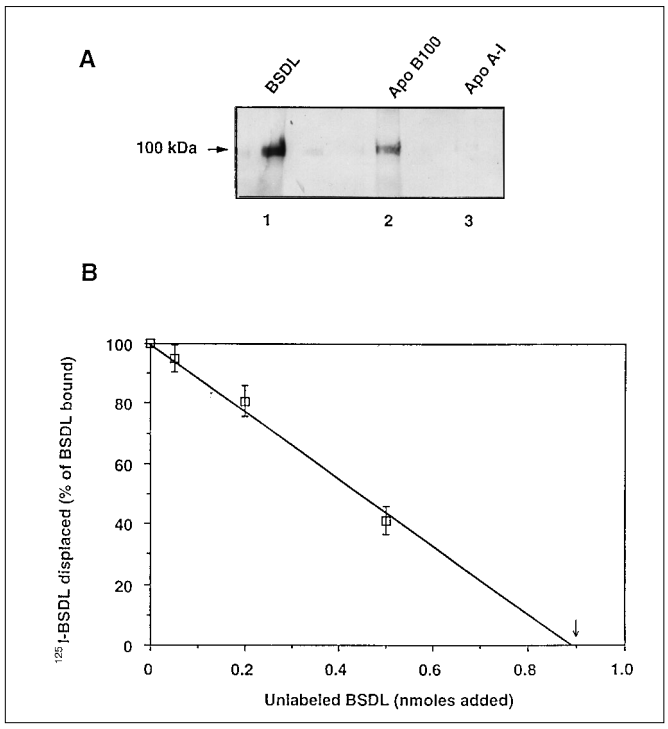

FIG. 4. Association of BSDL with Apo B100. (A) Apo B100 and Apo A-I were isolated by centrifugation over a KBr density gradient and analyzed by SDS-polyacrylamide gel electrophoresis. Proteins were then electrotransferred onto a nitrocellulose membrane and probed with antibodies specific for human pancreatic BSDL (*pAb L64*). Lane 1, pure BSDL (0.7 ng loaded); lane 2, Apo B100 (15 µg); lane 3, Apo A-I (15 µg). (B) Displacement of ^{125}I-BSDL bound to Sepharose-immobilized Apo B100. ^{125}I-BSDL was firstly incubated with Sepharose-immobilized Apo B100, the bound radiolabeled protein (which represents more than 80% of loaded material) and then was displaced with increasing amounts of unlabeled BSDL as indicated. Extrapolation of the regression line ($y = 101.5 - 118.3x$, $r = 0.997$) to the origin gives the amount of unlabeled BSDL (0.87 nmole, arrow) required for the complete displacement of radioactive BSDL. See Figures 1 and 3 for abbreviations.

complete displacement of ^{125}I-labeled BSDL could be achieved with 0.87 ± 0.07 nmoles of unlabeled BSDL. Because 1 nmole of Sepharose-immobilized Apo B100 was used in these experiments, one may suggest that the stoichiometry of the binding of BSDL to Apo B100 was 1:1. These data suggest that in LDL one molecule of Apo B100 may be able to bind one molecule of circulating BSDL.

DISCUSSION

Besides its role in lipid digestion, BSDL which transits through the enterocyte, was demonstrated to exert a systemic action in serum on oxidized LDL (9). Oxidized LDL is enriched in lysophosphatidylcholine which is thought to mediate deleterious effects on vascular endothelium (12). Because oxidation of LDL occurs after LDL enters the subintimal space, to hydrolyze lysophosphatidylcholine, the best location for BSDL to exert its function would be arterial tissue. In human aorta, BSDL immunoprecipitated by specific antibodies to pancreatic BSDL was characterized (9). The source of arterial pancreatic-like BSDL could be multiple. It could originate from the circulating pool derived from the pancreas (4, 5), or from circulating cells such as eosinophils (21). Lastly, aortic BSDL may be synthesized by the vascular endothelial cells.

It is clear that given its ability to hydrolyze lysophospholipids (1), pancreatic-like BSDL, independent of its origin, could be a protective factor against atherogenesis (9). Therefore, it appeared natural to examine whether a linkage between circulating BSDL and serum lipids exists. Recent studies suggested that at least two isoforms of BSDL were secreted by the pancreas (22), one of them being 10 times more active on cholesteryl esters and 4-nitrophenyl hexanoate (23). Because *pAb L64* does not discriminate between these two isoforms of BSDL, the serum level of BSDL determined by enzyme-linked immunosorbent assay cannot be directly correlated with enzyme activity. To overcome this fact, we attempted to find a rapid and convenient way to detect BSDL activity in serum. For this purpose the esterolytic activity of serum was investigated in the absence of a BSDL activator (i.e., sodium taurocholate) or after treatment of serum with a BSDL inhibitor (i.e., DFP) and subtracted from values obtained in the presence of the BSDL activator or before treatment with the inhibitor. The difference represents the serum esterolytic activity which is bile salts-activated and DFP-inhibited, respectively. In both cases, this esterolytic activity was similar. Two other lipases, the lipoprotein-lipase (LPL) and hepatic lipase released into plasma on intravenous injection of heparin, may present esterolytic activity (24,25). LPL and hepatic lipase are distinct enzymes but have very similar hydrolytic functions. They both hydrolyze lipoprotein triglycerides and are potentially active on water-soluble substrates such as 4-nitrophenyl butyrate (26). Although both LPL and hepatic lipase are inhibited by serine protease inhibitors (27,28), the contribution of these two enzymes to the esterolytic activity in serum appeared very low in the absence of intravenous heparin administration to patients (29,30). The fact that the fraction of esterolytic activity, which is inhibited by DFP, was within experimental errors similar to that activated by bile salts and to that immunoprecipitated by polyclonal antibodies specific for BSDL, suggested that the fraction of DFP-inhibited esterolytic activity determined on 4-nitrophenyl hexanoate was representative of the BSDL activity in serum. Under these conditions, BSDL activity was related to cholesterol and particularly to LDL-cholesterol as BSDL activity increased with increasing amounts of LDL-cholesterol. A significant relationship was also detected between BSDL activity and Apo B100 concentration in serum. Indeed, in light of the increasing activity of BSDL with LDL-cholesterol, the relationship with Apo B100 was expected. The question then was to determine whether BSDL was able to interact with LDL and in part with Apo B100. Indeed, data presented in the study indicated that, first ^{125}I-BSDL coeluted in gel filtration with LDL, second BSDL can be detected in Apo B100 preparations, and third BSDL can bind to Apo B100 in

a 1:1 stoichiometry. Consequently, it is suggested that BSDL is able to bind to circulating LDL by a specific interaction with Apo B100. This agreed with previous data indicating that BSDL activity on cholesteryl esters can be inhibited by LDL (6) and that BSDL was able to degrade oxidized LDL (9). Because BSDL transcripts were not detected in normal human adult tissues, other than pancreatic and mammary glands (31), these results suggested that BSDL found in endothelial vascular tissue (32) may originate from the LDL-associated BSDL. Since oxidation of LDL is thought to occur within the endothelium of the arterial wall (33), the LDL-associated BSDL may have the correct intracellular location to degrade oxidized LDL, once captured by aortic endothelial cells.

In conclusion, it is shown for the first time that BSDL activity may be detected in serum and that this activity increases with LDL-cholesterol. It is also shown, for the first time, that circulating BSDL may be partly associated with LDL and may have a specific interaction with Apo B100. Taken as a whole with previously published data (9), it is strongly suggested that pancreatic-like serum BSDL may have positive effects against the atherogene processes.

ACKNOWLEDGMENTS

This work was financed in part by a grant awarded from the Association pour la Recherche sur le Cancer (Villejuif, France) and financial support from Conseil Général des Bouches-du-Rhône (Marseille, France). ABSTRACT: Adipocere formation is well known as a later postmortem change. We collected adipocere from five male victims which had been submerged under the sea or fresh water for 1 mon to 4 yr. Fresh subcutaneous fat of a male victim who died from a cerebral contusion was used as the control. The samples were homogenized, and the lipids were extracted with chloroform and methanol followed by injection into a gas chromatograph and a gas chromatograph–mass spectrometer. We detected hydroxy fatty acids (10-hydroxyoctadecanoic acid and 10-hydroxyhexadecanoic acid) as well as 10-ketooctadecanoic acid in adipocere, but not in the control. In addition, we found for the first time a cholesterol-related peak with a molecular ion of 388 in adipocere and identified it as epicoprostanol, suggesting not only oxidation but also reduction had occurred during the formation of adipocere. In addition, we showed the time-course of epicoprostanol accumulation. The relationship between the time of adipocere formation and the characteristic lipid composition is discussed.
Lipids 32, 1155–1160 (1997).

Adipocere is one of the later postmortem changes. It is seen in bodies immersed in water or in damp and warm environments. It is caused by hydrolysis and hydration of adipose tissue, leading to the formation of a greasy or waxy substance. Adipocere is said to take several months to develop, although development can be as short as several weeks. Adipocere contains palmitic, oleic, and stearic acids (1,2). Investigations have shown that adipocere contained 10-hydroxyoctadecanoic and 10-hydroxyhexadecanioc acids (3–5) as well as 10-ketooctadecanoic and 10-ketohexadecanoic acids (5,6).

In the present study, we collected adipocere samples from five victims who had been submerged in water from 1 mon to 4 yr. The lipids obtained for the adipocere samples were analyzed by gas chromatography (GC) and GC–mass spectrometry (MS) to determine if the composition of the various lipids in the adipocere is dependent upon the length of the period of immersion of the victim after death.

Abbreviations: GC, gas chromatography; GC–MS, GC-mass spectrometry; IS, internal standard; Rt, retention time; TIC, total ion chromatogram.

MATERIALS AND METHODS

Subjects. Selected case reports are presented below.

Case 1: This 44-year-old man was found dead in a fisherman's net in the sea 1 mon after he was reported missing. The cause of death was drowning. Adipocere was partially formed.

Case 2: This 61-year-old man was found dead by a fisherman in an irrigation channel 2 mon after he was reported missing. The cause of death was unknown. Adipocere was partially formed.

Case 3: This 49-year-old man was found dead in his car which was found sunk in a pond 4 mon after he was reported missing. The cause of death was estimated drowning. Adipocere was formed on almost the entire body.

Case 4: This man in his forties was found dead in a fisherman's net in the sea 4 to 6 mon after he was reported missing. The cause of death was estimated drowning. Adipocere was formed on almost the entire body.

Case 5: This 23-year-old man was found dead in his car which was found sunken in the sea 4 yr after he was reported missing. The cause of death was unknown. Skeletonization of almost the entire body was seen, whereas the remains formed adipocere.

Control: This 36-year-old man fell in front of his house and died from a cerebral contusion. The abdominal subcutaneous fat tissue was collected during the autopsy 15 h after his death.

Chemicals. Methyl esters of *cis*-11-eicosenoic (20:1) acid and hentriacontanoic (31:0) acid were purchased from Sigma (St. Louis, MO). Cholesterol, cholestanol, epicholestanol, coprostanol, and epicoprostanol were purchased from Steraloids, Inc. (Wilton, NH). Hydrogen chloride (5%, wt/vol) in methanol was obtained from Nachalai Tesque, Inc. (Kyoto, Japan). 10-Hydroxyoctadecanoic acid was provided by Prof. Takatori of Tokyo University. The methyl ester was obtained by transmethyl-esterification with diazomethane. All other chemicals were of analytical grade.

Extraction. Adipocere (0.2 to 0.5 g) and the subcutaneous fat from the control were weighed, minced with scissors, homogenized, and extracted at room temperature essentially

by the method of Folch *et al.* (7). The chloroform was evaporated under a nitrogen stream. The crude lipids were placed in a screwcap-sealed reactivial with hydrogen chloride in methanol and heated at 110°C for 1 h to convert the lipids into their methyl esters. Methanol was evaporated under a nitrogen stream, and the lipid residue was redissolved in chloroform.

GC–MS and GC. A 1 μL aliquot of the sample was injected into a DB-1 fused-silica megabore column (30 m × 0.53 mm i.d., film thickness 1.5 μm) (J&W Scientific, Folsom, CA) which was mounted in a Model QP5000 Shimadzu GC–MS (Kyoto, Japan). The following chromatographic conditions were used. Helium was used as the carrier gas at a flow rate of 20 mL/min. The column temperature was 140°C for 2 min, then programmed to 310°C at 4°C/min, and finally maintained at 310°C for 10 min. The injection port temperature was 240°C and the separator temperature 250°C. The ionization voltage was 70 eV, ionization current 60 μA, and scan interval 0.5 s. All peaks corresponding to the methyl esters of the fatty acids were identified by their retention times (Rt) and mass spectra. Quantitative determinations by selected ion monitoring were carried out. The following ions were focused on: *m/z* 215, fragment ion of epicoprostanol; *m/z* 386, M^+ ion of cholesterol; and *m/z* 143, fragment ion of an internal standard (IS, 31:0). Standard curves were prepared by selected ion monitoring analyses of 10, 20, and 40 μg/mL of epicoprostanol and cholesterol with 50 μg/mL of IS. The peak areas of the ions monitored were measured, and the ratios of the fatty acids to the IS were computed for the standard compounds and for the lipid extracts of the specimens.

The GC was a Shimadzu GC-7A equipped with a flame-ionization detector. The esters were separated on a Omegawax TM 530 fused-silica megabore column (30 m × 0.53 mm i.d., film thickness 0.5 μm) (Supelco, Inc., Bellefonte, PA). The following chromatographic conditions were used. Helium was used as the carrier gas at a flow rate of 20 mL/min. The column temperature was 150°C for 1 min, then programmed to 270°C at 8°C/min, and finally maintained at 270°C for 2 min. The injection and detector temperature were 260°C. The individual peak areas of the fatty acids were calculated by a Model C-R6A chromatopac (Shimadzu).

RESULTS

Figure 1 shows the total ion chromatograms (TIC) for adipocere and normal adipose tissue by GC–MS. The lipids in both the control and the adipocere contained fatty acids [main components: myristic (14:0), palmitoleic (16:1), palmitic (16:0), linoleic (18:2), oleic (18:1), and stearic (18:0)]. In the adipocere peaks 1, 2, and 4 appeared near peak 18:0, and peak A appeared before cholesterol.

Peak A in Figure 1 was subjected to electron-impact MS. Mass spectra of peak A, standard epicoprostanol, coprostanol, cholestanol, and epicholestanol are shown Figure 2. Peak A has a molecular ion (M^+) at *m/z* 388 which is consistent with

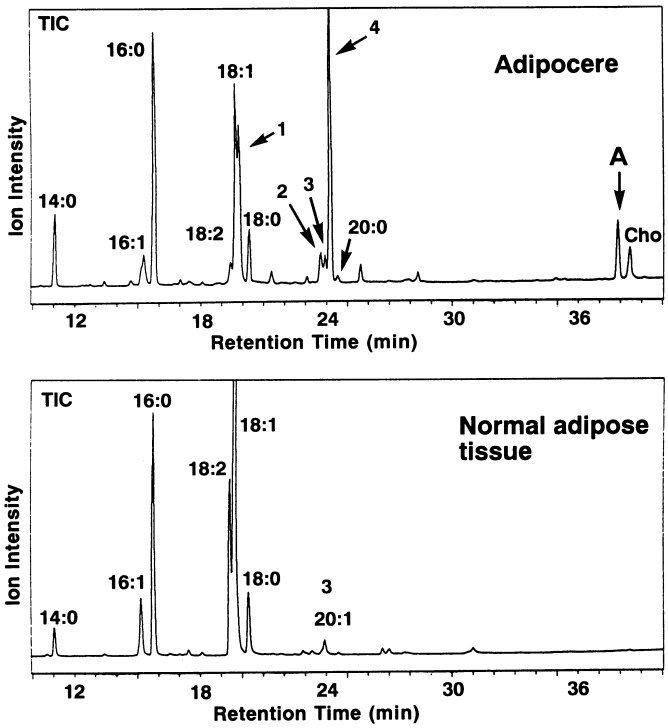

FIG. 1. Total ion chromatograms (TIC) for adipocere and normal adipose tissue (control). 1, 10-Hydroxyhexadecanoic acid (10-OH 16:0); 2, 10-ketooctadecanoic acid (10-keto 18:0); 3, eicosenoic acid (20:1); 4, 10-hydroxyoctadecanoic acid (10-OH 18:0); A, epicoprostanol; Cho, cholesterol.

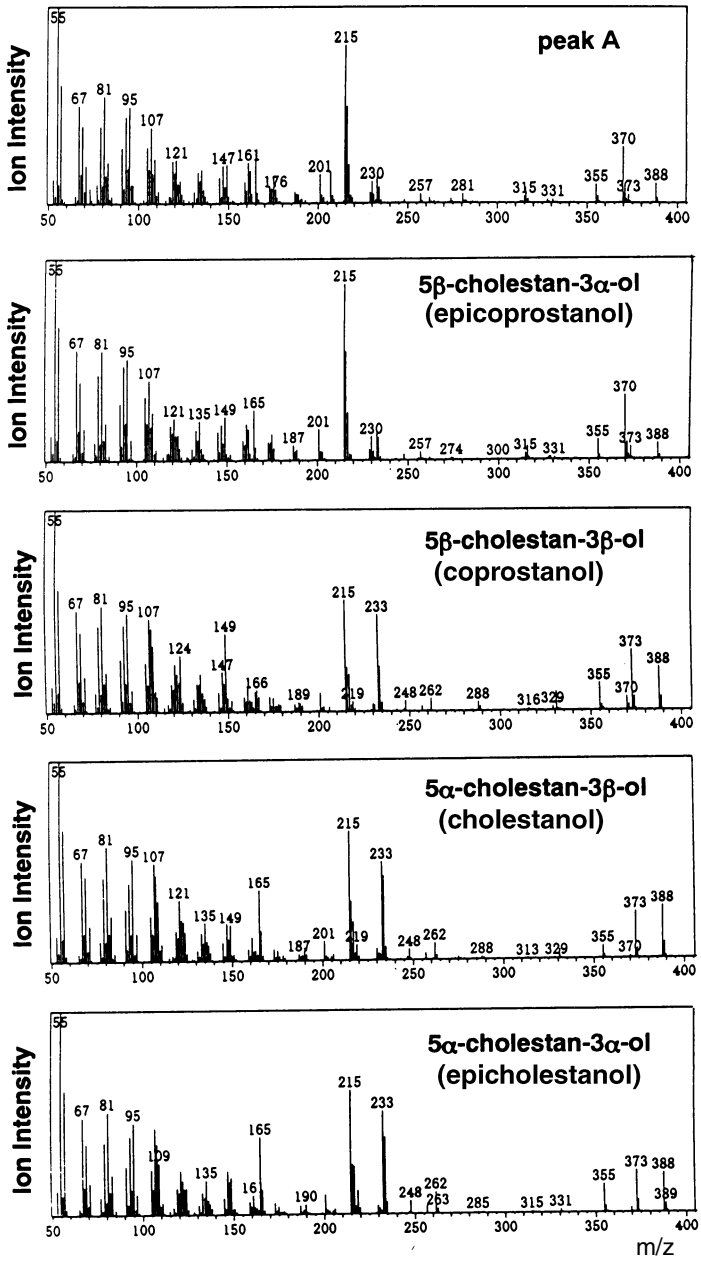

FIG. 2. Electron-impact mass spectra of peak A from adipocere and standard epicoprostanol, coprostanol, cholestanol, and epicholestanol.

epicoprostanol, the reduced compound of cholesterol. Figure 3 shows TIC for standard epicoprostanol with IS (31:0) and adipocere with IS. The Rt of peak A was consistent with that of epicoprostanol. Mass chromatograms at *m/z* 215, 370, 230, and 388 for the adipocere and the control are also shown in Figure 3. No peaks appeared in monitoring at *m/z* 215, 370, and 388 in the control sample. The Rt and the ratio of the ion intensity at *m/z* 215 to 233 of four stereoisomers of 5-cholestan-3-ol are shown in Table 1. Thus, peak A was identified as epicoprostanol.

The levels of epicoprostanol and cholesterol were determined by selected ion monitoring, and the ratio of epicoprostanol to cholesterol in the adipocere samples is shown in Table 2. The ratio increased as the period after death increased.

Next, peaks 1, 2, 3, and 4 were subjected to electron-impact MS. As shown in Figure 4, peak 2 with fragment ions at *m/z* 214, 199, 157, and 156 was assumed to be 10-ketooctadecanoic acid because these were the characteristic ions reported by Takatori and Yamaoka (3). Peak 3, appearing at Rt of 23.9 min with fragment ions at *m/z* 292 and 250 and M^+ ion at *m/z* 324, was consistent with standard 20:1. Peak 4, appearing at Rt of 24.3 min with fragment ions at *m/z* 169, 172, and 201, was consistent with standard 10-hydroxyoctade-

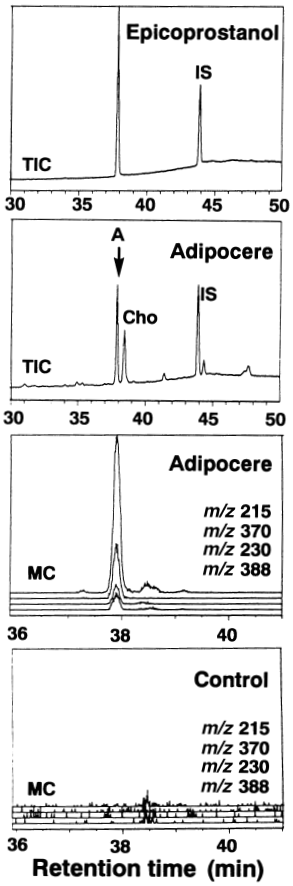

FIG. 3. TIC between 30 and 50 min for standard epicoprostanol with internal standard (IS, 31:0) and adipocere with IS. Mass chromatograms (MC) with monitoring at *m/z* 215, 370, 230, and 388 from adipocere and control. See Figure 1 for abbreviations.

canoic acid (*m/z* 169, 172, and 201). Thus, peak 4 was identified as 10-hydroxyoctadecanoic acid.

TIC from 19 to 21.5 min in control and adipocere are shown in Figure 5. Mass chromatogram 1 in adipocere at *m/z* 201, 172, 169, and 143, being the characteristic ions to 10-hydroxyhexadecanoic acid, is also shown in Figure 5. Thus, peak 1 was assumed to be 10-hydroxyhexadecanoic acid. Mass chromatogram 2 at *m/z* 128, 157, and 214, being the characteristic ions of 10-ketohexadecanoic acid reported by Takatori and Yamkaoka (6), is shown in Figure 5. It was possible that the peaks indicated by C were due to 10-ketohexadecanoic acid.

Figure 6 shows the gas chromatogram of methyl esters of fatty acids in adipocere. To separate peaks of 20:1, 10-ketooctadecanoic acid and 10-hydroxyoctadecanoic acid, we used different column in GC–MS. The peak for 10-ketooctadecanoic acid was assumed by comparison with TIC of GC–MS. The fifth case (the 23-year-old man in the sea 4 yr) was used for Figures 1–6.

The fatty acid composition of the five adipocere samples and the control is shown in Table 3. The control, Case 1, and Case 2 which do not contain 10-ketooctadecanoic acid have 18:2 present greater than 10%. The amount of 18:2 was much

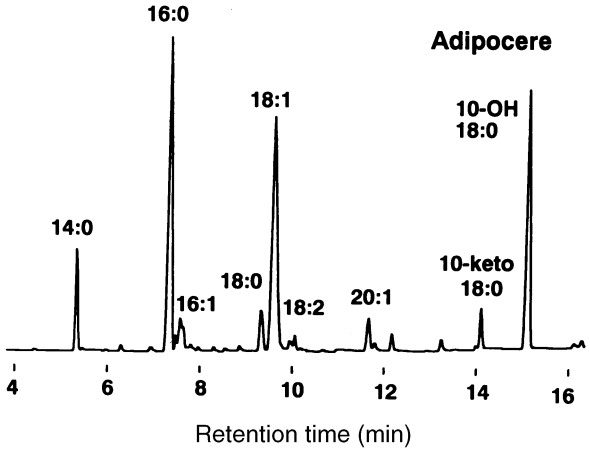

FIG. 6. Gas chromatographic profiles of methyl esters of fatty acids in adipocere. Column of gas chromatography: Omegawax TM530 (Supelco, Inc., Bellefonte, PA).

less in Cases 3, 4, and 5 which contained 10-ketooctadecanoic acid. The amount of 10-hydroxyoctadecanoic acid increased as the length of time the victim was submerged in water increased.

DISCUSSION

The results of the present study show for the first time that the adipocere of the victims contained significant amounts of epicoprostanol, whereas this compound was essentially absent from normal adipose tissue. The structure was confirmed by the mass spectrum on GC–MS.

Coprostanol is the major metabolite of cholesterol in the intestine by the bacterial microflora (8). The relative amounts of cholesterol and its metabolite found in human feces are as follows: cholesterol makes up about 20% of the neutral sterol concentration; coprostanol, 65%; coprostanone, 10%; and cholestanol, cholestanone, and epicoprostanol, collectively about 5% of the neutral sterols in feces (9). Only a trace amount of epicoprostanol has been found in human feces. Korpela (10) analyzed fecal samples from eight healthy young men who were on a normal Finnish diet and found epicoprostanol in only one sample. Accordingly, little is known about the occurrence of epicoprostanol in humans. An elevated cholestanol level was found in serum of patients with cerebrotendinous xanthomatosis, a hereditary disorder (11).

Epicoprostanol formation is considered to occur as follows. 4-Cholesten-3-one is formed by the oxidation of the 3β-hydroxy group of cholesterol to a ketone and isomerization of the 5-6 double bond to the 4-5 position. Coprostanone is formed by the reduction of the 4-5 double bond. Subsequently, coprostanol and epicoprostanol are formed by the reduction of the 3-keto group to the 3β-hydroxy and 3α-hydroxy groups, respectively. As we did not find cholestanol, epicholestanol, and coprostanol, we propose that in adipocere

[a]Values are expressed as percentage by weight of total fatty acids. Period: postmortem time of samples.

epicoprostanol is more easily produced than the other metabolites of cholesterol.

Next, some authors have postulated the sequence leading to adipocere formation (4,6,12–14).

Tomita (4) showed that hydroxy and keto fatty acids in adipocere of mice rose to 60% (maximum) in only 2 mon and fell to 10% in 6 mon as adipocere formation reached completion. In contrast, Takatori and Yamaoka (6) reported that the relative amount of hydroxy fatty acids was 3% in adipocere of a victim immersed for 3 mon, while in two adipocere samples immersed for 6 mon, the amount of fatty acids including keto fatty acids reached about 20%. In the present study of adipocere of two victims immersed for 1 mon and 2 mon, the amount of hydroxy fatty acid was only 1%, but the amounts of 18:2 were 13 and 15%. In the adipocere of three victims immersed from 4 mon to 4 yr, the amounts of hydroxy fatty acids rose from 14 to 22%, but those of 18:2 fell to only several percentage. Consequently, our results regarding hydroxy fatty acid composition were not consistent with the results of Tomita (4), but were similar to those of Takatori and Yamaoka (6). Both of them failed to show hydroxy and keto fatty acids as well as ordinary fatty acids in the same chromatogram, whereas we successfully demonstrated them by GC. Furthermore, we showed that in the adipocere of the victims immersed for less than 3 mon, keto fatty acids did not develop, and that the ratio of epicoprostanol to cholesterol was 0.1, whereas the ratio rose from 1.1 to 2.1 in the adipocere of three victims immersed over 4 mon when adipocere formation seemed to be complete. Thus, the analysis of epicoprostanol might be of value to determine the time of death.

Finally, we clarified the relationship of the characteristic lipids in adipocere to the total time of immersion by comparing the composition of adipocere from the five victims.

ABSTRACT: The objective of this study was to obtain functional information associated with the prevention by n-3 polyunsaturated fatty acids (PUFA) of ischemia-induced fatal cardiac ventricular arrhythmias in the intact, conscious, exercising dog. Thirteen dogs susceptible to ischemia-induced ventricular fibrillation were prepared surgically by ligation of their anterior descending left coronary artery and placement of an inflatable cuff around their left circumflex artery. After 4 wk of recovery, exercise-plus-ischemia tests were performed without and then with an intravenous infusion of an emulsion of free n-3 PUFA just prior to occluding the left circumflex artery while the animals were running on a treadmill. One week later the exercise-plus-ischemia test was repeated but with a control infusion replacing the emulsion of n-3 PUFA. The infusion of the free n-3 PUFA in quantities of 1.0 to 10 g prevented ventricular fibrillation in 10 of the 13 dogs tested ($P < 0.005$), apparently without esterification of the PUFA into membrane phospholipids. The antiarrhythmic effect of the n-3 PUFA was associated with slowing of the heart rate, shortening of the QT-interval (electrical action potential duration), reduction of left ventricular systolic pressure, and prolongation of the electrocardiographic atrial-ventricular conduction time (P-R interval). These effects are comparable with those we have reported in studies with cultured neonatal rat cardiac myocytes. *Lipids 32*, 1161–1168 (1997).

Abbreviations: DHA, *cis*-5,8,11,14,17,20-docosahexaenoic acid (22:6n-3); ECG, electrocardiogram; EPA, *cis*-5,8,11,14,17-eicosapentaenoic acid (20:5n-3); NEFA, nonesterified fatty acids [fraction of plasma lipids which includes the free fatty acids of which over 99.9% are bound to albumin and other plasma proteins plus a very small fraction of monomeric free or aggregated clusters of fatty acids (lamellar or micellar aggregates) in plasma water]; P-R interval, duration of conduction time from the start of the auricular P-wave to start of the ventricular R-wave conventionally measured from the ECG; PUFA, polyunsaturated fatty acids (denotes the n-3 class of essential long-chain PUFA, but more generally applied to both the n-3 and n-6 classes); QT interval, an electrocardiographic interval from the start of the Q-wave to the start of the T-wave of the ECG (equivalent to the duration of the action potential observed in individual cardiac myocytes as an abrupt rise and fall in the transmembrane potential when their resting or diastolic membrane potential is depolarized and measured with an intracellular electrode and an external reference electrode; the electrical signal that initiates contractions of the heart muscle; TLC, thin-layer chromatography; VF, ventricular fibrillation, a fatal cardiac arrhythmia when sustained, characterized by grossly irregular, rapid, and chaotic beating; VT, ventricular flutter, a very rapid but regular beating rate which is also fatal if sustained.

Coronary heart disease is the leading cause of death in all Western industrialized countries. Despite considerable improvement since the mid-1960s, almost half a million individuals die yearly in the United States of America from myocardial infarctions, and 50 to 60% of these die within 1 h, mostly from ventricular arrhythmias (1). Thus, a safe and simple intervention that would prevent ischemia-induced lethal ventricular arrhythmias would have considerable public health benefit.

Based on sporadic earlier suggestions that the n-3 long-chain polyunsaturated fatty acids (PUFA) might have antiarrhythmic effects (2,3), McLennan *et al.* (4,5) have shown that feeding rats a diet in which saturated fat or monounsaturated fat (olive oil) was the major fat source was associated with a high incidence of lethal ventricular arrhythmias upon subsequent coronary artery ligation. In contrast, diets in which a vegetable oil, sunflower seed oil, was the major fat significantly reduced the arrhythmias, while tuna fish oil prevented the ventricular fibrillation (VF). They have supported these findings in nonhuman primates (6).

In 1994 we reported initial confirmatory findings in surgically prepared dogs susceptible to ischemia-induced VF in which seven of the eight animals tested were protected from the expected VF (7). In this group of animals, the fish oil fatty acids were infused as an emulsion intravenously just prior to the ischemic challenge. This route of administration was chosen purposely. If prevention of the arrhythmias occurred, then we considered this would provide convincing evidence that some ingredient(s) of the infused fish oil concentrate was the active agent. In the earlier feeding studies there was, at the time, considerable disagreement as to what dietary change was protective. The present report enlarges the number of animals studied and reports associated physiologic changes, which will be important in the understanding as to how the prevention of ischemia-induced VF is produced by these essential, dietary PUFA.

METHODS

Experiments were performed on 13 conscious, exercising mongrel dogs (14.5–18.3 kg) which had been previously prepared surgically, as described (8–10). Briefly, the animals were anesthetized and instrumented to measure left circumflex coronary artery blood flow and ventricular electrograms.

A hydraulic occluder was also placed around the left circumflex coronary artery. Finally, the left anterior coronary artery was ligated, producing an anterior wall myocardial infarction. After a period of at least 4 wk to allow the dogs to recover from surgery and the acute effects of the myocardial infarction, the animals ran on a treadmill with the workload increased every 3 min for 18 min or until a target heart rate of 210 beats per min (70% of maximum) was attained. During the last minute of exercise, the cuff was inflated, occluding the left circumflex coronary artery. At the end of 1 min, the treadmill was stopped. The occlusion was maintained for an additional minute. When VF or sustained ventricular flutter (VT) occurred, as soon as consciousness was lost the animals were promptly defibrillated. The brief episodes of ischemia, VF, and defibrillation in the exercise-plus-ischemia tests had no residual effects on cardiac function as evidenced by the normal ventricular electrograms exhibited within minutes after the defibrillation, i.e., no ST (segment of electrocardiogram connecting the S and T waves) changes and a normal sinus rhythm were present. Also in the animals in which left ventricular pressures were measured, no elevation in end diastolic pressure or depression of left ventricular dp/dt occurred. Approximately two-thirds of animals tested were susceptible to prompt development of VF. The resistant animals were excluded from the study. Earlier studies (8–10) had demonstrated that the exercise-plus-ischemia test reliably, and for at least 16 wk after infarction, reproduced the VF response in the susceptible animals.

One week after the control study, the exercise-plus-ischemia test was repeated but just after the infusion of an emulsion of 1.0 to 10.0 g of free n-3 PUFA. Preparation K6000; Pronova-Biocare, Lysaker, Norway, containing 70% n-3 PUFA of which free *cis*-5,8, 1 1,14,17-eicosapentaenoic acid (20: 5n-3, EPA) was 33.9% and free *cis*-5,8, 11,14,17,20-docosahexaenoic acid (22:6n-3, DHA) was 25.5%]. This emulsion was injected slowly intravenously over a period of 40 to 60 min. One week later the same animal had another control exercise-plus-ischemia test performed just as with the fish oil emulsion but with either a saline infusion ($n = 8$) or with soybean oil [10% Intralipid® (Baxter, Deerfield, IL); 100 mL] containing only triglycerides ($n = 5$). Intralipid® is used clinically for parenteral nutrition and contains the identical emulsifying vehicles used for the n-3 fatty acids infusion with its fatty acid content all esterified in triglycerides. Thus, each animal tested served as its own control with a control infusion and exercise-ischemia test before and following the test with infusion of the free nonesterified n-3 PUFA.

The principles governing the care and treatment of animals as expressed by the American Physiologic Society were followed at all times during this study. In addition, the procedures used were approved by the Ohio State University Institutional Animal Care and Use Committee.

Analysis of plasma fatty acids. The fatty acid composition of plasma triglycerides and phospholipids was analyzed as described previously (11). Plasma (250 µL) was extracted with chloroform/methanol (2:1, vol/vol). Samples were sealed under nitrogen and stored at −70°C unti1 thin-layer chromatography (TLC) was performed. For TLC, the samples were dried under nitrogen and reconstituted in 80–100 µL chloroform. TLC plates were activated at 90–100°C for 1 h, and chromatography was run using petroleum ether/ethyl ether/acetic acid (80:20:1, by vol) as the solvent. Bands were made visible with 0.01% 8-anilino-1-naphthalenesulfonic acid, and gel scrapings of the triglyceride and phospholipid fractions were collected for methylation. To obtain fatty acid methyl esters, 1.5 mL boron trifluoride in methanol (14%) and 2 mL hexane were added to the gel scrapings and then heated 1 h at 100°C. After this procedure, 1 mL of water was added and mixed vigorously. Tubes were allowed to stand for at least 30 min before removing the hexane phase. Samples were then dried under nitrogen and reconstituted in 100 µL isooctane, of which 2 µL were analyzed by gas–liquid chromatography. An Omegawax™ column (30 m; Supelco, Bellefonte, PA) was used in a Hewlett-Packard 5890A gas chromatograph (Hewlett-Packard, Avondale, PA). Carrier gas was hydrogen (2.39 mL/min), injected with a split ratio of 1:31. The initial temperature was 165°C for 5 min; then temperature was increased to 195°C at 2.5°C/min and from there to 220°C at 5°C/min. Temperature was held for 10.5 min and then decreased to 165°C at 27.5°C/min. Peaks were identified by comparison with fatty acid standards (Nu-Chek-Prep, Elysian. MN), and area percentage for all resolved peaks was analyzed using a Perkin Elmer M1 integrator (Norwalk, CT). By comparison with areas of nearby standard fatty acid peaks, the molar concentrations of the pertinent fatty acids of plasma triglycerides and phospholipids were derived.

Because the emulsifier used for the n-3 PUFA emulsion contained 625 mg of purified egg yolk lecithin (Avanti Polar Lipids, Alabaster, AL) per 50 mL of 10% emulsion, the fatty acid composition of the egg yolk lecithin was analyzed for its fatty acid content. For each of the common PUFA of interest, its content in the plasma phospholipids was subtracted from the total phospholipid fatty acid content of the plasma to obtain the corrected fatty acid content of the plasma free of that contributed by the infused fish oil emulsions. To calculate the concentration of the egg yolk lecithin added to the plasma, it was estimated that the administered 625 mg per 5.0 g of n-3 PUFA would be distributed over the expected 1000-mL plasma volume of a 20-kg dog.

Statistical analyses. Differences of means were analyzed by analysis of variance; other results were evaluated by the χ^2-test or the Fisher Exact Test, as indicated, when any of four values of the 2 by 2 χ^2 table was smaller than 5. Results are expressed as means ± SEM. A significant difference is accepted if $P < 0.05$.

RESULTS

The infusion of the fish oil emulsion prevented lethal ventricular arrhythmias in 10 of the 13 animals tested, whereas these 13 "susceptible" dogs all developed VT or VF with control

infusions both 1 wk before and 1 wk after the n-3 PUFA trial (Fisher Exact Test, $P = 0\ 000536$). By comparison, of the five dogs tested with the fish oil and soybean emulsion, all five receiving the fish oil were protected and none was protected by the Intralipid (five of five protected, Fisher Exact Test, $P = 0.00397$); of the eight dogs tested with fish oil and saline, five of eight were protected (Fisher Exact Test, $P = 0.0120$). Since none of the 26 control studies with both saline or Intralipid was protected, we have combined the data and report an overall protection rate with $P < 0.005$.

Representative recordings obtained from the same animal during the control and 1 wk later following infusion of the

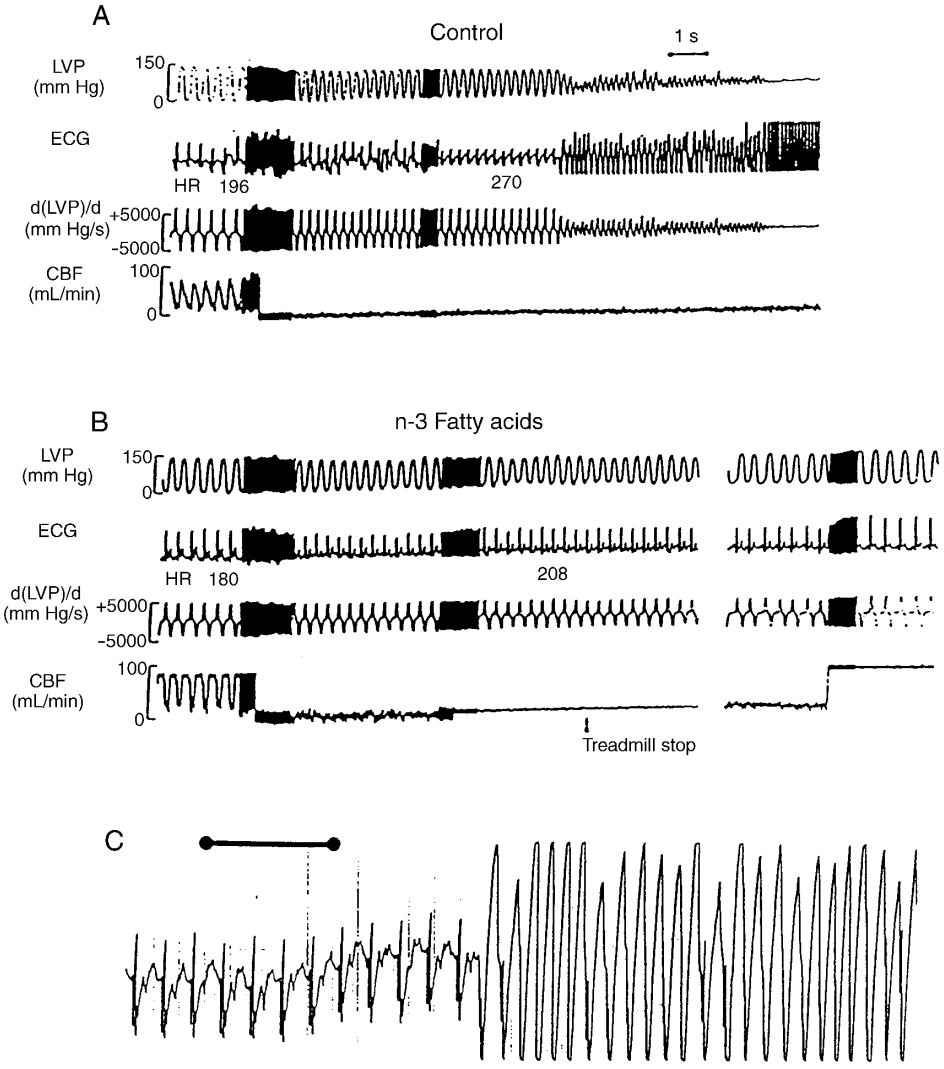

FIG. 1. A representative exercise-plus-ischemia test from the same animal before and after intravenous administration of an emulsion of the n-3 polyunsaturated fatty acid (PUFA). (A) Initial exercise–ischemia control. The dog ran on a treadmill for 18 min with the workload increasing every 3 min. During the last minute of exercise, the cuff was inflated to obstruct blood flow in the left circumflex coronary artery (CBF), as indicated by the abrupt cessation of blood flow in the line marked "CBF." At the end of 1 min of obstruction of the left circumflex artery, the treadmill was stopped and the occlusion was maintained for an additional minute. The chart speed is indicated for 1.0 s (top right), but when the chart speed was slowed twice during the control tracings and three times during the n-3 fatty acid test to condense the tracing, the solid black tracings were recorded. When ventricular arrhythmia occurred, the animal was promptly defibrillated, as soon as consciousness was lost. (B) The repeat exercise–ischemia test 1 wk after the control test following infusion of 5 g of n-3 PUFA intravenously just prior to the exercise–stress test. No arrhythmia occurred, and there were minimal changes in the functional parameters measured despite the obstruction of the CBF. Not shown in this figure was the repeat exercise-plus-ischemia test done 1 wk later in all dogs with either an infusion of 5–7 g of emulsified soybean oil [Intralipid® (Baxter, Deerfield, IL); $n = 5$] or saline ($n = 8$), which in all 13 animals failed to prevent sustained ventricular flutter, or tachycardia (VT) or ventricular fibrillation (VF). LVP = left ventricular pressure; CBF = left circumflex coronary blood flow; d(LVP)/dt was used as an index of the left ventricular contractility. (C) An enlargement of the electrocardiogram (ECG) from Figure 1A showing the arrhythmia that developed with the control exercise–ischemia test in this dog. The arrhythmia is VT, which commenced at a rate of some 270 beat/min and rose to over 400 beats/min by the end of the tracing. At the latter rate it can be seen in A that there was complete circulatory failure as indicated by the cessation of ventricular systolic pulses and of ventricular dP/dt. Such VT occurring in these animals invariably deteriorates into VF, so the dog was promptly defibrillated, as soon as consciousness was lost. The time bar indicates 1.0 s.

fish oil emulsion are displayed in Figure 1. The abrupt drop in the blood flow measured in the left circumflex coronary artery distal to the cuff indicates the time and completeness of occlusion of that artery. The decreases of the left ventricular pressure (LVP) and of the ventricular d (LVP)/dt maximum (an index of ventricular contractility) which occurred with the onset of the ventricular tachycardia seen on the electrocardiogram (ECG) shortly before the treadmill was stopped are evident in the upper control tracings, By contrast, 1 wk later when the identical exercise–ischemia procedure was repeated, but the emulsion of n-3 free fatty acids was infused just prior to the test, the lower tracing shows the minimal changes in these hemodynamic parameters despite the same completeness of the occlusion of the circumflex artery by inflation of the cuff. The second control, 1 wk later, in which the arrhythmic response predictably and reproducibly occurred is not shown since it was the same as this first control. Figure 1C is an enlargement of the tracing of the arrhythmia, VT, experienced by this dog and shows the quite regular beating rate that commenced at a rate of some 270 beats per min and rose to over 400 beats per min by the end of this tracing associated with complete failure of the circulation, as evidenced by the cessation of left ventricular systolic pressure and of left ventricular dP/dt. Our experience is that such ischemia-induced VT deteriorates quickly into VF, so the dog was promptly defibrillated as soon as consciousness was lost. The average time from the occlusion of the left circumflex coronary artery to the onset of VT or VF was 57.4 ± 1.4 s for the first controls and 47.8 ± 8.6 s for the second controls. These data demonstrate that the acute intravenous administration of the free PUFA can prevent the occurrence of malignant ventricular arrhythmias induced by ischemia in this dog model of sudden cardiac death.

The hemodynamic effects of the fish oil emulsion are shown in Table 1 (n = 13 for all comparisons except for the measurements of ventricular systolic pressure and left ventricular dP/dt which were performed on five animals, but with significant changes obtained). The fish oil emulsion significantly attenuated the heart rate in the resting animals (Table 1) and also during exercise (Fig. 2) as well as with the response to the coronary occlusion (control: before, 204.7 ± 9.2, and during occlusion 228 ± 9.2, compared to fish oil: 168 ± 10.6 and 171 ± 15.2 beats/min, respectively). Infusion of the n-3 fatty acids in these dog studies elicited a reduced inotropic effect (decreased left ventricular dP/dt with a reduced ventricular systolic pressure). Table 1 also shows that the PUFA produced a significant shortening of the QT interval (QT is an electrocardiographic interval from the start of the Q-wave to the start of the T-wave of the ECG) corrected for changes in pulse rate (QTc) (12), indicating a shortening of the action potential duration and prolongation of the P-R interval (P-R interval is the duration of conduction time from the start of the auricular P-wave to the start of the R-wave conventionally measured from the ECG). Representative portions of two ECG tracings are shown in Figure 3 to allow visualization of the PR and QT interval changes produced by the PUFA. Both the control strip and the strip following infusion of the n-3 PUFA were taken with the dog in the resting state. The time bars for both strips indicate that 25 mm represents 250 ms. The control heart rate was 107 beats/min and the n-3 PUFA slowed the pulse rate to 40 beats/min, a larger than average slowing effect in this dog. The PR-interval increased from 10 mm or 100 ms to 13 mm or 130 ms, and most of the prolongation occurred during the isoelectric portion of the interval. The QT interval was 150 ms before the infusion and was 170 ms afterward. After correcting for the change in heart rate (12), the QTc-interval values were 200 and 140 ms, respectively. Thus, the n-3 PUFA reduced the QT interval. All

TABLE 1
The Hemodynamic Effects of the Intravenous Infusion of the n-3 PUFA[a]

	Control	Fish oil emulsion	*P*
Resting heart rate (beats/min)	124 ± 4	85 ± 4	<0.001
Ventricular systolic pressure (mm Hg), n = 5	154 ± 6	117 ± 4	<0.001
Left ventricular dP/dt (maximum mm Hg/s), n = 5	5070 ± 353	2960 ± 497	<0.01
QTc interval (ms)	266 ± 7	242 ± 5	<0.02
P-R interval	102 ± 4	122 ± 6	<0.02

[a]The resting heart rate was significantly reduced following infusion of the emulsion containing the n-3 polyunsaturated fatty acids (PUFA). Ventricular systolic pressure and left ventricular dP/dt were determined by a pressure transducer implanted in the left ventricle. Both were significantly reduced by the n-3 PUFA, indicating a reduced inotropic effect. QTc is the OT interval from the electrocardiogram corrected for changes in pulse rate. Note: QT is an electrocardiographic interval from the start of the Q-wave to the start of the T-wave of the electrocardiogram.

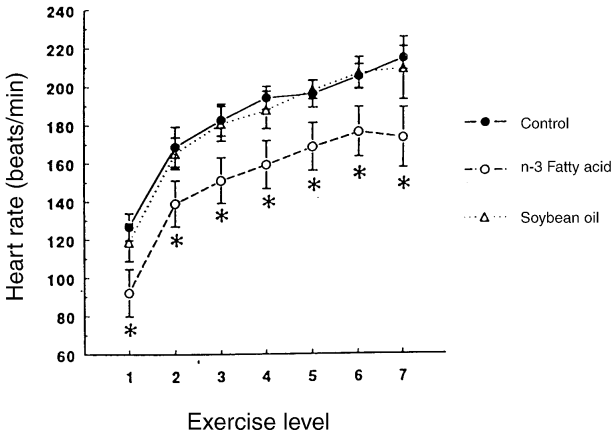

FIG. 2. The heart rate response to submaximal exercise with and without the prior infusion of an emulsion of lipid. These data are from the five animals that received an infusion of n-3 PUFA and a similar infusion of soybean oil (Intralipid®) as a second control. In the remaining eight animals a similar response was observed when normal saline infusion was used as the control. Asterisk indicates control vs. n-3 PUFA, $P < 0.01$, two-factor analysis of variance with repeated measures. For abbreviation and manufacturer see Figure 1.

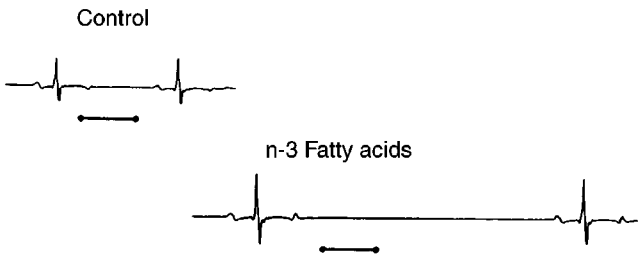

FIG. 3. In a representative portion of an ECG tracing is shown effects of changes in heart rate on the PR and OT intervals produced by the PUFA. Both the control strip and the strip following infusion of the n-3 PUFA were taken with the dog in the resting state. The time bars for both strips indicate 250 ms. The control pulse rate was 107 beats/min, and the n-3 PUFA slowed the pulse rate to 40 beats/min, a larger than average slowing effect in this dog. The PR-interval increased from 100 ms to 120 ms, and most of the prolongation occurred during the isoelectric portion of the interval. The effect of the changes in pulse rate on the QT interval caused by the PUFA can also be demonstrated in these strips. The uncorrected QT interval was measured as 150 ms before the infusion of the PUFA and 170 ms after the infusion. But the QT interval is inversely related to the pulse rate: Slowing the pulse increases the QT interval and vice versa; thus the Bazett's correction (12) is classically made ($QTc = QT/(R–R)^{1/2}$, where QTc is the QT interval corrected for the pulse rate and R-R is the interval between one R-wave and the next one expressed in seconds). Accordingly, QTc is 200 ms before and was reduced to 140 ms after the infusion of the PUFA. See Figure 1 for abbreviations.

these changes in the whole animal relate to specific effects of these PUFA that we have reported in isolated cardiomyocytes, as will be discussed.

Finally, plasma n-3 fatty acids in the nonesterified fatty acid (NEFA), triglyceride, and phospholipid fractions of the serum were analyzed by gas chromatography. After infusion of the fatty acid emulsion, the content of free n-3 fatty acids rose considerably in the NEFA fraction of plasma, as expected (Table 2). However, during the approximate 90 min from the start of the infusion of the emulsion to the end of the study, only minimal EPA and DHA were incorporated into plasma triglycerides with no detectable enrichment in plasma phospholipids. One sees in Table 2 that in all four of the dietary fatty acids of interest which were contained in the egg yolk lecithin (neither linolenic acid LNA nor EPA was detected) there appeared actually to be a decline in their concentration in plasma phospholipids after administration of n-3 PUFA. This unexpected finding might have occurred if we had overcorrected for the possible contribution of the fatty acids in the added egg yolk lecithin. Therefore, in Table 3 we show that, even if no subtraction is made from the total analyzed plasma phospholipids for possible addition of these fatty acids from the egg yolk emulsificant, there occurred no detectable increase in the phospholipids by the time the expected cardiac arrhythmias would have occurred. Incorporation of the PUFA into phospholipids by the liver is rapid and expected to precede incorporation into membrane phospholipids. These PUFA, when incorporated in triglycerides or membrane phospholipids, have not been found to be promptly antiarrhythmic (11,13). With these considerations, our *in vitro* studies are supported that it is only the free form of these fatty acids in the NEFA of the plasma which is responsible for preventing the arrhythmias (13). Indeed, in a single experiment, the infusion of the same PUFA as the ethyl ester failed to prevent arrhythmias during ischemia (data not shown). To minimize use of dogs in these costly experiments, and since similar negative results with the triglyceride and the ethyl ester were obtained *in vitro* (13), further negative studies were not pursued in the dog.

DISCUSSION

The present study demonstrates that the long-chain n-3 PUFA contained primarily in fish oils in contemporary diets can prevent ischemia-induced fatal ventricular arrhythmias in dogs surgically prepared to be susceptible to cardiac sudden death. Thus, we report a statistically significant prevention of ischemia-induced VT or VF in conscious, exercising dogs by the acute infusion of n-3 fatty acids. We further demonstrate the functional effects in these dogs, which are similar to effects we have reported in studies with isolated cardiac myocytes.

Prior *in vitro* studies demonstrated that all long-chain PUFA of the two classes of essential fatty acids, both n-6

[a]FA compositions were determined before (Control) and after infusion of n-3 PUFA. Values are the means ± SEM. $n = 7$ dogs. Blood samples were obtained prior to starting the n-3 PUFA infusion (Control) and after the infusion but just prior to the exercise–ischemia test (After). Each animal served as its own control. with one control test a week prior to the n-3 PUFA infusion and another a week following the n-3 PUFA infusion. The dose of n-3 PUFA varied from 1.0 to 5 g: the three failures were not dose-related and all occurred with the 5-g dose. They are included in the seven analyses. Since the pure egg yolk lecithin included four of the six FA included in this table (no LNA or EPA were detected), the concentrations of the phospholipid FA were "corrected" in Table 2 by subtracting the estimated concentration of the respective FA contributed from the egg yolk lecithin from the total concentration of these four FA in the plasma phospholipids. LA, linoleic acid; AA, arachidonic acid; LNA, linolenic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid; NEFA, nonesterified fatty acids. See Table 1 for other abbreviation.

TABLE 3
Mean of the Paired Differences, Δ*x*, Between the Concentration of EPA and of DHA in Plasma Triglycerides and Phospholipids Following the Infusion of the Fish Oil Emulsion[a]

	(Fish oil) – (Control) Δ*x* ± SEM (mM)	*P*
Triglycerides[b]		
EPA	0.022 ± 0.006	<0.005
DHA	0.0084 ± 0.0034	<0.025
Phospholipids		
EPA	0.0013 ± 0.001	0.2
DHA	0.0034 ± 0.0019	0.1

[a]Infusion of the n-3 PUFA emulsion produced a small incorporation of EPA and DHA in plasma triglycerides, but no detectable incorporation of the EPA or DHA into plasma phospholipids at the time ischemia was induced. In this Table the changes in the phospholipid values found on analysis of the phospholipid fraction after the n-3 PUFA emulsion was infused are uncorrected and therefore include both the content of these four FA in the plasma plus that contributed from the egg yolk lecithin. Nevertheless, as the analysis shows, there is still no detectable increase in the phospholipid content of these FA. See Tables 1 and 2 for abbreviations.

PUFA (abundant in most vegetable oils) and n-3 PUFA (abundant largely in marine foods but present in a few plant oils as well—canola, soybean, flaxseed oils) possess antiarrhythmic actions (13,14). This effect is not shared by the monounsaturated fatty acid, oleic acid, nor by saturated fatty acids. Because of the anomalous behavior of *cis*-5,8,11,14-eicosatetraenoic acid (arachidonic acid, 20:4n-6), which in a portion of our experiments produced arrhythmias that can be blocked by cyclooxygenase inhibitors (13), we have recommended that, for potential future clinical applications, studies should focus on the antiarrhythmic actions of the n-3 PUFA, which we have not observed to be proarrhythmic. Therefore, in this study we have examined only the n-3 PUFA of a fish oil concentrate to save on the number of animals needed and to contain the expense of the study.

Free fatty acids are rapidly incorporated by esterification into both plasma triglycerides and phospholipids. The finding in this study, that the prevention of lethal, ischemia-induced ventricular arrhythmias occurred before there was time for any significant incorporation of the n-3 PUFA into plasma phospholipids and minimal incorporation even into triglycerides, suggests that it was the infused free fatty acid form of the PUFA that was antiarrhythmic. These findings confirm our earlier report in isolated myoctes that only the free PUFA, by partitioning into the phospholipid membranes, are necessary to prevent tachyarrhythmias induced by a variety of arrhythmogenic agents (11,13).

Thus these data support the hypothesis that the action of the free, nonesterified PUFA are sufficient for the prompt prevention of ischemia-induced VF in the whole animal, and this can be accomplished by their intravenous administration. Since feeding studies may be confounded by unsuspected variables, we have tested the effectiveness of the n-3 PUFA when administered intravenously as an emulsion of the free fatty acids just prior to inducing myocardial ischemia in the dogs. We have used this protocol to ensure that, if an intravenous emulsion largely of free EPA and DHA prevents arrhythmias, we can with considerable certainty ascribe the protection to an action of the free n-3 PUFA.

When these PUFA are ingested in their natural triglyceride or synthetic ethyl ester form, the intestinal and plasma esterases liberate the free fatty acids and monoglycerides in the intestines. But with absorption they pass through the liver where the free fatty acids are efficiently resynthesized into triglycerides so that the free fatty acid in the NEFA fraction of the plasma lipids is not increased. In the tissues lipoprotein lipases liberate the fatty acids from the transported triglycerides, and the free fatty acids are then carried in the plasma noncovalently bound largely to serum albumin from which they are rapidly transferred to cells. The rate of transfer of bound free fatty acids on albumin is indeed rapid. The time it takes for the fatty acids to leave the albumin in the proximity of cells and to flip-flop across the phospholipid bilayer has been measured and found to be 23 ms or less (15) and is not rate-limiting for the transfer of fatty acids to cell membranes (16), from which the fatty acids can be internalized and be metabolized or incorporated in triglycerides or phospholipids. From the latter stores, the free fatty acid can be liberated by lipases, and it is these liberated free fatty acids which apparently provide the antiarrhythmic effects following stresses which activate the appropriate lipases. With ischemia and myocardial infarction, the catecholamine response will activate lipase activity. If n-3 PUFA are stored in triglycerides or phospholipids as a result of dietary ingestion, they may be available locally at such times to provide protection of the ischemic myocardium from arrhythmias. It has been shown repeatedly that the concentration of free fatty acids rises very promptly in the heart following experimentally induced coronary artery occlusion, though their actual concentration at their site of action on the cardiomyocytes is not known. When we infuse an emulsion of free fatty acids, the aggregates of micellar or laminar forms presumably would deliver their content of free fatty acids directly to cells, bypassing the albumin step to provide the antiarrhythmic effects in the myocardium to subjects who were deficient in stored n-3 PUFA owing to inadequate dietary intake of these protective fatty acids. At present, the question of what constitutes a physiological protective concentration of the free n-3 PUFA at the site of individual cardiomyocytes in the ischemic heart cannot be answered. nor do we know whether the infused emulsion delivers free fatty acids to partition into the cell membrane phospholipids to modulate ion channels at concentrations similar or grossly in excess to that which can be supplied from endogenous stores. We have reported inhibition of the L-type calcium currents in isolated rat heart cells seen with as little as ~20 nM EPA added to the superfusate (17), which is in the physiological concentration of monomeric free fatty acids in the aqueous phase of plasma reported in humans (18,19), but it is the concentration (electrochemical activity) of free n-3 fatty acids that have partitioned into the phospholipids of myocyte membranes that modulate the ion channels, not their concentration in the aqueous phase of plasma. Clearly more research is needed before understanding of the transport and movement in the environment of aqueous plasma of highly hydrophobic mole-

cules, like these fatty acids, provides a definitive answer to this important question. It seems probable to us that the mechanism of the electrically stabilizing, antiarrhythmic effect of the free PUFA on cardiomyocytes, whether ingested or administered acutely intravenously, is the same, but our studies do not exclude the possibility that other additional protection may not be afforded by the PUFA while still incorporated within the membrane phospholipids (20).

The slowing of the heart rate and the prevention of ischemia-induced ventricular fibrillation by the intravenous infusion of n-3 fatty acids in the conscious, exercising prepared dogs were expected from our results with the simpler, isolated, neonatal rat myocyte preparation. In that preparation, in the absence of neural or humoral factors, the PUFA slow the spontaneous beating rate of the cells (13). But they also block the tachyarrhythmias induced by the β-adrenergic receptor agonist, isoproterenol, and its intracellular second messenger, c-AMP (21). Both effects, however, are secondary to the direct, primary electrophysiologic effects of the PUFA on the heart cells (22), which in turn result from modulating effects of the PUFA on ionic currents through membrane ion channels in cardiac myocytes (17,23). The slowing of the heart rate from these actions could contribute to the antiarrhythmic effects of the PUFA.

In these dog studies the effects of the n-3 PUFA included (Table 1) a significant reduction in left ventricular contractility, d(LVP)/dt and in ventricular systolic pressure. Reduced ventricular dP/dt can be caused by a direct depressing effect on the myocardium, but it can also result from changes in blood pressure and heart rate. These same fatty acids decrease blood pressure (24) owing to their vasodilatory actions (25,26) lowering systemic vascular resistance. Since the measurements shown in Table 1 were made before and following administration of the PUFA emulsions, but prior to running on the treadmill, the dogs' heart rates were generally reduced. Ventricular dp/dt is also known to be altered by load conditions both preload and afterload. Therefore, reduction of afterload in this study resulting from the systemic vasodilatation caused by the n-3 PUFA could have contributed to reduction of dP/dt. Although the reduction in inotropy observed in these whole animal studies is significant, it cannot be solely ascribed, from the data available, as resulting from a direct depressing effect on the myocardium.

The antiarrhythmic action of these fatty acids indicates that in the fish oil feeding studies in animals (4–6,20,27) and the one fish and one n-3 fatty acid secondary, randomized clinical trials in humans (28,29) the significant reduction in mortality from sudden death can probably be attributed to the ingestion of these fatty acids. We cannot, however, yet claim that the mechanism for the antiarrhythmic effect is the same when the fatty acids are administered by these different routes, though this seems probable based on the specificity of their antiarrhythmic action (13,17,22,23,30).

The slowing of the heart rate and the reduced QT interval are changes associated with Class Ib antiarrhythmic drugs which prolong the duration of the inactivated state of the voltage-gated sodium channels (31), an effect of the PUFA observed in the isolated myocytes (23). The prolongation of the P-R interval without a change in the P-wave indicates slowing of conduction through the atrio-ventricular node consistent with the inhibition of L-type calcium channels (17) or a β-blocking effect (21) by the PUFA, demonstrated in isolated cardiomyocytes.

The dose of the free acidic PUFA administered in these studies ranged from an initial high dose of 10 g, delivered as a phospholipid emulsion, progressively down to 1 0 g, administered on an albumin carrier to only one animal in this series. Of the three animals not protected from VF by the PUFA, all occurred in dogs that had received 5 g of the n-3 PUFA. Since the other animals were protected by doses that varied from 10 g down to 1.0 g, there was no apparent relation in the 13 animals of this study between the dose and the failure rate.

The free fatty acids cannot be administered intravenously with impunity. The first two animals that received the 100 mL of 10% emulsion rapidly, almost as a bolus injection, died suddenly before the study started. Before the rate of infusion was sufficiently decreased, death occurred several hours later with this high dose in a dog from what appeared to be acute respiratory distress associated with marked hemolysis resulting from the detergent action of the free fatty acids on blood cells. With a slower rate of administration (50 to 60 min) there were no more deaths from the administered PUFA, but hemolysis was visible in the serum and the animals had hematuria on the full 10-g doses. Decreasing the total dose progressively to 7.5, 5, 2.5, and 1.0 g of the emulsion reduced the hemolysis and the hematuria but still afforded protection from fatal arrhythmias. The minimal effective intravenous dose is yet to be determined, but in practice for primary or secondary prevention the oral route will be preferred, though the intravenous use may have application in some acute cardiac emergencies.

In conclusion, the acute intravenous administration of free n-3 PUFA prevents ischemia-induced lethal ventricular arrhythmias in this canine model of sudden cardiac death, and several features of cardiac function induced by the infused n-3 PUFA were similar to the effects of these PUFA in the *in vitro* cardiomyocyte preparation. It is apparent that there is an important regulation of cardiac function based on simple dietary choices of ingested fatty acids, which merits further investigation. Our electrophysiologic studies suggest nervous and other excitable tissues should also be affected by these fatty acids, and this has been shown by others (32–36) and by us (37). There is need now for careful clinical trials by both the oral and parenteral route to determine the efficacy and the optimal safe dose of these n-3 fatty acids in preventing malignant arrhythmias in subjects with/or at risk from cardiovascular diseases—a major public health problem.

ACKNOWLEDGMENTS

This study was supported in part by a grant from the American Heart Association, Ohio Affiliate, and the National Institutes of Diabetes and Digestive and Kidney Diseases of the National Institutes of Health, grant DK38165. We thank PronovaBiocare, Lysaker, Norway, for their generous gift of the fish oil n-3 fatty acid preparations used in this study.

Biliary Excretion of Dolichols and β-Hexosaminidase—Effect of Ethanol and Glucagon

Kari Humaloja, Mikko Salaspuro*, and Risto P. Roine

Research Unit of Alcohol Diseases, Helsinki University Central Hospital, Helsinki, Finland

ABSTRACT: Alcohol has been reported to increase the urinary excretion of dolichols, and urinary dolichols are suggested to be derived from the lysosomes of the renal cells. In the present study we examined the effects of alcohol and glucagon on the biliary excretion of dolichols in rats. Chronic ethanol treatment decreased both biliary dolichol and β-hexosaminidase excretion. The absolute amount of dolichol excreted into the bile correlated highly significantly with the absolute amount of biliary β-hexosaminidase. Our results indicate that biliary dolichols are—at least in part—derived from hepatic lysosomes. Decreased biliary dolichol output during chronic alcohol administration suggests that urinary and biliary dolichol excretions are regulated independently of each other.

Lipids 32, 1169–1172 (1997).

Dolichols are long-chain polyisoprenoid alcohols generally restricted to chain lengths of 14–24 isoprene units (1). They are synthesized in microsomes and stored in lysosomes (1). Dolichols are widely distributed among the tissues of a variety of eucaryotes, in which they occur as free alcohols, esters with long-chain fatty acids, and phosphomonoesters (2,3). The phosphorylated form of dolichol acts as an essential intermediate in the biosynthesis of asparagine-linked glycoproteins (4,5). The free and esterified dolichols have been suggested to play a role in the regulation of membrane fluidity, stability, and permeability (6–11).

Urinary dolichol excretion is increased in a variety of clinical conditions. These include pregnancy (12), severe bacterial infections (12), and malignancies (12,13). Aspirin has been shown to increase the urinary excretion of dolichol and lysosomal enzymes (β-hexosaminidase and β-glucuronidase), which suggests that urinary dolichols may be derived from the lysosomes of the renal cells (14). In addition, alcoholics have elevated urinary (15,16) and blood (17) dolichol levels. Glucagon—a substance known to acutely modify hepatocyte lysosomal function—has been shown to decrease the biliary output of lysosomal enzymes (18). The effect of alcohol on biliary excretion of dolichols has so far not been investigated, although biliary excretion has been considered to be an important elimination route for dolichols (19). Acute ethanol administration has been shown to decrease biliary lysosomal enzyme output in liver perfusate (20). Chronic ethanol feeding, however, has been shown to have no effect on biliary cholesterol or phospholipid output (21).

The aim of the present study was to examine possible mechanisms of biliary dolichol excretion by comparing it to the biliary output of β-hexosaminidase under various *in vivo* conditions.

MATERIALS AND METHODS

General experimental procedure. Male Wistar rats weighing 265–620 g were used for all experiments. Under sodium pentobarbital anesthesia (40 mg/kg), the common bile duct was cannulated just below the hepatic duct bifurcation above the entrance of the pancreatic duct with PE-10 polyethylene tubing. Bile was first collected for 1.5 h. This was followed by the administration of ethanol or glucagon (or an equal amount of saline for control rats) whereafter bile was collected for another 1.5 h. Ethanol [2 g/kg body weight (b.w.)] was administered intraduodenally as a 30% solution whereas glucagon (Novo Nordisk A/S, Bagsvaard, Denmark) was injected intravenously (1 mg/kg b.w.) into the outer jugular vein.

After the total collection period of 3 h, all rats were sacrificed and their livers were removed and weighed. The volumes of collected bile were determined by weighing, assuming a density for bile of 1.0 g/mL.

In the chronic alcohol intake study, a model shown to produce alcoholic liver injury was used (22). After 5 wk of chronic alcohol consumption, the complete bile fistula was created and samples were collected as described above.

Analytical methods. All bile samples were transferred into plastic tubes and kept frozen at −20°C until analyzed. Saponification and extraction of dolichols from bile (0.5 mL) and analysis with a high-performance Varian Vista 5500 liquid chromatograph (Palo Alto, CA) were performed as reported previously (17,23).

β-Hexosaminidase activity (E.C. 3.2.1.30) was determined by a spectrophotometric method using *p*-nitrophenyl-*N*-acetyl-β-glucosamine (Sigma Chemical Co., St. Louis, MO) contained in 0.34 mol/L citrate buffer, pH 4.5 as a substrate (24,25).

Statistical calculations. All results are expressed as means ± SEM. Statistical differences between the treatment groups and controls were calculated using Student's *t*-test. Logarithmic transformations were carried out when necessary to ensure that the distributions of the results met the criteria for normality. Spearman's correlation was used in the calculation of correlations. A *P*-value of <0.05 was considered significant.

RESULTS

In all rats, biliary dolichol and β-hexosaminidase excretion tended to decrease during the second collection period. The results of the acute experiments are therefore expressed as the percentage decrease of dolichol or β-hexosaminidase excreted during the second collection period as compared to the first collection period. In the glucagon-treated rats (n = 11), the decrease in biliary dolichol excretion during the second collection period (70 ± 3% decrease of that found in the first collection period) was significantly ($P < 0.01$) larger than that observed in the saline-treated controls (53 ± 5%, n = 10, Fig. 1). The same was also true for β-hexosaminidase (70 ± 5% in glucagon-treated, n = 10, vs. 49 ± 3% in controls, n = 10, $P <$ 0.01, Fig. 1). By contrast, acute ethanol administration had no significant effect on biliary dolichol or β-hexosaminidase excretion during the second collection period as compared to saline-treated controls. Bile flow after acute glucagon administration did not differ significantly from that observed in the controls (0.13 ± 0.02 mL/h/100 g b.w., n = 13, vs. 0.14 ± 0.03 mL/h/100 g b.w., n = 13). The same was also true after ethanol administration (0.18 ± 0.02 mL/h/100 g b.w., n = 14, vs. 0.16 ± 0.02 mL/h/100 g b.w., n = 13).

Chronic alcohol administration led to a decrease in biliary dolichol excretion as compared to controls, and the same was also true for β-hexosaminidase (Table 1). On the other hand, liver weight and bile flow were not different in ethanol-treated and control rats (Table 1).

Combining all experiments for analysis revealed that the absolute amount of dolichol excreted into the bile during a given collection period correlated highly significantly (r = 0.84, $P < 0.0001$) with the absolute amount of β-hexosaminidase excreted (Fig. 2). Similarly, the change observed in biliary dolichol excretion during the first and second collection periods in the acute experiments correlated significantly (r = 0.64, $P < 0.0001$) with the change observed in β-hexosaminidase excretion.

DISCUSSION

Liver plays a central role in the metabolism of dolichols. Radioactively labeled exogenous dolichol is taken up by the hepatocytes and is excreted into the bile in the perfused rat liver (26). Dolichol synthesized by the liver is mainly stored in the

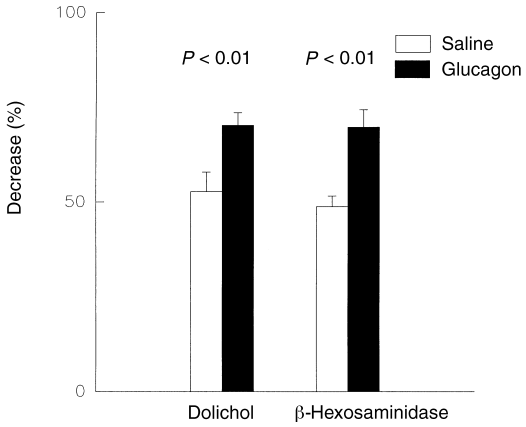

FIG. 1. The percentage decrease (mean ± SEM) in biliary dolichol and β-hexosaminidase excretion after intravenous administration of saline or glucagon to male Wistar rats.

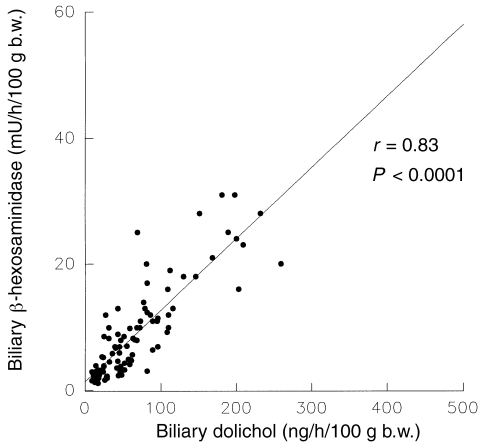

FIG. 2. The correlation between the absolute amount of biliary dolichol and β-hexosaminidase excreted into the bile during the first and second collection period. Abbreviation: b.w., body weight.

TABLE 1
The Effect of Chronic Alcohol Treatment (5 wk) on Biliary Dolichol and β-Hexosaminidase Excretion (mean ± SEM) in Rats[a]

	Dolichol (ng/h 100 g b.w.)	β-Hexosaminidase (mU/h 100 g b.w.)	Bile flow (mL/h 100 g b.w.)	Liver weight (g)
Alcohol (n = 6)	40 ± 8	5.7 ± 1.4	0.18 ± 0.01	12.8 ± 0.7
Control (n = 6)	93 ± 26	11 ± 3	0.22 ± 0.02	12.6 ± 1.2

lysosomes (27). Bile is the only known route for the excretion of substantial amounts of dolichols from the body (19). Mechanisms that regulate biliary dolichol output are largely unknown. Lysosomes constitute the compartment which contains the highest concentration of dolichols in the hepatocytes, and it has been speculated that vesicular transport from lysosomes is involved in the biliary excretion of dolichols (28). Our results confirm that significant amounts of dolichols are excreted into the bile in rats *in vivo*.

Urinary excretion of dolichols is increased after aspirin administration, and this is paralleled by an increased urinary output of two lysosomal enzymes (β-hexosaminidase and β-glucuronidase), which suggests that urinary dolichols are derived from the lysosomes of the renal cells (14). It has been proposed that there also exists a lysosome-to-bile hepatic excretory pathway by which endogenous and exogenous material within the hepatocyte lysosomes may undergo biliary excretion (29). There is also evidence that lysosomes play a role in biliary iron (30) and copper (31,32) excretion.

Glucagon decreased biliary excretion of dolichols and β-hexosaminidase in our experiments. This is in line with previous experiments in which it was shown that glucagon decreases the biliary excretion of lysosomal enzymes in rats (18). The absolute amount of biliary dolichol excretion correlated highly significantly with that of β-hexosaminidase excretion during a given collection period. Similarly, the change observed in dolichol excretion during the first and second collection periods correlated significantly with the change observed in biliary β-hexosaminidase excretion in the acute experiments. The results indicate thus that biliary dolichols are —at least in part—derived from hepatic lysosomes and that biliary excretion of dolichols and lysosomal enzymes may be regulated partly by the same mechanisms.

Chronic ethanol administration decreased the biliary excretion of dolichol and β-hexosaminidase in our settings. The mechanism behind this effect is unclear, but alcohol may somehow disturb the function of lysosomes in the hepatocyte. It has been proposed that ethanol may either impair the movement of lysosomes to the bile canalicular membrane or impair the fusion of lysosomes with the canalicular membrane (20).

The level of dolichol in blood is rather constant under normal conditions (33), and there is no diurnal variation (23). Blood dolichol levels have been reported to be normal in most common diseases as well as in pregnancy (23,33). By contrast, serum dolichol concentration is reported to be highly elevated in two rare lysosomal storage diseases, aspartylglucosaminuria and mannosidosis (34), and to a lesser extent in alcoholics (17). On the other hand, patients suffering from neuronal ceroid lipofuscinosis have a decreased serum dolichol concentration as compared to normal controls (35). The mechanism behind these changes in blood dolichol concentration has been suggested to be a disturbance in lysosomal function (34,35). If dolichols are excreted into the bile by a suggested lysosome-to-bile hepatic excretory pathway (26) and biliary excretion is the main elimination route for dolichols from the body, a disturbance in lysosomal function may explain—at least in part—the elevated serum dolichols found in rare lysosomal storage diseases (34) and alcoholics (17).

Although supporting the concept of lysosomal origin of biliary dolichols, our results—especially the decreasing chronic effects of alcohol on biliary dolichol excretion—indicate that urinary and biliary dolichol excretion are regulated independently of each other or that the kidney is in that respect much more susceptible to the effects of alcohol than the liver.

Effect of Curcumin and Capsaicin on Arachidonic Acid Metabolism and Lysosomal Enzyme Secretion by Rat Peritoneal Macrophages

Bina Joe and B.R. Lokesh*

Department of Biochemistry and Nutrition, Central Food Technological Research Institute, Mysore-570 013, India

ABSTRACT: The inflammatory mediators secreted by macrophages play an important role in autoimmune diseases. Spice components, such as curcumin from turmeric and capsaicin from red pepper, are shown to exhibit antiinflammatory properties. The influence of these spice components on arachidonic acid metabolism and secretion of lysosomal enzymes by macrophages was investigated. Rat peritoneal macrophages preincubated with 10 μM curcumin or capsaicin for 1 h inhibited the incorporation of arachidonic acid into membrane lipids by 82 and 76%: prostaglandin E_2 by 45 and 48%; leukotriene B_4 by 61 and 46%, and leukotriene C_4 by 34 and 48%, respectively, but did not affect the release of arachidonic acid from macrophages stimulated by phorbol myristate acetate. However, the secretion of 6-keto PG $F_{1\alpha}$ was enhanced by 40 and 29% from macrophages preincubated with 10 μM curcumin or capsaicin, respectively, as compared to those produced by control cells. Curcumin and capsaicin also inhibited the secretion of collagenase, elastase, and hyaluronidase to the maximum extent of 57, 61, 66%, and 46, 69, 67%, respectively. These results demonstrated that curcumin and capsaicin can control the release of inflammatory mediators such as eicosanoids and hydrolytic enzymes secreted by macrophages and thereby may exhibit antiinflammatory properties.

Lipids 32, 1173–1180 (1997).

Inflammation is a necessary response of the host to counteract the threat of infectious agents and other foreign bodies (1). The inflammatory response is coordinated by the number of immune cells such as macrophages, B and T lymphocytes, basophils, eosinophils, and mast cells. A large number of mediators produced by these cells play a key role in inflammatory response. These include arachidonic acid metabolites like prostaglandins (PG) and leukotrienes (LT), reactive oxygen species like superoxide anions and hydroxyl radicals, hydrolytic enzymes like proteases and glycosidases, cytokines, complement-derived peptides, and kinins (2–4). These mediators act in concert to eliminate the source of infection. However if these mediators are produced in an uncontrolled manner, they can lead to the destruction of connective tissue matrix as has been observed in autoimmune diseases like rheumatoid arthritis (5). Enzymes such as collagenase, elastase, and hyaluronidase play a key role in the destruction of cartilage in the joints in arthritic conditions (6). The inflammatory responses can also be exacerbated by cytokines, reactive oxygen species, and arachidonic acid metabolites (4,7). Macrophages present at the site of inflammation are an important source of these various mediators (5). The tissue macrophages at the site of inflammation are supplemented by blood-derived monocytes and lymphocytes which infiltrate the vasculature in large numbers in response to complement activation products, connective tissue fragments, and other endogenously derived stimuli (4,8). Binding of the stimuli to cells leads to transmembrane signaling which ultimately leads to the secretion of lysosomal enzymes (9). To restrict the uncontrolled response of accumulated cells, treatments such as lymphocytopheresis, nonsteroidal antiinflammatory drugs, gold compounds, D-penicillamine, hydroxychloroquinine, corticosteroids, and immunosuppressants are often used (6). These treatments reduce the secretory functions of macrophages and other cells, resulting in the lowering of inflammatory responses.

Although usage of antiinflammatory drugs is in vogue, the continued administration of these drugs over a long period of time can have adverse side effects (5,6,10). Therefore, there is a need to explore alternative strategies to lower the formation of inflammatory mediators with the help of nontoxic natural products. Recently we have demonstrated that phenolic compounds, such as curcumin from the spice turmeric and capsaicin from red pepper, exhibit antiinflammatory properties on carrageenan-induced paw inflammation as well as in adjuvant-induced arthritis in rats (11,12). These effects are comparble to some of the known antiinflammatory drugs such as aspirin, indomethacin, piroxicam, and phenylbutazone (12,13). However, the mechanism by which curcumin and capsaicin exhibit antiinflammatory properties is not very clearly understood yet.

Activation of mononuclear cells plays a very important role in inflammation (5). Since our earlier studies and that of other investigators clearly established the efficacy of cur-

Abbreviations: BSA, bovine serum albumin; DMEM, Dulbecco's modified Eagle's medium; HBSS, Hanks' balanced salt solution; LT, leukotriene; PG, prostaglandin; PMA, phorbol myristate acetate.

cumin and capsaicin to reduce the inflammation in arthritis and other model systems (11,12,14), it is of interest to study the effect of these phenolic compounds on macrophage activation with reference to secretion of inflammatory mediators. We report in this investigation that curcumin and capsaicin inhibit the incorporation of arachidonic acid into macrophage lipids, which in turn decreases the formation of PGE_2, LTB_4, and LTC_4. Curcumin and capsaicin also transiently reduced the secretion of lysosomal enzymes such as collagenase, elastase, and hyaluronidase in activated macrophages. These studies indicated that the antiinflammatory properties of curcumin and capsaicin may be mediated by their inhibitory effects on the secretion of inflammatory mediators of mononuclear cells.

MATERIALS AND METHODS

Dulbecco's modified Eagle's medium (DMEM), phorbol myristate acetate (PMA), calcium ionophore A23187, Zymosan A, fatty acid-free bovine serum albumin (BSA), indomethacin, *N*-acetyl glucosamine, collagenase (Type VII from *Clostridium histolyticum*), elastase (from bovine pancreas), hyaluronidase (from bovine testes), hyaluronic acid, Dextran T-70, PGE_2, 6-keto prostaglandin $F_{1\alpha}$ and LTB_4 and LTC_4 were obtained from Sigma Chemical Co. (St. Louis, MO). 5,6,8,9,11,12,14,15[^{3}H]Arachidonic acid (specific activity 211.2 Ci/mmol), 6-keto [5,8,9,11,12,14,15(*N*)]-[^{3}H]-$PGF_{1\alpha}$ (specific activity 185 Ci/mmol), and [5,6,8,11,12,14,15(*N*)-[^{3}H]-PGE_2 (specific activity 183 Ci/mmol) were purchased from Amersham International plc (Amersham, United Kingdom). Antisera for 6-keto $PGF_{1\alpha}$ and PGE_2 were purchased from Advanced Magnetics Inc. (Cambridge, MA). DNP-peptide III and Suc-Ala-pNA were bought from Peptide Research Institute (Osaka, Japan). Natural capsaicin was from Aldrich Chemical Co. (Milwaukee, WI). Curcumin (99% pure) was purchased from Flavours and Essences (Mysore, India). Linalool (97% pure) and cuminaldehyde (90% pure) were purchased from Fluka (Buchs, Switzerland). Gelatin was obtained from Difco Laboratories (Detroit, MI). All other chemicals and solvents used were of analytical grade.

Animals. Adult male Wistar rats [OUTB-Wistar, IND-cft (2c), CFTRI animal house facility, Mysore, India] weighing approximately 250 g were used for all the studies.

Isolation of peritoneal macrophages. Macrophages were isolated from the rat peritoneal exudates in Hanks' balanced salt solution (HBSS) as described previously (15).

Uptake of [^{3}H]-arachidonic acid by macrophages. Macrophage monolayers (2.5×10^6 cells) in 1.5 mL of DMEM were incubated with [^{3}H]-arachidonic acid (0.01 μCi complexed to 1 mg BSA/mL) for 15 h at 37°C in a humidified incubator (16). The culture supernatant was aspirated, and the adhering cells were washed three times with DMEM containing 0.1% BSA. The adhering cells were scraped in 1 mL of saline containing 0.01% Triton-X 100, and the lipids were extracted by the method of Bligh and Dyer (17). The lipid extracts were taken in scintillation vials, evaporated to dryness with nitrogen, and dissolved in 5 mL of toluene-based scintillant. The incorporation of [^{3}H]-arachidonic acid was quantitated using a Beckman liquid scintillation counter (Model LS-100; Fullerton, CA).

Release of [^{3}H] arachidonic acid. Macrophage lipids were labeled with [^{3}H]-arachidonic acid as described above and washed three times with DMEM containing 0.1% BSA. The cells were incubated for 2 h in 1.5 mL of DMEM containing 2.5 mg/mL BSA, 3 μM indomethacin, and 0.1 μM PMA (16). Control cells were incubated under similar conditions in the absence of PMA. The radiolabeled arachidonic acid released into the medium was extracted by the Bligh and Dyer procedure (17). The [^{3}H]-arachidonic acid released was quantitated in a Beckman scintillation counter (16).

Release of PG. Macrophage monolayers (2.5×10^6 cells/1.5 mL DMEM) were incubated with 5 μg/mL of Ca^{2+} ionophore A23187 for 90 min. The PGE_2 and 6-keto $PGF_{1\alpha}$ released were extracted from the medium (in 2 mL of ethyl acetate × 3) after acidifying the supernatant with 100 μL of 3% formic acid to pH 3 (18). The combined ethyl acetate extracts were evaporated under a stream of nitrogen and suspended in 100 μL of phosphate-buffered saline containing 1% gelatin. Appropriate dilutions of this solution were used for quantifying the PG by radioimmunoassay (18).

Analysis of LT. Macrophages (2.5×10^6 cells/1.5 mL of DMEM) were activated with 5 μg/mL of Ca^{2+} ionophore A23187 for 90 min. The LT released into the medium were extracted with 2 vol of methanol. The extract was acidified with 3% formic acid to pH 3.0 and prepurified on Sep-Pak C-18 column (Waters, Millipore Corp., Milford, MA) (19). The LT extract was concentrated and loaded on a Supelcosil C-18 high-performance liquid chromatographic column (Supelco, Bellefonte, PA) of pore size of 5 μ. The LT were eluted with acetonitrile/methanol/acetic acid/water (65:10:1:24, by vol) adjusted to pH 5.6 with ammonia. LTC_4 and LTB_4, which eluted at the retention times of 4.7 and 16.9 min, were monitored at 280 nm. The LT were identified and quantitated by comparison with chromatography of authentic standards.

Effect of spice principles on the incorporation and release of arachidonic acid. The macrophages were preincubated with increasing concentration of spice principles (in 10 μL of ethanol) for 60 min prior to the addition of [^{3}H]-arachidonic acid for incorporation studies or prior to the addition of activators in the release reaction. The cells that were incubated with spice principles were thoroughly washed with HBSS containing 2% BSA and used for further studies. Uptake of spice principles by macrophages was monitored by high-performance liquid chromatography analysis as described earlier (15).

Hydrolytic enzymes. Macrophage monolayers (2.5×10^6 cells) were incubated with or without spice principles in 1 mL of HBSS containing 500 μg of Zymosan A for 18–72 h. The hydrolytic enzymes collagenase, elastase and hyaluronidase, released in the culture supernatants by activated macrophages, were measured.

Collagenase activity. Collagenase activity was measured colorimetrically at 365 nm using the synthetic substrate DNP peptide III (DNP-pro-Gln-Gly-Ile-Ala-Gly-Gln-D-Arg) (20). The amount of DNP peptide hydrolyzed was quantitated using a molar extinction coefficient of 1.49. Collagenase activity is expressed as µM/mg protein (20).

Elastase activity. The activity of elastase was assayed at 405 nm as described by Kawabata *et al.* (21) using the synthetic substrate Suc-Ala-Pro-Ala-pNA in 0.1 M Tris-HCl buffer (pH 5.0). One unit of elastase activity was defined as the quantity of enzyme that liberates 1 µmol of *p*-nitrosanilide in 60 min.

Hyaluronidase activity. Hyaluronidase activity in the culture supernatant was determined by the amount of *N*-acetyl glucosamine released from hyaluronic acid (22,23).

Protein estimation. Total protein was estimated by the method of Sedmak and Grossberg (24) using BSA as reference standard. Macrophage protein was quantified after digesting the cells (2.5×10^6 cells) in 1 mL of 1 N NaOH overnight.

Statistical analysis. The data were statistically analyzed by Student's *t*-test (25).

RESULTS

Effect of spice principles on: (i) Incorporation of arachidonic acid. Macrophages preincubated with curcumin or capsaicin for 1 h incorporated a lesser amount of [^{3}H]-arachidonic acid in membrane lipids as compared to control cells which were incubated with vehicle (10 µL of ethanol) alone. This effect was dependent on the concentration of spice principles used in the incubation medium. Thus, 1, 2.5, 5, 7.5, and 10 µM curcumin inhibited [^{3}H]-arachidonic acid incorporation by 9, 27, 42, 54, and 82%, respectively, at 1 h of incubation (Fig. 1). However, this inhibitory effect of curcumin on fatty acid incorporation was reduced if macrophages were incubated with [^{3}H]-arachidonic acid for a longer period of time. Thus curcumin at 1, 2.5, 5, 7.5, and 10 µM reduced the incorporation of [^{3}H]-arachidonic acid by only 0, 3, 11, 28, and 78% by the end of 2 h. By 6 h of incubation, curcumin at 1 to 5 µM did not inhibit the incorporation of [^{3}H]-arachidonic acid by macrophages. Similarly, the inhibitory effects of curcumin at 10 µM on [^{3}H]-arachidonic acid incorporation were decreased with time, and by 10 h of incubation, curcumin even at high concentrations failed to influence the ability of macrophages to incorporate arachidonic acid (Fig. 1). Capsaicin at 1, 2.5, 5, 7.5, and 10 µM reduced the incorporation of [^{3}H]-arachidonic acid into macrophage lipids by 21, 46, 52, 66, and 76% at 1 h, 3, 11, 18, 36, and 45% at 2 h, 0, 0, 0, 20, and 35% at 6 h, 0, 0, 0, 10, and 27% at 8 h, and there was no reduction at 10 h of incubation. These studies indicated that the inhibitory effect of curcumin and capsaicin on the incorporation of arachidonic acid by macrophages is short-lived and is fully reversible with time. Therefore, the incorporation of arachidonic acid into macrophage lipids was inhibited by spice principles only in the initial period of incubation (<10 h at 10 µM). The macrophages incubated with spice principles were fully viable at all the time points as judged by trypan blue exclusion. Macrophages preincubated with other spice principles such as cuminaldehyde (from cumin) and linalool (from coriander) even at 500 µM had no effect on the incorporation of [^{3}H]-arachidonic acid at all the times tested (Fig. 1). These studies indicate the specificity and the efficacy of individual spice principles in reducing the incorporation of arachidonic acid into macrophage lipids.

The inhibitory pattern of arachidonic acid incorporation into macrophage lipids was associated with intact curcumin or capsaicin inside the cells (Table 1). However, when these spice principles were modified by the cells, the inhibition was reduced. More than 95% of intact curcumin and 87% of capsaicin internalized by the cells are modified by the end of 9 h of incubation (Table 1). However, we were unable to identify the metabolites of curcumin or capsaicin by spectroscopic methods, thin-layer chromatography, or high-performance liquid chromatography. Cuminaldehyde and linalool, though taken up to a maximum extent of 92%, failed to influence the incorporation of arachidonic acid. The cells were fully viable as judged by trypan blue exclusion method at all concentrations of spices used for preincubation.

(ii) Release of arachidonic acid. The macrophages labeled with [^{3}H]-arachidonic acid were preincubated with various spice principles for 1 h. After washing the cells, they were activated with PMA, and arachidonic acid release was quantitated. There was no significant difference in the amount of arachidonic acid released by macrophages preincubated with 1–10 µM curcumin, 1–10 µM capsaicin, 500 µM cuminaldehyde, or 500 µM linalool as compared to that observed with control cells (Table 2). This indicated that spice principles do not affect the phospholipase activity in macrophages. Spice principles alone did not cause the release of arachidonic acid from macrophages. Known inhibitors of phospholipase A_2, like bromophenacyl bromide, inhibited the release of arachidonic acid in a dose-dependent manner (Table 2).

TABLE 1
Internalization of Spice Principles by Macrophages[a]

Time of incubation (h)	Curcumin uptake (µM)	Capsaicin (µM)	Cuminaldehyde (µM)	Linalool (µM)
0.25	0.96	3.29	202	44
0.50	2.75	4.82	300	97
0.75	6.13	7.80	365	239

24.00	n.d.	0.63	0.53	n.d.

[a]Macrophages (2.5×10^6 cells) were incubated in 1 mL of Hanks' balanced salt solution containing curcumin (10 µM), capsaicin (10 µM), cuminaldehyde (500 µM), or linalool (500 µM) in 10 µL ethanol. The spice principles internalized were quantitated by high-performance liquid chromatography (Ref. 15). Values are mean of three independent experiments; n.d., not detected.

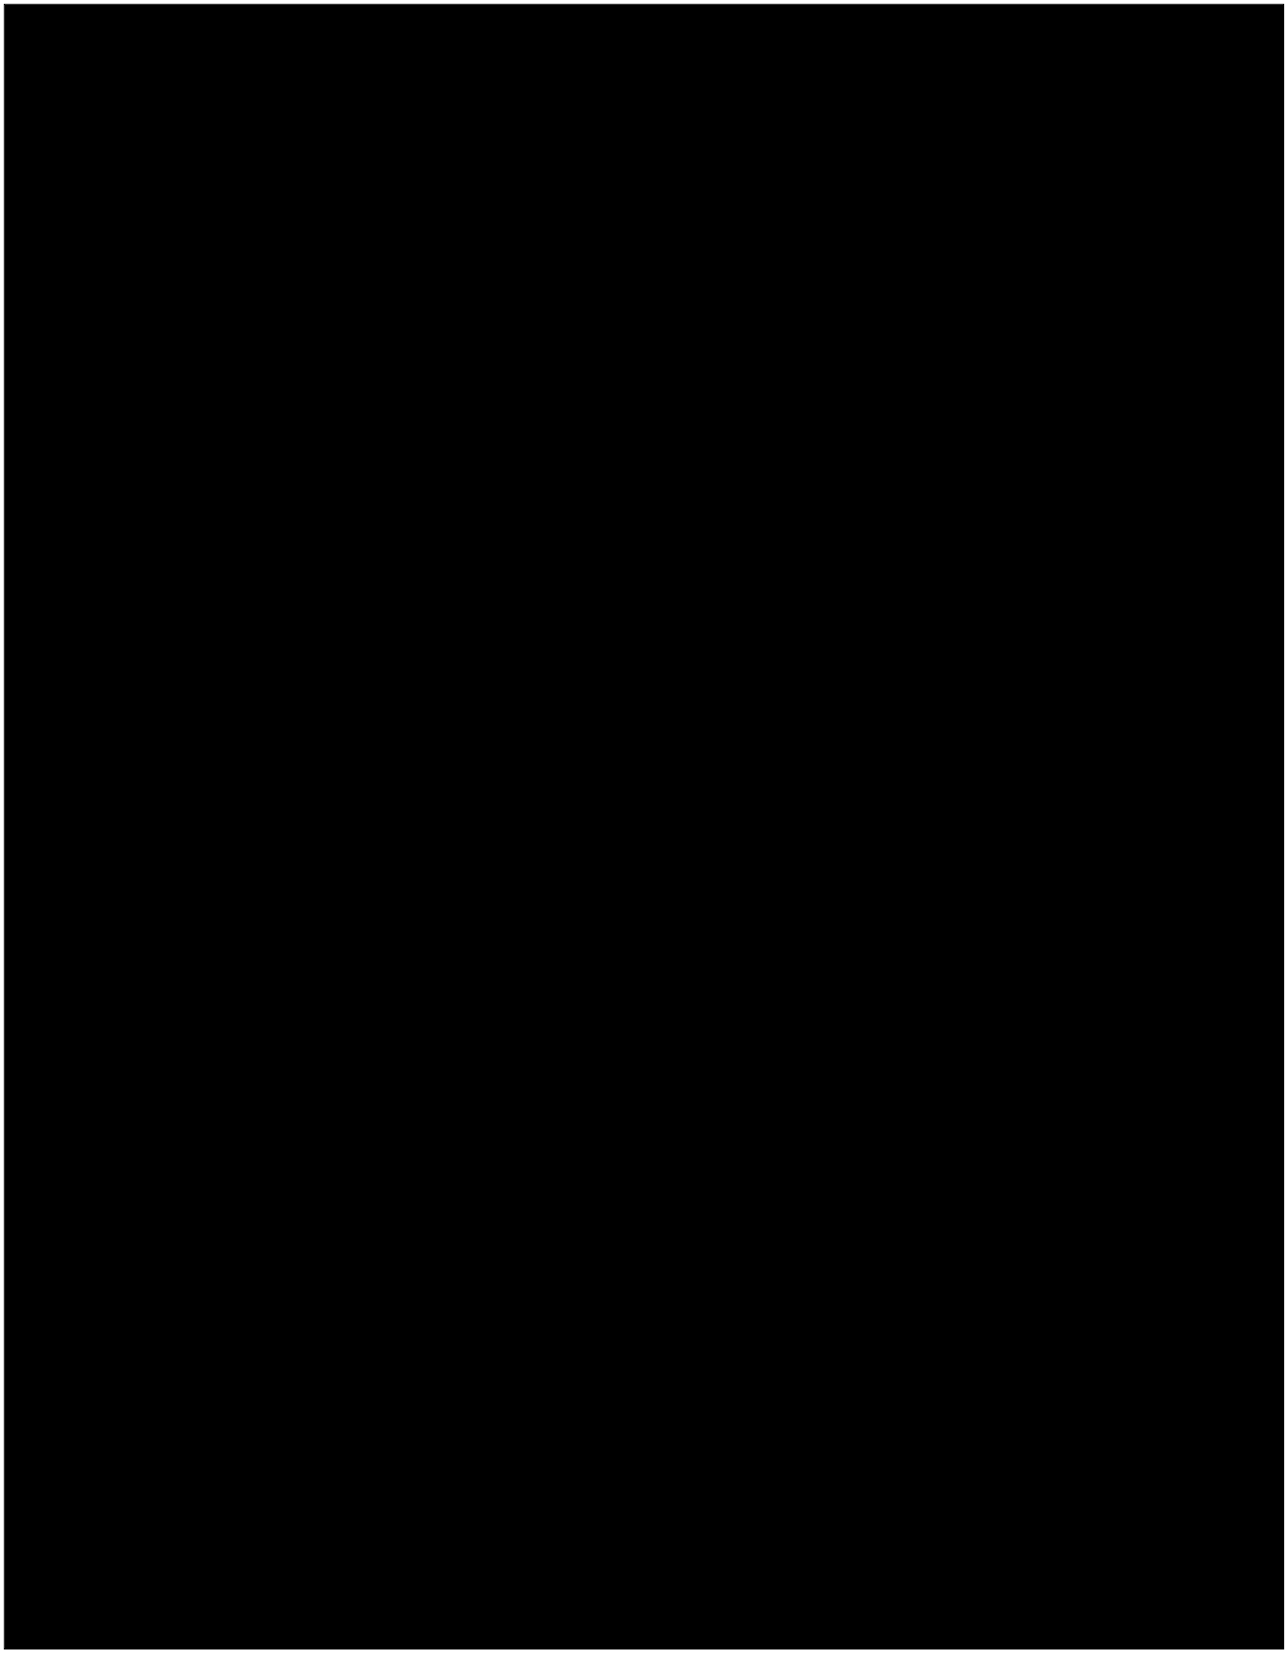

FIG. 1. Effect of spice principles on the incorporation of [^{3}H]-arachidonic acid into macrophage lipids *in vitro*. The incorporation of [^{3}H]-arachidonic acid into macrophage lipids was determined after incubation with (A) curcumin or (B) capsaicin at the following concentrations: A: 0; B: 1 μM; C: 2.5 μM; D: 5 μM; E: 7.5 μM, and F: 10 μM or (C) cuminaldehyde or (D) linalool at 500 μM concentrations. Arachidonic acid incorporation was measured at the time intervals indicated. Values with same superscripts are not significantly different from each other at $P < 0.05$. Abbreviation: NS, not significantly different from the control value.

TABLE 2
Effect of Spice Principles on the Release of [^{3}H]-Arachidonic Acid from Macrophages

Compound added (μM)	[^{3}H]-Arachidonic acid released (cpm/mg protein/h)
Nil	16338 ± 235
Curcumin	
1.0	16637 ± 400
5.0	15987 ± 259
10.0	16365 ± 103
Capsaicin

[a]Macrophages (2.5×10^6 cells/mL Dulbecco's modified Eagle's medium) were preincubated with [^{3}H]-arachidonic acid–bovine serum albumin complex followed by spice principles for 60 min. The release of [^{3}H]-arachidonic acid was measured in the supernatant after activating the cells with phorbol ester as described in the Materials and Methods section. Values are means ± SD, n = six experiments.

(iii) Effect on PG formation. Since arachidonic acid uptake was influenced by curcumin and capsaicin, their effects on arachidonic acid metabolites (PG and LT) were determined. Macrophages preincubated with curcumin or capsaicin secreted lower levels of PGE_2 as compared to that produced by control cells when activated with calcium ionophore (Table 3). Thus, macrophages preincubated with 1 and 10 μM curcumin produced 22% ($P < 0.05$) and 45% ($P < 0.05$) lower amounts of PGE_2, respectively, compared to control cells. Similarly, preincubation of macrophages with 1 and 10 μM capsaicin produced 40% ($P < 0.05$) and 48% ($P < 0.05$) lower amounts of PGE_2, respectively, compared to that produced by control cells.

TABLE 3
Effect of Spice Principles on the Release of Prostaglandins by Macrophages *in vitro*[a]

Spice principle added (μM)	PGE_2 (μg/mg protein)	6-Keto-$PGF_{1\alpha}$ (μg/mg protein)
Nil	49.16^a ± 5.95	58.08^a ± 3.05
Curcumin		
0.1	47.50^a ± 4.93	55.17^a ± 13.82
1.0	38.33^b ± 1.66	$70.b8^b$ ± 6.54
10.0	27.00^c ± 3.32	81.25^c ± 5.84
Capsaicin		
0.1	44.17^a ± 2.76	52.38^a ± 3.05
1.0	29.33^c ± 6.63	67.04^b ± 9.74
10.0	25.34^c ± 3.23	75.10^b ± 13.82
Cuminaldehyde		
500	50.14^a ± 2.93	56.77^a ± 2.19
Linalool		
500	52.49^a ± 4.15	49.56^a ± 3.96

[a]Values with different superscripts in the same column are significantly different from the control values (without spice principles) ($P < 0.05$). Values are means ± SD of three experiments. PGE_2, prostaglandin E_2; $PGF_{1\alpha}$, prostaglandin $F_{1\alpha}$.

However, 6-keto $PGF_{1\alpha}$ release was consistently increased in macrophages incubated with curcumin or capsaicin. Curcumin treatment at 1 and 10 μM enhanced 6-keto $PGF_{1\alpha}$ by 22% ($P < 0.05$) and 40% ($P < 0.05$), respectively, while capsaicin at 1 and 10 μM enhanced 6-keto $PGF_{1\alpha}$ by 15% ($P < 0.1$) and 29% ($P < 0.05$), respectively, compared to control cells (Table 3). Macrophages treated with cuminaldehyde and linalool, even at 500 μM levels, had no influence on secretion of PGE_2 and 6-keto $PGF_{1\alpha}$.

(iv) Effect on LT formation. LT are potent inflammatory lipoxygenase products. Macrophages preincubated with increasing concentrations of curcumin or capsaicin (1–10 μM) secreted lower amounts of LTB_4 and LTC_4 (Fig. 2). The inhibitory effects on LTB_4 and LTC_4 secretion were observed even at low concentrations of curcumin or capsaicin. A maximum inhibition of 61 and 46% LTB_4 formation was observed ($P < 0.05$) when macrophages incubated with 10 μM curcumin or capsaicin, respectively. Similarly, LTC_4 was decreased by 34 and 48% ($P < 0.05$) when macrophages were incubated with 10 μM curcumin or capsaicin, respectively (Fig. 2). Cuminaldehyde and linalool even at 500 μM did not affect LT formation in macrophages (data not shown).

(v) Effect on lysosomal enzymes. Hydrolytic enzymes play an important role in the tissue destruction observed in autoimmune diseases. Macrophages, when treated with curcumin (10 μM) or capsaicin (10 μM), secreted lower levels of lysosomal enzymes like collagenase, elastase, and hyaluronidase (Fig. 3). With curcumin, the amount of collagenase secreted by macrophages activated with Zymosan was reduced by

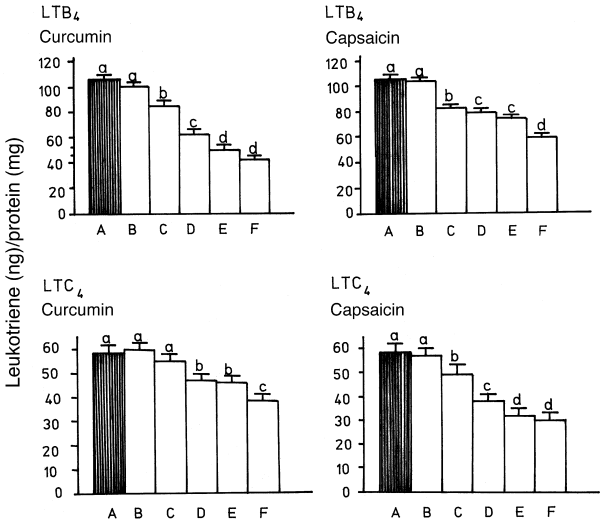

FIG. 2. Effect of spice principles on the release of leukotrienes by macrophages *in vitro*. Leukotrienes B_4 (LTB_4) and C_4 (LTC_4) released by macrophages preincubated with curcumin or capsaicin were quantitated by high-performance liquid chromatography as described in the Materials and Methods section. The concentrations of curcumin or capsaicin added to macrophage monolayers in Dulbecco's modified Eagle's medium (DMEM) were as follows: A: 0, B: 1 μM; C: 2.5 μM; D: 5 μM; E: 7.5 μM; and F: 10 μM. Values are means ± SD of six experiments. Values with the same superscripts are not significantly different from each other at $P < 0.05$.

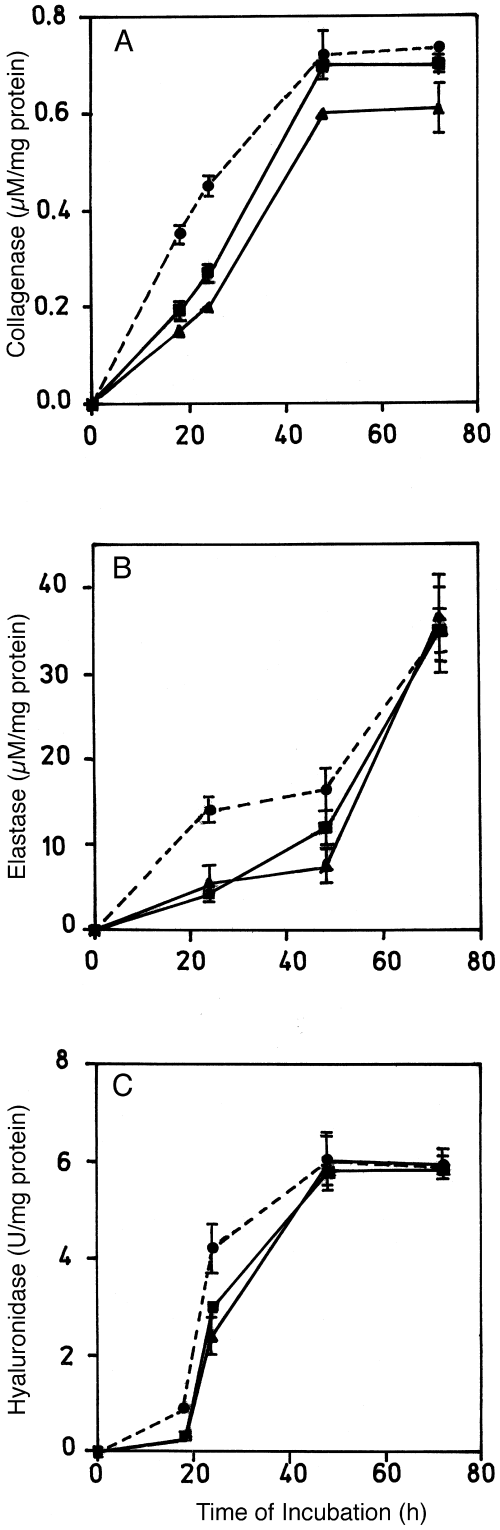

FIG. 3. Effect of spice principles on the secretion of hydrolytic enzymes by macrophages *in vitro*. Macrophages (2.5×10^6 cells/mL DMEM) were incubated with 10 μM curcumin (----) or 10 μM capsaicin (——) along with Zymosan A for different time intervals. The release of hydrolytic enzymes (A) collagenase, (B) elastase, and (C) hyaluronidase was assayed as described in the Materials and Methods section and compared with that of control cells (●---●) incubated under similar conditions in the absence of spice principles. Values are means ± SD of six experiments. See Figure 2 for abbreviation.

57% ($P < 0.001$), 56% ($P < 0.001$), 17% ($P < 0.001$), and 17% ($P < 0.001$) at the end of 18, 24, 48 and 72 h, respectively. Similarly, elastase secretion was reduced in curcumin-treated macrophages by 61% ($P < 0.001$) and 55% ($P < 0.001$), respectively, at the end of 24 and 48 h (Fig. 3). Hyaluronidase secretion was decreased in macrophages incubated with curcumin by 66% ($P < 0.001$) and 43% ($P < 0.001$) at 18 and 24 h, respectively (Fig. 3). The inhibitory effect of curcumin on elastase and hyaluronidase secretion by macrophages was, however, completely overcome when macrophages were incubated for a longer period of time (>72 h). Similarly, capsaicin-inhibited collagenase secretion from macrophages by 46% ($P < 0.001$) and 40% ($P < 0.001$) at the end of 18 and 24 h, respectively; elastase secretion by 69% ($P < 0.001$) and 25% ($P < 0.05$) at 24 and 48 h, respectively; and hyauronidase secretion by 67 ($P < 0.001$) and 30% ($P < 0.05$) at the end of 18 and 24 h of incubation, respectively (Fig. 3). Here again, the inhibitory effects on lysosomal enzyme secretion were not observed when the cells were incubated for longer periods of time with capsaicin (>72 h) (Fig. 3). Spice principles themselves did not affect the activities of collagenase, elastase, and hyaluronidase (data not shown).

DISCUSSION

These studies indicate that macrophage functions are altered by curcumin and capsaicin. Both these phenolic compounds, in a dose-dependent manner, inhibit the incorporation of arachidonic acid into macrophage lipids. However, when macrophages were subsequently activated with PMA after the incorporation of arachidonic acid, no significant differences in the percentage of arachidonic acid released were observed in curcumin- and capsaicin-treated macrophages as compared to that released by control cells. This indicated that curcumin and capsaicin did not affect the release of arachidonic acid from macrophage lipids. The incorporation of arachidonic acid into tissue lipids requires activation of fatty acids by fatty acyl CoA synthetase and transfer by fatty acyl transferase (26). The specific effects of curcumin and capsaicin on these two enzymes have yet to be ascertained. Curcumin is reported to inhibit Δ^6 desaturase in *Mortierella alpina* and rat liver microsomes (27). This lowers the conversion of linoleic to arachidonic acid. As a consequence of these effects on Δ^6 desaturase and fatty acid uptake, curcumin lowers the overall arachidonic acid levels in the tissues. The lower levels of arachidonic acid subsequently reflected in reduced production of PGE_2, LTB_4, and LTC_4, which are major arachidonic acid metabolites formed from cyclooxygenase and lipoxygenase pathways. These results are in agreement with those found in neutrophils (28) and skin fibroblasts (29) where curcumin decreased eicosanoid formation. However, the formation of 6-keto $PGF_{1\alpha}$ was consistently enhanced after the treatment of macrophages with curcumin and capsaicin. This indicated a differential influence of these phenolic compounds on PG and prostacyclin synthetases. It is also possi-

ble that arachidonic acid may be channeled into prostacyclin synthesis by these compounds. Antioxidants such as ascorbate have been shown to enhance the formation of 6-oxo $PGF_{1\alpha}$ in ram seminal vesicles (30). Capsaicin also produces activation of a number of biochemical systems increasing cellular cGMP, diacylglycerol, and inositol triphosphate (31). It is interesting to note that capsaicin and its structural analogs are reported to have vasodilatory effects (32). Prostacyclin is a vasodilatory compound which is enhanced in macrophages by curcumin and capsaicin treatment. Analogs of capsaicin have analgesic and antiinflammatory properties (31). Capsaicin has been used to treat a number of painful clinical conditions such as cluster headache, postmastectomy pain, diabetic neuropathy, and rheumatoid arthritis (33,34). Similarly, antiinflammatory properties of curcumin have also been reported. Srivastava *et al.* (35) have demonstrated that curcumin inhibits platelet aggregation and eicosanoid formation in human blood platelets. Thus, curcumin and capsaicin can alter arachidonic acid metabolism and the generation of other inflammatory mediators.

The mononuclear cells are known to generate enzymes which are potent mediators of inflammation that can destroy tissues (5). These cells may contribute to the excessive levels of collagenase and PG in synovitis (9,36). This, in turn, may contribute to the destruction of connective tissues and the erosion of bone, cartilage, and soft connective tissues. Therefore, controlling the secretion of lysosomal enzymes, such as collagenase, elastase and hyaluronidase, from mononuclear cells may reduce inflammatory responses. Curcumin and capsaicin inhibit the secretion of these various enzymes from macrophages in the early stages of activation. Nirmala and Puvanakrishnan (37) reported that curcumin can lower the elevated levels of lysosomal hydrolases such as β-glucuronidase, β-*N*-acetyl glucoseaminidase, cathepsin B, cathepsin D, and acid phosphatase in myocardial infarction. Similarly, Srivastava and Srimal (34) have shown that curcumin stablizes the lysosomal membranes and inhibits the liver acid phosphatase and cathepsin D activities. The release of collagenase by human leucocytes is enhanced by PGE_2 and cAMP (38). Curcumin and capsaicin inhibited the synthesis of PGE_2. As a consequence of this, the release of collagenase and other lysosomal enzymes may have been decreased in the cells treated with curcumin and capsaicin. Our earlier studies have shown that the formation of reactive oxygen species in macrophages is also inhibited by curcumin and capsaicin (15). Nitric oxide is known to activate metalloprotease enzymes in articular cartilage (39). Reducing nitric oxide by spice principles lowers the activation of proteases and thereby exerts antiinflammatory properties. Therefore, several of the mediators of inflammation secreted by macrophages could be reduced by curcumin and capsaicin.

The effects of curcumin and capsaicin on macrophages, however, are reversible. The inhibitory effects of these compounds on arachidonic acid metabolism are evident only when intact molecules are present in the cells. Macrophages are capable of metabolizing these compounds since the parent molecules were not found in the cells with increasing time of incubation. Our attempts to identify the metabolites of curcumin and capsaicin by conventional methods were not successful. Similarly, Vijayalakshmi and Chandrasekhara (40) earlier demonstrated the rapid turnover of curcumin in rats but were unable to detect the metabolites. Recently Oi *et al.* (41) have shown a capsaicin-degrading enzyme in rat liver microsomes. Here, again, the end product was not identified. However, the effects of curcumin and capsaicin on lysosomal enzymes were observed even after intact spice principles disappeared from macrophages.

The studies with spice components have already established the nontoxic, antimutagenic, antioxidant, antimicrobial, and antiinflammatory effects of curcumin and capsaicin (33,42–44). No adverse side effects have been found with the consumption of curcumin even at a very high dose of 1% in the diet (45). The spices are unlikely to accumulate in the body and cause any adverse side effects due to their rapid turnover. Mega doses of curcumin (1800 to 2500 mg/day) have been successfully used on human arthritic subjects with encouraging results in the alleviation of inflammation (42). Therefore, phenolic compounds from spices, like curcumin and capsaicin, may provide an adjunctive means to reduce the production of inflammatory mediators from mononuclear cells.

ACKNOWLEDGMENTS

The authors thank the director and the head of the department of Biochemistry and Nutrition, CFTRI for their support and encouragement. The help of M. Vijaya Kumar in finalizing the manuscript is acknowledged. Bina Joe gratefully acknowledges the Council of Scientific and Industrial Research, India, for the award of Senior Research Fellowship.

Generation and Remodeling of Highly Polyunsaturated Molecular Species of Rat Hepatocyte Phospholipids

Patricia C. Schmid, Ilona Spimrova, and Harald H.O. Schmid*

The Hormel Institute, University of Minnesota, Austin, Minnesota

ABSTRACT: Freshly isolated rat hepatocytes were incubated for 20 min with [U-^{14}C]glycerol in the presence or absence of unlabeled linoleic (18:2n-6), arachidonic (20:4n-6), or docosahexaenoic (22:6n-3) acid, added as albumin complex in 10% ethanol. Most of the radioactivity (~95%) recovered in hepatocyte lipids was present in phosphatidylcholine (PC), phosphatidylethanolamine (PE), and triacylglycerol (TAG). The presence of exogenous fatty acids resulted in (i) higher incorporation of [U-^{14}C]glycerol, (ii) higher percentage of label in TAG, and (iii) enhanced formation of PC and PE molecular species bearing the exogenous fatty acid at both the *sn*-1 and *sn*-2 positions of glycerol. In each case, these molecular species contained 60 to 70% of the label in that lipid class. Further incubation of the cells for 40 and 80 min in the absence of labeled substrate and exogenous fatty acids resulted in a redistribution of label among PC and PE molecular species due to deacylation–reacylation at the *sn*-1 position of glycerol.

Lipids 32, 1181–1187 (1997).

The glycerophospholipids of mammalian cells, including rat hepatocytes, consist of specific molecular species which differ from one another in their relative amounts, physical properties, and half-life times. They most likely fulfill certain structural requirements as membrane components and serve as resources for the generation of signaling molecules (for reviews see Refs. 1–4). All cellular glycerophospholipids are continually synthesized, remodeled, transported between organelles and membranes, and degraded. The regulation of these processes is of particular importance for the major membrane lipids, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) which, in rat hepatocytes, constitute over 75% of the cell's glycerophospholipids (5).

It has long been known that individual molecular species of rat hepatocyte PC and PE have drastically different half-life times ranging from 1 to 20 h (6,7). Based on both stable isotope and radioisotope-labeling experiments, we have proposed that the molecular species of both PC and PE are generated by continuous *de novo* synthesis and remodeling by deacylation–reacylation at both the *sn*-1 and *sn*-2 positions of glycerol.

Much evidence exists that phospholipid synthesis and turnover in hepatocytes are highly compartmentalized and that interorganelle movement (8,9) as well as lipoprotein assembly and secretion involve newly synthesized phospholipids (10–13). It is therefore logical to assume that remodeling by deacylation–reacylation also involves newly synthesized molecular species of PC and PE (14,15).

Based on acyl turnover measurements by ^{18}O incorporation from $H_2{}^{18}O$-containing media, we have proposed that *de novo* synthesis and remodeling of rat hepatocyte PC and PE are quantitatively similar and linked temporally and spatially. In this scheme, *de novo* synthesis *via* the Kennedy pathway (16) would result in the formation of primarily four molecular species, and the major remodeling step would be the introduction of stearic acid (18:0) and arachidonic acid (20:4) at the *sn*-1 and *sn*-2 positions, respectively, of newly formed PC and PE (5). This hypothesis is in agreement with a great variety of early data on the labeling patterns of PC and PE in liver cells and subcellular preparations (reviewed in Refs. 1,2).

Although stearic and arachidonic acids are primarily introduced into PC and PE by the remodeling pathway, small amounts of 1,2-diarachidonoyl PC exist in many cells (17–19), including rat hepatocytes where they appear to be synthesized *de novo via* glycerophosphate (15). If these and other highly unsaturated molecular species are continually synthesized but remain at low levels, they must be either continually degraded or remodeled into other species. Furthermore, if cells are exposed to excess fatty acids they would be expected to be taken up into glycerolipids by the *de novo* pathway owing to the finite amounts of precursor species available for remodeling. Indeed, we have shown that excess fatty acids, including arachidonic acid, are incorporated into PC primarily by the *de novo* pathway resulting in the initial formation of molecular species having the exogenous fatty acid esterified at both the *sn*-1 and *sn*-2 positions. In the case of 20:4-20:4 PC, rapid remodeling occurred at the *sn*-1 position resulting in the formation of the predominant molecular species 18:0-20:4 PC (15).

The purpose of the present study was to determine if other polyunsaturated fatty acids, when present in excess, are in-

corporated into glycerolipids by analogous pathways and whether newly synthesized polyunsaturated molecular species of PE are remodeled at the *sn*-1 position as previously shown for PC (15).

MATERIALS AND METHODS

Materials. Male Sprague-Dawley rats, 200–350 g, were obtained from Sasco, Inc. (Omaha, NE). Collagenase Type IV from *Clostridium histolyticum*, phospholipase C from *Bacillus cereus*, 4-dimethylaminopyridine, 3,5-dinitrobenzoylchloride, and dilinoleoyl PC were from Sigma (St. Louis, MO). Diarachidonoyl PC was from Serdary Research Labs (Englewood Cliffs, NJ), [U-^{14}C]glycerol (130 Ci/mol) was from American Radiolabeled Chemicals, Inc. (St. Louis, MO); unlabeled fatty acids and tridocosahexaenoylglycerol were from Nu-Chek-Prep (Elysian, MN). 1,2-Didocosahexaenoylglycerol was prepared by the Grignard procedure (20,21). Briefly, 10 mg tridocosahexaenoyl glycerol was dissolved in 1.5 mL diethyl ether. Fifty μL of ethyl magnesium bromide (3 M solution in diethyl ether; Aldrich Chemical Co., Milwaukee, WI) was added. After 30 s at room temperature, the reaction was terminated with 50 μL of glacial acetic acid followed by 1 mL of water. 1,2-Diacylglycerols (DAG) in the organic phase were purified by thin-layer chromatography (TLC) on silica gel H, developed in hexane/diethyl ether/glacial acetic acid, (50:50:1, by vol).

Preparation of cells. Hepatocytes were prepared by collagenase perfusion of rat liver according to Krebs *et al.* (22) as described previously (5,14,15). Cells were counted in a hemacytometer after mixing with trypan blue in order to assess viability, which was better than 87% at the beginning and 77–81% at the end of the experiments.

Incubations. Fatty acids were dissolved in 95% ethanol, and 0.1 mL of this solution was added to 0.9 mL of incubation buffer (Krebs-Ringer Hepes containing 10 mM glucose and 0.4% fatty acid-free bovine serum albumin). The mixtures were vortexed and sonicated to obtain a homogeneous suspension. Of these suspensions, 50-μL aliquots were added for each milliliter of incubation buffer. Hepatocytes were incubated at a concentration of 4×10^6 cells/mL of incubation buffer which also contained 1 μCi (7.7 nmol) [U-^{14}C]glycerol/mL and 300 nmol fatty acid/mL. Control incubations contained ethanol only. For each regimen, 2.4×10^7 cells (6 mL) were incubated for 20 min in a 70-mm plastic culture dish, swirled gently in an atmosphere of O_2/CO_2, 95:5, at 37°C. The cells were then washed and resuspended in 6 mL of fresh incubation buffer. Two 1-mL aliquots were removed and extracted immediately, and four 1-mL aliquots were transferred to 30-mm plastic culture dishes and incubated further for 40 and 80 min in the absence of fatty acid and [U-^{14}C]glycerol. Duplicate samples were extracted and analyzed separately. All primary data represent average values from duplicate incubations.

Lipid analysis. Cells were harvested by centrifugation and extracted with chloroform/methanol (2:1, vol/vol) and partitioned against 0.9% aqueous NaCl (23). The lipid extracts were taken to dryness and redissolved in 1 mL of chloroform/methanol, 2:1, containing 0.01% butylated hydroxytoluene. Aliquots of the lipid extracts were fractionated by TLC on Whatman LK5 plates (Whatman, Inc., Clifton, NJ), using chloroform/methanol/ammonium hydroxide/water (65:35:5:1, by vol) as developing solvent. Distribution of radioactivity in lipid classes was determined by scanning the plate with a Berthold LB2842 TLC Linear Analyzer (Berthold Analytical Instruments, Inc., Nashua, NH). Total phospholipids and individual phospholipid classes were quantified by phosphorus assay (24).

Both PC and PE were isolated by preparative TLC on layers of Silica Gel H (Merck, EM Science, Gibbstown, NJ) using the same solvent system. They were checked for purity, hydrolyzed to DAG, and converted to 3,5-dinitrobenzoates (DNB) as described (5,14,15). DAG–DNB were separated on a 3.9×300 mm Waters Nova Pak C18 (Millipore Corp., Milford, MA) column, using a Beckman high-performance liquid chromatography (HPLC) system consisting of two 114 M solvent delivery modules, a Model 406 Analog Interface Module, a Model 168 Diode Array Detector, and System Gold software (Beckman Instruments, Inc., Fullerton, CA). The absorbance at 254 nm was monitored on the computer screen and the fraction collector (Frac-100, Pharmacia Biotech, Inc., Piscataway, NJ) was advanced manually at the beginning of each peak.

Separation and analysis of molecular species as DAG–DNB were done as previously described (5,14,15). Briefly, one-half of each sample was separated by reverse-phase HPLC in a solvent system of methanol/isopropanol/glacial acetic acid (80:20:0.01, by vol), and the peaks were collected in 7-mL scintillation vials. After evaporation of the solvent, 3 mL of Ecolume scintillation fluid (ICN Pharmaceuticals, Costa Mesa, CA) was added, and radioactivity was determined in a Beckman LS7500 scintillation counter. Radioactivity in each fraction was expressed as a percentage of radioactivity recovered in all fractions. The second half of each sample was separated in the same manner, and the peaks were collected for subsequent separation of coeluting species in a solvent of acetonitrile/isopropanol (70:30, vol/vol). Mol% of each molecular species was determined by integration of the HPLC peaks obtained with the two solvent systems. Data from the first and second separations were combined to give radioactivity percentage and mol% of all major molecular species of PC and PE.

RESULTS

Incorporation of [U-^{14}C]glycerol into hepatocyte glycerolipids in the presence and absence of exogenous fatty acids. When primary isolates of rat hepatocytes were incubated for 20 min with [U-^{14}C]glycerol in the presence or absence of unsaturated fatty acids, most of the radioactivity (~95%) was recovered in PC, PE, and triacylglycerol (TAG) (Table 1). Further incubation for 40 and 80 min after removal of labeled substrate led to increased levels of radioactivity in

	100	103.3 (14.1)	99.1 (13.6)	526.6 (72.2)

[a]Data are averages of two separate incubations; they do not include small amounts of radioactivity in other lipid classes.
[b]Total phospholipid P recovered in the lipid extract.
[c]Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; TAG, triacylglycerols.

control cells. However, no changes in the distribution of radioactivity among these lipid classes occurred, suggesting that there had been some continued synthesis from labeled intracellular precursors. This was not the case with incubations containing exogenous fatty acids. The presence of exogenous fatty acids resulted in increased overall [U-^{14}C]glycerol incorporation and a higher percentage of radioactivity in TAG. Although there was some variability in the levels of radioactivity, the distribution of label among these three lipid classes remained approximately the same for each experiment after withdrawal of the labeled substrate.

Generation of highly polyunsaturated molecular species. Both PC and PE were isolated by preparative TLC, hydrolyzed by phospholipase C, and the resulting DAG were converted to their DNB. Reverse-phase HPLC of DAG–DNB followed by recovery and refractionation of unresolved mixtures resulted in the separation and analysis of individual molecular species. They were identified by the use of synthetic standards and gas chromatographic analysis of their constituent fatty acids, essentially as described previously (15).

As shown in Figure 1, the presence of exogenous fatty acids in the incubation medium resulted in the generation of molecular species having these fatty acids esterified at both the *sn*-1 and *sn*-2 positions of glycerol. After 20 min of incubation in the presence of 18:2, the 18:2-18:2 PC increased from about 1 mol% of total molecular species to 2.3%. In the presence of 20:4, the fraction containing the 20:4-20:4 species increased from 0.3 to 1.8%, and incubation with 22:6 resulted in the appearance of a 22:6-22:6 species (0.7%) that was not detectable (<0.1%) in the control experiment. These data demonstrate that rat hepatocytes can utilize exogenous polyunsaturated fatty acids for the synthesis of highly unsaturated glycerolipid molecular species, and the major newly synthesized species have the exogenous fatty acid at both the *sn*-1 and *sn*-2 positions of glycerol.

Further incubation of hepatocytes for 40 and 80 min in the absence of exogenous fatty acids reduced the amounts of

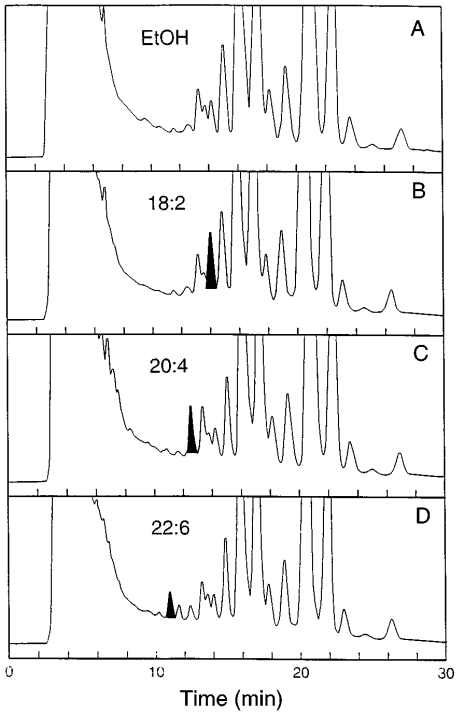

FIG. 1. Fractionation of phosphatidylcholine (PC) molecular species as diacylglycerol dinitrobenzoate (DAG–DNB) derivatives. The tracings represent first-run high-performance liquid chromatography (HPLC) separations of samples obtained from hepatocytes incubated for 20 min with ethanol (A), and 0.3 mM each of linoleic acid (B), arachidonic acid (C), and docosahexaenoic acid (D). Shaded peaks represent molecular species bearing the exogenous fatty acid at both the *sn*-1 and *sn*-2 positions of glycerol. HPLC conditions are described in the Materials and Methods section.

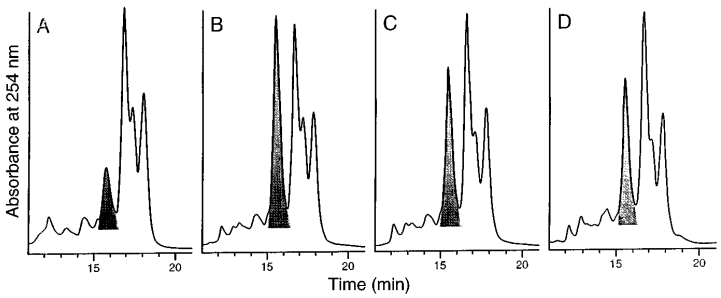

FIG. 2. Fractionation of highly unsaturated molecular species of rat hepatocyte PC as DAG–DNB derivatives. Reverse-phase HPLC on a Waters Nova Pak C18 column (Milford, MA) using methanol/isopropanol/glacial acetic acid (90:10:0.01, by vol). A: control; B: incubation for 20 min with 0.3 mM arachidonic acid; C and D: further incubation without arachidonic acid for 40 and 80 min, respectively. Shaded peak: 20:4-20:4 DAG–DNB. For abbreviations see Figure 1.

these newly synthesized molecular species. This is illustrated for 20:4-20:4 PC in Figure 2. On the basis of our previous data (15), we suggest that this reduction is primarily due to remodeling rather than degradation.

Remodeling of newly synthesized polyunsaturated molecular species. As expected from previous experiments (15), [U-^{14}C]glycerol was incorporated primarily into molecular species containing the exogenous fatty acids at the *sn*-1 and *sn*-2 positions. In Figure 3, the incorporation and redistribution of radioactivity in PC and PE molecular species are shown for control hepatocytes (ethanol only) and cells incubated in the presence of 18:2. Radioisotope data are compared to mass distribution data for the same molecular species. Uptake and redistribution in control cells followed a pattern similar to previously published data (14), except that in the present experiment highly unsaturated molecular species were as-

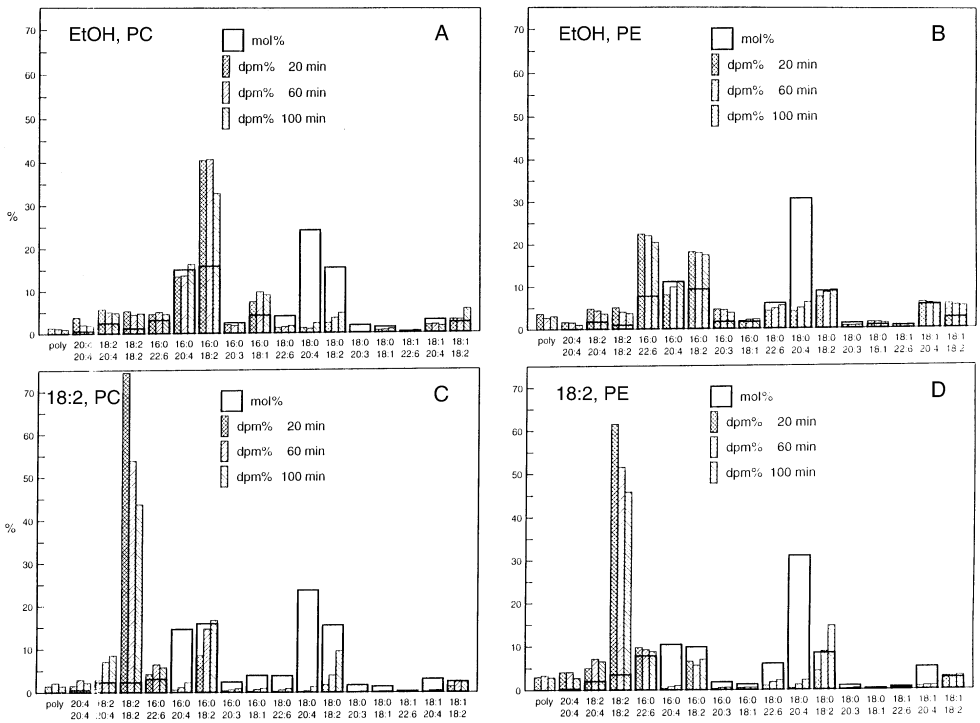

FIG. 3. Distribution of radioactivity from [U-^{14}C]glycerol in PC and phosphatidylethanolamine (PE) molecular species of rat hepatocytes incubated for 20 min with ethanol (A,B) or 0.3 mM linoleic acid (C,D), followed by further incubation for 40 and 80 min in the absence of labeled substrate, ethanol, and fatty acid. Polyunsaturated fractions emerging before the 20:4-20:4 peak were collected together (poly). Data are averages of two separate incubations and analyses. For abbreviations see Figure 1.

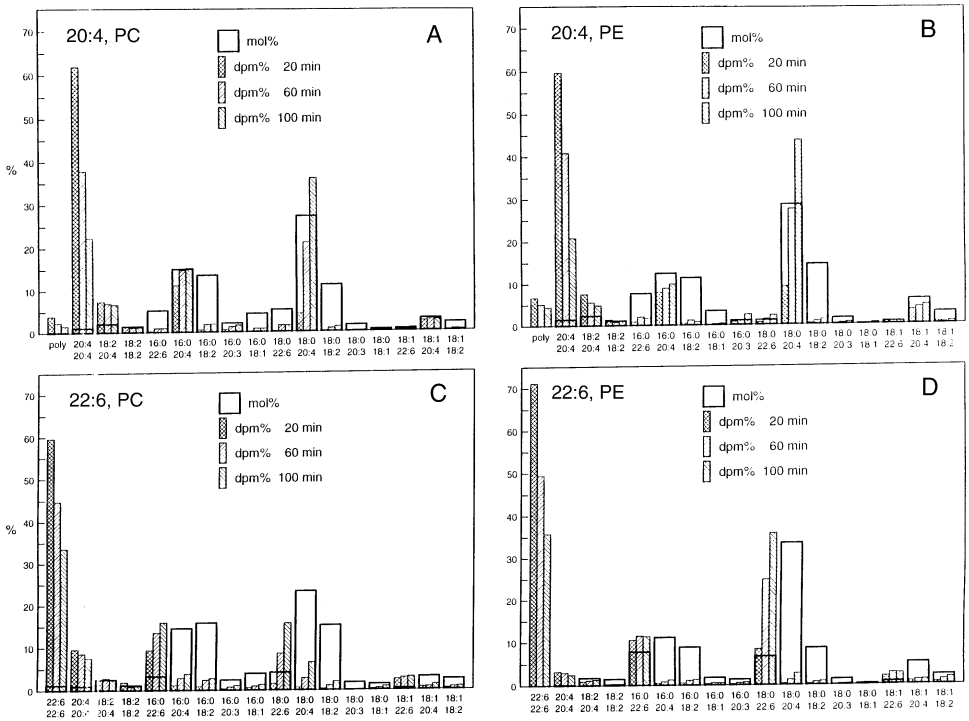

FIG. 4. Distribution of radioactivity from [U-^{14}C]glycerol in PC and PE molecular species of rat hepatocytes incubated for 20 min in the presence of 0.3 mM arachidonic (A,B) and docosahexaenoic acid (C,D), followed by further incubation for 40 and 80 min in the absence of labeled substrate and fatty acid. Polyunsaturated fractions emerging before the 20:4-20:4 peak in the 20:4 experiment (panels A,B) were collected together. The fraction identified as 20:4-20:4 in the 22:6 experiment (panels C,D) also contained 18:2-22:6 (Ref. 15). Data are averages of two separate incubations and analyses. For Abbreviations see Figure 1.

sayed separately and were found to exhibit very high specific activity. For both PC and PE, initial high specific radioactivity, decreasing after removal of the substrate, signifies *de novo* synthesis, whereas initially low but increasing radioactivity indicates generation by remodeling from precursor molecular species. In the case of 18:2, by far the highest percentage of glycerol label (74% in PC and 63% in PE) was originally present in the 18:2-18:2 molecular species. Remodeling of this molecular species was more rapid within PC where it apparently involved both the *sn*-1 acyl group leading to 16:0-18:2 and 18:0-18:2 PC and the *sn*-2 acyl group resulting in the formation of 18:2-20:4 PC. Remodeling of 18:2-18:2 PE occurred only at *sn*-1 and led to the formation of 18:0-18:2 PE as the major product.

Remodeling of both PC and PE molecular species was even more pronounced after incubation of hepatocytes in the presence of arachidonic and docosahexaenoic acids, resulting in the formation of 20:4-20:4 and 22:6-22:6 PC and PE (Fig. 4). Initially, 60–70% of the total radioactivity in PC and PE was in the 20:4-20:4 and 22:6-22:6 species, respectively, and remodeling occurred primarily by replacement of the *sn*-1 acyl groups with 18:0 and, to some extent, with 16:0. Reacylation with 18:0 was more pronounced in PE than in PC, resulting in an increase of radioactivity from less than 10% to about 45 and 37% of total radioactivity being associated with 18:0-20:4 PE and 18:0-22:6 PE, respectively (Fig. 4 B and D).

DISCUSSION

It is generally accepted that *de novo* biosynthesis of PC and PE *via* glycerophosphate (16) exhibits positional specificity which results in the formation of molecular species containing primarily saturated (plus monounsaturated) fatty acids at the *sn*-1 position and polyunsaturated (plus monounsaturated) fatty acids at the *sn*-2 position (reviewed in Refs. 1–4). However, Sundler *et al.* (25) first reported that, in the presence of excess fatty acids, hepatocytes synthesize molecular species containing the added fatty acid at both the *sn*-1 and *sn*-2 positions. Specifically, the addition of oleic and linoleic acids yielded relatively large proportions of dioleoyl and dilinoleoyl glycerophospholipids as well as trioleoyl- and trilinoleoylglycerols (25). Owing to the methodology available at that time, molecular species with a total of eight or more double bonds could not be identified, and subsequent studies were similarly limited (26–29).

Our present data suggest that *de novo* synthesis of glycerolipids by the Kennedy pathway is the main route of incorporation of excess fatty acids taken up from the media and that molecular species of both PC and PE containing the exogenous

fatty acid at both the *sn*-1 and *sn*-2 positions are the principal products. The highly unsaturated molecular species of both PC and PE are readily remodeled into more saturated species, primarily by replacement of the *sn*-1 acyl group with stearate (18:0). Because levels of radioactivity in PC and PE remained fairly constant after the [U-^{14}C]glycerol pulse, remodeling rather than degradation must have been the major metabolic conversion of the newly synthesized molecular species. This is in agreement with our earlier conclusions regarding PE turnover in rat hepatocytes (5,14) but in conflict with the results of pulse-chase experiments with labeled ethanolamine over a 24-h period. These data suggested that different molecular species of PE in rat hepatocytes are synthesized and degraded at different rates rather than being converted into one another through remodeling (30,31). Remodeling clearly occurs for the PE species synthesized in the present experiment.

It is important to consider that the concentrations of exogenous fatty acids used in the present study do not represent physiological levels, and hence our data constitute the results of model experiments. However, small amounts of very highly unsaturated molecular species, including 18:2-18:2, 20:4-20:4, 18:2-20:4 and 18:2-22:6 PC and PE, occur naturally in hepatocytes and other cells, and they exhibit a relatively high rate of turnover, most likely through *de novo* synthesis and remodeling (15,32). Recently we have shown that agonist-induced liberation of arachidonic acid from macrophage glycerolipids results in increased turnover not only through lysophospholipid reacylation but also through enhanced *de novo* synthesis of polyunsaturated PC molecular species, including 20:4-20:4 PC (32).

With respect to the large amounts of exogenous fatty acids taken up by hepatoctyes in the present study, we suggest that esterification of exogenous fatty acids, especially polyunsaturated fatty acids, into TAG may be the purpose of enhanced *de novo* glycerolipid synthesis. The synthesis of triarachidonoyl glycerol has been shown in HL-60 cells incubated with arachidonic acid (21), and we have observed a rapid and selective increase in arachidonic acid (from 1.7 to 15.4 mol%) in TAG of rat hepatocytes incubated with a mixture of palmitic, oleic, and arachidonic acids (5). Rat hepatocyte TAG exhibit rapid acyl turnover, even in the absence of exogenous fatty acids. Whether this occurs only through *de novo* synthesis and complete degradation or through deacylation–reacylation steps involving DAG or monoacylglycerols is not known at this time and deserves further study.

Analysis of the Seed Oil of *Heisteria silvanii* (Olacaceae) —A Rich Source of a Novel C_{18} Acetylenic Fatty Acid

Volker Spitzer[a,*], Werner Tomberg[b], Rudolf Hartmann[b], and Reiner Aichholz[c]

[a]Faculty of Pharmacy, Federal University of Rio Grande do Sul (UFRGS), 90.610.000 Porto Alegre/RS, Brazil, [b]Physiologisch-Chemisches Institut, Universität Bonn, 53115 Bonn, Germany, and [c]Novartis Pharma AG, Research, Core Technology Area/Analytics, CH-4002 Basel, Switzerland

ABSTRACT: Besides some usual fatty acids (FA), two conjugated ene-yne acetylenic FA [*trans*-10-heptadecen-8-ynoic acid (pyrulic acid) (7.4%), and *trans*-11-octadecen-9-ynoic acid (ximenynic acid) (3.5%)], a novel ene-yne-ene acetylenic FA [*cis*-7, *trans*-11-octadecadiene-9-ynoic acid (heisteric acid) (22.6%)], and 9,10-epoxystearic acid (0.6%) could be identified in the seed oil of *Heisteria silvanii* (Olacaceae). Two further conjugated acetylenic FA [9,11-octadecadiynoic acid (0.1%) and 13-octadecene-9,11-diynoic acid (0.4%)] were identified tentatively by their mass spectra. The FA mixture has been analyzed by gas chromatography/mass spectrometry (GC/MS) of their methyl ester and 4,4-dimethyloxazoline derivatives. The structure of heisteric acid was elucidated after isolation *via* preparative silver ion thin-layer chromatography and by various spectroscopic methods [ultraviolet; infrared; ^1H, ^{13}C nuclear magnetic resonance (NMR); ^1H-^1H and ^1H-^{13}C correlation spectroscopy]. To determine the position of the conjugated ene-yne-ene system, the NMR spectra were also measured after addition of the lanthanide shift reagent Resolve-Al EuFOD™. Furthermore, the triyglyceride mixture was analyzed by high-temperature GC and high-temperature GC coupled with negative chemical ionization MS. A glass capillary column coated with a methoxy-terminated 50%-diphenyl-50%-dimethylpolysiloxane was used for the separation of the triacylglycerol (TAG) species. No evidence of decomposition of the TAG species containing conjugated ene-yne-ene FA was observed. Twenty-six species of the separated TAG were identified by means of their abundant quasi molecular ion $[M - H]^-$and their corresponding carboxylate anions $[RCOO]^-$ of the fatty acids, respectively. The major molecular species of the TAG were found to be 16:0/18:1/18:1, 16:0/18:1/18:3 (heisteric acid), 17:2 (pyrulic acid)/18:1/18:1, 18:1/18:1/18:3 (heisteric acid). The TAG containing acetylenic FA showed an unexpected increase of the retention time in comparison to the TAG containing usual FA, thus making the prediction of the elution order of lipid samples containing acetylenic FA difficult.
Lipids 32, 1189–1200 (1997).

The plant family Olacaceae can be divided into the three subfamilies Anacolosoideae, Olacoideae, and Schoepfioideae containing 30 genera with about 250 species. It occurs mainly in the tropical and subtropical hemisphere (1). Only a few Olacaceae species have been examined chemically, and a clear chemotaxonomical evaluation is already difficult. However, the samples analyzed up to now demonstrated that most of them yield oily seeds and that the lipid components were found to be unusual in that acetylenic fatty acids (FA), partially with additional keto and hydroxy groups (2–4), ricinoleic acid (2), very long-chain monounsaturated FA with up to 30 carbon atoms (2), and about 4% of all-*cis*-1,4-polyisoprene (5) could be identified. It is noteworthy that in some cases the seed triacylglycerols (TAG) were identical with those in the roots and the leaves of the Olacaceae plants (6).

In order to extend the knowledge of the seed oil chemistry of the Olacaceae, the species *Heisteria silvanii* (popular name: "casca-de-tatu") was included in our current research project on Brazilian seed oils. The native southern Brazil plant (7) is a medium-sized tree of 3–20 m height that yields single-seeded oily stone-fruits with a diameter of about 1.5 cm. The wood of the trees can be used for the production of high-quality flooring and firewood, but is not commercially explored (7).

Only a few literature references have been reported on the chemistry of the genus *Heisteria* (1,6), the largest genus of Olacaceae with 33 subspecies (8). In the seed oil of *H. elegans* (syn. *H. parvifolia*), 60% of oleic acid and 23% of an unknown FA were analyzed (1). The fresh fruits of *H. olivae* ("cacaito") contain the tropan alkaloid scopolamine and are used occasionally as a hallucinogenic drug in Venezuela (6).

The present paper deals with the analysis of the FA and TAG by spectroscopic methods, capillary gas chromatogra-

phy/mass spectrometry (GC/MS), high-temperature capillary gas chromatography (HTGC) and high-temperature capillary GC/negative chemical ionization mass spectrometry (HTGC/NCI-MS), respectively. Both high-temperature techniques were applied to a sample containing acetylenic FA for the first time. Furthermore, the isolation and structural elucidation of a novel C_{18} acetylenic FA from *H. silvanii* are described in detail. To the best of our knowledge, this is the first report on the chemistry of the plant *H. silvanii*.

MATERIALS AND METHODS

Seeds and oil extraction. The fruits from *H. silvanii* Schwacke were collected in December 1995 near the city of Porto Alegre, Rio Grande do Sul, Brazil. The air-dried, crushed seeds were extracted in a Soxhlet apparatus for 4 h with petroleum ether (40–60°C). After extraction, the solvent was removed by vacuum distillation at 30°C, flushed with nitrogen, and stored at −18°C until use. The yield was 46.6% of a pale-yellow oil.

Derivatization reactions. Transesterification to the fatty acid methyl esters (FAME) was carried out with 0.5 N sodium methoxide in anhydrous methanol as described by Christie (9). Silanization of the FAME mixture was made with *N,O*-bis-(trimethylsilyl)-trifluoroacetamide (BSTFA) (Fluka, Buchs, Switzerland) (10). The 4,4-dimethyloxazoline derivatives (DMOX) were prepared by reaction of one part free FA mixture (obtained after hydrolysis of the oil with 1 N potassium hydroxide in 95% ethanol and subsequent acidification with HCl to pH 1) with five parts of 2-amino-2-methylpropanol for 1 h at 175°C (11).

Before the HTGC analysis, the total lipid mixture was derivatized with BSTFA to avoid contamination of the column with nonvolatile minor compounds. For this purpose, 1 mg sample was diluted in 1.75 mL pyridine, and 0.25 mL BSTFA was added. The mixture was allowed to react 20 min at ambient temperature, then the sample was diluted with pyridine and an aliquot was injected for HTGC analysis.

Alkaloid screening. For detection of alkaloids, the petroleum ether extract was analyzed using standard procedures that involve the use of the spray reagents Draggendorff, iodinoplatinate, and Marquis (12).

Thin-layer chromatography (TLC). For analytical purposes, commercial aluminum plates (5 × 10 cm) coated with 0.25 mm silica (Merck, Darmstadt, Germany) have been used. Preparative separations were carried out using glass plates (20 × 20 cm) coated with 0.6-mm silica layers and silica layers impregnated with silver nitrate (10%), respectively. To isolate the usual FAME fraction (FR-1) and the FAME fraction with acetylenic groups (FR-2), the total FAME was chromatographed using petroleum ether/diethyl ether (96:4, vol/vol) as solvent system. FR-2 was further subfractionated into the fractions AG-1 and AG-2 by using silver nitrate-impregnated silica plates and toluene as solvent system. The separation process was carried out in a refrigerator (4°C) within a tank containing a mixture of ice and NaCl. The bands of interest were scraped off [detected with ultraviolet (UV) light (254 nm) and 2′,7′-dichlorofluorescein] and eluted with diethyl ether. Monitoring of the individual fractions was carried out by GC, infrared (IR), UV, and nuclear magnetic resonance (NMR) spectroscopy.

GC and GC/MS analysis. A GC-17A (Shimadzu, Tokyo, Japan) equipped with a flame-ionization detector (260°C) and a split/splitless injector 260°C (split 1:100) with glass insert was used for separation and quantification of the FAME. Helium was carrier gas at an inlet pressure of 80 kPa. For peak integration, the software package Class CR-10 (Shimadzu) was used. Separation of the compounds was achieved on a BPX-70 (SGE, Weiterstedt, Germany) fused-silica capillary column (30 m, 0.22 mm i.d., 0.25 μm film thickness) using a temperature program (130–255°C, 2°C/min). GC/MS was done with a GCMS-QP5000 (Shimadzu) operating with an ionization energy of 70 eV and an interface temperature of 250°C. The separation conditions for the FAME and DMOX derivatives were the same as used in the GC analysis.

HTGC analysis of the seed oils. The HTGC system consists of a Carlo Erba Mega 5160 GC equipped with an on-column injector, a constant-flow pressure regulator (CP-CF 516) and a flame-ionization detector, which was fitted with a ceramic jet and heated to 400°C. Separation of the total lipid mixture was carried out on a Duran glass capillary column with a length of 10 m and 0.2 mm inner diameter. The capillary column was pretreated and coated with a 0.10 μm film of SOP-50 (50%-diphenyl-50%-dimethylpolysiloxane, methoxy-terminated), respectively. The column was conditioned at a temperature of 400°C (13). Further detailed descriptions of the preparation of high-temperature capillary columns were given in Ref. 14.

The oven temperature was programmed as follows: 1 min at 70°C, from 70 to 250°C at 12°/min, from 250 to 380°C at 4°/min. Hydrogen was employed as carrier gas with a linear velocity of 0.5 m/s.

Data acquisition was carried out on a Spectra Physics Labnet System (San Jose, CA) (Spectra Physics Integrator 4270 linked to a PC 3/86 data station).

HTGC/MS analysis of the seed oils. For HTGC/MS analyses a Carlo Erba Mega 5160 GC was coupled *via* a specially designed high-temperature interface (370°C) (15) to a Finnigan TSQ-700 mass spectrometer (San Jose, CA). The TSQ-700 was equipped with two corrosive gas stable turbo molecular pumps (Type 360C; Balzers-Pfeiffer GmbH, Asslar, Germany) at the source chamber (bottom and right flange) and one turbo molecular pump (Type 360, Balzers) at the analyzer chamber of the manifold of the mass spectrometer, respectively. This configuration provided sufficient vacuum capacity for the use of hydrogen as a carrier gas and chemical inertness against corrosive reagent gases. NCI was carried out using ammonia as an NCI reagent gas. The ion source was heated to a temperature of 180°C, filament current was 20 mA, electron multiplier voltage 1400 V, the conversion dynode was set to 15 kV, and the acquisition mass range was 200–1300 m.u. in 2 s. Separation during the HTGC/MS

analysis was achieved with the same type of column described above using the same temperature program.

Spectroscopic analyses of the oil and the isolated FAME fractions. The UV spectra were recorded from 400–200 nm in cyclohexane solution using a UV-2201 (Shimadzu) spectrophotometer. IR spectra were obtained with an FTIR-8101 (Shimadzu) in a liquid film. The ^{1}H NMR and ^{13}C NMR spectra were run in deuteriochloroform solution on a Varian VLX-200 (Palo Alto, CA) and on a Bruker (Karlsruhe, Germany) AC400 spectrometer with tetramethylsilane (TMS) as internal standard. The isolated heisteric acid methyl ester (ME) was examined by ^{1}H NMR, ^{1}H-^{1}H-2D shift correlation (COSY), ^{13}C NMR, distortionless enhanced polarization transfer (DEPT), and ^{1}H-^{13}C 2D heteronuclear shift correlation experiments on a Bruker AMX500 spectrometer. Additional spectra were measured after adding increasing amounts [up to 200 µL (20 mM in $CDCl_3$) in 500 µL of the total solution] of the lanthanide shift reagent Resolve-Al EuFOD™ 99+% (16,093-8; Aldrich Chemical Company, Milwaukee, WI).

RESULTS AND DISCUSSION

Preliminary analytical data on the seed oil. The UV spectrum exhibited absorption maxima at 282, 267, 255, 241 and 230 nm, indicating the presence of conjugated double/triple bond systems (16). In the IR spectrum, the absorption bands that appear in common seed oils such as soybean oil were accompanied by additional peaks at 2216 (vw), 2189 (vw), and 953 cm^{-1} (s). These are characteristic for triple bonds and double bonds in a *trans*-ene-yne linkage, respectively (16). The ^{13}C NMR (broadband decoupled and DEPT mode) signals in the range between δ 172–173.3 for the carbonyl atoms and δ 62–69 for the glycerol atoms indicated that the oil consisted mainly of TAG. No peaks for free FA, hydroxy FA, keto FA, or di- and monoacylglycerols could be detected under the experimental conditions. The occurrence of hydroxy and keto FA was already reported for other Olacaceae seed oils (2). In the range of the double-bond carbon signals (δ 100–150), a series of peaks at about δ 109 and 142–144 pointed to the presence of FA with conjugated double/triple bonds (4,17). This finding was confirmed by six quaternary (DEPT experiment) carbon signals (δ 79.3, 79.4, 84.8, 88.3, 88.5, and 92.6) that appeared in the range of the acetylenic groups between δ 78–93 (4,17). The signals at δ 32.9, 33.2, 19.27, and 19.3 could be attributed to methylene groups in allylic position to *trans* double bonds and to methylene groups in propargylic position to an acetylenic bond (18).

The presence of alkaloids could be proven neither by the spectroscopic data of the oil nor by the chemical test methods.

Identification of the individual FA of H. silvanii. In order to identify the FAME (Fig. 1; Table 1) and DMOX GC peaks (data not presented), various analysis and separation procedures were utilized. The peak numbers of the FA in the following text correspond with the numbers in Figure 1 and Table 1. The gas chromatograms of the FAME (Fig. 1) and

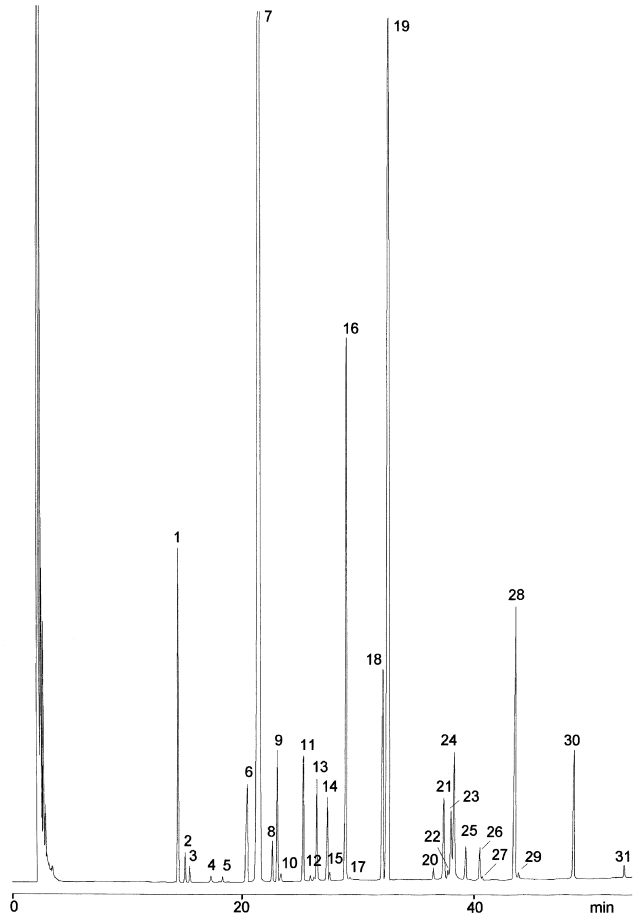

FIG. 1. Gas chromatogram of the fatty acid methyl esters of the seed oil of *Heisteria silvanii*. For experimental conditions, see the Materials and Methods section. The peak numbers correspond with those in Table 1.

DMOX derivatives, obtained with the BPX-70 column, did not show a noticeable difference in the total peak number and the individual peak areas (Table 1), respectively. Thus, it can be concluded that the DMOX derivatization procedure did not cause a significant degradation of the individual compounds under the reaction conditions.

Identification of the usual FA (peaks 1–7, 9, 11, 13, 14, 24, 28, 30, 31). FAME with known retention characteristics were identified by GC and GC/MS against authentic standards. In addition, the DMOX derivatives were examined by GC/MS, which enables the unequivocal location of the double bond(s) (11).

Identification of pyrulic and ximenynic acid (peaks 16, 18). TLC analysis of the total FAME revealed two main bands (FR-1 with $R_f = 0.88$ and FR-2 with $R_f = 0.77$). FR-2 was directly detectable under UV light, pointing to the presence of UV chromophores. For more detailed analysis, FR-1 and FR-2 were separated by preparative TLC. The GC analysis of FR-1 showed that this fraction contained the FA already identified as usual FA. The FR-2 consisted mainly of the FA 16, 18 and 19, respectively. By preparative argentation TLC, it was possible to separate the FR-2 into the fractions Ag-1 (R_f = 0.86) and Ag-2 ($R_f = 0.76$). GC analysis showed that the frac-

tion Ag-2 contained the peaks 16 and 18, and that the fraction Ag-1 contained only the peak 19. The mass spectra of the FAME and DMOX derivatives of the peaks 16 and 18 were identical with those published for *trans*-10-heptadecen-8-ynoic acid (pyrulic acid) and *trans*-11-octadecen-9-ynoic acid (ximenynic acid) (4,17). The broad UV band at 229 cm^{-1} supported the conjugated ene-yne structure element (16). The presence of a *trans* double bond was also confirmed by the absorption band at 955 cm^{-1} in the IR spectrum (16). The ^1H (shift values and coupling constants) and ^{13}C NMR data of fraction Ag-2 were also in complete agreement with those of an analogous fraction from the seed oil of *Iodina rhombifolia* that contains pyrulic and ximenynic acid (17), previously analyzed in our laboratory. By considering all these spectroscopic data, the two FA from the fraction Ag-2 were unequivocally identified in terms of the chain length, and the position and stereochemical configuration of the ene-yne system. There was no evidence of an analogous derivative with *cis* configuration of the double bond as was detected in the seed oil of *Curupira tefeensis* (4) and *Santalum spicatum* (19).

Elucidation of heisteric acid (peak 19). The FAME isolated as fraction Ag-1 was subsequently elucidated as *cis*-7, *trans*-11-octadecadiene-9-ynoic acid ME by a combination of various spectroscopic methods. The UV spectrum of Ag-1 showed peak maxima at 280, 266, and 256 nm, suggesting the presence of a conjugated double/triple bond system with three unsaturated carbon-carbon linkages (16). The IR spectrum presented the following absorption bands: 3029, 2928, 2857, 2190, 1742, 1717, 1456, 1437, 1260, 1199, 1169, 953, and 727 cm^{-1}. The absorption band at 953 cm^{-1} (m) was assigned to a *trans* double bond in conjugation with a triple-bond system (16). Only a very weak band for an acetylenic bond was observed at 2190 cm^{-1}. The mass spectrum of the FAME of peak 19 (Fig. 2) revealed a series of highly unsaturated hydrocarbon fragments [*m/z* 41, 55, 67, 79, 91 (base peak), 105, 117, etc.] in the low-mass range. These ions are known as the result of rearrangement reactions of the unsaturated system in the ion source and are typical for highly unsaturated FAME (20) and FAME with acetylenic bonds (21). The molecular ion at *m/z* 290 suggested a FAME derivative with a C_{18} chain and four double-bond equivalents due to a molecular formula of $C_{19}H_{30}O_3$, respectively. Other weak ions in the higher mass range were found at *m/z* 259 ($M^+ - OCH_3$), 247 ($M^+ - C_3H_7$), 233 ($M^+ - C_4H_9$), 219 ($M^+ - C_5H_{11}$), and 205 ($M^+ - C_6H_{13}$). The latter ion series (*m/z* 247, 233, 219, 205) was considered to arise from methylene cleavages at the CH_3 end of the FA chain. The fact that this series was not further continued and that the ion at *m/z* 219 (allylic cleavage) was the most intense in this mass range suggested that the conjugated unsaturated system could be located at the n-7 end of the hydrocarbon chain (Fig. 2). Similar mass spectrometric characteristics were reported for a naturally occurring conjugated tetraenoic acid (22). It is noteworthy that the mass spectrum of Ag-1 lacked the prominent even-numbered fragment ions which are typical for acetylenic and conjugated olefinic-acetylenic FAME (23). This can be explained by the fact that the triple bond of Ag-1 is located between two double bonds, and thus the fragmentation mechanism observed for FAME that have an acetylenic system in direct neighborhood of a methylene group must be suppressed.

As the mass spectra of the DMOX derivatives of acetylenic FA in some cases are easily interpretable in terms of the position of the unsaturated system (4,17,24,25), the spectrum of the corresponding DMOX derivative of peak 19 was examined carefully (Fig. 2). The molecular ion was detected at *m/z* 329, which is in agreement with its FAME derivative. In the low-mass range, the typical intense ion peaks for the DMOX derivative at *m/z* 113 (McLafferty rearrangement) and 126 (cyclization-elimination reaction) were detected (11). The expected ion series of *m/z* 126 + 14n m.u. (140, 154, 168, ...), representing the cleavage at each methylene group, was not found to be well defined. The theoretically expected ions at *m/z* 140 and 154 were accompanied by other intense ions in the same region. Instead of the expected ion peak at *m/z* 168, peaks at *m/z* 164 and 166 could be observed. Comparison with the literature data of ene-yne derivatives (25) suggested that for the ene-yne-ene structure at C-7 of Ag-1 an ion series *m/z* 168-180-194-204-218-230-244-258 (see Fig. 2) could theoretically be expected. However, the

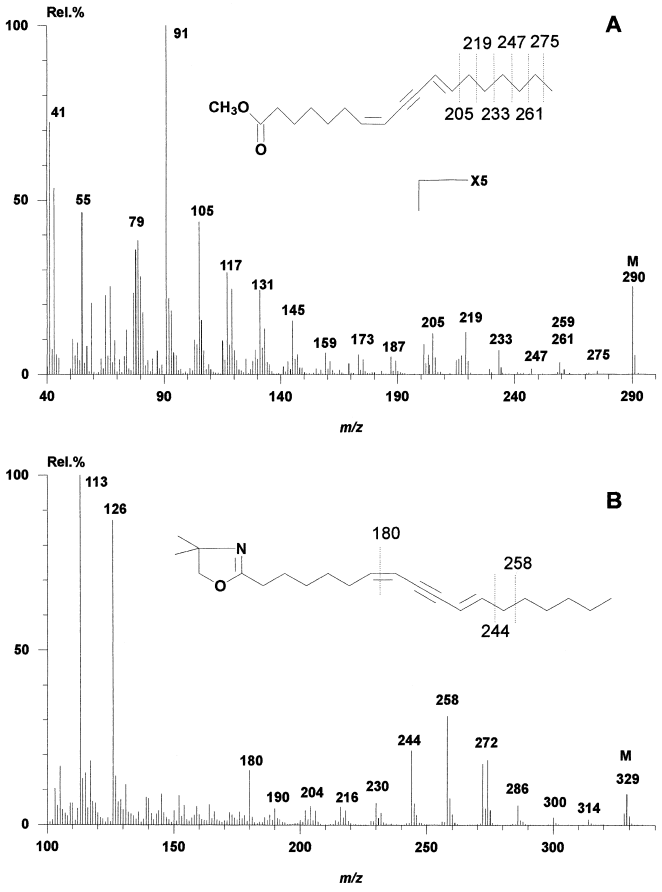

FIG. 2. The electron impact mass spectra of the methyl ester (A) and the 4,4-dimethyloxazoline derivative (B) of heisteric acid (*cis*-7, *trans*-11-octadecadiene-9-ynoic acid).

measured spectrum showed that this peak sequence appeared only partially. The ion at *m/z* 180 was the most intense in the region between *m/z* 140 and 230. This peak theoretically represents the ion produced by a cleavage between C-6 and C-7 of the FA chain. Instead of the ion at *m/z* 194, an unexpected peak at *m/z* 190 was observed. The following ion series at *m/z* 204-218-230-244-258 appeared as predicted, and the latter signal was found to be the third-most intense in the spectrum. This can be explained by the energetically preferred allylic cleavage (Fig. 2). The following ions up to the molecular ion showed the regular 14 m.u. ion series. These mass spectral data demonstrated that the DMOX derivative of Ag-1 can be helpful in locating the unsaturated system but that the complete identification of the individual unsaturated carbons is not possible. Obviously, the appearance potential of the conjugated system of Ag-1 must be similar to that of the oxazoline ring. Thus, the oxazoline ring and the unsaturated ene-yne-ene system can compete as preferred ionization center and the suppression of the hydrogen migration by the oxazoline ring during the ionization does not work as well as in the case of other unsaturated FA (26). Thus, the fragmentation reactions do not follow completely the rules established for ene-yne FA (4,17,24,25).

For further structure analysis, the NMR spectra were examined in detail. The ^{1}H and ^{13}C NMR spectral data are summarized in Tables 2 and 3, respectively. The assignment of the individual signals was possible by applying the chemical shift theory, by interpretation of the coupling patterns, by ^{1}H-^{1}H and ^{1}H-^{13}C chemical shift correlation experiments (COSY and HETCOR), by DEPT experiments, and by using the lanthanide shift reagent Resolve-Al EuFOD™ 99+%. Consistent with the proposed molecular formula, the NMR data revealed the presence of 10 aliphatic methylenes (one of them in allylic position to a *trans* and the other one to a *cis* double bond), four olefinic methines, two acetylenic carbons, two methyl groups, and one carbonyl group.

The ^{1}H NMR spectrum revealed nine signal groups (Table 2). It is noteworthy that the signal for the methylene group in allylic position to the *cis* double bond (C-6) appeared at the same shift value (δ 2.3) as the signal for the methylene group at C-2. The methylene group in allylic position to the *trans* double bond (C-13) arose at δ 2.1. In FA with isolated double bonds, the corresponding signal is found at higher field (δ 2.0). Obviously, the conjugated system caused a downfield shift on the methylene hydrogens in the allylic position. This was already observed in the ^{1}H NMR spectrum of the seed oil of *Sebastiana brasiliensis* that contains the conjugated α-parinaric acid (27). The COSY experiment demonstrated coupling from the allylic methylene signal at δ 2.3 through the olefinic proton signals at δ 5.85 [1H, *J* = 10.8(*d*); 7.4(*t*) Hz] to δ 5.55 [1H, *J* = 10.8(*d*) Hz].

[a]The regiospecific distribution of the fatty acyl residues has not been differentiated. Fatty acids with acetylene bonds are bolded.
[b]ACN is the total acyl carbon number and *n* the combined number of double bonds and triple bonds. Triacylglycerols with acetylene acyl groups are bolded.
[c]Compound has no triglyceride structure. HTGC/NCI–MS, high-temperature capillary gas chromatography/negative chemical ionization–mass spectrometry.

The value of about 11 Hz for the coupling constants within the latter double bond signals demonstrated, that their stereochemical configuration must be *cis*. The observed shift values, the coupling patterns, and the fact that no other couplings outgoing from δ 5.55 could be detected in the COSY spectrum demonstrated that this *cis*-olefinic structure element must be linked with the acetylenic group. The following partial structure was thus confirmed: $–CH_2–CH=CH$(*cis*)–C≡C–. The COSY experiment demonstrated moreover a coupling from the second allylic methylene signal at δ 2.1 through the olefinic proton signals at δ 6.15 [1H, J = 15.8(*d*); 7.2(*t*) Hz] to δ 5.65 [1H, J = 15.8(*d*) Hz]. The high value of about 16 Hz for the coupling constants within the double-bond system signals revealed here that its stereochemical configuration must be *trans*. Analogous to the *cis* double-bond protons, the observed shift values, the coupling patterns, and the lack of other couplings outgoing from δ 5.65 showed that the *trans*-olefinic structure element must also be linked directly with the acetylenic group. As the allylic methylene signals at δ 2.1 and 2.3 showed further couplings with other methylene groups, the partial structure $–CH_2–CH_2–CH=CH$(*cis*)–C≡C–CH=CH(*trans*)–$CH_2–CH_2–$ was proven.

Since the methylene signals in the ^{1}H NMR and COSY spectra were not completely resolved, it was not possible to identify the relative position of the conjugated ene-yne-ene system in the FA chain. Consequently, the NMR experiments were completed by using the lanthanide shift reagent Resolve-Al EuFOD™ [tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium] in increasing concentrations. The nucleophilic part of the FAME can build a reversible complex with the lanthanide central atom and the chemical shifts of the protons in neighborhood to this complex increase with the amount of EuFOD™ (28). The ^{1}H NMR spectra obtained by addition of 100 μL of the shift reagent (20 mM in $CDCl_3$) to 500 μL of the $CDCl_3$ solution of Ag-1 are shown in Figure 3. In comparison to the original spectrum (Fig. 3), four new signals could be observed. The COSY spectrum obtained with the same solution revealed clearly the linear array of the hydrogen atoms from C-2 to C-8 (Fig. 4). Coupling was observed in the following sequence: δ 4.0 (H-2)-2.7 (H-3)-1.85 (H-4)-1.70 (H-5)-2.45 (H-6)-5.85

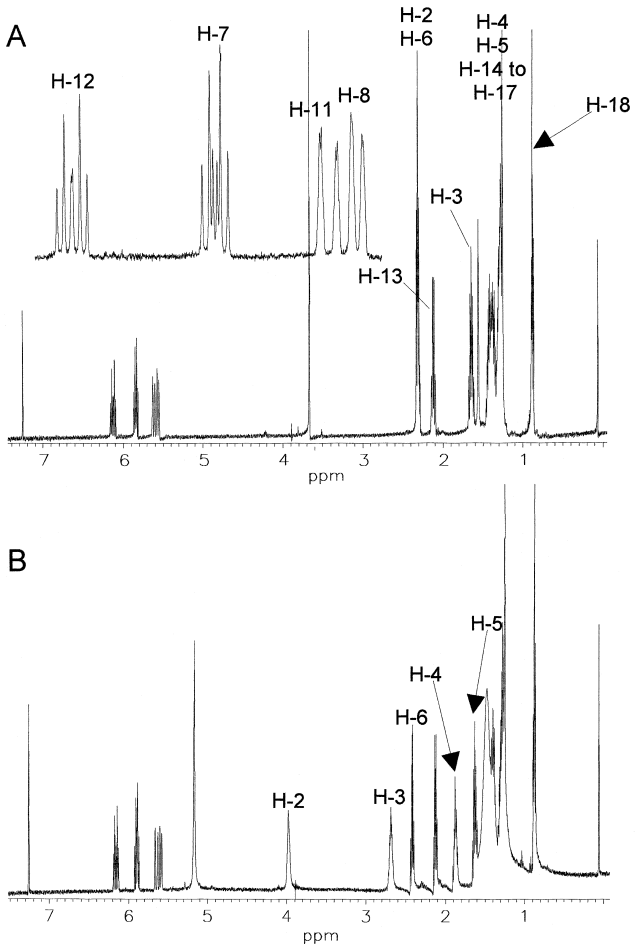

FIG. 3. The ^{1}H nuclear magnetic resonance spectra of heisteric acid (*cis*-7, *trans*-11-octadecadiene-9-ynoic acid) methyl ester recorded at 500 MHz in $CDCl_3$ solution (A) and after addition of 100 µL of Resolve-Al EuFOD™ 99+% (Aldrich Chemical Company, Milwaukee, WI) (B).

(H-7)-5.55 (H-8). These data demonstrated unambiguously that the conjugated unsaturated system begins at C-7 with the *cis* double bond. Considering all the other spectroscopic data, the structure of Ag-1 was thus elucidated as *cis*-7, *trans*-11-octadecadiene-9-ynoic acid ME. To our knowledge, this compound was, up to now, neither isolated from natural sources nor reported as a synthetic derivative. Since it occurs as one of the main compounds in the seed oil of *H. silvanii,* we propose the trivial name *heisteric acid*.

Further structure confirmation was obtained by ^{13}C NMR and HETCOR experiments (Table 2). The ^{13}C signals for the methylene carbon in allylic position to the *cis* and *trans* double bond appeared at δ 30 and 33.3, respectively. In usual *cis* unsaturated FA such as oleic acid, the corresponding ^{13}C signals appear at about δ 27 (18). The shift value for the second signal was again comparable to the corresponding signal in *trans* FA with the double bond at a similar chain position (18). Obviously, the signal for the methylene carbon in allylic position to the *cis* double bond suffered a significant downfield shift that was also observed in the ^{1}H spectrum. The signal pattern for the double (δ 109.5, 109.8, 143, 144.6)- and triple (δ 92.7, 84.9)-bond carbons demonstrated the unsymmetrical nature of the conjugated system. The lack of a ^{13}C signal for propargylic methylene groups at about δ 19 (18) further confirmed that the acetylenic bond must be located between the two double bonds.

Identification of 9,10-epoxystearic acid [peak 23 (Fig. 1)]. The mass spectrum of peak 23 (see Table 1) was found to be identical with that of 9,10-epoxystearic acid ME. Saturated epoxy esters produce mass spectra, the interpretation of which is so straightforward that epoxidation and MS form an established procedure to locate double bonds (29). After reaction with the silylation reagent mixture, peak 23 disappeared and a new peak eluted at lower temperature. Its mass spectrum was identical with that of 9,10-diTMS octadecanoic acid ME. Thus, the identity of peak 19 with 9,10-epoxystearic acid ME was unambiguously confirmed.

Information on other minor peaks (peaks 8, 10, 12, 15, 17, 20–22, 25–27, 29). Peaks 20 and 25 were identified tentatively as 9,11-octadecadiynoic acid and 13-octadecene-9,11-diynoic acid by comparison of their mass spectra of the FAME and DMOX derivatives with the spectra of the same derivatives published previously (4). A series of other unknown minor peaks was detected during the GC and GC/MS analyses. Their FAME mass spectra showed highly unsaturated hydrocarbon fragments in the low-mass range and no molecular ion was detectable. Unfortunately, the DMOX spectra did not provide further valuable structure information. From the GC and MS data, it is probable that these compounds are highly unsaturated and consist in C_{17} and C_{18} chains.

High-temperature GC and high-temperature GC/MS analyses. To obtain information about the FA distribution of the intact lipid species in the seed oil of *H. silvanii,* the sample was investigated by HTGC and HTGC/NCI-MS. In HTGC the use of polarizable stationary phases with a high content of phenyl groups is well known. The distinct selectivity of this type of stationary phase to double bonds facilitates a detailed investigation of neutral lipids. Separation of TAG according to their acyl carbon number (ACN) and within each ACN according to the number of double bonds could be achieved, whereby the retention time increased with the increasing number of double bonds (30–32). Therefore, HTGC analysis of the seed oil of *H. silvanii* was carried out on a glass capillary column coated with a thin film of a methoxy-terminated SOP-50. This stationary phase was designed for the special purposes of HTGC (13,33) and yielded, in the long-term, high-temperature stable glass capillary columns with high inertness and low bleeding even at high temperatures (13). The resulting FID chromatogram (Fig. 5) showed one main peak (peak 6) and one peak with medium height (peak 12); both towered above a number of minor compounds. No evidence of decomposition of the TAG species containing conjugated ene-yne-ene FA, in comparison to seed oils which were rich in TAG containing conjugated ene-ene-ene FA (Aichholz, R., Spitzer, V., and Lorbeer, E., 1997, unpublished), was observed.

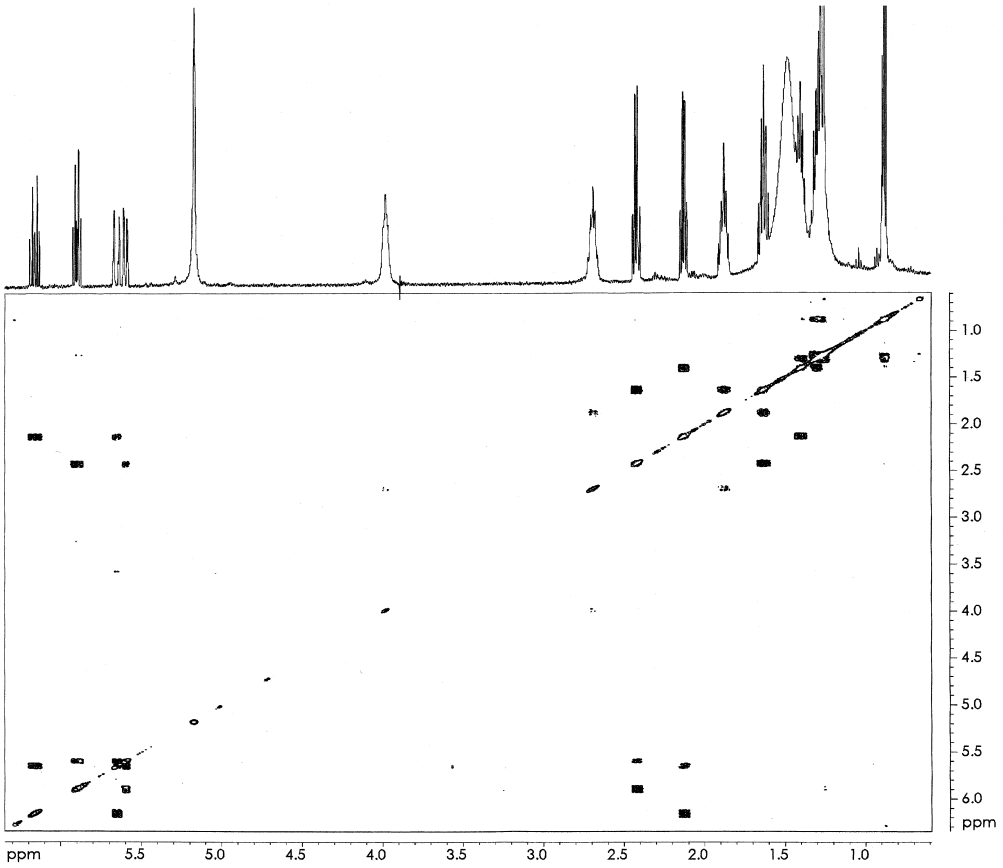

FIG. 4. The ^{1}H-^{1}H two-dimensional shift correlation nuclear magnetic resonance spectrum of heisteric acid (*cis*-7, *trans*-11-octadecadiene-9-ynoic acid) methyl ester recorded at 500 MHz after addition of 100 µL of Resolve-Al EuFOD™ 99+%. See Figure 3 for company source.

HTGC/NCI-MS was carried out, and the composition of the acyl moieties of 26 lipid species of *H. silvanii* was determined (Table 3). The peak pattern of Figure 5 showed an unusual retention behavior on the SOP-50 column of the investigated TAG. For instance, peak 6 consists of two TAG species with the ACN 52 and 54 containing the FA acyl groups 16:0/18:1/18:2(acetylene) and 18:1/18:1/18:1, respectively. Obviously, the presence of an acetylenic FA in the lipids species results in an unexpected increase of the retention time. A further special feature in the elution pattern is the occurrence of peaks 13 and 19. Both compounds eluted after a compound with a higher unsaturation (see Table 3), respectively. Thus, a prediction of the elution order of lipid samples containing acetylenic FA is difficult and needs identification with authentic standards and/or additional information about the constitution of the separated lipid species *via* HTGC/MS analysis.

HTGC/NCI-MS using ammonia as a reagent gas yielded characteristic mass spectra for the TAG with abundant ions at $[M - H]^-$ and $[RCOO]^-$ (34,35). Base peak for all TAG was the quasi molecular ion $[M - H]^-$. The mass spectra of peaks 12 and 26 (see Table 3) are shown in Figures 6 and 7, respectively. The occurrence of prominent quasi molecular ions enables the easy localization of the individual lipid species up to a molecular ion at *m/z* 1026 (see Fig. 8). However, the interpretation of the mass spectra of minor compounds was sometimes disturbed by uncharacteristic ions in the mass range between *m/z* 257 and 269 (see Fig. 6). The presence of a carboxylate anion at *m/z* 281, corresponding to the FA 18:1 $[RCOO]^-$, appeared in all identified lipid species and is in good agreement with the analysis of the total FA composition *via* their ME as listed in Table 1. The identification of the lipid species containing the esterified unusual long-chain FA chain 24:0 ($[RCOO]^-$ = *m/z* 367), 26:0 ($[RCOO]^-$ = *m/z* 395), 28:0 ($[RCOO]^-$ = *m/z* 423) and those containing the esterified acetylene FA 17:2 ($[RCOO]^-$ = *m/z* 263), 18:2 ($[RCOO]^-$ = *m/z* 277) and 18:3 ($[RCOO]^-$ = *m/z* 275) was also possible. The method failed only in the identification of FA with a content <1% in the total FA composition. Furthermore, the regiospecific distribution of the FA (*sn*-2 vs. *sn*-1/3), differentiation of the position of the unsaturation along the FA chain and differentiation of *cis/trans*-isomers cannot be distinguished with this method.

Chemotaxonomic and nutritional considerations. All of the main C_{17} and C_{18} acetylenic FA from the seed oil of *H. silvanii* have their conjugated unsaturated system at the n-7

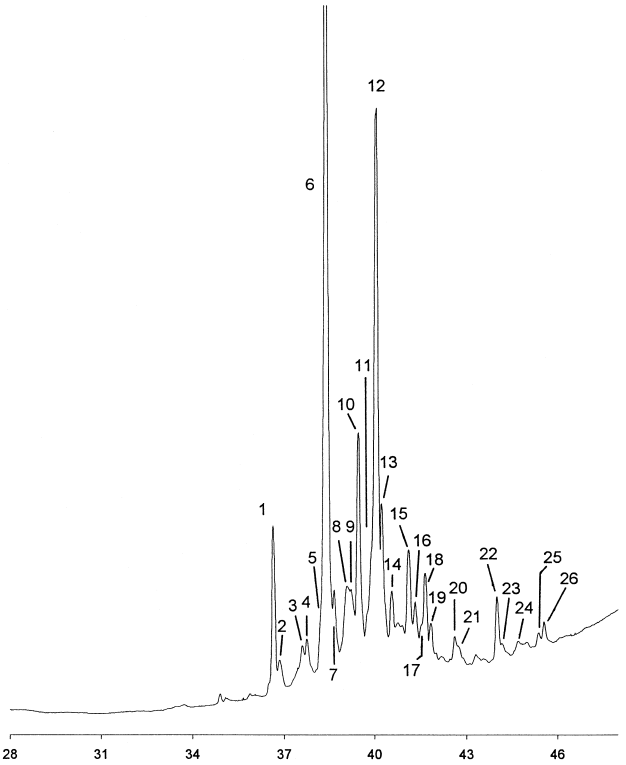

FIG. 5. Flame-ionization detection chromatogram of the seed oil of *Heisteria silvanii* achieved by high-temperature gas chromatography. Analytical details are described in the Materials and Methods section. Peak numbers refer to Table 3.

terminal of the hydrocarbon chain. Up to now, this type of compounds was only found in the two closely related plant families Santalaceae and Olacaceae (both members of Santalales), and they are therefore of chemotaxonomic importance (1). It was observed that the Olacaceae show a preponderance of FA with two acetylenic groups (6) which is not the case in the seed oil of *H. silvanii*. The 9,10-epoxystearic acid, which could be an intermediate product during the biosynthesis of higher unsaturated FA outgoing from oleic acid (36), has been detected already as a minor compound in some other seed oils (2) without a close relationship. There was no evidence of 9-hydroxystearic acid that has been found in the oils of *Ongokea gore* (37) and *I. rhombifolia* (17) that both belong to the Santalales. The presence of relative high amounts of very long-chain saturated FA without being accompanied by the homologous monounsaturated FA was not reported before for an Olacaceae seed oil.

From the nutritional point of view, the seeds and the oil of *H. silvanii* cannot be recommended as the physiological properties of the novel heisteric acid are still unexplored. Furthermore, in a recent work it was demonstrated that conjugated acetylenic FA as xymenynic acid can have a significant influence on the prostaglandin metabolism (38).

ACKNOWLEDGMENTS

The authors thank Marcos E. Sobral for collection and identification of the plant material and Simone Quintana de Oliveira for laboratory assistance. Lipid Specificity and Location of the Sterol Carrier Protein-2 Fatty Acid-Binding Site: A Fluorescence Displacement and Energy Transfer Study[1]

Andrey Frolov[a], Kimberly Miller[a], Jeffrey T. Billheimer[b], Tae-Hyeon Cho[a], and Friedhelm Schroeder[a,*]

[a]Department of Physiology and Pharmacology, Texas A&M University, TVMC, College Station, Texas 77843-4466, and [b]Cardiovascular Department, DuPont Merck Pharmaceutical Company Experimental Station 400-3231, Wilmington, Delaware 19898-0400

ABSTRACT: Although it was recently recognized that sterol carrier protein-2 (SCP-2) interacts with fatty acids, little is known regarding the specificity of SCP-2 for long-chain fatty acids or branched-chain fatty-acid-like molecules. Likewise the location of the fatty-acid binding site within SCP-2 is unresolved. A fluorescent *cis*-parinaric acid displacement assay was used to show that SCP-2 optimally interacted with 14–22 carbon chain lipidic molecules: polyunsaturated fatty acids > monounsaturated, saturated > branched-chain isoprenoids > branched-chain phytol-derived fatty acids. In contrast, the other major fatty-acid binding protein in liver, fatty-acid binding protein (L-FABP), displayed a much narrower carbon chain preference in general: polyunsaturated fatty acids > branched-chain phytol-derived fatty acids > 14- and 16-carbon saturated > branched-chain isoprenoids. However, both SCP-2 and L-FABP displayed a very similar unsaturated fatty-acid specificity profile. The presence and location of the SCP-2 lipid binding site were investigated by fluorescence energy transfer. The distance between the SCP-2 Trp^{50} and bound *cis*-parinaric acid was determined to be 40 Å. Thus, the SCP-2 fatty-acid binding site appeared to be located on the opposite side of the SCP-2 Trp^{50}. These findings not only contribute to our understanding of the SCP-2 ligand binding site but also provide evidence suggesting a potential role for SCP-2 and/or L-FABP in metabolism of branched-chain fatty acids and isoprenoids.
Lipids 32, 1201–1209 (1997).

Eukaryotic cells contain a variety of lipid transfer proteins (1–3). While some of these, such as fatty-acid binding proteins (FABP) and fatty acyl CoA binding protein, appear localized primarily to the cell cytoplasm (2,3), others such as sterol carrier protein-2 not only are found in cytoplasm but also are highly enriched in peroxisomes (4–7). The origin and function of the cytoplasmic form of SCP-2 are unclear at this time. Furthermore, the ligand specificities of many of the lipid transfer proteins are quite broad. This range of specificity is best exemplified by SCP-2, also called the nonspecific lipid transfer protein. SCP-2 is a soluble 13.2 kDa basic protein found in all mammalian tissues examined (8–13). Studies *in vitro* indicate that SCP-2 transfers nearly all phospholipids tested (except cardiolipin) (14,15), glycosphingolipids and gangliosides (16), and sterols (1,8,17–26). Furthermore, SCP-2 stimulates a variety of terminal enzymatic reactions in cholesterol biosynthesis and cholesterol esterification *in vitro* (8,9,18). Although the physiological function(s) of SCP-2 may relate to its ability to transfer the above lipids, this has been established only for cholesterol in permanently transfected L-cells (27) and in transiently transfected Chinese hamster ovary cells (28).

The location of the SCP-2 ligand binding site has not been identified. While the structure of apo SCP-2 has been determined by nuclear magnetic resonance (NMR) spectroscopy, that of the holo-SCP-2 has not been reported (29). Resolution of an SCP-2 ligand binding site has been difficult owing to: (i) Poor aqueous solubility and/or propensity of phospholipids and sterols to form membranous or micellar structures at very low, often nanomolar concentrations; (ii) Inability to obtain saturation binding of a putative SCP-2 ligand binding site with sterols or phospholipids *in vitro* (10,14,15,18,30,31); (iii) The use of organic solvents as a vehicle for the lipid ligands. Organic solvents such as ethanol and propylene glycol may interfere with the binding of ligands to SCP-2 (32); (iv) Loss of putative ligand(s) during the SCP-2 purification procedure. It was reported that SCP-2 purified from tissues has no bound ligand (33,34).

Recently, it was shown that SCP-2 has a fatty-acid binding site (32,35). The present investigation explores the acyl specificity and location of the SCP-2 fatty-acid binding site by use of a fluorescent displacement assay and fluorescence energy transfer from the SCP-2 intrinsic aromatic amino acid residue (Trp^{50}) to bound *cis*-parinaric acid (9*Z*,11*E*,13*E*,15*Z*-octadecatetraenoic acid) serving as an energy transfer acceptor. This study takes advantage of the recent observation that *cis*-parinaric acid binds to SCP-2 with saturation kinetics (32,35) and

Abbreviations: SCP-2, sterol carrier protein-2; L-FABP, liver fatty-acid binding protein; NMR, nuclear magnetic resonance; *cis*-parinaric acid, 9*Z*,11*E*,13*E*,15*Z*-octadecatetraenoic acid.

the presence of a single aromatic amino acid residue, Trp^{50}, in SCP-2 (8).

MATERIALS AND METHODS

Materials. Cis-parinaric acid was obtained from Molecular Probes (Eugene, OR). *Cis*-parinaroyl CoA was synthesized and purified as described earlier (36). Dimethylallyl pyrophosphate, farnesyl pyrophosphate, geranyl pyrophosphate, geranyl geranyl pyrophospate, CoA (CoASH), phytanic acid, acyl-CoA synthase, and ATP were from Sigma Chemical Co. (St. Louis, MO). Saturated and unsaturated fatty acids were obtained from Nu-Chek-Prep Inc. (Elysian, MN). Phytenic acid was kindly provided by Drs. K. Tomer and Cary Weinberger (National Institutes of Health, Research Triangle Park, NC). Pristanic acid was a generous gift from Dr. A. Moser (Johns Hopkins University, Baltimore, MD). L-Tryptophan was from Calbiochem (San Diego, CA). All other chemicals were reagent grade or better.

Methods. Recombinant human SCP-2 and native rat liver fatty-acid binding protein (L-FABP) were isolated and purified as described earlier (37,38). L-FABP was delipidated as described (39). Protein purity was >99% as determined by silver-stained SDS polyacrylamide gel electrophoresis. SCP-2 and L-FABP concentration were determined by Bradford assay (40) (Bio-Rad Laboratories, Richmond, CA). L-FABP concentration determined by the Bradford assay was corrected according to amino acid analysis (41). The Bradford assay overestimates the L-FABP concentration by 1.69-fold.

Absorption and steady-state fluorescence spectroscopy. Absorption spectra were measured at room temperature (~24°C) using a UV/VIS Lambda 2 Double-Beam Spectrophotometer (Perkin-Elmer Inc., Norwalk, CT). Corrected (unless otherwise noted) steady-state fluorescence spectra were measured with an ISS PC1 photon counting spectrofluorimeter (ISS Instruments, Champaign, IL) in a quartz fluorescence cuvette, optical path length 1 cm. Temperature was maintained at 25°C (±0.1°C) in a thermostated cell holder. The excitation and emission bandwidths were 4 and 8 nm, respectively.

Displacement of cis*-parinaric acid bound to SCP-2 or L-FABP by fatty acids*. SCP-2 (0.18 μM) or L-FABP (0.10 μM) in 25 mM phosphate buffer (pH 7.4) were incubated with 0.44 and 0.30 μM *cis*-parinaric acid, respectively, for 5 min at 25°C to obtain stable fluorescence. Protein-bound *cis*-parinaric acid was displaced by fatty acids (3.0–4.5 μM) with acyl chain lengths ranging from 10 to 20 carbons. After addition of displacing fatty acid, the sample was allowed to equilibrate for 5 min before measurement of *cis*-parinaric acid fluorescence.

The form in which the fatty acids were added to the incubation mixture was important owing to the relatively low solubility of long-chain fatty acids in aqueous buffer. The critical micellar concentration of long-chain fatty acids is in the micromolar range (42,43). Thus, displacement by a very soluble medium-chain fatty acid (C_{10}) would not be complicated by the presence of micellar equilibria while, in contrast, the displacement by the long-chain fatty acid (C_{20}) would be complicated by multiple equilibria reflecting the affinities of both the micelle and the SCP-2 for the fatty acid. To minimize these complications related to the differential solubility of the displacing fatty acids, all displacing fatty acids were used as their sodium salts. The critical micellar concentration for the C_{10}–C_{20} fatty acid salts is 1000-fold higher, ~ several millimolar (44), as compared to the corresponding free fatty acids. Fatty acid sodium salts were prepared by dissolving free fatty acids in 10 mM NaOH. It should be noted that fatty acids with chain lengths shorter than C_{10} did not displace bound ligands (data not shown). Measurements were corrected for the blank (ligand or protein only) and for photobleaching (<1%).

Fluorescence quantum yield. Fluorescence quantum yield of SCP-2 in phosphate buffer (ϕ_{prot}) was measured by a relative method (45) as:

$$\phi_{prot} = \phi_{ref}\left[\frac{1-10^{-D_{ref}}}{1-10^{-D_{prot}}}\right]\left(\frac{S_{prot}}{S_{ref}}\right)\left(\frac{n_{prot}}{n_{ref}}\right)^2 \quad [1]$$

where ϕ_{prot} and ϕ_{ref} are the protein and the reference fluorescence quantum yield, respectively; S_{prot} and S_{ref} are integral emission of the protein and the reference, respectively; D_{ref} and D_{prot} are optical densities at excitation wavelength for the reference and the protein, respectively; and n_{prot} and n_{ref} are the respective protein and reference refractive indices. L-Tryptophan in phosphate buffered saline was used as the reference, $\phi_{ref} = 0.14$ at 25° (46). The value of n_{prot} was assumed to be 1.4 (47). The relative error in the measurement of ϕ_{prot} was ≤0.02.

RESULTS

Fatty-acid specificity of the SCP-2 and L-FABP fatty-acid binding sites. Cis-parinaric acid is a naturally occurring 18-carbon, kinked-chain, fluorescent analog of oleic acid that fluoresces poorly in aqueous solution, possibly owing to strong electrostatic interactions of this fluorophore with water molecules. When bound to SCP-2 or L-FABP, *cis*-parinaric acid fluoresces strongly, and Scatchard analysis indicates this fatty acid binds to SCP-2 and L-FABP with 1:1 and 2:1 stoichiometry, respectively. The respective binding affinities were estimated to be $K_d = 0.18$ and 0.41 μM, respectively (32,35).

The *cis*-parinaric acid binding assay was adapted to examine fatty-acid specificity of SCP-2 binding site *via* displacement of bound *cis*-parinaric acid. As shown in Figure 1, SCP-2 bound *cis*-parinaric acid was displaced by a variety of 10–22 carbon length fatty acids. However, this displacement ability was highly dependent on the chain length and degree of saturation of the various fatty acids. Among the saturated fatty acids, the C_{14} and C_{16} fatty acids were the most efficient displacers while shorter- or longer-chain fatty acids were very poor displacers (Fig. 1A). The monounsaturated fatty acids of equal chain length had approximately similar ability as the corresponding saturated fatty acids to displace SCP-2 bound *cis*-parinaric acid (Fig. 1B vs. 1A). In contrast, the polyunsat-

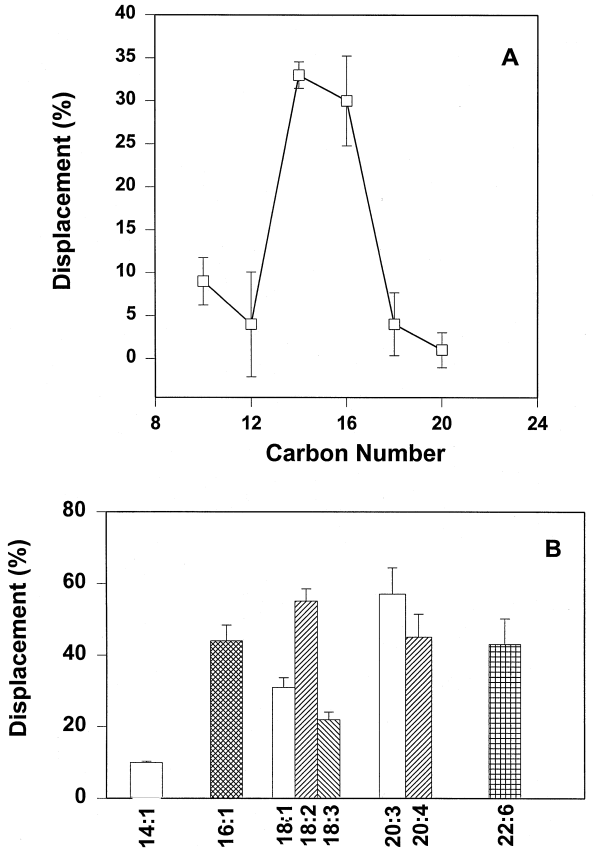

FIG. 1. Displacement of sterol carrier protein-2 (SCP-2) bound *cis*-parinaric acid by fatty acids. SCP-2 (0.18 μM) was preincubated with *cis*-parinaric acid (0.44 μM) followed by addition of displacing fatty acid (4.5 μM) as described in the Methods section. Values represent the mean ± SE (n = 3).

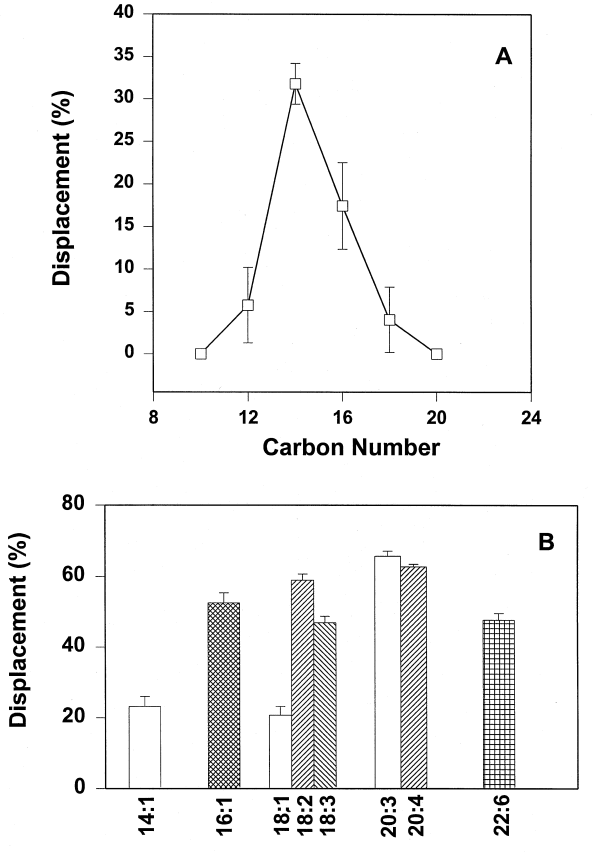

FIG. 2. Displacement of liver fatty-acid binding protein (L-FABP) bound *cis*-parinaric acid by fatty acids. L-FABP(0.1 μM) was preincubated with *cis*-parinaric acid (0.3 μM) followed by addition of displacing fatty acid (3 μM) as described in the Methods section. Values represent the mean ± SE (n = 3).

urated fatty acids were in general much more efficient displacers than the corresponding chain length saturated fatty acids (Fig. 1B vs. 1A).

The *cis*-parinaric acid binding assay was also applied to examine fatty-acid specificity of L-FABP *via* displacement of bound *cis*-parinaric acid. As shown in Figure 2, L-FABP bound *cis*-parinaric acid was readily displaced by a variety of 12–22 carbon length fatty acids. This displacement ability was also highly dependent on the chain length and degree of saturation of the various fatty acids. Among the saturated fatty acids, the C_{14} and C_{16} fatty acids were the most efficient displacers while shorter- or longer-chain fatty acids were very poor displacers (Fig. 2A). This pattern was very similar to that observed for SCP-2 (Fig. 1A). The monounsaturated fatty acids of equal chain length had approximately equal or similar ability as the corresponding saturated fatty acids to displace L-FABP bound *cis*-parinaric acid (Fig. 2B vs. 2A). In contrast and as observed for SCP-2, the polyunsaturated fatty acids were, in general, much more efficient displacers of L-FABP-bound *cis*-parinaric acid than the corresponding chain length saturated fatty acid (Fig. 1B vs. 1A).

Interaction of isoprenoids with the SCP-2 and L-FABP fatty-acid binding site. The *cis*-parinaric acid displacement assay was applied to further examine the specificity of SCP-2 and L-FABP fatty-acid binding sites for other hydrophobic molecules such as isoprenoids. Isoprenoids such as dimethylallyl-PP (C_5), farnesyl-PP (C_{10}), geranyl-PP (C_{15}), and geranyl geranyl-PP (C_{20}) are branched-chain aliphatic molecules that are intermediates in the microsomal and/or peroxisomal synthesis of cholesterol, dolichol, and ubiquinone. They are basically comprised of isopentyl units with increasing chain length. As shown in Table 1, the pyrophosphate derivatives of C_5 to C_{20} isoprenoids displaced SCP-2 and L-FABP bound *cis*-parinaric acid. Unlike the fatty acid displacers (Figs. 1 and 2), short-chain isoprenyl pyrophosphates efficiently displaced SCP-2 bound, and less so L-FABP bound, *cis*-parinaric acid (Table 1). In both cases the geranyl geranyl pyrophosphate was a more efficient displacer than the shorter-chain isoprenyl pyrophosphates. Surprisingly, isoprenyl pyrophosphates with chain length from 4–12 were much more efficient in displacing SCP-2 than L-FABP bound *cis*-parinaric acid (Table 1). However, the longest chain length C_{16} geranyl geranyl pyrophosphate was equally effective in displacing SCP-2 and L-FABP bound *cis*-parinaric acid (Table 1). These data suggest that both SCP-2 and L-FABP may play different role(s) in cellular metabolism of isoprenoids.

TABLE 1
Displacement of *cis*-Parinaric Acid Bound to Fatty Acid-Binding Proteins by Isoprenoids[a]

	Displacement (%)	
Displacing agent	SCP-2	L-FABP
Dimethylallyl pyrophosphate	34 ± 2.3	8 ± 0.9
Farnesyl pyrophosphate	40 ± 1.7	17 ± 2.1
Geranyl pyrophosphate	34 ± 2.1	13 ± 1.4
Geranyl geranyl pyrophosphate	65 ± 1.2	68 ± 0.9

[a]Sterol carrier protein-2 (SCP-2) and liver fatty-acid binding protein (L-FABP) (0.18 μM) were preincubated with *cis*-parinaric acid (0.45 μM) followed by the addition of displacing ligands (4.5 μM). Values represent mean ± SEM (n = 3–5).

Interaction of branched-chain fatty acids with the SCP-2 and L-FABP fatty acid-binding site. The *cis*-parinaric acid displacement assay was applied to examine if SCP-2 and L-FABP also interacted with branched-chain fatty acids such as those derived from phytol. In ruminants, the phytol side-chain of chlorophyll is cleaved to release phytol which is oxidized to phytanic acid by enteric bacteria such that both the phytanic acid and its precursor phytol are present in human diets containing ruminant fats and dairy products (48). Daily human consumption of phytanic acid is 50–100 mg (49). Phytanic acid is absorbed, transported to the liver, and metabolized (oxidized) in peroxisomes (50). Normal human serum levels of phytanic and phytenic acid are 6 and 2 μM, respectively (51). The C_{16} carbon phytol-derived fatty acids displaced SCP-2 bound, more so than L-FABP, bound *cis*-parinaric acid (Table 2). Phytenic acid displaced both SCP-2 and L-FABP bound *cis*-parinaric acid to the same degree, 22 and 26%, respectively (Table 2). In contrast, phytanic acid and pristanic acid were more effective in displacing L-FABP than SCP-2 bound *cis*-parinaric acid (Table 2). These data suggest that both SCP-2 and L-FABP may play different role(s) in branched-chain fatty-acid metabolism within the cell.

Location of SCP-2 fatty-acid binding site as determined by fluorescence energy transfer from SCP-2 to the bound cis*-parinaric acid*. Although the structure of the L-FABP fatty-acid binding sites was recently reported by X-ray crystallography (52), similar progress has not yet been made with regard to the SCP-2 fatty-acid binding site. The nucleotide sequence of SCP-2 indicates the presence of a single Trp at position 50 and no tyrosine residues in the SCP-2 polypeptide chain (28). Hence, the Trp^{50} may serve as an internal "ruler" or reference point for locating the putative fatty-acid binding site in SCP-2. The proximity of SCP-2 Trp^{50} to the fatty-acid binding site can be determined by fluorescence energy transfer from Trp^{50} to a bound *cis*-parinaric acid. The absorbance spectrum of the SCP-2 bound *cis*-parinaric acid was determined at a fatty acid to protein molar ratio of 1:10, which corresponds to approximately 90% of the fatty acid bound to SCP-2. The unbound free *cis*-parinaric acid poorly absorbs in aqueous buffers owing to strong electrostatic interactions with water molecules. These factors allowed determination of the absorption spectrum of SCP-2 bound *cis*-parinaric acid by measuring the differential spectrum with SCP-2/*cis*-parinaric acid in the sample and SCP-2 in the reference. This explains why the protein absorption component is not shown in Figure 3. The absorbance spectrum of *cis*-parinaric acid bound SCP-2 displayed maxima near 292, 306, and 320 nm (Fig. 3, dashed line). The nonzero absorbance of *cis*-parinaric acid at 250 nm was due to nonactive absorbance of the aqueous buffer which was very difficult to compensate owing to strong absorption of water in that spectral region.

Upon excitation at 310 nm, a nonstructured emission spectrum was observed with a peak at ~416 nm (data not shown). As shown in Figure 3 (solid line), the SCP-2 Trp^{50} fluorescence emission spectrum significantly overlaps the absorption spectrum of *cis*-parinaric acid. This provides the resonance conditions required for remote dipole-dipole electron excitation energy transfer (Forster energy transfer) from the SCP-2 Trp^{50} (donor) to the bound *cis*-parinaric acid (acceptor). Forster energy transfer from Trp to *cis*-parinaric acid has been previously used to measure interatomic distances in intestinal FABP (53). The efficiency of Forster energy transfer from SCP-2 Trp^{50} to *cis*-parinaric acid was examined in experiments where SCP-2 was excited at 255 nm, and SCP-2 Trp^{50} fluorescence emission at 332 nm was monitored upon titration of SCP-2 with increasing amounts of *cis*-parinaric

[a]SCP-2 and L-FABP (0.18 μM) were preincubated with *cis*-parinaric acid (0.45 μM) followed by the addition of displacing ligands (4.5 μM). Values represent mean ± SEM (n = 3–5). See Table 1 for abbreviations.

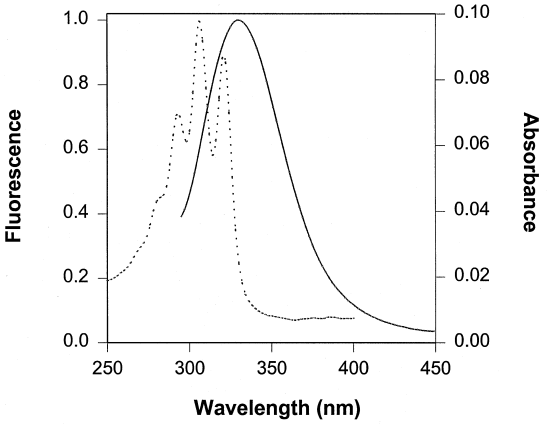

FIG. 3. Spectral characteristics of SCP-2 and *cis*-parinaric acid. Fluorescence emission spectra of SCP-2 (1 μM) in phosphate buffer, pH 7.4 (excitation at 280 nm, solid line). Absorption spectrum of *cis*-parinaric acid (1.3 μM) bound to SCP-2 (dotted line). See Figure 1 for abbreviation.

acid acceptor (Fig. 4A). SCP-2 Trp^{50} was excited at 255 nm because at this wavelength the acceptor, *cis*-parinaric acid, had negligible absorbance over the concentration range used in the titration experiments. As shown, upon titration of SCP-2 with increasing amounts of *cis*-parinaric acid, the tryptophanyl emission of SCP-2 gradually declined to ~40% of its initial level (legend to Fig. 4A). Such gradual decrease of tryptophanyl emission was accompanied by the appearance of an additional fluorescence emission band near ~420 nm (Fig. 4B) which can be attributed to the sensitized emission of *cis*-parinaric acid. It should be noted that no detectable SCP-2 fluorescence quenching was observed when the protein emission was monitored during SCP-2 titration with nonfluorescent oleic acid (data not shown). This observation strongly suggests that SCP-2 tryptophanyl fluorescence quenching detected in the presence of fluorescent *cis*-parinaric acid cannot be explained by direct interaction of two fluorophores, or by conformational changes of the protein induced by a bound fatty acid. Therefore, taken together, the above observations regarding the SCP-2 fluorescence quenching in the presence of *cis*-parinaric acid are consistent with the predominant mechanism of this quenching process being fluorescence energy transfer from SCP-2 Trp^{50} to the bound *cis*-parinaric acid. The efficiency of SCP-2 fluorescence quenching by *cis*-parinaric acid was estimated as 60% (Fig. 4A). Based on this energy transfer efficiency, the critical distance of energy transfer, R_o, for the SCP-2 Trp^{50} and *cis*-parinaric acid donor/acceptor pair was calculated as (54):

$$R_o = (9.765 \times 10^3)(K^2JQn^{-4})^{1/6} \quad [2]$$

where Q is the quantum yield of the donor in the absence of the acceptor; n, the refractive index; J, the overlap integral is defined as:

$$J = \int F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 d\lambda \Big/ \int F_D(\lambda)d\lambda \quad [3]$$

where $F_D(\lambda)$is the normalized emission spectrum of the donor; $\varepsilon_A(\lambda)$ is the absorption spectrum of acceptor. Finally K^2 is the orientation factor ranging from 0 to 4. Energy transfer efficiency, E, is related to the distance between the donor and the acceptor r by:

$$E = R_o^6 \Big/ (R_o^6 + r^6) \quad [4]$$

The values of the parameters describing the Forster energy transfer in the SCP-2 Trp^{50}/*cis*-parinaric acid donor/acceptor pair are presented in Table 3. The calculated intermolecular distance between SCP-2 Trp^{50} and the *cis*-parinaric acid, based on the assumption that $K^2 = 2/3$ (i.e., for random orientation of the donor and the acceptor moments) was $r = 40$ Å (Table 3).

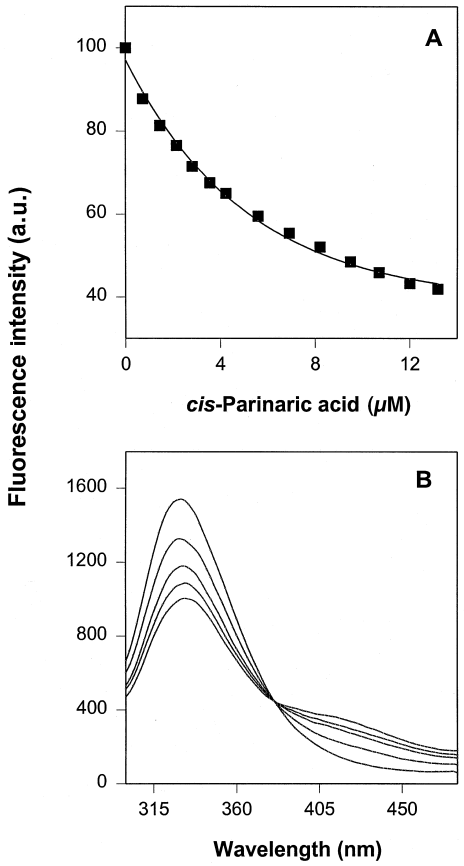

FIG. 4. Forster energy transfer between SCP-2 tryptophanyl (the donor) and bound *cis*-parinaric acid (the acceptor). (A) SCP-2 (1 μM) fluorescence quenching upon its titration with fatty acid. Excitation at 255 nm, emission at 332 nm. (B) Fluorescence emission spectra of SCP-2 (1 μM) in the presence of increasing amounts of *cis*-parinaric acid. From top to bottom: 1 μM SCP-2; 1 μM SCP + 0.5 *cis*-parinaric acid; 1 μM SCP + 1.0 μM *cis*-parinaric acid; 1 μM SCP + 1.5 μM *cis*-parinaric acid; 1 μM SCP + 2 μM *cis*-parinaric acid; 1 μM SCP + 2.5 μM *cis*-parinaric acid. Excitation at 255 nm. See Figure 1 for abbreviation.

TABLE 3
Forster Energy Transfer Parameters for Fluorescence Energy Transfer from SCP-2 Trp^{50} to Bound *cis*-Parinaric Acid (PA)[a]

Donor/acceptor	J (M^{-1} cm^3)	R_o[b] (Å)	E (%)	$r_{2/3}$[c] (Å)
Trp/*cis*-PA	9.82 10^{-15}	43	60	40

[a]J, overlap integral; R_o, critical distance at which 50% energy transfer occurs; E, energy transfer efficiency; $r_{2/3}$, actual distance between two residues, with the assumption $K^2 = 2/3$ (where K^2 is the orientation factor).
[b]Calculated for $\phi_{prot} = 0.27$; $n = 1.4$, and $K^2 = 2/3$, where ϕ_{prot} is quantum yield and n is refractive index.
[c]Calculated for $K^2 = 2/3$. See Table 1 for other abbreviation.

DISCUSSION

Liver hepatocytes and intestinal enterocytes both contain SCP-2 and L-FABP (reviewed in Ref. 55). The physiological function of neither protein is known. Therefore, a knowledge on the ligand binding specificities of these proteins is important to begin understanding their potential functional role(s). While SCP-2 is known to enhance the intermembrane transfer of cholesterol, glycolipids and phospholipids, identification of a ligand binding site has been problematic owing to the poor aqueous solubility of the ligands involved as well as their high affinity for membranes (8,9,18,56,57).

Only recently was it recognized that SCP-2 binds fatty acids (32,58). Specific binding of fatty acids was previously not detected with the standard Lipidex 1000 (Sigma Chemical Co.) radioligand competition binding assay, because of the sensitivity of the SCP-2 fatty-acid binding site to the organic solvent vehicle used in this competition assay (32,59). In contrast, the level of organic solvent used in the Lipidex 1000 assay did not interfere with fatty-acid binding to L-FABP (32,59). Furthermore, unlike the L-FABP whose X-ray crystal structure with bound fatty acid is now available (52), little is known regarding the specificity of SCP-2 for long-chain aliphatic molecules or the location of the SCP-2 fatty-acid binding site. Although previous studies have examined the fatty-acid specificity of L-FABP, the respective ligands were generally used as the free fatty acids rather than the fatty-acid salts (reviewed in Refs. 2,43,60–62). As pointed out previously (11) and in the introductory section, this may provide an apparent fatty-acid binding ability complicated by the solubility of the fatty acid.

The present investigation examined for the first time the specificity of the fatty-acid binding site of SCP-2 and L-FABP by use of sodium salts of the fatty acids. In a displacement assay involving protein-bound fluorescent *cis*-parinaric acid, a series of unbranched saturated and unsaturated fatty acids, isoprenoids, as well as branched-chain fatty acids were examined. The data demonstrated that SCP-2 bound a variety of fatty acids with a similar chain length and unsaturation specificity pattern as did L-FABP. Furthermore, both proteins bound a series of isoprenyl pyrophosphates and branched-chain fatty acids derived from phytol. These ligands were able to displace SCP-2 and L-FABP bound *cis*-parinaric acid to similar extents as did the normal fatty acids. However, the two proteins exhibited distinct differences in their binding of these branched aliphatic chain ligands. It should be noted that the displacement assay does not measure absolute binding affinities, but rather utilizes a fixed set of conditions to compare the relative ability of a series of lipophilic molecules to displace SCP-2 bound *cis*-parinaric acid. Conclusions regarding the absolute values of the respective ligand affinities cannot necessarily be made from displacement assays. This has been shown for fatty-acid vs. fatty acyl-CoA binding to SCP-2, wherein the binding affinity of SCP-2 for these ligands differs two orders of magnitude (35). However, when the displacement conditions were optimized for the lower-affinity ligand, fatty acid, the relative displacement of fluorescent fatty acid by both fatty acid and fatty acyl-CoA did not reflect the absolute differences in K_ds (35).

The significance of the data obtained with regard to SCP-2, which has been localized to peroxisomes (both interior and cytoplasmic surface) and to a lesser extent other organelles such as mitochondria and endoplasmic reticulum (5,6), is several-fold: First, SCP-2 may enhance import of fatty acids and/or fatty acyl-CoA into peroxisomes or mitochondria and thereby stimulate fatty-acid β-oxidation. Second, by binding phytol-derived fatty acids, SCP-2 may enhance import of branched-chain fatty acids into peroxisomes for α-oxidation. Third, there is growing evidence that peroxisomes contain most of the enzymes for cholesterol biosynthesis (63). Therefore, by binding isoprenyl pyrophosphates, SCP-2 may be involved in peroxisomal as well as microsomal cholesterol biosynthesis. Fourth, by binding a variety of short- and long-chain isprenyl pyrophosphates, SCP-2 may influence dolichol biosynthesis. Dolichol is an important molecule involved in glycosylation of proteins, and SCP-2 has already been shown to enhance the activity of microsomal *cis*-prenyltransferase (64). Fifth, experiments with transfected L-cell fibroblasts expressing SCP-2 have shown that the microsomal esterification of cholesterol is enhanced (65). Thus, by exhibiting fatty acyl chain selectivity, SCP-2 may be involved in the subsequent utilization of fatty acyl-CoA for microsomal esterification of fatty acids to cholesteryl esters. Similar considerations for L-FABP must be modified by its preferential location in cell cytosol and in the region of the endoplasmic reticulum (reviewed in Ref. 66). In summary, the interaction of SCP-2 as well as L-FABP with a wide variety of aliphatic molecules (branched-chain fatty acids, and isoprenoids) as well as normal fatty acids suggests new potential roles for these proteins in lipid metabolism.

Although SCP-2 stimulates the intermembrane transfer of many different lipids, including sterols, phospholipids, glycolipids, etc., it is unclear whether these activities actually require a ligand binding site in the protein. As a basic protein SCP-2 may, by binding to the anionic surface of membranes, disrupt membrane structure and thereby enhance the desorption of lipid molecules from the membrane. Recent findings, however, indicate that this is not likely for SCP-2 (23). In order to function in intermembrane sterol transfer, for example, SCP-2 must bind sterol (23). The location of this sterol binding site has not been determined. Neither is it known whether any of the other lipids transferred by SCP-2 also bind to the same or different sites in SCP-2.

The first major step in resolving a putative SCP-2 ligand binding site was the determination of the tertiary structure of the apo SCP-2. Based on NMR data, it was concluded that apo SCP-2 is comprised of a polypeptide chain with three α-helixes, a five-stranded β-sheet, with the rest as turn or random coil (29). SCP-2 Trp^{50} is located on one side of the SCP-2 molecule in the middle of β-sheet II. However, the orientation (facing the aqueous or the hydrophobic interior) of the tryptophanyl aromatic ring in β-sheet II is not known. On the opposite side of the molecule is located β-sheet V, representing the C-terminal β-sheet, to which is attached a randomly oriented "tail." The NMR data further show that the overall shape of apo SCP-2 is roughly spherical or slightly ellipsoidal (29). This is in agreement with recently presented data that the rotational correlation time and hydrodynamic radius of the entire SCP-2 protein are consistent with a nearly spherical or slightly elliptical protein (35). The apo SCP-2 Trp^{50} fluorescence dynamics showed an overall protein rotational correlation time of 8.4 ns and a hydrodynamic radius of 20 Å, which is very similar to that of the theoretical radius (18 Å) of a 13.2 kDa (the molecular weight of apo SCP-2)

globular protein. This was also confirmed by the measurements of the rotational dynamics of SCP-2 bound *cis*-parinaric acid, which yielded a hydrodynamic radius of 20.5 Å (35). These data indicate that SCP-2 is a globular, slightly elongated protein. In contrast, an early fluorescence study of apo SCP-2 Trp^{50} fluorescence dynamics measured a much longer rotational correlation time of 13.8 ns and suggested that apo SCP-2 is highly elliptical with an axial ratio of nearly 3:1 (31). The reason for the discrepancy between the latter study vs. the NMR and the present results is not clear. However, in the earlier work, the longer 13.8 ns rotational relaxation time was obtained at high SCP-2 concentration, 10 μM (31), and suggests the presence of SCP-2 dimers. Indeed, at concentrations of 10 μM (instead of the 0.18 μM used in the present work), we have observed a similar longer rotational relaxation time near 15 ns, indicative of SCP-2 dimers (data not shown).

The second major contribution to resolving the location of an SCP-2 ligand binding site came from results of site-directed mutagenesis (67). As mentioned above, the apo SCP-2 polypeptide chain is comprised of three α-helixes and a five-stranded β-sheet, one of which (β-sheet V) is on the opposite side of the SCP-2 Trp^{50} (located in β-sheet II) (29). Site-directed mutagenesis indicates that deletion and/or mutations in β-sheet V abolish SCP-2 transfer activity of sterols and phospholipids. Two other parts of the SCP-2 molecule (helix A and amino acids next to Cys^{71}) are very near the β-sheet V and are also necessary for sterol and phospholipid transfer activity (29). Although the site-directed mutagenesis data do not provide definitive proof, they suggest that a sterol and/or phospholipid binding site may be in a cleft formed by β-sheet V, a portion of helix A, and amino acids around Cys^{71}.

The present results show, for the first time, direct data on the location of the fatty-acid binding site in holo SCP-2. Earlier results from this laboratory showed that SCP-2 binds fluorescent fatty acids with saturation kinetics and high affinity, K_ds 0.2–0.4 μM (32,35). Nevertheless, the location of the SCP-2 fatty-acid binding site and/or its relation to putative cholesterol and/or phospholipid binding/transfer site(s) were not known. The data presented herein show that SCP-2 Trp^{50} is able to transfer energy to bound *cis*-parinaric acid with high efficiency near 60%. This tryptophan was not exposed to aqueous solvent, as shown by the emission maximum wavelength (λ = 332 nm), and by the lack of oleic acid effect on the Trp^{50} emission intensity/spectrum. Therefore, the aromatic ring of Trp^{50}, located on β-sheet II, appears to be turned inward to the hydrophobic core of the protein. Forster energy transfer showed that the estimated distance between SCP-2 Trp^{50} and bound *cis*-parinaric acid was near 40 Å, based on an assumed random orientation of the donor and the acceptor. The experimentally determined and theoretically calculated diameters for apo SCP-2 were 41 and 37.6 Å, respectively (35). The experimentally determined diameter for holo-SCP-2 containing bound oleic acid was 49 Å (35). It should be noted that the orientation of the fatty acid in the SCP-2 binding site is with the carboxylate exposed near the surface (35). An examination of the structure of *cis*-parinaric acid indicates that the tetraene fluorophore extends from the middle of the molecule to its methyl terminal of the *cis*-parinaric acid, i.e., about 8–10 Å away from the carboxyl terminus (35). This would suggest that the assumed orientation factor used to calculate the distance between SCP-2 Trp^{50} and bound *cis*-parinaric acid, 40 Å, was reasonable. More importantly, an intermolecular distance of 40 Å betweeen Trp^{50} and the fluorophore of *cis*-parinaric acid would place the fatty-acid binding site of SCP-2 on the opposite side of the SCP-2 from the β-sheet II Trp^{50}.

In summary, SCP-2 interacted with a wide variety of aliphatic ligands: C_{12} to C_{14} fatty acids, C_{16} branched-chain fatty acids, and C_4 to C_{16} isoprenyl pyrophosphates. The SCP-2 fatty-acid binding site was located approximately 40 Å from (and on the opposite side of) the location of SCP-2 Trp^{50}. The latter observation is consistent with site-directed mutagenesis studies (67), indicating that the β-sheet V, opposite from Trp^{50}, is essential for sterol and phospholipid transfer activity. One interpretation of these facts is that the ligand binding site that interacts with fatty acids, sterols, and phospholipids may be the same site. These ligand binding data may provide new insights into the physiological importance of SCP-2 in the cell.

ABSTRACT: Selected elution factors were determined for model oxotriacylglycerols as an aid in identification of the peroxidation products of natural triacylglycerols by reverse-phase high-performance liquid chromatography (HPLC) with electrospray mass spectrometry (LC/ES/MS). For this purpose synthetic triacylglycerols of known structure were converted to hydroperoxides, hydroxides, epoxides, and core aldehydes and their dinitrophenylhydrazones by published procedures. The oxotriacylglycerols were resolved by normal-phase thin-layer chromatography and reverse-phase HPLC, and the identities of the oxotriacylglycerols confirmed by LC/ES/MS. Elution factors of oxotriacylglycerols were determined in relation to a homologous series of saturated triacylglycerols, ranging from 24 to 54 acyl carbons, and analyzed by reverse-phase HPLC, using a gradient of 20–80% isopropanol in methanol as eluting solvent and an evaporative light-scattering detector. It was shown that the elution times varied with the nature of the functional group and its regiolocation in the triacylglycerol molecule. A total of 31 incremental elution factors were calculated from chromatography of 33 oxygenated and nonoxygenated triacylglycerol species, ranging in carbon number from 36 to 54 and in double-bond number from 0 to 6.

Lipids 32, 1211–1218 (1997).

High-performance liquid chromatography (HPLC) is widely used to analyze natural triacylglycerols, and numerous authors have noted their orderly elution under isocratic (1–4) and solvent gradient (5–7) elution conditions. Although the elution characteristics of triacylglycerols with functional groups also have been determined (1,8–14), only a few systematic studies have been reported (11–14). Mixtures of oxygenated natural triacylglycerols are difficult to analyze by chromatographic methods because of the presence of a large variety of homologs and of regio- and geometric isomers, which tend to overlap with each other and with homologs of unoxidized parent compounds. In principle, it should be possible to identify and quantify overlapping species by combining HPLC with on-line mass spectrometry (MS), which can provide mass-to-charge (*m/z*) ratios for both molecular and fragment ions characteristic of particular triacylglycerols. The thermospray (13,15) and chemical ionization (5,15) routines employed for this purpose, however, are not entirely satisfactory for analysis of the unstable hydroperoxides of triacylglycerols. In contrast, the milder electrospray ionization yields the molecular ion as the major or sole species for each triacylglycerol (16) or its hydroperoxide, epoxide, and core aldehyde (17,18), and usually does not yield fragment ions, unless the ionization voltage is greatly increased (15). Furthermore, many oxotriacylglycerols possess molecular masses which match the various ordinary triacylglycerols, or their M + 1 or M + 2 ions. In order to provide a rationale for identification of overlapping and unknown triacylglycerols, it is critical to know the relative retention times of the triacylglycerols containing various combinations of oxygenated and nonoxygenated fatty acids. The following study reports the incremental elution factors obtained for model oxotriacylglycerols on reverse-phase HPLC, from which the retention times of unknown oxotriacylglycerols can be estimated by summation and extrapolation, permitting identification of triacylglycerol oxidation products using a single quadrupole liquid chromatography/electrospray/MS (LC/ES/MS) instrument.

MATERIALS AND METHODS

Chemicals and reagents. Tert-butyl hydroperoxide (TBHP) was purchased from Sigma Chemical Co. (St. Louis, MO) and 2,4-dinitrophenylhydrazine (DNPH) and 3-chloroperoxybenzoic acid from Aldrich Chemical Co. (Milwaukee, WI). Methanol (HPLC grade) was obtained from Mallinckrodt

E-mail: arnis.kuksis@utoronto.ca.

Abbreviations: DNPH, 2,4-dinitrophenylhydrazine; ECN, equivalent carbon number; ES, electrospray; F_i, correction factor; HPLC, high-performance liquid chromatography; LC, liquid chromatography; M, molecular ion; MS, mass spectrometry; TBHP, *tert*-butyl hydroperoxide; TCN, theoretical carbon number; TLC, thin-layer chromatography; TPP, triphenylphosphine.

Chemicals, Inc. (Paris, KY) and 2-propanol (HPLC grade) from Caledon Laboratories, Ltd. (Georgetown, Ontario, Canada). All other chemicals and solvents were of reagent grade or better quality and were obtained from local suppliers. Synthetic saturated monoacid triacylglycerols were included in HPLC standard (G-1) obtained from Nu-Chek-Prep, Inc. (Elysian, MN). Synthetic 1,3-distearoyl-2-oleoyl and 1,3-dipalmitoyl-2-linoleoyl-*sn*-glycerols were purchased from Sigma Chemical Co. Synthetic 1,2-distearoyl-3-oleoyl, 1-oleoyl-2,3-dipalmitoyl, 1,3-distearoyl-2-oleoyl, 1,2-dioleoyl-3-stearoyl, 1,2-distearoyl-3-linoleoyl, 1,2-dilinoleoyl-3-stearoyl, 1,3-distearoyl-3-linolenoyl, 1,2-dilinolenoyl-3-stearoyl, and 1,2-distearoyl-3-eicosenoyl-*sn*-glycerols were prepared in the laboratory by reacting 1,2-distearoyl-, 3-stearoyl-, or 2,3-dipalmitoyl-*sn*-glycerol with oleoyl, linoleoyl, linolenoyl, and 11-eicosenoyl chlorides in the presence of dry pyridine (19). The 1,2-distearoyl-, 3-stearoyl-, and 2,3-dipalmitoyl-*sn*-glycerols were gifts from Dr. Buchnea. Table 1 lists the synthetic triacylglycerols along with their oxo-derivatives prepared in this study.

Preparation of core aldehydes. Core aldehyde standards were obtained by triphenylphosphine (TPP) reduction of ozonides as previously described (8,17,20). Briefly, 1–40 mg of triacylglycerols were dissolved in 4 mL hexane and ozonized for 5 min in a dry ice/acetone bath. After blowing down the solvent, the ozonides were redissolved in 2–4 mL chloroform and reduced to aldehydes by reacting with 20–40 mg TPP for 1 h at room temperature. The aldehydes were purified by thin-layer chromatography (TLC) as described below. Part of the aldehydes were converted into the DNPH derivatives by treating with 5–10 mL of the DNPH reagent (1 mg DNPH in 2 mL of 1 M HCl) at room temperature overnight (21). The DNPH derivatives were recovered from the solution by chloroform extraction and were further purified by TLC. Specifically, monoaldehydes (Id–e, IId–e) were prepared from monounsaturated triacylglycerols (I–II); see Table 1 for details of name terminology. Dialdehydes (IIId–e) were prepared from triacylglycerols (III, VI–VII) containing two unsaturated fatty acids and one saturated fatty acid.

Preparation of hydroperoxides. Hydroperoxides (Ia, IIa,

XII	470–890	Series of saturated TAG (24:0–54:0)[f]			

[a]Abbreviations : ALD, aldehyde; DNPH, dinitrophenylhydroxide; TAG, triacylglycerol.
[b]Nominal mass.
[c]Position of an epoxy group has been marked as an underlined double bond.
[d]These references were also prepared from triacylglycerols VI and VIII.
[e]These compounds were prepared but not used to estimate elution factors.
[f]Reference compounds were co-injected with this series of saturated TAG.

IIIa, VIa) were obtained by oxidizing 0.25–10 mg of a triacylglycerol (I–VI) with 0.5–2.0 mL of 70 mM TBHP for 20 min to 30 h at 22°C or 37°C (13,22). Lipids were extracted with chloroform/methanol (2:1, vol/vol) and the excess TBHP was washed out with water. Some hydroperoxides (IVa, VIa–b) were also prepared by the photosensitized oxidation method described by Neff *et al*. (23). About 2–3 mg triacylglycerol (IV, VI) was added to 3 mL 0.1 mM methylene blue in dichloromethane in a 5-mL beaker on an ice bath, which was placed under a 500 W photographer's lamp.

Preparation of hydroxy triacylglycerols. Hydroperoxides (Ia, IIa, IIIa, IVa, Va, VIa–b) were reduced to the corresponding hydroxytriacylglycerols (Ib, IIb, IIIb, IVb, Vb, VIc–d) by sodium borohydride (24). One mg of hydroperoxide was dissolved in 1 mL of chloroform/methanol (2:1, vol/vol), mixed with 1 mL of 0.1 M $NaBH_4$ in methanol, and allowed to react 1 h at 4°C. The hydroxy compounds were recovered by washing the reaction mixture twice with water, blowing down the solvent, and redissolving the residue as required for subsequent HPLC. Alternatively, the hydroperoxides were reduced with TPP (25). Some 10–11 mg TPP in 0.3–1 mL solvent (hexane) was added to 1–5 mg sample of a hydroperoxy triacylglycerol (IV). The hydroxy derivative (IVa) was purified and TPP was removed by TLC.

Preparation of epoxides. Epoxides (Ic, IIc, IIIc, IVc) were obtained by the method of Deffense (26). A sample of 2–5 mg unsaturated triacylglycerol (I–IV) was reacted with 6–8 mg 3-chloroperoxybenzoic acid in 300–400 μL dichloromethane at room temperature for 1–2 h followed by purification using TLC as described next.

TLC. Normal-phase TLC was used to purify triacylglycerols and their derivatives in a neutral solvent system (27). Briefly, H-plates were prepared in the laboratory, and heptane/isopropyl ether/acetic acid (60:40:4, by vol) solution was used as a mobile eluent. The resolved components were recovered from the silica gel by extraction with chloroform/methanol 2:1 (vol/vol). Extracts were washed with distilled water and dried using Na_2SO_4. Triacylglycerols and their hydroperoxy, hydroxy, and epoxy compounds were detected in ultraviolet light after spraying with 2,7-dichlorofluorescein. Free core aldehydes showed a strong purple color with a Schiff base reagent (27). In the same system, the DNPH derivatives of core aldehydes were seen as yellow bands.

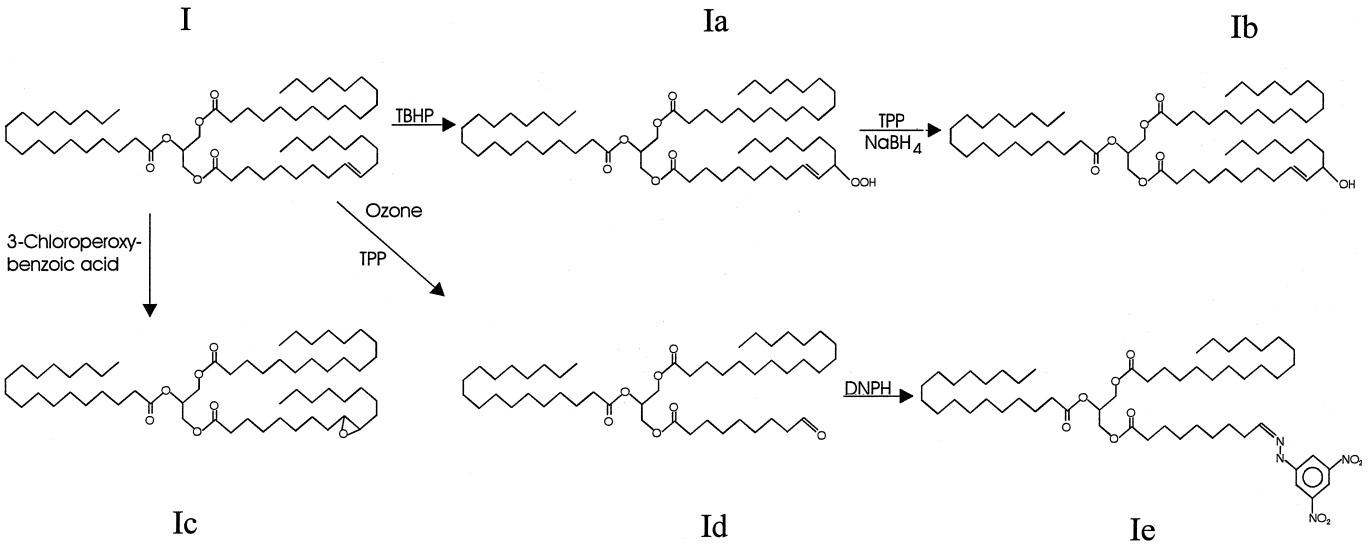
HPLC and LC/ES/MS. Standard oxotriacylglycerols and normal triacylglycerols were resolved by reverse-phase HPLC on a Supelcosil LC-18 column (250 mm × 4.6 mm i.d.; Supelco, Inc., Mississauga, Ontario, Canada) using a linear gradient of 20–80% 2-propanol in methanol (0.85 mL/min) in 30 min (13,17). The instrument was a Hewlett-Packard (Palo Alto, CA) Model 1050 liquid chromatograph, coupled to a Varex ELSD II light-scattering detector (Varex Co., Rockville, MD) using nitrogen as nebulization gas and evaporation temperature of 85°C. The identities of the oxotriacylglycerols were confirmed by LC/MS using a Hewlett-Packard Model 1090 liquid chromatograph interfaced with a nebulizer-assisted ES ionization source connected to a Hewlett-Packard Model 5989A quadrupole mass spectrometer (13,17). The ionization (capillary exit) voltage of this instrument was set at 100 V but could be increased to 300 V, to obtain fragment ions from any clearly resolved components (pseudo MS/MS). The HPLC conditions were the same as just described except that, for ionization, ammonia/isopropanol (1%) was added postcolumn at a flow rate of 0.15 mL/min. The unoxidized and oxidized triacylglycerols were identified as $[M + NH_4]^+$ or $[M + Na]^+$ in positive ion mode, whereas the DNPH derivatives of triacylglycerol core aldehydes were detected as $[M - H]^-$ ions in negative ion mode. Mass spectra were acquired in the 300–1300 mass range over the entire elution profile. The triacylglycerol samples were dissolved in isopropanol (mg/mL) by heating for 2–3 min at 80°C prior to injection. Addition of chloroform to assist dissolution of triacylglycerols was avoided as it caused distortion of peak shape and variation in retention times.

RESULTS AND DISCUSSION

Preparation of reference compounds. The general scheme of preparation of reference compounds is illustrated in Scheme 1 using 1,2-distearoyl-3-oleoyl-*sn*-glycerol as an example. Compounds I to Ie are identified as shown in Table 1. Triacylglycerol (I) was oxidized to a hydroperoxide (Ia) using TBHP. The triacylglycerol hydroperoxide (Ia) was reduced to the hydroxy triacylglycerol (Ib) using TPP. Triacylglycerol (I) was converted into the triacylglycerol core aldehyde (Id) by reaction with ozone followed by reduction of the ozonide intermediate with TPP. The core aldehyde (Id) was converted into the triacylglycerol dinitrophenyl hydrazone (Ic) by reaction with DNPH. The triacylglycerol epoxide (Ic) was prepared by treating triacylglycerol (I) with 3-chloroperoxybenzoic acid. Separate structures are not shown for positional and geometric isomers of the derivatives.

Triacylglycerols containing oleic acid in both primary and secondary positions yielded regioisomers, which could be resolved under appropriate chromatographic conditions. Chromatography also allowed the resolution of the *syn* and *anti* isomers of the DNPH derivatives (see below).

Ozonization has been used for the quantitative preparation of lipid ester core aldehydes (8,17,20). In the present experiments the oleoyl, linoleoyl, and linolenoyl triacylglycerols gave essentially pure 9-oxononanoate esters, which were resolved from the parent triacylglycerols and their ozonides by normal-phase TLC. Upon LC/ES/MS, the free aldehydes showed 32 mass units higher mass than anticipated in both sodiated and ammoniated forms. The increase by 32 mu was attributed to formation of hemiacetal from free aldehyde and methanol, which apparently was formed postcolumn after introduction of ammonia. Substitution of acetonitrile for methanol prevented the formation of the higher mass ions, but aldehydes eluted as broad bands instead of the sharp peaks seen in the isopropanol/methanol system. The mass spectra of the DNPH derivatives of the core aldehydes showed a minor peak with the same mass eluting after the monoaldehyde peak. This



SCHEME 1

peak was attributed to the separation of the *syn* and *anti* isomers. As a result, a total of four isomers of the DNPH derivatives was obtained from a mixture of triacylglycerols containing aldehyde functions in primary and secondary positions of glycerol. Table 2 gives the R_f values of the various oxotriacylglycerols and their derivatization products on normal-phase TLC. The preparation of the triacylglycerol core aldehydes by ozonization and TPP reduction has been discussed recently (17).

Cumene and TBHP have been widely used for the preparation of lipid ester hydroperoxides (28). In the present study, TBHP was added to reference triacylglycerols of known structure to produce the hydroperoxides of oleoyl and linoleoyl triacylglycerols as the main products according to the predictions of Porter *et al.* (29). The 1,3- and 1,2-distearoyl-*sn*-glycerol oleates were more resistant to hydroperoxidation than the corresponding linoleates or the 1,2-dipalmitoyl-*sn*-glycerol linoleate. Some 25–60% of intact monoenes remained after 30–31 h of peroxidation of the oleates compared to 5–30% of intact dienes after only 20–45 min of oxidation of the linoleates. The exact ratio of products to starting materials depended on the ratio of the starting material to the oxidant. In addition to hydroperoxides and original triacylglycerols, the peroxidation mixture also contained other reaction products, which were eluted from the reverse-phase HPLC column between the peaks of the parent triacylglycerols and the hydroperoxides. However, hydroperoxides and residual triacylglycerols were clearly resolved from these compounds. Alternately, photosensitized oxidation (23) provided a fast method to produce sufficient amounts of mono- and dihydroperoxides of 1,2-dilinoleoyl-3-stearoyl. Figure 1 shows the LC/ES/MS profile of a photooxidation mixture

TABLE 2
Average R_f Values of TAG and Oxotriacylglycerols as Obtained on Silica Gel Using a Neutral Lipid Solvent System[a]

Species	R_f value
TAG	0.66 ± 0.04
Monoepoxy	0.48 ± 0.04
Monohydroperoxy	0.46 ± 0.04
Monoaldehyde	0.37 ± 0.04
Monoaldehyde DNPH	0.36 ± 0.04
Monohydroxy	0.36 ± 0.04
Dihydroperoxy	0.34 ± 0.04
Diepoxy[b]	0.34 ± 0.04
Diepoxy[c]	0.29 ± 0.04
Dihydroxy	0.24 ± 0.04
Dialdehyde-DNPH	0.19 ± 0.04
Dialdehyde	0.13 ± 0.04

[b,c]Epoxy groups located on different fatty acids and on the same fatty acid, respectively. For abbreviation see Table 1.

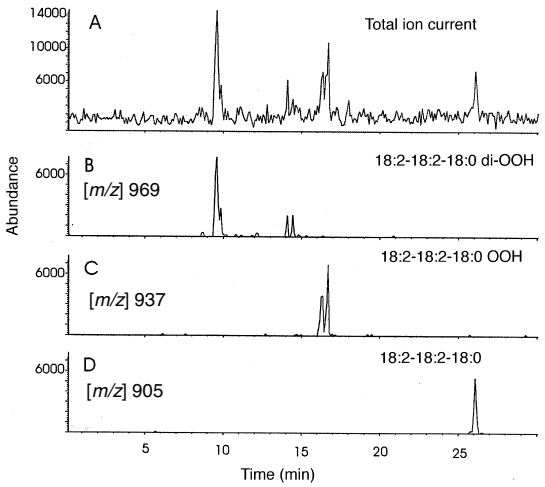

FIG. 1. Total ion chromatogram of the high molecular weight products from photosensitized oxidation of 1,2-dilinoleoyl-3-stearoyl-*sn*-glycerol as obtained by reverse-phase liquid chromatography/electrospray/mass spectroscopy (LC/ES/MS). Regioisomers of hydroperoxides are partly resolved as discussed in text. Mass values shown are for the sodium adducts $[M + Na]^+$ detected in the positive ion mode. Reverse-phase high-performance liquid chromatography (HPLC) column and instrumentation are described in the Materials and Methods section. Solvent gradient: 20–80% 2-propanol in methanol (0.85 mL/min) over 30 min.

with total ion plot. In this study, *cis, trans* or *trans,trans* linoleic 9- or 13-hydroperoxides were not resolved but yielded only one peak for oxidized 1,2-dipalmitoyl-*sn*-glycerol linoleate. Neff *et al*. (23) were able to separate and identify eight different regioisomers of monohydroperoxides in autoxidized trilinoleoylglycerol using analytical normal-phase HPLC. They showed also that bis- and trishydroperoxides were formed from further oxidized monohydroperoxides. Our system corresponds to prepative reverse-phase HPLC used by Neff *et al*. (23) for separation of mono-, bis-, and trishydroperoxides from unoxidized trilinoleoyl glycerol. However, regioisomers of monohydroperoxides were partly resolved, which can been seen in Figure 1. A single-ion plot of the monohydroperoxide of 1,2-dilinoleoyl-3-stearoyl (*m/z* 937) shows a double peak which is due to the *sn*-position of a hydroperoxy group in a glycerol molecule. We also oxidized individually regioisomers of 1,3-distearoyl-2-oleoyl and 1,2-distearoyl-3-oleoyl-*sn*-glycerols. Their hydroperoxy derivatives were first analyzed separately and then together, showing that regioisomers of hydroperoxides were partly resolved by LC/MS and HPLC with a light-scattering detector. The triacylglycerols with the hydroperoxy function in the *sn*-2-position were eluted ahead of their regioisomers, as well as ahead of the corresponding core aldehyde derivatives already discussed. Positional isomers of hydroperoxy triacylglycerols have been previously identified in autoxidized trilinolenoylglycerol preparations and in synthetic triacylglycerols containing linoleate (12,13) and linolenate (12).

The reduction of the mono- and dihydroperoxy triacylglycerols with sodium borohydride or with TPP yielded the corresponding hydroxides as single products, as indicated by reverse-phase LC/ES/MS and cochromatography with potential by-products. Their regioisomers were also partly separated as their hydroperoxy compounds. Monohydroperoxides showed approximately 3–5 times and dihydroperoxides about 10–20 times higher relative response as the $[M + NH_4]$ ions compared to the $[M + 1]^+$ ions of the corresponding unsaturated triacylglycerols on LC/ES/MS using neutral lipid solvents. The hydroperoxides also showed higher response than the corresponding parent compounds on reverse-phase HPLC with a light-scattering detector.

Epoxy triacylglycerol derivatives were prepared by a new method of epoxidation, which has been reported to yield quantitative transformation (26). The epoxidation of the unsaturated triacylglycerols yielded both mono- and diepoxides as the reaction products. The compounds were resolved from the parent triacylglycerols and the hydroperoxy and hydroxy derivatives by normal-phase TLC or reverse-phase HPLC. Regioisomers of monoepoxides were not separated by reverse-phase HPLC, although a slight difference was obtained in elution factor as they were estimated separately with a series of saturated triacylglycerols. However, triacylglycerols with two epoxy groups located in one linoleate eluted later than two epoxy groups located on two oleates in reverse-phase HPLC.

Determination of HPLC retention times. The relative retention times of the oxotriacylglycerols were determined by reverse-phase HPLC under optimal conditions of separation using a light-scattering detector, which gave nearly comparable intensities for equal masses of the solutes. The triacylglycerols of known structure were oxidized separately to give unambiguous products. The retention times were obtained by injecting (individually or in small sets) the oxotriacylglycerols together with the homologous series of the saturated triacylglycerols. A linear gradient of isopropanol/methanol 20–80% was found to be a good mobile phase for the resolution of the native and modified triacylglycerols, including the core aldehydes and their DNPH derivatives. Under these conditions, coefficients of variance of retention time ($n = 6$) ranged from 0.17 (triheptadecanoylglycerol) to 0.35% (trioctanoylglycerol) during elution times ranging from 6.12 to 33.73 min. The other homologous triacylglycerols showed variance of retention time within these extremes. Figure 2 shows the elution profile obtained for the homologous saturated triacylglycerols coinjected with the free core aldehydes [1,2-distearoyl-2-(9-oxo)nonanoyl-*sn*-glycerol (A) and 1,2-distearoyl-3-(9-oxo)nonanoyl-*sn*-glycerol (B)] and their DNPH derivatives (C and D, respectively). There is a clear indication of the separation of the positional isomers, with the 2-isomer emerging ahead of the 1(3)-isomer. On reverse-phase HPLC, the dialdehyde-containing triacylglycerols were eluted earlier than the monoaldehyde derivatives, as already established for other positional isomers of acylglycerols (17). Likewise, the dihydroperoxy triacylglycerols were eluted earlier than the monohydroperoxy derivatives, and the dihydroxytriacylglycerols earlier than the monohydroxy derivatives, and the diepoxytriacylglycerols earlier than the monoepoxytriacylglycerols. The hydroperoxide group was observed to have only slightly more polar effect in reverse-phase HPLC. A part of the 1,2-distearoyl-3-linoleoyl-*sn*-glycerol hydroperoxide was reduced to the corresponding hydroxytriacylglycerol, and they were analyzed together. The hydroperoxides were eluted just ahead of the corresponding hydroxytriacylglycerols.

Estimation of elution factors. The incremental elution factors of the oxotriacylglycerols were obtained by plotting the retention times, recorded using a linear gradient of 20–80% isopropanol/methanol, against the theoretical carbon number (TCN). TCN (2) was obtained from the equivalent carbon number (ECN) by adding a correction factor (F_i):

$$\text{TCN} = \text{ECN} + \Sigma\,(F_i) \qquad [1]$$

The ECN (2) was obtained by subtracting two carbon numbers (CN) for each double bond (n) present in the triacylglycerol molecule:

$$\text{ECN} = \text{CN} - 2\,n \qquad [2]$$

The curve-fitting procedure was adopted from Myher *et al*. (6). Saturated fatty acids were assumed to have a correction factor value of 0. A polynominal equation of fifth to seventh order was used to fit the TCN values of unsaturated triacylglycerols and oxotriacylglycerols to the elution times of the saturated triacylglycerols. A comparison of the TCN values

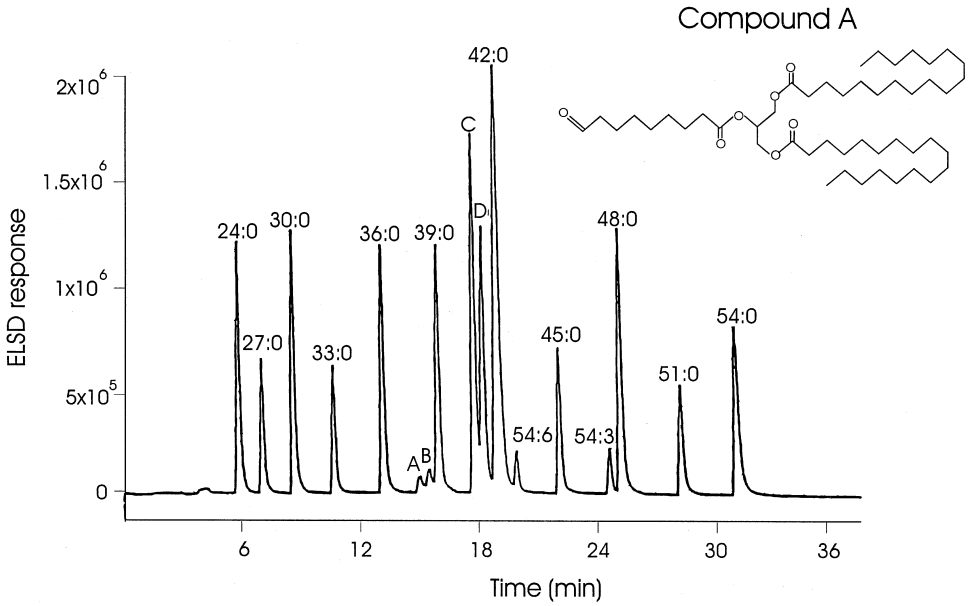

FIG. 2. Reverse-phase HPLC of homologous saturated triacylglycerols coinjected with the free core aldehydes and their 2,4-dinitrophenylhydrazine (DNPH) derivatives as detected by a light-scattering detector. Core aldehydes are identified as follows: A, 1,2-distearoyl-2-[9-oxo]nonanoyl-*sn*-glycerol; B, 1,2-distearoyl-3-[9-oxo]nonanoyl-*sn*-glycerol; C and D are DNPH derivatives of A and B, respectively. Triacylglycerol homologs are identified by their total acyl carbon:double-bond numbers. Abbreviation and reverse-phase HPLC conditions are given in Figure 1. ELSD, evaporative light-scattering detector.

calculated for the unsaturated and oxotriacylglycerols allowed one to estimate the effect of a double bond and a functional group upon the elution time. The calculated incremental elution factors are given in Table 3. As a result, a reference curve was obtained for the homologous series of saturated triacylglycerols and the oxotriacylglycerol standards vs. the retention time (Fig. 3). The various functional groups added to the triacylglycerol molecule, however, did not constitute totally independent contributions to the retention time, and therefore the calculated incremental elution factors differ slightly from the simple sums of the individual contributions. The functional groups apparently interacted with neighboring groups (30), and this interaction altered their polarity. Thus, for triacylglycerols containing two hydroperoxy groups, the elution factors showed a 7–9% reduction from the total sum of the elution factors estimated for monohydroperoxides, depending on the exact location of the substituents. Likewise, triacylglycerol dialdehydes yielded 9–16% lower elution factors than the sum of the individual elution factors of a monoaldehyde. That differences in elution factors were seen for 18:1*cis*9 and 20:1*cis*11 fatty acids was in agreement with earlier work (3,6). The elution factor observed for linoleic acid varied from 0.19 to 0.31, depending on the number of linoleic acids in a triacylglycerol molecule.

TABLE 3
Estimated Elution Factors for Functional Groups and Fatty Acids of Triacylglycerols

Fatty acid	One fatty acid	Two fatty acids[a]	Three fatty acids[a]
18:1	–0.51 ± 0.05	–0.74 ± 0.05	–0.55 ± 0.05
18:2	0.22 ± 0.05	0.38 ± 0.05	0.92 ± 0.05
18:3	0.77 ± 0.05	1.82 ± 0.05	
20:1	–0.64 ± 0.05		

Functional group	*sn*-1/3-position	*sn*-2 position	Two groups in *sn*-1/3- and *sn*-2-positions
–OOH (18:1)	–8.87 ± 0.1	–8.97 ± 0.1	–16.30 ± 0.1
–OOH (18:2)	–8.40 ± 0.1	–8.56 ± 0.1	–15.57 ± 0.1

–OH (18:2)	–8.17 ± 0.1	–8.36 ± 0.1	–14.42 ± 0.1
–epoxy (18:1)	–4.55 ± 0.1	–4.62 ± 0.1	–8.73 ± 0.1
–epoxy (18:2)			–7.20 ± 0.1
–CHO	–6.51 ± 0.1	–7.04 ± 0.1	–11.79 ± 0.1
–CHO DNPH	–3.66 ± 0.1	–4.11 ± 0.1	–6.44 ± 0.1

[a]Total effect of double bonds or functional groups.

When a functional group was attached to a double bond, the polarity of the molecule was amplified, decreasing the retention time and TCN of a triacylglycerol molecule in reverse-phase HPLC, resembling the effect of bromine addition to a fatty acid moiety (3). Hydroperoxy groups on an oleic acid residue enhanced the polarity (eluted earlier) of a triacylglycerol by 0.4 carbons more than a hydroperoxy group on a linoleic acid residue in a similar triacylglycerol molecule (Fig. 4). The retention times did not seem to be affected by the positional location of the functional group on the fatty acid moiety. A hydroxyl group reduced the retention time of a hydroxytriacylglycerol by 8.2–8.7 carbons in our reverse-phase system. In another solvent system (11), the reduction in retention time had been estimated to be six carbons. The relative retention time and therefore the incremental elution factor are clearly affected by the solvent system. The elution factor of an epoxy group was about 50% of hy-

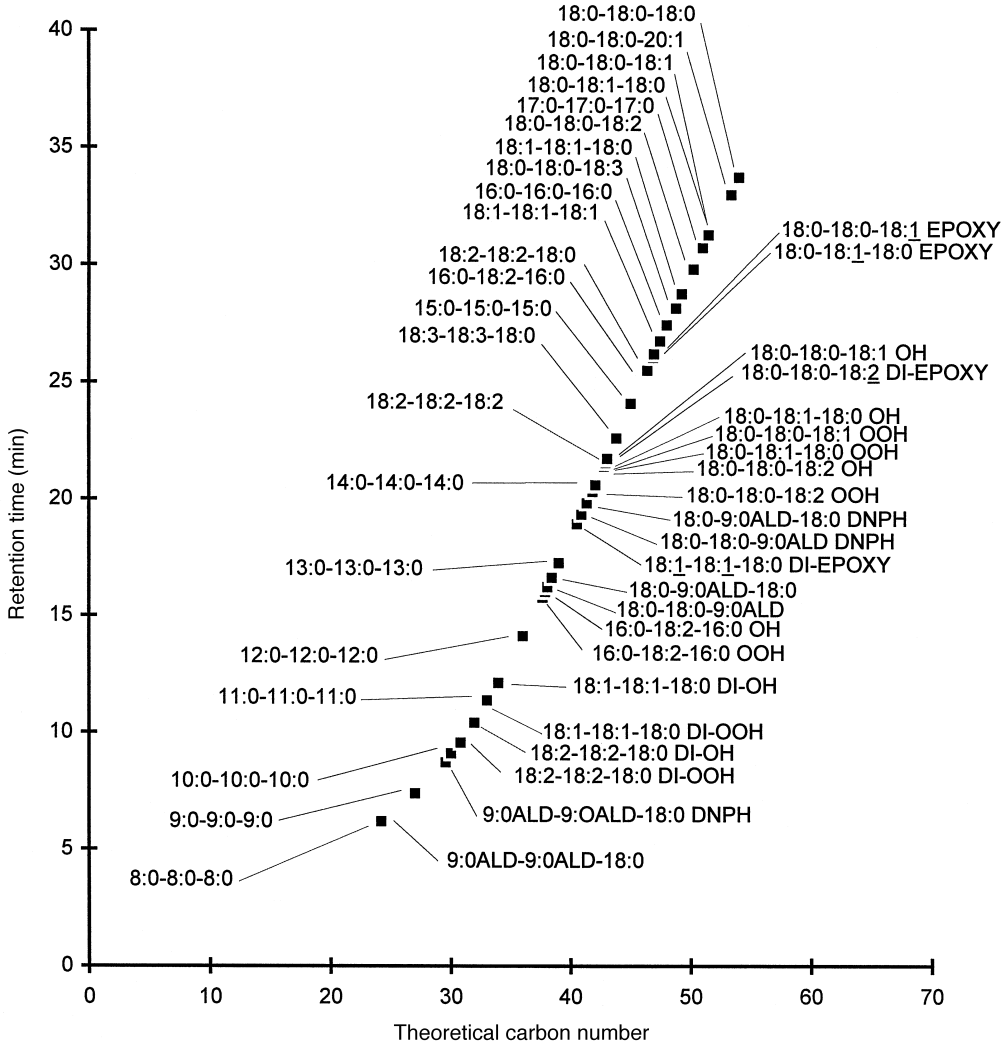

FIG. 3. A plot of theoretical carbon numbers (TCN) vs. retention times of reference compounds along with a series of saturated monoacid triacylglycerols. TCN and correction factors were calculated for oxotriacylglycerols and unsaturated triacylglycerols using saturated triacylglycerols as a reference curve. Unsaturated and oxotriacylglycerols were co-injected individually or in small sets with the series of the saturated triacylglycerols. Abbreviation: ald, aldehyde. For other abbreviation see Figure 2. Position of an epoxy group is marked as an underlined double bond.

droxyl group, which is in accordance with earlier results (31). The accuracy of the estimates of the incremental elution factors could be further improved by preparing reference standards containing two or more homologous or heterologous functional groups per triacylglycerol molecule. Nevertheless, the knowledge of even a limited set of elution factors allows the calculation of the relative retention times of unknowns with considerable accuracy, which helps to choose among likely structures represented by the same molecular weight during reverse-phase LC/ES/MS in oxidized vegetable oils as shown elsewhere (32).

ABSTRACT: Milk analysis is receiving increased attention. Milk contains conjugated octadecadienoic acids (18:2) purported to be anticarcinogenic, low levels of essential fatty acids, and *trans* fatty acids that increase when essential fatty acids are increased in dairy rations. Milk and rumen fatty acid methyl esters (FAME) were prepared using several acid- (HCl, BF_3, acetyl chloride, H_2SO_4) or base-catalysts ($NaOCH_3$, tetramethylguanidine, diazomethane), or combinations thereof. All acid-catalyzed procedures resulted in decreased *cis/trans* (Δ9*c*,11*t*-18:2) and increased *trans/trans* (Δ9*t*,11*t*-18:2) conjugated dienes and the production of allylic methoxy artifacts. The methoxy artifacts were identified by gas–liquid chromatography (GLC)-mass spectroscopy. The base-catalyzed procedures gave no isomerization of conjugated dienes and no methoxy artifacts, but they did not transesterify *N*-acyl lipids such as sphingomyelin, and $NaOCH_3$ did not methylate free fatty acids. In addition, reaction with tetramethylguanidine coextracted material with hexane that interfered with the determination of the short-chain FAME by GLC. Acid-catalyzed methylation resulted in the loss of about 12% total conjugated dienes, 42% recovery of the Δ9*c*,11*t*-18:2 isomer, a fourfold increase in Δ9*t*,11*t*-18:2, and the formation of methoxy artifacts, compared with the base-catalyzed reactions. Total milk FAME showed significant infrared (IR) absorption due to conjugated dienes at 985 and 948 cm^{-1}. The IR determination of total *trans* content of milk FAME was not fully satisfactory because the 966 cm^{-1} *trans* band overlapped with the conjugated diene bands. IR accuracy was limited by the fact that the absorptivity of methyl elaidate, used as calibration standard, was different from those of the other minor *trans* fatty acids (e.g., dienes) found in milk. In addition, acid-catalyzed reactions produced interfering material that absorbed extensively in the *trans* IR region. No single method or combination of methods could adequately prepare FAME from all lipid classes in milk or rumen lipids, and not affect the conjugated dienes. The best compromise for milk fatty acids was obtained with $NaOCH_3$ followed by HCl or BF_3, or diazomethane followed by $NaOCH_3$, being aware that sphingomyelins are ignored. For rumen samples, the best method was diazomethane followed by $NaOCH_3$.

Lipids 32, 1219–1228 (1997).

Interest in milk fatty acid composition was renewed because of ongoing studies to increase the essential fatty acid content (1,2), to determine accurately the *trans* content (3–8), and lately, to quantitate the conjugated octadecadienes (9–15) which have been associated with inhibition of carcinogenesis and tumorigenesis (16–18). Milk and rumen fatty acid compositions are complex (1,19–21). Not only is there a large range in chain length from C_4 to C_{26}, including branch-chain fatty acids, but milk also contains many positional and geometric isomers of mono-, di-, and tri-unsaturated fatty acids, and many of these fatty acids are present in very low concentrations. In 1991, Jensen *et al.* (19) estimated 400 fatty acids to be present in bovine milk.

No single method is presently able to resolve all 400 fatty acids. The availability of long polar capillary columns (50 to 100 m) for gas–liquid chromatography (GLC) has improved the resolution of many positional and geometric fatty acid isomers (3–8,10–12,15,22). Prior separations with argentation chromatography still show several regions with overlapping peaks particularly in the mono- and diunsaturated fatty acid region (3–8,22–25). The development of a routine method for the analysis of total milk and rumen fatty acids, without extensive secondary fractionations, would be desirable.

Difficulty may occur in quantitatively preparing esters from such a great variety of fatty acids and lipid classes that are present in milk and rumen lipids. Sodium methoxide ($NaOCH_3$)-catalyzed methylations have been used (3,9), but free fatty acids and *N*-acyl lipids (i.e., sphingolipids and glycosphingolipids) are not methylated under these conditions (26). Acid-catalyzed methylations convert all known lipid classes; however, reports have indicated that the conjugated dienes are isomerized (12,27–29). The very short-chain fatty acid methyl esters (FAME) are difficult to quantitate because the methyl esters are volatile, water-soluble, and require correction factors (30,31). Some of the difficulties with the very

short-chain fatty acids were avoided by preparing H_2SO_4-catalyzed isopropyl esters for milk analyses (4,6,8,24,32).

In the present study, several acid- and base-catalyzed methylation methods were evaluated for the analyses of milk and rumen lipids, including a combination of methods. The methods included the following catalysts in anhydrous condition: HCl/methanol (33), BF_3/methanol (34), acetyl chloride/methanol (35), $NaOCH_3$/methanol (36), tetramethylguanidine/methanol (13,27,37), H_2SO_4/isopropanol (4,6,24,32), and diazomethane in diethyl ether/methanol (26). Several criteria were considered in evaluating methods for the analysis of milk and rumen lipids: (i) completion of methylation of free fatty acids and *O*- and *N*-esters as judged by thin-layer chromatography (TLC); (ii) coextraction of artifacts with hexane that may interfere with the direct analysis of the hexane extract by GLC; (iii) extent of isomerization of conjugated dienes and methoxy artifact formation as judged by GLC; and (iv) comparison of total *trans* content determined by GLC and infrared (IR) spectroscopy. A chromatographic separation is presented using a 100-m capillary column that resulted in the separation of about 180 peaks from milk lipids.

MATERIALS AND METHODS

Materials. Milk and rumen samples were obtained from cows used in two separate experiments to test the effect of ionophores on milk and rumen fatty acid composition. Other reports have detailed the effect of ionophores on rumen and milk lipids (38–40). Methyl ester (Nu-Chek-Prep, Inc., Elysian, MN) and phospholipid (Matreya Inc., Pleasant Gap, PA) standards were obtained commercially.

Extraction of lipids. Total rumen lipids were extracted with chloroform/methanol (2:1, vol/vol) as described previously (38). Total milk lipids were extracted with a modified Folch procedure described by Jensen (41). The total lipids were taken up in 10 mL of chloroform and stored at −70°C until analyzed.

Preparation of fatty acid esters. The total rumen and milk lipids were methylated in 15-mL culture tubes equipped with Teflon-lined screw caps, under N_2, and in anhydrous conditions. HCl/methanol (33), acetyl chloride/methanol (35), and H_2SO_4/isopropanol (6,32) were heated for 1 h at 80°C. $NaOCH_3$/methanol (36) and 14% BF_3/methanol (34) were heated for 10 min at 50°C. Tetramethylguanidine/methanol was heated for 2 min at 100°C (27,37). Diazomethane in diethyl ether/methanol was left for 10 min at room temperature (26). The excess diazomethane and solvents were then removed by a stream of nitrogen and the residue dissolved in 2 mL hexane and analyzed directly by GLC. To all other reactions, 5% water was added to the alcohol solution, and the esters were extracted with 2 mL of hexane and analyzed directly by GLC. To avoid any loss of short-chain esters, the hexane layer was not reduced in volume. Base-catalyzed reactions were neutralized with aqueous HCl prior to hexane extraction. To ensure completion of reaction, the total lipids were extracted using the Bligh and Dyer mixture (42). The extent of neutral lipid esterification was checked by TLC using the developing solvent hexane/diethyl ether/acetic acid (85:15:1, by vol). The polar lipids were checked by TLC using the developing solvent chloroform/methanol/water (65:25:4, by vol). The FAME were extracted with hexane and analyzed directly by GLC to determine the extent of isomerization of conjugated dienes.

Several combinations of methylations were also tested with standard neutral- and phospholipids mixtures: $NaOCH_3$/methanol for 10 min at 50°C followed by an excess of HCl/methanol for 10 min at 80°C; $NaOCH_3$/methanol for 10 min at 50°C followed by an excess of BF_3/methanol (43) for 10 min at 50°C; and diazomethane for 10 min at room temperature followed by evaporation to dryness in a stream of N_2, and reaction with $NaOCH_3$/methanol for 10 min at 50°C. The extent of methylation of the total lipid extract was checked by TLC, while the extent of isomerization of the conjugated dienes was checked by GLC.

Analyses of esters by GLC. FAME were analyzed by GLC (model 5890; Hewlett-Packard, Palo Alto, CA) using a SP-2560 fused silica capillary column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Supelco Inc., Bellefonte, PA), H_2 as the carrier gas, a 1:15 split mode, and a flame-ionization detector. For comparison, FAME were also analyzed using a CP-Sil 88 WCOT fused silica column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Chrompack, Middleburg, The Netherlands). Both columns were operated at 70°C for 4 min, then temperature-programmed at 13°C/min to 175°C, held there for 27 min, programmed at 4°C/min to 215°C, and finally held there for 31 min; total run was 80 min. Starting at 70°C permitted the resolution of the short-chain FAME. Maintaining the temperature at 215°C for a longer period of time allowed the emergence of the very long-chain FAME. The temperature program for the isopropyl esters was similar to FAME except that it was started at 90°C, taken to 195°C, and held at 215°C for 36 min.

Fractionation of FAME by high-performance liquid chromatography (HPLC). Total milk and rumen FAME were separated on a reverse-phase Supelcosil™ LC-8DB column (25 cm × 4.6 mm i.d.; 5-μm particle size; Supelco Inc.) using an HPLC (model 1090; Hewlett-Packard) equipped with an autosampler. The system was operated at room temperature with a flow rate of 1.5 mL/min. A portion of the eluate was diverted (three-way valve #02-0124; Alltech Associates Inc., Deerfield, IL) to an evaporative light-scattering detector (model MKIII; Varex Alltech Associates Inc.) operated at 75°C and 2.5 L/min of N_2, and the remainder was collected using a fraction collector (Gilson model 203; Mandel Scientific Co. Ltd., Guelph, Ontario, Canada). Approximately 1 mg of total lipids in 25 μL hexane was applied onto the column. Fractions were eluted isocratically with 87.5% methanol and 12.5% water and collected at 1-min intervals from 3 to 35 min. After each run, the column was regenerated with dichloroethane.

Analyses of FAME by GLC–FTIR (Fourier transform infrared) spectroscopy and GLC–MS (mass spectrometry). The same GLC conditions as described above were used to ana-

lyze the FAME by GLC–FTIR using a Hewlett-Packard system (models 5890 and 5965B) as described previously (38). In addition, the FAME were analyzed by a GLC–MS system (model 4500; Finnigan, San Jose, CA) using the same GLC conditions. Mass spectra were acquired in 1-s increments ranging in mass from 30 to 500.

Measurement of trans *absorption of FAME by attenuated total reflection (ATR)–FTIR spectroscopy.* An FTIR spectrometer (model FTS-60A; Bio-Rad, Digilab Division, Cambridge, MA) was used equipped with a Graseby Specac (Fairfield, CT) Golden Gate Single Reflection Diamond ATR cell that required about 1 µL test sample. This accessory contained a 2×2 mm diamond with an active sampling area of 0.6 mm in diameter. It was prealigned in the factory, and preattached to its baseplate that attached to the floor of the FTIR spectrometer sample compartment. Mounting holes and pegs in the baseplate ensured its proper positioning and alignment.

Neat (without solvent) FAME test aliquots (1 µL) were placed without weighing on the horizontal (face-up) diamond sampling surface of the cell. For quantitative work, the test aliquots had to cover all of the horizontal surface of the diamond. Two hundred and sixty-four scans were collected at 4 cm^{-1} resolution. After a measurement was made, the surface of the diamond was cleaned by wiping it with low-lint paper.

ATR quantitation was based on the measurement of the integrated area between the limits of 990 and 945 cm^{-1}, which included all C-H out-of-plane deformation absorptions of isolated *trans* double bonds, and *trans* contained in methylene and nonmethylene-interrupted 18:2 isomers at 966 cm^{-1}. The contribution of overlapping conjugated *cis,trans* and *trans,trans* diene bands at 985 and 948 cm^{-1} (44) was subtracted digitally. A calibration plot of "area" vs. "percentage" *trans* FAME was generated for reference mixtures in the range of 0.81–14.4% methyl elaidate in methyl oleate which was used as the infrared (IR) reference material. The regression line parameters for the *trans* standards were 0.001194 (intercept) and 0.01777 (slope), with a correlation coefficient of 0.9996. A commercial FAME reference mixture was used which consisted of 16:0 (6%), 18:0 (3%), 18:1n-9 (35%), 18:2n-6 (50%), 18:3n-3 (3%), and 20:4n-6 (3%) (#RM-1; Matreya Inc., Pleasant Gap, PA); all double bonds were *cis.* Absorption spectra were obtained by "ratioing" the test sample single-beam spectra against that of the reference mixture. For test samples, the percentage of total *trans* was calculated from the absorption area between the limits of 990 and 945 cm^{-1}, and the linear regression equation that described the calibration plot. The lower limit of quantitation was about 1%. Using cells with 1.5 mL and 50 µL capacity, the ATR method was successfully used to determine the *trans* levels in hydrogenated oils and commercial food products (45,46), and this method was recently adopted as Recommended Practice (47).

Statistics. Milk and rumen FAME were analyzed by the analysis of variance.

RESULTS AND DISCUSSION

Analysis of milk FAME by GLC. A typical GLC chromatogram of total milk FAME using a 100-m polar fused silica capillary column (SP-2560; Supelco Inc.) is shown in Fig-

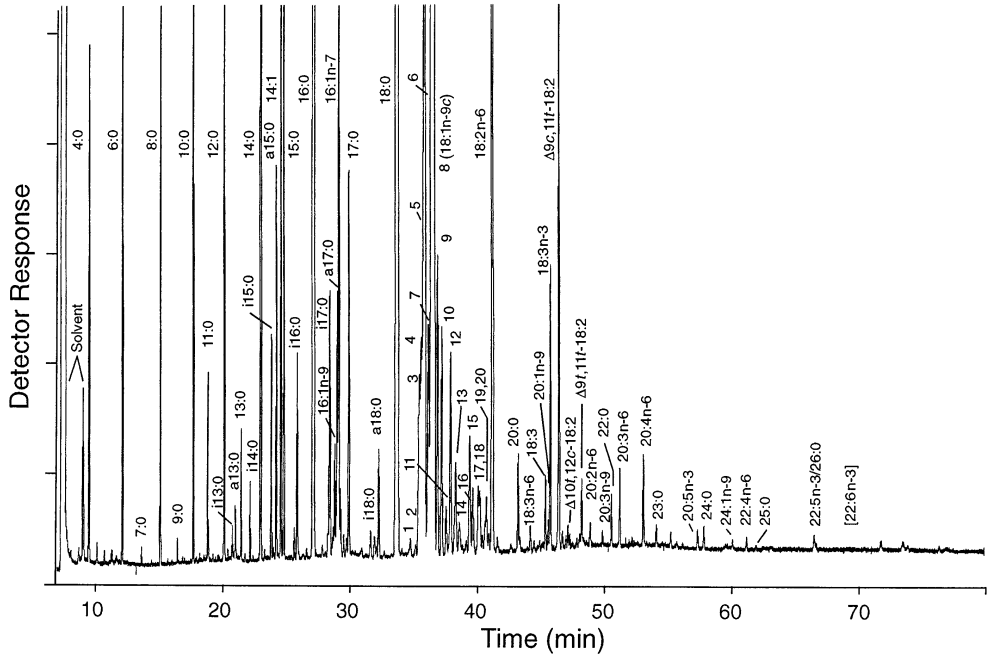

FIG. 1. A typical gas–liquid chromatogram of total bovine milk fatty acid methyl ester prepared by $NaOCH_3$/methanol (10 min at 50°C) followed by HCl/methanol (10 min at 80°C), and separated on a 100-m fused silica capillary column (SP-2560; Supelco Inc., Bellefonte, PA). i, iso; a, anteiso; numbers 1–20 are an arbitrary consecutive numbering of all the peaks in the region between 18:0 and 18:2n-6 using this column. [22:6n-3] is not present in these milk samples but the position at which it should emerge in the chromatogram is indicated.

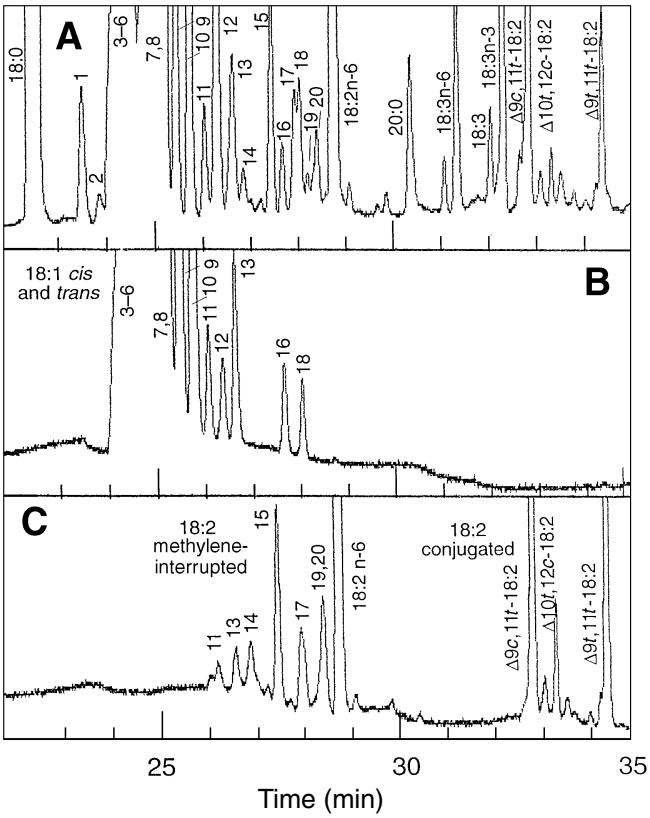

FIG. 2. The methyl stearate (18:0) to conjugated octadecadiene region of the gas–liquid chromatogram of total bovine milk fatty acid methyl esters (A), and methyl octadecenoates [B; emerged at 8 min from high-performance liquid chromatography (HPLC) column] and methyl octadecadienoates (C; emerged at 11 min from HPLC column) isolated from total milk fatty acid methyl esters by HPLC. Gas–liquid chromatography (GLC) analysis was on the same type of column as Figure 1. Numbers 1–20 refer to the same numbers as in Figure 1 between 18:0 and 18:2n-6.

ure 1. Using a temperature program from 70 to 215°C permitted a separation from the short-chain (4:0) to the very long-chain saturated (26:0) and polyunsaturated (20:2n-6, 20:3n-6, 20:4n-6, 20:5n-3, 22:4n-6, 22:5n-3) FAME found in milk. A total of about 180 peaks were observed. Many of the peaks were identified by comparison to known FAME standards and confirmed by GLC–MS and GLC–FTIR. The 100-m CP-Sil 88 WCOT fused silica column gave similar results to the SP-2560 column with a few minor exceptions. There appeared to be a better resolution of *trans*-16:1 and iso-17:0, anteiso-17:0 and 16:1n-7, and 20:1n-9 and 18:3n-3 with the CP-Sil 88 column, while the resolution of 22:1n-9 and 20:3n-3, and 20:5n-3 and 24:0 was better with the SP-2560 column. Resolution of critical pairs was sometimes improved by changing the column temperature, as shown previously (48). However, that process was limited, because a compromise was needed to deal with the wide range of fatty acids present in milk and rumen lipids.

The major unresolved peaks with either column occurred between 18:0 and 18:2n-6 and included several positional isomers of *cis*- and *trans*-18:1, and the methylene-interrupted and noninterrupted 18:2 isomers, many of them overlapping. The 18:1–18:2 region was resolved by HPLC into mono- and diunsaturated FAME (Fig. 2). With the use of GLC–FTIR, the identity of the major *cis* and *trans* absorption peaks was determined, but not the minor peaks (i.e., peaks 1,2,11,13–20). Based on the HPLC separation and GLC–FTIR results, the peaks in 18:1–18:2 region were identified as *trans*-18:1 (peaks 3–7, and part of peak 10), *cis*-18:1 (peaks 8–13,16,18), and 18:2-isomers (peaks 11,13–15,17,19,20). No attempt was made to further separate *cis*- and *trans*-18:1 or identify each of the isomers, since this was adequately described by others in recent publications on milk and milk fat lipids (4–8,22–25).

Analysis of conjugated dienes using either base- or acid-catalyzed methylations. The composition of the conjugated dienes was greatly affected by the catalyst used in the methylation procedure. Base-catalyzed methylation of milk using $NaOCH_3$ showed Δ9*c*,11*t*-18:2 as the major conjugated diene, with smaller amounts of eight other isomers including Δ9*t*,11*c*-18:2, Δ10*t*,12*c*-18:2, Δ9*c*,11*c*-18:2, and Δ9*t*,11*t*-18:2 (Fig. 3). On the other hand, all acid-catalyzed methylation procedures resulted in decreased Δ9*c*,11*t*-18:2 and increased Δ9*t*,11*t*-18:2, and the formation of additional peaks between 20:2n-6 and 20:3n-9 (Fig. 3). The peaks formed during acid-catalyzed methylation were identified as positional allylic methoxy isomers of 18:1 by GLC–MS. All the methoxy artifacts had molecular ion at *m/z* 326. These allylic methoxy compounds could have been formed from hydroxy 18:1 present in milk (19). We also confirmed that these allylic methoxy derivatives were formed from the conjugated dienes by heating the standard methyl esters of Δ9*c*,11*t*-18:2 and Δ9t,11t-18:2 with HCl/methanol for 1 h at 80°C. The GLC and GLC–MS of the resultant FAME showed the formation of the corresponding methoxy derivatives as major product (data not shown). The formation of methoxy artifacts during acid-catalyzed methylations of conjugated dienes was first pointed out in a letter to the editor of *Lipids* as early as 1972 (29), but there was no follow-up manuscript, and its findings appeared to be largely ignored by many investigators. Similar allylic methoxy derivatives were reported recently following acid-catalyzed methylation of allylic hydroxy oleates (49). The GLC–MS results, isomer identification, and possible mechanism of formation of these allylic methoxy derivatives formed during acid-catalyzed methylation of milk lipids will be presented in a separate publication.

Acid-catalyzed methylation has been used extensively for the analysis of conjugated dienes in milk and dairy products. The catalysts used by several groups included HCl (16,17,28), acetyl chloride (20,27,35,50), BF_3 (5,10–12,15,20,22,23,27, 32,43,48,50), and H_2SO_4 (4,6,8,24,32). Some authors recognized the isomerization of the conjugated dienes during acid-catalyzed methanolysis and recommended that the reaction of BF_3/methanol (12,15) or HCl/methanol (28) be carried out at room temperature to reduce this isomerization. Our TLC results showed that methylation was not complete with either BF_3 or HCl as a catalyst under these mild conditions (data not shown). GLC analyses showed evidence of isomerization and artifact (methoxy) for-

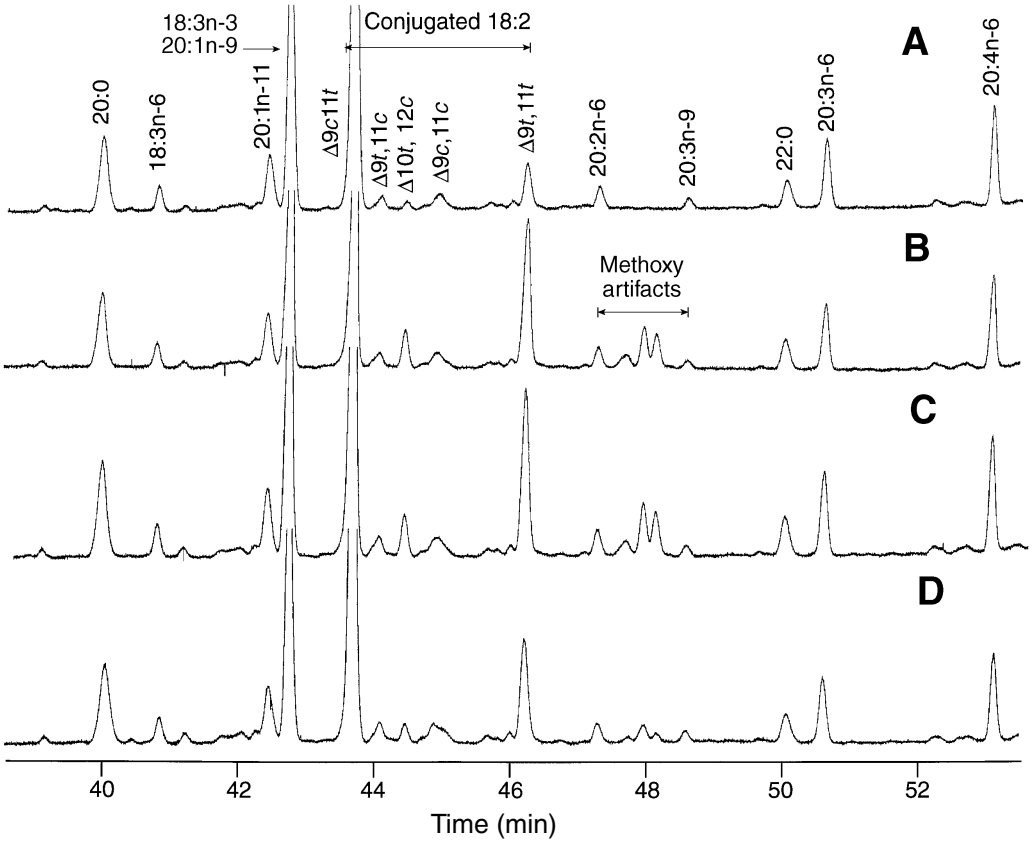

FIG. 3. The methyl eicosanoate (20:0) to methyl arachidonate (20:4n-6) region of the GLC of total bovine fatty acid methyl esters prepared by using the following catalysts in anhydrous methanol: (A) $NaOCH_3$, (B) HCl, (C) acetyl chloride, or (D) BF_3. Analysis was on the same type of GLC column as Figure 1. See Figure 2 for abbreviation.

mation. In one of the milk samples, the ratio of Δ9*c*,11*t*-18:2 to Δ9*t*,11*t*-18:2 was 3.6 with $NaOCH_3$ and 2.7 with either HCl or BF_3 at room temperature. Therefore, not even mild acid-catalyzed methylation at room temperature is appropriate for the analysis of conjugated dienes. Furthermore, it should be pointed out that in two publications additional peaks were observed in the GLC chromatogram of conjugated dienes after acid-catalyzed methylation (12,27), but the peaks were not identified.

In several recent publications, Wolff's group recommended the preparation of isopropyl esters using H_2SO_4 as catalyst (4,6,8,24,32). This method was proposed to overcome the need for the use of correction factors for the short-chain FAME (24,30,32) and to improve the resolution of 4:0 from the solvent front (4). However, this method did not address the issue of isomerization of conjugated dienes. Reevaluation of H_2SO_4-isopropanol methylation reaction showed extensive isomerization of conjugated dienes and artifact formation, just as for HCl/methanol. In one publication (32) isopropyl esters were prepared by acid (H_2SO_4) and base (Na) catalysts, but no comparison was made of the distribution of 18:2 *cis,trans* conjugated dienes. However, their results showed a higher content of total conjugated dienes (18:2 *c,t*) with base- than with acid-catalyzed methylation (Table V, Ref. 32), which was similar to our finding (Table 1).

Recently, Shantha *et al.* (27) proposed the use of tetramethylguanidine, a base-catalyzed reagent developed by Schuchardt and Lopes (37), for the analysis of conjugated dienes. It was reported that tetramethylguanidine caused little isomerization of the *cis/trans* to the *trans/trans* conjugated dienes (27) and that free fatty acids were methylated (27,37). At first glance, this method appeared to be an ideal methylation reagent for total milk lipids. However, we found that tetramethylguanidine gave incomplete methylation of phosphatidylcholine, and did not methylate sphingomyelin as judged by TLC. Furthermore, hexane coextracted unknown material after the reaction which interfered with the determination of 4:0, and 8:0 to 10:0, present in milk. Introducing a water wash was unsuccessful in removing the interfering broad peaks, but a significant reduction was observed in the content of 4:0 and 6:0 FAME after the extra wash. For these reasons, tetramethylguanidine alone was not considered suitable for the methylation of total milk lipids.

Evaluating a combination of catalysts for the methylation of total milk lipids. Total milk lipids contain about 98% triacylglycerols, 1% phospholipids (phosphatidylcholine, phosphatidylethanolamine and sphingomyelin in about equal proportions), 0.3% cholesterol, 0.3% diacylglycerols, and trace amounts of cholesteryl esters and free fatty acids (20). Methylation using only $NaOCH_3$/methanol gave no isomerization of conjugated dienes and artifact formation, but did not methylate free fatty acids and sphingomyelin. The AOCS

[a]As measured by gas–liquid chromatography (GLC) and attenuated total reflection infrared (IR) spectroscopy. The experimental conditions of these studies are published elsewhere (Ref. 40).
[b]The total fat extract of each milk sample was analyzed by both methods.
[c]The GLC method involved summing all *trans* monounsaturates (peaks 3–7, half of 10; Fig. 1), *cis/trans* 18:2 (peaks 14,15,17,19,20; Fig.1) and total conjugated dienes.
[d]Each GLC value represented the mean of the milk from 10 cows.
[e]Total *trans* determined by GLC ([c]) minus total conjugated dienes (CD).
[f]The IR values represented the total *trans* absorption from monoenes, and methylene- and nonmethylene-interrupted 18:2. Conjugated dienes were excluded, see text.
[g]Each IR value represented the mean of two determinations. Milk samples 1 to 5 and 6 to 10 were combined because of insufficient material.
[h]Acid-catalyzed methanolysis showed interferences in the *trans* IR region, see text.

method recommends a combination of $NaOCH_3$ and BF_3/methanol (43). We tried the combination of $NaOCH_3$ (10 min at 50°C) followed by either BF_3/methanol (10 min at 50°C), or HCl/methanol (10 min at 80°C). The results showed that both these methods methylated free fatty acids, and most of the sphingomyelin as judged by TLC (data not shown). The GLC results showed that the ratio of Δ9*c*,11*t*-18:2 to Δ9*t*,11*t*-18:2 was only slightly reduced, with the formation of trace amounts of methoxy derivatives. This combination of methods appears to be the best compromise for the methylation of total milk lipids. A saponification followed by diazomethane has been used successfully for the analysis of conjugated dienes (51), but this method also ignores the sphingomyelins which are not saponified.

Quantitative analysis of conjugated dienes and trans *FAME of milk.* A summary of the milk fatty acid composition determined by using either $NaOCH_3$/methanol or HCl/methanol is compared in Table 1. Milk samples were obtained from ongoing studies at Agriculture and Agri-Food Canada to test the effect of ionophores on milk fatty acid composition (39,40). The most noted difference between methods was on the complex mixture of conjugated diene isomers (Fig. 3). $NaOCH_3$/methanol gave ~12% higher values of total conjugated dienes compared with HCl/methanol (Table 1). Of the total conjugated dienes, ~74% consisted of the Δ9*c*,11*t* isomer using $NaOCH_3$/methanol, compared with only ~35% when HCl/methanol was used, while the Δ9*t*,11*t* isomer increased from ~9% with $NaOCH_3$ to ~39% with HCl. The ratio of Δ9*c*,11*t* to Δ9*t*,11*t* for the two methods decreased from ~8 to 0.9 (Table 1). Some of the conjugated dienes were converted to allylic methoxy derivatives during acid-catalyzed methylation. However, the sum of the conjugated dienes plus the methoxy derivatives in acid-catalyzed methanolysis gave ~18% higher values than those observed for the $NaOCH_3$/methanol method (Table 1). This suggests that some of the methoxy derivatives may have been derived from preexisting hydroxy fatty acids (49). The methoxy artifacts did not appear to be derived from either 18:1 (*cis* or *trans*) or 18:2n-6 in milk during these acid methylation conditions, since the levels of these fatty acids were not significantly different between the two methods; see Table 1. In addition to the changes in conjugated dienes, HCl/methanol also gave slightly higher values for the long-chain saturated (20:0–26:0) and polyunsaturated fatty acids (n-6 and n-3) compared with $NaOCH_3$/methanol (Table 1). This was not surprising, since the acid catalyst methylated all the lipid components, including sphingomyelin rich in long-chain saturates, and free fatty acids plus minor acidic lipids which also contain polyunsaturated fatty acids.

Based on the GLC analyses, the total *trans* content of milk samples was similar using either $NaOCH_3$ or HCl as catalyst (Table 2). The total *trans* content was obtained by adding the relative percentage of all *trans* monounsaturated fatty acids (peaks 3–7, and half of peak 10; Fig. 1), *cis/trans* 18:2 (peaks 14,15,17,19,20; Fig. 1), and total conjugated dienes in the milk chromatograms (Table 2). In the milk samples investigated, the *trans* content increased from about 5 to 8% (Experiment 1, Table 2), and from about 5 to 14% (Experiment 2,

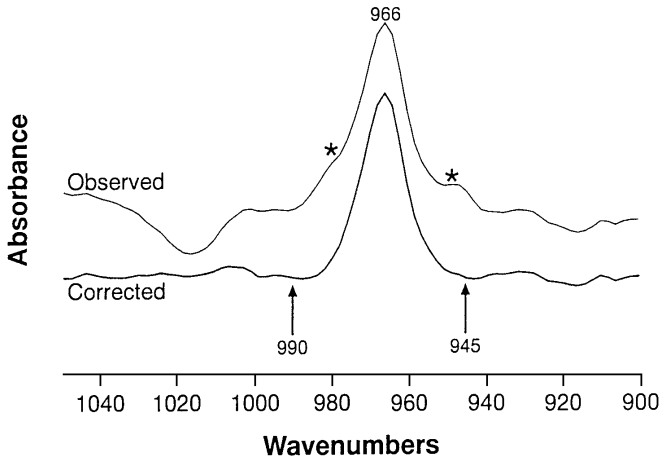

FIG. 4. Expanded infrared spectral range showing the out-of-plane deformation bands of isolated *trans* (966 cm^{-1}), and "*trans*-containing" conjugated dienes (985 and 948 cm^{-1}, denoted by asterisks) present in total bovine milk fatty acid methyl esters prepared by $NaOCH_3$/methanol (observed). The total *trans* area was integrated between the limits of 990 and 945 cm^{-1}, after subtracting the contribution of the conjugated dienes (corrected).

Table 2). The total FAME from the two experiments and the two methylation methods were subsequently analyzed by ATR–IR spectroscopy, which has been applied to rapid quantitation of total *trans* content in food products (45,46). The IR spectra (Fig. 4) showed absorbances due to the *trans* monounsaturated fatty acids and methylene-interrupted and noninterrupted 18:2 at 966 cm^{-1} and absorbances due to "*trans*-containing" conjugated dienes at 985 and 948 cm^{-1} (44). The IR calibration was based only on the absorptivity of methyl elaidate, which appeared to be inappropriate for the quantitation of conjugated dienes. Therefore, the absorbances at 948 and 985 cm^{-1} were subtracted before quantitation. However, even after removing the conjugated diene contribution, the remaining IR *trans* values were sometimes higher than those determined by GLC minus the conjugated dienes (Table 2). This may be due to additional unknown or overlapping *trans* isomers in the GLC chromatogram with different absorptivities than those of methyl elaidate. Until an appropriate *trans*-free reference material is found that is close to that of milk fat composition both in isolated and conjugated *trans* fatty acids, the accurate determination of total *trans* content in milk by IR will be difficult. The results in Table 2 showed that HCl methylation leads to lower *trans* values as determined by IR, due to the production of interfering material with absorbances in the *trans* region, which made these IR determinations of total trans content unreliable. This pointed to a further disadvantage of preparing total milk FAME using only HCl/methanol.

Preparation and analysis of total rumen FAME. Rumen lipids contain a complex mixture of phospho-, sphingo-, neutral-, and sterol lipids including high levels of free fatty acids, mainly from plant origin (21). The present study was undertaken to develop a method for the preparation of FAME from total rumen lipids. $NaOCH_3$/methanol was ineffective because of the high content of free fatty acid, while diazomethane methylated the free fatty acids, but it did not react with the ester lipids. Diazomethane did not isomerize the conjugated dienes or produce methoxy artifacts (Fig. 5A). On the other hand, HCl/methanol caused isomerization of the conjugated dienes, but did not form allylic methoxy derivatives (Fig. 5B). There is no explanation for this finding, but it may suggest the absence of hydroxy fatty acids in rumen lipids or an effect of free fatty acids. A combination of $NaOCH_3$ (10

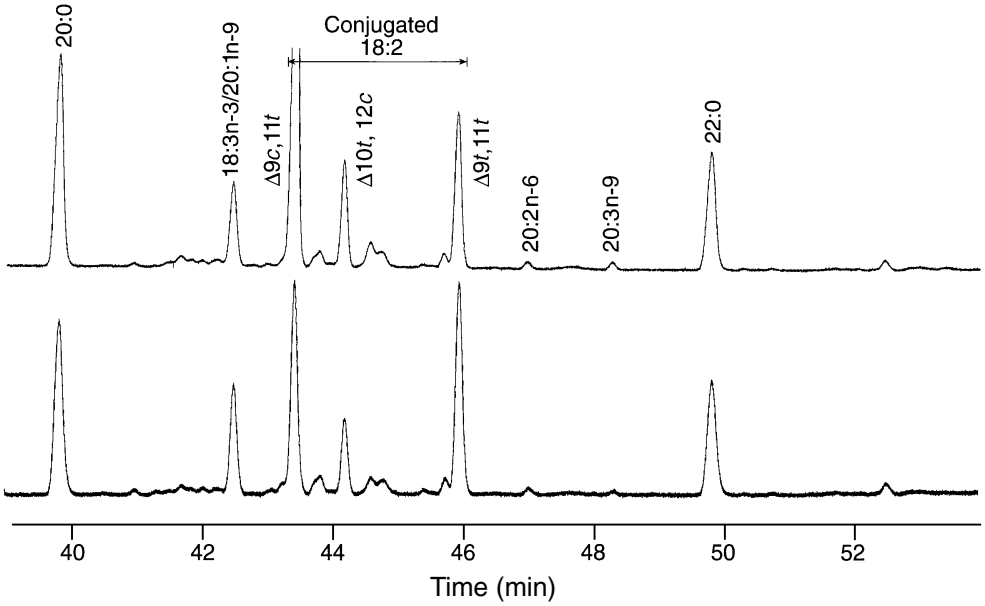

FIG. 5. The methyl eicosanoate (20:0) to methyl arachidonate (20:4n-6) region of the gas–liquid chromatogram of total rumen fatty acid methyl esters prepared by using (A) diazomethane and (B) HCl as catalysts in anhydrous methanol. Analysis was on the same type of GLC column as Figure 1. See Figure 2 for abbreviation.

min at 50°C) and HCl (10 min at 80°C) gave a Δ9*c*,11*t*-18:2 to Δ9*t*,11*t*-18:2 ratio of 4:3, while a combination of diazomethane and $NaOCH_3$ gave a ratio of 4:1. Both methods would appear to be suitable for total rumen FAME preparation. In our previous study (38), HCl/methanol was used to prepare the FAME of total rumen lipids which isomerized the conjugated dienes. However, in that study (38), only the total conjugated dienes were presented, which should be only slightly lower than if a base catalyst had been used (~12% based on milk results; Table 1).

Rumen FAME showed a similar pattern to that observed in milk FAME except for greatly reduced levels of very short-chain saturated (4:0–10:0) and long-chain C_{20} and C_{22} PUFA, and a higher content of *trans*-18:1 isomers and long-chain (22:0 to 26:0) saturated fatty acids (compare with Refs. 38 and 39). A comparison of the content of conjugated dienes suggests that it was twice as high in milk (present study, Table 1) than in rumen samples (39), both in control (0.7 vs. 0.3%) and ionophore treatments (1.4 vs. 0.7%), respectively. The content of Δ9*c*,11*t*-18:2 found in control milk (0.7%) agrees well with the value obtained by others (3) when a base-catalyzed method was used (0.85%).

Summary. The analysis of the conjugated dienes in milk and dairy products needs to be accurate, in view of their beneficial claims, and the assumption that only one of the isomers (Δ9*c*,11*t*-18:2) may be active in carcinogenesis and tumorigenesis (18). The evidence suggests that the formation of the conjugated dienes is enzymatic both by rumen bacteria (52–54) and in biological material as products of free radical *in vivo* lipid peroxidation (55–57). Careful analysis of the conjugated dienes in biological material, using only base-catalyzed methods that do not isomerize the conjugated diene system, has shown that Δ9*c*,11*t*-18:2 was the only isomer present (51). The presence of larger amounts of other isomers suggests subsequent isomerization during processing or improper (acid-catalyzed) methodology. There are many references in the literature reporting the content of conjugated dienes in milk and dairy products (3,4,6,8–15,24,27). Many of these studies show a high content of isomers other than Δ9*c*,11*t*-18:2 (10–13,15,27). Reinvestigation using proper techniques is needed.

Given the data presented here, a single procedure cannot simultaneously methylate all milk or rumen lipid components and avoid isomerization of conjugated dienes and the formation of allylic methoxy artifacts. Base-catalyzed methods caused no isomerization and produced no methoxy artifacts. However, $NaOCH_3$ did not methylate free fatty acids and *N*-acyl lipids, and diazomethane did not methylate esters. Tetramethylguanidine did not methylate sphingomyelin or phospholipids completely, which makes this method unsuitable for tissue lipids high in these lipids, as was reported recently (58). In addition, tetramethylguanidine gave undesirable products that extracted with hexane and interfered with the analyses of short-chain FAME, such as found in milk. Acid-catalyzed methods (HCl, BF_3, acetyl chloride, and H_2SO_4) methylated all lipid classes. However, these catalysts caused extensive isomerization of conjugated dienes, formed allylic methoxy artifacts, and are therefore not recommended by themselves for the analysis of milk and rumen lipids. A combination of methods appears to be most suitable, but that increases the loss of short-chain FAME during solvent removal or excessive handling. For milk, $NaOCH_3$-HCl (or BF_3) resulted in small losses of unconverted sphingomyelin, and minor isomerization of conjugated dienes and allylic methoxy formation, while diazomethane-$NaOCH_3$ ignored the sphingomyelin lipids. For rumen, either diazomethane-$NaOCH_3$, or $NaOCH_3$-HCl (or BF_3) gave good results. Analysis of isopropyl, instead of methyl esters, has the added advantage of not requiring the use of correction factors for FAME (24,30–32), but the isopropyl esters need to be prepared using Na isopropionate as catalyst instead of H_2SO_4/isopropanol (6,32). The determination of total isolated *trans* content in milk by IR methods was complicated by interferences from significant amounts of conjugated dienes.

ACKNOWLEDGMENTS

The authors thank R.C. Fouchard (CFAR) and Arran Bibby (Graseby Specac) for their technical support, and Graceby Specac for the generous loaning of a diamond ATR cell for the duration of the study. Contribution number 2425 from the Center of Food and Animal Research. Conjugated dienes were a gift from R.O. Adlof, USDA, Northern Regional Laboratory, Peoria, IL.

Effects of High Pressure and Temperature on Micelle Formation of Sodium Deoxycholate and Sodium Dodecylsulfate

Michiko Kato, Shogo Ozawa, and Rikimaru Hayashi*

Laboratory of Biomacromolecular Chemistry, Graduate School of Agriculture, Kyoto University, Kyoto 606-01, Japan

Pressure, as well as temperature, causes lipid phase transitions and changes the fluidity of membranes. For example, membrane intrinsic protein (Na, K)-ATPase is inhibited by increasing hydrostatic pressure, because increased pressure decreases the membrane fluidity to inhibit the conformational transition necessary for the (Na, K)-ATPase reaction (1). However, the effect of pressure on the lipid component in cell membranes of living organisms is not well known. For full understanding of this subject, studies of the behavior of natural and artificial lipids under high pressure are required.

In this study, sodium deoxycholate (DOC) and sodium dodecylsulfate (SDS) are used as a model of lipids, and critical micelle concentration (CMC) under high pressure is measured to investigate the pressure effects on the aggregation or the hydrophobic interaction of lipid molecules.

Absorbance under high pressure was measured with a thermocontrolled high-pressure photometer cell with sapphire windows (Teramecs Co., Kyoto, Japan) which is connected with a hand-type high-pressure pump and attached to a ultraviolet (UV)-visible spectrophotometer (UV-2500PC; Shimadzu Co., Kyoto, Japan).

A series of aqueous amphiphile solutions containing 48.4 μM Coomassie brilliant blue R-250 (Nacalai Tesque, Inc., Kyoto, Japan) were made according to the method of Courtney *et al.* (2), and 1.5 mL of the sample solution was introduced to the high-pressure cell and incubated for 3–10 min at a given temperature and pressure. Then, the absorbance at 596 nm was measured. It was checked for 15 min to obtain the stable value. The wavelength of maximum dye absorption shifts from 550 to 596 nm when amphiphiles form micelles. CMC was determined as the break point when the absorbance at 596 nm vs. the logarithm of amphiphile concentration was plotted on a graph.

CMC values of various amphiphiles determined by the Coomassie brilliant blue method at 25°C are compared with those of other methods including the conductivity method in Table 1. The values obtained by the dye method are in good agreement with those reported in the literature, except for a notably different value from Reference 3. Furthermore, it was confirmed that change of the dye concentration (12.1–48.4 μM) caused no change in CMC values obtained. Thus, the dye method employed in the present experiments is considered to be reliable.

TABLE 1
Critical Micelle Concentration (CMC) of Various Amphiphiles Determined at 25°C

Amphiphiles	CMC (mM)	
	Present result[a]	Literature value (ref. no.)
Sodium deoxycholate	3.11 ± 0.005	3.1 (4)
Sodium dodecylsulfate	4.59 ± 0.24	8.1 (3)[b], 5.9 (2), 5.4 (5)
Triton X-100	0.159 ± 0.002	0.2 (2), 0.22 (6)
Tween 20	0.105 ± 0.013	0.068 (2), 0.11 (5)

[a]Average of three or four measurements.
[b]Exceptionally high for unknown reason.

The CMC of DOC and SDS at various pressures up to 400 MPa and at temperatures of 20 to 45°C were determined (Fig. 1). In case of SDS, the pressure dependency at various temperatures was in fairly good agreement with published data (3), although the dye method tended to give somewhat lower values than the conductivity method. At any temperature, pressure dependency showed a convex curve with maximum at 100 MPa as already reported with SDS (7). The CMC of DOC increased slightly up to 100 MPa and then decreased at 100 MPa or higher at 25, 35, and 45°C (Fig. 1). However, a strong decrease in the CMC was observed at 100 MPa or

Abbreviations: CMC, critical micelle concentration; DOC, sodium deoxycholate; SDS, sodium dodecylsulfate.

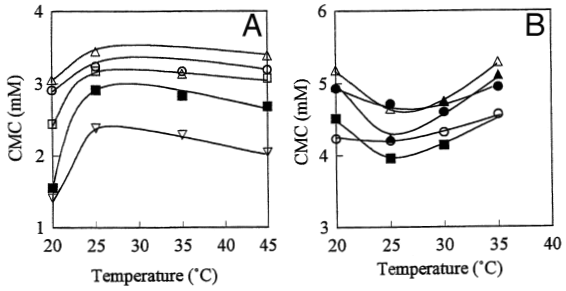

FIG. 2. Effects of temperature on critical CMC of (A) sodium deoxycholate and (B) sodium dodecylsulfate at various pressures. ○: 0.1; ●: 50; △: 100; ▲: 150; □: 200; ■: 300; ▽: 400 MPa.

higher pressures at 20°C. These results indicate that aggregation of DOC and SDS is dependent on the pressure. It may be expressed that molecular interaction of DOC and SDS decreased up to 100 MPa and increased over 100 MPa. It should be noted, however, that the CMC of SDS changed more than that of DOC when pressure changed from 0.1–100 MPa (Fig. 1).

The temperature dependence of the CMC of DOC and SDS at different pressures is shown in Figure 2. As a whole, the CMC of DOC increased up to 25°C and then decreased slightly over 25°C at any pressure, although such change was marked at higher pressure. In contrast to CMC of DOC, the temperature-dependent change of CMC of SDS showed a concave curve with a minimum at 25°C (Fig. 2). These results indicate that molecular aggregation of DOC decreased up to 25°C and increased at higher temperatures, but the aggregation of SDS increased and then decreased at 25°C.

The different behavior observed between DOC and SDS may result from the different structure of these compounds; DOC has a cyclic hydrocarbon structure with two hydroxyl groups which form hydrogen bonds in addition to the hydrophobic bonding due to the rest of molecule, whereas SDS has a linear hydrocarbon chain which makes only hydrophobic bonds. Pressure and temperature effects on hydrogen bonding and hydrophobic interaction are complicated depending on the structural properties. Therefore, complete understanding of the present results awaits systematic study of a series of lipids and of other properties including micellar radius (8,9).

Isomers in Commercial Samples of Conjugated Linoleic Acid

Sir:

In connection with our analytical activities (MRS Lipid Analysis Unit), we have analyzed several commercial samples of conjugated linoleic acid (CLA). Most of these have been prepared by alkali-isomerization of linoleic acid or of oils, such as sunflower or safflower, rich in this acid. (i) We have examined the methyl esters, which must be prepared from the acids avoiding the use of acidic catalysts, by gas chromatography (GC). With a 25-m carbowax capillary column, most of the samples show two major peaks which are well-resolved from each other, along with minor peaks running later which are first the all-*cis* and then the all-*trans* dienes. The two major peaks are usually considered to be only the 9*c*,11*t* and 10*t*,12*c* isomers. This interpretation is not consistent with the GC/mass spectrometry (MS) data reported below. When examined on a highly polar 100-m capillary column (CP Sil 88), the GC trace is more complex. Several samples show a new peak for 11,13 diene, and some indicate the presence of several other isomers. We also have evidence that the 9,11 peak contains the 8,10 isomer though we have been unable to resolve these. (ii) GC–MS of the diene adducts formed through reaction with 4-methyl-2,3,4-triazoline-3,5-dione (MTAD derivatives), with selected ion monitoring, shows the presence of 8,10; 9,11; 10,12; and 11,13 dienes (1). For example, Figure 1 illustrates the selected ion chromatogram for one of the diagnostic ions from each isomer in a commercial CLA preparation. It is clear that four unresolved isomers are present. The proportions of these vary widely (presumably depending on the conditions of alkali-isomerization) and even more isomers are sometimes present. GC–MS of the dimethyloxazoline derivatives confirmed the identity of the major products. (iii) High-resolution ^{13}C nuclear magnetic resonance spectroscopy confirmed the presence of at least four *cis,trans* conjugated dienes and gave quantitative results in line with those obtained by GC–MS analysis.

We conclude that most samples of CLA, though rich in the 9,11 (probably mainly if not entirely the 9*c*,11*t* isomer) and 10,12 dienes (probably mainly if not entirely the 10*t*,12*c* isomer) also contain at least the 8,10 and 11,13 *cis,trans* dienes, sometimes at quite high levels. These are accompanied by all-*cis* and all-*trans* dienes. In one commercial sample of CLA, we found the following dienes: 8,10 (14%), 9,11 (30%), 10,12 (31%), and 11,13 (24%).

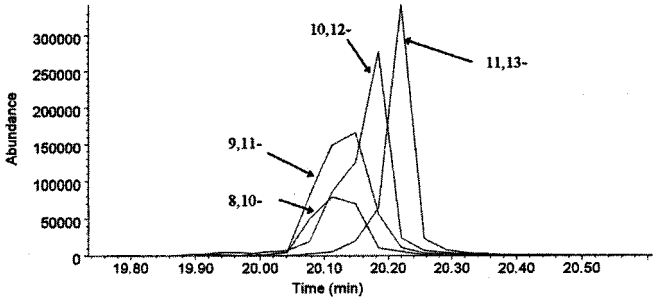

FIG. 1. Selected ion scan in gas chromatography–mass spectrometry of methyl triazoline dione adducts of a commercial conjugated linoleic acid preparation (methyl esters). The characteristic ions are at *m/z* = 264 (8,10–18:2), 250 (9,11–18:2), 236 (10,12–18:2), and 222 (11,13–18:2).

It is important that those who produce these materials and use them for research purposes appreciate the complex nature of their products. To our knowledge, the identity of the biologically active CLA is not known although it is generally assumed to be 9*c*,11*t*-18:2. Nor is it known how the activity of this isomer may be influenced by the presence of other isomeric CLA.

Fatty Acyl Desaturation in Isolated Hepatocytes from Atlantic Salmon (*Salmo salar*): Stimulation by Dietary Borage Oil Containing γ-Linolenic Acid

Douglas R. Tocher*, J. Gordon Bell, James R. Dick, and John R. Sargent

NERC Unit of Aquatic Biochemistry, Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, Scotland

ABSTRACT: The effects of different dietary oils on the fatty acid compositions of liver phospholipids and the desaturation and elongation of [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 were investigated in isolated hepatocytes from Atlantic salmon. Atlantic salmon smolts were fed diets containing either a standard fish oil (FO) as a control diet, a 1:1 blend of Southern Hemisphere marine oil and tuna orbital oil (MO/TO), sunflower oil (SO), borage oil (BO), or olive oil (OO) for 12 wk. The SO and BO diets significantly increased the percentages of 18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6, and total n-6 polyunsaturated fatty acids (PUFA) in salmon liver lipids in comparison with the FO diet. The BO diet also increased the percentage of 20:4n-6. Both the SO and BO diets significantly reduced the percentages of all n-3 PUFA in comparison with the FO diet. The OO diet significantly increased the percentages of 18:1n-9, 18:2n-6, total monoenes, and total n-6 PUFA in liver lipids compared to the FO diet, and the percentages of all n-3 PUFA were significantly reduced. With [1-^{14}C]18:3n-3, the recovery of radioactivity in the products of Δ6 desaturation was significantly greater in the hepatocytes from salmon fed SO, BO, and OO in comparison with the FO diet. The BO diet also increased the recovery of radioactivity in the products of Δ5 desaturation. Only the BO diet significantly affected the desaturation of [1-^{14}C]18:2n-6, increasing recovery of radioactivity in both Δ6- and Δ5-desaturation products. In conclusion, dietary BO, enriched in γ-linolenic acid (18:3n-6), significantly increased the proportions of both 20:3n-6 and 20:4n-6 in salmon liver phospholipids and also significantly increased the desaturation of both 18:2n-6 and 18:3n-3 in salmon hepatocytes. The possible relationships between dietary fatty acid composition, tissue phospholipid fatty acid composition, and desaturation/elongation activities are discussed.

Lipids 32, 1237–1247 (1997).

The fatty acid compositions of animal tissues are determined both by the type of dietary lipid ingested and the ability of the individual species to modify that dietary input *via* both catabolism and by pathways of desaturation and elongation (1–4). Both the fatty acid-desaturating and -elongating enzyme systems are microsomal, consisting of electron transport chains linked to terminal desaturase and elongase activities (5–7). As such, they represent membrane-bound systems whose activities, like all membrane-bound enzymes and receptors, are highly dependent upon membrane fatty acid compositions (8–11). Therefore, hepatic desaturation and elongation of fatty acids are modulated by nutritional state including the content and composition of dietary lipids and fatty acids (5,6). For instance, fish oil-containing diets, rich in eicosapentaenoic acid (20:5n-3; EPA) and docosahexaenoic acid (22:6n-3; DHA), tended to reduce rat liver microsomal Δ6-desaturase activity, particularly with 18:2n-6 as substrate, in comparison with diets rich in 18:2n-6 or 18:3n-3 (12–14). However, fatty acyl desaturase activities will themselves alter cellular fatty acid compositions, and it is unclear what precise relationship exists between dietary fatty acids, fatty acid desaturation, and tissue fatty acid compositions.

Freshwater fish are able to elongate and desaturate 18:3n-3 to 22:6n-3, whereas marine fish lack or have a very low activity of Δ5 desaturase and so require the long-chain polyunsaturated fatty acids (PUFA), EPA and DHA, to be supplied by the diet (15–17). Dietary specialization is an important factor in determining this difference since many freshwater fish are herbivorous or omnivorous, whereas the limited number of marine fish studied to date are predominantly carnivorous (17,18). Therefore, in terms of desaturase activities, freshwater fish are similar to terrestrial omnivores such as rodents and humans, but marine fish are more similar to terrestrial carnivores such as cats, which have relatively low desaturase activities (19–21). Atlantic salmon (*Salmo salar*) is an anadromous fish which begins life in freshwater and migrates to the sea after 1–2 yr, before returning to freshwater to breed after spending 1–3 yr at sea. Like other salmonids, such as trout, the desaturase profile of salmon appears to be that of freshwater fish (22,23). However, the commercial culture of most fish species, including salmon, is currently highly dependent on diets containing fish oil and fish meal which are increasingly expensive and whose supply is both volatile/variable

*To whom correspondence should be addressed. E-mail: drt1@stir.ac.uk.

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; BHT, butylated hydroxytoluene; BO, borage oil diet; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FAF-BSA, fatty acid-free bovine serum albumin; FAME, fatty acid methyl esters; FO, standard Northern Hemisphere fish oil diet; GLA, γ-linolenic acid; HBSS, Hanks' balanced salt solution; MO, marine oil; OO, olive oil diet; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acid(s); SO, sunflower oil diet; TLC, thin-layer chromatography; TO, tuna orbital oil diet.

and becoming increasingly environmentally undesirable owing to the overexploitation of unsustainable marine fish stocks (24). Fish oils are also in increasing demand as direct sources of n-3 PUFA for human nutrition (25). Several studies have investigated the use of other oils in the nutrition of salmon (25–27). Different dietary oils have been shown to significantly alter tissue phospholipid fatty acid compositions in salmon (28,29) and have significant effects on functional activities including phospholipase A activity (30), eicosanoid metabolism (31), and immune function (32). However, despite the importance of understanding the relationship between dietary fatty acids, tissue fatty acid compositions and fatty acyl desaturation, there are few data on the effects of dietary oils and fatty acids in modulating desaturase activities in fish and none on the commercially important salmon (33,34).

In the present study, we investigated the effects of different dietary oils on the desaturation of both [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 in isolated hepatocytes from Atlantic salmon. Because the long-chain n-3 PUFA, EPA, and DHA are known to be inhibitory to fatty acyl desaturases (5,19), oils were chosen to alter tissue EPA and DHA levels. With a standard fish oil diet as the control diet, one diet contained a blend of Southern Hemisphere fish oil (high EPA) and tuna orbital oil (high DHA) to increase EPA and DHA. Other diets were formulated to reduce cellular EPA and DHA by using combinations of 18:1n-9, 18:2n-6, and 18:3n-6. The results showed that dietary borage oil (BO), enriched in γ-linolenic acid (GLA; 18:3n-6), significantly increased the proportions of both 20:3n-6 and 20:4n-6 in salmon liver phospholipids and also significantly increased the desaturation of both 18:2n-6 and 18:3n-3 in salmon hepatocytes.

MATERIALS AND METHODS

Animals and diets. Five hundred fifty Atlantic salmon S1 smolts (initial mean weight 38 g) were obtained from the S.O.A.E.F.D. Fish Cultivation Unit (Aultbea, Wester Ross, Scotland) and distributed randomly into five tanks of 500-L capacity each, which were supplied with seawater at a rate of 10 L/min. The fish were subject to natural photoperiod, and the water temperature during the experimental period (July–October) varied from 9–17°C. Diets were fed for 12 wk and were supplied by automatic feeders which were adjusted to supply 25 g/kg biomass/day. Fish were weighed individually at the start and finish of the experiment and weighed in bulk every 28 d and the ration adjusted accordingly. The experiment was conducted in accordance with the British Home Office guidelines regarding research on experimental animals.

The diets were formulated to satisfy the nutritional requirements of salmonid fish and contained 48% crude protein and 25% lipid (35). The exact formulation of the diets is shown in Table 1. All diets were prepared to order by Ewos Ltd. (Technology Centre, Livingston, United Kingdom). Pellets, containing 3% fish oil, were manufactured by extrusion, and experimental oils (160 g/kg) were then added after addition of an antioxidant mix (0.4 g/kg; composition as described in Table 1) to each oil before mixing with the other ingredients. The dietary oils were a standard Northern Hemisphere fish oil (FO) (Fosol; Seven Seas Ltd., Hull, United Kingdom) as a control diet, a 1:1 mix of a Southern Hemisphere fish oil [marine oil (MO)] (Marinol K; Fishing Industry Research Unit, Rosebank, Republic of South Africa) and DHA-rich tuna orbitol oil (TO) (Croda Universal Ltd., Hull, United Kingdom), sunflower oil (SO) (Tesco Ltd., Cheshunt, United Kingdom), borage oil (BO) (Croda Universal Ltd.), and olive oil (OO) (Tesco Ltd.). The fatty acid compositions of the five diets are shown in Table 2.

TABLE 1
Formulation of Diets[a]

Component	Content (g/kg)
Fish meal[b]	620
Soya meal (full fat)	80
Wheat meal	66
Mineral mix[c]	24
Vitamin mix[d]	10
Choline chloride (40% wt/vol)	10 mL (4 g)
Feeding stimulant[e]	6
Fish Oil[f]	30
Oil coating[g]	160

[a]Diets were manufactured to order by Ewos Ltd., Technology Centre, Livingston, United Kingdom. Base pellets containing 3% fish oil were prepared by extrusion. Experimental oils were then added to the base pellets.
[b]LT94, Low-temperature fish meal (Ewos Ltd., Bathgate, United Kingdom).
[c]Supplied (per kg diet): KH_2PO_4, 22 g; $FeSO_4 \cdot 7H_2O$, 1.0 g; $ZnSO_4 \cdot 7H_2O$, 0.13 g; $MnSO_4 \cdot 4H_2O$, 52.8 mg; $CuSO_4 \cdot 5H_2O$,12 mg; $CoSO_4 \cdot 7H_2O$, 2 mg; and KI, 2 mg.
[d]Supplied (mg/kg diet): ascorbic acid, 1000; myoinositol, 400; nicotinic acid, 150; calcium pantothenate, 44; all-*rac*-α-tocopheryl acetate, 40; riboflavin, 20; pyridoxine hydrochloride, 12; menadione, 10; thiamine hydrochloride, 10; retinyl acetate, 7.3; folic acid, 5; biotin, 1; cholecalciferol, 0.06; cyanocobalamin, 0.02.
[e]Finnstim (Ewos Ltd., Bathgate, United Kingdom).
[f]Norsalmoil (United Fish Products, Aberdeen, United Kingdom).
[g]The experimental oils were: A control diet containing a standard Northern Hemisphere fish oil (Fosol; Seven Seas Ltd., Hull, United Kingdom); a 1:1 mix of a Southern Hemisphere fish oil (Marinol K; Fishing Industry Research Unit, Rosebank, Republic of South Africa) and docosahexaenoic acid-rich tuna orbital oil (Croda Universal Ltd., Hull, United Kingdom); sunflower oil (Tesco Ltd., Cheshunt, United Kingdom); borage oil (Croda Universal Ltd.); olive oil (Tesco Ltd.). All experimental oils had antioxidant mix [dissolved in propylene glycol and containing (g/L): butylated hydroxyanisole, 60; propyl gallate, 60; citric acid, 40] added prior to coating.

Lipid extraction, glycerophospholipid separation, and fatty acid analysis. Fish were killed by a blow to the head and livers were dissected from four fish per dietary treatment and immediately frozen in liquid nitrogen. Samples were stored at −40°C prior to lipid extraction. Total lipid was extracted from liver and diet samples by the method of Folch *et al.* (36). Samples of liver total lipid (3–4 mg) were applied to a 4-cm origin on a thin-layer chromatography (TLC) plate, and the polar lipid classes were separated using methyl acetate/propan-2-ol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) as developing solvent (37). Lipid

classes were visualized under ultraviolet light after spraying with 2,7-dichlorofluorescein. Individual glycerophospholipid classes were scraped into stoppered test tubes and transmethylated directly on the silica after addition of 1 mL toluene and 2.5 mL 1% sulfuric acid in methanol, and fatty acid methyl esters (FAME) prepared as described below. FAME were prepared from total lipid and individual glycerophospholipid classes by acid-catalyzed transmethylation at 50°C for 16 h (38) and were extracted and purified as described previously (39). FAME were analyzed in a Packard 436 gas chromatograph (Canberra Packard, Pangbourne, United Kingdom) equipped with a CP Wax 52CB fused-silica capillary column (30 m × 0.32 mm i.d., Chrompack U.K. Ltd., London, England), with on-column injection using hydrogen as carrier gas and a biphasic thermal gradient from 50 to 225°C. FAME were identified by comparison with known standards and a well-characterized fish oil and by reference to published data as described previously (39) and were quantified using a Shimadzu CR6A data processor (Kyoto, Japan). All solvents contained 0.01% butylated hydroxytoluene (BHT) as an antioxidant.

Preparation of isolated hepatocytes. Intact, metabolically viable liver parenchymal cells were prepared by the technique of *in vitro* collagenase dispersion essentially as described in detail previously (23). Briefly, fish were killed by a blow to the head and the liver dissected immediately. The gall bladder was removed carefully from the liver and the main blood vessels removed. The liver was perfused *via* the hepatic vein with solution A [calcium- and magnesium-free Hanks' balanced salt solution (HBSS) + 10 mM HEPES + 1 mM EDTA], using a syringe fitted with a 23-gauge needle, to clear blood from the tissue. The liver was chopped finely with scissors and incubated with 20 mL of solution A containing 0.1% (wt/vol) collagenase in a 25 mL "Reacti-flask" in a shaking water bath at 20°C for 45 min. The digested liver was filtered through 100-μm nylon gauze and the cells collected by centrifugation at 1000 × *g* for 5 min. The cell pellet was washed with 20 mL of solution A containing 1% wt/vol fatty acid-free bovine serum albumin (FAF-BSA) and recentrifuged. The hepatocytes were resuspended in 10 mL of Medium 199 (Sigma Chemical Co., Poole, United Kingdom) containing 10 mM HEPES, 2 mM glutamine, 100 U/mL penicillin, and 0.1

mg/mL streptomycin. One hundred μL of cell suspension was mixed with 400 μL of Trypan Blue, and hepatocytes were counted and their viability assessed using a hemacytometer. One hundred μL of the cell suspension was retained for protein determination.

Preparation of isotopes for addition to cell cultures. The radioactive isotopes, [1-^{14}C]18:3n-3 or [1-^{14}C]18:2n-6, were added to cells as complexes with FAF-BSA. Briefly, 25 μCi of fatty acid (0.5 μmol) in ethanol was placed in a reaction vial, solvent was evaporated under a stream of nitrogen, and 100 μL of 0.1M KOH were added. The mixture was stirred for 10 min at room temperature before 5 mL of 50 mg/mL FAF-BSA in HBSS containing 10 mM HEPES buffer was added and the mixture stirred for 45 min at 20°C.

Assay of hepatocyte fatty acyl desaturation/elongation activities. Five mL of each hepatocyte suspension was dispensed into two 25-cm^2 tissue culture flasks. Hepatocytes were incubated with 0.25 μCi of either [1-^{14}C]18:3n-3 or [1-^{14}C]18:2n-6, added as complexes with FAF-BSA prepared as described above. After addition of isotope, the flasks were incubated at 20°C for 3 h. After incubation, the cell layer was dislodged by gentle rocking, transferred to glass conical test tubes, and the flasks were washed with 1 mL of ice-cold HBSS containing 1% FAF-BSA. The cell suspensions were centrifuged at 300 × *g* for 2 min, the supernatants discarded, and the cell pellets washed with 5 mL of ice-cold HBSS/FAF-BSA. The supernatants were discarded and the tubes placed upside down on paper towels to blot for 15 s before extraction of total lipid using ice-cold chloroform/methanol (2:1, vol/vol) containing 0.01% (wt/vol) BHT essentially as described by Folch *et al.* (36) and as detailed previously (40).

Total lipid was transmethylated and FAME were prepared as described above. The methyl esters were redissolved in 100 μL hexane containing 0.01% BHT and applied as 2.5-cm streaks to TLC plates impregnated by spraying with 2 g silver nitrate in 20 mL acetonitrile and preactivated at 110°C for 30 min. Plates were fully developed in toluene/acetonitrile (95:5, vol/vol) (41). Autoradiography was performed with Kodak Biomax MR-2 film for 4–7 d at room temperature. Silica corresponding to individual PUFA was scraped into scintillation minivials containing 2.5 mL of scintillation fluid (Ecoscint A. National Diagnostics, Atlanta, GA) and radioactivity determined in a TRI-CARB 2000CA scintillation counter (United Technologies Packard, Pangbourne, United Kingdom). Results were corrected for counting efficiency and quenching of ^{14}C under exactly these conditions.

Protein determination. Protein concentration in isolated hepatocyte suspensions was determined according to the method of Lowry *et al.* (42) after incubation with 0.25 mL of 0.25% (wt/vol) SDS/1 M NaOH for 45 min at 60°C.

Materials. [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 (both 50–55 mCi/mmol) were from NEN [DuPont (U.K.) Ltd., Stevenage, United Kingdom)]. HBSS, HEPES buffer, glutamine, penicillin, streptomycin, collagenase (type IV), FAF-BSA, BHT, and silver nitrate were obtained from Sigma Chemical Co. TLC plates, precoated with silica gel 60 (without fluorescent indicator), were obtained from Merck (Darmstadt, Germany). All solvents were HPLC-grade and were obtained from BS & S Ltd. (Edinburgh, Scotland).

Statistical analysis. Significance of difference between dietary treatments ($P < 0.05$) was determined by analysis of variance (ANOVA). Analyses were performed using a Statgraphics (system 3.0) computer package (Statistical Graphics Corp., Rockville, MD). Data which were identified as nonhomogeneous (using Bartlett's test) were subjected to either arcsin square root or log transformation before analysis. Where appropriate, differences between means were determined by Tukey's test.

RESULTS

The mean initial weight of all the fish was 37.9 ± 10.8 g, and after 12 wk on the diets the final weights of the fish were 150.0 ± 49.5 g (FO), 159.5 ± 40.0 g (TO/MO), 128.8 ± 48.2 g (SO), 137.9 ± 32.8 g (BO), and 150.5 ± 47.7 g (OO). The only difference in mean final weights that was significant (one-way ANOVA) was between the TO/MO and SO diets.

Replacing the control fish oil (Fosol; FO) with the combination of Southern Hemisphere MO and TO increased the EPA, DHA, total n-3 PUFA, and total PUFA contents of the diet at the expense of saturates (Table 2). The SO and BO both increased the total n-6 PUFA contents of the diets, owing solely to increased 18:2n-6 in SO and 18:2n-6 and 18:3n-6 in BO, at the expense of all other fatty acids compared to the control diet. The OO diet contained increased 18:1n-9, 18:2n-6, total monoenes, and total n-6 PUFA compared to the FO diet and proportions of saturated fatty acids and n-3 PUFA similar to those of the SO and BO diets (Table 2).

The MO/TO diet did not significantly affect the percentages of EPA, DHA, or total n-3 PUFA in salmon liver total lipid in comparison with the control diet (Table 3). However, the MO/TO diet significantly reduced the percentages of 20:1 and 22:1 and the n-3/n-6 ratio and increased the proportion of saturated fatty acids. The SO diet significantly increased the percentages of 18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6, and total n-6 PUFA in total lipid from salmon liver in comparison with the FO diet (Table 3). The BO diet had similar effects to those of SO except that it also increased the percentage of arachidonic acid (20:4n-6; AA). However, the levels of 18:2n-6 and 20:2n-6 were significantly lower in the BO-fed fish compared to the SO-fed fish, whereas the percentages of 18:3n-6, 20:3n-6, and 20:4n-6 were all significantly higher in the BO diet (Table 3). There was no difference between the SO and BO diets in the percentages of n-3 PUFA in the liver total lipid although both the SO and BO diets significantly reduced the percentages of all n-3 PUFA in comparison with the FO diet. The OO diet significantly increased the percentages of 18:1n-9, 18:2n-6, total monoenes, and total n-6 PUFA in liver total lipid compared to the FO diet, and the percentages of all n-3 PUFA were significantly reduced and similar to the levels observed in the SO- and BO-fed fish (Table 3).

The differences in specific fatty acids observed in liver total

[a]Results are expressed as percentage of weight and are means ± SD ($n = 4$). The significance of differences between the dietary treatments was analyzed by one-way analysis of variance. Mean values with different superscript letters within a given row are significantly different ($P < 0.05$) as determined by Tukey's multiple range test. [1], Predominantly n-7 isomer; [2], predominantly n-9 isomer; [3], includes C_{16} and n-9 PUFA present in all samples at percentages varying from 0.3 to 0.6 and 0.2 to 0.4, respectively; n.d., not detected; PUFA, polyunsaturated fatty acids. See Table 2 for company sources.

lipid were associated with specific phospholipid classes related to the unique fatty acid compositions of the individual phospholipid classes (Tables 4–7). Therefore, in the fish fed the SO diet which, in particular, significantly increased the percentages of 18:2n-6 and 20:2n-6, the increases were most prominent in phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (Tables 4–6). With the BO diet, which showed the highest 18:3n-6 and 20:3n-6 in liver total lipid, the increased percentage of 18:3n-6 was mainly found in PC, whereas the increased percentages of 20:3n-6 were found in both PC and PE (Tables 4,5). The level of 20:4n-6 was significantly increased by both the SO and BO diets in PC and PE (Tables 4,5). However, the percentages of 20:4n-6 were greatest in phosphatidylinositol which was also the class most resistant to dietary effects with only the OO diet resulting in a significantly lower level of 20:4n-6 in phosphatidylinositol (Table 7).

Two-way ANOVA showed that less radioactivity was recovered unmetabolized with [1-^{14}C]18:3n-3 as substrate compared to [1-^{14}C]18:2n-6, whereas significantly more 18:2n-6 was metabolized by elongation to the so-called "dead-end product," 20:2n-6, compared to the similar product, 20:3n-3, arising by elongation of 18:3n-3 (Table 8). The amount of radioactivity recovered as either 18:3n-3 or 18:2n-6 and, therefore, unmetabolized, as a percentage of the total radioactivity recovered in PUFA was significantly lower in fish fed BO compared to fish on any of the other diets (Table 8). There was no significant difference between the fish on the FO, TO/MO, SO, and OO diets in the amount of radioactivity recovered unmetabolized as either 18:3n-3 or 18:2n-6. The percentage of radioactivity recovered in the elongation products, 20:3n-3 and 20:2n-6, was significantly lower in BO-fed fish compared to fish fed the diets containing fish oils, FO and TO/MO (Table 8). There was no significant difference between the fish on the FO, TO/MO, SO, and OO diets in the amount of radioactivity recovered as either 20:3n-3, but the OO diet significantly reduced the recovery of radioactivity in 20:2n-6 compared to the diets containing fish oil.

The total amount of desaturation of [1-^{14}C]18:3n-3 was significantly greater in the hepatocytes from salmon fed the n-6 PUFA-rich oils and OO in comparison with both the diets containing fish oil (Table 9). Both the n-6 PUFA-rich oils and OO increased the amount of radioactivity recovered in the Δ6 products compared to the fish oil diets, whereas the BO diet also markedly increased the recovery of radioactivity in the

Δ5 products, which was 2.6-fold greater than with any other diet, and the Δ6* products (hexaenes, predominantly 22:6n-3; formerly termed Δ4 products). Two-way ANOVA showed that as well as the significant effects of diet, there was a very significant effect of substrate with significantly greater desaturation activity toward [1-^{14}C]18:3n-3 compared to [1-^{14}C]-18:2n-6 with significantly greater recovery of radioactivity in the Δ6-, Δ5- and total-desaturation products (Table 9). The

desaturation of [1-^{14}C]18:2n-6 was much less affected by diet but, as with the desaturation of [1-^{14}C]18:3n-3, the fish fed BO displayed significantly greater recoveries of radioactivity in Δ6- (over 2.4-fold greater than any other diet), Δ5-, and total-desaturation products (Table 9). There was no significant difference between the two diets containing fish oil, FO and MO/TO, in the desaturation of either [1-^{14}C]18:3n-3 or [1-^{14}C]18:2n-6 although the MO/TO diet consistently gave the lowest percentages of radioactivity recovered in almost all the fatty acid fractions.

[a]Hepatocytes were isolated and incubated with either [1-^{14}C]18:3n-3 or [1-^{14}C]18:2n-6 as described in the Materials and Methods section. Results are expressed as the amount of radioactivity recovered in the fractions as percentages of total radioactivity recovered. The significance of differences between the dietary treatments was analyzed by one-way analysis of variance (ANOVA). Mean values with different superscript letters within a given row are significantly different ($P < 0.05$) as determined by Tukey's multiple range test. The results of two-way ANOVA were: substrate—significant for both the C_{18} ($P = 0.0000$; mean values for 18:3 and 18:2 being 65.9 and 72.8) and C_{20} ($P = 0.0000$; mean values for 20:3 and 20:2 being 14.3 and 17.4); diet—significant for both the C_{18} [$P = 0.0000$; mean value for borage oil (BO) being significantly lower than all other diets at 60.7, with other diets varying between 69.6 and 72.8 and no significant difference between them] and C_{20} ($P = 0.0019$; mean value for BO being significantly lower than all other diets at 9.5, with other diets varying between 13.7 and 20.5 with some significant differences). See Table 2 for company sources.

TABLE 9
Effects of Diet on the Desaturation of [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 by Isolated Hepatocytes from Atlantic Salmon (*Salmo salar*)[a]

Δ6*	0.3 ± 0.1^{c}	0.6 ± 0.1^{c}	1.9 ± 0.5^{b}	4.2 ± 0.8^{a}	1.7 ± 0.0^{b,c}
Total	12.6 ± 1.9^{c}	8.9 ± 0.3^{c}	20.8 ± 2.5^{b}	40.5 ± 1.1^{a}	21.3 ± 1.8^{b}
[1-^{14}C]18:2n-6					
Δ6	4.5 ± 2.0^{b}	3.3 ± 1.4^{b}	6.3 ± 0.6^{b}	15.4 ± 0.5^{a}	6.2 ± 0.9^{b}
Δ5	1.4 ± 0.1^{b}	0.8 ± 0.2^{b}	1.3 ± 0.3^{b}	2.4 ± 0.1^{a}	1.0 ± 0.0^{b}
Δ6*	1.4 ± 0.2	1.5 ± 0.3	1.9 ± 0.4	1.5 ± 0.1	2.2 ± 0.2
Total	7.3 ± 1.6^{b,c}	5.6 ± 1.8^{c}	9.5 ± 0.8^{b}	19.3 ± 0.8^{a}	9.4 ± 0.7^{b,c}

[a]Hepatocytes were isolated and incubated with either [1-^{14}C]18:3n-3 or [1-^{14}C]18:2n-6 as described in the Materials and Methods section. Results are expressed as the amount of radioactivity recovered in the various desaturated products as percentages of total radioactivity recovered. The significance of differences between the dietary treatments was analyzed by one-way analysis of variance (ANOVA). Mean values with different superscript letters within a given row are significantly different ($P < 0.05$) as determined by Tukey's multiple range test. Δ6, products of Δ6 desaturation (18:4 and 20:4 for n-3, and 18:3 and 20:3 for n-6); Δ5, products of Δ5 desaturation (20:5 and 22:5 for n-3, and 20:4 and 22:4 for n-6); Δ6*, hexaene products for n-3 and pentaene products for n-6. The results of two-way ANOVA were: diet—Δ6, Δ5, Δ6* and total all significant ($P = 0.0000$); substrate—Δ6, Δ5 and total all significant ($P = 0.0000$), but Δ6* ns, $P = 0.7342$ with the differences (Tukey's) being Δ6, n-3 > n-6 (9.66 vs. 6.74); Δ5, n-3 > n-6 (8.48 vs. 1.33); total, n-3 > n-6 (19.76 vs. 9.75); interaction—Δ6, Δ5, Δ6* and total all significant $P = 0.0000$ except Δ6 $P = 0.0006$. See Table 2 for company sources.

DISCUSSION

In the present study, the use of intact hepatocytes to determine the metabolism of fatty acids by desaturation and elongation was preferred to the use of microsomes. Therefore, it should be noted that the present data do not measure desaturase enzyme activity as directly as with microsomal preparations. Microsomal preparations, though, are limited, particularly in relation to 18:3n-3 metabolism in fish, in that the production of DHA cannot be determined in microsomes alone because peroxisomes are also required (7). The utilization of intact hepatocytes enables the whole desaturation/elongation pathway to be assayed. Furthermore, dietary influences of membrane fatty acid composition will extend to all cell membranes including plasma membranes. Therefore, altered membrane fatty acid compositions may affect other membrane processes such as fatty acid uptake into the cell (43). Fatty acids also have to be transported intracellularly and activated by acyl-CoA synthetase, and so there are other enzyme activities whose modulation could contribute to the overall level of fatty acyl desaturation observed (44). Nonetheless, assaying fatty acyl desaturation/elongation in intact hepatocytes can

arguably be regarded as more accurately reflecting the effect of diet on all these processes compared to subcellular microsomal preparations. However, diet is known to directly affect desaturase activities in mammals (5,19) and the differential effects of an individual diet on Δ6, Δ5 and Δ6* activities suggest that much of the dietary effect may be on the desaturation/elongation enzyme systems themselves.

The results clearly demonstrated that 18:3n-3 and n-3 PUFA in general were the preferred substrates for desaturation in salmon hepatocytes, irrespective of diet. Less [1-^{14}C]18:3n-3 was recovered unmetabolized with a greater proportion recovered as desaturated products, compared to [1-^{14}C]18:2n-6. This observation is in agreement with previous studies in rats (3), rainbow trout (45), Atlantic salmon parr (23), and established fish cell lines (46). In contrast, it was noteworthy that a greater proportion of [1-^{14}C]18:2n-6 was converted by elongation to 20:2n-6 compared to the production of 20:3n-3 from [1-^{14}C]18:3n-3.

The MO/TO diet was formulated to contain more n-3 PUFA than the FO diet, with less of the long-chain monoenes, such as 20:1 and 22:1, characteristic of Northern Hemisphere fish oil. However, it was clear from the liver lipid data that the MO/TO diet resulted in fatty acid compositions very similar to the FO diet, and this was reflected in the fatty acid metabolism data where there were no differences between the two diets containing fish oil. However, the vegetable oil diets, SO, BO and OO, resulted in very significant effects on the liver phospholipid fatty acid compositions compared to the fish oil diets, and there were also clear differences between the diets containing fish oil and vegetable oils in their effects on PUFA metabolism. Most obvious was the fact that the desaturation of [1-^{14}C]18:3n-3 was considerably greater in hepatocytes from fish fed diets containing vegetable oils. The desaturation of [1-^{14}C]18:2n-6 was less affected but also tended to be increased in fish fed diets containing vegetable oils. It is probably appropriate to interpret such data as inhibition of fatty acyl desaturation by long-chain n-3 PUFA in the fish oil diets since such long-chain n-3 PUFA are known to be inhibitory to the desaturation of both 18:3n-3 and 18:2n-6 in rats (13,47,48) and rainbow trout (45). The present study confirms that in this respect fish are no different from mammals and that diets containing long-chain n-3 PUFA-rich fish oils suppress hepatic fatty acyl desaturation. Similarly, it was noteworthy that there was very little difference between SO and OO in their effects on hepatic fatty acyl desaturation in salmon. Previously it was shown that there was no difference in Δ6-desaturase activity in duodenal mucosa microsomes from dogs fed SO or OO (49).

Although the difference between diets containing fish oil and diets containing vegetable oil was very clear, the most significant finding in the present study was that BO greatly increased hepatic fatty acid desaturation. In hepatocytes from fish fed BO, the total desaturation products were double that found with any other diet and almost fourfold that of the lowest level of desaturation observed in the MO/TO diet. Dietary 18:3n-6 has been reported to have variable and conflicting effects in rats. An early study reported that 18:3n-6 in the form of evening primrose oil did not modify liver Δ6- or Δ5-desaturase activities in rats after 11 wk of feeding (50). However, in young rats fed a diet containing 18:3n-6, Δ5-desaturase activity was depressed (51). In contrast, a diet containing evening primrose oil depressed liver Δ6-desaturase activity in 8-mon-old rats but not in 3-wk-old rats (52). Borage oil (18:3n-6 only) and blackcurrant oil (18:3n-6 and 18:4n-3) both tended to decrease liver microsomal Δ6- and Δ5-desaturase activities in younger rats but tended to increase both activities in older rats (53). Clearly, age of the animal and possibly the different fatty acid compositions of the oils containing 18:3n-6 that were used in these studies have contributed to the conflicting data obtained. Certainly, rat liver Δ6-desaturase activity decreases with age (5), and it was shown that dietary supplementation of GLA in the form of evening primrose oil could reverse this aging effect in rats (54). There are no data on the effects of aging on desaturase activities in fish, but considering the very significant results from the present study, it appears that hepatic fatty acyl desaturation fish may be more affected by dietary GLA than in mammals.

The present study also revealed some other dietary effects that were noteworthy. Two-way ANOVA showed significant interactions indicating that the effects of the diets were dependent upon the substrate fatty acid used. For instance, the greatest effect of BO on the desaturation of 18:3n-3 was at the Δ5 level, whereas it was at the Δ6 level for the desaturation of 18:2n-6. Most previous work in mammals has focused on the effects of diet on Δ6-desaturase activity, regarded as the rate-limiting step of the desaturase pathway (5,19). Although some studies have also measured Δ5 desaturation, few have investigated the effects on 18:3n-3 metabolism or of dietary 18:3n-6 (12).

As the diet containing BO was significantly different from the diets containing SO and OO in its effects on fatty acid desaturation, the question must be what were the major differences in liver fatty acid compositions between the diets containing vegetable oil that may be influencing factors. Liver total lipid of salmon fed the BO, SO, and OO diets all had very similar levels of EPA, DHA, and total n-3 PUFA, and although there were slight differences in the distribution of n-3 PUFA in individual phospholipids between the diets containing vegetable oil, it was not likely that differences in n-3 PUFA inhibition were responsible. Total PUFA levels in liver phospholipids in the BO-fed fish were also very high indicating that a generally low PUFA level was not a factor. Similarly, the levels of 18:2n-6 and 18:3n-3 did not correlate with levels of desaturation activity as the level of 18:2n-6 in BO-fed fish was intermediate between SO and OO, and hepatic 18:3n-3 levels were very low in all diets. However, 20:3n-6, and to a lesser extent AA, were generally significantly higher in liver lipids in the BO-fed fish compared to all the other diets. AA is the preferred precursor substrate PUFA for eicosanoid synthesis in fish, despite EPA being more abundant in tissue phospholipids (15,55), and increasing the levels of 20:3n-6 in cell phospholipids significantly increases the

production of 1-series prostaglandins and inhibits the production of 2- and 3-series prostaglandins in fish (55). There are few data on the effects of eicosanoids on fatty acid desaturation, but it is possible that modulation of eicosanoids may play a role in the effect of GLA on hepatic fatty acid desaturation in the present study.

This was not a nutritional study, and so the direct application of the results in the modification of salmon diets in the future is limited. However, in the present study the vegetable oil diets did not result in significantly lower final weights compared to the control FO diet. There was considerable variation though, and fish on the SO diet were significantly lighter than fish on the TO/MO diet, suggesting that diets with very high 18:2n-6 were potentially detrimental. The study also showed that the vegetable oil diets increased the desaturation of [1-^{14}C]18:3n-3 in salmon liver, consistent with other studies that have shown that salmon can utilize vegetable oils, providing the oils contain sufficient 18:3n-3 to satisfy essential fatty acid requirements (28,30–32). In the previous studies, linseed oil diets were not associated with adverse effects, whereas sunflower oil diets were shown to have potentially detrimental effects in salmon (31). Recently, however, we have shown that a blend of 18:3n-3 and 18:2n-6 fed to salmon parr enhanced hepatic desaturase activities and were beneficial in effecting successful seawater transfer (23). Similarly, the present study has indicated that if vegetable oils are used to replace fish oils in salmon smolt diets, the inclusion of borage oil in the blends may be beneficial.

ACKNOWLEDGMENT

We thank all the S.O.A.E.F.D. personnel involved in running the Fish Cultivation Unit, Aultbea, Scotland, for their expertise and assistance with fish husbandry.

Docosahexaenoic Acid-Rich Fish Oil Does Not Enhance the Elevation of Serum Transaminase and Liver Triacylglycerol Induced by Carbon Tetrachloride in Mice

Satoshi Yasuda, Shiro Watanabe*, Tetsuyuki Kobayashi, and Harumi Okuyama

Department of Biological Chemistry, Faculty of Pharmaceutical Sciences, Nagoya City University, Nagoya 467, Japan

ABSTRACT: Carbon tetrachloride (CCl_4) is metabolized to trichloromethyl radical and induces liver injury with elevated serum transaminase and increased hepatic triacylglycerols (TG). To answer the question whether dietary polyunsaturated fatty acids (PUFA) enhance free radical-mediated liver injury, a docosahexaenoic acid (DHA)-rich fish oil (FO) or a saturated and monounsaturated fatty acid-rich beef tallow diet was fed to mice for 4 wk and then CCl_4 was administered. When thiobarbituric acid-reactive substances (TBARS) were measured in the absence of antioxidant, the FO diet and CCl_4 treatment markedly increased liver TBARS values synergistically, apparently supporting the interpretation that the highly autoxidizable DHA accelerates lipid peroxidation induced by CCl_4. However, no such marked interaction was observed between diet and CCl_4 treatment in liver TBARS values measured in the presence of an antioxidant in the assay mixtures as well as in conjugated diene contents. Furthermore, the FO diet did not enhance CCl_4-induced elevation of serum transaminase but lowered liver TG levels. The proportion of DHA, the most easily autoxidizable among common PUFA, was increased but those of eicosanoid precursors were decreased in liver phospholipids by CCl_4 treatment, possibly reflecting the inflammation-related mobilization of eicosanoid precursors but not lipid peroxidation. These results indicate that dietary enrichment with DHA does not enhance CCl_4-induced liver injury through the so-called free radical-mediated propagative autoxidation of DHA in mice.

Lipids 32, 1249–1255 (1997).

Dietary fish oil (FO) rich in the n-3 series fatty acids eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA) has been suggested to be beneficial for cardiovascular and inflammatory diseases (1,2). Inhibition of eicosanoid synthesis from arachidonic acid (20:4n-6, AA) by n-3 polyunsaturated fatty acids (PUFA) as well as their hypolipidemic effects is assumed to be possibly responsible for their beneficial effects (3). On the other hand, these n-3 PUFA have more methylenic hydrogens between the two double bonds than does arachidonic acid (AA), and in air are more easily autoxidized to lipid peroxides (4). In fact, liver microsomal membranes from rats fed an FO diet have been shown to be more susceptible to lipid peroxidation *in vitro* (5). In addition, elevated levels of lipid peroxides and reduced concentrations of α-tocopherol, an endogenous antioxidant, in blood and tissues have been observed in rats fed FO diets (6), although another study reported that the elevation of lipid peroxides caused by an FO diet was not prevented completely even in the presence of added antioxidants (7). These observations led to the concept that an intake of excess amounts of n-3 PUFA over n-6 PUFA stimulates so-called free radical-mediated diseases by enhancing lipid peroxidation in tissues, impairing the α-tocopherol status. A similar concept has been accepted widely as a free radical/lipid peroxide theory of aging, carcinogenesis, and atherosclerosis (8–12).

Carbon tetrachloride (CCl_4) has been used extensively to induce liver injury in experimental animals. CCl_4 is metabolized by liver microsomal cytochrome P-450 to the trichloromethyl radical ($CCl_3\cdot$), which incorporates O_2 to form the trichloromethylperoxy radical ($CCl_3O_2\cdot$) which then withdraws allylic hydrogens from PUFA to initiate lipid peroxidation (13). The peroxidative degradation of membrane PUFA is implicated in liver cell damage (14). Furthermore, the administration of α-tocopherol has been reported to lower the elevated lipid peroxide level and protect against liver injury in rats treated with CCl_4 (15–17).

This study was initially designed to assess the possibility that dietary supplementation with highly autoxidizable DHA may cause adverse effects on CCl_4-induced liver injury in the presence of α-tocopherol.

MATERIALS AND METHODS

Animals and diets. Female ICR mice at 3 wk of age (Shizuoka Laboratory Animals Co., Ltd., Shizuoka, Japan) were fed the test diets for 4 wk. The test diets were prepared by mixing a conventional diet (CE-2; Clea Japan, Inc., Tokyo, Japan) con-

Abbreviations: AA, arachidonic acid; ALT, alanine aminotransferase; AST, aspartate aminotransferase, BHT, butylated hydroxytoluene; BT, beef tallow; CCl_4, carbon tetrachloride; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FO, fish oil; PI, peroxidizability index; PL, phospholipid; PUFA, polyunsaturated fatty acid; TBARS, thiobarbituric acid-reactive substances; TG, triacylglycerol.

taining 3% (w/w) lipids and beef tallow (Wako Pure Chemical Co., Osaka, Japan) or DHA-rich FO (Harima Chemicals Inc., Tokyo, Japan) at 9:1 weight ratio and the final lipid content was 12.7% (w/w) (29.7 energy percentage). The fatty acid compositions of the diets are shown in Table 1. A peroxidizability index (PI) was calculated by Equation 1 (Ref. 18):

$$\% \text{ monoenoate} \times 0.025 + \% \text{ dienoate} \times 1 + \% \text{ trienoate} \times 2 + \% \text{ tetraenoate} \times 4 + \% \text{ pentaenoate} \times 6 + \% \text{ hexaenoate} \times 8 \quad [1]$$

α- and γ-Tocopherol concentrations in the test diets were adjusted to 190 and 530 mg/kg of diet, respectively, by adding α-tocopherol (Sigma, St. Louis, MO) and γ-tocopherol (Ohta Oil Co., Ltd., Aichi, Japan). The test diets were kept frozen at −20°C for less than 2 wk until serving. Diets were replaced every other day to keep the peroxide values of ingested diets below 30 meq/kg of oil. Mice were kept at 23 ± 2°C and given free access to the test diets.

CCl_4 administration. After 4 wk of feeding, mice were injected subcutaneously with 1 mL of CCl_4/kg dissolved in olive oil or with olive oil only (vehicle-treated control). Mice were sacrificed 24 h after the injection to obtain blood and liver, or at 30 min after the injection for the determination of conjugated dienes (19). The excised livers were frozen quickly in liquid nitrogen. Sera and livers were stored at −20 and −80°C, respectively, until analysis.

Determination of thiobarbituric acid-reactive substances (TBARS) in liver. Liver was weighed and homogenized in cold 1.15% KCl to prepare 10% (wt/vol) homogenates. The content of TBARS in the liver homogenate was measured according to the method of Ohkawa *et al*. (20) or Kikugawa *et al*. (21). The two methods differed in that the coloring reactions were developed in the absence (20) or the presence (21) of butylated hydroxytoluene (BHT) (200 μg/mL of reaction mixture). A calibration curve for the quantitation of liver TBARS content was established by using known amounts of malonaldehyde-bis(dimethylacetal) (Aldrich, Milwaukee, WI).

Determination of conjugated dienes in liver. Liver was weighed and homogenized in cold 0.3 M sucrose and 3 mM EDTA (pH 7.4) to yield 10% (wt/vol) homogenates. The conjugated diene content of total lipids extracted by Bligh and Dyer method (22) was determined by measuring the optical density at 233 nm and was expressed as nmol of diene equivalent/gram liver ($\varepsilon = 27{,}000\ M^{-1}\ cm^{-1}$) (23).

Determination of alanine aminotransferase and aspartate aminotransferase activities in serum. Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities were measured using a spectrophotometric method (24). For the determination of serum ALT activity, serum samples were incubated in 500 mM L-alanine, 12 mM 2-oxoglutarate, 100 mM Tris, 0.18 mM NADH, 0.11 mM pyridoxal phosphate, and 1200 U/L lactate dehydrogenase (pH 7.3). On the other hand, serum samples were incubated in 240 mM L-aspartate, 12 mM 2-oxoglutarate, 91 mM Tris, 0.16 mM NADH, 0.11 mM pyridoxal phosphate, 420 U/L lactate dehydrogenase, and 930 U/L malate dehydrogenase (pH 7.8) for AST determination.

Determination of tocopherols. α- and γ-Tocopherols were extracted from serum with *n*-hexane and those from liver and diet were extracted with chloroform/methanol (22). The extract of diets was saponified with 1 N ethanolic KOH in the presence of 5.5% (wt/vol) of pyrogallol and, the tocopherols were extracted with *n*-hexane. The tocopherol isomers were measured by straight-phase high-performance liquid chromatography (25,26) on a LiChrosorb 5 NH_2 column (4.6 × 150 mm) (GL Sciences Inc., Tokyo, Japan) equilibrated with *n*-hexane/isopropanol (98:2, vol/vol) (0.8 mL/min) at 40°C. The elution of tocopherol isomers was monitored fluorometrically (excitation at 298 nm and emission at 325 nm). 2,2,5,7,8-Pentamethyl-6-hydroxychroman (Wako) was added prior to the extraction steps as an internal standard.

Analyses of triacylglycerol (TG) and phospholipid (PL) in serum and liver. Total lipids were extracted from serum and liver according to the method of Bligh and Dyer (22). TG and PL were separated by thin-layer chromatography on a silica gel plate with petroleum ether/diethyl ether/acetic acid (80:30:1, by vol) as a developing solvent. The lipids were visualized under ultraviolet light after spraying with an ethanolic solution of Rhodamine 6G (Tokyo Kasei; Tokyo, Japan) and were extracted from the adsorbent by the method of Bligh and Dyer (22). Fatty acids in the TG and PL fractions were converted to methyl esters by treatment with 5% (wt/vol) HCl in methanol for 1 h in a boiling water bath and then quantitated by gas–liquid chromatography using a capillary column (DB-225; J&W Scientific, Folsom, CA). A triheptadecanoylglycerol and a 1,2-diheptadecanoyl-L-α-phosphatidylcholine

TABLE 1
Fatty Acid Composition of Experimental Diets[a]

Fatty acid	Beef tallow diet	Fish oil diet
14:0	2.0	2.0
16:0	23.5	14.7
16:1	2.2	4.5
18:0	13.6	2.5
18:1n-9[b]	39.3	16.2
18:2n-6	15.8	16.7
18:3n-3	1.2	1.8
20:1	0.6	1.3
20:4n-6	0.1	1.7
20:5n-3	0.6	7.0
22:5n-6	n.d.	1.6
22:6n-3	0.6	29.5
n-6/n-3[c]	6.43	0.53
PI[d]	30.0	316.5

[a]The fatty acid composition in the diets (% of total fatty acids) was analyzed by gas–liquid chromatography. n.d., not detected.
[b]The position of the double bond numbered from the methyl terminus is designated as n-9, n-6, or n-3.
[c]n-6/n-3 indicates the total n-6 fatty acids/total n-3 fatty acids ratio.
[d]Peroxidizability index = (% monoenoate × 0.025) + (% dienoate × 1) + (% trienoate × 2) + (% tetraenoate × 4) + (% pentaenoate × 6) + (% hexaenoate × 8) (Ref. 18).

(Sigma) were added prior to lipid extraction as internal standards for the quantitation of TG and PL, respectively.

Statistical analysis. Data are presented as means ± SD. The significance of the effects of diet, CCl_4 treatment, and their interaction were analyzed by a two-way analysis of variance (StatView-J 4.02, Abacus Concepts Inc., Berkeley, CA). A probability below 0.05 was considered significant.

RESULTS

Content of TBARS in liver. Determinations of TBARS in tissues have been used extensively as an assay of lipid peroxides. We first performed the TBARS assay without adding antioxidant to the reaction mixture for the coloring reaction, which corresponds to the original method reported by Ohkawa *et al.* (20). Liver TBARS contents were significantly increased by each FO diet ($P < 0.0001$) or CCl_4 treatment ($P < 0.0001$), and their interaction was also significant ($P < 0.0001$), indicating that an FO diet and CCl_4 treatment synergistically increased TBARS contents of liver (Fig. 1A). In contrast, when the TBARS assay was performed in the presence of BHT in the reaction mixture for the coloring reaction (21), the overall liver TBARS contents decreased to approximately one-tenth of those observed without BHT (Fig. 1B). The TBARS content was significantly higher in the FO diet group than in the beef tallow (BT) diet group ($P < 0.05$), but the significant effect of CCl_4 treatment observed in the original TBARS assay (Fig. 1A) disappeared. We confirmed that BHT itself did not interfere directly with the coloring reaction of thiobarbituric acid and malondialdehyde, indicating that most of the TBARS in the absence of BHT were actually produced during the assay.

Conjugated diene content in liver. Since Kim and LaBella (19) have reported that the levels of conjugated dienes in liver peaks 30 min after CCl_4 administration, and then decreases to near the unstimulated levels by 24 h, we determined conjugated diene contents in liver at 30 min after CCl_4 treatment (Fig. 2). The conjugated diene contents of liver were slightly but significantly higher in the FO diet group than in the BT diet group ($P < 0.05$) and tended to increase after CCl_4 treatment ($0.05 < P < 0.1$), although no significant interaction between the diet and CCl_4 treatment was observed.

Serum and liver α-tocopherol concentrations. As α-tocopherol status might be further impaired when the FO diet was combined with CCl_4 treatment (6,27), we determined α-tocopherol concentrations in the sera and livers of mice fed BT or FO diets in the absence or presence of CCl_4 treatment (Fig. 3). In the vehicle-treated mice, the serum α-tocopherol concentration in the FO diet group was significantly lower than in the BT diet group ($P < 0.01$) (Fig. 3A). CCl_4 treatment significantly decreased the serum α-tocopherol concentration in the BT diet group but not in the FO diet group. On the other hand, liver α-tocopherol concentrations were significantly lower in the FO diet group than in the BT diet group ($P < 0.0001$) but were not influenced by CCl_4 treatment (Fig. 3B).

CCl_4-induced liver injury. As shown above, the FO diet and CCl_4 treatment synergistically increased the TBARS content in liver. Therefore, we examined the severity of liver injury by measuring serum transaminase activities, ALT and AST, after CCl_4 treatment. CCl_4 treatment markedly increased these transaminase activities in serum in both the BT and FO diet groups as compared with the respective vehicle-treated control groups (Fig. 4). However, no significant difference was observed in both ALT and AST activities of the two dietary groups.

TG and PL in serum and liver. Feeding the FO diet lowered the serum PL concentration significantly ($P < 0.01$) (707 ± 129 mg/mL in the BT diet group and 464 ± 112 mg/mL in the FO diet group, $n = 10$), but serum TG concentrations were not much different ($0.05 < P < 0.1$) (751 ± 340

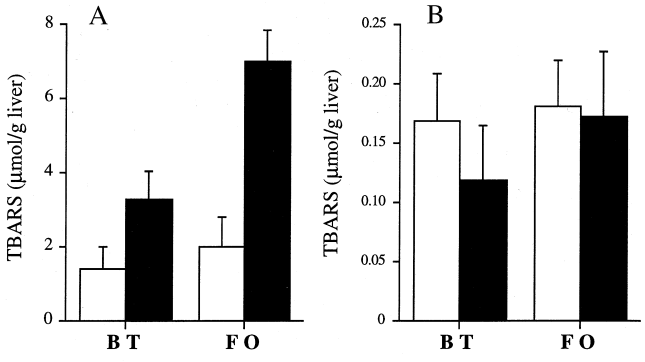

FIG. 1. Liver thiobarbituric acid-reactive substances (TBARS) contents determined without (A) or with (B) butylated hydroxytoluene (BHT) in the reaction mixture (200 μg/mL). Female ICR mice were fed beef tallow (BT) or fish oil (FO) diets for 4 wk and were sacrificed 24 h after vehicle (open bar) or carbon tetrachloride (CCl_4) (solid bar) treatments (1 mL of CCl_4/kg). In the two-way analysis of variance (ANOVA), there were effects of diet ($P < 0.0001$), CCl_4 treatment ($P < 0.0001$) and the interaction between diet and CCl_4 treatment ($P < 0.0001$) in liver TBARS (−BHT) (A); and there was an effect of diet ($P < 0.05$) in liver TBARS (+BHT) (B). Each column with a bar represents the mean ± SD for eight mice.

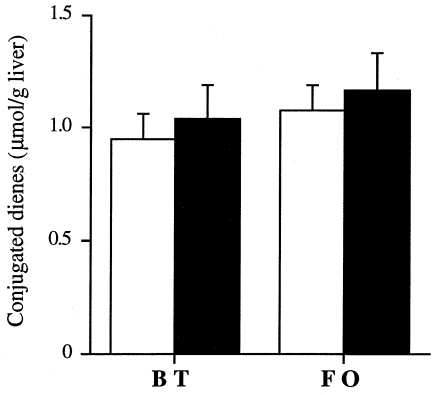

FIG. 2. Liver conjugated diene contents in mice fed BT or FO diets for 4 wk. Samples were taken 30 min after vehicle (open bar) or CCl_4 (solid bar) treatments. Liver conjugated dienes were assayed by measuring optical density at 233 nm and expressed as nmol of diene equivalent/gram liver. In the two-way ANOVA, there was an effect of diet ($P < 0.05$) but not CCl_4 treatment ($P = 0.082$). Each column with a bar represents the mean ± SD for seven to eight mice. See Figure 1 for abbreviations.

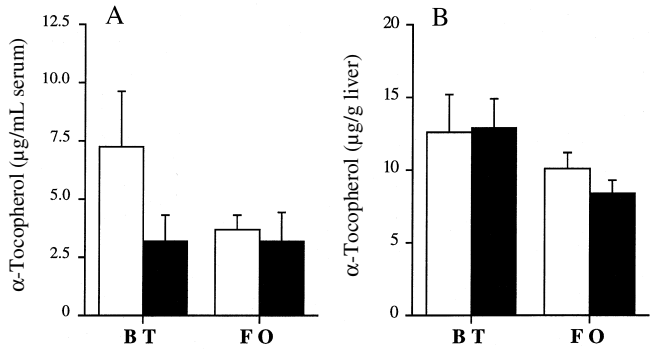

FIG. 3. Serum (A) and liver (B) α-tocopherol contents in mice fed BT or FO diets for 4 wk. Samples were taken 24 h after vehicle (open bar) or CCl_4 (solid bar) treatments. In the two-way ANOVA, there were effects of diet ($P < 0.005$), CCl_4 treatment ($P < 0.0005$), and the interaction between diet and CCl_4 treatment ($P < 0.005$) on serum α-tocopherol (A); and there was an effect of diet ($P < 0.0001$) on liver α-tocopherol (B). Each column with a bar represents the mean ± SD for seven to eight mice. See Figure 1 for abbreviations.

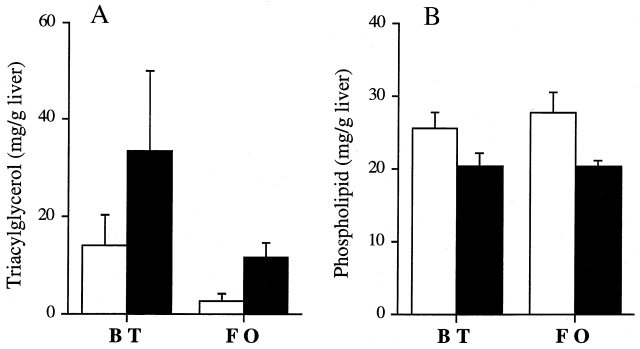

FIG. 5. Liver triacylglycerol (TG) (A) and phospholipid (PL) (B) contents of mice fed BT or FO diets for 4 wk. Samples were taken 24 h after vehicle (open bar) or CCl_4 (solid bar) treatments. Lipids were extracted from liver with chloroform/methanol, and TG and PL were separated by thin-layer chromatography on a silica gel and quantified by gas–liquid chromatography. In the two-way ANOVA, there were effects of diet ($P < 0.001$) and CCl_4 treatment ($P < 0.005$) but not of the interaction between diets and CCl_4 treatment on liver TG (A); and there was an effect of CCl_4 treatment ($P < 0.0001$) on liver PL (B). Each column with a bar represents the mean ± SD for five mice.

mg/mL in the BT diet group and 506 ± 269 mg/mL in the FO diet group, $n = 10$). There was no significant influence of CCl_4 treatment on the levels of either serum lipid (data not shown). In the vehicle-treated control groups, the liver TG concentration in the FO diet group was significantly lower than in the BT diet group (Fig. 5A). CCl_4 treatment significantly increased liver TG concentrations in both dietary groups. The interaction between the diet and CCl_4 treatment was not significant, although the level obtained by CCl_4 treatment in the FO diet group was still lower than in the BT diet group. In contrast, liver PL concentrations were significantly decreased by CCl_4 treatment in both dietary groups with no difference being observed between the two groups (Fig. 5B).

The fatty acid compositions of liver PL differed markedly between the FO and BT diet groups; the proportions of EPA (20:5n-3) ($P < 0.0001$) and DHA (22:6n-3) ($P < 0.0001$) were significantly increased whereas those of linoleic acid (18:2n-6) ($P < 0.0001$) and AA (20:4n-6) ($P < 0.0001$) were decreased in the FO diet group as compared with the BT diet group (Table 2). These differences in the proportions of PUFA led to a significant elevation of PI values in the FO diet group as compared with the BT diet group. Furthermore, notable changes associated with CCl_4 treatment were significant increases in the proportion of DHA ($P < 0.05$) and decreases in those of dihomo-γ-linolenic acid (20:3n-6) ($P < 0.0001$), AA ($P < 0.0001$) and EPA ($P < 0.005$), all eicosanoid precursors, in the liver PL of both dietary groups.

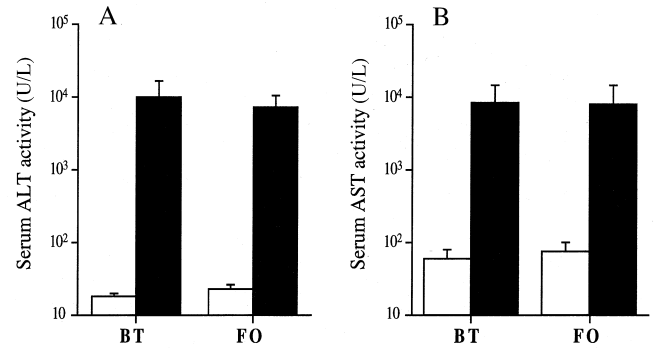

FIG. 4. Serum alanine aminotransferase (ALT) (A) and aspartate aminotransferase (AST) (B) activities in mice fed FO or BT diets for 4 wk. Samples were taken 24 h after vehicle (open bar) or CCl_4 (solid bar) treatments. In the two-way ANOVA, there was an effect of CCl_4 treatment ($P < 0.0001$) but not of diet on serum ALT (A) and AST (B) activities. Each column with a bar represents the mean ± SD for six to eight mice. See Figure 1 for abbreviations.

DISCUSSION

The TBARS assay detects mainly aldehydes formed as decomposition products of lipid peroxides (20). The conjugated diene assay relies on the rearrangement of 1,4-nonconjugated dienes to the conjugated diene form (19); this assay will also detect hydroxylipids having conjugated dienes (i.e., reduction products of lipid hydroperoxides). A more direct method for detecting PL hydroperoxides, a chemiluminescence-high-performance liquid chromatography method was developed, and by using this assay, significantly increased levels of phosphatidylcholine hydroperoxides were noted in livers of rats fed an FO diet (15) or administered CCl_4 (27). However, the values reported for serum PL hydroperoxides differ significantly among different laboratories (15,28), and the extent to which hydroperoxides produced during assays contribute to the measured values has not been evaluated accurately.

In the present study, dietary FO and CCl_4 treatment markedly increased liver TBARS contents measured in the absence of BHT in a synergistic manner, but no such marked effect was apparent in liver TBARS values measured in the presence of BHT and in conjugated diene contents (Figs. 1 and 2). These results suggest that significant amounts of BHT-

inhibitable artifacts (>90% of the values) are formed during the coloring reaction used for the original and most of modified TBARS assays. Furthermore, we suspect that lipid peroxides generated at higher rates *in vivo* in FO diet group might be cleared rapidly by endogenous antioxidants as well as antioxidative enzyme systems. Garrido *et al.* (5) have shown that liver microsomal membranes isolated from rats fed FO diet are more susceptible to *in vitro* oxidative stress induced by NADPH-ferric ion-ADP to produce greater amounts of TBARS. However, their study determined TBARS values in the absence of antioxidant in the assay, and isolated membranes are deficient of scavenger systems such as glutathione peroxidases, endogenous antioxidant vitamins, and their reducing enzyme systems present *in vivo*. Thus, the TBARS values measured in the absence of antioxidant as well as peroxidizability of isolated membrane preparations do not appear to reflect *in vivo* phenomena. A more specific, easy, and reliable assay for determining lipid peroxides present in tissues is still required, but our data indicate that liver lipid peroxides measured as TBARS with antioxidant BHT and as conjugated dienes are not increased by the CCl_4 treatment to levels which the difference in PI values of the diets predicts; more than a 10-fold difference in PI values of the diets resulted in less than a 1.15-fold difference in conjugated diene contents .

The fact that feeding highly autoxidizable PUFA decreases the concentrations of tissue α-tocopherol in animals (6) and humans (29) has been interpreted as being the consequence of oxidative consumption of α-tocopherol and has led to the suggestion for an increased dietary α-tocopherol requirement. However, serum α-tocopherol is transported by lipoproteins, and its concentration appears to be regulated both by the amounts and types of dietary fats (30,31). In addition, the tissue lipid contents also influence the tissue α-tocopherol levels (30,31). Therefore, the reduction of α-tocopherol concentrations in serum and liver by the FO diet (Fig. 3) might well be the consequence of decreased serum and liver lipid levels induced by FO (31). Furthermore, CCl_4 treatment caused no further reduction of α-tocopherol concentrations in either the serum or liver of mice fed the FO diet but did reduce serum α-tocopherol in the BT diet group (Fig. 3). We interpret that α-tocopherol status is not an indirect index for lipid peroxide tone in body but is more a reflection of lipid metabolism (i.e., the amounts of lipids in blood and tissues).

CCl_4 treatment induces TG accumulation in liver by inhibiting lipoprotein secretion (32). Although fatty liver was induced similarly in both the BT and FO diet groups, the liver TG concentration in the FO diet group was significantly lower than in the BT diet group, apparently indicating that the FO diet suppressed fatty liver induction by CCl_4 treatment. We have no evidence that easily autoxidizable DHA suppressed CCl_3·-induced liver injury, but most probably the relatively lower TG content in liver of the FO diet group is a consequence of decreased TG synthesis associated with preferential β-oxidation of DHA in peroxisomes (33).

Liver PL concentrations were reduced by CCl_4 treatment but not affected by dietary fatty acids (Fig. 5B). One might assume that the observed reduction of liver PL concentrations

by CCl_4 treatment is due to free radical-initiated degradation of PL enriched with autoxidizable PUFA. However, the decreases in liver PL concentrations were similar between the BT and FO diet groups (Fig. 5), despite significantly higher PI values of liver PL from the FO diet group (Table 2). In addition, it should be noted that no preferential decrease in DHA content was observed, but rather it increased, and dihomo-γ-linolenic acid, AA, and EPA all decreased in liver PL after CCl_4 treatment (Table 2). These observations indicate that mechanism(s) other than peroxidative consumption of PUFA account for the reduction of liver PL concentrations during CCl_4 treatment. Furthermore, the autoxidizabilities of PUFA estimated for air (4) appear not to be applicable to the observed changes in PUFA *in vivo* during CCl_4-induced liver injury. The amount of DHA, which is more easily autoxidizable than AA in air atmosphere, was relatively unchanged whereas that of AA was reduced by CCl_4 treatment. We suggest that CCl_4 treatment is toxic to PL-synthesizing enzymes and other enzymes in liver and may activate phospholipases to mobilize dihomo-γ-linolenic acid, AA and EPA, but that DHA is relatively stably enriched in PL under these conditions (Table 2). In fact, an *in vitro* study has indicated that AA is released upon exposure of hepatocytes to CCl_4, independent of free-radical generation by CCl_4 metabolism (34).

Needless to say, CCl_4 treatment under antioxidant deficiency leads to irreversible oxidative damage through lipid peroxidation as evidenced by elevated ethane exhaustion, an alternative measure of lipid peroxidation *in vivo*, and increased mortality in rats (35). In the presence of appropriate amounts of antioxidants and antioxidative enzyme systems, however, *in vivo* evidence is lacking that feeding highly autoxidizable PUFA such as α-linolenic acid, EPA, and DHA accelerates the development of oxidative stress-induced injury. Contrarily, many lines of evidence have indicated that long-term feedings of oils enriched in α-linolenic acid, EPA, or DHA suppress the so-called free radical diseases (i.e., aging, carcinogenesis, and atherosclerosis) as summarized elsewhere (36).

Fatty Acid Carbon Isotope Ratios in Humans on Controlled Diets

Sue K. Rhee[a], Roberta G. Reed[b], and J. Thomas Brenna[a,*]

[a]Division of Nutritional Sciences, Cornell University, Ithaca, New York 14853, and [b]M.I. Bassett Research Institute, Cooperstown, New York 13326

ABSTRACT: Carbon stable isotope ratios for six serum fatty acids (FA) are reported for human subjects on controlled fat diets to determine the range of natural isotope abundance and to demonstrate the leveling effect of a well-controlled diet. Twenty-nine subjects were randomly assigned to one of three controlled diets containing high, medium, or low fat. Diets were consumed for 8 wk. Serum samples were collected at baseline (0), 5, 6, 7, and 8 wk. FA were extracted and methylated. Isotope ratios were analyzed by high-precision gas chromatography combustion–isotope ratio mass spectrometry. At baseline, mean $\delta^{13}C$ for 16:0[b], 16:1[a], 18:0[a], 18:1[c], 18:2n-6[d], and 20:4n-6[bc] were –24.1, –21.7, –21.6, –25.6, –29.6, and –25.0‰, respectively, with an average standard deviation of 1.9‰. Most $\delta^{13}C$ decreased during the diet period and appeared to have stabilized by week 5 at –25.3, –21.9, –22.3, –26.5, –30.1, and –24.5‰, respectively. Between-subject variability decreased from 1.74 to 1.20‰ on the controlled diets. Measurement variability was 0.53‰. The within-subject variability during weeks 5–8 was 0.57‰ (range of 0.32–0.84‰), showing a minimum biological fluctuation on controlled diets. There was no diet group effect on $\delta^{13}C$ of serum FA. Except for 18:2, the $\delta^{13}C$ of experimental diets was lower than that of serum FA, consistent with observations in animals. These data show that carbon isotope ratios stabilize in response to controlled diets within 5 wk, reflecting the isotope ratio of their dietary source, and establish isotope ratio fluctuations for endogenous compounds for future studies.

Lipids 32, 1257–1263 (1997).

Stable isotopes are increasingly used for metabolic studies where radiotracers are undesirable and for studies involving natural variability where radiotracers are not applicable. Rapidly advancing high-precision mass spectrometry instrumentation and methods have particularly expanded the range of stable isotope nutritional studies. Familiar nutritional applications using high-precision tracer analysis include doubly labeled water for energy expenditure (1), labeled amino acids for protein turnover (2), and a variety of ^{13}C substrate-based breath tests (3–6). Elucidation of the human nutritional implications of stable isotope variation due to natural processes has been slow, but such information is widely used for ecological studies including diet studies in free-living animals, insects, and plants (7).

Thus far, few baseline $^{13}C/^{12}C$ studies have been reported; the few that have appeared are limited in subject number: serum cholesterol in 4 subjects (8) and in 1 subject (9), and urinary steroids (10) in 12 subjects. Mendelsohn *et al.* (8) evaluated the feasibility of using stable ^{13}C as a tracer for studying cholesterol metabolism *in vivo* by measuring ^{13}C content of commonly consumed foods and the stability of the ^{13}C content of serum cholesterol in four adults living in South Africa. They reported a very small difference between the carbon isotope composition of the diet and the cholesterol and no significant change of human serum cholesterol over time. Guo *et al.* (9) evaluated baseline fluctuations for stable isotope studies of human cholesterol metabolism. Becchi *et al.* (10) measured $^{13}C/^{12}C$ isotope ratio of urinary steroids to detect misuse of testosterone in sports. Their data suggest that the constant difference in $\delta^{13}C$ between precursor cholesterol and product testosterone can be exploited to detect the presence of exogenous synthetic testosterone, which generally has a $\delta^{13}C$ different from that of endogenous human testosterone, and thereby serves as a test for illicit use of performance-enhancing endogenous drugs.

The natural $^{13}C/^{12}C$ ratio in biological materials including food and tissues varies over about 1.09 ± 0.1 atom %. It is related to several factors, most prominently the mix of C_3 and C_4 plants from which dietary carbon is ultimately derived, the amount of marine food in the diet, the mixture of metabolic fuels, and the subject's physiological state (11). Background levels and their fluctuations must be established to permit calculation of excess isotope representing tracer. A recent study evaluating hydrogen and oxygen variability among waters showed that estimates of CO_2 production by the doubly labeled water method derive two-thirds of their variability from natural baseline fluctuations (3.23% of 4.90% coefficient of variation) (12). Real biological (between-subject) variability in any measured analyte contributes to overall error and must be taken into account in power calculations to establish subject numbers and dose sizes for tracer studies.

The recent wide availability of high-precision gas chromatography–combustion isotope ratio mass spectrometry

(GCC–IRMS) facilitates stable isotope studies of individual biomolecules. Examples of human nutrition applications using artificial and natural tracers include work with fatty acids (FA) (3,14–16), and glucose kinetics (17).

Since normal FA $^{13}C/^{12}C$ fluctuations in free-living humans depend on dietary intake, minimum fluctuations can only be evaluated in subjects on a controlled diet. The relationship of dietary FA $^{13}C/^{12}C$ to plasma FA $^{13}C/^{12}C$ has yet to be established. Here, we report measurement of the $^{13}C/^{12}C$ ratio of six serum FA in 29 humans upon entry and during an 8-wk controlled diet trial to establish (i) the range of FA $^{13}C/^{12}C$ upon entry, (ii) the stabilization of FA $^{13}C/^{12}C$ after 5–8 wk on a controlled diet, (iii) the relationship of serum FA $^{13}C/^{12}C$ to dietary FA 13C/12C, and (iv) trends in the absolute serum FA $^{13}C/^{12}C$.

MATERIALS AND METHODS

Subjects and diets. Twenty-nine healthy adults, recruited as a part of the multicenter Dietary Effects on Lipoproteins and Thrombogenic Activity study described in detail elsewhere (18–20), were included in the current analysis. Briefly, subjects were randomly assigned to one of three controlled diets differing only in saturated fat content. The controlled diets were identical in all nutrients except for fat and were consumed for 8 wk. Diets were designed to provide 37, 30, and 26% of calories as fat with 16, 9, and 5% calories as saturated fatty acid, designated as Average American Diet (AAD), Step One (S1), or Very Low Saturated Fatty Acid (SFA) Diet (LS), respectively. Calories were made up with carbohydrate for diets S1 and LS, and all other components including monounsaturated FA at 14% of total calories, polyunsaturated FA at 7% of calories, and cholesterol, at 300 mg/d, were held constant. Diets were prepared by adding different amounts of various fats to otherwise low-fat meals. All fat sources were centrally procured in single lots that were used for the entire study to ensure uniformity. Fasting blood samples were collected before the study (0) and during weeks 5, 6, 7, and 8 of the controlled diet period.

Extraction and methylation. Serum was separated from red blood cells by centrifugation at 4°C and stored at −80°C. A 200-μL serum sample was saponified using 2 mL of 0.5 N KOH in ethanol with heating at 60°C for 1 h (21). After cooling to room temperature, nonsaponifiables were removed by washing twice with 2 mL of hexane, and internal isotopic standard heptadecanoic acid was added. The samples were then acidified with 1 mL of 1 N HCl, and 2 mL hexane was added. The total lipids were extracted by taking the upper hexane layer (22). Fatty acid methyl esters (FAME) were prepared by adding 1 mL 14% BF_3 in methanol and heating at 100°C for 4 min. Hexane (2 mL) was then added and the tubes vortexed. After 2 mL of saturated NaCl solution was added, tubes were centrifuged at 3,000 rpm, and the top hexane layer containing the FAME was transferred to another tube. The FAME were dried under N_2 and resuspended in a measured amount of hexane for analysis. All serum samples were split into two aliquots, which were extracted, treated, and analyzed in parallel. Replicate aliquots were used to assess measurement error reflecting total error for extraction, methylation, and instrument error.

Homogeneous aliquots of each of the three diets were prepared for FA isotope ratio analysis (23,24). Eight daily menus, representing a complete diet cycle, were frozen and shipped to the Food Analysis Laboratory Control Center at Virginia Tech University. Each eight-menu sample was composited and individual aliquots removed for fatty acid isotopic analysis. Samples of 0.1–0.2 g were extracted with 10 mL total of solvent in duplicate, and were prepared using the same method as for serum.

Isotopic analysis and calculations. FAME prepared from 16:0, 16:1, 18:0, 18:1, 18:2n-6, and 20:4n-6 were analyzed by GCC–IRMS, which has been described in detail elsewhere (25). Briefly, a Varian 3400 GC (Varian Analytical Instrument, San Fernando, CA) was connected to an 850°C combustion furnace linked to a Finnigan MAT 252 (Bremen, Germany) high sensitivity, high-precision IRMS for $^{13}C/^{12}C$ ratio analysis. The GC was equipped with a J&W DB-23 (60 m × 0.32 mm i.d., 0.25 μm film thickness) column. The combustion furnace was nominally held at 850°C and contained oxidized Cu wire and Pt as a catalyst. The GC effluent was directed by He carrier gas into a combustion furnace where organic compounds were quantitatively converted into CO_2 and H_2O. The water was trapped in a Nafion (DuPont, Wilmington, DE) tube, and only CO_2 gas was admitted to the ion source of a Finnigan 252 IRMS, with dedicated detectors for three major ions, m/z = 44, 45, and 46, and absolute sensitivity of about 103 molecules/ion detected. The isotope ratio $^{13}C/^{12}C$ was calculated using the m/z = 46 to correct the contribution of ^{17}O-substituted CO_2 appearing at m/z = 45. The analytical precision of replicate measurements is <0.3‰.

The standard notation for expression of high-precision gas IRMS is the $\delta^{13}C$ notation defined as in Equation 1.

$$\delta^{13}C = \left(\frac{R_{SPL} - R_{PDB}}{R_{PDB}}\right) \times 1000 = \left(\frac{R_{SPL}}{R_{PDB}} - 1\right) \times 10 \qquad [1]$$

where $R_x = {}^{13}C/{}^{12}C$ and SPL refers to the sample and PDB refers to the international standard Pee Dee Belemnite, R_{PDB} = 0.0112372. Most PDB was chosen as a standard partly because it is relatively rich in ^{13}C; the carbon of most biological compounds is depleted in ^{13}C relative to this standard owing to fractionation during photosynthesis so that most compounds are described with a negative $\delta^{13}C$. The notation emphasizes that high precision is achieved as a relative measure, and has the convenient feature of eliminating several leading, unchanging digits. For example, R = 0.0112372 and R = 0.0112260 correspond to $\delta^{13}C$ = 0‰ and −1‰, respectively. Interpretation is considerably simplified as the analytical precision is typically SD ($\delta^{13}C$) < 0.4‰, and most biological compounds derived from contemporary life are in the $\delta^{13}C$ = −5 to −40 range.

TABLE 1
$\delta^{13}C$ of Six Serum Fatty Acids from 29 Free-Living Adults[a]

Fatty acid	$\delta^{13}C$ Mean	SD
16:0	–24/07[b]	1.74
16:1	–21.68[a]	2.37
18:0	–21.64[a]	1.10
18:1n-9	–25.59[c]	1.59
18:2n-6	–29.63[d]	1.58
20:4n-6	–24.98[b,c]	2.77
Average	–24.60‰	1.86‰

[a]Different superscripts (a–d) indicate significant difference at the level of $\alpha = 0.05$.

Carbon within a molecule is converted to CO_2 prior to analysis so that all positions contribute to measured isotope ratio. Derivative carbon isotope ratios reflect both the isotopic composition of the reagent and any kinetic isotope effects associated with the derivatization reaction. This latter effect mandates the use of an empirical internal standard since the reagent carbon isotope ratio cannot be taken as representative of the derivative carbon. This effect is implicitly taken into account in tracer studies where a baseline isotope ratio is subtracted. However, for studies of absolute isotope ratio such as this, an internal isotopic standard is required. FA $\delta^{13}C$ (‰) were corrected using C17:0 with known isotope ratio as reported previously (26). When no artificially enriched tracers are involved, a mass balance equation can be used for the isotope ratio of the derivative methyl group as described previously (15), in Equation 2.

$$n_{FAME}\,\delta^{13}C_{FAME} = \delta^{13}{}_{Me} + n_{FA}\,\delta^{13}C_{FA} \qquad [2]$$

where n_{FA} is the moles of C per mole FA, and the subscripts Me, FA, and FAME refer to the methyl group, the FA, and the measured FAME, respectively. $\delta^{13}C$ for the methyl group is assumed to be uniform for all FAME and identical to that for the internal standard Me17:0.

Statistical analysis. The Statistical Analysis System, SAS 6.11 (SAS Institute, Cary, NC) was used for regression and analysis of variances. The mixed model procedure was employed for assessment of within-subject, biological (between-subject), and measurement variability. Tukey's pairwise comparison at the level of $\alpha = 0.05$ was used for comparing means among treatments in Minitab Release 11.11 (Minitab, Inc., State College, PA).

RESULTS

FA $^{13}C/^{12}C$ upon entry. Means and standard deviations in $\delta^{13}C$ (‰) units for six serum FA in 29 subjects upon entry into the study are presented in Table 1. At baseline, the mean $\delta^{13}C$ ranged from –29.6 for 18:2 to –21.64 for 18:0, respectively, with an average of –24.60‰. The average standard deviation was 1.86‰ for all six FA. Since the overall analytical error for workup and isotopic analysis is <0.6‰, the predominant factor in the standard deviation is real biological variability.

Time and diet effect. The mean $^{13}C/^{12}C$ ratios of six serum FA were similar for all three diet groups; for brevity Table 2 summaries the data for S1 Diet only. There are significant and persistent differences between FA. In this group, only the last 18:1 isotope ratio is significantly different from the baseline, which may reflect the relatively large pool of this FA. Figure 1 presents a plot of the ^{13}C content of serum FA in group AAD from 0 through 8 wk to illustrate the effects of continuing diet consumption. The ^{13}C content of serum FA changed substantially from week 0 to week 5 and then stabilized through week 8; plots from diet groups S1 and LS were qualitatively similar. From the analysis of variance, there was a significant time effect in each of the six FA, indicating the controlled diets did alter the $^{13}C/^{12}C$ of serum FA.

To test the hypothesis that the isotope ratios were stable in the latter part of the diet period from weeks 5 through 8, a linear regression was performed using each of the six FA isotope values for weeks 5–8 for each subject with the resulting significance of the slopes evaluated. Only 14 of the 174 slopes, or about 8%, were significantly different from 0 at the

[a]Groups Average American Diet (AAD) and Very Low Saturated Fatty Acid Diet (LS) were similar. Each number in parentheses reflects standard deviation of 10 subjects in the diet group. Different letter superscripts (a,b) indicate significant difference among times at the level of $\alpha = 0.05$; different number superscripts (1–5) indicate significant difference among fatty acid (FA) at the level of $\alpha = 0.05$. S1, Step One Diet.

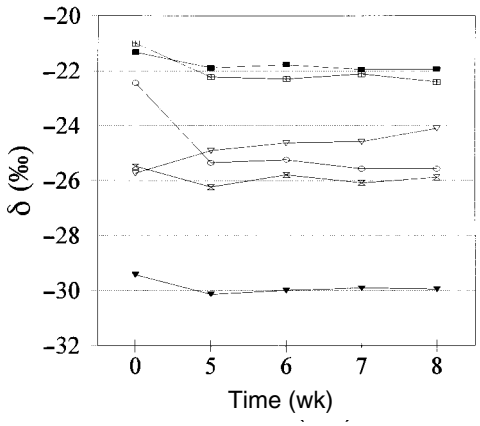

FIG. 1. $^{13}C/^{12}C$ in $\delta^{13}C$ (‰) units of serum fatty acid in diet group average American diet measured upon study entry, assigned week 0, through 8 wk. Overall error averages 0.56‰. Symbols: ○, 16:0; □, 16:1; ■, 18:0; ⧖, 18:1; ▼, 18:2; ▽, 20:4.

$P < 0.05$ level, indicating that most FA had stabilized by weeks 5–8. Original data on slopes and their significance can be found elsewhere (27). Serum FA data for weeks 5 through 8 were pooled for further statistical analyses.

Analysis of variance was performed to investigate the diet treatment effect in stabilizing the isotope ratio. There was no significant diet group effect in stabilization of ^{13}C content in serum FA except 18:1. For 18:1, group AAD is different from group C; however, the difference as shown in Table 2 was very small, less than 1‰. Therefore, serum FA data for all three diet groups were combined for further statistical analyses unless otherwise specified.

Measurement, between-subject, and biological variability. Intersubject, intrasubject, and measurement variability were evaluated using the mixed model procedure in SAS, and results are summarized in Table 3. Average between-subject variability was 1.74‰ at week 0, and decreased to 1.20‰ for weeks 5–8. Subject variability decreased by an average of about 0.5‰ in the controlled diet period in all FA except 18:2, showing that the uniform isotope ratio of the diet FA induced the isotope ratios to converge in most cases. The convergence of isotope ratios on controlled diets is illustrated in Figure 2, which shows results for 16:0. The top histogram shows the distribution of isotope ratios upon entry to the study, which range from −28 to −21‰. Figure 2B shows the aggregate isotope ratios for weeks 5–8, which range from −27 to −23‰.

Measurement variability represents variability between replicate measurements which included extraction, FAME preparation, and imprecision of GCC–IRMS instrument measurement. Table 3 presents measurement variability for six serum FA evaluated at entry and for weeks 5–8, and averaging about 0.56‰. Overall, measurement variability was smallest for 16:0, which is present in high concentration and gives a sharp peak because of its early elution time. Consistent with this, measurement variability was greatest for 20:4, which is a minor FA eluting last of those reported.

Within-subject (biological) variability for weeks 5–8 averaged 0.57‰ which can be taken as a minimum baseline fluctuation in the ^{13}C content of serum FA on controlled diets.

Serum and dietary FA. The FA ^{13}C content in representative, homogenized aliquots of the three experimental diets was analyzed. The results are summarized in Table 4. No significant differences were detected among the diets for 18:0, 18:1, or 18:2. Statistically significant differences were observed in 16:0 of <2‰ and 16:1 of <0.4‰, which may be due to sampling error, and no data were obtained for 20:4 since its concentration was extremely low.

The mean ^{13}C content of serum FA before and during the dietary period is plotted along with the diet levels in Figure 3. The ^{13}C content of the diet FA was lower than that of serum FA for 16:0, 16:1, 18:0, and 18:1, but not 18:2. Isotope ratios of serum FA decreased during the controlled dietary period, indicating that isotope ratios of serum FA were approaching those of dietary FA. The ^{13}C content of 18:2 in diet was about 2‰ higher than that of serum suggesting that the ^{13}C content of this essential FA was different from that of nonessential FA.

DISCUSSION

The major findings in this study are (i) serum FA carbon isotope ratios stabilize within 5 wk in adults on controlled diets, (ii) measurement variability including extraction and derivatization was about 0.56‰, (iii) variability attributable to subjects decreased from a mean of 1.74‰ upon entry to 1.20‰ on the controlled diets, indicating a significant narrowing of isotope ratio under controlled dietary conditions, and (iv) mean FA carbon

TABLE 3
Summary of Intersubject, Measurement, and Intrasubject Variability ‰

	Between subject		Measurement		Within subject
Fatty acid	wk 0	wk 5–8	wk 0	wk 5–8	wk 5–8
16:0	1.38	0.71	0.45	0.35	0.32
16:1	2.28	1.35	0.75	0.69	0.84
18:0	1.09	0.94	0.42	0.51	0.53
18:1	1.51	0.80	0.58	0.45	0.53
18:2	1.50	1.60	0.64	0.50	0.50
20:4	2.70	1.78	0.88	0.54	0.71
Average	1.74‰	1.20‰	0.62‰	0.51‰	0.57‰

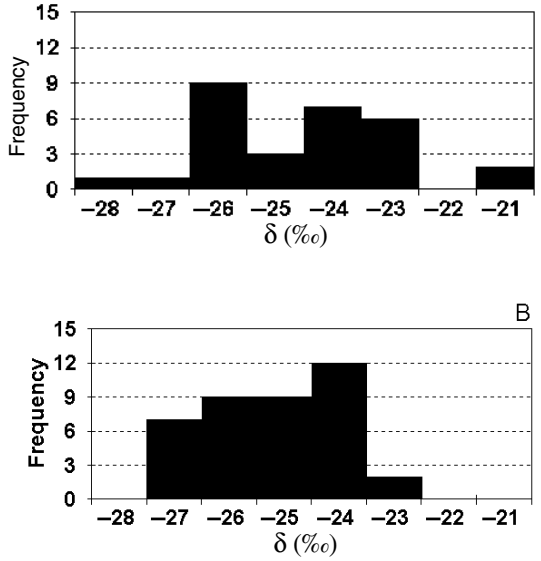

FIG. 2. (A) Histogram showing the distribution of $^{13}C/^{12}C$ of serum 16:0 from the 29 subjects upon entry to the study. (B) Histogram showing $^{13}C/^{12}C$ of serum 16:0 averaged over weeks 5–8. The distribution has narrowed considerably on the controlled diets.

isotope ratios are related to that of their dietary source and are enriched in ^{13}C for nonessential FA, as expected; surprisingly, they are depleted for the only essential FA measured in this work, linoleic acid.

There was no change in the ^{13}C content of serum 18:2 on the controlled diets. Since 18:2 is an essential FA, the overwhelming percentage of serum 18:2 is derived directly from the diet, with very small amounts synthesized from 16:2 (28). It can therefore be concluded that the controlled diet 18:2 isotope ratio was nearly identical to that of the average uncontrolled diet. All dietary 18:2 is ultimately derived from vegetable oils, since 18:2 in animal foods originates in plants. This observation therefore suggests a surprising dietary homogeneity of vegetable sources. An alternative hypothesis supported by observation of gross isotope ratios in pigs is that there is a greater response to a more negative $\delta^{13}C$ diet than to a more positive $\delta^{13}C$ diet compared to $\delta^{13}C$ of body FA. In pigs, the change of tissue $\delta^{13}C$ when diets were switched over from C_3 to C_4 plants (low to high $\delta^{13}C$) was much smaller than that from C_4 to C_3 (high to low $\delta^{13}C$), although there are no known mechanisms for this difference (29).

The qualitative relationship of stable isotope ratio between diet and serum FA was similar in all nonessential FA, where the isotopic distribution is a function of the relative contributions of *de novo* synthesis and assimilation from the diet. Limited information is available on turnover rates in tissues and specific biochemicals in large animals. It has been reported that fat equilibrates with diet more slowly than other major compounds such as lactose, casein, and whey of cow's milk when the dietary isotope ratio is switched (30,31). No data on specific FA have been reported.

In vivo studies of human and animal metabolism using ^{13}C-labeled substrates are commonly used to derive several types of information such as absorption and oxidization of dietary nutrients, biosynthesis and turnover of biochemicals, assessment of disease status, and observed activity of specific enzymes (3,32). The present data represent the most extensive study of baseline $^{13}C/^{12}C$ in specific biocompounds under controlled conditions, and can be used in power calculations to inform design of kinetic modeling studies using ^{13}C-labeled substrates.

Fry and Sherr (33) summarized studies of the relationship between animal tissue isotope ratio and their foods. Most studies that compared whole body or tissue isotope ratios found that $\delta^{13}C$ values are within ± 2‰ of the diets (33). A study of small animals such as *Musca* and *Caliphora* fed horsemeat or pork showed enrichments of 1.5–3.0‰ in tissue lipids compared to dietary lipids (34). Similar results were obtained for carbohydrates, but only a 1‰ enrichment was observed for protein fractions. Although there is no clear biochemical mechanism to explain these results, the well-known depletion of breath CO_2 of about 2‰ compared to dietary sources suggests that ^{12}C is preferentially catabolized leaving behind ^{13}C-enriched compounds to assimilate into tissue (34–37). This general mechanism would explain our results, since nonessential FA are composed of the preformed dietary FA that escape oxidation as well as FA synthesized *de novo* from acetate from partially oxidized glucose. This does not explain why serum 18:2 is 3‰ depleted in ^{13}C compared to dietary 18:2, for which we can only speculate that ^{12}C is discriminated against at the first committed step in β-oxidation.

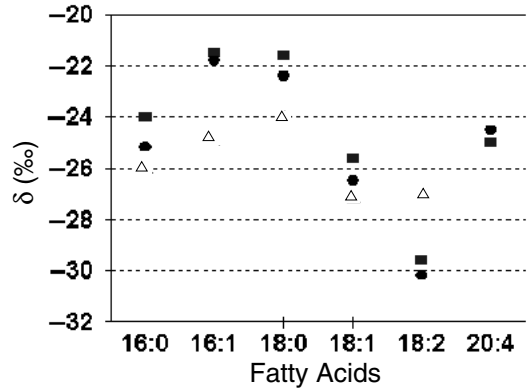

FIG. 3. Comparison of $^{13}C/^{12}C$ between serum fatty acids at week 0 (■), average of weeks 5–8 (●), and diet (△).

Studies of whole body and tissue isotope ratio are routine methods for establishing food-web relationships in terrestrial and aquatic ecology (e.g., Ref. 38), which focus on identifying food sources using isotope relationships. For instance, the foods of animals living in seagrass meadows may be distinguished since offshore foods ultimately derive their carbon from phytoplankton, with $\delta^{13}C = -21‰$, while native seagrasses and algae have $\delta^{13}C = -10$ to $-14‰$. Schoeller *et al.* (39) have discussed the application of a similar strategy to determination of the North American human food web, and have found carbon isotope abundances in several tissues to be accurate predictors of carbon derived from C_4 plants.

In ongoing studies, Haggarty *et al.* are applying this strategy to the study of human food sources (40). Docosahexaenoic acid (DHA) can be consumed preformed in marine foods, or can be synthesized from its precursor FA α-linolenic acid (ALA) normally derived from terrestrial sources. Marine food sources are generally depleted in ^{13}C relative to terrestrial food sources. Thus, a comparison of the ^{13}C content of DHA and ALA should be similar in humans consuming diets principally of terrestrial origin, whereas humans consuming larger proportions of their diets as marine foods would cause the $\delta^{13}C$ of DHA and ALA to diverge. Measurements of breast milk FA from lactating omnivore mothers in Scotland showed that most DHA was synthesized, indicating a low marine consumption in that particular population.

Natural variability in carbon isotope abundance can be purposefully exploited for low-enrichment tracer studies. A recent study of arachidonic acid (AA) synthesis from linoleic acid precursor was performed by switching breast-fed or formula-fed infants to a corn oil-based formula (14) and following the increase in AA isotope ratio over time; the data facilitated an estimate that 23% of plasma AA was synthesized from corn oil-derived linoleic acid consumed in the previous 4 d.

In conclusion, this study shows that $^{13}C/^{12}C$ isotope ratios stabilize in response to controlled diets by week 5. Serum FA take on isotope ratios reflecting their dietary source, with some modification related to metabolic activity for each FA. Metabolic differences between essential and nonessential FA may affect the ^{13}C content of serum FA. Biological fluctuation of 0.57‰ during controlled diet period (weeks 5–8) suggests a minimum $\delta^{13}C$ fluctuation of serum FA for human FA metabolism study.

ACKNOWLEDGMENTS

This work was supported by NIH grants GM49209 and HL49659, and the USDA-CSREES. The authors are indebted to Drs. Penny Kris-Etherton and Satya Sonalogadda of The Pennsylvania State University for providing serum samples for this study, to Dr. Kent Stewart of Virginia Polytechnic and State University for providing aliquots of the food composites, and to the Dietary Effects on Lipoproteins and Thrombogenic Activity steering committee for approving this protocol and releasing dietary information.

Dietary Fatty Acid Profile Affects Endurance in Rats

Kerry J. Ayre* and A.J. Hulbert

Department of Biological Sciences, University of Wollongong, Wollongong N.S.W. 2522, Australia

ABSTRACT: Typically, athletes are advised to increase their consumption of carbohydrates for energy and, along with the general population, to reduce consumption of saturated fats. It is now recognized that fats are not identical in their influence on metabolism, and we argue that the composition of the polyunsaturated fat component should not be ignored. The aim of this study was to manipulate the dietary fatty acid profile in a high-carbohydrate diet in order to investigate the effect of dietary polyunsaturates on submaximal endurance performance in rats. Rats were fed one of three isoenergetic diets containing 22 energy percentage (E%) fat for 9 wk. The diets comprised an essential fatty acid-deficient diet (containing mainly saturated fatty acids); a diet high in n-6 fatty acids, High n-6; and a diet enriched with n-3 fatty acids, High n-3. Submaximal endurance in rats fed the High n-3 diet was 44% less than in rats fed the High n-6 diet ($P < 0.02$). All rats were then fed a standard commercial laboratory diet for a 6-wk recovery period, and their performances were reevaluated. Although endurance in all groups was lower than at 9 wk, it was again significantly 50% lower in the High n-3 group than the High n-6 group ($P < 0.005$). Although n-3 fats are considered beneficial for cardiovascular health, they appear to reduce endurance times, and their side effects need to be further investigated.
Lipids 32, 1265–1270 (1997).

A vast literature (and indeed a vast industry) advises athletes to consume high-carbohydrate diets in order to maximize physical performance. In doing so, athletes have often been advised to reduce their consumption of fats. This seems to stem from studies of cardiovascular disease where advice is that patients should reduce their total fat consumption while increasing their consumption of n-3 fats, but these recommendations for athletes have little comprehensive research support. However, fats are at least as physiologically important and their metabolism is as complex as carbohydrates. Clearly, the consequences and side effects of this changed dietary profile in humans need to be investigated.

Abbreviations: ANOVA, analysis of variance; EDL, extensor digitorum longus; EFAD, essential fatty acid-deficient; E%, energy percentage; High n-6, diet high in n-6 fatty acids; High n-3, diet high in n-3 fatty acids; PUFA, polyunsaturated fatty acid; S,M,P_{n-6},P_{n-3}, ratio of saturated to monounsaturated to n-6 PUFA to n-3 PUFA; $\dot{V}O_2$max, maximal rate of oxygen consumption.

Although classical studies have led to the concept of carbohydrate loading for optimal physical performance (1), at least six articles published since 1983 have shown that performance in rats (2–4), dogs (5), and humans (6,7) may actually be improved when a high-fat diet is consumed for a short time. Surprisingly, the effects on endurance of different types of fats (whether saturated or unsaturated) have not been investigated, even though they have clearly been shown to have a multitude of physiological effects. The few studies which have investigated the effects of dietary fat manipulation on physical performance (8–10) have shown that altered levels of n-3 fatty acids do not affect maximal oxygen consumption, but none of these studies has investigated possible changes in endurance. Although the current dogma is that the diets of endurance athletes should be high in carbohydrates, we argue that the fat component should not be ignored. Specifically, the classes of fatty acids should not be treated identically because (i) different fatty acids are oxidized at different rates (11) and (ii) we have recently shown that a diet rich in saturated fats is detrimental to endurance performance compared to diets rich in unsaturated fats or carbohydrates (12).

This study was a part of a larger study examining the effects of changes in dietary essential polyunsaturated fats on muscle phospholipid composition (13), isolated muscle performance *in vitro* (14), and physical performance of whole animals. For 9 wk, rats were fed one of three isoenergetic test diets which differed only in their fatty acid composition. The diets were (i) deficient in the essential fatty acids, EFAD; (ii) high in n-6 fatty acids, High n-6; and (iii) enriched with n-3 fatty acids, High n-3. Following this, the rats were fed a commercial stock diet in order to determine the reversibility of any dietary effects on endurance.

We now report the effects of these same dietary fatty acid manipulations on the endurance of rats, as well as the extent to which these dietary effects were reversed after returning animals to the stock diet.

MATERIALS AND METHODS

Animals and diets. All experiments were approved by the University of Wollongong's Animal Experimentation Ethics Committee. Male weanling Wistar rats, bred at the University of Wollongong (housed individually at 22 ± 2°C and 57 ± 2% relative humidity, age 21–23 d, mean weight of 54 ± 1 g) were

randomly assigned, one per litter, to each of three dietary groups. Groups of eight rats were maintained on each test diet for 9 wk. Endurance was then assessed using a graded submaximal treadmill running test. Following this test, all rats were fed a common rat commercial diet [Allied Rat and Mouse Cubes (mean energy composition 12 E% fat, 64 E% carbohydrate, and 24 E% protein), Fielders' Agricultural Products, Tamworth, Australia)] for a 6-wk "recovery" period. At all times, rats were given free access to food and water, and food intake and body mass were recorded throughout the study.

All test diets were identical except for their lipid composition (22 E% fat, 56 E% carbohydrate, 22 E% protein). They contained (g/kg) sucrose 560, protein (casein) 220, oil 100, water 50, mineral mix 50, vitamin mix 10, cellulose 10. Details of the mineral mix and vitamin mix as well as of the methods of lipid analysis used are given in Ayre and Hulbert (13). The EFAD diet contained 100 g/kg coconut oil (ETA Food Services, Wollongong, Australia) as the only source of fat and was therefore lacking both n-6 and n-3 essential polyunsaturated fatty acids (PUFA) (the ratio of saturated to monounsaturated to PUFA, S,M,P_{n-6},P_{n-3} ratio, was 95:4:1:0). The High n-6 diet contained 100 g/kg sesame oil (Meadowlea Foods, Sydney, Australia) which is high in n-6 fatty acids; in this diet the S,M,P_{n-6},P_{n-3} ratio was 16:30:50:4. The High n-3 diet contained 70 g/kg sesame oil and 30 g/kg Max EPA oil (R.P. Scherer, Melbourne, Australia) containing 30% n-3 fatty acids. It was therefore enriched with n-3 PUFA and in this diet the S,M,P_{n-6},P_{n-3} ratio was 21:25:35:16. The S,M,P_{n-6},P_{n-3} ratio of the rat commercial diet was 33:32:30:2. The specific fatty acid content of the test diets and the stock diet is given in Ayre and Hulbert (13). In another group of rats fed the same diets, the fatty acid composition of phospholipids extracted from both the soleus and extensor digitorum longus (EDL) muscles was determined. The methods are presented in Reference 13.

Testing program. We assigned a cryptic code number to each rat, and endurance tests were performed so that the dietary group of each animal was concealed from the tester. Rats were fasted overnight and all littermates were tested in random order on the same day toward the end of the light cycle. Submaximal endurance was assessed while rats ran on a single-lane motor-driven treadmill. In the week prior to each testing period (i.e., after both 8 wk on the test diets and 5 wk on the commercial diet), rats underwent a habituation program (15). Each rat was given a 5-min exercise period with treadmill speed and incline increasing daily to 25.2 m/min and 10°, respectively. Endurance tests were then performed both after 9 wk on the three test diets and following 6 wk recovery on the commercial stock diet, following the protocol of Baldwin *et al.* (15). Rats commenced running at 12 m/min speed, 0° incline for 3 min, after which the treadmill was raised 2° and speed was increased to 27 m/min and held constant. Thereafter, the angle of incline was increased by 2° every 10 min. We measured time to exhaustion during treadmill running in order to provide an estimate of endurance. The length of time each rat could keep running at this workload was recorded. To ensure that rats ran to exhaustion, we routinely stimulated them with jets of compressed air while they were running free on the treadmill. A rat was considered to have reached exhaustion when it positioned itself at the back of the chamber for 10 s or more and no longer responded to repeated jets of compressed air. The amount of work performed by each rat was calculated as the product of body mass (i.e., force in kiloponds), distance traveled, and percentage grade (i.e., the product of the sine of the treadmill angle and 100), as described by Powers and Howley (16).

Statistical methods. All values are expressed as mean ± SEM. The *a priori* alpha level was 0.05. A one-way analysis of variance (ANOVA) was used to test for heterogeneity of food intake and rat weights. To test for significant differences in endurance and work between the dietary groups, we used the statistical package, SAS (SAS Institute, Cary, NC: 1979) to perform Model lll two-factor ANOVA without replication; the fixed factor was diet and the random factor was litter and/or day of testing. Since only one rat per litter was allocated to each treatment and each litter was tested on a different day, it is not possible to determine whether significant effects of this factor are litter effects as such, or the product of day-to-day variation in experimental conditions. However, the design ensures that variation among litters and days of testing does not obscure the effects of the diets. Two separate ANOVA were performed: after 9 wk on the test diets and after 6 wk on the common diet. Wherever ANOVA revealed significant effects of diet, we used Tukey's studentized range test to determine which dietary groups produced significantly different responses (17).

RESULTS

There was no significant effect of diet on body mass, either after the 9-wk experimental period (EFAD = 363 ± 20 g; High n-6 = 387 ± 14 g; High n-3 = 405 ± 5 g), or after 6 wk on the common diet (EFAD = 411 ± 24 g; High n-6 = 445 ± 14 g; High n-3 = 463 ± 7 g). There were significant effects of the diets on the fatty acid composition of muscle membranes (see Table 1). The percentage of total unsaturates in membranes was not influenced by diet, but the relative content of the different types of unsaturates was dramatically influenced by diet. For example, the different diets resulted in a 10-fold range in the n-3 polyunsaturate content of muscle phospholipids. The influence of diet was similar for both the fast (EDL) and the slow (soleus) muscle types.

Almost all rats ran willingly and there was surprisingly little variation within dietary groups (Fig. 1). The overall endurance performance for all groups decreased between the two endurance tests by approximately 50%. Dietary manipulation had a highly significant effect on exercise performance (Fig. 1). The endurance of both the High n-3 and EFAD groups was markedly lower than that of the High n-6 group both after 9 wk on the test diets and after 6 wk on the common diet. After the 9-wk experimental period, rats on the

[a]—, Not detected; phospholipid fatty acid composition of soleus and extensor digitorum longus muscles after 9 wk on the three test diets, High n-6, EFAD, and High n-3. Only fatty acids detected at levels greater than 0.1 g/100 g of total fatty acids are listed.
[b]Values are means ± SEM, $n = 4$. The statistical significance of variation in mean phospholipid fatty acid levels among dietary treatments was assessed by one-way analysis of variance. Significantly different treatment means are denoted by different superscript roman letters. Abbreviation: EFAD, essential fatty acid-deficient.

High n-3 diet ran only 56% as long as those on the High n-6 diet ($P < 0.02$). The endurance of the EFAD group was also relatively low, being only 73% of that of the High n-6 group, although this difference was nonsignificant. Similarly, the amount of work done was significantly lower in both the High n-3 and EFAD groups [46 and 52% of the work performed by the High n-6 group ($P < 0.005$), respectively]. Very similar relationships persisted following recovery, where the High n-3 group ran for only 50% of the High n-6 group's mean endurance time ($P < 0.005$), and the High n-3 and EFAD rats did only 25 and 42% as much work as the High n-6 group ($P < 0.01$), respectively. Mean endurance time decreased by 49–55% for the three groups during the recovery period, and mean amount of work performed decreased by 73–85%.

We detected several litter effects throughout this study. For example, there were significant litter effects on endurance both after 9 wk on the test diet ($P < 0.02$) and after the 6 wk recovery period ($P < 0.05$). Although several rats needed encouragement to run, there were few that refused. Those that did were not included in the dataset. One rat that refused to run at 9 wk also refused following recovery. Also, his two littermates, which ran well after the 9-wk test diet, refused to run after the 6-wk recovery diet. These litter effects may represent real effects of variation among litters, or show day-to-day variation in experimental conditions. However, since all littermates were tested on the same day, and litter was one of the two factors considered in the ANOVA, these effects do not "interfere" with the description of the effects of dietary treatments.

DISCUSSION

Our study demonstrates that manipulation of the composition of dietary fatty acids can affect whole-animal physical performance in rats. We found three important effects: (i) that treadmill endurance (both "time to exhaustion" and "work performed") was influenced by the relative composition of n-6 and n-3 PUFA in the diet, (ii) that this effect may not be easily reversed, in that the differences between dietary groups persisted even after all rats were fed a common stock diet for 6 wk after being fed the test diets, and (iii) that treadmill endurance decreased in all groups when they were fed the same common diet after the experimental period.

Endurance and work were both dramatically reduced by consumption of the High n-3 diet, compared with those fed the High n-6 diet. Rats fed the High n-3 diet ran for only 56% as long as the High n-6 rats. These diets had the same total fat content, but the n-6 PUFA content in the High n-6 diet was partly replaced with n-3 fatty acids in the High n-3 diet. To our knowledge, this is the first study to report a substantial influence of the type of dietary polyunsaturated fat on whole-animal performance. These results were part of a larger study examining the role of dietary polyunsaturates (using the same three diets) on (i) composition of muscle phospholipids (13)

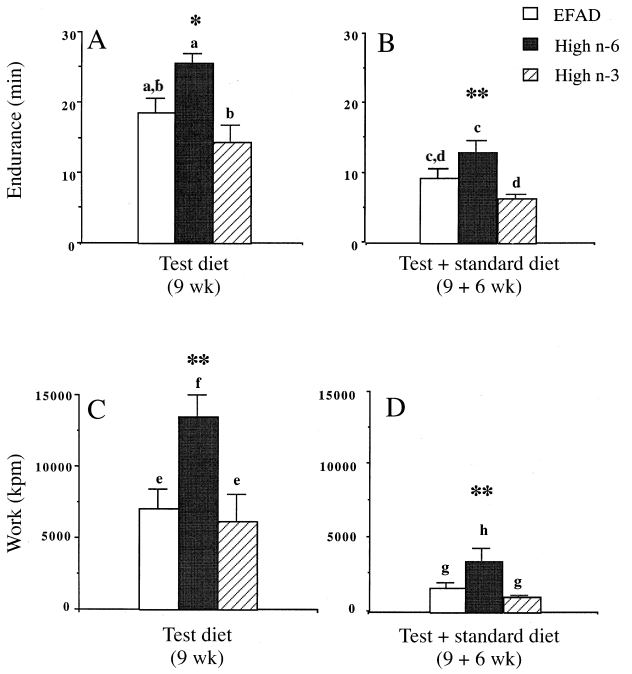

FIG. 1. The influence of diets of differing fatty acid composition on the submaximal treadmill endurance of rats. Figures A and B show the effect on endurance time whereas Figures C and D show the effect on work performed. Figures A and C show the effect after 9 wk on the test diets, and Figures B and D show the results obtained after a further 6 wk on a stock laboratory diet for all groups. Columns with different letters are significantly different from each other. $^{*}P < 0.05$; $^{**}P < 0.01$. Abbreviations: EFAD, essential fatty acid-deficient; High n-6, diet high in n-6 fatty acids; High n-3, diet high in n-3 fatty acids.

and (ii) contractile properties of isolated muscles (14), and whole-animal performance in rats. Recently, we have also shown that a diet rich in saturated fats is detrimental to endurance performance of rats when compared to diets either low in fat (i.e., carbohydrate-rich) or containing mainly n-6 polyunsaturated fats (12).

Whole-animal endurance during treadmill running is possibly influenced by a wide and complex range of physiological parameters. For example, limiting factors may sometimes occur in the respiratory and/or cardiovascular systems rather than the muscles themselves and similarly, the role of motivational differences is not easy to determine. In this study, we were particularly careful in trying to negate motivational influences between experimental groups by concealing the dietary treatment of each rat from the tester.

We have no direct knowledge of the possible mechanistic basis of the effects we have observed, but our previous studies can give some insight. The fact that the current dietary manipulations do not have any substantial influence on the *in vitro* contractile properties (including time to fatigue) of either isolated fast or slow muscles of rats (14) implies that the current dietary effects are not related to changes in the contractile properties of the muscles *per se*.

Limitation in substrate supply is a potential mechanism relating the type of dietary fat to treadmill endurance. A recent examination of the substrate and oxygen pathways during exercise at 40% maximal rate of oxygen consumption ($\dot{V}O_2$) max in both the highly aerobic dog and less aerobic goat has shown that about 70% of the energy requirements are provided from fat, and that at 60% $\dot{V}O_2$ max, its relative contribution is decreased to approximately half of total energy turnover (18). About 65–70% of the fat metabolized in these cases is from intramuscular triglyceride stores, which illustrates the relative importance of these stores during submaximal exercise. Whether the current diets resulted in different intramuscular triglyceride reserves in the rat is unknown. It is of interest that dietary n-3 fats increase the insulin sensitivity of muscle in rats (19). In humans, there is an inverse relationship between muscle insulin sensitivity and muscle triglyceride content (20). If this is also the case in rats, then the difference in treadmill endurance between rats fed the High n-6 and High n-3 diets may in turn be related to differences in intramuscular triglyceride stores. This possibility requires further investigation.

Dietary n-3 fats restore tissue insulin sensitivity in rats that are insulin-resistant, and thus they increase glucose entry and utilization in rat muscles (21). However, such effects may not be important in explaining the current results since oxidation of circulating glucose is only responsible for about 10–20% of total aerobic metabolism during treadmill exercise of dogs and goats (22). If, however, insulin-regulated glucose entry into muscle is important in determining treadmill endurance of rats, then we would expect that dietary n-3 enrichment would result in an increased endurance whereas we observed the opposite effect, a decrease in treadmill endurance.

Different types of fatty acids are metabolized *in vivo* at different rates. In rats, n-3 linolenic acid is metabolized more rapidly than n-6 linoleic acid (11). Furthermore, the rate of oxidation of n-3 linolenic acid is known to be influenced by the nature of the other fats in the diet, with linolenic acid being metabolized most rapidly when the other dietary fats are saturated and slowest when the other fats are predominantly n-6 polyunsaturates (19). Whether such differences are related to the endurance difference observed in the current study is unknown.

Dietary n-3 fats have been shown to have substantial influences on cardiovascular function and most of these are regarded as beneficial (23). If reduced cardiovascular function during exercise is the mechanism behind our dietary effect, then increased dietary intake of n-3 fats may not be so beneficial as generally thought. Using the same treadmill protocol, Baldwin *et al*. (15) showed that rats with (drug-induced) enlarged hearts have only a slightly greater endurance ($P < 0.1$) than normal rats.

Both n-6 and n-3 fatty acids are intimately involved in many aspects of physiological regulation in that they are both important membrane constituents and are also precursors of the eicosanoids, which are important chemical messengers (24). Whether the different diets resulted in different levels of eicosanoid production is unknown, but it is possible that the effects we report here are the result of such changes in eicosanoid messenger levels.

The second important finding of this study was that, although all rats were transferred to a common stock diet for 6 wk following the 9-wk test diet period, the relative differences between the experimental groups remained. This may indicate that the diet-induced differences are long-term and at least partly irreversible. Using the same diets, we have shown that in both slow (soleus) and fast (EDL) muscles the relative n-3 and n-6 composition of muscle phospholipids is related to their relative dietary presence (13; and see Table 1) and that even after 6 wk on the common diet the relative n-3 and n-6 composition of muscle phospholipids was little changed from what it was on the test diets. As we reported previously (13), the levels of n-3 fatty acids in the phospholipids of both soleus and EDL muscles were still significantly higher in rats from the High n-3 group than the other two groups after 6-wk recovery. This may be related to the persistent decrease in endurance seen in these rats after the recovery period.

All groups showed the same relative decrease in endurance when transferred to the common stock diet. Since all rats were 6 wk older and 50–60 g heavier, it may be that general aging was the cause. In a separate group of rats fed the same diets, there were no significant decreases in muscle mass or length following the common diet (14). This suggests that muscle atrophy is not an important component of the decline in treadmill endurance. Another explanation could be that the test diets were all 22E% fat, whereas the stock diet contained only 12E% fat. A number of studies have shown that an increase in the fat content of the diet can result in improved exercise performance in rats (2–4), dogs (5), and humans (6,7). Thus, it may be that a decrease in the fat content of the stock diet, compared to all three test diets, is the common factor that explains the decreased endurance in all groups. However, the important point is that the pattern of results was almost identical to the results after 9 wk on the test diets.

We have shown that rats fed diets with the same fat content but different lipid compositions show different endurances during submaximal running on a treadmill. The most surprising result was that the balance of n-3 and n-6 polyunsaturated in the diet has a highly significant influence on exercise performance of rats. We have used sedentary rats in the current study. Whether the same is true for trained rats or for humans is yet to be determined. Similarly, knowledge of the underlying mechanisms awaits further research.

In general, recommendations for weight reduction and amelioration of coronary artery disease have lead to increased consumption of PUFA containing high levels of n-6 fatty acids (25) and thus an increase in the dietary n-6/n-3 ratio. However, since the n-3 PUFA have been associated with decreased coronary artery disease, decreasing the dietary n-6/n-3 ratio will reduce the risks from deleterious eicosanoid production. Owing to publicity surrounding the findings that n-3 fatty acids are beneficial for the cardiovascular system and neural development, there has been an increase in human consumption of foods such as canola-based products and fish. Clearly however, the side effects of such increased consumption on physical performance in humans need to be investigated.

In conclusion, dietary fatty acids clearly exert significant effects on whole-animal performance. What determines submaximal treadmill running endurance is not known and difficult to ascertain. Effects on whole animals may reflect changes in muscles themselves or in the levels of eicosanoids, which are known to exert effects on secretory, cardiovascular, and immune functions (24). At present, diets containing a high level of PUFA relative to saturated fatty acids (and particularly the n-3 fatty acids) are recommended owing to their obvious benefits for the cardiovascular system (26). However, our results show a striking difference in effect for two diets that differ only in their ratio of the n-6 and n-3 fatty acids and point to the need for further research on the effects of such diets.

ACKNOWLEDGMENTS

This work was supported by an Australian Research Council grant and funds from the Australian Flora and Fauna Research Centre at the University of Wollongong. We thank David Ayre, Bill Buttemer, Paul Else, Andy Sinclair, and Len Storlien, who provided extremely useful advice and comments on the manuscript. We are grateful to Meadowlea Foods and R.P. Scherer, Pty. Ltd. for providing the sesame oil and Max EPA oil, respectively.

ABSTRACT: The fatty acid composition of a new strain of *Vibrio alginolyticus*, found in the alga *Cladophora coelothrix*, was studied. Among 38 different fatty acids, a new fatty acid, 9-methyl-10-hexadecenoic acid and the unusual 11-methyl-12-octadecenoic acid, were identified. Linear alkylbenzene fatty acids, such as 10-phenyldecanoic acid, 12-phenyldodecanoic acid and 14-phenyltetradecanoic acid, were also found in *V. alginolyticus*. The alga contained 43% saturated fatty acids, and 28% C_{16}–C_{20} polyunsaturated fatty acids of the n-3 and n-6 families.

Lipids 32, 1271–1275 (1997).

The association of marine bacteria with their invertebrate hosts is quite intriguing and of importance in marine biotechnology despite the fact that true symbiosis is difficult to assess (1). Most marine bacteria are found in heterogeneous aggregations, mostly adhered to inanimate surfaces. These surface interactions are dynamic and important in bacterial reproduction and survival (1). For example, marine algae are often found to be associated with a large variety of bacterial strains (2).

Despite the fact that much is known about the fatty acid composition of marine bacteria, recent findings indicate that there are still many unrecognized bacterial strains, either in seawater or associated with marine invertebrates, with unprecedented and/or unusual fatty acids that have not been fully studied or characterized (3). In the present study we report the fatty acid composition of a *Vibrio alginolyticus* and a Gram-positive bacillus associated with the alga *Cladophora coelothrix* from the Black Sea. Although these bacterial strains may not be widely distributed in association with the alga, they do contain several unusual fatty acids, in particular the previously unreported 9-methyl-10-hexadecenoic acid (**1**), the unusual 11-methyl-12-octadecenoic acid (4), and linear alkylbenzene fatty acids.

Algae from the genus *Cladophora* (Chlorophyta, Siphonophyceae, Cladophoraceae) are found worldwide, and some of these algae have the ability to survive up to 100% salinity (5). Only a few algae can survive such a change in salinity as the *Cladophora* (5). The principal fatty acids in the Chlorophyta are C_{16} and C_{18} polyunsaturated fatty acids such as 16:4n-3 and 18:3n-3 (6). The fatty acid composition of *C. coelothrix* has not been reported before.

MATERIALS AND METHODS

Instrumentation. Gas chromatography/mass spectrometry (GC/MS) data was collected at 70 eV in a Hewlett-Packard 5972A MS ChemStation (Palo Alto, CA) equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) cross-linked with 5% phenyl methylpolysiloxane. The temperature program for the analyses was as follows: 130°C for 2 min, then increased at 3°C/min to 270°C and maintained for 40 min.

Collection. Cladophora coelothrix was collected in September 1994 at a beach near the village of Ravda, at the southern part of the Bulgarian Black Sea coast. The samples were covered by seawater and transported the same day to Sofia. Water samples were also collected at the same site. A part of the alga was also acclimated in an aquarium with seawater for one year in order to determine which original marine bacteria can survive under these conditions. The seawater parameters were kept constant with addition of artificial seawater (Provasoli; Sigma Chemical Co., St. Louis, MO).

Bacterial isolation. Cladophora coelothrix was cut into small pieces and ground in a porcelain mortar. The homogenates obtained were diluted in standard nutrient broth with a final salt concentration of 16‰ (equal to the concentration of salts in the Black Sea). The following dilutions were used: 10^{-1} (0.1 mL water or homogenate + 0.9 mL

Abbreviations: ECL, equivalent chainlength; GC/MS, gas chromatography/mass spectrometry; SAM, *S*-adenosyl methionine.

broth), 10^{-2}, 10^{-3}, and 10^{-4}. From every dilution, 0.1 mL were taken and inoculated into two Petri dishes containing standard nutrient agar with a final concentration of 16‰ NaCl. After incubation at 37°C for 24 h, the morphology of the material obtained was established. The bacterial isolates were repeatedly streaked to fresh nutrient agar plates in order to ensure that they were in pure culture. In most cases a single cultivation was enough. Each strain was transferred to separate flasks and cultivated in standard nutrient broth, with aeration at 37°C, in order to obtain enough quantity for chemical analyses. We used 37°C because: (i) at this temperature, pathogenic bacteria are easily isolated, and (ii) the production of bacterial biomass is intensified. No qualitative differences were observed in our bacterial composition in a temperature range of 20–45°C. The bacterial biomass thus obtained, from every strain, was separated by centrifugation of the cultured liquid (6000 rpm for 20 min), and the lipids were extracted as described by Christie *et al.* (7).

Bacterial identification. Isolated bacterial strains were identified as *V. alginolyticus* (MB-1) and Gram-positive bacillus (OB-5 as well as other strains labeled by us as AB-1 and AB-2) (8–10). Characterization was done by routine biochemical and antibiotic tests modified for marine bacteria. The API 20E system (Analytab Products, Plainview, NY) was also used for characterization, as recommended by MacDonell *et al.* (11) for marine isolates.

Fatty acid isolation. The lipids from *C. coelothrix*, and from the associated bacteria, were extracted with chloroform/methanol (2:1, vol/vol) and saponified. The nonsaponifiables were removed, and the acids were methylated with 1% sulfuric acid in methanol (7).

Derivatives. The methyl esters were hydrogenated in 10 mL of absolute methanol and catalytic amounts of platinum oxide (PtO_2). The double-bond positions in the monoenoic fatty acid methyl esters were determined by dimethyl disulfide derivatization (12). Pyrrolidide derivatives were also prepared as previously described (13). Mass spectral data for methyl 9-methyl-10-hexadecenoate and methyl 11-methyl-12-octadecenoate, as well as their corresponding dimethyl disulfide derivatives, follows.

Methyl 9-methyl-10-hexadecenoate. MS *m/z* (relative intensity) M^+ 282(1), 251(2), 239(1), 227(1), 199(1), 183(2), 166(4), 143(11), 140(5), 111(9), 87(25), 83(33), 81(15), 74(43), 69(63), 67(21), 59(20), 57(23), 55(100).

Methyl 9-methyl-10,11-bis(methylthio)hexadecanoate. MS *m/z* (relative intensity) M^+ 376(3), 346(1), 299(3), 281(1), 245(8), 213(3), 197(6), 185(3), 165(9), 147(7), 131(15), 99(8), 97(14), 95(14), 87(16), 83(28), 81(23), 74(22), 71(29), 69(44), 67(25), 61(34), 59(21), 57(65), 55(100).

Methyl 11-methyl-12-octadecenoate. MS *m/z* (relative intensity) M^+ 310(1), 279(2), 211(2), 194(3), 179(2), 171(5), 152(1), 140(7), 138(3), 133(1), 125(7), 123(3), 111(6), 109(4), 97(14), 95(9), 87(11), 81(14), 74(23), 69(65), 67(22), 57(22), 55(100).

Methyl 11-methyl-12,13-bis(methylthio)octadecanoate. MS *m/z* (relative intensity) M^+ 404(3), 373(1), 310(1), 274(4), 273(21), 241(8), 171(3), 169(1), 157(2), 131(29), 109(10), 97(16), 95(21), 87(18), 83(38), 81(26), 74(32), 69(46), 67(26), 61(51), 55(100).

RESULTS

Fatty acid composition of C. coelothrix. The fatty acid composition of *C. coelothrix,* as well as that of associated microorganisms, is presented in Table 1. In contrast to other Chlorophyta, such as *Cladophora stimpsonii*, significant amounts of 16:3n-6 and 18:3n-6 were found in *C. coelothrix* (6). Hexadecanoic acid (16:0) was the most abundant (28% of the total) fatty acid. The typical bacterial *iso/anteiso* fatty acids with chainlengths between C_{15}–C_{17} were also identified in *C. coelothrix.*

Fatty acid composition of V. alginolyticus. Several associated bacterial strains were isolated from *C. coelothrix*, probably as epiphytes. Gram-positive bacilli and a new strain of *V. alginolyticus* were identified as described in the Materials and Methods section. The new strain of *V. alginolyticus* was only detected in *C. coelothrix*, and it was not found in the surrounding seawater. The fatty acid composition of *V. alginolyticus* is also presented in Table 1. The principal fatty acids identified in *V. alginolyticus* correspond to those previously reported for other *Vibrio* (14). However, 38 different fatty acids were identified in this *V. alginolyticus*, in contrast to only 17 fatty acids that were previously reported in other *Vibrio* strains (14). Of the 38 fatty acids identified in *V. alginolyticus*, 34% were saturated, 44% monounsaturated, 15% branched *iso/anteiso*, and 7% were linear alkylbenzene fatty acids (Table 1). The monounsaturated fatty acid profile of this bacterium was complex, but in general Δ9 desaturation predominated. Most of the monounsaturated fatty acids had the *cis* stereochemistry, but two *trans* fatty acids were also identified by their equivalent chainlength (ECL) values and corresponding mass spectra of their methyl esters. These acids were (*E*)-9-hexadecenoic acid and (*E*)-11-octadecenoic acid, the latter probably arising from a two-carbon extension of the former.

Two unusual methyl-branched fatty acids were identified in *V. alginolyticus*. These were characterized as 9-methyl-10-hexadecenoic acid (**1**) and 11-methyl-12-octadecenoic acid, which were characterized as methyl esters. To the best of our knowledge, **1** is novel and 11-methyl-12-octadecenoic acid has only been detected before in *Mycobacterium fallax* (4). Methyl 9-methyl-10-hexadecenoate presented an ECL value of 16.03, while methyl 11-methyl-12-octadecenoate presented an ECL value of 18.06 in capillary GC, indicating monounsaturation and methyl branching in the middle of the chain. The mass spectra of the methyl ester of **1** and its longer chain analog displayed molecular ion peaks at M^+ 282 and M^+ 310, respectively, with their corresponding $M^+ - 32$ peaks at *m/z* 250 and *m/z* 279. Upon catalytic hydrogenation of the whole fatty acid methyl ester mixture, methyl 9-methylhexadecanoate (ECL = 16.37) and methyl 11-methyloctadecanoate (ECL = 18.39) were obtained as two of the products. The mass spectrum of methyl 9-methylhexadecanoate displayed a M^+ 284,

[a]The MB-1 bacteria was identified as *Vibrio alginolyticus*. It was only detected in the alga.
[b]The OB-5 bacteria was identified as a Gram-positive bacillus. It was initially detected in both the seawater and the alga. Other similar strains, with similar fatty acid composition, were isolated from the alga and not the water when the alga was cultivated in an aquarium with artificial seawater.

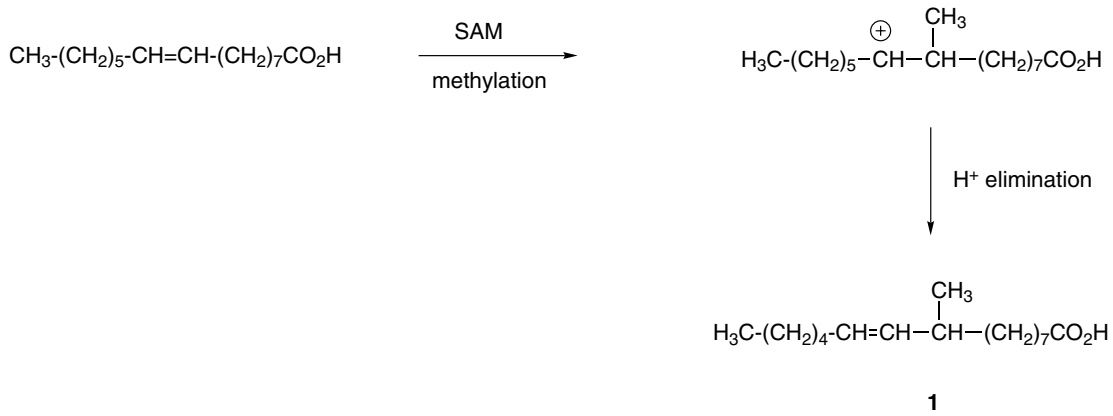
and strong fragmentations at *m/z* 157 (7%) and *m/z* 185 (14%), together with a diminished peak at *m/z* 171 (2%), indicative of methyl substitution at C-9. On the other hand, the mass spectrum of methyl 11-methyloctadecanoate displayed a M^+ 312, and strong fragmentations at *m/z* 185 (11%) and *m/z* 213 (8%), together with a diminished peak at *m/z* 199 (1%), indicative of methyl substitution at C-11. Once the methyl substitutions were defined, the double-bond positions were determined by dimethyldisulfide derivatization (12). Upon reaction of the whole fatty acid methyl ester mixture with dimethyl disulfide and I_2, methyl 9-methyl-10,11-bis(methylthio)hexadecanoate and methyl 11-methyl-12,13-bis(methylthio)octadecanoate were obtained as two of the products. The mass spectra of these derivatives presented molecular ion peaks at M^+ 376 and M^+ 404. The key fragmentations in methyl 9-methyl-10,11-bis(methylthio)hexadecanoate were observed at *m/z* 131 (15%) and *m/z* 245 (8%). On the other hand, the key fragmentations in methyl 11-methyl-12,13-bis(methylthio)octadecanoate were observed at *m/z* 131 (29%) and *m/z* 273 (21%), indicative of double-bond substitution at C-12. All of the above mass spectral data confirm methyl 9-methyl-10-hexadecenoate and methyl 11-methyl-12-octadecenoate as the most probable structures.

An interesting finding in *V. alginolyticus* was the identification of the linear alkylbenzene fatty acids 10-phenyldecanoic acid, 12-phenyldodecanoic acid, 14-phenyltetradecanoic acid, and 16-phenylhexadecanoic acid. These linear alkylbenzene fatty acids were identified, as methyl esters, by MS comparing to reported mass spectral data (National Institute of Standards and Technology/Environmental Protection Agency/National Institutes of Health mass spectral library from the U.S. Department of Commerce). The mass spectra of these methyl esters were all similar, i.e., a base peak at *m/z* 91, and abundant fragmentations at *m/z* 55, 74, 104, and a strong $M^+ - 32$ peak. The straight alkyl chain was further confirmed by pyrrolidine derivatization, since the mass spectra of the pyrrolidide derivatives presented a continuous series of ion clusters, 14 amu apart, starting at the carbonyl end of the chain and finishing at the penultimate carbon before the benzene ring, where a gap of 91 amu was observed before the molecular ion peak (13). Moreover, a linear plot was observed when the capillary GC retention times of these C_{10}–C_{16} methyl phenylalkanoates were plotted against carbon chainlength.

Fatty acid composition of an associated Gram-positive bacillus. Several associated Gram-positive bacilli were found in *C. coelothrix*. The fatty acid composition of one of them, namely OB-5, is presented in Table 1. This bacillus was initially detected in both the seawater and the alga, and therefore it seems to be not exclusive of the alga. This Gram-positive bacillus presented a complete saturated fatty acid profile. In particular, branched *iso*/*anteiso* fatty acids with chainlengths between C_{13}–C_{17} were the most abundant. No monounsaturated fatty acids were detected.

DISCUSSION

Our findings with *V. alginolyticus* and *C. coelothrix* present new perspectives in terms of the fatty acid composition of microorganisms associated with algae. The identification of so



1

SCHEME 1

many different unusual fatty acids in a single *Vibrio* species is rare (14). The characterization of the novel 9-methyl-10-hexadecenoic acid (**1**) is also of interest. Its longer-chain analog 11-methyl-12-octadecenoic acid has only been reported before from *Mycobacterium fallax* (4). In *M. fallax* it was shown, by feeding [methyl-$^2H_3$]L-methionine, that 11-methyl-12-octadecenoic acid originated from 11-octadecenoic acid by a process of *S*-adenosyl methionine (SAM) methylation followed by hydrogen elimination (4). In our *V. alginolyticus,* 9-methyl-10-hexadecenoic acid (**1**) may have originated from 9-hexadecenoic acid, which was particularly abundant in this *V. alginolyticus*, by a similar process of SAM methylation followed by hydrogen elimination (Scheme 1).

A comparison of the fatty acid composition of the associated bacterial strains with that of the alga *C. coelothrix* reveals some common fatty acids. For example, saturated fatty acids between C_{14}–C_{18} are common in all of the studied species (Table 1). The branched *iso*/*anteiso* fatty acids with chainlengths between C_{15}–C_{17}, which were also found in *C. coelothrix*, clearly have a bacterial origin. The monounsaturated fatty acids 9-hexadecenoic acid and 11-octadecenoic acid were also found in *C. coelothrix* and in *V. alginolyticus* (Table 1). The fact that this *V. alginolyticus* was only detected in the alga and not in the surrounding seawater is indicative that it could be a symbiont.

The identification of linear C_{10}–C_{16} alkylbenzene fatty acids in our strain of *V. alginolyticus* is also of interest. These alkylbenzene fatty acids could have originated from linear alkylbenzene hydrocarbons present in the sea. Linear alkylbenzenes are starting materials for the industrial manufacturing of linear alkylbenzene sulfonate surfactants *via* the process of sulfonation (15). In most cases the sulfonation process, although efficient, does not go to completion, and unreacted linear alkylbenzenes, typically between C_{10}–C_{14} carbons, are carried into detergents. Some marine bacteria, such as *Alcaligenes* sp. and *Acinetobacter* sp., have been shown to degrade alkylbenzenes in high yields (16). The biodegradation process follows a classical mechanism, i.e., oxidation at the terminal methyl end of the chain followed by a series of β-oxidation steps until final conversion to benzoic acid (16). Nevertheless, there is still the possibility that the alkylbenzene fatty acids could have arisen from *de novo* biosynthesis from benzoic acid. Work is in progress in our laboratories elucidating the fatty acid composition of marine bacteria and their invertebrate hosts.

ABSTRACT: Various fatty acids were fed to the yeast *Dipodascopsis uninucleata* UOFS Y 128, and the extracted samples were analyzed for the accumulation of 3-hydroxy metabolites with the help of electron impact gas chromatography–mass spectrometry. Fatty acids containing a 5*Z*,8*Z*-diene system (5*Z*,8*Z*,11*Z*-eicosatrienoic, 5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic, and 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-eicosapentaenoic acids) yielded the corresponding 3-hydroxy-*all*-*Z*-eicosapolyenoic acids. Moreover, linoleic acid (9*Z*,12*Z*-octadecadienoic acid) and 11*Z*,14*Z*,17*Z*-eicosatrienoic acid were converted to the 3-hydroxylated metabolites of shorter chain length, e.g., 3-hydroxy-5*Z*,8*Z*-tetradecadienoic acid and 3-hydroxy-5*Z*,8*Z*,11*Z*-tetradecatrienoic acid, respectively. In contrast, no accumulation of a 3-hydroxy metabolite was observed with oleic acid (9*Z*-octadecenoic acid), linolelaidic acid (9*E*,12*E*-octadecadienoic acid), γ-linolenic acid (6*Z*,9*Z*,12*Z*-octadecatrienoic acid), and eicosanoic acid as substrate. These findings pinpoint that the 3-hydroxylation of a fatty acid in *Dipodascopsis uninucleata* requires a 5*Z*,8*Z*-diene system either directly or following initial incomplete β-oxidation. Following analysis of the enantiomer composition, the arachidonic acid metabolite was identified as 3*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid, which rules out a normal β-oxidation as biosynthetic route to this new class of oxylipins.

Lipids 32, 1277–1283 (1997).

Long-chain hydroxy fatty acids and other oxygenated fatty acid derivatives (oxylipins) are widely distributed in both the animal and plant kingdom and exert a plethora of biological actions (1–3). During the past 10 yr, plenty of knowledge has accumulated regarding the synthesis of oxylipins by fungi and related organisms. A large number of unsaturated hydroxy fatty acids which are formed by either lipoxygenase, dioxygenase, or cytochrome P-450-mediated pathways have been found in various fungal species and oomycetes (4–11). These compounds carry one or more hydroxy groups at carbon atoms 5, 7, 8, 9, 12, 13, 15, or 17 of the fatty acid molecule. While the majority of fungal oxylipins are formed from oleic or linoleic acid, there are only a few examples for arachidonic acid (AA)-derived oxylipins (eicosanoids) in fungi. The 15*S*-hydroxyeicosanoids have been identified in *Saprolegnia* and *Achlya* species (4,5). In earlier communications, we have reported on the formation of 3-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid (3-HETE) by the yeast *Dipodascopsis uninucleata* fed with AA (12–13). In the present study, we demonstrate that 3-hydroxy fatty acids are produced by *D. uninucleata* from other polyenoic fatty acids, provided that they contain a 5*Z*,8*Z*-diene system either directly or upon preceding β-oxidation. Moreover, the stereochemical identification of the 3-hydroxy group (3*R*) rules out a normal β-oxidation as putative biosynthetic pathway for these oxylipins.

EXPERIMENTAL PROCEDURES

The compound 3-HETE was isolated and purified as described elsewhere (12). The methylation and trimethylsilylation were performed according to the instructions supplied with the kits from Aldrich (Deisenhofen, Germany) and Merck Chemicals (Darmstadt, Germany), respectively. Fatty acids 18:1 (9*Z*) and 18:2 (9*Z*:12*E*) were obtained from Sigma (Deisenhofen, Germany); all other fatty acids were supplied by Cayman (Ann Arbor, MI).

*Synthesis of 3*R- *and 3*S-*HETE.* The synthetic strategy for 3*R*- and 3*S*-HETE involved a convergent approach coupling chiral aldehyde with Wittig salt; these were derived from 2-deoxy-D-ribose and AA, respectively (14). Briefly, lead tetraacetate oxidation of readily available methyl 5,6-dihydroxyeicosatetraenoate (15) and $NaBH_4$ reduction of the resultant aldehyde gave an alcohol. Alcohol to bromide interconversion under standard conditions followed by displacement with triphenylphosphine in acetonitrile generated a phosphonium salt. The 3*R*-*t*-butyldiphenylsilyloxy *d*-valerolactone (16) prepared from 2-deoxy-D-ribose as described

(17) was converted to an ester *via* saponification and treatment with ethereal diazomethane, the oxidation of which with pyridinium chlorochromate yielded chiral aldehyde. The condensation of chiral aldehyde with the ylide of phosphonium salt gave, after fluoride-mediated deprotection and high-performance liquid chromatography (HPLC) purification, methyl 3*R*-hydroxy-5,8,11,14-eicosatetraenoate. Mitsunobu inversion of it using chloroacetic acid, saponification of the resultant ester, and diazomethane esterification yielded methyl 3*S*-hydroxy-5,8,11,14-eicosatetraenoate. The corresponding free acids were prepared by saponification of the respective esters.

Cultivation of the yeast D. uninucleata*. Dipodascopsis uninucleata* UOFS Y128 was grown to stationary phase (sexual stage) after which 12.5 mg/L of the fatty acid (Table 1) were added. Following 6 h of incubation, the cells were harvested. The growth and harvesting procedures were as described earlier (12).

Extraction of fatty acid metabolites from the yeast. The cells obtained in each experiment were mixed with absolute ethanol to a final concentration of 80% ethanol. The suspension was kept at 5°C for 18 h and then filtered. The filtrate was adjusted to 15% aqueous ethanol. The yeast sample was acidified to pH 3.0 with formic acid and chromatographed on a preconditioned Sep-Pak C_{18} cartridge (Millipore, Bradford, MA) as described (18). The AA metabolites were finally eluted with 5 mL of freshly distilled ethyl acetate. The eluate was evaporated under a stream of nitrogen, and the fatty acid metabolites were separated from other hydrophobic compounds by applying their triethylamine salts on Sep-Pak silica gel cartridges and eluting them with 15% ethanol. Following evaporation of ethanol under a stream of nitrogen, the samples were adjusted to pH 3.0 and extracted with ethyl acetate as described above. Each sample was again chromatographed on a preconditioned Sep-Pak C_{18} cartridge as described before and finally dissolved in chloroform.

Thin-layer chromatography (TLC). Chloroform fractions obtained from yeasts fed with the polyenoic fatty acid in the presence or absence of 1 mM acetylsalicylic acid were chromatographed together with the 3-HETE standard prepared in our own laboratory on silica gel plates (Merck) as described (12). The compounds were visualized by placing the TLC plates in an iodine tank.

Electron impact mass spectra. Electron impact mass spectra of 3-HETE and other 3-hydroxy fatty acids were recorded on a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) equipped with a Hewlett-Packard 5972 MSD at 1447 EM Volts. An HP-1 fused-silica capillary column (30 m × 0.25 mm i.d.) was used for separation with helium as carrier gas. Other operating conditions were: ion source 170°C and electron impact energy 70 eV.

Prior to analysis, the methyl–trimethylsilyl (ME–TMSi) derivatives of the samples were prepared as described (19) and reconstituted in 100 µL chloroform/hexane (1:4) before injection. Samples were injected by split ratio of 1:50 at 230°C and the column temperature programmed from 140–300°C at 5°C per min.

Analysis of enantiomeric composition of 3-HETE. Enantiomeric analysis of 3-HETE from *D. uninucleata* was performed on an Apex Chiral AU 50 HPLC column (4.6 × 250 mm; Jones Chromatography, Hengoed, Glamorgan, United Kingdom) with a variable wavelength ultraviolet-detector (Pharmacia, Freiburg, Germany) using 1% isopropanol in *n*-hexane as isocratic solvent system. The flow rate was 1.0 mL/min. The ultraviolet absorption peaks were monitored at 208 nm.

[a]As judged by the detection of a fraction comigrating with 3-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid in thin-layer chromatography.

RESULTS

A number of fatty acids were fed to *D. uninucleata.* After 6 h the fatty acids which were not incorporated in cellular lipids were extracted by ethanol and separated as described in the Experimental Procedures section. It is evident from Table 1 that a selected number of fatty acids produced various compounds which comigrated =in TLC with authentic 3-HETE. These compounds were isolated, converted to their ME–TMSi derivatives, and their structures were established by gas chromatography/electron impact mass spectrometry (Figs. 1–4). The characteristic fragments of the compounds are listed in Table 2. All compounds exhibited a base peak of *m/z* 175 [$CH_3O(CO)–CH_2–CHO–TMSi$] which is indicative of a hydroxylation at C-3 position. A 3-hydroxy derivative accumulated when 5*Z*,8*Z*,11*Z*-eicosatrienoic, 5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic (AA), 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-eicosapentaenoic, 11*Z*,14*Z*,17*Z*-eicosatrienoic, or 9*Z*,12*Z*-octadecadienoic (linoleic) acids were fed to the yeast. From the structural identification of the corresponding derivatives, it was evident that the first three fatty acids were 3-hydroxylated without alteration of the chain length, whereas the other two were shortened by six and four carbon atoms, respectively. In contrast, 3-hydroxy derivatives were not observed upon feeding of 9*Z*-octadecenoic (oleic), 9*E*,12*E*-octadecadienoic (linolelaidic), 6*Z*,9*Z*,12*Z*-octadecatrienoic (γ-linolenic), or eicosanoic acids, although these fatty acids were shown to be metabolized to a large extent by the yeast, most probably *via* β-oxidation. Feeding experiments with C_{22} polyenoic fatty acids failed

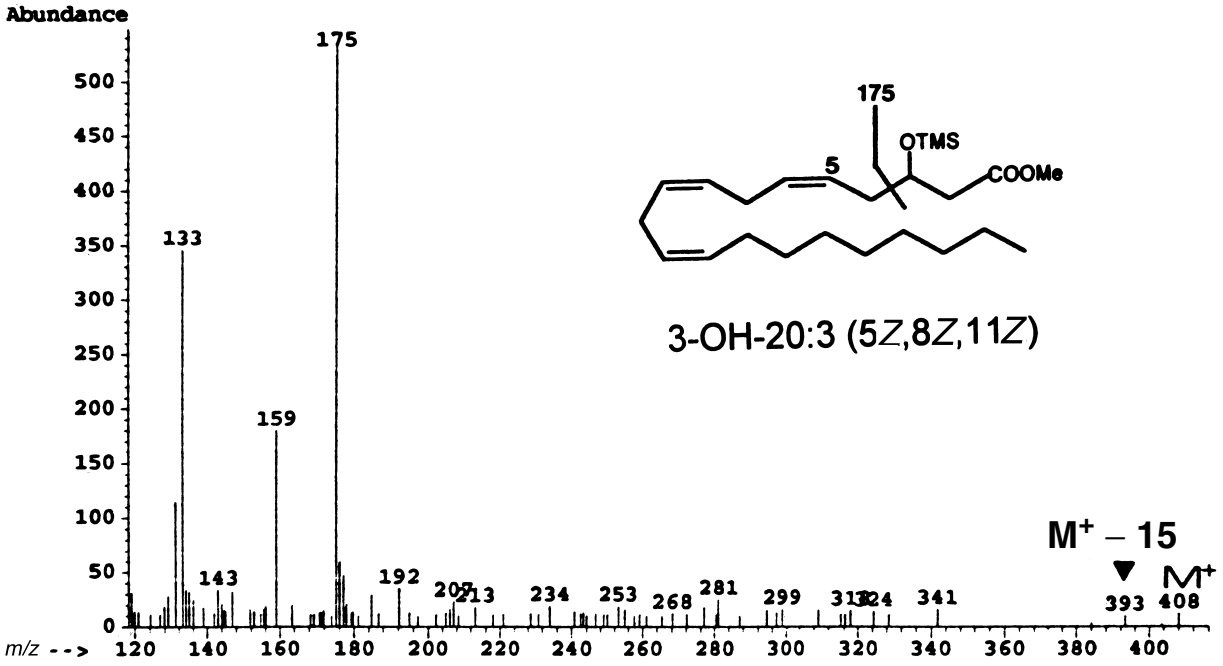

FIG. 1. Electron impact–mass spectra of methyl-trimethylsilylated 3-hydroxy 20:3 (5*Z*,8*Z*,11*Z*).

since the latter turned out to be toxic to *D. uninucleata*. The accumulation of the 3-hydroxy polyenoic fatty acids was generally suppressed by 1 mM acetylsalicylic acid.

For the product from AA, 3-HETE, an analysis of the enantiomeric composition was performed. Figure 5A shows the resolution of the enantiomers when injected in a ratio of 4:1 (40 µg 3*R*-HETE and 10 µg 3*S*-HETE). The retention volumes were 3.0 and 3.8 mL solvent, respectively. Figure 5B clearly shows that the natural 3-HETE from *D. uninucleata* consists of 95% 3*R*-HETE. Interfering peaks were not observed in the HPLC chromatogram at the above retention volumes (Fig. 5C). [In independent experiments these data were confirmed by Dr. M. Hamberg, Karolinska Institute, Stockholm, Sweden, who analyzed a sample of 3-HETE from *D. uninucleata* supplied by Dr. J. Friend, University of Hull, United Kingdom (personal communication).]

DISCUSSION

In this report we have demonstrated that *D. uninucleata* produced a 3-hydroxy derivative not only from AA but also from a variety of other polyenoic fatty acids, including linoleic acid which contributes to about one-fourth of the total fatty acids of this yeast (13). It is interesting to note that 3-HETE exhibited an enantiomeric ratio of 95:5 (*R/S*). On the basis of structural similarities between 3*R*-HETE and other 3-hydroxy fatty acids, we postulate that the other 3-hydroxy fatty acids should also bear the *R*-configuration. The observation that a number of other fatty acids, among them saturated fatty acids, oleic acid and γ-linolenic acid, were not converted to detectable amounts of 3-hydroxy derivatives, despite the fact that they were metabolized, suggests some specific structural requirements for the 3*R*-hydroxylation. From the comparison of the structures of the hydroxylation-susceptible and nonsusceptible fatty acids, and of those of the hydroxy derivatives, it follows that the presence of a 5*Z*,8*Z*-diene system in the fatty acid molecule is a prerequisite for 3*R*-hydroxylation by *D. uninucleata*. Such a diene arrangement can also be accomplished by a preceding partial breakdown of the fatty acid *via* β-oxidation, which explains the formation of 3-hydroxylated C_{14} polyenoic fatty acids from linoleic acid and 11*Z*,14*Z*,17*Z*-eicosatrienoic acid.

The 5*Z*,8*Z*-diene system in the fatty acid does not take part in the aforementioned biotransformation reaction, nor does it seem to be capable of activating the methylene group at the

C-3 position at which hydroxylation occurs. Therefore, the 5*Z*,8*Z*-diene system might fulfill a signal function for the recognition of the substrate by the corresponding enzyme in *D. uninucleata via* binding at the active site.

At first sight, a 3-hydroxy fatty acid may be principally formed *via* incomplete β-oxidation. In that case, however, the 3*S* enantiomer (corresponding to 3-[L] according to the Fischer nomenclature) would have been found as the main metabolite. Since we clearly demonstrated that *D. uninucleata* produced nearly exclusively 3*R*-HETE (3-[D]-HETE)

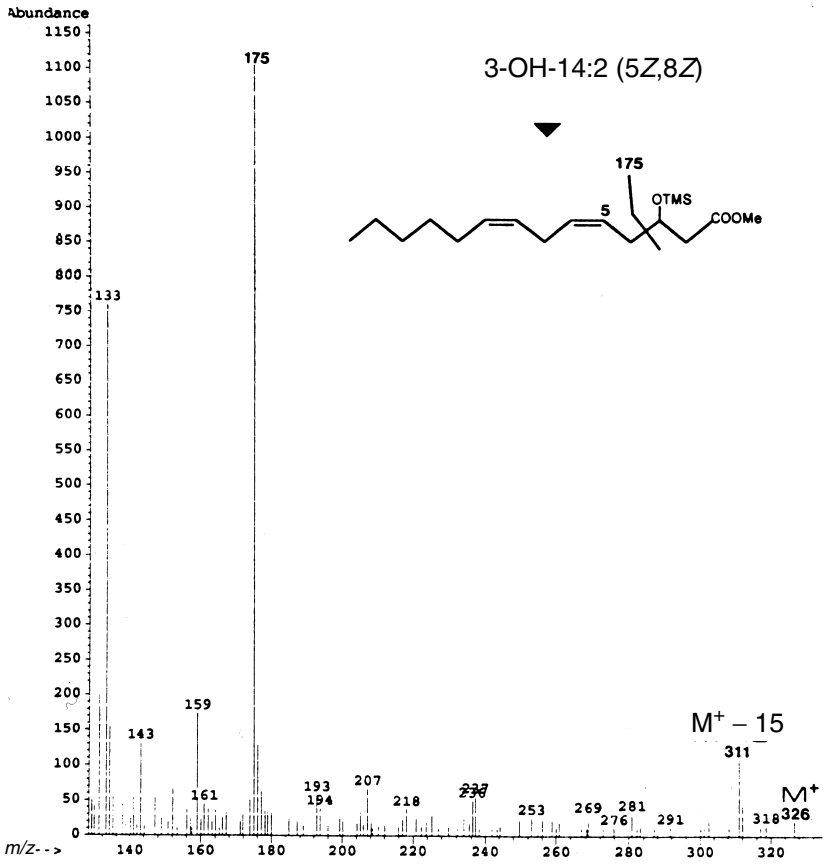

FIG. 3. Electron impact–mass spectra of methyl-trimethylsilylated 3-hydroxy 14:2 (5*Z*, 8*Z*). See Figure 1 for abbreviations.

from AA, such an assumption has to be rejected. The different stereospecificities of the biosynthetic pathway in *D. uninucleata* and β-oxidation further imply that the 3*R*-hydroxy fatty acids cannot be degraded *via* normal β-oxidation, which might be the reason for the accumulation of these oxylipins upon feeding of the corresponding precursor fatty acids to the yeast.

The capability of producing 3*R*-hydroxy fatty acids is apparently not restricted to *D. uninucleata* alone. *The* 3*R*-hydroxypalmitic acid and related saturated compounds have been reported in other yeasts such as *Rhodotorula graminis, Rh. glutinis* (20), and *Saccharomycopsis malanga* (21). Moreover, medium-chain 3-hydroxy fatty acids have been shown to be present in the glycolipids of the smut fungi *Ustilago zeae* and *U. nuda* (22). Finally, saturated 3*R*-hydroxy fatty acids with 10, 12, and 14 carbons are encountered in Lipid A, the component of the lipopolysaccharides of Gram-negative bacteria that is essential for endotoxin activity (23). The biosynthetic system in *D. uninucleata* appears to differ, however, from those of other fungi and of bacteria in its marked preference for polyunsaturated fatty acids possessing a 5*Z*,8*Z*-diene system.

The biosynthetic pathway to the 3*R*-hydroxy polyenoic fatty acids remains to be elucidated. Lipoxygenase- or dioxygenase-mediated reactions can be excluded since they would require a neighboring double-bond system (at C-2 and/or C-4). The same is true for the involvement of prostaglandin endoperoxide synthase, even though the synthesis of the 3*R*-hydroxy fatty acids was found to be inhibited by acetylsalicylic acid (12). It should be stressed that the action of acetylsalicylic acid on enzymes is fairly unspecific. Moreover, acetylsalicylate and salicylate act in higher plants as hormones inducing certain hypersensitivity reactions by changing the gene expression program (24,25). Thus, two metabolic routes to 3*R*-hydroxy fatty acids are conceivable: (i) a reaction sequence analogous to β-oxidation, however, implicating a 2-enoyl-CoA hydratase with opposite steric specificity; and (ii) a direct monooxygenase reaction at C-3, e.g., by a cytochrome P-450 type enzyme.

The conversion of linoleic acid to 3*R*-hydroxy-5*Z*,8*Z*-tetradecadienoic acid needs special attention in view of the fact that the precursor fatty acid contributes to about one-fourth of the total fatty acid content of *D. uninucleata* (13). Therefore, this oxylipin could exert a regulatory function during the sexual phase of the reproductive cycle of this yeast as has been shown to be the case for other fungal oxylipins (9).

Since *D. uninucleata* does not synthesize adequate amounts of AA, the conversion of the latter to 3*R*-HETE does not appear to be of major importance for the reproduction biology of this yeast. This reaction may, however, play a pivotal role in the cell-cell interaction with AA-producing organisms. In separate investigations we found that 3*R*-HETE af-

fects signal transduction processes in human neutrophils and tumor cells in multiple ways (Nigam, S., Grierman, M., Schewe, T., Kock, J.L.F., Botha, A., Kumar, G.S., and Franke, J., submitted for publication). Thus, this novel eicosanoid may be capable of modifying inflammatory processes and mitogenesis. In view of these observations, it would be of vital interest to investigate whether 3*R*-HETE and related compounds can also be produced by those fungal strains that are pathogenic to humans.

Identification of Milk Fat Triacylglycerols by Capillary Supercritical Fluid Chromatography–Atmospheric Pressure Chemical Ionization Mass Spectrometry

Päivi Laakso[1,*] and Pekka Manninen

Department of Biochemistry and Food Chemistry, University of Turku, FIN-20014 Turku, Finland

ABSTRACT: Identification of milk fat triacylglycerols was accomplished by capillary supercritical fluid chromatography (SFC) combined with atmospheric pressure chemical ionization mass spectrometry [(APCI)MS]. Supercritical carbon dioxide was the carrier fluid in SFC. Ionization was achieved by introducing vapor of ammonia in methanol into the ionization chamber, which resulted in the formation of abundant $[M + 18]^+$ and $[M - RCOO]^+$ ions of triacylglycerols. These ions defined both the molecular weight and the fatty acid constituents of a triacylglycerol, respectively. SFC on a nonpolar stationary phase provided an efficient separation of triacylglycerols according to the combined number of carbon atoms in the acyl chains of a molecule. In addition to the identification of the major chromatographic peaks representing molecules with 26–54 acyl carbons, minor peaks representing triacylglycerols with an odd number of acyl carbons were separated and identified. Furthermore, compositional information on partially separated isobaric triacylglycerols, which differed substantially in the chain length of the fatty acyl residues, was achieved within some of the peaks. A new finding of the present study was the formation of abundant $[M + 18]^+$ ions of saturated triacylglycerols in addition to diagnostic fragment ions, being of primary importance in structure elucidation. This extends the applicability of capillary SFC–(APCI)MS in the analysis of both saturated and unsaturated triacylglycerols.

Lipids 32, 1285–1295 (1997).

Capillary supercritical fluid chromatography (SFC) has been shown to be a useful technique for the determination of triacylglycerols of various samples, such as berry oils (1–3), milk fat (2,4,5), and fish oil (1,2,6,7). Both nonpolar and polar stationary phases have been applied for the separation of milk fat triacylglycerols: SFC on a nonpolar stationary phase results in separation mainly according to the molecular size, i.e., the combined number of acyl carbons in the acyl chains of a triacylglycerol, whereas both the molecular size and the degree of unsaturation of a triacylglycerol affect the separation on a polar stationary phase. Capillary SFC is most often combined with a flame-ionization detector (FID), which does not allow structural elucidation of triacylglycerols.

Detailed information on molecular species compositions of triacylglycerols can only be obtained by combining chromatographic separation with detection by mass spectrometry (MS). Both high-temperature gas chromatography (GC) (8–13) and high-performance liquid chromatography (HPLC) (14–16) combined with MS have been utilized for the analysis of milk fat triacylglycerols. An ideal mass spectrum consists of ions which define both the molecular weight and the fatty acid moieties of a triacylglycerol. GC–MS with electron ionization at 70 eV results in extensive fragmentation of triacylglycerols, yielding mostly ions characterizing the fatty acid constituents of a molecule (17). The abundances of $M^{+\cdot}$ and $[M - 18]^+$ ions, which define the molecular weight, are typically low, if they are present at all. Chemical ionization (CI) is a softer ionization technique providing typically less fragmentation than electron ionization. GC–MS in ammonia positive-ion CI mode results in the formation of abundant ions containing the intact molecules, such as $[M + NH_4]^+$ ions (9), and to a lesser extent fragment ions, whereas negative-ion CI with ammonia provides only fragment ions (13). On the other hand, positive-ion CI with methane has been reported to yield only $[M - RCOOH]^+$ ions of most milk fat triacylglycerols (11). The mass spectra of milk fat triacylglycerols achieved by HPLC–MS in positive-ion CI mode, using a mixture of acetonitrile and propionitrile as a mobile phase, exhibited mostly $[MH - RCOOH]^+$ ions (15,16), whereas chloride-attachment negative-ion CI provided spectra exhibiting only $[M + Cl]^-$ ions (14). Thus, combining the data produced by positive-ion CI and negative-ion CI is in most cases needed for interpretation of the results. Other problems may be caused by the column bleed in GC–MS analyses, which may result in unreliable interpretation of spectra. In addition, high temperatures required for volatilization of triacylglycerols cause degradation or polymerization of highly unsaturated molecules (18,19). Utilization of a direct liquid inlet for

interfacing HPLC to mass spectrometer requires efficient splitting of the effluent flow before introduction into the MS, which decreases sensitivity. During the last few years, interest in atmospheric pressure ionization techniques in lipid analysis has increased. Byrdwell *et al.* (20,21) were the first to report the analysis of triacylglycerols by reversed-phase HPLC combined with atmospheric pressure chemical ionization (APCI). Since then, (APCI)MS has also been applied to the identification of triacylglycerols separated by silver-ion HPLC (22).

Recently, a simple interfacing of a capillary supercritical fluid chromatograph with a mass spectrometer utilizing a commercially available HPLC–MS interface has been introduced (23). Capillary SFC–(APCI)MS of triacylglycerols, using methanol as a reactant-ion solvent, resulted in the formation of abundant $[M + H]^+$ and $[M - RCOO]^+$ ions, which characterized both the molecular weight and the fatty acid constituents of a molecule. The capillary SFC–MS method has been applied to the identification of triacylglycerols in berry oils (23,24). In our previous studies (2,5), a good separation of milk fat triacylglycerols has been achieved by capillary SFC combined with an FID on a nonpolar stationary phase. The objectives of the present research were to examine the ionization of relatively saturated triacylglycerols present in milk fat and to identify the triacylglycerols by using capillary SFC–(APCI)MS.

MATERIALS AND METHODS

Materials. Triacylglycerols of a milk sample collected after 7 d of parturition were analyzed in this study. The sample was the same (from cow 1) as described in our previous study (5). The milk fat sample was dissolved in dichloromethane (Rathburn Chemicals Ltd., Walkerburn, Scotland) to a concentration of approximately 20 mg/mL.

SFC. The SFC separations were conducted with a Lee Scientific Series 600 supercritical fluid chromatograph (Dionex, Salt Lake City, UT) combined with a Finnigan MAT TSQ-700 triple quadrupole mass spectrometer (San Jose, CA). The interfacing of the capillary SFC to the mass spectrometer was done utilizing a commercial HPLC–APCI source (Finnigan MAT) as described elsewhere (23). An electrically and pneumatically controlled Valco switching valve (Houston, TX) with an internal loop volume of 1.0 μL was used for timed split/dynamic split injections with a loop-open time of 1.0 s. Frit restrictors (30 cm × 50 μm i.d.; Dionex) were installed both at the dynamic split outlet and at the detector end of the analytical column. SFC-grade CO_2 (Scott Specialty Gases, Plumsteadville, PA) was used as a carrier fluid with a column flow rate of 0.37 mL/min measured with propane at the initial conditions of the chromatographic program with FID. An SB-Octyl-50 column (10 m × 50 μm i.d. with 0.25 μm film; Dionex) was used with a linear density programming of CO_2 from 0.140 g/mL with a rate of 0.010 g/mL/min at a constant temperature of 140°C for the elution of triacylglycerols.

MS. Triacylglycerols were ionized by using the APCI technique. Ionization of triacylglycerols was facilitated by introducing vapor of reactant-ion solvent, i.e., methanol (gradient grade; Merck, Darmstadt, Germany) or 0.5% ammonia in methanol (25% ammonia solution [p.a.-plus, Riedel-de Haën, Seelze, Germany)/methanol, 1:49, vol/vol]), into the ionization chamber *via* the sheath gas flow as reported elsewhere (23). The APCI vaporizer temperature was kept at 425°C and the APCI capillary at 200°C. The corona needle current was set at 5.0 μA. The sheath gas (nitrogen) pressure was 15 psi and the auxiliary gas (nitrogen) flow rate was 5 mL/min. The gases were preheated before being introduced into the APCI source. The mass spectrometer was operated in a full-scan mode using quadrupole 1 for scanning. Positively charged ions with *m/z* values 200–950 were scanned with a scan time of 0.8 s.

RESULTS AND DISCUSSION

Ionization of milk fat triacylglycerols. Introduction of methanol vapor into the ionization chamber in capillary SFC–(APCI)MS has been reported to yield abundant $[M + H]^+$ and $[M - RCOO]^+$ ions of unsaturated triacylglycerols of berry oils (23,24). The ions characterized the molecular weight and the fatty acid moieties of triacylglycerols, respectively. The ion abundances were affected by the molecular compositions of triacylglycerols, i.e., the degree of unsaturation, the regiospecific distribution of fatty acyl residues, and the acyl chain length and the number of double bonds and their positions in the fatty acyl residue (23,24). In general, the ion abundance of a protonated molecular ion increased with increasing degree of unsaturation of a molecule. Furthermore, triacylglycerols having 0–2 double bonds in the acyl chains were found to produce very weak or no $[M + H]^+$ ions. Instead of methanol, ammonia may be a good reactant ion for the ionization of relatively saturated triacylglycerols, as suggested in our previous study (23).

In this study, methanol vapor and 0.5% ammonia in methanol as a reactant-ion solvent were tested for the ionization of milk fat triacylglycerols analyzed by capillary SFC–(APCI)MS. The weakest possible reactant ion is formed with mixed reactant-ion solvents (25), i.e., NH_4^+ from the solution of 0.5% ammonia in methanol. The reconstructed ion chromatograms of milk fat triacylglycerols achieved by using either ammonia or methanol as a reactant-ion solvent were comparable and, thus, only the one produced by using ammonia is shown in Figure 1. Examples of the (APCI)MS spectra of milk fat triacylglycerols, produced either by methanol or by ammonia in methanol, are presented in Figure 2. The main differences are found in the molecular ion regions, whereas the $[M - RCOO]^+$ ion regions are very similar in both cases. The mass spectrum, achieved by using methanol as a reactant-ion solvent, exhibited small amounts of $[M + H]^+$ and $[M + 18]^+$ ions being only a few percentage in relative abundance (Fig. 2B). Most milk fat triacylglycerols yielded only a weak (<2%) $[M + H]^+$ ion or no ion. Reliable identification of triacylglycerols is not possible based on this information

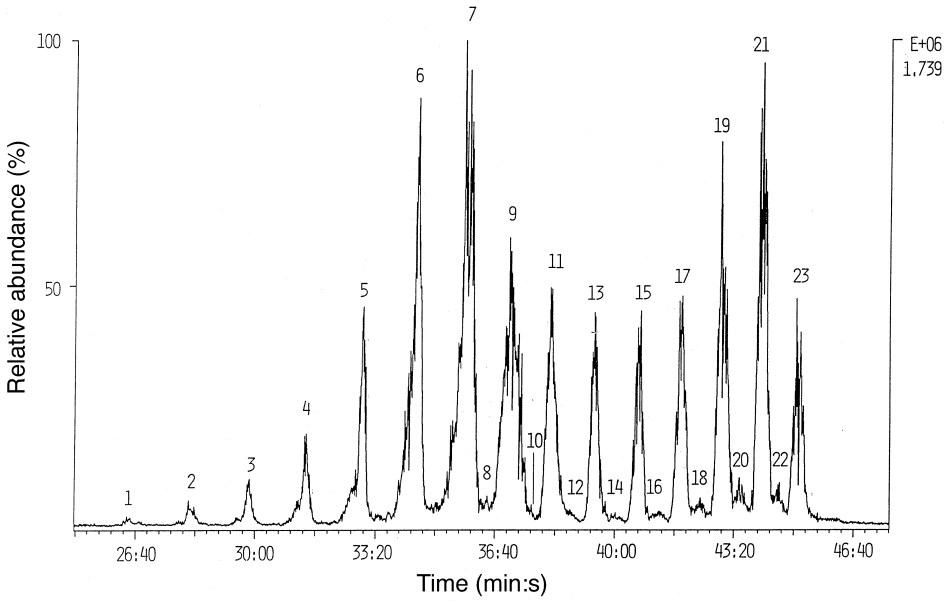

FIG. 1. Reconstructed ion chromatogram of milk fat triacylglycerols analyzed by capillary supercritical fluid chromatography–atmospheric pressure chemical ionization mass spectrometry using ammonia as a reactant ion (without smoothing).

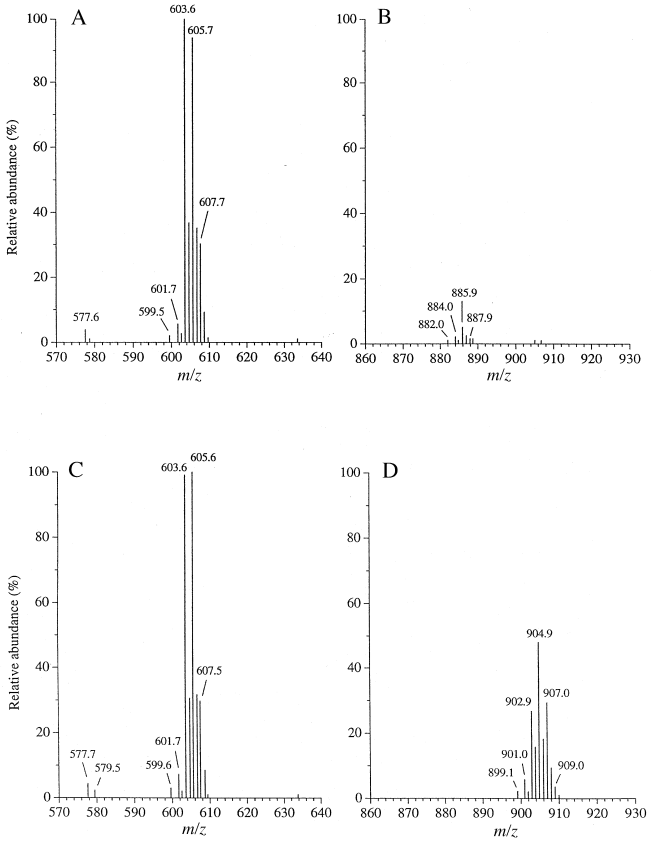

FIG. 2. Atmospheric pressure chemical ionization mass spectrometry [(APCI)MS] spectra of the chromatographic peak number 23 in Figure 1 representing milk fat triacylglycerols with 54 acyl carbons produced by using methanol (A, B) or 0.5% ammonia in methanol (C, D) as the reactant-ion solvent: (A) the region of $[M - RCOO]^+$ ions and (B) the region of $[M + H]^+$ ions produced by methanol; (C) the region of $[M - RCOO]^+$ ions and (D) the region of $[M + 18]^+$ ions produced by 0.5% ammonia in methanol.

only. The use of ammonia resulted in the formation of abundant $[M + 18]^+$ and $[M - RCOO]^+$ ions of milk fat triacylglycerols separated by capillary SFC (Fig. 2C and D). The $[M + 18]^+$ ions defined the molecular weight and, thus, the number of carbon atoms and double bonds in the acyl chains of a triacylglycerol, whereas the $[M - RCOO]^+$ fragment ions provided information on the fatty acid constituents of a molecule. The formation of $[M + 18]^+$ ions of saturated triacylglycerols is a new finding allowing reliable identification of molecular weight species of triacylglycerols.

Identification of milk fat triacylglycerols. The chromatographic resolution of milk fat triacylglycerols achieved by capillary SFC–(APCI)MS on an SB-Octyl-50 column (Fig. 1) was comparable to that reported earlier by capillary SFC-FID (2,5). The sensitivity of (APCI)MS was better than that of FID; therefore, it was possible to reduce the sample amount injected to the column. No baseline drifting was observed during the density programming of supercritical carbon dioxide.

Triacylglycerols were mainly separated according to their acyl carbon numbers (ACN; combined number of carbon atoms in the acyl chains of a triacylglycerol). Figure 2C and D show, as an example, the mass spectrum of the chromatographic peak representing triacylglycerols with 54 acyl carbons. The $[M + 18]^+$ ions defined the number of acyl carbons and the number of double bonds in a triacylglycerol: *m/z* 899.1 corresponded to the triacylglycerol 54:5, *m/z* 901.0 to 54:4, *m/z* 902.9 to 54:3, *m/z* 904.9 to 54:2, *m/z* 907.0 to 54:1, and *m/z* 909.0 to 54:0 (Fig. 2D). The presence of 54:0 in the sample was unlikely, because the ion *m/z* 909.0 abundance was contributed by the isotope ion of 54:1, containing two ^{13}C isotopes or one ^{18}O isotope. The interpretation of the $[M - RCOO]^+$ ion region was more complicated (Fig. 2C). Most of the $[M - RCOO]^+$ ions represented the loss of different fatty acyl residues from different triacylglycerols. For ex-

ample, 54:2 may yield the fragment ions *m/z* 603.6, *m/z* 605.6, and *m/z* 607.6, representing the loss of stearic acid, oleic acid, and linoleic acid, respectively. Furthermore, the loss of one fatty acid constituent from 54:3 may produce the ions *m/z* 601.7, *m/z* 603.6, *m/z* 605.6, and *m/z* 607.6, corresponding to the loss of stearic acid, oleic acid, linoleic acid, and linolenic acid. The interpretation of the mass spectra of most of the chromatographic peaks was easier compared with ACN 54 due to the presence of fewer molecular weight species in a single chromatographic peak.

Examples of the mass spectra extracted from the chromatographic peaks corresponding to triacylglycerols with ACN 26, 40, 46, and 49 are shown in Figure 3. Each mass spectrum exhibited $[M + 18]^+$ ions, which characterized the molecular weight species of triacylglycerols present in the peak. For example, peak number 1 in Figure 1 consisted of a single molecular weight species of triacylglycerol 26:0 (Fig. 3A), whereas peak number 9 represented triacylglycerols 40:0, 40:1, and 40:2 (Fig. 3B). Furthermore, the $[M - RCOO]^+$ ions provided information on the fatty acid moieties of triacylglycerols. For example, the mass spectrum of peak number 1 shows clearly the loss of fatty acids 4:0, 6:0, 8:0, 10:0, 12:0, 14:0, and 16:0 from the triacylglycerol 26:0. However, this kind of data does not provide direct information on the molecular associations of fatty acids in single triacylglycerols. The interpretation of the mass spectra of peaks number 9, 15, and 18 in Figure 1 was more complicated owing to the presence of several molecular weight species in a single chromatographic peak. Instead of information on single fatty acid moieties, the $[M - RCOO]^+$ ion region in the mass spectra consisted of ion clusters representing the loss of, for example, C_{18} or C_{16} fatty acids from the triacylglycerols. In most cases, unambiguous identification of the loss of different C_{18} fatty acids from a single triacylglycerol was not possible: for example, the ion *m/z* 495.4 in the mass spectrum of peak number 15 may be formed by the loss of 18:3 from triacylglycerol 46:3, or by the loss of 18:2 from 46:2, or by the loss of 18:1 from 46:1, or by the loss of 18:0 from 46:0 (Fig. 3C). The loss of 4:0, 6:0, and 8:0 from a triacylglycerol could be identified from each molecule. In addition to triacyl-

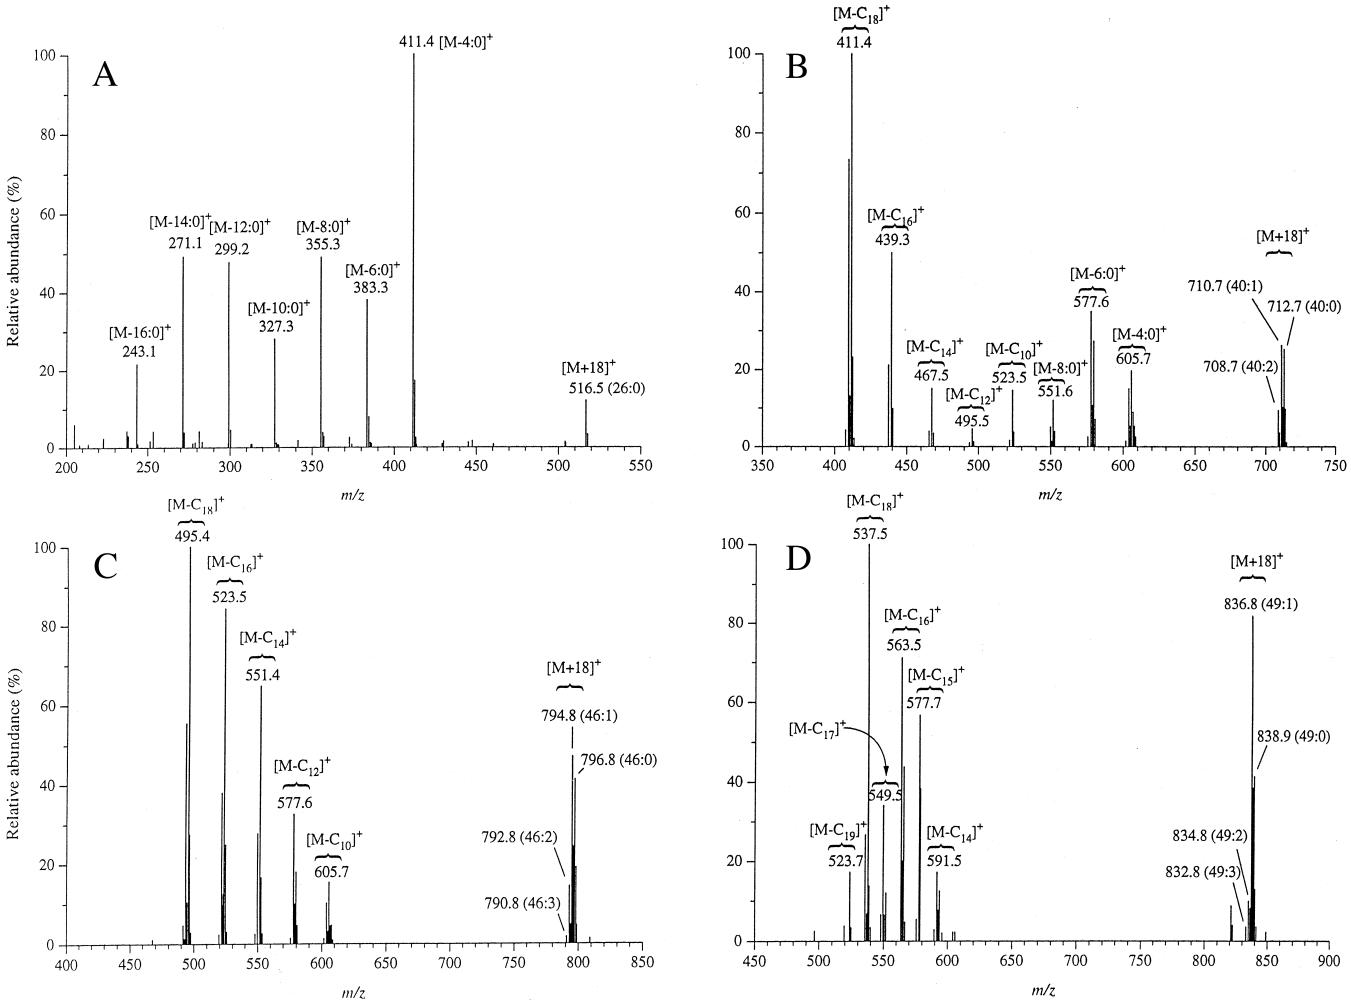

FIG. 3. Examples of the (APCI)MS spectra of four chromatographic peaks of milk fat triacylglycerols, separated by capillary supercritical fluid chromatography, representing triacylglycerols with (A) acyl carbon number (ACN) 26 (peak number 1), (B) ACN 40 (peak number 9), (C) ACN 46 (peak number 15), and (D) ACN 49 (peak number 18). Peak numbers refer to those presented in Figure 1. For other abbreviation see Figure 1.

glycerols with an even number of acyl carbons, also triacylglycerols with an odd ACN were identified. The mass spectrum of peak number 18 representing triacylglycerols with ACN 49 showed the presence of C_{15}, C_{17}, and C_{19} fatty acids in these molecules (Fig. 3D).

Previously, partial separation of isobaric triacylglycerols, differing substantially in the chain length of the fatty acyl residues, was reported on the SB-Octyl-50 column (5). Capillary SFC–(APCI)MS allowed the examination of compositional differences of the separated molecules. Figure 4A presents the mass spectrum of the whole peak number 4 in Figure 1, representing triacylglycerols 32:0 and 32:1. The possible fatty acid constituents of the triacylglycerols were 4:0, 6:0, 8:0, C_{10}, C_{12}, C_{14}, C_{16}, and C_{18} acids. The shoulder in front of the peak represented triacylglycerols which did not contain 4:0 acid (Fig. 4B). Furthermore, the relative abundances of ions corresponding to the loss of C_{12}–C_{18} acids were found compared with the total peak. According to this data, milk fat triacylglycerols with 32 acyl carbons containing 4:0 do not have other short-chain fatty acids in the same molecule. In addition, triacylglycerols containing 4:0 had stronger interaction with the column stationary phase than the others. Further evidence of the same phenomenon is provided in Figure 5, which shows the mass spectra extracted from different parts of peak number 5 in Figure 1. The fatty acid constituents of the molecules eluting in the latter part of the peak were 4:0 and C_{12}–C_{18} (Fig. 5C). In addition, there was a complete absence of C_6–C_{10} fatty acids in the spectrum, which resulted in great chain-length differences of acyl chains within a triacylglycerol and thus enhanced retention to the stationary phase. Triacylglycerols eluting in the beginning of the peak consisted of a wider range of fatty acids, i.e., from C_6–C_{18}

[a]Peak numbers refer to those presented in Figure 1.

[b]ACN = acyl carbon number.

[c]Abbreviation describes the number of acyl carbons and the number of double bonds in the acyl chains of a triacylglycerol (ACN:*n*).

[d]Loss of a fatty acid moiety (FA) from a triacylglycerol. Abbreviation: n.d., not detected.

(Fig. 5B). The ion *m/z* 521.6 was formed by the loss of 4:0 from 34:1, whereas no loss of 4:0 from 34:0 was recorded. This may be explained by a slightly weaker interaction of 34:1 with the stationary phase than 34:0. This conclusion is supported by earlier studies, where double bonds have been reported to reduce the retention of unsaturated molecules on this stationary phase (2). The same phenomenon, but to a lesser extent, is also seen in Figure 4.

Capillary SFC–(APCI)MS on an SB-Octyl-50 column resulted in separation of milk fat triacylglycerols according to their ACN (26–54). The chromatographic separation efficiency and the detection sensitivity allowed the identification of the molecular weight species and the fatty acyl residues of triacylglycerols of 23 chromatographic peaks, as presented in Table 1. The loss of possible fatty acid constituents was judged based on the fatty acid composition of milk fat triacylglycerols (5,26). Although the molecular associations of fatty acyl residues of triacylglycerols could not be determined, data on possible fatty acid constituents were achieved: for example, 4:0 acid was determined only in peaks representing triacylglycerols with ACN ≤ 40.

The major accomplishment of this study was the formation of $[M + 18]^+$ ions of saturated molecules, which is essential for the structural identification of triacylglycerols. The drawback in most studies concerning GC–MS (10–13) or HPLC–MS (15,16) of milk fat triacylglycerols has been the nearly complete absence of ions characterizing the molecular weight of intact molecules in the mass spectra. For example, Evershead (13) achieved direct information on the fatty acyl residues, based on the $RCOO^-$, $[RCOO - 18]^-$, and $[RCOO - 19]^-$ ions of milk fat triacylglycerols analyzed by GC–MS using ammonia negative-ion CI. However, the ACN identification of triacylglycerols was done according to the retention times only, owing to the absence of molecular ions in the spectra. On the other hand, some techniques, i.e., chloride-attachment negative-ion CI, provided only molecular weight information on triacylglycerols without formation of fragment ions (14). In addition to chromatography–MS combinations, milk fat triacylglycerols have been identified and quantified, for example, by fractionation of triacylglycerols by HPLC followed by analysis of the fatty acid compositions of the collected fractions by GC (27,28). A lot of valuable information has been produced by using this kind of approach, but the major drawback of these studies is the lack of information on native molecules. In the present study, a single SFC–MS determination provided information on both the molecular weights and the fatty acid constituents of saturated as well as unsaturated milk fat triacylglycerols, which is a new finding. However, the interpretation of the fatty acids was not unambiguous, owing to the elution of triacylglycerols having equivalent carbon numbers in a single chromatographic peak on an SB-Octyl-50 stationary phase. Therefore, no direct judgment of the fatty acid compositions of triacylglycerols could be done in this study. In order to simplify the interpretation of capillary SFC–(APCI)MS spectra, fractionation of milk fat triacylglycerols according to the degree of unsaturation by argentation chromatography (11,16,27) before SFC separation is recommended. Still, it is evident that several isobaric triacylglycerols remain unseparated because of the great complexity of milk fat triacyglycerols. In general, the capillary SFC–(APCI)MS method presented, utilizing ammonia in methanol for ionization purposes, is an excellent choice for the identification of milk fat triacylglycerols in comparison with the other techniques available. In this study, valuable information on the molecular compositions of milk fat triacylglycerols was achieved. In addition to the major components, structural information was also obtained from the minor components, such as triacylglycerols with odd ACN, as well as on partially separated isobaric triacylglycerols.

Lipase-Based Quantitation of Triacylglycerols in Cellular Lipid Extracts: Requirement for Presence of Detergent and Prior Separation by Thin-Layer Chromatography

ABSTRACT: A protocol, based on the use of *Pseudomonas* lipase, is presented to measure quantitatively the amount of triacylglycerols in extracts from cultured cells or tissues. Since the lipase also acts on di- and monoacylglycerols, separation of the extracts by thin-layer chromatography is recommended. In order to allow the lipase-catalyzed hydrolysis to proceed efficiently, lipid extracts or eluates from silica scrapings were mixed with the detergent Thesit [dodecylpoly(ethylene glycol ether)], prior to drying. After dissolution of the dried residues in water, the amount of triacylglycerols was quantified using *Pseudomonas* sp. lipase, glycerol kinase, glycerol-phosphate oxidase, and peroxidase. The activity of the latter enzyme was followed either colorimetrically in the presence of 4-aminoantipyrine and 2,4,6-tribromo-3-hydroxybenzoic acid or fluorimetrically in the presence of homovanillic acid.
Lipids 32, 1297–1300 (1997).

During the course of our investigations on the role of androgens in prostate cancer, accumulation of intracellular lipid droplets was observed in androgen-stimulated LNCaP cells, cells derived from a lymph node carcinoma of human prostate. Based on thin-layer chromatography (TLC) analysis, combined with enzymatic measurements, these lipids appear to be cholesteryl esters and triacylglycerols (TAG) (1). Routine procedures for the quantitation of TAG are nowadays based on enzymatic methods. By means of lipase (sometimes combined with esterase), TAG are hydrolyzed and the amount of liberated glycerol is monitored by indicator reactions. A convenient indicator reaction, incorporated in some commercial kits, is based on the combined use of glycerol-kinase and glycerol-3-phosphate oxidase whereby the produced H_2O_2 is captured by peroxidase in the presence of suitable H donors (2–4). When trying to measure the amount of TAG in lipid extracts from LNCaP cells, directly or after TLC separation, by means of a commercial kit [Sigma triglyceride (GPO-Trinder) reagents; Sigma Chemical Co., St. Louis, MO], some problems were encountered. Such kits are intended for the analysis of serum in which TAG are bound to lipoproteins. Despite the presence of surface-active compounds in the assay medium, dissolution of dried TAG was not adequate as revealed by the use of triolein standards. Based on further investigations on the use of detergents to solubilize the dried lipids and on the specificity of the lipase, an improved colorimetric or fluorescent procedure was developed to measure TAG in cellular lipid extracts.

Abbreviations: AAP: 4-aminoantipyrine; LNCaP, lymph node carcinoma of the prostate; TAG, triacylglycerol; TBHB: 2,4,6-tribromo-3-hydroxybenzoic acid; TLC, thin-layer chromatography.

EXPERIMENTAL PROCEDURES

Cell culture and lipid extraction. LNCaP cells were cultured as described in Ref. 1. After washing and scraping the monolayers in phosphate buffered saline, cells were collected by centrifugation, resuspended in 0.8 mL of phosphate buffered saline, and extracted with chloroform/methanol using 1 M NaCl during phase separation (5). Aliquots of the organic extract were analyzed for phospholipids (5) and for TAG, either directly or after separation by TLC on silica G 60 plates (0.25 mm thickness; Merck, Darmstadt, Germany) using heptane/diethyl ether/acetic acid (60:40:1, by vol) as solvent. Lipids were transiently visualized with iodine, and spots corresponding to TAG were scraped into glass tubes and eluted quantitatively with 2 mL of chloroform/methanol (1:1, vol/vol).

Colorimetric TAG assay. Trioleoylglycerol standards and aliquots of the cellular lipid extracts or of the silica eluates, freed from silica particles by centrifugation, containing up to 40 nmoles of TAG, were mixed with 10 μL of 20% (wt/vol) of the detergent Thesit [dodecylpoly(ethylene glycol ether)] (Boehringer, Mannheim, Germany) (in chloroform) and dried. To the oily residue was added 50 μL of water, tubes were placed in a shaking water bath for 10 min to allow dissolution of the lipids, and reactions were started by adding 450 μL of assay mixture and incubated at 30°C. Final concentrations were 0.1 M Tris pH 7.5, 2 μM FAD, 1 mM ATP, 3 mM $MgCl_2$, 2 mM 4-aminoantipyrine (AAP), 8 mM 2,4,6-tribromo-3-hydroxybenzoic acid (TBHB) (Research Organics, Cleveland, OH), 8 U/mL *Pseudomonas* sp. lipase (Sigma), 1 U/mL glycerol kinase (*Candida mycoderma*; Boehringer), 2 U/mL glycerol-3-phosphate oxidase (Boehringer), and 8 U/mL peroxi-

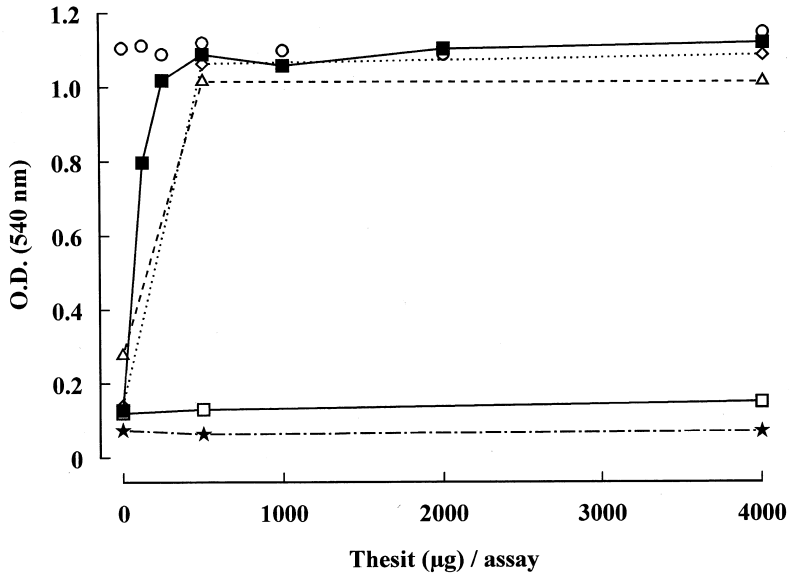

FIG. 1. Influence of the detergent dodecylpoly(ethylene glycol ether) (Thesit; Boehringer, Mannheim, Germany) on the quantitation of triacylglycerols. Chloroform solutions, containing 50 nmoles of trioleoylglycerol (■—■), 1,2-dipalmitoylglycerol (◇—◇), and 1-monooleoylglycerol (△—△) were pipetted at the bottom of glass tubes and mixed with the indicated amount of Thesit, dissolved in chloroform, before drying. After dissolution of the lipids in 50 µL of water, reactions were started by adding 0.45 mL of assay mixture [reconstituted Sigma GPO-Trinder reagents (Sigma Chemical Co., St. Louis, MO)]. After incubation at 30°C for 30 min, absorbance was measured at 540 nm. When the glycerides solutions were dried in the absence of detergent, followed by solubilization in 50 µL of water containing the indicated amounts of Thesit, almost no hydrolysis occurred (only shown for 50 nmoles of trioleoylglycerol; (□—□). No influence of the detergent was seen on the color formation either when using 50 nmoles of L-glycerol-3-phosphate (○) or of glycerol standards (data not shown), both being quantitatively converted, or on blanks (★—★).

dase (horseradish; Boehringer). Full-color development was achieved after 45 min. When relying on the reported ε value (Ref. 6; 28,000 $M^{-1} \cdot cm^{-1}$ at 511 nm), we recommend to read absorbances after 1 h of incubation.

Fluorimetric TAG assay. Trioleoylglycerol standards and aliquots of the cellular lipid extracts or silica eluates, containing up to 10 nmoles of TAG, were mixed with 5 µL of 20% (wt/vol) Thesit (dissolved in chloroform), dried, and dissolved in 50 µL of water. After dissolution, 150 µL of reaction mixture was added. Final concentrations were exactly as described for the colorimetric assay except that AAP and TBHB were replaced by 1.2 mM homovanillic acid. After incubation at 30°C for 1 h, reactions were quenched by adding 2 mL of 0.5 M carbonate buffer pH 10.7 containing 10 mM EDTA (7) and fluorescences were read in an Aminco SPF500 Fluorimeter (excitation at 327 nm; slit 2 nm; emission at 420 nm; slit 8 nm) (American Instruments Company, Silver Spring, MD). Standardization of the readings by means of uric acid/urate oxidase (7) indicated full conversion of the triolein to homovanillic acid dimer.

RESULTS AND DISCUSSION

To study the nature of the neutral lipid accumulation in androgen-treated LNCaP cells (1), a commercial kit [Sigma triglyceride (GPO-Trinder) reagents] was evaluated for the analysis of TAG in lipid extracts prepared from these cells. No color formation was observed, however. Since we also saw no response with dried trioleoylglycerol standards, we investigated the use of detergents to solubilize the dried lipids before assaying. Addition of cholate, reported to stimulate lipase (4), and some nonionic detergents [Triton X-100, Thesit, octylglucoside, and octanoyl-*N*-methylglucamide (all from Boehringer)] was not effective, although glycerol or glycerol-3-phosphate standards were quantitatively measured in the presence of these detergents. The addition of Thesit, dissolved in chloroform, to the standards and lipid extracts prior to drying, resulted in effective dissolution in an aqueous medium and hydrolysis of the TAG. As shown in Figure 1, the extent of hydrolysis was dependent on the amount of Thesit added. Although it has been claimed that *Pseudomonas* sp. lipase (the enzyme present in the Sigma kit) only acts on TAG (in the presence of cholate and isotridecanol polyglycol ether) (8), our data show that diacylglycerols (1,2-dipalmitoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol) and monoacylglycerols (1-monooleoyl-*rac*-glycerol, 3-monopalmitoyl-*sn*-glycerol) also are quantitatively converted to glycerol (Fig. 1; Fig. 2; Van Veldhoven, P.P., unpublished data). Hence, when applied to crude tissue or cell extracts or sera, TAG levels might be overestimated (see below).

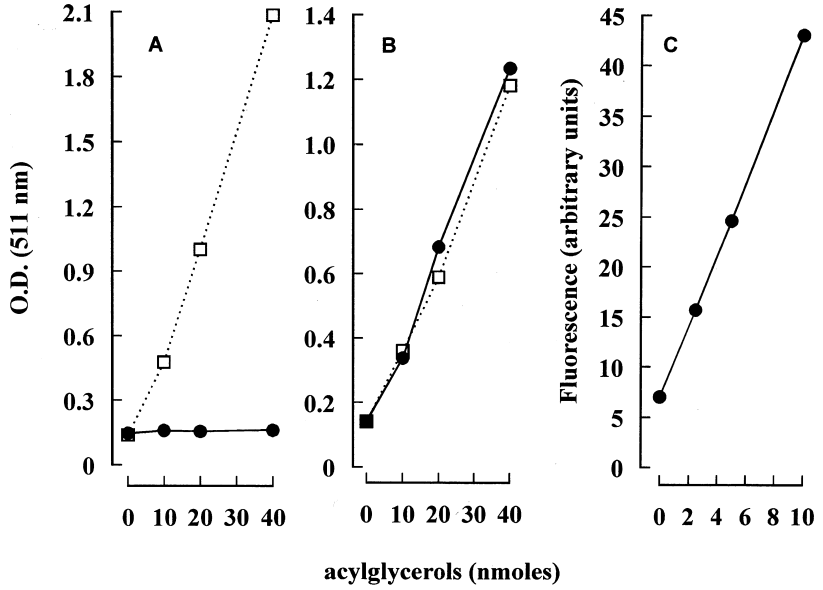

FIG. 2. Comparison of lipase activity on trioleoylglycerol in the presence of Thesit and linearity in function of trioleoylglycerol concentration in colorimetric and fluorimetric assays. (A) Indicated amounts of trioleoylglycerol (●) and 1-monopalmitoylglycerol (□) were mixed with 10 µL of 20% (wt/vol) Thesit (in chloroform) and processed as described in the Experimental Procedures section [colorimetric triacylglycerol (TAG) assay], but using *Rhizopus arrhizus* lipase (Boehringer) (final concentration 50 U/mL) and O.D. were measured after 20-min incubation. Full-color formation requires longer incubation times, being 25 min. (B) As panel A, except that the reaction mixture contained *Pseudomonas* sp. lipase (Sigma) (final concentration 8 U/mL). O.D. were measured after 20 min of incubation. (C) Indicated amounts of trioleoylglycerol (●) were analyzed as described in the Experimental Procedures section (fluorimetric TAG assay). See Figure 1 for other abbreviations and company sources.

In order to be able to analyze the influence of different androgen analogs using fewer cultured cells, we subsequently tried to increase the sensitivity of the assay. For the Trinder reaction, AAP and *N*-ethyl-*N*-(3-sulfopropyl)-*m*-anisidine are used in the kit, resulting in an ε value of 11,000 $M^{-1} \cdot cm^{-1}$ (for glycerol). Substituting the phenol (or its derivative) by TBHB results in a better sensitivity (9). In an indicator reaction, formulated on the basis of commercially obtained enzymes and chemicals, using optimized concentrations of TBHB and AAP (6), an extinction coefficient of 28,000 $M^{-1} \cdot cm^{-1}$ was obtained (for glycerol and L-glycerol-3-phosphate). Two lipase preparations were tested, one from *Rhizopus arrhizus*, the other one from *Pseudomonas* sp. Both lipases hydrolyzed monoacylglycerols, but as shown in Figure 2 (panels A and B), only the (more expensive) *Pseudomonas* enzyme was active on TAG in the presence of Thesit. If still higher sensitivities are required, the indicator reaction is easily adapted to a fluorimetric determination of the formed hydrogen peroxide by replacing AAP/TBHB by homovanillic acid (10) (Fig. 2C). In a representative experiment the levels of TAG (expressed per 100 nmoles of phospholipids to correct for possible losses during extraction) as determined directly in lipid extracts of LNCaP cells with the fluorimetric procedure were 11.9 ± 0.25 nmol (mean ± SEM of determinations on three separate culture dishes). After treating the cultures with 10^{-8} M R1881 (methyltrienolone; Dupont-New England Nuclear, Brussels, Belgium) during 4 d, the levels increased to 69.2 ± 5.0 (n = 3) nmol. If the extracts were first subjected to TLC, these values decreased by about 30%, being 9.21 ± 0.21 and 49.5 ± 1.9 nmol per 100 nmoles of phospholipids. This decrease is consistent with the levels of di- and monoacylglycerols present in these cells and that were measured, after TLC separation, in an analogous manner. In later experiments, we found that the basal levels of TAG in LNCaP cells can vary considerably. Contributing factors appear to be the culture conditions (different batches of serum) and cell passage number (Esquenet, M., Swinnen, J.V., Verhoeven, G., and Van Veldhoven, P.P., unpublished data).

Summarizing, in order to quantify enzymically the mass of TAG in extracts from tissues or cultured cells, we recommend an initial separation of the lipid extracts by TLC. To allow an efficient hydrolysis by *Pseudomonas* lipase, the silica eluates are dried in the presence of Thesit. The formed glycerol is measured by means of glycerol-kinase, glycerol-3-phosphate oxidase and peroxidase, either colorimetrically using AAP/TBHB or fluorimetrically. Owing to the nonspecificity of the lipase, similar approaches can be used to measure other glycerol esters such as mono- and diacylglycerols.

ACKNOWLEDGMENT

Special thanks to Els Meyhi for dedicated technical assistance.

Biochemistry, Chemistry, and Function of Steroids

Edward J. Parish and W. David Nes

This issue of *Lipids* contains a collection of research and review articles which resulted from papers presented at the 88th American Oil Chemists' Society's (AOCS's) Annual Meeting & Expo in Seattle, Washington, at the Washington State Convention & Trade Center on May 11–14, 1997. A number of internationally known speakers participated in the symposium on "Biochemistry, Chemistry, and Function of Steroids" which was held on Monday, May 12. This symposium was sponsored by the Biotechnology Division of the AOCS. The program included topics on nitrogen-containing steroids, sterol methylation reactions with an emphasis on drug design and testing, sterols of primitive marine fungi, the role of *N*-nitroso bile acid amides in gastrointestinal cancer, synthesis and molecular modeling in the area of brassinosteroid research, recent developments in the field of plant steroid hormones, and the remote functionalization of steroid side chains with chromyl acetates. The symposium was very successful, and the topics presented were the focus of lively discussions at the end of each presentation. These topics have been expanded upon and are presented in this issue of *Lipids*. It is our hope that these papers will stimulate further research activities in the steroid field.

Recent Developments in the Field of Plant Steroid Hormones

Trevor C. McMorris*

Department of Chemistry and Biochemistry, University of California, San Diego, La Jolla, California 92093-0506

ABSTRACT: Brassinolide and related brassinosteroids are a novel group of steroids which appear to be ubiquitous in plants. There is compelling evidence, particularly from recent genetic studies, that these steroids are essential for normal plant growth and development. Synthesis of brassinosteroids and aspects of their biochemistry are reviewed.
Lipids 32, 1303–1308 (1997).

Because of their great importance in the function and structure of animals and plants, steroids, more than any other group of low molecular weight natural products, have commanded the interest of organic chemists for many decades. Much of the effort in synthesis of steroids occurred from about 1940, following the discovery of mammalian adrenocortical and sex hormones (1). In more recent times, there has been renewed interest in synthesis because of the isolation of new steroids possessing functionalized side chains. These include 25-hydroxy vitamin D_3 (calcidiol), 1α, 25-dihydroxy vitamin D_3 (calcitriol), and analogs of these hormones (2); ecdysterone and other insect molting hormones (3), a large group which are also found in plants (3); fungal sex hormones antheridiol, deoxyantheridiol, dehydro-oogoniol and oogoniol (4); and the relatively new class of steroids, the plant growth hormone brassinolide, and related brassinosteroids (5) (Scheme 1).

A remarkable feature of these hormones is that they retain the side chains of their biosynthetic precursors, i.e., cholesterol, fucosterol, and campesterol. This is in contrast to adrenocortical and sex hormones where the side chain is completely or almost completely missing. It turns out that the stereochemistry of the side chain is important for biological activity. Therefore, the challenge for synthetic chemists is to construct these molecules stereochemically pure.

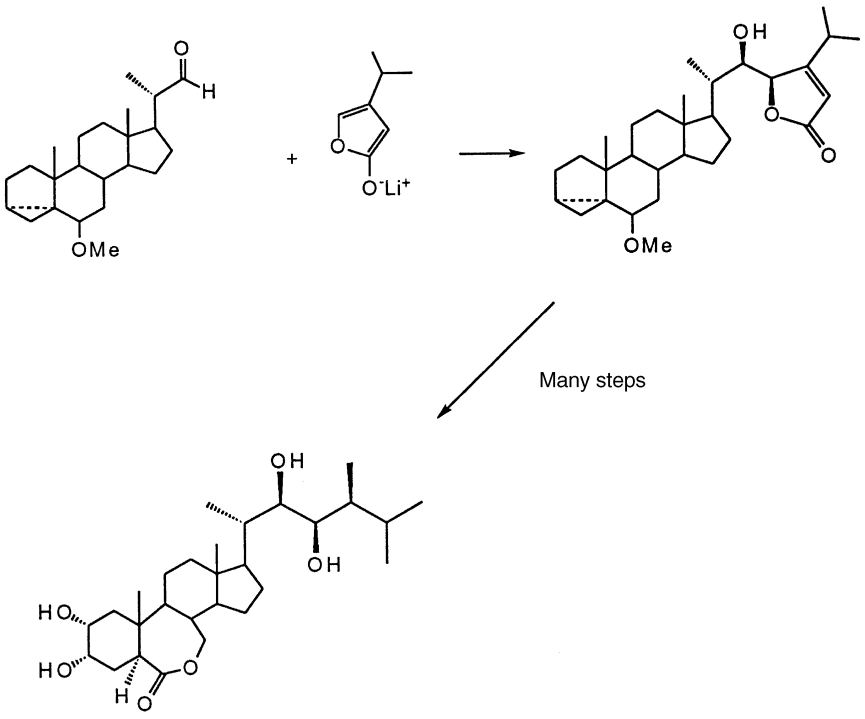


SCHEME 2

We and other investigators have found that the most practical way to build side chains of fungal and plant hormones is to start from readily available compounds such as 17-keto steroids, 20-keto steroids, or steroids with a C_{22} aldehyde function. These are generally prepared from abundant plant or animal sterols, e.g., stigmasterol, ergosterol, sitosterol, and cholic acids. We have succeeded in synthesizing antheridiol, dehydro-oogoniol, oogoniol (6), and brassinolide (7) in this way. Because of widespread interest in brassinolide and related steroids, we have continued our synthetic studies and have collaborated with other investigators in biological studies of brassinosteroids.

Elucidation of the structure of brassinolide was first reported in 1979 (8). This achievement was the result of many years' effort by John W. Mitchell and other scientists at the USDA laboratories in Beltsville, Philadelphia, and Peoria to identify the substance in pollen of the rape plant *Brassica napus* responsible for accelerated growth of internode sections of bean plants. The so-called bean second-internode assay had been developed for detecting gibberellins. Brassinolide was extremely active, and at a concentration of 0.1 μg per plant it caused the unique effect of splitting the internode.

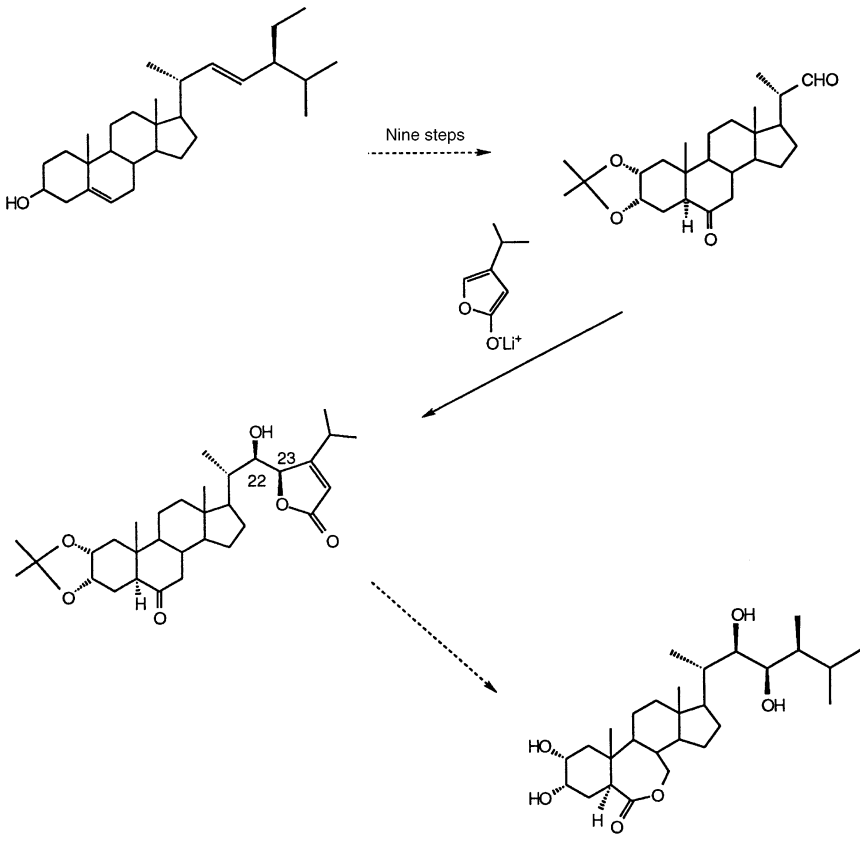
In the past 18 yr, over 60 analogs of brassinolide (brassinosteroids) have been detected in a wide variety of plants. Brassinolide remains the most biologically active brassinosteroid. It acts at very low concentrations (10^{-9} M) in eliciting cell elongation and/or proliferation, and showing strong synergistic interactions with auxin and additive interactions with gibberellins, in many test systems (5).

Synthetic studies. In our first synthesis of brassinolide, the key step was condensation of a C_{22} aldehyde with the anion derived from 3-isopropylbut-2-enolide (Scheme 2). The product was then converted into brassinolide by manipulation of functional groups on the side chain and on the tetracyclic nucleus (7) (Scheme 2).

We improved our synthesis by employing an aldehyde containing 2α,3α-dihydroxy and 6-keto functional groups (9). It was readily prepared in nine steps from stigmasterol as illustrated in Scheme 3.

A noteworthy feature of the aldol condensation of the aldehyde with the anion from isopropylbutenolide is that the main product was obtained with desired 22*R*, 23*R* stereochemistry and in high yield. The side chain could then be converted into the brassinolide side chain in five steps. The overall yield of brassinolide from stigmasterol was 7% (9). Many grams of pure brassinolide have been obtained using this method. Several syntheses of brassinolide have also been reported by other groups (10,11).

Among the naturally occurring brassinosteroids, 24-epibrassinolide and 28-homobrassinolide have attracted the interest of synthetic chemists. They possess structures which should, in principle, be readily prepared from the abundant ergosterol and stigmasterol, respectively. However, hydroxylation of the side chains of these steroids with osmium tetraoxide gives mainly the undesired 22*S*, 23*S* product. By

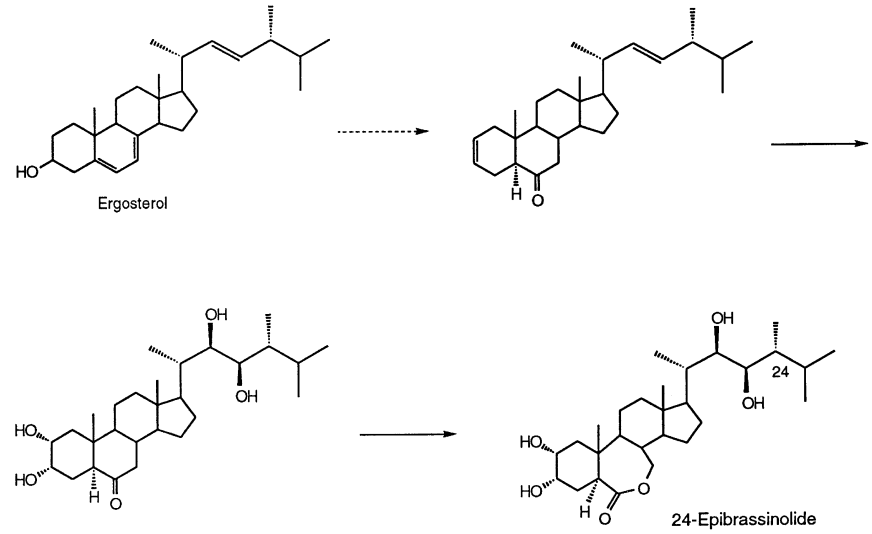


SCHEME 3

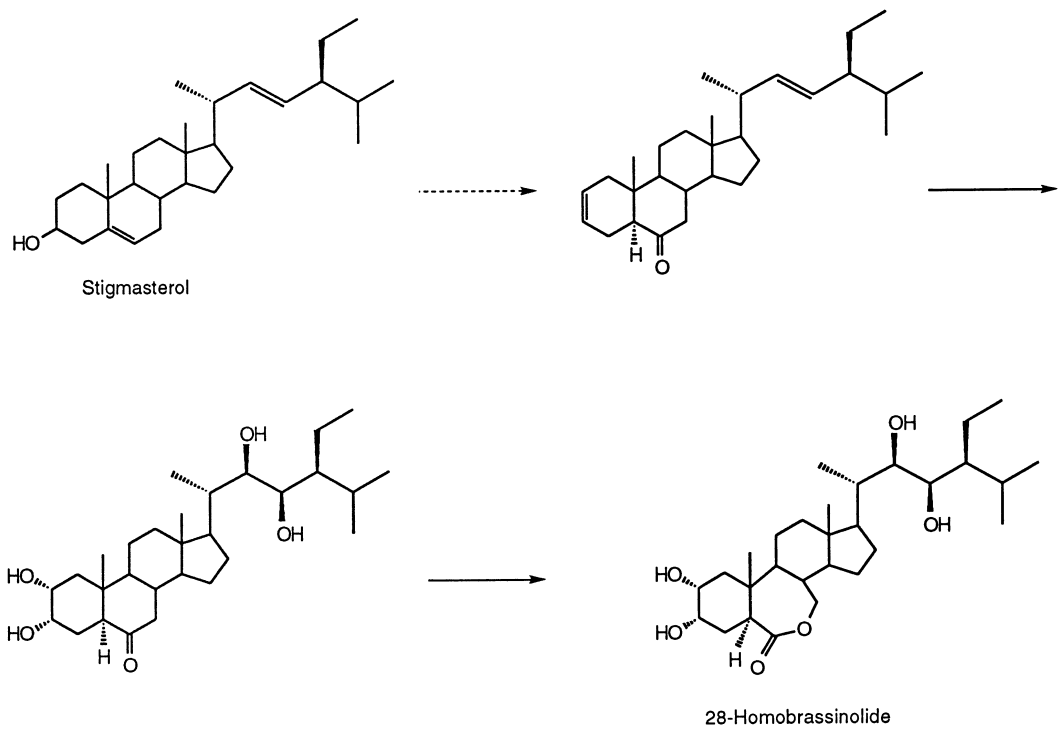
employing the method of asymmetric dihydroxylation, first reported by Sharpless *et al*. (12) [O_sO_4, $K_3Fe(CN)_6$ with the chiral ligand dihydroquinidine 4-chlorobenzoate in 2-methyl-2-propanol] the desired 22*R*,23*R* products were obtained in high yield (Schemes 4 and 5) (13,14).

Several groups besides ours have accomplished practical syntheses of naturally occurring brassinosteroids which are now commercially available (10,15–17).

Structure–activity relationships. Having prepared several brassinosteroids and their isomers, it was of interest to exam-



SCHEME 4



SCHEME 5

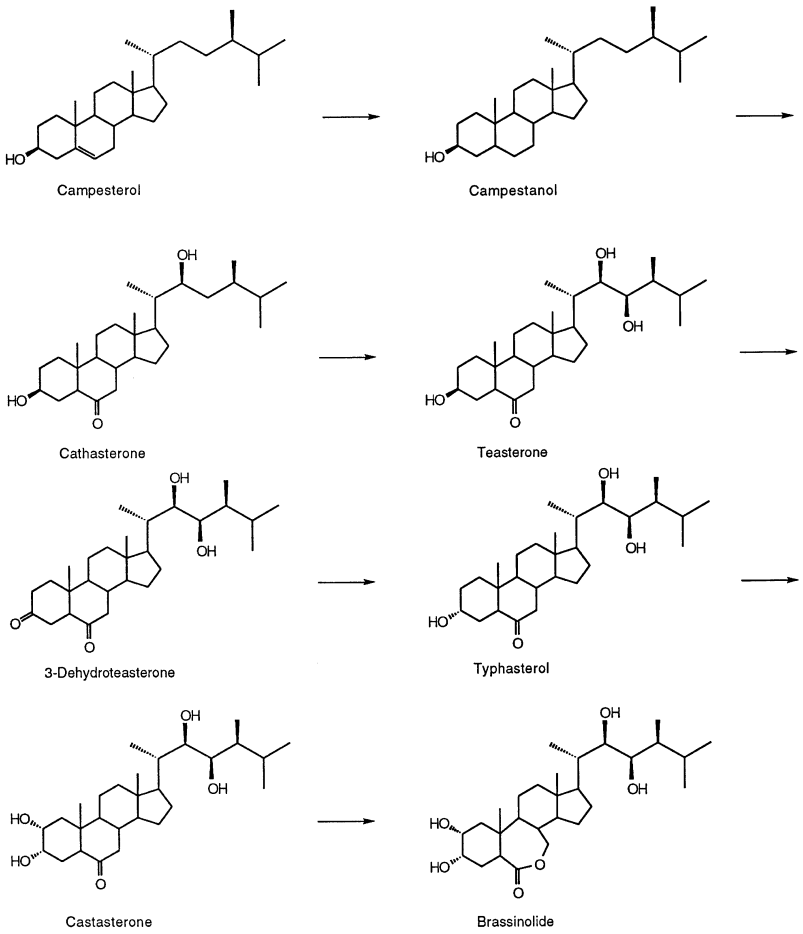
ine and compare their biological activity. These studies were carried out by my colleague, Professor Steven Clouse, using the soybean epicotyl elongation assay. Brassinolide and 28-homobrassinolide were found to elicit similar activity over a range of concentrations (Fig. 1) although brassinolide was more effective at lower concentrations. Homobrassinolide was also compared with 24-epibrassinolide, 22*S*, 23*S*-24 epibrassinolide and 22*S*, 23*S*-homobrassinolide. The first two steroids had similar activity to homobrassinolide, but 23*S*, 23*S*-homobrassinolide was substantially less active at all concentrations tested (14).

In seeking an explanation for this lower activity, we examined the molecular structures of the five steroids by comparing energy-minimized conformations for differences in nonbonded distances between various atoms in the side chains. A reference point, C_{16}, was selected on the rigid tetracyclic skeleton and distances between C_{16} and various atoms were determined. The results show that, apart from the C_{16}/C_{22} and C_{16}/C_{28} distances, all computed distances for 22*S*, 23*S*-homobrassinolide differ substantially more from the corresponding distances for brassinolide than is the case with the other isomers. These differences may be reflected in the poorer fit of 22*S*, 23*S*-homobrassinolide into the active site of a receptor for the hormone, thus resulting in lower biological activity.

Molecular genetic studies. Both plant and animal hormones effect gene expression before onset of cellular and physiological changes. Recently Zurek and Clouse (18) have shown that brassinosteroids regulate expression of specific genes in soybean hypocotyls and epicotyls and whole plants of *Arabidopsis*. The first cloning of a gene regulated specifically by brassinolide has been accomplished. This brassinosteroid upregulated gene has extensive homology with genes in other plants that code for xyloglucan endotransglycosylases which mediate cell wall loosening.

Other evidence of gene expression mediated by brassinolide comes from examination of biosynthetic intermediates between campesterol and brassinolide (Scheme 6). This scheme has been defined by several groups in Japan (19). A mutant of *Arabidopsis* has been described (DET2: de etiolated) which, when grown in light, results in an extremely dwarfed phenotype, and other changes. The gene (DET2) involved in this loss-of-function mutation has been cloned by Li *et al.* (20) and found to possess a surprising homology to mammalian steroid 5α-reductases that catalyze the NADPH-dependent conversion of testosterone to dihydrotestosterone. It has been proposed that the DET2 gene is required for brassinolide biosynthesis, specifically for the reduction of campesterol to campestanol. Feeding experiments with the DET2 mutant have shown that brassinolide rescued the DET2 phenotype to wild type in a dose-dependent manner both in the light and the dark.

Another mutant of *Arabidopsis* has been studied with a phenotype similar to DET2 (but nonallelic). This mutant (CPD: constitutive photomorphogenesis and dwarfism) has been found to have a gene (CPD) which encodes a protein with 50–60% sequence identity with conserved domains of microsomal cytochrome P 450 monoxygenases (21). The CPD gene appears to encode another enzyme in brassinolide



SCHEME 6

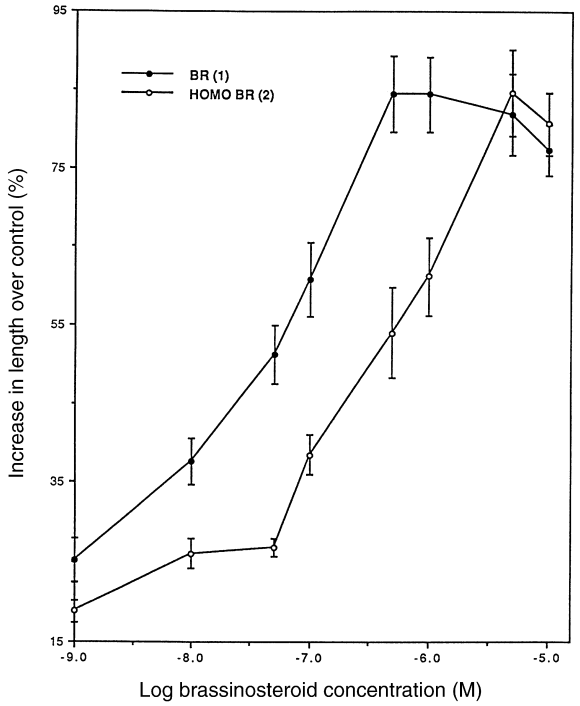


FIG. 1. Effect of brassinolide (BR) and homobrassinolide (HOMO BR) on soybean epicotyl elongation. Twenty replicate epicotyl sections (1.5 cm) were auxin-depleted in KPSC buffer (10 mM potassium phosphate, pH 6.0, 2% sucrose, 50 µg/mL chloramphenicol) for 2 h followed by incubation in the indicated compound for 19 h. Error bars are ± SE (14).

biosynthesis, this time involving a hydroxylation step. When the cpd mutant was grown in the presence of C_{23} hydroxylated brassinolide precursors including teasterone, 3-dehydroteasterone, typhasterol and castasterone, it was completely rescued to wild-type phenotype in light or darkness. However, cathasterone and its precursors which lack a hydroxyl at C_{23}, failed to rescue the CPD mutant, suggesting that the CPD protein causes hydroxylation of cathasterone to teasterone. These experiments clearly demonstrate the importance of brassinolide in the growth and differentiation of *Arabidopsis*. Brassinosteroids are now established as a new class of plant hormones.

Sterols of the Phylum Zygomycota: Phylogenetic Implications

J.D. Weete* and S.R. Gandhi

Department of Botany and Microbiology, Alabama Agricultural Experiment Station, Auburn University, Auburn, Alabama 36849

ABSTRACT: The sterol composition of 42 fungal species representing six of the eight orders of the Zygomycota was determined using gas–liquid chromatography–mass spectrometry to assess whether the distribution of major sterols in this phylum has taxonomic or phylogenetic relevance. Ergosterol, 22-dihydroergosterol, 24-methyl cholesterol, cholesterol, and desmosterol were detected as the major sterols among the species studied. Ergosterol was the major sterol of the Dimargaritales, Zoopagales, and 13 of the 14 Mucorales families included in this study. Desmosterol appeared to be the characteristic sterol of the Mortierellaceae (Mucorales). 24-Methyl cholesterol was the major sterol of the Entomophthorales genera *Entomophthora*, *Conidiobolus* and *Basidiobolus*, but cholesterol was the sole sterol detected in *Delacroixia coronatus*. The Kickxellales species analyzed in this study were characterized by 22-dihydroergosterol as the major sterol. These results suggest that certain orders of the Zygomycota may be distinguished on the basis of major sterol. Also, if sterol structure has phylogenetic implications, then orders might be arranged in the order Kickxellales (C_{28} $\Delta^{5,7}$) → Dimargaritales, Zoopagales and Mucorales (C_{28} $\Delta^{5,7,22}$) on the basis of evolution of the predominant and presumably most competent sterol, ergosterol. Although the Entomophthorales would be expected to be more primitive than the above orders based on the predominance of C_{28} Δ^5, it is not apparent from these data that members of the Zygomycota with ergosterol or its precursors as major sterols evolved from this taxon or the Chytridiomycota.

Lipids 32, 1309–1316 (1997).

Ergosterol [**I**, (22*E*, 24*R*)-24-methyl-cholesta-5,7,22-trienol] is considered to be the "fungal sterol," and is typically present at greater than 50% and often up to 85 to 96% of the total sterols in most species of higher fungi, i.e., Ascomycota and Basidiomycota (1). However, there are well-known exceptions to this such as the Uredinales (rust fungi) which produce no ergosterol but have C_{29} Δ^7 and C_{29} $\Delta^{7,24(28)}$ sterols as major sterols, and members of the Taphrinales which produce brassicasterol [(24*R*)-24-methyl-cholesta-5,22-dienol] as the major sterol. On the other hand, the most primitive of the true fungi, i.e. Chytridiomycota, do not produce ergosterol but instead produce either cholesterol (**III**, cholest-5-enol) and/or Δ^5 C_{28} and/or C_{29} monoenes as major sterols (2).

Ergosterol also appears to be the primary sterol of most species of the Zygomycota (1), but this is based on the analyses of relatively few species, mainly from the order Mucorales. However, there are also known exceptions to this such as in *Mortierella alpina,* where there is no ergosterol and where desmosterol (**II**, cholesta-5,24 dienol) is the principal sterol (3), and in *Absidia glauca* and *Mucor hiemalis*, where 22-dihydroergosterol is the major sterol and is accompanied by ergosterol (4). The number of representatives of the various orders and families that have been studied in this regard is insufficient to know whether these are simply exceptions or taxonomic trends that may have phylogenetic implications. Because some of the most primitive fungi have mainly cholesterol or corresponding C_{28} or C_{29} derivatives as the major sterols, and the most advanced fungi have ergosterol as the main sterol, it is reasonable to expect that progressive structural changes from C_{27} Δ^5 to C_{28} $\Delta^{5,7,22}$ sterols might exist within the phylogenetically intermediate phylum Zygomycota. Therefore, fungi representing most orders of the class Zygomycetes, and most families of the order Mucorales, were examined in this study to determine if ergosterol is indeed the principal sterol of the Zygomycota as it currently seems, or if structural differences occur among the orders and families of this phylum that may have phylogenetic implications. In addition, one species of the class Trichomycetes was included in this study.

MATERIALS AND METHODS

Sources of fungi and cultivation of fungi. Fungi analyzed in this study were obtained from various sources as shown in Tables 1 and 2. *Smittium micronatum* was obtained from Dr. R. Lichtwardt (University of Kansas, Lawrence, KS) and *Basidiobolus ranarum* was obtained from Dr. Meredith Blackwell (Louisiana State University, Baton Rouge, LA). They were grown in a 2% glucose, 1% yeast extract medium at 24°C for 6 d unless otherwise noted. Mycelia were harvested by suction filtration, washed with water, dried by lyophilization, and stored at −70°C prior to analysis.

Except as noted elsewhere, the taxonomic placement of the species in this study into families and others is according to Alexopoulos *et al.* (5).

Lipid extraction. Total lipid was extracted from dry cells

[h]Data from Beilby (Ref. 19).

(*ca.* 70 mg) using the Bligh and Dyer (6) procedure that was modified according to Kates (7), but with twice the solvent volume-to-tissue dry weight ratio recommended by the latter. All extractions and subsequent manipulation of the samples were conducted at low light intensity.

Sample derivatization and gas–liquid chromatographic analysis (GLC). To obtain the nonsaponifiable lipid, a portion of the total lipid (*ca.* 20 mg) was heated for 2.5 h in 5 mL of 95% ethanol containing 0.5 mL of 33% (wt/vol) KOH (7). The nonsaponifiable lipids were removed from the hydrolysate by washing it three times with 5 mL of hexane. The combined hexane washes were washed twice with 5 mL 3% KOH, twice with 5 mL H_2O, and then brought to dryness under a stream of nitrogen gas.

Sterols in the nonsaponifiable fraction were analyzed by GLC as their trimethylsilylether (TMS) derivatives. Steryl-TMS derivatives were prepared by heating a portion (*ca.* 5 mg) of the nonsaponifiable lipid obtained as described above with 1 mL bis-(trimethylsilyl) trifluoroacetamide/trimethylchlorosilane (99:1, vol/vol) (Supelco Inc., Bellefonte, PA) at 70°C for 25 min. The solvent was evaporated under nitrogen gas and the samples were diluted with hexane prior to analysis by GLC. The gas chromatograph (Hewlett-Packard model 5710; Palo Alto, CA) was equipped with a 25 m × 0.25 mm i.d. fused-silica DB-5MS column (J&W Scientific, Folsom, CA). Injector and detector temperatures were 300°C, and the oven temperature was 270°C isothermal.

GLC–mass spectrometry. GLC–mass spectrometry analysis of the total sterols was performed using a VG 70E high-resolution mass spectrometer (Manchester, United Kingdom)

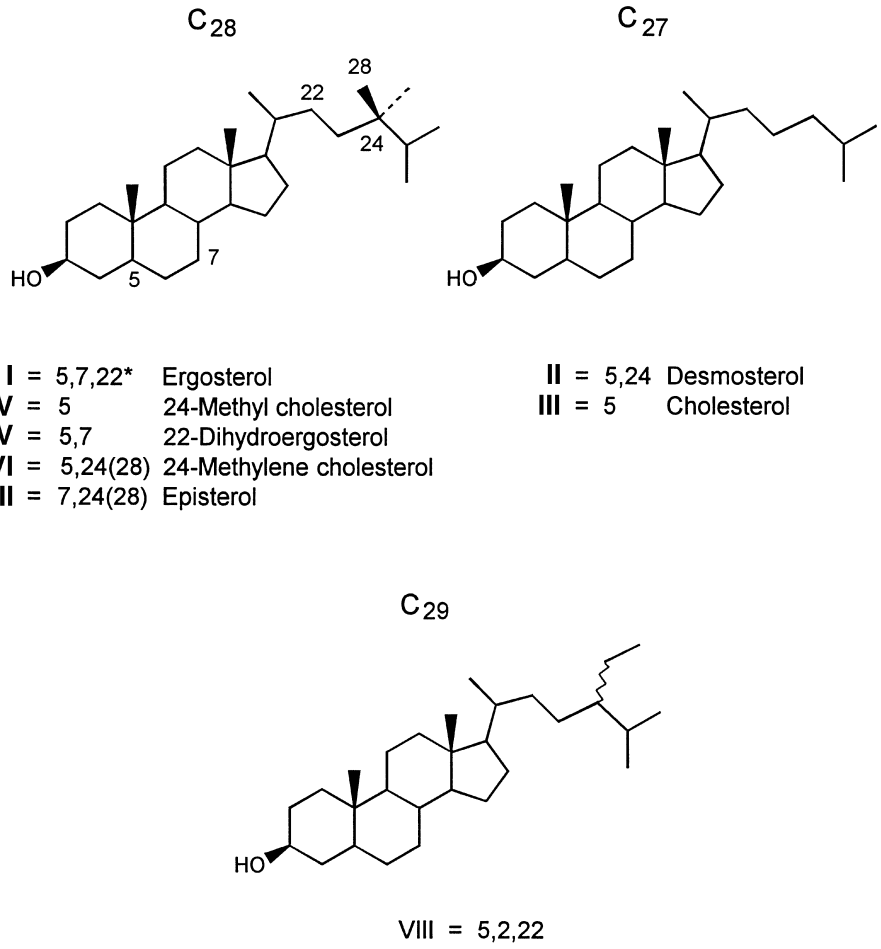
linked to a Varian 3700 gas chromatograph (Palo Alto, CA) equipped with a 25 m × 0.25 mm i.d. DB-5MS fused-silica capillary column as the sample inlet, and operated in the electron impact mode at 70 eV with the source temperature at 200°C.

RESULTS AND DISCUSSION

Identification of sterols. The number of sterols detected in the species analyzed in this study ranged from 1 to 18 depending on the species. Only the major sterols of each species are reported here with no more than two sterols per species given. A second major sterol is included if the primary major sterol constitutes less than 80% of the total sterols and another sterol represents 10% or more.

Five different sterols were considered primary major sterols in the fungi of this study according to the above criteria, the most common of which was ergosterol (**I**) (Scheme 1). The mass spectra of the TMS derivative of ergosterol, 24-methyl cholesterol (**IV**, 24-methyl-cholest-5-enol), cholesterol, and desmosterol matched those of authentic standards and are consistent with previously published spectra of these



SCHEME 1

sterols (8) (Table 3). Identification of 22-dihydroergosterol (**V**, 24-methyl cholesta-5,7-dienol) was based on the molecular ion (M^+) at *m/z* 470 and prominent $M^+ - 131$ fragment ion that is characteristic of the TMS derivative of a C_{28} $\Delta^{5,7}$ diene (8).

Several other sterols were detected and included as second major sterols according to the above criteria. The identification of 24-methylene cholesterol [**VI**, 24-methyl cholesta-5,24(28)-dienol] was based on the molecular ion at *m/z* 470 for the TMS derivative, presence of the $M^+ - 129$ and prominent *m/z* 129 which are indicative of the double bond at C-5(6) (8), and prominent fragment ions at *m/z* 296 and 386 for the double bond at C-24(28) (9). Episterol [**VII**, 24-methyl-cholesta-7,24(28)-dienol] was identified on the basis of *m/z* 470 (M^+), 386, and base peak at *m/z* 343. 24-Ethyl-cholesta-5,7,22-trienol (**VIII**) was identified on the basis of m/z 482 (M^+) and major fragment ions corresponding to those of the TMS derivative of ergosterol but 14 mass units higher (Table 3). 22-Dihydroergosterol was detected as a second major sterol in several species (Tables 1 and 2).

Three other sterols were detected as second major sterols, two of which were C_{28} dienes. Only one of the dienes contained a double bond in the C-5(6) position, but location of the second double bond was uncertain (Diene #1). The other diene (Diene #2) did not have a double bond at the C-5(6) position based on the absence of the $M^+ - 129$ fragment ion for the TMS derivative. This sterol was distinguished by the 100% fragment ion at *m/z* 255 and a very prominent molecular ion and is probably 24-methyl cholesta-7,22-dienol (Table 3). The third unidentified sterol was a C_{28} tetraene characterized by *m/z* 466 (M^+), 376, and base peak at 251 suggesting that three of the double bonds are located in the nuclear ring system. Based on the occurrence of known C_{28} sterols with four double bonds (1), the most likely candidate for this sterol has double bonds at the 5,7,9 and 24(28) positions.

Sterols of the Dimargaritales. The sterol composition of representatives from three of the four genera of this monotypic order were analyzed in this study, and ergosterol was the major sterol in each (Table 1). The sterol profiles of *Dimargaris bac-*

TABLE 3
Major Sterols of Fungi of the Phylum Zygomycota[a]

Systematic name (common name)	Symbol	Major fragment ions (*m/z*)
Major sterols		
I. Cholesta-5, 24-dienol (desmosterol)	$C_{27}\ \Delta^{5,24}$	456 (M^+), 441, 372, 366, 351, 343, 327 ($M^+ - 129$) 253, 129, 69 (100%)
II. 24-Methyl-cholesta-5,7,22-trienol (ergosterol)	$C_{28}\ \Delta^{5,7,22}$	468 (M^+), 378, 363 (100%), 337, 253, 69
III. 24-Methyl-cholesta-5,7-dienol (22-dihydroergosterol)	$C_{28}\ \Delta^{5,7}$	470 (M^+), 455, 378, 363 (100%), 337 ($M^+ - 131$), 253
IV. 24-Methyl-cholest-5-enol (24-methyl cholesterol)	$C_{28}\ \Delta^{5}$	472 (M^+), 457, 382, 367, 343 (100%), 261, 255, 213, 129
Minor sterols		
V. 24-Methyl-cholesta-5, 24(28)-dienol (24-methylene cholesterol)	$C_{28}\ \Delta^{5,24(28)}$	470 (M^+), 455, 386, 343, 296, 227, 213, 83 (100%)
VI. 24-Methyl-cholesta-7,24(28)-dienol (episterol)	$C_{28}\ \Delta^{7,24(28)}$	470 (M^+), 455, 386, 343 (100%), 296, 227, 213
VII. 24-Ethyl-cholesta-5,7,22-trienol	$C_{29}\ \Delta^{5,7,22}$	482 (M^+), 392, 377 (100%), 351, 253
	C_{28} Diene #1	470 (M^+), 455 ($M^+ - 15$), 380, 365, 341 ($M^+ - 129$), 271, 129 (100%)
	C_{28} Diene #2	470 (M^+), 455 ($M^+ - 15$), 427, 372, 365, 343, 318, 255 (100%), 229, 213, 75
	C_{28} Tetraene	466 (M^+), 451 ($M^+ - 15$), 376, 361, 251 (100%)

[a]See Scheme 1 for sterol structures.

cillispora and *Dispiria simplex* were essentially the same, with episterol accompanying ergosterol at 19 and 16% of the total sterols, respectively (Table 1). *Tieghemiomyces californicus* contained 92% ergosterol.

Sterols of the Entomophthorales. The sterol composition of four genera representing three of the six families was determined in this study, i.e., three *Entomophthora* species of the Entomophthoraceae, and four *Conidiobolus* species and one *Delacroixia* species of the Ancylistaceae, and *B. ranarum* of the Basidiobolaceae. *Entomophthora* and *Conidiobolus* species were distinct from those in the other Zycomycota orders with 24-methyl cholesterol as the major sterol at 87 to 94% of the total sterols in six of the seven species analyzed. *Conidiobolus adiaeretus* and *B. ranarum* contained only 51 and 70% of this sterol, respectively (Table 1). The latter species contained 24-methylene cholesterol as the second major sterol. Distinguishing *Conidiobolus* from *Entomophthora* species on the basis of morphology has proven difficult and has required the use of nuclear characters to separate them (10), and representatives of the two genera could not be distinguished on the basis of sterol composition.

On the other hand, *Delacroixia coronatus*, formally *C. coronatus*, contained cholesterol as the single sterol detected. More species must be analyzed to determine if this departure from the $C_{28}\ \Delta^5$ structure is an exception or a trend within the Ancylistaceae family.

Sterols of the Kickxellales. Starr *et al.* (11) reported that cholesterol was the only sterol detected in *Dipsacomycetes acuminosporus* and *Linderina pennispora*. However, Weete and Laseter (12) did not detect cholesterol or ergosterol in spores of *L. pennispora* but instead reported a C_{28} diene among two other sterols detected. In this study, the major sterol of *D. acuminosporus* was the C_{28} diene 22-dihydroergosterol at 96% of the total sterols (Table 1). This sterol may be characteristic as the principal sterol of this order since it was also predominant in *Coemansia erectus* and *Martensiomyces pterosporus* (Table 1).

Sterols of the Zoopagales. Only one species from one of the four families of this order was included in this study, i.e., *Syncephalis spherica* of the Piptocephalidaceae, which contained 49% ergosterol and 35% 22-dihydroergosterol (Table 1).

Sterols of the Mucorales. Twenty-five species belonging to the order Mucorales, representing 14 of the 16 families (5,13) were examined in this study for sterol composition. With one exception, the major sterol of the species from the various Mucorales families was ergosterol (Table 2). In *Heliocostylum pulchrum* (Thrammidiaceae), 22-dihydroergosterol occurred in about equal proportions with ergosterol at 46% of the total sterols, whereas the other two species from this family analyzed in this study contained 78% or more ergosterol (Table 2). In this study, *Absidia spinosa* contained 79% ergosterol and 16% 22-dihydroergosterol, but McCorkindale *et al.* (4) reported that *A. glauca* contained 83% of the latter sterol and 12% of the former.

The exception noted above was the Mortierellaceae where ergosterol was absent from *Mortierella alpina* (IS-4) and desmosterol was the major sterol (3). We have found this to be true for another strain of this species (Table 2). Desmosterol may be characteristic of this family because *Echinosporangium transversale*, also of the Mortierellaceace, contained

desmosterol as the major sterol, and no ergosterol was detected (Table 2). This is unusual because with few exceptions C_{28} sterols tend to be predominant in fungi that are phylogenetically more advanced than those in the phylum Chytridiomycota (1). Although a C_{27} sterol is the primary major sterol of *M. alpina* and *E. transversale,* they are capable of carrying out the alkylation at C-24 as indicated by the presence of C_{28} sterols such C_{28} $\Delta^{5,?}$ in *E. transversale* and 24-methylene cholesterol in *M. alpina* as second major sterols (Table 2), and several other C_{28} alkylsterols in each species. These results are consistent with the taxonomic uncertainty of the Mortierellaceae (14) and reinforce the question of whether this family should be included in the Mucorales.

In other studies with Mucorales fungi, ergosterol has been detected as the major sterol in *Rhizopus arrhizus* (15) and *Mucor* species (16,17). However, there may be exceptions such as *M. hiemalis,* where 22-dihydroergosterol was the principal sterol (4), but Mucoraceae is a large family and many more species representing such genera should be analyzed before definitive conclusions can be drawn.

The only families of the order Mucorales that remain to be studied with respect to sterol composition are the Saksenacaceae and Sigmoidiomycetaceae which are single-genus and two-genus families, respectively (5).

Other orders. To our knowledge, representatives of the Endoglonales have not been studied with respect to sterol composition, but the vesicular-arbuscular mycorrhizal fungi *Acaulospora laevis* and *Glomus caledonius* of the order Glomales reportedly produce cholesterol and 24-methyl cholesterol as major sterols (18), and 24-ethyl cholesterol along with 24-methyl cholesterol and cholesterol, respectively, but no ergosterol (19).

Sterols of the Trichomycetes. Because of the possible close affinity of members of the order Harpellales with those of the Kickxellales and of the possible uniqueness of the major sterols in the latter group, i.e., 22-dihydroergosterol (Table 1), *Smittium micronatum* was included in this study. Desmosterol was reported in all but two of 14 *Smittium* isolates, and cholesterol, ergosterol, and a C_{28} diene were detected in some of them (11). In this study, the principal sterol of *S. micronatum* was ergosterol at 63% of the total sterols; 22-dihydroergosterol, as a relatively minor component at only 6%, may be the M^+ 470 component (TMS derivative) detected by Starr *et al.* (11). Other sterols detected in this species were a C_{28} monoene (Δ^7 or Δ^8) (7%), a C_{28} diene (11%), and a C_{30} diene (13%), none of which had a double bond in the C-5 position. Neither cholesterol nor desmosterol was detected in this species.

As we have suggested previously (1), it is unlikely that sterols alone are useful taxonomic characters for distinguishing fungi at the species or even genus levels of classification. However, the results of this study indicate that the designation of ergosterol as the "fungal sterol" does not apply to all orders of the phylum Zygomycota, i.e., members of some orders have primary major sterols other than ergosterol. Although relatively few zygomycetous fungi have been studied in this regard, the results of this study indicate that two of the orders of this phylum, i.e., Entomophthorales and Kickxellales, might be distinguished from one another, and from the orders Dimargaritales, Mucorales and Zoopagales, on the basis of their primary major sterol, i.e., 24-methyl cholesterol and 22-dihydroergosterol, respectively, opposed to ergosterol.

There appear to be no trends with respect to the second major sterols, except possibly that species in the Dimargaritales, Entomophthorales, and Kickxellales exhibited less tendency to accumulate such sterols than members of the other orders. Generally, in cases where the primary major sterol was less than 80%, no other sterol accumulated to greater than 10% of the total sterols in these taxa. Exceptions to this were *Syncephalis spherica* of the Zoopagales and many species of the Mucorales (Tables 1 and 2). In the latter order, 16 of the 25 species contained second major sterols, ranging from 10 to 46% of the total sterols, but there was no obvious pattern to their distribution among the families (Table 2).

Cholesterol is the principal sterol in some species of the most primitive fungi (e.g., Chytridiomycota) as well as in the evolutionarily most advanced organisms (e.g., mammals). It sometimes functions in artificial membranes, and it supports the growth of a sterol-requiring prokaryotic microbe better than others tested (20), including ergosterol (21). Nevertheless, ergosterol is the main sterol of fungi at the top of the fungal evolutionary hierarchy, Ascomycota and Basidiomycota; and cholesterol is absent in these taxa (1), suggesting that this sterol may perform a specific function in fungi related to its structure or offer some advantage that is unique to these fungi. Ergosterol satisfies the sterol requirement for the growth of yeast cultured under anaerobic conditions better than cholesterol and others tested (22). Parks and Casey (23) suggested that ergosterol may be the preferred sterol because it serves as a consensus sterol in satisfying multiple functions.

Although only a relatively few species of chytrids have been analyzed in this regard, there is no apparent pattern to the distribution of sterols among the four orders represented, i.e., cholesterol is the major sterol in a species of three of the four orders whereas other species of these orders have other dominant sterols in the absence of cholesterol (2). This is consistent with the contention that there is considerable phylogenetic divergence among the chytrids (24). Because members of the Blastocladiales (*Blastocladiella emersonii* and *Allomyces macrogynus*) have cholesterol as the major sterol (2), and they are believed to be among the more primitive of the chytrids, then this sterol may be considered the most primitive sterol, at least in eucaryotes, and alkylation at C-24 might be considered to be associated with the move toward the evolution of more advanced fungi. One of the structural differences between cholesterol and ergosterol is the presence of the 24-methyl group (Scheme 1). Alkylation at C-24 occurs prior to the demethylation of lanosterol at C-4 and C-14 during the formation of ergosterol in at least the few higher fungi and zygomycetes that have been studied in this regard (25). Although whether alkylation occurs before or after (as in yeast, Ref. 25) the demethylation of lanosterol in the chytrids

has not been tested, some species of this taxa can carry out this reaction as indicated by the presence of 24-alkyl sterols.

Although it appears as a second major sterol in Hyphochytridiomycetes and the chytrid *Monoblepharella* sp. (2), 24-methyl cholesterol was found as the major sterol only in species belonging to the Entomophthorales, with the exception of *D. coronatus* which contained cholesterol as the principal sterol. As in the entomophthoralean fungi, 24-methyl cholesterol was the major sterol of *B. ranarum* but, unlike other Entomophthorales species or any other fungus of this study, a significant second major sterol of this species was 24-methylene cholesterol which is common in the Oomycota (4) and *Rhizophydium sphaerotheca* (Chytridales) (2). However, molecular analysis placed *B. ranarum,* which is considered to be an entomophthorean fungus based on morphological characteristics (5), in a cluster with the chytrids *Chytridium*, *Spizellomyces* and *Neocallimastrix* rather than the cluster with *Entomophthora, Conidiobolus* and *Zoophthora* (24). Therefore, the taxonomic placement of *B. ranarum* in either the Chytridiomycota or Entomophthorales cannot be resolved on the basis of major sterol composition. Cavalier-Smith (26) considered the entomophthoralean fungi to be ancestral zygomycetes derived from the chytrids. The sterol composition is consistent with this view if we consider 24-methyl cholesterol to be a more primitive sterol than ergosterol but not unequivocal (Fig. 1).

The other structural features that distinguish ergosterol from cholesterol are the double bonds at C-7 and C-22. Since $\Delta^8 \rightarrow \Delta^7 \rightarrow \Delta^{5,7} \rightarrow \Delta^5$ is considered to be the reaction sequence in the sterol ring system in the latter stages of cholesterol and ergosterol formation (25), it is likely that the first step toward ergosterol biosynthesis arose as a defect in the formation of 24-methyl cholesterol, i.e. loss of the ability to reduce the double bond at C-7, thus giving rise to 22-dihydroergosterol (C_{28} $\Delta^{5,7}$). If this sterol occurs throughout the order Kickxellales as may be the case based on the results of this study, then the occurrence of 22-dihydroergosterol as the principal sterol may have evolutionary implications. This suggests that the Kickxellales are among the most primitive Zygomycetes, but whether the evolutionary process occurred directly from a chytrid, or *via* the Entomophthorales, cannot be disinguished from this data (Fig. 1).

The next step leading to the formation of ergosterol would be the capacity to introduce a double bond at C-22. If the evolution of fungi is associated with the ability to introduce a double bond at this position, and 7-dihydroergosterol is not a major sterol, then the Dimargaritales, Mucorales, and Zoopagales should be phylogenetically more advanced than the Kickxellales on the basis of sterol composition. Although ongoing RNA sequencing research may shed some light on this in the near future, unfortunately our knowledge of the evolutionary relationships among the zygomycetous fungi at the order level of classification is insufficient at this time to be able to arrange them in a definitive sequence from the most primitive to the most advanced.

Although several functions for ergosterol have been detected in yeast (27), the precise nature of these functions is not known, except for their role in membranes (28). Two of the functions are the bulk or membrane role, which has the lesser structural specificity and requires more sterol, and the sparking role, which has the greater structural specificity and requires the lesser amount, i.e., requirement for the double bond at C-5(6) (27). Based on structure–function studies whereby genes for essentially all of the steps in the postcyclization stage of ergosterol biosynthesis have been inactivated and tested individually for their essentiality, and the cells with the lesions are viable and able to grow, it is difficult to rationalize the driving force for the evolution of the ergosterol structure. However, it has been shown recently that the further back toward lanosterol that inactivation of a step in ergosterol biosynthesis occurs, at least in *Saccharomyces cerevisiae*, the less competitive the strain containing the lesion is with the wild type (29).

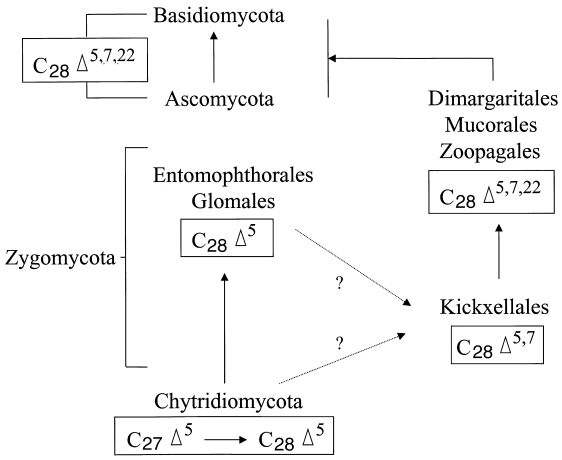


FIG. 1. Schematic showing the possible evolution of sterols from cholesterol to ergosterol from the primitive phylum Chytridiomycota through the phylum Zygomycota to the Ascomycota and Basidiomycota.

Bloch (30) speculated that evolutionary pressures were responsible for driving structural modifying events (i.e., demethylation at C-4 and C-14) that led to improvement in the functional competence of sterols, i.e., lanosterol → cholesterol. He also pointed out that there was an increase in the ability of sterol biosynthesis intermediates differing by decreasing degrees of methylation at C-4 and C-14 to function in artificial membranes and showed that the ability of these sterols to support the growth of a sterol-requiring microbe was correlated to the progressive loss of methyl groups at these positions. In this context, it is tempting to speculate that retention of the double bond at C-7 and introduction of the double bond at C-22, which lead to ergosterol formation, may have conferred a competitive advantage to the species acquiring these modifications and therefore played a role in the evolution of these fungi. However, based on structure–function studies, double bonds at these positions seem to be the least important from the standpoint of function in supporting growth (yeast) (29).

ACKNOWLEDGMENTS

This research was supported in part by the Alabama Agricultural Experiment Station, Project No. ALA 06-008 (JDW). We are grateful to Drs. Kerry O'Donnell, (U.S. Department of Agriculture, Peoria, IL) and Gerald Benny (University of Florida, Gainesville, FL) for supplying some of the cultures used in this study. We would also like to thank Dr. Benny and Dr. Meredith Blackwell (Louisiana State University, Baton Rouge, LA) for their discussions and insights on the taxonomic relationships of the fungi in this study, and Dr. Leo W. Parks (North Carolina State University, Raleigh, NC) for supplying a preprint of his work on sterol functions in yeast.

ABSTRACT: *Heliothis zea* (corn earworm), an insect that fails to synthesize sterols *de novo*, was reared on an artificial diet treated with 18 different sterol supplements. Larvae did not develop on a sterol-less medium. Δ^5-Sterols with a hydrogen atom, a methylene group, an *E*- or *Z*-ethylidene group, or an α- or β-ethyl group (cholesterol, ostreasterol, isofucosterol, fucosterol, sitosterol, and clionasterol, respectively) at position C-24, and Δ^5-sterols doubly substituted in the side chain at C-24 with an α-ethyl group and at C-22 with a double bond (stigmasterol) supported normal larval growth to late-sixth instar (prepupal: maturity). The major sterol isolated from each of these sterol treatments was cholesterol, suggesting that *H. zea* operates a typical 24-dealkylation pathway. The sterol requirement of *H. zea* could not be met satisfactorily by derivatives of 3β-cholestanol with a 9β,19-cyclopropyl group, *gem* dimethyl group at C-4, a $\Delta^{5,7}$-bond or Δ^8-bond, or by side-chain modified sterols that possessed a $\Delta^{25(27)}$-24β-ethyl group, $\Delta^{23(24)}$-24-methyl group or 24-ethyl group, or $\Delta^{24(25)}$-24-methyl or 24-ethyl group. The major sterol recovered from the larvae (albeit developmentally arrested larvae) treated with a nonutilizable sterol was the test compound. Sterol absorption was related to the degree of sterol utilization. The most effective sterols absorbed by the insect ranged from 27 to 66 μg per insect, whereas the least effective sterols absorbed by the insect ranged from 0.6 to 6 μg per insect. Competition experiments using different proportions of cholesterol and 24-dihydrolanosterol (from 9:1 to 1:9 mixtures) indicated that abnormal development of *H. zea* may be induced on less than a 1 to 1 mixture of utilizable (cholesterol) to nonutilizable (24-dihydrolanosterol) sterols. The results demonstrate new structural requirements for sterol utilization and metabolism by insects, particularly with respect to the position of double bonds in the side chain and functionalization in the nucleus. The novel sterol specificities observed in this study appear to be associated with the dual role of sterols as membrane inserts (nonmetabolic) and as precursors to the ecdysteroids (metabolic).

Lipids 32, 1317–1323 (1997).

Insects, unlike plants, are unable to synthesize sterols *de novo*, and therefore acquire sterols from feeding on plants and/or from symbionts (1,2). The resulting sterol ecology that evolved in insect–plant interactions has contributed to the design of novel insect control technologies based on modification of the phytosterol pathway (3). Most insects can be reared on sterols that share the same structural characteristics of cholesterol (cholest-5-en-3β-ol), viz., a 3β-hydroxyl group, a planar tetracyclic nucleus, and an intact side chain of 8 to 10 carbon atoms (1–3). Phytophagous insects may absorb and utilize a variety of dietary sterols, structurally similar to cholesterol as tissue sterols (1,2). In many insects, C-24 dealkylation of phytosterols is a critical step in ecdysteroid production (3). It can be assumed that several possible intermediates of sitosterol production, including the C-24 dealkylation reaction of phytosterols, should satisfy the sterol requirement of insects. The pathway of phytosterol C-24 dealkylation has been shown to proceed from 24-ethylcholesterol to cholesterol in four major steps: (i) dehydrogenation of the C-24 ethyl group; (ii) formation of a C-24(28)-epoxide; (iii) deethylation of the C-24(28)-epoxide; and (iv) reduction of the 24,25-double bond (Fig. 1) (3,4). Interruption of this pathway by inhibitors designed to interfere with steps ii and iv has been found to prevent ecdysone synthesis (step v, Fig. 1) and impair normal larval growth and development (2–4).

The objectives of the present study were to establish the structural requirements of sterols in the C-24 dealkylation pathway and to ascertain whether the nutritional requirement for a sitosterol-type sterol by *Heliothis zea* (=*Helicoverpa zea*) was absolute. To this end, various sterols synthesized by plants were fed to *H. zea* singly and in a sparing (partly replace) capacity. As first hypothesized by Clark and Bloch (5), underlying this approach is the recognition that sterols play a dual role in insects: as a membrane insert (nonmetabolic) and as a precursor to the ecdysteroids, molting hormones, (metabolic). Δ^5-Phytosterols such as sitosterol, which are end products of plant metabolism (6), may, after conversion to cholesterol, perform both sterol functions in insects (1,2). On the other hand, sterols which are intermediates in phytosterol turnover, such as 24-ethyldesmosterol (6), may be capable of only partly replacing sitosterol in *H. zea* , because the insect cannot transform the sterol. Phytosterol intermediates might be able to perform only one of the essential sterol functions (e.g., architectural), and thereby must spare cholesterol (metabolic) for the insect to grow. However, for cholesterol to be sparred there must be a source of cholesterol available for ecdysteroid production. When cholesterol is not available and the dietary phytosterol cannot undergo metabolism to cholesterol

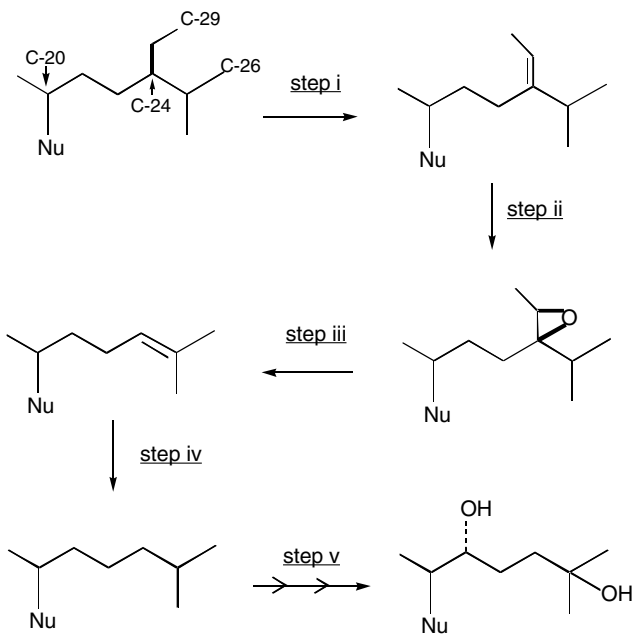

FIG. 1. Hypothetical 24-dealkylation pathway in *Heliothis zea*: a 24-ethylsterol is converted to a Δ^5-24-desalkylsterol in four steps, after which the side chain of the 24-desalkyl sterol is oxidized at C-22 and C-24 to form the side chain of ecdysone (step v involves many steps including oxidation of the side chain and nucleus). See text for further details.

by the insect, then the nutritional sterol is nonutilizable and larval death should ensue. Ritter (7–10), studying sterol structure–activity relationships in *H. zea,* has shown that the type and amount of sterol available to the insect diet influence growth and development. In our comparative studies on metabolism of 4-desmethyl, 4-monomethyl and 4,4-dimethyl sterols fed to *Manduca sexta*, we found that sterol utilization was associated with the level of phytosterol in the medium preparation and the degree of sterol metabolism by the insect (11).

We describe experiments herein designed to shed light on utilization and metabolism of dietary phytosterols by *H. zea*. Our results indicate a heretofore unrecognized sterol specificity in the type of sterols that may serve as membrane inserts and/or as precursors of ecdysteroid production. We chose to study *H. zea* for three reasons: (i) a relatively sterol-free diet has been designed to grow the insect (7); (ii) there has been a series of sterol structure–function studies performed on the insect (7–10); and (iii) *H. zea* is a major pest of corn, causing substantial crop damage annually. *Heliothis zea* has been shown to convert sitosterol to cholesterol (10) and to synthesize ecdysone and 20-hydroxyecdysone (12), suggesting that *H. zea* operates the sitosterol-to-ecdysteroid pathway commonly found in insects (3).

MATERIALS AND METHODS

Culturing of H. zea. Eggs were originally obtained from the Department of Entomology, University of Illinois (Urbana, IL). The stock insects were reared at the United State Department of Agriculture laboratory in Peoria, IL, using sterile procedures on a pinto bean-based diet. Moths were fed 10% sucrose (13). Cultures were maintained at 27 ± 1°C, at 40 ± 10% relative humidity on a 14:10 light–dark photoperiod (13). The artificial diet of Ritter and Nes (7) was used to rear the insects on different sterol supplements. The experimental diet contained Bacto agar, which is known to contain trace contamination of cholesterol (14), otherwise the experimental diet was sterol-free. Sterols were solubilized in acetone. Aliquots of the solutions were added to a warm sterol-free, still-liquid diet, the material mixed thoroughly with the diet using a stir plate, and the organic solvent allowed to evaporate. To each of twenty 35-mL plastic cups was added 1 mg of sterol (equivalent to 200 ppm) and 1 insect at the first instar stage of development. The larvae were allowed to grow and mature for 20 d. The fresh weight and length of 20-d larvae were recorded. Ritter and Nes (7) found that by day 20, *H. zea* larvae are in the final stage of larval development (sixth instar), after which time the larvae may pupate and develop into the moth form. In some sterol treatments, we allowed the larvae to pupate and develop further. We observed that neonate larvae failed to molt to the second instar when sterol was absent from the diet, but as also observed by Ritter and Nes (7), some of these insects may survive for longer periods, presumably due to sparing of egg cholesterol. The minimal dietary concentration of cholesterol necessary for larvae to grow and pupate was found by Ritter and Nes (7) to be 0.01% of the experimental diet. We used 0.02% (200 ppm) to ensure that a nonlimiting amount of the test sterol was available in the experimental diet and growth rates would be maximized.

Sterol source and analysis. Sterols were obtained from our sterol collection (6,15,16, and references cited therein) or synthesized from appropriate sterol substrates that were from the sterol collection. Sterol isolation, purification, quantitation, and identification by chromatographic and spectral methods were as described in our earlier papers (6,15). All sterols were greater than 99% pure, except the $\Delta^{23(24)}$-24-alkylsterols, which were *ca.* a 1-to-1 mixture of *E*- and *Z*-23,24-double bond isomers. Sterols recovered from the nonsaponifiable lipid fraction were analyzed by gas–liquid chromatography–mass spectrometry (6,16) and found to contain long-chain fatty alcohols (17). These fatty alcohols may comigrate with sterols during thin-layer chromatography and interfere with sterol quantitation, particularly that of cholesterol. Therefore, in order to confirm the identity and amount of cholesterol in each insect, an aliquot of the nonsaponifiable lipid fraction was injected into a reversed-phase high-performance liquid chromatograph. The fraction migrating with cholesterol was eluted from the column (in some cases this sample was subfractionated on a second high-performance liquid chromatography column, cf. Ref. 6) and examined by gas–liquid chromatography–mass spectrometry. An authentic specimen of 24,28-fucosterol epoxide was supplied to us by Dr. James Svoboda (United States Department of Agriculture/Agricultural Research Service, Beltsville, MD) for use as a chromatographic standard. Chromatographic

and spectral data of sterols isolated from the larvae matched authentic specimens available to us from earlier studies (4,6,15).

RESULTS AND DISCUSSION

Heliothis zea was found to utilize 7 of 18 naturally occurring phytosterols for growth (Table 1). Many of the phytosterols which are nonutilizable occur in corn plants (6). The mode of action of these sterols on growth and maturation was found to be related to their degree of absorption and metabolism. The corn earworm fed ostreasterol, fucosterol, isofucosterol, sitosterol, clionasterol, and stigmasterol grew and developed normally in the same manner as those reared on cholesterol (Table 1). The utilizable sterols (Fig. 2) were absorbed to similar levels (27 to 71 μg per insect), and converted to cholesterol in high yield by the insect. There was no evidence for fucosterol 24,28-epoxide in the chromatograms of larval sterols, suggesting rapid turnover of the polar intermediates during C-24 dealkylation. From these results, we conclude that *H. zea* operates a typical C-24 alkylation pathway that acts on 24-alkyl Δ^5-sterols. The hypothetical pathway operates as follows: sitosterol conversion to fucosterol; fucosterol conversion to fucosterol 24,28-epoxide; fucosterol 24,28-epoxide conversion to desmosterol; and desmosterol conversion to cholesterol (Fig. 1). Cholesterol is then presumably converted to ecdysone.

The amount of tissue cholesterol that is necessary to support growth is not clear. We examined the influence of cholesterol mixed in different proportions with 24-dihydrolanosterol, (utilizable and nonutilizable sterols, respectively) (Table 2). Insect growth was found to be impaired on a 30:70 mixture and completely inhibited on a 10:90 mixture of cholesterol to 24-dihydrolanosterol (Table 2). Adequate amounts of cholesterol are absorbed by larvae from a 50:50 mixture of cholesterol to 24-dihydrolanosterol to promote growth. The level of cholesterol in these insects represents *ca.* 18 μg cholesterol per insect. The 24-dihydrolanosterol absorbed by the insects is not harmful to growth, and apparently does not compete in a negative manner with cholesterol as a precursor to ecdysteroid production. The amount of cholesterol in the 10:90 cholesterol/24-dihydrolanosterol treatment absorbed by the insect apparently falls below the threshold value necessary to promote growth. Thus, we assume the lower limit of utilizable sterol(s) to promote growth and maturation must be at or below 18 μg per insect. This limit is much different from that for other insects, such as for aphids and the tobacco hornworm (11,17), which are very different-sized insects. The inability of 24-dihydrolanosterol to replace cholesterol as a growth supplement indicates that one or more sterol features on the 24-dihydrolanosterol constitution are harmful to activity.

Larvae fed cholest-8-enol, 24-dehydropollinastanol, 24-methyl cholesta-5,23-dienol, 24-ethyl cholesta-5,23-dienol,

[a]Structures of sterols are reported in Figure 2.

[b]Growth on cholesterol produced larva that at 20 d weighed, on average, 323 mg and possessed a length of 30 mm. Generally 16 of 20 insects survived on cholesterol to pupate and develop into moth form. The growth response on test sterols is relative to the growth (larval length) on cholesterol which is normalized to 100%. 24-Methyl cholesta-5,23-dienol was found to develop into pupae and into adult forms. However, these insects exhibited congenital deformities. Insects in the nonutilizable category generally weighed less than 100 mg per insect, and their length ranged from 1.5 to 15 mm, with 6 to 12 insects alive at day 20.

[c]Sterols isolated from insect tissues, after the gut was purged of its contents, were analyzed by reversed-phase high-performance (HPLC) (6) and gas–liquid chromatography–mass spectrometry (GLC–MS) (6); n.d., not determined; and Ts, test sterol.

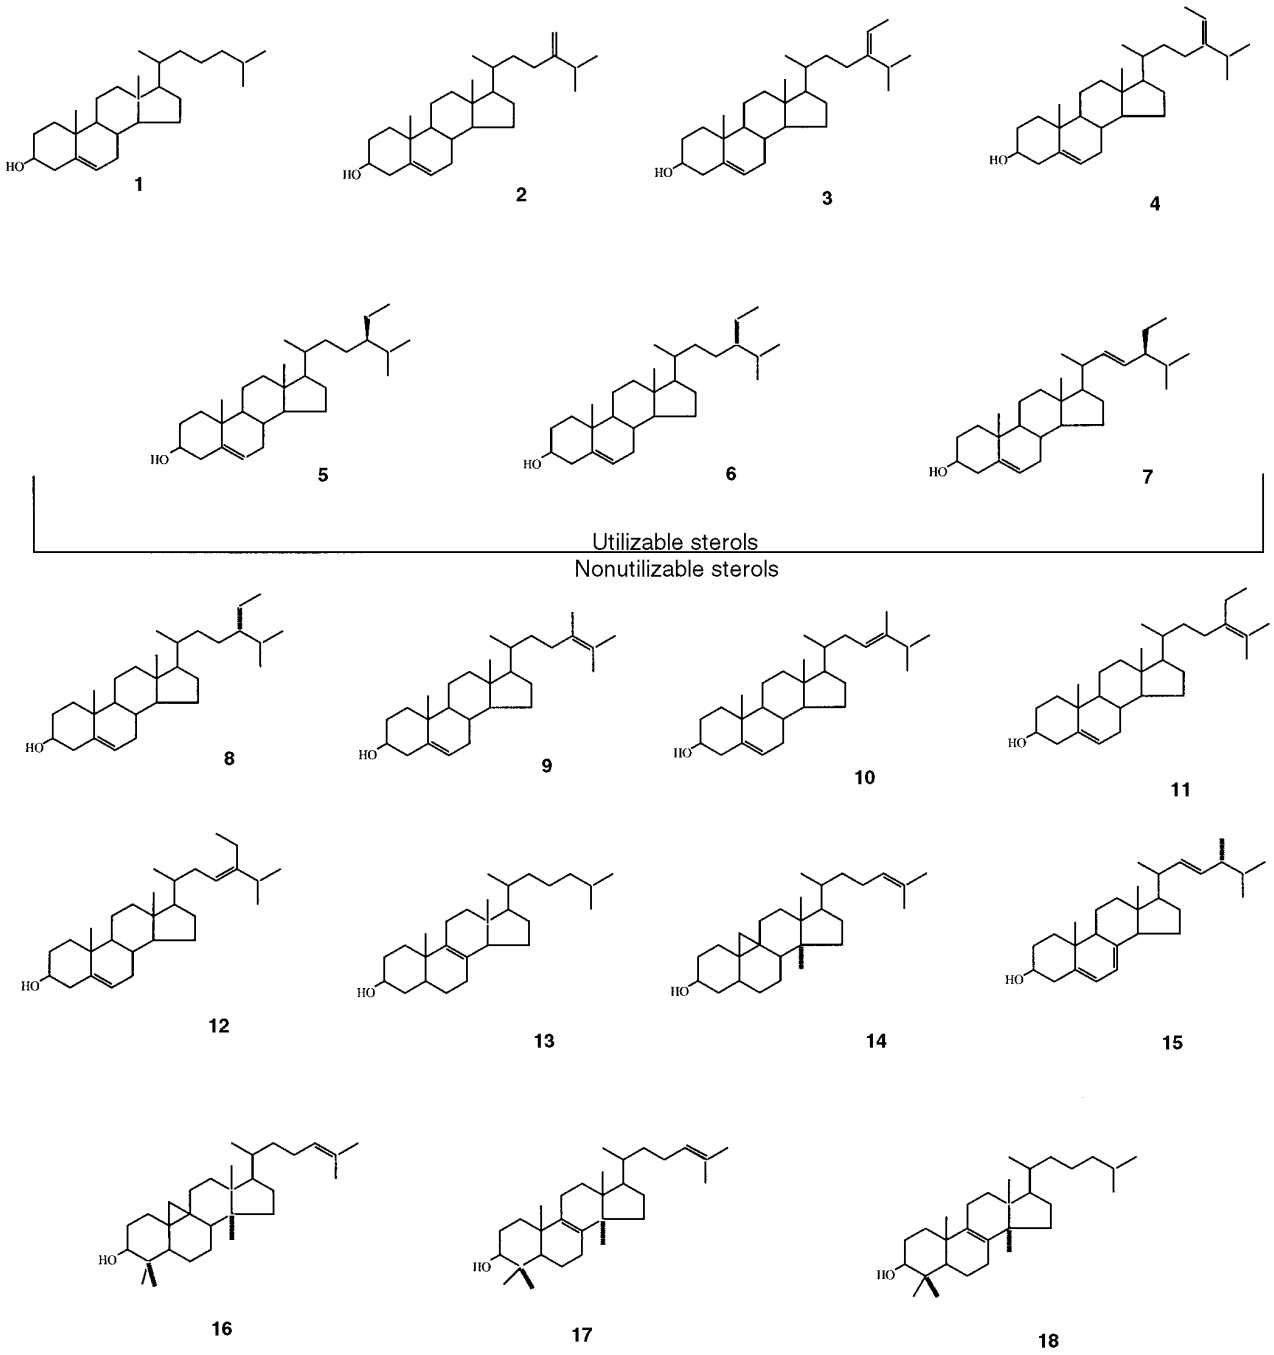

FIG. 2. Structures of sterols fed to *Heliothis zea,* trivial names and (systematic names): (1) cholesterol (cholest-5-en-3β-ol); (2) ostreasterol [cholesta-5,24(28)-dien-3β-ol]; (3) isofucosterol [(24*Z*)-24-ethylidenecholesta-5,24(28)*Z*-dien-3β-ol; (4) fucosterol (24*E*)-24-ethylidene cholesta-5,24(28)*E*-dien-3β-ol; (5) sitosterol [24(*R*,α)-ethylcholest-5-en-3β-ol]; (6) clionasterol [24(*S*,β)-ethylcholest-5-en-3β-ol]; (7) stigmasterol [24(*S*,α)-ethylcholesta-5,*22E*-dien-3β-ol]; (8) clereosterol [24*R*,β)-ethylcholesta-5,25(27)-dien-3β-ol]; (9) 24-methyldesmosterol (24-methylcholesta-5,24-dien-3β-ol); (10) no trivial name (24-methyl cholesta-5,23-dien-3β-ol); (11) 24-ethyldesmosterol (24-ethylcholesta-5,24-dien-3β-ol); (12) no trivial name (24-ethylcholesta-5,23-dien-3β-ol); (13) no trivial name (cholest-8-en-3β-ol); (14) 24-dehydropollinastanol (14α-methyl-9β,19-cyclo-5α-cholesta-8,24-dien-3β-ol); (15) ergosterol [24(*R*,β)-methylcholesta-5,7,22*E*-trien-3β-ol]; (16) cycloartenol (4,4,14-trimethyl-9β,19-cyclo-5α-cholesta-8,24-dien-3β-ol); (17) lanosterol (4,4,14-trimethyl-5α-cholesta-8,24-dien-3β-ol); (18) 24-dihydrolanosterol (4,4,14-trimethyl-5α-cholest-8-en-3β-ol). The sterol numbering system that we prefer to use is based on the biosynthetic side-chain rule discussed in Reference 6 (and references cited therein).

24-methyl cholesta-5,24-dienol, 24-ethyl cholesta-5,24-dienol, clereosterol, ergosterol, cycloartenol, lanosterol, and 24-dihydrolanosterol (Fig. 2) failed to grow normally. These 11 compounds may be considered nonutilizable sterols (Table 1). Larvae from treatments with the nonutilizable sterols either died by day 20 or underwent delayed growth and pupation. The resulting pupae were found to possess aberrant forms, which after development into moth forms exhibited

congenital deformities. Similar observations were made by Ritter (10), studying *H. zea* fed $\Delta^{5,7}$-sterols, and Coste *et al.* (18), studying locusts fed plant diets containing high levels of cyclopropyl sterols. The possibility that one or more metabolites were toxic to the insects was ruled out by a careful examination of the sterol composition of the larvae; only the test compound or a utilizable sterol metabolite was detected in the insect.

A second possibility is that inadequate absorption of sterols from the intestinal gut led to a sterol content in the larvae that was below the threshold value necessary to promote growth, and therefore generated a nonutilizable sterol. This line of reasoning might imply that the level of sterol, and not small changes in the structure, gives rise to nonutilization. However, as we subsequently discovered, both the amount and type of sterol absorbed by the insects determine the sterol efficacy. All the nonutilizable sterols were recovered from larvae in the range between 0.6 and 6 μg per insect. Larvae treated with a nonutilizable sterol contained trace amounts of cholesterol that ranged between 80 and 300 ng of cholesterol. The larval cholesterol was most likely derived from the agar and/or from carryover from cholesterol originally present in the eggs (*ca.* 80 ng of cholesterol per egg was detected, similar to the cholesterol content of eggs from the fire ant, Ref. 15). Since the treatment with 24-methylcholesta-5,23-dien-3β-ol sparred cholesterol to grow and mature, the lower limit of cholesterol for development appears to be at or above 300 ng per insect. Although more study is warranted, we hypothesize that about 18 μg of sterol is required for normal *H. zea* growth (based on sparing studies with cholesterol and 24-dihydrolanosterol); of that utilizable sterol, approximately 10.0% is required for ecdysteroid production (based on the level of cholesterol generated in the 24-methylcholesta-5,23-dien-3β-ol treatment), the remaining sterol functioning as a membrane insert.

Sterols that may be grouped into the utilizable category contain a 3β-hydroxyl group, a planar nucleus with a Δ^5-bond, and an intact side chain of 8 to 10 carbon atoms. Neither the geometry of the 24(28)-ethylidene group nor the stereochemistry of the C-24 alkyl group was essential for activity, since isofucosterol and fucosterol, and sitosterol and 24-episitosterol (clionasterol) were found to support growth, and each compound was converted to cholesterol in high yield. A series of cholesterol analogs with side-chain modifications at C-24 and double bonds introduced in the side chain at Δ^{23}-, Δ^{24}-, and Δ^{25}-positions induced pronounced growth-retarding effects, suggesting an important role in the structure of the side chain of sterols grouped into the nonutilizable category. Trace amounts of cholesterol in the clereosterol treatment suggest that *H. zea* may not synthesize a $\Delta^{25(27)}$-reductase enzyme. Alternatively, since desmosterol (cholesta-5,24-dien-3β-ol) and stigmasterol may be considered intermediates to cholesterol, then *H. zea* must possess at least two side-chain reductase-type enzymes, viz., a $\Delta^{24,25}$-reductase and a $\Delta^{22,23}$-reductase. Based on our studies with stigmasterol and ergosterol and that of Ritter and Nes, who also examined ergosterol and brassicasterol (24β-methylcholesta-5,22*E*-dien-3β-ol), we infer that catalytic competence of the $\Delta^{22,23}$-reductase is sensitive to the size of the 24-alkyl group, since the 24-methylsterols were converted to a saturated side chain by *H. zea* less effectively than 24-ethylsterols. 24-Methyldesmosterol and 24-ethyldesmosterol were found to be recovered from the insects in unchanged form (Table 1), suggesting that the 24,25-reductase is also sensitive to the addition of substitutents which can can add steric bulk at position C-24. From the $\Delta^{23(24)}$-24-alkyl treated larvae, trace cholesterol was recovered. This low level of cholesterol is assumed to be from the diet rather than from metabolism of the dietary sterol. Thus, the insect may also not synthesize a $\Delta^{23(24)}$-reductase enzyme. The inability for either the $\Delta^{23(24)-}$ or $\Delta^{25(27)}$-sterols to satisfy the sterol requirement of *H. zea* suggests that there is a high degree of regiospecificity for the double bond to be located at C-24(28) in the side chain for C-24 dealkylation pathway to proceed to desmosterol production.

The corn earworm can tolerate certain modifications in the nucleus, as shown earlier by Ritter (8–10), studying a series of Δ^0-, Δ^5-, and Δ^7-, and Δ^8-sterols. However, we found that many phytosterols that are transformed naturally by plants, such as those with a 4,4-dimethyl group (24-dihydrolanosterol, lanosterol, and cycloartenol), a 9β,19-cyclopropane

group (24-dehydropollinastanol and cycloartenol), a $\Delta^{8(9)}$-bond (cholest-8(9)-en-3β-ol) were ineffective nutritional supplements and were recovered from larvae in unchanged form (Table 1), suggesting a much stricter sterol specificity than was recognized by Ritter (8–10). For mechanistic reasons, 24-dihydrolanosterol should pass through cholest-8(9)-en-3β-ol onto cholesterol (19). Our inability to detect (trap) cholest-8-en-3β-ol in the 24-dihydrolanosterol treated larvae is consistent with our observation that 24-dihydrolanosterol was not converted to cholesterol and that the cholesterol in the larvae was from contamination (carryover from the eggs and agar). The accumulation of significant amounts of cholest-5,7-dien-3β-ol (7-dehydrocholesterol) from the ergosterol-treated insects suggests there is little metabolism of $\Delta^{5,7}$-sterols by the insects, which is consistent with the findings of Ritter (9). We interpret these results to imply that *H. zea* fails to synthesize several enzyme systems synthesized by plants that act on the nucleus of sterols: a 4-demethylase, a cyclopropyl to Δ^{8}-isomerase, a $\Delta^{8(9)}$-to $\Delta^{7(8)}$-isomerase, a Δ^{7}-reductase, and a Δ^{7}-desaturase. The inability of *H. zea* to metabolize either lanosterol or cycloartenol is in sharp contrast to the strong 24,25-reduction of these two sterols by the tobacco hornworm (4,11). Ritter (9) claimed that *H. zea* could metabolize lanosterol to cholesterol, suggesting that *H. zea* synthesized all the requisite enzymes to carry out lanosterol turnover to a Δ^{5}-sterol. However, our results, reported in Table 1, do not support her findings.

In postulating a structural function for nonutilizable sterols, we have implied that the sterols are incorporated *per se*, or at any rate are not converted into any metabolically useful products. Support for this view has been obtained by feeding *H. zea* larvae, for instance, 24-methylcholesta-5,23-dien-3β-ol, and by showing that the bulk of it can be recovered in unchanged form. Alternatively, utilizable sterols are those compounds that may function in both roles, nonmetabolic and metabolic. It is concluded that some nonutilizable sterols can spare (e.g., 24-methyldesmosterol), but cannot replace, cholesterol in the nutrition of *H. zea* and these sterols serve in some structural rather than metabolic function. Either enzyme specificity acts on the nonutilizable sterols, such that one or more substituents on the molecule interfere with normal transformation of the phytosterol to ecdysteroid, or the insect lacks one or more enzyme systems necessary to convert the compound to cholesterol. In the case of 24-methylcholesta-5,23-dien-3β-ol, the double bond is positioned incorrectly for 24(28)-epoxidation during the initial phase of C-24-dealkylation, whereas for 24-dehydropollinstanol the insect lacks minimally an active 9β,19-cyclopropyl to $\Delta^{8(9)}$-isomerase. The inability to transform clereosterol, with a $\Delta^{25(27)}$-bond, to cholesterol is consistent with the mechanism of C-24 dealkylation which requires hydrogen migration from C-25 to C-24 during 24,25-double bond formation (2, 4). It is expected that plants that can be treated with specific sterol biosynthesis inhibitors or genetically engineered to produce sterol enzymes that give rise to altered enzyme efficiencies and product distributions will possess modified phytosterol compositions that accumulate 4,4-desmethyl 9β,19-cyclopropyl sterols or may generate clereosterol and related novel $\Delta^{23(24)}$-and $^{\Delta 24(25)}$-24-alkyl sterols as replacements of the normal Δ^{5}-24-alkyl sterols. This potentially environmentally friendly biotechnology can lead to broad-based insect resistance.

Remote Functionalization of the Steroid Side-Chain

Edward J. Parish,* Nida Aksara, and Terrence L. Boos

Department of Chemistry, Auburn University, Auburn, Alabama 36849

ABSTRACT: By using classical methods of organic synthesis, the introduction of chemical modifications into the saturated side-chains of steroids usually requires a multistep synthesis to construct new side-chains to be added to the steroid nucleus. In order to circumvent these earlier methods, new procedures have been developed to directly introduce functionality onto the steroid side-chain to produce useful products. These initial products may also provide an entry toward the further modification of the side-chain to produce steroids which could previously be obtained only with great difficulty.

Lipids 32, 1325–1330 (1997).

The side-chains of naturally occurring steroids vary in their structure and composition (1–4). Individually, they represent unique challenges to the organic chemist with the task of chemically modifying intact side-chains or constructing new ones through multistep synthesis. Chemical modification of an existing side-chain, which may contain unsaturation, is a much easier task than the construction of a new side-chain which may be time-consuming and may require many chemical steps. Many naturally occurring steroids contain side-chains that are saturated and are devoid of any functionality which the chemist might use as an intermediate in the modification process.

Chemical functionalization of the saturated side-chain of steroids (e.g., cholesterol) is a difficult problem for the organic chemist. The need to modify the saturated side-chain of certain steroids may arise through the study of enzymatic transformations of the side-chain and the requirement to have authentic standards for the identification of potential metabolites. Also, the synthesis of biochemical inhibitors would require introducing functionality at selected positions on the side-chain. Collectively, the necessity to modify the saturated side-chain of steroids has been the driving force for developing facile methods to accomplish this goal.

Historically, the side-chain of steroids could be modified by using unsaturation already available in a naturally occurring steroid. In this way, steroids such as desmosterol (cholesta-5,24-dien-3β-ol) (5,6), fucosterol (24-methylene-cholest-5-en-3β-ol (7,8), stigmasterol (24α-ethylcholest-5,22-dien-3β-ol) (9,10), and lanosterol (lanosta-8,24-en-3β-ol) (11–14) easily could be converted into side-chain derivatives for various purposes. Unfortunately, steroids such as desmosterol and fucosterol may not be readily available in larger quantities and are costly starting materials.

The earlier literature, describing the construction of side-chains from an existing steroid nucleus, has been reviewed (15). There are also many more recent examples of these types of modification reactions, and we have attempted to categorize a number of these which may be of interest. One approach is to use a C-17 ketone (usually 3β-hydroxyandrost-5-en-17-one) as a starting material and convert it into a side-chain-bearing steroid in a multistep synthesis (16–18). Another approach involves the use of a C-20 ketone (19–22) or aldehyde (23) as a starting material, which is modified into an appropriate side-chain derivative. Also, an aldehyde (24–27), alcohol (28), or carboxylic acid (29) function at C-21 has been used to lengthen the side-chain of steroids. Modification of a C-22 alcohol (30) or carboxylic acid (usually 3β-hydroxy-5-cholen-22-oic acid) (31) has been used to extend the terminal carbons of side-chains. In a similar manner, C-24 aldehydes and alcohols (31) (usually derivatives of 3β-hydroxy-5-cholen-24-oic acid) have also been used to modify and extend the existing side-chains of steroids.

An alternative approach is to directly introduce side-chains, with various functional groups, onto an existing steroid nucleus. This approach usually requires a multistep synthesis, and in most cases the final product is produced in low or very moderate overall yields. This area of research continues to be very active, and many different investigators have directed their talents to the construction of steroid side-chains. These may contain diverse functionality, including unsaturation, which could be further modified in an additional sequence of reactions. This approach usually involves constructing a side-chain by modifying carbon atoms 17–24 (15–33).

An alternative method to the functionalization of steroid side-chains involves the direct introduction of a modification into the side-chain in a single chemical reaction. This approach is termed "remote functionalization" and represents a rapidly developing area in steroid chemistry which promises to streamline the synthesis of many difficult-to-obtain steroids. Through the earlier work of Breslow and colleagues (34–38), methods for the remote functionalization of the steroid nucleus have become well-known reactions. The functionalization of remote positions on the steroid nucleus and side-chain represents some of the most important advances in

the steroid field. Remote functionalization of a saturated steroid side-chain usually involves oxidation on the tertiary carbon at C-25 to produce a 25-hydroxysterol. In most studies, these reactions have been developed in the cholesterol series, and the end product of these reactions is cholest-5-en-3β-diol (25-hydroxycholesterol).

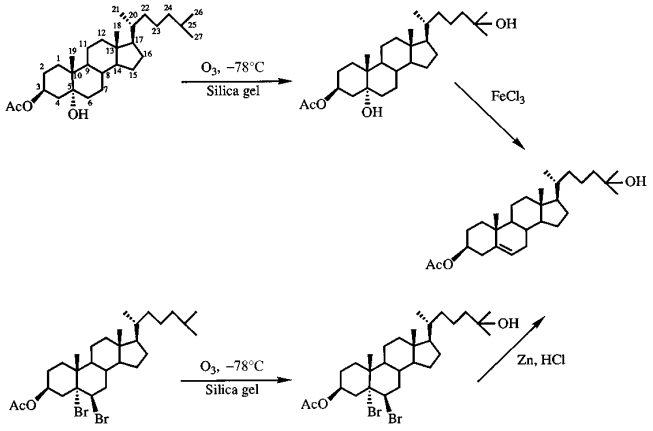
The predominant target molecule in many studies has been 25–hydroxycholesterol owing to its interesting biological properties and its ability to be dehydrated to desmosterol which can be further chemically modified. 25-Hydroxycholesterol is a member of a class of sterols known as oxysterols which possess a second oxygen function in addition to that at C-3 and are known to have diverse biological activities (39–48). Some of these include cytotoxicity, atherogenicity, carcinogenicity, mutagenicity, hypocholesterolemia, and various effects on specific enzymes. 25-Hydroxycholesterol is known to be a very potent inhibitor of 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase, a key regulatory enzyme in cholesterol biosynthesis ($IC_{50} < 1$ μM) (39,42).

Repression of the synthesis of immunoprecipitable HMG-CoA reductase by this oxysterol has been demonstrated by Faust *et al.* (49) in a Chinese hamster ovary (CHO)-derived compactin-resistant cell (UT-1) line that overproduces the enzyme and by Sinensky *et al.* (50) in CHO cells. Lutsky *et al.* (51) have shown that the level of mRNA for the reductase in UT-1 cells is reduced in the presence of oxysterol. Similar results were obtained by Kandutsch *et al.* (52–54) in wild-type CHO cells. These results were utilized by Kandutsch and Thompson (55), who proposed the following model for the regulation of HMG-CoA reductase activity by oxysterols: The oxysterol binds to a cellular protein, and the resultant oxysterol–protein complex then acts to repress transcription of the gene for reductase production. In support of this model, Kandutsch *et al.* (52–54) have isolated a protein which exhibits high affinity and low capacity for 25-hydroxycholesterol and other oxysterols which are known to suppress reductase production. In support of this model, Kandutsch *et al.* (54,56–58) have isolated a protein which exhibits high affinity and low capacity for 25-hydroxy and other oxysterols which are known to suppress reductase activity. Although 25-hydroxycholesterol has been isolated from cells, there is no direct evidence that this oxysterol functions as a natural regulator of cholesterol biosynthesis (59). This model was in direct contrast to the prevailing view that cholesterol, accumulating in cells after endocytosis of low density lipoprotein (containing cholesteryl esters), is the regulatory messenger molecule (60).

Primary metabolism in mammalian systems is known to produce side-chain oxysterols. Derivatives of cholesterol hydroxylated in the 25- or 26-positions are produced in liver during bile acid synthesis. Another mode of oxysterol biosynthesis has been described which utilizes the isopentenoid pathway to produce side-chain derivatives of cholesterol and lanosterol (61). Such compounds are derived from squalene 2,3-epoxide by the introduction of a second oxygen function to form 2,3;22,23-dioxidosqualene prior to cyclization. Thus, this intermediate has been shown to form 24(*S*),25-epoxylanosterol, 24(*S*),25-epoxycholesterol, and 25-hydroxycholesterol in mammalian systems (62–65). 24(*S*),25-Epoxycholesterol has been isolated from cultured mouse L-cell, Chinese hamster lung fibroblasts, and human liver (59). These oxygenated side-chain derivatives have been shown to be potent inhibitors of HMG-CoA reductase and sterol biosynthesis and possess a high affinity for the oxysterol binding protein (59,62–65). These results add further support to the hypothesis that oxysterols may be natural regulators of cholesterol biosynthesis in mammalian cells (53,65,66). This dioxidosqualene pathway has recently been reviewed (65,66). Also, its occurrence in plants, animals, and microorganisms (67,68) and its evolution in a variety of organisms have been reviewed (69).

Early attempts to obtain 25-hydroxycholesterol directly from cholesterol included attempts to enhance the air or autoxidation process (46). Fieser *et al.* (70) examined cholesterol samples differing only in age and concluded that cholesterol undergoes oxidation to the 3β,25-diol on storage in the crystalline state in the presence of air. Bubbling air through a refluxing solution of crystalline cholesterol in benzene only resulted in air oxidation products other than the 3β,25-diol. It was therefore concluded that the observed selectivity of hydroxylation at the C-25 position, in the air oxidation of cholesterol, was a consequence of the regular arrangement of the steroid molecules on the major faces of the plate-like crystals (71). On this basis a more general hypothesis was advanced that when molecules are observed in a close-packed array the mutual steric effect of one upon the other may hinder reactions at the usual position and thus enhance oxidation of more exposed terminal areas. Using this approach, experiments were conducted in which barium sulfate or neutral alumina bearing absorbed cholesterol was heated in air or oxygen in the presence of an initiator, or irradiated with ultraviolet light. In each of these experiments some 3β,25-diol was formed, but the yields (approximately 3%) were less than those obtained by autoxidation of the crystalline steroid, and the product mixtures were very complex (72). The poor results of these earlier experiments are not surprising since the C-5 double bond, which is a major site for autoxidation, is not chemically protected and thus contributes to the low yields of the 3β,25-diol.

A related approach to the direct functionalization of side-chains with diatomic oxygen is the use of ozone. Mazur and colleagues (73,74) have developed useful procedures for the ozonolysis of steroid substrates adsorbed on dry silica gel to introduce oxygen into unactivated tertiary C-H bonds. This method involves preadsorption of substrate on chromatographic-grade silica gel and passage over it of ozone at temperatures between −75 and −45°C, followed by elution with an appropriate organic solvent. The reactivity of the tertiary C-H bonds toward ozone depends both on the electronegativity and the steric availability of the carbon atom (73). In this way, the dry ozonation of 1α,3β-diacetoxy-6,7-dibromo-5α-cholestane led to the C-25 hydroxylated derivative as the only

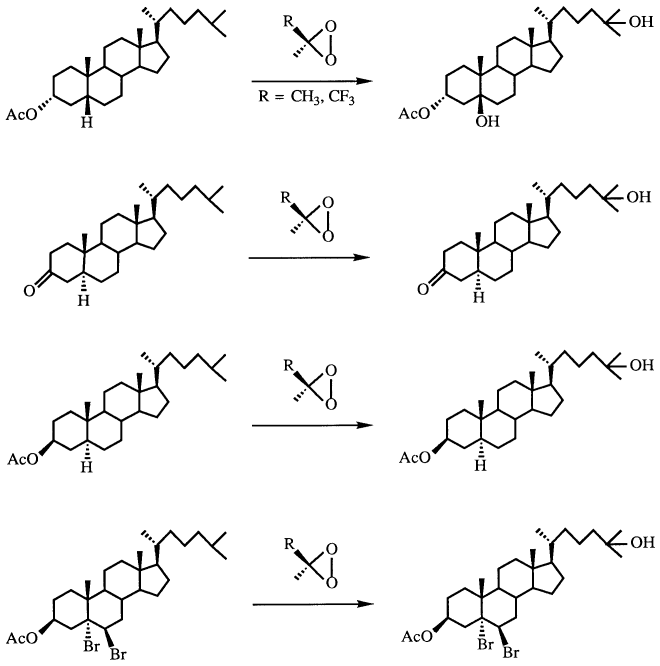


SCHEME 1

isolated product (11% conversion and 51% yield) (73). In a later study, a number of saturated cholestane derivative substituted at positions 5, 6, and 7 which served as protecting groups for ring-B double bonds were ozonized on silica gel to produce the C-25 hydroxylated products (Scheme 1). Also, a 3β-acetoxy-6,7-dibromo-5α-cholestane was ozonated to its C-25 hydroxy derivative and further dehydrobromination led to the respective 5,7-diene (73). The protecting groups, for the ring-B double bonds, served a dual function. In addition to their protecting role, they sterically hindered the approach of ozone to the other tertiary carbon atoms on the steroid nucleus and allowed an increased yield of the C-25 hydroxylated products.

In other studies of side-chain remote functionalization, the Gif system has been used to oxidize cholestane derivatives to the corresponding C-20 ketones (75–78). The oxidation of cholest-4-en-3-one by the Gif system to give progesterone has been studied. The optimal temperature was ~20°C, and a reaction temperature below 0°C gave 25-hydroxycholest-4-en-3-one as the major product (79). A long-range intramolecular functionalization of an irradiated 7α-hypoiodite derivative of cholestane has been reported to yield the C-25 hydroxysteroid as a final product (80) . Another report describes the C-25 hydroxylation of cholesterol by a membrane-spanning Mn(III) porphyrin positioned in a synthetic bilayer assembly (81). This synthetic porphyrin is capable of mimicking the hydroxylation activity of certain cytochrome P-450 enzymes.

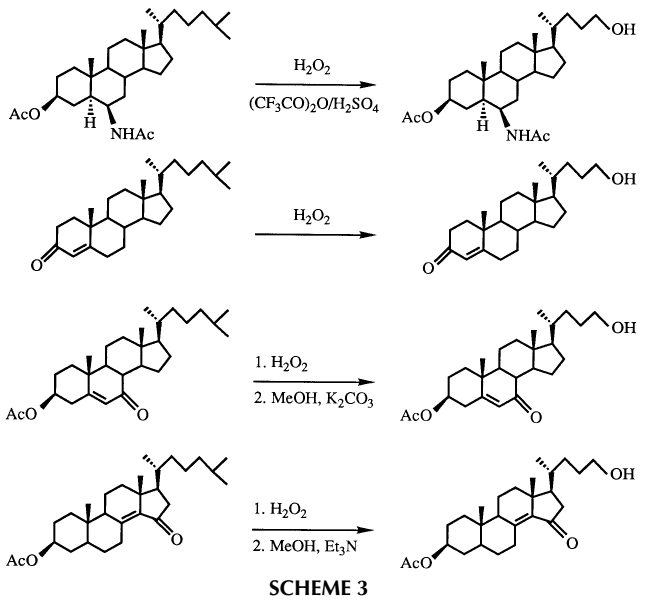
Recently, remote functionalization to produce hydroxylation at C-25 has been achieved using dioxiranes. Dioxiranes had previously been described as highly effective reagents in oxyfunctionalization of saturated hydrocarbons and the steroid nucleus (82,83). Both dimethyldioxiran and methyltrifluoromethyl dioxirane converted 3α-acetoxy-5β-cholestane to 3α-acetoxycholest-5β,25-diol in a simultaneous double oxyfunctionalization (Scheme 2) (84). In a related study, the direct and high yield oxyfunctionalization of 5α-cholestan-3-one, 3β-acetoxy-5α-cholestane, and 3β-acetoxy-5α,6β-dibromocholestane was achieved to produce the C-25 hydroxy derivative under mild conditions using dimethyldioxirane or its trifluoromethyl analog (Scheme 2) (85). The



SCHEME 2

latter steroid was cleanly (yield 93%) converted to 3β-acetoxycholest-5-en-25-ol upon debromination with zinc in acetic acid, thus restoring the $\Delta^{5,6}$ double bond that had been protected by the dibromide.

Another successful approach to remote functionalization involves the use of a mixture of hydrogen peroxide and trifluoroacetic anhydride (trifluoroperacetic acid) together with sulfuric acid to oxidize and cleave steroid side-chains. Deno *et al.* (86,87) initially developed this method which was also utilized by Takano and Ogasawara (88) to oxidize selected steroids to the corresponding C-24 alcohols. In this way, an amide derivative of cholesterol (which was finally converted



SCHEME 3

into the $\Delta^{5,6}$ double bond), cholest-4-en-3-one, and 3β-acetoxycholest-5-en-7-one were oxidized to give the C-24 hydroxy derivatives in modest yields (17–19%) (Scheme 3). A significant improvement in this procedure was described by Schroepfer *et al.* (89–92) which allowed the isolation of the end product in much higher yields. In this procedure, 3β-acetoxycholest-8(14)-en-15-one was oxidized to a crude mixture of products which was further treated with triethylamine in methanol to provide 3β-acetoxy-24-hydroxy-chol-8(14)-en-15-one in 61% yield (Scheme 3). In these studies, Schroepfer *et al.* described the use of their C-24 alcohol as a key intermediate to modify the steroid side-chain.

An additional approach to remote functionalization that has been useful for introducing a 14α-hydroxyl group onto steroids devoid of a side-chain is the use of chromyl acetate (93–95). This reagent is made *in situ* from acetic anhydride and chromium trioxide and was previously used for the oxidation of hydrocarbons (96). We became interested in this reagent for possible development into a new method for direct hydroxylation at C-25. This procedure possessed the desirable properties of being simple, convenient, and applicable to larger-scale reactions. After optimization, we were able to isolate the C-25 hydroxy derivative of 3β-acetoxy- or 3β-benzoyloxy-5α,6β-dichloro-5α-cholestane in yields of 14–18% (Scheme 4) (97,98). The success of this procedure depends on maintaining some starting material during the course of reaction to prevent further oxidation of the initially formed C-25 hydroxylated product. The accessibility of the relatively less hindered C-25 on the side-chain allowed an initial selective oxidation at this position followed by partial oxidation of other tertiary carbons on the steroid nucleus which would result in complex oxidation products. The initial C-25 hydroxylated product was then treated with zinc in acetic acid to remove the 5α,6β-dichloride and restore the $\Delta^{5,6}$ double bond (94), and the ester function at C-3 was removed by mild base hydrolysis (12) to produce 25-hydroxycholesterol (Scheme 4).

In related experiments, we were able to improve these results through the use of the reagent trifluorochromyl acetate which can be prepared *in situ* from the reaction of trifluoroacetic anhydride and chromium trioxide (99). Again, this reagent system has a history of oxidizing hydrocarbons (99). After optimization and using the same techniques described, we were able to isolate the C-25 alcohol of the previously described starting material in yields of 40–60% (Scheme 3) (97,98). We believe this procedure will prove to be a useful method for the remote functionalization at C-25 in steroid side-chains and will be an attractive alternative to other known procedures.

In conclusion, the remote functionalization of steroid side-chains is a continuing challenge in synthetic organic chemistry. The application of new and known reagents, with a demonstrated ability to oxidize hydrocarbons, has the potential to increase the number of reagents which can be used in the steroid fields for this purpose.

Studies on *N*-Nitroso Bile Acid Amides in Relation to Their Possible Role in Gastrointestinal Cancer

Bishambar Dayal* and Norman H. Ertel

Departments of Medicine, New Jersey Health Care System, V.A. Medical Center, East Orange, New Jersey 07018, and University of Medicine and Dentistry of New Jersey (UMDNJ)—New Jersey Medical School, Newark, New Jersey 07103

ABSTRACT: Cancers of the gastrointestinal tract account for a large proportion of neoplastic diseases which afflict humans. The etiology of gastrointestinal cancer has been attributed in part to exogenous carcinogens, such as food substances and environmental pollutants. Recent hypotheses suggest that carcinogens may arise endogenously. Evidence suggests that some bile acids and their isomeric metabolites may be involved in the pathogenesis of colon cancer. However, the mechanism responsible for their cancer-promoting effect is not clear. We and others propose that one mechanism for the mitogenic effects of bile acids may be *N*-nitrosation of their glycine and taurine amides; human gastric aspirates do contain small quantities of *N*-nitroso compounds of other substrates. Many foods contain nitrites and nitrates, which can react with bile acid amides to form *N*-nitroso derivatives. Our recent studies demonstrated the potential for *N*-nitroso conjugate formation from ursodeoxycholic acid, a 7β-epimer of chenodeoxycholic acid used as a drug Actigall® to dissolve gallstones. The *N*-nitroso derivative of this compound, a direct-acting carcinogen, has a long half-life and, once nitrosated, is stable enough to survive passage through the gastrointestinal tract. We describe the synthesis of *N*-nitrosated derivatives of various bile acid conjugates and mechanisms of decomposition of (*Z*)- and (*E*)-bile acid diazoates. Studies of the effects of enzymes such as cholylglycine hydrolase on the *N*-nitroso bile acid conjugates and their reaction with DNA are also described. These studies may have important implications in the interplay of diet with endogenous substrates in the etiology of cancers of the stomach, liver, and colon.

Lipids 32, 1331–1340 (1997).

Gastrointestinal cancer is a major malignancy worldwide (1,2). In 1995, the American Cancer Society reported 124,000 deaths in the United States from gastrointestinal cancers, second only to the 157,000 deaths due to lung cancer (3). Epidemiologic evidence supports the theory that dietary fiber consumption is protective against gastric and colorectal cancer (4) especially when the fiber is derived from a diet high in fruits and vegetables. It is difficult to separate the epidemiological effects of high fiber from the low fat content of such diets.

A low-fat diet may protect against colon cancer. Data from the Harvard School of Public Health (5) indicated that men with the lowest fat intake—an average of 24% of calories from fat—had only half the rate of colonic adenomatous polyps, a precursor of colon cancer, as men with the highest fat intake of 41%. In countries like Japan, where the average diet contains less than 10% of calories from fat, there is less colon (and breast) cancer.

The mechanism for the increased cancer rate in individuals and groups ingesting a high-fat diet is not clear. Recent interest has focused on the carcinogenic role of *N*-nitroso compounds derived from the consumption of preserved, smoked, and cured foods (6–9). A variety of *N*-nitroso compounds have been found to produce tumors in more than 40 animal species (6). In addition to *N*-nitroso compounds derived from exogenous carcinogens, such as food substances and environmental pollutants, endogenous sources have been identified. Thus, gastric cancer has been associated with chronic infection with *Helicobacter pylori*; other cancers are associated with chronic bacterial, viral, and parasitic infections (10–12). Nitric oxide, a short-lived free radical produced by many cells for important physiological functions, is increased in these infections and can produce endogenous carcinogenic *N*-nitroso compounds (13). Recent data have suggested that enhanced production of NO has the potential to induce mutagenic and possibly carcinogenic alterations in the gut epithelium *via* the formation of potent *N*-nitrosating agents derived from the spontaneous decomposition of NO in oxygenated solutions (13,14). In this regard, we and others have suggested that some bile acids, synthesized in the liver from cholesterol for the purpose of aiding in the digestion of fats, may be *N*-nitrosated in the stomach or intestines to form potentially mitogenic compounds (15,16). The most likely human exposure to direct-acting *N*-nitroso compounds (*N*-nitroso bile acid amides) would result from their *in vivo* formation because of their inherently unstable chemical nature.

Abbreviations: CA, cholic acid (3α,7α,12α-trihydroxy-5β-cholan-24-oic acid); CDCA, chenodeoxycholic acid (3α,7α-dihydroxy-5β-cholan-24-oic acid); DCA, deoxycholic acid (3α,12α-dihydroxy-5β-cholan-24-oic acid); EEDQ, *N*-ethoxy-carbonyl-2-ethoxy-1,2-dihydroquinoline; ESI, electrospray ionization; Et_3N, triethylamine; FAB, fast atom bombardment; GCA, glycocholic acid; GUDCA, glycoursodeoxycholic acid; MS, mass spectrometry; NMR, nuclear magnetic resonance; NOGC, *N*-nitrosoglycocholic acid; NOGDCA, *N*-nitrosoglycodeoxycholic acid; NOGUCA, *N*-nitrosoglycoursocholic acid; NOGUDCA, *N*-nitrosoglycoursodeoxycholic acid; NOTC, *N*-nitrosotaurocholic acid; NOTUDCA, *N*-nitrosotauroursodeoxycholic acid; TLC, thin-layer chromatography; TUDCA, tauroursodeoxycholic acid; UCA, ursocholic acid (3α,7β,12α-trihydroxy-5β-cholan-24-oic acid); UDCA, ursodeoxycholic acid (3α,7β-dihydroxy-5β-cholan-24-oic acid).

Considerable research has been directed toward formation and biological activation of the *N*-nitrosamines; less effort has focused upon the *N*-nitrosamides, which require no activation and are known to be potent direct-acting mutagens and carcinogens (17–19). As described above, the major source of nitrosable amides in the human body is the conjugated bile acids. Hepatocytes synthesize bile acids as oxidative degradation products of cholesterol (20,21). Then, the bile acid-conjugating enzyme, bile acid coenzyme A: amino acid: *N*-acyltransferase, specifically couples the bile acids with either of two amino acids, taurine or glycine (22). The conjugated bile acids enter the upper intestinal tract and, having performed their function of assisting in the absorption of fat, they are reabsorbed and recirculated in the enterohepatic circulation (23). The "pool" of bile acids circulates two or three times during each meal, or five to ten times daily. Since the body maintains a constant amount of 2 to 4 g of bile acids, theoretically 10 to 40 g of conjugated bile acids travel through the small intestine daily (20–23). At the terminal ileum, special receptors actively absorb most of the bile acids and return them to the liver in portal venous blood. The remaining bile acids enter the large intestine, where they are degraded by intestinal bacteria, and free bile acids are passively absorbed in the colon. However, a percentage of the bile acids, approximately 500 mg or more per day, are not reabsorbed by the terminal ileum or colon. Consequently, some are excreted in the feces whereas a few may bind to the tissues in the region of the ileum and colon (21–24).

The most likely human exposure to direct-acting *N*-nitroso bile acid conjugates would result from their *in vivo* formation potentially at several organ sites. A number of investigators have proposed that nitrosamides are produced in the stomach from amides and nitrite derived from food and that they act in that organ to induce cancer (25–30). The acidic environment of the stomach after meals is ideal because amide nitrosation is catalyzed by acid (28). Nitrite enters the stomach (*ca*. 4.3 mg/person/day) from two sources: 20% arises from nitrite in the diet, and 80% from the reduction of salivary nitrate by oral and gastric bacteria, especially under mildly acidic conditions (28). Cured meat, baked goods, cereals, and vegetables contribute to dietary nitrite, thus increasing gastric nitrite levels at the same time that the conjugated bile acids are circulating. Furthermore, nitrite disappears from the stomach because gastric acid converts it to nitrous acid (HNO_2), which upon decomposition to NO reacts with nitrogen compounds such as the nitrosamides to yield *N*-nitroso derivatives (29). Nitrous acid was the reagent used in the chemical synthesis of *N*-nitroso bile acid conjugates in the present study (15). Nitrosation can also be mediated by bacteria and activated macrophages in infected and inflamed organs (30). Endogenously occurring *N*-nitroso compounds may induce DNA modification by the formation of DNA adducts. In addition, time–dose relationships observed for tumor formation in animals indicate that lifetime or chronic exposure to even low levels of certain carcinogenic *N*-nitroso compounds may represent a greater cancer risk to people because of their long life spans (31).

Thus far, studies of *N*-nitrosated bile acid conjugates have been limited to derivatives of a naturally occurring hydrophobic bile acid, cholic acid (3α,7α,12α-trihydroxy-5β-cholan-24-oic acid, CA); *N*-nitrosotaurocholic acid (NOTC) and *N*-nitrosoglycocholic acid (NOGC) (31,32) were found to be mutagenic, in the absence of activation, in both forward and reversion bacterial mutation assays, while their precursors taurocholic acid and glycocholic acid were not. In a human lymphoblast assay, NOGC was approximately 9000 times more potent than NOTC in causing mutations (31). Investigation of the carcinogenic activities of NOTC and NOGC in rats showed that both induced significant levels of hepatocellular carcinoma and malignant stomach tumors (32).

Furthermore, the most significant studies concerning the formation and fate of nucleic acid and protein adducts derived from *N*-nitroso glyco bile acid conjugates (NOGC) have been reported from the laboratory of Shuker *et al*. (33). ^{14}C-NOGC reacted with calf thymus DNA to give a number of carboxymethylated adducts, namely, 7-carboxymethylguanine (0.025%), 3-carboxymethyladenine (0.006%), and O^6-carboxymethylguanine (0.0026%) (33,34). The behavior of NOGC in forming carboxymethyl electrophilic alkylating agents which bind with DNA nucleotides is consistent with its expected decomposition as an *N*-nitrosamide (see Scheme 1, a generalized description of the decomposition of *N*-nitroso glyco-bile acid conjugates) (15,16,18,19,26,29,30). These results suggested that

O^6-methylguanine, which has been observed in DNA from gastrointestinal tissues, may be derived from intragastric nitrosation of glycine or related compounds (34).

Our laboratory's long-term interest in the chemistry, biochemistry, and physiology of naturally occurring hydrophobic and hydrophilic bile salts has encouraged us to investigate in detail the role of the *N*-nitrosated derivatives of bile acid conjugates in the development of cancer, particularly those of the 7β configuration. Chemical synthesis, structural analysis, and decomposition of *N*-nitroso amides of some hydrophilic bile salts (see Scheme 2, on conjugates of bile acids with glycine and taurine, and Scheme 3, on *N*-nitrosation of bile acid conjugates) were recently reported from our laboratory (15), along with their pH-dependent activities and stabilities, the half-life ($t_{1/2}$), and stability under conditions likely to be encountered in the gastrointestinal tract (15).

The present studies summarize the chemistry and biochemistry of various *N*-nitroso derivatives of bile acids and their characterization by high-resolution ^{1}H nuclear magnetic resonance (NMR) and fast atom bombardment–mass spectrometry (FAB–MS) or electrospray ionization–MS (ESI–MS). Additional studies such as mechanisms of decomposition of (*Z*)- and (*E*)-bile acid diazoates and the effects of enzymes such as cholylglycine hydrolase on the *N*-nitroso bile acid conjugates and their mutagenic potential by reacting with DNA are also described.

EXPERIMENTAL PROCEDURES AND RESULTS

Ursodeoxycholic acid (UDCA), ursocholic acid (UCA), and deoxycholic acid (DCA) of pharmaceutical grade were donations of Prodotti Chimici e Alimentari S.p.A. (Alessandria, Italy). Reactions were monitored by thin-layer chromatography (TLC) using 0.25-mm precoated Silica Gel-60 plates (F-254; Merck). Solvent systems 26:8:4:2 $CHCl_3$/MeOH/CH_3COOH/H_2O (A), 40:6:4 $CHCl_3$/MeOH/CH_3COOH (B), 70:50:5 (C), $CHCl_3$/$(Me)_2CO$/MeOH and 70:50:10 $CHCl_3$/$(Me)_2CO$/MeOH (D) were used as appropriate (35,36). The spots were made visible with 3.5% phosphomolybdic acid in isopropanol and 10% (wt/vol) sulfuric acid. A commercial microwave oven (Whirlpool, 2450 MHz, total cooking power 650 Watts) was used in irradiation experiments. The reaction mixture was held in an Erlenmeyer flask, covered with an inverted funnel, and placed in a beaker containing water (*ca.* 150 mL). The beaker served as a heat sink to dissipate excess microwave energy (37–39).

The ^{1}H NMR spectra were recorded on a Varian XL-400 (400 MHz) spectrometer in dimethylsulfoxide (DMSO) solution. Proton chemical shifts are reported relative to tetramethylsilane. FAB–MS studies were conducted in the positive ion mode using nitrobenzyl alcohol as a matrix, dimethylsulfoxide as the solvent, and NaCl to enhance the peaks (35,36). ESI–MS was performed in the negative ion mode in MeOH as the solvent as described previously (15).

The bile acid conjugates were prepared using a new technique (37–39) which employs a domestic microwave oven, as shown in Scheme 2 (15,40,41). This new methodology is currently under active use in our laboratory to synthesize substrates on a large scale for a variety of important clinical research projects.

Glyco-bile acid conjugates **2a**–**2c** (Scheme 2) were synthesized by reacting the corresponding free bile acid **1** with the ethyl ester of glycine in the microwave, followed by hydrolysis of the ester with potassium carbonate and ethanol, also in the microwave oven. Tauro-bile acid conjugates **2d** and **2e** were synthesized by the reaction of **1** with taurine in the microwave oven. After the usual work-up, the desired products were isolated in good to excellent yields (15). A representative procedure is provided next.

*Glycoursodeoxycholic acid (GUDCA) (***2a***, Scheme 2).* UDCA (392 mg, 1 mmol), glycine ethyl ester hydrochloride (396 mg, 2.82 mmol), *N*-ethoxy-carbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 403 mg, 1.63 mmol), triethylamine (Et_3N, 2.3 mL), and absolute EtOH (20 mL) were mixed in an Erlenmeyer flask and stirred manually, and the clear solution was heated in a domestic microwave oven for a period of 5–7 min at 70% power (total microwave output 650 Watts). In most cases, irradiating in intervals was appropriate. After cooling, the residual ethanol was evaporated and the reaction mixture dissolved in ethyl acetate and washed with water, 0.5 N NaOH, and 0.5 N HCl. The organic phase was washed with water again, dried (using anhydrous Na_2SO_4), and concentrated under reduced pressure to yield the ethyl ester of ursodeoxycholyl glycine, which was subsequently hydrolyzed to free acid by dissolution in EtOH (10 mL), treatment with potassium carbonate (10% aqueous solution, 7 mL), and irradiation for a total of 4 min in the microwave oven. The final solution was then poured into ice water (100 mL) with vigorous stirring, and acidified with 0.5 N HCl. The white solid which precipitated was collected by filtration and dried to yield **2a** (391 mg, 87%). By TLC, the R_f was 0.21 with solvent system A, and 0.54 with solvent system B. In ^{1}H NMR, δ = 7.03 (1H, *tr*, *J* = 4 Hz, N*H*), 3.26 (2H, *d*, *J* = 4 Hz, NH-CH_2) (15).

*Tauroursodeoxycholic acid (TUDCA) (***2d***, Scheme 2).* A mixture of UDCA (73.0 mg, 0.2 mmol), EEDQ (62.0 mg, 0.25 mmol), taurine (50 mg, 0.4 mmol), *N*-methylmorpholine or Et_3N (0.35 mL), and absolute EtOH (6.0 mL) were irradiated for 3.0 min in an Erlenmeyer flask in a commercial microwave oven. After cooling, the reaction mixture was poured slowly into chilled anhydrous ether (25 mL). The suspension was stirred at 5°C for 30 min and then filtered. The solid was dissolved in chloroform (10 mL) and filtered to remove unreacted taurine. The filtrate was poured into chilled anhydrous ether (25 mL). TUDCA was filtered and dried under vacuum (66.9 mg, 67%). By TLC, R_f was 0.80 with solvent system A. In ^{1}H NMR, δ = 7.67 (1H, *tr*, N*H*), 3.28 (2H, *q*, NH-CH_2), 2.50 (2H, *tr*, CH_2-SO_3). ESI–MS (in the negative ion mode) $[M - H]^-$ = 498 and other polymeric ions, $[2M - H]^-$ = 997, $[2M - 2H + Na]^-$ = 1019 and $[3M - 3H + 2Na]^-$ = 1540, were also observed (15).

*Tauroursocholic acid (***2e***, Scheme 2).* Tauroursocholic acid

TABLE 1
Chemical Shifts of the Side Chain for the Bile Acid Conjugates and Their Respective *N*-Nitroso Derivatives

Bile acid[a]	Side chain	Chemical shift
UDCA	R–CO–NH–CH_2–COOH	7.03 (*tr*, NH, *J* = 4 Hz); 3.26 (*d*, NH–CH_2, *J* = 4 Hz)
UDCA	R–CO–N(NO)–CH_2–COOH	4.42 [*s*, N(NO)–CH_2]; 13.25 (*s*, COOH)
UDCA	R–CO–NH–CH_2–CH_2–SO_3H	7.67 (*tr*, NH); 2.50 (*tr*, CH_2–SO_3H); 3.28 (*q*, NH–CH_2)
UDCA	R–CO–N(NO)–CH_2–CH_2–SO_3H	3.93 [*tr*, N(NO)–CH_2, *J* = 8 Hz]; 2.36 (*tr*, CH_2–SO_3H)
UCA	R–CO–NH–CH_2–COOH	8.09(*tr*, NH, *J* = 6 Hz); 3.70 (*d*, NH–CH2, *J* = 6 Hz); 12.4 (*s*, COOH)
UCA	R–CO–N(NO)–CH_2–COOH	4.42 [*s*, N(NO)–CH_2]
DCA	R–CO–NH–CH_2–COOH	8.10 (*tr*, NH, *J* = 6 Hz); 3.70 (*d*, NH–CH_2, *J* = 6 Hz); 12.45 (*s*, COOH)
DCA	R–CO–N(NO)–CH_2–COOH	4.41 [*s*, N(NO)–CH_2]; 12.0 (*s*, COOH)

[a]DCA, deoxycholic acid (3α,12α-dihydroxy-5β-cholan-24-oic acid); UCA, ursocholic acid (3α,7β,12α-trihydroxy-5β-cholan-24-oic acid); and UDCA, ursodeoxycholic acid (3α,7β-dihydroxy-5β-cholan-24-oic acid).

was prepared from UCA in 65% yield following the same procedure that was used for the preparation of TUDCA. In TLC, R_f was 0.60 with solvent system A. ESI–MS (in the negative ion mode) $[M - H]^-$ = 514 and similar clusters of polymeric ions as in TUDCA were observed: $[2M - H]^-$ = 1029, $[2M - 2H + Na]^-$ = 1051 and $[3M - 3H + 2Na]^-$ = 1588.

N-*Nitroso glycoursodeoxycholic acid (NOGUDCA) (***3a***, Scheme 3)*. In view of the hazardous nature of *N*-nitroso compounds, all work was carried out in an efficient fume hood. GUDCA (100 mg, 0.22 mmol) was dissolved in concentrated glacial acetic acid (2 mL) in a three-necked round-bottom flask. The flask was kept at 2–4°C in an ice bath, and the contents were stirred by magnetic stirrer. In a separate round-bottom flask, sodium nitrite (10 g) was allowed to react with concentrated hydrochloric acid (15 mL), added dropwise through a separatory funnel. The liberated nitrous acid (HNO_2) gas was passed through a rubber tube and was bubbled into the reaction flask containing the bile acid conjugate dissolved in glacial acetic acid. After all the nitrous acid gas had passed (*ca*. 15 min.) and a green color persisted, TLC was taken while the mixture was kept frozen. The reaction was terminated if the TLC showed complete disappearance of the GUDCA (R_f = 0.21, solvent system D) and therefore maximal formation of the *N*-nitroso derivative (R_f = 0.44, solvent system A).

We have chemically synthesized (15) the following *N*-nitroso derivatives (Scheme 3) of 7β-hydroxylated bile acid conjugates: (i) *N*-nitrosoglycoursodeoxycholic acid (NOGUDCA), (ii) *N*-nitrosoglycoursocholic acid (NOGUCA), (iii) *N*-nitrosotauroursodeoxycholic acid (NOTUDCA), and (iv) *N*-nitrosotauroursocholic acid. In addition, *N*-nitrosoglycodeoxycholic acid (NOGDCA), a derivative of the secondary bile acid that has recently been widely implicated in colon cancer (42,43), was synthesized.

The structure and stereochemistry of the compounds in Scheme 3 were confirmed by high-resolution proton NMR, FAB–MS, and ESI–MS studies. The ^1H NMR spectra of the *N*-nitroso bile acid conjugates as well as of their respective bile acid conjugates were obtained. Table 1 contains a summary of the significant chemical shifts of the side chain. The major part of the spectrum, δ 0–2.2, contains peaks corresponding to the steroid backbone and remains essentially unchanged for all the molecules.

For all of the *N*-nitroso bile acid conjugates prepared, MS indicated that the first fragment involved rearrangement and the loss of N_2. The FAB–MS of the *N*-nitroso glyco-bile acid conjugates were taken in NaCl in the positive ion mode, and consequently they showed sodiated molecular ions at *m/z* 501 = $[M + Na]^+$ for NOGUDCA and NOGDCA. A molecular ion peak at *m/z* 517 = $[M + Na]^+$ was observed for NOGUCA. In the ESI–MS negative ion mode, the *N*-nitrosotauro-bile acid conjugates showed $[M - H]^-$ peaks at *m/z* 542.8 for *N*-nitrosotauroursocholic acid and *m/z* 527.1 for NOTUDCA. Table 2 shows the first three major mass spectral peaks and the fragmentation pattern for these compounds. Especially important are the carboxymethyl and 2-sulfoethyl moieties from the side chain of the *N*-nitrosated bile acid con-

TABLE 2
Major Mass Spectral Peaks for the *N*-Nitroso Derivatives[a]

(FAB–MS) positive ion mode				
Glyco-derivative	MW	$[M + Na]^+$	–N_2,–H	–CH_2–COOH
NOGUDCA	478	501.4	472.4	413.4

SCHEME 4

jugates because of their roles in the alkylation of DNA.

Decomposition of N-*nitroso glyco-bile acid conjugates (Scheme 1).* The glyco-compounds, NOGUDCA, NOGUCA, and NOGDCA decomposed between pH 6 and 9 in aqueous buffer solutions, indicating a $t_{1/2}$ of 5–7 h on average at zero buffer concentration and neutral pH. Under the same conditions, NOTUDCA indicated a much longer $t_{1/2}$ of approximately 15–17 h. The kinetics of decomposition were found to be first-order over three half-lives. The decomposition that we have observed is significantly slower than the $t_{1/2}$ of 2–4 h reported for NOTC and NOGC (15,16). We plan to use four compounds for biological studies, namely (i) NOGUDCA, (ii) NOGUCA, (iii) NOTUDCA, and (iv) NOGDCA. The behavior of NOTUDCA and NOGC in forming carboxymethyl electrophilic alkylating agents which bind with DNA nucleotides is consistent with its expected decomposition as an *N*-nitrosamide (Scheme 1) (15,16,19,26,29,30).

Mechanism of decomposition of some alkanediazoates. Hydrolysis of N-*nitroso bile acid conjugates, TUDCA and CA with cholylglycine hydrolase (Scheme 4).* The complete nitrosation of TUDCA and GCA was confirmed by TLC analysis, using the solvent system chloroform/methanol 40:3 (vol/vol). Further resolution of the reaction mixture on a preparatory TLC plate indicated *E*- and *Z*-rotomeric populations in ratio of 60:40. The *E*- and *Z*-rotomers depend upon the rotation of the NO molecule in relation to the ketonic group of the conjugated bile acid (Scheme 4). The final product was recovered by washing with methanol and precipitating with ether. The precipitate was filtered and stored in the freezer to minimize decomposition.

As the *N*-nitroso bile acid conjugates decompose, several carcinogenic species are generated (Schemes 1,4). First, an alkyl diazoate is formed which is subsequently protonated. This species then loses nitrogen (N_2) and forms either glycolic acid (from NOGCA) or isethionic acid (from NOTUDCA). Another species which exists is a diazoglycolic acid or diazoisethionic acid, corresponding to NOGUDCA and NOTUDCA, respectively. These decomposition products were neatly isolated by using preparatory TLC and identified and characterized by chemical ionization mass spectroscopy. Mass spectrum results showed peaks at 126, 137, and 154 *m/z* corresponding to the decomposition fragments isethionic acid, diazoisethionic acid, and the protonated diazoate intermediate, respectively. The mass spectrum analysis displayed the highest abundance for the isethionic acid (a urinary metabolite of taurine) peak at 126 *m/z*. These electrophilic species described above are implicated in the alkylation of DNA which results in the tumorigenesis associated with colorectal carcinomas. In conjunction with these products, the free bile acid UDCA was also formed. Successful synthesis of the *N*-nitrosated bile acids enabled a series of decomposition assays which aided in the elucidation of the specific mechanism implied in the decomposition pathway resulting in the aforementioned products.

The compound NOTUDCA was subjected to the enzymatic cleavage reaction with cholylglycine hydrolase, a bac-

terial enzyme (44,45) which cleaved the *N*-nitrosated bile acid conjugate at the peptide bond. TLC analysis further revealed that this assay generated several decomposition products. This result was further substantiated when products with similar R_f values were generated in an alkaline cleavage assay conducted with lithium hydroxide in isopropranol. Both assays cleaved the NOTUDCA at the peptide bond generating the free bile acid UDCA and three major decomposition products which were confirmed by chemical ionization mass spectroscopy.

The results obtained in these studies, specifically the identification of the diazoate intermediate as revealed by the mass spectrum peak at 154 *m/z,* further substantiate that the decomposition route follows a mechanism which generates diazonium compounds (18,19,46). Following decomposition, the diazo compounds lose N_2 to produce isethionic acid in the highest abundance due to its high stability.

DISCUSSION

The hypothesis that the *N*-nitroso bile acid conjugates may be involved in carcinogenesis is based on several well-founded premises. Although they have not yet been detected *in vivo* owing to a lack of appropriate methodology, our work suggests that they can be formed. The etiology of stomach cancer is linked to a diet rich in nitrate or nitrite, consumption of smoked foods, and damage to the gastric mucosa by irritants such as salts (47). According to a gastric cancer model proposed by Correa (26), a rise in gastric pH allows bacteria that convert nitrate to nitrite to flourish. Nitrite can then participate in nitrosation reactions in acidic solutions to form *N*-nitroso compounds. A characteristic of the conjugated bile acids is a decreased pK in comparison to the free bile acids and thus increased solubility in acidic solutions (48). The reaction of the bile acid conjugates with nitrite (or other nitrosating agents) is more likely to take place in the acidic environment of the stomach when certain clinical states cause the reflux of bile acids into the stomach from the intestine or bile duct (49). In the unoperated stomach, these states include reflux gastritis and chronic gastritis (50). Carcinoma in the stomachs of patients who have undergone Billroth II gastrectomies has been associated with enterogastric reflux (51).

It is essential to note that CA and chenodeoxycholic acid (3α,7α-dihydroxy-5β-cholan-24-oic acid, CDCA) are two primary bile acids in the human gastrointestinal tract, and many other stereoisomeric and ketonic products are formed by bacterial action (21–23,52,53). Once in the hepatocyte, primary bile acids are conjugated with glycine or taurine to form the corresponding *N*-acyl conjugates (21–23). As conjugates they are secreted from the hepatocyte into the bile and with the bile they enter the intestine. In the distal small intestine and in the colon, these conjugates are converted by bacterial enzymes into the corresponding secondary bile salts by initial deconjugation, followed by 7α-dehydroxylation (52). This process in the case of CA leads to the formation of deoxycholic acid (3α,12α-dihydroxy-5β-cholan-24-oic acid, DCA), and lithocholic acid (3α-monohydroxy-5β-cholan-24-oic acid) results from CDCA. Most of the lithocholic acid that is formed is excreted from the body by a sulfation process. DCA, however, often becomes a major bile acid in the enterohepatic circulation in human adults because 7-rehydroxylation does not occur (21,23). While the mechanism responsible for the putative cancer-promoting effects of bile acids is not defined, the suspect causative bile acids such as DCA and CDCA are cytotoxic to colon epithelial cells (54,55) and promote chemically induced colon cancer (56,57). DCA has been implicated in the promotion of adenoma growth and polyp formation, although the mechanism by which this occurs is not clear (42,43,58–60).

In addition, numerous other products, mainly epimers of the major bile acids having 3β, 7β, and 12β stereochemistry, may also be produced by the bacterial action in the distal ileum or colon (52,53). Bile acids of the urso family, with a 7β configuration, include ursocholic acid (3α,7β,12α-trihydroxy-5β-cholan-24-oic acid, UCA) and UDCA which are 7β epimers of CA and CDCA, respectively. UDCA, present in bear's bile, is of special interest because it has been approved by the U.S. Food and Drug Administration as an efficient gallstone solubilizer (Actigall®, Ursodiol) and is being consumed daily in large amounts by those suffering from gallstone disease and primary biliary cirrhosis (61–64). Recently, the taurine conjugate of UDCA has also been reported to have superior cholesterol-solubilizing properties (61–63). Although the toxicity of UDCA has been observed to be minimal thus far, the long-term consequences of therapy with this drug or its conjugate remain to be discovered.

N-Nitroso bile acid conjugates of the 3β, 7β, and 12β stereochemistry may form endogenously, and their end products upon decomposition may be very potent alkylating agents. *N*-Nitroso compounds occur in normal gastric juice (65). However, in subjects who were prone to develop gastric cancer or had undergone Billroth I or II operations these compounds were found to be increased (65). Analytical methods cannot identify the specific endogenous compounds until they have been purified, identified, and biologically assayed (33,34,65).

It is essential to keep in mind that a large pool of bile acid conjugates, 10–40 g, travels through the enterohepatic circulation daily (23), including large amounts of the primary bile acids, CA and CDCA, and of the secondary bile acid, DCA. In addition, UDCA is present in large amounts in the bile of patients taking this compound as medication. If *N*-nitroso amides from these bile acids do form in the stomach, they may flow into the intestine with the rest of the semiliquid mass from the stomach. Because the half-lives of the *N*-nitroso bile acid conjugates are relatively long, and the conjugates are stable under the conditions (15) that might be encountered in the gastrointestinal tract, it is likely that they can travel through the intestines. While many of the bile acid conjugates are deconjugated in the intestine by bacteria, it is important to study the effects of intestinal enzymes such as cholylglycine hydrolase on the *N*-nitroso bile acid conjugates

(44). It has been found that when TUDCA is conjugated with a "cyclopropylog," the presence of the cyclopropyl ring adjacent to the amide bond makes the molecule resistant to degradation (66). The nitroso group on the other side of the amide bond may also have an interesting effect. Indeed, when the compounds NOTUDCA and NOTCA were subjected to the enzymatic cleavage reaction with cholylglycine hydrolase (44,45), a bacterial enzyme (Scheme 4), it cleaved the *N*-nitrosated bile acid conjugate at the peptide bond resulting in the formation of three major decomposition products which were confirmed by chemical ionization mass spectroscopy. These experiments substantiated that the decomposition route follows a mechanism which generates diazonium compounds. These further decompose to give electrophilic species, which react with DNA to give rise to methyl adducts (Scheme 4).

Recently several papers from Vogelstein's laboratory (67–69) have delineated the mechanism of colon cancer as a distinct type of genetic disease in which not one, but several, mutations are required. According to the authors, the development of a colorectal carcinoma involves the inactivation of at least three tumor suppressor genes, p53 (70,71), APC (Adenomatous Polyposis Coli), and DCC (Deleted in Colorectal Carcinomas) (69–71). Each mutation creates a wave of cellular multiplication associated with gradual increase in malignancy. Approximately 5 to 10% of colorectal cancers are hereditary and classified as hereditary nonpolyposis colorectal cancer (70). One of the genes involved in hereditary nonpolyposis colorectal cancer is hMLH1, a human mismatch repair gene, and a mutation of hMLH1 can disrupt the gene product (70,71). A variety of factors may be responsible for the mutations, although mutations caused by endogenously formed compounds are a possibility that requires further investigation. ^{14}C-NOGC has been found to form carboxymethylated adducts with the nitrogenous bases guanine and adenine in calf thymus DNA *in vitro*. The detection of carboxymethylated nucleic acid bases and proteins appears to be a useful way of monitoring endogenous formation of NOGC and related compounds (34). It is urgent to develop such methodology so that patients with cancers of the stomach, liver, or colon may be screened (72,73) for the *N*-nitroso bile acid conjugates.

There are many avenues for further research on the topic of *N*-nitroso bile acid conjugates. We are in the process of synthesizing *N*-nitroso derivatives of CA, CDCA, and lithocholic acid having 3β, 7β, and 12β stereochemistry. We will then study the chemical interactions of the molecules with calf thymus DNA. DNA adduct formation will be analyzed by spectroscopic methods including proton magnetic resonance, differential Fourier transform infrared spectroscopy, and circular dichroism. Polymerase chain reactions will be employed to replicate the adducted calf thymus DNA, and the mutation of this DNA in comparison to pure calf thymus DNA will be observed by Southern blot.

ACKNOWLEDGMENTS

We are indebted to Chandan Sircar, undergraduate participant from Pennsylvania State University, for his skillful technical assistance. This work was supported in part by a grant from the New Foundation for Diabetes and a grant US-PHS, HL-17818. We also wish to thank Kenneth Mizrach, Director, V.A. New Jersey Health Care System for his encouragement and continuing support.

Synthesis and Molecular Modeling: Related Approaches to Progress in Brassinosteroid Research

Carme Brosa*, Ismael Zamora, Emma Terricabras, Lídia Soca, Rosa Peracaula, and Carlos Rodríguez-Santamarta

Institut Químic de Sarrià, CETS, Universitat Ramon Llull, E 08017-Barcelona, Spain

ABSTRACT: In the field of brassinosteroids, which are potent plant growth regulators, we have developed a quantitative structure–activity relationship study to develop knowledge from a structural point of view and to find out new requirement definitions. This will help identify other suitable active brassinosteroid derivatives with a good activity/synthetic cost ratio for further application in agriculture. The methodology used to achieve this goal represents a multidisciplinary study involving synthesis, molecular modeling calculations, and bioactivity evaluation. The influence of different molecular properties in the bioactivity of a set of synthetic compounds (i.e., molecular electrostatic potential and the ability to form H bonds) is discussed. The molecular electrostatic potential is expressed in terms of the electrostatic Carbó similarity index (CI) between brassinolide (**1**) and other brassinosteroids. We have found that the electrostatic charges of the functional groups play an important role in the description of the activity, as evidenced by its good correlation with the CI in most cases. Deviation from this rule could be explained by the H bonding abilities of some of these compounds, which we believe may play an essential role in binding to the natural receptors.

Lipids 32, 1341–1347 (1997).

Brassinosteroids are potent naturally occurring plant growth regulators widely spread in the vegetal kingdom. They have an exciting potential use in agriculture owing to their capability of improving crop yield and quality as well as minimizing environmental stress and herbicidal injury and controlling pathogenic diseases (1,2).

At least 36 natural brassinosteroids have been identified from different parts of plants: pollen, seeds, leaves, shoots, etc., brassinolide (**1**) being the most potent natural brassinosteroid (3). From a structural point of view, brassinosteroids are polyhydroxylated steroids differing in their functionalities and the stereochemistry present in the A and B rings and the side chain.

Brassinosteroids have been tested as plant growth-promoting hormones in more than 20 bioassays typical for phytohormones such as auxins, gibberellins, or cytokinins (1). From all of them, the rice lamina inclination test is one of the most specific for brassinosteroids, being widely used for activity evaluation (4,5).

Because of the interest of such compounds and the high synthetic cost of the most active brassinosteroids, the goal of our study was to find other suitable active derivatives, with a good activity/synthetic cost ratio for agricultural application. For this purpose, minimal structural requirements for brassinosteroid activity should be known.

Different qualitative structure–activity relationships have already been established from the activity data obtained in special bioassay systems (6,7). Although these relationships are more or less strictly dependent upon the bioassay used, it is generally accepted that the structural requirements for a high brassinosteroid activity are: (i) 2α,3α-diol in A ring, (ii) 7-oxalactone better than 6-ketone in B ring, (iii) A/B *trans* fused ring junction, (iv) a *cis* C_{22},C_{23} diol preferably with 22*R*,23*R* configuration, and (v) a C_{24} methyl or ethyl substituent. Nevertheless, a closer look into these requirements and into how they were established (only a limited number of brassinosteroid analogs with few structural modifications have been assayed) reveals that they are far from being general from two points of view.

First, the brassinosteroid functionalities cannot be considered independently, as shown in these requirements, since we have found that they are closely related. Figure 1 shows activity data for nine brassinosteroids, measured using our modified rice lamina inclination test (Brosa, C., Soca, L., and Terricabras, E., manuscript in preparation) based on the procedure developed by Takeno and Pharis (4). In agreement with the general rule, it can be observed that compounds with lactone in B ring (**2**, **3**, **6**, and **7**) elicit higher activity than their corresponding 6-ketone analogs (**4**, **5**, **8,** and **9**). (see Scheme 1 for structures). In the same sense, compounds with 22*S*,23*S* configuration at the side-chain diol (**3**, **5**, **7,** and **9**) are less active than the corresponding 22*R*,23*R* ones (**2**, **4**, **6,** and **8**), but the values strongly depend not only on the configuration of the diol at C_{22},C_{23} but also on the type of alkyl substituent at C_{24}. Thus, for a similar functionality in the skeleton, compounds with stigmastane side chain (**2** to **5**) are more active than those with an ergostane side chain (**6** to **9**) except for **7** which is more active than **3**. Moreover, with respect to con-

Abbreviations: CI, electrostatic Carbó similarity index; 3D, three-dimensional.

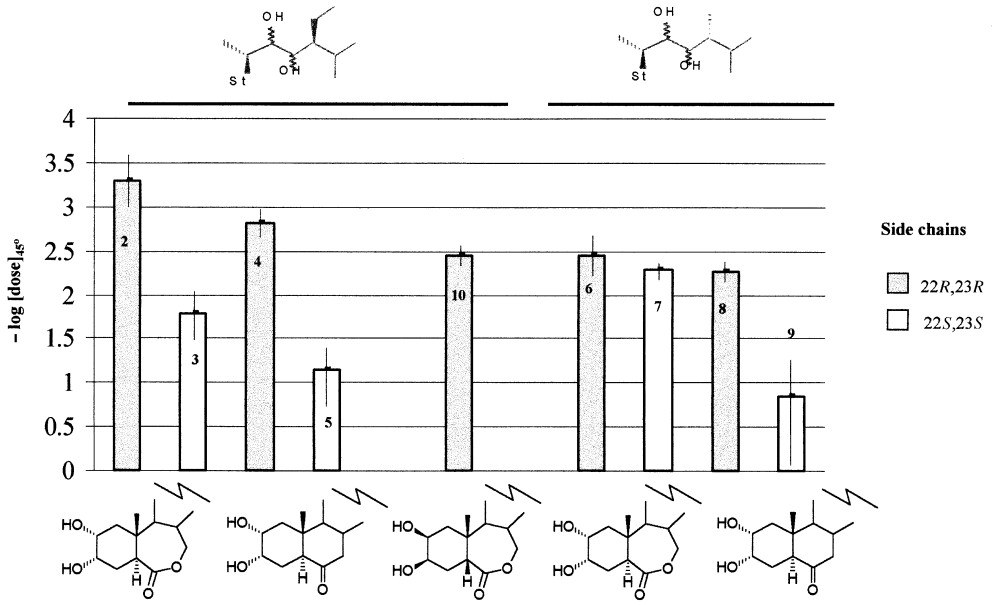

FIG. 1. Brassinosteroid activity in the rice lamina inclination test. Numbers on bars correspond to compounds in Scheme 1. Bars represent the activity value of each compound.

figuration of the diol, lactone **6** is less active than the 22*R*,23*R* ketone analog **4**, thereby not meeting the requirements. But when the configuration changes from 22*R*,23*R* to 22*S*,23*S* the activity also changes, and now becomes higher for **7** than for **5**. Therefore, these results clearly indicate the existence of a relationship between functionalities and thus a strong interdependence among requirements (ii), (iv), and (v). Furthermore, similar relationships are observed for the rest of the requirements.

The second point for which we believe that these requirements are far from being general is related to the brassinosteroids involved. The postulated requirements limit the scope of applicability to the functionalities involved in the tested set of brassinosteroids. For instance, they were developed without taking into account analogs having a 2β,3β diol and/or A/B *cis* junction. No brassinosteroids with these functionalities were examined. So, why were they not considered for the requirements if there was no proof of their activity? After synthesizing such compounds and evaluating their activity, we obtained a very high activity for **10**, with 2β,3β diol and A/B *cis* junction (Fig. 1) (8,9).

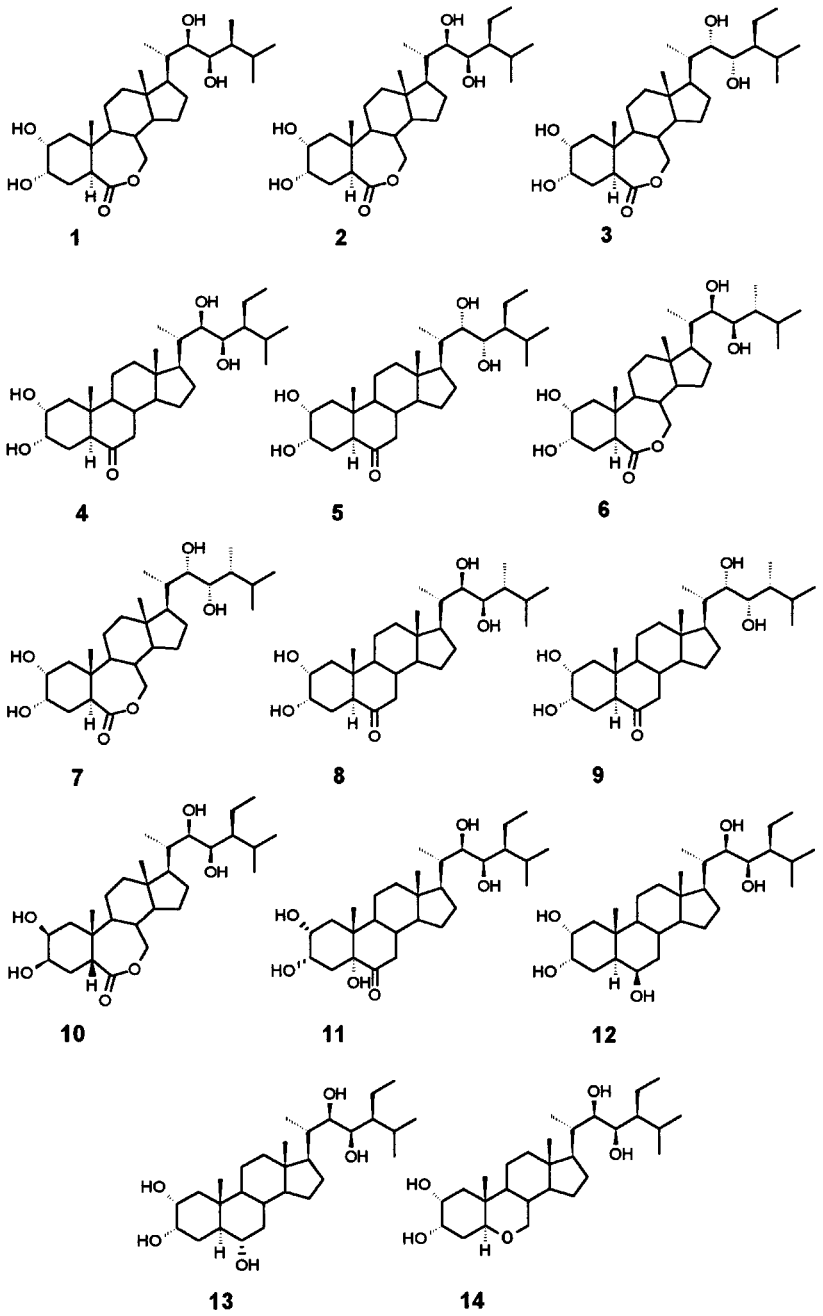
In short, the close relationship between the brassinosteroid functionalities and the high activity elicited by this new brassinosteroid **10** indicates the weakness of the requirements postulated in the literature for a high brassinosteroid activity. Thus, a more accurate way to define the structural requirements should be found.

In assuming that brassinosteroids may act at the molecular level through a mechanism similar to that of animal steroid hormones, a receptor/ligand complex which binds to nuclear or cytoplasmatic sites to regulate the expression of specific genes should be involved. Therefore, the active brassinosteroids should have a single defined three-dimensional (3D) "active conformation" which best fits the receptor or receptors. On this active conformation, the atoms directly involved in binding with the brassinosteroid receptor ought to have the same spatial situation in all active molecules. Thus, the more complementary is the active conformation of a defined brassinosteroid to the 3D structure of the receptor, the more active it should be. Since brassinolide (**1**) is the most active natural brassinosteroid found, we can assume that its active conformation will be the one that best fits to the receptor and that can be taken as reference. In this sense, a new way to define the structural requirements for a high brassinosteroid activity has been considered.

The strategy to achieve this goal involves molecular modeling techniques which also enable the establishment of a quantitative structure–activity relationship (QSAR). Apart from providing information about brassinosteroid receptor binding, the results will eventually be of help in the design of the most suitable brassinosteroids for agricultural applications. An analysis of the results obtained in the application of this approach is presented here.

MATERIALS AND METHODS

To establish a QSAR, a broad set of brassinosteroids having sufficient structural modifications, together with their corresponding strictly homogeneous activity data with statistical parameters, has been used. Different parameters have been calculated and their correlations with activity have been investigated. In Scheme 1 are presented the brassinosteroids mentioned in the present paper. Except for brassinolide (**1**), we have synthesized all of them (8–15). The first difficulty in this strategy is the lack of homogeneity and statistical parameters on the activity data obtained from the literature, so a bioassay was developed in order to derive strictly homogeneous activity data and their corresponding statistical para-



SCHEME 1

meters (Brosa, C., Soca, L., and Terricabras, E., manuscript in preparation).

In following this methodology, a modified active analog approach has been used to obtain the active conformer for each brassinosteroid. This study involves a conformational analysis, a 3D structure comparison, and a conformer alignment (16). The conformational analysis has been carried out by a systematic tree analysis and corroborated by molecular dynamics. For the 3D structure comparison, a program has been developed to calculate three different similarity indexes among the conformers of each compound: the square residue (SQR), the root mean square (RMS), and the molecular overlay volume (MOV). In the last step, the structure alignment was performed by optimization of the electrostatic Carbó similarity index (CI) (17) calculated using the ASP program (18).

The ability to form H bonds has been calculated with the GRID program (19). The preliminary results are given using water as a probe.

RESULTS AND DISCUSSION

The CI was selected to align the molecules since it is a measure of the similarity of electrostatic potential between two molecules. Moreover, these kinds of electrostatic interactions

[a]Compound numbers correspond to structures presented in Scheme 1.
[b]The value of the CI depends on the alignment. The confidence limit is ±0.05.

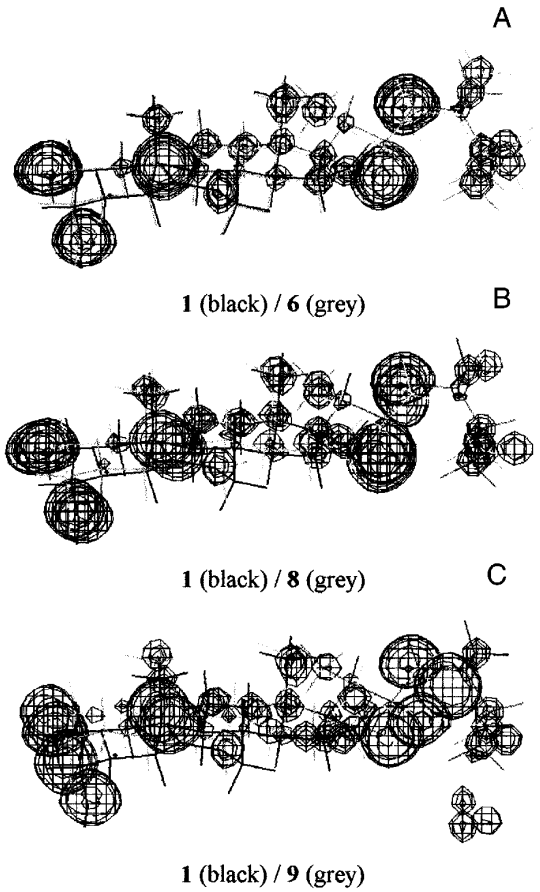

FIG. 2. Overlaid molecular electrostatic potential maps at –30 KT level between brassinolide (**1**) (in black) and three brassinosteroids (**6**, **8**, **9**) (in grey). The electrostatic Carbó similarity index/activities for these compounds are: (A) 24-epibrassinolide (**6**), 0.97/2.45; (B) 24-epicastasterone (**8**), 0.81/2.27; and (22*S*, 23*S*) 24-epicastasterone (**9**), 0.54/0.84.

are very important for compound binding to a receptor. Thus, the more similar a compound is to brassinolide (1), the higher the CI.

Table 1 shows the CI and the activity data for some of the brassinosteroids studied. In general, activity correlates with the CI and is higher when the CI is over 0.75, although there are some exceptions.

For example, Figure 2 shows how the electrostatic potential contour map at –30 KT for brassinolide (**1**) overlays with that of **6** (Fig. 2A), **8** (Fig. 2B), and **9** (Fig. 2C). In agreement with its high activity, all the electrostatic potential sites for 24-epibrassinolide (**6**) (in grey) overlay perfectly with brassinolide (**1**) (in black), with a very high CI (0.97). In the case of 24-epicastasterone (**8**), which shows lower activity than **6**, only the B-ring region does not overlay well with the lactone of brassinolide (**1**), decreasing its CI (0.81). Finally, in the case of (22*S*,23*S*) 24-epicastasterone (**9**), which displayed very low activity, neither the region of the A ring and side chain nor the region of the B ring overlays well with brassinolide (**1**), as is indicated by its very low CI (0.52). These compounds are a good example of how the activity decreases along with CI.

Furthermore, a similar relationship is observed for compounds **2**, **4**, **12**, and **13**, differing only on the B ring (Fig. 6A).

Note that 28-homobrassinolide (**2**), 28-homocastasterone (**4**), 24-epibrassinolide (**6**), and 24-epicastasterone (**8**) fulfill the requirements postulated in the literature, although they show different activities, ranging from 3.29 to 2.27 in a logarithmic scale. These activity differences are better explained through their CI. Thus, it seems that this similarity index (CI) is a more precise way to establish the requirements. Nevertheless, in some cases the activity cannot be explained by the CI. Thus, in the case of the lactone **10**, the activity is higher than expected for a CI of 0.76. Conversely, the activity of the 6-oxa analog **14** is lower than expected for a CI of 0.67.

Moreover, the three compounds represented in Figure 3 (**4**, **10**, and **11**) have a very similar CI but they elicit different activities. Looking at the overlaid maps (Fig. 3), one can observe that, for **10** (Fig. 3A), although having a 2β,3β-diol and A/B *cis* junction, all the electrostatic potential sites of this compound overlay very well with the ones of brassinolide (**1**) except for the region near the hydroxy group at C_2. This could indicate the minor importance of this hydroxy group to the activity. Concerning the hydroxyketone **11** (Fig. 3B), the regions corresponding to the diols of the side chain and A ring are larger than those of brassinolide (**1**). Therefore, although this similarity index proved to be better than the previous requirements, it is not enough to set up a brassinosteroid CI-related activity index. Other factors may be involved.

In considering the initial hypothesis, if brassinosteroids acted through a mechanism similar to that of animal steroid hormones, the brassinosteroid receptor complex could involve H bonds between the protein residues and the steroid. Thus, if the region where the probability to form H bonds and the interaction energy for these compounds was found, it should be possible to discriminate between them and, moreover, to gain more information about the mechanisms of brassinosteroid receptor interaction.

The GRID methodology (19) has been used to calculate

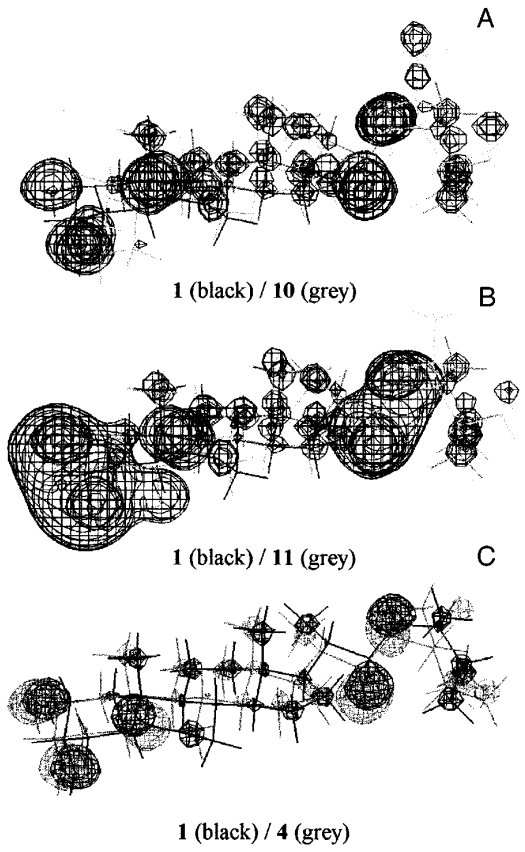

FIG. 3. Overlaid molecular electrostatic potential maps at –30 KT level between brassinolide (**1**) (in black) and three brassinosteroids (**4**, **10**, **11**) (in grey). The electrostatic Carbó similarity index/activities for these compounds are: (A) **10** 0.76/2.45; (B) **11** 0.76/1.53; (C) 28-homocastasterone (**4**), 0.76/2.80.

the energy interaction between the brassinosteroid and a probe that simulates an interaction by the H bond. On this preliminary calculation, water has been chosen as probe owing to its capability to act both as acceptor and donor of H bonds.

Figure 4 shows the GRID map at a –4 kcal/mol for brassinolide (**1**); the areas in white represent the highest probability to form H bonds.

Figure 5 shows the GRID map junctions only for the A and B rings between brassinolide (**1**) and **4**, **10**, and **11**, the same three compounds whose electrostatic potential maps are shown in Figure 3. The junction (in white) represents the common area between brassinolide (**1**) and each compound with a higher probability to form H bonds. As it has been indicated, all these compounds have the same CI but elicit very different activities. From these pictures, we see that, whereas the area corresponding to the hydroxy groups on the A ring for **4** and **11** is similar to that of brassinolide (**1**), there is only a small area on this region in **10**. This is in agreement with what was observed on the electrostatic potential map of **10** (Fig. 3), where the hydroxy group at C_2 was far more distant. If one takes into account the junction on the B ring, one observes that **4** presents a hole in the center and that its activity falls from 5.93 for brassinolide (**1**) to 2.80. This area becomes smaller for the hydroxyketone **11** and the activity falls again to 1.53. Moreover, in this case, another factor could decrease the ability of H bonding with the receptor owing to its capability of forming an intramolecular H bond between the two hydroxy groups at C_3,C_5. This phenomenon is observed in the active conformation found for **11** (16). Therefore, the size and shape of the area where the probability to form H bonds is higher seem to be activity-related. For the lactone **10**, two fea-

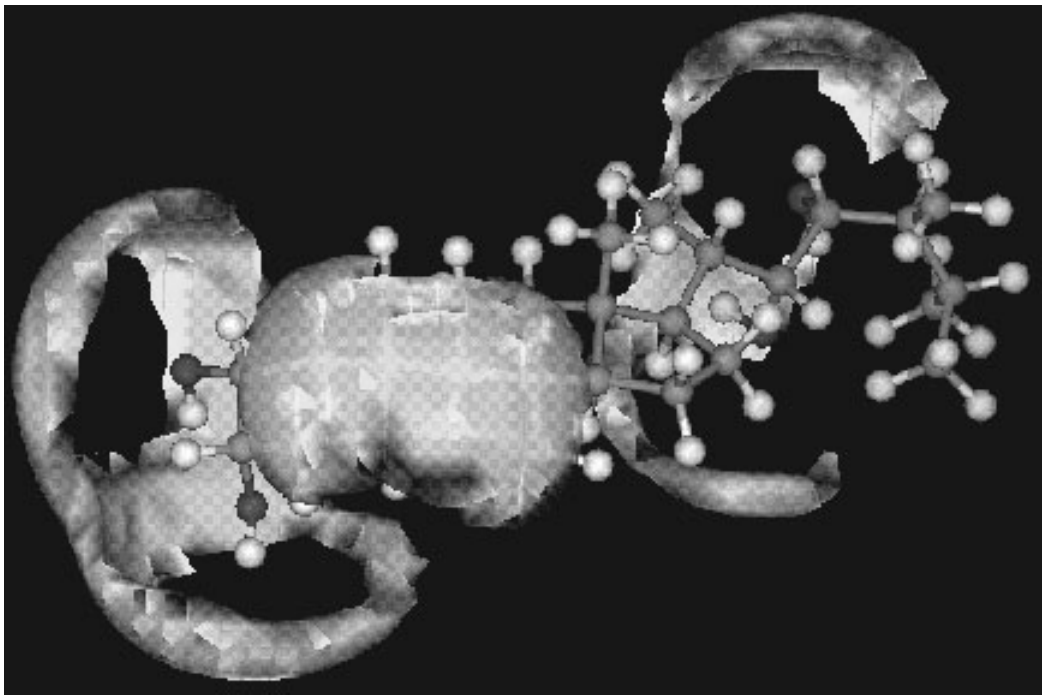

FIG. 4. GRID map for brassinolide (**1**) using a water probe at –4 kcal/mol.

tures of the molecule seem to compensate each other. On one hand, the area of the B ring is highly similar to brassinolide (**1**), so the activity should be higher than elicited; on the other hand, there is only a small common area for the hydroxy group at C_3, which forces its activity to decrease. Therefore, qualitatively one can assume that the ability to form H bonds

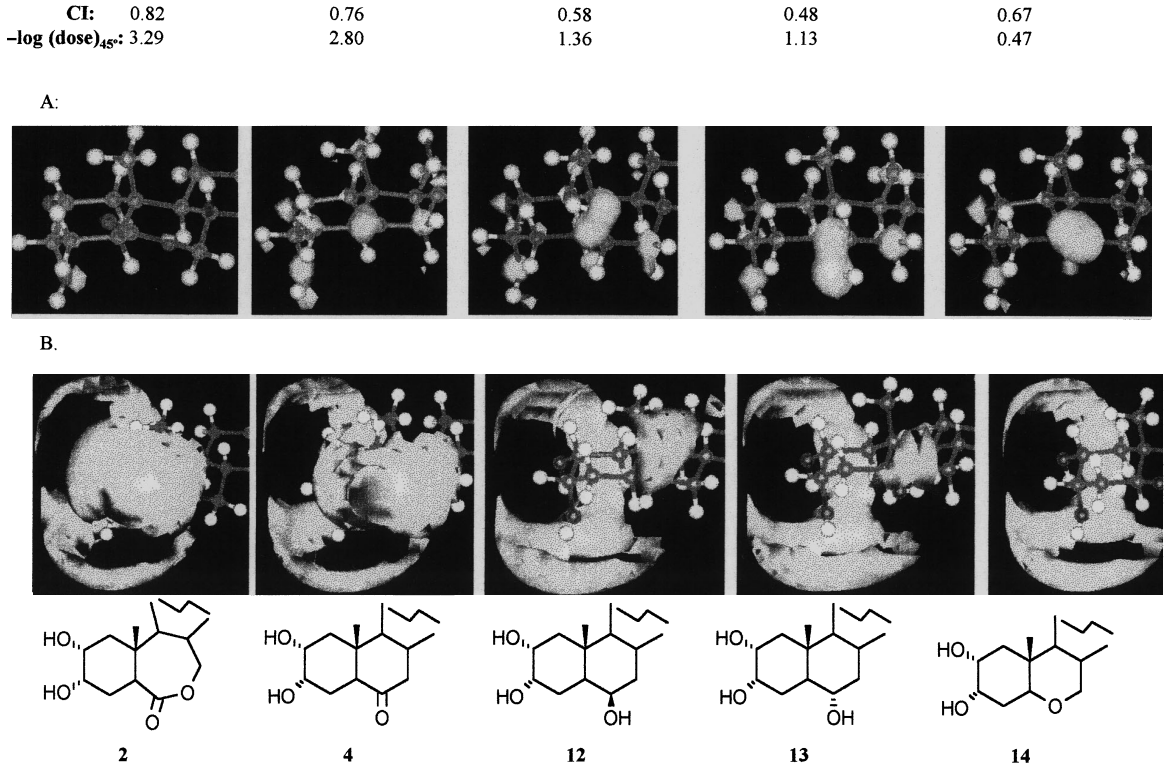

FIG. 6. (A) Surface difference in molecular electrostatic potential between brassinolide (**1**) and five brassinosteroids (**2**, **4**, **12**, **13**, **14**). See Figure 5 for abbreviation.

to the receptor could be suitable to describe the activity.

The 6-oxabrassinosteroid **14** is another example on how the ability to form H bonds is activity-related. Thus, on Figure 6A, the surface difference of molecular electrostatic potentials (in white) for A and B rings, between brassinolide (**1**) and 5 analogs differing only in B ring (**2**, **4**, **12**, **13**, and **14**) is shown. Qualitatively, one can observe that the white area, which is the difference between the electrostatic potential map for brassinolide (**1**) and each compound, increases and the activity decreases progressively in all cases as well as with the CI, except for the 6-oxabrassinosteroid **14**, for which its CI is higher than expected. An explanation for this exception can be found, again bearing in mind the ability of this group to form H bonds.

Looking at the surface junction of GRID maps between brassinolide (**1**) and the same five analogs already mentioned (**2**, **4**, **12**, **13**, and **14**) (Fig. 6B), one can see that the area on B ring, where the probability to form H bond is higher, gradually decreases in the series from **2**, up to disappearance for **14**. Qualitatively there is a very close relationship between this area and the activity. So, the impossibility of forming H bond on the B ring of the 6-oxa analog **14** is in agreement with its very low activity even with a CI higher than expected.

These results are the first reported evidence of the limit of scope of applicability and the weakness of the requirements so far postulated for a high brassinosteroid activity. In this sense, our new brassinosteroids having 2β,3β-diol and A/B *cis* ring junction (**10**), hydroxyketone (**11**), 6-hydroxy (**12** and **13**) or 6-oxa (**14**) functionalities, which had not been considered in these requirements, have shown activity as plant growth regulators and in some cases have even shown a high activity.

Moreover, in our aim to find new requirements definition, we found that the electrostatic charges of the functional groups play an important role in the description of the activity as evidenced by its good correlation with the CI in most of the cases studied. The differences observed in some of them could be explained by their ability to form H bonds. This could be one of the ways through which brassinosteroids interact with the receptor or receptors.
