ARTICLE

Pathways for Fatty Acid Elongation and Desaturation in *Neurospora crassa*

Thomas A. McKeon*, Marta Goodrich-Tanrikulu, Jiann-Tsyh Lin, and Allan Stafford

USDA, ARS, Western Regional Research Center, Albany, California 94710

ABSTRACT: *Neurospora crassa* incorporated exogenous deuterated palmitate (16:0) and ^{14}C-labeled oleate (18:1$^{\Delta 9}$) into cell lipids. Of the exogenous 18:1$^{\Delta 9}$ incorporated, 59% was desaturated to 18:2$^{\Delta 9,12}$ and 18:3$^{\Delta 9,12,15}$. Of the exogenous 16:0 incorporated, 20% was elongated to 18:0, while 37% was elongated and desaturated into 18:1$^{\Delta 9}$, 18:2$^{\Delta 9,12}$, and 18:3$^{\Delta 9,12,15}$. The mass of unsaturated fatty acids in phospholipid and triacylglycerol is 12 times greater than the mass of 18:0. Deuterium label incorporation in unsaturated fatty acids is only twofold greater than in 18:0, indicating a sixfold preferential use of 16:0 for saturated fatty acid synthesis. These results indicate that the release of 16:0 from fatty acid synthase is a key control point that influences fatty acid composition in *Neurospora*.
Lipids 32, 1–5 (1997).

The fatty acid composition of lipids determines their structural and functional properties. However, the biochemical control of fatty acid composition is not well understood. The use of model systems has provided considerable insight in elucidating fatty acid and glycerolipid metabolism.

The filamentous fungus *Neurospora crassa* has advantages as a model system for comparison to plants: it is one of few well-studied microbes able to produce the polyunsaturated fatty acids *de novo* that plants also make (1). It is also capable of incorporating exogenous fatty acid into its lipids (2–4). In addition, several mutants with defects in the synthesis of fatty acids and glycerolipids (3–7) have been described, and the lipid composition of wild type and mutants has been examined under varying conditions of temperature, medium, and fatty acid supplementation (2–4,8–10).

In *Neurospora*, as in plants, the pathway for biosynthesis of the major fatty acids begins with formation of 16:0 from acetyl-CoA and malonyl-CoA. In the major pathway of fatty acid biosynthesis, other fatty acids are derived from 16:0: 16:0 is first elongated to stearate (18:0), which undergoes consecutive desaturations to form 18:1$^{\Delta 9}$, 18:2$^{\Delta 9,12}$, and 18:3$^{\Delta 9,12,15}$ (1). We have examined the metabolism of exogenous palmitate (16:0) and oleate (18:1$^{\Delta 9}$) by *Neurospora* to better understand the regulation of fatty acid biosynthesis and control of fatty acid composition.

EXPERIMENTAL PROCEDURES

Growth of cultures, fatty acid-supplementation conditions, and label incorporation. Neurospora crassa wild-type strain 74-OR8-1a was obtained from the Fungal Genetics Stock Center, University of Kansas Medical Center (Kansas City, KS). Conidia (1×10^5) were inoculated into culture flasks containing 50 mL of liquid Vogel's medium N (5) and incubated at 34°C with shaking for 24 h. The concentration of labeled fatty acids was 30 μM: Deuterated 16:0's [7,7,8,8-$^2H_4$]16:0; [2,2-$^2H_2$]16:0, [16,16,16-$^2H_3$]16:0, all 98% purity, Cambridge Isotope Laboratories (Andover, MA) were not diluted, and [1-^{14}C]18:1$^{\Delta 9}$—86.4 kBq [^{14}C]18:1$^{\Delta 9}$, 1.11-2.22 GBq/mmol, ICN Pharmaceuticals, Inc. (Costa Mesa, CA) was diluted with unlabeled 18:1$^{\Delta 9}$ (Sigma, St. Louis, MO). Cultures were incubated for another 24 h before lipid extraction. Under these conditions, addition of the fatty acid had no apparent effect on rate of growth or final culture weight.

Lipid analysis. Lipids were extracted from cultures, fractionated on Sep-Pak silica columns to yield neutral lipids, phospholipids, and glycolipids; the triacylglycerols were separated from other neutral lipids by thin-layer chromatography as previously described (5). Radiolabel incorporation into lipid fractions was determined by scintillation counting of aliquots.

Fatty acids were analyzed as fatty acid methyl esters by gas chromatography with flame-ionization detection as described (5), using methyl heptadecanoate as internal standard. The column was a fused silica capillary column (30 m × 0.25 mm) coated with Stabilwax (df = 0.2 μm) (Restex, Bellefonte, PA). Label incorporation into fatty acids of ^{14}C-labeled samples was monitored by high-performance liquid chromatography of fatty acid methyl esters as in Reference 11.

Gas chromatography–mass spectrometry (fused silica capillary, 20 m by 0.18 mm, coated with DB-WAX and df = 0.3 μm; J&W Scientific, Folsom, CA) was used to confirm the identity of fatty acid derivatives and to determine the metabolic fate of deuterated 16:0 (5). Identification was based on comparison of spectra from sample runs to those of standards and published spectra.

The metabolic fate of [7,7,8,8-$^2H_4$]16:0 was followed by operating the mass spectrometer in the selected ion monitoring mode to monitor the M^+ and $(M + 4)^+$ ions of fatty acid

methyl esters from C_{14} to C_{24}, as well as the $(M + 2)^+$ ions for C_{18} unsaturated fatty acids (since desaturation at the 9,10-position following elongation to 18:0 leads to loss of two of the ^2H). The fraction of each fatty acid which was deuterated was calculated from peak areas for the M^+ and $(M + 4)^+$ or $(M + 2)^+$ ions for each fatty acid methyl ester. Correction was made for the fraction of $(M + 2)^+$ ions present due to normal isotope abundance in fatty acid standards (Alltech, Deerfield, IL). A similar procedure was used for 16:0 deuterated at other carbons.

Double-bond location in the monounsaturated fatty acids was determined from mass spectrometry of pyrrolidide derivatives prepared from fatty acid methyl esters (12).

RESULTS AND DISCUSSION

Supplementation of *Neurospora* cultures with 30 μM $18:1^{\Delta 9}$ or 16:0 had only a minor effect on the relative fatty acid composition of lipids, as shown in Figure 1A, B, and C. In previous studies (2–5), *Neurospora* lipids were enriched in the supplemented fatty acid, although these studies used higher concentrations of fatty acid than our study. We observed slightly increased concentrations of unsaturated fatty acids for $18:1^{\Delta 9}$-supplemented and of saturated fatty acids for 16:0-supplemented cultures, compared to unsupplemented cultures.

Over 97% of the exogenous [1-^{14}C]$18:1^{\Delta 9}$ was taken up by the cultures, and 59% of that taken up was converted to $18:2^{\Delta 9,12}$ and $18:3^{\Delta 9,12,15}$ (Fig. 2A), and to a lesser extent (1–2% of total label), to $20:1^{\Delta 11}$, a minor fatty acid in *Neurospora*. Thus, the added $18:1^{\Delta 9}$ was readily desaturated and a small amount elongated. Specific activities (cpm/mmol) of the individual ^{14}C-labeled fatty acid differed (Fig. 2A); in phospholipid, which includes the phosphatidylcholine substrate for $18:1^{\Delta 9}$ and $18:2^{\Delta 9,12}$ desaturation, the specific activity of $18:2^{\Delta 9,12}$ was 0.8×10^9 cpm/mmol while the specific activities of $18:1^{\Delta 9}$ and $18:3^{\Delta 9,12,15}$ were greater (by 73 and 112%, respectively). This difference suggests preferential use of the [^{14}C]$18:2^{\Delta 9,12}$ for desaturation. The proportion of ^{14}C-label incorporated into each lipid class was similar to the proportion of its fatty acid mass, with the exception of the lower amount of label vs. mass in the glycolipid fraction (Table 1).

Cultures supplemented with [7,7,8,8-$^2H_4$]16:0 incorporated the deuterated fatty acid, with different levels of label incorporation in individual fatty acids (Fig. 2B). Twenty percent of the [^{2}H]16:0 was elongated to [^{2}H]18:0 as an end product, and both labeled compounds were incorporated into triacylglycerol. Further elongation of 18:0 to longer-chain saturated fatty acid (20:0, 22:0, and 24:0) in triacylglycerol and phospholipid was similarly efficient, with label in 20–22% of the longer-chain fatty acid. The relative proportion of [^{2}H]-labeled fatty acid in the lipid classes differed from the fatty acid mass (Table 1); a lower amount of label was incorporated into phospholipids, and a higher amount into triacylglycerol. This observation is consistent with the role of triacylglycerol as storage lipid that can accommodate a higher relative level of saturated fatty acid than phospholipids, which are desaturation substrates and, as components of membranes, appear to regulate fatty acid composition more strictly (9).

In contrast to the efficient incorporation of label from [^{2}H]16:0 into saturated fatty acids, label was relatively poorly incorporated into the major unsaturated fatty acids (Fig. 2B). Although the unsaturated fatty acids were present at 12 times the mass of 18:0 in the phospholipid and triacylglycerol, they contained only 37% of the incorporated [^{2}H]16:0. The lowest

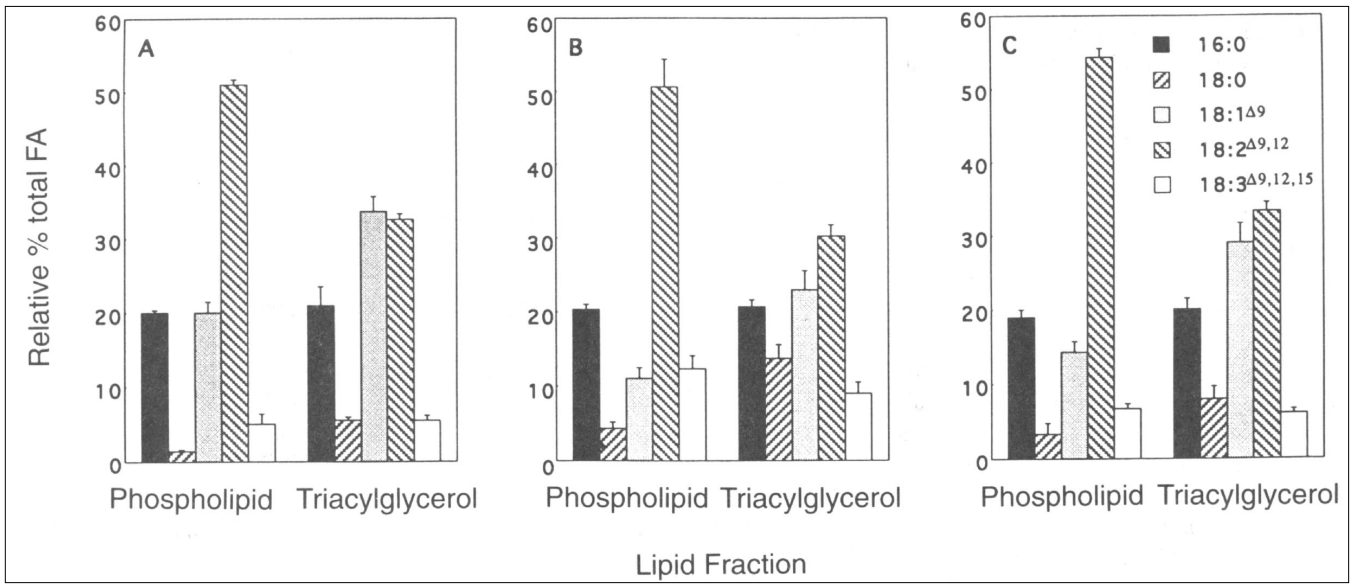

FIG. 1. Fatty acid (FA) composition of *Neurospora* lipids. A, 50 mL cultures supplemented with 30 μM [1-^{14}C]$18:1^{\Delta 9}$ (specific activity 3.3×10^9 cpm/mmol) as described in the Experimental Procedures section; B, cultures supplemented with 30 μM [7,7,8,8-^2H]$_4$16:0; C, unsupplemented cultures. Values are means ± SE of three or more experiments. (Balance in minor fatty acids contributes 2% or less of the total.)

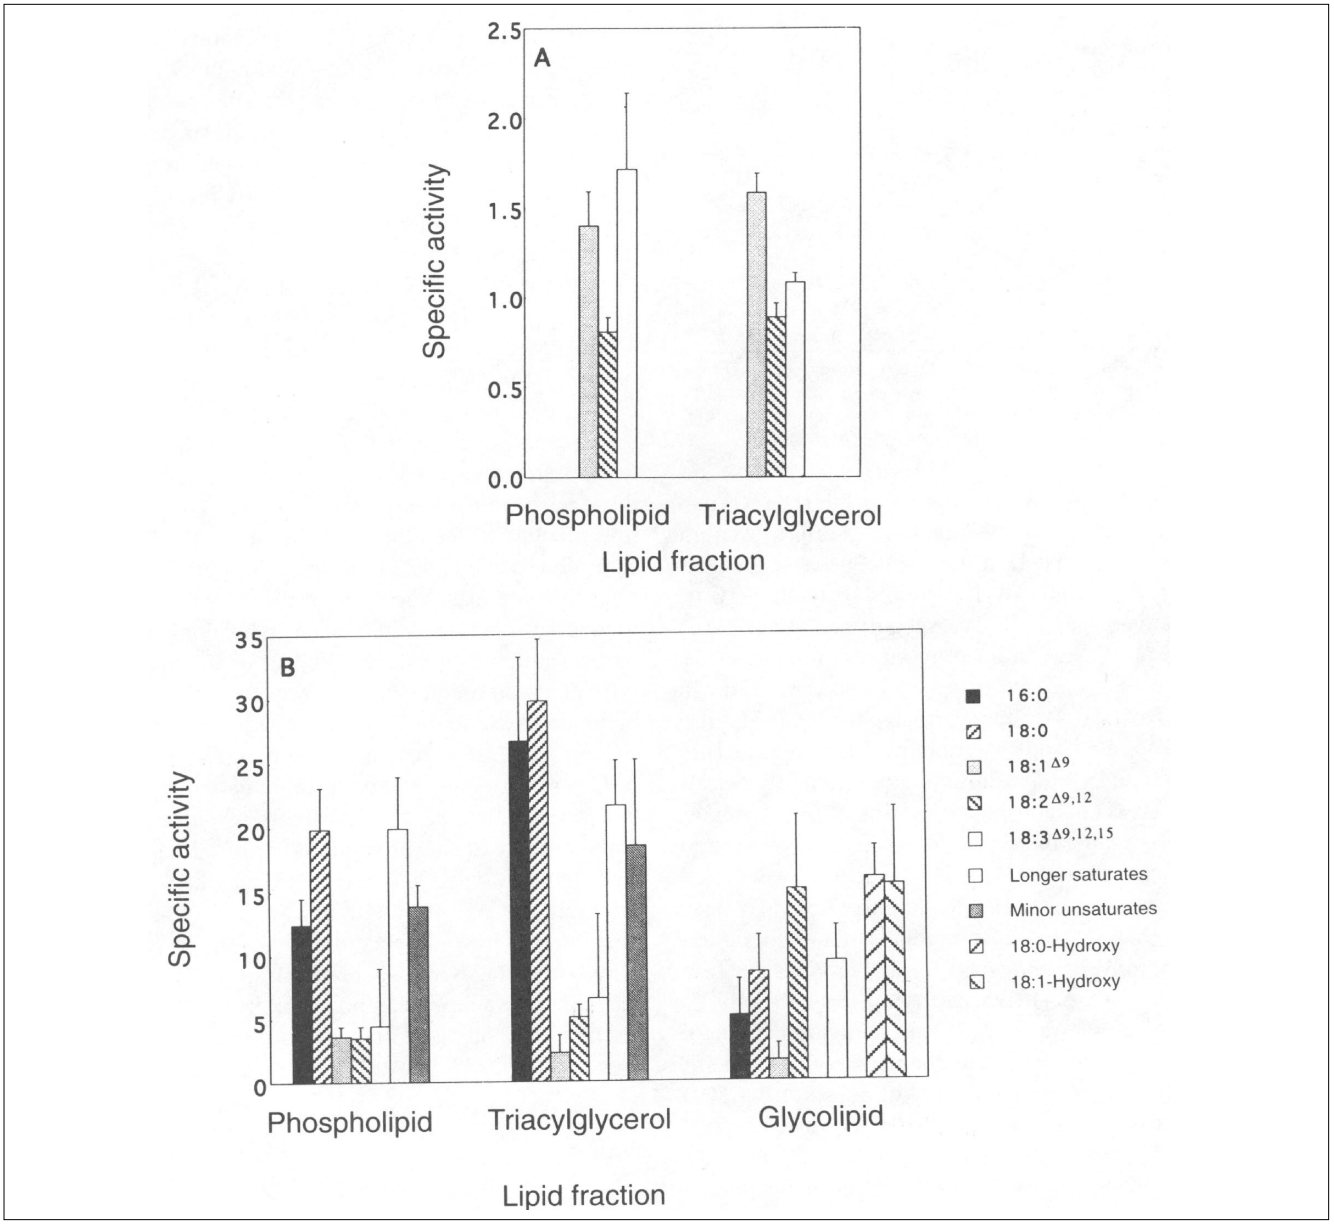

FIG. 2. Specific activity of fatty acids in *Neurospora* lipids. A, Cultures supplemented with 30 μM [1-^{14}C]18:1$^{\Delta 9}$ (label incorporation into glycolipids not detectable). Samples were analyzed for label incorporation by high-performance liquid chromatography and for fatty acid mass by gas chromatography with flame-ionization detection. Values are average specific activities (10^9 cpm/mmol) for six samples; error bars indicate SE calculated from normalized values. B, Cultures supplemented with 30 μM [7,7,8,8-$^2H_4$]16:0. Deuterium incorporation determined by gas chromatography/mass spectrometry with selective ion monitoring. Values are average specific activity (% deuterated) ± SE for three experiments. Long-chain saturated fatty acids, average for 20:0, 22:0, 24:0; minor unsaturated fatty acids, 16:1$^{\Delta 9}$ and 18:1$^{\Delta 11}$. Missing values (both panels) indicate that insufficient material was present to calculate specific activity.

level of deuteration was found in 18:1$^{\Delta 9}$. In phospholipid, the percentage deuterated 18:0 (specific activity, Fig. 2B) is five times greater than the percentage deuterated 18:1$^{\Delta 9}$. This five-fold dilution must occur as the result of endogenously produced 18:1$^{\Delta 9}$, indicating that desaturation of 18:0 to 18:1$^{\Delta 9}$ is more efficient for 18:0 synthesized *de novo* by the fatty acid synthase. The polyunsaturated fatty acids had higher levels of deuteration than 18:1$^{\Delta 9}$, indicating that once 18:1$^{\Delta 9}$ is formed, it is readily used by the desaturation pathway. The lower level of deuterated unsaturated fatty acids formed from the exogenous 16:0 is not due to inhibition of desaturation by [^{2}H]16:0, since the fatty acid composition of these cultures is similar to

TABLE 1
Relative Amounts of Total Fatty Acid in Lipid Fractions of *Neurospora* Cultures[a]

Supplement	Lipid fraction	Total fatty acid mass[b] (%)	Total label[b] (%)
[1-^{14}C]18:1$^{\Delta 9}$	Phospholipid	74.03 ± 4.20	71.97 ± 4.09
	Triacylglycerol	16.28 ± 3.67	18.98 ± 4.44
	Glycolipid	0.95 ± 0.30	0.26 ± 0.02
[7,7,8,8-$^{2}H_4$]16:0	Phospholipid	76.80 ± 5.89	58.81 ± 9.12
	Triacylglycerol	18.63 ± 1.03	35.07 ± 9.11
	Glycolipid	1.87 ± 0.34	3.15 ± 1.41

[a]Total fatty acid, [^{14}C]18:1$^{\Delta 9}$-supplemented, 911 µg/culture (average of 6); [^{2}H]16:0-supplemented, 1005 µg/culture (average of 3).

that of cultures grown without exogenous [^{2}H]16:0 (Figure 1B and 1C). A primary isotope effect that inhibits desaturation of only the deuterated 18:0 is possible, because the elongation product of [7,7,8,8-$^{2}H_4$]16:0 would be the [9,9,10,10-$^{2}H_4$]18:0. However, a similarly low specific activity of 18:1$^{\Delta 9}$ relative to its precursors and products was also observed when wild-type *Neurospora* cultures were supplemented with [2,2- or 16,16,16-^{2}H]16:0 (Table 2) or [1-^{14}C]16:0 (13). Since exogenous, deuterated 16:0 is efficiently elongated to 18:0, while the deuterated 18:0 produced is not efficiently desaturated to 18:1$^{\Delta 9}$, we conclude that elongation of the exogenous 16:0 to 18:0 occurs in a metabolic pool separate from that of *de novo* fatty acid synthesis.

[^{2}H]16:0 was also converted into palmitoleate (16:1$^{\Delta 9}$) and *cis*-vaccenate (18:1$^{\Delta 11}$) (Fig. 2B), products of a minor desaturation pathway in *Neurospora* (3). The 16:1$^{\Delta 9}$ results from formation of 16:0-CoA and desaturation, probably by the stearoyl-CoA Δ9-desaturase, which inserts a double bond in the 9,10-position of the fatty acid chain. The yeast and animal forms of this enzyme are capable of desaturating 16:0-CoA (14). Subsequent elongation of 16:1$^{\Delta 9}$ produces 18:1$^{\Delta 11}$.

Glycolipids are a relatively minor, though important, component of *Neurospora* lipids. Although 24-carbon saturated hydroxy fatty acids have been identified as the major components of *Neurospora* glycosphingolipids (15), we found that 60–70% of the total glycolipid fatty acid was C_{18} hydroxy fatty acid (2-hydroxystearate and 2-hydroxyoctadecenoate) and about 10% was C_{20}–C_{24} hydroxy fatty acid, with the remaining fatty acid not hydroxylated. Label from [^{2}H]16:0 was readily incorporated into both C_{18} hydroxy fatty acids (Fig. 2B). [^{2}H]16:0 incorporation into glycolipids was proportionally higher than [^{14}C]18:1$^{\Delta 9}$ incorporation (Table 1), presumably due to the 2-hydroxy fatty acid in this fraction being derived from elongation products of 16:0.

The percentage deuterated fatty acid (specific activity, Fig. 2B) present in saturated fatty acids ranged from 20–30%, and in minor fatty acids is 14–18%, while it ranged from 2–6% for the major unsaturated fatty acids. Thus, the exogenously added [^{2}H]16:0 was less efficiently utilized for the major desaturation pathway. We infer that the [^{2}H]18:0 produced by elongation of [^{2}H]16:0 is not as accessible to desaturation as 18:0 formed *de novo*. Therefore, 18:0 derived from exogenous [^{2}H]16:0 behaves as if in a separate metabolic pool. Our evidence is consistent with two pathways of biosynthetic reactions leading from 16:0. One is the main pathway leading to unsaturated fatty acids, originating from the fatty acid synthase reaction *via* elongation of 16:0 to 18:0, then desaturation to 18:1$^{\Delta 9}$. The other pathway leads to accumulation of saturated fatty acids. These appear to be formed primarily after thioesterase hydrolysis of the 16:0 fatty acid synthase product to free fatty acid which can be elongated to 18:0 and longer saturated fatty acids. While a small amount of this free fatty acid can reenter the pathway to 18:1$^{\Delta 9}$, much of it remains in the saturated fatty acid pathway and is directed as such into both storage and structural lipid.

Our results suggest a hitherto unrecognized control point that governs fatty acid composition. A mutation at this point could alter synthesis of saturated or unsaturated fatty acids. *Neurospora ufa* and *pfa* mutants (3–6), which are impaired in production of unsaturated fatty acids, have until now been presumed to have defects in desaturases, associated reductases, or in the synthesis of substrate lipids. These results, then, provide a new focal point for efforts in determining the regulation of fatty acid composition.

Correlation of ATP/Citrate Lyase Activity with Lipid Accumulation in Developing Seeds of *Brassica napus* L.

Colin Ratledge[a,]*, Moray D.V. Bowater[b], and Philip N. Taylor[c]

[a]Department of Biological Sciences, University of Hull, Hull HU6 7RX, United Kingdom, [b]Coombe Farmhouse, Devon, United Kingdom, and [c]GeneCo, St. Margaret's Farm, Kent, United Kingdom

ABSTRACT: The temporal distribution of ATP/citrate lyase (ACL) activity in developing seeds of *Brassica napus* L. closely paralleled both that of acetyl-CoA carboxylase and the overall rate of lipid biosynthesis. Maximum ACL activities (250 nmol acetyl-CoA formed $min^{-1} \cdot$ g fresh seed) were recorded between 35 to 42 d after pollination and, if the *in vitro* data could be extrapolated to the situation *in vivo,* could account for half of the acetyl-CoA required for the measured rate of fatty acid biosynthesis during seed development. The enzyme appeared to be localized in a subcellular compartment, which was clearly separated from mitochondria on a sucrose gradient and by differential centrifugation, and which corresponded to the chloroplast organelle.

Lipids 32, 7–12 (1997).

During oilseed development, significant amounts of sugar provided by photosynthesis are converted to storage triacylglycerols by the developing seed. The pathway from sugars to storage oil has been extensively investigated in plants, and the main site of biosynthesis of fatty acids up to oleic acid occurs in the plastid stroma (1). This is in contrast to other eukaryotic cells, including yeasts, where fatty acid biosynthesis occurs in the cytoplasm. All plant fatty acids are synthesized ultimately from CO_2, but the point at which the pathway commits the fixed carbon to lipid biosynthesis is the conversion of acetyl-CoA to malonyl-CoA by the action of acetyl-CoA carboxylase (EC 6.4.1.2). However, as Ohlrogge and Browse (2) have elegantly summarized, "Our understanding of how carbon moves from photosynthesis into acetyl-CoA is clouded by an abundance of potential pathways. . . . It is more than likely that more than one pathway may contribute to maintaining the acetyl-CoA pool, and which pathway is used may vary with tissue, developmental stage, light/dark conditions and species."

The principal candidate route for acetyl-CoA formation is *via* pyruvate dehydrogenase (PDH) which acts on pyruvate transported from the cytosol into the plastid (3,4). There are, though, some objections to this as PDH activity is insufficient in nongreen plastids to account for observed rates of fatty acid biosynthesis (5). Roughan and Ohlrogge (6) have suggested that a route involving free acetate entering the plastids, there to be activated *via* acetyl-CoA synthetase, may be a key route. Malate (7) and glucose 6-phosphate (4) also have been proposed as precursors of acetyl-CoA either alone or in conjunction with other pathways. What is clear, however, is that the acetyl-CoA to be used in fatty acid biosynthesis must be synthesized in the subcellular compartment in which it is to be used since subcellular membranes are impermeable to acetyl-CoA (3). In plants, this means that acetyl-CoA for *de novo* fatty acid biosynthesis must be synthesized in the plastid.

Plants which produce oil-rich seeds accumulate large amounts (up to 60% in some seeds) of storage lipid and may therefore have methods of providing acetyl-CoA for this process which other nonoleaginous plants do not or are unlikely to have. The fact that seed tissues in oil-bearing plants synthesize so much oil and so rapidly in comparison to other plant tissues probably means that these tissues have a highly efficient, and probably highly seed-specific, system for synthesizing the metabolic precursors of fatty acids—including acetyl-CoA.

In eukaryotic cells, other than plants, fatty acid synthesis occurs in the cytoplasm. Citrate, produced *via* glycolysis and citrate synthase in the mitochondria, is exported into the cytoplasm and there cleaved by ATP/citrate lyase (ACL) (EC 4.1.3.8). The acetyl-CoA produced is used in fatty acid synthesis and the oxaloacetate recycled to the mitochondria. Not surprisingly, the activity of ACL is closely linked to the onset of lipogenesis in rats and humans (8–10) and also to the accumulation of lipid in oleaginous yeasts and fungi: the presence or absence of the enzyme either conferring or removing the capacity for oleagenicity from yeasts grown under the appropriate nutritional conditions (11–15).

There have previously been a number of reports of ACL activity in plant tissues. The activity of the enzyme has been linked to fatty acid biosynthesis (16–19), sesquiterpenoid biosynthesis (20), and carotenoid biosynthesis (21). We have therefore set out to investigate whether ACL is present in the developing seeds of *Brassica napus* L., as a typical oleagi-

nous plant, and to determine what role it may play in fatty acid biosynthesis.

MATERIALS AND METHODS

Preparation. Brassica napus L. cv. Weber, a rapid cycling variety, was grown in greenhouses, in soil-based compost. Plants were given a minimum of 16 h daylight, natural light being supplemented when necessary with artificial light. Flowers were hand-pollinated. Developing pods were harvested periodically up to 70 d after flowering and stored at 4°C until used. All seeds were used on the same day as they were harvested.

Crude extracts of developing *Brassica napus* L. seed were prepared by removing the seed from the pods and grinding 2 g (fresh weight) in a prechilled mortar with a prechilled pestle in 10 mL extraction buffer containing 100 mM KH_2PO_4, pH 7.2, 50 mM NaF, 0.1 mM EDTA, 1 mM dithiothreitol, 1 mM $MgCl_2$ and 1 mM *p*-aminobenzamidine as a protease inhibitor. The resulting homogenate was filtered through four layers of sterile muslin to remove large debris and then centrifuged at 36,000 × *g* for 30 min. The supernatant was removed, taking care not to disturb the lipid layer at the top of the tube, and this crude extract was used in the subsequent enzyme assays. ACL was assayed by the coupled spectrophotometric method (22) with reactions being routinely initiated with ATP after 5-min incubation. Fumarase (23), $NAD(P)^+$-malic enzyme (24), glucose-6-phosphate dehydrogenase (G6PDH) (25), and acetyl-CoA carboxylase (26) were assayed as indicated.

Density gradient centrifugation. Subcellular components were prepared at 4°C, on 12 mL step-gradients of between 30 and 60% (w/w) sucrose in equal 5% steps. Fresh tissue, 2 g, was roughly chopped in 5 mL 330 mM sorbitol, 100 mM KH_2PO_4, 0.1 mM EDTA, and 1 mM $MgCl_2$. The resulting fragments of seed were then pushed through a fine nylon mesh (mesh size approx. 0.1 mm), the pulp was collected, and 2 mL of the through-flow then loaded onto the top of the cold gradient. The gradients were unloaded from the bottom up in 1-mL fractions and particulate material pelleted by centrifugation. Protein was estimated by the Bradford method (27).

Differential centrifugation. Fresh seed tissue was collected about approximately 40 d postpollination (dpp) and homogenized as detailed in the Density gradient centrifugation section. After filtering the unfractionated homogenate through four layers of muslin, a crude plastid fraction was prepared by centrifugation (800 × *g,* 2 min at 4°C followed by 2000 × *g* for 10 min at 4°C). The supernatant was removed and retained and the pellet gently resuspended in 3 mL homogenization buffer (see above). This was termed the crude plastid fraction. The supernatant was then centrifuged at 12,000 × *g* for 10 min at 4°C and the supernatant removed. This was termed the crude cytosolic fraction. The 12,000 × *g* pellet was resuspended in 3 mL homogenization buffer and termed the crude mitchondrial fraction.

Radioactive incorporation. Incorporation experiments of [1-^{14}C]acetic acid and [1,5-^{14}C]citric acid into lipid were performed on crude plastid, crude mitochondrial, and crude cytosolic fractions. The plastid fraction was prepared by centrifugation of the homogenate (described above for the step gradients) at 800 × *g* for 2 min at 4°C followed by 2000 × *g* for 10 min at 4°C. The resulting supernatant was removed and retained and the pellet carefully resuspended in 3 mL homogenization buffer. To obtain the mitochondrial fraction, the retained supernatant was centrifuged at 12,000 × *g* for 10 min at 4°C and the pellet was resuspended in a 3 mL homogenization buffer. The supernatant from this centrifugation was termed the cytosolic fraction. Between 100 µL and 1 mL of each fraction were incubated in a reaction mixture containing, in 3 mL, $KHCO_3$ (30 µmol), $MgCl_2$ (5 µmol), β-mercaptoethanol (2 µmol), ATP (15 µmol), NADPH (2.5 µmol), NADH (2.5 µmol) and CoA (2.5 µmol) plus either [1,5-^{14}C]citric acid (10 nmol, 1 µCi) and trisodium citrate (1.2 µmol) or [1-^{14}C]acetic acid (18 nmol, 1 µCi) and sodium acetate (1.2 µmol). Reactions were incubated for 2 h at 30°C with constant, gentle shaking and illumination in small, stoppered Warburg manometer flasks with a center well containing a filter-paper wick soaked in 0.5 mL ethanolamine to absorb CO_2. After 2 h, the flasks were removed from the shaker, placed on ice in the dark, and the reactions stopped by adding 0.5 mL 15% (wt/vol) methanolic KOH. The wicks and ethanolamine were removed and the center wells washed with 1.5 mL polyethylene glycol monoethyl ether. The wicks and washings were pooled, placed in plastic scintillation vials with 10 mL scintillation fluid, and counted directly by liquid scintillation. The reaction mixture was transferred to a 50 mL centrifuge tube, and the inside of each manometry flask was washed with 2 mL distilled water and 2 mL chloroform/methanol (2:1, vol/vol). Washings and reaction mixture were combined and 5 mL chloroform/methanol (2:1, vol/vol) and 2 mL distilled water added. The aqueous phase was extracted three times with 5 mL chloroform/methanol (2:1, vol/vol) and the organic fractions combined and evaporated to dryness under a stream of N_2. The dried organic extract was dissolved in 10 mL scintillation fluid and counted. All radioactive counts were corrected for quenching using internal and external standards.

RESULTS

Enzyme assays for ACL were optimized using seeds 42 dpp. Maximum catalytic activity occurred at pH 7.8 with 50% of maximum activity at pH 6.8 and 8.4. Addition of citrate or glycerol to the extraction buffer had no stabilizing effect on the activity of the enzyme from *B. napus* L. The reaction was dependent on ATP and CoA and was optimal between 34 and 37°C.

Enzyme activities were measured during the course of seed development, from 14 dpp to final desiccation of the seeds which occurred approximately 70 dpp. Measurements of lipid content and enzyme activities are given in Figure 1. Results are presented in activities per mg fresh weight of the

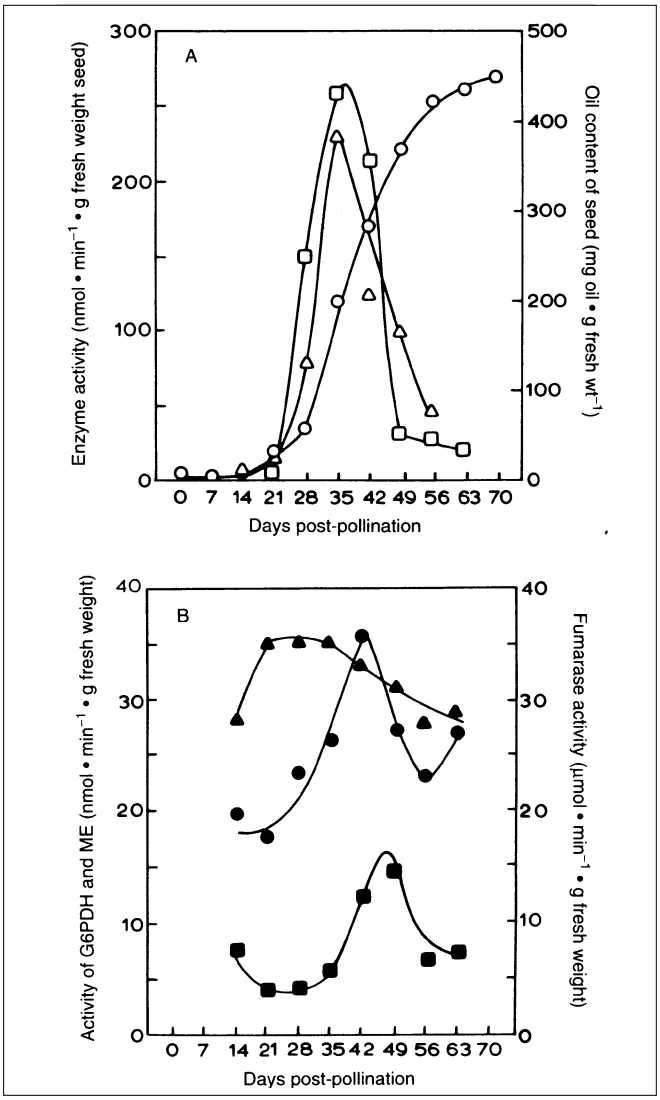

FIG. 1. Activities of various enzymes in developing, greenhouse-grown rape seed with the increase in oil content of the seeds. A: ATP/citrate lyase (△), acetyl-CoA carboxylase (□); total oil content of seeds (○); B: fumarase (▲), $NADP^+$-malic enzyme (ME) (■), and glucose-6-phosphate dehydrogenase (G6PDH) (●).

seeds to avoid errors associated with the accumulation of nonenzymatic, storage protein during seed development. The drawback of presenting the data in relation to seed dry weight is that during desiccation, seed weight inevitably drops and, as a result, the activity of the enzymes and lipid content may appear to rise. The results presented here indicated that this was occurring with unexpected increases in seed lipid between 63 and 70 dpp and in the activities of $NADP^+/NAD^+$-malic enzyme, glucose-6-phosphate dehydrogenase and fumarase between 56 and 63 dpp. ACL and acetyl-CoA carboxylase (ACC) activities, however, were not affected. Since this imprecision arose late in seed development and after the main phase of lipid accumulation had finished, it was considered acceptable to measure enzyme activities in terms of the fresh weight of seeds and particularly for determinations during early seed development.

ACL activity was first detected 14 dpp and reached a maximum of 232 nmol min^{-1} · g fresh weight (FW) at 35 dpp (Fig. 1A). It then decreased until it became undetectable at 70 dpp. The changes in the activity of the enzyme closely followed the increases and decreases in the rate of lipid accumulation in the seed. Changes in ACL activity also closely paralleled changes in the activity of ACC. Although ACC activity was slightly lower than ACL activity during the early part of seed development, the rate of increase of ACC activity was greater after 21 dpp and maximum ACC activity of 258 nmol min^{-1} · g FW was reached at the same time as maximum ACL activity. The activities of the other enzymes investigated did not show such a close correlation (Fig. 1B). Activity of NAD(P)-malic enzyme appeared to peak during the period of maximum oil biosynthesis although overall its activity was much lower than either that of ACL or ACC. The cytosolic and mitochondrial markers, respectively glucose-6-phosphate dehydrogenase (G6PDH) and fumarase, showed no correlation in activity during the period of maximum lipid accumulation; however the changes in fumarase activity were similar to those of malic enzyme, suggesting a possible, but functionally uncertain, linkage. Correlation coefficients between ACL and ACC activity and the rate of oil accumulation were 0.707 and 0.936, respectively, both of which are significant. Maximum catalytic activity of G6PDH at 261 nmol min^{-1} · g FW is sufficient to provide approximately 35% of the total NADPH required for the measured rate of lipid biosynthesis at this stage of seed development. This may explain why malic enzyme activities are so low since the extra NADPH which this enzyme produces, and is essential in animals and yeast, may not be needed as sufficient will be produced by the two enzymes of the pentose phosphate pathway, G6PDH and 6-phosphogluconate dehydrogenase, and by photosynthesis.

The fractions taken from the density gradients of homogenized rapeseed taken after 35 to 42 dpp were analyzed for ACL and fumarase activity, as well as for protein and chlorophyll concentration (Table 1). ACL activity was detected in fractions 10 to 2 from the density gradients with maximum activity in fractions 10, 8, and fraction 3. The fractions 10, 9, and 8 represent the cytosolic and broken organelle component of the homogenate while fractions 3 and 4 contain unbroken chloroplasts. As the chlorophyll concentration was higher in fraction 4 than in fraction 3, the latter possibly may be developing chloroplasts, with buoyant densities of between 1.2 and 1.22 g/mL. Fraction 6 gave the highest fumarase activity, indicating that this fraction contained unbroken mitochondria with a buoyant density of 1.14 g/mL. High fumarase activities in fractions 10 and 9 are indicative of considerable mitochondrial rupture during preparation of the homogenates and the gradients: 73% of the total fumarase activity was found in fractions 10 to 8. Equivalent levels of plastid breakage could be assumed suggesting that the ACL activity in fractions 10 to 8 was the result of the plastid rupture and not native, cytoplasmic ACL.

To establish whether ACL was isolated within the plastid stroma or was membrane-bound, the pellet recovered from

[a]Along with protein and chlorophyll contents, in homogenates of developing rapeseed (taken 35 to 42 dpp) and fractionated by centrifuging in a 30 to 60% (wt/vol) stepped sucrose density gradient; Chl, chlorophyll; dpp, days postpollination.

fraction 3 of the density gradients (see Table 1) was resuspended in homogenization buffer with and without sorbitol and recentrifuged (40,000 × *g* for 1 h). ACL activity remained in the soluble (i.e., nonsedimentable) fraction in both cases indicating that it was not a membrane-associated activity in the original fraction 3. ACL therefore appeared to be genuinely associated with the plastid fraction.

In an attempt to establish a clear role for ACL within developing rapeseed, further preparations of plastids, mitochondria, and cytosol were obtained by differential centrifugation. Each preparation was measured for ACL and fumarase activity to establish the degree of contamination of each fraction with the other. The results (Fig. 2) indicated that organelles had been successfully separated. The total ACL activity recovered in the plastid fraction was over 70% of the total ACL activity in all three fractions. Each of these fractions was then tested for its ability to convert either citrate or acetate into lipid and CO_2 (Fig. 3). In crude preparations of plastids, acetate was clearly a better precursor of fatty acid biosynthesis than was citrate. This has already been widely reported (1,2,28). However, the cytosolic fractions also efficiently incorporated label from both acetate and citrate into lipids with citrate being the marginally more efficient precursor. Mitochondrial fractions did not efficiently incorporate label from either acetate or citrate into lipid but were extremely effective at converting both precursors to CO_2.

DISCUSSION

Although the availability of acetyl-CoA is probably not limiting the rate of fatty acid biosynthesis in developing rapeseed under physiological conditions, it is obvious that an adequate supply of this precursor is needed to initiate and maintain the process. As indicated at the beginning of this paper, the origins of acetyl-CoA for fatty acid biosynthesis in plant tissues still appear to be uncertain (see Refs. 2 and 4 for further details) but, given the large difference in quantities of acetyl-CoA needed in developing rapeseed in comparison to leaf tissue, it would not be surprising for an additional and specific pathway to be operating in these particular tissues. The high activity of ACL, its close relationship to the rate of oil biosynthesis, and the localization of the enzyme within the plastid would all suggest that a significant portion of the required acetyl-CoA was being provided *via* this enzyme in the tissues studied here. Peak *in vitro* ACL activities reported (232 nmol min^{-1} · g FW; see Fig. 1A) would produce, if they occurred

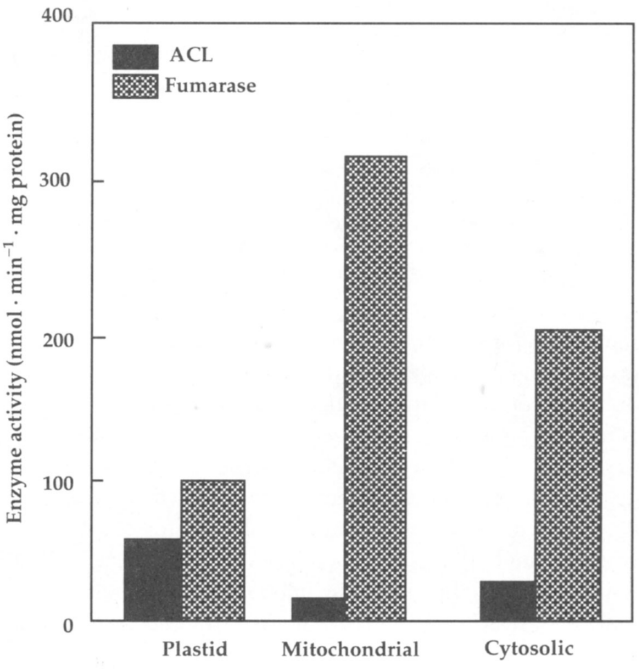

FIG. 2. Activities of ATP/citrate lyase (ACL) and fumarase in plastid, mitochondrial and cytosolic fractions of seed tissue prepared by differential centrifugation (see the Materials and Methods section). The total amount of protein in each of the three fractions was, respectively, 4, 1, and 2.5 mg.

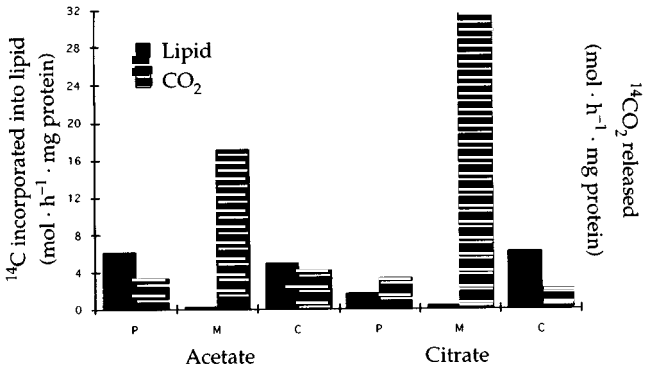

FIG. 3. Incorporation over 2 h of [1-^{14}C]acetate (1.22 μmol, 1 μCi) or [1,5-^{14}C]citrate (1.21 μmol, 1 μCi) into lipid (chloroform/methanol soluble fraction) or released as $^{14}CO_2$ by isolated subcellular fractions of developing rapeseed prepared as in Figure 2. P, plastid; M, mitochondrial; C, cytosolic fractions. No allowance is made for citrate only providing 1 mol acetate for fatty acid biosynthesis: i.e., effectively only 50% of the radioactivity of the acetate is available for incorporation into lipid.

in vivo, sufficient acetyl-CoA for the synthesis of 10.6 mg palmitate per day. This compares to a rate of lipid accumulation at this stage of seed development of just under 20 mg per day per g FW. On the basis of this, ACL could be providing up to half of the acetyl-CoA needed for fatty acid biosynthesis in these oleaginous seeds at this stage of their development and perhaps even a higher proportion if the assay of ACL activity was suboptimal.

The results from the density gradients appear to suggest that ACL is present in a plastid with a buoyant density 1.20 to 1.22 g/mL. As the same fractions contain the second highest chlorophyll concentrations of any of the fractions, this would suggest that the organelles are chloroplasts. This conclusion is consistent with previous reports of ACL in germinating castor bean endosperm which indicated that the enzyme was plastid localized (16). The confirmed presence of ACL in a plastid further supports the proposition that this acetyl-CoA is for fatty acid biosynthesis. If this is the case, it would indicate that at least one of the pathways to fatty acid biosynthesis in rapeseed may be comparable to the pathway found in mammals and oleaginous microorganisms (12–15).

Although some lipid synthesis was found in the cytosolic fraction (Fig. 3), this may have been as a result of the release of plastidic components. However, the incorporation of citrate into lipid by the cytosolic fraction may have a number of explanations: possibly, and some results from the density gradients support this proposition, native ACL is present in the cytoplasm, and the incorporation is a result of citrate cleavage to acetyl-CoA and its subsequent use in fatty acid chain elongation. Alternatively, the ACL found in the cytosolic fraction may be a result of plastid breakage, releasing both ACL and other components of the fatty acid synthesis machinery.

The results presented here demonstrate that ACL activity is present in plant tissues and is at its highest activity when the physiological demand for acetyl-CoA is highest. We therefore suggest that the role of this enzyme in plants is to maintain the cellular flux of the acetyl-CoA during those periods when lipid is being synthesized as a storage material in seeds. ACL activity varies in response to demand for acetyl-CoA and therefore would only be expressed at strategic times during plant development. Acetyl-CoA carboxylase, which must work in conjunction with ACL, parallels the activity of ACL, suggesting that a coordinated response is occurring during seed development. ACL would not be part of the "housekeeping" system but may be activated when the need is greatest. It would be less complicated for the plant to maintain a number of enzymes at fairly constant activities, and respond to increases and decreases in demand by activating or inhibiting one enzyme, than to keep constant and fine control of a large number of different enzymes. If this is the case, ACL activity should be detectable in plants under conditions where there is a large demand for acetyl-CoA for biosynthetic processes irrespective of what these might be.

Digestion of the 1-*O*-Alkyl Diacylglycerol Ethers of Atlantic Dogfish Liver Oils by Atlantic Salmon *Salmo salar*[1]

ABSTRACT: Dogfish *(Squalus acanthias)* liver poses a waste disposal problem in Canada because it is not utilized for any commercial purpose. The liver of Atlantic dogfish, which is often up to 20% of the weight of the fish, contains 40–70% oil. The oil contains about 30–40% 1-*O*-alkyl diacylglycerol ethers (DAGE) which render it unacceptable for human use, and it has also not been considered satisfactory for animal feed use. Polyunsaturated fatty acids (20:5n-3 and 22:6n-3) are present in dogfish liver oils at levels comparable to those in herring oil. Dogfish liver oil could be a source of essential fatty acids for Atlantic salmon *(Salmo salar),* but their ability to hydrolyze DAGE from dogfish oil has not been examined. Experiments were designed to measure the digestibility of fatty acids of DAGE in salmon. The fatty acid moieties were liberated by the digestive enzymes of the fish and made readily available as a source of energy. The 1-*O*-alkylglycerol ether moiety was absorbed to a small extent but should not constitute a health problem in either the fish or the human fish consumer. The long-chain polyunsaturated fatty acids were particulary well absorbed, with an apparent digestibility in salmon of 87–95% when feeding on dogfish liver oil. The total fatty acids and other lipids were in fact both absorbed to the extent of approximately 85%.
Lipids 32, 19–30 (1997).

The Atlantic dogfish *Squalus acanthias* is a very large resource (1,2). A growing fishery in southwestern Nova Scotia sells backs, bellies, skins, and fins to different markets. There is, however, a waste disposal problem with the livers, which amount to 20% of the weight of the fish and are at least 40% oil. This oil is easily recovered (3,4) and contains approximately 30% 1-*O*-alkyl diacylglycerols (DAGE), usually simply called glyceryl ethers, rendering it unfit for human use as the 1-*O*-alkylglycerol ether proper cannot be absorbed, and similarly it is not acceptable for most animal feed purposes (chicken, pigs, etc.) (5). The popular use of glyceryl ethers (DAGE) as a descriptive term should be restricted to 1-*O*-alkylglycerol ethers. The balance of the oil is triacylglycerol (TAG) with 1–5% free fatty acids (FFA). The FFA are produced by enzymatic hydrolysis, their proportion reflecting storage and handling. Marine oils are sources of the longer-chain polyunsaturated fatty acids of the n-3 (ω-3) family, especially eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). These are essential for the diets of Atlantic salmon (6,7), and we wished to examine their availability from DAGE *in vivo*. The DAGE are widely distributed in nature, and their biological role is highly significant (8). It is common knowledge that GE are found in marine animals of various types (8–11). Lie and Lambertsen (12) examined the digestion of these lipids in Atlantic cod (*Gadus morhua*). Other predatory fish such as Atlantic salmon would presumably be able to digest the DAGE abundant in marine animal prey.

Determination of lipid absorption *in vivo* requires determination of lipid in the food and unabsorbed residues in feces. This is generally achieved either by collection of total fecal matter excreted after consumption of a known amount of food, or measurement of the concentration of a marker in both feed and feces. Total collection of fecal matter from fish is tedious and often impossible. Chromium oxide is the most commonly used digestibility marker (13,14); however, it has two main disadvantages as a lipid digestibility marker in that it is not fat-soluble and has to be determined separately from fat or fatty acids. Improved technology for studying the digestive process of fats in trout and salmon has recently been developed by Sigurgisladottir *et al*. (15) employing cholestane as a digestibility marker. The present study, designed to evaluate the ability of Atlantic salmon to hydrolyze DAGE of Atlantic dogfish liver oil and to determine the digestibility

of all the fatty acids in dogfish liver oil by Atlantic salmon smolts, was based on the use of cholestane as an indicator of fat absorption.

MATERIALS AND METHODS

Fish and diets. Sixty Atlantic salmon averaging 500 g each were acclimated to feed, aquaria, and standardized environmental conditions at the Department of Fisheries and Oceans, Halifax. Six tanks were used, each containing 10 Atlantic salmon smolts, allowing duplication of three dietary groups. Fresh water was supplied to each tank at a flow rate of 3 L/min and maintained at a temperature of 17 ± 1°C. The photoperiod was controlled automatically (scheduled as 12 h of light and 12 h of dark). Feeding to satiation was by hand twice during the light period.

A casein–gelatin based purified diet which contained 30% water was used in this study. Three diets were formulated (Table 1), with the diets differing only in two lipid sources or these in a 1:1 ratio (15% of diet). The following lipid supplements were tested: 15% Atlantic dogfish liver oil (diet 1), a mixture (1:1) of Atlantic dogfish liver oil and herring oil (diet 2) or 15% Atlantic herring oil (diet 3). The dogfish liver oil used in this experiment was extracted from commercial Nova Scotian dogfish livers by a conventional heating method (3), and commercial herring oil was obtained from Department of Fisheries and Oceans stocks. Cholestane (Sigma, St. Louis, MO) was dissolved in the various lipid sources, before they were mixed with the basal diet, to give a level of 0.7 mg/g diet.

Diet, fecal, and muscle lipid analyses. Duplicate samples of each experimental diet (10 g), sampled 15 d apart, were weighed, placed in a beaker with 50 mL of water and sonicated for 20 min (16). The solution was then mixed in a Waring Blendor® for chloroform/methanol extraction of lipid by the method of Bligh and Dyer (17). After two weeks on the experimental diets fed *ad lib*, the fish in each tank were anaesthetized by immersion in fresh water containing MS222 (ethyl 3-aminobenzoate methanesulfonate); feces were then collected from the rectal region by applying gentle pressure to the surface of the fish. The fish were returned to the tank and the procedure was repeated after five days. Samples from duplicate tanks were pooled on each occasion. A small proportion of each feces sample was dried at 105°C to constant weight for moisture analyses. The remaining part of the sample (four for each diet) was used for lipid extraction. The recovered fatty acids (as methyl esters) and the cholestane were determined in duplicate by capillary gas–liquid chromatography (GLC). The cholestane in diets and feces was applied to lipid recovery by modifying the calculations for the Cr_2O_3 method of Arthur (18).

Fish were killed by a blow on the head and filleted. Muscle from fish in each duplicate tank was pooled and extracted separately by the method of Bligh and Dyer (17). Each lot was then analyzed for lipid classes.

Isolation of chylomicrons. On two occasions all fish from each tank were sampled six hours after feeding. A blood sample was drawn from the experimental fish in a heparinized syringe, and after coagulation, blood serum was separated by low-speed centrifugation (3,000 × *g*) for 20 min.

All serum samples from each tank were pooled for analysis of chylomicrons. An antibacterial agent (0.01% sodium azide) and EDTA (1 mg/mL) were added in order to protect the chylomicrons from any oxidative degradation which might be catalyzed by free metal cations. Chylomicrons were isolated from serum by flotation after centrifugation at 15,000 × *g* for 30 min. Fractionations were performed at 10°C in a Beckman L5 50B centrifuge with a 50 Ti rotor (Fullerton, CA) according to Fremont *et al*. (19). Lipid class analyses were conducted in duplicate on each chylomicron sample.

Lipids were extracted from feces, muscle, and chylomicrons by the method of Folch *et al*. (20) as modified by Christie (21). Moistures of diet and feces were determined using recommended procedures (22). Individual lipid mixtures, isolated lipids, methyl esters, etc. were always analyzed in duplicate, as a minimum, but if two samples were available the results were also averaged ($n = 4$) for standard deviations.

Lipid class determination and isolation. A Mark III Iatroscan thin-layer chromatography/flame ionization detection (TLC/FID) analyzer (Iatron Laboratories, Inc., Tokyo, Japan; Canadian Distributor, Scientific Products & Equipment, Concord, ON) was utilized for the quantitative analysis of the lipid classes from each sample after separation on silica-gel coated Chromarods-SIII (23). The general procedure was modified for partial scan and redevelopment as shown by Parrish (24). One to 5 μL of a chloroform solution of the sample was applied to the Chromarods with Drummond disposable micropipets. After spotting, rods were placed in a constant

TABLE 1
Composition of the Experimental Diet

Feed ingredients	Amounts (w/w%)
Casein	40.0
Gelatin	8.0
Dextrin	9.5
Starch	9.8
d-Glucose	4.0
Carboxymethylcellulose	2.0
Alpha cellulose	5.0
Vitamin mixture[a]	1.0
Mineral mixture[b]	4.0
DL-Methionine	0.5
L-Arginine-HCl	1.0
Choline chloride	0.2
Lipid supplement[c]	15.0
Cholestane[d]	0.07

[a]Vitamins added to supply the following levels (mg/kg unless otherwise stated); thiamine, 50; riboflavin, 60; d-calcium pantothenate, 200; biotin, 1; folic acid, 20; vitamin B_{12}, 0.1; niacin, 250; pyridoxine, 40; ascorbic acid, 1000; inositol, 400; vitamin A, 8000 IU; vitamin D, 2400 IU; vitamin E, 300 IU, and vitamin K 40 IU, respectively.
[b]Minerals added to supply the following levels (mg/kg): manganese, 50; iron, 60; zinc, 120; copper, 25.
[c]Lipid supplements used were as follows: diet 1, dogfish liver oil; diet 2, dogfish liver oil + herring oil (1:1 w/w); diet 3, herring oil.
[d]Cholestane was dissolved in the lipid supplements, prior to mixing.

humidity tank over a saturated sodium chloride solution for 10 min and then transferred immediately to the developing tank. The Chromarods-SIII were developed in a sequence of solvent systems to enhance separation of different lipid classes. Firstly, total lipid on the Chromarod-SIII was developed with hexane/diethyl ether/formic acid (97:3:1, by vol) for 55 min, to separate neutral from polar lipids; secondly, hexane/chloroform/isopropanol/formic acid (85:14.5:0.75:0.1, by vol) for 40 min served to partially separate DAGE from FFA; and thirdly, acetone 100% for 30 min was used to separate the GE, diacylglycerols (DAG), and monoacylglycerols (MAG) from polar lipids. Developed rods were placed in an oven at 110°C for 3 min to evaporate the solvents and then transferred to the scanning frame of the Iatroscan analyzer for each partial or complete scan.

Separate fractions of DAGE, TAG, and FFA were obtained from each lipid lot by preparative TLC by streaking on "Prekotes" (Adsorbosil-5 silica gel TLC plates, 20 × 20 cm; Applied Science Laboratories, College Park, PA). The solvent development system was hexane/diethyl ether/acetic acid (85:15:1, by vol). Bands were visualized by spraying the plate with a 0.01% solution of 2′,7′-dichlorofluorescein in ethanol and viewing under ultraviolet (UV) light. Each band was scraped off the TLC plate, and the silica gel extracted with a mixture of chloroform/methanol (50:50, vol/vol). The MAG plus free GE bands were pooled and rechromatographed to permit recovery of enough GE for one analysis of fecal material from diets 1 and 2. The isolated DAGE were saponified with KOH in ethanol according to AOCS Official Method Ca 66-53. The unsaponifiable matter containing 1-*O*-alkylglycerol ether was recovered with freshly distilled diethyl ether. The DAGE of muscle was estimated from the GE in the unsaponifiable matter from direct saponification of muscle total lipids because the amount of actual DAGE in muscle was too low for an effective TLC separation.

Preparation of derivatives of glyceryl ethers and hydrogenation. Isopropylidene derivatives of 1-*O*-alkylglycerols were prepared by acetonization at room temperature in the presence of perchloric acid according to a modification of the method of Wood (25). Briefly, 1 mL of acetone containing 0.1 μL of 70% perchloric acid was added to the sample. The mixture was allowed to stand at room temperature for 20 min and 1–2 drops of concentrated NH_4OH were added, then the reaction was terminated by adding water and the product was extracted three times with hexane/diethyl ether (50:50, vol/vol). Further purification of these derivatives was achieved by TLC using the solvent system hexane/diethyl ether/acetic acid (40:60:1, by vol) prior to analysis by GLC.

For hydrogenation, the lipid samples (10–20 mg) were dissolved in methanol containing sufficient (5–10 mg) platinum oxide catalyst and stirred under a current of hydrogen at atmospheric pressure and room temperature for 2 h (26). In all cases this achieved complete hydrogenation.

Preparation of methyl esters. Up to 20 mg of lipid, 1.0 mL hexane, and 1.0 mL of 8% BF_3–methanol solution were placed in a screw-capped (Teflon-lined cap) centrifuge tube. The tube was flushed with nitrogen, sealed, and heated for one hour at 100°C. After cooling, 3 mL of water was added to the tube and the hexane layer removed to another tube. The aqueous layer was again extracted two times with hexane (2 mL each). The combined hexane extract was washed once with 3 mL H_2O, dried over anhydrous Na_2SO_4, and concentrated as required for GLC analysis of the methyl esters.

GLC and GLC–mass spectrometry (MS) analysis. The alkyl chain compositions of the 1-*O*-alkyl-2,3-isopropylidene glycerol derivatives were determined by GLC using a Perkin-Elmer 8420 gas chromatograph (Norwalk, CT) fitted with a FID and a flexible fused-silica Omegawax-320 (bonded polyglycol phase) open-tubular column (30 m × 0.32 mm i.d.; Supelco, Bellefonte, PA). The injector and detector were held at 250 and 270°C and the column at 210°C. The split ratio was 1:50. Helium was used as the carrier gas at a constant inlet pressure of 12 psig. Fatty acid compositions of the methyl esters of fatty acids were determined by GLC using the same instrument and column but with the following program of column temperature: initially 185°C for 8 min, then an increase in temperature of 3° per min to 230°C, and a final hold for 10 min. Helium was also used as the carrier gas at a pressure of 12 psig. The injection port and detector were maintained at 250 and 270°C, respectively, for all analyses. Only component fatty acids of biochemical or nutritional importance (27) are tabulated, but all GLC peaks were identified using authentic fatty acid methyl esters or other technology (21) and were converted to weight percentage by correcting for the FID response of different chainlengths (28).

For 1-*O*-alkylglycerol ether peak identification GLC–MS data were obtained using an ITD (Finnigan MAT 700 ion trap detector; San Jose, CA) operated with an IBM personal computer. The column was operated in a Perkin Elmer 990 gas chromatograph and passed through a heated transfer line to connect directly to the ITD. The column and isothermal conditions for the GLC part were the same as for the GLC–FID analysis of the isopropylidene derivatives.

RESULTS AND DISCUSSION

Atlantic salmon (*Salmo salar*) (29) and some other fish species, such as red sea bream, rockfish and globefish (30), have a limited capacity for chain elongation and desaturation of 18:3n-3 to 20:5n-3 and 22:6n-3 (7). These species therefore require a certain level of 20:5n-3 and 22:6n-3 in the diet. Although n-3 fatty acids are essential nutrients in salmonids generally (31), there might be an upper limit to the level at which n-3 fatty acids will promote healthy growth in salmonids [2.5% of the diet and higher (32)]. We (6,33) and others (34) have found that several types of fats are readily absorbed (15) by Atlantic salmon, but these have been practical diets including fish meal, etc. In this experiment the experimental period in our study of three weeks was too short to measure growth, but all fish accepted the semisynthetic diets and ate well except for a few hours after being handled.

Total fatty acids. The total fatty acids of the three dietary

Total polyunsaturated	19.8	19.5	18.6	10.9	11.2	11.3

[a]Mean and standard deviation of two analyses for diets, four analyses for feces.
[b]Added fats were: diet 1, dogfish liver oil only; diet 2, dogfish liver oil and herring oils mixed 1:1; diet 3, herring oil only.

fats (Table 2) were not radically dissimilar in most respects since the herring and dogfish share the same habitat, and the former is probably a major food item for the latter. The herring oil had higher levels of 22:1 than of 20:1 fatty acids, often a characteristic of this oil (35). The dogfish liver oil details resembled that for contemporary dogfish liver oil produced in Great Britain (4). In a report on Pacific dogfish liver oil (36), the 20:1 and 22:1 were much lower, and 18:1 much higher, than in the Atlantic oils. Other fatty acids were similar in proportions. The Atlantic dogfish liver oil had less 14:0 and more 18:0 than the herring oil, and also more 18:1n-9 but less 18:1n-7. All of these differences fitted the composition of the equal amounts of the oils blended for diet 2. The total fatty acids of the feces (Table 2) showed the same trends in the three saturated fatty acids, the 18:1 fatty acid, and the 22:1 fatty acids. In the latter a curiosity was the higher proportion of 22:1n-9 relative to 22:1n-(11+13) in the diets from the dogfish liver oil relative to those from the herring oil diet (Table 2). This was faithfully reproduced in the fecal fatty acids (Table 2). The ready absorption of 18:4n-3 is indicated by the two-thirds decrease of this polyunsaturated fatty acid which was similar to the excellent absorption of 20:5n-3. The 22:6n-3, in contrast, was presumably less well hydrolyzed and/or absorbed, but in all three cases the relative proportions among the three diets were preserved in the fecal total fatty acids. Overall the similarity in the composition of dietary fatty acids and those of feces reflected unhydrolyzed TAG as well as other lipid classes, but primarily unabsorbed FFA (Table 3).

In a previous study (15) we have confirmed the work of others, especially of Lie and Lambertsen (12) for cod to the effect that shorter chains of fatty acids were favored for hydrolysis and absorption over longer chain lengths among the saturated and monounsaturated fatty acids. We also had found the absorption of 20:5n-3 and 22:6n-3 to be excellent (≥95%). In the present study the digestibility of the saturated fatty acids declined with chainlength as expected (Fig. 1). The monounsaturated fatty acids followed suit. In the latter group the principal isomers 16:1n-7 and 18:1n-9 were almost equally well absorbed, but there was less absorption of 20:1 and even less of 22:1n-(11+13). Although the percentage numbers for digestibility for these two types of fatty acids were slightly less than those found previously in our laboratory (15) for Atlantic salmon, those of both 20:5n-3 and 22:6n-3 were again nearly the same with that of 20:5n-3 slightly exceeding 22:6n-3 (Table 4, Fig. 1). This was also found in Atlantic cod by Lie and Lambertsen (12). The total fatty acids and lipids were, in fact, both absorbed to the extent of approximately 85% (Fig. 1D). This argues for a minimal effect of the DAGE found in the dogfish liver oil on the total digestive process in Atlantic salmon.

Fecal lipids. Figure 2 compares the lipids of the three diets with the fecal lipids when examined qualitatively by plate TLC. An unexpected finding was the presence of cholesteryl

18:3n-3	88.8 ± 5.27	94.7 ± 1.34	89.4 ± 2.84
18:4n-3	94.2 ± 2.52	94.7 ± 1.34	94.7 ± 1.30
20:4n-3	90.8 ± 1.50	91.7 ± 2.24	88.4 ± 2.89
20:5n-3	95.6 ± 2.49	94.1 ± 1.43	93.6 ± 1.56
22:5n-3	90.2 ± 3.41	80.0 ± 5.47	76.5 ± 6.83
22:6n-3	87.0 ± 7.19	86.7 ± 3.17	87.2 ± 3.39
Total fatty acids	86.4 ± 3.00	85.1 ± 1.83	84.8 ± 3.43
Lipids[c]	84.2 ± 1.98	85.8 ± 2.77	86.2 ± 2.37

[a]Data are the mean ± SD of four determinations of the proportion (%) of the fatty acids.
[b]Added fats were: diet 1, dogfish liver oil only; diet 2, dogfish liver oil and herring oils mixed 1:1; diet 3, herring oil only.
[c]Digestibility of lipids is determined by comparing the proportion of lipid and cholestane content of dry weight feed and feces.

or wax esters in all three feces samples (Table 3). These could only be confirmed in the TLC/FID quantitative analysis by overloading, otherwise being at or below the lower limit of detectability (Fig. 3). Unhydrolyzed DAGE were also just barely visible on the plate in the lipids from feces of fish fed diets 1 and 2 but could not be definitely determined in the TLC/FID analysis (Table 3). It must be borne in mind that if the two acyl chains are hydrolyzed off the glycerol the mass of the original DAGE is diminished by two-thirds. Despite this having ~5% of the starting material mass of diet 1 as 1-*O*-alkyl diacylglycerol, it could not be resolved with certainty from the expected MAG by TLC/FID. In Figure 3, for example, the TLC/FID peak at or near the origin was nearly the same size, relative to other peaks, in all three sets of fecal lipids. This component peak of the fecal lipids was presumably mostly made up of MAG since DAGE were not included in diet 3. The FID response of TLC/FID is reduced by three of the carbons being already "oxidized," reducing their contribution for combustion in the flame (23).

FFA. The FFA in the dietary fats (Table 3) were so minor a proportion of the fat that they can be ignored when looking at the total picture. They are, however, the dominant lipid class in feces (Fig. 3). Table 3 also shows feces lipids from diet 3 having the lowest proportion of FFA, which in fact show a decrease from diet 1 through diet 2 to diet 3. Conversely there are offsetting increases in other lipid classes except polar lipids which also decrease. This argues for more extensive absorption of both FFA and polar lipids by the salmon receiving a diet supplemented with TAG only. The total lipid recoveries from feces were, respectively, 6.9 ± 0.7, 6.2 ± 0.08, and 6.3 ± 0.04 % (w/w) for diets 1, 2, and 3, somewhat in agreement with this suggestion.

The fatty acid compositions of the fecal FFA are given in Table 5 and may be compared with the total dietary fatty acids and the total fecal fatty acids of Table 2. There are no major differences that can be related to the digestive process and most numbers reflect those of the diets.

Digestion of TAG. It was unexpected to find intact TAG at approximately 10% of fecal lipids (Table 3), and of some interest to try and find compositional details revealing resistance to enzyme attack. Comparison of the dietary TAG with those recovered from the feces (Table 6) shows higher proportions of 20:1 and 22:1 fatty acids in the fecal TAG. These

[b]Added fats were: diet 1, dogfish liver oil only; diet 2, dogfish liver oil and herring oils mixed 1:1; diet 3, herring oil only.

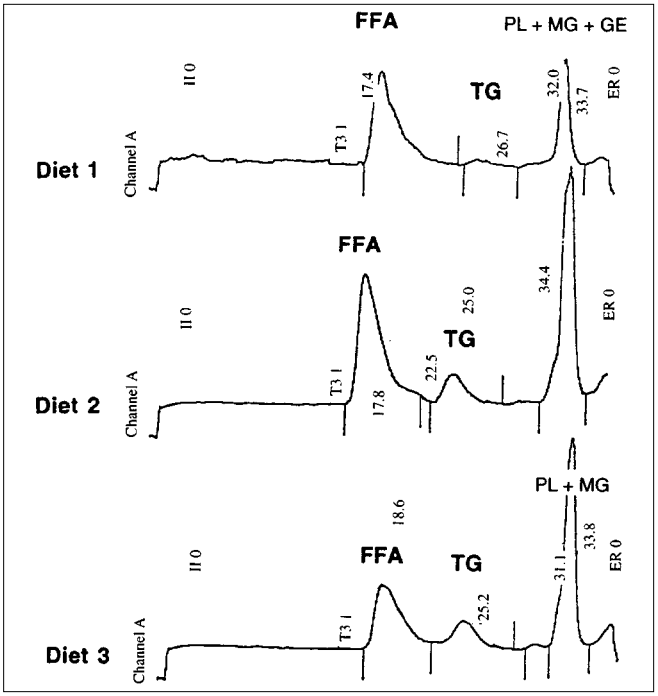

FIG. 3. TLC/FID chromatograms of the lipid classes in feces of Atlantic salmon fed different diets: diet 1 = dogfish liver oil; diet 2 = a mixture of dogfish liver oil and herring oil; diet 3 = herring oil. For operating conditions see text.

fatty acids are probably located in the *sn*-3 position on the glycerol (27), usually considered a focal point for attack by pancreatic lipase (37,38). There are, however, considerable reductions in the longer-chain polyunsaturated acids which formerly were thought to be principally located in the *sn*-2 position. It is now known that in fish oils these fatty acids can also be found in the *sn*-3 (and *sn*-1) positions on a modest proportion of the mixed TAG of fish oils (38). If so, they could have a positive effect on enzyme activity. A particularly interesting point is that 20:5n-3 is reduced much more than 22:6n-3 in the recovered fecal triglycerides. This fits the greater digestibility of the 20:5n-3 (Fig. 1C). Whether this is meaningful in terms of the effect of the position of the ethylenic bond nearest the carboxyl group (39) has led to much speculation (40), but the unequal distribution on glycerol may be a more likely reason. Our work with the DAGE may cast some light on this and other problems. For example, one hypothesis could be that the addition of the 1-*O*-alkyl DAG to diets 1 and 2 could lead to more persistent micelles in the digestive system, carrying more TAG along to the feces. Table 3 shows exactly the opposite effect, with MAG, DAG, and TAG all being highest in feces from diet 3 which was free of the DAG ethers. The higher proportion of long-chain monoenes may be a better explanation in this particular case.

Fatty acid composition of dietary 1-O-*alkyl DAGE*. The dogfish liver oil DAGE in diets 1 and 2 were recovered and examined for both acyl groups and the 1-*O*-alkylglycerol ester. Since the same oil was simply diluted, this fatty acid analysis provided a check on the methods of analysis and with the exception of 14:0, subject in most lipid procedures to losses from solubility and volatility (41) the results were reasonably coherent. A surprising feature (Table 7) was the high proportion (≤50%) of 22:5n-3 compared to 22:6n-3. This relationship is usually a property of oils from marine mammals (37,42). The TAG from the dogfish liver oil and the Atlantic herring oil showed the more usual ratio of about 1 part of 22:5n-3 to 5 parts of 22:6n-3 (Table 6). The 20:5n-3 of the fatty acids of DAGE seemingly was reduced relative to the amount in the TAG, with the total for these two pentaenoic fatty acids being approximately equal to the 22:6n-3 in DAGE both before and after passage through the fish. The conversion of 20:5n-3 to 22:6n-3 is now thought to go through 22:5n-3, 24:5n-3, and 24:6n-3 (43). Since the GE are biosynthesized in the dogfish liver, there seems to be a degree of specificity for the DAGE of a failed attempt to increase 22:6n-3. The corresponding TAG acyl groups are closer to the norm for fish oils (44,45) and presumably reflect dietary fatty acid intake.

Digestion of DAGE. Unexpectedly the 16:1n-7 was increased two or threefold in the fatty acids of the DAGE recovered from the feces (Table 8), compared to the diet figures (Table 7), possibly also leading to a slight enrichment of 18:1n-7 relative to 18:1n-9. Unlike fecal TAG, both 20:1 and 22:1 were slightly lower in the fecal DAGE than in the diet DAGE. The figures for the polyunsaturated acids did not agree very well for the fecal DAGE from the two diets (Table 8). However the 22:5n-3, relative to 22:6n-3, was rather high for fish oils in both DAGE. Both 20:4n-6 and 20:5n-3 may have resisted digestive hydrolysis (*cf.* Table 7). By including 18:4n-3 in these comparisons, it seems likely that in DAGE polyunsaturated fatty acids with ethylenic bonds in the Δ4 (22:6n-3), (22:5n-6), Δ5 (20:5n-3), (20:4n-6), and Δ6 (18:4n-3) positions resist hydrolysis, while that with the bond in the Δ7 position (22:5n-3) is more readily hydrolyzed by Atlantic salmon digestive enzymes. In the TAG (Table 6), the 22:5n-6 (Δ7) seemed to resist hydrolysis compared to 18:4n-3, 20:5n-3, 22:5n-3, and 22:6n-3. This view is within the polyunsaturated groups which otherwise were well absorbed (Table 4).

1-O-*Alkylglycerol ethers*. Tables 7 and 8 also provide a comparison of the glyceryl ether skeletons of the DAGE. The original composition is typical of marine GE (10,45). Compared to the triglycerides, FFA, and diacyl fatty acids of the DAGE, the 16:1n-7 in the alkyl chains seem to be very high (Tables 7 and 8), but does not affect the 18:1n-9/18:1n-7 ratio. An unusual feature not previously reported for marine GE is the isomer compositions of the 20:1 chains. The 20:1n-7 isomer exceeds the 20:1n-9 isomer. As expected, the 20:1n-9 was higher in each case than the adjacent 20:1n-11 shoulder (Table 7, not shown separately) but actual numbers for n-11, n-9, and n-7 were 0.50, 2.31, 5.20 for diet 1; 0.35, 3.35, 6.55 for diet 2. The proportions of all components, including these isomers (not shown in detail) were very similar in the alkyl chains of the DAGE recovered from the feces. Other than the

presumed origin in 16:1n-7, no explanation can be offered for this proportion of 20:1n-7 in the GE alkyl chains. Unfortunately Lie and Lambertsen (12) do not include these details. The 22:1 alkyl chains were very minor components and isomer ratios not very reliable. The C_{18} polyunsaturated alkyl chains of the GE in the diets (Table 7) did not appear in the DAGE of the feces, but were observed in the GE of the feces (Table 8). This difference is likely an artifact of manipulative oxidation of the DAGE and is not considered metabolically important. Digestion did not obviously affect the GE alkyl chain composition.

Serum and muscle lipids. Major lipid class results for diet, feces, chylomicron, and muscle are compared in Figure 4. The analysis of the recovered chylomicrons (Tables 3 and 9, Fig. 4) showed that TAG and DAGE were absorbed and circulated in chylomicrons roughly in accord with proportions in the diet. This did not influence the TAG, sterols, or sterol esters, but may have had some slight effect on the serum polar lipids. Given the large standard deviation of data for this lipid class (Table 3), such an effect may be an artifact of the method.

The fatty acids of the chylomicron lipids were almost identical for all three diets, so only those for the fish on diet 1 are presented (Table 9). The total lipid fatty acids would be influenced by the fatty acids of the stable polar lipids, presumably high in 22:6n-3. The TAG did not show a composition very close to the dietary total fatty acids of Table 2, presumably having been selectively hydrolyzed from original TAG positions and reassembled with the inclusion of fatty acids already circulating in the fish. Probably different lipids were hydrolyzed and absorbed at different points in the intestine, and some fatty acids (saturated, monoethylenic) could be biosynthesized by the salmon. The fatty acids of the chylomicron DAGE showed a strong emphasis on saturated fatty acids, mostly at the expense of the monoethylenic fatty acids, and were also depleted in polyunsaturated fatty acids compared

[a]Includes 22:1n-9; TAG, triacylglycerols. See Table 3 for other abbreviation.

to those of the TAG. These details suggest selective hydrolysis of the original structure, but it is not known if this is an effect in the intestine or in the intestinal wall, where absorption of residual 1-*O*-alkylglycerol might be expected or on reesterification as proposed by Lie and Lambertsen (12) for cod. A noteworthy feature of the 1-*O*-alkyl GE of the chylomicron DAGE is the inclusion of a peak in the position for 20:1n-7. This component was also apparent in the Tables 7 and 8 results for the original and fecal DAGE and GE. Probably the 18:1n-7 alkyl chain is also increased in the fecal GE relative to 18:1n-9, lending support to the proposed structure 20:1n-7. Compared to dietary GE (Table 7), 22:1 GE was unexpectedly high in the chylomicrons. In cod chylomicrons, the GE 20:1 was elevated relative to diet, but was reported as 20:1n-11 while 22:1 was not listed (12).

The muscle lipids were dominated by TAG to the extent that direct measurement of DAGE by TLC/FID was not practical. Accordingly the total muscle lipid was saponified and the unsaponifiable were recovered. The extremely low uptake of DAGE by muscle is reassuring. Many highly regarded fish and shellfish food products contain low levels of either 1-*O*-alkyl- or 1-*O*-alkenyldiacylglycerols (e.g., 11), and it is evident that the traces in salmon muscle would not be objectionable.

Conclusions. Overall, we anticipated that the liver oil of Atlantic dogfish would be similar to that of the Pacific dogfish, widely regarded as the same species (46). That oil also contained DAGE and included 10–15% longer-chain n-3 fatty acids that could be liberated by saponification of both TAG and DAGE (36). Atlantic dogfish liver oil is a very underutilized by-product of one of the few remaining fish stocks in the Atlantic coast of Canada and the United States. It has 1-*O*-dialkylglycerol ethers with industrial potential (47). However the TAG fatty acid composition is virtually the same as that of herring oil, providing sufficient longer chain ω-3 fatty acids for the growth and health of farmed Atlantic salmon. The fatty acids of the DAGE are similar and are liberated by digestive enzymes in this species and add to the supply. The residual 1-*O*-alkylglycerol ethers are adsorbed and circulated to a limited extent but are not deposited to any extent in the edible muscle of the salmon. Thus, dogfish liver oil should be entirely satisfactory as a lipid source for incorporation in Atlantic salmon feeds.

ABSTRACT: The influence of diet on the kinetics of the overt form of rat liver mitochondrial carnitine palmitoyltransferase (CPT I; EC 2.3.1.21) was studied using rats fed either a low-fat diet (3% w/w fat), or diets which were supplemented with either olive oil (OO), safflower oil (SO) or menhaden (fish) oil (MO) to 20% w/w of fat (high fat diets). When animals were fed each of these four diets for 10 days, the order of the apparent maximal activity (v_{max}) of CPT I toward various individual fatty acyl CoA, when measured under a fixed molar ratio of acyl CoA/albumin, was 16:1n-7>18:1n-9 >18:2n-6>16:0>22:6n-3, and was thus not affected by the fat composition of the diet. However, in all but one case, the SO and MO diets elicited a higher v_{max} for each substrate than either the LF diet or the high fat OO diet. The apparent $K_{0.5}$ for the different acyl CoA esters was generally lowest in LF-fed animals, and highest in those fed the high-fat SO diet. Moreover, when compared with the situation of animals fed high-fat diets, the $K_{0.5}$ values of CPT I in LF-fed animals for palmitoyl CoA and oleoyl CoA were low. This possession by CPT I of a high "affinity" toward these nonessential fatty acyl CoAs, but a lower "affinity" toward linoleoyl CoA, the ester of an essential fatty acid, may enable this latter fatty acid to be spared from oxidation when its concentration in the diet is low. The data also emphasize that palmitoleoyl CoA, if available in the diet, is likely to be utilized by CPT I at a high rate.
Lipids 32, 31–37 (1997).

The overt form of carnitine palmitoyltransferase (CPT I; EC 2.3.1.21) catalyzes the reaction that commits to oxidation, within the mitochondria, the long-chain acyl CoA esters that are formed in the cytosol (1), and thus occupies a key regulatory step in the metabolism of long-chain fatty acids. CPT I has been shown to display different kinetic properties toward different acyl CoA, thereby determining the extent to which these compounds serve as substrates for β-oxidation (2,3). Since the maximal activity (v_{max}) and the substrate concentration at which one-half maximal activity is attained ($K_{0.5}$) differ for individual acyl CoA, the ultimate flux through CPT I to β-oxidation *in vivo* is determined by the relationship between the relative maximal activity and affinity of this enzyme for each potential substrate.

Although there have only been a few studies of the substrate selectivity of CPT I, it is evident that this selectivity can differ markedly between species. For example, whereas the relative activity of rat liver CPT I is 18:3n-3>18:2n-6> 20:5n-3≈16:0>20:4n-6>18:1n-9>22:6n-3>18:0 at 10 μM (2), that of the Antarctic fish *Notothenia* sp. is 16:1n-7> 20:5n-3>18:2n-6≈18:1n-9>22:6n-3>20:4n-6>18:3n-3 (3). Moreover, the relative activity of this enzyme toward C_{22} polyunsaturated acyl CoA of the n-3 series is low in the rat (2), but relatively high in *Notothenia* sp. (3). Likewise, in comparison with the substrate preference of CPT I in rat liver, the activity of this enzyme in *Notothenia* sp. is also relatively high toward other marine-type fatty acids such as 16:1n-7 and 20:5n-3, but relatively low toward 18:3n-3.

Evidence that CPT I displays a marked difference in its kinetic behavior toward various acyl CoA and that the pattern of substrate preference differs between species whose diets are qualitatively different suggests that the kinetic characteristics of this enzyme may be determined by the fatty acid composition of the diet. This could be achieved either through the expression of enzyme more favorably disposed to particular fatty acyl CoA, or by changes to the biophysical properties of the outer mitochondrial membrane, in which certain domains of the CPT I protein reside (1).

Previous work has shown that the v_{max} of CPT I toward palmitoyl CoA and the sensitivity of this enzyme to inhibition by malonyl CoA are influenced profoundly by the fatty acid composition of the diet (4). It also demonstrated that, of a range of different high-fat diets, the one which was supplemented with safflower oil to 20% w/w of fat encouraged highest CPT I activity toward palmitoyl CoA. Since diet directly influences the composition of the cytosolic acyl CoA pool available to CPT I in the liver, it might be advantageous if the kinetics of this enzyme were able to reflect a preference for the predominant types of fatty acid in the diet, thus regulating the types of fatty acids that are oxidized when the relative

Abbreviations: BSA, bovine serum albumin; CPT I, overt form of mitochondrial carnitine palmitoyltransferase, $K_{0.5}$, total substrate concentration at which one-half maximal velocity (v_{max}) is attained; LF, low fat; MO, menhaden oil; OO, olive oil; SO, safflower oil.

proportions and/or tissue content of the fatty acids change. The influence of certain fat diets on the level of CPT I activity in the liver, which determines the partitioning of acyl CoA between oxidation and esterification, has been examined recently by Moir *et al.* (5). By employing the elegant procedure of labeling the acyl moiety of cholesteryl esters incorporated into apoC-depleted lipoproteins (6), Moir *et al.* (5) encouraged a labeled acyl group ([1-^{14}C]-oleate) to be taken up selectively by the liver. Their results showed that the partitioning of the acyl group was diet-dependent. However, the extent to which these differences are determined by the specific kinetic properties of CPT I at the "branchpoint" between oxidation and esterification is yet to be established.

Thus, the present study has examined the influence of diet on the kinetic behavior of CPT I using acyl CoA esters of a range of fatty acids which differed in chain length and/or the extent of unsaturation. The acyl CoA were synthesised enzymatically by employing the acyl CoA synthetase method of Crockett and Sidell (3), and used subsequently as substrates for estimating CPT I activity by the standard radiochemical assay (7). However, a constant 6.1:1 molar ratio of acyl CoA/albumin was adopted to enable the apparent ν_{max} and $K_{0.5}$ values to be determined more accurately (see below for rationale). Comparisons between the maximal activities and $K_{0.5}$ values of CPT I toward different acyl CoA substrates, in animals maintained on different diets, indicate that the kinetic behavior of this key regulatory enzyme is influenced by the fatty acid composition of the diet.

TABLE 1
The Fatty Acid Composition of the Experimental Diets[a]

	Composition of the diets (mol%)			
Fatty acids	LF	OO	SO	MO
12:0	2.2	—	2.2	—
14:0	2.4	—	0.4	10.9
16:0	31.6	11.0	11.8	24.7
16:1n-7	—	—	—	16.9
18:0	7.4	3.9	4.4	4.4
18:1n-9	21.1	69.9	20.8	13.8
18:2n-6	31.5	15.2	60.4	5.5
18:3n-3	—	—	—	2.3
18:3n-6	—	—	—	—
20:5n-3	—	—	—	11.7
22:6n-3	—	—	—	5.2
Others	3.8	—	—	4.6

[a]Lipid from a sample of each diet was extracted using chloroform/methanol (2:1, vol/vol). Fatty acids were prepared by saponification in methanolic KOH and extracted into ethyl acetate. Fatty acids were then methylated using diazomethane, and the fatty acid methyl esters were analyzed by gas chromatography as described previously (4). Data are the mean of two determinations. (—) indicates not detected. Abbreviations: LF, low-fat control diet; OO, olive oil diet; SO, safflower oil diet; and MO, menhaden oil diet. Where a fatty acid was detected at less than 0.2 mol%, it was included in the minor category "Others."

MATERIALS AND METHODS

Animals and diets. Male weanling Wistar rats (40–50 g) were purchased from the Animal Resource Centre (Perth, Western Australia) and housed under temperature-controlled conditions. They were exposed to a 12-h light–dark cycle and provided for 10 d with one of four experimental diets.

The low-fat (LF) semisynthetic diet contained 3% w/w basic fat (1% beef tallow + 1% safflower oil + 1% corn oil), 52% w/w carbohydrate (20.8% corn starch + 31.2% sucrose), 16% w/w protein (sodium caseinate), and 29% w/w nondigestible material (cellulose). The three high-fat diets were supplemented to a total of 20% w/w fat, using either olive oil (OO), safflower oil (SO), or menhaden oil (MO). The high-fat diets contained the same amounts of carbohydrate, basic fat and protein, but the amount of nondigestible material was lowered proportionately to accommodate the increased fat content. The fatty acid composition of LF, OO, SO, and MO diets are given in Table 1. All diets contained 1.2 g · kg^{-1} vitamin E as an antioxidant, and adequate amounts of vitamins and minerals. The weight gain and food intake of all animals were monitored throughout the experimental period and did not differ significantly between animals on each of the four diets. Animals were killed by CO_2 asphyxiation.

Chemicals. The L-[methyl ^{3}H]-carnitine hydrochloride was supplied by the Radiochemical Centre (Amersham, Buckinghamshire, United Kingdom). Oleic acid (sodium salt), linoleic acid (sodium salt), palmitoleic acid (free acid), docosahexaenoic acid (free acid), palmitoyl CoA, and all other biochemicals were purchased from the Sigma Chemical Co. (St. Louis, MO). The sucrose and butanol were supplied by BDH Chemicals (Poole, United Kingdom), and the acyl CoA synthetase (*Pseudomonas* spp.) by Boehringer (Mannheim, Germany).

*Synthesis of fatty acid salts***.** Since fatty acid salts were required for the enzymatic synthesis of acyl CoA esters (3), the fatty acids that were unavailable commercially as salts (palmitoleic acid and docosahexaenoic acid) were converted into their corresponding potassium salts by reacting them with a 30% molar excess of potassium (as 0.1M KOH) at 60°C under a gentle stream of nitrogen. For example, in the case of palmitoleic acid, the fatty acid was dissolved in ethanol (10 mg/mL) with gentle mixing, and a 0.016 mL aliquot (0.16 mg) removed and added to 0.5 mL ethanol plus 0.020 mL 0.1 M ethanolic KOH. The solvents were evaporated under a gentle stream of nitrogen, and the dry salt of the fatty acid was stored in a sealed vial under nitrogen at −80°C until use (within 24 h).

Synthesis of acyl CoA esters. Acyl CoA esters were synthesized by a modification of the method of Crockett and Sidell (3). The reaction mixtures for the syntheses contained 0.62 mM sodium or potassium salt of a fatty acid, 0.7 mM CoASH, 5 mM ATP, 20 mM $MgCl_2$, 0.5 units acyl CoA synthetase/mL (1 unit = 1 µmol of product formed/min) in 150 mM Tris-HCl (pH 7.8 at 25°C). (Subsequently it was found that when fatty acids were converted to their potassium salt immediately prior to esterification they were more readily esterified to their corresponding acyl CoA.) Butylated hydroxytoluene (BHT) was included in the synthesis at 0.005% wt/vol to prevent oxidation of the unsaturated acyl chains. The syn-

theses were conducted at 25°C, with occasional, gentle agitation to maintain complete solubilization of the fatty acids.

The extent to which each fatty acid salt was esterified was monitored periodically by following the reduction of 5,5′-dithiobis-(2-nitrobenzoic acid) by residual CoASH at 412 nm in samples of the reaction mixture as described by Bar-Tana *et al.* (8). A 1.5 mM solution of 5,5′-dithiobis-(2-nitrobenzoic acid) was prepared in 150 mM Tris-HCl (pH 7.8 at 25°C). The results of these biosyntheses are given in Figure 1. Once fully converted, each fatty acyl CoA was diluted to 500 µM with a stock bovine serum albumin (BSA) solution (prepared in deionized H_2O) to achieve an acyl CoA/BSA molar ratio of 6.1:1 and then frozen at –80°C until use.

The preparation of mitochondria. Animals, which had been on one of the four experimental diets for 10 d, were killed at 0800 hours at the end of the dark phase. Liver mitochondria were prepared as previously described (4) using a method which substantially reduces contamination by other organelle sources of CPT activity. Protein was measured by the method of Gornall *et al.* (9) but with a 30-min preincubation of all mitochondrial aliquots with 2.0 M NaOH to ensure that the protein was completely solubilized prior to assay.

CPT I assay. The activity of CPT I was measured in the direction of radiolabeled acylcarnitine formation using a procedure similar to that of Grantham and Zammit (7). This method is frequently chosen because of the ease with which the co-substrate (labeled carnitine) can be separated from the reaction product (labeled acylcarnitine), and because the activity of palmitoyl CoA hydrolase does not interfere with this system as much as it does when labeled palmitoyl CoA is used as a tracer (10). Albumin is a necessary ingredient in the assay because it stabilizes the outer mitochondrial membrane by reducing the detergent properties of acyl CoA, thus minimizing any contribution of CPT II to the assay (11). However, in the presence of fixed amounts of albumin in the assay medium, CPT I can demonstrate an activity vs. substrate concentration plot that is sigmoidal because albumin competes with the enzyme for binding to free acyl CoA substrate. The apparent sigmoidicity seen by some workers (10,12) has thus been attributed to substrate binding by albumin (10). At low acyl CoA concentrations, binding sites on albumin may compete very effectively for acyl CoA, resulting in an underestimation of the actual CPT I activity for the total concentration of acyl CoA in the assay medium. At higher concentrations, the binding sites on albumin become saturated, thus "relinquishing" more substrate to CPT I and thereby enabling relatively higher activities to be detected (13). Thus, as acyl CoA concentration increases under conditions of a fixed amount of albumin, increasing CPT I activity is due to increasing ratios of free to bound acyl CoA. It has therefore been concluded that this increasing molar ratio of acyl CoA/albumin, rather than the total concentration of acyl CoA present, is responsible for the sigmoidal relationship (10).

In order to "correct" for this artifactual sigmoidicity, Pauly and McMillin (10) measured CPT I against increasing concentrations of palmitoyl CoA, but at a number of different fixed ratios of palmitoyl CoA/albumin. Since Scatchard analysis has shown that albumin possesses five or six high-affinity binding sites for palmitoyl CoA, a 6.1:1 molar ratio of palmitoyl CoA/albumin was chosen by Pauly and McMillin (10) in order to saturate almost completely the binding capacity of albumin and yield an activity-vs.-substrate concentration plot for CPT I that is hyperbolic. Under these conditions, a Lineweaver-Burk plot is linear, from which a more accurate ν_{max} and $K_{0.5}$ can be determined. However, it must be recognized that, although fixing the molar ratio of acyl CoA to albumin ensures consistent competition between albumin and the enzyme for free acyl CoA, the precise free concentration remains unknown. It is also not known whether the affinity of albumin varies for the different acyl CoA. Consequently, the terminology "apparent ν_{max}" for the maximal activity, and "apparent $K_{0.5}$" for the total substrate concentration at which half-maximal enzyme activity is attained, has been adopted in agreement with other workers (2,10,14).

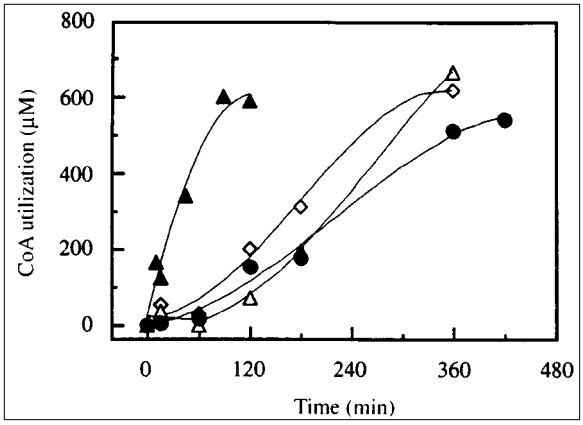

FIG. 1. The utilization of CoA against time by acyl CoA synthetase. Acyl CoA esters were synthesised *in vitro* using purified acyl CoA synthetase from *Pseudomonas* sp. The fatty acid concentration available for esterification to CoA was 0.62 mM in each case. Data represent a single synthesis of each acyl CoA ester by 0.5 Units of enzyme. Acyl CoA esters of the following fatty acids were synthesized: palmitoleic acid (16:1n-7, ▲), oleic acid (18:1n-9, ●), linoleic acid (18:2n-6, △), and docosahexaenoic acid (22:6n-3, ◇). See the Materials and Methods section for a full explanation of the assay system.

RESULTS

Substrate saturation curves for CPT I. Substrate saturation curves for the hepatic CPT I activity, in animals fed either a LF, OO, SO or MO diet and when assayed in the presence of a 6.1:1 molar ratio of acyl CoA/albumin, are presented in Figure 2. CPT I exhibits hyperbolic kinetic behavior over the range of concentrations chosen for each acyl CoA.

The mean ν_{max} for palmitoyl CoA (16:0) decreased in the following order of diets MO>SO>LF>OO (Table 2). The apparent $K_{0.5}$ for palmitoyl CoA of the CPT I of each group of animals decreased in the order SO>MO>OO>LF (Table 3).

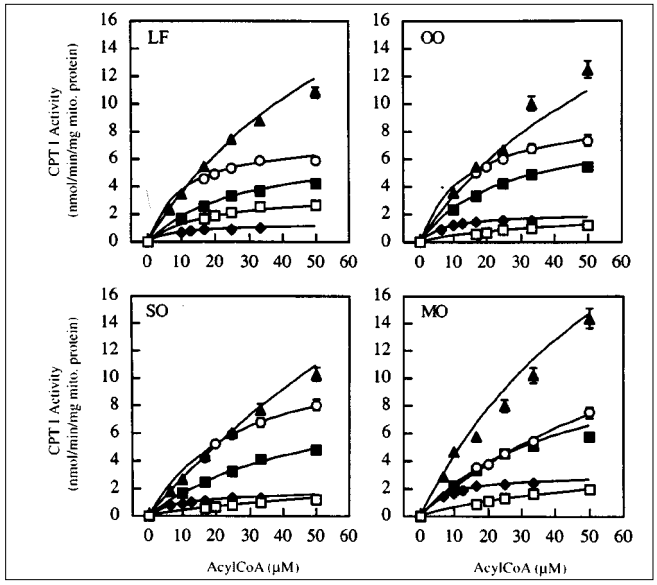

FIG. 2. Liver mitochondrial CPT I activity as a function of acyl CoA concentration. Rats were fed for 10 d on either an LF or one of three high-fat diets, and liver mitochondrial CPT I activity was measured. Michaelis-Menten curves were constructed from the activity of CPT I toward different acyl CoA substrates at a range of concentrations, and at constant ratio (6.1:1) of acyl CoA/BSA. The following acyl CoA were used: palmitoyl CoA (16:0, □), palmitoleoyl CoA (16:1n-7, ▲), oleoyl CoA (18:1n-9, ○), linoleoyl CoA (18:2n-6, ■) and docosahexaenoyl CoA (22:6n-3, ◆). See the Materials and Methods section for a full explanation of the assay system.

Since the mean $K_{0.5}$ of LF-fed animals for 16:0 is 2- to 6-fold lower than that of animals fed high-fat diets, CPT I activity is likely to saturate at a much lower endogenous concentration of palmitoyl CoA within the liver of these animals.

The decreasing order of the mean ν_{max} toward palmitoleoyl CoA (16:1n-7) was SO>MO>LF>OO (Table 2). Activity toward this acyl CoA, like that for palmitoyl CoA, was higher in SO- and MO-fed animals than in OO- and LF-fed animals (Table 2). The order of the apparent $K_{0.5}$ for palmitoleoyl CoA, which is SO>MO≈OO≈LF, revealed that the $K_{0.5}$ of the enzyme for this acyl CoA in LF-, OO-, or MO-fed animals did not differ greatly (Table 3). However, for animals fed SO, the CPT I had an approximately 2.5-fold higher $K_{0.5}$ for palmitoleoyl CoA.

TABLE 2
The Effect of Diet on the Apparent ν_{max} of Mitochondrial CPT I for Different Acyl CoA Substrates[a]

Acyl CoA	ν_{max} of CPT I ± SEM (nmol · min^{-1} · mg mitochondrial protein^{-1})			
	LF	OO	SO	MO
16:0	3.7 ± 0.2[b]	2.2 ± 0.2	4.2 ± 1.1	4.5 ± 0.7[b]
16:1n-7	30.0 ± 5.3	27.6 ± 2.6	53.9 ± 6.8[a,b]	37.7 ± 2.0[b]
18:1n-9	7.5 ± 0.3	9.5 ± 0.2[a]	12.5 ± 0.8[a,b]	22.6 ± 1.9[a,b,c]
18:2n-6	7.3 ± 0.5	8.8 ± 0.3	10.1 ± 1.5	13.0 ± 0.4[a,b]
22:6n-3	1.3 ± 0.1	2.1 ± 0.2[a]	1.8 ± 0.1[a]	3.0 ± 0.6[a]

[a]Rats were fed for 10 d on either a LF diet or one of three high-fat diets, and the ν_{max} of mitochondrial CPT I for each of five different acyl CoA substrates was determined from Lineweaver-Burk plots. Data are the mean ± SEM from three animals fed each diet. Statistical significance was determined using analysis of variance and an unpaired Student's *t*-test: a value for $P < 0.05$ was taken to indicate significance. Where they occur, significantly higher values of the ν_{max} of CPT I for individual acyl CoA substrates are indicated as follows: [a]vs. LF; [b]vs. OO; and [c]vs. SO. See the Materials and Methods section for an explanation of the diet composition, mitochondrial preparation, and assay method.

TABLE 3
The Effect of Diet on the Apparent $K_{0.5}$ of Mitochondrial CPT I Toward Different Acyl CoA Substrates[a]

Acyl CoA	$K_{0.5}$ of CPT I ± SEM (μM)			
	LF	OO	SO	MO
16:0	19.8 ± 1.9	44.2 ± 6.3[a]	114.2 ± 14.4[a,b,d]	65.2 ± 12.2[a]
16:1n-7	77.1 ± 19.1	77.6 ± 22.5	197.7 ± 24.1[a,b,d]	78.6 ± 2.7
18:1n-9	10.4 ± 1.3	14.5 ± 1.7	28.8 ± 1.7[a,b]	103.7 ± 18.9[a,b,c]
18:2n-6	31.4 ± 3.5	27.9 ± 3.4	54.9 ± 13.6	49.1 ± 2.9[a,b]
22:6n-3	8.4 ± 1.7	8.8 ± 0.8	11.2 ± 1.9	7.4 ± 2.0

[a]Rats were fed for 10 d on either a LF diet or one of three high-fat diets, and the $K_{0.5}$ of mitochondrial CPT I for each of five different acyl CoA substrates was determined from Lineweaver-Burk plots. Data are the mean ± SEM from three animals fed each diet. Statistical significance was determined using analysis of variance and an unpaired Student's *t*-test: a value for $P < 0.05$ was taken to indicate significance. Where they occur, significantly higher values of the $K_{0.5}$ of CPT I for individual acyl CoA substrates are indicated as follows: [a]vs. LF; [b]vs. OO; [c]vs. SO, and [d]vs. MO. See the Materials and Methods section for an explanation of the diet composition, mitochondrial preparation, and assay method.

The hepatic CPT I of all animals fed high-fat diets displayed a higher ν_{max} toward oleoyl CoA (18:1n-9) than LF-fed animals (Table 2). The decreasing order was MO>SO>OO>LF, with MO-fed animals exhibiting an approximately 3-fold higher mean ν_{max} than LF-fed animals. The concentration of substrate required to half-saturate the enzyme decreased in the order MO>>SO>OO≈LF (Table 3). Thus, the CPT I of animals fed either the LF or OO diet shared a similar $K_{0.5}$ for this acyl CoA. The enzyme of the SO-fed animals displayed a 2- to 3-fold higher $K_{0.5}$ for 18:1n-9, whereas that of the MO-fed animals exhibited a much higher $K_{0.5}$, being 7- to 10-fold higher.

The ν_{max} of CPT I toward linoleoyl CoA (18:2n-6) did not differ significantly between animals fed either a LF, OO, or SO diet (Table 2). Although the ν_{max} of the enzyme toward this substrate was significantly higher in animals fed the MO diet, the magnitude of the difference was small compared with other substrates such as oleoyl CoA. The apparent $K_{0.5}$ of the enzyme did not differ significantly between the LF, OO, and SO diets, whereas that of the MO-fed animals was marginally higher (Table 3).

The activity of CPT I toward docosahexaenoyl CoA (22:6n-3) was significantly higher in animals fed high fat diets than in those fed the LF diet, although generally, the ν_{max} toward this acyl CoA was relatively low for all animals (Table 2). The $K_{0.5}$ of the enzyme toward this substrate was also relatively low, with the half-saturating substrate concentration being similar in all animals (Table 3).

Thus, a consistent pattern in the ν_{max} of the enzyme for

each substrate is evident irrespective of which diet the animals were provided. The substrate for which the enzyme activity is highest is palmitoleoyl CoA, followed by oleoyl CoA, linoleoyl CoA, palmitoyl CoA, and docosahexaenoyl CoA (i.e., 16:1n-7>18:1n-9>18:2n-6>16:0 >22:6n-3). Moreover, the ν_{max} of CPT I toward all substrates was higher in animals fed either a high-fat SO or MO diet, when compared with that of animals fed either a LF or a high-fat OO diet (with only one exception, namely the ν_{max} towards 22:6n-3 of the OO- vs. SO-fed animals; Table 2). Wherever there were significant differences in the apparent $K_{0.5}$ for particular acyl CoA, the CPT I of animals fed the LF diet had a lower apparent $K_{0.5}$ than that of animals fed any of the high-fat diets (with the single exception of the $K_{0.5}$ values for 18:2n-6). Furthermore, for four of the five acyl CoA, the $K_{0.5}$ values were highest in those animals fed a high-fat SO diet (Table 3).

DISCUSSION

The range recorded in the present study of the apparent $K_{0.5}$ for palmitoyl CoA, the standard acyl CoA used in assays of CPT I, was 20–114 μM, which extends beyond the range of 30–60 μM reported by McGarry *et al.* (15), for rats fed a standard chow diet, as well as the values of 48 μM (16) and 60 μM (14) that were reported more recently. Higher values of $K_{0.5}$ for palmitoyl CoA have been reported in mitochondria from the liver of rats subjected to starvation (17,18), indicating that dietary manipulation can lead to higher $K_{0.5}$ values. It should be noted, however, that $K_{0.5}$ values from different laboratories are not strictly comparable due to differences in the albumin concentrations used in the assay, the level of which would modify the free concentration of acyl CoA available to CPT I. One should also be aware that since free CoA has been shown to inhibit CPT I activity (19), it is possible that the $K_{0.5}$ values may have been influenced by residual CoA in the acyl CoA preparations. However, this effect was probably negligible in the present investigation because free CoA is known to be highly unstable under the conditions in which the acyl CoA solutions were prepared and stored (20).

Although the data of the present investigation suggest that some fatty acyl CoA may be used preferentially by CPT I when animals are given particular diets, it is not possible to extrapolate the *in vitro* kinetic data of CPT I to the precise fatty acyl CoA partitioning that is likely to occur *in vivo*. In order to do so, it would be necessary to assess the potential influence that the diet may have on other processes that determine the free levels of acyl CoA within the liver. Thus, the relative amounts of different acyl CoA within the liver will be determined not only by the fatty acid composition of the diet but also, for example, by the extent to which individual fatty acids are absorbed, incorporated into chylomicrons, released to the peripheral tissues by lipoprotein lipase, directed to the liver as components of chylomicron "remnant" particles, and ultimately converted to acyl CoA by acyl CoA synthetase.

The decreasing order of the ν_{max} of CPT I for the different acyl CoA remained consistently as 16:1n-7>18:1n-9>18:2n-6>16:0>22:6n-3, irrespective of diet. However, the ν_{max} of CPT I toward all substrates was higher in animals fed either a high-fat SO or MO diet, when compared with those of animals fed a LF diet. It is possible that the fatty acids in these high-fat diets increased the transcription of CPT I mRNA, as has been recently reported (21), thereby increasing the enzyme concentration. However, since the increased ν_{max} were accompanied by alterations in the $K_{0.5}$ values, other mechanisms are likely to have contributed to the overall effect of these two diets. This is consistent with the observation that the OO diet generated only modest changes in the ν_{max} values, even though oleic acid, a major component of this diet, is equipotent with other long-chain fatty acids at inducing CPT I mRNA (21). It is well established that the fatty acid composition of the mitochondrial membranes is influenced by the relative contributions of the dietary fatty acids (22). CPT I interacts strongly with the outer mitochondrial membrane, and its kinetics are determined to some extent by the nature of the membrane lipids (1). It is thus possible that the diets used in the present study may have affected the biophysical properties of the outer membrane, thereby altering the conformation of CPT I resulting in a modification to its kinetic properties toward different acyl CoA.

A further possibility is that the high-fat diets may have influenced the malonyl CoA-sensitivity of CPT I, an important locus of control of this enzyme. The fact that polyunsaturated fatty acids have been found to reduce both the malonyl CoA content of liver (23) and the sensitivity of hepatic CPT I to inhibition by this ligand (4,24) may favor the oxidation of these acyl CoA when such fatty acids are consumed. A lower endogenous malonyl CoA concentration, and hence greater flux through CPT I, has been suggested by Moir *et al.* (5) to account for the decreased esterification of acyl CoA seen in liver following fish oil feeding in rats. A significantly lower sensitivity to malonyl CoA inhibition has been observed after 2 d of feeding rats on high unsaturated-fat diets similar to those used in the present investigation, when compared with animals fed either a LF diet or a high-fat diet containing a predominance of saturated fatty acids (25). The influence that the lipid components of the outer mitochondrial membrane has on the ability of malonyl CoA to transmit a conformational change to the CPT I protein is discussed elsewhere (26). It may also be possible that, since the malonyl CoA-sensitivity of CPT I appears to differ according to the type of acyl CoA utilized (27), the pattern of partitioning of acyl CoA between oxidation and esterification *in vivo* may be determined by an interplay between the composition of the acyl CoA pool and the prevailing malonyl CoA concentration.

The data show that animals given a high-fat diet demonstrate a higher CPT I activity toward the essential fatty acid 18:2n-6, when compared with animals fed a LF diet. This difference is evident in spite of the fact that the LF diet used in the present study contained amounts of 18:2n-6 considered to be adequate for normal requirements. Since CPT I in LF-fed animals possesses a comparatively high $K_{0.5}$ and a low ν_{max}

toward 18:2n-6, this may permit the sparing of this acyl CoA from β-oxidation, thus conserving this fatty acid for essential cellular processes (e.g., for the synthesis of arachidonic acid, a key component in phospholipids). Sparing of linoleic acid could also be achieved if the affinities of the mitochondrial and microsomal forms of glycerol phosphate acyltransferase, which commit acyl CoA to esterification to diacylglycerol, are comparatively higher than that of CPT I.

The oxidation of linoleate has been previously shown to be spared in animals in which the dietary availability of linoleate is compromised. Reid and Husbands (27) found that, although the CPT I specific activity was higher with linoleate and oleate than with palmitate in both sheep and rat liver, a finding consistent with the ν_{max} data for rat liver in the present investigation, the total oxidation of linoleate was lower than with the other two substrates in sheep. This "sparing" of linoleate oxidation is thought to be important in ruminant animals, because substantial amounts of this essential fatty acid are lost through the action of bacterial enzymes (biohydrogenation) in the rumen. Reid and Husbands (27) found that, in sheep, the oxidation of linoleate was inhibited at much lower concentrations of malonyl CoA than that of palmitate. It was thus concluded that the mechanism for discriminating against linoleate oxidation resides in a greater sensitivity of CPT I to malonyl CoA when utilizing linoleoyl CoA. From the results of the present investigation on rats, it is proposed that differences in the $K_{0.5}$ may provide another mechanism whereby linoleate can be conserved.

The remarkable ability of palmitoleoyl CoA to be rapidly catalyzed to its acylcarnitine by CPT I raises the possibility that this fatty acid, which is found in great abundance in the lipids of fish, may be a significant energy source for organisms whose diets contain fish oil. The dietary intake of this fatty acid may thus provide a substrate that is directed preferentially toward β-oxidation, thereby reducing the propensity to store this fatty acid as depot triacylglycerol, in situations when the dietary fat intake is not excessive. The question also arises as to why CPT I is so reactive toward this particular fatty acid. Poikilothermic animals, such as fish, contain significant amounts of long-chain polyunsaturated fatty acids (e.g., 22:6n-3) which enable their membranes to remain fluid in colder aquatic environments. However, since such fatty acids are relatively poor substrates for CPT I, there may have been strong evolutionary selection pressures for the retention, in their fat stores, of other fatty acids (e.g., 16:1n-7) that potentially offer higher rates of β-oxidation than those required for structural purposes.

ACKNOWLEDGMENTS

This work was supported in part by the Australian Research Council. GWP was a Rhodes Scholar, and thanks the Rhodes Trust for support during his period *in statu pupillarae* at Magdalen College, Oxford. The authors also thank Dr. Elizabeth Crockett for advice on the method for acyl CoA synthesis, Dr. Philip Calder for help with fatty acid analyses, Professor Ian Potter for helpful discussions during the preparation of this manuscript, and Lee Stonell and Khaled Abo-Hashema for technical assistance.

ABSTRACT: Human endothelial cells in culture were examined in different growth conditions. The human endothelial cell line, EA.hy 926 cell line, was used and cells were studied either in exponential growth phase, at confluence, or growth-arrested by serum deprivation. Phospholipids were separated and analyzed by high-performance thin-layer chromatography, and their fatty acids were quantified by gas–liquid chromatography. No significant differences in the phospholipid distributions were found between exponentially growing and confluent endothelial cells in which phosphatidylcholine (PC) represented the major phospholipid. In comparison, serum-deprived cells exhibited higher proportions of sphingomyelin and lower content of PC. We also found that among the total lipids, cholesterol level for dividing endothelial cells was lower than for cells growth-arrested either by serum deprivation or by contact inhibition at confluence. The global fatty acid distribution was not affected by the growth conditions. Thus, oleate (18:1n-9 and 18:1n-7), palmitate ($C_{16:0}$), and stearate ($C_{18:0}$) were the main components of endothelial cell membranes. However, the fatty acid distributions obtained from each phospholipid species differed with the growth status. Altogether, the data indicated that subtle modulations of endothelial cell metabolism appear upon cell growth. The resulting membrane-dependent cellular functions such as cholesterol transport and receptor activities can be expected to be relevant for lipid trafficking within the vessel wall *in vitro* and *in vivo*.
Lipids 32, 39–44 (1997).

The endothelium which lines the arterial wall is exposed to nutrients that regulate endothelial cell metabolism (1). This vascular endothelium plays an active role in physiological processes such as homeostasis, vascular permeability, and regulation of vessel tone. It is now widely recognized that cell injury that disrupts endothelium integrity is involved in pathological states such as the early events leading to the proliferation of smooth muscle cells (SMC) and the atherosclerotic lesion formation (2). The repair process in response to injury is mainly under the control of endothelial cells, tightly regulated by soluble components from the circulating blood and the surrounding cells.

In this context, phospholipids have important functions not only at a membrane level for the control of membrane fluidity and/or integrity, activity of membrane-bound enzymes, transport of molecules, and signal transduction pathways, but also at the cellular level for cell cycling, proliferation, and differentiation processes (3,4). It is likely that the growth and migration of endothelial cells alter membrane phospholipids and subsequently endothelium functions. Although phospholipid compositions of cultured endothelial cells for different species and from different origins have been reported (3,5–9), little is known about the influence of growth conditions. In an attempt to address this concern, the study described herein was designed to characterize the lipid composition of human endothelial cells as a function of the cell growth.

This work was performed with confluent, sparse serum-deprived, and exponentially growing human endothelial cells (EA.hy 926 line). We used this permanent human endothelial cell line since it maintains the characteristics of the parent human umbilical vein endothelial cells, such as the presence of factor VIII-related antigen (10), endothelin-converting enzyme activity (11), synthesis of prostaglandin I_2 and thrombomodulin (12), secretion of tissue-type plasminogen activator and plasminogen activator inhibitor (13), uptake of acetylated low density lipoprotein (LDL) (14), transport of cellular cholesterol (15), high density lipoprotein (HDL) binding (16).

MATERIALS AND METHODS

Materials. Dulbecco's minimal essential medium (DMEM), phosphate buffer saline (PBS), fetal calf serum (FCS), and L-glutamine were purchased from Gibco (Cergy Pontoise, France). Hypoxanthine–aminopterin–thymidine (HAT) and trypsin–EDTA (0.25–0.02%) were from Seromed (Berlin,

*To whom correspondence should be addressed at LRM, CNRS URA 502, Institut Galilée, Université Paris XIII, Av. J.B. Clément, 93 430 Villetaneuse, France.

Abbreviations: DMEM, Dulbecco's minimal essential medium; EDTA, ethylenediaminetetraacetic acid; EA.hy 926, human endothelial cell line; FCS, fetal calf serum; GLC, gas–liquid chromatography; HAT, hypoxanthine–aminopterin–thymidine; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin layer chromatography; LDL, low density lipoprotein; NL, neutral lipids; PBS, phosphate buffer saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; SMC, smooth muscle cells; TLC, thin-layer chromatography.

Germany). Solvents of high-performance liquid chromatography (HPLC) grade were from Farmitalia-Carlo Erba (Rueil-Malmaison, France). Cell culture plates from Costar (Cambridge, MA) were used. Phospholipids and fatty acids for chromatography standards were obtained from Sigma (St. Louis, MO). Silica gel (silica gel 60, 70–230 mesh) and high-performance thin-layer chromatography (HPTLC) plates (60 WRF 25 4S) were from Merck (Darmstadt, Germany).

Endothelial cell culture. Human endothelial cells (EA.hy 926 line) were kindly provided by Dr. C.-J. Edgell (University of North Carolina). They were routinely cultured in DMEM supplemented with 10% FCS, 2 mM L-glutamine and HAT (100 µM hypoxanthine, 0.4 µM aminopterin, 16 µM thymidine) at 37°C in a 5% CO_2 incubator. Cell morphology was examined under conventional light microscope (Axiovert 100; Zeiss, Oberkochen, Germany). Absence of mycoplasma contamination was checked using the fluorescent Hoeschst 33258 dye. Protein content was determined by the Lowry method (17).

For lipid analysis, EA.hy 926 cells seeded in 162 cm^2 flasks were grown either to confluence or until the indicated density (exponential growth). In parallel experiments, some cells were growth-arrested after washing with serum-free media and incubation for 2 d in DMEM supplemented with only 0.4% FCS.

The cells were harvested using trypsin-EDTA, and the cell number was determined using a Coulter Counter (ZM type; Coultronics, Beds, United Kingdom). The doubling time (DT) (time required for the doubling of the cell population) was calculated during the exponential growth phase from the following equation:

$$DT = (t - t_0)\ \ln 2/(\ln N - \ln N_0) \quad [1]$$

where N_0 is the cell number at time t_0 and N the number at the considered time t.

Lipid analysis. Lipids were extracted by chloroform from the fixed cells according to Bligh and Dyer (18). Before thin-layer chromatography (TLC) analysis, fractionation of lipids was carried out by adsorption chromatography on silica gel in the proportion of 300 mg in chloroform for 10 mg of lipid extract. Neutral lipids were first eluted by 10 mL of chloroform. Elution of glycolipids followed with 15 mL of acetone/methanol (9:1, vol/vol), and phospholipids were recovered with 10 mL of methanol. Each fraction was evaporated, dissolved in chloroform/methanol (2:1, vol/vol), then stored at −18°C under nitrogen. Neutral lipids and phospholipids were analyzed on silica gel HPTLC plates prewashed with isopropanol and dried at 120°C for 30 min. Neutral lipid separations were performed using hexane/diethyl ether/acetic acid (70:30:1, by vol). Phospholipids were separated using HPTLC with automated multiple development. Repeated development of the plates was performed with a gradient elution, over increasing migration distances in the same dimension. The development solvent for each successive run differed, permitting a stepwise gradient to be obtained (19). All lipids were visualized by immersing plates in acetone/water (4:1, vol/vol) containing 0.5% primulin. Plates were then scanned for fluorescence at 366 nm. The CATS evaluation software package (CAMAG, Switzerland) was further used to quantify lipids. Each phospholipid class was identified by the front solvent ratio value (R_f) and compared with authentic lipid standards for calibration. R_f for phospholipids were found as follows: sphingomyelin (SM) = 0.20; phosphatidylcholine (PC) = 0.28; phosphatidylserine (PS) = 0.39; phosphatidylinositol (PI) = 0.43; phosphatidylethanolamine (PE) = 0.54.

For determination and quantification of acyl chains, total lipid extracts or lipid spots isolated from HPTLC plates were transmethylated (20). Fatty acid methyl esters of total lipids or of phospholipid species were analyzed by gas–liquid chromatography (GLC). The GC system consisted in a gas chromatograph (Autosystem Perkin Elmer, Norwalk, CT) provided with a flame-ionization detector maintained at 300°C and a programmable split/splitless injector (PSS; Perkin Elmer, Palo Alto, CA). PSS was equipped with 2-mm internal diameter liner packed with silanized glass wool. The temperature was programmed from 40°C (for 7 min) to 250°C (200°C/min) hold for 15 min. For GC separation, a 50 m × 0.22 mm internal diameter column, coated with 0.25 µm BPX 70, was used, applying helium as carrier gas. The temperature was programmed from 35°C (for 7 min) to 150°C (20°C/min), and from 150 to 230°C (1.5°C/min) hold for 5 min. Fatty acids and natural extracts of known compositions were used as standards for column calibration. Data collection was done and integrated by Turbochrom integration system (Perkin Elmer) which analyzed the weight percentage composition of the fatty acid methyl ester mixture. Values were then normalized to the total amount of identified fatty acids. The analysis procedure allows the accurate separation of double-bound position isomers. Only 18:4n-4 and 20:1n-11, which together account for less than 0.5% of the total fatty acid amount, were not resolved. Variation in surface area determination between identical injected samples was less than 2%.

Statistics. Results were expressed as mean values ± SD. The difference between two groups was tested for significance using the Student's *t*-test.

RESULTS

Cell growth. We investigated the effect of growth conditions on the lipid composition of the human endothelial cell line, EA.hy 926 (10–16,21). Three growth conditions were defined: Cells were growth-arrested by serum deprivation. They were seeded at low density ($0.8–1.2 \times 10^4$ cells/cm^2) and maintained quiescent for a two-day period in 0.4% FCS. In these culture conditions, no growth was observed. However, the cells were viable as assessed by trypan blue exclusion test, and a normal growth was recovered when serum-deprived medium was changed for 10% FCS (Fig. 1). Cells were analyzed in the exponential growth phase from day 2. In 10% FCS, these cells were actively dividing with a doubling time

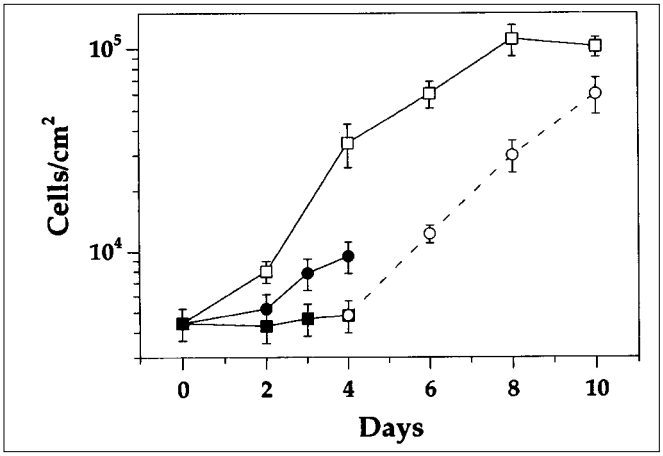

FIG. 1: Growth of human endothelial cells. EA.hy 926 cells in quadruplicate wells were seeded at 4×10^3 cells/cm^2 and cultured in DMEM supplemented with L-glutamine and HAT containing either 10% FCS (□), or 2% FCS (●). In parallel experiments, cells maintained in 0.4% FCS (■) were then allowed to grow in 10% FCS (○, dashed line). Cell numbers were determined using a Coulter counter. Mean values ± SD are indicated.

of 22.5 h. In lower serum content (2% FCS), the doubling time was on the order of 40 h. At last, confluent cells that reached a plateau at the end of the growth curve were contact-inhibited and the cell number remained constant at about 9×10^4 cells/cm^2. In this case, the typical "cobblestone" morphology of endothelial cells at confluence was observed.

Lipid composition of endothelial cells. The total lipid extracts were separated on a silica column into three species, i.e., neutral lipids (NL), glycolipids, and phospholipids. Among the total lipids, NL represented 11% of the extract, as determined by [^{14}-C]acetate incorporation (data not shown). Phospholipid compositions of EA.hy 926 cells were then determined by HPTLC with automated multiple development and densitometric scanning (Table 1). For exponentially growing cells, PC was the major phospholipid class (55.9% of total phospholipids) and smaller amounts of SM, PE, PI, and PS were found. This distribution among the individual phospholipid classes was not significantly different when compared to the one of confluent cells (Table 1). Interestingly, cells that were growth-arrested by serum deprivation differed in the phospholipid distribution, with an increase in SM and PS and a decrease in PC content.

We also investigated the cholesterol levels as a function of the growth status. With an average of 159 ± 64 µg protein/10^6 cells (n = 5), determined by the Lowry assay (17), the content of cholesterol was 40.3 ± 13.9 µg/mg cell protein for confluent cells, a value similar to those described for EA.hy 926 cells by Bernini *et al.* (16) with 32.2 µg/mg cell protein and by Kilsdonk *et al.* with 46.3 ± 5.0 µg/mg cell protein (15) and 45.3 ± 4.0 µg/mg cell protein (22). The total cellular cholesterol per cell basis (µg/10^6 cells) in the three stages of cell growth is as follows (n = 3): 1.5 ± 0.5, 6.4 ± 1.4 , and 8.7 ± 0.9 respectively for exponential, confluent and serum-deprived cells. It is worth noting that the amount of cholesterol for dividing cells is lower than for arrested cells (confluent or serum-deprived).

Fatty acid composition of endothelial cells. Table 2 shows the fatty acid distribution of total lipids recovered from endothelial cells in the three growth conditions. In confluent cells, oleate (18:1n-9; 25.6% and 18:1n-7; 6.8%), palmitate

TABLE 1
Phospholipid Composition of EA.hy 926 Cells in Different Growth Stages[a]

Phospholipids	Exponential	Confluence	Serum-deprived
PC	55.9 ± 2.4	55.1 ± 2.4	29.1 ± 1.3**
SM	20.6 ± 2.3	23.0 ± 4.1	33.5 ± 0.4*
PE	13.6 ± 0.8	14.0 ± 0.6	12.1 ± 0.7
PI	10.4 ± 2.2	7.0 ± 1.9	8.6 ± 1.8
PS	4.2 ± 0.2	3.1 ± 0.2	18.8 ± 0.8**

[a]EA.hy 926 cells grown in 162-cm^2 flasks were cultured in exponential growth phase (2.0×10^4 cells/cm^2), until confluence (7.7×10^4 cells/cm^2), or were growth-arrested by serum deprivation (1.2×10^4 cells/cm^2). The cells were harvested and total lipid extracts were separated in three species (neutral lipids, phospholipids and glycolipids). Phospholipid compositions of EA.hy 926 cells were determined by high-performance thin-layer chromatography with automated multiple development and densitometric scanning as detailed in the Materials and Methods section. Data are means ± SD of at least two separate experiments. Values are expressed as percentage of the five identified phospholipids: PC, phosphatidylcholine; SM, sphingomyelin, PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine. *significantly different from exponentially growing cells ($P < 0.05$); **significantly different from exponentially growing cells ($P < 0.001$).

Saturated	44.4	40.1	43.6
Monounsaturated	42.7	41.2	44.2
Polyunsaturated	12.9	18.7	12.2

[a]EA.hy 926 cells grown in 162-cm^2 flasks were growth-arrested by serum deprivation, cultured in exponential growth phase, or until confluence. The cells were harvested and total lipids extracted as detailed in the Materials and Methods section. Data shown are expressed as percentage of the identified fatty acids and represent the average ± SD of three separate experiments. n.d., not detected.

(16:0; 23.0%), stearate (18:0; 14.9%), and palmitoleate (16:1n-7; 4.9% and 16:1n-9; 3.4%) were the main fatty acid components of endothelial cells. The other fatty acids were present in proportions lower than 7%. In all growth conditions, saturated and monounsaturated fatty acids represented more than 80% of the total molecular species. However, saturated fatty acids for confluent cells exhibited lower values (40.1%) than for the two other growth conditions (43.6% for serum-deprived cells and 44.4% for exponentially growing cells). The proportion of polyunsaturated fatty acids represented 18.7, 12.9, and 12.2%, respectively, for confluent, exponential, and serum-deprived cells. In particular, levels of 16:2n-6, 18:2n-6, 20:4n-6, and 22:6n-6 were highest in confluent cells.

The fatty acid compositions of PC, SM, PE, PI, and PS are shown in Table 3. The main fatty acids were 16:0, 16:1, 18:0, and 18:1. Each phospholipid species exhibited a unique fatty acid distribution (Table 3), in agreement with studies of others with cultured endothelial cells (7,23). For instance with confluent cells, 18:1 levels were as low as 10.9% in SM, but represented the major fatty acid component in PS with 53.4%. Culture conditions influenced the fatty acid distribution of each phospholipid class, a result not evidenced on the global fatty acid extracts. For serum-deprived cells, 18:0 was expressed at higher levels for each phospholipid class than in the two other growth conditions. Differences were observed for the fatty acid proportions in PI of exponentially growing cells (16:0/18:1 = 1.1), confluent (16:0/18:1 = 1.7), and serum-deprived cells (16:0/18:1 = 8.9). On the contrary, PC fatty acid distribution was less affected by growth conditions.

TABLE 3
Fatty Acid Composition of PC, SM, PE, PI, and PS from Endothelial Cells[a]

Phospholipids	Fatty acids	Exponential	Confluence	Serum-deprived
PC	16:0	49.1 ± 4.1	62.3 ± 7.5	52.1 ± 4.5
	16:1	11.3 ± 4.6	10.9 ± 7.3	11.3 ± 0.9

[a]EA.hy 926 cells were cultured in 162-cm^2 flasks. Cells were either in the exponential growth phase (2.0×10^4 cells/cm^2), growth-arrested by serum deprivation at sparse density (1.3×10^4 cells/cm^2), or confluent (7.7×10^4 cells/cm^2). Lipids from harvested cells were extracted, and phospholipids were separated and methylated for gas–liquid chromatography analysis. Data are means ± SD of three separate experiments. Values are expressed as percentage of the predominant fatty acids (16:0, 16:1, 18:0, 18:1; see Table 2) that represented >5% of fatty acids in the total phospholipid extracts. *$P < 0.05$ vs. exponential conditions.

DISCUSSION

In physiological conditions, endothelial cells form a tightly confluent layer in the internal lumen of the vessel walls. In response to injury, proliferation of endothelial cells is a required step. Thus, atherosclerosis involves damage to or dysfunction of the vascular endothelium (2). Endothelial cell growth control is also of particular importance in wound healing and angiogenesis (24,25). Unfortunately, phospholipid compositions of cultured endothelial cells were mainly described in the literature for confluent endothelial cells (3,5–9). In order to study the regulation mechanisms of growth, we investigated the proliferation-dependent alterations in phospholipid composition of human endothelial cells in culture. We performed the analyses not only with confluent endothelial cells that would be analogous to the phenotype of *in vivo* unstimulated cells but also with exponentially growing cells and with cells whose growth was arrested by serum deprivation.

Using the HPTLC with the automated multiple development (Table 1) or a [^{14}-C]acetate incorporation (data not shown), we found that PC was the predominant species (>50%) for confluent EA.hy 926 endothelial cells. PC contents for confluent endothelial cells were similar in the literature whatever the analytical methods—TLC (5), HPLC (6), or radiolabeled tracers (8,9). PI, PE, and PS proportions determined here were also close to those previously described (5,6,8,9). Passage numbers could affect the global phospholipid composition of endothelial cells from primary culture (5,26). Lipid distribution reported in Table 1 for the human endothelial cell line EA.hy 926 was identical within 35 passages, allowing extensive investigations. The availability of this immortalized human endothelial cell line is advantageous since it increases reproducibility in longitudinal studies with an economical supply of homogeneous cellular material, unlimited replication potential, and clonal purity.

No significant differences were found for the phospholipid distribution between exponentially growing and confluent endothelial cells. However, lipid extracts obtained from serum-deprived cells exhibited higher amounts of SM and lower contents of PC. This could reflect different regulation pathways in lipid metabolism of endothelial cells. For instance, modulation of PC content by growth conditions may be relevant for the activation of protein kinase C in endothelial cells (27). On the other hand, the phospholipase C activity devoted to second-messenger production was not significantly altered by PC, while SM inhibited all phospholipase C activities (28). The enrichment of SM in serum-deprived endothelial cells may have physiological significance (29). Indeed, SM and its hydrolysis product by sphingomyelinase into ceramide participate in important cellular processes such as differentiation,

proliferation, and apoptosis (30,31). Modulation of cell growth by physical factors such as shear stress or by addition of growth-regulating compounds (25,32–36) that mediated lipid metabolism remains to be explored in great detail with cultured endothelial cells. These precise cellular and molecular regulatory processes in relation to cell growth are likely to play a significant role both *in vitro* and *in vivo*.

Lipoprotein uptake by vascular endothelial cells has been implicated in the initiation and development of atherosclerosis. Cholesterol trafficking may contribute to HDL and oxidized LDL binding in atherogenesis. HDL is believed to play a key role in the transfer of excess cellular cholesterol *via* an interaction of HDL with a membrane receptor (15,37). It was also shown that EA.hy 926 cells represent a valid model for studying the *in vitro* interaction of HDL with human endothelial cells (16). For these cells, cholesterol enrichment participates in the upregulation of HDL binding (15,16). Low cellular cholesterol levels were found in exponentially growing EA.hy 926 cells. This differential regulation may be indicative of regulation processes occurring at the LDL receptor level. This is important since LDL receptor and the scavenger receptor are the two main cell surface receptors by which vascular cells and macrophages bind and internalize LDL cholesteryl ester and deliver cholesterol to the cells.

We then investigated the fatty acid distribution of EA.hy 926 cells in different growth conditions (Table 2). Again, the global fatty acid distributions are only described in the literature for confluent endothelial cells. The levels of fatty acids obtained with confluent EA.hy 926 cells were similar to those described for other confluent endothelial cells (7,22,38). When we compared the three growth conditions, we observed that confluent cells exhibited higher amounts of polyunsaturated fatty acids than the two other growth stages. For instance, arachidonic acid in confluent cells reached 5% of the total fatty acids, whereas this level was only 3.5% for the other growth conditions. In fact, arachidonic acid metabolism is described as a key factor for the regulation of the endothelial cell proliferation (26). It is also interesting to note that growth-arrested cells obtained either by contact inhibition of confluent monolayers or by serum deprivation differed in their content of polyunsaturated fatty acid. This result evidences that macroscopic observation of nonproliferation is, at least partially, controlled by lipid metabolism. Fatty acid distributions were also obtained here for each individual phospholipid. These distributions were already described with rabbit coronary microvessel endothelial cells (7) and arteries and veins from human umbilical cords (5), but to our knowledge this is the first report of fatty acid distributions in each phospholipid from the human endothelial cell line, EA.hy 926. The results showed that different distributions were obtained among PC, SM, PE, PI, and PS (Table 3). Substantial changes were found as a function of growth. The differences pointed out both in the fatty acid distribution for a given phospholipid, and in the content for one fatty acid among the five analyzed phospholipids. Thus, the specific phospholipid composition related to membrane fluidity and integrity is dependent on the cell growth stage. The resulting alterations of human endothelial cell membranes are relevant for pharmaceutical treatments and should be of interest in the understanding of the pathophysiology of the vascular walls.

In conclusion, it is important to take into account the complexities of phospholipid metabolism in living cells when studying the effects of parameters that could affect the cell behavior. Their modulating role in endothelial cells is relevant for lipid trafficking within the vessel wall. Our results indicated that the lipid composition of the permanent human endothelial cell line, EA.hy 926, was in good agreement with the compositions described for primary cultures of endothelial cells. Moreover, the importance of growth status on lipids extracted from endothelial cells has been underlined. This work will support further investigations in the control of growth for endothelial and smooth muscle cells from the vascular wall submitted to physical and chemical stresses.

ACKNOWLEDGMENTS

This work was supported by the Centre National de la Recherche Scientifique (CNRS). The authors want to thank Dr. C.-J. S. Edgell (U. North Carolina, Chapel Hill, NC) for generously providing the EA.hy 926 cells, Dr. A. Trémolières (CNRS URA 1128, Gif, France) for advice concerning the lipid and fatty acid determinations, and Dr. P. Durand (IFREMER, Nantes, France) for his help in HPTLC analysis.

ABSTRACT: Phospholipid extracts were made of a murine mammary adenocarcinoma implanted in the dorsum of the foot of C3H/He mice before and 96 h after 17 Gy irradiation or 150 mg/kg cyclophosphamide. Extracts of untreated tumors, which had grown for a further 96 h, were also studied. Although previous studies have shown significant changes in the precursors and catabolites of phosphatidylcholine and phosphatidylethanolamine following therapy, ^{31}P nuclear magnetic resonance analysis of extracts showed no changes in these membrane constituents and other observed phospholipid species. A significant decrease in 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine, however, was observed 96 h following cyclophosphamide treatment. *Lipids 32,* 45–49 (1997).

It has been well documented that the precursors of phospholipids, the phosphomonoesters, change significantly in tumors in response to different therapies (1–5). In previous studies we have shown an increase in the ratio downfield component of the phosphomonoester region of ^{31}P nuclear magnetic resonance spectrum, comprised of primarily PEth and nucleoside monophosphates (PME′)/phosphocholine (*P*Cho) following both radiotherapy *in vivo* (6,7) and *in vitro* (8) and following cyclophosphamide chemotherapy *in vivo* (9). PME′ was defined in these studies as the downfield phosphomonoester peak, comprised principally of phosphoethanolamine (*P*Etn) and nucleoside monophosphates. Other studies have shown similar increases in *P*Etn/*P*Cho following chemotherapy (10,11). Similar increases in phospholipid catabolites, including the phosphodiesters, have been noted post therapy (6–9,12); other reports, however, have noted a decrease (13,14).

The phospholipids themselves are constituents of cell membranes and, as such, are relatively immobile molecules. This immobility causes spin-spin relaxation times (T_2) to be very short causing resonances in the nuclear magnetic resonance (NMR) spectrum to be very broad *in situ*. This means that changes in the composition of the phospholipid membrane are less well understood than those of their metabolites. In order to investigate the composition of tumor membrane phospholipids, it is necessary to make lipid extracts of cells and tissues, so that they can be studied in solution, where the T_2 are much longer. Tumor spheroids, which showed changes in phosphomonoester levels with increasing size, were found to have a tightly regulated phosphatidylethanolamine/phosphatidylcholine (PtdEtn/PtdCho) ratio (15). Merchant *et al.* (16), however, observed an increase in PtdEtn/PtdCho following high doses of radiation *in vivo*, correlating with an increase in *P*Etn/*P*Cho. The objective of this study was to further investigate any changes in membrane phospholipid composition following either radiotherapy or chemotherapy in a mouse tumor model.

METHODS

Animals. MCa tumors, a mouse mammary adenocarcinoma tumor (17), were grown on the dorsum of the foot of male C3H/He mice (Jackson Laboratory, Bar Harbor, ME) as described previously (6). Tumors of 245 ± 24 mm^3 volume were either treated with 17 Gy irradiation, 150 mg/kg cyclophosphamide, or were untreated. Treated animals and one group of untreated animals were sacrificed at 96 h post treatment; a second untreated group were sacrificed at zero hours. Each group consisted of six or eight animals. Two tumors were combined for each extract.

Extraction. Tumors were excised by incising at right angles to the dorsal surface of the skin adjacent to the tumor and then were freeze clamped by immediately dropping into liquid nitrogen. This freeze-clamping technique, for tumors of this size, has been shown to be not significantly different from freezing between liquid nitrogen-cooled aluminum blocks (18). The tumor tissue was then ground to a powder in a liquid nitrogen-cooled mortar. Chloroform/methanol extracts were then made as described by Meneses and Glonek (19).

*To whom correspondence should be addressed at Department of Medical Physics, Memorial Sloan-Kettering Cancer Center, 1275 York Ave., New York, NY 10021.

Abbreviations: ANOVA, analysis of variance; Cer*P*Cho, sphingomyelin; LPC, lysophosphatidylcholine; NMR, nuclear magnetic resonance; PA, phosphatidic acid; *P*Cho, phosphocholine; *P*Eth, phosphoethanolamine; PlaCho, 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; PlsEtn, ethanolamine plasmalogen; PME′, downfield component of the phosphomonoester region of ^{31}P nuclear magnetic resonance spectrum, comprising primarily *P*Eth and nucleoside monophosphates; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; Ptd_2Gro, cardiolipin; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine.

The pulverized tissue was vortexed for 2 min with 20 vol of chloroform/methanol (2:1, vol/vol). This was then washed with 4 tumor volumes of KCl (0.1 M) and vortexed for a further 1 min. This emulsion was allowed to separate overnight. The lower chloroform phase was removed and evaporated to dryness by passing a stream of air over it. The resulting lipid residue was reconstituted in 1 mL deuterated chloroform and 0.5 mL methanol:0.2 M Cs-EDTA, pH 6.0 (4:1, vol/vol).

NMR. Gated proton decoupled ^{31}P NMR spectra of extracts were obtained on a Bruker AC 250 MHz spectrometer (Karlsruhe, Germany) using a 5-mm quad probe operating at 101.25 MHz, as described by Meneses and Glonek (19). The spectral parameters used were a 45° pulse width (2.8 µs), acquisition delay of 500 µs, relaxation delay of 500 ms, 2000 Hz spectral width, and 4k data points (1.02 s acquisition time). Transients (2048) were accumulated. Relative saturation effects were not detectable under these conditions (19). Spectra were referenced to trimethyl phosphate at 0 ppm, and peak assignments were made by comparison of spectra to previously reported data using similar techniques (16,20). The signal-to-noise ratio for PtdCho was typically 45:1 for a spectrum of a pre-treatment specimen, and better in spectra of larger tumors. For quantitation of peak areas, spectra were zero-filled and processed by Fourier transform and estimated by integration. Under these conditions all of the spectral components quantified were fully resolved. The spectrum shown in Figure 1 was transformed with 0.6 Hz exponential line-broadening for display purposes. Differences were analyzed using analysis of variance and least squared means tests. Error limits are ± 1 SD of the mean, except where stated.

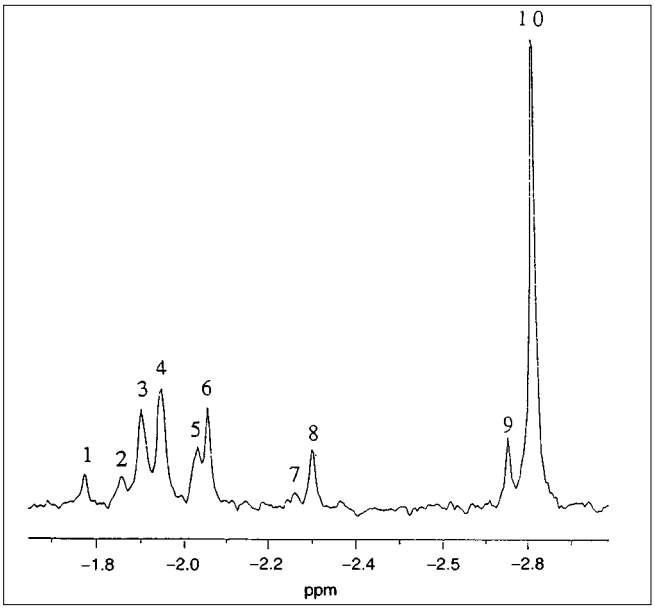

FIG. 1. ^{31}P nuclear magnetic resonance spectrum of phospholipid extract of untreated MCa tumor at zero hours. Peak assignments are as follows: 1) phosphatidic acid; 2) cardiolipin; 3) ethanolamine plasmalogen; 4) phosphatidylethanolamine; 5) phosphatidylserine; 6) sphingomyelin; 7) lysophosphatidylcholine; 8) phosphatidylinositol; 9) 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; and 10) phosphatidylcholine.

RESULTS

Previous studies with the MCa tumor model (7,9) have shown significant growth delay following 17 Gy irradiation (n = 16), 150 mg/kg cyclophosphamide (n = 8) compared to untreated tumors (n = 7) (both $P < 0.05$ after 96 h). The mean volumes (±1 SD) of the treated tumors used for the phospholipid extracts, at the time of extraction, were 337 ± 51 mm^3 for 17 Gy treated tumors and 410 ± 63 mm^3 for cyclophosphamide treated tumors. The extracted untreated tumors had a volume of 245 ± 24 mm^3 at zero hours and 632 ± 263 mm^3 after 96 h. The tumor growth delay to reach double the volume for these therapies was 3 d and 2 d following 17 Gy irradiation and 150 mg/kg cyclophosphamide, respectively. Post therapy (96 h) was chosen for harvesting of tumors for lipid extraction, as this time point yielded the greatest changes in phospholipid metabolites *in vivo* (7,9).

Figure 1 shows a typical ^{31}P NMR spectrum of a phospholipid extract of an untreated tumor. Addition of Cs-EDTA as a chelating agent in the final step of the extraction protocol caused significant narrowing of line widths (19), allowing ten phospholipid species to be identified. This improved spectral resolution has allowed us to investigate changes in the phospholipid composition of tumors upon growth and following therapy. Sphingomyelin (Cer*P*Cho) and phosphatidylserine (PtdSer) could not be resolved sufficiently in most of the spectra for purposes of quantitation. The peak at −2.75 ppm in Figure 1, 0.06 ppm downfield of PtdCho, has been assigned by some workers to choline plasmalogen (19,21) and 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (PlaCho) by others (22–24). Comparison of the tumor extract spectrum with that of beef heart PtdCho (Sigma, St Louis, MO), which contains approximately 30% plasmalogens and a small quantity of PlaCho, indicated that the peak observed in the tumor spectrum was that of PlaCho rather than the plasmalogen. The plasmalogen peak was separated from the PtdCho peak by approximately 0.02 ppm. These assignments are in agreement with Edzes *et al.* (23) who identified this peak, using 2D NMR and saponification techniques. These workers observed not only PlaCho but also choline plasmalogen at a different chemical shift, closer to PtdCho.

Absolute quantitation of metabolites dissolved in chloroform is very difficult owing to the inaccuracies associated with dispensing small volumes of a volatile organic solvent with a low surface tension. This has necessitated the use of phospholipid ratios (16) or mole percentages (22,23), rather than absolute values of concentration, for purposes of quantitation in most previous studies. Table 1 shows the tumor content of phosphatidic acid (PA), cardiolipin (Ptd_2Gro), lysophosphatidylcholine (LPC), and phosphatidylinositol (PtdIns) relative to PtdCho under each of the conditions studied. It can be seen that each of these ratios was invariant both with tumor growth and following both 17 Gy irradiation and

TABLE 1
^{31}P Nuclear Magnetic Resonance Phospholipid Ratios of Minor Phospholipid Components, Relative to Phosphatidylcholine (PtdCho)[a]

	Control (0 h)	Control (96 h)	Cyclophosphamide (150 mg/kg)	Irradiation (17 Gy)
PA/PtdCho	0.05 ± 0.01	0.06 ± 0.01	0.05 ± 0.04	0.05 ± 0.01
Ptd_2Gro/PtdCho	0.06 ± 0.02	0.10 ± 0.07	0.07 ± 0.03	0.04 ± 0.01
LPC/PtdCho	0.02 ± 0.01	0.02 ± 0.01	0.03 ± 0.01	0.03 ± 0.01
PtdIns/PtdCho	0.10 ± 0.03	0.09 ± 0.03	0.12 ± 0.04	0.11 ± 0.02

150 mg/kg cyclophosphamide. Figure 2A shows the ratios of PtdEtn/PtdCho and PlsEtn/PlaCho under the four conditions studied. The ratio PtdEtn/PtdCho was 0.31 ± 0.03, 0.31 ± 0.01, 0.28 ± 0.05 and 0.31 ± 0.05 for control tumors at zero hours, control tumors at 96 h, tumors treated with cyclophosphamide and 17 Gy irradiated tumors, respectively. None of these ratios are significantly different from each other. ANOVA, however, indicated that the various conditions resulted in signifi-cant differences in PlsEtn/PlaCho (F = 12.5; P = 0.001). PlsEtn/PlaCho following cyclophosphamide treatment was significantly higher than both control groups and following irradiation, as determined by least squared means ($P < 0.001$). PlsEtn/PlaCho was 3.29 ± 0.60 in cyclophosphamide treated animals, 1.97 ± 0.16 in controls at 96 h and 1.98 ± 0.18 in controls at 0 h. This ratio in 17 Gy irradiated tumors was 2.04 ± 0.18. Figure 2B shows the ratios PlsEtn/PtdEtn and PlaCho/PtdCho. There was no significant change in the ratio PlsEtn/PtdEtn upon growth of tumors or following therapy. PlsEtn/PtdEtn for control tumors at 0 h and untreated tumors after 96 h were 0.79 ± 0.10 and 0.67 ± 0.06, respectively. Following cyclophosphamide therapy and radiotherapy, PlsEtn/PtdEtn was 0.82 ± 0.12 and 0.66 ± 0.04, respectively. PlaCho/PtdCho was 0.12 ± 0.02 for controls at 0 h, 0.11 ± 0.01 for untreated tumors after 96 h, 0.07 ± 0.02 for cyclophosphamide treated tumors, and 0.10 ± 0.01 for 17 Gy irradiated tumors. ANOVA indicated significant differences in PlaCho/PtdCho between the different groups (F = 7.5; P = 0.006). Least squared means analysis indicated that PlaCho/PtdCho was significantly lower than both control groups ($P < 0.003$) but was not significantly different from irradiated tumors. Also, there was no significant change in this ratio upon growth of the tumor or following radiotherapy.

DISCUSSION

The data presented here indicate that there was no change in the ratio PtdEtn/PtdCho, although our previous studies with this tumor model have shown significant alterations in the phosphomonoesters and phosphodiesters, intermediates of the biosynthetic and degradative pathways of phospholipids, respectively, following radiation and cyclophosphamide therapy (7–9). These results suggest that levels of these major constituents of the tumor membrane are tightly regulated, despite apparent changes in their metabolism. This is in agreement with Ronen *et al.* (15) who observed no change in PtdEtn/PtdCho upon growth of T47D human breast cancer

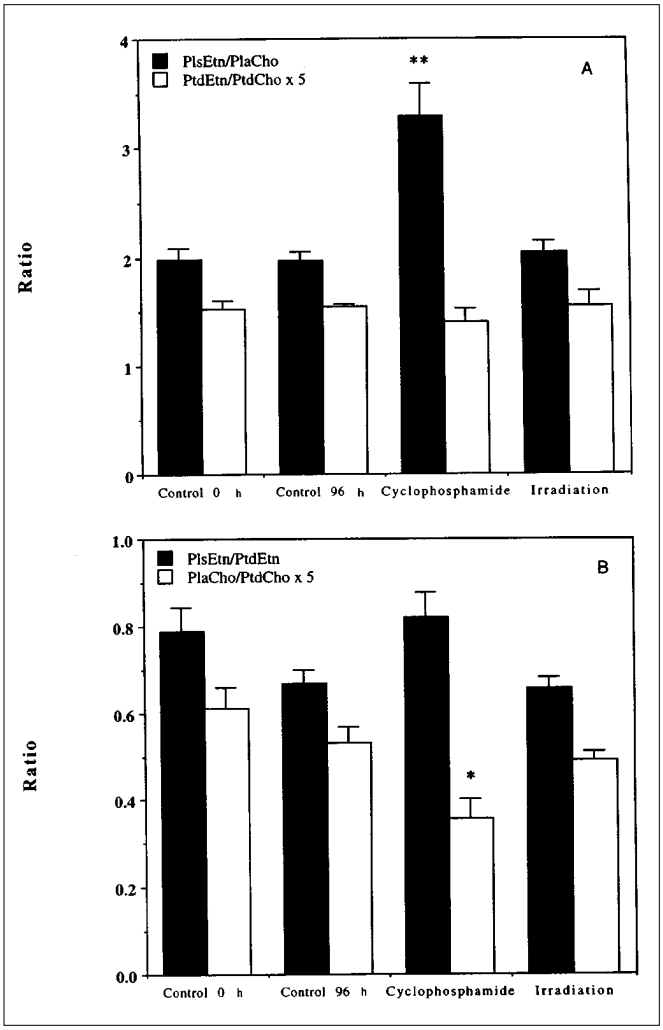

FIG. 2. Chart showing phospholipid ratios observed in ^{31}P nuclear magnetic resonance spectra of extracts of MCa tumors. A) ethanolamine plasmalogen/1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (PlsEtn/PlaCho) and phosphatidylethanolamine/phosphatidylcholine (PtdEtn/PtdCho) and B) PlsEtn/PtdEtn and PlaCho/PtdCho. PtdEtn/PtdCho and PlaCho/PtdCho have been multiplied by a factor of five for ease of comparison. Error bars are standard error of the mean. *Significant differences relative to controls of $P < 0.003$. **A difference relative to controls of $P < 0.001$.

spheroids, despite a significant change in *P*Etn/*P*Cho. Merchant *et al.* (16), however, reported an increase in PtdEtn/PtdCho following radiotherapy in MCa tumors. The doses of irradiation, 32 and 65 Gy, used in that study were much higher than that used here and may have caused extensive cell damage including direct damage to cellular proteins, inhibition of glycolysis, and membrane damage mediated by free radicals as well as effects on DNA and RNA (25). In addition to PtdEtn and PtdCho, there was no change in the membrane composition of a number of other phospholipid species, including PA, Ptd_2Gro, LPC, PtdIns, and PlsEtn. It is well documented that changes occur in both phosphomonoesters and phosphodiesters following therapy (26), suggesting that any membrane changes in these metabolites following therapy are due to an effect on membrane turnover rather than a direct effect of therapy on membrane composition.

The only significant changes observed in the phospholipid profile of tumors in response to therapy in this study were a decrease in PlaCho/PtdCho and an increase in PlsEtn/PlaCho following cyclophosphamide. Given that no other ratios were affected, this indicates a reduction in PlaCho. No change was observed following 17 Gy irradiation, or in untreated tumors, suggesting that this may be a cyclophosphamide-specific change, although a similar response at higher doses of radiation cannot be ruled out. In fact Merchant *et al.* (16) did observe an increase in PlaCho at higher doses of radiation. Although the function of plasmalogens and alkylacyl glycerophospholipids remain obscure, diradylglycerols, metabolites of plasmalogens and alkylacyl glycerophospholipids, have been shown to activate protein kinase C (27), and PlaCho is known to be a precursor of platelet-activating factor (28). Elevated levels of PlaCho have been correlated with metastatic potential in rat mammary carcinomas (29) and in clones of T3 cells of different metastatic potential (30). It is possible therefore that the reduction in PlaCho following cyclophosphamide therapy in this study is related to a loss in the metastatic potential of the tumor.

In this study we found that levels of the major phospholipid components of tumor cell membranes, PtdEtn and PtdCho, were not affected by antitumor therapies which have previously been shown to have significant effects on their anabolites and catabolites. This suggests that these changes in metabolism reflect a change in phospholipid turnover, i.e., a change in the rate of synthesis and breakdown of phospholipid following arrest of tumor growth, rather than a gross change in the composition of the membrane itself. In addition we have observed a decreased proportion of PlaCho following cyclophosphamide.

Dietary Very Long Chain Fatty Acids Directly Influence the Ratio of Tetracosenoic (24:1) to Tetracosanoic (24:0) Acids of Sphingomyelin in Rat Liver

W.J. Bettger* and C.B. Blackadar

Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, ON, N1G 2W1, Canada

ABSTRACT: Twenty-one groups of weanling male Wistar rats were fed semipurified diets containing 5% (w/w) of different dietary fats. After 2 wk, liver sphingomyelin (SM) fatty acid composition was determined. The ratio of 24:1 to 24:0 in liver SM varied over a tenfold range in response to dietary fat type. Stepwise multiple regression analysis indicated that dietary 24:1, 24:0, and 22:1 were the most significant factors in predicting the 24:1/24:0 ratio of liver SM. The mathematical relation between the dietary fatty acid composition and liver SM 24:1/24:0 was $y = 1.88$ (24:1) -1.49 (24:0) + 0.21 (22:1) + 0.01 (18:1) + 0.26, $r^2 = 0.95$, $P < 0.0001$. These results were confirmed by a second experiment in which the rats were fed olive oil-based diets supplemented with various fatty acid ethyl esters.
Lipids 32, 51–55 (1997).

Dietary fat type has been shown to alter the fatty acid composition of tissue sphingomyelin (SM) in various species (1–7): however, the relationships between the intake of specific fatty acids and the changes in tissue SM fatty acid composition have not been defined. Recently, we reported that rats fed diets containing 5% herring oil had over fourfold higher level of the 24:1/24:0 ratio in SM in liver and heart compared with rats fed diets containing 5% corn oil (8). The present experiments were designed to investigate the relationship between the intake of specific dietary fatty acids and the 24:1/24:0 ratio in rat liver SM.

MATERIALS AND METHODS

Male weanling Wistar rats (45–50 g) were fed, for 14 d, a semipurified diet consisting of vitamin-free casein (20%), DL-methionine (0.3%), glucose hydrate (65%), fat (5%), cellulose (5%), choline bitartrate (0.2%), vitamins and minerals as previously described (9), but providing 30 mg Zn/kg diet. The rats were housed under controlled conditions of temperature (22°C), humidity (50%), and lighting (12 h day/night) and were provided with food and distilled water *ad libitum*.

In experiment 1, the rats were fed the experimental diets with a variable fat source ($n = 3$, 21 diets). Menhaden oil was obtained from Sigma Chemical (St. Louis, MO). Borage and Lorenzo's oils were obtained from Dr. B.J. Holub (University of Guelph) and herring oil from Dr. C.Y. Cho (University of Guelph). All other fats and oils were obtained from local supermarkets and health food stores. Egg yolk fat was fed as whole egg yolk from hard-boiled eggs. The dietary fats were transesterified and the fatty acid methyl esters analyzed by gas–liquid chromatography as previously described (10); fatty acid profiles are shown in Table 1. In experiment 2, the rats ($n = 3$) were fed a diet of 5% olive oil plus the ethyl esters of 20:0, 20:1 (*cis*-11-eicosanoic acid), 22:0, 22:1 (*cis*-13-docosenoic acid), 24:0, or 24:1 (*cis*-15-tetracosenoic acid) (Sigma Chemical) at a level of 2.0 wt% of the oil (0.1 wt% of the total diet). The analytical methods for SM extraction, purification, and analysis of fatty acid methyl esters were previously described (10).

Data from the experiments were analyzed by general linear modeling with multiple means comparisons using Tukey's test. Linear regression of each fatty acid in the dietary oil with the corresponding fatty acid in SM was performed. Stepwise multiple regression between dietary fatty acids and the 24:1/24:0 ratio in SM was performed on the data from experiments 1 and 2.

RESULTS

At the end of the two-week feeding trials, all rats appeared healthy. Body weight gain was not significantly different between the groups of rats fed the experimental diets.

The effects of different dietary oils on the fatty acid composition of rat liver sphingomyelin are shown in Table 2. There was significant variation of SM fatty acid composition between groups of rats fed diets containing the 21 test oils. Specifically, there was significant variation (Tukey's test, $P < 0.05$) in 18:0, 18:1, 20:0, 22:1, 23:0, iso 24:0, 24:0, 24:1, and 24:2 of SM. A regression analysis between fatty acids in the diet with the corresponding fatty acid in SM demonstrated that there was a significant positive correlation of dietary 24:1 with SM 24:1 ($r^2 = 0.35$, $P < 0.0001$), dietary 22:1 with SM 22:1 ($r^2 = 0.38$, $P < 0.0001$), and dietary 22:0 with SM 22:0

[a]Values are means of n = 3, expressed as mol%. ND, <0.005 mol%. PUFA, polyunsaturated fatty acids; MUFA monounsaturated fatty acids; SAT, saturated fatty acids. Alm, almond oil; Bor, borage oil; But, butter; Can, canola oil; Cbt, cocoa butter; Coc, coconut oil; Cod, cod liver oil; Her, herring oil; Lor, Lorenzo's oil; Men, menhaden oil; Oli, olive oil; Pea, peanut oil; Prim, evening primrose oil; Saff, safflower oil, Shr, vegetable oil shortening; Soy, soybean oil.

($r^2 = 0.23$, $P < 0.0001$). A regression analysis between dietary polyunsaturated fatty acids (PUFA), monounsaturated fatty acids and saturated fatty acids, and the 24:1/24:0 ratio in SM indicated that there was a significant positive correlation of dietary monounsaturated fatty acids ($r^2 = 0.34$, $P < 0.0001$) and significant negative correlations of dietary saturated fatty acids ($r^2 = 0.07$, $P < 0.05$) and PUFA ($r^2 = 0.08$, $P < 0.02$), with the 24:1/24:0 ratio in SM. Stepwise multiple linear regression between the fatty acid composition of the diet (Table 1) and the 24:1/24:0 ratio in SM (Table 2) indicated that 24:1, 24:0, 22:1, and 18:1 had the greatest effects; the regression formula was $y = 1.88\ (24:1) - 1.49\ (24:0) + 0.21\ (22:1) + 0.01\ (18:1) + 0.26$, $r^2 = 0.95$, $P < 0.0001$ (Table 3). The concentration unit of the fatty acids in the regression formula is expressed as mole percentage of total fatty acids in the dietary fat, based on assay diets containing 5% added fat. The plot of predicted versus observed effects is shown in Figure 1.

The effects of different fatty acid ethyl esters supplemented in the diets of rats on liver SM fatty acid composition are shown in Table 4. The feeding of fatty acid ethyl ester-

supplemented diets resulted in significant variation (Tukey's test, $P < 0.05$) in 18:1, 20:0, 22:0, 24:0, and 24:1 in SM. Stepwise multiple linear regression analysis between the fatty acid ethyl esters in the diet and the fatty acids in SM, shown in Table 5, gave the following equation: $y = 1.42\ (24:1) - 0.23\ (24:0) + 0.50\ (22:1) + 0.17\ (20:1) + 0.61$, $r^2 = 0.98$, $P < 0.0001$. The plot of predicted vs. observed effects is shown in Figure 2. As in experiment 1, 24:1 is the largest positive factor and 24:0 is the largest negative factor in the regression formula.

DISCUSSION

The results of these experiments demonstrate clearly that dietary fat type can alter rapidly the 24:1/24:0 ratio in SM in rat liver over a tenfold range. Multiple regression analysis of fatty acid composition of the diet with rat liver SM fatty acid composition demonstrates that some very long chain fatty acids, particularly 22:1, 24:0 and 24:1, were potent factors in influencing the 24:1/24:0 ratio in liver SM. Our data indicate

that 24:1 and 24:0, when present in trace [<0.1% (w/w)] amounts in the diet, significantly influence liver SM fatty acid composition.

The mathematical model resulting from our experiments helps to understand dietary fat-induced changes in the 24:1 and/or 24:0 in tissue SM reported by other investigators. For example, dietary intake of high erucic acid rapeseed oil increased the 24:1 and decreased the 24:0 content of SM in lung (11) and heart (7) of rats and in heart of swine (5); rats fed a low erucic acid rapeseed oil also had increases in 24:1 and decreases in 24:0 in heart SM relative to rats fed peanut oil (12). Mice fed diets containing peanut oil had higher 24:0 in liver SM than mice fed diets containing olive oil (2); mice fed diets containing borage oil had higher 24:1 and lower 24:0 in kidney SM than mice fed diets containing corn oil (13). Humans given supplements of borage oil (3) or cod liver oil (14) had significant increases of 24:1 in platelet SM. Patients with adrenoleukodystrophy given supplements of Lorenzo's oil had a dramatic increase in 24:1 and decrease in 24:0 in plasma SM (6). Our mathematical model, based on a rat liver bioassay, appears to be useful in predicting effects of dietary fatty acid intake on 24:1/24:0 ratio of SM in multiple species and in multiple tissues.

Our data indicate that dietary very long chain fatty acids are not the only dietary fatty acids, or fat components, to alter SM fatty acid composition. Dietary 18:1 was a significant positive factor in predicting the 24:1/24:0 ratio in liver SM but did not correlate with the 18:1 content of SM. This result is similar to that found by Neelands and Clandinin (15) in rat liver plasma membranes. Similarly, 18:2n-6 was a significant positive factor ($r^2 = 0.35$, $P < 0.0001$) in predicting the 24:2n-6 content of SM but did not correlate with the 18:2n-6 content of SM; PUFA-rich diets have been reported to increase the 24:2n-6 content of SM in canine erythrocytes and platelets and in swine erythrocytes (4).

The present experiments illustrate the need for more research in two areas regarding the effects of dietary fat on SM metabolism and function: the mechanism(s) by which dietary fatty acid intake alters SM fatty acid composition and the physiological effects of diet-induced changes in SM fatty acid composition. Moreover, the data suggest that further study on the nutritional and/or pharmacological value of 24:1 and 24:0 in humans and animals is warranted.

ABSTRACT: The aim of this study was to determine whether or not testosterone regulates the lipid concentration in rat lung tissue. Rats were either sham-operated controls, castrated, or castrated and injected with testosterone. Twenty-one days after castration, we observed in relation to the control: (i) Total lipids, phospholipids, and total cholesterol increased, while triglycerides decreased in whole lung. (ii) Phospholipid concentration increased in microsomes, lamellar bodies, and alveolar macrophages, but it decreased in extracellular surfactant. (iii) On a percentage basis, the concentration of phosphatidylcholine increased in microsomes, lamellar bodies, and alveolar macrophages, and it decreased in extracellular surfactant. (iv) Protein concentration decreased in extracellular surfactant and increased in microsomes, lamellar bodies, and alveolar macrophages. (v) The incorporation of [^{14}C]glycerol into phospholipids of lung slices increased. (vi) The activity of CTP:phosphocholine cytidylyltransferase bound to the microsomal fraction increased without any change in the activity of the soluble form of the enzyme in the lung. The results obtained when testosterone was administered to castrated rats were similar to those obtained in the control in all cases. These results suggest that the lipid concentration in the lung is regulated at least partly directly or indirectly by androgens.
Lipids 32, 57–62 (1997).

Sex-related differences in fetal lung development are now widely recognized. In various species, it is clear that lung maturation occurs sooner in females than in males (1). Male infants are at a greater risk of developing respiratory distress syndrome than females (2). It is known that the administration of dihydrotestosterone to pregnant rabbits during the course of fetal sexual differentiation eliminates the difference by inhibiting surfactant production in the female fetus (3). There are several reports of attempts to elucidate the mechanism responsible for sex differences in pulmonary surfactant production in fetal lung (4). However, there is no report on the effect of testosterone on the lipid composition of lung tissue in adult male rats (5). In this study we measured the amount of different lipids in adult male rat lung after castration in order to determine whether or not they are under testosterone regulation. We report evidence that testosterone regulates the amount of lipids in the adult male rat.

MATERIALS AND METHODS

Chemicals. All reagents were of analytical grade. Standards of cholesterol, triglycerides, phospholipids, and protein were purchased from Sigma Chemical Co. (St. Louis, MO). Testosterone enantate was obtained from Testosteron Depot Schering A.G. (Berlin, Germany). Serum total lipids, cholesterol, and triglycerides were determined using assay kits from Wiener Laboratory (Rosario, Argentina). [U-^{14}C] Glycerol, 3700 M Bq/mmol, 10.0 mCi/mmol and [Me-^{14}C] phosphorylcholine, 3.7 M Bq/mL, 50 mCi/mmol were obtained from New England Nuclear Corp. (Boston, MA).

Animals and feeding procedure. Wistar adult male rats, 4 months old, 200 g weight, were separated into three groups. The first group was sham-operated and used as control (Co); the second was subjected to castration by simple orchidectomy (Ca); and the third received by intramuscular (i.m.) injection testosterone (100 μg/kg body weight) 15 d after castration (Ca + T). Twenty-one days after castration, all rats were anesthetized by an i.m. injection of urethane (250 mg/100 g body weight in 1 mL of saline solution). The lungs were quickly removed, lavaged with ice-cold 0.9% saline solution, and weighed.

Isolation of extracellular pulmonary surfactant and macrophages. In another experiment, the trachea of anesthetized rats was cannulated, and the lungs were filled with 2.5 mL ice-cold 0.9% saline solution. Lavages containing the extracellular surfactant were then collected. This procedure was repeated nine times with fresh 0.9% saline. The combined lavages were centrifuged at 4°C and 580 × *g* for 10 min to sediment macrophages. The resulting supernatant was centrifuged at 100,000 × *g* for 1 h in a Beckman ultracentrifuge (LS 65 B, 65 Ty rotor; Fullerton, CA) to obtain a surfactant pellet (6).

Isolation of lamellar bodies and microsomes. After obtaining the extracellular pulmonary surfactant fraction, the lavaged lungs were used to isolate lamellar bodies and microsomes (6).

Lipid analyses. Lipids were extracted from total lung tissue, microsomes, lamellar bodies, extracellular surfactant, and

Abbreviations: Ca, castrated rat; Co, control rat; LPC, lysophosphatidylcholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI + PS, phosphatidylinositol + phosphatidylserine; Sph, sphingomyelin; TLC, thin-layer chromatography.

macrophages (7). Total lipids were determined by dry weight. The lipids were resuspended in chloroform/methanol 2:1, vol/vol. Aliquots were taken for determining phospholipids and measuring phosphorus (8) and total cholesterol (9). Other parts of the extract were used for the separation of the different lipids on thin-layer chromatography (TLC) plates coated with silica gel G (Merck, Darmstadt, Germany) using hexane/diethyl ether/acetic acid (80:20:1, by vol) as solvent. The lipids were detected by exposing the plates to iodine vapors. They were scraped off and used directly for determinations of phospholipids (8), triglycerides (10), free and esterified cholesterol (11).

Analysis of phospholipid composition. Phospholipids were separated into component species by TLC using silica gel H plates and chloroform/methanol/water (65:25:4, by vol) as solvent (12). The individual phospholipids were identified and recovered as above and quantified (8). The position of the phospholipids was determined using the respective standards. The results were expressed as the percentage of total phospholipid phosphorus.

Incorporation of [U-^{14}C] glycerol into phospholipids. The lung slices (250–350 mg) were immediately placed in individual flasks containing 4 mL Krebs-Ringer bicarbonate solution and 0.6 mL of 0.1 mM glucose (pH 7.4). The medium was aerated with a 95:5 mixture of O_2/CO_2. Slices were preincubated for 5 min at 37°C in a Dubnoff metabolic shaking incubator. [^{14}C] glycerol was added (1 mCi/incubation flask) to start the reaction. After 60 min of incubation, the reaction was stopped by placing the flask in an ice bath. The lipids were extracted (7).

Duplicate samples (10 mL each) were used for the separation of the different labeled phospholipids by TLC. The different phospholipid spots were detected using iodine vapors. In each case only one sample was used for determining radioactivity in a Beckman LS 100 C liquid scintillation counter, and the other sample was used for determining phosphorus (8). Quantitative recovery of each phospholipid component was about 98% .

CTP:phosphocholine cytidylyltransferase assay. Lungs of castrated and noncastrated rats were used for the separation of cytosol and microsomes for enzymatic determination (13). Assay mixtures contained 20 mM Tris/succinate pH 7.8, 6 mM $MgCl_2$, 8 mM CTP, and 4 mM [Me-^{14}C] phosphorylcholine (sp. radioactivity 0.15 μCi/μmol). The reaction was started by the addition of enzyme (100 μg protein), and the assay mixture was incubated for 30 min at 37°C in a reaction volume of 200 μL. The reaction was stopped by boiling for 2 min, and the protein was removed by centrifugation (1000 × *g* for 10 min). A 50-μL sample was taken from the supernatant, mixed with 2 nmol of unlabeled phosphorylcholine as carrier, and subjected to TLC on precoated silica gel G 60 (Merck) with methanol: NaCl 0.15 M: conc. NH_4OH (50:50:5, by vol) as solvent for the isolation of the reaction product. The CDP-choline spots were detected with iodine vapor, scraped off the plates into scintillation vials, and assayed for radioactivity. Under these conditions, the reaction rate was linear over time and with protein concentration.

Electron microscopy. The pellets of isolated lamellar body and microsomes were fixed with 2.5% glutaraldehyde and analyzed (14).

Enzyme markers. To determine if lamellar body was contaminated with microsomal mitochondrial or cell membranes, the activities of NADPH-cytochrome c reductase (16), succinate dehydrogenase (17) and 5′ nucleotidase (18), respectively, were measured.

Protein assay. Protein content was determined by the Layne method (14) using fraction V bovine serum albumin as standard.

Statistical analysis. Results are expressed as means ± standard deviations. Statistical differences were tested by analysis of variance test and Tukey test.

RESULTS

Effect of castration on body weight and lung weight. After 21 d of castration, the gain of weight was lower in Ca rats compared to controls. The lung weight of Ca rat was higher than that of Co. When testosterone was administrated to Ca, the lung weight was similar to that of the control (Table 1).

Total lipids, cholesterol, and triglycerides in serum and whole lung. Total lipids and triglycerides decreased while cholesterol increased in the serum of Ca compared to that in Co. Total lipids and total free cholesterol increased, esterified cholesterol did not change, and triglycerides decreased in whole lung of Ca compared to Co (Table 1).

TABLE 1
Body and Lung Weights, and Lipids from Serum and Lung of Male Rat[a]

	Control	Castrated	Castrated testosterone
Body weight (g)			
Initial	288 ± 26	287.5 ± 27	280 ± 32
Final	325 ± 30	315 ± 31	320 ± 27
Gain	43 ± 13^b	23.83 ± 9^c	33 ± 7^b
Lung weight (g)	1.66 ± 0.3^d	1.91 ± 0.2^e	1.63 ± 0.2^d
Serum (g/L)			
Total lipids	4.70 ± 0.80^d	2.07 ± 0.70^e	n.d.
Cholesterol	0.94 ± 0.13^d	1.60 ± 0.30^e	1.25 ± 0.30^d
Triglycerides	1.00 ± 0.30^d	0.40 ± 0.10^e	n.d.
Whole lung (mg/g lung)			
Total lipids	65 ± 4.7^b	81.00 ± 3.1^n	65 ± 7.6^b
Cholesterol			
Total	6.50 ± 1.6^d	8.50 ± 1.6^e	n.d.
Free	4.30 ± 0.8^d	6.50 ± 1.2^e	n.d.
Esters	0.70 ± 0.16	0.94 ± 0.16	n.d.
Triglycerides	0.305 ± 0.08^d	0.191 ± 0.02^e	0.316 ± 0.01^d
Macrophages (mg/g lung)			
Total cholesterol	0.055 ± 0.00^b	0.093 ± 0.00^n	0.056 ± 0.00^b

[a]Results given as mean ± SD; $n = 12$ for each case. Across a row, values with different superscript letter indicate significant difference, by analysis of variance and Tukey test. $^{b,c}P < 0.05$; $^{d,e}P < 0.01$; $^{b,n}P < 0.001$; n.d., not determined.

Phospholipid concentration in intracellular and extracellular compartments of lung. The phospholipid concentration increased in whole lung, microsomes, and lamellar bodies, while in extracellular surfactant it decreased in Ca compared to Co (Table 2).

On a percentage basis, the phospholipid composition in whole lung and other particles studied was modified after castration compared to that in control animals. In whole lung, phosphatidylcholine (PC), phosphatidylserine (PS) + phosphatidylinositol (PI), lysophosphatidylcholine (LPC) and phosphatidylglycerol (PG) increased; sphingomyelin (Sph) and phosphatidylethanolamine (PE) decreased. In microsomes PC and PE increased, PI + PS and LPC decreased, but Sph and PG were not changed (Table 3). In lamellar bodies, PC and PS + PI increased; LPC, Sph, PE, and PG decreased. In extracellular surfactant, after castration the amount of PC and PE decreased and LPC, Sph, PI + PS increased compared to controls. In alveolar macrophages LPC, Sph, PC, and PG increased while PE decreased and PS + PI did not change (Table 3).

Incoporation of [U- ^{14}C] glycerol into phospholipids of lung slices. The specific activity of PC, PI + PS, PE, LPC, and PG increased in Ca compared to Co, while the specific activity of Sph was not modified by castration in relation to that in the control (Table 4).

Activity of CTP:phosphocholine cytidylyltransferase. The enzyme activity binding to endoplasmic reticulum membranes increased, but it did not change in the cytosol of Ca (Table 2).

Protein concentration. Protein concentration did not change in whole lung. It increased in microsomes, lamellar bodies, and alveolar macrophages and decreased in extracellular surfactant (Table 2).

Electron microscopy and enzyme markers. Analysis by electronic microscopy showed that 95% of the counted particles were lamellar bodies and microsomes. The activities of marker enzymes showed that the isolated fractions were 98% pure.

DISCUSSION

While the role of androgens in the maturation of the fetal lung has received much attention, the role of these hormones in the adult rat lung has not been studied. Androgen receptors are present in the lung, and the function of these receptors in lung maturation has been demostrated in mice with the testicular feminization syndrome, in which androgen receptors are absent (19). Our results obtained in the different fractions of lungs show that castration could cause changes in the synthesis, secretion, and clearance of phospholipids in surfactant. Lipids and protein of surfactant are synthesized by alveolar type II cells, and they are stored prior to secretion in intracellular organelles called lamellar bodies (20).

In our experiment, the low gain of body weight observed in Ca compared to Co confirms previous results (21). The higher lung weight of Ca compared to Co could be a consequence of accumulation of substances as total lipids, as it has been in our experiments.

Phosphatidylglycerol	42727 ± 4700[c]	50239 ± 2000[b]

[a]Results given as mean ± SD; $n = 11$ for each group. Across a row values with different superscript letter indicate significant difference by analysis of variance and Tukey test. [c,b]$P < 0.001$, [d,n]$P < 0.01$.

It is known that castration increases the cholesterol concentration in serum (22). Cholesterol is the major neutral lipid component of extracellular surfactant, and it is accepted that most cholesterol in the lung is taken up from circulating low density (LDL) or high density lipoprotein (HDL) (23). The increment of cholesterol in serum could be a cause of the increased cholesterol concentration observed in whole lung and macrophages in Ca compared to Co. Studies utilizing isolated perfused rat lung have demonstrated the uptake of very low density lipoproteins from the perfusion medium (24).

The decreased triglyceride concentration observed in the whole lung of Ca could be a consequence of more utilization of this as precursor for synthesizing phospholipids or it could be a consequence of decreased triglyceride concentration observed in serum of Ca. In our laboratory we have found that the synthesis of triglycerides decreased in liver after castration (25).

The protein concentration was not modified in whole lung by castration, probably because the lung has more than 40 different types of cells, and androgen could have different regulatory effects on each one. However, we observed an increment in the protein concentration in microsomes, lamellar bodies, and macrophages. These results are probably associated with changes in the concentration of specific proteins. The low protein concentration of the extracellular surfactant could be a consequence of decreased secretion of this from lamellar bodies or decreased synthesis of specific protein of extracellular surfactant. We could infer that the phospholipid increment in microsomes and lamellar bodies in lungs of rats could be a consequence of a greater synthe-

sis in microsomes with transfer to lamellar bodies. There was more incorporation of [^{14}C] glycerol into phospholipids as well as an increment in the activity of CTP:phosphocholine cytidylyltransferase, the regulatory enzyme of PC synthesis. The activity of this enzyme is regulated by various effector molecules (26,27). The lower content of phospholipid in extracellular surfactant may be a consequence of greater uptake by macrophages or increased recycling by neumocytes type II for synthesis of new surfactant (28,29). In our experiment we observed an increased phospholipid concentration in alveolar macrophages of Ca compared to Co. This increment may be due to two causes: (i) An increment in the removal rate of surfactant. Evidence has been obtained which suggests that alveolar macrophages phagocytize surfactant material and that some of the surfactant lipids may be degraded (30). (ii) An increment in the amount of cholesterol that increases the synthesis of PC through stimulation of CTP:phosphocholine cytidylyltransferase (31). In our experiment we observed simultaneously an increment of cholesterol and phospholipids in macrophages from Ca compared to Co.

At this time we do not know if the increased activity of CTP:phosphocholine cytidylyltransferase is due to a pre- or posttranslational regulation. It may be that the increment in cholesterol concentration is an indirect cause of the increased activity of this enzyme observed in lung of Ca. We believe that androgen may be an important regulator of lipid synthesis in lung directly or indirectly.

ABSTRACT: This multicenter, parallel group study determined plasma phospholipid and red blood cell (RBC) phosphatidylcholine and phosphatidylethanolamine fatty acids, plasma cholesterol, apo A-1 and B, growth and visual acuity (using the acuity card procedure) in term infants fed from birth to 90 d of age with formula containing palm-olein, high oleic sunflower, coconut and soy oil (22.2% 16:0, 36.2% 18:1, 18% 18:2n-6, 1.9% 18:3n-3) (n = 59) or coconut and soy oil (10.3% 16:0 18:6% 18:1, 34.2% 18:2n-6, 4.7% 18:3n-3) (n = 57) or breast-fed (n = 56) with no formula supplementation. Different centers in North America were included to overcome potential bias due to differences in n-6 or n-3 fatty acids at birth or in breast-fed infants that might occur in a single-site study. Plasma and RBC phospholipid docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6), cholesterol and apo B were significantly lower in the formula- than breast-fed infants. There were no differences in looking acuity or growth among the breast-fed and formula-fed infants. No significant relations were found between DHA and looking acuity, or AA and growth within or among any of the infant groups. This study provides no evidence to suggest the formula provided inadequate n-6 or n-3 fatty acids for growth and looking acuity for the first 3 mon after birth.

Lipids 32, 63–72 (1997).

The physiological importance of docosahexaenoic acid (DHA, 22:6n-3) in normal visual and brain function is now recognized (1–4). Several studies have shown that the brain and eye contain all the enzymes necessary for synthesis of DHA from the dietary essential fatty acid α-linolenic acid (LNA, 18:3n-3) (5–7). Other studies, however, have shown DHA from plasma is taken up and incorporated into central nervous system (CNS) lipids (2,8). Plasma DHA can be derived from DHA in the diet, or from DHA synthesized from LNA in the liver and secreted in lipoproteins. Arachidonic acid (AA, 20:4n-6) is also present in high concentrations in CNS phospholipids and is important in many biochemical pathways including eicosanoid metabolism (2). AA can be synthesized from the dietary essential fatty acid linoleic acid (LA, 18:2n-6), but as for DHA, the pathway by which developing brain normally acquires AA is not clear.

Synthesis of DHA requires adequate activity of the fatty acid desaturase enzymes, an adequate dietary intake of LNA, and an appropriate balance of LA to LNA (9). Recent studies have shown conversion of LNA to DHA, and LA to AA in term and preterm infants (10,11). It is not clear, however, if the rates of DHA and AA synthesis are sufficient to meet the tissue needs of young infants.

Human milk contains small but variable amounts of DHA, usually ranging from about 0.2–0.4% fatty acids, and about 0.5% fatty acids as AA (11). Infant formulae containing vegetable and oleo oils contain LA and LNA but, in contrast to human milk, infant formulae in North America have no preformed AA or DHA. Term and preterm infants fed formula containing no AA or DHA have lower blood lipid levels of AA and DHA than infants fed human milk (12–15). The physiological significance of the lower blood lipid DHA and AA in formula-fed than breast-fed term gestation infants is controversial. Some studies have found no differences in tests of visual acuity or in electrophysiological tests of visual function between breast-fed and formula-fed term gestation infants (12,16,17). Others, however, have found evidence of lower visual function in term infants fed formula without DHA than in breast-fed infants (13,18–20), with no significant difference in visual function between infants fed formula with DHA and those who were breast-fed (20). The reason for the discrepancy in the results of different studies is not yet clear.

Studies with very premature infants have suggested an inverse relationship between blood lipid AA and growth (21). In other recent work, a potential negative effect of increasing LNA in formula on growth was suggested (22). Few previous studies have given a direct comparison of growth between infants fed formula with higher compared to lower levels of LNA. Differences in growth, however, have not been found in other recent studies with infants fed formula or breast-fed from birth to 3–4 mon of age (12,14,23).

Abbreviations: AA, arachidonic acid; CNS, central nervous system; DHA, docosahexaenoic acid; LA, linoleic acid; LNA, linolenic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; RBC, red blood cell; VEP, visual evoked potential.

The objective of this study was to determine the effect of infant formula containing differing amounts of LA and LNA with no AA or DHA on the blood lipid fatty acids, preferential looking acuity, and growth of healthy term gestation infants, with reference to normal breast-fed infants. Because the formulae studied also differed in levels of saturated, monounsaturated and polyunsaturated fatty acids, the effects on plasma cholesterol and apolipoprotein (apo) A-I and apoB were also measured. The study was undertaken at several centers in the United States and Canada selected to represent a typical North American breast-feeding population. The study included measures of growth through 90 d of age, analysis of plasma and erythrocyte phospholipid fatty acids at 14 and 90 d of age, and looking acuity, utilizing the Acuity Card Procedure at 90 d of age. The study duration was 90 d because solid foods are typically introduced between 3 and 4 mon after birth, and birth to 3 mon is the time of most rapid development of preferential looking acuity (24,25).

MATERIALS AND METHODS

Infants and diets. This was a multicenter, parallel-group study conducted simultaneously at seven different centers in the United States and Canada, with all the centers following a common study protocol. Infants were eligible to participate if they were term gestation, 37–41 wk gestation with a birth weight >2500 g to <4500 g, were less than 14 d of age, and if the mother had chosen to exclusively breast-feed or feed formula for at least 3 mon. Breast-fed infants who received formula later than 6 d after birth were not eligible. Infants with congenital problems or disease considered likely to interfere with normal feeding or nutrient metabolism, with feeding intolerance, poor milk or formula intake, or with abnormal eye exam, as judged by the infant's physician were also ineligible. Formula-fed infants were randomly assigned to receive one of two cow milk-protein based formulae (Mead Johnson Nutritionals, Evansville, IN) which differed only in the fat blend and fatty acid composition (Table 1). The computer-generated randomization schedules used to assign formula-fed infants to one of the two formulae were prepared centrally and distributed to each participating center. Formula 1 (Enfamil; Mead Johnson Nutritionals) had (percentage total fatty acids) 18.0% linoleic acid (LA, 18:2n-6), 1.9% linolenic acid (LNA, 18:3n-3) with an LA/LNA ratio of 9.5:1. Formula 2 had 34.2% 18:2n-6 and 4.7% 18:3n-3 with an LA/LNA ratio of 7.3:1 (Table 1). Neither formula had any detectable AA, DHA, or other carbon chain (C) 20 or 22 n-6 or n-3 fatty acids.

Breast-fed infants were breast-fed from birth, and from 6 d after birth could receive no infant formula for the first 30 d of the study, then no more than 6 ounces of formula per day. The group of breast-fed infants was subsequently stratified to those who received no supplemental formula and those who did. The parents were instructed not to feed solid foods and to record any incidence of feeding with anything other than the assigned formula or breast milk. Infants who received more than 10% dietary energy from sources other than the assigned formula or breast milk for 5 d or more were withdrawn from the study. The infants were monitored for any adverse reactions, concomitant medications, and illnesses or symptoms of concern. Infants who had formula intolerance, who were not brought for blood sampling, or with illness or other

TABLE 1
Major Fatty Acid Components (weight percentage total fatty acids) of Human Milk and Formula[a]

Fatty acid	Human milk 14 d $n = 55$	Human milk 90 d $n = 56$	Formula 1	Formula 2
12:0	5.6 ± 2.3	5.1 ± 1.7	9.3	16.8
14:0	5.8 ± 2.0	5.8 ± 1.6	5.2	7.8
16:0	21.4 ± 2.0	21.2 ± 2.4	22.2	10.3
16:1	3.0 ± 0.9	2.9 ± 0.8	0.2	0.1
18:0	7.7 ± 1.5	8.1 ± 1.7	5.2	4.6
18:1	36.4 ± 3.9	37.3 ± 4.6	36.2	18.6
18:2n-6	14.4 ± 3.9	14.6 ± 4.2	18.0	34.2
18:3n-3	1.0 ± 0.4	1.2 ± 0.6[b]	1.9	4.7
20:2n-6	0.5 ± 0.1	0.3 ± 0.1[b]	0.1	0.1
20:3n-6	0.5 ± 0.1	0.3 ± 0.1[b]	n.d.	n.d.
20:4n-6	0.6 ± 0.1	0.5 ± 0.1[b]	n.d.	n.d.
20:5n-3	<0.1	<0.1	n.d.	n.d.
22:4n-6	0.1 ± 0.0	0.1 ± 0.0[b]	n.d.	n.d.

22:5n-6	0.1 ± 0.0	<0.1	n.d.	n.d.
22:6n-3	0.3 ± 0.1	0.2 ± 0.1[b]	n.d.	n.d.

[a]Values for human milk are means ± SD, and for the formulae are the average of three separate analyses for each.
[b]Value for human milk on day 90 significantly different from value for the same fatty acid on day 14, $P < 0.01$.
n.d., Not detected. <0.1 indicates value of >0 to ≤0.05.

circumstances which resulted in dietary intakes <50% of normal for 5 d or more were withdrawn. The study protocol and procedures were reviewed and approved by the Institutional Review Board at each site at which infants were enrolled. Informed, written consent was obtained from a parent for all infants prior to participation.

Growth and blood collection. Body weight, length, and head circumference were recorded for all infants at birth, enrollment, 1, 2 and 3 mon of age. Breast-feeding mothers provided a midfeed sample of breast milk at 14 d and 3 mon postpartum. The milk samples were immediately frozen then transferred to storage at −70°C. Blood samples were collected by venipuncture with EDTA as the anticoagulant from each infant at 14 d and at 90 ± 4 d (3 mon) of age and within 2 h of feeding. The tubes containing the blood samples were immediately placed on ice, then the plasma and erythrocytes separated by centrifugation. The erythrocyte pellet was washed and repelleted, and the plasma and erythrocyte pellets were stored at −70°C prior to shipment to Vancouver for analysis of fatty acids (12,14).

Visual acuity. Binocular preferential looking (visual) acuity was tested at 90 ± 4 d of age using the acuity card procedure (26) with Acuity Cards from Vistech, Inc. (Dayton, OH) essentially as outlined in the Teller Acuity Card Handbook. The cards were presented to the infants in stepwise sequence from the coarsest to finest grating, commencing with 0.32 cycles/cm and progressing in 0.5 octave steps. Acuity was recorded as the finest grating that the infant could repeatedly and reliably resolve, as judged by the tester based on the looking behavior of the infant. Confidence ratings, indicative of the tester's confidence in their assessment of each infant's acuity, were recorded using a 5-point scale in which 1 was lowest. The infants were tested at a distance of 38 cm under controlled lighting conditions by trained testers. In order to standardize the testing procedure, all the testers from all the sites were trained by author VD during the same week using a standardized training and testing procedure.

Analytical methods. Plasma and erythrocyte lipids were extracted, plasma phospholipid and erythrocyte phosphatidylcholine (PC) and phosphatidylethanolamine (PE) separated, and fatty acid analyses undertaken exactly as described elsewhere (12,14,27). The fatty acid composition of the milk samples was determined following preparation of methyl esters without solvent extraction (28) as in previous studies (12). Plasma total cholesterol and triglycerides, and apoA-I and B were analyzed using enzymatic, and specific immunoassays, respectively (29,30).

Data analysis. Looking acuity scores in cycles/cm were converted to cycles per degree, and a $\log_2$ transformation was applied to the data prior to statistical analyses. The vanElteren test, which is a nonparametric test, was used to detect any statistical significance among the groups (31). Two-way analyses of variance were used to determine the effect of age (14 d compared to 3 mon) and diet (breast-feeding compared to formula feeding) on plasma and erythrocyte fatty acids, plasma cholesterol, and growth. Formal tests of differences between diets at each age and between ages within a diet group were based on least-square means and standard errors calculated from SAS statistical software (Version 6; SAS Institute, Cary, NC).

RESULTS

Two hundred thirty-eight infants were enrolled in this multicenter study, with 24, 39, 10, 43, 54, 33, and 35 infants enrolled at the seven different centers. There were 99, 69, and 70 infants in the breast-fed, Formula 1, and Formula 2 groups, respectively. Of these, 191 successfully completed the protocol with 75, 59, and 57 in each of the same groups, respectively. Of the infants in the breast-fed group, 56 had no documented incidence of feeding with formula. The results for analyses of blood lipids, fatty acids, and visual acuity given for the breast-fed infants are for this group only. No significant differences in body weight, length, or head circumference which could be attributed to breast feeding or formula feeding were found at 3 mon (Table 2), or at 1 or 2 mon of age (data not shown). There were no statistically significant differences in body weight or growth among the different study centers for any of the diet groups.

TABLE 2
Indices of Growth Among Term Gestation Infants Who Were Breast-Fed or Fed Formula to 90 Days of Age[a]

	Weight (g)	Length (cm)	Head circumference (cm)
Birth			
Breast-fed (n = 56)	3466 ± 64	51.6 ± 0.3	35.1 ± 0.2
Formula 1 (n = 59)	3540 ± 61[b]	52.2 ± 0.3	34.8 ± 0.2
Formula 2 (n = 57)	3326 ± 62	51.6 ± 0.3	34.5 ± 0.2
90 d			
Breast-fed (n = 56)	6120 ± 98	61.3 ± 0.3	41.0 ± 0.2
Formula 1 (n = 59)	6110 ± 93	61.2 ± 0.3	40.7 ± 0.2
Formula 2 (n = 57)	5984 ± 95	60.5 ± 0.3	40.8 ± 0.2

[a]Values are means ± SEM. There were no statistically significant differences in the indices of growth among the diet groups at 90 d of age.
[b]At birth, infants in the group randomized to receive Formula 1 were significantly heavier than those in the group randomized to receive Formula 2, P = 0.046.

TABLE 3
Plasma Cholesterol, Triglycerides, Apo A-1, and Apo B of Term Infants Fed Human Milk or Formula at 14 and 90 d of Age[a]

	Breast-fed	Formula 1	Formula 2
14 d			
Cholesterol (mmol/L)	3.20 ± 0.06 (n = 52)	2.58 ± 0.06[b] (n = 54)	2.56 ± 0.06[b] (n = 53)
Triglyceride (mmol/L)	0.98 ± 0.10 (n = 52)	1.21 ± 0.08 (n = 54)	1.17 ± 0.09 (n = 53)
Apo A-1 (g/L)	1.24 ± 0.03 (n = 49)	1.24 ± 0.03 (n = 53)	1.23 ± 09.03 (n = 51)
Apo B (g/L)	0.48 ± 0.02 (n = 48)	0.30 ± 0.01[b] (n = 53)	0.31 ± 0.02[b] (n = 52)
90 d			
Cholesterol (mmol/L)	3.60 ± 0.07 (n = 54)	2.98 ± 0.06[b] (n = 56)	2.83 ± 0.06[b] (n = 57)
Triglyceride (mmol/L)	1.56 ± 0.10 (n = 54)	1.63 ± 0.08 (n = 56)	1.35 ± 0.08[c] (n = 57)
Apo A-1 (g/L)	1.40 ± 0.03 (n = 51)	1.32 ± 0.03 (n = 54)	1.29 ± 0.03[d] (n = 54)
Apo B (g/L)	0.62 ± 0.02 (n = 51)	0.41 ± 0.01[b] (n = 54)	0.40 ± 0.01[b] (n = 56)

[a]Values are means ± SEM. The statistical analyses utilized repeated measures of analysis of variance. The analyses shown were derived from comparing the groups at 14 and 90 d from the diet group age term.
[b]Significantly different from value for the breast-fed group, $P < 0.0001$.
[c]Significantly different from value for infants fed Formula 1, $P < 0.05$.
[d]Significantly different from value for the breast-fed group, $P = 0.008$.

The fatty acid composition of the breast milk (Table 1) was similar to that reported for other North American and European women (11). On day 90 postpartum, the milk fatty acids had (mean ± SD) 14.6 ± 4.2% LA, 1.2 ± 0.6% LNA, 0.5 ± 0.1% AA, and 0.2 ± 0.1% DHA. Levels of LNA were significantly higher, but AA and DHA, as well as 20:2n-6, 20:3n-6 and 22:4n-6 were significantly lower in milk collected at 90 d compared to 14 d postpartum. In comparison to the human milk, Formula 1 had 18.0% and 1.9% and Formula 2 had 34.2% and 4.7% LA and LNA, respectively, with no detectable AA or DHA in either product (Table 1).

At both 14 and 90 d of age, the breast-fed infants had significantly higher plasma concentrations of total cholesterol and apo B ($P < 0.0001$) but similar concentrations of triglycerides to the infants fed formula (Table 3). The plasma concentrations of apo A-I were significantly lower in the 90-d-old infants fed Formula 2 ($P = 0.0008$), but not in infants fed Formula 1 ($P = 0.054$), than in the breast-fed infants. There were no significant differences in the plasma cholesterol, apo A-I, or apo B concentrations between infants fed Formula 1 and infants fed Formula 2 at either 14 or 90 d of age. Infants fed Formula 2, however, had a lower ($P = 0.014$) plasma triglyceride concentration than infants fed Formula 1 at 90, but not at 14 d of age.

The composition of n-6 and n-3, as well as the saturated and monounsaturated fatty acids in the infant plasma phospholipids, and erythrocyte PC and PE at 90 d of age are given in Tables 4, 5, and 6, respectively. Only results for breast-fed infants who were not given any formula are included.

Compared with the breast-fed infants, the groups of infants fed Formula 1 and Formula 2 both had significantly higher levels of 18:2n-6, and significantly lower levels of 20:3n-6, 20:4n-6, 20:5n-3, and 22:5n-3 and 22:6n-3 in plasma phospholipids (Table 4) and erythrocyte PC (Table 5), and higher 18:2n-6, 20:2n-6 and 20:3n-6, but lower 20:4n-6, 20:5n-3, and 22:6n-3 in erythrocyte PE (Table 6). Infants fed Formula 2 also had a significantly higher percentage 20:2n-6, 18:3n-3, and 18:0 and lower 18:1 in plasma phospholipids and erythrocyte PC and PE than the breast-fed infants. In contrast to infants fed Formula 2, infants fed Formula 1 had a significantly higher 16:0 and 18:1 and lower 18:0 in plasma phospholipid, higher 16:0 and lower 18:0 in erythrocyte PC, and higher 18:1 and lower 22:5n-3 in erythrocyte PE than the breast-fed infants. The lower plasma and red blood cell (RBC) phospholipid levels of AA in the infants fed formula than in the breast-fed infants was not associated with lower body weight at 90 d of age; neither were there any significant relations between plasma phospholipid (Fig. 1) or RBC, PC or PE (data not shown), AA and growth or birthweight in the group of infants as a whole, or in the individual diet groups.

The amounts of LA and LNA in the formula clearly resulted in differences in the levels of LA (18:2n-6) and LNA (18:3n-3), as well as the longer chain n-6 and n-3 fatty acids in plasma and erythrocyte lipids between the two groups of formula-fed infants. As expected, there were no statistically significant differences in the infant plasma or RBC phospholipid fatty acids among the different study centers. Infants fed Formula 2, which was higher in LA and LNA than Formula 1, had significantly higher levels of 18:2n-6 and 18:3n-3 as well as 20:5n-3, 22:5n-3 and 22:6n-3, and lower 20:3n-6 and

[c]Significantly different from value for infants fed Formula 1, $P < 0.05$.

22:5n-6 in plasma phospholipids (Table 4), higher 18:2n-6, 18:3n-3, 20:2n-6, 20:5n-3 and 22:5n-3, and lower 20:3n-6 and 22:5n-6 in erythrocyte PC (Table 5), and higher 18:2n-6, 20:2n-6, 18:3n-3, 20:5n-3 and 22:5n-3 and lower 20:3n-6, 20:4n-6, 22:4n-6 and 22:5n-6 in erythrocyte PE (Table 6) than infants fed Formula 1. Presumably, the higher levels of 18:3n-3, 20:5n-3, and 22:5n-3 in the blood lipids of infants fed Formula 2 than in infants fed Formula 1 reflects the difference in the level of 18:3n-3 in the two formula (percentage 18:3n-3, 1.9% and 4.7% for Formulae 1 and 2, respectively).

The differences in composition of saturated and monounsaturated fatty acids in the formulae also had a significant effect on the plasma and erythrocyte phospholipid fatty acids of the formula-fed infants. Infants fed Formula 1, which had higher levels of 16:0 and 18:1 than Formula 2, had significantly higher 16:0 and 18:1 and lower 18:0 in plasma phos-

pholipids and erythrocyte PC, and lower 18:0 and higher 18:1 in erythrocyte PE than infants fed Formula 2. Although the 16:0 and 18:1 levels in Formula 1 were similar to those in the human milk (Table 1), the plasma phospholipid 16:0 and 18:1, the erythrocyte PC 16:0, and the erythrocyte PE 18:1 were significantly higher in infants fed Formula 1 than in the breast-fed infants.

There were no significant differences in preferential look-

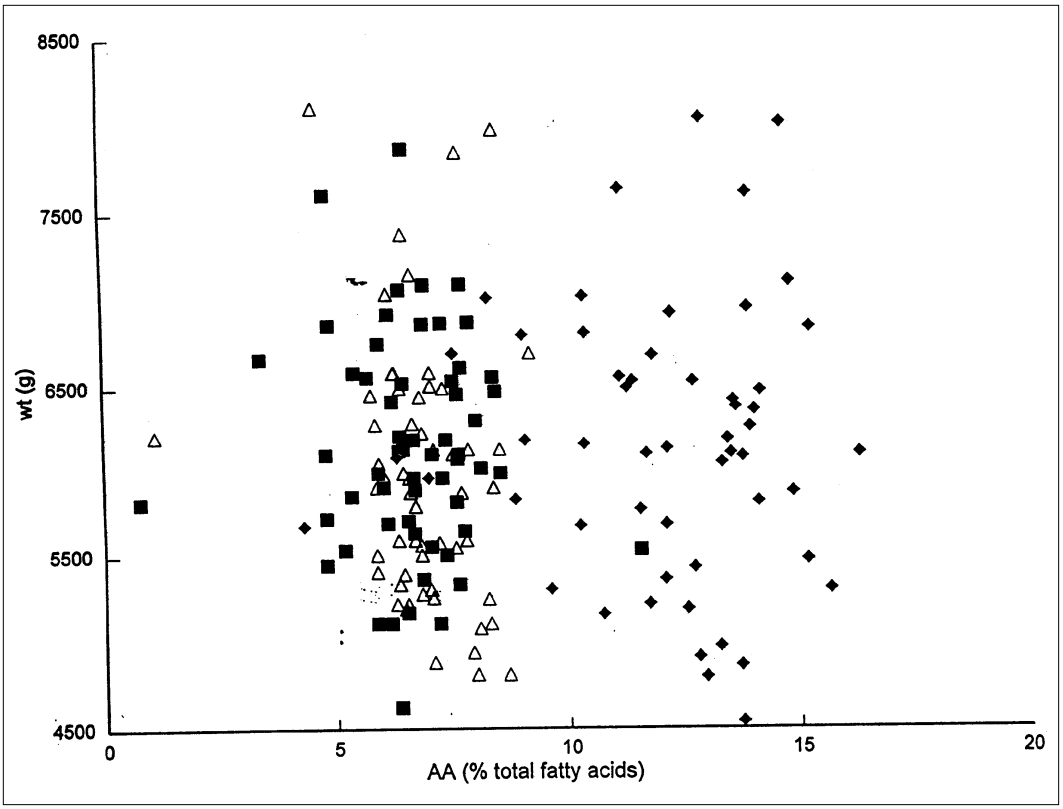

FIG. 1. Plasma phospholipid arachidonic acid (AA) and weight of 90-day-old infants who were breast-fed with no formula supplementation (◆), or fed formula 1 (■) or formula 2 (△). No statistically significant relations were found either for the group as a whole or for the individual diet groups.

TABLE 7
Preferential Looking Acuity in 90-Day-Old Term Infants Fed Human Milk or Formula[a]

Fatty acid	Breast-fed[b] (n = 56)	Formula 1 (n = 59)	Formula 2 (n = 57)
Acuity	2.79 ± 0.77	2.51 ± 0.50	2.67 ± 0.64
Range	0.22–5.53	1.11–4.49	1.11–6.77

[a]Values are given as means in cycles/degrees ± SD in octaves, with the range of acuity in cycles/degree. The statistical analyses utilized repeated measures of analysis of variance. The analyses shown were derived from comparing the groups at 90 d from the diet group age term.
[b]Infants who were breast-fed with no formula supplementation. There were no statistically significant differences among the groups.

ing acuity among the 90-day-old breast-fed and formula-fed infants, when comparisons were made with either the entire group of breast-fed infants (n = 75, P = 0.071) or the group of breast-fed infants (n = 56, P = 0.089) who received no formula supplementation (Table 7). Further, no significant differences in visual acuity scores were found among the study centers for the different groups. The visual acuity for all infants in the human milk group (n = 75) was 2.81 cycle/degrees ± 0.69 octaves, and was not different from the acuity results of the other groups. One infant in the group of breast-fed infants had a visual acuity of 0.22 cycles/degree, the next lowest acuity recorded for infants in this group was 1.11 cycles/degree. Removal of the result for this infant did not change the results of statistical analysis. A poststudy power analysis was done to ensure this study had sufficient power to detect a clinically relevant difference of 0.5 octaves in visual acuity between the groups, with an alpha level of 0.05. These calculations showed that this study had a power of at least 97% to detect a 0.5 octave difference in visual acuity among the groups. Tester confidence ratings for the 56, 59, and 57 infants who were breast-fed only, or fed Formula 1 or 2, were: 5 points, 43, 41, 40, 4 points, 13, 16, 15, and 3 points, 0, 2, 2 respectively. Confidence ratings of 1 or 2 were not recorded for any visual acuity test. One of the potential problems with a multicenter study is the possibility of variability in the infant populations at the different study centers. This study found no statistically significant differences in visual acuity scores among infants from the different centers. Analyses were also undertaken to explore potential relations between visual acuity and DHA in the plasma and erythrocyte PC (data not shown) and erythrocyte PE (Fig. 2). No statistically significant relations were found between DHA in any lipid fraction analyzed and visual acuity either for the group of infants as a whole or within the groups of breast-fed (with or without formula supplemented) or formula-fed infants.

DISCUSSION

This multicenter, prospective study found no difference in growth or in preferential looking acuity at 90 d of age among breast-fed infants and infants fed a formula with 18.0% LA (18:2n-6) and 1.9% LNA (18:3n-3), or 34.2% LA and 4.7% LNA with no AA or DHA. The looking acuities found here are well within recently reported binocular tolerance limits for visual acuity at 3 mon of age as measured using the acuity card procedure (24). The findings of these studies are also consistent with a large cross-sectional study of over 400 9-mon-old infants (17), as well as with other prospective studies that show similar preferential looking acuity in healthy term gestation breast-fed infants and infants fed formula with about 18% LA and 2.0% LNA with no AA or DHA from birth to 90 d (12), or to 1 year of age (16). In the latter study, visual evoked potential (VEP) and scores in developmental tests were also similar between breast-fed infants and infants fed formula without AA or DHA when measured from birth to 14 months of age (16,32). Another study using similar formula, however, found lower looking acuity in formula-fed than breast-fed infants at 2 but not at 4 mon of age (18). Studies by Jorgensen *et al.* (19) in Denmark also reported a higher increase in looking acuity from 2 to 4 mon of age in a group of breast-fed compared to formula-fed infants and similarly, studies in Australia have found a lower VEP acuity at 5 mon of age in a group of 8 formula-fed infants than in 8 breast-fed infants (13). Another recent study from Australia described a lower mean acuity, when extrapolated from VEP data, at 16 and 30 wk of age in infants fed formula with about 16.8% LA and 1.6% LNA than in breast-fed infants. Infants fed a formula with 0.3% 18:3n-6, 0.5% 22:5n-3, and 0.4% 22:6n-3 from evening primrose oil and fish oil had VEP acuity results which were not significantly different from the group of breast-fed infants. It is not clear if differences in the results among studies are explained by differences in LNA content, LA/LNA ratio, or other nutrients in the formulae, or by other socioeconomic or environmental differences in the groups of nonrandomized breast-fed and formula-fed infants. Differences in the methodologies used to assess visual function could also potentially explain some of the discrepancies in the findings. However, although acuity is higher when measured with electrophysiological methods, there is a close correlation between visual acuity measured with acuity cards and both sweep and steady-state VEP in infants (33).

An important feature of the study reported here which could influence the ability to detect significant group differences in visual acuity was the use of a multicenter design. Two aspects of the acuity card procedure, however, make it particularly suitable for multicenter studies. First, test duration is short, with an average test duration of 3–5 min, and the equipment and procedures are well standardized. Second, al-

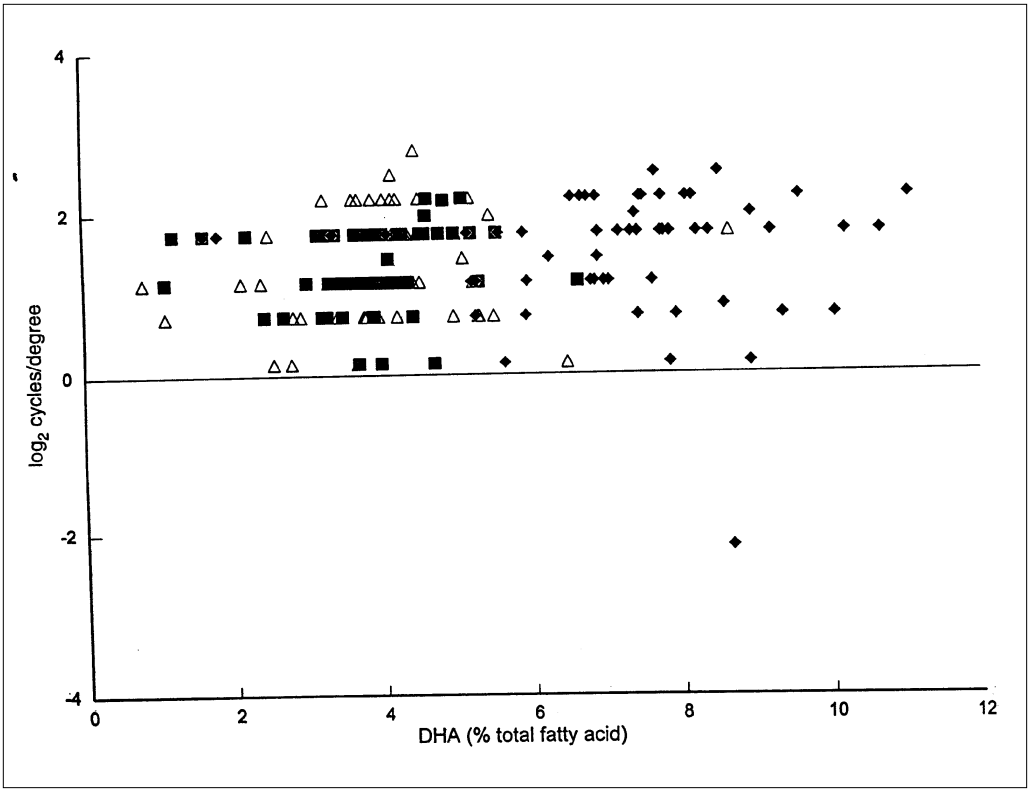

FIG. 2. Erythrocyte phosphatidylethanolamine docosahexaenoic acid (DHA) and visual acuity in $\log_2$ cycles/degree of 90-day-old infants who were breast-fed with no formula supplementation (◆), or fed formula 1 (■) or formula 2 (△). No statistically significant relation between DHA and visual acuity is present for the group as a whole, or for the individual diet groups.

though the testing procedure requires training and practice, no particular technical skills are needed (34). For this study, group training and practice was provided for all of the testers at a single center. A limitation of the methodology, however, is that it was not possible to obtain measures of intertester reliability. Genetic and/or environmental variables among subjects and differences in the test environment among the centers may also decrease the power to find differences due to diet.

Evidence for an inverse relation between blood lipid AA and growth in premature infants has been reported (21), and a recent preliminary report described lower growth among infants fed formula with 4% compared to 1% LNA (22). In the study reported here, the growth of healthy term infants fed formula was not different from that of breast-fed babies, despite the two-fold difference in plasma phospholipid AA level between the breast-fed and formula-fed infants. Further, no effect of the formula content of LNA (4.7% compared to 1.9%), or palmitic acid (16:0), oleic acid (18:1) or LA/LNA ratios of 9.5 and 7.3 on growth was found. Consistent with these results, other studies have also found that term gestation infants fed formula grow at least as well as breast-fed infants (12,14,23,35).

Dietary polyunsaturated and monounsaturated fatty acids result in lower plasma total and LDL cholesterol than saturated fatty acids, particularly 14:0 and 16:0 (36,37). Polyunsaturated, but not monounsaturated fatty acids, however, can also lower high density lipoprotein (HDL) cholesterol. The studies reported here included analyses of apo A-I and apo B, which are the major apoprotein components of HDL and LDL, respectively, in infants fed formulae which differed in saturated, monounsaturated, and polyunsaturated fatty acids and in breast-fed infants. As shown by others (35,38,39), the plasma total cholesterol and apo B concentrations in infants fed formula was uniformly lower than in breast-fed infants. Despite a two-fold difference in the 16:0 content of the formulae (22.2 and 10.3% 16:0), neither the plasma total cholesterol nor the apo B concentration differed between the groups of formula-fed infants. Infants fed the formula which was high in polyunsaturated fatty acids (Formula 2, 34.2% LA and 4.7% LNA) did have significantly lower plasma apo A-I levels than infants who were breast-fed. This finding is consistent with information that shows polyunsaturated, but not monounsaturated, fatty acids may lower plasma HDL (36). Whether these differences in plasma lipoproteins are of any physiological significance to the young infant is not yet clear. Possibly, the lack of an effect of the differences in dietary saturated fatty acid intake on plasma cholesterol in the formula-fed infants in these studies is explained by the absence of significant amounts of cholesterol in liquid formu-

lae. In this regard, although studies by van Biervliet *et al.* show that addition of cholesterol to formula can increase plasma cholesterol in formula-fed infants, Hayes and Khosla (40) have hypothesized that dietary 16:0 does not raise serum cholesterol when the cholesterol intake is very low.

As is now well known (12–15), and again shown here, infants fed formula without AA or DHA have lower blood lipid levels of AA and DHA than breast-fed infants. In the study reported here, infants fed a formula with 4.7% LNA in a LA/LNA ratio of about 7.3:1 had modestly but significantly higher plasma phospholipid levels of DHA than infants fed a formula with 1.9% LNA, in a LA/LNA ratio of about 9.5:1. The difference in DHA between infants fed the two formulae was accompanied by an inverse change in the plasma phospholipid 22:5n-6. A similar difference in 22:5n-6 was present in both the erythrocyte PC and PE. Previous studies have found lower erythrocyte PC and PE 22:5n-6 and higher PE DHA in 4.5–6-month-old term infants fed formula with 45.1% LA and 5.0% LNA than in infants fed formula with 14.0% LA and 1.2% LNA (15). These findings suggest that relatively high compared to lower amounts of LA in formula (up to 34% fatty acids) do not limit the conversion of LNA to DHA at least when provided in LA/LNA ratios under 10:1. It also seems that higher amounts of LA in formulae do not result in preferential synthesis of AA or its elongation and further desaturation. For example, Formula 1 with 18% LA resulted in a significantly higher infant erythrocyte PE AA than Formula 2 which had 34.2% LA. Presumably, the lower levels of 22:5n-6 found in association with higher LA in formulae in this and previous studies (15) are explained by the accompanying higher amount of LNA resulting in inhibition of n-6 fatty acid desaturation. This suggestion is consistent with the inverse relationship between plasma and tissue levels of 22:5n-6 and the dietary LNA supply (2).

Providing levels of 16:0 and 18:1 in formulae similar to the mean levels in human milk of about 21 and 36% total fatty acids, respectively, resulted in plasma phospholipid levels of 18:0 and 18:1 in formula-fed infants closer to those of breast-fed infants. The significance of differences in plasma saturated and monounsaturated fatty acids in young infants is not known, but in young piglets these differences are accompanied by differences in the saturated and monounsaturated fatty acid composition of liver phospholipids (41). Thus, it seems reasonable to assume that formulae should provide a balance of monounsaturated fatty acids which result in blood lipid monounsaturated fatty acid levels similar to those of breast-fed infants.

In summary, the results of this multicenter trial show no measurable differences in visual acuity, as measured with the acuity card procedure, or growth among 90-day-old infants fed formula with 1.9% or 4.7% LNA and no DHA or AA, and breast-fed infants. Continued study of the dietary requirement for various n-6 and n-3 fatty acids and of their role in infant development is clearly needed to resolve the different findings from others working on this issue.

[a]The United Graduate School of Agricultural Sciences, Gifu University, Gifu 501-11, Japan, [b]CCI Corporation, Seki, Gifu 501-32, Japan, and [c]National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Ibaraki 305, Japan

ABSTRACT: A novel derivative of vitamin E, vitamin E glucoside, was synthesized from 2-hydroxymethyl-2,5,7,8-tetramethylchroman-6-ol and maltose in a solution containing DMSO by transglycosylation with α-glucosidase from *Saccharomyces* species. The glycosylated product was identified as 2-(α-D-glucopyranosyl)methyl-2,5,7,8-tetramethylchroman-6-ol (TMG) by mass spectrometry and nuclear magnetic resonance spectroscopy. The optimal pH of transglycosylation was 5.5, and the yield of TMG increased as the concentration of maltose increased. TMG has high solubility in water (>1×10^3 mg/mL). The 1,1-diphenyl-2-picrylhydrazyl radical scavenging activity of TMG was found to be nearly the same as those of α-tocopherol, Trolox (2-carboxy-2,5,7,8-tetramethylchroman-6-ol), and ascorbic acid.

Lipids 31, 73–78 (1996).

Many of the most serious human diseases, including cancer and heart disease, at some stage involve oxidation processes mediated by free radicals (1). Much attention has been focused on the protective effect by antioxidants against damage caused by active oxygen and free radicals *in vivo*. There has been considerable interest in the effectiveness of antioxidants in the therapy and prevention of human disease. Among the antioxidants, the effectiveness of vitamin E, a chain-breaking antioxidant, is well known (2–6). Vitamin E is a lipophilic compound, and it is generally accepted that it is incorporated into biological membranes and is especially effective as a lipid-peroxyl radical scavenger (4,7,8). Vitamin E also scavenges active oxygen species such as superoxide anion radical (9), singlet molecular oxygen (10), and hydroxyl radical (11). The antioxidant properties of vitamin E are based on the ability of the chromanoxyl ring to interact with different free radicals (3,12). Since the mobility of vitamin E in the biological membranes is restricted due to its long phytyl side chain, it seems to be unlikely to scavenge active oxygens which might be generated in aqueous phase. In recent studies, the significance of a water-soluble analog of vitamin E, Trolox (2-carboxy-2,5,7,8-tetramethylchroman-6-ol, Scheme 1), has been reported (13–17). In practice, however, Trolox is nearly insoluble in water. We believe that introduction of glucose into the molecule of vitamin E analog will increase its water solubility to scavenge reactive oxygen species in the aqueous phase efficiently.

Enzymatic transformation has been utilized to improve the chemical properties and physiological functions of biologically useful substances (18–20). α-Glucosidase (EC 3.2.1.20) has been found to catalyze transglycosylation (21,22). If the carboxyl group of Trolox is reduced to the corresponding alcohol, 2-hydroxymethyl-2,5,7,8-tetramethylchroman-6-ol (TM), the chemical properties, and the solubility in water of

this vitamin E derivative might be easily modified by the transglycosylation reaction. In this paper, we describe the synthesis of a novel vitamin E glucoside, 2-(α-D-glucopyranosyl)methyl-2,5,7,8-tetramethylchroman-6-ol (TMG), by α-glucosidase-catalyzed transglycosylation using an aqueous–organic solvent system. The water-solubility and free-radical scavenging activity of TMG are also described.

EXPERIMENTAL PROCEDURES

Materials. (*R,S*)-Trolox and its optically active isomers, (*R*)- and (*S*)-forms, were obtained from Aldrich Chemical Co. (Milwaukee, WI). *RRR*-α-Tocopherol was obtained from Eisai Co. (Tokyo, Japan). α-Glucosidase from *Saccharomyces* sp. (Diagnostic Reagent Grade) and β-glucosidase from sweet almond (Diagnostic Reagent Grade) were obtained from Toyobo Co. (Osaka, Japan). Centrifugal ultrafiltration tubes (Ultrafree MC-LG, 0.2 mm pore size) were purchased from Millipore (Milford, MA). All other reagents were of analytical grade.

Preparation of TM. Trolox was reduced with $LiAlH_4$ to produce the corresponding TM. To a solution of (*R,S*)-Trolox (2.0 g) in diethyl ether (200 mL) was added 1.0 g of $LiAlH_4$. The suspension was refluxed for 20 h. After cooling on an ice bath, the reaction was stopped by adding 15 mL of concentrated HCl. The diethyl ether phase was washed with water, dried over anhydrous Na_2SO_4, and the solvent was removed *in vacuo*. The resulting pale-yellow powder of TM was purified by silica-gel column chromatography with hexane/ethyl acetate (1:1, vol/vol) as the solvent. The elution was checked by thin-layer chromatography (TLC) on a precoated silica gel 60 plate (E. Merck, Darmstadt, Germany) using hexane/diethyl ether/acetic acid (50:60:1, by vol). The TM fraction that gave a single spot (R_f 0.69) on the TLC plate was combined, passed through a 0.45-μm filter, and the solvent was removed *in vacuo*. Pure (*R,S*)-TM was thus obtained as a white powder (1.8 g yield) (23,24): infrared (IR) (KBr) ν_{max} 3400, 2920, 1640, 1460, 1420, 1380, 1260, 1150, 1110, 1085, 1060, 1050, and 920 cm^{-1}; ^1H NMR dimethyl sulfoxide [(DMSO)-d_6] δ 1.14 (*s*, 3H), 1.60–1.88 (*m*, 2H), 1.98 (*s*, 3H), 2.02 (*s*, 3H), 2.05 (*s*, 3H), 2.51 (broad *t*, 2H), 3.35 (*q*, *J* = 10.7 Hz, 2H), 4.78 (broad *s*, 1H), and 7.38 (broad *s*, 1H). The (*R*)- and (*S*)-forms of TM were also prepared from (*R*)- and (*S*)-forms of Trolox, respectively.

Glucosidase activity. The α-glucosidase activity was determined by measuring the amount of glucose formed. The reaction mixture contained 100 μL of 4% maltose solution, 300 μL of 0.1 M potassium phosphate buffer (pH 6.5), and 40 μL of enzyme solution. After the mixture was incubated at 37°C for 20 min, the reaction was stopped by heating in a boiling water bath for 5 min. The glucose content was determined by the glucose oxidase method (25) using a glucose assay kit (Wako Pure Chemical Industries, Osaka, Japan). One unit of α-glucosidase activity was defined as the amount of enzyme which hydrolyzed 1 μmol of maltose per min.

Enzyme reaction. The enzyme reaction was carried out in an aqueous–organic solvent system using DMSO as the organic solvent. The standard reaction mixture contained 1.0 mL of 40% maltose in 50 mM potassium phosphate buffer (pH 6.0), 200 μL of 5% TM in DMSO, and 50 μL of α-glucosidase (5 U) in 50 mM potassium phosphate buffer (pH 6.5). The reaction was carried out at 40°C for 20 h. An aliquot (200 μL) sample was withdrawn, dissolved in 1.0 mL of acetonitrile/water (1:1, vol/vol), and analyzed by TLC and high-performance liquid chromatography (HPLC).

HPLC. HPLC was done with a Hitachi L-6300 pump equipped with a L-4250 ultraviolet (UV)-visible and a L-3350 refractive index detectors (Hitachi Co., Tokyo Japan). TM and its glucoside, TMG, in the reaction mixture were analyzed by an Inertsil ODS-2 column (6.0 × 150 mm; GL Sciences Inc., Tokyo, Japan) developed with acetonitrile/water (40:60, vol/vol) at a flow rate of 1.0 mL/min. The eluent was monitored by an absorbance at 280 nm. The *R/S* ratio of TMG was analyzed by a Wakosil-II 5C18 HG column (4.6 × 250 mm; Wako Pure Chemical Industries) developed with acetonitrile/water/10% H_3PO_4 (20:80:0.1, by vol) at a flow rate of 0.5 mL/min. Maltose and glucose were analyzed by a Shodex Asahipak NH2P-50 column (4.6 × 250 mm; Showa Denko, Tokyo, Japan) with acetonitrile water (75:25, vol/vol) at 1.0 mL/min. The eluent was monitored by a refractive index.

Spectral analysis. UV spectra were measured with a Hitachi U-3210 spectrophotometer. IR spectra were measured on potassium bromide pellets using a Jasco FT/IR-8000 IR spectrophotometer (Japan Spectroscopic Co., Tokyo, Japan). Fast atom bombardment–mass spectrometry (FAB–MS) was done with a Shimadzu 9020-DF instrument (Shimadzu Co., Kyoto, Japan) with a xenon fast atom bombardment gun. Samples were placed in the 5.5 kV xenon atom beam on a probe with glycerol as the matrix. ^1H (270.17 MHz) and ^{13}C (67.9 MHz) nuclear magnetic resonance (NMR) spectra were recorded at 25°C on a Jeol GX-270 FT-NMR spectrometer (Jeol, Tokyo, Japan) using DMSO-d_6 as solvent and tetramethylsilane as internal standard. Specific rotations were determined with a Union PM-201 automatic digital polarimeter (Union Gikken, Osaka, Japan).

Preparation of TMG. The reaction mixture contained 80 mL of 60% maltose in 50 mM potassium phosphate buffer (pH 6.0), 16 mL of 5% TM in DMSO, and 0.1 mL of α-glucosidase (400 U) in 50 mM potassium phosphate buffer (pH 6.5). After the reaction was carried out at 40°C for 20 h, the reaction mixture was applied on an Amberlite XAD-4 column (4 × 40 cm) equilibrated with 30% methanol. The column was washed with the same solvent to remove DMSO and sugars. TMG and TM were then eluted with 80% methanol. The eluent was checked by TLC using chloroform/methanol/acetic acid/water (40:10:2:1, by vol). Compounds were visualized by spraying with H_2SO_4/methanol (1:1, vol/vol) followed by charring. Spots with reducing power were detected by spraying with the ferric chloride/bathophenanthroline reagent (26). The TMG fraction was combined, and the solvent was removed *in vacuo*. The resulting white powder was further pu-

rified by silica-gel column chromatography using ethyl acetate/methanol (5:1, vol/vol). Pure TMG was obtained as a white powder (200 mg yield).

Enzymatic hydrolysis of TMG. The reaction mixture containing 1.0 mL of 5 mM TMG in 50 mM potassium phosphate buffer (pH 6.0) and 50 μL of a glucosidase (5 U, α-glucosidase from *Saccharomyces* sp. or β-glucosidase from sweet almond), incubated at 40°C for 3 h. An aliquot (200 μL) was withdrawn and mixed with 1.0 mL of acetonitrile/water (1:1, vol/vol). The TM and TMG were analyzed by HPLC. The liberated glucose was analyzed by the glucose oxidase method (25).

Solubility of vitamin E analogs. Each vitamin E analog (300 mg) was put into a 3 mL glass vial, after which 250 μL of water was added. The mixture was placed on a water bath equipped with a magnetic stirrer, and was stirred at 200 rpm at 25°C for 20 h. The mixture was then transferred into a centrifugal ultrafiltration tube and centrifuged at 2000 × *g* for 10 min. The amount of each vitamin E analog in the filtrate was determined by revered-phase HPLC.

Scavenging of 1,1-diphenyl-2-picrylhydrozyl (DPPH). Free-radical scavenging activity of each antioxidant was assayed using a stable free radical, DPPH, according to the method of Blois (27). The reaction mixture contained 1 mL of 0.5 mM DPPH in ethanol and 4 mL of 0.1 mM antioxidant in ethanol/water (50:50, vol/vol). Finally, the total volume of the reaction mixture was adjusted to 5 mL with ethanol. After the reaction was carried out at room temperature for 20 min, the free-radical scavenging activity of each antioxidant was quantified by the decolorization of DPPH at 516 nm.

RESULTS

Transglycosylation of maltose to TM. α-Glucosidase from *Saccharomyces* sp. could catalyze the transglycosylation to TM from maltose to produce a novel vitamin E glucoside, TMG, in an aqueous DMSO solution. Figure 1 shows the α-glucosidase-catalyzed reaction product of TM with maltose after 20 h incubation. A peak corresponding to the glucoside of TM appeared at 3.3 min. The glucoside gave a red spot (R_f 0.40) on a TLC plate by the ferric chloride/bathophenanthroline reagent, indicating the presence of the reducing power (26).

A large amount of TMG was prepared from (*R,S*)-TM and maltose according to the procedure as described in the Materials and Methods section. TMG was hydrolyzed by α-glucosidase (the degree of hydrolyis was 80%) and produced an equimolar ratio of TM and glucose. On the other hand, β-glucosidase did not hydrolyze TMG. The FAB–MS of TMG showed a molecular ion at *m/z* 398 (M^+, 100%) in addition to other fragment ions: 237 (98), 219 (26), 205 (27), 191 (16), and 165 (75). Table 1 shows the ^{13}C NMR spectra of (*R,S*)-, (*R*)-, and (*S*)-forms of TMG and (*R,S*)-TM in DMSO-d_6. The ^{13}C chemical shifts of the chromanol moiety were essentially the same as those of TM except for the C-2 and C-2a shifts. The C-2a signal of TMG was shifted downfield (3.3 ppm) relative to that of TM, and the C-2 signal was shifted slightly upfield (1.0 ppm). The signals of C-2 carbon atom could be resolved by the data of optically active (*R*)- and (*S*)-forms of TMG. The remaining signals of TMG were assigned as the carbons of α-D-glucopyranosyl moiety. The α-configuration of the D-glucosyl residue in the TMG was confirmed by the C-1 signal at δ 98.8. From these data and other spectral data, the structure of TMG was identified as 2-(α-D-glucopyranosyl)methyl-2,5,7,8-tetramethylchroman-6-ol: UV (ethanol) λ_{max} 291 nm (ε 3000); IR (KBr) ν_{max} 3400, 2920, 1640, 1460, 1420, 1380, 1260, 1150, 1110, 1030, and 920 cm^{-1}; and $[\alpha]_D^{25}$ +85.6 (c 0.500, ethanol). (*R*)-TMG, $[\alpha]_D^{25}$ +90.4 (c 0.500, ethanol); and (*S*)-TMG, $[\alpha]_D^{25}$ +79.6 (c 0.500, ethanol). The *R/S* ratio of TMG produced from (*R,S*)-TM was determined to be 1.3:1 by the HPLC analysis.

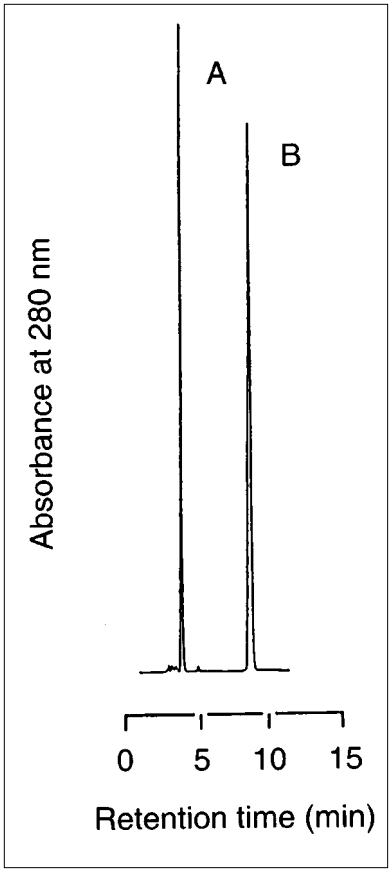

FIG. 1. Reversed-phase high-performance liquid chromatography (HPLC) of the transglycosylation products from maltose to TM by α-glucosidase. The reaction was carried out at 40°C for 20 h as described in the Experimental Procedures section. HPLC was done with an Inertsil ODS-2 column (4.6 × 150 mm) (GL Sciences, Inc., Tokyo, Japan) which was developed with acetonitrile/water (40:60, vol/vol) at 1.0 mL/min. Peak A, the transglycosylation product of TM; and peak B, TM. See Scheme 1 for other abbreviation.

Figure 2 shows the effect of pH on the hydrolysis of maltose and on the synthesis of TMG by α-glucosidase. While the optimal pH for hydrolysis of maltose was 7.0, the pH for synthesis of TMG was 5.5. On the other hand, the two reactions had the same optimal temperature to be at 40°C (data not shown). The effect of maltose concentration on the syn-

thesis of TMG is shown in Figure 3. The yield of TMG increased as the concentration of maltose increased, and reached to maximal level at 60%. The effect of TM concentration on the synthesis of TMG is shown in Figure 4. TM is scarcely soluble in water, and the solubility of TM depends on the concentration of DMSO in the reaction mixture. To evaluate the optimal concentration of TM for the transglycosylation reaction, the volumetric ratios between the acceptor solution (as 5% TM in DMSO) and the donor solution (as 40% maltose in buffer) were changed. When the ratio between the two solutions was changed from 1:11 to 4:8 by volume, the amount of TMG formation increased as ratios of the TM solution until the ratio came to be 3:9. In contrast, the proportion of TM used for the production of TMG in the re-

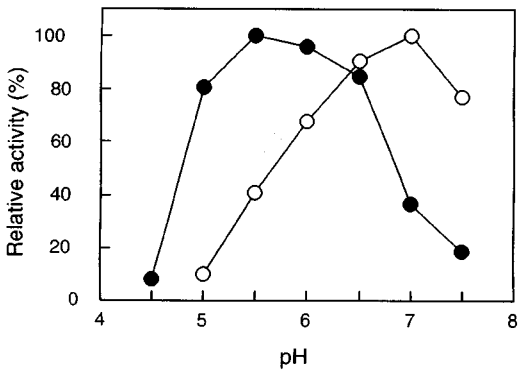

FIG. 2. Effect of pH on the hydrolysis of maltose and the synthesis to TMG. The hydrolysis activities (○) were determined as described in the Experimental Procedures section, except that the pH was varied. The reaction mixture containing 100 μL of 4% maltose, 300 μL of 0.1 M buffer, and 40 μL of α-glucosidase was incubated at 37°C for 20 min. The transglycosylation activities (●) were determined by the measurement of the TMG formed as described in the Experimental Procedures section. The reaction mixture containing 1.0 mL of 40% maltose in 50 mM potassium buffer, 200 μL of 5% TM in dimethyl sulfoxide, and 50 μL of α-glucosidase (5 U) was incubated at 40°C for 20 h. See Scheme 1 for abbreviations.

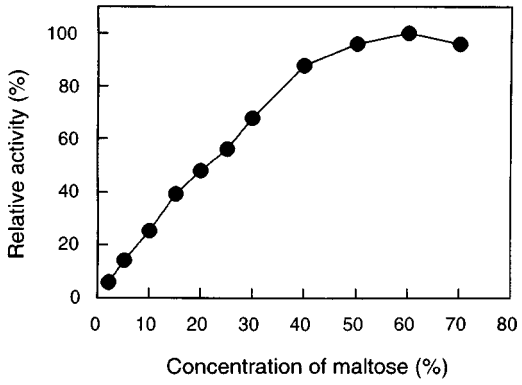

FIG. 3. Effect of maltose concentration on the synthesis of TMG. The reaction mixture containing 1.0 mL of maltose solution, 200 μL of 5% TM in dimethyl sulfoxide, and 50 μL of α-glucosidase (5 U) was incubated at 40°C for 20 h. Relative activity was expressed as a percentage vs. the maximum values obtained. See Scheme 1 for abbreviations.

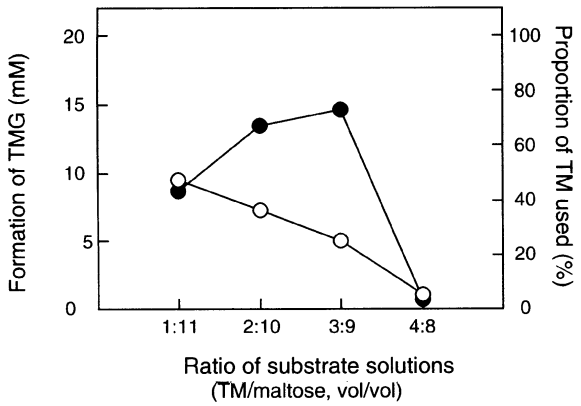

FIG. 4. Effect of TM concentration on the synthesis of TMG. The reaction mixture consisted of 1.2 mL of substrate solution and 50 μL of α-glucosidase (5 U). The ratio between two substrate solutions (5% TM in dimethyl sulfoxide and 40% maltose in 50 mM potassium phosphate buffer, pH 6.0) was varied from 1:11 to 4:8 by volume as indicated. The reaction was carried out at 40°C for 20 h. The amounts of TM and TMG in the reaction mixture were determined by HPLC. The proportion of TM used was expressed as a percentage vs. the initial amounts of TM in the reaction mixture. ○, the TM used; and ●, TMG. See Scheme 1 and Figure 1 for abbreviations.

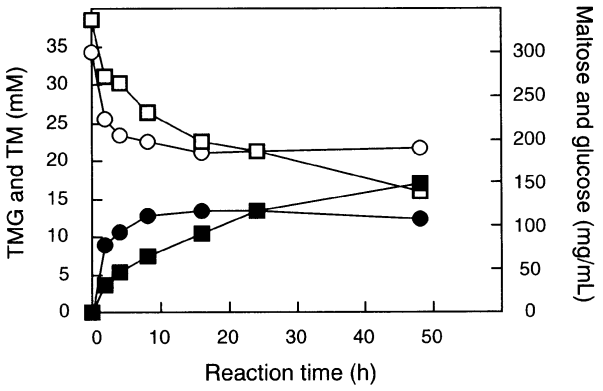

FIG. 5. Time course for the synthesis of TMG. The reaction mixture containing 1.0 mL of 40% maltose solution, 200 μL of 5% TM in dimethyl sulfoxide, and 50 μL of α-glucosidase (5 U) was incubated at 40°C. The amounts of TM, TMG, maltose, and glucose were determined by HPLC as described in the Experimental Procedures section. ●, TMG; ○, TM; □, maltose; and ■, glucose. See Scheme 1 and Figure 1 for abbreviations.

action mixture decreased with the increase of the TM solution ratio. Figure 5 shows the time course for the synthesis of TMG. TM was rapidly converted into TMG with decrease of maltose, and the transglycosylation reaction attained equilibrium after the 16-h incubation. There was no further increase in the amount of TMG even if another fresh α-glucosidase (5 U) was added to the reaction mixture after the 24-h incubation (data not shown).

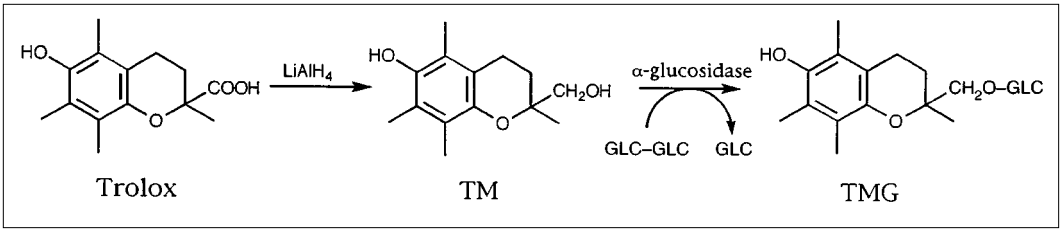
Water solubility of TMG. The solubility (mg/mL) of TMG and other vitamin E analogs in water are TMG, $>1 \times 10^3$; TM, 1.01; Trolox, 0.16. TMG showed the extremely highest solubility ($>1 \times 10^3$ mg/mL) against water among the vitamin E analogs. The value was about 6×10^3 times higher than that of Trolox and was about 1 x 10^3 times than that of TM, respectively.

DPPH scavenging activity. The free-radical scavenging activities of TMG and some other antioxidants were determined by the use of a stable free-radical, DPPH. Comparing the scavenging activities to that of cysteine, 1 molecule of TMG reacted with two molecules of DPPH (27). Thus, one molecule of TMG would trap two molecules of free radicals during the scavenging reactions. This level of activity was nearly the same as those of α-tocopherol, Trolox, and ascorbic acid: antioxidant (20 μM), relative, respectively, are cysteine (1.0); TMG (1.9); TM (1.9); Trolox (2.0); α-tocopherol (1.8); ascorbic acid (1.8).

DISCUSSION

Vitamin E is regarded as the major lipid-soluble antioxidant preventing oxidative attack of membrane lipids and other membrane compounds. The chromanol structure of vitamin E is responsible for the radical scavenging activity and, in particular, the hydroxyl group at the C-6 position is essential for this activity (3,12). If the chromanoxyl ring might be water-soluble, it would scavenge the free radicals produced in aqueous phase efficiently. Therefore, we have studied the synthesis of a water-soluble vitamin E analog: a chromanol compound having hydroxymethyl group, TM, was prepared by the reduction of Trolox; using this derivative, a selectively glycosylation to the hydroxylmethyl group was attempted by α-glucosidase. We have succeeded in the synthesis of a novel water-soluble vitamin E analog, TMG, by this procedure (Scheme 2).

Enzymatic transglycosylation has been utilized to improve the chemical properties of some compounds (18–22). In general, the acceptor (TM) and donor (maltose) should be in a soluble state in the reaction mixture to increase the efficiency of transglycosylation, and the higher the ratio of the acceptor to the donor is necessary. Because TM is barely soluble in water, the addition of a water-miscible solvent to the reaction mixture is required to dissolve the TM in the solution of maltose. The rate of transglycosylation from maltose to TM was examined in the presence of water-miscible organic solvents. When DMSO was used as the water-miscible solvent, the transglycosylation product was found to be formed by α-glucosidase from *Saccharomyces* sp. However, the addition of other solvents, such as ethanol, methanol, acetonitrile, acetone, and *N,N*-dimethylformamide, in the reaction mixture scarcely formed the transglycosylation product (data not shown). Thus, we concluded that DMSO was the most suitable solvent for the synthesis of TMG. On the other hand, a higher concentration of DMSO added in the reaction mixture decreased the efficiency of TMG formation (Fig. 4). In general, enzymes become unstable and lose their activity in a mixture of water and a water-miscible organic solvent. Therefore, the concentration of DMSO should be lowered to minimize the inactivation of α-glucosidase during the glycosylation of TM. The transglycosylation reaction reached to be a plateau at the 16 h incubation under the present conditions (Fig.



SCHEME 2

5). This may be due to the achievement of an equilibrium state, because the addition of another α-glucosidase did not enhance the production of TMG. Furthermore, the concentration of TMG decreased slightly with increase of TM after the 48-h incubation due to the hydrolysis of TMG. There is no other transglycosyl product during the reaction.

The water-solubility of TMG is very high compared with those of another vitamin E analogs, Trolox and TM. Moreover, TMG exhibited a scavenging activity against a stable free-radical, DPPH, as the same degree as those of α-tocopherol, Trolox, and ascorbic acid. α-Tocopherol has been demonstrated to have multiple effects on various diseases. Thus, TMG may be therapeutically a useful antioxidant. We are undertaking further studies to elucidate its antioxidant activity and protective effect against the free-radical damages in biological tissues and fluids.

Biotransformations of Tocopherols by *Streptomyces catenulae*

Brigitte Rousseau, Larry Dostal, and John P. N. Rosazza*

Division of Medicinal & Natural Products Chemistry and Center for Biocatalysis & Bioprocessing, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: *Streptomyces catenulae* catalyzed the oxidation of α-tocopherol to α-tocopherolquinone. Nitrotocopherols isolated from *S. catenulae* grown in defined culture medium containing δ- and γ-tocopherols are formed by a combination of enzymatic nitrate reduction to nitrite, and subsequent nonenzymatic acid-catalyzed nitration. The incorporation of $^{15}N^{18}O_3^-$ into nitrated tocopherols confirmed the origin of the nitrating species. Structures of chromatographically purified products obtained from *S. catenulae* transformations of tocopherols were deduced by spectral (mass spectrometry, ^{1}H-, and ^{13}C-nuclear magnetic resonance) analyses.
Lipids 32, 79–84 (1997).

The tocopherols are naturally occurring phenolic benzopyrans which display antioxidant activities *in vivo* and *in vitro*. Since their initial discovery, both chemical and biological systems have been exploited to elucidate their mechanisms of action and to identify the products of oxidation. Much interest has been focused on chemical oxidations of tocopherols catalyzed by agents such as $FeCl_3$ (1), $AgNO_3$ (2), and alkylperoxyl radicals (3–6). Surprisingly no work has been reported on microbial oxidations or transformations of tocopherols. In this paper we describe the results obtained from microbial transformations of α-, δ- and γ-tocopherols.

MATERIALS AND METHODS

Chemicals. α–, δ-, and γ-Tocopherols and α-tocopherolquinone were obtained from Eastman Kodak Company (Rochester, NY). Tocored was prepared as a standard by the oxidation of α-tocopherol with $AgNO_3$ (2). Labeled products including 98% $Na^{15}NO_3$ and 95–98% $H_2{}^{18}O$ were purchased from Cambridge Isotope Laboratories (Andover, MA). Doubly labeled $Na^{15}N^{18}O_3$ was prepared by the exchange reaction between 125 mg $Na^{15}NO_3$ and 0.5 mL $H_2{}^{18}O$ in presence of 0.1 mL of fuming nitric acid in a sealed ampoule at 80°C for 4 d as described in literature (7). The ampoule was opened and the salt was dried by standing at 80°C for two more days. The isotopic composition of labeled nitrate was determined by negative ion fast atom bombardment (FAB) mass spectrometry to show that the $Na^{15}N^{18}O_3$ contained 82% ^{15}N and 81% ^{18}O.

Instrumentation. Thin-layer chromatography (TLC) was carried out on 0.25-mm layers of silica gel GF_{254} (Merck, Darmstadt, Germany) prepared on glass plates with a Quickfit Industries (London) spreader. Plates were air-dried and activated at 120°C for 1 h before use. Mass spectra were obtained by FAB on a Fisons ZAB-HF mass spectrometer (Beverly, MA). ^{1}H- and ^{13}C-nuclear magnetic resonance (NMR) spectra were obtained on a Bruker WM-360 spectrometer (Bruker Instruments, Billerica, MA) equipped with an IBM Aspect-2000 processor. The signals were assigned on the basis of heteronuclear multiple quantum correlation spectroscopy and heteronuclear multiple bond correlation spectroscopy spectra recorded on a Bruker AMX-600 spectrometer. Tetramethylsilane was used as an internal standard. Chemical shift values are reported in parts per million and coupling constants are given in Hertz. Abbreviations for NMR are as follows: *s*, singlet; *d*, doublet; *t*, triplet; *dd* doublet of doublets; *m*, multiplet. Ultraviolet (UV) spectra were recorded on a Shimadzu (Tokyo, Japan) (UV160U) UV-visible recording spectrophotometer, infrared (IR) spectra on a Nicolet 205 FT-IR spectrometer (Nicolet Instruments, Madison, WI).

Microorganisms. All microorganisms were from the University of Iowa, College of Pharmacy culture collection (UI). They were maintained on Sabouraud-maltose agar slants and stored at 4°C. Microorganisms initially screened for their ability to transform tocopherols were from the following genera: six *Aspergillus* spp., four *Bacillus* spp., three *Candida* spp., one *Corynebacterium* sp., four *Cunninghamella* spp., one *Cylindrocarpon* sp., three *Mucor* spp., two *Mycobacterium* spp., four *Nocardia* spp., two *Penicillium* spp., six *Pseudomonas* spp., three *Rhizopus* spp., one *Rhodotorula* sp., two *Saccharomyces* spp., and five *Streptomyces* spp. *Streptomyces catenulae* (UI-5965) was used for further experiments in biotransformation of tocopherols because of its reproducibly excellent yield of products and relatively fast conversion rates. This microorganism is a substrain of *SS. catenulae* (ATCC 23893) obtained as a result of numerous serial transfers. While the parent strain ATCC 23893 forms uniform white sporulated colonies, the substrain UI-5965 grows as moist asporogenous grey colonies with traces of white spores

on the colony extremities. Fatty acid analysis for both of these strains using the MIDI/Hewlett-Packard microbial identification system by Analytical Services, Inc. (Williston, VT) confirmed the relationship of both *S. catenulae* strains.

Screening procedure. Cultures were grown in 25 mL of soybean meal–glucose medium (by a two-stage incubation procedure) or in mineral salts–glucose medium (by a one-stage incubation procedure), held in stainless-steel-capped 125 mL DeLong flasks. The soybean meal–glucose medium contained (in g/L) 20 dextrose, 5 yeast extract, 5 soybean meal, 5 NaCl, and 5 K_2HPO_4 in distilled water and was adjusted to pH 7.0 with 6 N HCl. The mineral salts–glucose medium contained in g/L: 2 dextrose, 15 $NaNO_3$, 1.1 KCl, 1.1 NaCl, 0.01 $Ca(NO_3)_2 \cdot 4\ H_2O$, 3.4 $KH_2PO_4 \cdot H_2O$, 4.4 K_2HPO_4, 0.5 $MgSO_4 \cdot 7\ H_2O$, 3×10^{-4} $FeSO_4 \cdot 7\ H_2O$ and 5 mL of a stock solution containing in g/L, 0.29 $ZnSO_4 \cdot 7\ H_2O$, 0.24 $CaCl_2 \cdot 4\ H_2O$, 0.24 $CuCl_2 \cdot 6\ H_2O$, 0.25 $CuSO_4 \cdot 5\ H_2O$, 0.17 $MnSO_4 \cdot H_2O$, in distilled water resulting in a pH of 6.5. Media were autoclaved at 121°C for 15 min before being inoculated. Cultures were incubated with shaking at 250 rpm at 28°C on New Brunswick Scientific G25 Gyrotory shakers. The two-stage incubation procedure consisted of growing cultures in stage I for 60 h and transfering a 10% inoculum of these cultures to 25 mL of medium in 125 mL flasks for the stage II culture. For either incubation protocol, 25 mg of tocopherols in 0.1 mL of *N,N*-dimethylformamide was added to 24-h old cultures which were incubated as before. Samples (4 mL) were taken at 24, 72, and 144 h after addition of substrate. After determination of pH, they were acidified to pH 2.0 with 6 N HCl and extracted with 1 mL of ethyl acetate/propanol (9:1, vol/vol). The organic layers were used for analysis in which 30 to 40 µL samples were spotted on TLC plates which were developed with hexane/isopropanol (97:3 vol/vol). Developed chomatograms were visualized under 254 nm UV light and sprayed with Emmerie-Engel reagent (8) which consisted of a 1:1 mixture of solution A (0.2% $FeCl_3$ in 95% EtOH) and solution B (0.5% α,α′-dipyridyl in 95% EtOH).

Preparative biotransformations of tocopherols. The two-stage incubation process was the same as for screening experiments.

For γ-tocopherol (**1c**), a total of 680 mg of substrate was distributed evenly among 27, 125 mL DeLong flasks each holding 25 mL of 24 h old mineral salts–glucose medium culture. Substrate-containing cultures were incubated for 144 h at which time the reaction media were combined, acidified to pH 2.0, and extracted with ethyl acetate. The organic extract was examined by TLC (hexane–isopropanol 97:3 vol/vol) to show three major spots with R_f 0.69 (yellow), 0.1 (red), and 0.06 (colorless) detected by 254 nm UV light. None of these spots gave purple colors with the Emmerie Engel spray reagent. The extract was dried over Na_2SO_4 and concentrated under vacuum. A brown oily residue was obtained (670 mg).

Biotransformation products obtained from γ-tocopherol (**1c**) were isolated by chomatography over a column of 45 g Baker-40 µm silica gel (hexane/isopropanol 99:1–95:5, vol/vol) to afford two fractions. A pure oily yellow product, **2b** (R_f = 0.69) was obtained in 40% yield (295 mg) and subjected to spectral analysis: UV (hexane) λ_{max} 261, 305 and 415 nm; IR (neat) (ν, cm^{-1}), 2952, 2927, 2868, 1535 (NO_2), 1452, 1411, 1379, 1321, 1261, 1178, 1099; ^{1}H-NMR ($CDCl_3$) δ, 0.84, 0.86, 0.863, 0.864 (4 × *d*, 12 H, *J* = 6.6, 4 × CH_3), 1.27 (*s*, 3H, CH_3-2), 1-1.41 (*m*, 18 H), 1.48-1.61 (*m*, 3 H), 1.69-1.8 (*m*, 2 H, H_2-3), 2.18 (*s*, 3 H, CH_3-8), 2.22 (*s*, 3 H, CH_3-7), 3.01 (*m*, 2 H, H_2-4), 10.73 (*s*, 1 H, OH); ^{13}C-NMR ($CDCl_3$) δ, 12.01 (CH_3-7), 13.27 (CH_3-8), 19.62, 19.72, 20.91, 21.72 (4), 22.6, 22.7, 23.56 (CH_3-2), 24.43, 24.79, 27.96, 30.9 (3), 32.63, 32.78, 37.27, 37.31, 37.37, 37.42, 39.36, 39.58, 75.43 (2), 113.4 (10), 125.3 (7), 131.9 (5), 137.0 (8), 145.2 (9), 148.4 (6); MS (3-NBA) *m/z* 462 (35, $(M + H)^+$), 461 (100, M^+), 446 (34), 445 (25), 444 (44), 431 (27), 430 (29), 428 (27), 416 (21), 236 (60), 234 (41), 230 (21), 220 (98), 204 (88).

The second fraction contained a mixture of red spots at R_f = 0.1 and R_f 0.05, **2b**, starting material (R_f = 0.3), and traces of compounds sensistive to Emmerie-Engel reagent (Rf = 0.7 and 0.73). Those at R_f 0.7 and 0.73 were also detected in controls containing no cultures, and thus were not analyzed further. Repeated chomatography attempts to isolate the red spot at R_f 0.1 failed because of its apparent instability on silica gel. It was indirectly identified as tocored (**3**) by comparison with a standard. Its degradation product at R_f 0.05 was isolated and identified as tocored dimer **4** which had the following physical properties: UV (hexane) λ_{max} 208, 288, 440 nm; IR (neat) (ν, cm^{-1}) 2952, 2927, 2867, 1677, 1648, 1622, 1582, 1462, 1393, 1326, 1189, 910, 733; ^{1}H-NMR ($CDCl_3$) δ, 0.83-0.87 (*m*, 24 H, 8 × CH_3), 1.0-1.45 (*m*, 38 H), 1.45-1.85 (*m*, 14 H), 2.05 (*s*, 6 H, 2 × CH_3-7), 2.43 (*m*, 4 H, 2 × H_2-4), 2.64 (*s*, 4 H, 2 × H_2-8); ^{13}C-NMR ($CDCl_3$) (2 carbons for each peak) δ, 11.77, 15.46, 19.57, 19.71, 21.26, 22.6, 22.69, 24.4, 24.45, 24.76, 26.36, 27.94, 29.18, 32.68, 32.75, 37.24, 37.27, 37.31, 37.4, 39.33, 39.72, 82.32, 111.2, 14.9, 145.2, 162.3, 177.6, 180.8; MS (thioglycerol) *m/z* 860 (11), 859 (12, $(M + H)^+$), 445 (11), 432 (38), 431 (100), 329 (11), 205 (170), 167 (96).

For δ-tocopherol (**1b**), a total of 545 mg of substrate was added at 24 h to *S. catenulae* cultures to a final concentration of 1 mg/mL of culture medium. Substrate-containing cultures were harvested at 144 h following substrate addition, the cultures were combined, adjusted to pH 2.0 with 6 N HCl, and exhaustively extracted with ethyl acetate. The oily extract obtained was examined by TLC (hexane/isopropanol 97:3) to show a yellow product at R_f 0.65 representing about 10% yield.

Product from δ-tocopherol. δ-Tocopherol (**1b**) afforded a metabolite at R_f 0.65 in 10% yield as estimated by TLC. Column chomatography over 40 g of silica gel with hexane/isopropanol 99:1–95:5 (vol/vol) gave 55 mg pure metabolite identified spectrally as **2a**: UV (hexane) λ_{max} 259, 296, and 408 nm; IR (CCl_4) (ν, cm^{-1}) 2955, 2930, 1548 (NO_2), 1460, 1320, 1258, 1220, 1005, 980; ^{1}H NMR ($CDCl_3$) δ, 0.84, 0.86, 0.864, 0.865 (4 × *d*, 12H, *J* = 6.6, 4 × CH_3), 1.27 (*s*, 3H, CH_3-2), 1-1.65 (*m*, 21H), 1.76 (*m*, 2H, H_2-3), 2.20 (*s*, 3H, CH_3-8), 3.05 (*m*, 2 H, H_2-4), 6.82 (*s*, 1 H, H-7), 10.32 (*s*, 1 H, OH);

^{13}C-NMR ($CDCl_3$) δ, 17.25 (8a), 19.61, 19.72, 20.86, 21.89 (4), 22.6, 22.69, 23.57 (2a), 24.42, 24.78, 27.96, 30.71 (3), 32.64, 32.77, 37.26, 37.35, 37.37, 37. 41, 39.35, 39.52, 75.53 (2), 116.3 (10), 118.4 (7), 132.1 (5), 138.8 (8), 145.9 (9), 149.6 (6); MS (3-NBA) *m/z* 448 (18, $(M + H)^+$), 447 (53, M^+), 432 (26), 430 (30), 414 (19), 402 (16), 222 (53), 206 (100), 191 (28), 190 (64), 189 (52), 188 (40), 182 (20), 176 (28), 175 (27), 166 (44).

For α-tocopherol, 530 mg of substrate was evenly distributed among 21, 125 mL DeLong flasks containing 25 mL of 24-h old *S. catenulae* cultures grown in mineral salts medium. Incubations were continued for 144 h when cultures were combined, acidified to pH 2 with 6 N HCl, and exhaustively extracted with ethyl acetate. TLC (hexane–isopropanol 97:3) evaluation of the organic extract revealed two bands detected by 254 nm UV light. These were light yellow (R_f = 0.18) and red (R_f = 0.14) and neither of these was sensitive to Emmerie-Engel reagent.

Product from α-tocopherol. Chromatography of the extract obtained from *S. catenulae* UI 5965 over 40 g silica gel (hexane–isopropanol 99:1 to 95:5, vol/vol) failed to resolve the yellow biotransformation product at R_f 0.18 from the red one at R_f 0.1. However it accomplished the removal of traces of other contaminating products to afford a 460 mg mixture of the yellow and red products. The second column using the same system afforded two fractions for spectral analysis. The yellow oily fraction (R_f 0.18, 195 mg) was identified as α-tocopherol quinone (**5**) by comparison with a standard: ^{1}H NMR ($CDCl_3$) δ 0.84-0.88 (*m*, 12 H, 4 × CH_3), 1-1.65 (*m*, 26 H), 2.0 (*s*, 6 H, 2 × CH_3), 2.04 (*s*, 3 H, CH_3), 2.55 (*m*, 2 H, CH_2); ^{13}C-NMR ($CDCl_3$) δ 11.85, 12.18, 12.26, 19.62, 19.66, 21.25, 21.34, 22.53, 22.63, 24.4, 24.7, 26.46, 27.87, 32.68, 32.7, 37.19, 37.35, 37.55, 39.27, 40.11, 42.2, 72.48, 140.1, 140.3, 140.4, 144.4, 187.1, 187.5.

The second fraction was again a mixture of yellow and red compounds. The red compound was identified as tocored by chromatographic comparison with standard.

Nitration of γ–tocopherol with $Na^{15}NO_3$ and $Na^{15}N^{18}O_3$. Biotransformations were conducted as previously described with 7 mg tocopherol in 5 mL medium containing 35 mg of unlabeled $NaNO_3$, 35 mg $Na^{15}NO_3$ or 35 mg doubly labeled $Na^{15}N^{18}O_3$ in 50 mL DeLong flasks. To avoid possible label exchanges, nitrate was added after sterilization of the medium. After 144 h incubation, the mixtures were separately acidified and extracted with ethyl acetate. The 5-nitro-γ-tocopherol product of each reaction was isolated by short column chomatography on Baker-40 μm silica gel (hexane/isopropanol 97:3 vol/vol) and analyzed by mass spectrometry.

Conversion of nitrate to nitrite by S. catenulae *(UI-5965).* Cultures of *S. catenulae* (UI-5965) were grown as usual in 25 mL of mineral salts–glucose medium. Samples taken at intervals of 0, 4, 24, 48, 72, 96, 120, and 168 h were diluted 20-fold with distilled water. For analysis, 1 mL of diluted sample was mixed with 0.5 mL Griess reagent (9) (1:1 vol/vol mixture of 1% sulfanilamide in water and 0.1% naphthylethylenediamine in 2% phosphoric acid). Mixtures were vortexed and allowed to stand at room temperature for 15 min before their absorbances were measured at 543 nm. Nitrite concentrations were estimated by comparisons of samples with a standard curve over a range of 0.1 to 1.5 mmol/L prepared freshly with sodium nitrite in water.

RESULTS

A total of 117 microorganisms were screened for their abilities to catalyze biotransformations of tocopherols. Initially, all cultures were grown in a soybean meal–glucose medium using a standard two-stage incubation protocol. No bioconversions were detected. A series of *Streptomyces* spp. were then grown in mineral salts–glucose medium, and apparent tocopherol biotransformations were reproducibly observed with *S. viridosporus* (T-7A), *S. badius* (UI-252), *S. griseus* var. *erizensis* (NRRL-3242), and *S. catenulae* (UI-5965).

Of all organisms screened for their abilities to transform tocopherols, a substrain of *S. catenulae* derived by multiple serial transfer of the culture reproducibly achieved conversions of tocopherols in good yield. Colonies of the substrain (UI 5965) and the parent *S. catenulae* American Type Culture Collection (Rockville, MD) (ATCC) 23893 grown on Sabouraud maltose agar were similar in size, but different in sporulation. When viewed from the bottoms of Petri plates, both colonies were dark grey in color. However, the original ATCC culture produced abundant white spores while the substrain was asporogenous except for traces of white spores on colony extremities. The MIDI/Hewlett-Packard microbial identification was used to demonstrate that both *S. catenulae* strains produced the same fatty acid profile, thus, confirming their relationship to one another. This substrain was used for preparative-scale incubations with α-, δ-, and γ-tocopherols as substrates.

When the biotransformation of **1c** to **2b** was conducted in medium containing 98% $Na^{15}NO_3$, ^{15}N-nitro-γ-tocopherol was obtained (Fig. 1). The mass spectrum of **2b** gave a molecular ion at *m/z* 462 (Fig. 1B) whereas that for unlabeled **2b** occurs at *m/z* 461 (Fig. 1A). From incubations with $Na^{15}N^{18}O_3$, mass spectral analysis demonstrates that **2b** was labeled in both the nitrogen (about 80%, *m/z* 462), and oxygen atoms. From relative intensities of peaks at M + 2 (*m/z* 464) and M + 4 (*m/z* 466) (Fig. 1C), oxygen enrichment in **2b** was estimated to be mono-^{18}O ($^{15}N^{18}OO_2$, 12%) and di-oxygen labeled ($^{15}N^{18}O_2O$, 2%).

DISCUSSION

Microbial transformations have been studied with practically every naturally occurring and biologically active compound. Surprisingly, there have been no reports in the literature dealing with microbial conversions of tocopherols. Initial screening with 117 cultures using our standard biotransformation protocol in a soybean meal–glucose medium failed to identify any microorganisms capable of yielding metabolites with α-, δ-, or γ-tocopherols as substrates. Upon changing to a sim-

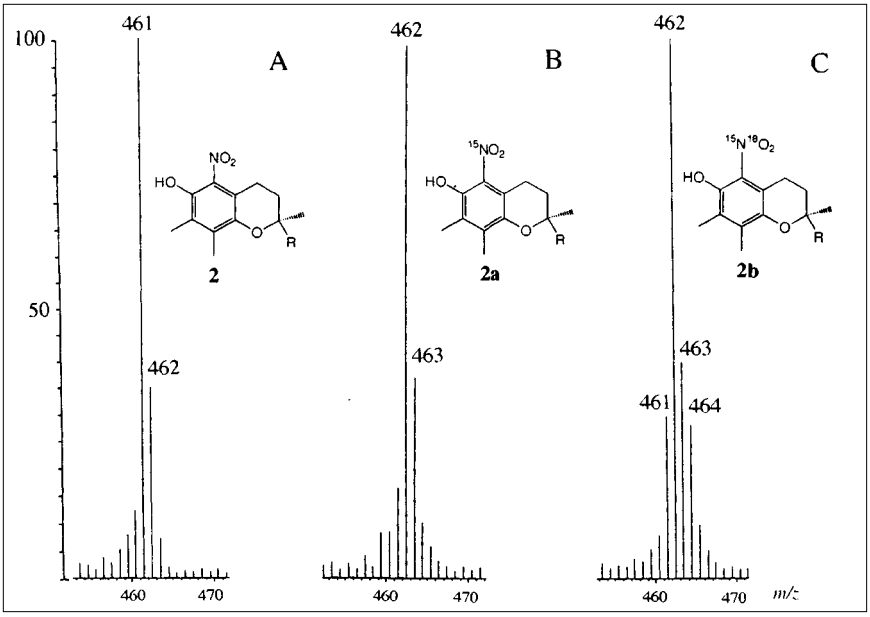

FIG. 1. Molecular ions from mass spectra of 5-nitro-γ-tocopherols produced by biotransformation of γ-tocopherol (**1c**) in the presence of A) NO_3^-, B) $^{15}NO_3^-$, and C) $^{15}N^{18}O_3^-$.

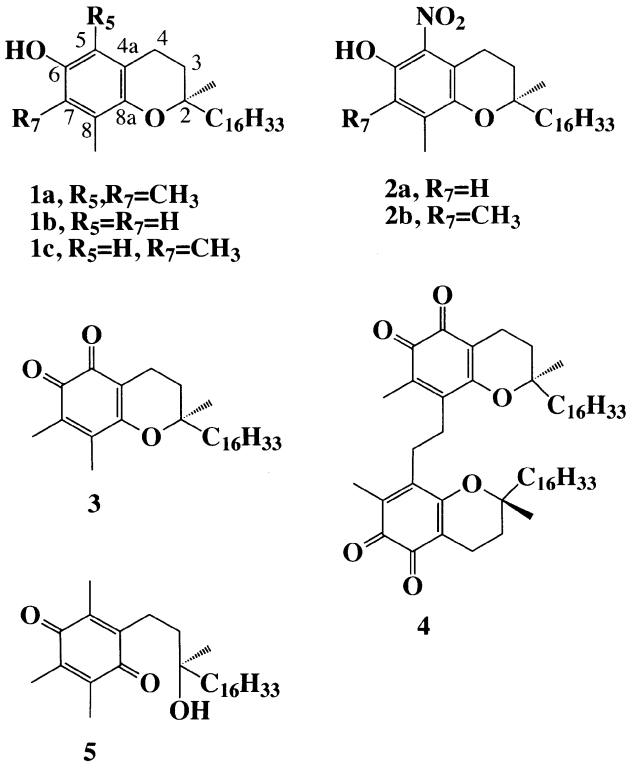
pler mineral salts culture medium, several Streptomycetes showed the capacity for producing metabolites of these tocopherols. Metabolites of yellow and red colors were obtained, but only traces of those demonstrating positive colors with the Emmerie-Engel reagent were obtained. The most reproducible and major yields of metabolites were obtained with a substrain of *S. catenulae*, and this culture was used to preparatively form metabolites from the three tocopherols.

The major metabolite obtained in 40% yield from γ-tocopherol (**1c**) was identified as **2b** by UV, MS, ^{1}H-, and ^{13}C-NMR spectroscopy (Scheme 1). The 5-nitro-γ-tocopherol obtained with *S. catenulae* was identical to **2b** described in the literature (10). This product known as tocoyellow (10) was obtained in studies concerned with the oxidation of γ-tocopherol with rat insulinoma cells and with nitrite. An additional unstable product obtained from *S. catenulae* cultures was tentatively identified as tocored (**3**) by comparison with a standard of the orthoquinone prepared by chemical oxidation (2). The unstable tocored (**3**) dimerizes during chomatography to **4**, tocored-dimer, which was isolated and characterized. With α-tocopherol as substrate, the only identified product was **5**, or α-tocopherolquinone obtained by oxidation of the tocopherol ring system. With δ-tocopherol (**1b**), the only identifiable metabolite was 5-nitro-δ-tocopherol (**2a**) which was characterized spectrally. Nitrations of tocopherols occurred in excellent yield. Since microbiological nitrations of substrates is a relatively rare reaction, we investigated the nature of this reaction further.

Microbial nitration has been previously reported for compounds with tocopherol related structures. An *o*-nitrophenol metabolite was isolated from a mixed culture of soil microorganisms grown in presence of a 6-chromanol derivative (11). Also, 5-chromanol derivatives related to canabinoids were nitrated by cultures of *Pseudomonas putida* (12). However, as-



SCHEME 1

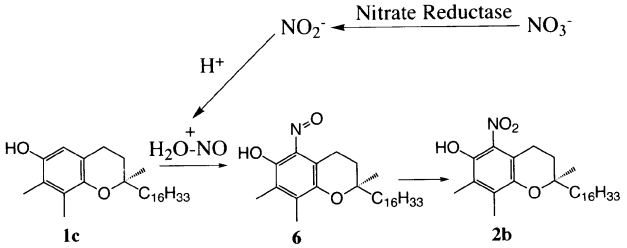
pects of the mechanism of microbial nitration of these phenolic substrates were not determined.

Besides their antioxidant activities, tocopherols are potent antinitrosating agents (13). α- and γ-Tocopherols prevent the formation of nitrosamines by very rapidly reacting with the nitrosating species. Kamm *et al.* (14) demonstrated that *in vitro* α- and γ-tocopherols accelerate the disappearance of nitrite in simulated gastric fluids. Formation of α-tocopherolquinone was observed during the reaction of α-tocopherol while the product from the reaction of γ-tocopherol was not identified. However, nitration of γ-tocopherol to **2b** occurred in hexane solutions containing nitrogen dioxide (NO_2) (10). Interestingly, **2b** was also identified in RINm5F cells containing γ-tocopherol. The source of nitrating species was presumed to be from the endogenous formation of nitric oxide (NO·) formed in these mammalian cells (10). These previous studies suggested the possibility that Streptomycetes produced nitrated tocopherols by converting inorganic nitrate in the culture medium to nitrating species. To test this possibility, a series of experiments were conducted using labeled nitrate.

These results indicate that bacterial transformation of nitrate to an active nitrating species had occurred. A reasonable pathway for nitrate reduction to active nitrating species would involve initial reduction of NO_3^- to NO_2^-, which under acidic conditions can form protonated nitrous acid (H_2ONO^+) as a phenol nitrosating or nitrating species. Nitrosation of the phenol in the first step to **6** and subsequent oxidation of **6** to **2b** (Scheme 2) would account for the loss of label in the nitrated product **2b**. Low recovery of enrichment in ^{18}O in the product could thus be explained by two phenomena: an exchange reaction between the nitrate and water could occur during the enzymatic reaction, and chemical nitration by nitrite in acidic medium.

The reduction of nitrate to nitrite is a common reaction among denitrifing bacteria. However, the reduction of NO_3^- to NO_2^- by *Streptomyces* species has been rarely reported. The ability of *S. catenulae* to produce nitrite during growth in the mineral salts medium was evaluated using the Griess reaction. Nitrite was detected after 24 h of incubation and reached levels of 8 to 14 mM after 48 h.

Since nitrite levels of 8–14 mM were detected in growing cultures of *S. catenulae,* we examined the possible reactivity of tocopherols toward nitrite. γ-Tocopherol was previously reported to react very rapidly with sodium nitrite under faintly acidic conditions yielding **2b** (15). The pH of the medium was nearly neutral thoughout *S. catenulae* incubation. However, during work-up of the reaction mixture, samples were acidified to pH 2 before extraction for analysis or isolation. To determine whether the nitration of γ-tocopherol to **2b** occurred biocatalytically or by chemical catalysis following bacterial reduction of nitrate to nitrite, cultures were grown in mineral salts–glucose medium containing nitrite in place of nitrate. Incubations and controls containing γ-tocopherol but no microorganism were subjected to both acidic and neutral extractions. The nitrated product **2b** was detected only after acidic extraction in both inoculated and control flasks. This is consistent with nitration which occurred by microbial reduction



SCHEME 2

of nitrate to nitrite followed by chemical reaction. None of the identified products was formed in control incubations and only in mineral salts medium restricted to Streptomyces.

Many bacteria are capable of catalyzing *N*-nitrosation reactions at neutral or almost neutral pH (16–18), the most effective being those having nitrate reductase and nitrite reductase activities. It would be interesting to verify the antinitrosation effect of γ-tocopherol with these bacteria and to identify the metabolites for better understanding of the mechanism of action of tocopherols.

This work describes the first microbial transformation study of tocopherols. *Streptomyces catenulae* (UI-5965) nitrate reductase activity was demonstrated by the measurement of NO_2^- in culture media, and by the conversion of $^{15}N^{18}OO$-labeled nitrate into labeled 5-nitro-γ-tocopherol. The results demonstrate that nitration or nitrosation reactions are possible with *Streptomycetes* when they can enzymatically reduce nitrate to nitrite in acidic soils.

METHOD

Tandem Mass Spectrometric Approach for Determining Structure of Molecular Species of Aminophospholipids

Su Chen

Department of Chemistry, The University of Warwick, Coventry CV4 7AL, United Kingdom

ABSTRACT: Aminophospholipids, including glycerophosphatidylethanolamine, glycerophosphatidylserine and their Lyso analogous, have been analyzed by positive and negative ion liquid secondary ion ionization coupled to tandem mass spectrometry. The mass spectra of aminophospholipids obtained by tandem mass spectrometers with different configuration (liquid secondary ion-electric-magnetic sector coupled to quadrupole mass analyzer (low-energy collision) or electric-magnetic sector (high-energy collision), as well as electrospray ionization-quadrupole mass analyzer combined with quadrupole mass analyzer (low-energy collision), are compared. The mass spectra produced by low-energy collisionally induced dissociation of the deprotonated molecules from aminophospholipids contain fragment ions for characterizing polar head moieties as well as fatty acid composition and position. The mass spectra generated by high-energy collisionally induced dissociation of both protonated and deprotonated molecules from aminophospholipids show numerous product ions for identifying polar heads, composition, and location of fatty acid chains in molecular species. Triple quadrupole mass spectrometer with electrospray ionization exhibits remarkable superiority in detection sensitivity. Liquid secondary ion with electric-magnetic sector coupled to quadrupole mass analyzer or electric-magnetic sector instrument has the advantage of the capability of properly determining location of fatty acid chains in molecular species. This paper also describes an approach for structurally analyzing aminophospholipid species as 9-fluorenylmethyloxycarbonyl derivatives by positive and negative ion liquid secondary ion mass spectrometry and high-energy collisionally induced dissociation tandem mass spectrometry. It has been found that the derivatives of glycerophosphatidylethanolamine and glycerophosphatidylserine can readily be analyzed by the negative ion liquid secondary ion and tandem mass spectrometric methods.

Lipids 32, 85–100 (1997).

Aminophospholipids, including glycerophosphatidylethanolamine (GPE), glycerophosphatidylserine (GPS), lysophosphatidylethanolamine (LysoPE) and lysophosphatidylserine (LysoPS), are present as essential components in biological membranes and located preferentially on the inner monolayer. The structural diversity of these lipid molecules is mainly due to (i) different polar head moieties, such as phosphoethanolamine and phosphoserine, linked to phosphate at the *sn*-3 position of the glycerol backbone; (ii) a variety of diacyl-, alkyl-acyl, and alkenyl-acyl-linked fatty chains esterified at the *sn*-1 and *sn*-2 positions, and (iii) location of the double bond(s) (between 1 and 6) within unsaturated fatty chains with a number of carbon atoms (between 14 and 22). Lyso analogous of aminophospholipids, which usually contain only one fatty chain (acyl or alkyl or ether group) at the *sn*-1 position of the glycerol backbone, are found as minor components in membranes. A number of studies have demonstrated that the phospholipids have played an important role in the fields of pharmacology (1–4), immunology (5), and oncology (6).

Several approaches have been taken in the chemical analysis of aminophospholipids: thin-layer chromatography (7,8), and normal-phase high-performance liquid chromatography (HPLC) (9,10) are commonly employed for the separation and identification of phospholipid classes; gas chromatography is an effective method for analyzing fatty acid composition within aminophospholipids rather than for determining structures of individual molecular species. The identification of molecular species and of fatty acid chain location by means of reversed-phase HPLC separation of chromatography-purified aminophospholipid class, following by enzymatic treatment and gas chromatographic analysis of hydrolyzed fatty acids (11,12) is laborious, time-consuming, and material-consuming. The approach is suitable for the routine analysis of aminophospholipids, but is inappropriate in structurally elucidating molecular species from new natural sources.

Mass spectrometry has been employed for the structural analysis of molecular species of glycerophospholipids since 1969 (13), and some papers have reported studies of aminophospholipids using a variety of ionization modes, including electron impact (13), chemical ionization (14), field desorption (15), liquid secondary ion (LSI) [or fast atom bombardment (FAB) (16)], thermospray (17), electrospray ionization (ESI)(18) and matrix-assisted laser desorption (19). This method allows to analyze molecular species of aminophospholipids from picomole or lower quantities of material, and the structure of a single species can be tentatively designated

Abbreviations: CID, collisionally induced dissociation; ESI, electrospray ionization; FAB, fast atom bombardment; Fmoc, 9-fluorenylmethyloxycarbonyl; GPE, glycerophosphatidylethanolamine; GPS, glycerophosphatidylserine; HPLC, high-performance liquid chromatography; LSI, liquid secondary ion; LysoPE, lysophosphatidylethanolamine; LysoPS, lysophosphatidylserine.

by conventional mass spectrometry. Classical methods coupled to ESI mass spectrometry, such as HPLC combined with ESI, is appropriate in initially identifying the glycosylated derivatives of aminophospholipid molecular species (20). However, when applied in characterizing an aminophospholipid molecule from molecular species mixtures or crude extracts, the structural information on the composition and location of fatty acid chains in the glycerol backbone in conventional mass spectra is usually insufficient. For example, identical ions at *m/z* 792 were observed in conventional positive ion LSI mass spectra of GPE classes from both rainbow trout liver and water snail *Lymnaea stagnalis* kidney, corresponding to the protonated molecules of GPE 40:6 [*X*:*Y* (for example GPE 40:6), where X is the total carbon number of fatty acids esterified at the *sn*-1 and *sn*-2 position and *Y* is the total number of the degree of unsaturation of fatty acid chains. The code GPE *X*:*Y* or GPS *X*:*Y* is usually used for expressing general structural information on polar heads and fatty acids in molecular species, which is obtained by conventional mass spectrometry.]. For further details, GPE 18:0–22:6 [*N*:*M*-*n*:*m* (for example GPE 18:0–22:6), where *N* is the total number of carbon in the *sn*-1 fatty chain, *M* is the total number of double bond(s) in the fatty acid esterified at the *sn*-1 position; *n* is the total number of carbon in the *sn*-2 fatty chain, *m* is the total number of double bond(s) in the fatty acid esterified at the *sn*-2 position. The code GPE *N*:*M*-*n*:*m* or GPS *N*:*M*-*n*:*m* is often used for indicating the nature of polar head moieties and the positions of two fatty chains in the glycerol backbone, which can be obtained by tandem mass spectrometry.] is present in the former and GPE 20:2–20:4 being in the latter, and the correct structure of a molecular species can readily be designated based on information obtained by CID tandem mass spectrometry (21,22).

Tandem mass spectrometry (23), by means of mass selection of ions and followed by CID mass spectrometric analysis in multisector or multiquadrupole instruments, is an increasingly important method for characterizing the structure of a wide range of phospholipids. Although field desorption, thermospray, and matrix-assisted laser desorption ionization can yield protonated and deprotonated molecules of molecular species of aminophospholipids, the irreproducibility of $[M - H]^-$ or $[M + H]^+$ ions, generated by the ionization modes above, makes it difficult to carry out CID experiments. The tandem mass spectrometric approach of $[M - H]^-$ ions from aminophospholipids, produced by negative ion LSI (FAB) and ESI ionization, has been widely applied to the structural identification of molecular species (24,22). The major advantage of this method is that it is able to readily provide diagnostic information on the characterization of polar head moieties and the composition and location of fatty acid chains in lipid molecules. Jensen and Gross (25) as well as Murphy and Harrison (26) have given excellent reviews on the analysis of intact glycerophospholipids by negative ion LSI (FAB) mass spectrometry and CID tandem mass spectrometry. Positive ion LSI (FAB) mass spectrometry have been reported to yield abundant protonated molecules of aminophospholipids (27,28), and product ions obtained by CID of $[M + H]^+$ ions of aminophospholipid species are structurally informative (29). Mechanisms of high energy (keV, main electronic excitation) and low energy (eV, mainly vibrational excitation) CID of ions have been well discussed (30).

On the other hand, the qualitative determination of aminophospholipids is also of importance in investigating biological and pharmacological functions of these lipid species. Because trace amounts of aminophospholipids are present in some biological samples, such as plasma lipoproteins, HPLC coupled to chromophore detection is difficult to assay both underivatized aminophospholipid class and molecular species. The main reason is that aminophospholipid molecules lack a common moiety that can be readily detected under ultraviolet or fluorescence detection. The facile route chosen in the structural modification of aminophospholipids is the replacement of ethanolamine or serine phosphate by a colorimetric group or the introduction of a chromophore group to polar head moieties of the species. The direct introduction of various groups [a biphenyl carbonyl (31) or a dimethylaminonaphthalene-5-sulfonyl (32) or a naphthyl (33) or a trinitrophenyl (34) moiety] to aminophospholipids followed by HPLC separation of the derivatives has been achieved, but the methods overlooked the structural elucidation of derivatized molecular species. The introduction of 9-fluorenylmethyloxycarbonyl (Fmoc) group into the primary amine in peptides has been well documented (35,36) because of advantages of (i) the formation of stable derivatives and (ii) very low detecting levels under fluorescence detection. By using this mode, Fmoc group has been readily introduced into the primary amine in polar head moieties of GPE, GPS, and their lyso compounds with a good yield (more than 92%). A satisfactory separation of Fmoc derivatives of aminophospholipid classes and molecular species has been achieved on aminopropyl normal-phase and octadecylsilyl reversed-phase HPLC column (not shown). The low detecting levels under fluorescence detection is as little as 125 femtomoles. Details on the analysis of aminophospholipids as Fmoc derivatives by HPLC will be reported in a separate paper.

Work described in the present study was involved first of all in comparing (i) CID mass spectra of molecular species of underivatized aminophospholipids, obtained by positive and negative ion LSI and ESI coupled to low-energy CID (the results of ESI low-energy CID of aminophospholipids were collected from Refs. 37–39 cited in the paper) as well as positive and negative ion LSI combined with high-energy CID experiments; and then (ii) positive and negative ion LSI mass spectrometry and tandem mass spectrometry of Fmoc derivatives of molecular species of GPE and GPS. The advantage and disadvantage of the three sort of tandem mass spectrometers [the hybrid (EBQQ) instrument, the triple quadrupole (QQQ) mass spectrometer and the four-sector (EBEB) machine], which are commercially available and are being used in biomedical mass spectrometry laboratories, in structurally analyzing molecular species of aminophospholipids are discussed.

EXPERIMENTAL PROCEDURES

Chemicals. All aminophospholipid species used were purchased from Sigma Company (St. Louis, MO). All natural aminophospholipids used were prepared by the methods as described (40). Diethanolamine (DEA) obtained from Fluka (Buchs, Switzerland) was used as liquid matrix in this study.

Mass spectrometry. Positive and negative ion LSI high-energy CID tandem mass spectrometric experiments were performed with a CONCEPT II HH four-sector (EBEB) mass spectrometer (Kratos Analytical Ltd., Manchester, United Kingdom), equipped with LSI source and a scanning-array detection system as reported (41). Positive and negative ion LSI low-energy CID spectra of $[M + H]^+$ and $[M - H]^-$ ions of aminophospholipid species were obtained on a VG 70SEQ (EBQQ) instrument (Fisons Analytical, Manchester, United Kingdom). Cesium ions with a translational energy of 18 keV were applied as the ion beam. The accelerating voltage was 8 kV. Precursor ions were mass-selected with a resolution of 1,000 using the electric-magnetic sector (EB) part of the mass spectrometer. CID was carried out in quadruple collision cell with argon as collision gas at a pressure of approximately 5×10^{-6} bar and at a collision energy of 50 eV. Product ion spectra were obtained in the continuous accusation mode with accumulation of 15–20 scans at unit resolution of the quadrupole mass analyzer. The surface precipitation technique of LSI (FAB) mass spectrometry has proven to be particularly useful in analyzing all kinds of phospholipids (42), especially serine containing phospholipids (43,44).

RESULTS

Comparison of High- and Low-Energy CID of Molecular Species of Aminophospholipids

Glycerophosphatidylethanolamine

Low-energy CID. The fragmentation observed in low-energy CID spectra of diacyl- and alkenylacyl-GPE molecular species is summarized in Table 1. Data of ESI CID of

TABLE 1

[a]Low-energy CID (L-CID) and high-energy CID (H-CID) tandem mass spectrometry; GPE, glycerophosphatidylethanolamine; CID, collisionally induced dissociation; LSI, liquid secondary ion; ESI, electrospray ionization. [b](a) Abundant ion. [c](w) Weak ion.

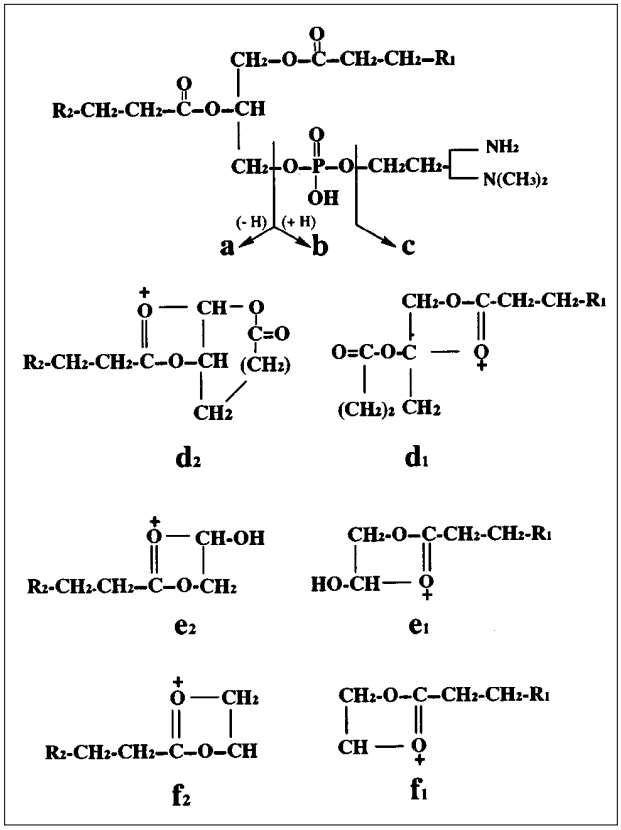
GPE was collected from References 37 and 38 cited in this paper.

Positive ion CID mass spectra. CID of LSI-generated $[M + H]^+$ ion (*m/z* 692) of GPE 16:0-16:0 yields a single fragment at *m/z* 551 (not shown), formed by the loss of phosphoethanolamine from its $[M + H]^+$ ion. The abundant information of this ion may be used for characterizing the polar-head group of GPE. None of other informative signals corresponding to fatty acid chains can be observed in the spectrum. The identical ion pattern was also found in the CID spectrum of *N,N*-dimethyl-GPE 16:0-16:0 species (not shown). CID experiments of LSI-generated $[M + H]^+$ ions of alkenylacyl-GPE species gave identical results as those of diacyl-GPE species (see Table 1). CID spectra (37) of ESI-generated $[M + H]^+$ ions of diacyl- and alkenylacyl-GPE species are similar to those of the related species obtained by the LSI CID experiment. CID of ESI-generated $[M + Na]^+$ ions of diacyl- and alkenylacyl-GPE mainly produces $[M + Na - 141]^+$ and $[M + Na - 163]^+$ ion (38), which are useful for characterizing the polar head of GPE (Table 1).

Negative ion CID spectra. Carboxylate anions resulting from CID of LSI-generated $[M - H]^-$ ions of GPE are produced in an abundant ratio of approximately 1:3 for fatty acyl chains esterified at the *sn*-1 and *sn*-2 positions, respectively, and by which the composition and location of two carboxylate chains in a GPE species can be identified properly. Tandem mass spectrometry of the $[M - H]^-$ ion from GPE 40:7 from rainbow trout liver (not shown) gives quite abundant carboxylate anions at *m/z* 281 (18:1; oleic acid) and *m/z* 327 (22:6; docosahexaenoic acid), relating to the two fatty acyl chains. The intensity of the signal at *m/z* 327, resulting from the chain at the *sn*-2 position, is more abundant than that of the anion at *m/z* 281, corresponding to the fatty acyl chain esterified at the *sn*-1 position (45). A weak peak, due to $[M - R_2CO]^-$, appeared in the spectrum as well (not shown). This species is identified as GPE 18:1-22:6. CID spectrum of LSI-generated $[M - H]^-$ ion of alkenylacyl-GPE species (45) contains only one carboxylate anion corresponding to $[R_2COO]^-$ ion. Alkenylacyl-GPE species can be distinguished from alkylacyl-GPE species by the combination of mild acid hydrolysis of the former with subsequent tandem mass spectrometric analysis of the latter (45). These ion patterns have been confirmed by CID of ESI-generated $[M - H]^-$ ion of diacyl- and alkenylacyl-GPE (37,38) (Table 1).

High-energy CID. Product ions in high-energy CID mass spectra of diacyl- and alkenylacyl-GPE species are listed in Table 1.

Positive ion CID mass spectra. CID of LSI-generated $[M + H]^+$ ions of GPE species induces several fragmentation processes (Scheme 1 shows proposed structures of product ions yielded by CID of $[M + H]^+$ ions of GPE, based on results from Ref. 29 cited in this paper). Product ions, $[M + H - \text{ethanolamine phosphate}]^+$, $[\text{phosphoethanolamine} + H]^+$ and $[CH_2CH_2NH_2]^+$, due to **a**, **b**, and **c** fragments, are useful for characterizing the nature of polar head moieties of different GPE. Figure 1 shows CID spectra of LSI-generated $[M + H]^+$ ions of GPE 16:0-16:0 (Fig. 1A) and *N,N*-dimethyl-GPE 16:0-16:0 (Fig. 1B) species. Peaks at *m/z* 551 (**a** type fragmentation) are formed by the loss of phosphoethanolamine or *N,N*-dimethylphosphoethanolamine from their protonated molecules at *m/z* 692 (the former) and *m/z* 720 (the latter), respectively. Alternative fragment ions for identifying polar head groups of the two GPE also appear at *m/z* 141 and 169 ($[\text{phosphoethanolamine} + H]^+$ and $[\text{*N,N*-dimethylphosphoethanolamine} + H]^+$), due to **b** type fragmentation, as well as at *m/z* 44 and 72 ($[\text{ethanolamine}]^+$ and $[\text{*N,N*-dimethylethanolamine}]^+$), due to **c** type fragmentation. **d**, **e**, and **f** type product ions (Scheme 1) are useful in identifying fatty acid composition in GPE species. The location of fatty acyl chains is indicated by the presence of $[R_2COOCHCH_2]^+$ and $[R_1COOCHCH_2]^+$ (f_2 and f_1 ions) as well as $[R_2COOCHCH_2CH_2O]^+$ and $[R_1COOCHCH_2CH_2O]^+$ ions (e_2 and e_1 ions) and by the intensity differences of f_2 and f_1 fragments, respectively. The abundance of $[R_2COOCHCH_2]^+$ ion is greater than that of $[R_1COOCHCH_2]^+$ peak, and the ion intensity ratio of f_2/f_1 is always more than 1. This conclusion was based on results obtained by LSI-generated $[M + H]^+$ ions of various asymmetric GPE species. Figure 2A exhibits CID spectrum of LSI-generated $[M + H]^+$ ion of trout liver GPE 40:6. This species is identified as GPE 18:0-22:6 since the abundance of the ion resulting from the *sn*-2 position (*m/z* 354 due to f_2 ion) is richer than that of the peak relating to the



SCHEME 1

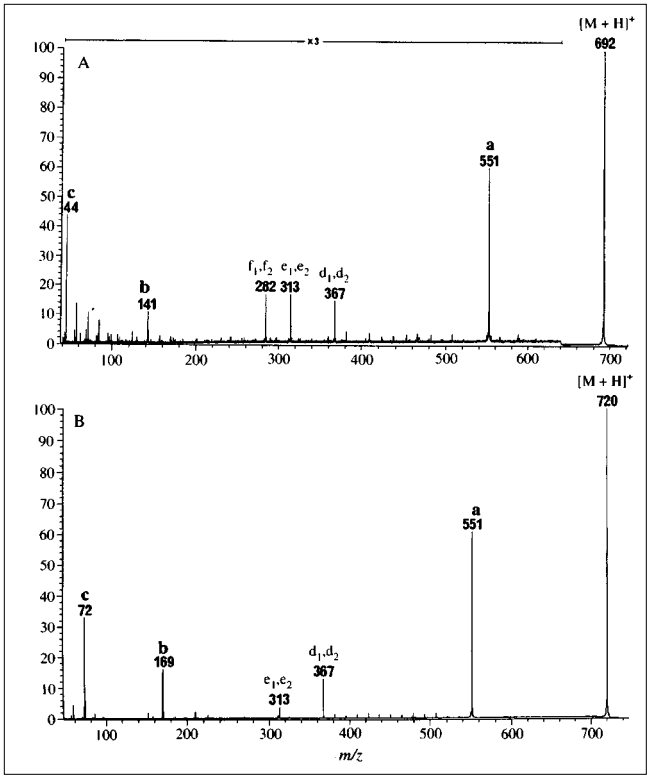


FIG. 1. High-energy CID spectra of protonated molecules of GPE 16:0-16:0 (A) and *N,N*-dimethyl-GPE 16:0-16:0 (B).

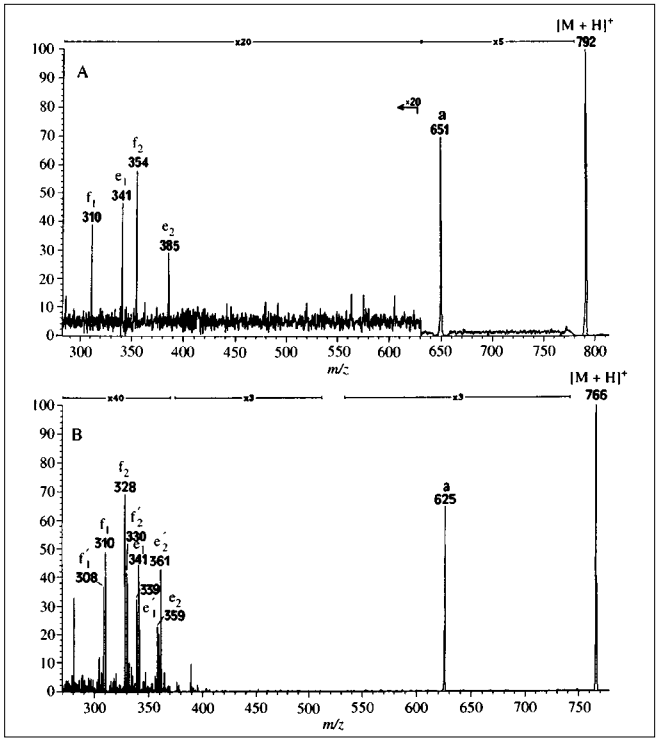

FIG. 2. High-energy CID spectra of protonated molecules of rainbow trout liver GPE 18:0-22:6 (A) and *Lymnaea stagnalis* kidney GPE 18:0-20:5 (B) and GPE′ 18:1-20:4 (B).

sn-1 position (*m/z* 310 due to f_1 ion) (29). **d** and **e** type fragments (*m/z* 365 and 361 due to e_2 and e_1 ions) cannot be differentiated unambiguously for diagnostics of the fatty acyl chain position, and the former is absent in CID spectra of $[M + H]^+$ ions of molecular species containing polyunsaturated fatty acids at the *sn*-2 position. The identical fragment pattern is also observed in CID mass spectrum of LSI-generated $[M + H]^+$ ions of GPE 18:0-20:5 and GPE 18:1-20:4 from *L. stagnalis* kidney (Fig. 2B). CID of $[M + H]^+$ ion of *N,N*-dimethyl-GPE 16:0-16:0 (Fig. 1B) yields product ions due to **d** and **e** cleavages, which are useful for identifying the composition of fatty acyl chains in the species (Table 1). This approach also provides the possibility of analyzing GPC species by CID of $[M + H]^+$ ions of *N,N*-dimethyl-GPE species derived from GPC molecules after chemical treatment (46). The study is in progress and will be reported in a separate paper. Diacyl-GPE can be distinguished from alkenylacyl-GPE species depending upon the absence of $[R_1COOCHCH_2]^+$ and $[R_1COOCHCH_2CH_2O]^+$ ions in the CID spectrum (29).

Negative ion CID spectra. High-energy CID mass spectra of $[M - H]^-$ ions of GPE species contain identical information as those obtained by low-energy CID of $[M - H]^-$ ions (Table 1). The CID mass spectrum of LSI-generated $[M - H]^-$ ion of GPE 16:0-18:2 (not shown) exhibits fragment ions due to the fatty acyl chains, and the intensity of the carboxylate anion lost from the *sn*-2 position (*m/z* 279; $[R_2COO]^-$) is higher than that of the ion resulting from the *sn*-1 position (*m/z* 255; $[R_1COO]^-$). The molecular species of plasmalogen GPE can be identified by absence of $[R_1COO]^-$ ion in CID spectra (45).

Lysophosphatidylethanolamine

Low-energy CID. Product ions yielded by low-energy CID of monoacyl- and alkenyl-LysoPE (plasmalogen) species are listed in Table 2. Data of ESI CID is collected from Reference 39 cited in the paper.

Positive ion CID spectra. CID of LSI-generated $[M + H]^+$ ion (*m/z* 482) of LysoPE 18:0 induces two fragments at *m/z* 341 and 464, corresponding to [M + H − ethanolamine phosphate]$^+$ and $[M + H - H_2O]^+$ (shown in Fig. 3A), for characterizing the polar head group and fatty acid chain in the species. CID of LSI-generated $[M + H]^+$ ion (*m/z* 466) of plasmalogen LysoPE 18:0 (Fig. 3B) produces three product ions at *m/z* 295 ([M + H − ethanolamine phosphate − $CH_2OH]^+$, *m/z* 312 ([M + H − ethanolamine phosphate − $CH_2]^+$, and *m/z* 448 ([M + H − $H_2O]^+$). [M + H − ethanolamine phosphate]$^+$ ion is absent in CID spectrum of plasmalogen LysoPE. CID of ESI-generated $[M + Na]^+$ ions (*m/z* 502) of LysoPE 18:1 regioisomers produces abundant fragment ions at *m/z* 459 ([M + Na − 43]$^+$), *m/z* 441 ([M + Na − 61]$^+$), *m/z* 339 ([M + Na − 163]$^+$) and *m/z* 164 ([phosphoethanolamine + Na]$^+$. The structures of the two regioisomers can be distinguished by the intensity differences of the product ions (38) derived from CID of their $[M + Na]^+$ ions (Table 2).

Negative ion CID spectra. CID of LSI-generated $[M - H]^-$

TABLE 2
Fragmentation of LysoPE Generated by CID Tandem Mass Spectrometry[a]

[a]Low-energy CID (L-CID) and high-energy CID (H-CID) tandem mass spectrometry; LysoPE, lysophosphatidylethanolamine. See Table 1 for other abbreviations. [b](a) Abundant ion. [c](w) Weak ion.

ion of LysoPE produces only an abundant $[R_1COO]^-$ anion (not shown) for identifying fatty acyl chain in the species. This anion is absent in CID mass spectra of LSI-generated $[M - H]^-$ ion of plasmalogen LysoPE (not shown). CID of ESI-generated $[M - H]^-$ ions of LysoPE species yields abundant carboxylate anion, corresponding to $[R_1COOH]^-$. Plasmalogen LysoPE can be identified by both the appearance of $[O{=}CHCH(CH_2)_{15}CH_3]^+$ ion and absence of $[R_1COO]^-$ anion in the spectra, compared with CID of $[M - H]^-$ of LysoPE molecules (39) (Table 2).

High-energy CID. The fragmentation observed in high-energy CID spectra of monoacyl- and alkenyl-LysoPE (plasmalogen) species is summarized in Table 2.

Positive ion CID spectra. CID of LSI-generated $[M + H]^+$ ions of LysoPE yields fragment ions of $[M + H -$ ethanolamine phosphate$]^+$ and $[$ethanolamine$]^+$ for determining the polar head group. The fatty acyl chain at the *sn*-1 position can be identified as the peak of $[M + H - PO_4H_2CH_2CH_2NH_2]^+$. Plasmalogen GPE species is detected by the absence of the ion due to $[M + H -$ ethanolamine phosphate$]^+$.

Negative ion CID spectra. Product ions yielded by CID of LSI-generated $[M - H]^-$ ions of LysoPE and plasmalogen LysoPE are identical to those obtained by the low-energy CID tandem mass spectrometry of the related species (see Table 2).

Glycerophosphatidylserine

Low-energy CID. The fragmentation obtained by low-energy CID of GPS species is summarized in Table 3. Data of ESI CID of GPS was collected from References 37 and 38 cited in this paper.

Positive ion CID mass spectra. Abundant protonated molecules of GPS species ($[M + H]^+$) can be produced by LSI mass spectrometry using the surface precipitation technique (28). CID of LSI-generated protonated molecule of GPS 16:0-16:0 (not shown) only yields a single fragment ion at *m/z* 551 ($[M + H -$ phosphoserine$]^+$), formed by the loss of serine phosphate from its $[M + H]^+$ ion. None of product ions due to fatty acid structure appears in the CID spectrum. CID of ESI-generated $[M + Na]^+$ ion of GPS species has been reported (37,38) to yield product ions corresponding to $[M + Na - CHCHCOOH(NH_2)]^+$, $[M + Na -$ phosphoserine$]^+$ and $[$phosphoserine + Na$]^+$ for characterizing the polar head moiety (Table 3).

Negative ion CID spectra. Abundant deprotonated molecule ($[M - H]^-$) of GPS species can be readily produced by LSI mass spectrometry using the surface precipitation technique (28). The polar head moiety of GPS is detected by the ion of $[M - H - CH_2CH(NH_2)COOH]^-$, due to $(M - 88)$. The characterization of fatty acyl chains esterified can be identified by appearances of anions, corresponding to $[M - 88 -$

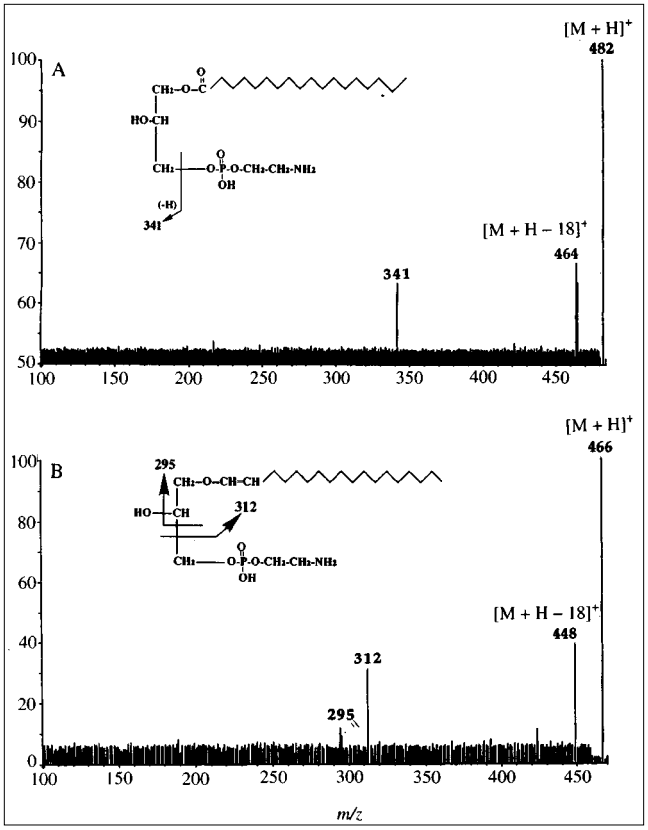

FIG. 3. Low-energy CID spectra of protonated molecules of LysoPE 18:0 (A) and plasmalogen LysoPE 18:1 (B).

$R_2COOH]^-$, $[R_2COO]^-$ and $[R_1COO]^-$, and the intensity of carboxylate fragment derived from the *sn*-1 position ($[R_1COO]^-$) is higher than that of the ion relating to fatty acid esterified at the *sn*-2 position ($[R_2COO]^-$) (not shown). This conclusion was based on results obtained by CID of LSI-generated $[M - H]^-$ ions of GPS 16:0-18:1, GPS 18:0-18:1 and GPS 18:0-22:6. The relative intensity ratio of $[R_1COO]^-/[R_2COO]^-$ is slightly affected by the chainlength of fatty acids and the degree of unsaturation of fatty acyl groups, but is always greater than 1. CID of ESI-generated $[M - H]^-$ ion of GPS species gives the result (38) identical to that obtained by CID of LSI-generated $[M - H]^-$ ion of GPS (Table 3).

High-energy CID. The fragmentation yielded by high-energy CID of $[M + H]^+$ and $[M - H]^-$ ions of GPS is listed in Table 3.

Positive ion CID spectra. CID of LSI-generated $[M + H]^+$ ions of the molecular species of GPS produces six fragmentation processes (Scheme 2 shows proposed structures of product ions obtained by CID of $[M + H]^+$ ions of GPS, based on results from Reference 29 cited in this paper). The polar head of GPS is characterized by **a**, **b,** and **c** type fragment ions, due to $[M + H -$ phosphoserine$]^+$, $[$phosphoserine $+ H]^+$ and $[CH_2CH(NH_2)COOH]^+$. CID of $[M + H]^+$ ions of GPS 16:0-16:0 (Fig. 4A) and GPS 18:0-18:1 (Fig. 4B) also yield the product ions, due to **d**, **e**, and **f** type fragmentation, for the identification of fatty acid composition in the species. Positions of the two fatty acyl chains in GPS 18:0-18:1 (4B) can

TABLE 3
Fragmentation of GPS Generated by CID Tandem Mass Spectrometry[a]

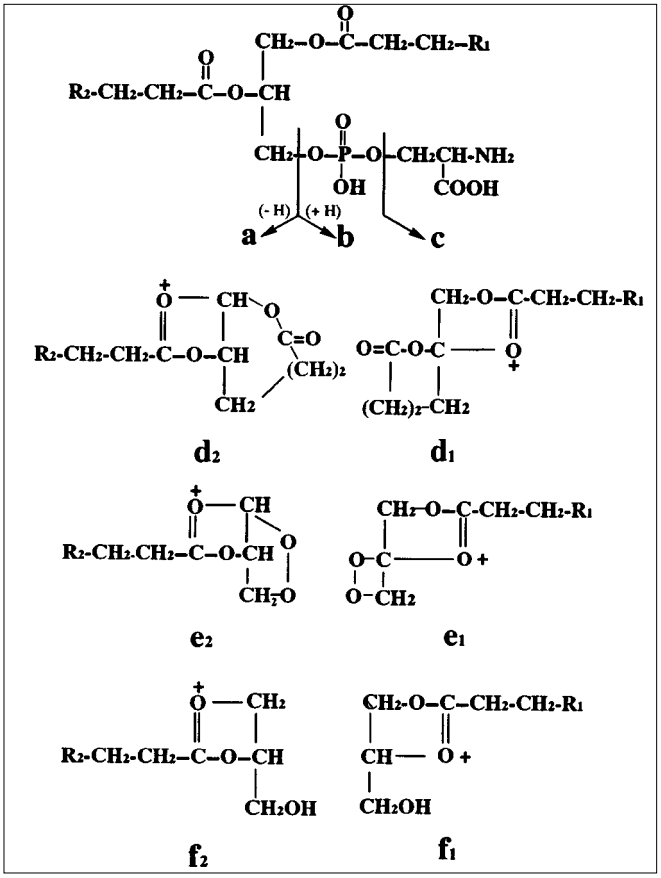
		H-CID	$[M + H -$ phosphoserine$]^+$ $[$phosphoserine $+ H]^+$ $[CH_2CH(COOH)NH_2]^+$	$[R_1COOCH(CH_2)_2CH]^+$(a)[b], $[R_2COOHCH(CH_2)_2CH]^+$(w)[c] $[R_1COOCHO(CH_2)_2O]^+$, $[R_2COOCHO(CH_2)_2O]^+$ $[R_1COO(CH)_2CH_2COO(CH_2)_2]^+$, $[R_2COO(CH)_2CH_2COO(CH_2)_2]^+$
	$[M - H]^-$	L-CID	$[M - CH(COOH)NH_2]^-$(M-88)	$[R_1COO]^-$(a), $[R_2COO]^-$(w) $[M - 88 - R_2COOH]^-$(a), $[M - 88 - R_1COOH]^-$(w) $[M - 88 - R_2CO\text{-}H]^-$(a), $[M - 88 - R_1CO\text{-}H]^-$(w)
		H-CID	$[M - CH(COOH)NH_2]^-$(M-88)	$[R_1COO]^-$(a), $\{R_2COO]^-$(w) $[M - 88 - R_2COOH]^-$(a), $[M - 88 - R_1COOH]^-$(w) $[M - 88 - R_2CO\text{-}H]^-$(a), $[M - 88 - R_1CO\text{-}H]$_(w)
1,2-Diacyl-GPS (ESI)	$[M + Na]^+$	L-CID	$[$phosphoserine $+ Na]^+$ $[M + Na -$ phosphoserine$]^+$ $[M + Na - CH_2CH(COOH)NH_2]^+$	
	$[M - H]^-$	L-CID		$[R_1COO]^-$(a), $[R_2COO]^-$(w), $[M - 88 - R_2CO\text{-}H]^-$(a) $[M - 88 - R_1CO\text{-}H]^-$(w), $[M - 88 - R_2COOH]^-$(a), $[M - 88 - R_1COOH]^-$(w)

[a]Low-energy CID (L-CID) and high-energy (H-CID) CID tandem mass spectrometry; GPS, glycerophosphatidylserine. See Table 1 for other abbreviations. [b](a) Abundant ion. [b](w) Weak ion.



SCHEME 2

be identified on the basis of intensity differences of f_2 (*m/z* 339) and f_1 (*m/z* 341) ion (see Scheme 2). The abundance of the f_2 is weaker than that of the f_1 (f_2/f_1 ratio <1). The explanation for obtaining the opposite intensity ratio of product ions of GPS, compared with that of GPE, is that LSI-generated $[M + H]^+$ ions of GPS are probably the fragment ions of $[M + H + \text{diethanolamine}]^+$ peaks, the solvated protonated molecules of GPS. The diversity of kinetic energy of the selected precursor ions makes the different patterns (29).

Negative ion CID spectra. High-energy CID spectra of LSI-generated $[M - H]^-$ ions of GPS species contains structural information, which includes: the characterization of polar head, the mass of fatty acids in species and location of fatty acyl chains. Figure 5 illustrates CID spectra of $[M - H]^-$ ions of underivatized 16:0-18:1 (a) and 18:1-16:0 (b) isomers. Signals at *m/z* 673 are formed by losses of 88 Da ($[CH_2CH(NH_2)COOH]^-$) from the deprotonated molecules of the two species. Product ions at *m/z* 255 (palmitic acid; 16:0) and 281 (oleic acid; 18:1) correspond to fatty acyl chains. However, intensities of a couple of anions give an opposite ratio, compared with those of carboxylate fragment ions obtained by CID of $[M - H]^-$ ions of underivatized GPE species, and the abundance of the peaks eliminated from the *sn*-2 fatty acid residues are weaker than those of the ions derived from the acids at the *sn*-1 position (47,48). This fact is mainly due to the favorable formation of glycerophosphatidic acid fragment ($[M - 88]^-$) that governs the fragmentation derived from it (49). The diversity of the pathways to yield fatty acid anions leads to the differences in the relative abundance of carboxylate product ions derived from $[M - H]^-$ parent ions (47).

Lysophosphatidylserine

Low-energy and high-energy CID. Product ions yielded by low- and high-energy CID of $[M + H]^+$ ion from LysoPS species are listed in Table 4.

Positive ion CID mass spectra. Low-energy CID of LSI-generated $[M + H]^+$ ions of LysoPS species produces fragment ion $[M + H - \text{phosphoserine}]^+$, which is useful for characterizing the polar head moiety and fatty acid chain in the species (not shown) (Table 4). High-energy CID of LSI-generated $[M + H]^+$ ion of LysoPS 14:0, shown in Figure 6, yields ions at *m/z* 299 $[M - PO_3CH_2CH(NH_2)COOH]^+$, *m/z* 285 $[M + H - \text{phosphoserine}]^+$, and *m/z* 88 $[CH_2CH(NH_2)COOH]^+$ for characterizing polar head moiety and fatty acid chain in the species.

Negative ion CID spectra. Low- and high-energy CID of LSI-generated $[M - H]^-$ ion of LysoPS species produces only an abundant anion $[R_1COO]^-$, which relates to the fatty acyl chain in LysoPS species (not shown) (Table 4).

TABLE 4
Fragmentation of LysoPS Generated by CID Tandem Mass Spectrometry[a]

			Polar head group	Fatty acid composition and location
Acyl-LysoPS (LSI)	$[M + H]^+$	L-CID	$[M + H - \text{phosphoserine}]^+$	
		H-CID	$[M + H - \text{phosphoserine}]^+$ $[M + H - \text{phosphoserine} + O]^+$ $[CH_2CH(COOH)NH_2]^+$	
	$[M - H]^-$	L-CID		$[R_1COO]^-$

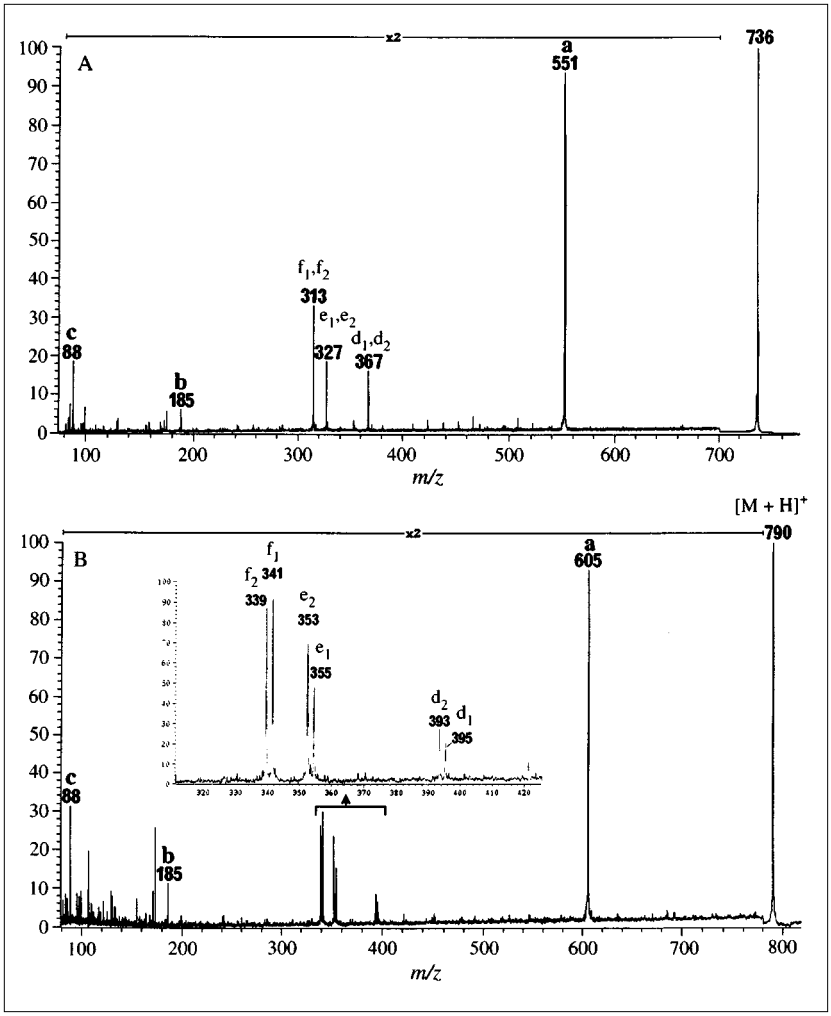

FIG. 4. High-energy CID spectra of protonated molecules of GPS 16:0-16:0 (A) and GPS 18:0-18:1 (B).

Liquid Secondary Ion Mass Spectrometry and Tandem Mass Spectrometric Analysis of Molecular Species of GPE and GPS as Fmoc Derivatives

Fmoc derivatives of GPE. *Positive ion LSI and high-energy CID mass spectra.* The protonated molecules of Fmoc GPE species are absent in conventional LSI mass spectra. CID of $[M + Na]^+$ ion (*m/z* 935) of Fmoc GPE 16:0-16:0 (not shown) yields mainly an abundant ion at *m/z* 386, corresponding to [Fmoc-phosphoethanolamine + $Na]^+$, which is useful for characterizing the polar head group.

Negative ion LSI and high-energy CID mass spectra. Figure 7A shows the conventional negative ion LSI mass spectrum of Fmoc-GPE18:0-20:4. The peak at *m/z* 988 corresponds to the deprotonated molecule of this derivative. The ion at *m/z* 766 is formed by the loss of a Fmoc group from its $[M - H]^-$ parent ion. Fragment ions due to fatty acyl chains are present at *m/z* 283 (stearic acid) and 303 (arachidonic acid). The conventional mass spectrum of reversed-phase HPLC-purified Fmoc derivative of GPE from rat kidney exhibits an abundant peak at *m/z* 960, which relates to the deprotonated molecule of 36:4 species (not shown). The ion at *m/z* 738 ($[M - H - 44]^-$) is formed by the loss of an ethanolamine group from the $[M - H]^-$ ion. However, it is difficult to identify fatty acyl chains in the species, and the structural information regarding acyl chain positions in Fmoc derivatives of 1,2-diacyl-GPE species can only be obtained by CID of LSI-generated $[M - H]^-$ ions. Figure 7B exhibits CID spectrum of LSI-generated $[M - H]^-$ ion (*m/z* 960) of Fmoc-36:4 species. Product ions appeared at *m/z* 255 (palmitic acid) and 303 (arachidonic acid) furnish correct information on the composition and location of two fatty acyl chains. This species is identified as GPE 16:0-20:4 since the abundance of the anion at *m/z* 303 is richer than that of *m/z* 255 peak (47). This determination is in a good agreement with results published (50). Alkenylacyl-GPE (plasmalogen GPE) can be distinguished from diacyl-GPE depending on the absence of an anion, corresponding to the fatty chain at the *sn*-1 position (47). The fragment pattern of high-energy CID spectra of Fmoc GPE species is identical to

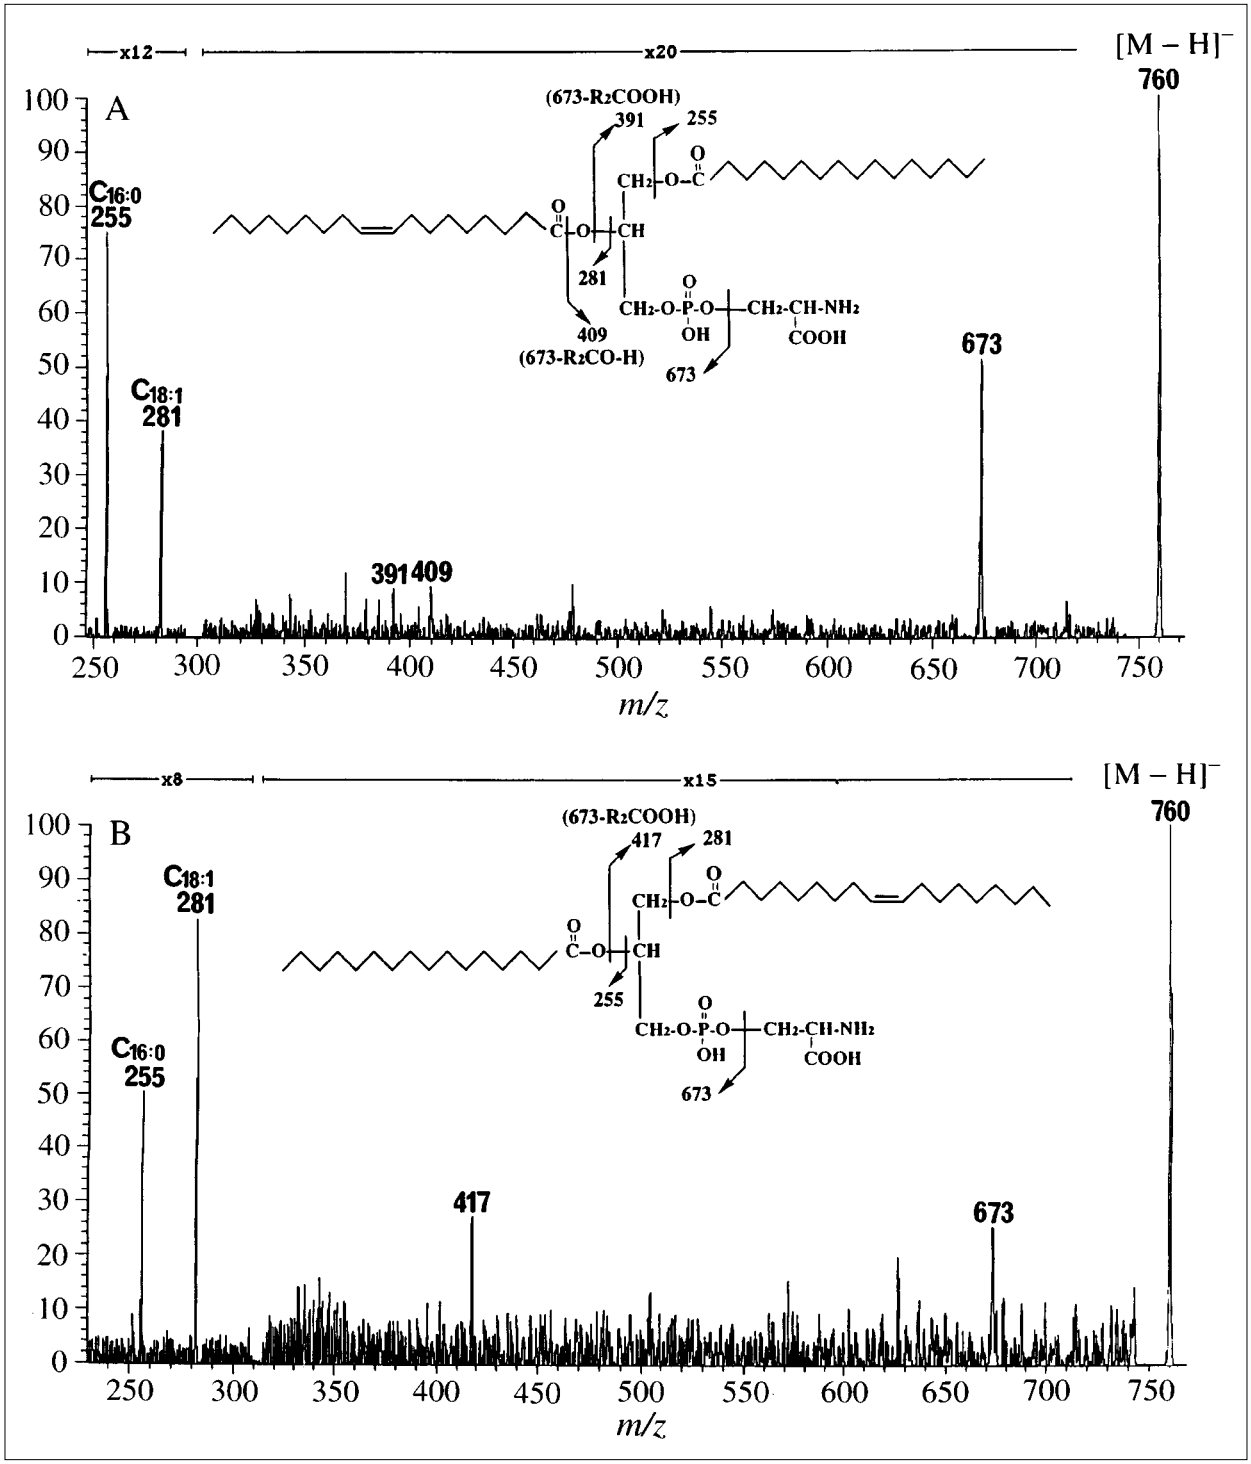

FIG. 5. High-energy CID spectra of deprotonated molecules of GPS 16:0-18:1 (A) and GPS 18:1-16:0 (B).

that of high-energy CID of underivatized GPE molecules (see Table 1).

Fmoc derivatives of GPS. *Positive ion LSI and high-energy CID mass spectra.* Both $[M + H]^+$ and $[M + Na]^+$ ions are absent in the conventional positive ion LSI mass spectra of Fmoc derivatives of GPS species. CID of $[M + 2\ Na - H]^+$ ion (*m/z* 1002) of Fmoc-16:0-16:0 species (not shown) generates product ions mainly at *m/z* 957 ($[M + 2\ Na - H - COOH]^+$), 693 ($[M + 2\ Na - H -$ Fmoc-serine$]^+$), 509 ($[M + 2\ Na - H -$ Fmoc-serine $- C_{13}H_{28}]^+$), 437 ($[M + 2\ Na - H -$ Fmoc-serine $- R_1COOH]^+$ or $[M + 2\ Na - H -$ Fmoc-serine $- R_2COOH]^+$), 143 ($[H_2PO_4 + 2\ Na]^+$), and 125 ($[H_2PO_4 + 2\ Na - H_2O]^+$) (29).

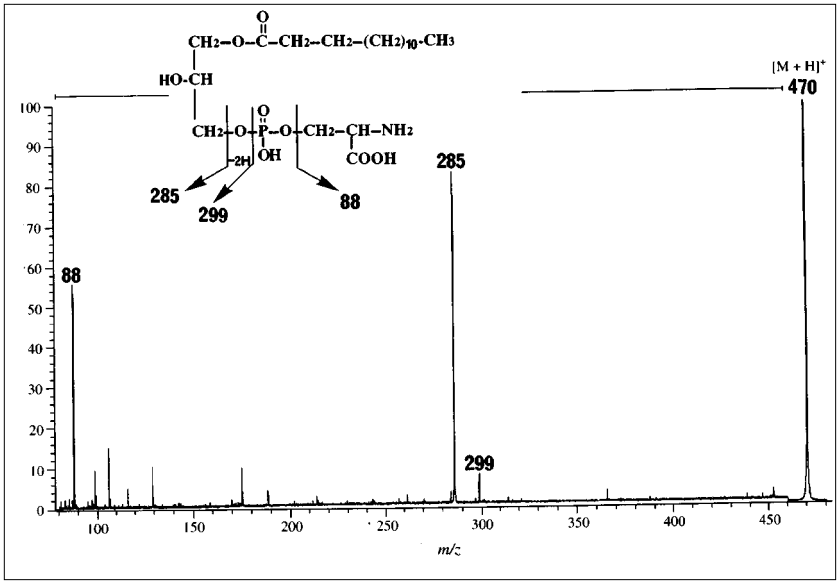

FIG. 6. High-energy CID spectrum of protonated molecule of LysoPS 14:0.

Negative ion LSI and high-energy CID mass spectra. The conventional negative ion LSI mass spectrometry produces abundant deprotonated molecules of Fmoc derivatives of GPS species. Figure 8 exhibits the conventional mass spectrum of Fmoc-16:0-18:1 (A) and Fmoc-18:1-16:0 (B) isomers. Anions at *m/z* 982 correspond to the deprotonated molecules of the two derivatives. Losses of Fmoc-serine moieties from $[M - H]^-$ ions give strong peaks at *m/z* 674. Signals at *m/z* 255 (palmitic acid) and 281 (oleic acid) are diagnostic ions of fatty acyl chains, the intensities of $[R_1COO]^-$ ions are greater than those of $[R_2COO]^-$ peaks. Abundance of the peaks at *m/z* 409 ($[M - Fmoc - 88 - R_2CO - H]^-$) and 391 ($[M - Fmoc - 88 - R_2COOH]^-$) from Fmoc-16:0-18:1, as well as *m/z* 435 ($[M - Fmoc - 88 - R_2CO - H]^-$) and 391 ($[M - Fmoc - 88 - R_2COOH]^-$) from Fmoc-18:1-16:0 are significantly high (47). Because of the presence of significantly abundant $[M - Fmoc - 88 - R_2CO - H]^-$ and $[M - Fmoc - 88 - R_2COOH]^-$ fragment ions in conventional LSI mass spectra of Fmoc GPS species, the feasibility of identifying composition and location of fatty acid chains by conventional mass spectrometry of Fmoc GPS, after reversed-phase HPLC separation, has been established (47).

Figure 9 shows the conventional LSI mass spectrum of Fmoc derivative of GPS species from rat kidney. The abundant peak at *m/z* 1032 is the deprotonated molecule of Fmoc GPS 38:4. Anions at *m/z* 810 and 724 are formed by losses of Fmoc and Fmoc-serine moieties, respectively. Ions arising at *m/z* 303 ($[R_2COO]^-$; arachidonic acid), *m/z* 283 ($[R_1COO]^-$; stearic acid), *m/z* 437 ($[M - Fmoc - 88 - R_2CO - H]^-$) and *m/z* 419 ($[M - Fmoc - 88 - R_2COOH]^-$) indicate both composition and location of fatty acyl chains in this species. This lipid is identified as Fmoc GPS 18:0-20:4 (28). The other three minor species, corresponding to the weak deprotonated molecules at *m/z* 1004, 1008 and 1010, are tentatively determined as Fmoc-GPS 36:4 (16:0-20:4), -GPS 36:2 (18:1-18:1 or/and 18:0-18:2) and -GPS 36:2 (18:0-18:1), based on $[M - Fmoc - 88]^-$ fragments at *m/z* 695, 699 and 701. The fragmentation pattern of high-energy CID spectra of Fmoc GPS species is identical to that of high-energy CID of underivatized GPS species (47,48) (see Table 3).

DISCUSSION

The low- and high-energy CID of protonated and deprotonated molecules from aminophospholipids produce a wealth of information on the structure of molecular species. Tandem mass spectra obtained by low-energy CID of $[M - H]^-$ ions from aminophospholipids contain anions which are useful for characterizing polar head moieties and fatty acid chains esterified in molecular species. High-energy CID of both $[M + H]^+$ and $[M - H]^-$ ions from aminophospholipids yields numerous product ions, which are structurally informative for identifying polar heads as well as the composition and location of fatty chains in molecular species.

The negative ion LSI or ESI CID tandem mass spectrometry is commonly used in structurally determining aminophospholipid molecular species. A decision on the position of fatty acyl residues in unknown 1,2-diacyl aminophospholipid molecular species can be made based on a general rule for CID mass spectra of GPE and GPS that the intensity ratio of carboxylate anions ($[R_2COO]^-/[R_1COO]^-$) > 1 for GPE (45,47); and ($[R_2COO]^-/[R_1COO]^-$) < 1 for GPS (47,48) reflects the location of fatty acyl chains esterified. Therefore, the reproducibility of $[R_2COO]^-$ and $[R_1COO]^-$ ions in intensity, which are produced by CID of $[M - H]^-$ precursors, is essential in the structural determination of molecular species. Data presented in this study and others suggest that the kinetic energy of precursor ions ($[M - H]^-$) is presumably associated

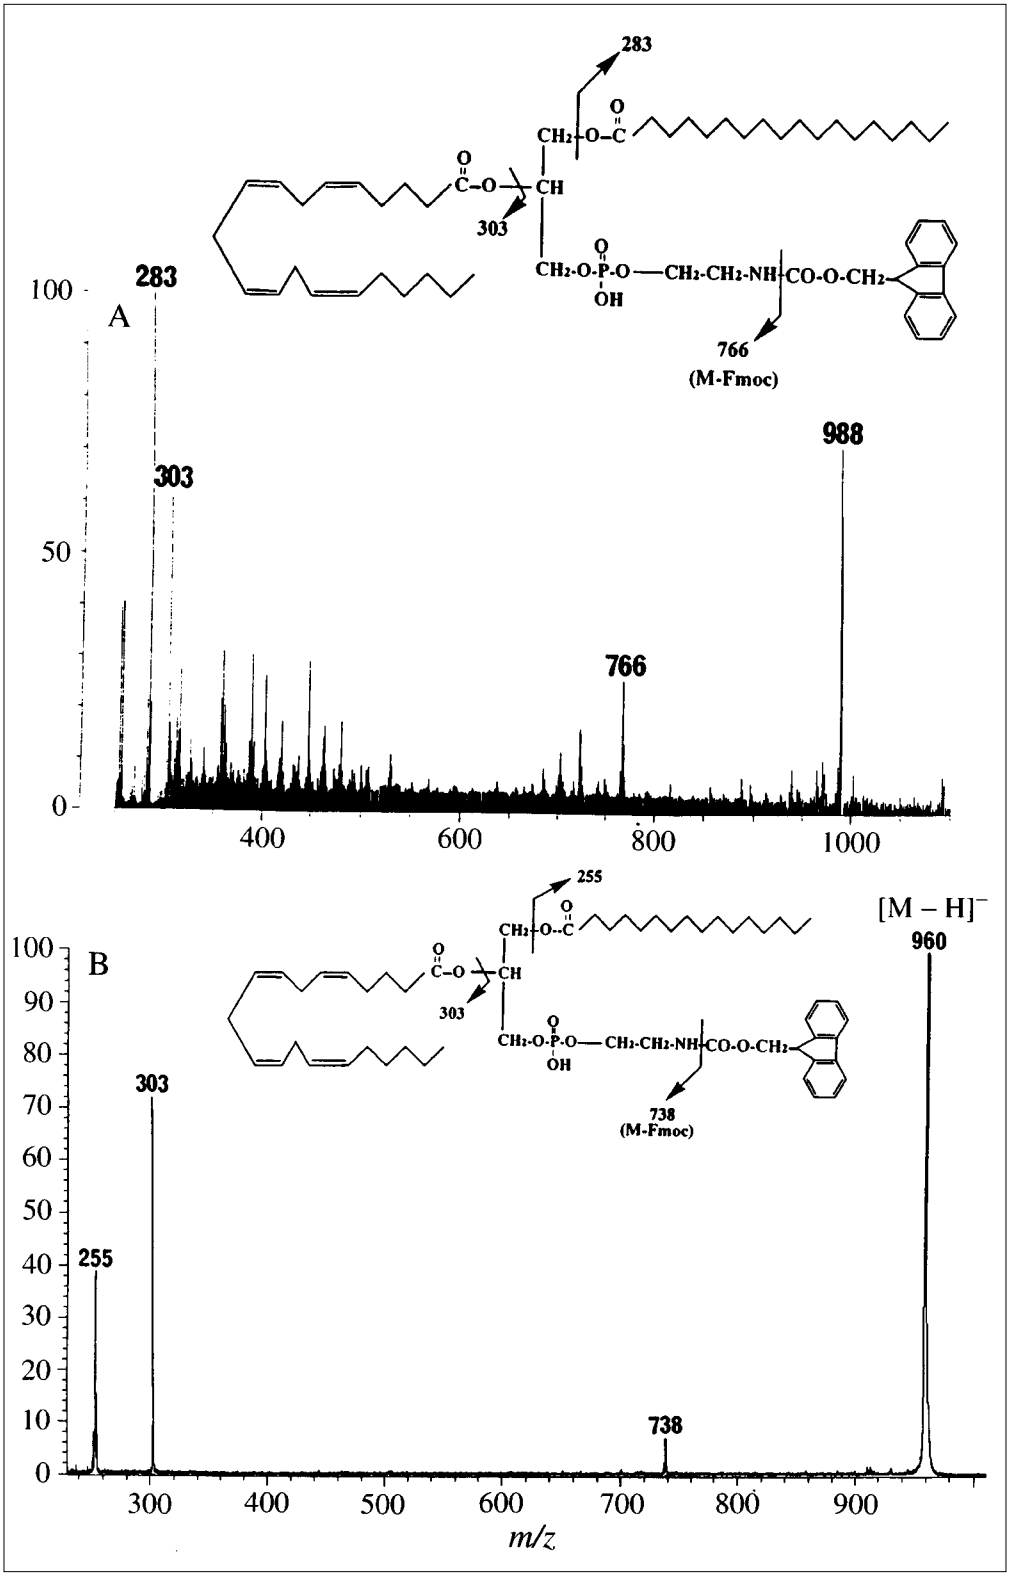

FIG. 7. Negative ion LSI mass spectrum of Fmoc derivative of GPE 18:0-20:4 (A) and high-energy CID spectrum of deprotonated molecule of reversed-phase HPLC purified-Fmoc derivative of rat kidney GPE 16:0-20:4 (B).

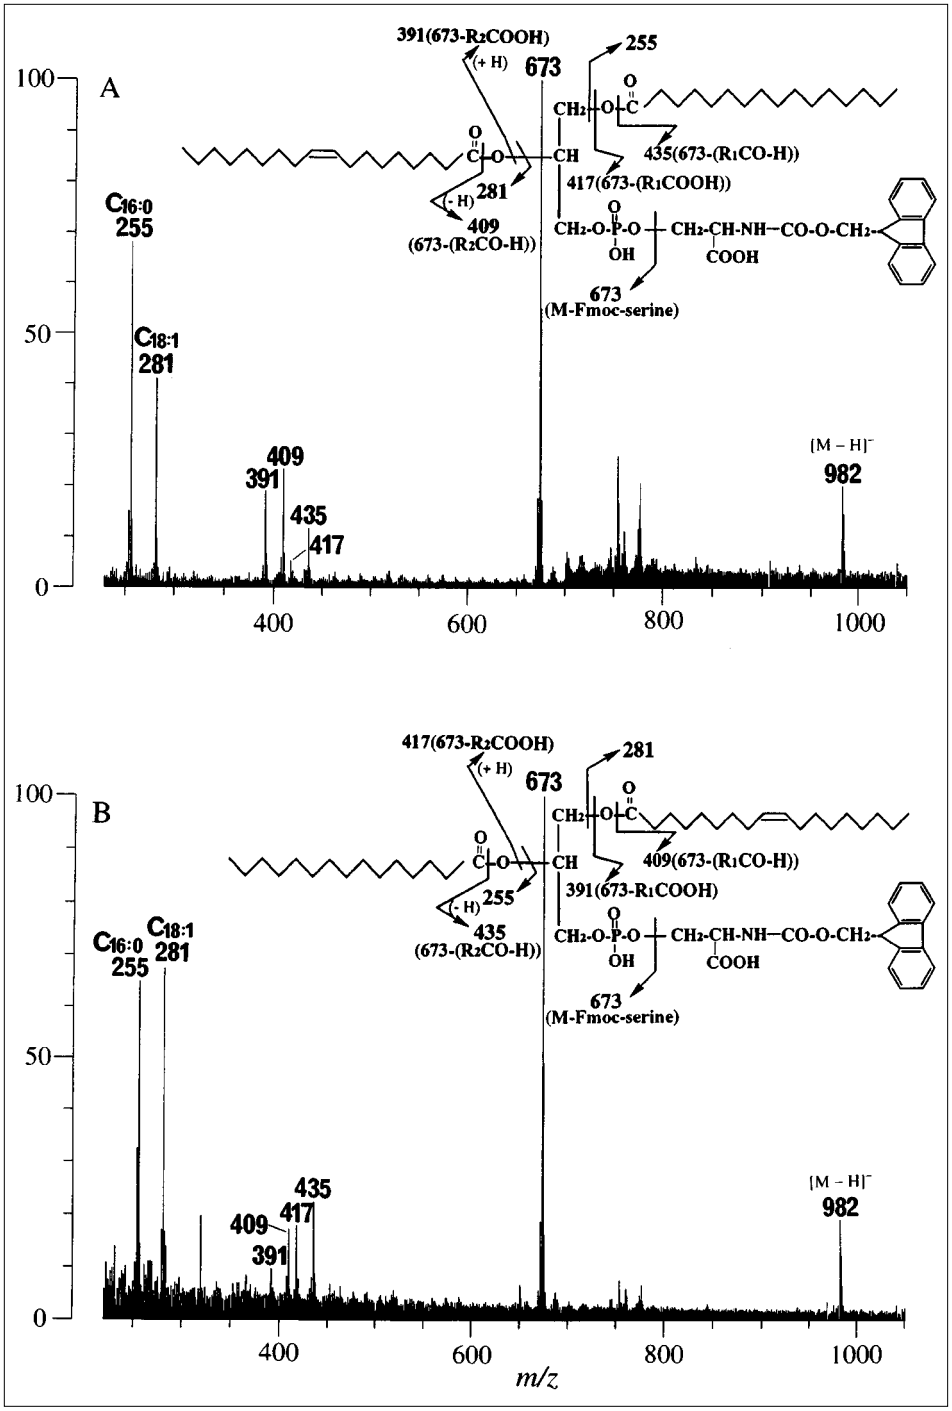

FIG. 8. Negative ion LSI mass spectra of Fmoc derivatives of GPS 16:0-18:1 (A) and GPS 18:1-16:0 (B).

with the abundance of carboxylate anions derived from them. For example, CID mass spectra of $[M - H]^-$ ions from various GPE species were produced by (i) the electric-magnetic sector coupled to low- or high-energy CID (spectra of GPE 18:0-20:4 and GPE 16:0-22:6 shown in References 47 and 48 cited in the paper); and (ii) the quadrupole mass analyzer combined with low-energy CID (spectra of GPE 18:0-22:6 shown in Refs. 37 and 26, as well as spectra of GPE 18:0-20:4 shown in Refs. 38 and 45 cited in the study) experiments, respectively. But the intensity of carboxylate anions produced by the former (47,48) rather than the latter (37,26) fully meet the general rule (45) described above. It could be explained by the fact that the kinetic energy of ion source-produced precursor ions transmitted through the electric-magnetic sector is different from that of some precursor ions transmitted through the quadrupole mass analyzer. The kinetic energy di-

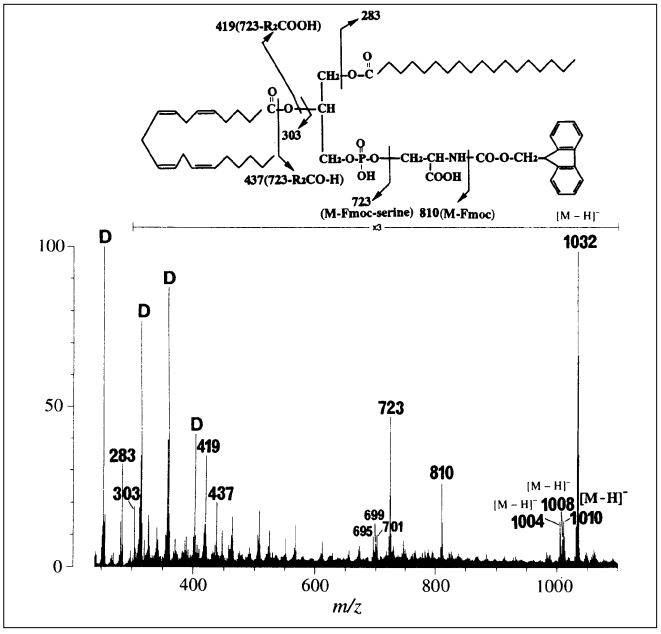

FIG. 9. Negative ion LSI mass spectrum of Fmoc derivatives of rat kidney GPS. D peaks are due to diethanolamine matrix used.

versity of ion source-produced precursor ions transmitted through the quadrupole mass analyzer might lead to the intensity irreproducibility of carboxylate anions derived from the precursors. The ESI CID method exhibits remarkable superiority in analyzing structures of aminophospholipids at the picomole levels within minutes. The electric-magnetic sector coupled to quadrupole mass analyzer or electric-magnetic sector mass spectrometers have the advantage of the capability of properly determining the location of fatty acid chains in molecular species. The combination of tandem mass spectrometry should be taken into account in interpreting CID mass spectra of molecular species of aminophospholipids. The three sorts of tandem mass spectrometers exhibit the capability of identifying the structure of various underivatized Lysophospholipids, such as LysoPE, Plasmalogen LysoPE and LysoPE regioisomers.

An approach has been developed for the structural analysis of aminophospholipid species as Fmoc derivatives in order to meet the requirements of both quantitative determination of classes and molecular species by HPLC coupled to chromophore detection and full characterization by mass spectrometry of aminophospholipid derivatives. Negative ion LSI mass spectrometry of Fmoc derivatives of GPE and GPS yields abundant $[M - H]^-$ ions and informative fragment ions which are useful for identifying structures of molecular species. High-energy CID mass spectra of the derivatized species exhibit fragmentation modes identical to those of high-energy CID of underivatized GPE and GPS. The low limit of producing a useful conventional and CID mass spectrum of the Fmoc derivatives is approximately 2 and 30 nanograms, respectively. Furthermore, a novel derivative of animophospholipid, ethyltriphenyphosphonium (ethyl-TPP) of GPS, has been prepared, and the preliminary result shows that CID of LSI-generated $[M]^+$ ion of ethyl-TPP GPS 16:0-16:0 not only provide information on the composition and location of fatty acyl chains but also allow structures of esterified-fatty acid to be identified. Further studies on HPLC separation and CID fragmentation of ethyl-TPP derivatives of aminophospholipids are in progress.

[a,b,c]Research Service and [a]GRECC, VA Medical Center, Minneapolis, Minnesota 55417 and the Departments of [a]Psychiatry, and [d,e]Biochemistry, University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT: A rapid method for the simultaneous determination of cholesterol and its oxidation products as well as α-tocopherol and tocopherolquinone in brain subcellular fractions is described. The samples are saponified and extracted with hexane. It is not necessary to remove cholesterol in the sample before analyzing for oxysterols. The hexane extract can be used for the assay of cholesterol compounds by capillary gas chromatography and tocopherol compounds by liquid chromatography using a procedure reported previously. Oxidation of synaptosomes by a mixture of Fe^{2+} plus ascorbate resulted in the production of 7-keto-, 7α-hydroxy-, 7β-hydroxy-, and 5α,6α-epoxycholesterols. The identities of these products were confirmed with gas chromatography/mass spectrometry. Cholesterol oxidase treatment did not result in the formation of any of the above compounds. Thus the types and amounts of the products of oxidation of cholesterol were dependent upon the oxidizing agent. Extraction of the oxysterols under milder conditions without saponification using sodium dodecyl sulfate cannot be used since such treatment results in low recovery of oxysterols. Oxidation of synaptosomes by low concentrations of ferrous iron and ascorbate resulted in (i) low levels of oxidation of cholesterol which could be followed by estimating the production of oxysterols and (ii) oxidation of a substantial percentage of α-tocopherol. The proposed procedure will be useful in monitoring the oxidation of small quantities of membrane cholesterol *in vitro*.

Lipids 32, 101–107 (1997).

Cholesterol and phospholipids in membranes are known to undergo peroxidation which can result in structural and functional damage. Numerous oxidation products of cholesterol produced under a large variety of conditions have been identified (1). The majority of the known cholesterol oxidation products are biologically active as cytotoxic, atherogenic, mutagenic, carcinogenic, or enzyme inhibitory substances (2). Therefore, it is important to monitor the production of oxysterols during biological oxidative stress. However, little, if anything, is known about the formation of oxysterols in brain under conditions of free radical-induced oxidative stress. The biological effects of specific oxysterols upon brain function can be determined only after knowing the types and amounts of oxysterols formed in brain during peroxidative reactions. A capillary gas chromatographic (GC) method for the determination of oxysterols in brain subcellular fractions is described in this paper.

Our laboratory has been investigating the relationship between consumption of the lipid antioxidant vitamin E and oxidation of membrane cholesterol during the *in vitro* oxidation of biological samples. The experimental procedure consists of incubation of subcellular fractions from brain with oxidizing agents followed by determination of the decreases in concentrations of α-tocopherol and cholesterol and the increases in concentrations of the respective oxidation products. Only small quantities of subcellular fractions are usually available for such experiments. Hence, a method was needed for the determination of tocopherol compounds, cholesterol, and oxysterols within the same sample. We have developed a simple and rapid procedure for such analyses, and the details are reported here. A GC method for the analysis of cholesterol oxidation products in lipoprotein samples has been proposed by Addis *et al.* (3). This procedure involves extraction of lipids with chloroform plus methanol, saponification of the extracted lipids for 18–20 h at room temperature, and extraction of the unsaponified compounds with ether. This is then followed by derivatization and GC analysis. Sevanian *et al.* (4) have used GC and liquid chromatography (LC) coupled with mass spectrometry (MS) for determining oxysterols in human plasma samples. Their method also involves several steps. Determination of cholesterol oxidation products by isotope dilution–MS also has been published (5). The latter techniques require expensive equipment that is not readily available in most laboratories. The procedure used in this report is simpler and faster and involves saponification followed by a single solvent extraction step. One portion of the extract is used for determining cholesterol and its oxidation products by the procedure proposed in this paper. Another portion of

Abbreviations: BHT, butylated hydroxytoluene; GC, gas chromatography; HPLC, high-performance liquid chromatography; LC = liquid chromatography; MS, mass spectrometry; TMCS, trimethylchlorosilane. Trivial names of sterols: cholest-5-ene-3β,7α-diol = 7α-hydroxycholesterol; cholest-5-ene-3β,7β-diol = 7β-hydroxycholesterol; 3β-hydroxycholest-5-ene-7-one = 7-ketocholesterol; 5,6,α-epoxy-5α-cholestan-3β-ol = 5α,6α-epoxycholesterol.

the extract can be utilized for determination of tocopherol and its quinone by a LC method (6). The data in this report focus primarily on the application of this technique to monitor free radical-induced oxidation of cholesterol in rat brain synaptosomes.

EXPERIMENTAL PROCEDURES

Chemicals. The chemicals used were of reagent-grade purity from standard sources. Solvents were high-performance liquid chromatography (HPLC) grade from Fisher Scientific (Pittsburgh, PA). Other special chemicals used were purchased from the following sources. Cholesterol oxidase (EC1.1.3.6) from *Cellulomonas* was purchased from Sigma Chemical Company (St. Louis, MO). The hydroxy- or ketocholesterols, 5α-,6α-epoxide and cholesterol (Sigma grade: standard for chromatography) were obtained from Sigma Chemical Company, or Research Plus Inc. (Bayonne, NJ). The 5β-,6β-epoxide of cholesterol was from Steraloids, Inc. (Wilton, NH). Regisil with 1% trimethylchlorosilane (TMCS) was used for silylation of the sterols and was purchased from Regis Technologies Inc. (Morton Grove, IL). Absolute ethanol was obtained from Midwest Solvents Company (Pekin, IL) and was redistilled prior to use. Ferrous sulfate heptahydrate from Sigma Chemicals was used as the source of ferrous iron. Most of the reagent grade chemicals were from Sigma Chemicals. The DB1 column was from J&W Scientific (Folsom, CA).

Biochemical assays. Concentration of total protein was determined by the Lowry technique as modified by Markwell *et al*. (7).

Extraction of analytes from sample. The procedure was essentially the same as published earlier (6). Briefly, 2 mL ethanol containing 0.025% (wt/vol) butylated hydroxytoluene (BHT) and 0.1 mL of 30% (wt/vol) ascorbic acid were pipetted into tubes containing samples for analyses. The mixture was heated at 60°C for 30 min after the addition of 1 mL of 10% potassium hydroxide solution. Tubes were cooled, and 2 mL of water was added followed by 2 mL of hexane containing 0.025% (wt/vol) BHT. Cholesterol, α-tocopherol, and their oxidation products were extracted into the hexane phase by vortexing for 1 min.

One portion of the hexane phase (usually 0.5 mL) was separated out and used for the analysis of cholesterol and oxysterols. Samples containing high levels of cholesterol could be analyzed with smaller volumes of the hexane extract whereas larger volumes had to be used with samples such as mitochondria containing smaller amounts of cholesterol. The extract was evaporated down under a stream of nitrogen, or the solvent was removed under vacuum at 60°C. The residue was mixed with 100 µL Regisil [*bis* (trimethyl silyl) trifluoroacetamide plus 1% trimethylchlorosilane] as derivatizing agent and 25 µL pyridine and then heated at 60°C for 1 h. The silylated cholesterol and its oxidation products were analyzed by a capillary GC method: Hewlett-Packard 5880 GC with autosampler (Palo Alto, CA), injection port 230°C, flame-ionization detector 280°C, splitless injection; DB1 column, 30 meters × 0.324 mm i.d., film thickness 0.25 µm; temperature programming—oven temperature initial 50°C, initial time 3 min, program rate 30°C per min, final value 290°C, second program rate 1°C per min, final temperature 300°C and keep at 300°C for 5 min.

The second portion of the extract was used for assays of tocopherol compounds using the HPLC procedure reported earlier (6).

Identification of cholesterol oxidation products by GC/MS. The mass spectral analyses were performed on a Kratos MS-25 GC/MS (Kratos Analytical, Ramsey, NJ). Electron impact (EI) mass spectra were acquired with an electron ionization potential of 70 eV and ion source temperature of 220°C. The conditions of derivatization and GC were the same as described in the above paragraph.

Preparation of subcellular fractions from rat brain. Four-month-old, male Fisher 344 rats were used. The subcellular fractions were isolated from cerebral hemispheres by standard centrifugation methods (8). Brain tissue was homogenized in 10 vol of ice-cold isolation medium containing 0.32 M sucrose, 10 mM HEPES, and 1 mM EDTA at pH 7.4, using a glass-glass homogenizer. The homogenate was centrifuged at 1300 × *g* for 3 min and the supernatant saved. The pellet was resuspended in 10 mL of the isolation medium, rehomogenized, and centrifuged at 1300 × *g* for 3 min. The pooled supernatants were centrifuged at 17,000 × *g* for 10 min to get the crude mitochondrial fraction. The resulting pellet was resuspended in 15 mL of isolation medium. Half of this suspension was layered over 11 mL of 7.5% (wt/vol) Ficoll medium which had been layered over 11 mL of 10% (wt/vol) Ficoll medium. The tubes were centrifuged in a Beckman SW 28 rotor (Fullerton, CA) at 99,000 × *g* for 45 min. The fraction at the interface between the two Ficoll solutions was removed, diluted 1:5 with isolation medium, and centrifuged for 10 min at 17,000 × *g* to isolate the synaptosomes. The purity of the synaptosomal fraction was tested by electron microscopy and also by estimating the activities of the marker enzyme Na-K-ATPase (9). The activity of the ATPase was usually enriched two- to three-fold in synaptosomes compared with the crude homogenate. The synaptosomes isolated are metabolically active and have been used in studies of transmitter uptake and release. Even though we used only the synaptosomes in this report, other subcellular fractions such as mitochondria and myelin also can be isolated using this procedure.

Protocol for incubations. Synaptosomes were incubated in a medium simulating extracellular fluids or plasma and contained: 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, 10 mM glucose and a pH of 7.4. HEPES (10 mM) was also added for additional buffering capacity. The oxidizing agents such as ferrous salt and ascorbate were added and the tubes incubated. When higher levels of oxidation were desired, the concentrations of oxidants and the times of incubation were increased. After incubation, the tubes were placed on ice. The reaction mixture was then cen-

trifuged for 30 min at 17,000 rpm in a Sorvall (Dupont, Hoffman Estates, IL) SS 34 rotor (35,000 × *g*) to sediment the synaptosomes. The sedimented fractions were then analyzed for various components.

In a few cases, brain subcellular fractions were incubated with cholesterol oxidase. Typically, samples of synaptosomes (500 μg of protein in a total volume of 2 mL) were incubated at 37°C for 2 h in the buffer described above in the presence of either 0.15 or 0.3 units per mL of the enzyme. After incubation, the samples were placed on ice and centrifuged immediately to sediment the synaptosomes. The pellet was then processed for the GC and LC assays.

RESULTS

A sample containing a mixture of standard oxysterols was carried through the procedure, and the chromatogram obtained is shown in Figure 1 and the corresponding reagent blank in Figure 2. It can be seen that the oxysterols of interest are separated well. The retention times in minutes of cholesterol and a few selected oxysterols were as follows: cholestane (internal standard) = 14.82; cholesterol 17.26; 7α-hydroxycholesterol (A) 16.97; 19-hydroxycholesterol (B) 17.91; 7β-hydroxycholesterol (C) 18.30; 5α,6α-epoxycholesterol (D) 18.75; 22-ketocholesterol (E) 19.19; 7-ketocholesterol (F) 20.63.

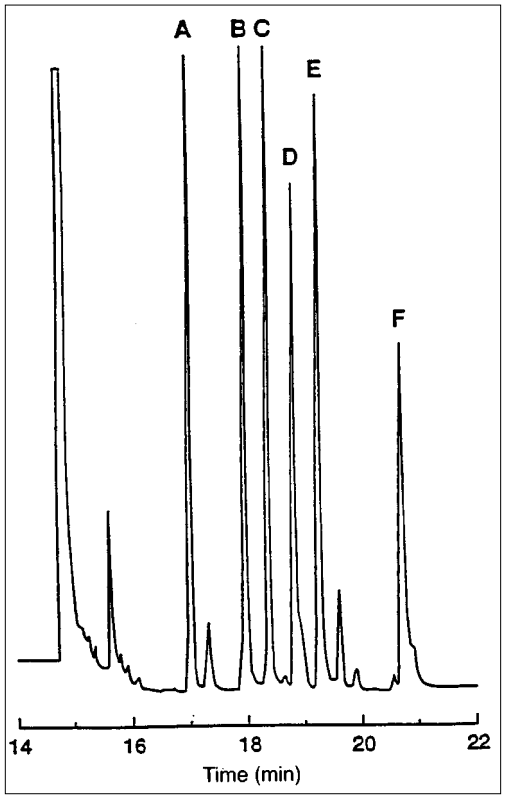

FIG. 1. Chromatogram from the analysis of a mixture of oxysterols by the current method. A mixture of standard commercial oxysterols was processed as described and analyzed by capillary gas chromatography. The peaks identified by capital letters are: 7α-hydroxycholesterol (A); 19-hydroxycholesterol (B); 7β-hydroxycholesterol (C); 5α,6α-epoxycholesterol (D); 22-ketocholesterol (E); 7-ketocholesterol (F).

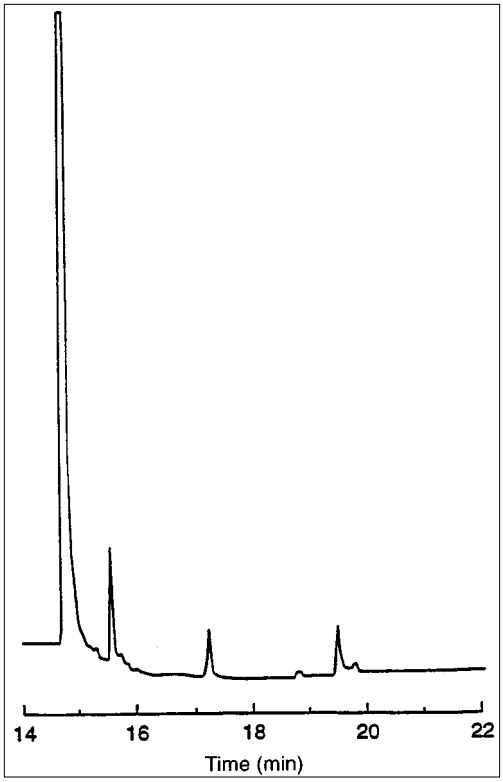

FIG. 2. Chromatogram from the analysis of a mixture of reagents used in the proposed technique. This figure serves as a reagent blank chromatogram for Figure 1.

Samples of synaptosomes were obtained from the cerebral hemispheres of four-month-old rats and were incubated *in vitro* with a mixture of 25 μM Fe^{2+} and ascorbate for 3 h. Such mixtures of $Fe^{2+}$and ascorbate have been used as sources of hydroxyl radicals in numerous investigations. The chromatogram obtained after processing the sample is given in Figure 3. The corresponding chromatogram obtained after processing a control sample of synaptosomes is shown in Figure 4. Even though many oxysterols have been reported to exist in biological systems under various conditions, peroxidation of synaptosomes resulted in the production of only a few oxysterols. The oxysterols observed chromatographically were: 7α- and 7β-hydroxycholesterol, 7-ketocholesterol and 5α,6α-epoxycholesterol. The 5β,6β-epoxycholesterol was also probably formed under the same conditions. However, we could not demonstrate this consistently.

In some cases it may be desirable to avoid saponifying the sample and extract the cholesterol derivatives using milder techniques to prevent oxidation of membrane components. One of the recommended procedures for extraction of tocopherols from biological samples without saponification involves the use of SDS to disrupt the membrane (10) . An experiment utilizing this method for extraction was performed. The final

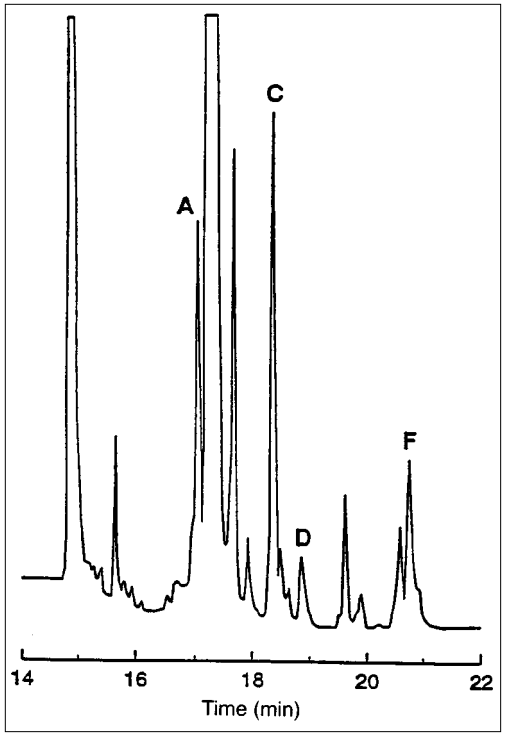

FIG. 3. Chromatogram from the analysis of a sample of synaptosomes that was incubated in the presence of a mixture of Fe^{2+} and ascorbate (25 μM each). Rat brain synaptosomes were isolated and incubated for 3 h with a mixture of Fe^{2+} and ascorbate. The cholesterol and the oxysterols produced were assayed by the recommended method.

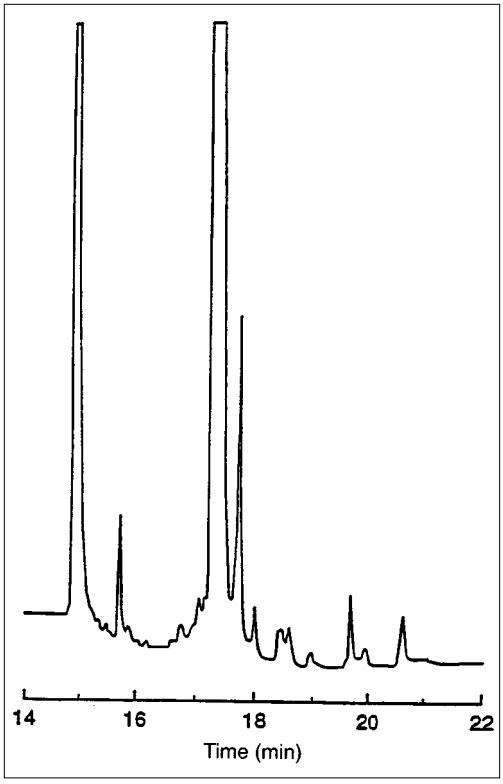

FIG. 4. Chromatogram from the analysis of a sample of synaptosomes that was incubated for 3 h with no oxidant. This chromatogram serves as control for Figure 3.

SDS concentrations used were either 0.04 M or 0.1 M. The results of this study are shown in Table 1. Substantial amounts of the oxysterols remain unextracted in the aqueous phase, causing a reduction in recoveries. In fact, higher concentrations of SDS in the medium resulted in lower recoveries of the oxidized cholesterol compounds. Thus, even though solvent extraction in the presence of SDS has been used successfully for the isolation of tocopherols, it is not suitable for quantitative extraction of oxysterols. This is not surprising since oxysterols are more water-soluble than cholesterol itself and detergents could decrease the recovery of these compounds.

The applicability of the method for quantitative analysis of oxysterols was also tested. When 4 to 30 picomoles of the sterol derivatives were injected on the column, the standard curves obtained were linear within limits of experimental error. The correlation coefficients were usually higher than 0.99. This was true for all cholesterol derivatives shown in Figure 1. The percentage recoveries of the various cholesterol derivatives added to samples of synaptosomes were as follows: 7α-hydroxycholesterol = 87 ± 3 (SD); 7β-hydroxycholesterol = 98 ± 1.7; 7-ketocholesterol = 97 ± 4.6; 22-ketocholesterol = 88 ± 4.2; and 5α,6α-epoxycholesterol = 80 ± 3.6. The lower recovery of the epoxide may reflect the instability of this compound during sample processing and chromatography. The detection limits (expressed as picomoles injected on the capillary column) for the various compounds were as follows: 7-ketocholesterol = 2, epoxide = 1, and the hydroxycholesterols = 0.5. Sevanian *et al.* (4) have reported the detection limits to be in the range of 2.5 to 5 picomoles, and the two methods are quite comparable in this respect.

TABLE 1
The Effect of SDS upon the Extractability of Oxysterols

	7α-Hydroxycholesterol			7-Ketocholesterol			5α,6α-Epoxycholesterol		
Concentration of SDS	Amount added	Amount recovered	Percentage recovery	Amount added	Amount recovered	Percentage recovery	Amount added	Amount recovered	Percentage recovery
0.04 M	5.46[a]	2.33	43	6.86	4.4	64	6.21	5.4	87
0.1 M	5.46	0.94	17	6.86	2.6	38	6.21	4.2	67

[a]The values for amount added and recovered are in nanomoles. The various amounts of oxysterols were extracted and processed for assays in the presence of the two levels of SDS. Quantitation was done by capillary gas chromatography.

One of the advantages of this procedure is that the bulk of the cholesterol in the samples need not be removed prior to the chromatographic determination of oxysterols. The effect of cholesterol content of the sample upon the reliability of the method was tested. This was done by adding different amounts of cholesterol to oxidized synaptosomes and then assaying for oxysterols. Samples of synaptosomes (600 μg of protein) were oxidized with mixtures of Fe^{2+} and ascorbate. The synaptosomal sample was expected to contain about 200 nanomoles of cholesterol. Known amounts of cholesterol, either 194 or 388 nanomoles, were added to some of the tubes, and the oxysterols were assayed by the recommended method. The results showed that the concentrations of oxysterols produced during the oxidations were not significantly different, irrespective of the amount of cholesterol present in each tube. Thus, the added cholesterol did not get oxidized during the sample processing and give rise to erroneously high levels of oxysterols. Interestingly, we found that the levels of oxysterols in control unoxidized samples of synaptosomes were quite low; the levels were lower than those found in standard cholesterol that had been kept in the laboratory for several years. In any case, the method provides reliable data on oxysterol concentrations in brain subcellular fractions without the need for cholesterol separation.

The aim of the next experiment was to compare the results of analysis of oxidized synaptosomal samples by the current method with those obtained by the method of Addis *et al*. (3). In this experiment, the synaptosomal samples were oxidized with a mixture of Fe^{2+} and ascorbate. The results are given in Table 2. It can be seen that the two methods provide comparable concentrations of oxysterols.

Many investigators have used cholesterol oxidase to alter membrane cholesterol concentrations. After incubations with cholesterol oxidase the percent oxidation of membrane cholesterol was: 2.4 ± 1.2 and 16.2 ± 1.5 with 0.15 or 0.3 units per mL of the enzyme, respectively. The α-tocopherol concentration was not changed during treatment with cholesterol oxidase. The gas chromatogram of oxysterols contained two peaks whose retention times were close to 19-hydroxycholesterol. Since the main product of cholesterol oxidation with the oxidase enzyme is the 3-keto derivative, these peaks may have been derived from this compound. Since the focus of our investigations is the analysis of oxysterol production during free radical-induced peroxidation, we did not attempt to characterize and identify these unknown peaks. It is interesting to note that none of the peroxidation products such as the 7-hydroxy or 7-keto derivatives were formed during treatment with cholesterol oxidase.

To show the utility of this technique, we subjected a few samples of synaptosomes to oxidation in the presence of a mixture of Fe^{2+} and ascorbate (10 μM each). The data are shown in Table 3. Firstly, it can be seen that no significant change can be observed in the levels of total cholesterol as a result of oxidation. If cholesterol oxidation was followed simply by examining whether there was a decrease in cholesterol concentration after the *in vitro* treatment, one would have concluded erroneously that cholesterol was not oxidized. However, data on the production of cholesterol oxidation products clearly show that a mixture of Fe^{2+} and ascorbate causes oxidation of membrane cholesterol. Secondly, the pattern of distribution of the oxidation products of cholesterol is characteristic of oxidations induced by hydroxyl radicals. Thirdly, even though little cholesterol was consumed, a substantial portion of α-tocopherol was oxidized. Hence, α-tocopherol is indeed acting as a chain-breaking antioxidant, preventing the oxidation of substantial amounts of membrane cholesterol. Table 3 represents the type of data on cholesterol and α-tocopherol and their oxidation products that can be obtained from the analysis of a single extract from the subcellular fraction. It can be seen that the proposed method provides a significant amount of information on the oxidation of the two important membrane components, cholesterol and tocopherol.

The cholesterol oxidation products were identified by GC/MS. Both mass spectral fragmentation patterns and GC retention times of the compounds as their trimethylsilyl-ether derivatives were compared to authentic standards and found to be the same. The 7α- and 7β-hydroxycholesterols had a molecular ion of *m/z* 546, a base peak at *m/z* 456, and an ion fragment at *m/z* 366. The 7-ketocholesterol had a molecular ion and base peak at *m/z* 472 and ion fragments at *m/z* 382 and 387. The 5α,6α-epoxycholesterol had a molecular ion of *m/z* 474 and ion fragments at *m/z* 459, 384, and 386. All of the compounds had the characteristic retention times noted earlier. The mass spectra of oxidized samples from synaptosomes matched with the mass spectra of standards at the specific retention times. It was mentioned above that oxysterol concentrations were very low in samples of synaptosomes in-

cubated with no oxidizing agent. We could not observe any oxysterols by GC/MS under these conditions.

DISCUSSION

One of the main advanatages of this method is the use of a single solvent extract for the determination of tocopherol, cholesterol, and their oxidation products. In addition, the method also allows the GC determination of cholesterol as well as oxysterols in biological samples. Even though the concentration of cholesterol is much higher than those of the oxidation products, it is not necessary to separate the bulk of cholesterol prior to the GC assay. A part of the extract can be used for the LC determination of tocopherol using methodology which has been published (6,11).

Oxidation of cholesterol would be expected to yield hydroperoxy derivatives. Biological tissues contain peroxidases which would catalyze the reduction of these hydroperoxides to the corresponding alcohols. A study by Thomas *et al*. (12) has shown that the phospholipid hydroperoxide glutathione hydroperoxidase enzyme which is present in many membranes can hydrolyze cholesterol hydroperoxides. Hence the levels of cholesterol hydroperoxides in tissues would be expected to be small, and the hydroxylated compounds would serve as reliable indicators of cholesterol oxidation in biological samples. This was our rationale for developing the current method for assaying hydroxylated and keto derivatives of cholesterol. Methods for the separation and quantitation of cholesterol hydroperoxides have been reported. For example, Korytowski *et al*. (13) used HPLC with electrochemical detection to quantitate cholesterol hydroperoxides produced by photodynamic action. Another HPLC method for the assay of four oxidation products of cholesterol from muscle and liver tissue has been reported by Csallany *et al.* (14). The procedure involved lipid extraction with chloroform/methanol and normal phase LC with ultraviolet detection. Even though these procedures are useful, the current technique involving analyses of oxysterols by capillary GC will have the ability to separate many more of the oxysterols in the same chromatographic run.

The method proposed by Sevanian *et al*. (4) involves GC or HPLC with MS. The processing of samples is quite lengthy and involves extraction of lipids, preliminary purification using column chromatography, and alkaline saponification followed by GC analysis. The GC separation of cholesterol oxidation products is somewhat similar to the procedure that we have used. As expected, the elution order of the various oxidation products in the procedure of Sevanian *et al*. (4) is identical to that observed by us.

The experiments with cholesterol oxidase show that the procedure can be used for following the mechanism of different types of oxidation of cholesterol in biological membranes. The chromatographic profile of cholesterol oxidation products after cholesterol oxidase treatment was qualitatively different from that from incubations with Fe^{2+} and ascorbate. It is interesting to note that the 7-position of cholesterol is susceptible to oxidation and that hydroperoxy, oxy, and hydroxy derivatives in this position are formed quite frequently as a result of autoxidation. Cholesterol derivatives which are hydroxylated in the side chain or 5,6-epoxides can also be formed as minor products of autoxidation of cholesterol (1). We found that significant amounts of epoxides were formed after attack of membrane cholesterol by hydroxyl radicals.

The concentrations of cholesterol in biological membranes are quite high, and it would be very difficult to follow oxidation of cholesterol by monitoring small declines in cholesterol concentrations during oxidations. However, cholesterol oxidation can be monitored by determining oxysterol concentrations as proposed in this paper. The efficiency of capillary columns can be exploited in developing chromatographic conditions to separate and analyze the various oxysterols. The proposed technique has the potential to be a useful method for the analysis of oxysterols generated *in vitro* in biological samples by a variety of oxidants.

The Effects of Infusion of Trieicosapentaenoyl–Glycerol Emulsion on Extravascular Lung Water During Myocardial Ischemia and Reperfusion in Dogs

Toshio Izuoka[a,*], Yutaka Kimura[a], Tomohito Hamazaki[b], Teruhiro Tamura[a], Shuji Kitashiro[a], Tetsuro Sugiura[a], Toshimitsu Jikuhara[a], and Toshiji Iwasaka[a]

ABSTRACT: To test the effects of eicosapentaenoic acid (EPA) infusion on pulmonary edema induced by coronary ligation and reperfusion, extravascular lung water (EVLW) was measured *in situ* by the thermal-dye double indicator dilution method in dogs. In the control group of five dogs, 30 mL of a 10% soybean oil emulsion was infused through a leg vein. One hour after infusion, the left anterior descending coronary artery below the first diagonal branch was ligated for 15 min and then reperfused for 30 min. In the EPA group, six dogs were similarly treated with an emulsion of a 10% trieicosapentaenoyl–glycerol (90% pure). EVLW, pulmonary capillary wedge pressure, mean pulmonary artery pressure, mean blood pressure, and cardiac index were measured before and 15 min after coronary ligation, and 15 min and 30 min after coronary reperfusion. There were no significant differences in the hemodynamic indices between the two groups. EVLW significantly increased up to two times of baseline during coronary ligation in the control group ($P < 0.05$) and more during reperfusion ($P < 0.01$), whereas EVLW did not increase in the EPA group. In conclusion, EPA inhibited EVLW accumulation and may be useful for ameliorating one of the ischemia–reperfusion-induced complications, pulmonary edema.

Lipids 32, 109–114 (1997).

Pulmonary edema during myocardial ischemia is generally believed to result from high pulmonary microvascular pressure. However, the edema may take place even at normal pulmonary wedge pressure (1–6). Increased pulmonary microvascular permeability (1–6) is probably the cause of the edema if the pulmonary capillary wedge pressure is normal. A few mechanisms are considered for increased pulmonary vascular permeability. Among them are platelet-activating factor (6) and leukotriene B4 (LTB_4). On the other hand, reperfusion after coronary ligation also induces formidable complications such as ventricular arrhythmia, vascular damage and no-reflow, myocardial functional stunning (7), and even pulmonary edema as shown in the present study.

One of the authors (T.H.) has been developing an infusible emulsion of trieicosapentaenoyl–glycerol (EPA–TG), and his group has found that the LTB_4 production by rabbit polymorphonuclear leukocytes is markedly reduced 6 h after intravenous infusion of the emulsion (8). This finding prompted us to investigate the possibility that a prior infusion of EPA–TG might reduce microvascular permeability through the reduction of LTB_4 synthesis and hence extravascular lung water (EVLW) during coronary reperfusion. If the infusion of EPA–TG emulsion reduced EVLW, we might be able to have a new tool to control one of the complications of myocardial ischemia and reperfusion.

EXPERIMENTAL PROCEDURES

General preparation. Thirteen mongrel dogs weighing 18 ± 5 kg were anesthetized with intravenous pentobarbital (25 mg/kg) and supplemented as necessary during the experiment. Dogs were ventilated through a cuffed orotracheal tube by a Harvard animal respirator at the tidal volume of 15 mL of room air/kg and the rate of 13 to 15 breaths/min. The dogs' lungs were inflated every 15 min to minimize microatelectasis.

A 7F Swan-Ganz catheter was placed into a pulmonary artery from a femoral vein, and the position of the catheter was determined from pressure recordings. A 5F lung water catheter (Model 96B-020; Edwards Laboratory, Irvine, CA) was advanced into the descending aorta from a femoral artery. The pacing wire was placed at the right atrium and constantly paced at the rate of 120 beats/minute. Schematic illustration is shown in Figure 1.

Emulsions. A 10% emulsion of EPA–TG (90% EPA and 5% arachidonic acid) was prepared as described previously (8) with slight modifications. We used a 10% soybean oil emulsion (Intralipid; Otsuka Pharmaceutical Co., Tokyo, Japan) as a control emulsion. About 60% of the oil in the control emulsion was linoleic acid. The emulsifier of the two

Abbreviations: EPA, eicosapentaenoic acid; EPA–TG, trieicosapentaenoyl-glycerol; EVLW, extravascular lung water; LT, leukotriene.

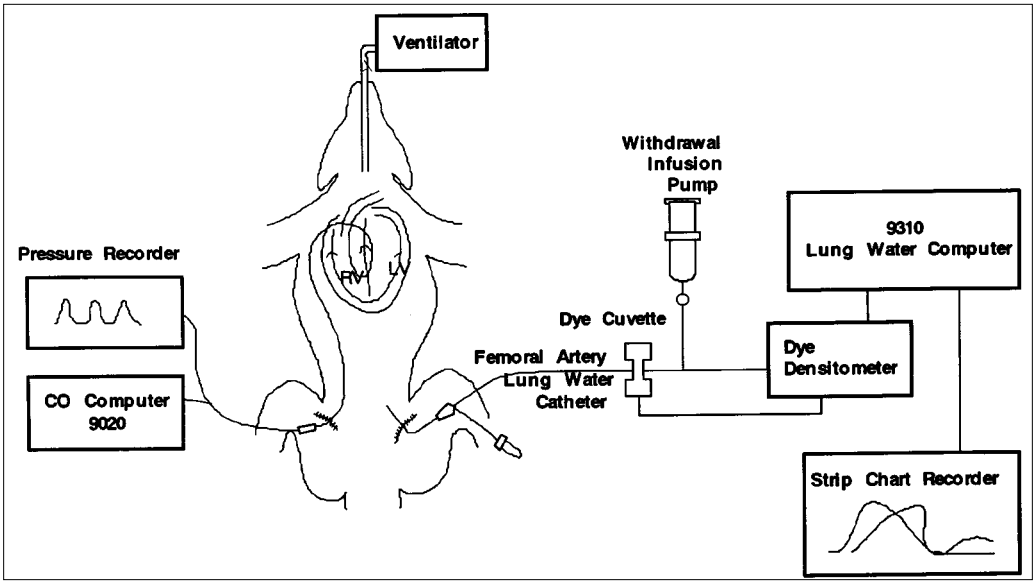

FIG. 1. Schematic illustration of measurement of hemodynamic indices and EVLW.

emulsions was egg yolk lecithin, comprising 1.2% of the total weight of emulsion (8).

Measurements. EVLW was measured by injecting 10 mL of a cold (0°C) saline containing 5 mg of indocyanine green into the right atrium through the Swan-Ganz catheter. Blood was simultaneously withdrawn by a syringe pump through a densitometer cuvette (DC-410; Waters, Rochester, MN) attached to the femoral lung water catheter. A dye signal proportional to dye concentrations was generated in the densitometer, and a thermal signal was generated in a thermistor located at the end of the lung water catheter. Both signals were fed into a computer (Model 9310; Edwards Laboratory, Santa Ana, CA) that simultaneously determined the mean transit times of the two indicators and the cardiac output. EVLW was derived as follows: EVLW = cardiac output × (mean thermal transit time minus mean dye transit time). Blood pressure was measured by a transducer connected to the femoral arterial catheter. Pulmonary arterial pressure and pulmonary capillary wedge pressure were obtained from another transducer connected to the Swan-Ganz catheter. Measurements were performed during a 10 s breath-hold at end expiration. The limb and epicardial leads in electrocardiogram were continuously monitored to evaluate heart rate and myocardial ischemia throughout the experiment.

The lung was biopsied immediately before the infusion and at 1.75 h after completion of the infusion for the measurement of EPA concentrations. Biopsied tissues were minced and rinsed with saline before analysis. The fatty acid composition of the total phospholipid fraction was analyzed by gas chromatography (a GC-14 gas chromatograph, Shimadzu, Kyoto, Japan; with a Supelcowax-10 capillary column, Supelco, Bellefonte, PA) (9).

Experimental protocol. After the dogs were treated as shown in the section of General preparation, dogs in the control group ($n = 7$) were infused with 30 mL of the soybean oil emulsion over 30 min, and those in the EPA group ($n = 6$) were done so with the EPA–TG emulsion. A suture was placed around the left anterior descending artery below the first major diagonal branch. Coronary ligation was started one hour after the infusion was completed, and the artery was ligated for 15 min. Myocardial ischemia was confirmed by the change of myocardial color from its usual red to a dusky blue, the changes in the ST segment in epicardial electrocardiogram, abnormal regional contraction in the distribution of the ligated vessel, and postmortem macroscopic examination of the heart. EVLW and hemodynamic indices were measured immediately before the lung biopsy, before and 15 min after coronary ligation, and 15 and 30 min after reperfusion as shown in Figure 2. In the control group, two dogs developed ventricular fibrillation during coronary ligation and reperfusion. One dog died, and the other could not maintain stable hemodynamics after counter shock. Therefore, the remaining five dogs were as a control group. In the EPA group, none developed ventricular fibrillation.

All experimental studies were performed along with the animal use guideline set by the National Institutes of Health and the American Physiological Society.

Statistics. Values are expressed as means ± SD. With regard to hemodynamic indices and EVLW, two-way analysis of variance was used, and intragroup comparisons with baseline were performed by Scheffe's method if analysis of variance detected significant difference. For intragroup comparisons of the fatty acid composition, paired *t*-test was used. Differences at baseline between the control and EPA groups were analyzed by unpaired *t*-test for all parameters. $P < 0.05$ was considered significant.

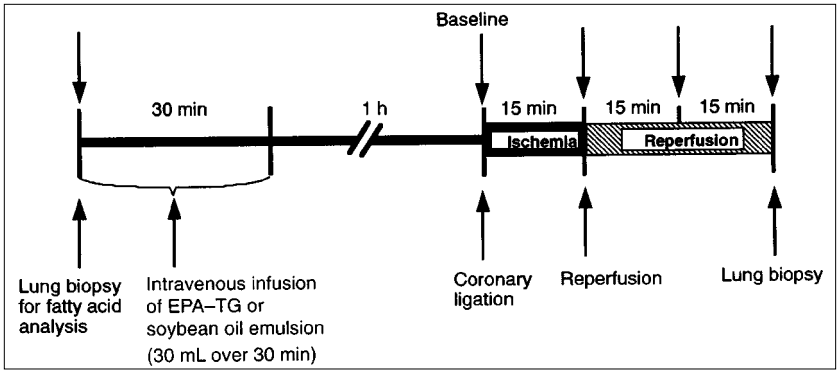

FIG. 2. Experimental protocol. Measurement (extravascular lung water, cardiac index, pulmonary capillary wedge pressure). Experiments started following the general preparation as written in the text. Abbreviation: EPA–TG, trieicosapentaenoyl–glycerol.

RESULTS

Changes in hemodynamic indices after coronary ligation and reperfusion. Pulmonary capillary wedge pressure and mean pulmonary artery pressure increased significantly after coronary ligation in both groups (Table 1). However, there were no significant differences in any measured hemodynamic indices between the control and EPA groups.

Changes in EVLW after coronary ligation and reperfusion. Except for the two control dogs that developed ventricular fibrillation, there were no serious arrhythmias in either group. There was no significant difference in EVLW between the two groups at baseline. In the control group, EVLW increased significantly after coronary ligation and reperfusion. However, EVLW did not increase significantly after coronary ligation and reperfusion in the EPA group. EVLW was significantly larger in the control group than in the EPA group after coronary reperfusion($P < 0.01$, Fig. 3).

Changes in the fatty acid composition in the lung tissue before and after infusion. As shown in Table 2, there were no significant changes in the important unsaturated fatty acids of the lung total phospholipid fraction in the control group. On the other hand, EPA increased about 2.5 times in the EPA group (Table 2).

DISCUSSION

The thermal-dye technique is a good method for EVLW measurement because an excellent correlation has been found in a few laboratories (10–12) including ours (5) between this technique and gravimetric estimates in normal and edematous lungs of animals. Therefore, we did not employ an additional method for EVLW measurement.

We chose a soybean oil emulsion (Intralipid) as the control emulsion because we had thought that the fatty acid composition of the lung would probably be constant even after

TABLE 1
Changes in Hemodynamic Indices[a]

Indices	Groups	Baseline	Coronary ligation (15 min)	Reperfusion 15 min	Reperfusion 30 min
Pulmonary capillary wedge pressure (mmHg)	Control	8.2 ± 0.8	11.2 ± 0.8[b]	8.4 ± 0.9	7.6 ± 0.9
	EPA	7.5 ± 1.0	9.8 ± 1.0[b]	7.5 ± 1.0	7.2 ± 1.2
Mean pulmonary artery pressure (mmHg)	Control	14.9 ± 0.4	17.8 ± 2.2[b]	15.7 ± 0.6	157.7 ± 1.5
	EPA	14.3 ± 1.2	16.6 ± 1.5[b]	15.0 ± 1.3	15.0 ± 1.0
Cardiac index (mL/min/kg)	Control	153 ± 71	136 ± 60	137 ± 64	137 ± 68
	EPA	130 ± 27	120 ± 47	132 ± 43	123 ± 40
Mean blood pressure (mmHg)	Control	85 ± 11	79 ± 12	80 ± 18	81 ± 20
	EPA	79 ± 8	71 ± 25	79 ± 24	72 ± 23

[a]Hemodynamic indices were measured before coronary ligation and afterward as shown in Figure 2. There were also no significant differences between the two groups in any parameters shown above by analysis of variance. Pre-infusion values of the above parameters were very similar to baseline (data not shown).
[b]$P < 0.05$ vs. baseline; EPA, eicosapentaenoic acid.

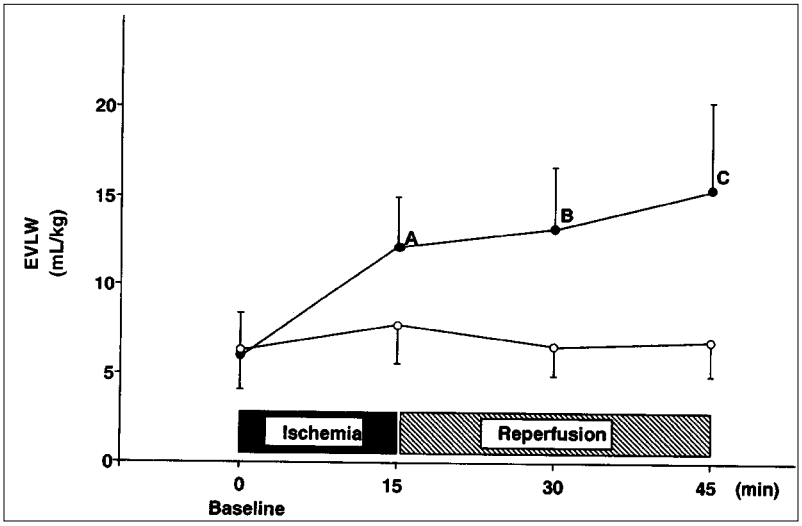

FIG. 3. Changes of EVLW. EVLW was measured at the indicated points. Pre-infusion values were very similar to baseline (data not shown). There was a significant difference between the two groups ($P < 0.01$ by ANOVA). ●, the control group ($n = 5$); ○, the EPA group ($n = 6$). The control group A: significantly different from baseline at $P < 0.05$. B: significantly different from baseline at $P < 0.01$. C: significantly different from baseline at $P < 0.001$.

soybean oil infusion. In case of rabbit polymorphonuclear leukocytes, the fatty acid composition in the total phospholipid fraction did not change 6 h after the infusion of a soybean oil emulsion (8). In fact there were no significant changes in the fatty acid composition in the control group in the present study, which suggests that this emulsion is the ideal control emulsion. If this emulsion had changed the lung phospholipid fatty acids, the comparison between the control and EPA emulsions would have become far more difficult. We showed ischemia–reperfusion induced pulmonary edema in our previous study (Izuoka, T., Takayama, Y., Sugiura, T., Taniguchi, H., Tamura, T., Kitashiro, S., Jikuhara, T., and Iwasaka, T., submitted for publication). In that experiment the accumulation of EVLW after ischemia–reperfusion in the control dogs, which had received only a small amount of saline (10 mL) before coronary ligation, proceeded exactly like the present control dogs. This finding also indicates appropriateness of the control emulsion.

The emulsifier of the two emulsions in the present study was egg yolk lecithin, the major unsaturated fatty acid of which was oleic acid (~25%). That oleic acid did not increase in the total phospholipid fraction in the lung in either group (Table 2) indicates that the two emulsions were fine enough to escape direct trapping in lung microvasculature.

In studies of oral administration of fish oil, arachidonic acid usually decreases in the phospholipid fraction to compensate increased EPA and docosahexaenoic acid (13). However, this is not always true in case of intravenous infusion of EPA (8). As shown in Table 2, arachidonic acid concentrations did not decrease in the EPA group in the present study either. The presence of arachidonic acid (5%) in the EPA–TG preparation used in the present study partly explains the sta-

TABLE 2
Changes in Important Unsaturated Fatty Acids (mol%) After Infusion of Emulsions in the Lung Phospholipid Fraction[a]

	Groups			
	Control ($n = 5$)		EPA ($n = 6$)	
Fatty acids	Preinfusion	Postinfusion	Preinfusion	Postinfusion
Oleic acid	13.2 ± 2.5	12.8 ± 1.2	12.1 ± 2.1	12.1 ± 2.0
Linoleic acid	8.6 ± 2.1	8.6 ± 0.2	7.4 ± 1.9	6.9 ± 1.7[b]
Arachidonic acid	9.3 ± 2.2	9.7 ± 1.3	10.9 ± 2.1	10.6 ± 2.9
EPA	0.67 ± 0.42	0.67 ± 0.40	0.62 ± 0.18	1.50 ± 0.41[c]
Docosahexaenoic acid	0.82 ± 0.21	0.77 ± 0.23	0.80 ± 0.25	0.84 ± 0.30

[a]Dogs were infused with 30 mL of either a 10% soybean oil emulsion (in the control group) or a 10% EPA emulsion (in the EPA group). Lung tissues were obtained before the infusion and 1.75 h after completion of the infusion. The postinfusion fatty acid composition of the total phospholipid fraction of lung was compared with preinfusion values.

[c]$P < 0.001$. See Table 1 for abbreviation.

bility of arachidonic acid concentrations in tissue phospholipids. Long-term oral administration of fish oil appears to inhibit the elongation/desaturation process of dietary linoleic acid, which decreases the tissue arachidonic acid concentration (13). This long-term effect is not possible in a short-term experiment like ours. From these reasons, the stable arachidonic acid concentration in tissue phospholipids after EPA infusion is not surprising.

EPA is the major n-3 polyunsaturated fatty acid of fish oil. In humans, dietary fish oil supplementation has favorable effects on hyperlipidemia (14) and blood pressure in hypertensive patients (15). In fact, intervention with fish oil reduced death rates in a secondary prevention trial (16). Reduction in myocardial infarct size after coronary artery ligation has also been demonstrated in animal models given dietary fish oil supplementation (17–19). Moreover, McLennan *et al*. (20) showed that dietary fish oil prevented ventricular fibrillation following coronary ligation and reperfusion. These reports on fish oil indicate beneficial effects of fish oil during myocardial ischemia and reperfusion. However, dietary supplementation with fish oil is recommended only before the coronary event or afterward, and certainly not during the acute phase, since it takes at least a couple of weeks for fish oil to take effect. This is one of the major weak points of dietary fish oil supplementation. In this context, an infusible EPA emulsion may play its major role.

Using specially prepared dogs, Billman *et al*. (21) showed that the intravenous infusion of an emulsion of a fish oil concentrate containing free EPA and docosahexaenoic acid into those dogs prevented ventricular fibrillation induced by the exercise-induced ischemia test that would predictably develop ventricular fibrillation, whereas infusion of a soybean oil emulsion did not prevent ventricular fibrillation at all. Since the purpose of our present study was different from that of Billman *et al*. (21), our dogs were not prepared for arrhythmia. Nonetheless, it is interesting that none of the EPA-infused dogs developed ventricular fibrillation.

Since there were no significant differences between the two groups in hemodynamic indices, the difference in EVLW between the two groups indicates the difference in vascular permeability between them. In fact EVLW continued to increase during reperfusion in the control group even though pulmonary capillary wedge pressure returned to preligation levels. The substances responsible for reperfusion injury include overloaded calcium, oxygen free radicals, platelet activating factor, and eicosanoids (6,22–24), many of which increase vascular permeability. LTB_4, one of the eicosanoids, has been shown to increase pulmonary vascular permeability in the presence of polymorphonuclear leukocytes without affecting pulmonary artery and pulmonary capillary wedge pressures (25).

We have shown that infusion of EPA–TG into rabbits tended to reduced LTB_4 production by 26% in 1 h and significantly reduced it by 68% in 6 h (8). Consequently, increase of EVLW might have been prevented in the EPA group at least partly owing to the depression of LTB_4 production by EPA infusion. Because we stopped the measurement of EVLW at 30 min of reperfusion, there is a possibility that EVLW in the EPA group might have increased to the level of the control group afterward. However, that seems unlikely because LTB_4 production decrease as time passed after EPA infusion as in the case of the rabbits (8). Mechanistic studies and longer observation of EVLW remain to be investigated.

In conclusion, prior EPA infusion prevented the increase of EVLW during ischemia and in the early phase of reperfusion.

ARTICLE

Altered Acyl Chain Length Specificity of *Rhizopus delemar* Lipase Through Mutagenesis and Molecular Modeling

Robert R. Klein*, Gregory King, Robert A. Moreau, and Michael J. Haas

ERRC, ARS, USDA, Wyndmoor, Pennsylvania 19038

ABSTRACT: The acyl binding site of *Rhizopus delemar* prolipase and mature lipase was altered through site-directed mutagenesis to improve lipase specificity for short- or medium-chain length fatty acids. Computer-generated structural models of *R. delemar* lipase were used in mutant protein design and in the interpretation of the catalytic properties of the resulting recombinant enzymes. Molecular dynamics simulations of the double mutant, val209trp + phe112trp, predicted that the introduction of trp112 and trp209 in the acyl binding groove would sterically hinder the docking of fatty acids longer than butyric acid. Assayed against a mixture of triacylglycerol substrates, the val209trp + phe112trp mature lipase mutant showed an 80-fold increase in the hydrolysis of tributyrin relative to the hydrolysis of tricaprylin while no triolein hydrolysis was detected. By comparison, the val94Trp mutant, predicted to pose steric or geometric constraints for docking fatty acids longer than caprylic acid in the acyl binding groove, resulted in a modest 1.4-fold increase in tricaprylin hydrolysis relative to the hydrolysis of tributyrin. Molecular models of the double mutant phe95asp + phe214arg indicated the creation of a salt bridge between asp95 and arg214 across the distal end of the acyl binding groove. When challenged with a mixture of triacylglycerols, the phe95asp + phe214arg substitutions resulted in an enzyme with 3-fold enhanced relative activity for tricaprylin compared to triolein, suggesting that structural determinants for medium-chain length specificity may reside in the distal end of the acyl binding groove. Attempts to introduce a salt bridge within 8 Å of the active site by the double mutation leu146lys + ser115asp destroyed catalytic activity entirely. Similarly, the substitution of polar Gln at the rim of the acyl binding groove for phe112 largely eliminated catalytic activity of the lipase.
Lipids 32, 123–130 (1997).

Lipases (acylglycerol acylhydrolases, EC 3.1.1.3) are enzymes that catalyze reversibly the cleavage of ester bonds of triacylglycerols to yield free fatty acids, diacylglycerols, and monoacylglycerols. Lipases are unique among the family of serine esterases in that their catalytic activity is greatly enhanced by the presence of a lipid–water interface, a phenomenon known as interfacial activation (1–3). Various lipases show strong regiospecificity and varying degrees of selectivity and stereospecificity toward different fatty acids (4–6). For industrial application, lipases with pronounced specificity (regio-, stereo-, or fatty acid specificity) are of special interest as these specificities may be exploited to produce products not obtainable by conventional chemical catalysts (7,8).

The fungus *Rhizopus delemar* (presently designated *R. oryzae*) produces extracellular lipases, one of which has been extensively characterized. The *R. delemar* lipase (*Rd* lipase) has been purified and characterized (9), a complementary DNA (cDNA) encoding the enzyme cloned and sequenced (10), and the mature (269 amino acids) and proenzyme (includes 97 amino acid propeptide) forms of the lipase expressed to high levels in *Escherichia coli* (11). *Rd* lipase, like the closely related *Rhizomucor miehei* and *Humicola lanuginosa* lipases, is termed a 1,3-specific lipase, as it exhibits strong preference for the hydrolysis of ester bonds at the *sn*-1 and *sn*-3 positions of a triacylglycerol. The crystal structure of *Rd* lipase has been solved at 2.6 Å resolution (12). The molecular architecture of the enzyme comprises a single, roughly spherical domain containing predominantly parallel β-sheets with conserved α-helices packed on either side. The active center consists of a triad of ser145, his257 and asp204, while an oxyanion hole, presumably formed in the active species by the hydroxyl and main-chain amide groups of thr83, is postulated to stabilize the tetrahedral transition state intermediate (12). In *Rd* lipase, as in all lipases studied, the catalytic center is buried beneath a surface loop or lid consisting of a short amphipathic helix (2,12). The acyl binding region of *Rd* lipase consists of a short hydrophobic trough on the enzyme surface beneath the lid. After absorption to the lipid–water interface, the lid helix is displaced. As a result of this conformational change, the active site is exposed, the oxyanion hole is formed and a large hydrophobic surface is created. This conformational change along with the composition of the lipid substrate constitutes the dominant factors in modulating lipase activities at the oil–water interface (2,12,13).

A major objective of protein engineering efforts is to improve the substrate specificity of the enzyme or create novel catalytic activities by site-directed mutagenesis. Engineering the substrate binding region may tailor the lipase to a particu-

Abbreviations: cDNA, complementary DNA; IPTG, isopropyl-B-D-thiogalactoside; Phe, phenylalanine; *Rd, Rhizopus delemar*; TB, tributyrin; TC, tricaprylin; TL, trilaurin; TO, triolein; Tris, *tris*(hydroxymethyl)aminomethane; val, valine.

lar substrate, alter enantioselectivity, or even broaden the substrate specificity of the enzyme. Joerger and Haas (14) initiated studies to alter the chain length selectivity of *Rd* lipase through site-directed mutagenesis. The authors utilized the crystal structure of *R. miehei* lipase (15,16) to identify corresponding residues in the substrate binding region of *Rd* lipase to target for mutagenesis. The recent elucidation of the three-dimensional structure of *Rd* lipase determined by X-ray crystallography (12) provided necessary structural information for more precise identification of the molecular determinants of fatty acyl chain specificity of this enzyme. Utilizing computer-aided molecular modeling, we have constructed a series of single and double amino acid substitution mutants in the acyl binding groove of *Rd* lipase in an attempt to identify the molecular determinants of acyl chain length specificity. The effect of amino acid substitutions on catalytic activity and chain length specificity is discussed in relation to the structural effect of the mutation as predicted by computer-aided molecular models.

MATERIALS AND METHODS

Site-directed mutagenesis. To facilitate site-directed mutagenesis, an 1100 bp *Nco*I-*Bam*HI fragment from plasmid pET 11d-1231 (pET11d recombinant plasmid containing *Rd* prolipase open reading frame sequence; Ref. 14) was subcloned into M13BM20RF phage (Boehringer Mannheim Corp., Indianapolis, IN). Site-directed mutants were generated as detailed in the site-directed mutagenesis protocol provided by the supplier (Amersham Corp., Arlington Heights, IL). To construct double mutants, single-strand DNA containing single amino acid substitutions was used as template for an additional cycle of site-directed mutagenesis. Mutated *Nco*I-*Bam*HI fragments were sequenced (17) and cloned into plasmid pET 15b (Novagen Corp., Madison, WI) for synthesis of recombinant prolipase in *E. coli*. To obtain the same mutations in the mature form of the *Rd* lipase, a 600 bp *Kpn*I-*Eco*RI fragment encompassing the mutations in the prolipase gene was subcloned into plasmid pET 11d-f1-431 (pET 11d recombinant plasmid harboring complete *Rd* mature lipase encoding sequence; Ref. 14) in place of wild-type sequences.

Synthesis and purification of recombinant lipases. Escherichia coli BL21(DE3) cells were transformed with recombinant pET-lipase plasmids and grown in liquid culture media (M9ZB + 100 µg/mL carbenicillin) at 37°C as previously described (18). Synthesis of recombinant lipase was induced by the addition of IPTG to a final concentration of 10 µM (culture OD_{600} = 1.0). Cells were harvested 1.5 to 2 h after IPTG addition by centrifugation (5,500 × *g*, 15 min). Cell pellets were resuspended, lysed, and proteinaceous inclusion bodies obtained (11). Proteinaceous inclusion bodies were solubilized with 8 M urea and the enzyme refolded essentially as described (11) except that the refolded lipases were not further purified by affinity chromatography.

Determination of lipase activity. Initial visual screening of lipase activity utilized a rhodamine plate assay (19). BL21(DE3) cells harboring pET-prolipase plasmids were induced with IPTG and collected by centrifugation. Cells were lysed by sonicating in 50 mM Tris (pH 7.5), 2 mM EDTA, 35 µg/mL phenylmethylsulfonyl fluoride, 1.75 µg/mL leupeptin, and 0.7 µg/mL pepstatin at 4°C. Under these conditions, approximately 1 to 5% of the expressed prolipase was soluble and catalytically active (11,14). Aliquots of *E. coli* lysates containing recombinant prolipases were spotted on media containing a triacylglycerol and rhodamine B. Lipase activity was visualized under ultraviolet light.

Quantitative determination of lipase hydrolytic activity using single triacylglycerol substrates was determined titrimetrically using a VIT 90 Video Titrator (Radiometer, Copenhagen, Denmark). Standard emulsions contained 200 mM olive oil, tricaprylin or tributyrin, 15 mM $CaCl_2$, and 4.2% (wt/vol) gum arabic. Reactions were conducted at 26°C with a set point pH of 7.5. Lipase activity was calculated from the maximum rate of titrant addition using a lipase titrimetric program (20). Titrimetric assays were run in duplicate or triplicate.

Competitive hydrolysis of triacylglycerols was examined in a reaction media containing 100 mM Tris (pH 7.5), 15 mM $CaCl_2$, and equiweight mixtures of tributyrin, tricaprylin, and triolein (2.0% wt/vol). Triacylglycerol mixtures were sonicated and reactions initiated by the addition of lipase (5–10 µg/mL reaction volume). After 30 min (28°C, 250 rpm), reactions were quenched on ice and 5 mg stearyl alcohol (in 100% ethanol) added as an internal standard. Reaction mixtures were extracted with 5 vol hexane for 2 h (250 rpm). Five to 10 µL of the hexane phase were injected into a Hewlett-Packard (Avondale, PA) high-performance liquid chromatograph model 1050 ternary gradient system equipped with an Alltech-Varex Mark III evaporative light-scattering detector (Deerfield, IL) and a 3 × 100 mm LiChrosorb DIOL column (5 µm inner diameter; Chrompack, Inc., Raritan, NJ). The solvents were: A, hexane/acetic acid (1000:1, vol/vol); and B, hexane/isopropanol (100:1, vol/vol). The linear gradient timetable was: 0 min, 100:0; 8 min, 100:0; 10 min, 75:25; 40 min, 75:25; 41 min, 100:0; 60 min 100:0 (% solvent A/% solvent B). Peaks in the chromatograms were identified by comparing retention times to those of triacylglycerol standards. Standard curves were generated for tributyrin, tricaprylin, and triolein based on the injection of seven different amounts of a standard mixture of triacylglycerols. Lipolytic activities were determined by quantifying the disappearance of triacylglycerol substrates compared to control reactions with boiled lipase.

Molecular modeling. All molecular modeling work was conducted using the SYBYL (version 6.0) software package (Tripos Associates, St. Louis, MO) on a SGI Indigo2 workstation (Silicon Graphics, Mountain View, CA). Tripos forcefield parameters were used for all molecular mechanics and molecular dynamics simulations. Nonbonded interaction cutoff of 8 Å was used as was a distance-dependent dielectric constant for electrostatic interactions. All essential protein hydrogens were included in the molecular models. Kollman

United-atoms charges were assigned to all protein atoms while Gasteiger-Huckel charges were assigned to all nonprotein (e.g., lipid) atoms. Energy minimizations were performed with the Powell algorithm, using a change in the rms gradient of less than 0.05 kcal/mol/Å as the convergence criterion. The coordinates of *Rd* lipase were obtained from Z. Derewenda (University of Virginia, Charlottesville, VA). The crystal structure of *Rd* lipase consists of two molecules of the enzyme: one in the closed lid conformation and the second in a conformation intermediate between the closed and open state (12). The coordinates of the enzyme molecule with the partially open lid were used for molecular modeling and substrate docking. The lid was rearranged to a completely open conformation by using the interatomic distances between the α carbons of the lid region of *R. miehei* (Brookhaven Protein DataBase, file 4TGL) (15,16) as constraints in the *Rd* lipase in conjunction with force constants of 50 kcal/mol/Å^2. The structure was subsequently refined *via* energy minimization and molecular dynamics simulations carried out in vacuum at 50 K (total simulation time of 10 ps) followed by a final energy minimization.

To obtain molecular models of mutant *Rd* lipases, the selected amino acid residues were replaced with mutant residues. The optimal conformations of the side chains of mutated residues were obtained by performing systematic grid searches of the relevant torsional angles (at 30° increments). The relevant torsion angles explored included C_α-C_β bonds, C_β-C_α bonds (etc.) as appropriate for the particular substituted amino acid side chain. The lowest energy conformations found in these searches were then refined *via* energy minimization and molecular dynamics simulations. Molecular dynamics simulations were carried out in vacuum at 50 K (total simulation time of 10 ps) followed by a final energy minimization. These structures were utilized as initial enzyme models for docking triacylglycerol substrates.

Models of the triacylglycerol substrates were constructed and energy minimized with the SYBYL version 6.0 software. Initial models of lipase–substrate transition states were obtained by manually positioning the *sn*-3 acyl side chain in the acyl binding groove as defined by transition state analogs (15,21). To build a tetrahedral covalent lipase–substrate complex, the carbonyl carbon of the substrate was converted from its sp^2 configuration to an sp^3-hybridized carbon atom. The conversion of the carbonyl carbon to an sp^3-hybridized carbon atom was necessary to create the correct tetrahedral geometry present in the acyl–enzyme transition state intermediate. The position of the carbonyl carbon of the substrate was adjusted manually to permit hydrogen bonds between the protonated his257, the Oγ of the ser145 hydroxyl group and the oxygen leaving group of the substrate. Furthermore, the distances between the oxyanion of the transition state and the hydroxyl group and main chain amide of thr83 (which comprises the oxyanion hole) were constrained. These bond distances were constrained during the docking procedure and subsequent energy minimization and molecular dynamics simulations. Energy minima of the lipase–substrate complex were found by molecular dynamics simulations in vacuum at 50 K (total simulation time of 10 ps). Molecular dynamics simulations were conducted at low temperature (50 K) to prevent corruption of the conformation of the peptide backbone. Following molecular dynamics simulation, the conformations were subjected to a final energy minimization.

Miscellaneous. Protein concentrations were determined using the bicinchoninic acid protein assay method (Pierce Laboratories, Rockford, IL) using bovine-γ-globulin as protein standard. SDS–12.5% polyacrylamide gel electrophoresis (PAGE) was performed and protein bands on gels were visualized by silver staining (22). Estimates of the relative intensities of protein bands were obtained by video densitometry and analysis of the digitized profile with ImageQuaNT 4.2 software (Molecular Dynamics, Sunnyvale, CA).

RESULTS AND DISCUSSION

Joerger and Haas (14) initiated efforts to alter the acyl chain length specificity of *Rd* lipase through site-directed mutagenesis. Lacking a crystal structure of *Rd* lipase, conserved amino acid residues shown to form the acyl binding groove of *R. miehei* were targeted for mutagenesis in *Rd* lipase. In the present study, we extended the previous mutagenic study aided by the recent elucidation of the crystal structure of *Rd* lipase (Fig. 1). Single and double amino acid substitutions were engineered at discrete positions in the acyl binding groove based largely on structural predictions resulting from molecular dynamics simulations (Fig. 2). Several strategies for altering *Rd* lipase chain length specificity through rational mutagenesis were examined including: introduction of bulky hydrophobic trp residues at discrete positions in the acyl binding groove; creating salt bridges (ionic pairs) across the acyl binding groove by substituting polar or charged residues in the acyl binding groove; and substituting polar amino acids for hydrophobic residues in the acyl binding groove. An additional strategy involved combining selected point mutations of Joerger and Haas (14) into one mutant lipase in an attempt to develop an enzyme with greater substrate specificity.

To engineer a lipase with specificity for short-chain fatty acids, the double mutation F112W + V209W was constructed. Joerger and Haas (14) determined that substitution of trp for phe112 or val209 increased specificity for short-chain (C_4) compared to long-chain fatty acids ($C_{18:1}$). Molecular dynamics simulations of the double mutant V209W + F112W predicted that trp side chains at amino acid positions 112 and 209 of *Rd* lipase would project across the acyl binding groove, thereby posing geometric or steric constraints for the binding of fatty acids longer than butyrate in the acyl groove (Fig. 2A). When screened on rhodamine media containing tributyrin (TB), tricaprylin (TC), trilaurin (TL), or olive oil, hydrolytic activity of the V209W + F112W prolipase was visible only for media containing TB (data not shown). To quantify hydrolytic activity for prolipase and mature lipase mutants, titrimetric assays utilizing single triacylglycerol emulsions were conducted (Figs. 3 and 4). The V209W + F112W mutations resulted in

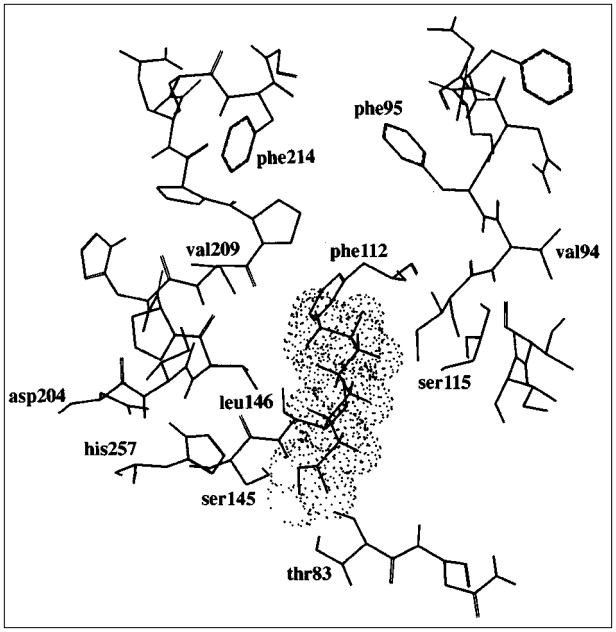

FIG. 1. Structure of the active site region of *Rhizopus delemar* lipase with the *sn*-3 acyl side chain of tricaprylin shown docked into the catalytic center. Only the *sn*-3 acyl side chain of tricaprylin is shown while the remainder of the triacylglyceride is not displayed. The catalytic residues ser, asp, and his are labeled along with thr83 which constitute the oxyanion hole. Selected residues lining the acyl binding and catalytic sites are shown. Sides chains of residues that form part of the acyl binding site targeted for mutagenesis are labeled. The displayed portion of the substrate is depicted with *van der Waals* dots. Models of the docked substrate were calculated by energy minimization and molecular dynamics simulations with bond distance constraints as defined in the Materials and Methods section.

increased specificity for TB though the specific activity of the prolipase and mature lipases for TB was reduced 10- and 1.6-fold, respectively, compared to wild-type enzyme. However, the relative activity of the V209W + F112W mutant toward TB increased substantially since hydrolysis of TC and olive oil was minimal. Relative to wild-type prolipase, the V209W + F112W showed a 9-fold increase in the ratio of TB to olive oil hydrolysis and a 15-fold increase in the ratio of TB to TC hydrolysis. Similarly, the mature lipase V209W + F112W mutant showed an 8.5- and 24-fold increase in the ratio of TB to olive oil and TB to TC hydrolysis, respectively, compared to wild-type lipase.

Quantifying the hydrolytic activities of lipases against single triacylglycerol emulsions provided an initial view of substrate specificity. A more accurate assessment of substrate specificity is obtained by competitive hydrolysis assays utilizing mixed triacylglycerol substrates. In competitive hydrolysis assay conditions, the V209W + F112W prolipase and mature lipase mutants showed strong selectivity for TB. The hydrolytic activity of prolipase V209W + F112W for TB was 10-fold greater than that observed for TC or triolein (TO) (Fig. 5). By comparison, the wild-type prolipase enzyme hydrolyzed TB, TC, and TO to a similar extent in mixed substrate assays. Mature lipase mutant V209W + F112W showed an 80-fold increase in the ratio of TB to TC hydrolysis compared to wild-type lipase while hydrolysis of TO by the V209W + F112W mature lipase was not detected under the present competitive hydrolysis conditions (Fig. 6). The results obtained with either single or mixed triacylglycerol substrates showed that the V209W + F112W double mutant exhibited much stronger selectivity for tributyrin than either of the single amino acid substitutions described by Joerger and Haas (14). The experimental results are in agreement with predictions from molecular dynamics simulations of this double mutant which suggested that the binding of medium- or long-chain length fatty acids may be sterically or geometrically constrained, thereby resulting in a mutant lipase with short-chain fatty acid specificity. It should be noted, however, that the molecular dynamics simulations could not account for the observed reduction in the specific activity of the mutant for tributyrin compared with wild-type enzyme. These observations suggest that the V209W and F112W mutations may have pleiotropic effects on protein structure that remain to be elucidated.

In an attempt to improve the specificity of *Rd* lipase for medium-chain length fatty acids, trp was substituted for V94 in the acyl binding groove. Molecular dynamic simulations predicted that this substitution may pose steric or geometric constraints to the docking of fatty acids longer than caprylate (C_8) in the acyl binding groove (Fig. 2B). The V94W mutation had a modest effect on fatty acid chain length specificity in both the prolipase and mature enzyme. In single substrate hydrolysis assays, a modest 1.6- to 1.8-fold increase in TC hydrolysis relative to TB was observed for V94W enzymes (Figs. 3 and 4). In contrast, the hydrolysis of TC relative to TO by the prolipase and mature enzyme was not altered by the V94W mutation. The results obtained with competitive hydrolysis assays utilizing mixed triacylglycerol substrates paralleled those obtained with single substrate emulsions (Figs. 5 and 6). Compared to wild-type prolipase, the V94W mutant showed a modest 30% reduction in the hydrolysis of TB and TO while the hydrolysis of TC was similar to wild-type levels. The only notable change in hydrolytic activity by introducing this mutation into mature form of *Rd* lipase was a 40% increase in hydrolysis of TC relative to TO. These results indicate that the single substitution of a bulky trp residue at the given location in the acyl binding groove did not markedly alter acyl chain length specificity as predicted by molecular dynamics simulations. The modest increase in specificity for tricaprylin, however, does suggest that a minor molecular determinant of chain length specificity may reside in this position of the acyl binding groove. Hence, it may be feasible to engineer an enzyme with much greater specificity for medium chain length fatty acids by combining the V94W mutation with mutations in other regions of the acyl binding groove shown to impact substrate specificity.

An approach to modify lipase substrate specificity is to alter the structure of the acyl binding groove by creating a salt bridge at discrete positions in the groove. The creation of a salt bridge may alter the conformation of the acyl groove,

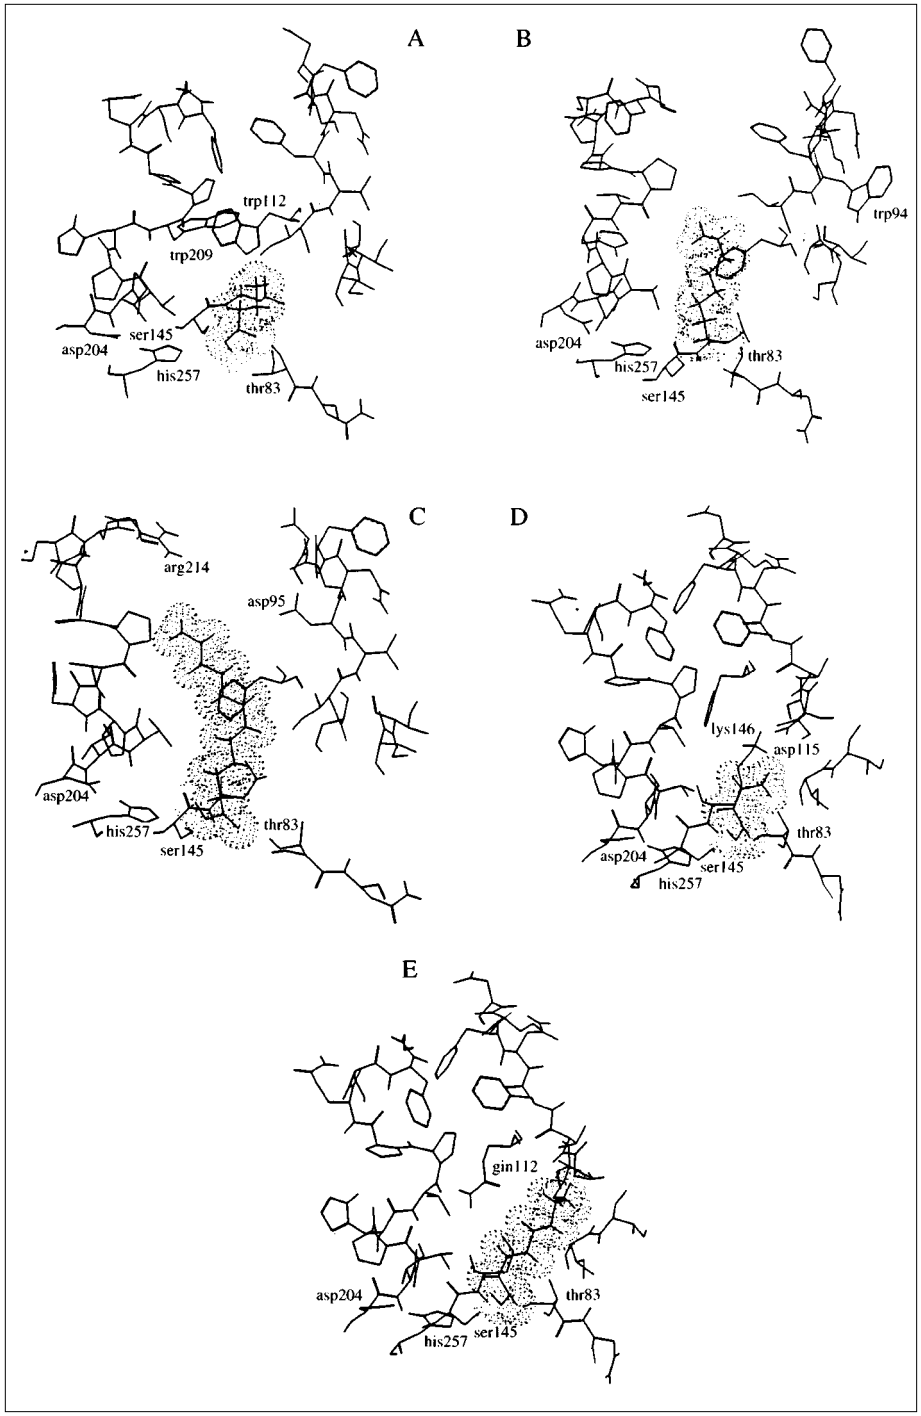

FIG. 2. Models of the active site region of mutated *Rhizopus delemar* lipase with the *sn*-3 acyl side chain of triacylglycerol substrates shown docked in the catalytic center. Only the *sn*-3 acyl side chain of each triacylglycerol is shown while the remainder of the lipid is not displayed. (A) F112W + V209W mutant with docked tributyrin (TB); (B) V94W mutant with docked tricaprylin (TC); (C) F95D + F214R with docked trilaurin (TL); (D) S115D + L146K mutant with docked TB; and (E) F112Q with docked TC. Models of the docked substrates were calculated by energy minimization and molecular dynamics simulations.

thereby constraining or enhancing the binding of select fatty acids. In an attempt to increase selectivity for medium chain length fatty acids, the double mutant F214R + F95D was engineered to position a salt bridge across the distal end of the acyl binding groove (Fig. 2C). In single substrate assays, the prolipase F214R + F95D mutant showed only a slight increase in preference for TC compared to wild-type prolipase (Fig. 3). By comparison, the mature lipase F214R + F95D

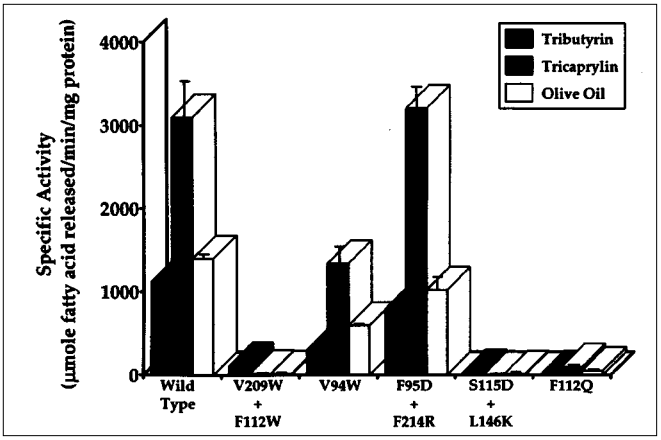

FIG. 3. Comparison between the specific activities of mutant and wild-type *Rhizopus delemar* prolipase using single triacylglycerol substrates. Specific activities were measured titrimetrically against single triacylglycerol emulsions of tributyrin, tricaprylin, or olive oil. Each specific activity is the mean of two or three independent assays.

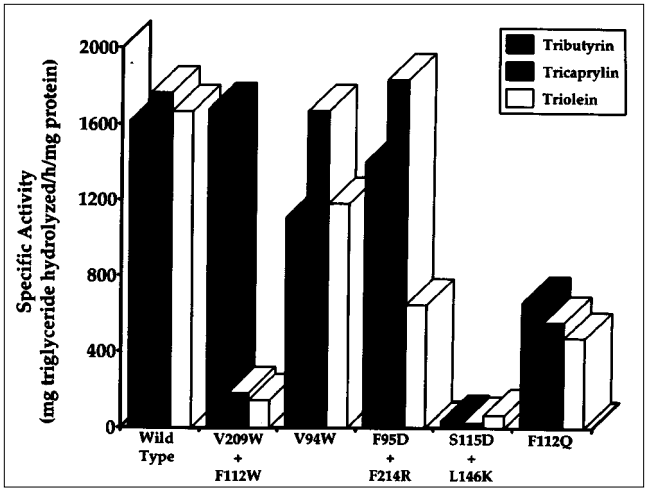

FIG. 5. Comparison between the specific activities of mutant and wild-type *Rhizopus delemar* prolipase using mixed triacylglycerol substrates. Hydrolytic activities were determined by quantifying the amounts of unhydrolyzed triacylglycerols remaining after prolipase incubation with an equiweight mixture of tributyrin, tricaprylin, and triolein. The amount of each triacylglycerol remaining after 30-min incubation with prolipase was determined by HPLC. Competitive hydrolysis assays were conducted a minimum of four times for each enzyme and a representative data set is shown.

mutation showed a 3.3-fold increase in the specific activity toward TC compared to wild-type lipase (Fig. 4). The increased specific activity of the F214R + F95D mature lipase for TC resulted in a 2-fold increase in the relative activity toward TC compared with either TB or olive oil. In competitive hydrolysis assays with triacylglycerol mixtures, the prolipase F214R + F95D mutant exhibited a 2.5-fold increase in the hydrolysis of TC relative to TO while the same mutations in the mature lipase showed a 3.1-fold increase in hydrolysis of TC relative to TO (Figs. 5 and 6). Hence, the introduction of the F95D and F214R mutations increased lipase specificity for medium chain length fatty acids especially for mutations in the mature form of *Rd* lipase. Structurally, whether a salt bridge was actually created between arg214 and asp95 has not been determined although molecular dynamics simulations predicted the ionic pairing of these residues. Nevertheless, it is evident that molecular determinants of acyl chain length specificity reside in this region of the acyl binding site and are amenable to modification.

The double mutation S115D + L146K was engineered to determine the feasibility of introducing charged residues nearer the catalytic center with an objective of impacting acyl chain length specificity (Fig. 2D). Molecular dynamics simulations predicted that the S115D + L146K mutations would create a salt bridge across the acyl binding groove approximately 8 Å from the catalytic center. The position of the salt bridge was predicted to hinder the docking of medium- and

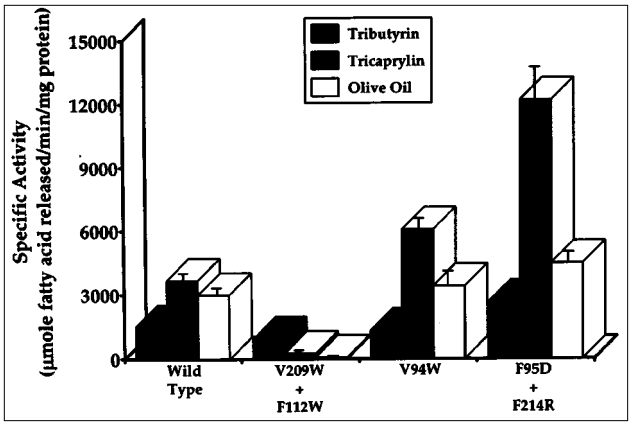

FIG. 4. Comparison between the specific activities of mutant and wild-type mature *Rhizopus delemar* lipase using single triacylglycerol substrates. Specific activities were measured by titrimetric assay against single triacylglycerol emulsions as described for Figure 3.

long-chain fatty acids and favor the docking of short (C_4) fatty acids in the acyl binding groove. An additional mutation, F112Q, was engineered to determine whether the substitution of a polar residue near the rim of the acyl binding groove would impact acyl chain length specificity (Fig. 2E). The residue phe112 was targeted for mutagenesis since it had been determined that this site is amenable to substitution and molecular dynamics simulations predicted that the docking of long fatty acid chains in the acyl binding groove would be sterically hindered by a polar residue at this position. Hydrolysis assays revealed that the prolipase S115D + L146K mutant was catalytically inactive (Fig. 3). Similarly, introduction of a polar gln for phe112 largely eliminated activity in single substrate emulsions (Fig. 3) and reduced the hydrolytic activity for all three triacylglycerols in mixed emulsions assays (Fig. 5). To determine whether the loss of catalytic activity of the S115D + L146K mutant is due to one or both amino acid substitutions, the single amino acid mutations were examined for catalytic activity. Rhodamine plate and single substrate hydrolysis assays showed that neither the S115D nor the L146K mutants possessed catalytic activity (data not shown). The close proximity of S115 and L146 to the catalytic triad of ser145, his257 and asp204 and the oxyanion hole (thr83) may explain the disruption of catalytic activity. L146 resides within 4 Å of S145 (distance between α carbons). In contrast, F112 is located approximately 12 Å from catalytic ser145 and is located at the rim of the acyl binding groove. Nevertheless, these amino acid substitutions largely eliminated the catalytic activity of the prolipase. The loss of catalytic activity may relate to the disruption of some step in catalysis after the binding of the substrate or to the prevention of efficient penetration of the lipid interface, resulting in lower activity (23). It should be noted that the introduction of polar or charged residues in the acyl binding groove is not necessarily lethal as evidenced by the F95D + F214R mutant and a second double mutant, V206T + F95D, which show strong substrate specificity for medium chain length fatty acids (Klein, R.R., Villeneuve, P., King, G., McNeill, G.P., Moreau, R.A., and Haas, M.J. manuscript in preparation). Hence, our present knowledge of lipase structure–function relationships does not permit an accurate prediction of the lipase phenotype that results from the introduction of charged or polar residues in the acyl binding groove.

In summary, the present study describes attempts toward engineering novel biocatalysts *via* protein engineering of *Rd* lipase. Similar approaches for the rational modification of this lipase are being conducted in other laboratories as well (24). The observed mutant phenotypes indicate that tailoring the substrate specificity of *Rd* lipase is feasible as evidenced by the F112W + V209W and F95D + F214R double mutants. As expected, the major difficulty was predicting the effect of the mutation on catalytic activity. Increasing the likelihood of creating the desired catalytic activity may require mutagenic strategies that simultaneously introduce multiple mutations in a gene (25–27). Computer-aided molecular models may make the process more efficient by identifying critical regions (cassettes) to target for multiple amino acid substitutions, insertions, or deletions. The *Rd* prolipase expression system is well suited for such a mutagenic strategy since a rapid fluorescence visual screen for hydrolytic activity has been developed (14). Unfortunately, the prolipase crystal structure has not been solved, and the presence of the propeptide has significant impact on substrate specificity. Resolution of the crystal structure of the *Rd* prolipase would aid in our understanding of protein structure–function relationship and aid in the tailoring of lipase substrate specificity through protein engineering.

ABSTRACT: Recent studies provide extensive evidence for the importance of carotenoids in protecting against oxidative stress associated with a number of diseases. In particular, reactions of carotenoids with phenoxyl radicals generated by peroxidase-catalyzed one-electron metabolism of phenolic compounds may represent an important antioxidant function of carotenoids. To further our understanding of the antioxidant mechanisms of carotenoids, we used in the present work two different phenolic compounds, phenol and a polar homologue of vitamin E (2,2,5,7,8-pentamethyl-6-hydroxychromane, PMC), as representatives of two different types of phenols to study reactions of their respective phenoxyl radicals with carotenoids in cells and in model systems. We found that phenoxyl radicals of PMC did not oxidize β-carotene in either HL-60 cells or in model systems with horseradish peroxidase (HRP)/H_2O_2. In contrast, the phenoxyl radicals generated from phenol (by native myeloperoxidase in HL-60 cells or HRP/H_2O_2 in model systems) effectively oxidized β-carotene and other carotenoids (canthaxanthin, lutein, lycopene). One-electron reduction of the phenoxyl radical by ascorbate (assayed by electron spin resonance-detectable formation of semidehydroascorbyl radicals) prevented HRP/H_2O_2-induced oxidation of β-carotene. PMC, but not phenol, protected β-carotene against oxidation induced by a lipid-soluble azo-initiator of peroxyl radicals. No adducts of peroxidase/phenol/H_2O_2-induced β-carotene oxidation intermediates with phenol were detected by high-performance liquid chromatography–mass spectrometry analysis of the reaction mixture. Since carotenoids are essential constituents of the antioxidant defenses in cells and biological fluids, their depletion through the reaction with phenoxyl radicals formed from endogenous, nutritional and environmental phenolics, as well as phenolic drugs, may be an important factor in the development of oxidative stress.
Lipids 32, 131–142 (1997).

There are three major paths by which one-electron free radical intermediates of oxidation of phenolic compounds, phenoxyl radicals, are generated in cells and biological fluids. One is associated with antioxidant defense mechanisms and occurs by the interaction of natural and/or synthetic phenolic chain breaking antioxidants (e.g., vitamin E, ubiquinol, probucol) with peroxyl radicals (1–4):

$$ROO + Ph\text{-}OH \rightarrow ROOH + Ph\text{-}O$$

Another involves the one-electron catalytic oxidation of low molecular weight phenols by several important enzymes (e.g., peroxidases, tyrosinase, prostaglandin synthase) (5–8). In the third path, tyrosyl residues in proteins are converted to phenoxyl radicals, and are catalytic intermediates detectable in a number of proteins and enzymes such as ribonucleotide reductase (9). While in the latter case, the reactivity of the tyrosine phenoxyl radical (Tyr122 in the B_2 subunit) is essential for oxidation of two thiol groups (Cys754 and Cys759 in the B_1 subunit), and the formation of the thiyl radical and its oxidative attack on ribose (9,10), the relative reactivities of the various low molecular weight phenoxyl radicals formed in the first two paths may also be very important physiologically. The different reactivities of the phenoxyl radicals formed from phenolic free radical scavengers determine their relative antioxidant effectiveness (vs. their prooxidant chain-propagating effects). Formation of phenoxyl radicals from toxic phenolic compounds may represent the key mechanism by which they exert their cytotoxic and mutagenic effects, causing futile "thiol pumping" and yielding oxygen-centered free radicals (8). Thus, the relative reactivities of phenoxyl radicals may be pivotal for both normal metabolism and pathological mechanisms.

Recent studies demonstrate that reactivities of phenoxyl radicals can be surprisingly high. For example, experiments in model systems (nonaqueous solvents) have shown that rate constants for hydrogen atom abstraction by the phenoxyl radicals are 100–300 times greater than those for peroxyl radicals (11). Several studies also demonstrate that both unhindered and hindered phenoxyl radicals can directly oxidize thiols (glutathione, dihydrolipoic acid) and protein sulfhydryls (8,12,13). Enzymes such as peroxidases (e.g., myeloperoxidase) and prostaglandin synthase, as well as the peroxidase activity of hemoglobin and myoglobin, are promoters of low density lipoprotein (LDL) lipid oxidation

Abbreviations: AAPH, 2,2'-azo-*bis*(2-amidinopropane)dihydrochloride; AMVN, 2,2'-azo-*bis*(2,4-dimethylvaleronitrile); DOPC, 1,2-dioleoylphosphatidylcholine; ESR, electron spin resonance; HPLC, high-performance liquid chromatography; HRP, horseradish peroxidase; LDL, low density lipoprotein; MS, mass spectrometry; PMC, 2,2,5,7,8-pentamethyl-6-hydroxychromane; PMSF, phenylmethylsulfonyl fluoride; THF, tetrahydrofuran; UV, ultraviolet.

(14–16). It has been suggested that the mechanism of thiol oxidation involves the generation of an intermediate radical, such as the phenoxyl radical of tyrosine or vitamin E, which then rapidly consumes antioxidants and propagates free radical-based lipid peroxidation (17). Direct reactions of phenoxyl radicals with lipids or lipid antioxidants (e.g., carotenoids), however, have not been studied in cells or under physiologically relevant conditions.

The biological activity of carotenoids is a direct consequence of the chemistry of their long polyene chain: a highly reactive, electron-rich system of conjugated double bonds susceptible to attack by electrophilic reagents, thus responsible for the ability of carotenoids to act as reductants (and their susceptibility to oxidation). Carotenoids react rapidly with peroxyl radicals and can compete with the allylic hydrogens of polyunsaturated fatty acids in membranes, thereby acting as antioxidants (18–23). The antioxidant effect of β-carotene is apparent at low O_2 concentrations in which the carotenyl radical functions as an efficient chain terminator. In the presence of O_2, however, the β-carotene peroxyl radical is formed, which triggers further oxidations (24). While reactions of carotenoids with peroxyl radicals as well as with oxygen radicals and singlet oxygen have been extensively studied (18,19,22,25–27), their interactions with phenoxyl radicals have not been investigated. The interrelationships between carotenoids and phenoxyl radicals of phenolic antioxidants and cytotoxic phenols are of special importance in view of their potential role in attenuating or enhancing oxidative stress.

In the present work, we used two different phenolic compounds, phenol and 2,2,5,7,8-pentamethyl-6-hydroxychromane (PMC) (a polar homologue of vitamin E), as representatives of two different types of low molecular weight phenols. The former, a cytotoxic compound, and the latter, an antioxidant protector, were used to study reactions of their respective phenoxyl radicals with carotenoids in cells and in model systems. We present evidence that the phenoxyl radical of PMC does not oxidize β-carotene in HL-60 cells nor in model systems. In contrast, the phenoxyl radical generated from phenol (by native myeloperoxidase in HL-60 cells or horseradish peroxidase (HRP) in model systems) effectively oxidizes β-carotene and other carotenoids. The oxidation of phenol was prevented by ascorbate, which reduces phenoxyl radicals to form the semidehydroascorbyl radical.

MATERIALS AND METHODS

Reagents. Acetonitrile, toluene, and acetic acid were obtained from Fisher Scientific (Pittsburgh, PA). All other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO).

Preparation of liposomes and "micelles." Solutions of 1,2,-dioleoylphosphatidylcholine (DOPC) in chloroform and β-carotene in tetrahydrofuran (THF) were mixed and the solvents evaporated with a stream of N_2. After evaporation, phosphate buffer (50 mM) containing NaCl (100 mM), pH 7.4, was added and the suspension was sonicated (six 15-s pulses in an ice bath) using a tip sonicator (Ultrasonic Homogenizer 4710 Series; Cole-Parmer Instrument Co., Chicago, IL). The concentrations of β-carotene and DOPC were 20 and 510 μM, respectively. For our experiments, solutions of 2×10^{-3} M β-carotene were prepared in THF, 10 μL of which was injected into 1 mL of phosphate buffer. Spectrophotometric analysis showed a final concentration of 20 μM β-carotene in the 1% THF solution. The structure of the β-carotene/THF complex in aqueous solution is unknown. It is known that THF in water forms azeotropic solutions, so the likely structure is a cage of THF around one or more β-carotene molecules, with the latter maintained in a constrained, fluid state. Presumably, the oxygen atom of THF is directed outward toward the aqueous environment, while its nonpolar end solubilizes the carotenoid. Use of THF as a co-solvent allows the highly lipophilic carotenoids to be solubilized in an aqueous medium, and in a readily bioavailable form (which, for convenience, we term as "micelles"). Except for lycopene, which was not homogeneously dispersed in the phosphate buffer and was better analyzed by integration into DOPC liposomes, all other carotenoids were prepared by the same method used for β-carotene.

HL-60 cell culture. HL-60 cells (obtained from Prof. J.C. Yalowich, Department of Pharmacology, University of Pittsburgh) were grown in RPMI 1640 medium supplemented with 10% fetal calf serum at 37°C in a 5% CO_2 atmosphere. Cells from passages 25–40 were used in experiments. The density of cells at collection time was 1.5×10^6 cells/mL. Cell viability was determined microscopically by trypan blue exclusion.

Myeloperoxidase activity. Myeloperoxidase activity in HL-60 cells was determined by the oxidation of guaiacol (28). Cells were disrupted by lysis with Tris HCl (100 mM), NaCl (200 mM), EDTA (5 mM), and phonylmethylsulfonyl fluoride (PMSF) (0.1 mM), pH 7.4. Aliquots of the lysate were combined with 3-amino-1,2,4-triazole (2.5 mM), cetyltrimethylammonium bromide (0.03%), and guaiacol (15 mM) in phosphate buffer (100 mM), pH 7.4. Myeloperoxidase activity was determined by the change in absorbance at 470 nm using $\varepsilon = 26.6\ mM^{-1}\ cm^{-1}$. The enzyme activity was determined to be 5.4 nmol/min/10^6 cells at 20°C.

Incorporation of β-carotene into HL-60 cells. HL-60 cells were diluted to a density of 1.5×10^6 cells/mL in L1210 buffer containing NaCl (115 mM), KCl (5 mM), $MgCl_2$ (1 mM), NaH_2PO_4 (5 mM), glucose (10 mM) and Hepes (25 mM), pH 7.4. β-Carotene was dissolved in THF, then added to the cell suspension to give a final concentration of 50 μM. The β-carotene-enriched cells were incubated at 37°C in a shaking bath in sterile lab air in the dark for 30 min. After incubation, β-carotene not associated with the cells was removed by centrifugation at $800 \times g$ for 10 min. The cells collected after this procedure were determined to be 96% viable.

Incubation of HL-60 cells containing β-carotene with phenol and PMC. β-Carotene-enriched cells were diluted to a density of 1.0×10^6 cells/mL in L1210 buffer. Phenol (300 μM)

or PMC (300 μM) were added to the cell suspension and incubated in the presence or absence of H_2O_2 (400 μM) at 37°C. Reactions were terminated by the addition of sodium azide (4 mM). The cells were determined to be 95% viable following this procedure.

High-performance liquid chromatography (HPLC) assay of β-carotene. Aliquots (200 μL) were taken from cell suspensions at given time intervals and transferred to borosilicate glass tubes containing chloroform/methanol (2:1, vol/vol; 1 mL) then vortexed for 1 min. This mixture was centrifuged for 5 min at 1000 × *g*, and the upper aqueous phase was discarded. The lower organic layer was evaporated to dryness under N_2 and the residue was reconstituted in methanol/toluene (3:1, vol/vol) for HPLC analysis. A reversed-phase C_{18} HPLC column [(ODS Hypersil, 5 μm particle size, 4.6 × 200 mm; Hewlett-Packard, Palo Alto, CA)] was employed for separations on a Shimadzu LC-10A HPLC with an LC-60 pump equipped with an SPD-10AV ultraviolet (UV) detector (Tokyo, Japan). Chromatograms were generated from effluent absorbance at 450 nm. The data acquired were exported from the SPD-10AV UV detector using Shimadzu EZChrom software. The mobile phase, used at a flow rate of 1 mL/min, consisted of methanol containing 0.5% aqueous ammonium acetate (wt/vol)/toluene (33:7, vol/vol). The retention time for β-carotene under these conditions was 8.7 min. Control experiments showed that the recovery of β-carotene with this procedure was >98%.

HPLC–mass spectrometric (MS) analyses. Pneumatically-assisted electrospray mass spectra of β-carotene and its oxidation products were obtained with a Perkin Elmer/Sciex API 1 mass spectrometer (Thornhill, Ontario, Canada) equipped with an atmospheric pressure ionization source and an articulated IonSpray interface maintained at 5 kV. The orifice was operated at 70 V, high purity N_2 flowing at 0.6 L/min and heated to 55°C served as the curtain gas, and high purity air maintained at 40 psi was used for nebulization. Samples were introduced using a Hewlett-Packard 1090 Series II liquid chromatograph equipped with a 1040A diode array detector, connected in tandem to the mass spectrometer with glass capillary tubing. Analytes in the samples were separated with a 2.1 × 100 mm Hewlett-Packard 5 μm Hypersil ODS C_{18} column using methanol containing 0.15% aqueous ammonium acetate (wt/vol)/toluene (19:1, vol/vol) as the mobile phase, flowing at a rate of 0.2 mL/min. Mass spectra were acquired over the range *m/z* 200 to *m/z* 1500 with a resolution of *m/z* 0.1 at the rate of 9–12 s/scan.

HPLC assay of phenol. Aliquots (200 μL) were taken from the reaction mixtures at given time intervals and transferred to borosilicate glass tubes containing 200 μL of CH_3OH. The dispersion thus formed was filtered through a 1 mL C_{18} Sep-Pak cartridge (Waters Division of Millipore, Millipore Co., Milford, MA), and the filtrate was analyzed by HPLC using the 4.6 × 200 mm column and the Shimadzu LC system (detection was by absorbance at 272 nm). The mobile phase used was CH_3OH/H_2O (31:19, vol/vol) adjusted to pH 3.1 with CH_3COOH at a flow rate of 1 mL/min. Under these conditions the retention time for phenol was 4.8 min. Recovery of phenol using the above described procedure was >98%.

HPLC assay of PMC. Aliquots (200 μL) were taken at given time intervals and transferred from the reaction mixtures into borosilicate glass tubes. The PMC extraction was carried out as described (29). SDS (100 mM, 200 μL) was added to the samples, and briefly mixed by vortexing. Reagent-grade ethanol (400 μL) and hexane (400 μL) were added and the resulting mixtures were vigorously mixed by vortexing for 2 min. The mixtures were centrifuged for 5 min at 1000 × *g* to separate the layers. Each upper phase was transferred to a small borosilicate glass tube and dried under N_2. The residues were separately dissolved in ethanol and analyzed by HPLC using the 4.6 × 200 mm column and the Shimadzu LC system (detection was by absorbance at 292 nm). The mobile phase used was CH_3CN/H_2O (8:5, vol/vol) adjusted to pH 3.0 with CH_3COOH at a flow rate of 1 mL/min. Under these conditions the retention time for PMC was 8.6 min. Control experiments showed that recovery of PMC with this procedure was >98%.

Electron spin resonance (ESR) spectral detection of the PMC phenoxyl and semidehydroascorbyl radicals. ESR measurements were performed on a JEOL-RE1X spectrometer (Tokyo, Japan) at 25 and 37°C in gas-permeable Teflon tubing (0.8 mm internal diameter, 0.013 mm thickness; obtained from Alpha Wire Corp., Elizabeth, NJ). The tube (approximately 8 cm in length) was filled with 60 μL of sample, folded into quarters, and placed in an open 3.0 mm internal diameter ESR quartz tube in such a way that all of the sample was within the effective microwave irradiation area. Spectra of the PMC phenoxyl radical were recorded at 335.5 mT center field, 40 mW power, 0.2 mT field modulation, 10 mT sweep width, a receiver gain of 2000, and a 0.3-s time constant. Spectra of the semidehydroascorbyl radical were recorded at 335.5 mT center field, 10 mW power, 0.04 mT field modulation, 10 mT sweep width, a receiver gain of 1000, and a 0.3-s time constant.

Spectrophotometric assay of β-carotene oxidation in model systems. In "micelles" and liposomes, carotenoids were oxidized with HRP (0.1–1.0 U/mL)/H_2O_2 (400 μM) system at 25°C. 2,2′-Azo-*bis*(2-amidinopropane)dihydrochloride (AAPH) (50 mM)- or 2,2′-azo-*bis*(2,4-dimethylvaleronitrile) (AMVN) (1.0 mM)-induced oxidation of β-carotene in DOPC liposomes was carried out at 37°C. When HRP (0.1 U/mL) was used for oxidation of β-carotene in both aqueous solutions and in liposomes, the oxidation was linear for 300 s. When the oxidation of β-carotene was induced by more than 0.1 U/mL HRP, the reaction was linear for 120 s. The rate of β-carotene consumption, in μM/min, was determined using these time intervals. The numbers were obtained from the formula: μM/min = $(C_0\text{-}C)/t$, where C_0 was the concentration of β-carotene at time zero (20 μM), C was its measured concentration (μM) at different time points in the reaction when the oxidation was linear, and t was the time in s when the measurement was made. The rate constants were obtained with the formula: $k = (2.303/t) \times \log(C_0/C)$, where t

was the time in s at which a measurement was made (when the oxidation of β-carotene was linear), C_0 was the concentration (from the optical density) of β-carotene (20 μM) at time zero, and *C* was its concentration at the given time point in the linear portion of the oxidation reaction. In most experiments, serial UV-VIS spectra of carotenoids were recorded in the range 350–600 nm at scanning intervals of 2 min. A Shimadzu 160U spectrophotometer (equipped with Shimadzu PC 160 PLS software) was employed for all UV-VIS measurements. In some experiments, carotenoids were extracted from "micelles" or liposomes at specific time intervals with chloroform/methanol (2:1, vol/vol), solvents were evaporated under N_2, the residue was dissolved in THF, then analyzed spectrophotometrically.

RESULTS

Effects of H_2O_2 and phenolic compounds (phenol and PMC) on β-carotene in HL-60 cells. Treatment of HL-60 cells with β-carotene resulted in its incorporation to the level of 0.33 nmol/10^6 cells. Such treatment and loading levels did not produce cytotoxic effects in the time frame of our experiments. Incubation of β-carotene-loaded cells with phenol/H_2O_2 resulted in the consumption of β-carotene to 65% of its initial level during the first 5 min (Fig. 1), and a further decrease to 44% of its initial level after 15 min (data not shown). β-Carotene levels did not significantly change in control cells incubated for the same time period without phenol/H_2O_2. Similarly, when the incubation medium contained all reactants except phenol or H_2O_2, no significant decrease of the β-carotene content was observed. In cells pretreated with azide, an inhibitor of myeloperoxidase, the β-carotene-consuming effect of phenol/H_2O_2 was not observed.

In contrast to phenol, addition of PMC/H_2O_2 did not affect β-carotene content in preloaded HL-60 cells. Neither PMC alone nor the PMC/H_2O_2 combination in cells treated with azide caused any detectable decrease in β-carotene content.

H_2O_2-induced oxidation of phenol and PMC in β-carotene-loaded HL-60 cells. In the absence of H_2O_2, HL-60 cells loaded with β-carotene oxidized phenol or PMC slowly. The rate of oxidation of PMC under such conditions was three times higher than that of phenol (Table 1). In the presence of H_2O_2, the oxidation of phenol was increased about 15-fold, while that of PMC was increased by less than 3-fold: i.e., the rate of phenol oxidation was enhanced to twice that of PMC by addition of H_2O_2. Since, in the presence of H_2O_2, oxidation of phenol and PMC occurred at comparable rates, the dramatic difference in the oxidation of β-carotene caused by PMC and phenol (lack of oxidation by PMC/H_2O_2 and significant oxidation by phenol/H_2O_2) cannot be attributed simply to differences in the rates of oxidation of the two phenolic compounds.

Effect of phenol and PMC on the consumption of β-carotene induced by HRP/H_2O_2. We wished to gain a better understanding of the mechanism(s) underlying the different effects of phenol and PMC on the consumption of β-carotene in HL-60 cells. A simple model system consisting of HRP/H_2O_2 was thus employed to measure the oxidation of β-carotene and several other carotenoids.

Since β-carotene has characteristic absorbance features in the visible range, its oxidation can be studied spectrophotometrically (Fig. 2). In the absence of HRP/H_2O_2, β-carotene was stable, and only small changes in its absorption spectrum were observed (data not shown). HRP/H_2O_2 caused slow oxidation of β-carotene that was substantially accelerated by the addition of phenol (Fig. 2B). A simultaneous increase in absorbance at 412 nm due to accumulation of phenol oxidation products was observed (30). The consumption of β-carotene was directly proportional to the amount of HRP added (Fig. 3). When sodium azide was added to the incubation mixture containing HRP/H_2O_2, the β-carotene level remained constant regardless of the presence or absence of phenol.

In contrast to phenol, PMC did not enhance HRP/H_2O_2-

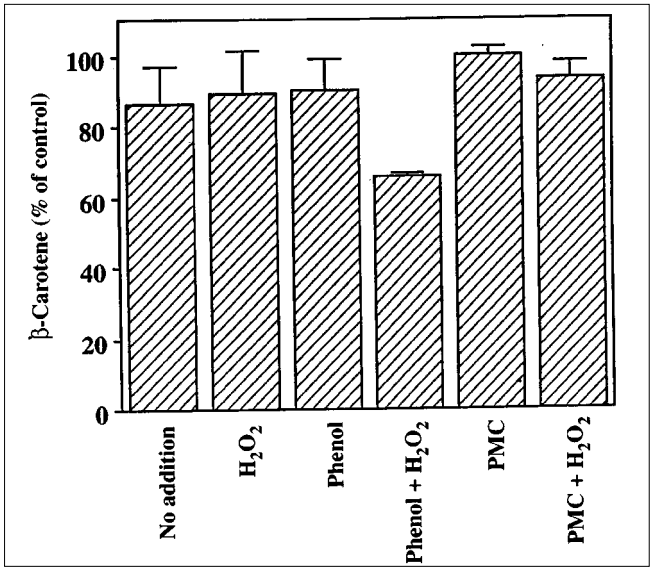

FIG. 1. Effect of phenol and 2,2,5,7,8-pentamethyl-6-hydroxychromane (PMC) on the oxidation of β-carotene in HL-60 cells in the presence or absence of H_2O_2. Reaction conditions: β-carotene-loaded HL-60 cells (1.0×10^6) were incubated in L1210 medium in the presence of phenol (300 μM) or PMC (300 μM) and H_2O_2 (400 μM) at 37°C. The initial concentration of β-carotene was 0.33 nmol/10^6 cells. Results are means + standard deviations ($n = 3$).

TABLE 1
Rate of Phenol and PMC Oxidation in HL-60 Cells by Endogenous Myeloperoxidase

Additions	nmol/min/1 × 10^6 cells	
	Phenol[a]	PMC
no H_2O_2	0.21 ± 0.01	0.61 ± 0.02
H_2O_2	3.31 ± 0.10	1.61 ± 0.08

[a] The concentrations of phenol and 2,2,5,7,8-pentamethyl-6-hydroxychromane (PMC) in the incubation system were 300 μM; that of H_2O_2 was 400 μM. The rates of oxidation of phenol and PMC in HL-60 cells were linear during 5 min after induction of oxidation. Data from this time period was used for determination of the oxidation rates of these compounds.

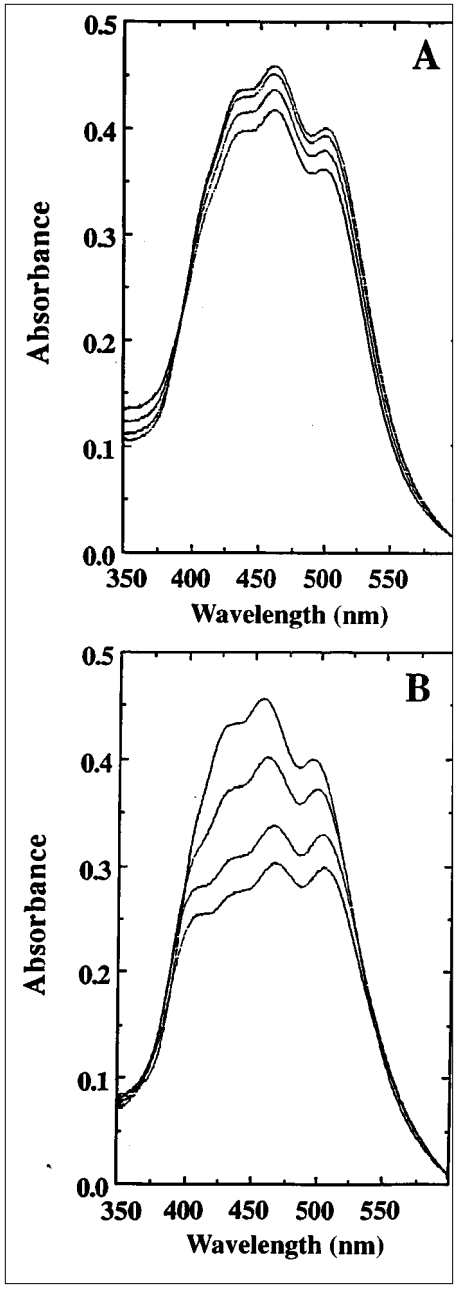

FIG. 2. Intensity decay of and changes in absorbance spectra of β-carotene "micelles" exposed to horseradish peroxidase (HRP)/H_2O_2 (A) and HRP/H_2O_2/phenol (B) at 25°C. Reaction conditions: β-carotene dissolved in tetrahydrofuran was added to phosphate buffer (50 mM), containing NaCl (100 mM), pH 7.4, to give a final concentration of 20 μM. A spectrum was taken, HRP (0.1 U/mL), H_2O_2 (400 μM), and phenol (100 μM) were then added, and spectra were recorded at 5, 15, and 30 min.

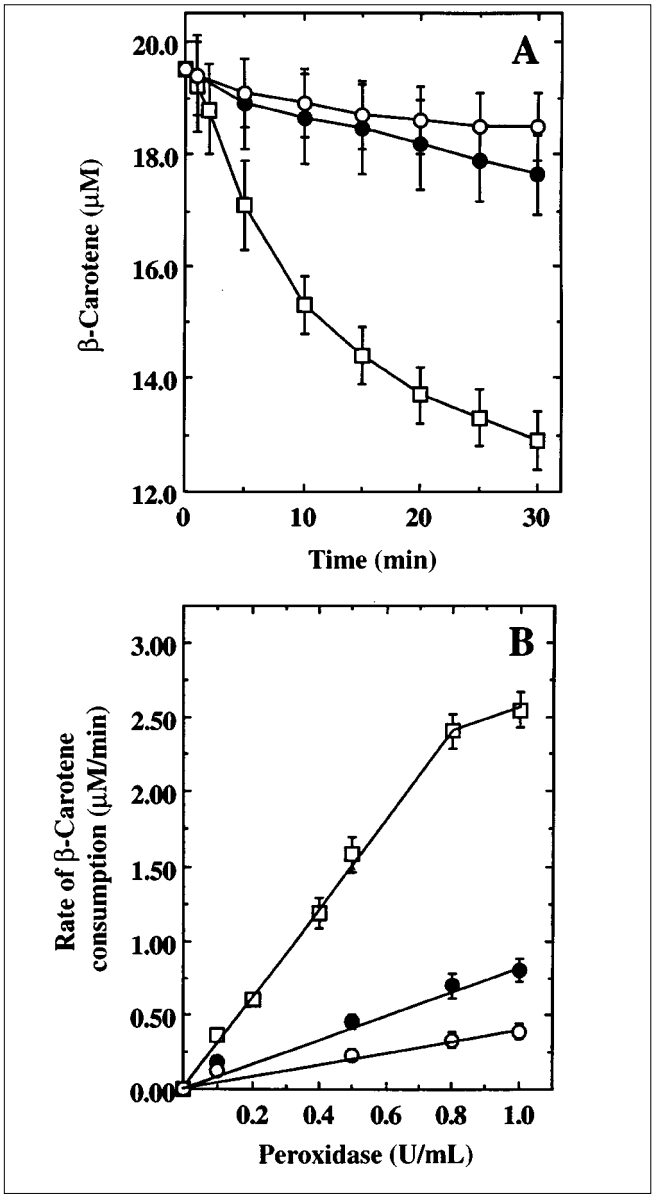

FIG. 3. Time course (A) and dependence on HRP concentration (B) of β-carotene oxidation by HRP/H_2O_2 and phenol (□), PMC (○), or no phenolic compound (●). Reaction conditions: incubation was performed in phosphate buffer (50 mM) containing NaCl (100 mM), pH 7.4, using β-carotene (20 μM), HRP (its concentration in A was 0.1 U/mL), H_2O_2 (400 μM), and phenol (100 μM) or PMC (100 μM, added as a concentrated ethanolic solution). See Figures 1 and 2 for abbreviations.

induced consumption of β-carotene. No oxidation of β-carotene occurred during incubation with the peroxidase in the absence of H_2O_2.

In order to determine which of the products of phenol oxidation (e.g., quinones, polyhydroxylated products, or intermediates such as the phenoxyl radical) were involved in β-carotene degradation in the HRP/H_2O_2/phenol system, β-carotene was added to an incubation mixture containing products of the exhaustive oxidation of phenol. Incubation of β-carotene with pre-formed (and thus likely not the phenoxyl radical) oxidation products did not induce its consumption (data not shown). Repeated addition of phenol, however, stimulated the oxidation of β-carotene. Thus, the phenoxyl radical appeared to be the sole or major contributor to the degradation of β-carotene in the HRP/H_2O_2/phenol reaction.

Analysis by HPLC–MS of the consumption of β-carotene

in the presence of phenol by HRP/H_2O_2. To determine if β-carotene-phenol adducts were formed during peroxidase-catalyzed oxidation, we examined the reaction mixtures described above by HPLC–UV-electrospray MS. As reported by Liebler and McClure, detected as a weak quasi-molecular ion of *m/z* 537.4 ([M + H]+) β-carotene 536.4 amu, and structures derived from it contained a substantial mass defect of ca. 0.5 amu (31). When the reactions were quenched by the addition of azide, a single major product appeared with an HPLC retention time identical to that of β-carotene, but an apparent mass of 549.4 amu (i.e., detected as an assumed quasi-molecular ion of *m/z* 550.4 ([M + H]+)). This product had a UV spectrum that was essentially indistinguishable from that of β-carotene, and was not formed when reactions were quenched by cooling to 0°C. Because of its odd mass and the lack of its appearance when azide was omitted, we can only tentatively identify this product as an azide adduct of β-carotene (detected in the mass spectrometer after loss of N_2), possibly arising from reaction of azidyl radical with β-carotenyl radical (32).

In the absence of azide, numerous products were detected after the cooled reaction mixtures were lyophilized, reconstituted in methanol/toluene, and promptly analyzed by HPLC–MS (Fig. 4). Two of the minor products were identified as likely arising from simple oxygenation of β-carotene, yielding quasi-molecular ions of *m/z* 551.4 ([M + (O − 2 H) + H]$^+$) and *m/z* 567.5 ([M + (O_2 − 2 H) + H]$^+$). The major products from this reaction exhibited dramatically altered (mainly blue-shifted) UV spectra and high molecular masses (>700 amu). We can only assume that these products arose from a complex set of addition and termination reactions of β-carotenyl radicals and their disproportionation products with themselves and oxygen. We found no evidence of any simple phenol adducts with β-carotene in the mass range of 625–650 amu (mono addition to β-carotene or its oxygenated adduct) nor 720–760 amu (*bis* addition to β-carotene or its oxygenated adducts).

ESR detection of semidehydroascorbyl radical and effects

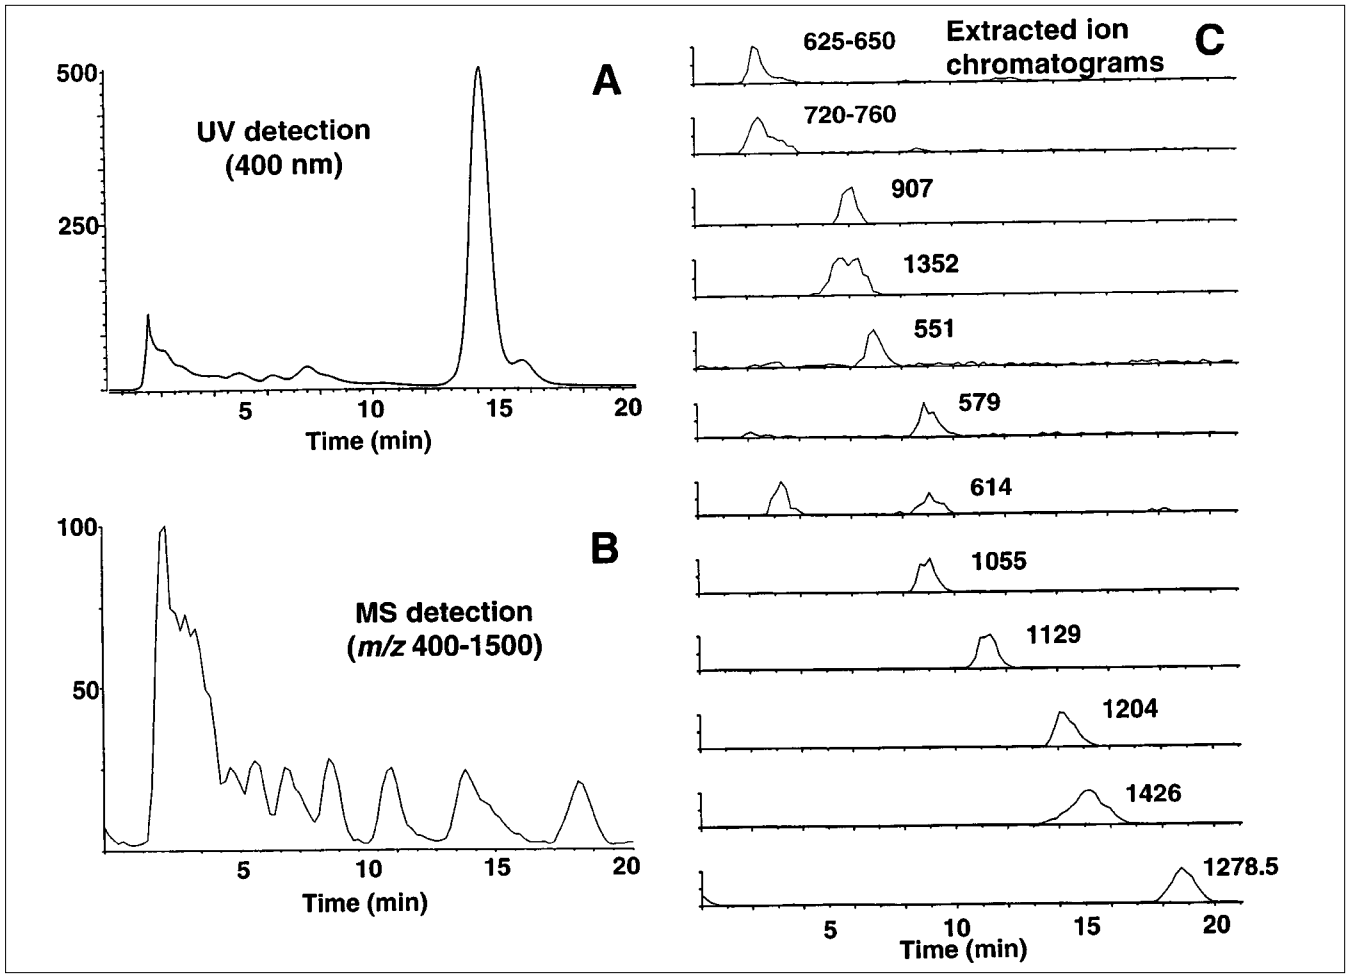

FIG. 4. High-performance liquid chromatography ultraviolet–(UV) mass spectrometry–(MS) analysis of β-carotene/phenol/horseradish peroxidase/H_2O_2 reaction mixture quenched by cooling to 0°C. (A): UV-detected (400 nm) chromatogram of products. Note that β-carotene had a retention time of 7.5 min in this system. (B): Total ion chromatogram (m/z 400-1500) of products. The large, early-eluting signals were also evident in control reaction mixtures (time = *ca.* 0). (C): Extracted ion chromatograms of some of the ion signals detected from the reaction products. Note the lack of signals in the ranges *m/z* 625–650 and *m/z* 720–760 where phenol adducts of β-carotene are expected to appear.

of ascorbate on β-carotene consumption by HRP/H_2O_2 in the presence of phenol or PMC. Since phenol oxidation products were apparently not involved in the degradation of β-carotene, we further tested the hypothesis that the phenoxyl radical (or similar intermediates) was responsible for its oxidation. The phenoxyl radical is very short-lived and cannot be detected directly by conventional ESR (33). We therefore documented the participation of the phenoxyl radical in the oxidation of β-carotene by using ascorbate, which is highly reactive toward phenoxyl radicals (34). In the absence of ascorbate, incubation media containing β-carotene "micelles" and HRP/H_2O_2 did not produce any ESR-detectable signals (Fig. 5). Incubation of ascorbate with HRP/H_2O_2 generated a weak semidehydroascorbyl radical ESR signal, the intensity of which dramatically increased upon addition of phenol. In the absence of phenol, the weak semidehydroascorbyl radical ESR signal could be observed for 50–60 min without any change in its magnitude. Addition of phenol, on the other hand, caused an almost immediate increase in the intensity of the semidehydroascorbyl signal that, under the conditions used, completely disappeared from the spectra after 30 min of incubation. Importantly, we found that oxidation of β-carotene by HRP/H_2O_2/phenol was prevented by ascorbate during the period when the semidehydroascorbyl radical was discernible in ESR spectra (Fig. 6).

Peroxidase/HRP/H_2O_2-induced oxidation of PMC in the presence of β-carotene was accompanied by the formation of the characteristic five-line ESR signal of PMC phenoxyl radical (35). Addition of ascorbate resulted in the disappearance of the PMC phenoxyl radical signal and appearance of the characteristic doublet semidehydroascorbyl radical signal (Fig. 5).

Effects of phenol and PMC on oxidation of β-carotene induced by azo-initiators (AMVN and AAPH) in DOPC-liposomes. β-Carotene can be oxidized by peroxyl radicals, and this oxidation can be prevented by phenolic antioxidants (22). If phenoxyl radicals formed by reaction of a phenolic compound with a peroxyl radical are reactive enough to directly oxidize β-carotene, however, no protection should be granted by the phenolic compound. We used hydrophilic and hydrophobic azo-initiators of peroxyl radicals, AAPH and AMVN, respectively, to study the effects of phenol and PMC on the oxidation of β-carotene in DOPC-liposomes (Fig. 7). We found that both AAPH and AMVN caused oxidation of β-carotene. PMC protected β-carotene against oxidation induced by either azo-initiator. In contrast, phenol did not inhibit AAPH- or AMVN-induced oxidation of β-carotene. Moreover, a weak but enhanced oxidation of β-carotene occurred in the presence of phenol when hydrophobic AMVN was used to initiate peroxyl radical formation.

Effect of phenol on the consumption of different carotenoids in model systems by HRP/H_2O_2. To test whether the results we had observed were unique to β-carotene or could also be extended to the oxidation of other, similar compounds, we studied the effects of phenol on the consumption of several representative carotenoids by HRP/H_2O_2 (Table 2). We found that not only β-carotene, but also canthaxanthin, lutein and lycopene were readily oxidized by this system. In the presence of phenol, the oxidation rate constants for canthaxanthin and lutein were even higher than that for β-carotene. Oxidation rates were 2- to 4-fold lower in the absence of phenol. While lycopene had a lower oxidation rate both in the presence and in the absence of phenol, the conditions under which it was studied were necessarily different from those used for the other carotenoids. Since we could not

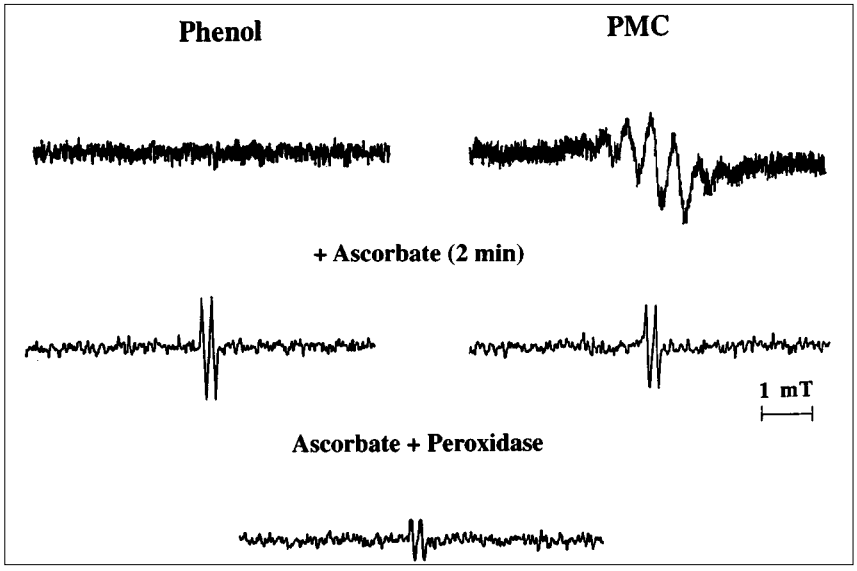

FIG. 5. Electron spin resonance spectra of PMC phenoxyl radical and semidehydroascorbyl radical induced by horseradish peroxidase/H_2O_2 in "micelles" of β-carotene. Reaction conditions: incubation was performed in phosphate buffer (50 mM) containing NaCl (100 mM), pH 7.4, with β-carotene (20 μM), HRP (0.1 U/mL)/H_2O_2 (400 μM) and phenol (100 μM) or PMC (100 μM). See Figure 1 for other abbreviation.

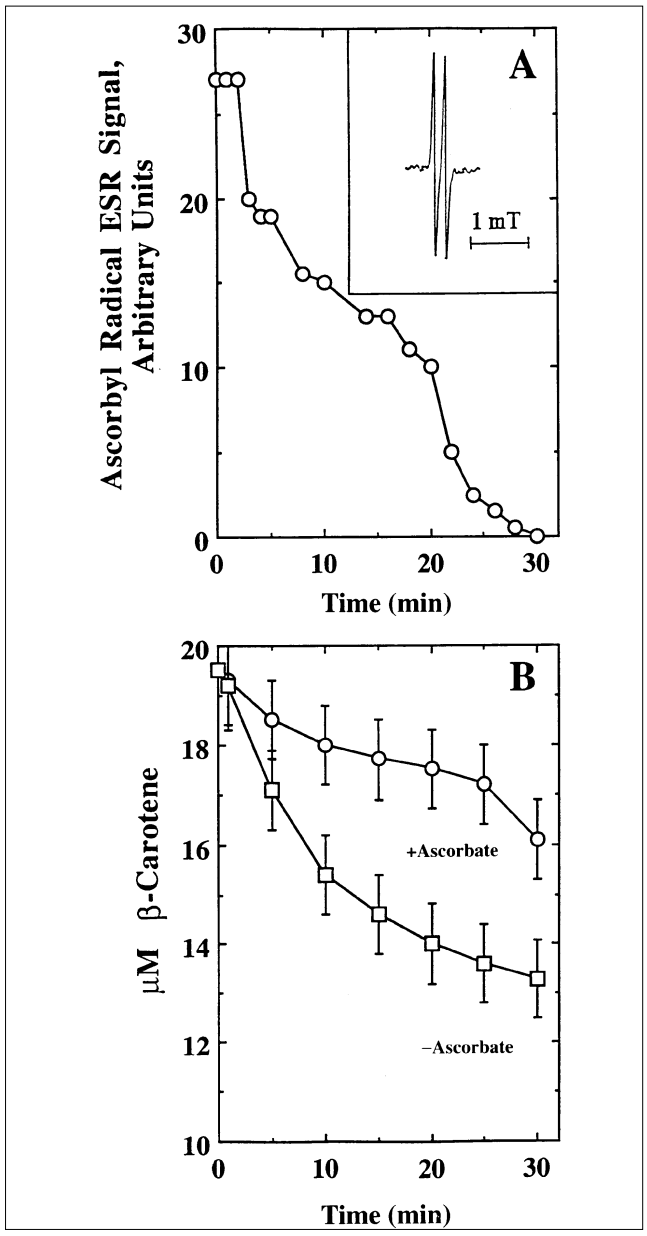

FIG. 6. Time course of semidehydroascorbyl radical (A) and β-carotene oxidation (B) by horseradish peroxidase-catalyzed oxidation of phenol. The electron spin resonance (ESR) spectra spectrum of semidehydroascorbyl radical is shown (A, insert). Reaction conditions: β-carotene added to phosphate buffer (50 mM) containing NaCl (100 mM), pH 7.4, was incubated at 25°C with HRP (0.1 U/mL)/H_2O_2 (400 μM) and phenol (100 μM) either in the absence (□) or presence (○) of ascorbate (30 μM).

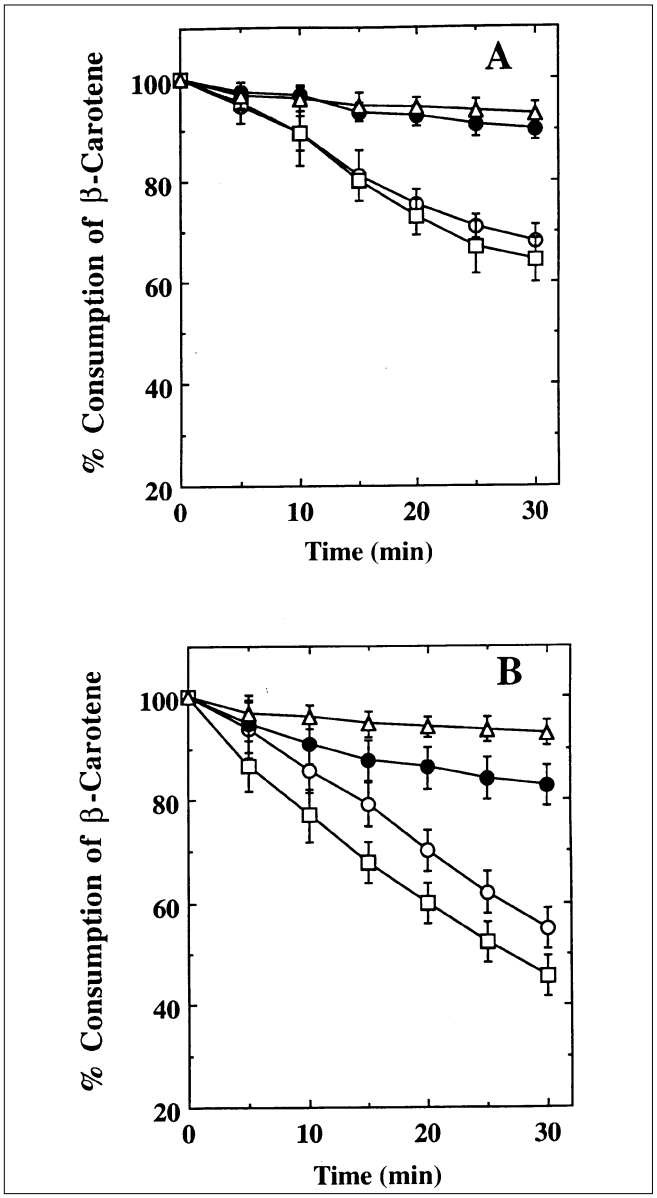

FIG. 7. Effect of phenol and PMC on β-carotene oxidation in 1,2,-diolerylphosphatidylcholine (DOPC) liposomes in the presence of 2,2'-azo-*bis* (2-amidinopropane)dihydrochloride (AAPH) (A) or 2,2'-azo-*bis*(2,4-dimethylvaleronitrile) (AMVN) (B). Reaction conditions: liposomes of DOPC (510 μM) and β-carotene (20 μM) were incubated in phosphate buffer (50 mM) containing NaCl (100 mM), pH 7.4, at 37°C with: (A) AAPH (50 mM) (○), phenol (100 μM) and AAPH (50 mM) (□), or PMC (100 μM) and AAPH (50 mM) (●); or with (B) AMVN (1 mM) (○), phenol (100 μM) and AMVN (1 mM) (□), or PMC (100 μM) and AMVN (1 mM) (●), or without additions (△). See Figure 1 for other abbreviation.

find conditions useful for the preparation of fine homogenous "micelles" of lycopene in phosphate buffer, we integrated it into DOPC liposomes and then performed incubations in the presence of HRP (0.5 U/mL) and H_2O_2 (400 μM).

DISCUSSION

The unsaturated carbon-carbon bonds of membrane lipids are the primary targets for free radicals reactions *in vivo*. Their consequent peroxidation results in membrane damage (36). In addition to reductive enzymes, the antioxidant defense system includes water- and lipid-soluble free radical scavengers (vitamin C, thiols, vitamin E, coenzyme Q, and carotenoids) whose activities are enhanced by synergistic interactions through their recycling mechanisms (34,37,38). In particular, the importance of redox-cycling cascades such as thiols → ascorbate → tocopherol and NAD(P)H → electron transport

TABLE 2
Rate Constant of Carotenoid Oxidations by Peroxidase/H_2O_2

Carotenoids	Rate constants, K (10^{-4} s^{-1})		Structures of carotenoids
	− Phenol	+ Phenol	
β-Carotene[a]	2.1 ± 0.1	4.4 ± 0.3	Canthaxanthin[a]	1.6 ± 0.1	6.2 ± o.4	Lutein[a]	2.2 ± 0.1	5.4 ± 0.3	Lycopene[b]	0.9 ± 0.1	2.1 ± 0.1	
[a]Incubation mixtures contained micelles of carotenoids prepared by addition of tetrahydrofuran solutions of the respective compound to 50 mM phosphate buffer, pH 7.4, containing peroxidase (0.1 U/mL), H_2O_2 (400 μM), and with or without phenol (100 μM).
[b]Since lycopene could not be homogeneously dispersed in the phosphate buffer, it was integrated in 1,2-dioleoylphosphatidylcholine liposomes and then incubated in the presence of peroxidase (0.5 U/mL) and H_2O_2 (400 μM) with or with phenol (100 μM).

enzymes → coenzyme Q → vitamin E has been established (39). In several epidemiological studies, dietary consumption of carotenoids has been correlated with a decreased risk of cancer at several tissue sites (40); yet, a statistically significant increased lung cancer incidence (18%) has been reported in male smokers (41). While carotenoids are known to be precursors of vitamin A (42), their important protective properties, such as enhancing the immune response, inhibiting mutagenesis, reducing tumor development and causing tumor regression *in vivo*, lowering cell transformation *in vitro*, and preventing sister chromatid exchange, have been associated with their antioxidant function (20,43), independent of their metabolism to vitamin A (44). Antioxidant mechanisms of carotenoids include effective quenching of singlet oxygen (40) as well as chainbreaking scavenging of carbon-centered and oxygen radicals, which is efficient at low oxygen pressures (21–24).

The antioxidant activity of carotenoids is dependent on their concerted action with other chainbreaking lipid-soluble antioxidants (44). In particular, phenolic antioxidants, vitamin E and coenzyme Q, act to protect carotenoids against oxidative destruction (45). For example, in LDL exposed to a steady flux of aqueous peroxyl radicals, ubiquinol-10 is the first antioxidant to be consumed, followed by α-tocotrienol and α-tocopherol, all of which disappear before the carotenoids are consumed (46). If the reactivity of phenoxyl radicals formed from phenolic antioxidants is high, phenoxyl radical-induced oxidation of carotenoids, rather than their protection by phenolic compounds, is likely to occur. Recently, Bowry *et al.* (47) suggested that phenoxyl radicals of vitamin E may be responsible for oxidation of lipids in LDL, at least under some conditions.

Our previous work demonstrated that phenoxyl radicals generated from phenol and the phenolic antitumor drug etoposide (VP-16) induce one-electron oxidation of protein sulfhydryls and GSH in cells and model systems, subsequently generating thiyl radicals, disulfide anion radicals, and superoxide (in the presence of molecular oxygen), thus triggering the chain of events ultimately resulting in oxidative stress (8,13). Oxidation of thiols was not observed when phenoxyl radicals were generated from vitamin E or its homologues (13). To further understand the reactions of phenoxyl radicals with physiologically important molecules, in the present work we used two representative phenolic compounds, phenol and PMC, to study interactions of their respective phenoxyl radicals toward carotenoids.

Myeloperoxidase-catalyzed oxidation of β-carotene in HL-60 cells. Our results demonstrated that β-carotene associated with HL-60 cells was oxidized by phenol/H_2O_2, but not by either agent alone. HL-60 cells contain very high myeloperoxidase activity (48). Since azide inhibited oxidation of phenol (i.e., inhibited peroxidase activity) and simultaneously inhibited oxidation of β-carotene, we suggest that oxidation of β-carotene was catalyzed by endogenous myeloperoxidase.

While inhibition by azide is not strictly specific for myeloperoxidase and may involve other hemoproteins, myeloperoxidase is the most abundant hemoprotein in HL-60 cells (48).

In contrast to phenol, PMC/H_2O_2 was ineffective in oxidizing β-carotene. One possible explanation for this difference may be that myeloperoxidase-catalyzed oxidation of these two phenolic compounds proceeds at dramatically different rates. Our direct measurements showed that phenol was oxidized at a rate twice that of PMC. Thus, the qualitative difference—fast oxidation of β-carotene in the presence of phenol vs. lack of its oxidation in the presence of PMC—can hardly be explained by differences in the kinetics of the myeloperoxidase-catalyzed oxidation of phenol and PMC.

Previous studies show that leukocyte myeloperoxidase causes a rapid destruction of β-carotene in the presence of H_2O_2/halides (49). The myeloperoxidase/H_2O_2/halide system produces potent oxidants, such as hypochlorous acid and singlet oxygen (50), that are known to readily oxidize different lipids (including carotenoids) (51) and proteins. (52). The mechanism of myeloperoxidase/H_2O_2/halide-induced oxidation of carotenoids is likely to differ from that of myeloperoxidase-catalyzed oxidation in the presence of H_2O_2 and phenolic compounds. The peroxidase-catalyzed release of phenoxyl radicals has been shown to induce oxidation of critical biomolecules and thus cause cytotoxic effects (28,53). The myeloperoxidase-catalyzed activation of phenol and other phenolic metabolites of benzene (e.g., hydroquinone, benezenetriol) in bone marrow is often invoked as the mechanism responsible for benzene-induced aplastic anemia and leukemia (5,54,55). The reactivity of phenoxyl radicals toward lipid-soluble antioxidants and lipids, causing the formation of mutagenic lipid peroxidation products, may contribute to the carcinogenicity of benzene. To the best of our knowledge, we have demonstrated for the first time that intracellular myeloperoxidase-catalyzed oxidation of phenol in the presence of H_2O_2 results in oxidation of a carotenoid, i.e., depletion of an important lipid-soluble antioxidant. While it is conceivable that phenoxyl radicals generated by myeloperoxidase in HL-60 cells were responsible for the oxidation of incorporated β-carotene, an explanation should exist to explain the different effects of phenol and PMC. To this end we performed experiments in simple model systems where HRP/H_2O_2 and phenol or PMC were used to oxidize β-carotene in "micelles."

Phenoxyl radicals directly oxidize β-carotene in the HRP/H_2O_2/phenol system. Our model experiments clearly demonstrated that oxidation of β-carotene by HRP/H_2O_2/phenol was not due to phenol oxygenation products (e.g., quinones), but rather involved reactions with free radical intermediates. Specifically, phenoxyl radicals of phenol (but not of PMC) directly oxidized β-carotene in a reaction catalyzed by HRP in the presence of H_2O_2. The reaction was inhibited by ascorbate, and this inhibition was accompanied by generation of semidehydroascorbyl radical, a one-electron product of ascorbate oxidation. Previous studies have shown that ascorbate is an effective one-electron reductant for different phenoxyl radicals (34,37,38). The phenoxyl radical of PMC, which is directly observable by ESR, was also reduced by ascorbate to produce the identical characteristic ESR signal of semidehydroascorbyl radical. These results suggest that different relative reactivities of phenoxyl radicals toward β-carotene may be responsible for the different behaviors of phenol and PMC.

Since the relative reactivities of phenoxyl radicals may govern the protective (antioxidant) vs. toxic effects of phenolic radical scavengers, we subsequently compared the effects of phenol and PMC on oxidation of β-carotene induced by water- and lipid-soluble azo-initiators of peroxyl radicals (56). We found that PMC protected β-carotene against oxidation induced by either AAPH or AMVN. In both cases, phenol afforded no protection; rather, it enhanced the oxidation of β-carotene. These results fully concur with our previous findings on the protection of proteins against oxidation by vitamin E homologues and, vice versa, the prooxidant effects of phenol (*via* its phenoxyl radical) in both cells and in model systems.

Recently, Liebler and McClure (31) provided direct proof for the antioxidant mechanism of β-carotene by demonstrating formation of carotenoid–radical adducts when oxidation was induced by thermolysis of AMVN. We found no evidence of direct reaction of phenoxyl radicals with β-carotene or β-carotenyl radicals. This suggests that β-carotene is not likely to terminate phenoxyl radical-induced oxidation reactions, at least not those catalyzed by peroxidase. Given that the peroxidase-catalyzed reaction is considered an important and physiologically-relevant oxidation mechanism in plasma (15), our results suggest that β-carotene does not seem a likely candidate for protection of LDL against oxidative stress.

Finally, the prooxidant effects of the phenol phenoxyl radical are not limited to β-carotene, but may embrace other carotenoids (e.g., lycopene, lutein, canthaxanthin). While the results presented in the study were obtained with phenol, intracellular phenoxyl radicals generated from other phenolic compounds may be involved in the oxidative degradation of carotenoids. In particular, tyrosine phenoxyl radical (TyrO·) has been detected recently in a number of proteins (57). Calculated spin densities for the respective phenoxyl radicals of phenol and tyrosine differ from each other by less than 0.03, implying that the unpaired electron of TyrO(·) resides entirely on the aryloxyl portion of the molecule. Since carotenoids are essential constituents of the antioxidant defenses used by cells and biological fluids (42), their depletion through the reaction with phenoxyl radicals formed from endogenous, nutritional and environmental phenolics (e.g., estrogens, flavonoids, polyphenols, chlorinated phenols) or phenolic drugs (e.g., etoposide, acetaminophen) may be an important factor in the development of oxidative stress. Not surprisingly, peroxidase-catalyzed oxidation of LDL is now considered an indispensable model in studies of oxidative mechanisms of atherosclerosis (17). The question remains whether other polyunsaturated lipids (e.g., methylene-interrupted fatty acid residues of membrane phospholipids) may also be involved in oxidations by phenoxyl radicals generated from different phenolic

compounds.

NOTE ADDED IN PROOF

In a recent paper, Mortensen and Skibsted [*Free Radical Res. 25*:515–523 (1996)] present evidence for the formation of adducts between phenoxyl radicals generated by laser flash photolysis and β-carotene. These conditions (when both phenoxyl radicals and β-carotenyl radicals might be simultaneously present and thus directly interact with each other) are distinctly different from those used in our experiments (peroxidase-catalyzed phenoxyl radicals could only attack β-carotene).

Stearic Acid Modifies Very Low Density Lipoprotein Lipid Composition and Particle Size Differently from Shorter-Chain Saturated Fatty Acids in Cultured Rat Hepatocytes

Tonkun Pai and Yu-Yan Yeh*

Department of Nutrition, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT: Stearic acid as compared to myristate, palmitate, or oleate is poorly incorporated into triacylglycerol, a major lipid component of very low density lipoprotein (VLDL). The present study investigated the effects of these fatty acids on VLDL metabolism in cultured rat hepatocytes. All fatty acids stimulated [2-^{3}H] glycerol incorporation into VLDL lipids and secretion of [^{3}H]-labeled VLDL by hepatocytes. However, the rate of [^{3}H]-labeled VLDL secretion in the presence of nonlabeled stearate (12.8 ± 0.7 pmol/mg protein/4 h) was 46, 59, and 22% of that observed for those treated with myristate, palmitate, and oleate, respectively. [1-^{14}C]Stearate as a substrate was also less effective than other labeled fatty acids to be incorporated into VLDL lipids. Of total VLDL lipids synthesized from [1-^{14}C] stearate, triacylglycerol accounted for 78% as compared to 88–97% of that derived from palmitate, myristate, and oleate. The amounts of apoB100 and apoB48 were the same in hepatocytes treated with or without exogenous fatty acids. Similarly, the rate of apoB synthesis from [^{35}S] methionine was not affected by exogenous fatty acids. The treatment of cells with various saturated fatty acids increased the particle size of VLDL to different extents. The largest particles of VLDL, with a mean diameter of 79.3 ± 11.9 nm, were seen in the cells treated with stearate, followed by those treated with palmitate and myristate (45.5 ± 9.8 and 38.6 ± 6.8 nm, diameter, respectively). Clearly, hepatocytes treated with stearate secrete less VLDL and produce larger VLDL particles than those treated with shorter-chain saturated fatty acids.

Lipids 32, 143–149 (1997).

The neutral effect of stearate on plasma cholesterol concentration is well defined (1–5). Despite the effect, current diet recommendations do not differentiate stearate from other saturated fatty acids in their influence on the plasma cholesterol level (6,7). This may be attributed in part to a lack of complete understanding of the mechanism(s) underlying the neutral effect of stearate, although poor intestinal absorption of stearate, (8) desaturation of stearate to oleate (9), and absence of inhibitory effect of stearate on low density lipoprotein (LDL)-receptor activity (10) have been proposed as possible explanations. The roles of dietary saturated and polyunsaturated fats in regulating plasma cholesterol level and LDL metabolism have been extensively investigated in animals and humans (11,12). However, the importance of individual fatty acid in cholesterol metabolism, especially very low-density lipoprotein (VLDL) synthesis and secretion, has not been established. Since plasma VLDL is a precursor of LDL, any alteration in VLDL metabolism is bound to change LDL concentration (13). Physical and biochemical characteristics of lipoproteins are known to be altered by saturated and unsaturated fatty acids in the diet. For example, chylomicrons are smaller in rats fed a diet high in saturated fatty acids than those fed a diet high in unsaturated fatty acids (14). Larger sized chylomicrons and VLDL are cleared faster than the smaller ones from plasma (15,16). Fish oil rich in eicosapentaenoic and docosahexaenoic acids is effective in reducing plasma level of triacylglycerol due primarily to a decrease of hepatic VLDL-triacylglycerol secretion in humans (17). Fish oil has also been shown to increase the degradation of apoB in the rat hepatocytes (18).

We have previously shown that stearate treatment markedly inhibited triacylglycerol synthesis in cultured rat hepatocytes (19). Since triacylglycerol is a major component of VLDL (20,21), it is conceivable that the impaired triacylglycerol synthesis could decrease VLDL synthesis and secretion. The present study was, therefore, designed to evaluate the effects of various saturated fatty acids on VLDL secretion as well as chemical and physical properties of VLDL particles. The results showed that stearate compared to other saturated fatty acids not only reduced VLDL secretion but also increased the particle size of VLDL.

MATERIALS AND METHODS

Animals and diets. Sprague-Dawley male rats (100–150 g body weight), obtained from Harlan Sprague-Dawley (Indi-

*To whom correspondence should be addressed at 129 South Henderson Building, Department of Nutrition, The Pennsylvania State University, University Park, PA 16802.

Abbreviations: apoB, apolipoprotein B; DMEM, Dulbecco's modified Eagle medium; FBS, fetal bovine serum; HDL, high density lipoprotein; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

anapolis, IN), were fed *ad libitum* rat chow (Ralston Purina Co., St. Louis, MO) and had free access to tap water. All animals were housed individually in steel-mesh cages in a room with controlled temperature and lighting (22°C and 12 h light–dark cycle). The animal protocol was approved by the Pennsylvania State University Institutional Animal Care and Use Committee (University Park, PA).

Hepatocyte isolation and culture. Hepatocytes were isolated from rats (225–250 g body weight) by the method of Berry and Friend (22) as modified by Seglen (23). As detailed elsewhere (24), the procedure involved collagenase perfusion *via* hepatic portal vein, tissue mincing, filtration and centrifugation, and further purification by cell adherence. The isolated cells were resuspended in Dulbecco's modified Eagle medium (DMEM) supplemented with 5.6 mmol/L glucose, 10% fetal bovine serum (FBS), and antibiotics (penicillin, 100 units/mL and streptomycin, 100 μg/mL). Cell viability was determined by trypan blue exclusion for each isolation. Cell preparations with 95% or higher viability were used throughout the experiments. A 2-mL aliquot of cell suspension ($0.7–0.8 \times 10^6$ cells/mL) was transferred to culture plates, each containing six wells (3.5 cm diameter), and incubated at 37°C under an atmosphere of 95% air and 5% CO_2. Six hours after incubation, cells adhering to the flask were refed with DMEM and incubated under the same conditions for 24 h.

Synthesis and isolation of VLDL. The cultured cells obtained after 24 h incubation were washed three times with 2 mL of FBS-free DMEM followed by incubation in the same medium containing [2-^{3}H]glycerol (specific activity of 7.4 MBq/mmol) at 25 μmol/L in the presence or absence of one of the unlabeled fatty acids at 0.5 mM. Fatty acids were provided as an albumin complex in a molar ratio of 5.6:1 (fatty acid/albumin). Stock solutions (100 mmol/L) were prepared from the sodium salt of each fatty acid. An aliquot of the stock solution was added to DMEM containing 0.58% bovine serum albumin and sonicated prior to incubation with hepatocytes.

At the end of 4 h incubation, the medium (2 mL) was transferred to centrifuge tubes for isolation of VLDL (25). The density of the medium was adjusted to 1.21 g/mL by adding 1.3 g potassium bromide and 2 mL saline. Salt solution with a density of 1.0063 g/mL (1.15% NaCl (wt/vol)) was carefully layered over and centrifuged at $100{,}000 \times g$ for 22 h. After the centrifugation, VLDL on the top of the solution was collected, and VLDL lipid was extracted according to the method of Folch *et al.* (26). The radioactivity of VLDL lipids was measured by liquid scintillation spectrometry (LS8100; Beckman Instruments Inc., Palo Alto, CA). The rate of glycerol incorporation into VLDL lipids was expressed as pmol glycerol incorporated/mg protein/4 h. The rate of VLDL secretion was measured by [2-^{3}H]glycerol recovered in the medium VLDL (27).

Apolipoprotein B synthesis. Cultured hepatocytes were incubated with 2 mL of FBS-free DMEM containing 0.2 mM [^{35}S]methionine (specific activity of 0.82 MBq/mmol). After 4 h incubation, apolipoprotein B(apoB) was immunoprecipitated by the method of Wang *et al.* (18). ApoB was separated by electrophoresis in a 3.5% polyacrylamide–18% glycerol gel (28). After fixing and staining the gel, the density of each band was measured by using a laser densitometer to determine the mass of apoB (29). The amount of apoB determined for hepatocytes treated with exogenous fatty acids was expressed as percentage of density detected in the gel of control hepatocytes. After the densitometeric measurements, each band was excised from the gel and dissolved in 35% H_2O_2 overnight. The radioactivity of each band was measured by liquid scintillation counting. The rate of [^{35}S]methionine incorporation into apoB was expressed as cpm/mg protein/4 h.

Synthesis of VLDL lipids. Cultured cells obtained after 24 h incubation were washed three times with 2 mL of FBS-free DMEM and were incubated in FBS-free medium containing 0.5 mmol/L [9,10-^{3}H]myristate, [1-^{14}C]palmitate, [1-^{14}C]-stearate, or [1-^{14}C]oleate, and nonradioactive fatty acid with a specific activity of 37 MBq/mmol. After 4 h incubation, VLDL was isolated as above, and VLDL lipids were extracted. The extracted lipids were separated into phospholipid, triacylglycerol, diacylglycerol, monoacylglycerol, and cholesterol esters by thin-layer chromatography (30). Bands containing the individual lipid classes were scraped from the plate and reextracted with chloroform/methanol (2:1; vol/vol). The radioactivity derived from lipid classes was measured as described above. The rate of lipid synthesis was expressed as nmol substrate incorporated/mg protein/4 h.

VLDL particle size measurements. Cultured hepatocytes were incubated with 2 mL of FBS-free DMEM containing individual fatty acids (0.5 mmol/L) and glycerol (25 μmol/L) and processed according to the procedure described above for synthesis of VLDL. After the VLDL isolation by gradient centrifugation, VLDL was negatively stained with 2% phosphotungstate (pH 7.4) and viewed in a Jeol 1200EXII transmission electron microscope (Jeol USA, Peabody, MA) at 60 KeV. The diameter of VLDL particle was measured by using Image Archival Imix, version seven (PGT, Princeton, NJ). Briefly, the transmission electron microscope images of VLDL were electronically transferred to the Image Archival Imix program, and the size of VLDL was determined by measuring the diameter of each VLDL particle with a laser digitizer.

Materials. Chemical reagents were purchased from Sigma Co. (St. Louis, MO) unless otherwise indicated. Collagenase D was purchased from Boehringer Mannheim Co. (Indianapolis, IN). [2-^{3}H]Glycerol, [9,10-^{3}H]myristate, [1-^{14}C]palmitate and [1-^{14}C]stearate, [1-^{14}C]oleate, [1-^{14}C]linoleate, and [^{35}S]methionine were obtained from Amersham Co. (Arlington Heights, IL). DMEM, FBS and antibiotics (penicillin and streptomycin) were products of Life Technologies, Inc. (Grand Island, NY). Silica gel H plates (20×20 cm, 250 μm layer thickness) were supplied by Alltech Associates, Inc. (Deerfield, IL).

Statistical analysis. Data are expressed as mean $\pm$ SD. Results from the multiple fatty acid treatments were compared by analysis of variance. Duncan's Multiple Range Test was applied to identify the significant differences at $P < 0.05$.

RESULTS

The effects of fatty acids on VLDL secretion were determined by measuring the rate of [2-^{3}H] glycerol incorporation into lipids of VLDL detected in the culture medium. The rates of [2-^{3}H]glycerol incorporation were 12.8 ± 0.7, 18.6 ± 2.7, 29.7 ± 3.8, and 63.7 ± 2.6 pmol/mg protein/4 h in the hepatocytes treated with stearate, palmitate, myristate, and oleate, respectively, compared to 6.6 ± 0.3 pmol/mg protein/4 h seen in the control untreated hepatocytes. Clearly, all fatty acids markedly stimulated [2-^{3}H]glycerol incorporation into VLDL lipids (Fig. 1). However, the percentage of stimulation was the lowest by stearate (195%) and the highest by oleate (970%). Interestingly, the degree of stimulation by saturated fatty acids was inversely related to the carbon chain length. The secretion of VLDL was also determined by measuring the incorporation of [^{3}H]- or [^{14}C]-labeled fatty acids into VLDL lipids recovered in the culture medium. The rate of [1-^{14}C]stearate incorporation into VLDL total lipids was 16, 16, and 6% of that for palmitate, myristate, and oleate, respectively (Table 1). The rate of [1-^{14}C] oleate incorporation was the highest among all fatty acids. Regardless of the labeled fatty acid substrates, triacylglycerol was the predominant product. Thus, the differential effects of fatty acids on total lipid synthesis resulted primarily from differences in their incorporation into triacylglycerol. The rate of phospholipid synthesis was the highest from oleate and palmitate, and the lowest from stearate. The rate of palmitate incorporation into diacylglycerol was higher than that of other fatty acids. However, there were no differences in the incorporation among stearate, myristate, and oleate (Table 1). The rate of stearate incorporation into cholesteryl ester was markedly lower than that of oleate, palmitate, and myristate. Consequent to the disproportional incorporation of fatty acids into various lipids, of the radioactivity recovered in total lipids, triacylglycerol accounted for 97, 96, 88, and 78% from labeled oleate, myristate, palmitate, and stearate, respectively. The reduced percentage of triacylglycerol from stearate was accompanied by slight increases in phospholipid and diacyl-

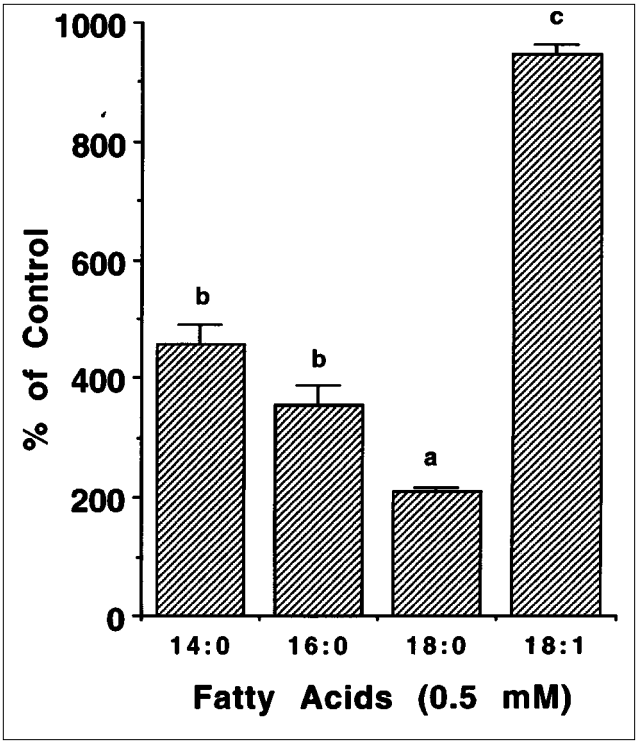

FIG. 1. Incorporation of [2-^{3}H]glycerol into very low density lipoprotein (VLDL) as affected by exogenous fatty acids in cultured rat hepatocytes. Values are mean ± SD for four samples. [2-^{3}H]Glycerol was incubated with 0.5 mM fatty acid for 4 h. Percentage of control is defined as the amount of [^{3}H] lipid radioactivity recovered in VLDL secreted by individual fatty acids treated hepatocytes divided by that secreted by hepatocytes without any fatty acid treatment, multiplied by 100.

[a]Values are means ± SD for four samples. Hepatocytes were incubated with 0.5 mM [^{3}H]- and [^{14}C]-labeled fatty acid for 4 h. Very low density lipoprotein (VLDL) in the medium was isolated for analysis of lipids by thin-layer chromatography and liquid scintillation spectrometry. Values with different superscript letters in the same row are significantly different at $P < 0.05$.

[b]Total represents the sum of the four lipid classes listed and other minor lipids such as free cholesterol, free fatty acids, and monoacylglycerol.

glycerol. However, the percentage of cholesteryl ester from palmitate was higher than that from stearate (Table 1).

The particle size of VLDL was measured in subsequent experiments. The VLDL particles secreted by hepatocytes of control group had the smallest mean diameter (35.6 ± 4.8 nm diameter) as compared to other groups (Fig. 2). The largest particles with a mean diameter of 79.3 ± 11.9 nm were obtained from the cells treated with stearate. The mean particle diameters for the cells treated with palmitate and myristate were 45.5 ± 9.8 and 38.6 ± 6.8 nm, respectively. The mean diameter of VLDL (71.6 ± 15.6 nm) of oleated-treated cells was comparable for that of stearate-treated counterparts. The frequency distribution of VLDL from oleate could not be determined because of insufficient number of particles. The distribution of VLDL particle size from control and myristate-treated cells was similar with the range falling between 25 and 55 nm in particle diameter. The peak frequencies fall at 35 nm from both groups, but the peak frequency represents 41% for the control and 28% for the myristate-treated group. The VLDL particles derived from palmitate-treated cells were distributed over a wider range (20 to 75 nm in diameter). There was no sharp peak in frequency in this group; however, 61% of particles fall between 40 and 50 nm range. The distribution of the particles derived from stearate-treated cells falls beyond the range of those obtained from control, myristate, and palmitate-treated cells, although there was some overlap with the palmitate-treated group. The particle size of stearate-treated cells ranged from 55 to 105 nm in diameter with greater than 58% of the population falling between 75 and 90 nm.

The results of apoB experiments are presented in Table 2. The relative content of apoB was determined on the basis of the apoB density on the gel prepared from the cells treated without exogenous fatty acids. The treatment of the cells with fatty acids did not alter apoB100 and apoB48 contents measured in the cells and the culture medium (Table 2). Approximately 40–50% of apoB100 and apoB48 was released into the medium presumably in the form of VLDL. The rate of apoB synthesis was measured using [^{35}S]methionine as a substrate. The recoveries of radioactivity in apoB48 in the cells and the medium were not altered by the exogenous fatty acids. Similarly, fatty acids did not affect the incorporation of [^{35}S]-labeled methionine incorporation into the apoB100 detected in the medium. However, stearate, palmitate, and oleate decreased the radioactivity recovery in the cellular apoB100 (Table 2). When the amounts of radioactivity recovered in both the cells and the medium were added together, the rate of synthesis of apoB100 and apoB48 did not differ among the groups treated with or without the fatty acids. Approximately 82–87% of the newly synthesized apoB100 was secreted from the cells into the medium, whereas 62–74% of the apoB48 was secreted, and the secretions of both were not affected by the fatty acids present in the incubation medium.

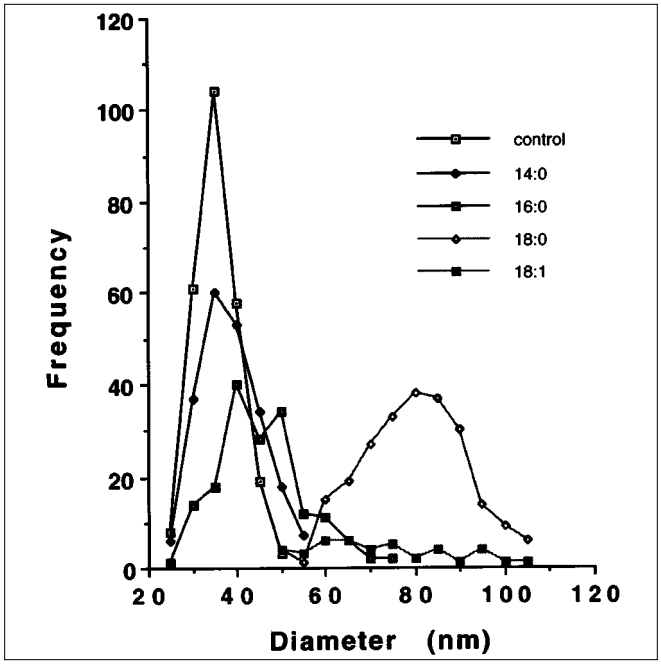

FIG. 2. Particle size distribution of VLDL secreted by hepatocytes treated with saturated fatty acids. After 4 h incubation of the cells with 0.5 mM fatty acid, VLDL in the medium was isolated. Percentage distribution is defined as the percentage of VLDL particles of which the diameters fall within the 5-nm interval. A total of 253, 215, 168, and 231 VLDL particles obtained from the cells treated with no fatty acid, myristate, palmitate or stearate, respectively, were included in the calculation. See Figure 1 for abbreviation.

DISCUSSION

The production of VLDL, a triacylglycerol-rich lipoprotein, takes place in the liver and is dependent on the availability of triacylglycerol, phospholipid, free and esterified cholesterol, and apolipoproteins (20,21). Since we have previously demonstrated an impairment in triacylglycerol synthesis by stearate (19), it was speculated that stearate treatment would decrease synthesis and secretion of VLDL. Indeed, the rate of VLDL secretion, as measured by [2-^{3}H]glycerol and [^{3}H] or [^{14}C]-labeled fatty acid incorporation into lipids of VLDL recovered in the medium, was the lowest in the stearate-treated cells. These observations coincided with the previous study showing that [1-^{14}C] stearate was incorporated into hepatocyte triacylglycerol at a rate markedly lower than that of labeled myristate, palmitate, or oleate (19). Taken together, these results indicate that an impairment of triacylglycerol synthesis is in part responsible for the depressed VLDL assembly and secretion by hepatocytes treated with stearate.

In addition to the requirements of lipid components, the synthesis of VLDL is dependent on the supply of apoB in the liver (31). Accordingly under the conditions when hepatic VLDL secretion is stimulated, the amount of newly synthesized apoB is increased and so is the amount secreted by the liver (32). Conversely, decreased hepatic secretion of VLDL is accompanied by a reduction of apoB secretion (31). However, it has been demonstrated that dietary fish oil reduces hepatic secretion of VLDL without parallel changes in apoB synthesis (18) and secretion (33). Consistent with this, the

[a]Values are means ± SD for four samples. Hepatocytes were incubated with 0.5 mM fatty acids and [^{35}S] methionine for 4 h. Apolipoprotein B (apoB100) and apoB48 were immunoprecipitated and separated by SDS gel electrophoresis. ApoB contents were determined by gel densitometry.
[b]% in medium = medium apoB/(cellular apoB + medium apoB) × 100. Values with different superscript letters in the same row are significantly different at P 0.05.

present study showed that stearate and other fatty acids did not alter cellular contents of apoB100 and apoB48, or the rate of apoB synthesis. Extensive degradation of apoB in the endoplasmic reticulum, however, may limit apoB abundance for synthesis and secretion of VLDL (34,35). Eicosapentaenoic acid and docosahexaenoic acid, for example, have been shown to increase the degradation of the intracellular apoB with a concomitant reduction in VLDL secretion by the cultured rat hepatocytes (18). Although the degradation of apoB was not determined in the present study, the unaltered apoB content and rate of synthesis suggest that stearate and other fatty acids have no effect on degradation. Also, it should be noted that although chylomicrons, VLDL, intermediate density lipoprotein, and LDL are known to contain apoB100 and/or apoB48, an apoB48-containing particle with the density of high density lipoprotein (HDL) has been identified (36). Unlike HDL, apoB48-containing HDL-like particle is destined to VLDL formation by acquiring lipids (36). Oleate has been shown to stimulate the conversion of the HDL-like particle to VLDL (36). It is not clear, however, whether such stimulation could explain the present results demonstrating an increase in VLDL lipid secretion by exogenous fatty acids without increasing apoB48.

The clearance of VLDL from the circulation is an important determinant of plasma VLDL and LDL concentrations (33). The rate of VLDL clearance, on the other hand, is determined by their particle size (15,37). In general, larger VLDL particles are removed more rapidly than smaller counterparts *via* LDL-receptor apoE-specific binding (38,39). Further, larger VLDL particles are enriched with apoE (37,40), and the enrichment of apoE may be responsible for the facilitated removal of large VLDL from the blood through LDL receptor mediated mechanism (41). Although no attempt was made to quantify apoE in the present study, VLDL particles produced by the cultured hepatocytes treated with stearate had a mean particle size which was 1.7 and 2.0 times that of the cells treated with palmitate and myristate, respectively. LDL is derived primarily from VLDL conversion in the circulation (38,42), although direct synthesis of LDL in the liver has been reported (42). It is therefore reasoned that, aside from a reduction in VLDL secretion, the increased VLDL particle size by stearate could further limit the availability of the precursor for LDL synthesis.

The mechanism by which stearate increases VLDL particle size is not readily understood. Large VLDL particles are known to contain more triacylglycerol and less cholesteryl

ester than small VLDL (38,43). Interestingly, VLDL particles of stearate-treated cells contained less both newly synthesized cholesteryl ester and triacylglycerol. It should be pointed out that VLDL particle size is also influenced by the ratio of triacylglycerol to apoB (44). A decrease in the ratio by decreasing lipids and either increasing or maintaining the same apoB content could lead to small VLDL particle size (44). In direct contrast, the present study showed that stearate increased particle size despite a reduction in triacylglycerol secretion and constant apoB100 content. The reason for this unexpected observation is obscure. It is known that the capacity of apoB100 to assemble lipids into VLDL is dependent on length of apoB100 polypeptides. The lipid assembly capacity is the highest by full-length polypeptide of 4536 amino acids and decreases with decreasing the peptide chain (36). Whether stearate inhibits the synthesis of full-size apoB100 and hence reduces lipid content of VLDL is yet to be investigated.

In summary, among saturated fatty acids, stearate has the least stimulatory effect on VLDL secretion. Conversely, stearate increases VLDL particle size more markedly than other fatty acids. These metabolic changes may explain in part the neutral effects of stearate on plasma cholesterol reported by other investigators (1–5).

ABSTRACT: Fruits and vegetables have protective effects against many human cancers, including pancreatic cancer. Isoprenoids are one class of phytochemicals which have antitumor activity, but little is known about their effects on cancer of the pancreas. We tested the hypothesis that isoprenoids would inhibit the growth of pancreatic tumor cells. Significant (60–90%) inhibition of the anchorage-independent growth of human MIA PaCa2 pancreatic tumor cells was attained with 25 μM farnesol, 25 μM geranylgeraniol, 100 μM perillyl amine, 100 μM geraniol, or 300 μM perillyl alcohol. We then tested the relative *in vivo* antitumor activities of dietary farnesol, geraniol, and perillyl alcohol against transplanted PC-1 hamster pancreatic adenocarcinomas. Syrian Golden hamsters fed geraniol or farnesol at 20 g/kg diet exhibited complete inhibition of PC-1 pancreatic tumor growth. Both farnesol and geraniol were more potent than perillyl alcohol, which inhibited tumor growth by 50% at 40 g/kg diet. Neither body weights nor plasma cholesterol levels of animals consuming isoprenoid diets were significantly different from those of pair-fed controls. Thus, farnesol, geraniol, and perillyl alcohol suppress pancreatic tumor growth without significantly affecting blood cholesterol levels. These dietary isoprenoids warrant further investigation for pancreatic cancer prevention and treatment.

Lipids 32, 151–156 (1997).

Numerous epidemiological studies have revealed that high consumption of fruits, vegetables, and other plant products correlates with a reduction in cancer incidence (1–3). Among the cancers exhibiting reduced incidence in people consuming high levels of plant foods are epithelial cancers of the pancreas (3), colon, breast, and lung (1). Given that these cancers are especially difficult to treat with existing therapeutic modalities, the identification of dietary phytochemicals that have antitumor activity and the investigation of their mechanisms of action may lead to significant advances in the prevention of human cancer by dietary or other means.

Monoterpenes and other isoprenoids are non-nutritive dietary phytochemicals found in the essential oils of citrus fruits, cherry, spearmint, dill, caraway, and other plants. These phytochemicals share the common feature of an isoprenoid structure which is derived from intermediates in the mevalonate pathway. For example, in spearmint and other plants, the monoterpene *d*-limonene is formed by the cyclization of geranylpyrophosphate (4). Limonene then serves as a precursor to other plant monoterpenoids such as perillyl alcohol (Scheme 1). Geraniol, farnesol, and geranylgeraniol (Scheme 1) are the alcohol metabolites of the corresponding pyrophosphates (5,6) which are key intermediates in the mevalonate pathway of both plants and mammals (7). Some specific dietary sources of isoprenoids include perillyl alcohol in cherry and spearmint; *d*-limonene in orange peel oil, caraway, and dill; and geraniol and farnesol in lemongrass.

Some dietary isoprenoids are known to have antitumor activity (8). Limonene has antitumor activity against rodent mammary, liver, lung, stomach, and skin cancers (9–14). Similarly, perillyl alcohol has chemopreventive activity against rat liver cancer (15) as well as chemotherapeutic activity against rodent mammary (16) and pancreatic cancers (17). Geraniol, an acyclic monoterpene, has *in vivo* antitumor activity against murine leukemia, hepatoma, and melanoma cells when administered before and after tumor cell transplantation (18,19). Another dietary isoprenoid, farnesol, has antiproliferative effects on cultured tumor cells (20–22), but its *in vivo* effects on tumor growth are unknown.

Cancer of the pancreas is one of the most deadly of all human cancers, with a 5-year survival rate of only 4% (23).

Abbreviation: NMR, nuclear magnetic resonance.

Patients with pancreatic cancer are usually unresponsive to available chemotherapy. As a result, there is an urgent need for novel, effective treatments for pancreatic cancer. We have recently reported that the dietary monoterpenoid perillyl alcohol has antitumor activity against pancreatic cancer in the hamster (17), but the antitumor effects of other dietary isoprenoids toward pancreatic cancer have not yet been reported. We therefore tested the hypothesis that dietary isoprenoids would inhibit the *in vitro* and *in vivo* growth of pancreatic tumor cells.

MATERIALS AND METHODS

Cell culture. MIA PaCa2 human pancreatic carcinoma cells and PC-1 hamster pancreatic ductal carcinoma cells were cultured as described previously (17,24). All cell lines were maintained in a humidified 37°C, 5% CO_2 incubator and, unless otherwise stated, all tissue culture reagents were purchased from Life Technologies, (Grand Island, NY). All isoprenoids except perillyl amine (see below) were purchased from Aldrich (Milwaukee, WI). Cell proliferation was measured by counting cells on a hemocytometer. To measure anchorage-independent growth, MIA PaCa2 cells were plated in 0.4% agar noble (Difco, Detroit, MI) in DMEM-10% fetal bovine serum over a 0.6% agar noble/DMEM-fetal bovine serum base. Fresh control or isoprenoid medium was added daily for 19 d, at which time colonies of more than 50 cells were scored.

Perillyl amine synthesis. Perillyl amine was synthesized from *N*-perillyl phthalimide as follows. Diisopropylazodicarboxylate (168 μL, 0.85 mmol) was added dropwise in the dark to a solution of perillyl alcohol (100 mg, 0.66 mmol), phthalimide (126 mg, 0.85 mmol), and triphenylphosphine (223 mg, 0.85 mmol) in dry tetrahydrofuran (5 mL) at 23°C. After the solution had been stirring for 4 h, water (20 mL) was added and the aqueous phase was extracted with hexane (3 × 15 mL). The combined organics were washed with brine, dried over $MgSO_4$, and filtered. The filtrate was evaporated *in vacuo* and the resulting residue applied to a 2 × 13 cm silica gel column. Flash chromatography using 1% ethyl acetate/hexane provided *N*-perillyl phthalimide (181 mg, 98%) as a white solid: ^{1}H nuclear magnetic resonance (NMR) δ 7.8, 7.7 (two *m*, 4 H, aromatic), 5.63 (*br s*, 1H, C=CH), [4.70, 4.66 (two *br s*, 2H, C=CH_2)] (*d*, 2H, C=CH_2), 4.18 (*s*, 2H, CH_2N), 2.12 (*m*, 5H, C=CCH_2 and CH), 1.8, 1.4 (*m*, 2H, CH_2), 1.69 (*s*, 3H, CH_3); ^{13}C NMR δ 168.1, 149.6, 133.8, 132.1, 131.9, 123.7, 123.2, 108.7, 43.3, 40.7, 30.3, 27.3, 27.1, 20.6.

N-Perillyl phthalimide (130 mg, 0.46 mmol) was dissolved in 0.3 M methanolic hydrazine hydrate (5 mL). After the solution had stirred for 0.5 h at 23°C, 5% HCl (2 mL) was added and the reaction was stirred for an additional 12 h. The resulting suspension was filtered, and the filtrate was diluted with an equal amount of water, acidified (pH <2) and washed with ether. The organic layer was discarded, and the aqueous layer was basified with solid KOH (pH >10) then extracted twice with ether. The combined ethereal layers were washed with brine, dried over $MgSO_4$, and concentrated *in vacuo*. An analytical sample was prepared by passing the residue through a silica gel plug using 3% methyl alcohol/CH_2Cl_2 as an eluent to give pure perillyl amine (62 mg, 88%): ^{1}H NMR δ 5.56 (*br s*, 1H, C=CH), 4.69 (*br s*, 2H, C=CH_2), 3.15 (*br s*, 2H, CH_2N), 2.0 (*m*, 5H, C=CCH_2 and CH), 1.9, 1.5 (*m*, 2H, CH_2), 1.72 (*s*, 3H, CH_3), 1.59 (*br s*, 2H, NH_2); ^{13}C NMR δ 149.9, 138.8, 119.9, 108.5, 48.0, 41.3, 30.5, 27.7, 27.0, 20.7.

In vivo *antitumor activity.* Male Syrian golden hamsters, Eppley colony (Sasco, Omaha, NE), 8–9 wk of age at the time of arrival, were housed in a room with a 12-h light/dark cycle and controlled temperature and humidity. Hamsters were given free access to water and food (meal form Harlan-Teklad rodent diet, Madison, WI) unless otherwise indicated. After a 7–14 d adaptation period, 10-wk-old hamsters were injected s.c. with 4×10^6 PC-1 hamster pancreatic ductal adenocarcinoma cells (passage 17) as described by Egami *et al.* (25). PC-1 cells of passages later than 20 were less capable of forming tumors (data not shown). The s.c. implantation of tumors enabled tumor size to be monitored at multiple timepoints, as described below. In experiment 1, one week prior to PC-1 cell transplantation, 15 hamsters per diet group were randomly assigned to either the control diet or an isoprenoid diet containing 40 g/kg diet perillyl alcohol, 20 g/kg diet farnesol, or 20 g/kg diet geraniol, and these diets were continued for the remainder of the experiment. These were the maximal isoprenoid doses that allowed the hamsters to at least maintain their body weight (data not shown). In experiment 2, 36 hamsters were injected s.c. with PC-1 cells as described above, and, at the time of appearance of a tumor >2 mm in diameter, hamsters were randomly assigned to either the control diet or an isoprenoid diet containing 20 g/kg diet farnesol or 20 g/kg diet geraniol. In both experiments, the isoprenoids were mixed with the meal form diet in a food processor.

All diets were stored at −20°C, and fresh diet was given every day to minimize evaporation of the isoprenoids. Hamster body weight was measured twice weekly, and food intake was recorded daily. Because the animals did not spill significant amounts of food, food intake was measured by weighing the hanging feeder and food before and after the hamster was allowed to eat for 24 h. Control animals were pair-fed to the farnesol animals on a daily basis by providing them with a quantity of food equal to that consumed by the farnesol group on the day before. Food intake among the isoprenoid groups was not different (data not shown). Hamsters were palpated twice weekly, and tumor diameter was measured with calipers. When tumors grew to >20 mm in diameter, or by four weeks on therapy, hamsters were killed by CO_2 asphyxiation, and tumors were removed and measured. All animal procedures were carried out in accordance with institutional approval.

Plasma cholesterol analyses. Plasma was isolated from blood samples obtained at necropsy from the control and isoprenoid-fed animals from experiment 1 and stored at −20°C prior to total cholesterol analyses. Briefly, 1 mL of choles-

terol reagent (Sigma Diagnostics, St. Louis, MO) containing cholesterol esterase, cholesterol oxidase, and peroxidase was added to 10 µL of plasma or a standard solution containing 100–400 mg/dL total cholesterol (Sigma). The samples were incubated at 37°C for 5 min, and the A_{500} was measured within 30 min. A standard curve of A_{500} vs. cholesterol concentration was plotted, and sample total cholesterol concentrations were calculated from the slope of the standard curve.

Statistical analyses. Student's *t*-test and chi-square analyses were carried out with StatisticaMac software, version 4.1, (StatSoft, Inc., Tulsa, OK).

RESULTS

The effects of a number of dietary isoprenoids were first tested on cultured human MIA PaCa2 pancreatic ductal adenocarcinoma cells. We have previously reported that perillyl alcohol inhibits the growth of these cells with an IC_{50} of 290 µM (17). Here, the relative effects of other isoprenoids on PaCa2 cell growth were tested. First, dose-response cell proliferation studies were conducted with 0–400 µM of each isoprenoid. All isoprenoids tested readily inhibited PaCa2 cell growth (Fig. 1). The IC_{50} values for the isoprenoids, determined by extrapolation from the graph depicted in Figure 1, were: geranylgeraniol 25 µM; farnesol 39 µM; perillyl amine 45 µM; and geraniol 265 µM. Then, the effects of these isoprenoids on the anchorage-independent growth of the MIA PaCa2 cells were determined. As shown in Fig. 2, all isoprenoids tested inhibited the growth of the human pancreatic tumor cells. Significant (60–90%) inhibition of human pancreatic tumor cell soft agar growth was attained with 25 µM farnesol, 25 µM geranylgeraniol, 100 µM perillyl amine, 100 µM geraniol, or 300 µM perillyl alcohol ($P < 0.05$ vs. control by Student's *t*-test for each isoprenoid at the indicated concentrations).

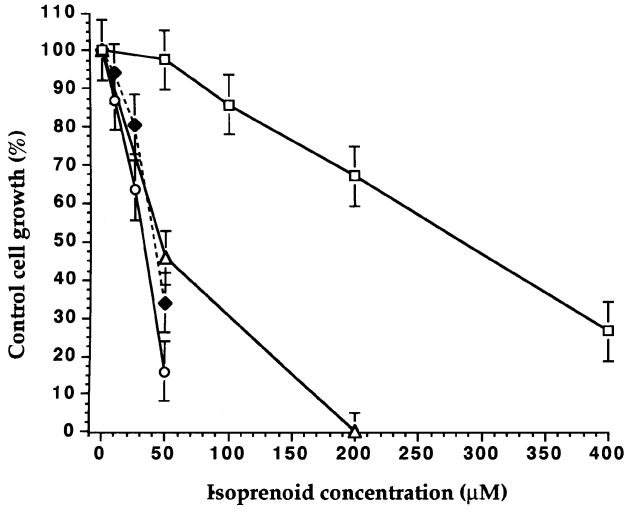

FIG. 1. Inhibition of human pancreatic tumor cell growth by isoprenoids. MIA PaCa2 human pancreatic adenocarcinoma cells were plated at 10,000 per well on day 0 and, beginning on day 1, were treated with 0–400 µM geraniol (◆), farnesol (●), perillyl amine (▲), or geranylgeraniol (■) for 2 d. Cells were harvested and counted on a hemocytometer on days 1 and 3. The cell growth rate, expressed as a percentage of the control, is plotted vs. isoprenoid concentration. The data represent the mean ± SEM, $n = 5$ and are representative of two independent experiments.

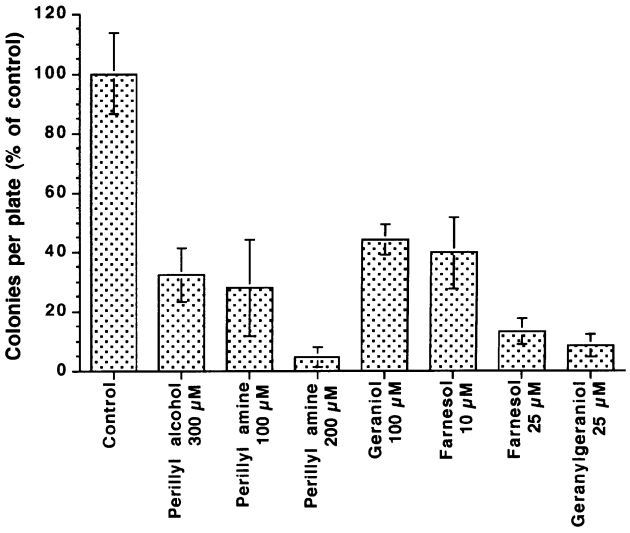

FIG. 2. Suppression of the anchorage-independent growth of human pancreatic tumor cells by isoprenoids. MIA PaCa-2 human pancreatic adenocarcinoma cells were seeded in soft agar at a density of 1000 cells per 60 mm plate, and were incubated in the presence of the indicated isoprenoid for 3 wk. The number of colonies per plate is expressed as a percentage of the control. The data represent the mean ± SEM, $n = 5$ and are representative of two independent experiments.

We then compared the *in vivo* antitumor activity of farnesol, geraniol, and perillyl alcohol in Syrian Golden hamsters bearing transplanted pancreatic tumors (the other isoprenoids were not available in sufficient quantities for animal feeding studies). In experiment 1, hamsters were fed control diet or an isoprenoid diet containing 20 g/kg diet farnesol, 20 g/kg diet geraniol, or 40 g/kg diet perillyl alcohol for 1 wk prior to injection of PC-1 hamster pancreatic ductal adenocarcinoma cells. The animals continued to consume these diets for the remainder of the experiment. The tumor incidence was 5/15 for the control group, 3/15 for the farnesol and geraniol groups, and 4/15 for the perillyl alcohol group. The body weights of the animals consuming the farnesol, geraniol, and perillyl alcohol diets did not differ significantly from one another or from the pair-fed control; group means ranged from 119–127 g at baseline to 119–122 g at the end of the study. Hamsters fed either farnesol or geraniol at 20 g/kg diet exhibited complete inhibition of pancreatic tumor growth ($P < 0.05$ and $P < 0.025$ vs. control, respectively; Fig. 3). Both of these isoprenoids were more potent than perillyl alcohol, which reduced tumor growth by 50% when fed at a dose of 40 g/kg diet (Fig. 3) but did not inhibit tumor growth at a lower dose of 20 g/kg diet (data not shown). Plasma total cholesterol concentrations were then determined for these

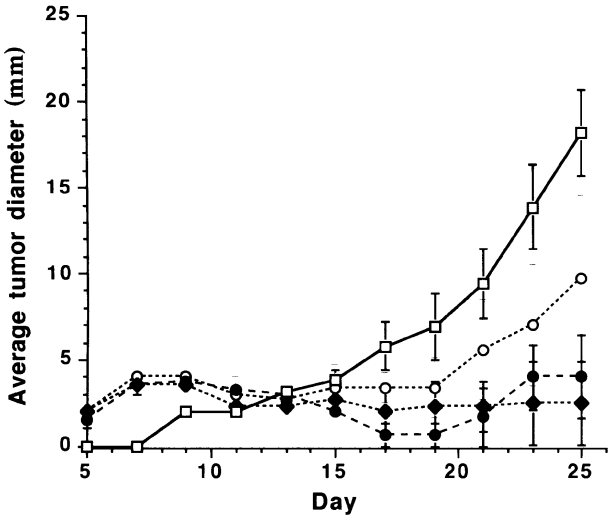

FIG. 3. Inhibition of hamster pancreatic tumor growth by dietary isoprenoids. Hamsters were allowed to acclimate to the control or isoprenoid diets for one week prior to the s.c. injection of PC-1 tumor cells. Average tumor diameter is plotted vs. days after tumor cell injection for animals fed the control diet (❑), 40 g/kg diet perillyl alcohol (○), 20 g/kg diet geraniol (◆), or 20 g/kg diet farnesol (●). The data represent the mean ± SEM, $n = 3$. On day 25, the average tumor diameters of the farnesol and geraniol groups were lower than that of the control ($P < 0.05$ and 0.025, respectively, by Student's *t*-test).

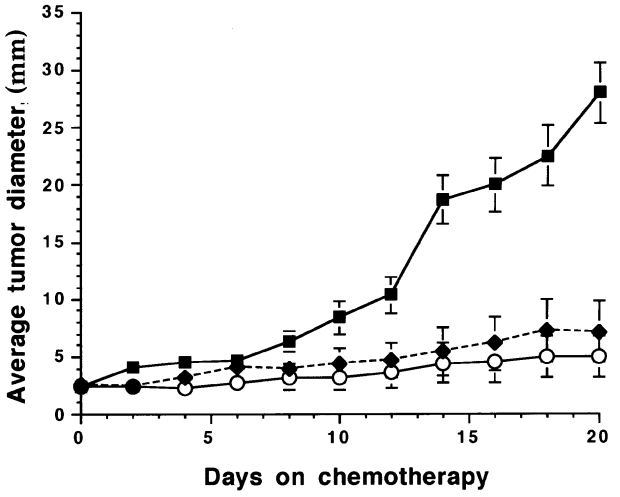

FIG. 4. Chemotherapeutic activity of dietary isoprenoids against pancreatic cancer in the hamster. Animals were randomly assigned to the control (❑), 20 g/kg diet geraniol (◆), or 20 g/kg diet farnesol (○) groups after the detection of a tumor. Average tumor diameter is plotted vs. days on chemotherapy. The data represent the mean ± SEM, $n = 8$. On day 20, the tumor sizes of the farnesol and geraniol animals were significantly less than that of the controls ($P < 0.05$ by Student's *t*-test).

hamsters after 32 d on the respective diets (i.e., 25 d after tumor cell injection). The total plasma cholesterol levels of all hamsters fed farnesol, geraniol, or perillyl alcohol diets were not significantly different from those of the pair-fed control hamsters; group means at the end of the experiment were 135 ± 7; 154 ± 10; 164 ± 11; and 154 ± 10. Similarly, when total plasma cholesterol concentrations of only the tumor-bearing animals were analyzed, there were no statistically significant differences among the diet groups.

Then, in experiment 2, the *in vivo* antitumor activities of farnesol and geraniol were tested in a chemotherapy experiment. Hamsters were injected with PC-1 pancreatic tumor cells as above. Then, when tumors became palpable, the tumor-bearing hamsters were assigned to the 20 g/kg diet farnesol, 20 g/kg diet geraniol, or the pair-fed control group for the remainder of the study. Dietary farnesol or geraniol completely inhibited the growth of the pancreatic tumors ($P < 0.05$ vs. control; Fig. 4). As in experiment 1, the body weights of the isoprenoid-fed animals did not differ from those of the pair-fed controls (data not shown).

Some of the tumor-bearing animals consuming isoprenoid diets exhibited tumor regression, i.e., a tumor that was nonpalpable for three weeks or more. Table 1 contains tumor regression data pooled from experiments 1 and 2. Farnesol and geraniol both caused 8/19 tumors to regress, whereas none of the control tumors regressed. One of the three tumors treated with perillyl alcohol regressed in experiment 1, consistent with our previous observations that 5/31 hamster pancreatic tumors treated with perillyl alcohol regressed (17).

TABLE 1
Isoprenoid-Induced Pancreatic Tumor Regressions

Diet	Tumor regressions[a]	No regression
Control	0	8
Geraniol	8[b]	11
Farnesol	8[b]	11

[a]Tumor regression data are summarized from experiments 1 and 2. Complete tumor regression was scored when tumors were unpalpable for a minimum of three consecutive weeks. Complete tumor regressions were confirmed at necropsy.
[b]Chi-square = 4.79, $P < 0.029$ vs. control.

DISCUSSION

Here, we demonstrate that the dietary isoprenoids farnesol and geraniol effectively inhibit *in vivo* growth of pancreatic tumors either when they are given prior to and following tumor cell injection, or when they are administered following tumor appearance in a chemotherapy setting. These results are consistent with the antitumor activity of geraniol against transplanted murine hepatomas, melanomas, and leukemias (18,19). Farnesol is known to inhibit the growth of cultured tumor cells (20–22), but the data presented here demonstrate for the first time that this isoprenoid has *in vivo* antitumor activity. All of the antitumor effects observed in these experiments occurred at dietary doses that did not cause significant toxicity to the animals. Thus, diet-derived isoprenoids hold promise for improvement in human pancreatic cancer prevention and therapy with low toxicity. While the doses used in this study exceed those likely to occur in foodstuffs, these

diet-derived isoprenoids may be useful as diet supplements or pharmacological agents. The observations that perillyl amine and geranylgeraniol have growth suppressive effects on cultured human pancreatic adenocarcinoma cells suggest that other naturally occurring isoprenoids and isoprenoid analogs may also be effective at preventing and treating pancreatic cancer.

Several interesting structure–activity relationships among the isoprenoids are apparent from these studies. Perillyl amine is more potent than perillyl alcohol in the inhibition of pancreatic tumor cell soft agar growth (Fig. 3), since greater inhibition occurs with 200 μM perillyl amine than with 300 μM perillyl alcohol ($P < 0.05$ by Student's *t*-test). The relative effects of the isoprenoids on cultured human pancreatic carcinoma cell proliferation and soft agar growth were similar (Figs. 1,2). Farnesol was at least sevenfold more potent than either geraniol or perillyl alcohol in the inhibition of culture pancreatic tumor cell growth (17; Figs. 1,2). Geraniol was similar in potency to perillyl alcohol in cultured cells, but was more potent than perillyl alcohol *in vivo*, exhibiting antitumor activity equivalent to that of farnesol (Figs. 3,4). The difference in the relative effects of geraniol and the other isoprenoids may be due to differences in their metabolism or pharmacokinetics in cultured cells and *in vivo*. Perillyl alcohol is extensively metabolized *in vivo* (14,26), but less is known about the metabolism and pharmacokinetics of farnesol (27) and geraniol (28) in mammals.

Isoprenoids have multiple effects on mevalonate metabolism, and some of these effects may account for their antitumor activities in some cell types or species (8). The monoterpenes limonene and menthol inhibit hepatic HMG-CoA reductase activity in the rat (29,30) and can reduce serum cholesterol (31). More recently, perillyl alcohol has been shown to inhibit ubiquinone and cholesterol biosynthesis in cultured NIH3T3 murine fibroblast cells (32). In these cells, the inhibition of cholesterol biosynthesis occurred at the conversion of lanosterol to cholesterol, i.e., downstream of HMG-CoA reductase. Farnesol, a metabolite of the mevalonate pathway intermediate farnesylpyrophosphate (5), has been proposed as a negative regulator of HMG-CoA reductase (33,34). In the experiments described here, substantial inhibition of hamster pancreatic tumor growth by farnesol and by geraniol (Figs. 3,4) was attained in the absence of an effect on total plasma cholesterol. Thus, the mechanism by which isoprenoids inhibit pancreatic tumor growth in the Syrian golden hamster is not likely to involve suppression of HMG-CoA reductase activity.

Both farnesol (21) and perillyl alcohol (15) have been reported to induce apoptosis. Farnesol induces cell death in lymphoma, cervical carcinoma, and other cell types (20–22), and this effect is more pronounced in malignant cells than in normal cells. Similarly, perillyl alcohol has been shown to significantly induce apoptosis in chemically-induced rat liver tumors (15). Thus, it is possible that the antitumor activities of perillyl alcohol, farnesol, and other isoprenoids against pancreatic cancer are due to isoprenoid stimulation of apoptosis. In addition, the recent identification of a rat nuclear receptor that is activated by farnesol (35) suggests that farnesol and perhaps other isoprenoids may have transcriptional effects that play a role in their anticancer activities. The testing of this hypothesis will await the identification of farnesol receptor-responsive genes.

Impaired Cholesterol Esterification in the Plasma in Patients with Breast Cancer

Papasani V. Subbaiah[a,*], Ming Liu[b], and Thomas R. Witt[c]

ABSTRACT: An important factor which determines the movement of cholesterol in and out of the cells is the free cholesterol (FC)/esterified cholesterol (EC) ratio in the plasma. Although this ratio has been shown to be increased in several types of malignancies in humans as well as experimental animals, it is not known whether such an abnormality is found in breast cancer patients. Furthermore, the reasons for such an increase in cancer patients are unknown. We studied the plasma lipid composition and the activity of lecithin–cholesterol acyltransferase (LCAT), the enzyme responsible for the formation of most of EC in human plasma, in 12 women with breast cancer and 9 age-matched control women. The plasma EC concentration was found to be significantly decreased in cancer patients, whereas the FC concentration was unchanged, leading to increased FC/EC ratios ($P < 0.05$). The concentration of phosphatidylcholine, the acyl donor in the LCAT reaction, was decreased significantly, whereas all other phospholipids were unaffected. The cholesterol-esterifying activity of LCAT was significantly lower in cancer patients, whether assayed with endogenous substrates ($P < 0.05$), or with an exogenous substrate ($P < 0.01$). However, another function of the enzyme, namely the lysolecithin acyltransferase activity, was increased ($P < 0.02$), indicating that the enzyme concentration in plasma may not be decreased. These results show that the increase in the FC/EC ratio in cancer patients is due to an impaired esterification of cholesterol by plasma LCAT, probably due to an alteration in the composition of substrate lipoproteins, or the presence of an inhibitory factor.

Lipids 32, 157–162 (1997).

Several studies have reported abnormalities in the lipid and lipoprotein composition in various types of malignancies in humans as well as in experimental animals. These abnormalities include hypocholesterolemia (1,2), hypertriglyceridemia (3), and decreased high density lipoproteins (HDL), especially the HDL_2 subfraction (1,3–5). Many of the lipid disorders appear to be reversed following chemotherapy (6), indicating that they may be the result of malignancy itself.

One of the compositional abnormalities found in various types of human malignancies is an increased ratio of free cholesterol (FC)/esterified cholesterol (EC) (7). When mice were transplanted with ascites tumor, the ratio of FC/EC in plasma increased 2.5 fold within 7 d, although the total cholesterol decreased significantly (8). A similar increase in this ratio was reported in nude mice with pancreatic acinar cell carcinoma (9). This increase primarily resulted from a decrease in EC concentration, whereas the FC concentration remained unchanged. In contrast to other cancer patients, it is not known whether there is an increase in the FC/EC ratio of breast cancer patients. The original study of Saier *et al.* (7) included only 3 breast cancer patients and the results were inconclusive. Other workers reported an increase in FC but no change in EC in the plasma of breast cancer patients (10). Since FC is required for the growth of all cells and since the FC/EC ratio in the surrounding medium affects the movement of cholesterol in and out of cells (11), it is important to determine the mechanisms by which the FC/EC ratio is increased, and whether it is directly related to tumor growth. The possible causes of the increase are: an increase in the synthesis of FC by tissues and its subsequent secretion into circulation, a decreased clearance of FC from plasma, an accelerated selective uptake of EC, and an impaired esterification of cholesterol in the plasma. Although enhanced cholesterogenesis has been shown to occur in growing tumors (12), it is unlikely that an increase in the synthesis of FC is responsible because the total plasma cholesterol is reduced in most cancer patients. On the other hand, a decreased esterification of plasma cholesterol by lecithin–cholesterol acyltransferase (LCAT) may explain not only the increase in FC/EC ratio, but also the decrease in HDL_2 concentration, because the conversion of HDL_3 to HDL_2 is an LCAT-dependent process (13). Most of the EC in human plasma is formed by the action of LCAT, which transfers a fatty acid from phosphatidylcholine (PC) to FC (14). Only a small percentage of plasma EC is derived from the action of tissue acyl CoA/cholesterol acyltransferase in humans, although this reaction may contribute a significant percentage of plasma EC in other species (15,16). The possible role of decreased LCAT activity in cancer patients has not

Abbreviations: EC, esterified cholesterol; FC, free cholesterol; FER, fractional esterification rate; HDL, high density lipoproteins; LAT, lysolecithin acyltransferase; LCAT, lecithin–cholesterol acyltransferase; LDL, low density lipoproteins; MER, molar esterification rate; PC, phosphatidylcholine; TG, triacylglycerol; TLC, thin-layer chromatography.

been investigated in detail. Studies in leukemic patients (17) and in mice bearing ascites tumors (8) found no significant alteration in the enzyme activity, whereas a significant reduction was found in mice with pancreatic cancer (9). To our knowledge, no studies have been carried out in breast cancer patients.

The aim of the present study was to investigate whether the FC/EC ratio is increased in breast cancer, and to determine the possible mechanisms for the increase. The results presented here show that the plasma FC/EC ratio is indeed significantly increased in breast cancer patients, and that this increase is most likely due to a decreased LCAT activity.

MATERIALS AND METHODS

Patients. Plasma samples were obtained from 12 women with histologically proven breast carcinoma, and 9 control subjects. One of the 12 patients had bilateral cancer. The mean age was 53 years (range 40–73 years). The pathology included infiltrating ductal carcinoma in 11 tumors, infiltrating lobular carcinoma in one, and ductal carcinoma *in situ* without invasion in one. The average tumor size was 2.4 cm (range 0.8 cm to 5.2 cm). Five of the 12 patients had histologically involved axillary lymph nodes. The estrogen receptor status was positive in 10 tumors, negative in 1, and borderline in 2. The progesterone receptors were positive in 12 and negative in 1. There was no evidence of metastasis in liver or any other distant site. Definitive local regional management included partial mastectomy with axillary dissection and subsequent radiation therapy in 9 patients, modified radical mastectomy with subsequent radiation therapy in 1, modified radical mastectomy alone in 1, and Halsted radical mastectomy with subsequent radiation therapy in 1. Postoperatively, 5 patients received adjuvant cytotoxic chemotherapy, and 6 patients received adjuvant hormonal therapy (tamoxifen). No patient was on chemotherapy, hormone therapy, or radiation therapy at the time of blood drawing. Control subjects were healthy women volunteers (ages 35–65) who had no history of cancer. None of the patients or controls had hyperlipidemia, diabetes, or hepatic or renal disease, and none was on medications which are known to affect plasma lipid concentrations. Informed consent was obtained from all subjects, and the blood samples were drawn in EDTA, following the overnight fasting. Patient and control samples were processed at the same time, under the same conditions.

LCAT assays. LCAT activity was determined by two different procedures. In the proteoliposome method, which employs an exogenous substrate (18), the labeled proteoliposomes containing 4-^{14}C labeled FC (25,000 dpm/reaction; NEN Dupont, Boston, MA) egg PC, and apoprotein A-I at the molar ratios of 12.5:250:0.8, respectively, were prepared by the cholate–dialysis, and aliquots of plasma (20 μL) were incubated with this substrate and 5 mM mercaptoethanol for 60 min at 37°C, in a final volume of 0.4 mL. The reaction was stopped by the addition of 1 mL methanol and the total lipids were extracted (19). FC and EC were separated on silica gel thin-layer chromatography (TLC) plates with the solvent system of petroleum ether/ethyl acetate (85:15, vol/vol), visualized by exposure to iodine vapors, and were identified with the help of authentic standards run on the same plate. The spots corresponding to FC and EC were scraped, and their radioactivity was determined in a liquid scintillation counter following the addition of 5 mL of scintillation fluid (CytoScint; ICN Biomedical, Costa Mesa, CA). The enzyme activity is expressed as the percentage of labeled cholesterol esterified per hour (fractional esterification rate or FER).

In the endogenous substrate assay (20), labeled FC was first equilibrated with endogenous cholesterol in the presence of 2 mM DTNB, a reversible inhibitor of LCAT, at 37°C for 4 h. The inhibition of the enzyme was then released by the addition of 12 mM mercaptoethanol, and the sample was further incubated for 30 min at 37°C. The lipids were extracted (19), and the percentage of labeled cholesterol esterified (FER) was determined as described above. The molar esterification rate (MER) was determined by multiplying the FER with the FC concentration of the plasma.

Lysolecithin acyltransferase (LAT) activity. The LAT activity of LCAT was estimated by the conversion of labeled lyso PC to PC (21). 1-[1-^{14}C]-palmitoyl lyso PC (250,000 dpm/mL; NEN Dupont) was dispersed by vortexing in 10 mM Tris-Cl buffer pH 7.4, at a concentration of 3 mM. An aliquot of this dispersion (100 μL) was incubated with 100 μL of plasma for 2 h at 37°C, in the presence of 5 mM mercaptoethanol, in a final volume of 0.4 mL. The reaction was stopped by the addition of 1 mL methanol, and the total lipids were extracted (19). Lyso PC and PC were separated on TLC plates with the solvent system of chloroform/methanol/water (65:25:4, by vol). The spots corresponding to these two lipids were scraped, and their radioactivity determined in a liquid scintillation counter, after the addition of 0.5 mL water and 5 mL scintillation fluid. The percentage of lyso PC esterified (FER) was calculated from the radioactivity values. The MER was calculated by multiplying the FER with the concentration of lyso PC in the reaction mixture (lyso PC concentration in 100 μL plasma plus 0.3 μmol present in the labeled substrate).

Lipid estimations. FC, total cholesterol, and triacylglycerol (TG) were determined enzymatically using commercial assay kits (21). The EC concentration was derived by subtracting the FC concentration from total cholesterol. For the determination of phospholipids, the total lipids were first extracted from an aliquot of whole plasma, and separated on silica gel TLC plates, with the solvent system of chloroform/methanol/water (65:25:4, by vol). The spots corresponding to lyso PC, sphingomyelin, PC, phosphatidylinositol and phosphatidylserine and phosphatidylethanolamine were scraped, and the lipid phosphorus was determined by the modified Bartlett procedure (22).

Statistics. All differences between the cancer patients and controls were tested for statistical significance by the Student's *t*-test (two-tailed). Correlations between EC concentration and other parameters were analyzed by the Pearson cor-

relation coefficients (SPSS for Windows software; SPSS Inc., Chicago, IL).

RESULTS

Neutral lipid composition of plasma samples from control and cancer subjects is presented in Figure 1. There was no difference in the concentration of FC, but the concentration of EC was significantly lower in breast cancer patients compared to controls. Consequently, the FC/EC ratio was significantly higher in the plasma of cancer patients (Fig. 2). Similar results were previously reported for other types of malignancies (7). Although the TG concentration was higher in cancer plasma, the difference between controls and patients was not statistically significant, because of high variance.

The phospholipid composition of plasma is shown in Figure 3. While there was no statistically significant difference in most phospholipids, the concentration of PC, which is the substrate for LCAT, and is the most abundant plasma phospholipid, was found to be significantly lower in cancer patients, compared to controls. Similar decrease in PC was reported earlier in the HDL subfractions of breast cancer patients (4).

In order to determine whether the increased FC/EC ratio in cancer patients is due to impaired esterification of cholesterol in plasma, the activity of LCAT was assayed by two different methods. In the proteoliposome method, an exogenous labeled substrate was added to the plasma, and the esterification of labeled cholesterol was determined following a 30-min incubation at 37°C. This assay measures the activity of the enzyme without the influence of endogenous substrates and activators, and is therefore believed to reflect the concentration of the active enzyme in the plasma. In the Stokke and Norum procedure (20), labeled cholesterol is first equilibrated with the endogenous substrate before allowing the enzyme reaction to occur. This procedure measures the activity of the enzyme, as influenced by endogenous substrates, activators, and inhibitors, and therefore represents the *in vivo* activity in circulating plasma. In addition to estimating the LCAT activity by these two methods, we also determined the LAT activity of the enzyme, which measures the transfer of an acyl group from PC to lyso PC instead of FC (23). Since this reaction is activated by low density lipoprotein (LDL) instead of apoprotein A-I, this activity also represents the intrinsic activity of the enzyme, without the influence of HDL, which has been shown to be decreased in some cancer patients (1,3–5). However, this activity is affected by the LDL concentration of plasma (24).

Figure 4 shows the various activities of the enzyme, expressed as FER (percentage of substrate esterified per hour). The cholesterol esterification rate, assayed by both exogenous and endogenous substrates, was significantly lower in breast cancer patients. On the other hand, the LAT activity of the enzyme was significantly higher in patients, compared to controls. However, when expressed as molar esterification rate (nmol of substrate esterified/h/mL plasma), the LAT activity was not significantly different in controls and patients (Fig. 5). The cholesterol esterification reaction, in contrast, was significantly lower in patients, even when expressed as MER. Since this value takes into consideration the concentra-

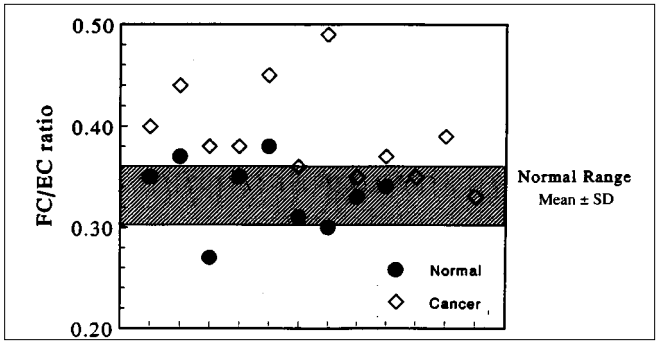

FIG. 2. Individual values of FC/EC ratio in the plasma of patients and controls. The shaded area represents the mean ± 1 SD of normal values. See Figure 1 for abbreviations; ●, normal; ◇, cancer.

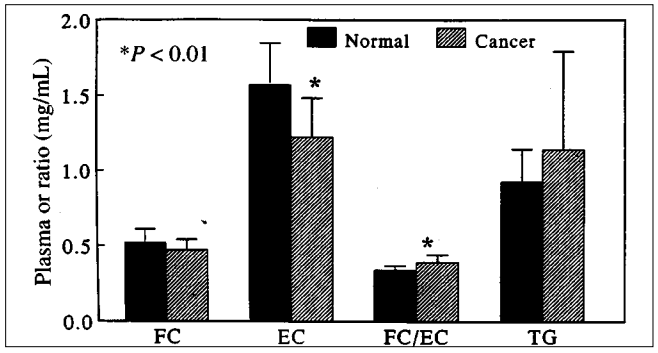

FIG. 1. Neutral lipid composition in plasma of women with breast cancer (n = 12) and in controls (n = 9). Values are expressed as mean ± SD. The significance of difference between the control and cancer samples was determined by Student's t-test. Abbreviations: FC, free cholesterol; EC, esterified cholesterol; TG, triacylglycerol.

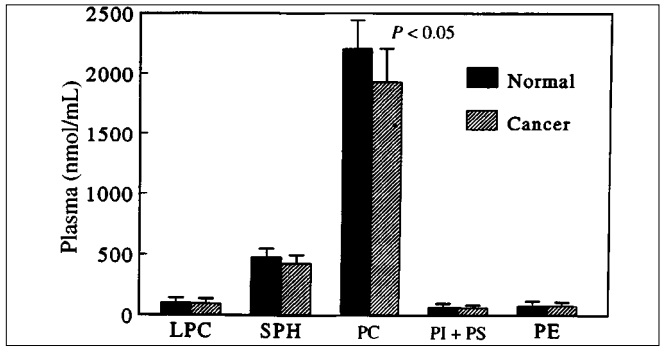

FIG. 3. Plasma phospholipid composition in women with breast cancer (n = 12), and control women (n = 9). Only the differences in PC values were statistically significant. Abbreviations: LPC, lysophosphatidylcholine; SPH, sphingomyelin; PC, phosphatidylcholine; PI + PS, phosphatidylinositol + phosphatidylserine; PE, phosphatidylethanolamine.

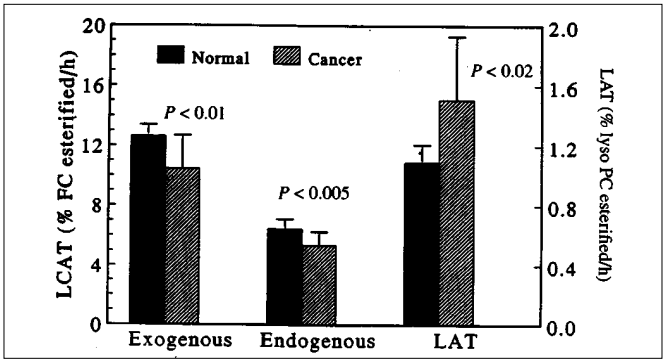

FIG. 4. Fractional esterification rates (FER) of lecithin–cholesterol acyltransferase (LCAT) and lysolecithin acyltransferase (LAT) reactions. LCAT reaction was determined using either an exogenous substrate (proteoliposomes) or endogenous substrates, as described in the text.

tion of endogenous cholesterol, it probably represents the *in vivo* activity more closely. The ratio of cholesterol esterification/lyso PC esterification (LCAT/LAT) was also significantly lower in cancer patients, when expressed as molar activities. Since both activities are carried out by the same enzyme, using endogenous substrates and activators, this decrease in the ratio suggests a specific impairment of cholesterol esterification activity.

Correlations. Since the reason for the increased FC/EC ratio in cancer patients is the decrease in EC rather than an increase in FC, we calculated the correlation of EC concentration with the other parameters measured, in order to determine the possible contributing factors. As expected, the molar LCAT activity (endogenous substrate esterification) showed strong positive correlation with the plasma EC concentration in normal subjects (Table 1). However this correlation was not significant in cancer patients. This suggests that, in addition to the decreased enzyme activity, other unknown factors may have contributed for the lower EC concentration in cancer patients. The EC concentration correlated positively with

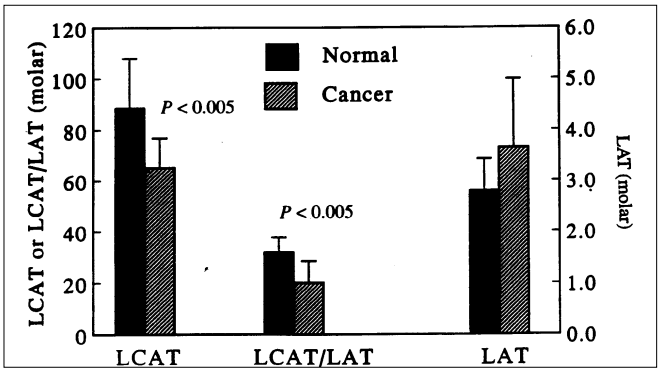

FIG. 5. Molar esterification rates (MER) of LCAT and LAT, and their ratios. The MER for LCAT was calculated by multiplying the FC concentration of plasma with the FER, as obtained in the endogenous substrate assay. The MER of LAT was calculated by multiplying the FER with the concentration of lyso PC present in the plasma and the added labeled substrate. See Figures 1 and 4 for other abbreviations.

TABLE 1
Pearson Correlation Coefficients (*r* values) with EC Concentration[a]

Parameter	Normal (n = 9)	Breast cancer (n = 12)
LCAT, FER (endogenous)	0.19	–0.30
LAT, FER	0.68*	0.02
LCAT, MER	0.77*	0.46
LAT, MER (endogenous)	0.60	0.26
FC	0.80*	0.87**

FC concentration in both the controls and the patients. It also correlated positively with PC, as well as total phospholipids in cancer patients, but not in controls. FC/PC ratio correlated with the EC concentration in both control and cancer subjects, but the correlation was significant only in the former. It was also of interest to note that the LCAT molar activity correlated positively with LAT activity (both FER and MER) in normal subjects, but negatively in cancer patients (results not shown).

DISCUSSION

Cholesterol is an essential membrane component of all mammalian cells, and although all the cells in the body have the capacity to synthesize it, most peripheral cells obtain it from the plasma lipoproteins through the receptor-mediated pathways. In human plasma, over 70% of the cholesterol is in esterified form (EC), and most of this EC is formed in the plasma compartment itself, by the action of LCAT (14). Although an abnormal increase in the ratio of FC/EC was reported in the plasma of experimental animals with tumors and in patients with several other types of cancer (7–9), it is not known whether this abnormality exists in breast cancer patients. The lipid metabolism in breast cancer patients appears to be different from that in other types of cancer. Thus while the total cholesterol is generally decreased in most cancer patients, it was reported to be increased in breast cancer patients (10). Similarly, whereas the EC is decreased in lung cancer and hematologic cancer, it was reported to be unchanged in breast cancer (10).

Our studies clearly show a significant increase in the FC/EC ratio of breast cancer plasma. This increase is primarily due to a decrease in the EC concentration, not to an increase in FC. This observation is in contrast to the results of Alexopoulos *et al.* (10), who reported no change in EC but an increase in FC. The reason for this discrepancy is not clear,

but the patient selection, degree of metastasis, and age of patients may all influence the relative concentrations of FC and EC. It should also be noted that in the study of Alexopoulos *et al.* (10) the concentration of FC in breast cancer patients was not actually higher than in other types of cancer or of other control plasma. The "increase" in FC is mainly due to an unusually low concentration of FC in the specific group of control samples used for comparison.

The decrease in plasma EC appears to be directly related to a decrease in the LCAT activity, as determined by two different assay methods. The lower LCAT activity in cancer patients could be due to a reduction in the plasma concentration of the enzyme, its apoprotein activators, or its lipoprotein substrates. The decrease in the activity as assayed by the proteoliposome method, where the substrates and the activator proteins are not limiting, suggests that the concentration of active enzyme in the plasma may indeed be lower. It has been shown that tumor necrosis factor α is increased in some breast cancer patients (3). Since this cytokine has been shown to inhibit the synthesis of LCAT in experimental animals (25), it is possible that the hepatic synthesis of LCAT is reduced in some breast cancer patients. On the other hand, there was a significant increase in the LAT activity of the enzyme in cancer patients, suggesting that the concentration of the enzyme may be normal, but the activator/inhibitor concentrations may be different in control and breast cancer patients. The LAT activity of the enzyme is activated by LDL, whereas the cholesterol esterification reaction occurs mainly on the HDL particles (23). Since the concentration of HDL is decreased in breast cancer (3,4), it is possible that the cholesterol esterification activity is affected by the concentration or composition of the HDL, or both. It should also be pointed that there is significant decrease in the concentration of PC (Fig. 3) (4), the acyl donor for cholesterol esterification. Another possibility is the presence of an inhibitor of LCAT in cancer plasma. For example, it is known there is an increase in the concentration of certain gangliosides in cancer plasma (26). Our preliminary results show that the gangliosides, such as GM_3 and GM_1, are powerful inhibitors of the enzyme (Liu, M., and Subbaiah, P.V., unpublished observations), suggesting that they may also inhibit the enzyme in some cancer patients. However, further studies are needed to confirm this possibility.

The consequence of lower LCAT activity may not only be related to the higher FC/EC ratio in the plasma but also to the lower HDL levels previously reported (1,3–5). Furthermore, an increase in the FC/EC ratio may favor an influx of FC into the cells, similar to the increased FC/PC ratio, thus providing more cholesterol for cell growth and proliferation. The FC/PC ratio in whole plasma was also slightly higher in cancer patients (0.64 ± 0.10 vs. 0.60 ± 0.12) but was not statistically significant. However, it is possible that this ratio is significantly higher in certain lipoprotein subfractions involved in cholesterol efflux. Previous studies (27,28) have shown that an inhibition of LCAT activity in the serum leads to almost complete inhibition of net cholesterol removal from the cells, and an increase in cellular cholesterol content. A decrease in plasma LCAT activity would therefore lead to an inhibition of the reverse cholesterol transport, and possibly increased tumor growth. It would be of great interest to investigate whether the LCAT activity is restored to normal levels when the tumor is eliminated through surgery and chemotherapy. A recent report (29) showed that the plasma FC is decreased and EC is increased following tamoxifen treatment of postmenopausal women who had breast cancer, suggesting an increase in LCAT activity, although these authors did not specifically determine the LCAT activity in these patients.

Effects of Dietary Cholesterol and Triglycerides on Lipid Concentrations in Liver, Plasma, and Bile

Michael L. Booker*, Wayne W. LaMorte, Eve R. Beer, and Susan R. Hopkins

Department of Surgery, Boston University Medical Center,Boston, Massachusetts 02118

ABSTRACT: Dietary cholesterol (CHL) and triglycerides (TG) can influence plasma, hepatic, and biliary lipid composition, but effects on lipids in these three compartments during the early stages of CHL gallstone formation have not been studied in parallel. We fed prairie dogs diets containing one of four test oils (safflower, coconut, olive, or menhaden) at either 5 or 40% of calories, in the presence of 0 or 0.34% CHL, for 3 wk. In the absence of dietary CHL, increases in dietary TG produced 50–200% increases in the concentrations of biliary CHL and hepatic cholesteryl ester (CE), while the concentrations of hepatic free CHL (FC) as well as plasma FC and CE remained relatively unchanged. Increasing dietary CHL to 0.34% resulted in increases in hepatic FC of approximately 50% for all four fats regardless of whether they were supplied at 5 or 40% of calories. CHL supplementation caused more pronounced increases in biliary CHL (200–400%), hepatic CE (50–200%), plasma FC (up to 100%), and plasma CE (up to 150%), and these increases were exacerbated by concurrent supplementation of dietary fat and CHL (biliary CHL: 300–700%; hepatic CE: 100–250%; plasma FC: up to 165%; plasma CE: 100–350%). These results indicate that enhanced secretion of biliary CHL and, to a lesser extent, increased synthesis of hepatic CE, may be primary mechanisms for maintaining the hepatic FC pool. Furthermore, dietary CHL and high levels of fat intake are independent risk factors for increasing biliary CHL concentrations, and adverse effects on lipid concentrations in plasma and bile tend to be exacerbated by ingestion of diets rich in both fat and CHL.

Lipids 32, 163–172 (1997).

Diet exerts an important influence over lipid homeostasis, and perturbations in lipid metabolism are important contributing factors in the etiology of diseases such as atherosclerosis and cholesterol (CHL) cholelithiasis. It is now almost universally accepted that hypercholesterolemia is an important independent risk factor for atherosclerosis (1–3), and a number of reports indicate that high levels of dietary CHL (4–7) or saturated fat (8–10) lead to an elevated concentration of plasma CHL carried in the atherogenic low density lipoprotein (LDL) fraction. In addition, high levels of dietary CHL and saturated fat have been linked to secretion of bile supersaturated with CHL (11,12), which is a pre-condition for the development of CHL gallstones (13,14). Diet also has an impact on the levels of plasma triglycerides (TG), and hypertriglyceridemia may be relevant to both atherosclerosis (15) and CHL gallstone disease (16).

It is now widely held that the population should be advised to reduce dietary CHL and saturated fat, but controversy exists over the optimal levels of total fat intake as well as which dietary TG represents the optimal substitute for saturated fats. Evidence suggests that n-6 polyunsaturated fats are effective in lowering plasma CHL concentrations, with most of the reduction occurring in the atherogenic LDL fraction (17,18). However, a potential drawback to the use of these dietary fats is a reported decrease in the antiatherogenic high density lipoprotein (HDL) fraction (19,20). Monounsaturated fats also reduce levels of plasma CHL (17–20), with the added advantage that the reduction appears to be specific for the LDL fraction (19,20). Finally, the n-3 polyunsaturated fats derived from marine sources appear to be highly effective in the treatment of hypertriglyceridemia (21–23), but they have been reported to both decrease (22–24) and increase (25,26) plasma CHL concentrations.

One potential problem with recommending consumption of oils which lower plasma lipoproteins is they may be associated with increased biliary secretion of CHL. A group of men ingesting a hypocholesterolemic diet enriched in n-6 polyunsaturated vegetable oils demonstrated an increased incidence of CHL gallstones (27). A recent study in prairie dogs also suggested that consumption of n-6 TG might increase the biliary secretion of CHL (28). However, the effect of dietary TG on biliary lipid secretion has not been systematically examined.

The present studies were undertaken to examine lipid metabolism during the early stages of CHL gallstone formation in the prairie dog, a commonly used animal model for CHL cholelithiasis (29,30). The prairie dog is a particularly good model for these studies, since similarities with humans have been demonstrated for both plasma (31) and biliary lipids (32). By analyzing the effects of varying levels of dietary CHL as well as varying types and levels of dietary fat on he-

patic, plasma, and biliary lipids in the prairie dog, these experiments examined the role of diet in lipid homeostasis.

MATERIALS AND METHODS

Animal studies. Animal studies were approved by the Institutional Animal Care and Use Committee at Boston University School of Medicine. Adult female prairie dogs *(Cynomys ludovicianus)* weighing 0.8–1.2 kg were purchased from R-Zoo (Neshkoro, WI). During an initial 1 wk equilibration period, all animals received a standard rodent chow diet (Purina, Purina Mills, Inc., St. Louis, MO). Six animals were then assigned to each of 16 diets for 3 wk as follows: (i) four diets containing trace CHL and 5% of calories from one of the following test oils: safflower, coconut, olive, or menhaden oil; (ii) four diets containing trace CHL and 40% of calories from test oil; (iii) four diets containing 0.34% CHL and 5% of calories from test oil; or (iv) four diets containing 0.34% CHL and 40% of calories from test oil. All diets contained at least 1 g of safflower oil/kg diet to prevent essential fatty acid deficiency. Tables 1 and 2 provide a detailed description of the diets. All diets appeared to be equally well accepted by the animals.

Three weeks after assignment to one of the 16 dietary groups, animals were fasted overnight and anesthetized with ketamine HCl 100 mg (Ketalar; Parke-Davis, Division of Warner-Lambert Co., Morris Plains, NJ) and acepromazine maleate 2 mg (PromeAce; Fort Dodge Laboratories, Fort Dodge, IA), delivered together as a single intramuscular injection. The gallbladder was removed, and its contents were aspirated for analysis of biliary lipids. A 1 g sample of liver was harvested from the inferior edge of the right lobe for measurement of hepatic lipids. Blood was collected from the inferior vena cava for measurement of plasma lipids, and a fatal dose of anesthetic was administered.

Lipid assays. Samples of gallbladder bile were stored at –20°C prior to analysis of total bile salts (BS) by the hydroxysteroid dehydrogenase method of Talalay (33) as modified by Admirand and Small (34). The sample of liver was homogenized in methanol immediately after harvesting, and lipids were extracted from fresh aliquots of bile, plasma, and liver homogenate by the method of Folch *et al.* (35). Hepatic, plasma, and biliary phospholipids (PL) were measured by the method of Bartlett (36). Biliary CHL was measured by the method of Rudel and Morris (37). The CHL saturation index (CSI) was calculated as described by Kuroki *et al.* (38). Plasma total CHL was saponified in ethanolic KOH, and plasma total and free CHL (FC) were measured by the CHL oxidase method (39). Plasma cholesteryl ester (CE) was determined as the difference between total and free CHL. Hepatic FC and CE were separated by thin-layer chromatography on silica gel G plates in the solvent system hexane/diethyl ether/acetic acid (70:30:1) and eluted with chloroform/methanol/diethyl ether (1:1:1). After saponification of the CE fraction in ethanolic KOH, hepatic FC and CE were measured by the CHL oxidase method (39). Hepatic and plasma TG were measured using a commercially available kit (Sigma Chemical Co., St. Louis, MO).

Analysis of bile salt species by HPLC. The relative proportions of individual BS species in gallbladder bile were measured as described by Rossi *et al.* (40). High-performance liquid chromatography (HPLC) was performed with a Shimadzu (Columbia, MD) system consisting of an LC-6A solvent delivery system, an SPD-6A variable wavelength detector, and a C-R3A Chromatopac integrator; elution was performed with an Ultrasphere ODS 4.6 × 250 mm reverse-phase column (Beckman Instruments, Fullerton, CA).

Data analysis. Results for groups of animals (n = 4–6) are reported as the mean ± SEM. All tests of significance were conducted using Statistical Analysis Software (SAS) licensed to Boston University. Differences among the 16 dietary

groups were tested for statistical significance by analysis of variance using the General Linear Models procedure. When analysis of variance indicated significant differences among the groups, *post hoc* multiple comparisons were conducted with Least Squares Means. Relationships between dietary parameters (type of oil, % fat, and % CHL) and hepatic, plasma, and biliary lipids also were examined with three-factor analysis of variance using the General Linear Models procedure.

RESULTS

Free cholesterol concentrations. Changes in the levels of dietary TG and CHL influenced FC concentrations in liver, plasma, and bile, but the pattern of change differed among these three compartments. Not surprisingly, the lowest levels of FC were seen with diets which did not contain CHL. Figure 1 (A and B) shows that supplementation with olive, safflower, or menhaden oil in the absence of dietary CHL resulted in similar low concentrations of FC in liver and plasma. Coconut oil tended to give slightly higher values for both hepatic and plasma FC. Increasing dietary TG from 5 to 40% of calories had no influence on the levels of FC in either liver ($P = 0.30$) or plasma ($P = 0.16$), regardless of the type of dietary TG. A different pattern of response was seen in bile, however, in which FC concentrations were low for all four dietary TG when provided at 5% of calories, but increased by

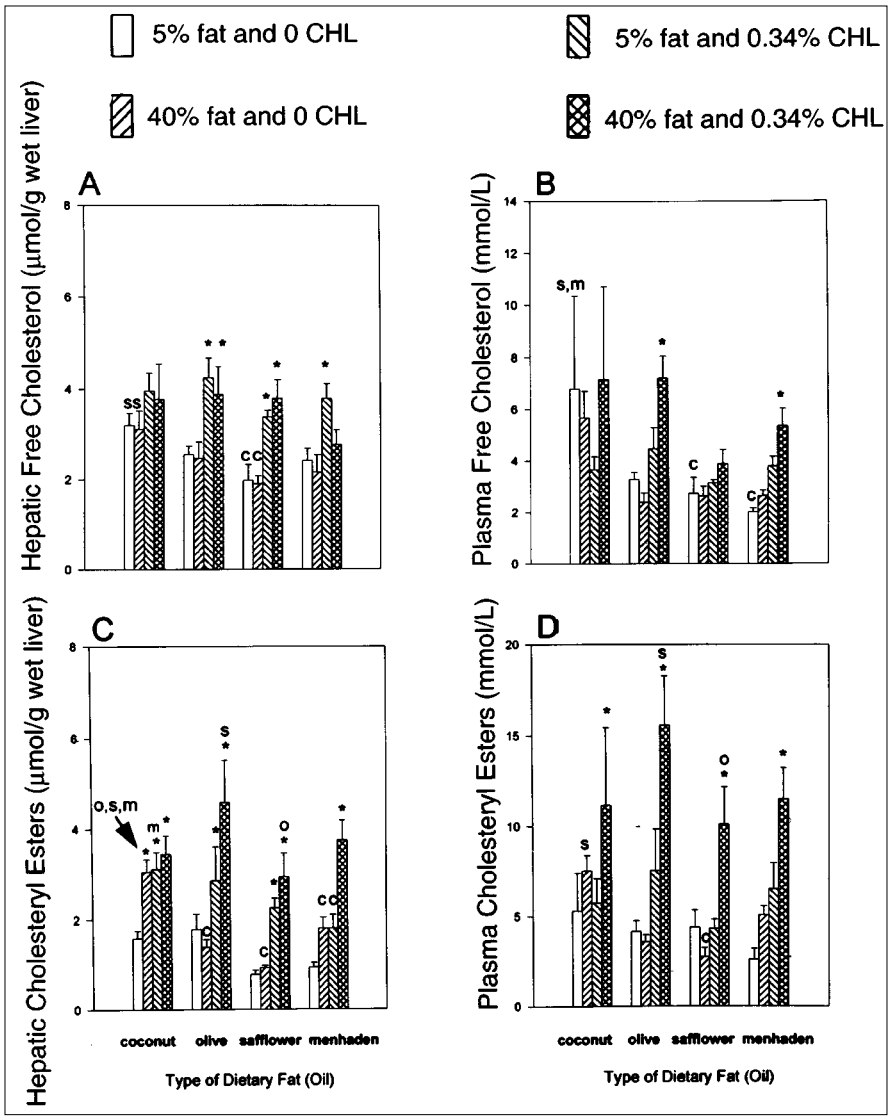

FIG. 1. Effect of dietary fat and cholesterol on the concentrations of cholesterol (CHL) in liver and plasma. A: Hepatic free cholesterol. B: Plasma free cholesterol. C: Hepatic cholesteryl ester. D: Plasma cholesteryl ester; c: $P < 0.05$ compared to coconut oil; o: $P < 0.05$ compared to olive oil; s: $P < 0.05$ compared to safflower oil; m: $P < 0.05$ compared to menhaden oil; *$P < 0.05$ compared to 5% fat, no CHL group within same dietary oil.

50–200% when dietary fat caloric intake was increased to 40% ($P = 0.0001$) (Fig. 4A).

As shown in Figures 1B and 3A, dietary supplementation with CHL increased the concentrations of FC in plasma by up to twofold ($P = 0.04$) and in bile by 200–400% ($P = 0.0001$). Furthermore, in these two compartments, there was a trend for the CHL-induced increases in FC to be exacerbated by concurrent high levels of dietary TG. With the exception of biliary CHL in the menhaden oil group, this additive effect was observed with all four types of dietary fat. The concentration of FC in plasma increased by up to 165% in response to supplementation with both fat and CHL ($P = 0.06$), with safflower oil having the least detrimental effect. The changes were even more dramatic in bile, where the concentration of FC increased by 300–700% for all types of oil but menhaden. In contrast to the results obtained in plasma and bile, Figure 1A shows that the inclusion of 0.34% CHL in the diets consistently caused hepatic FC levels to rise, but regardless of the type or amount of dietary TG, hepatic FC only increased by approximately 50% to 3.5–4.0 µmol/g liver. In the case of hepatic FC, there was no additive effect of dietary fat and CHL ($P = 0.67$).

Cholesteryl ester concentrations. As illustrated in Figure 1C, hepatic concentrations of CE were similar among the four dietary oils when provided at 5% of calories without dietary CHL. Hepatic CE increased in response to dietary CHL ($P = 0.0001$) and increases in fat ($P = 0.0001$), but the effect varied depending on the type of dietary TG. With coconut oil or menhaden oil, hepatic CE rose in response to both dietary CHL (coconut: 140%; menhaden: 60%) and an increase in dietary fat (coconut: 140%; menhaden: 60%). In contrast, with olive oil or safflower oil, increases in dietary fat alone had no apparent effect on CE, but supplementation of dietary CHL caused significant increases in CE (olive: 60%; safflower: 200%). Despite these apparent differences, there was a trend in each of the four oil groups for the greatest elevations in hepatic CE (100–250%) to occur when diets were enriched with both fat and CHL ($P = 0.16$).

Figure 1D shows a somewhat similar pattern of response in plasma CE. Increases in dietary fat had a variable influence ($P = 0.0004$), with modest increases in plasma CE occurring only in response to increases in coconut oil or menhaden oil. Dietary CHL alone also had a variable effect ($P = 0.0001$), with 80 and 150% increases in plasma CE for olive oil and menhaden oil, respectively. Nevertheless, marked increases of 100–350% were seen with diets containing both CHL and a high level of dietary fat for all four dietary oils ($P = 0.004$).

TG concentrations. Figure 2A shows that when fat intake was limited to 5% of calories, the concentration of hepatic TGs did not differ significantly among the four types of di-

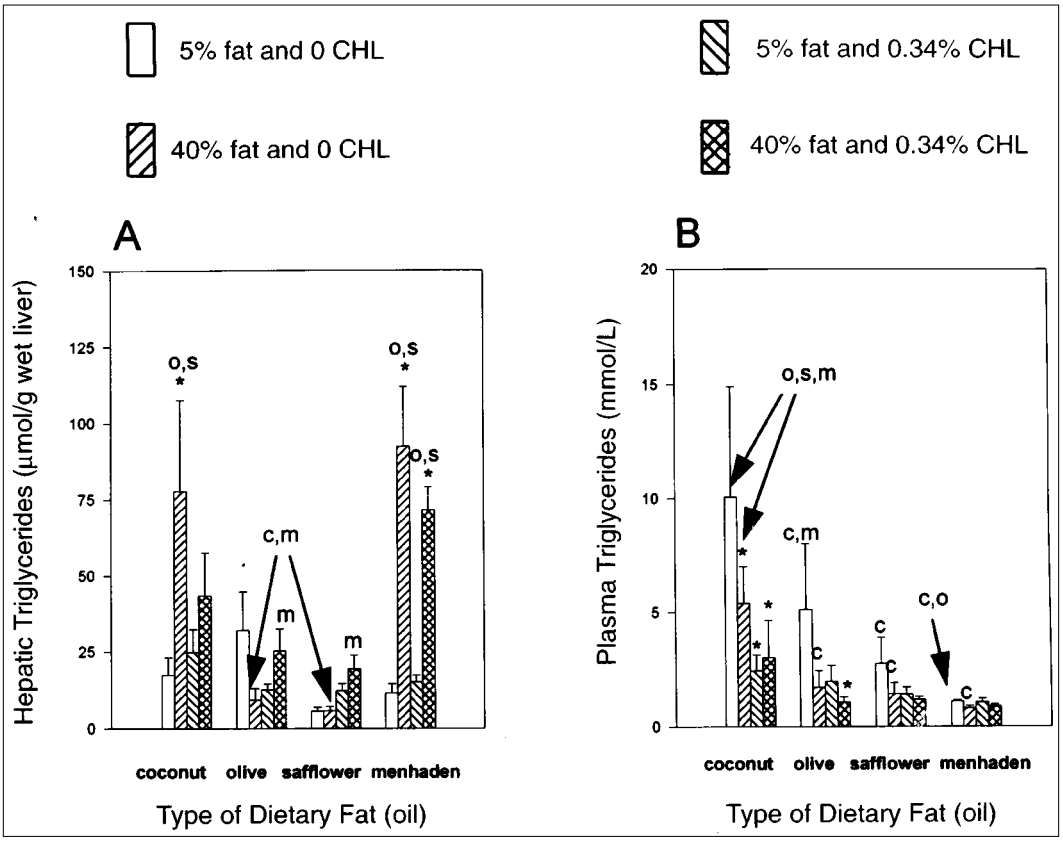

FIG. 2. Effect of dietary fat and cholesterol on the concentrations of triglyceride in liver and plasma. A: Hepatic triglyceride. B: Plasma triglyceride. c, o, s, m, * and abbreviation as described in Figure 1.

etary oils, and hepatic TG concentrations also appeared to be relatively unaffected by dietary supplementation with CHL ($P = 0.71$). On the other hand, there was a variable effect of increased dietary fat among the four dietary oils ($P = 0.0001$). Diets with high levels of coconut oil or menhaden oil produced substantial increases in hepatic TG concentrations, while increases in olive oil or safflower oil did not. The highest concentrations of hepatic TG were seen with the two diets containing 40% of calories from menhaden oil. The increases in TG concentrations in the liver in response to coconut or menhaden oil were not accompanied by similar increases in plasma TG (Fig. 2B). In fact, the menhaden oil diets consistently produced the lowest concentrations of TG in plasma. The highest plasma TG concentrations were seen with 5% coconut oil and 5% olive oil in the absence of dietary cholesterol, but plasma TG levels varied substantially within these two groups.

Hepatic and plasma phospholipid (PL) concentrations. There were few significant changes in the concentration of either hepatic or plasma PL (data not shown).

Biliary lipid concentrations. The effects of dietary fat and CHL on the lipid composition of gallbladder bile are illustrated in Figure 3. As noted above, the FC concentration in gallbladder bile was low for all four dietary TG when provided at 5% of calories, but increased when any of the dietary fats was increased to provide 40% of calories. Biliary FC concentrations increased even more when the diet was supplemented with 0.34% CHL, and, except for menhaden oil, the greatest concentrations in biliary FC occurred when diets contained both CHL and high levels of fat. Changes occurred in biliary

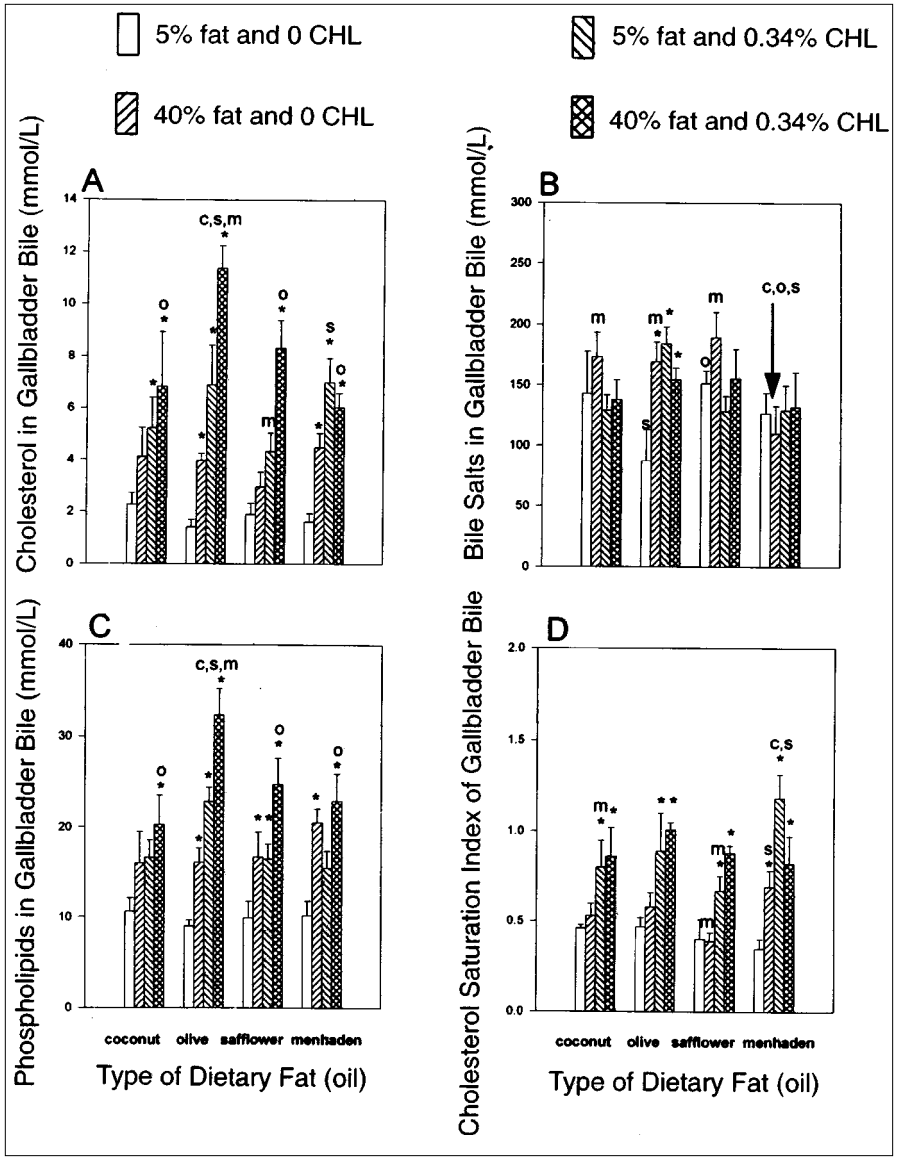

FIG. 3. Effect of dietary fat and cholesterol on the concentrations of lipids in gallbladder bile. A: Cholesterol. B: Bile salt. C: Phospholipid. D: Cholesterol saturation index. c, o, s, m, * and abbreviation as described in Figure 1.

PL concentrations in response to dietary CHL ($P = 0.0001$) or increased dietary fat ($P = 0.0001$), and they tended to mirror changes in biliary FC. The greatest increases in FC and PL concentrations in bile were seen in the animals fed diets containing CHL and high levels of olive oil. The concentrations of BS varied from diet to diet, but differences tended to be minimal, and there was no distinct effect which could be attributed to the type or amount of dietary fat or to the presence of CHL in the diet. As shown in Figure 3D, the highest values for CSI were obtained with diets containing CHL ($P = 0.0001$), although in general bile tended to remain unsaturated.

Analysis of the BS species in gallbladder bile by HPLC revealed that in the prairie dog, the predominant species are taurocholate (TCA) and taurochenodeoxycholate (TCDCA) (Fig. 4). A shift from TCA to TCDCA was associated with both supplementation with dietary CHL ($P = 0.0001$) and increases in dietary fat ($P = 0.0001$), with concurrent supplementation having an additive effect ($P = 0.005$). The ratio of TCA/TCDCA showed an inverse relationship to the concentration of FC in gallbladder bile ($r = -0.61$; $P = 0.0001$).

DISCUSSION

Many studies have examined the effects of dietary lipids on plasma lipoproteins, and other studies have demonstrated that dietary CHL and TG intake can also influence biliary lipid composition. The liver, of course, plays a critical role in determining how diet will ultimately affect lipid concentrations

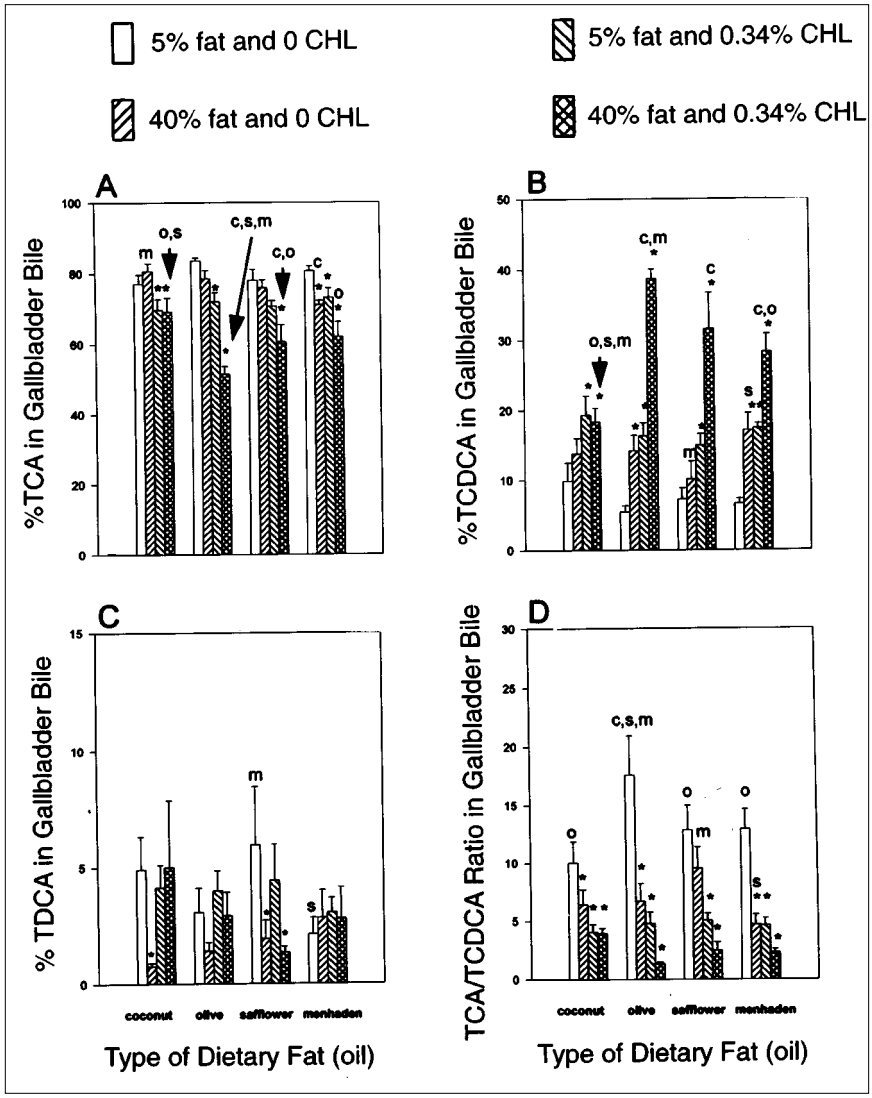

FIG. 4. Effect of dietary fat and cholesterol on the relative concentrations of bile salt species in gallbladder bile. A: Taurocholic acid (TCA). B: Taurochenodeoxycholic acid (TCDCA). C: Taurodeoxycholic acid (TDCA). D: Taurocholic acid/taurochenodeoxycholic acid (TCA/TCDCA) ratio. c, o, s, m, * and abbreviation as described in Figure 1.

in either plasma or bile. The studies reported here are somewhat unique because, first, they explored the impact of dietary CHL and TG on all three compartments (liver, plasma, and bile) simultaneously, and second, the effects of diet were examined by comparing 16 different diets in which the type of dietary TG, the amount of TG, and the amount of dietary CHL were systematically varied. In addition, the studies were designed to examine lipid concentrations prior to the formation of CHL gallstones, since the presence of stones in the gallbladder can potentially alter lipid metabolism. The major findings obtained from this experimental approach were as follows: (i) supplementation with dietary CHL resulted in increases in the CHL levels in liver, plasma, and bile, (ii) the effects of an increase in dietary fat were less extensive, with increases occurring primarily in biliary CHL, but also to some extent in hepatic CE, (iii) increases in both dietary CHL and fat frequently had a synergistic effect, resulting in the highest levels of plasma and biliary CHL, (iv) the type of dietary oil had a more profound effect on TG levels than on CHL, and (v) increases in hepatic FC concentrations were more limited than the increases in FC in bile or plasma.

Increased dietary fat consumption probably raised the input of CHL to the hepatic compartment. However, hepatic FC levels remained relatively normal, whereas the concentrations of biliary CHL and, to a lesser extent, hepatic CE increased. Larger increases in hepatic CHL levels, such as those in response to ingestion of CHL-supplemented diets, resulted in expansion of the hepatic FC pool. However, even in these cases, the increase in hepatic FC was modest compared to the dramatic elevations in biliary CHL and hepatic CE. Although neither the secretion of biliary CHL nor the synthesis of hepatic CE was measured directly, these results suggest that alterations in the levels of these two lipids are important for maintaining the hepatic FC pool. Furthermore, while there was evidence that input of total CHL to the hepatic compartment was increased by supplementation with either dietary fat or CHL, concurrent supplementation produced hepatic FC concentrations no higher than those resulting from CHL supplementation alone. However, the highest levels of hepatic CE and biliary CHL were observed in those animals receiving high levels of fat and CHL simultaneously. These findings imply that although it is possible to increase hepatic FC above normal levels if the input of CHL to the liver is high enough, there is a limit above which excess FC will either be excreted or converted to a storage form. Finally, the concentrations of plasma CHL became elevated only in the presence of severe increases in hepatic CHL, suggesting that the primary response to an increased input of CHL into the hepatic compartment is an augmented biliary CHL secretion.

The finding in this study that coconut oil raised plasma CHL concentrations in comparison to olive, safflower, and menhaden oils in the absence of dietary CHL supplementation is consistent with previous reports of the link between saturated fats and hypercholesterolemia (8–10), and also with studies demonstrating a hypocholesterolemic effect of monounsaturates (17–20) and n-6 (17,18) and n-3 polyunsaturates (22–24). On the other hand, in the presence of 0.34% dietary CHL, the concentrations of plasma CHL were elevated for all dietary oils. Given the prevalence of CHL in the human diet, these results support current recommendations for the reduction of total fat consumption, regardless of the degree of unsaturation. It should be noted that in this study the amount of CHL ingested per kg of body weight was probably about 10–12 times greater than in a "typical" American diet (41). The 0.34% CHL diet was chosen because it is a frequently used "lithogenic" diet in this animal model. However, in view of our findings, it would be of interest to examine the metabolic responses to a more moderate dietary CHL load.

Menhaden oil supplementation resulted in the lowest levels of plasma TG, similar to previous studies reporting a hypotriglyceridemic effect of marine n-3 polyunsaturated fats (21–23). Some controversy exists as to the mechanism by which this reduction in TG occurs. Several reports indicate that fish oil and n-3 polyunsaturated fatty acids reduce hepatic TG synthesis (42–44), while other evidence suggests that n-3 oils reduce plasma TG by inhibiting hepatic secretion (45,46). The present study suggests that fish oil decreases hepatic TG secretion, since the 40% menhaden oil diet resulted in low plasma TG concentrations in the presence of high levels of hepatic TG. However, as TG synthesis was not measured directly in this study, the possibility exists that both synthesis and secretion were reduced, with the change in synthesis masked by the accumulation of TG which would likely occur as the result of the inhibition of secretion.

Recent studies indicate that dietary CHL can induce hypertriglyceridemia in the rat *via* an increased synthesis of fatty acid and secretion of TG by the liver (47,48). However, in the present study, dietary CHL actually reduced the concentration of plasma TG for all oil groups. Furthermore, the only lipid parameter which failed to show a significant response to dietary CHL supplementation was the concentration of hepatic TG. A potential explanation is that in the prairie dog, rather than stimulating TG synthesis, CHL derived from the diet is converted in the liver to CE and preferentially secreted in very low density lipoprotein (VLDL) at the expense of TG.

Diet also influences the hepatic secretion of biliary lipids, particularly CHL. Increased biliary CHL secretion is probably the primary factor responsible for CHL cholelithiasis in western populations. In this study the concentration of biliary CHL increased as a result of dietary fat supplementation, although significant differences in comparison to the low fat, trace CHL animals were obtained for the olive and menhaden oil groups only. In light of previous studies which cited increases in biliary CHL in response to dietary saturated fats (12) as well as to n-6 (49,50) and n-3 polyunsaturated fats (51,52), it is interesting to note that in the present study, the highest concentrations of biliary CHL were obtained during CHL supplementation in the olive oil group. Since the predominant fatty acid contained in olive oil is oleic acid, these results suggest that an increased dietary intake of the n-9 monounsaturated fats may also result in an enhanced secre-

tion of CHL into bile. The saturation of bile with CHL was not substantially increased by supplementation with dietary fat alone, because there were corresponding increases in biliary PL. Biliary PL also increased in response to elevations in dietary CHL, but a proportionally greater increase in biliary CHL produced significant increases in CSI. Nevertheless, gallbladder bile generally remained unsaturated in this study due to the relatively brief duration of feeding of experimental diets. In our experience, supplementation with CHL at the level of 0.34% requires a minimum of 3–4 wk to induce CHL-saturated bile.

The concentrations of BS were not significantly influenced by diet in this study, although changes in BS secretory rate may have occurred. However, ingestion of dietary fat and CHL did induce alterations in the species of BS secreted, and these changes may have physiological significance as well. Chenodeoxycholic acid possesses a greater equilibrium CHL solubility than cholic acid (53), and relative increases in the concentration of the former in conjunction with increases in bile lithogenic index have been reported (54,55). In the present study, the TCA/TCDCA ratio significantly decreased with dietary CHL supplementation, in agreement with previous reports in humans (54), hamsters (56), and prairie dogs (29). Dietary fat supplementation also significantly decreased the TCA/TCDCA ratio for all oils tested. To our knowledge, this is the first evidence that dietary fat exerts an independent effect on the relative composition of BS species. Furthermore, there was a trend toward even lower ratios when dietary fat and CHL were increased concurrently, a situation which yielded the highest concentrations of biliary CHL. One possible explanation is that a shift toward TCDCA synthesis occurs whenever there is an increase in the hepatic FC pool and therefore a need to secrete more CHL into bile.

The changes in lipid concentration which were documented in this study could have occurred through several physiological mechanisms. Evidence exists that the regulatory pool of FC within the liver is maintained by coordination of the activities of hydroxymethylglutaryl-CoA reductase (57,58), acyl CoA-cholesterol acyltransferase (59,60), and cholesterol 7 α-hydroxylase (61,62). In addition, the hepatic LDL-receptor provides an important level of control in lipid homeostasis (63,64). Finally, the regulation of apoprotein synthesis influences the assembly and metabolism of the plasma lipoproteins (64,65). Modulation of any of these regulatory factors in response to diet is possible, and further work in each of these areas is currently underway in this laboratory. This study provided a broad examination of the overall effects of dietary fat and CHL on lipid concentrations, but more detailed information regarding the changes occurring at the molecular level will be crucial for a better overall understanding of the complexities of lipid homeostasis.

ACKNOWLEDGMENTS

This work was supported primarily by a grant from Scotia Pharmaceuticals Ltd., Guildford, England, and also by funding from the Charles H. Tyler Fund and National Institutes of Health Grant #HL49268. The authors gratefully acknowledge the help of the Zapata Haynie Corporation (Reedville, VA) for generously supplying the menhaden oil used in the test diets.

The Influence of Dietary Lipids on the Composition and Membrane Fluidity of Rat Hepatocyte Plasma Membrane

A.G. Clamp[a], S. Ladha[b,*], D.C. Clark[b], R.F. Grimble[a], and E.K. Lund[b]

[a]Department of Human Nutrition, University of Southampton, Southampton, SO9 3TU, and [b]Institute of Food Research, Norwich Laboratory, Norwich Research Park, Colney, NR4 7UA Norwich, United Kingdom

ABSTRACT: Weanling male Wistar rats were fed for five weeks on standard rat chow (23 g fat/kg diet) or one of four synthetic diets with butterfat, coconut oil, corn oil, or fish oil as the main lipid source (100 g fat/kg diet). In all diets, 10% of the fat was provided as corn oil to prevent essential fatty acid deficiency. Significant differences were observed in the saturated, monounsaturated, and polyunsaturated fatty acid composition, and in the ratio of cholesterol to phospholipid, in the hepatocyte membranes. The fluidity of hepatocyte plasma membranes was assessed using the fluorescence recovery after photobleaching technique and steady-state fluorescence anisotropy of diphenylhexatriene. No significant differences were found in the fluidity of plasma membranes between animals on the different fat diets, despite diet-induced changes in their fatty acid composition. However, the proportion of lipid free to diffuse in the plasma membrane varied with diet, being significantly greater ($P < 0.05$) in animals fed chow (63.7%), coconut oil (61.5%), and butterfat (57.6%) diets than in those fed the corn oil (47.3%) diet. Animals fed fish oil showed an intermediate (50.0%) proportion of lipid free to diffuse. The data support the hypothesis that dietary lipids can change both the chemical composition and lateral organization (lipid domain structure) of rat hepatocyte plasma membranes.
Lipids 32, 179–184 (1997).

The fatty acid composition of the cell membrane modulates its structure, fluidity, and function (1,2). Cellular functions, including production of eicosanoids and other secondary messengers (3–6), receptor function (7–9), and enzyme activity (10,11) may be altered by changes in the membrane composition. Such changes may be achieved through manipulation of dietary lipid intake (12,13). Membrane fluidity is influenced by changes in the level of unsaturation of the phospholipid fatty acyl chains (14,15), phosphatidylethanolamine ratios (16), cholesterol to phospholipid, or protein to lipid ratios (17–19) and fatty acyl chain length (20). The fluidity of the membrane has been shown to modulate cellular functions such as secretion, chemotaxis, signal transmission, and susceptibility to microorganism invasion (21–23).

In vivo, the ratio of saturated to unsaturated fatty acids and the amount of cholesterol in the membrane are closely regulated. This may represent a mechanism for maintaining membrane fluidity within certain limits for optimal membrane function known as "homeoviscous adaptation" (14,24). These mechanisms may be expected to influence the composition of the membrane following manipulation of dietary lipid intake, and hence resist attempts to alter membrane fluidity. Current evidence suggests that the cell membrane is not homogenous in character, but is composed of lipid "domains" which vary in size, composition, and, potentially, fluidity (11,25). Compositional changes may not therefore occur in a uniform manner throughout the membrane. Furthermore, changes in the fluidity of the domains may take place, without any change being measured in overall or "bulk" fluidity.

The present study uses steady-state anisotropy and fluorescence recovery after photobleaching (FRAP) to investigate the extent to which chronic changes in dietary lipid intake affect the composition and physical properties of rat hepatocyte plasma membranes. Steady-state anisotropy determines rotational motion and is sensitive to changes in the packing of the lipid molecules in the membrane, whereas FRAP measures the freedom of molecules to diffuse laterally in the plane of the membrane. Measurement of rotational diffusion provides information about molecular motion on a molecular length scale and in the case of FRAP, measurements of lateral diffusion provide information about molecular motion on a larger scale, determined by the dimensions of the illuminated spot on the membrane surface. Thus this latter measurement is sensitive to the presence of barriers to diffusion that may be present within the membrane, resulting in domain formation.

MATERIALS AND METHODS

Animals and diets. Twenty weanling male Wistar rats were maintained for five weeks on a diet composed of either standard rat chow (23 g fat/kg diet) (Special Diets Services,

*To whom correspondence should be addressed.

Abbreviations: C/PL, cholesterol to phospholipid; D, lateral diffusion coefficient; DPH, diphenylhexatriene; FRAP, fluorescence recovery after photobleaching; HBSS, Hank's balanced salts solution; ODAF, 5-*N*-(octadecanoyl) aminofluorescein; %R, percentage recovery.

Witham, Essex, United Kingdom), or one of four synthetic diets (100 g fat/kg diet) containing butterfat (Dairy Crest, Surbiton, Surrey, United Kingdom), coconut oil (Booker Foodstuffs, Dorset, United Kingdom), corn oil (Mazola/CPC, Esher, Surrey, United Kingdom), or fish oil (MaxEPA; Seven Seas Healthcare, Hull, United Kingdom) as the main lipid source. In all diets, 10% of the fat was provided as corn oil to prevent essential fatty acid deficiency. (For fatty acid composition of diets, see Table 1). The diets were otherwise identical and adequate in protein (177 g casein/kg diet, 3 g dL-methionine/kg diet), carbohydrate (285 g sucrose/kg diet, 285 g starch/kg diet), fiber (100 g cellulose powder/kg diet), vitamins and minerals (50 g vitamin E-free vitamin and mineral mixture/kg diet, (Special Diets Services), supplemented with appropriate levels of vitamin E to provide 90 mg vitamin E/kg of diet). Care was taken with respect to storage and allocation of the diets to minimize susceptibility to oxidation. The animals were individually housed in wire-bottomed cages at 22°C on a 12-h light/dark cycle, with free access to food and water.

Hepatocyte isolation. After five weeks, the livers were excised, macerated and hepatocytes isolated by incubation with Ca^{2+}/Mg^{2+}-free Hank's balanced salts solution (HBSS) (Sigma Chemical Company, Poole, Dorset, United Kingdom) for 5 min, followed by 10 mg/100 mL collagenase (Boehringer Ltd., Lewes, Sussex, United Kingdom) in Ca^{2+}/Mg^{2+}-containing HBSS (Sigma), at 37°C pH 7.4, for 20 min. Dispersed liver cells were filtered, washed, and resuspended in Ca^{2+}/Mg^{2+}-containing HBSS. This cell suspension was used for the isolation of plasma membranes and the measurement of lateral mobility of the membrane lipids.

Plasma membrane preparation. Rat liver plasma membranes were prepared according to the method of Loten and Redshaw-Loten (26).

Membrane composition. Total lipids were extracted from the isolated plasma membrane preparations by the method of Bligh and Dyer (27), and phospholipids separated from nonpolar lipids by thin-layer chromatography. Phospholipids were methylated by heating with boron trifluoride–methanol (Sigma), and the fatty acid derivatives separated on a gas chromatograph (Hewlett-Packard 5890 Series II, Palo Alto, CA). This method provided quantitative analysis of the fatty acids present by comparison with internal standards. Free cholesterol content was assayed enzymically using cholesterol oxidase (28,29).

Lateral mobility of membrane lipids. This was measured using the fluorescence recovery after photobleaching (FRAP) technique (30), using 5-*N*-(octadecanoyl) aminofluorescein (ODAF) (Molecular Probes, Eugene, OR) as the fluorescent probe. This technique measures the lateral diffusion coefficient (D) of a fluorescent lipid analogue that has been introduced into the plasma membrane. In addition, the proportion of membrane lipids that are mobile, i.e., free to diffuse out of the *ca*. 1 µm diameter measured region of the plasma membrane during the time course of the experiment, can be calculated from the data and expressed as a percentage recovery (%R) of fluorescence. A suspension of hepatocytes (50 µL) was incubated for 15 min on ice with 20 µL ODAF (33 µM), made up to 500 µL with Ca^{2+}/Mg^{2+}-containing HBSS. The labeled hepatocytes were centrifuged at 100 × *g* for one minute, washed twice with HBSS, and finally resuspended in 50 µL HBSS. A sample of this suspension was loaded by capillary action into a microslide (viewing path length 0.05 mm) (Camlab Ltd., Cambridge, United Kingdom) and was viewed on a Nikon Optiphot microscope equipped with a 100× objective lens and using brightfield or full-field epi-fluorescent illumination. Following selection and alignment of the target cells for FRAP measurement, a small region of the cell (1.3 μm^2) was illuminated using an attenuated laser beam (Coherent Innova 100, Palo Alto, CA). The FRAP measurement was computer-controlled and comprised a prebleach phase (*ca*. 0.5 s), a bleach period (7 ms) and a recovery phase (*ca*. 2 s). For each sample of hepatocytes, three sets of 10 FRAP measurements were taken, a different cell being used for each reading. Values for the diffusion coefficient and percentage recovery were calculated from each set of 10 FRAP measurements using methods described previously (30). The microslide was kept at a temperature of 37°C during the course of the experiment.

Membrane order. This was determined by fluorescence anisotropy of the probe diphenylhexatriene (DPH, Molecular Probes) under steady-state conditions using a spectrofluorometer (Perkin-Elmer LS-5, Norwalk, CT) coupled with an L-format polarization unit (31). DPH prepared as a 2-mM stock solution in tetrahydrofuran was stored refrigerated and protected from light. Equal volumes (0.5 mL) of hepatocyte plasma membranes (100 µg protein/mL) and DPH dispersion (2 µM) were mixed and incubated at 25°C for 30 min. Sample temperature was then adjusted and fluorescence measured over a range of temperatures with constant stirring. Temperature was monitored continuously using a digital thermometer with an accuracy of ±0.1°C. Excitation and emission wave-

lengths were 355 and 428 nm, respectively. The results were corrected for light scattering (32,33).

The equation used to determine anisotropy (r) is given below:

$$r = \frac{I_{VV} - G \cdot I_{VH}}{I_{VV} + 2G \cdot I_{VH}} \quad [1]$$

where I_{VV} and I_{VH} are the emitted light components polarized vertically (V) and horizontally (H) with reference to the polarization orientation of the excitation light and G is an instrumental correction factor (30). Membrane fluidity is inversely proportional to anisotropy.

Statistics. All data were analyzed using unpaired Student's *t*-tests, with a probability level of 5% or less being accepted as statistically significant. Correlation coefficients were calculated by linear regression analysis.

RESULTS

Body weights and food intakes of the animals were recorded throughout the experiment, and no significant differences were found between the five dietary groups.

Plasma membrane phospholipid fatty acid compositions in rats fed the various diets are shown in Table 2. Considerable variation from the chow controls was observed. In chow-fed animals, the predominant fatty acid species were 16:0, 18:0, 18:2n-6, and 20:4n-6. In butter-fed animals, the membrane phospholipids had a significantly reduced 18:2n-6 content, with a concomitant increase in 18:0 and 18:1n-9. Coconut oil-fed rats demonstrated a significant depletion of 16:0 and 18:2n-6, and an increase in 18:0 and 18:1n-9 compared to chow controls, and had double the 20:4n-6 content of their membrane phospholipids. Feeding the corn oil diet elicited similar changes to the coconut oil diet, with a significant depletion of 16:0 and increased 18:0 and 20:4n-6 content. The effects of fish oil largely opposed the other experimental diets with significantly increased 16:0, 18:1n-9, 18:3n-3, 20:5n-3, and 22:6n-3 content being observed, relative to controls, with notable depletion of 18:0, 18:2n-6, and 20:4n-6 fatty acids.

The ratio of unsaturated to saturated fatty acids did not vary significantly from the control in any of the experimental groups. The ratio of n-3 to n-6 fatty acids in hepatocyte membrane phospholipids was significantly greater in the animals fed fish oil (0.75) than in any of the other experimental diets, or in chow-fed controls (0.13). Cholesterol to phospholipid (C/PL) ratios varied significantly from control in all rats fed experimental diets except those fed butterfat. Ratios were lower in coconut- and fish-oil fed animals, and higher in those fed corn oil. The C/PL ratio was negatively correlated with the ratio of n-3 to n-6 fatty acids in the membrane phospholipids ($r = 0.95$, $P < 0.05$).

Lateral diffusion coefficients in hepatocyte plasma membranes from the various dietary groups showed no significant variations from the chow-fed controls (Fig. 1). Lateral diffusion was positively correlated with the ratio of n-3 to n-6 fatty acids in the membrane phospholipids ($r = 0.89$, $P < 0.05$), and, to a lesser extent, negatively correlated with the C/PL ratio ($r = 0.76$, ns). However, the proportion of membrane lipids which were mobile as determined by FRAP analysis (%R) was influenced by dietary manipulation (Fig. 2). Corn oil-fed rats (47.3%) were found to have significantly reduced mobility relative to controls (63.7%).

Table 3 shows the values obtained for the fluorescence anisotropy (r) of DPH at 37°C in the hepatocyte plasma membranes of animals fed the different diets. Higher values indicate a smaller range and rate of motion of the DPH probe, suggesting a less fluid membrane. Values of r ranged from 0.1176 in the coconut oil-fed animals to 0.1455 in those ani-

mals fed corn oil diets. There were no significant differences in membrane fluidity between the dietary groups.

DISCUSSION

Plasma membrane fatty acid composition is determined by the availability and biotransformation of stearic acid (18:0) to oleic acid (18:1n-9, and oleic, linoleic (18:2n-6) and linolenic (18:3n-3) acids to polyunsaturated fatty acids (1). In the present study, quantities of oleic acid were increased, and those of linoleic acid decreased, in animals fed the experimental diets compared with chow-fed controls. Quantities of arachidonic acid (20:4n-6) were significantly different in all diets, increasing in content in the order fish oil < chow < butterfat < corn oil < coconut oil. Membrane phospholipids from fish oil-fed animals contained significantly greater quantities of n-3 fatty acids, and less n-6 fatty acids, than those from any of the other diets. Thus the fatty acid composition of the diet significantly influenced that of the hepatocyte membrane phospholipids.

The lateral diffusion coefficient of ODAF in the hepatocyte plasma membrane was not influenced significantly by the diet-induced changes in the fatty acid composition of hepatocyte membrane phospholipids. Lateral diffusion coefficients were positively correlated with the ratio n-3 to n-6 fatty acids, and, to a lesser extent, negatively correlated with the ratio of C/PL in the membranes. The observed effects of the experimental diets on C/PL ratios were consistent with results from other studies (7,24,34). Since cholesterol increases the order of lipids in the membrane, leading to reduced fluidity (13), the negative correlation found between diffusion rates and C/PL ratios was expected, and agrees with results from other studies (17,18).

Steady-state fluorescence anisotropy of DPH in the hepatocyte plasma membranes was also not influenced significantly by diet. This result is consistent with other findings (35,36), and suggests that packing of the lipid molecules of the plasma membrane is largely unaffected by the diets. It is also interesting to note that both FRAP and anisotropy measurements provide consistent results. For example, hepatocyte cell membranes from animals fed corn oil diets exhibit both the lowest rates of lipid lateral diffusion and the highest values for fluorescence anisotropy, suggesting that these membranes are the least fluid. This result may be due to the C/PL ratio of the membranes, which is highest in the corn oil group.

Membrane fluidity is not influenced by dietary manipulation, of the type described in the present study probably due to homeoviscous adaptation. There is evidence to suggest that homeoviscous adaptation occurs *in vivo* (14,24), maintaining membrane fluidity within narrow limits. To a certain extent, this will be achieved through the specificity of the *sn*-1 and

TABLE 3
Fluorescence Anisotropy (*r*) of Hepatocyte Plasma Membranes at 37°C[a]

Diet	Chow	Butterfat	Coconut oil	Corn oil	Fish oil
r	0.1276 ± 0.0069	0.1201 ± 0.0038	0.1176 ± 0.0097	0.1455 ± 0.0055	0.1219 ± 0.0080

[a]Values are expressed as mean ± SEM for four observations per dietary group. No significant differences were found between the dietary groups.

sn-2 positions of the major phospholipids for saturated and unsaturated fatty acids, respectively (13). This is reflected in the lack of any significant differences between the unsaturated to saturated fatty acid ratios in the membrane phospholipids in animals fed the different fat diets, and is consistent with results from other studies (13,24,37). Homeoviscous adaptation may be involved in the "fine tuning" of membrane fluidity, by regulating membrane cholesterol content, phospholipid class distribution, and/or the activities of the membrane-bound desaturase and elongase enzymes. These activities may be regulated by membrane fluidity itself *via* a negative feedback mechanism (20,38). The existence of homeoviscous adaptation implies that maintenance of membrane fluidity, within certain limits, is important for membrane function.

Homeoviscous adaptation may also be an important factor to consider when examining plasma membrane composition. The composition of the membrane will be determined both by the diet and by the changes initiated by the cell in response to any change in membrane fluidity. Whether a homeoviscous adaptation response has occurred in the present study, and to what extent the membrane compositional changes are due to diet alone, or to a combination of diet and homeoviscous adaptation, is unclear. Furthermore, owing to the domain-like nature of the plasma membrane, it is possible that the fluidities of the various membrane domains may change without a significant change in the overall fluidity. The fluidity of certain areas may therefore be significantly influenced by manipulation of dietary lipids, although no overall change is detected.

Although there were no significant differences observed in plasma membrane diffusion coefficients between the dietary groups, differences were seen in the %R of the membranes. Hepatocyte membranes from animals fed corn oil had a significantly lower value for %R than those fed chow, coconut oil, or butterfat. This would seem to indicate that there was a greater proportion of immobile lipid in hepatocyte cell membranes from animals fed the corn oil diet. This change in the physical state of the membrane may have functional significance. The low value for %R found in hepatocyte plasma membranes from corn oil-fed animals may have been expected, since these membranes have the greatest C/PL ratio and cholesterol has been shown to rigidify membranes (17,18). The extra cholesterol is probably not, however, evenly distributed throughout the membrane, leading to "cholesterol-poor" (relatively mobile) domains (25). As the cholesterol content of the membrane increases, so does the size of the cholesterol-rich domains, leading to a greater proportion of immobile lipid, and consequently a lower %R. Nevertheless, the %R of hepatocyte membranes from animals fed the fish oil diet was not significantly greater than that found in the corn oil-fed animals, despite the former having the lowest C/PL ratio of any of the dietary groups. Evidence suggests, however, that the highly unsaturated phospholipids associated with membranes from animals fed fish oil are unlikely to associate with cholesterol, and may thus create extremely fluid domains containing mostly phospholipid fatty acyl group which are highly unsaturated and more rigid cholesterol-rich domains leading to no overall change in membrane fluidity (39). Although there is less cholesterol overall in fish oil-supplemented membranes, it is confined to specific immobile domains, and hence a lower %R is determined by FRAP. This phenomenon might be thought to result in greater interdomain variation in hepatocyte plasma membranes from animals on the fish oil diet when compared to animals on the other diets. The results of the present study suggest that this is indeed the case.

In summary, rat hepatocyte plasma membrane composition can be altered by feeding animals diets of different fatty acid composition. Diet-induced membrane compositional changes do seem to influence, to a limited extent, the lateral diffusion of membrane lipid but significantly alter the lipid domain structure of the cell membrane. Whether these changes in the chemical composition and physical state of the membrane have any significant functional implications remains to be determined.

ACKNOWLEDGMENTS

We are grateful to the BBSRC for providing a research studentship to Alan G. Clamp and for supporting part of this work. S. Ladha, E. Lund, and D. Clark were supported by OST funding from the BBSRC. We also acknowledge recurrent research support to The Ministry of Agriculture, Fisheries and Food for England and Wales. We thank Seven Seas Health Care for the gift of MaxEPA and Dairy Crest for the gift of butter. We are grateful to W. Vas Dias for providing the fatty acid composition of the fish oil diet.

Early Dietary Intervention with Structured Triacylglycerols Containing Docosahexaenoic Acid. Effect on Brain, Liver, and Adipose Tissue Lipids

Merete Myrup Christensen and Carl-Erik Høy*

Center for Food Research, Department of Biochemistry and Nutrition,
The Technical University of Denmark, DK-2800 Lyngby, Denmark

ABSTRACT: Newborn rats were fed liquid diets containing 7 wt% fat in which 3.8% of the total fatty acids were 22:6n-3. The fats were either a specific structured oil with 22:6n-3 mostly located in the *sn*-2 position or a randomized oil with 22:6n-3 equally distributed in the triacylglycerol (TAG) molecules. The oils were manufactured by interesterification of fish oil TAG with free fatty acids from butterfat. The pups were tube-fed three times a day and stayed with their dams during the night. After 14 d they were fed solid diets containing the same oils for the next 7 d. A reference group stayed with the dams and received ordinary rat chow at weaning. In general no significant differences between the two dietary treatments were observed in the tissues examined except for adipose tissue. The levels of 22:6n-3 were significantly increased in brain phosphatidylcholines (PC) and phosphatidylserines (PS) of both experimental groups compared with the reference group after three weeks, whereas no differences were found in brain phosphatidylethanolamines (PE) and phosphatidylinositols (PI). In all groups and all phospholipids examined, the levels of 20:4n-6 generally decreased from 1 to 3 wk and were significantly lower in the experimental groups compared with the reference group at 3 wk except for PI. In liver, PC and PE 22:6n-3 remained constant in the experimental groups but decreased significantly in the reference group, whereas in liver PS 22:6n-3 increased in all groups, but reached significantly higher levels in the experimental groups than in the reference group. In adipose tissue, 22:6n-3 increased in the experimental groups during the study period, but decreased in the reference group, suggesting that a surplus of dietary 22:6n-3 was stored.
Lipids 32, 185–191 (1997).

Polyunsaturated fatty acids (PUFA), especially docosahexaenoic acid (22:6n-3), are present in high amounts in the central nervous system (CNS) (1). They accumulate during the first 15 d after birth in the rat (2) and in humans in the fetal state and the first 6–10 mon after birth (3). The newborn rat is therefore a relevant model for the pre-term infant.

The biochemical significance of the enrichment in 22:6n-3 in the CNS is unclear. It takes, however, up to three generations to introduce n-3 deficiency in rats (4), indicating a strong ability to maintain these fatty acids in the brain and CNS. Prenatal deficiency in n-3 PUFA affects the fatty acid composition of the brain by reducing, in particular, the levels of 22:6n-3 (5,6), which correlates with reduced visual ability in rhesus monkeys (7). Brain fatty acid profiles of growing animals following recovery from n-3 fatty acid deficiency change very slowly compared to other tissues in both rats and monkeys (4,7). The adult brain is resistant to changes in dietary fatty acid composition (8), whereas the developing brain is much more plastic (9).

It is not known whether an optimal level of 22:6n-3 in brain phospholipids exists or which phospholipids are most important. In this context we have demonstrated that feeding fish oil as a source of n-3 PUFA affects rat brain phospholipids more than dietary flaxseed oil (10). We have also recently shown that the lymphatic absorption of a PUFA is enhanced when the PUFA is situated in the *sn*-2 position in the dietary TAG both under normal conditions (11) and in pancreatic insufficiency (12), and that the TAG structure of dietary fats influences the clearance rate of chylomicrons as well as the tissue uptake (13).

Interesterified oils made from medium-chain TAG and long-chain TAG have proven beneficial in patients with lipid malabsorption symptoms providing both essential fatty acids and readily oxidizable energy in the form of medium-chain fatty acids (MCFA) (14). Since the lipases in the gastrointestinal tract are *sn*-1/3 specific and enhanced absorption of the fatty acid in the *sn*-2 position is observed (11), specific structured TAG made by enzymatic interesterification, which preserves the PUFA in the *sn*-2 position, may improve the availability of PUFA. In the present investigation we therefore compared the dietary effect of a specific structured oil with 22:6n-3 located in the *sn*-2 position and a randomized oil, with the same fatty acid profile but with 22:6n-3 distributed evenly in the TAG molecule, on the accumulation of (n-3)

Abbreviations: CNS, central nervous system; MCFA, medium-chain fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SCFA, short-chain fatty acids; TAG, triacylglycerol; TLC, thin-layer chromatography.

PUFA in the brain phospholipids of the newborn rat. The specific structured oil contained short- and medium-chain fatty acids from butter in the 1- and 3-positions. To examine the general accretion of 22:6n-3 in other organs or tissues, liver phospholipids and adipose tissue TAG were also examined.

MATERIALS AND METHODS

Synthesis of the specific structured and the randomized oil. The specific structured oil (Table 1) was manufactured by interesterification of a fish oil (Thyborøn Fiskeolieindustri A.m.b.a., Thyborøn, Denmark) and free fatty acids from butterfat using an *sn*-1/3 specific lipase (Lipozyme®; Novo Nordisk A/S, Bagsværd, Denmark) (15,16). By this procedure, long-chain PUFA were maintained in the *sn*-2 position whereas short- and medium-chain fatty acids from the butterfat were incorporated into the *sn*-1/3. The randomized oil (Table 1) was made from the specific structured oil by interesterification with sodium methoxide (17). The fatty acid compositions of the *sn*-2 position (Table 1) were determined following regiospecific Grignard degradation (11).

[a]Fatty acid composition of triacylglycerols (TAG). Values are in mole%, averages of two determinations.
[b]Fatty acid composition in the *sn*-2 position, determined by Grignard degradation.
[c]Short- and medium-chain fatty acids (S/M FA): 4:0 to 12:0; n.d., not detected.

Animals. Pregnant Wistar rats (Møllegård Breeding Centre A/S, Ll; Skensved, Denmark) were housed in plastic cages and provided with tap water *ad libitum*. Room temperature was maintained at 24°C, the relative humidity was 45%, and the light/dark cycle was 12/12 h. Following delivery, dams and pups were divided into three groups. Two groups each of 4 dams and 24 pups received diets with structured oil or randomized oil, respectively, and a reference group of 3 dams each with 8 pups received rat chow (Altromin C0199; Altromin Inc., Lange, Germany). The chow contained 4 wt% fat with the following fatty acid profile: 14:0, 1.1%; 16:0, 27.5%; 18:0, 1.4%; 18:1, 14.4%; 18:2, 50.2%; 18:3, 4.9%). The pups stayed with their dams the first two days. At 8 a.m. on the third day, pups and dams were separated, and the pups were placed under a lamp at 30°C. At 10 a.m., and at 1 p.m. and 4 p.m., the pups were weighed and then fed 0.1 g liquid diet (see below) through a polyethylene tube mounted on a glass pipette. After the last feeding at 4 p.m., the pups were returned to their dams where they stayed until next morning. The weight of the feed per meal was gradually increased during the experimental period to 0.3 g. This feeding regimen continued for two weeks, whereafter they received a solid diet (see below) containing the same oils as the liquid diets. The pups in the reference group stayed with their dams throughout the feeding period, and were given rat chow at the time of weaning. On the third day (day 1 in the feeding regimen) before the feeding started, and after 1 and 3 wk five pups were decapitated and brain, liver, and adipose tissue dorsal to the kidneys were immediately excised and frozen in liquid nitrogen.

Liquid diets. Powder diet for rats (Altromin C189a without fat; Altromin Inc., Lange, Germany) was mixed with water and the manufactured oil in the ratio 60 g powder/15 g oil/150 mL water and mixed overnight with a magnetic stirrer. The composition of diet was (in wt%) protein, 8.4%; carbohydrates, 14.3%; fat, 6.7%.

Rat milk. The dams of the reference group were milked on day 5 and the fatty acid composition was determined (18) (Table 1).

Solid diets. After weaning, the pups were fed *ad libitum* a diet composed of (in wt%): 40% starch, 20% fat (the manufactured oils), 20% casein, 10% sucrose, 5% salt mixture, 4% cellulose powder, 0.5% choline chloride, and 0.5% vitamin mixture (19).

Analyses of tissue lipids. Brain, liver, and adipose tissue were extracted according to Folch *et al*. (20). Phospholipid classes in brain and liver were separated by thin-layer chromatography (TLC) (10) and methylated with BF_3 (21). Adipose tissue TAG was isolated by TLC (22), and methylated with KOH (23). The fatty acid methyl esters were analyzed by gas–liquid chromatography using a Fisons Instruments HRGC Mega 2 series 8560 gas chromatograph with flame-ionization detection (Fisons Instruments, Milano, Italy), and a BPX-70 fused silica capillary column (25 m × 0.22 mm i.d.) (SGE, Melbourne, Australia). On-column injection was applied. Initial oven temperature was 40°C for 2 min, followed by a tempera-

ture gradient of 10°C/min until 150°C, followed by a gradient of 3°C/min until 215°C, followed by a gradient of 5°C/min until a final temperature of 220°C which was maintained for 5 min. Identification was made by comparison with authentic standards (Nu-Chek-Prep Inc., Elysian, MN). Only fatty acids contributing more than 0.5% of total fatty acids are shown in the tables, except for the potential 22:6n-3 precursor 20:5n-3.

Statistics. Fatty acid determinations were compared by one-way analysis of variance, followed by Newman-Keuls Multiple Range Test. Testing was made on a 5% significance level.

RESULTS

Animals. The differences between the diets affected neither body weight nor the weights of organs examined.

Brain phospholipids. After 1 wk no differences in n-3 PUFA of brain phospholipids were found, whereas at 3 wk both experimental diets increased the levels of 22:6n-3 in phosphatidylserine (PS) (Table 2) and phosphatidylcholine (PC) (Table 3) significantly compared with the reference group and 0 wk, but there were no differences between the two experimental groups. No effects of the diets were found in phosphatidylethanolamine (PE) (Table 2) and phosphatidylinositol (PI) (Table 3), but all groups doubled the 22:6n-3 level in PI. At three weeks, there were small but significant incorporations of 20:5n-3 in the experimental groups. In general larger changes in n-3 PUFA with time were observed in the experimental groups than in the reference group. In all groups and all phospholipids, 20:4n-6 decreased with time. The changes were similar in the two experimental groups and the final levels were significantly lower than in the reference group. In the experimental groups, the levels of 22:4n-6 decreased significantly in PE, whereas they remained constant in the reference group. Also 22:5n-6 was significantly reduced in PE. The level of 18:1 generally increased during the experiment in all groups and all phospholipids. Only in PS was a difference between the experimental groups and the reference group observed. The levels of 16:0 decreased in all groups with time, whereas 18:0 increased (PC) or was unaffected (PE, PS, and PI) by time and diets.

Liver phospholipids. In general only minor effects related to TAG structure were found. After 1 wk the levels of 22:6n-3 had increased significantly in PS, whereas they remained constant in PE and PC during the experiment (Table 4). The reference group also increased the 22:6n-3 in PS, but to a significantly smaller extent and decreased the levels in PC and PE. No effects of TAG structure were seen. Major replacements of 20:4n-6 by 20:5n-3 were observed in PC and PE and were most pronounced in the group fed the randomized TAG. Decreases in 20:4n-6 in PS for all groups were followed mostly by incorporation of 22:6n-3 and only moderate levels of 20:5n-3 as a function of time. Linoleic acid increased in the reference group with time, but not in the experimental groups. A general increase of 18:1n-9 in all groups with time was observed for PC and PE. Saturated fatty acids, i.e., 16:0 and 18:0, were little affected by the diets and the time. In the reference group a significant decrease in 16:0 in PC was found.

Adipose tissue. The TAG structure had some effect on the deposition of n-3 PUFA. The highest levels of 22:6n-3 and 20:5n-3 were found in the group fed randomized fat. The dietary fats also increased 16:1, 18:1 and 20:1, and decreased 18:2n-6 and 20:4n-6. At the start the adipose tissue contained 14% 10:0 plus 12:0, which significantly decreased during the experiment. In the reference group 18:2n-6 accumulated.

DISCUSSION

In the present experiment, we examined if it was possible to increase the accumulation of 22:6n-3, especially in the brain of newborn rats, by dietary intervention using two different

[a]For each phospholipid and each fatty acid: Values (mean) not bearing the same superscript letter are significantly different at $P < 0.05$. If no superscript appears, values are not different; $n = 5$ in each data set. See Tables 2 and 3 for abbreviations.

types of TAG containing similar levels of 22:6n-3, but having different TAG structure, i.e., a specific structured TAG and a randomized TAG containing 56 and 33%, respectively, of the 22:6n-3 in the *sn*-2 position. Both rat milk and human milk contain MCFA as well as short-chain fatty acids (SCFA). The TAG were therefore manufactured from fish oil and butterfat, which are available fats that provide n-3 PUFA and MCFA, respectively. The SCFA and MCFA in the diet of the newborn are important because these fatty acids are readily oxidized and thus provide energy to the growing infant. The interesterified fats had considerably higher levels of PUFA than rat milk and lower levels of SCFA and MCFA. This could affect their degradation by maternal milk lipase (24) available during the night when the pups stayed with their dams as well as by lingual lipase (25). On the other hand this did not result in different body weights in the present experiment. Previous studies have demonstrated that randomized TAG containing MCFA and PUFA are well absorbed (26), but it has also been demonstrated that specific structured TAG may possess superior absorption properties at low intestinal hydrolytic activity (12). In all mammals, the milk has a particular TAG structure with 16:0 located preferentially in the *sn*-2 position, which allows for a high energy uptake (27). In formulas for pre-term infants, this TAG structure may not be optimal if a high uptake of n-3 PUFA is desired since n-3 PUFA are released slowly from the *sn*-1,3 positions of TAG by pancreatic lipase (28).

[a]For each fatty acid: Values (mean) not bearing the same superscript letter are significantly different at $P < 0.05$. If no superscript appears, values are not different; $n = 5$ in each data set.

It was possible to increase the level of 22:6n-3 in brain PS and PC, but not in brain PE and PI compared with the reference group fed solely rat milk. The physiological significance of these changes is not clear. The increase in 22:6n-3 in the brain phospholipids was accompanied by decreases in n-6 PUFA: 20:4n-6, 22:4n-6, and 22:5n-6, which has also been found by others (8,29). These fatty acids decreased in all three groups as a function of time, but to significantly lower levels in the experimental groups than in the reference group. The brain is able to synthesize 22:6n-3 from 18:3n-3 (30), but the majority of the accumulating 22:6n-3 seems to be synthesized in the liver (31) if 18:3n-3 is the main source of n-3 PUFA and transported, possibly by chylomicrons (32), to the brain. If dietary 22:6n-3 is available this probably can be transported to the brain either in chylomicrons or in very low density lipoprotein. In the brain phospholipids no effects of the TAG structure on the deposition of 22:6n-3 could be detected (Tables 2,3). This may reflect that the specific structured TAG did contain some 22:6n-3 in the *sn*-1/3 positions or that in slowly growing tissues like the brain the uptake is independent of TAG structure at least if sufficient n-3 PUFA is available. In contrast to this, we have previously demonstrated that the dietary TAG structure is reflected in the chylomicron TAG structure (33) which again affects the clearance of chylomicrons and short-term deposition in, e.g., the liver and kidney (34).The decrease in 20:4n-6 is of particular interest since 20:4n-6 has an important role in signal transduction (35) and is a precursor for eicosanoids (36). The resistance of PI, phosphatidylinositol, and phosphatidylinositol-bisphosphate to even multigeneration exposure to n-3 PUFA has been described before (10,37). However, a decrease in 20:4n-6 in PI is a general phenomenon from 0 to 3 wk as also found by Bourre *et al.* (5). The changes in fatty acid profile may reflect the onset of brain myelinization during which large saturated and monounsaturated fatty acids accumulate in the myelin sheets (38). In the rat this is initiated in the first week of life, peaks at about 14 d after birth and continues into the fourth week of life (39) and in humans starts before birth and peaks at about five months (40). We find no influence of the dietary fat on the deposition of 18:1 in the brain phospholipids during this process. This again may reflect that the rats were fed diets supplying adequate fatty acids.

The fatty acid composition in the liver phospholipids was, as shown by others (8,41), much more susceptible to influence by dietary fatty acids than the brain. No major differences related to TAG structure were observed. This may result from the relatively high levels of 22:6n-3 in both experimental diets. The experimental fats were, however, able to maintain high hepatic levels of 22:6n-3 while a major reduction in 22:6n-3 from PC and PE in the reference group occurred during this period. The experimental fats resulted also in deposition of 22:6n-3 in PS. In liver PE and PC, the level of 22:6n-3 was nearly constant in the study period in the experimental groups, whereas the level decreased significantly from 1 to 3 wk in the reference group. In liver PS the level of 22:6n-3 increased in all groups as a function of time, but reached significantly higher levels in the experimental groups. In the liver PE and PC are the major phospholipids, contributing approximately 75% of all phospholipids, and the decrease in 22:6n-3 may reflect the transport of synthesized 22:6n-3 to the developing CNS. Since the brain phopholipids are relatively unaffected by the dietary n-3 PUFA and the liver increases the content, we conclude that surplus of n-3

PUFA is deposited in the liver, but it must be noted that this has profound influence on the liver fatty acid profile and may later be mobilized. The effect is, however, solely related to the dietary level of n-3 PUFA and in this experiment not affected by TAG structure. As in the brain, the level of 20:4n-6 in the liver decreased as a function of time and was replaced by 20:5n-3, except in PE where the level in the reference group increased from 1 to 3 wk. This may reflect an export of 20:4n-6 from the liver, and also that the dietary level of 18:2n-6 was lower in the experimental groups than in the control group. The level of 20:4n-6 in plasma and the growth of newborn infants are correlated (41), indicating that dietary 20:4n-6 for newborn infants may be as important as 22:6n-3, which is supported by observed growth retardation correlated with reduced 20:4n-6 contents in red blod cells (42).

The growth of the pups as well as the incorporation of n-3 fatty acids indicates that the fats were well absorbed and with similar efficiency. Significantly higher deposition of n-3 PUFA following intake of the randomized fat in the adipose tissue may result from the activity of lipoprotein lipase which is *sn*-1,3 specific, since the chylomicron TAG structure largely reflects the TAG structure of the dietary fat (34). This may indicate that larger differences in tissue depositions could have resulted if the dietary fats had been more specific in TAG structure. The postnatal demand for long-chain PUFA may be met by dietary supplies, as well as by stores in the newborn formed during the embryonic period by export from the maternal body. In the present experiment, small amounts of both 20:4n-6 and 22:6n-3 were found in the adipose tissue of the newborn rats (2.1 and 1.2%, respectively, at 0 wk, and a total amount of long-chain (C_{20} and C_{22}) PUFA of 5.3%). After three weeks, the level of 22:6n-3 was reduced by almost 50% in the reference group, either by depletion for use elsewhere in the body or by dilution with accumulated fatty acids in the adipose tissue. In the experimental groups, the level of 22:6n-3 was significantly increased in the same period, suggesting that the demand for PUFA from the CNS was met and that surplus PUFA accumulated in the adipose tissue. The level of 22:6n-3 in the intervention diet was 3.8% of total fatty acids which is approximately six times the level in the milk from rats fed ordinary rat chow. At this dietary level, only minor effects of the TAG structure of dietary fat used in this experiement are observed.

ACKNOWLEDGMENTS

M.Sc. Steen Balchen, Technological Laboratory, Danish Ministry of Fisheries, synthesized the structured oil. Steffen Radich Johansen, Aarhus Oliefabrik A/S, performed the randomization of the oil. Kirsten Kjær from Thyborøn Andelsfiskeindustri provided the fish oil used in the experiment. MD Foods A.m.b.a. provided financial support for M. Myrup Christensen.

Phospholipid Fatty Acid Composition in Type I and Type II Rat Muscle

William G. Blackard[1], Jing Li, John N. Clore*, and William B. Rizzo

Departments of Medicine and Pediatrics, Medical College of Virginia/Virginia Commonwealth University, Richmond, Virginia 23298

ABSTRACT: The fatty acid composition of the membrane phospholipids phosphatidylcholine (PC) and phosphatidylethanolamine in insulin-sensitive Type I (soleus) and insulin-resistant Type II (EDL) muscle is not known. In the present studies, soleus and EDL muscles were removed from 250–300 g Sprague-Dawley rats, and the fatty acid composition of total and individual phospholipid (PL) species was quantitated. As expected, triglyceride content was increased twofold in soleus muscle. No quantitative differences in the individual PL species or cholesterol content were found between the two muscles. However, a striking difference in PL fatty acid composition was observed in the PC fraction. An increase in 16:0 with decreases in 18:0, 18:1, 22:5n-3, and 22:6n-3 ($P < 0.001$ for each) was observed in the PC fraction of EDL compared to that from soleus, consistent with reduced elongation of PC fatty acids. Inhibition of fatty acid oxidation with the carnitine palmitoyl transferase-I inhibitor, etomoxir, did not alter the fatty acid pattern in either muscle. We conclude that an alteration in PL fatty acid composition consistent with reduced elongation of both saturated and unsaturated fatty acids is observed in Type II muscle. The restriction of these alterations to the PC fraction has important implications.

Lipids 32, 193–198 (1997).

Type I and Type II muscle fibers differ in their responsiveness to insulin. Type I muscle (slow-twitch), with its greater number of mitochondria and greater oxidative capacity, is more responsive to insulin than is Type II muscle (fast-twitch) with its greater glycolytic capacity (1–7). Differences in insulin receptor number (8–10) and receptor tyrosine kinase activity (10) have been variably reported, but no *in vitro* study has shown the expected rightward shift in the insulin dose-response curve consistent with these characteristics of Type II muscle. A more attractive explanation for the enhanced responsiveness of Type I muscle is its greater capacity for glucose transporter (Glut-4) recruitment compared to that in Type II muscle (5,7,11). Since phospholipid (PL) composition is known to influence membrane protein incorporation as well as enzyme activity and receptor function (12,13), differences in membrane PL fatty acid composition may play an important role in insulin responsiveness.

The present study examines the PL content of Type I and Type II muscle in the rat. Since the major PL in the outer layer of the sarcolemma bilayer is phosphatidylcholine (PC) (14), whereas phosphatidylethanolamine (PE) is preferentially concentrated in the inner layer, the fatty acid composition of these two predominant PL species (choline, PC and ethanolamine, PE) as well as the quantitatively less significant phosphatidylinositol (PI) in muscle have been emphasized. To our knowledge, no studies to date have examined the fatty acid composition of PC and PE in Type I and Type II muscle. To determine if differences in fatty acid oxidation in Type I and Type II muscle contribute to putative differences in the PL fatty acid composition, the carnitine palmitoyl transferase I (CPT-1) inhibitor, etomoxir, was administered in a separate series of experiments. The studies have demonstrated a striking variation in the fatty acid composition of PC in the two muscle types which was not present in either PE or the other classes of PL.

METHODS

Overnight fasted male Sprague-Dawley rats with a mean weight of 276.1 ± 7.0 g (range 250–300 g) were killed by cervical dislocation after undergoing ether anesthesia. Serum was obtained by cardiac puncture, and soleus and extensor digitorum longus (EDL) muscles were removed for PL analyses. Soleus muscle consists mainly of slow-twitch, Type I (84%) red fibers, and EDL muscle consists mainly of Type II white fibers (38% Type IIA; 59% IIB) (15).

In experiments to examine the effect of inhibition of fatty acid oxidation, etomoxir (a CPT-1 inhibitor) was administered at a dose of 15 mg/kg/d S.Q. for six weeks (16). The muscle PL composition was compared to that of litter mates fed *ad libitum*. Body weights of control and etomoxir-fed animals were measured at the end of the treatment period.

Lipid analysis [PL, triglycerides (TG), and cholesterol]. Soleus and EDL muscles (100–120 mg) were removed from the overnight-fasted male rats. The muscles were homogenized in chloroform and methanol (2:1, vol/vol) containing

[1]Deceased (June 28, 1996).

0.01% butylated hydroxytoluene using a Rockwell homogenizer, and total lipids were extracted by the method of Folch *et al.* (17). Serum samples were also treated with chloroform and methanol prior to extraction. To quantitate the various PL species, cholesterol, and TG, lipids from the Folch extraction were separated by high-performance thin-layer chromatography as described by Alvarez and Ludman (18). Following chromatography, the plates were dipped into 10% $CuSO_4$ in 8% H_3PO_4 and oven-charred at 130°C for 30 min. The plates were scanned immediately using an ultrascan XL laser densitometer (Pharmacia LKB Biotechnology, Uppsala, Sweden) and quantitated according to Macala *et al.* (19). As the charring method is only semiquantitative, the major PL species (PC and PE) were also determined by the Naphthol Blue Black staining method which has been validated for accuracy (20).

PL fatty acid composition. PL fatty acid composition was analyzed according to Storlien and coworkers (21) with minor modifications. Hemi-muscles (50–60 mg) were homogenized as described above and total lipids were extracted by the method of Folch *et al.* (17). The lipid extracts were dried under nitrogen, dissolved in 10 mL of hexane and applied to 3 mL silica gel columns (J.T. Baker, Inc., Phillipsburg, NJ). After elution of the less polar lipids with 20 mL hexane followed by 10 mL dichloromethane, PL were eluted with 10 mL methanol. The methanol eluates were dried under nitrogen and transmethylated with 1.5 mL 1 N methanolic HCl at 80°C overnight. Fatty acid methyl esters were extracted with 6 mL hexane and dried under nitrogen.

To determine the fatty acid composition of individual PL species, PC, PE, sphingomyelin (SM), PI, cardiolipin (CA), and phosphatidylserine (PS) were first separated by thin-layer chromatography on silica gel G plates (Whatman LK6D, Clifton, NJ) using a solvent system consisting of chloroform/ethanol/triethylamine/water (30:34:30:8, by vol) for the first development and hexane/dimethyl ether (50:50, by vol) for the second development. PL were visualized under ultraviolet (UV) light after spraying the plate with rhodamine G. The separated PL spots were collected by scraping and placed into glass tubes. Fatty acid methyl esters were prepared as described above by treatment with methanolic HCl.

Fatty acid methyl esters from the total PL fractions as well as the individual PL species were redissolved in 20 μL hexane and analyzed on a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) equipped with a 30 m × 0.2 mm fused silica capillary column (Omega wax 320; Supelco, Inc., Bellefonte, PA) and flame-ionization detector. The injection temperature was 250°C and detector temperature was 300°C. The initial oven temperature was 140°C. After five minutes, the oven temperature was increased from 140 to 200°C at a rate of 20°C/min, then to 280°C at 5°C/min. Fatty acids were identified by comparing their retention times with those of authentic standards.

Most of the gas chromatograph peaks were identified as specific fatty acid methyl esters. In the total PL and PC preparations, these fatty acid methyl esters accounted for 87 and 93% of the total integrated area, respectively, whereas they comprised only 79% of the integrated area in the PE fraction. In all samples, however, there were peaks immediately preceding palmitate (16:0) and stearate (18:0), which were suspected to be dimethyl acetal derivatives of fatty aldehydes released from ether PL (plasmalogens). To confirm this identification, PE from bovine brain containing 60% plasmalogens (Sigma Chemical Co., St. Louis, MO) was chromatographed before and after mild acid fume hydrolysis (22). After mild acid fume hydrolysis and separation on thin-layer chromatography plates, the peaks before 16:0 and 18:0 suspected of being derived from plasmalogens completely disappeared, confirming their identity as dimethyl acetals.

PL, TG, cholesterol, and fatty acid standards were obtained from Sigma. High-performance pre-coated silica gel Hp-K plates (10 cm × 10 cm) were purchased from Whatman. All other reagents and solvents were of analytical or HPLC-grade from Sigma or Fisher (Pittsburgh, PA).

RESULTS

Figure 1 displays the lipid composition of soleus and EDL muscles as determined by the charring method after separation by thin-layer chromatography. All six of the PL species were expressed as a percentage of total PL, whereas TG and cholesterol were expressed as a percentage of total lipids, (PL, TG, and cholesterol). There were no significant differences in PL species between the two muscles which collectively accounted for approximately 75% of total tissue lipids. The major intermuscle difference was the twofold greater TG composition in soleus muscle. Because the charring method is only semiquantitative, the two major PL species (PC and PE) were quantitated by the more accurate Naphthol Blue Black staining method. Using this technique, the concentration of PC was greater than that of PE, but no significant difference in the PC/PE ratios was noted in the two muscles (PC/PE ratio 1.41 ± 0.07 in soleus and 1.46 ± 0.07 in EDL).

The fatty acid composition of total PL and the individual PL classes was determined by gas chromatography. Approximately 90% of the chromatographic peaks were identified as

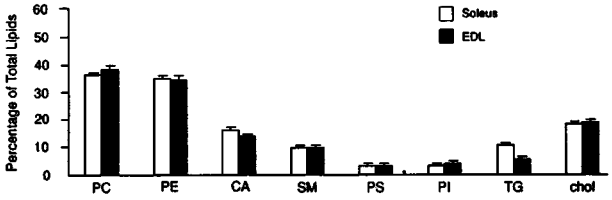

FIG. 1. Lipid composition of soleus and extensor digitorum longus (EDL) muscles. Phospholipid species are expressed as a percentage of total phospholipids, whereas triglycerides and cholesterol are expressed as a percentage of total lipids (including all phospholipids); PC, phosphatidylcholine; PE, phosphatidylethanolamine; CA, cardiolipin; SM, sphingomyelin; PS, phosphatidylserine; PI, phosphatidylinositol; TG, triglyceride; CHOL, cholesterol. Means ± SEM shown. $n = 12$ animals. Triglycerides are significantly increased in soleus ($P < 0.001$).

specific fatty acid methyl esters or dimethyl acetal derivatives of plasmalogen PL. Two major dimethyl acetal peaks (16:0 dimethyl acetal and 18:0 dimethyl acetal) derived from ether phospholipids (plasmalogens) were observed predominantly in the chromatograms of PE. These peaks accounted for 10.02 ± 0.28% (soleus) and 9.03 ± 0.35% (EDL) of the total methylated derivatives (fatty acids + aldehydes) on the chromatograms of PE. In contrast, these same peaks contributed only 0.69 ± 0.13% (soleus), and 0.66 ± 0.08% (EDL) of the peak area on chromatograms of PC. The plasmalogen content of PE is known to be greater than that of PC (23). These dimethyl acetal derivatives were quantitatively similar in the two muscles.

The fatty acid composition of the total PL fractions from the two muscles as well as from rat serum are shown in Table 1. The major differences in PL fatty acid composition between the two muscles were an increase in 16:0 and a decrease in 18:0 in Type II (EDL) muscle. The very different PL fatty acid composition of muscle compared to serum is indicative of local membrane remodeling (24). For example, the percentage of docosahexanoic acid (22:6n-3) was five times greater in muscle PL than in serum, whereas the percentage of oleic acid (18:1n-9) was almost twofold greater in serum.

The fatty acid compositions of individual PL classes are shown in Table 2. The increased palmitate in PC and increased stearate in PE are consistent with the known predilection of PC- and PE-synthesizing enzymes for diacylglycerol (DAG) with palmitate or stearate in the *sn*-1 position, respectively (25). The PE-synthesizing enzymes also favor synthesis from DAG with docosahexanoic acid (22:6n-3) in the *sn*-2 position (25), thus explaining the two- to threefold increase in this fatty acid in PE compared to that in PC.

The greatest difference in PL fatty acid content between the two muscles was observed in the saturated fatty acids of the PC species (Table 2). Choline PL from EDL muscle had a much higher 16:0 composition, and a significantly lower 18:0 composition than that from soleus muscle. This was reflected by a PC palmitate (16:0) to stearate (18:0) ratio of 3:1 in EDL compared to the 1:1 ratio in soleus (Fig. 2). Importantly, this ratio was minimally altered by muscle fiber type in the other PL classes (PE, CA, and SM). The longer chain saturated fatty acids (19:0, 20:0, 22:0, 24:0) of PC were also reduced in the EDL compared to the soleus, although the difference was significant only for 19:0. As shown in Table 2, oleic acid (18:1), an elongation as well as desaturation product of palmitate, was reduced in EDL, whereas linoleic (18:2n-6) and linolenic (18:3n-6) acids, two essential fatty acids, were not significantly different in the two muscles. However, the n-3 elongation products 22:6n-3 and docosapentaenoic acid (22:5n-3) were significantly reduced in the PC fraction of EDL muscle.

In contrast to PC, the differences in fatty acid composition of the PE fractions between the two muscle types were relatively trivial (Table 2). As shown in Figure 2, the 16:0 to 18:0 ratio in PE was slightly but significantly increased in EDL compared to soleus (0.16 ± 0.01 to 0.19 ± 0.01, $P < 0.003$). The ratio of 16:0 to 18:0 in the SM and CL fractions was almost identical between the two muscles (Fig. 2). Thus, the minimal intermuscle differences in fatty acid composition of these other PL classes reduced the magnitude of the difference detected when the fatty acid composition from total PL was compared in the two muscles. In fact, in the case of 22:6n-3, the significant reduction of this fatty acid in PC of EDL (Table 2) was effectively masked in the fatty acid analysis of the total PL fraction by the increase in PE 22:6n-3 in EDL (Tables 1 and 2).

Because of the putative role of PI in muscle signaling, the fatty acid composition of this species is shown (Table 3), despite its low content in rat muscle PL (2.5%). Stearate was the predominant saturated fatty acid in PI, being higher than in any of the other species. Stearate was significantly higher ($P < 0.002$) in the EDL and the 16:0 to 18:0 ratio (0.048 ± 0.006 vs 0.039 ± 0.004) was slightly but significantly lower in the EDL (opposite to the ratio observed in PC). No differences in arachadonate (20:4n-6) content in PI were found be-

TABLE 1
Phospholipid Fatty Acid Composition in Serum and Muscle

Fatty acid (%)	Serum PL	Soleus PL	EDL PL
14:0	0.93 ± 0.11[a]	0.37 ± 0.03	0.34 ± 0.04

24:1n-9	0.33 ± 0.05	0.23 ± 0.05	0.45 ± 0.08	0.47 ± 0.07

[a]$P < 0.001$, soleus compared to EDL.Phospholipid fatty acids accounting for less than 0.5 % of the total are not shown; $n = 12$ for overnight-fasted rats. See Table 1 for abbreviation.

tween soleus and EDL muscles. However, the content of 18:2n-6 was significantly increased in soleus compared to EDL (Table 3)

To determine whether differences in fatty acid oxidation rates of the two muscles might be responsible for the alteration in PC fatty acid content, the fatty acid composition of muscle PC and PE from rats treated for six weeks with the CPT-1 inhibitor etomoxir was compared to that of untreated animals. In Figure 3, it can be observed that the 16:0/18:0 ratio of PC was not altered in etomoxir-treated animals. Thus, greater rates of fatty acid oxidation in Type I (soleus) compared to Type II (EDL) muscle are unlikely to explain the divergent 16:0 to 18:0 ratios in PC. Although the mean weights of control animals and etomoxir-treated animals were not significantly different, the etomoxir-treated animals exhibited cardiac hypertrophy (0.0029 ± 0.0003 vs. 0.0025 ± 0.0002 heart/body weight ratio, $P < 0.005$) and visibly fatty livers corroborated by marked increase in TG content as assessed by thin-layer chromatography.

DISCUSSION

Since membrane PL may play a role in signal transduction (26), as well as influence membrane fluidity affecting membrane enzyme and receptor activity (12,13), we characterized the PL in membranes of the two muscle types disparate for insulin responsiveness (soleus, Type I and EDL,Type II). PL were determined on total cell lipid extracts rather than on isolated membrane fractions. However, it is generally considered that the measurement of total cell PL reflects that of cell membranes, and that the ranking of the major PL fatty acids is preserved among the various cell membranes (27). No differences in the PL species composition of soleus and EDL muscles were noted.

Analysis of the total PL fatty acid composition was not so informative as the fatty acid composition of the individual PL species. Since PC and PE contributed over 70% of the total PL, the major focus was on the analysis of the fatty acid composition in these two classes. Striking differences in the fatty acid composition of soleus and EDL were observed in the PC

TABLE 3
Fatty Acid Composition of Phosphatidylinositol from Soleus and EDL Muscles[a]

Fatty acid	Saturated fatty acids		
(%)	Soleus	EDL	*P* value
16:0	1.67 ± 0.19	1.46 ± 0.12	
18:0	35.16 ± 0.58	37.80 ± 1.06	<.05
	Unsaturated fatty acids		
18:1n-9	3.61 ± 0.013	2.99 ± 0.51	
18:2n-6	2.82 ± 0.18	1.96 ± 0.14	<.001
20:4n-6	27.62 ± 1.12	25.74 ± 0.62	
22:4n-6	2.83 ± 0.20	2.57 ± 0.17	
22:5n-3	4.48 ± 0.17	4.9 2 ± 0.19	
22:6n-3	9.77 ± 0.35	10.56 ± 0.23	

[a]Because of low phosphatidylinositol (PI) content, PI was pooled from each pair of muscles from four animals. Fatty acids accounting for more than 1% of total PI fatty acids are shown, $n = 4$. See Table 1 for other abbreviation.

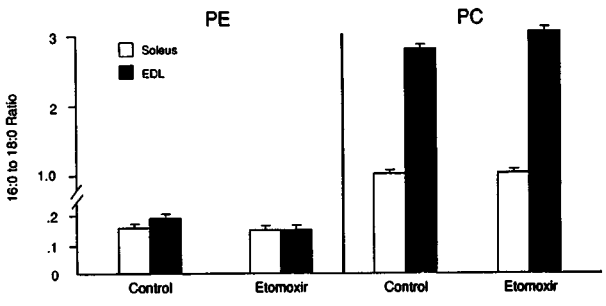

FIG. 3. Fatty acid "elongation ratio" (16:0 to 18:0) in phosphatidylethanolamine and phosphatidylcholine fractions from soleus and EDL muscles removed from control and etomoxir-treated rats. Data are expressed as means ± SEM. Ratio is significantly elevated in PC of EDL muscle from both control and etomoxir-treated animals ($P < 0.0001$); $n = 12$ overnight-fasted animals. See Figure 1 for abbreviations.

fraction. However, because of minor intermuscle differences in fatty acids from the other PL classes (PE as well as SM, CL, and PI), the dramatic differences in 16:0 and 18:0 seen in PC were partially masked when the fatty acid profiles of total PL were analyzed. In addition, the reduction in 22:6n-3 observed in the PC fraction from EDL was obscured in the total PL measurements by the increase in this fatty acid in PE.

Major differences in the fatty acid composition of PC were observed between soleus and EDL muscles. In addition to the relative increase in 16:0 and the decrease in 18:0 in EDL, oleic acid (18:1), a desaturase product of 18:0, was also reduced in EDL PC. Linoleic (18:2n-6) and linolenic (18:3n-6) acids, essential fatty acids not synthesized *in vivo*, were not decreased. Elongation products of n-3 fatty acids (22:5n-3 and 22:6n-3) were also decreased in the PC fraction from EDL compared to soleus. However, this was not the case for elongation products of n-6 fatty acids such as 20:4n-6. Since 22:6n-3 inhibits elongation of n-6 fatty acids (28), the failure to demonstrate a reduction in 20:4n-6 in EDL may be secondary to a reduced content of 22:6n-3 and loss of its inhibitory effect on elongation of n-6 fatty acids. The reciprocal changes in 22:6n-3 in EDL PL (decreased in PC and increased in PE) initially raised the possibility of reduced methylation in Type II muscles. In some tissues as much as 40% of PC is formed by methylation of PE, and PE containing 22:6n-3 is a favored substrate for this reaction. However, evidence suggests that synthesis of PC by methylation of PE occurs only in the liver and not in muscle (29).

Although reduced elongation of fatty acids destined for PL in EDL seems a reasonable explanation for the changes in fatty acid profile of the two muscles, it is not clear why such a reduction should be observed in the PC fraction only. We first considered the possibility that the lower rates of fatty acid oxidation in EDL muscle might result in preferential oxidation of elongation products of 16:0 prior to incorporation into membrane PL. However, results from experiments using the CPT-I inhibitor, etomoxir, suggest that this is not the case. Despite clear evidence for an inhibitory effect of etomoxir on fatty acid oxidation, we observed no change in the PL fatty acid profile of the two muscles compared to untreated control animals. Other possibilities for the altered fatty acid profile include differences in substrate specificity for PC biosynthesis or degradation (30). The known preference of the PC-synthesizing enzymes for substrate DAG with 16:0 in the *sn*-1 position (25) could be even more enhanced in Type II muscle such that proportionally less 18:0 is incorporated, providing a profile consistent with reduced elongation activity. This possibility not withstanding, the generalized reduction in elongation products observed in the present studies is more consistent with a global reduction in fatty acid elongation in the PC species obtained from Type II muscle rather than differential multiple substrate specificities for biosynthesis or degradation in the two muscles.

The restriction of intermuscle variations in fatty acid composition to the PC class of PL has important implications for other studies. Borkman and coworkers (31), in their important studies on PL fatty acid composition in man, may not have detected a decreased elongation profile in insulin-insensitive muscle because the entire PL fraction, rather than just PC, was used for analysis. Even so, the negative correlation of palmitate and the positive correlation of stearate with insulin sensitivity in their transformed data suggests the possibility that in man, insulin sensitivity correlates negatively with the PL fatty acid elongation profile (16:0 to 18:0 ratio). These same authors, in conjunction with scientists working with the Pima Indians, have recently reported an decrease in elongase activity in obese, insulin-resistant, Pima Indians (32) which supports this contention.

Conjugated Linoleic Acid Modulates Hepatic Lipid Composition in Mice

Martha A. Belury* and Anna Kempa-Steczko

Department of Foods and Nutrition, Purdue University, West Lafayette, Indiana 47907

ABSTRACT: Conjugated linoleic acid (CLA) is a chemoprotective fatty acid that inhibits mammary, colon, forestomach, and skin carcinogenesis in experimental animals. We hypothesize that the ubiquitous chemoprotective actions of dietary CLA in extrahepatic tissues are dependent upon its role in modulating fatty acid composition and metabolism in liver, the major organ for lipid metabolism. This study begins to evaluate the role of CLA in lipid metabolism by determining the modulation of fatty acid composition by CLA. Female SENCAR mice were fed semipurified diets containing 0.0% (Diet A), 0.5% (Diet B), 1.0% (Diet C), or 1.5% (Diet D) CLA (by weight) for six weeks. Mice fed Diets B, C, and D exhibited lower body weights and elevated amounts of extractable total lipid in livers compared with mice fed diets without CLA (Diet A). Analyses of the fatty acid composition of liver by gas chromatography revealed that dietary CLA was incorporated into neutral and phospholipids at the expense of linoleate in Diets B, C, and D; oleate increased and arachidonate decreased in neutral lipids of CLA diet groups. In addition, increasing dietary CLA was associated with reduced linoleate in hepatic phospholipids. In an *in vitro* assay, CLA was desaturated to an unidentified 18:3 product to a similar extent as linoleate conversion to γ-linolenate (9.88, and 13.63%, respectively). These data suggest that CLA may affect metabolic interconversion of fatty acids in liver that may ultimately result in modified fatty acid composition and arachidonate-derived eicosanoid production in extrahepatic tissues. In addition to determining how dietary CLA modulates eicosanoid synthesis, further work is needed to identify enzymatic products that may result from desaturation of CLA.

Lipids 32, 199–204 (1997).

Conjugated linoleic acid (CLA) refers to a group of octadecadienoate (18:2) -derived isomers that are protective against tumorigenesis in several tissues in experimental animals (reviewed in Ref. 1). In particular, CLA inhibits chemically-induced forestomach neoplasia and skin tumor initiation and promotion in mice as well as mammary and colon carcinogenesis in rats (1–5).

CLA is derived from linoleic acid (18:2; *cis*9, *cis*12) and has been identified in cooked meats such as fried ground beef and pork as well as heat-processed dairy products such as cheeses and pasteurized milk and dairy foods (6). Studies designed to determine the chemoprotective effects of CLA have used a synthetic preparation containing several positional and geometric isomers with double bonds predominantly at 9 and 11 or 10 and 12 carbons and various combinations of *cis* and *trans* configurations at each double bond. While CLA constitutes a relatively minor component of the total fatty acid composition of foods, the chemoprotective properties of CLA have been associated with very low levels of CLA in the diet (as low as 0.05% by weight; Ref. 7) either as free or triglyceride esterified fatty acid (3). The relatively low levels of CLA that effectively inhibit carcinogenesis are in contrast to the higher levels of n-6 and n-3 (>5.0% by weight of diet) polyunsaturated fatty acids (PUFA) shown to modulate carcinogenesis (reviewed in Ref. 1).

In early studies, chemoprotection by CLA was associated with incorporation into rat mammary tumor and mouse forestomach phospholipids (8,9). This may be significant in the development of cancer since phospholipid-associated PUFA and their biologically active eicosanoid products mediate several tumor-related events in mammary gland (10), colon (11) and skin (12). The impact of dietary CLA on the relative composition and interconversion of nonconjugated fatty acids (i.e., saturated, and n-3 and n-6 unsaturated) in neutral and phospholipids in liver has not yet been investigated. Furthermore, while desaturated metabolites of CLA may play a role in chemoprevention (13), the relative ability of CLA vs. linoleate to be a substrate for the rate limiting step in linoleate conversion to arachidonate (Δ6 desaturase) has not been definitively established. Because of the interactive effects of n-6 and n-3 PUFA on modulating cancer in extrahepatic tissues, the role of CLA in carcinogenesis may be dependent on altering the metabolism of fatty acids such as linoleate and arachidonate.

The lack of understanding of the physiological impact of CLA on tissue fatty acid composition and metabolism *in vivo* has impeded the elucidation of a mechanism(s) for CLA chemoprevention. Therefore the objectives of the present study were to: (i) evaluate the effects of increasing levels of dietary CLA (0.5–1.5% by weight of diet) on the composition of neutral and phospholipids of mouse liver, the major site of lipid metabolism; and (ii) determine whether CLA is able to act as a substrate for Δ6 desaturase in a manner similar to

linoleate in order to gain a better understanding of how CLA may affect the metabolic interconversion of fatty acids [i.e., linoleate conversion to its more desaturated, elongated product, arachidonate (20:4)].

MATERIALS AND METHODS

Materials. The [1-^{14}C]-linoleic acid (50 mCi/mmol: >98.8% radiochemical purity) was purchased from American Radiolabel Company (St. Louis, MO) and [1-^{14}C]-CLA (50 mCi/mmol: >98% radiochemical purity) was custom-synthesized from a portion of radiolabeled parent compound according to the method of Ip *et al.* (8) by American Radiolabel Company. Unlabeled linoleate and CLA (free fatty acids and methyl esters) as well as γ-linolenate methyl ester were purchased from Nu-Chek-Prep (Elysian, MN). Phenylmethylsulfonyl fluoride and ATP were obtained from Sigma Chemical (St. Louis, MO), and solid-phase silica Prep-Sep™ columns were purchased from Fisher Scientific (Fairlawn, NJ). Authentic fatty acid standards were obtained from Sigma Chemical, Supelco (Bellefonte, PA) and Matreya Inc. (Pleasant Gap, PA), and bicinchoninic acid assay reagent was purchased from Pierce Chemicals (Rockford, IL). Diet components were obtained from Dyets, Inc. (Bethlehem, PA). All solvents and other chemicals were of the highest grade commercially available.

Diets and animals. Four experimental diets based on the AIN-76 formulation (14) containing various levels of CLA (Diet A, 0.0%; Diet B, 0.5%; Diet C, 1.0%; or Diet D, 1.5% by weight of diet) shown to modulate mammary tumorigenesis and mouse skin tumor promotion (2) were used in these studies. Various levels of CLA were added to a 5.0% corn oil diet at the expense of dextrose and the fatty acid composition of dietary oils is shown in Table 1. The approximate isomeric composition of CLA (96% pure) reported by Nu-Chek-Prep was 43% *c*9,*t*11- and *t*9,*c*11-CLA, 45% *t*10,*c*12-CLA, 6% *c*9,*c*11-, *c*10,*c*12-, *t*9,*t*11-, *t*10,*t*12-CLA, 2% linoleate and 4% unidentified compound. Diets were prepared on the premises and stored (−20°C) under nitrogen atmosphere in airtight containers for no longer than 2 wk. Diets were fed every other day in clean powder feeders with stainless-steel grids and mice (n = 12 per diet group; 42 d of age; Harlan Sprague-Dawley, Indianapolis, IN) were allowed free access to food and water. Body weights were measured weekly and average food consumption estimated by measuring differences in weight of freshly supplied diet and diet remaining in feeders two days later. After maintaining mice on experimental diets for six weeks, animals were euthanized and livers isolated and frozen in liquid nitrogen. Tissue was stored at −80°C until analyses were performed.

[a]Combinations of oils present in experimental diets were methylated and quantitated using gas chromatography as described in the Materials and Methods section. Results are expressed as a percentage of total fatty acids.
[b]UNFA, unidentified fatty acid; CLA, conjugated linoleic acid; LA, linoleic acid; n.d., not detected; P/S, polyunsaturated/saturated ratio.

Lipid extraction and fatty acid analyses. Total lipids were extracted from liver homogenates by the method of Bligh and Dyer (15). The silica Sep Pack column procedure described by Hamilton and Comai (16) was used to separate phospholipids and neutral lipids. Fatty acid methyl esters (FAME) of neutral and phospholipid fractions were prepared by incubating extracts with tetramethylguanidine at 95°C (17) and quantified by gas-liquid chromatography using a 30-m Omegawax 320 capillary column (Supelco Chromatography Products). Helium flow rate was 30 mL/min, and oven temperature was programmed to start at 175°C for 4 min and increase to 220°C at a rate of 3°C/min. Identification of FAME was accomplished by comparing retention times of FAME to retention times of pure standards spiked with CLA methyl ester preparations. FAME were quantified by determining areas under identified peaks (ChemStation Software; Packard Instrument Company, Meriden, CT).

Δ6 Desaturase activity. In order to determine whether CLA is able to act as a substrate for Δ6 desaturase, the percentage conversion of [1-^{14}C]-linoleate or [1-^{14}C]-CLA to [1-^{14}C]-γ-linolenate or [1-^{14}C]-conjugated 18:3, respectively, in liver microsomes of mice fed chow diets was determined. Microsomes were isolated from liver homogenates in 0.05 M potassium phosphate buffer containing 0.25 M sucrose (pH 7.0), with 100 mM phenylmethylsulfonyl fluoride (18). The microsome-containing pellet was resuspended in ice-cold 0.25 sucrose buffer containing 0.15 KCl (pH 7.2), and protein concentrations were determined using bicinchoninic acid reagent. Because 2.0 mg protein was previously determined to support maximal enzymatic conversion of linoleate to γ-linolenate under identical assay conditions (18), this protein concentration was used in the present studies. A duplicate set of each sample was boiled for 30 min to destroy desaturase activity for determination of nonenzymatc conversion of 18:2 to 18:3. Radiolabeled linoleate or CLA was diluted with unlabeled fatty acid to a specific activity of 6.6 mCi/mmol and incubated with the microsomal protein in potassium phosphate buffer (80 μM; pH 7.2) containing 6.67 μmol ATP, 0.13 μmol coenzyme A, 1.20 μmol nicotinamide adenine dinucleotide, 10.00 μmol $MgCl_2$, 3.00 μmol glutathione, and 83.30 μmol potassium fluoride at 37°C for 25 min (18). The reaction was stopped by the addition of chloroform/methanol (2:1, vol/vol). Fatty acid extracts were methylated, and 18:2 and 18:3 products were separated by reverse-phase thin-layer chromatography

(Analtech, Newark, DE) using acetonitrile/water solvent (90:10, vol/vol) at 40°C. Radiolabeled FAME which co-migrated with authentic standards for 18:2 (linoleate and CLA methyl esters), and 18:3 (γ-linolenate) methyl esters were identified by staining with iodine vapor and autoradiography. Bands were scraped into vials and counted by liquid scintillation. Results of Δ6 desaturase activity were expressed as percentage conversion of [1-^{14}C]-18:2 to [1-^{14}C]-18:3 where enzymatic conversion was quantified by determining the difference between the average total conversion minus nonenzymatic (boiled sample) conversion (18).

To date, metabolites of CLA have not yet been identified so that thin-layer chromatography analyses of CLA metabolites were not compared to an authentic conjugated triene standard. Because [1-^{14}C]-CLA produced a discrete band in reactions containing viable enzyme and this band co-migrated with the triene, γ-linolenate, the unidentified band is assumed to be a triene product of CLA.

Statistical analysis. Data from these studies were analyzed by analysis of variance (General Linear Model, Tukey) using Statistical Analysis System (SAS; Cary, NC).

RESULTS

Body weights and food intake. Body weights were significantly lower ($P < 0.05$; Table 2) in mice fed Diets C and D throughout the six-week feeding period; however, average food intake as measured by food disappearance was similar among the diet groups (Table 3). Due to the lower amounts of weight gain in animals fed higher levels of dietary CLA, the feed/weight gain ratio (feed efficiency) was increased between 1.5- and 2.0-fold in mice fed 0.5 –1.5% dietary CLA (Diets B, C, and D) compared to those fed diets without CLA (Diet A).

Lipid composition of liver. When liver lipids were extracted, a positive association between increasing amounts of dietary CLA and total lipid extracted per gram liver tissue was observed. Livers of mice fed Diets C and D contained approximately twice the amounts of lipid compared to mice fed Diets A or B ($P < 0.05$; Fig. 1). Increasing levels of dietary CLA exhibited dose-responsive effects on the content of several fatty acids in neutral lipids (Table 4); CLA (9,11 and 10,12) was significantly elevated ($P < 0.05$), and linoleate and arachidonate were significantly reduced ($P < 0.05$) in mice fed Diets C and D compared with mice fed diets with lower (Diet B) or no (Diet A) CLA. In addition, the monounsaturated fatty acid, oleate (18:1), was significantly elevated in hepatic neutral lipids of mice fed Diet D compared to mice fed Diets A, B, or C. The total lipids of livers from mice exhibited similar trends to neutral lipids (data not shown). Liver phospholipids of mice fed Diet D contained significantly elevated 9,11-CLA and reduced linoleate compared with mice fed Diets A, B, or C.

Ability of CLA to act as a substrate for Δ6 desaturase. Enzymatic conversion of [1-^{14}C]-linoleate or [1-^{14}C]-CLA to 18:3 products by Δ6 desaturase was similar. The percentage conversion 18:2 to 18:3 was 13.30 ± 2.50 (SD) and 11.78 ± 2.16 (SD) for linoleate and CLA, respectively, ($n = 4$ for linoleate, $n = 5$ for CLA assayed in triplicate). These data suggest that Δ6 desaturase does not utilize either CLA or linoleate preferentially as a substrate; however, competition between these two fatty acids for the enzyme was not determined in the present studies.

DISCUSSION

Numerous studies have shown a correlation between dietary fatty acid-mediated reduction of arachidonate-derived eicosanoids and carcinogenesis (10–12). Because we and others (9,19) have shown that CLA is readily incorporated into cell membrane phospholipids, it is plausible that CLA may inhibit carcinogenesis in extrahepatic tissues by modulating fatty acid composition and subsequent eicosanoid metabolism (reviewed in Ref. 1).

Although biological roles of eicosanoids vary widely, eicosanoids mediate several different processes required for tumorigenesis including cell proliferation (i.e., induction of ornithine decarboxylase and DNA synthesis) and inflammation (i.e., local and systemic immune responses). The fatty acid, arachidonate, can be metabolized to form eicosanoids after being released from phospholipids *via* activation of phospholipase A_2. Arachidonate-derived eicosanoids known to modulate carcinogenesis in the mammary gland and skin include prostaglandin E_2, prostaglandin $F_{2\alpha}$, and prostaglandin D_2 *via* the cyclooxygenase pathway and several products from the lipoxygenase pathway, i.e., hydroxyeicosatetraenoates and leukotrienes. Although each eicosanoid has been shown to exhibit slightly different modulatory effects on tumorigenesis, prostaglandin E_2 production is most often associated with the enhancement of tumor induction. Inhibition of prostaglandin E_2 synthesis by indomethacin in both the mammary gland and

TABLE 2
Effect of Experimental Diets on Body Weight[a]

Diet	Body weights (g)[b]				
	Week 2	Week 3	Week 4	Week 5	Week 6
A	28.20 ± 1.06^{c,d}	31.86 ± 1.70^{d}	33.62 ± 1.57^{d}	35.30 ± 2.00^{d}	37.80 ± 2.47^{d}
B	27.14 ± 0.64^{d,e}	30.16 ± 0.76^{d,e}	31.42 ± 0.83^{d,e}	32.80 ± 1.15^{d,e}	34.86 ± 1.20^{d,e}
C	25.98 ± 1.11^{e}	28.84 ± 0.97^{e}	30.46 ± 1.05^{e}	31.78 ± 2.32^{d,e}	32.90 ± 0.91^{e}
D	25.86 ± 1.72^{e}	28.30 ± 1.79^{e}	29.24 ± 1.65^{e}	31.50 ± 1.92^{e}	32.46 ± 2.25^{e}

[a]At the commencement of the study, mice were weighed and randomly assigned to a diet group. Initial weights of mice were 25.78 ± 3.22 g with no significant difference between diet groups. Mice ($n = 12$ per diet) were fed assigned experimental diets for six weeks.
[b]Values represent means ± SD of body weights (g). Values within each column with different subscripts $^{c, d, e}$ are significantly different ($P < 0.05$).

TABLE 3
Effect of Experimental Diets on Food Disappearance, Body Weight Gain, and Feed Efficiency in Mice

Diet	Food disappearance (g)[a]	Average weight gain (g)[b]	Feed efficiency[c]
A	7.056 ± 2.326	12.02	0.587
B	7.913 ± 1.773	9.08	0.872
C	7.068 ± 1.820	7.12	0.993
D	8.393 ± 2.395	6.68	1.256

[a]Food disappearance was measured during two two-week intervals during the study. Values represent combined means ± SD of food disappearance (g) per mouse per day. There was no significant difference for food disappearance between diet groups.
[b]Average weight gain per diet group was calculated as follows: final average body weight for each diet group – the initial body weight of animals at the commencement of the study (25.78 g).
[c]Feed effeciency = food disappearance/average weight gain.

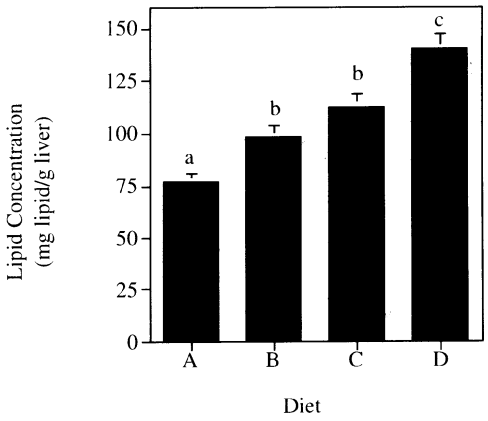

FIG. 1. Effect of dietary conjugated linoleic acid (CLA) on lipid concentration of liver. Mice were fed one of four diets containing various levels of CLA for six weeks. Values represent mean ± SD (n = 4–6 samples). Different superscripts denote significantly different ($P < 0.05$) values for lipid accumulation.

skin has correlated with reduced tumorigenesis in each of these organs (reviewed in Ref. 12). Dietary-induced modifications in phospholipid fatty acid composition where arachidonate is partially replaced with other fatty acids, i.e., n-3 PUFA or linoleate, have correlated with reduction of prostaglandin E_2 (10,20,21). In the case of the mammary gland and pancreas, inhibition of tumor formation was also observed (10,22).

Based on our findings that CLA is a suitable substrate for Δ6 desaturase, membrane-bound CLA and its desaturated and/or elongated products are likely to compete with other PUFA for phospholipases, cyclooxygenase, and lipoxygenase enzyme families. While some studies have shown significant incorporation of 9,11 CLA into mammary and forestomach phospholipids (9,19), others have suggested that the chemoprotective effects of CLA in mammary gland and colon are due to incorporation of CLA into neutral lipids of nontumor-bearing tissue (4,5). Cook *et al.* (23) recently showed dietary CLA (0.5%; w/w) partially displaced arachidonate in rat fat pads; tissue CLA increased and arachidonate decreased significantly ($P < 0.05$) while linoleate decreased slightly. Numerous studies have shown dietary lipids (i.e., n-3 rich PUFA or linoleate-rich diets) result in decreased phospholipid arachidonate with concurrent reduction of arachidonate-derived eicosanoid synthesis and tumorigenesis. Therefore, CLA reduction of phospholipid arachidonate is likely to inhibit eicosanoid synthesis and affect tumorigenesis. The effects of dietary CLA on eicosanoid synthesis are not yet known.

Our studies are the first to show that diets containing incremental levels of CLA with constant amounts of linoleate in the form of corn oil (~2.8% by weight of all diets) are associated with accumulation of both CLA and oleic acid in hepatic neutral lipid fractions. Accumulation of fatty acids appears to occur with a concurrent reduction of linoleate. Previous studies using similar diet designs have demonstrated CLA deposition into liver tissue was not at the expense of altered ratios of other fatty acids (i.e., linoleate and oleate); however, these earlier studies did not report all major fatty acid constituents of neutral and phospholipid fractions but rather reported selected fatty acids including CLA, linoleate, γ-linolenate, and/or arachidonate (5,8). Three lines of evidence suggest that CLA may

[a]Values are means ± SD expressed as percentage total fatty acid. n = 5–6 liver samples per diet group. Means with different superscripts ([b,c,d]) within the same row within neutral or phospholipid samples (Diets A–D) are significantly different ($P < 0.05$). [e]Not detected in measurable quantities and estimated to account for less than 0.09% total fatty acid. See Table 1 for abbreviations.

compete with linoleate for Δ6 desaturase, the rate-limiting step in the conversion of linoleate to form arachidonate. First, when available as a sole substrate, our studies demonstrate radiolabeled ^{14}C-CLA was desaturated to a similar extent as ^{14}C-linoleate by Δ6 desaturase. Second, dietary CLA (1.0 and 1.5%, Diets C and D) was associated with reduced arachidonate in mouse liver, suggesting less linoleate was converted to arachidonate. Finally, because oleate is a substrate for Δ6 desaturase, dietary CLA induction of oleate accumulation in total and neutral lipids suggests CLA was desaturated at the expense of oleate. Together these data suggest that dietary CLA modulation of Δ6 desaturase activity may reduce phospholipid-associated arachidonate, resulting in an overall decrease in arachidonate-derived eicosanoids.

In the present and previous studies from our laboratory (2), dietary CLA has been associated with reduced body weights in female SENCAR mice independent of food intake. These results are in contrast with findings in female rats where dietary CLA has displayed no significant effect on body weights (3,4,7,8,24). In addition to effects on body weights, results from our lab demonstrate that dietary CLA is associated with increased liver lipid accumulation. To our knowledge, effects of dietary CLA on lipid concentrations in rodent liver have not previously been reported; however, recent studies from Pariza and coworkers have suggested that CLA modulates fat and protein metabolism in mice, rats, and chickens (24). Furthermore, a hypolipidemic effect has been associated with diets containing 1.0% CLA compared to diets without CLA in rabbits (25). These data together suggest that dietary CLA has a potent effect on lipid transport and metabolism *in vivo.*

CLA has several physiological (i.e., reduced body weights and enhanced hepatic lipid content) and structural similarities to the fatty acid-like class of chemicals known as peroxisome proliferators. Recent findings from our lab have demonstrated that diets containing 1.0 and 1.5% CLA were associated with hepatic peroxisome proliferation (Belury, M.A., and Vanden Heuvel, J.P., submitted for publication). Peroxisome-specific enzymes include acyl-CoA oxidase, the rate-limiting enzyme in peroxisomal β-oxidation (26), liver fatty acid binding protein, a cytosolic lipid transport protein thought to be involved with shuttling fatty acids to and from the plasma membrane (27), and cytochrome p450IVA1, a lipid-metabolizing enzyme involved in ω-hydroxylation of fatty acids (28). Because each of these peroxisome-specific enzymes contribute to β-oxidation of fatty acids, peroxisomes are likely to be involved in maintaining cellular lipid homeostasis. Although the role of CLA in lipid metabolism is largely unknown, induction of peroxisome-specific fatty acid catabolic enzymes may shed some light on how CLA modulates fatty acid metabolism and carcinogenesis in extrahepatic tissues.

Linear, Steroidal, and Triterpene Esters, and Steryl Glycosides from *Festuca argentina*

Adriana C. Casabuono and Alicia B. Pomilio*

PROPLAME-CONICET, Departamento de Química Orgánica, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, 1428 Buenos Aires, Argentina

ABSTRACT: Ester waxes and steryl glycosides of the grass *Festuca argentina* were studied. Saponification of the waxes from the petroleum ether extract led to *n*-hexacosanol as the major single linear alcohol, along with pentacyclic triterpenols, such as β-amyrin, germanicol, isobaurenol, lupeol, hopenol-a and hopeol, and low amounts of sterols, such as cholesterol, campesterol, stigmasterol, sitosterol and dihydrositosterol, identified by gas chromatography/mass spectrometry (GC/MS). Fatty acids were identified as methyl esters as $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{18:2}$, and $C_{20:0}$. The occurrence of a wide chainlength range of fatty acids and a single linear alcohol closely matched for other reports on the tribe Festuceae. On the contrary, pentacyclic triterpenols with a variety of skeletons, especially isobauerenol, are not usual as esters of fatty acids in the Gramineae. Low amounts of steryl glycosides were also obtained from the methylene chloride percolate of the methanol extract. Upon acetylation followed by hydrolysis, aglycones were identified by capillary gas–liquid chromatography (GLC) and GC/MS. As Δ^7-cholesterol, campesterol, stigmasterol, sitosterol, dihydrositosterol, and the sugars as glucose, xylose, and arabinose by GLC of the respective alditol acetates. This is the first report on the linear, steryl, and triterpenyl esters of *F. argentina*. It is noteworthy that Δ^7-steryl glycosides are rare, and steryl monoarabinosides have not been previously reported on the family Gramineae.

Lipids 32, 205–210 (1997).

Festuca argentina (Speg.) Par. (Gramineae; common name: "coirón negro," "coirón duro") is a perennial xerophyte Patagonian grass popularly known as toxic to sheep (1) that grows in the pre-Andinian region, and eastward around the Gulf of San Jorge (2) in the Patagonian coast of Argentina.

We have previously reported on free sterols and triterpenes from this species (3). The Δ^5-, Δ^7-, and dihydrosterols were identified as well as pentacyclic triterpenones with a variety of skeletons, such as oleanene/ursene (Δ^{12}-oleanen-3-one or β-amyrenone, Δ^{18}-oleanen-3-one = germanicone), lupene (lupen-3-one), hopene ($\Delta^{22(29)}$-hopen-3-one) and multiflorene (Δ^8-multiflorenone = isomultiflorenone) and a cyclopropane tetracyclic triterpenone (cycloartanone), the two latter being rare in the Gramineae. However, the expected 4-methylsterols, 3-methoxytriterpenes and arborene and/or fernene triterpenoids were not detected in this species, although widespread in the Gramineae (4).

In continuation of our work on members of the tribe Festuceae, we want to report in this paper the composition of the ester waxes and steryl glycosides of *F. argentina* that, in contrast to other grasses, showed to be rich not only in a linear alcohol but also in both bound sterols and triterpenols.

Wax esters from other members of the Gramineae usually accounted for esters of fatty acids–*n*-alcohols, e.g., *Bromus inermis*, *F. ovina* (5), *Secale cereale* (6), three wheat species (7–9), and *Agropyron desertorum* and *A. intermedium* (10), due to interesterification of a wide range of acids with a much smaller chainlength range *n*-alcohols. Combined alcohols from waxes of festucoid grasses (5,11) generally contain one major component, C_{26} or C_{28}, with the same chainlength as the major free alcohol of the wax. However, in *Agropyron smithii* (tribe Triticeae) a wide chainlength range of both acids and alcohols from the ester waxes were obtained without any prevalent long-chain major component (12), the alcohol portion also containing unusual appreciable percentage of α- and β-amyrins (40%). A wide range of chainlength linear alcohols and triterpenol esters was also typical of species of the subfamily Eragrostoideae (13).

Detailed information on the identities of naturally-occurring phytosterols as glycosides is far from complete. So far, up to now these compounds have not been described as characteristic of any family, and they are scarcely distributed, except for sitosterol 3-*O*-glucoside, in agreement with earlier biosynthetic studies in *Triticum aestivum*, showing that UDP-glucose is the most active glycosyl donor (14). We have detected in *F. argentina* several steryl glycosides composed of a variety of steryl and sugar moieties. The occurrence of these compounds may be related to a sterol storage function, instead of simple waste products as considered by some plant physiologists especially interested in the role of free sterols (14).

MATERIALS AND METHODS

Plant material. Plants of *F. argentina* (Speg.) Par. (family: Gramineae) were collected by Prof. Ing. Angel Soriano in Río

*To whom correspondence should be addressed at PROPLAME-CONICET, Departamento de Química Orgánica, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires. Pabellón 2, Ciudad Universitaria, 1428 Buenos Aires, Argentina.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; GLC, gas–liquid chromatography; MPLC, medium-pressure liquid chromatography; MS, mass spectra; MW, molecular weight; PE, petroleum ether; R_f, retention front; R_t, retention time; TLC, thin-layer chromatography.

Mayo (EE-INTA Río Mayo; Patagonia), Province of Chubut, Argentina, and identified by Dr. Elisa Nicora (Instituto de Botánica Darwinion, San Isidro, Argentina); voucher specimen were deposited in the Instituto de Botánica Darwinion (Argentina) SI 28004. This is a monocotyledonous matted grass with blades, roots, and spikelets with minute structures which are important markers of taxa. Spikelets of grass species within a genus differ in the rachilla joints, glumes, lemmas, or paleas. In addition it has a distinct festucoid-type embryo. The plant material used in this study was harvested in February (summer season in southern hemisphere) in the so-called fruit stage/period; it was composed of leaves (blades) and adventitious fibrous roots, and devoid of spikelets.

Materials and chromatographic conditions. Analytical thin-layer chromatography (TLC) plates (silica gel G, F-254, 250 μm layer), silica gel G and silica gel H were purchased from Merck (Darmstadt, Germany); polyamide for chromatography was purchased from Woelm (Eschwede, Germany). Preparative TLC (20 cm × 20 cm; 1000 μm layer) were prepared in our laboratory using a suspension of silica gel G (30 g) in distilled water (60 mL). Freshly prepared plates were kept at room temperature for 24 h and further activated at 110–120°C for 1 h prior to use. Spots were visualized under ultraviolet (UV) light at 254 nm and/or by spraying the plates with H_2SO_4/AcOH (1:1) and heating at 110–120°C for 2 min. Medium-pressure liquid chromatography (MPLC) was carried out on silica gel H (Merck) columns with an impulse solvent bomb Prominent-Electronic 1001 SCJ (Heidelberg, Germany) with a pulse damper. Flash dry chromatography was performed under vacuum through a fritted Pyrex glass funnel membrane (Thomas Scientific, Swedesboro, NJ). Organic solvents were obtained from Sintorgan (Buenos Aires, Argentina) followed by distillation, except for petroleum ether (PE) and *n*-hexane which were freed from olefines in the usual way prior to distillation. All solvent mixtures are expressed in volume (vol/vol).

Extraction of the plant material. As soon as it was collected, fresh material was air-dried in the laboratory in an air-circulating oven at 25°C to remove soil adhered to roots and blades; then it was ground and immediately extracted in a Soxhlet with PE (60–80°C) followed by MeOH. Flash dry chromatography of PE extract (1.6 % relative to dry weight) using gradients of *n*-hexane/EtOAc as previously reported (3) followed by TLC analysis led to six main fractions, termed 1-6. TLC (*n*-hexane/EtOAc, 98:2) of fraction 2 gave a main pink spot at R_f 0.60 typical of waxes, a brown spot at R_f 0.53 due to aldehydes, and a light-orange spot at R_f 0.38 due to terpenoids. Separation of these components (subfractions 2a, 2b, and 2c) was afforded by repeated preparative TLC (*n*-hexane/EtOAc, 97:3). Bands were eluted with chloroform and monitored by analytical TLC, and the waxes were characterized by infrared spectra (KBr) using a Perkin-Elmer 710-B spectrophotometer (Palo Alto, CA). The MeOH extract was further percolated on polyamide with CH_2Cl_2, H_2O, and finally MeOH, rendering 1.0, 2.8, and 2.3% relative to dry plant, respectively. The CH_2Cl_2 percolate was worked up as described before (15) yielding a subfraction 2 that was purified by MPLC (EtOAc). A Liebermann-Burchard positive (16) fraction that gave a diffuse pink spot of R_f 0.65 by TLC (EtOAc/MeOH, 95:5) contained steryl glycosides (3 mg; 0.005% relative to dry plant) which were acetylated (Ac_2O/anhydrous pyridine) to overcome their insolubility in organic solvents (R_f 0.80 and 0.85, high-performance thin-layer chromatography: EtOAc/MeOH, 95:5), and further hydrolyzed.

Saponification of waxes. Saponification was performed by stirring the waxes (0.13 g) under reflux with 20% KOH in MeOH for 4 h. The reaction was monitored by TLC. The mixture was then evaporated to dryness. Water was added to the residue and the aqueous layer was further extracted with $CHCl_3$. The organic layers were combined, dried over anhydrous Na_2SO_4 and the chloroform was evaporated under vacuum to give the alcohols. The remaining aqueous layer was acidified and the acidic compounds were extracted with $CHCl_3$. This chloroform layer was dried over anhydrous Na_2SO_4 and then evaporated to dryness to give the organic acids. These organic acids were methylated (CH_2N_2/Et_2O) for 14 h at room temperature.

Hydrolysis of the steryl glycosides. The acetylated glycosides were hydrolyzed with 6% HCl in MeOH. The reaction mixture was heated until dissolution of the glycosides and drops of water were added until there was slight turbidity. Then it was kept at 75°C in a sealed tube for 2 h. After neutralization with $NaHCO_3$ and evaporation of the solvent, the residue was partitioned with CH_2Cl_2/H_2O (1:1). The CH_2Cl_2 layer was dried with anhydrous Na_2SO_4 and evaporated at 40°C, yielding sterols. The aqueous layer containing the sugars was desalted with Amberlite MB-3/thymolphthalein (Sigma, St. Louis, MO) to prepare the alditol acetates ($NaBH_4$, room temperature, 12 h; Ac_2O/pyridine, 1:0.8).

Gas–liquid chromatography (GLC) and gas chromatography/mass spectrometry (GC/MS) analysis of the compounds. GLC was performed on a Hewlett-Packard 5840 A chromatograph (Palo Alto, CA) with flame-ionization detection (FID) and nitrogen as gas carrier. Capillary GC/MS were performed at 70 eV on a Hewlett-Packard 5890A chromatograph coupled with a selective mass detector 5970B. Mass spectra (MS) data were processed by a Lab Base GC-MS data system (40 to 800 mass scanning). The respective alcohol mixtures from the hydrolysis of the waxes and of the glycosylsterols were chromatographed on a bonded-phase fused silica capillary column (DB-1, 30 m length × 0.245 mm id, 0.25 μm film thickness; J&W Scientific, Folsom, CA). Oven temperature was set at 180°C for 1 min with a 5°C/min temperature ramp up to a final temperature of 300°C for the alcohols from the ester waxes, and 200–300°C, rate 10°C/min for the aglycones from the glycosylsterols. The identities of *n*-hexacosanol, β-amyrin, germanicol, lupeol and hopeol, as well as the sterols were confirmed by capillary GLC with standards. In addition, the mixtures were examined by GC/MS on a 25 m × 0.25 mm, 0.33 μm film thickness Ultra-1 capillary column, temperature programmed from 240–300°C at 3°C/min for wax alcohols, and 200–300°C, rate 15°C/min for glycosides aglycones.

Fatty acids from the wax hydrolysis were separated as methyl esters on a 1.8 m × 2 mm 8% NPGS packed column on Chromosorb W-AW-DMCS, 60-80 mesh, at 190°C, using authentic fatty acid methyl ester standards. Identification was confirmed by GC/MS spectrometry on a 1.2 m length × 2 mm i.d. SP-2340 column (Supelco, Bellefonte, PA) programmed from 60–270°C at 8°C/min. Sugars from steryl glycosides were analyzed by capillary GLC of their alditol acetates against synthetic standards (SP 2330, 30 m length × 0.25 mm id, 0.20 μm film thickness; Supelco).

RESULTS AND DISCUSSION

Ester waxes. Repeated chromatographic purification techniques applied to the PE extract of *F. argentina* yielded a subfraction with an infrared spectrum typical of high molecular weight (MW) ester waxes [2895 ($\nu_{C\text{-}H}$), 1742 ($\nu_{C=O}$), 1475 ($\delta_{C\text{-}H}$), 1180 ($\nu_{C\text{-}O}$) and 740 cm^{-1} ($\delta_{C\text{-}H}$)]. Upon hydrolysis, a homologous series of saturated fatty acids with even carbon atom from C_{12} to C_{20} was obtained, which showed typical fragmentation pattern (17) by GC/MS analysis of their respective methyl esters with *m/z* 74 as base peak, and M^+ at *m/z* 214, 242, 270, 298, and 326, respectively. In addition, M^+ 294 was shown to be a fatty acid of C_{18} containing two unsaturations ($C_{18:2}$) by its mass fragmentation pattern. The acid composition of the ester waxes from *F. argentina* is shown in Table 1, with hexacosanoic acid being the major component among the seven identified fatty acids.

By contrast, the wax alcohols (Table 1; Fig. 1) showed a single major linear alcohol, *n*-hexacosanol ($C_{26:0}$), which accounted for 61% of the total alcohol wax composition, along with triterpene alcohols (31.2%) and low amounts of sterols (7.6%) (Fig. 1A). The low levels of triterpenols and sterols were detected by GC/MS in the 15 to 24 min region of the amplified chromatogram (Fig. 1B). The MS of the respective sterols showed M^+ 386, 400, 412 and 414, and the fragmentation pattern typical of Δ^5-sterols (Table 2) (18), corresponding to cholesterol, campesterol, stigmasterol, sitosterol, along with another sterol of R_t and M^+ higher than that of sitosterol, and an intense ion *m/z* 233 in agreement with dihydrositosterol (19). The GC/MS of the pentacyclic triterpenoid alcohols were in the range of retention time (R_t) 20.34 to 22.99 min. The compound of R_t 20.34 min, M^+ 426, and *m/z* 218 as base peak showed a fragmentation pattern (Table 2) of a Δ^{12}-ursene/Δ^{12}-oleanene triterpenol (20), confirmed as β-amyrin by capillary GLC with authentic samples, due to the fact that both skeletons are undistinguishable by MS. The compound of R_t 20.52 min (Table 2) presented a M^+ 426 followed by loss of 15 amu, and an intense ion at *m/z* 177 (98.5%) typical of a Δ^{18}-oleanene or Δ^{18}-friedelene (20); the low abundance (14.7%) of ion *m/z* 203, usually very high in Δ^{18}-friedelene (20) provided evidence for a Δ^{18}-oleanene, further confirmed by GLC comparison with a germanicol sample. The compound of R_t 20.93 min, M^+ 426, *m/z* 247 as base peak and other ions (Table 2) was characteristic (21) of a D:C-friedo-oleanane/D:C-friedo-ursane skeleton with one unsaturation either at Δ^7-(multiflorenol/bauerenol) or at Δ^8-(isomultiflorenol/isobauerenol), prevailing the bauerene series (20) by the intense *m/z* 247 and the low abundant *m/z* 205. Comparison of relative abundances was required for the Δ^7/Δ^8 location of the double bond, e.g., base peak, M^+ and M^+-Me of isobauerenol (22) and β-bauerenol (23), thus leading to isobauerenol (bauer-8-en-3-β-ol) only once reported in Gramineae (24). Compounds with R_t 21.18, 22.76, and 22.99 min showed similar MS (Table 2) concerning the molecular ion (M^+ 426) and the highly abundant *m/z* 207, arising from hydroxyl-containing rings A/B of saturated triterpenols without directing groups. The fact that *m/z* 189 is more intense than *m/z* 191, along with the low intensity or absence of M^+–

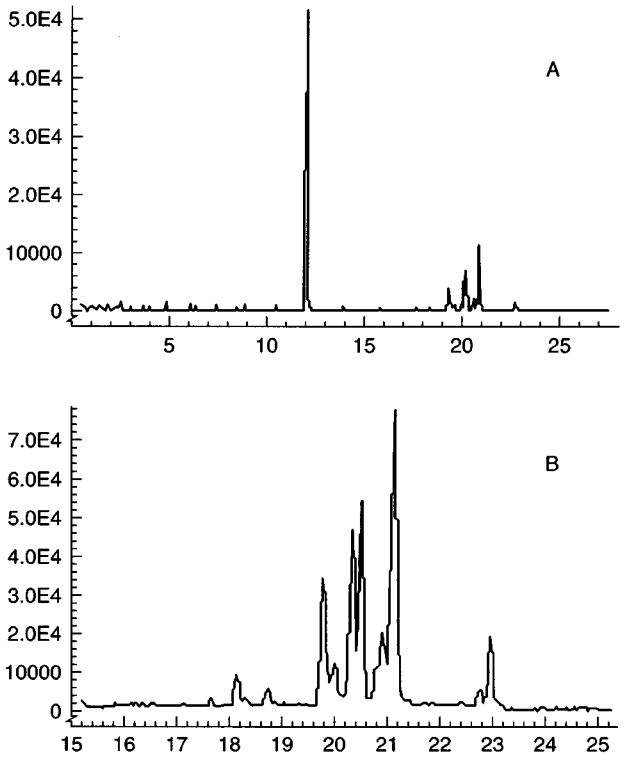

FIG. 1. Gas chromatography/mass spectrometry of the alcohols from ester wax hydrolysis. (A) general chromatogram; (B) chromatogram of the amplified 15 to 24 min region.

TABLE 1
Composition of Acids and *n*-Alcohols from *Festuca argentina* Waxes

	12:0	14:0	16:0	18:0	18:2	20:0	26:0
Esterified acids[a]	1.9	4.0	38.8	25.7	19.8	5.7	—
Esterified alcohols[b]	—	—	—	—	—	—	61.0

[a]Fatty acids analyzed as methyl esters by gas–liquid chromatography (GLC) on 8% NPGS and comparison with standards. Identification confirmed by gas chromatography/mass spectrometry (GC/MS) on a SP-2340 column. For details, see the Materials and Methods section.

[b]Alcohols were analyzed by capillary GLC on DB-1. Identification of *n*-hexacosanol is based on cochromatography with a known standard and GC/MS as indicated in Table 2.

TABLE 2
Alcohols from the Saponification of *Festuca argentina* Waxes

Alcohol[a]	R_t (min)	Characteristic mass peaks (*m/z*) (% relative abundance)
n-Hexacosanol	12.52	364 ($M^+ - H_2O$, 5.2), 336 (364 – $CH_2 = CH_2$, 2.5), 308 (0.5), 280 (0.8), 266 (0.7), 252 (0.9), 238 (1.0), 224 (1.2), 210 (1.5), 195 (2.3), 181 (3.3), 167 (4.5), 153 (6.6), 139 (10.6), 125 (19.7), 111 (37.2), 97 (72.9), 83 (83.7), 73 (1.5), 71 (56.9), 69 (69.0), 57 (100.0), 55 (62.2), 43 (76.9), 41 (21.9).
Cholesterol	17.59	387 ($M^+ + 1$, 29.2), 386 (M^+, 100.0), 371 (M^+ – Me, 31.2), 368 ($M^+ - H_2O$, 39.7), 353 ($M^+ - H_2O$ – Me, 32.5), 301 (M^+ – 85, 49.1), 275 (M^+ – 111, 37.5), 273 (M^+ – side chain, 21.0), 247 (M^+ – 139, 7.4), 231 (M^+ – side chain – 42, 17.9).
Campesterol	18.10	401 ($M^+ + 1$, 29.6), 400 (M^+, 100.0), 385 (M^+ – Me, 29.3), 382 ($M^+ - H_2O$, 39.9), 367 ($M^+ - H_2O$ – Me, 28.5), 315 (M^+ – 85, 43.2), 289 (M^+ – 111, 27.6), 273 (M^+ – side chain, 18.9), 261 (M^+ – 139, 5.5), 231 (M^+ – side chain – 42, 16.8).
Stigmasterol	18.68	413 ($M^+ + 1$, 23.0), 412 (M^+, 68.9), 397 (M^+ – Me, 6.1), 394 ($M^+ - H_2O$, 5.0), 379 ($M^+ - H_2O$ – Me, 7.3), 369 (M^+ – 43, 8.9), 351 (369 – H_2O, 15.8), 300 (M^+ – 112, 20.2), 271 (M^+ – side chain – 2H, 19.6).
Sitosterol	19.79	415 ($M^+ + 1$, 19.7), 414 (M^+, 63.1), 399 (M^+ – Me, 16.9), 396 ($M^+ - H_2O$, 24.7), 381 ($M^+ - H_2O$ – Me, 17.5), 329 (M^+ – 85, 24.4), 303 (M^+ – 111, 12.5), 275 (M^+ – 139, 3.3), 273 (M^+ – side chain, 10.9).
Dihydrositosterol	19.99	417 ($M^+ + 1$, 30.8), 416 (M^+, 100.0), 401 (M^+ – Me, 38.8), 398 ($M^+ - H_2O$, 2.7), 383 ($M^+ - H_2O$ – Me, 14.9), 234 (M^+ – side chain – 41, 48.2), 233 (M^+ – side chain – 41 – H, 75.2), 215 (57.8).
β-Amyrin	20.34	427 ($M^+ + 1$, 0.6), 426 (M^+, 2.7), 411 (M^+ – Me, 0.5), 393 (M^+ – Me – H_2O, 0.9), 219 (18.7), 218 (RDA, rings D and E, 100.0), 205 (rings D and E or rings A and B, 0.5), 203 (218 – Me, 39.3), 189 (207 – H_2O and/or rings D and E – 29, 4.5).
Germanicol	20.52	427 ($M^+ + 1$, 8.5), 426 (M^+, 31.7), 411 (M^+ – Me of C – 17, 26.0), 393 (M^+ – Me – H_2O, 1.9), 218 (rings D and E + C – 11 + C – 12,), 207 (rings A and B, 19.7), 206 (15.3), 205 (rings D and E + C – 12, 37.6), 204 (rings D and E + C – 12, 100.0), 203 (218 – Me, 14.7), 191 (18.1), 190 (205 – Me, 24.9), 189 (93.8), 178 (21.4), 177 (RDA in ring D + C – ring, 98.5).
Isobauerenol	20.93	427 ($M^+ + 1$, 7.8), 426 (M^+, 21.9), 411 (M^+ – Me, 14.1), 393 (M^+ – Me – H_2O, 5.1), 259 (rings A + B + C + Me – 26, 15.5), 247 (RDA ring C and rupt. C – 15 – C – 16, 100.0), 229 (57.3), 205 (rings D and E, 8.8).
Lupeol	21.18	427 ($M^+ + 1$, 12.0), 426 (M^+, 38.0), 411 (M^+ – Me, 13.4), 408 ($M^+ - H_2O$, 1.7), 393 (M^+ – Me – H_2O, 3.2), 383 (M^+ – isopropyl, 3.8), 218 (rings D and E, 89.3), 207 (rings A and B, 59.3), 204 (28.7), 203 (37.4), 191 (26.8), 190 (7.8), 189 (60.8),135 (64.1), 121 (65.3), 109 (70.9), 108 (47.9), 107 (78.8), 105 (46.5), b.p. 43.
Hopenol-a	22.76	427 ($M^+ + 1$, 18.0), 426 (M^+, 47.8), 207 (rings A and B, 85.7), 204 (24.2), 191 (35.4), 190 (43.5), 189 (207 – H_2O and/or rings D and E, 100.0).
Hopeol	22.99	427 ($M^+ + 1$, 11.9), 426 (M^+, 36.6), 218 (16.9), 217 (rings D and E + C – 11 + C – 12, 7.2), 208 (RDA, rings A and B, 20.6), 207 (79.6), 205 (22.8), 204 (24.3), 203 (22.9), 191 (32.5), 190 (33.4), 189 (RDA, rings D and E – H, 89.1), 135 (60.0), 121 (70.3), 109 (86.6), 107 (76.5), 105 (33.4), b.p. 43.

[a]Identification confirmed on a 25-m capillary column Ultra-1 by GC/MS (EI-70 eV). For details, see the Materials and Methods section. See Table 1 for abbreviation.

43, is indicative of an isopropenyl group in the molecule, thus supporting the occurrence of either lupane or hopane skeletons, which usually lack a characteristic fragmentation pattern. Consequently, the identity of compounds with R_t 21.18 and 22.99 min was confirmed by capillary GLC comparison with authentic samples of lupeol and hopeol (hopenol-b = hop-22(29)-en-3-β-ol), respectively. The MS of the minor compound of R_t 22.76 min showed only two fragments in the high-mass region suggesting a difference in the double-bond location of the isopropenyl group relative to the two latter compounds, thus leading to hopenol-a.

Steryl glycosides. Successive MPLC purification steps of the MeOH extract of *F. argentina* gave rise to a Liebermann-Burchard positive fraction (16) composed of steryl glycosides, which accounted for 0.005% relative to dry weight. Its chromatographic behavior (TLC, R_f region) was in agreement with nonacylated steryl monoglycosides. No changes were observed upon *O*-methylation (ethereal CH_2N_2), indicating the absence of uronic acids (25). After acid hydrolysis of the acetate derivatives, both sterols (aglycones) and sugars (as alditol acetates) were identified by capillary GLC and capillary GC/MS analysis. Glucitol (16.4%), xylitol (28.9%), and

arabinitol (54.7%) were characterized and further confirmed by capillary GLC comparison with synthetic standards. Accordingly, 3-*O*-monoglycosides of cholesterol (11.3%), Δ^7-cholesterol (14.2%), campesterol (13.9%), stigmasterol (14.5%), Δ^7-sitosterol (15.3%), sitosterol, and 5,6-dihydrositosterol (30.8%) occur in *F. argentina*, some of them as 3-*O*-monoglucosides, 3-*O*-monoxylosides, and 3-*O*-monoarabinosides. Although sitosterol 3-*O*-glucopyranoside is widespread in nature (26–28), only few other Δ^5-steryl 3-*O*-monoglycosides have been reported, such as stigmasterol 3-*O*-glucopyranoside (29), sitosterol 3-*O*-β-D-xylopyranoside (30), sitosterol 3-*O*-α-D-riburonofuranoside (25), sitosterol 3-*O*-α-D-xyluronofuranoside (31), and sitosterol 3-*O*-β-D-glucuronopyranoside (32). To the best of our knowledge, the isolation and identification of monoglycosides of dihydrosterols and Δ^7-sterols from natural sources is rare, such as 3-*O*-β-D-glucopyranoside and 3-*O*-β-D-galactopyranoside of (24*R*)-stigmast-7,22(*E*)-dien-3-α-ol (epichondrillasterol) (33). Moreover, D-glucose is the usual sugar moiety (34) of monoglycosides of a variety of Δ^5-phytosterols, steryl 3-*O*-monoarabinosides being so rare in nature that stigmasterol α-L-arabinopyranoside has only been isolated once, from *Wallenia yunquensis* (35).

In summary, free (3), esterified and glycosylated 4-demethylsterols were found in *F. argentina*, whereas pentacyclic triterpenols merely occurred as esters of high-MW fatty acids. These findings closely resemble earlier reports on *Sorghum vulgare* (36). Thus, our results show that Δ^5-sterols and dihydrositosterol are found in free (3), esteryl and glycosyl forms, while Δ^7-sterols are present only free (3) and/or as glycosyl derivatives. Nevertheless, the relative percentage of the sterols in free and bound forms are distinctly variable, e.g., free cholesterol (1.3%) (3), glycosyl cholesterol (11.3%), and only traces of esterified cholesterol. Conversely, the proportion of free sitosterol and dihydrositosterol appears to be higher (56.3%) than the glycosylated (30.8%) and esterified (6.46%) forms.

ACKNOWLEDGMENTS

Thanks are due to CONICET (Argentina) and Universidad de Buenos Aires (Argentina) for financial support; to Prof. Ing. A. Soriano and Dr. Dubcovsky for collection of the plant material; to Dr. E. Nicora (Instituto de Botánica Darwinion, Argentina) for identification of the plant material, and to LANAIS-EMAR (Argentina) for GC/MS facilities.

ABSTRACT: Our objective was to develop a suitable probe to study metabolism of polyunsaturated fatty acids by ^{13}C nuclear magnetic resonance (NMR) in the suckling rat pup. [3-^{13}C] γ-Linolenic acid was chemically synthesized, and a 20 mg (Experiment 1) or 5 mg (Experiment 2) dose was injected into the stomachs of 6–10-day-old suckling rat pups that were then killed over a 192 h (8 d) time course. ^{13}C NMR showed that ^{13}C in γ-linolenate peaked in liver total lipids by 12-h post-dosing and that [5-^{13}C]-arachidonic acid peaked in both brain and liver total lipids 48–96 h post-dosing. ^{13}C enrichment in brain γ-linolenic acid was not detected by NMR, but gas chromatography–combustion–isotope ratio mass spectrometry showed that its mass enrichment in brain phospholipids at 48–96 h post-dosing was 1–2% of that in brain arachidonic acid. ^{13}C was present in liver and brain cholesterol and in perchloric acid-extractable water-soluble metabolites in the brain, liver and carcass. We conclude that low but measurable amounts of exogenous γ-linolenic acid do access the suckling rat brain *in vivo*. The slow time course of [5-^{13}C] arachidonic acid appearance in the brain suggests most of it was probably transported there after synthesis elsewhere, probably in the liver. Some carbon from γ-linolenic acid is also incorporated into lipid products other than n-6 long-chain polyunsaturated fatty acids.

Lipids 32, 211–217 (1997).

γ-Linolenic acid (18:3n-6; GLA) is formed by desaturation at the C6–C7 bond of linoleic acid (18:2n-6) and is an intermediate fatty acid in the desaturation/chain-elongation pathway between linoleic and arachidonic acid (20:4n-6; AA) (1). In mammals, GLA is usually present in tissue lipids in low amounts, mainly because it appears to be readily converted to dihomo-γ-linolenate (20:3n-6) before subsequent, slower desaturation to AA (2). GLA is not commonly found in the diet, but it is present in human breast milk. Concentrated edible sources of GLA are mostly limited to the oil in the seeds of the evening primrose, black currant, or borage plants (3).

AA is the main n-6 polyunsaturated fatty acid (PUFA) in the brain, but the origin of brain AA has not been established, i.e., the relative contributions of diet, synthesis outside the brain or synthesis within the brain are not known. Establishing the dependence of the brain on pre-formed AA would help determine the need to provide AA or closer precursors than linoleic acid in the diet. AA is present in small amounts in adipose tissue and milk, but it can also be synthesized in organs such as the liver, gut, or in the brain itself. Brain levels of GLA are usually <0.2% of total fatty acids, but whether this is due to low access of GLA to the developing brain or to rapid conversion to n-6 long-chain (LC) PUFA is unknown at present. Dietary GLA is known to increase the level of AA in liver and other organs of experimental animals (4,5), but whether it affects the amount of AA destined for the developing mammalian brain is unknown. More radiolabeled GLA than linoleic acid was incorporated into brain AA in the suckling rat, but the time course of its conversion to AA and the relative importance of the liver were not reported (6).

Our objective was to develop a probe of neonatal AA synthesis that could be detected by noninvasive nuclear magnetic resonance (NMR) methodology and was safe for potential use in humans. ^{13}C is a stable isotope safe for human use and by locating the ^{13}C-enriched carbon at C-3 of GLA, the ^{13}C enrichment is detectable by *in vivo* ^{13}C-NMR spectroscopy in living rats (7). In the present study, we have used high-resolution ^{13}C-NMR to detect the original [3-^{13}C]-GLA vs. its conversion to [5-^{13}C]-AA. Gas chromatography (GC)–combustion–isotope ratio mass spectrometry (GC–C–IRMS) provided precise enrichment values for the ^{13}C-labeled fatty acids. These analytical methods offer complementary data on carbon-by-carbon ^{13}C enrichment and precise quantitation of ^{13}C enrichment, respectively (8–10).

Abbreviations: AA, arachidonic acid; APE, atom % excess; GC, gas chromatography; GLA, γ-linolenic acid; IRMS, isotope ratio mass spectrometry; LC, long chain; NMR, nuclear magnetic resonance; PUFA, polyunsaturated fatty acids.

METHODS

Synthesis of [3-^{13}C] γ-linolenate. Ethyl [3-^{13}C]-all *cis*-6,9,12-GLA was prepared using classical methodology developed for chemical synthesis of labeled PUFA (11,12). The all-*cis*-3,6,9-pentadecatrienol, easily obtained by catalytic hydrogenation of the C_{15}-triynol precursor (13), was converted *via* the corresponding mesylate to the labeled nitrile (14). Acidic methanolysis of the crude nitrile under carefully controlled reaction conditions provided the methyl all-*cis*-4,7,10-hexadecatrienoate (15) which was reduced to an alcohol. Chain elongation of the resulting C_{16}-alcohol, using malonic ester synthesis (16), provided GLA. After distillation and chromatographic purification, esterification under standard conditions gave the desired ethyl [3-^{13}C]-GLA. GC analysis indicated there was 88% all-*cis* GLA, 2.4% heptadecanoate, 4.0% linoleate, and 3.7% *trans*-GLA. Labeling at carbon-3 was calculated to be in excess of 99% as established by spectroscopic methods and microanalysis of ^{12}C (found 73.93% vs. 74.22% in theory), ^{13}C (found 4.23% vs. 4.22% in theory), and hydrogen (found 11.20% vs. 11.15% in theory). ^{13}C NMR of the [3-^{13}C]-GLA in chloroform solution showed one major peak at 24.7 ppm corresponding to the ^{13}C-enriched carbon atom, and some very low peaks corresponding to expected peaks for unenriched carbons of GLA plus some others that were unidentified (Fig. 1).

Tracer protocol and tissue collection. All procedures involving animals followed protocols approved by the University of Toronto Animal Care Committee. Pregnant Sprague-Dawley rats (Charles River, St. Constant, QC, Canada) were housed singly and had *ad libitum* access to tap water and rodent chow (Ralston-Purina, St. Louis, MO). Two experiments were performed. In the first experiment, 6-day-old suckling rats were dosed directly into the stomach with 20 mg of [3-^{13}C] GLA. The rat pups were killed in groups of 3–4 at the following times after dosing: 1, 2, 4, 6, 8, 10, 12, 24, 48, 96, or 192 h (8 d). Controls were also killed at matched ages (6, 7, 8, 10, or 14 d old). Following euthanasia and decapitation, the brains and livers were excised, weighed, and immediately immersed in liquid N_2 and then stored on dry ice for analysis. Prior to lipid extraction, the organs were pulverized to a powder under liquid N_2 using a mortar and pestle. In Experiment 1, brains and livers were pooled separately at each time point (n = 3–4/time point) to obtain the highest possible signal/noise ratio in NMR spectra. In Experiment 2, 5 mg [3-^{13}C]-GLA was dosed into 10-day-old suckling rat pups, and the time points studied were 48 and 96 h post-dosing with 2–4 separate measurements/time point.

Extraction and analysis of water- and lipid-soluble metabolites. For lipid extraction, the powdered organs were transferred to vials containing 20 volumes/tissue volume of chloroform/methanol (2:1), and the total lipid extracts were recovered by standard procedures (17). Water-soluble metabolites were extracted from organ samples collected in the first 10 h after dosing with [3-^{13}C] GLA while lipid-soluble metabolites were extracted from samples collected 12–192 h post-dosing.

^{13}C enrichment in an aliquot of the dried brain and liver lipid extracts was determined by continuous flow combustion (C)–IRMS [Metabolic Solutions, Merrimack, NH) using an automated elemental analyzer (model ANCA and 20-20 IRMS; Europa Scientific, Crewe, Cheshire, United Kingdom)]. A second lipid aliquot was applied to thin-layer chromatography plates and developed in a neutral lipid solvent system for separation of total phospholipids from free cholesterol. ^{13}C enrichment in the separated total phospholipids and cholesterol of brain and liver was also analyzed by IRMS (Metabolic Solutions).

A third aliquot was taken from the total lipid extracts at the time of maximal ^{13}C enrichment for measurement of ^{13}C levels in individual fatty acids in liver and brain. Fatty acid methyl esters were prepared, and carbon isotope ratios were

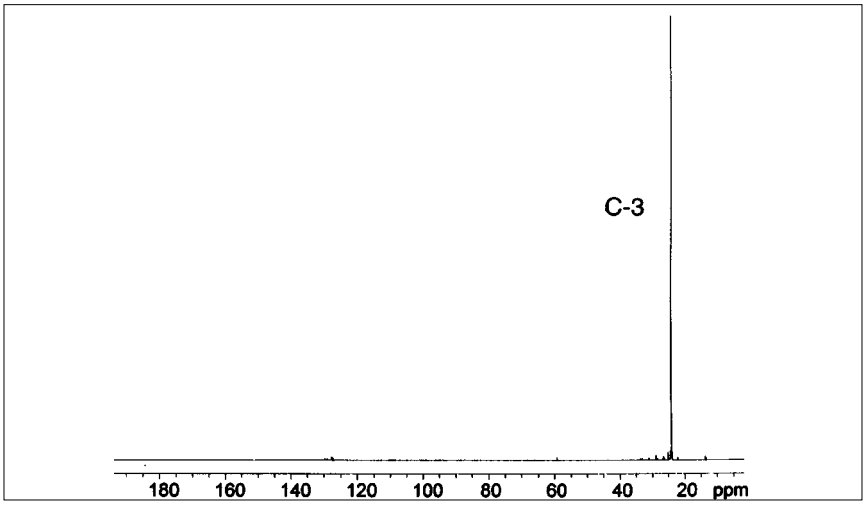

FIG. 1. ^{13}C nuclear magnetic resonance spectrum of [3-^{13}C]-γ-linolenic acid showing the ^{13}C-enrichment at 24.7 ppm which is assigned to C-3 of γ-linolenic acid.

determined by GC–C–IRMS as previously described in detail (9). Briefly, a GC (Varian Associates, Palo Alto, CA) operated in splitless mode was interfaced to an IRMS (Finnigan MAT 252; Bremen, Germany) *via* a combustion furnace/water trap system. The GC capillary column used was 0.25 mm × 60 m (DBWAX; J&W Scientific, Folsom, CA), and the oven temperature was programmed to ramp from 60 to 255°C with three plateaus. Isotope ratios were calibrated against a standard gas which was periodically calibrated against USGS 24 (National Bureau of Standards, Washington, D.C.). The standard gas was admitted when no analyte was entering the furnace and was integrated along with analyte peaks. The remainder of each lipid extract was dissolved in 500 µL deuterated chloroform (MSD Isotopes, Montreal, QC, Canada) and transferred to a 5-mm NMR tube. ^{13}C NMR spectra were obtained at 75 MHz (Bruker AM 300; Karlsruhe, Germany) as previously described (8).

To obtain water-soluble metabolites, organ samples were pulverized under liquid N_2 and homogenized in 6% perchloric acid. After centrifugation, the supernatants were neutralized, salts were removed on an ion exchange column, and the remaining material was freeze-dried. A sample of the dry, powdered perchloric acid extracts was assayed for ^{13}C content by combustion IRMS (Metabolic Solutions).

Data presentation. In the first experiment, organ weights, organ lipid content, and IRMS data are expressed as single values from 3–4 pooled samples because of the need to maximize the quality of ^{13}C NMR spectra by having the highest possible solute concentration. Isotope ratios were converted to atom % ^{13}C, and atom % excess (APE) was calculated by subtracting the atom % of the controls. In the second experiment, the data are given as mean ± SD for 2–4 samples/data point.

RESULTS

Experiment 1: ^{13}C NMR spectra of liver and brain lipids. ^{13}C NMR spectra of liver and brain total lipid extracts from rat pups dosed with ^{13}C-GLA at 6 d old had two particular regions of interest: the resonance for C-3 of GLA (24.7 ppm), and the resonance for C-5 of AA (128.9 ppm) (Figs. 2–4). The assignment of the peak at 24.7 ppm to C-3 of GLA was based on the ^{13}C-NMR spectrum of the pure tracer before dosing (Fig. 1). The assignment of C-5 of AA at 128.9 ppm is based on the metabolism of GLA in which C-3 becomes the C-5 olefinic carbon of AA; unequivocal assignments of the carbons of AA have not been reported to our knowledge. Control spectra of liver or brain total lipids had no detectable signal at C-3 of GLA. The C-3 signal for GLA was very prominent in liver lipid spectra 12–24 h after dosing with [3-^{13}C] GLA but then decayed rapidly and disappeared by 96 h post-dosing (Fig. 2B). The NMR signal for C-5 of liver AA at 128.9 ppm was highest at 48 h and was quite prominent from 24 to 96 h post-dosing (Fig. 2A). Hence the peak ^{13}C enrichment in liver AA occurred at a time when enrichment in ^{13}C in liver GLA was almost back to baseline values (Fig. 4).

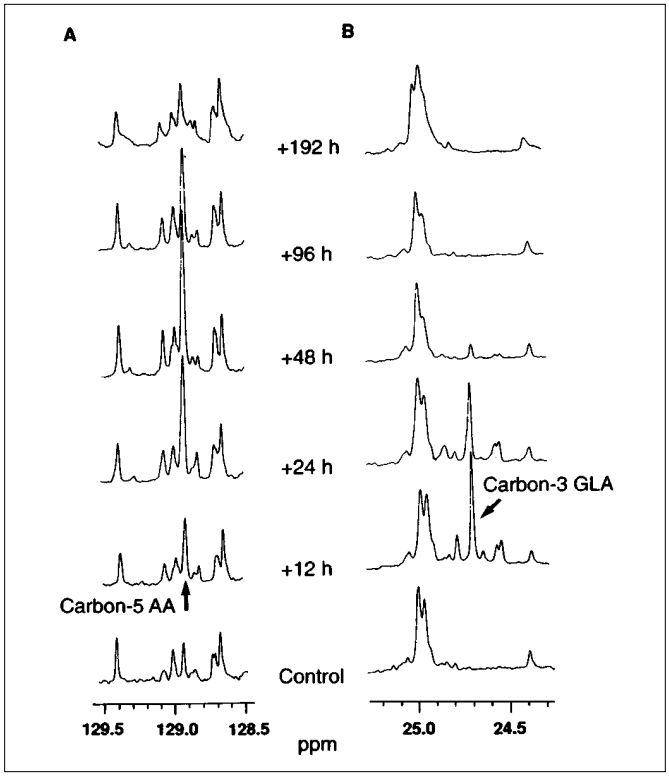

FIG. 2. The time course of ^{13}C enrichment at carbon (C)-5 of arachidonic acid (A) and C-3 of γ-linolenic acid (B) in ^{13}C nuclear magnetic resonance spectra of liver total lipid extracts. Suckling rats were dosed with [3-^{13}C]-γ-linolenic acid on day 6 and the time course lasted to day 14.

Other ^{13}C-enriched NMR signals in the spectra of liver lipids occurred in the region immediately surrounding C-3 of GLA (24.5–24.9 ppm). These signals have not yet been identified due to a lack of appropriate standards, but they may arise from C-3 of GLA esterified to different lipid classes or to GLA at different positions on phospholipid or triglyceride molecules. NMR-detectable ^{13}C enrichment was not readily identified with C-5 of dihomo-γ-linolenic acid or C-7 of adrenic acid (22:4n-6) in liver lipids because these resonances are not well-resolved among many other aliphatic carbons between 29–30 ppm.

In ^{13}C NMR spectra of brain total lipids, no ^{13}C enrichment was detected at any time point at the resonance of C-3 of GLA (Fig. 3B). However, C-5 of AA (128.9 ppm) was enriched with a maximum peak 48 h after dosing with the [3-^{13}C] GLA (Fig. 3A).

Experiment 1: IRMS of liver and brain total lipids. In Experiment 1, the atom % of ^{13}C-GLA in liver phospholipids rose within 48 h to 2–3 times natural abundance levels but for ^{13}C-AA, the ^{13}C enrichment only increased 9% above natural abundance levels (Table 1). However, relative to the total GLA or AA pool in liver phospholipids, total mass of ^{13}C enrichment in AA was 7 times higher than in GLA at 24 h and 16 times higher at 48 h post-dosing (Table 1). In liver triglycerides, ^{13}C enrichment in GLA reached 3–4 atom % and the

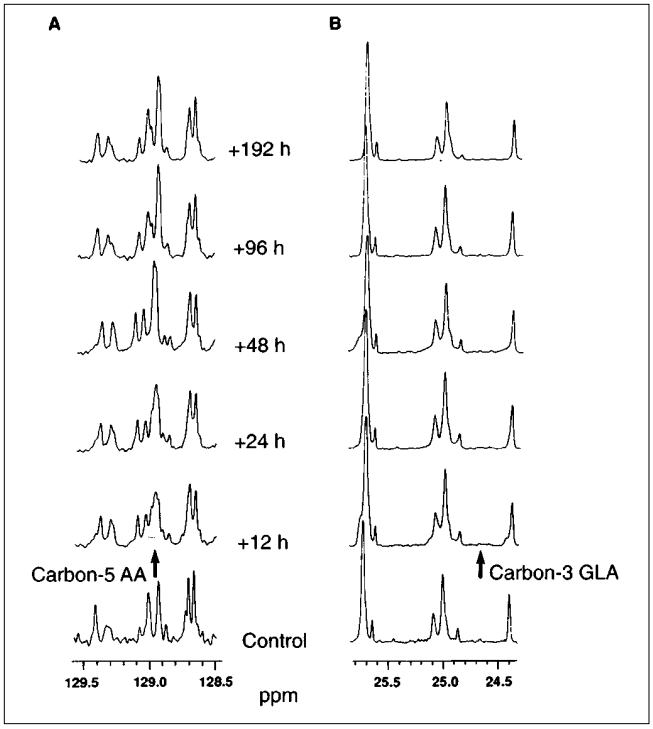

FIG. 3. The time course of ^{13}C enrichment at carbon-5 of arachidonic acid (A) and carbon-3 of γ-linolenic acid (B) in ^{13}C nuclear magnetic resonance spectra of brain total lipid extracts. Suckling rats were dosed with [3-^{13}C]-γ-linolenic acid on day 6 and the time course lasted to day 14.

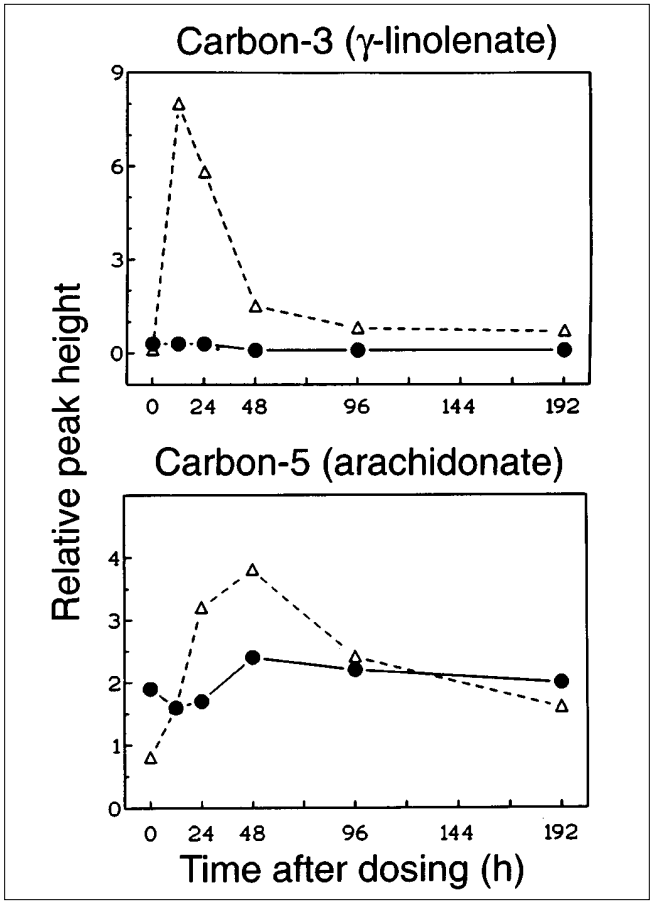

FIG. 4. Peak height for carbon (C)-3 of γ-linolenic acid and carbon (C)-5 of arachidonic acid in ^{13}C nuclear magnetic resonance spectra of total lipids of liver (△--△) and brain (●—●) from suckling rats after dosing with [3-^{13}C]-γ-linolenic acid. Peak heights are shown relative to peak for the n-3 carbons of n-3 polyunsaturated fatty acids (132 ppm) which cannot be enriched with ^{13}C.

peak mass of ^{13}C in GLA did not exceed 30% of that in AA (data not shown). In brain phospholipids, peak ^{13}C enrichment occurred 48–96 h post-dosing and the atom % ^{13}C-GLA rose by 5–14%; the atom % increase in ^{13}C-AA was about 4% (Table 2). High ^{13}C enrichment was detected 48 h in GLA of brain free fatty acids but ^{13}C mass in this pool was not determined. Relative to the total pools of GLA and AA in brain phospholipids, ^{13}C mass enrichment in AA was 44 and 130 times higher than in GLA at the 48 h and 96 h points, respectively (Table 2).

In brain total lipids, ^{13}C enrichment peaked at 48 h post-dosing and plateaued near peak levels between 96–192 h (Fig. 5A). The ^{13}C enrichment curve for brain phospholipids (Fig. 5B) was similar to that for C-5 of AA (Fig. 4) suggesting the ^{13}C mass enrichment of AA accounted for most of the ^{13}C in brain phospholipids. Since brain weight and total lipid content increased over the study period (Fig. 6), the plateau

[c]ng ^{13}C/g tissue, based on ^{13}C at a natural abundance of 1.09560% in GLA and AA, and on 2 μg/g GLA and 350 μg/g AA in brain phospholipids at 8–10 days old (Ref. 21).

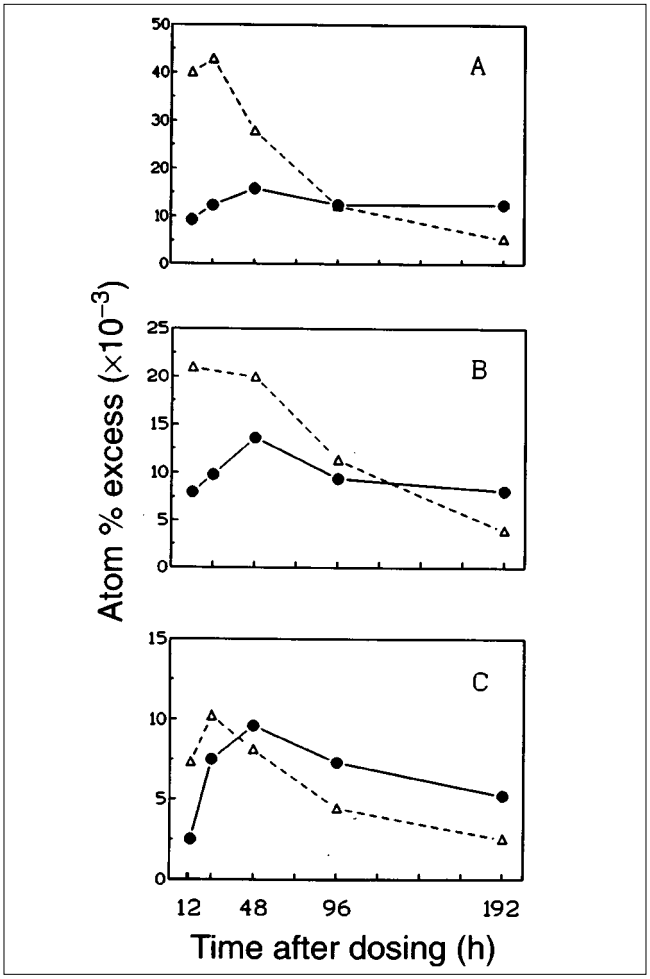

FIG. 5. The time course of ^{13}C enrichment (atom % excess) in rat brain (●—●) and liver (△– –△) total lipids (A), phospholipids (B), and free cholesterol (C) after dosing with [3-^{13}C] γ-linolenic acid. Suckling rats were dosed at day 6, and the time course lasted to day 14. Each point represents data from 3–4 tissue samples which were pooled together before being analyzed in duplicate.

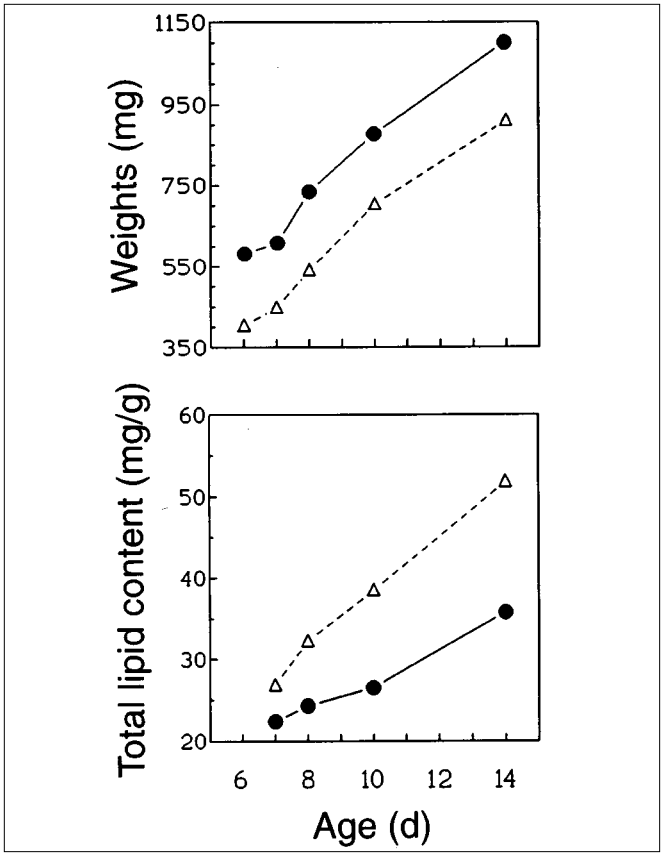

FIG. 6. Brain (●—●) and liver (△– –△) weights, and total lipid content of suckling rats.

in ^{13}C APE in brain total lipids indicated that ^{13}C mass in brain total lipids increased in parallel with increasing brain weight. ^{13}C enrichment in brain lipids increased faster in cholesterol than in total phospholipids but peaked in both lipid classes about 48 h after dosing with [3-^{13}C] GLA (Fig. 5B,C). In liver total lipids, ^{13}C APE peaked 24 h post-dosing and then decreased to 192 h (Fig. 5A). Since liver weight and lipid content increased over the study (Fig. 6) while ^{13}C enrichment decreased, net mobilization of ^{13}C-enriched lipids from the liver must have occurred over the course of the study. ^{13}C APE in liver phospholipids was about twice as high as in liver free cholesterol (Fig. 5B,C).

Experiment 1: water-soluble metabolites. ^{13}C enrichment in water-soluble metabolites peaked in the brain 2 h after dosing, peaked in the liver 2–6 h after dosing, and peaked in the remaining carcass 2 h after dosing with [3-^{13}C] GLA (Fig. 7). Maximal ^{13}C enrichment was similar in water-soluble metabolites of liver, brain, and carcass at about 20×10^{-3} APE.

Experiment 2: lower dose ^{13}C-GLA. The separation of liver and brain fatty acids by GC prior to ^{13}C analysis by GC–C–IRMS showed that ^{13}C enrichment was present in several n-6 PUFA derived from GLA (Table 3) but was not present in other fatty acids including palmitic, stearic, oleic, linoleic, or in n-3 PUFA (data not shown).

Each point represents data from 3–4 tissue samples which were pooled together before being analyzed in duplicate.

DISCUSSION

The present results show that a single tracer dose of [3-^{13}C]-GLA given by a physiological route is readily detected by ^{13}C-NMR of extracted liver lipids, but only a low mass of GLA itself accessed the lipids of the suckling rat brain within 96 h of dosing. By the time that ^{13}C levels in liver GLA had nearly returned to baseline (48 h), ^{13}C enrichment in AA had peaked in both liver and brain lipids (Fig. 4). Most ^{13}C-AA in the brain peaked at about the same time as in the liver. Data acquired by GC–C–IRMS clearly showed that ^{13}C was present in GLA in brain free fatty acids and that some [3-^{13}C]-GLA entered brain phospholipids. In view of the small pool of GLA in total brain lipids, the mass of [3-^{13}C]-GLA entering brain phospholipids within 96 h of providing a high dose of tracer (20 mg) was very low and equivalent to about 1–2% of the mass of ^{13}C-labeled AA in brain phospholipids (Table 2).

Combined with the relatively low brain uptake of ^{13}C-GLA itself, these data suggest that AA in the brain is derived primarily from ^{13}C-AA synthesized outside the brain, probably mostly in the liver; the ^{13}C NMR data (Fig. 3) and the GC–C–IRMS (Fig. 5, Table 2) as well as other studies in the literature (18) are in agreement on this point. In the context of similar work done using cultured neurons and astrocytes (19), it appears that if some conversion of [3-^{13}C]-GLA to [5-^{13}C]-AA occurred in the brain, it would probably have happened in astrocytes.

In addition to GLA, some linoleic acid also accesses the brain of the suckling rat (20), so it appears that the developing rat brain can derive AA either directly from the diet (maternal milk at the age studied here), from AA stores in adipose tissue, or from synthesis inside or outside the brain. Lean tissue triacylglycerols are also rich in PUFA including AA in the suckling period (21). Without AA in the diet, the adequacy of its endogenous synthesis remains in question and probably depends on maturity at birth, nutritional status, age of study, and species. The species difference or the difference in maturity at birth is evident when the present data are compared to those previously reported for the piglet, in which essentially no ^{13}C-AA was detectable by NMR in brain lipids after dosing with ^{13}C-GLA (8). With the caveat that measuring levels of ^{13}C in the whole brain may mask more rapid utilization of GLA for AA synthesis by some cell types in the brain (19), the present results indicate that the low levels of GLA in the mammalian brain are probably due to relatively low uptake of GLA by the brain and are less likely to be due to rapid conversion of dietary GLA to AA in the brain itself.

We did not evaluate oxidation of ^{13}C-GLA in this study but Leyton *et al.* (22) have shown that about 30% of a single bolus dose of [1-^{14}C]-GLA given to adult rats is oxidized to $^{14}CO_2$ within 24 h of dosing which is considerably less than for linoleic or α-linolenic acids. Thus, once formed, GLA seems less prone to oxidation than other 18-carbon PUFA. Nevertheless, our data on ^{13}C recovered in water-soluble metabolites (Fig. 7) and in brain and liver cholesterol (Fig. 5) indicate that some GLA was oxidized and that ^{13}C was recycled into lipids synthesized *de novo*. This route of metabolism of PUFA carbon into lipids synthesized *de novo* has previously been demonstrated for linoleic (23) and for α-linolenic acids (17). Keto acids such as acetoacetate and β-hydroxybutyrate are important lipogenic substrates in suckling rats (24,25) and probably constitute the main ^{13}C-labeled metabolites in the water-soluble extracts we prepared (26).

We conclude that in suckling rats, a low amount of exogenous GLA has direct access to brain lipids and that most brain AA derived from exogenous GLA is probably synthesized elsewhere first. This study only addressed the utilization of GLA, and so the proportion of brain AA which is derived *via* synthesis compared to that which may have been transported to the brain from adipose tissue or maternal milk cannot be determined from our data. Whether dietary GLA may be a

more efficient precursor to brain AA if the suckling rats were receiving no dietary AA was also not addressed in the present study. This would require artificial rearing using a formulated semipurified liquid diet to control the exact PUFA type and intake. Our ongoing research is addressing the applicability of ^{13}C-GLA as an *in vivo* probe for noninvasive NMR studies.

ACKNOWLEDGMENTS

The University Research Incentive Fund, Milupa AG (Friedrichsdorf, Germany), the NIH (grant no. GM49209), and the Bundes Ministerium fur Forschung (Germany) provided financial support for this study. The laboratory of Dr. Sheila Cohen (Merck, Nutley, NJ) is thanked for providing a detailed PCA extraction protocol. Mary-Ann Ryan and Chantale Menard provided excellent technical assistance.

ABSTRACT: Loss of fluorescence from *cis*-parinaric acid (cPnA) is a sensitive indicator of lipid peroxidation. The purpose of this study was to utilize cPnA to determine, at the level of the intact immune cell, whether enrichment of membranes with polyunsaturated fatty acids (PUFA) increased lipid peroxidation. P388D1 macrophages were labeled by addition of cPnA as an ethanolic solution. Within two minutes of addition, in the absence of serum, cPnA rapidly intercalated into the plasma membrane. Lipid peroxidation was initiated by addition of Fe^{2+}-EDTA resulting in a dose-dependent decrease in fluorescence with increased oxidant concentration. Cells previously enriched with PUFA and labeled by intercalation showed no differences in spontaneous or Fe^{2+}-induced lipid peroxidation. In separate experiments, 20 μM cPnA in ethanolic solution was injected into cell culture media containing 0.1% essentially fatty acid free bovine serum albumin (BSA). Cells were resuspended and incubated for 90 min at 37°C. After washing with BSA to remove cPnA which had not incorporated, 0.5% (0.1 μM) of the added cPnA was found esterified within cellular lipids. This level of cPnA provided a 100-fold increase over basal autofluorescence levels. Cells labeled in this manner also lost fluorescence in a dose-dependent manner as levels of oxidant stress increased. Cells enriched with PUFA and labeled by esterification had significantly increased rates and total amounts of lipid peroxidation. Co-incubation with α-tocopherol and PUFA resulted in a decrease in lipid peroxidation which was not significantly different from control cells. In conclusion, esterification of cPnA into membrane phospholipids can sensitively detect changes in lipid peroxidation induced by alteration of membrane PUFA and/or vitamin E content.

Lipids 32, 219–226 (1997).

Membrane fatty acid composition can be rapidly modified by changing the source of dietary lipid (1,2). In fact, when polyunsaturated oils are increased in the diet as a means of decreasing saturated fat, tissues become enriched with polyunsaturated fatty acids (PUFA) such as eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and arachidonic acid (AA). Membranes containing increased levels of these fatty acids are more easily oxidized (3,4). Indeed, increased lipid peroxidation has been observed in rats (5–9) and humans (10,11) upon feeding fish oil which is rich in EPA and DHA. Tissue damage resulting from lipid peroxidation has been implicated in conditions such as atherosclerosis, sickle cell anemia, hemochromatosis, ischemia-reperfusion injury, and arthritis (12,13).

Vitamin E is widely accepted to be the primary lipid-soluble antioxidant responsible for protection of unsaturated membrane components. Increasing dietary PUFA has been reported to be antagonistic to vitamin E status (14–17). Both the antagonistic effect of dietary PUFA and the proposed increased requirement at the level of the PUFA-enriched membrane have provided a basis for an increase in the dietary vitamin E requirement (16–19). Increases in membrane unsaturation without concomitant increases in membrane vitamin E could render cells more susceptible to oxidative stress. Macrophages, which produce reactive oxygen species (e.g., $O_2^{-\cdot}$, H_2O_2) for phagocytic killing, could be at potentially greater risk than other cells and tissues (20,21). Consequently, the ability to measure lipid peroxidation at the level of the intact cell becomes important in the determination of an overall dietary vitamin E requirement.

Although numerous methods are available for measuring lipid peroxidation, these methods are discontinuous and indirect, requiring time point sampling. Oxidative by-products are monitored rather than the actual, continuous process of lipid peroxidation. These methods require tissue homogenization and sample preparation which may include lipid extraction, denaturing of protein and chemical derivatization, possibly introducing artifacts (13,22,23). Recently, a new method has been described which allows direct measurement of lipid peroxidation at the level of the cell membrane without disruption of cellular integrity and function (24–26). This sensitive method which is both direct and continuous, uses *cis*-parinaric acid (9, 11, 13, 15-*cis*-*trans*-*trans*-*cis*-octadecatetraenoic acid, cPnA), a naturally occurring fatty acid with conjugated tetraene structure which renders it fluorescent in a

lipid environment. Exposure of erythrocyte ghosts or intact erythrocytes to ethanolic cPnA results in rapid intercalation of the free fatty acid into the membrane bilayer. Rearrangement of the tetraene structure of cPnA after electron abstraction during lipid peroxidation causes loss of fluorescence and is therefore a direct measure of lipid peroxidation which may be monitored as it occurs.

One of the overall goals of our laboratory is to understand the interaction between dietary PUFA and vitamin E, relative to lipid peroxidation, at the level of the immune cell. Our objective was to use cPnA in intact immune cells to assess the effect of modulating membrane components (i.e., PUFA and α-tocopherol), on the susceptibility of living cells to lipid peroxidation. Here, we present evidence that with minor modifications to the published method, useful information about nutritional modulation of lipid peroxidation in immune cells can be obtained.

MATERIALS AND METHODS

Materials. Solvents were high-performance liquid chromatography grade or Fisher Optima grade (Fisher Scientific Co. St. Louis, MO). Silica gel thin-layer chromatography (TLC) plates were purchased from Fisher Scientific Co. (St. Louis, MO). α-Tocopherol was the kind gift of Eastman Kodak Chemical (Rochester, NY). Arachidonic acid (AA) and eicosapentaenoic acid (EPA) were purchased from Cayman Chemical Co. (Ann Arbor, MI). cPnA was purchased from Molecular Probes Inc. (Plano, TX). Stock solutions of cPnA (2 μM in study #1, 20 μM in study #2), α-tocopherol, and fatty acids were made in absolute ethanol, previously deoxygenated by bubbling with nitrogen gas. Stock solutions were stored at −80°C under nitrogen gas. The murine monocyte cell line, P388D1, was obtained from American Type Culture Collection (ATCC, Rockville, MD). Cell culture reagents were obtained from the Cell and Immunobiology Core Facilities (University of Missouri, Columbia, MO).

Cell culture. P388D1 cells were maintained in RPMI 1640 supplemented with 15% fetal bovine serum (FBS), 1 mM glutamine, 100 μg/mL penicillin, and 100 units/mL streptomycin (complete medium). Cells were grown in 75 cm^2 flasks with confluent cells subcultured after detaching by mild scraping.

Enrichment of P388D1 cells with α-tocopherol and/or AA and EPA. For all experiments involving cellular enrichment with α-tocopherol or the polyunsaturated fatty acids (PUFA), AA and EPA, stock solutions in absolute ethanol were added to complete media which was then used to seed cells grown to near confluence (90%). At no time did total ethanol addition exceed 0.2% of the total volume. Incorporation of these membrane constituents was promoted by allowing cells to incubate at 37°C for 12 h under a humidified atmosphere of 95% air and 5% CO_2. After this culture period, cells were harvested by gentle scraping as previously described. Addition of an equal concentration of absolute ethanol into complete media was used in control cell cultures. Viability of cells, as determined by trypan blue exclusion, exceeded 90% under all culture conditions described.

Intercalation of fluorescent probe in cellular membranes. P388D1 cells were found to have a low level of autofluorescence (less than four arbitrary fluorescence units) at 324 and 413 nm for excitation and emission, respectively. Injection of 2 μM cPnA into the cell suspension resulted in a dramatic and immediate rise in fluorescence (i.e., 400-fold increase). In the presence of a 30% filter, fluorescence stabilized within two minutes and was determined to be a linear function of probe concentration between 1 and 4 μM cPnA. A cell concentration of 4×10^5 cells/mL was sufficient to completely incorporate 4 μM cPnA such that cPnA remaining in the water phase was minimal. Therefore for our studies with the monocyte cell line, we chose injection of 2 μM ethanolic cPnA solution into a cell suspension containing 4 to 6×10^5 cells/mL of phosphate buffered saline (PBS) without Ca^{+2} and Mg^{+2} followed by a two-minute equilibration period for the intercalation experiments. Each compound used in the assay (e.g., ethanol, $FeCl_2 \cdot 4\ H_2O$, ethylenediaminetetraacetate, vitamin E) was tested individually to check for autofluorescence and/or quenching of the cPnA signal prior to establishing individual protocols.

Incorporation of fluorescent probe into cellular lipids. The labeling protocol for esterification experiments was established as 20 μM cPnA in 0.1% essentially fatty acid-free bovine serum albumin (BSA) in RPMI 1640 for 90 min. The increase in cPnA concentration was necessary to provide a 100-fold increase in fluorescent signal over the basal autofluorescence. cPnA in ethanolic solution was injected into complete media which was then used to resuspend cells for incubation. After a 90-min incubation at 37°C, cells were washed three times with RPMI 1640 containing albumin (0.1% BSA), which was sufficient to remove nonesterified cPnA from the cells. The amount of cPnA not incorporated into the cells was determined by separate extraction of the lipids in the original supernatant and each of the three wash supernatants with 4 vol of chloroform/methanol (2:1, vol/vol). The cPnA in each fraction was quantified by ultraviolet (UV) absorbance (304 nm) after the sample was resuspended in absolute ethanol.

The incorporation of cPnA into the cellular lipids of P388D1 was assessed by extracting total lipids from cell pellets. Briefly, 4 vol of chloroform/methanol (2:1, vol/vol) were mixed with the thawed cell pellet. The lower phase was placed into a glass tube and evaporated in a 40°C water bath under a stream of N_2 gas. The total lipid extract was resuspended in a small volume of chloroform/methanol (2:1, vol/vol), and applied to a 2-cm lane of a TLC plate (27). Total cellular lipids were separated into major lipid classes (i.e., phospholipid, triglyceride, cholesterol ester, free cholesterol, free fatty acids) using hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) as the developing solvent (28). Identity of lipid classes was verified with commercial standards. Individual lipid classes were removed from the plate by scraping and then extracted with 750 μL double-distilled H_2O and 3 mL chloroform/methanol (2:1, vol/vol). Individual lipid classes

were resuspended in absolute ethanol and the cPnA concentration determined by UV absorbance at 304 nm.

In order to provide gas chromatographic verification that cPnA was esterified into membrane phospholipids, it was necessary to modify the labeling conditions. P388D1 cells were harvested at 90% confluence and pelleted by centrifugation at $250 \times g$ for 10 min. Cells were resuspended at a concentration of 10^6 cells/mL in complete media to which 40 μM cPnA had been added then incubated. After a 24-h incubation at 37°C, cells were harvested and cellular lipids were extracted using the methods described previously. Lipid classes (i.e., phospholipid, free fatty acid, triglyceride, cholesterol ester) were separated as previously described. Isolated lipids were transmethylated with 4% H_2SO_4 in methanol (88°C, 1 h). Some cell lipid extracts were subjected to two-dimensional TLC in order to determine the incorporation of cPnA into individual phospholipid classes. In this case, methyl esters were prepared by transmethylation using 0.5M NaOH in methanol (28). Fatty acid methyl esters were extracted and then injected into a Hewlett-Packard gas chromatograph (Sunnyvale, CA) Model 5890A with a 30-m capillary column (Supelcowax 10; Supelco, Bellefonte, PA). Results, expressed as the percentage of total fatty acids, were determined by electronic integration (Hewlett-Packard 3380A integrator).

Lipid peroxidation assay. Two mL of cells in PBS (0.4 to 0.6×10^6 cells/mL), which had been labeled with cPnA either by intercalation or esterification, were placed in each of four cuvettes in a Perkin-Elmer spectrofluorometer MPF-66 (Norwalk, CT), equipped with a stirring apparatus and a jacketed, automated four-chamber cuvette holder to maintain the cells at 37°C for the time course of the experiment. Fluorescence was monitored by excitation at 324 nm and determining emission at 413 nm (29). Intercalation experiments were conducted in the presence of a 30% light filter. After measurement of initial fluorescence from each cuvette, lipid peroxidation was initiated by addition of an equimolar solution of $FeCl_2 \cdot 4H_2O$ and EDTA such that final concentrations were 10 and 100 μM Fe^{+2} in 10 and 100 μM EDTA, respectively (30). Lipid peroxidation has been shown to be initiated by hydroxyl radicals derived from a Fenton-type reaction when ferrous iron and EDTA are present in equimolar concentrations (30–32). Loss of fluorescence, which served as a measure of lipid peroxidation, was monitored simultaneously every 2 min for each of four cuvettes, in real time and is expressed as the percentage of initial fluorescence remaining at a given time point. Since cPnA fluorescence has been found to undergo spontaneous decay after exposure to light, a cuvette containing cPnA-labeled cells with no additives or added oxidant stress was monitored simultaneously as a control for each experiment (24). The rate of spontaneous decay of cPnA signal in control cells was measured with and without enrichment with α-tocopherol. The presence of this antioxidant did not change either the rate or amount of fluorescence lost, indicating that loss of signal in control cells was probably due to photobleaching rather than lipid peroxidation of the probe.

Statistical analysis. All data were analyzed as a repeated, split-plot analysis of variance as outlined by Gil and Hafs (33). The linear statistical model contained the effect of treatment, replicate within treatment, time and treatment × time (34,35). The main effect of treatment was tested using replicate within treatment as the denominator of F. All trend analyses were tested using the residual error term. Each experiment was run in duplicate with values averaged for each treatment. Each experiment was replicated from three to six times as indicated in the figure legends. A one-degree-of-freedom polynomial linear and quadratic contrast was used for testing trend analyses (36).

RESULTS

Location of esterified label. To determine the quantity and location of cPnA esterified into cellular lipids, a series of experiments were conducted utilizing the UV properties of this fatty acid. This approach is more sensitive than gas chromatography. After 90 min incubation with 20 μM cPnA in the presence of 0.1% essentially fatty acid free BSA, the incorporation of cPnA into cellular lipids was less than 1% (0.6%) of the added cPnA. In order to ensure that the fluorescent signal was coming from esterified rather than intercalated cPnA, cells were washed with RPMI which contained 0.1% essentially fatty acid-free BSA to facilitate removal of any cPnA intercalated into the plasma membrane. Total lipids from wash supernatants were extracted and the cPnA concentration determined. Over 98% of the cPnA originally added was recovered in the incubation supernatant with less than 1% recovered in the first wash and less than 0.2% in each of the subsequent two washes. Results from five separate experiments showed that under these conditions, approximately 50% of the incorporated cPnA was found in the phospholipids, 20% in the triglycerides, 18% in the cholesterol esters, and 12% in the free fatty acid fraction. Although less than 1% of the added cPnA was esterified into cellular lipids (0.1 μM), this amount was sufficient to provide an adequate fluorescence with which to conduct these studies. Furthermore, the majority of the cPnA was located in the membrane phospholipid fraction of these cells.

Chromatographic evidence for cPnA incorporation into phospholipid is provided in Figure 1 and was accomplished by increasing both the concentration of cPnA and the length of incubation time. The peak identified as cPnA was present in the TLC isolated phospholipid fraction of cells incubated with cPnA, but was absent in cells incubated without exogenous cPnA. The cPnA peak in enriched cells eluted at the same time as did the methyl ester of the free fatty acid. Separation of P388D1 phospholipid classes by two-dimensional TLC gave evidence that cPnA was in the phosphatidylcholine and phosphatidylethanolamine fractions. In contrast, when P388D1 cells were incubated with cPnA in medium without a source of albumin (e.g., no FBS), incorporation of cPnA into phospholipids was not observed (data not shown).

The effect of labeling method on the sensitivity of cPnA to increasing levels of oxidant stress. P388D1 cells were labeled

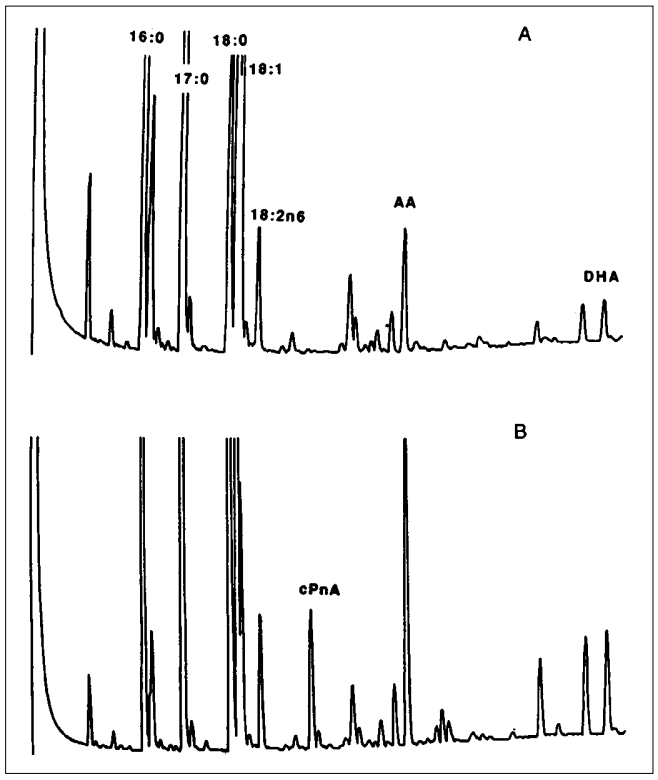

FIG. 1. Gas chromatogram of phospholipid extracted from P388D1 cells and separated by one-dimensional thin-layer chromatography, incubated without (A) or with (B) 40 μM *cis*-parinaric acid, 9, 11, 13, 15-*cis-trans-trans-cis*-octadecatetraenoic acid (cPnA) in the presence of 0.1% essentially fatty acid-free bovine serum albumin for 24 h; DHA, docosahexaenoic acid; AA, arachidonic acid.

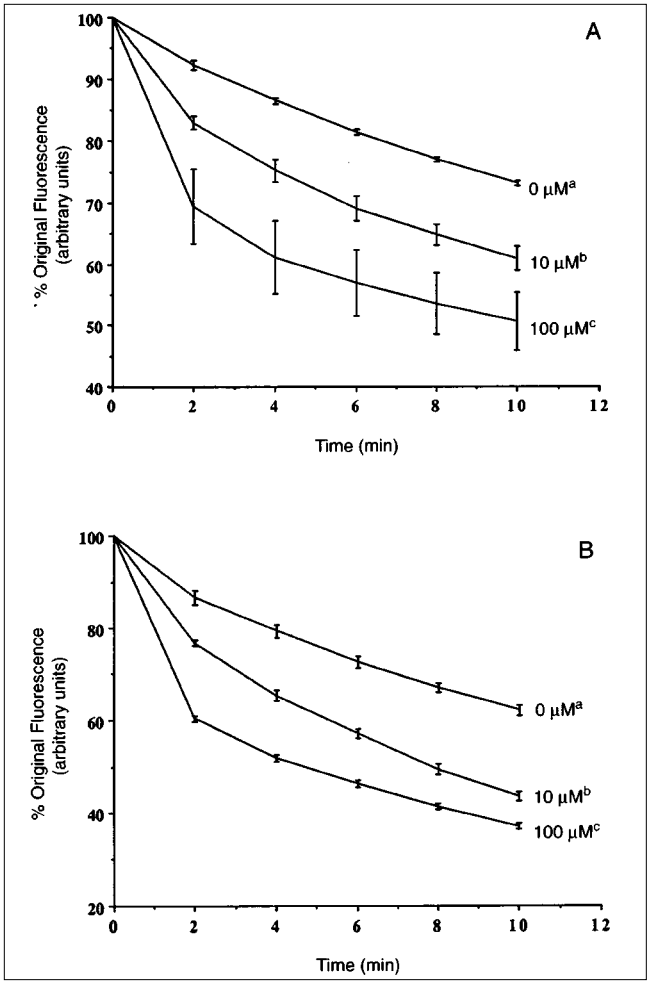

FIG. 2. (A) Effect of increasing oxidant stress on loss of fluorescence in P388D1 cells, labeled with 2 μM cPnA by intercalation for two minutes. Cell concentration was 0.5×10^6 cells/mL in phosphate-buffered saline without calcium or magnesium. Lipid peroxidation was induced at time zero by addition of 10 or 100 μM $FeCl_2 \cdot 4\ H_2O$ in equimolar EDTA. Zero μM represents spontaneous decay of signal from control cells in the presence of the light source. Values used are means ± SEM for three separate experiments. Curves assigned different superscript letters are significantly different ($P < 0.05$) based on linear and quadratic analysis. (B) Effect of increasing oxidant stress on loss of fluorescence in P388D1 cells, labeled by esterification with 20 μM cPnA in 0.1% bovine serum albumin for 90 min. Cell concentration was 0.5×10^6 cells/mL in phosphate-buffered saline without calcium or magnesium. Lipid peroxidation was induced at time zero by addition of 10 or 100 μM $FeCl_2 \cdot 4\ H_2O$ in equimolar EDTA. Zero μM represents spontaneous decay of signal from control cells in the presence of the light source. Values used are means ± SEM for three separate experiments. Curves assigned different superscript letters are significantly different ($P < 0.05$) based on linear analysis. Quadratic analysis shows that the shapes of the curves for the 0 and 100 μM treatment groups were not different from each other, but were significantly different from those exposed to 10 μM $FeCl_2$ ($P < 0.05$). See Figure 1 for abbreviations.

by the intercalation method, and then subjected to increasing levels of oxidative stress (i.e., Fe^{2+}-EDTA complex). The rate at which fluorescence was lost increased in a dose-dependent fashion (Fig. 2A). Both the rate at which lipid peroxidation occurred and the total amount of probe oxidized were significantly affected by treatment as evidenced by significant differences in linear and quadratic function ($P < 0.05$). Cells labeled by esterification of cPnA (Fig. 2B) responded in a similar manner to increasing levels of oxidant stress as provided by ferrous-EDTA. Each increasing dose of ferrous-EDTA resulted in a significant increase in both rate and total fluorescence lost ($P < 0.05$). Cells labeled by esterification lost from 13 to 17% more fluorescence (10 and 100 μM Fe^{2+}–EDTA complex, respectively) than did cells labeled by intercalation. When differences in the kinetics of photobleaching were taken into consideration, this difference was reduced to only 5%.

Oxidant stress provided by enrichment with long-chain PUFA. To further evaluate the use of cPnA as a means to assess lipid peroxidation in immune cells, we incubated P388D1 cells in media supplemented with two long-chain PUFA (i.e., 5 μM EPA plus 5 μM AA). After 12 h, the degree of membrane unsaturation was greatly increased. This was primarily a result of the replacement of linoleic acid with EPA and AA in membrane phospholipids. For example, the AA content of the phosphatidylcholine fraction from these cells was increased from 0.915 to 2.08 nmoles/10^6 cells and EPA from 0.0 to 0.41 nmoles/10^6 cells for EPA with a concomitant

30% decrease in linoleic acid. We hypothesized that such an enrichment in unsaturation would lead to significantly greater loss of cPnA upon oxidative challenge. However, the increased levels of long-chain PUFA did not increase the loss of basal fluorescence or loss of signal in the presence of an oxidant stress when cells were labeled by the intercalation method (data not shown). In contrast, upon exposure to the light source, without addition of our exogenous oxidant stress, cells enriched with PUFA and then labeled by esterification were found to have a significantly greater lipid peroxidation (i.e., loss of fluorescence) as compared to control cells

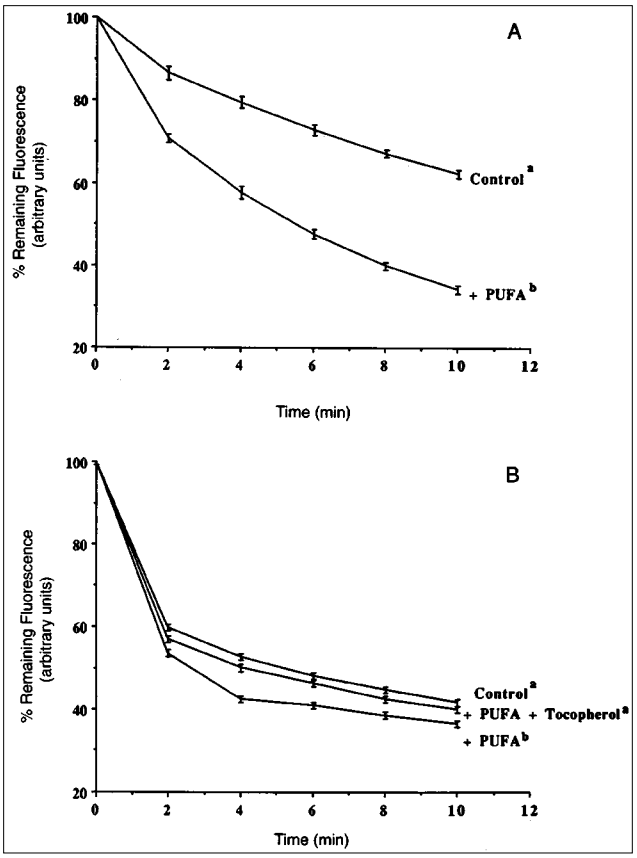

FIG. 3. (A) Effect of incubation with or without 5 μM arachidonic acid (AA) and 5 μM eicosapentaenoic acid on the spontaneous loss of fluorescent signal in P388D1 cells, labeled by esterification with 20 μM cPnA in 0.1% bovine serum albumin for 90 min. Cell concentration was 0.5×10^6 cells/ mL in phosphate-buffered saline. Values used are means ± SEM for three separate experiments. Curves assigned different superscript letters are significantly different based on linear and quadratic analysis ($P < 0.05$). (B) Effect of incubation with or without 5 μM arachidonic and 5 μM eicosapentaenoic acid and 250 μM d-α-tocopherol for 12 h on the loss of fluorescent signal in P388D1 cells, labeled by esterification with 20 μM cPnA in 0.1% bovine serum albumin for 90 min. Cell concentration was 0.5×10^6 cells/ mL in phosphate-buffered saline. Lipid peroxidation was induced at time zero by addition of 10 μM $FeCl_2 \cdot 4\ H_2O$ in equimolar EDTA. Values used are means ± SEM for six separate experiments. Curves assigned different superscript letters are significantly different based on linear and quadratic analysis ($P < 0.05$); PUFA, polyunsaturated fatty acids. See Figure 1 for other abbreviations.

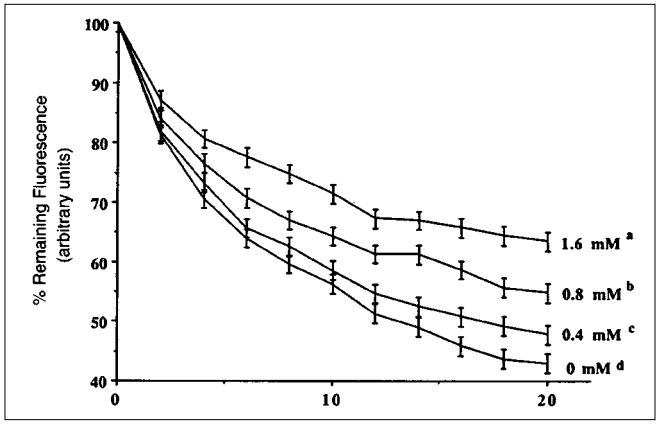

FIG. 4. Effect of incubation with increasing concentrations of d-α-tocopherol: 0.0, 0.4, 0.8, or 1.6 mM for 12 h, on the loss of fluorescence in P388D1 cells, labeled by esterification with 20 μM *cis*-parinaric acid, 9, 11, 13, 15-*cis-trans-trans-cis*-octadecatetraenoic acid (cPnA) in 0.1% bovine serum albumin for 90 min. Cell concentration was 0.5×10^6 cells/mL in PBS. Lipid peroxidation was induced at time zero by addition of 100 μM $FeCl_2 \cdot 4\ H_2O$ in equimolar EDTA. Values used are least square means ± SEM for three separate experiments. Curves assigned different superscript letters are significantly different based on linear analysis ($P < 0.05$). Quadratic analysis shows that the shapes of the curves from the 0.0 and 0.4 mM additions of d-α-tocopherol were significantly different from that of the 1.4 mM d-α-tocopherol, but not from the 0.8 mM d-α-tocopherol.

(Fig. 3A). When these cells were exposed to an additional oxidant stress, the PUFA-enriched cells lost significantly more fluorescence than did control cells. The addition of 250 μM α-tocopherol in the incubation media along with the long-chain PUFA, prevented the increase in lipid peroxidation noted when cells were incubated with PUFA alone (Fig. 3B).

Protection against lipid peroxidation by α-tocopherol. Cells were enriched with vitamin E by incubating them in complete media to which 250 μM α-tocopherol had been added. Control cells were incubated in complete media without the addition of α-tocopherol. After 12 h, control and α-tocopherol-enriched cells were split and labeled by intercalation and by esterification, then subjected to different levels of oxidant stress. At either level of oxidative stress, loss of fluorescence in the cells labeled by intercalation was not significantly affected by overnight incubation of cells in tocopherol-enriched media. In contrast, cells enriched with α-tocopherol and labeled by esterification of cPnA lost significantly less fluorescence than did control cells ($P < 0.05$, data not shown). The effect of increasing α-tocopherol concentration in the incubation media from 0, 0.4, 0.8, and 1.2 mM for 12 h on lipid peroxidation induced by 100 μM ferrous-EDTA is shown in Figure 4. Although cells labeled by intercalation showed no differences in lipid peroxidation due to increasing concentrations of vitamin E (data not shown), when cells were labeled by esterification, vitamin E significantly reduced the rate at which fluorescence was lost, in a dose-dependent fashion ($P < 0.05$).

DISCUSSION

One of the overall goals of our laboratory is to understand the interaction between dietary PUFA, particularly fish oil, and vitamin E. Increases in dietary PUFA are rapidly reflected in the type of fatty acids found in the membrane. Since part of the suggested increase in dietary requirement of vitamin E is based on increased lipid peroxidation in membranes enriched with PUFA, it was particularly relevant for us to be able to examine lipid peroxidation at the level of the immune cell.

Our initial objective was to use the published method of intercalating cPnA into intact immune cells to assess the effects of modulation of membrane components (i.e., PUFA and α-tocopherol) on the susceptibility of living cells to lipid peroxidation. The intercalation of cPnA as a method for monitoring lipid peroxidation, originally published for use in liposomes (24), has been successfully adapted for use in erythrocyte ghosts (25,37,38), sarcoplasmic reticulum vesicles (39,40), intact erythrocytes (25,26,41,42), and Chinese hamster ovary cells (43). Tsuchiya and coworkers (44) were able to utilize cPnA and a model membrane system (i.e., liposomes) to characterize the antioxidant properties of α-tocopherol, β-carotene, and ubiquinol in response to a lipid-soluble, free radical initiation system. In an attempt to adapt the method to immune cells, we chose to work with the murine monocyte cell line P388D1, with which we have experience modulating the cellular content of both α-tocopherol and PUFA.

We observed increased lipid peroxidation in response to increased levels of oxidant stress provided by chelated ferrous iron. When ferrous iron and EDTA are present in equimolar concentrations, lipid peroxidation is initiated by hydroxyl radicals. Cells labeled with cPnA by intercalation and esterification showed increased rate and total amount of peroxidation as the oxidant stress was increased from 10 to 100 μM Fe-EDTA. These data parallel the effect of *in vivo* administration of ferrous iron. For example, Hu and coworkers (7) found a positive correlation between the concentration of ferrous iron injected intraperitoneally into rats and indices of lipid peroxidation in various tissues such as serum, liver, and kidney. In comparing both methods of labeling our cells, we observed that the esterified cPnA label was slightly more sensitive to the same level of oxidant stress than cells labeled by intercalation. When corrected for basal loss of fluorescence, the 13 to 17% increased sensitivity observed in the esterified cells is reduced to a 5% difference. Although we have characterized the loss of cPnA fluorescence in untreated cells as photobleaching because it was not altered by exogenous vitamin E, it is also possible that this is a background oxidation. Greater oxidation of cPnA in intercalated cells where the label is closer to the surface of the cell and therefore the interface of cell to media may alter the kinetics of background loss of fluorescence due to lipid peroxidation not initiated by the experimenter. Since the goal of these experiments was to investigate whether we could show greater susceptibility of PUFA-enriched cells toward oxidation relative to cells with lower concentrations of PUFA, we chose not to pursue the question of differences between methods.

Using the intercalation method, we were not able to detect increases in lipid peroxidation due to membrane PUFA enrichment. No significant differences in loss of basal fluorescence or loss of fluorescence in the presence of an exogenous oxidant stress were found in the cells PUFA-enriched vs. nonenriched cells labeled with cPnA by intercalation. Our data are in agreement with those of Van den Berg and coworkers (26) who reported that cPnA intercalated into intact erythrocytes was not able to detect increased lipid peroxidation associated with membrane PUFA enrichment. However, in that study erythrocytes from fish oil-fed rabbits lost significantly more total membrane PUFA as determined by lipid extraction and gas chromatographic analysis than those from control rabbits. To our knowledge, this is the first report of lipid peroxidation determined by cPnA that did not have a strong positive correlation with other methods of lipid peroxidation that were run simultaneously. In the direct measurement of lipid peroxidation of submitochondrial particles, de Hingh and coworkers (45) found excellent positive correlation between values determined by cPnA and oxygen consumption. We concluded that although intercalated cPnA works well as an indicator of lipid peroxidation in most cases, it does not reflect increased lipid peroxidation due to PUFA enrichment.

Rather than abandoning the protocol, we examined the potential for cPnA incorporation into membrane phospholipids. We hypothesized that altering the membrane location such that cPnA was incorporated as a normal membrane component would allow greater sensitivity in detection of lipid peroxidation. Previously, Chinese hamster ovary cells have been reported to be capable of incorporating exogenously supplied cPnA into their membrane phospholipids. That cPnA was provided with a source of albumin such as fetal calf serum was essential (28). Sklar and Dratz (46) reported similar incorporation into bovine retinal rod outer segments. Harris and Stahl (47) suggested that the uptake of cPnA into phospholipids is an enzymatic process mediated by acyl-CoA acyltransferase and have shown its uptake is competitively inhibited by oleic acid. They further report that 71% of the esterified cPnA was found in phosphatidylcholine and 20% in phosphatidylethanolamine. Stuhne-Sekalec *et al.* (48), using guinea pig liver microsomes, have shown that cPnA is preferentially esterified at the *sn*-2 position although small quantities were found at the *sn*-1 position. Further, they showed that cPnA could be readily cleaved by phospholipase A_2. Several authors have also shown that as a naturally occurring fatty acid, cPnA can be bound to cellular lipid transfer proteins such as fatty acid binding protein and sterol carrier protein (49) and can be esterified into cellular phospholipids (50). Prows and coworkers (52) have demonstrated that uptake of cPnA into the plasma membrane in the absence of serum is very rapid. Further, the total quantity of cPnA incorporated was significantly increased when fibroblasts were transfected with liver fatty acid binding protein. Although this technique provides a ready source of cPnA for incorporation into mem-

branes, less than 3% of cPnA was esterified after a 30-min incubation. Our experience with P388D1 cells showed that they could rapidly esterify PUFA into membrane phospholipids when these fatty acids were introduced as fatty acid–albumin complexes. It must be noted, however, that only 0.5% of the total cPnA was esterified in 90 min in contrast to the rapid uptake of 2 μM cPnA when no albumin is present. Therefore, although cPnA can be esterified into mammalian cells, it must be emphasized that the total amount is very small. Also, the cPnA that is incorporated by esterification is distributed throughout all cellular membranes (43) rather than concentrated into the plasma membrane.

The idea of esterifying the fluorescent probe to the membrane phospholipid was a particularly appealing one. Researchers have proposed that membrane α-tocopherol is physically associated with certain membrane phospholipids (52–56). Therefore, esterification of cPnA into the *sn*-2 position of the membrane phospholipid renders the cPnA in proper orientation for interaction with membrane α-tocopherol. Thus, this approach provides a physiologically relevant model for monitoring lipid peroxidation within cell membranes and the effect of alterations in membrane phospholipid PUFA and α-tocopherol on this process. We believe that cPnA orientation during intercalation may result in a lack of proximity among intercalated cPnA, membrane phospholipids, and vitamin E and that these factors are important determinants for success in examining differences in lipid peroxidation due to alterations of cell membrane components.

In conclusion, we have shown that esterification of low concentration of cPnA (<0.1 μM) into membrane phospholipids provides a sensitive real time method for observing relative differences in rate and amount of oxidation as a function of immune cell PUFA and vitamin E content. This method allows direct monitoring of the process of lipid peroxidation as it is occurring. It requires no processing of samples such as homogenization or lipid extraction and should therefore be subject to less artifactual error. We propose that it may be useful as a means for *in situ* examination of the initial stages of lipid peroxidation and their modulation by membrane components in isolated immune cells.

ACKNOWLEDGMENTS

Financial support for this research was provided by: USDA grant #91-37200-6184; Food-for-the-21st Century, College of Agriculture, The University of Missouri and The Missouri Agriculture Experiment Station. The authors wish to acknowledge the contribution of Dr. Mark Ellersieck, Missouri Agricultural Experiment Station, for assisting in experimental design and data analysis. We also thank Patricia Susemihl for diligent cell culture work.

Novel Oxylipins from the Temperate Red Alga *Polyneura latissima*: Evidence for an Arachidonate 9(*S*)-Lipoxygenase

Zhi-Dong Jiang and William H. Gerwick*

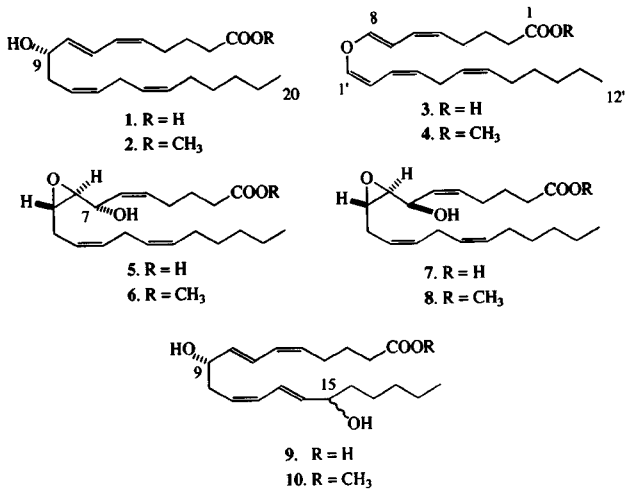
College of Pharmacy, Oregon State University, Corvallis, Oregon 97331

ABSTRACT: The oxylipin chemistry of the temperate red alga *Polyneura latissima* has been investigated. The structures of three novel oxylipins, 8-[1′(*Z*),3′(*Z*),6′(*Z*)-dodecatriene-1′-oxy]-5(*Z*),7(*E*)-octadienoic acid, 7(*S**)-hydroxy-8(*S**),9(*S**)-epoxy-5(*Z*),11(*Z*),14(*Z*)-eicosatrienoic acid, 7(*R**)-hydroxy-8(*S**),9(*S**)-epoxy-5(*Z*),11(*Z*),14(*Z*)-eicosatrienoic acid, together with two known eicosanoids, 9(*S*)-hydroxy-5(*Z*),7(*E*),11(*Z*),14(*Z*)-eicosatetraenoic acid, and 9,15-dihydroxy-5(*Z*),7(*E*),11(*Z*),13(*E*)-eicosatetraenoic acid, were elucidated by spectroscopic methods and chemical degradation. The oxygenation pattern of these oxylipins suggests that *P. latissima* metabolizes polyunsaturated fatty acids *via* a 9(*S*)-lipoxygenase.

Lipids 32, 231–235 (1997)

It is well established in mammalian tissues that arachidonic acid can be oxygenated at different positions by lipoxygenases of varying positional specificity, and that this leads to a wide array of physiologically and pathologically important eicosanoids (e.g., HETE, hepoxilins, and leukotrienes). Interestingly, several marine algae have yielded eicosanoids that are identical to mammalian metabolites (1–3). However, our continued exploration of new oxylipins from diverse marine algae has led to the discovery of a number of structurally unique compounds that are without parallel in mammals (4,5).

The red alga *Polyneura latissima* is widely distributed along the Pacific coast of North America from Alaska to Mexico in the lower intertidal and subtidal zones to a depth of 10–20 meters. The initial analysis of a *P. latissima* crude extract from northern California indicated that this red alga contained eicosanoids different from those previously isolated from marine plants. The promising fractions produced by initial chromatography were treated with diazomethane and then further purified by additional column chromatography and high-performance liquid chromatography (HPLC) to provide the pure methyl ester derivatives.



The northern California collection of *P. latissima* provided compounds **2**, **6**, **8,** and **10** as well as a very small amount of compound **4**. A second collection made from the state of Washington provided an additional amount (7.1 mg) of compound **4** and enabled completion of its structural elucidation. The structures of these methyl ester derivatives were developed from consideration of various spectroscopic data, particularly two-dimensional nuclear magnetic resonance (NMR), in concert with chemical degradations.

EXPERIMENTAL PROCEDURES

Instruments. Infrared (IR) spectra were recorded on Nicolet 5 DXB FT 15 and Nicolet 510 spectrophotometers, (Madison, WI). NMR spectra were recorded on Bruker AC 300 and AM 400 spectrometers (Karlsruhe, Germany) with trimethylsilyl (TMS) as internal standard. Finnigan 4023 (San Jose, CA) and Kratos MS 50TC (Ramsey, NJ) spectrometers were used to obtain low resolution (LR) mass spectral (MS) resolution and high resolutions (HR) MS. Gas chromatography–mass

*To whom correspondence should be addressed.

Abbreviations: COSY, correlation spectroscopy; diHETE, dihydroxyeicosatetraenoic acid; GC–MS, gas chromatography–mass spectrometry; HETCOR, heteronuclear correlation; HETE, hydroxyeicosatetraenoic acid; HpETE, hydroperoxyeicosatetraenoic acid; HPLC, high-performance liquid chromatography; HR EIMS, high-resolution electron impact mass spectrometry; IR, infrared; LR, low resolution; MS, mass spectral; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography; TMS, trimethylsilyl; UV, ultraviolet.

spectrometry (GC–MS) was carried out with a Hewlett-Packard Model 5970B mass selective detector (Palo Alto, CA) connected to a Hewlett-Packard Model 5890 gas chromatograph. HPLC was performed using a Waters M-6000 pump (Milford, MA) and U6K injector. Optical rotation was measured on a Perkin-Elmer 141 polarimeter (Norwalk, CT). Thin-layer chromatography (TLC) used Merck (Darmstadt, Germany) aluminum-backed TLC sheets (silica gel 60 F_{254}). All solvents were distilled prior to use.

Collection, extraction, and isolation. The first collection of *P. latissima* was made from the intertidal zone at Duxberry Reef on the California coast on June 22, 1989. The alga was immediately frozen with CO_2 (s) after collection and stored frozen until work-up. The defrosted alga (0.3 kg dry weight) was homogenized in $CHCl_3$/MeOH (2:1, vol/vol), warmed for 15 min, and then filtered. The chloroform and water layers were separated, and the former was evaporated *in vacuo* to give 0.37 g of dark green oil. The extract was fractionated by silica gel chromatography in the vacuum mode using a gradient of EtOAc in hexanes. The fraction eluting with 15% EtOAc/hexanes contained trace amounts of compound **4**. The materials eluting with 30% EtOAc/hexanes were methylated with diazomethane. The methylated materials were further purified by vacuum chromatography to give compound **2** (14.4 mg, 3.9% yield of the crude extract). The materials eluting with 50% EtOAc/hexanes were also methylated with diazomethane and fractionated over silica gel. The compounds eluting with 15–30% EtOAc/hexanes were further isolated by HPLC to give compound **6** (1.5 mg, 0.4% yield of the crude extract), compound **8** (2.6 mg, 0.7% yield of crude extract), and compound **10** (0.5 mg, 0.14% yield of the crude extract.

A second collection of the alga was made from the Puget Sound area, Washington. The seaweed (90 g dry weight) gave 2.6 g of crude extract. Fractionation of 2.4 g of this extract in a manner similar to that described above gave an additional 7.1 mg of compound **4** (0.3% yield).

*Compound **2***. A colorless oil; $[\alpha]_D^{23} = +11.1^0$ (c = 0.56, MeOH); ultraviolet (UV) (MeOH) λ_{max} = 236 nm (ε = 21,500); IR (neat) 3450, 3011, 2953, 2927, 2858, 1737, 1439, 1210, 1163, 987, 723 cm^{-1}; TMS-ether electron impact mass spectrometry (EI MS) *m/z* (rel. int. %) 406 (0.4), 391 (2), 375 (0.6), 316 (1), 285 (0.8), 255 (99.4), 226 (13.9), 181 (8), 151 (22), 133 (31), 105 (45), 73 (100).

*Steric analysis of compound **2***. A small amount of compound **2** was ozonized for 12 min in 1 mL $CHCl_3$ at –20°C. The volume of the solution was reduced under N_2. The menthoxycarbonyl derivative was formed in a solution of 50 µL toluene, 50 µL menthoxychlorocarbonate, and 10 µL pyridine for 30 min at room temperature The reaction mixture was partitioned 3× between hexane and H_2O. The hexane solubles were treated with peracetic acid at 50°C overnight, reduced under argon, dissolved in MeOH, and then treated with CH_2N_2. The methylated material was purified *via* preparative TLC (25% EtOAc/hexanes), eluted with Et_2O, and analyzed by GC–MS vs. standards. The steric composition at C-9 was found to be 93% *S* and 7% *R*.

*Compound **4***. A colorless oil; UV (MeOH) λ_{max} = 268 (ε = 32,000), 206 (ε = 21,000); IR (neat) 2954, 2931, 2870, 1736, 1440, 1376, 1164, 1124, 1073, 972 cm^{-1}; LR EIMS *m/z* (rel. int. %) 333 (0.7), 332 (3), 266 (0.7), 221 (0.8), 189 (2), 179 (2), 169 (1), 170 (2), 163 (2), 153 (3), 137 (6), 109 (9), 96 (14), 91 (16), 84 (10), 43 (100); HR EIMS *m/z* obs. $[M]^+$ 332.2351 ($C_{21}H_{32}O_3$, 0.0 mmu dev.).

*Compound **6***. A colorless oil; $[\alpha]_D^{23} = +70°$ (c = 0.07, $CHCl_3$); IR (neat) 3448, 3091, 2926, 2860, 1735, 1651, 1544, 1450, 1371, 1241, 1155, 1036, 732, 680 cm^{-1}; LR EIMS *m/z* (rel. int. %) 332 (0.3, $M^+ - H_2O$), 319 (0.3), 303 (0.4), 290 (1.4), 231 (1.4), 215 (1.7), 193 (4), 170 (7), 157 (24), 125 (37), 95 (41), 79 (75), 67 (65), 55 (82); HR EIMS *m/z* obs. $[M + H]^+$ 351.2500 ($C_{21}H_{35}O_4$, –3.5 mmu deviation), 333.2430 ($[M + H]^+ - H_2O$, $C_{21}H_{33}O_4$, 0.0 mmu deviation).

*Compound **8***. A colorless oil; $[\alpha]_D^{23} = -58°$ (c = 0.19, $CHCl_3$); IR (neat) 3448, 3010, 2927, 2859, 1735, 1652, 1445, 1369, 1317, 1213, 1161, 1123, 1084, 1024, 943, 893, 868, 766, 717 cm^{-1}; LR EIMS *m/z* (rel. int. %) 332 (0.3, $M^+ - H_2O$), 319 (0.3), 303 (0.5), 290 (1.4), 231 (1.4), 215 (1.7), 193 (4), 170 (8), 157 (22), 125 (38), 95 (41), 79 (77), 67 (67), 55 (81).

*Compound **10***. A colorless oil; $[\alpha]_D^{23} = -7.5°$ (c = 0.05, MeOH); UV (MeOH) λ_{max} = 238 nm (ε = 49,600), 232 nm (ε = 47,700), 204 (ε = 18,000); IR (neat) 3406, 2951, 2929, 2860, 1735, 1438, 1247, 1215, 1164, 987, 952 cm^{-1}; LR EIMS of TMS-ether derivative of **10** *m/z* (rel. int. %) 422 (0.03), 373 (0.5), 329 (0.4), 313 (0.7), 255 (100), 239 (3), 223 (4), 181 (5), 165 (12), 151 (13), 133 (21), 123 (12), 105 (21), 73 (64).

RESULTS AND DISCUSSION

Compound **2**, the most abundant eicosanoid metabolite of *P. latissima,* showed $[\alpha]_D^{23} = +11.1^0$ (c = 0.56, MeOH). Its ^1H NMR spectrum was quite similar to that of methyl 12-HETE, the only difference being the shape of multiproton signals between δ5.4 and δ5.5 (6). The HETE nature of this compound was clearly visible by ^1H-^1H correlation spectroscopy (COSY) in which the olefinic proton at δ5.71 of the *cis-trans* conjugated diene (10.9 and 15.2 Hz coupling) was spin-coupled with an α-hydroxy proton at δ4.22. Nevertheless, the position of oxidation in this compound was not clear from NMR data alone because of overlapping signals between δ5.4 and δ5.5. The mass spectrum of the TMS-ether derivative of compound **2** yielded a molecular ion at *m/z* 406 with crucial fragments at *m/z* 255 and 151 (cleavage of C-9–C-10) which placed the hydroxyl group at C-9. By analysis of ^1H-^1H coupling constants and ^{13}C NMR chemical shifts, compound **2** was identified as methyl-9-hydroxy-5(*Z*),7(*E*),11(*Z*),14(*Z*)-eicosatetraenoate. Previously, 9-HETE has been observed from human psoriatic skin (7) and has been chemically synthesized (8,9). The stereochemistry of compound **2** was determined by GC–MS analysis of a menthoxycarbonyl derivative of dimethylmalate which was produced from **2** by ozone degradation and methylation, and showed that C-9 in compound **2** was predominantly of *S* configuration (see the Experimental Procedures section).

Compound **4** was a colorless oil and had UV absorption at 268 and 206 nm. HR EIMS gave its molecular formula as $C_{21}H_{32}O_3$ in which 6° of unsaturation could be easily as-

signed by ^{13}C NMR analysis to one ester group and five double bonds. By ^{1}H-^{1}H COSY and ^{1}H-^{13}C heteronuclear correlation (HETCOR) spectra, two highly polarized double bonds (δ106.61and δ147.91; δ105.54 and δ142.10) were shown to be components of two separate spin systems, one consisting of 12 carbon atoms (C-1′ to C-12′) and the other of 7 carbon atoms (C-2 to C-8). In addition to the carbomethoxy group (Table 1), the partial structures given above represented all of

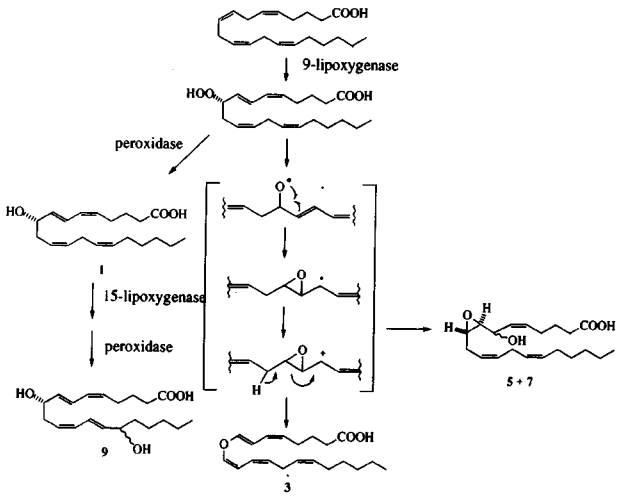
[d]Assignments exchangeable.
[e]Overlapped signals not assigned.

the atoms in the molecule except for one oxygen atom which must therefore connect the two spin systems. Furthermore, the coupling constants of 11.7 Hz and 6.1 Hz for the two pairs of olefinic protons on the two polarized double bonds were diagnostic for their stereochemistry (C-7,8 is *E* and C-1′,2′ is *Z*). Vinyl ether compounds, such as ethyl propenyl ether (10) and colneleic acid (11), exhibit coupling constants of 6–7 Hz between *cis* olefinic protons and 11–12 Hz between *trans* protons. This combination of data allowed deduction of structure **4** as methyl 8-[1′(*Z*),3′(*Z*),6′(*Z*)-dodecatrienyloxy]-5(*Z*),7(*E*)-octadienoate. The corresponding natural product, 8-[1′(*Z*),3′(*Z*),6′(*Z*)-dodecatrienyloxy]-5(*Z*),7(*E*)-octadienoic acid (**3**), is a new substance in nature to which we assign the trivial name "polyneuric acid."

In the 1970s, Galliard and coworkers (11–13) reported on the discovery of the unusual divinyl ethers colneleic acid and colnelenic acid from potato tubers. Later, Corey *et al.* (14) synthesized colneleic acid and found that this molecule was an effective inhibitor of potato lipoxygenase. Fahlstadius and Hamberg (15) showed that enzymatic removal of the *pro-R* hydrogen from C-8 of 9*S*-hydroperoxyoctadecadienoic acid was involved in colneleic acid biosynthesis. Polyneuric acid (**3**) is structurally similar to colneleic acid and colnelenic acid but differs in chain length and the geometry of one of the two double bonds attached to the bridging oxygen atom.

From HR and LR EIMS, compounds **6** and **8** had the same molecular formula of $C_{21}H_{34}O_4$ and almost identical MS fragmentation patterns. Their structural similarity was also revealed in their ^{1}H NMR spectra where the only significant difference was the chemical shift of a proton geminal to a hydroxyl group (Table 1). By ^{13}C NMR data, four of the five degrees of unsaturation inherent in their molecular formulas were attributable to three double bonds and one carbomethoxy group. In the ^{1}H-^{1}H COSY of compound **8**, the proton at δ4.30 was correlated to a midfield proton at δ 2.85 which was further coupled to another midfield proton at δ3.00 by 2.2 Hz, suggestive of an epoxide. This relationship of functional groups, which compound **6** possessed as well, was reminiscent of a hepoxilin (16). From the ^{1}H-^{13}C HETCOR data for compound **8**, the protons at δ2.85 and δ3.00 were correlated to carbons at δ60.75 and δ55.86, respectively, thereby confirming the epoxide functionality. Having accounted for all of the degrees of unsaturation, functional groups and heteroatoms in **6** or **8**, it only remained to assign the location of oxidation and stereochemistry in these two metabolites.

The position of the epoxy-alcohol functionality in compounds **6** and **8** was identified by the LR EIMS fragmentation pattern (fragment masses *m/z* 157 and 193 result from cleavage of C7–C8 in both **6** and **8**)(see the experimental Procedures section). The stereochemistry of the hydroxyl groups relative to the epoxy functionality was determined by comparing the chemical shifts and coupling patterns of the α-hydroxyl protons of both compounds to model compounds (17,18). The α-hydroxyl proton of the *threo*-isomer is consistently at higher field than that of the *erythreo*-isomer (17). The epoxide for each compound was shown to be *trans* by virtue of a 2.2–2.4 Hz coupling between the epoxide protons. Although double-bond



SCHEME 1

geometries could not be identified by conventional coupling constant analysis, they were effectively revealed by the ^{13}C NMR chemical shifts of the carbons vicinal to the olefins (19,20). A carbon vicinal to a *trans* double bond shows a chemical shift 4–6 ppm downfield as compared to that vicinal to a *cis* double bond (21). Analysis of ^{13}C NMR shifts for compounds **6** and **8** showed all double bonds to be of *cis* configuration. By these data, compound **6** was identified as methyl 7(S^*)-hydroxy-8(S^*),9(S^*)-epoxy-5(*Z*),11(*Z*),14(*Z*) eicosatrienoate and compound **8** was identified as methyl 7(R^*) -hydroxy-8(S^*),9(S^*)- epoxy-5(*Z*),11(*Z*),14(*Z*) eicosatrienoate.

Compound **10**, a colorless oil, showed $[\alpha]_D^{23} = -7.5°$ (c = 0.05, MeOH). The ^{1}H-^{1}H COSY of **10** showed that the α-hydroxyl protons (δ4.26 and δ4.17) correlated to two overlapping conjugated systems [λ_{max} = 238 nm (ε = 49,600), 232 nm (ε = 47,700)]. Despite this degeneracy, it was still possible by very careful analysis to map out the proton connectivity from the C-2 methylene (δ2.33) to the C-20 methyl group (δ0.88). The coupling constants of the olefinic protons were clarified by proton-decoupling experiments; each diene was of the expected *cis-trans* configuration. Additional support for the location of oxidation in **10** was obtained from LR EIMS of the TMS-ether derivative which showed ions at *m/z* 255 (cleavage of C9–C10) and *m/z* 239 (cleavage of C15–C16)(see the Experimental Procedures section). Compound **10** was thus identified as methyl 9(S^*),15-dihydroxy 5(*Z*),7(*E*),11(*Z*),13(*E*)-eicosatetraenoate. Interestingly, Reddy *et al.* (22) have reported the detection of 9,15-diHETE along with other diHETE from the oxidation of arachidonic acid by potato tuber lipoxygenase.

In this work, we have demonstrated that *P. latissima* produces oxylipins quite different from those found previously in other red marine algae. All of these reasonably derive from a 9(*S*)-lipoxygenase-initiated metabolic pathway, in this case acting on arachidonic acid to produce 9(*S*)-hydroperoxy-eicosatetraenoic acid (9(*S*)-HpETE) as a central intermediate (Scheme 1). Simple peroxidase-type reduction of this hy-

droperoxide would yield 9(*S*)-HETE (**1**). Rearrangement of this 9(*S*)-HpETE, possibly catalyzed by a hydroperoxide dehydrase or hydroperoxide isomerase (23), could yield the hepoxilin-like metabolites **5** and **7**. Alternatively, through an epoxyallylic carbocation intermediate (24) with resulting proton losses and rearrangements as for colneleic acid (15), 9(*S*)-HpETE could be converted to polyneuric acid (**3**). Finally, 9,15-diHETE (**9**) could be produced by further lipoxygenase-type oxygenation and reduction of 9(*S*)-HpETE or 9(*S*)-HETE (22).

ACKNOWLEDGMENTS

We thank R. Kohnert for help with high field NMR studies (OSU Chemistry) and B. Arbogast and D. Griffin (OSU Agricultural Chemistry) with HR and LR MS. This work was supported by grant no. NA36RG0451 (project no. R/BT-18) from the NOAA to OSU Sea Grant and the Oregon State Legislature.

Photo-Initiated Peroxidation of Lipids in Micelles by Azaaromatics

L.R.C. Barclay*, E. Crowe, and C.D. Edwards

Chemistry Department, Mount Allison University, Sackville N.B., E0A 3C0, Canada

ABSTRACT: The monoazaaromatics, pyridine (**1**), hexyl nicotinate (**2**), and quinoline (**3**) and diazaaromatics, pyrimidine (**4**) and purine (**5**), readily act as photo-initiators for the peroxidation of methyl linoleate in 0.50 M SDS at 37°C giving free radical chain oxidations of linoleate. Quantitative kinetic runs on the order in substrate, RH, and in the rate of chain initiation, R_i, showed that the classical rate law for autoxidation, $-d[O_2]/dt = (k_p/(2\ k_t^{1/2}))[RH] \times R_i^{1/2}$, is applicable to these photo-initiated oxidations. The oxidizability of methyl linoleate under these conditions is 2.92×10^{-2} $M^{-1/2}$ $s^{-1/2}$. These peroxidations were inhibited by chromanol phenolic antioxidants of the vitamin E class, such as lipid-soluble 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMHC) and water-soluble 2-carboxy-2,5,7,8-tetramethyl-6-hydroxychroman (Trolox) and derived rate constants for inhibition of peroxidation were k_{inh} (PMHC) = 4.35×10^4 M^{-1} s^{-1} and k_{inh} (Trolox) = 2.81×10^4 M^{-1} s^{-1} during inhibited oxidation of methyl linoleate photo-initiated by **4**. The products from photo-initiated peroxidation of methyl linoleate by **1** through **5** were determined by reduction and high-performance liquid chromatography analyses to be the 9- and 13-positional hydroperoxides of the four geometrical isomers: *cis*-9, *trans*-11 (**6**), *trans*-10, *cis*-12 (**7**), *trans*-9, *trans*-11 (**8**), and *trans*-10, *trans*-12 (**9**)–octadecadienoates typical of the free radical chain mechanism of lipid peroxidation. Products from dye-sensitized oxidation by Methylene Blue or Rose Bengal of methyl linoleate gave a product distribution of six hydroperoxides typical of oxidation by singlet oxygen. Thermal or photo-initiated peroxidation of methyl linoleate in SDS gave some selectivity of oxidation at the 13-position of the linoleate chain. The ratio of 13- to 9-oxidation varied in the range 1.23 to 1.14 as the *cis/trans* to *trans/trans* ratio of geometrical isomers varied from 0.44 to 1.25 during photooxidation of increased amounts of linoleate in SDS. This selectivity is attributed to loss of the *pseudo* symmetry around the pentadienyl system in the lipid chain in the SDS system during the peroxidation.

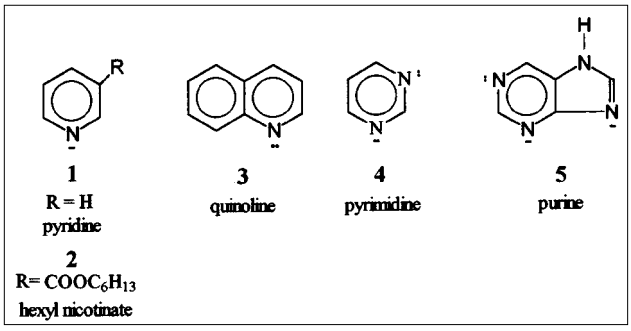
Lipids 32, 237–245 (1997).

Six-membered nitrogen heterocyclic aromatic compounds, azaaromatics and their derivatives, are widely distributed in nature. Their photochemistry has received considerable attention, but their possible role as initiators of photooxidation, the purpose of this investigation, is relatively unknown. This is surprising since the photogenerated (n,π^*) states of various azaaromatics are well known to abstract H-atoms from donors. Such studies have included a variety of monoazaaromatics (1–9), such as pyridine, quinoline, isoquinoline and acridine, and a number of diazaaromatics (10,11). The earlier research on the photochemistry of azaaromatics has been reviewed (12).

Since hydrogen abstraction from organic substrates by n,π^* states of various azaaromatics has been well established, this process is expected to be a method of photo-initiated peroxidation of organic substrates. The role that biologically important azaaromatics, such as the DNA/RNA bases purine and pyrimidine, might play in photooxidation is of particular interest because of the role this process could play in initiating degenerative diseases such as skin cancer.

Although the advantages of the photochemical method of lipid peroxidation have recently been reviewed (13), there was no example cited where an azaaromatic was used as the photo-initiator. The objective of the research reported herein was to employ these compounds in a quantitative study of lipid peroxidation in a biphasic system to mimic a membrane. Consequently we now report on the following quantitative study of photo-initiated lipid peroxidation.

(i) The aromatic azaaromatic amines selected include monoazaaromatics (Scheme 1): pyridine (**1**), hexyl nicotinate (**2**), and quinoline (**3**) and the model bases pyrimidine (**4**) and purine (**5**).



SCHEME 1

*To whom correspondence should be addressed.

Abbreviation: PMHC, pentamethyl-6-hydroxychroman.

(ii) The system selected for the reactions is 0.50 M SDS. This biphasic aqueous/hydrophobic system has proved useful as a model system, which mimics lipid membranes in some respects and is convenient for quantitative kinetic studies, such as kinetic orders of oxygen absorption, and analytical studies (14–24).

(iii) The substrate used is linoleate (methyl linoleate and linoleic acid). Product studies performed on the peroxidized substrate provide important evidence on the mechanism of peroxidation, e.g., free radical chain peroxidation as compared to reaction products resulting from attack by singlet oxygen. Singlet oxygen reactions are also studied in the SDS system by sensitization in the presence of Methylene Blue or Rose Bengal.

MATERIALS AND METHODS

Materials. Methyl linoleate and linoleic acid were obtained from Nu-Chek-Prep (Elysian, MN) (purity >99%) and stored in sealed vials at –30°C until used. Trolox was purchased from Aldrich Chemicals (Milwaukee, WI). 2,2,5,7,8-Pentamethyl-6-hydroxychroman (PMHC) was synthesized by a known procedure (25). Pyridine, hexyl nicotinate, quinoline, pyrimidine, and purine were obtained from Aldrich Chemicals. Quinoline was distilled under reduced pressure before use. Benzophenone was purchased from Fisher Scientific and recrystallized from pentane before use. Methylene Blue and Rose Bengal were obtained from Aldrich Chemicals. SDS was electrophoresis purity obtained from Bio-Rad (Richmond, CA). The phosphate buffer (pH 7.0) was prepared from 0.05 M each of Na_2HPO_4 and NaH_2PO_4 in deionized distilled water containing 10^{-4} M EDTA. The buffer was passed through a column of Bio-Rad Chelex 100 (50–100 mesh) to remove traces of heavy metal ions. Organic solvents used were Omni Solv (BDH, Toronto, Ontario, Canada) spectroscopic grade.

Preparations. Solutions of 0.50 M SDS were prepared in phosphate buffer and stored at 0°C in the dark until used. Solutions of the various photo-initiators and of the phenolic antioxidant, PMHC, were prepared in the 0.50 M SDS by vortex stirring known amounts of each in known volumes of SDS. Their concentrations were checked by diluting aliquots with methanol and water and by comparison of their ultraviolet spectra with that of solutions of known concentration prepared separately in methanol and water. The initiator-SDS stock solutions were stored at 0°C and in the dark before use.

The autoxidation/inhibition procedures. Autoxidations were generally carried out at 37°C/760 torr under oxygen using a sensitive, calibrated dual channel pressure transducer system that is described in detail elsewhere (26). Autoxidations using pyridine as the photo-initiator were carried out using a YSI Model S-18053 Oxygen Monitor System with a Clark oxygen electrode (Yellow Springs, OH).

In a typical experiment, 2.00 mL samples of 0.50 M SDS–phosphate buffer were equilibrated at 37°C under oxygen in the pressure transducer system. Then a known amount of azaaromatic solubilized in a few μL of 0.50 M SDS was injected into the sample channel cell followed by a known amount of linoleic acid or methyl linoleate. The sample was allowed to equilibrate again by shaking the system under oxygen. When a stable baseline was observed, the sample was irradiated with a 200 W super pressure Hg arc lamp through a glass filter. The lamp intensity was monitored throughout the experiment using a fiber optics cable attached to a phototube and picoammeter detector. Kinetic measurements with respect to substrate were performed by adding the substrate from a μL precision syringe and measuring the oxygen uptake after each addition. The effect of variation of light intensity was followed by using a series of seven neutral density filters of known transmittance. Inhibition periods by PMHC or Trolox were obtained by injecting known amounts of the inhibitors and measuring the time (τ) until the oxygen uptake rate returned to the uninhibited rate.

Analyses. Concentrations of the azaaromatics and of PMHC prepared in the stock 0.50 M SDS solutions were checked by diluting known aliquots in (1:1) methanol/distilled water. The spectra were then recorded on a Shimadzu UV-1201 Spectrometer (Kyoto, Japan). Trolox was prepared in a known concentration in pH 7.0 phosphate buffer. Analyses for oxidation products were carried out as reported earlier (27). Samples from an oxidation run were immediately reduced to the hydroxy derivatives by triphenylphosphine using a known procedure (18). The products were extracted in hexane and analyzed at 234 nm on a Hewlett-Packard HP1050 HPLC (Palo Alto, CA) interfaced for computer analyses. Separations were achieved using a LiChrosorb Si60 (E. Merck, Darmstadt, Germany) (5 μm) silica column and a solvent system containing hexane/isopropyl alcohol/acetone mixture in the ratio 992:4:4. The solvent system was distilled before use. Gas–liquid chromatography analyses were done on a Varian Model 3700 gas chromatograph (Palo Alto, CA). The concentrations of quinoline used in a run (initial and final) were measured from aliquots containing *n*-butanol as internal standard. The analyses were performed on a $1' \times ¼''$ 8% Carbowax column (Chromatographic Specialities, Brockville, Ontario, Canada) using helium at 30 mL/min and 130°C for 3 min, followed by a program at 20°C/min to 220°C. The concentrations of hexyl nicotinate and of pyrimidine used in oxidations were determined by extraction of the samples with hexane and gas–liquid chromatography analysis on an $8' \times ¼''$ 10% Silar column (Chromatographic Specialities) using methyl benzoate as an internal standard. Helium was the carrier gas at 30 mL/min and 120°C for 1 min, followed by a program at 15°C/min to 210°C.

RESULTS

The quantitative kinetic method. Free radical chain autoxidations of organic substrates are well known to follow a classical rate law for oxygen uptake, Equation 1:

$$\frac{-d[O_2]}{dt} = \frac{k_p}{(2k_t)^{1/2}} \times [RH] \times R_i^{1/2} \qquad [1]$$

where k_p is the rate constant for chain propagation by hydrogen abstraction from the substrate, RH, by peroxyl radicals and 2 k_t is the rate constant for termination by recombination of peroxyl radicals. This classical equation applies to the autoxidation of many organic substrates in homogeneous solution, and it is also known to be applicable in certain cases to substrates in biphasic systems such as aqueous micelles and membranes (17,20,24). When this relationship applies, one can quantify the susceptibility of a substrate to undergo peroxidation, known as its oxidizability, by Equation 2.

$$\text{Oxidizability} = \frac{k_p}{(2k_t)^{1/2}} = \frac{-d[O_2]/dt}{[RH] \times R_i^{1/2}} \quad [2]$$

For quantitative studies, the rate of chain initiation, R_i, must be known and controlled. This is often done by using thermal azo initiators with known rate constants of decomposition and efficiency. In our present photochemical method, it is accomplished by using a monitored light source, selected filters, and known amounts of the azaaromatics. The R_i in each experiment was measured by adding a phenolic antioxidant (ArOH), known to trap two peroxyl radicals (e.g., with a stoichiometric factor, n, of 2), and by measuring the inhibition period, τ , during which oxygen uptake is suppressed. Under these controlled conditions, Equation 3 applies.

$$R_i = n[\text{ArOH}]/\tau \quad [3]$$

During inhibited peroxidation, peroxyl radicals are terminated by mechanisms represented by Equations 4 and 5.

$$\text{ROO}^{\cdot} + \text{ArOH} \xrightarrow{k_{inh}} \text{ROOH} + \text{ArO}^{\cdot} \quad [4]$$

$$\text{ROO}^{\cdot} + \text{ArO}^{\cdot} \xrightarrow{\text{fast}} \text{nonradical products} \quad [5]$$

Under these conditions the suppressed oxygen uptake is given by Equation 6.

$$\frac{-d[O_2]}{dt} = \frac{k_p}{k_{inh}} \times [RH] \times \frac{R_i}{n[\text{ArOH}]} \quad [6]$$

An integrated version of this equation, Equation 7, is useful to measure the antioxidant activities of inhibitors.

$$\Delta[O_2]_t = \frac{-k_p}{k_{inh}} \times [RH] \times \ln\left(1 - \frac{t}{\tau}\right) \quad [7]$$

The absolute rate constant for inhibition, k_{inh} , is determined from a linear plot of the oxygen uptake during the course of the inhibition period, $\Delta[O_2]$, vs. $-\ln(1 - t/\tau)$ where the slope $= (k_p/k_{inh})[RH]$.

These quantitative methods proved useful for kinetic measurements, e.g., of k_{inh} values, in SDS employing thermal azo initiators (21) and earlier using photochemical initiation by benzophenone (18). In the present study, it was desirable first to determine if the azaaromatics **1–5** photo-initiate peroxidation of linoleate in SDS micelles and then determine the kinetic orders of oxygen uptake in substrate (linoleate) and in the rate of chain initiation, R_i, for the various azaaromatic photo-initiators used; in other words determine if the classical rate law, Equation 1, is applicable for this method of initiation in this biphasic system.

Kinetic orders in substrate and R_i. The azaaromatics used exhibited characteristic absorption in the near ultraviolet in methanol/water (1:1) as follows: pyridine (**1**), λ_{max} 250.5 nm, ε = 2617; hexyl nicotinate (**2**), λ_{max} 243, ε = 3072; quinoline (**3**), λ_{max} 313, ε = 2818; pyrimidine (**4**), λ_{max} 291, ε = 388 and purine (**5**), λ_{max} 262, ε = 7943. Measurable oxygen uptake occurred on irradiation of a 0.50 M SDS solution of linoleic acid or methyl linoleate containing each of these amines. Although the ultraviolet maxima for compounds **1**, **2**, and **5** are well below the "cut-off" for the glass filter used, their very broad absorption bands tail off past the cut-off allowing sufficient absorption of light to initiate photooxidation of the reactive substrate.

In order to test the effect of varying the micellar linoleate concentration on the oxygen uptake, a series of experiments were conducted with each amine initiator. Linoleate concentrations were varied over at least a fivefold range. The results of these kinetic measurements involving the monoazaaromatics are illustrated in Figure 1 (concentrations given assume that the linoleate and initiators partition into the SDS phase). Linear plots in linoleate concentration (not shown) were also observed using the diazaaromatics **4** (0.0197 M) and **5** (0.0272 M) and linoleate concentrations ranges of 0.0850 to 0.483 and 0.0794 to 0.435 M. Quinoline (2.19 mM) initiator in homogeneous solution of methyl linoleate (0.0578 to 0.167 M) in *tert*-butyl alcohol gave a kinetic order of 1.08 in substrate (not shown). Linear plots for the kinetic order in micellar linoleate were observed in all cases for the concentrations ranges studied and the kinetic orders in oxygen uptake were close to unity; all lying in the range 0.96 to 1.12.

The dependence of the rate of oxygen consumption on variation of the rate of initiation (R_i) was determined by vary-

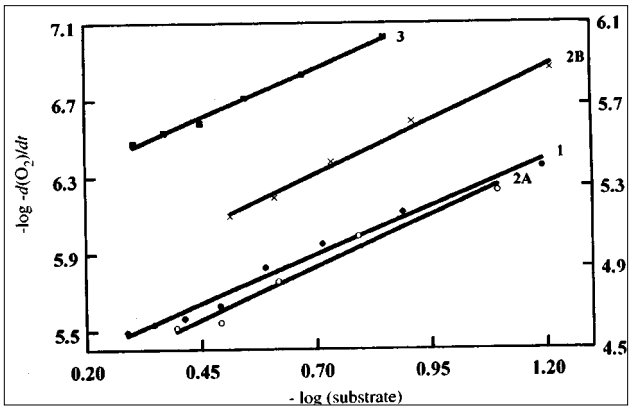


FIG. 1. Kinetic order plots of oxidation with respect to linoleate concentration for photo-initiated peroxidation by monoazaaromatics in 0.50 M SDS, phosphate buffer, pH 7.0, at 37°C. 1, linoleic acid (0.063 to 0.515 M), pyridine (0.618 M). 2A, methyl linoleate (0.0805 to 0.402 M), hexyl nicotinate (0.0186 M). 2B, linoleic acid (0.0613 to 0.306 M), hexyl nicotinate (0.0187 M). 3, methyl linoleate (0.0707 to 0.495 M), quinoline (0.0217). The y range for line 3 is from 4.5 to 6.0.

ing the light intensity as reported before by initiation using benzophenone (18). Typical results from at least five different light intensities are shown in Figure 2 for the monoazaaromatic initiators. Similar kinetic orders in light intensity (not shown) were obtained using the diazaaromatics **4** (0.0197 M) with methyl linoleate (0.402 M) and **5** (0.0272 M) and methyl linoleate (0.4345 M). Experiments to measure the dependence of the rate of oxidation on light intensity in solution of *tert*-butyl alcohol (not shown) using methyl linoleate (0.0759 M) and quinoline (2.19 mM) gave a kinetic order of 0.49. The results show linear variation of the rate of oxidation with light intensity across a wide range of micellar linoleate concentrations (0.0707 to 0.4345 M), and the reaction orders obtained from the slopes were approximately half order, all lying in the range of 0.42 to 0.60.

Kinetic results from inhibited peroxidation. Typical experimental profiles of oxygen uptake of uninhibited and inhibited peroxidation of linoleate in 0.50 M SDS are shown in Figures 3–5. These are typical results for photo-initiation using various combinations of water-soluble initiators (pyridine **1**, pyrimidine **4**, and purine **5**) and lipid-soluble ones (hexyl nicotinate **2** and quinoline **3**) and inhibition by the water-soluble antioxidant, 2,5,7,8-tetramethyl-2-carboxy-6-hydroxychroman (Trolox), and by the lipid-soluble one, 2,2,5,7,8-PMHC, both known to trap two peroxyl radicals in chain terminating peroxidation (28,29) (Equation 3, $n = 2$). For example, Figure 3 shows the inhibiting effect of PMHC for reaction initiated by water-soluble **1**, and inhibition by Trolox during initiation by the lipid-soluble derivative, **2**, and Figure 4 shows results from the combination of initiation by lipid-soluble quinoline and inhibition by Trolox. Figure 5 demonstrates that reactions initiated by water-soluble pyrimidine or purine can be inhibited effectively by either Trolox or PMHC.

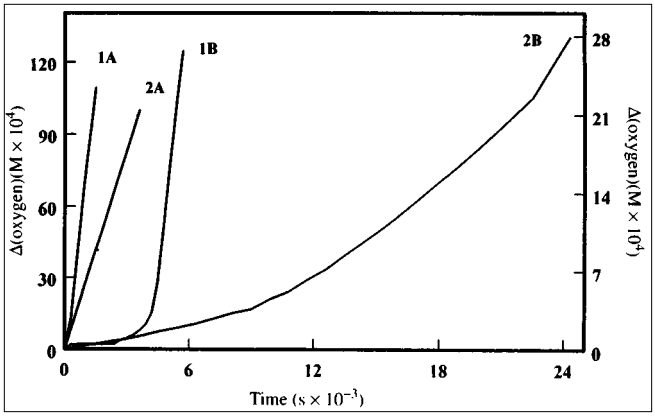

FIG. 3. Peroxidation of methyl linoleate photo-initiated in 0.50 M SDS, pH 7.0, at 37°C. 1A, uninhibited reaction. Methyl linoleate (0.097 M), pyridine (0.182 M). 1B, inhibited by PMHC (1.124×10^{-8} mol). The scale of oxygen uptake is shown on the right for 1A and 1B as 0 to 28 $M \times 10^{-4}$. 2A, uninhibited reaction. Methyl linoleate (0.241 M), hexyl nicotinate (0.0187 M). 2B, inhibited by Trolox (0.652×10^{-8} mol).

(i) Oxidizability. The results on kinetic orders in substrate and light intensity indicate that the classical rate law is applicable to peroxidation of linoleate in micelles under the conditions used. In addition, the R_i can now be determined from the results of these inhibition studies and calculated using Equation 3. Consequently, requirements are met to determine the susceptibility of linoleate to undergo free radical peroxidation, its oxidizability, by application of Equation 2. Results of such measurements using methyl linoleate in 0.50 M SDS employing the azaaromatic photo-initiators and PMHC or Trolox to measure the R_i are summarized in Table 1. The results show the oxidizability, $k_p/(2\,k_t)^{1/2} = 2.92 \pm 0.29 \times 10^{-2}$ $M^{-1/2}\,s^{-1/2}$, to be the same, within experimental error, for the various methods of initiation and inhibition. Substantial kinetic chain lengths, in the range of 77 to 253 for the uninhibited reaction, were obtained under the conditions used.

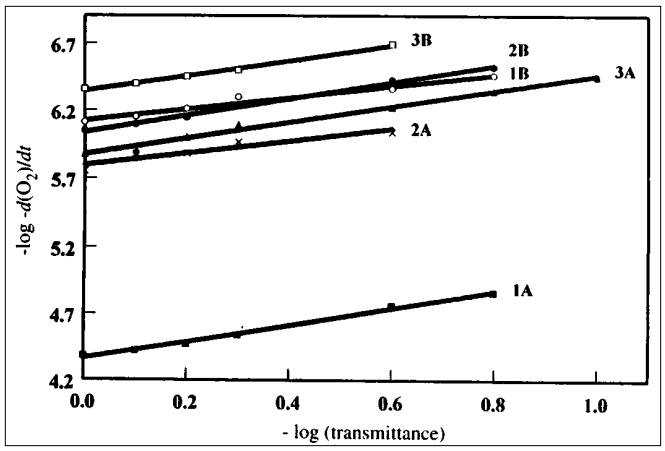

FIG. 2. Kinetic order plots of oxidation with respect to light intensity (transmittance) for photo-initiated peroxidation of linoleate in 0.50 M SDS, phosphate buffer, pH 7.0, at 37°C. 1A, methyl linoleate (0.0966 M), pyridine (0.306 M). 1B, linoleic acid (0.129 M), pyridine (0.618 M). 2A, methyl linoleate (0.241 M), hexyl nicotinate (0.0186 M). 2B, linoleic acid (0.306 M), hexyl nicotinate (0.0187 M). 3A, methyl linoleate (0.0707 M), quinoline (0.0217 M). 3B, linoleic acid (0.130 M), quinoline (0.0252 M).

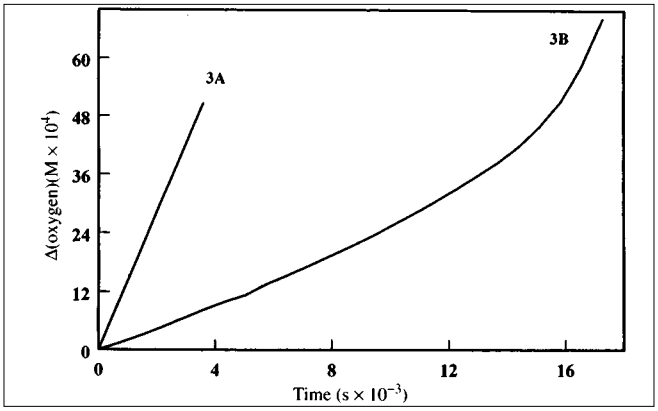

FIG. 4. Peroxidation of methyl linoleate (0.566 M) in 0.50 M SDS, pH 7.0, at 37°C, photo-initiated by quinoline (0.0192 M). 3A, uninhibited reaction. 3B, inhibited by Trolox (4.10×10^{-8} mol).

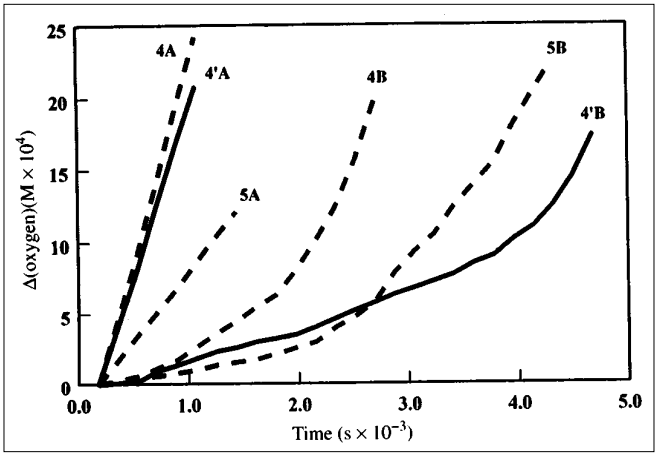

FIG. 5. Peroxidation of methyl linoleate photo-initiated in 0.50 M SDS, pH 7.0, at 37°C. The same light intensities were used for each pair of uninhibited and inhibited experiments. 4A, uninhibited reaction, methyl linoleate (0.563 M), initiated by pyrimidine (0.284 M). 4B, inhibited by Trolox (0.639×10^{-8} mol). 4′A, uninhibited reaction, methyl linoleate (0.503 M), initiated by pyrimidine (0.284 M). 4′B, inhibited by PMHC (1.56×10^{-8} mol). 5A, uninhibited reaction, methyl linoleate (0.435 M), initiated by purine (0.0349 M). 5B, inhibited by Trolox (0.205×10^{-8} mol).

(ii) Antioxidant activities. In order for kinetic studies to be applied to the determination of activities of antioxidants during peroxidation, specific conditions must be met, namely, (i) there must be a definite inhibition period during which oxygen uptake is suppressed so that this period (τ) can be measured, (ii) there should be a measurable chain reaction remaining during this inhibition period so that the steady-state approximation (Equation 6) is applicable and suppressed oxygen uptake can be measured, and (iii) the propagation rate constant, k_p, must be known. Linear plots of $\Delta[O_2]$ vs. $-\ln(1 - t/\tau)$ (Equation 7) and the known k_p for linoleate in SDS (15) were used to obtain the rate constant of inhibition for lipid-soluble PMHC ($k_{inh} = 3.42 \times 10^4$ M^{-1} s^{-1}) and for water-soluble Trolox ($k_{inh} = 4.35 \times 10^4$ M^{-1} s^{-1}) during photo-initiation by water-soluble pyrimidine.

Analyses of lipid hydroperoxides and of initiators. It is well known that the free radical peroxidation of methyl linoleate produces four conjugated regio-geometric isomers: the 9- and 13-perhydroxy *cis, trans* (*c,t*) and *trans,trans* (*t,t*) isomers (30,31). In contrast, singlet oxygen oxidation of methyl linoleate yields both conjugated and nonconjugated isomers in approximately equal amounts (32,33), presumably by the concerted ene reaction with singlet oxygen, rather than *via* a peroxyl radical intermediate.

We carried out product studies of the isomers formed by photo-initiated oxidation of methyl linoleate by different initiators. The results of these studies are given in Table 2. In addition, the trend in product formation with linoleate concentration was followed during photo-initiation by pyrimidine, as shown. In each case the isomers were separated and analyzed as the corresponding four isomeric alcohols (see Fig. 6), formed by reduction of the products with triphenylphosphine after low extent of oxidation (less than 5%). In all cases, the four isomers formed (**6–9**) are consistent with a free radical peroxidation pathway.

In addition, a few experiments were conducted using dye-sensitized oxidation of methyl linoleate in 0.50 M SDS, conditions which lead to reaction by singlet oxygen and an entirely different profile of products. Under these conditions, six isomers were formed with both conjugated and nonconjugated structures. These results are outlined in Table 3.

In the system photo-initiated by pyrimidine, the trend in the ratio of *c,t* to *t,t* isomers with different linoleate concentration was followed. The data for these results are included in Table 2. A plot of the trend is illustrated in Figure 7, along with the trend in oxidation products formed at position 13 compared to position 9 at the different concentrations (the 13:9 ratio). The linear variation in *c,t* to *t,t* ratio with linoleate concentration follows the expected trend. As Porter (34) reported, the ratio of *c,t*/*t,t* isomers depends directly on the H-atom donating ability of the system, here the concentration of the bisallylic system, linoleate. However, our observed variation of the 13:9 ratio is unusual, since this ratio was reported to be 1:1 in all other cases, even when experiments were conducted which should reveal if there is any preference for oxidative attack at the 9- or 13-position of the chain (27,35). We also found that the 13:9 ratio varies from unity

[a]The nonconjugated 10-hydroxy *trans*-8, *cis*-12 and 12-hydroxy *cis*-9, *trans*-13-octadecadienoate products (see Ref. 32). The ratio of **10** to **11** was unity, but these ratios are not on the same scale as isomers **6** to **9** because of the different absorptivities of these isomers at the wavelength used for high-performance liquid chromatography analyses.

when oxidation was initiated with a thermal azo initiator (di-*tert*-butyl hyponitrite) in SDS, and this trend is also shown in Figure 7.

Analyses for loss of initiators during the photolyses were performed by ultraviolet spectrophotometry and gas–liquid chromatography. Pyridine is very soluble in the aqueous phase, and we were not successful in extracting it in quantitative yield from the aqueous phase with an organic solvent. In addition, it appears that a significant amount remains in the vapor state above the sample. This factor also caused experimental difficulty in determining the order of oxygen consumption in light intensity using the pressure transducer system. That procedure assumes that the pyridine remains entirely in the aqueous–micellar phase. For this reason, the kinetic order was determined using the oxygen electrode where the sensor is isolated from the vapor phase.

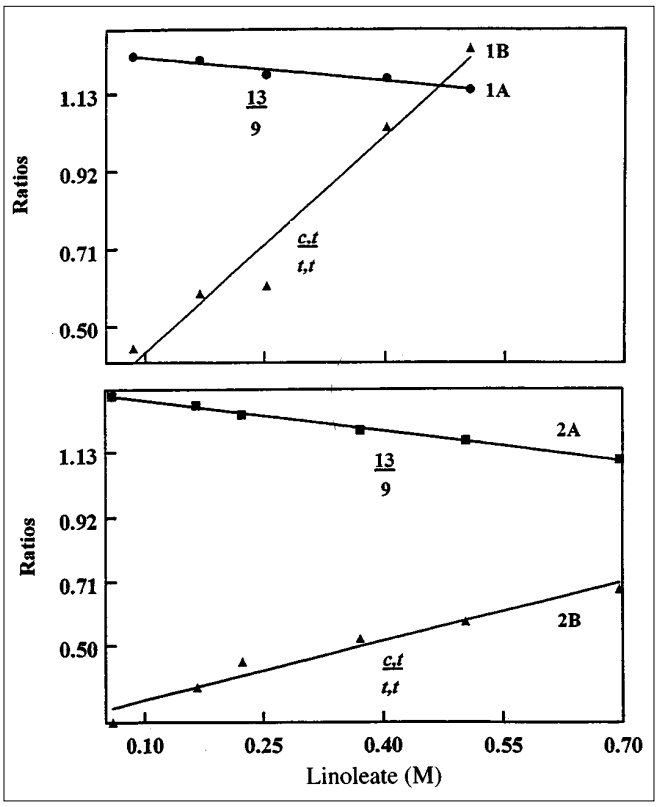

FIG. 7. Concentration dependence in linoleate of product ratios of *cis,trans* to *trans,trans* hydroxy fatty esters [(**6** + **7**)/(**8** + **9**), Fig. 6] and 13:9 ratios of position isomers from peroxidation of linoleate in 0.50 M SDS. 1A, Ratio of 13- and 9-hydroperoxides formed from oxidation of methyl linoleate, photo-initiated by pyrimidine. Data taken from Table 2. 1B, Ratio of *cis,trans* and *trans,trans* hydroperoxides formed from oxidation of methyl linoleate, photo-initiated by pyrimidine. Data taken from Table 2. 2A, Ratio of 13- and 9-hydroperoxides formed from oxidation of linoleic acid, thermally initiated by di-*tert*-butylhyponitrite. Data taken from Reference 18. 2B, Ratio of *cis,trans* and *trans,trans* hydroperoxides formed from oxidation linoleic acid, thermally initiated by di-*tert*-butylhyponitrite. Data taken from Reference 18.

Experiments using hexyl nicotinate as the photo-initiator showed that the maximum amount lost during the course of an experiment was 5%, according to analysis by ultraviolet spectrophotometry of an experimental sample from which the initiator was extracted in a layer of hexane. Gas chromatography analysis of a sample extracted using the same procedure indicated a loss of only 2% of the hexyl nicotinate.

Ultraviolet analyses were performed directly on the experimental samples which were photo-initiated by pyrimidine and purine. These samples contained the photo-initiator, SDS, and methyl linoleate, and analyses were performed prior to, and following, the photooxidation reactions. The analyses indicated that there was no loss of pyrimidine, and that the maximum amount of purine lost even after extensive irradiation was only 7%.

DISCUSSION

Our results demonstrate for the first time that both water-soluble and lipid-soluble azaaromatics readily photo-initiate peroxidation by near ultraviolet irradiation of an unsaturated lipid in a model biphasic system of SDS micelles. All of the data indicate a typical free radical chain peroxidation. Appreciable kinetic chain lengths were observed for the oxidations and the kinetic orders in substrate (linoleate) concentration and R_i show that the oxidations follow the classical rate law for autoxidation. The oxidizability of methyl linoleate was determined to be 2.92×10^{-2} $M^{-1/2}$ $s^{-1/2}$, similar to the value reported for linoleic acid in SDS using a thermal initiator (4.48×10^{-2} $M^{-1/2}$ $s^{-1/2}$) (19). Unlike the case for thermal initiation, there is not a simple relationship between the oxygen uptake and the azaaromatic employed in this study (see Table 1). The efficiency of initiation using these photoinitiators will depend on the light absorbed which in turn varies with the molar absorptivities. In addition the system is complicated by different distributions of the initiators between the aqueous phase and reaction phase containing the substrate in the micelles and these distributions are not known.

These peroxidations were readily inhibited by a water-soluble or lipid-soluble antioxidant of the hydroxychroman (vitamin E) class. Typical antioxidant activities for the antioxidants used, lipid-soluble PMHC, $k_{inh} = 3.42 \times 10^4$ M^{-1} s^{-1} and water-soluble Trolox, $k_{inh} = 4.35 \times 10^4$ M^{-1} s^{-1}, are in agreement with those found in SDS micelles for PMHC by thermal methods of initiation ((21), $k_{inh} = 3.96 \times 10^4$ M^{-1} s^{-1}) and for Trolox by photo-initiation methods ((18), $k_{inh} = 2.81 \times 10^4$ M^{-1} s^{-1} at 30°C). Oxidation was not initiated in the absence of the azaaromatics on methyl linoleate in SDS micelles under our conditions.

The results from high-performance liquid chromatography analyses of the hydroperoxides formed during a photo-initiated run involving azaaromatics are consistent with a reaction mechanism involving H-abstraction from the lipid doubly allylic $-CH_2-$ group followed by attack by oxygen at the 9- and 13-positions of the resulting pentadienyl radical (Fig. 6). There was no evidence for oxidation by singlet oxygen, which might be expected to form by energy transfer, since we have confirmed that this pathway gives rise to different products from linoleate during dye-sensitized peroxidation in SDS.

The observation of 13:9 ratios higher than unity (Table 2) is of interest and appears to be unique. We also find an inverse linear trend of the 13:9 ratios when plotted along with the *cis,trans/trans,trans* ratios, with higher 13:9 ratios corresponding to lower *c,t/t,t* ratios for both photo-initiated oxidation and thermal oxidation using the earlier procedure (18; Fig. 7). We speculate that the unusual 13:9 ratios are due to several factors. (**1**). The *cisoid* and *transoid* conformers of the pentadienyl radical are not in thermal equilibrium (36,37), and peroxidation at the *transoid* end of the linoleate pentadienyl radical is more facile than at the *cisoid* terminus (38). (**2**). The ratios of the kinetic products to thermodynamic products (*c,t* to *t,t*) are directly related to the H-atom donating ability of the medium (34). (**3**). The linoleate chain is expected to be in a nonuniform environment in our SDS system. Bilayer soap molecules, such as palmitate, are known to exhibit increased conformational freedom toward the chain terminus (39) and SDS above the critical micelle concentration is known to undergo a phase change from micellar to such bilayer structures (Robinson, B.H., Private Communication). So the linoleate chain in 0.50 M SDS is expected to be subject to nonuniform effects. If the polar headgroup is positioned near the SDS headgroup as is expected, the hydrocarbon tail would be in the region of lower microviscosity where the derived peroxyl radical initially formed at position 13 would be free to rotate to the *transoid* conformation. On the other hand, the larger $C(9)HOO(CH_2)_7COOCH_3$ at position 9 would be more constrained from rotation about the C(9) to C(10) bond axis. As a result, position 13 more readily sets up the *transoid* conformer for more rapid oxodation. This possibility is shown schematically in Figure 8.

Analyses for the azaaromatic initiators indicate that they are recovered almost completely unreacted at the end of the usual photooxidation. This recycling of the initiators is a useful phenomenon because it provides for a constant R_i throughout the experiments. A possible scheme for this recycling is given in Figure 9 for for compound **2** whereby it is recovered by H-atom transfer from the excited pyridyl radical to oxygen and/or to a lipid peroxyl radical. A similar pathway was proposed earlier for the recycling of benzophenone used in photooxidation (18).

The SDS biphasic system is a useful one to use for these initial studies employing the azaaromatics as photo-initiators. Studies are in progress to apply these methods to the photoperoxidation of phospholipid membranes where the results are expected to more closely mimic the behavior of biomembranes subject to ultraviolet irradiation.

Effects of Cationic Liposome–DNA Complexes on Pulmonary Surfactant Function *in vitro* and *in vivo*

Pinar Boncuk, Matthew Kaser*, Yip Yu, and H. William Taeusch

Department of Pediatrics, University of California San Francisco and San Francisco General Hospital, San Francisco, California 94110

ABSTRACT: Cationic liposome–DNA complexes are being evaluated as potential gene therapy agents for the lung. Cations have strong effects on the biophysical functions of lung surfactant. Therefore, we assessed whether cationic liposomes [composed of *N*-(1-(2,3-dioleyloxy) propyl)-*N,N,N*-trimethyl-ammonium chloride and dioleylphosphatidylethanolamine] with or without DNA affect behavior of four types of surfactant *in vitro*. Experiments were carried out using a modified Wilhelmy surface balance. The ability of surfactants that contain protein and anionic lipids to lower surface tension was inhibited in the presence of cationic liposomes. Inactivation was less when DNA was preincubated with cationic liposomes. Surfactant that contained neither protein nor anionic lipids was not inactivated. Mechanical properties of the lung were studied to assess *in vivo* surfactant function after intratracheal instillation of a cationic liposome–DNA complex into adult rats. Pressure–volume deflation curves were shifted by 18% compared with those from normal (untreated) animals, but this effect was transient and not different from that observed in animals who received a similar volume of saline. These findings indicate that cationic liposomes alone may have deleterious effects on behavior of some surfactants possibly by disrupting charge interactions between negatively charged phospholipids and surfactant proteins. When DNA is added to liposomes before exposure to surfactants, the adverse charge interactions may be obviated by charge neutralization of liposomes by DNA.

Lipids 32, 247–253 (1997).

The lung has unique advantages as a site for somatic cell gene therapy because it can be targeted using intratracheal, intravenous, or aerosol routes (1–6). The entry of DNA into the cell and its subsequent expression has been demonstrated using a variety of transfection techniques that include fusion agents, polycations, neutral, or charged liposomes, viruses with specific tropism for airway epithelial cells, replication-deficient adenovirus, as well as reagents such as calcium phosphate, or DEAE–dextran. Limitations exist with all transfection techniques. Transfection using charged liposomes has been hampered by sonication-induced DNA degradation and low efficiency of cellular uptake and expression. Adenovirus vectors have advantages over liposomes in regard to efficacy of *in vivo* gene transfer; however, this technique may result in low levels of adenoviral gene products that lead to immunogenicity and inflammation in target tissues (7). Cationic liposomes are used to introduce genomic material into cultured cells and into animals. Pulmonary surfactant lines the pulmonary epithelial lumen and is known to be affected by charge interactions. Both positive and negative effects of cations on surface properties of lung surfactant have been shown (8–11). In general, surfactant function requires modest concentrations of mono- or divalent cations and is inhibited by higher concentrations of di- or trivalent cations. Increase in the surface tension at the air/lipid/aqueous interface after addition of these compounds to surfactant has been explained by cation association with anionic constituents of surfactant that may affect the electrostatic formation of cation–phosphatidylcholine bridges and phospholipid–protein interactions (11). In order to determine the salience of charge interactions between cationic liposomes and surfactant, we have studied whether addition of cationic liposomes with or without DNA has adverse effects on surfactant function *in vitro* and *in vivo*.

METHODS

Liposome preparation. Dioleylphosphatidylethanolamine (DOPE) (Avanti Polar Lipids, Alabaster, AL) dissolved in chloroform (10 μg/μL) and *N*-(1-(2,3-dioleyloxy)propyl)-*N,N,N*-trimethylammonium chloride (DOTMA) (Syntex Corp., Palo Alto, CA) dissolved in ethanol were mixed at DOPE/DOTMA (1:1, by weight) and evaporated to dryness on a rotary evaporator. Two–three mL of buffer solution (50 mM Tris, pH 7.4, 0.5 mM EDTA, 50 mM NaCl, 100 μM $ZnCl_2$) were added to bring the lipids to 5 mg/mL, and the mixture was sonicated in a bath sonicator (55 kHz) under argon for 20 min at room temperature (24°C).

Surface tension measurements. Surfactant preparations were diluted with appropriate amounts of buffered normal

Abbreviations: DOPE, dioleylphophatidylethanolamine; DOTMA, N-(1-(2,3-dioleyloxy) propyl)-*N,N,N*-trimethyl-ammonium chloride; DPPC, dipalmitoylphosphatidylcholine; DS, dog surfactant; pCMVβ, cytomegalovirus promoter β-galactosidease fusion gene plasmid construct.

saline to give a lipid concentration of 0.3 mg/mL and incubated for 16 h at 4°C. Survanta® (Ross Laboratories, Columbus, OH), Curosurf® (Chiesi Laboratories, Parma, Italy), Exosurf® (Burroughs Wellcome Co., Research Triangle Park, NC), or surfactant obtained from alveolar lavage from dogs (DS) by density gradient centrifugation (12) were each mixed with liposomes at surfactant lipid/liposome lipid (50:1, 10:1, 5:1, 1:1, by weight) then incubated at room temperature for 30 min. Experiments were repeated with plasmid DNA, cytomegalovirus promoter β-galactosidase fusion gene plasmid construct (pCMVβ), added to the mixtures at a liposome/DNA ratio of 5:1 by weight. This ratio was based on optimal ratios used in transfection experiments by us and others (13,14).

A Wilhelmy-Langmuir surface balance at room temperature was used to determine the surface tension-lowering properties of each of the above preparations *in vitro*. Test samples were applied to the surface or into the subphase of 30 mL saline in the Wilhelmy balance, allowed to absorb for 2 min, and minimum surface tension changes were recorded at the first and fifth compression according to previously published methods (15). To ensure that the observed effects were not due to nonspecific lipid chemistry, we repeated the experiments with Survanta® and DS at 37°C. (Others have indicated that performing analyses at either 22 or 37°C does not qualitatively affect the properties of lipid–protein monolayers (16) since the gel-to-liquid crystalline transition for dipalmitoylphosphatidylcholine (DPPC) is 41°C.

Pressure–volume relationships. Adults rats (340–450 g) were anesthetized with 90 mg/kg ketamine (Fort Dodge Laboratories, Fort Dodge, IA) and 10 mg/kg xylazine (Rugby Laboratories, Rockville Centre, NY) given intraperitoneally. Direct tracheal intubation was carried out using an 18-gauge Angiocath® (Becton-Dickinson, Franklin Lakes, NJ) after visualizing the glottis by means of a laryngoscope (Miller 0). Animals were randomly assigned to three groups. The first group (n = 10) was instilled with liposome–DNA preparation, the second group (n = 10) was instilled with saline, and the third group (n = 10) was lavaged with saline.

A solution containing 500 μg liposome (250 μg DOTMA, 250 μg DOPE) complexed with 100 μg DNA (pCMV β; galactosidase cDNA) made up to a total volume of 1 mL with saline (pH 7.0) was incubated at room temperature for 15 min then instilled in the trachea of animals in the first group as a bolus. Dosage of liposome–DNA was based on the following considerations. Adult rat lung contains an estimated 10–15 mg/kg body weight surfactant lipid (17). Rats weighed 340–450 g. Therefore, liposomes were given at a dose of 500 μg to achieve an estimated endogenous surfactant lipid/liposome ratio of 10:1 by weight. Plasmid DNA was added to the liposome preparation at a 1:5 mass ratio (0.00003:1 mole/mole), as explained previously in this article. The DNA/lipid charge ratio (–/+) was determined to be 1:1.11.

The second group was given a similar volume of normal saline delivered into the trachea. This volume was determined in separate experiments to optimize gross dispersion throughout the lung using either Coomasie brilliant blue or [^{14}C]-L-3-phosphatidylcholine, 1,2-di[^{14}C]oleoyl) as indicators of distribution. The dye and the radioactive signal were seen equally in both lungs, out to the periphery. Studies to identify cell type were not done.

Animals in the third group underwent pulmonary lavage using an aliquot of saline (10 mL) instilled and withdrawn from the trachea four times. After instillation of cationic liposome–DNA mixtures or saline, all animals breathed room air and were allowed to fully recover from anesthesia for either 3 1/2 h or for 6 h, at which time they were killed with a lethal (200 mg/kg intraperitoneal) dose of pentobarbital. Two time points were chosen to assess the reversibility of the potential effects of cationic liposome–DNA mixtures upon lung function, as determined by pressure–volume deflation curve analysis. Lungs and heart were removed en bloc, a 5 French vinyl catheter was secured in the trachea, and the lungs were degassed at a pressure of not less than 20 torr in an evacuated bell jar. Next, a pressure transducer (Gould® Windograf; Gould Instrument Systems, Valley View, OH) was used to monitor pressure changes in the lungs while lungs were manually inflated with an airtight syringe to a maximum of 30 cm H_2O at room temperature. Maximum inflating pressure was maintained for 1 min. The lungs were then deflated in steps over approximately 2 min while recording quasistatic pressure and volume changes. Lung volumes were corrected for gas compression in the syringe and tubing. Total lung capacity was defined as lung volume after 1 min at 30 cm H_2O pressure.

Data analysis. Results are expressed as mean ± standard error of the mean. Intergroup comparisons were done by unpaired t-test. Statistical significance was accepted as $P < 0.05$.

RESULTS

Surface tension measurements on modified Wilhelmy balance. Neither incubation with up to 37.5 μg DOTMA/DOPE nor addition of DNA to the liposomes changed the surface properties of 37.5 μg Exosurf (Fig. 1). We found an impairment of the surface tension-lowering properties of the three lung-derived surfactant preparations when mixed with cationic liposomes. Significant inactivation (defined as minimum surface tension >10 mN/m) was evident starting at a surfactant lipid/cationic lipid ratio of 10:1 for Survanta®, Curosurf®, and DS (Figs. 2–6). A squeeze-out phenomenon was not seen, and there were no differences in the above findings when the mixtures were applied to the subphase instead of the surface of the trough. Minimum surface tensions at 25°C obtained with Curosurf®, Survanta®, and DS were 3 ± 0.5 mN/m (n = 5), 7 ± 0.1 mN/m (n = 5), and 2 mN/m (n = 1), respectively (Figs. 2–4). When the surfactants were combined with liposomes at 1:1 (g lipid/g lipid) ratio, these values increased to 16 ± 0.6 mN/m (n = 5), 15 ± 3 mN/m (n = 5) ($P <$ 0.05), and 15 mN/m (n = 1). However when surfactant, cationic lipids, and DNA were mixed together, at a 1:1:0.2 (g lipid/g lipid/g DNA) ratio, minimum surface tensions of Curosurf®, Survanta®, and DS were 9 ± 1 mN/m (n = 5), 12 ± 0.4 mN/m (n = 5) ($P < 0.05$), and 14 mN/m (n = 1), respectively. The

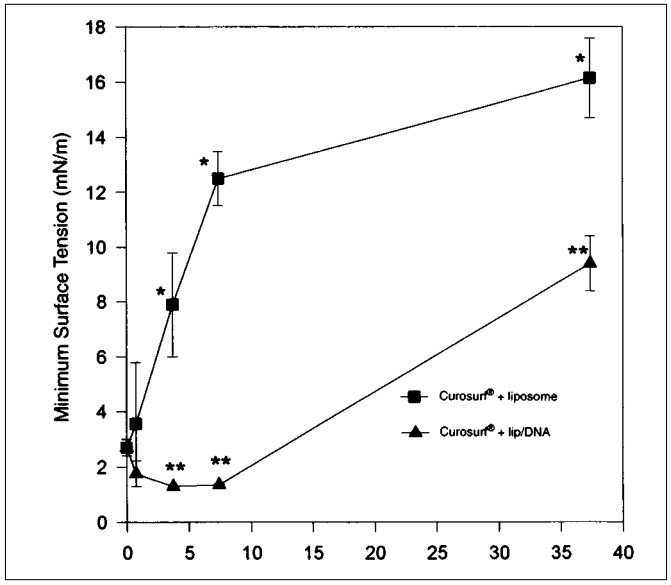

FIG. 1. Minimum surface tensions at 25°C of Exosurf® (Burroughs Wellcome, Research Triangle Park,) on Wilhelmy balance when mixed with cationic liposomes. A constant amount of 37.5 μg surfactant lipid was mixed with varying amounts of liposome (lip) *N*-(1-(2,3-dioleyloxy)propyl)-*N,N,N*-trimethylammonium chloride/dioleylphosphatidylethanolamine (DOTMA/DOPE) to give ratios of (by mass lipid) 50:1, 10:1, 5:1, and 1:1 (■). 37.5 μg surfactant lipid was mixed with increasing amounts of 5:1 (w/w) liposome/DNA complex (▲). Results at the fifth compression are shown. Data are means of between three and eight different experiments. Inactivation by DOTMA/DOPE was not significant.

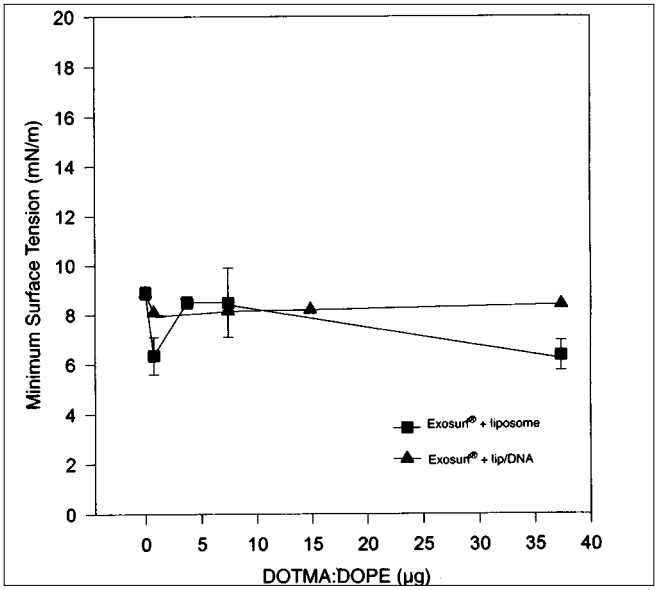

FIG. 2. Minimum surface tensions at 25°C of Curosurf® (Chiesi Laboratories, Parma, Italy) on Wilhelmy balance when mixed with cationic liposomes. A constant amount of 37.5 μg surfactant lipid was mixed with varying amounts of liposome (DOTMA/DOPE) to give ratios of (by mass lipid) 50:1, 10:1, 5:1, and 1:1 (■). 37.5 μg surfactant lipid was mixed with increasing amounts of 5:1 (w/w) liposome/DNA complex (▲). Results at the fifth compression are shown. Data are means of between three and eight different experiments. Inactivation by DOTMA/DOPE was significant starting at a ratio of 10:1 (*: $P < 0.05$). Addition of DNA decreased surfactant inactivation significantly (**: $P < 0.05$ compared with DOTMA/DOPE). See Figure 1 for abbreviations.

amount of liposome required to cause an increase in the surface tension to > 10 mN/m was approximately six times more in the presence of DNA.

Similar effects on minimum surface tension were obtained when Survanta® or DS were analyzed with cationic liposomes or cationic liposome–DNA complexes at 37°C (Figs. 5,6), substantiating the above findings.

Pressure–volume curves. Deflation stability of the rat lung was evaluated 3 1/2 or 6 h following tracheal instillation by comparing the gas volumes retained in the resected lungs at 5 cm H_2O pressure on the deflation limb of the curve. Deflation stability at 3 1/2 h in liposome–DNA-treated lungs at 5 cm H_2O was 18% lower than the mean for the untreated lungs ($P < 0.05$); however, a similar change from untreated controls was seen also in lungs from saline-treated rats (Fig. 7). This effect seen in the liposome–DNA group was transient since pressure–volume curves measured at a later time (6 h) were close to normal (Fig. 8).

DISCUSSION

Surface tension activity of the synthetic pulmonary surfactant Exosurf® was unaffected either by cationic liposomes or by cationic liposome–DNA mixtures. Our major findings support the notion that cationic liposomes affect the function of Curosurf®, Survanta®, and DS. Addition of DNA to cationic liposomes reduces the ability of liposomes to inactivate Curosurf®, Survanta®, and DS. That is, the addition of DNA to cationic liposomes increases the amount of liposome needed to cause inactivation of these surfactants, possibly by neutralizing liposome charge. Cationic liposome–DNA mixtures have transient effects on lung function *in vivo* that are no greater than those seen with saline alone.

We found that lung-derived surfactants were nevertheless susceptible to some inactivation *in vitro* by cationic liposome–DNA mixtures when the cationic lipid/surfactant lipid ratio was greater than 1:5 in the case of Curosurf® and Survanta®, or when cationic liposome lipid/surfactant lipid ratios were greater than 1:10 in the case of DS. We used an estimated cationic lipid/lung surfactant lipid ratio of 1:10 *in vivo*, primarily since this was the approximate amount that other workers had used in tracheal instillation of liposome–DNA mixtures to achieve *in vivo* transfection (1–3,5,6,13,23,24,26). We found that these amounts of liposome–DNA had no significant effect upon lung function, as measured by lung pressure–volume changes, when compared with instillation of a bolus of saline. Future investigators who might wish to enhance transfection efficiencies by treatment with much greater amounts of cationic liposomes may cause inactivation of the endogenous surfactant, followed by loss of lung function. These inactivation effects might be reduced if cationic liposome–DNA mixtures were to be instilled in the presence of an inert surfactant,

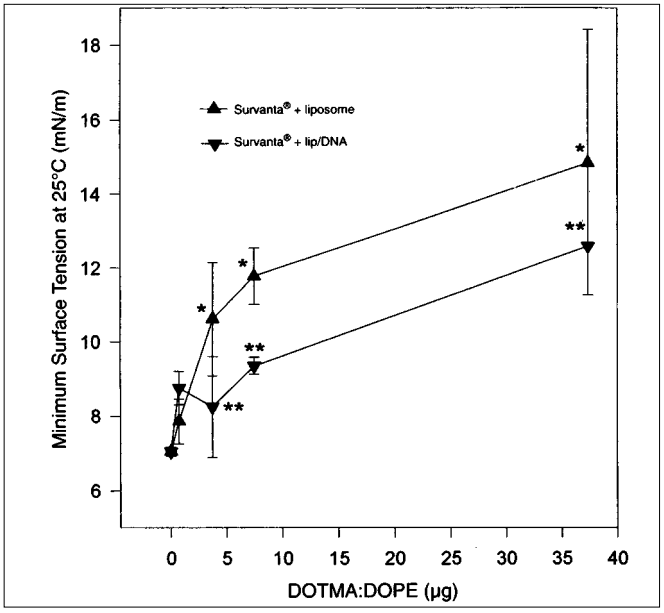

FIG. 3. Minimum surface tensions at 25°C of Survanta® on Wilhelmy balance when mixed with cationic liposomes. A constant amount of 37.5 µg surfactant lipid was mixed with varying amounts of liposome (DOTMA/DOPE) to give ratios of (by mass lipid) 50:1, 10:1, 5:1, and 1:1 (△). 37.5 µg surfactant lipid was mixed with increasing amounts of 5:1 (w/w) liposome/DNA complex (hatched triangle). Results at the fifth compression are shown. Data were mean of between three and eight different experiments. Inactivation by DOTMA/DOPE was significant starting at a ratio of 10:1 (*: $P < 0.05$). Addition of DNA decreased surfactant inactivation significantly (**: $P < 0.05$ compared with DOTMA/DOPE). See Figure 1 for abbreviations.

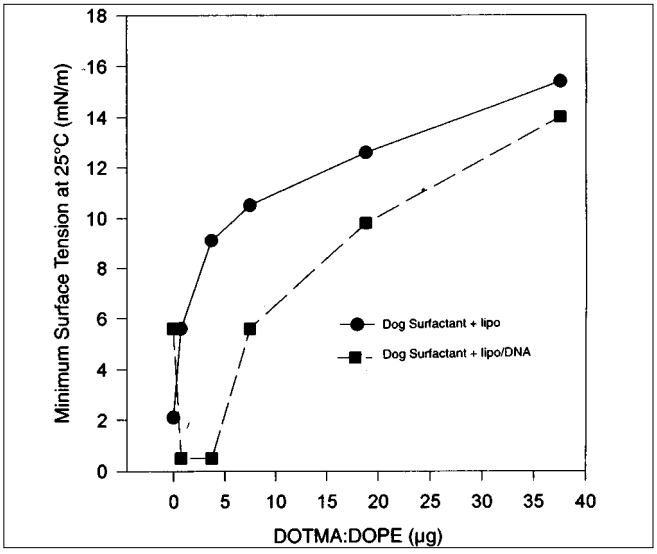

FIG. 4. Minimum surface tensions at 25°C of dog surfactant on Wilhelmy balance when mixed with cationic liposomes. A constant amount of 37.5 µg surfactant lipid was mixed with varying amounts of liposome (DOTMA/DOPE) to give ratios of (by mass lipid) 50:1, 10:1, 5:1, 2:1, and 1:1 (●). 37.5 µg surfactant lipid was mixed with increasing amounts of 5:1 (w/w) liposome/DNA complex (■). Results at the fifth compression are shown. Data were from a single experiment of one extract. Replicate experiments gave similar results. Dog surfactant was inactivated by DOTMA/DOPE; this inactivation was partly reversible by addition of DNA. See Figure 1 for abbreviations.

such as Exosurf®. Results from our laboratory suggest that these assumptions are correct (13).

Various alternative explanations are possible. We may have underestimated the surfactant-to-liposome ratio that exists in our *in vivo* experiments for our *in vitro* experiments. Others have found that increasing surfactant-to-inactivator ratio reduces the degree of surfactant dysfunction. Alternatively, liposome inactivation of surfactant may occur in mixing experiments, but not when surfactant preexists as a surface film at high surface pressure as would be the case in normal lungs. In addition, if this reasoning is correct, then liposome–DNA mixtures might have a greater than expected adverse effect in lungs with preexisting damage, that is to say, the sort of lungs in which gene therapy might be considered.

Susceptibility of various surfactants to inactivation *in vitro* by cationic liposomes varies. Survanta is a natural bovine lung extract containing phospholipids, neutral lipids, fatty acids, and surfactant-associated proteins to which dipalmitoylphosphatidylcholine (DPPC), palmitic acid, and tripalmitin are added. Curosurf is made from minced pig lung by chloroform–methanol extraction and liquid–gel chromatography. It contains saturated phosphatidylcholine along with other phospholipids and proteins, but no triglycerides, cholesterol, or free fatty acids. Exosurf® is a synthetic, protein-free surfactant composed of DPPC, hexadecanol (cetyl alcohol), and tyloxapol, a detergent that disperses DPPC. Hexadecanol is metabolized to palmitic acid which is later utilized in the synthesis of phospholipids. It may serve the same function in Exosurf® as palmitic acid does in Survanta®. Palmitic acid in natural lung surfactant is claimed to fluidize and separate the normally rigid DPPC bilayers in solution to enhance dispersion of the surfactant and increase absorption to interfaces (18). Previous work indicates that Survanta® and Curosurf® are more resistant to inactivation by albumin, fibrinogen, and hemoglobin when compared with Exosurf® when assessed by the pulsating bubble surfactometer (19). Our experiments, using a different measurement of inactivation (Wilhelmy balance), indicate that DS, Curosurf®, and Survanta® are all inactivated to the same degree in the presence of cationic liposomes, but Exosurf® is not. Exosurf® differs from the animal-derived surfactants in two major respects; it lacks surfactant-specific proteins and it lacks anionic lipids. Because the addition of negatively charged DNA to DS, Curosurf® and Survanta® reduces the liposome inactivation observed in the Wilhelmy balance experiments, we conclude that liposome–surfactant charge interaction is most likely responsible for the inactivation observed. These results are consonant with previous work that indicates charge interactions are potent inactivators of surfactant function *in vitro* (11,20). The ability of the cationic liposomes to fuse with negatively charged liposomes is strongly reduced in the presence of DNA (21). It is also possible that the *in vitro* measures on the Wilhelmy balance are more sensitive in detecting changes in surface activity than the measure of pressure–volume relation-

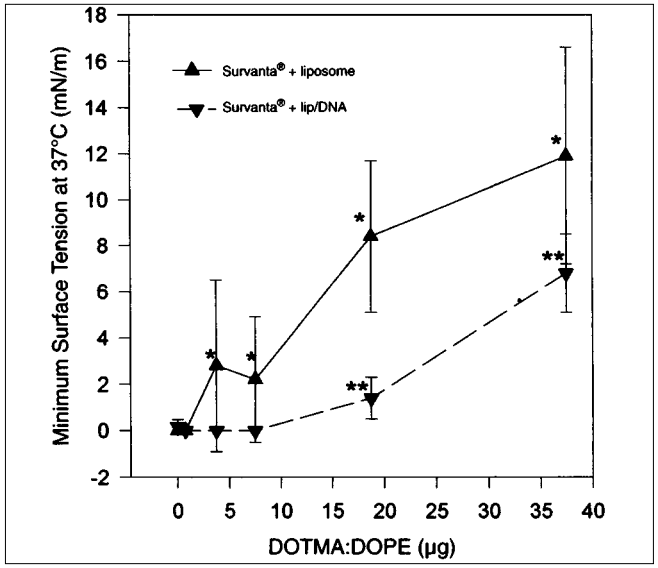

FIG. 5. Minimum surface tensions at 37°C of Survanta® on Wilhelmy balance when mixed with cationic liposomes. A constant amount of 37.5 µg surfactant lipid was mixed with varying amounts of liposome (DOTMA/DOPE) to give ratios of (by mass lipid) 50:1, 10:1, 5:1, 2:1, and 1:1 (Δ). 37.5 µg surfactant lipid was mixed with increasing amounts of 5:1 (w/w) liposome/DNA complex (▽). Results at the fifth compression are shown. Data were mean of three different batches. Inactivation by DOTMA/DOPE was significant starting at a ratio of 50:1 (* : $P < 0.05$). Addition of DNA decreased surfactant inactivation significantly (** : $P < 0.05$). See Figure 3 for company source. See Figure 1 for abbreviations.

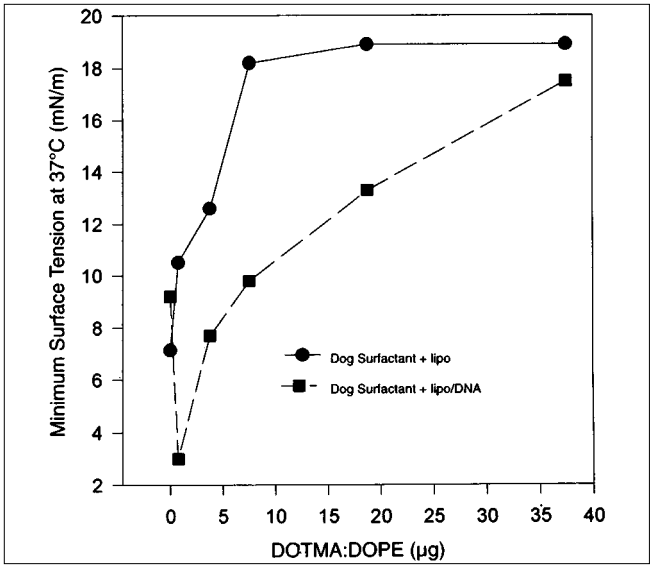

FIG. 6. Minimum surface tensions at 37(C of dog surfactant on Wilhelmy balance when mixed with cationic liposomes. A constant amount of 37.5 (g surfactant lipid was mixed with varying amounts of liposome (DOTMA:DOPE) to give ratios of (by mass lipid) 50:1, 10:1, 5:1, 2:1, and 1:1 (filled circles). 37.5 (g surfactant lipid was mixed with increasing amounts of 5:1 (w/w) liposome:DNA complex (filled squares). Results at the fifth compression are shown. Data were from a single experiment of one extract. Replicate experiments gave similar results. Dog surfactant was inactivated by DOTMA:DOPE; this inactivation was partly reversible by addition of DNA.

ships *in vivo*. Finally, although we carried out distribution experiments, it is possible that microdistribution of liposome–DNA was not widespread enough for *in vivo* changes to be detected.

The modest and transient effects on pulmonary mechanics of liposome–DNA mixtures are no greater than effects found with saline alone. These transient effects on mechanical properties of the lung most likely are secondary to the volume load of 1 mL (2.5–3 mL/kg) that could decrease total lung capacity by about 20%. Alternatively, inflammation with saline has been observed as early as 4 h after instillation into swine and rat lungs (6,22).

Others have studied whether liposomes used for DNA delivery affect lung function. Recently Canonico and coworkers (23) have shown that repeated weekly intravenous or aerosol administration of plasmid DNA complexed to cationic liposomes resulted in no adverse effects on pulmonary histology, gas exchange, compliance, or resistance over a 4-wk period when given to rabbits in an aerosol or intravenous solution (2500 µg liposome and 500 µg DNA in a total volume of 2.5 mL per 1.0–1.3 kg rabbit). Our study differs from theirs because we assessed the short-term effects of liposomes when administered as a bolus intratracheally. We used a dose of liposome–DNA similar to that used by Canonico and coworkers (23) and administered in a slightly larger volume: 1 mL per 0.3–0.4 kg rat. In other experiments meant to assess potential toxic side effects, liposomes have been tested on human volunteers in an aerosolized form (24). There were no changes in oxygen saturation or the spirometric values at 1 h after administration. Cationic liposome as a delivery agent for the human cystic fibrosis transmembrane conductance gene has no effects on spirometric values or the nasal potential difference in human subjects treated intranasally (25). In general, our results agree with these previous studies in that cationic liposome–DNA mixtures delivered by the airway appear to have transient and probably inconsequential effects.

A recent approach in pulmonary gene therapy has been to admix the liposome–DNA complex with pulmonary surfactant (13,26). The transfection efficiency with adenovirus increased when mixed with Survanta® before being instilled into the airways (26). Exosurf® mixed with DOTMA/DOPE–DNA preparations results in a fivefold increase in transfection efficiency, using cationic liposome–DNA preparations alone (13).

In summary, our *in vitro* experiments indicate that cationic liposomes with or without DNA affect different surfactants differently. Results imply that charge interactions are important for adequate surfactant function *in vitro*. Cationic liposome–DNA mixtures that contain up to 500 µg of cationic liposome per 0.3–0.4 kg weight (1.6 g/kg) with a liposome/DNA ratio of 5:1 exhibit effects on pulmonary mechanics that are transient and are no greater than those seen with saline alone. These results and those of others indicate that cationic liposome–DNA delivery to the lungs will not ad-

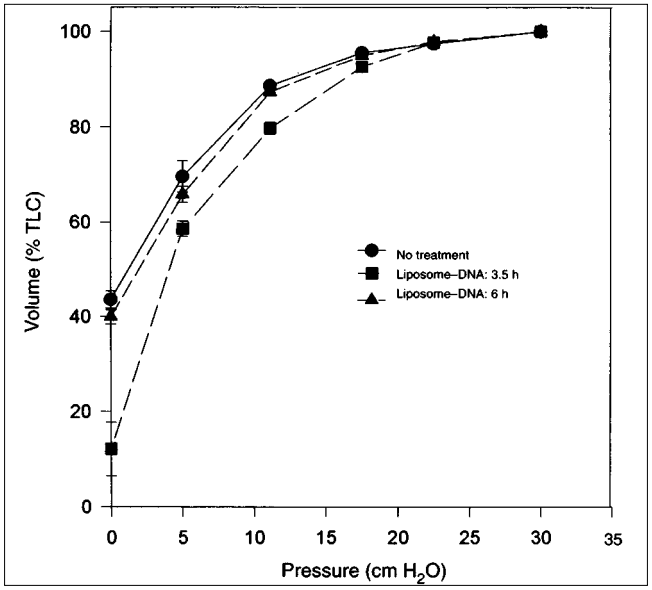

FIG. 7. Pressure–volume deflation curves in control (filled hexagons), liposome/DNA-treated (●), saline-treated (■), and lavaged rats (▲). Lungs were isolated 3.5 h following treatment. The difference between the liposome/DNA- or saline-treated lungs was not significant ($P > 0.1$). Volume is expressed as percentage of total lung capacity (TLC).

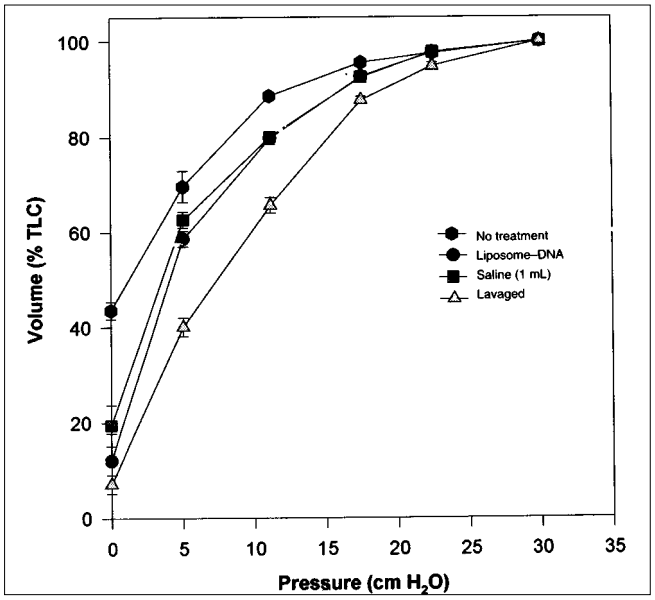

FIG. 8. Pressure–volume deflation curves in control (●), liposome/DNA at 3.5 h (■), and 6 h (▲) following tracheal instillation. The difference between control or liposome/DNA-treatment 6 h following instillation was not significant ($P > 0.1$). Volume is expressed as percentage of total lung capacity (TLC).

versely affect surfactant function in normal lungs where the amounts of monovalent cationic lipid do not exceed 10% (w/w) of estimated pulmonary surfactant lipid.

ACKNOWLEDGMENTS

The authors thank Dr. Jon Goerke for helpful discussions, Dr. Sam Hawgood and Tania Sargeant for their assistance in extraction of surfactant from dog lung lavage, Dr. Thomas Hazinski for supplying pCMVβ and Chiesi Laboratories for donating Curosurf®. Simvastatin Impairs Mitogen-Induced Proliferation of Malignant B-Lymphocytes from Humans—*in vitro* and *in vivo* Studies

S. Vitols[a,*], B. Angelin[b], and G. Juliusson[c,1]

[a]Department of Clinical Pharmacology, Karolinska Institute at Karolinska Hospital, Stockholm, Sweden, [b]Center for Metabolism and Endocrinology, Department of Medicine, Karolinska Institute at Huddinge University Hospital, Huddinge, Sweden, and [c]Department of Medicine, Karolinska Institute at Huddinge University Hospital, Huddinge, Sweden

ABSTRACT: Chronic lymphocytic leukemia (CLL) cells express lower low density lipoprotein (LDL) receptor activity and higher 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase activity than normal mononuclear blood cells indicating that CLL cells may depend on cholesterol synthesis for their proliferation. We studied the effects of competitive inhibitors of HMG–CoA reductase on malignant lymphocyte proliferation *in vitro* and *in vivo*. Tumor B-cells from 13 patients with CLL, hairy cell leukemia, or immunoblastic B-cell lymphoma were cultured for 4 d in the presence of B-cell mitogens and cholesterol synthesis inhibitors. Simvastatin and lovastatin suppressed, in a concentration-dependent manner, the mitogen-induced cellular thymidin uptake in medium with 10% human AB-serum or lipoprotein-deficient serum. Pravastatin was active only in medium with lipoprotein-deficient serum. Ten previously untreated patients with CLL received simvastatin orally, 40 mg daily for 12 wk. Mean reductions in total plasma and LDL cholesterol were 30% (range 9–46%) and 37% (range 16–63%), respectively. Cells from four patients showed moderate to minor increases in the degradation rate of ^{125}I-LDL suggesting that the need for exogenous cholesterol had increased, three patients showed an increase in HMG–CoA reductase activity, and the cells from one patient showed both. There was no significant change in the clinical disease status during medication. However, four of the ten patients developed a therapy-demanding progressive disease during the subsequent year. Further clinical studies with cholesterol synthesis inhibitors in leukemia are warranted.

Lipids 32, 255–262 (1997).

Chronic lymphocytic leukemia (CLL) is the most common leukemia in the Western world. It affects elderly people, median age at diagnosis is about 65 yr, and about 10% of the patients are diagnosed before the age of 50 yr. The CLL cell is a B-lymphocyte with a mature appearance, and it coexpresses B-cell markers and the pan-T-cell marker CD5. Most patients with CLL do not require therapy at diagnosis, but subsequently progressive disease is common. The median therapy-free survival is about 4 yr. First-line therapy with alkylating agents usually ameliorates symptoms, but often drug resistance develops. Infections and cytopenias are the major clinical problems in advanced disease. The median survival of about 80 mon is significantly shorter than age- and sex-matched controls (1).

Proliferating cells have a demand for cholesterol for membrane synthesis. The cellular cholesterol requirements are met by receptor-mediated uptake of low density lipoprotein (LDL) and/or by endogenous synthesis of cholesterol, the rate-limiting enzyme in the synthesis pathway being 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase (2). LDL is the major cholesterol-carrying lipoprotein in human plasma, containing approximately 70% of total plasma cholesterol. Once bound to the specific LDL receptor, LDL is internalized and degraded in lysosomes. The released cholesterol is available for incorporation into cellular membranes or stored in reesterified form (2). Cellular cholesterol requirements may be increased in acute myelogenous leukemia, since leukemic cells from such patients have elevated receptor-mediated uptake of LDL as compared with white blood cells from healthy individuals (3,4).

CLL cells have a reduced ability to form LDL receptors (5), whereas HMG–CoA reductase activity is elevated (6), indicating that CLL cells may depend on cholesterol synthesis for their proliferation. If so, pharmacological suppression of cholesterol synthesis should prevent proliferation of malignant B-lymphocytes. This study was undertaken to test this hypothesis, utilizing both *in vitro* and *in vivo* experiments.

METHODS

Growth inhibitory effects of HMG–CoA reductase inhibitors in vitro: cells. For the *in vitro* studies, cells from 13 patients with B-cell malignancies were used, 11 with CLL, 1 with immunoblastic B-cell lymphoma, and 1 with hairy cell leukemia. Mononuclear cells were isolated from peripheral blood by centrifugation on Lymphoprep (density 1.077 g/mL; Nyegaard A/S, Oslo, Norway) and washed with ice-cold phosphate buffered saline (140 mmol/L NaCl, 2.7 mmol/L KCl, 9.5 mmol/L Na_2HPO_4, and 9.5 mmol/L KH_2PO_4, pH

[1]Present address: Department of Hematology, University Hospital, Linköping, Sweden.

Abbreviations: CLL, chronic lymphocytic leukemia; HMG–CoA, 3-hydroxy-3-methylglutaryl–CoA; LDL, low density lipoprotein; LPDS, lipoprotein-deficient serum.

7.4) as described (5). All cell samples were analyzed for B-cell clonality by surface immunoglobulin staining.

Culture conditions. The cells were cultured at a concentration of 2×10^6/mL in Eagle's medium containing 10% heat-inactivated human AB-serum or 10% human lipoprotein-deficient serum (LPDS) prepared as previously described (4). Triplicate cultures of 0.2 mL were set up in 96-well microplates (Falcon; Becton, Dickinson and Co., Oxnard, CA) and incubated at 37°C in humified air containing 5% CO_2. CLL cells can be induced to proliferate *in vitro* by polyclonal B-cell activators, i.e., ligands with a capability of activating normal B-cells without utilizing the specific B-lymphocyte receptor, the immunoglobulins. We here used tetradedecanoyl-phorbol-13-acetate (2 μmol/L; Sigma Chemical Co., St. Louis, MO) or pokeweed mitogen (5 μg/mL; Sigma Chemical Co.), which was added to the cultures with or without the competitive HMG–CoA reductase inhibitors lovastatin (former name mevinolin), simvastatin, or pravastatin, each at the concentrations 2 μg/mL and 20 μg/mL.

1.0 μ Ci of tritium-labelled thymidine (Radiochemical Centre, Amersham, United Kingdom) was added to the microplate cultures on day 3. Harvesting was performed on day 4 using a Skatron Harvesting Machine (Lierbyen, Norway), and the radioactivity was measured with a scintillation spectrophotometer (Intertechnique, Nanoteknik, Sweden).

Statistical analyses. A paired ratio *t*-test, with the *t*-statistic mean−1/SD/$\sqrt{n}$ was used to test for differences in mitogen-induced thymidine uptake and drug effects in cell cultures with two types of sera. In the first case, a ratio between the net cpm in each type of sera was calculated for each paired sample (Table 1). In the latter, the ratios between mitogen-induced thymidine uptake with and without cholesterol synthesis inhibitors were first calculated in each type of sera wherafter the ratios from paired samples were compared with the paired ratio *t*-test (Table 2). A mean ratio significantly different from 1 denotes a significant difference in thymidine uptake between the two types of culture conditions or different drug efficacy in the two types of sera. A *P*-value ≤0.05 was considered as statistically significant.

In vivo *study: patients.* Ten patients with previously untreated B-cell CLL were given simvastatin (Zocord®; Merck, Sharp and Dohme, Stockholm, Sweden), 40 mg daily by a single oral dose for twelve weeks. Clinical characteristics of the patients are given in Table 3. The patients underwent blood and serum chemistry analysis and clinical examination twice monthly during medication, and at least every third month prior to and after the therapy period. The study was approved by an Institutional Review Board.

Lipoproteins. LDL (density 1.020–1.063 g/mL) and human LPDS (density >1.215 g/mL) were isolated from serum of healthy blood donors by sequential ultracentrifugation (7). The purity of LDL and LPDS preparations was examined by agarose gel electrophoresis, and the absence of cholesterol in LPDS was confirmed by enzymatic cholesterol analysis (Merck, Darmstadt, Germany). ^{125}I-labeled LDL (specific activity 140–260 cpm/ng protein) was prepared as described by Langer *et al.* (8). Less than 1% of the radioactivity in the ^{125}I-LDL preparations was present as free iodide. The concentrations of LDL refer to protein.

LDL receptor and HMG–CoA reductase determinations. Mononuclear cells from peripheral blood were isolated as described above. An aliquot of the washed cells was used for immediate determination of LDL receptor activity. The high affinity (receptor-mediated) degradation rate of ^{125}I-LDL was used as a measure of LDL receptor activity (4). In brief, 3×10^6 leukemic cells were incubated with 25 μg of ^{125}I-LDL at 37°C in 1 mL of RPMI 1640 supplemented with 10% LPDS. Cellular degradation of ^{125}I-LDL was determined from the formation of acid-soluble radioactivity in the incubation medium. The high affinity degradation rate was calculated by subtracting the degradation of ^{125}I-LDL in the presence of a 20-fold excess of unlabeled LDL (unspecific degradation) from the degradation in the absence of unlabeled LDL (total degradation). Cells were also subjected to a 48-h incubation in medium containing 10% LPDS so as to study the induction of LDL receptor activity. Cells were plated at a concentration of 3×10^6 cells/mL in 1 mL, and after 48-h cellular LDL receptor activity was determined as described above without

changing the medium (5). HMG–CoA reductase activity in cell-free extracts was determined from the rate of conversion of 3-hydroxy-3-methyl(3-^{14}C)glutaryl CoA to ^{14}C-mevalonate in detergent-solubilized extracts (9). HMG–CoA reductase activity is expressed as picomoles of ^{14}C-mevalonate formed per min per mg of detergent-solubilized protein. Protein concentration was determined with bovine serum albumin as standard (10).

Plasma lipid analysis. Lipoprotein quantitation was performed by a combination of ultracentrifugation and precipitation (11,12). Briefly, plasma obtained under fasting conditions was spun at 35.000 rpm for 18 h at 4°C in an ultracentrifuge (Centrikon T-2060; Contron Roche, Zurich, Switzerland) equipped with a 45.6 rotor. The tubes were sliced, and the supernatant as well as the infranatant were analyzed for cholesterol and triglyceride content using standard enzymatic techniques (Boehringer-Mannheim, Mannheim, Germany). A portion of the infranatant was treated with phosphotungstic acid in order to precipitate apo B-containing lipoproteins.

RESULTS

Effects of HMG–CoA reductase inhibitors in vitro. The mitogens always induced cell proliferation, as indicated by an increased thymidine uptake in cell cultures. The proliferative results were similar in malignant B-cells from patients with CLL as compared to those from patients with other B-cell malignancies, and the data were therefore pooled. The mitogen-induced thymidine uptake was significantly lower in cells cultured in LPDS compared to those in standard human serum (Table 1), whereas the difference as regards the unstimulated thymidine uptake between cultures in media with the different sera was not significant.

Lovastatin and simvastatin reduced the mitogen-induced thymidine uptake in a concentration-related manner; the thymidine uptake was significantly more reduced at 20 μg/mL than at 2 μg/mL. The thymidine uptake in cultures with LPDS was lower than in cultures with standard serum (Table 1). However, the inhibitory effect of lovastatin and simvastatin on the mitogen-induced thymidine uptake was similar in cultures with serum with and without lipoproteins, as indicated by the ratios in Table 2.

Simvastatin was a more potent inhibitor of mitogen-induced thymidine uptake than lovastatin (20 μg/mL: $P < 0.01$; 2 μg/mL: not significant, Student's *t*-test for paired observations), whereas both simvastatin and lovastatin were more effective than pravastatin (20 μg/mL: both $P < 0.01$; 2 μg/mL: both $P < 0.05$).

Pravastatin did not significantly reduce the mitogen-induced thymidine uptake in standard serum cultures. However, in cultures with LPDS, there was a significant effect of pravastatin at 20 μg/mL (Table 2).

In vivo *study*. Ten previously untreated patients with CLL received simvastatin, 40 mg daily orally for 12 wk. No patient experienced adverse reactions during medication. Some patients had slight changes in the degree of lymphadenopathy during simvastatin medication (Table 3). However, all these changes were compatible with "stable disease." Similarly, the hemoglobin level and platelet counts were stable during the medication in all 10 patients. The lymphocyte counts at baseline, after 12 wk of medication, and at 3 mon poststudy are given in Table 3. In most patients, there was a mild to moderate increase in lymphocyte counts during medication.

Before treatment, total plasma cholesterol ranged from 2.3 to 7.0 mmol/L (mean, 5.4 mmol/L). Mean reductions in total plasma and LDL cholesterol during simvastatin medication were 30% (range 9–46%) and 37% (range 16–63%), respectively (Table 3). Table 4 provides detailed lipid data at baseline and after 12 wk of therapy.

[a]All concentrations are in mmol/L. Chol, cholesterol; TG, triglycerides; w0, week 0 (baseline level); w12, week 12 (after 12 wk of drug treatment). One patient (no. 2) was sampled after 10 wk of therapy. HDL, high density lipoprotein; VLDL, very low density lipoprotein. See Table 3 for other abbreviations.

The mean high affinity degradation rate of ^{125}I-LDL in mononuclear cells, directly after isolation from blood, was 0.12 (range 0–0.57) ng × h^{-1} × 10^6 $cells^{-1}$ (n = 10). During simvastatin therapy, cells from patient no. 1 showed the highest absolute increase in the high affinity degradation rate of ^{125}I-LDL, whereas cells from three other patients (nos. 4, 5, 6) only showed minor increases (Fig. 1). Following 48 h of incubation in medium with 10% LPDS, the inducible LDL receptor activity increased mainly in cells from the same patients (Fig. 2). HMG–CoA reductase activity seemed to increase during simvastatin medication in three patients (nos. 4, 9, 10; Fig. 3) with the maximum levels reached at end of therapy (week 12). Patient no. 2 showed a late and marked increase from week 10 to week 28. He was not assayed at week 12.

During follow-up, four patients developed progressive disease. One patient (no. 1) with massive lymphadenopathy had recently acquired slight general symptoms at inclusion into study. These symptoms remained unchanged during simvastatin medication, and he was put on chlorambucil and prednisone immediately after withdrawal of simvastatin. Chlorambucil and prednisone also failed to improve his status, and he subsequently received intensive combined chemotherapy. Patient no. 6 developed blastic transformation in neck lymph nodes 3 mon after the withdrawal of simvastatin, and was put on chemotherapy. Patient no. 4 developed progressive lymphadenopathy and slowly but steadily increasing general symptoms, and responded well to chlorambucil given 8 mon after the end of the simvastatin therapy. A fourth patient (no. 7) developed progressive splenomegaly with slight anemia and thrombocytopenia, and was splenectomized a year after simvastatin therapy. Patients nos. 2 and 10 had fludarabine for progressive disease between 2 and 3 yr after stopping simvastatin.

DISCUSSION

We here show that the mitogen-induced thymidine uptake of cultured CLL cells is suppressed by the cholesterol synthesis inhibitors lovastatin, simvastatin, and pravastatin. Suppression by pravastatin was evident only when cells were cultured in medium with LPDS.

To detect suppression of cell proliferation, there must be a significant proliferation in the control culture. Since malig-

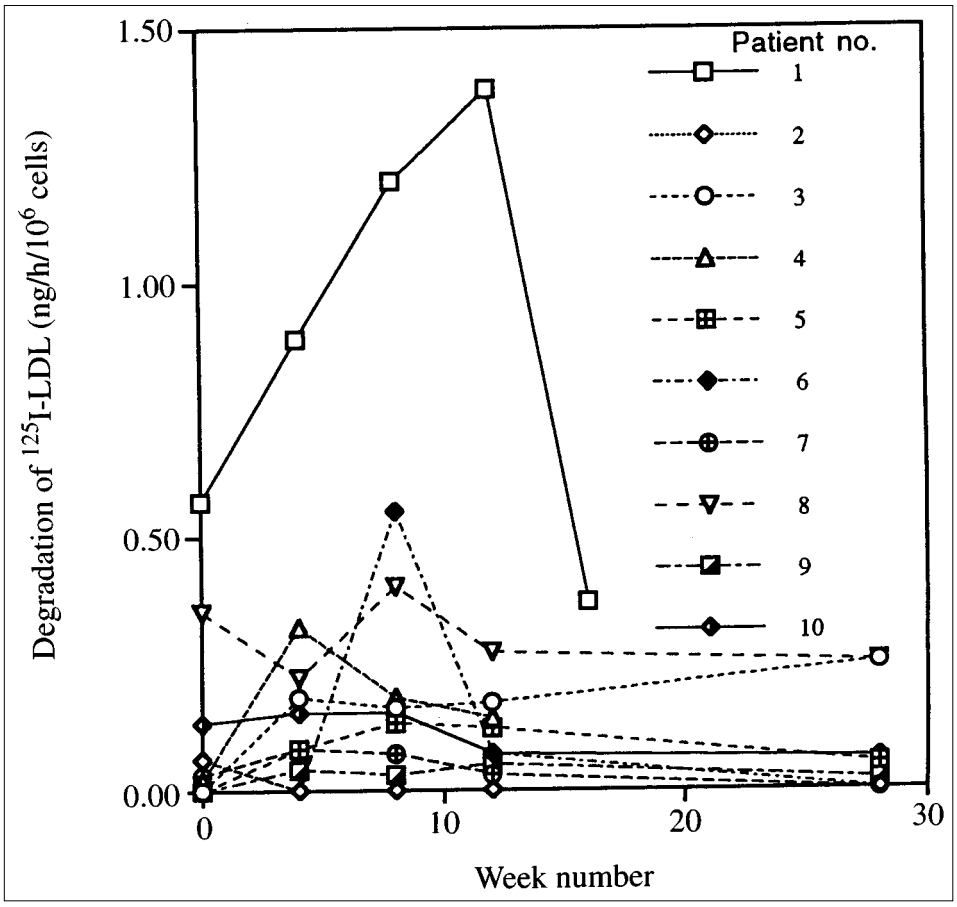

FIG. 1. High affinity degradation rate of ^{125}I-low density lipoprotein (LDL) in mononuclear blood cells from 10 patients with chronic lymphocytic leukemia directly after isolation from blood. Week 0 denotes the degradation value prior to medication. Simvastatin medication was from week 0 to week 12.

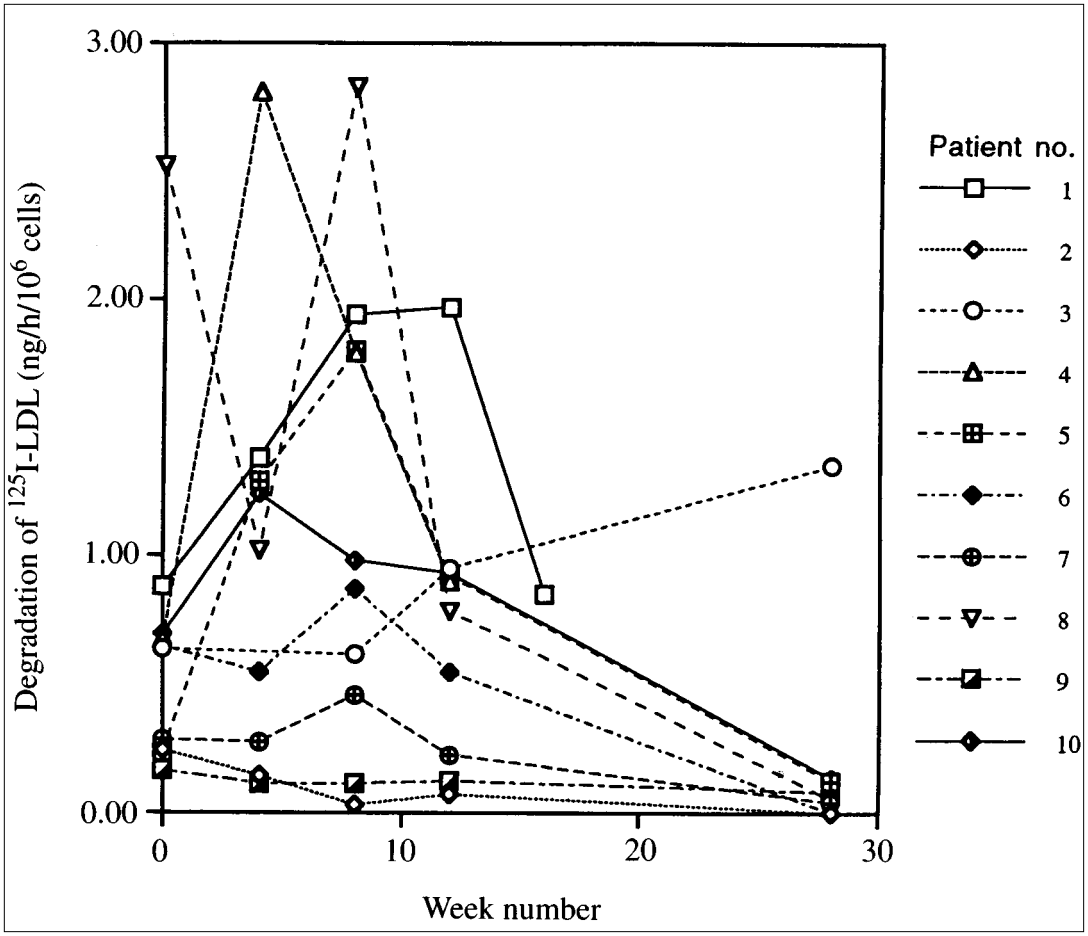

FIG. 2. High affinity degradation rate of ^{125}I-LDL in mononuclear blood cells from 10 patients with chronic lymphocytic leukemia following 48 h of incubation in medium containing 10% lipoprotein-deficient serum. Week 0 denotes the degradation value prior to medication. Simvastatin medication was from week 0 to week 12. See Figure 1 for abbreviation.

nant B-lymphocytes in general are nonproliferating *in vitro,* we have used a test system in which proliferation was induced by B-cell mitogens (13). Thymidine uptake in B-cell mitogen-stimulated CLL cell cultures reflects the proliferative activity of the malignant B-cells more than that of contaminating normal cells. This has previously been demonstrated by cytogenetic studies (14), by mitogen-induced change in CLL cell phenotype (15), and by the induction of clonal Ig-secretion in B-cell mitogen-stimulated CLL cell cultures (13,16). However, similar effects were also seen in spontaneously proliferating cells, such as bone marrow cells from CLL patients (data not shown). Thus, the drug effect is not likely to be directed against the action of the mitogen but rather against the cells' ability to proliferate.

We have previously found that CLL cells have a greatly reduced LDL receptor activity, both when freshly isolated and following incubation in medium with LPDS. The low LDL receptor activity in freshly isolated cells (mean 0.12 ng $\times$ h^{-1} $\times$ 10^6 cells^{-1}) in the current study confirms previous findings (5). For comparison, in mononuclear cells from healthy individuals, the mean high affinity degradation rates of ^{125}I-LDL were 0.35 (range 0.22–0.56, n = 18) (3) and 0.50 (range 0.25–0.83, n = 23) (17) ng $\times$ h^{-1} $\times$ 10^6 cells^{-1}, respectively. Since proliferating cells have a demand for cholesterol for their membrane synthesis, the reduced CLL cell proliferation in the presence of cholesterol synthesis inhibitors is probably due to reduced availability of cholesterol. Normal cells should be able to compensate for this lack of endogenous cholesterol synthesis by increasing their LDL receptor activity and take up more LDL cholesterol from blood, whereas CLL cells should be more severely affected. The finding in this study that simvastatin and lovastatin showed similar efficacy in cultures with standard serum as compared to LPDS is encouraging and supports that cholesterol in plasma does not counteract the antiproliferative effect of the drugs toward CLL cells. That the antiproliferative effects by cholesterol synthesis inhibitors in this study were mediated by inhibition of HMG–CoA reductase is supported by the facts that mevalonate has been shown to counteract inhibition of mitogen stimulated lymphocyte proliferation (18) and tumor cell growth (19) by lovastatin.

Lovastatin and simvastatin have few side effects, as

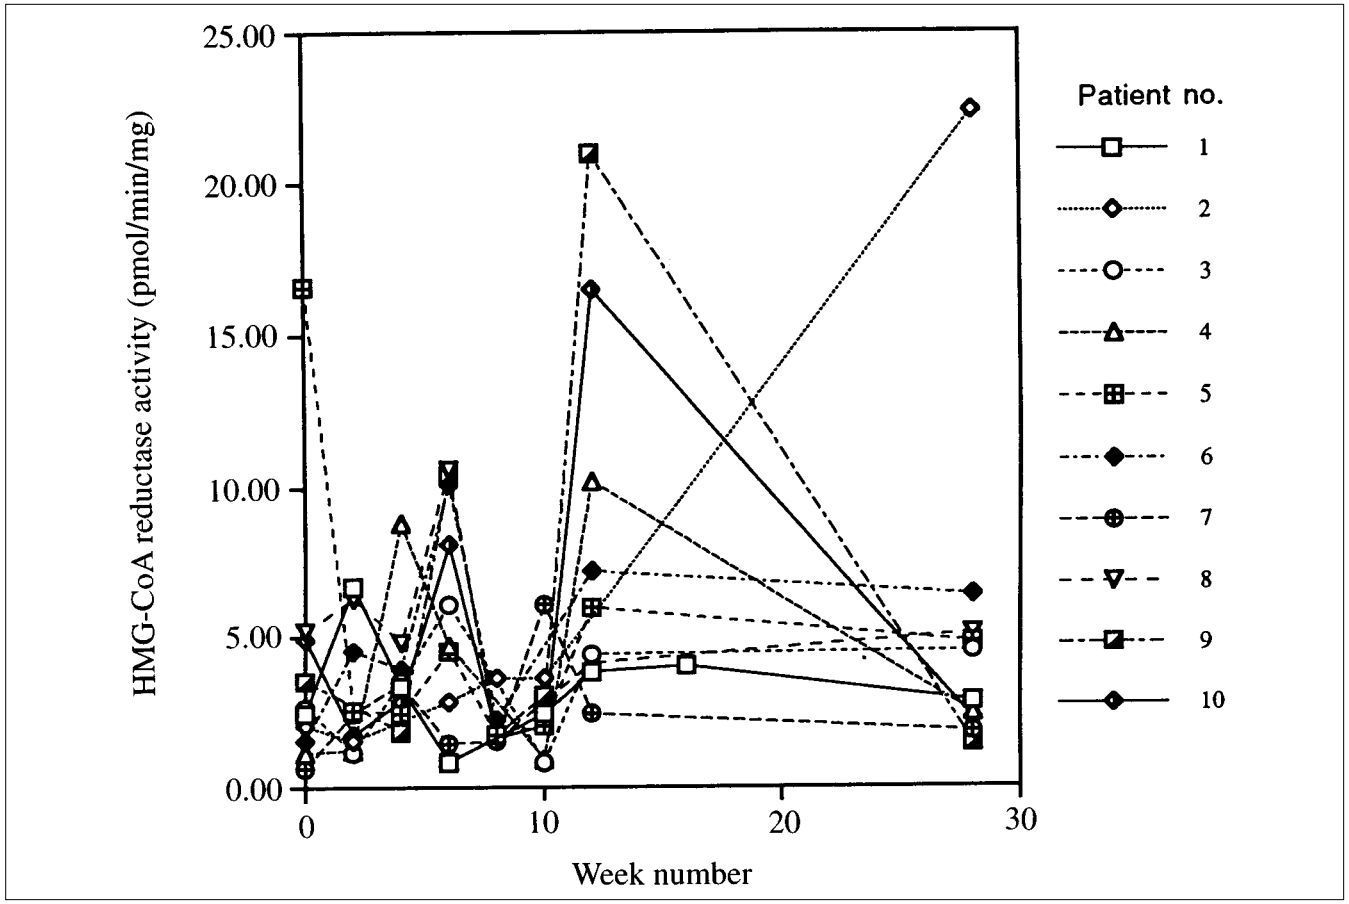

FIG. 3. 3-Hydroxy-3-methylglutaryl–CoA reductase activity in mononuclear blood cells from 10 patients with chronic lymphocytic leukemia directly after isolation from blood. Week 0 denotes the degradation value prior to medication. Simvastatin medication was from week 0 to week 12.

demonstrated in large-scale studies of treatment for hypercholesterolemia. Previous studies have shown that lovastatin suppressed murine neuroblastoma growth *in vivo* (20), and antitumoral effects have also been demonstrated with lovastatin in an animal tumor model of pancreatic adenocarcinoma (19). It has also been recently shown that simvastatin could selectively inhibit the growth of acute myelogenous leukemia cells *in vitro* (21). Interestingly, lovastatin has also been shown to block the activity of the oncogen *ras* (22,23) although *ras*-activation has not been shown to be involved in CLL pathogenesis (24). A phase I study, evaluating maximum tolerated dose of orally given lovastatin to cancer patients, recently has also been conducted (25).

We tested, in an open nonrandomized pilot study, the hypothesis that simvastatin could prevent progression of CLL. Thus, 10 CLL patients with a wide range of initial plasma cholesterol were given 40 mg simvastatin daily for 12 wk. Plasma cholesterol and LDL cholesterol were reduced to about two-thirds of initial values during treatment, which is not different from the expected result in a nonleukemic population (26). No significant change in tumor volume could be detected during the treatment period. None of the ten patients had evidence of progressive disease during simvastatin medication, and none became symptomatic. However, four of the patients developed progressive CLL disease upon cessation of therapy during the subsequent year.

CLL cells from some of the patients showed moderate to minor increases in LDL receptor and/or HMG–CoA reductase activities during medication. The mechanism behind this phenomenon can only be speculated upon. It is possible that this reflects a drug effect on the CLL cells per se, but we cannot rule out the possibility that this is an effect secondary to the reduced serum cholesterol levels. The fact that, during simvastatin medication, cells from some patients also had higher LDL receptor activity following incubation for 48 h in medium with LPDS does not necessarily imply that a higher maximum capacity was reached. It could, for example, be explained by a "kinetic advantage" owing to the fact that higher degradation values are reached more rapidly since cells from these patients also had elevated receptor activity directly after isolation from blood. Cells from some CLL patients may therefore have the capacity to circumvent cholesterol deprivation by upregulating the synthesis of HMG–CoA reductase and/or increase the expression of LDL receptors. It is noteworthy that patient no.1, who had an aggressive disease, had the most pronounced increase in LDL receptor activity during medication. This patient also had the lowest serum cholesterol level at baseline, highest LDL receptor activity at

baseline, and showed an increase in the white blood cell count during medication. A prospective analysis of such a compensatory capacity before patients are entered in any future trial with the goal to correlate with eventual treatment effects should be of interest.

It is known that the inhibitory effect of oral simvastatin on HMG–CoA reductase activity is very low in blood and peripheral tissues, due to extensive first-pass metabolism, high extraction by the liver, and high protein binding in plasma of drug and active metabolites (27). We are aware that an optimal dose was not chosen in the current pilot study. It is also possible that antitumoral effects develop more slowly and that the study has to be considerably prolonged. Thus, the hypothesis that simvastatin may prevent CLL cell proliferation *in vivo* cannot be rejected at this stage. A larger controlled study, preferably using higher doses of an intravenously administered HMG–CoA reductase inhibitor, should be of interest in CLL.

ABSTRACT: Microbial extracellular glycolipids, succinoyl trehalose lipid (STL), and mannosylerythritol lipid (MEL) inhibited the growth of a human promyelocytic leukemia cell line, HL60, and induced their morphological changes. The results of specific and nonspecific leukocyte esterase activities showed that STL induced monocytotic differentiation while MEL induced granulocytic differentiation. STL and MEL markedly increased common differentiation-associated characteristics in monocytes and granulocytes, such as nitroblue tetrazolium (NBT) reducing ability, expression of Fc receptors, and phagocytic activities in HL60 cells, respectively. Neither sugar moieties nor fatty acids in the free form, the individual components of STL and MEL, were effective at inducing the differentiation of HL60 cells. The induction of differentiation was not due to surface activities of STL and MEL on the basis of the complete ineffectiveness of the analogues tested. The composition of cell surface glycosphingolipids (GSL) changed such that the G_{M3}/LacCer ratio increased in STL-treated cells, whereas it decreased in MEL-treated cells. HL60 cells treated with STL and MEL exhibited a significant decrease in the activity of the intracellular phospholipid- and Ca^{2+}-dependent protein kinase (protein kinase C). Furthermore, the serine/threonine phosphorylations in intact HL60 cells were clearly inhibited by the presence of G_{M3} and MEL, but not by LacCer and STL. These results suggest that the differentiation-inducing activity of STL and MEL is not due to a simple detergent-like effect but due to a specific action on the plasma membrane. The inhibitory effect of STL on protein kinase activity was through increasing G_{M3}, but MEL had a direct inhibitory effect.

Lipids 32, 263–271 (1997).

Several species of microorganisms are known to produce compounds which have surface-active characteristics generally termed "biosurfactants." Biosurfactants are typical amphiphilic molecules, containing both a lipophilic and hydrophilic moiety. Succinoyl trehalose lipid (STL) (R^{1-4} = 2× succinoyl + 2× alkanoyl) (Scheme 1) and mannosylerythritol lipid (MEL) (R^{1-4} = 2× acetyl + 2× fatty acid) (Scheme 2) are glycolipid-type biosurfactants produced by *Rhodococcus erythropolis* SD-74 grown on *n*-hexadecane (1) and *Candida antarctica* T-34 on soybean oil (2), respectively. Under optimized culture conditions, they were produced in concentrations of about 40 g per liter of culture broth (3,4).

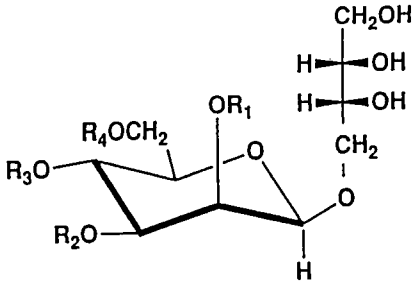

SCHEME 2

Recently, it is reported that gangliosides and glycosphingolipids (GSL), which are ubiquitous membrane components, modulate cell growth, adhesion, and transmembrane signaling, because of dramatic changes in GSL composition and metabolism observed during oncogenesis, differentiation, and oncogenic transformation (5). In the case of mammalian glycolipids, the lipid portion of the molecule is attached *via* an *O*-glycosidic linkage to the reducing end of the oligosaccharide moiety. On the other hand, in the case of STL or MEL, the lipid part of the molecule is attached *via* an ester linkage to the ring hydroxyl groups. Although many obvious differ-

Abbreviations: GSL, glycosphingolipids; MEL, mannosylerythritol lipid; NAE, α-naphthyl acetate esterase; NBT, nitroblue tetrazolium; NCAE, naphthol AS-D-chloroacetate esterase; PBS, phosphate buffered saline; PKC, protein kinase C; STL, succinoyl trehalose lipid.

ences exist between mammalian glycolipid and STL or MEL, such structures as glycolipids are similar. Therefore we assessed whether STL and MEL have an ability to induce cell differentiation using human cell line, HL60. It is a human promyelocytic leukemia cell line (6) that has been induced to differentiate into mature granulocytes (7,8) and macrophage-like cells (6,9) and consists of stem-like cells that are bipotent with respect to myeloid or macrophage differentiation (10).

In this study, we found of the microbial extracellular glycolipids, STL induced monocytoic differentiation while MEL induced granulocytic differentiation of HL60 cells, and the two glycolipids increased common differentiation characteristics in monocytes and granulocytes. In order to assess the mechanisms of HL60 cell differentiation-induction by STL and MEL, we examined the effects of their components and surface activities on the induction of cell differentiation. Furthermore, we analyzed the changes of GSL on cell surface membrane, the PKC activities, and the serine/threonine phosphorylation patterns during cell differentiation by STL or MEL treatment. In this paper, we show the leukemia cell differentiation–induction by microbial extracellular glycolipids and discuss its mechanisms.

MATERIALS AND METHODS

Materials. Succinic acid, trehalose, SDS, and sorbitan monolaurate (Span 20) were purchased from Wako Pure Chemicals (Osaka, Japan). GSL GM3 and LacCer, and hexadecanoate and tetradecanoate were purchased from Funakoshi (Tokyo, Japan). Sucrose monocaprate (SE 10) was purchased from Dojin Laboratories (Kumamoto, Japan).

Preparation of STL and MEL. STL was prepared by the method of Uchida *et al.*(1). Seed cultures were prepared by inoculating loopfuls of cells of strain SD-74 grown on the slants into 300-mL Erlenmeyer flasks containing a seed culture medium (30 mL), followed by incubation at 30°C for 2 d on a rotary shaker. The seed cultures (4 mL) were transferred to 500-mL Erlenmeyer flasks containing 50 mL of media containing 10% (vol/vol) *n*-hexadecane, and were shaken at 30°C for 7 d on a rotary shaker ($200 \times g$). The culture broths were centrifuged at $10{,}000 \times g$ for 30 min. The aqueous layer was carefully siphoned, collected, and acidified with 6 N HCl to pH 3.0. The acidic exolipids were precipitated as voluminous gel mass. The gel mass was washed twice with water and mixed with hot methanol (300 mL). The mixture was washed three times with *n*-hexane to remove minor lipids and remaining *n*-hexadecane, then concentrated. The residue was dried over P_2O_5 under reduced pressure and used as the mixture of the main exolipids. The mixture of main exolipids was dissolved in ethyl acetate (200 mL) and kept in cold room. STL was mainly obtained as precipitates. After repeated recrystallization with ethyl acetate, STL was obtained as a colorless powder. The long fatty acid composition of STL was hexadecanoate (87%) and tetradecanoate (13%). Found: C, 61.21; H, 8.97%. Calcd. for $C_{52}H_{90}O_{19}$ (hexadecanoate): C, 61.27; H, 8.90%.

MEL was prepared by the method of Kitamoto *et al.* (2). Seed cultures were prepared by inoculating cells grown on slants into 300-mL Erlenmeyer flasks containing 30 mL of a seed culture medium, followed by incubation at 30°C for 2 d on a rotary shaker ($200 \times g$). The seed cultures (2 mL) were transferred to twenty 500-mL Erlenmeyer flasks containing 50 mL of a basal fermentation medium, followed by incubation at 30°C for 7 d on a rotary shaker. The culture broths were combined acidified with 6 N HCl to pH 3.0, and centrifuged at $2{,}850 \times g$ for 30 min. The precipitate was washed twice with water by centrifugation, and the heavy oil was extracted twice with methanol (300 mL). The combined extracts were concentrated (100 mL) then washed twice with two volumes of *n*-hexane to remove the remaining oil and free fatty acids. Chloroform (200 mL) and water (100 mL) were added to the washed concentrate, and the mixture was shaken. The lower chloroform layer was evaporated to dryness after dehydration with Na_2SO_4. Removal of the solvent left a syrup, which was used as the mixture of biosurfactants in the following experiments. The mixture of biosurfactants was dissolved in chloroform and placed on a column (3×40 cm) of silica gel (Wakogel C-200; Wako). The column was first washed with 400 mL of chloroform/eyhyl acetate (4:1). The component (MEL) was eluted with 800 mL of chloroform/acetone (7:3). The long fatty acid composition of MEL consists octanoate (17.5%), decanoate (10.1%), and tetradecanoate (1.1%). Found: C, 59.95; H, 8.60%. Calcd. for $C_{34}H_{60}O_{13}$ (2 acetyl, 2 decanoyl): C, 60.33; H, 8.94%.

MEL and the long-chain fatty acid of MEL were obtained by deacylation. After acidification of the reaction mixture, the long-fatty acids were extracted with *n*-hexane and evaporated. The aqueous layer containing MEL was desalted and concentrated.

Cells and cell culture. HL60 cell line was obtained from Riken Cell Bank (Tsukuba, Ibaraki, Japan). The cells were cultured in a serum-free ERDF (Kyokuto Pharmaceutical Kogyo Co., Tokyo, Japan)–ITES medium at 37°C in humidified 5% CO_2/95% air. ITES is 5 μg/mL insulin, 10 μg/mL iron-free human transferrin, 25 μM ethanolamine, and 25 nM selenite (RD-1; Kyokuto Pharmaceutical Kogyo Co.). Growth of HL60 cells is known to be insulin-dependent (11).

The cells were counted using a hemacytometer, and the viability was estimated by the Trypan blue dye exclusion method. Test samples, such as STL, MEL, their components, and other surfactants dissolved in phosphate buffered saline (PBS) were sonicated and sterilized by passage through a MILLEX-GV 0.22 μm filter unit (Millipore Products Division, Bedford, MA). They were added to the culture medium at the desired sample concentration. The final PBS concentration was kept at 0.1%. For control, the cultured cells were added with only PBS (without sample treatment).

Determination of cell differentiation. HL60 cells were cultured with STL or MEL for 5 d. Cells that adhered to the culture vessels were removed with a Nunc 179693 plastic cell scraper (Nunc Inter Med., Roskilde, Denmark) and both adhered and nonadhered cells were investigated.

For cytochemical assessment of cell differentiation, specific and nonspecific leukocyte esterase activities (12) were determined cytochemically by the esterase double-staining method for α-naphthyl acetate esterase (NAE) and naphthol AS-D-chloroacetate esterase (NCAE) using reagents for determination of esterase (Sigma Chemical Co., St. Louis, MO). Specific and nonspecific esterase activities were examined on days 2 and 5.

To assess the differentiation of HL60, common differentiation-associated characteristics in monocytes and granulocytes, such as nitroblue tetrazolium (NBT) reducing ability, expression of Fc receptors, and phagocytic activities were investigated.

The NBT-reducing ability was determined by the modified method of Takeda *et al*. (13). Briefly, after treatment with STL or MEL for 2 d, viable cells (2×10^5) were washed once with ERDF medium and were suspended in 2 mL of ERDF medium containing 5% fetal bovine serum, 0.1% NBT dye in a 12-well plate for 2 h at 37°C in a 5% CO_2 incubator. The percentage of cells containing blue–black formazan deposits was determined by counting at least 200 cells under microscope for each experimental point.

The expression of Fc receptors on the cell surface of HL60 was assayed by EA rosette formation. HL60 cells (2×10^5) were washed with ERDF medium after being treated with STL or MEL for 3 d, and suspended in 2 mL of 0.9% NaCl, then incubated with suspension of bovine erythrocytes (5×10^6/mL) sensitized with rabbit IgG antibodies (Funakoshi) at 22°C for 60 min. Cells with more than three attached erythrocytes were counted as positive. At least 200 cells were examined for each experimental point (14). The phagocytic activity of HL60 cells was measured by counting the percentage of the cells that phagocytosed yeast particles.

The yeast–phagocytic activity was investigated with opsonized yeast. Heat-killed yeast particles (*Saccharomyces cerevisiae:* Wako Pure Chemical Industries Ltd.) were incubated with three times volumes of mouse serum (Funakoshi) for 30 min at 37°C and washed with Hanks balanced salt solution. After treatment with STL or MEL for 3 d, the cell (2.0×10^5) pellet was mixed with 5.0×10^6 of opsonized yeast particles suspended in 2 mL of Hank's balanced salt solution and incubated for 60 min at 37°C. Cells were washed again and 2 mL of 0.01% fuchsin solution was added to the cell pellet. The cells containing yeast particles were scored as phagocytosis positive, and at least 200 cells were counted for each experimental point (13).

Extraction and determination of GSL composition. GSL from the cell were extracted and determined by the modified method of Tsuruoka *et al.* (15). Harvested 10^7 cells were washed with 1 mL of Ca^{2+}- and Mg^{2+}-free PBS. After centrifugation, the packed cells were combined with 0.5 mL of isopropyl alcohol/hexane/water (55:25:20, by vol) and homogenized by sonication. The pellet was extracted twice with the same solvent and finally extracted three times with 0.5 mL of chloroform/methanol (2:1). All the extracts were evaporated to dryness under N_2 stream. The residue was dissolved in 0.5 mL of 0.1M KCl, passed through a Seppak Plus C_{18} Cartridge (Millipore Corporation), and washed with 2 mL of 0.1 M KCl followed by 5 mL of distilled water and eluted with 2 mL of CM (2:1). The final elute was evaporated to dryness, and the residue was dissolved in 200 µL of CMW (2:1:0.05). The sample was analyzed on a high-performance thin-layer chromatography (HPTLC) plate (HPTLC-Fertigplatten, Kieselgel 60; Merck AG, Darmstadt, Germany) and developed with CMW (50:40:10). The GSL were detected by 0.2% orcinol in 2 M sulfuric acid. The relative amounts of the components on the chromatograms were estimated with a densitometer (TLC Scanner CS-920; Shimadzu, Tokyo, Japan).

Kinase assay of PKC. After treatment with STL or MEL for 24 h, 10^7 cells were washed twice with cold Ca^{2+}- and Mg^{2+}-free PBS. After centrifugation at $3350 \times g$ for 2 min, the packed cells were homogenized with 200 µL of homogenized solution (20 mM Tris-HCL, pH7.5, 2 mM EDTA, 0.25M sucrose, 50 mM 2-mercaptoethanol, 0.1 mg/mL leupeptin, 2 mM PMSF) by sonication with 3 strokes at 4°C. The sonicate was centrifuged at $8500 \times g$ for 25 min at 4°C and obtained about 200 µL of cytosol (16). The cytosol was assayed for nonradioactive detection of protein kinase C (PKC) by PepTag™ Assay (Promega Corporation, WI).

Western analysis of the cells treated with glycolipids. HL60 (2×10^6 cells) were incubated with 50 µM of GM3, 50 µM of LacCer, 5 µM of STL and 10 µM of MEL. The reactions were stopped by adding 100 µl of cell suspension to the same volume of 2× Laemmli's sample buffer (1× is 62.5 mM Tris-HCl, pH 6.8, 4% SDS, 5% β-mercaptoethanol, 8.5% glycerol, 2.5 mM orthovanadate, 10 mM paranitrophenylphosphate, 12 µg/mL leupeptin, 12 µg/mL aprotinin, 1.25 mM PMSF, 0.025% bromophenol blue) preheated at 95°C. The samples were boiled for 5 min to completely denature the proteins and were then loaded onto 12.5% SDS-PAGE (17).

Electrophoretic transfer cells were used to transfer proteins from the gels to Immobilon PDVF membranes (Millipore Corporation). Nonspecific sites were blocked using 1X Block Ace (Dainihon Pharmaceutical Industry, Osaka, Japan) for 2 h at room temperature. The anti-phosphoserine (mono, X80; Daiichi-Kagaku, Tokyo, Japan) and phosphothreonine (mono, X160) antibodies were then incubated with the membranes for 2 h at room temperature in fresh blocking solution. The membranes were washed three times at room temperature in TBS-Tween and then incubated with horseradish peroxidase-labeled sheep anti-mouse IgG (Cosmo Bio, Tokyo, Japan) for 1 h at room temperature at a final dilution of 1:1500 in 10X Block Ace. The membranes were washed three times with TBS-Tween and the phosphopeptide bands were revealed using Konica Immunostein HRP-1000 (Konica, Tokyo, Japan).

RESULTS

Effect of STL and MEL on HL60 cell growth and cell differentiation. The effects of STL and MEL on the growth of HL60 were examined. During the 5 d of culture, STL at a con-

centration of 5.0 μM almost inhibited the growth of HL60. On day 5, the cell numbers which were treated with 2.5 μM of STL were less than 50% as compared to control. It was toxic to the HL60 cells at higher concentrations (>15 μM) (Fig. 1A). MEL at a concentration of 10.0 μM completely inhibited the growth of HL60 during the 5 d of culture, and was toxic at higher concentrations (>25 μM). MEL (5.0 μM) also inhibited the growth of HL60 cells (Fig. 1B). On the second day of cultivation, morphological changes of HL60 were observed in both STL- and MEL-treated cultures. HL60 cells treated with STL aggregated and were characterized by an increase in cell size, and the nuclear/cytoplasmic ratio was decreased (Fig. 2B). HL60 cells treated with MEL exhibited drastic morphological changes, and adhered to the bottom of the flask (Fig. 2C).

When HL60 cells were cultured with STL, the number of NAE-positive cells remarkably increased in a time-dependent manner. STL (5.0 μM) induced more than 65% NAE-positive

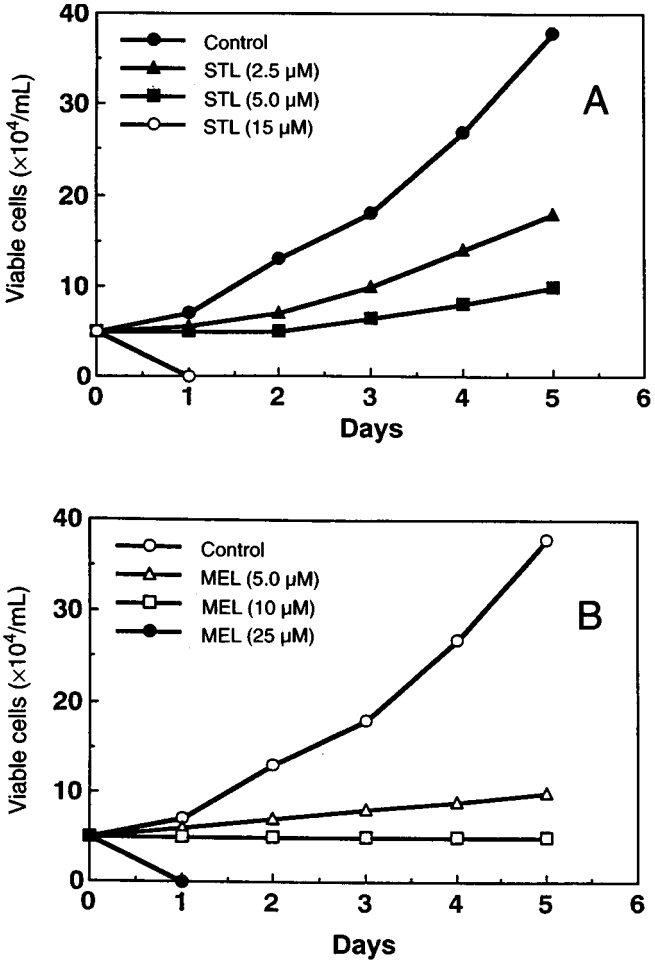

FIG. 1. Effect of succinoyl trehalose lipid (STL) (A) or mannosylerythritol lipid (MEL) (B) on growth of HL60 HL60 cells were seeded at an initial concentration of 5.0×10^4 cells per mL and grown in the ERDF–ITES medium with or without STL or MEL. Cells were counted with a hemacytometer, and viability was estimated by Trypan blue dye exclusion. Each data point represents the mean of three measurements. Standard deviation was <10%.

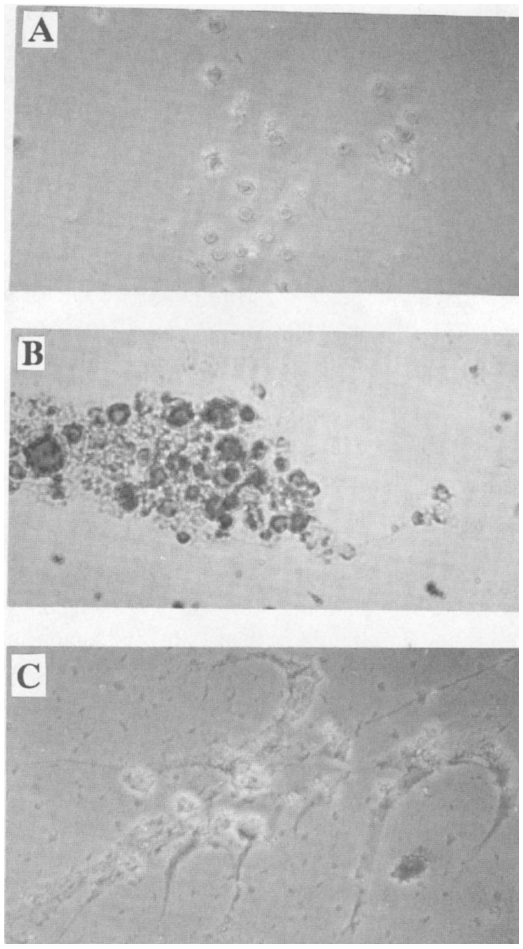

FIG. 2. Specific and nonspecific esterase staining of HL60 cells cultured in the ERDF–ITES medium with 5 μM of STL or 10 μM of MEL for 2 d. Specific and nonspecific leukocyte esterase activity was determined cytochemically by the esterase double-staining method as described in the Materials and Methods section Untreated HL60 cells (A), 5 μM of STL-treated HL60 cells (B) and 10 μM of MEL-treated HL60 cells (C). See Figure 1 for abbreviations.

cells on day 2, and on day 5, almost 80% cells were stained-NAE-positive. The cells treated with 2.5 μM of STL were also observed to be 55% NAE-positive (Fig. 3A). This esterase activity indicated the specificity for the monocytic lineage. On the other hand, when treated with MEL, NCAE-positive cells increased in a time-dependent manner. MEL (10.0 μM) induced almost 80% NCAE-positive cells on day 2, and it reached 90% on day 5 (Fig. 3-B). This esterase activity indicated the specificity for the granulocytic lineage.

From these results, HL60 cells treated with STL or MEL were assumed to be a manifestation of the differentiation of these cells to monocytes or granulocytes. To confirm this assumption, the following differentiation-associated characteristics of HL60 cells were investigated: NBT-reducing ability, Fc receptor expression and phagocytic activity.

NBT-reducing ability is often used as a marker for neutrophile, monocyte, macrophage, and lymphocyte which are known to exhibit toxicity on the numerous pathogenic bacteria

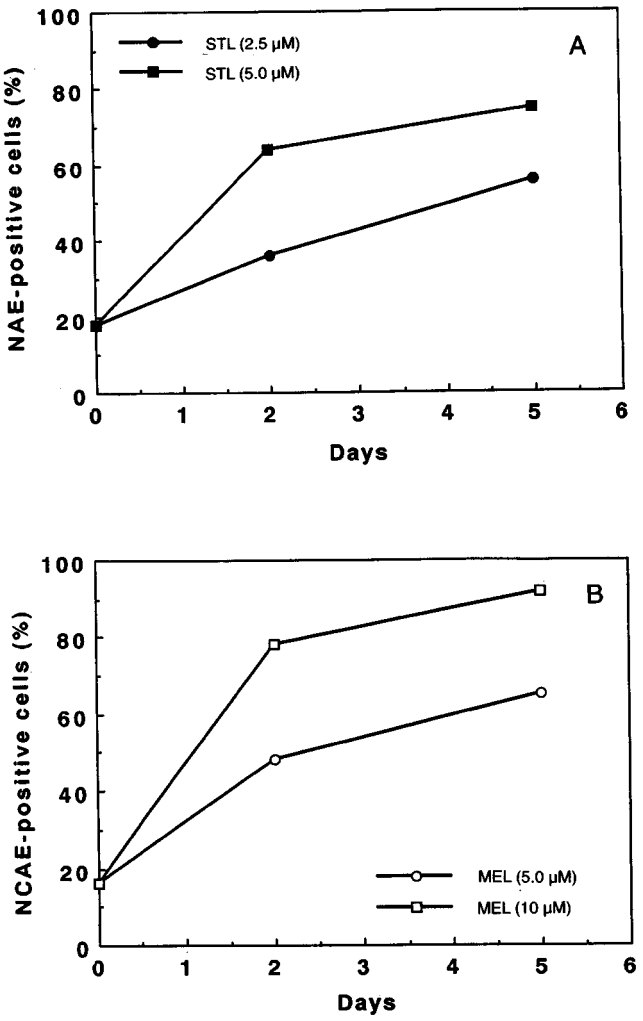

FIG. 3. α-Naphthyl acetate esterase (NAE) activity of STL-treated HL60 cells (A) and Naphthol AS-D-chloroacetate esterase (NCAE) activity of MEL-treated cells (B). HL60 cells were cultured in the ERDF–ITES medium with 2.5, 5.0 μM of STL or 5.0, 10.0 μM of MEL for 5 d. NAE and NCAE activities were determined by the method as described in the Materials and Methods section. The number of NAE- or NCAE-positive cells were determined on day 2 and day 5 of culture. Values are mean of three determinations. Standard deviation was <10%; NBT, nitroblue tetrazolium. See Figure 1 for other abbreviations.

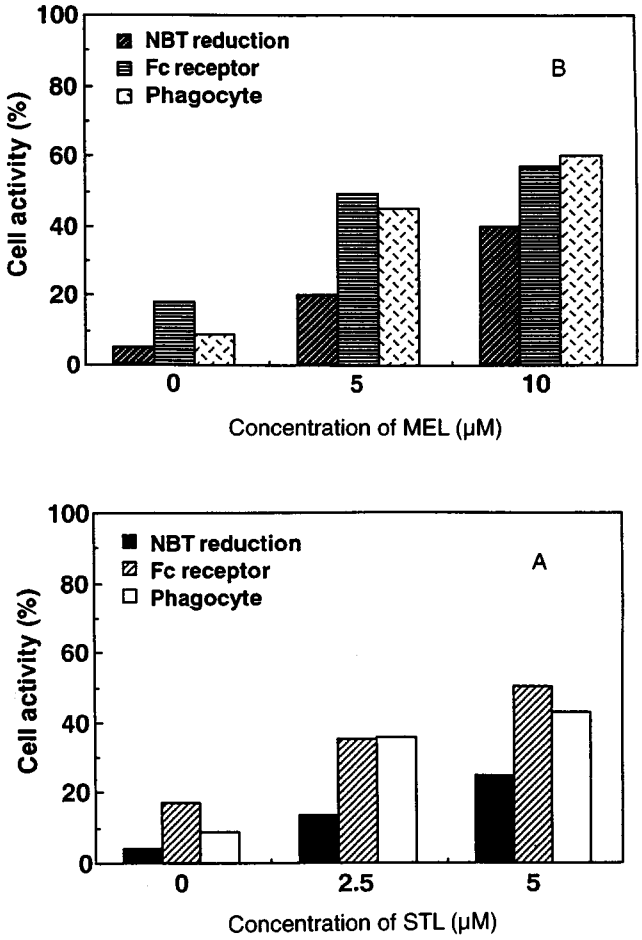

FIG. 4. Differentiation-associated characteristic properties of STL (A) or MEL (B) treated cells. NBT-reducing activity was determined by colorimetric assay. Assay of the appearance of Fc receptors was performed by standard techniques for erythrocyte–antibody rosette formation. Phagocytic activity is expressed as the percentage of cells ingesting yeast particles. They were described in the Materials and Methods section. Values are mean of three determinations. Standard deviation was <10%. See Figures 1 and 2 for abbreviations.

or cancer cells. This toxic response is demonstrated by their ability to reduce the water-soluble nitroblue tetrazolium dye to insoluble intracellular blue–black formazan due to O_2^- and H_2O_2 released upon activation. On the other hand, the process of phagocytosis by leukocyte involves two steps. The first step is bacterial recognition by leukocyte through bacterial surface immunoglobulin molecule (Fc). This step requires Fc receptor expression on the cell surface. The second step is the uptake of the bacteria into the leukocyte.

As shown in Figure 4A and B, both STL and MEL, respectively, induced the occurrence of NBT reducing ability, expression of Fc receptors, and phagocytic activities in HL60 cells significantly. The differentiation-associated characteristics of MEL-treated cells were above those of STL-treated cells. Especially, treatment of HL60 cells with 10 μM of MEL resulted in a remarkable increase in their Fc receptor expression and phagocytic activity reaching over 60%.

Effect of STL and MEL components and their surface activity. To assess the effect of components of glycolipids, the various components of the STL molecule, namely, succinic acid, trehalose and fatty acids as well as those of MEL such as mannosylerythritol and fatty acid, were added to HL60 cell cultivation separately, and the leukocyte esterase activity was examined. The growth of the cells treated with various components was not inhibited, and no morphological changes were detected. Each component of STL molecule, succinic acid, trehalose, the mixture of hexadecanoate and tetradecanoate as well as that of MEL such as mannosylerythritol and long-chain fatty acid had no effectiveness on the differentiation of HL60 cells in both cases of separate and simultaneous addition (Fig. 5). It was apparent that the ester molecule itself was responsible for the activity, since neither sugar

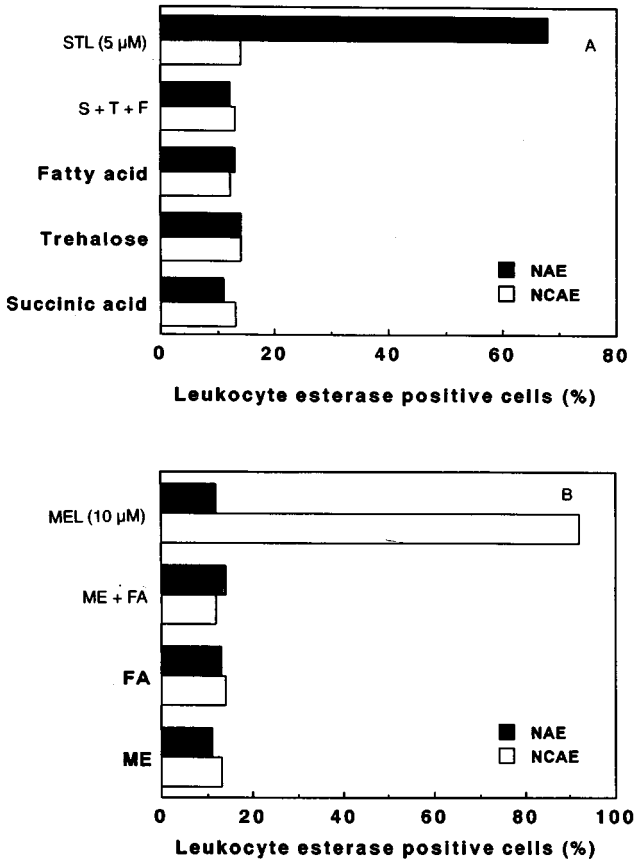

FIG. 5. Effect of components of STL molecule, succinic acid, trehalose, and fatty acids (A) and MEL molecule, mannosylerythritol (ME) and fatty acids (FA) (B) on differentiation–induction of HL60 cells. They were added to HL60 cell cultivation separately and leukocyte esterase activity examined. S + T + F means succinic acid, trehalose and fatty acid were together added to the culture medium. Values are mean of three determinations. Standard deviation was <10%. See Figure 1 for abbreviations.

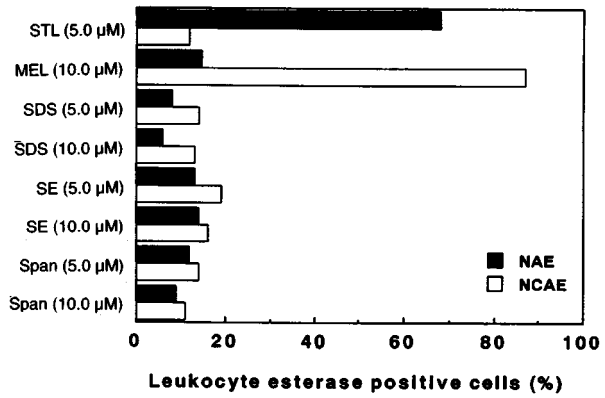

FIG. 6. Effect of analogues of STL and MEL on differentiation–induction of HL60 cells. 5.0 or 10.0 μM of STL or MEL and their analogues, SDS, sucrose monocaprate (SE 10) and sorbitan monolaurate (Span 20) were added to HL60 cell cultivation separately, and leukocyte esterase activities were examined. Values are mean of three determinations. Standard deviation was <10%. See Figures 1 and 5 for abbreviations.

moieties nor fatty acids of STL and MEL in the free form proved to be effective in inducing differentiation of cells.

On the other hand, it is reported that STL and MEL can act as anionic surfactant and nonionic surfactant with detergent properties, respectively (18,19). To confirm whether or not the ability of inducing differentiation of HL60 cells could be attributed to surface activities of these biosurfactants, we used analogues of STL and MEL. These were SDS (which is a typical anionic surfactant), sucrose monocaprate SE 10, and sorbitan monolaurate Span 20 (the last two being nonionic glycolipid-type synthetic surfactants). The results showed that surface activity had no effect on the induction of differentiation on the basis of the complete ineffectiveness of the samples tested (Fig. 6). From these results, we supposed that the differentiation-inducing activity of STL and MEL is not due to a simple detergent-like effect but due to a specific action on the plasma membrane.

GSL composition of STL- or MEL-treated HL60 cells. To confirm whether STL and MEL have specific action on the plasma membrane, the changes of GSL on cell surface membrane during cell differentiation were analyzed. The GSL pattern of non-treated and STL- or MEL-treated cells are shown in Figure 7. The major GSL of HL60 cells were identified as LacCer, Gb3Cer, GM3, and GM1 ganglioside by its TLC mobility, and the quantities of GSL in both nontreated and glycolipid-treated cells were shown in Table 1. GM3 ganglioside was increased in STL treated cells whereas LacCer was increased in MEL-treated cells compared to nontreated HL60 cells. The relative GM3/LacCer ratio of nontreated, STL-treated, and MEL-treated cells was 1.17, 2.45, and 0.30 on day 3, respectively.

Inhibition of kinase activity of PKC. The PepTag™ Assay utilizes brightly colored, fluorescent peptide substrates that are highly specific for PKC. Phosphorylation by PKC of their specific substrate alters the peptide's net charge from +1 to –1. This change in the net charge of the substrate allows the

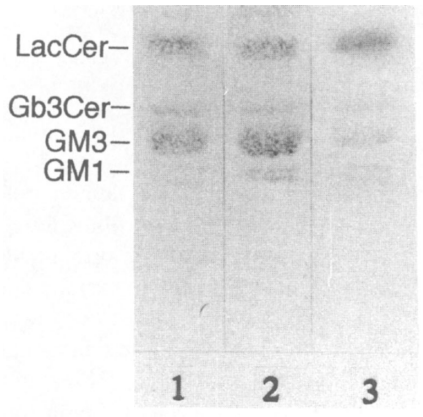

FIG. 7. High-performance thin-layer chromatography (HPTLC) pattern of neutral glycosphingolipids and ganglioside fraction of HL60 cells treated with or without STL and MEL. Samples were prepared as described in the Materials and Methods section. Each fraction was dissolved in 200 μL of CM (2:1), and 5 μL aliquots were spotted on HPTLC plates and developed with CMW (50:40:10). Lane 1, nontreated HL60 cells; Lane 2, STL-treated HL60 cells; Lane 3, MEL-treated HL60 cells. See Figure 1 for other abbreviations.

TABLE 1
Quantities of GSL in HL60 Treated with STL and MEL

	Chemical quantity[a] of			
	LacCer	Gb3Cer	GM3	GM1
Control	18.1	7.3	21.3	6.3
STL	24.1	7.4	59.1	7.3
MEL	37.8	5.3	11.5	3.3

[a]μg Equivalent to standard LacCer per 1 mL of packed cells. GSL, glycosphingolipid; STL, succinoyl trehalose lipid; MEL, mannosylerythritol lipid.

phosphorylated and unphosphorylated versions of the substrate to be rapidly separated on an agarose gel at neutral pH. The phosphorylated species migrates toward the positive electrode while the unphosphorylated substrate migrates toward the negative electrode.

On the control cells, phosphorylated peptide migrated toward the anode (+), while nonphosphorylated peptide migrated toward the cathode (–). On the other hand, on both cells which were treated with 5.0 μM of STL and 10.0 μM of MEL, phosphorylated peptide migrations were not detected (Fig. 8). These results showed that both STL and MEL at the concentration which induced differentiation of HL60 cells inhibited PKC activity in intact cells.

Comparison of the protein phosphorylation pattern. HL60 cells were treated with various glycolipids, and the resulting protein phosphorylation monitored. The results of threonine phosphorylation pattern after treatment of 3 h are shown in Figure 9. An examination of these data indicates that the threonine phosphorylation of a 30 kDa protein was observed in nontreated cells, and 50 μM of LacCer clearly enhanced the level of threonine phosphorylation. On the other hand, the phosphorylation of a 30 kDa protein was clearly inhibited by the presence of 50 μM of GM3 and 10 μM of MEL, but was only marginally inhibited by 5 μM of STL. After treatment with STL for 24 h, the phosphorylation of a 30 kDa protein was not observed (data not shown). With the use of the serine phosphorylation antibody, similar patterns were observed after treatment of both 3 h and 24 h (data not shown).

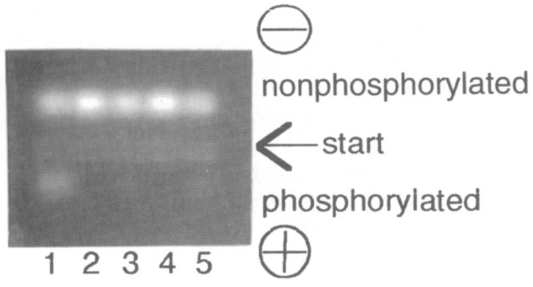

FIG. 8. Detection of protein kinase C. Samples were prepared as described in the Materials and Methods section. The samples were loaded on a 0.8% agarose gel and run at 100 V for 15 min. Phosphorylated peptide migrated toward the anode (+), while nonphosphorylated peptide migrated toward the cathode (–). The gel was photographed on a transilluminator. Lane 1, nontreated HL60 cells; Lane 2, 5.0 μM of STL-treated HL60 cells; Lane 3, 2.5 μM of STL-treated HL60 cells; Lane 4, 10.0 μM of MEL-treated HL60 cells; Lane 5, 5.0 μM of MEL-treated HL60 cells. See Figure 1 for abbreviations.

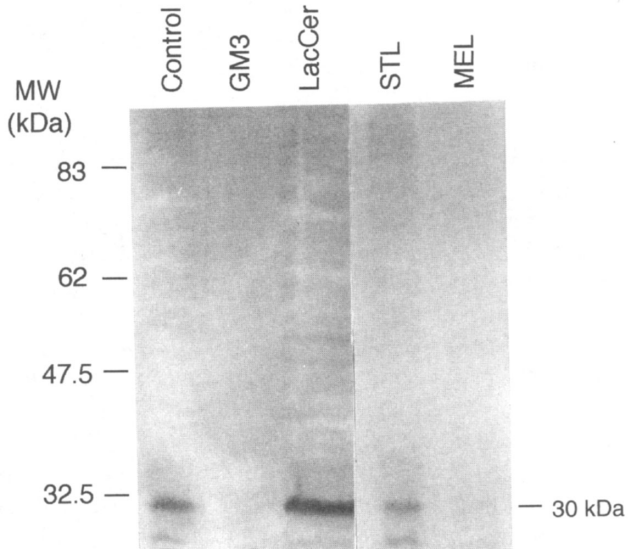

FIG. 9. Threonine phosphorylation pattern in non-, GM3, LacCer, STL, and MEL-treated HL60 cells for 3 h. Immunoblotting and revelation of phosphoserine and phosphothreonine were conducted, as described in the Materials and Methods section. See Figure 1 for abbreviations; MW, molecular weight.

DISCUSSION

In this paper, we have shown the differentiation–induction of HL60 cells by microbial extracellular glycolipids, STL and MEL. STL and MEL inhibited the insulin-dependent growth of HL60 cells and were also found enhancing the common differentiation-associated characteristics in monocyte and granulocyte, significantly. The cytologic demonstration of specific and nonspecific leukocyte esterase showed that STL induced monocytoic differentiation while MEL induced granulocytic differentiation. To investigate the mechanisms of their function on HL60 cells, the individual components of STL and MEL were examined, and neither sugar moieties nor fatty acids in the free form proved to be effective in inducing differentiation of cells. The induction of differentiation was not due to surface activities of STL and MEL on the basis of the complete ineffectiveness of the analogues tested. From these results, we supposed that the differentiation-inducing activity of STL and MEL is not due to a simple detergent-like effect but due to a specific action on the plasma membrane. Actually the GSL compositions of cell surface membrane were changed so that GM3 ganglioside increased after being treated with STL, whereas LacCer was increased after being treated with MEL compared to nontreated cells. GM3 and LacCer are components of cell surface membrane GSL, and also main components of monocyte–macrophages and granurocytes, respectively (20). Furthermore, both STL and MEL at the concentration which induced differentiation of HL60 cells exhibited a significant decrease of PKC activity. PKC comprises a family of serine/threonine protein kinases implicated in the cell regulation, differentiation, and proliferation (21,22). Inhibitors of PKC are expected to be antitumor agents because the tumor-

promoting phorbol esters are known to activate PKC directly (23,24). To confirm whether STL and MEL regulated protein kinases in HL60 cells directly or indirectly through inducing GSL such as GM3 and LacCer, the serine/threonine phosphorylation patterns were examined by the western analysis. The results showed that the serine/threonine phosphorylation of a 30 kDa protein which was observed in nontreated cells was clearly inhibited by the presence of 50 μM of GM3 and 10 μM of MEL, but was only marginally inhibited by 5 μM of STL in 3 h. After treatment with STL for 24 h, the serine/threonine phosphorylation of a 30 kDa protein was not observed. These results suggested that both STL and MEL may have interacted on the cell membrane, changed the GSL composition on the cell surface, and downregulated the serine/threonine kinase activities, then induced differentiation of HL60 cells, but the effects of STL or MEL were different. It was very likely that ganglioside GM3 that was specifically induced after STL treatment might be actually inhibiting the serine/threonine kinase, but MEL had direct inhibitory effect on it. Polysialogangliosides, lysoganglioside, and GM3 are reported to decrease PKC activity of HL60, brain, and A431, respectively (28). The critical micelle concentration of STL and MEL are 960 and 2.7 μM, respectively (17,18). As the effective concentration of STL (5 μM) is far less than the critical micelle concentration, while that of MEL (10 μM) is above CMC, MEL is assumed to form micelles, which could interact more on the cell membrane than STL.

It has been reported that certain gangliosides were found to induce differentiation of hepatopoietic cells upon exogenous addition to culture media (25–27). Nojiri *et al*. (28,29) reported that ganglio-series ganglio GM3 induced monocytoid differentiation, while neolacto-series ganglioside induced granulocytic differentiation of HL60. HL60 cells, which are bipotent with respect to the myeloid or monocytic pathway of differentiation, exhibited distinct quantitative changes in the GSL composition, depending not only on the differentiation stage but also on the differentiation direction. A remarkable increase in ganglio-series ganglioside GM3 with a concomitant decrease in lacto-series gangliosides is observed in the process of macrophage-like cell differentiation.

Concerning signal transduction of GSL, specific types of ganglioside are reported to inhibit receptor-associated tyrosine kinase activity, and therefore, gangliosides in the lipid bilayer surrounding the receptors are considered to have an important role in modulation of cell proliferation through direct or indirect interaction with receptor-associated tyrosine kinase (30–34).

Many obvious differences exist between mammalian glycolipids and STL or MEL, but they have similarities in both structures and functions. Further studies on the exact mechanism, linear signal transduction of differentiation–induction by microbial extracellular glycolipids are needed.

ABSTRACT: We examined the changes in phospholipid metabolisms in sodium butyrate-treated C6 glioma cells. Treatment of 2.5 mM sodium butyrate for 24 h induced an increase in the activity of glutamine synthetase, suggesting that these cells were under differentiation. Similar treatment was associated with (i) increased arachidonic acid incorporation into phosphatidylcholine, and (ii) decreased arachidonic acid incorporation into phosphatidylinositol and (iii) phosphatidylethanolamine. These effects were subsequently investigated by examining the acylation process, *de novo* biosynthesis, and the agonist-stimulated phosphoinositides hydrolysis in these cells. Our results indicated that sodium butyrate stimulated the acylation of arachidonic acid into lysophosphatidylcholine, lysophosphatidylethanolamine, and lysophosphatidylinositol. The glycerol incorporation into these lipids was not affected, but the inositol incorporation into total chloroform extracts and PI and phosphatidylinositol 4-phosphate was decreased in the sodium butyrate-treated cells. Moreover, the accumulation of the rapid histamine-stimulated phosphoinositide metabolites, i.e., inositol monophosphate, inositol diphosphate, and inositol triphosphate (IP_3) was decreased in these cells. To elucidate whether the decreased inositol phosphates were due to a decrease in the phosphoinositides hydrolysis, we measured the transient IP_3 production directly by a receptor-binding assay. Our results indicated that histamine-stimulated transient IP_3 formations were decreased. Taken together, these results indicated that multiple changes by multiple mechanisms of phospholipid metabolisms were found in sodium butyrate-treated C6 glioma cells. The decreased IP_3 formation and its subsequent action, i.e., Ca^{2+} mobilization, may play an early but pivotal role by which sodium butyrate induces C6 glioma cell differentiation.
Lipids 32, 273–282 (1997).

Sodium butyrate is known to stimulate differentiation of mouse erythroleukemic Friend cells (1), and regulate gene expression and cell cycle in HeLa cells (2). It has been shown to effect morphological and protein level changes in C6 glioma cells (3–5). By stimulating the activities of CoA-ligase in an oligodendroglial cell line (CB-II), our earlier studies indicated that sodium butyrate's ability to induce morphological transformation was correlated with an increase in the incorporation of [^{3}H]arachidonic acid into phosphatidylcholine (PC) and a decrease in the labeling of phosphatidylethanolamine (PE) (6,7). However, information is lacking concerning the effect of sodium butyrate on phosphoinositide metabolism and differentiation in C6 glioma cells. Recently, the decreases in phosphoinositide metabolism have been shown to correlate with cell differentiation (8–11). Our results pointed out that the incorporation of [^{3}H]arachidonic acid into various classes of phospholipids was altered in the sodium butyrate-treated C6 glioma cells. A greater proportion of [^{3}H]arachidonic acid has been found in the phosphatidylinositol (PI) in C6 glioma cells than in the PI in CB-II cells. Sodium butyrate caused an increase in the incorporation of arachidonic acid into PC and a decrease in PI and PE. Thus, changes in the phospholipid metabolism could play a role in C6 differentiation. In this study, we examine the phospholipid metabolism and the agonist-stimulate phosphoinositide hydrolysis in sodium butyrate-treated C6 cells.

MATERIALS AND METHODS

Materials. AG 1-X 8 resin (100–200 mesh, formate form) was purchased from BIO-RAD (Hercules, CA). Adenosine triphosphate (ATP), bovine serum albumin (BSA, essential fatty acid free), carbachol, histamine, L-glutamic acid-γ-monohydroxamate, hydroxylamine, imidazole-HCl, phenylmethanesulfonyl floride (PMSF), PC, PI, pyruvate kinase, sodium butyrate, sodium chloride and L-glutamate, were purchased from Sigma Chemical Co. (St. Louis, MO). [^{3}H]Arachidonic acid (specific radioactivity, 100 Ci/mmol), and myo-[2-^{3}H]inositol (specific radioactivity, 20.5 Ci/mmol) were purchased from NEN/DuPont (Wilmington, DE). Ham's F10 medium was purchased from Gibco BRL (Gaithersburg, MD), and fetal bovine serum (FBS) was obtained from Hyclone Laboratories Inc. (Logan, UT) and PAA laboratory (Linz, Austria). Gentamicin was purchased from JRH Biosciences (Lenexa, KS). Organic solvents and high-performance thin-layer chromatograph plates (HPTLC, Kieselgel 60, 10 × 10 cm) were purchased from E. Merck (Darmstadt, Germany). Tissue culture plasticware was purchased from Corning (Corning, NY).

Abbreviations: BSA, bovine serum albumin; CB-II, cerebellum derived clonal oligodendrocyte cell line; FBS, fetal bovine serum; HPTLC, high-performance thin-layer chromatography; IP, inositol monophosphate; IP_2, inositol 1,4-diphosphate; IP_3, inositol 1,4,5-triphosphate; LiCl, lithium chloride; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; LPI, lysophosphatidylinositol; NaB, sodium butyrate; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PEpl, plasmalogen phosphatidylethanolamine; PI, phosphatidylinositol; PI hydrolysis, phosphoinositides hydrolysis; PIP, phosphatidylinositol 4-phosphate; PIP_2, phosphatidylinositol 4,5-diphosphate; TCA, trichloroacetic acid.

Cell culture. Later passages (>300) of C6 glioma cells originally obtained from the American Type Culture Collection (Rockville, MD) were stock cultured in T-75 flasks as monolayers in culture medium (Ham's F10 medium supplemented with 10% FBS and 50 µg/mL gentamicin) in a humidified atmosphere of 95% air and 5% CO_2 at 37°C. At confluence, the cells were rinsed with 0.02 M phosphate buffer (pH 7.4) containing 0.1% glucose (PBG) and then dissociated with 3 mL trypsin-EDTA (Gibco) for 3 min at 37°C. The cells were resuspended in culture medium, and aliquots of this suspension were then transferred to T-75 flasks or 60-mm dishes for the experiment.

Glutamine synthetase activity. Glutamine synthetase activity was determined according to the method of Palmiljan *et al*. (12). Cells were incubated in culture medium in the presence of 2.5 mM sodium butyrate for 12–48 h. The incubations were terminated by aspirating the media, and the cells were rinsed with PBG, scraped by a rubber policeman, and then transferred to a test tube. The cells were centrifuged at $200 \times g$ for 10 min, resuspended in imidazole-HCl buffer (0.05 M imidazole pH 7.2, 0.1% Triton X-100), and homogenized by a polytron for 10 s at 0°C. The homogenates were then centrifuged at $100{,}000 \times g$ at 4°C for 30 min, and the resultant supernatant was removed as the cytosolic fraction. The cytosolic protein concentrations were determined by Lowry's method, and the protein concentrations were adjusted with imidazole buffer to a final concentration of 1 µg/µL. Each of the cytosolic samples (100 µL) was then mixed with 900 µL of reaction buffer (0.2 M $MgCl_2$; 0.95 M glutamate; 2 M hydroxylamine; 0.5 M 2-mercaptoethanol; 0.2 M 2-phosphoenol pyruvate; 1 mg/mL pyruvate kinase; 10 mM ATP) and incubated at 37°C for 15 min. After incubation, the reaction was stopped by the addition of 1.5 mL ferric chloride buffer consisting of 0.37 M $FeCl_3$, 0.67 N HCl, and 0.2 M trichloroacetic acid (TCA). The optic density of glutamine was measured by spectrophotometry at wavelength 535 nm, and the result was expressed as percentage of the control.

The [^{3}H]arachidonic acid incorporation assay. The incorporation of [^{3}H]arachidonic acid into intact C6 cells was conducted by subculturing the cells in culture medium in 60-mm dishes for 1 d. The culture medium was then changed to fresh culture medium in the presence of 0–5 mM sodium butyrate for 22 h. The culture medium was removed, and [^{3}H]arachidonic acid (0.5 µCi per dish) in Ham's F10 medium supplemented with 2.5% FBS (the label medium) and 0–5 mM sodium butyrate was added. At the end of this 2-h labeling process, the label medium was removed, and the reaction was stopped by adding 1.3 mL of ice-cold methanol to the cultures.

The [^{3}H]arachidonic acid acylation. In the assay system, cells were cultured in T-75 flasks in culture medium for at least 3 d. Subconfluent cultures were removed by trypsin, and cell number and protein determined. After washing with PBG, cells were suspended (2×10^6/mL) in 50 mM Tris-HCl (pH 7.4) and were homogenized by a Potter-Elvehjem homogenizer (Tri-R Instrument Rockville Center, NY). Aliquots of 0.5 mL cell homogenate were incubated with 1 µCi [^{3}H]arachidonic acid, 0.1% fatty acid-free BSA, 0.1 mM CoA, 0.3 mM dithiothreitol, 2.5 mM ATP, 10 mM $MgCl_2$, and 50 mM Tris-HCl, pH 7.4 in the absence or the presence of sodium butyrate to a total of 1 mL per test tube as described earlier (7) and according to the method of Lin *et al*. (13). All incubations were carried out at 37°C for 5 min, and 4 µM LPI, 20 µM LPC, and 20 µM bovine brain LPE were used (7). The lipids, cofactors, and sodium butyrate together with cell homogenates in buffer were kept in an ice-cold water bath and vortexed vigorously for 20 s prior to incubation. After incubation, the reaction was stopped by adding 4 vol of chloroform/methanol (2:1, vol/vol).

Short-term [^{3}H]thymidine incorporation and myo-1, 2-[^{3}H]inositol incorporation into total chloroform extracts assays. The cells were cultured in T-75 flasks and pretreated with 2.5 mM sodium butyrate in culture medium for 24 h. The cells were harvested by trypsin, counted, and subcultured into 60-mm dishes at a density of 1×10^6/dish. The cells were then incubated with 0.5 µCi/mL [^{3}H]thymidine or 4 µCi/mL myo-1, 2-[^{3}H]inositol for 2 h in 5% CO_2 incubator at 37°C. The [^{3}H]thymidine incorporation reaction was terminated by aspiration, and the cells were scraped onto a test tube containing 500 µL 1% Triton X-100 plus 5 mL 6% TCA and incubated for 10 min at room temperature. Following incubation, the samples were transferred to a filtration unit with GF/C filter papers and rinsed five times with 6% TCA and once with 70% ethanol. The radioactivity of the filter papers was determined by scintillation spectrophotometry. The myo-1, 2-[^{3}H]inositol incorporation reactions were stopped by aspiration and the addition of 1.3 mL ice-cold methanol. The cells were scraped, lipids extracted, and the radioactivity of the chloroform extracts determined by scintillation spectrometry.

Prolonged myo-1, 2-[^{3}H]inositol incorporation into total chloroform extracts assays. The incorporation of [^{3}H]inositol into intact C6 cells was conducted by subculturing the cells in culture medium in 60-mm dishes for 1 d. The culture medium was then changed to medium supplemented with 2.5% FBS, in the presence of 4 µCi/mL [^{3}H]inositol, in the presence or absence of 2.5 mM sodium butyrate for 24 h. At the end of this 24-h labeling process, the reaction was stopped by aspiration and the addition of 1.3 mL ice-cold methanol. The cells were scraped, lipids extracted, and the radioactivity of the chloroform extracts determined by scintillation spectrometry.

Lipid extraction and separation. For lipid extraction, 4 vol of chloroform/methanol (2:1, vol/vol) were added to 1 vol of cell suspension. After mixing, the tubes were briefly centrifuged at 400 g to allow phase separation. The lower organic phases were removed and transferred to the test tubes. In order to obtain a complete recovery of the acidic phospholipids, the aqueous phase was further extracted by adding 2 vol of chloroform/methanol/12 N HCl (225:75:0.75, by vol). The acidic organic phase was removed and neutralized with 1 drop of 4 N NH_4OH before being recombined with the first organic extract. The combined organic extracts were evaporated to dryness, redissolved in chloroform, and applied to HPTLC

plates (Kieselgel 60, 10 × 10, E. Merck). Phospholipids, i.e., PI, PS, PC, PEpl and PE, were separated by a two-dimensional solvent system (7) according to the original method of Sun *et al.* (14). Briefly, plates were developed in the first dimension using chloroform/methanol/acetone/12 M NH_4OH (35:20:5:5, by vol). After development, the plate was removed from the tank, dried, and exposed to HCl fumes for 3 min before removing the HCl fumes by a stream of warm air for 10 min. The plates were then developed in the second dimension by chloroform/methanol/acetone/glacial acetic acid/0.2 M ammonia acetate (35:15:14:1:1.75, by vol). After development, the lipid fractions were visualized by exposure to iodine vapor, and the individual phospholipid spots were scraped into scintillation vials for counting.

For separation of phosphoinositides (PI, PIP, and PIP_2), the lipids were spotted on HPTLC Silica gel plates (E. Merck). These plates were impregnated with 1% potassium oxalate dissolved in methanol/H_2O (3:2, vol/vol) containing 2 mM EDTA. The plates were developed in a first solvent system containing chloroform/methanol/acetone/16 M NH_4OH (70:40:10:10, by vol). After development, the solvent was removed from the plates by blowing with an air gun for 5 min. The HPTLC plates were then developed in the same direction with a second solvent system containing chloroform/methanol/16 M NH_4OH/H_2O (36:28:2:6, by vol) according to Lin *et al.* (13). After the second solvent development, the plates were exposed to iodine vapors, the corresponding lipid bands were scraped, and radioactivity measured as described above.

Phosphoinositide hydrolysis and IP accumulation assay. Phosphoinositide hydrolysis was assessed by measuring the accumulation of IP in cells prelabeled with myo-1, 2-[^{3}H]inositol for 24 h. Cells (1×10^6 cells) were subcultured on T-25 flasks or 60-mm dishes and were incubated with 2 mL of labeled medium (F10 supplemented with 2% FBS and 4 μCi/mL of myo-1, 2-[^{3}H]inositol), in the presence of 2.5 mM sodium butyrate for 24 h in 5% CO_2 at 37°C. LiCl (10 mM) was added into the label medium 1 h before termination of the reaction. At termination, cells were then washed three times with assay buffer (111 mM NaCl; 26.2 mM $NaHCO_3$; 1 mM NaH_2PO_4; 2.5 mM KCl; 1.5 mM $MgSO_4$; 20 mM glucose; 10 mM LiCl; pH 7.4) and then incubated with histamine at a final concentration of 30 μM for 1–30 min at 37°C. The reaction was stopped by aspiration followed by the addition of ice-cold methanol. The accumulations of glycerol phosphoinositide (GPI), IP, inositol 1,4-diphosphate (IP_2), and inositol 1, 4, 5-triphosphate (IP_3) were assayed by using AG-1X 8 (formate form, 100–200 mesh; BIO-RAD) column and were eluted with 5 mM sodium borate/60 mM sodium formate, 0.2 N ammonium formate/0.1 N formic acid, 0.4 N ammonium formate/0.1 N formic acid, and 1 N ammonium formate/0.1 N formic acid to separate GPI, IP, IP_2, and IP_3, respectively, according to Berridge (15). In order to standardize the data, the total chloroform extracts of these samples were saved and the radioactivity measured.

Determination of inositol 1,4,5 P_3 (IP_3) mass by radioreceptor binding assay. The procedure for determination of IP_3 concentration in cells followed the method originally described by Bredt *et al.* (16) with modifications (17). In brief, cellular IP_3 was extracted by TCA from the supernatants and by washing five times with 2 vol of water-saturated diethyl ether. Residual ether was then removed by blowing with N_2 for 15 min, and the remaining cell extract was neutralized with 500 mM Tris buffer (pH 8.4) and stored at −80°C. The membranes containing receptors for the binding assay were isolated by homogenizing rat cerebella in 30 vol of Tris buffer (50 mM, pH 7.7) containing EDTA (1 mM) and 2-mercaptoethanol (1 mM) followed by centrifugation for 15 min at 4°C. The pellets were washed three times, resuspended in the same buffer (final protein concentration 4 mg/mL), and stored at −80°C. The concentrations of IP_3 were determined by incubating cell extracts and cerebellar membranes in Tris buffer (50 mM, pH 8.4) containing 1 nM [^{3}H]IP_3 (17 Ci/mmol). A standard curve was constructed using unlabeled IP_3 (1–100 nM) to replace cellular IP_3, and nonspecific binding was determined in the presence of 2 μM IP_3. The mixture was incubated at 4°C for 15 min, and the reactions were terminated by centrifugation at $15{,}000 \times g$ for 5 min. The pellets were solubilized with NaOH and neutralized with HCl, and radioactivity was determined by liquid scintillation spectrometry.

RESULTS

Effect of sodium butyrate on glutamine synthetase activities. To elucidate the effect of sodium butyrate on C6 glioma cells, the cytosolic glutamine synthetase activities were measured in the cells pretreated with 2.5 mM sodium butyrate for 0–48 h. As shown in Figure 1, increases in glutamine synthetase activities were detected in cells treated with sodium butyrate for 24–48 h, but not in cells treated with sodium butyrate for 12 h, suggesting that a longer time treatment is required for this induction.

Effect of sodium butyrate on [^{3}H]arachidonic acid incorporation into C6 glioma cells. The effect of sodium butyrate on phospholipid metabolism was studied by analysis of the arachidonic acid incorporation in these cells. When control C6 cells were labeled with [^{3}H]arachidonic acid for 2 h, 50% of the radioactivity was found in PC and 30% in PI. Less than 10% radioactivity was found in PE and less than 5% in PS, and PEpl in these cells. As shown in Table 1, sodium butyrate stimulated increases in the labeling of PC and decreases in the labeling of PI and PE. In cells treated with 2.5 mM sodium butyrate for 24 h, the labeling of PC was increased 28% and the labeling of PI was decreased 30%, suggesting that sodium butyrate may alter the acylation of arachidonic acid among these phospholipids differently.

Effect of sodium butyrate on acylation of [^{3}H]arachidonic acid. To further elucidate the changes in PC, PE, and PI labeling, we analyzed the incorproation of [^{3}H]arachidonic acid by an acylation assay. As shown in Table 2, the amount of [^{3}H]arachidonic acid in PI in the absence of exogenous substrates was three times greater than PC and PE by this assay. In the presence of LPI, LPC, and LPE, the labeling of PI, PC,

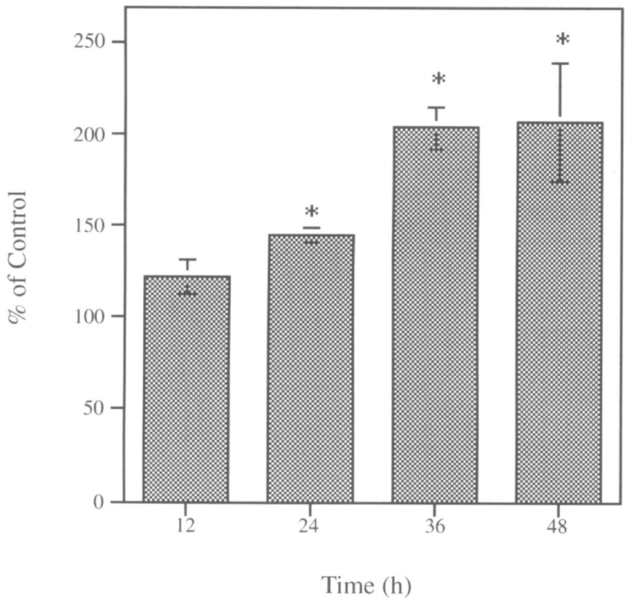

FIG. 1. The effect of sodium butyrate on glutamine synthetase activity of C6 cells. Cells were cultured in the absence (control) or the presence of 2.5 mM sodium butyrate for 12–48 h as indicated. The cytosolic glutamine synthetase activities were assayed as described in the Materials and Methods section. Data represent mean ± SD from three determinations and the symbol * denotes a significantly different mean from the controls as determined by nonpaired Student *t*-test with $P \leq 0.05$.

and PE was increased about 2-fold, 6-fold, and 3-fold, respectively. The addition of 2.5 mM sodium butyrate to the incubation system further increased the labeling of PI (1.7-fold), PC (1.7-fold), and PE (1.6-fold). These results indicated that C6 cells contain a very active alternative biosynthesis system to transfer arachidonic acid into LPI, LPC, and LPE for the synthesis of PI, PC, and PE.

Effect of sodium butyrate on the incorporation of [^{3}H]glycerol into phospholipids. To further elucidate the effect of sodium butyrate on the biosynthesis of phospholipids, cells were labeled with [^{3}H]glycerol in the absence or the presence of sodium butyrate. As shown in Table 3, a major proportion of radioactivity was found in PC, and lesser amounts were found in PI and PE. The labeling of PC and PE was only slightly altered in the sodium butyrate-treated cells, indicating that sodium butyrate may not affect the *de novo* phospholipid biosynthesis pathway in these cells.

Effect of sodium butyrate on [^{3}H]thymidine incorporation, protein concentration, and [^{3}H]inositol incorporation into total chloroform extracts by a short-term assay. To further elucidate the timing of the onset of sodium butyrate-induced C6 cell differentiation and to correlate it with changes in phosphoinositides metabolism, we monitored [^{3}H]thymidine incorporation, protein concentrations, and [^{3}H]inositol incorporation into total chloroform extracts on C6 cells pretreated with 2.5 mM sodium butyrate for 0, 2, 6, 12, and 24 h. As shown in Table 4, the onset of decreases in [^{3}H]thymidine incorporation and [^{3}H]inositol incorporation were observed in cells pretreated with sodium butyrate for 6 h, indicating that an initial effect must have occurred within 6 h. Equilibrium may be reached between 12 and 24 h in these cells.

Effect of sodium butyrate on [^{3}H]inositol incorporation into PI, PIP, and PIP_2 of C6 glioma cells. The effect of sodium butyrate on prolonged [^{3}H]inositol incorporation into PI, PIP, and PIP_2 was further elucidated by TLC analysis of the chloroform extract. As shown in Figure 2, the [^{3}H]inositol incorporation into PI and PIP was significantly lower in the sodium butyrate-treated C6 cells.

Effect of sodium butyrate on IP, IP_2, and IP_3 accumulation. To correlate the changes in phosphoinositide biosynthesis associated with reduction in the phospholipid-derived second-messenger productions, we measured the accumulation of inositol IP, IP_2, and IP_3 in sodium butyrate-treated C6 cells. A time-course study of the accumulation of IP, IP_2, and IP_3 (Fig. 3) showed decreasing levels of IP, IP_2, and IP_3.

Effect of sodium butyrate on agonist-stimulated inositol IP_3 production. The effect of sodium butyrate on the transient IP_3 production was further investigated by a receptor binding assay. A time-course study (5–30 s) was carried out in which cells were previously treated with 2.5 mM sodium butyrate for

24 h. The results demonstrated that histamine stimulated IP_3 production at 5 s and reached a maximum within 10 s. As shown in Figure 4, IP_3 production was decreased almost to the basal level in the sodium butyrate-treated cells. To further confirm that the decreased IP_3 production is from PI turnover, we subsequently measured the temporal response of intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) in these cells by the Fura-2 method. Results indicated that the $[Ca^{2+}]_i$ concentrations were decreased in the sodium butyrate-treated C6 cells 5 s after the addition of the histamine (data not shown), suggesting that the decreased IP_3 resulted from a decreased PI hydrolysis.

DISCUSSION

The glutamine synthetase (GS) (E.C. 6.3.1.2) has been used as a marker for C6 cells (18) and astrocytes in rat brain (19, 20). An early report has shown that sodium butyrate alone increased GS protein synthesis through stimulation of post-transcriptional regulation in C6 cells (21). In this study, treating C6 cells with sodium butyrate for 24 h induced an increase in GS activities (Fig. 1), suggesting that the treatment induced cell differentiation. An initial increase was obtained after 24 h and maximal increase obtained after 36 h. This result correlated with a recent report indicated that staurosporine induced differentiation of C6 cells and an initial increase in GS activity obtained after 24 h and maximal effect obtained between 24–48 h (22). A similar initial effect but a delayed (72 h) maximal effect was also found in the interleukin-4 induced C6 differentiation (23).

To determine whether the effect of sodium butyrate on phospholipid metabolism is associated with C6 differentiation, we analyzed the incorporation of arachidonic acid, glycerol, and inositol into these cells. Our results demonstrated that, similar to our earlier findings in an oligodendrocyte cell line (CB-II) (7), sodium butyrate increased the incorporation of arachidonate into PC and decreased its incorporation into PE. On the other hand, butyrate stimulated arachidonate incorporation into LPC, LPI, and LPE. Thus butyrate may also affect the turnover of arachidonate in these cells. The PE decrease was probably due to an inhibition of the transfer of arachidonic acid from PC to PE by a transacylation mechanism. An earlier time-course study in CB-II oligodendrocytes has shown that arachidonic acid was rapidly incorporated into PC (6). Compared with PC,

[f]Not detected.

the incorporation of arachidonic acid into PE was slow and had a late onset. It is possible that arachidonate was transfered from PC to PE in C6 cells, and sodium butyrate could inhibit this process. To investigate this possibility, we incubated arachidonic acid-prelabeled C6 cells in culture medium in the presence of sodium butyrate, and found that arachidonic acid was transferred from PC to PE and PI. Sodium butyrate decreased PE but not PI labeling in these cells as compared with the control cells (data not shown). This PE-transacylation pathway remains to be more clearly characterized.

Compared with CB-II cells (6, 7), [^{3}H]arachidonic acid was more actively incorporated into PI in C6 cells. Radioactivity of PI decreased in the sodium butyrate-treated C6 cells but not CB-II cells. In the absence of exogenous lysophospholipids, the amount of radioactivity found in PI was three times that in PC and PE (Table 2), suggesting that there was abundant endogenous LPI in these cells. Based on this finding, the differences in the distribution of radioactivity of [^{3}H]arachidonic acid may be mostly due to the availability of the endogenous lysophospholipids. The results also imply that C6 membrane contains enzymes (i.e., CoA–ligase and acyltransferase) to synthesize PI, PC, and PE. When substantial amounts of exogenous LPI, LPC, and LPE were added into the incubation system, a respective 2-fold, 6-fold, and 3-fold increase in the labeling of PI, PC, and PE was observed. This result confirms our earlier observation that acylation of these phospholipids was very active in the glial cells. It may also provide support for the widely held belief that different lysophospholipid acyltransferases are involved with acylation of PC, PE, and PI (24). Since there is 4–6 times as much PC as PI, the turnover of PI may be higher than PC in C6 cells. As shown in Table 2, sodium butyrate stimulated a similar fold of increase (1.7-fold) in the transfer of arachidonate into LPI, LPC, and LPE. Taken

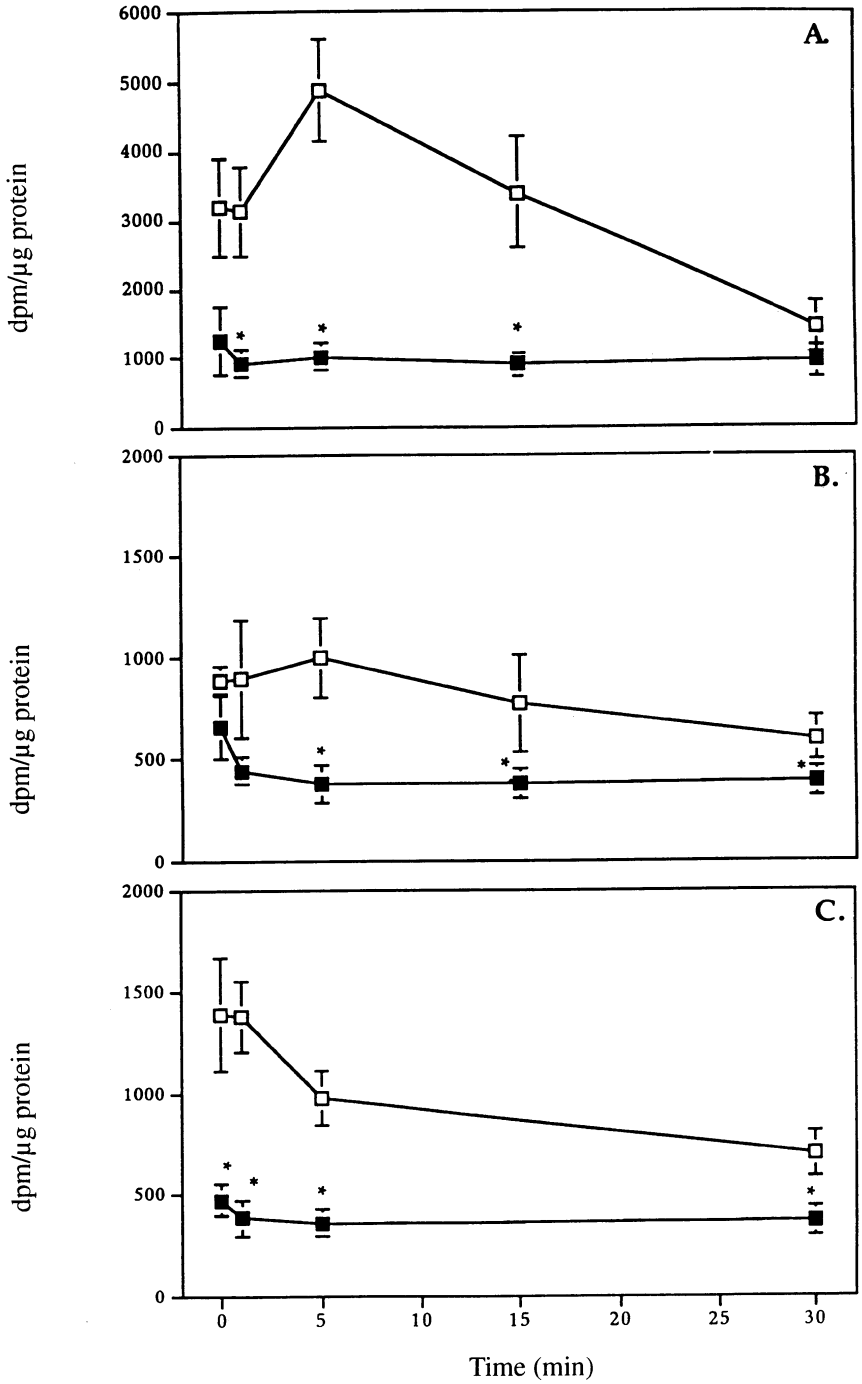

FIG. 3. Effect of sodium butyrate on histamine-stimulated accumulation of (A) IP, (B) IP_2, and (C) IP_3. C6 cells were seeded in 60-mm dishes and preincubated with 4 µCi/mL [^{3}H]inositol in the absence (□) or the presence (■) of 2.5 mM sodium butyrate for 24 h. The medium was removed and the cells were stimulated with 30 µM of histamine for the indicated time period (1–30 min) before being eluted by Dowex column. Radioactivity was determined by scintillation spectrometry as described in the Materials and Methods section. Data (dpm/100 µg protein) represent mean ± SD from three determinations and the symbol * denotes a significantly different mean from the respective control (i.e., at the same time point) by nonpaired Student's *t*-test with $P \leq 0.05$.

together, when lysophospholipids were available, sodium butyrate stimulated a similar mode of increase in the transfer of arachidonic acid into LPI, LPC, and LPE through the stimulation of a common mechanism, the CoA–ligase (7).

We have demonstrated that inositol incorporation into total chloroform extracts and TLC-separated PI and PIP were significantly lower in the sodium butyrate-treated C6 cells, suggesting that the biosynthesis of phosphoinositides was

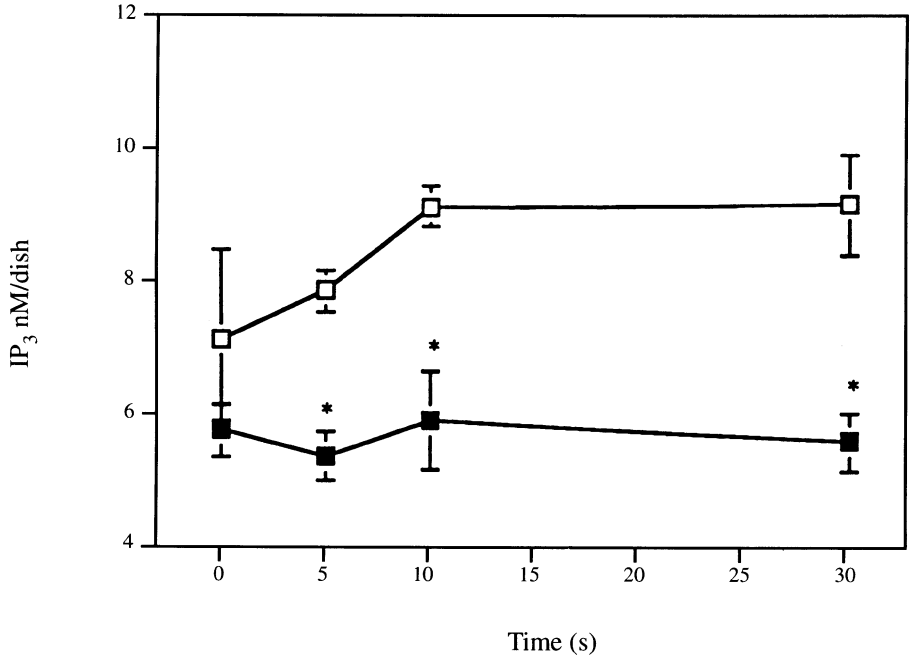

FIG. 4. Effect of sodium butyrate on histamine-stimulated inositol 1,4,5 triphosphate (IP_3) production. The C6 cells were seeded in 35-mm dishes and preincubated in the absence (□) or the presence (■) of 2.5 mM sodium butyrate for 24 h. The media were removed and the cells rinsed and incubated with 30 μM of histamine for the indicated time periods (0–30 s). The IP_3 was measured by radioreceptor binding assay as described in the Materials and Methods section. Data, nM/dish, represent mean ± SD from three determinations and the symbol * denotes a significantly different mean from the control at the same time point by nonpaired Student's *t*-test with $P \leq 0.05$.

decreased in these cells. Short-term (30–120 min) treatment did not affect thymidine incorporation in these cells (data not shown). A sodium butyrate time-course study, which was conducted by incubating the same number of cells (1×10^6) with [^{3}H]thymidine for 2 h, indicated that the decrease in thymidine incorporation is time- (Table 4) and concentration-dependent (data not shown). The time-course study further indicated that the onset of decrease in thymidine incorporation started as early as 6 h after the addition of sodium butyrate and was correlated with decreased inositol incorporation. This finding makes it likely that the real effect of butyrate on C6 differentiation and decrease in inositol incorporation would have occurred even earlier.

The decreased IP_3 in the sodium butyrate-treated cells indicated that PI hydrolysis and the generation of phospholipid-derived second messengers were affected in these cells. In addition to the generation of IP_3 reported in this study, we have confirmed that histamine also stimulated a transient Ca^{2+} response *via* H_1 receptors 5 s after the addition of agonists (data not shown). This would agree with the earlier findings by others that histamine H_1-receptor mediated PI hydrolysis in primary astrocyte culture (25) and in 131N1 astrocytoma cells (26). Furthermore, it is also in agreement with another finding in UC-11MG astrocytes that histamine stimulates a significant Ca^{2+} response *via* H_1 receptors (27,28). In this study, two different assay methods both showed that histamine-stimulated rapid accumulation of IP_3 was decreased in sodium butyrate-treated cells. Moreover, the transient histamine-stimulated Ca^{2+} mobilization was also decreased although the H_1 receptors were actually increased in the sodium butyrate-treated cells (data not shown). Thus, by eliminating the possibility that decreased phosphoinositide hydrolysis was due to changes in receptor, these results confirm that decreased phosphoinositide hydrolysis reflects changes in phosphoinositide metabolism. Since sodium butyrate did not decrease phosphoinositides labeling when cells were incubated with [^{3}H]glycerol for 24 h, this result suggests that butyrate does not decrease the mass of inositol-containing lipids. However, that sodium butyrate decreased the inositol incorporation of PI and PIP suggests that sodium butyrate must affect the *de novo* synthesis of inositol-containing lipids. Furthermore, there is a 59% decrease in inositol incorporation into total chloroform extracts by short-term incorporation. As short-term inositol and arachidonate incorporation, baseline mass of the inositol phosphate second messengers, the inositol phosphate response to histamine, and the subsequent Ca^{2+} mobilization are all reduced, it seems likely that butyrate decreases the turnover of agonist-sensitive pool of phosphoinositide. Our results are similar to those of Ponzoni and Lanciotti (9) and Lanciotti and Longone (29), who have reported a retinoic acid-induced Lan-1 neuroblastoma cell differentiation involving a rapid decrease of inositol

phospholipid turnover.

In conclusion, we have shown that sodium butyrate-induced glial cell differentiation is accompanied by enhanced arachidonic acid incorporation into PC and decreases in phosphoinositide turnover. Sodium butyrate may also inhibit the transfer of arachidonic acid from PC to PE. The decreases in phosphoinositide turnover lead to decreases in the generation of the phospholipid-derived second messengers, IP_3 and its subsequent action, the Ca^{2+} mobilization. Taken together, these results provide evidence that sodium butyrate-stimulated C6 cell differentiation is correlated with multiple changes in phospholipid metabolism, the production of their metabolites, and the physiological action of the metabolites by which sodium butyrate signals may be transduced. Thus, changes in phospholipid may play an early but pivotal role in the sodium butyrate-induced glioma cell differentiation.

Polyunsaturated Fatty Acids Increase the Sensitivity of 36B10 Rat Astrocytoma Cells to Radiation-Induced Cell Kill

Sujata Vartak[a,*], Mike E.C. Robbins[a], and Arthur A. Spector[b]

[a]Radiation Research Laboratory, Department of Radiology, and [b]Department of Biochemistry, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: Polyunsaturated fatty acids (PUFA) such as γ-linolenic acid (GLA, 18:3n-6), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3) have been shown to be cytotoxic to tumor cells. The objective of this work was to study the effects of PUFA on the radiation response of a 36B10 rat astrocytoma cell line. Supplementation of the astrocytoma cells with 15–45 μM GLA, EPA, or DHA produced marked changes in the fatty acid profiles of their phospholipids and neutral lipids. The methylene bridge index of these lipids increased significantly. These PUFA also exerted cytotoxic effects, as determined using the clonogenic cell survival assay. While GLA and DHA produced a moderate cell-killing effect, EPA was extremely cytotoxic, especially at a concentration of 45 μM. The monounsaturated oleic acid (OA, 18:1n-9) did not affect cell survival. Further, all three PUFA, and particularly GLA, increased the radiation-induced cell kill; OA did not enhance the effect of radiation. α-Tocopherol acetate blocked the enhanced radiation sensitivity of GLA- and DHA-supplemented cells. In conclusion, GLA, EPA, and DHA supplementation prior to, during, and after irradiation can enhance the radiation-induced cytotoxicity of rat astrocytoma cells. GLA and DHA supplementation post-irradiation also enhanced the radiation response of the 36B10 cells. Because GLA maximally increases the radioresponsiveness of a rat astrocytoma, this PUFA might prove useful in increasing the therapeutic efficacy of radiation in the treatment of certain gliomas.

Lipids 32, 283–292 (1997).

In the treatment of brain tumors with radiation, damage to the surrounding normal tissue is a major dose-limiting factor since injury to the brain could lead to severe functional disabilities in patients. Malignant gliomas are extremely radioresistant and hence particularly difficult to treat (1–3). Therefore, to increase the therapeutic efficacy of radiation in the treatment of these tumors, it is extremely important to selectively kill tumor cells.

In recent years, there has been a growing interest in the potential of polyunsaturated fatty acids (PUFA) to selectively enhance the response of tumors to various forms of anticancer therapy. Fatty acid supplementation produces changes in the lipid composition of cells which can alter their physical and functional properties (4). Further, several studies have shown that supplementation with PUFA can influence tumor incidence, growth, and metastasis (5–8).

The cytotoxic action of PUFA is thought to be mediated predominantly *via* the generation of free radicals and lipid peroxidation (9–11). Incorporation of PUFA into tumor cells leads to increased potential for oxidative stress (12) and increases the susceptibility of the cells to therapies that generate reactive oxygen species. For example, increased incorporation of PUFA leads to enhanced sensitivity of tumor cells to hyperthermia (4) and some anticancer drugs such as adriamycin and methotrexate (13,14). Since radiation also generates oxidative stress in cells, supplementation of membrane lipids with PUFA could augment radiation-induced cell kill. However, the effect of PUFA on the radiation response of tumor cells has not been well documented (15). The purpose of this study was to determine whether PUFA can alter the response of a malignant rat astrocytoma cell line to radiation.

MATERIALS AND METHODS

Cell and culture conditions. The cell line used was the ethylnitrosourea-induced 36B10 malignant rat astrocytoma (16). The 36B10 cells were cultured at 37°C under a humidified atmosphere of 95% air: 5% CO_2 in Dulbecco's modified Eagle's medium containing 10% fetal bovine serum and L-glutamine (2 mM), penicillin (50 IU/mL), and streptomycin (50 μg/mL). All cell culture reagents were purchased from Gibco (Grand Island, NY). Stock cultures were maintained as monolayer cultures in tissue culture flasks by routine passage twice a week by trypsinization.

Lipid extraction and assays. The fatty acid composition of 36B10 cells was determined by gas–liquid chromatography (17). Incorporation of fatty acids into the cells was determined by adding 15–45 μM of docosahexaenoic acid (DHA, 22:6n-3), eicosapentaenoic acid (EPA, 20:5n-3), or γ-linolenic acid (GLA, 18:3n-6) to the growth medium. The monounsaturated fatty acid, oleic acid (OA, 18:1n-9), was also used as a fatty acid control. Fatty acids were purchased

Abbreviations: AA, arachidonic acid; DGLA, dihomo-γ-linolenic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; DTA, docosatetraenoic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid, OA, oleic acid; PUFA, polyunsaturated fatty acids.

from Cayman Chemical Company (Ann Arbor, MI). The fatty acid solutions were prepared in ethanol such that the concentration of alcohol in the medium was <0.2%. After incubation for 24 h, lipids were extracted using chloroform/methanol (2:1, vol/vol) following the standard protocol of Folch *et al.* (18). A measured quantity of heptadecanoic acid (17:0) was also added as an internal standard to quantify the amounts of fatty acids present in the samples.

Total cholesterol in the cell lipid extracts was determined using an enzymatic kit (Sigma Diagnostics, St. Louis, MO). The phospholipid content of samples was determined colorimetrically using the malachite green assay for inorganic phosphorus (19).

Neutral and phospholipid fractions were separated using silicic acid columns (20). Columns were prepared by washing with *n*-heptane. Lipid extracts suspended in chloroform/methanol (1:1, vol/vol) were loaded onto the column, and the column was washed with 1 mL heptane. Neutral lipids were eluted with 6 mL chloroform/methanol (100:2, vol/vol) and phospholipids with 8 mL methanol/distilled water (100:2, vol/vol).

For analysis of fatty acid composition, the lipid extracts were transesterified with 12% BF_3 in methanol at 95°C for 45 min (21). The resulting fatty acid methyl esters were extracted into *n*-heptane and separated using a Hewlett-Packard 5890 system (Palo Alto, CA) containing a 1.9 m × 2 mm glass column packed with 10% SP2330 on 1000/120 mesh Chromosorb WAW (Supelco, Bellefonte, PA). N_2 was used as the carrier gas at a flow rate of 25 mL/min. The column injector was maintained at 250°C while the oven temperature was programmed to remain at 175°C for 7 min and then increased to 240°C at 2°/min. Fatty acid methyl esters were detected by flame ionization at 250°C and quantified using an HP 3990A integrator. Chromatogram peaks were identified by comparison with the retention times of standards purchased from Nu-Chek-Prep (Elysian, MN).

For determination of methylene bridge index, the number of *bis*-allylic methylene bridge positions contained in each fatty acid methyl ester was multiplied by its respective nanogram quantity and summed for all fatty acids detected. The mean number of *bis*-allylic methylene bridge positions per fatty acyl chain was then expressed as the methylene bridge index.

Cell survival analyses. The radiation response of the 36B10 cells was determined using the clonogenic cell survival assay. A single cell suspension was obtained by trypsinization of 90% confluent cell cultures. Viable cells were counted using 0.4% erythrosin B with a hemocytometer (viability >95%) and seeded at varying densities (depending on radiation dose) onto 60 mm plates. After 2–3 h, the cells were exposed to 0–10 Gy γ-rays (^{137}Cs γ-source, 1.5 Gy/min). The cells were allowed to grow for one week, the medium being changed once every 2 d. At the end of this incubation, the cells were stained with 0.1% crystal violet for 60 min, and the colonies (>50 cells/colony) were counted using a dissecting microscope.

To determine the effect of fatty acids, the cells were incubated in medium supplemented with 15–45 μM GLA, EPA, DHA, or OA for 24 h prior to seeding and were continued on the fatty acid-supplemented media throughout the duration of the experiment. In order to investigate whether lipid peroxidation played a role in the effects of PUFA on the astrocytoma cells, 50 or 100 μM of α-tocopherol acetate was added to the media in addition to the fatty acids, and the clonogenic survival was determined. The cells were maintained in the antioxidant-rich media throughout the duration of the experiment. The effect of fatty acid supplementation post-irradiation was studied by incubating the cells in unsupplemented media prior to and during irradiation. Within 1 h of irradiation, the medium was replaced with fatty acid-supplemented media. Cells were then continued on supplemented media until the end of the experiment. To determine whether incubation of cells with fatty acids only prior to irradiation was sufficient to exhibit cytotoxic effects, and to study the influence of time between supplementation and irradiation, cells were incubated in fatty acid-supplemented media for 24 h. The cells were then returned to unsupplemented media. At intervals of 0, 24 and 48 h, the cells were seeded onto 60-mm plates and irradiated with 5 Gy γ-rays; control cells were treated similarly but not irradiated. Cells were then allowed to grow in unsupplemented media for one week and stained with 0.1% crystal violet for 60 min.

Statistical analysis. Statistical analysis of the radiation response data was performed using simple linear regression. Simple linear regression models of the form "log (surviving fraction) = β dose" were fitted. Student's *t*-tests were used to compare each slope to the control slope; P values ≤0.05 were considered to be statistically significant. D_0 values, defined as the dose (Gy) required to reduce the fraction of surviving cells to 37% of its previous value, were estimated by the negative reciprocal of the slope. Standard errors for D_0 values were computed from the standard errors of the estimated slopes using Taylor series variance approximations (the delta method). Statistical significance of data on fatty acid incorporation was analyzed using the Student's *t*-test. Data with P values ≤0.05 were considered to be statistically significant.

RESULTS

Incorporation of fatty acids. Table 1 shows the effects of 15–45 μM GLA, EPA, DHA, and OA supplementation on the total PUFA content of phospholipids and neutral lipids in rat astrocytoma cells. When the cells were supplemented with 15–45 μM OA, no changes in PUFA content of phospholipids or neutral lipids were observed. However, incubation of the cells with either GLA, EPA, or DHA led to dose-dependent increases in the total PUFA contents of the phospholipids and neutral lipids. As expected, the extent of increase was much more pronounced in the neutral lipids as compared with phospholipids, although the absolute amount was smaller. For example, supplementation of the astrocytoma cells with 45 μM GLA resulted in a 2-fold increase in the PUFA content of

TABLE 1
Effect of Fatty Acid Supplementation on the Total PUFA Content of Phospholipids and Neutral Lipids in 36B10 Astrocytoma Cells[a]

	Total PUFA content (nanograms/10^5 cells)

45 μM	248.56 ± 27.48	trace

[a]Values represent mean ± SE from four separate cultures. Cells were grown in 15–45 μM of the fatty acids for 24 h prior to lipid extraction. Statistical analysis was performed using Student's *t*-test; PUFA, polyunsaturated fatty acids. *$P < 0.05$ and **$P < 0.01$ significantly different from controls (no fatty acid supplement) Trace: Fatty acid was not detected in all samples; the amount was <5 nanograms when present.

phospholipids; the PUFA content in the neutral lipids increased about 14-fold. Similar increases in total PUFA content were observed for cells supplemented with EPA and DHA. Although the increases in total PUFA content were similar for cells supplemented with GLA, EPA or DHA, the specific nature of the changes depended on the fatty acid with which the cells were incubated.

Figure 1 illustrates the effect of incubation of cells with increasing concentrations of GLA. Supplementation with 15–45 μM GLA not only resulted in a dose-dependent increase in the content of this fatty acid but also elevated the levels of dihomo-γ-linolenic acid (DGLA, 20:3n-6) and to a lesser extent arachidonic acid (AA, 20:4n-6) and docosatetraenoic acid (adrenic acid; DTA, 22:4n-6) (Fig. 1). Thus, the total DGLA/AA ratio also increased in a dose-dependent manner from 0 in the control group to 0.32 in the cells incubated with 45 μM GLA. While the quantities of GLA, DGLA, AA, and DTA increased in the cell phospholipids, the amounts of other unsaturated fatty acids such as palmitoleic acid (16:1n-7), OA, and linoleic acid (18:2n-6) decreased when the cells were exposed to increasing GLA concentrations (data not shown). In the neutral lipids, however, only a decrease in palmitoleic acid was observed. Docosapentaenoic acid (22:5n-6) was not detected in any of the samples analyzed.

Figure 2 shows the fatty acid profiles of cells following 15–45 μM EPA supplementation. Cells incubated with EPA showed dose-dependent increases in quantities of EPA and DPA (22:5n-3) in their phospholipids and neutral lipids as

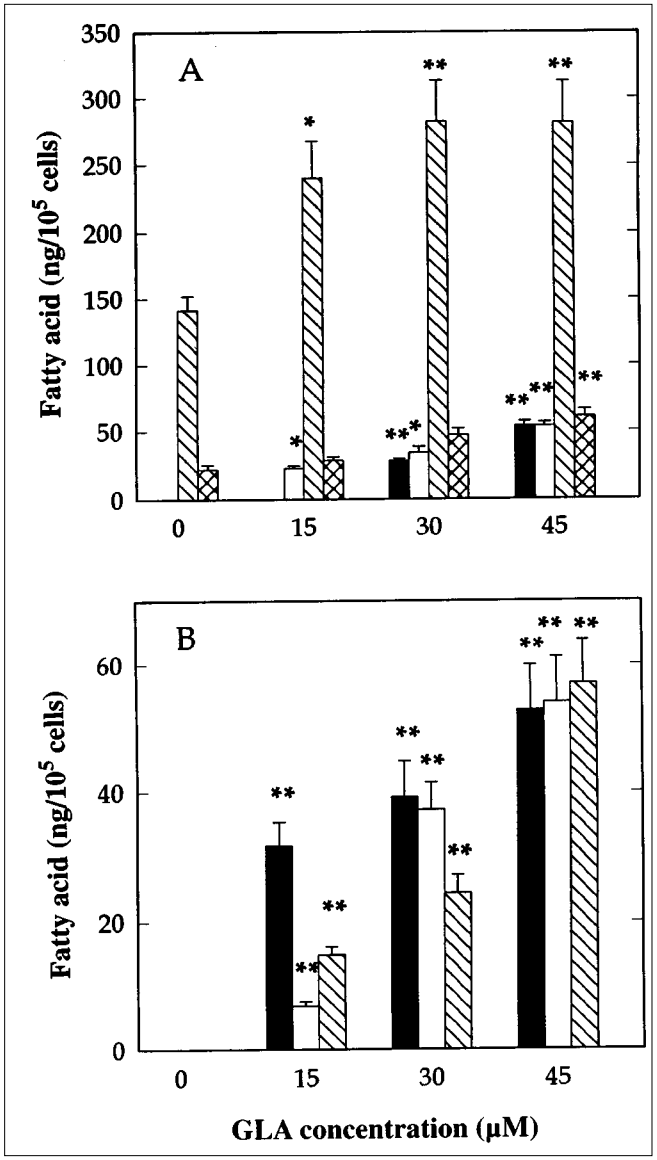

FIG. 1. Effect of 15–45 μM γ-linolenic acid (GLA) supplementation on the amounts of (■) GLA, (□) dihomo-γ-linolenic acid, (diagonally striped bar) arachidonic acid, and (cross-hatched bar) docosatetraenoic acid in (A) phospholipids and (B) neutral lipids of 36B10 cells. Cells were supplemented with GLA for 24 h. Values represent mean ± SE from four observations. *Significantly different from unsupplemented controls, $P < 0.05$; **significantly different from unsupplemented controls, $P < 0.01$.

compared with controls. DHA was not detected in any of these extracts.

The effect of 15–45 μM DHA supplementation on 36B10 cells is illustrated in Figure 3. Incubation of cells with 15–45 μM DHA increased the quantity of this fatty acid in the phospholipid and neutral lipid fractions. EPA and DPA were not detected in any of these cell extracts.

Cells incubated with 15–45 μM of OA showed a 10–25% increase in incorporation of this fatty acid into phospholipids and neutral lipids (data not shown). A decrease in the palmitoleic acid and linoleic acid content of phospholipids was also observed.

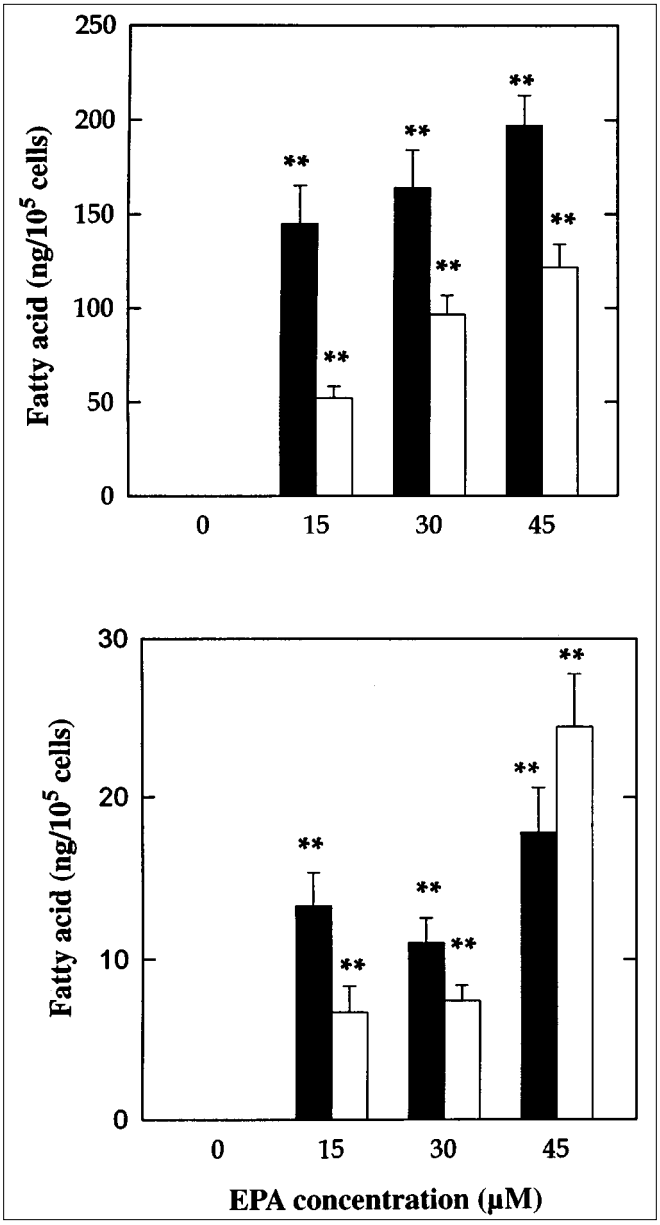

FIG. 2. Effect of 15–45 μM eicosapentaenoic acid (EPA) supplementation on the amounts of (■) EPA and (□) docosapentaenoic acid in (A) phospholipids and (B) neutral lipids of 36B10 cells. Cells were supplemented with EPA for 24 h. Values represent mean ± SE from four observations. **Significantly different from unsupplemented controls; $P < 0.01$.

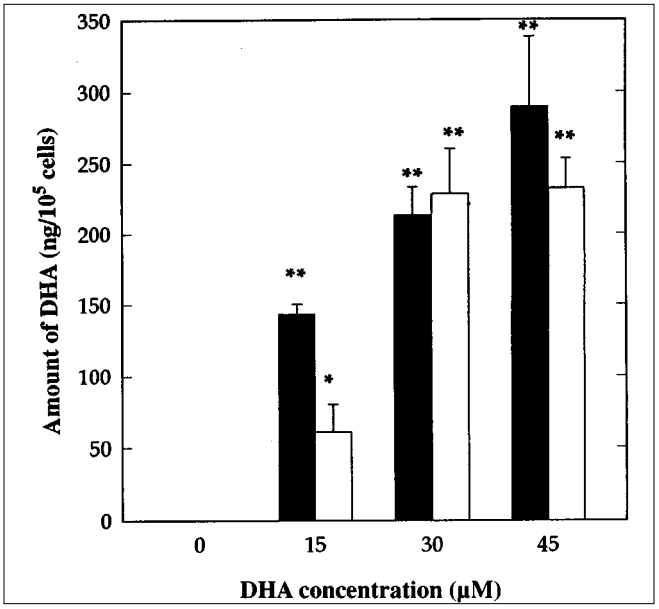

FIG. 3. Effect of 15–45 μM docosahexaenoic acid (DHA) supplementation on the amounts of DHA in the (■) phospholipids and the (□) neutral lipids of 36B10 cells. Cells were supplemented with DHA for 24 h. Values represent mean ± SE from four observations. *Significantly different from unsupplemented controls, $P < 0.05$; **significantly different from unsupplemented controls, $P < 0.01$.

Figure 4 shows the effects of GLA, EPA, DHA, and OA on the methylene bridge indices of phospholipids and neutral lipids of rat astrocytoma cells. GLA, EPA, and DHA supplementation resulted in a dose-dependent increase in the methylene bridge indices of phospholipids and neutral lipids (Fig. 4A, B and C). As observed in the case of total PUFA content and the fatty acid profiles, the extent of increase produced was greater in the neutral lipids. Further, the increases in methylene bridge index after fatty acid supplementation were similar for cells incubated with GLA or EPA (Fig. 4A and B). However, when the cells were incubated with 30 or 45 μM DHA, the methylene bridge indices were higher as compared with those obtained by supplementing the cells with similar concentrations of GLA or EPA (Fig. 4C). OA did not change the methylene bridge index of phospholipids or neutral lipids at any of the concentrations used (Fig. 4D).

Supplementation for 24 h with 15–45 μM GLA, EPA, or DHA produced only minor changes in the cholesterol and phospholipid content of cells (data not shown). Moreover, the cholesterol/phospholipid ratios did not change, except for cells supplemented with DHA, where a small decrease in cholesterol/phospholipid ratio was observed.

Effect of fatty acids on cell survival. Figure 5 shows that incubation of the 36B10 astrocytoma cells with GLA, EPA, and DHA throughout the experimental period reduced their clonogenic survival. Supplementing cells with 45 μM GLA and DHA decreased the surviving fraction of cells to 55.2 ± 8.8% and 64.8 ± 7.0% of the control value, respectively. EPA was extremely cytotoxic; supplementing with 15 μM EPA reduced the surviving fraction of cells to 25%. The cytotoxic effects of EPA increased in a dose-dependent fashion and at 45 μM EPA, no cells survived. OA was not cytotoxic at any of the concentrations used (Fig. 5).

Effect of fatty acids on the radiation response of 36B10 cells. The effect of supplementation of 36B10 cells with GLA, EPA, DHA, and OA prior to, during, and after irradiation on their response to radiation is shown in Figure 6. OA

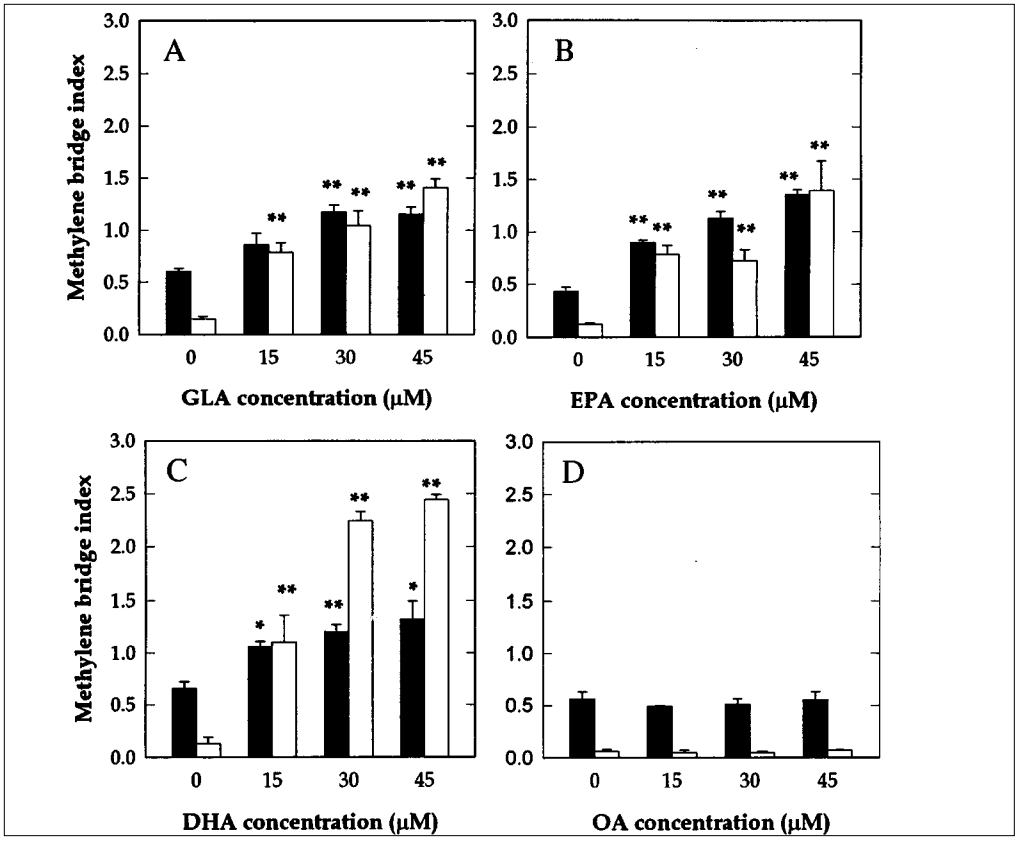

FIG. 4. Effect of (A) GLA, (B) EPA, (C) DHA, and (D) oleic acid (OA) supplementation on the methylene bridge index of the phospholipids (■) and neutral lipids (□) in 36B10 cells. Cells were supplemented with 15–45 μM of the fatty acid for 24 h. Values represent mean ± SE from four observations. *Significantly different from unsupplemented controls, $P < 0.05$; **significantly different from unsupplemented controls, $P < 0.01$. See Figures 1–3 for other abbreviations.

had no effect on survival when the cells were exposed to 0–10 Gy γ-rays (Fig. 6A). On the other hand, GLA (Fig. 6B), DHA (Fig. 6C), and EPA (Fig. 6D), when combined with radiation, led to a substantial increase in cell kill as compared with either radiation or these fatty acids alone. The increase in radiation-induced cell kill by EPA and DHA was significant at concentrations of 30 μM ($P < 0.05$; D_0 Gy = 1.97 ± 0.06) and DHA at 45 μM ($P < 0.01$; D_0 Gy = 2.26 ± 0.05), respectively. EPA was too cytotoxic at 45 μM to allow reliable estimates of additional effects of irradiation. GLA significantly enhanced the radiation response of the cells at concentrations ≥15 μM ($P < 0.01$). Thus, GLA was the most effective of these fatty acids in selectively increasing the sensitivity of cells to radiation across all dose levels. The mean (±SE) D_0 Gy value obtained for cells supplemented with GLA was significantly reduced ($P < 0.01$; D_0 Gy = 1.92 ± 0.04 for 45 μM GLA concentration) as compared with that of cells which received no fatty acid supplement (D_0 Gy = 2.70 ± 0.04).

Effect of the time of fatty acid supplementation on the radiation response of 36B10 cells. To determine whether supplementation with the fatty acids before, during, and after irradiation was essential for the cells to express a modified radiation response, the cells were incubated with fatty acid-supplemented media at different times prior to or after irradiation, and clonogenic survival was subsequently determined. Table 2 shows the effect of a single 24-h incubation of cells with GLA, followed by irradiation (5 Gy) immediately or at intervals of 24 or 48 h, on the survival of cells. None of the fatty acid concentrations, when supplemented for only 24 h, produced cytotoxic effects on their own. When cells were irradiated immediately after supplementation for 24 h with 15–45 μM GLA, they exhibited increased radiation-induced cell kill. However, with increasing interval between GLA supplementation and irradiation, the survival of the GLA-supplemented groups returned to control values. In similar experiments with EPA, DHA or OA, no increase in radiation induced cell kill was observed when the cells were incubated with these fatty acids only for the 24 h prior to irradiation (data not shown).

The radiation response of cells supplemented with 15–45 μM GLA or DHA after irradiation with 2.5–10 Gy γ-rays is shown in Figure 7. Addition of GLA (≥15 μM) or DHA (≥30

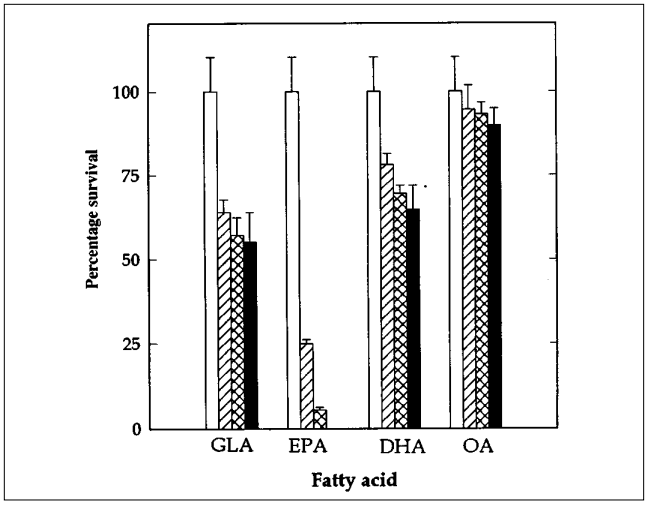

FIG. 5. Effect of GLA, EPA, DHA, and OA supplementation on the survival of 36B10 cells. Cells were supplemented with (diagonally striped bar) 15, (cross-hatched bar) 30, or (■) 45 μM of the fatty acid throughout the duration of the experiment. Control cells (□) received no supplemental fatty acid. Bars indicate values obtained from six separate cultures (mean ± SE). See Figures 1–4 for abbreviations.

μM) increased radiation-induced cell kill ($P \leq 0.01$). The enhanced cell kill increased with radiation dose and concentration of the fatty acid. The dose-response curves were similar to those obtained when the fatty acid was present before, during, and after irradiation (compare Fig. 6B and C with Fig. 7A and B). GLA and DHA also reduced the D_0 Gy values for the astrocytoma cells to 2.02 ± 0.04 ($P < 0.01$) and 2.05 ± 0.06 ($P < 0.01$), respectively (45 μM concentration), as compared with 2.70 ± 0.04 when the cells received no fatty acid supplement. In contrast, supplementation of 36B10 cells with EPA and OA after irradiation did not alter the radiation response of the cells (data not shown).

Effect of α-tocopherol acetate on the radiation response of GLA- and DHA-supplemented cells. α-Tocopherol acetate, on its own, did not affect the survival of the astrocytoma cells (data not shown). When added to GLA- or DHA-supplemented media however, it blocked the cytotoxic action of both the fatty acids (data not shown). Furthermore, the addition of 50 or 100 μM α-tocopherol acetate also blocked the enhanced radiation-induced cell kill caused by 45 μM GLA and DHA (Fig. 8).

TABLE 2
Effect of Time of Irradiation Following GLA Exposure on 36B10 Astrocytoma Cell Survival[a]

GLA concentration (μM)	Surviving fraction of cells		
	0 h[b]	24 h[b]	48 h[b]
Control	0.18 ± 0.015	0.18 ± 0.015	0.18 ± 0.015
15	0.13 ± 0.009*	0.17 ± 0.005	0.20 ± 0.028
30	0.11 ± 0.008*	0.14 ± 0.025	0.22 ± 0.018
45	0.09 ± 0.004**	0.11 ± 0.011*	0.19 ± 0.009

[a]Cells were supplemented for 24 h with 15–45 μM γ-linolenic acid (GLA) and returned to unsupplemented media. The cells were then irradiated at intervals of 0, 24, or 48 h thereafter with 5 Gy. Control cells received no GLA supplement. Each value represents mean ± SE from at least six separate cultures. All values have been normalized with respect to their respective unirradiated controls. *$P < 0.05$ and **$P < 0.01$ significantly different from the unsupplemented group.
[b]Interval in hours between 24 h GLA supplementation and 5 Gy irradiation.

DISCUSSION

The present results show that supplementation of astrocytoma cells with PUFA produces marked changes in the fatty acid composition of their phospholipids and neutral lipids. GLA, EPA, and DHA produce cytotoxic effects on the cells. Further, the radiation-induced cytotoxicity of these cells can be enhanced by GLA, EPA, or DHA supplementation.

Changes in fatty acid composition as a result of alterations in the type of fatty acid available have been reported *in vivo* and *in vitro* (15). However, most of these investigations have measured changes in fatty acid composition of total lipids or in phospholipids, and the effects on the cells have been mainly attributed to changes in membrane phospholipid composition (4). Our results show that in addition to altering the phospholipid content, PUFA supplementation produces marked changes in the fatty acid composition and methylene bridge index of the neutral lipids. In fact, the relative changes produced in neutral lipids are much greater than those produced in phospholipids. These results suggest that neutral lipid composition also might play a role in the effects of PUFA on tumor cell properties or their responsiveness to anticancer therapy.

Supplementation with each of the three PUFA produced some cytotoxicity, even without subsequent irradiation. This may be due to a lesser ability of astrocytoma cells to protect themselves against the level of free radical formation that occurs under basal conditions. Antioxidant enzymes such as superoxide dismutase, catalase, and glutathione peroxidase are the primary mechanisms for scavenging reactive oxygen species. The activities of these antioxidant enzymes are decreased in many tumor cells (22–24). Tumor cells have a lower PUFA content than nonmalignant tissues (25,26), possibly as a compensation that protects against their sensitivity to free radicals. In addition, tumor cells often are also deficient in fatty acid Δ-6 desaturase, an enzyme that is required to further desaturate linoleic and α-linolenic acid to metabolic products such as GLA, AA, and EPA (27). The content of highly unsaturated fatty acids is low in these tumors as a result of this, probably accounting for the fact that tumor cells are reported to exhibit less lipid peroxidation than normal cells even though they are more inherently sensitive to oxidants (28,29). The PUFA in these cells is replaced by OA, which is not a highly reactive substrate for lipid peroxidation (30,31). Preliminary studies in our laboratory show that the OA content of normal rat astrocytes is 75% less than in the 36B10 astrocytoma when grown under similar conditions. Brain tumors also contain more OA and less PUFA than normal brain tissue (26)

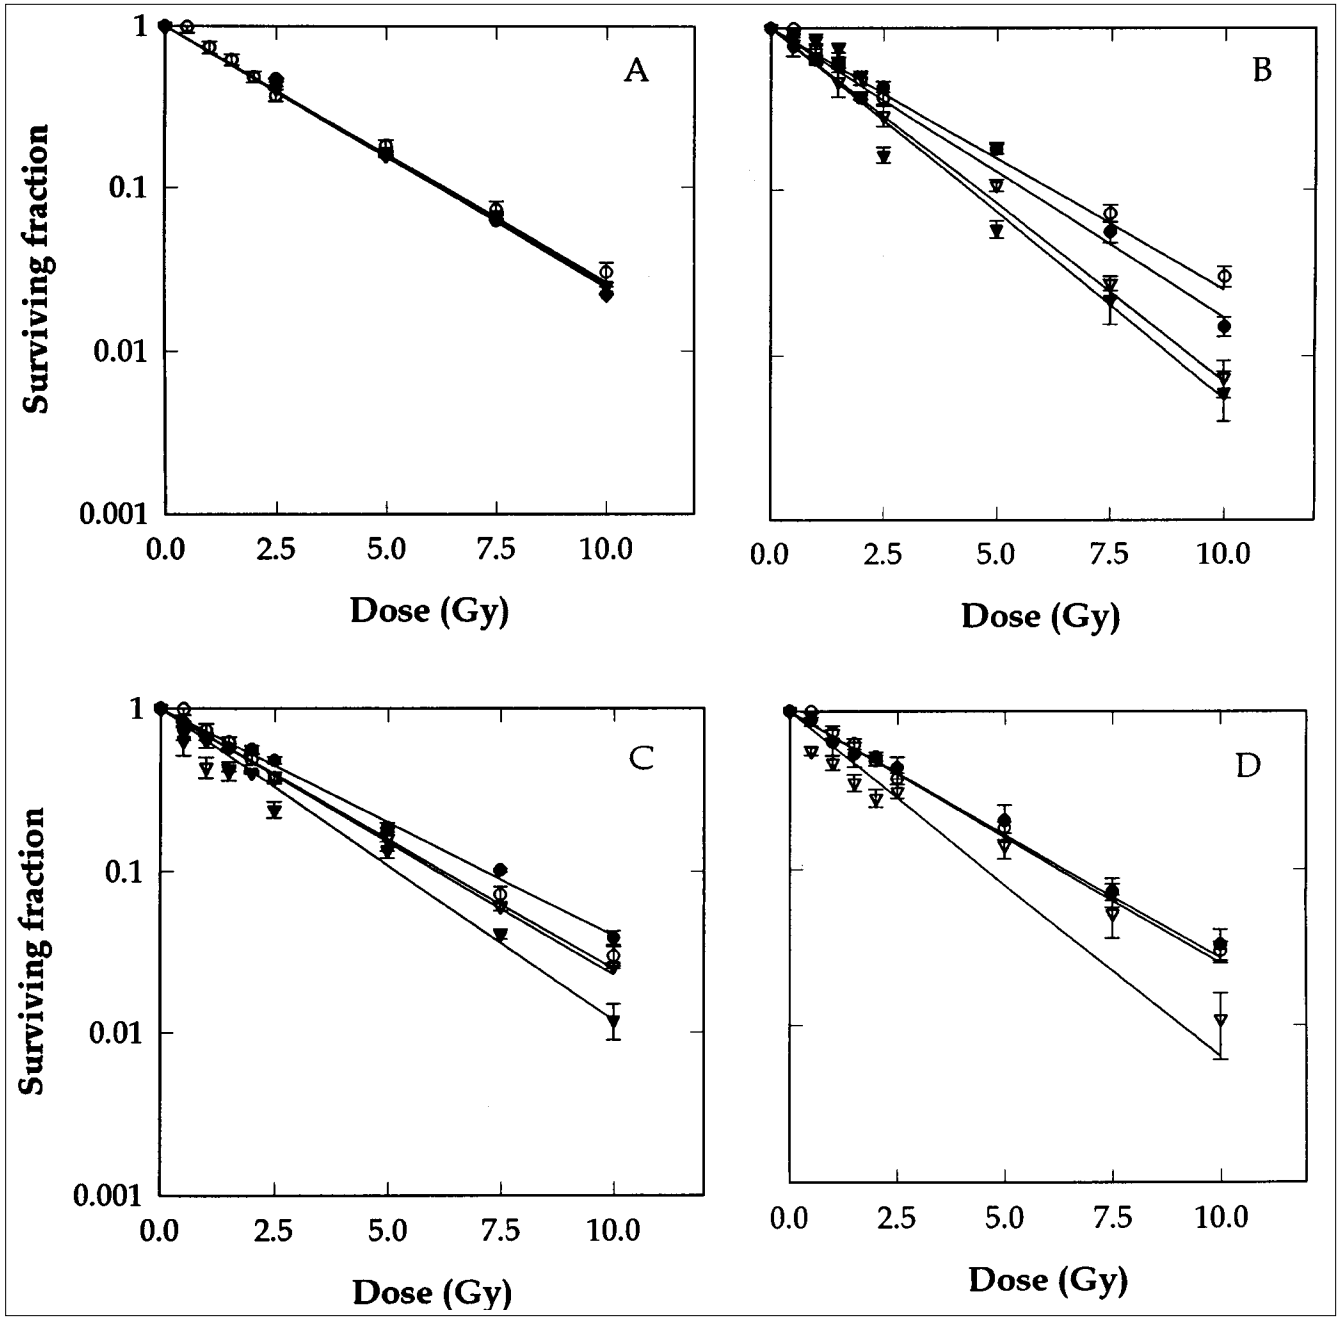

FIG. 6. Effect of (A) OA, (B) GLA, (C) DHA, and (D) EPA supplementation on the radiation response of 36B10 cells. Cells were supplemented with (●) 15, (▽) 30, or (▼) 45 μM of the fatty acid for 24 h prior to and during irradiation and were continued in the fatty acid-enriched media throughout the duration of the experiment. Control cells (○) received no supplemental fatty acid. The symbols indicate values obtained from six separate cultures (mean ± SE). The lines were drawn using scattered linear regression analysis. See Figures 1–4 for abbreviations.

Supplementation of the astrocytoma cells with GLA, EPA, or DHA provided these cells with an excess of substrate for lipid peroxidation. The lesser ability of the astrocytoma cells to neutralize the resulting increase in free radical formation in response to ordinary levels of oxidant stress may account for the PUFA-induced cytotoxicity seen in the absence of radiation. Indeed, providing the cells with the α-tocopherol acetate to increase membrane antioxidant defenses blocked the cytotoxic effects of GLA and DHA. This supports our hypothesis that the cytotoxic effect is in part due to increased oxidative stress resulting from PUFA supplementation. While GLA and DHA at the concentrations used produced a relatively small cytotoxic effect under basal conditions, EPA was extremely cytotoxic to the cells. The reason for the greater toxicity of EPA is not known and needs to be investigated. Further, although the increase in methylene bridge index was

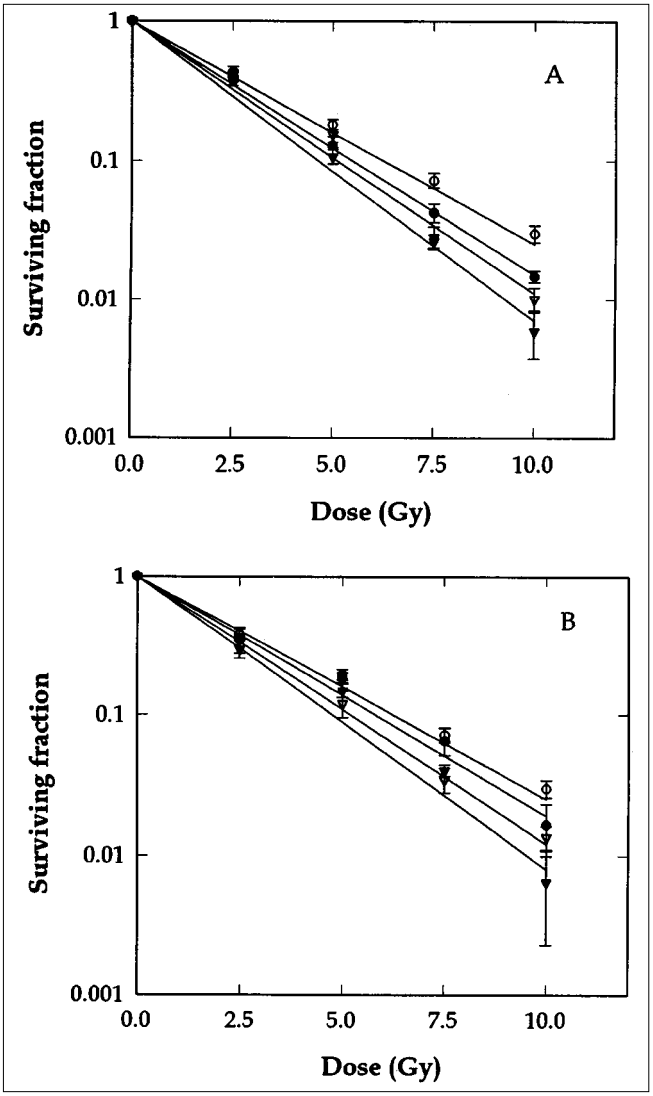

FIG. 7. Effect of (A) GLA, and (B) DHA supplementation post-irradiation on the radiation response of 36B10 cells. Cells were supplemented with (●) 15, (▽) 30, or (▼) 45 μM of the GLA or DHA within 1 h following irradiation and were incubated in the fatty acid-enriched media throughout the remainder of the experiment. Control cultures, ○, were not exposed to supplemental fatty acid. The symbols indicate values obtained from six separate cultures (mean ± SE). The lines were drawn using scattered linear regression analysis. See Figures 1 and 3 for abbreviations.

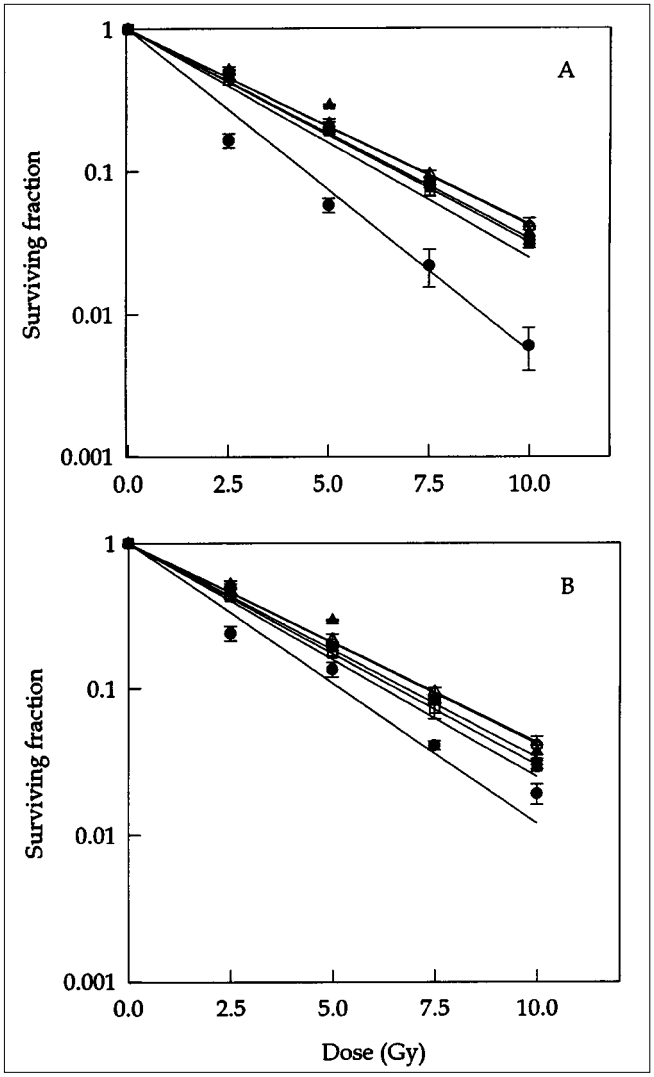

FIG. 8. Effect of α-tocopherol acetate on the radiation response of 36B10 cells enriched with (A) GLA, and (B) DHA. Cells were incubated in 50 or 100 μM α-tocopherol acetate with or without 45 μM GLA or DHA. (○) Controls, (●) 45 μM GLA or DHA, (▽) 50 μM α-tocopherol acetate, (▼) 100 μM α-tocopherol acetate, (□) 50 μM α-tocopherol acetate + GLA or DHA, (■) 100 μM α-tocopherol acetate + GLA or DHA. The symbols indicate values obtained from six separate cultures (mean ± SE). The lines were drawn using scattered linear regression analysis. See Figures 1 and 3 for abbreviations.

greater for cells supplemented with DHA, this fatty acid was only moderately cytotoxic. These results suggest that the cytotoxic effects of PUFA may not be the result of a single straightforward mechanism such as membrane disruption due to lipid peroxidation, but may also involve other mechanisms such as generation of biologically active fatty acid oxidation products.

DHA increased the radiation response of the astrocytoma cells only at a concentration of 45 μM. Although EPA increased the radiation response of cells at 30 μM, this fatty acid on its own was extremely cytotoxic. Data on the clonogenic cell survival assay using EPA alone yielded very few colonies. Therefore, the results using EPA and radiation must be interpreted with caution; without including EPA, GLA was most effective in increasing the responsiveness of the astrocytoma cells to radiation at concentrations ≥15 μM. There have been several reports describing antitumor effects of GLA (32-33). The cytotoxic effect of GLA in tumor cells is accompanied by increased thiobarbituric acid-reactive substances and thought to be mainly the result of increased generation of free radicals and lipid peroxidation (33,34). Free radical release and lipid peroxidation in cells is further aug-

mented when PUFA-supplemented cells are exposed to an oxidant such as iron (35,36).The enhancement in radiation-induced cell kill by GLA observed by us could be the result of radiation, like iron, acting as an oxidant which induces free radical formation and lipid peroxidation.

An important aspect of the antitumor effects of PUFA is that PUFA cause little or no damage to normal cells. *In vivo* studies on modulation of radiation-induced skin (37,38) and central nervous system (39) injury show that dietary PUFA significantly decrease the severity of radiation-induced injury to these normal tissues. Further, preliminary *in vitro* studies in our laboratory using GLA and DHA suggest that these PUFA on their own, or when combined with radiation, exert no deleterious effects on normal rat astrocytes. This suggests that GLA and DHA might selectively increase the radiation response of astrocytomas without causing measurable normal brain toxicity, a finding that has potential therapeutic implications.

In summary, supplementation of cells with 15–45 μM GLA, EPA, or DHA produces significant alterations in the lipid composition of 36B10 rat astrocytoma cells. *In vivo* studies also indicate that dietary supplementation with PUFA can alter PUFA composition of not only normal brain tissue (40,41) but also that of intracerebrally implanted tumor tissue (42). Our results indicate that such alterations in fatty acid composition of brain tumors might make these tumors more susceptible to therapy with radiation. This suggests that PUFA may be potential tools for improving the efficacy of radiotherapy for certain malignant brain tumors.

Incorporation of Long-Chain n-3 Fatty Acids in Tissues and Enhanced Bone Marrow Cellularity with Docosahexaenoic Acid Feeding in Post-Weanling Fischer 344 Rats

Trevor G. Atkinson, Heather J. Barker, and Kelly A. Meckling-Gill*

Department of Human Biology and Nutritional Sciences, Animal Science and Nutrition Building, University of Guelph, Guelph, Ontario, N1G 2W1, Canada

ABSTRACT: We wanted to examine the effects of an oil rich in docosahexaenoic acid (DHA), without eicosapentaenoic acid, on the composition of membrane phospholipid in a variety of tissues. Our *in vitro* studies had previously shown that DHA could modify glucose and nucleoside transport in cells in culture and also increase selectivity of the nucleoside drug, arabinosylcytosine (araC) toward tumor cells. Here we wanted to examine what effect DHA supplementation would have in the whole animal in terms of the chemosensitivity of normal bone marrow, the dose-limiting tissue during chemotherapy, to araC. The purpose was to determine whether fatty acid supplementation might be useful as an adjuvant to chemotherapy. We fed diets containing 5% (w/w) low fat–corn oil (LF–CO group), 10% moderate fat–safflower oil (MF–SO group), or 10% DHASCO™ (MF–DHA group) to weanling Fischer 344 rats for 8–9 wk. Feed intake and growth were not different between the different diets. Similarly, treatment of animals with the chemotherapeutic drug araC did not differentially affect growth, feed intake, or tissue fatty acid composition for the different diet groups. Fatty acid compositions of bone marrow, liver, red blood cells, plasma phospholipid and triglyceride, as well as skeletal and cardiac muscle, were substantially different between the dietary groups. The DHASCO™ oil contained 46%DHA (22:6n-3) and resulted in profound incorporation of DHA in all tissues examined. The most dramatic response was seen in skeletal muscle of MF–DHA fed animals where DHA represented 46% of membrane phospholipid fatty acids. This is likely to have consequences to muscle function. Although DHASCO™ contains a similar level of saturated fatty acids (42%), few differences in saturates were noted between the various dietary groups for most of the tissues examined. Both LF–CO and MF–SO diets were hypercholesterolemic, and the LF–CO was also hypertriglyceridemic compared to the chow-fed animals. Animals fed the MF–DHA diet had the lowest triglyceride levels of any of the treatment groups and cholesterol levels comparable to chow-fed animals. MF–DHA had substantially higher numbers of colony-forming units–granulocyte macrophage (CFU–GM) as reflected in a twofold higher bone marrow cellularity than either chow or LF–CO animals, suggesting expansion of the bone marrow compartment with DHA feeding. Although higher than LF–SO, the number of CFU–GM in MF–SO animals was not significantly higher than animals fed chow. Bone marrow from LF–CO animals appeared to be more resistant to araC treatment than either MF group. Thus, DHA, fed as DHASCO™, has advantages over low or moderate n-6 diets and chow as it is has both hypolipidemic- and bone marrow-enhancing properties in weanling Fischer 344 rats. This suggests that DHA supplementation may be useful in adjuvant chemotherapy.

Lipids 32, 293–302 (1997).

Populations that consume a high proportion of fish and aquatic mammals such as Greenland Inuit and Japanese tend to have lower incidence of a number of diseases including coronary artery disease and mammary and colon cancers (1, for review see 2). The long-chain ω3 polyunsaturated fatty acids, eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3) have been suggested to be the major dietary constituents responsible for reducing the incidence of chronic disease. Recently, intervention trials with fish oil supplements have shown hypotriglyceridemic effects in hyperlipidemic subjects and reduced the incidence and progression of tumors in a number of animal models, human cell lines, and in one study of human metastasis (3–10). The mechanisms by which ω3 fatty acids achieve their putative protective activity in cardiovascular disease development are being intensively investigated and presumably include their activity as hypotriglyceridemic agents and in altering the composition and number of lipoproteins in the circulation. The ω3 fatty acids can also modulate the production of eicosanoids and prostaglandins (reviewed in 11) influencing immune responses and cellular growth and differentiation processes critical to cardiovascular disease and tumor development. Purified EPA has been tested in animal studies (12,13), and on some human cell lines (14,15), but there are

few reports on the specific action of purified DHA on adolescent animal growth, as a hypolipidemic agent or as a cancer-preventive agent. Neither has the possible use of DHA as an adjuvant chemotherapeutic agent been extensively studied in clinical or experimental animal models.

We recently demonstrated that dietary fish oil results in decreased rates of uptake of nucleosides into human erythrocytes and this correlated with changes in the fatty acid composition of membrane phospholipids in these cells (16). Our *in vitro* results comparing murine leukemia cells to normal bone marrow-derived macrophages showed that both DHA and EPA sensitized L1210 leukemia cells to the nucleoside drug arabinosylcytidine (araC) and the anthracycline drug adriamycin (17). In another study, we reported that purified DHA inhibited growth of transformed rat-2 fibroblasts in culture and additionally protected normal rat-2 fibroblasts from araC (18). The n-6 fatty acids linoleic and linolenic acids had no such activity. The current trial set out to determine whether changes in drug toxicity observed *in vitro* using purified DHA, would be mimicked in whole animal feeding of a DHA (EPA-free) diet. In our current investigation, weanling Fischer 344 rats were fed a 5% n-6 fat, 10% n-6 fat, or DHA-rich diet (10% fat) for two months. One week before the end of the trial, one-half of the animals were treated with a single six-day course of araC. Toxicity indices, including hair loss, diarrhea, and bone marrow suppression, were then compared between dietary treatment groups. Because DHA feeding in the absence of EPA has not been extensively examined, our study design also allowed us to assess the hypolipidemic effects of DHA directly and to examine specific tissue distribution of this fatty acid and its effects on overall fatty acid composition of a variety of tissues.

MATERIALS AND METHODS

Materials. Weanling male Fischer rats were purchased from Harlan Sprague-Dawley, Inc. (Indianapolis, IN). Diet ingredients were purchased from the following sources: DHASCO™ (a gift from Martek Biosciences Corp., Columbia, MD), corn oil (Mazola, local distributor), safflower oil (President's Choice, local distributor), minerals (BDH, Pool, England, and Fisher, Fairlawn, NJ), ferric citrate (Sigma, St. Louis, MO), cornstarch (Casco, Etobicoke, Ontario, Canada), casein (ICN, Aurora, OH), and all other diet components (United States Biochemicals, Cleveland, OH). Cholesterol (procedure 352) and triglyceride (procedure 339) quantitation kits were obtained from Sigma Chemical Co.

Animal care and feeding. Three-week-old male Fischer rats were received, weighed, and acclimated on Purina rat chow for 3 d. Animals were housed individually in wire-bottom cages and provided with 15-cm diameter plastic tubing for environmental enrichment. Animals were maintained in a climate-controlled animal facility with 12-h light/12-h dark cycle. Procedures were approved by the University of Guelph, Animal Welfare Committee, in accordance with the Guidelines from the Canadian Council on Animal Care. On experimental day 0, animals were weighed and randomly assigned to dietary treatment groups (16–18 animals/group). An additional group of 11 animals was fed Purina rat chow *ad libitum.* Dietary treatment groups were designated: low fat–corn oil (LF–CO), moderate fat–safflower oil rich (MF–SO), and moderate fat–docosahexaenoic acid rich (MF–DHA). The energy composition of the LF–CO, MF–SO, and MF–DHA and chow diets were 11.7, 25.6, 25.6, and 11.3% of energy as fat, 67.6, 53.7, 53.7 and 62.9% of energy as carbohydrate, for each diet, respectively. All semipurified diets contained 20.7% of energy from protein with a total energy content of 16.2 MJ/kg diet. Chow contained 25.8% of energy from protein and a total energy content of 14.9 MJ/kg diet. The complete composition of the semipurified diets is shown in Table 1. Diets were prepared weekly by gassing with nitrogen and vacuum packing and were then stored at –20°C. Oxidation status of feeds was estimated by the TBARS assay and were well below acceptable limits (19) for CO, 0.4; MF–SO, 0.4; MF–DHA, 1.1 nmol malondialdehyde equivalents/g diet.

Animals were allowed free access to diets, and intake and weight gain were measured frequently over an 8-wk period. Feed was replaced daily. Seven days before the end of the study, half of the animals in each diet (except chow) were assigned to receive araC while the other half of the animals received saline injections (Therefore final animal numbers were 8–9 per group). Animals were injected once per day for six

TABLE 1
Diet Composition[a]

Component	LF–CO	MF–SO	MF–DHA
Casein	200	200	200
DL methionine	3	3	3
Choline bitartrate	2	2	2
Vitamin mix[b]	10	10	10

Corn starch	550	415	415
Corn oil	50	10	10
Safflower oil	—	100	—
DHASCO™[d]	—	—	100

[a]Grams per kilogram diet; MF–DHA, moderate fat–docosahexaenoic acid; LF–CO, low fat–corn oil; MF–SO, MF–safflower oil.
[b]Vitamin mix contains the following ingredients per kg mixture: 600 mg thiamin-HCl, 600 mg riboflavin, 700 mg pyridoxine-HCl, 3 g nicotinic acid, 1.6 g D-calcium pantothenate, 200 mg folic acid, 20 mg D-biotin, 1 mg cyanocobalamin, 400,000 IU vitamin A (800 mg retinyl palmitate), 5,000 IU vitamin E (5 g dl-α-tocopherol acetate), 2.5 mg cholecalciferol, 5.0 mg menaquinone, sucrose finely powdered to make up to 1000 g.
[c]Mineral mix contains the following ingredients per kg mixture: 500 g calcium phosphate dibasic, 74 g sodium chloride, 220 g potassium citrate monohydrate, 52 g potassium sulfate, 24 g magnesium oxide, 3.5 g manganous carbonate, 6 g ferric citrate, 1.6 g zinc carbonate, 0.3 g cupric carbonate, 0.01 g potassium iodate, 0.01 g sodium selenite, 0.55 g chromium potassium sulfate and the remaining mixture was made up to 1000 g with sucrose.
[d]The composition of the DHASCO™ was as follows: 10:0, 0.8%; 12:0, 6.2%; 14:0, 19.1%; 16:0, 16.1%; 16:1, 1.7%; 18:0, 0.3%; 18:1, 10.3%; 18:2n-6, 0.5%; 22:6n-3, 44.6%. Antioxidants in the oil were 0.005% tocopherol and 0.025% ascorbyl palmitate.

days subcutaneously with 50 mg/kg araC or an equivalent volume of saline solution. The injection sites were rotated between left and right flank each day. At the end of the experimental period, animals were drug-free for 24 h, fasted for 12 h, euthanized using metophane anesthetic followed by cardiac puncture and decapitation. An aliquot of the blood collected by cardiac puncture was frozen for future analysis or placed in tubes containing 0.129 M buffered sodium citrate (Vacutainer tubes; Becton Dickinson #6419, Franklin Lakes, NJ) and centrifuged to separate red cells and plasma and stored at −20°C.

Immediately after decapitation samples of liver, skeletal muscle (red quadriceps) and heart were recovered and quick frozen in liquid nitrogen. Tissues were stored in liquid nitrogen until they could be analyzed.

Bone marrow preparation and CFU-GM assay. Immediately after decapitation, femurs were recovered from the hind limbs and two–three aliquots (5 mL each) of Iscove's Modified Dulbecco's Medium (IMDM) containing 50 units/mL streptomycin and penicillin, 100 µg/mL gentamycin (Gibco-BRL, Burlington, Ontario, Canada) and 15% fetal bovine serum (FBS, Gibco-BRL) was flushed through (syringe and an 18-gauge needle) the marrow cavity to dislodge the marrow into a sterile 15-mL tube. Complete (at least 95%) removal of marrow from the femur was confirmed by visual and microscopic examination. Cells were dissociated by rapidly pipetting up and down and an aliquot counted using a Coulter Counter (Model ZM; Coulter Electronics, Burlington, Ontario, Canada) equipped with a channelizer. Confirmation that a single cell suspension was achieved was confirmed using a hemocytometer and microscope. Using the channelizer, at least three populations of cells could be identified by their differing size distribution profiles. Cells were washed twice in complete medium, counted and plated at 5×10^5 cells per dish (60 mm culture dish containing 5 mL) in 0.8% methylcellulose containing 20% FBS, antibiotics (as above), 10% WEHI-3 conditioned medium (containing the growth factors interleukin-3 and granulocyte–macrophage colony stimulating factor) and 10% L-cell conditioned medium (containing Macrophage colony stimulating factor at final concentration of 2000 units/mL). Seven days later the number of colonies in each of triplicate dishes for each animal was counted using an inverted light microscope. Colonies were scored blind using a cutoff of 16 cells/colony. The remaining bone marrow cells not plated were washed twice with IMDM and frozen in liquid nitrogen at 5×10^7 cells/mL in IMDM.

Fatty acid and lipid analyses. Bone marrow cells that had been washed a total of four times (two times in PBS and two times in IMDM) were frozen at the time animals were euthanized. Red cells were prepared by spinning in a clinical benchtop centrifuge and removing plasma. On one sample of plasma, total triglyceride (procedure #339; Sigma) and cholesterol (procedure #352; Sigma) estimates for all animals were made according to manufacturer's instructions. Red cells were washed three times in PBS, and the pellet frozen in liquid nitrogen. Frozen tissues or bone marrow and red blood cell samples were thawed, and total lipid was extracted according to the method of Bligh and Dyer (20). The phospholipid and triglyceride fractions were separated from other lipids by thin-layer chromatography on Silica Gel G Redi/Plates® (Fisher, Unionville, Ontario, Canada) developed with heptane/isopropyl ether/acetic acid (60:40:3). The origin, containing phospholipids, and the triglyceride fraction were scraped after visualization with 0.1% aminonaptholsulfonic acid and after elution from the cellulose, 3 µg 17:0 standard was added to the eluent and fatty acids methylated by adding 3 mL of methylating reagent (94% vol/vol methanol, 6% vol/vol sulfuric acid) and incubation at 80°C for 2 h. Ether extracts of fatty acids were prepared, ether removed, and fatty acids dissolved in carbon disulfide. Methylated fatty acids were analyzed by gas phase chromatography (21) using a 30-meter DB225 megabore column (J&W Scientific Inc., Folson, CA). Peaks were identified by comparison with a nerve standard containing fatty acids from 12 to 24 carbons in length.

RESULTS

Weanling Fischer 344 rats were acclimated for 3 d on Purina rat chow before being switched to one of the three experimental diets. Over the 8–9-wk feeding period, there were no differences in the consumption or growth patterns on any of the experimental diets (data not shown). During the araC drug treatment phase (the last six days of the experimental protocol), there was very modest weight loss that was not significantly different between diets (6.2, 4.3, and 7.6 g for LF–CO, MF–SO, and MF-DHA, respectively). We observed only minimal hair loss from araC-treated animals and none of the animals developed diarrhea or substantive anorexia.

We examined the plasma cholesterol and triglyceride levels from all three dietary groups including saline- and araC-treated animals as well as from control chow-fed rats. Drug treatment had no effect on either cholesterol or triglyceride levels (Table 2). Both moderate fat (25.6% of calories from fat) diets resulted in substantially lower total cholesterol and triglyceride levels than in the LF diet (11.7% of calories from fat). The MF–SO group had plasma cholesterol levels 19% lower than the LF–CO group. MF–DHA rats had cholesterol levels 48% lower than the LF–CO group and 41% lower than the MF–SO group. Chow-fed animals had cholesterol values essentially identical to those in DHA-fed animals and lower than both n-6 groups. The MF diets produced triglyceride levels that were 44% (MF–SO) and 49% (MF–DHA) lower than the LF–CO group. On the other hand, chow-fed animals had intermediate triglyceride levels that were not significantly different from any of the experimental diets. Therefore, both the safflower- and DHA-rich diets, despite being quite high in fat, still resulted in substantial hypolipidemia when compared to the LF–CO diet and gave similar lipemic responses to those seen in chow fed (4.5% dietary fat) animals.

Both plasma phospholipid and triglyceride fatty acid compositions were remarkably susceptible to our dietary manipulations (Table 3). In particular arachidonic acid (AA, 20:4n-6) was decreased by 92% by the MF–DHA diet rela-

Cholesterol and TG Levels in Plasma from Rats Fed the Experimental Diets[a]

	LF–CO saline ($n = 7$)	LF–CO araC ($n = 7$)	MF–SO saline ($n = 9$)	MF–SO araC ($n = 9$)	MF–DHA saline ($n = 9$)	MF–DHA araC ($n = 7$)	Chow ($n = 11$)
Chol (mg/dl)	105 ± 9^{c}	96 ± 4^{c}	75 ± 7^{b}	78 ± 7^{b}	44 ± 4^{a}	49 ± 4^{a}	44 ± 2^{a}
TG mg/dl)	$172 \pm 16^{b,c}$	198 ± 24^{c}	114 ± 13^{a}	111 ± 17^{a}	107 ± 10^{a}	95 ± 15^{a}	$137 \pm 7^{a,b}$

[a]Chol, cholesterol; TG, triglyceride; values represent means ± the standard error of the mean. Values not sharing a superscript within a row are statistically different by analysis of variance followed by Student-Newman Keuls, $P < 0.05$. See Table 1 for abbreviations.

tive to the LF–CO and MF–SO diets. Docosatetraenoic acid (DTA, 22:4n-6) was decreased to undetectable levels and docosapentaenoic acid (DPA, 22:5n-6) by 90% in MF–DHA-fed animals. Predictably, DHA levels were 5–8-fold higher in the phospholipid fraction from MF–DHA animals compared to both the LF–CO and MF–CO groups. EPA levels were similarly affected. Because there is no detectable EPA in the DHASCO™ oil, this latter observation suggests considerable retroconversion of DHA back to EPA.

The fatty acid composition of plasma triglyceride was affected in a similar fashion to plasma phospholipid (Table 3). We observed a higher level of linoleic acid (LA, 18:2n-6) in the MF–SO group compared to the LF–CO group. This difference may be due to the different content of LA in CO (61%) compared to SO (78%). LA levels were lowest in the MF–DHA rats. AA levels were affected in a similar manner to LA levels, highest in MF–SO, intermediate in LF–CO, and lowest in MF–DHA fed animals. Changes in triglyceride EPA, DPA, and DHA were analogous to those seen in the phospholipid fraction of plasma.

Of all of the tissues examined, skeletal muscle and heart appeared to be the most profoundly affected in terms of in-

[a]Following termination of the feeding trial tissues were excised and quick frozen in liquid nitrogen. Lipids were extracted as described in the Materials and Methods section. For all tissues, the fatty acid composition as a percentage of total fatty acids in the phospholipid fraction is given. For serum, the fatty acid composition of both the phospholipid and triglyceride fractions was examined. Values represent means ± the standard errror of the mean. Numbers of animals examined is given in brackets. Values in a row not sharing a superscript are significantly different by analysis of variance followed by Student-Newman-Keuls post-test, $P < 0.05$; n.d. = not detected.

[a]See Table 3 footnote.

corporation of long-chain PUFA reflective of the dietary oil used (Table 4). Oleic acid (OA, 18:0), LA, and docosatetraenoic acid (DTA) levels were modestly decreased, while AA and DPA levels were profoundly depressed (by nearly 95% for AA and to undetectable levels for DPA) in MF–DHA relative to the other groups. These decreases in n-6 PUFA are completely compensated for by substantial increases in EPA, and more importantly DHA, in MF–DHA-fed animals. DHA accounted for a remarkable 42 and 44.6% of the fatty acids in phospholipid from heart and quadriceps muscle, respectively. For muscle, this corresponds exactly to the composition of the oil supplement.

Liver fatty acid composition was also markedly affected by the dietary oil used (Table 5). OA levels were decreased in MF–DHA animals, and AA and DPA levels were markedly decreased relative to the LF–CO and MF–SO groups. Unlike the other tissues, however, LA and DTA levels were not lower in MF–DHA relative to the LF–CO and MF–SO groups. Predictably, DHA levels were much higher in the MF–DHA group compared to both n-6 rich diets. EPA levels in the liver were much higher than in any other tissue examined, suggesting that considerable retroconversion of DHA to EPA had occurred in this tissue. We also noted increases in the short-chain saturated fatty acids, (14:0) and palmitic acid (16:0) which may have been an attempt by the liver to moderate fluidity changes induced by the substantial incorporation of long-chain PUFA in response to DHA feeding.

[a]See Table 3 footnote.

The final two tissues we examined were red blood cells and bone marrow (Table 6). Both tissues, like the others described, were responsive to dietary lipids. We observed lower concentrations of stearate, and markedly lower AA, DTA, and DPA levels in the MF–DHA relative to both the LF–CO and MF–SO groups, with little difference between blood and bone marrow. DHA and EPA levels were also much higher in DHA-fed animals relative to the other n-6 rich groups.

Overall, the fatty acid profiles of the various tissues appear to be substantially altered by dietary fatty acids. Although differences in fatty acid compositions between the LF–CO and MF-SO group were observed, these were often very small, particularly when compared to the MF–DHA group. No differences in fatty acid composition were observed for animals treated with the chemotherapeutic agent, araC (not shown). Thus, the major determinant of the lipid composition of the various tissues appeared to be the quality of the fat in the diet.

Because one of the long-term goals of this research is to examine the utility of lipid supplementation both as an adjuvant in cancer chemotherapy and also potentially as a chemopreventive agent, it was important to know what the effects of DHA might be on some host tissues. Since one of the major deleterious consequences of drug therapy is bone marrow suppression, we examined not only the fatty acid composition but also the bone marrow cellularity, colony-forming ability, and the Coulter channelizer profiles of the extracted bone marrow.

All animals treated with araC exhibited moderate neutropenia with no differences between diet groups (not shown). However this observation alone tells us little about the ability of this animal to repopulate this compartment. A more direct measure of this capacity is assessment of the bone marrow compartment. Total bone marrow yield was substantially affected by the level of fat in the diet. The untreated, MF–DHA group had twice the number of bone marrow cells per femur, whether expressed as cells/femur or cells/femur/g body weight when compared to chow-fed animals or those on the LF–CO diet (Fig. 1A). There was also a trend for the DHA-fed animals to have a higher bone marrow cellularity than the MF–SO group (P = 0.068). Although the differences in the araC-treated groups were not statistically significant, once again there was a trend for the MF–DHA-fed animals to have higher bone marrow yields than both the n-6 rich diets (P = 0.077 vs. MF–SO and P = 0.10 vs. LF–CO). Both MF groups treated with araC had lower bone marrow cell yields than their saline-injected counterparts, and although the araC LF–CO group appeared to have bone marrow cell numbers that were lower than saline-injected animals, this did not reach statistical significance (Fig. 1A).

We measured the ability of these bone marrow preparations to support the formation of CFU–GM. Aliquots of

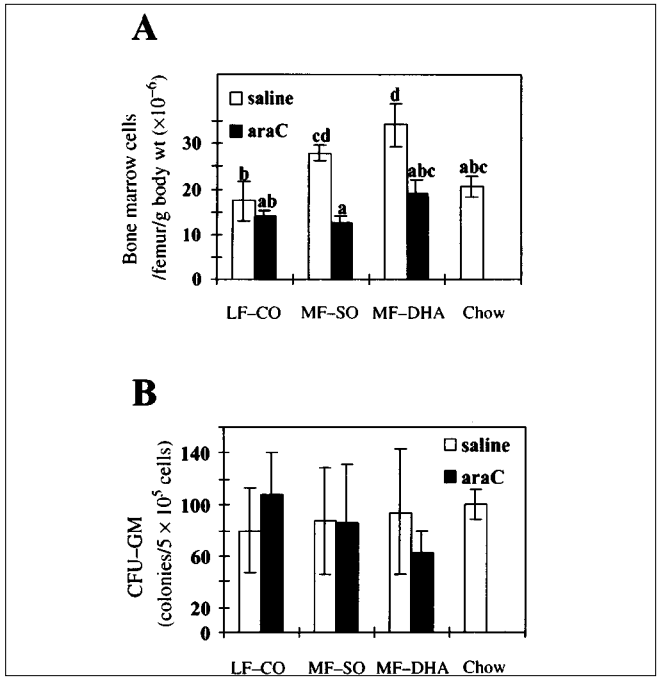

FIG. 1. Bone marrow cellularity and granulocyte/macrophage colony-forming ability. Seven days before the end of the trial animals were injected daily with saline or 50 mg/kg arabinosylcytosine as described in the Materials and Methods section. Injections were stopped 24 h before animals were sacrificed. On the final experimental day, bone marrow was harvested and the total number of cells per femur estimated by Coulter counting (A). Following washing, three aliquots of each bone marrow sample were plated in methylcellulose and granulocyte/macrophage colonies counted seven days later (B). Bars represent the mean values ± standard error of the mean. Bars not sharing a letter are statistically different by analysis of variance followed by Student Newman-Keuls post-test, $P < 0.05$. Low fat–corn oil (LF–CO)-saline, n = 8; LF–CO-arabinosylcytosine (araC), n = 9; moderate fat–safflower oil (MF-SO)-saline, n = 9; MF–SO-araC, n = 9; MF-docosahexaenoic acid (DHA)-saline, n = 9; MF–DHA–araC, n = 9; chow, n = 11; CFU–GM, colony-forming units–grandulocyte macrophage.

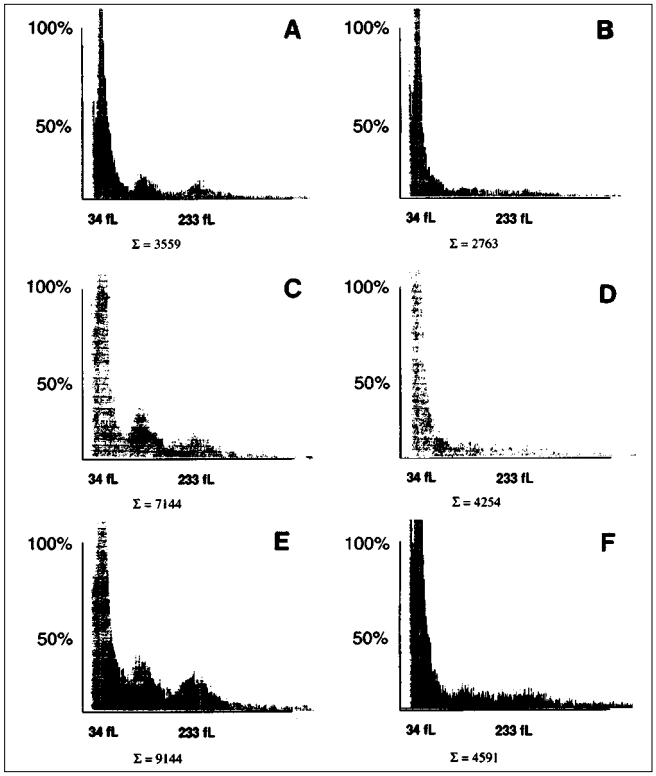

FIG. 2. Coulter channelizer distributions for bone marrow cell populations. Bone marrow was recovered from the femur of each animal as described in the Materials and Methods section. After producing a single cell suspension, cells were counted on a Coulter counter (model ZM) equipped with a 256-channel analyzer. Shown are distributions for representative, nontumor-bearing animals, with the percentage of the population on the y-axis and the approximate cell volume on the x-axis. The two cursor lines mark volumes of 34 and 233 fL, for the left and right cursor, respectively. The total number of events recorded is shown by the Σ =. (A) LF–CO; (B) LF–CO–araC; (C) MF–SO; (D) MF–SO–araC; (E) MF–DHA; (F) MF–DHA–araC.

washed bone marrow cells were plated in methylcellulose and colonies counted a week later. No differences in the colony-forming ability were observed for any of the dietary groups, nor did a single course of araC treatment appear to target the granulocyte/macrophage precursor population specifically (Fig. 1B). Thus, the differences in total bone marrow cellularity could not be explained by differences in the relative proportion of CFU–GM.

Qualitatively the Coulter channelizer profiles from the different dietary groups showed that araC-treated animals had lost populations of larger cells to differing degrees depending on the dietary treatment (Fig. 2). DHA-fed animals appeared to retain more of these larger cells following araC treatment than did the other two groups. The identity of these populations remains undetermined but, as demonstrated above, these would not seem to represent GM precursors, as we found no differences in colony-forming ability between the different diet and drug treatment groups.

DISCUSSION

Feeding DHASCO™ at 10% by weight (25% of calories) results in a 50% decrease in total cholesterol compared to a LF diet and a 40% decrease compared to a LA-rich diet. Diets rich in either LA or DHA reduce serum triglycerides by 50% compared to a LF diet. The hypotriglyceridemic effect is one that is common to both human trials feeding fish/fish oil and trials feeding fish oils, and now DHA, to rats (4). Although we can not exclude the involvement of EPA in this process (because of substantial retroconversion of DHA to EPA), the fact that a supplement containing no EPA itself could achieve this means that EPA need not be present in the diet to meet these objectives. Our results are similar to those reported by Ikeda and coworkers (22) who showed that adding DHA (as the ethyl ester) at 1% of the diet reduced triglyceride levels to ~118 mg/dL and cholesterol to 5.7 mg/dL in growing Sprague-Dawley rats. However, our results contrast those of Willumsen and coworkers (23), who recently suggested that purified DHA (92%) had no triglyceride-lowering activity.

The major difference between our study and theirs is that they used purified DHA as a supplement in a soya oil-based diet while we used a triglyceride preparation of DHA as the major oil in our diet. The DHASCO™, in addition to containing DHA, also contains a substantial portion of saturated fatty acids (42%) which could have interacted with the DHA to produce the observed hypocholesterolemic and hypotriglyceridemic effects observed in our study. This is supported by a study by Garg *et al.* (24), showing that fish oil dramatically lowered serum triglyceride levels in rats fed a high saturated fatty acid diet. The interaction between the saturated fatty acids and DHA needs to be further studied.

We were able to profoundly modify the fatty acid compositions of a wide variety of tissues with DHA feeding at relatively modest levels of total dietary fat (10% by weight). In fact, the changes we have observed in this *in vivo* model are even larger than we have observed in *in vitro* cell culture models, where DHA incorporation is at best 18% of total phospholipid (18). Therefore substantive changes in lipid composition are clearly achievable *via* the dietary route of administration. Considerable intertissue variation was observed, particularly in the n-6 rich diets. The high variability between tissues in the n-6/n-3 ratio observed in either the LF–CO or MF–SO diets was normalized by DHASCO™ feeding. Thus, tissues appear to be unable to resist n-3 substitution for n-6 when presented with high circulating n-3 fatty acids.

The fatty acid composition of skeletal and cardiac muscle was the most sensitive to changes in dietary fatty acids and contains as much as 46% DHA in membrane phospholipids. We have recently shown that basal- and hormone-stimulated glucose transport is altered in the adipocytes of MF–DHA-fed animals (25) and have shown that *in vitro* supplementation of DHA results in increased transport of purine nucleosides in leukemic cells (26). We also recently showed that nucleoside transport in red blood cells from humans given fish oil supplements is lower than in the unsupplemented condition and that only modest changes in the red cell fatty acid composition were necessary to achieve this (16). However, it remains to be seen whether the profound fatty acid changes we have induced here translate into altered muscle cell function or altered function of any of the other tissues besides adipose. The observation that nucleoside transport can be modified by n-3 feeding is relevant to the current study in that araC (used here) is a commonly used chemotherapeutic drug and therefore factors that affect its transport/metabolism will impact on both tumor and normal cell toxicity.

Our study shows that bone marrow readily incorporates DHA and in skeletal and cardiac muscle to even higher levels. The DHASCO™ contains 42.5% saturated fatty acids, but the content of saturated fatty acids in most of the tissues (i.e., the bone marrow) of the MF–DHA animals was not different from the LF–CO or MF–SO groups. Although Burns and Spector (27) have proposed that bone marrow is more disposed to incorporate saturated fatty acids into phospholipid, this conclusion may have been based on studies comparing incorporation in coconut oil and sunflower oil fed animals (28). Since the long-chain PUFA and saturates were not presented simultaneously in these studies, this could have been why bone marrow appeared to prefer saturated fatty acids when compared to other tissues. Our study directly compared levels of incorporation of n-3 and saturated fatty acids. Therefore, one would have to conclude that given a choice, many tissues will preferentially incorporate n-3 PUFA over saturated fatty acids into membrane phospholipid.

One of the major novel findings of this study was the remarkable effect of the level of fat in the diet on bone marrow cellularity. We are not aware of previous reports documenting an effect of lipid level or fat type on bone marrow development in the post-weanling rat. A twofold increase in the number of bone marrow cells, without a change in the proportion of GM precursors means that the MF–DHA and MF–SO animals have nearly twice as many GM precursors per animal (or per g body weight). It is likely that this would have consequences on immune function and disease resistance as well as the capacity to maintain normal circulating blood cell populations. In the current study only a single time point (at necropsy) was examined for peripheral neutrophil counts demonstrating that all araC animals were neutropenic to the same extent. In future studies, it will be important to look at how quickly the animals recover from aggressive chemotherapy. We also observed differences between dietary groups, on the level of bone marrow suppression seen following chemotherapeutic challenge. Bone marrow from LF–CO animals appeared to be less sensitive to the S-phase specific drug, araC, when compared to both moderate fat groups. We believe this to be an actual loss of bone marrow cells rather than a failure of the moderate fat diets to allow bone marrow expansion in the presence of araC. We conclude this based on the fact that the araC treatment period is only six days and unlikely to be sufficient time for the level of bone marrow expansion required to achieve these differences in final cell number. Having established a model which results in substantial changes in tissue fatty acid incorporation, we can now examine the effect this has on the sensitivity of these normal tissues and a transplantable tumor to aggressive chemotherapeutic drug treatment. Our first trial suggests that DHASCO™ feeding increases the number of bone marrow cells and specifically the number of CFU–GM. Our early araC results also suggest that a larger proportion of bone marrow precursor cells are killed in the moderate fat dietary groups compared to the LF group. Despite the large loss in bone marrow cells in DHASCO™-fed animals, the compartment remaining appears to be indistinguishable from the LF araC-treated group and from untreated chow-fed animals. Future experiments will address whether increased CFU–GM is a regular pattern during DHASCO™ feeding, whether differences in drug sensitivity between diet groups will be maintained at a higher araC doses and whether the DHA/EPA content established in skeletal muscle following DHASCO™ feeding has impact on muscle metabolism/function.

We observed no overt signs of toxicity of DHA in any of the animals over a relatively long time period (8–9 wk), nor

did we observe any growth inhibition or change in the behavior of the animals. However, we have previously reported that the MF–DHA diet does produce glucose intolerance in these animals and reduced hormonal stimulation of glucose transport in adipocytes (25). Therefore, not all of the effects of DHA are positive in terms of health. However, one should keep in mind that the levels used here are 10–100 times the levels previously included in animal diets for toxicity testing of the DHASCO™ supplement (29). The goal of this research is to investigate the potential role for DHA-containing oils as adjuvants for chemotherapy. The levels being used here are clearly in the therapeutic range, and therefore the risk/benefit is a more relevant measure of efficacy.

In conclusion, DHA induces profound hypotriglyceridemia and hypocholesterolemia in post-weanling Fischer 344 rats compared to a LF n-6 diet. In addition to its lipid-lowering activity, we also demonstrated that DHA feeding has substantial bone marrow enhancing activity, resulting in a twofold increase in cell numbers over n-6 or chow-fed animals. Further examination of DHASCO™ as a supplement to animal and possibly human diets, or in pharmacologic doses as part of a chemotherapy regime for cancer treatment is certainly warranted.

ACKNOWLEDGMENTS

We would like to thank Derek Ruthig, Mickie Bhatia, Michele Ap-Simon, Kristin Roovers, Lorraine DeForest, and Lyn Hillyer for their help with the feeding trial. We thank Dr. Diana Philbrick for her assistance with fatty acid analysis and Ken Stark for TBARS measurements on the diets. We thank Martek Biosciences for providing DHASCO™ and Kim Boswell for helpful discussions during the progress of this work. This work was supported by the American Institute for Cancer Research.

ABSTRACT: Oryzanol is a class of nonsaponifiable lipids of rice bran oil (RBO). More specifically, oryzanol is a group of ferulic acid esters of triterpene alcohol and plant sterols. In experiment 1, the mechanisms of the cholesterol-lowering action of oryzanol were investigated in 32 hamsters made hypercholesterolemic by feeding chow-based diets containing 5% coconut oil and 0.1% cholesterol with or without 1% oryzanol for 7 wk. Relative to the control animals, oryzanol treatment resulted in a significant reduction in plasma total cholesterol (TC) (28%, $P < 0.01$) and the sum of IDL-C, LDL-C, and VLDL-C (NON-HDL-C) (34%, $P < 0.01$). In addition, the oryzanol-treated animals also exhibited a 25% reduction in percent cholesterol absorption vs. control animals. Endogenous cholesterol synthesis, as measured by the liver and intestinal HMG-CoA reductase activities, showed no difference between the two groups. To determine whether a lower dose of oryzanol was also efficacious and to measure aortic fatty streaks, 19 hamsters in experiment 2 were divided into two groups and fed for 10 wk chow-based diets containing 0.05% cholesterol and 10% coconut oil (w/w) (control) and the control diet plus 0.5% oryzanol (oryzanol). Relative to the control, oryzanol-treated hamsters had reduced plasma TC (44%, $P < 0.001$), NON-HDL-C (57%, $P < 0.01$), and triglyceride (TG) (46%, $P < 0.05$) concentrations. Despite a 12% decrease in high density lipoprotein cholesterol (HDL-C) ($P < 0.01$), the oryzanol-treated animals maintained a more optimum NON-HDL-C/HDL-C profile (1.1 ± 0.4) than the control (2.5 ± 1.4; $P < 0.0075$). Aortic fatty streak formation, so defined by the degree of accumulation of Oil Red O-stained macrophage-derived foam cells, was reduced 67% ($P < 0.01$) in the oryzanol-treated animals. From these studies, it is concluded that a constituent of the nonsaponifiable lipids of RBO, oryzanol, is at least partially responsible for the cholesterol-lowering action of RBO. In addition, the cholesterol-lowering action of oryzanol was associated with significant reductions in aortic fatty streak formation.

Lipids 32, 303–309 (1997).

Abbreviations: HDL-C, high density lipoprotein cholesterol; HMG-CoA reductase, 3-hydroxy-3-methylglutaryl CoA reductase; IDL-C, intermediate density lipoprotein cholesterol; LDL-C, low density lipoprotein cholesterol; NON-HDL-C, the sum of IDL-C, LDL-C, and VLDL-C; PBS, phosphate-buffered saline; RBO, rice bran oil; TC, total cholesterol; TG, triglyceride; TLC, thin-layer chromatography; VLDL-C, very low density lipoprotein cholesterol.

The cholesterol-lowering effect of rice bran oil (RBO) has recently been reported by several investigators (1–7). A number of studies have suggested that the nonsaponifiables in the RBO may play a very important role in the cholesterol-lowering effect of RBO (1–3,5–8). When the nonsaponifiable lipids extracted from RBO were fed to rats in an amount equivalent to that in the RBO (2), similar cholesterol-lowering effects were observed. When oryzanol, a constituent of the nonsaponifiable lipids in RBO, was added to a diet containing purified RBO (8), it further decreased the serum total cholesterol (TC) level in rats compared to purified alone, suggesting that the hypocholesterolemic activity of RBO is attributable to oryzanol and to some other components in the nonsaponifiable matter. A study in nonhuman primates demonstrated that serum cholesterol levels decreased as the level of RBO in the diet increased, and this reduction in serum cholesterol level was not entirely explained by the fatty acid composition of the dietary lipids, suggesting a component of RBO other than its fatty acid content was responsible for its hypocholesterolemic effect (5).

RBO, unlike most vegetable oils, contains a relatively high proportion of nonfatty acid components (the nonsaponifiable lipids). Refined RBO may contain 1.5–2.6% of nonsaponifiable lipids, and crude RBO may contain up to 5% of nonsaponifiable lipids (9). In contrast, most common refined vegetable oils contain only 0.3–0.9% of nonsaponifiable lipids (10). The nonsaponifiables of RBO contain sterols (43%), triterpene alcohols (28%), 4-methyl sterols (10%), and less polar components (19%) (11). In the crude oil, about 20% of the nonsaponifiables of RBO are in the form of ferulic acid esters, which are a mixture of esters of ferulic acid (4-hydroxy-3-methoxycinnamic acid) with sterols (16% campesterol, 7% β-sitosterol) and triterpene alcohols (30% cycloartenol, 23% 24-methylene-cycloartanol, and 22% cyclobranol) (11). This mixture of ferulic acid esters has been named oryzanol since it was originally found in RBO and contained a hydroxyl group. The structure of oryzanol is shown in Figure 1. Recently, it has been reported that oryzanol also has a cholesterol-lowering property when fed to humans (12–14) and animals (15–17).

A recent study in our laboratory demonstrated that physically refined RBO, which can contain up to 3.5% nonsaponifi-

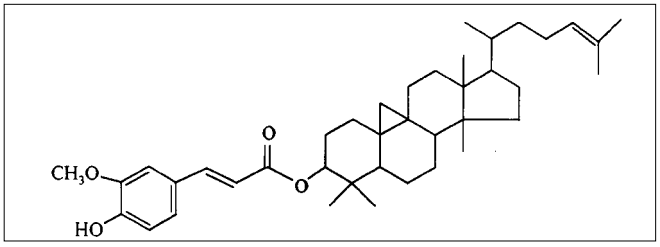

FIG. 1. Oryzanol comprises any of several plant sterols esterified to ferulic acid; the example shown here is cycloartenyl ferulate.

able components and more than 10 times the oryzanol content than alkali-refined RBO, prevented diet-induced hypercholesterolemia by inhibiting dietary cholesterol absorption and enhancing fecal neutral sterol excretion (7). These types of changes were associated with reductions in early atherosclerosis.

The present studies were designed to examine the effect of oryzanol, one of the nonsaponifiable components in RBO, on whole body cholesterol metabolism and early atherosclerosis by measuring: (i) plasma lipid and lipoprotein levels; (ii) dietary cholesterol absorption; (iii) liver and intestinal cholesterol synthesis; and (iv) aortic fatty streak formation as defined by accumulation of Oil-Red-O positive macrophage-derived foam cells. The results of our studies suggest that oryzanol feeding prevented the typical plasma TC and the sum of intermediate density lipoprotein cholesterol (IDL-C), low density lipoprotein cholesterol (LDL-C), and very low density lipoprotein cholesterol (VLDL-C) (NON-HDL-C) increase and aortic fatty streak formation associated with dietary saturated fat and cholesterol feeding. These effects may be partially explained by the ability of oryzanol to inhibit cholesterol absorption.

MATERIALS AND METHODS

Experiment 1. Animals. Thirty-two male F_1B Golden hamsters, 8 wk of age (Biobreeder, Fitchburg, MA), were used in this experiment. The study was approved by the Institutional Animal Care and Use Committees at The University of Massachusetts-Lowell and at the USDA Human Nutrition Research Center on Aging at Tufts University. Animals were individually housed in hanging cages in a 12/12 light/dark cycle with the light cycle starting at 1500 h.

Experimental protocol and diets. After arrival, animals were acclimatized for 3 d with regular Purina Rodent Chow. They were then fed a hypercholesterolemic diet (control) containing 0.1% cholesterol and 5% coconut oil (Pureco 76, Capital City) added to the Purina Rodent Chow (Purina 5001; Purina Mills Inc., St. Louis, MO) for 2.5 wk to acclimatize the animals to diet. Baseline values of plasma TC, high density lipoprotein cholesterol (HDL-C), and triglycerides (TG) were measured at 2.5 wk. The NON-HDL-C was calculated as TC minus HDL-C. This plasma NON-HDL-C value was used to divide animals into two groups of of 16 with similar starting NON-HDL-C values, each fed the control or the oryzanol diet for the next 8.5 wk. The oryzanol group was fed the same control diet but with 1.0% oryzanol added at the expense of Chow. Both cholesterol and oryzanol (TSUNO, Osaka, Japan) were dissolved in coconut oil heated to 95°C. The oil mixture was mixed with powdered Chow soon after the cholesterol and oryzanol were dissolved in the oil. A chow-based, rather than a semipurified diet, was used because published data from our laboratory (18) and those from another (19) have demonstrated that the chow-based diet produced a lipoprotein profile (predominately NON-HDL-C) more similar to humans. All diets and water were fed *ad libitum* throughout the study except as otherwise noted. Blood samples were drawn at 5 and 7 wk of the treatment period for plasma lipid and lipoprotein determination. At week 8, cholesterol absorption was measured, after which, animals were euthanized and their livers and small intestines collected for measurement of 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase activity.

Chemicals. Cholesterol and TC reagents were purchased from Abbott (Chicago, IL). HDL-C precipitating reagent ($PTA/MgCl_2$) was from Sigma Chemical (St. Louis, MO). Calibration standards for cholesterol, HDL-C, and TG were from Verichem Labs (Providence, RI). Controls for cholesterol, HDL-C, and TG were from Soloman Park Labs (Kerkland, WA). [4-^{14}C]-Cholesterol (57.1 mCi/mmol) and [1,2-^{3}H(N)]-cholesterol (51.3 Ci/mmol) were from New England Nuclear (Boston, MA). Carrier cholesterol was from Sigma Chemical Co. Absolute ethanol (200 proof) was from Aaper Alcohol and Chemical Co (Shelbyville, KY), and Ensure® liquid diet was from Ross Laboratory (Columbus, OH). Glucose-6-phosphate, $NADP^+$, glucose-6-phosphate dehydrogenase, trypsin inhibitor (soybean trypsin inhibitor, type 1-s) were from Sigma Chemical Co. [3-^{14}C] HMG-CoA (57 mCi/mmol], [5-^{3}H] mevalonolactone (24 Ci/mmol), and Aquasol-2 were from New England Nuclear (Boston, MA). Silica gel thin-layer chromatography (TLC) plates were from Eastman Kodak (Rochester, NY). Fetal bovine serum protein standard and Coomassie Blue dye reagent were from Bio-Rad Laboratories (Richmond, CA). Oryzanol was from TSUNO Inc.

Plasma lipid and lipoprotein determination. After an overnight fast, hamsters were tranquilized with 50% CO_2/ 50% O_2 and blood samples drawn from the retro-orbital sinus into Eppendorf tubes containing 5 µL heparin. After centrifugation at 4000 rpm for 8 min, plasma was collected for TC, NON-HDL-C, HDL-C, and TG measurements. TC (20) and TG (21) were quantified using enzymatic methods, and HDL-C was estimated after phosphotungstate precipitation (22) of VLDL-C and LDL-C. The NON-HDL-C fraction was determined by the difference between TC and HDL-C and includes IDL-C, VLDL-C, and LDL-C. The assays were standardized by participation in the Centers for Disease Control—National Heart, Lung and Blood Institute Standardization Program.

Measurement of cholesterol absorption. (i) Preparation of oral dose (per hamster): The percentage of an oral dose of cholesterol absorbed was measured by the dual-isotope plasma ratio method described by Zilversmit *et al*. (23,24), with minor modifications. [4-^{14}C] Cholesterol (0.5 μCi) containing 5.0 mg cholesterol was dissolved in 400 μL absolute ethanol. The ethanol mixture was evaporated to dryness under a stream of nitrogen. For the control dose, the content of the dry tube was redissolved in 250 μL corn oil. For the experimental dose, 50 mg oryzanol was dissolved in the 250 μL corn oil. The oil mixtures were then suspended with an aliquot of liquid diet (2 mL Ensure®) by sonication (Polytron, Brinkmann Instruments Inc., Westbury, NY) for 2 min. The amount of fat, cholesterol, and oryzanol included with the tracer dose mimicked that in the diet in a 24-h period, had the animals been allowed to eat. The oral doses were prepared a few hours before use. (ii) Preparation of intravenous (IV) dose (per hamster): [1,2-^{3}H] Cholesterol (1.0 μCi) containing 6.5 μg cholesterol was dissolved in 30 μL absolute ethanol. Colloidal cholesterol was prepared by adding 0.37 mL sterile saline just prior to dosing. (iii) Administration of oral and IV dose: All animals were fasted 18 h (starting at the beginning of the dark cycle) prior to oral and IV dosing with the isotopes. Hamsters were anesthetized with 50% CO_2/50% O_2. The external jugular vein of the hamster was exposed under sterile conditions and the IV isotope dose (approximately 0.4 mL) was injected into the hamster. The oral isotope dose (about 2 mL) was gavaged to the stomach immediately following the injection of the IV dose. Food was withheld for an additional 6 h before animals were fed their experimental diets. Blood samples were drawn from the retro-orbital sinus 72 h after dosage. Preliminary data showed a plateau by 48 h after dosing. The percentage cholesterol absorption was calculated based on the plasma isotope ratio of the oral (^{14}C) and IV (^{3}H) doses (23).

Measurement of HMG-CoA reductase activity. (i) Buffered solutions: TEDK buffer contains 50 mM Tris-HCl (pH 7.5), 1.0 mM EDTA, 5.0 mM dithiothreitol, and 70 mM KCl. TEDF buffer contains 50 mM Tris-HCl (pH 7.5), 1.0 mM EDTA, 5.0 mM dithiothreitol, and 70 mM NaF. TEDK-TI (trypsin inhibitor) buffer contains TEDK with 0.04% trypsin inhibitor (0.4 mg/mL). (ii) Preparation of hepatic microsomes: Hepatic microsomes for measurement of hepatic HMG-CoA reductase activity were prepared as described by Harwood *et al*. (25) with minor modification. Immediately after each hamster was killed in a chamber filled with 100% CO_2, a piece of liver (1.0 g) was removed and homogenized at 4°C in TEDK and TEDF buffers (3 mL buffer per gram liver), using a Dounce tissue homogenizer (15 strokes) with a loose pestle. Homogenates were first centrifuged at 10,000 × *g* (4°C, 15 min), and the resultant supernatant was centrifuged at 175,000 × *g* (4°C, 90 min). The resulting microsomal pellets were lightly rinsed and resuspended in the TEDK and TEDF buffers (3.0 mL buffer per gram liver), using a Dounce tissue homogenizer (10 strokes) with a tight pestle. The microsomes were then stored at −70°C before further analysis. The protein contents of the microsomes were determined by the method of Bradford (26), using bovine serum albumin as standard. (iii) Preparation of intestinal microsomes: Intestinal microsomes were prepared for the assay of total HMG-CoA reductase activity. Microsomes were prepared from intestinal mucosal scrapings based on the method described by Harwood *et al.* (27) with minor modification. Intestinal segments from the whole small intestine (from the pylorus to the ileojunction) were removed from animals, split open longitudinally and rinsed free of fecal material with 4°C saline. The mucosa was then scraped free from the vasculature with two glass slides on a piece of ice-cold glass. The scrapings were immediately homogenized with 4 mL TEDK-TI buffer using a Dounce homogenizer with a loose pestle. The homogenates were further processed for microsomes similar to the preparation of hepatic microsomes with the exception that the final microsomal pellets were resuspended in TEDK-TI buffer (3 mL per scraping), and stored at −70°C. The protein concentrations of intestinal microsomes were also determined by the Bradford protein assay (26). (iv) Measurement of hepatic and intestinal HMG-CoA reductase activity: HMG-CoA reductase (EC 1.1.1.34) activity was measured as described by Harwood *et al.* (27). Microsomal proteins, 75 μg (50 μL) from hepatic microsomes, and 50 μg (50 μL) from intestinal microsomes were preincubated for 30 min at 37°C. Following the preincubation, the reaction of HMG-CoA reductase was initiated by adding 25 μL cofactor cocktail containing 3.4 mM $NADP^+$, 30 mM glucose-6-phosphate, 0.2 unit glucose-6-phosphate dehydrogenase, 66.7 μM DL-3-[glutaryl-3-^{14}C]-HMG-CoA (12 cpm/pmol), 12,000–13,000 cpm RS-[5-^{3}H(N)] mevalonate (27.8 Ci/mmol) as an internal standard, and 68 mM EDTA. The microsomes were incubated for 40 min (37°C) for the measurement of both hepatic and intestinal HMG-CoA reductase activity. At the end of incubation, 10 μL of 6 N HCl was added to terminate the reaction and to bring about the cyclization of mevalonate into mevalonolactone. The reaction vials were then centrifuged (Beckman microcentrifuge, 5 min, setting 12) and the supernatant applied to silica gel TLC. After developing the TLC (toluene/acetone 1:1), the region containing mevalonolactone (R_f 0.4 ~ 0.8) was removed and counted for ^{3}H and ^{14}C. HMG-CoA reductase activity is expressed as pmoles of mevalonate formed per minute per mg microsomal protein.

Experiment 2. Animals. Nineteen 10-week-old male F_1B golden hamsters (Biobreeder, Fitchburg, MA) were used in this experiment. The study was approved by the Institutional Animal Care and Use Committee at the University of Massachusetts-Lowell. Animals were individually housed in hanging cages in a 12/12 h light/dark cycle. All diets were fed *ad libitum* throughout the study.

Diet. Animals were fed for 10 wk a chow-based diet (for reasons given in experiment 1) composed of 10% coconut oil (w/w) and 0.05% cholesterol as the control diet to which was added 0.5% oryzanol.

Plasma lipid and lipoprotein measurement. At 4, 8, and 10

wk on treatment, blood samples were withdrawn and plasma was prepared and analyzed for TC, HDL-C, NON-HDL-C, and TG as described in experiment 1.

Fixation of the aorta. Hamsters were anesthetized with an IP injection of sodium pentobarbital. The animals were cut open and their hearts were exposed. Blood was collected through a cardiac puncture in the left ventricle, and the right atrium was also punctured to provide an outlet for the fixative. A perfusion needle was inserted into the left ventricle and the fixative, 4% formaldehyde in phosphate-buffered saline (PBS), was allowed to flow through the animal's cardiovascular system with physiological pressure. After two minutes, the flow was slowed and fixation was continued for another 25 min. The heart and aorta were removed and fixation was completed by pinning down in its natural shape in fixative overnight. The specimens were stored in a vial containing PBS for subsequent analysis.

Aortic morphometric analysis. The heart and the descending aorta were removed and discarded. The aortic arch was rinsed with PBS and dropped in a vial containing Oil Red O stain (0-0625; Sigma Chemical Co.) in isopropanol for 15 min. The arch was cleaned by carefully removing all the Oil Red O-stained tissue from its surface. The arch was then cut vertically into two pieces which were opened longitudinally and mounted on a glass slide with their epithelial sides up. Specimens were covered with cover slips and observed under 100× magnification. An image analysis system (Image Technology Corp., Cresskill, NJ), which is attached to a light microscope, was used to measure the total Oil Red O-stained macrophage-derived foam cells which constituted the fatty streak in the aortic arch. Units of measurement of fatty streak area are $\mu m^2/mm^2 \times 10^3$ of aortic tissue.

Statistical analysis. Statistical Analysis System (SAS-PC) (28) was used for all statistical analysis. Data are presented as mean ± standard error of the mean. A paired *t*-test ($P < 0.05$) was used to determine the statistical significance of mean values between the two groups for all variables. To normalize the data and stabilize the variance, it was necessary to transform the plasma TC, NON-HDL-C, and TG data to their $\log_{10}$ values before the statistical analysis.

RESULTS

Experiment 1. Effects of oryzanol on plasma lipids, lipoproteins and body weight. Following 2.5 wk of basal diet, animals were sorted into the control and the oryzanol groups with similar plasma NON-HDL-C concentration (340 mg/dL) to start the experimental period. Although measurements were performed at both weeks 5 and 7, only data from the seventh week were used since the other dependent variables were measured after the seventh week. The oryzanol group showed a significant reduction in plasma TC (28%) and NON-HDL-C concentrations (34%) with respect to control ($P < 0.01$) (Table 1). There were no statistically significant differences in plasma HDL-C and TG levels although the latter were reduced 33% in the oryzanol group relative to the control. There was also no significant difference between the body weights of the control (111 ± 3) and oryzanol (113 ± 2) groups at the end of the experiment.

TABLE 1
Plasma Lipid, Lipoprotein, and Body Weight Values in Hamsters Fed Control and Oryzanol Diets in Experiment 1[a]

	Group	
	Control	Oryzanol
TC	342 ± 32[a]	245 ± 6[b]
NON-HDL-C	273 ± 32[a]	179 ± 7[b]
HDL-C	70 ± 2	66 ± 2
TG	237 ± 45	158 ± 10
Body weight (g)	111 ± 2	113 ± 1

[a]Values (mg/dL) are expressed as mean ± SEM ($n = 16$). Values not sharing a common superscript are significantly different at $P < 0.01$. Measurements were taken 7 wk after the initiation of the control and oryzanol diet groups. TC, total cholesterol; NON-HDL-C, the sum of intermediate density lipoprotein cholesterol, low density lipoprotein cholesterol, and very low density lipoprotein cholesterol; HDL-C, high density lipoprotein cholesterol; TG, triglyceride.

Effects of oryzanol on cholesterol absorption. Cholesterol absorption following 8 wk of dietary treatment with oryzanol was significantly reduced (25%) compared to the control group (Table 2).

Effects of oryzanol on hepatic and intestinal cholesterol synthesis. Although endogenous cholesterol synthesis, as measured by hepatic and intestinal HMG-CoA reductase activities was reduced 15 and 17%, respectively, in oryzanol-fed animals following 8.5 wk dietary treatment (Table 2), these observations were not statistically significant ($P < 0.08$).

Experiment 2. Relative to the control animals, oryzanol-treated hamsters had reduced plasma TC (44%, $P < 0.01$), NON-HDL-C (57%, $P < 0.01$), and TG (46%, $P < 0.01$) (Table 3). Despite a 12% decrease in HDL-C, the oryzanol-treated animals maintained a more optimal NON-HDL-C/HDL-C profile (1.1 ± 0.4 vs. 2.5 ± 1.4 $P < 0.0075$). The body weights at the beginning and end of the experiment were 108 ± 4 (mean ± SEM) and 128 ± 4 g for the control group and 108 ± 5 and 128 ± 8 g for the oryzanol group, respectively.

TABLE 2
Cholesterol Absorption and HMG-CoA Reductase Activities in Liver and Small Intestines of Hamsters Fed Control and Oryzanol Diets in Experiment 1[a]

	Group	
Organs	Control	Oryzanol
Cholesterol absorption (%)	57.3 ± 2.1[a]	42.9 ± 2.0[b]
Liver HMG-CoA reductase (pmol/min per mg protein)	14.1 ± 0.7	12.0 ± 0.9
Small intestine HMG-CoA reductase (pmol/min per mg protein)	36.3 ± 3.8	30.4 ± 3.1

[a]Values are expressed as mean ± SEM ($n = 16$). Values not sharing a common superscript are significantly different at $P < 0.0001$. Measurements were taken 7 wk after the initiation of the control and oryzanol groups; HMG-CoA, 3-hydroxy-3-methylglutaryl CoA reductase.

TABLE 3
Plasma Lipids, Lipoprotein Cholesterol and Fatty Streak Area in F_1B Hamsters Fed Control and Oryzanol Diets in Experiment 2[a]

	Group	
	Control	Oryzanol
TC	220 ± 29[a]	124 ± 14[b]
NON-HDL-C	156 ± 29[a]	67 ± 11[b]
HDL-C	65 ± 2	57 ± 4
TG	218 ± 41[a]	118 ± 10[b]
Fatty streak area ($\mu m^2/mm^2 \times 10^3$)	15 ± 3[a]	5 ± 1[b]

[a]Values are expressed as mean ± SEM (n = 10 for control and n = 9 for oryzanol—mg/dL). Values not sharing a common superscript are significantly different at $P < 0.01$, except TG, which are $P < 0.05$. See Table 1 for abbreviations.

DISCUSSION

The present studies were designed to investigate whether oryzanol, a unique constituent in the nonsaponifiables of RBO, is an active ingredient responsible, at least in part, for the hypocholesterolemic action of RBO. The results of experiment 1 showed that the addition of oryzanol (1%) to a hypercholesterolemic diet for 7 wk was associated with a 34% decrease in plasma NON-HDL-C level as compared to the controls. In experiment 2, in which oryzanol was added to a hypercholesterolemic diet at 0.5% (w/w) and fed for 10 wk, NON-HDL-C was reduced 57%. These two observations indicate that oryzanol is responsible, at least in part, for the observed cholesterol-lowering activity of RBO.

The cholesterol-lowering activity of oryzanol has been previously demonstrated by other investigators (12–17). Shinomiya *et al.* (15) showed that when 0.5 and 2.0% oryzanol were fed to rats on a high cholesterol diet (1.0% cholesterol + 0.5% cholic acid) for 4, 8, and 12 wk, plasma TC decreased on the fourth, eighth, and twelfth week in the group fed 2.0% oryzanol, and the eighth and twelfth week in the group fed 0.5% oryzanol. Plasma LDL-C and VLDL-C levels and liver cholesterol esters decreased in the group fed 2.0% oryzanol. In a study reported by Seetharamaiah and Chandrasekhara (16), 7 wk following oryzanol feeding, plasma NON-HDL-C levels significantly decreased in rats fed all levels of oryzanol (0.2, 0.5, 1.0, and 2.0%) as compared to the control group. When oryzanol was added to a cholesterol-free diet, no effects on plasma lipids or lipoproteins were observed, suggesting that oryzanol may affect cholesterol metabolism by altering dietary cholesterol absorption. One of the early studies with oryzanol reported that when oryzanol was fed to mice for 30 d (1 mg/day per kg body weight), it resulted in a decreased liver cholesterol biosynthesis as indicated by the lower ^{14}C-acetate or ^{14}C mevalonate incorporation into hepatic cholesterol. When oryzanol was injected (IP) to the mice, it caused an increased excretion of fecal sterols as indicated by the increased fecal excretion of total sterol-^{14}C and total bile acid-^{14}C derived from cholesterol-^{14}C injection (16). The cholesterol-lowering effect of oryzanol has also been reported in humans (12–14). When oryzanol was administered to patients with hyperlipidemia (type IIa, IIb, and IV) for 3 mon (300 mg/day), plasma TC and LDL-C levels decreased in Type IIa, IIb and type IV patients; oryzanol feeding also caused an increase in the plasma HDL-C levels in type II patients (12,13). In a study on chronic schizophrenic patients with dyslipidemia (TC ≥ 220 mg/dL, TG ≥ 150 mg/dL, or HDL-C ≤ 40 mg/dL), oryzanol feeding (3 × 100 mg/day) reduced plasma TC, LDL-C, and Apo B levels (14).

The cholesterol-lowering effect of RBO has been attributed to its higher nonsaponifiable content (1–3,5–8). A recent study by our laboratory has demonstrated that RBO prevents hypercholesterolemia induced by a high-cholesterol diet in hamsters by suppressing cholesterol absorption and enhancing fecal sterol excretion (7). It has been reported that feeding the nonsaponifiable lipids extracted from RBO in rats caused the increased fecal sterol excretion (2). The effect of nonsaponifiables, or oryzanol, on cholesterol absorption has not been previously reported. The present study has demonstrated that oryzanol feeding in hamsters caused a decreased dietary cholesterol absorption, and this suppressed cholesterol absorption was at least partially responsible for the lower plasma TC and NON-HDL-C levels induced by oryzanol feeding.

Oryzanol, which constitutes 20% of the nonsaponifiables of RBO, is a mixture of ferulic acid esters of plant sterols and triterpene alcohols. The mechanism by which oryzanol affects cholesterol absorption cannot be elucidated from our experiment. The mechanism by which plant sterols affect cholesterol absorption has been studied for many years but is still not fully understood. Several mechanisms have been hypothesized (27,29). These include: (i) plant sterols may form a nonabsorbable complex with cholesterol in the intestinal lumen; (ii) plant sterols may interact with and alter the size and/or stability of cholesterol-containing micelles in the intestinal lumen and thereby alter the efficiency with which cholesterol is delivered to the mucosal surface; (iii) plant sterols may interfere with cholesterol esterification in the mucosa cell; and (iv) plant sterols may interact with protein receptors on the mucosal cell surface which are necessary for cholesterol absorption. Unpublished results of our laboratory showing that one single oral bolus of oryzanol inhibits cholesterol absorption suggests that oryzanol interferes with cholesterol absorption at least by the mode of luminal action as well as or instead of intracellular events which reflect long-term effects of a feeding regimen. It is also possible that oryzanol exercises its effects on cholesterol metabolism at sites other than the intestine since other pharmacological responses of oryzanol, such as a growth-accelerating action, regulation of the estrous cycle, ability to promote skin capillary circulation (30), and antioxidant activity (31) have been reported.

The results in the oryzanol feeding experiments in the present studies showed that oryzanol induced lower cholesterol absorption without changing *de novo* cholesterol synthesis in the intestinal mucosa. This differs from that shown in the RBO feeding experiment in our previous study (7) in which

the lower cholesterol absorption in the RBO group was associated with a reciprocal increase in *de novo* cholesterol synthesis as indicated by the increased intestinal HMG-CoA reductase activity. This suggests that the other constituents in the nonsaponifiables of RBO may also exert certain effects on cholesterol metabolism in the intestinal mucosa.

In experiment 2 it was demonstrated for the first time that the oryzanol effects in plasma TC, NON-HDL-C, and cholesterol metabolism were associated with a significant decrease (67%) in early atherosclerosis. The simplest explanation for the decrease in macrophage-derived foam cells which constitute the aortic fatty streak area for the oryzanol group is the reduction in the NON-HDL-C fraction. However, other properties of oryzanol may be contributing to its antiatherogenic properties *via* other mechanisms. For example, the ferulic acid component of the oryzanol fraction has been shown to have antioxidant activity (32). Thus it is possible that the prevention of fatty streak formation in the oryzanol-fed hamsters could be associated with the inhibition of LDL oxidation by oryzanol, and in particular the ferulic acid component. The sensitivity of the hamster to the antioxidant activity of tocopherol and probucol as it relates to LDL oxidation and early atherosclerosis has recently been demonstrated (33). Finally, in light of the effects of RBO and the nonsaponifiables of RBO on fecal sterol excretion (2), it is plausible that oryzanol may alter the fecal sterol excretion in addition to its effect on cholesterol absorption.

The doses of oryzanol used in the first and second experiments, as a percentage of dietary energy, were approximately eightfold and fourfold that which could be obtained by an individual using physically refined rice bran oil as the major source of fat in their diet. These doses were used in order to study the mechanism(s) by which oryzanol affects cholesterol metabolism. Future studies could focus on the minimal amount of oryzanol needed for an optimal response.

In conclusion, this communication demonstrates that oryzanol, an unsaponifiable component of RBO, reduced plasma TC and NON-HDL-C by reducing cholesterol absorption. These properties were associated with a reduction in early atherosclerosis.

ACKNOWLEDGMENTS

The authors are grateful to TSUNO Inc., Osaka, Japan, for their generous donation of oryzanol for the testing. Effect of Nicotine on Lipoprotein Metabolism in Rats

L. Ashakumary and P.L. Vijayammal*

Department of Biochemistry, University of Kerala, Kariavattom, Thiruvananthapuram-695 581, Kerala, India

ABSTRACT: Nicotine, a major component of cigarette smoke, plays an important role in the development of cardiovascular disease and lung cancer in smokers. The effect of nicotine on lipoprotein metabolism was studied using rats as the experimental animal. There was a significant increase in the total cholesterol, phospholipids, and triglycerides as well as the amount of lipids associated with very low density lipoprotein (VLDL) and low density lipoprotein (LDL) in sera of nicotine-treated rats. The incorporation of ^{3}H labeled leucine into the apo B was found to be increased both in the medium and associated cells in the hepatocytes isolated from nicotine-treated rats indicating an increased synthesis and secretion of the apo B containing lipoproteins. This was further confirmed by the higher incorporation of ^{14}C acetate into total and individual lipids of LDL and VLDL secreted into the medium as well as that associated with different lipids in the cell layer. The activity of lipoprotein lipase in extrahepatic tissues and plasma lecithin cholesterol acyl transferase activity were significantly lower in nicotine-treated rats. These results indicate that nicotine exerts hyperlipidemic effects particularly by increasing the synthesis and secretion of triglyceride-rich lipoproteins. Since nicotine is one of the major hazardous components present in cigarette smoke and tobacco, one can extrapolate that the deleterious effect exerted by nicotine on rats extends to cigarette smokers and those who use other forms of tobacco.

Lipids 32, 311–315 (1997).

Nicotine, one of the most pharmacologically active tobacco components, has a wide range of cardiovascular effects (1–4). Short-term experiments with rabbits (5) and humans (6) have shown that oral administration of the alkaloid raises plasma low density lipoprotein (LDL) cholesterol and lowers high density lipoprotein (HDL) cholesterol. These observations are clinically important because of the widespread use of smokeless tobacco products (7) and the increased prescription of nicotine-containing chewing gum in smoking cessation therapy (8). Treatment of 2 mg nicotine gum for 60 d in nonsmokers resulted in an increase in HDL and LDL cholesterol (9). Burch *et al.* (10) reported that the serum levels of total cholesterol triglycerides and LDL cholesterol were elevated in nicotine-treated rats. It appears that the accelerated synthesis of LDL through enhanced lipolytic conversion of precursor lipoproteins is one metabolic process responsible for creation of a lipoprotein profile by nicotine (11). Since liver is the major site of plasma lipoproteins, particularly very low density lipoprotein (VLDL) and LDL, we carried out some studies in isolated hepatocytes of nicotine-treated rats.

MATERIALS AND METHODS

Male albino rats (Sprague Dawley strain; age about 45 d, body weight 120–150 g) maintained on normal laboratory diet (Goldmohur rat feed) were used for these experiments. Water was provided *ad libitum*. The rats were divided into two groups of 15 rats each as follows: Group 1: control rats; Group 11: rats given nicotine. Nicotine 98% (Chemische Fabric CH-9470 Buchs, Fluka AG, Buchs, Switzerland) dissolved in physiological saline and pH adjusted to 7.2 with sterile 0.1 N HCl was administered orally for the experimental group. The daily dose of nicotine was 3.5 mg/kg body weight. The control rats received the same volume of physiological saline daily. The experimental period was 90 d.

Isolation of hepatocytes. Hepatocytes from nicotine-treated and control rats were isolated by collagenase perfusion according to the procedure by Seglen (12) and Sudhakaran *et al.* (13). Cells were suspended in Eagle's essential medium containing streptomycin (100 mg/mL), penicillin (100 mg/mL), insulin (0.6 mg/mL), and fetal bovine serum and were then plated in 35-mm plastic petri dishes. Cultures were maintained at 37°C in 95% air–5% CO_2 atmosphere. The medium was removed after 4–5 h, and the cell monolayer was washed with serum-free medium. The yield of hepatocytes from both control and nicotine-treated rat livers was comparable (control rat: 205×10^6 cells/liver, nicotine-treated rat: 200×10^6 cells/liver). More than 90% of the cells from both preparations were viable as assessed by trypan blue exclusion. The plating efficiency was also comparable. About 60% of the cells from both preparations attached to collagen coated overslips in 1 h after plating.

Metabolic labeling with ^{3}H leucine and ^{14}C acetate. The monolayer of hepatocytes was subsequently incubated with 2 mL of serum-free medium that contained radiolabeled and/or unlabeled metabolites. In radiolabeling experiments, ^{3}H leucine (30 μCi/mL) or ^{14}C acetate (10 μCi/mL) was added to each dish. Cells were incubated for different time intervals. At the end of the incubation period, the medium and cells were separately collected for lipoprotein analysis.

Isolation of lipoproteins. Lipoproteins, mainly VLDL, se-

creted into the medium by the cells were separated by preparative sequential ultracentrifugation according to the procedure of Havel *et al.* (14), in the presence of carrier serum in a Sorval ultracentrifuge (Dupont, Boston, MA).

Preparation of antisera against rat apo B. Rat serum VLDL and LDL were duplicated, 1 mL of VLDL or LDL was mixed with 1 mL of isopropanol at 4°C. It was then centrifuged and the supernatant discarded. The residue was again washed with isopropanol and dissolved in electrophoresis sample buffer and electrophoresed in a Hoeffer electrophoretic apparatus (San Francisco, California) at 30 mA for 8 h, using 7.0% SDS polyacrylamide gel electrophoresis according to Laemmli (15). The gel was then stained with Coomassie brilliant blue. The top-most band corresponding to apo B was then cut out, destained, and extensively washed with distilled water and dispersed finely using a hypodermic syringe in normal sterile saline. The suspension was mixed with Freund's complete adjuvant to get a fine emulsion. It was then injected subcutaneously into a rabbit at various sites. A booster dose was given on 14th d. A second booster dose was also given on 21st d (after 7 d). The animal was bled on 31st d (after 10 d of second booster), and antiserum was collected and dispensed as 0.5 mL aliquots in microcentrifuge tubes and kept at −20°C. The crossreaction of the serum with apo B was then checked by double diffusion technique using rat VLDL and LDL as antigens. The antiserum was found to be specific for rat serum apo B as it did not show any crossreaction with rat serum HDL, albumin, or human serum VLDL and LDL.

Immuno precipitation. Labeled apo B associated with lipoproteins was precipitated by adding anti-rat apo B serum, raised in rabbit. The antigen–antibody complex was collected by incubating with protein-A-Sepharose beads (16) and separated by SDS polyacrylamide gel electrophoresis (15). The gel slices were dissolved in 20% H_2O_2 and the radioactivity was measured using a scintillation counter.

Thin-layer chromatography and lipid analysis. Lipids associated with cells as well as VLDL and LDL were extracted by the method of Folch *et al.* (17). Individual lipids were separated by thin-layer chromatography (18) and fractions, mainly triglycerides, cholesterol, cholesterol esters and phospholipids, were scraped and quantitated by scintillation counting.

Cholesterol, triglycerides, and phospholipids were estimated in serum and tissues (19).

Other methods. Cellular protein was measured by the method of Lowry *et al.* (20). Rate of protein synthesis was determined by measuring the incorporation of ^{3}H leucine into trichloroacetic acid-insoluble materials using bovine serum albumin as carrier. Lipoprotein lipase (21) and lecithin cholesterol acyl transferase (22,23) were also assayed. Blood nicotine concentration was determined spectrophotometrically (24).

RESULTS

Concentration of lipids in serum and tissues. No significant change was noticed in gain in body weight of nicotine-treated rats (125 ± 4.2 g) when compared to control rats (135 ± 4.5 g).

Nicotine administration resulted in a significant increase in serum cholesterol, triglycerides, and phospholipids when compared to control group. Liver cholesterol, triglycerides, and phospholipids were also higher in nicotine-administered rats. Cholesterol, phospholipids, and triglycerides associated with the serum VLDL and LDL were also significantly higher in nicotine-treated rats (Tables 1 and 2)

Synthesis and secretion of apo B in hepatocytes in culture. In order to study whether the increased levels of VLDL and LDL observed in nicotine-treated rats were due to altered production of the lipoproteins in liver, hepatocytes isolated from animals were metabolically labeled with ^{3}H leucine and the apo B-containing lipoprotein secreted into the medium was analyzed. Primary cultures of hepatocytes derived from nicotine-treated rats showed increased incorporation of ^{3}H leucine into apo B-containing lipoproteins secreted into the medium, indicating increased synthesis and secretion of apo B (Fig. 1). The incorporation of radioactivity in cell-associated apo B was also higher in hepatocytes from nicotine-treated rats (Fig. 2). A pulse-chase experiment was carried out to find whether the rate of secretion of apo B-containing lipoproteins into the

TABLE 1
Concentration of Lipids in Serum and Tissues

	Serum (mg/100 mL)		Liver (mg/100 g tissue)	
Lipids	Control	Nicotine	Control	Nicotine
Cholesterol	60.52 ± 1.45	70.05 ± 1.69[a]	343.20 ± 7.55	454.10 ± 16.80[a]
Triglycerides	7.41 ± 0.17	10.21 ± 0.39[a]	445.20 ± 10.20	531.80 ± 18.08[a]
Phospholipids	128.20 ± 3.07	157.30 ± 6.13[a]	2212.00 ± 53.08	2690.00 ± 102.20[a]

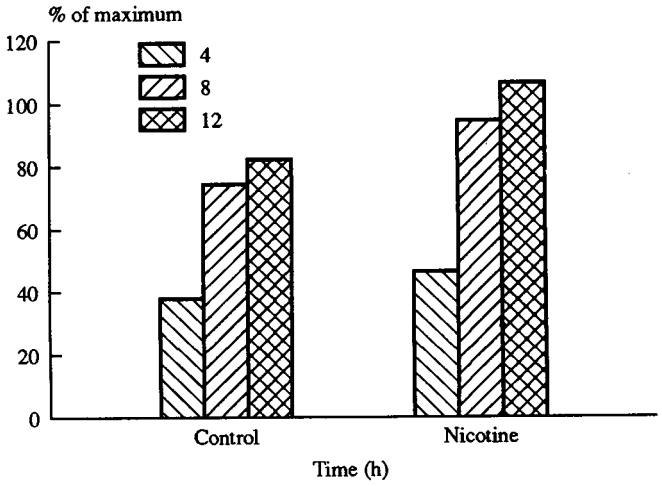

FIG. 3. Secretion of ^{3}H apo B (pulse chase experiment).

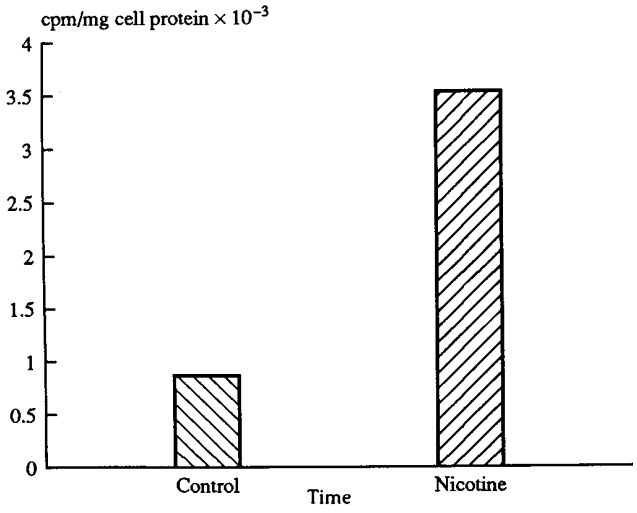

FIG. 2. Incorporation of ^{3}H leucine into apo B in cell layer.

medium was affected. The cells were preincubated in leucine-free medium for 1 h and were then pulse-labeled with 100 μCi of ^{3}H leucine for 3 h. Medium was removed and the cells were maintained in a medium containing nonradioactive leucine. The apo B secreted into the medium at different time intervals was immunoprecipitated and quantitated and expressed as the percentage of that secreted in 12 h in each case (Fig. 3). The fraction of the total ^{3}H-apo B released into the medium by hepatocytes isolated from nicotine-treated rats was significantly higher when compared to control rats. At 6 h nearly 60% of the total secreted apo B was released by hepatocytes derived from rats fed nicotine while control rat hepatocytes released 48%.

Incorporation of ^{14}C acetate into lipids associated with lipoproteins secreted by hepatocytes. The synthesis and secretion of lipoprotein by hepatocytes from nicotine-treated rats were also studied by metabolic labeling with ^{14}C acetate. Incorporation of ^{14}C acetate into cholesterol, phospholipids, triglycerides, and ester cholesterol of VLDL and LDL secreted into the medium was significantly higher in nicotine-treated rats when compared to control rats. ^{14}C acetate incorporation into cell-associated cholesterol, phospholipids, triglycerides, and ester cholesterol was significantly higher in the case of hepatocytes derived from nicotine-treated rats (Table 3).

Activity of lipoprotein lipase of extrahepatic tissue and plasma LCAT. Rats administered nicotine showed significantly lower lipoprotein lipase activity in aorta, heart, and adipose tissue when compared with control rats (Table 4).

Plasma LCAT activity was also decreased in nicotine-administered rats (Table 4).

Concentration of nicotine. The blood nicotine concentration in nicotine-treated rat was 10 μg/mL blood.

DISCUSSION

Nicotine has a definite effect on the concentration of lipids in different tissues, but the nature of the effect varies with the nature of the lipid and is different in different tissues. The reports on the effect of administration of nicotine are also not in agreement. Cluette Brown *et al.* (11) observed that oral administration of nicotine had no effect on plasma triglycerides, whereas it increased the cholesterol concentration. David and Turner (25) reported that nicotine caused an increase in the accumulation rate of triglycerides. Our findings, i.e., the increased concentration of different lipids in serum, is in agreement with the report of Booyse *et al.* (5) who observed a 26% increase in serum triglycerides and a 71% increase in total cholesterol by nicotine administration to rabbits and Lagrue *et al.* (9) who reported an increased level of plasma total cholesterol and triglycerides in nonsmokers following nicotine intake. The present study of serum LDL cholesterol confirms the earlier observation that nicotine-treated monkeys showed significantly higher levels of plasma LDL cholesterol (26).

The increased incorporation of ^{3}H leucine into apo B associated with hepatocytes as well as that secreted into the medium suggests that synthesis and secretion of apo B, the major apoprotein secreted as VLDL and LDL, is higher in nicotine-treated rats. Results reported from our laboratory as well as those reported by others showed that hepatocytes in primary culture can synthesize both VLDL and LDL (27–31). Bell-Quinet and Forte (30) found that, apart from VLDL, some amounts of LDL can also be produced by liver cells in culture. It has been suggested that part of the VLDL at longer time intervals may be converted to LDL. Cluette Brown *et al.* (11) reported that chronic oral nicotine intake caused an elevation in both LDL protein and cholesterol suggesting that the alkaloid promotes an increase in the entire lipoprotein particles. Since a substantial amount of oral nicotine is absorbed in the intestine and then metabolized by hepatic microsomes (1,32), the alkaloid could enhance LDL synthesis by modifying hepatocyte smooth endoplasmic reticulum, where lipoproteins are manufactured prior to secretion. In this regard, chronic oral administration of nicotine increases hepatic microsomal enzyme system and stimulates protein synthesis (33). Increased incorporation of ^{14}C acetate into cholesterol and cholesterol esters associated with LDL and VLDL secreted by hepatocytes observed in the present study also indicates increased production of VLDL and LDL by hepatocytes from nicotine-treated rats.

Cellular cholesterol is a critical component in VLDL assembly. Any condition which causes an increase in cholesterol ester production is associated with an increased secretion of apo B as VLDL. A positive correlation between cholesterol ester content and apo B secreted as VLDL has been observed (31). Plasma lecithin cholesterol acyl transferase is the enzyme involved in the esterification of cholesterol. The esterification takes place on the surface of HDL. Both this enzyme and HDL are involved in the transfer of cholesterol from tissue to the liver for degradation. The increased concentration of cholesterol observed in nicotine-treated rats may be due to the decreased activity of this enzyme.

Increase in serum lipid level can also be due to decreased clearance of lipoproteins by extrahepatic tissues. Lipoprotein lipase is involved in the uptake of triglyceride-rich lipoproteins (chylomicrons and VLDL) by the extrahepatic tissues. Decreased activity of lipoprotein lipase in extrahepatic tissues in nicotine-administered rats may result in decreased uptake of serum VLDL, resulting in an increased levels of VLDL.

Cigarette smoking, chewing tobacco, and snuff using are the major forms of nicotine intake. The intake of nicotine per cigarette averaged 1.0 mg but ranged from 0.37 to 1.56 mg (34). A study of nicotine intake from smokeless tobacco reported an average of 3.6 mg nicotine from 2.5 g of oral snuff and 4.6 mg of nicotine from an average of 7.9 g of chewing tobacco, when both are kept in the mouth for 30 min (35). In our present work, the blood nicotine concentration in experimental animals was minute (10 μg/mL), but low-level nicotine caused significant changes in lipoprotein metabolism and produced atherosclerotic conditions. These results show the deleterious effect of nicotine in cigarette smokers and in users of smokeless tobacco.

ABSTRACT: Recently it has been postulated that membrane fatty acid composition may be involved in the pathogenesis of insulin resistance and non-insulin dependent diabetes mellitus (NIDDM). The aim of this study was to determine whether alterations in tissue phospholipid (PL) fatty acids are present in hyperglycemic and hyperinsulinemic *Psammomys obesus*. On a native diet of salt bush, *P. obesus* (Israeli sand rat) remains lean and free of diabetes; however, when placed on a normal laboratory chow, a significant proportion of these animals develops a number of metabolic disorders associated with NIDDM, providing an ideal animal model of obesity and NIDDM. Four groups of mature *P. obesus* were studied: group A: normoglycemic and normoinsulinemic; group B: normoglycemic and hyperinsulinemic; group C: hyperglycemic and hyperinsulinemic; and group D: hyperglycemic and hypoinsulinemic. In liver and red gastrocnemius muscle, there were no significant differences between groups A, B, and C in fatty acid composition of PL. Minor differences in individual fatty acids were demonstrated in group D animals (increased liver 20:4n-6 and increased muscle 22:5n-3); however, the unsaturation indices in liver and muscle were not significantly different between any of the groups. In considering that the minor changes in group D animals were not demonstrated in hyperinsulinemic group B animals or hyperglycemic, hyperinsulinemic group C animals, it is likely that the differences in group D animals were secondary to the more severe disturbances in glucose homeostasis and hypoinsulinemia present in these animals. The results of this study suggest that in this rodent diabetic model significant disturbances in glucose homeostasis and hyperinsulinemia may develop independently of changes in tissue fatty acid composition.
Lipids 32, 317–322 (1997).

Recent interest has focused on the importance of tissue fatty acid phospholipid (PL) composition in the modulation of insulin action. A number of animal studies have examined the effect of different dietary fats on tissue fatty acid composition and correlated changes in fatty acid composition with insulin action (1,2), metabolic rate, and weight gain (3,4). These animal studies have also been recently supported by cross-sectional human studies where decreased insulin sensitivity was associated with a decreased concentration of polyunsaturated fatty acids in skeletal muscle PL (5), and a prospective study by Vessby and coworkers (6) in which individuals who later developed non-insulin dependent diabetes mellitus (NIDDM) had a higher proportion of saturated fatty acids in their serum cholesterol esters 10 years prior to the development of NIDDM. As a result of a number of these studies, it has been postulated that membrane fatty acid composition may be involved in the pathogenesis of insulin resistance and non-insulin dependent diabetes mellitus (5,7). However, it is not possible to separate secondary changes attributable to dietary factors from genetically determined differences in these studies. In an effort to examine this question further, we have utilized *Psammomys obesus*, an animal model of diabetes that naturally develops a range of defects in glucose metabolism and insulin action when fed standard laboratory chow (8). The aim of this study was to determine whether the development of hyperglycemia and hyperinsulinemia in *P. obesus* (Israeli sand rat) was accompanied by changes in the composition of membrane PL fatty acids in two important insulin-sensitive tissues—liver, and a representative skeletal muscle, red gastrocnemius. Impairment of insulin action in both the liver and skeletal muscle is central to the spectrum of metabolic disturbances observed in NIDDM in both rodent models (7,9) and humans (10). Membrane PL fatty acids were analyzed in four groups of animals studied: group A: normoglycemic and normoinsulinemic; group B: normoglycemic and hyperinsulinemic; group C: hyperglycemic and hyperinsulinemic; and group D: hyperglycemic and hypoinsulinemic.

MATERIALS AND METHODS

Animals. Mature, 18-wk-old male *P. obesus* ($n = 28$) (bred in Deakin University Animal House, Geelong, Victoria, Australia) were divided into four groups based on fed blood glu-

[c,d,e]($P < 0.05$).

cose and insulin levels measured sequentially at 4, 8, and 12 wk of age (see Table 1). Animals were housed in a temperature-controlled room (22 ± 1°C) with a 12-h light/dark cycle and were fed standard laboratory grain-based food (Barastoc, Victoria, Australia). The diet consisted of the following major fatty acids: 14:0 (1.1%), 16:0 (18.6%), 18:0 (1.9%), 18:1 (29.9%), 18:2n-6 (39.3%), 18:3n-3 (2.8%), 20:5n-3 (1.2%), and 20:6n-3 (2.2%). Blood samples were collected in the fed state for glucose and insulin measurements, and animals were anesthetized with an intraperitoneal injection of pentobarbitone sodium (60 mg/kg), then liver and red gastrocnemius muscle were quickly removed and stored at −70°C. Plasma insulin levels were measured in plasma using a double-antibody solid-phase radioimmunoassay (Phadeseph, Kabi Pharmacia Diagnostics, Uppsala, Sweden). Whole-blood glucose concentrations were measured enzymatically using a YSI glucose analyzer (model 1500 Sidekick; Yellow Springs Instrument Co., Yellow Springs, OH). All experiments were approved by the Animal Experimental Ethics Committee at Deakin University and complied with NHMRC of Australia guidelines for the care and use of laboratory animals.

Lipid extraction and fatty acid analysis. Lipids were extracted from liver and muscle with chloroform/methanol, followed by thin-layer chromatographic separation of the fatty acid classes to obtain the PL fraction (11). The total lipid content of the tissue was determined gravimetrically (11). The PL were subjected to saponification and methylation (11), and the resultant fatty acid methyl esters were separated by capillary gas–liquid chromatography (DANI 6500 HR, ICI International; Melbourne, Australia) on a 60 m × 0.32 mm i.d. Rtx-2330 crossbonded column of phase thickness 0.25 μm. Helium was used as the carrier gas with a flow rate of 43 cm^3/s. Cold on-column injection (60 to 260°C in 0.8 min) was used, and the flame-ionization detector temperature was 280°C. The column temperature was maintained at 95°C for the first 3 min, then increased at 10°C per min until 190°C was reached and maintained for a further 24 min until the final peaks were eluted. Individual fatty acid methyl esters were identified by comparison of their retention times with those of a standard fatty acid methyl ester mixture and by inclusion of an internal standard of diheptadecanoyl phosphatidylcholine in the aliquots prior to methyl ester formation. The results were corrected by use of response factors which were calculated using standard fatty acid methyl esters.

Statistical analysis. All results are expressed as mean ± SEM. Differences between groups were established using one-way analysis of variance. Fisher's least significant difference test was used to discriminate significant differences ($P < 0.05$) between groups.

RESULTS

Glucose and insulin. Table 1 describes mean glucose, insulin levels, and body weight for the four groups of *Psammomys obesus*. Animals were selected for each category on the basis of hyperglycemia being defined as whole-blood glucose levels of 8 mmol/L or more and hyperinsulinemia being defined as plasma insulin levels of 150 μU/mL as described previously (8). Group A animals were normoglycemic and normoinsulinemic at 18 wk and at all earlier times (glucose ≤8.0 mmol/L, insulin ≤150 μU/mL); group B animals at 18 wk were normoglycemic and hyperinsulinemic (glucose ≤8.0 mmol/L, insulin >150 μU/mL); group C animals at 18 wk were hyperglycemic and hyperinsulinemic (glucose >8.0 mmol/L, insulin >150 μU/mL), and group D were hyperglycemic and hypoinsulinemic (glucose >8.0 mmol/L, insulin ≤150 μU/mL) at 18 wk of age after displaying hyperglycemia and hyperinsulinemia at one or more of the earlier time points. The majority of animals that displayed either hyperglycemia or hyperinsulinemia at week 18 had similar glucose and insulin values at 12 wk of age. The body weights of groups B and C animals were heavier than animals in group A ($P < 0.05$).

Table 1 also describes the total percentage tissue lipid in groups A, B, C, and D animals. In the liver, groups B and C had a higher percentage lipid compared with group A ($P < 0.05$). Group D liver lipid levels were lower than group B and C and not significantly different from group A. In muscle, there were no significant differences in the lipid content between any of the four groups.

Fatty acid analysis. Tables 2 and 3 describe liver and muscle PL fatty acid composition for each group of animals fed standard laboratory food. In liver, there were no significant differences in the PL fatty acids between groups A, B, and C. The only significant differences were found in group D animals which had higher levels of 20:4n-6. No significant differences in the unsaturation index were found between groups A, B, C, or D. The n-6/n-3 ratio was similar in all

[f]Unsaturation index = average number of double bonds per fatty acid residue × 100.

groups; however, group D animals had a significantly higher ratio of 20:4n-6/20:3n-6 and 20:4n-6/22:5n-3. In muscle there were no significant differences in the PL fatty acid composition between groups A, B, or C. However, group D compared with groups A, B, and C had significantly higher levels of 22:5n-3 and lower 20:5n-3. No significant differences were demonstrated in the unsaturation index between any of the groups. The ratio of 20:4n-6/20:5n-3 was higher in group D animals than groups A and B, but not group C. Total monounsaturated fatty acid levels were significantly lower in group D animals than groups B and C, although not group A.

DISCUSSION

The results of the current study clearly demonstrate that hyperinsulinemia and hyperglycemia can develop in animals independently from major alterations in membrane PL fatty acid composition.

Psammomys obesus is an ideal animal model in which to examine the development of NIDDM. These animals display a heterogeneous development of hyperinsulinemia and hyperglycemia when consuming standard laboratory food and can be divided into four groups (A, B, C, D) based on glucose and insulin levels as previously described (8). Group A animals are normoglycemic and normoinsulinemic, group B are normoglycemic and hyperinsulinemic, group C are hyperglycemic and hyperinsulinemic, and group D are hyperglycemic and hypoinsulinemic. In previous studies we have demonstrated that group C animals, when compared with group A animals, have increased body weight, increased epididymal and perirenal fat stores (12,13), and significant hyperphagia (12,13). From the current study, it is clear that metabolic changes in group C animals were not accompanied by any significant differences in individual tissue PL fatty acids when compared with group A or B animals. In addition, individual tissue fatty acid compositions were similar between all groups as was the unsaturation index and n-6/n-3 ratio of fatty acids.

On the other hand, group D animals, which develop severe diabetes and are hyperglycemic and hypoinsulinemic, demonstrated some differences in PL fatty acid composition, including increased 20:4n-6 in liver and increased 22:5n-3 in muscle. These animals also demonstrated an increased 20:4n-6/22:5n-3 ratio in liver and 20:4n-6/20:5n-3 in muscle. Despite these relatively minor changes, no significant differences were apparent in the unsaturation index of liver or muscle in group D animals compared with A, B, or C. In considering the relatively minor fatty acid differences in group D animals, and the fact that such changes were not demonstrated in hyperinsulinemic group B animals or hyperglycemic, hyperinsulinemic group C animals, it is most likely that the fatty acid changes in the group D animals were secondary to the more severe disturbances in glucose homeostasis and hypoinsulinemia.

This study presents the first report of PL fatty acid profile of this novel rodent model of diabetes. Interestingly, *P. obesus* individuals have tissue membrane 20:4n-6 levels less than half of values reported in several rodent species (14,15). Furthermore, tissue membrane 22:6n-3 levels, particularly in the red gastrocnemius, were greater than double those reported for other rodents (14,15).

In the presence of diabetes, most studies in rodents, although not all (16), have reported reduced 20:4n-6, and increased or unaltered 18:2n-6 content in tissue and membrane PL fractions (15,17,18). These alterations are consistent with the insulin-sensitive nature of the Δ-6 and Δ-9 desaturase enzymes, with reduced activity present as a consequence of insulin insufficiency or severe insulin resistance (19). In the diabetic group D of *P. obesus,* the absence of significant alterations in both 20:4n-6 and 18:2n-6 in the red gastrocnemius muscle and the elevation in 20:4n-6 in the liver would suggest that in these diabetic animals, sufficient insulin was available to prevent an impairment of the Δ-6 and Δ-9 desaturase activity, despite the failure of the circulating insulin levels to maintain normoglycemia. However, it should be noted that in insulin-deficient streptozotocin diabetic rats the altered fatty acid profile of the major PL was varied, with phosphatidylcholine and phosphatidylinositol most susceptible to the diabetes-induced alterations (15). The differential alterations in fatty acid composition of the major PL classes suggest that the evaluation of total PL fatty acid composition, as analyzed in the current study, may fail to detect pronounced fatty acid changes in one or more PL classes. Similarly, PL isolated from differing tissues (20) and subcellular membrane fractions may demonstrate varied responses prior to and during the development of diabetes. Yet despite these potential concerns, the absence of significant alterations in total membrane PL fatty acids in the insulin-resistant group B and group C *P. obesus* suggests that a specific defect in membrane fatty acid composition is unlikely to be central to the development of insulin resistance in this rodent model. Moreover, in the absence of specific alterations in fatty acid composition consistent with insulin deficiency in the diabetic group D animals, the changes in membrane fatty acid composition are likely to occur as a consequence of the altered metabolic state. The secondary nature of these changes is consistent with previous reports on diabetic rodents in which insulin treatment ameliorates many of the alterations in membrane PL fatty acids (21,22)

Although not directly examined in this study, disturbances in fat metabolism may underly the development of hyperglycemia. Group C animals are hyperinsulinemic, hypertriglyceridemic, have increased body weight, increased fat stores (8,12,13), and in the present study, a significant increase in liver fat accumulation suggesting a significant disturbance in energy balance and fat metabolism. It is possible that these disturbances in fat metabolism interfere with glucose metabolism, as first suggested by Randle and coworkers (23), and contribute to the hyperglycemia demonstrated in group C animals. Recent evidence

also suggests that fat accumulation may contribute to the pancreatic defect that results in hypoinsulinemia (24). It is then, only after the development of severe insulin resistance with hyperglycemia and hypoinsulinemia, that secondary changes in PL fatty acid composition occur as seen in group D animals.

In contrast to studies in animal models fed standard diets, dietary intervention studies have clearly demonstrated the effectiveness of different dietary fats in altering membrane PL fatty acid composition and subsequent effects on insulin action. A positive relationship has been described between membrane PL long-chain n-3 fatty acid content and muscle insulin action (25,26); when diets high in saturated fat were supplemented with long-chain polyunsaturated n-3 fatty acids, the resultant increase in the unsaturation content of membranes correlated with improved insulin sensitivity (27). These dietary intervention studies have been supported by *in vitro* studies which have demonstrated that increased levels of polyunsaturated fatty acids increased membrane fluidity (28), and insulin action (1,29,30). It is clear from these studies that altering the membrane fatty acid composition (either *in vivo* or *in vitro*) will be accompanied by changes in insulin action, and it is possible that the metabolic effects of different dietary fatty acids may in fact be mediated *via* alterations in membrane composition. In a cross-sectional human study, Bjorkman and coworkers (5) examined the relationship between the fatty acid composition of skeletal muscle PL and insulin sensitivity in normal subjects and demonstrated that decreased insulin sensitivity was associated with decreased concentration of polyunsaturated fatty acids in skeletal muscle PL of normal men. In addition, a recent longitudinal study by Vessby and coworkers (6) demonstrated significantly increased saturated fatty acids in the serum cholesterol esters of subjects who developed NIDDM compared with those who remained normoglycemic. As discussed by these workers (5,6), the degree to which these changes reflect environmental differences rather than genetic predisposition is unclear. Clearly, it is possible that dietary fats, *via* modification of membrane PL fatty acids, play an important role in the development of insulin insensitivity. However, in *Psammomys obesus*, a genetically susceptible rodent model of diabetes, no significant changes in liver or red gastrocnemius muscle membrane PL were present despite hyperinsulinemia and/or hyperglycemia in the group B and C animals. With severe diabetes (group D), significant alterations in PL fatty acid composition were measured although these changes were inconsistent with previous reports in diabetic rodent models. From the results of this study, it can be postulated that the changes in total membrane PL fatty acids may reflect environmental differences, as a consequence of diabetes, with significant defects in insulin sensitivity and glucose metabolism potentially developing independent of the membrane fatty acid composition.

ABSTRACT: This paper describes a simple method for the analysis of tocopherols in tissues by which frozen tissues –70°C were pulverized at dry ice temperatures (–70°C) and immediately extracted with hexane. There was no need to remove the coeluting lipids from tissues by saponification, since at that level of neutral lipids in the sample, there was no reduction in fluorescence response. For the analysis of oil, in which large amounts of neutral lipids were coextracted, a 20% reduction of fluorescence response was observed, but the response was equal for all tocopherol forms, and was appropriately corrected. Saponification was used only when tocopherol esters were present, and only after an initial hexane extraction to remove the free tocopherols in order to avoid their loss by saponification, particularly non α-tocopherol and tocotrienols. All the tocopherols and tocotrienols were separated on a normal-phase diol (epoxide) column that gave consistent and reproducible results, without the disadvantages of nonreproducibility with silica columns, or the lack of separation with reversed-phase columns. The tocopherols were quantitated by using a tocopherol form not present in the sample as an internal tocopherol standard, or using an external tocopherol standard if all forms were present, or when the sample was saponified. Piglet heart and liver samples showed the presence of mainly α-tocopherol, with minor amounts of β- and γ-tocopherol and α-tocotrienol, but no δ-tocopherol. Only small amounts of tocopherol esters were present in the liver but not in the heart.

Lipids 32, 323–330 (1997).

Vitamin E has received much attention recently because of its antioxidant activity and its possible preventative role in degenerative disease processes. "Vitamin E" is a generic term which includes a mixture of tocopherols (T) and tocotrienols (T_3) which differ in the number and position of methyl groups on the fused chromanol ring, and the absence or presence of three double bonds in the isoprenoid side chain. The major naturally occurring tocopherol forms are 5,7,8-trimethyltocol (α-T), 5,8-dimethyltocol (β-T), 7,8-dimethyltocol (γ-T), and 8-methyltocol (δ-T), and the corresponding tocotrienols are 5,7,8-trimethyltocotrienol (α-T_3), 5,8-dimethyltocotrienol (β-T_3), 7,8-dimethyltocotrienol (γ-T_3), 8-methyltocotrienol (δ-T_3) and no methyl groups—tocol (Scheme 1).

In general, the current procedures for the analyses of tocopherols in tissues involve the removing of the tissue from the animal, analyzing it fresh, or more often, storing the sample at –70 to –80°C until it is analyzed, followed by thawing and mechanically homogenizing the sample (1–14). After addition of ethanol, the homogenate is extracted with hexane, or acetone (1,2,6,13) and analyzed directly for tocopherols (1,2,4,9–11,13), or saponified with alkali to remove the coextracted neutral lipids prior to analysis (3,5–8,12,14). Saponification has been recommended by some for tissue analyses (3,8), despite the fact that it causes extensive loss of all tocopherols (7,15), and tocotrienols (16), and that the loss is different for the various forms (7,15).

The analyses of tocopherol in foods and feeds (1,8,9,14,15, 17–20), oils and seeds (1,19,21–27), plasma (2,4,6–10, 13–15,28-32), platelets (30), and red cells (4,7,28,32) are the

Abbreviations: CP, cross polarization; HPLC, high-performance liquid chromatography; MAS, magic angle spinning; NMR, nuclear magnetic resonance; T, tocopherol; T_3, tocotrienols; TAG, triacylglycerol.

same as for tissues, except for the prior homogenization step. Foods or feeds are ground and extracted directly (1,9) or saponified and extracted (1,8,14,15,17–20), vegetable oils are directly extracted (21–25,27) or saponified and then extracted (19,25,26), and plasma, platelets and red cells are treated with ethanol (2,6–10,13–15,28–31) or detergents (4,32) to remove proteins by precipitation, followed by hexane extraction.

The tocopherols are separated by high-performance liquid chromatography (HPLC) on normal-phase (1,3–5,8–11,15, 18,19,21–23,25–27), or reversed-phase columns (2,6–8, 12–14,17,19,20,24,28–32). A normal-phase column, bonded with amino–cyano groups, was used successfully to separate all vitamin E forms (9,19,23). Generally, tocopherols and tocotrienols are detected by fluorescence, although ultraviolet (3,13,19,28) or evaporative light-scattering detection (24,25) has also been used. However, these latter detectors are not selective (19,21) and less sensitive (19,21,25).

In this communication, a simplified method is presented which avoided the thawing and mechanical homogenization step that may cause loss of tocopherols. There was no need for added antioxidants to minimize loss of tocopherols. Direct injection of the hexane extract and detection by fluorescence was shown to be quantitative, and the various forms were not affected differently by the presence of triacylglycerol (TAG) in the mixture. Furthermore, a diol column was used for the separation of all eight tocopherol and tocotienols. The "diol" column, which is really an "epoxide" column, had the advantage of both giving more reproducible and consistent separations than silica columns (15,19,23) and separating all forms, unlike reverse-phase columns (7,8,19,20,28,31)

MATERIALS AND METHODS

Materials. Solvents were HPLC grade (Fisher Scientific, Nepean, Ontario, Canada) except absolute ethanol. The tocopherol forms α-, β-, γ- and δ-tocopherol (T), and 5,7-dimethyltocol (5,7-T; synthetic) were purchased from Matreya, Inc. (Pleasent Gap, PA). α-T_3 isolated from oats was a gift from Dr. Bill Collins (Center for Food and Animal Research, Ottawa, Ontario, Canada). Red palm oil, an enriched tocopherol and tocotrienol fraction from palm oil (Nutrolein, Golden Palm Olein) was a gift from the Malaysian Palm Oil Council of America, Inc. (Chicago, IL). Triolein was obtained from Nu-Chek-Prep, Inc. (Elysian, MN).

Tissue preparation. Heart and liver samples were taken from experiments in which newborn piglets were fed milk replacer diets for 4 wk as previously described (33). All the milk replacer diets contained additional α-T succinate (100 IU per kg diet) besides the natural tocopherols and tocotrienols in the dietary ingredients. The lactation and piglet starter diets were prepared to contain vitamin E acetate at 54 and 81 IU/kg, respectively.

The tissues were removed from the piglets at the end of the experiment and immediately frozen between blocks of dry ice and stored at −70°C until analyzed. The same general areas of the liver and heart were selected by the pathologist for vitamin E analysis. All operations for vitamin E analyses were carried out in a low-light environment. Two separate samples of approximately 1 g tissue were accurately weighed in the frozen state on a watch glass (cooled on dry ice) and immediately pulverized using a steel mortar and pestle at dry ice temperature, as described previously (34). The pulverized tissue was placed into 50-mL conical tubes with cap (Falcon™ polypropylene tubes; Becton Dickinson Labware, Franklin Lakes, NJ) containing 2 mL of water chilled in an ice bath. Polypropylene tubes were used for safety reasons during sonication. Five mL of cold absolute ethanol was added immediately to wash down any sample that stuck to the sides of the tube. In addition, 4 μg of one of the tocopherols was added as internal standard to each tube. (For choice of internal standard, see below.) The samples were sonicated (Model W-225; Heat Systems-Ultrasonic Inc., Farmingdale, NY) at 50% power setting for 45 s while the tubes were maintained in an ice bath. The sonication probe was rinsed with an additional 5 mL of cold absolute ethanol. Ten mL of ice-cold hexane was added to the tube, and the contents were mixed with a vortex for 30 s. The samples were centrifuged at 2500 rpm for 15 min at 0°C, after which 5 mL of the hexane layer was removed (to avoid picking up some of the lower phase) into a 100-mL round-bottom flask. The hexane was removed by flash evaporation using a rotary evaporator, then immediately taken up in 1 mL of hexane, and transferred to a 1.5-mL amber HPLC vial. The flask and vial were flushed with nitrogen. The vials were stored at −70°C until analyzed by HPLC, usually the same day. Samples were occasionally tested a week later and the results were found to be the same.

Extraction of tocopherols from diets and oils. If tocopherol esters were present in the diet, a modified saponification step was used. Ten mL of cold ethanol and an internal tocopherol standard was added to about 1 g of diet. The samples were sonicated, mixed using a vortex, and extracted with three portions of 10 mL of hexane to remove all TAG and vitamin E. The hexane layers were combined, reduced in a rotary evaporator, taken up in 1 mL of hexane, and analyzed. This fraction represented the free tocopherols in the diet. To the remaining ethanol mixture, 100 mg of ascorbic acid, 2 mL of a 60% KOH (wt/v), but no internal standard were added, and the solution was heated at 70°C for 10 min. The sample was then reextracted with three portions of 10 mL of hexane. The hexane extract could be washed with water to remove any traces of KOH. The hexane layers were combined, reduced, and taken up in 1 mL of hexane and analyzed. This fraction represented the esterified tocopherols in the diet, and it was quantitated with α-T as the external standard, since α-T esters are the usual form of vitamin E added to diets. Tocopherols and tocotrienols were directly extracted from oils with hexane after addition of ethanol and an internal tocopherol standard.

HPLC method. Tocopherols were analyzed by an HPLC (Model 1090, Hewlett-Packard, Palo Alto, CA) equipped with an autosampler (25 μL syringe), a fluorescence detector (Model FL2000; Spectra-Physics Analytical, Fremont, CA), and a data acquisition system (HP 3365 Series II ChemSta-

tion). A normal-phase Supelcosil LC-Diol column (25 cm × 4.6 mm, 5 μ particle size; Supelco Inc., Bellefonte, PA) was used, operated at room temperature, with hexane/propan-2-ol (99:1) as the mobile phase for 25 min, at a flow rate of 1 mL/min. The solvent mixture was prepared fresh each day and sparged with helium for 10 min. Continuous sparging with helium led to an increase in retention time of δ-T from 16 to 21 min over a 6-h period. This was due to a reduced content of propan-2-ol in the mixture from 1.00 to 0.61% during 6 h sparging, as measured by gas–liquid chromatography. The reason was that hexane/propan-2-ol formed an azeotropic mixture (77:23) which was selectively removed during sparging because of its lower boiling point at 62.7°C (35). This decrease of propan-2-ol lowered the polarity of the solvent, and therefore increased the retention times of the tocopherols. To avoid this annoyance, sparging was discontinued after 10 min, since sparging is not critical for fluorescence detection. The fluorescence detector excitation wavelength was 296 nm with an emission wavelength of 330 nm.

Quantitation. The samples were quantitated using selected tocopherol forms both as internal and external standard. The choice of internal standard depended on which tocopherol was absent in the samples to be analyzed. Liver and heart tissues, as well as red palm oil, contained no δ-T, which was therefore used as the internal standard. The dietary oils contained no α-T_3, and therefore, 5,7-T (a commercial product) was chosen as the internal standard, because on this column, α-T_3 did not separate from 5,7-T. An external standard was selected when all forms of vitamin E were present in the sample to be analyzed, or when a sample was saponified. α-T was the external standard of choice, because it is the major form of vitamin E present in biological samples, and the usual form added to diets. To measure the recovery, the detector response of the internal standard was compared to identical amounts of the same tocopherol measured externally. The average recovery of tocopherols was found to be 95 ± 7% (n = 10). The fluorescence detector was tested for linearity over the range from 10 to 100 ng for all vitamin E forms.

Measurement of nuclear magnetic resonance (NMR) spectra. The solid state ^{13}C CP/MAS NMR (cross polarization, magic angle spinning, NMR) spectra were recorded on a modified NT-270 Nicolet NMR spectrometer (Madison, WI). Spectra were obtained in natural abundance at a frequency of 68.055 MHz. CP/MAS were performed using a multinuclear CP/MAS probe equipped to accommodate 7.0-mm diameter spinners. MAS was carried out at 4.0 KHz. The magic angle was adjusted using the aromatic resonance line of the ^{13}C CP/MAS spectrum of hexamethylbenzene. ^{13}C spectra were acquired with a contact time of 2 ms, high power proton decoupling during acquisition, a recycle delay of 3 s, and a spectral width of 20 KHz. Typically, 10,000 transitions were accumulated. The chemical shifts were referenced to tetramethylsilane.

Statistics. All data were analyzed using the general linear models procedure, and the mixed models procedure of SAS (36), with terms for litter, diet, litter by diet interaction, animal variation within litter by diet, and variations between determinations. Where the variance component was zero for litter by diet interaction, this term was pooled with the "among piglets" term to test for diet differences.

RESULTS AND DISCUSSION

Pulverization and extraction step. This method was developed to avoid the thawing and mechanical homogenization step presently used in the analyses of vitamin E (1–14). Generally, tissues are removed immediately from experimental animals and stored at −70 to −80°C until analyzed. The technique described here maintains the tissues at that temperature (−70°C) during the weighing and pulverization step. The pulverized sample was then transferred directly into tubes containing water and ethanol at 0°C, and sonicated to provide dispersion of the tissue, before extraction of vitamin E with hexane. The addition of ascorbic acid or pyrogallol was not found to be necessary to protect vitamin E against degradation during the pulverization at −70°C. We have previously reported the same pulverization method at dry ice temperature for the extraction of intact total lipids from tissues and found that it protected lipids from lipolysis and oxidation (34).

Is saponification necessary? The extraction of vitamin E from tissues with hexane coelutes neutral lipids which interfered with the identification of the vitamin E forms, if ultraviolet (13,21,28,31) or evaporative light-scattering detectors (24,25) were used. These interfering lipids were removed by saponification, but this step reduced the recovery of all tocopherols, and in particular, δ-T (7,8,15,16,20,23) and α-T_3 (16). The reduction was dependent on the concentration of KOH (15), the temperature of saponification [room temperature (15,20) vs. 70°C (7,8,16)], and the TAG content (7). Despite this inherent problem, the saponification step is still recommended (3,7,8,15,19,20,21). The use of fluorescence detection should not cause interference, since this detector is specific for the chromanol chromaphore found in vitamin E. Even though several authors have demonstrated that tocopherols were measured successfully in the presence of neutral lipids (1,21,23,25,27), there seems to be a reluctance to delete the saponification step. A systematic evaluation was therefore undertaken to determine the effects of TAG on the quantitation of the tocopherols and tocotrienols using fluorescence detection (see section below). To reduce the neutral lipid content particularly from oils and oil seeds, some have suggested methanol extraction (27) or 1:10 dilutions of the hexane extract (24).

Separation of the tocopherols on a normal-phase diol column. The diol column gave consistent and reproducible separations of all four tocopherols (α-T, β-T, γ-T, and δ-T) and four tocotrienols (α-T_3, β-T_3, γ-T_3, and δ-T_3). Figure 1 shows a separation of a mixture of the four tocopherol standards and an extract from red palm oil. Red palm oil was chosen because it is known to contain all four tocotrienols (24), which are not commercially available. 5,7-Dimethyltocol, although commercially available, was of limited value as an internal

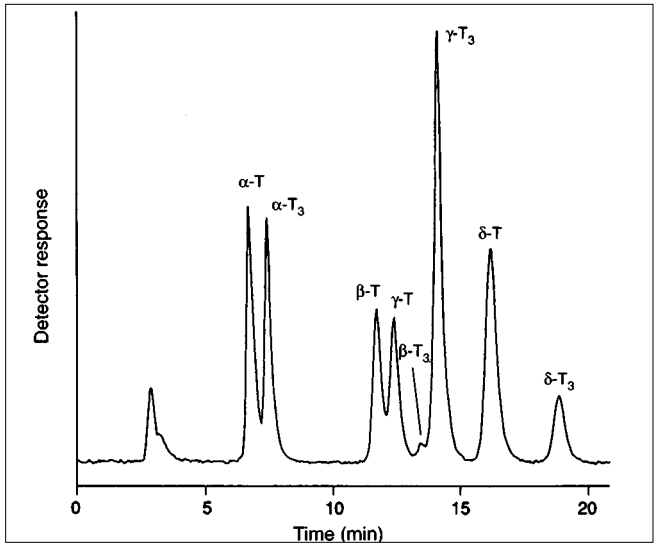

FIG. 1. Separation of tocopherol (T) and tocotrienol (T_3) by high-performance liquid chromatography on a normal-phase Supelcosil LC-diol column (Supelco Inc., Bellefonte, PA) using hexane/propan-2-ol (99:1) as the mobile phase and a flow rate of 1 mL/min.

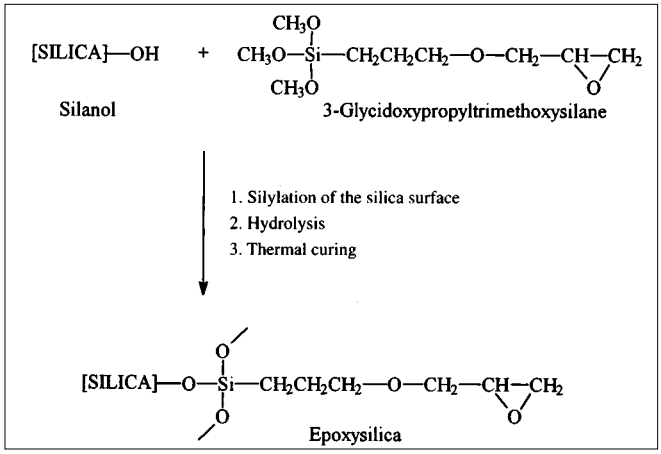

SCHEME 2

standard, since it had the same retention time as α-T_3 that is generally found in small amounts in tissues. Tocol (for structure see Scheme 1), not commercially available, would have been a better choice as a general internal standard, because it is not present in tissues or oils, and it separated well from all tocopherols and tocotrienols on normal-phase columns as reported by some investigators (3,7).

The diol column behaved as a normal-phase column separating all the eight forms of vitamin E, as expected using silica-based columns (1,7,8,15,18,19,21–23,25,27). However, silica columns were reported to be unstable, occasionally yielding poor reproducibility (8,15,19,23,25), as experienced in our laboratory. For this reason, Rammell and Hoogenboom (23) proposed the use of an amino–cyano polar phase column in which cyano and amino groups were bonded to the surface hydroxyl groups of silica. This resulted in greater reproducibility and improved resolution of all tocopherols and tocotrienols. However, the amino group ionized with use of polar organic solvents, and caused increased retention times and peak broadening. This problem was eliminated by incorporating formic acid into the eluate. However, the authors expressed concern that the stability of the column may be affected by continued use of formic acid (23). On the other hand, the diol column has no ionizable groups.

The diol column was prepared by reacting 5 μm spherical silica particles containing surface silanol (Si-OH) groups with 3-glycidoxypropyltrimethoxysilane (Scheme 2) to furnish a bonded phase with a ligand density of 3.8 μmoles/m^2 on the silica. Evidence for the intact epoxy ring system on the bonded phase was provided by solid-state ^{13}C CP/MAS NMR of the packing material, which exhibited signals at δ 7.8 ppm (Si–*C*H_2), δ 23.4 ppm (Si–CH_2*C*H_2), δ 42.3 ppm (O–*C*H_2–CH of epoxy ring), δ 49.8 ppm (C*H*$_2$–O– of epoxy ring), and δ 70.9 ppm (double intensity, *C*H–O of epoxy ring plus Si–CH_2CH_2*C*H_2–O). If the epoxy ring had cleaved into a diol, the signal at δ 42.3 ppm would be absent and the intensity of the signal at δ 70.9 ppm would be reduced to half its value. In addition, new signals at δ 64.2 ppm (*C*H_2–OH) and δ 72.1 ppm (*C*H–OH) would be registered. No signals corresponding to the diol were observed in the ^{13}C CP/MAS NMR spectrum of the packing material. Intentional hydrolysis of the epoxide ring under the refluxing conditions with 0.1 M HCl for 2 h did not produce any significant cleavage of the epoxy ring, as deduced from NMR. Therefore, this column should not really be considered as "diol" functionalized, but rather an "epoxide" structure. The observed superior performance of this epoxy column is attributable to its stability to polar and nonpolar solvents, its incapability to form any strong hydrogen-bonded structures with proton-donor analytes, and its moderate polarity.

Influence of TAG on the quantitation of tocopherols using fluorescence detection. Figure 2 shows the relationship between different levels of triolein (10 to 400 mg) on the fluorescence response of α-T, β-T, γ-T, δ-T and 5,7-T, and α-T_3 (50 ng each). There appears to be no difference in response between the different tocopherol forms or α-T_3 to the amount of coexisting TAG. This made it possible to use any of the tocopherols as an internal standard that was not present in the sample. The similar effect of all tocopherol forms in the presence of TAG was in marked contrast to the effect of TAG after saponification in which recoveries of 90% were observed for α-T, 65% for β-T, 60% for γ-T, and 20% for δ-T at 500 mg corn oil (7). Others reported that α-T_3 was completely destroyed (16).

The recovery of all tocopherols was >95% at 25 mg/mL TAG (Fig. 2). This amount of TAG was much greater than generally observed in tissues, except adipose tissue. The neutral lipid content of most tissues was about 1 to 3%, or 0.5 to 1.5 mg/mL from a 1 g sample of tissue (since only half the hexane extract was used in the analyses). On the other hand,

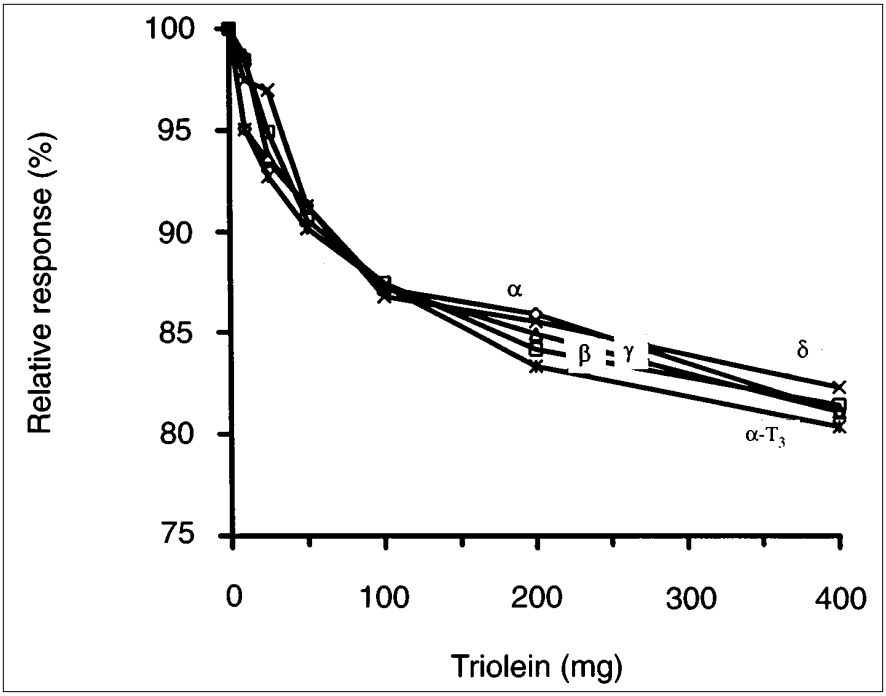

FIG. 2. The fluorescence detector response of tocopherols (T) and α-tocotrienol (α-T_3), 50 ng each, in the presence of different amounts (10 to 400 mg) of triolein. The results are means of three determinations (pooled SEM 2.33), and there were no significant differences at any concentration of triolein.

the analyses of one gram of diet, which contained 20% fat, gave 100 mg/mL TAG with an average recovery of 87% for all tocopherols, while one gram of oil gave about 400 to 500 mg/mL of TAG with an average recovery of 80% (Fig. 2). Analyses of diets and oils were corrected appropriately.

Calibration curves for the tocopherols are shown in Figure 3. The fluorescence detector response was linear over the range 10 to 100 ng of each of the vitamin E forms (all *r* values >0.99). The integrated area response for the same amount of vitamin E form was least for α-T and most for δ-T. Therefore, the following correction factors were applied for α-T (2.30), β-T (1.52), γ-T (1.32), δ-T (1.00), and α-T_3 (1.19). These results were completely contrary to those reported by Thompson and Hatina (1) that the different forms of vitamin E gave similar fluorescence detector response. Many subsequent reports have relied on these results (15,18–21,23,27,30,31), and therefore, the results were not corrected for differences in fluorescence response between the different vitamin E forms. However, two studies have recently appeared showing differences in detector responses for the various tocopherol forms using evaporative light-scattering (24) and fluorescence detection (25).

Quantitation of tocopherols in tissues. The liver and heart tocopherol values of newborn piglets fed four different experimental diets or sow milk for 4 wk are presented in Table 1. The results showed that both tissues contained mainly α-T with minor amounts of β-T, γ-T, and α-T_3, but no δ-T. These complete analyses of tissue tocopherols and tocotrienols have not been reported previously. The levels of α-T reported here were generally higher than those reported previously in pig tissues (9,10,12,14), and may indicate the success of this method to recover more of the tocopherols from tissues. Only trace amounts of vitamin E were observed in the second hexane extract of tissues which justified the use of only one hexane extraction. There were consistent diet differences, except for sow-reared piglets which showed higher liver than heart α-T (Table 1). β-T was present only in trace amounts in sow-reared piglets, but was found in piglets fed milk replacers which contained oils with β-T (see Table 2). The occurrence of β-T in either heart or liver has not been reported previously. γ-T was present at concentrations reflecting the high levels of γ-T in the dietary oils. Others have also reported the occurrence of γ-T in pig (9,12) and monkey (11) livers. In one of the studies (12), the sum of β-T and γ-T must have been reported, since a reversed-phase column was used that does not separate these two forms. We could not detect δ-T in piglet tissue, which is in agreement with another study (9). For this reason, δ-T was chosen as the internal standard for tissue tocopherol quantitation. Finally, α-T_3 was found in both liver and heart of pigs, irrespective of diet; there were generally no significant differences between diets. The occurrence of α-T_3 in pig liver was reported in one previous study in which an amino–cyano column was used (9). However, in that study, neither β-T nor γ-T was detected.

To check whether tissues contained esterified tocopherols, the residue of tissue hexane extraction was saponified and then reextracted with hexane. Less than 0.5 μg/g α-T, and no other tocopherols or α-T_3 were found in the liver, and no to-

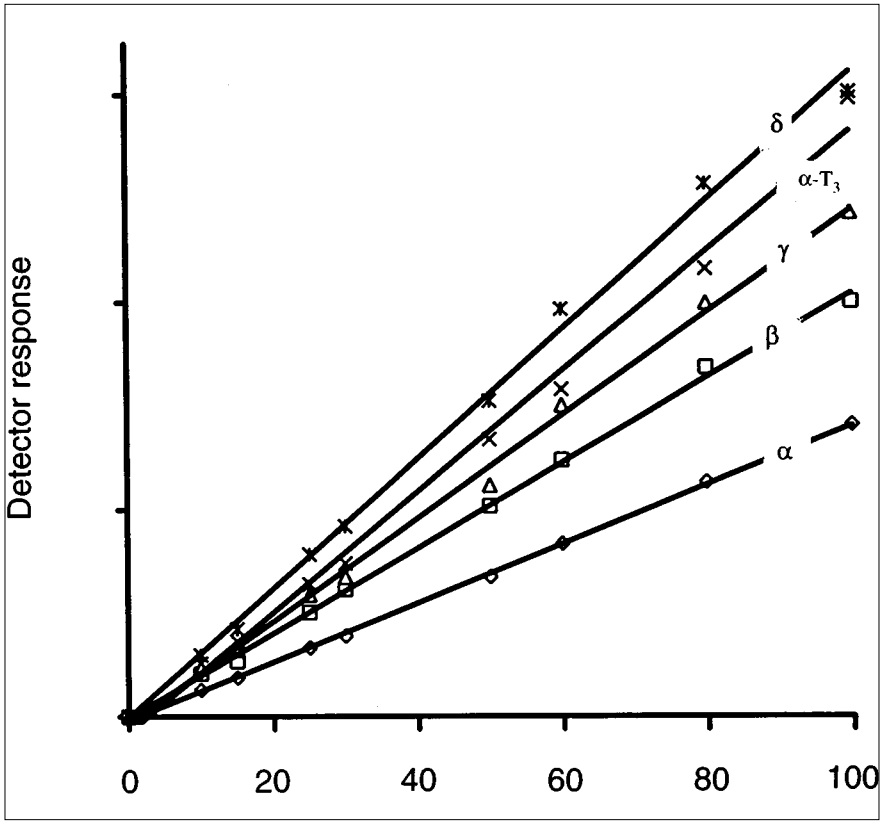

FIG. 3. Calibration curves for the fluorescence detector responses of tocopherols (T) and α-tocotrienol (α-T_3).

copherols were present in the heart after saponification. This indicated that only minor amounts of esterified tocopherol were present in liver. Incomplete extraction of the tocopherols was ruled out, because similar levels of α-T should have been found in the heart as the liver, and none was detected in the heart after saponification.

The overall error of tissue vitamin E analyses (Table 1) was large, despite randomizing diets within litter, due to variation among animals. Similar locations of the tissues were selected from the piglets to reduce variation. There was a high degree of reproducibility between repeat analyses of the same extract (data not shown). The reproducibility of duplicate determinations was also high, evident by the low error and no significant differences (Table 1). It should be noted that most of the error among determinations may be due to the fact that separate one-gram tissue samples were analyzed in this study, without prior homogenization of the total selected tissue from each piglet, and that representative subsamples were taken. The recovery of the internal standard δ-T used in the present study was 95 ± 7% (n = 60), determined by comparing the detector response of the internal standard in the sample to that of the same amount of the same tocopherol standard used externally.

Quantitation of tocopherols in diet. The analyses of the diets are shown in Table 2. Values were presented for the free tocopherols in the diet obtained by extracting with hexane and using 5,7-T as the internal standard. The latter was chosen because there was no α-T_3 present in these diets, and 5,7-T and α-T_3 had the same retention time on this column. The remaining ethanol layer was then saponified after addition of ascorbic acid and extracted to give values for α-T from the α-T succinate that was added to the diets. For the saponification step, α-T was used as an external standard to avoid differential loss during saponification of any of the other tocopherols one could have selected as an internal standard. Small amounts of the other tocopherols were also found after saponification, which suggests that other tocopherols also existed in the ester form. This modification of the method permitted the analyses of the free, naturally occurring tocopherols of diets or tissues, without differential loss during saponification, followed by a check on the amount of added tocopherol ester, usually of α-T. The recovery of the added D-α-T succinate (at 45.5 μg/g diet) in this study was 87 ± 5%.

In conclusion, a method was described to pulverize frozen tissues directly at −70°C, to eliminate the thawing and homogenization steps, and to increase the recovery of the tocopherols without the addition of any antioxidant to protect vitamin E. There was no need to remove the coeluting lipids by saponification, since they did not interfere with the quanti-

[e]Pooled standard error of the mean.

tative analyses of the tocopherol forms, except when tocopherol esters were measured that were added to the diet. The fluorescence response was different for the various tocopherol forms, affected slightly by the presence of large amounts of TAG, but the latter response was similar for all tocopherol forms. For tissue analyses, the response was >95%, and for oils it was about 80%. The normal-phase diol column for HPLC gave reproducible and consistent separations of all the tocopherol and tocotrienol forms, without the disadvantages of nonreproducibility when silica columns were used, or the lack of separation with reversed-phase columns.

ACKNOWLEDGMENTS

Contribution number 2419 from the Center for Food and Animal Research. We thank the statistician Gail Butler for her help in analyzing the tissue vitamin E results.

Analysis of Lipoxygenase-Derived Fatty Acid Hydroperoxides by Electrospray Ionization Tandem Mass Spectrometry

Claus Schneider, Peter Schreier, and Markus Herderich*

Lehrstuhl für Lebensmittelchemie, Universität Würzburg, D-97074 Würzburg, Germany

ABSTRACT: A rapid method is described for the identification of fatty acid hydroperoxides by electrospray ionization–tandem mass spectrometry coupled to liquid chromatography without any derivatization required prior to analysis. Localization of fatty acid hydroperoxides in complex mixtures was achieved by monitoring the loss of hydrogen peroxide using constant neutral loss scanning. In the presence of 5 mM NH_4OAc in methanol–water, adduct ions $[M + NH_4]^+$ were formed almost exclusively, directly revealing the molecular mass of the thermolabile hydroperoxides. In addition, low energy collision-induced dissociation of precursor ions $[M + NH_4]^+$ led to characteristic product ions from both the 9- and 13-regioisomers. Thus, electrospray ionization–tandem mass spectrometry provides a straightforward approach for the study of the regioselectivity of lipoxygenase catalysis without any derivatization step required prior to analysis.

Lipids 32, 331–336 (1997).

Fatty acid hydroperoxides are labile key intermediates in plant and mammalian lipid metabolism, acting as progenitors of a variety of lipid-derived mediators such as prostaglandins and leukotrienes (1,2). They are formed by lipoxygenase (LOX) action on polyunsaturated fatty acids containing a 1,4-*Z,Z*-pentadiene moiety such as linoleic and linolenic acid. LOX from different sources not only show distinct enantioselectivity but also exhibit a characteristic positional specificity (3): whereas soybean lipoxygenase-1 selectively produces 13-*S*-hydroperoxides, LOX isoenzymes 2 and 3 from the same source generate a racemic mixture of both 9- and 13- isomers (3). In contrast, tomato LOX almost exclusively yields the 9-*S*-hydroperoxides (4).

The conventional analysis of the thermolabile regioisomeric fatty acid hydroperoxides by gas chromatography–mass spectrometry requires a tedious derivatization procedure including reduction of the hydroperoxide moiety followed by methylation of the carboxy function and silylation of the hydroperoxide-derived hydroxyl group (5). Nonetheless, specific detection of 9- and 13-regioisomers has proved to be difficult, since the resulting trimethylsilyl-derivatives exhibit very similar chromatographic and spectroscopic properties (6). Thus, hydrogenation of the carbon-carbon double bond has to be included as an additional derivatization step prior to gas chromatography–mass spectrometry analysis.

Recently, development of electrospray ionization (ESI) has pioneered the coupling of liquid chromatography (LC) with mass spectrometry (7). In particular, the efficient on-line characterization of polar and labile intermediates by tandem mass spectrometry (MS/MS) in combination with electrospray ionization (ESI) opens further dimensions in the field of bio-organic analysis. By LC–ESI–MS/MS, both molecular mass and substructure-specific data are available without the need of derivatization and laborious sample clean-up.

Spurred by recent reports on the analysis of lipid-derived mediators such as carboxylate anions, applying ESI in the negative mode (8,9), we developed a strategy based on LC–ESI–MS/MS for the detection of fatty acid hydroperoxides in complex samples followed by identification of the corresponding regioisomers.

MATERIALS AND METHODS

Chemicals and materials. Linoleic acid (99% pure) was obtained from Fluka (Neu-Ulm, Germany). Linolenic acid (99% pure), ammonium acetate, and soybean LOX (EC 1.13.11.12) (type I-S, L-8383) were from Sigma (Steinheim, Germany). High-performance liquid chromatography (HPLC)-grade solvents, water, and methanol were from Merck (Darmstadt, Germany); tetrahydrofuran (THF) from Roth (Karlsruhe, Germany); and acetic acid from Baker Chemicals (Deventer, The Netherlands). Tomatoes were purchased at the local market. All other chemicals were of analytical grade quality; solvents were redistilled before use.

Isolation of LOX. Tomato LOX was prepared using a modified procedure described by Bonnet and Crouzet (10). Five hundred grams of tomato fruit (*Lycopersicon esculentum*) were washed and cooled at 4°C, cut into slices, and blended in a mixer with 500 mL 0.5 M Tris-HCl buffer (pH 8.0) containing 1% (wt/vol) ascorbic acid, 1% (wt/vol) EDTA, and 1 mM phenylmethylsulfonylfluoride for 3 min at 4°C. The homogenate was filtered through two layers of cheesecloth. To the filtrate, 2% (vol/vol) 1 M $CaCl_2$ was added and 2 h later the suspension was centrifuged at 15,000 × *g* for 20 min. Protein was precipitated by adding solid ammonium sulfate up to 60% saturation to the supernatant. The precipitate was collected by centrifugation at 15,000 × *g* for 20 min, dissolved in 5 mL of 0.1 M phosphate buffer (pH 6.5), and dialyzed overnight against the same buffer. This solution (0.7 U LOX/mL) was used as the source of LOX.

Soybean LOX-2 was purified from soybean seeds as previously described (11) and freeze-dried after addition of 0.1 N sodium chloride. This preparation (12 U LOX/mg) was used as the source of LOX-2.

Preparation of fatty acid hydroperoxides. 13-*S*-hydroperoxy-9-*Z*,11-*E*-octa-decadienoic acid (13-*S*-HPOD) and 13-*S*-hydroperoxy-9-*Z*,11-*E*,15-*Z*-octadecatrienoic acid (13-*S*-HPOT) were prepared using soybean LOX (Sigma, L-8383). Typically, 5 mg fatty acid was diluted in 10 mL of 0.1 M borate buffer (pH 9.0) in a conical flask. The solution was mixed by magnetic stirring and flushed with oxygen while the temperature was maintained at 0°C. The reaction was initiated by addition of 1 mg soybean LOX; progress of the enzymatic conversion was monitored photometrically at 234 nm. When the reaction was almost completed, the pH was adjusted to pH 3 with 1 N HCl. The solution was saturated with sodium chloride, and the mixture was extracted three times with 5 mL of diethyl ether each. The combined extracts were washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was dissolved in methanol and further purified by reversed-phase HPLC.

9-*S*-hydroperoxy-10-*E*,12-*Z*-octadecadienoic acid (9-*S*-HPOD) and 9-*S*-hydroperoxy-10-*E*,12-*Z*,15-*Z*-octadecatrienoic acid (9-*S*-HPOT) were prepared using tomato LOX. Five mg fatty acid was dissolved in 10 mL of 0.1 M phosphate buffer (pH 6.5) and maintained at 0°C. The solution was flushed with oxygen and stirred magnetically. The reaction was started adding 1 mL of freshly prepared tomato LOX and allowed to proceed for about 5 h. The solution was adjusted to pH 3.0 with 1 N HCl and extracted as described above.

Conversion of linoleic acid with soybean LOX-2 was carried out as described for the preparation of 13-*S*-isomers using 0.1 M phosphate buffer (pH 6.5) and limiting reaction time to 2 h.

For estimation of regioselectivity hydroperoxides derived from LOX-2 oxidation were quantified using product ions *m/z* 195 (13-HPOD) and *m/z* 155 (9-HPOD):

$$\frac{\text{9-HPOD}_{\text{sample}}}{\text{13-HPOD}_{\text{sample}}} = \left[\frac{\text{intensity } m/z\ 155}{\text{intensity } m/z\ 195}\right]_{\text{sample}} \times \left[\frac{\%\ m/z\ 195}{\%\ m/z\ 155}\right]_{\text{reference}} \quad [1]$$

A complex biological sample for detection of fatty acid hydroperoxides was prepared using a crude enzyme extract from soybean. One gram homogenized and defatted soybean seeds was extracted for 1 h with 10 mL of 0.2 M sodium acetate buffer pH 4.5 containing 5 mM EDTA. After centrifugation, the supernatant was used to oxidize 10 mg of linoleic acid in 20 mL of 0.1 M phosphate buffer pH 6.5 at ambient temperature. Work-up was as described above.

Chromatographic purification of fatty acid hydroperoxides as reference compounds. Fatty acid hydroperoxides were further purified by reversed-phase HPLC (12). The isomeric LOX products were analyzed on a Spherisorb ODS-2 column (5 µm, 4.6 × 250 mm) (Knauer, Berlin, Germany) using an ultraviolet (UV) detector (variable wavelength detector, Knauer) set to 234 nm for detection of conjugated dienes. Isocratic elution (HPLC pump 64, Knauer) was performed with THF/MeOH/water/acetic acid (18:48:33.9:0.1, by vol) at a flow rate of 0.8 mL/min. Semipreparative purification of hydroperoxides required multiple injections and collection of the corresponding peaks. The purified hydroperoxides were evaporated *in vacuo* and dissolved in the starting buffer of HPLC analysis to a final concentration of 0.026 mM. Configuration of double bonds in 9- and 13-HPOD was assigned by HPLC with UV detection according to standard procedure (13).

Mass spectrometric analysis of fatty acid hydroperoxides. For LC–ESI–MS/MS, chromatographic separation was performed on Eurospher 100 C-18 column (5 µm, 2 × 100 mm; Knauer) with a binary gradient delivered by an Applied Biosystems 140B pump (Foster City, CA). Solvent A was THF/MeOH/water/acetic acid (25:30:44.9:0.1, by vol), solvent B was MeOH/water (9:1, vol/vol). Both solvents A and B contained 5 mM NH_4OAc. HPLC was programmed as follows: pressurizing 1 min with 50% solvent A at 1 mL/min, target time 1 min at 0.2 mL/min, equilibration time 5 min at 90% solvent A, gradient elution: 0 min to 5 min 90% A isocratically, 5 to 10 min 90% A to 50% A and 10 min to 15 min isocratically at 50% A with a flow rate of 0.2 mL/min. Injection volume was 1 µL for reference compounds (30 pmol on column) and 5 µL for biological samples (50 pmol on column), respectively. HPLC–MS analysis of all reference compounds and biological samples was performed on a Finnigan TSQ 7000 tandem mass spectrometer (Finnigan MAT, Bremen, Germany) which was tuned with MRFA-(Met-Arg-Phe-Ala)-myoglobin solution. For pneumatically assisted ESI the spray capillary voltage was set to 4 kV and the temperature of the heated inlet capillary serving simultaneously as repeller electrode (20 V) was 180°C. Nitrogen served both as sheath (70 psi) and auxiliary gas (10 L/min). Positive and negative ions were detected scanning from 250 to 400 u with a total scan duration of 1.0 s for a single full spectrum. MS/MS experiments were performed at a collision gas pressure of 1.8 mTorr Argon scanning a mass range from 20 to 350 u with a total scan duration of 3.0 s for a single full spectrum. All spectra presented reflect the average of five or more full scans which were corrected for background.

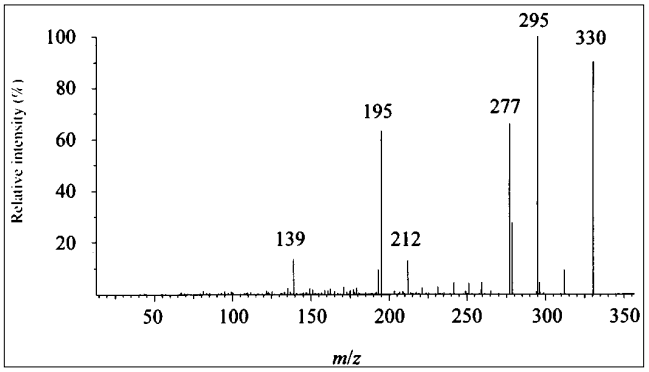

FIG. 3. Product ion spectrum of 13-*S*-hydroperoxy-9-*Z*-11-*E*-octadienoic acid, precursor ion *m/z* 330 (positive mode, –7 eV, 1.8 mTorr argon as collision gas).

RESULTS AND DISCUSSION

Molecular mass determination of fatty acid hydroperoxides by LC–ESI–MS. LC–ESI–MS analysis in methanol–water–ammonium acetate of pure 9- and 13-*S*-HPOD and 9- and 13-*S*-HPOT revealed prominent adduct ions $[M + NH_4]^+$ with *m/z* 330 for 9/13-*S*-HPOD (Fig. 1) and *m/z* 328 for 9/13-*S*-HPOT. In contrast, acetonitrile–water–trifluoroacetic acid as solvent failed to yield abundant protonated molecular ions.

By setting the temperature of the heated inlet capillary to 180°C, only negligible intensities (less than 5%) of dehydrated ions *m/z* 312 (hydroperoxyoctadecadienoic acid, HPOD, Fig. 1) and *m/z* 310 (hydroperoxyoctadecatrienoic acid, HPOT) were detected. Further reduction of the heated capillary temperature did not result in higher intensities of adduct ions $[M + NH_4]^+$ because of problems with incomplete desolvation and formation of cluster ions $[M + (MeOH)_n + NH_4]^+$ (n = 1–3). The solvent system MeOH–water containing 5 mM NH_4OAc also allowed detection of anions without change of eluent; thus, deprotonated molecular ions $[M - H]^-$ *m/z* 311 and *m/z* 309 were generated from HPOD and HPOT, respectively. Again, loss of water was negligible (about 5%).

MS/MS analysis of fatty acid hydroperoxides. Product ion spectra obtained by low-energy collision-induced dissociation (CID) (7 eV) of $[M + NH_4]^+$ precursor ions derived from fatty acid hydroperoxides revealed characteristic fragment patterns (Figs. 2 and 3). The most abundant product ions in both 9-/13-HPOD and HPOT resulted from the consecutive loss of water

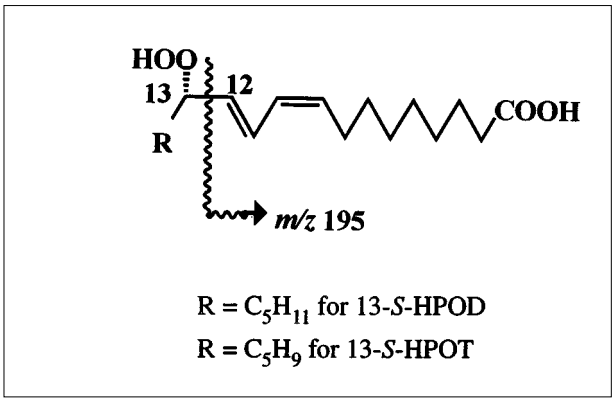
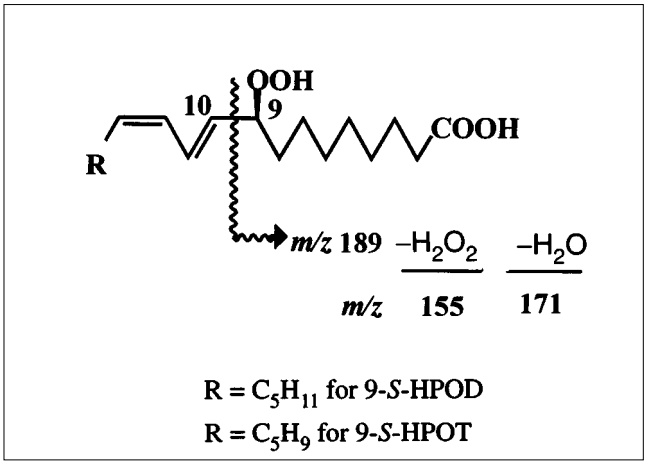
(Table 1). Product ions indicative for the hydroperoxy moiety were formed by loss of hydrogen peroxide which resulted in *m/z* 279 from 9/13-HPOD and *m/z* 277 from 9/13-HPOT. This fragmentation pathway was confirmed by corresponding neutral loss experiments, which clearly revealed the elimination of either H_2O_2 (–34 u) or [H_2O_2 + NH_3] (–51 u) from $[M + H]^+$ and $[M + NH_4]^+$ precursor ions, respectively. Control experiments with 13-*S*-HOD exclusively showed elimination of water (–18 u). Thus the loss of 34 u or 51 u was indicative for the hydroperoxy moiety and allowed detection of hydroperoxides in complex matrices by constant neutral loss scanning.

Product ions *m/z* 195 and *m/z* 212 were characteristic for 13-regioisomers (Fig. 3). The prominent ion *m/z* 195 $[C_{12}H_{19}O_2]^+$ apparently was formed by cleavage of the C_{12}–C_{13} bond (see Scheme 1) as it occurred in both 13-*S*-HPOD and 13-*S*-HPOT. A similar fragmentation has been observed while studying 13-HPOD applying negative ESI followed by CID of the molecular anion (9).



SCHEME 1

In case of 9-regioisomers (Fig. 2), characteristic product ions *m/z* 171 ($[C_9H_{17}O_4 - H_2O]^+$) and *m/z* 155 ($[C_9H_{17}O_4 - H_2O_2]^+$) resulted from the fission of the corresponding C_9–C_{10} bond and subsequent elimination of water or H_2O_2, respectively (see Scheme 2):



SCHEME 2

In addition, fragment *m/z* 211 was characteristic for 9-regioisomers as *m/z* 212 was for 13-regioisomers, but the identity of these ions remains to be established.

As can be seen from the characteristic product ions of both 9- and 13-regioisomers, a preferred and diagnostic fragmentation of unsaturated hydroperoxides was observed which is based on an α-cleavage between the carbon bearing the hydroperoxy moiety and the carbon of the adjacent double bond. Thus, not only did MS/MS allow localization of fatty acid hydroperoxides by monitoring the loss of H_2O_2, but also product ion spectra of unsaturated hydroperoxides enabled assignment of the corresponding regioisomers without any derivatization step required prior to analysis.

LC–ESI–MS/MS analysis of linoleic acid oxidation products in complex samples. Soybean LOX-2 initiated oxidation of linoleic acid is known to produce a mixture of 9- and 13-HPOD (3). In addition, the corresponding keto and hydroxy fatty acids as well as by-products have been observed (2). Thus, we incubated linoleic acid with soybean LOX-2 and analyzed the reaction products directly by means of LC–ESI–MS/MS. The only clean-up step required prior to analysis was separation of fatty acid-derived products from protein in the incubation mixture. Subsequently, the crude extract was directly analyzed by monitoring product ions of precursor ion *m/z* 330 ($[M + NH_4]^+$). Under the chromatographic conditions selected, 9- and 13-HPOD were not separated in the total ion chromatogram (Fig. 4, lower trace) as well as in the UV trace (235 nm, data not shown). Nevertheless, the reconstructed ion chromatogram for *m/z* 195 and *m/z* 155 clearly demonstrated the presence of both 13- and 9-HPOD. Thus, even fatty acid hydroperoxides which appeared by UV-detection to coelute could be identified unequivocally by LC–ESI–MS/MS.

Interpretation of the chromatogram in Figure 4 revealed a ratio of 9- to 13-HPOD of 1 to 1.3 according to the intensities of *m/z* 155 and *m/z* 195 in the spectra. This ratio was in good agreement with results obtained by the standard procedure after extraction, reduction, and methylation followed by normal phase HPLC (data not shown).

As outlined before, product ion spectra of all fatty acid hydroperoxides under investigation showed a characteristic loss of hydrogen peroxide. As a demonstration of the poten-

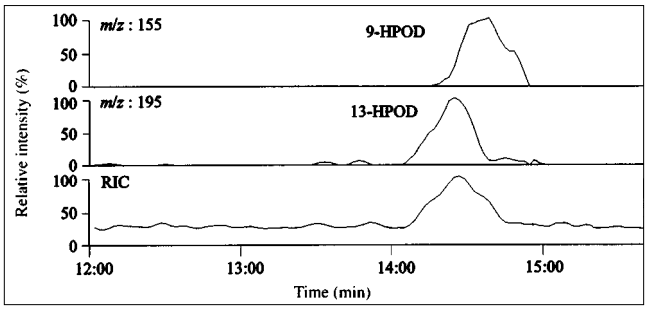


FIG. 4. Liquid chromatography–tandem mass spectrometry analysis of soybean lipoxygenase-2 oxidation of linoleic acid. Product ions of *m/z* 330 (positive mode, –7 eV, 1.8 mTorr argon as collision gas). Abbreviations: 9-HPOD, 9-hydroperoxyoctadecadienoic acid; 13-HPOD, 13-hydroperoxyoctadecadienoic acid; RIC, reconstructed ion chromatogram..

tial of the constant neutral loss scanning as an efficient screening technique for detection of fatty acid hydroperoxides, a reaction mixture obtained by incubation of linoleic acid with a crude enzyme preparation from soybeans was analyzed.

Prior to MS/MS experiments, the resolution of both quadrupole mass filters was adjusted to 0.6 u (full peak width at half maximum height) in order to exclude interference between neutral loss of 34 u (H_2O_2) and 35 u ($H_2O + NH_3$). Monitoring the loss of 34 u or 51 u ($H_2O_2 + NH_3$), respectively, led to detection of 9- and 13-HPOD together with monohydroperoxides with *E,E*-configured double bonds (Fig. 5, trace C).

In addition, one putative hydroperoxide showing a prominent precursor ion *m/z* 346 $[M + NH_4]^+$ was localized among the more polar reaction products (Fig. 5, upper trace). By ESI in the negative mode, a deprotonated molecular ion *m/z* 327 was observed, establishing a molecular mass of 328 u for the polar hydroperoxide.

Additional LC–MS/MS experiments revealed the presence of 9- and 13-keto-octadecadienoic acids (Table 1) and, to a smaller extent, the presence of hydroxyoctadecadienoic acids, which were identified by their molecular mass and UV spectra (Fig. 5, trace B). Again, LC–MS/MS proved to be more reliable than UV detection because structures of even coeluting compounds were assigned successfully.

In summary, we detected adduct ions $[M + NH_4]^+$of fatty acid hydroperoxides formed by ESI. MS/MS experiments allowed structure-specific detection of these metabolites in complex samples. After low-energy CID of $[M + NH_4]^+$ precursor ions, 9- and 13-regioisomeric fatty acid hydroperoxides were identified by their characteristic product ion spectra. Thus, LC–ESI–MS/MS proved to be more reliable than UV detection, because structures of even coeluting compounds were successfully assigned. This method opens a versatile analytical approach for the structure-specific determination of labile lipid mediators in biological samples.

Stable-Isotope Method for Determining the Gastrointestinal Handling of [1-^{13}C]Palmitic Acid

Michael Stolinski, Jane L. Murphy, Amanda E. Jones, Alan A. Jackson, and Stephen A. Wootton*

Institute of Human Nutrition, University of Southampton, Southampton, SO16 6YD, United Kingdom

ABSTRACT: The ^{13}C enrichment in individual fatty acids extracted from human feces following the oral administration of [1-^{13}C]palmitic acid has been determined using a novel approach based upon gas chromatography–isotope ratio mass spectrometry. The method was established and tested for precision and repeatability. Analytical precision was determined from 10 repeated injections of a sample containing 16:0 and 18:0 with levels of δ^{13}C abundance measured at –34.01 ± 0.60 and –23.62 ± 0.95 delta per mil (parts per thousand) (‰), respectively (mean ± SD). For the repeatability study, measurement of enrichment of the same mixture of unlabeled fatty acid methyl ester (FAME) standards (13:0, 14:0, 16:0, and 18:0) was found to have standard deviations (0.45, 0.56, 1.46 and 1.54‰, respectively). When labeled [1-^{13}C]palmitic acid was serially diluted with naturally enriched palmitic acid, a linear relationship was obtained to a dilution of 10% enriched compound (530‰). FAME were prepared from two fecal samples from a normal healthy adult; the first, a baseline specimen, containing no added label and the second, followed a single oral dose of [1-^{13}C]palmitic acid and was enriched. Enrichment in ^{13}C was confined to the solvent-soluble fraction following lipid extraction, and was only identified with prior acidification. The enrichments were measured in triplicate, baseline sample –32.66 ± 0.5‰, enriched sample +268.61 ± 8.0‰. Enrichment was restricted to the labeled species consumed, 16:0. The methodology described here allows for the separation of compounds prior to the determination of enrichment and can be utilized to contribute to a more complete description of the gastrointestinal handling of labeled substrates than previously obtained.

Lipids 32, 337–340 (1997).

There are few good noninvasive approaches to characterize how dietary lipid is handled by the gastrointestinal tract in children and adults. The most frequently used approach has been to conduct balance studies in which either the total lipid content of feces (1) or the concentrations of individual fatty acids in feces are determined (2,3). By using these approaches, it is not possible to determine with confidence whether the lipid measured in feces is derived directly from the diet, or carries a contribution from endogenous sources, such as biliary and other secretions, desquamated cells, or even the products of bacterial metabolism. As an alternative, fatty acids labeled with ^{14}C and ^{13}C have been used to determine the extent of digestion and absorption of dietary lipid (4). For example, Jones *et al.* (5) were able to assess the extent to which [1-^{13}C] stearic, oleic, and linoleic acids were absorbed from the rate of excretion of ^{13}C-label in feces using isotope ratio mass spectrometry (IRMS). They found that the apparent absorption of individual fatty acids, orally administered as the free acid, increased with degree of unsaturation. The methods used in these studies were complex and involved extensive preparative procedures.

We have previously determined the fate of label from orally administered [1-^{13}C]palmitic acid in healthy young women, by determining the proportion of label excreted in feces. In this study, the total ^{13}C enrichment in feces was measured using automated continuous flow (CF)–IRMS (CF–IRMS) (6). It was not possible to determine the nature of the species bearing the ^{13}C label, and the assumption was made that the label in feces was in the same form as that ingested. The introduction of on-line separation of fatty acids by gas chromatography–IRMS (GC–IRMS) makes it possible to determine the level of enrichment of specific fatty acids in biological specimens (7). Recently, Binnert and coworkers (8) have reported the application of GC–IRMS to determine the movement of label from ingested triacylglycerol to circulating lipids in blood.

In the present report, we describe a method for the on-line separation and determination of enrichment of fatty acids extracted from fecal samples. The precision and repeatability of the technique to measure the enrichment in fatty acid methyl ester (FAME) standards and also the ^{13}C abundance of long-chain fatty acids present in feces were determined. The results show that this relatively simple methodology can be used on a routine basis to characterize the nature of the compounds bearing the label within feces.

EXPERIMENTAL PROCEDURES

Chemicals. Chemicals were obtained from Sigma Chemical Co. Ltd. (Poole, United Kingdom) unless otherwise stated. All solvents were of Analar grade or high-performance liquid chromatography (HPLC) grade with hexane 99% pure as determined by capillary GC.

Measurement of ^{13}C-enrichment. For the measurement of total ^{13}C enrichment, 2 mg samples were weighed into tin capsules (Elemental Microanalysis, Okehampton, United Kingdom) and analyzed by CF–IRMS (ANCA system; Europa Scientific Ltd., Crewe, United Kingdom) using methods previously described (6).

The determination of enrichment in FAME was performed on a gas chromatograph (Model 5890, Hewlett-Packard, Palo Alto, CA) interfaced to an IRMS (Orchid GC interface and ANCA-*NT* IRMS; Europa Scientific Ltd. Fatty acids were separated by GC as methyl esters on a BPX-70 column (33 mm i.d., 50 m; SGE Ltd, Milton Keynes, United Kingdom). Helium was used as the carrier gas at a column head pressure of 120 kPa. The injector port temperature was set at 270°C, and the detector set at 295°C. Samples were injected split mode and then detected by flame-ionization detector (FID). FAME were identified by comparison with known standards. For isotopic mass spectrometric analysis following GC separation, the sample was diverted to a combustion tube containing platinized copper oxide powder (Elemental Microanalysis) maintained at 800°C. Water was removed by the use of a hygroscopic ion exchange membrane (Perma Pure Inc., Toms River, NY) in a continuous drying treatment. This process resulted in discrete samples of CO_2 flowing directly into the source of the IRMS. The mass spectrometer was equipped with triple collectors for the simultaneous recording of CO_2^+ ions. The instrument was calibrated to measure the major CO_2^+ ions: m/z = 44[$^{12}C^{16}O^{16}O$], 45[$^{13}C^{16}O^{16}O$ or $^{12}C^{17}O^{16}O$], and 46[$^{12}C^{18}O^{16}O$]. Data processing and enrichment measurements were determined using the software provided by the manufacturer (VANCA-GC; Europa Scientific Ltd.). Enrichment of FAME standards were calculated automatically against undecanoic acid (11:0) with a known enrichment value of –27.45‰. Enrichments of FAME obtained from fecal samples were calculated against tricosanoic acid (23:0; –32.45‰) added prior to the injection of the sample. All samples were injected in amounts calculated to give peak areas of comparable beam strengths to those used with the standards.

Validation studies. With all FAME standards, the column temperature was held at 160°C for 2 min and then increased to 280°C at 4°C/min. The precision of the system was calculated from ten consecutive 1 μL injections of palmitic acid (16:0), and stearic acid (18:0), from a stock solution of 2 mg/mL total FAME dissolved in hexane. For the repeatability study, the enrichment of a mixture of FAME standards—tridecanoic acid (13:0), myristic acid (14:0), palmitic acid (16:0), and stearic acid (18:0)—was measured on 35 occasions over a 4-mon period. The FAME standards were obtained from Europa Scientific Ltd. and dissolved in hexane at a concentration of 2 mg/mL and stored at 4°C. All measurements were separated by at least 24 h with the mass spectrometer tuned for the optimal signal prior to each occasion.

A calibration curve was obtained by measuring enrichment following the addition of increasing proportions, from 0 to 10%, of [1-^{13}C]palmitic acid (99 APE; Mass Trace Technologies Inc., Somerville, MA) to natural palmitic acid, 2 mg/mL for each injection.

Efficiency of label extraction. Fecal samples, known to be enriched, were obtained from a previous study. They were collected from a normal healthy adult on the third day following a single oral dose of [1-^{13}C]palmitic acid (10 mg/kg body weight). The feces had been freeze-dried and aliquots of dry powder, 100 mg, were taken for lipid extraction. Lipids were extracted from feces in two ways: the method of Folch *et al.* (9) was used with and without prior acidification. Samples were acidified to pH <3 by the addition of 6 M HCl. The solvent wash as well as the remaining residue following solvent extraction for both the acidified and nonacidified samples was then freeze-dried (Genevac, Ipswich, United Kingdom). All fractions were analyzed for total enrichment by CF–IRMS as described above.

Determining the nature of label within stool. The nature of the label within stool was determined by GC–IRMS following the addition of 0.5 mg of heptadecanoic acid (17:0) to 100 mg dry fecal matter as an internal standard. Lipids were saponified with KOH, methylated in 1% H_2SO_4 in methanol overnight at 50°C with FAME taken up in hexane for GC–IRMS analysis. For GC analysis, the column temperature was held at 160°C for 2 min, increased to 170°C at 4°C/min and held for 15 min. This was followed by a ramp to 280°C at 10°C/min and held at this temperature for 3.5 min.

Notation/calculations. The standard notation for the expression of enrichment results is ‰, defined in Equation 1 as:

$$\delta^{13}C(‰) = \frac{\left(^{13}C/^{12}C_{SAMPLE}\right) - \left(^{13}C/^{12}C_{PDB}\right)}{\left(^{13}C/^{12}C_{PDB}\right)} \times 1000 \qquad [1]$$

where PDB (Pee Dee Belemnite) refers to the ^{13}C abundance of an international standard. For a compound with a lower natural abundance than PDB, the value for enrichment will be negative; the lower the natural abundance of a compound the more negative the value. For carbon isotopes, a 1% excess in fractional ^{13}C content relative to natural abundance corresponds to approximately 1000‰.

Results for the standard curve were expressed as moles percentage excess (MPE) as described by Binnert *et al.* (8) to enable comparison between different GC–IRMS systems. Values were determined by converting the atom percentage excess (APE), calculated by subtracting the basal ^{13}C abundance of palmitic acid from the ^{13}C enrichment of the samples containing the label and multiplying by 17 (the number of carbon atoms in the derivatized molecule).

All results are expressed as mean ± SD; associations between variables were tested by the Pearson product moment correlation coefficient (r).

RESULTS

Validation studies. To determine precision, the enrichment in two fatty acids was measured in 10 consecutive injections and was −34.01 ± 0.60‰ for 16:0 and −23.62 ± 0.95‰ for 18:0. For repeatability, measurement of ^{13}C enrichment of the same mixture of unlabeled FAME standards (13:0, 14:0, 16:0, and 18:0) on 35 different occasions were found to have standard deviations of (0.45, 0.56, 1.46 and 1.54‰, respectively).

The standard curve showed a linear relationship between measured enrichment of palmitic acid with increasing proportion of labeled fatty acid added to unlabeled fatty acid. There was a progressive increase in the measured enrichment as labeled palmitic acid was added to unlabeled palmitic acid, from −31.23‰ for baseline enrichment of unlabeled fatty acid to 530‰ when 10% of the total palmitic acid was present in the labeled form. The equation of the line was y = 53.80x − 31.57; r = 0 .9999

Extraction of ^{13}C label from feces. Acidification of the sample, prior to lipid extraction, resulted in the recovery of label in the solvent extract of feces, with no label identified in the residue. When the acidification step was omitted, the recovery of label in the solvent extract was significantly reduced, with a substantial part of the label being measured in the residue which remained after solvent extraction (Table 1).

The nature of stool lipid. Figure 1 shows a GC–IRMS chromatogram of fatty acids extracted from a sample of human feces, for the *m/z* = 44 signal. Peak 2 represents 17:0, an internal standard added prior to lipid extraction. Peak 6 represents 23:0, a standard of known enrichment against which the enrichment in all other peaks could be compared. The main peaks identified correspond to the following fatty acids: 16:0 (peak 1), 18:0 (peak 3), 18:1 (peak 4), and 18:2 (peak 5). Table 2 shows the enrichment of the major FAME in the two fecal samples. The results show a large rise in enrichment in 16:0, the labeled species consumed by the subject, with virtually no change in enrichment in any other detected FAME.

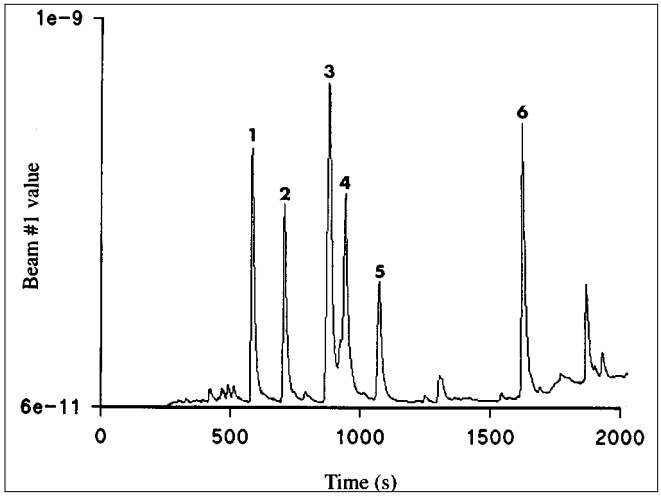

FIG. 1. Gas chromatography–isotope ratio mass spectrometry detection of fatty acid methyl esters from a three-day stool sample. The chromatogram shows the CO_2 peaks obtained from the *m/z* = 44 detector following fatty acid combustion after separation by gas chromatography. Peak 2, 17:0 (internal standard); Peak 6, 23:0 (enrichment standard); Peak 1, 16:0; Peak 3 18:0; Peak 4 18:1; and Peak 5, 18:2.

DISCUSSION

The chromatographic system described here has been utilized to follow the gastrointestinal handling of a labeled lipid substrate. These studies have also shown that GC–IRMS methodology offers good precision and low variability for the determination of ^{13}C abundance in long-chain fatty acids. Values for these parameters were found to be consistent with those specified by the manufacturers, i.e., precision levels of approximately 0.3‰following repeated injections (10) and consistent with those described by others using different GC–IRMS systems (8,11,12). In addition, GC–IRMS has been described as being approximately 1000 times more sensitive than conventional GC–MS in selected ion mode (7). This increase in sensitivity is of great benefit when using stable-isotopes as they are often expensive, may only be available in small quantities, or may be present in low concentrations in test materials.

When establishing the nature of the label, we were careful to ensure that all of the ^{13}C label in feces could be accounted for, this being required for accurate balance studies. By extracting lipid with prior acidification of the fecal sample and showing that no label was associated with the residue following extraction, we demonstrated that the label was only asso-

ciated with the lipid component of feces. The reason for the label being detected in fecal residue without its prior acidification was likely to be due to the formation of nonextractable fatty acid salts. The acidification step hydrolyzed these compounds, releasing the fatty acid component into the solvent extraction medium (13).

It has been demonstrated for the first time that the nature of ^{13}C enrichment following oral administration of the labeled [1-^{13}C]palmitic acid was primarily restricted to the labeled species consumed by the subject as extracted in the feces. This suggests that there was minimal metabolism of the fatty acid within the gastrointestinal tract and implies that the substrate was either absorbed or excreted intact. It also indicates that our presupposition in a previous paper (6) concerning the gastrointestinal handling of the labeled palmitic acid was appropriate; however, this methodology needs to be substantiated over a larger subject group. Although analysis was not performed on fresh samples, there was no evidence to suggest that a transfer of label to other fatty acids present within the sample could have taken place during storage.

The high enrichment levels obtained suggest that less label could have been administered without compromising analytical precision, since precision degrades at high enrichments (see Table 1). Nevertheless the calibration curve was found to be linear over the range of enrichments measured. Furthermore, the curve could also be used to provide a quantitative measure of the concentration of the labeled species, a vital component for any balance study. The curve was found to be of a similar order to that obtained by Binnert and coworkers (8), who also utilized [1-^{13}C]palmitic acid (99 APE ^{13}C) as a labeled substrate.

Chromatography in GC–IRMS is subject to more overlaps than conventional GC. This is due to the specific requirements such as furnaces and dryers, which convert the chemical into the required gaseous form and also purify it before introduction into the ion source. The large number of connections between the chromatography column and the detector influence peak shape and generally reduce chromatographic efficiency. Thus, $m/z = 44$ chromatograms are much broader than those obtained with work by GC–FID. The peak of interest in this particular study was relatively well separated from any other detected fatty acids, as confirmed by GC–FID analysis. Furthermore, analysis also demonstrated that there was minimal carryover of highly elevated signals as detected in neighboring FAME (see Table 2).

In conclusion, the GC–IRMS methodology described in this paper offers considerable potential for the analysis of the gastrointestinal handling of lipid substrates in human studies. It has been demonstrated that following oral administration of [1-^{13}C]palmitic acid the nature of the label within the stool was primarily associated with the lipid extract and more specifically confined to the form of the administered labeled fatty acid species.

COMMUNICATION

Dietary Docosahexaenoic Acid as a Source of Eicosapentaenoic Acid in Vegetarians and Omnivores

Julie A. Conquer and Bruce J. Holub*

Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, Ontario, N1G 2W1, Canada

ABSTRACT: The utilization of dietary docosahexaenoic acid (DHA; 22:6n-3) as a source of eicosapentaenoic acid (EPA; 20:5n-3) *via* retroconversion was investigated in both vegetarians and omnivores. For this purpose, an EPA-free preparation of DHA was given as a daily supplement (1.62 g DHA) over a period of 6 wk. The dietary supplement provided for a marked increase in DHA levels in both serum phospholipid (from 2.1 to 7.1 mol% in vegetarians and 2.2 to 7.6 mol% in omnivores) and platelet phospholipid (from 1.1 to 3.4 mol% in vegetarians and 1.4 to 3.9 mol% in omnivores). EPA levels rose to a significant but much lesser extent, while 20:4n-6, 22:5n-6, and 22:5n-3 all decreased. Based on the serum phospholipid data, the retroconversion of DHA to EPA *in vivo* was estimated to be 9.4% overall with no significant difference between omnivores and vegetarians.

Lipids 32, 341–345 (1997).

Previous animal and *in vitro* studies in isolated rat liver cells have demonstrated that docosahexaenoic (DHA; 22:6n-3) can be retroconverted to eicosapentaenoic acid (EPA; 20:5n-3) (1–3). Human studies (4,5) using supplemented fish oil-derived preparations rich in DHA have supported the *in vivo* retroconversion of DHA to EPA based on the appearance of EPA in plasma phospholipid (4,5) as well as platelet phospholipid (5). However, the DHA concentrates employed in these studies contained some residual EPA (4,5). The 6-d study by Von Schacky and Weber (4) observed a rise in EPA in plasma, but not platelet, phospholipid following DHA ingestion. On the other hand, in the study by Sanders and Hinds (5), the EPA rise in plasma as well as platelet phospholipid occurred with a dietary DHA concentrate having 22% DHA and 8.5% EPA. Further support for the *in vivo* retroconversion of DHA to EPA was published recently by Brossard *et al.* (3) after giving a single dose of ^{13}C-DHA. In addition to the importance of DHA in brain and retinal phospholipid for neuronal functioning and optimal visual performance, respectively (reviewed in Ref. 6), DHA levels in serum/plasma phospholipid (7,8) and EPA levels in platelet phospholipid (9) have been inversely correlated with cardiovascular disease. The primary purpose of the present study was to evaluate the potential for an EPA-free preparation of DHA (DHASCO™; Martek Biosciences Corp., Columbia, MD: derived from an algal source) to provide for EPA as derived *via* retroconversion when the DHA supplement was consumed by vegetarians and omnivores over a 6-wk period, and the fatty acid composition of both plasma and platelet phospholipid was measured. The inclusion of vegetarian subjects in this study was of interest since they consume very minor amounts of EPA/DHA relative to omnivores (10), and various studies have shown that vegetarians have lower serum and/or platelet levels of DHA (11–14). Thus, a comparison of the estimated potential for human retroconversion of DHA to EPA in vegetarians vs. omnivores was of added interest.

MATERIALS AND METHODS

Subjects and experimental design. The subjects were 20 healthy persons [12 vegetarian (6 female, 6 male) and 8 omnivore (4 female, 4 male)] selected from the Guelph community. The vegetarians reported having no meat, poultry, or fish for a period of at least 6 mon. Approval for this study was granted by the Human Ethics Committee of the University of Guelph, and written informed consent was obtained from each subject. Both groups (vegetarians and omnivores) consumed 9 capsules (500 mg each) per day, with meals, of an algae-derived triglyceride oil (DHASCO™) (total 1.62 g DHA/day as measured by quantitative gas–liquid chromatography). The fatty acid composition of the DHA supplement is given in Table 1. Each group consumed the capsules for a period of 42 d beginning on day 0. After 42 d of capsule ingestion, both groups completed a washout period for 21 d during which there was no supplementation. Subjects were weighed on each visit (days 0, 21, 42, 63), and height was measured at entry. Subject characteristics (n = 20) at entry were age (26.8 ± 1.6 y; mean ± SE), weight (67.5 ± 3.4 kg), height (1.73 ± 0.03 m), and body mass index (22.5 ± 1.2 kg/m^2) with no significant differences in these parameters between the groups ($P > 0.05$). The overall weight of the subjects was not significantly affected throughout the supplementation period in either group. All subjects completed the study. Compliance was monitored by a capsule count at the end of the study as well as by determining the fatty acid composition of serum and platelet phospholipid at 3 and 6 wk.

Blood collection. At day 0 (presupplementation), and days 21 and 42 (supplementation) and day 63 following a 21-d washout, blood was collected by antecubital venipuncture into siliconized tubes (containing no anticoagulant or the anticoagulant ACD [2.5% Na citrate, 2% dextrose, 1.4% citric acid (all from Fisher Chemicals, Nepean, Canada)]. In the tube without anticoagulant, whole blood was centrifuged at 1250 × *g* for 15 min to obtain serum. Serum was used for measurement of the fatty acid contents of total phospholipid. Serum was stored at −20°C until all samples were collected and thawed just before lipid analysis. In the tube containing ACD, washed platelet suspensions were prepared according to the method of Turini *et al.* (15) and stored at −20°C until analysis of total platelet phospholipid.

Fatty acid analysis of phospholipid. The fatty acid compositions of total phospholipid from serum and washed platelet suspensions were determined following lipid extraction, thin-layer chromatography, transmethylation, and gas–liquid chromatography by procedures similar to those previously described (16,17). Gas–liquid chromatography of the fatty acid methyl esters was performed using a Varian 3800 gas chromatograph (Palo Alto, CA) with a 30 m DB-23 capillary column (0.32-mm internal diameter).

Statistical analysis. All data is reported as mean ± SEM. Data was analyzed by Student's unpaired *t*-test. Significance is reported if $P < 0.05$.

RESULTS AND DISCUSSION

Table 2 shows the levels of fatty acids (mol%) in the total phospholipid of human serum before and after supplementation with DHA. Serum total phospholipid fatty acid profiles at entry, including EPA and DHA levels, were not significantly different between the two groups. Changes were seen in various n-3 and n-6 fatty acids after 3 wk of DHA supplementation and those neared maximal changes in some, but not all, cases when compared to the 6-wk data. Relative rises (at 6 wk) in the DHA content (by 247% overall in vegetarians and 240% in omnivores) and the EPA content (by 122% overall in vegetarians and 58% in omnivores) over baseline occurred with DHA supplementation. This was coupled with a rise in the DHA/AA (arachidonic acid; 20:4n-6) ratio (by 414% overall in vegetarians and 318% in omnivores) and the EPA/AA ratio (by 228% in vegetarians and 94% in omnivores). AA (−32 and −19%) and the n-6/n-3 fatty acid ratio (−62 and −60%) decreased in vegetarians and omnivores, respectively. In contrast to the other n-3 fatty acids, the levels

[a]Values are reported as mean ± SEM. Similar superscripts within individual rows are not significantly different (within and between groups). Lipids were analyzed according to the methods referenced in 16,17; AA, arachidonic acid; see Table 1 for other abbreviations. Significance is reported if $P < 0.05$.

of 22:5n-3 were also lowered (by –53 and –46% in vegetarians and omnivores, respectively) as were those of 22:5n-6. By week 9 (following 3 wk of DHASCO™ withdrawal), DHA levels, as well as n-6/n-3 EPA/AA and DHA/AA ratios, in the serum phospholipid of both vegetarians and omnivores were returning to presupplementation levels although they were still significantly different from week 0 (Table 2).

The levels of fatty acids (mol%) in platelet phospholipids before and after supplementation with DHA are shown in Table 3. At entry, omnivores had a significantly ($P < 0.05$) higher level of DHA (1.4 vs. 1.1 mol%) than vegetarians. EPA and 22:5n-3 levels were similar between the two groups. The alterations in the n-3 plus n-6 fatty acids noted at 3 wk were near maximal in most cases when compared to the 6-wk values. After 6 wk of DHA supplementation, a rise was noted in the DHA content of platelets (by 218% overall in vegetarians and 193% in omnivores), as well as in the EPA content of platelets (157% in vegetarians and 151% in omnivores). This was coupled with a rise in the DHA/AA ratio (245% in vegetarians and 199% in omnivores) and the EPA/AA ratio (179% in vegetarians and 156% in omnivores). A decrease in AA (–8% in vegetarians) and the n-6/n-3 ratio (–44% in vegetarians and –41% in omnivores) was noted. Following the pattern in serum phospholipid, there was a decrease in 22:5n-3 levels (–61% in vegetarians and –57% in omnivores) as well as in 22:5n-6. Most fatty acids approached (but not to completion) baseline values after a 3-wk washout period (Table 3).

Table 4 shows the net mol % increase in DHA (Δ DHA) and EPA (Δ EPA) in the serum and platelet phospholipids of vegetarians and omnivores. After 6 wk of consumption of DHA capsules, DHA levels in total phospholipids of serum increased from 2.1 mol% in vegetarians to 7.1% (net 5.1 mol% increase) and from 2.2% in omnivores to 7.6% (net 5.4 mol% increase). In platelets, DHA values increased from 1.1 mol% to 3.4 mol% (net 2.3 mol% increase) in vegetarians and from 1.4 to 3.9% (net 2.6 mol% increase) in omnivores. In vegetarians, EPA levels increased by 0.7 mol% in serum and 0.3% in platelets. EPA levels increased by 0.4 mol% in serum and platelets of omnivores. Thus, the total net mol% increase in EPA + DHA (Δ EPA + Δ DHA), after 6 wk of supplementation with DHA, was 5.7% in the serum of vegetarians and 5.8% in the serum of omnivores and 2.6 and 3.0% in platelets of vegetarians and omnivores, respectively. The (net mol% rise in EPA/net mol% rise in EPA + DHA) × 100 can provide an estimated percentage retroconversion of DHA to EPA. Based on this approach (Table 4), the estimated retroconversion of DHA to EPA is 7.4–11.4% (based on serum phospholipid data) and 12.3–13.8% (based on the platelet phospholipid data) with no significant differences between omnivores and vegetarians. Since DHA retroconversion is considered to actively occur in liver (2), and serum phospholipid is derived primarily from hepatic sources, the value of 9.4% (mean of both groups at week 6 based on serum phospholipid data) may be a better estimate of *in vivo* retroconversion in humans. This estimate does not take into consideration possible differences in oxidation of EPA vs. DHA or the levels of these fatty acids in different lipid classes. Furthermore, it is possible that a plateau in the EPA/DHA levels are not completely reached even by 6 wk although the levels of these fatty acids at 3 and 6 wk were not significantly different from each other (Table 2). Our estimated value for retroconversion (9.4%) is much higher than that estimated recently in human subjects by Brossard *et al.* (3) (1.4%); however, this difference may be due to the duration of DHA supplementation (6 wk in our trial vs. a one time dose of ^{13}C-DHA). Interestingly, the latter authors also reported a 9% retroconversion of DHA to EPA based on their rat trial (3). Measures of EPA and DHA in serum/plasma phospholipid have been considered to provide useful biological indicators for EPA/DHA intake and nutritional status (18–20).

TABLE 4
Effect of DHA Supplementation on the Net Increase in EPA and DHA Levels in Serum and Platelet Phospholipid[a]

	Omnivore (n = 8)		Vegetarian (n = 12)	
Parameter	Serum	Platelet	Serum	Platelet
Δ EPA (mol%)	0.43 ± 0.14[a,b]	0.41 ± 0.07[a,b]	0.65 ± 0.12[b]	0.32 ± 0.05[a]
Δ DHA (mol%)	5.4 ± 0.4[a]	2.6 ± 0.2[b]	5.1 ± 0.3[a]	2.3 ± 0.2[b]
Δ EPA + Δ DHA (mol%)	5.8 ± 0.4[a]	3.0 ± 0.1[b]	5.7 ± 0.3[a]	2.6 ± 0.2[b]
Δ EPA/Δ EPA + Δ DHA (as relative %)	7.4 ± 1.3[a]	13.8 ± 1.6[b]	11.4 ± 1.7[a,b]	12.3 ± 1.8[b]

[a]Values are reported as means ± SEM as a result of 6 wk of DHASCO™ supplementation. Similar superscripts within individual rows are not significantly different. See Table 1 for abbreviations. Significance is reported if $P < 0.05$.

Our 6-wk supplementation trial in vegetarians and omnivores employed an EPA-free preparation of DHA wherein all other n-3 polyunsaturated fatty acids were present at levels less than 0.3%. Our vegetarian subjects exhibited significantly lower levels of DHA in platelet phospholipid relative to omnivores as reported by others (13,14). Unlike previous studies (11–14), the lower EPA/DHA levels in the serum phospholipid of our vegetarian subjects (relative to the omnivores) did not reach statistical significance, perhaps because our subject group of healthy Canadian vegetarians was unlike the subject groups in the other studies (vegans, rheumatoid arthritis patients, people of Asian Indian background). Previous studies in omnivores employing DHA preparations containing residual EPA have shown significant rises of EPA in serum phospholipid (4,5) with (5) or without (4) a corresponding rise in EPA in platelet phospholipid. The study of Sanders and Hinds (5), which showed a rise in EPA in platelet phospholipid over 6 wk, employed a supplemented preparation which contained 22% DHA and 8.5% of residual EPA which does not allow for a calculation of retroconversion in humans. The study by Von Schacky and Weber (4) showed a rise in EPA in serum but not platelet phospholipid when a DHA concentrate was given orally for 6 d to human volunteers. The failure of the latter study to exhibit a rise in EPA in platelet phospholipid, in contrast to our present findings, likely lies with the duration of the study employed (6 d as compared to 42 d in the present investigation). Recent studies have indicated that the hepatic retroconversion of DHA to EPA is a peroxisomal function (2).

It remains to be established whether the rise in DHA and also EPA *via* retroconversion in vegetarian subjects upon consuming an algal source of DHA (DHASCO™) provides any health benefits. Future studies on varying dose levels of DHA in both vegetarians and omnivores likely will be of interest considering the accumulating evidence that DHA is an essential nutrient, in the brain and retina, for neuronal and visual functioning, respectively (6). Furthermore, the dietary intake of EPA/DHA from seafood has been associated with a reduced risk of primary cardiac arrest (21); also, DHA levels in serum phospholipid (7,8) and EPA levels in platelet phospholipid (9) have been inversely correlated with cardiovascular disease.

Interestingly, the dietary DHA supplement suppressed the levels of both 22:5n-6 and 22:5n-3 in both serum and platelet phospholipid. Whether these biochemical changes represent competition at the level of fatty acid esterification into the corresponding cellular phospholipid (at the level of *de novo* phospholipid synthesis or acyl transferase reactions) or other modification of polyunsaturated fatty acid metabolism (effects on 22:5n-6 and 22:5n-3) remains to be studied further.

In conclusion, the present results indicate that an EPA-free concentrate of DHA consumed over a period of 6 wk can significantly enrich the level of DHA as well as EPA in both serum and platelet phospholipid of omnivores and vegetarians. The estimated retroconversion of dietary DHA to EPA based on these studies is 9.4% with no significant differences apparent between omnivores and vegetarians. Future studies using deuterated precursors which study the metabolism and turnover of DHA and its fatty acid products *in vivo* will be of interest in further determinations of the estimated retroconversion as derived from our present study.

ACKNOWLEDGMENTS

We would like to thank Margaret Berry and Dr. Indu Mani for their help in all aspects of this investigation. We would also like to thank Drs. David Kyle and Eeva-Kaarina Koskelo of Martek Biosciences Corporation for supplying the DHA capsules for this investigation. This research was primarily funded by a grant from the Heart and Stroke Foundation of Ontario. J.A.C. was a recipient of a Postdoctoral Heart and Stroke Foundation of Ontario Prevention Fellowship.

ARTICLE

Phospholipid Biosynthetic Enzymes in Human Brain

Brian M. Ross[a,b,*], Anna Moszczynska[b], Jan K. Blusztajn[d], Allan Sherwin[e], Andres Lozano[c], and Stephen J. Kish[a,b]

[a]Department of Psychiatry, University of Toronto, [b]Human Neurochemical Pathology Laboratory, Clarke Institute of Psychiatry, and [c]Toronto Hospital, Toronto, Ontario, Canada, [d]Department of Pathology, Boston University Medical School, Boston, Massachusetts, and [e]Montreal Neurological Institute, Montreal, Québec, Canada

ABSTRACT: Growing evidence suggests an involvement of brain membrane phospholipid metabolism in a variety of neurodegenerative and psychiatric conditions. This has prompted the use of drugs (e.g., CDPcholine) aimed at elevating the rate of neural membrane synthesis. However, no information is available regarding the human brain enzymes of phospholipid synthesis which these drugs affect. Thus, the objective of our study was to characterize the enzymes involved, in particular, whether differences existed in the relative affinity of substrates for the enzymes of phosphatidylethanolamine (PE) compared to those of phosphatidylcholine (PC) synthesis. The concentration of choline in rapidly frozen human brain biopsies ranged from 32–186 nmol/g tissue, a concentration similar to that determined previously for ethanolamine. Since human brain ethanolamine kinase possessed a much lower affinity for ethanolamine (K_m = 460 μM) than choline kinase did for choline (K_m = 17 μM), the activity of ethanolamine kinase *in vivo* may be more dependent on substrate availability than that of choline kinase. In addition, whereas ethanolamine kinase was inhibited by choline, and to a lesser extent by phosphocholine, choline kinase activity was unaffected by the presence of ethanolamine, or phosphoethanolamine, and only weakly inhibited by phosphocholine. Phosphoethanolamine cytidylyltransferase (PECT) and phosphocholine cytidylyltransferase (PCCT) also displayed dissimilar characteristics, with PECT and PCCT being located predominantly in the cytosolic and particulate fractions, respectively. Both PECT and PCCT exhibited a low affinity for CTP (K_m approximately 1.2 mM), suggesting that the activities of these enzymes, and by implication, the rate of phospholipid synthesis, are highly dependent upon the cellular concentration of CTP. In conclusion, our data indicate different regulatory properties of PE and PC synthesis in human brain, and suggest that the rate of PE synthesis may be more dependent upon substrate (ethanolamine) availability than that of PC synthesis.

Lipids 32, 351–358 (1997).

The first committed step of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) synthesis is base phosphorylation by choline or ethanolamine kinase. This is followed by the incorporation of CTP to form CDPcholine or CDP-ethanolamine by the enzymes phosphocholine cytidylyltransferase (PCCT) and phosphoethanolamine cytidylyltransferase (PECT), respectively. Although the cytidylyltransferase-catalyzed reaction has been considered the rate-limiting step of the pathway, the activities of the kinases, as well as choline and ethanolamine availability, may also play a regulatory role [for a full discussion see Kent (1)]. CDPcholine and CDP-ethanolamine then react with diacylglycerol (or 1-alkyl-2-acylglycerol) to produce a molecule of phospholipid, reactions catalyzed by choline phosphotransferase and ethanolamine phosphotransferase, respectively. This latter reversible reaction operates close to equilibrium and does not appear to play a regulatory role in the pathway (1).

Abnormal membrane breakdown and/or turnover has been implicated in several human brain disorders including Alzheimer's disease (2,3), cerebral ischemia (4,5), schizophrenia (6–8), and cerebellar ataxia (9,10). This has prompted some investigators to consider the use of inhibitors of membrane breakdown or stimulators of membrane synthesis as potential therapeutic agents in these diseases. One compound in particular, cytidine (5′)-diphosphocholine (CDPcholine or Citicoline), which elevates the rate of brain phospholipid synthesis (11), appears to be effective in the treatment of cerebral ischemia (12,13) and head injury (14), and in ameliorating age-associated memory deficits (15). CDPcholine is completely hydrolyzed to cytidine and choline in the periphery (16,17), and appears to act by increasing levels of these compounds in the brain. However, the relative importance of each hydrolysis product (cytidine or choline) in mediating the beneficial effects of the drug is unknown. To address this question, one must first determine the substrate kinetics of the enzymes involved, which, although available for nonhuman species [reviewed in Kent (1)], are unavailable for the human enzymes. Thus, we have determined some important kinetic properties of the human brain enzymes, in order to better understand how their characteris-

tics might relate to the mechanism of action of drugs such as CDPcholine.

METHODS

Materials. Temporal (Brodmann area 21) cortex was dissected from the brains of four neurologically normal subjects age 52 ± 4 yr (mean ± SEM), 10 ± 1 h after death (Table 1). The brains were frozen at autopsy and stored at −80°C. All tissue used was free of gross infarct and tumors, and showed no indication of neurological disease as assessed by neuropathological examination. Biopsied temporal cortex, frozen in liquid nitrogen immediately after removal, was obtained from individuals (age 31 ± 4) who had undergone temporal lobectomy for epileptic seizures (Table 1). Biopsied tissue was from nonspiking regions as determined by electrode electrography (18). Radiochemicals were purchased from New England Nuclear (Boston, MA), Amersham International (Amersham, United Kingdom), and American Radiolabeled Chemicals (St. Louis, MO). All other reagents were obtained from either BDH (Poole, United Kingdom) or the Sigma Chemical Company (St. Louis, MO). Thin-layer chromatography (TLC) plates were 20-cm Whatman silica gel 150A plates (Maidstone, England) (type LK5D) with linear-K loading strip.

Tissue preparation. Tissue was disrupted by sonication in 5 vol of 1 mM EDTA, 1 mM EGTA, 50 mM HEPES, pH 7.4, and cytosolic and particulate fractions prepared as described previously (18).

PECT activity assay. Approximately 50 µg cytosolic or 80 µg of particulate protein was incubated for 1 h at 37°C in a buffer (final volume 50 µL) containing 15 mM magnesium chloride, 10 mM CTP, 1 mM ^{3}H-phosphoethanolamine (2 nCi/nmol), and 100 mM HEPES, pH 7.5, with alterations as described in the text. Following incubation, water-soluble products were extracted by the sequential addition of 200 µL chloroform/methanol [1:2 (vol/vol)], 50 µL chloroform, and 50 µL water (19). A 150 µL aliquot of the aqueous phase was dried by vacuum centrifugation, the residue resuspended in 30 µL of water containing 5 µg of ethanolamine, 10 µg of phosphoethanolamine, and 10 µg of CDPethanolamine, and applied to a silica gel TLC plate. Following development in 96% ethanol/water/25% ammonia solution [75:25:3 (by vol)] (20), amines were visualized with 0.2% ninhydrin and the spot corresponding to CDPethanolamine scraped into scintillation fluid and radioactivity quantified.

PCCT activity assay. This was carried out as for PECT except that (i) 225 µg cytosolic or 50 µg particulate protein was used, (ii) phosphoethanolamine was replaced by 1 mM ^{14}C-phosphocholine (4 nCi/nmol) for the cytosolic enzyme, or 2 mM ^{14}C-phosphocholine (1 nCi/nmol) for the particulate enzyme, with alterations as described in the text, (iii) following drying, the residue was resuspended in 30 µL of water containing 100 µg of choline, 500 µg of phosphocholine, and 800 µg of CDPcholine, and (iv) the TLC plate developed in 96% ethanol/water/25% ammonia solution [60:40:3 (by vol)], followed by visualization with iodine vapor, and quantification of the radioactivity in the CDPcholine spot.

Choline kinase. Approximately 30 µg of cytosolic protein was incubated for 1 h at 37°C in a buffer (final volume 100 µL) containing 10 mM magnesium chloride, 10 mM ATP, 100 mM HEPES, pH 8.0, 200,000 dpm ^{14}C-choline, and varying choline concentration, and other modifications, as described in the text. Following incubation, water-soluble products were extracted, and phosphocholine quantified by ion exchange chromatography as described previously (19). Column recovery was corrected for by running radiolabeled phosphocholine standards in each assay.

Ethanolamine kinase. This was carried out as for choline kinase except that 100 µg of cytosolic protein was used, and ethanolamine replaced choline. Isolation of phosphoethanolamine was accomplished by modifying the procedure used for isolating phosphocholine (19), namely, the column was washed first with 2 mL of water, and phosphoethanolamine was eluted with 8 mL of water, as determined by comparision with a radiolabeled phosphoethanolamine standard. This procedure resulted in a recovery of approximately 60% for phosphoethanolamine, which was corrected for by running radiolabeled phosphoethanolamine standards in each assay. Recovery of phosphoethanolamine was not affected by the co-application of 1 µmol phosphocholine or choline to the column, amounts in excess of that employed in the inhibitor studies of ethanolamine kinase.

Determination of tissue choline content. The choline content of brain tissue was determined as described previously (2).

Nonlinear curve fitting. This was accomplished using the "Prism" computer software program (Graphpad, San Diego, CA), which uses an iterative procedure to fit dual and single K_m models to data. Both K_m and V_{max} values were left unconstrained and were determined automatically by the program. The program was also used to statistically compare the goodness-of-fit of each model.

pH sensitivity. The buffers used at each pH were 5.0–6.5, MES; 7.0–8.0, HEPES; 8.5–10, borate.

Effect of adding lipid to cytosolic protein. Homogenates were separated into cytosolic and particulate fractions as described above. The cytosolic fraction was then placed on ice

TABLE 1
Human Brain Tissue Used in This Study[a]

Subject	Sex	Age (yr)	Post-mortem interval (h)	Cause of death
Biopsy 1	F	19	NA	NA
Biopsy 2	M	32	NA	NA
Biopsy 3	M	28	NA	NA
Biopsy 4	M	34	NA	NA
Biopsy 5	F	41	NA	NA
Autopsy 1	M	41	8	Multiple injuries
Autopsy 2	M	65	11	Myocardial infarction
Autopsy 3	F	54	14	Drowning
Autopsy 4	M	48	9	Multiple injuries

[a]Tissue was obtained from the temporal cortex; NA, not applicable.

TABLE 2
Enzyme Activities in Biopsied and Autopsied Human Brain[a]

Enzyme	Fraction	Biopsied (nmol/h/mg)	Autopsied (nmol/h/mg)
EK	Cytosol	22 ± 1	20 ± 1
CK	Cytosol	27 ± 2	29 ± 3
PECT	Cytosol	38 ± 3	35 ± 2
	Particulate	5 ± 1	4 ± 2
PCCT	Cytosol	0.7 ± 0.5	0.8 ± 0.2
	Particulate	42 ± 3	45 ± 4

[a]Values are mean ± SEM activities assayed in preparations of four autopsied or four biopsied (Biopsies 1–4; see Table 1) human temporal cortices. Ethanolamine kinase (EK) and choline kinase (CK) activities were determined using 2 mM ethanolamine and 2 mM choline, respectively. Phosphoethanolamine cytidylyltransferase (PECT) and phosphocholine cytidylyltransferase (PCCT) were assayed as described in the Methods section. No significant differences were detected between activity in biopsied and autopsied brain (two-tailed Student's *t*-test; $P > 0.4$).

while lipid was extracted form the particulate fraction (21). The lipid extract was then resuspended by sonication in a small volume of water, and added to an aliquot of the cytosolic fraction in a proportional manner. The cytosolic fractions with and without added lipid were sonicated on ice for 1 min, and left on ice for a further 30 min before use.

Proteins were assayed using the Bio-rad protein assay (Richmond, CA) according to the manufacturer's instructions.

RESULTS

Enzyme activities in autopsied and biopsied human brain. The reaction rate of each enzyme in human brain homogenates was linear with respect to time for at least 1 h at 37°C, and up to at least 200 µg of cytosolic protein for ethanolamine and choline kinase, and 300 µg of cytosolic or particulate protein for PECT and PCCT (data not shown). Activity of all enzymes was not significantly different in homogenates of autopsied and biopsied homogenates of human brain (Table 2), indicating that each activity was stable post mortem and suitable for futher study in autopsied tissue.

Choline content of biopsied human brain. The levels of choline in biopsied samples of three human temporal cortices were 40 nmol/g in Biopsy 1 (see Table 1), 186 nmol/g in Biopsy 2, and 32 nmol/g in Biopsy 5. Assuming a water content of 90% tissue weight, these values correspond to aqueous concentrations of 44 µM, 206 µM, and 36 µM, respectively. Choline concentration was not assayed in the remaining biopsies due to tissue limitations.

Ethanolamine and choline kinase. Both choline and ethanolamine kinase activities were localized almost exclusively (>90%) in the cytosolic fraction, and possessed a pH optimum of approximately 8.0 (data not shown). Both enzymes exhibited Michaelis–Menten kinetics for ATP up to a concentration of 10 mM, with higher substrate concentrations being inhibitory (Fig. 1B). As shown in Table 3, the K_m of ATP for ethanolamine ki-

	Particulate	PCh (20–5000 µM)	10 mM CTP	310 ± 30	58 ± 11

[a]Values are mean ± SEM of each parameter measured the indicated cell fraction of 3–4 autopsied human temporal cortices analyzed in independent experiments. Abbreviations: EK, ethanolamine kinase; CK, choline kinase; Eth, ethanolamine; Ch, choline; PCh, phosphocholine; PEth, phosphoethanolamine. K_m and V_{max} values were calculated using 7–11 substrate concentrations per subject, and derived by Eadie–Hofstee transformation, except for choline with CK for which nonlinear curve fitting was used to derive dual K_m values (see the Results section). The values in parentheses following the K_m values are the same parameter recalculated using substrate concentrations corrected approximately for the presence of endogenous substrate, the values used being: choline, 250 µM; phosphocholine, 350 µM; ethanolamine, 250 µM; phosphoethanolamine, 250 µM (Ref. 2).

[b]When the K_m for choline and the V_{max} of CK are calculated by Eadie–Hofstee transformation using choline concentrations up to 200 µM (i.e., the first plateau in the substrate/activity relationship, see Fig. 1), the K_m is 17 ± 3 µM (24 ± 3 µM corrected for endogenous choline), and V_{max} is 33 ± 5 nmol/h/mg.

[c]Kinetics were not derived for the particulate fraction owing to the high CTPase activity of this fraction (Ref. 40).

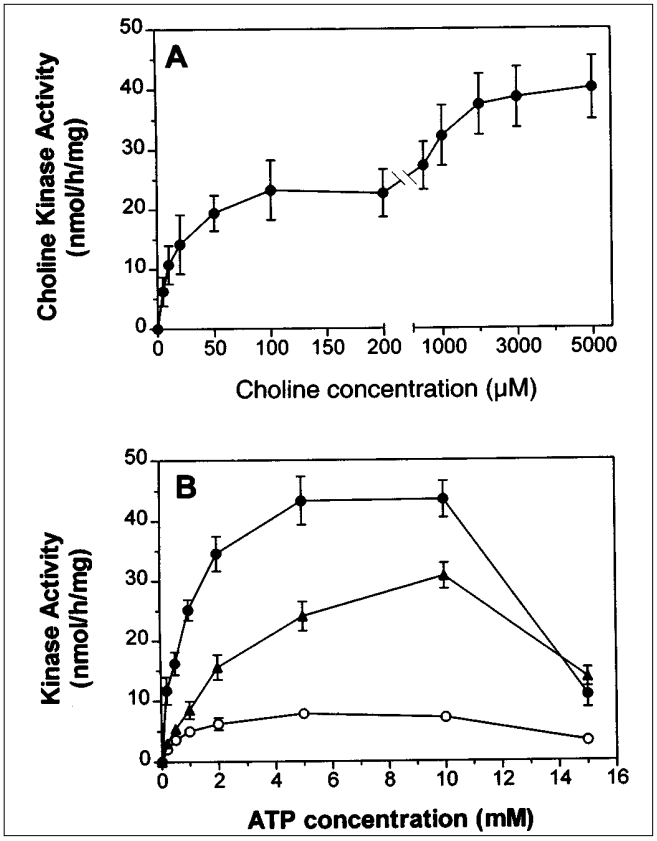

FIG. 1. Selected kinetic curves. (A) Cytosolic choline kinase under varying choline concentrations (note break in x axis) using an ATP concentration of 10 mM, and (B) ethanolamine kinase (▲) using 2 mM ethanolamine, and choline kinase using 1.2 mM (●) or 10 μM (○) choline, under varying ATP concentrations. Each point gives the mean activity of 3–4 autopsied human temporal cortices analyzed in separate experiments. All substrate concentrations shown were used in each experiment, with each brain preparation analyzed giving qualitatively similar results. Error bars indicate the SEM.

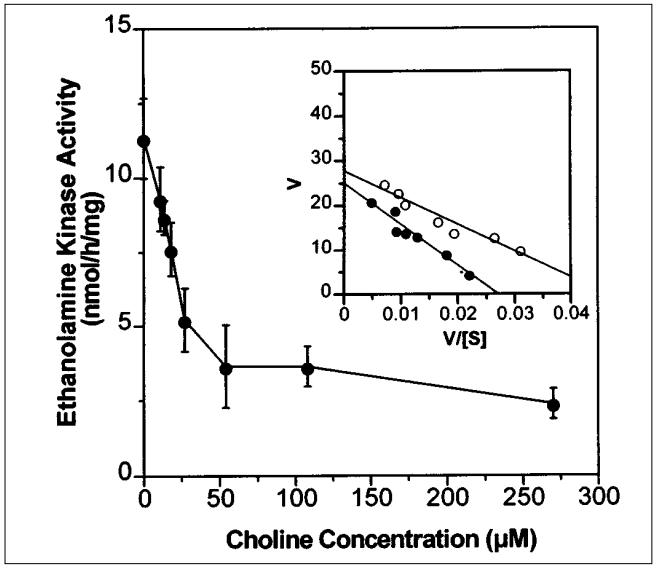

FIG. 2. Effect of choline on ethanolamine kinase activity. Main figure: Ethanolamine kinase was assayed using 0.5 mM ethanolamine (approximate K_m concentration) and 10 mM ATP, under varying choline concentrations. Each point gives the mean activity of three autopsied human temporal cortices analyzed in separate experiments. Bars indicate the SEM. Inset: Eadie–Hofstee plot of a representative experiment in which ethanolamine kinase was assayed under varying ethanolamine concentrations (50–5000 μM) and 10 mM ATP in the presence (●) or absence (○) of 15 μM choline.

nase (2200 ± 320 μM) was somewhat higher than that for choline kinase (620 ± 70 μM). Ethanolamine kinase also displayed Michaelis–Menten kinetics with respect to ethanolamine, which possessed a K_m of approximately 0.5 mM for the enzyme (Table 3). In contrast, choline kinase possessed two distinct saturation points, the first at approximately 100–200 μM choline, and the second at approximately 2–5 mM choline (Fig. 1A). Analysis of these experiments using nonlinear curve fitting produced a better fit using a dual K_m model, with K_m values of approximately 10 μM and 1.2 mM (Table 2), than that produced using a single K_m model (F-test; $P < 0.005$; $n = 4$). The use of high (1.2 mM) or low (10 μM) choline concentrations did not affect the pH optimum of choline kinase (data not shown), or the K_m of ATP for the enzyme (Table 3).

Choline was a potent inhibitor of ethanolamine kinase, with 50 μM choline inhibiting the enzyme by 65 ± 7% ($n = 3$) using 500 μM ethanolamine as substrate (i.e., substrate concentration 10 times that of the inhibitor) (Fig. 2). Choline appeared to act as a competitive inhibitor since 10 μM choline raised the K_m of ethanolamine kinase to 940 ± 160 μM from 460 ± 20 μM (no choline added) ($n = 3$), but did not alter V_{max} (Fig. 2). However, it should be noted that at higher choline concentrations (>50 μM), inhibition of ethanolamine kinase activity was somewhat less than that theoretically predicted by a competitive inhibition model (Fig. 2). Employing the formula $K_m' = K_m (1 + [I]/K_i)$ (22), an approximate K_i of 10 ± 3 μM can be calculated for choline. In contrast, choline kinase was not inhibited by ethanolamine added at concentrations between 0.5 and 10 times that of choline (data not shown). The lack of inhibition of choline kinase by ethanolamine was observed at choline concentrations of 10 μM (up to 100 μM ethanolamine added) and 1.2 mM (up to 12 mM ethanolamine added).

Ethanolamine kinase was also inhibited by phosphocholine, though less potently than that observed using choline, with 200 μM phosphocholine causing 34 ± 6% inhibition using 2 mM ethanolamine as substrate (i.e., substrate concentration 10 times that of the inhibitor) (Fig. 3A). Higher concentrations of phosphocholine also inhibited choline kinase (Fig. 3A). Again, it appeared that inhibition was competitive since although phosphocholine did not alter the V_{max} of either enzyme, 100 μM phosphocholine increased the K_m of ethanolamine kinase to 1130 ± 190 μM from 460 ± 20 μM in the absence of phosphocholine ($n = 3$; Fig. 3B), while 1 mM phosphocholine raised the K_m of choline kinase to 32 ± 4 μM from 17 ± 3 μM in the absence of phosphocholine ($n = 3$; calculated by Eadie–Hofstee transformation using choline

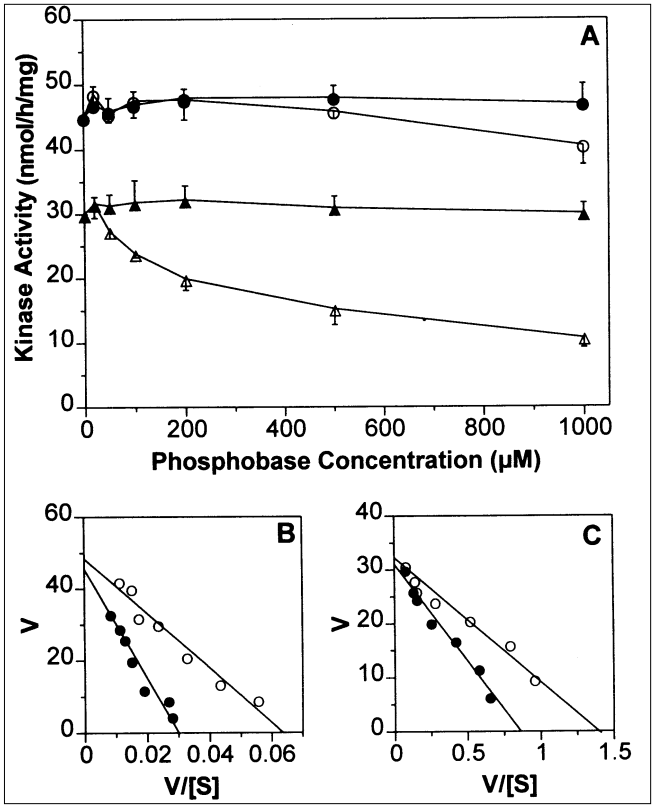

FIG. 3. Effect of phosphobases on choline and ethanolamine kinase activity. (A) Cytosolic choline kinase (●,○) and cytosolic ethanolamine kinase (▲,△) activities were assayed in the presence of varying concentrations of phosphocholine (△,○) and phosphoethanolamine (▲,●). Each enzyme was assayed using 10 mM ATP and 2 mM choline/ethanolamine. Each point gives the mean activity of three autopsied human temporal cortices analyzed in separate experiments. Bars indicate the SEM. (B) and (C). Eadie–Hofstee plots of a representative experiment in which (B) ethanolamine kinase was assayed under varying ethanolamine concentrations (50–5000 μM) and 10 mM ATP in the presence (●) or absence (○) of 100 μM phosphocholine, and (C) choline kinase under varying choline concentrations (5–200 μM) and 10 mM ATP in the presence (●) or absence (○) of 1 mM phosphocholine.

concentrations up to 200 μM) (Fig. 3C). Approximate K_i values for phosphocholine are 69 ± 12 μM for the inhibition of ethanolamine kinase, and 1133 ± 60 μM for the inhibition of choline kinase. In contrast, phosphoethanolamine, used at concentrations up to 1 mM, did not inhibit the activity of either enzyme under the conditions tested (Fig. 3A).

PECT and PCCT. The majority of PECT activity was found in the cytosolic compared to particulate fractions, with the reverse being true for PCCT activity (see Table 2). Both enzymes possessed a pH optimum of 7.5 (data not shown), and exhibited Michaelis–Menten kinetics for both CTP and the phosphobase (Table 3). The K_m of PE for PECT was similar in both particulate and cytosolic fractions; however, the K_m of PC for PCCT was significantly higher (approximately 2.5-fold) in the particulate compared to cytosolic fractions (Table 3). This did not appear to be due to the absence of lipid in the cytosolic fraction since, when lipid extracted from the particulate fraction was added in a proportional manner to the cytosolic fraction (see the Methods section for details), no significant change in the K_m of phosphocholine for cytosolic PCCT was apparent, although V_{max} increased slightly (K_m of phosphocholine and V_{max} were 157 ± 20 μM and 1.7 ± 0.05 nmol/h/mg, respectively, for cytosol plus lipid, compared to 141 ± 11 μM and 1.0 ± 0.1 nmol/h/mg, respectively, for cytosol minus lipid; $n = 3$).

To investigate the substrate specificity of PECT and PCCT, either phosphocholine or phosphoethanolamine was added to the assay of PECT and PCCT, respectively. The activity of both enzymes was unaltered by the addition of these compounds used at up to 10 times the concentration of substrate (data not shown; CTP was 1.2 mM in all cases, phosphocholine was 150 μM for PCCT, and phosphoethanolamine 150 μM for assaying cytosolic PECT activity and 300 μM for particulate PECT activity). Finally, the addition of 1 mM serine, choline, or ethanolamine did not alter the activity of either PECT or PCCT (data not shown).

DISCUSSION

We have characterized four enzymes central to the synthesis of phospholipids in brain, and have shown some differences in the features of those enzymes involved in PE synthesis compared to those in the PC pathway.

Choline and ethanolamine kinase. The non-Michaelis–Menten relationship between choline concentration and choline kinase activity suggests the presence of either two forms of choline kinase in human brain or two sites on the same enzyme in which catalysis can take place, one with low affinity for choline (millimolar K_m), and another with a high affinity (approximately 10 μM K_m). The relative importance of these two sites depends on the actual concentration of choline present in human brain. Although this value was previously available for autopsied tissue (approximately 250 μM) (2), we have determined, to our knowledge for the first time, the concentration of choline in biopsied human brain. Owing to the short time between tissue dissection and freezing, the abundance of free choline in these tissue samples likely reflects the choline concentration *in vivo* at the time of collection. One biopsy had choline concentrations approximately five times those of the other two, possibly indicating the occurrence of ischemia in the brain tissue from which the biopsy was taken, since ischemia leads to a rapid rise in tissue free choline concentration (42). However, in two biopsies, tissue choline concentration was approximately 40 μM, a value comparable to that found in rodent brain (30–60 μM (23,24). Thus, under normal conditions, human brain choline kinase may be viewed as a single enzyme half maximally active at choline concentrations of approximately 20 μM (see Fig. 1 and Table 3). In this case, assuming an *in vivo* choline concentration of approximately 40 μM, human brain choline kinase will be operating at approximately two times the K_m for choline. Thus, increasing choline levels further, e.g., to 200 μM (see Fig. 1), for example, by the ad-

ministration of choline-containing compounds, e.g., PC, CDPcholine, should result in only a modest rise in flux through this enzyme. While it is not known whether phosphocholine levels rise in human brain in response to choline administration, an elevation of brain phosphocholine levels does occur in an animal model following choline supplementation (43). Assuming similar characteristics of human and rat choline kinases, such observations are consistent with the *in vivo* activity of PCCT being much lower than that of choline kinase (1). In such a scenario, small increases in choline kinase activity would be expected to have a relatively greater effect upon phosphocholine levels. Alternatively, the presence of some form of "channeling" of choline between the choline transporter and choline kinase may take place, occurring in the absence of equilibration with total intracellular pools. Indeed, some evidence exists for the presence of a functional link between individual steps of PC biosynthesis in cultured glioma cells (44).

Perry *et al.* (25) reported that the concentration of ethanolamine in biopsied human brain is in the order of 70 μM, well below its K_m of approximately 500 μM for ethanolamine kinase. Thus, the activity of ethanolamine kinase in human brain may be much more dependent upon cellular levels of its substrate ethanolamine than choline kinase activity is upon cellular choline levels. Indeed, the major limiting factor for PE biosynthesis in rat liver appears to be the availability of ethanolamine (26). The possibility therefore exists that compounds designed to elevate ethanolamine levels in the brain may be more effective at increasing phospholipid synthesis than those which increase choline.

Ethanolamine kinase was found to be inhibited by both choline and phosphocholine at concentrations normally present in the brain [this study and Nitsch (2)]. Thus, in the absence of some form of compartmentation, choline-containing compounds may partly inhibit ethanolamine kinase *in vivo*. The role of such a mechanism is unclear, but may serve to quickly increase the synthesis of PE in times of low choline availability, thus facilitating increased synthesis of PC *via* the methylation pathway. Indeed, in rat liver, choline deficiency results in elevated PE levels in the absence of increased activity *in vitro* of the synthetic enzymes (27,28). Similarly, choline deficiency stimulates the rate of PE synthesis in cultured adrenal medullary cells (29). Our observations also suggest that excessive elevation of choline levels may actually decrease the rate of PE synthesis in brain due to the inhibition of ethanolamine kinase, as appears to occur in the heart (30).

Cytidylyl transferase. The PECT and PCCT activities of human brain are most clearly differentiable by their location within the cell, with PECT being a predominantly cytosolic enzyme, whereas the majority of PCCT is found in the particulate fraction, in a similar manner to rat liver (33). However, a significant proportion of PECT activity is also found in the particulate fraction, in contrast to rat liver in which the enzyme possesses an exclusively cytosolic location (33), suggesting that a proportion of PECT activity is associated with cellular structures in human brain.

Phosphocholine and phosphoethanolamine possess concentrations of approximately 350 μM and 250 μM, respectively, in autopsied human brain (2). These values are most likely similar to concentrations found *in vivo*, since phosphoethanolamine levels are stable post mortem (25). Referring to Table 3, it is evident that both enzymes are operating with phosphobase concentrations close to their K_m, implying that flux through this step of the pathway is moderately sensitive to the cellular concentrations of these compounds. We also observed that the K_m of phosphocholine for particulate PCCT was significantly higher than that for the cytosolic enzyme, and that this difference was likely not due to the absence of lipids in the cytosolic fraction. This suggests that the cytosolic enzyme could be distinct from that in the particulate fraction, possibly as a consequence of posttranslational modifications such as phosphorylation, as has been observed in other systems (34,35).

CTP was found to possess a millimolar K_m for human brain PECT and PCCT, in contrast to its concentration within the brain of only 100 μM (36). A similarly high K_m of CTP has been reported for PCCT activity in rat lung microsomes in which CTPase activity had been inhibited (1 mM) (40), rat lung cytosol (0.7–1.0 mM) (40), PCCT transfected s*f*9 cells (0.7 mM) (35), CHO cells (0.5 mM) (41), and rat brain (10 mM) (31). However, the K_m of CTP for human brain PECT (approximately 1.3 mM) is much higher than that reported for rat liver PECT activity (approximately 50 μM) (20,32). The high K_m/concentration ratio for CTP may underlie observations that cytidine supplementation increases the rate of phospholipid synthesis in cell culture and brain slice models (37,38), and suggests that the major mechanism by which CDPcholine elevates phospholipid levels in the brain is by increasing the availability of cytidine, rather than that of choline. This may well explain why, under some conditions, CDPcholine administration increases levels of brain PE in addition to that of PC (17,37), since CTP is common to both pathways. It should be noted that elevation of brain PE levels by CDPcholine is a smaller and less consistent effect of the drug, with Lopez-Coviella *et al.* (17) reporting increases under only some experimental conditions, and Agut *et al.* (39) observing unchanged abundance after 90 d of treatment.

In summary, we have derived the basic kinetic parameters of the two regulatory steps of phospholipid biosynthesis of human brain and have shown some differences in the characteristics of the pathways of PC and PE biosynthesis. This information will be useful in determining the mode of action of compounds designed to stimulate membrane synthesis, such as CDPcholine, as well as suggesting ways in which such drugs may be improved. Furthermore, since the activity of PECT, PCCT, ethanolamine kinase, and choline kinase is similar in autopsied and biopsied brain, it is likely that each enzyme is stable up to at least 12 h post mortem, thereby allowing examination of how the phospholipid biosynthetic pathway is affected by diseases of the brain.

Isolation and Characterization of Inositol Sphingophospholipids from *Phytophthora parasitica* Dastur[1]

Maud Bruneteau[a,*], Florence Fournol[a], Corinne Gandon[a], Michel Becchi[b], and Véronique Pivot[a]

[a]Laboratoire d'Ecologie Microbienne du Sol, UMR-CNRS 5557, Université Claude Bernard Lyon 1, F-69622 Villeurbanne Cedex, France, and [b]CNRS, Service Central d'Analyses, F-69390 Vernaison, France

ABSTRACT: Several inositol sphingophospholipids (ISPL) were isolated from mycelia of *Phytophthora parasitica* Dastur, a phytopathogenic fungus of carnation. The ISPL structures were determined by fast atom bombardment. All ISPL consisted of ceramides linked to inositol phosphate. We investigated the effect of growth conditions on the ISPL produced in four different media that are commonly used for fungal cultures. We showed that *P. parasitica* Dastur synthesized four major classes of compounds with molecular weights of M_r = 751, 807, 835, and 849 containing the 16:1 base and the 16:0 or 20:0 or 22:0 or 22h:1 *N*-acyl group. The relative abundance of the different ISPL is dependent on growth conditions.
Lipids 32, 359–362 (1997).

Inositol sphingophospholipids (ISPL) have been found in plants (1–5), yeasts (6–8), fungi (9), and protozoa (10–12), and all were shown to be derived from myoinositol phosphorylceramide (7,10). The ceramides typically contain C_{16}- or C_{18}-sphingosine or C_{18}-phytosphingosine (7,10) as long-chain base (LCB), which is acylated with palmitic, stearic (10, 11), 2- or 3-hydroxyhexacosanoic or 4-hydroxy-2-docosenoic acid (7) to form the backbone of the glycosphingophospholipids (13).

In a previous work, we isolated ISPL from mycelia of *Phytophthora capsici*, a phytopathogenic fungus of pepper (*Capsicum annuum* cv. Yolo Wonder) (14). The amide-linked fatty acids were found to have chains of 16, 20, and 22 carbon atoms. The LCB were identified as trimethylsilyl derivatives and shown to be C_{16}-sphingosine and C_{16}-dihydrosphingosine. We showed that *P. capsici* synthesized one major class of compounds with molecular weights of M_r = 833 and 835 containing the 16:1 base and the 22:1 or the 22:0 *N*-acyl group, independent of the growth medium used (15).

These ISPL induce a protective response by cotyledons of young peppers against necrotic lesions caused by the pathogen *P. capsici* (14,15).

In continuation of our work on ISPL of the *Phytophthora* genus, we determined whether ISPL were present in the strain 26 of *P. parasitica* Dastur, a phytopathogenic fungus of carnation and whether their composition was dependent on growth conditions.

MATERIALS AND METHODS

Microorganism and growth. The isolate 26 of *P. parasitica* Dastur from the fungal culture collection of INRA Antibes was grown on M1, M2, M3, and M4 media.

M1 was the Huguenin medium (16) which contained (g/L): glucose, 10; K_2HPO_4, 0.2; KH_2PO_4, 0.8; K_2SO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.2; $CaCO_3$, 0.2; KNO_3, 1; thiamine, 0.002; $FeSO_4 \cdot 7H_2O$, 0.0005; $ZnSO_4 \cdot 7H_2O$, 0.0005; $CuSO_4 \cdot 7H_2O$, 0.00002; $MnCl_2 \cdot 7H_2O$, 0.00002; $Mo_7O_{24}(NH_4)_2$, 0.00002; after sterilization M1 was supplemented with 10 mL of alcoholic solution which contained 2 mg/mL of cholesterol. M2 was the Hall medium (17) which contained (g/L): glucose, 30; L-asparagine, 10; K_2HPO_4, 0.26; KH_2PO_4, 0.47; $MgSO_4 \cdot 7H_2O$, 0.01; $FeSO_4 \cdot 7H_2O$, 0.001; thiamine, 0.001; $CaCl_2 \cdot 2H_2O$, 0.01; $ZnSO_4 \cdot H_2O$, 0.001; $CuSO_4.5H_2O$, 0.0003; $Na_2Mo \cdot 2H_2O$, 0.0002; $MnCl_4 \cdot 4H_2O$, 0.0002; with pH adjusted to 6.5. M3 was the Plich and Rudnicki medium (18) which contained (g/L): glucose, 25; yeast extract, 5; L-asparagine, 1; KH_2PO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 1; thiamine, 0.001; with pH adjusted to 6. M4 was a chemically defined medium which contained (g/L): glucose, 20; L-asparagine, 1; KH_2PO_4, 0.6; $K_2HPO_4 \cdot 3H_2O$, 0.125; KNO_3, 0.7; $MgSO_4 \cdot 7H_2O$, 0.25; $Ca(NO_3)_2$, 0.3; $ZnSO_4 \cdot 7H_2O$, 0.004; $MnSO_4 \cdot H_2O$, 0.0015; H_3BO_3, 0.001; $Na_2MoO_4 \cdot 2H_2O$, 0.001; $CuSO_4 \cdot 5H_2O$, 0.00002; KI, 0.00002; $CaCl_2 \cdot 6H_2O$, 0.00002; $FeSO_4 \cdot 7\ H_2O$, 0.0055; sodium ethylenediaminetetraacetate, 0.0075; nicotinic acid, 0.001; pyridoxine, 0.001; calcium pantothenate, 0.001; thiamine, 0.001; with pH adjusted to 6.

Fungi were grown at 24°C under 16 h of light per day on M1, M2 and M4, and in the dark on M3 medium. Mycelia were collected after 3 wk of growth on M1 and M3 media, after 10 d of growth on M4 medium, and after 3 d on M2 medium.

Extraction and fractionation of lipids. Mycelial walls were isolated from fungi as described by Fabre *et al.* (19), and were treated with chloroform/methanol (2:1, vol/vol). The extracted

[1]This work is dedicated to the memory of Professor G. Michel.

Abbreviations: GC, gas chromatography; FAB, fast atom bombardment; HPTLC, high-performance thin-layer chromatography; ISPL, inositol sphingophospholipid; LCB, long-chain base; MS, mass spectrometry.

lipids dissolved in a minimum volume of chloroform were separated into neutral and polar lipids by column chromatography on Bio-Sil HA silicic acid (BioRad, Ivry sur Seine, France) (20). Neutral lipids were eluted with chloroform, and polar lipids were eluted with chloroform/methanol (95:5, vol/vol; 90:10, vol/vol; 75:25, vol/vol; 50:50, vol/vol) and pure methanol. ISPL were eluted with chloroform/methanol (50:50, vol/vol).

Thin-layer chromatography of lipid fractions eluted from the silicic acid column. Lipid fractions were analyzed by high-performance thin-layer chromatography (HPTLC) on silica gel 60 plates (Merck; Darmstadt, Germany) that were developed with the solvent system described by Heape *et al.* (21). The detection of lipid fractions was carried out by spraying the plates with various reagents: 0.2% (wt/vol) vanillin in sulfuric acid/water (1:9, vol/vol), Dittmer and Lester reagent as modified by Vaskovsky and Kostetsky (22), Draggendorf reagent as modified by Wagner *et al.* (23). Identifications were made by comparison with authentic standards.

Analytical methods. Hydrolysis of phospholipids was performed with 1 M HCl for 16 h at 100°C or 6 M HCl for 48 h at 100°C. Hydrolysates were reduced and acetylated according to the method of Sawardeker *et al.* (24). Alditol acetates were analyzed by gas chromatography (GC) using Intersmat instrument (Model 120 FL; Intersmat, Lyon, France) fitted with an SP2380 glass capillary column (0.32 mm × 30 m). The column temperature was programmed from 140 to 260°C at 4°C/min.

Mass spectrometry (MS). Fast atom bombardment (FAB) mass spectra of phospholipids were recorded in the negative ion mode on a VG ZAB2 SEQ mass spectrometer (Manchester, United Kingdom). The instrument was equipped with a VG FAB standard source with a cesium ion gun delivering about 2 μA of cesium ion current at about 35 kV.

Spectra were obtained at a magnet scan rate of 20 s/decade over a mass range of *m/z* 200–2000 at 8 kV. The mass range was calibrated using cesium iodine clusters. The spectra were collected and processed using the VG II-250 J data system. Samples were dissolved in chloroform/methanol (1:1, vol/vol) and mixed with an equal volume of triethanolamine. The sample (2 μL) was deposited on the FAB probe tip mixed with matrix, i.e., glycerol.

RESULTS AND DISCUSSION

The percentages of total lipids extracted from the mycelial cell walls are given in Table 1. *Phytophthora parasitica*, strain 26, is characterized by a large total lipid content. The same percentage was observed when strain 26 was grown on M2, M3, and M4 media whereas this fungus is characterized by the lowest amount of lipids in the M1 medium.

Total lipids were fractionated on a column of Bio-Sil HA silicic acid to measure the relative amounts of neutral (eluted with chloroform) and polar (eluted with chloroform containing increasing concentrations of methanol) lipids as detailed in the Materials and Methods section (Table 1). The differences indicate that the relative abundance of neutral and polar lipids is dependent on growth conditions. The presence of L-asparagine in the medium or the time of growth of the fungus affected the percentage of polar lipids. The amount of polar lipids found in strain 26 grown on medium M3 was lower than in M1 medium without L-asparagine for the same time of growth. In the M4 medium the percentage of polar lipids was higher than in the M3 medium. M3 and M4 media contained the same amount of L-asparagine, but the time of growth was longer in M3 medium. The polar lipids consisted of phospholipids as revealed by HPTLC and spraying with reagent for phospholipids. HPTLC analysis of phospholipids eluted with chloroform/methanol (50:50, vol/vol) showed the presence of a major compound that comigrated with and had the molecular ion of, ISPL, as previously described (14,15). No other additional peaks were observed. This indicates that the ISPL was essentially pure, and that any other phospholipids eluting with it are present in very small amounts. No compound was revealed by specific reagent for tertiary amines. *Phytophthora parasitica* does not produce phosphatidylcholine. Previously, Pivot *et al.* (25) have shown that

TABLE 1
Lipid Accumulation in *Phytophthora parasitica* Dastur, Strain 26[a]

Culture medium	Total lipid content[b] (%, w/w)	Percentage of each lipid fraction[c] (%, w/w)	
		Neutral lipids	Polar lipids
M1	16.5	52.8	47.2
M2	32.0	55.0	45.0
M3	35.0	81.8	18.2
M4	35.0	28.5	71.5

[a]Strain 26 of *P. parasitica* Dastur was grown on M1, M2, M3, and M4 media. M1 was the Huguenin medium (Ref. 16); M2 was the Hall medium (Ref. 17); M3 was the Plich and Rudnicki medium (Ref. 18); M4 was a chemically defined medium. The compositions of M1, M2, M3, and M4 media and the conditions of cultures were described in the Materials and Methods section.
[b]These cultures were used to prepare the lipid extracts from fungal cell walls. The wt% of total lipids content was expressed as a percentage of the dry weight of fungal cell walls.
[c]The weight percentage of neutral and polar fractions eluted with chloroform and chloroform containing increasing concentrations of methanol and pure methanol, respectively, from Bio-Sil HA silicic acid chromatography (BioRad, Ivry sur Seine, France) was expressed as a percentage of total lipids extracted.

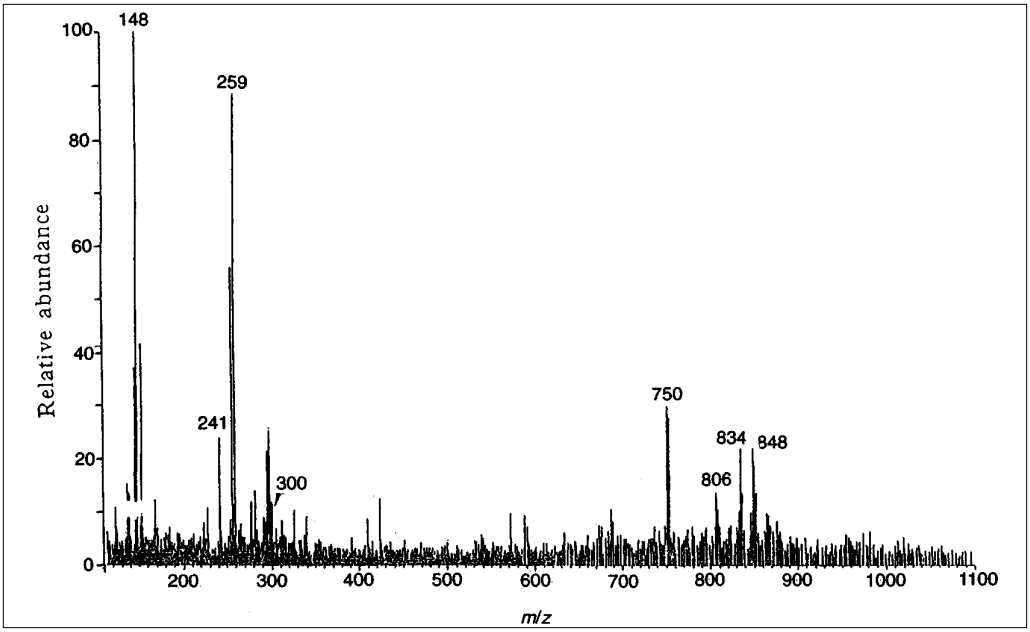

FIG. 1 . The negative fast atom bombardment mass spectrum of inositol sphingophospholipids from *Phytophthora parasitica* Dastur strain 26, grown on M2 medium. The ions at *m/z* 750, 806, 834, 848 correspond to individual molecular species present. Fragments in the spectrum at *m/z* 241, 259, and 300 are characteristic of an inositol sphingophospholipid as reported by Dommon and Costello (Ref. 27) and Ohashi (Ref. 29).

strain 107 of *P. capsici* grown on a chemically defined medium (26) produced dihexadecanoyl phosphatidylcholine.

The ISPL structure was determined by FAB MS. The negative ion FAB mass spectrum of the ISPL fraction from strain 26 grown on M1, M2, M3, and M4 media showed molecular species with $[M - H]^-$ ions at *m/z* 750, 752, 806, 808, 832, 834, 848, and 850. As an example, Figure 1 shows the mass spectrum of the ISPL fraction from strain 26 grown on M2 medium. This mass spectrum is similar to that of the ISPL previously described (15). It shows the characteristic ion corresponding to the cleavage of the inositol–phosphate bond [M − H − 162], and ions at *m/z* 241 and 259, the formation of which has been previously reported (11,27–29). The results indicate that in strain 26 of *P. parasitica* Dastur grown on M1, M2, M3, and M4 media the major ISPL correspond to the compounds of molecular weights 751, 807, 835, and 849. Although the same ISPL are present in the strain 26 grown on all media, there are significant differences in their relative abundance depending on growth conditions. This is especially true in regard to the ISPL corresponding to the compounds of molecular weights 751, 835, and 849. The ISPL, $M_r = 751$ is a major compound when strain 26 is grown on Huguenin medium (M1) and on Hall medium (M2). The ISPL with $M_r = 835$ and $M_r = 849$ were observed to be the most abundant compounds found in strain 26 grown on Plich and Rudnicki medium. Strain 26 grown on synthetic medium (M4) produced the four molecular species in similar percentage. Earlier studies have shown that *P. capsici*, strains 197, 107, and 375 synthesize only one major class of compounds with molecular weights of $M_r = 833$ and 835. It seems that *P. parasitica* is different and is characterized by the presence of four major molecular species, the amounts of which are affected by growth conditions.

The data from tandem MS, reported earlier (15,27), suggested that these different ISPL were compounds mainly of a C_{16}-dihydrosphingosine LCB linked *via* a hexacosanoyl (16:0) or eicosanoyl (20:0) or docosanoyl (22:0) or hydroxydocosenoyl (22:1) amide bond (Fig. 2).

ISPL produced by *P. parasitica* Dastur are not glycosylated. Hydrolysis of ISPL fraction with 1 M or 6 M HCl at 100°C for 16 h or 48 h gave only inositol, identified by GC of the acetyl derivative. No sugar was found in the hydrolysate. They are similar to ISPL isolated from *P. capsici* (15). This structure seems characteristic of the genus *Phytophthora*. It is similar to ISPL from *Saccharomyces cerevisiae* (7) and *Leishmania donovani* (10).

The biological activity of the sphingophospholipids had already been previously demonstrated (14,15). They induce a

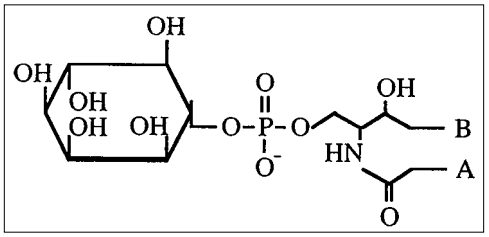

FIG. 2 . Structures of major molecular species of inositol sphingophospholipids of molecular weights 751 (B = -CH=CH-$(CH_2)_{10}$-CH_3; A = -$(CH_2)_{14}$-CH_3), 807 (B= -CH=CH-$(CH_2)_{10}$-CH_3; A = -$(CH_2)_{18}$-CH_3), 835 (B= -CH=CH-$(CH_2)_{10}$-CH_3; A = -$(CH_2)_{20}$-CH_3) and 849 (B= -CH=CH-$(CH_2)_{10}$-CH_3; A = -CH=CH-CH(OH)-$(CH_2)_{17}$-CH_3).

protective response by cotyledons of young peppers against necrotic lesions caused by the pathogen *P. capsici*. They are good models for studies in host–parasite interactions.

ABSTRACT: Hypochlorous acid generated by neutrophil myeloperoxidase has been shown to convert cholesterol into three different chlorohydrin isomers which previously had not been fully characterized. We have reacted hypochlorous acid with cholesterol/1,2-dipalmitoyl phosphatidylcholine liposomes to give these three major products and established that they are 6β-chloro-5α-cholestane-3β,5-diol (chlorohydrin **1**), 5α-chloro-6β-cholestane-3β,6-diol (chlorohydrin **2**) and 6α-chloro-5β-cholestane-3β,5-diol (chlorohydrin **3**). These products were separated by thin-layer chromatography and fully characterized by ^{1}H, ^{13}C, attached proton test, doublequantum correlation spectroscopy, total correlation spectroscopy, heteronuclear multiple bond correlation and heteronuclear multiple quantum coherence nuclear magnetic resonance spectroscopy.
Lipids 32, 363–367 (1997).

Hypochlorous acid is a strong oxidant generated from H_2O_2 and Cl^- by the myeloperoxidase system of neutrophils and monocytes (1). It reacts readily with a wide range of biological molecules including thiols, thioethers, iron–sulfur centers, heme groups, and amines (2–4). As such, HOCl is a likely contributor to tissue injury in inflammation. HOCl is known to form chlorohydrin addition products with unsaturated fatty acids and cholesterol when they are exposed as isolated lipids (5–8), red cell membranes (8), and possibly lipoproteins (9). The pathophysiological significance of these products is not known.

Three major products have been identified from cholesterol liposomes treated with reagent or myeloperoxidase-derived HOCl (Fig. 1). Two have been characterized by mass spectrometry (MS) and comparison with synthesized standards (7,8) as the chlorohydrin isomers **1** and **2**. The third product has been shown by MS to be a chlorohydrin (7,8), but until now has not been fully characterized. In this paper we have used one-dimensional and two-dimensional nuclear magnetic resonance (NMR) spectroscopy to show that this product is 6α-chloro-5β-cholestane-3β,5-diol **3**, a product that has previously been found after chlorine bleaching of wood pulp (10,11). A similar assignment was also carried out on **1** and **2** for comparison.

EXPERIMENTAL PROCEDURES

Materials. Cholest-5-en-3β-ol, 5,6α-epoxy-5α-cholestan-3β-ol (epoxide **4**), 5,6β-epoxy-5β-cholestan-3β-ol (epoxide **5**), and 1,2-dipalmitoyl phosphatidylcholine (DPPC) were obtained from Sigma Chemical Co. (St. Louis, MO). Reference samples of 6β-chloro-5α-cholestane-3β,5-diol (chlorohydrin **1**) and 5α-chloro-6β-cholestane-3β,6-diol (chlorohydrin **2**) were synthesized from cholesterol epoxides **4** and **5**, as previously described (8). Other biochemicals and high-performance liquid chromatography grade solvents were obtained from BDH Laboratory Supplies (Poole, England). Silica gel thin-layer chromatography (TLC) plates were obtained from Merck (Darmstadt, Germany). Sodium hypochlorite was obtained from Reckitt and Colman (Auckland, New Zealand). This was diluted in phosphate-buffered saline (PBS) and brought to physiological pH with aqueous HCl before standardizing by reacting with 5-thiobis(2-nitrobenzoic acid) and measuring the change in A_{412} (ε = 14100 M^{-1} cm^{-1}) (12).

Treatment of cholesterol with HOCl. Cholesterol/DPPC (1:1) liposomes were prepared in PBS and treated with HOCl as described previously (8). After 30 min at room temperature, the solution was acidified with a small amount of aqueous HCl and extracted twice with two times the volume of dichloromethane. Purification by TLC gave the chlorohydrins **1**, **2** (28% combined), **3** (24%), and 29% of unreacted cholesterol (7,8,13). The chlorohydrin **3** was also prepared by adding a tenfold excess of HOCl to a solution of cholesterol

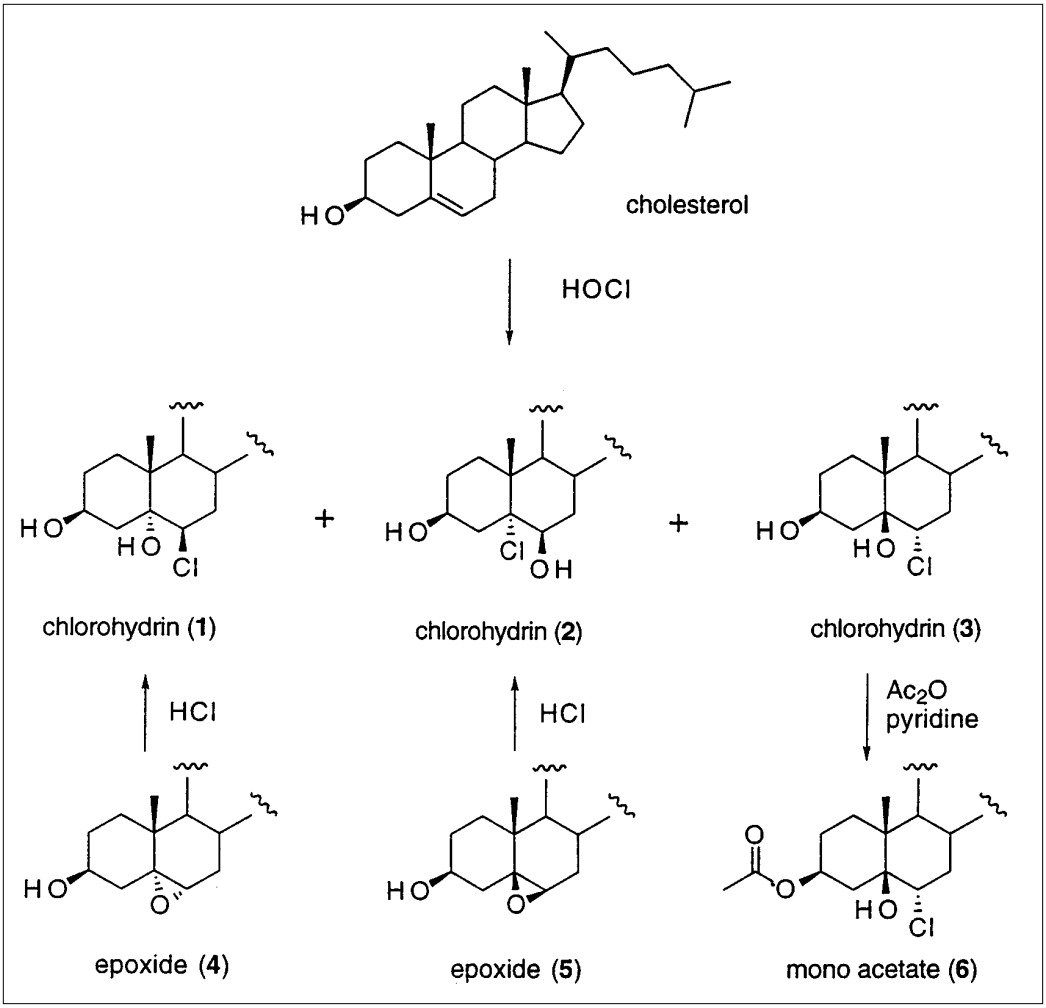

FIG. 1. Preparation of compounds **1–3** and **6.**

in acetonitrile/isopropanol (1:1) at room temperature. An equal volume of water was added after 30 min, and the mixture was extracted twice with dichloromethane. TLC gave the chlorohydrin **3** (30% of starting material) (10,11). The products were characterized by electrospray ionization MS as described previously (8,14).

Sample derivatization. The monoacetate **6** (3β-acetoxy-6α-chloro-cholestan-5β-ol) was prepared by dissolving **3** in pyridine containing an excess of acetic anhydride and reacting this overnight at room temperature (see Fig. 1). The solution was diluted with dichloromethane and washed sequentially with 5% aqueous HCl, 5% aqueous $NaHCO_3$, and water before drying with $MgSO_4$. The final solution was filtered and concentrated under N_2 for NMR analysis.

NMR. NMR spectra were recorded in $CDCl_3$ solution on Varian XL-300 and Varian UNITY 300 spectrometers (Palo Alto, CA) equipped with a Varian 5-mm broad band probe and a Nalorac Z-SPEC 3-mm inverse detection probe (Varian), respectively, and operating at 300 and 75 MHz for ^1H and ^{13}C, respectively. Chemical shifts are reported in ppm relative to tetramethylsilane. Doublequantum correlation spectroscopy (DQCOSY), total correlation spectroscopy (TOCSY), attached proton test (APT), heteronuclear multiple bond correlation spectroscopy (HMBC), and heteronuclear multiple quantum coherence spectroscopy (HMQC) experiments were recorded using standard Varian pulse sequences.

RESULTS

The structure and configuration of the chlorohydrin **3** were determined by ^1H NMR, ^{13}C NMR, ^1H-^1H COSY, TOCSY, APT, HMQC, and HMBC experiments. An assignment of the ^1H and ^{13}C NMR chemical shifts is given in Tables 1 and 2 with atom numbering shown in Figure 3. The ^1H NMR spectrum of the chlorohydrin **3** (Table 1 and Fig. 2) gave diagnostic resonances for the methyl groups at 0.65 ppm (singlet due to H_{18}), 0.84/0.85 ppm (two doublets due to H_{26} and H_{27}), 0.91 ppm (doublet due to H_{21}) and 0.99 ppm (singlet due to H_{19}). Other chemically distinct and diagnostic resonances were observed at 3.30 ppm (broad, D_2O exchangeable, C_3- and C_5-OH), 4.18 ppm (broad singlet, H_3) and 4.30 ppm (*dd,* J = 4.9, 12.7 Hz, H_6). By comparison, H_3 appears as a com-

[a]Overlapping resonances. [b]Tentative assignments. [c]Overlapping resonances.

Acetylation of **3**, using an excess of acetic anhydride in pyridine, gave a monoacetate **6** in which the H_3 resonance was characteristically shifted downfield to 5.38 ppm (11). A single acetate methyl resonance was also observed at 2.10 ppm for **6**. These results are consistent with **3** containing a single secondary alcohol at C_3, a tertiary alcohol at C_5, and a chlorosubstituent at C_6.

The assignment of the ^{1}H and ^{13}C NMR data of **3** (Tables 1 and 2) was undertaken, using literature data and the information detailed below, to confirm the A and B ring configurations and the substitution pattern as shown in Figure 3. A number of key proton connectivities were determined by DQCOSY spectroscopy. In particular, strong correlations were observed between 4.30 ppm (H_6) and both 1.35 ppm (H_7) and 2.05 ppm (H_7). That the resonances at 1.35 and 2.05 ppm were due to a methylene group was confirmed by a strong, mutual DQCOSY correlation and also by HMQC data (see later). The resonance due to H_3 at 4.18 ppm gave strong correlations to resonances at 2.12 ppm (H_4), 1.90 ppm (H_4), and 1.60 ppm H_2. The methylene assignments were established as above by HMQC (see later), and the observation of a strong DQCOSY correlation between the resonances at 2.12 and 1.90 ppm (H_4 methylene group). Numerous other correlations were evident in the DQCOSY spectrum of **3**, but these were difficult to assign unambiguously due to overlapping resonances. The sequences from H_2 through to H_4 and H_6 through to H_7 were confirmed by two-dimensional TOCSY correlations.

The literature on ^{13}C NMR data of steroids has been extensively reviewed (15) such that the base values for the chemical shifts of all carbons are clearly indicated. In addition, extensive sets of substituent effects are available to aid the assignment of new systems. An APT experiment established the methine resonances at 28.00, 35.70, 42.81, 56.09, 67.24, and 67.77 ppm and the methyl resonances at 11.97 (C_{18}), 16.73 (C_{19}), 18.61 (C_{21}), and 22.55, 22.80 ($C_{26/27}$) ppm (Table 2). The assignment of the remaining quaternary and methyl resonances was then possible.

An HMBC experiment provided a key starting point for the complete assignment of the ^{13}C resonances of **3** (see Fig. 3 and Table 2). In particular, the C_{18} methyl group protons correlated with resonances at 56.09 (C_{14} and C_{17}, coincident), 42.78 (C_{13}), and 39.72 ppm (C_{12}). The resonance due to the C_{19} methyl group at 0.99 ppm gave characteristic correlations to resonances at 77.12 (C_5), 42.70 (C_{10}), 42.81 (C_9), and 25.72 ppm (C_1). The resonance due to the C_{21} methyl group at 0.91 ppm correlated with resonances at 56.09 (C_{17}) and 35.70/36.09 ppm (C_{20} and C_{22}). The resonances for the C_{26} and C_{27} methyl groups gave characteristic correlations to 39.45 (C_{24}), 28.00 (C_{25}), and 22.55/22.80 ppm ($C_{26/27}$). Diagnostic long-range correlations were also evident for C_5-OH at 3.30 to 77.12 (C_5), 67.77 (C_6), and 42.70/42.78 ppm (C_{10}). Similarly, the resonance due to H_6 at 4.30 ppm gave correlations to 77.12 (C_5) and 31.45 ppm (C_4).

An HMQC experiment enabled the assignment of a number of other ^{13}C resonances of **3** (Table 2). In particular, the

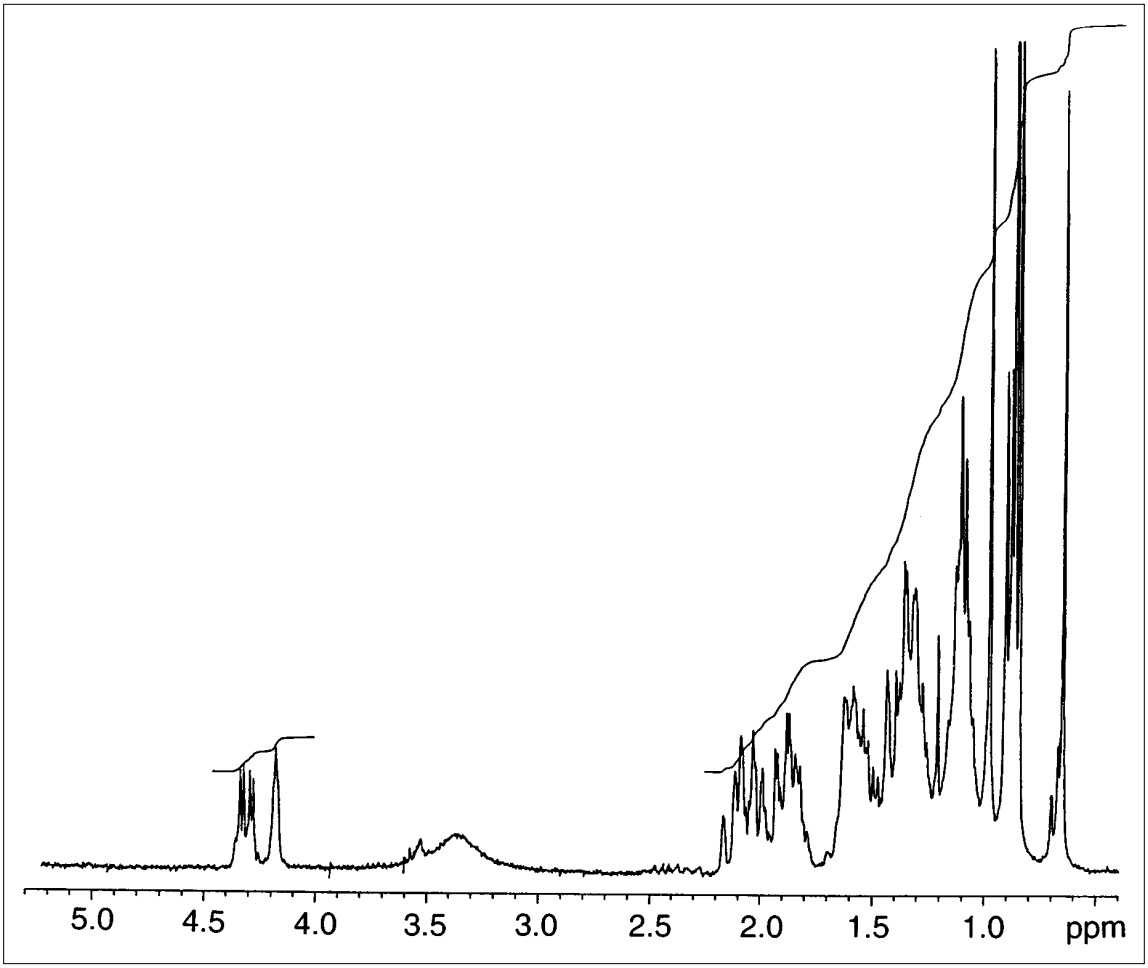

FIG. 2. ^{1}H nuclear magnetic resonance spectrum of **3**.

methylene proton resonances for H_1, H_2, H_4, H_7, H_{12}, and H_{22} correlated to ^{13}C resonances at 25.72, 27.55, 31.45, 38.84, 39.72, and 35.70 ppm, respectively. Other key correlations were evident between H_3 (4.18 ppm), H_6 (4.30 ppm), H_9 (1.30 ppm), H_{18} (0.65 ppm), H_{19} (0.99 ppm), H_{20} (1.36 ppm), H_{21} (0.91 ppm), and $H_{26/27}$ (0.84 and 0.85 ppm) and ^{13}C resonances at 67.24, 67.77, 42.81, 11.97, 16.73, 35.70, 18.61, and 22.55/22.80 ppm, respectively. The remaining ^{13}C NMR resonances were assigned by comparison with tabulated literature reference values.

A similar analysis was carried out on the alternative *trans*-fused (5α,10β) chlorohydrins **1** and **2** (Table 2). Again, APT and HMBC data provided the key to the assignment of the ^{13}C NMR data. A comparison of the ^{13}C NMR data obtained for **1**, **2**, and **3** reveals that variations in chemical shifts are limited to the A and B ring carbons, little change is evident for C_{11}–C_{18} and C_{20}–C_{27} resonances (Table 2). Of particular note is the effect, at C_5 and C_6, of a chloro vs. a hydroxyl substituent (compare the 5-OH, 6-Cl isomers **1** and **3** with the 5-Cl and 6-OH isomer **2**). The influence of a 5β-configuration (**3**) relative to a 5α-configuration (**1** and **2**) is most pronounced at C_1, C_2, C_4, C_6–C_{10}, and C_{19}.

DISCUSSION

Recent work by us (8) and others (7,13) has shown that the reaction of HOCl with cholesterol liposomes forms not only the chlorohydrins **1** and **2** but also another chlorohydrin isomer (**3**) which, until now, had not been fully characterized. Previous evidence for this product being a chlorohydrin was based on analysis by electrospray MS after TLC separation (8). Using ^{1}H and ^{13}C NMR techniques, we have been able to identify this product as 6α-chloro-5β-cholestane-3β,5-diol **3**. It is of interest to note that **3** had previously been reported by Lindgren (10,11) as resulting from the bleaching of wood components by chlorine. We have extended these original studies, using modern spectral techniques, in view of the possible pathophysiological significance of cholesterol chlorohydrin formation.

The configuration of **3** was assigned as shown in Figure 3, based on the partial assignment of the ^{1}H and ^{13}C spectral data of **3** summarized in Tables 1 and 2. The H_3 proton is axial in *trans*-fused (5α,10β)-steroids (e.g., the chlorohydrins **1** and **2** and the epoxide **4**) and appears as a complex multiplet at 4.03, 4.32, and 3.95 ppm, respectively. By comparison, the

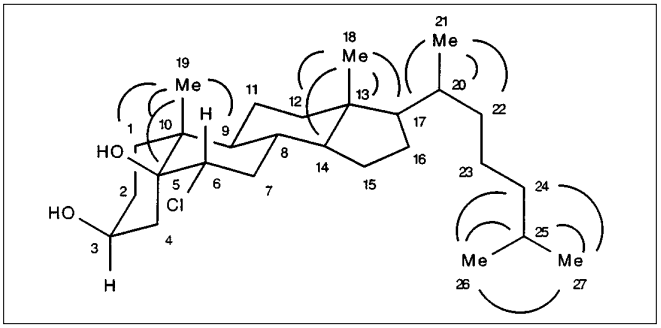

FIG. 3. Molecular structure of chlorohydrin **3** showing key heteronuclear multiple bond correlation spectroscopy correlations.

H_3 resonances of the *cis*-fused (5β,10β)-steroids, **3** and **5**, show less defined vicinal coupling to H_2 and H_4 such that H_3 is observed as a broad resonance at 4.18 and 3.70 ppm, respectively. The upfield position of the resonance for H_{19} in **3** (0.99 ppm), relative to **1** (1.27 ppm) and **2** (1.27 ppm), is also consistent with the proposed structure. Further support for the proposed configuration of **3** (Fig. 3) came from the observation of a nuclear overhauser enhancement between H_6 and H_{19}. The chlorohydrin **3** also gave a characteristic OH stretch at 3468 cm^{-1} in its infrared spectrum.

A number of 6-chloro *cis*-fused withanolides, bearing the same (5β,6α,10β)-configuration as **3**, have been previously characterized by X-ray crystallography and ^1H and ^{13}C NMR spectroscopy. Significantly, the chemical shift of C_6 in **3** (67.77 ppm, Table 2) is consistent with a 6β-chloro substituent as reported for the related withanolides [C_6 = 63.8–65.5 ppm (16,17)]. The chemical shift and coupling pattern observed for the H_6 resonance of **3** (doublet of doublets at 4.30 ppm, J = 4.9, 12.7 Hz, Table 2) and the literature 6-chloro withanolides [doublet of doublets at 4.40 ppm, J = 6, 10.5 Hz (16,17)] are also particularly diagnostic of a (5β,6α,10β)-configuration. The corresponding H_6 resonances of the *trans*-fused (5α,6β,10β) and chlorohydrins **1** and **2** show little or no coupling to the two H_7 protons.

The chlorohydrin **3** is a major product when cell membrane lipids are treated with HOCl or the myeloperoxidase/H_2O_2/Cl^- system (8). The increased stability and the decreased planarity of this chlorohydrin (Fig. 3), relative to the chlorohydrins **1** and **2**, may prove to be more disruptive to membranes. Further investigation of its biological properties is needed to establish whether it and related chlorohydrins are involved in neutrophil-mediated injury. It is known that the incorporation of small amounts of oxysterols into cell membranes can cause cytotoxicity (18). Similar cytotoxic effects may be expected for cholesterol chlorohydrins and these are currently being investigated.

ABSTRACT: We have developed an assay for the isolation and quantitation by gas chromatography–mass spectrometry (GC–MS) of free 9- and 13-hydroxyoctadecadienoic acid (9-HODE, 13-HODE) in the mammary glands of female mice. Internal standards consisting of $^{18}O_2$-labeled analogs of 9- and 13-HODE are added to pulverized frozen tissue prior to extraction with ethanol. Nonlipid materials are removed in a chloroform/methanol/water extraction step. The remaining lipid material is methylated with ethereal diazomethane, and much of the nonoxygenated fatty acid methyl esters are removed *via* silica solid-phase extraction. Samples are either further derivatized with bis(trimethylsilyl)trifluoroacetamide to form the trimethylsilyl ethers for quantitative analysis by GC–MS or are analyzed as the methyl esters by chiral high-performance liquid chromatography to determine the enantiomeric distribution of the 9- and 13-HODE. The extraction and quantitation protocol was applied to the analysis of mammary glands for free 9- and 13-HODE from mice fed isocaloric diets containing 20% corn oil, 5% corn oil, or 20% beef tallow. Chiral analysis of the products showed higher production of 13(*S*)-HODE relative to 13(*R*)-HODE; the enantiomeric excess is most likely due to enzymatic production of 13-HODE superimposed on a background of autoxidative production of 13(*R*)- plus 9(*S*)- and 9(*R*)-HODE. In addition, the effect of sample handling and storage conditions on the formation of 9- and 13-HODE in the samples was assessed by exposing aliquots of a common pool of rat mammary gland tissue to specified conditions prior to analysis. This methodology will be important during investigations of the contribution of linoleate oxidation products to the enhancement of mammary tumorigenesis by dietary fat.
Lipids 32, 369–375 (1997).

Numerous international population correlation studies report a strong positive linear relationship between dietary fat consumption and human breast cancer incidence and/or mortality. The amount and/or type of dietary fat also has a profound effect on the development of mammary gland tumors in mice and rats. Increased amounts of ingested fat, in particular fats rich in the polyunsaturated fatty acid, linoleic acid, have been reported to increase the development of mammary gland tumors in an array of mouse and rat experimental animal models (1). In addition, the amount and/or type of dietary fat substantially influences growth of human breast carcinomas maintained (transplanted) in immune-deficient mice (2). While it is clear that the amount and/or type of dietary fat can enhance mammary gland tumorigenesis in experimental animals and can stimulate the growth of human breast carcinomas maintained in immune-deficient mice, the mechanism by which this dietary constituent stimulates these tumorigenic processes is not known.

Although a number of mechanisms have been reported to explain the stimulatory effect of high levels of dietary fat to mammary tumorigenic processes, to date, none of these mechanisms has proven to be entirely satisfactory. In this communication, we provide evidence that oxygenated metabolites (products) of linoleic acid, formed *via* free radical and/or enzymatic processes, are elevated in the mammary gland of mice consuming high-fat diets. We propose that these oxygenated products may contribute to the stimulation of mammary tumorigenesis associated with fat hyperalimentation.

The oxygenated products of primary interest to us are 9- and 13-hydroxyoctadecadienoic acid (9-HODE, 13-HODE) as these products have been shown to have a growth stimulatory effect in experimental animals in an array of organ sites including the mammary gland (1,3–6).

Numerous reports describe the isolation of hydroxylated polyunsaturated fatty acids, but none of the methods is directly applicable to the isolation of these compounds from mammary gland tissue, since the tissue contains an unusually high concentration of fat (7). Therefore, we report on the development of an effective methodology for the quantitation of 9- and 13-HODE in the mammary glands of mice fed isocaloric diets containing different types and/or amounts of fat.

Abbreviations: ANOVA, analysis of variance; BHT, butylated hydroxytoluene; BSTFA, bis(trimethylsilyl)trifluoroacetamide; GC–MS, gas chromatography–mass spectrometry; 9-HODE, 9-hydroxyoctadecadienoic acid; 13-HODE, 13-hydroxyoctadecadienoic acid; HPLC, high-performance liquid chromatography; ME, methyl ester; TMCS, trimethylchlorosilane; TMS, trimethylsilyl.

EXPERIMENTAL PROCEDURES

Chemicals and materials. Bis(trimethylsilyl)trifluoroacetamide + 1% trimethylchlorosilane (BSTFA + 1% TMCS) was purchased from Supelco, Inc. (Bellefonte, PA). Diazomethane was prepared from Diazald® purchased from Aldrich (Milwaukee, WI). Butyrylcholinesterase was purchased from Sigma Chemical Company (St. Louis, MO). Oxygen-18 labeled water (97.4 atom %^{18}O) was from Isotec, Inc. (Miamisburg, OH). 13(*R,S*)-hydroxy-(*Z,E*)-9,11-octadecadienoic acid, 13(*S*)-hydroxy-(*Z,E*)-9,11-octadecadienoic acid, 9(*R,S*)-hydroxy-(*E,Z*)-10,12-octadecadienoic acid, and 9(*S*)-hydroxy-(*E,Z*)-10,12-octadecadienoic acid were purchased from Cayman Chemical Company (Ann Arbor, MI). Silica solid-phase extraction columns were purchased from Baxter Health Care Corporation (McGaw Park, IL). The Anspec Company, Inc. was the supplier for the J&W DB5-MS capillary GC column (Folsom, CA). Reverse-phase high-performance liquid chromatography (HPLC) was performed on a μBondapak C18 column from Waters (Milford, MA). Chiral HPLC was performed on a Chiralcel OD column from Chiral Technologies, Inc. (Exton, PA).

Preparation of internal standards. The preparation of $^{18}O_2$-labeled 9- and 13-HODE utilized the procedure of cholinesterase-catalyzed oxygen exchange (8,9). Oxygen-18 labeled HODE were prepared by the addition of 50 μg of 9- or 13-HODE dissolved in 20 μL methanol to 500 μL $H_2{}^{18}O$ containing 30 units of butyrylcholine esterase. After incubation for 24 h at 37°C, the reaction mixture was extracted four times with ethyl acetate, combined, dried under nitrogen, and redissolved in ethanol. The concentration of the solution was determined by measuring the absorbance at 234 nm and using a value of 23000 (10) mol L^{-1} cm^{-1} for the molar absorptivity constant (ε). Standards were stored at –20°C.

Diet study. Twenty-four female Balb/c mice (Harlan Sprague-Dawley, Indianapolis, IN) were divided into three groups at three weeks of age. Each group (eight mice/group) was placed on one of three chemically purified isocaloric diets differing only in the amount or type of fat. The mice were fed either a high-saturated-fat diet (20%, by weight, beef tallow), a low-unsaturated-fat diet (5%, by weight, corn oil), or a high-unsaturated-fat diet (20%, by weight, corn oil) for five weeks. The composition of these diets was as previously described (11). At the end of the five-week period, mice from each of the diet groups were sacrificed on the day the glands were to be extracted, and three mammary gland pairs were excised. The mammary glands excised from each mouse were processed and analyzed separately. The excised tissue was immediately placed in liquid nitrogen. All of the glands from each mouse were pulverized in liquid nitrogen and divided into two approximately equal samples: one for quantitation by gas chromatography–mass spectrometry (GC–MS), the other for chiral analysis.

Sample preparation and derivatization. A protocol for sample preparation including isolation and derivatization of 9- and 13-HODE from mammary gland tissue is shown in Figure 1. The 50-μL aliquots of $^{18}O_2$-labeled 9- and 13-HODE (18.8 and 29.1 ng/μL, respectively) were added to the pulverized tissue prior to extraction with ethanol for those samples analyzed by GC–MS. The samples for chiral analysis received no internal standard.

The mammary gland sample (100–200 mg) was pulverized in liquid nitrogen prior to two extractions in ethanol (10 and 5 mL). These extracts were combined and centrifuged in a refrigerated room (10°C). The supernatant was transferred to a pear-shaped flask, and the ethanol was evaporated *in vacuo*. Nonlipid material was removed (12) from the residue by extraction with dichloromethane/methanol/water (4:2:1.5, by vol). [Dichloromethane was used here because it has been reported that dichloromethane is less likely to promote autoxi-

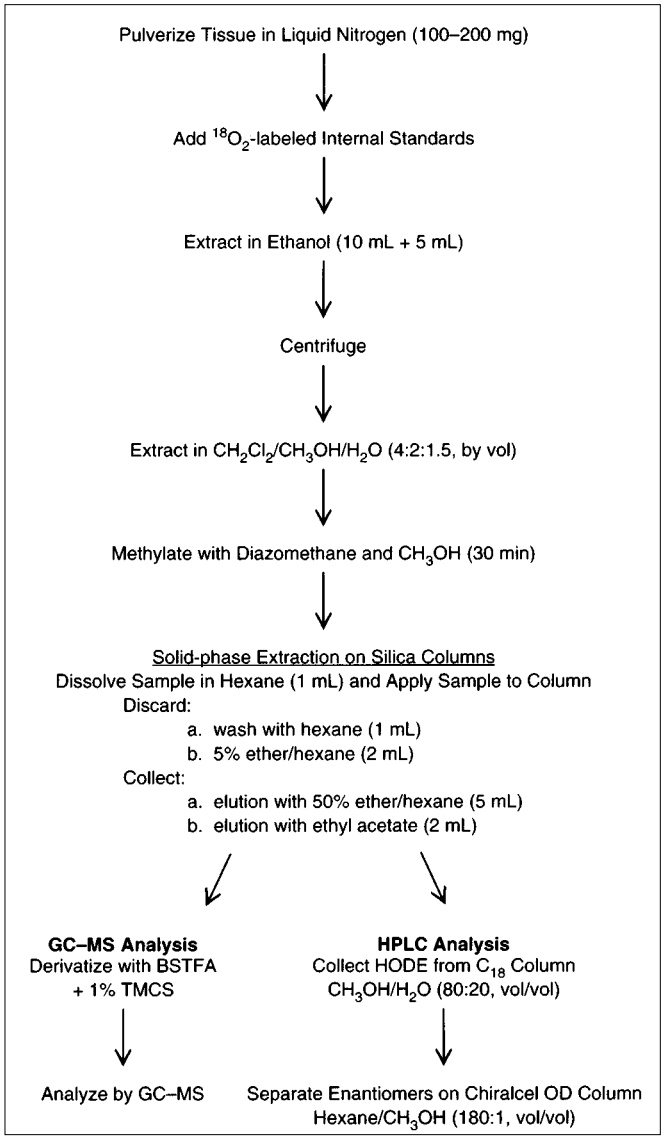

FIG. 1. Extraction procedure for isolating and derivatizing hydroxylated fatty acids from mammary gland tissue. dation of the sample (13,14)]. The mixture of dichloromethane/methanol/water separated into two phases; the upper phase was pipetted off and discarded. The lower phase was evaporated *in vacuo*, and the residue was methylated with ethereal diazomethane and methanol. After 30 min, the reaction mixture was evaporated under nitrogen, and the residue was redissolved in 1 mL hexane. The esterified extract was applied to a 200-mg silica solid-phase extraction column that had been preconditioned with 2 mL hexane, 2 mL 50% ether/hexane, and 2 mL hexane. Following application of the samples to the columns, the nonpolar (nonhydroxylated) esters were eluted from the column with 2 mL 5% ether/hexane and discarded. Methyl esters (ME) of the hydroxylated analytes were eluted and collected with 5 mL 50% ether/hexane (15) followed by 2 mL ethyl acetate, then dried *in vacuo*. Those sample extracts (fraction containing hydroxylated esters) for analysis by GC–MS were derivatized with 50 µL BSTFA + 1% TMCS in pyridine at 60°C for 30 min; sample extracts to be analyzed by HPLC were redissolved in hexane.

Detection by GC–MS. Analysis of the mammary gland extract by GC–MS was performed on a Varian Saturn II ion trap mass spectrometer (Walnut Creek, CA). Samples were chromatographed on a J&W DB5-MS 30 m × 0.25 mm i.d. column with a 25-µm film thickness in a Varian 3400 gas chromatograph. The GC temperature program was 100°C (2-min hold) to 160°C at 10°C/min, 2°C/min to 225°C, and 40°C/min to 300°C (hold for 5 min). Peak areas under profiles at selected *m/z* values (*m/z* 382 for the analyte, *m/z* 386 for the internal standard: ^{18}O-labeled 9- and 13-HODE) at designated times were used for quantitation. The concentration of the 9- and 13-HODE in the extracted sample was calculated by Equation 1 (16):

$$\frac{\text{area } (m/z\ 382)}{\text{area } (m/z\ 386)} \times \frac{\text{amount of internal standard added}}{\text{mg tissue}} = \frac{\text{amount HODE}}{\text{mg tissue}} \quad [1]$$

HPLC analyses. The HPLC system used for these analyses was constructed from the following components: a Waters Corporation (Milford, MA) 6000A pump, a Rheodyne (Cotati, CA) 7125 manual injector with a 5-µL sample loop, and a Kratos Analytical (Anspec, Ann Arbor, MI) Spectroflow 757 absorbance detector set to a wavelength of 234 nm. Data were collected and processed with a Waters Corporation Millennium Data System.

Prior to chiral analysis, 9- and 13-HODE ME were collected from a reverse-phase separation on a µBondapak C_{18} column with a methanol/water (80:20, vol/vol) mobile phase at flow rate of 1 mL/min. This fraction was dried *in vacuo* and redissolved in hexane. The enantiomers of 9(*R,S*)- and 13(*R,S*)-HODE were separated on a Chiralcel OD chiral stationary phase with a hexane/methanol (180:1, vol/vol) mobile phase at a flow rate of 1 mL/minute. The elution order of the enantiomers was determined by coinjection of a racemic mixture of the HODE with 9(*S*)- and 13(*S*)-HODE. Enantiomeric ratios were calculated by comparing the peak areas representing the enantiomers.

RESULTS

The GC–MS characteristics of 9- and 13-HODE ME/trimethylsilyl (TMS) ethers (ME/TMS) can be seen in Figure 2. These compounds are characterized by a peak at *m/z* 382 for the molecular ion ($M^{+\cdot}$), and fragment ions represented by peaks at *m/z* 311 and *m/z* 225 (17). A representative reconstructed total ion chromatogram and mass spectra from analysis of a 100-mg rat mammary gland extract are shown in Figure 3. The O^{18}-labeled internal standards and the analytes have identical retention times. The fragments containing the two ^{18}O-atoms are represented by peaks at *m/z* 386 ($M^{+\cdot}$) and *m/z* 315.

Recovery experiment. Before applying the extraction protocol to the analysis of mammary glands from mice in the diet study, the reliability of the extraction protocol was tested. Recovery experiments were performed using [^{14}C]-13-HODE prepared by soybean lipoxygenase-catalyzed oxygenation of ^{14}C-labeled linoleic acid followed by sodium borohydride reduction of the resulting 13-hydroperoxyoctadecadienoic acid (3,4,18). The labeled HODE was dissolved in ethanol, and its purity was determined by HPLC. The concentration of the standard solution was 3.1 mM with a specific activity of 2.68 µCi/µmole. The labeled HODE was added to pulverized tissue prior to extraction with ethanol. The average recovery was 72% with a 5% relative standard deviation.

Sample handling. To address the possibility that the mammary gland samples might undergo autoxidation during sample workup or during sample storage, a study was designed to evaluate the influence of sample handling on analytical results using a pooled mammary gland tissue sample. The pooled sample was divided into aliquots of 100–200 mg, which were extracted in triplicate. Selected aliquots were ex-

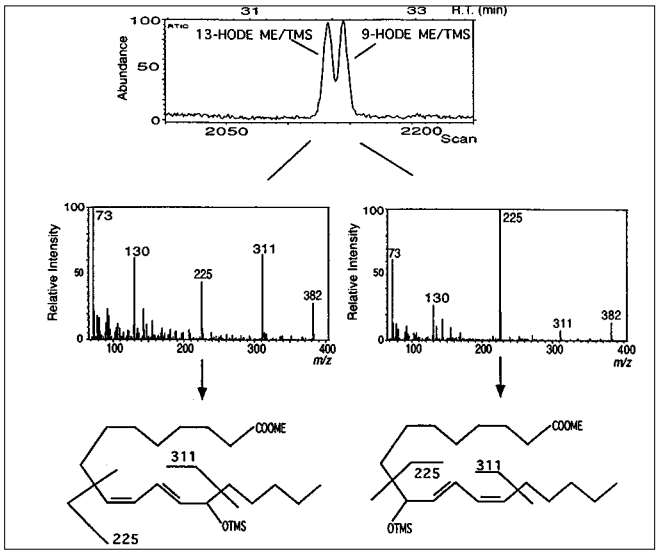

FIG. 2. GC–MS characteristics of 9- and 13-HODE methyl ester/trimethylsilyl (ME/TMS): upper panel is the reconstructed total ion chromatogram; middle panel shows electron ionization mass spectra. See Figure 1 for other abbreviation.

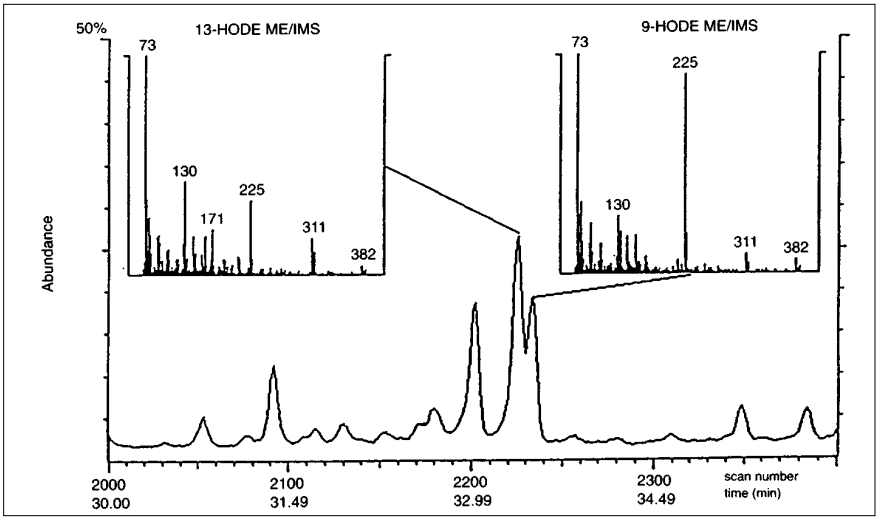

FIG. 3. Reconstructed total ion chromatogram and mass spectra of 9- and 13-HODE ME/TMS from 100 mg mammary gland tissue. See Figures 1 and 2 for abbreviations.

tracted after one-day storage at −80°C, after one-week storage at −20°C, after one-month storage −20°C, and after one-month storage at −80°C. The data from this study (see Table 1) show that extended storage at −20°C does increase the tissue content of both HODE. In contrast, storage at −80°C has relatively little effect on the amount of HODE detected.

We also performed experiments to assess the amount of autoxidation during workup compared to that occurring in the tissue prior to extraction. Samples of mammary gland were extracted in the presence and absence of butylated hydroxytoluene (BHT). The samples were then analyzed by reverse-phase, straight-phase [hexane/0.8% isopropyl alcohol; Lichrosorb Si-60 column (EM Reagents®, Cincinnati, OH)], and chiral-phase chromatography. The results of these experiments are shown in Figure 4. As shown, the presence of BHT during the extraction does reduce the amounts of oxidized linoleate metabolites detected. Nonetheless, in the presence and absence of antioxidant, the *S/R* ratio for 13-HODE indicates a preponderance of the biologically produced isomer relative to the product derived from autoxidation.

Diet study. To evaluate the applicability of the described method for our interest in determining levels of 9- and 13-HODE in mammary gland tissue, a dietary study was performed in which mice were fed one of three isocaloric diets for 5 wk, each diet differing in fat content. The mice were sacrificed, and the amounts of 9- and 13-HODE in the mammary

Experimentally Determined Concentration of 9- and 13-HODE in Aliquots of a Common Pool of Rodent Mammary Gland Tissue as a Function of Storage Time and Temperatures[a]

Storage conditions	9-HODE	13-HODE
One day (–80°C)	0.43 ± 0.08	1.1 ± 0.1
One month (–80°C)	0.64 ± 0.08	1.0 ± 0.1
One week (–20°C)	0.98 ± 0.06	1.19 ± 0.04
One month (–20°C)	1.3 ± 0.3	1.9 ± 0.4

[a]Values reported as mean ± standard error of the mean, ng HODE/mg tissue. 9-HODE, 9-hydroxyoctadecadienoic acid; 13-HODE, 13-hydroxyoctadecadienoic acid.

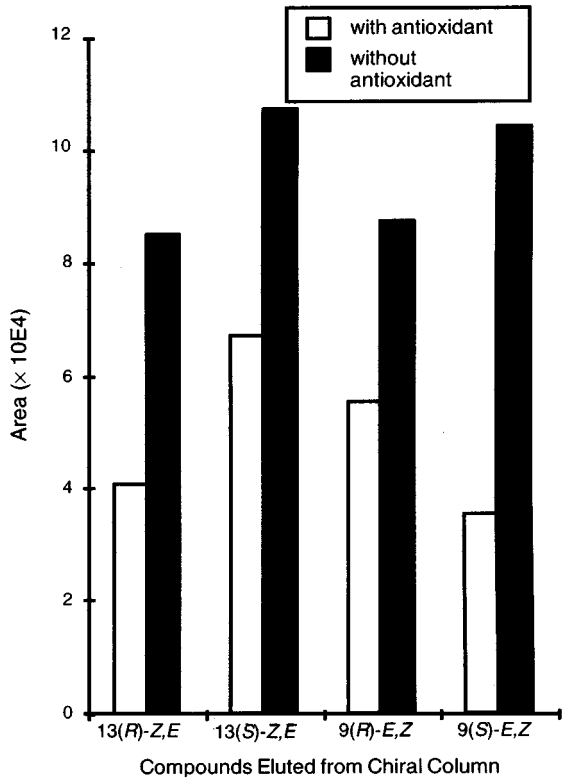

FIG. 4. Enantiomeric abundance of 9- and 13-HODE ME from mammary gland tissue collected from an HPLC separation on a silica column then injected onto a chiral column from samples with and without BHT.

glands were determined. The average (eight mice per diet group) tissue concentrations in the diet study are summarized in Table 2.

An analysis of variance (ANOVA) for the 13-HODE content shows significance ($P < 0.006$) as does an ANOVA for the 9-HODE data ($P < 0.002$). ANOVA examines the main effects of independent variables and potential interactions among them; it does not report which of the pairwise comparisons are statistically different from each other. To determine differences between groups, a Tukey's test for making pairwise comparisons was employed. Tukey's test on both the 9- and 13-HODE data finds no differences between HODE levels in the glands from mice fed the 20% beef tallow diet and from those fed the 5% corn oil diet. However, there are significant differences in the levels of 9- and 13-HODE in the glands of mice fed the 20% corn oil diet vs. the 20% beef tallow diet ($P < 0.05$), and between those fed the 20% corn oil diet vs. the 5% corn oil diet ($P < 0.05$).

Given the high unsaturated fat content of the tissue under investigation, it is necessary to evaluate the relative contributions of autoxidative vs. enzymatic processes to the production of 9- and 13-HODE. Analysis of the distribution of stereoisomers of the products provides a means for identifying product formation by either of the two processes. A representative chromatogram from the enantiomeric separation of the HODE enantiomers from a mammary gland extract is shown in Figure 5. The identity of the 9- and 13-HODE enantiomers was confirmed by coinjection of racemic standards of 9(*R,S*)-(*E,Z*)- and 13(*R,S*)-(*Z,E*)-HODE. In Figure 5, the 13-(*S*)-(*Z,E*) HODE peak also contains 7–10% of the 13(*R*)-(*E,E*) isomer, and the 9(*R*)-(*E,Z*) peak contains a similar percentage of the 13(*S*)-(*E,E*) isomer. These percentages were determined by comparing the distribution of products between mammary gland extracted in the presence and absence of BHT which gives an estimate of autoxidation in the matrix of interest. In spite of the occurrence of low levels of autoxidation, the contribution of the autoxidation products does not alter the conclusions based upon comparison of enantiomeric ratios. In more recent analyses, we have been able to eliminate the contribution of autoxidation products in chiral analysis by separating the *Z,E* and *E,Z* isomers from the *E,E* by straight-phase HPLC. The resulting pure *Z,E* and *E,Z* isomers are then analyzed by chiral-phase chromatography.

Average values for the enantiomeric ratios of 9(*R,S*)-(*E,Z*)- and 13(*R,S*)-(*Z,E*)-HODE are listed in Table 3. The ratios are reported as *S/R* for 13-HODE, but as the reciprocal, *R/S*, for 9-HODE as the *R* enantiomer was more abundant. In calculating the averages for 13-HODE (*S/R*) ratios in the glands of mice fed the 5% corn oil diet and those fed the 20% corn oil diet, individual values were assessed by the Q-test to evaluate their fit within the sample set. The small unlabeled peaks in the chromatogram have not been identified.

TABLE 2
Experimentally Determined Concentrations of 9- and 13-HODE in the Mammary Glands of Female Mice Fed Diets Differing in Fat Content[a]

Diet groups	Number of samples	9-HODE	13-HODE
20% Beef tallow	8	0.2 ± 0.1[a]	0.9 ± 0.2[a]
5% Corn oil	8	0.2 ± 0.1[a]	0.8 ± 0.2[a]
20% Corn oil	8	2.4 ± 0.6[b]	2.7 ± 0.7[b]

20% Corn oil	1.4 ± 0.1	3 ± 1

[a]Values reported as mean ± standard error of the mean. See Table 1 for abbreviations.

DISCUSSION

We have developed methodology for extraction and selective detection of 9- and 13-HODE and their enantiomers in rodent mammary gland tissue. The methodology developed in this laboratory showed that application of published extraction protocols for polyunsaturated fatty acids from other tissue systems was not directly applicable to processing mammary gland tissue due to the large quantity of nonhydroxylated fatty acids in the tissue.

The initial application of this methodology to the analysis of mouse mammary gland tissues that had been stored in the freezer at –20°C for one month showed that there were ap-

proximately equal amounts of 9- and 13-HODE in the tissue. The formation of equal amounts of the two isomers suggests formation *via* autoxidation in the tissues either during sample workup or during sample storage. As can be seen from the results in Table 1, the levels of 9- and 13-HODE increase with storage time at −20°C, as does the variance. On the other hand, storage at −80°C for up to one month does not significantly increase the amount of HODE over that determined from freshly extracted tissue. Experiments to evaluate the amount of autoxidation during sample workup indicated some autoxidation in the absence of added antioxidant. However, the workup-derived autoxidation products are not produced in sufficient quantities to alter our conclusion that the majority of HODE production in mammary glands of mice in the diet study was of biological (enzymatic) origin based upon chiral analysis as described below. It is clear that autoxidation products are present in the mammary gland lipids prior to the addition of the antioxidant. However, it is not known whether these autoxidation products arose during removal of the glands from the animal or were present prior to sacrifice.

Application of the methodology to a study of mammary glands from animals fed different levels and types of fat shows that there are significant differences in the levels of 9- and 13-HODE as a function of dietary fat. It was not apparent from these data whether the increased hydroxy fatty acid content arose from biological processes or from autoxidation of lipid pools. To address this issue, we performed analyses of the distribution of stereoisomers of both 9- and 13-HODE. Enzymatic oxidation results in the production of a single stereoisomer whereas autoxidation produces a racemic mixture. The enantiomeric separation of the (*R,S*)-HODE showed that nonracemic mixtures exist in these tissues, with 13(*S*)-(*Z,E*)- and 9(*R*)-(*E,Z*)-HODE being the more abundant isomers. These data suggest formation of 9- and 13-HODE *via* enzymatic rather than autoxidative processes.

Most of the studies reported in the literature have focused on *in vitro* studies of enzymatic oxidation of linoleic acid by various lipoxygenase enzymes (19–21). However, Baer *et al.* (22) reported that the principal *in vivo* oxygenase products of linoleic acid in psoriatic skin scale are 13-HODE (*S/R* = 1.9) and 9-HODE (*R/S* = 2.4). Further, *in vitro* studies by these investigators with cell cultures and radiolabeled linoleic acid produced an enantiopure 13(*S*)-[^{14}C]-hydroxyoctadecadienoic acid. The difference between the *in vivo* and *in vitro* results was explained as follows (23): The discrepancy between the pure (*S*) stereospecificity of the *in vitro*-produced 13-HODE and nonracemic stereospecificity of the *in vivo* compound suggested that there is autoxidation of linoleic acid in the epidermis, resulting in a nonenzymatically derived racemic 13-HODE and an enzymatically produced 13(*S*)-HODE.

It seems likely that a phenomenon similar to that reported by Baer *et al.* (22) is occurring in the mammary gland. In particular, the production of an excess of 13(*S*)-HODE is indicative of enzymatic oxidation. This is especially pronounced in the mice fed the highly unsaturated corn oil diet relative to those fed the more highly saturated beef tallow. In addition, the relatively low constant ratio of 9(*R/S*)-HODE in all dietary groups suggests a significant portion of the 9-HODE is formed by autoxidative processes with only minor contribution from enzymatic oxidation. These data are analogous to those from psoriatic skin in which 13(*S*)- and 9(*R*)-HODE were produced in enantiomeric excess against background racemic products from autoxidation (22). Alternatively, the possibility must be considered that the enzymes responsible for metabolism of either the HODE or the putative hydroperoxide precursors demonstrate stereospecificity. Such a situation could lead to an isomeric excess in the absence of stereospecific formation of a particular isomer; however, since lipoxygenases in general are fairly stereospecific, this seems unlikely.

The method developed in the current work does not include a transesterification or hydrolysis reaction and therefore detects only free fatty acid oxidation products. It is not clear from the present study whether the formation of HODE is from esterified linoleate which is subsequently released or if fatty acid release is followed by oxidation. We are in the process of developing methods for the analysis of esterified HODE which should allow us to address the question of the source of linoleate for HODE production.

In conclusion, an analytical methodology has been developed for analysis of 9- and 13-HODE in rodent mammary gland tissue. GC–MS was used to quantitate the absolute amounts of these metabolites in the tissues. Chiral-phase HPLC analysis was used to provide a qualitative assessment of the degree of enzymatic vs. autoxidative production of HODE. The methodology has been successfully applied to analyses of mouse mammary gland tissues to assess the influence of diets consisting of different amounts and/or types of fat on the production of 9- and 13-HODE. Our experiments demonstrated significant differences between the levels of 9- and 13-HODE in mammary gland tissue from mice in the different diet groups. The enantiomeric distribution of 9(*R,S*)- and 13(*R,S*)-HODE in mouse mammary gland tissue as a function of diet indicates that a combination of enzymatic and nonenzymatic factors contributes to the production of oxidized linoleate products in this tissue. The methodolgy reported in this communication will be critically important in our efforts to understand the importance of oxygenated linoleic acid metabolites in mammary tumorigenic processes.

ABSTRACT: The present study investigated the effect of liposome-encapsulated hemoglobin (LEH), an experimental oxygen-carrying resuscitation fluid, on triglyceride, total cholesterol, and low density lipoprotein (LDL), and high density lipoprotein (HDL) cholesterol measurements. *In vivo,* the intravenous infusion of LEH (5.6 mL/kg, $n = 6$) elevated serum triglycerides (+92% vs. baseline, $P < .05$), total cholesterol (+25% vs. baseline, $P < .01$), LDL cholesterol (+72% vs. baseline, $P < .01$) and had no effect on serum HDL cholesterol. In addition, LEH did not alter the elevation in serum triglycerides (+302% vs. baseline, $P < .01$) and LDL cholesterol (+86% vs. baseline, $P < .01$) induced by lipopolysaccharide (3.6 mg/kg, i.v., $n = 6$). *Ex vivo,* measurements of triglycerides and total cholesterol as well as LDL and HDL cholesterol in whole blood from naive rats were not changed by the addition of LEH (0–50%, $n = 6$). *In vitro,* the addition of a fixed concentration of LEH (50%, $n = 6$) to varying concentrations of cholesterol solution (0–50%), or *vice versa,* had no effect on cholesterol determination. It is therefore concluded that LEH only minimally affects serum levels of triglycerides, total cholesterol, LDL cholesterol, and HDL cholesterol and does not interfere with their measurement.

Lipids 32, 377–381 (1997).

Liposome-encapsulated hemoglobin (LEH) is an artificial oxygen-carrying fluid currently under evaluation for the treatment of hemorrhagic shock (for review see Refs. 1,2). The outer layer of LEH, i.e., the phospholipid liposome, consists of 10:9:0.9:0.1 mole percentage of distearoyl phosphatidylcholine/cholesterol/dimyristoyl phosphatidylglycerol/α-tocopherol. Because liposomal cholesterol is known to exchange with cholesterol in lipoproteins (3,4), other liposomes (5–7), and cellular membranes (8,9), it is possible that LEH infusion may affect serum cholesterol and/or lipoprotein levels. Such potential effects could be clinically relevant, especially following the recent demonstration that LEH can modulate endotoxin-induced sepsis (10), in which serum lipoproteins and chylomicrons play a protective role (11–16). To address this issue, the effect of intravenously infused LEH on serum levels of triglycerides and total cholesterol as well as low density lipoprotein (LDL) and high density lipoprotein (HDL) cholesterol was evaluated in the rat. In addition, *in vitro* and *ex vivo* studies were conducted to determine whether these lipids can be accurately measured in the presence of LEH.

Abbreviations: HDL, high density lipoprotein; LDL, low density lipoprotein; LEH, liposome-encapsulated hemoglobin; LPS, lipopolysaccharide; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Materials. LEH. LEH produced by the Naval Research Laboratory (Washington, D.C.) was used. The manufacturing method and physicochemical and oxygen-carrying properties of LEH have been previously described (17,18). The phospholipid bilayer of LEH consisted of distearoyl phosphatidylcholine, cholesterol, dimyristoyl phosphatidylglycerol, and α-tocopherol in a mole ratio of 10.0:9.0:0.9:0.1. Lipopolysaccharide (LPS) concentration in LEH was 2.5 ng/mL as measured using the *Limulus* Amebocyte Lysate Pyrochrome Chromogenic Test Kit (Associates of Cape Cod Inc., Woods Hole, MA).

Cholesterol. An aqueous calibrator solution of cholesterol certified at 200 mg/dL by the Center for Disease Control and National Cholesterol Education Program was used (Sigma, St. Louis, MO).

Endotoxin. LPS from *Escherichia coli* 0111:B4 (Sigma) was used as a fresh solution in 0.9% NaCl.

Animals. Male Sprague-Dawley rats (250–300 g: Taconic Farms, Germantown, NY) were kept in individual plastic cages with food and water *ad libitum* at 22°C, 12-h dark/light cycle (0600–1800). Animals were fasted 12 h prior to the experiment.

EXPERIMENTAL PROCEDURES

In vivo. Rats were anesthetized (1% halothane in 100% oxygen) and the femoral artery and vein cannulated for blood sampling and LEH and LPS infusion. Catheters were tun-

neled subcutaneously to the nape of the neck, exteriorized, and secured with a spring wire. Following a 2-h recovery period, a basal blood sample (1.0 mL, exchanged with an equivolume of 0.9% NaCl) for triglycerides as well as total, HDL, and LDL cholesterol assay was collected. LEH ($n = 6$) was infused (1 mL/min) intravenously at 5.6 mL/kg and blood samples for the above assays collected at 15 and 45 min as well as at 1, 1.5, 2.5, and 4.5 h. A similar protocol was repeated with the addition of intravenous bolus infusion of LPS (3.6 mg/kg, $n = 6$) at 30 min after LEH administration.

Ex vivo. Whole blood harvested from naive rats was diluted with increasing amounts of LEH in 8 × 49 mm Ultra-Clear tubes (Beckman, Palo Alto, CA) to give a final concentration of 0–50% in a volume of 1.5 mL. The mixture was centrifuged for 1 h at 100,000 × *g* and serum taken for triglycerides as well as total, LDL, and HDL cholesterol assays. Measured values were compared to values calculated based on the dilution of whole blood *per se*.

In vitro. A volume of 250 µL of the stock cholesterol solution (200 mg/dL) was added to a 250-µL solution containing varying concentrations of LEH (0, 2, 20, 50, and 100% diluted in 0.9% NaCl) ($n = 6$). The mixture was centrifuged in 8 × 49 mm Ultra-Clear tubes for 1 h at 100,000 × *g* and serum taken for total cholesterol assay. Measured values were compared with expected values based on the dilution of the cholesterol solution. A similar experiment was repeated ($n = 6$) with 250 µL of LEH (100%) added to 250-µL solution of varying concentrations of the cholesterol stock solution (0, 2, 20, 50, and 100% diluted in 0.9% NaCl).

ASSAYS

All assays were kindly performed at SmithKline Beecham Clinical Laboratories (Norristown, PA).

Total cholesterol. Total cholesterol was measured using an Olympus cholesterol reagent (Olympus America Inc., Lake Success, NY) which employs a series of coupled enzymatic reactions. In these reactions, free cholesterol hydrolyzed from cholesterol esters is oxidized by cholesterol oxidase to produce cholest-4-en-3-one and hydrogen peroxide. The hydrogen peroxide reacts to produce a chromophore which is measured biochromatically at 540/600 nm using the Olympus AU5200 Chemistry Analyzer. This procedure is linear to 500 mg/dL and has a sensitivity of 0.6 mg/dL.

LDL cholesterol. LDL cholesterol was assayed utilizing the Direct LDL Immunoseparation Reagent (Genzyme, Cambridge, MA) which removes HDL and VLDL from the sample by using latex beads coated with purified goat polyclonal antisera to specific apolipoproteins. The remaining LDL cholesterol is then quantified using the above enzymatic cholesterol assay with a sensitivity of 7.6 mg/dL.

HDL cholesterol assay. Quantitative separation of HDL was performed using an HDL Precipitating Reagent (DMA, Arlington, TX) followed by an enzymatic cholesterol assay as detailed above. The HDL cholesterol assay is linear to 200 mg/dL.

Triglyceride assay. Triglycerides were measured using the Olympus triglyceride procedure which entails the hydrolysis of triglycerides to free fatty acids and glycerol. Enzymatically phosphorylated glycerol is oxidized to produce hydrogen peroxide which reacts with chromogen 4-aminoantipyrine with the resultant production of a chromophore. The produced chromophore is then measured biochromatically at 520/660 nm using the Olympus AU5200 Chemistry Analyzer and is linear to 1200 mg/dL.

DATA ANALYSIS

Data in text and figures are mean ± SD for the indicated number of animals or samples. One-way analysis of variance followed by Student-Newman-Keuls test was used for statistical analysis. P value of less than 0.05 was considered significant.

RESULTS

In vivo studies. Baseline triglyceride (43 ± 24 mg/dL), total cholesterol (76 ± 17 mg/dL), LDL cholesterol (33 ± 7.3 mg/dL), and HDL cholesterol (47 ± 12 mg/dL) levels did not statistically differ among groups and were in agreement with reported values in the rat (19–22). LEH infusion elevated serum triglyceride (Fig. 1A) as well as total (Fig. 1B) and LDL (Fig. 1C) cholesterol but had no effect on serum HDL cholesterol (Fig. 1D). The intravenous administration of LPS elevated serum triglycerides (146 ± 40 mg/dL, $P < 0.01$ vs. baseline and LPS vehicle, Fig. 1A) and LDL cholesterol (63 ± 17 mg/dL, $P < 0.01$ vs. baseline and LPS vehicle, Fig. 1C) but failed to alter serum total (Fig. 1B) and HDL cholesterol (Fig. 1D). These responses were not affected by pretreatment with LEH (Fig. 1).

Ex vivo studies. The addition of LEH to whole blood from naive rats did not induce statistically significant differences between measured and calculated (based on dilution) values of triglycerides (Fig. 2A), total cholesterol (Fig. 2B), LDL cholesterol (Fig. 2C), and HDL cholesterol (Fig. 2D).

In vitro studies. Cholesterol measurement in solutions containing cholesterol and increasing amounts of LEH (Fig. 3A) did not deviate from expected values calculated based on dilution. Similarly, the addition of increasing concentrations of cholesterol to a fixed amount of LEH did not alter measured cholesterol values as compared to expected values (Fig. 3B).

DISCUSSION

The main findings of the present study are: (i) LEH has a minimal effect on serum levels of triglycerides, HDL cholesterol, LDL cholesterol, and total cholesterol, and (ii) LEH does not interfere with the measurement of these lipids. All experimental paradigms used supported these conclusions. *In vivo*, LEH only marginally elevated serum triglycerides, total, and LDL cholesterol levels and did not affect HDL cholesterol concentration. Also, endotoxin-induced serum levels of triglycerides, HDL cholesterol, LDL cholesterol, and total

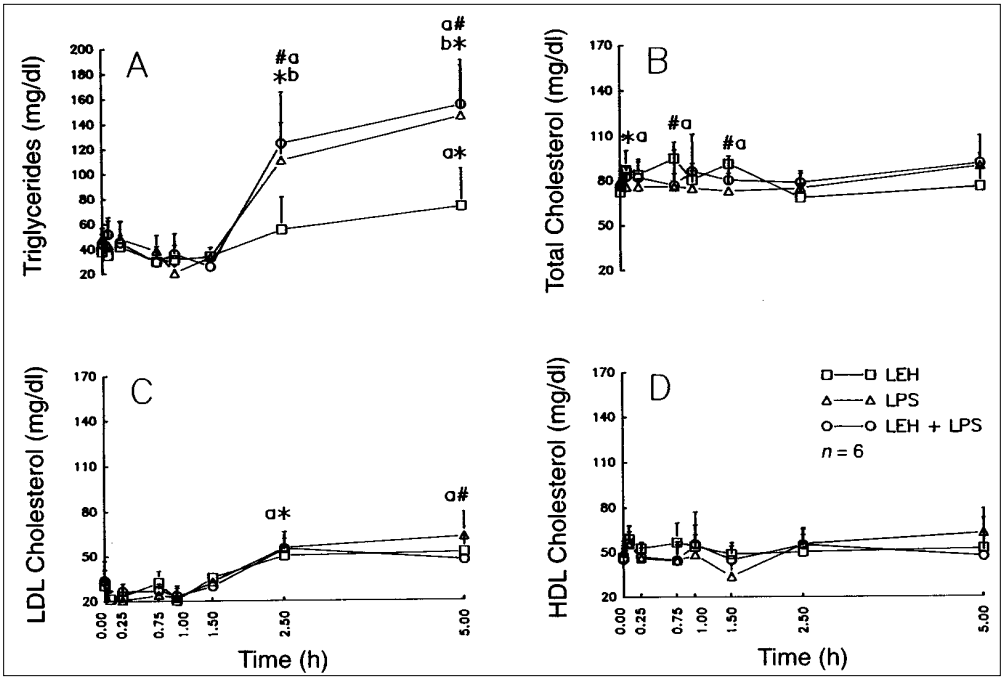

FIG. 1. Effect of liposome-encapsulated hemoglobin (LEH) (10% of calculated blood volume) on basal or lipopolysaccharide (LPS) (3.6 mg/kg, i.v.)-induced serum levels of triglycerides (A), total cholesterol (B), low density lipoprotein (LDL) cholesterol (C), and high density lipoprotein (HDL) cholesterol (D) *in vivo*. $^{*}P < 0.05$; $^{\#}P < 0.01$; a, vs. baseline; b, vs. LEH. Data are presented as mean ± standard deviation.

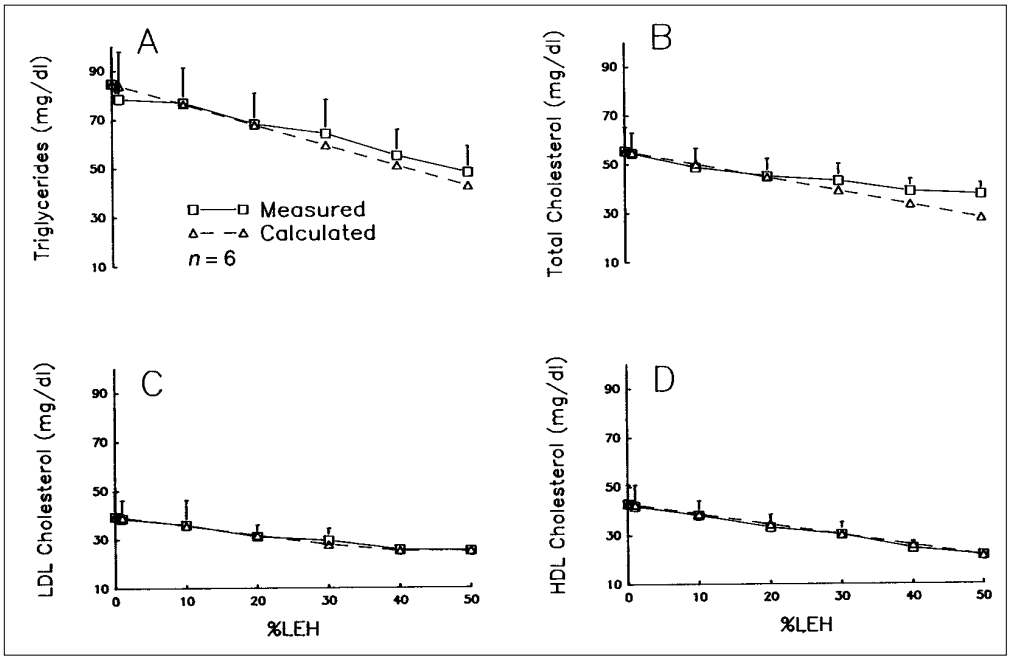

FIG. 2. Effect of LEH (0, 10, 20, 30, 40, and 50%) on triglyceride (A), total cholesterol (B), LDL cholesterol (C), and HDL cholesterol (D) measurements in whole blood harvested from naive rats. Calculated values represent estimates based on the dilution of whole blood *per se*. Data are presented as mean ± standard deviation. See Figure 1 for abbreviations.

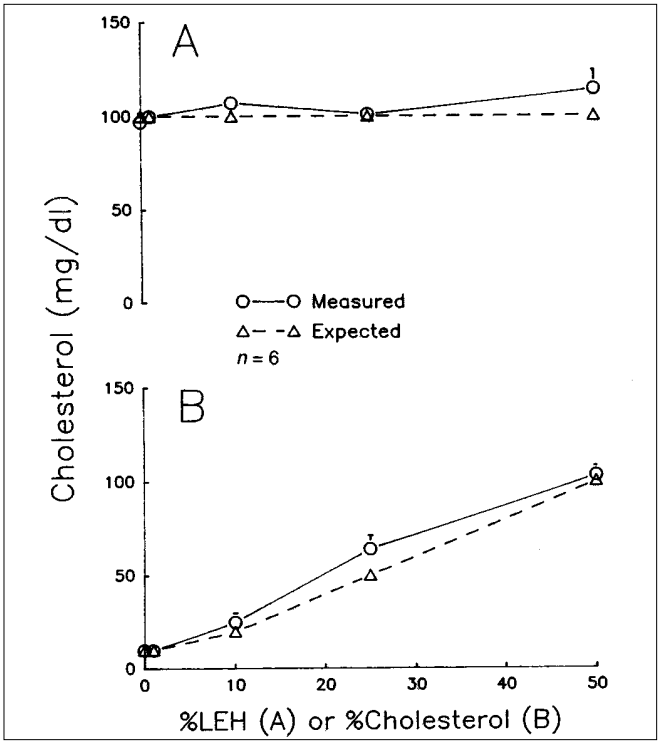

FIG. 3. Effect of LEH on cholesterol measurement *in vitro.* A, LEH (0, 10, 25, and 50%) added to a fixed concentration of aqueous cholesterol (100 mg/dL). B, Cholesterol (0, 10, 25, and 50%) added to a fixed concentration of LEH (50%). Calculated values represent estimates based on dilution *per se.* Data are presented as mean ± standard deviation. See Figure 1 for abbreviation.

cholesterol remained unaffected by LEH infusion. Similarly, when tested in the more restrictive *ex vivo* environment, LEH did not affect the assaying of these compounds in whole blood harvested from naive animals. Furthermore, under the stringent conditions of an isolated *in vitro* system containing only LEH and cholesterol, LEH did not interfere with the determination of cholesterol levels.

The fact that LEH only minimally affected serum levels of triglycerides, HDL cholesterol, and LDL cholesterol and the lack of LEH effect on endotoxin-induced responses of these lipids are clinically relevant. Very recently, LEH has been shown to increase serum TNFα and 24-h mortality in endotoxin-induced sepsis (10) in which VLDL, LDL, HDL, and chylomicrons have been implicated to play a protective role (11–16). Thus, interactions of LEH with these lipids could account for a possible modulatory effect of LEH on the development of sepsis. Such mechanism could be adherence of endotoxin to LEH which competes with endotoxin binding to lipoproteins, the presumed protective mechanism of lipids in sepsis (12–14). However, based on the minor effects of LEH on serum lipoprotein and cholesterol concentrations, it is conceivable that LEH–lipoprotein interactions do not participate in the modulation of sepsis by LEH.

The mechanism(s) of LEH-induced elevation of triglycerides and total and LDL cholesterol are still obscure. Nevertheless, several observations suggest that a likely mechanism could be an exchange of LEH cholesterol with endogenous lipid components. First, cholesterol molecules from liposomes have been previously shown to relocate or exchange with cholesterol in other cellular membranes (8,9). Second, liposome cholesterol is known to freely exchange with cholesterol in chylomicrons as well as very low density lipoprotein, LDL, and HDL cholesterol *ex vivo* (3,4).

In vivo, endotoxin elevated serum triglyceride levels. This is in agreement with numerous studies which characterized the LPS-induced hypertriglyceridemia in a variety of species including the mouse (23,24), rat (25,26), rabbit (27,28), and monkey (29,30). The hypertriglyceridemia observed following endotoxin stimulation was attributed to several mechanisms including increased *de novo* synthesis and mobilization of fatty acids as well as decreased levels of lipoprotein and hepatic triglyceride lipase (31,32). Endotoxin also minimally increased serum concentrations of LDL cholesterol in agreement with earlier hamster (33) and rat (34) studies in which LPS tended to elevate serum levels of both compounds, but no statistical significance was reached. In line with previous reports (20), endotoxin had no effect on serum total and HDL cholesterol within 4.5 h after infusion.

In summary, the present study demonstrated that LEH very mildly elevates serum levels of triglycerides, total cholesterol, and LDL cholesterol and does not interfere with their measurement. Thus, it is conceivable that LEH interaction with these compounds is an unlikely mechanism of LEH modulation of sepsis.

ABSTRACT: Serum cholesterol, triglyceride and phospholipid levels, liver cholesterol concentration, bile flow, biliary cholesterol, phospholipid and bile acid secretion rates, fecal sterol and bile acid levels and their bile acid compositions were examined in young–old parabiotic rats and compared with those in young and old control rats and young–young parabiotic rats. Bile acid composition was expressed in terms of the cholic acid group/chenodeoxycholic acid group (CA/CDCA) ratio. Body weight (BW) gain decreased after parabiosis especially in old rats, but the liver weight (g/100 g BW), diet-intake, feces dry weight, liver cholesterol concentration and fecal sterol level were almost the same in all the groups. The biliary bile acid secretion rate was higher and the fecal bile acid level was lower in old rats than those in young rats but both the levels became comparable with those in young rats after parabiosis of old rats with young rats. Young rats, however, showed no changes in these levels after parabiosis. The serum cholesterol level and the biliary and fecal CA/CDCA ratios in old rats were higher than those in young rats but decreased after parabiosis with young rats, although they were still higher than those in young rats. The serum cholesterol level in young rats increased after parabiosis with old rats, but not after parabiosis with young rats, and the fecal bile acid level and the CA/CDCA ratio were not changed in either case. It is concluded from these findings that the serum cholesterol level and the CA/CDCA ratio increased with age and that these increases were prevented after parabiosis with young rats, while young rats, although their serum cholesterol level was increased, showed no increase in the CA/CDCA ratio after parabiosis with old rats.
Lipids 32, 383–390 (1997).

Bile acids are synthesized from cholesterol in the liver, and the major primary bile acids are cholic acid and chenodeoxycholic acid in many animal species. In rats, chenodeoxycholic acid is further transformed to muricholic acids in the liver (1). Therefore, the major bile acids formed in the rat are cholic and β-muricholic acids.

Bile acid synthesis alters with age (2–6). In Wistar rats, cholic acid synthesis increases and chenodeoxycholic acid (mainly β-muricholic acid in the rat) synthesis decreases with aging, while the total bile acid synthesis remains almost constant in rats (3–5), and the cholic acid/chenodeoxycholic acid (CA/CDCA) ratio increases linearly with age (6). Since bile acids are synthesized only in the liver, these changes may reflect age-related alterations in liver function. Therefore, to examine whether the age-related abovementioned changes are directly related to the liver function, we prepared young–old parabiotic rats and examined the changes after parabiosis.

Parabiosis technique has been used in the study of the humoral transmission of many substances including hormones (7) and factors relating to aging (8–13) or immunity (14,15). If the alterations in bile acid metabolism are caused by the age-related changes in humoral factors, the increase in CA synthesis or the decrease in CDCA synthesis in aged rats will be prevented by the parabiosis with young rats, or the bile acid metabolism in young rats will be shifted to an aged state after parabiosis with old rats.

MATERIALS AND METHODS

Male Wistar rats bred in our laboratory were kept in an air-conditioned room (25 ± 1°C, 50–60% humidity) with free access to rat chow (Japan Clea CA-1 diet) and tap water. Parabiosis was performed by the technique described by Shipley (7) under Na·pentobarbital anesthesia (50 mg/kg, i.p.) making young–old and young–young pairs. Control young (4 mon old) and old (14–17 mon old) rats and parabiotic rats were kept individually for 1, 2, and 4 mon after the operation, and the last 2-d feces from the control rats were collected for analysis. In the case of parabiotic rats, a 5% solution of patent blue was given twice orally to one of the rats in each parabiotic pair (1 mL/rat at 1700 on the day before and 1.5 mL/rat on the day) before feces collection, and the 2-d feces not dyed with patent blue were collected. Then, the dye was given to the other rat in each pair 5 d after the first trial and the 2-d feces not dyed were collected for analysis.

At the end of the experiment, the rats were anesthetized with Na·pentobarbital (50 mg/kg, i.p.), and the bile duct was cannulated with PE-10 polyethylene tubing (Clay Adams, Parsippany, NJ) to collect bile for 30 min, while the rectal temperature was controlled at 37°C using an electrically heated plate (16). Blood was then withdrawn from the abdominal aorta and the liver was removed.

*To whom correspondence should be addressed at Strategic Information Unit, Shionogi & Co., Ltd., Shibuya-ku, Tokyo 150, Japan.

Abbreviations: CA/CDCA, cholic acid/chenodeoxycholic acid group; HDL, high density lipoprotein.

Blood was kept for at least 30 min at room temperature, and serum was obtained by centrifugation at 3000 rpm for 15 min. The serum total cholesterol level was determined with a Determiner-TC 555 Kit (Kyowa Medics Co., Tokyo, Japan), free cholesterol with a Determiner-FC 555 Kit (Kyowa Medics Co.), triglycerides with a Triglysime-V Eiken Kit (Eiken Co., Tokyo, Japan), phospholipids with a phospholipid B-Test Wako (Wako Pure Chemical Industries, Osaka, Japan) and serum high density lipoprotein (HDL)-cholesterol with an HDL-cholesterol test Wako (Wako Pure Chemical Industries). Serum very low density lipoprotein–low density lipoprotein-cholesterol level was taken as the difference between total cholesterol level and HDL-cholesterol level. About one gram of liver tissue was homogenized with chloroform–methanol (2:1, vol/vol, 3×10 mL) and filtered. The liver cholesterol level was determined by a calorimetric method (17).

Bile was extracted by reflux with 40 vol of ethanol at 90°C for 10 min. After filtration, a portion of the extract was evaporated to dryness under a stream of nitrogen. To the residue was added 2 mL of 1.25 N NaOH solution, and it was allowed to undergo hydrolysis at 120°C for 6 h. Sterols were extracted with diethylether, and bile acids were then extracted after acidification with 2 N hydrochloric acid solution (4,18). Feces were lyophilized and ground with a small mill, and fecal sterols and bile acids were determined as reported previously (4,18). Briefly, dried and powdered feces were extracted with absolute ethanol and hydrolyzed in NaOH solution at 120°C under pressure. The sterols and bile acids were then quantified by gas–liquid chromatography. A Hewlett-Packard gas chromatograph Model HP5890A (Palo Alto, CA) equipped with a hydrogen flame-ionization detector, a capillary column (15 m × 0.25 mm, i.d.) coated with DB-17 (J&W Scientific, Folsom, CA), and an HP7673A autoinjector was used in this experiment. Column temperature was kept at 250°C for sterols or programmed to increase from 220–280°C at a rate of 5°C/min for bile acids, the injection port at 280°C, and the detector at 300°C (19).

The amount of diet intake becomes almost constant after maturation, while the body weight and the liver weight continue to increase in rats (4). The fecal bile acid level, which is considered to roughly represent the amount of bile acids synthesized in the liver, remains almost constant after maturation (4), probably due to the dietary cholesterol intake being constant. Based on these facts, the present data on biliary and fecal bile acid levels are expressed in terms of the amounts per rat, instead of those per gram liver weight or body weight.

Statistical analysis was performed by Tukey's test, and a P value less than 0.05 was considered to be significant.

RESULTS

The animals were sacrificed 1, 2, or 4 mon after the parabiosis operation. General profiles of the rats used in this experiment such as rat age at autopsy, final body weight, body weight gain, liver weight, diet intake, and feces dry weight are listed in Table 1. The body weight gain was lower in the

[d]Values by a parabiotic pair of rats.

parabiotic rats, especially in old rats, but the liver weight expressed in terms of g/100 g body weight showed no significant change. Diet intake was also determined, but the value in the case of parabiotic rats was the amount consumed by one pair of rats. Therefore, precise values could not be determined for the parabiotic rats, but individual feces weight could be measured by use of the dye. The feces dry weight seemed to be slightly lowered in parabiotic rats, but the difference was insignificant except in two groups, the young parabiotic rats after 2 and 4 mon, suggesting that the diet intake of parabiotic rats was not markedly decreased.

Serum cholesterol, triglyceride, and phospholipid levels are shown in Table 2. The serum lipid levels in old rats were much higher than those in young rats, but they were markedly decreased after parabiosis, where the triglyceride and phospholipid levels decreased to those of young rats but the cholesterol level was still higher than that of young rats. In contrast, the serum lipid levels in young rats increased after parabiosis with old rats but not after parabiosis with young rats. The serum-esterified cholesterol values in old rats were lower than those in young rats. The value seemed to increase in old rats and decrease in young rats after parabiosis, but the changes were minor.

The changes in serum cholesterol levels are plotted in Figure 1, demonstrating the individual values. The serum cholesterol level in old rats was markedly higher than that in young rats, but the level decreased in old rats and increased in young rats after young–old parabiosis. No increase in the serum cholesterol level was detected in young–young parabiotic rats. Since the serum cholesterol level in young control rats increased 4 mon after the start of the experiment, no difference was found between the control and the parabiotic rats.

Table 3 shows liver cholesterol concentration, bile flow, biliary lipid secretion, and biliary bile acid composition (CA/CDCA ratio). The liver cholesterol concentration was almost constant in all groups showing values of 2.2–2.8 mg/g. The bile flow in old rats was similar to that in young rats but decreased after parabiosis of old rats with young animals, when expressed in terms of volumes per rat. The bile flow in young rats was slightly decreased after parabiosis with old rats, but the decrease was statistically insignificant.

The biliary cholesterol secretion rates were almost the same in all groups. The biliary phospholipid and bile acid secretion rates in old rats were higher than those in young rats, but they decreased after parabiosis with young animals giving similar values to those in young rats.

Rat bile contains various bile acids, but they were classified as belonging to the CA group and CDCA group according to their origin. The CA group was comprised of CA, deoxycholic 7-oxo-deoxycholic acid, 12-oxo-chenodeoxycholic and 12-oxo-lithocholic acids, and the CDCA group was comprised of CDCA, α-muricholic, β-muricholic, lithocholic, hyodeoxycholic, ursodeoxycholic, β-hyocholic (ω-muricholic), 7-oxo-lithocholic, and 6-oxo-lithocholic acids. The ratios of

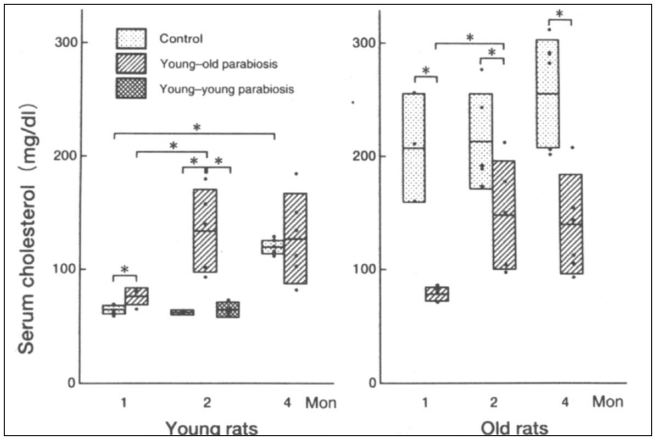

FIG. 1. Serum cholesterol level in control and parabiotic rats.

both bile acid groups (CA/CDCA ratio) were calculated and are listed in Table 3. The CA/CDCA ratio in old rats was higher than that in young rats and decreased after parabiosis with young rats.

Table 4 shows fecal excretion of sterols and bile acids. The major sterols found in rat feces were cholesterol and coprostanol, and their composition ratios were almost the same. Sitosterol was also found, but it was not included in the calculation since this sterol came from the diet and was scarcely absorbed by the rats.

The fecal total sterol excretion was fairly constant in all groups, and the composition ratio of coprostanol, and therefore that of cholesterol, remained almost constant. The fecal bile acid excretion in old rats was lower than that in young rats and seemed to increase slightly after parabiosis, but these differences were mostly insignificant. Interestingly, the composition ratio of the CA group was higher and that of the CDCA group was lower in old rats resulting in an increase in the CA/CDCA ratio. The CA/CDCA ratio in old rats decreased after parabiosis with young rat, but the ratio in young rats was not increased even after parabiosis with old animals.

Changes after parabiosis were presumed to be dependent on the time after the operation, but the differences among the different experimental periods were minor. All the data on biliary and fecal bile acids were therefore gathered without regard to the experimental period, grouped young control rats, young rats in young–old parabiosis, young rats in young–young parabiosis, old control rats and old rats in young–old parabiosis, and are shown in Tables 5 and 6, and Figures 2 and 3.

Table 5 shows the biliary bile acid composition and Table 6 the fecal bile acid composition in the rats grouped as mentioned above. CA and β-muricholic acid were major constituents in the bile, while deoxycholic acid, β-hyocholic acid, and hyodeoxycholic acid were major in the feces. The CA/CDCA ratios in feces were lower than those in bile of the corresponding rat groups.

Figure 2 shows the changes in biliary bile acid secretion

and biliary CA/CDCA ratio. The biliary bile acid secretion in old rats was higher than that in the young, but decreased to the level of young rats after parabiosis with young rats. The biliary CA/CDCA ratio was also high in old rats, and it decreased after parabiosis with young rats, but the level was still higher than that of young rats. The biliary CA/CDCA ratio in young rats, however, was not increased after parabiosis with old rats.

As shown in Figure 3, the level of fecal bile acids in old rats was lower than that in young rats but showed a trend to be increased after parabiosis with young rats. The level of fecal bile acids in young rats was not changed after young–old or young–young parabiosis. The fecal CA/CDCA ratio in old rats was apparently higher than that in young rats, and decreased after parabiosis with young rats, but was still higher than that in the parabiotic young rats.

DISCUSSION

The major primary bile acids in rats are CA and β-muricholic acid, accounting for over 80% of the biliary bile acids in normal rats (4–6,19). In the enterohepatic circulation, these primary bile acids are transformed to secondary bile acids (20). Since these secondary bile acids are absorbed from the intestine to some extent and excreted into bile, biliary bile acids are comprised of various primary and secondary bile acids, although their composition ratios of the secondary bile acids are low. However, the secondary bile acids become major constituents of fecal bile acids (4–6,19). These secondary bile acids can be classified into the CA group and CDCA group according to their origin (21). The compositions of both bile acid groups were explained in the Results section, and changes in the CA/CDCA ratios in bile and feces were discussed in this report.

Bile acids are essential for cholesterol absorption, but *in vivo* the effects of bile acids reflect the actions of CA and not of bile acids related to CDCA (22–24). When cholesterol absorption was examined *in situ* by the small intestinal loop method, taurocholic acid was found to enhance cholesterol

absorption dose-dependently, while tauro-β-muricholic acid showed almost no effect (25). When both of these bile acids were added together to the small intestinal loop, cholesterol absorption was entirely dependent on the concentration of taurocholic acid (25). Therefore, the CA/CDCA ratio was presumed to be an adequate index of the influence of bile acids on cholesterol absorption.

In the present study, the serum cholesterol level and the biliary and fecal CA/CDCA ratios in old rats were higher than those in young rats, and these findings coincided well with our previous results (4–6). CA synthesis increased and CDCA (mainly β-muricholic acid in the rat) synthesis decreased with age, while the total bile acid synthesis remained almost constant in both conventional (3,4,26) and germ-free rats (5,6) when expressed in terms of the amounts per rat. The mechanisms through which CA synthesis increased and CDCA synthesis decreased with age are not yet known, but the increase in serum cholesterol level in old rats was at least partially due to the change in bile acid composition, i.e., an increase in the CA/CDCA ratio, which enhances cholesterol absorption (22–25) for one hand and depresses cholesterol conversion to bile acids or inhibits bile acid synthesis (27–29) for the other hand. Hydrophobic bile acids such as CA and deoxycholic acid show more significant suppression of cholesterol 7α-hydroxylase (27–29) and cholesterol 26-hydroxylase (29) activities than hydrophilic bile acids including muricholic acids and ursodeoxycholic acid.

Since bile acids are synthesized only in the liver, the changes in bile acid composition may be a reflection of changes in liver function. Therefore, biliary and fecal bile acid levels and their compositions, and also serum and liver cholesterol levels, were examined in young–old parabiotic rats in comparison with those in young and old control rats and young–young parabiotic rats in this study.

Young–old parabiotic rats have been used in experiments to elucidate age-related changes in old rats (9–13). Biochemical activities such as Ca^{2+} uptake by the aorta, cholesterol transfer from the serum to the aorta and muscle, or collagenase activity in old rats after parabiosis with young rats seemed to shift closer to those in young control rats, while the activities in the young partner rats remained at the levels of the young controls (9–11). On the other hand, histological characteristics such as hepatic cell size and number in young rats after parabiosis with old rats shifted closer to those in old control rats, and those in old partner rats shifted to those in young controls (12,13).

The biliary and fecal CA/CDCA ratios in old rats decreased after parabiosis with young rats, but they were still higher than those in young controls. The fecal bile acid level which would correspond to the amount of bile acid synthesized in the liver was not changed in parabiotic old rats. Therefore, it is presumed that the liver function responsible for synthesis of bile acids in old rats shifted to that in younger animals after parabiosis with young rats.

On the other hand, the serum cholesterol level and the serum levels of other lipids in old rats decreased after parabiosis, and both very low density lipoprotein–low density lipoprotein–cholesterol and HDL-cholesterol levels decreased almost in parallel with the total cholesterol level, although they fluctuated to an extent after parabiosis. Which humoral factors are involved in the decrease in CA/CDCA ratio in old parabiotic rats could not be defined from the present study, but the serum cholesterol level decreased in these animals.

Young rats, however, showed no changes in either the fecal bile acid level or CA/CDCA ratio after parabiosis with old rats, but their serum cholesterol levels were elevated. Young rats may have a good capacity to tolerate hypercholesterolemia.

It is concluded from these findings that the serum cholesterol level and the CA/CDCA ratio increase with age in rats, and that these increases were prevented after parabiosis with young rats. In contrast, young rats showed no increase in the CA/CDCA ratio after parabiosis with old rats, although the serum cholesterol levels increased.

ACKNOWLEDGMENTS

We sincerely thank Michiko Katayama of Shionogi Research Laboratories and Yoshiko Kurosawa of The Cell Science Research Foundation for their help in preparation of the manuscript.

Comparative Hypocholesterolemic Effects of Capybara *(Hydrochoerus hydrochaeris dabbenei)* Oil, Horse Oil, and Sardine Oil in Cholesterol-Fed Rats

Michihiro Fukushima[a], Yasuyoshi Takayama[a], Tsuyoshi Habaguchi[b], and Masuo Nakano[a,*]

[a]Department of Bioresource Chemistry, and [b]Laboratory of Radioisotope Science, Obihiro University of Agriculture and Veterinary Medicine, Hokkaido 080, Japan

ABSTRACT: The hypocholesterolemic efficacy of various polyunsaturated fatty acids was compared in rats given cholesterol-enriched diets. Capybara oil (CO, linoleic + α-linolenic acids), horse oil (HO, α-linolenic acid), and sardine oil (SO, eicosapentaenoic + docosahexaenoic acids) were added to diets at 50 g/kg. The weight gain, food intake, and liver weight in the CO-fed group were significantly higher than those in other groups during the 6-wk experimental period. The serum total and very low density lipoprotein (VLDL) + intermediate density lipoprotein (IDL) + low density lipoprotein (LDL) cholesterol concentrations of the CO-fed and SO-fed groups were significantly lower than in the HO-fed group after 6 wk. The serum high density lipoprotein cholesterol concentration in the SO-fed group was significantly higher than that in the CO-fed and HO-fed groups. The fecal neutral sterol concentration in the CO-fed group was reduced significantly compared with the other groups, and the fecal bile acid concentration in the HO-fed group was significantly higher than that in the SO-fed group. The results of this study demonstrate that CO lowers the serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations in the presence of excess cholesterol in the diet as well as SO.

Lipids 32, 391–395 (1997).

Alteration of the fatty acid profile of dietary fat has been shown to affect several metabolic processes such as those involving plasma lipids and lipoproteins (1,2). In fish oil, the long-chain n-3 polyunsaturated fatty acids, eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), are active in lowering plasma lipid levels. Fish oils (e.g., salmon oil) affect platelet function by reducing platelet aggregation and adhesion (3), plasma lipids by reducing the plasma concentrations of very low density lipoprotein (VLDL), and triacylglycerols (TG) (4). As for plant oil, there are several reports on the effects of various n-6/n-3 ratios of dietary fatty acids on lipid metabolism (5–9). There also are several reports on the effects of animal oils on lipid metabolism (10,11). Herzberg and Rogerson (10) reported that a tallow diet with fructose reduced serum cholesterol more than a corn oil diet with fructose.

Oil from the rodent capybara, which contains 19.6% linoleic acid (LA, 18:2n-6) and 17.9% α-linolenic acid (ALA, 18:3n-3) is used as a dietary oil in a traditional remedy in Paraguay. The purpose of the present study was to investigate the effect of capybara oil (CO) on the lipid metabolism in rats as compared with sardine oil (SO) and horse oil (HO), which contain abundant EPA and DHA, and abundant ALA, respectively.

MATERIALS AND METHODS

Animals and diets. Male F344/DuCrj rats (4 wk old) were purchased from Charles River Japan Inc. (Yokohama, Japan). Nineteen rats were housed individually in cages in a room controlled for temperature (23 ± 1°C), humidity (60 ± 5%), and lighting (12-h light/dark cycle). The composition of the experimental diet was as follows (wt%): casein, 20; fat, 5; cornstarch, 15; cellulose powder, 5; vitamin mixture, 1 (AIN-76) (12); mineral mixture, 3.5 (AIN-76) (12); choline bitartrate, 0.2; DL-methionine, 0.3; cholesterol, 1; sodium cholate, 0.25; and sucrose to 100. The CO was kindly provided by Dr. S. Kobayashi, Department of Veterinary Medicine, Asunción University (Asunción, Paraguay). SO and HO were obtained from commercial sources. The lipid class of each oil was as follows: CO was composed of 85% TG, 6% sterol, 4% polar lipids, and other components; SO was composed of 84% TG, 6% sterol, 5% polar lipids, and other components; HO was composed of 85% TG, 8% sterol, 2% polar lipids, and other components.

Table 1 shows the fatty acid compositions of the dietary fats. CO, SO, and HO have polyunsaturated fatty acid/satu-

P/S[a]	1.50	1.14	0.70
Cholesterol (mg/g oil)	0.43	4.02	0.58

[a]Polyunsaturated fatty acid/saturated acid (P/S) = (18:2 + 18:3 + 20:4 + 20:5 + 22:6)/(14:0 + 16:0).

rated fatty acid (P/S) ratios of 1.50, 1.14, and 0.70, respectively, and n-6/n-3 ratios of 1.12, 0.18, and 0.27, respectively. All animals were fed a fat- and cholesterol-enriched diet containing 200 g of palm oil, 10 g of cholesterol, and 2.5 g of sodium cholate/kg for 4 wk as a preliminary diet to create hypercholesterolemic rats. The rats (8 wk old) were divided into a group of seven rats and two groups of six rats each. The rats were allowed free access to experimental diets and water for 6 wk. Body weight and feed consumption were recorded every week. To avoid autooxidation of the fat, each diet was stored at −30°C and freshly prepared each day. All animal procedures described conformed to standard principles (see Ref. 13) .

Analytical procedures. Blood samples (2 mL) were collected weekly between 0800 and 0900 h from the jugular veins of fed rats. The samples were taken into tubes without anticoagulant and, after standing at room temperature for 2 h, sera were prepared by centrifugation at 1500 × *g* for 20 min. At the end of the experimental period of 6 wk, all fecal excretion during 3 d was collected. Fecal dry weights did not differ among groups. The rats were killed by ether inhalation, and the livers quickly removed, washed with cold saline (9 g NaCl/L), blotted dry on filter paper, and weighed before freezing for storage.

Chemical analysis. Total cholesterol and high density lipoprotein (HDL)-cholesterol concentrations in the serum were determined enzymically using commercially available reagent kits (assay kits for the TDX system; Abbott Lab. Co., Irving, TX). The VLDL + intermediate density lipoprotein (IDL) + low density lipoprotein (LDL)-cholesterol concentration was calculated as follows: [VLDL + IDL + LDL-cholesterol] = [total cholesterol] − [HDL-cholesterol].

Total lipids were extracted from liver and feces by a mixture of chloroform/methanol (2:1, vol/vol) (14). The neutral sterol in each total lipid obtained by saponification was acetylated (15) and analyzed by gas–liquid chromatography using a Shimadzu 14A chromatograph (Kyoto, Japan) with a DB17 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA) with nitrogen as the carrier gas. Acidic sterols in feces were measured by gas–liquid chromatography following the method of Grundy *et al*. (16). The liver phosphatidylcholine (PC) was separated by two-step single-dimensional thin-layer chromatography (step one, chloroform/methanol 95:5, vol/vol; step two, chloroform/acetone/methanol/acetic acid/water 50:20:15:10:5, by vol). The fatty acids of the PC fraction were methylesterified in HCl/methanol (50 mL/L) for 2 h at 125°C (17) and analyzed by gas–liquid chromatography (Shimadzu 9A) with a 10% DEGS packed column (2 mm × 2.6 m, support shimalite w; Shimadzu) with nitrogen as the carrier gas.

Rat liver enzyme preparation. The liver was homogenized in 2 vol of cold medium containing 50 mM KCl, 2 mM $MgCl_2$, 20 mM Tris-HCl (pH 7.6), and 250 mM sucrose in a Potter-Elvehjem-type homogenizer. After homogenization with only four strokes, the mixture was centrifuged at 1000 × *g* for 10 min, and the supernatant fraction was then centrifuged at 12,000 × *g* for 15 min. The supernatant fraction from this centrifugation was further fractionated by centrifugation at 105,000 × *g* for 60 min, and the resulting pellet was called the microsomal fraction. This microsomal fraction was washed by centrifugation at 12,000 × *g* for 15 min and then at 105,000 × *g* for 60 min in the suspension medium, and finally suspended in 150 mM KCl (pH 7.6) containing 1 mM EDTA.

Determination of cholesterol 7α-hydroxylase (E.C. 1.14.13.17) activity. The procedure followed is described elsewhere (18). One milligram of microsomal protein was added to a 0.1 M potassium phosphate buffer (pH 7.4), 50 mM NaF, 5 mM dithiothreitol, 1 mM EDTA, 200 g/L glycerol and 0.15 g/L 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS), and the mixture was incubated for 5 min at 37°C. The reaction was initiated by adding NADPH regeneration components, the final concentrations of which were 5 mM sodium isocitrate, 5 mM $MgCl_2$, 0.5 mM NADPH, and 0.075 units of isocitrate dehydrogenase, all in a final reaction volume of 1.0 mL. The reaction mixture was incubated at 37°C for 20 min, unless otherwise indicated, in a shaking (90 strokes/min) water bath. The reaction was terminated by adding 30 μL of 200 g/L sodium cholate, and 1 μg of 7β-hydroxycholesterol as an internal recovery standard. The final reaction was initiated by adding 44 μL of 1 g/L cholesterol oxidase (E.C. 1.1.3.6) in a 10 mM potassium phosphate buffer (pH 7.4) containing 1 mM dithiothreitol and 200 g/L glycerol. This reaction mixture was incubated for 10 min at 37°C, and the reaction terminated by adding 2 mL of 950 g/L ethanol. The cholesterol metabolites from this reaction mixture were extracted by adding 6 mL of petroleum ether, vortexing, incubating at 37°C for 3 min, and then centrifuging (1200 × *g*) for 3 min. The upper ethereal layer was collected and dried at 40°C under a nitrogen gas atmosphere. Residues from the various extractions were analyzed by C-18 reverse-phase, high-performance liquid chromatography (Shimadzu 10A), using a Zorbax ODS (4.6 mm × 0.25 m, octadecylsilane, 5–6 μm; MAC-MOD Analytical

Inc., Ford, PA) column equilibrated with acetonitrile/methanol (7:3, vol/vol). The residues were resuspended in 0.1 mL of the same solvent mixture, and 0.02 mL was injected into the column. The metabolites were eluted with the same solvent system at a flow rate of 0.8 mL/min. After 15 min, the flow rate was increased to 2.0 mL/min for 15 min. The amount of product formed was determined by monitoring the absorbance of the effluent at 240 nm and calculating the number of nanomoles from a calibration curve.

Statistical analysis. Results are reported as means and standard deviations for each group. The mean and standard deviation for serum total cholesterol, VLDL + IDL + LDL-cholesterol, and HDL-cholesterol for each time point were calculated. The significance of differences between treatment groups was determined by analysis of variance with Duncan's multiple-range test (SAS Institute, Cary, NC). The differences were considered significant at $P < 0.05$.

RESULTS

Food intake, body weight, and liver weight. The results are summarized in Table 2. Body weight gain, food intake, and liver weight were significantly greater in rats fed CO than in the other dietary treatment groups.

Tissue lipid concentration. The total and VLDL + IDL + LDL-cholesterol concentrations in all groups at 6 wk were significantly lower than those at 0 wk. In particular, the total and VLDL + IDL + LDL-cholesterol concentrations in the SO-fed and CO-fed groups were significantly lower than in the HO-fed group at 6 wk (Table 3). There were no significant differences in the HDL-cholesterol concentration of the HO-fed group throughout the experimental period. However, the HDL-cholesterol concentrations in the SO-fed and CO-fed groups were significantly higher than those of the HO-fed group at 6 wk.

Table 4 illustrates the total lipid and cholesterol concentrations in the livers of rats at the end of the 6-wk feeding period. There were no significant differences in the total lipid and liver cholesterol concentrations among the three groups.

TABLE 3
Serum Total, HDL- and VLDL + IDL + LDL-Cholesterol Concentrations in Rats Fed Capybara Oil, Sardine Oil, or Horse Oil for Six Weeks[a]

Diet	0 Wk	3 Wk	6 Wk
Total cholesterol (mmol/L)			
Capybara oil ($n = 7$)	13.7 ± 2.4[a]	5.5 ± 1.1[c,d]	4.8 ± 1.2[d]
Sardine oil ($n = 6$)	13.8 ± 0.8[a]	4.0 ± 0.6[d]	3.9 ± 0.9[d]
Horse oil ($n = 6$)	12.5 ± 0.7[a]	6.8 ± 1.8[c]	8.8 ± 3.1[b]
HDL-cholesterol (mmol/L)			
Capybara oil ($n = 7$)	0.5 ± 0.2[e]	1.2 ± 0.2[c]	2.0 ± 0.6[b]
Sardine oil ($n = 6$)	0.5 ± 0.1[e]	2.3 ± 0.3[a]	1.8 ± 0.6[b]
Horse oil ($n = 6$)	0.7 ± 0.2[d,e]	1.1 ± 0.3[c,d]	1.0 ± 0.2[c,d]
VLDL + IDL + LDL-cholesterol (mmol/L)			
Capybara oil ($n = 7$)	13.3 ± 2.5[a]	4.3 ± 1.0[c,d]	2.8 ± 1.1[d,e]
Sardine oil ($n = 6$)	13.4 ± 0.9[a]	1.6 ± 0.9[e]	2.1 ± 1.3[e]
Horse oil ($n = 6$)	11.9 ± 0.9[a]	5.7 ± 1.8[c]	7.8 ± 3.3[b]

[a]Values are means ± standard deviations. Means within total, HDL, and VLDL + LDL bearing different superscripts are significantly different ($P < 0.05$). VLDL, very low density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein.

Cholesterol 7α-hydroxylase activity in the liver. There were no significant differences in the activity of cholesterol 7α-hydroxylase in the microsomal fraction among the three groups (Table 4).

Fatty acid compositions of the tissue. The fatty acid composition of PC in the liver is shown in Table 5. The level of 18:2n-6 was significantly greater, whereas the level of 22:6n-3 was significantly lower in the CO-fed group than in the SO-fed and HO-fed groups. The level of 20:5n-3 in the SO-fed group was significantly higher than in the other groups.

Fecal lipid concentration. Table 6 shows the effects of the dietary oils on fecal neutral sterol and bile acid concentrations in rats at the end of the experimental period. Dietary CO lowered the coprostanol and cholesterol concentrations significantly compared with dietary HO and dietary SO. The excretion of chenodeoxycholic acid was lowered significantly in the CO-fed group.

TABLE 2
Body Weight Gain, Food Intake, and Liver Weight in Rats Fed Capybara Oil, Sardine Oil, or Horse Oil for Six Weeks[a]

	Diet		
Component	Capybara oil ($n = 7$)	Sardine oil ($n = 6$)	Horse oil ($n = 6$)
Body initial weight (g)	195.1 ± 11.6[a]	195.3 ± 7.0[a]	198.1 ± 5.4[a]
Body weight gain (g/6 wk)	115.5 ± 10.2[a]	77.1 ± 10.9[b]	82.5 ± 16.9[b]
Food intake (g/6 wk)	841.9 ± 52.7[a]	749.4 ± 42.5[b]	787.1 ± 47.9[a,b]
Liver weight (wet g/100 g body weight)	6.2 ± 0.2[a]	5.2 ± 0.4[c]	5.7 ± 0.2[b]

[a]Values are means ± standard deviations. Means within the same rows bearing different superscripts are significantly different ($P < 0.05$).

[a]Values are means ± standard deviations. Means within the same rows bearing different superscripts are significantly different ($P < 0.05$).

DISCUSSION

This study demonstrated that dietary animal oils influence both serum and fecal cholesterol levels and the fatty acid composition of the liver. Fish oils have hypocholesterolemic activity compared with animal and plant oils (19–22). Though the SO contained about 10 times as much cholesterol as the other animal oils, in the diet, which was 1% cholesterol, this difference was negligible. The HO contained abundant 18:3n-3. The high α-linolenate concentration in plant oils such as perilla oil lowers cholesterol levels in the serum and liver more than dietary high-linoleate safflower oil (20). Though the HO lowered the total cholesterol concentration through the experimental period, it had poor hypocholesterolemic function as compared with fish oil and CO. On the other hand, the CO had a hypocholesterolemic function comparable to that of the SO. O'Brien (11) reported that consumption of a beef polar lipid fraction containing 10.6 g LA/100 g polar lipid, as compared with beef tallow containing 3.5 g LA/100 g tallow, seemed to induce hypocholesterolemia. Lee *et al.* (21) reported that serum and liver cholesterol levels were lowered up to a P/S ratio of approximately 2 when the n-6/n-3 ratio was kept relatively constant (5.6–6.4). In this study, the ratios of P/S and n-6/n-3 of the oils that had a hypocholesterolemic function were 1.14 and 0.18 (SO) and 1.50 and 1.12 (CO), respectively. However, the ratios of P/S and n-6/n-3 of the HO were 0.70 and 0.27, respectively. The hypocholesterolemic effect of the CO may be due to the dietary LA/ALA balance being rare in animal oils.

TABLE 6
Fecal Sterol Concentrations in Rats Fed Capybara Oil, Sardine Oil, or Horse Oil for Six Weeks[a]

	Diet (μmol/100 g body weight/d)		
Component	Capybara oil (n = 7)	Sardine oil (n = 6)	Horse oil (n = 6)
Coprostanol	0.29 ± 0.10[b]	0.76 ± 0.40[a]	0.74 ± 0.26[a]
Cholesterol	42.1 ± 14.7[b]	74.4 ± 12.1[a]	66.9 ± 13.1[a]
CA	<0.01	0.50 ± 0.15[b]	1.10 ± 0.34[a]
CDCA	0.18 ± 0.09[b]	0.35 ± 0.10[a]	0.34 ± 0.09[a]
DCA	2.56 ± 1.05[a]	1.28 ± 0.29[b]	2.81 ± 1.23[a]
LCA	0.59 ± 0.30	0.41 ± 0.28	0.50 ± 0.25

[a]Values are means ± standard deviations. Means within the same rows bearing different superscripts are significantly different ($P < 0.05$). The body weights of the three oil groups at 6 wk were not equal: the capybara oil-fed group, 311.6 ± 17.4 g; the sardine oil-fed group, 272.5 ± 15.5 g; the horse oil-fed group, 280.6 ± 13.0 g. CA, cholic acid; CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; LCA, lithocholic acid.

The lipid compositions and the enzyme activities of the liver and the sterol compositions of feces were examined to elucidate the cholesterol-lowering mechanism of the dietary CO in this study. The body weight gain and liver weight in the CO-fed group were significantly higher than those in the other groups. This may have been due to food intake differences among the three treatment groups. Though there were no significant differences in the cholesterol concentration and total lipid concentration in the liver among the three treatment groups, the total lipid concentration in the CO-fed group increased 9 and 27% as compared with the HO-fed and SO-fed groups, respectively, and the cholesterol concentration in the CO-fed group decreased 15 and 24% compared to the SO-fed and HO-fed groups, respectively. There were no significant differences in the hydroxymethylglutaryl–CoA (HMG–CoA) reductase (E.C. 1.1.1.34) activity (Fukushima, M., unpublished data) and cholesterol 7α-hydroxylase activity in the liver among the three treatment groups. AL-Shurbaji *et al.* (23) have reported that there was no difference between the effects of dietary fish oil and sunflower oil on HMG–CoA reductase and cholesterol 7α-hydroxylase activities in rats, though treatment with dietary n-3 fatty acids resulted in a slight reduction in serum total cholesterol (17%). It has also been reported that administration of fish oil by intravenous infusion results in a marked reduction of serum cholesterol, HMG–CoA reductase activity, and cholesterol 7α-hydroxylase activity compared to intravenous infusion of soybean oil (23). Our study of dietary oils yielded similar results. The reductions of 20:5 and 22:6 levels in the liver PC in the CO-fed group might be due to competition between major pathways of fatty acid biosynthesis by LA or ALA contained in the CO (24).

The HO containing major n-3 fatty acids and poor n-6 fatty acids stimulated cholesterol, coprostanol, and chenodeoxycholic acid secretions (Table 6). However, CO containing major n-6 and n-3 fatty acids suppressed fecal sterol secretions (Table 6) and lowered the serum VLDL + IDL + LDL-cholesterol concentration (Table 3). The results showed that the cholesterol-lowering effect of the CO was not due to fecal excretion of neutral and acidic sterols. It may be that the synthesis of apoliproprotein B-100, which is the major protein component of circulating VLDL + IDL + LDL (25), was lowered in the liver and small intestine, the LDL receptor levels elevated in the liver (26), or that the transfer of cholesterol ester from HDL to VLDL + IDL + LDL was lowered as a result of consumption of CO.

In conclusion, the results of this study demonstrate that CO lowers the serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations in the presence of excess choles-

terol in the diet. Thus, CO, which is a little-used animal resource containing large amounts of linoleate and α-linolenate, is effective in lowering cholesterol levels in hypercholesterolemic rats.

ABSTRACT: Arachidonic acid (AA), an n-6 long-chain polyunsaturated fatty acid (LC-PUFA), serves an important role in the body as a structural fatty acid of many tissues including neurological tissues. It is also a precursor of the n-6 class of eicosanoids and is the most abundant n-6 LC-PUFA found in human breast milk. We have optimized the production of a microfungal source of a triglyceride oil (ARASCO®) which is enriched in AA to about 40% by weight. To establish the safety of this oil as a food, we evaluated the effect of ARASCO® in Sprague-Dawley rats (20/sex/group) gavaged at dose levels of 1.0 and 2.5 g/kg/d for a period of 90 d, paying special attention to any potential neurotoxicity of the oil. Two groups of control animals received either untreated standard laboratory diet (untreated control) or the same diet and vehicle oil at the same dose volume administered to the treated animals (vehicle control). Physical observations, ophthalmoscopic examinations, body weight, food consumption, clinical chemistry, hematology parameters, neurobehavioral assessments, and macroscopic as well as microscopic postmortem evaluations were performed. Tissue fatty acid analyses indicated that the AA levels in the brain, heart, and liver of the high-dose ARASCO®-fed animals increased by 8, 59, and 76%, respectively, indicating that the AA in the oil was readily incorporated into tissue lipids. In spite of this high elevation in tissue AA levels, no developmental, histopathological, or neuropathological differences were seen in the animals administered ARASCO® compared with the vehicle control animals. Being highly enriched in AA, ARASCO® offers the means to study the effect of this fatty acid in experimental settings and in human metabolic studies.
Lipids 32, 397–405 (1997).

Arachidonic acid (AA) is a 20-carbon, long-chain polyunsaturated fatty acid (LC-PUFA) with double bonds at the 5, 8, 11, and 14 positions. It is the n-6 precursor of prostaglandins and eicosanoids, and can therefore have a multitude of physiological effects such as mediation of the inflammatory response, regulation of blood pressure, and induction of blood clotting. Low blood levels of AA have been associated with various pathologies such as cirrhosis (1), schizophrenia (2), multiple sclerosis (3), depression (4), and tardive dyskinesia (5). Many of these disorders also exhibit a reduction of docosahexaenoic acid (DHA), suggesting a general Δ6-desaturase deficiency condition. On the other hand, many disorders seem to be associated with some excessive formation of n-6 eicosanoids such as thrombotic stroke (6).

As a structural lipid, AA is especially important in human growth and development. It is provided to the developing fetus *in utero* by the placenta, and to the growing infant postnatally from its mother's breast milk. Most commercially available infant formulas (including all of those available in the United States) do not contain AA, but rather provide a large excess of its metabolic precursor, linoleic acid (LA). In spite of receiving an abundance of dietary LA compared with that found in human milk, formula-fed babies exhibit significantly lower erythrocyte and plasma AA levels compared with breast-fed babies (7). Moreover, Carlson and colleagues (8,9) showed that if preterm babies received a formula supplemented with fish oil containing eicosapentaenoic acid (EPA), the babies' serum AA levels were lowered even further leading to a significant reduction of growth rate. Jensen and colleagues (10,11) later showed that when babies were supplemented with α-linolenic acid (ALA) at levels as high as 4.0% as a precursor to DHA, the consequent elevation of serum EPA was sufficient to depress the babies' AA levels, and growth inhibition was observed. Therefore, the possibility exists that the supplementation of infant formulas with DHA may also need to be accompanied by supplementation with AA at the levels found in human milk. In recognition of the need to match the LC-PUFA composition of human breast milk, the British Nutrition Foundation (BNF), the FAO/WHO Expert Committee on Fats and Oils in Human Nutrition, and the International Society for the Study of Fatty Acids and Lipids (ISSFAL) all have recommended that both AA and DHA be included in the formulas designed to be the sole source of nutrition for infants at levels equivalent to those in human milk (12–14).

ARASCO® (Martek Biosciences Corporation, Columbia, MD) is a triglyceride oil which contains 40% AA, no n-3 fatty acids, and small amounts of other LC-PUFA. It is produced

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; APPT, activated partial thromboplastin time; ARASCO®, arachidonic acid single cell oil; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FDA, Food and Drug Administration; LA, linoleic acid; LC-PUFA, long-chain polyunsaturated fatty acid.

by conventional fermentation processes from the common soil microfungus *Mortierella alpina* according to Kyle and colleagues (15), and the triglyceride oil product is extracted and processed using unit operations common to the vegetable oil industry. This oil was developed to provide an acceptable source of AA which could be used in infant formula to provide an LC-PUFA composition which more closely matches that of human milk than other sources of AA such as egg yolk. We have previously reported that this oil exhibited no measurable mutagenic or cytotoxic effects, nor could we observe any acute or 28-d subchronic effects at dose levels of 20 g/kg and 2.5 g/kg/d, respectively (16). The purpose of this investigation, as part of a more extensive toxicological study, was to further evaluate the safety of the ARASCO® oil with a standard 90-d toxicity and neurotoxicity assessment in rats. We also studied the incorporation of the AA from ARASCO® into various tissues.

MATERIALS AND METHODS

All toxicological tests were conducted at the laboratories of Huntingdon Life Sciences (formerly Pharmaco LSR) (East Millstone, NJ) in compliance with Part 58 of 21 CFR (FDA Good Laboratory Practice Standards). The "Redbook I" (17) of the Food and Drug Administration (FDA) and the revised "Redbook II" (draft) were used as guidelines for the study design.

Test materials. The material tested was ARASCO® (lot no. A013-DS), a single-cell triglyceride oil produced by *M. alpina* under tightly controlled production procedures (15) following U.S. FDA Good Manufacturing Practices (GMP) for food products. The final product was assayed for elemental composition, chemical characteristics, and fatty acid composition and met previously set specifications (Table 1). Ascorbyl palmitate (0.025%) and mixed natural tocopherol (0.025%) were added to the final product to enhance stability. For this study, additional tocopherol (3 g/kg) was added to ARASCO® to prevent vitamin E deficiency which might occur when high doses of LC-PUFA-containing oils are administered (18). The same amount of extra tocopherol was also added to the high-oleic sunflower oil that was used as the vehicle.

[a]Used in the 90-d oral gavage toxicity study in rats. ARASCO® (Martek Biosciences Corporation, Columbia, MD).

Animals. Male and female 25-d-old rats (Crl: CD®BR) were obtained from Charles River Breeding Laboratories, Inc. (Stone Ridge, NY) and acclimated for approximately 2 wk before initiation of treatment. At initiation of the test material administration, the rats were approximately 6 wk old, the males weighing from 208 to 273 g, and the females weighing from 146 to 194 g. The animals were examined by a veterinarian during the acclimation period, and those considered unsuitable for the study based on physical examination, body weight, or clinical laboratory data were eliminated prior to assignment to groups. The remaining animals were randomly distributed into four groups of 40 animals each (20 animals/sex) so that the body weight means for each group were comparable. During the treatment period, the animals were housed individually in stainless-steel wire-mesh cages and kept in an environment maintained at 20 to 24°C, 20–74% humidity, and a 12-h light/dark cycle. Certified rodent diet #5002 meal from PMI® Feeds, Inc. (St. Louis, MO) was provided *ad libitum*, except when the animals were fasted. Water was also provided *ad libitum*.

Test material preparation and administration. Test material doses of 1.0 g (low-dose ARASCO®) and 2.5 g (high-dose ARASCO®) ARASCO®/kg/d were prepared by diluting the ARASCO® with high-oleic sunflower oil (lot no. SC 4080; SVO Specialty Products, Eastlake, OH) so as to provide a constant total oil dose of 3 mL/kg/d to each animal based on the most recently recorded body weights. The fat content of the basal diet was 5% (w/w, PMI® #5002). The additional fat bolus gavaged daily varied from 33–52% of the total fat content, depending on the time of the study as the food consumption per body weight (initially approximately 120 g/kg/d) rapidly decreased during the first 4 wk of the study and then leveled out at about 45–55 g/kg/d. Therefore, the additional fat represented 8 to 16% of the energy intake. Fresh dosing solutions were prepared monthly, divided into daily aliquots, and stored frozen. All dose levels were assayed at the time of preparation to verify the concentrations. Daily aliquots were thawed to room temperature before use, and each dose was administered by oral gavage once daily for 91 to 93 d, depending on the day of sacrifice. One group of control animals was untreated, while the other group was dosed with vehicle oil only (high-oleic sunflower oil) (Table 1). The experimental design is outlined in Table 2.

Observation, body weights, and food consumption. The animals (20 animals/sex/group) were observed twice daily, once in the morning and once in the afternoon, for mortality and gross signs of toxicologic effects. A detailed, weekly examination was performed for signs of local or systemic toxicity and tissue masses. The animals underwent an ophthalmoscopic examination prior to test material administration and at termination. Body weights were measured twice prior to

[a]Untreated control group received untreated standard laboratory chow. Necropsy was done on all survivors; complete postmortem evaluations were performed on animals which were found dead during the study; A.R. = as required; M = male; F = female. See Table 1 for ARASCO® company supplier.
[b]Control animals received vehicle in the same volume received by the high-dose animals.

test material administration, weekly during treatment, and at termination. Food consumption was measured weekly beginning one week prior to treatment.

Hematology and clinical chemistry. At the end of the treatment period, the animals were fasted overnight, lightly anesthetized with CO_2/O_2, and blood was collected from the retrobulbar orbital plexus from 10 animals per sex per group. Hemoglobin concentration, hematocrit, erythrocyte count, reticulocyte count smear (prepared and stored for possible future examination if deemed necessary), platelet count, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, prothrombin time (PT), activated partial thromboplastin time (APTT), total and differential leukocyte counts, and erythrocyte morphology were measured. Serum samples were also analyzed for aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, blood urea nitrogen, fasting glucose, total protein, albumin, globulin, albumin/globulin ratio, creatinine, total bilirubin, sodium, potassium, chloride, calcium, inorganic phosphorous, and γ-glutamyl transferase.

Pathology. At the end of the treatment period, the animals were fasted overnight and sacrificed by exsanguination following carbon dioxide inhalation. A complete postmortem macroscopic examination was performed on all animals. For all survivors not designated for neuropathology (15 animals/sex/group), the following organs were weighed at the scheduled sacrifice: adrenal glands, brain, kidneys, testes with epididymides, thyroid/parathyroid glands (weighed postfixation), liver, ovaries, thymus, and spleen. Paired organs were weighed together. Organ-to-body weight and organ-to-brain weight ratios were calculated. A total of 40 tissues were collected from each animal and preserved in 10% neutral buffered formalin (16). After fixation, the tissues from those animals which died prior to termination of the study and those from animals in the vehicle control and high-dose ARASCO® group were embedded in paraffin, cut at a microtome setting of 4–7 microns, mounted on glass slides, stained with hematoxylin and eosin, and examined by light microscopy. Gross lesions were examined for all animals.

Neuropathology. Five animals per sex per group were anesthetized with an intraperitoneal injection of sodium pentobarbital and transcardially perfused with phosphate-buffered saline followed by 4% paraformaldehyde/1% glutaraldehyde in the same buffer. The brain, spinal cord (cervical, thoracic, and lumbar segments), sciatic nerve, tibial nerve, and sural nerve were collected from each animal and preserved in 4% paraformaldehyde/1% glutaraldehyde. Slides of each of the above were prepared, and the following regions were examined from the animals in the vehicle control and high-dose ARASCO® group: forebrain, cerebral cortex, hippocampus, basal ganglia, midbrain, cerebellum and pons, medulla, cervical, thoracic and lumbar cord (cross and longitudinal sections), and sciatic, tibial and sural nerves (cross and longitudinal sections).

Neurobehavioral studies. Before initiation of test material administration and at weeks 5, 9, and 13 of treatment, 10 animals per sex per group were monitored for motor activity using an automated Photobeam Activity System (San Diego Instruments, Inc., San Diego, CA). At the same time points, 10 animals per sex per group were also evaluated for neurological condition using a functional observational battery of assessments (Table 3). Most of the assessments were based on qualitatively scaled observations of the animals' behavior/status. Grip strength was measured using a Grip Strength Meter (Columbus Instruments International Corporation, Columbus, OH). Landing foot splay was measured by applying a small dot of paint to each hindpaw, dropping the animal from a height of 2 feet above a flat surface, and measuring the distance between the marks left by the hindpaws. Air-righting ability was assessed by dropping the animal from an upside down position from a height of 2 feet above a container of bedding and observing the landing position.

Tissue fatty acid analysis. In addition to the routine tissue analysis and histology, samples of the brain, heart, and liver were collected from all animals (15/sex/group) not designated for neuropathology evaluations. The organs were frozen in liquid nitrogen and maintained frozen at −80°C until lyophilized. Lipids in the dried organ samples were transmethylated by the following procedure for subsequent gas chromatography (GC) analysis. Each dried sample (50 mg) was weighed into a 15-mL glass tube. To each tube was added 1.5 mL of methanolic base reagent (#3-3080; Supelco, Bellefonte, PA), and the tube was flushed with nitrogen, sealed with a Teflon-lined screw cap, and vortexed. Samples were

incubated for 15 min in a 65°C water bath, then removed and allowed to cool to room temperature for approximately 10 min. To each tube were added 2 mL of distilled water and 2 mL of *n*-hexane, and the tubes were flushed with nitrogen, capped, and vortexed. Tubes were then centrifuged at 1800 × *g* for 10 min to separate the phases. The top hexane phase containing the methyl esters was dried under nitrogen to a volume of 0.4 mL.

After concentration of the hexane phase, a precipitate was noted in some of the brain samples, resulting in interfering peaks on the chromatograms. This precipitate was removed from these samples by column chromatography or by centrifugation at high speeds. For column chromatography, the hexane phase was loaded onto 300 mg Sep-Pak silica gel columns (Waters/Millipore, Milford, MA) pre-wetted with hexane. The methyl esters were eluted with 2 mL of 10% ether in hexane, dried under nitrogen, and resuspended in 0.4 mL of hexane. Alternatively, the concentrated hexane phase was spun in 1.5 mL microfuge tubes at 13,000 × *g* for 10 min, and the clarified supernatant used for GC analysis. In all samples, the final methyl esters in hexane were transferred to GC autosampler vials, containing sodium sulfate as a drying agent, prior to GC analysis.

Quantitation of the fatty acid methyl esters was performed on a Hewlett-Packard (HP) 5890 Series II GC (Palo Alto, CA). Separations were made on an Omegawax 250 capillary column (30 m, 0.25-mm i.d., 0.025-µm film; Supelco) with helium as the carrier gas at 1.8 mL/min. Each sample (1 µL) was introduced with an HP 7673 autosampler, through a 60:1 split injection at an injector temperature of 260°C. Column temperature was maintained at 205°C throughout the run. Detection was made with a flame-ionization detector at 260°C. Peak identifications were assigned based on retention times of authentic standards. Results for each fatty acid are reported as area percentage of all integrated peaks. Results on >0.10% of total fatty acids are reported. Some brain tissue samples were used for methods development, and thus the number of samples used for final analysis was smaller.

Statistical analysis. Body weight, weight gain, food consumption, hematology and clinical chemistry parameters, organ weights, and organ/body and organ/brain weight ratios were evaluated. Statistical evaluation of equality of means was made by the appropriate one-way analysis of variance technique, followed by a multiple comparison procedure if needed. First, Bartlett's test was performed to determine if groups had equal variance. If the variances were equal, parametric procedures were used; if not, nonparametric procedures were used. The parametric procedures were the standard one-way analysis of variance using the F distribution to assess significance. If significant differences among the means were indicated, Dunnett's test was used to determine which means were significantly different from the control. If a nonparametric procedure for testing of means was needed, the Kruskal-Wallis test was used, and if differences were indicated, a summed rank test (Dunn) was used to determine which treatments differed from control. A statistical test for trend in the dose levels was also performed. In the parametric case (i.e., equal variance), standard regression techniques with a test for trend and lack of fit were used. In the nonparametric case, Jonckheere's test for monotonic trend was used. The test for equal variance (Bartlett's) was conducted at the 1%, two-sided risk level. All other statistical tests were conducted at the 5 and 1%, two-sided risk level. The tissue fatty acid results were evaluated using Student's *t*-test at the 1% two-tailed probability level comparing the high-dose ARASCO® and low-dose ARASCO® groups to the vehicle control group.

For all the tests except tissue fatty acid analysis, the non-vehicle control group was first tested against the vehicle control and, if no difference was found, the vehicle control was used as the true control for the ARASCO® groups.

RESULTS

Mortality. One male from the high-dose ARASCO® group died during the study due to intubation error, and one female from the high-dose ARASCO® group was found dead during the study. In the absence of morphologic changes and clinical signs of toxicity, the deaths of these animals were not attributed to administration of ARASCO®. All other animals survived to the scheduled sacrifice.

Observations, body weights, and food consumption. There were no ARASCO®-related physical observations or ocular

abnormalities noted during the treatment period. Neither the high-dose ARASCO® group nor low-dose ARASCO® group differed from the control group in body weight (Fig. 1) or food consumption.

Hematology and clinical chemistry. There were no ARASCO®-related effects on mean hematology values including PT and APTT at the termination of the study. There were also no differences in the clinical chemistry including liver enzyme activities (Table 4).

Pathology. No ARASCO®-related macroscopic findings were revealed during necropsies of the animals, including signs indicative of micronutrient deficiencies. There were no significant differences in the organ weights between vehicle control and treatment groups. However, the spleen-to-body weight ratios were significantly higher in males in both ARASCO® groups as compared with those in the vehicle control group, but there was no dose response, and the differences were within normal limits compared with historical control data. The differences were not considered to be ARASCO®-related. There were no differences in the spleen-to-brain weight ratios in the same animal groups. No histopathological findings were observed in the tissues examined in either ARASCO® group: adrenal glands, aorta, sternum, bone marrow, brain, epididymides, esophagus, eyes with optic nerve, heart, kidney, intestine, cecum, colon, duodenum, ileum, jejunum, rectum, liver, lungs, lymph nodes, mammary gland, muscle, sciatic nerve, ovary, pancreas, pituitary gland, prostate gland, salivary glands, seminal vesicles, skin, spinal cord, spleen, stomach, testes, thymic region, thyroid/parathyroid glands, trachea, urinary bladder, and uterus.

Neuropathology and neurobehavioral studies. There were no ARASCO®-related microscopic findings in the brain, spinal cord, sciatic, tibial, or sural nerves, and no changes in motor activity for either sex in either of the ARASCO® groups. Most of the tests used for the functional observational battery were ranked on a qualitative scale of 1–6 including home cage, open field, handling evaluations, and reflex evaluations. There were no differences between the control and the ARASCO® groups in this neurological testing at the pretest or at weeks 5, 9, and 13. No abnormal movements were observed in any of the groups. Landing foot splay and grip strength for both ARASCO® groups were comparable to the control groups or within the range of normal variation (Table 5).

Tissue fatty acid analysis. The fatty acid compositions of the brain, heart, and liver for high-dose ARASCO®, low-dose ARASCO®, and vehicle control groups are presented in Tables 6–8. Although significant differences in various fatty

[a]See Table 6 footnotes.

levels in the brain lipids increased by 8% in the high-dose group and by 7% in the low-dose group. At both levels of supplementation, ARASCO® significantly decreased the levels of 18:1n-9, 18:2n-6, 22:5n-3 (for all $P < 0.001$), and 20:3n-6 ($P < 0.001$ for low-dose, $P < 0.01$ for high-dose).

In the heart tissue, high- and low-dose ARASCO® supplementation resulted in significant decreases in 16:0, 18:1n-9, 18:2n-6, and EPA (for all $P < 0.001$ except for low-dose 18:1n-9, $P < 0.01$). Moreover, a significant increase in AA ($P < 0.001$; 59 and 39%, respectively) and in 22:4 ($P < 0.001$) when compared with the vehicle control group was seen in both dose groups. When used at the high-dose, ARASCO® resulted in significantly decreased levels of 22:5n-3 and DHA ($P < 0.001$ for both) and of 17:0 ($P < 0.01$).

The liver tissue showed the greatest changes as a consequence of the dietary ARASCO®. The 18:1n-9, 18:2n-6, and EPA (for all $P < 0.001$) were significantly decreased in both the high- and low-dose ARASCO® groups while 17:0, 22:4, and AA (for all $P < 0.001$) were significantly increased in both ARASCO® groups (for AA 76 and 39%, respectively). Supplementation with the high dose of ARASCO® resulted in decreased levels of 14:0, 16:0, 16:1, 18:1n-7, 18:3n-3, and 20:1 ($P < 0.001$, $P < 0.01$, $P < 0.001$, $P < 0.01$, $P < 0.01$, $P < 0.001$, respectively) and increased levels of 18:0 and 20:3n-6 ($P < 0.01$, $P < 0.001$, respectively).

DISCUSSION

By using conventional 90-d toxicity testing, we found no signs of toxicity in rats supplemented with ARASCO® at levels as high as 2.5 g/kg/d which corresponds to about 1.0 g AA/kg/d. Dietary AA intake has been estimated to be about 200 mg AA per person per day which is equal to 2.9 mg AA/kg/d for a 70-kg adult (19). Therefore, if directly applicable to humans, this toxicity study represents about a 350-fold safety margin for dietary AA. In addition to the standard battery of toxicity tests, detailed neurobehavioral studies further confirmed the absence of neurotoxicity. Analysis of the tissues from animals in this study also showed that AA from ARASCO® is readily bioavailable. Considerable concern has been expressed about the adverse physiological response caused by AA based on a previous study which showed augmented prostaglandin synthesis in humans after high-dose ethyl arachidonate administration (20). We have demonstrated in this study that high doses of ARASCO® in rats were nontoxic, and also that high doses of AA (up to 1.0 g/kg/d) had no adverse physiological effects when given orally to rats for subchronic periods. The rat is a generally recognized toxicological model with a 70% prediction rate of human toxicity (21).

AA is an important structural lipid, and its role in nutrition has been associated with growth, and *via* modulation of eicosanoid production, immunological status and platelet function. One of the most profound effects that has been reported is that lowered blood levels of AA inhibit growth in premature infants (8). This study showed that an overabundance of AA does not have any effect on food intake or growth in rats. Furthermore, even though *in vitro* studies have shown AA-induced apoptosis in neutrophils (22), this *in vivo* study showed no changes in the differential count of white blood cells. Also, no changes were found in the activity of liver enzymes, reflecting no dysfunction of the liver as a result of the high-AA doses.

Nelson and colleagues (23–27) have studied the effects of dietary supplementation of 4.5 g ARASCO®/d in humans and found no change in platelet aggregation. Platelet aggregation was not measured in this study, but we found no changes in PT and APTT reflecting normal liver function in producing clotting factors. PT and APTT are generally believed to be more sensitive measurements in this respect than platelet count (28).

ARASCO® has been shown to be readily bioavailable in humans (29) as well as in various animal models (16,30,31). In humans it is difficult to analyze the tissue levels of a specific fatty acid, and AA level in blood phospholipids is usually used as a surrogate marker of tissue AA. Animal studies, on the other hand, provide the possibility to also analyze various tissue levels of AA in response to dietary intervention. In a previous study (16), we had used the same doses of ARASCO® (1.0 g AA/kg/d) as in this study (high-dose group) and found similar changes in tissue fatty acids within 28 d. The longer supplementation period in this study (90 d) resulted in only a few additional significant changes in brain fatty acid levels (18:1n-9, 20:3n-6, 20:4n-6, 22:5n-3, 20:4n-6) which were not observed after the 28-d supplementation. This suggests that the brain is somewhat resistant to changes in membrane fatty acids. In contrast, clear dose responses in the liver and heart tissue could be seen (see Tables 7 and 8). The significant decrease in the ARASCO® groups in the levels of 18:1n-9 may be a result of feedback inhibition, whereas the increase in 22:4 is likely to be the result of elongation of AA. Whelan and colleagues (32) have proposed that AA is preferentially incorporated into the tissue when both the precursor 18:2n-6 and AA are available. Our study supports this idea, showing a significant decrease in 18:2n-6 in all the tissues while AA is significantly increased. The decrease in the EPA concentrations in the liver and heart tissues in the ARASCO®-supplemented groups reflects the inverse relationship of dietary AA and EPA on tissue levels as also shown in previous studies (33,34).

Greater changes in the fatty acid composition of liver and heart tissue compared with brain were measured, suggesting that these changes reflect more of an acute effect resembling the effect seen in plasma lipids. Nelson and coworkers (26) have shown that various plasma lipid fractions exhibit marked differences in the degree of arachidonic acid enrichment after ARASCO® supplementation, whereas no differences could be measured in the adipose tissue fatty acid composition. This may be due to tissue selectivity for AA incorporation or simply due to the dilution of the dietary AA in a large pool of adipose tissue. In studies with patients having peroxisomal disorder where ARASCO® has been given orally alone or in combination with a DHA-rich algal oil, the level of AA was

normalized in plasma phospholipids and in red blood cells within 6 wk (Raymond, G., personal communication).

In conclusion, we have demonstrated that very high levels of dietary AA (1.0 g/kg/d), when provided orally to rats as the triglyceride ARASCO® over a period of 90 d, resulted in no significant toxicological, physiological, or behavioral consequences. This dose level represents about a 350-fold safety margin compared with normal dietary AA in humans with no observable effects.

ACKNOWLEDGMENT

The authors wish to acknowledge the technical personnel of Huntingdon Laboratories for their contribution in completing this study.

COMMUNICATION

Possible Fatty Acyl Pheromone Precursors in *Spodoptera littoralis*. Search for 11- and 12-Hydroxytetradecanoic Acids in the Pheromone Gland

Isabel Navarro, Gemma Fabriàs*, and Francisco Camps

Departamento de Química Orgánica Biológica, Centro de Investigación y Desarrollo, Consejo Superior de Investigaciones Científicas, Barcelona, Spain

ABSTRACT: Lipidic extracts of *Spodoptera littoralis* pheromone glands submitted to acid methanolysis using: (i) sulfuric acid/methanol/benzene (0.1:4:2, by vol) at 90°C for 1 h; (ii) 12 N HCl/methanol (1:2, vol/vol) at 90°C for 1 h, or (iii) 14% BF_3–MeOH at 90°C for 1 h did not reveal the presence of either 11- or 12-hydroxytetradecanoic acid in the extracts, as concluded from the gas chromatography–mass spectrometry analyses. Under the above methanolysis conditions, a synthetic sample of methyl (14,14,14-$^2H_3$) 12-hydroxytetradecanoate remained unaltered. These results may indicate that formation of (*E*)-11-tetradecenoic acid from tetradecanoic acid does not occur in the pheromone gland by dehydration of an intermediate hydroxyacid. Acid methanolysis of a lipidic extract using BF_3–MeOH led to the formation of a mixture of methoxy fatty acid methyl esters, identified by gas chromatography–mass spectrometry. These methoxy derivatives should arise from BF_3-catalyzed addition of methanol to the double bond of the natural monounsaturated fatty acyl derivatives present in the gland. Thus, under the same conditions, a synthetic sample of methyl (*Z*)-11-tetradecenoate was partially transformed into methyl 11-methoxytetradecanoate and methyl 12-methoxytetradecanoate. This reaction might be a useful alternative procedure to obtain methoxy derivatives of olefins, which are very helpful for the structural characterization of the parent alkenes.

Lipids 32, 407–412 (1997).

The analysis of pheromone gland composition in different moth species has revealed the occurrence of unusual fatty acids that have been proposed as precursors of pheromone components (1). The identification of these intermediates is normally carried out by gas chromatography coupled to mass spectrometry (GC–MS) analysis of the fatty acid methyl esters (FAME) obtained by either acidic or basic methanolysis of pheromone gland lipids.

Abbreviations: FAME, fatty acid methyl esters; GC–MS, gas–chromatography coupled–mass spectrometry; 11-MeO-16:Me, methyl 11-methoxyhexadecanoate; 12-MeO-16:Me, methyl 12-methoxyhexadecanoate; 9-MeO-14:Me, methyl 9-methoxytetradecanoate; 10-MeO-14:Me, methyl 10-methoxytetradecanoate; 11-MeO-14:Me, methyl 11-methoxytetradecanoate; 12-MeO-14:Me, methyl 12-methoxytetradecanoate; *Z*11-14:Me, methyl (*Z*)-11-tetradecenoate.

The characteristic fatty acids involved in the biosynthetic pathway of *Spodoptera littoralis* sex pheromone blend were identified as tetradecanoic, (*Z*)-9-tetradecenoic, (*Z*) and (*E*)-11-tetradecenoic, (*Z*,*E*)-9,11-tetradecadienoic, hexadecanoic, and (*Z*)-11-hexadecenoic acids (2). The biochemical routes through which these compounds are interconverted to give rise to the pheromone blend were also elucidated (3). In this biosynthetic pathway, the main pheromone component, (*Z*,*E*)-9,11-tetradecadienyl acetate, is formed from tetradecanoic acid by sequential *E*-11 and *Z*-9 desaturations followed by reduction and acetylation.

Whereas *Z* desaturases have been the focus of attention in studies of biosynthesis of fatty acids and their derivatives, the *E* desaturation reaction has been so far less explored. In this context, we undertook a study aimed at investigating the mechanism of formation of (*E*)-11-tetradecenoic acid from tetradecanoic acid in *S. littoralis*. A possible mechanism would involve isomerization of the parent (*Z*)-fatty acid (4). However, recent work carried out in our laboratories has demonstrated that isomerization of (*Z*)-11-tetradecenoic acid to the (*E*)-compound does not occur in *S. littoralis* pheromone glands (Navarro, I., Mas, E., Fabrias, G., and Camps, F., submitted for publication). In light of the rising evidence (5,6) that desaturases and hydroxylases are structurally related at the protein level, *de novo* synthesis of (*E*)-fatty acids might involve initial biohydroxylation of a saturated precursor followed by dehydration of the resulting hydroxy fatty acyl derivative. Thus, according to this approach, formation of (*E*)-11-tetradecenoic acid from tetradecanoic acid might occur through dehydration of either 11- or 12-hydroxytetradecanoic acids. In this context, the aim of this article was the analysis of *S. littoralis* pheromone gland extracts for the presence of the above-mentioned hydroxy fatty acids, since their detection would support the hydroxylation–dehydration proposed mechanism.

EXPERIMENTAL PROCEDURES

Acid methanolysis of standard *Z*11-14:Me (100 ng) was performed by reaction in sealed tubes with 100 μL each of a solution of: (i), sulfuric acid/methanol/benzene (0.1:4:2, by vol) at 90°C for 1 h; (ii), 6 N HCl/methanol (1:2, vol/vol) at 90°C

for 1 h; or (iii) 14% BF_3–MeOH (Merck, Darmstadt, Germany) at 90°C for 1 h. After the reaction, solvents were evaporated and the residues were extracted with 0.5 mL of hexane, and the organic extracts were stored at −30°C until analysis.

To obtain the lipidic extracts, groups of three pheromone glands were soaked in 100 µL of chloroform/methanol (2:1, vol/vol) overnight at −4°C. Samples to be methanolyzed were evaporated to apparent dryness with a stream of nitrogen, and acidic methanolysis was performed by reaction of the resulting residues under conditions (i), (ii) and (iii) as indicated above and, additionally, by treatment with 100 µL of 14% BF_3–MeOH at 4°C for 15 h.

Analyses were performed by electron–ionization GC–MS, at 70 eV, using a Fisons (Rodano, Italy) gas chromatograph (8000 series) coupled to a Fisons MD-800 mass selective detector. The system was equipped with an apolar Hewlett-Packard (Palo Alto, CA) HP-1 capillary column (30 m × 0.20 mm i.d.), which was programmed from 80 to 300°C at 12°C/min after a 2-min delay (analyses of methoxy fatty acids) or a polar SGE (Ringwood Vic, Australia) BP-20 capillary column (30 m × 0.20 mm i.d.), which was programmed from 80 to 260°C at 5°C/min after a 2-min delay (analyses of hydroxy FAME). Injections were carried out in the splitless mode, with a purge of 40 s after injection. Helium was used as carrier gas at a pressure of 12 psi.

RESULTS AND DISCUSSION

Preliminary analyses of base-methanolyzed lipidic extracts of *S. littoralis* pheromone glands did not reveal the presence of

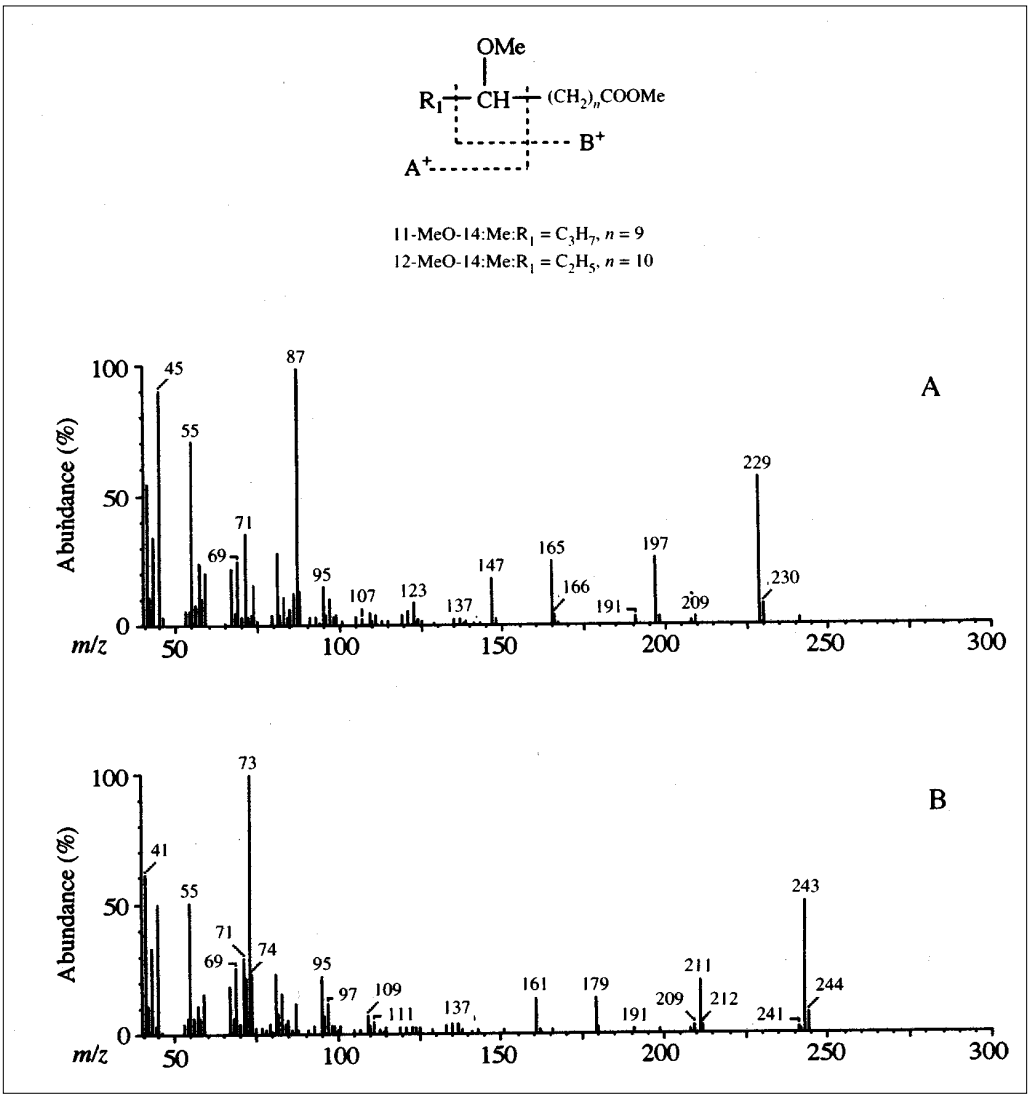

FIG. 1. Mass spectra of methyl 11-methoxytetradecanoate (A) and methyl 12-methoxytetradecanoate (B), formed by treatment of methyl (*Z*)-11-tetradecenoate with a solution of 14% BF_3–MeOH (90°C/1 h) as indicated in the Experimental Procedures section. Structure of ions A^+ and B^+ is also shown. Diagnostic fragments are: 11-MeO-14:Me, 87 (ion A^+) and 229 (ion B^+) and 12-MeO-14:Me, 73 (ion A^+) and 243 (ion B^+). 11-MeO-14:Me, methyl 11-methoxytetradecanoate and 12-MeO-14:Me, methyl 12-methoxytetradecanoate.

either 11- or 12-hydroxytetradecanoic acid in the extracts (data not shown). However, although the acyl moiety of the putative hydroxy fatty acyl derivative is probably ester-linked and is thus hydrolyzable under basic conditions, the hydroxyl group might not be free, but bound to a biological derivative only cleavable under acidic conditions, such as an ether lipid, for example. Therefore, we planned to submit the lipidic extract to acidic methanolysis, which would release both the carboxyl moiety and the hydroxyl group. Acid-catalyzed addition of water to double bonds is a common reaction of olefins (7). Since *S. littoralis* pheromone glands contain both (*E*) and (*Z*)-11-tetradecenoyl moieties (2,3), such reaction might give methyl 11-hydroxy and 12-hydroxytetradecanoates as artifacts. Therefore, to avoid misleading results, we first examined the outcome of acid methanolysis of synthetic methyl (*Z*)-11-tetradecenoate (*Z*11-14:Me) under the following conditions: (i) sulfuric acid/methanol/benzene (0.1:4:2, by vol) at 90°C for 1 h (8); (ii) 6 N HCl/MeOH (1:2, vol/vol) at 90°C for 1 h; and (iii) 14% BF_3–MeOH at 90°C for 1 h. Starting material remained unaltered under conditions (i) and (ii), as concluded from the absence in the GC–MS traces of any additional peak besides that corresponding to *Z*11-14:Me. However, treatment of *Z*11-14:Me (100 ng) with 14% BF_3–MeOH led to the formation of small amounts of methyl 11-methoxytetradecanoate (11-MeO-14:Me, 7 ng) and 12-methoxytetradecanoate (12-MeO-14:Me, 6 ng), which were identified by MS (Fig. 1). Methoxy alkanes and derivatives thereof show mass spectra with diagnostically significant fragment ions A^+ and B^+ (see Fig. 1) arising from carbon–carbon cleavage on either side of the methoxy group, with the charge being retained on the oxygen-containing fragment (9,10). Since, as indicated above, almost the same amounts of each methoxy derivative, 11-MeO-14:Me and 12-MeO-14:Me, are formed from *Z*11-14:Me, these artifacts arise probably from a nonregioselective BF_3-catalyzed addition of methanol to the *Z*11-14:Me double bond. Formation of methoxy derivatives as artifacts has also been reported in the acidic methanolysis of cyclopropane fatty acids (11).

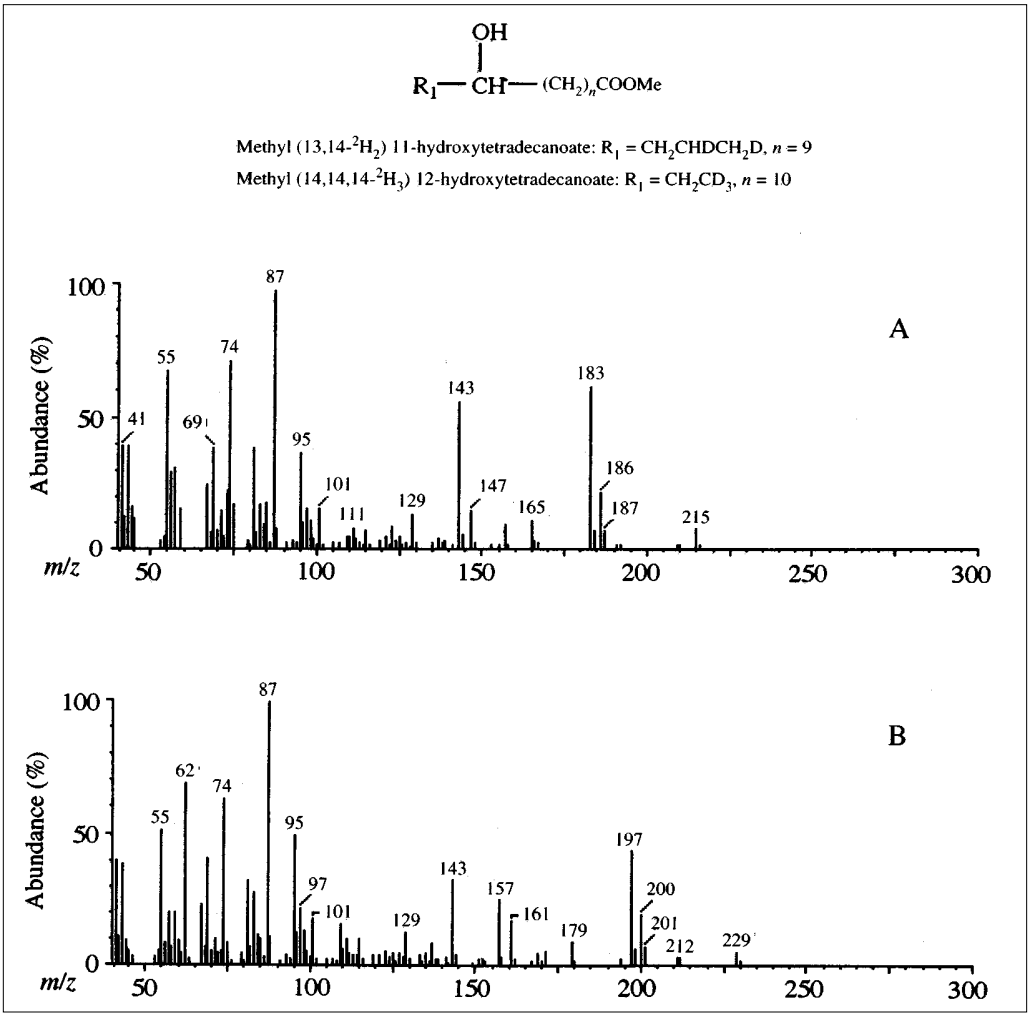

FIG. 2. Mass spectra of methyl (13,14-$^2H_2$) 11-hydroxytetradecanoate (A) and methyl (14,14,14-$^2H_3$) 12-hydroxytetradecanoate (B). Diagnostic fragments are: methyl (13,14-$^2H_2$) 11-hydroxytetradecanoate, 215 (M – R_1) and 183 (M – R_1 – CH_4O) and methyl (14,14,14-$^2H_3$) 12-hydroxytetradecanoate, 229 (M – R_1) and 197 (M – R_1 – CH_4O).

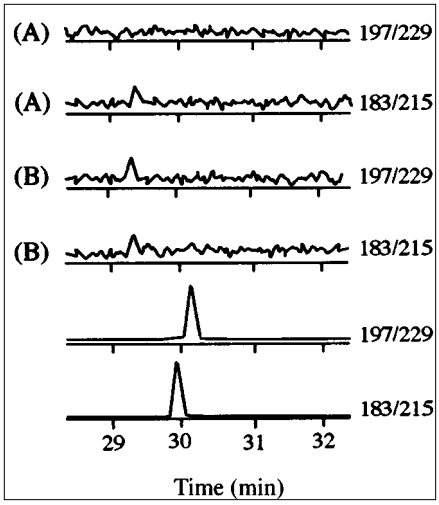

FIG. 3. GC–MS traces of *Spodoptera littoralis* pheromone glands after acid methanolysis with sulfuric acid/methanol/benzene (0.1:4:2, by vol) (90°C/1 h) (A) and 6 N HCl/MeOH (1:2, vol/vol) (90°C/1 h) (B) by monitoring the diagnostic ions for methyl 11-hydroxytetradecanoate (*m/z* 183 and 215) and methyl 12-hydroxytetradecanoate (*m/z* 197 and 229). The two bottom traces correspond to standard methyl (13,14-$^2H_2$) 11-hydroxytetradecanoate (retention time 29.94 min) and methyl (14,14,14-$^2H_3$) 12-hydroxytetradecanoate (retention time 30.17 min), whose mass spectra are shown in Figure 2.

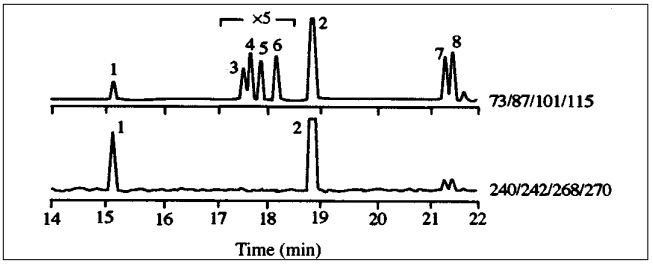

FIG. 4. GC–MS traces of *Spodoptera littoralis* pheromone glands after acid methanolysis with 14% BF_3–MeOH at 4°C for 15 h (A). A trace of unreacted FAME extract (B) is also depicted to show the presence of the monounsaturated FAME. Analyses were performed under SCAN mode, selecting, in each trace, the ions shown at right, which correspond to: 240, methyl (*Z*)-9, (*E*)-11 and (*Z*)-11-tetradecenoate; 242, methyl tetradecanoate; 268, methyl (*Z*)-11-hexadecenoate, 270, methyl hexadecanoate; 73, 12-MeO-14:Me; 87, 11-MeO-14:Me; 101, 10-MeO-14:Me and 12-MeO-16:Me, and 115, 9-MeO-14:Me and 11-MeO-16:Me. Peaks are: 1, methyl tetradecanoate; 2, 9-MeO-14:Me; 3, 10-MeO-14:Me; 4, 11-MeO-14:Me; 5, 12-MeO-14:Me; 6, methyl hexadecanoate; 7, 11-MeO-16:Me; 8, 12-MeO-16:Me; 9, methyl (*Z*)-9-tetradecenoate; 10, methyl (*E*)-11-tetradecenoate; 11, methyl (*Z*)-11-tetradecenoate; and 12, methyl (*Z*)-11-hexadecenoate. Mass spectra of compounds 2 to 5, 7, and 8 are shown in Figure 5.

In light of the above results, showing that *Z*11-14:Me is stable under acidic methanolysis conditions (i) and (ii), both procedures were considered suitable for acidic methanolysis and further reliable analysis of the occurrence of hydroxy FAME in natural extracts.

Authentic samples of methyl (13,14-$^2H_2$) 11-hydroxytetradecanoate and (14,14,14-$^2H_3$) 12-hydroxytetradecanoate, previously synthesized in our laboratory (12), were first analyzed by GC–MS. The mass spectra of both hydroxy derivatives exhibited, besides the base peak at *m/z* 87, ions corresponding to the loss of R_1 from the molecular ion, as well as a characteristic fragment arising from loss of CH_4O from the $M - R_1$ ion (Fig. 2). Natural extracts were then prepared by acidic methanolysis and analyzed by GC–MS, monitoring the characteristic expected ions for both methyl 11-hydroxytetradecanoate (*m/z* 183 and 215) and methyl 12-hydroxytetradecanoate (*m/z* 197 and 229). None of the above procedures gave rise to the expected hydroxy FAME, as concluded from the absence of the corresponding peaks in the GC–MS traces (Fig. 3). The possibility that the hydroxyacyl derivatives, if any, might have decomposed under the methanolysis conditions was ruled out by submitting a sample of methyl (14,14,14-$^2H_3$) 12-hydroxytetradecanoate to the same reactions. Analysis by GC–MS revealed that no product other than the starting hydroxy ester was present in the chromatogram (data not shown). In conclusion, the present results indicate that 11- or 12-hydroxytetradecanoic acids are absent in *S. littoralis* pheromone glands, which, in addition to our previous data of mass-labeling experiments (12), indicates that formation of (*E*)-11-tetradecenoic acid does not involve hydroxylation and further dehydration of tetradecanoic acid, but probably the direct action of an *E*-11 desaturase on this saturated precursor. This possibility is currently being investigated in our laboratories.

On the other hand, transformation of alkenes into methoxy derivatives has been reported as a simple and convenient microanalytical technique for the location of double bonds in alkenes and the further characterization of monounsaturated hydrocarbons (9,10). Those methoxy derivatives have generally been obtained by methoxy mercuration followed by demercuration of the parent olefin (9,10). The result obtained with standard *Z*11-14:Me indicates that reaction of olefins with BF_3–MeOH may be a simple alternative method for derivatization of alkenes to their corresponding methoxy derivatives. This procedure was validated in the location of double bonds of *S. littoralis* sex pheromone biosynthetic precursors. When a lipidic extract was submitted to conditions (iii), GC–MS analyses of the resulting extract showed, in addition to methyl esters derived from the usual fatty acyl intermediates, the presence of low amounts,

TABLE 1
Retention Times and Characteristic Ions of the Methoxy Fatty Acid Methyl Esters Formed from the Monoene Biosynthetic Intermediates of *Spodoptera littoralis*

Compound	Retention times (min)[a]	Diagnostic ions[b]	
		A^+	B^+
9-MeO-14:Me	17.67	115	201
10-MeO-14:Me	17.75	101	215
11-MeO-14:Me	17.89	87	229
12-MeO-14:Me	18.19	73	243
11-MeO-16:Me	21.34	115	229
12-MeO-16:Me	21.44	101	243

[a]See the Experimental Procedures section for GC–MS conditions.
[b]Structure of ions A^+ and B^+ is depicted in Figure 1.
Abbreviations: 9-MeO-14:Me, methyl 9-methoxytetradecanoate; 11-MeO-16:Me, methyl 11-methoxyhexadecanoate, and so on.

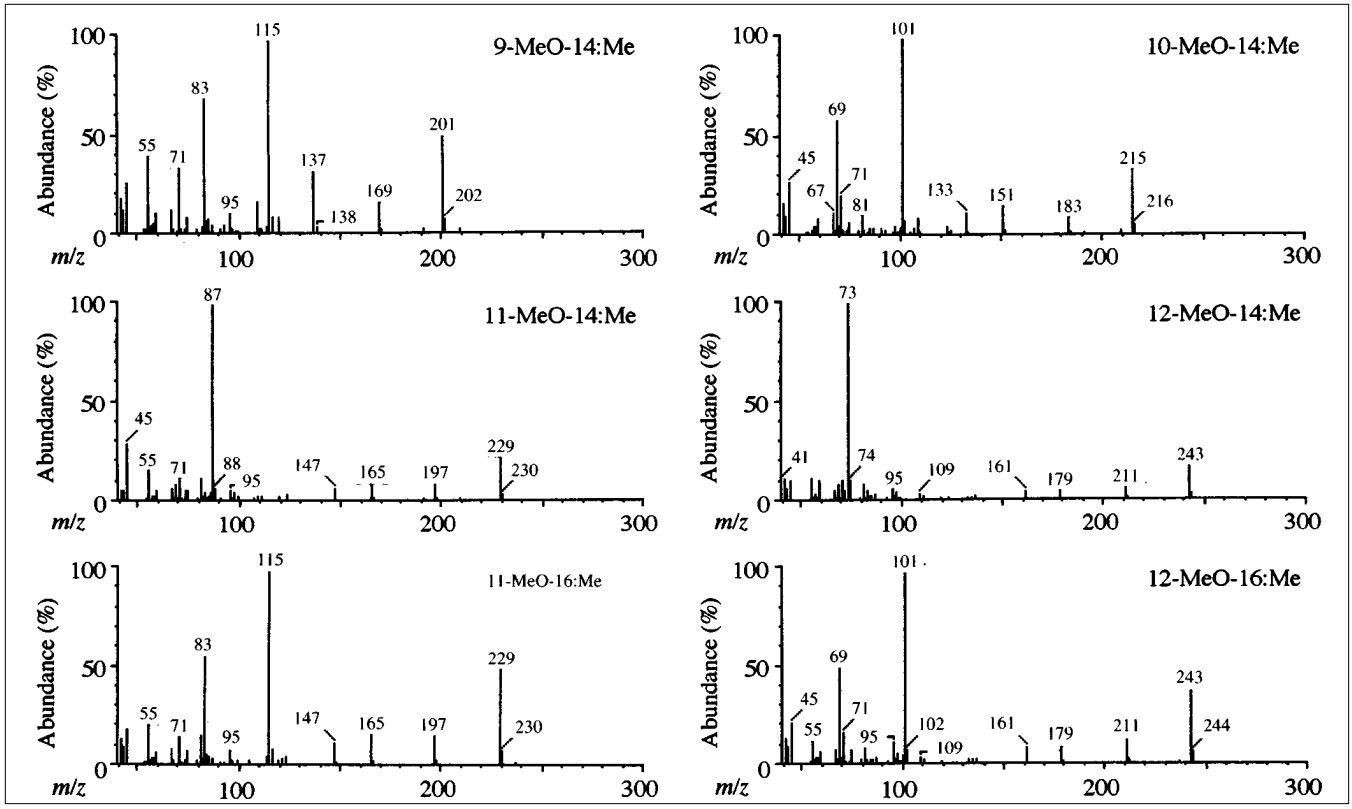

FIG. 5. Mass spectra of the methoxy fatty acid methyl esters found in samples prepared by acid methanolysis with 14% BF_3–MeOH (4°C/15 h) of a lipidic extract of *Spodoptera littoralis* pheromone glands. Mass spectra correspond to peaks 2 (9-MeO-14:Me); 3 (10-MeO-14:Me); 4 (11-MeO-14:Me); 5 (12-MeO-14:Me); 7 (11-MeO-16:Me); and 8 (12-MeO-16:Me) of Figure 4. Diagnostic fragments for each methoxy derivative are indicated in Table 1.

around 10% of the parent monoene, of a mixture of methoxy FAME (Fig. 4, Table 1), including methyl 9-methoxytetradecanoate (9-MeO-14:Me), 10-methoxytetradecanoate (10-MeO-14:Me), 11-methoxytetradecanoate (11-MeO-14:Me), 12-methoxytetradecanoate (12-MeO-14:Me), 11-methoxyhexadecanoate (11-MeO-16:Me) and 12-methoxyhexadecanoate (12-MeO-16:Me). All these compounds exhibited in their mass spectra the two characteristic oxygen-containing fragments A^+ and B^+ (Fig. 5, Table 1) resulting from cleavage between the adjacent methoxy-containing carbons.

Although treatment with BF_3–MeOH at 90°C for 1 h led to partial formation of these adducts, when the methanolysis was carried out at 4°C for 15 h all the monounsaturated FAME were completely transformed into the corresponding methoxy derivatives, as concluded from the absence of monounsaturated FAME in the GC–MS traces (Fig. 4). It is worth mentioning that these methoxy fatty esters were not formed in samples coming from lipidic extracts submitted to acid methanolysis under conditions (i) or (ii). Thus, treatment of lipidic extracts with 14% BF_3–MeOH at 4°C for 15 h is a very simple alternative procedure to obtain methoxy derivatives of monounsaturated fatty acids, which are very useful for the location of the double bond in the parent alkene. Thus, in this case, the detection of 9-, 10-, 11- and 12-MeO-14:Me and 11- and 12-MeO-16:Me in acid-methanolyzed lipidic extracts of *S. littoralis* pheromone glands agrees with the occurrence of the parent C_{14} and C_{16} monounsaturated fatty acyl intermediates previously identified (2) in this species.

A Human Dietary Arachidonic Acid Supplementation Study Conducted in a Metabolic Research Unit[1]

Arachidonic acid is arguably the single most important fatty acid in the panoply of lipid metabolism. Indeed, its importance in human physiology cannot be overemphasized. Arachidonic acid itself is an important component of phospholipids and cell membranes. It is the unique precursor of most of the eicosanoids with significant biological activity. Although most higher mammals, with perhaps the exception of the cat family, can synthesize arachidonic acid from linoleic acid, so it is not an essential dietary component, it is a normal part of the human diet particularly among those of us who eat animal products. Despite arachidonic acid's acknowledged importance in human metabolism, few human feeding studies using arachidonic acid have been reported. Investigators have exhibited a marked lack of enthusiasm for such studies perhaps because many investigators viewed dietary arachidonic acid as a potentially harmful substance. This supposition was based mainly on the work of Seyberth *et al.* (1) in humans, and other investigators in nonhuman species (2,3). Also, sufficient quantities of arachidonic acid for human feeding studies were not easy to obtain. Still, there was a body of literature that suggested that dietary arachidonic acid was not harmful (4–6).

With the recent availability of an edible oil containing 50% arachidonic acid as mixed triglycerides, we decided to mount a human feeding study in which arachidonic acid would be fed to a group of healthy men under rigidly controlled conditions. The study was conducted at the Agricultural Research Service's Western Human Nutrition Research Center in San Francisco, California, during 1994. It involved the collaboration of investigators from several laboratories and the donation to the United States Department of Agriculture of the arachidonic acid-containing oil (ARASCO®, Martek Biosciences Corp., Columbia, MD). This symposium marks the first presentation of the results gleaned from the mass of data collected during the study. There were six presentations at the symposium covering various aspects of the study—from the effect of arachidonic acid on blood platelets to eicosanoid metabolism, immune response, and intermediate metabolism of arachidonic acid precursors. We have now gathered the presentations as papers and are publishing them here as a unit allowing interested readers to obtain a complete overview of this study in a single place. The principal investigators for this study hope the results justify their efforts and, more importantly, lead to further studies of dietary arachidonic acid in humans.

ABSTRACT: While there are many reports of studies that fed arachidonic acid (AA) to animals, there are very few reports of AA feeding to humans under controlled conditions. This 130-d study was conceived as a controlled, symmetrical crossover design with healthy, adult male volunteers. They lived in the metabolic research unit (MRU) of the Western Human Nutrition Research (WHNRC) for the entire study. All food was prepared by the WHNRC kitchen. The basal (low-AA) diet consisted of natural foods (30 en% fat, 15 en% protein, and 55 en% carbohydrate), containing 210 mg/d of AA, and met the recommended daily allowance for all nutrients. The high-AA (intervention) diet was similar except that 1.5 g/d of AA in the form of a triglyceride containing 50% AA replaced an equal amount of high-oleic safflower oil in the basal diet. The subjects (ages 20 to 39) were within −10 to +20% of ideal body weight, nonsmoking, and not allowed alcohol in the MRU. Their exercise level was constant, and their body weights were maintained within 2% of entry level. Subjects were initially fed the low-AA diet for 15 d. On day 16, half of the subjects (group A) were placed on the high-AA diet, and the other group (B) remained on the low-AA diet. On day 65, the two groups switched diets. On day 115, group B returned to the low-AA diet. This design, assuming no carryover effect, allowed us to merge the data from the two groups, with the data comparison days being 65 (low-AA) and 115 (high-AA) for group B and 130 (low-AA) and 65 (high-AA) for group A. The main indices studied were the fatty acid composition of the plasma, red blood cells, platelets, and adipose tissue; *in vitro* platelet aggregation, bleeding times, clotting factors; immune response as measured by delayed hypersensitivity skin tests, cellular proliferation of peripheral blood mononuclear cells in response to various mitogens and antigens, natural killer cell activity, and response to measles/mumps/rubella and influenza vaccines; the metabolic conversion of deuterated linoleic acid to AA and the metabolic fate of deuterated AA in the subjects on and off the high-AA diet; and the production of eicosanoids as measured by excretion of 11-DTXB_2 and PGI_2-M in urine. The results of these studies will be presented in the next five papers from this symposium.
Lipids 32, 415–420 (1997).

Arachidonic acid (AA) is the immediate metabolic precursor of the major biologically active eicosanoids (1,2), such as prostaglandins, thromboxanes, prostacyclins, and leukotrienes as well as a large number of hydroxy eicosatetraenoic acids and their metabolic products. It is also a normal constituent of the human diet (3) if one is not a vegan. Lacto-ovo vegetarians would consume AA from egg yolks. The average amount of AA in Western diets is not certain but has been estimated at between 50 and 300 mg per day (4,5). Jonnalagadda *et al*. (6) reported that the U.S. diet contains approximately 100 mg/d of AA based on the USDA Nationwide Food Consumption Survey for 1987–1988. Sinclair and O'Dea (7) reported that the Australian diet contained between 80 and 100 mg/d of AA. It is likely that general food consumption surveys based on computerized food composition tables underestimate the amount of AA in the daily diet because most food composition data were generated by food analysis that either did not report values for AA or underreported the true amount in the product.

Because of its metabolic importance, there is considerable interest in the metabolic and physiological effects of dietary AA, but most of the data available currently come from animal experiments (8–12). Also, AA has a reputation as being a harmful substance if it is consumed in significant amounts. AA injected as the free acid intravenously in rabbits causes rapid disseminated intravascular coagulation and the death of the animals (13,14). In animal studies, large amounts of AA in the ester form do not seem to cause significant harm to the animals in the short term (8–12,15,16). Seyberth *et al*. (17) reported a human feeding study in which 6 g/d of AA were given to normal male subjects in the form of ethyl ester. Although the study was planned to continue for a month, it was

terminated after 3 wk because of markedly increased *ex vivo* ADP-induced aggregation (10 to 60%) by platelets from the volunteers. Ever since this 1975 report (17), feeding studies using AA in any form in humans have been avoided, presumably out of fear of adverse consequences.

Given the large number of animal feeding studies (8–12, 15,16) demonstrating little or no harmful effects of dietary AA when fed in the ester form, and the fact that even in the study by Seyberth *et al*. (17) there was no actual physical harm to the subjects coupled with the fact that AA is a normal constituent of the human diet, it seems that human feeding studies with AA could be conducted safely. More recently Sinclair and colleagues (18) investigated the effects of dietary AA in Australians using all natural food diets with modestly elevated amounts of AA (7,18) In addition, within the last decade a natural triglyceride produced by selected strains of algae (ARASCO®) that contained 50% AA became commercially available. Thus, because of the physiological and metabolic importance of eicosanoids in humans and the sparse availability of good data from human feeding studies using AA, we decided to mount a human feeding study in which we fed healthy male subjects 1.5 g of AA per day for 50 d. The study was conducted in a metabolic ward setting in which all aspects of the volunteers' lives could be strictly controlled. The major hypothesis to be tested was that dietary AA at this level would be metabolized differently from AA synthesized *in vivo* from linoleic acid and that it has significant influence on platelet function, immune response, and eicosanoid production.

The main physiological and biochemical parameters to be studied were platelet aggregation *in vitro,* blood lipid levels, the fatty acid composition of various tissues, the immune response as measured by response to several antigens, vaccines, and the delayed hypersensitivity skin tests, production of thromboxane and prostacyclin as measured by their metabolic products in urine, and the actual metabolism of dietary fatty acids (FA) as determined by feeding deuterium-labeled FA and measuring the metabolic products in blood over a time course of up to 72 h. This paper will describe the design of the study, the diets and the FA composition of the ARASCO® oil and the actual diets, and the timing of the blood draws. Subsequent papers in this symposium will present the results obtained in the study to date on platelet function, blood lipids, lipoproteins and apoproteins, tissue FA composition, effect on eicosanoid metabolism, immune response, and the metabolism of 20:3n6 in high- and low-AA diets.

STUDY DESIGN

The design was a single blind crossover, feeding study in which healthy volunteers lived in the metabolic unit (MRU) of the Western Human Nutrition Research Center (San Francisco, CA) for 130 d. A schematic of the design is presented in Figure 1. The physical parameters of the 10 male volunteers who completed the study are: age, yr, 31.6 ± 6.7; weight, kg, 72.7 ± 7.7; body mass index, kg/m^2, 23.5 ± 3.6; blood pressure, systolic, 115.9 ± 9.5; blood pressure, diastolic, 73.2 ± 7.8; no smokers. The study had a symmetrical design in which all subjects were fed a stabilization diet for 15 d after they entered the MRU. On day 16 of the study, six of the subjects, designated Group A, were switched to a diet containing 1.7 g/d of AA (210 mg from the basal diet and 1.5 g from ARASCO® oil). The remaining six subjects, designated Group B, continued to consume the basal diet which contained 210 mg of AA. On day 65 of the study, the two groups switched diets. On day 115, the study Group B was returned to the basal diet. The subjects were discharged from the MRU on day 130 of the study.

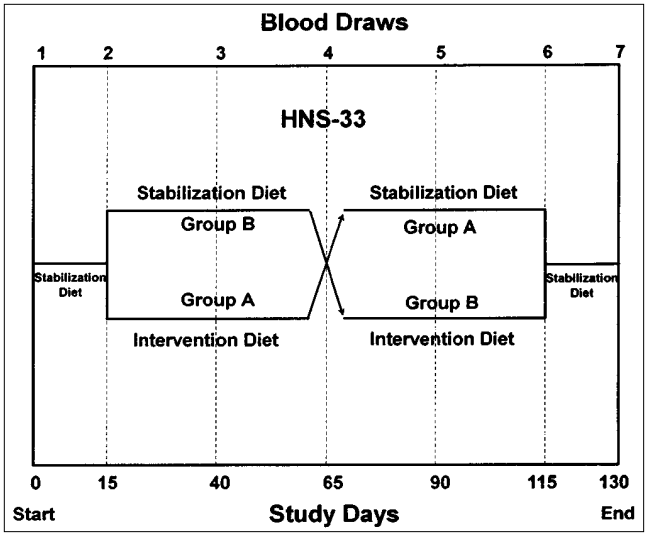

FIG. 1. A schematic plan of the crossover design for this feeding study showing the days of the blood drawn and dietary periods. Note that the values were compared for each group after 50 d on the intervention diet to those obtained after 65 d on the stabilization diet. Thus, the data for group A were comparing the data obtained at day 65 with those obtained at day 130, while in group B the data obtained from day 115 were compared to those obtained on day 65.

This design provided a 50-d intervention period and a 65-d control period for each subject. We assumed that a 65-d washout period for Group A was long enough to eliminate any carryover effect from the high-AA diet. This design allowed the two groups to be merged for statistical purposes, and for most analyses we used an n = 10 (two subjects dropped out of the study prior to completion).

MATERIALS AND METHODS

Source and purity of AA (ARASCO® oil). AA, in the form of a natural triglyceride manufactured and purified from algae (Martek Biosciences Corporation, Columbia, MD), was incorporated into salad dressings and yogurt desserts. The ARASCO® oil produced by the Martek Corporation meets all the requirements for an edible oil for human consumption and contains (wt%) 49.7% AA in the form of mixed triglycerides. The other major FA components of ARASCO® oil are 11.1%

16:0; 10.6% 18:0; 8.7% 18:1n-9; 6.5% 18:2n-6; 3.8% 18:3n-6; 0.9% 20:0; 2.5% 20:2n-6; 1.6% 22:0; and 1.2% 24:0. It is refined and purified by the standard methods used in the edible oil processing industry in the United States. It contains 0.025% α-tocopherol and 0.025% ascorbyl palmitate as antioxidants. The Western Human Nutrition Research Center has conducted human feeding studies with polyunsaturated, long-chain FA for over 10 yr. The oil was kept under nitrogen and at −20°C until it was needed for the food preparation. Open bottles were flushed with N_2 before they were resealed and returned to the freezer. Samples from the ARASCO® oil were taken periodically for analysis of their peroxide values and FA composition. As we fed the AA in a cold yogurt cocktail, it is unlikely that any oxidative degradation took place between the time the food was prepared and when it was eaten.

Subjects. The volunteers were recruited from the West Coast of the United States, and consisted of men between the ages of 20 and 39. Initially 12 volunteers were included in the study, but 2 were unable to complete the protocol. The volunteers were given complete physical examinations. Body weights had to be within −10 to +20% of ideal body weights using the Metropolitan Life Insurance Company tables (medium-frame values from the 1983 edition) (19). Evidence of existing illness or chronic disease was an exclusion criterion. Mild hypertension was not an exclusion criterion, but the group that was recruited tended to have blood pressures slightly below average for men in this age group. Smoking, excessive alcohol consumption, or evidence of narcotic abuse were also exclusionary.

Experimental protocol. All the volunteers were confined to the Nutrition Research Suite of the Western Human Nutrition Research Center for the duration of the study. As the subjects stayed within the confines of the Nutrition Suite except for occasional supervised outings, they had no opportunity to consume any food except that provided by the Center. Thus, compliance with the protocol was, of necessity, 100%. In addition, all food intake was monitored, portions were weighed, and subjects were required to consume everything provided them during their meals. (A rubber spatula was provided to ensure that all food was scraped from the plates and eaten.) Food spills were carefully monitored and recorded, and fluid intake, while *ad libitum,* was also measured precisely.

The protocol for this study was approved by the Institutional Review Boards of the University of California at Davis (Davis, CA) and the United States Department of Agriculture (USDA; Washington, D.C.). A crossover design was used so that the subjects acted as their own controls. The subjects were fed the stabilization diet (SD), containing about 30% of calories as fat, for 15 d. The SD had a target macronutrient composition of 30 en% fat, 15 en% protein, and 55 en% carbohydrate. On day 16 of the study, they were divided randomly into two groups. Group B remained on the SD for 50 d. Group A was placed on a diet in which 1.5 g/d of AA (in the form of a triglyceride containing 50% AA, ARASCO®) was added to the diet for 50 d. After 50 d, day 65 of the study, the groups switched diets for the next 50 d of the study. On day 115 of the study, Group B was returned to the SD. On day 130, all the volunteers were discharged from the study and returned to free living status in the community.

During the confinement period, there were blood draws on study days 2, 16, 40, 65, 90 115, and 130. For most analyses, values from samples obtained on days 65 and 130 for group A and days 65 and 115 for group B were pooled, and the data used for statistical analysis. Data from day 65 for Group A and day 115 for Group B were the end of the AA feeding periods, while data from day 130 for Group A and day 65 for group B were the baseline period.

Diets. The diets consisted of natural foods. No dietary supplements were given. The macronutrient composition of the diets is given in Table 1. (A complete description of the diets, listing all the major and minor nutrients, is available upon request.) A 5-d menu cycle was used throughout the study. Proximate analysis was made on five individual diet composite samples taken from each menu once during the study for both the SD and intervention diets. The results for the seven composite samples were averaged to find the actual composition of the diets. No alcohol was included in these diets. The nutrient composition of the diets was calculated from a computerized nutrient data bank using the data from the *USDA Handbook 8* (20), and adjusted to provide at least the recommended daily allowance for known essential nutrients (21).

Table 2 gives the measured FA composition of both diets. Inspection of Table 2 indicates that all the major FA were very similar except that the level of AA was elevated in the high-AA diet and the level of oleic acid was reduced. The 210 mg of AA found in the SD represents the level of AA found in the natural food used in this study. The theoretical level calculated from *Handbook 8* values was only 150 mg. We believe that this difference is caused by missing values and inaccurate analyses in *Handbook 8*. At the beginning of the

study, each participant's caloric intake was estimated, and the caloric content of the meals calculated to maintain current body weight. As the estimates were subject to error, the participants were weighed every day, and the caloric value of their meals adjusted occasionally, if necessary, to maintain their weight within the limits of the study. Thus, the average weights of the participants did not vary significantly during the 130 d of the study. If all the intakes for each volunteer were averaged during the entire study, the mean energy intake was approximately 2800 Kcal/d.

Measurements. Blood was drawn between 7:00 and 8:00 a.m. after an overnight fast of at least 12 h. Blood was drawn into vacutainers with appropriate anticoagulants, using a Teflon catheter (Angiocath; Deseret Medical, Sandy, UT) for FA analysis, or syringes containing 1 mL of citrate solution for platelet studies.

Studies with deuterated AA. The first experiment involved deuterated AA fed to three subjects eating high-AA diet. A second group of three subjects eating the low-AA diet also received the deuterated AA. An equal amount of deuterated oleic acid was fed at the same time. Blood samples were drawn immediately before feeding the tracers and at 4, 6, 8, 12, 24, 48, and 72 h. A second experiment using different subjects (three from each diet group) from this study fed deuterated 18:2n-6 to subjects pre-fed the diets described in the first experiment above. Details of this studies are found in the paper by Emken *et al.* (22).

Physiological parameters examined. We determined the blood lipid concentrations, FA composition of the tissue samples, eicosanoid levels in urine, blood, and media from cultured cells. Bleeding times *in vivo* and platelet function *in vitro* were determined. Deposition of AA in the adipose tissue was followed using tissue biopsies. The volunteers' immune status was evaluated by determining the number of lymphocytes and their subsets, monocytes and granulocytes, lymphocyte proliferation in response to T and B cell mitogens, *in vitro* production of IL-1, IL-2, IL-2R, IL-6, and TNF and by determining their concentration through ELISA assays. Other indices of immune response tested included natural killer cell activity, delayed hypersensitivity skin response to a battery of seven recall antigens, and primary and secondary antibody responses to viral and bacterial antigens (23,24).

RESULTS

In this study we could detect very few physiological effects from dietary AA when consumed at the level of 1.7 g/d for 50 d. Plasma PL and cholesterol esters showed a marked increase in their content of AA, while the plasma triglyceride level exhibited only minimal incorporation of AA. Adipose tissue did not incorporate any significant amount of AA during this study. Blood lipid levels showed no changes nor did the apoproteins and lipoproteins. Perhaps most importantly we detected no changes in platelet aggregation or bleeding times contrary to the report by Seyberth *et al*. (17). Most indices of the immune response were not affected either. The detailed results to date from this study are presented in the next five papers from this symposium.

DISCUSSION

For several decades now polyunsaturated FA have been considered beneficial compared to saturated FA in the diet (25–27). This was particularly true between 1950 and 1970. Then, with greater knowledge of the role of eicosanoids in human physiology and the rise in interest in n-3 polyunsaturated FA, some investigators (28–30) questioned the wisdom of raising the level of n-6 FA in the diet above that commonly consumed in a Western diet. AA in particular was considered an undesirable dietary constituent, particularly as it was known to have adverse effects in animals (13,14), coupled with the report of Seyberth *et al.* (17) that indicated that AA in the human diet increased the tendency for platelets to aggregate. Conversely, more recent work in infant nutrition has suggested that newborn infants require dietary AA for optimal growth and development (31,32). Still, very little work has been reported in humans on AA feeding studies since the report of Seyberth *et al*. (17) in 1975. Sinclair and colleagues (18,33,34) have reported some studies on AA in human diets from Australia with selected food that increases the level of AA in the diet, although well below the levels used in the study by Seyberth *et al*. (17). Sinclair and colleagues (18,33,34) observed no adverse effects from their AA-enhanced diets.

Of course, none of these negative results from this study should be taken to mean that dietary AA has no metabolic in-

fluences in humans. We did detect significant changes in the production of urinary eicosanoids. In addition, we (22) found changes in the metabolism of the polyunsaturated FA in the presence of elevated dietary AA. Furthermore, while the amount of AA fed in this study was 5 to 10 times that in the typical Western diet (6,35), it was still well below that used in the study reported by Seyberth *et al*. (17). We cannot predict whether higher levels of dietary AA, or longer feeding period, will have major metabolic and physiological consequences. However, it is interesting that in 1961 Kingsburg *et al.* (36) fed 10 g/d of ethyl AA to two students for 11 d without any reported ill effects. The results from this study suggest that dietary AA fed at 1.5 g/d is not harmful to humans nor does it affect blood lipid levels [Kingsburg *et al.* (36) reported a cholesterol-lowering effect from 10 g of ethyl arachidonate] or platelet function while only having minimal effects on the normal immune response. Perhaps the most important implication from this work is the suggestion that the physiological control mechanisms for FA homeostasis in humans shunt dietary AA into specific metabolic pathways. These pathways then tightly control AA utilization and conversion to other compounds in the body. Whether these control mechanisms can be overwhelmed by increasing the amount of AA in the diet remains to be determined. The detailed results for this collaborative study effort are presented in the five other arachidonic acid symposium papers (22, 37–40).

ACKNOWLEDGMENTS

The authors wish to acknowledge the help of the staff at our Center. We are especially indebted to the Metabolic Research Unit staff, without whose help this study could not have been conducted, including the nursing staff who drew the blood and the dietetics staff who prepared the food. We also wish to thank the Bio-analytical Lab staff who did the plasma cholesterol and triglyceride, lipoprotein and apoprotein analyses.

ABSTRACT: Arachidonic acid (AA) is the precursor of thromboxane and prostacyclin, two of the most active compounds related to platelet function. The effect of dietary AA on platelet function in humans is not understood although a previous study suggested dietary AA might have adverse physiological consequences on platelet function. Here normal healthy male volunteers (n = 10) were fed diets containing 1.7 g/d of AA for 50 d. The control diet contained 210 mg/d of AA. Platelet aggregation in the platelet-rich plasma was determined using ADP, collagen, and AA. No statistical differences could be detected between the aggregation before and after consuming the high-AA diet. The prothrombin time, partial thromboplastin time, and the antithrombin III levels in the subjects were determined also. There were no statistically significant differences in these three parameters when the values were compared before and after they consumed the high-AA diet. The *in vivo* bleeding times also did not show a significant difference before and after the subjects consumed the high-AA diet. Platelets exhibited only small changes in their AA content during the AA feeding period. The results from this study on blood clotting parameters and *in vitro* platelet aggregation suggest that adding 1.5 g/d of dietary AA for 50 d to a typical Western diet containing about 200 mg of AA produces no observable physiological changes in blood coagulation and thrombotic tendencies in healthy, adult males compared to the unsupplemented diet. Thus, moderate intakes of foods high in AA have few effects on blood coagulation, platelet function, or platelet fatty acid composition.
Lipids 32, 421–425 (1997).

Although arachidonic acid (AA) is a normal constituent of the human diet (1) if one is not a vegan, it has been suggested that higher levels of AA in the diet may have adverse consequences (2). In 1975 Seyberth *et al.* (3) reported a human feeding study in which 6 g/d of AA were given to healthy male subjects in the form of the ethyl ester. Although the study was planned to continue for longer period, it was terminated after 3 wk because of marked increase in *in vitro* platelet aggregation (10 to 60%) in response to ADP in samples taken from the volunteers.

Despite the caveat introduced into human feeding studies with AA by the Seyberth *et al.* (3) report, there is considerable interest in the metabolic and physiological effects of dietary AA, although most of the data available currently come from animal experiments (4–9). AA injected as the free acid intravenously in rabbits causes rapid disseminated intravascular coagulation and the death of the animals (10,11). In animal studies, large amounts of AA in the ester form do not seem to cause significant harm to the animals in the short term (4–9,12).

Given the large number of animal feeding studies (4–9,12) demonstrating little or no harmful effects of dietary AA when fed in the ester form, and the fact that even in the study by Seyberth *et al.* (3) there was no actual physical harm to the subjects coupled with the fact that AA is a normal constituent of the human diet, it seems that human feeding studies with AA could be conducted safely. In addition, within the last decade a natural triglyceride produced by selected strains of algae (trademarked ARASCO®; Martek Biosciences Corporation, Columbia, MD) that contained 50% AA became commercially available. Thus, because of the physiological and metabolic importance of eicosanoids in humans and the sparse availability of good data from human feeding studies using AA, we decided to mount a human feeding study in which we fed healthy male subjects 1.5 g of AA per day for 50 d. The study was conducted in a metabolic ward setting in which all aspects of the volunteers life could be strictly controlled.

STUDY DESIGN

The study design has been described in the previous paper in this series (13) The design was a single-blind cross-over feeding study in which 12 healthy volunteers lived in the metabolic unit (MRU) of the Western Human Nutrition Research Center (San Francisco, CA) for 130 d. The study had a symmetrical design in which all subjects were fed a stabilization diet for 15 d after they entered the MRU. On day 16 of the study, six of the subjects, designated Group A, were switched

Abbreviations: AA, arachidonic acid; FA, fatty acid; MRU, metabolic research unit; PRP, platelet-rich plasma.

to a diet containing 1.7 g/d of AA—210 mg from the basal diet and 1.5 g from ARASCO® oil). The remaining six subjects, designated Group B, continued to consume the basal diet which contained 210 mg of AA. On day 65 of the study the two groups switched diets. On day 115 of the study Group B was returned to the basal diet. The subjects were discharged from the MRU on day 130 of the study.

MATERIALS AND METHODS

A description of the oil (ARASCO®) and its fatty acid (FA) composition are given in the previous paper (13). The oil was kept under nitrogen and at −20°C until it was needed for the food preparation. Open bottles were flushed with N_2 before they were resealed and returned to the freezer. As we fed the AA in a cold yogurt cocktail, it is unlikely that any oxidative degradation took place between the time the food was prepared and when it was eaten.

Subjects. The physical characteristics of the subjects and the recruitment process were described in the previous paper (13). Initially, 12 volunteers were included in the study, but two were unable to complete the protocol.

Experimental protocol. Details of the experimental protocol were given in the previous paper (13). The protocol for this study was approved by the Institutional Review Boards of the University of California at Davis and the United States Department of Agriculture (USDA), Washington, D.C.). A crossover design was used so that the subjects acted as their own controls. The subjects were fed the stabilization diet, containing about 30% of calories as fat for 15 d and then divided into two groups and fed either the stabilization diet or the high-AA diet for 50 d, at which time (study day 65) the two groups were crossed over for the remainder of the study.

During the confinement period, blood was drawn on study days 2, 16, 40, 65, 90 115, and 130. For most analyses, values from samples obtained on days 65 and 130 for group A and days 65 and 115 for group B were pooled and the data used for statistical analysis. Data from day 65 for Group A and day 115 for Group B were the end of the AA feeding periods, while data from day 130 for Group A and day 65 for group B were the baseline period.

Diets. The nutrient composition of the diets was calculated from a computerized nutrient data bank using the data from *USDA Handbook* (8). *The Composition of Foods* (14) and adjusted to provide at least the recommended daily allowance for known essential nutrients (15). A complete description of the diet is given in the previous paper (13). A complete description of the diets, listing all the major and minor nutrients, is available upon request.

Measurements. Blood was drawn according to the schedule shown in Figure 1 of Reference 13 between 7:00 and 8:00 a.m. after an overnight fast. It was drawn into vacutainers with appropriate anticoagulants using a Teflon catheter, through a 20-gauge needle (Angiocath; Deseret Medical, Sandy, UT) for FA analysis, or syringes containing 1 mL of citrate solution for platelet aggregation studies. Platelet-rich plasma (PRP) was prepared by low-speed centrifugation at 4°C for 10 min at $100 \times g$. Platelet-poor plasma was prepared by respinning the blood at 4°C after removal of the PRP for 15 min at $400 \times g$. Red cells for FA analysis were prepared from the residue by resuspending the cells in 10 mL of phosphate-buffered saline and recentrifuging the cells at $400 \times g$ for 15 min three times. The supernatant was discarded. The red cells were frozen at −70°C until their lipids could be extracted.

Platelet aggregation. Platelet aggregation tests were performed as previously described (16). Briefly, solutions of the aggregating agents were prepared as recommended by Chrono-log (Chrono-log Corp., Havertown, PA) as follows: ADP, 1 μM/μL; collagen, 0.5 μg/mL; AA, 0.05 μM. The *in vitro* aggregation characteristics of the subjects' platelets were measured in a Chrono-log Model 560 (Chrono-log Corp., Havertown, PA) dual channel aggregometer. Briefly, 0.45 mL of PRP was added to an aggregation tube containing a Teflon-coated stirring bar. The blank was 0.5 mL of the individual platelet-poor plasma, unstirred. The instrument was zeroed to 10% transmission of the sample vs. the blank. An appropriate amount of aggregating reagent was added to the PRP and aggregation was measured as the increase in transmission of light through the PRP. Generally the sample was monitored until the curve became flat or with some reagents, notably ADP, disaggregation occurred. The threshold for aggregation was defined when the amount of a particular reagent produced approximately 50% of maximum aggregation within 15 min of its addition to the PRP. All aggregation tests were performed within 4 h of the initial blood draw with PRP that was kept a 0°C until warmed to 37°C for the aggregation test.

Platelets counts. Platelet counts were determined with an electronic particle counter, a Baker-Serono Model 9000 Differential Cell Counter (Allentown, PA) electronic particle counter and cytometer using the manufacturer's recommended procedures (17).

Bleeding time. Bleeding times were measured between 10 and 11 a.m. on the left or right proximal forearm of each subject using a 1-mm deep by 1-cm long incision using a Simplate II bleeding time device (Organon Teknika, Durham, NC). A wipe of the incision was made every 30 s. Time was measured with a hand-held stop watch.

Clotting factors. Prothrombin time and the partial thromboplastin times were measured by the methods described by Houghie (18). Briefly platelet-poor plasma was prepared as described and the prothrombin time and partial thromboplastin time were measured using the Bio/Data Corporation Model MCA 110 instrument (Bio/Data Corporation, Hatboro, PA) with Organon Teknika coagulation reagents. All tests for the clotting factors were performed within 1 h of the separation of the plasma from the whole blood. Plasma samples were kept on ice until warmed to 37°C for the test.

Lipid extraction and FA analysis. Platelets were extracted by the procedures described by Nelson (19,20) using chloroform/methanol (2:1, vol/vol). Samples were then transmethy-

lated with methanolic HCl (7%, w/w) by the procedures described elsewhere (21,22). When the total lipid extract was transmethylated, the impurities, extracted into the hexane phase after termination of the reaction, were removed by thin-layer chromatography as described by Nelson (20). Because the amount of material available from human platelets for FA analysis was limited, FA methyl esters were obtained by direct transmethylation of the intact tissue without prior solvent extraction as described in an earlier publication (23). The conditions of the capillary gas–liquid chromatography have been described previously (21). Briefly, the column was a 30-m by 0.025-mm fused quartz column coated with SP-2340 purchased from Supelco, Inc. (Bellefonte, PA). The gas–liquid chromatography data were processed with Hewlett-Packard (Palo Alto, CA) ChemStation software running on an IBM-compatible desktop computer.

Statistical analysis. The clotting data and aggregation data were analyzed using the paired T-test with an $n = 10$ or analysis of variance with repeated measures. Analysis of variance was used to determine if Group A and Group B data were comparable. The FA data were analyzed with a single-tailed T-test. All the statistical analyses were performed with the PC SAS data system, version 6.11, obtained under license from the SAS Institute (Chapel Hill, NC, 1993).

RESULTS

In this study we could detect very few physiological changes in the blood clotting systems, platelet function, or the platelet FA composition in our subjects resulting from increased levels of dietary AA when consumed at the level of 1.7 g/d for 50 d. The average bleeding times for the 10 subjects after consuming the high-AA diet for 50 d were 3.94 and 3.56 min after they had consumed the low-AA diet, respectively. The difference between these values did not reach statistical significance ($P = 0.06$).

Table 1 lists the platelet aggregation *in vitro* and the platelet counts determined after 50 d on high-AA diets and 65 d on the low-AA diet for the 10 subjects in this study. Again there were no statistically significant changes in either the aggregation values or the platelet counts when the results from the two diets are compared. Table 2 lists some values for the soluble blood coagulation parameters for these subjects after the high-AA or the low-AA diets. The prothrombin time was significantly lower ($P < 0.03$) after the subjects consumed the high-AA diet for 50 d than when they consumed the low-AA diet for 65 d. Neither the partial thromboplastin time nor antithrombin-III values were different after the subjects consumed either diet.

TABLE 1
Platelet Aggregation and Cell Count[a]

	High-AA diet	Low-AA diet	*P* value
Agonist			
ADP (μM)	0.20 ± 0.1	0.17 ± 0.11	0.31
Collagen (μ/mL)	2.33 ± 0.96	2.64 ± 2.08	0.43
AA (mM)	0.40 ± 0.19	0.39 ± 0.11	0.40
Count (1000/mm^3)	339 ± 52	357 ± 60	0.15

[a]($n = 10$); AA, arachidonic acid; mean ± SD.

TABLE 2
Blood Coagulation Properties[a]

Parameter	High-AA diet	Low-AA diet	*P* value
Prothrombin time (s)	11.22 ± 0.44	12.48 ± 0.73	0.03
Partial thromboplastin time, (s)	28.08 ± 2.69	28.45 ± 3.13	0.33
AntiThrombin-III (%)	83.76 ± 19.18	91.32 ± 22.12	0.23

[a]($n = 10$). See Table 1 for abbreviation; mean ± SD.

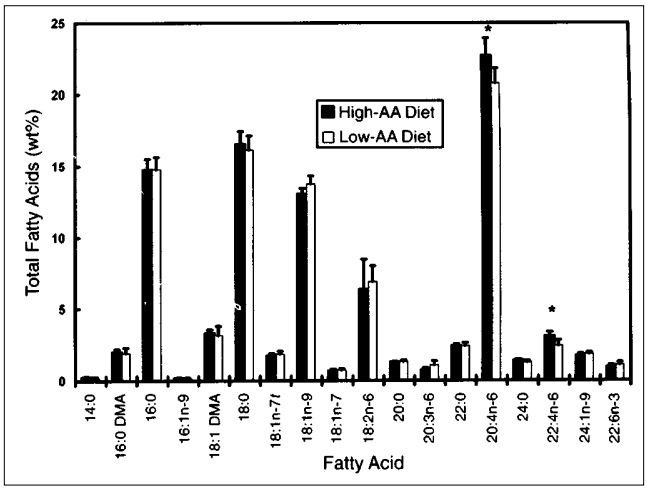

FIG. 1. The total fatty acid composition of the platelets after the consumption of the low-arachidonic acid (AA) and high-AA diets by the subjects in this study. Individual fatty acids are designated by carbon chain length/number of double bonds in the molecule and the position of the first double bond from the methylene end of the molecule. The asterisks designate fatty acids that are significantly different between the two diet groups with P values <0.05. Only fatty acids present in amounts greater than 0.5% of the total fatty acids are displayed in this figure; *t, trans* fatty acid; DMA, dimethylacetal.

Figure 1 compares the total FA composition of the whole platelets after the subjects consumed the high-AA diet for 50 d or the low-AA diet for 65 d. Only the AA and 22:4n-6 content of the platelets showed statistically significant changes between the two diets. The percentages of both of these FA increased in the platelets of the subjects after they had consumed the high-AA diets for 50 d when compared to their platelet FA composition on the low-AA diet for 65 d. This is normalized weight percentage data, and if the percentage of one or more FA increases then, obviously, one or more FA must decrease. The percentage of stearic, oleic, and linoleic acids in the platelets did decrease slightly after the subjects consumed the high-AA diet, but the changes did not reach statistical significance, probably because of the relatively small changes and the size of the standard deviations in these measurements.

DISCUSSION

Dietary AA has been consider a potentially hazardous substance to feed to humans for over two decades, particularly if fed in amounts exceeding those found in typical human diets. This presumption was based largely on the study published by Seyberth *et al.* (3) that showed a marked decrease in *in vitro* platelet aggregation times in healthy men consuming 6 g/d of pure ethyl arachidonate. This information, coupled with the supposition that increased production of eicosanoids, as postulated by Lands and colleagues (2,24) and others (25), would have major adverse effects on human health, has discouraged investigators from human feeding studies with AA. During this same period, several animal studies have been published that did not indicate adverse consequences from the consumption of AA (4–9,12).

As our knowledge of FA metabolism and effects of dietary FA has expanded, it became apparent that dietary FA often had metabolic effects and physiological consequences different from endogenously synthesized FA (26,27). Of course, dietary AA is not essential for human health, provided that one's diet contains adequate amounts of linoleic acid. Indeed, it is likely that linoleic acid has essential roles in human physiology beyond being simply a precursor of AA (28–30). If one wanted to investigate AA metabolism and physiological effects, it was safer to feed linoleic acid rather than AA. However, investigators were left with the paradoxical concept that dietary AA was harmless when fed to animal at levels well above those found in nature, but harmful to humans at levels well below those fed to animals. This conflicting information led us to believe that the metabolic effects of dietary AA in humans should be reinvestigated under controlled condition.

The *in vitro* platelet aggregation characteristics were not different in these subjects after they consumed the high-AA diet, nor was the *in vivo* bleeding times. Contrary to our expectations, the mean bleeding times were slightly longer after the subjects had consumed the high-AA diet compared to the value determined after they had consumed low-AA diet although the two values were not statistically different. In addition, our platelet aggregation results conflict with those presented by Seyberth *et al.* (3), who reported a marked shortening of the *in vitro* platelet aggregation after 3 wk of supplementation with 6 g/d of ethyl arachidonate. Here we fed only 1.5 g/d and in the form of a natural triglyceride, containing about 40% AA, mixed with natural foods. Thus, there are several factors that may account for the differences found between this study and the study by Seyberth *et al.* (3). Our conclusion is simply that at the level of AA used in our study AA does not affect platelet aggregation or the bleeding time *in vivo*.

One significant change we noted when the subjects consumed the high-AA diet for 50 d was that their prothrombin time decreased slightly but statistically significantly. Still, both the values observed when the subjects consumed the low-AA diet for 65 d or high-AA diet for 50 d were well within the normal physiological range reported for this coagulation parameter. Thus, there may be no physiological significance to this difference, particularly considering that the antithrombin-III levels were unaffected by the high-AA diet. Antithrombin-III is considered a measure of the tendency for the blood to undergo thrombosis *in vivo* and has been correlated with increased incident of myocardial infraction in humans (31–34).

In this study we increased the amount of AA consumed daily by a factor of eight. This increase had little effect on the level of platelet AA after 50 d on the high-AA diet compared to the AA levels in the platelets when the subjects consumed the low-AA diet. The AA level went from 21 to 24% when the subjects consumed the high-AA diet, but this is hardly an eight fold increase. Platelets normally contain rather large quantities of AA compared with most other tissues (14,35–37). Some hypotheses that could explain this lack of change are: (i) platelets are saturated with AA and cannot absorb any more of this substance; (ii) because of AA's importance in platelet function, its content in platelets is under very strict control; or (iii) the total amount of AA fed during the study (75 g in 50 d) was not enough to significantly influence the body pools of AA that control the platelet FA composition.

If the first hypothesis is correct, it would suggest that the acyl transferases that control the FA composition of the phospholipids in the cell membranes are in equilibrium with the amount of AA normally present and cannot increase the level in platelets further. It may be possible to shift this equilibrium with higher levels of AA in the diet and further increase the percentage of AA in platelets beyond that observed here. Also, it may be that the ratio of AA to other FA, particularly the n-3 FA, may be the most important factor controlling the FA composition of platelets *in vivo*. The argument against the second hypothesis is that when high levels of n-3 FA are incorporated into human diets they are rapidly incorporated into the platelets, causing a reduction in the AA levels and also in the linoleic and oleic acid levels in the platelets. Another experiment, with longer feeding periods or larger amounts of AA, would be needed to test the third hypothesis. We can conclude, however, that the level of AA in platelets is unlikely to be altered much by the variations encountered in AA intake in the typical Western diet.

ACKNOWLEDGMENTS

The authors wish to acknowledge the help of the staff at our Center. We are especially indebted to the Metabolic Research Unit staff, without whose help this study could not have been conducted, including the nursing staff who drew the blood and the dietetics staff who prepared the food. We also wish to thank the Bio-analytical Lab staff who did the plasma cholesterol and triglyceride, lipoprotein and apoprotein analyses.

ABSTRACT: Normal healthy male volunteers (n = 10) were fed diets (high-AA) containing 1.7 g/d of arachidonic acid (AA) for 50 d. The control (low-AA) diet contained 210 mg/d of AA. Dietary AA had no statistically significant effect on the blood cholesterol levels, lipoprotein distribution, or apoprotein levels. Adipose tissue fatty acid composition was not influenced by AA feeding. The plasma total fatty acid composition was markedly enriched in AA after 50 d ($P < 0.005$). The fatty acid composition of plasma lipid fractions, cholesterol esters, triglycerides, free fatty acids, and phospholipid (PL) showed marked differences in the degree of enrichment in AA. The PL plasma fraction from the subjects consuming the low-AA diet contained 10.3% AA while the subjects who consumed the high-AA diet had plasma PL fractions containing 19.0% AA. The level of 22:4n-6 also was different (0.67 to 1.06%) in the plasma PL fraction after 50 d of AA feeding. After consuming the high-AA diet, the total red blood cell fatty acid composition was significantly enriched in AA which mainly replaced linoleic acid. These results indicate that dietary AA is incorporated into tissue lipids, but selectively into different tissues and lipid classes. Perhaps more importantly, the results demonstrate that dietary AA does not alter blood lipids or lipoprotein levels or have obvious adverse health effects at this level and duration of feeding.
Lipids 32, 427–433 (1997).

Arachidonic acid (AA) is a normal constituent of the human diet (1) if one is not a vegan, and is found in all cells and tissues in significant amounts (2–4). Human studies using AA have been limited, probably because of suggestions in the literature that higher levels of AA in the diet may have adverse consequences (5,6). Nevertheless, there have been many feeding studies in animals using high levels of AA that have not shown any major adverse effects (7–10). Furthermore, several human studies (5,11–13) have not resulted in any actual harm to the subjects despite some potential adverse changes in a few physiological parameters such as platelet aggregation *in vitro* (5).

Because of its major role in human physiology, there is much interest in the metabolism and physiological function of dietary AA (14,15). In view of the animal studies, the lack of actual adverse consequence of dietary AA in humans, and the commercial availability of a natural triglyceride (TG) containing 50% AA, we decided to conduct a human feeding study with AA in a metabolic research unit (MRU). The details, protocol, and design of the study have been described in a previous paper (16).

Here we report the effects on several lipid parameters of supplementing a natural food diet (containing 210 mg/d AA) with 1.5 g/d of AA in the form of a TG. The supplementation period was 50 d. We examined the blood lipid levels; fatty acid (FA) composition of the plasma, red cells, and adipose tissue (AT); lipoprotein cholesterol levels, and some apoprotein levels.

STUDY DESIGN

The study design was described in detail in the previous paper in this series (16). The design was a single-blind cross-over feeding study in which 12 healthy volunteers lived in the MRU of the Western Human Nutrition Research Center (San Francisco, CA) for 130 d. The study had a symmetrical design in which all subjects were fed a stabilization diet for 15 d after they entered the MRU. On day 16 of the study, six of the subjects, designated Group A, were switched to a diet containing 1.7 g/d of AA (210 mg from the basal diet and 1.5 g from ARASCO® oil; Martek Biosciences Corporation, Columbia, MD). The remaining six subjects, designated Group B, continued to consume the basal diet which contained 210 mg of AA. On day 65 of the study, the two groups switched diets. On day 115 of the study, Group B was returned to the basal diet. Two subjects did not complete the study. The re-

maining subjects were discharged from the MRU on day 130 of the study.

MATERIALS AND METHODS

A description of the oil (ARASCO®) and its FA composition is given in the previous paper (16). The oil was kept under nitrogen and at −20°C until it was needed for food preparation. Open bottles were flushed with N_2 before they were resealed and returned to the freezer. As we fed the AA in a cold yogurt cocktail, it is unlikely that any oxidative degradation took place between the time the food was prepared and when it was eaten.

Subjects. The physical characteristics of the subjects and the recruitment process were described in the previous paper (16). Initially, 12 volunteers were included in the study, but two were unable to complete the protocol.

Experimental protocol. Details of the experimental protocol were given in the previous paper (16). The protocol for this study was approved by the Institutional Review Boards of the University of California at Davis and the United States Department of Agriculture (USDA, Washington, D.C.). A crossover design was used so that the subjects acted as their own controls. The subjects were fed the stabilization diet, containing about 30% of calories as fat for 15 d and then divided into two groups and fed either the stabilization diet or the high AA diet for 50 d, at which time (study day 65) the two groups were crossed over for the remainder of the study.

During the confinement period, blood was drawn on study days 2, 16, 40, 65, 90 115, and 130. Although analysis of the various parameters under study was performed on all volunteers on these study days, for most analyses, values from samples obtained on days 65 and 130 for group A and days 65 and 115 for group B were pooled and the data used for statistical analysis. Data from day 65 for Group A and day 115 for Group B were the end of the AA feeding periods, while data from day 130 for Group A and day 65 for group B were the baseline period. The samples from study days 2 and 16 showed no significant differences between groups A and B.

Diets. The nutrient composition of the diets was calculated from a computerized nutrient data bank using the data from *USDA Handbook 8, The Composition of Foods* (17), and adjusted to provide at least the recommended daily allowance for known essential nutrients (18). A detailed description of the low-AA and high-AA diets is given in the previous paper (16). A complete description of the diets, listing all the major and minor nutrients, is available upon request.

Measurements. Blood was drawn according to the schedule described previously (16) between 7:00 and 8:00 a.m. after an overnight fast. It was drawn into vacutainers with appropriate anticoagulants using a Teflon catheter (Angiocath; Deseret Medical, Sandy, UT) for fatty acid analysis. Red cells for FA analysis were prepared from the residue by resuspending the cells in 10 mL of phosphate-buffered saline and recentrifuging the cells at $400 \times g$ for 15 min three times. The supernatant was discarded. The red cells were frozen at −70°C until their lipids could be extracted. AT biopsies were taken from the buttocks using a hypodermic syringe equipped with 13-gauge stainless-steel needles (19). The samples (10 to 50 mg) were immediately transferred to cold (0°C) isotonic saline. The samples were transferred within an hour to a −70°C freezer and stored until further processing.

Lipid extraction and FA analysis. Plasma and red cell samples were extracted by the procedures described by Nelson (20,21) using chloroform/methanol (2:1, vol/vol). Samples were then transmethylated with methanolic HCl (7%, w/w) by the procedures described previously (22,23). When the total lipid extract was transmethylated, the impurities, extracted into the hexane phase after termination of the reaction, were removed by thin-layer chromatography as described elsewhere (21). The conditions of the capillary gas–liquid chromatography have been described previously (22). Briefly, the column was a 30 m by 0.025 mm fused quartz column coated with SP-2340 purchased from Supelco, Inc. (Bellefonte, PA). The gas–liquid chromatography data were processed with Hewlett-Packard ChemStation software running on an IBM-compatible desktop computer.

Apoprotein analysis. The apoproteins AI and B were analyzed in the Laboratory of Dr. Ernst Schaefer of the USDA Center on Nutrition and Aging, Tufts University Medical Center (Boston, MA). The plasma apolipoproteins, ApoA-I and ApoB, were measured by a turbidimetric procedure using a Spectrum CCX analyzer (Abbott Diagnostics with reagents and calibrators from INCSTAR (Stillwater, MN) (24, 25). The Lp(a) was determined in collaboration with Dr. Steven Silbermann of Perlimmune, Inc. (Rockville, MD), using an ELISA technique developed in Dr. Silbermann's laboratory (26,27).

Plasma lipid analyses: TG and cholesterol determinations. Plasma cholesterol, TG, high density lipoprotein (HDL)-cholesterol, and low density lipoprotein (LDL)-cholesterol were analyzed in a Cobas-Faras centrifugal analyzer using automated enzymatic methods as described by McGowan *et al*. (28) and Allain *et al*. (29).

AT FA analyses. The FA analyses of the AT samples were performed in the laboratory of Dr. Stephen Phinney at University of California at Davis. The procedures have been published previously (19,30).

Statistical analysis. The lipid data and lipoprotein data were analyzed using the paired *T*-test with $n = 10$ or analysis of variance with repeated measures. Analysis of variance was used to determine if Group A and Group B data were comparable. The fatty acid data were analyzed with a single-tailed *T*-test. All the statistical analyses were performed with the PC SAS data system, version 6.11, obtained under license from the SAS Institute, PC-SAS (31).

RESULTS

The addition of 1.5 g/d of AA to a natural food diet for 50 d had no effect on the total plasma lipid levels (See Table 1). The total cholesterol level was identical prior to and after the

TABLE 1
Effect of AA Supplementation on Plasma Cholesterol, Lipoprotein Cholesterol, and TG Concentrations[a]

	Low-AA diet (mg/dL)	High-AA diet (mg/dL)
Total cholesterol	161.90 ± 32.48	161.83 ± 32.23
LDL-cholesterol	89.45 ± 24.72	90.71 ± 20.42
HDL-cholesterol	38.71 ± 7.37	37.79 ± 7.22
TG	95.47 ± 59.75	101.70 ± 61.01

AA supplementation. As one would expect from the lack of change in the blood lipid levels, the apoprotein levels measured here did not change. Although the Lp(a) did decrease by about 5 mg/dL, this change was not statistically significant either (see Table 2).

Significant changes were detected in the total plasma FA composition in all subjects, with a near doubling of the AA level and 20% reduction in the serum linoleic acid level when they consumed the high-AA diet (see Fig. 1). In Group B there were no significant changes in the FA composition of the subjects tissues during the first 50 d when they consumed the low-AA diet. When the high-AA diet was consumed, a smaller reduction in the plasma oleic acid content was noted, as was a small, but statistically significant, rise in the stearic acid content. None of the other plasma FA levels changed significantly. The changes in the FA composition of the individual lipid classes were also analyzed and showed major differences from the pattern found in the total plasma FA composition. The plasma TG do not contain much AA, about 2% on the low-AA diet. This increased to 3% on the high-AA diet (see Fig. 2). Almost all of the increase was compensated for by a decrease in the oleic acid content of the TG without any significant change in the TG's linoleic acid content. In contrast, the changes in the FA composition of the cholesterol esters (see Fig. 3) were in the AA levels (increased) and the linoleic acid levels (decreased). No other FA showed significant changes in the cholesterol ester fraction. The phospholipid (PL) fraction's FA composition showed the most marked changes after the subjects consumed the AA supplement (see Fig. 4). The AA level rose from 10.3 to 19.0%, and the linoleic acid level dropped from 23 to 17%. There was a slight drop in the level of oleic acid and a slight rise in the level of stearic acid, the source of the increase in stearic acid content

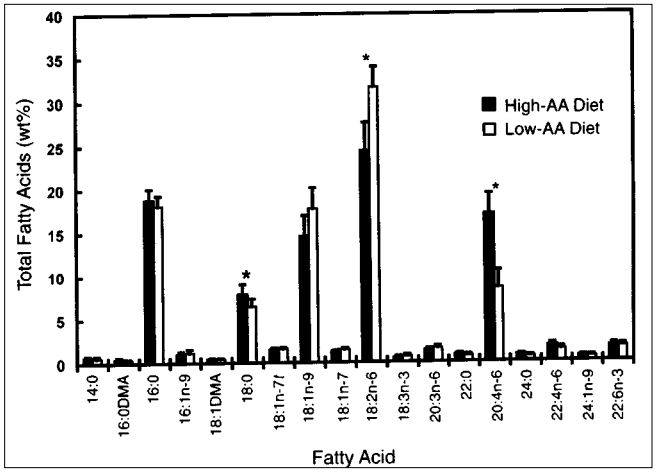

FIG. 1. The mean ($n = 10$) values for the major fatty acids in the subjects' plasma after the subjects had been on the low-arachidonic acid (AA) (65 d) or high-AA diet (50 d). Fatty acids are designated by chain length, number of double bonds in the molecule, and the position of the first double bond from the methylene end of the molecule. See Figure 1 for abbreviations.

changes in the FA composition were observed after the AA supplementation in either the TG or PL fractions. Table 3 gives the AA and 22:4n-6 levels in these two fractions. There is a trend toward increased AA levels in the PL of the AT after AA supplementation although the trend did not reach statistical significance in either fraction. The TG of AT contained very little AA (<0.5%), and there was no evidence of any increase in the AT TG after the dietary supplementation.

Red blood cells. Figure 8 shows the FA composition of the red cells before and after dietary supplementation with AA. AA supplementation appeared to increase the level of

palmitic, stearic, and AA and lower the level of linoleic, nervonic, and docosahexaenoic acid in the red blood cells when AA levels in the diet are increased.

DISCUSSION

When the level of AA in the diet is increased for 50 d from 210 mg/d to 1.7 g/d in an isocaloric substitution for oleic acid, there are no detectable changes in the plasma lipids or lipoprotein profile. The individuals studied in this work were all healthy, normolipidemic subjects (18), and it is more difficult to achieve lipid reductions in normolipidemic persons than in hyperlipidemic subjects (32,33). Also, the polyunsaturated/saturated ratio was held constant in this study at 1:1. Hayes and Khosla (34,35) suggested that plasma lipid levels show little alteration with changes in the amount of FA in the diet if the linoleic acid content of the diet is above 7%, as it was in this study. Lp(a) levels did decrease slightly, but the decrease was not statistically significant, perhaps because the intervention period was too short or the amount of AA fed was too small. Increased levels of dietary n-6 polyunsaturated FA have been reported to decrease HDL and LDL levels in hyperlipidemic subjects (36,37). In this study we added about 0.5% of calories of polyunsaturated n-6 FA while holding the saturated fat content of the diet constant. At this level no effect on the LDL or HDL levels was apparent. Thus, this study suggests that dietary AA at levels found in normal human diets will have no effect on the blood lipid levels or lipoprotein profile in normolipidemic individuals.

In contrast to the blood lipids and lipoproteins, a 1.5 g/d increase in dietary AA has significant effects on the FA profile of the plasma. Normally, the plasma FA profile reflects the dietary FA profile (2,3,38,39). It appears as if dietary AA disproportionately influences the AA level in the plasma. In a typical, fasting normolipidemic individual, there is a pool of 15 g of plasma FA in the circulation. If one calculates the increase in the percentage of AA found in the plasma in this study (from about 8 to 16%), all of one day's dietary AA is found in the plasma. This is in marked contrast to some other FA such as linolenic acid (3) or stearic acid (39) in which very little of the ingested material appears in the plasma FA.

Most of the increase in plasma AA level was found in the plasma PL and cholesterol ester fractions, although the increase in AA content of the plasma cholesterol ester, though significant, was intermediate between the PL and TG levels. The plasma TG showed relatively little increase in their AA levels. One interesting observation was that AA replaced oleic acid in the plasma TG, and primarily linoleic acid in cholesterol esters and PL.

As AA in the plasma FFA is a substrate for cyclooxygenase (40,41), it is probably beneficial that AA level in the

TABLE 3
AA and 22:4n-6 Content of Adipose Tissue Triglycerides and Phospholipids After High-AA or Low-AA Diets[a]

	Lipid (mean value ± SD, n = 10)		
Lipid fraction	Fatty acid	High-AA diet	Low-AA diet
Triglyceride	20:4n-6	0.33 ± 0.07	0.30 ± 0.07
	22:4n-6	0.11 ± 0.02	0.10 ± 0.02

	22:4n-6	0.33 ± 0.16	0.48 ± 0.68

[a]wt% of total fatty acids. See Table 1 for abbreviation.

plasma FFA is only marginally influenced by dietary AA. Here we found that AA level in the FFA in plasma was 2% in subjects on the low-AA diet and increased to 3% when they consumed to high-AA diet. The analytical variation in the level of other FA present in the plasma FFA was large, but none showed any statistically significant variation before and after consumption of the high-AA diet in these subjects.

The lack of deposition of AA in the AT was interesting, particularly in view of the data of Phinney *et al*. (19,30), suggesting that weight loss alone can have a significant effect on the AA content of the AT. In human tissues, AA is not present in high levels in TG (2,30,42). Here we found only a small increase in the AA level in the plasma TG and no increase in the level in AA in the AT. These subjects were in caloric balance. Weight loss or gain was restricted to less than 2% of their body weight at entry into the study (16). Apparently, none of the 75 g of AA consumed during the 50 d of the intervention was stored in the AT of these subject during that period except as a direct exchange with AA already present in the tissue. The reason for this is not known, but we can speculate that (i) the increased dietary AA is rapidly metabolized to other products and, hence not available for incorporation into AT, or (ii) that the turnover of FA in the AT is so slow in subjects with constant weight that an increase in the AA level could not be detected under the conditions of this experiment.

The half-life of red blood cells (RBC) is approximately 120 d in humans. Thus, the RBC FA composition data presented here represent a nonequilibrium state and, hence, are difficult to interpret. It is interesting, however, to note that the increase in the AA level was small, but the decrease in the linoleic acid level in the red cells was much larger. The decrease in linoleic acid was compensated for by increases in the palmitic and stearic acid levels rather than the AA level in the RBC of these subjects. There are no readily apparent explanations for these changes. One can speculate, however, that increased dietary AA interferes with incorporation of linoleic acid into RBC. The RBC then compensate by incorporating *in vivo* synthesized palmitic and stearic acid into their PL in place of linoleic acid.

In conclusion, this study demonstrates that dietary AA in a level eightfold above that found in a typical Western diet has little or no effect on blood lipid, lipoprotein, or apoprotein levels. Dietary AA at these levels does markedly alter the AA levels in the plasma, particularly the plasma PL. Also, dietary AA is not readily incorporated into AT. The effects of dietary AA on RBC FA are complex and not readily interpreted in a 50-d study. In terms of blood lipids and lipoproteins that are risk factors for cardiovascular disease, there are no obvious benefits or adverse effects from consuming an eightfold increase in dietary AA for 50 d.

ACKNOWLEDGMENTS

The authors wish to acknowledge the help of the staff at the Western Human Nutrition Research Center. We are especially indebted to the Metabolic Research Unit staff, without whose help this study could not have been conducted, including the nursing staff who drew the blood and the dietetics staff who prepared the food. We also wish to thank the Bio-analytical Laboratory staff who did the plasma cholesterol and triglyceride, and lipoprotein analyses.

ABSTRACT: Data on the effect of dietary arachidonic acid (AA) (20:4n-6) on the synthesis of thromboxane and prostacyclin (PGI_2) in humans are lacking. We measured the effect of 1.5 g/d (*ca.* 0.5 en%) of 20:4n-6 added isocalorically to a stabilization (low-AA) diet on the excretion of 11-dehydrothromboxane B_2 (11-$DTXB_2$) and 2,3-dinor-6-oxo-$PGF_{1\alpha}$ (PGI_2-M). In a crossover design, 10 healthy men, living in a metabolic unit, were fed a diet (low-AA) containing 210 mg/d of 20:4n-6 for 65 d and an identical diet (high-AA) that contained 1.5 g/d of additional 20:4n-6 for 50 d. Three-day urine pools were collected at the end of each dietary period and analyzed for eicosanoids by gas chromatography–electron capture negative ion–tandem mass spectrometry. Mean excretion of 11-dehydrothromboxane B_2 was 515 ± 76, 493 ± 154, and 696 ± 144 ng/d (SD; $n = 10$) during the acclimation (15 d) low-AA diet and high-AA diet periods, respectively (41% increase from low-AA to high-AA diet, $P = 0.0037$); mean excretion of PGI_2-M was 125 ± 40, 151 ± 36, and 192 ± 55 ng/d (SD; $n = 10$) during acclimation (15 d) low-AA and high-AA diets, respectively (27% increase from low-AA to high-AA diets; $P = 0.0143$). Thus, both the metabolites of thromboxane and PGI_2 increase on the high-AA diet. Furthermore, both indicated changes in metabolite excretion may be associated with measurable effects on several physiologically significant cellular functions, such as platelet aggregation *in vivo* and inflammation in response to immune challenges.

Lipids 32, 435–439 (1997).

Eicosanoids are a group of oxygenated metabolites of arachidonic acid (AA) (20:4n-6) which are ubiquitous in mammalian tissues. They produce a remarkably broad spectrum of effects that embraces nearly every biological function. Hence, inhibition and enhancement of their biosynthesis can be important tools of therapeutic strategies. In 1971 Vane (1) demonstrated that aspirin inhibits the synthesis of eicosanoids, specifically those arising through the cyclooxygenase pathway, and that this inhibition is the mechanism of action of aspirin-like drugs. Many other drugs have since been shown to alter eicosanoid production.

The immediate biochemical precursor of all the major physiologically active eicosanoids is AA which is normally present in very small quantities in the human diet (approximately 200 mg/d) but can be synthesized, in the human, from linoleic acid (18:2n-6), a much more abundant lipid component in the occidental diet (2). This relationship justifies the hypothesis that the endogenous synthesis of eicosanoids can also be influenced by manipulations of dietary polyunsaturates. Indeed, it has been shown that prostaglandin E_2 synthesis can be increased by supplementing the intake of AA (3). Nonprostaglandin precursor fatty acids, e.g., saturated fatty acids, have also been suggested to modulate eicosanoid biosynthesis (4,5).

Thromboxane (TXA_2), a powerful inducer of platelet aggregation and vasoconstriction, and prostacyclin (PGI_2), one of the most potent hypotensive and antiaggregatory agents, are key eicosanoids in vascular physiology. According to a model developed by Moncada and Vane (6), PGI_2 and TXA_2 represent biologically opposite poles of a mechanism for regulating platelet-vessel wall interaction and the formation of the hemostatic plug and intra-arterial blood clots. A number of groups have found that dietary eicosapentaenoic (20:5n-3) acid, a major component of marine lipids, tends to reduce arachidonate metabolism to thromboxane and PGI_2 in humans (7–13). Studies in humans (12,13), monkeys (14), and rats (15), however, have also been reported to show that dietary fish oil does not reduce the rate of PGI_2 synthesis. Given the broad spectrum of biological activities of eicosanoids, it is conceivable that an increase in their output may be desirable under certain clinical and/or experimental circumstances. Whelan *et al.* (16,17) have recently demonstrated that AA is a more effective eicosanoid modulator in mice than is eicosapentaenoic acid, both *in vitro* and *in vivo*. In humans, there are no reported data on the effect of dietary 20:4n-6 on the endogenous output of TXA_2 and PGI_2. Additionally, it is of interest to learn what effect, if any, AA will have on eicosanoid output in diets already rich in linoleic acid. In the

present study conducted with 10 volunteers, we quantified the effect of an isocaloric addition of AA (*ca.* 0.5 energy percentage, or en%) on the excretion of 11-dehydrothromboxane B_2 (11-DTXB_2) and 2,3-dinor-6-oxo-PGF$_{1\alpha}$ (PGI_2-M).

MATERIALS AND METHODS

Subjects. Initially, 12 healthy, nonobese male subjects between the ages of 20 and 38 were selected from residents of the San Francisco Bay area. Those who met preliminary selection criteria (nonsmoking, relatively stable body weight, no history of alcohol abuse, and moderate physical activity) were given a physical examination and were subjected to hematological and chemical screening. Those with test results within normal ranges were entered into the study. They were housed at the Human Nutrition Suite, Western Human Nutrition Research Center, USDA, ARS, Presidio of San Francisco, California, for the duration of the study (130 d). They were required not to ingest aspirin or any other anti-inflammatory agents and to report any medication prescribed by a physician during the study. The subjects were fully informed of the purpose of the study, procedures to be followed, samples to be collected, risks, benefits, and payment associated with the study. All procedures were approved by the University of California, Davis, Human Subjects Committee, and the USDA, ARS Human Studies Review Committee.

Controlled diets. Two low-fat diets, designated as low-AA (stabilization) and high-AA (intervention) diets, consisted of natural foods purchased from local food suppliers. All nutrients, including micronutrients, were provided by the diets in amounts to meet or exceed the Recommended Daily Allowances (RDA) (18) as estimated from data in *USDA Handbook 8* (19). The amount of vitamin E was estimated to be twice the RDA. Such excess was intended to counteract any increase in oxidative stress induced by the increase in polyunsaturated fatty acid intake in the high-AA diet. The high-AA diet was identical to the low-AA diet except that it contained 3 g of a triglyceride (called ARASCO®) produced by the Martek Biosciences Corporation (Columbia, MD) from algae. ARASCO® oil, which was 50% AA, isocalorically replaced the high-oleic safflower oil used in the stabilization (low-AA) diet. The study used a 5-d rotating menu cycle, and no food or food supplement other than what was provided by the study was allowed. *Handbook 8*, *The Composition of Foods*, (19) and in-house nutrient databases were utilized to determine the nutrient composition of the diets.

Duplicate sets of 5-d representative composites of both diets were analyzed separately for fatty acids by gas–liquid chromatography. Table 1 shows the mean fatty acid composition in the two diets. Energy contribution (en%) from proteins, carbohydrates, and lipids was virtually identical in both diets: 15%, 55%, and 30%, respectively. Alcoholic beverages were not allowed, whereas consumption of decaffeinated coffee or tea, and water was unrestricted. The energy values of the meals were adjusted, daily if necessary, to maintain the participants' body weights. We made adjustments so that the fatty acid composition of the diet remained constant. The calories were reduced (or increased) by reducing (or increasing) the subject's intake of all nutrients proportionally, while the 1.5 g/d of AA remained constant. Thus, the average weights of the subjects did not vary significantly during the 130 d of the study. The mean energy intake for all subjects during the entire study was about 2800 Kcal/d. Further details concerning the diets have been reported elsewhere (20).

Experimental protocol. All subjects were initially fed diet low-AA containing 210 mg/d of AA from natural foods. On day 15, one-half of the subjects (Group A) switched to a diet (high-AA) identical to the low-AA diet except that it contained 3 g of a triglyceride consisting of 50% 20:4n-6, while the others (Group B) remained on the low-AA diet. On day 65, the two groups were crossed over: Group B now received the high-AA diet and Group A received the low-AA diet. On day 115, Group A was returned to the low-AA diet. All subjects were released on day 130.

Urine collection. For eicosanoid analysis, 24-h urine samples were collected in polyethylene bottles and kept refrigerated during the collection period. Urine was collected during days 13 to 15, 63 to 65, 113 to 115, and 128 to 130. After the 24-h collections were completed, urine volumes were measured, and 2% portions of each 24-h (three consecutive day) collection were pooled and stored at −70°C until analyses could be performed. The subjects, who had no access to normal toilet facilities, were under constant supervision and received detailed instructions about urine collection.

Measurement of 11-DTXB_2 and PGI_2-M. Analyses of 11-DTXB_2 and 2,3-dinor-6-oxo-PGF$_{1\alpha}$ (PGI_2-M) were per-

formed on 10-mL aliquots of the 72-h pools prepared as described above. This enabled us to assess the mean total synthesis of TXA_2 and PGI_2 during the 72-h periods. Specifically, to estimate the effect of dietary changes on eicosanoid excretion, analyses were performed on days 63–65 (high-AA diet) and days 128–130 (low-AA diet) urine pools in Group A subjects. In Group B subjects, the analyses were performed on days 63–65 (low-AA diet) and days 113–115 (high-AA diet) urine pools. (See scheme of study depicted in Ref. 20). Quantification was achieved by capillary gas chromatography–electron capture negative ion–tandem mass spectrometry. As reported previously, the interassay coefficient of variation (precision) for the 11-$DTXB_2$ assay was 1–2% (21) and about 5% for PGI_2-M (22). Detailed procedures and instrumental conditions were described previously (21,22).

Statistical analysis. We evaluated the 11-$DTXB_2$ and PGI_2-M 24-h excretion rates and AA intakes using the PROC MIXED package of the SAS Institute (Cary, NC). *P* values less than 0.05 were considered statistically significant.

RESULTS

Two subjects, both from Group B, withdrew from the study. We were thus left with a 6:4 subject distribution between the groups. The 11-$DTXB_2$ and PGI_2-M data were tested for carryover effects, and none achieved statistical significance ($F = 1.87$, $P = 0.2083$; $F = 2.27$, $P = 0.1705$, respectively). We also compared the fatty acid composition of plasma, platelets, and red cells on day 15 to day 130 (23,24). As they were identical, we assumed that the washout period was adequate in this regard. The mean 11-$DTXB_2$ urinary excretion was 515 ± 24 ng/d after 15 d of the low-AA diet, 493 ± 49 ng/d (SE; $n = 10$) after 65 d of the low-AA diet, and 696 ± 45 ng/d with the high-AA diet (41% increase, $P = 0.0037$); the mean PGI_2-M excretion at these same points was 125 ± 13 ng/d, 151 ± 11 ng/d and 192 ± 17 ng/d (SE; $n = 10$), respectively (27% increase, $P = 0.0143$). Excretion values for individual subjects are shown in Tables 2 and 3. Values at the end of the two diet periods for each of the 10 individuals who completed the study are shown graphically in Figures 1 and 2.

DISCUSSION

This study quantifies the effect of an eightfold increase in AA intake on the biosynthesis of TXA_2 and PGI_2 as measured by the urinary excretion of their respective metabolites. Ten male volunteers, when subjected to isocaloric supplementation with 1.5 g/d of AA, synthesized an average of 41% more TXA_2 and 27% more PGI_2 than they did when they were consuming a stabilization diet containing 210 mg/d of AA. The magnitude of these increases is, in our opinion, remarkable as they occurred through the action of only 0.5 en% of added AA and in the presence of relatively large quantities of dietary linoleate, the precursor of AA (Table 1). In contrast, a previous study supplementing dietary AA at a fourfold higher level than in our study found a rather modest increase in PGE metabolite excretion (3). Under normal physiological conditions, platelets provide approximately 80% of TXA_2. Whereas endothelial cells are the major source of PGI_2, there is evidence that in rats the gastrointestinal tract is another site of PGI_2 synthesis from dietary precursor fatty acids (25). However, to our knowledge, it has not been demonstrated that in humans PGI_2 is absorbed through the gut and thereby subjected to the normal catabolic pathway leading to PGI_2-M. An increase in PGI_2 production in response to AA supplementation has been previously observed in rats, both *in vitro* and *in vivo*, by Mann *et al.* (26). The authors also observed that there was a significant positive correlation between the two methods: *in vitro* production of 6-oxo-$PGF_{1\alpha}$ by arterial preparations and *in vivo* PGI_2 production as measured by the urinary level of PGI_2-M.

Our study confirms previous observations (12–14) that the synthesis of TXA_2 is more accessible than the synthesis of PGI_2 to diet-induced alterations. Indeed, in a fish-oil supple-

[d]Low-AA compared with high-AA diet; $P < 0.014$.

mentation (15 g/d) study conducted at the USDA Center (Beltsville, MD), the mean 11-DTXB$_2$ excretion was reduced by 38% while the mean excretion of PGI$_2$-M was reduced by only 22% after 10 wk, compared to a basal diet (9,10). A similar observation was made by Sanigorski *et al.* (27) in a rat study whose results demonstrated the ability of n-3 fatty acids, in this case provided as 18:3 n-3 from linseed oil, to selectively decrease TXA$_2$ production while having little or no effect on PGI$_2$-M production *in vitro*. The greater TXA$_2$ response may be related to the magnitude of diet-induced changes in arachidonate and eicosapentaenoate in platelet and endothelial lipid stores. Because of the antagonistic physiological activities of TXA$_2$ and PGI$_2$-M (as regards platelet aggregation and vasoconstriction), the greater TXA$_2$ response observed in this study (41% vs. 27% increase) might become significant, in terms of increased risk of thrombosis, with increasing dietary AA intake. The effects of the high-AA diet on plasma, platelet and tissue fatty acid composition, platelet function and blood clotting, plasma lipoprotein distribution and apoproteins from this study are reported elsewhere (23,24). Although changes in platelet function and bleeding time were not detected in our healthy, nonsmoking subjects, this may not be true in patients with vascular disease.

The results of this study, together with those of our fish oil study (9,10), agree with observations made by Whelan *et al.* (16,17) in studies with mice and hamsters that AA is a more effective modulator of eicosanoid biosynthesis than n-3 marine fatty acids. Similarly, Sanigorski *et al.* (28) demonstrated that in rats fed high-fat diets, 30 mg/d of dietary AA abolishes the depression of TXA$_2$ and PGI$_2$ production induced by 100 mg/d of n-3 polyunsaturated fatty acids. As shown in Table 1, and as previously stated in the Materials and Methods section under *Controlled diets*, the higher 20:4n-6 intake in the high-AA diet is largely at the expense of oleic acid. To our knowledge, there is no support in the literature for the proposition that the observed shift of the eicosanoid balance is attributable to the minor reduction of oleic acid intake. Thus, in this study we are possibly observing a pure AA effect. Finally, it

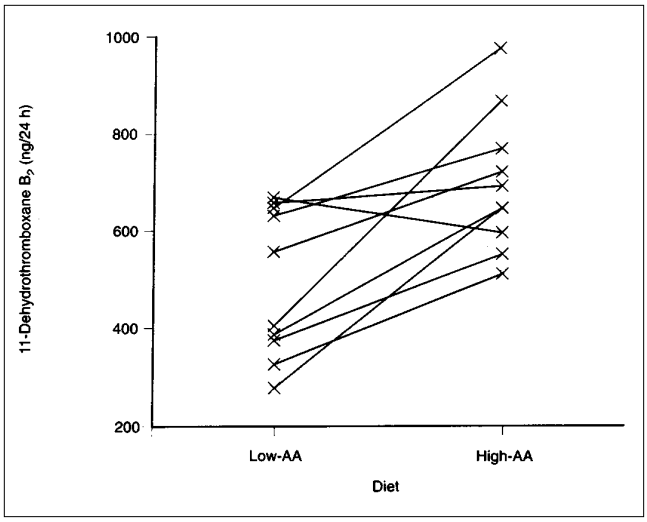

FIG. 1. 11-Dehydrothromboxane B$_2$ excretion rates of the 10 subjects who completed the study; AA, arachidonic acid.

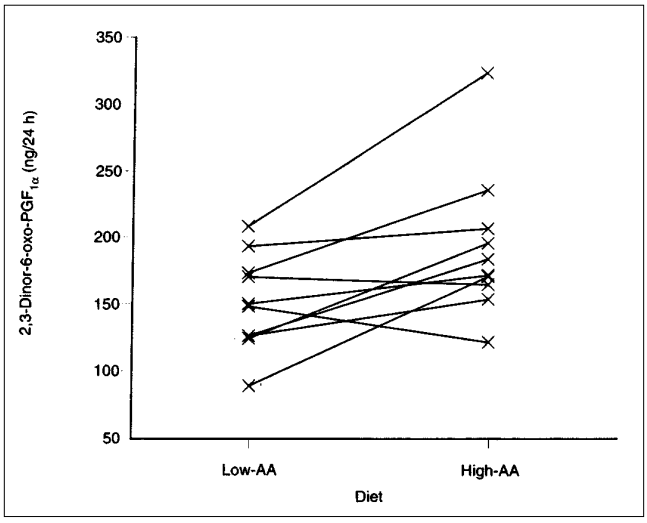

FIG. 2. 2,3-Dinor-6-oxo-PGF$_{1\alpha}$ excretion rates of the 10 subjects who completed the study. See Figure 1 for abbreviation.

is noteworthy that, with regard to both 11-DTXB$_2$ and PGI$_2$-M excretion rates, subject 12 exhibited a response to the high-AA diet which is contrary to the response of all the other subjects. Available data do not allow us to conclude whether this is an example of biological variability or the consequence of unknown factors.

ABSTRACT: This study investigated the influence of dietary arachidonic acid (20:4n-6) on Δ5 desaturation and incorporation of deuterium-labeled 8*cis*,11*cis*,14-eicosatrienoic acid (20:3n-6) into human plasma lipids. Adult male subjects ($n = 4$) were fed diets containing either 1.7 g/d (HI20:4 diet) or 0.21 g/d (LO20:4 diet) of arachidonic acid for 50 d and then dosed with a mixture containing ethyl esters of 20:3n-6[d4] and 18:1n-9[d2]. A series of blood samples was sequentially drawn over a 72-h period, and methyl esters of plasma total lipid, triacylglycerol, phospholipids, and cholesteryl ester were analyzed by gas chromatography–mass spectrometry. Based on the concentration of 20:3n-6[d4] in total plasma lipid, the estimated conversion of 20:3n-6[d4] to 20:4n-6[d4] was 17.7 ± 0.79% (HI20:4 diet) and 2.13 ± 1.44% (LO20:4 diet). The concentrations of 20:4n-6[d4] in total plasma lipids from subjects fed the HI20:4 and LO20:4 diets were 2.10 ± 0.6 and 0.29 ± 0.2 μmole/mL plasma/mmole of 20:3n-6[d4] fed/kg of body weight. These data indicate that conversion of 20:3n-6[d4] to 20:4n-6[d4] was stimulated 7–8-fold by the HI20:4 diet. Phospholipid acyltransferase was 2.5-fold more selective for 20:3n-6[d4] than 18:1n-9[d2], and lecithin:cholesterol acyltransferase was 2-fold more selective for 18:1n-9[d2] than 20:3n-6[d4]. These differences in selectivity were not significantly influenced by diet. Absorption of ethyl 20:3n-6[d4] was about 33% less than ethyl 18:1n-9[d2]. The sum of the n-6 retroconversion products from 20:3n-6[d4] in total plasma lipids was about 2% of the total deuterated fatty acids. Neither absorption nor retroconversion appears to be influenced by diet.

Lipids 32, 441–448 (1997).

The ratio of 20:3n-6 to 20:4n-6 in tissues is involved in the regulation of the balance between the series-1 and series-2 eicosanoids which effects their physiological impact. Because dihomo-γ-linolenic acid (20:3n-6) and arachidonic acid (20:4n-6) are substrates for the synthesis of these eicosanoids, the possibility has been suggested that diets rich in 20:4n-6 decrease the ratio of 20:3n-6 to 20:4n-6 in tissues and may have a negative effect on a variety of chronic diseases such as heart disease, arthritis, asthma, and hypertension (1–3). Conversely, supplementation of diets with the precursor of 20:3n-6, γ-linolenic acid (18:3n-6), has been reported to have beneficial health effects (1–4). For these reasons, a better understanding of the influence of dietary 20:4n-6 on 20:3n-6 metabolism has potential nutritional and health importance.

A number of studies have used isotope-labeled 18:3n-6 and 20:3n-6 to investigate the metabolism of 20:3n-6 in animal models and *in vitro* (1,5). The metabolism of 20:3n-6 in human subjects has been investigated in studies from two groups (6,7), and there is no information available for the effect of dietary 20:4n-6 on 20:3n-6 metabolism in man. Of the two human studies that have investigated the metabolism of 20:3n-6, one study investigated the effect of single and multiple oral doses of unlabeled 20:3n-6 on the ratio of 20:3n-6 to 20:4n-6 in plasma, platelet, and red cell lipids of three volunteers. The other study used deuterium-labeled 20:3n-6 to follow incorporation and desaturation in four normal and four diabetic subjects. In neither study was the fatty acid composition of the subjects' diets controlled. Results from both studies provide evidence that in humans the conversion of 20:3n-6 to 20:4n-6 by Δ5 desaturation is low In contrast, Δ5-desaturase activity in rats and mice is much higher than in humans (5,6).

This metabolism study in adult male subjects was part of a dietary arachidonic acid study that investigated the effect of dietary 20:4n-6 on platelet function, eicosanoid production, lipoprotein concentrations, immune status, and the fatty acid composition of plasma, red cell, and adipose lipids. The questions addressed by this report are whether the addition of 20:4n-6 to a human diet alters the desaturation of 20:3n-6 to 20:4n-6, the absorption and incorporation of 20:3n-6 into plasma lipid classes relative to 18:1n-9, or the retroconversion of 20:3n-6 to 18:3n-6 and 18:2n-6.

EXPERIMENTAL PROCEDURES

Deuterated fatty acids. Deuterium-labeled oleic acid (9*cis*-18:1-9,10-d2) and dihomo-γ-linolenic acid (8,11,14-20:3-17,17,18,18-d4) were synthesized, purified, and converted to their ethyl esters by previously described methods (8-10). The isotopic purity for 9*cis*-18:1-9,10-d2 was 79.5% d2, 18.4%

[a]Diets: 2800 total calories; 27.1–27.8 energy percentage (en%) total fat, 15 en% protein, 57 en% carbohydrate.

d1, 2.0% d0 and 93.4% d4, 3.6% d3, 2.9% d5 for 8,11,14-20:3-17,17,18,18-d4. Chemical purity was 98.8% for 9c-18:1-9,10-d2 and 98.3% for 8,11,14-20:3-17,17,18,18-d4. The impurities in these samples were *trans* isomers, and the 20:3-17,17,18,18-d4 sample contained no deuterium-labeled 20:4n-6.

Study design. The subjects were four Caucasian males between the ages of 20 and 28. Medical histories, physical examinations, and clinical blood profile data indicated that the subjects were in good health and had no history of congenital ailments. The subjects' height/weight ratios, blood pressure, fasting serum cholesterol and triglyceride (TG) concentrations were within normal ranges. Serum TG values were 217 and 143 mg/dL, and total cholesterol values were 190 and 139 mg/dL for the subjects in the LO20:4 diet group. Serum TG concentrations were 37 and 64 mg/dL, and total cholesterol was 133 and 146 mg/dL for subjects in the HI20:4 diet group. Institutional ethical approval was obtained for the study protocol from the Agricultural Research Service's Human Studies Review Committee (Washington, D.C.). Informed consent was obtained from each subject prior to initiation of the study.

The subjects were housed in a metabolic ward and provided diets that contained 1.7 g of 20:4n-6 (HI20:4) or 0.21 g of 20:4n-6 (LO20:4). ARASCO® oil (3 g/d), provided by Martek Bioscience Corp. (Columbia, MD), was added as the source of 20:4n-6 in the HI20:4 diet. An equal amount of high-oleic safflower oil (3 g/d) was added to the LO20:4 diet. The subjects were fed these diets for 50 d prior to being fed the mixture of deuterated fatty ethyl esters. The fatty acid composition of the diets is summarized in Table 1. The ARASCO® oil contained 0.025% of tocopherol and 0.025% of ascorbyl palmitate as antioxidants. The peroxide value was 0.4 meq/kg. Analysis by gas chromatography (GC), GC–mass spectrometry (MS), and thin-layer chromatography (TLC) detected only traces of oxidation products. The fatty acid composition of the ARASCO® oil (wt%) was: 0.5% 14:0; 0.2% 15:0; 11.1% 16:0; 0.5% 17:0; 10.6% 18:0; 8.7% 9*c*-18:1; 0.2% 11*c*-18:1; 6.5% 18:2n-6; 3.8% 18:3n-6; 0.9% 20:0; 0.4% 20:1n-9; 0.6% 20:2n-6; 0.6% 5,11,14-20:3; 2.5% 20:3n-6; 49.7% 20:4n-6; 1.6% 22:0; 1.2% 24:0; 0.2% 22:4n-6. Trace amounts of other fatty acids are not listed. Complete detailed information for the diet compositions is described elsewhere (11).

All meals were prepared from weighed food portions and their consumption monitored. Duplicate meals were collected and analyzed for fatty acid composition. Values for total fat, protein, and carbohydrate were obtained by analysis of diet composites. The data used by this computer program are based mainly on the food composition data in a USDA handbook (12). No significant changes in the subjects' weights were observed during the controlled diet period, indicating a stable energy balance. The subjects fasted for 12 h before the experimental meals were fed.

The deuterated 18:1n-9[d2] and 20:3n-6[d4] ethyl esters were mixed with 112 g of no-fat yogurt, and the mixtures were fed between 7:00 and 7:30 a.m. Subjects were provided a no-fat breakfast at 8:00 a.m. to avoid dilution of the labeled fatty acid with exogenous fatty acids. A low-fat (*ca*. 15% fat calories) lunch was provided at 12:00, and the usual diets were fed at 5:00 p.m. and on subsequent days. The amount of deuterated fatty acid ethyl esters in the mixture fed to each subject is given in Table 2. The μmole data for the deuterated fatty ethyl esters fed have been adjusted by multiplying the weighted amounts by their percent isotopic and chemical purity.

Sample collection. Blood samples (*ca*. 14 mL each) were collected by venipuncture at 0, 4, 6, 8, 12, 24, 48, and 72 h for analysis of plasma lipid class fatty acids. Additional blood samples (*ca*. 11 mL) were collected at 2, 4, 6, and 8 h for analysis of the chylomicron total lipid. Standard preparative ultracentrifuge methods (13) were used to separate the chylomicron fraction. An aliquot of the chylomicron samples was analyzed by electrophoresis to confirm the purity of the chylomicron fractions (14).

[a]Data include corrections for isotopic and chemical purity.

Analysis of plasma lipid fatty acids. Plasma total lipids (TL) were extracted with 2:1 chloroform/methanol (15). Preparative TLC was used to isolate TG, cholesteryl ester (CE), and phospholipid (PL) from plasma lipids (16,17). Known weights of triheptadecanoin, cholesteryl heptadecanoate, and diheptadecanyl-*sn*-phosphatidylcholine (Applied Science, State College, PA) were added as internal standards to the TL extract. The 17:0 internal standard data were used to determine the concentrations (μmole/mL) of each deuterated and nondeuterated fatty acid in the plasma lipid classes. Methyl esters of the isolated lipid classes were prepared by heating the samples with a 5% HCl–methanol solution (10). Quantitative analysis of the deuterium-labeled fatty acids incorporated into plasma and lipoprotein lipids was by GC–MS analysis of their methyl esters (18).

Fatty acid percentages and concentrations for both labeled and unlabeled fatty acids were obtained by analysis of their methyl esters with a Hewlett-Packard model 5988A quadrupole mass spectrometer (Palo Alto, CA) operated in a positive chemical ionization mode with isobutane as the ionization reagent. The GC–mass spectrometer was equipped with a Supelcowax 10 fused-silica column (30 m × 0.25 mm; Supelco Inc., Bellefonte, PA) and was temperature programmed from 165 to 265°C at 5°C/min with a 20-min final hold. The GC–MS methodology utilized selected ion monitoring of the appropriate ion masses for the fatty acid in each GC peak. The areas for each of the ion masses monitored were obtained by integration of the peaks. The specific operating conditions and computer-assisted storage and processing of the MS data have been described previously (18,19).

Determination of the weight data for both the isotope-labeled and nonlabeled fatty methyl ester derivatives of the plasma lipid samples was based on the known weight of 17:0 added as an internal standard prior to conversion of the lipid classes to their methyl esters. Response factors were determined by analysis of standard mixtures containing weighed amounts of pure fatty methyl esters purchased from Nu-Chek-Prep Inc. (Elysian, MN) and Applied Science. The accuracy of the GC–MS data was determined by adding known weights of 9*c*-18:1n-9[d2], 20:3n-6[d4], and 20:4n-6[d4] to TG, PL, and CE samples isolated from plasma samples drawn from subjects that were not fed the deuterated fatty ethyl ester mixture. The weight for each of the deuterated fatty esters added was equal to about 0.57% of the total unlabeled fatty acids in the samples. Standard deviations were based on three replicate analyses. The range for the standard deviations for the18:1n-9[d2], 20:3n-6[d4], and 20:4n-6[d4] in the TG, PL, CE spiked samples was 0.005 to 0.008%.

The quantitation of the unlabeled methyl ester data obtained by GC–MS analysis was confirmed by analysis of a subset of samples using a Varian model 3400 gas chromatograph (Varian, Walnut Creek, CA) equipped with a 100 m × 0.25 mm SP2560 fused-silica capillary column (Supelco) and a flame-ionization detector. Operating conditions were: split ratio, 1:100; linear velocity of helium, 21 cm/s; detector and injection temperature, 235°C. Methyl ester GC peaks were identified and quantitation of peak areas was confirmed by analysis of authentic standards and mixtures of known composition.

Statistical analysis and calculations. Data were analyzed with the SAS-PC statistical software package from Statistical Analysis System Institute (Cary, NC). For lipid classes, least square means were compared by analysis of variance and 18:1n-9[d2] vs. 20:3n-6[d4] comparisons used a two-tailed, pairwise *t*-test (20).

The concentrations (μg/mL plasma) of the deuterated fatty acids and their metabolites were calculated by integrating the areas under the time-course curves produced by plotting the deuterated fatty acid data for the eight samples collected between 0 and 72 h, as described previously (21). The values obtained are weighted averages of the eight plasma lipid samples collected over the 72-h time period. Examples of these time-course plots for plasma TG and PL samples from a subject fed the HI20:4 diet are shown in Figures 1 and 2. Plots are included also for percentage enrichment times 100. When the concentration of a lipid class is relatively constant between samples, the curves for percentage enrichment and μg/mL data are generally similar (see Fig. 2), but for TG the concentration of the lipid class varies considerably and percentage enrichment data underestimate the incorporation of the deuterated fatty acids. For this reason, concentration data were used rather than enrichment data to compare the effect of the HI20:4 and LO20:4 diets on incorporation and conversion of the deuterium-labeled fatty acids. The μg/mL data were converted to μmol/mL data and corrected for the differences in the body weight of the subjects and the amounts of

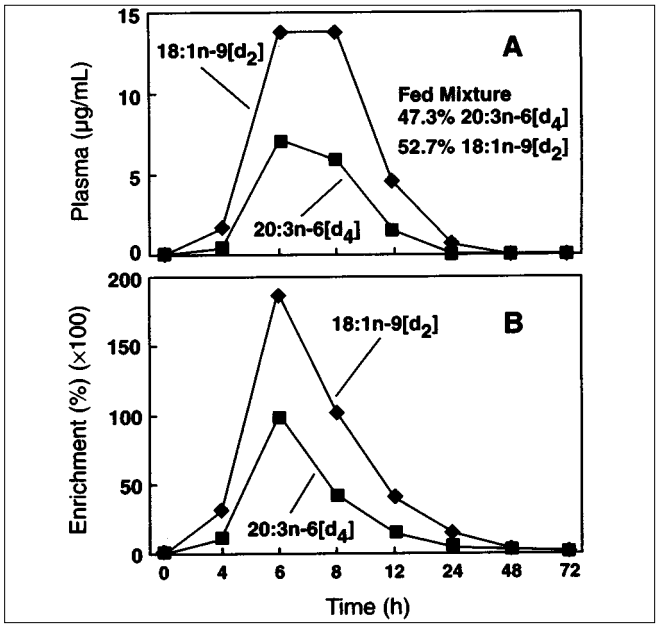

FIG. 1. Time-course plots for incorporation of deuterium-labeled 18:1n-9 and 20:3n-6 into plasma triglyceride samples from subjects fed 1.7 g/d (HI20:4 diet) of 20:4n-6; (A) μmole/mL plasma data; (B) percentage enrichment (×100) of total fatty methyl esters.

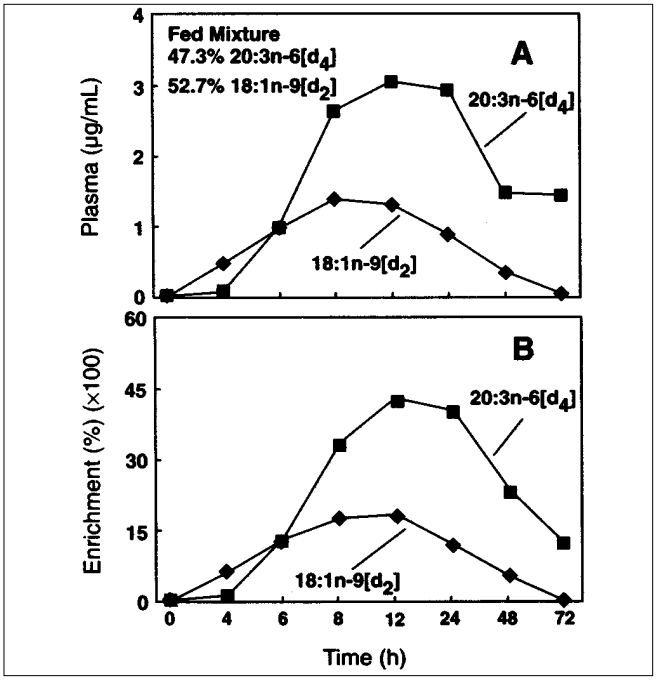

FIG. 2. Time-course plots for incorporation of deuterium-labeled 18:1n-9 and 20:3n-6 into plasma total phospholipid samples from subject fed 1.7 g/d (HI20:4 diet) of 20:4n-6 ; (A) µmole/mL data; (B) percentage enrichment (×100) in total fatty methyl esters.

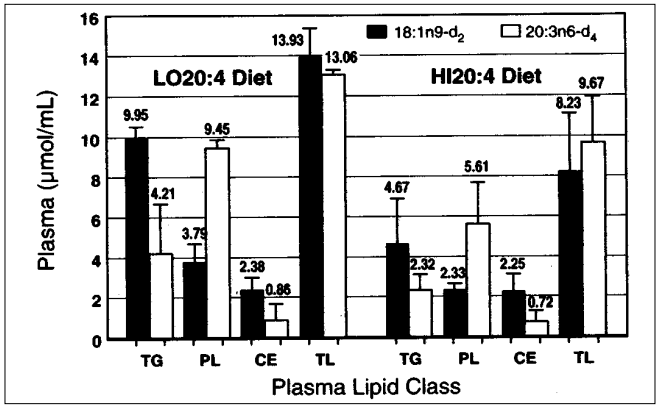

FIG. 3. Concentrations of 18:1n-9[d2] and 20:3n-6[d4] in plasma lipid classes and total lipid from male subjects fed diets containing 0.2 g/d (LO20:4 diet) and 1.7 g/d (HI20:4 diet) of 20:4n-6. Error bars equal standard deviation. Abbreviations: TG, triglyceride; PL, phospholipid; CE, cholesterol ester; TL, total lipid.

deuterated fatty esters fed. This correction was achieved by dividing the µmole/mL plasma data by the mmole of deuterated fatty ester fed per kg of body weight. The total area values obtained from the µmole/mL plasma plots were used to compare the relative uptake and accumulation of deuterated 18:1n-9[d2] and 20:3n-6[d4] fatty acids into plasma lipid fractions and to calculate an estimate of the percentage 20:3n-6[d4] converted to 20:4n-6[d4]. The µmole/mL plasma/mmole deuterated fat fed/kg body weight data was converted to percentage data by dividing the plasma data for individual deuterated fatty acids by the sum of the deuterated fatty acids.

RESULTS

The percentage of deuterated fatty acids in chylomicron TL samples was 57.2 ± 1.77% 18:1n-9[d2] and 42.8 ± 1.77% 20:3n-6[d4] for the subjects fed the HI20:4 diet and 62.7 ± 2.54%18:1n-9[d2] and 37.3 ± 2.54% 20:3n-6[d4] for the subjects fed the LO20:4 diet. The difference between these chylomicron data for the HI20:4 vs. LO20:4 diet groups was not significant at $P < 0.05$. The mean for the chylomicron data from all subjects was 59.9 ± 3.1% for 18:1n-9[d2] and was significantly different ($P < 0.002$) from the mean of 40.1 ± 3.1% for 20:3n-6[d4]. This difference indicates that ethyl 20:3n-6[d4] was about 33% less well absorbed than ethyl 18:1n-9[d2].

The deuterated fatty acid concentrations (µmole/mL) in plasma TL, TG, PL, and CE are plotted in Figure 3. Concentrations of 18:1n-9[d2] and 20:3n-6[d4] in plasma lipid classes for subjects fed the LO20:4n-6 diet were higher than the data for subjects in the HI20:4 diet group, but the data were not significantly different at $P < 0.01$. This lack of a statistically significant effect of diet on the concentrations of the deuterated fatty acids may be the result of a type II error due to the small number of subjects. If a 4-subject per diet group and the same variance as the actual data are assumed, diet would have had a significant effect ($P < 0.01$) on incorporation of 18:1n-9[d2] into TG, PL, and TL but not CE. Also the 20:3n-6[d4] concentrations shown in Figure 3 for plasma TL and PL would have been significantly lower ($P < 0.01$) for the subjects fed the HI20:4 diet compared to the data for the subjects fed the LO20:4 diet. The 20:3n-6[d4] data are consistent with the fatty acid composition data for plasma, red cell, and platelet. Only the total red cell lipids from subjects in the HI20:4 diet group contained a significantly lower ($P < 0.05$) percentage of 20:3n-6 (22). The 20:3n-6[d4] results when combined with the fatty acid composition results indicate that 20:4n-6 dietary supplementation has a limited effect on the incorporation of 20:3n-6 in plasma lipids.

For comparison of 18:1n-9[d2] vs. 20:3n-6[d4] in plasma lipid classes, the concentration of 18:1n-9[d2] was greater than 20:3n-3[d4] in the TG ($P < 0.04$) and CE ($P < 0.012$) fractions, and the concentration of 20:3n-6[d4] in PL was greater ($P < 0.02$) than 18:1n-9[d2]. For TL, the concentrations of 18:1n-9[d2] and 20:3n-6[d4] were not significantly different. The concentrations for 18:1n-9[d2] and 20:3n-6[d4] in plasma TL from subjects fed the LO20:4 diet were significantly higher ($P < 0.005$) than the concentrations of these deuterated fatty acids in TL from subjects fed the HI20:4 diet.

The mean fasting plasma TL concentration of fatty acids was 52% greater (average of 24- and 48-h samples) for subjects from the LO20:4 diet group (3.2 mg/mL) than for subjects from the HI20:4 diet group (2.1 mg/mL). In comparison, the concentrations for the total deuterated fatty acid methyl

esters in plasma TL were 51% greater in subjects from the LO20:4 diet group (27.0 μg/mL) than for the subjects from the HI20:4 diet group (17.9 μg/mL). Since the differences in total plasma lipid concentrations and deuterated fatty acid concentrations were proportional, the difference in the concentration of the deuterated fatty acid concentrations between groups can be explained by the difference between the plasma lipid concentrations of the subjects in the HI20:4 and LO20:4 diet groups.

The μmole/mL data in Figure 3 are replotted as a 100% stacked bar chart in Figure 4 to illustrate the differences between incorporation of the deuterated fatty acids into plasma lipid fractions. The patterns for the concentration data for 18:1n-9[d2] and 20:3n-6[d4] (Fig. 3) and the percentage data (Fig. 4) for the plasma lipid fractions were not influenced by dietary 20:4n-6. The percentage 18:1n-9[d2] in all lipid classes was different from 20:3n-6 at $P < 0.015$. These results suggest that fatty acid structure influenced incorporation and that dietary 20:4n-6 did not influence the selectivity of the acyltransferases for these deuterated fatty acids.

The concentrations of deuterated 20:4n-6 (μmole 20:4n-6[d4]/mL plasma per mmole of 20:3n-6[d4] fed/kg body weight) in plasma TG, PL, CE, and TL are compared in Figure 5 for subjects fed the HI20:4 and LO20:4 diets. For individual lipid classes (TG, PL, CE), the concentrations of 20:4n-6[d4] were two to four times higher in samples from subjects fed the HI20:4 diet than in samples from subjects fed the LO20:4 diet. The differences were significant for PL ($P < 0.03$) and CE ($P < 0.05$) but not for TG. The concentration of 20:4n-6[d4] was about seven times higher in plasma total lipid from subjects fed the HI20:4 diet than in plasma lipids from the subjects fed the LO20:4 diet ($P < 0.001$). In contrast to the concentration data in Figure 3, the difference in the concentration of 20:4n-6[d4] for subjects from the two diet groups was not proportional to the difference in plasma lipid concentration. If the 20:4n-6[d4] data are adjusted for the 50% lower plasma lipid concentration in the subjects fed the HI20:4 diet compared to the subjects fed the LO20:4 diet, the concentration of 20:4n-6[d4] is about 14 times greater for the HI20:4 diet group and reflects the "true" effect of diet.

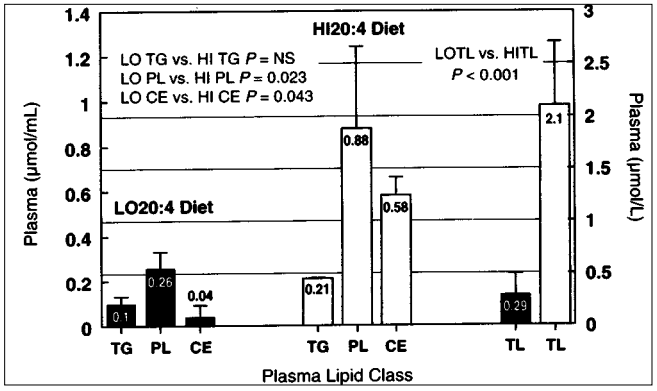

FIG. 5. Concentration of 20:4n-6[d4] in plasma lipids of male subjects fed diets containing 0.2 g/d (LO20:4 diet) and 1.7 g/d (HI20:4 diet) of 20:4n-6. Error bars equal standard deviation. Note that the right side Y-axis scale is used for TL. See Figure 3 for abbreviations.

The effect of diet on the percentage conversion of 20:3n-6[d4] to 20:4n-6[d4] is shown in Figure 6. The percentages for 20:3n-6[d4] conversion were calculated by dividing the 20:4n-6[d4] μmole/mL plasma data by the sum of the 20:3n-6[d4] plus 20:4n-6[d4] μmole/mL plasma data. Percentage conversion based on plasma TL data was 17.7 ± 0.79% for the subjects receiving the HI20:4n-6 diet and 2.1 ± 1.44% for the subjects fed the LO20:4 diet. The 8.3-fold difference in percentage conversion of 20:3n-6[d4] to 20:4n-6[d4] was significant at $P < 0.006$.

The 12-h total PL samples contained the highest concentrations of 20:3n-6[d4]. The percentage enrichment for 20:3n-6[d4] in the 12-h PL samples was 16.8 ± 1.7% for subjects fed the HI20:4 diet and 6.8 ± 1.2% for samples from subjects fed the LO20:4n-6 diet. These percentage enrichment data for 20:3n-6[d4] were significantly different at $P < 0.02$. The 72-h total PL samples contained the highest concentration of 20:4n-6[d4] and the percentage enrichment for

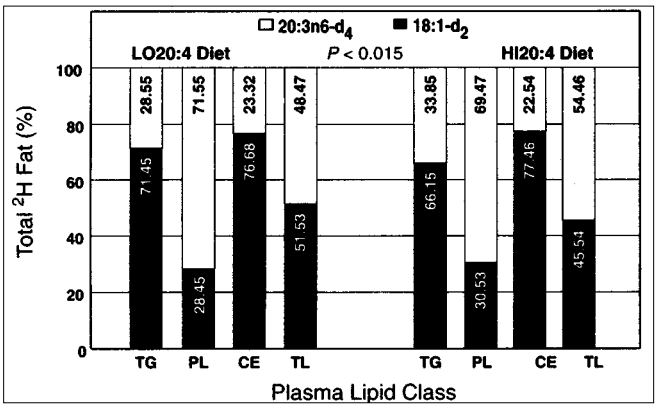

FIG. 4. Percentage of 18:1n-9[d2] and 20:3n-6[d4] in plasma lipid classes and TL from male subjects fed diets containing 0.2 g/d (LO20:4 diet) and 1.7 g/d (HI20:4 diet) of 20:4n-6. See Figure 3 for abbreviations.

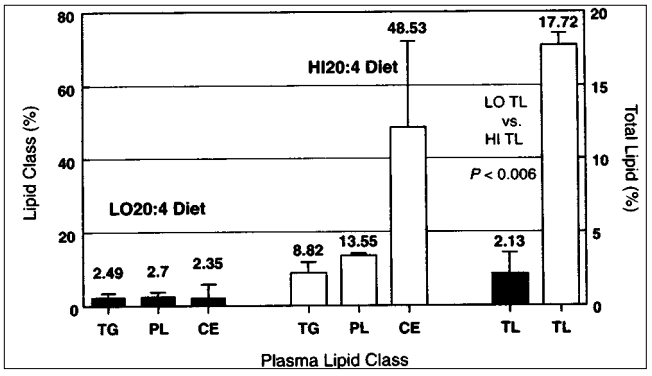

FIG. 6. Percentage conversion of 20:3n-6[d4] to 20:4n-6[d4] in plasma lipid classes and TL from male subjects fed diets containing 0.2 g/d (LO20:4 diet) and 1.7 g/d (HI20:4 diet) of 20:4n-6. Error bars equal standard deviation. See Figure 3 for abbreviations.

20:4n-6[d4] in these 72-h samples was 0.34 ± 0.07% for subjects fed the HI20:4 diet and 0.07 ± 0.054% for subjects fed the LO20:4n-6 diet. The 20:4n-6[d4] percentage enrichment data for the HI20:4 and LO20:4 diet groups were significantly different at $P < 0.05$.

The chain-shortened products (18:3n-6[d4], 18:2n-6[d4], 16:2n-6[d4]) of 20:3n-6[d4] were detected in the plasma lipids of all subjects. The sum of these three products in total plasma lipid from the subjects fed the HI20:4 diet was 0.11 ± 0.01 μmole/mL or 1.1 ± 0.25% of the 20:3n-6[d4]. The total concentration of the chain-shortened products in plasma TL from the subjects fed the LO20:4 diet was 0.37 ± 0.14 or 2.76 ± 0.95% of the 20:3n-6[d4]. The difference between the percent of retroconversion products in plasma TL was not significant. Trace amounts of the 22:3n-6[d4] elongation product of 20:3n-6[d4] and the 22:4n-6[d4] elongation product of 20:4n-6[d4] were detected in 10–15% of the samples. A few samples contained measurable amounts of 22:5n-6[d4], and none of the samples contained detectable amounts of 24:4n-6[d4] or 24:5n-6[d4].

DISCUSSION

Absorption. The absorption of 18- and 20-carbon n-6 and n-3 fatty acids as their ethyl esters, free fatty acids, or TG has been the subject of numerous studies (23). The results from studies that have compared the absorption of unsaturated 18- and 20-carbon fatty acids are not consistent. Studies in humans and rats indicate that 20:5n-3 and 18:1n-9 are equally well absorbed when fed either as their ethyl esters or as TG (24–27) and that 20:4n-6 and 18:1n-9 are equally well absorbed (28), but others have concluded that 20:5n-3 is 30–50% less well absorbed than 18:3n-3 or corn oil (29,30).

The conclusion from this study is that the absorption of ethyl 20:3n-6[d4] was 33% lower than 18:1n-9[d2] which is consistent with results from studies that have compared absorption of 20- to 18-carbon unsaturated fatty acids. Since this conclusion is based on chylomicron TL, there are explanations other than absorption differences that could explain the results. One is that the chylomicron data are a reflection of a more rapid removal of 20:3n-6[d4] than 18:1n-9[d2] from the chylomicron samples. Other possible explanations are that a greater portion of the 20:3n-6[d4] than 18:1n-9[d2] may have been incorporated into intestinally derived very low density lipoprotein TG rather than chylomicron particles or that the absorption of 20:3n-6[d4] was delayed relative to 18:1n-9[d2] in a manner similar to that described for 20:4n-6 (28) .

Incorporation. Owing to the similarity of the patterns for the deuterated 18:1n-9 and 20:3n-6 plasma lipid class data (Figs. 3 and 4), it appears that dietary supplementation with 1.7 g/d of 20:4n-6 for 50 d did not affect the uptake and accumulation of 18:1n-9[d2] relative to 20:3n-6[d4] into plasma lipid classes. For all subjects, the concentration of deuterated fatty acids in the plasma lipid classes was proportional to the concentration of the subject's plasma lipids. Thus the difference shown in Figure 3 for the concentrations of the deuterated fats from the subjects fed the HI20:4 and LO20:4 diets is not believed to be due to the difference in the 20:4n-6 contents of the diets.

The difference in the concentrations of 18:1n-9[d2] and 20:3n-6[d4] in plasma TG, CE, and PL (Fig. 3) and the percentage data shown in Figure 4 illustrate the difference in the selectivity of the TG, PL, and lecithin:cholesterol acyltransferases (LCAT) for 18:1n-9 and 20:3n-6. The difference for accumulation of 18:1n-9[d2] and 20:3n-6n-6[d4] in plasma PL primarily reflects LCAT selectivity and is in contrast to the nonselective incorporation of carbon-14 labeled 18:2n-6 and 20:3n-6 in PL of rat liver microsomes, which reflects acyl CoA cholesterol acyltransferase selectivity (31). Previous results from human subjects fed deuterated 18:1n-9 and 18:2n-6 showed that *in vivo* PL acyltransferase was about 5-fold more selective for 18:2n-6 than 18:1n-9 (32). In this study, the selectivity was 2.44-fold higher for 20:3n-6[d4] than for 18:1n-9[d2]. The combined results from previous studies and this study show that fatty acid chainlength influences n-6 fatty acid accumulation in PL. The high 20:3n-6[d4] to 18:1n-9[d2] ratio of 2.44 in plasma PL is consistent with the recognized high selectivity of PL acyltransferase for n-6 fatty acids. The low 20:3n-6[d4] to 18:1n-9[d2] ratio of 0.34 in plasma CE is consistent with the higher selectivity of LCAT and acyl CoA cholesterol acyltransferase for 18:1n-9 relative to 20:3n-6 and 20:4n-6 (33) and is in contrast to the 18:2n-6 to 18:1n-9 ratio of about 3 in plasma CE for subjects fed deuterated 18:2n-6 and 18:1n-9 (32). The results show that supplementation of diets with 1.5 g/d of 20:4n-6 did not influence significantly the selectivity of the acyltransferases involved in the incorporation of 18:1n-9[d2] and 20:3n-6[d4] into plasma lipids.

Retroconversion. Considerable retroconversion of 20:3n-3 to 18:3n-3 has been observed in mice (18,34), but the retroconversion *in vivo* of 20:3n-6 has not been reported. The approximate 35% retroconversion of deuterated 20:3n-3 observed in mice (18) is in marked contrast to the approximately 2% retroconversion of 20:3n-6[d4] in the human subjects used in this study. The estimate of retroconversion is based on the sum of the deuterated 18-carbon n-6 retroconversion products of 20:3n-6[d4] in total plasma lipid, and it likely underestimates retroconversion because much of the 18:2n-6[d4] and 18:3n-6[d4] chain-shortened products are probably oxidized to acetyl CoA or carbon dioxide. These data indicate also that retroconversion of 20:3n-6[d4] was not significantly influenced by supplementation of the diet with 1.5 g/d of 20:4n-6 for 50 d.

Desaturation. The diet of the LO20:4 subject group contained 0.21 g/d of 20:4n-6 and is probably typical of normal U.S. diets. For these subjects, conversion of 20:3n-6[d4] to 20:4n-6[d4] was low (2.13 ± 1.44%) which is consistent with other reports that humans do not extensively desaturate 20:3n-6 (6,7). The results are also consistent with the low percentage conversion of 18:2n-6 to 20:4n-6 observed in subjects fed deuterated 18:2n-6 (32).

In contrast to the results discussed above, the concentrations of the desaturated product, 20:4n-6[d4], in plasma TL,

TG, PL, and CE were significantly higher for the subjects fed the HI20:4 diet (Fig. 5). Plasma TL percentage conversion data (Fig. 6) suggest that total conversion of 20:3n-6[d4] to 20:4n-6[d4] increased by 8.3-fold when the 20:4n-6 content of the diet was increased to 1.7 g/d. Plasma TL concentration data show a 7.2-fold difference in the amount of 20:4n-6[d4]. The size of this difference for total conversion of 20:3n-6[d4] to 20:4n-6[d4] indicates that a relative small increase (1.5 g/d) in 20:4n-6 intake may markedly influence the 20:3n-6 to 20:4n-6 ratio in tissues and has the potential to produce a change in the amount of eicosanoids synthesized.

The reason the relative pattern of the percentage conversion data in Figure 6 for the individual lipid classes is different from the pattern for the concentration data in Figure 5 is that calculation of the estimated percentage conversion is dependent on the amount of both 20:4n-6[d4] and 20:3n-6[d4]. For example, in Figure 6 the percentage conversion for CE is larger than for PL because the concentration of 20:3n-6[d4] in CE is small rather than because 20:4n-6[d4] is large.

For subjects fed the LO20:4 diet, the μmole/mL plasma data and percentage data in Figures 5 and 6 are consistent with the low conversion of 20:3n-6 observed with rabbit and hamster models relative to rat and mouse models which have higher Δ5-desaturase activity than rabbits, hamsters, and humans (6). Comparison of the HI20:4 and LO20:4 diet data indicates that, in humans, conversion of 20:3n-6[d4] to 20:4n-6[d4] by Δ5 desaturation was stimulated by dietary supplementation with 1.5 g/d of 20:4n-6 for 50 d. These *in vivo* data in humans are supported by results from cell culture studies that report a 40–50% higher conversion of 18:2n-6[^{14}C] to 20:4n-6[^{14}C] with cells incubated in media containing added 20:4n-6 (35–37).

Classical enzyme kinetic theory suggests that dietary 20:4n-6 intake should influence the metabolism of 20:3n-6 due to the substrate–product relationship. Thus classical theory would predict that an increase in dietary 20:4n-6 should reduce conversion of 20:3n-6[d4] to 20:4n-6[d4] because of product feedback inhibition. Since stimulation of 20:3n-6 conversion to 20:4n-6 by dietary 20:4n-6 supplementation cannot be explained by simple enzyme kinetic data, our results suggest that conversion *in vivo* of 20:3n-6 to 20:4n-6 is controlled by mechanisms other than or in addition to the rate of Δ5 desaturation.

It is known that Δ5 desaturase prefers the CoA thioester derivative of 20:3n-6 as a substrate rather than 1-acyl-2-eicosatrienoyl-*sn*-glycerol-3-phosphorylcholine (38). Also, most of the 20:3n-6 in tissue lipids is in the 2-acyl position of PL (1,5,32), and 20:3n-6, like 20:4n-6, is conserved by an efficient deacylation–reacylation mechanism that rapidly reincorporates these fatty acids into PL after hydrolysis (39). The combined effect of these observations suggests that most of the 20:3n-6 and 20:4n-6 in tissue lipids are "locked" into PL structures, and only small amounts are available as substrates for other reactions.

Thus, we propose as a working hypothesis that an increase in dietary 20:4n-6 increases the PL deacylation–reacylation reaction rates or the turnover rate for 20:3n-6 and 20:4n-6. A higher turnover rate would increase the availability in the free fatty acid pool of 20:3n-6[d4] that had been incorporated into PL and thus allow formation of its CoA derivative and its subsequent desaturation. This sequence could explain the increased conversion of 20:3n-6[d4] to 20:4n-6[d4] that was observed. The possibility that dietary 20:4n-6 greatly increased the direct desaturation of the 20:3n-6[d4] incorporated into the PL pool is unlikely because supplementation with 20:4n-6 did not have a significant effect on the μmole of 20:3n-6[d4] incorporated per mg of total PL. In contrast, the percentage enrichment for 20:3n-6[d4] in plasma total PL for the HI20:4 diet group subjects was 2.5-fold higher than for the LO20:4 diet group. This difference indicates that dietary supplementation with 20:4n-6 increased the turnover rate of 20:3n-6 in the PL pool. The percentage enrichment for 20:4n-6[d4] was 5-fold higher for samples from subjects fed the HI20:4 diet which is additional evidence in support of a higher turnover rate.

The implication of the results from this study is that, if dietary 20:4n-6 intake is low, dietary 20:3n-6 should increase the 20:3n-6 to 20:4n-6 ratio in tissue lipids because the 20:3n-6 levels would increase, but the 20:4n-6 levels would not greatly increase. This change in the 20:3n-6 to 20:4n-6 ratio might in turn influence the production or balance of eicosanoids synthesized from these fatty acids. If the dietary intake of 20:4n-6 is high, supplementation with 20:3n-6 could paradoxically lower rather than increase the 20:3n-6 to 20:4n-6 ratio owing to enhanced conversion of 20:3n-6 to 20:4n-6. However, the effect of dietary supplementation with large amounts of 20:3n-6 on 20:3n-6 conversion to 20:4n-6 and on 20:4n-6 metabolism is not known. Nevertheless, the results from this study on the incorporation, absorption, and conversion of 20:3n-6[d4] to 20:4n-6[d4] illustrate that there is still much that needs to be learned about the effect of dietary n-6 fatty acids and the regulation of their metabolism.

ABSTRACT: Arachidonic acid (AA) is a precursor of eicosanoids, which influence human health and the *in vitro* activity of immune cells. We therefore examined the effects of dietary AA on the immune response (IR) of 10 healthy men living at our metabolic suite for 130 d. All subjects were fed a basal diet containing 27 energy percentage (en%) fat, 57 en% carbohydrate, and 16 en% protein (AA, 200 mg/d) for the first and last 15 d of the study. Additional AA (1.5 g/d) was incorporated into the diet of six men from day 16 to 65 while the remaining four subjects continued to eat the basal diet. The diets of the two groups were crossed-over from day 66 to 115. *In vitro* indexes of IR were examined using the blood samples drawn on days 15, 58, 65, 108, 115, and 127. The subjects were immunized with the measles/mumps/rubella vaccine on day 35 and with the influenza vaccine on day 92. Dietary AA did not influence many indexes of IR (peripheral blood mononuclear cell proliferation in response to phytohemagglutinin, Concanavalin A, pokeweed, measles/mumps/rubella, and influenza vaccines prior to immunization, and natural killer cell activity). The post-immunization proliferation in response to influenza vaccine was about fourfold higher in the group receiving high-AA diet compared to the group receiving low-AA diet ($P = 0.02$). Analysis of variance of the data pooled from both groups showed that the number of circulating granulocytes was significantly ($P = 0.03$) more when the subjects were fed the high-AA diet than when they were fed the low-AA diet. The small increases in granulocyte count and the *in vitro* proliferation in response to influenza vaccine caused by dietary AA may not be of clinical significance. However, the lack of any adverse effects on IR indicates that supplementation with AA may be done safely when needed for other health reasons.

Lipids 32, 449–456 (1997).

Both the concentration and type of dietary fat have been reported to alter immune response (IR) in several human studies. Decreasing the amount of fat in the diet enhanced several indexes of IR, and the converse was true when fat intake was increased (1–3). Supplementing diets with n-3 polyunsaturated fatty acids (PUFA) from flaxseed or fish oils inhibited several indexes of IR (4–7), while a moderate increase in the intake of n-6 PUFA inhibited IR in some but not in other studies(1–3,8). The source of n-6 PUFA used in the above studies was oils rich in linoleic acid (LA), which can be converted to arachidonic acid (AA) in healthy individuals through desaturation and chain elongation. LA can have some direct effects on metabolic functions, but most of its effects are due to its conversion to AA. AA is one of the major fatty acids of the membranes and is a precursor for eicosanoids. Dietary AA is not required for humans, but it has been reported to alter tissue fatty acid composition and the eicosanoids produced in humans (9,10). Results from a study with Syrian hamsters indicate that dietary AA was metabolized differently from the endogenously synthesized AA (11). Addition of AA or its metabolites to cultured immune cells altered their activity and the eicosanoids produced *in vitro* (12–17). These studies suggest that AA and its metabolites may play an important role in modulating IR, and that the metabolism of AA may be altered depending on its source.

There is currently no recommended daily allowance (RDA) for AA or other fatty acids for humans. Diets rich in eggs and organ meats are high in AA. The estimates for the daily intake of AA in the United States for adults consuming eggs and meats range from 200–1000 mg with an average of about 500 mg (18,19). Others, however, have estimated the daily intakes of AA from Western diets to range from 100–500 mg (20–23).

No human or animal studies have examined the effects of dietary AA on IR. The purpose of this study was to examine the effects of dietary AA on several indexes of human IR, particularly the adverse consequences from the increased intake of AA. Considering the safety of the subjects and the minimum amount of AA needed to perturb the tissue fatty acid composition, we modified the diets of 10 healthy men to contain additional AA (1.5 g/d for 50 d) using a crossover design. The indexes of IR examined in this study were those that have previously been shown to be affected by the amount and type of dietary fat; these included lymphocyte

MATERIALS AND METHODS

Subjects, protocol, and diets. The research protocol and informed consent form were approved by the Institutional Review Board of the University of California, Davis, and by the Human Studies Review Committee of the Agricultural Research Service, U.S. Department of Agriculture (Washington, D.C.). Twelve healthy men (ages 20–38 yr) were selected to participate in the study after medical and physiological screening. Only subjects that were nonsmokers, had no history of alcohol or drug abuse, had moderate physical activity and body weight within −10 to +20% of ideal body weight, and had hematological and chemical measurements within normal ranges were included in the study. Data from two subjects, who did not complete the study, were not included.

The participants lived and ate all meals at the Western Human Nutrition Research Center (WHNRC) (San Francisco, CA) for 130 d (August 14–December 22, 1994). All subjects consumed the basal/reference (low-AA) diet during the first 15 d (metabolic period 1, MP1). For the next 50 d (MP2), six subjects (Group 1) consumed the high-AA diet and the other four (Group 2) continued to consume the basal diet. Diets of the two groups were switched on day 66, and the new diets were fed between days 66 and 115 (MP3). Both groups were fed the low-AA diet between days 116 and 130 (MP4). Body weights of the subjects were maintained constant throughout the study by adjusting the caloric intake and by maintaining a constant physical activity. All subjects went for two two-mile walks every day. Blood samples from the subjects were collected on days 16, 58, 65, 108, 115, and 127 to study *in vitro* indexes of IR. All subjects were immunized with measles/mumps/rubella (MMR) vaccine on day 35 and with influenza vaccine on day 92. Antigens for DTH skin response were injected into all subjects on days 65 and 115.

Both diets were composed of natural foods and were adequate in all nutrients. Diets were fed on a 5-d rotating menu with three meals and two snacks every day. The planned percentage of energy from carbohydrate, fat, and protein in both diets was 55, 30, and 15% respectively. The 30% calories from fat in the basal diet were intended to come 10% from each of the saturated, monounsaturated, and n-6 PUFA. On an average, the basal diet provided 200 mg AA and 250 mg cholesterol every day. The calculated level of vitamin E in both diets was at twice the RDA for this nutrient. ARASCO® oil, a gift from Martek Biosciences Corporation (Columbia, MD), was the source of additional AA for the high-AA diet. This oil is purified from algae and contains fatty acids as natural triglycerides. Its fatty acid composition by weight percentage is AA 50, palmitic acid 9, stearic acid 14, oleic acid 9, linoleic acid 6, γ-linolenic acid 4, homo-γ-linolenic acid 3, and other fatty acids 5. AA (1.5 g/d from 3 g of ARASCO® oil) was incorporated into the diets by replacing an equivalent amount of the monounsaturated fat from the basal diet. ARASCO® oil was kept at −20°C under nitrogen until ready to be served in cold yogurts or salad dressings. Other details of the study design are given in a preceding paper in this journal volume (24).

Laboratory procedures. Blood samples were collected by antecubital venipuncture into evacuated tubes containing heparin for cell culture experiments, or EDTA for blood cell count and phenotypic analysis, or without anticoagulants for preparation of sera. Blood samples for all subjects were collected after an overnight fast, between 0700 and 0800 h.

Blood cell count and lymphocyte phenotypic analysis. For each blood draw, a complete and differential cell count was performed by using a Serono Baker Automated system (model 9000 diff; Allentown, PA). Phenotypic analysis of the various lymphocyte subsets was done using Becton-Dickinson FACStar flow cytometer (San Jose, CA). Whole blood collected in EDTA-containing vacutainer tubes was transferred into tubes containing fluorochrome-labeled monoclonal antibodies against specific cluster differentiation (CD) antigens. After incubation for 30 min, the red cells were lysed with formaldehyde and removed by washing the leukocytes twice with Dulbecco's phosphate buffered saline without calcium and magnesium. The stained lymphocytes were fixed in 1% paraformaldehyde prior to analysis with the flow cytometer. The percentage of lymphocytes of a given phenotype was determined from a total of 10,000 lymphocytes counted.

Isolation and culture of peripheral blood mononuclear cells (PBMNC). The PBMNC were isolated using Histopaque-1077 as previously reported (25). The culture medium used was RPMI-1640, (Gibco, Grand Island, NY) containing 10% autologous serum and L-glutamine (2 mmol/L), penicillin (100 KU/L), streptomycin (100 mg/L), and gentamicin (20 mg/L). One hundred μL of the culture medium containing 1×10^5 PBMNC was inoculated in each well of a 96-well flat-bottom culture plate. An additional 100 μL of the culture medium with or without the mitogens was added to each well. The mitogens used were phytohemagglutinin (PHA), Concanavalin A (Con A), and pokeweed (all from Sigma Chemical Co, St. Louis, MO). Each mitogen was used at two concentrations; final concentrations (mg/L) in the culture media were 10 and 20 for both PHA and Con A, and 0.005 and 0.05 for pokeweed. Separate cultures of PBMNC were also stimulated with influenza and MMR vaccines at three different concentrations (1:250, 1:500, 1:1000 dilutions). Trivalent influenza virus vaccine (Fluzone, 1993–1994 Formula) was from Connaught Laboratories Inc. (Swiftwater, PA) and the MMR live vaccine, MSD, was from Merck, Sharp & Dohme (West Point, PA). PBMNC stimulated with mitogens were cultured for 72 h and those stimulated by antigens for 120 h; [^{3}H] thymidine, 37 K Bq, in 50 μL, was added to each well during the last 24 h. PBMNC were collected on filter strips and the radioactivity was determined using a Packard β-gas counter. The [^{3}H]thymidine incorporation into cellular DNA (Bq/1000 cell) was used as the index of PBMNC proliferation.

Determination of NK cell activity. A fraction of the PBMNC isolated above was suspended in serum-free RPMI to a final concentration of $3–5 \times 10^6$/mL to be fractionated for determining NK cell activity. PBMNC suspension (3 mL) was mixed with 7 mL of RPMI 1640 containing 10% fetal bovine serum (FBS), and incubated in T75 culture flasks for 1 h at 37°C in a 5% CO_2 incubator. Parallel flasks with the addition of interleukin-2 (IL-2) (30,000 IU/L) and interferon γ (INF_γ, $I \times 10^6$ IU/L) to stimulate NK cell activity were also prepared. After 1 h incubation, the flasks were gently shaken and the nonadherent cells were transferred into 15-mL conical tubes and centrifuged for 5 min at $500 \times g$. The pellet was resuspended in 1 mL RPMI containing 10% FBS, and cell concentration determined, and adjusted to 6.6×10^6/mL. ^{51}Cr-labeled K-562 cells were used as the target cells, and their concentration was determined by using the Elzone Particle Counter (Particle Data Inc., Los Angeles, CA). The cell concentration was adjusted to 2×10^5 cells/mL with RPMI 1640 containing 10% FBS. Cell suspension (50 μL) containing 10,000 of K-562 cells was added to each well of the 96-well round-bottom plates. The nonadherent PBMNC isolated above were then added at concentrations of $(0.50, 0.25, 0.125, 0.063, 0.031) \times 10^6$ to each well of the 96-well plate to give effector/target cell ratios of 50:1, 25:1, 12.5:1, 6.2:1, and 3.1:1. Six wells were used for each effector cell concentration and for the spontaneous and maximum release (caused by 3% centrimide) of ^{51}Cr.

Plates were incubated for 4 h at 37°C in 5% CO_2 and then centrifuged for 10 min at $200 \times g$. The supernatant (100 μL) was removed from each well into vials and the radioactivity released was determined by using a Packard gamma counter (Hewlett-Packard, Palo Alto, CA). Percentage lysis was calculated in Equation 1.

$$\% \text{ lysis} = \frac{(\text{experimental cpm} - \text{spontaneous cpm})}{(\text{maximum cpm} - \text{spontaneous cpm})} \times 100 \quad [1]$$

DTH. DTH response to seven recall antigens was assayed by intradermally injecting 0.1 mL of each antigen solution into the forearm. The antigens used were tuberculin purified-protein derivative (one international test unit), mumps (four complement-fixing test units), tetanus toxoid (1:100, vol/vol dilution of a solution containing four flocculation units/0.5 mL), candida (1:100, vol/vol dilution), trichophyton (1:30, vol/vol dilution), streptokinase streptase (100 KU/L), and coccidioidin (bioequivalent to U.S. reference coccidioidin 1:100; provided by the Office of Biologics, Food and Drug Administration, Washington, D.C.). The antigens were diluted with a diluent containing, per liter, 3 mL normal human serum and 9 g sodium chloride. Tuberculin purified-protein derivative, mumps, and tetanus toxoid were supplied by Connaught Laboratories Inc. (Swiftwater, PA). Candida (Dermatophyton O), trichophyton, and the antigen diluent were obtained from Hollister Stier (Spokane, WA). Streptokinase streptase, and coccidioidin were purchased from Behringwereke Ag (Marburg/Lahn, Germany) and Berkeley Biologicals (Berkeley, CA), respectively. Response to these antigens was determined by measuring mean induration diameters (mm) at 48 and 72 h after injections. Induration diameters with less than 4 mm were scored negative. Data are reported as the sum of induration diameters for all positive responses (induration score) and the number of positive responses to the seven antigens (antigen score).

Data analysis. The data were analyzed with analysis of variance by using SAS/STAT PROC GLM (26). The crossover design model included effects of order, subject (order), period, and diet, using subject (order) as an error term for order. If the period effects were not significant, the data from two groups were pooled (e.g., leukocyte counts), otherwise analyzed separately (e.g., DTH skin response, NK cell activity, and PBMNC proliferation in response to mitogens). The significance of the differences between the effects of the two diets was assessed from the *P* values for the diet main effects. The data from the two groups were analyzed separately using a paired *t*-test when the treatment was given only during one period, such as immunization with MMR or influenza vaccines. Changes in the variables examined are considered significant for $P < 0.05$ or otherwise stated.

RESULTS

As stated in the Materials and Methods section, the 10 subjects included in this study were divided into two groups. The high-AA diet was fed to subjects in Group 1 ($n = 6$) from study days 16 to 65, and to those in Group 2 ($n = 4$) from study days 66 to 115. The mean ± SEM for age (yr), weight (kg), height (cm), and body mass index (kg/m^2) for subjects in Groups 1 and 2 were 31.2 ± 3.2 and 32.2 ± 2.9, 73.8 ± 2.4 and 71.0 ± 5.4, 177.4 ± 3.6 and 175.5 ± 1.8, 23.8 ± 1.8 and 23.0 ± 1.3, respectively. None of these parameters was statistically different between the two groups.

Dietary intake data prior to entering the study were not collected; however, all subjects consumed a typical American diet, which provides 35–40% calories from fat. The mean daily intake of nutrients from the low- and high-AA diets are shown in Table 1. These intakes are based on an average daily intake of 2800 kcal, which did not differ between the two diets or two groups. The proximate analysis for the macronutrients showed that the energy percentage (en%) from the protein, fat, and carbohydrate were not different between the two diets. These analyzed values were 27, 57, and 16 en% from fat, carbohydrate, and protein, respectively, which were close to the planned values of 30, 55, and 15% respectively.

The weight percentage fatty acid compositions of the two diets are shown in Table 2. While there are minor differences in the concentration of other fatty acids between the two diets, the major difference is in the concentration of AA, which is nine times higher in the AA diet than in the basal diet. The high-AA diet contained about 2% less oleic acid than that found in the low-AA diet.

White blood cell counts and lymphocyte subsets. The data

TABLE 1
Mean Daily Nutrient Intake[a]

Nutrient	Low-AA diet	High-AA diet
Protein		
(g)	104.6 ± 3.1	106.0 ± 5.3
(% of energy)	15.8 ± 0.5	15.2 ± 0.8
Total fats		
(g)	91.6 ± 4.7	85.2 ± 6.7
(% of energy)	27.1 ± 1.5	27.9 ± 2.2
Carbohydrates		
(g)	388.7 ± 9.8	401.8 ± 11.1
(% of energy)	57.1 ± 1.4	57.0 ± 1.6
Ash (g)	17.0 ± 1.3	19.5 ± 1.6
Copper (mg)	1.27	1.26
Iron (mg)	23.5	22.1

[a]Mean ± SEM (n = 5). Proximate analysis was performed on a composite sample of each diet prepared for each day of the 5-d rotating menu. For copper and iron, analysis was done on pooled samples from the individual composites; AA, arachidonic acid.

for leukocyte counts (Fig. 1) and lymphocyte subsets (not shown) could be pooled from all 10 subjects to determine the effects of the two diets, since the period effects (carryover) for these variables were not significant. The rank transformation was used to stabilize the subject variances among groups and periods, so the difference is in terms of means of ranks. For the diet effect, the crossover analysis of variance model tested the difference between the average of the high-AA diet and the low AA-diet. Figure 1 shows that compared to the baseline values the number of circulating leukocytes increased during the study in both groups, but the difference between the high- and low-AA diets did not attain statistical significance (P = 0.1). This increase in leukocyte numbers was primarily due to the increase in circulating granulocytes (Fig. 1), and the number of circulating monocytes and lymphocytes did not change (not shown). The increase in the number of circulating granulocytes was significantly (P = 0.03) higher when the subjects were fed the high-AA diet than when they were fed the low-AA diet.

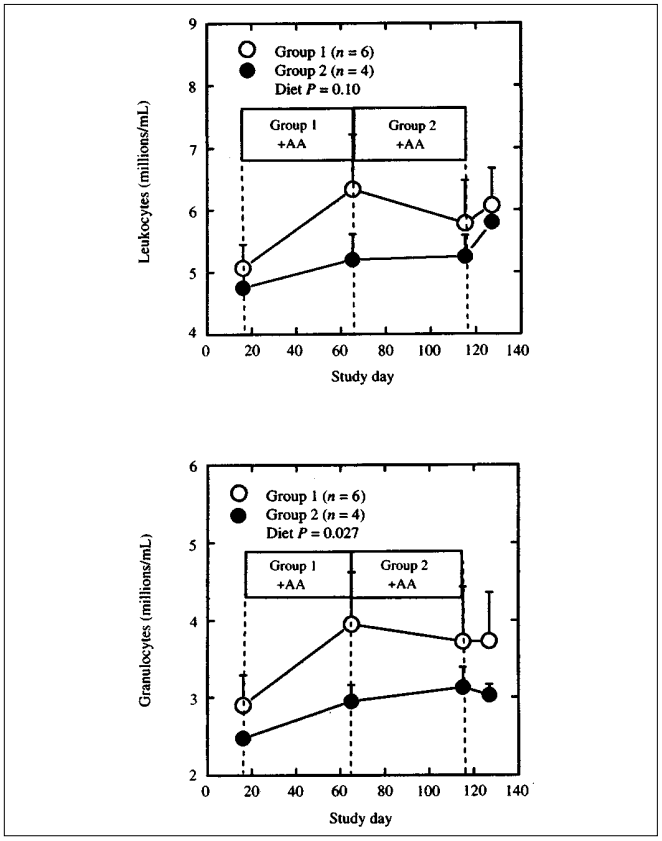

FIG. 1. Effect of low- and high-arachidonic acid-(AA) diets on the number of circulating leukocytes and granulocytes. Mean ± SEM. Group 1 was fed high-AA diet between days 16 and 65 and group 2 between days 66 and 115; low-AA diet was fed for all other days. Crossover analysis of variance model for the rank transformed data showed a significant (P = 0.027) difference between the number of circulating granulocytes when subjects were fed the high- vs. the low-AA diets, while the increase in the number of leukocytes was not significant (P = 0.1).

[a]Mean ± SEM (n = 5); n.d. = none detected; DMA = dimethyl acetal of (9*Z*)-octadecenal. See Table 1 for abbreviation.

Proliferation of PBMNC cultured with antigens and mitogens. Proliferation of PBMNC cultured with three different dilutions (1:250, 1:500, and 1:1000) of influenza vaccine are shown in Figure 2. This figure shows that prior to *in vivo* immunization the proliferation of PBMNC cultured with all three dilutions of the vaccine did not differ between the two groups, and that it significantly increased in both groups following *in vivo* immunization on day 92. The increases in PBMNC proliferation were, however, different between the two groups. For Group 1 consuming the low-AA diet, the maximum increase in proliferation caused by the influenza vaccine was about 100%, with P values of 0.355, 0.047, and

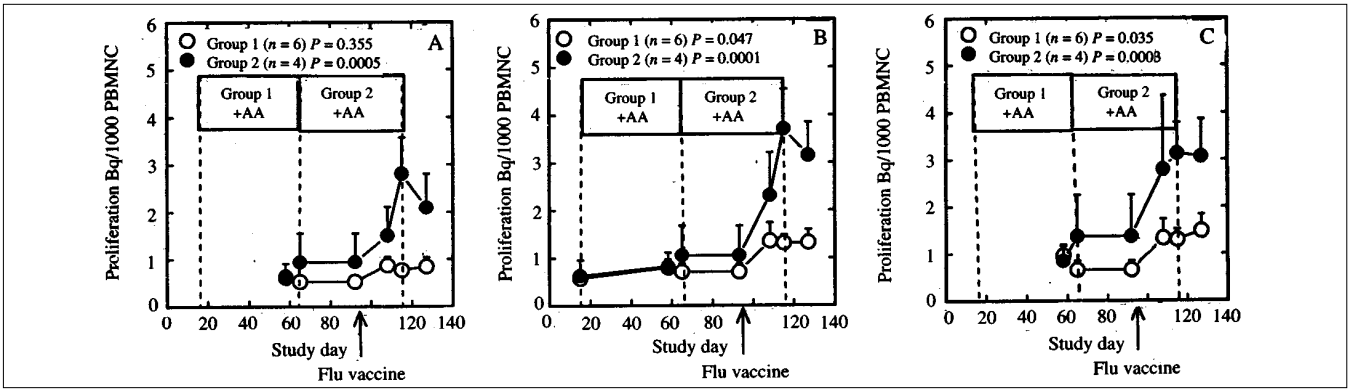

FIG. 2. Effect of low- and high-AA diets on the proliferation of peripheral blood mononuclear cells (PBMNC) cultured with influenza vaccine. X ± SEM. Diet schedule same as in the legend to Figure 1. Analysis of variance showed no difference between the two groups prior to the *in vivo* immunization on day 92. After the *in vivo* immunization, proliferation increased in both groups, and the increase was significantly ($P = 0.02$) higher in group 2 than in group 1. See Figures 1 and 2 for other abbreviations. Dilutions: (A) 1:1000 (B) 1:500 (C) 1:250.

0.035 at the vaccine dilutions of 1:1000, 1:500, and 1:250, respectively. For Group 2, which was consuming the high-AA diet, the maximum increase in PBMNC proliferation in response to influenza vaccine was about 400% and the *P* values for the three dilutions of the vaccine were 0.0005, 0.0001, and 0.0003. The difference between the two groups in PBMNC proliferation *in vitro* after *in vivo* immunization with the influenza vaccine was significant ($P = 0.02$). The three dilutions of MMR vaccine that were tested (1:1000, 1:500, and 1:250) failed to stimulate *in vitro* PBMNC proliferation above the basal level both at pre- and postimmunization with this vaccine (not shown).

Figure 3 contains the data regarding proliferation of PBMNC cultured with three different mitogens: PHA and Con A (20 mg/L) and pokeweed (0.05 mg/L). These concentrations caused the maximum proliferation of PBMNC for each mitogen. This figure shows that PBMNC proliferation in response to PHA and Con A was different in the two groups at the start of the study; however, by the end of the study, the proliferation levels in the two groups were not different. There was no effect of dietary AA on PBMNC proliferation in response to all three mitogens in both groups. The basal diet, however, caused significant increases in PBMNC proliferation in response to Con A and pokeweed in both groups and PHA in Group 2 only. Results obtained with the second concentration of these mitogens (10 mg/L for PHA and Con A, and 0.005 mg/L for pokeweed, not shown) were similar to those shown in Figure 3. The proliferation of PBMNC cultured without mitogens was about 1% of that obtained with pokeweed (not shown). No effect of AA or basal diet could be detected on the proliferation of PBMNC cultured without mitogens.

DTH. All 10 subjects responded to tetanus and mumps, six to candida, three to trichophyton, and two to each of streptokinase, tuberculin, and coccidioidin.The cumulative induration scores determined 48 h after the application of DTH antigens for Group 1 at day 65 and day 115 were 20.1 ± 4.2 and 46.6 ± 13.3 mm (mean ± SEM), and for Group 2 were 31.9 ± 6.1 and 54.2 ± 10.1 mm. The corresponding antigen scores (number of antigens testing positive) for Group 1 were 2.33 ± 0.42 and

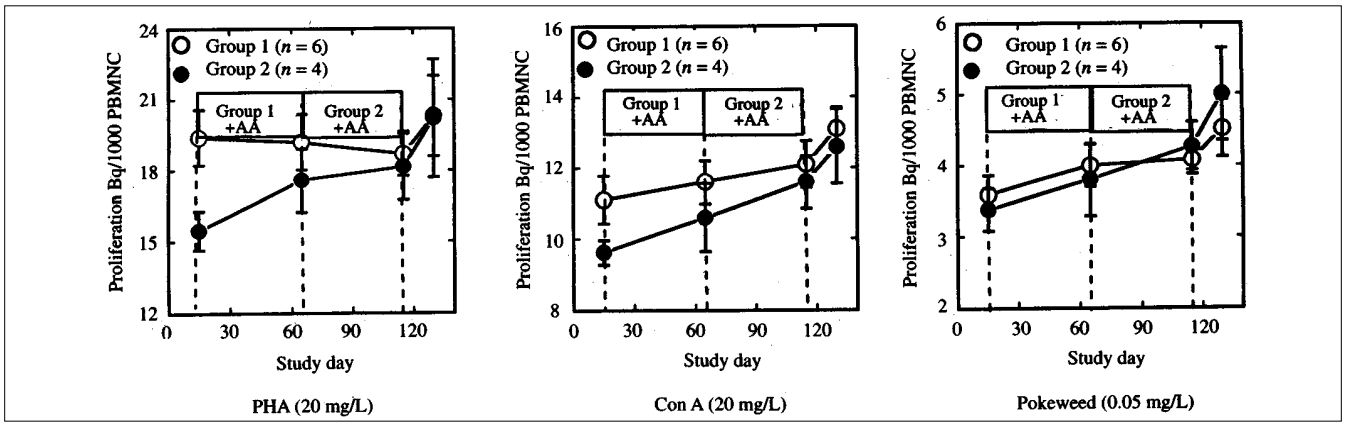

FIG. 3. Effect of low- and high-AA diets on the proliferation of PBMNC cultured with mitogens. X ± SEM. Diet schedule same as given in the legend to Figure 1. Analysis of variance showed no effect of AA on all variables included in this figure; however, there was a significant ($P < 0.05$) increase with time for all variables except the phytohemagglutinin response in group 1.

3.17 ± 0.6, and for Group 2 were 3.25 ± 0.48 and 3.75 ± 0.85, respectively. In both groups, induration and antigen scores on day 115 were higher than those on day 65. This was perhaps caused by the low-fat basal diet. There was no difference in the induration and antigen scores between the subjects fed the high- or low-AA diet. Induration results obtained at 72 h were similar to those at 48 h in Group 1, but in Group 2 the difference between the induration found on days 65 and 115 was not significant (not shown).

NK cell activity. In both groups of subjects, the basal level (unstimulated) NK cell activities determined at effector/target ratios of 50:1, 25:1, 12.5, 6.25:1, and 3.1:1 did not change during the study from their values at study day 16 (not shown). These data suggest that NK cell activities were not affected by the low- and high-AA diets. Incubation of NK cells *in vitro* with IL-2 and INFγ caused a 30–35% increase in the percent lysis caused by them at all effector/ target cell ratios when compared to the corresponding percent lysis caused by nonstimulated cells. However, again there was no effect of the low- or high-AA diet on NK cell activity.

DISCUSSION

In this study, we attempted to define the effect of dietary AA on human IR by feeding a natural triglyceride of AA. We had intended to feed AA at 3.0 g/d for 50 d, but in order to minimize health risk to the subjects, the Human Use Committee approved only 1.5 g/d. The study was designed assuming that there will be no period effect (effect of basal diet or that of the residual AA fed in the previous period), and that data from all subjects could be pooled. However, the statistical analysis of the data showed that for several of the variables there were significant period effects, for which the data from two groups had to be analyzed separately. Our results show that dietary AA significantly increased the number of circulating granulocytes, and the secondary response to influenza vaccine. Several other indexes of IR, including DTH skin response, PBMNC proliferation in response to PHA, Con A, and pokeweed, NK cell activity, number of circulating lymphocytes bearing markers for B and T cells, helper, suppressor, cytotoxic, and NK cells were not affected by the additional intake of AA. The cumulative effect of AA used in this study may actually be lower than that of AA-rich diets based on eggs and meats eaten for years. Lymphocyte proliferation in response to mitogens, and the number of circulating leukocytes were increased by both the low- and high-AA diets when compared to the corresponding values at the start of the study (day 16). The DTH response at day 115 was also significantly higher than the corresponding values on day 65 in both groups of subjects. Some of these changes may be due to the low-fat nutritionally balanced basal diet, as we previously observed (1,2).

We are not aware of any human or animal studies where AA consumption has been reported to increase the number of circulating granulocytes (neutrophils). However, injection of AA metabolites [prostaglandin E (PGEs) and leukotrienes] into human skin induced a dose-dependent erythema by increasing the supply of blood to the inflamed site (27–29). The circulating neutrophils are thought to be in dynamic equilibrium with their marginating pools. Neutropenia can be caused by inflammatory factors like endotoxin and C5a (30,31), and neutrophilia can be caused by exercise or adrenaline infusion (32). Leukotriene B_4 (LTB_4) is a chemoattractant for neutrophils, and addition of AA *in vitro* has been found to enhance neutrophil chemotaxis and diapedesis (33). The increase in the consumption of AA in our study may have increased the circulating levels of LTB_4 and other chemoattractant AA metabolites, which may have led to the increase in the number of circulating neutrophils. There also appears to be an AA-independent increase in the number of circulating neutrophils, which was the difference in the values at the end of the low-AA diet and at the end of the stablization period. This increase could have been caused by several factors, including a latent infection, confinement stress, increased exercise, and the effects of dietary components other than AA. We believe it was most likely due to the daily four-mile walks, as exercise has been reported to increase the number of circulating neutrophils (32).

Prior to immunization with the influenza vaccine, the proliferation of PBMNC stimulated with the same vaccine *in vitro* was comparable between the subjects fed the low- and high-AA diets (Fig. 2). However, following *in vivo* immunization, the *in vitro* proliferation in response to this vaccine was significantly higher in the group fed the high-AA diet than in the group fed the low-AA diet (Fig. 2). Thus, AA effect on PBMNC proliferation in response to influenza vaccine seems to be on the secondary rather than on the primary response of lymphocytes. Whether the increased lymphocyte proliferation will translate into increased antibody production cannot be determined from our data because we did not examine *in vitro* cell differentiation or antibody production. Enhancement of secondary antibody response to keyhole limpet hemocyanin has been reported by the addition of AA to rabbit popliteal lymph node cells *in vitro* (34). Similarly, in humans the secondary antibody response to influenza A-victoria was significantly enhanced by indomethacin, an inhibitor of AA metabolism through the cyclooxygenase pathway (35). These results imply that the secondary antibody response was enhanced by the increased production of lipoxygenase products. We believe the difference in PBMNC proliferation in response to influenza vaccine between the two groups was due to stimulation of this response by AA in Group 2. However, it is also possible that it is due to an inhibition by the residual AA in Group 1. Our study design cannot distinguish between these two possibilities.

The effect of AA on PBMNC proliferation was specific for influenza vaccine, because no stimulation was found when PBMNC were stimulated with MMR, PHA, Con A, or pokeweed. The failure to find an AA effect on MMR vaccine may simply be due to our failure to detect the effect of this vaccine or the AA effect may be antigen-specific. We do not have a specific explanation for the failure of MMR to stimulate PBMNC proliferation *in vitro* after immunization with the same vaccine *in vivo*; it may a defective vaccine or the way

of our testing. The lack of an AA effect on lymphocyte proliferation in response to polyclonal mitogens may be due to a relatively much higher stimulation by the mitogens compared to the stimulation caused by a specific antigen.

Our results showing no effect of dietary AA on proliferation of PBMNC cultured with mitogens are at variance to those results showing stimulation or inhibition of this response by the *in vitro* addition of AA to human lymphocytes and monocytes (36–38). In these studies AA concentrations up to 1.0 μg/mL enhanced the PHA-stimulated proliferation of human PBMNC cultured in lipid-poor medium (36); concentrations higher than 5 μg/mL inhibited their growth (37,38). The discrepancy between our results and those from previous studies may be due to the differences in the effects of free fatty acids (36–38) vs. those of the natural triglycerides (our study) and due to the differences in the concentrations and the metabolism of AA.

Previous studies have examined the effect of LA-rich diets on human IR, but not that of AA-rich diets. In a study with total dietary fat of 25 en%, increasing the LA content to 13 en% for 11 wk had no adverse effects on the IR of healthy men (1). Similar results with LA were obtained in a study with healthy women (2). LA is metabolized rapidly in humans, with only a limited conversion to AA, and thus should not have the same physiologic effects as the dietary AA. Direct comparisons between different studies should be made with caution, because several factors including total fat, chain length of different fatty acids and the ratios between them, antioxidant and other nutrient status, duration of feeding, and nutritional and health status of subjects determine the overall effects of diets on IR. Furthermore, not all indices of IR are affected equally by a given nutrient—as in the present study some indexes were stimulated (PBMNC proliferation with influenza vaccine), and others were unaffected by AA supplementation.

Infections of the upper respiratory tract were found in some individuals during the study; however such symptoms did not show any definite pattern and were randomly distributed in both dietary groups. At no time during the study did the basal (unstimulated) level of PBMNC proliferation for any given subject show more than two-fold variation. These observations indicate that the stimulation of IR was caused by AA and not by any latent viral infection. Furthermore these effects were not seen in the group devoid of AA, which also indicates that those were not caused by the stress of confinement at the metabolic unit. These observations indicate that the feeding of AA for a limited period did not significantly increase their risk for infections, although it may be increased in studies involving longer duration of AA feeding.

Even with the small number of subjects in the study (six in group 1; four in group 2), the results are encouraging, because there were no adverse effects of increased AA consumption as indicated in a previous study where esters of AA were fed (9). In our study, none of the indexes of IR tested were inhibited by AA feeding. Two of the indexes were significantly increased by AA, but the clinical significance of this increase is uncertain. It is possible that some other indexes would have been significantly affected, if AA was supplemented for more than 50 d or if there were more subjects in the study. These issues will be addressed in future studies with AA. Findings presented in this paper show neither any benefit from increased AA consumption by the healthy subjects nor any health risk if increased AA consumption was needed in cases of essential fatty acid deficiency. Further studies are needed before recommendations regarding daily intake of AA can be made.

ARTICLE

Age-Related Changes in Catalytic Activity, Enzyme Mass, mRNA, and Subcellular Distribution of Hepatic Neutral Cholesterol Ester Hydrolase in Female Rats

Ramesh Natarajan, Shobha Ghosh, and W. McLean Grogan*

Department of Biochemistry and Molecular Biophysics, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298-0614

ABSTRACT: Activity and protein mass of hepatic neutral cholesteryl ester hydrolase (CEH) were measured in liver cytosol and washed microsomes of female Sprague-Dawley rats aged 3, 4, 7, 9, 12, and 16 wk. CEH mRNA was also measured. The microsomal component varied with age and contributed a greater fraction of total activity in females than previously reported in males. Nevertheless, the cytosolic component accounted for 62–80% of activity and 77–94% of immunoreactive protein in postmitochondrial fractions. Cytosolic and microsomal CEH specific activities, relative to total protein, decreased 94 and 83%, respectively, from 3 to 4 wk, prior to onset of puberty at 5 wk, and increased 360 and 137%, respectively, from 12 to 16 wk. These results contrast with an earlier study, in which cytosolic CEH activity of males increased with puberty and declined after 12 wk. Although cytosolic CEH was activated by protein kinase A and inhibited by alkaline phosphatase treatment at all ages, protein kinase activation peaked at 4 wk, coinciding with the initial decrease in specific activity. Specific activity in cytosol and microsomes correlated with CEH mass at all ages, suggesting that this CEH accounts for most variation in cellular activity. In contrast, CEH mRNA varied little from 3–16 wk, indicating that transcriptional regulation does not make a major contribution to the variation in CEH activity and mass in females, although it may make an important contribution to male–female differences in CEH expression. Specific activities of cytosolic and microsomal CEH, relative to immunoreactive CEH protein mass, exhibited changes consistent with posttranslational regulation. These results indicate gender-specific multivalent regulation of hepatic CEH by posttranslational mechanisms during development of female rats.
Lipids 32, 463–470 (1997).

Hepatic cholesterol synthesis, degradation, and excretion undergo extensive changes during aging (1–6). The hepatic levels of free and esterified cholesterol are regulated by the combined activities of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase, cholesterol 7α-hydroxylase (C7αH), acyl-CoA:cholesterol acyl transferase (ACAT), and cholesterol ester hydrolase (CEH). Although age-related changes in HMG–CoA reductase, C7αH, and ACAT are reported in the literature (2,4,6,7–13), these studies did not address the effects of aging on CEH. Other studies have provided evidence that the rat hepatic neutral cytosolic CEH is highly regulated in concert with the other three enzymes (14–16). Moreover, reported activation of CEH by protein kinase is consistent with a role for this enzyme in regulation of cholesterol homeostasis (17). Erickson *et al.* (18) recently reported very low levels of cytosolic CEH activity during postpartum development of male and female rats. However, activity was not measured under optimal conditions for cytosolic CEH. Moreover, enzyme protein levels were not reported in that study.

Although sex-related differences in cholesterol metabolism have been reported in experimental animals and humans (19–24), most of the available data result from studies on HMG–CoA reductase, the rate-limiting enzyme in cholesterol synthesis, and C7αH, the rate-limiting enzyme in bile acid synthesis. Choi *et al.* (25) reported that the activities of HMG–CoA reductase and C7αH are higher in female than in male rats and that the regulatory mechanisms for these enzymes are more sensitive in female than in male rats. Carlson *et al.* (21) also reported higher activities for these enzymes in female rats and that these differences became apparent at the time of sexual maturity. In contrast, Innis (24) reported higher levels of ACAT activity in young male rats than in females of the same age. However, sex-related differences in cytosolic CEH have yet to be reported.

The major cytosolic cholesterol ester hydrolyzing enzyme in rat liver has been purified and characterized in this laboratory (17,26–28) and its cDNA identified, cloned, and expressed (29). These studies indicated that CEH is predominantly cytosolic in male rats, although a minor fraction of activity and immunoreactive protein persisted in washed

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; C7αH, cholesterol 7α-hydroxylase; cAMP, adenosine 3′,5′-cyclic monophosphate; CEH, cholesterol ester hydrolase; HMG–CoA, 3-hydroxy-3-methylglutaryl–CoA; PVDF, polyvinylidene difluoride; SDS-PAGE, SDS-polyacrylamide gel electrophoresis, SEM, standard error of the mean; SSC, 3.0 M sodium chloride and 0.3 M sodium citrate, pH 7.0; TCA, trichloroacetic acid.

microsomes (27). The properties which differentiate this enzyme from other esterases and lipases are reported and discussed elsewhere (28,29). We recently reported age-related changes in mRNA, protein mass, and specific activity of cytosolic CEH in male rats aged 6–24 wk, before and after puberty (30). In the current study we have measured hepatic neutral cytosolic, and microsomal CEH specific activities, cytosolic and microsomal CEH masses, and CEH mRNA levels in female rats, aged 3–16 wk, before and after puberty, in order to determine the effects of sex, puberty and age on CEH, identify potential regulatory mechanisms, and elucidate the role of this enzyme in cholesterol homeostasis during postpartum development.
