Chemicals and supplies. Cholesterol [1-^{14}C] oleate (56.6) mCi/mmol) was purchased from New England Nuclear (Boston, MA). All solvents were purchased from Fisher Scientific (Columbia, MD). ATP disodium salt, $MgCl_2$, adenosine 3′,5′-cyclic monophosphate (sodium salt), and alkaline phosphatase (Type IX from bovine liver) were purchased from Sigma Chemical Co. (St. Louis, MO). GENESCREEN membrane was purchased from NEN Research Products (Boston, MA). SDS-polyacrylamide gel electrophoresis (PAGE) and Western blot supplies were purchased from Bio-Rad Laboratories (Richmond, CA). All other chemicals were of analytical grade.

Sprague-Dawley rats with certified dates of birth were purchased from Zivic Miller Laboratories (Zellenople, PA) and fed TEKLAD Rodent Diet (Harlan Teklad, Madison, WI) *ad libitum* until use. Rats were maintained on a uniform 12-h light/12-h dark cycle at all times.

Preparation of cytosol. Rats were euthanized by decapitation and livers were removed and washed in 20 mM Tris HCl buffer, pH 7.5, containing 5 mM 2-mercaptoethanol, 100 mM sucrose and 80 mM KCl. Livers were homogenized with a loose Teflon pestle in 2 mL buffer/g tissue buffer. Cytosol (104,000 × *g* supernatant, S104) was prepared by differential centrifugation as described elsewhere (17). The pellet was resuspended in the same volume of homogenizing buffer and centrifuged again at 104,000 × *g* to obtain washed microsomes. This procedure has been used to remove loosely associated CEH protein and activity from male rat microsomes (27).

Enzyme assays. CEH activity was assayed in S104 and in microsomes by the radiometric method described previously (17). Cholesteryl oleate substrate was added as a droplet dispersion, which yields optimal levels of activity with the cytosolic CEH and enhances microsomal activity several orders of magnitude over phospholipid dispersions. Endogenous cAMP-dependent protein kinase was activated as described elsewhere (17), by preincubating the reaction mixture for 1–2 min with 1 mM $MgCl_2$, 5 mM ATP and 100 μM cAMP, followed by addition of substrate and an additional 30-min incubation. For alkaline phosphatase inactivation, the reaction mixture was preincubated with 0.1 unit phosphatase for 30 min, followed by addition of substrate and an additional 30-min incubation, as described previously (17). All assays were done in triplicate with two different protein concentrations within the linear range of the assay, for each of three rat livers/age group. All data were analyzed by the Student's *t*-test, analysis of variance and Bonferroni's test, with $P < 0.05$ as the minimal threshold for statistical significance.

Western blot analysis. Cytosolic or microsomal proteins were separated by SDS-PAGE and electroblotted onto Immobilon-polyvinylidene difluoride (PVDF) membranes using the Bio-Rad Trans Blot Cell. Western blots were reacted with polyclonal antibody to hepatic cytosolic CEH and developed as described previously (27), substituting 2% gelatin in TNT (20 mM Tris containing 500 mM NaCl and 0.05% Tween 20, pH 8.0) for 5% nonfat dry milk in the blocking solution. For quantitation, Western blots were scanned at 350 nm with a Shimadzu densitometer (Tokyo, Japan). A standard curve was constructed using different concentrations of hepatic CEH purified to a single band on SDS-PAGE by the procedure of Ghosh and Grogan (26). The standard curve was linear over the range of CEH protein concentrations measured in rat liver cytosol ($R = 0.97$). Three different concentrations of cytosolic protein were analyzed from each of three rat livers. Each of these concentrations yielded CEH values in the linear range of the standard curve and equivalent values when normalized for total cytosolic protein.

Northern blot analysis. Total RNA was prepared from isolated livers using TriReagent according to the manufacturer's instructions. An aliquot estimated to contain 10 μg of total RNA was electrophoresed on a 1% agarose gel in the presence of formaldehyde. The RNA was stained with ethidium bromide and the integrity of the isolated RNA verified by presence of 28*S* and 18*S* rRNA bands. According to the manufacturer's instructions, RNA was transferred to GENESCREEN membrane and simultaneously hybridized to ^{32}P-labeled full-length cDNA (29) for CEH and ^{32}P-labeled 0.8 kb probe for cyclophilin mRNA, used as a constitutive internal loading standard (31). After a high stringency wash (0.2 × SSC + 0.1% SDS at 65°C for 15 min), positive hybridization was detected by exposure to Kodak-2 films (Eastman Kodak Co., Rochester, NY) for 18 h at −70°C. Autoradiograms were scanned with a densitometer for quantitation and values normalized to cyclophilin.

Protein estimation. Protein was trichloroacetic acid (TCA)-precipitated and estimated by the bicinchoninic acid procedure (32).

RESULTS

Specific activity, mass, and mRNA levels of hepatic cytosolic CEH were measured in female rats at 3, 4, 7, 9, 12, and 16 wk after birth. As seen in Figure 1A, CEH specific activity (−protein kinase) decreased 94% from 3 wk to 4 wk of age ($P < 0.001$). It remained at this level through 12 wk and then in-

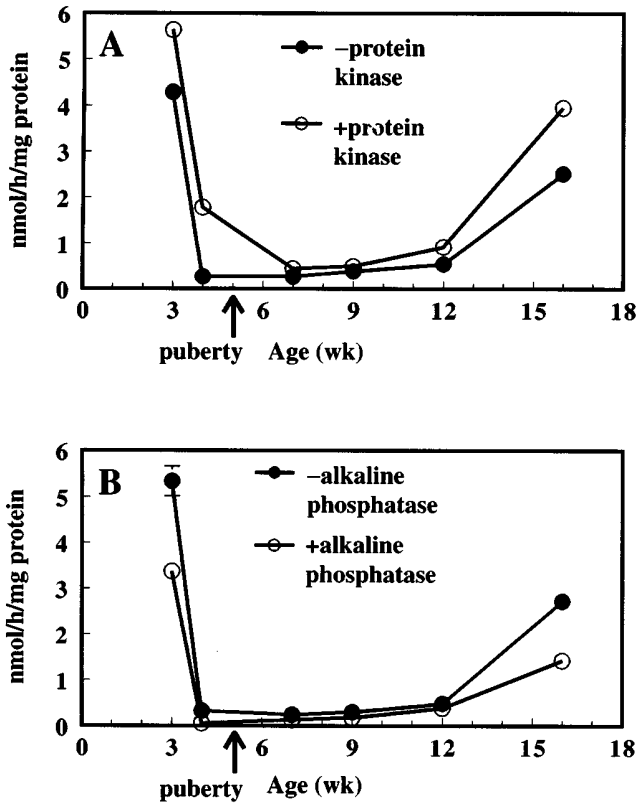

FIG. 1. Hepatic cytosolic CEH activity in female rats of various ages, with and without protein kinase A (Fig. 1A) or alkaline phosphatase (Fig. 1B) treatments. Figure 1A: CEH activity was measured radiometrically in 104,000 × *g* supernatants, in presence and absence of protein kinase A cofactors (1 mM $MgCl_2$, 5 mM ATP, 100 μM cAMP) added 1–2 min prior to addition of cholesteryl oleate substrate. Figure 1B: CEH was measured in 104,000 × *g* supernatants after incubation with or without alkaline phosphatase for 30 min. Arrow indicates onset of puberty. Each data point is the mean ± SEM for 3–6 rats, each rat was assayed in triplicate using two protein concentrations. Where not visible, error bars are within symbols.

creased again. By 16 wk, CEH specific activity had increased by 360% over the level in 12-wk-old rats ($P < 0.001$).

Previous studies with adult male rats have shown 100–140% stimulation of hepatic cytosolic CEH by cAMP (17), apparently mediated by endogenous cAMP-dependent protein kinase (30,33). These earlier studies also showed that this CEH is inactivated by exogenous alkaline phosphatase as well as by an endogenous Mg^{+2}-dependent phosphatase in rat liver cytosol (17). To evaluate the contribution of protein phosphorylation to the observed changes in hepatic CEH activity in the female rat between 3 and 16 wk of age, CEH activity was assayed, in the presence or absence of cofactors for cAMP-dependent protein kinase, or in the presence or absence of alkaline phosphatase (Figs. 1,2). As shown in Figure 1A, activators of endogenous protein kinase A increased CEH activity in all age groups, although this activation did not substantially alter the relative activities among the various age groups. The magnitude of this activation relative to basal CEH activities (Fig. 2) did not differ significantly with age, except at 4 wk, when activation was 588%, 8–20-fold greater than that seen at other ages. This is consistent with the earlier report of a peak in endogenous protein kinase A activity in rats of this age (34) and suggests that the level of phosphorylation may play a more important role in regulation of CEH activity at this stage of development. As depicted in Figure 1B, treatment with alkaline phosphatase decreased CEH activity by 20–62%, consistent with previous reports of regulation by phosphorylation/dephosphorylation in males (17,30). However, the relative activities before and after phosphatase treatment remained substantially the same among the various age groups. Thus, neither protein kinase activation nor alkaline phosphatase treatment significantly altered the pattern of age-dependent changes in CEH activity, as seen in Figure 1.

In previous studies from this and other laboratories, the predominant hepatic neutral CEH activity in male rats was

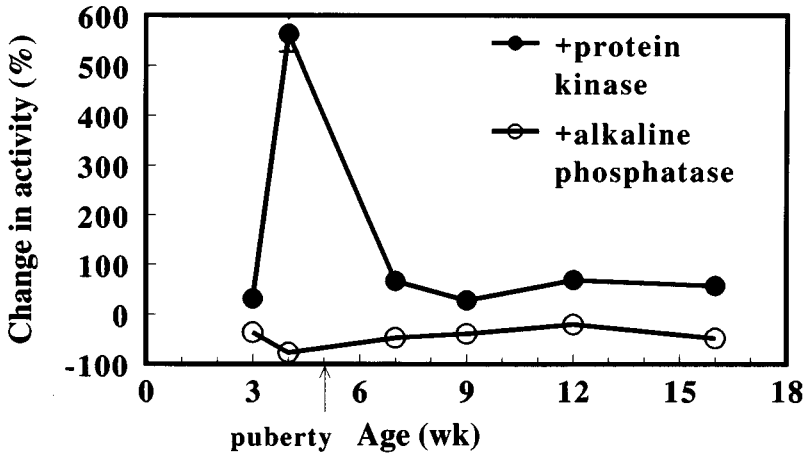

FIG. 2. Relative effects of protein kinase A and alkaline phosphatase on activity of hepatic cytosolic CEH in female rats of various ages. See legend, Figure 1, for treatments and assay conditions. Values are percentage difference from corresponding controls ± SEM for 3–6 rats/group, each rat assayed in triplicate, using two protein concentrations. Where not visible, error bars are within symbols.

isolated in the cytosolic fraction (26,35). In an earlier study from this laboratory, hepatic CEH activity and immunoreactive protein levels were very low (<10% of total activity) in microsomes from male rat liver (27). However, in the current study of female rats, microsomal CEH specific activities relative to total protein were similar to those of cytosol and much higher than those previously reported in males (Fig. 3A). Immunoreactive CEH mass (see Fig. 4 for representative Western blot) followed roughly the same general trend as specific activity in both cytosol and microsomes, decreasing from 3 to 7 wk and increasing thereafter (Fig. 3B), consistent with the view that this enzyme accounts for most of the observed variation in CEH activity in both subcellular fractions.

For comparison of the contributions of cytosolic and microsomal neutral CEH to the total cellular activity, the distribution of total neutral CEH catalytic activity and mass between the two subcellular fractions is shown in Table 1. Whereas the contribution of microsomal CEH activity varied from 20–38%, the contribution of microsomal immunoreactive protein varied from 6–23%. Although the distributions of mass and activity were similar only at 3 and 16 wk, both were consistently higher in cytosol than in microsomes at all ages. These data indicate that the predominant CEH activity is cytosolic in females, as previously reported in males (27), although the microsomal component contributes a substantially greater fraction of total activity in females. These data also reflect substantial differences in specific activity relative to CEH mass (nmol/h/μg CEH protein) between cytosolic and microsomal fractions at ages 4–12 wk, contrasting with specific activities at 3 and 16 wk, which were similar in the two fractions (see Table 1). This may reflect differential regulation of CEH in the two fractions.

Despite the variations with age and differences in specific activities relative to CEH mass between cytosol and microsomes, specific activities relative to cytosolic or microsomal protein correlated well (R = 0.94 and 0.96, respectively) with the corresponding specific masses of CEH (Fig. 5). However, as seen in Figure 5, regression lines for cytosol and microsomes diverged at low activities and masses and appeared to converge with higher activities and masses, consistent with

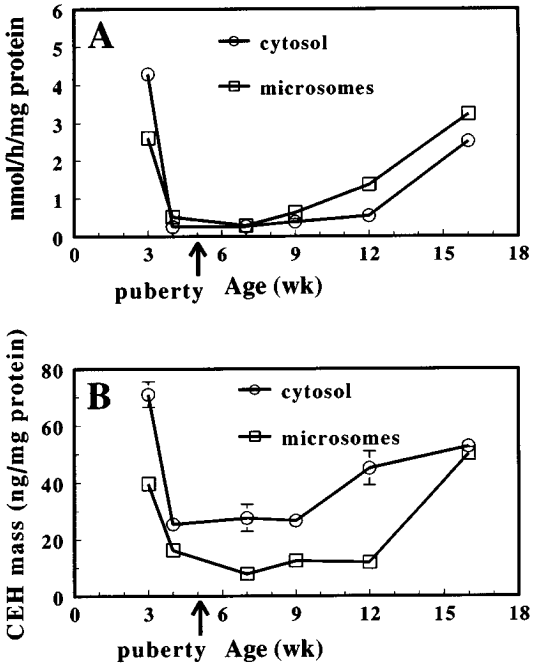

FIG. 3. Distribution of hepatic neutral CEH catalytic activity and mass between cytosol and microsomes from female rats of various ages. Figure 3A: CEH catalytic activity was measured in cytosol and resuspended washed microsomes as described in legend, Figure 1. Each data point is the mean ± SEM specific activity, relative to cytosolic or microsomal protein, for 3–6 rats, each rat assayed in triplicate, using two protein concentrations. Figure 3B: CEH mass was measured in cytosol or resuspended washed microsomes by quantitative Western blotting, as described in the Materials and Methods section. Each data point is the mean ± SEM CEH mass, relative to cytosolic or microsomal protein, for 3–6 rats; three different protein concentrations were assayed in the linear range of a standard curve obtained with an appropriate range of purified rat liver CEH. Where not visible, error bars are within symbols.

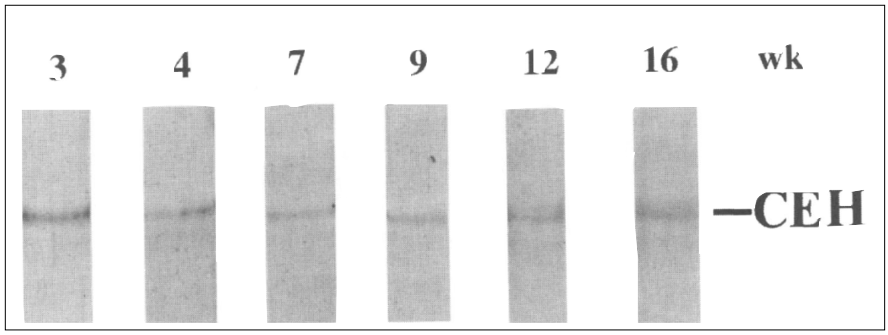

FIG. 4. Representative Western blot analysis of rat liver cytosols with polyclonal antibody to rat liver CEH, depicting variation of CEH mass in 3-, 4-, 7-, 9-, 12-, and 16-wk-old female rats. Blots were scanned densitometrically and values converted to corresponding masses by comparison with a standard curve obtained with varying concentrations of purified rat liver CEH. Resulting values are depicted in Figures 3B, 6, and 8B.

TABLE 1
Distribution of Neutral CEH Catalytic Activity and Anti-CEH Immunoreactive Protein Between Liver Microsomes and Cytosol in Female Rats of Various Ages

Age (wk)	Specific activity[a] (nmol/h/μg) CEH		Microsomal fractional content[b] (% total postmitochondrial)	
	Cytosol	Microsomes	CEH activity	CEH mass
3	62 ± 6	66 ± 2	24 ± 1	23 ± 2[k]
4	10 ± 1[c,h]	33 ± 5[d]	19 ± 2	8 ± 1[d,k]
7	9 ± 1[c,h]	36 ± 2[c,i]	22 ± 6	6 ± 1[d,j]
9	14 ± 2[d,h]	51 ± 6	36 ± 3[f,j]	13 ± 0[e]
12	13 ± 2[d,h]	122 ± 29[l]	38 ± 7	6 ± 1[d,j]
16	48 ± 1	66 ± 5	20 ± 2	15 ± 2[g]

[a]Specific activity relative to cholesterol ester hydrolase (CEH) mass was calculated as the ratio (specific activity relative to cytosolic or microsomal protein/specific CEH mass relative to cytosolic or microsomal protein). All values are means for 3–6 rats ± SEM.
[b]Microsomal fractional content for CEH activity = 100 (microsomal CEH activity/g liver)/[(microsomal CEH activity/g liver) + (cytosolic CEH activity/g liver)]; for CEH mass = 100 (microsomal CEH mass/g liver)/[(microsomal CEH mass/g liver) + (cytosolic CEH mass/g liver)]; statistical differences = [c]different from 3 wk, $P < 0.001$; [d]different from 3 wk, $P < 0.005$; [e]different from 3 wk, $P < 0.01$; [f]different from 3 wk, $P < 0.02$; [g]different from 3 wk, $P < 0.05$; [h]different from 16 wk, $P < 0.001$; [i]different from 16 wk, $P < 0.01$; [j]different from 16 wk, $P < 0.02$; [k]different from 16 wk, $P < 0.05$; [l]different from 7 wk, $P < 0.05$.

the previously cited convergence of specific activities (see Table 1). Inasmuch as the regression line for microsomal CEH passed through the origin, the immunoreactive CEH protein accounts for essentially all of the catalytic activity in this fraction and essentially all of the immunoreactive protein in this fraction appears to be active under the assay conditions. In contrast, the regression line for cytosolic CEH intercepts the mass axis at a protein mass > 0. Whereas this observation suggests that the immunoreactive protein accounts for the catalytic activity in cytosol, it also indicates that a substantial fraction of immunoreactive protein is not catalytically active, perhaps reflecting posttranslational regulation. Such a component of inactive CEH may account for the above-cited discrepancies in specific activities of cytosol and microsomes relative to CEH mass, which are most prominent at lower mass levels (see Table 1).

As shown in Figure 6, CEH mRNA levels measured by quantitative Northern blot analysis varied little, with the exception of a transient increase at 4 wk, which was not statistically significant ($N = 5$). Thus, transcriptional regulation does not appear to play an important role in the observed variation in CEH activity in females, although it may contribute to female/male differences.

DISCUSSION

This is the first reported measurement of CEH specific activity, mass, and mRNA in female rats and the first developmental study in which CEH specific activities are correlated with enzyme mass in both cytosolic and microsomal compartments. These results contrast markedly with those obtained in a similar study of developmental changes in CEH in male rats (30). In females, the specific activities relative to cytosolic protein dropped precipitously at 4 wk and remained at very low levels through 12 wk, after which it rose again (Fig. 1). In contrast, specific activities in male rats rose from 6 to 10 wk, and then declined after 12 wk (30). Thus, in females, highest specific activities were present just prior to onset of puberty (approximately 5 wk) and after 12 wk, whereas, in males, highest activities were seen just after onset of puberty (approximately 8 wk) and prior to 12 wk. These trends were also seen with CEH mass, which decreased in females with

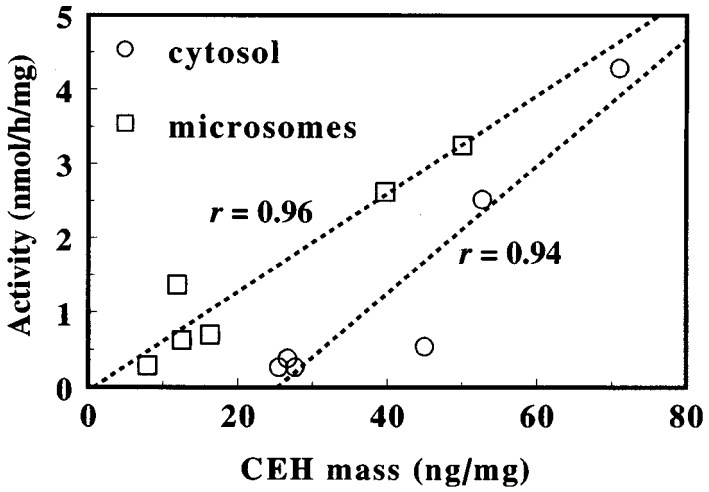

FIG. 5. Correlations between immunoreactive protein and catalytic activity in cytosolic and microsomal fractions of female rats of various ages. Broken lines depict best-fit linear regression for all cytosolic ($R = 0.94$) and microsomal ($R = 0.96$) values, respectively. Each data point is the mean for 3–6 rats. See Figure 4 for description of experimental procedures and standard errors of the means for both variables, which are contained within the symbols for most data points.

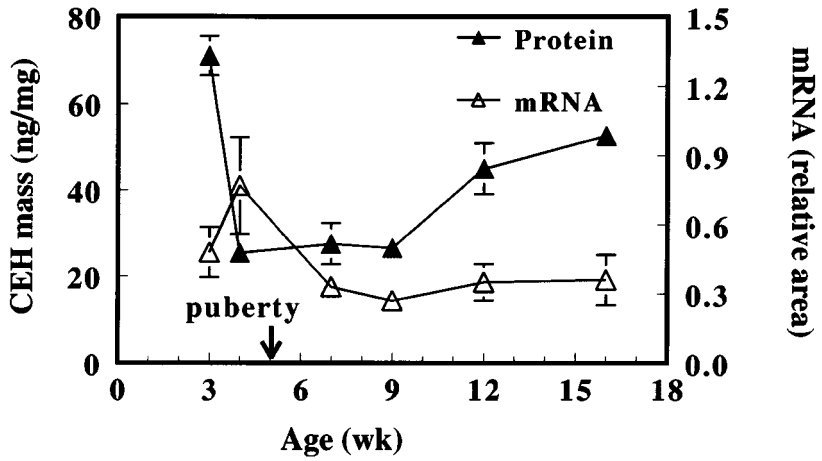

FIG. 6. Hepatic CEH mRNA and cytosolic CEH mass in female rats at various ages. CEH mRNA was measured (relative to constitutive cyclophilin mRNA) by quantitative Northern blot analysis with full length CEH cDNA (see Fig. 7, for representative autoradiogram), as detailed in the Materials and Methods section. CEH mass was measured by quantitative Western blot analysis as detailed in the Materials and Methods section. The arrow indicates the onset of puberty in female rats. Each data point is the mean ± SEM for 3–6 rats, each rat assayed in triplicate. Where not visible, error bars are contained within symbols.

onset of puberty and rose after 12 wk (Fig. 3), whereas it increased in males during puberty and declined after 12 wk (30). In contrast, whereas CEH mRNA levels in male rats corresponded to CEH activity and mass (30), mRNA levels in females did not parallel activity or mass (Fig. 6). Nevertheless, both CEH mass and mRNA levels were consistently lower in females (Fig. 6) than males (30) at comparable ages. These results suggest that age-related changes in CEH in female rats reflect primarily posttranscriptional mechanisms, whereas transcriptional regulation may contribute to the female/male differences in CEH activity and mass. The pattern of susceptibility to protein kinase A was also quite different in female rats (Fig. 2) in comparison with males, which showed a sustained increase in susceptibility after puberty (30).

Since marked changes in CEH mass, catalytic activity, and susceptibility to protein kinase A coincide with onset of puberty, this regulation may be mediated, directly or indirectly, by gonadal steroids. Consistent with this view are previous reports that hepatic CEH activity is suppressed by estradiol (36,37) and induced by progesterone (16,38). Other enzymes of cholesterol homeostasis are also differentially expressed in females and males or known to be regulated by gonadal steroid hormones. Whereas the activities of HMG–CoA reductase and C7H are reported to be greater in adult females than in males (25), ACAT activity was greater in males (24). Like CEH, HMG–CoA reductase and C7αH are reported to be stimulated by progesterone (38–40). Moreover, C7αH is also inhibited by estradiol (38). In contrast to CEH, ACAT is reported to be inhibited by progesterone (16,41,42) consistent with the antagonistic roles of these enzymes in the cholesteryl ester cycle.

Assignment of changes observed in females during weeks 3–4 to onset of puberty is confounded by the close proximity to weaning. Since female rats were weaned only 3 d prior to the initial 3-wk data points, it is possible that 3-wk data and/or changes occurring in the subsequent week may reflect alterations in diet or other maternal influences. Although no comparable data have been reported for female rats, similar studies with HMG–CoA reductase in male rats, which enter puberty 2 wk later than females, have shown transient increases in HMG–CoA reductase specific activity and mass after weaning (7,8). However, these changes occurred immediately and persisted for only a few days, after which specific activity and mass of HMG–CoA reductase returned to initial levels. Increases in HMG–CoA reductase and C7αH mRNA were also reported immediately after weaning (43), similar in magnitude to the increase in CEH mRNA at 4 wk in the current study (Fig. 6), although the duration of those changes was not reported. Nevertheless, the transient increase in susceptibility of CEH to activation by cAMP-dependent protein kinase at 4 wk (Fig. 2) is probably associated with onset of puberty, since it is absent at 3 wk, 3 d after weaning.

As suggested by earlier studies indicating that <10% of liver CEH activity or mass was present in adult male microsomes (27), these studies provide additional evidence that CEH is predominantly cytosolic, as initially proposed by Deykin and Goodman (35). Nevertheless, 6–23% of immunoreactive protein remained associated with washed microsomes and correlated well with catalytic activity (Table 1), indicating that this enzyme makes a major contribution to microsomal as well as cytosolic CEH activity.

Although microsomal CEH activity and mass generally paralleled cytosolic activity and mass (Fig. 3), the distribution of CEH mass between the subcellular fractions varied significantly with age (Table 1), suggesting that redistribution

may play a role in regulation of this enzyme. Moreover, the substantial variations in specific activity relative to CEH mass in both males and females among the various age groups (see Table 1) and between cytosolic and microsomal components suggest additional posttranslational mechanisms of regulation. One such mechanism is suggested by the variable susceptibility of this enzyme to modulation by phosphorylation/dephosphorylation, as indicated by this and previous studies cited earlier. An additional posttranslational mechanism is suggested by the earlier report of a cytosolic factor which exhibits variable inhibitory activity with age (44). Since this factor was more active in adult females than in males (44), variability in its expression could account for the greatly reduced specific activity of cytosolic CEH in females at 4, 7, 9, and 12 wk, in the absence of concomitant changes in microsomal specific activity (Table 1).

These studies suggest that the hepatic neutral CEH plays an important role in regulation of cholesterol homeostasis in the female rat during development and that its regulation is complex, multivalent, and distinct from the pattern expressed in males. Although it is not yet clear how differential expression may serve the needs of females and males at different stages of development, CEH is apparently regulated in concert with HMG–CoA reductase, C7αH and ACAT, to maintain adequate levels of intracellular free cholesterol for bile acid synthesis, biliary cholesterol secretion, and assembly of membranes and lipoproteins. As with HMG–CoA reductase, transcriptional regulation of CEH is complemented by other modes of regulation, to permit independent or opposing modulation of the two enzymes capable of increasing hepatic free cholesterol.

Metal Ion Stimulation of Phospholipase D-Like Activity of Isolated Rat Intestinal Mitochondria

M. Madesh and K.A. Balasubramanian*

The Wellcome Trust Research Laboratory, Department of Gastrointestinal Sciences, Christian Medical College & Hospital, Vellore 632 004, India

ABSTRACT: Presence of phospholipase D-like (PLD) activity in the intestinal mitochondria was identified using endogenous phospholipids as substrate. The enzyme had a pH optimum of 6.5, did not show *trans*-phosphatidylation activity in the presence of ethanol or butanol, and the product formed was phosphatidic acid (PA). This was confirmed by separation of reaction products by high-performance liquid chromatography and analysis of composition of the PA formed which gave phosphate/fatty acid ratio of 1:2. PLD-like activity was further confirmed by the formation of ethanolamine and choline as products of enzyme action. This activity was stimulated by various metal ions; when stimulated by Mg^{2+} and Ba^{2+}, it hydrolyzed both phosphatidylcholine and phosphatidylethanolamine, and when stimulated by Ca^{2+}, it preferentially hydrolyzed phosphatidylethanolamine. There was no requirement for sodium oleate for the PLD-like activity in mitochondria. These results suggest that intestinal mitochondria have an active PLD-like enzyme which differs in certain properties from phospholipase D from other tissues.

Lipids 32, 471–479 (1997).

A number of studies have shown that phosphatidic acid (PA) is involved in cell signaling (1,2). PA can either be formed by the action of phospholipase D (PLD) on phospholipids or by phosphorylation of diacylglycerol. PLD can be activated in response to various stimuli and phorbol esters activate PLD through protein kinase C (3,4). Protein kinase C activation of PLD takes place by both phosphorylation-dependent and independent mechanisms (5,6). Lipopolysaccharide stimulates cellular PLD activity, and this requires an increase in intracellular Ca^{2+} (7). Exposure to oxygen-derived free radicals also stimulates cellular PLD activity (8,9). Using PLD from various sources, it has been shown that divalent metal ions can activate this enzyme (10,11).

Calcium plays an important role in many cellular functions, and intracellular calcium is stored mainly in endoplasmic reticulum and to a small extent in the mitochondria (12). Under certain pathological conditions, such as oxidative stress, increase in cytosolic Ca^{2+} occurs and this in turn increases the Ca^{2+} sequestration by mitochondria (13,14). It has been proposed that PA may act as a Ca^{2+} ionophore (15,16) and facilitate the influx of Ca^{2+} through the plasma membrane. Although presence of PLD activity has been shown in liver, skeletal muscle and brain mitochondria, very little is known on the properties of mitochondrial enzyme (17–19). Since mitochondria are important in calcium homeostasis and PA might play a role in this process, the present study looks at the possible presence of PLD-like activity and its properties in the intestinal mitochondria.

MATERIALS AND METHODS

Various lipid standards, Hepes, fluorescamine, *p*-bromophenacylbromide (pBPB), chlorpromazine (CHLP), and bovine serum albumin (BSA) were all obtained from Sigma Chemical Company (St. Louis, MO). Standard phosphatidylethanol and phosphatidylbutanol were prepared using egg phosphatidylcholine and cabbage PLD in presence of ethanol or butanol (20). All other chemicals used were of analytical grade.

Preparation of mitochondria. Rats weighing 150–200 g, fasted overnight, were decapitated, the small intestine removed and washed with ice-cold saline. Mitochondria were isolated from enterocytes as described by Masola and Evered (21). Isolated mitochondrial fraction was suspended in EGTA-free medium containing 250 mM sucrose/5 mM Hepes pH 7.4 and stored in ice at protein concentration of 8–10 mg/mL. Isolated mitochondria were relatively pure as judged by the mitochondrial marker enzyme succinic dehydrogenase. Microsomal and lysosomal contamination in the mitochondrial preparation were checked by assaying marker enzymes, namely, glucose-6-phosphatase, acid phosphatase and arylsulfatase, and these activities were not detectable. Protein was measured using BSA as standard (22).

Enzyme assay. Mitochondrial PLD-like activity was measured using endogenous mitochondrial phospholipids as substrate. Mitochondria (1 mg protein per mL in 0.25 M sucrose, 5 mM Hepes buffer pH 7.4) were incubated at 37°C for 30 min. Following incubation, total lipids were extracted by

Abbreviations: PA, phosphatidic acid; pBPB, *p*-bromophenacylbromide; PLD, phospholipase D; DAG, diacylglycerol; CHLP, chlorpromazine; TLC, thin-layer chromatography; HPLC, high-performance liquid chromatography; PE, phosphatidylethanolamine; PC, phosphatidylcholine.

Bligh and Dyer's method (23) and the PA was separated by thin-layer chromatography (TLC) and quantitated by phosphate estimation. Extracted lipids were spotted on silica gel G plates impregnated with 0.5 M oxalic acid and separated using the solvent system chloroform/methanol/conc. HCl (85:13:0.5, by vol) (24). PA spots corresponding to standard were identified by iodine exposure, scraped, and eluted from the plates. PA was quantitated by phosphate estimation after acid digestion (25). PA formed was also separated and identified along with standard using two other solvent systems (26,27). Formation of PA was further confirmed by separation of extracted lipids on TLC followed by isolated PA spot separated by high-performance liquid chromatography (HPLC) (28). A normal-phase silica 5-µm column was used with the solvent gradient of 1–9% water in hexane/2-propanol (3:4, vol/vol) at a flow rate of 1 mL/min and the eluents monitored at 220 nm. Transphosphatidylation was checked by inclusion of 300 mM ethanol or butanol in the incubation mixture, and extracted lipids were separated on silica gel G plates using the upper phase of ethyl acetate/isooctane/acetic acid/water (13:2:3:10, by vol) (27). PA formation in the presence of ethanol was further checked by HPLC. Metal ion stimulation of phosphatidylcholine degradation generated choline which was separated by TLC, using the solvent system methanol/0.6% NaCl/ammonia (50:50:5, by vol). This was identified after exposure to iodine vapor (29).

Lipid analysis. Neutral lipids were separated on silica gel G plates using the solvent system hexane/diethyl ether/acetic acid (80:20:1, by vol). Spots were identified by iodine exposure, scraped, and eluted. Cholesterol (30), diglycerides, and triglycerides (31) were estimated as described. Free fatty acids were methylated and quantitated by gas chromatography after separation on a 5% EGSS-X column. Heptadecanoic acid was used as internal standard. Individual phospholipids were separated on silica gel H plates using the solvent system chloro-form/methanol/acetic acid/water (25:15:4:2, by vol) (32) and quantitated by phosphate estimation after acid hydrolysis. Individual aminophospholipids were also quantitated after derivatization with fluorescamine and separation on silica gel H plates impregnated with 3% magnesium acetate using the solvent system chloroform/methanol/NH_4OH/water (60:40:5:2, by vol) (33). Eluted individual spots were quantitated using Shimadzu SF 5000 spectrofluorometer (Tokyo, Japan) with excitation at 395 nm and emission at 468 nm.

Separation and analysis of ethanolamine. Following incubation, enzyme activity was terminated with 10% trichloroacetic acid. After cooling on ice, the mixture was transferred

to a test tube, shaken on a vortex mixer for a minute, left for 15 min and then centrifuged. The sediment was washed twice with 2 mL of 3% trichloroacetic acid and the supernatants pooled together. Trichloroacetic acid from the supernatant was removed by repeated extraction with diethyl ether, and the solution was dried with nitrogen. The samples were dissolved in 150 µL of 0.2 M boric acid pH 9.0, and 50 µL of fluorescamine (2 mg in 0.25 mL acetone) was added. The reaction with fluorescamine was allowed to proceed for at least 5 min to hydrolyze the excess reagent. After derivatization, the samples were separated by TLC on silica gel G plates (solvent system, chloroform/methanol/conc. ammonia/water (60:40:5:2.5, by vol). Fluorescamine-labeled ethanolamine was seen under ultraviolet light. This was scraped and eluted with 3.5 mL of methanol/4% ammonia (95:5, vol/vol) and quantitated using a spectrofluorometer with an excitation at 395 nm and emission at 468 nm. Standard ethanolamine was also derivatized with fluorescamine, and the fluorescence response of standard derivatized ethanolamine was linear in the concentration range of 25 to 1000 µM.

Statistical analysis. The values represent mean ± SEM of three separate estimations, and Mann-Whitney U-test was done to compare the changes.

RESULTS

The PLD-like activity in the isolated intestinal mitochondria was determined by measuring the PA formation from endogenous mitochondrial phospholipids. Figure 1 shows the effect of various divalent metal ions (Ca^{2+}, Mg^{2+}, Ba^{2+}, Co^{2+}, Mn^{2+}, and Zn^{2+}) at two different concentrations (0.1 and 1 mM) on PA formation. As shown, Ca^{2+}, Mg^{2+} and Co^{2+} activated at both concentrations, whereas with Ba^{2+}, Mn^{2+} and Zn^{2+}, maximum activation was seen at 0.1 mM concentration. Mitochondrial PLD-like enzyme did not show transphosphatidylation activity. Inclusion of either 200 and 300 mM ethanol or butanol in the incubation medium did not result in the formation of phosphatidylethanol or phosphatidylbutanol when stimulated by metal ions. Under these conditions, all the product formed was recovered as PA (60.7 ± 1.5 nmoles PA in presence of Ca^{2+} + ethanol, 61.8 ± 2.4 in presence of Ca^{2+} alone, 55.4 ± 1.7 in presence of Mg^{2+} + ethanol and 53.9 ± 1.9 in presence of Mg^{2+} alone). Figure 2 shows the TLC separation of PA and phosphatidylethanol after Ca^{2+} activation of mitochondrial PLD-like activity which showed the absence of phosphatidylethanol formation in the presence of ethanol. This was further confirmed by HPLC separation of PA formed in the absence and presence of ethanol. Control mitochondria had very little PA which was increased when incubated with Ca^{2+}. In the presence of ethanol and Ca^{2+}, all the product was recovered as PA, as evidenced by HPLC separation (Fig. 3). Table 1 shows the phosphate content and fatty acid composition of PA isolated

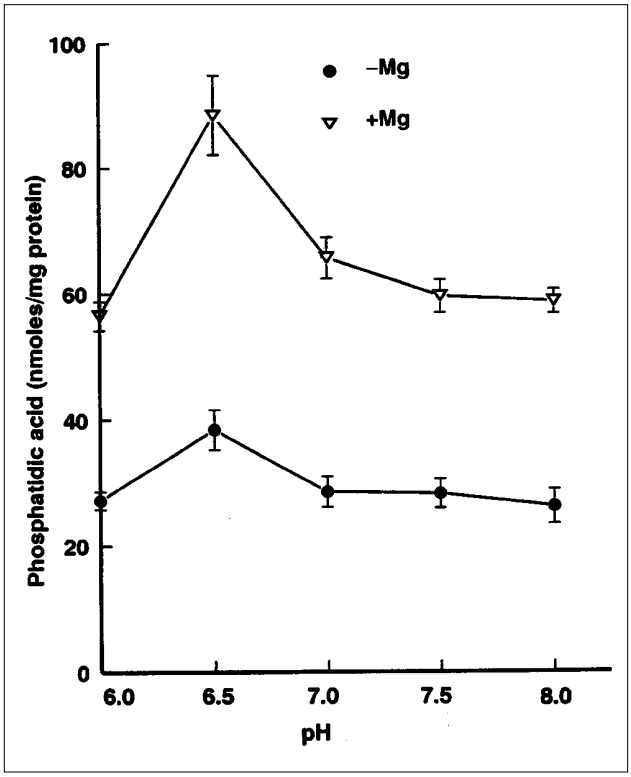

FIG. 4. Effect of different pH on phospholipase D activity of intestinal mitochondria in the presence and absence of 1 mM Mg^{2+}. Each value represents mean ± SEM of three separate estimations.

TABLE 2
Neutral Lipid Composition (nmole/mg protein) of Intestinal Mitochondria Incubated with Metal Ions[a]

Lipids	Control	Control incubated	Incubated in presence of Ca^{2+}	Mg^{2+}	Ba^{2+}
Total cholesterol	139 ± 11.2	142 ± 9.9	133 ± 7.4	136 ± 12.4	141 ± 2.5
Triglyceride	94 ± 6.6	86 ± 5.3	93 ± 5.3	94 ± 2.3	88 ± 4.1
Diglyceride	59 ± 4.5	59 ± 3.6	56 ± 4.7	59 ± 6.2	58 ± 5.1
Free fatty acids	101 ± 12.0	116 ± 9.7	114 ± 10.5	112 ± 14.9	113 ± 2.8

[a]Each value represents mean + SEM of three separate estimations. Ca^{2+} (1 mM), Mg^{2+} (1 mM), and Ba^{2+} (0.1 mM) (final concentration) were used.

from the reaction mixture, and the ratio of phosphate to fatty acid was found to be 1:2, which confirms that the product formed was indeed PA. To rule out the possibility of PA formation from diacylglycerol (DAG) by DAG kinase, isolated mitochondria were incubated with 400 μM DAG (exogenous) and 1 mM ATP at 37°C for 30 min with and without metal ions. Following this, lipids were extracted; DAG and PA were quantitated. The addition of exogenous DAG did not alter the PA formation in the presence of metal ions (Ca^{2+} alone: 59.8 ± 2; Ca^{2+} + DAG: 61 ± 2.6; Mg^{2+} alone: 54 ± 1.9; and Mg^{2+} + DAG: 55 ± 2.3 nmoles/mg protein). Levels of DAG also remained the same in control and metal ion-treated samples (data not shown). Mitochondrial PLD-like enzyme showed a pH optimum of 6.5, and this remained the same even when activated by metal ion (Fig. 4). The possible influence of endogenous metal ions on mitochondrial PLD activity was checked in the absence and presence of 2, 5, and 10 mM EDTA. Unincubated mitochondria had a PA content of 12.58 ± 1.36 nmoles/mg protein, which increased to 23.06 ± 3.16 nmoles after incubation for 30 min without any metal ions. Inclusion of various concentrations of EDTA did not alter the PA content (data not shown).

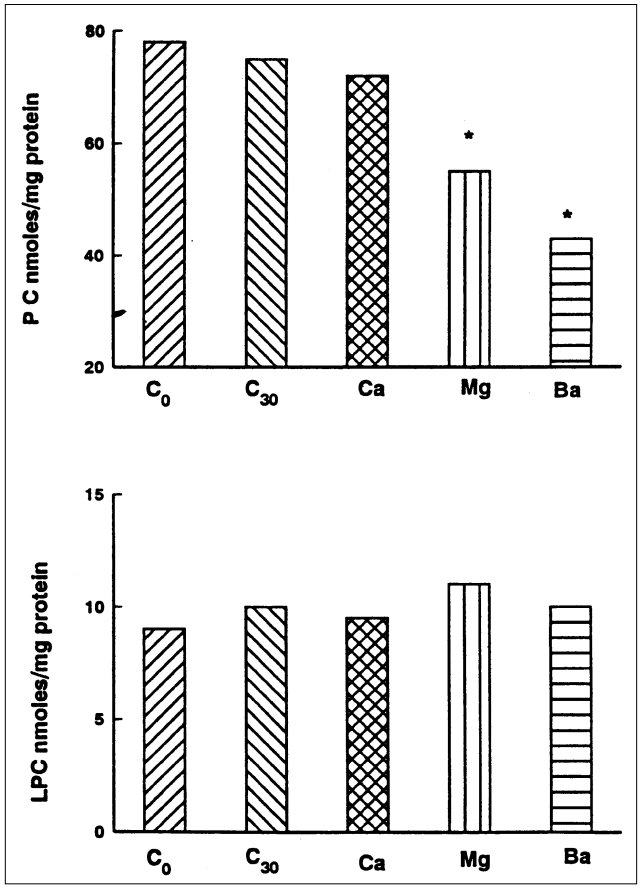

FIG. 5. Phosphatidylcholine (PC) and lyso PC (LPC) content of mitochondria incubated with Ca^{2+} (1 mM), Mg^{2+} (1 mM), and Ba^{2+} (0.1 mM). C_o represents unincubated mitochondria, and C_{30} represents mitochondria incubated for 30 min without metal ions.

PLD is known to act on both phosphatidylcholine (PC) and phosphatidylethanolamine (PE). To check the endogenous substrate for mitochondrial enzyme, mitochondrial lipids were analyzed after metal ion activation of PLD-like activity. As can be seen from Table 2, no significant change was seen in neutral lipids. Phospholipid separation by TLC indicated that in the case of Ca^{2+} activation, PLD-like enzyme preferentially used PE as substrate, whereas with Mg^{2+} and Ba^{2+}, both PC and PE were hydrolyzed. Figure 5(A and B) shows PC and lyso PC content of mitochondria after metal ion activation of the enzyme. As can be seen, with both Mg^{2+} and Ba^{2+} stimulation, PC content decreased whereas Ca^{2+} stimulation did not alter the PC content. Moreover there was no significant change in the content of lyso PC after metal-ion activation. PC hydrolysis by PLD-like enzyme in the presence of Mg^{2+} and Ba^{2+} was further confirmed by the formation of choline which was separated and identified by TLC and is shown in Figure 6. Ca^{2+} stimulation of the enzyme did not produce choline, whereas Mg^{2+} and Ba^{2+} stimulation resulted in the formation of choline; and the maximum amount of choline formation occurred with Ba^{2+} stimulation of enzyme. Amino phospholipids were quantitated by fluorescamine derivatization followed by TLC separation. As shown in Figure 7(A and B), Ca^{2+}, Mg^{2+}, or Ba^{2+} stimulation decreased the PE content, and there was no significant change in the level of lyso PE following metal ion activation. Ethanolamine, the other product of PLD degradation of PE, was separated by TLC after fluorescamine derivatization and is shown in Figure 8. Quantitation of ethanolamine formed showed that all three

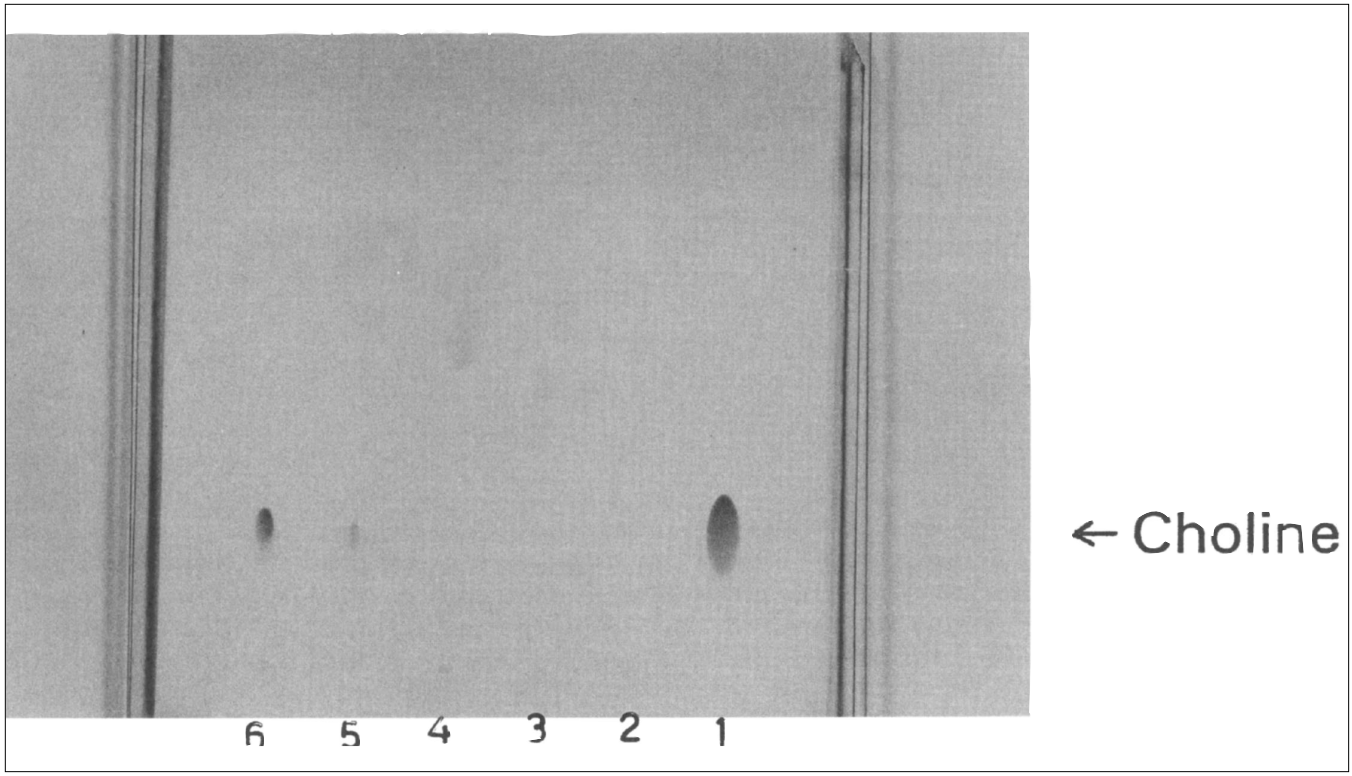

FIG. 6. Choline formation in response to Ca^{2+}, Mg^{2+}, and Ba^{2+} by mitochondrial phospholipase D. The methodology is described in the text. 1. Standard choline; 2. control unincubated mitochondria; 3. control mitochondria incubated for 30 min; 4. incubated with Ca^{2+}; 5. incubated with Mg^{2+}; 6. incubated with Ba^{2+}.

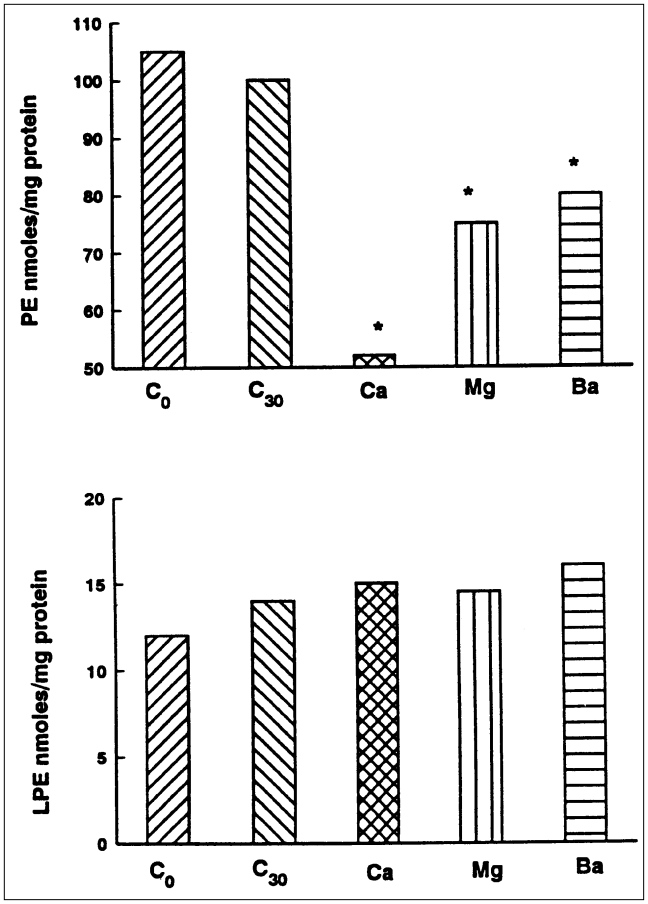
metal ions stimulated the formation, and Ca^{2+} stimulation of the enzyme resulted in the maximum formation of ethanolamine (Fig. 9). PLD-like activity was also checked in presence of phospholipase A_2 inhibitors, namely, CHLP and pBPB. CHLP and pBPB as such stimulated PLD activity and this activity was further enhanced by the presence of Ca^{2+} or Mg^{2+} (data not shown).

DISCUSSION

This study has demonstrated the presence of an active PLD-like activity in the intestinal mitochondria and, using endogenous lipids as substrate, some of the properties of this enzyme were studied. Although PLD activity has been shown in whole cells and subcellular membranes (1,2), very little is known on mitochondrial PLD activity (18,19). PLD activity is usually assayed by PA formation or by measurement of phosphatidylethanol, which is the transphosphatidylation product of PA in the presence of alcohol. In the case of intestinal mitochondrial PLD, no phosphatidylethanol formation could be detected using endogenous substrate, as confirmed by both TLC and HPLC separation. This was further confirmed using mitochondrial enzyme and egg PC as substrate (data not shown). It was found that even in the presence of metal ions, phosphatidylethanol formation could not be detected. Moreover the PA content remained the same whether ethanol was present or not. PA formation by mitochondrial PLD was confirmed by HPLC which gave an identical retention time to that of the authentic standard. Furthermore, analysis of the PA formed showed a phosphate to fatty acid ratio of 1:2 which indicated that PA is the reaction product. That PLD-like enzyme indeed was responsible for PA formation was further confirmed by identifying the other products of reaction, namely, choline and ethanolamine. It may be that either the intestinal mitochondrial PLD-like enzyme does not catalyze transphosphatidylation or this enzyme does not have the transphosphatidylation activity, which was shown to be different from PLD activity in rat brain membranes (34).

Metal ions have been shown to activate or inhibit PLD activity depending on the source of the enzyme (8,35–37). Intestinal mitochondrial PLD-like enzyme was activated by various metal ions, and it was concentration-dependent. Increased PA formation in mitochondria in the presence of metal ions was not due to DAG kinase activity since incubation of mitochondria in presence of DAG and ATP did not increase the PA formation. Moreover, all the DAG added was recovered. Earlier, Rider and Baquet (38) reported that DAG exogenously added to liver microsomes caused 8–10-fold stimulation of inorganic phosphate incorporation in the PA. Kanoh and Akesson (39) also observed a similar stimulation



of the DAG kinase reaction by exogenous DAG. Since mitochondrial PA formation was not influenced by exogenously added DAG, this suggests that PA formation in mitochondria in the presence of metal ions is due to PLD-like activity rather than DAG kinase activity. It has been suggested that PA formed by the action of PLD may be hydrolyzed by the phosphatidate phosphatase to DAG, and this may make the quantitation of the PLD product, PA, difficult. In the case of intestinal mitochondria, it appears that the PA formed is stable, and this may be due to the absence of PA phosphatase activity. This was further supported by our observation that metal ion activation did not increase the level of DAG in mitochondria. Maximal PLD-like activity was obtained at pH 6.5, and activation by metal ions did not alter the pH optimum. This is similar to an earlier report on brain plasma membrane PLD activity (10), but differs from a neutral PLD from rat brain synaptosomal membranes (11). Analysis of mitochondrial lipids suggested that both PC and PE were used as substrate when activated by Mg^{2+} or Ba^{2+}, whereas PE was preferentially used when activated by Ca^{2+}. There are reports on PE preferring PLD activity (1). The basal

FIG. 7. Phosphatidylethanolamine (PE) and lyso PE content of intestinal mitochondria after incubation with Ca^{2+} (1 mM), Mg^{2+} (1 mM), and Ba^{2+} (0.1 mM). PE and lyso PE were derivatized with fluorescamine and separated by thin-layer chromatography and quantitated by spectrofluorimetry as described in the text. Each value represents mean ± SEM of three separate estimations. activity in the mitochondria was not influenced by the presence of EDTA. Our attempts to solubilize the mitochondrial enzyme and partially purify it were not successful since the enzyme was very unstable. Various attempts to stabilize the enzyme was also not successful.

Unlike PLD from other sources, intestinal mitochondrial enzyme does not require sodium oleate for activity. This may be due to large amount of free fatty acids associated with intestinal mucosal membranes (40,41).

It has been suggested that in certain pathological conditions, mitochondria may sequester cytosolic Ca^{2+} in order to prevent cellular damage (12,14). During this process, it may act as a storage organelle for intracellular Ca^{2+}. Mitochondrial membranes are known to have bound Mg^{2+} (42), and the presence of metal ions in close proximity to the mitochondrial PLD might stimulate this enzyme, resulting in alteration of mitochondrial membrane lipids.

Membrane Lipid Metabolism and Phospholipase Activity in Insect *Spodoptera frugiperda* 9 Ovarian Cells

Li-Hong P. Yeh[a,1], Rakesh K. Bajpai[a], and Grace Y. Sun[b,*]

Departments of [a]Chemical Engineering and [b]Biochemistry, University of Missouri, Columbia, Missouri

ABSTRACT: Although there is increasing use of insect ovarian Sf9 cells for the production of recombinant proteins, namely, via the baculovirus vector expression system, little is known about the lipids in the cell membrane and whether endogenous phospholipases are present for regulation of the cell membrane lipids. In this study, analysis of membrane lipids of Sf9 cells indicated the presence of phosphatidylethanolamine (PE) (diacyl type) and phosphatidylcholine as major phospholipids, followed by phosphatidylserine and phosphatidylinositol (PI), and only trace amounts of ethanolamine plasmalogen. These phospholipids contain high proportions of monoenoic fatty acids, e.g., 16:1 and 18:1, which comprise more than 70% of the total fatty acids although small amounts of polyunsaturated fatty acids such as 18:2 and 20:4 are also present. When Sf9 cells were incubated in a culture medium containing [^{14}C]oleic acid and [^{14}C]arachidonic acid, a large portion of the labels were incorporated into membrane phospholipids. Using [^{14}C]arachidonoyl-phospholipids as substrates for incubation with cell homogenate and subcellular fractions, results indicate the presence of a $Ca2^{+}$-independent phospholipase A (PLA_2) in the Sf9 cell cytosol fraction. This PLA_2 shows a high preference for hydrolysis of PE and is active at a pH range of 7–9. Unlike the brain cells which contain active phospholipase C (PLC) specific for phosphatidylinositol, only limited amount of diacylglycerol (DAG) was released from [^{14}C]arachidonoyl-PE in the Sf9 cells. Taken together, this study demonstrates active metabolism of membrane phospholipids in Sf9 cells, most likely mediated by acyltransferases and PLA_2. Furthermore, despite the absence of PLC for PI, limited amount of DAG could be generated through hydrolysis of PE.

Lipids 32, 481–487 (1997).

Recent advances in molecular biological techniques have focused on the use of insect ovarian *Spodoptera frugiperda* (Sf9) cells for the production of recombinant proteins, mainly *via* the baculovirus vector expression system (1). There are several advantages in the use of these cells in biotechnology, e.g., their ability to grow in a chemically defined medium at ambient temperature, their rapid growth rate, and possibility of large-scale production of cells grown in suspension. In the biotechnology of mass protein production, it is important to consider the ability of the host cells to carry out post-translational modifications and processing, e.g., phosphorylation, acylation, glycosylation and in the case of membrane proteins, translocation and incorporation into the membrane. In the study by De Carvalho *et al.* (2), there is evidence that expression of the 84 kDa cytosolic phospholipase A_2 (PLA_2) in Sf9 cells resulted in a phosphorylated protein which is actually the active form of the enzyme (3). The study of Leimer *et al.* (4) demonstrated that overexpression of rat synaptophysin in Sf9 cells resulted not only in the synthesis of the complete polypeptide which is a *N*-glycosylated integral membrane protein, but also incorporation of the protein into membrane vesicles. Other studies also show that Sf9 cells are capable of synthesizing functionally active proteins which are subsequently incorporated into the plasma membranes as channels (5) or receptors (6,7). A recent review on the G-protein-coupled receptors in insect cells gave evidence suggesting that these cells are suitable for large-scale expression and characterization of cloned receptor genes (8)

In order to better understand the Sf9 cells expression system, it is important to know the characteristic metabolic activities in these cells. For example, it would be of interest to obtain information on the membrane lipid composition and the enzymes metabolizing the lipids in these cells. It would be of interest to find out whether different phospholipases are present in these cells and whether second messengers, e.g., inositol (1,4,5) trisphosphate and diacylglycerol (DAG), are released upon stimulation of the cell surface receptors (9). These second messengers are important in mediating intracellular calcium homeostasis and in turn, responsible for regulation of a number of cellular metabolic pathways (10).

In this study, the lipids present in Sf9 cells were character-

Abbreviations: AA, arachidonic acid; BSA, bovine serum albumin; DAG, 1,2-diacylglycerol; DITC, homogenate of immortalized astrocytes; FAME, fatty acid methyl ester; FBS, fetal bovine serum; FFA, free fatty acid; HPTLC, high-performance thin-layer chromatography; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PE_{p1}, ethanolamine plasmalogen; PI, phosphatidylinositol; PS, phosphatidylserine; PLA_2, phospholipase A_2; PLC, phospholipase C; STE, sucrose-Tris-EDTA buffer; TAG, triacylglycerol; UV, ultraviolet.

ized, and metabolism of labeled fatty acids and labeled phospholipids was examined. We obtained evidence that the insect Sf9 cells can actively take up fatty acids from the culture medium and that the cell cytosol contains an active calcium-independent PLA_2.

MATERIALS AND METHODS

Cell culture and subcellular fractionation. Sf9 cells were grown in stationary T175 culture flasks at 28°C in TNM-FH medium supplemented with 10% fetal bovine serum (FBS) (1). The cells were subcultured twice a week, and experiments were carried out shortly after cells reached confluency. In some experiments, cells were harvested and subjected to a subcellular fractionation protocol for isolation of crude mitochondrial and microsomal fractions. Briefly, cells were homogenized in an STE buffer containing 0.32 M sucrose, 50 mM Tris, and 1 mM acid free EDTA (pH 7.4) and centrifuged at $1,000 \times g$ to remove unbroken cells and nuclei. The suspension was then centrifuged at $20,000 \times g$ for 30 min at 4°C. The pellet containing the crude mitochondrial membrane fraction was resuspended in sucrose-Tris-EDTA (STE) buffer and stored at −20°C until further use. The supernatant was centrifuged at $100,000 \times g$ for 60 min to yield a microsomal pellet which was suspended in STE buffer and stored at −20°C. The remaining supernatant was the cytosol fraction.

Analysis of cell membrane lipids and their acyl group composition. Cell samples containing 1×10^7 cells were collected, centrifuged at 800 rpm for 5 min, and resuspended in 2 mL Hank's balanced salt solution. Cells were disrupted using a glass-homogenizer, and protein content in the cell homogenates was determined using the Bio-Rad procedure (11) with bovine serum albumin (BSA) as a protein standard. Protocols for lipid extraction and analysis were essentially those described previously by Sun (12). Lipids from cell homogenate were extracted by adding 4 mL of chloroform/methanol (2:1, vol/vol) to a 1 mL aliquot of cell homogenate followed by vortexing for 30 s. After a low-speed centrifugation ($800 \times g$), the lower organic phase was filtered through an anhydrous Na_2SO_4 column, dried under N_2, and reconstituted in 1 mL of chloroform/methanol (2:1, vol/vol).

For separation of the neutral lipids, a 0.5 mL aliquot of the reconstituted organic phase was applied to high-performance thin-layer chromatography (HPTLC) plate (silica gel HP-K, 10×10 cm, Whatman, Hillsboro, OR) and developed twice in a solvent system containing hexane/diethyl ether/acetic acid (85:15:2, by vol). Using this solvent system, neutral lipids, including triacylglycerol (TAG), free fatty acid (FFA), and diacylglycerol (DAG)/cholesterol were separated from phospholipids which remained at the origin. For visualization of lipid bands, the HPTLC plate was either exposed to iodine vapors (for counting of radioactivity) or sprayed with 1% 2′,7′-dichlorofluorescein in methanol and viewed under an ultraviolet (UV) lamp (for analysis of fatty acids).

The phospholipids that remained at origin of the HPTLC plate were recovered by suspending the mixture in a two-phase system containing chloroform/methanol/1% acetic acid (8:4:3, by vol). The phospholipids in the organic phase were recovered and separated by a two-dimensional HPTLC system (12). The first solvent system contained chloroform/methanol/acetone/16 N NH_4OH (70:40:10:10, by vol). After solvent development, the plates were thoroughly dried by blowing with an air-gun and were exposed to HCl fumes for 3 min. This procedure separates the plasmalogens from the diacyl-phospholipids. After removing the residual HCl by blowing, the HPTLC plates were turned 90° and developed in the second solvent system containing chloroform/methanol/acetone/acetic acid/0.1 M ammonium acetate (70:30:27.5:2.3:5, by vol). After solvent development, plates were either exposed to iodine vapors or sprayed with 2′,7′-dichlorofluorescein, and lipid spots corresponding to phosphatidic acid (PA), phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidylcholine (PC), ethanolamine plasmalogen (PE_{pl}) and phosphatidylethanolamine (PE) were removed from the plate by scraping. Samples were either used for measurement of radioactivity (iodine) or further processed for fatty acid analysis (2′,7′-dichlorofluorescein).

For analysis of the acyl group composition of phospholipids, samples were subjected to base methanolysis using 1 mL of 0.5 N NaOH in methanol together with heptadecanoic acid methyl ester (17:0 FAME) as internal standard (12). The fatty acid methyl esters (FAME) were recovered by partitioning the reaction mixture into the chloroform/methanol/H_2O system. The organic solvent containing the FAME was removed and solvent evaporated under N_2. In some instances, FAME were further purified by HPTLC using the hexane/ether/acetic acid system. FAME were analyzed by gas–liquid chromatography using a Hewlett-Packard Gas Chromatograph (model 5890A; Wilmington, DE) equipped with a flame-ionization detector and a plotter-integrator unit and a fused-silica capillary column (0.32 mm i.d. × 30 m length; Supelco Co., Bellefonte, PA).

Uptake of labeled oleic acid into cell membrane lipids. In order to determine whether Sf9 cells can take up labeled fatty acids from the culture medium, the solvent used for dissolving [1-^{14}C]oleic acid (1 mCi/mL, specific activity 3000 Ci/mmol; New England Nuclear, Boston, MA) was evaporated under N_2, and the fatty acid was suspended in TNM-FH medium containing 2% FBS and vortexed vigorously. Sf9 cells were harvested and were added to the medium containing the label (0.1 μCi/mL) and incubated for 30 min. After incubation, the reaction was terminated by adding 4 mL of chloroform/methanol (2:1, vol/vol) to 1 mL of the incubation mixture. Lipids were extracted and analyzed as described above. Lipid spots were removed from HPTLC plates to scintillation vials for measurement of radioactivity by a Beckman LS 5800 scintillation spectrometer (Fullerton, CA).

Preparation of labeled substrates. PC, PS, PE, and PI labeled with [^{14}C]arachidonic acid (AA) (20:4) were synthesized in our laboratory by incubating the rat pheochromocytoma cells (PC-12) with [1-^{14}C]AA (2 μCi/60 mm dish) for 6 h as described elsewhere (13). [1-^{14}C]Oleate-labeled PE and PC substrates were prepared by incubating Sf9 cells with

[1-^{14}C]oleic acid for 6 h. [1-^{14}C]Palmitate-PC was prepared by incubating PC-12 cells with [1-^{14}C]palmitic acid for 6 h. Briefly, after incubation with labeled fatty acids, cells were harvested and lipids extracted and separated by two-dimensional HPTLC system as described above (12). After separation, the HPTLC plates were sprayed with 2′,7′-dichlorofluorescein and visualized under a UV lamp. Individual lipid spots were transferred to test tubes, and the labeled phospholipids were recovered in the lower organic phase after partitioning the sample into a two-phase system by addition of 4 mL chloroform/methanol (2:1, vol/vol) and 1 mL of 0.1 N NaOH. For estimation of the specific radioactivity of the lipid substrates, a separate dish of cultured cells was used and lipids were separated by the same two-dimensional HPTLC protocol. The amount of fatty acids from individual phospholipids was determined together with 17:0 methyl ester as an internal standard. From this assay, it is possible to determine specific radioactivity of the fatty acids in each phospholipid.

Assay of phospholipase A_2 (PLA_2) and phospholipase C (PLC) activity. For assay of PLA_2 and PLC activities in Sf9 cell homogenates and subcellular fractions, solvent for dissolving the labeled phospholipids (5000 to 10,000 dpm) was evaporated under N_2 and mixed with 100 µL of the incubation buffer containing 1 mM EGTA, 1 mM EDTA, 6 mM $CaCl_2$, 1 mg/mL BSA, and 50 mM HEPES (pH 7.4). Enzyme reaction was initiated by adding 100 µL of the cell homogenate or subcellular fractions, and incubation was carried out at 37°C for 30 min or time indicated. Reaction was terminated by adding 4 mL of chloroform/methanol (2:1, vol/vol) followed by 0.8 mL of 0.1 N HCl. Lipids in the lower organic phase together with DAG and FFA standards were applied to HPTLC plates and separated using a solvent system containing hexane/ethyl ether/acetic acid (85:15:2, by vol). After solvent development, the HPTLC plates were exposed to iodine vapors for visualization. Lipid bands corresponding to phospholipids (origin), DAG, and FFA were identified and transferred to scintillation vials for measurement of radioactivity. In each experiment, a negative control ($t = 0$) was carried out by mixing homogenate with incubation buffer and label and immediately stopping the reaction with 4 mL of chloroform/methanol (2:1, vol/vol). PLA_2 activity was expressed as nmol of FFA released per 100 µg protein per unit time. Similarly, PLC activity was expressed as nmol of DAG released per 100 µg protein per unit time.

RESULTS

Membrane lipids and acyl group composition in Sf9 cells. Analysis of the lipids in Sf9 cells indicated a phospholipid profile similar to those present in mammalian cells (Fig. 1). The major phospholipid is the diacyl form of PE (41.8%) followed by PC (36.4%), PI (14.5%), and PS (7.3%). Despite the fact that PE is the major phospholipid, only trace amounts of PE_{pl} are present. Data in Figure 1 further show that noticeable amounts of sphingomyelin and cardiolipin are present in these cells.

An example of the elution profile of FAME derived from total phospholipid extract of Sf9 cells is shown in Figure 2.

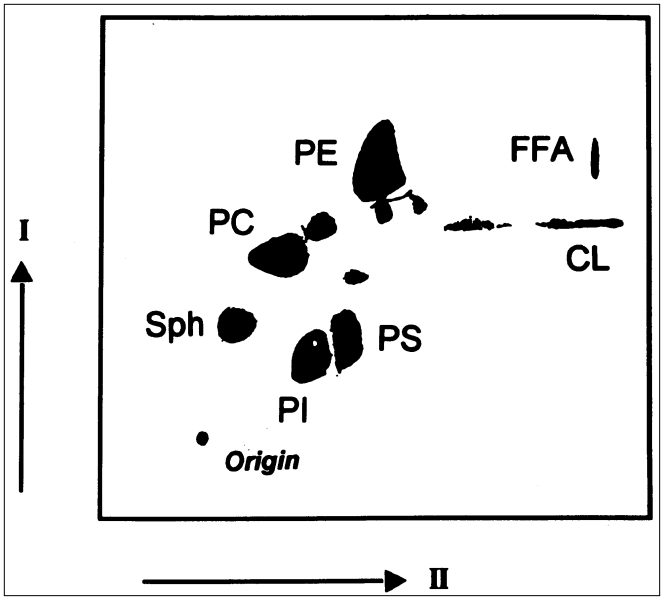

FIG. 1. A typical picture depicting the phospholipids of *Spodoptera frugiperda* cells. *Spodoptera frugiperda* cells (1×10^7 cells) were harvested, washed, and lipids extracted by chloroform/methanol (2:1, vol/vol). The lipid extract was separated by two-dimensional high-performance thin-layer chromatography according to a procedure described by Sun (12); PS, phosphatidylserine; PI, phosphatidylinositol; Sph, sphingomyelin; CL, cardiolipin; PC, phosphatidylcholine (split into two spots); PE, phosphatidylethanolamine; FFA, free fatty acid. Note: Minor spots in the chromatogram were not identified.

These cells exhibit a relatively simple fatty acid profile with monounsaturated fatty acids, e.g. 16:1, 18:1, constituting more than 70% of the total fatty acids. Saturated fatty acids include 16:0, 18:0, and 20:0. (The identity of 20:0 was confirmed by co-chromatography with a known standard.) Polyunsaturated fatty acids such as 18:2 and 20:4 are present at low levels. When the acyl group composition of individual phospholipids was analyzed, both PE and PC constitute high proportions of 16:1 and 18:1 whereas PS/PI show high proportions of 18:0 and 18:1 (Table 1). Interestingly, 20:0, a unique fatty acid of Sf9 cells, is concentrated in the PS/PI fraction (10.3% as compared to 3.1% in the total homogenate).

Uptake and incorporation of labeled oleic acid by Sf9 cells. The ability of Sf9 cells to take up and incorporate [1-^{14}C]oleic acid into membrane phospholipids and other glycerolipids was examined. Results show that labeled oleic acid was taken up from the culture medium and incorporated into phospholipids as well as TAG. The incorporation of labeled oleic acid into TAG reached a plateau by 2 h, whereas the incorporation into phospholipids did not attain a plateau until after 4 h (Fig. 3). When the lipids were separated by two-dimensional HPTLC, incorporation of labeled oleate was highest in PE, followed by PC and very low in PI and PS (Fig. 4).

We further examined the uptake profile of [^{14}C]oleic acid among the glycerolipids in two subcellular membrane fractions of Sf9 cells. In this experiment, cells were incubated with [^{14}C]oleic acid (0.1 µCi/mL) for 6 h. After harvesting the cells,

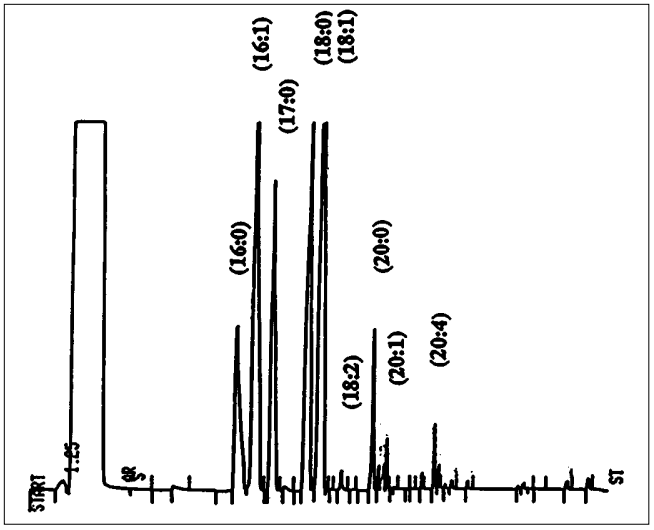

FIG. 2. The fatty acid profile of total phospholipids from *Spodoptera frugiperda* cells. Phospholipids were separated from other lipids by one-dimensional high-performance thin-layer chromatography. Fatty acids from the phospholipids (together with a known amount of 17:0 methyl ester) were converted to fatty acid methyl esters by basic base-catalyzed methanolysis and analyzed by gas–liquid chromatography.

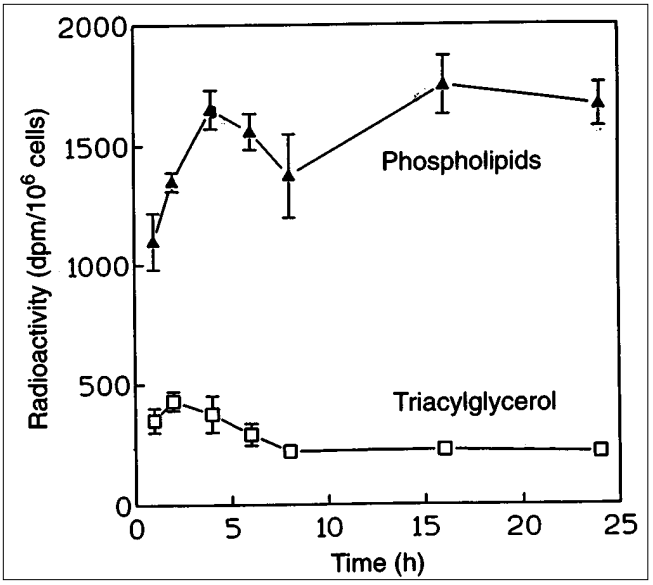

FIG. 3. Time course of [^{14}C]oleic acid uptake into phospholipids and triacylglycerol of *Spodoptera frugiperda* cells. *Spodoptera frugiperda* cells (1×10^6 cells per 35-mm dish) were incubated in 1 mL of TNM-FH medium containing [1-^{14}C]oleic acid (0.1 μCi/dish). At specified time, cells were washed twice, each with 1 mL of Hank's balanced salt solution, and the lipids were extracted with chloroform/methanol (2:1, vol/vol). Lipids were separated by the one-dimensional high-performance thin-layer chromatography to give the triacylglycerol band and phospholipids (at origin). Results are mean ± SD from three samples for each time point. Two other experiments showed similar results.

they were homogenized in a sucrose-Tris buffer. Cell homogenate was subjected to differential centrifugation to yield a crude mitochondria and a microsomal fraction. The membrane lipids were extracted and were separated into neutral lipids and phospholipids using the HPTLC protocols as previously described. In the crude mitochondria fraction, 15% of the label was in neutral lipids and 85% in the phospholipids. Analysis of the phospholipids indicated a labeling order of PE > PC > PI = PS = PA (Fig. 5). When the labeling pattern of glycerolipids in microsomes was compared to the mitochondrial fraction, glycerolipids in the microsomes indicated a higher proportion of radioactivity in TAG and polyphosphoinositide and a lower proportion in PE (Fig. 5).

TABLE 1
Fatty Acid Composition (wt%) of Total and Individual PL in *Spodoptera frugiperda* Cells[a]

Fatty acids	PL	PE	PC	PS + PI
16:0	7.6	3.3	5.4	4.6
16:1	31.3	23.4	26.4	18.0
18:0	14.6	9.7	11.1	35.1
18:1	40.3	55.5	52.4	26.8
20:0	3.1	4.6	2.7	10.3
20:1	0.9	3.0	1.7	2.5
20:4	1.2	0.6	0.3	2.7

[a]Lipid extract from *Spodoptera frugiperda* cells was separated by high-performance thin-layer chromatography first by the one-dimensional system to obtain total phospholipids (PL) and followed by a two-dimensional system for individual PL. PL were subjected to base-catalyzed methanolysis, and the fatty acid methyl esters were subsequently analyzed by gas–liquid chromatography. Data are expressed as weight percentage of total fatty acids (average of two samples from a typical experiment); PE, phosphatidylethanolamine; PC, phosphatidylcholine; PS, phosphatidylserine; PI, phosphatidylinositol.

Using Sf9 cell homogenate, we compared the labeling profile due to incorporation of [^{14}C]AA and [^{14}C]oleic acid into the glycerolipids. Data in Figure 6 show that labeled AA was

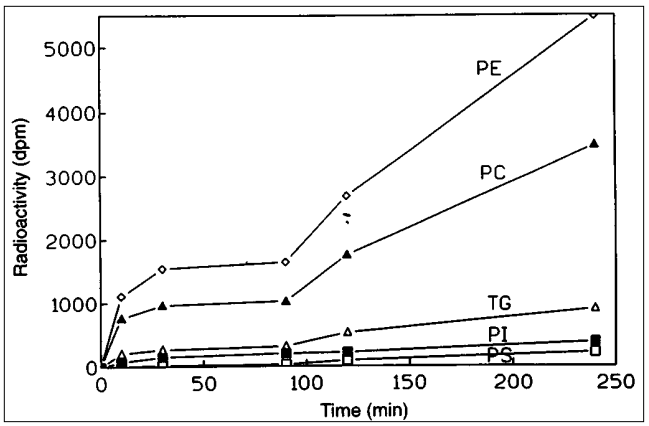

FIG. 4. Time course of [^{14}C]oleic acid incorporation into individual phospholipid species and triacylglycerol of *Spodoptera frugiperda* cells. Incubation conditions were the same as in Figure 3 except that lipids were separated by one-dimensional high-performance thin-layer chromatography (for separation of triacylglycerol and phospholipids) followed by recovering the phospholipids for two-dimensional high-performance thin-layer chromatography as described in the text. Results are depicted as radioactivity of lipids (average of two samples) recovered from 1×10^6 cells.

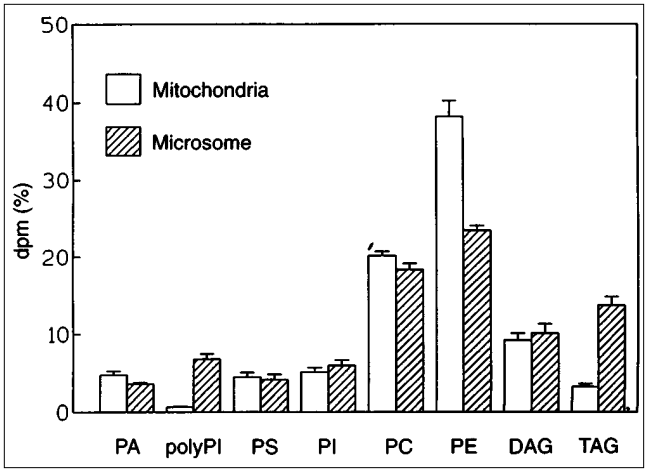

FIG. 5. Percentage distribution of [^{14}C]oleic acid among glycerolipids in mitochondrial and microsomal fractions of *Spodoptera frugiperda* cells. *Spodoptera frugiperda* cells (10×10^8) were incubated with [^{4}C]oleic acid for 6 h. After labeling, cells were washed and subjected to subcellular fractionation to yield the mitochondrial and microsomal fractions. Analysis of lipids from the subcellular fractions was similar to that described in Figure 4. Data represent percentage distribution of radioactivity among glycerolipids and are mean ± SD from three samples; PA, phosphatidic acid; DAG, diacylglycerol; TAG, triacylglycerol. See Figure 1 for other abbreviations.

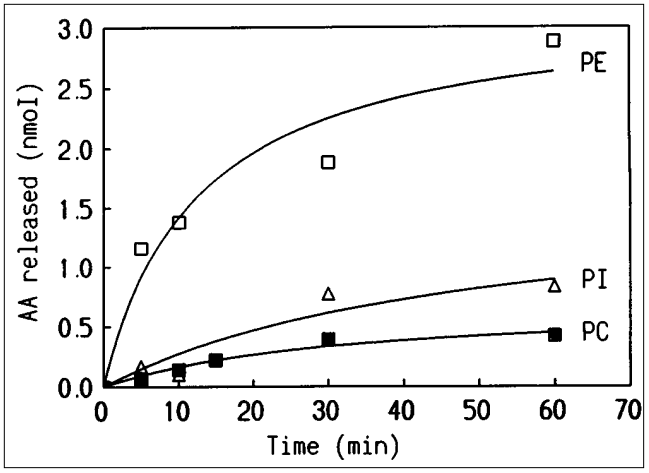

FIG. 7. Time course of arachidonic acid (AA) release from *Spodoptera frugiperda* cell homogenate after incubation with different [^{14}C]20:4-phospholipids. The incubation mixture contained cell homogenates (100 µg protein) and labeled phospholipids in a buffer made of bovine serum albumin (1 mg/mL), $CaCl_2$ (6 mM), EGTA (1 mM), EDTA (1 mM) and HEPES (pH 7.4). Incubation was carried out at 37°C for different time periods. After termination of reaction, labeled AA were separated by one-dimensional high-performance thin-layer chromatography. Phospholipase A_2 activity is represented by the release of labeled AA (nmol/100 µg protein) during the specified times. Results are average values of two samples from a typical experiment. See Figure 1 for other abbreviations.

more actively incorporated into PI and PC and less into PE and TAG as compared to the pattern due to labeled oleic acid.

Test for PLA$_2$ and PLC activity in Sf9 cells. In order to test for the presence of PLA$_2$ and PLC in Sf9 cells, cell homogenates were incubated with [^{14}C]20:4-PC, PE, PI, and PS at 37°C for 30 min. These lipid substrates were prepared by incubating PC-12 cells with [^{14}C]AA as described in the Materials and Methods section. Data in Figure 7 show the time-dependent release of labeled FFA upon incubation of Sf9 cell homogenate with labeled PE, PC, and PI. Results show that the release of labeled AA from PE was several-fold higher than that of labeled PI and PC (Fig. 7).

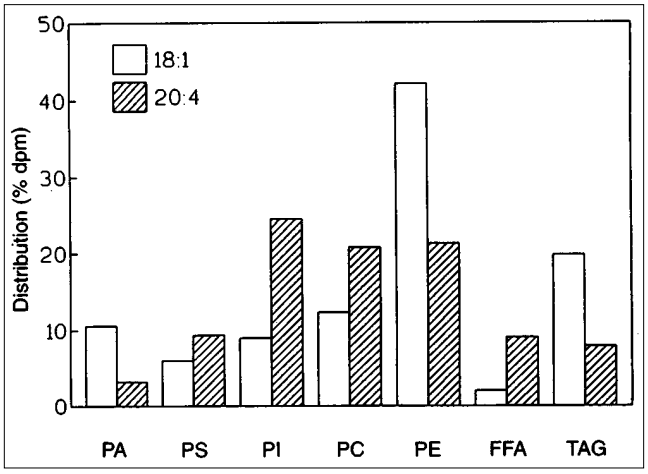

FIG. 6. Percentage distribution of [^{14}C]oleic acid and [^{14}C]arachidonic acid in glycerolipids of *Spodoptera frugiperda* cells. *Spodoptera frugiperda* cells (1×10^6 cells per 35-mm dish) were incubated in 1 mL of TNM-FH medium containing the respective labeled fatty acids. Analysis of lipids was similar to the described in Figure 4. Data are percent distribution of radioactivity among glycerolipids and are average from two samples. Note: Radioactivity in the free fatty acid (FFA) fraction depicts the amount of radioactivity of free fatty acids retained within the cells. See Figures 1 and 5 for other abbreviations.

In a separate experiment, the ability of Sf9 cell homogenate to hydrolyze different [^{14}C]20:4-phospholipids was compared with the homogenate of immortalized astrocytes (DITNC) derived from rat brain (14). Data in Table 2 show that Sf9 cell homogenates preferentially hydrolyzed [^{14}C]20:4-PE over other labeled phospholipids, whereas DITNC cells show a clear order of PE > PC > PI > PS. Besides the release of FFA, incubation of DITNC cells with labeled PI resulted in a large release of labeled DAG. In fact, there was more labeled DAG released than

TABLE 2
Incubation of [14C]20:4-PL with *Spodoptera frugiperda* Cell Homogenate[a]

	Sf9		DITNC	
	FFA	DAG	FFA	DAG
[^{14}C]20:4-PE	13.9	0.19	0.48	0.077
[^{14}C]20:4-PI	0.17	n.d.	0.13	0.56
[^{14}C]20:4-PI	0.17	n.d.	0.016	0.005
[^{14}C]20:4-PC	0.071	0.026	0.26	0.037

[a]*Spodoptera frugiperda* cell homogenate (100 µg protein) was incubated with individual labeled PL at 37°C for 30 min as described in text. Values are nmol of substrates free fatty acid (FFA) and diacylglycerol (DAG) released per 100 µg protein per 30 min and are average of duplicate incubations from a typical experiment; n.d., not detected; DITNC, homogenate of immortalized astrocytes. See Table 1 for other abbreviations.

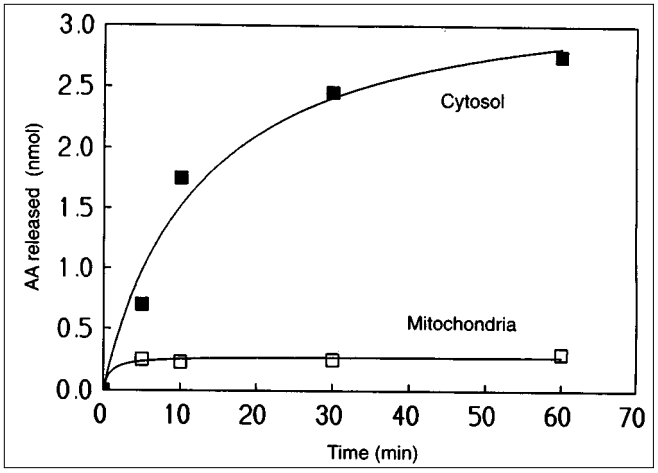

FIG. 8. Measurement of phospholipase A_2 activity in mitochondrial and cytosol fractions of *Spodoptera frugiperda* cells. Subcellular fractions were prepared as described in the text. Samples were incubated with [^{14}C]20:4-phosphatidylethanolamine as described in Figure 7. Data are expressed as nmol of fatty acids released per 100 µg of protein and are averages from two samples.

FFA. On the other hand, the only labeled phospholipid substrate which can give an observable labeled DAG in Sf9 cells is [^{14}C]20:4-PE (Table 2).

Subcellular localization of phospholipases. In this experiment, Sf9 cells (3×10^7 cells) were washed, homogenized, and subjected to differential centrifugation to yield the mitochondrial and cytosolic fractions. Aliquots of these fractions were used in a time-course study with [^{14}C]20:4-PE. Surprisingly, there was a 10-fold higher release of labeled 20:4 from PE by the cytosol fraction compared to the mitochondrial fraction (Fig. 8). When the cytosol fraction was incubated with different labeled phospholipids, a similar substrate profile with preference on [^{14}C]arachidonoyl-PE was observed (data not shown). We also tested the ability of cell cytosol to hydrolyze [^{14}C]oleoyl-PE and PC as well as [^{14}C]palmitoyl-PE. However, none of these substrates showed activity comparable to the [^{14}C]arachidonoyl-PE (data not shown).

Calcium and pH on cytosolic PLA_2 in Sf9 cells. In order to test for Ca^{2+} dependency, cell cytosol was incubated with [^{14}C]20:4-PE in a buffer containing either EGTA or EGTA with Ca^{2+} giving final [Ca^{2+}] from 0 to 2.7 mM, respectively. To our surprise, the release of FFA from [^{14}C]20:4-PE was highest in the samples with EGTA alone. Addition of Ca^{2+} to the incubation system did not cause an obvious inhibition until concentrations well over 2 mM (data not shown). When aliquots of cytosol (100 µg protein) were incubated with [^{14}C]20:4-PE in a Ca^{2+}-free buffer ranging from pH 5 to 9, PLA_2 activity was found at pH 7 and over (data not shown).

DISCUSSION

In this study, we present novel information on the phospholipids and their fatty acid composition in insect ovarian Sf9 cells. Unlike mammalian cells which show a high proportion of PC as the predominant phospholipid and where the PE was comprised of both the diacyl and alkenylacyl form, insect Sf9 cells contain a high proportion of PE which is present mainly in the diacyl form. Analysis of the fatty acids of phospholipids in Sf9 cells revealed that these cells have a fatty acid pattern comprising high proportions of 16:1 and 18:1 with only low proportions of polyunsaturated fatty acids.

When labeled fatty acids were added to the culture medium, it is clear that Sf9 cells can take up and utilize exogenous fatty acids for their cell membrane lipids. Nevertheless, it is not possible to predict from results of this study whether the incorporation is through the lysophospholipid/acyl–CoA acyltransferase or the *de novo* biosynthesis pathway.

Incubation of Sf9 cell homogenates with [^{14}C]20:4-phospholipids resulted in the release of labeled fatty acid, suggesting the presence of PLA_2 in these cells. Under these *in vitro* assay conditions, this PLA_2 shows a high preference for PE. Incubation of labeled PE also resulted in the release of a small amount of DAG suggesting the presence of a PE-specific PLC in Sf9 cells. In the brain cells, incubation of labeled PI resulted in the release of labeled FFA and DAG, indicating the presence of both PLA_2 and PLC. The lack of a PLC toward labeled PI in Sf9 cells is a strong indication that these cells lack the polyphosphoinositide signaling cascade. So far, the only agonist reported for these cells is octopamine, a biogenic amine known to couple to the adenylate cyclase system (15,16). Despite the absence of PI–PLC in Sf9 cells, results show that some DAG may be derived from hydrolysis of PE instead. However, more studies are needed to test whether the DAG pool generated from PE is responsible for regulation of the protein kinase C in these cells.

Besides showing a preference for the hydrolysis of [^{14}C]20:4-PE, the PLA_2 in Sf9 cells present in the cytosolic fraction is Ca^{2+}-independent and exhibits activity at the alkaline pH range. A Ca^{2+}-independent PLA_2 is found in the fat body of the tobacco hornworm *Manduca sexta* (17). Although little is known about PLA_2 in insect cells, Ca^{2+}-independent PLA_2 is widespread in the cytosol of many mammalian systems (18–20). Because Sf9 cells grow rapidly, it is possible that active PLA_2 is required for regulating membrane phospholipid turnover in these cells. Obviously, more studies are needed to further elucidate the mechanism for activation of this cytosolic PLA_2 in the insect Sf9 cells.

ABSTRACT: In an attempt to understand the metabolism by the liver of fatty acids (FA) of different chain length, we have studied the incorporation of [1-^{14}C]-labeled C_2, C_8, C_{10}, C_{12}, and C_{16} into cellular lipids by HepG-2 cells. Over 90% of the radiolabeled FA were detected in phospholipids (PL) and triacylglycerols (TAG). The incorporation of C_{12} and C_{16} was three to four times higher than that of C_8 and C_{10} (and reached 35 nmoles per mg protein after 1.5 h). The radioactivity of C_2, C_8, and C_{10} was recovered mainly in PL. C_{12} and C_{16} were incorporated at approximately equal amounts into PL and TAG. The radioactivity of both C_2 and C_8 was recovered exclusively in long-chain FA, suggesting oxidation of C_8 into C_2 units prior to FA synthesis. C_{10} likewise yielded mainly long-chain FA. However 10% of unchanged C_{10} was found in PL and up to 30% in TAG. ^{14}C-C_{12} was largely incorporated unchanged. Under these conditions, the presence of C_{10} and C_{12} in PL and TAG was shown also by gas–liquid chromatography. In the presence of either C_2, C_8, or C_{10}, up to 30% of ^{14}C-monounsaturated FA were detected in PL and TAG. With C_{12} and C_{16}, the fraction of ^{14}C-monounsaturated FA was much smaller suggesting that extensive desaturation occurred during *de novo* synthesis.
Lipids 32, 489–495 (1997).

The influences of both enterally and parenterally administered triacylglycerols (TAG) composed of fatty acids (FA) of different chain lengths on serum lipids and lipoproteins and on biliary lipids have been the subject of many investigations in recent years (1–8). In these dietary studies, the TAG were composed of long-chain fatty acids (LCFA), i.e., FA with 14–18 carbons (1–9). Recently, the effects of medium-chain TAG (MCT) were studied (10–14). These studies demonstrated that varying the FA composition of dietary TAG affected plasma lipid composition very markedly. Specifically, feeding healthy volunteers with MCT resulted in a three-fold increase of plasma TAG level and a significant alteration of the FA composition of TAG in comparison to volunteers fed with long-chain TAG (LCT) (13,14).

In our recent clinical studies, we have observed marked differences in the lipid composition of blood and bile following short-term infusion (24 h) of TAG of different chain lengths (7) while a mixture of MCT and LCT (50%:50%, w/w) given to patients prior to cholecystectomy caused an increase in the concentrations of biliary phospholipids (PL) and cholesterol; less pronounced effects were observed with LCT. The FA composition of biliary PL was similar in patients treated with the different lipid emulsions. In an attempt to understand the results of the latter studies, we have carried out a systematic *in vitro* study presented in this paper on the metabolism of FA of different chain length by liver cells. Since lipid emulsions are rapidly hydrolyzed in the circulation (2), a large fraction of FA uptake by the liver involves unesterified, albumin-bound LCFA and free FA of short- and medium-chain (SCFA and MCFA) length (15). SCFA and MCFA may also reach the liver *via* the portal circulation when TAG containing these FA are fed.

HepG-2 cells were chosen since these cells were found to express a wide variety of liver-specific functions (16). The cells were incubated with different radiolabeled (^{14}C) FA and their incorporation into cellular lipids was followed. C_{12} and C_{16} were incorporated unchanged into cellular TAG and PL. By contrast, octanoic acid (C_8) was apparently utilized only after complete degradation into C_2 units, which were then used for *de novo* synthesis of LCFA. Decanoic acid (C_{10}) was metabolized by both these pathways: it was detected as unchanged ^{14}C-C_{10} in cellular lipids, mainly TAG, or as ^{14}C-LCFA.

MATERIALS AND METHODS

Materials. Minimal essential Eagle's medium (MEM), fetal calf serum (FCS) and penicillin–streptomycin solution were obtained from Biological Industries (Beth Haemek, Israel).

Abbreviations: BSA, bovine serum albumin; C_2, acetic acid; C_8, octanoic acid; C_{10}, decanoic acid; C_{12}, dodecanoic acid (lauric acid); C_{16}, hexadecanoic acid (palmitic acid); FA, fatty acids; FCS, fetal calf serum; GLC, gas–liquid chromatography; LCFA, long-chain fatty acids; LCT, long-chain triacylglycerols; MCFA, medium-chain fatty acids; MCT, medium-chain triacylglycerols; MEM, minimal essential Eagle's medium; PBS, phosphate-buffered saline; PL, phospholipids; SCFA, short-chain fatty acids; TAG, triacylglycerols; TLC, thin-layer chromatography; UV, ultraviolet.

[1-^{14}C] Sodium acetate (52.1 mCi/mmol), [1-^{14}C] lauric acid (52.8 mCi/mmol), and [1-^{14}C] palmitic acid (57.0 mCi/mmol) were obtained from Amersham (Little Chalfont, United Kingdom), [1-^{14}C] sodium octanoate (55.0 mCi/mmol) from NEN (Boston, MA), and [1-^{14}C] sodium decanoate (10.6 mCi/mmol) from Sigma (St. Louis, MO). All the FA were obtained from Sigma. Thin-layer chromatography (TLC) plates were as follows: silica gel 60 (0.25 mm) from Merck (Darmstadt, Germany), KC18 Silica gel 60 (0.2 mm) from Whatman (Maidstone, England). All solvents were of analytical grade (Merck). Scintillation fluid-Ultima Gold was obtained from Packard (Meriden, CT). Polystyrene dishes were obtained from Corning (Corning, NY).

Tissue cultures. Human hepatoma HepG-2 cells were used in the experiments. HepG-2 cells were routinely grown in MEM supplemented with 10% FCS and 100 IU/L penicillin–streptomycin, in a 37ºC incubator with 5% CO_2. The experiments were done in 35-mm plastic dishes. When cells reached confluency, the growth medium was removed and replaced by 2 mL of fresh medium containing 0.1 mM of ^{14}C-labeled FA. All radiolabeled FA, except sodium decanoate, were mixed with the corresponding nonlabeled FA to a specific radioactivity of 10 mCi/mmole. These were dissolved in a small volume of ethanol (final concentration 0.05–0.1%), added to the growth medium, and incubated for 30 min at 37ºC (to ensure binding of the LCFA to albumin) prior to filtration through 0.22 µm sterile Millipore filters.

Under our experimental conditions, the cultures were incubated with the ^{14}C-FA for 1.5, 3, and 6 h. At the end of incubation, the media were removed, cells were washed once with 1% BSA in phosphate-buffered saline (PBS) to remove free FA and twice with PBS. All incubations were done in triplicate. Results are normalized for mg protein and represent the mean of three independent determinations. Variations did not exceed 5%.

Lipid extraction and analysis. Cells attached to the plates were extracted twice with hexane/isopropanol (3:2, vol/vol), first with 1.5 mL for 60 min and then with 1 mL for 15 min (17). The amount of the radioactivity in the extracts was determined using a Kontron-Betamatic counter (Zurich, Switzerland). Aliquots of the lipid extract were used for TLC. The hexane/isopropanol extracts were dried with a gentle stream of N_2 and the lipids dissolved in chloroform. Neutral lipids were separated on Silica gel G plates employing hexane/diethyl ether/methanol/acetic acid (90:20:3:2, by vol) as solvent. PL were separated using chloroform/methanol/acetic acid/water (100:20:12:5, by vol) as solvent.

TLC plates were dried and subsequently sprayed with 0.02% 2,7-dichlorofluorescein in ethanol. Lipid spots were detected under ultraviolet (UV) light, scraped into scintillation vials, and suspended in 3.5 mL of scintillation fluid for determination of radioactivity. The overlapping spot of diglycerides and cholesterol on the TLC plates was scraped and saponified with 0.5 M methanolic KOH for 30 min at 50°C. Samples were then acidified (with HCl 6 N) and extracted with hexane. Aliquots were placed on TLC plates as described above.

To determine the chain length of the FA which were incorporated into PL and TAG, the corresponding spots were collected and saponified with 0.5 M methanolic KOH for 30 min. FA were extracted with hexane after acidification. The solvent was removed with a gentle stream of N_2 at 37°C. FA were separated according to their chain length by reversed-phase TLC employing KC18 plates utilizing acetonitrile/methanol/water (6:3:1, by vol.) as solvent. Under our experimental conditions, 18:0 and 18:1 co-migrated with 16:0. This procedure was adapted from a method described for the separation of methyl esters on silanized silica gel G plates (18). FA were detected after spraying with Rhodamine 6G (0.1% in ethanol) under UV light. Spots were scraped directly into scintillation vials, and the radioactivity was counted immediately after addition of scintillation fluid.

Saturated and unsaturated fatty methyl esters were separated on $AgNO_3$-impregnated plates (19) employing hexane/diethyl ether (80:20, vol/vol) as solvent. FA were methylated with diazomethane according to Schlenk and Gellerman (20). The methyl esters were detected under UV light after spraying with 0.02% 2,7-dichlorofluorescein and scraped directly into scintillation vials, and the radioactivity was counted immediately after addition of scintillation fluid.

Methyl esters were separated by gas–liquid chromatography (GLC) on a 30-m PAG (polyalkylene glycol) column (0.25 µm film thickness; Supelco, Bellefonte, PA) at a temperature range of 185–220°C employing a Hewlett-Packard 5790A Gas Chromatograph (Palo Alto, CA) equipped with a flame-ionization detector. The relative composition of FA mixtures was calculated employing a Hewlett-Packard 3396 integrator. For quantitative analysis, heptadecanoic acid was added as an internal standard assuming that the response of the detector for all methyl fatty esters was identical.

To determine the secretion of radiolabeled lipids from the cells, medium was collected at the end of the incubation period. Media from three identical plates were pooled. Floating cells and debris were removed by centrifugation in the cold. The supernatant was extracted with chloroform/methanol according to Bligh and Dyer (21). Lipids were analyzed as described above.

Protein determination. Cells (after lipid extraction) were incubated overnight at room temperature with 2 mL 0.2 M NaOH to extract protein. Protein was determined according to the method of Markwell *et al.* (22). Each plate contained approximately 1.5 mg protein.

RESULTS

Incorporation of radioactive FA into cellular lipids by HepG-2 cells. To study the metabolism of FA of different chain lengths by HepG-2 cells, confluent cultures were incubated with 2 mL medium in the presence of 200 nmoles (0.1 mM) of [1-^{14}C]-labeled FA (C_2, C_8, C_{10}, C_{12}, and C_{16}) for 1.5, 3, and 6 h. Figure 1 shows the incorporation of these FA into cellular lipids. As can be seen from this figure, the incorporation of all the FA increased as a function of time. The incor-

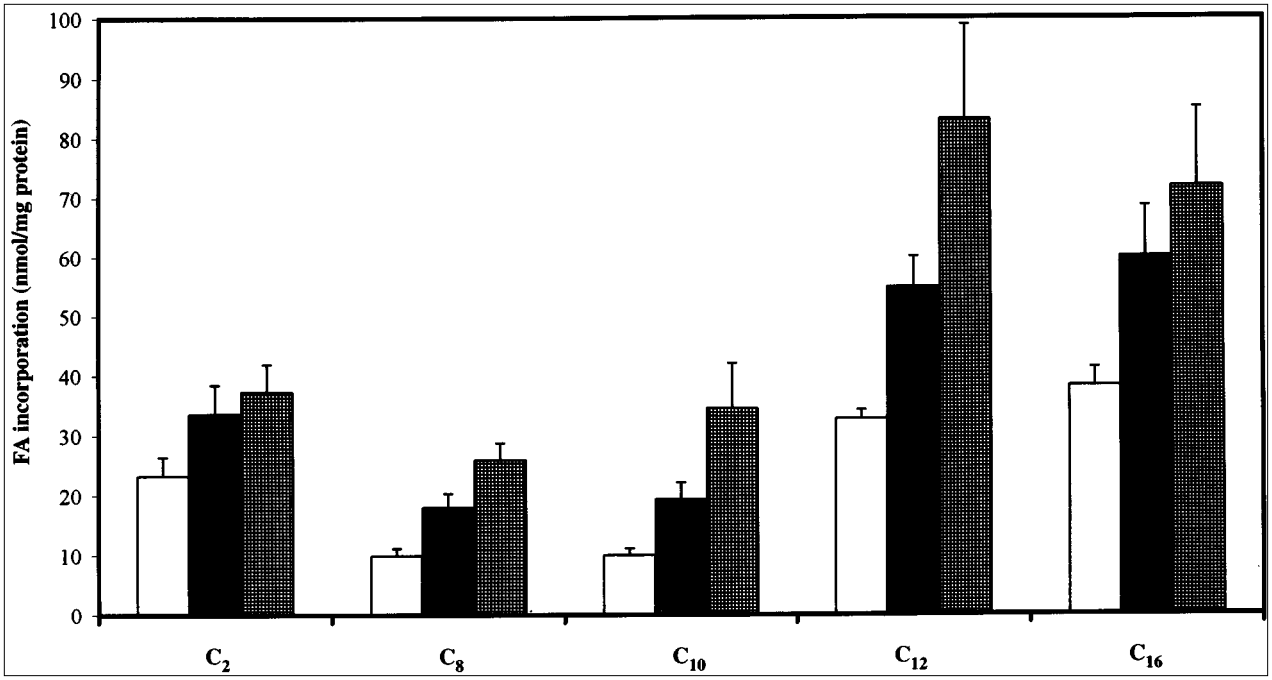

FIG. 1. Incorporation of different fatty acids (FA) into cellular lipids by HepG-2 cells. Confluent cultures were incubated for 1.5 [open box], 3 [diagonally striped box], and 6 h [hatched box], with 2 mL medium containing 200 nmoles (0.1 mM) of ^{14}C-labeled C_2, C_8, C_{10}, C_{12}, and C_{16}. The incorporation of ^{14}C into cellular lipids was determined as described in the Materials and Methods section. Each plate contained approximately 1.5 mg protein. Each point is the mean of three separate incubations ± SD.

poration of LCFA (C_{12} and C_{16}) was three to four times faster than that of MCFA (C_8 and C_{10}). After 1.5 h of incubation with LCFA, 17.5–20% of the added FA (35–40 nmoles per mg protein) were incorporated into cellular lipids as compared to 5% (10 nmoles per mg protein) of MCFA. C_2 showed a relatively high incorporation during the first 1.5 h, and the subsequent increase was smaller. Nevertheless the incorporation of C_2 was higher at all times than that of C_8 and C_{10}. The incorporation of C_{16} was rapid and amounted to approximately 50% of the applied radioactivity (70 nmoles/mg protein) after 3 h of incubation, thereafter, the rate of incorporation declined.

Distribution of labeled FA among cellular lipids. With all FA used, most of the radioactivity detected in the cells, at all times, was found in PL and TAG (Table 1). Only trace amounts of radioactivity were found in cholesterol, diacylglygerols, free FA, and cholesterol ester (not shown). As shown in Table 1, when cells were incubated for 1.5 h with C_2 or C_8, 85% of the radioactivity in cellular lipids was detected in PL. After 6 h, the fraction of radioactivity found in PL decreased (55% for C_2, 76% for C_8) while the radioactivity contained in TAG increased. The distribution of radioactivity in PL and TAG from C_{12} and C_{16} was approximately equal at all times. C_{10} yielded intermediate results. After 1.5 h of incubation, 78% was found in PL, decreasing to 61% after 6 h.

Separation of the PL by TLC showed that under our experimental conditions 70–72% of the radioactivity incorporated into PL was in phosphatidylcholine, 17–18% in phosphatidylethanolamine, and 10% migrated with lyso-PL (not shown).

In all cases, the amounts of the ^{14}C-labeled lipids synthesized in the cells and released into the medium did not exceed 1 to 2%. Similar results were reported by other investigators (23,24).

FA composition of newly synthesized PL and TAG. Following separation of the radiolabeled cellular PL and TAG, their FA were isolated and separated according to chain length as described in the Materials and Methods section. C_2 and C_8 were used exclusively for the synthesis of LCFA (not shown). With C_{16} as precursor, all the radiolabeled FA found in both TAG and PL, after 1.5, 3, or 6 h of incubation, were LCFA (not shown). ^{14}C-C_{12} was largely incorporated unchanged. As can be seen from Figure 2, 55 to 65% of the FA found in PL, and about 87% of the labeled FA in TAG were ^{14}C-C_{12}. ^{14}C-C_{10} yielded intermediate results. A significant fraction of the C_{10} taken up by the cells was recovered as C_{10} in TAG and PL. As can be seen from Figure 2, approximately 10% of the ^{14}C-FA detected in PL were C_{10} (the rest being LCFA). In TAG, up to 40% of the radioactive FA were ^{14}C-C_{10}.

Separation of the radiolabeled FA according to the degree of unsaturation showed that a considerable fraction of the ^{14}C-FA were monounsaturated (Table 2). Only negligible amounts of radioactive polyunsaturated FA were detected (not shown). The fraction of monounsaturated FA in both PL and TAG as studied after various periods of incubations de-

TABLE 1
Incorporation of Different Fatty Acids (FA) into Cellular Phospholipids (PL) and Triacylglycerols (TAG)[a]

FA added	Radioactivity incorporated (%)

C_8	10.81 ± 1.51	85.45 ± 1.37	13.54 ± 2.12	82.29 ± 2.65	19.04 ± 0.51	76.48 ± 0.58
C_{10}	18.17 ± 2.3	78.12 ± 2.43	25.43 ± 1.31	71.61 ± 1.10	33.97 ± 4.15	61.81 ± 4.20
C_{12}	44.21 ± 4.98	51.43 ± 4.76	47.40 ± 4.59	47.53 ± 4.50	52.66 ± 2.86	43.56 ± 2.86
C_{16}	36.11 ± 1.07	59.26 ± 0.98	40.97 ± 1.34	55.10 ± 1.10	42.32 ± 3.17	54.45 ± 3.42

[a]Cells were incubated with ^{14}C-labeled FA as described in the legend to Figure 1. Aliquots of the lipid extracts were subjected to thin-layer chromatography, and separated with hexane/diethyl ether/methanol/water (90:20:3:2, by vol). Lipid spots were detected with 2,7-dichlorofluorescein, scraped directly into scintillation vials, and the radioactivity determined as described in the Materials and Methods section. Each result is a mean (± SD) of three separate determinations.

pended on the chain length of the FA added to the incubation medium. The fraction of monounsaturated FA was highest (25–30%) after incubation with C_2 and did not change throughout the incubation period. In the presence of ^{14}C-labeled longer-chain FA, the percentage of ^{14}C monounsaturated FA was smaller. After 1.5 h of incubation with C_8 and C_{10} or C_{12} and C_{16}, approximately 15% and 10–12%, respectively, were detected in the PL. These amounts doubled after 6 h and reached 27% for C_8 and C_{10} and 20–24% for C_{12} and C_{16}. The percentage of ^{14}C-monounsaturated FA in TAG did not change markedly during the incubation period and remained at 25–27% for C_8 and C_{10} and 13–17% for C_{12} and C_{16}. The synthesis of more ^{14}C-monounsaturated FA in the presence of C_2 suggests that extensive desaturation occurs mainly during *de novo* synthesis of LCFA.

In an attempt to detect changes in the overall FA composition of cellular PL and TAG due to incubation with externally added FA, the composition of these lipids after 3 h of incubation was resolved by GLC as described in the Materials and Methods section. An important finding of this analysis, as shown in Table 3, is that following incubation with C_{12} a significant fraction of the FA in PL (1.9%) and TAG (9.8%) was C_{12}. A similar but much smaller effect was found after incubation with C_{10}. Neither C_{12} nor C_{10} was detected in cells following incubation in any other medium. To compensate for the incorporation of C_{12} into TAG, a significant reduction occurred in 18:1 (from 46.4 to 37.7%). A smaller reduction was noted in the percentage of 18:0. C_{10} caused much smaller changes in 18:1. Likewise, when cells were incubated in the presence of C_{16}, the percentage of C_{16} in cellular TAG in-

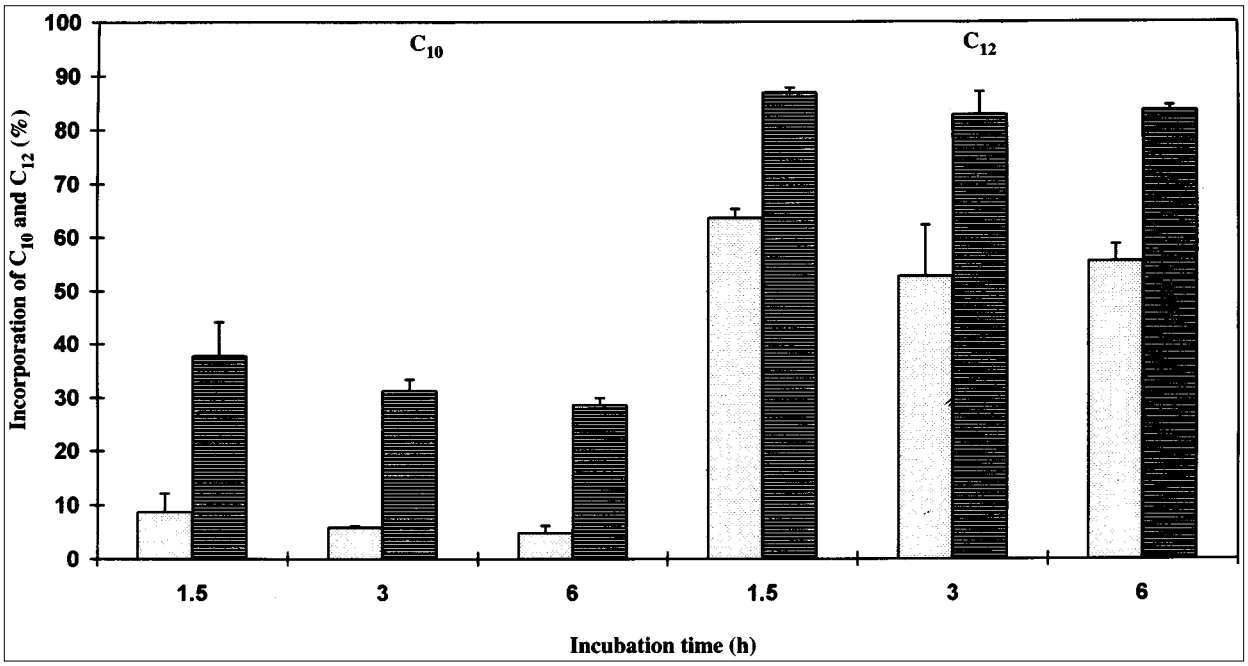

FIG. 2. Recovery of C_{10} and C_{12} in cellular phospholipids and triacylglycerols. Cells were incubated as described in the legend to Figure 1. Lipid extracts of three incubations were pooled and separated by thin-layer chromatography (TLC) as described in Table 1; phospholipids [dotted box] and triacylglycerols [vertically striped box] were scraped off the plate and subjected to alkaline hydrolysis. Fatty acids were recovered and separated by reverse-phase TLC as described in the Materials and Methods section. Each point is the mean of three separate incubations ± SD. C_2, C_8 and C_{16} yielded only long chain fatty acid.

TABLE 2
Occurrence of Radiolabeled Monounsaturated FA[a]

FA added	Radiolabled monounsaturated FA (%)					
	1.5 h		3 h		6 h	
	TAG	PL	TAG	PL	TAG	PL

[a]Cells were incubated with ^{14}C-labeled FA as described in the legend to Figure 1. The methyl fatty esters obtained from PL and TAG were separated on $AgNO_3$-impregnated plates as described in the Materials and Methods section. Spots corresponding to saturated and monounsaturated FA were scraped directly into scintillation vials and radioactivity determined immediately as described in the Materials and Methods section. See Table 1 for abbreviations.

TABLE 3
FA Composition of Cellular PL and TAG[a]

FA		10:0	12:0	14:0	16:0	16:1	18:0	18:1	18:2	20:3	20:4	20:5	22:6

[a]Cells were incubated with ^{14}C-labeled FA for 3 h as described in the legend to Figure 1. Extracts of triplicates were pooled, PL and TAG were separated by thin-layer chromatography as described in the legend to Table 1. The spots corresponding to PL and TAG were collected and subjected to alkaline hydrolysis. FA were recovered after acidification, methylated with diazomethane, and separated by gas–liquid chromatography as described in the Materials and Methods section.
[b]Cells were grown on a different batch of fetal calf serum. See Table 1 for abbreviations.

creased while 18:1 decreased. Cells grown in the presence of C_2 contained 18.7% 16:0 and 57.1% 18:1 in cellular TAG, in contrast to cells grown in the presence of C_{16} which contained 30.3% 16:0 and 42.7% 18:1. The changes in the FA composition of PL were much smaller. However since the cells contained approximately four times more PL than TAG these differences can be easily explained. We have noted in several experiments (not shown) that the FA composition of the FCS markedly affects the FA composition of the HepG-2 cells. A new batch of FCS was used for the incubation of cells with ^{14}C-C_2 and ^{14}C-C_{16}. This can explain the relatively high percentage of 18:1 and low percentage of 16:0 found in these cells when incubated in the presence of C_2. The GLC results as shown in Table 3 indicate the occurrence of 6.4 and 8.5 nmoles/mg protein of C_{12} in PL and TAG, respectively. These results are 40–50% of the accumulation expected from ^{14}C-C_{12} incorporation experiments, probably indicating losses of methylated C_{12} (which is much more volatile than the free acid) during preparation of samples for GLC analysis.

DISCUSSION

In an attempt to explain the results of our recent clinical studies (7) in which we have observed marked changes in the composition of plasma and biliary lipids following the infusion of MCT/LCT, a study of the metabolism of FA of different chain lengths by isolated liver cells was undertaken. Our experimental approach involved incubation of HepG-2 with ^{14}C-FA of different chain length for up to 6 h and subsequent analysis of the incorporation of these FA or their metabolites into cellular PL and TAG. These studies showed that the metabolism of C_{10} was unique:

C_2 and C_8 were used exclusively for the synthesis of saturated and monounsaturated LCFA, suggesting that C_8 was oxidized to C_2 units prior to being used for FA synthesis, as has been shown previously (25). The newly synthesized ^{14}C-FA were incorporated preferentially (85%) into PL (Table 1).

C_{12} and C_{16} were incorporated, mostly unchanged, in approximately equal amounts into cellular PL and TAG (Figs. 1 and 2; Table 1). Recently it was shown by Gibbons *et al.* (26) that cultured HepG-2 cells readily incorporated ^{14}C-oleate into cellular lipids, approximately 90% into TAG and 10% into PL.

The fate of C_{10} was more complex; it was different from that of both LCFA and SCFA and represented an intermediate between these pathways. ^{14}C-C_{10} yielded ^{14}C-LCFA, either by elongation of internalized ^{14}C-C_{10} or by *de novo* synthesis after oxidation to C_2 units, but considerable amounts of un-

changed ^{14}C-C_{10} were detected in PL—10%—and TAG—40% (Table 1, Fig. 2).

Separation by GLC of the FA obtained from PL and TAG showed the accumulation of C_{12} and to a lesser extent C_{10} only when HepG-2 cells were incubated in the presence of the respective FA. These results demonstrate that in addition to the mammary gland, liver cells can incorporate C_{10} and C_{12} into cellular lipids. Woollett *et al.* (5) did not find C_{10} in cellular liver lipids. In our studies with HepG-2 cells, the concentration of preformed lipids was much smaller than in intact liver, and hence the dilution of externally added FA was much smaller which allows their detection by GLC.

The mechanism of FA uptake by hepatic parenchymal cells is not well understood (27), and the chain length dependence of this process has not been systematically investigated thus far. Two factors that are likely to play an important role in the observed chain length-dependence of FA uptake are the binding to albumin (in the incubation medium) and to the intracellular fatty acid-binding proteins. Both these proteins have much higher binding affinities for LCFA than for SCFA and MCFA (27–29). Recent studies have indicated that serum albumin has a direct role in FA uptake, rather than merely a passive role as a carrier of LCFA, through interaction with the cell surface (15). These observations may explain the faster incorporation of C_{12} and C_{16} in comparison to C_2 and C_8 and C_{10}. An alternative mechanism for the uptake of FA into hepatocytes is supported by the recent demonstration of an FA-transporter in hepatocyte membranes (30). The affinity of this transporter to SCFA and MCFA has yet to be tested.

In addition to the dependence of internalization rates on FA chain length, differences in the intracellular utilization also occur. When taken up by hepatocytes, a large fraction of both SCFA and MCFA is oxidized by the mitochondria to acetyl CoA (11,31).

Our results have several important implications with respect to human nutrition. Prolonged infusion of MCT (rich in C_8, C_{10}, and C_{12}) can be expected to result in enrichment of plasma lipoproteins with C_{10} and C_{12} TAG, as has in fact been shown (32). The possible enrichment of hepatic PL with C_{10} and C_{12} may affect membrane fluidity and cell function. Furthermore, changes in biliary PL composition may occur which will affect cholesterol solubility and gallstone formation (33). Recently we have observed that upon perfusion of rat liver with radiolabeled FA of different chain lengths, significant amounts of ^{14}C-C_{10} and ^{14}C-C_{12} became incorporated into biliary PL (Pakula, Ronit, and Alisa Tietz, unpublished results).

Effect of Docosahexaenoic Acid on Mouse Mitochondrial Membrane Properties

William Stillwell*, Laura J. Jenski, F. Thomas Crump, and William Ehringer

Department of Biology, Indiana University-Purdue University at Indianapolis, Indianapolis, Indiana 46202

ABSTRACT: Long-chain polyunsaturated (n-3) fatty acids have been proposed to be involved in a wide variety of biological activities. In this study, mitochondrial docosahexaenoic acid (DHA) levels were increased by either dietary manipulation or by fusing the mitochondria with phospholipid vesicles made from 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (18:0/22:6 PC). The fused mitochondria exhibited a DHA-induced decrease in respiratory control index (RCI) and membrane potential and an increase in proton movement. The modified mitochondria also demonstrated an increase in fluidity (as detected by 1,6-diphenyl-1,3,5-hexatriene anisotropy) and changes in membrane structure detected by the fluorescence probes MC540 and pyrene decanoate. Proton movement in lipid vesicles made from mitochondrial lipid extracts was shown to be enhanced by incorporated 18:0/22:6 PC. Mitochondria were isolated from young (5-mon) and old (24-mon) mice which were maintained on either a diet rich in saturated fats (hydrogenated coconut oil) or rich in n-3 polyunsaturated fats (menhaden oil). Mitochondrial bioenergetic function was followed by RCI, state 3 respiration, ATP level, and phosphate uptake. In addition, lipid composition, phospholipid area/molecule, and extent of lipid peroxidation were also determined. Decreases in RCI for the menhaden oil diet-modified mitochondria paralleled those in which DHA levels were enhanced by fusion with phospholipid vesicles. RCI reductions are attributed to DHA-induced increases in H^+ movement, producing diminished mitochondrial membrane potentials. One purpose of this project was to determine if the deleterious effects of aging on mitochondrial bioenergetic function could be reversed by addition of n-3 fatty acids. The experiments reported here indicate that incorporation of long-chain polyunsaturated n-3 fatty acids into mitochondrial membranes does not appear likely to reverse the effects of age on mitochondrial function.

Lipids 32, 497–506 (1997).

The n-3 fatty acids have recently received a great deal of attention due to their potential role in treating a number of human afflictions including cancer, heart disease, and arthritis (1). While the molecular mode of action of these fatty acids remains a mystery, it has been shown that they are efficiently taken up into rapidly growing cells where they may alter membrane events (2,3). Because membrane structure is known to reflect its fatty acid composition (chain length and number of unsaturations) (4), it is not surprising that long-chain polyunsaturated n-3 fatty acids, particularly docosahexaenoic acid (DHA, $22:6^{\Delta 4,7,10,13,16,19}$), have been shown to substantially influence membrane structure/function (1,5,6).

A variety of reports have indicated that the mode of action of DHA may involve perturbations of the plasma membrane. DHA incorporation into phospholipid vesicles as either free acid or 18:0/22:6 phosphatidylcholine (PC) has resulted in large increases in membrane permeability. T27A tumor cells (6) and JURKAT leukemia cells (7) were shown by ^{51}Cr release to become leaky in the presence of sufficient free DHA (7). Permeability was also augmented after fusing the T27A cells with lipid vesicles made from 18:0/22:6 PC (6). Burns and Spector (8) have shown that ascites lymphoblastic leukemia cells became permeable to the anticancer drugs mitoxentrone and doxorubicin upon incorporation of DHA. Membranes of the rod outer segment (ROS), known to be highly enriched in DHA (9), are very permeable to K^+ (10). While all of these reports indicate that DHA increases membrane permeability, none link the increase with a change in a specific physiological process.

Here we investigate the effect of DHA on H^+ permeability (movement) across the mitochondrial inner membrane. Mitochondria are an excellent system to study permeability because DHA membrane levels are easily manipulated, and a correlation between permeability (to H^+) and a biological process (bioenergetics) is readily monitored. Mitochondrial DHA levels are controlled by either fusing isolated mitochon-

dria with phospholipid vesicles composed of 18:0/22:6 PC or by feeding mice a diet rich in DHA (menhaden oil). If DHA increases mitochondrial membrane permeability, as it does for lipid vesicles, tumor cells and the ROS, we would anticipate finding substantial DHA-induced alterations in proton gradient-dependent bioenergetic events.

EXPERIMENTAL PROCEDURES

Materials. The fluorescent probes BCECF, BCECF-AM, $DiSC_3(5)$, DPH, MC540, pyrene decanoate (1-pyrene hexadecanoate), and TMA-DPH were purchased from Molecular Probes (Eugene, OR). The phospholipids 18:0/18:1 PC and 18:0/22:6 PC were from Avanti Polar Lipids (Alabaster, AL). BF_3/methanol was from Sigma Chemical Co. (St. Louis, MO).

Mice and diets. Experiments in which mitochondria were fused with lipid vesicles containing DHA were performed with BALB/c male mice. Four-week-old mice were purchased from Harlan Sprague Dawley (Indianapolis, IN) and fed a modified AIN-76 diet (referred to here as the HCO diet) containing 2 g of vitamin E per kg diet, 0.5% corn oil for essential fatty acids, and an additional 10% fat as hydrogenated coconut oil (HCO) (ICN, Cleveland, OH) for three weeks before being euthanized.

For the diet experiments involving young and old mice, 2-mon-old (young) and 21-mon-old (old) CBA/Ca female mice were purchased from The National Institute of Aging Colonies, Charles River Laboratories (Wilmington, MA) and enrolled for 7 wk, 5 d on the HCO diet. The HCO-fed mice were then either switched to a diet in which the HCO was replaced by 10% menhaden oil (MO) (the MO was supplied by Zapata-Haynie Corp., Reedville, VA) or maintained on the 10% HCO. After 3 wk on the experimental diets, the mice were euthanized and their livers extracted for the mitochondrial studies. At 21 mon old, CBA female mice are nearing the end of their lifespan and so indeed are "old." The average lifespan reported by the Jackson Laboratory for virgin CBA/J females is about 18 mon, and about 22 mon for several common inbred mouse strains. The diet used here is based on a previous study from our laboratory (11). The function of the initial HCO diet is to reduce the membrane DHA content accumulated during a lifetime on "chow" which contains fish meal. The subsequent 3-wk diet is average for liver modification studies, which have regimens ranging from 10 d to 5 wk (12–14). Due to the age of the test animals, more prolonged feeding experiments were not possible. The saturated fat HCO diet is used as a model of the typical Western diet and provides a sharp contrast to the n-3-rich MO diet.

Mitochondria. Mouse liver mitochondria were isolated by the method of Johnson and Lardy (15). The isolation buffer contained 250 mM sucrose, 20 mM Tris-HCl, 0.5 mM EDTA, and 0.1% bovine serum albumin (pH 7.4). Mitochondrial protein was determined by the method of Bradford (16). Isolated mitochondria were always kept on ice in the dark until they were tested for respiratory control index (RCI), state 3 respiration, ATP level, phosphate uptake, lipid composition, lipid area/molecule, extent of lipid peroxidation, proton movement (permeability), fluidity, membrane structure, and membrane potential.

Lipid vesicle–mitochondria fusion studies. Small unilamellar vesicles (SUV) were made by sonication (2 min at level 5 on a Heat Systems-Ultrasonics Model W-380; Plainview, NY) of either 18:0/18:1 PC or 18:0/22:6 PC multilamellar vesicles at 5 mg lipid/mL of mitochondrial isolation buffer. Mitochondria (5 mg protein/mL) were gently mixed on ice for 35 min with SUV to give a final PC concentration of 0, 0.5, 1.0, 1.5, or 2.0 mg/mL. Fused mitochondria were separated from nonfused SUV by centrifugation at 5,000 rpm. After a wash in the isolation buffer, the pelleted mitochondria were resuspended in the same buffer to a final protein concentration of 3 mg/mL.

Fatty acid compositions. Total mitochondrial lipids were extracted with chloroform/methanol 2:1 (vol/vol) (17) and filtered on Millipore filters (Milford, MA). Phospholipid content was determined as outlined by Ames (18). This same extract was also used to determine the fatty acid profiles (19). The phospholipids were first saponified in 0.5 N NaOH by refluxing the solution for 1 h in the presence of 0.2% of the antioxidant *tert*-butyl hydroquinone. Methyl esters were made by addition of 14% BF_3/methanol and additional refluxing for 30 min. The methyl esters were extracted into hexane three times and evaporated to a small volume and then injected into a Shimadzu G17A Gas Chromatograph (Tokyo, Japan) equipped with an autosampler. Retention times were measured on a stabilwax capillary column (Restek, Bellefonte, PA) and were compared to methyl ester standards purchased from Nu-Chek-Prep (Elysian, MN). Lipid peroxidation was followed by fluorescent detection of malondialdehyde with 2-thiobarbituric acid. The method is that outlined by Tatum *et al.* (20), with the following modification: Total mitochondrial lipid was extracted by $CHCl_3$/MeOH (2:1) and the phases separated upon the addition of aqueous 0.5 N NaCl. The protein-free lipid extract was used for the peroxidation assays.

Mitochondrial bioenergetics. Mitochondrial oxygen consumption was followed by the method of Estabook (21) as modified by Gazzotti *et al.* (22) using polarography with Clark-type electrodes. Oxygen consumption was measured on a YSI 5300 Biological Oxygen Monitor System (Yellow Springs Instruments, Yellow Springs, OH). Temperature was controlled at 30°C by a Haake Circulating Water Bath (Karlsruhe, Germany). High-sensitivity membranes were used for all measurements. Mitochondria (approximately 2–5 mg of protein) were added to 3.0 mL of the oxygen consumption buffer (5 mM KH_2PO_4, 120 mM KCl, 20 mM Tris, pH 7.4). Substrate (60 μL of a 250 mM glutamate solution) was injected into the sealed mitochondrial chamber, and the respiration rate was followed for 2 min. To initiate state 3 respiration, 30 μL of a 50 mM solution of ADP was then injected into the suspension. Respiratory control indices (RCI) were calculated by measuring the state 3 to state 4 respiration rates.

ATP levels were estimated by using a Sigma Diagnostics kit (Cat.# 366-UV) (St. Louis, MO) and are expressed as µg ATP/mg protein.

Mitochondrial swelling. Alterations in the activity of the mitochondrial phosphate carrier were followed by osmotic volume changes (swelling) (23). This assay was selected because it is known to be particularly affected by age and membrane lipid composition (23). Mitochondrial swelling (30°C) in 125 mM $(NH_4)_2PO_4$, 5 mM HEPES, 0.5 mM EDTA, pH 7.4 was followed by light scattering at 540 nm on a Perkin-Elmer Lambda 4C UV/Vis Spectrophotometer interfaced to a Perkin-Elmer 7700 Professional Computer and run by PECUV software (Palo Alto, CA). Absorbance (A) changes were monitored for the first 30 s and the initial swelling velocity calculated and expressed as d(1/A)/dt percentage (24).

Mean molecular area. The chloroform/methanol 2:1 (vol/vol) (13) extracts, dried under nitrogen and vacuum, were employed for the mean molecular area determinations. Stock solutions of 1 mg/mL were made in triply distilled benzene and were spread over a subphase of 10 mM Tris, 10 mM sodium acetate, pH 7.4 in deionized, glass distilled, Milli-Q water (Millipore Corp., Bedford, MA). Benzene was allowed to evaporate for 3 min before the compressions were started. Mean molecular area was calculated using a KSV Minitrough (KSV Instruments, Helsinki, Finland) interfaced to an Epson Equity 2+ computer and run by LB5000 software. Monolayers were compressed at 1 mN/min with a final target pressure of 20 mN/M. All measurements were made at 30°C, and the results are the average of three separate compressions.

Proton movement. Proton movement was determined using the fluorescent probe BCECF-AM (25). Mitochondria were incubated for 20 min at 27°C with BCECF-AM at 5 µg probe/2 mg mitochondrial protein. A pH gradient was established across the mitochondrial inner membrane by titrating a small volume of 6 N HCl into three mL of the mitochondrial suspension (5 mg protein/mL) in the initial isolation buffer. Fluorescence was monitored for one minute (27°C) on a Perkin-Elmer MPF-66 fluorimeter (Norwalk, CT). Excitation and emission wavelengths were 500 nm and 530 nm, respectively. The initial pH was 7.4 and the final pH between 4.9 and 5.2. Proton movement was also determined for lipid vesicles made from the chloroform/methanol 2:1 (vol/vol) (17) extract augmented with increasing levels of 18:0/22:6 phosphatidylcholine (PC).

Mitochondrial membrane potentials. Relative mitochondrial membrane potentials were determined using the fluorescent probe $DiSC_3(5)$ (26). To 3.0 mL of a mitochondrial suspension containing 1 mg protein/mL in isolation buffer, 10 µL of $DiSC_3(5)$ (0.33 mg/mL in DMSO) was added. Membrane potential was established by addition of 12 µL of 500 mM succinate. Fluorescence (excitation at 620 nm and emission at 670 nm) was monitored for 2 min.

Fluorescent membrane probes. Docosahexaenoic acid (DHA) effect on membrane fluidity was followed with the fluorescence probes DPH and TMA-DPH while qualitative DHA-induced changes in membrane structure were probed with MC540 and pyrene decanoate. All measurements were made on a Perkin-Elmer MPF-66 fluorimeter, temperature controlled to 27 ± 0.1°C. Very dilute mitochondrial suspensions were employed to diminish light scattering, and samples were always kept in the dark to prevent photobleaching.

DPH and TMA-DPH. The fluorescent probe (in tetrahydrofuran carrying solvent) was incubated with 0.5 mg mitochondrial protein/mL for 30 min at 27°C. Probe to lipid molar ratio was 1:200. Anisotropies were measured upon exciting the samples at 358 nm with emission at 426 nm.

Pyrene decanoate. Pyrene decanoate (1-pyrene hexadecanoate in tetrahydrofuran/DMSO, 1:1) was incubated with 0.5 mg mitochondrial protein/mL for 30 min at 27°C. Probe/lipid molar ratio was 1:100. Excitation was at 340 nm, and the emission spectra followed from 360–560 nm.

MC540. MC540 was added to the mitochondrial suspensions from an aqueous stock solution (25 µM in 0.01M Na acetate, pH 7.4) to give a 1:150 probe to lipid molar ratio. MC540 was excited at 540 nm, and the emission spectra recorded from 560 to 650 nm.

RESULTS

DHA was incorporated into mitochondria by two methods. Either isolated mitochondria were fused with 18:0:22:6 PC vesicles or mice were enrolled on a diet rich in DHA [menhaden oil (MO) diet].

Mitochondrial fusion with 18:0:22:6 PC vesicles. Fatty acid analysis of mitochondria incubated with 18:0/22:6 PC SUV, revealed increasing DHA levels with increasing lipid concentrations of SUV (Fig. 1). DHA levels in the unmodified mitochondria were normally quite low, less than 1% of the total fatty acids present. The other predominant fatty acids

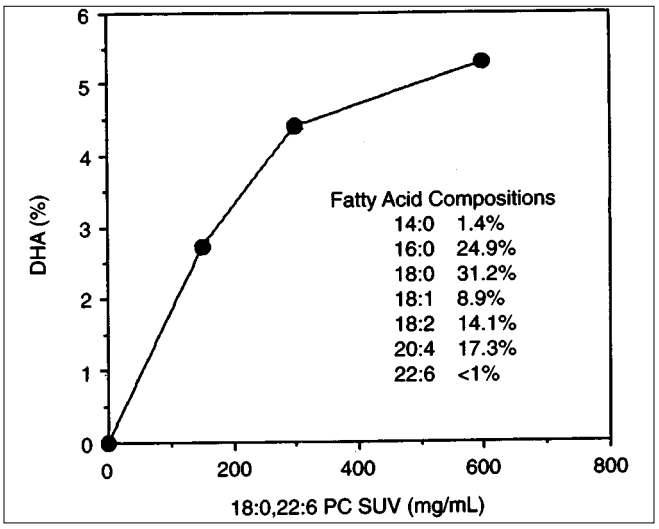

FIG. 1. Incorporation of docosahexaenoic acid (DHA) (expressed as the mol%) into mitochondria by fusion with increasing amounts of 18:0/22:6 PC SUV in the bathing solution. A profile of the major mitochondrial fatty acids is reported in the insert.

found in the BALB/c mouse mitochondria are listed in the insert of Figure 1. The highest level of DHA we obtained after fusion was about 7% for mice that were maintained on a well-defined AIN-76 diet. Care must be taken with conventional rodent diets since they contain fish meal, an excellent source of DHA. We found mice on conventional diets often contained more than 10% DHA in their mitochondria, even when the diet was not supplemented with an additional n-3 source. Variations in DHA levels, commonly reported for mouse mitochondria, likely reflect prior consumption of conventional diets.

In our experiments, we found decreases in mitochondrial bioenergetic functions associated with increasing DHA levels. Tightly coupled mitochondria isolated from 2-mon-old BALB/c mice were uncoupled (expressed as a decrease in RCI) upon the accumulation of small amounts of 18:0/22:6 PC (but not 18:0/18:1 PC) in the mitochondria (Fig. 2). For the 18:0/22:6 PC-augmented mitochondria, there was about a 30% decrease in the RCI with 5% incorporation of DHA. Associated with this was a 60% increase in H+ movement and a 30% decrease in membrane potential (Fig. 3). In contrast, 18:0/18:1 PC augmentation had little effect on the measured RCI (Fig. 2).

Fluorescent probes were used to detect DHA-induced changes in physical properties of the lipid bilayer component

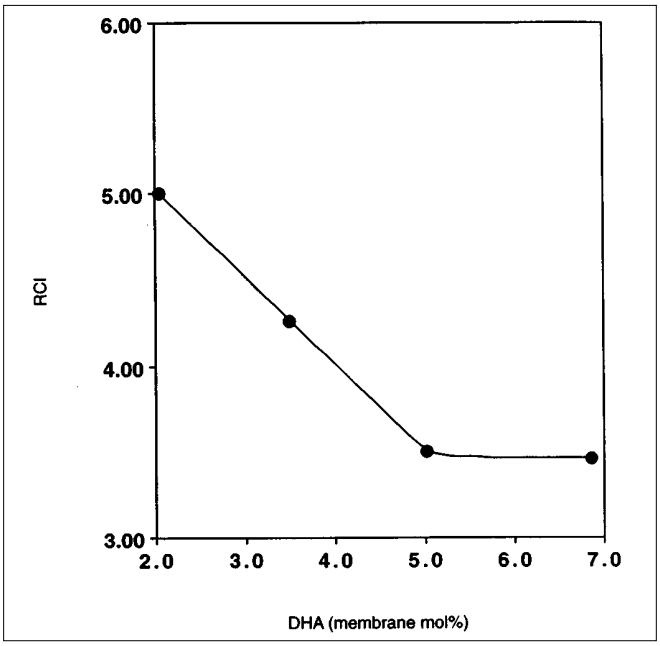

FIG. 2. Respiratory control indices (RCI) for mitochondria, isolated from young mice, that were fused with 18:0/22:6 phosphatidylcholine (PC) vesicles. The incorporation of DHA (22:6) increased from 2.0% for the unfused control to 6.9% for the mitochondria fused with 2.0 mg/mL of 18:0/22:6 PC. For all experiments, unfused mitochondria had less than 0.5% DHA. Controls were performed by fusing 18:0/18:1 PC with the mitochondria at the same concentrations used for the 18:0/22:6 PC fusions. This control lipid had no deleterious effect on RCI values which remained between 5.3 to 5.6. Results are the mean of three determinations. See Figure 1 for abbreviation.

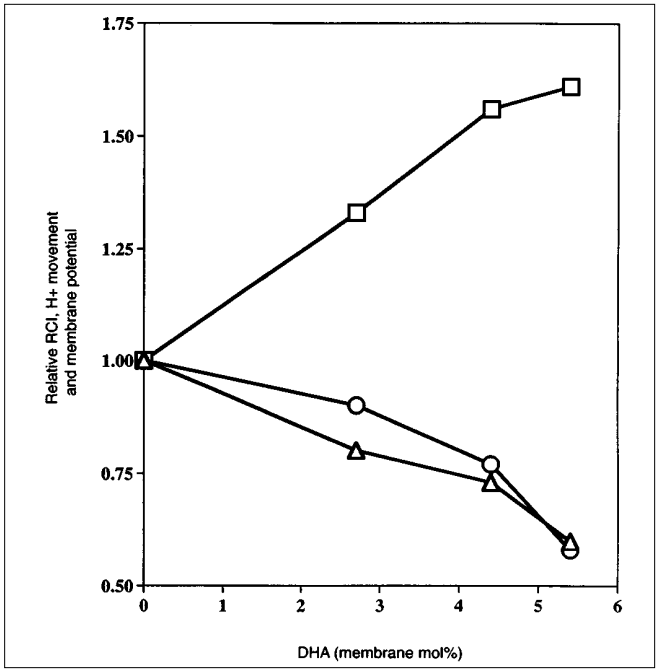

FIG. 3. Relative RCI (-△-), H+ movement (-□-) and membrane potential (-○-) for mitochondria that were fused with 18:0/22:6 PC. RCI were determined by polarography, proton permeability by use of the fluorescent probe 2′,7′-bis(2-carboxyethyl)-5-(and-6)-carboxyfluorescein, acetoxymethyl ester, and membrane potentials by the fluorescent probe $DiSC_3(5)$. Values are normalized to the unfused controls. Experimental details are outlined in the Materials and Methods section. See Figures 1 and 2 for abbreviations.

of the mitochondrial membrane. A small DHA-dependent decrease in anisotropy (increase in fluidity) was noted for the membrane interior probe DPH while the companion probe, TMA-DPH, did not detect any DHA-induced change at the aqueous interface (results not shown). MC540 and pyrene decanoate also demonstrated a DHA-induced change in membrane structure. The fluorescent membrane probe MC540 (merocyanine 540) has been used extensively to determine relative phospholipid packing on the outer surface of membranes (27). A fluorescence increase at 590 nm, as reported in Figure 4, can be interpreted as resulting from a decrease in lipid packing on the membrane outer leaflet. The increase in 590 nm fluorescence is linearly proportional to the level of incorporated DHA (insert, Fig. 4). The fluorescent probe pyrene decanoate has been extensively used to monitor membrane viscosity. Two fluorescence peaks are of particular interest. The peak at 480 nm is due to excimers and is enhanced in liquid crystalline state, while the peak at 398 nm is due to monomers and reflects gel state in membranes. Therefore the DHA-dependent increase in fluorescence intensity at 480 nm (Fig. 5) indicates that the bilayer is exhibiting a more fluid environment in the liquid crystalline state. The small change at 398 nm indicates that DHA has less effect on the gel state component. In the insert of Figure 5, the E/M (excimer/monomer) ratio is plotted against the amount of DHA incorporated

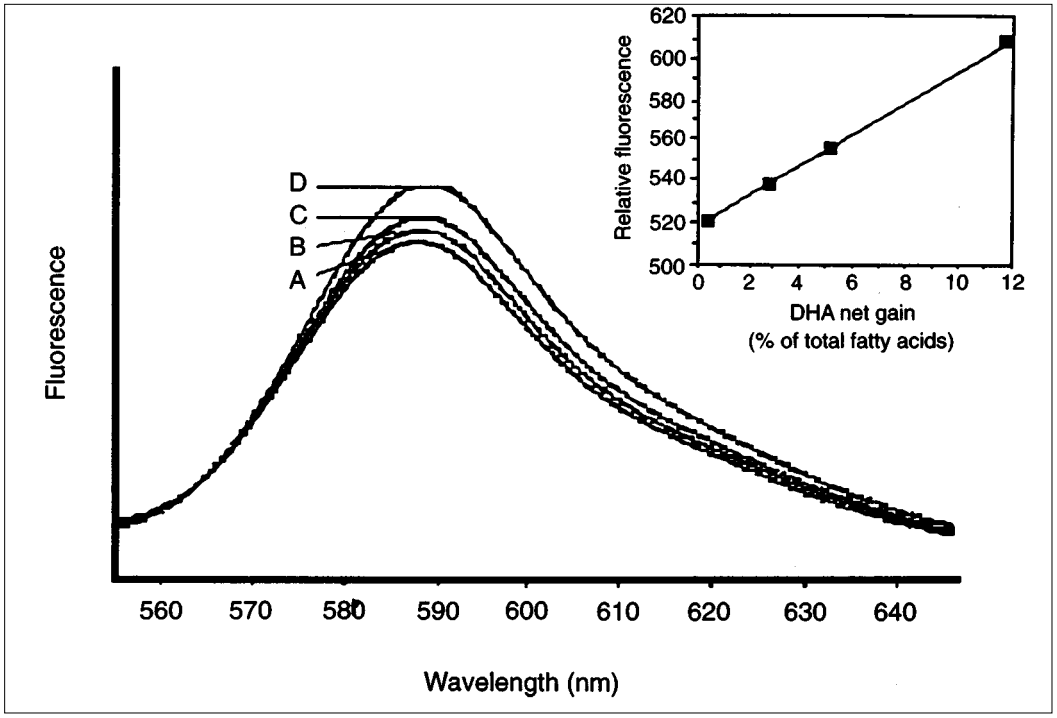

FIG. 4. Mitochondrial membrane structure (monitored by the surface probe MC540) as a function of increasing amounts of incorporated DHA. Insert compares the relative fluorescence at 590 nm as a function of the amount of membrane-incorporated DHA. See Figure 1 for abbreviation.

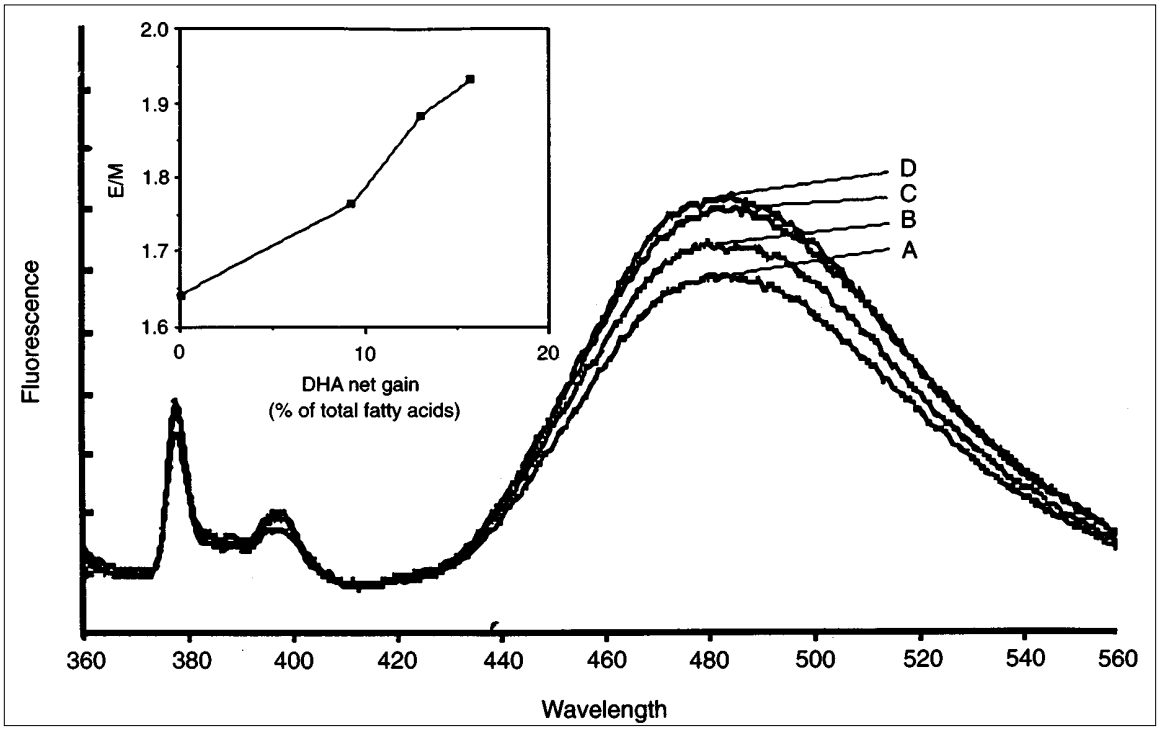

FIG. 5. Mitochondrial membrane structure (monitored by the probe pyrene decanoate) as a function of increasing amounts of incorporated DHA. Insert compares the excimer/monomer ratio (fluorescence intensity at 480 nm/398 nm) as a function of the amount of membrane-incorporated DHA. See Figure 1 for abbreviation.

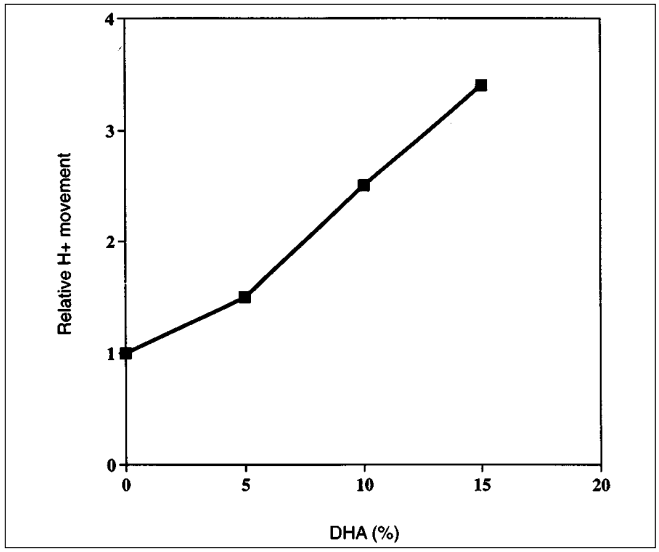

FIG. 6. Relative proton movement of small unilamellar vesicles made from mitochondrial lipid extracts as a function of incorporated 18:0/22:6 phosphatidylcholine expressed as percentage DHA. See Figure 1 for abbreviation.

into the mitochondrial membranes. The increase in E/M indicates that incorporation of DHA into the mouse mitochondrial membrane is associated with increased fluidity (Fig. 5).

Lipids that were extracted from nonfused BALB/c mitochondria were mixed with varying amounts of 18:0/22:6 PC, and SUV were made in the presence of BCECF. After removing the nonsequestered BCECF on a Sephadex G-50 column, a pH gradient was established and changes in H^+ movement monitored. In Figure 6, H^+ movement is shown to be proportional to the level of incorporated 18:0/22:6 PC while added 18:0/18:1 PC had no measurable effect (results not shown).

TABLE 1
Fatty Acid Compositions of Hydrogenated Coconut Oil and Menhaden Oil

Fatty acid	Percentage of total fatty acids: Hydrogenated coconut oil	Menhaden oil
14:0	46.2	7.9
16:0	23.1	27.0
18:0	30.1	2.7
18:1(n-9)	0	14.6
18:2(n-6)	0	2.1
18:3(n-3)	0	1.6
20:5(n-3)	0	15.9
22:6(n-3)	0	16.1

Mitochondria and dietary DHA. Mitochondria were isolated from young (5-mon-old) and old (24-mon-old) CBA/Ca mice that had been maintained on identical diets with the exception of the fat source. Half of the mice in each age group were fed HCO while the other half were given MO. Both diets contained 0.5% corn oil for essential fatty acids. HCO is rich in saturated fats while MO is rich in long-chain polyunsaturated n-3 fatty acids. The fatty acid composition of each oil is listed in Table 1.

The relative compositions of the predominant fatty acids for mitochondria isolated from the different mice are listed in Table 2. Mitochondrial fatty acid composition was markedly affected by both age and diet. As expected, after 3 wk the percentage of the n-3 long-chain fatty acids DHA and EPA (eicosapentaenoic acid) increased dramatically for mice on the MO diet while the level of arachidonic acid (20:4) decreased. To further define age and diet-related changes, we calculated the unsaturation index, that is, the sum of the amount times the number of unsaturations for each unsaturated fatty acid divided by the total amount of all fatty acids.

[a]Isolated from young mice maintained on the HCO diet (Y-HCO), young mice maintained on the MO diet (Y-MO), old mice maintained on the HCO diet (O-HCO), or old mice maintained on the MO diet (O-MO). A: absorbance; t: time.

The unsaturation index was much larger for the MO-fed mice than for the HCO mice [unsaturation index: young (Y)-HCO, 121; Y-MO, 265; old (O)-HCO, 165, O-MO, 187]. After 3 wk on the MO diet, both the young and old mice had high levels of DHA associated primarily with phosphatidylethanolamine (PE) and PC.

Mitochondrial bioenergetics, studied by several techniques, was shown to be affected by age. The 24-mon-old mice had much lower ATP levels, RCI, State 3 respiration rates, and phosphate-dependent swelling velocities than did the 5-mon-old mice (Table 3). For all bioenergetic properties tested, addition of MO to the diet not only failed to halt or reverse the age-dependent decrease in function, it actually amplified the decrease.

Studies with monolayers composed of mitochondrial phospholipid extracts show the phospholipid area/molecule increases with the amount of incorporated DHA for the MO diet compared to the HCO diet (Table 3). The increase in phospholipid area/molecule measured with mitochondria isolated from mice maintained on the MO diet relative to the more saturated HCO diet is consistent with the measured increase in unsaturation index. We therefore measured total lipid peroxidation in the various mitochondrial lipid extracts by a malondialdehyde assay (16). These measurements indicate that while the malondialdehyde levels do indeed increase in the MO-fed mouse mitochondria, the levels are quite low. The malondialdehyde values for mice on the various diets were: Y-HCO, 0.176 nmol/mg P; Y-MO, 0.82 nmol/mg P; O-HCO, 0.282 nmol/mg P; and O-MO, 0.407 nmol/mg P.

DISCUSSION

Although the effects of lipids on mitochondria are very complex and alterations of any fatty acid may influence function, we nevertheless have decided here to concentrate on DHA. Since DHA is the most unsaturated biological fatty acid commonly found in nature (28), it is a likely target for oxidation. One possibility is that the DHA-dependent decrease in mitochondrial function is simply the result of accumulated oxidized products (29). Indeed our prior experminents with phospholipid vesicles have demonstrated that DHA influences general membrane properties, including permeability, more than other common fatty acids (6,30). It is reasonable to propose that mitochondrial function, which is dependent on maintaining an intact barrier to H+ leakage, would be particularly susceptible to DHA-induced permeability changes, and therefore mitochondria may be an ideal model system to search for the membrane structure/function relationship of n-3 fatty acids. It was the purpose of the experiments described here to test this hypothesis by monitoring the effect of DHA on mitochondrial H^+ movement and associated bioenergetic functions.

A variety of mitochondrial functions have often been reported to be controlled, in part, by the lipid composition of the inner membrane. Lipid compositions have been experimentally manipulated by obtaining animals of different ages, putting the animals on fatty acid-deficient diets or by supplementing a minimal diet with specific fatty acids. However, there have been few unequivocal experiments linking fatty acid composition to mitochondrial function, and the literature is fraught with obvious contradictions. Chiu and Richardson (31) have suggested that reports of discrepancies are the consequence of comparing mitochondria isolated from different organisms or different tissues from the same organism, or organisms of different age, or use of different substrates employed in the bioenergetic measurements. A survey of the literature suggests that with increasing age there is a decrease in the number of mitochondria per cell (32,33). Also age-related decreases in the activity of many mitochondrial enzymes (33–35), most notably those involved in translocation, have been reported (23,36–38). Decreases in respiratory and bioenergetic activities (37,39–42) and increases in superoxide radicals (41,43) have been described in older mitochondria. Finally structural and compositional membrane changes have been demonstrated as mitochondria age. Old mitochondria have enhanced permeability (44,45) that is likely related

to cholesterol (37,46) and cardiolipin (46) content, saturated/unsaturated fatty acid ratios (35,41,47), cholesterol/phospholipid ratios (37,46,48), PC/PE ratios (37), and n-6/n-3 fatty acid ratios (37). The reported changes in lipid content associated with aging may be partially responsible for concomitant changes in membrane potential (44) and fluidity (33–35,46,47).

Among the many membrane-associated processes known to be affected by age (49), bioenergetic events occurring at the mitochondrial inner membrane are of particular interest. Alterations in membrane lipid composition of older mitochondria may be related to their gross structural abnormalities (50,51), and changes in membrane potential (44), organization, fluidity (52), and permeability (45). The aged cell's reduced ability to produce ATP may be related to these changes (37,39–42). Because of the age-related reduction in mitochondrial function, Harman (33) has proposed that mitochondria may act as "biological clocks."

Many reports have indicated that mitochondrial lipid composition is susceptible to dietary manipulation. It has been shown that mitochondrial fatty acid profiles resulting from fatty acid deficiency can be rapidly restored through diet (53). Tahin *et al.* (53) reported maximal uptake of a variety of dietary fatty acids into mitochondrial membranes in less than 3 wk, while Yamaoka *et al.* (54) reported maximal fatty acid changes in PC and PE after only 10 d of dietary sardine oil. Most of the same properties reported to change upon aging have also been shown to be altered through diet (55,56). However, as with the aging studies, there is considerable controversy as to whether dietary fatty acids actually alter mitochondrial bioenergetics. Reports demonstrating dietary fatty acid-induced decreases in RCI, State 3 and State 4 respiration and P/O ratios (54,57–59) are offset by reports demonstrating no or contradictory effects on the same properties under similar conditions (60–62).

Since it is generally (although not universally) accepted that aging results in significant decreases in many mitochondrial activities that are related to changes in the lipid component of the mitochondrial inner membrane, and mitochondrial lipid composition can be readily altered through diet, Barzanti *et al.* (63) suggested that perhaps dietary lipids can significantly modify the age-related decline in mitochondrial activity.

The experiments reported here confirm that mitochondrial bioenergetic activity does in fact decrease with age (Table 3). We also confirm that mitochondrial fatty acid profiles can be rapidly altered by dietary fat and that n-3 fatty acids, in particular DHA, can be effectively accumulated into mitochondria of young and old mice (Table 2). While incorporation of DHA does alter lipid bilayer physical properties as detected by the fluorescence probes DPH (results not shown), MC540 (Fig. 4), pyrene decanoate (Fig. 5) and area/molecule measurements, it did not enhance any of the bioenergetic properties tested. In fact, all bioenergetic properties tested appeared to decrease upon DHA incorporation.

Ex vivo experiments enhancing DHA levels through diet were complemented *in vitro* by experiments in which 18:0/22:6 PC SUV were mixed with mitochondria. Upon incorporation of 18:0/22:6 PC into mouse mitochondria, a marked decrease in RCI associated with an increase in H^+ movement and decrease in membrane potential were measured (Fig. 3). The DHA-induced increase in H^+ movement may be due to changes in the lipid bilayer component of the mitochondrial membrane, since SUV made from mitochondrial lipid extracts also demonstrate a parallel DHA-induced enhancement in H^+ movement (Fig. 6). The fluorescent membrane probes DPH, MC540, and pyrene also support this conclusion by indicating changes in mitochondrial membrane bilayer structure induced by DHA (Figs. 4 and 5).

Complete explanations for changes in complex biological processes such as oxidative phosphorylation are difficult. We have explained the DHA-dependent decreases in bioenergetic activities to be, in part, the result of membrane perturbations caused by DHA. This seems reasonable in light of the work of Brand and colleagues (64,65) on the effect of lipid composition on mitochondrial H^+ leakage. We realize, however, that other interpretations including extensive lipid peroxidation, increases in phospholipase A_2 activity (66), changes in adenylate cyclase activity (67), and alterations in prostanoid levels may also play a role.

We conclude that although mitochondrial membrane composition can be easily altered with dietary n-3 fatty acids, changing mitochondrial membranes in this way does not alter bioenergetic function in a manner likely to reverse the deleterious effects of age.

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, 1900-La Plata, Argentina

ABSTRACT: The influence of a fat-free diet on the molecular species composition of phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylinositol (PI) of rat liver microsomes was studied by using reversed-phase high-pressure liquid chromatography. In the three phosphoglyceride classes analyzed, the fat-free diet produced a large decrease in the 18:0/20:4n-6 species but less important changes were found in the 16:0/20:4n-6 species. In PC, the most abundant phosphoglyceride class of rat liver microsomes, the fall in the 18:0/20:4n-6 species was counterbalanced mainly by an enhancement in the 16:0/18:1n-9 species although it was not evident in PE. In PI, the decrease in the 18:0/20:4n-6 species was counterbalanced by an increase in the 18:0/20:3n-9 species. Fluorescence polarization measurements of 1,6-diphenyl-1,3,5-hexatriene in liposomes of 16:0/18:1n-9-, 18:0/18:1n-9-, 16:0/20:4n-6-, and 18:0/20:4n-6-PC indicated that the change in the saturated fatty acid in the *sn*-1 position accompanying the replacement of 20:4n-6 by 18:1n-9 could be very important for a homeoviscous compensation, maintaining the membrane physical properties without large alterations in spite of the essential fatty acid deficiency due to the fat-free diet.
Lipids 32, 507–513 (1997).

The major function of essential fatty acids (EFA) is to be precursors of biooxygenated derivatives such as eicosanoids and docosanoids. However, only a small fraction of the requirements of these acids in the mammal diet can be explained by this role (1). Since large amounts of these acids and their derivatives are present in membrane phospholipids, a structurally specific role in the membranes has been also attributed to these acids (2,3). Although some authors have minimized the importance of EFA for the structural properties of membranes (4), others have suggested that they could modify the conformational freedom of the acyl chains of lipid bilayers with participation in lipid–protein interactions and membrane function (5,6). The influence of unsaturation on the bilayer structural and dynamic properties is strongly dependent on the position of double bonds (7–9). Since only EFA and their derivatives are able to place double bonds in the deep part of the membrane leaflet (3,10,11), their deficiency could result in altered transversal double-bond distribution and physical properties of the membranes.

EFA-deficient and fat-free diets modify the fatty acid composition of several membranes in different species (3,10–17). Although it depends to some extent on the particular membrane, tissue and species, these diets produce, in general, a fall in the n-6 fatty acids 18:2 and 20:4 and an increase in the nonessential 18:1n-9 fatty acid. Appreciable amounts of the nonessential fatty acid 20:3n-9, which is present only in trace amounts in EFA-sufficient animals, appear as a consequence of EFA or fat-free diets in rat (10,12,13) but not in guinea pig liver microsomes (14–17).

Several studies using spectroscopic methods such as fluorescence (14,16,17) or electron spin resonance (3,6,15) have indicated that EFA or fat-free diets affect the physical properties of different membranes, such as guinea pig liver microsomes (14–17) or piglet jejunum brush border membranes (3,6). This is attributed to changes in the fatty acid composition of membrane lipids, since no changes are observed either in the phospholipid class distribution or in the relative content of cholesterol, phospholipid, and protein. In some membranes, however, as is the case for rat erythrocyte (10) and liver microsomal (10,13) membranes, in spite of large changes in fatty acid composition, membrane lipid order and dynamics remain unaltered, suggesting that some homeoviscous compensation could occur (10). As already shown in artificial membranes of synthetic phosphatidylcholines (PC), the influence of an unsaturated fatty acid in the *sn*-2 position on the viscotropic properties is largely dependent on the saturated one in *sn*-1 (9). Thus, to understand the mechanism of this homeoviscous compensation, it was necessary to study the changes in the phospholipid molecular species resulting from a fat-free diet. This should supply more detailed information than the fatty acid compositional changes.

This study shows that the largest change evoked by a fat-free diet in rat liver microsomes is the replacement of

18:0/20:4n-6-PC by 16:0/18:1n-9-PC. Fluorescence anisotropy measurements of 1,6-diphenyl-1,3,5-hexatriene (DPH) in liposomes of these PC in comparison with 16:0/20:4n-6- and 18:0/18:1n-9-PC suggest that the replacement in the *sn*-1 position of 18:0 by 16:0 could be very important for the homeoviscous compensation observed in liver microsomes of rats fed on the fat-free diet.

EXPERIMENTAL PROCEDURES

Materials. DPH was obtained from Aldrich Chemical Co. (Milwaukee, WI). A stock solution of 2.0 mM in tetrahydrofuran was prepared. The 16:0/18:1n-9-, 18:0/18:1n-9-, 16:0/20:4n-6-, and 18:0/20:4n-6-PC (dissolved in chloroform) were obtained from Avanti Polar Lipids (Alabaster, AL).

Animals and diets. After weaning, male Wistar rats were fed either a control diet: 52% starch, 19% casein, 23% sunflower oil plus minerals (4%) and vitamins (2%) (18) or a fat-free diet: 66% starch, 28% casein, minerals (4%) and vitamins (2%). The rats were killed by decapitation either one or three months later, and the livers were excised.

Microsome preparation. Livers were homogenized in 0.25 M sucrose, 1 mM EDTA, pH 7.0. Microsomes were obtained by centrifugation as previously described (19) and stored at −80°C. The protein content of microsomal preparations was measured by the method of Lowry *et al*. (20).

Extraction and separation of lipid fractions. Total microsomal lipids were extracted according to the procedure of Folch *et al*. (21) with chloroform/methanol 2:1 (vol/vol). Glycerophospholipid classes were separated by one-dimensional thin-layer chromatography on 20×20 cm plates coated with a mixture of silica gel H–florisil 9:1 (w/w) with a double development solvent system (22): chloroform/methanol/30% ammonium hydroxide/water 140:50:7:3 (by vol) in the first run and chloroform/methanol/acetic acid/water 320:40:8:3 (by vol) in the second run. The extreme ends of the plates were sprayed with an iodine solution to visualize the spots. The unexposed part of the bands corresponding to PC, phosphatidylethanolamine (PE), and phosphatidylinositol (PI) were scraped off and extracted with methanol/chloroform 2:1 (vol/vol).

Fatty acid composition analysis. After evaporation of the solvent under vacuum, the total lipid extracts and the different phospholipid fractions were transesterified by heating at 64° for 3 h in 10% boron trifluoride in methanol (from Sigma Chemical Co., St. Louis, MO). The resulting methyl esters were separated on a column of 10% SP 2330 on 100–120 mesh Chromosorb WAW (Supelco, Bellefonte, PA) using a Hewlett-Packard 5840 A gas–liquid chromatograph (Palo Alto, CA). The fatty acids were identified by comparison of their relative retention times with those of reference standards.

Phospholipid molecular species analysis. The analysis of phospholipid molecular species was essentially made as described by Patton *et al*. (23) with some modifications. PC, PE, and PI molecular species were separated on a 4×250 mm Bio-Sil ODS-5S column (Bio-Rad, Richmond, CA), eluted with 50 mM choline chloride in methanol/water/acetonitrile 90:7.5:8 (vol/vol) at a flow rate of 1.5 mL/min using a Merck-Hitachi L-6200 pump (Darmstadt, Germany). Detection was performed by absorption at 205 nm using a Merck-Hitachi L-4200 ultraviolet–visible (UV-VIS) detector. For the identification and quantification of the molecular species, 400 µg of each phosphoglyceride were injected onto the column. Individual peaks were collected and mixed with 40 µg of di-20:1(n-9)-PC used as internal standard. They were extracted with chloroform and after the evaporation of the solvent under vacuum; they were transesterified as described above for the fatty acid analysis. Gas–liquid chromatography (GLC) analysis of each high-performance liquid chromatography (HPLC) peak made possible the identification of the fatty acids which were present in each molecular species. The relative GLC–flame-ionization detection (FID) response with respect to the internal standard 20:1 made possible the quantification of each molecular species. Relative response factors for the HPLC UV absorption detection were calculated for each molecular species of phosphoglyceride. These factors were used to calculate the composition in molecular species of the individual samples directly from the HPLC chromatograms obtained by injecting 200-µg phosphoglyceride samples.

Fluorescence anisotropy of 1,6-diphenyl-1,3,5-hexatriene. Multilamellar liposomes of 16:0/18:1-, 18:0/18:1-, 16:0/20:4, and 18:0/20:4-PC were prepared in 20 mM sodium phosphate pH 7.1 using the procedure described by Kutchai *et al*. (24). For labeling with DPH, 2 mL of a 2.5 µM probe dispersion in 20 mM phosphate buffer pH 7.1 were mixed with the same volume of liposome preparations, agitated, and incubated at 40°C for 30 min. All procedures were carried out under N_2 atmosphere. For background corrections, unlabeled blanks with the same concentration of liposomes were also prepared (25).

Steady-state anisotropy was measured at 20°C in an SLM 4800 C spectrofluorometer (SLM Instruments, Inc., Urbana, IL) as described (26). The excitation wavelength was 361 nm, and the emission was observed through a sharp cut-off filter (Schott KV 389; Glass Technologies, Inc., Duryea, PA).

RESULTS

Table 1 shows the effect of a 1-mon treatment with a fat-free diet on the fatty acid composition of rat liver microsomes. This is in agreement with our previous findings (10,13). The fat-free diet resulted in a highly significant decrease in the n-6 acids 18:2 and 20:4. With respect to the minor n-3 acids, although a significant redistribution was produced by the treatment, the total amount was not changed. The decrease in n-6 acids was counterbalanced by a rise in the nonessential n-9 monoenoics 16:1 and 18:1 and the trienoic 20:3n-9. An increase in 16:0 was compensated by a decline in 18:0, and no net change in the total saturated acid content occurred. In this way, the ratio of unsaturated to saturated acyl chains was not

significantly altered. After 3 mon of the fat-free diet treatment, the same changes were basically found in the fatty acid composition (not shown).

Table 1 also shows the effect of a 1-mon treatment with a fat-free diet on the fatty acid composition of the three major phosphoglyceride classes of rat liver microsomes: PC, PE, and PI. Although microsomes contain minor phospholipid classes such as phosphatidylserine and sphingomyelin, PC, PE and PI make more than 80% of the microsomal lipids. The changes in the fatty acid composition produced by the fat-free diet were different in each one of these phospholipid classes. A decrease in 18:2n-6 was produced in all the phospholipid classes, but there was no large decrease in 20:4n-6 in the PE fraction as a result of fat deprivation. The highest increase in monoenoic acids was found in the PC fraction. In the PI fraction containing the largest amount of 20:4n-6 but the smallest amount of 18:2n-6, the fat-free diet produced the highest increase in the nonessential trienoic 20:3n-9 and no increase in monoenoic acids. As in the total microsomal lipids, the 3-mon treatment resulted in similar changes in the fatty acid composition of each phospholipid class (not shown) as those observed for the 1 mon-treatment.

Figure 1 shows typical chromatograms obtained for the HPLC separation of the molecular species of PC, PE, and PI from liver microsomes of rats fed on a control or a fat-free diet. In the PC and PE fractions of fat-fed animals, eight major molecular species were observed. Two new species containing 20:3n-9 became detectable in animals fed the fat-free diet. Only two major molecular species (16:0/20:4n-6 and 18:0/20:4n-6) were observed in the PI fraction of control animals, and 18:0/20:3n-9 became observable in the animals fed the fat-free diet.

Table 2 shows changes produced by the fat-free diet on the composition in molecular species of the major phosphoglyceride classes from rat liver microsomes. The two major molecular species in PC, PE, and PI were those containing arachidonic acid (16:0/20:4n-6 and 18:0/20:4n-6). The fat-free diet produced a marked decrease in the 18:0/20:4n-6 species of the three phosphoglycerides analyzed. However, in the case of 16:0/20:4n-6, the fat-free diet evoked only a small decrease in the PC fraction, a small increase in the PE fraction and no significant change in the PI fraction. A second major change produced by the fat-free diet was a large increase in 16:0/18:1n-9-PC. The amount of 16:0/18:1n-9 species of PE, however, was not significantly changed by the treatment. The nonessential polyenoic 20:3n-9 fatty acid, which appeared as a consequence of the fat deficiency, was found in two molecular species of PC and PE (16:0/20:3n-9 and 18:0/20:3n-9) but in only one species of PI (18:0/20:3n-9). Although the fat-free diet produced a significant decrease in the content of the 18:2n-6 fatty acid in PC and PE (see Table 1), no significant changes were observed in the 16:0/18:2n-6 and 18:0/18:2n-6 species of these phosphoglycerides. This fact could be due to the presence of other minor molecular species which were not detected by the HPLC analysis.

In accordance with previous studies (19), the fat-free diet did not evoke significant changes in the phospholipid class distribution and in the lipid/protein or cholesterol/phospholipid ratios of rat liver microsomes (not shown). The PC, PE, and PI contents of both groups of liver microsomes were 0.32, 0.15, and 0.055 μmol/mg of protein, respectively. The amount of each phosphoglyceride molecular species (in nmol/mg of protein) was calculated and is given in Table 2. It shows that the major change produced by the fat-free diet was the decrease in 18:0/20:4n-6 PC, which was mainly replaced by 16:0/18:1n-9.

It was our interest to know if the change in the saturated fatty acid in *sn*-1 (18:0 by 16:0) which accompanies the change in the unsaturated one in *sn*-2 (20:4n-6 by 18:1n-9) could play some role in the compensation observed in the fat-deficient condition. For this reason, steady-state fluorescence anisotropy of DPH in multilamellar liposomes of 18:0/20:4

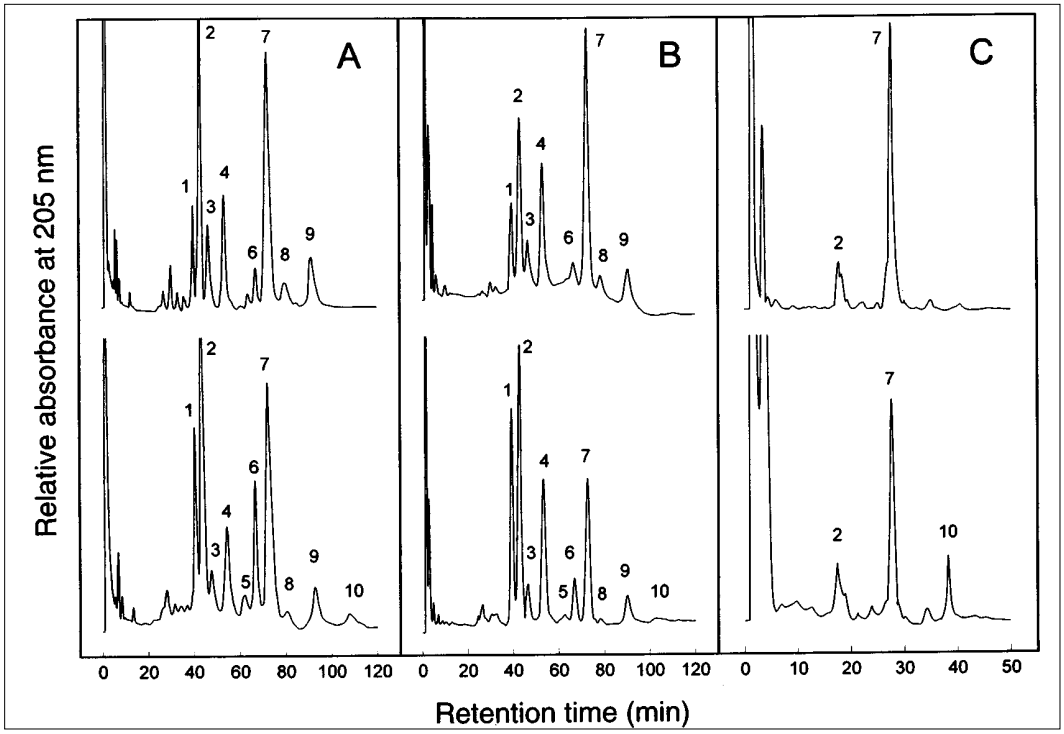

FIG. 1. Reversed-phase high-performance liquid chromatographic separation of molecular species of phosphatidylcholine (A), phosphatidylethanolamine (B), and phosphatidylinositol (C) of liver microsomes from rats fed on a control (top chromatograms) or a fat-free (bottom chromatograms) diet. About 200 µg of the corresponding lipids were chromatographed as described in the Experimental Procedures section. Identified peaks are numbered in sequence of elution: 1, 16:0/22:6n-3; 2, 16:0/20:4n-6; 3, 16:0/18:2n-6; 4, 16:0/22:5n-3; 5, 16:0/20:3n-9; 6, 16:0/18:1n-9; 7, 18:0/20:4n-6; 8, 18:0/18:2n-6; 9, 18:0/22:5n-3; and 10, 18:0/20:3n-9.

n-6-, 18:0/18:1n-9-, 16:0/20:4n-6- and 16:0/18:1n-9 PC, was measured. Figure 2 shows that fluorescence anisotropy was lower in liposomes of the 20:4n-6-containing species compared with those of the 18:1n-9-containing species. Fluorescence anisotropy was higher in liposomes of the 18:0-containing PC than in those of the 16:0-containing ones. The increase in fluorescence anisotropy produced by the change of 20:4n-6 for 18:1n-9 in *sn*-2 was largely compensated by the change of 18:0 for 16:0 in the *sn*-1 position.

DISCUSSION

Differential polarized phase fluorescence studies dealing with probes of different localization in the lipid bilayer, using either two fixed frequencies (10) or multiple modulation frequencies for the excitation (27), indicated that the order and dynamics of the lipid bilayer of rat liver microsomes are not significantly modified by the EFA deficiency produced by fat-free diets. Only a small decrease in the rate of dipolar relaxation at the interfacial level, where phospholipid polar groups are located, was detected using Laurdan as probe (27). These studies suggest that changes in the fatty acid composition produced by fat deficiency would occur in such a way that the lipid bilayer properties are largely compensated.

The present work shows that a fat-free diet affects differentially the composition in molecular species of the main phosphoglyceride classes of rat liver microsomes and that the changes in the unsaturated fatty acids of *sn*-2 are accompanied by changes in the saturated acids in *sn*-1. In the three phosphoglyceride classes analyzed, fat deficiency produced a large decrease in the 18:0/20:4n-6 species but small changes in the 16:0/20:4n-6 species. In PC, the most abundant phosphoglyceride class of rat liver microsomes, the decrease in the 18:0/20:4n-6 species was mainly counterbalanced by an increase in the 16:0/18:1n-9 species. However, in PI, the decrease in the 18:0/20:4n-6 species was counterbalanced by an increase in the 18:0/20:3n-9 species.

Since the fat-free diet evoked no change in the phospholipid class distribution and PC is the major lipid class of rat liver microsomes, the replacement of 18:0/20:4n-6 PC by 16:0/18:1n-9 PC was the major change produced by the treatment. These results also show that the increase in the fluorescence steady-state anisotropy of DPH due to the change of 20:4n-6 by 18:1n-9 in the *sn*-2 position of PC was largely compensated by the change of 18:0 by 16:0 in the *sn*-1 position. This fact indicates that the change in the saturated fatty acid in *sn*-1 accompanying the replacement of 20:4n-6 by 18:1n-9 in *sn*-2 could be very important for a homeoviscous compensation, maintaining the membrane physical proper-

ties without large alterations under the fat-deficient condition.

Differential polarized phase fluorescence studies using several probes of different localization in the lipid bilayer were previously made in multilamellar liposomes of these PC (9). They showed that order and viscous resistance to motion in the external bilayer region sensed by 2- and 7-(9-anthroyloxy) stearic acids are similar for 16:0/18:1 PC and 18:0/20:4 PC liposomes. However, in 18:0/20:4 PC liposomes, the deep region of the bilayer is somewhat more disordered, allowing a faster motion to 12-(9-anthroyloxy) stearic acid than in the case of 16:0/18:1 PC liposomes (9). This indicates that, although a large compensation in the microsomal membrane viscotropic properties is produced by the replacement of 18:0/20:4n-6 PC for 16:0/18:1n-9 PC, it is not enough to reach the almost exact compensation observed in fat deficiency (10). Table 2 shows that relatively minor but significant changes in other phosphoglyceride molecular species were produced by the fat-free diet in addition to the pronounced changes in 18:0/20:4n-6 PC and 16:0/18:1n-9 PC. Several of these relatively minor changes could help maintain unaltered the dynamic properties of rat liver microsomes in fat deficiency. The influence of the double-bond number and position in *sn*-2 on the acyl chain dynamics at different bilayer depths seems to be complex and seems to depend on the fatty acid in *sn*-1. In order to learn the role of these relatively minor changes for the viscotropic compensation in the fat-free condition, further measurements in liposomes of these individual phosphoglyceride species are necessary.

Another important subject is the metabolic origin of the phosphoglyceride molecular species. The 18:0/20:4n-6 PC is known to originate appreciably by methylation of PE (28), whereas the 16:0/18:1n-6 PC mainly comes from the *de novo* path. Since PE methylation seems to be sensitive to the membrane lipid dynamics (28), an interesting question to resolve in the future is whether the fat-free diet might alter the flux along the different paths.

ABSTRACT: The aim of this study was to measure the changes in lipid metabolism which occur during smoltification and seawater transfer in Atlantic salmon *(Salmo salar)*. Duplicate groups of Atlantic salmon parr were fed diets containing either fish oil (FO) or a blend of linseed and rapeseed oils, vegetable oil (VO), from October (week 0) to seawater transfer in May (week 26). From May to August (weeks 26–43), all fish were fed a fish oil-containing diet. Fatty acyl desaturation and elongation activity were followed in isolated hepatocytes incubated with radioactive 18:3n-3 and 18:2n-6. Metabolism of 18:3n-3 was consistently around 5-fold greater than metabolism of 18:2n-6, and total metabolism of both substrate polyunsaturated fatty acids (PUFA) was increased in fish fed both VO and FO up to seawater transfer after which desaturation activities were reduced. Desaturation activities with both 18:3n-3 and 18:2n-6 were significantly greater in fish fed VO, compared to fish fed FO, at 22 and 26 wk. Arachidonic acid (20:4n-6; AA) in liver polar lipids (PL) of fish fed VO increased consistently from weeks 0–22 but varied after seawater transfer. In fish fed FO, AA in liver PL remained constant up to week 17 before increasing at seawater transfer and leveling off thereafter. Eicosapentaenoic acid (20:5n-3; EPA) in liver PL of fish fed VO decreased significantly from week 0–22 before rising at seawater transfer and increasing rapidly posttransfer. EPA in liver PL of fish fed FO showed a similar trend except EPA was always greater in the freshwater phase compared to fish fed VO. Docosahexaenoic acid (DHA) levels in liver PL of fish fed VO remained constant in the freshwater phase before increasing following seawater transfer. In fish fed FO, DHA in liver PL increased from weeks 0–17 reducing and leveling off postseawater transfer. The levels of $PGF_{2\alpha}$ and $PGF_{3\alpha}$ were measured in isolated gill cells stimulated with calcium ionophore A23187. $PGF_{2\alpha}$ production in fish fed VO increased significantly between 0–7 wk before decreasing toward seawater transfer. After transfer, $PGF_{2\alpha}$ production increased to a peak at 35 wk. $PGF_{2\alpha}$ production in fish fed FO was not significantly altered during the trial period. The changes in $PGF_{3\alpha}$ production were broadly similar to those occurring with $PGF_{2\alpha}$, but the latter was always in excess of the former (2- to 4-fold). Plasma chloride concentrations in fish subjected to seawater challenge at 20 wk were significantly lower in fish fed VO compared to those fed FO. This study has provided new information on the changes in lipid metabolism which accompany parr-smolt transformation and suggests that diets which have a fatty acid composition more similar to that in aquatic invertebrates may be beneficial in effecting successful seawater adaptation.

Lipids 32, 515–525 (1997).

The fatty acid compositions of fish tissues are determined both by the type of dietary lipid ingested and the ability of the individual fish species to modify that dietary input *via* both catabolism and by pathways of desaturation and elongation (1,2). Freshwater fish appear able to elongate and desaturate 18:3n-3 to 22:6n-3 (3) whereas marine fish, which lack or have a very low activity of Δ5-desaturase, require the long-chain polyunsaturated fatty acids (PUFA), eicosapentaenoic acid (20:5n-3; EPA), and docosahexaenoic acid (22:6n-3; DHA) to be supplied by the diet (4). The low Δ5 desaturase activity in marine fish reflects the abundance of EPA and DHA in the marine food chain (5), which makes a Δ5-desaturase activity largely redundant, while the freshwater food chain, which tends to lack DHA but is rich in the C_{18} PUFA 18:2n-6 and 18:3n-3, requires fish to desaturate and elongate C_{18} precursor fatty acids to form physiologically important PUFA, such as DHA (6,7).

The Atlantic salmon (*Salmo salar)* is an anadromous fish which begins life in freshwater and migrates to the sea after 1–2 yr, before returning to freshwater to breed after spending 1–3 yr at sea. The seaward migration of salmonid juveniles, or parr, is accompanied by profound changes in morphology, behavior and physiology, known collectively as parr–smolt transformation or smoltification (8). The process involves activation of neuroendocrine and endocrine systems which re-

sults in biochemical reorganizations within the tissues which prepare the fish, while still in freshwater, for life in the marine environment (9,10). Studies with the steelhead trout (*Oncorhynchus mykiss)* and the masu salmon (*O. masou)* suggest that the change in tissue fatty acid compositions from a typical freshwater pattern, which is relatively low in PUFA, to a typical marine pattern which is relatively rich in long-chain PUFA particularly EPA and DHA, occurs as a preadaptive response to seawater entry (11,12). In addition, Li and Yamada (12) found that masu salmon which had undergone smoltification, but which were maintained in freshwater on the same diets, underwent a desmoltification process which was accompanied by a reversion to a "freshwater type" lipid composition, suggesting that lipid metabolism could be modified in response to ambient salinity changes.

A number of studies have also observed a significantly elevated level of arachidonic acid (20:4n-6; AA) in tissues of wild parr and smolts compared to their cultured counterparts (13–15). The cultured parr and smolts all contained considerable amounts of dietary-derived 18:2n-6 which was not desaturated and elongated to AA and led to the suggestion by Ackman and Takeuchi (13) that these reactions might not be possible in salmon undergoing smoltification. The importance of long-chain PUFA in adaptation to salinity changes has been observed in essential fatty acid (EFA) deficient trout, which had reduced ionic permeability in brush border membranes (16) while a similar EFA-deficiency caused morphological changes in the gills of turbot (17). In addition, membrane fatty acid composition is known to affect the activity of a number of ion pumps and membrane-bound enzymes, including Na^+,K^+-ATPase (18,19). The C_{20} PUFA are substrates for eicosanoid synthesis, and AA is the preferred substrate in fish, despite EPA being more abundant in fish phospholipids (20,21). Prostaglandins are known to mediate fluid and electrolyte fluxes in fish gill and kidney and are therefore important in adaptation to changes in salinity (22,23).

In the present study, duplicate groups of Atlantic salmon parr were fed either a control diet containing a Northern hemisphere fish oil, similar to that in commercial feeds used in the salmon farming industry, or a blend of rapeseed and linseed oils providing a fatty acid composition more closely resembling that of freshwater invertebrates. Fish were sampled on a regular basis from 6 mon before seawater transfer to 4 mon after seawater transfer. At each sampling time, fatty acyl desaturation and elongation activity were determined in isolated hepatocytes and prostaglandin F isomers, derived from both AA and EPA, were measured in isolated gill cells stimulated with the calcium ionophore A23187. Samples of liver and gill were also collected for lipid compositional analysis. Seawater tolerance tests were performed on the fish in the weeks preceding seawater transfer.

MATERIALS AND METHODS

Animals and diets. Atlantic salmon parr (1,160) supplied by Marine Harvest McConnell Ltd. (MHM) (Highland, Scotland) were distributed randomly into four 2 m × 2 m tanks at the MHM smolt cultivation unit in Invergarry, Invernesshire, Scotland, in October 1994. Each tank contained 1520 L and was supplied with freshwater at a rate of 45 L/min. The fish oil-containing diet (FO) and the vegetable oil-containing diet (VO) were fed to satiation, to duplicate tanks of fish, using automatic feeders. Experimental diets were prepared by BOCM-Pauls (Renfrew, Scotland). The composition of the diets is shown in Table 1. The freshwater diets (FO and VO) contained 54% protein and 19% lipid while the posttransfer diet contained 49% protein and 24% lipid. The fatty acid compositions of the diets are shown in Table 2. All diets were formulated to satisfy the nutritional requirements of salmonid fish (24).

In late April, 240 fish which had undergone smoltification (i.e., those which had changed to silver coloration) were transferred to the MHM research unit at Inverailort, Invernesshire, Scotland. Fish were distributed randomly into four 1 m × 1 m tanks of 250 L capacity. Fish were initially acclimated in freshwater for a few days before being switched to seawater, supplied at 6 L/min. All fish were then switched to the posttransfer diet which was fed to satiation by automatic feeders. At the outset of the experiment in October, the water temperature was 10.8°C which fell to 0.7°C in January after which the freshwater temperature rose slowly to 5.5°C in April. On transfer to seawater in early May (week 26), the temperature was 9°C and increased to a maximum of 14°C in August. Six fish per dietary treatment were sampled at regular intervals between October 1994 and August 1995.

Lipid extraction and phospholipid fatty acid analysis. Intact gill arches and liver were dissected from three fish per dietary treatment at each time point and immediately frozen in liquid nitrogen. Samples were stored at −20°C prior to lipid extraction. Total lipid was extracted from gill, liver, and diet samples by the method of Folch *et al.* (25). Total polar lipid (PL) fraction was prepared by separating neutral lipids from PL by thin-layer chromatography (TLC) using hexane/diethylether/acetic acid (80:20:2, by vol) as developing solvent. The PL retained on the origin was scraped and subjected to acid-catalyzed transesterification as described by Christie (26). The fatty acid methyl esters were separated and quanti-

TABLE 1
Feed Components (% of dry diet)

Component	FO diet	VO diet	Posttransfer diet
Fish meal[a]	55	29	65

[c]Totals include 16:1n-9 and 20:1n-7.
[d]Totals include 18:3n-6, 20:3n-6, and 22:5n-6. See Table 1 for other abbreviations.

fied by gas–liquid chromatography (Carlo Erba Vega 8160; Fisons Ltd., Crawley, United Kingdom) using a 30 m × 0.32 mm capillary column (CP wax 52CB; Chrompak Ltd., London, United Kingdom). Hydrogen was used as carrier gas, and temperature programming was from 50 to 150°C at 40°C/min and then to 230°C at 2.5°C/min. Individual methyl esters were identified by comparison to known standards and by reference to published data (27).

Preparation of isolated hepatocytes and gill cells. Fish were killed by a blow to the head and the liver and gill arches dissected immediately. The gall bladder was removed carefully from the liver and the main blood vessels removed. The liver was perfused *via* the hepatic vein with solution A [calcium- and magnesium-free Hank's balanced salt solution (HBSS) + 10 mM HEPES + 1 mM EDTA] to clear blood from the tissue. The liver was chopped finely with scissors and incubated with 20 mL of solution A containing 0.1% (wt/vol) collagenase in a 25-mL "Reacti-flask" in a shaking water bath at 20°C for 45 min. The digested liver was filtered through 100 μm nylon gauze and the cells collected by centrifugation at 1000 × *g* for 5 min. The cell pellet was washed with 20 mL of solution A containing 1% wt/vol fatty acid-free bovine serum albumin (FAF-BSA) and recentrifuged. The hepatocytes were resuspended in 10 mL of Medium 199 containing 10 mM HEPES, 2 mM glutamine, 100 U/mL penicillin, and 0.1 mg/mL streptomycin. One hundred μL of cell suspension was mixed with 400 μL of Trypan Blue, and hepatocytes were counted and their viability assessed using a hemocytometer. One hundred μL of the cell suspension was retained for protein determination.

The gills were blotted on tissue paper to remove blood clots and water after which they were chopped with scissors and incubated in 30 mL solution A containing 0.1% collagenase as described above. Gill cells were prepared as described previously (1) and were resuspended finally in 1 mL of HBSS containing 2 mM $CaCl_2$. Fifty μL were removed for protein determination.

Assay of hepatocyte fatty acyl desaturation/elongation activities. Five mL of each hepatocyte suspension were dispensed into two 25 cm^2 tissue culture flasks. Hepatocytes were incubated with 0.25 μCi of either [1-^{14}C] 18:3n-3 or [1-^{14}C] 18:2n-6, added as complexes with FAF-BSA. Briefly, 25 μCi of fatty acid (0.5 μmol) in ethanol were placed in a reaction vial, solvent evaporated under a stream of nitrogen and 100 μL of 0.1M KOH added. The mixture was stirred for 10 min at room temperature before 5 mL of 50 mg/mL FAF–BSA in HBSS containing 10 mM HEPES buffer were added and the mixture stirred for 45 min at 20°C. After addition of isotope, the flasks were incubated at 20°C for 3 h. After incubation, the cell layer was dislodged by gentle rocking, the cell suspension transferred to conical glass test tubes, and the flasks washed with 1 mL of ice-cold HBSS containing 1% FAF-BSA. The cell suspensions were centrifuged at 300 g for 2 min, the supernatant discarded, and the cell pellets washed with 5 mL of ice-cold HBSS/FAF-BSA. The supernatant was discarded, and the tubes placed upside down on paper towels to blot for 15 s before extraction of total lipid using ice-cold chloroform/methanol (2:1, vol/vol) containing 0.01% (wt/vol) butylated hydroxytoluene (BHT) essentially as described by Folch *et al.* (25) and as described in detail previously (28).

Total lipid was transmethylated, and fatty acid methyl esters prepared as described above. The methyl esters were redissolved in 100 μL hexane containing 0.01% BHT and applied as 2.5 cm streaks to TLC plates impregnated by spraying with 2 g silver nitrate in 20 mL acetonitrile and preactivated at 110°C for 30 min. Plates were fully developed in toluene/acetonitrile (95:5, vol/vol) (29). Autoradiography was performed with Konica A2 film for 4–7 d at room temperature. Silica corresponding to individual PUFA was scraped into scintillation minivials containing 2.5 mL of scintillation fluid (Ecoscint A, National Diagnostics, Atlanta, GA) and radioactivity determined in a TRI-CARB 2000CA scintillation counter (United Technologies Packard, Pangbourne,

United Kingdom). Results were corrected for counting efficiency and quenching of ^{14}C under exactly these conditions.

Ionophore stimulation and eicosanoid extraction. Gill cell suspensions were incubated at 20°C in a shaking water bath and stimulated with A23187 (2 µL in dimethylsulfoxide, 10 µM final concentration) as described previously (1). The incubation was continued for 20 min after which the cells were removed by centrifugation (12,000 × *g*, 2 min) and the supernatant transfered to tubes containing 150 µL ethanol and 50 µL 2 M formic acid. Samples were frozen immediately in liquid nitrogen and stored at −20°C until extraction and measurement of eicosanoids. The frozen gill cell supernatants were thawed and centrifuged (12,000 × *g*, 2 min) to remove any precipitate. The supernatants were extracted using octadecyl silica (C18) Sep-Pak minicolumns (Millipore Ltd., Watford, United Kingdom) by the method of Powell (30) and as described in detail by Bell *et al.* (21). The final extract was dissolved in 0.1 mL of methanol prior to high-performance liquid chromatography (HPLC).

Separation and measurement of prostaglandin F (PGF) isomers. The PGF isomers were separated by reverse-phase HPLC largely as described in Bell *et al.* (21). The PGF isomers were separated using a Spherisorb 5 µm (ODS 2) column (25 cm × 4.6 mm i.d.; Anachem, Luton, United Kingdom). An isocratic solvent system was employed containing 17 mM phosphoric acid/acetonitrile (70:30, vol/vol) at a flow rate of 1 mL/min. Fractions corresponding to each PGF isomer were pooled and extracted as described previously (21). Measurement of PGF isomers of the 2- and 3-series was performed using an enzyme immunoassay kit for $PGF_{2\alpha}$ according to the manufacturer's protocols (SPI-Bio, Massy, France). Cross-reactivity of $PGF_{3\alpha}$ with the $PGF_{2\alpha}$ antibody was 100%.

Seawater challenge and plasma chloride determination. In late March, while still in freshwater, 20 fish per dietary treatment were subjected to a seawater challenge test to assess their ability to osmoregulate. The fish were transferred to a tank containing standardized seawater at a salinity of 35 parts per thousand in a static tank, with aeration, for a period of 24 h. Artificial seawater was produced by adding the appropriate volume of "Seamix" sea salts (Peacock Salt Ltd., Glasgow, Scotland) to freshwater. After 24 h, the fish were euthanized and blood removed *via* the caudal vein into heparinized tubes. Tubes were mixed, centrifuged immediately, and the plasma removed and stored at −20°C. Plasma chloride concentrations were measured using a Jenway Chloride meter (Model PCLM3; Fisons, Loughborough, United Kingdom) using the method described in the operating manual. Plasma chloride concentrations were measured again in early May following transfer to natural seawater at a salinity concentration of 33 parts per thousand.

Protein determination. Protein concentration in isolated gill cell and hepatocyte suspensions was determined according to the method of Lowry *et al.* (31) after incubation with 0.25 mL of 0.25% (wt/vol) SDS/1M NaOH for 45 min at 60°C.

Materials. [1-^{14}C]18:3n-3 and [1-^{14}C]18:2n-6 (both 50–55 mCi/mmol) were from NEN [DuPont (United Kingdom) Ltd., Stevenage, United Kingdom]. HBSS, Medium 199, HEPES buffer, glutamine, penicillin, streptomycin, collagenase (type IV), FAF-BSA, calcium ionophore A23187, BHT, and silver nitrate were obtained from Sigma Chemical Co. (Poole, United Kingdom). TLC plates, precoated with silica gel 60 (without fluorescent indicator) were obtained from Merck (Darmstadt, Germany). $PGF_{3\alpha}$ and $PGF_{2\alpha}$, both >98%, were obtained from SPI-bio. All solvents were HPLC grade and were obtained from BS & S Ltd. (Edinburgh, Scotland).

Statistical analysis. Significance of difference ($P < 0.05$) between observations at each time point, for each dietary treatment, was determined by analysis of variance using a Statgraphics (system 3.0) computer package (Statistical Graphics Corporation, Rockville, MD). Significance of difference between dietary treatments at each time point was determined by Student's *t*-test. Data which were identified as nonhomogeneous (Bartlett's test) were subjected to either arcsine, square root, or log transformation before analysis. Differences between means were determined by Tukey's test.

RESULTS

All fish grew well on both the FO and VO diets and there were no significant differences in growth rates between dietary treatments, during either the freshwater or seawater stages of the experiment (Table 3). The total C_{18} PUFA substrate further desaturated (and elongated) to tri-, tetra-, penta-, and hexaene products are shown in Figure 1. The metabolites of linolenic acid (18:3n-3) are shown in Figure 1A, and these were always around fivefold higher than metabolites derived from linoleic acid (18:2n-6) shown in Figure 1B. Fatty acid desaturation activity increased significantly, with both PUFA, and in fish fed both FO and VO, up to the time of seawater transfer (26 wk) after which desaturation/elongation was reduced. Desaturation/elongation activities with 18:3n-3 were significantly greater in fish fed VO, compared to fish fed FO, at 7, 22, and 26 wk, while with 18:2n-6 desaturation/elongation was significantly increased in fish fed VO only at 22 and 26 wk.

The levels of AA, EPA, and DHA in gill PL are shown in Figure 2. AA in the gill PL of fish fed VO increased significantly up to 22 wk, before decreasing immediately after sea-

TABLE 3
Growth Parameters During the 45-wk Experimental Period[a]

Parameter	FO diet	VO diet
Number of fish	580	580
Initial weight (g)	24.4 ± 4.7	21.9 ± 4.7
Weight (g) (week 25)[b]	36.8 ± 6.8	34.7 ± 7.2
Final weight (g)	122.5 ± 33.3	118.8 ± 24.4
Specific growth rate[c]	0.51	0.54

[a]Values for initial and final weights are mean ± SD.
[b]Mean weight ± SD immediately before seawater transfer.
[c]Specific growth rate calculated as percentage weight gain/day = $(e^{G_w} - 1) \times 100$, where G_w (daily growth rate) = $\ln W_1 - \ln W_0/T$ (W_1 = final weight, W_0 = initial weight, and T = time in days). See Table 1 for abbreviations.

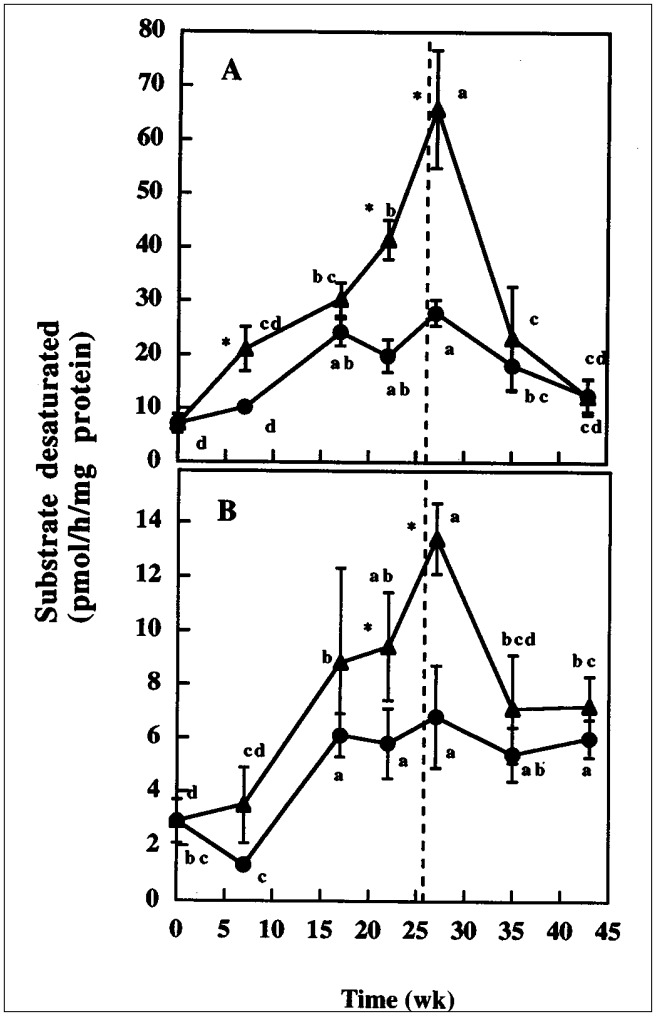

FIG. 1. Total amount of fatty acid desaturated and elongated/h/mg protein by isolated hepatocytes from Atlantic salmon juveniles fed diets containing either fish oil (FO) (●) or vegetable oil (VO) (▲). A, 18:3n-3; B, 18:2n-6. The vertical dotted line represents the time of seawater transfer (26 weeks). Each point represents the mean ± SD for three replicate samples. Points within the same dietary treatment having a different assigned letter are significantly different ($P < 0.05$). Points at the same sampling time assigned an asterisk (*) are significantly different between dietary treatments.

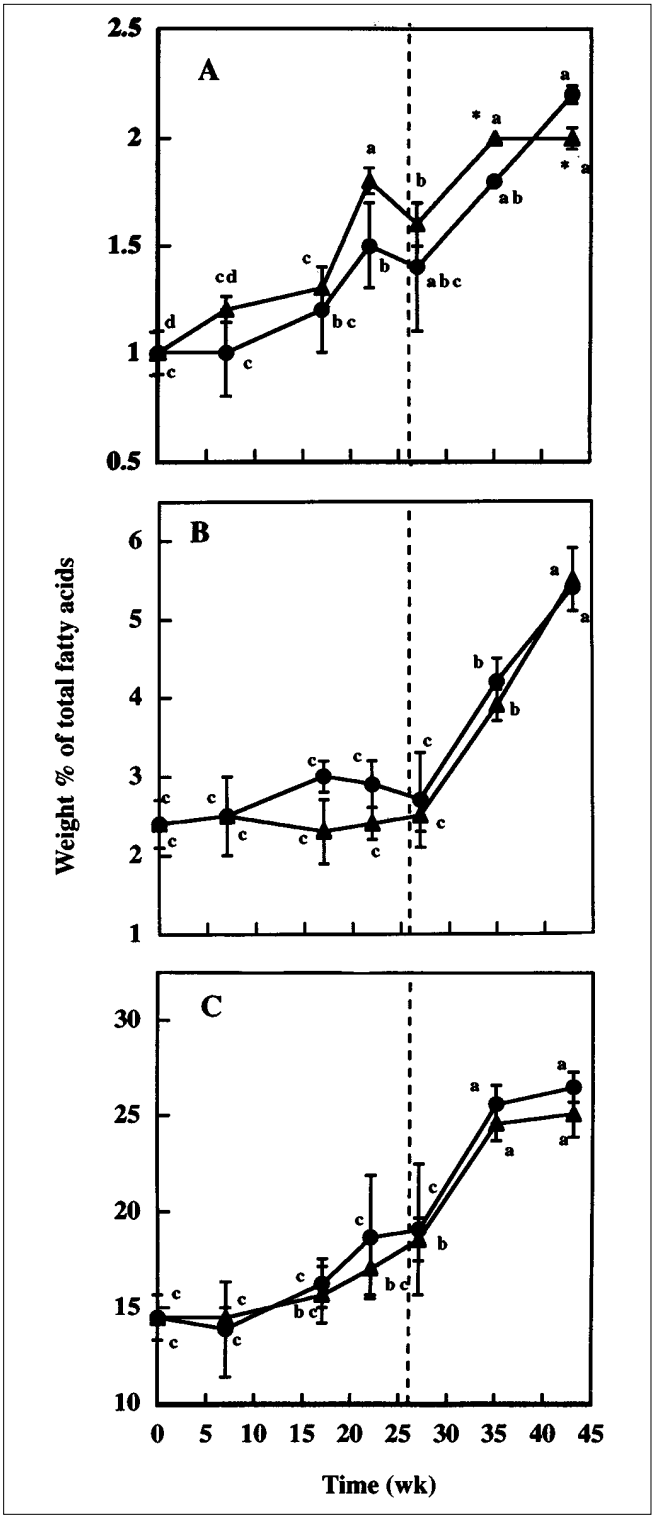

FIG. 2. Levels of the highly unsaturated fatty acids (20:4n-6, A; 20:5n-3, B and 22:6n-3, C) in polar lipids of gill from Atlantic salmon juveniles fed diets containing either FO (●) or VO (▲). The vertical dotted line represents the time of seawater transfer (26 wk).Values are percentage weight of total fatty acids and each point represents the mean ± SD for three replicate samples. Points within the same dietary treatment having a different assigned letter are significantly different ($P < 0.05$). Points at the same sampling time assigned an asterisk (*) are significantly different between dietary treatments. See Figure 1 for abbreviations.

water transfer, and thereafter returning to the pre-seawater transfer level (Fig. 2A). AA in gill PL of fish fed FO followed a very similar pattern to those fed VO although AA was significantly increased at 43 wk compared to the value immediately before seawater transfer (22 wk) (Fig. 2A). EPA in the gill PL of fish fed both diets remained constant in the period up to seawater transfer but increased significantly following seawater transfer (Fig. 2B). DHA in gill PL increased slightly, in fish fed both diets, during the period up to seawater transfer before rising significantly between 26 and 35 wk before leveling off thereafter (Fig. 2C).

The levels of AA, EPA, and DHA in liver PL are shown in Figure 3. The mean AA levels in liver PL of fish fed VO were

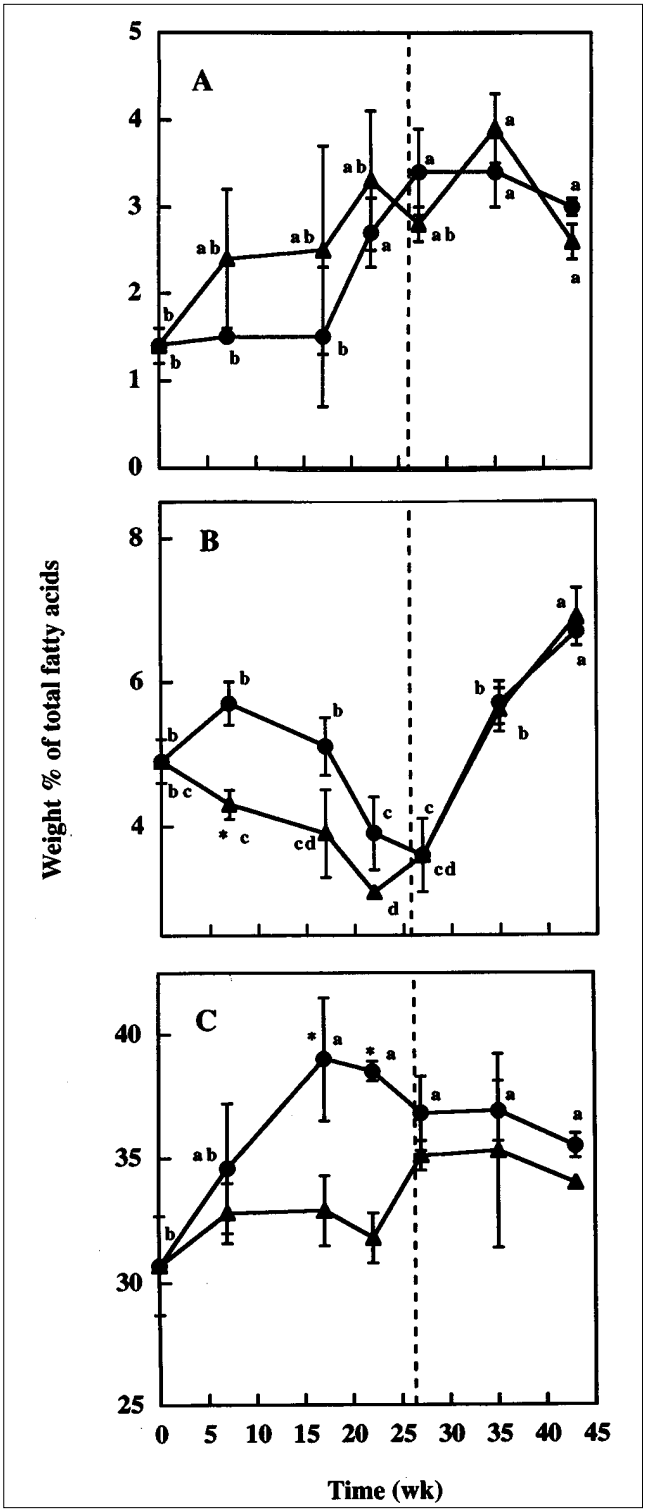

FIG. 3. Levels of the highly unsaturated fatty acids (20:4n-6, A; 20:5n-3, B and 22:6n-3, C) in polar lipids of liver from Atlantic salmon juveniles fed diets containing either FO (●) or VO (▲). The vertical dotted line represents the time of seawater transfer (26 wk).Values are percentage weight of total fatty acids, and each point represents the mean ± SD for three replicate samples. Points within the same dietary treatment having a different assigned letter are significantly different ($P < 0.05$). Points at the same sampling time assigned an asterisk (*) are significantly different between dietary treatments. See Figure 1 for abbreviations.

increased significantly at 35 and 43 wk compared to week 0 (Fig. 3A). AA in liver PL of fish fed FO remained constant until 17 wk before increasing significantly toward seawater transfer and leveling off thereafter (Fig. 3A). EPA levels in liver PL of fish fed VO decreased significantly between week 0 and week 22 before rising slightly at 26 wk and increasing rapidly and significantly thereafter (Fig. 3B). EPA in liver PL of fish fed FO showed a similar trend although levels of EPA were always greater in the freshwater phase, significantly so at 7 wk, compared to fish fed VO (Fig. 3B). DHA levels in liver PL of fish fed VO remained constant during the freshwater phase before increasing, although not significantly, following seawater transfer (Fig. 3C). DHA levels in liver PL of fish fed FO increased significantly from week 0 to week 17 before leveling off in the period immediately pre- and post-seawater transfer. DHA levels were significantly increased in liver PL of fish fed FO at weeks 17 and 22 compared to fish fed VO (Fig. 3C).

The AA/EPA ratios in gill and liver PL are shown in Figure 4. In gill polar lipid from fish fed VO, the AA/EPA ratio increased significantly between week 0 and week 22 before decreasing at seawater transfer and reducing to the initial value (week 0) by week 43 (Fig. 4A). In gill PL from fish fed FO, the AA/EPA ratio remained constant from week 0 to week 17 before increasing slightly, but significantly, at seawater transfer and then reducing to the initial value during the seawater ongrowing period. The AA/EPA ratio in gill PL was significantly increased in fish fed VO at weeks 17, 22, and 35 compared to fish fed FO (Fig. 4A). In liver PL, the changes in AA/EPA ratio due to smoltification and diet were qualitatively similar to those described in gill, although there were no significant differences between dietary treatments. (Fig. 4B).

The production of prostaglandins $PGF_{2\alpha}$ and $PGF_{3\alpha}$ by isolated gill cells stimulated with the calcium ionophore A23187 is shown in Figure 5. The levels of $PGF_{2\alpha}$ produced by stimulated gill cells were always in excess (2- to 4-fold) of $PGF_{3\alpha}$. The levels of $PGF_{2\alpha}$ in fish fed VO increased significantly between 0 and 7 wk before decreasing toward seawater transfer. After seawater transfer, $PGF_{2\alpha}$ levels increased in fish fed VO to reach a peak value at 35 wk (Fig. 4A). The levels of $PGF_{2\alpha}$ in fish fed FO were not significantly different during the trial period. Production of $PGF_{2\alpha}$ was significantly greater at week 17 and week 35 in fish fed VO compared to fish fed FO (Fig. 4A). The changes in $PGF_{3\alpha}$ production in stimulated gill cells during the experimental time course followed a broadly similar pattern, for both dietary treatments, to that described for $PGF_{2\alpha}$ (Fig. 4B). Production of $PGF_{3\alpha}$ was significantly greater at weeks 17, 35, and 43 in fish fed VO compared to fish fed FO (Fig. 4B).

The plasma chloride concentrations in fish subjected to seawater challenge at week 20 are shown in Figure 6. Regression analysis of the plasma chloride concentrations for fish fed VO (dotted line), compared to those for fish fed FO (solid line), indicated that the latter group exhibited higher plasma chloride concentrations, suggesting the FO-fed fish were less able to osmoregulate compared to those fed VO. The mean

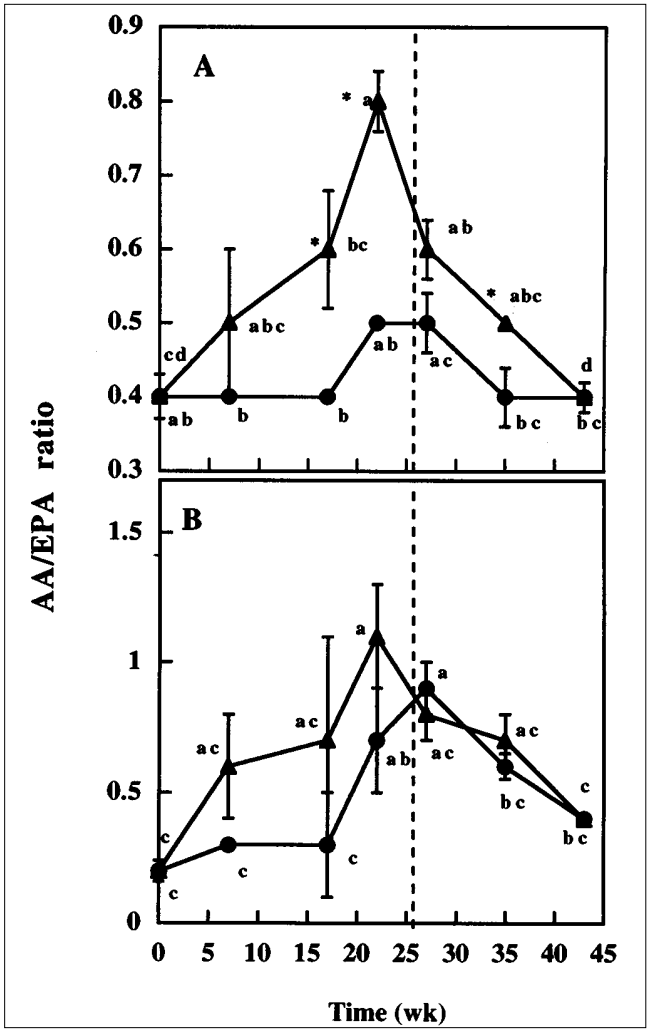

FIG. 4. The ratio of arachidonic acid 20:4n-6/eicosapentaenoic acid 20:5n-3 (AA/EPA) in the polar lipids of gill (A) and liver (B) from Atlantic salmon juveniles fed diets containing either FO (●) or VO (▲). The vertical dotted line represents the time of seawater transfer (26 wk). Each point represents the mean ± SD for three replicate samples. Points within the same dietary treatment having a different assigned letter are significantly different ($P < 0.05$). Points at the same sampling time assigned an asterisk (*) are significantly different between dietary treatments. See Figure 1 for other abbreviations.

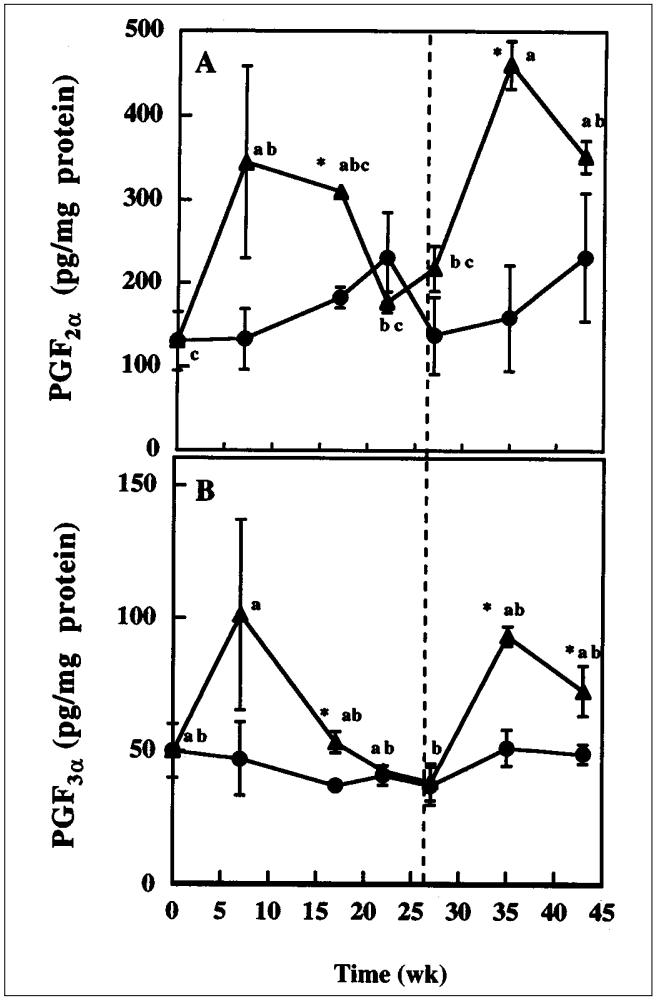

FIG. 5. Production of prostaglandin F analogues by isolated gill cells stimulated with the calcium ionophore A23187. Concentrations of prostaglandin F ($PGF_{2\alpha}$) (A) and $PGF_{3\alpha}$ (B) in pg/mg protein were measured in Atlantic salmon juveniles fed diets containing either FO (●) or VO (▲). The vertical dotted line represents the time of seawater transfer (26 wk). Each point represents the mean ± SD for three replicate samples. Points within the same dietary treatment having a different assigned letter are significantly different ($P < 0.05$). Points at the same sampling time assigned an asterisk (*) are significantly different between dietary treatments. See Figure 1 for other abbreviations.

values for plasma chloride concentration were 149.6 ± 7.4 and 163.2 ± 15.4 mM for fish fed VO and FO, respectively (significantly different, $P < 0.05$). The seawater tolerance test was repeated at week 26, 24 hr after transfer to seawater of 33 parts per thousand. The plasma chloride values recorded at that time were 133.4 ± 5.1 and 132.1 ± 6.3 mM for fish fed VO and FO, respectively.

DISCUSSION

The present study provides evidence that fatty acyl desaturation and elongation in Atlantic salmon hepatocytes is determined by an interplay between the genetic and environmental actions which constitute the smoltification or parr-smolt transformation processes and by dietary fatty acid composition. Fish fed FO showed increased desaturation activity, with both C_{18} substrate fatty acids, up to seawater transfer, with a subsequent reduction in activity posttransfer. Fish fed VO showed the same pattern although activities were higher (up to 3-fold) than in the FO fish, presumably at least partly owing to the greater supply of substrate fatty acids in the VO diet. At all times during the experimental period, 18:3n-3 was preferred over 18:2n-6 as the precursor in the desaturation and elongation pathways, the former being utilized at a rate around 5-fold higher than the latter. This observation is in agreement with previous studies in rats (32), rainbow trout

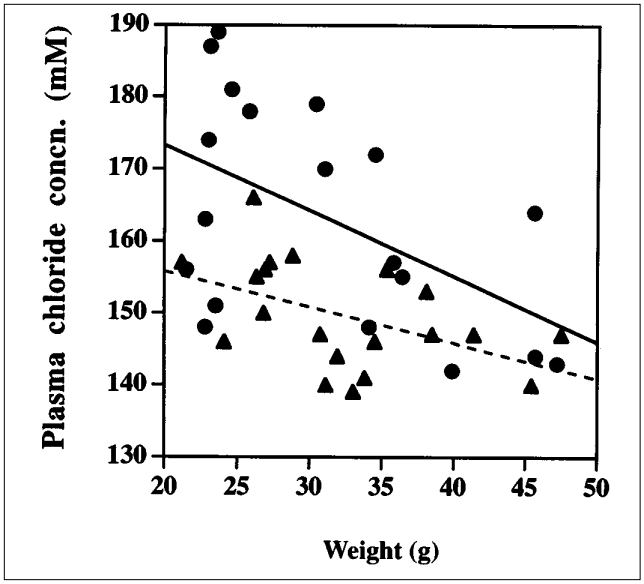

FIG. 6. Plasma chloride concentration (concn.) (mM) vs. weight (g) in Atlantic salmon parr fed diets containing either FO (●) or VO (▲) after being subjected to a seawater challenge at 20 wk as described in the Materials and Methods section. The regression lines for fish fed FO (—) or VO (---) are indicated. See Figure 1 for abbreviations.

(33), and established fish cell lines (34). Fish oils rich in long-chain n-3 PUFA are inhibitory to desaturation of both 18:3n-3 and 18:2n-6 in rats (35,36) and rainbow trout (37). The results of the present study in Atlantic salmon are also consistent with this and explain the apparent absence of 18:2n-6 desaturation products in farmed salmon, which were present in wild fish observed in a previous investigation (13). Given that most aquatic insects are rich in 18:2n-6 and 18:3n-3, it seems likely that the pattern of fatty acyl desaturation activity occurring during smoltification in wild fish would more closely resemble that found in fish fed VO compared to those fed FO.

It has been long established that marine lipids contain more PUFA, particularly long-chain n-3 PUFA, resulting in a high n-3/n-6 PUFA ratio compared to freshwater lipids (38). While this difference partly reflects the input from the respective food chains, it is also influenced by the modification of ingested dietary lipids *via* desaturation and elongation (5). The change in lipid composition from a "freshwater type" to a "marine type" has been observed in other salmonid species such as masu salmon (*O. masou)* and coho salmon *(O. kisutch)* (12,39), and these changes were regarded as a preadaptive response to the marine environment (11). During the course of this study, fish were subject to increasing water temperatures in the period leading up to, and beyond, seawater transfer. While temperature is known to affect PUFA metabolism and membrane phospholipid fatty acid compositions (40), all treatment groups were subject to the same temperature profile, and any differences between dietary treatments were independent of water temperature. The present study confirms that this preadaptation begins up to 6 mon prior to seawater migration and involves a significant "switch-on" of desaturation and elongation activity in hepatocytes.

While a number of studies have measured fatty acid compositions in salmonid parrs and smolts, these have generally involved one observation at each developmental stage (11–14,39). The present study is the first to follow changes in polar lipid fatty acid compositions in the period covering 6 mon prior to seawater transfer until 4 mon posttransfer. In gill polar lipid, DHA increased slowly in the freshwater phase, in both dietary treatments, up to seawater transfer and thereafter increased rapidly during the first 8 wk in seawater before leveling off. However, EPA remained constant in gill polar lipids up to seawater transfer before increasing rapidly in the period following seawater transfer. These results suggest that DHA is increased as a preadaptive response to life in the marine environment which is in agreement with previous observations (11) but also suggest that DHA, and EPA, continue to be incorporated into gill membrane lipid for a considerable period post-seawater transfer. Although the increase in gill DHA postseawater transfer may be due to an increased dietary supply of DHA (the total lipid content of the parr diet was 19% whereas the seawater diet contained 24% lipid), there was no similar increase in DHA in liver PL which suggests that the incorporation into gill has a specific physiological function. There is considerable evidence that the membrane fatty acid composition can influence membrane fluidity and thereby the activities of enzymes located within the membrane (18). More specifically, increased membrane DHA was observed in the gut of seawater-adapted trout (41), in several tissues of seawater-adapted guppies (42), and reduced dietary PUFA, and subsequently reduced membrane DHA, led to destruction of gill epithelia in the turbot (17). A number of studies with mammals have suggested that fish oils rich in EPA and DHA can alter membrane microenvironments and thereby the activity of enzymes such as Na^+, K^+-ATPase (19,43) which has important osmoregulatory functions, especially in fish subjected to changes in salinity.

The levels of AA, in both gill and liver PL, increased by over 100% during the course of the experimental period. In liver, AA levels were increased in fish fed VO compared to fish fed FO in the freshwater phase, while in the same period mean AA values in gill were higher in VO-fed fish compared to fish fed FO. In gill, AA levels continued to rise after seawater transfer suggesting that this n-6 PUFA is important in the smoltification process and in seawater acclimation. AA content of liver PL increased to 2.7 and 3.3% in FO and VO-fed fish, respectively, at week 22. These are comparable to the values of 2.1% observed in liver total lipid of wild salmon parr by Bolgova and Shchurov (14) and of 2.0% in liver phosphatidylcholine by Bell (15).

EPA levels remained virtually constant in gill PL but declined steadily in liver in both dietary treatments up to seawater transfer. This decline may reflect increased synthesis of DHA, required by tissues involved in osmoregulation, during preadaptation to the marine environment. In both gill and

liver, there was a rapid incorporation of EPA into PL in the period following seawater transfer with the level of EPA increasing more than 2-fold after transfer. While this increase may be due to increased dietary intake of EPA in the post-transfer diet as described above, a similar increased incorporation of DHA did not occur in liver and its absence suggests that there is an increased physiological requirement for EPA in post-smolts. It is interesting that, despite the differences in dietary fatty acid composition and fatty acid desaturase activities, the levels of AA, EPA, and DHA appeared to converge at seawater transfer. It would seem that there is a genetically predetermined value for these EFA which must be achieved to allow seawater transition to occur, and that this value was attained despite the differences in dietary fatty acid composition. However, by providing a diet which has a composition more closely resembling that of aquatic insects (6,7), the transitional EFA values may be attained at an earlier stage in the smoltification process and may permit a more successful seawater adaptation.

Both EPA and AA are precursors of biologically active eicosanoids, and the ratio of these two fatty acids varied considerably over the experimental period, especially in gill. In gill PL, the AA/EPA ratio was always greater in fish fed VO compared to those fed FO, with the highest values present immediately before seawater transfer. Production of the AA-derived $PGF_{2\alpha}$ was always in excess (2- to 4-fold) of the EPA-derived $PGF_{3\alpha}$, despite the abundance of the respective precursors being reversed. The preference for AA as an eicosanoid precursor has been observed in a number of fish species, tissues and cultured cells, despite EPA being present in greater abundance in cellular phospholipids (20,21,44). In the present study, both PGF analogues were produced in greater amounts by gill cells from VO-fed fish compared to those fed FO.

The explanation of these results is more complex than merely considering the respective ratios of the precursor PUFA, since eicosanoid production is modulated by a number of physiological and biochemical processes including hormones (23) and phosphospholipase A_2 activity which, in turn, can be influenced by the fatty acid composition of the membrane microenvironment (45,46). Although the physiological functions of eicosanoids have been less well studied in fish compared to mammals, they are involved in reproductive function, hormone release, cardiovascular function, neural function, and osmoregulation (23). Prostaglandins are modulators of ion and electrolyte balance in the kidney (22, 47) and in gills and opercular epithelium (48). In addition, prostaglandins operate synergistically with the hyperosmoregulatory hormone prolactin in the regulation of plasma Na^+ and Ca^{2+} concentrations (49). The studies of Van Praag *et al.* (48) suggest that prostaglandins may affect electrolyte balance at a number of sites including the Na^+/Cl^- co-transporter, the Na^+/K^+-ATPase, the apical chloride conductance, or the basolateral K^+ conductance. In the present study, a seawater challenge performed at 20 wk (6 wk before seawater transfer) showed that fish fed VO had lower concentrations of plasma Cl^- compared to those fed FO. However, when the fish were challenged at 26 wk, immediately after seawater transfer, the plasma Cl^- concentrations were similar for both dietary treatments. It appears that the ability to osmoregulate is related to prostaglandin production and the AA/EPA ratio in tissue PL, and that dietary manipulation can influence the smoltification process.

The present study has provided new information on the important changes in lipid metabolism which are involved in the highly complex physiological process of parr-smolt transformation. The results suggest that a diet utilizing vegetable oils, which more closely mimic the fatty acid composition of freshwater aquatic insects that make up the diet of wild salmon parr, could be more beneficial in effecting the smoltification process than the marine fish oils which are currently favored by the aquaculture industry.

Modifying the n-3 Fatty Acid Content of the Maternal Diet to Determine the Requirements of the Fetal and Suckling Rat

Philippe Guesnet*, Corinne Alasnier, Jean-Marc Alessandri, and Georges Durand

Institut National de la Recherche Agronomique (INRA), Laboratoire de Nutrition et Sécurité Alimentaire, CRJ, 78352 Jouy-en-Josas cédex, France

ABSTRACT: During perinatal development, docosahexaenoic acid (22:6n-3) accumulates extensively in membrane phospholipids of the nervous system. To evaluate the n-3 fatty acid requirements of fetal and suckling rats, we investigated the accumulation of 22:6n-3 in the brain and liver of pup rats from birth to day 14 postpartum when their dams received increasing amounts of dietary 18:3n-3 (from 5 to 800 mg/100 g diet) during the pregnancy–lactation period. The fatty acid composition of brain and liver phospholipids of pups, as well as that of dam's milk, was determined. At birth, brain 22:6n-3 increased regularly to reach the highest level when the maternal diet contained 800 mg 18:3n-3/100 g. On days 7 and 14 postpartum, brain 22:6n-3 plateaued at a maternal dietary supply of 200 mg/100 g. Docosapentaenoic acid (22:5n-6) had the opposite temporal pattern. The unusually high concentration of eicosapentaenoic acid (20:5n-3) in liver and dam's milk observed at the highest 18:3n-3 intake suggests an excessive dietary supply of this fatty acid. All these data suggest that the n-3 fatty acid requirements of the pregnant rat are around 400 mg 18:3n-3 and those of the lactating rat at 200 mg (i.e., 0.9 and 0.45% of dietary energy, respectively). The values for 18:3n-3 and 22:6n-3 milk content which allowed brain 22:6n-3 to reach a plateau value in suckling pups were 1% of total fatty acids and 0.9% (colostrum) to 0.2% (mature milk), respectively. These levels are similar to those recommended for infant formulas.

Lipids 32, 527–534 (1997).

Docosahexaenoic acid (DHA, 22:6n-3) is present at high concentrations in membrane phospholipids (PL) in the brain and retina, and is deposited primarily during the fetal and early postnatal periods in mammalian species (reviewed in Ref. 1). This suggests that 22:6n-3 plays an essential role in neuronal and visual development. To support this hypothesis, numerous studies have reported that n-3 fatty acid dietary deficiency during development causes functional disturbances in experimental animals, such as impaired learning behaviors and altered electroretinograms in rodents and nonhuman primates, and decreased visual acuity in nonhuman primates (2–4). These effects were related to a depletion of 22:6n-3 in the brain and retina PL (2,3,5). Recent observations of human infants fed a low n-3 fatty acid formula confirmed these relationships (6–8).

Accumulation of 22:6n-3 in the developing brain and retina depends on the dietary intake of n-3 fatty acids, both in the form of the precursor, α-linolenic acid (18:3n-3), and in its long-chain derivatives, eicosapentaenoic acid (20:5n-3) and 22:6n-3 (1). It also depends on the balance between linoleic (18:2n-6) and α-linolenic acids in the diet because of the competition between these two fatty acids for the pathway of desaturation–elongation (1). The precise determination of the nutritional requirements for n-3 fatty acids in humans could be drawn from animal models such as the developing piglet and rat. In comparison with the human species, the perinatal timing of brain growth spurt is very similar in the piglet but is delayed in the rat because the growth starts in the immediate postnatal period (1). The term gestation piglet model is the most suitable model for studying the specific requirements of formula-fed infants, whereas the rat model gives the possibility to easily and precisely assess the dose–effect relationship between the n-3 fatty acid supply of the dam's diet and the level of 22:6n-3 in the offspring (2,9,10). Moreover, the use of n-3-deficient female rats, at the beginning of the experimental design, avoids underestimating the requirements because there is no n-3 fatty acid store (11,12). Yet, the possible pitfall of this protocol can be that the results are affected by the short period of time (2 wk) between n-3 fatty acid refeeding and pregnancy. Previous studies have established that the minimal 18:3n-3 requirement of the developing rat is about 0.4% of dietary energy (i.e., 200 mg/100 g maternal food) with a 18:2n-6 to 18:3n-3 ratio of 6 (2,11). However, the fetal and neonatal requirements were confounded, and the level of n-3 fatty acids in the rat milk was not reported.

The aim of the present study was to determine the individual n-3 fatty acid requirements of the fetal and suckling rat, such as defined in a previous work by the minimal 18:3n-3 content in the maternal diet necessary to reach the plateau (or "optimal") level of 22:6n-3 in the pup brain and liver (2). The level of docosapentaenoic acid (22:5n-6) was also taken into

account because this fatty acid specifically replaces 22:6n-3 when the dietary n-3 fatty acid supply is insufficient (2,11,12). Data of 1-day-old-pups were used to estimate the 18:3n-3 requirement of the pregnant rat, and that of 3-, 7-, and 14-day-old pups of the lactating rat. The n-3 fatty acid concentration in the dam's milk was determined during the whole period of lactation to provide complementary data on the requirements of the suckling pup.

MATERIALS AND METHODS

Animals and diets. Fifty female Wistar rats from an n-3 fatty acid-deficient lineage (second generation) were reared as previously described (12). They were fed *ad libitum* a semisynthetic diet containing 5% (by weight) peanut oil which supplied about 1 g of 18:2n-6/100 g diet (2.25% of total dietary energy) but a very low 18:3n-3 content (5 mg/100 g diet)(deficient dietary group, Table 1). Two weeks before mating (8 wk of age), they were randomly divided into five dietary groups of $n = 10$ females per group. The first group continued receiving the low 18:3n-3 diet (group A), whereas the four others were fed 5% fat diets containing 100, 200, 400, or 800 mg 18:3n-3/100 g diet (0.22, 0.45, 0.90, or 1.80% total dietary energy, respectively), and designated as groups B, C, D, and E, respectively. The different 18:3n-3 contents were obtained by mixing peanut, rapeseed, or linseed oils as indicated in Table 1. All diets contained about 1 g 18:2n-6/100 g diet because this quantity is considered as the minimum n-6 fatty acid requirements for the brain and other organs in the developing rat (11). Their 18:2n-6 to 18:3n-3 ratios ranged from 1.3 to 10.1.

After parturition, dams were kept in individual plastic cages. In each dietary group, young pups from four different litters were sacrificed by decapitation on days 1, 3, 7, and 14 postpartum. Before sacrifice, all pups were separated from their mothers for 30 min. After a simple observation, pups which had an empty stomach were replaced with their mothers, then allowed to suckle 30 min and immediately sacrificed. With this experimental procedure, the percentage of each fatty acid of total lipids (TL) of the stomach content, and specifically that of medium-chain fatty acids, was similar to that of the milk triacylglycerols as described by Bitman *et al.* (13). The litters were systematically equalized to eight pups and body weights were recorded. The brain, liver, and stomach content (i.e., rat milk) of the pups were removed, weighed, pooled by litter (four pups on days 1 and 3 postpartum and two pups on day 7 postpartum), freeze-dried, and stored at −80°C until analysis.

Lipid analysis. TL of the brain, liver, and stomach content were extracted by the Folch *et al.* (14) procedure in the presence of 0.02% (wt/vol) butylhydroxytoluene. Brain and liver PL were separated using silicic acid cartridges (Supelco France, St. Germain en Laye, France) as described by Juaneda and Rocquelin (15), then transmethylated with 10% BF_3 in

[a]The experimental diets contained (g/kg diet): lipids, 50; casein, 220; DL-methionine, 1.6; cellulose, 20; starch, 438.4; saccharose, 220; vitamin mixture, 10; mineral mixture, 40 (caloric density: 3970 Kcal/kg or 16.61 MJ/kg). The vitamin mixture was a total vitamin supplement (United States Biochemical Corp., Cleveland, OH), and the mineral mixture was as follows (g/100 g): $CaHPO_4 \cdot 2H_2O$, 38.0; K_2HPO_4, 24.0; $CaCO_3$, 18.0; NaCl, 6.9; MgO, 2.0; $MgSO_4 \cdot 7H_20$, 9.0; $FeSO_4 \cdot 7H_2O$, 0.86; $ZnSO_4 \cdot H_2O$, 0.5; $MnSO_4 \cdot H_20$, 0.5; $CuSO_4 \cdot 5H_2O$, 0.1; NaF, 0.08; $CrK(SO_4)_2 \cdot 12H_2O$, 0.05; $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, 0.002; KI, 0.004; $CoCO_3$, 0.002; Na_2SeO_3, 0.002. Oils were a gift from Lesieur Alimentaire (Boulogne Billancourt, France).

methanol (Fluka, Socolab, Paris, France) (16). Milk TL were hydrolyzed by saponification, methylated in 10% BF_3 methanol, and fatty acid methyl esters (FAME) were extracted with hexane without any evaporation to avoid excessive loss of medium-chain FAME. FAME were analyzed by gas–liquid chromatography and identified as previously reported (17). The fatty acid composition was expressed as a percentage of total fatty acids (wt%).

Statistics. Results are mean ± SD for $n = 4$ values. Differences in the mean levels of fatty acids between the five dietary groups and the four stages of postnatal age were checked using a two-factor analysis of variance (ANOVA) (StatView SE+Graphics™; Abacus Concepts Inc., ASD Meylan, France). At each postnatal age, comparison between the dietary groups was done by one-way ANOVA. Means were compared by Scheffé's test, the level of significance being set at $P < 0.05$. Correlations between milk fatty acids were calculated by simple linear regression analysis.

RESULTS

Brain and liver fatty acid composition at birth. As shown in Table 2 for brain PL, the 18:3n-3 diet content modified only the percentages of n-6 and n-3 fatty acids. The percentages of 22:5n-3 and 22:6n-3 were slightly and considerably increased, respectively, from the dietary group receiving the lowest 18:3n-3 supply (group A) to that receiving the highest 18:3n-3 supply (group E), whereas that of 22:5n-6 had an inverse evolution. The 22:5n-6/22:6n-3 ratio, which is an index of n-3 fatty acid deficiency, was greater than 1 only in brain PL of deficient pups (group A). The percentages of 20:4n-6 and 20:5n-3 were unchanged. In order to obtain a more comprehensive view of the n-3 fatty acid requirements of the fetal rat, the variations of 22:6n-3 and 22:5n-6 contents both in brain and liver PL were reported (Fig. 1). The 22:6n-3 content in brain rose dramatically when the dietary 18:3n-3 was raised from 5 to 200 mg/100 g diet and then rose slowly to reach the highest value at 800 mg (11.1%, $P < 0.05$). No significant difference was noted, however, between dietary levels of 200 and 400 mg (8.7 vs. 9.2%). The 22:5n-6 content had an opposite evolution and reached the lowest value at 800 mg. In liver PL, the 22:6n-3 and 22:5n-6 contents were similarly affected by the quantity of 18:3n-3 in the maternal diet as described for the brain.

Milk fatty acid composition at birth. The percentages of saturated and monounsaturated fatty acids in milk TL at birth

[a]Values are means ± SD ($n = 4$). Means with different superscript (d–h) letters are significantly different ($P < 0.05$) by analysis of variance.
[b]SFA, saturated FA.
[c]MUFA, monounsaturated FA. The sum of minor FA (15:0, 17:0, 20:0, 22:0, 24:0, 20:3n-9, 24:1n-9, 24:4n-6, 24:5n-6, 18:3n-3, 18:4n-3) represents between 0.5 and 1% of total FA and is omitted in the table.

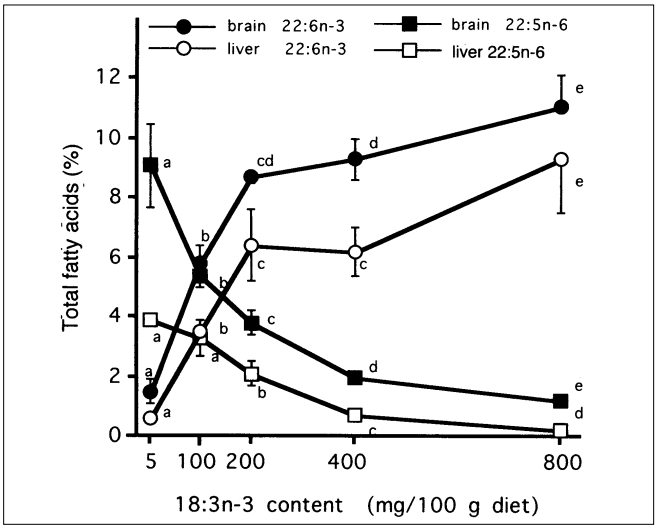

FIG. 1. Effect of the 18:3n-3 content of the maternal diet on the 22:6n-3 and 22:5n-6 contents in brain and liver phospholipids from one-day-old pups. Values are means ± SD ($n = 4$ in each dietary group). Means with different superscripts (a–e) indicate a significant effect of the 18:3n-3 dietary content ($P < 0.05$) by analysis of variance.

(colostrum) were not significantly modified by the 18:3n-3 content of the maternal diet, and accounted for 30–34% and 54–56% of total fatty acids, respectively (Table 3). Changes in n-3 fatty acid reflected the quantity of 18:3n-3 in the maternal diet. The 18:3n-3 content regularly increased from 0% (group A) to 2.4% at the highest dietary intake (group E), as for those of 18:4n-3 and 20:5n-3 (0 to 0.3% and 0 to 0.9%, respectively). For 22:5n-3 and 22:6n-3, a plateau level was reached when the maternal diet supplied 400 mg 18:3n-3/100 g diet (group D). Among n-6 fatty acids, the 22:5n-6 fell regularly to disappear in group E, whereas the 20:4n-6 and 22:4n-6 remained unchanged in the first four dietary groups (2.2–2.5 and 0.9–1.2%, respectively) and then significantly decreased in group E. The 18:2n-6 represented around 5–7% of total fatty acids, and the 18:2n-6/18:3n-3 ratio ranged from 18.3 (group B) to 3.0 (group E), and was systematically 1.7- to 2.4-fold higher than in dietary lipids.

The percentages of 18:3n-3 in colostrum TL, as well as those of n-3 long-chain derivatives (20:5n-3, 22:6n-3), were positively correlated with the dietary 18:3n-3 content ($P < 0.001$) (data not shown).

Long-chain n-3 and n-6 fatty acids in the brain and liver during postnatal development. Figures 2 and 3 illustrate postnatal changes in the percentage of C_{22} (22:6n-3, 22:5n-6) and C_{20} (20:5n-3, 20:4n-6) n-6 and n-3 fatty acids in brain and liver PL according to the dietary intake of 18:3n-3. The 22:6n-3 and 20:4n-6 significantly increased with postnatal age in both the tissues and all the dietary groups ($P < 0.001$), even in the deficient group for 22:6n-3. Conversely, the 20:5n-3 and 22:5n-6 decreased ($P < 0.001$ and $P < 0.04$, respectively), except in the deficient group for 22:5n-6 where it followed a postnatal evolution similar to that of 22:6n-3.

[a,b,c]See footnotes in Table 2. The percentages of the main SFA are: FA ≤ 14:0, 5–6%; 16:0, 22–24%; 18:0, 3%, respectively. Oleic acid (18:1n-9) represents 80% of total MUFA (44% of total fatty acids). The TL contents of colostrum are not significantly different between dietary groups by analysis of variance, and are (mg/g dry matter ± SD, $n = 4$): group A, 641 ± 26; group B, 681 ± 23; group C, 681 ± 45; group D, 689 ± 25; group E, 650 ± 44.
[d]Trace (<0.05% of total FA).
[e]ud, Undetermined.

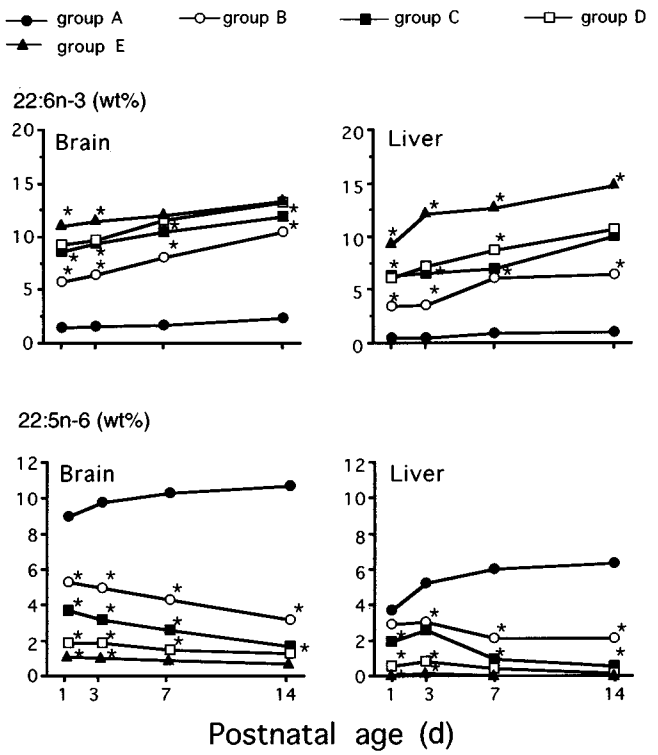

FIG. 2. Effect of the 18:3n-3 content of the maternal diet on the 22:6n-3 and 22:5n-6 contents in brain and liver phospholipids from pups during the first 2 wk of postnatal age. Values are means ± SD (n = 4 in each dietary group). * indicates a significant effect of the 18:3n-3 dietary content ($P < 0.05$) at each time point by analysis of variance, comparisons being as follows: group B vs. group A, group C vs. group B, group D vs. group C, and group E vs. group D. The P values obtained by the two-factor analysis of variance (18:3n-3 dietary content, postnatal age and 18:3n-3 dietary content × postnatal age) on the 22:6n-3 and 22:5n-6 contents in brain and liver are lower than 0.006, except for brain 22:6n-3 where $P = 0.28$ for the diet by postnatal age interaction, and for brain 22:5n-6 where $P = 0.53$ for the postnatal age effect and $P = 0.40$ for the diet by postnatal age interaction.

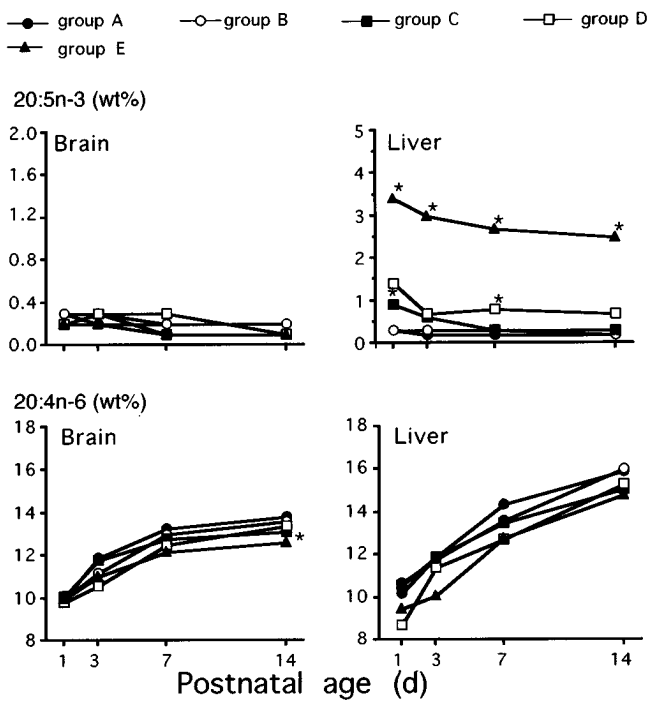

FIG. 3. Effect of the 18:3n-3 content of the maternal diet on the 20:5n-3 and 20:4n-6 contents in brain and liver phospholipids (PL) from pups during the first 2 wk of postnatal age. Values are means ± SD (n = 4 in each dietary group). * indicates a significant effect of the 18:3n-3 dietary content ($P < 0.05$) at each time point by analysis of variance, comparisons being as follows: group B vs. group A, group C vs. group B, group D vs. group C, and group E vs. group D. The P values obtained by the two-factor analysis of variance (18:3n-3 dietary content and postnatal age, 18:3n-3 dietary content × postnatal age) are lower than 0.03, except for brain 20:5n-3 where $P = 0.80$ for the diet by postnatal age interaction, and for 20:4n-6 where $P = 0.37$ for the 18:3n-3 by postnatal age interaction in brain and $P = 0.14$ for the diet effect in liver.

The 22:6n-3 reached the highest (plateau) value on days 7 and 14 postpartum (about 11 and 12.5% of total fatty acids, respectively) only in the brains of pups from dams fed 200 mg/100 g. When the maternal diet supplied at least 200 mg 18:3n-3/100 g, the 22:5n-6 reached the lowest value on days 7 and 14 postpartum, but unlike 22:6n-3, in both the brain and liver (a significant difference was only noted for the brain 22:6n-3 content between group C vs. groups D and E, $P < 0.05$). The percentages of 20:5n-3 and 20:4n-6 in both the tissues were not modified by the 18:3n-3 dietary content except for 20:5n-3 in liver where it rose from 0.2 to 2.5–3.5%.

Milk fatty acid composition during postnatal development. As illustrated in Figure 4, postnatal age-dependent changes in milk fatty acid percentages in all dietary groups were a significant increase in 18:3n-3 and decrease in n-6 and n-3 long-chain derivatives (20:4n-6, 22:5n-6, 20:5n-3, 22:6n-3) ($P < 0.001$). The 18:2n-6 peaked on postpartum day 3 and then returned to its initial level ($P < 0.001$).

No interaction of dietary 18:3n-3 was noted with 18:2n-6 except on day 1 postpartum (Table 3). By contrast, 18:3n-3 regularly increased with the 18:3n-3 dietary content at each time point ($P < 0.001$). In mature milk (Table 4), it represented between 0.5 and 1.2% of total fatty acids when the maternal diet supplied 100 to 400 mg 18:3n-3, and shot up to 3.5% at the highest dietary supply. A significant increase in each n-3 long-chain fatty acid and decrease in each n-6 long-chain fatty acid in interaction with the 18:3n-3 dietary content was noted ($P < 0.001$) (Fig. 4). In mature milk (day 7 postpartum), n-3 represented between 0.2% (group B) and 1.4% (group E) of total fatty acids (Table 4). The 22:6n-3 was the main component except at the highest 18:3n-3 dietary intake where 20:5n-3 represented 50% of long-chain n-3 fatty acids. With varying 18:3n-3 dietary content, postnatal changes in the 22:5n-6 content were inverse to those of 22:6n-3.

As noted in colostrum, the percentage of 18:3n-3 in milk was positively correlated with the dietary 18:3n-3 content ($P < 0.001$) at all times during lactation (data not shown).

FIG. 4. Effect of the 18:3n-3 content of the maternal diet on the n-3 and n-6 fatty acid composition of rat milk total lipids during the first 2 wk of postnatal age. Values are means ± SD ($n = 4$ in each dietary group). * indicates a significant effect of the 18:3n-3 dietary content ($P < 0.05$) at each time by analysis of variance, comparisons being as follows: group B vs. group A, group C vs. group B, group D vs. group C, and group E vs. group D. The P values obtained by the two-factor analysis of variance (18:3n-3 dietary content, postnatal age, 18:3n-3 dietary content × postnatal age) are lower than 0.005 for all fatty acids, except for 18:2n-6 and 20:4n-6 for the 18:3n-3 by age interaction ($P = 0.01$ and $P = 0.03$, respectively). The total lipid contents of rat milk are not significantly modified by the diet and the postnatal age, and are (mg/g dry matter ± SD, $n = 20$): day 1 postpartum, 661 ± 51; day 3 postpartum, 609 ± 32; day 7 postpartum, 618 ± 43; day 14 postpartum, 618 ± 37.

DISCUSSION

Bourre *et al.* (2) concluded that the n-3 fatty acid requirement of the female rat during the entire period of pregnancy–lactation was 200 mg 18:3n-3 per 100 g of maternal food (0.4% of total dietary energy). Indeed they found that the 22:6n-3 content in brain, retina, and synaptosome TL of 21-day-old rats plateaued at this dietary content. The aim of our work was to determine separately the fetal and suckling rat requirements with a larger range of dietary 18:3n-3 content. At birth, we observed that the 22:6n-3 content in pup brain PL increased rapidly up to 200 mg 18:3n-3. Beyond this value, it continued to rise but slowly without reaching a plateau as initially reported in the weaned rat (2). This may reflect a difference of regulation in the DHA synthesis and incorporation into brain PL between the fetal period and the postnatal period. In liver PL, the 22:6n-3 evolution was very similar to that of the brain PL, in agreement with the results of Bourre *et al.* (2). Docosapentaenoic acid (22:5n-6) specifically replaces 22:6n-3 when dietary n-3 fatty acid supply is suboptimal or low (2,11,12). Thus, by analogy with 22:6n-3, the optimal (lowest) value of 22:5n-6 in the brain or liver would be attained when the minimal n-3 fatty acid requirements are covered. As this optimal value of 22:5n-6 was also reached at 800 mg 18:3n-3, we can conclude that the 18:3n-3 requirements of the fetal rat would be at least 800 mg 18:3n-3/100 g of maternal diet. This dietary content appears somewhat excessive because many n-3 long-chain fatty acid intermediates (20:5n-3, 22:5n-3) were incorporated in liver PL and colostrum TL. Moreover, it reduced the level of 20:4n-6 in colostrum TL because of the competition between n-3 and n-6 fatty acids, as suggested by Holmann (18). As 22:6n-3 plateaued at 400 mg 18:3n-3 in colostrum, the accumulation of 20:5n-3 suggests a limited maternal conversion of 20:5n-3 to 22:6n-3 due to an excessive dietary supply of 18:3n-3. A similar high concentration of 20:5n-3 was found in milk from pastoral Chinese women consuming high levels of 18:3n-3 but no seafood (19). Taking into account the 22:6n-3, 20:5n-3, and 22:5n-6 proportions in the pup brain, liver, and maternal milk at birth, we can conclude that the minimal n-3 fatty acid requirement of the female rat during pregnancy is close to 400 mg 18:3n-3/100 g of diet (i.e., 0.9% of total dietary energy, 18:2n-6/18:3n-3 = 3), and that 800 mg has to be considered as an excessive dietary supply.

During the first 2 wk of postnatal life, the 22:6n-3 concentration in brain PL of pups increased regularly and, according to the maternal diet content of 18:3n-3, reached the optimal (plateau) value at 200 mg 18:3n-3/100 g from day 7 postpartum. Conversely, the 22:5n-6 concentration decreased and was the lowest at 200 mg 18:3n-3. These results suggest that the minimal n-3 fatty acid requirement of the suckling rat is 200 mg 18:3n-3/100 g maternal diet (i.e., 0.45% of the dietary energy). The high concentrations of 20:5n-3 in liver PL (>2.5% of total fatty acids) and milk TL (>0.5%) at 800 mg for all the studied periods confirm that this dietary content is excessive. However, the metabolism of n-6 fatty acids was not altered because the accretion of 20:3n-6 and 20:4n-6 in liver and brain remained unchanged, contrary to what happens when lactating mothers consume high levels of 20:5n-3 and 22:6n-3 in the form of fish oil (20). The use of 22:5n-6 in the determination of the n-3 fatty acid requirement is questionable because it seems that this fatty acid is a normal component of brain PL. Taking into account the fivefold lipid increase in the brain during the first 2 wk of postnatal life (240 mg at birth vs. 1.150 mg on day 14 postpartum), the total amount of 22:5n-6 in this organ was increased twofold at the highest 18:3n-3 dietary contents.

TABLE 4
FA Composition of Total Lipids (TL) of Rat Mature Milk (day 7 postpartum) in Relation to the α-Linolenic Content of the Maternal Diet[a]

FA	Dietary group (% total FA)

The studies exploring the effects of dietary fatty acids on the membrane composition of the nervous system in the developing rat have investigated the dam's milk composition only on day 14 postpartum (20–23). They give an incomplete view of the quantity of n-3 fatty acids ingested by the suckling pup because 22:6n-3 decreases during the maturation of milk (17,24). The changes in the fatty acid composition of dam's milk were detailed in our study to provide the maximum of data regarding the specific n-3 fatty acid requirements of the suckling rat when the maternal diet contains 200 mg 18:3n-3/100 g. From our data, we estimated the n-3 requirements to be about 0.8–1% of milk total fatty acids for 18:3n-3 and 0.9% (colostrum) to 0.2% (mature milk) for 22:6n-3. On the basis of the weight of milk lipids (mg/g dry matter) found in this study and of the lipid energy concentration of rat milk (25), this corresponds to about 0.5% and 0.1–0.4% of the total dietary energy, respectively. The 18:2n-6/18:3n-3 ratio was close to 9, and systematically 1.7 to 2.4 times higher than in maternal dietary lipids. This higher relative level of 18:2n-6 or lower level of 18:3n-3 in milk has been reported in other studies (20,21). It may result from preferential enrichment in plasma lipids and/or a selective uptake by the mammary gland.

In conclusion, the results of the present study show that pregnant female rats require twice as much dietary 18:3n-3 as lactating rats to satisfy the n-3 requirements of the fetus and suckling pup, respectively. It can also be considered that these increased requirements for dietary 18:3n-3 during pregnancy reflect a specific demand due to their recent n-3 deficient status (i.e., 2 wk before mating). Taking into account the differences in daily dietary intake between these two physiological periods (15 g/d vs. 38 g/d for pregnancy and lactation, respectively) (12), the 18:3n-3 requirements of lactating female rats were 25% higher than those of pregnant female rats (i.e., 75 mg/d vs. 60 mg/d). The n-3 fatty acid contents (18:3n-3 and 22:6n-3) in rat milk which satisfy the requirements of the suckling pup are comparable to those recommended for infant formulas (26,27). The 22:6n-3 content in the rat milk was directly related to the level of 18:3n-3 in the maternal diet, whereas this relation was not observed in human milk (17,24,28). This probably results from dietary habits (presence of 22:6n-3 in the human diet) rather than from species differences. Our data support the use of the suckling rat model to approach the infant fatty acid requirements, but the nutrition of pregnant and lactating rats, the perinatal timing of pup brain growth, and milk fat content and composition are not closely analogous to the human species. In the same way, recent data obtained from the artificially reared rat pup model argued that the rat model is relevant to the design of infant formulas (29), and demonstrated that high dietary intake of 18:3n-3 was unable to achieve adequate neural 22:6n-3 accretion. Future work on the relationship between changes in 22:6n-3 content and function in brain should help to specify the n-3 fatty acid requirements.

Lipid Peroxidation During n-3 Fatty Acid and Vitamin E Supplementation in Humans

Johane P. Allard*, Regina Kurian, Elaheh Aghdassi, Reto Muggli[1], and Dawna Royall

Department of Medicine, University of Toronto, Toronto, Ontario, M5G 2C4, Canada

ABSTRACT: The purpose of this study was to investigate in healthy humans the effect of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) intake, alone or in combination with dL-α-tocopherol acetate (vitamin E) supplements on lipid peroxidation. Eighty men were randomly assigned in a double-blind fashion to take daily for 6 wk either menhaden oil (6.26 g, n-3 fatty acids) or olive oil supplements with either vitamin E (900 IU) or its placebo. Antioxidant vitamins, phospholipid composition, malondialdehyde (MDA), and lipid peroxides were measured in the plasma at baseline and week 6. At the same time, breath alkane output was measured. Plasma α-tocopherol concentration increased in those receiving vitamin E ($P < 0.0001$). In those supplemented with n-3 fatty acids, EPA and DHA increased in plasma phospholipids ($P < 0.0001$) and plasma MDA and lipid peroxides increased ($P < 0.001$ and $P < 0.05$, respectively). Breath alkane output did not change significantly and vitamin E intake did not prevent the increase in lipid peroxidation during menhaden oil supplementation. The results demonstrate that supplementing the diet with n-3 fatty acids resulted in an increase in lipid peroxidation, as measured by plasma MDA release and lipid peroxide products, which was not suppressed by vitamin E supplementation.

Lipids 32, 535–541 (1997).

Fish oils, the most common of which are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have been shown in humans to lower plasma triglycerides (1), to be vasodilatory, to prolong bleeding time (2), and to decrease fibrinogen concentrations (3): all recognized as risk factors for the development of cardiovascular disease. Experimental studies have indicated that the most likely mechanism for the biochemical effects of fish oil relates to the competitive interaction between arachidonic acid (AA) and EPA for incorporation into cellular phospholipids and their further metabolism to eicosanoid products (4).

Fish oils are also highly unsaturated and readily susceptible to peroxidation (5). Peroxidation will give rise to lipid peroxides including malondialdehyde (MDA) and aldehyde breakdown products which have been implicated in the etiology of a number of diseases in humans including cardiovascular disease (6). Vitamin E, because of its antioxidant properties, may reduce the peroxidative damage caused by fish oils and thereby promote its beneficial effects. Fish oil supplements usually contain a small amount of vitamin E as an antioxidant (1 IU), but whether this is sufficient to achieve any beneficial effect is questionable (7).

The purpose of this study was to investigate in humans, in a randomized, double-blind, placebo-controlled fashion, the effect of n-3 fatty acid supplementation, alone or in combination with dL-α-tocopherol acetate (vitamin E), on different lipid peroxidation indices.

MATERIALS AND METHODS

Subjects and protocol. Eighty healthy men (20–60 yr) were recruited, primarily hospital staff and local area workers (social middle class). Informed consent was obtained, and the study protocol was approved by the Toronto Hospital Committee for Research on Human Subjects. Subjects were screened and excluded if they were smokers, had a medical condition (i.e., cancer, heart disease, hypertension, hyperlipidemia, diabetes, obesity, kidney/liver dysfunction, gastrointestinal abnormality, HIV+), had a high alcohol consumption (>30 g/d), or if any vitamin or medications had been taken in the past 4 wk.

The volunteers were also interviewed by a dietitian to ensure that they consumed a diet similar to a typical North American diet (30–40% of energy from fat and providing a polyunsaturated-to-saturated-fatty-acid (PUFA/SFA) ratio of 0.3:1. They were further instructed to avoid all types of fish (i.e., canned, frozen, fresh including shellfish) for the duration of the study and to avoid strenuous exercise.

The subjects returned 2 wk later and were randomized (using random number tables) in a double-blind fashion to supplement their usual diet for 6 wk with either menhaden oil

[1]Present address: F. Hoffmann-La Roche Ltd., Basel, Switzerland.

Abbreviations: AA, Arachidonic acid; BHT, butylated hydroxytoluene; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; LA, linoleic acid; LDL, low density lipoprotein; MDA, malondialdehyde; OA, oleic acid; PUFA, polyunsaturated fatty acid; Se-GSHPx, selenium-dependent glutathione peroxidase; TBA, thiobarbituric acid; TBHQ, *tert*-butylhydroquinone.

ethyl esters with *tert*-butylhydroquinone (TBHQ: 0.017%) (8 caps/d = EPA 3.062 g, DHA 2.262 g, total n-3: 6.26 g) (National Marine Fisheries Service, Charleston, SC) or olive oil ethyl esters with TBHQ (0.01%) and fish flavoring (8 caps/d = 6.08 g monoenes) with dL-α-tocopheryl acetate (vitamin E; Hoffmann-La Roche Ltd., Basel, Switzerland) (3 caps/d = 900 IU) or its placebo. Subjects were therefore randomized into one of four supplemented groups: menhaden oil + vitamin E; menhaden oil + vitamin E placebo; olive oil + vitamin E; olive oil + vitamin E placebo.

Breath collections and biochemical measurements were performed in the morning, in the fasted state, at baseline (week 0) and at week 6 of supplementation. Blood was collected in tubes containing lithium heparinate for phospholipids; 0.1% EDTA for tocopherols, β-carotene, ascorbic acid, MDA release, and lipid peroxides; additive-free tubes for cholesterol and triglycerides; and trace element-free for selenium-dependent glutathione peroxidase (Se-GSHPx). Samples were centrifuged promptly at 3000 rpm for 10 min. The plasma was removed, aliquoted separately for each assay, and frozen (−70°C) until analysis. For phospholipid analysis, plasma was stored in chloroform containing 0.02% butylated hydroxytoluene (BHT) as an antioxidant, in an oxygen-free environment at −70°C. Plasma for the vitamin C assay was stabilized immediately with 50 g/L metaphosphoric acid (HPO_3) (0.5 mL plasma plus 4.5 mL HPO_3).

Fatty acid analysis. Total lipids were extracted with chloroform/methanol (2:1, vol/vol), containing BHT as an antioxidant (8) and dried under nitrogen gas. The residue then dissolved in 0.1 mL chloroform and applied to silica gel thin-layer plates (Whatman Silica Gel60A K6F, 20 × 20 cm; Interscience Biotechnology, Markham, Ontario, Canada) to separate the phospholipids using a nonpolar solvent system (hexane/diethyl ether/acetic acid; 80:20:1). Phospholipid bands were scraped and transmethylated with boron trifluoride–methanol at 90°C for 30 min. Fatty acid methyl esters were separated on a fused-silica capillary column coated with a 25 μm cyanopropylphenyl film (Durabond 23, 30 m × 0.25 mm i.d.; J&W Scientific, Folsom, CA) in a Hewlett-Packard (HP) 5890A gas–liquid chromatograph (Palo Alto, CA) equipped with a flame-ionization detector (9).

Vitamin analyses. Tocopherols and β-carotene were analyzed using reverse-phase high-performance liquid chromatography (HPLC) and fluorescence spectrophotometry according to the method of Hess *et al.* (10). In this method, the samples are deproteinized by adding 500 μL of ethanol. The samples are then extracted by *n*-hexane and evaporated to dryness at ambient temperature under reduced pressure. The residue is dissolved in 100 μL ethanol/dioxane (1:1) and then 150 μL of acetonitrile is added. The sample extract (100 μL) is then injected into a reverse-phase HPLC. Ascorbic acid was analyzed fluorimetrically by the method of Brubacher Vuilleumier (11). The vitamin concentrations were measured in coded samples by the vitamin research laboratories of F. Hoffmann-La Roche Ltd. (Basel, Switzerland).

Breath analysis. Breath samples were collected and analyzed for ethane and pentane as described previously (12). Briefly, subjects are first required to breathe hydrocarbon-free air for 4 min to wash contaminating hydrocarbons from their lungs. Subsequently, expired air is collected for 2 min and analyzed by gas chromatography (Shimadzu 6-AM GC; Shimadzu Seisgkusho Ltd., Kyoto, Japan) using a Porasil D column (Chromatographic Specialties Inc., Brockville, Canada).

Plasma lipid peroxide analysis. MDA determination was measured by the thiobarbituric acid (TBA) method described by Draper *et al*. (13). Plasma proteins were denatured using 10% trichloroacetic acid solution and adding 0.05% BHT solution prior to digestion on a heating block. After centrifugation, the supernatant was combined with the TBA solution (1:1, vol/vol ratio) and heated. The reaction mixture was then extracted with 1 mL of *n*-butanol. An aliquot of the extract was mixed (2:1:1) with methanol and a mobile phase (15% acetonitrile and 0.6% tetrahydrofuran in 5 mM phosphate buffer) and 20 μL was injected onto a reverse-phase C_{18} μBondpak HPLC column. The standard solution used was 1,1,3,3-tetraethoxy propane (Sigma Chemical Co., St. Louis, MO).

Plasma lipid hydroperoxides were quantitated by calorimetry at 675 nm, measuring the methylene blue formation. Commercial kits (Kamiya Biochemicals Determiner LPO kit, Thousand Oaks, CA) were used.

Se-GSHPx enzyme activity was measured by the coupled enzyme assay (14,15). Changes in absorbance at 340 nm were recorded for 5 min on a spectrophotometer (U 2000 Hitachi Ltd., Tokyo, Japan). Se-GSHPx activity was expressed as μmoles NADPH oxidized $min^{-1} \cdot$ mg $protein^{-1}$ which was measured by the biuret method (16).

Supplement lipid peroxide analysis. A sample of menhaden and olive oil supplements also underwent peroxide analysis at 0 and 18 mon of storage to establish a peroxide value. A microtitrimetric method was used to determine all substances which oxidize potassium oxide in terms of milliequivalents of peroxide per 100 g of sample (17). This analysis was performed by the research laboratories of the National Marine Fisheries Service (Charleston, SC).

Plasma lipid analysis. Serum cholesterol, high density lipoprotein (HDL)-cholesterol, and triglyceride were analyzed using a commercially available kit (Boehringer Mannheim, Montreal, Canada). Low density lipoprotein (LDL)-cholesterol was calculated (cholesterol − (HDL-cholesterol + 0.46 × triglyceride).

Statistical analyses. It was estimated that 20 subjects were required in each group, assuming a dropout rate of 15%, to achieve 80% power using a 5% significance level for detecting at least a 10% difference in lipid peroxidation measured by breath ethane output between groups. All group data are expressed as means ± SEM. The study was a factorial design with the two factors being fish oil and vitamin E. The interaction between fish oil and vitamin E was hypothesized prior to the start of the study such that fish oil would be expected to have an effect on lipid peroxidation, which would not be evident with vitamin E. The comparison of pretreatment and

posttreatment tests was undertaken by an analysis of covariance on the change between baseline (week 0) and week 6 with an adjustment for the week 0 value (18). SAS (19) was used for these analyses.

RESULTS

Of the 80 subjects enrolled, 5 voluntarily withdrew from the trial due to noncompliance and another 3 withdrew because of unpleasant side effects of the therapy. These 3 subjects, all receiving n-3 fatty acid supplements, complained of fishy taste, belching, bloating, heartburn, and nausea. No other significant side effects were reported. Compliance, assessed by plasma α-tocopherol and fatty acids, was very good (Tables 1,2).

Plasma fatty acids and lipids. The fatty acids EPA, DHA, AA, linoleic acid (LA), and oleic acid (OA), expressed as percentage composition of phospholipids, were similar between groups at baseline (Table 2). Phospholipid content of DHA and EPA ($P < 0.001$) increased, and AA and LA composition decreased significantly and to the same extent ($P < 0.025$) in both groups of subjects receiving n-3 fatty acid supplementation. OA increased significantly ($P < 0.025$) and to the same extent in both groups receiving olive oil supplementation.

Serum total triglycerides and cholesterol (HDL-, LDL-cholesterol) showed no significant change (data not shown).

Plasma vitamin concentrations. Plasma α-tocopherol concentrations were comparable between groups at baseline (Table 1). The increase in α-tocopherol in the two vitamin E-supplemented groups ($P < 0.0001$) was significant compared to the two vitamin E placebo groups. Plasma ascorbic acid and β-carotene did not change in any groups during supplementation (Table 1), suggesting that there were no dietary changes during the study.

Lipid peroxidation products in menhaden and olive oil supplements. The peroxide value was 3.27 meq/kg for the menhaden oil supplements and 2.3 meq/kg for the olive oil supplements. An 18-mon storage stability study performed by the manufacturer of the supplements showed no effect of time stored at 5°C on the peroxide value.

Lipid peroxidation measurements in subjects. Breath ethane output was comparable between groups at baseline (Table 3). Supplementation of n-3 fatty acids either with or without vitamin E did not produce any significant changes in breath ethane output. The mean difference in the change of breath ethane output during menhaden oil supplementation between those subjects receiving vitamin E and those not receiving vitamin E supplementation was -1.0 pmol $\cdot$ kg^{-1} $\cdot$ min^{-1} (95% confidence interval, −7.2, 5.2). Breath pentane output did not differ significantly between groups at baseline, and neither n-3 fatty acid nor vitamin E supplementation produced a significant change from initial levels.

Baseline measurements of plasma MDA equivalents, lipid peroxides, and Se-GSHPx were not significantly different between groups (Table 3). In the two groups supplemented with n-3 fatty acids, plasma MDA generation ($P < 0.001$) and lipid peroxides ($P < 0.05$) were significantly increased at 6 wk. Vitamin E intake added to menhaden oil supplements had no effect on MDA or lipid peroxide values. Olive oil supplemented with vitamin E or placebo produced no change in MDA or lipid peroxide levels. Neither n-3 fatty acids nor vitamin E supplementation produced any change in Se-GSHPx activity.

DISCUSSION

The results of this randomized, double-blind, placebo-controlled study showed that n-3 fatty acid supplementation increased lipid peroxidation based on plasma lipid peroxides and MDA. Menhaden oil intake had no effect on breath alkane output. High doses of vitamin E did not provide adequate antioxidant protection as the lipid peroxidation products remained elevated.

The choice of dosage (6 g of n-3 fatty acids daily) used in this trial was based on studies investigating the effect of fish oil suppplementation on cardiovascular risk factors and lipid peroxidation parameters (20–23). A dose-response curve study (20) showed that in healthy humans 6 g of n-3 fatty acids had a beneficial effect on plasma phospholipid composition and triglyceride levels. However, 6 g had no effect on functional parameters such as blood pressure, bleeding time, erythrocyte deformability, or neutrophil function. For this reason, we did not measure functional parameters in addition to lipid peroxidation. Since our study's main endpoint was lipid peroxidation, 6 g a day of n-3 fatty acids was chosen on the basis of previous reports showing an increase in lipid peroxidation (22,23).

The amount of vitamin E supplementation used was also based on previous literature. Despite 400 IU of vitamin E, some investigators have found that 2.0 g EPA and 1.3 g DHA daily can increase plasma lipid peroxides and MDA (24,25). Our own studies in smokers, an oxidatively stressed population, demonstrated that vitamin E, 800 IU per day, had a significant effect in reducing lipid peroxidation (26). Thus a dose in similar range should have had an effect on lipid peroxidation during n-3 fatty acids supplementation. Data from the literature also indicate that for each gram of linoleic acid in the diet, a minimum additional requirement of 0.5 mg of α-tocopherol is desirable (27) to prevent lipid peroxidation. Based on Muggli's equation (27), 2.24 and 2.68 mg of supplementary dL-α tocopherol is needed for each gram of dietary EPA and DHA, respectively. Thus, the amount of α-tocopherol supplementation in our study should have been between 10 and 15 IU per day, a far lower dose than what we used.

The increase in plasma MDA and lipid peroxide levels observed during fish oil supplementation suggests that the antioxidant level, whether in the plasma or in the capsules, was not sufficient to protect against free radical generation. Ingestion of lipid peroxide products from the capsules would explain the persistent elevation in these lipid peroxidation indices despite vitamin E supplementation. This could also explain the lack of induction of Se-GSHPx enzyme activity since lipid peroxidation would have occurred *ex vivo*. However, in the menhaden and olive oil supplements, the peroxide value measuring the oxidation was within acceptable limits and was comparable between the two. To prevent oxidative deterioration of n-3 fatty acids, the American Institute of Nutrition recommends the addition of a synthetic antioxidant at a level of 0.02% (by weight of oil) to experimental diet containing polyunsaturated fatty acids (PUFA) (28) which was the amount of TBHQ added to our supplements. How-

ever, a recent study by Gonzalez *et al*. (29) suggested that this may not be sufficient to totally prevent oxidative deterioration, at least in animal diets high in fish oil. In that study, the addition of even 100 times this level (2% TBHQ), although decreasing the level of oxidation products, failed to totally prevent lipid peroxidation. These experiments were performed with purified animal diets and may not be applicable to the supplements used in our study. However, although the peroxide values measured in our supplements did not increase when tested, storage condition may not have been optimal once the supplements were given to the subjects. This could have induced lipid peroxidation within the supplements. Whether ingestion of lipid peroxidation products could have significantly increased plasma levels in humans is, however, not clear. Animal studies (29) have shown a significant increase in thiobarbituric acid reactive substances (TBARS) concentrations of different organs and whole body when mice were fed fish oil diet without antioxidants. The addition of high levels of antioxidants to the diet actually reduced these levels.

The increase in plasma MDA and lipid peroxides due to n-3 fatty acid supplementation with or without vitamin E intake was reported in small studies. Some reported that high intakes of fish oil concentrate led to increased TBARS irrespective of the vitamin E intake (24) while others reported a decrease in TBARS after fish oil supplementation with additional vitamin E (25). Both studies compared end point values to baseline and were not randomized. Another study (7) investigated the effect of long-term fish oil supplementation in women. There was a significant increase in plasma lipid peroxides while plasma vitamin E concentrations did not change. Similar results for plasma vitamin E levels were found in males (30). A double-blind, crossover study (31), conducted in 12 healthy volunteers, showed a decrease in plasma vitamin E and an increase in MDA with fish oil supplemented with 0.3 IU/g of vitamin E while levels of both plasma vitamin E and MDA remained normal with 1.5 IU/g. Peroxide values of both oils remain similar during storage, suggesting that lipid peroxidation occurred *in vivo*. Other studies in animals showed an increase in lipid peroxidation along with a reduction in antioxidant defense systems (32–35). Possible effects from lipid peroxidation products within the food cannot be completely ruled out (29,36).

No change in breath ethane output was detected in this study. Breath ethane output has received less attention in human studies as a measure of lipid peroxidation, likely because pentane represents the majority of PUFA (n-6) in the body (37). However, breath ethane output is a well-recognized index of lipid peroxidation (38–40) and has been reported to be elevated in smokers (41) and children with liver disease (42). But to our knowledge, other then the present report, there are no human studies published on dietary intake of PUFA and breath alkane output. On the other hand, in animals, increased production of ethane was demonstrated with high intake of n-3 fatty acids from cod liver oil (43). In our study with humans, this effect could not be demonstrated with menhaden oil supplementation. More extreme changes in n-3 vs. n-6 fatty acid intake may have been necessary in order to detect a change in ethane output. We attempted to control for

other factors known to influence breath alkane output such as the PUFA/saturated fatty acid ratio of the diet (39), exercise levels (44), and alcohol consumption (45,46) in order to reduce the inter- and intrasubject variability. However, unlike animal studies (43) done in a laboratory environment, this study was not performed in a clinical investigation unit, and thus strict control of these variables was not possible.

Vitamin C and β-carotene were measured in the plasma to ensure that concentrations remained stable throughout the study. Since these vitamins have an antioxidant effect, changes occurring because of sudden increase in intake could have influenced our results.

In conclusion, this study has shown that supplementing the diet with 6 g of n-3 fatty acids daily resulted in increased lipid peroxidation as measured by plasma MDA equivalents and lipid peroxides. However, breath ethane output did not increase and, in humans, may not be a method sensitive enough to measure lipid peroxidation due to changes in PUFA intake. Vitamin E supplementation (900 IU/d) did not protect against lipid peroxidation during n-3 fatty acid supplementation. The possibility of increased lipid peroxide products within the capsules, while stored by the subjects, could not be excluded.

ABSTRACT: We developed a water-in-oil-in-water (W/O/W)-type multiple emulsion of a new tacrolimus formulation. A potential approach to avoid the complications of systemic immunosuppression and simultaneously enhance immunosuppressive efficacy is to deliver immunosuppressive agents locally to the site of the target organs. The W/O/W emulsion is dispersed oil drops containing smaller water droplets that allow the delivery of drugs preferentially to the reticuloendothelial system (RES). Since the liver and the spleen are primary components of the RES, and the brain and the kidney have a poor RES, we hypothesized that a W/O/W emulsion of tacrolimus would possess the pharmacokinetic benefits of local immunosuppression. We evaluated this hypothesis in a rat model. The tacrolimus levels of whole blood, the liver, spleen, brain, and kidney in rats given intravenous emulsions of tacrolimus (W/O/W group) were compared with a group administered tacrolimus alone (T group). There were no significant differences between the pharmacokinetic parameters of W/O/W group and T group based on whole blood data. However, the W/O/W group had significantly decreased tacrolimus levels in the brain and kidney, and significantly increased levels in the liver and spleen compared with the T group. These data suggest that the W/O/W emulsion is applicable as an intravenous drug carrier for local immunosuppression.
Lipids 32, 543–548 (1997).

Tacrolimus, a macrolide with a mechanism of action similar to that of cyclosporine (1), has been widely studied in clinical trials and was approved for use in patients undergoing liver transplantation in April 1994. Tacrolimus is a very powerful immunosuppressive drug which has increased graft and patient survival in organ transplantation (2). However, primarily nephrotoxic and neurotoxic effects are three times more frequent in tacrolimus-treated patients than in cyclosporin-treated patients, restricting the permissible dosage of tacrolimus (3). A potential approach to reduce the adverse effects of systemic immunosuppression and simultaneously enhance the immunosuppressive efficacy is to deliver the immunosuppressants locally to the site of the target organs.

We developed a new formulation of tacrolimus by taking advantage of its suspension in a water-in-oil-in-water (W/O/W)-type multiple emulsion. This is a system of dispersed oil drops containing even smaller water droplets in which the tacrolimus is dissolved. Investigators in the pharmaceutical field have been particularly interested in the development of slow-release drug delivery systems (4,5) and in selectively transferring drugs into the lymphatic system using W/O/W emulsions (6). Although the W/O/W-type multiple emulsion was first reported by Herbert (7) in 1965, W/O/W emulsions have never been used intravenously because of the toxicity of oils and surfactants. Our W/O/W emulsion was prepared by a method different from that in Herbert's original report (7).

Local immunosuppression methods have been shown to achieve the goals of preventing rejection in rodent and canine models with reduced systemic drug exposure and toxicity (8). Drug targeting systems such as drug-impregnated polymer rods, (9) controlled-release matrices, (10) and liposomes (11) have been used to direct immunosuppressive agents to the transplanted target organs in rodent and canine models. Liposomal incorporation is a useful method for increasing the immunosuppressive efficacy of immunosuppressants in liver transplantation models (11,12).

We suspected that a W/O/W-type multiple emulsion of tacrolimus was unlikely to be distributed in the kidney and brain, with their poor reticuloendothelial system (RES), and was more likely to be distributed in the liver and spleen, with their rich RES. To reduce the adverse effects of tacrolimus without diminishing its immunosuppressive effects, we developed a W/O/W-type multiple emulsion which incorporated tacrolimus.

In the present study, a W/O/W-type multiple emulsion based in soybean oil was used as a model for the delivery of tacrolimus. The pharmacokinetic benefits and potential usefulness of the emulsion as a carrier were evaluated.

MATERIALS AND METHODS

Materials. Tacrolimus and soybean oil were purchased from Fujisawa Pharmaceutical Company Ltd. (Osaka, Japan) and

Abbreviations: AUC, area under the concentration time curve; β, apparent elimination rate constant; β-phase apparent volume of the distribution; CL_{tot}, total clearance; C_p, whole blood tacrolimus concentration; GE, glycerol fatty acid ester; RES, reticuloendothelial system; TEM, transmission electron microscope; $t_{1/2\beta}$, biological half-life of the elimination phase; V_c, apparent volume of the central compartment; $V_{d(\beta)}$, W/O/W, water-in-oil-in-water.

Wako Pure Chemical Ltd. (Osaka, Japan), respectively. Glycerol fatty acid ester (GE; Sunsoft No.818 NSM, Taiyo Chemical Co., Yokkaichi, Japan), lecithin from egg (Wako), and Pluronic F68 (Green Cross Pharmaceutical Co., Osaka, Japan) were used as surface agents. GE and lecithin are used as food additives, and Pluronic F68 has been approved as the stabilizer of red blood cell membrane.

Preparation of emulsion. This study used tacrolimus solution (10 mg/1 mL) containing an appropriate amount of ethanol and 400 mg castor oil derivative (HCO-60) for intravenous administration of tacrolimus. Tacrolimus solution (10 mg/1 mL) was diluted with 9 mL isotonic sodium chloride solution. To prepare the water-in-oil emulsion, 10 mg/10 mL tacrolimus solution was simply combined with a mixture of soybean oil, lecithin, and GE (tacrolimus solution/soybean oil/lecithin/GE, 10:18:1:1, mL/mL/g/mL) and stirred for about 15 min in an ice bath using an ultrasonic homogenizer (V-Level 200 μA; Nippon Seiki Co., Tokyo, Japan). The water-in-oil emulsion (30 mL) was dispersed in 70 mL of isotonic sodium chloride solution containing 3.0% (wt/vol) Pluronic F68, and then stirred with an ultrasonic homogenizer (V-Level 200 μA) for 10 min. W/O/W emulsions were microscopically checked by microphotography and transmission electron microscope (TEM). The diameter of the W/O/W emulsion was measured by a Shimazu Laser Diffraction Particle Size Analyzer, SALD-2001 (Kyoto, Japan). To determine the entrapping efficiency of tacrolimus in the internal aqueous phase of W/O/W emulsion, 3.0 mL of 6.0% (wt/vol) hydroxy ethylstarch (Kyourin Pharmaceutical Co., Tokyo, Japan) was added to 1.0 mL of the aqueous phase of the W/O/W emulsion which was separated by centrifugation (at 5°C, 4500 × *g*, 10 min). After centrifugation (at 5°C, 4500 × *g*, 10 min), the tacrolimus concentration in the separated external water was assayed by the enzyme immunoassay of Tamura *et al.* (13). The entrapping efficiency was calculated by the equation:

$$\text{entrapping efficiency (\%)} = 100 \cdot (A - 4 \cdot C_{ext} \cdot V_{ext})/A \qquad [1]$$

where A represents the values for total amount of tacrolimus in the W/O/W emulsion, C_{ext} represents the values for tacrolimus concentration in the separated external water of W/O/W emulsion, and V_{ext} represents the volume of the external aqueous phase of W/O/W emulsion.

Animals. All animals were housed, fed, and handled in accordance with the "Guidelines for Animal Experimentation of Hamamatsu University School of Medicine" (Shizuoka, Japan), with approval of the institution review board for animal experiments. Male DA/Slc rats weighing 180–220 g (SLC, Shizuoka, Japan) were used. The experiments described in this report were conducted according to the "Guide for the Care and Use of Laboratory Animals," and it is required that research adhere to the Declaration of Helsinki.

Experimental design. Animals were separated into two experimental groups. The first (W/O/W group) consisted of rats given the W/O/W emulsion of tacrolimus. The second group contained rats given 1 mg/10 mL tacrolimus solution which was diluted with isotonic sodium chloride solution (T group). Tacrolimus was administered intravenously into a cutaneous pedis vein at a dose of 1.0 mg/kg (W/O/W group; $n = 40$, T group; $n = 40$) under ethyl ether anesthesia. The test solution contained 0.1 mg of tacrolimus in 1 mL in each group. Venous blood samples and tissue samples were obtained predose ($n = 5$) and then 5 min ($n = 5$), 10 min ($n = 5$), 15 min ($n = 5$), 30 min ($n = 5$), 1 h ($n = 5$), 2 h ($n = 5$), and 6 h ($n = 5$) after drug administration. After laparotomy, blood samples were taken from the inferior vena cava and were collected in EDTA-containing tubes. Subsequently, brain, liver, spleen, kidney, and lung samples were excised. These unrinsed samples were immediately frozen at −20°C. Lungs were removed 6 h after drug administration and fixed in 10% formaldehyde solution. Then the lungs were prepared with Sudan-III stain for light microscopy.

Measurement of tacrolimus levels. Concentrations of tacrolimus in whole blood and tissue samples were assayed by enzyme immunoassay method using antitacrolimus monoclonal antibody as previously described (13). Rat whole blood standard and tissue samples standards in the range of 0.5–50 ng/mL were prepared using blank rat whole blood and homogenates of tissue samples. The standard curves were shown by four-parameter-fitting equation:

$$Y = (A - D)/\{1 + (X/C)^B\} + D \qquad [2]$$

where Y represents the values for optimal density, X represents the values for concentration of tacrolimus, and A, B, C, and D represent the values for parameter. The correlation coefficients of whole blood and tissue samples were more than 0.998 in both the free and emulsion forms of tacrolimus. For the determination of tissue levels of tacrolimus, tissue samples were homogenized in 10 vol of isotonic sodium chloride solution and analyzed. Tissue tacrolimus levels were calculated as the amount of tacrolimus in 1 g of tissue sample. We performed the control experiment that homogenized both brain and liver in the same mixture to account for intrinsic differences between the tissues' lipophilicity. Brain extractions were compared with liver extractions containing tacrolimus in the same concentration range. As shown in Figure 1, there was no significant effect of tissues' lipophilicity on the enzyme immunoassay for tacrolimus. Whole blood tacrolimus concentration (C_p) profiles were described by polyexponential equations:

$$C_p = \sum C_i e^{\lambda_i t} \qquad [3]$$

where $i = 2$ for T group and W/O/W group in whole blood. C_i and λ_i denote intercept coefficients and slopes. Data were subjected to nonlinear regression analysis. The area under the whole blood concentration–time curve (AUC) was calculated from the slopes and coefficients (AUC = $\sum C_i/\lambda_i$). The total

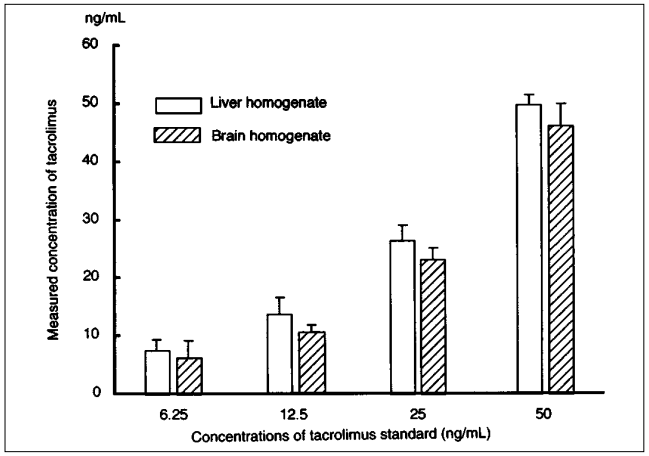

FIG. 1. Comparison of tacrolimus concentrations of standards with homogenized brain ($n = 3$) and liver ($n = 3$) in the same mixture. Values represent mean ± SD. There is no significant difference between tacrolimus concentrations extracted from liver and brain.

clearance (CL_{tot}) was calculated from Dose/AUC. The apparent volume of the central compartment (V_c) was obtained from Dose/$\sum C_i$. The β-phase apparent volume of distribution ($V_{d(\beta)}$) was calculated from CL/apparent elimination rate constant (β). The half life of the elimination phase ($t_{1/2\beta}$) was calculated from 0.693/β.

Statistics. Tacrolimus levels are presented as means ± standard deviation, and compared between the groups using the unpaired Student's *t*-test. $P < 0.05$ was considered significant.

RESULTS

The morphological findings of W/O/W emulsion droplets were demonstrated by TEM (Fig. 2). Each droplet contained many smaller water droplets. The mean diameter of the W/O/W emulsion droplets was 3.21 ± 0.10 μm. The entrapping efficiency of tacrolimus was 84.0 ± 4.0%, and did not change when the emulsion was stored at 5°C for 5 d.

Concentration of tacrolimus in blood. Mean whole blood concentration profiles of drug after intravenous injection of W/O/W group and T group at a dose of 1 mg/kg are shown in Figure 3 and Table 1. Whole blood profiles were described using a biexponential equation for both W/O/W group and T group in Figure 3. Whole blood concentrations of tacrolimus were significantly higher (5 min, 15 min, and 30 min: $P < 0.01$, 10 min: $P < 0.05$) in the W/O/W group than in the T group (Table 1). Table 2 lists the pharmacokinetic parameters based on whole blood concentration. There were no significant differences between the pharmacokinetic parameters of W/O/W group and T group.

Tacrolimus levels of organs. As shown in Table 3, the tacrolimus levels in the liver at 15 min were significantly higher ($P < 0.01$) in the W/O/W group than in the T group. But there were no significant differences between the liver concentration of W/O/W group and T group at 1 and 6 h, showing a marked decrease of liver concentration at 1 h in W/O/W group. The tacrolimus levels of the spleen in the W/O/W group were also significantly higher (15 min and 6 h: $P < 0.05$, 1 h: $P < 0.01$) than in the T group. In contrast, the tacrolimus levels in the brain were quite low compared with the levels in other organs at 15 min and 1 h after injection.

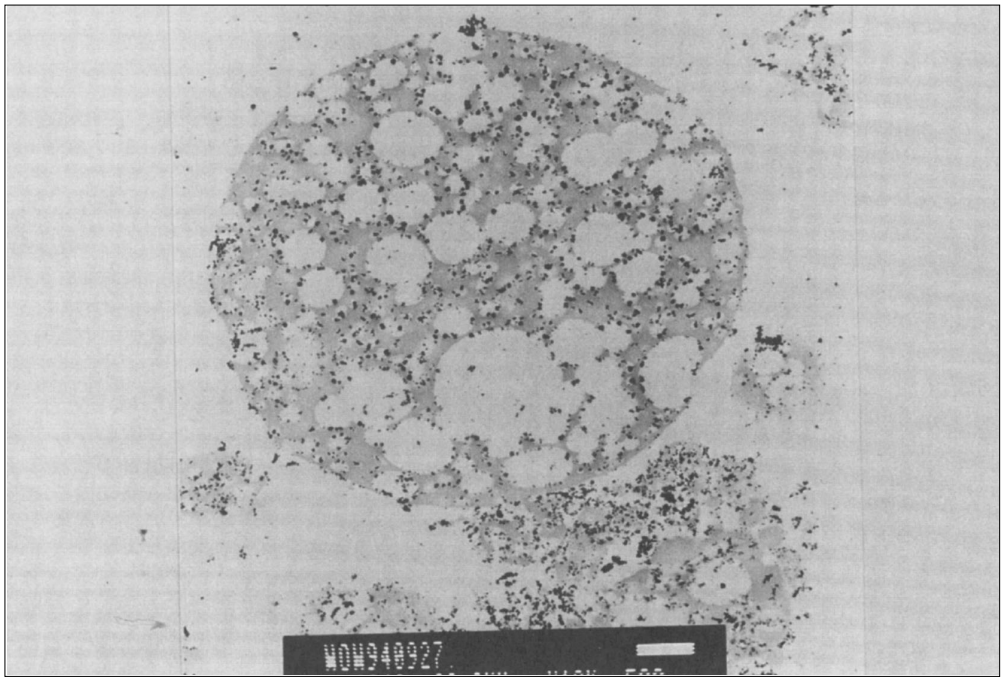

FIG. 2. Electron microscopic appearance of W/O/W-type multiple emulsion, which contains many smaller water droplets, scale bar = 500 nm.

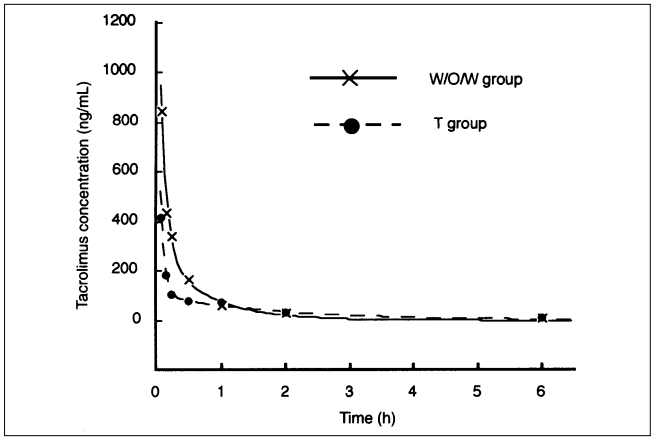

FIG. 3. Whole blood tacrolimus concentration profiles of W/O/W group and T group following single intravenous doses of 1.0 mg/kg to rats. (X), water-in-oil-in-water group (n = 5); (●), tacrolimus solution group (n = 5). Each point represents the mean of five rats. Solid and dotted lines represent curve-fitting of data to polyexponential equations. These profiles were described using a biexponential equation for both groups.

The brain concentrations at 1 h and 6 h were also significantly lower (1 h: $P < 0.05$; 6 h: $P < 0.01$) in the W/O/W group than in the T group. The tacrolimus levels in the kidney in the W/O/W group were significantly lower (15 min: $P < 0.05$, 1 h and 6 h: $P < 0.01$) than those in the T group. Also there were no significant differences between the lung concentration of tacrolimus in the W/O/W group and in the T group.

Histological findings of lung. Gross inspection at autopsy showed no change of lungs macroscopically, but the histological sections of lung in some samples microscopically demonstrated mild deposits of fat in the pulmonary blood vessels (Fig. 4).

DISCUSSION

This is the first study to document the pharmacokinetic benefits of an intravenously administered W/O/W emulsion incorporating tacrolimus. A W/O/W-type multiple emulsion was used as a carrier of tacrolimus *via* an intravenous route for the following reasons: W/O/W emulsions enter the lymphatic system easily (6); tacrolimus can be enclosed both easily and efficiently with multiple emulsion. To prepare the W/O/W emulsion, we used castor oil derivative (HCO-60) which may cause allergic symptoms (14,15). The feasibility of W/O/W emulsion as an alternative to the tacrolimus intravenous dosage form without HCO-60 should be assessed. The mean particle size of 3.21 μm is not small enough to avoid trapping in the lung. But the lung concentrations of tacrolimus were not significantly different between the W/O/W group and T group. Fat accumulation in the lung may not result in major changes in lung distribution. Further refinements in the formulation of this W/O/W emulsion would likely result in smaller particles and decreased fat accumulations in the lung. Toxicity was not investigated in this study because single intravenous doses of tacrolimus are not likely to evoke toxicity.

The pharmacokinetic parameters were calculated by whole blood concentrations. However, no significant differences be-

tween W/O/W group and T group in the pharmacokinetic parameters were found. Whole blood concentration profile was reported to be best fitted by triexponential equation for conventional intravenous dosage form of tacrolimus (16). Differences in pharmacokinetics at steady-state (γ phase) should be confirmed by whole blood concentrations in the W/O/W group and T group. The present pharmacokinetic study of the W/O/W group demonstrated significantly increased tacrolimus levels in the liver and spleen, and significantly decreased tacrolimus levels in the kidney and brain, relative to the T group. This indicates that the main site of W/O/W emulsion uptake after intravenous injection was the RES. The brain and kidney contain little in the way of RES, which may be the reason that the administration of W/O/W emulsion reduced the tacrolimus levels in those organs. A study of liposomal immunosuppressants has previously described the same distributions of immunosuppressants to these organs (17). Because the liver is the site of the allograft in liver transplantation and the spleen is a major lymphoid tissue, a W/O/W emulsion of tacrolimus may increase the immunosuppressive efficacy in liver transplantation. However, enhancement of the immunosuppressive effect by a W/O/W emulsion of tacrolimus will have to be confirmed in studies of experimental transplantation.

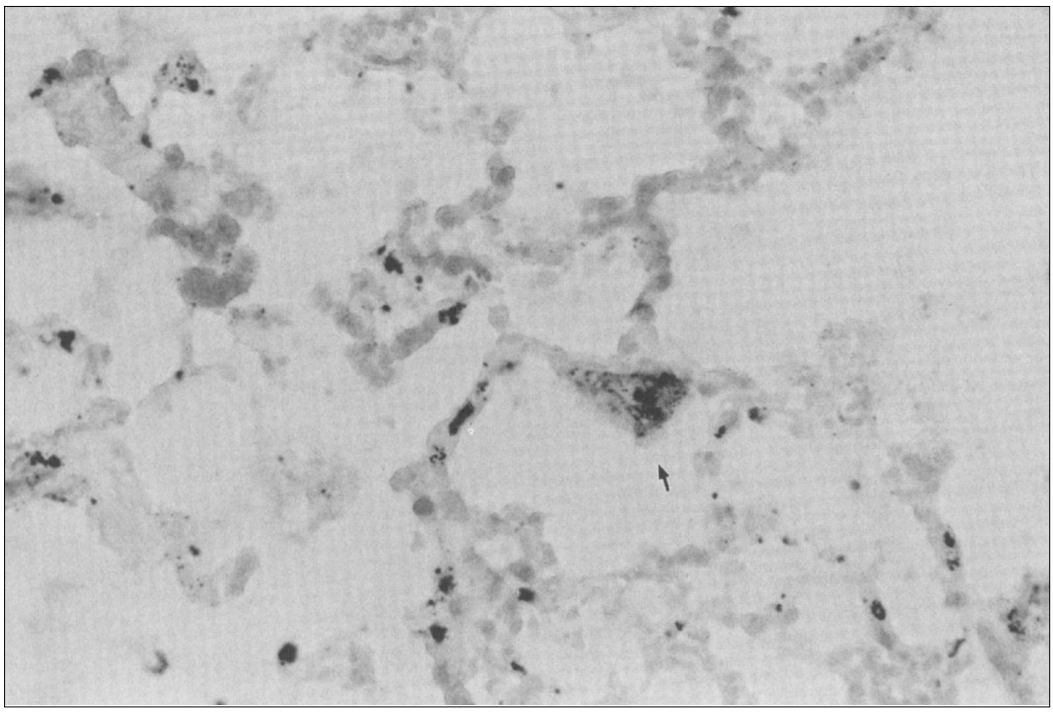

FIG. 4. A branch of the terminal bronchiole 6 h after administration of tacrolimus in the W/O/W group. The arrow indicates the site of fat deposit in pulmonary blood vessels (Sudan-III stain, ×100).

From the viewpoint of adverse effects, decreased tacrolimus levels in the kidney and brain following a W/O/W emulsion of tacrolimus may alleviate the nephrotoxicity and neurotoxicity. Our results suggest that the tacrolimus concentration in the brain was quite different from that in other organs because the brain is protected by the blood brain barrier. Other investigators working with tacrolimus delivered in liposomes have demonstrated decreased tacrolimus levels in the brain (17), but a recent study revealed that the brain had an extraordinarily high density of tacrolimus-binding protein, to which tacrolimus binds with high affinity (18). We need to explore whether reduced tacrolimus levels in brain tissue as a result of delivering it *via* W/O/W emulsions will result in contribution to decreased neurotoxicity. McCarley *et al.* (19) demonstrated that the nephrotoxicity of tacrolimus was dose-dependent, and that measures to decrease the quantity of drug required would reduce drug-induced renal damage. A previous study of local immunosuppression found that CsA liposomes had potential for use as an immunosuppressive agent with decreased nephrotoxicity relative to the commercially available form of intravenous CsA in an ischemic kidney model in the rat (11). The reduction of tacrolimus levels in the kidney by a W/O/W emulsion would be expected to reduce the nephrotoxicity of tacrolimus.

The use of immunosuppressive agents incorporated in a W/O/W-type multiple emulsion is a potentially useful method for the local delivery of the agents to target organs. By taking advantage of the concept of local immunosuppression, it may be possible to increase the immunosuppressive efficacy and decrease the adverse effects of systemically administered immunosuppressants. The optimal emulsion size, the likely increased therapeutic index of tacrolimus in experimental liver transplantation, and the alleviation of neurotoxicity and nephrotoxicity should be evaluated by further investigations in animal models.

Structure Analysis of an Allene-Containing Estolide Tetraester Triglyceride in the Seed Oil of *Sebastiana commersoniana* (Euphorbiaceae)[1]

Volker Spitzer[a,*], Werner Tomberg[b], and Gottfried Pohlentz[b]

[a]Faculty of Pharmacy, Post-Graduate Course, Federal University of Rio Grande do Sul (UFRGS), 90.610.000 Porto Alegre/RS, Brazil, and [b]Physiologisch-Chemisches Institut, Universität Bonn, 53115 Bonn, Germany

ABSTRACT: The seed oil of *Sebastiana commersoniana* (Euphorbiaceae) was separated into a triglyceride and an estolide fraction by preparative thin-layer chromatography. The triglyceride band was characterized by spectroscopic methods, and its fatty acids have been analyzed by gas chromatography (GC) and GC–mass spectrometry (MS) as their methyl esters. Linolenic acid was the main fatty acid (65%). The estolide band was examined by a combination of spectroscopic and chromatographic methods (ultraviolet, infrared, nuclear magnetic resonance, fast atom bombardment–MS, GC–MS of the fatty acids before and after silylation) and was identified as a tetraglyceride, where one α-carbon of the glyceride backbone was esterfied with 8-hydroxy-5,6-octadienoic acid, which itself was esterfied with *trans*-2,*cis*-4-decadienoic acid. The remaining positions of the glyceride backbone were occupied by common fatty acids.

Lipids 32, 549–557 (1997).

Seed oils of the Euphorbiaceae show a great variability in their lipid composition, and various unusual fatty acid derivatives and other lipid structures have been isolated (1). The seed oils from some members of this plant family, e.g., *Ricinus communis, Vernonia* spp. and *Aleurites* spp., play an important economic role in many countries and are used widely in pharmaceutical and technical applications (2).

Recently, we described the identification of α-parinaric acid from the seed oil of *Sebastiana brasiliensis* (3) and the occurrence of high amounts of vernolic acid in *Bernardia pulchella* (4), both from the Euphorbiaceae family. To extend the knowledge about seed oils of this plant family, we examined a sample of *S. commersoniana* seeds. This plant is a shrub or tree of 2–15-m height, which occurs in Brazil, Uruguay, Argentina, Paraguay, and Bolivia. Its wood is used as firewood, for house construction, and for making agricultural tools. In addition, the roots are considered medicinal (5). Each fruit of this plant contains three oily seeds, which were investigated as a part of our current research project about new seed oils and plant fatty acids from Brazil.

This paper deals with the spectroscopic structure elucidation of the estolide tetraester triglyceride fraction of the title plant, which contains 8-hydroxy-5,6-octadienoic acid and *trans*-2,*cis*-4-decadienoic acid besides other common fatty acids (Scheme 1).

This rare lipid component has already been found in seed oils from the Euphorbiaceae species *Sapium sebiferum* (6) and *Sebastiana ligustrina* (7). The authors (6,7) characterized the individual fatty acids and their linkage to the glycerol moiety by a combination of various chemical, chromatographic, and spectroscopic methods. In brief, the allenic acid was identified by gas chromatography (GC) and by ultraviolet (UV), infrared (IR), and ^{1}H nuclear magnetic resonance (^{1}H NMR) spectroscopy after reduction and acetylation to the corresponding 1,8-octanediol diacetate and 2,3-octadiene-1,8-diol diacetate, respectively. The conjugated *trans*-2,*cis*-4-decadienoic acid was characterized by its UV, IR, and mass spectral data. The linkage of these two rare fatty acids in the tetraester was proven by interpretation of the mass spectrum acquired from the hydrogenated tetraester and by interpretation of the IR and mass spectroscopic data obtained from the individual fractions after incomplete interesterification of the original tetraester.

In the present work, the allene-containing estolide tetraester triglyceride of the seed oil from *S. commersoniana* was elucidated by a combination of UV, IR, fast atom

MATERIALS AND METHODS

Seed material and oil extraction. The fruits from *S. commersoniana* were collected and botanically identified by Marcos Sobral in January 1995 in the National Park of Turvo, Derrubadas, State Rio Grande do Sul, South Brazil. For extraction of the oil, the air-dried seeds were repeatedly crushed and homogenized with a pestle in a mortar under petroleum ether (40–60°C). After filtration, the solvent was removed by vacuum distillation at 30°C, flushed with nitrogen, and the residue was stored in petroleum ether solution at −18°C until use. The yield was 19.7% of a yellow oil. To minimize autoxidation, all solvents were bubbled with nitrogen before use and contained 0.001% butylated hydroxytoluene (BHT).

Derivatization reactions. Transesterification to the fatty acid methyl esters (FAME) was carried out with 0.5 N sodium methoxide in anhydrous methanol at room temperature under nitrogen as described by Christie (8). Silanization of the FAME mixture was made with bis-(trimethylsilyl)-trifluoroacetamide (BSTFA) (9).

Separation of the estolide and triglyceride fraction. Preparative separation of the seed oil components was done with 0.6-mm preparative silica thin-layer chromatography (TLC) using petroleum ether/diethyl ether (80:20; vol/vol) as solvent system. Detection of the individual fractions was carried out under UV light at 254 nm and after spraying with 2′,7′-dichlorofluorescein under UV light at 340 nm. The TLC bands of interest were scraped off, eluted with diethyl ether, and further analyzed.

GC and GC–MS analyses. A Hewlett-Packard (Palo Alto, CA) 5890 GC Series II GC, a flame-ionization detector (230°C) and a split injector (1:50, 230°C) with glass insert and H_2 as carrier gas (head pressure 1.5 bar) were used to analyze the FAME. Separation of the compounds was achieved with an HP-20M (Hewlett-Packard) capillary column (50 m × 0.2 mm × 0.2 μm), using an oven temperature of 190°C. Peak integration was done with an HP3392A integrator (Hewlett-Packard). For estimation of the equivalent chain length values, the retention times were measured from the time of elution of the solvent, considered as unretained solute. GC–MS was done with the NERMAG AUTOMASS (France, Paris) operating with an ionization energy of 70 eV, a source temperature of 225°C, and an interface temperature of 220°C. The separation of the FAME derivatives was carried out with a BPX-70 (SGE, Weiterstadt, Germany) WCOT column (30 m × 0.22 mm × 0.25 μm) using a temperature program (160–230°C; 2°C/min). Helium was used as carrier gas (0.5 bar).

Spectroscopic procedures. IR spectra were obtained with a Shimadzu FTIR-8101 (Tokyo, Japan) instrument in a liquid film. UV spectra were recorded from 400–200 nm in cyclohexane solution using a Shimadzu UV-2201 spectrophotometer. The ^{1}H NMR, ^{1}H-^{1}H two-dimensional shift correlation (COSY) and ^{13}C NMR broad-band (BB) decoupled and attached proton test (APT) experiments were done on a Bruker AMX500 (Karlsruhe, Germany) spectrometer in deuterochloroform solution. Preliminary NMR data were obtained with a Varian VLX-200 (Palo Alto, CA) spectrometer with trimethylsilyl (TMS) as internal standard. FAB(+) mass spectra of the allene estolide were measured with a VG analytical ZAB-HF reversed geometry mass spectrometer (Manchester, United Kingdom) with xenon as bombardment gas. A mixture of 1-mercapto-2,3-propandiol and *meta*-nitrobenzylalcohol (1:1) was used as matrix, and sodium acetate was added. Spectra were recorded and evaluated on SAM II/68 K computer (KWS, Ettlingen, Germany) using the DP10 program from AMD (Harpstedt, Germany).

RESULTS AND DISCUSSION

Preliminary experiments. TLC analysis of the seed oil of *S. commersoniana* showed two main components (FR1: R_f = 0.78 and FR2: R_f = 0.54) along with other minor spots. FR1 showed the same migration characteristics as authentic triglycerides from sunflower oil. FR2 is generally not detectable in common seed oils and was the only component of the lipid mixture that was directly detectable under UV light at 254 nm. The UV spectrum of the oil showed a maximum at 260 nm and the other spectral data (IR, ^{1}H and ^{13}C NMR) also presented some characteristics which were not observed in common seed oils. Consequently, the two main fractions, FR1 (69%) and FR2 (31%), were isolated by preparative TLC and further examined.

Characterization of FR1. The IR, ^{1}H, and ^{13}C NMR data of FR1 showed the same features as triglycerides containing saturated and olefinic (oleic, linoleic, and linolenic acids) fatty acids. No UV absorption could be detected. These observations were in good agreement with the TLC data, suggesting that FR1 was a simple triglyceride fraction. The fatty acids of this fraction were analyzed after transmethylation by GC and GC–MS, and the results are summarized in Table 1. Linoleic (16%) and linolenic acid (68%) were found to be the main compounds. Identification of the fatty acids was made by co-injection of standard compounds and by comparison of the mass spectra with the spectra of standards.

Characterization of FR2. The UV spectrum of FR2 showed a broad absorption at 260 nm, attributable to the presence of carboxyl-conjugated fatty acids (6). The IR spectrum showed, in addition to the triglyceride bands, absorption peaks at 1717 cm^{-1} (s), 1635 cm^{-1} (m), 997 cm^{-1} (m), and 870 cm^{-1} (m), pointing to a conjugated *trans*-2,*cis*-4-dienoate system (10). A *cis*-2,*trans*-4-dienoate structure was excluded since its characteristic bands at 971 and 820 cm^{-1} did not appear. The band at 1966 cm^{-1} (w) in the IR spectrum was assigned to an allene structure (6).

GC and GC–MS analysis of the FAME of FR2 indicated the presence of common fatty acids with α-linolenic acid as

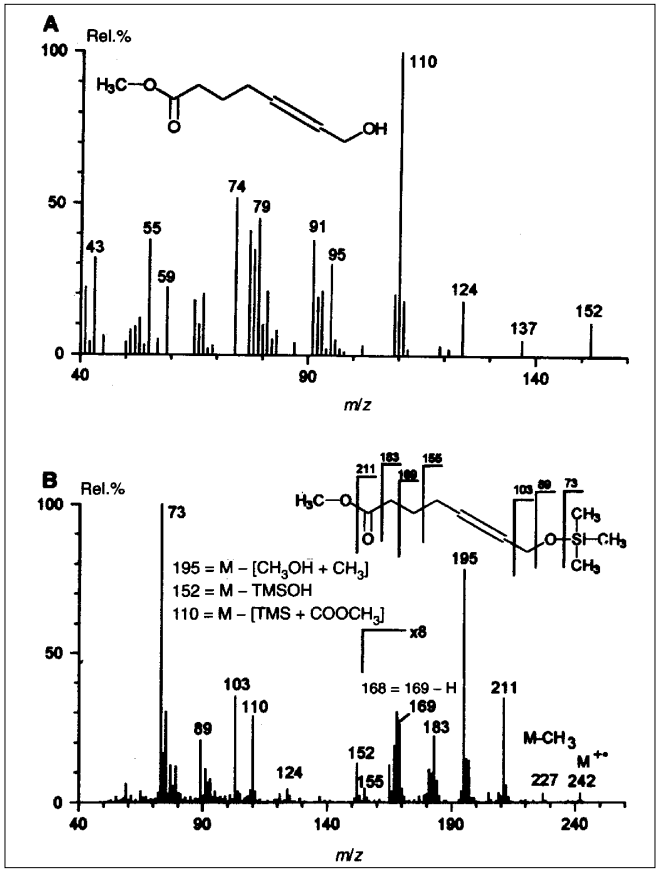

FIG. 1. The mass spectra of the methyl esters of 8-hydroxy-5,6-octadienoic acid [A = with free OH group, B = as its trimethylsilyl (TMS) derivative)].

the main fatty acid (Table 1). Furthermore, three GC peaks (P1a, P1b, and P2), which showed retention characteristics not usually found in seed oil fatty acids, were observed. The mass spectrum of P1a (equivalent chain length = 11.96) showed a molecular ion at *m/z* 182, suggesting the molecular formula $C_{11}H_{18}O_2$. The fragmentation pattern was identical to that published for deca-2,4-dienoic acid methyl ester (10). Taken together, the MS data and the UV, IR, and ^{13}C NMR data from FR2 were consistent with P1 being identified as 2-*trans*,4-*cis*-decadienoic acid methyl ester. The minor compound P1b (equivalent chain length = 12.4) appeared to be a stereoisomer of P1a since both compounds showed the same mass spectrum. The peak at equivalent chain length 16.65 (P2) disappeared after silanization, and instead, appeared as a new peak eluting between P1 and palmitic acid methyl ester. This behavior suggested that compound P2 contained a free hydroxyl group. The mass spectrum of P2 (Fig. 1), subsequently identified as 8-hydroxy-5,6-octadienoic acid methyl ester, was not very useful for further structure assignments. The peak with the highest mass value was observed at *m/z* 152, which was attributed to the loss of H_2O from the molecular ion at 170 mu ($C_9H_{14}O_3$). The base peak at *m/z* 110 was explained by the loss of the methyl ester moiety and simultaneous rearrangement of one hydrogen atom ($M - CH_3OCOH$?). In the low-mass range, the characteristic methyl ester ions (*m/z* 59, 74) were detected, and the highly unsaturated hydrocarbon fragments (*m/z* 41, 55, 79, 91, etc.) suggested that rearrangements occurred during ionization.

The fragmentation pattern of silylated P2 (Fig. 1) provided more structural information. The rearrangement reactions were suppressed in the silylated derivative. Suggested fragmentation ions are included in the mass spectrum of silylated P2 (Fig. 1). In the low-mass range, the ion series containing the TMS moiety (*m/z* 73, 89, and 103) appeared with abundance and *m/z* 73 was the base peak. The gap between the ions *m/z* 103 and 155 was diagnostic for the location of the allenic system, since direct cleavage at the double-bond system is energetically unfavorable. The ion series, containing the TMS moiety, was continued at *m/z* 155, 169, 183, and represented the successive cleavage at each methylene group beginning from the allylic methylene group in the direction of the methyl ester end (Fig. 1B). The weak signal at *m/z* 242 was attributed to the molecular ion, confirmed by the ions at *m/z* 227 ($M - CH_3$) and 211 ($M - OCH_3$). Further confirmation on the structure of P2 were obtained by the NMR data (see below). Since the IR spectrum did not show any absorption for a free hydroxy function, it was concluded that the hydroxy group was linked to another fatty acid in FR2.

The mass spectra of 8-hydroxy-5,6-octadienoic acid methyl ester and its corresponding TMS derivative have not been previously published. The mass spectrum published for the acetate of 8-hydroxy-5,6-octadienoic acid methyl ester (12) did not show clearly the molecular ion and was dominated by the $[COCH_3]^+$ fragment (*m/z* 43). The remaining fragmentation pattern of the published spectrum (12) was essentially similar to the nonacetylated derivative in this study (Fig. 1A), but the position of the allenic system had not been investigated previously (12).

The GC analysis of 8-hydroxy-5,6-octadienoic acid methyl ester was described as problematic in the literature. Sprecher *et al.* (6) mentioned that this compound was proba-

bly not detected during GC analysis because polymerization or decomposition of the highly reactive allylic alcohol may have occurred on the GC column. Similar observations were made by other research groups (7,13) who used packed GC columns for analysis. The gas chromatograms obtained with a Silar 5 CB WCOT capillary column from stillingia oil fractions (14), which also contained 8-hydroxy-5,6-octadienoic acid, did not show any evidence of this allenic fatty acid. The authors used BF_3/methanol for transesterification, and the C_8 fatty acid may have undergone side reactions during derivatization. Acidic conditions are generally not recommended for the transesterification of unusual fatty acids (8). The results from our GC analysis of the methyl esters from FR2 showed that 8-hydroxy-5,6-octadienoic acid was detected by GC by using mild transesterification conditions and a Carbowax 20M WCOT column. However, the integrated value of P2 demonstrated (Table 1) that the recovery may not be quantitative, and some decomposition may have occurred.

To obtain more detailed structure information, the FAB, MS, and NMR spectra of FR2 were studied. The quasi-molecular ions $[M + Na]^+$ in the range from *m/z* 901 to 929 in the FAB mass spectrum (Fig. 2 and Table 2) were compatible with a triglyceride structure that contained two mols of common saturated and unsaturated C_{16} and C_{18} fatty acids, one mol of 2-*trans*,4-*cis*-decadienoic, and one mol of 8-hydroxy-5,6-octadienoic acid. The peaks in the range from *m/z* 573 to 601 (E_2) and the peak at *m/z* 289 (R_3) showed clearly that 8-hydroxy-5,6-octadienoic acid was esterfied with 2-*trans*,4-*cis*-decadienoic acid, resulting in a "C_{18} chain." No ions that could prove a connectivity between 8-hydroxy-5,6-octadienoic acid and any one of the C_{16} and C_{18} fatty acids were observable. The observation of a base peak at *m/z* 151, derived from acyl cleavage from 2-*trans*,4-*cis*-decadienoic acid $[^+CO–CH=CH–CH=CH–(CH_2)_4CH_3]$, without accompanying fragments at *m/z* 151 + 74 and *m/z* 151 + 128, respectively, showed that this conjugated fatty acid was not directly linked to the glyceride moiety, but was esterfied to the hydroxyl group to 8-hydroxy-5,6-octadienoic acid. It is known that in triglycerides the fragments due to a cleavage at the acyl group are accompanied by peaks with mass numbers 74 and 128 units higher than each original acyl group. These ions show the connectivity for a fatty acid with the glyceride backbone (6) and were detected here for linoleic acid at *m/z* 261 (RCO^+), *m/z* 335 (261 + 74), and *m/z* 389 (261 + 128) in the mass spectrum. The explanations for the main fragments of the FAB mass spectrum of FR2 are summarized in Table 2. Unfortunately, these mass spectral data did not provide information whether the "C_{18} chain," containing 2-*trans*,4-*cis*-decadienoic acid and 8-hydroxy-5,6-octadienoic acid, was linked to the α- or β-hydroxy group of the glycerol moiety.

By careful interpretation of the NMR data, the structure elucidation of FR2 was completed. Comparison with standard compounds and literature data (15) permitted the assignment of most ^1H and ^{13}C NMR signals of FR2 (Tables 2 and 3). The presence of saturated and unsaturated fatty acids linked to a glyceride backbone was clearly evident. The assignment of the remaining signals was made in conjunction with ^1H NMR, ^1H-^1H two-dimensional shift correlation (COSY), ^{13}C NMR (BB decoupled and APT mode) spectroscopic experiments and by comparison with literature data.

The ^1H-^1H COSY NMR spectra (Fig. 3) were consistent with the identification of 8-hydroxy-5,6-octadienoic acid, made by GC–MS analysis of its TMS derivative: The triplet at δ 2.35 ppm showed a cross signal with the multiplet at δ 1.75 ppm. The latter signal was further correlated with the signal at δ 2.05 ppm that also showed a cross signal with δ 5.3 ppm. These correlation patterns were compatible with a partial structure $ROOC–CH_2–CH_2–CH_2–CH=$. The signal at

δ 4.6 ppm revealed only one cross signal with δ 5.3 ppm. In the 200 MHz ^{1}H NMR spectrum (Fig. 4) the signal at δ 4.6 ppm appeared as a double doublet (*dd*, *J* = 6.6, 2.2 Hz), suggesting a –CH=C=CH–C*H*$_2$–O–R structure. Obviously, the coupling of the CH_2–O–R protons extended up to the methylene protons at the other side of the allenic system, since in the 500 MHz ^{1}H NMR spectrum (Fig. 4) the signal at δ 4.6 ppm was split into a more complex multiplet. The theoretically possible 2,3-, 3,4-, 4,5-, and 6,7-octadienoic structures were excluded by the interpretation of the ^{1}H-^{1}H COSY data, and by comparison of the ^{1}H NMR shifts from synthetic positional isomers of methyl allenic fatty acids (16). The ^{1}H integral value of the signal at δ 4.6 ppm was identical to the integral value for the signals of the α-methylene protons from the glyceride backbone at δ 4.15 and 4.3 ppm. This observation demonstrated that the α-methylene protons from the glyceride backbone were present in the same molecular proportion as the methylene protons from the =CH–C*H*$_2$–O–R linkage. In agreement with the IR and FAB MS data, no signals for a free OH group were detected in the NMR spectra. The ^{1}H NMR signals of the *trans* carboxyl-conjugated system were observed at δ 5.85 ppm (2H, *m*), δ 6.15 ppm (1H, *dd*, *J* = 11,11 Hz) and δ 7.62 ppm (1H, *dd*, *J* = 15,11 Hz). The coupling constants, the multiplicity pattern, and the ^{1}H-^{1}H COSY correlation sequence (δ 5.85, 7.62, 6.15 ppm) were in agreement with the conjugated *trans*-2,*cis*-4-dienoate system.

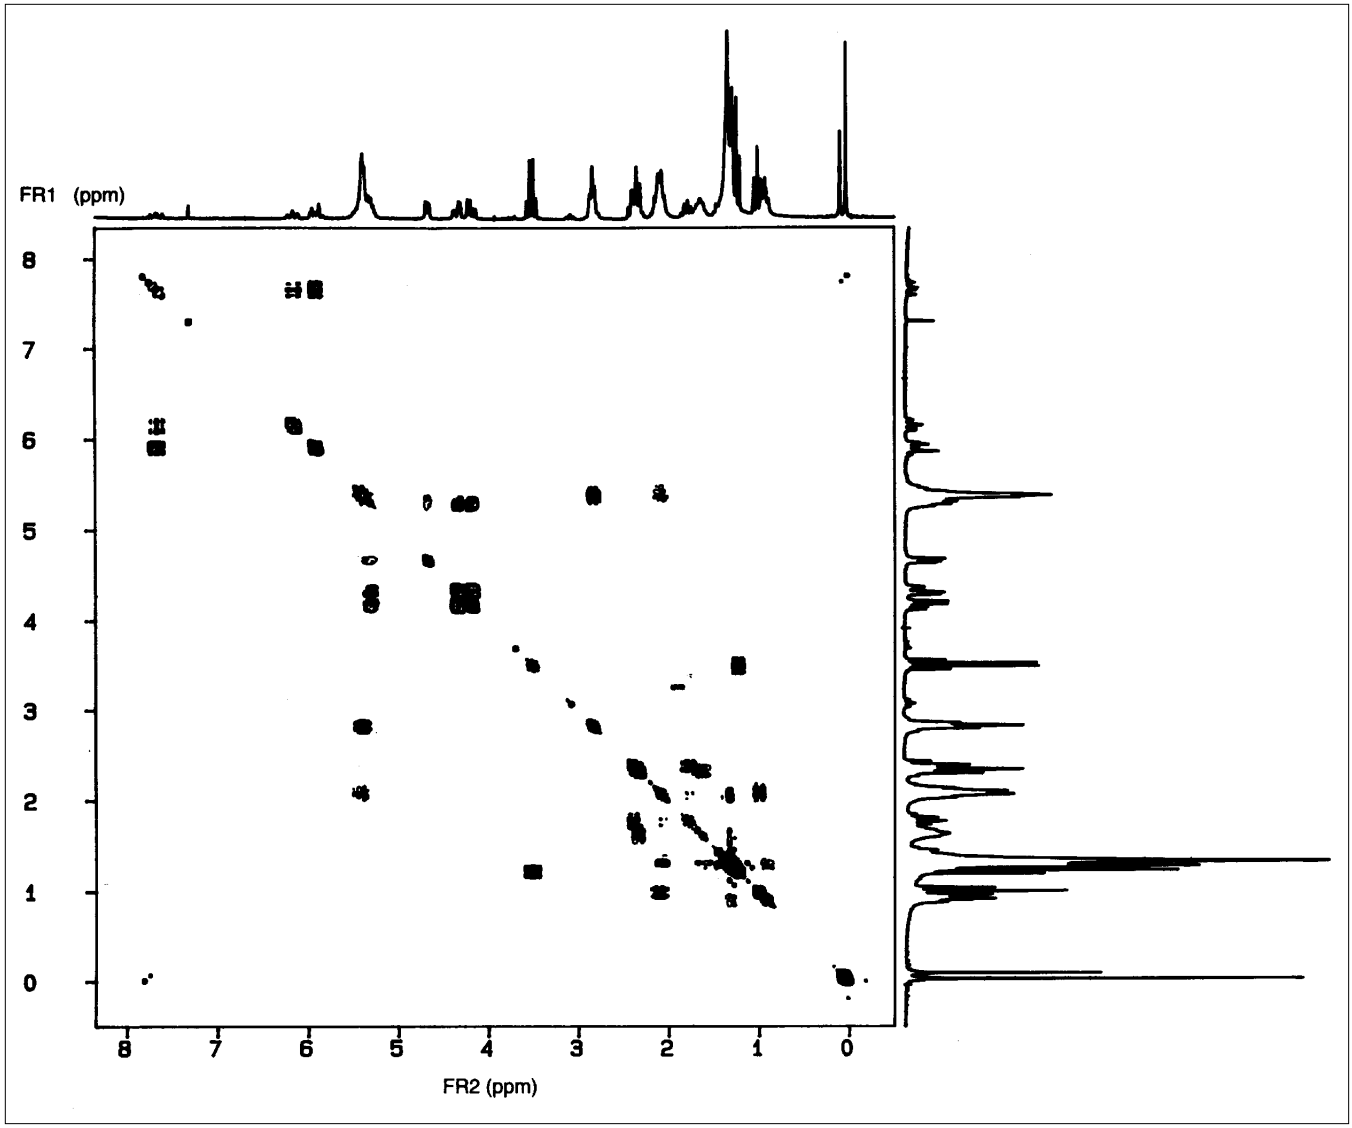

FIG. 3. The ^{1}H-^{1}H COSY NMR spectrum (200 MHz) of the estolide fraction FR2 of the seed oil from *Sebastiana commersoniana*.

Similar ^{1}H NMR data were observed for a comparable ketodiene structure in 13-keto-9-*cis*-11,*trans*-octadienoic acid methyl ester (17).

The ^{13}C spectra [BB decoupled (Fig. 5) and ATP mode] provided information about the linkage of the estolide part at the glyceride backbone (Table 4). In the range between δ 62 and 69 ppm, three –*C*H$_2$O– signals (δ 62.15, 62.3, and 62.6 ppm) and one –*C*HO– signal (δ 68.93 ppm) appeared with nearly identical intensity. Two of the *C*H$_2$O– signals were attributed to the two α-hydroxy carbons from glycerol, and the third *C*H$_2$O– signal was assigned to –CH=C=CH–*C*H$_2$O– of the estolide. In normal triglycerides, only one –*C*HO– signal and one double intense *C*H$_2$O– signal for the two CH$_2$ groups are observed (15). The fact that the *C*H$_2$O– signals for the two glyceride CH$_2$ groups were resolved into two signals was due to the influence of the allenic double bond system at C-5 of the estolide. This observation suggests that the estolide was linked to a α-hydroxy group of the glyceride moiety. If the estolide was linked to the β-hydroxy group of glycerol, no splitting of the two glyceride CH$_2$ groups would be expected. The possibility that FR2 was a mixture of triglycerides with the estolide connected to the α- and β-position of the glycerol moiety was excluded by the equal intensity of the three signals between δ 62 and 69 ppm.

The signals for the allenic double-bond system at δ 205.51 ppm (–CH=*C*=CH–), δ 87.76 ppm (–CH=C=*C*H–CH$_2$–O–R) and δ 91.95 ppm (–*C*H=C=CH–CH$_2$–O–R) were assigned by comparison with data from a synthetic allenic C$_{18}$ fatty acid methyl ester (16). The position of the double bonds in the hydrocarbon chain of the allenic fatty acid was confirmed by the comparison with the ^{13}C NMR data of 5,6-octadecadienoic acid methyl ester (16). The observed signals at δ 33.27, 24.1, 28.34 ppm were assigned to C$_2$ to C$_4$ in good agreement with the ^{13}C signals of C$_2$ to C$_4$ of the latter compound (16). It was

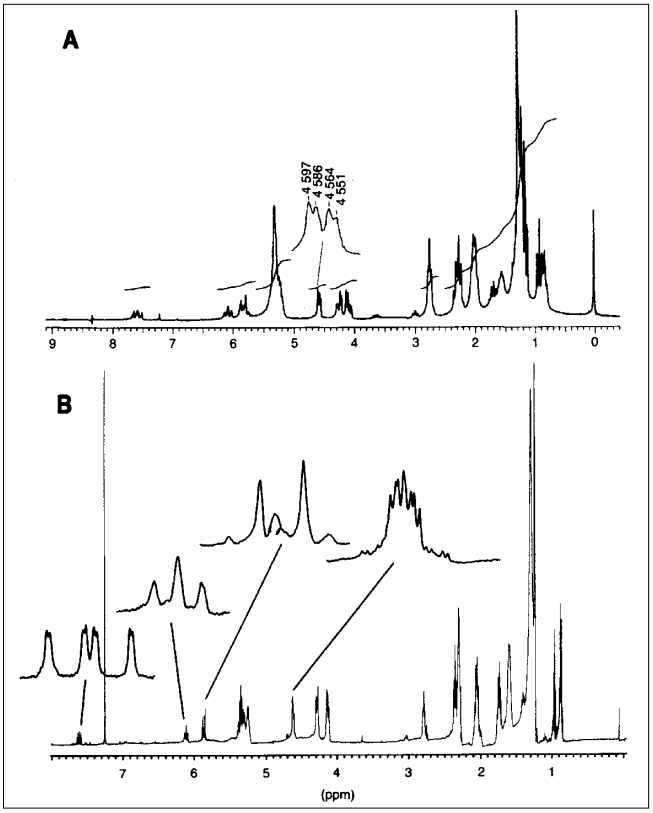

FIG. 4. The ^{1}H NMR spectrum (200 (A) and 500 MHz (B)) of the estolide fraction FR2 of the seed oil from *Sebastiana commersoniana*.

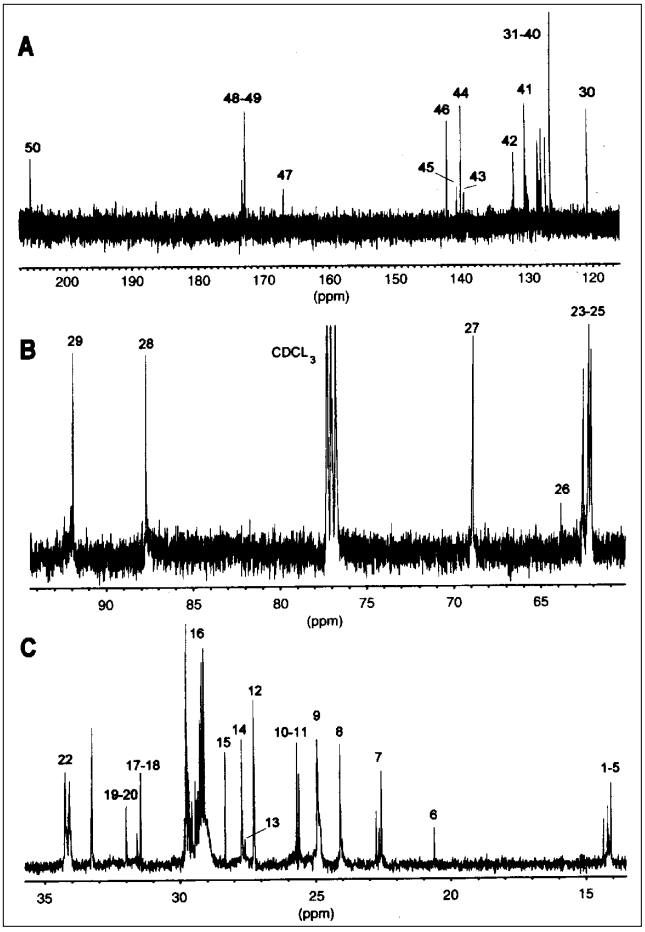

FIG. 5. The ^{13}C NMR spectrum [125 MHz (B)]) of the estolide fraction FR2 of the seed oil from *Sebastiana commersoniana* (A = 120–210 ppm; B = 60–94 ppm; C = 14–35 ppm). The peak numbers correspond with Table 4.

shown recently that ^{13}C NMR data permitted the characterization of 11 of 15 positional isomers of synthetic allenic C_{18} FAME (16). The remaining ^{13}C NMR signals were assigned to the 2-*trans*,4-*cis*-decadienoic acid part of FR2. The signal at δ 167.07 ppm was due to the carbonyl group in conjugation with the double bonds (18). The only signals in the ^{13}C NMR spectra that could not be assigned directly by data comparison appeared at δ 120.83, 126.47, 140.06 and 142.09 ppm, and could be due to the four conjugated double-bond carbons. Some minor signals in the double-bond range (δ 139.6 and 140.65 ppm) may be due to the olefinic carbons of the stereoisomer of 2-*trans*,4-*cis*-decadienoic acid detected in the GC–MS analysis.

In conclusion, interpretation of the combined spectroscopic and chromatographic data allowed for the identification of FR2 from *S. commersoniana* as a tetraester triglyceride composed of the allenic hydroxy acid 8-hydroxy-5,6-octadienoic acid jointed in an estolide linkage to 2-*trans*,4-*cis*-decadienoic acid. The same type of compound has already been isolated from *S. sebiferum* (6) and *S. ligustrina* (7). Christie (13) showed that the estolide from *S. sebiferum* occurs exclusively in the *sn*-3-position of the glyceride moiety and suggested that the optical activity of this molecule is mainly caused by the allenic system. The optical activity of the seed oil from *S. commersoniana* was not carried out in this study.

From a chemotaxonomic point of view, it is interesting to note that this estolide compound was not detected in the related species *S. brasiliensis* (3) and *Stillingia sylvatica* (7). In a preliminary analysis, it was shown that the seed oil of *Sapium japonicum* contained the same IR bands which had the same TLC and high-performance liquid chromatography properties as the allene triglyceride from *S. sebiferum* (19). A fraction isolated from *Stillingia texana* stem lipids also showed IR and mass spectroscopic evidences that a substance with some relationship to the allene estolide (7) was present.

The physiological functions and the biosynthesis of this rare estolide structure are unexplored. Recently, it was shown that 8-hydroxy-5,6-octadienoate methyl ester, isolated from the leaves of *S. japonicum*, has antifungal properties (12). Stillingia oil from *S. sebiferum* is considered nutritionally undesirable (20). The seed oil from *S. commersoniana* also can not be recommended for human diet. The high content of linolenic acid and the presence of the unstable estolides classifies the oil as a good drying oil.

Dipartimento di Chimica, Università della Calabria, I-87030- Arcavacata di Rende (CS), Italy

ABSTRACT: Lipophilic esters of saccharides belong to the family of nonionic surfactants widely employed in pharmaceutical and cosmetics formulations. A very simple method is presented whereby 6-*O*-esters of α- and β-glucose can be prepared and isolated. Good results have been obtained in the synthesis of 6-*O*-oleyl derivatives by simple acylation with appropriate oleyl chloride. The condensing agent bis(2-oxo-3-oxazolidinyl) phosphinic chloride (BOP-Cl) allows the preparations of the same esters with better regioselectivity but with yields strongly dependent on the aliphatic chain length of the carboxylic acids employed.

Lipids 32, 559–563 (1997).

Surfactants are molecules which exert a wide range of biological, pharmacological, and toxicological activity. The role of nonionic surfactants in drug delivery systems has received an enormous interest in recent years (1) since they are generally regarded as most suitable for pharmaceutical formulation (2). On the other hand, polyglycosides bearing alkyl chains are nowadays of paramount technological interest as moderately foaming material to be used as additives in cleaning products (3) or in cosmetics (4). Biocompatible nonionic surfactants can be obtained by linking a hydrophobic alkyl chain to a polyhydroxylated system, usually a carbohydrate molecule, through ester linkages (5–7). The surface-active behavior of these esters depends on the length of the lipophilic chain, the temperature, and the position of the ester group in the hydrophilic head of the sugar (7,8). The selected acylation of one out of the multiple hydroxyl groups present in a sugar substrate has been achieved by means of tributylstannosides (9), cobalt chelates (10), Mitsunobu reaction (11–13), and by using anhydrides and condensing agents (14,15). In particular, it has been recently demonstrated that bis(2-oxo-3-oxazolidinyl) phosphinic chloride (BOP-Cl) (16), a widely employed condensing agent (16–23), provides valuable and simpler alternatives to enzymatic procedures (24–30) in the regioselective esterification of primary (17) hydroxyl groups of both gluco- and mannopyranosides. Unfortunately, the straightforward esterification of saccharides with acyl chlorides leads to mixtures of mono- and polysubstituted derivatives which are often difficult to separate (31,32). Nonetheless the need of producing new surfactants with a high degree of purity and very simple chemistry has prompted the exploitation of the regioselective acylation of 1,2-isopropylidene-D-glucofuranose (**1**) with acyl chlorides or with correspondent carboxylic acids activated by means of BOP-Cl.

The 1,2-isopropylidene-D-glucofuranose **1** (Scheme 1) has already been used, in connection with a series of reactions, to introduce new functional groups into the D-glucopyranose ring (33,34). Although it is commercially available, **1** may be readily prepared from the less expensive 1,2:5,6-di-*O*-isopropylidene-D-glucofuranose by preferential hydrolysis of the more acid-labile 5,6-isopropylidene group (34). The furanose **1** therefore has been chosen as a suitable substrate in the formation of nonionic surfactants in the glucopyranose series, since it provides means for a facile deprotection of the anomeric hydroxyl group at the end of the synthesis.

RESULTS AND DISCUSSION

The reactivity of the free hydroxyl groups in compound **1** has been exploited with two independent acylating procedures (Scheme 1): (i) the conventional treatment with acyl chlorides **2a–d** (Method A) and (ii) the employment of BOP-Cl with carboxylic acids **3a–d** (Method B). The data reported in Table 1 show that method A gives, under the adopted experimental conditions, good to excellent yields of products **4a–d**, owing to the higher reactivity of primary vs. secondary hydroxyl groups of the furanoside. The expected (17) high re-

gioselectivity experienced with BOP-Cl was counterbalanced by the low isolated yields of the final product. The reaction of **1** with **2a–d** in pyridine affords mainly the products **4a–d** and other less polar polyacylated derivatives which were not isolated or identified. The adopted experimental conditions (Table 1) represent the best of many trials in terms of conversion-to-selectivity ratio.

When **1** was allowed to react with **3a–c** in the presence of BOP-Cl, the formation of side products was negligible, even though the total conversion was lower than with Method A. In the case of the oleic acid **3d**, a clean product **4d** was obtained, without any purification, at the expense of the total yield. It should be considered that if the goal is the obtainment of pure material the simpler acylation procedure (Method A), followed by chromatographic purification, is the method of choice.

Benzoyl chloride **2a** reacts faster than the aliphatic acyl chlorides **2b**, **c** and with a rate similar to the oleyl derivative **2d**. The latter gives also nearly quantitative yields of a single acylated product **4d**. It can be suggested that the acylation reaction is controlled, in this case, by steric hindrances alone, owing to the reduced number of rotational degrees of freedom of an unsaturated vs. saturated fatty acid chain. When, in fact, some of the rotational degrees of freedom are frozen by the introduction of a *cis*-9,10 double bond into the aliphatic chain, the reactivity of the fatty acid (**2d**) becomes similar to that of **2a**, within the expected experimental error made in determining the end of the reaction. When Method B is used, the acylating agent should likely be the mixed anhydride **5** (16) (Scheme 2). The latter reacts with the hydroxyl groups of the sugar substrate displacing the phosphodiester moiety which is a leaving group as good as the chloride ion (Method A). The kinetics of ester formation therefore might follow the same trend verified when acyl chlorides were used. Conversely, the derivatization of the substrate becomes more difficult on going from **3c** to **3d**. The increasing bulkiness experienced when acids **3a–c** were used could explain, by analogy with similar systems (17), the observed trend. The anomalous behavior of oleic acid (**3d**) might be due to factors, not clearly understood, which prevent the formation of the reacting mixed anhydride (**5**, Scheme 2).

The unprotected target molecules were obtained by removing the 1,2-isopropylidene protecting group in carefully controlled conditions in order to minimize the possible concomitant acid-catalyzed hydrolysis of the ester function.

Trifluoroacetic acid in tetrahydrofuran/water (4:1, vol/vol) at room temperature (8,35) left the molecules unchanged. Treatment of **4a–d** with 1 N sulfuric acid at 100°C did not give satisfactory results, whereas the degradation risk was too high (Scheme 3). The employment of BCl_3 (36) has been rejected to avoid deacylation. Finally the best results have been obtained by means of 70% aqueous acetic acid at 70°C for 20–40 h (Table 2) (37). The pyranoses **6a–d** have been obtained as mixture of α and β anomers, as detected by high-performance liquid chromatography (HPLC) analysis and ^1H nuclear magnetic resonance (NMR) spectroscopy. The lower yields observed in the deblocking of the dioxolane ring when the monosaccharide was esterified with an aliphatic carboxylic acid are due to the concomitant hydrolysis of the ester function which is more acid-labile than in the case of the derivative **4a**.

The regioselective formation of monosaccharide esters with long-chain fatty acids is considered a difficult task which can be fulfilled by adopting special conditions (27). The results discussed above show a very simple strategy, whereby these surfactant molecules of potential pharmacological and industrial interest can be synthesized by applying very simple chemical methodologies.

EXPERIMENTAL PROCEDURES

BOP-Cl and 1,2-isopropylidene-D-glucofuranose are commercially available or can be easily prepared as previously reported (18–23). Pyridine was distilled from calcium hydride and stored under nitrogen. Precoated silica gel plates were used for thin-layer chromatography (TLC) and Kieselgel 60 H (Merck, Gibbstone, NJ) without gypsum was used for short-column chromatography. HPLC system: BIOLC (Dionex, Sunnyvale, CA), sample loop: 20 µL, column 250 × 4.6 mm, Chromospher C_{18} 5 µm Chrompack; detection: ultraviolet 272 nm, Dionex (variable wavelength). Solvent A, 1% HOAc aq.; B, MeOH; 15% B in A to 30% B in A in 15 min; 30% B in A, 5 min; 30% B in A to 100% B in 5 min; 100% B, 5 min; 100% B to 15% B in A in 5 min; flow, 0.8 mL min^{-1}. NMR spectra were obtained from WM-300 Bruker spectrometer (Karlsruhe, Germany) with tetramethylsilane (TMS) as internal standard and hexadeuterodimethylsulfoxide or trideuteromethyl alcohol as solvents; *J* values are given in Hz. Structural assignments have been made after extensive decoupling experiments. Fast-atom bombardment (FAB)–mass spectra (MS) were obtained on a VG-micromass ZAB 2F mass spectrometer (Manchester, United Kingdom), from 2 mm^3 of *m*-nitrobenzyl alcohol or glycerol solution of sample by using the standard gun operated with neutral xenon beam of 8 keV and a neutral current of 10 µA. Melting points have been determined by Koefler hot-stage (Koefler Reichardt, Vienna, Austria) and are uncorrected.

*Synthesis of 6-*O*-acyl-1,2-isopropylidene-*D*-glucofuranoses* **4a–d**. *Method A*. A solution of **1** (0.22 g; 1.0 mmol) in dry pyridine (20 cm^3) was evaporated twice to half volume to allow azeotropic removal of traces of water. The appropriate acid chloride **2a–d** (1.25 mmol) was then added, and the mixture was stirred at room temperature for 2–6 h until a nearly complete conversion of **1** was achieved [TLC: $CHCl_3$–MeOH (90:10, vol/vol)]. Saturated aqueous $NaHCO_3$ (10 cm^3) was then added and the mixture was extracted first with ethyl ether (3 × 15 cm^3), to prevent the formation of emulsion, and then partitioned with $CHCl_3$ (3 × 15 cm^3). The chloroform layers were washed with brine and then evaporated to dryness (the pyridine present was removed by azeotropic distillation with toluene) to afford an oily residue, which was purified by short-column chromatography [$CHCl_3$–MeOH (97.5:2.5, vol/vol)] to give the products **4a–d** (Table 1).

Method B. A solution of **1** (0.22 g; 1.0 mmol) and appropriated carboxylic acid **3a–d** (1.20 mmol) in dry pyridine (20 cm^3) was evaporated twice to half volume as reported above. BOP-Cl (0.64 g; 2.5 mmol) was then added, and the mixture was stirred at room temperature for 2–24 h (Table 1). The workup and the purification of the crude final mixture were performed as for Method A.

*Synthesis of 6-*O*-acyl-α,β-*D*-glucopyranoses* **6a–d**. A solution of **4a–d** (0.50 mmol) in 70% HOAc aq. (10 cm^3) was stirred at 70°C until a nearly complete conversion of **4a–d** was achieved [TLC: $CHCl_3$–MeOH (90:10, vol/vol)]. The HOAc was removed by azeotropic distillation with toluene and the oily residue, which was purified by short-column chromatography [$CHCl_3$–MeOH (97.5:2.5, vol/vol)] to give the products **6a–d** (Table 2). The α and β isomers are clearly distinguishable by HPLC and could be separated.

*6-*O*-benzoyl-α,β-*D*-glucopyranose* **6a** *(α/β = 55:45).* ^{1}H NMR (300 MHz, [D_6]CD_3OD, 25°C, TMS): δ = 8.07 (2Hα and 2Hβ; ArH); 7.37–7.61 (3Hα and 3Hβ; ArH); 5.12 [*d*, $^3J(H_{1\alpha},H_{2\alpha})$ = 3.8, 1H; $H_{1\alpha}$]; 4.65 [*dd*, $^2J(H_{6a\beta},H_{6b\beta})$ = 11.9, $^3J(H_{6a\beta},H_5)$ = 2.1, 1H; $H_{6a\beta}$]; 4.58 [*dd*, $^2J(H_{6a\alpha},H_{6b\alpha})$ = 11.9, $^3J(H_{6a\alpha},H_5)$ = 2.3, 1H; $H_{6a\alpha}$]; 4.55 [*d*, $^3J(H_{1\beta},H_{2\beta})$ = 7.8, 1H; $H_{1\beta}$]; 4.55 [*m*, 2H, $H_{6b\alpha}$ and $H_{6b\beta}$]; 4.12 (*m*, 1H; $H_{5\alpha}$); 3.73 [*dd*, $^3J(H_2,H_3)$ = 9.3, $^3J(H_3,H_4)$ = 9.3, 1H; $H_{3\alpha}$]; 3.64 (*m*, 1H; $H_{5\beta}$); 3.37–3.48 (*m*, 4H; $H_{2\alpha}$, $H_{4\alpha}$, $H_{3\beta}$, $H_{4\beta}$); 3.20 [*dd*, $^3J(H_1,H_2)$ = 7.8, $^3J(H_2,H_3)$ = 9.0, 1H; $H_{2\beta}$]. ABSTRACT: The methanolic extract of the marine sponge *Ircinia felix* has yielded nine novel fatty acid esters, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin (5*Z*, 9*Z*)-22-methyltricosadienoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin (5*Z*, 9*Z*)-tetracosadienoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin hexadecanoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 10-methylhexadecanoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 15-methylhexadecanoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 14-methylhexadecanoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 9-octadecenoate, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin octadecanoate, and (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 2,11-dimethyloctadecanoate, along with the recently described (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 11-methyloctadecanoate. The characterization of the new fatty acids (5*Z*, 9*Z*)-22-methyltricosadienoic and 2,11-dimethyloctadecanoic acids is also described. The chemical structures were determined by extensive spectroscopic, chromatographic, and chemical analyses.
Lipids 32, 565–569 (1997).

Marine sponges of the genus *Ircinia* (order Dictyoceratida) are known as common sources of furanosesterterpene tetronic acids and of linear C_{21} furanoterpenes (1,2). During the course of our studies on *I. felix*, *I. campana,* and *I. strobilina* occurring in the Colombian Caribbean coast, we recently reported (3,4) on the occurrence of (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin as the major antimicrobial furanosesterterpene tetronic acid in the three *Ircinia* sponges examined, followed by medium levels of (8*E*, 13*Z*, 18*R*, 20*Z*)-strobilinin, (7*E*, 13*Z*, 18*R*, 20*Z*)-felixinin and lesser amounts of (8*Z*, 13*Z*, 18*R*, 20*Z*)-strobilinin and (7*Z*, 13*Z*, 18*R*, 20*Z*)-felixinin. More recently we detected in *I. felix* a complex mixture of fatty acid esters of furanosesterterpene tetronic acids, of which only the novel variabilin 11-methyloctadecanoate has so far been reported (5).

To continue our studies on *I. felix* collected in the Colombian Caribbean, we reisolated the furanosesterterpene tetronic acid fatty acid ester mixture in order to identify the rest of the esters present in this marine sponge. Thus, in this paper we report on the isolation of nine novel fatty acid esters of (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin as major components of the above-mentioned mixture along with two new fatty acids, whose chemical structures were determined by spectroscopic, chromatographic, and chemical analyses.

MATERIALS AND METHODS

Materials. All solvents used were of high purity at purchase (Merck, Darmstadt, Germany) and were redistilled before use.

Samples. Ircinia felix was collected by SCUBA at Santa Marta Bay on the Caribbean coast of Colombia, at a depth of 15–20 m. Voucher specimens have been deposited in the reference collection of the Instituto de Investigaciones Marinas de Punta Betín, Colombia. Local populations have been described by Zea (6).

Variabilin fatty acid esters extraction. A sample of thawed sponge (1.8 kg) was soaked in methanol (2 L) for 24 h and filtered. After concentration of the extract, it was partitioned between ethyl acetate/water (2:1, vol/vol). The organic layer was dried, and removal of the solvent yielded a brown residue (19.4 g). Part of this residue (4.4 g) was subjected to column chromatography on silica gel, eluting with hexane/ethyl acetate (5:1, vol/vol) to give 19 mg of crude variabilin fatty acid ester mixture. Although this fraction was detected as a single spot by thin-layer chromatography (TLC) analysis on silica gel, reversed-phase high-performance liquid chromatography (RP-HPLC) revealed it to be a complex mixture of esters which were separated on a preparative ODS HPLC column and identified on the basis of spectral, chromatographic, and chemical evidence.

High-performance liquid chromatography (HPLC). Preparative HPLC was performed on a Shimadzu Techno-Research PREP-ODS(H) column (250 × 20 mm i.d., 5 μm) using a Shimadzu Liquid Chromatograph 6A (Kyoto, Japan) and a Shimadzu SDD-6A ultraviolet (UV)-visible detector monitoring at 270 nm, with methanol as mobile phase (flow rate 5 mL/min). Fractions were collected as indicated by dotted lines in Figure 1.

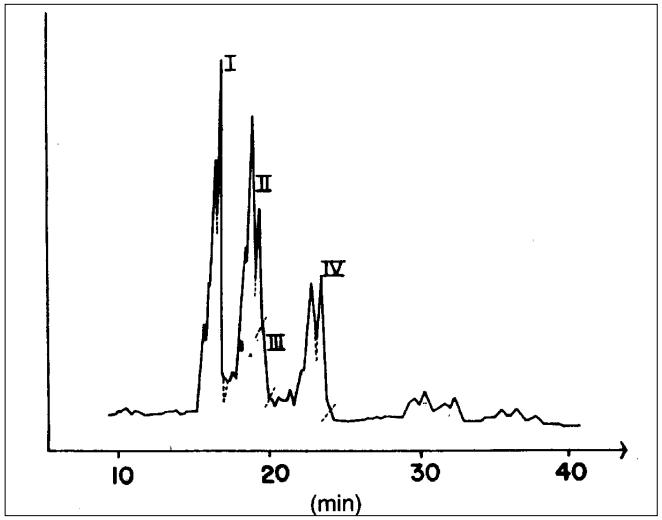

FIG. 1. High-performance liquid chromatography of the furanosesterterpene tetronic acid fatty acid ester mixture isolated from the marine sponge *Ircinia felix* on a PREP-ODS(H) column (250 × 20 mm i.d., 5 μm) (Shimadzu, Kyoto, Japan). Elution conditions are given in the Materials and Methods section. Fractions I–IV were as indicated by the dotted line, collected by monitoring at 270 nm.

Spectroscopic analyses of variabilin fatty acid esters. Fatty acid furanosesterterpene tetronic acids isolated by HPLC were subjected to analyses by absorption UV, electron impact–mass spectrometry (EI–MS) and/or fast atom bombardment–MS (FAB–MS) and ^{1}H nuclear magnetic resonance (NMR). UV spectra of methanol solutions were taken on a Beckman 25 instrument (Fullerton, CA). The mass spectra were determined with a Jeol AX505HA (Tokyo, Japan) instrument in the electron impact and/or in the FAB mode. In the former case 70 eV as electron energy was employed, maintaining the ion source at 305 C. A matrix of 3-nitrobenzyl alcohol (NBA), emission current of 10 mA, and an accelerating voltage of 6 KeV were used during MS in the FAB mode. ^{1}H NMR spectra ($CDCl_3$) were obtained using a Jeol JNM-EX400 instrument at 400 MHz. Chemical shifts are given in ppm relative to tetramethylsilane as internal standard.

Acid hydrolysis of the separated variabilin fatty acid esters. Each of the fatty acid ester fractions (about 1 mg each) isolated by HPLC was treated with 5 mL of 2 N HCl in methanol for 2 h. The hydrolysis products (furanosesterterpene tetronic acids and fatty acids) were extracted with diethyl ether. Half of this extract was derivatized with CH_2N_2 to afford the fatty acid methyl ester and the furanosesterterpene tetronic acid methyl ether derivatives which were characterized by capillary gas chromatography (GC) and capillary GC/MS analyses. Subsequently one part of the fatty acid methyl ester derivatives was converted into *N*-acyl pyrrolidides (7), and the other part was tranformed into *p*-bromophenacyl ester derivatives (obtained by treating the fatty acid methyl esters with *p*-bromophenacylbromide and diisopropylethylamine in methanol, followed by HPLC purification). The pyrrolidide derivatives were analyzed by capillary GC and capillary GC/MS and the *p*-bromophenacyl esters by ^{1}H NMR under the same conditions and instruments described above for variabilin fatty acid esters. The other part of the hydrolysate was treated with acetic anhydride/pyridine (1:1, vol/vol) giving variabilin acetate which was characterized by direct comparison on HPLC with an authentic sample of (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin acetate.

Capillary GC analyses. The fatty acid methyl esters and the variabilin methyl ether were analyzed by GC using a Hewlett-Packard 5890 (Palo Alto, CA) gas chromatograph series II with flame-ionization detector (FID) equipped with a Hewlett-Packard crosslinked OV-101 fused silica capillary column (25 m × 0.25 mm i.d.; film thickness, 0.25 μm). The temperature program was started at 170°C and raised at 2°C/min to 270°C. Flow rates of carrier and make-up gases were 1 mL/min and 30 mL/min, respectively. Detector and injector temperatures were kept at 250 and 300°C, respectively. The *N*-acyl pyrrolidides were analyzed under the same conditions used for the methyl esters except that the column temperature program was started at 230°C and raised at 4°C/min to 290°C.

Capillary GC/MS analyses. The GC/MS analyses were carried out on a Hewlett-Packard 5970 mass selective detector directly coupled to a Hewlett-Packard 5890 gas chromatograph series II, using the same conditions as mentioned above for capillary GC analyses of methyl ester and pyrrolidide derivatives. Other MS conditions were as follows: electron energy 70 eV and mass range 30–500. Below are the complete spectral data for the new esters.

Fraction I [(7*E*, 12*E*, 18*R*, 20*Z*)-Variabilin 22-methyl-5,9-tricosadienoate, **1,** + (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 5,9-tetracosadienoate, **2**)]. Colorless oil; UV and ^{1}H NMR data, *cf.* the Results and Discussion section. Acid hydrolysis of fraction I yielded 22-methyl-5,9-tricosadienoic acid, 5,9-tetracosadienoic acid and (7*E*, 12*E*, 20*Z*)-variabilin whose spectral data in their derivatized form are as follows: 22-methyl-5,9-tricosadienoic acid methyl ester: equivalent chain length (ECL) = 22.94; MS *m/z* (relative intensity) 378 (M^+, 19), 347 (9), 346 (10), 329 (4), 318 (1), 304 (8), 281 (22), 250 (7), 236 (11), 208 (15), 207 (27), 191 (9), 181 (11), 167 (10), 164 (10), 150 (23), 141 (44), 136 (22), 121 (17), 109 (45), 96 (33), 95 (35), 85 (12), 81 (100), 74 (21), 71 (23), 69 (51), 68 (34), 67 (76), 57 (42), 55 (80). *N*-(22-methyl-5,9-tricosadienoyl)-pyrrolidide: MS *m/z* (relative intensity) 417 (M^+, 2), 234 (5), 220 (1), 206 (1), 194 (1), 180 (16), 166 (1), 152 (1), 140 (1), 126 (13), 113 (100), 98 (25), 84 (10), 81 (5), 72 (25), 70 (20), 55 (50), 43 (70), 41 (40). 22-Methyl-5,9-tricosadienoic acid *p*-bromophenacyl ester: ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.86 (6H, *d*, *J* = 6.8 Hz, 22-Me, 23-Me), 1.26 (intense *br s*), 1.70 (2H, *qui*, *J* = 6.8 Hz, 3-H), 2.02 (2H, *q*, *J* = 6.8 Hz, 11-H), 2.08 (4H, *m*, 7-H, 8-H), 2.13 (2H, *q*, *J* = 6.8 Hz, 4-H), 2.48 (2H, *t*, *J* = 6.8 Hz, 2-H), 5.29 (2H, *s*), 5.32–5.46 (4H, *m*, 5-H, 6-H, 9-H, 10-H), 7.64 (2H, *d*, *J* = 7.8 Hz), 7.79 (2H, *d*, *J* = 7.8 Hz). ECL and MS data of 5,9-tetracosadienoic acid methyl ester and pyrrolidide were in good agreement with those previously reported (8,9). 5,9-Tetracosadienoic acid *p*-bromophenacyl ester: ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.88 (3H, *t*, *J* = 6.8 Hz, 24-Me), 1.26 (intense *br s*), 1.70 (2H, *qui*, *J* = 6.8

Hz, 3-H), 2.02 (2H, *q*, *J* = 6.8 Hz, 11-H), 2.08 (4H, *m*, 7-H, 8-H), 2.13 (2H, *q*, *J* = 6.8 Hz, 4-H), 2.49 (2H, *t*, *J* = 6.8 Hz, 2-H), 5.29 (2H, *s*), 5.32–5.46 (4H, *m*, 5-H, 6-H, 9-H, 10-H), 7.64 (2H, *d*, *J* = 7.8 Hz), 7.79 (2H, *d*, *J* = 7.8 Hz). (7*E*, 12*E*, 20*Z*)-Variabilin methyl ether: retention time (RT) in capillary GC = 35.3 min; MS *m/z* (relative intensity) 412 (M^+, 8), 397 (5), 331 (2), 203 (5), 167 (44), 149 (20), 135 (45), 123 (30), 109 (14), 95 (15), 81 (100), 69 (30), 55 (28). (7*E*, 12*E*, 20*Z*)-Variabilin acetate: RT in HPLC = 11.8 min.

Fraction II [(7*E*, 12*E*, 18*R*, 20*Z*)-variabilin hexadecanoate, **3**, + (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 10-methylhexadecanoate, **4**)]. Colorless oil. UV (λ_{max} 275 nm); FAB–MS data, the Results and Discussion section; ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.84 (*d*, *J* = 6.8 Hz), 0.88 (*t*, *J* = 6.4 Hz), 1.05 (*d*, *J* = 6.4 Hz), 1.26 (intense *br s*), 1.55 (*s*), 1.58 (*s*), 1.70 (*qui*, *J* = 6.8 Hz), 1.81 (*s*), 2.60 (*t*, *J* = 6.4 Hz), 2.82 (*m*), 5.04 (*d*, *J* = 9.8 Hz), 5.08 (*t*, *J* = 6.8 Hz), 5.17 (*t*, *J* = 6.8 Hz), 6.28 (*s*), 7.20 (*s*), 7.34 (*s*). Hydrolysis of fraction II yielded hexadecanoic acid, 10-methylhexadecanoic acid, and (7*E*, 12*E*, 20*Z*)-variabilin. ECL and MS data of hexadecanoic acid derivatives (methyl ester and pyrrolidide) were the same as reported by Duque *et al.* (8). Hexadecanoic acid *p*-bromophenacyl ester: ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.88 (3H, *t*, *J* = 6.8 Hz, 16-Me), 1.26 (intense *br s*), 1.70 (2H, *qui*, *J* = 6.8 Hz, 3-H), 2.48 (2H, *t*, *J* = 6.8 Hz, 2-H), 5.29 (2H, *s*), 7.64 (2H, *d*, *J* = 7.8 Hz), 7.79 (2H, *d*, *J* = 7.8 Hz). ECL and MS data of 10-methylhexadecanoic acid methyl ester and pyrrolidide are in good agreement with those reported previously by us (8). 10-Methylhexadecanoic acid *p*-bromophenacyl ester: ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.83 (3H, *d*, *J* = 6.8 Hz, 10-Me), 0.88 (3H, *t*, *J* = 6.8 Hz, 16-Me), 1.26 (intense *br s*), 1.70 (2H, qui, *J* = 6.8 Hz, 3-H), 2.49 (2H, *t*, *J* = 6.8 Hz, 2-H), 5.29 (2H, *s*), 7.64 (2H, *d*, *J* = 7.8 Hz), 7.79 (2H, *d*, *J* = 7.8 Hz). GC, GC/MS and HPLC data of (7*E*, 12*E*, 20*Z*)-variabilin methyl ether and acetate derivatives were found to be the same as for fraction I.

Fraction III [(7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 15-methylhexadecanoate, **5**, + (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 14-methylhexadecanoate, **6**)]. Colorless oil. UV (λ_{max} 275 nm); EI–MS spectrum showed only the characteristic fragments of the (7*E*, 12*E*, 20*Z*)-variabilin moiety (3); ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.86 (*d*, *J* = 6.4 Hz), 0.88 (*t*, *J* = 6.4 Hz), 1.05 (*d*, *J* = 6.8 Hz), 1.26 (intense *br s*), 1.55 (*s*), 1.58 (*s*), 1.70 (*qui*, *J* = 6.8 Hz), 1.81 (*s*), 2.60 (*t*, *J* = 6.4 Hz), 2.82 (*m*), 5.04 (*d*, *J* = 9.8 Hz), 5.08 (*t*, *J* = 6.8 Hz), 5.17 (*t*, *J* = 6.8 Hz), 6.28 (*s*), 7.20 (*s*), 7.34 (*s*). Hydrolysis of fraction III yielded 15-methylhexadecanoic acid, 14-methylhexadecanoic acid, and (7*E*, 12*E*, 20*Z*)-variabilin. ECL and GC/MS data of methyl ester and pyrrolidide derivatives of 15-methylhexadecanoic and of 14-methylhexadecanoic were the same as reported by Duque *et al.* (8). 15-Methylhexadecanoic acid *p*-bromophenacyl ester: ^{1}H NMR (400 MHZ, $CDCl_3$) δ 0.86 (6H, *d*, *J* = 6.8 Hz, 15-Me, 16-Me), 1.26 (intense *br s*), 1.70 (2H, *qui*, *J* = 6.8 Hz, 3-H), 2.48 (2H, *t*, *J* = 6.8 Hz, 2-H), 5.29 (2H, *s*), 7.64 (2H, *d*, *J* = 7.8 Hz), 7.79 (2H, *d*, *J* = 7.8 Hz). GC, GC/MS, and HPLC data of (7*E*, 12*E*, 20*Z*)-variabilin methyl ether and acetate derivatives were the same as reported for fraction I.

Fraction IV [(7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 9-octadecenoate, **7**, + (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin octadecanoate, **8**, + (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 11-methyloctadecanoate, **9**, + (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 2,11-dimethyloctadecanoate, **10**)]. Colorless oil. UV (λ_{max} 275 nm); FAB–MS *m/z* (relative intensity) 693 ($[M + H]^+$, 1), 679 ($[M + H]^+$, 5), 665 ($[M + H]^+$, 1), 663 ($[M + H]^+$, 1); ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.84 (*d*, *J* = 6.8 Hz), 0.88 (*t*, *J* = 6.4 Hz), 1.05 (*d*, *J* = 6.4 Hz), 1.26 (intense *br s*), 1.55 (*s*), 1.58 (*s*), 1.70 (*qui*, *J* = 6.8 Hz), 1.81 (*s*), 2.60 (*t*, *J* = 6.4 Hz), 2.82 (*m*), 5.04 (*d*, *J* = 10.8 Hz), 5.08 (*t*, *J* = 6.8 Hz), 5.17 (*t*, *J* = 6.8 Hz), 6.28 (*s*), 7.20 (*s*), 7.34 (*s*). Hydrolysis of fraction IV afforded 9-octadecenoic acid, octadecanoic acid, 11-methyloctadecanoic acid, 2,11-dimethyloctadecanoic acid, and (7*E*, 12*E*, 20*Z*)-variabilin. ECL and GC/MS data of 9-octadecenoic acid and octadecanoic acid derivatives (methyl esters and pyrrolidides) were in good agreement with those reported (8–10). ECL and GC/MS data of 11-methyloctadecanoic acid (methyl ester and pyrrolidide derivatives) and ^{1}H NMR data of 11-methyloctadecanoic acid *p*-bromophenacyl ester were the same as reported by Martínez *et al.* (5). 2,11-Dimethyloctadecanoic acid methyl ester: ECL = 19.14, MS *m/z* (relative intensity) 326 (M^+, 25), 297 (1), 283 (19), 269 (3), 255 (2), 241 (4), 227 (17), 213 (4), 199 (20), 185 (5), 171 (8), 157 (40), 143 (14), 129 (6), 115 (17), 101 (83), 88 (100), 85 (22), 83 (24), 71 (28), 69 (34), 57 (39), 55 (50). GC, GC/MS and HPLC data of (7*E*, 12*E*, 20*Z*)-variabilin methyl ether and acetate derivatives were the same as reported for fraction I.

RESULTS AND DISCUSSION

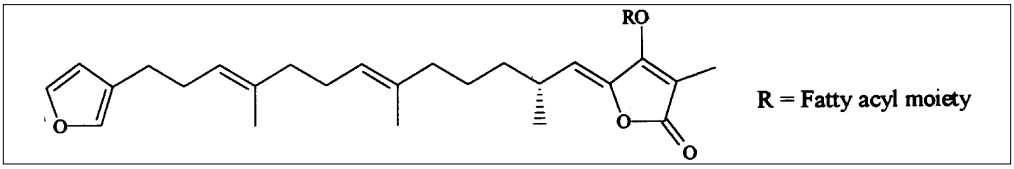
As seen in Table 1, HPLC analysis of the fatty acid ester fraction obtained from the marine sponge *I. felix* showed it to be a highly complex mixture. Previously we have separated only one compound, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin 11-methyloctadecanoate, **9**, from this mixture (5). However, further investigation on the same ester mixture has resulted in the isolation and identification of nine new esters (compounds **1**–**8** and **10**). Compounds **1**–**10** (Table 1) constituted about 49.5% of the ester mixture. The esters and their hydrolyzed products were readily identified in fractions I–IV (Fig. 1) by chemical, chromatographic, and spectroscopic methods as described below.

Fraction I. FAB–MS spectrum of fraction I could not be obtained. However, UV (λ_{max} 275 nm) analysis and ^{1}H NMR spectrum showing the characteristic signals of (7*E*, 12*E*, 20*Z*)-variabilin acetate (3), e.g., δ 1.05 (*d*, *J* = 6.6 Hz), 1.55 (*s*), 1.58 (*s*), 1.82 (*s*), 2.82 (*m*), 5.04 (*d*, *J* = 10.8 Hz), 5.08 (*t*, *J* = 6.8 Hz), 5.17 (*t*, *J* = 6.8 Hz), 6.28 (*s*), 7.20 (*s*), and 7.33 (*s*), and additional signals for one primary and two secondary methyl groups, a triplet at δ 2.60 ppm (*J* = 6.8 Hz) corresponding to an α-methylene to a carbonyl group, a quintet at δ 1.70 ppm assignable to a β-methylene to a carbonyl, and a multiplet at δ 5.35 ppm due to the resonance of olefinic protons clearly indicated the presence of at least two variabilin fatty acid esters (compounds **1** and **2**). Hydrolysis of fraction I followed by treatment with CH_2N_2 afforded 22-methyl-5,9-

TABLE 1.
Fatty Acid Esters of (7*E*, 12*E*, 18*R*, 20*Z*)-Variabilin from the Marine Sponge *Ircinia felix*

Compound number	Fatty acid linked to (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin[a]	Molecular weight	Abundance[b] (%)
1	(5*Z*, 9*Z*)-22-Methyltricosadienoic[c]	744	7.2
2	(5*Z*, 9*Z*)-Tetracosadienoic	744	13.7
3	*n*-Hexadecanoic	636	7.9
4	10-Methylhexadecanoic	650	8.3
5	15-Methylhexadecanoic	650	0.7
6	14-Methylhexadecanoic	650	1.0
7	9-Octadecenoic	662	0.7
8	*n*-Octadecanoic	664	0.5
9	11-Methyloctadecanoic	678	7.3
10	2,11-Dimethyloctadecanoic[c]	692	2.2

[a]



[b]In total isolated esters.
[c]Fatty acids reported here by the first time in nature.

tricosadienoic (M^+ 378, ECL = 22.94) and 5,9-tetracosadienoic (M^+ 378, ECL = 23.56) (8) methyl esters (characterized by capillary GC and capillary GC/MS analyses), and (7*E*, 12*E*, 20*Z*)-variabilin methyl ether which was also identified by capillary GC and GC/MS. Evidence for the location of the double bonds was obtained from the intense fragments at *m/z* 126 and 234 (allylic cleavages of the 3-4 and 11-12 bonds) and at *m/z* 180 (bisallylic cleavage of the 7-8 bond) in the pyrrolidide derivative mass spectra of 22-methyl-5,9-tricosadienoic and 5,9-tetracosadienoic acids. Double-bond unsaturations at C-5 and C-9 were also recognized in the pyrrolidide mass spectra of both derivatives due to a separation of 12 amu between fragments at *m/z* 140 and 152, and at *m/z* 194 and 206. It is known from the mass spectra of fatty acid pyrrolidides that if an interval of 12 amu, instead of the regular 14, is observed between the most intense peaks of clusters of fragments containing *n* and $n - 1$ carbon atoms in the acid moiety, then a double bond was present between carbon *n* and $n + 1$ in the molecule (7). The final evidence for the fatty acid structures was given by the ^{1}H NMR spectra of their *p*-bromophenacyl ester derivatives. The *p*-bromophenacyl ester of acid derived from **1** showed a signal at δ 0.86 ppm (6H, *d*, *J* = 6.8 Hz) due to 22- and 23-methyl groups in the ^{1}H NMR, whereas the same ester derived from **2** exhibited a signal at δ 0.88 ppm (3H, *t*, *J* = 6.8 Hz) due to a terminal methyl group. The geometry of the olefinic bonds was deduced from ^{1}H NMR spectral comparison of the two *p*-bromophenacyl esters (400 MHz) with methyl 22-methyl-5*Z*, 9*Z*-octacosadienoate (9). The chemical shifts (δ 5.32–5.46 ppm) as well as the shapes of the olefinic protons (H-5, -6, -9, and -10) of the *p*-bromophenacyl esters were essentially identical with those of the reference spectrum. Further, the chemical shifts and shapes of the allylic methylene protons (δ 2.08 ppm for H-7 and H-8, and δ 2.02 for H-11) were also closely similar to those of the reference spectrum. The methylene protons ascribable to C-2, C-3, and C-4 resonated at slightly shifted positions compared to the respective protons in the reference spectrum because of the difference in the ester group. These data are in support of a 5*Z*, 9*Z*-olefinic structure for the fatty acid portion of **1** and **2**. Additionally the alcoholic portion of the two esters of fraction I was also confirmed by treatment of the other part of the hydrolysate with Ac_2O-pyridine to afford (7*E*, 12*E*, 20*Z*)-variabilin acetate which was characterized as such by direct comparison on HPLC with an authentic sample. Based on these analyses, the structures of compounds **1** and **2** were established as (7*E*, 12*E*, 20*Z*)-variabilin (5*Z*, 9*Z*)-22-methyltricosadienoate and (7*E*, 12*E*, 20*Z*)-variabilin (5*Z*, 9*Z*)-tetracosadienoate, respectively.

Fraction II. FAB–MS spectrum of the separated fraction II exhibited two pseudomolecular ions $(M + H)^+$ at *m/z*: 637 and 651, indicating the presence of two furanosesterterpene esters (compounds **3** and **4**) of molecular formulas $C_{41}H_{64}O_5$ (the acid portion being a saturated C_{16}-acid) and $C_{42}H_{66}O_5$ (the acid portion being a saturated C_{17}-acid), respectively. The UV and ^{1}H NMR spectra clearly indicated the structure of (7*E*, 12*E*, 20*Z*)-variabilin for the alcoholic part and saturated fatty acids for the acyl moieties of compounds **3** and **4**. Alkaline hydrolysis followed by derivatization (methyl esters, pyrrolidides, and *p*-bromophenacylesters for the fatty acids and methyl ether and acetate for the furanosesterterpenyl moiety) afforded *n*-hexadecanoic and 10-methylhexadecanoic acids which were characterized by capillary GC and capillary GC/MS (8) and ^{1}H NMR analyses, and (7*E*, 12*E*, 20*Z*)-variabilin identified by capillary GC, GC/MS, and by direct comparison with an authentic sample in HPLC. These analyses clearly supported the structure of compound **3** as (7*E*, 12*E*, 20*Z*)-variabilin *n*-hexadecanoate and of compound **4** as (7*E*, 12*E*, 20*Z*)-variabilin 10-methylhexadecanoate.

Fractions III and IV. Fraction III was found to be composed of compounds **5** and **6** using the same methods as described above, and their structures were determined as (7*E*, 12*E*, 20*Z*)-variabilin 15-methylhexadecanoate and (7*E*, 12*E*, 20*Z*)-variabilin 14-methylhexadecanoate, respectively. Finally, investigation of fraction IV showed it to be a mixture of (7*E*, 12*E*, 20*Z*)-variabilin 9-octadecenoate, **7**; (7*E*, 12*E*, 20*Z*)-variabilin *n*-octadecanoate, **8**; (7*E*, 12*E*, 20*Z*)-variabilin 11-methyloctadecanoate, **9**; and (7*E*, 12*E*, 20*Z*)-variabilin 2,11-dimethyloctadecanoate, **10**. The 2,11-dimethyloctadecanoic acid was readily characterized by the analysis of its mass spectrum as methyl ester derivative. The molecular ion at *m/z* 326 was consistent with the molecular formula $C_{21}H_{42}O_2$, the fragment ion at *m/z* 88 indicated an acyl moiety having methyl substitution at C-2, and the intense fragments *m/z* 227 and 199, simultaneously with the diminished C_{11} fragment *m/z* 213, clearly showed 11-methyl branching.

The C-18 configuration for the ten (7*E*, 12*E*, 20*Z*)-variabilin fatty acid esters isolated from *I. felix* could be reasonably assigned as *R* based on the fact that this species contains enantiomerically pure (18*R*)-(7*E*, 12*E*, 20*Z*)-variabilin as the free form, and hydrolysis of a crude variabilin fatty acid mixture followed by acetylation and HPLC separation afforded (+)-(18*R*)-variabilin acetate (3).

We have recently characterized five furanosesterterpene tetronic acids, (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin, (7*E*, 13*Z*, 18*R*, 20*Z*)-felixinin, (8*E*, 13*Z*, 18*R*, 20*Z*)-strobilinin, (7*Z*, 13*Z*, 18*R*, 20*Z*)-felixinin, and (8*Z*, 13*Z*, 18*R*, 20*Z*)-strobilinin in the methanolic extract of *I. felix* (4). It is therefore reasonable to assume that the other four furanosesterterpenes occur in fatty acid bound form as well. Indeed, these furanosesterterpenes were identified in the hydrolysate of the total ester mixture in the present study (data not shown). A variety of combinations of the five furanosesterterpenes and 10 (or more) fatty acids could account for the complex HPLC pattern (Fig. 1).

Linear sesterterpenes characterized by a furan ring at one end and by a conjugated tetronic acid at the other, e.g., (7*E*, 12*E*, 20*Z*)-variabilin, are common natural products in marine sponges of the genus *Ircinia*. Similarly, most of the fatty acids [except (5*Z*, 9*Z*)-22-methyltricosadienoic acid and 2,11-dimethyloctadecanoate] bound to (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin had already been detected as phospholipid components in *Ircinia* species (11) including *I. felix* collected from other Caribbean sites. However, the rare combination of fatty acids linked to (7*E*, 12*E*, 18*R*, 20*Z*)-variabilin has no precedent in nature, and, this paper reports for the first time the presence in nature of the (5*Z*, 9*Z*)-22-methyltricosadienoic and 2,11-dimethyloctadecanoic acids.

ACKNOWLEDGMENTS

This work was supported by COLCIENCIAS. A.M. thanks Universidad de Antioquia for granting his leave of absence to pursue Ph.D. studies. Collection and classification of the sponge were performed by Prof. S. Zea of Universidad Nacional de Colombia at Instituto de Investigaciones Marinas de Punta Betín for which we are grateful. The authors also thank Prof. M. Morisaki and N. Kobayashi of Kyoritsu College of Pharmacy for preliminary GC/MS analysis of the fatty acid methyl esters.

ABSTRACT: Fatty acyl-CoA affect many cellular functions as well as serving as cellular building blocks. Several families of cytosolic fatty acyl-CoA binding proteins may modulate the activities of fatty acyl-CoA. Intestinal enterocytes contain at least three unique families of cytosolic proteins that bind fatty acyl-CoA: acyl-CoA binding protein (ACBP), fatty acid binding proteins (including the liver, L-FABP and intestinal, I-FABP), and sterol carrier protein-2 (SCP-2). Immortalized rat colon epithelial cell lines expressed only ACBP and SCP-2 at levels of 0.75 ± 0.13 and 0.42 ± 0.02 ng/μg protein. *Ras* and *src* transformation increased colon cell density and differentially altered ACBP and SCP-2 expression without affecting I-FABP or L-FABP levels. ACBP levels were 1.8-fold and 1.5-fold increased in *ras*- and *src*-transformed cells, respectively. In contrast, SCP-2 expression was significantly decreased 55 and 67% in *ras*- and *src*-transformed cells, respectively. Butyrate treatment of *ras*- and *src*-transformed cells decreased cell proliferation up to 60–85% as compared to 25–30% in control cells. Butyrate treatment decreased ACBP expression in all cell lines but had no effect on the levels of SCP-2, I-FABP, or L-FABP. These studies suggest that the differential expression of ACBP and SCP-2 in rat colonic cell lines, as well as their modulation by butyrate, may be altered by cell transformation.

Lipids 32, 577–585 (1997).

Colorectal adenocarcinoma is one of the leading causes of death due to cancer in North America (1). A number of environmental and genetic factors have been associated with the development and progression of colon carcinoma. Genetic changes include loss of potential tumor suppressor genes as well as activation of oncogenes (2,3). Activation of K-*ras* by a point mutation occurs in >40–50% of colon carcinomas (3). Activation of the tyrosine kinase of the c-*src* gene product ($pp60^{c\text{-}src}$) is also common, and activation occurs early in tumor development for both of these oncogenes (2,3). Several animal models and *in vitro* systems have been developed for analysis of factors contributing to tumor progression. Due to the inability to maintain long-term cultures of normal colon epithelial cells *in vitro,* immortalized, nontumorigenic fetal rat colon epithelial cell lines have been developed as a model and several oncogenes introduced to produce transformed, neoplastic cell lines (4). This model is useful for examination of the effects of transformation on the expression of various proteins within the cells as well as effects of therapeutic agents on colon cell proliferation.

Butyrate is a volatile short-chain fatty acid which is a by-product of bacterial degradation of certain types of dietary fiber (5). It has growth inhibitory and differentiation effects on various cell types, including colon cells, *in vitro* (reviewed 6,7). Butyrate affects cell proliferation by inhibiting DNA synthesis and arresting cells in G1 phase of the cell cycle (7). *In vivo,* butyrate has trophic effects on normal colonic epithelium and may inhibit growth of neoplastic cells (reviewed 6,7). In one study using a rat model of experimental colon epithelial cell neoplasia, feeding of fiber associated with production of high levels of butyrate correlated with lower tumor mass (5). In addition, butyrate administered by intravenous infusion inhibited growth of malignant colon carcinoma cells metastatic to the liver in mice (7).

Acyl-CoA binding protein (ACBP), fatty acid binding proteins (FABP), and sterol carrier protein-2 (SCP-2) represent three families of low molecular weight, cytosolic proteins that bind fatty acyl-CoA, and *via* this interaction may have an effect on cell signaling pathways involved in cell proliferation (reviewed 8). ACBP is a 10 kDa protein that was first discovered in 1983 in the brain and designated diazepam binding inhibitor based upon its ability to modulate $GABA_A$ (γ-amino butyric acid) receptors (9). In 1987, the same protein, designated acyl CoA-binding protein, was isolated from bovine liver and found to induce the synthesis of medium-chain acyl-CoA (10). ACBP is highly conserved from yeasts to mammals and has been found in all mammalian tissues tested (reviewed 8). It is abundant in normal liver and intestinal tract, including the colon. Levels almost as high as seen in liver (0.15 nmol/g wet weight) have been determined in rabbit colon (0.11 nmol/g wet weight) (reviewed 8).

FABP such as liver-FABP (L-FABP) and intestinal-FABP

Abbreviations: ACBP, acyl-CoA binding protein; DMEM, Dulbecco's Minimal Essential Medium; FABP, fatty acid binding proteins; $GABA_A$, γ-amino butyric acid; I-FABP, intestinal fatty acid binding protein; L-FABP, liver fatty acid binding protein; PBR, peripheral benzodiazepine receptor; PBS, phosphate buffered saline; PMSF, phenylmethyl sulfonyl fluoride; PVDF, polyvinylidene fluoride; SCP-2, sterol carrier protein-2; TBS, tris buffered saline; TBST, tris buffered saline + 0.05% Tween 20.

(I-FABP) belong to a large group of proteins including over 17 distinct members (11). These proteins are normally present in high concentration within the cell cytoplasm and bind hydrophobic ligands such as fatty acids, prostaglandins, and fatty acyl-CoA (12). L-FABP is expressed in high abundance in normal liver and small intestine but in reduced levels in the colon (13). I-FABP, which binds fatty acids (14) and fatty acyl-CoA (8), is expressed only in the intestinal tract but also exhibits a gradient of expression so that low levels are found in normal stomach and colon (13). In addition, SCP-2, also known as nonspecific lipid transfer protein, binds such ligands as fatty acids, phospholipids, glycolipids, cholesterol, and fatty acyl-CoA (8,14–16). Two forms of the protein are detectable by immunostaining. The 58 kDa form is present only in peroxisomes, while the 15 and 13.2 kDa forms of the protein are present in cytosol, mitochondria, peroxisomes, and near the endoplasmic reticulum (17). The 15 kDa pro-SCP-2 is not often detected in tissues because it undergoes rapid posttranslational cleavage of an N-terminal leader fragment to yield the mature 13.2 kDa form (18). SCP-2 protein levels are highest in normal rat liver and intestinal mucosal epithelial cells, with lower levels in other tissues (17).

Of these four fatty acyl-CoA binding proteins, only L-FABP and I-FABP expression have been examined in colon adenomas and adenocarcinomas. Carroll *et al*. (19) showed decreased expression of L-FABP in human colorectal adenomas and adenocarcinomas by Western immunoblotting and a mosaic of L-FABP positive cells by immunohistochemistry. In another study with experimental rat colon adenocarcinoma, a 10-fold and 50-fold decrease in I-FABP and L-FABP mRNA, respectively, was observed when compared with normal colon mucosal epithelial cells (20). Immunohistochemical analysis confirmed the decreased expression of I-FABP and L-FABP protein and showed that expression occurred in isolated foci of epithelial cells. Results of these studies suggest that changes in FABP expression may occur early in tumor development (adenomas exhibited the same pattern of immunostaining as carcinomas) and that FABP expression depends upon differentiation and possibly proliferative capacity of the cells. The purpose of the present study was to examine the effects of transformation with *ras* and *src* oncogenes and the effects of butyrate treatment on the expression of the four fatty acyl-CoA binding proteins—ACBP, L-FABP, I-FABP, and SCP-2—on colon epithelial cells grown *in vitro*.

MATERIALS AND METHODS

Materials. Prestained low molecular weight protein standards were purchased from Gibco (Gaithersburg, MD). Phenylmethyl sulfonyl fluoride (PMSF), leupeptin, pepstatin-A, EDTA, Trizma base, SDS, 4-chloro-1-naphthol, acrylamide, *n,n*-methylene bis-acrylamide, bovine actin, mouse anti-actin monoclonal antibody, 85% phosphoric acid, Coomassie brilliant blue G250, glycerol, bovine serum albumin, William's Medium E, Dulbecco's Minimal Essential Medium (DMEM), insulin, hydrocortisone, and holo-transferrin were obtained from Sigma Chemical Company (St. Louis, MO). Glycine, Tween 20, Tricine, 2-mercaptoethanol, methanol, ethanol, polyvinylidene fluoride (PVDF), and all sterile, disposable, tissue culture plasticware were from Fisher Scientific (Pittsburgh, PA). Fetal bovine serum was from Hyclone Labs (Logan, UT). Horseradish peroxidase conjugated goat antirabbit IgG was purchased from Bio-Rad (Hercules, CA). Biotinylated goat antirabbit IgG, biotinylated goat antimouse IgG, ABC alkaline phosphatase kit, and Vector black substrate kit were from Vector (Burlingame, CA). Rat liver ACBP and recombinant I-FABP, L-FABP, and SCP-2 were purified as previously described (21–23). L-[4,5-^{3}H] leucine (52 Ci/mmol) was from NEN Products (Boston, MA).

Antibody production. Polyclonal rabbit antirat liver ACBP, rabbit antirecombinant I-FABP, rabbit antirecombinant L-FABP, and rabbit antirat liver SCP-2 antibodies were prepared using specific pathogen-free New Zealand White rabbits as described in Harlow and Lane (24). Antibodies directed against one protein were not crossreactive with the other proteins (25).

Cell culture. The fetal rat colon cell line immortalized with the SV40 large T antigen (FRC/TEX/CL4D), and the *ras* and *src* transformants of CL4D (FRC/TEX/*RAS* and FRC/TEX/*SRC*, respectively) were kindly provided by Dr. Ian Summerhayes (4). Stock cultures were grown in a humidified atmosphere of 5% CO_2 at 37°C in William's Medium E supplemented with 9% fetal bovine serum, 10^{-8} M insulin, 20 µg/L hydrocortisone, 120 µg/L transferrin, penicillin G 100 units/mL, and streptomycin 100 µg/mL.

Measurement of protein turnover. Rates of protein synthesis and degradation were measured as previously described (26). Briefly, the cells were passaged into 24-well multiwell plates and incubated in DMEM as described below. At 18 h after addition of 3 mM butyrate, the medium was changed to one of exactly the same formulation, but also containing 10 µCi/mL and 2 mM ^{3}H-leucine, and the cells were pulse-labeled for 3 h. Then the monolayer was rinsed three times with Earle's salts containing 2 mM leucine before the cells were incubated in DMEM containing 2 mM leucine for the 3-h protein breakdown measurement period. Rates of protein degradation (percentage in 3 h) are reported as the percentage of total radioactivity soluble in 10% trichloroacetic acid. Rates of protein synthesis were measured using exactly the same protocol except that ^{3}H-leucine (10 µCi/mL and 2 mM) was added during the 3-h measurement period. Rates of protein synthesis are reported as nmol leucine incorporated per 3 h per mg protein.

Preparation of cell samples for protein determination, gel electrophoresis, and immunoblotting. Cells were plated at 3×10^5 cells/100 mm Petri dish in DMEM containing 9% fetal bovine serum, 10^{-8} M insulin, 20 µg/L hydrocortisone, 120 µg/L transferrin, penicillin G 100 units/mL, and streptomycin 100 µg/mL. After 24 h, the medium was changed to one containing 1% serum, and 24 h later to one containing 9% serum with and without 3 mM sodium butyrate. After a further 24 h, when the cells were in logarithmic growth, the medium was

aspirated, the monolayer was rinsed twice with cold phosphate-buffered saline (PBS), the cells were scraped into 10 mL cold PBS and centrifuged at 100 × *g* for 3 min, and the cell pellet stored at −75°. Subsequently the pellet was thawed and 0.1 to 0.5 mL of a buffer containing 500 µM PMSF, 1 mM EDTA, 5 µg/mL leupeptin, and 15 µg/mL pepstatin-A was added. The pellet was then vortexed well followed by sonication for a total of 30 s at 35% maximum speed with a Sonic Dismembrator Model 300 (Fisher, Pittsburgh, PA) to lyse the cells.

Protein determination. Total protein was determined by the method of Bradford (27). Three aliquots of each cell lysate were analyzed and the mean total protein content determined using bovine serum albumin as the standard.

Tricine gel electrophoresis and immunoblotting. An aliquot of each sample was prepared for electrophoresis by the addition of an equal volume of buffer containing glycerol, 2-mercaptoethanol, 100 mM tris-HCl, SDS, and Coomassie G250. Samples (7.5–150 µg protein/lane) were electrophoresed in 16.5% tricine gels as described by Schagger and von Jagow (28). Proteins were transferred to PVDF membranes, the membranes allowed to air-dry 2 h at room temperature, and immunoblotting was performed. Briefly, the blots were blocked with 5% nonfat dry milk in tris-buffered saline + 0.05% Tween 20 (TBST), incubated with a 1:1000 dilution of the appropriate primary antibody (rabbit anti-ACBP, rabbit anti-I-FABP, rabbit anti-L-FABP, rabbit anti-SCP-2, or mouse anti-actin) in TBST for 12–14 h. After washing with TBST three times, one of two techniques was utilized, depending upon the sensitivity desired. In general, blots were incubated with horseradish peroxidase conjugated goat antirabbit IgG, washed with tris-buffered saline (TBS) three times and 4-chloro-1-naphthol used as the substrate. For greater sensitivity, blots were incubated with 1.5 µg/mL biotinylated goat antirabbit IgG or biotinylated goat antimouse IgG for 2–3 h, washed with TBST three times, incubated with avidin-biotin complex-alkaline phosphatase 1–3 h, washed three times with TBS, and developed with Vector black substrate kit.

Quantitation of proteins on immunoblots. Photographs of immunoblots were obtained using an IS-500 computerized gel documentation system (Alpha-Innotech, San Leandro, CA). From each image, protein bands from the colon cell preparations in each lane were quantitated by comparing to known amounts of protein standards loaded on the same blot by using an NIH Image 1.60 program on a Power MacIntosh 8100/80AV computer (written by Wayne Rasband at the U.S. National Institute of Health and available from the Internet by anonymous FTP from zippy.nimh.gov or on a floppy disk from NYIS, 5285 Port Royal Rd., Springfield, VA). Protein was expressed as ng/µg sample.

Statistical analysis. Three cell lines in the absence or presence of butyrate were analyzed for each of the following categories: control (immortalized colon cells), *ras*-transformed colon cells, and *src*-transformed colon cells. ACBP, I-FABP, L-FABP, SCP-2, and actin protein content were determined in each cell line (see above), and the mean ± SE determined for each category (n = 4–7 experiments for ACBP; n = 2–3 experiments with I-FABP, L-FABP, SCP-2, and actin). An unpaired Student's t-test was performed for comparison of control immortalized colon cells vs. *ras*- and *src*-transformed colon cells and for comparison of the effects of butyrate treatment on each cell line.

RESULTS

The immortalized control cell line, CL4D, grew with a doubling time of approximately 1 d to a density of 1×10^5 cells per cm^2 (approximately 50 µg total cell protein/cm^2). The *ras* and *src* transformed cell lines grew more rapidly (doubling times of 0.5–0.7 d) to cell densities 2–3 times those of the control cell line. In keeping with their higher rates of proliferation, the two transformed cell lines also had higher rates of protein synthesis and lower rates of protein breakdown (see below) as has been found previously for other comparisons of normal and transformed cells (26).

The expression of ACBP in control, *ras*-transformed, and *src*-transformed colon cell lines was determined as described in the Materials and Methods section. Protein content was determined for each band at 10 kDa in each lane by comparison to a panel of standards containing a known amount of ACBP, applied on the same immunoblot. ACBP was expressed in relatively high amounts in the control cells, 0.75 ± 0.13 ng/µg cell protein, similar to the level expressed in colon and intestinal mucosa (reviewed 8). Transformation resulted in significantly higher expression of ACBP (1.30 ± 0.11 and 1.11 ± 0.10 ng/µg cell protein for *ras*- and *src*-transformed cell lines, respectively; n = 7). *Ras* transformation resulted in a 1.8-fold increase ($P < 0.01$) in ACBP protein levels as compared to controls while *src* transformation resulted in a 1.5 fold increase ($P < 0.05$). A representative immunoblot is shown in Figure 1A.

Both L-FABP and I-FABP were poorly expressed in immortalized rat colon cells *in vitro* where actual protein levels were measured by immunoblotting (Fig. 1B,C), similar to that obtained for colonic mucosal epithelial cells (13). Since *ras* and *src* transformation increased the level of ACBP expression in our study, it was important to determine the effect of transformation on I-FABP and L-FABP expression. Neither *ras* nor *src* transformation increased the expression of L-FABP or I-FABP. For all cell lines, up to 150 µg of cell homogenate was loaded per lane, and 0.05 ng purified protein standard was the lowest detectable level on each blot (Fig. 1B,C). Therefore, both control and transformed cell lines contained less than 0.6 picograms of L-FABP and I-FABP per microgram of homogenate protein.

The expression of SCP-2 in control, *ras*-transformed, and *src*-transformed cell lines was examined. Each immunoblot was analyzed as described for ACBP. SCP-2 expression in control immortalized colon cells was relatively high, 0.42 ± 0.02 ng/µg cell protein, and similar to that of intestine (17). The level of SCP-2 expression was significantly decreased by *ras* and *src* transformation compared to control cell lines. *Ras*

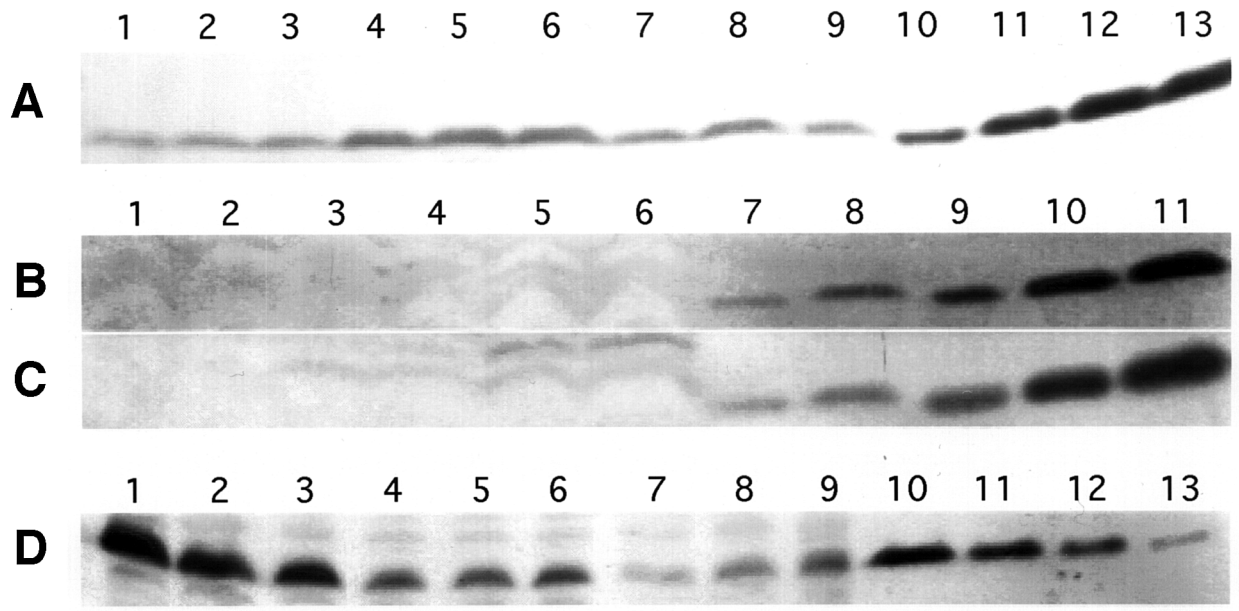

FIG. 1. Representative immunoblots of ACBP, I-FABP, L-FABP, and SCP-2 protein expression in rat colon epithelial cell lines. The cells were grown, protein was extracted, and immunoblotting performed as described in the Materials and Methods section. A: Lanes 1–3 were loaded with 25 µg of protein from control cell lines, 4–6 from *ras*-transformed cell lines, and 7–9 from *src*-transformed cell lines. Lanes 10–13 contain 5, 10, 15, and 20 ng, respectively, of purified rat liver ACBP. B: I-FABP protein expression in rat colon epithelial cell lines. Lanes 1 and 2 were loaded with 75 µg of protein from control cell lines, 3 and 4 from *ras*-transformed cell lines, and 5 and 6 from *src*-transformed cell lines. Lanes 8–12 contain 0.05, 0.1, 0.2, 0.5, and 1 ng, respectively, of purified I-FABP. C: L-FABP protein expression in rat colon epithelial cell lines. Lanes 1–6 were loaded the same as in B above. Lanes 8–12 contain 0.05, 0.1, 0.2, 0.5, and 1 ng, respectively, of purified L-FABP. D: SCP-2 protein expression in rat colon epithelial cell lines. Lanes 1–3 were loaded with 35 µg of protein from control cell lines, 4–6 from *ras*-transformed cell lines, and 7–9 from *src*-transformed cell lines. Lanes 10–13 contain 12, 9, 6, and 3 ng, respectively, of purified recombinant SCP-2.

transformation resulted in a 55% decrease ($P < 0.005$) in SCP-2 protein levels while *src* transformation resulted in a 67% decrease ($P < 0.005$) in SCP-2 expression, from 0.42 ± 0.02 to 0.19 ± 0.02 and 0.14 ± 0.03 ng/µg cell protein, respectively ($n = 2$). A representative immunoblot is shown in Figure 1D.

Butyrate treatment (3 mM) decreased cell proliferation much more in transformed cell lines than control (Fig. 2). In the control cell lines the decrease was modest with a 1.1-fold increase in the doubling time, whereas in the transformed cell lines doubling times increased 1.7-fold and 2.5-fold in the *ras*- and *src*-transformed cell lines, respectively. These changes in proliferation were evident at 24 h. In keeping with the changes in proliferation, butyrate also significantly decreased rates of protein synthesis ($P < 0.05$) and significantly increased rates of protein breakdown ($P < 0.05$) in all cell lines when compared to the respective untreated cell lines (Table 1). The effect of butyrate was particularly marked in the *src*-transformed cell lines.

To further assess the effects of butyrate upon general protein synthesis and to determine if decreased protein synthesis might account for changes in ACBP, L-FABP, I-FABP, or SCP-2 expression, the expression of actin was assessed. Actin is a component of the cytoskeleton of cells and considered to be a housekeeping protein normally expressed in constant levels within the cell. The levels of actin were: 4.2 ± 0.4, 2.1 ± 0.2, and 1.3 ± 0.1 ng/µg cell protein for immortalized, *ras*-transformed, and *src*-transformed cell lines, respectively. The levels of actin were higher in control cells and decreased by more than 50% in the transformed cell lines (Fig. 3). These data are consistent with previous reports in which actin expression and cytoskeletal organization were decreased in different types of transformed and neoplastic cells as compared to normal cells (29,30). Treatment with butyrate resulted in a mild decrease in actin expression, but this change was not significant in cell lines treated with butyrate compared to untreated cell lines (Fig. 3). The levels of actin were 3.2 ± 0.45,

TABLE 1
3-Hour Pulse-Chase After Treatment with Butyrate (for 24 h)[a]

Cell line	Protein synthesis	Protein degradation
CL4D	30.0 ± 1.1	12.12 ± 0.15
CL4D + butryate	24.7 ± 1.0*	14.09 ± 0.36*
ras	31.6 ± 1.0	11.66 ± 0.22
ras + butyrate	27.9 ± 1.1*	13.13 ± 0.13*
src	31.2 ± 0.9	11.62 ± 0.17
src + butyrate	20.4 ± 2.0*	13.45 ± 0.15*

[a]Protein synthesis is nmol leucine incorporated/mg protein in 3 h. Protein degradation is the percentage of total protein degraded in 3 h (after a 3-h pulse-chase); * = significant difference from the respective cell line without butyrate ($P < 0.05$).

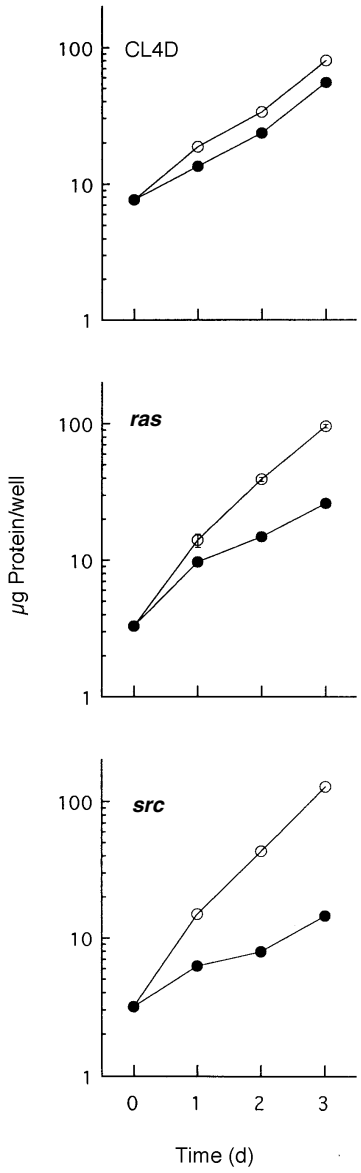

FIG. 2. Effect of butyrate on growth of rat colon epithelial cell lines. All cell lines were seeded on day −1, harvested at 24-h intervals, and protein was extracted and quantitated as described in the Materials and Methods section. The growth of untreated cell lines, ○; butyrate-treated cell lines, ●.

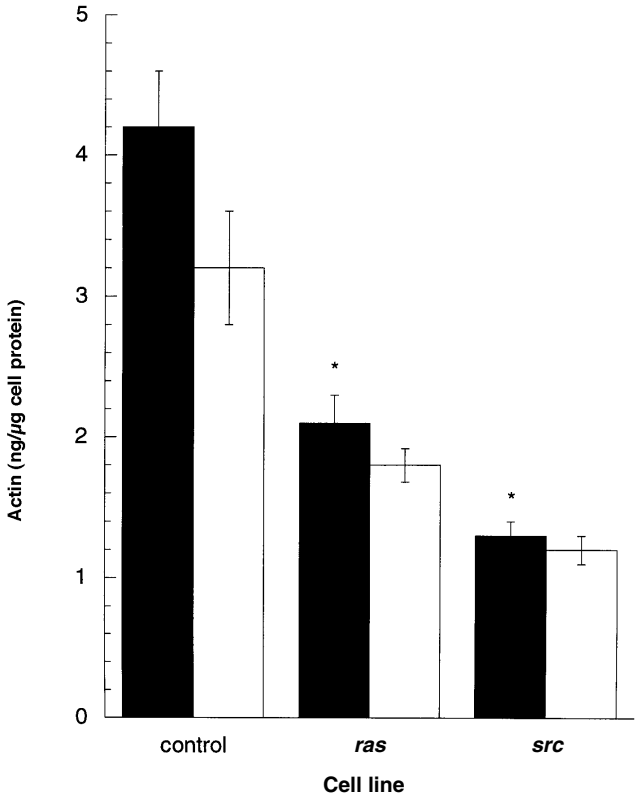

FIG. 3. Comparison of actin expression in control, *ras*-transformed, and *src*-transformed cell lines with and without butyrate treatment. The cells were grown, protein was extracted, and immunoblotting performed as described in the Materials and Methods section. Actin is expressed as ng/μg cell protein, and each bar represents the average ± SEM of three cell lines for $n = 3$ experiments. Open bars represent cell lines treated with butyrate. Solid bars represent cell lines without butyrate treatment. * = significant difference from the control cell line without butyrate treatment ($P < 0.05$). Statistical analysis was performed using an unpaired Student's *t*-test.

1.8 ± 0.12, and 1.2 ± 0.1 ng/μg cell protein in the butyrate-treated immortalized, *ras*-transformed, and *src*-transformed cell lines, respectively.

ACBP expression was examined in cell lines with and without butyrate treatment. Cells were harvested 24 h after beginning butyrate treatment and protein was determined as described in the Materials and Methods section; each immunoblot was analyzed as described in this section. Butyrate treatment resulted in decreased expression of ACBP in all cell lines. Figure 4 shows that ACBP was decreased by 40, 36, and 24% in control, *ras*-, and *src*-transformed cells treated with butyrate when compared to the respective untreated cells. Although butyrate decreased ACBP expression in all three cell lines, a statistically significant difference in ACBP expression was observed only in butyrate-treated *src*-transformed cells vs. butyrate-treated control cells. Thus, the reduction in cell proliferation and general protein synthesis observed in response to butyrate in the three cell lines was reflected in the decreased level of ACBP in response to butyrate treatment.

To determine if the effect of butyrate on inhibition of protein synthesis as exemplified by decreased expression of ACBP was a specific effect for this acyl-CoA binding protein, the level of expression of SCP-2 was examined. In contrast to ACBP, SCP-2 expression did not change in response to butyrate treatment (Fig. 5). While SCP-2 levels were decreased in *ras*- and *src*-transformed cell lines as before, butyrate treatment did not significantly alter expression of SCP-2 in either the control or transformed cells (Fig. 5). Thus, butyrate differentially modulated the expression of ACBP and SCP-2 in control and transformed colon cells. Moreover, these effects were distinct from the general inhibition of cell proliferation

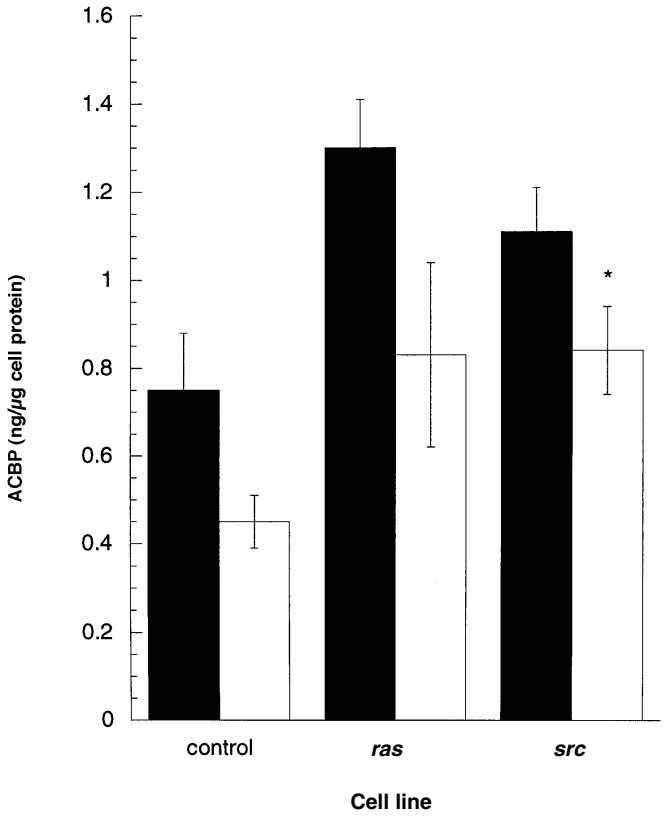

FIG. 4. Comparison of ACBP expression in control, *ras*-transformed, and *src*-transformed cell lines with and without butyrate treatment. The cells were grown, protein was extracted, and immunoblotting performed as described in the Materials and Methods section. ACBP is expressed as ng/μg cell protein, and each bar represents the average ± SEM of three cell lines; $n = 4$ experiments. Open bars represent cell lines treated with butyrate. Solid bars represent cell lines without butyrate treatment. The * indicates significant difference from control cell lines treated with butyrate ($P < 0.05$). Statistical analysis was performed using an unpaired Student's *t*-test.

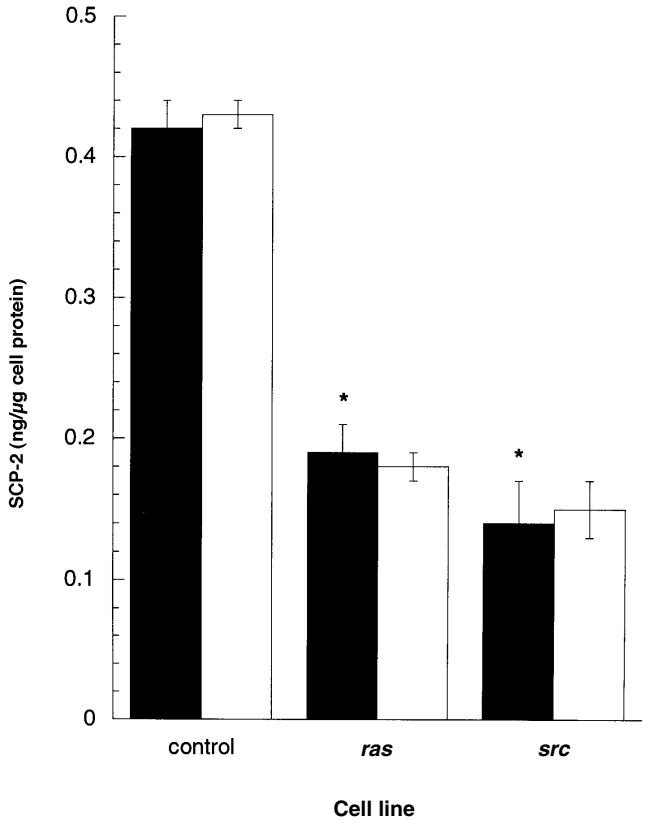

FIG. 5. Comparison of SCP-2 expression in control, *ras*-transformed, and *src*-transformed cell lines with and without butyrate treatment. The cells were grown, protein was extracted, and immunoblotting performed as described in the Materials and Methods section. SCP-2 is expressed as ng/μg cell protein, and each bar represents the average ± SEM of three cell lines, $n = 3$ experiments. Open bars represent cell lines treated with butyrate. Solid bars represent cell lines without butyrate treatment. * = significant difference from the control cell line without butyrate treatment ($P < 0.05$). Statistical analysis was performed using an unpaired Student's *t*-test.

and protein synthesis by butyrate in both control and transformed cells.

DISCUSSION

Of the four fatty acyl-CoA binding proteins examined, transformation differentially altered the expression of ACBP and SCP-2. ACBP was the only protein in which expression increased as a result of transformation with *ras* and *src* oncogenes. Increased ACBP expression has been demonstrated in a number of different human brain tumors *in vivo* such as astrocytomas, glioblastomas and medulloblastomas, and the highest expression occurred in the most anaplastic of these tumors. In contrast, ACBP levels were low to undetectable in normal brain and benign brain neoplasms such as meningiomas and pituitary adenomas (31). Other tumor cells in which ACBP has been identified include human prostatic adenocarcinoma cell lines, mouse adrenal and Leydig cell-derived tumor cell lines, rat insulinoma cell line, dimethylbenz(α)anthracene-induced mammary tumors in the rat, osteosarcoma cell line, neuroblastoma cell line, and the supernatant from a metastatic human malignant melanoma cell line (reviewed 8). However, quantitative differences in the level of ACBP expression in these tumor cells compared to control (untransformed) cells have not been determined.

The function of ACBP *in vivo* has not been fully characterized, but it may be involved in the regulation of the intracellular acyl-CoA pool and lipid metabolism, modulation of benzodiazepine receptors, regulation of glucose-induced insulin secretion, and regulation of cell growth (reviewed 8). The potential role of ACBP in cell growth of transformed colon cells *in vitro* could be explained by several possible mechanisms. First, transformed and neoplastic cells grow faster and have a higher metabolic activity than normal cells. Therefore, ACBP levels may be increased secondary to increased acyl-CoA levels and turnover within transformed cells. Second, ACBP may be involved directly in the regulation of cell growth *via* interaction with peripheral benzodiazepine receptors (PBR). PBR have been postulated to be involved in mitochondrial and cell proliferation (32). In studies

with a human Leydig-derived cell line and mouse 3T3 swiss fibroblasts, nanomolar concentrations of ACBP exerted a mitogenic effect possibly *via* interaction with PBR (33). In addition, increases in PBR were detected by immunohistochemical analysis in human brain neoplasms with increased ACBP, and increased PBR have been detected in human colon carcinomas and other tumor types (34,35).

Third, by regulating acyl-CoA transport and acyl-CoA levels within the cell, ACBP may alter cell signaling pathways through protein myristoylation and protein phosphorylation. Increased *N*-myristoyl-transferase activity has been observed in rat and human colon tumors when compared to normal colon tissue (36). Myristoylation is the covalent modification of proteins in which myristate or palmitate is covalently attached to the N terminus of cellular proteins. Many of these proteins are involved in signal transduction, and of particular interest in colon neoplasia are tyrosine kinases such as $pp60^{c\text{-}src}$ and the alpha subunit of several guanine nucleotide binding protein receptors (*ras* encodes p21, a membrane-bound G-protein) (37). Further studies will be necessary to determine how ACBP expression is involved in neoplastic transformation and its role in the regulation of cell proliferation.

Butyrate affected both cell proliferation and ACBP expression in the transformed rat colon epithelial cells. The effects of butyrate on cell proliferation in these cell lines are consistent with previous reports of its effects on other types of cells *in vitro*. However, the decreased ACBP expression upon butyrate treatment was not due to a general decrease in protein synthesis attributed to cell death, since the levels of actin and SCP-2 stayed the same in untreated and treated cells. Therefore, ACBP expression appears to be higher in the transformed, undifferentiated state in which cells are rapidly proliferating. Butyrate treatment apparently resulted in induction of a more differentiated state with decreases in DNA synthesis and cell proliferation and a simultaneous decrease in ACBP expression.

Although both L-FABP and I-FABP are expressed in intestinal mucosal epithelial cells, the level of expression is highest in the duodenum and jejunum, but decreases markedly in the colon (13). L-FABP and I-FABP were undetectable in the cell lines examined. Both L-FABP and I-FABP expression are markedly reduced in several liver and intestinal tumors, including human and rat colon carcinomas, as well as other types of transformed cell lines in culture (12, 19,20,38–40). Caco-2 and HT-29 cell lines (derived from two different human colon carcinomas), and several mouse- and rat-derived colon carcinoma cell lines did not express detectable levels of I-FABP mRNA (39,40) while only the Caco-2 cell line expressed detectable levels of L-FABP mRNA (40).

In contrast to ACBP expression, SCP-2 expression decreased in *ras*- and *src*-transformed cell lines. This is the first report of changes in SCP-2 expression in colon epithelial cells, but the findings are consistent with other studies in different systems. Rat hepatoma cells express lower levels of SCP-2 than normal rat hepatocytes, and transformed cells also showed decreased expression of SCP-2 (17,41). In addition, changes in the expression of SCP-2 have been reported in human adrenocortical tissue. A significant decrease in SCP-2 expression occurred in adrenocortical carcinomas when compared to normal tissue and benign neoplasms (42). Butyrate treatment did not affect SCP-2 expression in control or transformed cells. Therefore, SCP-2 does not appear to be associated with cell proliferation in this cell type and was not affected by changes in differentiation induced by this agent.

Actin expression decreased 50% or more in the transformed rat colon epithelial cell lines which is consistent with other reports in different types of cells. Actin has been shown to be a sensitive marker of transformation in NIH 3T3 fibroblasts (29). Transformation results in reduced synthesis of smooth muscle α-actin and various actin-binding proteins which results in changes in cytoskeletal organization and the transformed phenotype of these cells (29). Several other cell lines such as human fibrosarcoma, osteosarcoma, and MOLT-4 cells derived from a T-cell leukemia exhibit decreases in the level of β-actin (30). SCP-2 expression in the rat colon epithelial cell lines was approximately 10-fold lower than actin and transformation resulted in a decrease in SCP-2 similar to that of actin. Therefore, comparison of the ratio of actin to SCP-2 in control vs. transformed cell lines resulted in a similar ratio of 10, 11, and 9.3 in control, *ras*-transformed, and *src*-transformed cell lines, respectively. However, since ACBP expression increased in the transformed rat colon epithelial cells, the ratio of ACBP to actin increased significantly as a result of transformation (from 0.18 in control cell lines to 0.62 and 0.85 in the *ras*- and *src*-transformed cell lines, respectively) (Table 2). Likewise, comparison of the ratio of ACBP to SCP-2 expression in control vs. transformed cell lines resulted in a ratio of 1.8, 6.8, and 7.9 in control, *ras*-transformed, and *src*-transformed cell lines, respectively. Butyrate treatment decreased ACBP expression but did not affect actin or SCP-2 levels significantly. This resulted in ratios of ACBP to these proteins that were lower than those of the untreated cell lines. However, *ras* transformation with and without butyrate treatment resulted in an approximately 3.8–4.2-fold increase in the ratio of ACBP to SCP-2 while *src* transformation resulted in a 4.4–5.1-fold increase (Table 2). Therefore, changes in the ratio of SCP-2 to ACBP expression appear to be a sensitive marker of tranformation in the rat model of immortalized colon epithelial cells.

TABLE 2
Comparison of the Ratio of Expression of Actin, SCP-2, and ACBP With and Without Butyrate Treatment

	Without butyrate		With butyrate	
Cell line	ACBP/actin	ACBP/SCP-2	ACBP/actin	ACBP/SCP-2
Control	0.18	1.8	0.14	1.1
ras-transformed	0.62[a]	6.8[a]	0.46[a]	4.6[a]
src-transformed	0.85[a]	7.9[a]	0.70[a]	5.6[a]

[a]Significant difference from the respective control.

ABSTRACT: The effect of oat bran- (OBD) and wheat bran-enriched diets (WBD) on fatty acid composition of neutral lipids and phospholipids of rat lymphocytes and macrophages was investigated. In neutral lipids of lymphocytes, OBD reduced the proportion of palmitoleic acid (48%), whereas WBD reduced by 43% palmitoleic acid and raised oleic (18%), linoleic (52%), and arachidonic (2.5-fold) acids. In neutral lipids of macrophages, OBD increased palmitic (16%) and linoleic (29%) acids and slightly decreased oleic acid (15%). The effect of WBD, however, was more pronounced: It reduced myristic (60%), stearic (24%) and arachidonic (63%) acids, and it raised palmitic (30%) and linoleic (2.3-fold) acids. Neither OBD nor WBD modified the composition of fatty acids in phospholipids of lymphocytes. In contrast, both diets had a marked effect on composition of fatty acids in macrophage phospholipids. OBD raised the proportion of myristic (42%) and linoleic (2.4-fold) acids and decreased that of lauric (31%), palmitoleic (43%), and arachidonic (29%) acids. WBD increased palmitic (18%) and stearic (23%) acids and lowered palmitoleic (35%) and arachidonic (78%) acids. Of both cells, macrophages were more responsive to the effect of the fiber-rich diets on fatty acid composition of phospholipids. The high turnover of fatty acids in macrophage membranes may explain the differences between both cells. The modifications observed due to the effects of both diets were similar in few cases: an increase in palmitic and linoleic acids of total neutral lipids occurred and a decrease in palmitoleic and arachidonic acids of phospholipid. Therefore, the mechanism involved in the effect of both diets might be different.

Lipids 32, 587–591 (1997).

Volatile short-chain fatty acids (VSCFA) comprise the major solute fraction of fecal water, being produced by fermentation of water-soluble fiber by anaerobic bacteria normally resident in the large bowel (1). Acetic, propionic, and butyric acids are the predominant forms of the VSCFA in the gastrointestinal tract (2). Since dietary fiber reduces the incidence of colon cancer in humans (3), the possible role of these fatty acids in cell growth and differentiation has been investigated. It is widely accepted that butyrate causes a marked inhibition of the growth of several tumor cell lines in culture (4–6). A recent study from our laboratory has shown that propionate, at concentrations varying from 1 to 5 mmol/L, also inhibits the proliferation of tumor (HeLa-155 and KB-372) and normal (MA-104) cell lines *in vitro* (7). In addition, it has been found that propionate can influence the proliferation of lymphocytes: It stimulates proliferation at low concentrations (0.04 and 0.1 mmol/L) but inhibits proliferation at concentrations above 1 mmol/L (8).

Lymphocytes and macrophages utilize glucose and glutamine at high rates, but these substrates are only partially oxidized: Glucose is converted to lactate and glutamine to glutamate, aspartate, and lactate (9). Pyruvate generated by either substrate is not completely oxidized, but some of it may be converted to acetyl-CoA for lipid synthesis in these cells (10,11). Lipogenesis has been recognized to be important for the process of cell proliferation to take place. However, there is evidence that either lymphocytes (rapidly dividing cells) and macrophages (nondividing cells) export lipids produced from pyruvate (12). Propionate does not affect the rates of glycolysis or glutaminolysis, but it decreases the rate of lipogenesis in incubated lymphocytes (12), which may explain the inhibitory effect of the VSCFA on lymphocyte proliferation. Propionate at a concentration of 40 mmol/L decreases the incorporation of [1-^{14}C]-palmitate into phospholipids (86%), triacylglycerol (87%), and cholesterol ester (90%) in 24-h cultured lymphocytes (13). A similar effect of propionate in macrophages has been reported (14); this VSCFA inhibits the incorporation of [1-^{14}C]-palmitate into phospholipids, cholesterol, cholesterol ester and triacylglycerol, and the incorporation of [3-^{14}C]-pyruvate into phospholipids. The rate of phospholipid turnover and fatty acid incorporation in macrophage membranes is very high, probably owing to their

various endocytic and exocytic activities (15). It has been shown that a disproportional incorporation of saturated and polyunsaturated fatty acids into macrophages is able to regulate their ability to adhere to surfaces and to perform phagocytosis (16,17). Therefore, cellular deacylation processes, which remove the CoA moieties from the fatty acyl-CoA and so their ability to be incorporated into phospholipids, might play an important role for the normal function of macrophages. Propionate raises the activities of palmitoyl-CoA and oleoyl-CoA deacylases in macrophages (14) and lymphocytes (13). These findings support the proposition that this VSCFA might cause important changes in fatty acid composition of these cells by inhibiting lipogenesis and altering the deacylation process.

The information above and the current trend to encourage consumption of high-fiber diets led us to investigate the effect of fiber-rich diets on the fatty acid composition of total neutral lipids and phospholipids of lymphocytes and macrophages. These cells present high turnover of fatty acids, which might ensure the high proliferative capacity of lymphocytes and the endocytic and secretory activities of macrophages. Water-soluble fibers are the main source of VSCFA (18,19), therefore, fiber-rich diets presenting different soluble/insoluble fiber ratios were used: oat bran (0.3) and wheat bran (0.14).

MATERIALS AND METHODS

Animals and diet preparation. Just-weaned male Wistar rats weighing 50–60 g were obtained from the Animal House of Instituto de Ciências Biomédicas, USP, (São Paulo, Brazil). During the experiment, the rats were kept in groups of 5 at 23°C with a 12-h light/12-h dark cycle; lights on at 7:00. The rats were divided into three groups: (i) control—fed a regular diet (composition shown in Table 1 and similar to that reported by Anderson (20), (ii) oat bran-enriched diet (OBD)—prepared by addition of 300 g of oat bran in 1000 g of regular diet, and (iii) wheat bran-enriched diet (WBD)—prepared by addition of 300 g of wheat bran in 1000 g of regular diet. The soluble/insoluble fiber ratio was 0.22, 0.30, and 0.14 for control, OBD, and WBD, respectively. The fatty acid compositon of the three diets was similar to that shown in Table 1. The rats were fed the respective diet for 8 wk and, during this time, body weight, food intake, and fecal output were evaluated weekly. After this period, the rats were killed by decapitation and total blood, lymph nodes lymphocytes, and resident peritoneal macrophages were collected. Animals were always killed between 8:00 and 11:00 h.

Chemicals. Solvents were obtained from Fisons Scientific Apparatus (Loughborough, Leics., United Kingdom) and were redistilled before use. An ethereal solution of diazomethane was prepared from Diazald (Aldrich Chemical Co., Gillingham, Dorset, United Kingdom).

Preparation of lymphocytes and macrophages. Mesenteric lymph nodes were dissected from rats and lymphocytes were prepared as previously described (21).

For preparation of resident macrophages, the rats were intraperitoneally injected with 6 mL of cold saline 0.9% and the cells obtained as previously described (22).

TABLE 1
Basic Composition of the Regular Diet[a]

Component (g/kg of diet)	
Protein (casein)	180
Fat	40
Carbohydrates	455
Minerals and vitamins	80
Calcium	18
Phosphorus	8
Insoluble fiber	180
Soluble fiber	39
Fatty acid composition (g/100 g)	
Lauric acid	n.d.
Myristic acid	0.63
Palmitic acid	17.03
Palmitoleic acid	0.50
Stearic acid	2.62
Oleic acid	26.60
Linoleic acid	49.39
Linolenic acid	3.23
Arachidonic acid	n.d.
Vitamin mixture (units/100 g)	
Vitamin A	20,000 UI
Vitamin D_3	6,600 UI
Vitamin E	30.0 mg
Vitamin K	6.0 mg
Vitamin B_{12}	10.0 mcg
Vitamin B_2	8.0 mg
Niacin	95.0 mg
Pantothenic acid	24.0 mg
Thiamine	4.0 mg
Choline	2,000 mg
Piridoxin	6.0 mg
Biotin	0.1 mg
Folic acid	
Trace metals (units/100 g)	0.5 mg
Manganese	50.0 mg
Iodine	2.0 mg
Iron	65.0 mg
Zinc	35.0 mg
Copper	26.0 mg
Antioxidant (butylated hydroxytoluene–BHT)	100.0 mg

[a]Vitamin K was purchased from Roche Laboratories. BHT was obtained from Shell Chemical (Houston, TX).
n.d. = Not detected; UI, unsaturation index.

Lipid extraction and analysis. Macrophages and lymphocytes were resuspended in a small volume of phosphate buffered-saline and sonicated (three times of 15 s each at an amplitude of 12 μm) in an MSE sonicator (LAB-LINE Instruments Inc., Melrose Park, IL). Lipid was extracted with chloroform/methanol solution (2:1, vol/vol). Neutral lipids and phospholipids were separated using Sep-Pak columns (Waters Corporation, Milford, MA), as described by Hamilton and Comai (23). Columns were flushed with 12 mL hexane and the sample, dissolved in 1 mL methyl tertiarybutylether (MTBE), was applied. Neutral lipids were eluted using 10 mL MTBE/methanol/0.001 M ammonium acetate (100:0.2, vol/vol), and phospholipids were eluted using 10 mL

MTBE/methanol/0.001 M ammonium acetate (5:8:2, by vol). Fatty acids were prepared by overnight saponification at 70°C in methanolic 0.5 M KOH. Samples were neutralized using concentrated sulfuric acid, and fatty acids were extracted in ethyl acetate and methylated by reaction with diazomethane (24). A similar procedure has been employed in a previous study (17). Fatty acid methyl esters (dissolved in methyl acetate) were separated by gas chromatography in a Hewlett-Packard 5890A gas chromatograph (Palo Alto, CA) fitted with a 50 m × 0.3 mm bonded phase OV-1 fused-silica capillary column, film thickness 0.52 μm. Helium at 2.0 mL/min was used as the carrier gas, and the split/splitless injector was used in the split mode, with a split ratio of 15:1. Injector and detector temperatures were both 300°C, and the column oven temperature was programmed from 130 to 380°C at 2°C/min. The separation was recorded with a Servoscribe chart recorder (Hewlett-Packard), and quantitative data were recorded with a Hewlet-Packard 3390A recording integrator. Fatty acids were identified by comparison with standards run previously.

Data presentation and statistics. All data are presented as mean ± SD for the indicated number of samples. Statistical significance was determined using the two-tailed unpaired Student's test; a value for P of less than 0.05 was considered to indicate a statistically significant difference.

RESULTS AND DISCUSSION

The body weight gain, food intake, and output of feces were not different among the groups (data not shown).

The fatty acid composition of the blood was not markedly affected by OBD or WBD (data not shown). In fact, compared to control diet, the only significant difference was a 68% increase in the proportion of arachidonic acid in the serum of rats fed OBD. This increase in the proportion of arachidonic acid may reflect a modification of its metabolism and so of the production of eicosanoids (25), which could be important for regulating cell functions (26).

In contrast to this unique change found in the fatty acid composition of the blood, the fatty acid composition of lymphocytes and, more particularly, in macrophages was substantially modified by both fiber-rich diets (Tables 2–4). The OBD reduced the proportion of palmitoleic acid (by 48%) in the total neutral lipids of lymphocytes (Table 2). In contrast, the WBD had a pronounced effect on fatty acid composition of neutral lipids of lymphocytes: this diet reduced by 43% palmitoleic acid and raised the proportions of oleic (by 18%), linoleic (by 52%), and arachidonic (2.5-fold) acids. In total neutral lipids of macrophages (Table 3), the OBD increased the proportion of palmitic (by 16%) and linoleic (by 29%) acids and diminished that of oleic acid (by 15%). The effect

of the WBD was more pronounced. This diet reduced the proportions of myristic (by 60%), stearic (by 24%), and arachidonic (by 63%) acids, and it raised that of palmitic (by 30%) and linoleic (2.3-fold) acids. Both fiber-rich diets modified the fatty acid composition of the total neutral lipids of macrophages, whereas for lymphocytes a marked effect was observed after feeding the WBD only. The effect of WBD on macrophages was more pronounced than that of OBD.

OBD and WBD did not modify the fatty acid composition of phospholipids of lymphocytes (data not shown). In contrast, both diets had a marked effect on fatty acid composition of macrophage phospholipids (Table 4). The OBD increased the proportions of myristic (by 42%) and linoleic (2.4-fold) acids and decreased that of lauric (by 31%), palmitoleic (by 43%), and arachidonic (by 29%) acids. The WBD increased the proportion of palmitic (by 18%) and stearic (by 23%) acids and decreased the proportions of palmitoleic (by 35%) and arachidonic (by 78%) acids.

The fatty acid composition of macrophage phospholipids was more sensitive to the effect of fiber-rich diets than that of lymphocytes. The OBD did not cause any significant effect on the fatty acid composition of the neutral lipids or phospholipids of lymphocytes (data not shown). The high turnover of fatty acids in macrophage membranes may explain the differences between cell types. The rate of phospholipid turnover in macrophages is very high, probably owing to their various endocytic and exocytic activities (15) so that the rate of incorporation of fatty acids into macrophage membranes might be more readily achieved than incorporation into lymphocyte membranes (27). The changes in the fatty acid composition of phospholipids of macrophages (Table 4) were different from those observed for the total neutral lipids (Table 3). These observations led us to believe that fiber-rich diets might alter the turnover of fatty acids in membrane phospholipids. Whether this effect occurred through the deacylation process remains to be investigated.

Concluding remarks. The OBD, which has a soluble/insoluble fiber ratio of 0.3 compared with 0.14 for the WBD, induced marked changes in the fatty acid composition of neutral lipids and phospholipids of macrophages. However, the WBD, although having a lower soluble/insoluble fiber ratio, also caused marked changes in the fatty acid composition of neutral lipids and phospholipids of macrophages. Both diets increased the proportion of palmitic and linoleic acids in total neutral lipids and decreased the proportion of palmitoleic and arachidonic acids in phospholipids. The mechanism involved in each case, however, might be different.

Linoleic acid is the metabolic precursor of arachidonic acid. The arachidonic acid/linoleic acid ratio of lymphocyte phospholipids was decreased by WBD: 0.3 against 0.7 for the control group. In phospholipids of macrophages, both fiber-rich diets caused a decrease of arachidonic acid/linoleic acid ratio: 7.0 for control, 2.1 for OBD, and 0.8 for WBD. These findings led us to postulate that both fiber-rich diets, particularly the one enriched with wheat bran, might affect the biosynthesis of prostaglandins and thus macrophage function. An increase in the proportion of linolenic acid, a well-known reducer of intracellular arachidonic acid levels (28), does not seem to play a role in these findings, since it was not different among the groups.

The high production of VSCFA from the fermentation of soluble fibers is not the sole mechanism by which fiber-rich diets modify the fatty acid composition of macrophages. Insoluble fibers may affect the absorption of certain fatty acids or even the formation of chylomicrons. Further studies are needed to identify both the mechanism by which diets rich in soluble and insoluble fibers alter the fatty acid composition of cells of the immune system and the functional consequences of such changes.

ABSTRACT: The dietary effect of 1,3-biseicosapentaenoyl-2-γ-linolenoyl glycerol (STG) on the fatty acid composition of guinea pigs was examined and compared with that of an eicosapentaenoic acid ethyl ester (EPA-E) and of a soybean oil (SBO) diet. In terms of content of plasma lipid, EPA-E had a greater hypolipidemic effect than STG. On the other hand, in terms of EPA incorporation, contents of EPA in liver lipid were almost the same in the STG and EPA-E groups. Considering that the amount of EPA administered in the EPA-E group was almost 1.5 times that of the STG group, EPA may be absorbed more effectively as the glycerol ester than as the ethyl ester in guinea pigs. In all the tissue lipids, the STG group had a higher unsaturation index (UI) than the EPA-E group even though there is a lower UI in the STG diet than the EPA-E diet. These results suggest that greater amounts of desaturase products as a whole were synthesized in the STG group than in the other two groups. The dihomo-γ-linolenic acid/arachidonic acid (DGLA/AA) ratio in plasma total lipids in the STG group was 3.5 times that of SBO group, and the DGLA/AA ratio in the EPA-E group was half that of the SBO group. In liver lipid, the ratios of DGLA/AA and EPA/AA in the STG group were 0.687 and 0.488 (phosphatidylcholine fraction) and 0.237 and 0.752 (phosphatidylethanolamine fraction), respectively. The ratio of DGLA/AA as well as the high EPA/AA ratio obtained in the present study with the STG diet may lead to physiological alterations, including enhanced synthesis of 1- and 3-series eicosanoids.

Lipids 32, 593–598 (1997).

The nutritional value of γ-linolenic acid (GLA), the product of Δ6-desaturase from linoleic acid (LA), has been suggested by the reduced Δ6-desaturase activity that occurs in many cases like diabetes (1), cardiovascular disorder (2), viral infection (3), or aging (4). Supplementation with GLA not only bypasses the enzyme reaction from LA to GLA but also has been reported to cause stimulation of Δ6-desaturase both with n-6 (5,6) and n-3 (7) essential fatty acids (EFA) (8). As well as increasing dietary GLA itself, this stimulation caused higher levels of dihomo-γ-linolenic acid (DGLA), the precursor of PGE_1, which are considered to be anti-inflammatory compared with 2-series eicosanoids derived from arachidonic acid (AA) (9). The potential usefulness of n-3 EFA has also been under study since the first epidemiological report on the lower incidence of coronary heart diseases in Greenland Inuits (10). Among the many reported effects of n-3 EFA, a prominent one is the hypotriglyceridemic effect of eicosapentaenoic acid (EPA), the precursor of 3-series eicosanoids (11). Supplementation with EPA was reported, on the other hand, to depress DGLA levels in plasma phospholipids relative to baseline values (12), which could lead to a decrease in PGE_1 synthesis. In order to prevent this DGLA depression, combined treatment with evening primrose oil and fish oil containing GLA and EPA, respectively, has been examined and resulted in the increase of DGLA (13) or in the ratio of DGLA to AA in rats (14). In the present paper, we examined the dietary effect of 1,3-biseicosapentaenoyl-2-γ-linolenoyl glycerol [symmetrical triacylglycerol (STG)] on fatty acid composition of guinea pigs, which have Δ5-desaturase activity (from DGLA to AA) similar to that of humans (15).

EXPERIMENTAL PROCEDURES

Materials. An STG shown in Figure l was chemically synthesized from EPA, GLA, and dihydroxyacetone (16). EPA (and EPA ethyl ester: EPA-E), GLA and soybean oil (SBO) were purchased from Nippon Chemical Feed Co. Ltd. (Hakodate, Japan) Idemitsu Materials Co. Ltd. (Okayama, Japan), and Sanwa Yushi Kogyo Co. Ltd. (Tokyo, Japan), respectively. The purities of EPA, EPA-E, GLA, and STG used in the present study were confirmed to be over 95%. A 30% lipid emulsion (STG, EPA-E, and SBO) was prepared by mixing 1.5 mL lipid and 3.5 mL 0.9% NaCl containing 0.05 g arabic gum and

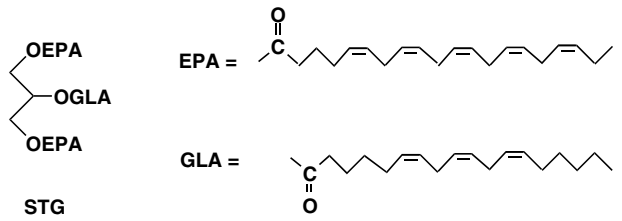

FIG. 1. Structural formula of a symmetrical triacylglycerol (STG).

0.05 g dL-α-tocopherol by ultrasonication with cooling on ice [similar to the method of Nilsson *et al.* (17)].

Animals. Five-week-old male Hartley strain guinea pigs (SLC, Japan Inc., Japan) were used. They were housed in a room maintained at a constant temperature (25°C) and kept on a 12:12 h light–dark cycle. All animals had free access to a standard pellet diet (RC-4; Oriental Yeast Co. Ltd., Tokyo, Japan) and water. The lipid emulsions were given by gavage once a day for 14 d. The amount of the lipid emulsion was adjusted to 1000 mg lipid/kg body weight/d. The guinea pigs were divided into four groups: STG ($n = 14$), EPA-E ($n = 12$), SBO ($n = 7$), and control with the standard diet only ($n = 10$).

Analysis of fatty acid composition. After 14 d of treatment, the animals were anesthetized by an injection of sodium pentobarbital into the femoral muscle (100 mg/kg). A common carotid artery was canulated to monitor arterial blood pressure (18). Heparinized blood (1% heparin, 1000 I.U.; Novo Industry, Bagsvaerd, Denmark) was collected from the carotid artery, and plasma was separated by centrifugation ($1000 \times g$, 10 min) and stored at −20°C until further analysis. After a catheter was inserted into the portal vein, the liver was perfused with saline solution to wash out blood, excised, and also stored at −20°C until further analysis. Plasma total lipids (TL) were measured by Hatch and Lees' method (19). A portion of the liver tissue was added to an ice-cooled solution of chloroform/methanol (1:2, vol/vol) and homogenized using an Ace Homogenizer AM-7 (Nihonnseiki-Seisakusho Ltd., Tokyo, Japan) at 10,000 rpm for 2 min. TL from the plasma and the homogenized liver were extracted by Bligh and Dyer's method (20). The extracted lipids from the liver were further separated by thin-layer chromatography (silica gel 60, 20 × 20 cm, 0.5 mm; Merck, Darmstadt, Germany) using chloroform/methanol/water (65:25:4, vol/vol/vol) as a developing solvent. The separated triacylglycerol (TG), phosphatidylcholine (PC), and phosphatidylethanolamine (PE) fractions were scraped and their fatty acid compositions determined. The fatty acids of these fractions were converted to their methyl esters using methanolic boron trifluoride after Metcalfe and Schmitz (21). The esters obtained were analyzed by gas–liquid chromatography using a Shimadzu GC-8A with a glass capillary column (SGE BPX-70; 0.25 mm × 25 m; Tokyo, Japan) at 200°C using nitrogen as a carrier gas (1.0 kg/cm^3). They were identified by the retention time of fatty acid methyl ester standards (Nu-Chek-Prep, Inc., Elysian, MN).

Statistical analysis. The results were expressed as mean ± standard error. Statistical significance was determined by one-way analysis of variance followed by post-hoc Duncan test.

RESULTS

There were no differences in weight or arterial blood pressure among four dietary groups, though the group fed the standard diet showed a slightly higher body weight at the end of the experimental periods. Thus, the four experimental groups with or without gavage of the lipid emulsions were comparable. Daily average amounts of the standard diet, whose fatty acid composition was close to that of SBO, given to the animals of four groups were in the range from 70 to 100 g/kg, or from 2.0 to 2.9 g lipid/kg. It followed that the three experimental groups were given additionally 1 g lipid/kg, i.e., from a half to one-third of the amount of lipid obtained from the standard diet.

The levels of cholesterol, TG, and phospholipid (PL) in plasma are shown in Table 1. The level of TG in the standard diet group was less than half of that in the SBO group in spite of similar fatty acid compositions in the diets of the two groups. This might be the effect of a lower consumption of dietary TG without gavage of lipid emulsion. Therefore, we omitted the standard diet group in the following comparison of fatty acid composition in tissue lipids. Compared with the SBO group, the EPA-E group had significant decreases in all the levels of cholesterol, TG, and PL ($P < 0.01$), indicative of a strong hypolipidemic effect of EPA-E. In the STG group, on the other hand, only the TG level was significantly decreased ($P < 0.05$).

The fatty acid compositions of plasma TL are shown in Table 2. In the EPA-E group, the levels of EPA and 22:5n-3 increased significantly compared with those of the SBO group ($P < 0.01$). As a result, the EPA/AA ratio in EPA-E group was more than 25 times that in the SBO group. The ratio of DGLA/AA in the EPA-E group was less than half that in the SBO group. In the STG group, on the other hand, both the levels of n-6 EFA (i.e., GLA, DGLA, and AA), and n-3 EFA (i.e., EPA and 22:5 n-3) were increased significantly compared with those of the SBO group ($P < 0.01$ except AA and $P < 0.05$ for AA). Increase in the AA level was less than those of GLA and DGLA. The ratio of DGLA/AA in the STG group was 0.367, i.e., 3.5 times that of the SBO group; the

EPA/AA ratio in the STG group was 18 times that of the SBO group.

The average carbon number of all the esterified fatty acids (AveCN in Table 2) was 15.5, longer than those in the other two groups. The unsaturation index (UI in Table 2), the average number of double bonds in each fatty acid molecule, of the STG group was 1.29, also higher than those of the other two groups.

The fatty acid composition of the liver lipids is shown in Tables 3–5. In PC (Table 3), the levels of GLA, DGLA; EPA, 22:5n-3; and 18:0 were increased in the STG group and the levels of EPA, 22:5n-3, and 18:0 were increased in the EPA-E group. However, the AA levels did not differ significantly among the three groups. As a result, the DGLA/AA ratio of the STG group was 0.687, i.e., 3.5 times as great as those of the SBO and EPA-E groups. At the same time, the EPA/AA ratios of the STG and EPA-E groups were more than 6 times that of the SBO group. Levels of both n-6 and n-3 EFA were largest in the STG group.

In PE (Table 4), the levels of AA as well as α-linolenic acid (ALA), 18:3n-3, were significantly decreased in both the STG and EPA-E groups compared with the SBO group. As reported (13), EPA seems to exert an inhibitory effect on the conversion of DGLA to AA, resulting in a lower level of AA in the two groups. Consequently, the DGLA/AA ratio of the STG group was 0.237, i.e., 6 times those of the other groups, a greater effect in PE than PC. The content of n-3 EFA in PE was about 14%, three times those in PC in both the STG and EPA-E groups. As a result, the EPA/AA ratios of the STG and EPA-E groups were 13 and 16 times, respectively, that of the SBO group.

Contrary to the results of PC and PE in which LA levels decreased in the STG and EPA-E groups, the LA levels in TG (Table 5) did not differ from that in the SBO group. The ratios of DGLA/AA and EPA/AA of the STG group were 11 and 3.8 times, respectively, those of the SBO group. The level of DGLA/AA in the EPA-E group was higher than that of the SBO group only in the liver TG fraction. The levels of UI and both n-6 and n-3 EFA were largest in the STG group.

DISCUSSION

There have been several studies on the dietary effect of combination of GLA and EPA in the form of TG mixtures using mainly evening primrose oil and fish oil, but there has been no previous study in the form of a synthetic, mixed TG. The combination of primrose oil and fish oil has been shown to have the following effects: inhibition of bone resorption (22), decrease in malignancy of mammary carcinomas of rats (23,24), favorable reduction of plasma cholesterol and TG levels in the nephrotic syndrome (25), modulation of the renal syndrome induced by cyclosporine (26), alleviation of gastric hemorrhage caused by aspirin (27), reduction of intrarenal calcification (28), amelioration of radiation damage to the skin (29), and amelioration of lung injury induced by endotoxin (30). Decreased *ex vivo* conversion from AA to T_XB_2 was observed in human platelets after the administration of both GLA and EPA in spite of increased AA content of the platelets (31).

In terms of effect on plasma lipids, EPA-E had greater hypolipidemic properties than STG. On the other hand, in terms of EPA incorporation, EPA content in liver lipid was almost the same in the STG and EPA-E groups, and EPA content in plasma TL was somewhat higher (though not significantly) in the STG group than in the EPA-E group. Considering that the amount of EPA administered in the EPA-E group was almost 1.5 times that of the STG group, EPA may be absorbed more effectively as the glycerol ester than as the ethyl ester in guinea pigs. Higher absorption of EPA glycerol than EPA-E was reported in the human (32,33), but the opposite results have been reported in rats (34). In all the tissue lipids, the STG group had higher UI than the EPA-E group even though there is a lower UI in the STG diet than in the EPA-E diet. These results suggest that greater amounts of desaturase products as a whole were synthesized in the STG groups than in the other two groups.

Crozier *et al.* (35) reported the effect of feeding black currant seed oil containing GLA (17.1 mol%) and ALA (12.7 mol%) to guinea pigs. The levels of GLA and DGLA in liver lipids increased but the levels of AA remained relatively stable, which was similar to the results of the present report, indicative of a low activity of Δ5-desaturase in these animals (15,36). Δ5-Desaturase activity was reportedly found in guinea pig megakaryocytes but not platelets (37). The ratios of DGLA/AA in liver PL with black currant oil and the STG can be compared, though GLA content of the diets and the way of dieting were not the same. The content of GLA in the black currant oil diet was 17.1 mol% (35) and that in the STG diet was estimated at about 10 mol%. This estimation was based on the amount of STG administered (1 g/kg/d at 33.3 mol% GLA) and the lipid from the standard diet (2–2.9 g/kg/d at 0% GLA), which gave 11.1–8.5 mol%. The ratios of DGLA/AA in PC and PE with black currant oil were 0.40 and 0.15, respectively, and 0.687 (PC, Table 3) and 0.237 (PE, Table 4) in the STG group. The apparently weaker effect of black currant oil on the increase in the ratio of DGLA/AA seems to be attributable to the higher GLA distribution in the 3-position of TG (38), indicating that TG molecules with GLA at the 2-position are more effective in increasing the level of n-6 EFA, just as 2-positioned EPA molecules are (32). Moreover, EPA in STG seems to inhibit the conversion of DGLA to AA as reported with EPA in fish oil (13). The ratio of DGLA/AA in the STG group obtained in the present study was eventually higher than when feeding black currant oil, in spite of lower GLA content.

Miller and Zibon (39) reported that the DGLA/AA ratio in epidermal PL of guinea pigs being fed borage oil (GLA: 25.2%) was 3 times larger than those fed safflower oil. Moreover, guinea pig epidermal homogenate was reported to form PGE_1 and 15-hydroxy-8,11,13-eicosatrienoic acid (9), the latter of which has been suggested to be an inhibitor of 5- and 12-lipoxygenases (40). High levels of these ratios may be responsible for antithrombotic effect of STG reported elsewhere (41).

The level of docosahexaenoic acid, 22:6n-3, in plasma and liver lipids remained relatively constant among the three groups suggesting that Δ4-desaturase activity or other pathways for increasing docosahexaenoic acid synthesis were very low in guinea pigs (15).

In summary, in terms of the ratios of DGLA/AA and EPA/AA, the STG group had a more favorable fatty acid profile than the EPA-E and SBO groups both in plasma and liver lipids. The ratios of DGLA/AA and EPA/AA in the STG group were 0.687 and 0.488 (in PC) and 0.237 and 0.752 (in PE), respectively. The ratio of DGLA/AA obtained in the present study with the STG diet, the highest so far reported in guinea pigs, as well as the high EPA/AA ratio may lead to physiological changes, including increased production of 1- and 3-series eicosanoids.

Distribution of Cholesterol Sulfate and Its Anabolic and Catabolic Enzymes in Various Rabbit Tissues

Yongxi Cui and Masao Iwamori*

Department of Biochemistry, Faculty of Medicine, The University of Tokyo, Tokyo 113, Japan

ABSTRACT: Cholesterol sulfate (CS) recently has been shown to be involved in signal transduction pathway. To evaluate its functional significance, we determined the concentration of CS, and the specific activities of cholesterol sulfotransferase and CS sulfatase in various tissues of rabbit, and compared them with the concentration of sulfoglycolipids in rabbit tissues. CS was present in the epithelia and mucosa, but not in the tunica muscularis, of the digestive tract, trachea, uterine endometrium and uterine cervix. It was also present in lung, spleen, kidney, prostate, skin, hair, and nail at relatively high concentrations. Its concentration in the uterine endometrium was nine times higher in pseudopregnant rabbits than in nonpregnant rabbits because of activation of cholesterol sulfotransferase and inhibition of CS sulfatase in the pseudopregnant rabbits. Sulfoglycolipids were not detected in the uterine endometria of either nonpregnant- or pseudopregnant rabbits. However, sulfoglycolipids were detected at relatively high concentrations in the cerebrum, cerebellum, stomach, duodenum, jejunum, testis, and kidney of rabbits and thus the tissues in which both sulfolipids were detected were the gastrointestinal tract and kidney. In the digestive tract, the concentration of CS decreased in the order esophagus, stomach, duodenum, and jejunum, but that of sulfatide increased in the same order, indicating distribution of CS in the squamous epithelium. In addition, both CS and sulfatide were detected in the serum. On the other hand, CS sulfatase activity was detected in all tissues examined, even in hair, from which the enzyme was liberated by brief sonication, and its highest specific activity was detected in the liver. The specific activity of cholesterol sulfotransferase varied among the tissues examined and was found to be significantly high in the esophageal epithelium and the uterine endometrium of pseudopregnant rabbit, indicating involvement of cholesterol sulfation in the formation of epithelium.

Lipids 32, 599–604 (1997).

Membrane constituents are known to change in composition and concentration in association with cellular proliferation and differentiation. In a previous study (1), we found that cholesterol sulfate (CS) was characteristically expressed in the uterine endometria of rabbits induced into pseudopregnancy by the administration of 17β-estradiol and chorionic gonadotropin. This suggested the involvement of CS in the process of implantation of a fertilized egg in the uterine endometria of pseudopregnant rabbits. In addition, CS was shown to be a major constituent of mammalian skin (2), in which synthesis occurred in the epidermal spinous layer (3), and the highest concentration was observed in the stratum granulosum (4), where it is important for normal desquamation (5–7). Its expression in keratinocytes was found to be a differentiation-associated phenomenon (8), and it exhibits an ability to activate protein kinase C-isoenzymes, eta, epsilon and zeta (9,10), suggesting its involvement in the multistep process of differentiation of keratinocytes. Although knowledge has been accumulated of the functional significance of CS, particularly in the epidermis, information on its distribution in various tissues was limited (11), which led us to examine its concentration in various tissues of rabbit. Also, we determined the specific activities of cholesterol sulfotransferase and CS sulfatase and compared them with the concentrations of sulfoglycolipids by thin-layer chromatography (TLC)-immunostaining with a newly established antisulfatide monoclonal antibody and TLC-densitometry.

MATERIALS AND METHODS

Preparation of tissues. Rabbits (New Zealand white, 6 mon old, virgin female) were purchased from Japanese Biological Materials Co. (Tokyo, Japan). Each rabbit was injected intramuscularly with 0.5 mg 17β-estradiol on the first day. After 72 h, 250 IU of human chorionic gonadotropin (Sigma, St. Louis, MO) in 0.5 mL saline solution was injected intravenously. The rabbit was sacrificed 4 d after the second injection by means of an intravenous injection of pentobarbital sodium. Various tissues were removed and washed with phosphate-buffered saline (PBS). The epithelial layer of the esophagus, stomach, duodenum, jejunum, and trachea and the uterine endometrium were scraped from the tunica muscularis. The tissues were homogenized in water with a Polytron homogenizer (Kinematica, Luzern, Switzerland) and then lyophilized for the quantitative analyses of lipids. A part of various tissues, including hair, was homogenized in 5 vol of 0.25 M sucrose with a Polytron homogenizer and an ultrasonicator and then centrifuged at 700 × *g* for 10 min to remove

Abbreviations: BSA, bovine serum albumin; CS, cholesterol sulfate; DG, 1-alkyl-2-acylglycerol; MG, 1-alkyl glycerol; NFA, nonhydroxy fatty acid; PBS, phosphate-buffered saline; TLC, thin-layer chromatography.

cell debris, and the resultant supernatant was used for the determination of cholesterol sulfotransferase and CS sulfatase. Protein was measured by the dye-binding method with bovine serum albumin (BSA) as the standard (12).

Preparation of lipids. Total lipids were extracted from the lyophilized powder of various tissues of rabbit with chloroform/methanol/water (20:10:1, 10:20:1, and 10:10:1, by vol), and the combined extracts were applied onto a column packed with DEAE-Sephadex A-25 (acetate form; Pharmacia, Uppsala, Sweden). After elution of the unabsorbed lipids with 3 vol of chloroform/methanol (1:1, vol/vol) and 1 vol of methanol, the acidic lipids absorbed on the column were eluted with 10 vol of 0.3 M sodium acetate in methanol, and then saponified with 0.5 M sodium hydroxide in methanol at 40°C for 40 min to cleave the ester-containing acidic phospholipids (13). After removal of salts by dialysis, the solution was evaporated to dryness and the acidic lipids obtained were dissolved in chloroform/methanol (1:1, vol/vol).

Assay of cholesterol sulfotransferase. Cholesterol sulfotransferase was measured with the supernatant obtained after centrifugation at $700 \times g$ for 10 min of the homogenates of various tissues of rabbit. The assay mixture comprised 0.2 mM cholesterol, 0.5 mM dithiothreitol, 1.35 μM ^{35}S-phosphoadenosine phosphosulfate (74.0 GBq/mmol; New England Nuclear, Boston, MA), 100 mM phosphate buffer, pH 7.3, 10 mg/mL 2-hydroxypropyl-β-cyclodextrin, and 50 μg enzyme protein in a final volume of 100 μL. After incubation at 37°C for 1 h, the reaction was terminated by the addition of 2 mL of chloroform/methanol (2:1, vol/vol) containing 0.4 μg of CS and 0.5 mL of H_2O. Then the solution was mixed well and centrifuged at $1500 \times g$ for 2 min. The upper phase was removed, and the lower phase was air-dried. The constituents of the residue were separated by TLC with chloroform/methanol/acetone/acetic acid/water (8:2:4:2:1, by vol) as the developing solvent. The radioactivity of the band corresponding to CS was counted with a BAS-2000 image analyzer (Fuji Film, Tokyo, Japan).

Assay of CS sulfatase. CS sulfatase was measured with the same supernatants as those used for cholesterol sulfotransferase. The assay mixture comprised 11.0 μM ^{3}H-1,2,6,7-CS, 50 mM imidazole-HCl, pH 7.0, 50 μg Triton X-100, and 50 μg enzyme protein in a final volume of 100 μL. After incubation at 37°C for 1 h, the reaction was terminated by the addition of 1.5 mL of chloroform/methanol (2:1, vol/vol) containing 0.2 μg of cholesterol and 0.5 mL of water. The solution was mixed well and then centrifuged at $700 \times g$ for 2 min. The upper phase was removed, and the lower phase was air-dried. The constituents of the residue were separated by TLC with chloroform/methanol/acetic acid (100:2:1, by vol) as the developing solvent. The band corresponding to that of cholesterol was cut out to count the radioactivity with a liquid scintillation counter (Liquid Scintillation Analyzer TRI-CARB 1500; Packard Co., Tokyo, Japan).

Monoclonal antibody. A murine monoclonal antisulfatide antibody, TCS-1, was prepared by immunizing C57BL mice with sulfatide purified from human brain, hybridizing splenocytes with myeloma cells (P3.X63.AG8.653), and then monitoring the antibody-producing hybridomas by enzyme-linked immunosorbent assay with sulfatide as the antigen.

TLC and TLC-immunostaining. Acidic lipids were chromatographed on a high-performance TLC plate (E. Merck Co., Darmstadt, Germany) with the solvent system of chloroform/methanol/0.5% $CaCl_2$ in water (55:45:10, by vol), and the bands were detected with cupric acetate–phosphoric acid for CS, orcinol–H_2SO_4 for sulfoglycolipids, resorcinol–HCl for sialoglycolipids, and ferric chloride–H_2SO_4 for steroids. The standards for quantitative determination by TLC were chemically synthesized CS, I^3SO_3-GalCer for sulfoglycolipids and II^3NeuAcα-LacCer for sialoglycolipids. The density of the spots was determined at a sample wavelength of 420 nm and a control wavelength of 700 nm with a TLC-densitometer (CS-9000; Shimadzu, Kyoto, Japan). The lower limit for detection was 0.1 μg, and the standard curves were linear up to 1.5 μg. For TLC-immunostaining of sulfolipids, a plastic-coated TLC plate (Sigma-Aldrich) was used for the development of acidic lipids with chloroform/methanol/water (65:35:8, by vol). After blocking the plate with 1% bovine serum albumin (BSA) in PBS at 4°C overnight, it was incubated with the murine monoclonal antisulfatide antibody diluted 1:500 with 1% BSA in PBS (wt/vol) at 37°C for 2 h, and was washed five times with 0.1% Tween-20 in PBS (wt/vol). The antibody remaining on the plate was detected with peroxidase-conjugated antimouse-IgG+M antiserum (Capple Lab., Cochranville, PA) diluted 1:500 with 1% BSA in PBS at 37°C for 1 h and enzyme substrate (H_2O_2 and 4-chloro-1-naphthol). The density of the spots was determined with a TLC-densitometer as described above.

RESULTS

Characterization of the monoclonal antisulfatide antibody. The epitope structure required for binding the monoclonal anti-I^3SO_3-GalCer antibody (TCS-1) was essentially identical with that reported by Fredman *et al.* (14), reacting with glycolipids having the galactose substituted at the 3-position with a sulfate group, I^3SO_3-GalCer, II^3SO_3-LacCer and I^3SO_3-GalDG (seminolipid), but not with II^3SO_3-Gg_3Cer or CS (Fig. 1). The lack of reactivity of I^3SO_3-GalMG with anti-I^3SO_3-GalCer antibody indicated that the structure of the hydrophobic side chain affected the reactivity of the carbohydrate epitope on the TLC plate. In fact, I^3SO_3-GalCer with 2-hydroxy fatty acid-sphingosine or nonhydroxy fatty acid (NFA)-phytosphingosine was more reactive than I^3SO_3-GalCer with NFA-sphingosine. And, although the reactivity of I^3SO_3-GalDG was similar to that of I^3SO_3-GalCer with NFA-sphingosine, that of II^3SO_3-LacCer was twice that of I^3SO_3-GalCer with NFA-sphingosine (Fig. 2).

Distribution of CS in various tissues of rabbit. On TLC of the acidic lipid fraction, corresponding to 2 mg of protein (Fig. 3), CS was found to be present in relatively high concentration in various tissues, other than heart, liver, adrenal gland, cerebrum, cerebellum and testis, of rabbit. Its structure

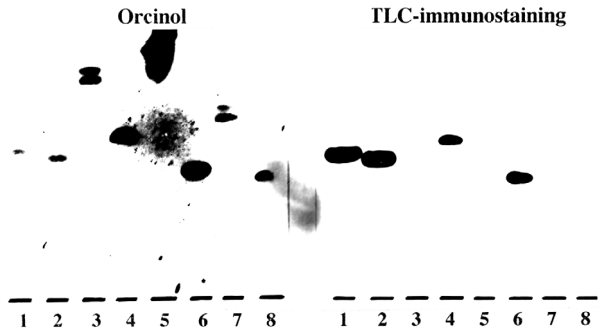

FIG. 1. Immunostaining characterization of the monoclonal anti-I^3SO_3-GalCer antibody (TCS-1). Standard glycolipids (0.5–1.5 μg), purified in our laboratory, were developed on a plastic-coated silia gel plate with chloroform/methanol/water (65:35:8, by vol), and then visualized with orcinol-H_2SO_4 reagent or monoclonal antibody TCS-1. 1, I^3SO_3-GalCer(NFA); 2, I^3SO_3-GalCer(HFA); 3, GalCer(NFA + HFA); 4, I^3SO_3-GalDG; 5, GalDG; 6, II^3SO_3-LacCer; 7, LacCer; 8, I^3SO_3-GalMG.

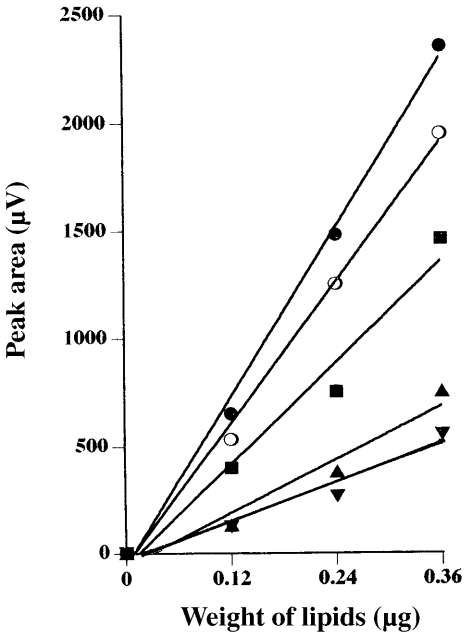

FIG. 2. Reactivities of several sulfoglycolipids with the monoclonal anti-I^3SO_3-GalCer antibody (TCS-1), as determined on TLC-immunostaining. Known amounts of several sulfoglycolipids were chromatographed with chloroform/methanol/water (65:35:8, by vol.), and then visualized with monoclonal antibody, TCS-1. The density of spots was determined with a TLC-densitometer as described in the text. ●, I^3SO_3-GalCer with HFA-sphingosine; ○, I^3SO_3-GalCer with NFA-phytosphingosine; ■, II^3SO_3-LacCer with NFA-sphingosine; ▲, I^3SO_3-GalCer with NFA-sphingosine; ▼, I^3SO_3-GalDG.

was confirmed by comparing its position on TLC with that of the standard CS, staining with ferric chloride reagent for steroid, and analyzing the materials from skin and uterine endometrium by negative ion fast atom bombardment mass spectrometry, which gave the ions characteristic for CS, $[M - H]^-$ at *m/z* 465, and sulfate-derived ions at *m/z* 80 and 97 (15). A relatively high concentration of CS (Table 1) was observed in the epithelia of the esophagus, uterine cervix and trachea, the mucosa of the gastrointestinal tract, the endometrium of the uterus from pseudopregnant rabbits, kidney, lung, skin, prostate, hair and nail. CS constituted 100 and 98.6% of the total acidic lipids in hair and nail, amounting to 2.3 and 1.4 nmol/g dry weight, respectively. Also, as reported previously (15), the concentration of CS in the uterine endometrium of pseudopregnant rabbits was confirmed to increase to 8.75 times higher than that in nonpregnant rabbits. In addition, CS was in the serum at a concentration of 0.1 nmol/mg protein, which was similar to that of I^3SO_3-GalCer in the serum. On the other hand, sulfoglycolipids showed a more restricted tissue distribution than that of CS. As shown in Figures 3 and 4, I^3SO_3-GalCer detected on TLC-immunostaining with anti-I^3SO_3-GalCer antibody was present in the mucosa of stomach, duodenum and jejunum, kidney, cerebrum, cerebellum, lung, and serum. Interestingly, the molar percentage of CS in the total sulfolipids in the digestive tract decreased in the order esophageal epithelium (100.0%), gastric mucosa (91.9%), duodenal mucosa (54.1%), and jejunal

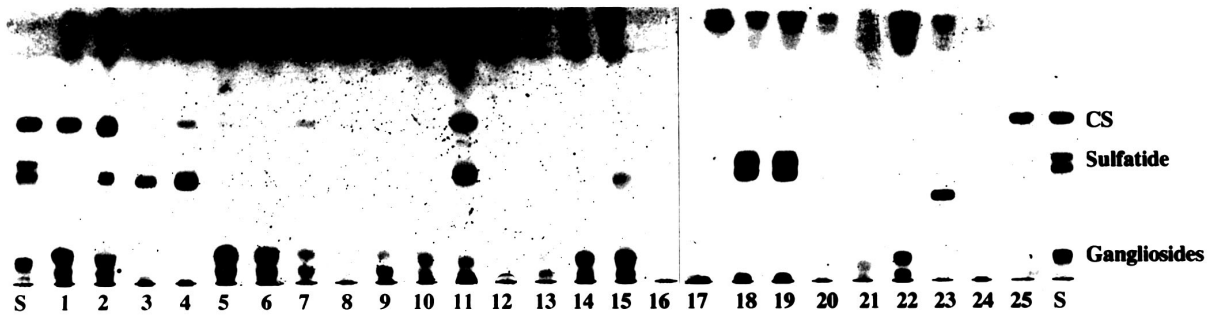

FIG. 3. TLC of acidic lipids from various tissues of rabbit. The developing solvent was chloroform/methanol/acetone/acetic acid/water (8:2:4:2:1, by vol), and the spots were visualized with cupric acetate-phosphoric acid reagent. 1, esophageal epithelium; 2, gastric mucosa; 3, duodenal mucosa; 4, jejunal mucosa; 5, tracheal epithelium; 6, uterine endometrium (nonpregnancy); 7, uterine endometrium (pseudopregnancy); 8, skin; 9, uterine cervical epithelium; 10, lung; 11, kidney; 12, heart; 13, liver; 14, spleen; 15, adrenal gland (female); 16, ovary; 17, thymus; 18, cerebrum; 19, cerebellum; 20, serum; 21, hair; 22, adrenal gland (male); 23, testis; 24, prostate; 25, nail; S, standard lipid mixture, CS, I^3SO_3-GalCer and II^3NeuAcα-LacCer.

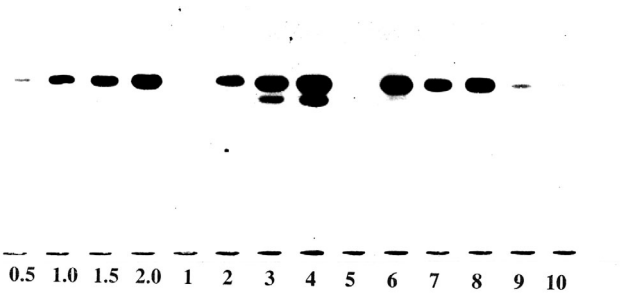

FIG. 4. TLC-immunostaining of acidic lipids from various tissues of rabbit. The developing solvent was the same as that in Figure 3, and the spots were located with the monoclonal anti-I^3SO_3-GalCer antibody. 0.5-2.0, μg of standard glycolipids, I^3SO_3-GalCer with NFA-sphingosine, purified in our laboratory. 1, esophageal mucosa; 2, gastric mucosa; 3, duodenal mucosa; 4, jejunal mucosa; 5, tracheal epithelium; 6, kidney; 7, cerebrum; 8, cerebellum; 9, serum; 10, lung.

mucosa (34.5%). Since the esophageal epithelium was composed of a laminated squamous epithelium, and the relative proportion of glandular epithelium increased in the order of gastric, duodenal and jejunal mucosas, in which I^3SO_3-GalCer was found to be highly concentrated in the apical and basal layers of glands on immunohistochemical staining with the anti-I^3SO_3-GalCer antibody (Cui Y. and Iwamori, M., to be published), CS was thought to be a component of the stratified and columnar epithelia in these digestive organs.

Specific activities of cholesterol sulfotransferase and CS sulfatase in various rabbit tissues. Relatively high specific activities of cholesterol sulfotransferase and CS sulfatase were observed in the esophageal epithelium of nonpregnant rabbits and the uterine endometrium of pseudopregnant rabbits, and in the liver, respectively (Table 2). The specific activity of cholesterol sulfotransferase in the uterine endometrium was 15 times higher in pseudopregnant rabbits than in nonpregnant rabbits, whereas that of CS sulfatase in pseudopregnant rabbits was one-third of that in nonpregnant rabbits. Thus, activation of cholesterol sulfotransferase and inhibition of CS sulfatase were found to contribute to the accumulation of CS in the endometrium of pseudopregnant rabbits. Although the specific activities of CS sulfatase in tissues other than liver were similar to each other, those of cholesterol sulfotransferase were quite different among the tissues examined and did not correspond with the concentration of CS. In addition, cholesterol sulfotransferase in the digestive tract and uterus was found to be present in the epithelial and endometrial layers but not in the tunica muscularis. Also, the specific activities of cholesterol sulfotransferase and dehydroepiandrosterone sulfotransferase in liver were 3.2 ± 0.7 pmol/mg protein/h and 1253.8 ± 15.0 pmol/mg protein/h, respectively, whereas those in the uterine endometrium of pseudopregnant rabbits were 1096.7 ± 283.7 pmol/mg protein/h and 1281.0 ± 89.4 pmol/mg protein/h, respectively, indicating that dehydroepiandrosterone sulfotransferase in liver is unable to catalyze the sulfation of cholesterol to the same level as that in the uterine endometrium. CS in the serum was thought to be derived through shedding from the tissues exhibiting synthetic activity for CS. Also, no synthetic activity was detected in hair exhibiting a high concentration of CS, which seemed to derive from the folliculus pili for the synthesis of hair, but the catalytic enzyme, CS sulfatase, was present in hair and was readily liberated by brief sonication, probably continuing the cleavage of CS in hair in the same manner as in the stratum corneum (5). Liver, testis, adrenal, ovary, cerebrum, and cerebellum tissues, in which CS was present in trace amounts, contained CS sulfatase, probably for processing of CS as a source of steroids.

DISCUSSION

CS has been characterized as a molecular marker for the epithelial differentiation of epidemal keratinocytes (8) as well as of tracheal epithelial cells (16), and has been proposed to act as an adhesive agent essential for the orderly adhesion-desquamation behavior of the epidermis (7). In accordance

TABLE 2
Specific Activities of Cholesterol Sulfotransferase and Cholesterol Sulfate Sulfatase in Various Tissues of Rabbit[a]

Tissues	Cholesterol sulfotransferase (pmol/mg protein/h)	Cholesterol sulfate sulfatase (pmol/mg protein/h)
Esophageal epithelium	1287.5 ± 522.9	8.4 ± 0.5
Gastric mucosa	10.0 ± 1.0	4.3 ± 0.4
Duodenal mucosa	2.6 ± 0.9	6.0 ± 0.5

Ovary	9.2 ± 2.9	26.5 ± 2.0
Thymus	0.5 ± 0.3	25.0 ± 1.5
Adrenal gland (female)	0	27.2 ± 1.9
Adrenal gland (male)	0	15.2 ± 0.9
Testis	56.9 ± 4.7	34.3 ± 2.1
Prostate	184.5 ± 77.4	25.5 ± 1.7

[a]Data are expressed as the mean of triplicate experiments. Tissues other than the uterine endometrium of pseudopregnant rabbits and the adrenal gland of male rabbits were obtained from nonpregnant female rabbits (6 mon old).

with those findings, CS was localized in the epidermal layers, but not in the tunica muscularis of the digestive tract and uterus, and in the skin including hair and nail. In the uterine endometrium of pseudopregnant rabbits, a formation of the dendritic structure due to dilation of the epithelium was found to be associated with activation of cholesterol sulfotransferase and accumulation of CS. Apparently, the synthesis of CS in the endometrium was associated with the formation of epithelium and was regulated with steroids, in a similar manner to that of dehydroepiandrosterone sulfotransferase (17).

In the cases of primary cultures of tracheal epithelial cells and epidermal keratinocytes, activation of cholesterol sulfotransferase and accumulation of CS were observed in the confluent stage (8,16,18), and were enhanced by treatment with phorbol-12-myristate-13-acetate, tumor growth factor-β, and high Ca^{2+}, which are agents that induce squamous differentiation. The reasons why the specific activity of cholesterol sulfotransferase in various tissues was not correlated with the concentration of CS were thought to be the broad substrate specificity and the association of the enzyme with differentiation. In addition, since CS sulfatase is an insoluble microsomal enzyme, contact of the enzyme with CS on the membrane seemed to be limited to give a longer half-life of CS (18). The tissues with high concentrations of CS and low specific activity of cholesterol sulfotransferase, such as gastric and duodenal mucosas, kidney, hair and nail, tended to accumulate CS as a membrane constituent, probably owing to the retarded cleavage of CS by insoluble CS sulfatase. However, the CS sulfatase in hair might be important for regulation of the CS/cholesterol ratio for normal desquamation, as in the stratum corneum (4,19). On the other hand, the tissue distribution of sulfated glycolipids was different from that of CS, being restricted to cerebrum, cerebellum, kidney, testis, and gastrointestinal tract. In the cerebrum and cerebellum, I^3SO_3-GalCer is known to be present in the myelin sheath (20) and to be a molecular marker of oligodendrocytes and Schwann cells (21,22), but its functional significance in other tissues is not clearly understood. However, our finding that the sulfated lipids induced in the human endometrium during the luteal phase and in rabbit endometrium during the pseudopregnancy were I^3SO_3-GalCer and CS, respectively, indicated the correlation of their morphologies, the human endometrium with a well-developed glandular structure containing I^3SO_3-GalCer (23) and rabbit endometrium with a dendritic epithelial structure containing CS (1). This finding coincided with the concentration gradients of CS and I^3SO_3-GalCer in the digestive organs of rabbit, as shown in Tables 1 and 2. The increase in the concentration of I^3SO_3-GalCer from the esophageal to the

jejunal mucosas was compensated for by the decreasing concentration of CS and was proportional to the relative glandular structure contents of the mucosa of the digestive tract. In fact, immunohistochemical staining of the mucosa with the monoclonal anti-I^3SO_3-GalCer antibody revealed the localization of I^3SO_3-GalCer in the apical and basal layers of glands in the gastric, duodenal and jejunal mucosas (Cui Y. and Iwamori, M., unpublished observation). Thus, the tissue-characteristic distribution of sulfolipids indicates the involvement of sulfolipids in the common functions of mammalian tissues.

Sesamol as an Inhibitor of Growth and Lipid Metabolism in *Mucor circinelloides via* Its Action on Malic Enzyme

James P. Wynn*, Andrew Kendrick[1], and Colin Ratledge

Department of Biological Sciences, University of Hull, Hull, HU6 7RX, United Kingdom

ABSTRACT: Sesamol, a nonoil component of sesame seed oil, inhibited growth, fatty acid synthesis, and desaturation by *Mucor circinelloides in vivo*. Although sesamol also inhibited the growth of other fungi and yeasts, its effect on the lipid metabolism of *M. circinelloides* was exceptional. An enzymological study demonstrated that sesamol affected lipid synthesis primarily by the inhibition of malic enzyme activity, thereby limiting the NADPH supply for fatty acid synthesis and desaturation. Sesamol itself had no inhibitory effect on malic enzyme activity *in vitro*. A metabolite of sesamol is therefore probably responsible for the *in vivo* effects of sesamol on lipid metabolism.
Lipids 32, 605–610 (1997).

Shimizu *et al.* (1), when examining the possible transformation of selected plant oils to more highly unsaturated fatty acids in *Mortierella alpina*, found that sesame seed oil diminished the normally high production of arachidonic acid (20:4) and caused a concomitant appearance of dihomo-γ-linolenic acid (20:3). This observation was explained by there being a nonoil component of the sesame seed oil that was acting as a specific inhibitor of the Δ5 desaturase which would normally have converted 20:3 to 20:4. The active component was subsequently shown to be sesamin (2). Sesamin had little or no effect on other desaturases (Δ6, Δ9, Δ12 desaturases were also studied) in *Mort. alpina*, but was equally effective against Δ5 desaturase activity in rat microsomes. Other nonoil components of sesame seed oil (episesamin, sesaminol, and sesamolin) were also inhibitors of Δ5 desaturases, but sesamol (another nonoil component of sesame seed oil) was not (2). These compounds have in common a methylene- bridged 3,4-dihydroxyphenol moiety and, with the exception of sesamol (which is 3,4-methylenedioxyphenol), are dimeric compounds.

In a study of the effect of plant oils, including sesame seed oil, on other fungi, we found that formation of arachidonic acid in *Entomophthora exitalis* was slightly inhibited by the nonoil component of sesame seed oil (3). It was considered, however, that the active component may have been sesamol and not sesamin (4). A further examination of sesamol has now shown that this compound is particularly inhibitory toward lipid biosynthesis and fatty acid desaturation in *Mucor circinelloides* though not in *E. exitalis*. *Mucor circinelloides* does not produce fatty acids longer than C_{18} and thus does not possess a Δ5 desaturase. It does, however, produce γ-linolenic acid (18:3 n-6) and is therefore of some commercial interest (5).

In this paper, we detail the effects of sesamol on the growth, lipid formation, and fatty acid desaturation in *M. circinelloides* and show that either sesamol, or more likely a derivative of it, causes an inhibition of malic enzyme (E.C. 1.1.1.40) activity. Malic enzyme has previously been shown to be associated with the provision of NADPH for both lipid biosynthesis (6,7) and fatty acid desaturation (6). Therefore, if it can be confirmed that sesamol exerts its effects by the inhibition of malic enzyme, sesamol may prove to be a useful agent by which to control lipid biosynthesis and accumulation.

MATERIALS AND METHODS

Chemicals. All fine chemicals were purchased from Sigma Chemical Corp. (St. Louis, MO) with the exception of sesamol which was purchased from Aldrich Co. Ltd. (Milwaukee, WI). Sodium salts were used throughout, unless otherwise specified.

Cultivation of microorganisms. Mucor circinelloides (CBS 108.16), *E. exitalis* (NRRL 92298), *Aspergillus niger* (ATCC 64108), *Aspergillus flavipes*, *Cryptococcus curvatus* (= *Apiotrichum curvatum* ATCC 20599), *Candida utilis*, *Saccharomyces cerevisiae* (NCYC 738), *Lipomyces starkeyi* (NCYC 1809), and *Rhodosporidium toruloides* (ATCC 226217) were cultivated in 1-L vortex-aerated bottles containing 800 mL of the high (40:1) C:N ratio medium described previously (6). The cultures were incubated at 30°C for 72 h. Biomass was harvested by filtration (filamentous fungi) or centrifugation (yeasts) at 10,000 × *g* for 10 min at 4°C and washed with distilled water.

Preparation of cell extracts. Biomass was suspended in 50 mM phosphate buffer (pH 7.0) containing: 250 mM sucrose, 2 mM benzamidine hydrochloride, and 2 mM dithiothreitol. Disruption of the biomass was achieved by passage, twice,

through a French press at 35 MPa, and the homogenate was centrifuged at 48,000 × *g* for 20 min at 4°C. The lipid layer was removed by filtration (Whatman No. 1; Maidstone, England) and the protein concentration of the extract determined (8) with bovine serum albumin as a standard.

Estimation of enzyme activities. With the exception of acetyl-CoA carboxylase EC 6.4.1.2, which was assayed using the high-performance liquid chromatography (HPLC) method of De Spiegeleer *et al.* (9), enzyme activities were determined using continuous spectrophotometric assays following the oxidation or reduction of NAD(P)(H) at 340 nm. All assays were carried out at 30°C.

With the exceptions of pyruvate dehydrogenase E.C. 3.1.3.43, pyruvate decarboxylase E.C. 4.1.1.1, and pyruvate carboxylase E.C. 6.4.1.1, the enzymes studied were assayed as described in the literature, with only minor modifications: ATP:citrate lyase E.C. 4.1.3.8 (10), at pH 8.6 with 10 mM sodium azide; malic enzyme E.C. 1.1.1.40 (11); malate dehydrogenase E.C. 1.1.1.37 (12); glucose-6-phosphate dehydrogenase E.C. 1.1.1.49 (13); 6-phosphogluconate dehydrogenase E.C. 1.1.1.44 (14); $NADP^+$/isocitrate dehydrogenase E.C. 1.1.1.42 (15); fatty acid synthetase complex (16).

Pyruvate dehydrogenase was determined using an assay volume containing 300 mM Tris/HCl (pH 8.5), 4 mM L-cysteine, 10 mM pyruvate, 0.12 mM CoA, 1.2 mM NAD^+, and 10 mM azide. Pyruvate decarboxylase was measured using an assay volume containing 50 mM KH_2PO_4/KOH (pH 6.5), 8 mM $MgCl_2$, 1.6 mM cocarboxylase, 2 mM L-cysteine, 0.15 mM NADH, 20 units yeast alcohol dehydrogenase, 5 mM pyruvate, and 10 mM sodium azide. Pyruvate carboxylase activity was determined using an assay volume containing 100 mM Tris/H_2SO_4 (pH 7.8), 3.5 mM ATP, 20 mM $KHCO_3$, 6.7 mM $MgSO_4$, 5 units malic dehydrogenase (from *Thermus flavua*), 84 μM acetyl-CoA, 10 mM pyruvate, 0.15 mM NADH, and 10 mM sodium azide.

Lipid analysis. Freeze-dried biomass was extracted using the method of Folch *et al.* (17) and the cell lipid content determined gravimetrically. Fatty acids were methylated using trimethylsulfonium hydroxide (18) and analyzed by gas chromatography using a packed column, 200 × 0.4 cm, of 10% (w/w) diethylene glycol succinate and 1% (w/w) H_3PO_4 on Chromosorb W-AW (80:100 mesh) (Alltech Associates Inc., Deerfield, IL). The column was run at 200°C with injector and detector at 230°C and N_2 as the carrier gas. Fatty acids were identified by comparison with authentic standards.

Determination of cell dry weights. Ten mL of culture was filtered onto preweighed glass fiber filters, Whatman GF/A (for filamentous fungi), or cellulose acetate filters, 0.45 μm pore size (for yeasts). Filters were washed with distilled water and dried at 100°C to constant weight, and reweighed.

Determination of alcohols in culture filtrates. The culture filtrate was extracted with diethyl ether and the solvent evaporated under reduced pressure to approximately 0.2 mL. The samples were analyzed by gas chromatography using a 5% (w/w) Carbowax 1500 column (on Graphpac 80:100) (Alltech) with N_2 as the carrier gas. The column was at 150°C with the injector and the detector at 175°C. Alcohols were identified by comparison with authentic standards and quantified by reference to a standard curve.

Inclusion of trihydroxybenzenes in enzyme assays. When trihydroxybenzenes were included in enzyme assays, 1 mg superoxide dismutase/mL (from bovine erythrocytes, 2500–7000 units/mg) was included in the assays, and the assays were carried out under N_2 so as to avoid the auto-oxidation of the trihydroxybenzenes.

Thin-layer chromatography. Thin-layer chromatography analysis was carried out on silica G-gel plates (0.25-mm thick, 20 × 20 cm; Merck, Darmstadt, Germany). The mobile phase contained chloroform/methanol/water/acetic acid (65:43:3:1, by vol) and spots were visualized by ultraviolet illumination.

Reproducibility of experimental data. All experiments were carried out on three separate occasions (unless otherwise stated), and the data obtained demonstrated reproducible trends in all cases. Owing, however, to the variation in the absolute values obtained in different experiments, representative data from single experiments are presented.

RESULTS AND DISCUSSION

Analysis of commercial sesamol. Thin-layer chromatographic analysis of commercial sesamol showed that it contained approximately 7.5% (w/w) impurities. Because these impurities, when isolated and tested separately, had no effect on the growth or lipid metabolism of *M. circinelloides*, the data presented here were obtained using commercial sesamol without further purification.

Effect of sesamol on the growth and production of lipid by M. circinelloides. Sesamol inhibited both the growth of and lipid production by *M. circinelloides* (see Table 1). Growth inhibition was evident at 1.5 mM sesamol, and at 10 mM was complete. The production of lipid by *M. circinelloides* was more sensitive to the presence of sesamol than cell growth. While the inclusion of 1.5 mM sesamol in culture medium caused less than a 10% decrease in fungal biomass, the lipid content of the mycelia was decreased by 75%. Increased concentrations further inhibited lipid production so that mycelia grown in the presence of greater than 4 mM sesamol contained only 1 to 2% (w/w) cell lipid. Since vegetatively growing *M. circinelloides* (in the absence of sesamol) contained approximately 5% (w/w) cell lipid (data not presented), it is probable that 1 to 2% (w/w) cell lipid represents the minimum lipid content that allowed cell survival.

Sesamol not only affected cell lipid accumulation quantitatively in *M. circinelloides*, but also the fatty acyl composition of the cell lipid produced (see Table 1). The 18:3 n-6 content of the cell lipid was most affected, being decreased by 50% in the presence of 1.5 mM sesamol with a concomitant increase in the content of linoleic acid (18:2). This decrease in the 18:3 n-6 content of the cell lipid was indicative of an inhibition of the Δ6 desaturase activity. As the concentration of sesamol was increased, the contents of both 18:3 n-6 and

UI	1.14	1.07	1.10	0.88	0.78	0.99	0.84	0.80

[a]Others = 14:0, 14:1, 14:2, 16:1, and 16:2, all were present at less than 0.5% (w/w) total cell lipid; UI = unsaturation index = [% monoene + 2(% diene) + 3(% triene)]/100.

18:2 decreased, and there was a gradual increase in the content of oleic acid (18:1) (to over 150% its initial value) and stearic acid (18:0) (to approximately twice its initial value). The increase in the content of saturated and monounsaturated fatty acids in the cell lipids, at the expense of the di- and triunsaturated fatty acids, indicated that sesamol was inhibiting both the Δ6 and Δ12 desaturases, even though to different extents, and suggested, because of the increase in 18:0, that the Δ9 desaturase may also be affected. That the inhibition of all three desaturases was occurring distinguishes the action of sesamol from that of the other nonoil components of sesame seed oil that have been shown to specifically inhibit the Δ5 fatty acid desaturase in other systems (2).

Supplementation of the culture medium with sesamol affected the intermediary metabolism of *M. circinelloides*, promoting the accumulation of alcohols by the fungus. The most abundant alcohols produced were ethanol (22 mM) and butan-2-ol (4 mM), giving a combined yield of approximately 1.5 g/L. No alcohol was detected in the culture filtrates of *M. circinelloides* grown in the absence of sesamol. A similar diversion of carbon from lipid production to ethanol production has been reported to occur in *Fusarium moniliforme* when exposed to high concentrations of Zn^{2+} (19).

Effect of sesamol on the growth and lipid production by a range of fungi and yeasts. The addition of sesamol to the culture medium inhibited the growth of all the microorganisms examined (see Table 2), with 7.2 mM sesamol causing total inhibition in all cases. In this regard the effect of sesamol on these organisms appeared even more pronounced than that on *M. circinelloides*. However the amount of cell lipid accumulated by these microorganisms was not affected by sesamol, even at concentrations that severely inhibited growth (data not presented), indicating that sesamol affected neither lipid biosynthesis nor fatty acid desaturation in these organisms. Thus the action of sesamol on the lipid metabolism of *M. circinelloides* appeared to be exceptional.

Effect of sesamol on the activity of key enzymes in vivo. To establish the mode of action of sesamol at the enzymic level, the activities of a number of enzymes were determined in *M. circinelloides* grown in the presence and absence of 5.7 mM sesamol (see Table 3). Of the enzymes detected, significant changes were observed only in the activities of pyruvate carboxylase (decreased by 85%), pyruvate decarboxylase (increased by 300%), $NADP^+$/isocitrate dehydrogenase (decreased by 57%), and malic enzyme (decreased by 98%). Pyruvate dehydrogenase and acetyl-CoA carboxylase activities were assayed but not detected in any extract of *M. circinelloides*. The failure to detect these two enzymes was presumably due to their lability and deactivation during the production of cell extracts rather than the absence of these enzymes in *M. circinelloides*.

The changes in the activities of pyruvate carboxylase, which was 85% inhibited, and pyruvate decarboxylase, which was stimulated 3-fold, can explain the accumulation of ethanol when *M. circinelloides* was grown in the presence of sesamol. Pyruvate carboxylase is one of the two enzymes (the other being pyruvate dehydrogenase) involved in channeling pyruvate into the citric acid cycle. Pyruvate decarboxylase, on the other hand, catalyzes the conversion of pyruvate to acetaldehyde, which is subsequently converted to ethanol. Thus the decrease in pyruvate carboxylase activity (which would limit citrate production) and the increase in pyruvate decarboxylase activity (leading to acetaldehyde accumulation) would lead to a diversion of carbon, at the level of pyruvate, from the citric acid cycle to acetaldehyde and subsequently into ethanol production.

The decreases in $NADP^+$/isocitrate dehydrogenase and malic enzyme activity both will affect the NADPH-generating capacity of the fungus and therefore may be responsible for the changes in lipid metabolism observed when *M. circinelloides* is exposed to sesamol. It is likely that the decrease in malic enzyme activity was the most important fac-

[a]The microorganisms were grown for 72 h in vortex-aerated bottles prior to determination of the cell dry weights and cell lipid contents.

tor affecting the lipid metabolism of the fungus as the change in this activity was the most dramatic. Also malic enzyme has been shown to be an important source of NADPH for the production of storage lipid in oleaginous fungi (6,7) and for fatty acid desaturation in *M. circinelloides* (6). Hence the almost complete absence of malic enzyme activity in *M. circinelloides* when the fungus was grown in the presence of sesamol would explain the inhibition of both lipid accumulation and fatty acid desaturation.

Effect of sesamol on enzyme activities in vitro. When 5 mM sesamol was added directly to the enzyme assays, it did not affect the activity of any of the enzymes given in Table 3. Even at 50 mM, sesamol did not inhibit malic enzyme activity. This lack of effect *in vitro* suggested that the action of sesamol on the activity of malic enzyme, $NADP^+$/isocitrate dehydrogenase, pyruvate carboxylase, and pyruvate decarboxylase in growing cells (see Table 3) may not be due to the presence of sesamol itself but to a product of sesamol formed by its metabolism by *M. circinelloides*.

An alternative suggestion, that the decreases in the activities of malic enzyme, $NADP^+$/isocitrate dehydrogenase and pyruvate carboxylase could be due to repression of the synthesis of these enzymes by sesamol or a metabolite of sesamol, was precluded. *Mucor circinelloides* was grown for 16 h in the absence of sesamol. Biomass was harvested, washed, and transferred to a medium containing either glucose (supplemented with 5 mM sesamol) or acetate (10 g/L, containing no sesamol) as the carbon source. Acetate represses malic en-

[a]The experiment was carried out in quadruplicate, and representative data are presented.

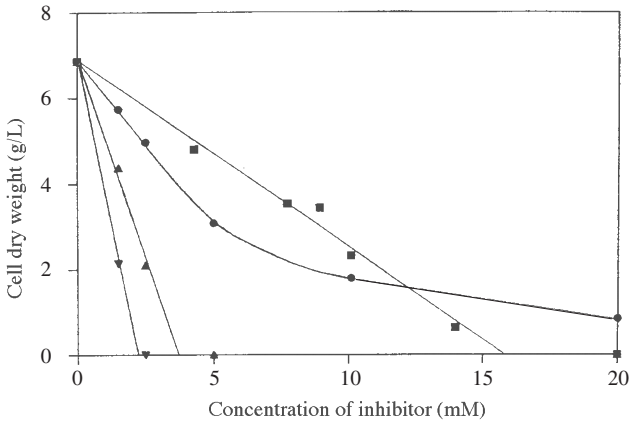

FIG. 1. Effect of sesamol and sesamol analogs on the growth of *Mucor circinelloides*. Methylenedioxybenzene-containing compounds were included in the culture medium up to 20 mM: sesamol (■), piperonyl butoxide (●), safrole (▲), and isosafrole (▼).

zyme activity in *Neurospora crassa* (20) and in *M. circinelloides* (data not presented). Transfer of biomass to a medium containing sesamol (with glucose as the carbon source) caused a 45% decrease in the activity of malic enzyme after 60 min, whereas there was no change in malic enzyme activity in biomass transferred to a medium containing acetate after 60 min. Repression of the malic enzyme activity in the acetate medium was not observed until after 3.5 h.

When the cell extracts produced from the cells exposed to sesamol for 1 h were dialyzed, malic enzyme activity was not restored, suggesting that the inhibition of malic enzyme activity involved an irreversible effect, with the active component either binding to the enzyme or causing posttranscriptional changes within its structure.

Effect of compounds containing a methylenedioxybenzene group on the growth of, and lipid production by, M. circinelloides. It was thought possible that the active breakdown product of sesamol, responsible for the inhibition of cell growth and effects on lipid metabolism, may contain a methylenedioxybenzene structure. Such compounds have long been recognized as being inhibitors of microsomal oxidases in mammalian and insect systems (21–23).

The inclusion of safrole, isosafrole, and piperonyl butoxide (all compounds containing a methylenedioxybenzene group) in the culture medium also inhibited growth. Indeed all three compounds were equally, or more, inhibitory to growth of *M. circinelloides* than sesamol (see Fig. 1). However, none of these compounds adversely affected lipid biosynthesis, fatty acid desaturation or, most significantly, malic enzyme activity in *M. circinelloides* (data not presented) and were therefore not thought to resemble the active metabolite responsible for the *in vivo* inhibition of malic enzyme activity.

Effect of a range of catechol derivatives on the activity of malic enzyme. Another possibility was that sesamol may undergo the removal of its methylene C atom to yield a catechol-like compound. Catechol-like compounds are formed (*in vivo*) from methylenedioxyphenyl compounds when these compounds are administered to both animals and insects (24). A range of catechol derivatives was therefore tested for their ability to inhibit malic enzyme activity *in vitro* (see Table 4).

Several of the compounds were potent inhibitors of malic enzyme *in vitro*, the most potent (1,2,3-trihydroxybenzoic acid) causing 50% inhibition of the activity (IC_{50} value) at 0.22 mM. The inhibition of malic enzyme activity appeared to depend upon the possession of two hydroxyl functions on adjacent carbons of the benzene ring. 1,3,5-Trihydroxybenzoic acid, a compound that possesses three hydroxyl groups separated from each other on the benzene ring by an unhydroxylated carbon, did not cause inhibition of malic enzyme

The Apparent IC_{50} Values for Sesamol and a Range of Catechol-Related Compounds with Respect to Malic Enzyme Activity Assayed *in vitro*[a]

Compound	Apparent IC_{50} value (mM)
Sesamol	No inhibition
Catechol	0.5
3-Methyl catechol	3.1
4-Methyl catechol	15.9
3-Isopropyl catechol	0.9
4-Tertiary butyl catechol	5.6
3,4-Dihydroxybenzoic acid	16
1,2,4-Trihydroxybenzoic acid	0.37
1,2,3-Trihydroxybenzoic acid	0.22
1,3,5-Trihydroxybenzoic acid	No inhibition
2-Hydroxybenzyl alcohol	2.8
3-Hydroxybenzyl alcohol	No inhibition
4-Hydroxybenzyl alcohol	No inhibition
Resorcinol	23.8
2,3-Dihydroxybiphenol	No inhibition

[a]IC_{50} value (inhibitory concentration 50%) was the concentration of each compound that resulted in the reduction in the apparent activity of malic enzyme to 50% of its initial value.

activity. The dialysis of extracts after the addition of the catechol-related inhibitors did not reinstate malic enzyme activity, demonstrating that the inhibition caused by these compounds was, like that of sesamol itself (when activated in the cell), irreversible.

Although catechol, 3-methyl catechol, and 2-hydroxybenzyl catechol were inhibitors of malic enzyme *in vitro*, none of these caused a decrease in malic enzyme activity *in vivo* when added to actively growing cells of *M. circinelloides*. This was attributed to these compounds not accumulating within the fungal cells, owing to either a lack of uptake or the rapid metabolism of these compounds within the cells.

It seems likely therefore that sesamol is a compound that, although it is not an inhibitor of malic enzyme itself, is readily assimilated by *M. circinelloides.* Once assimilated it is metabolized to form a catechol-like compound which inhibits malic enzyme activity and causes the inhibition of both fatty acid accumulation and desaturation by limiting the supply of NADPH.

Modification of Odd-Chain Length Unsaturated Fatty Acids by Hepatocytes of Rainbow Trout (*Oncorhynchus mykiss*) Fed Diets Containing Fish Oil or Olive Oil

C. Rodríguez*, R.J. Henderson, A.E.A. Porter, and J.R. Dick

N.E.R.C. Unit of Aquatic Biochemistry, Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: Hepatocytes isolated from rainbow trout fed on diets containing either fish oil or olive oil were incubated with individual odd-chain length unsaturated fatty acids (19:1n-9, 19:2n-6, 19:3n-3, 21:2n-6, 21:3n-6, 21:4n-6, 21:3n-3, and 21:5n-3) to examine whether these fatty acids were substrates for modification by desaturation and elongation. All odd-chain length fatty acids were readily assimilated into the lipids of hepatocytes from both dietary groups of fish, but their conversion to longer-chain, more unsaturated derivatives was more pronounced with cells from trout fed olive oil. Thus, the conversion of 19:2n-6 and 21:2n-6 to 21:3n-6 and 21:4n-6, and of 19:3n-3 to 21:4n-3 and 21:5n-3, was most obvious in cells from the olive oil group, as was the conversion of 21:3n-6 and 21:3n-3 to 21:4n-6 and 21:4n-3, respectively. Elongation of 19:1n-9 to 21:1n-9 and 23:1n-9 occurred in cells from both groups. No 23:6n-3 was detectable as a product of 19:3n-3 or 21:3n-3. However, this fatty acid was a major product formed by cells from fish fed olive oil presented with 21:5n-3. Cells from both groups of fish incorporated 21:4n-6 and 21:5n-3 into their lipids largely without modification but chain-shortened around 40, 23, and 19% of the incorporated 21:2n-6, 21:3n-3, and 19:1n-9, respectively. The results demonstrate that odd-chain length unsaturated fatty acids can act as substrates for the desaturation, elongation, and chain-shortening systems of trout hepatocytes.
Lipids 72, 611–619 (1997).

Fish, in common with other animals, are incapable of synthesizing polyunsaturated fatty acids (PUFA) *de novo* but can, depending on species, convert to a greater or lesser extent PUFA arising in the diet to their longer and usually more unsaturated counterparts (1). Despite the natural abundance of 22:6n-3 in the lipids of fish (2), little is known of how it is formed, although evidence gained from recent studies with trout hepatocytes (3) indicates that it is independent of a Δ4 desaturase and proceeds *via* C_{24} intermediates as has been established for rats (4).

The liver plays a critical role in various aspects of lipid metabolism such as the uptake, oxidation, and conversion of fatty acids and the supply of long-chain PUFA to the other tissues (5,6). Thus, isolated hepatocytes have proved to be a good metabolic model for the study of lipogenesis in fish (7).

Most previous studies on the biosynthetic pathways of PUFA in isolated fish cells, e.g. (3,8), have employed radiolabeled fatty acids as substrates but, although much information has been gained, details of the individual conversion steps have not been fully established. In early studies on the biosynthesis of n-6 PUFA in rat, the odd-chain length PUFA 17:2n-5 and 19:2n-7 were used to help establish the sequence of desaturation and elongation steps involved in the addition of two more double bonds (9). By analogy, odd-chain length unsaturated fatty acids (OCLUFA) can also be used to investigate the formation of the highly unsaturated fatty acids containing five or six double bonds in fish liver cells. Apart from the occurrence of very low levels of 21:5 in the lipids of some marine organisms (10–12) and of some n-6 odd-chain components in rat seminiferous tubules (13), odd-chain PUFA are very rare in nature. Thus, the use of OCLUFA as tracers for the enzymes of conversion should not be affected by the dilution of products by existing fatty acids. Although [1-^{14}C]- and, more recently, [3-^{14}C]-radiolabeled fatty acids have been used successfully to gain information on the pathways of PUFA formation in animal cells (3,14–16), the loss of their radiolabel after one or two cycles of β-oxidation makes it difficult to study the final fate of the substrate. The use of odd-chain length fatty acids as substrates does not have this disadvantage, since the actual mass of the substrates and their products in cell lipid can be measured.

The present study was undertaken to examine whether OCLUFA can help elucidate PUFA formation in trout hepatocytes. For this purpose, eight different odd-chain length substrates were synthesized, presented to hepatocytes, and the cell fatty acid composition examined for various products. Since it has been shown recently that the rate of 22:6n-3 synthesis from 18:3n-3 in trout hepatocytes *in vitro* is enhanced by maintaining the fish on a diet devoid of preformed long-

Abbreviations: BSA, bovine serum albumin; FAME, fatty acid methyl esters; FCS, fetal calf serum; GC, gas chromatography; HBSS, Hank's balanced salt solution; HPTLC, high-performance thin-layer chromatography; MS, mass spectrometry; OCLUFA, odd-chain length unsaturated fatty acids; OO, olive oil; PL, polar lipids; PUFA, polyunsaturated fatty acids; TAG, triacylglycerols; TL, total lipids; TLC, thin-layer chromatography.

chain n-3 PUFA (3), the uptake and modification of the odd-chain length substrates by hepatocytes prepared from trout maintained on diets containing fish oil or olive oil were compared.

EXPERIMENTAL PROCEDURES

Materials. Medium 199 (M199), Hank's balanced salt solution (HBSS), fetal calf serum (FCS), fatty acid-free bovine serum albumin (BSA), collagenase Type IV, antibiotics (penicillin/streptomycin, 5000 units/5 mg mL^{-1}), and the anesthetic 3-aminobenzoic acid ethyl ester were all obtained from Sigma (Poole, Dorset, United Kingdom).

Thin-layer chromatography (TLC) (20 × 20 cm × 0.25 mm) and high-performance thin-layer chromatography (HPTLC) (10 × 10 cm × 0.15 mm) plates precoated with Silicagel 60 (without fluorescent indicator) were purchased from Merck (Darmstadt, Germany). All organic solvents were of high-performance liquid chromatography grade and were purchased from Rathburn Chemicals (Walkerburn, Scotland, United Kingdom).

Experimental animal and diets. Juvenile rainbow trout, *Oncorhynchus mykiss* (70–100 g), were obtained from a commercial fish farm and maintained as two groups in 60-L self-cleaning circular tanks, with constantly flowing water at a temperature of 12°C. One group was fed on a control commercial diet containing fish oil (EWOS, Bathgate, United Kingdom) while the other was maintained on an experimental diet based on olive oil (OO) and deficient in both 20:5n-3 and 22:6n-3 (3). Fish were fed at a daily rate of 2% of their body weight and killed after 3 mon to prepare the hepatocytes.

Preparation of hepatocytes. Trout hepatocytes were prepared by modification of the methods of Moon *et al.* (7) and Klaunig *et al.* (17). Anesthetized fish were killed by a sharp blow to the head, and their livers rapidly removed. The hepatic portal vein or another suitable vessel was then cannulated to clear the liver of blood by perfusion with well-oxygenated (95% O_2/5% CO_2) HBSS, which contained 0.6 mM EDTA, 10 mM HEPES, and 25 mM $NaHCO_3$. The liver was then subjected to a second perfusion with HBSS containing 10 mM HEPES, 4 mM $CaCl_2$, 25 mM $NaHCO_3$ and 1 mg/mL of collagenase to yield a well-digested liver after 30–45 min. Poorly perfused areas were removed and the rest passed through a nylon screen of plankton netting (250 μm). Cells were collected by centrifugation at 100 × *g* for 5 min and washed twice with HBSS containing 10 mg/mL of BSA. The isolated hepatocytes were gently resuspended into M199 containing 2% of FCS and 1% of the antibiotic mixture. A sample was taken to establish the number and viability of cells by using trypan blue exclusion. Protein content of the hepatocytes was determined according to Lowry *et al.* (18).

Synthesis of odd-chain length unsaturated fatty acids. Eight odd-chain length fatty acids, 19:1n-9 [10-19:1], 19:2n-6 [10,13-19:2], 19:3n-3 [10,13,16-19:3], 21:2n-6 [12,15-21:2], 21:3n-6 [9,12,15-21:3], 21:3n-3 [12,15,18-21:3], 21:4n-6 [6,9,12,15-21:4], and 21:5n-3 [6,9,12,15,18-21:5], were synthesized from their respective C_{18} and C_{20} fatty acids as follows. The fatty acid (0.1 g) dissolved in anhydrous diethyl ether (10 mL) was added dropwise over 10 min to a magnetically stirred solution of an excess of lithium aluminum hydride in anhydrous ether (0.3 g/10 mL) under an atmosphere of argon. The solution was stirred for 4 h, and then a solution of saturated ammonium chloride (5 mL) added dropwise to destroy excess lithium aluminum hydride. The ether phase was separated, the residual aqueous phase washed with diethyl ether (3 × 10 mL), and the combined ether extracts dried over anhydrous magnesium sulfate, filtered, and evaporated to yield the crude alcohol.

The crude alcohol was dissolved in dry dichloromethane, and methane sulfonyl chloride (0.1 g) and 1 mL of pyridine were added to the solution which was then stirred overnight at room temperature under an atmosphere of argon. The dichloromethane was removed by evaporation under reduced pressure and the residue dissolved in diethyl ether (50 mL). The ether solution was extracted with 2 M HCl (4 × 25 mL), and the combined HCl extracts were back-extracted with ether (3 × 25 mL). The combined ether extracts were dried over anhydrous magnesium sulfate, filtered, and evaporated. The resultant crude mesylate was purified by flash column chromatography on silica, using a petroleum ether/ethyl acetate gradient (0–10%) to yield a homogeneous product as assessed by TLC using petroleum ether/ethyl acetate (9:1, vol/vol) as developing solvent.

To the purified mesylate dissolved in 10 mL of dry dimethylformamide, potassium cyanide (0.15 g, 97%) was added and the reaction mixture stirred at 80°C in the dark for 24 h. The reaction mixture was poured onto water (200 mL) and extracted with diethyl ether (6 × 50 mL). The combined ether extracts were backwashed with saturated sodium chloride solution, dried over $MgSO_4$, filtered, and evaporated to dryness on a rotary evaporator. Following purification by flash column chromatography as described above, the crude product was chromatographically homogeneous and displayed a characteristic nitrile stretch in the infrared spectrum at *ca.* 2245 cm^{-1}.

Finally, the purified nitrile was stirred overnight with a solution of 25% anhydrous hydrochloric acid in anhydrous methanol (10 mL) under an atmosphere of argon. The methanol was removed by rotary evaporation and the residue partitioned between water (10 mL) and diethyl ether. The ether layer was separated, and the aqueous phase washed with ether (3 × 25 mL). The combined ether extracts were dried, filtered, and evaporated to yield the crude fatty acid methyl esters (FAME) which were purified by flash column chromatography as described above. The product was chromatographically homogeneous and displayed characteristic ester carbonyl (1730 cm^{-1}) and double-bond (1650 cm^{-1}) stretches in the infrared spectrum.

Purity of the FAME product was assessed by gas chromatography (GC) as described below and was in excess of 97% for all the odd-chain length fatty acids. The identity of

individual OCLUFA was confirmed by GC–mass spectrometry (GC–MS) of their methyl esters using the system described below. After hydrolysis of the FAME (19), HPTLC analysis showed the products to be entirely in their free fatty acid form. For presentation to hepatocytes, the fatty acids were converted to their potassium salts by dissolving in a 10-fold molar excess of 0.1 M KOH solution followed by the addition to the solution of sufficient BSA to give a molar ratio of fatty acid to BSA of 6:1.

Hepatocyte incubation. Isolated hepatocytes were incubated as monolayers in sterile plastic Petri dishes at a concentration of 5.5×10^6 cells mL^{-1}, in 5 mL of M199 supplemented with FCS and antibiotics. The cells were incubated for 18 h at 10°C with 30 μM of one of the OCLUFA, which were added to the medium as their potassium salts bound to BSA. The incubation conditions were established in preliminary experiments which proved that a substrate concentration of 30 μM with an incubation time of 18 h yielded high fatty acid recoveries without adversely affecting the lipid class composition and cell viability. A control group of cells was also maintained under the same conditions without the addition of any fatty acid to their incubation media.

After 18 h of incubation, hepatocytes were aspirated into test tubes and subjected to the trypan blue viability test. Viability rate was not significantly affected ($P < 0.05$) by the addition of any of the OCLUFA in either dietary group and routinely exceeded 95%.

Lipid extraction. Hepatocytes were washed twice with M199 in test tubes and their lipids extracted with chloroform/methanol (2:1, vol/vol) as described by Christie (20). The organic solvent was evaporated under a stream of nitrogen and the lipid content determined gravimetrically.

Lipid class analysis. Lipid classes were separated by one-dimensional, double development HPTLC using methyl acetate/isopropanol/chloroform/methanol/0.25% (wt/vol) KCl (25:25:25:10:9, by vol) as the polar solvent system, and hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) as the neutral solvent system. Lipid classes were quantified by charring with copper acetate reagent followed by calibrated scanning densitometry using a Shimadzu CS-9000 dual wavelength flying spot scanner and DR-2 recorder (Tokyo, Japan) (21).

Fatty acid analysis. The polar lipid (PL) fraction and triacylglycerols (TAG) were separated by TLC using hexane/diethyl ether/glacial acetic acid (80:20:2, by vol) as the developing solvent. Chromatograms were sprayed with 2′,7′-dichlorofluorescein in 98% (vol/vol) methanol containing 0.01% (wt/vol) butylated hydroxytoluene and the separated lipids visualized under ultraviolet light.

Bands of adsorbent containing the PL fraction and TAG were scraped off the plates into test tubes and subjected to acid-catalyzed transmethylation to yield FAME (19). A portion of the total lipid (TL) was also subjected to the transmethylation procedure. Prior to transmethylation, 19:0 fatty acid was added as an internal standard to the TL, TAG, and PL fractions.

The analysis of FAME was performed using a Packard 436 gas chromatograph equipped with a capillary column of fused silica (25 m × 0.32 mm i.d.) coated with FFAP CB (Chrompack, Middleburg, The Netherlands). Hydrogen was used as carrier gas, and during each analysis the oven temperature was programmed to rise from 50 to 150°C at a rate of 39°C min^{-1} and then 2.5°C min^{-1} to a final temperature of 230°C. Individual FAME were identified by reference to authentic standards and to a composite standard prepared by mixing a well-characterized fish oil and the eight OCLUFA used in incubations with hepatocytes. To confirm the identity of the fatty acids derived from OCLUFA substrates, FAME prepared from hepatocyte lipids were subjected to analysis by GC–MS using a Carlo Erba 8000 GC coupled to a MD 800 MS (Fisons Instruments, Crawley, United Kingdom). The gas chromatograph was equipped with a fused-silica capillary column (15 m × 0.25 mm i.d.) coated with DB 5MS (J&W Scientific, Folsom, CA) and helium used as carrier gas. Samples were applied using on-column injection with the oven temperature programmed to rise from 50 to 225°C.

Statistical analysis. Data are presented as means of triplicates ± SD. For analysis by GC–MS of products derived from OCLUFA, triplicates of FAME samples were pooled and for this reason data corresponding to these products are expressed as a single value. Pairs of means were compared by a two-tailed Student's *t*-test. Comparisons between a mean and an undetected fatty acid were performed using a one-tailed *t*-test considering the absent fatty acid as zero.

Homogeneity of the OCLUFA recoveries was checked by using the Bartlett's variance test and when necessary data were normalized by arcsin transformation. Differences between the eight means were analyzed by one-way analysis of variance followed, where appropriate, by Tukey's multiple comparison test (22).

In all statistical tests used, *P* values of less than 0.05 were considered statistically different.

RESULTS

Lipid class composition of trout hepatocytes. Hepatocytes isolated from trout fed OO diet had a significantly higher lipid content than those prepared from fish maintained on the control diet (Table 1). Although differences were observed between the two dietary groups in hepatocyte lipid class composition, these were generally minor and the overall proportions of total polar and total neutral lipids were not significantly different between the two groups (Table 1). TAG and choline glycerophospholipids were always the major neutral and PL, respectively. The addition of OCLUFA to the incubation medium did not affect the lipid class composition of the hepatocytes (data not shown).

Fatty acid composition of dietary lipids and trout hepatocytes. The level of n-3 fatty acids present in the OO diet was very low in comparison with that of the control diet (0.9 vs. 19.4% of total fatty acids). More than 70% of the fatty acid in the OO diet was oleic acid (18:1n-9) with the rest being mainly palmitic (16:0) and linoleic (18:2n-6) acids (Table 2).

Unidentified	4.2	—

[a]Mainly 18:1n-9 isomer.
[b]Also includes 20:2n-6, 22:4n-6, and 22:5n-6. PUFA, polyunsaturated fatty acids; —, not detected; trace, fatty acid values < 0.4%.

The fatty acid compositions of hepatocytes from trout fed either the control or the n-3-deficient OO diet are shown in Table 3. The proportions of n-3 PUFA present in the TL decreased from 48.7% in the control cells to 21.7% in the hepatocytes from trout fed the OO diet. Conversely, these latter hepatocytes contained approximately double the levels of monounsaturated fatty acids and n-6 fatty acids in their TL than those from the control group.

The depletion of n-3 PUFA, particularly 22:6n-3 and 20:5n-3, in the hepatocytes of the OO dietary group was less pronounced in the PL fraction than in the TAG. The increments of n-9 fatty acids observed in both TAG and PL of these hepatocytes were caused mainly by the accumulation of 18:1n-9 together with the appearance of 20:2n-9 and especially 20:3n-9. At the same time, the total level of n-6 fatty acids increased, particularly in the PL, owing to increases in the proportions of 18:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6.

Incorporation of OCLUFA in trout hepatocytes lipids. The amounts of unmodified substrates recovered in the lipids of hepatocytes prepared from fish fed the control and OO diets are shown in Table 4. With the exception of 21:3n-6 and 21:3n-3, the amount of each unmodified OCLUFA recovered in the TL and TAG of cells was not significantly influenced by the diet fed to the fish. Hepatocytes from trout maintained on the OO diet assimilated less 21:3n-6 into TL and less 21:3n-3 into TAG than those from fish fed the control diet. An increased incorporation of OCLUFA substrates under n-3-deficient conditions was more evident in PL although this increment was only statistically significant for 19:2n-6, 21:4n-6, 21:3n-3, and 21:5n-3.

Notable differences existed between the eight substrates in terms of absolute amounts recovered in hepatocyte lipids (Table 4). With cells from both dietary groups, the levels of 19:3n-3 recovered in TL were significantly higher than those of 21:3n-3 or 21:2n-6. Differences between the substrates were less pronounced in the TAG, although the amounts of 19:3n-3 and 21:5n-3 recovered in this lipid class were always statistically higher than those of 21:3n-3. The recovery patterns of the OCLUFA substrates in hepatocyte PL differed between the two dietary groups. In hepatocytes from control fish significantly higher amounts of both 19:1n-9 and 19:3n-3 than 21:2n-6 and 21:3n-3 were present, whereas in the n-3-deficient cells recoveries of 19:3n-3, 21:4n-6, and 21:5n-3 in PL were higher than those of 21:2n-6, 21:3n-6, and 21:3n-3.

OCLUFA conversion products. The lipids of hepatocytes incubated with OCLUFA substrates contained measurable amounts of other OCLUFA derived from these substrates by chain-shortening, elongation, and desaturation (Tables 5–7). Thus, C_{17}, C_{21}, and C_{23} monounsaturated fatty acids were detected in cells incubated with 19:1n-9, and it was notable that 17:1 was always more abundant than 21:1 and 23:1, particularly in PL (Table 5). Likewise, cells from control fish presented with 19:2n-6 contained 17:2, 21:2, and 23:2, while those from fish fed olive oil contained in addition 21:3 and 21:4. The levels of C_{21} and C_{23} OCLUFA were higher in

[a]Footnote as in Table 5.

subjected to chain-shortening decreased in the order 19:1n-9 > 19:2n-6 > 19:3n-3 while the proportion of 19:3n-3 elongated and desaturated was greater than those of 19:2n-6 or 19:1n-9, particularly in hepatocytes from OO- fed fish. The chain-shortened products of 19:1n-9 and 19:2n-6 were notably more prominent in PL than in TAG. When incubated with the C_{21}n-6 substrates, 21:2, 21:3, and 21:4, cells prepared from the livers of fish fed the OO diet generated more OCLUFA products than cells from the livers of control fish (Table 6). Thus, in the TL of hepatocytes from control fish incubated with 21:2n-6, 19:2 and 17:2 were the main products along with a smaller amount of 23:2, whereas in cells from fish fed OO, 21:3 and 21:4 were also present in significant amounts. It was notable that 21:4 was the major OCLUFA in the PL fraction of the latter cells. Likewise, 21:4 was abundant in the lipids of cells presented with 21:3n-6, particularly those of trout fed OO which also contained small amounts of 19:4. Although the lipids of cells incubated with 21:4n-6 contained small amounts of 19:4, 17:4, and 23:4, the substrate itself was always the major odd-chain length fatty acid and no OCLUFA with more than four double bonds were detected.

The profiles of OCLUFA present in hepatocytes incubated with 21:3n-3 and 21:5n-3 are shown in Table 7. The lipids of cells from both dietary groups produced 19:3, 17:3, 21:4, and 21:5 when presented with 21:3n-3. The amounts of 21:5 and particularly 21:4 were higher in cells from fish maintained on OO with the highest levels being recovered in PL. When 21:5n-3 was the substrate, 19:5 and 23:5 were recovered in the lipids of cells from both the control and the OO-treated fish. In addition, hepatocytes from fish fed the OO diet contained 23:6 in both TL and PL and small amounts of 25:5 and 25:6 in TAG.

For the three n-3 OCLUFA used in the present study, the amounts of incorporated substrate and products recovered in hepatocyte total lipid were 19:3 > 21:5 > 21:3 for both the control and the n-3-deficient cells.

[a]Footnote as in Table 5.

DISCUSSION

The observed differences in fatty acid composition between hepatocytes from fish of the two dietary groups are all consistent with the known enhanced use of 18:1n-9 and 18:2n-6 as substrates for desaturation and elongation in the absence of dietary n-3 PUFA. It has been shown previously that the n-3 PUFA-deficient hepatocytes from trout fed OO exhibit an increased rate of conversion of 18:3n-3 to 22:6n-3 *in vitro* when presented with the former PUFA and offer a good system for the study of fatty acid desaturation and elongation (3). In view of their higher lipid content, hepatocytes from fish fed OO might have been expected to contain a higher proportion of TAG in their lipid than cells from control fish. The fact that the lipid class compositions of the two groups of cells were very similar may be due to the 18:1n-9-rich TAG of hepatocytes from fish fed OO being underestimated during staining and densitometry (23–25).

The occurrence of appreciable quantities of odd-chain length PUFA is not common in animal tissues although very small amounts of 21:5 have been reported in almost every phylum of marine animals including fish (10,11) and seals (12). Thus, in the present study, any odd-chain PUFA recovered in hepatocyte lipids could be assumed to have been derived from the OCLUFA included in the incubation medium. The recovery of significant amounts of all eight substrates examined in cellular lipid indicates that trout hepatocytes can readily assimilate long-chain unsaturated fatty acids having an odd number of carbons. The rates of uptake of 19:3n-3 by hepatocytes from fish fed the OO diet into TAG and PL and its overall rate of conversion to other more unsaturated derivatives are very similar to those found previously for ^{14}C-18:3n-3 with hepatocytes from trout maintained on a similar diet (3).

The range of odd-chain length fatty acids observed in hepatocyte lipids indicates that the assimilated OCLUFA were utilized as substrates for chain-shortening as well as desaturation and elongation. It was notable that of the eight substrates examined, 21:2n-6 was subjected most to chain-shortening by hepatocytes from trout of both dietary groups, followed by 21:3n-3 and 19:1n-9. The even number equivalents of 21:2n-6 and 21:3n-3, 20:2n-6, and 20:3n-3, respectively, are not major components of natural lipids, and it might be expected that these unusual fatty acids are chain-shortened in a manner similar to the induced peroxisomal oxidation which occurs in rat hepatocytes presented with high levels of 22:1n-9 and other long-chain monounsaturated fatty acids (26). In contrast, the C_{18} equivalent of 19:1n-9, 18:1n-9, occurs in naturally high levels in lipids and is not an inducer of peroxisomal oxidation. The presence of the extra carbon, however, may be sufficient to render 19:1n-9 a substrate for oxidation. Nevertheless, from the results obtained in the present study, it is not possible to conclude whether the oxidation of OCLUFA occurred in peroxisomes or mitochondria. Chain-shortening of fatty acids which are poorly oxidized by mitochondria has been considered the main physiological role of peroxisomal β-oxidation (27). Since OCLUFA are not common substrates in cell metabolism, it is possible that their oxidation is taking place in the peroxisomes, organelles which seem to have in fish a broader range of substrate selectivity than mitochondria (28). The oxidation of some C_{20}, C_{22}, and C_{24} members of the different fatty acid series has been reported to be initiated in peroxisomes rather than mitochondria (29,30), and it is known that PUFA are relatively poor substrates for mitochondrial β-oxidation in fish (31,32). With the exception of 19:1n-9, all the substrates used were PUFA and/or long-chain fatty acids, which brings us to speculate that peroxisomes are more likely to be responsible for the chain-shortening of these fatty acids.

The pattern of products observed is consistent with chain-shortening proceeding *via* the removal of two-carbon units, i.e. β-oxidation. On the basis of the recovery of small amounts of radioactivity from [U-^{14}C]-acetate in a whole range of odd chain length PUFA from 17:2 to 29:5, Aveldaño *et al.* (13) suggested that α-oxidation is involved in the formation of PUFA in rat testes. Although the removal of a single carbon by α-oxidation cannot be completely ruled out in the present study, no noticeable increases in the levels of 20:2n-6 and 20:3n-3 in lipids were observed in cells presented with 21:2n-6 and 21:3n-3, respectively, as might be expected if α-oxidation occurred actively.

The recovery of larger amounts of the chain-shortened products from 19:1n-9, 21:2n-6, and 21:3n-3 in PL of cells from both dietary groups suggests that the shorter-chain products are more acceptable for PL structure than the original substrates. In contrast, the original substrates can be readily esterified into TAG in keeping with its role as a store of fatty acids not required for PL synthesis. Since the proportions of fatty acids recovered as chain-shortened products were similar in TL of both groups of cells, it appears that the rate of chain-shortening is not greatly influenced by dietary lipid composition. However, there was a decrease in the incorporation of the chain-shortened fatty acids from 21:2n-6 and 21:3n-3 in the PL of cells from the OO-fed fish, together with an increment of their elongation–desaturation products in the same lipid fraction. This implies that chain-shortening may act in conjunction with elongation–desaturation to generate the desired PUFA.

The more extensive desaturation and elongation of n-6 and n-3 substrates observed with hepatocytes from trout maintained on OO than from control fish is in keeping with the former cells being deficient in PUFA, particularly n-3 PUFA, and having therefore an increased need to synthesize long-chain PUFA from shorter, less unsaturated PUFA, as has been demonstrated previously with radiolabeled substrates (3).

The extensive desaturation of 21:3n-6 to 21:4n-6 and of 21:3n-3 to 21:4n-3 and then to 21:5n-3 was particularly notable in the n-3 PUFA-deficient hepatocytes. The higher recovery of the resultant 21:4n-3 than 21:4n-6 in the PL of these n-3-deficient cells indicates that the substrate preference of the phospholipid esterification system for n-3 PUFA observed in fish (2,3) holds even for odd-chain PUFA.

It is difficult to conclude exactly how the 21:5n-3 was formed from 21:3n-3 since, although the action of a Δ6 desaturase on 21:3n-3 would produce 6,12,15,18-21:4, the subsequent direct conversion of this fatty acid to 21:5n-3 by Δ5 desaturase would not be feasible owing to the presence of the double bond at the C_6 position. Since the hepatocytes were active in chain-shortening it is possible that the 21:3n-3 substrate was first shortened to 10,13,16-19:3 which was desaturated to 6,10,13,16-19:4 followed by elongation to 8,12,15,18-21:4. This form of 21:4 would be a substrate for Δ5 desaturase to produce 5,8,12,15,18-21:5. Similar pathways may exist for the conversion of 21:2n-6 to 21:4n-6. The high levels of chain-shortened OCLUFA products found in the lipids of the trout hepatocytes suggest that such a pathway involving chain-shortening and Δ6 and Δ5 desaturases may operate. Consequently, the involvement of a Δ8 desaturase in the direct conversion of 21:3n-3 and 21:2n-6 to 21:5n-3 and 21:4n-6, respectively, is likely to be of minor importance, in keeping with results obtained recently by Schenck *et al.* (33) in the mouse liver.

The more extensive recovery of nonmodified 21:5n-3 and 21:4n-6 in hepatocyte lipids in comparison with the other substrates examined is in keeping with these structures being suitable for incorporation directly into cellular lipids without further elongation and desaturation or chain-shortening. Arachidonic acid, 20:4n-6, has been reported to be oxidized at a negligible rate in peroxisomes of rainbow trout (32). Although PUFA are substrates for peroxisomal β-oxidation in rodents (34,35) and at least one species of fish (28), a poor β-oxidation rate had been reported for 20:4n-6 and 20:5n-3 by Hovik and Osmundsen (34). While the low rate of chain-shortening of 21:4n-6 and 21:5n-3 observed in the present study may have been attributable to a discrimination against them by the oxidation system in control hepatocytes, such an explanation is unlikely in the cells from fish fed OO, since the virtual absence of long-chain PUFA in the hepatocyte lipids would favor the esterification of the substrates into cellular lipids rather than removal by chain-shortening.

In conclusion, the results presented here demonstrate that the pathways of PUFA conversions in trout hepatocytes can utilize odd-chain unsaturated fatty acids and that these substrates are subjected to chain-shortening as well as desaturation and elongation. The importance of chain-shortening in the formation of 22:6n-3 *via* a Δ4 desaturase-independent pathway has been firmly established in rat (4) and trout (3) hepatocytes, and it has also been demonstrated that 22:5n-6 arises from the partial oxidation of 24:5n-6 in rat liver (36). The occurrence of both 25:5n-3 and 25:6n-3 in hepatocytes incubated with 21:5n-3 is consistent with the production of 23:6n-3 by these cells involving C_{25} intermediates. The present results suggest that chain-shortening may be an integral part of PUFA metabolism. Further studies to determine the position of the double bonds in the desaturation products of the OCLUFA are necessary to characterize the positional specificity of the desaturases present in trout hepatocytes.

ACKNOWLEDGMENTS

The authors wish to thank Dr. M. Buzzi and Dr. J.G. Bell for assistance in preparing hepatocytes and experimental diets. We would also like to thank Professor J.R. Sargent for valuable comments on the manuscript. Dr. Covadonga Rodríguez was supported by a postdoctoral research grant from the Ministerio de Educación y Ciencia, Dirección General de Investigación Científica y Técnica, Spain.

Lipid Content and Fatty Acid Composition of 11 Species of Queensland (Australia) Fish

G.B. Belling[a], M. Abbey[a,*], J.H. Campbell[b], and G.R. Campbell[b]

[a]CSIRO Division of Human Nutrition, Adelaide, South Australia 5000, Australia, and [b]Centre for Research in Vascular Biology, Department of Anatomical Sciences, University of Queensland, Brisbane, Queensland 4072, Australia

ABSTRACT: The fatty acid composition of 11 species of fish caught off the northeast coast of Australia was determined. No fatty acid profiles have been previously published for fish from this area nor for nine of these species. Although the percentage of polyunsaturated fatty acid (PUFA) was the same as the calculated average for Australian fish (42.3%), the percentage of n-3 fatty acids was lower (24.4 ± 5.4% vs. 30.7 ± 10.1%) and the n-6 fatty acids higher (16.5 ± 4.5% vs. 11.2 ± 5.9%), $P < 0.001$ in each case. The major n-3 PUFA were docosahexaenoic (15.6 ± 6.3%) and eicosapentaenoic acid (4.3 ± 1.1%) while the major n-6 PUFA were arachidonic (8.3 ± 3.2%) and n-6 docosatetraenoic acid (3.1 ± 1.3%). The second-most abundant class of fatty acid was the saturates (31.6 ± 3.5%) while the monounsaturates accounted for 17.4 ± 4.3% of the total fatty acids. The monounsaturate with the highest concentration was octadecenoic acid (11.8 ± 2.6%). There was a positive correlation between the total lipid content and saturated and monounsaturated fatty acids ($r = 0.675$ and 0.567, respectively) and a negative correlation between the total lipid content and PUFA ($r = 0.774$).

Lipids 32, 621–625 (1997).

Long-chain polyunsaturated fatty acids (PUFA) of fish (20:5 n-3 eicosapentaenoic acid and 22:6 n-3 docosahexaenoic acid) have been reported to affect vascular function (1) which contributes to a decrease in the overall risk of cardiovascular disease. Incorporation of these long-chain PUFA into cardiovascular tissue membranes occurs readily, mainly at the expense of PUFA of the n-6 type (18:2 and 20:4). The benefits of fish oil fatty acids against thrombogenic cardiovascular risk factors such as platelet/vessel wall interactions are achieved *via* a favorable eicosanoid profile. For example, compared to the prostaglandins and thromboxanes of the 2-series (PGI_2 and TxA_2) which derive from membrane arachidonic acid (n-6, 20:4), n-3 PUFA result in the production of PGI_3 and TxA_3 (2,3). This 3-series of eicosanoids derived from n-3 PUFA have different thrombogenic potencies in comparison to those derived from n-6 PUFA. Thus, PGI_3 is equipotent to PGI_2 in antithrombotic actions while TxA_3 possesses only weak biological activity, thus the risk for ischemic heart disease is reduced (4). Studies have shown that dietary fish oil reverses impairment of endothelium-dependent relaxation (5), inhibits platelet activation (6), reduces monocyte attachment to arterial endothelium, and suppresses release of toxic, mitogenic, and prothrombotic agents (7). There has also been one Australian study showing that eating fatty fish improved hemostatic factors in humans (8).

Very little has been published on the fatty acid composition of Australian fish. Marine fish lipids are a rich source of n-3 fatty acids, and in addition it has been observed that many Australian fish are relatively rich sources of n-6 PUFA when compared with Northern Hemisphere fish (9). Collection areas for Australian fish for which fatty acid data have been published are the Sydney area (10–12), Northwest coast (13), Adelaide (14), Northwest shelf (15,16), and Victoria (17). These publications have been reviewed and the fatty acid data collated (9,18). We present the fatty acid composition of fish from another area of Australian waters, off the Queensland coast at a latitude of about 23°S.

MATERIALS AND METHODS

One hundred eleven fish representing 11 species and 6 families were caught off the reef at Heron Island. The fish were caught with hand-lines in January or June with a mixture of species on each occasion. The freshly caught fish were scaled and samples of about 3 g were dissected from a well-defined and constant part of the dorsal muscle between the dorsal fin and the head. Skin was included as this is usually eaten. The sampling was always done by the same person and was highly reproducible. The samples were added to preweighed vials containing 12 mL of chloroform/methanol (2:1) and the vials reweighed. The length and species of each fish were recorded. All fish were above the minimum legal size which is 23 cm for yellow fin bream; 30 cm for collared sea bream, sweetlip emperor, venus tuskfish, parrot fish and hussar; 35 cm for chickenwire cod, coral trout, red emperor, and yellow stripey. All species are commonly available in fish markets in Australia. Sweetlip emperor, red emperor, and coral trout are ex-

Abbreviations: MUFA, monounsaturated fatty acids; PGI_3, prostaglandin I_3; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TxA_3, thromboxane A_3.

cellent eating and are the most highly sought, collared sea bream, yellowtail bream, yellow stripey, and venus tuskfish are well accepted and readily obtainable in the fish markets. Chickenwire cod, longfin rock cod, parrot fish, and hussar are less popular in fish markets but still available and reasonably good eating.

Samples were cut into small pieces, returned to the chloroform/methanol solution, and extracted according to the method of Folch *et al.* (19). Total lipids were determined gravimetrically. Fatty acid composition was determined on the lipid extracts after methylation with 1% sulfuric acid in dry methanol (20). The fatty acid methyl esters were extracted with petroleum ether (B.P. 40–60°C) and contaminants removed by chromatography on florisil (Sigma Chemical Co., St. Louis, MO). The eluate was dried under nitrogen and the samples were taken up in isooctane. An aliquot was injected onto a gas chromatographic column of vitreous silica (30 m × 0.53 mm) coated with cross-linked free fatty acid phase in a Hewlett-Packard 5711A gas chromatograph (Hewlett-Packard, Avondale, PA) (21). Fatty acids were identified by comparison with authentic standards supplied by Nu-Chek-Prep (Elysian, MN) and a sample of fish oil (l8919BB) which had been analyzed by U.S. Department of Commerce Southeast Fisheries Science Center. Correction factors were used to convert area percentage to weight percentage.

RESULTS AND DISCUSSION

Table 1 shows the common and scientific names, the number analyzed, and the mean and range of total lipid content of the fish from this study. Generally the fish were lean: 74 had a total lipid content of less than 2% and only 9 of the 111 fish had a total lipid content greater than 5%. The species with the largest variation was collared sea bream with 17 of the 31 fish having less than 2% total lipids and 6 fish more than 5%.

Twenty-four fatty acids were identified in all samples of fish and Table 2 shows mean fatty acid profiles for these fatty acids in the 11 species. As well as these fatty acids, the column was able to resolve some minor unidentified fatty acids and the dimethylacetals of stearic and palmitic acids. Table 3 shows the total n-6 fatty acids, total n-3 fatty acids, the n-6/n-3 ratios, the totals of saturated (SFA), monounsaturated (MUFA), and PUFA, and the polyunsaturated-to-saturated ratio for each species.

The PUFA were the most abundant group of fatty acids for all species, accounting for 42.3 ± 6.9% of the total fatty acids. For the 111 samples representing the 11 species, the n-3 series PUFA were present as 24.4 ± 5.4% of the total fatty acids, and the n-6 series PUFA were present as 16.5 ± 4.5% of the total fatty acids, whereas Brown *et al.* (9) calculated means of 30.7 ± 10.1% and 11.2 ± 5.9% for n-3 PUFA and n-6 PUFA, respectively, for Australian fish. While the mean percentage of total PUFA is the same for Queensland (this study) and Australian fish (9), 42.3%, the percentage of n-6 PUFA is higher for the Queensland fish. Sinclair *et al.* (22) showed that the relative n-6 PUFA content of fish increased as the sampling point moved closer to the equator and suggested that the supply of n-6 PUFA in the marine food chain increased in tropical waters.

Gibson (14) and Sinclair *et al.* (13) have emphasized that fish from both southern Australian waters and from the northwest coast of Australia are rich in arachidonic acid. Brown *et al.* (9) have calculated that arachidonic acid on average constituted 6.6% of the total fatty acids in Australian fish. Arachidonic acid (20:4) was the major n-6 PUFA in the Queensland fish in our study (8.3 ± 3.2%) followed by n-6 docosatetraenoic acid (22:4) (3.1 ± 1.3%), n-6 docosapentaenoic acid (22:5) (1.9 ± 0.7%), and linoleic acid (18:2) (1.7 ± 0.8 %).

Most abundant of the n-3 PUFA was 22:6 (docosahexaenoic acid) (15.6 ± 6.3%), while 20:5 (eicosapentaenoic acid) and n-3 22:5 (docosapentaenoic acid) were also present in important proportions (4.3 ± 1.1% and 3.5 ± 0.9%, respectively).

The second-most abundant group of fatty acids was the SFA which constituted 31.6 ± 3.5% of the total fatty acids. The highest concentrations of SFA were palmitic acid (16:0)

TABLE 1
Total Lipid Content of Fish Samples

Common name	Scientific name	Number analyzed	Lipids (g/100 g) (wet weight basis)	
			Mean	Range
Collared sea bream (iodine bream)	*Gymnocranius audleyi*	31	2.7	0.2–10.8

19.9 ± 2.5%, stearic acid (18:0) 8.2 ± 0.9%, and myristic acid (14:0) 2.0 ± 1.1%. There were also small but noteworthy amounts of pentadecanoic acid (15:0), margaric acid (17:0), and arachidic acid (20:0).

MUFA accounted for 17.4 ± 4.3% of total fatty acids. The monoene with the highest concentration was octadecenoic acid (18:1) (11.8 ± 2.6%). The other major monoene was palmitoleic (16:1) (4.3 ± 1.9%). MUFA ranged from 9.6 to 26.1%. This is lower than the variation found by Gibson (14) for fish mostly from Adelaide, latitude 35°S (12.2–68%). The mean MUFA, 22.9 ± 9.7%, for Australian fish calculated by Brown *et al.* (9) is higher than that for Queensland fish in this study ($P < 0.001$); however, for fish caught off the northwest coast of Australia at a latitude of 17°S the mean was 17.0% (13) which indicates that there may be an association between proportion of MUFA and latitude.

[a]Abbreviations: SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids. [b]Includes 18:2. [c]Includes 18:3.

The mean n-6/n-3 ratio for all fish in our study was 0.7 which was higher than the 0.4 calculated for Australian fish by Brown *et al.* (9). This reflects both the higher n-6 PUFA and the lower n-3 PUFA of our samples. The ratios for individual fish varied between 0.2 and 1.4 and the means for species between 0.3 and 0.8.

There was a significant ($P < 0.01$) association between the total lipid content and SFA, MUFA, and PUFA. The proportion of SFA and MUFA rose with increasing lipid content while the concentration of PUFA fell. These relationships are shown in Figure 1. Fogerty *et al.* (16) showed that as the fat content of fish tissue increases beyond 0.8%, triacylglycerols become the predominant lipid. These authors also showed that the phospholipids and free fatty acids are richer in PUFA than the triacylglycerols, thus accounting for the correlations. It is possible that the correlations in the present study may be accounted for in a similar way. These relationships are even stronger when calculated for a single species, collared sea bream, with an appreciable number of samples (*n* = 31). Brown *et al.* (9) showed similar relationships for Australian fish.

No fatty acid profiles have previously been published for at least 9 of the 11 species of Australian fish represented in this study. The previously published mean fatty acid composition of red emperor, *Lutjanus sebae*, from a similar latitude on the other side of the continent (9) was similar to our results. Pearson (10,11) published results for samples of bream but did not give the scientific names for these fish.

The fatty acid profile of fish from this study was similar in many respects to the profile of the average Australian fish as calculated by Brown *et al.* (9). However, although the proportion of PUFA was essentially the same, the relative amount of n-6 PUFA was higher and approximately equal to that reported by Sinclair *et al.* (13) for fish collected from the northwest coast of Australia, which is at similar latitude on the other side of the continent. The proportion of MUFA was lower in this study than that calculated for the average Australian fish but again similar to that of fish from the northwest coast.

This study confirms the findings of others that Australian fish are a good source of both n-3 PUFA and n-6 PUFA and, importantly, shows that there is an association between the total lipid content and the proportions of saturates, monounsaturates, and polyunsaturates.

Plasma Kinetic Behavior in Hyperlipidemic Subjects of a Lipidic Microemulsion That Binds to Low Density Lipoprotein Receptors

ABSTRACT: It was previously reported that a protein-free microemulsion (LDE) with structure roughly resembling that of the lipid portion of low density lipoprotein (LDL) was presumably taken up by LDL receptors when injected into the bloodstream. In contact with plasma, LDE acquires apolipoproteins (apo) including apo E that would be the ligand for receptor binding. Currently, apo were associated to LDE by incubation with high density lipoprotein (HDL). LDE-apo uptake by mononuclear cells showed a saturation kinetics, with an apparent K_m of 13.1 ng protein/mL. LDE-apo is able to displace LDL uptake by mononuclear cells with a K_i of 11.5 ng protein/mL. LDE without apo is, however, unable to displace LDL. The uptake of ^{14}C-HDL is not dislocated by increasing amounts of LDE-apo, indicating that HDL and LDE-apo do not bind to the same receptor sites. In human hyperlipidemias, LDE labeled with ^{14}C-cholesteryl ester behaved kinetically as expected for native LDL. LDE plasma disappearance curve obtained from eight hypercholesterolemic patients was markedly slower than that from 10 control normolipidemic subjects [fractional clearance rate (FCR) = 0.02 ± 0.01 and 0.12 ± 0.04 h^{-1}, respectively; $P < 0.0001$]. On the other hand, in four severely hypertriglyceridemic patients, LDE FCR was not significantly different from the controls (0.07 ± 0.03 h^{-1}). These results suggest that LDE can be a useful device to study lipoprotein metabolism.
Lipids 32, 627–633 (1997).

After degradation of very low density lipoprotein (VLDL) by lipoprotein lipase, only small amounts of triglycerides remain in low density lipoprotein (LDL) particle core. LDL is therefore mostly made up of a core of cholesteryl esters surrounded by a monolayer of phospholipids and unesterified cholesterol. The protein part of LDL consists of a single molecule of apolipoprotein (apo) B100. LDL is removed from the circulation by specific cell receptors, often called B,E receptors, using apo B100 as the ligand (1). Defects in those receptors or in apo B100 may lead to LDL accumulation in the plasma.

Although a great number of LDL plasma kinetic studies in subjects have been performed, the laboratory procedure is time-consuming and impractical because only the autologous lipoprotein can be injected into the subjects. On the other hand, LDL is not a homogeneous fraction and comprises subpopulations of particles with different physical chemical properties and kinetic behavior (2,3). The need of standard preparations to test LDL metabolism was highlighted by Brown and Goldstein (1).

Homogeneous and stable microemulsions without protein with the size and general structure of LDL lipidic portion can be prepared from phospholipids and cholesteryl esters by ultrasonic irradiation of the constituent lipids in aqueous media (4). When apo B100 was associated to the artificial microemulsion, the complex was bound, internalized, and degraded by cultured human fibroblasts in a way similar to native LDL (5). Recently, Maranhão *et al.* (6–8) tested *in vivo* the behavior of the cholesteryl oleate/phosphatidylcholine microemulsion without addition of apo B100 prepared according to the method of Ginsburg *et al.* (4). The physical properties of the microemulsion had been well defined by those authors (4) and others (9). Injected into the circulation of rats, protein-free microemulsion (LDE) showed plasma kinetic behavior, suggesting that it is removed from the plasma by the LDL receptors (6). Although not containing apo B100, LDE picks up several exchangeable apo 1 from the native lipoproteins, and presumably binds to the receptor through apo E, which can be recognized by LDL receptors (10). LDE plasma kinetic behavior showed some similarities with that expected for LDL in rabbits and in humans (7,8). These results raised the possibility that LDE could be used to test *in vivo* LDL receptor function.

In the current study, the evidence that LDE is picked up by the LDL receptors was strengthened by experiments of competition with native lipoproteins for uptake by mononuclear cells. Furthermore, the plasma kinetics of LDE labeled with ^{14}C-cholesteryl ester and injected into subjects with normal

lipid levels as well as hypercholesterolemic or hypertriglyceridemic patients was determined. The results confirm that LDE may be useful to facilitate the study of some aspects of the lipoprotein metabolic pathway.

MATERIALS AND METHODS

Study subjects. Ten normolipidemic healthy subjects (8 males, 2 females, aged 50–67 yr; total cholesterol below 240 mg/dL; LDL up to 130 mg/dL and triglycerides below 250 mg/dL), 8 patients with hypercholesterolemia (7 males, 1 female; aged 53–70 yr; total cholesterol higher than 240 mg/dL; LDL higher than 160 mg/dL and triglycerides below 250 mg/dL), and 4 with severe hypertriglyceridemia (4 males, 32–42 yr; total cholesterol below 240 mg/dL and triglycerides higher than 650 mg/dL) were studied at the outpatient clinic of the Heart Institute of the University of São Paulo Medical School Hospital (São Paulo, Brazil). Controls and cases did not have clinical history of coronary artery disease; diabetes; hyperuricemia; obesity; thyroid, gastrointestinal, kidney or liver disease; or history of excessive alcohol drinking. In the group of hypercholesterolemic patients, those under hypolipidemic drugs had the treatment discontinued for at least 2 mon previously. All the hypertriglyceridemic patients were newly diagnosed, and the LDE clearance experiments were performed before the beginning of the treatment. The experimental protocol was approved by the Ethics Committee of the São Paulo University Medical School, and an informed consent was obtained from each participant.

Cells. Mononuclear cells were isolated from the blood of healthy normolipidemic subjects by centrifugation on a Ficoll-Hypaque gradient (11). Cell viability was >98% as evaluated by the trypan blue exclusion method.

Preparation of the emulsion. Egg phosphatidylcholine was purchased from Lipid Products (Surrey, United Kingdom); triolein, cholesteryl oleate, and cholesterol were from Nu-Chek-Prep (Elysian, MN); and radioactive lipids were acquired from Amersham (United Kingdom). Lipids were >98% pure as determined by thin-layer chromatography. The LDE used in this study was prepared from lipid mixtures composed of 40 mg of phosphatidylcholine, 20 mg of cholesteryl oleate, 1 mg of triolein, and 0.5 mg of unesterified cholesterol. Emulsification of lipids and purification of the emulsions were according to the procedure described by Ginsburg *et al.* (4) as modified by Maranhão *et al.* (8). Whenever possible, all the materials and instruments used in the preparation of LDE were put into an oven at 180°C for 4 h and autoclaved. Lipids were dissolved in chloroform/methanol (2:1) and dispensed into vials. Cholesteryl ^{14}C-oleate was added to the vials. The mixtures were dried under a nitrogen stream followed by overnight vacuum desiccation at 4°C to remove residual solvents. The dried lipids were resuspended in 10 mL of 0.01 M Tris-HCl at pH 8.0. The suspension was sonicated using a Branson Cell Disrupter model 450 (Branson Ultrasonics Co., Danbury, CT) equipped with a flat tip, with a 125-watt output in the "continuous" operating mode, for 180 min under N_2 atmosphere. Temperature was kept above 52°C, the melting point of cholesteryl oleate, as monitored by a thermocouple inserted in the vials during this procedure. The emulsified lipid suspension was then transferred to clean tubes for ultracentrifugation at 195,000 × *g* (30 min) in a TH 641 rotor of a Sorvall OTD-Combi ultracentrifuge (Newtown, CT) at 4°C. The top 10% of the solution, containing particles that float at background density of approximately 1.006 g/mL, was removed by aspiration with a needle. The remaining solution was adjusted to a background density of 1.21 g/mL by adding solid KBr. A second ultracentrifugation step was then performed at 195,000 × *g* (120 min) at 4°C. The top 20–30% of the sample was collected by aspiration, after attaining room temperature, and dialyzed overnight against 10 mM Tris-HCl buffer pH 8 to remove KBr. This LDE fraction (^{14}C-LDE) was sterilized by passage through a 0.2-μ filter. LDE was used in the experiments described below within 4 wk after it was prepared.

Emulsion lipid composition. For the analysis of the emulsion lipid composition, LDE was prepared as described above except that $2.4 \cdot 10^6$ Bq of cholesteryl ^{14}C-oleate, ^{14}C-cholesterol, ^{3}H-triolein, and ^{3}H-phosphatidyl choline were added. The recovery of each lipid was measured after thin-layer chromatography using hexane/ethyl ether/acetic acid (70:30:1, by vol) as moving phase and iodine vapor to develop. Radioactivity of each fraction was measured in scintillation solution (PPO/DM-POPOP/Triton X-100/toluene; 5 g/0.5 g/333 mL/667 mL) using a Packard Spectrometer (Palo Alto, CA). The composition was calculated based on the specific activity of each label.

In vitro *acquisition of apo by LDE.* The emulsion containing apo (LDE-apo) was prepared essentially as described in Reference 6. Briefly, 60 mg of LDE, prepared as described above, was incubated with 30 mg of HDL (protein determined as in Ref. 12) during 2 h at 37°C. After incubation, the density was adjusted to 1.063 g/mL with KBr and the mixture submitted to ultracentrifugation at 195,000 × *g* at 4°C for 4 h. LDE-apo recovered at the top of the tube had acquired 0.7 ng of protein/μg of total lipids. It was labeled with ^{125}I (13) and purified by gel filtration in a PD-10 column (Sephadex G-25m; Pharmacia LKB Biotechnology AB, Uppsala, Sweden) equilibrated and developed 0.15 M NaCl and 1 mM EDTA. With this procedure, 80% of the protein and 20% of the total emulsion lipids were radioactively labeled, and the specific activity obtained was 11,500 cpm/μg protein.

Preparation of high density lipoprotein (HDL) and LDL. HDL and LDL were obtained from the blood of healthy normolipidemic donors by sequential ultracentrifugation (14). After isolation, HDL (1.063–1.21 g/mL) was labeled with ^{14}C-cholesteryl oleate (specific activity obtained = 235 cpm/μg protein) (15), and LDL (1.02–1.063 g/mL) was labeled with ^{125}I (specific activity obtained = 250,000 cpm/μg protein) (13). The purification of the labeled lipoproteins was performed as described above.

Saturation studies. The 10^6 mononuclear cells were incubated with 10–200 ng of protein/mL of ^{125}I-LDE-apo or 10-200 μg/mL of ^{125}I-LDL during 2 h at 37°C, in 1 mL of RPMI-

1640 containing 100 units/mL of penicillin, 5 µg/mL of gentamycin, and 2.5 µg/mL of amphotericin B. After incubation, the cells were washed three times with RPMI 1640 at 4°C, treated with trypsin 0.5 mg/mL for 15 min at 37°C and lysed with 0.2 M NaOH. The incorporated lipoproteins were determined in a gamma counter (COBRA II, Auto-Gamma, Packard, Canberra, Australia).

Competition studies in mononuclear cells. The 10^6 viable cells were incubated with 10 µg/mL of labeled lipoprotein (^{125}I-LDL or ^{14}C-HDL) and increasing concentrations (10–300 µg of lipids/mL) of unlabeled LDE or LDE-apo (7–210 ng of protein/mL) for 2 h at 37°C, in 1 mL of RPMI-1640 containing 100 units/mL of penicillin, 5 µg/mL of gentamycin, and 2.5 µg/mL of amphotericin B. After incubation, the cells were washed and trypsin-treated, and the incorporated ^{125}I-LDL and ^{14}C-HDL were measured as described above.

Clearance studies. The participants were fasting at the commencement of the clearance studies, at approximately 9:00 a.m., but they were allowed two standard meals during the study, at approximately 12:30 p.m. and 7:00 p.m. They were injected intravenously in a bolus with $3.7 \cdot 10^4$ Bq (1 µCi) of radioactive cholesteryl ester, roughly 5–6 mg of emulsion total lipids, in a volume of 500 µL. Plasma samples were collected during 24 h, at 5 min, 1, 4, 12, and 24 h after injection. Aliquots (1.5 mL) of blood plasma were extracted with chloroform/methanol (2:1, vol/vol) (16), and the solvent phase was transferred into counting vials and dried under a nitrogen stream. Radioactivity was measured as described above.

Determination of cholesterol, triglycerides, and apo. Total plasma cholesterol and triglycerides of the subjects were determined after 12 h fasting with the aid of enzymatic kits [CHOD-PAP, Merck (Darmstadt, Germany), and Abbott (Abbott Park, IL), respectively]. HDL-cholesterol was determined by the same method, after precipitation of LDL and VLDL with $MgCl_2$ and phosphotungstic acid. VLDL-cholesterol was calculated assuming the relation: VLDL-cholesterol = (triglycerides/5) (17). LDL-cholesterol was calculated using Friedewald equation where LDL-cholesterol = total cholesterol – (VLDL- cholesterol + HDL-cholesterol) (18). Apo A1 and B were determined by single radial immunodiffusion (19) using Lipo-Partigen (apo A-1) and NOR-Partigen plates (apo B) (Behring, Behringwerke AG, Marburg, Germany).

Calculations. The Michaelis constant K_m for LDL and LDE-apo was calculated by nonlinear regression from the saturation experiments, using the Michaelis-Menten equation and the Grafit program version 3.01 (Robin J. Leatherbarrow-Erithacus Software Ltd., Staines, Middlesex, United Kingdom). The K_i was calculated from the data obtained from the competition in mononuclear cells experiments using the equation:

$$K_i = EC_{50}/(1 + L/K_m) \quad [1]$$

where L = ^{125}I-LDL concentration and LDL K_m = 1.6 µg/mL, as calculated from our saturation experiments. The program GraphPad InPlot version 4.00 (GraphPad Software Inc., San Diego, CA) was used for these calculations.

The experimental curves of the plasma decay of the cholesteryl ^{14}C-oleate radioactivity showed a biexponential aspect. The decay curve was analyzed by its decomposition in exponential components, initially by curve peeling. The profile of the experimental curves plotted in semilogarithmic graphic suggested that the last points of the curves fitted to a straight line. The intersection of this straight line with the y-axis defined the a_2 parameter, and its slope is defined as b_2. Each experimental point was then subtracted from the corresponding value on the straight line. These new data points were fitted to a second straight line, defining the slope b_1 and the intercept a_1. To obtain accurate values for these parameters, they were used as seeds for the subsequent process of fitting using the nonlinear least squares method applied to the function:

$$y = (a_1 \cdot e^{-b_1 x}) \cdot (a_2 \cdot e^{-b_2 x}) \quad [2]$$

The intercept parameters were normalized to obtain $a_1 + a_2 = 1$. The fractional clearance rate (FCR) is calculated according to the method described by Matthews (20), using the equation:

$$FCR = \left(\frac{a_1}{b_1} + \frac{a_2}{b_2}\right)^{-1} \quad [3]$$

Differences in LDE FCR, triglycerides, and total cholesterol and fractions between the groups were assessed using the nonparametric Mann-Whitney test (21). Two-tailed P values below 0.05 were considered significant.

RESULTS

Emulsion lipid composition. Prepared as described, the percentage molar composition of the emulsion is 48.0% cholesteryl esters, 47.8% phospholipids, 2.3% triglycerides, and 1.9% unesterified cholesterol.

Uptake of LDE-apo and LDL by mononuclear cells. Figure 1 shows the uptake of ^{125}I-LDE-apo (1A) and ^{125}I-LDL (1B) by mononuclear cells. A saturation kinetics was observed with a K_m of 13.1 ng/mL for LDE-apo and a K_m of 1.6 µg/mL for LDL.

In vitro *competition studies.* Figure 2B shows that the addition of increasing amounts of LDE does not inhibit the uptake of ^{125}I-LDL by mononuclear cells. However, when LDE acquires apo by pre-incubation with HDL, ^{125}I-LDL uptake is then progressively inhibited by LDE-apo (Fig. 2A). The K_i of LDE-apo is 11.5 ng/mL. This indicates that LDE-apo, but not LDE, is capable of competing with the native lipoprotein for binding to LDL receptors.

As it is shown in Figure 2C, the HDL cholesteryl ester oleate uptake by mononuclear cells is not inhibited by LDE-apo. Conversely, HDL did not inhibit LDE-apo uptake (Fig. 2D). These results indicate that the B/E receptor is the unique site of uptake of LDE-apo in this cell type.

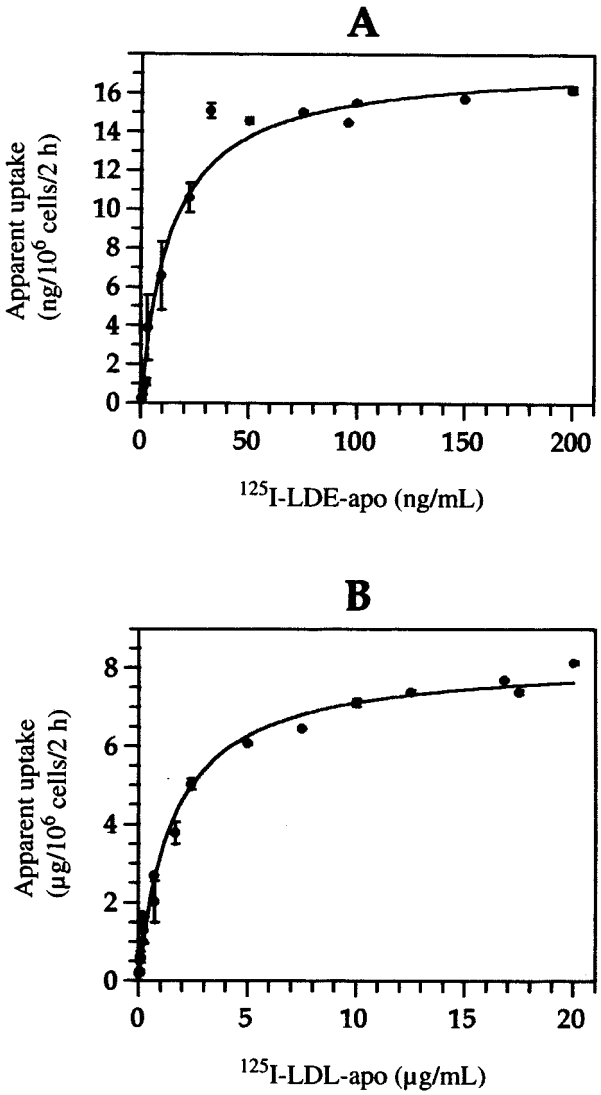

FIG. 1. Uptake of ^{125}I-LDE-apo and iodine-labeled low density lipoprotein (^{125}I-LDL) by mononuclear cells. 10^6 mononuclear cells were incubated with 10–200 ng of protein/mL of iodine-labeled protein-free microemulsion (^{125}I-LDE)-apo (A) or 10–200 µg/mL of ^{125}I-LDL (B) during 2 h at 37°C, in 1 mL of RPMI-1640. After incubation, the cells were washed, treated with trypsin, lysed, and the incorporated lipoproteins were determined in a gamma counter. Each point represents mean ± SEM of three experiments. The K_m determined were 13.1 ng/mL and 1.6 µg/mL for LDE-apo and LDL, respectively.

Plasma lipids and LDE kinetics. Table 1 shows the plasma lipids for the three groups studied (mean ± SEM). Figure 3A shows that the decay curve of ^{14}C-cholesteryl ester LDE obtained in patients with moderate hypercholesterolemia is pronouncedly slowed when compared to controls. In the patients with severe hypertriglyceridemia, the ^{14}C-cholesteryl ester LDE curve tended to approach that of the controls.

FCR was significantly different in the hypercholesterolemic patients compared with controls ($P < 0.001$) or the hypertriglyceridemic subjects (0.02 ± 0.01; 0.12 ± 0.01; and 0.07 ± 0.03 h^{-1}, respectively; Fig. 3B).

DISCUSSION

Several experimental observations have conveyed the concept that LDE is picked up by LDL receptors (6–8). When incubated with HDL, several exchangeable apo shift from the lipoprotein to the artificial emulsion (6) including apo E that could enable LDE binding to the LDL receptor (10). The emulsion clearance was accelerated in rats pretreated with 17α-ethinylestradiol which enhances the expression of these receptors (22). ^{99m}Technetium-labeled LDE biodistribution images showed a marked resemblance with those obtained with LDL in the rabbit as well as in humans. Liver is the predominant uptake organ. Furthermore, LDE had increased removal from plasma in patients with acute myeloid leukemia (AML) (7,8) as occurs with native LDL because receptors are upregulated in AML cells (23,24). Conversely, destruction of the AML cells by chemotherapy resulted in decreased LDE clearance, which then approaches normal values (8). LDE clearance was also increased in postmenopausal women after estrogen replacement therapy (25), as expected, since estrogen increases LDL receptors (26).

In the current study, the set of experiments performed with mononuclear cells provided direct evidence that LDE is indeed specifically taken up by the LDL receptors. First, it was shown that LDE-apo was taken up by the cells through a saturable mechanism. Second, the results clearly indicate that LDE-apo strongly competes with native LDL for cell uptake. The incorporation of apo was proven necessary to endow the emulsion with capacity to compete with LDL for the cell receptors. The experiment showing that the emulsion does not compete with HDL for cell uptake sites offers an additional assurance for the specificity of the LDE binding to the LDL receptors. This is important because it could be speculated that LDE could also interact with the HDL uptake mechanisms (27).

In the current investigation, the possibility of using the microemulsion as a tool to explore lipid metabolism was confirmed by determining LDE kinetics in primary hypercholesterolemia. In this condition, the receptor activity is decreased, resulting in reduction of LDL clearance, as documented in a number of studies by the injection of radioactive iodine-labeled LDL (28). Therefore, the reduction of LDE FCR found in our study is the effect expected for native LDL.

In hypertriglyceridemia, the generation of VLDL catabolic products is decreased because lipoprotein lipase function is defective. Poorly catabolized VLDL is not efficiently removed by the LDL receptor mechanisms, which are intrinsically normal. Therefore, the fact that LDE decay curve of three extremely hypertriglyceridemic patients was not different from that of the controls would also be expected for native LDL, as previously described (28).

LDE rates of removal from plasma appear much greater than those of native LDL. As showed in Figure 3A, 2 h after injection roughly 50% of LDE radioactivity had already been eliminated from the plasma of the controls. Lipoproteins containing multiple copies of apo E have higher affinity than apo

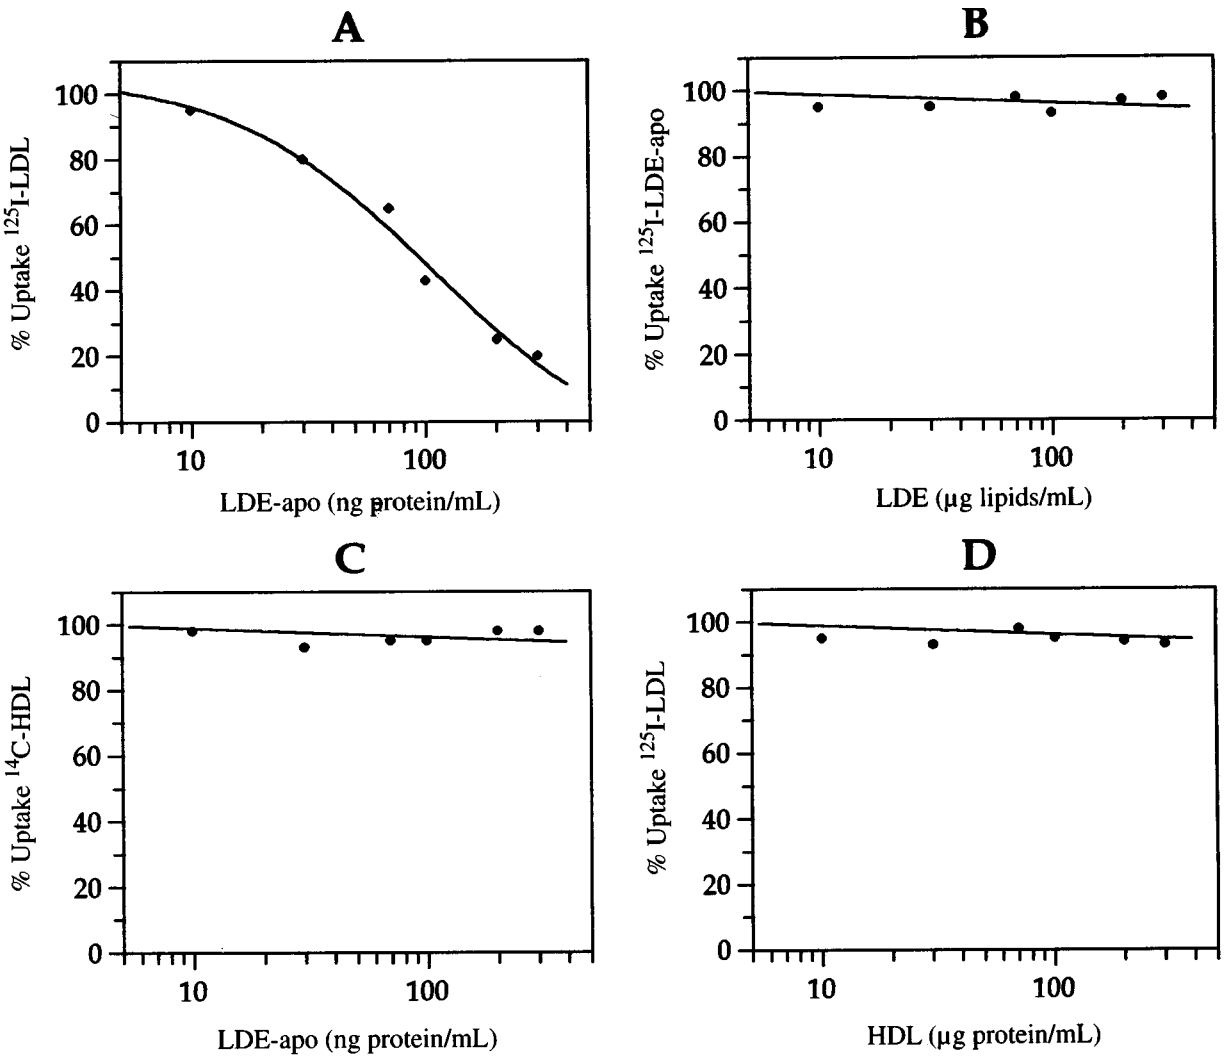

FIG. 2. Competition studies. Mononuclear cells were incubated with 10 µg/mL of ^{125}I-LDL (A and B), ^{14}C high density lipoprotein (HDL) (C), or ^{125}I-LDE apoprotein (apo) (D) and increasing amounts of LDE-apo (A and C), LDE (B) or HDL (D). ^{125}I-LDL uptake was inhibited only by LDE-apo (A), with a K_i of 11.5 ng protein/mL. HDL and LDE-apo did not compete for the same uptake sites (C and D). See Figure 1 for other abbreviations.

B for binding to the LDL receptor (10). Indeed, when apo B100 was associated to LDE and the complex injected into rats, the emulsion clearance was markedly decreased (29). We previously showed in rats that the presence of free cholesterol in the composition of microemulsions resembling LDL accelerates its removal from the plasma (30). This is an example of the operational advantages that an artificial emulsion system may offer. By manipulating the composition of the emulsion, it is possible to optimize experimental conditions or systematically observe the effect of one isolated component on the emulsion behavior. Acceleration of plasma clearance may be advantageous since the duration of the test can be shortened from some days, as with native LDL, to 24 or 12 h. In addition, artificial emulsion systems allow easy labeling with isotopes or other markers for the performance of metabolic studies.

TABLE 1
Lipid Profile and FCR of the Three Studied Groups[a]

Group (n)	Cholesterol (mg/dL)			TG	Apolipoprotein (g/L)[b]		
	Total	LDL	HDL	(mg/dL)	A1	B	FCR (h^{-1})
CT (10)	193 ± 10	118 ± 9	44 ± 4	128 ± 16	1.2 ± 0.2	1.2 ± 0.3	0.12 ± 0.01
Hch (8)	272 ± 11[d]	190 ± 10[d]	42 ± 2	166 ± 20	1.5 ± 0.3	1.8 ± 0.3[c]	0.02 ± 0.01[d]
Htg (4)	202 ± 16	n.d.	36 ± 1	2413 ± 1110[b]	0.9 ± 0.2[c]	1.0 ± 0.6	0.07 ± 0.03

[a]The values represent mean ± SEM; n.d., not determined; CT, control; Hch, hypercholesterolemic; Htg, hypertriglyceridemic; FCR, fractional clearance rate; LDL, low density lipoprotein; HDL, high density lipoprotein; TG, triglycerides. [b]$P < 0.01$. [c]$P < 0.05$. [d]$P < 0.001$.

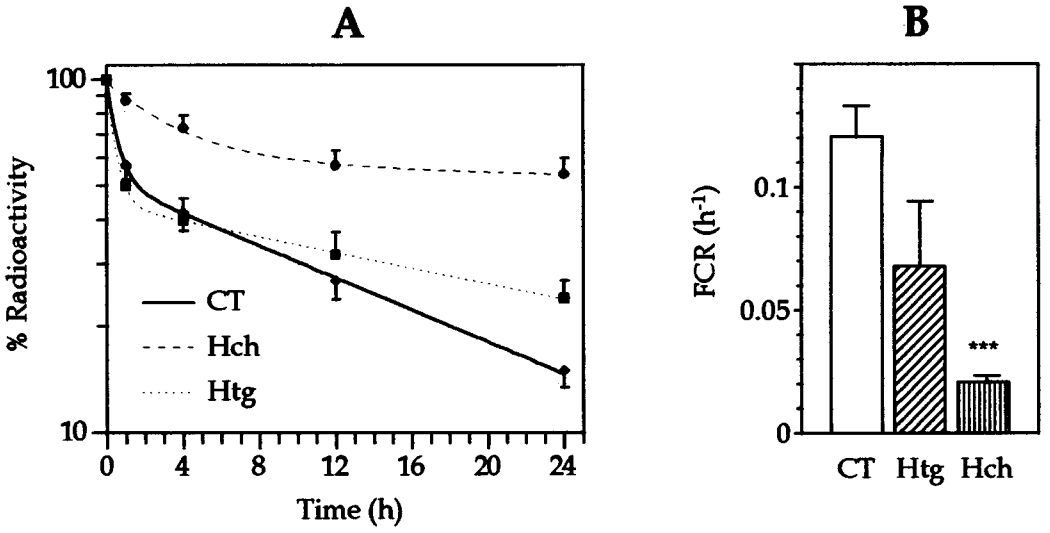

FIG 3. (A) Plasma kinetics of ^{14}C-LDE in normal subjects, hypertriglyceridemic (. . . . .), and hypercholesterolemic (-------) patients. Points represent mean ± SEM. The fractional clearance rate (FCR) (mean ± SEM) is shown in (B); CT = controls; Htg = hypertriglyceridemic; Hch = hypercholesterolemic patients. *** $P < 0.0001$.

There are three common isoforms of human apo E: apo E2, E3 and E4 (31). Roughly 70% of the Caucasian population carries the E3 variant, whereas the E4 isoform is the rarest. Apo E3 and E4 have similar affinity to the LDL receptor, but apo E2 has only 10% of the affinity of the other two. It is thus presumable that in the minority of persons possessing apo E2, LDE clearance should be smaller, especially in the homozygous form.

LDL accumulation and hypercholesterolemia can also result from genetically inherited defects of apo B100 affecting the binding domains of the apo (32). In those cases, LDE removal from plasma would not be expected to be altered, since the emulsion is recognized by the receptor for apo E. Therefore, the emulsion could eventually be used to screen for the existence of functional abnormalities of apo B or distinguish them from defects related to LDL receptor function.

In the current study, LDE was shown capable of specifically testing LDL receptor function in hyperlipidemic patients. As monitored by visual inspection and by repeated determination of the ratio of the isotopically labeled components, as well as by serial determination of its kinetics in rats, LDE is stable for at least 1 mon when kept at 4°C. Addition of antioxidants is likely to extend the long-run stability. Therefore, with a single LDE preparation, it is possible to study a great number of individuals over a long period of time. LDE may then be suitable for studies aiming to disclose disturbances of lipoprotein metabolism and lipoprotein receptor, pathophysiological processes, drug treatments, or dietary regimens.

ABSTRACT: Foods which increase tissue arachidonic acid levels have been proposed to increase thrombosis tendency, presumably through increased platelet aggregation. This study examined the effect of doubling the dietary arachidonic acid (20:4n-6) using meat- or fish-based diets on the systemic production of prostacyclin (PGI_2) and thromboxane (TXA_2) in 29 healthy, nonsmoking adults. There were three, 3-wk low-fat dietary periods (<15% energy as fat) in which subjects consumed a vegetarian diet for 1 wk followed by 2 wk on diets containing meat or fish as sources of 20:4n-6. Between each diet period, there was a 3-wk washout period, during which subjects returned to their normal diets. The level of 20:4n-6 consumed during the last 2 wk of each study was approximately double the usual intake (mean 140 mg/d), while the mean eicosapentaenoic acid (20:5n-3) content of the diets varied from 1 mg/d on the white meat diet to 70 mg/d on the red meat diet and to 847 mg/d on the fish diet. The serum phospholipid (PL) 20:4n-6/20:5n-3 ratios were 11:1 on the vegetarian diet, 15:1 on the white meat diet, 8:1 on the red meat diet, and 2:1 on the fish diet ($P < 0.001$). Neither white nor red meat diets affected platelet 20:4n-6 levels, platelet aggregation, *ex vivo* platelet TXB_2 production, or the systemic PGI_2 or TXA_2 production as measured by gas chromatography–mass spectrometry analysis of the excretion levels of the principal urinary metabolites 2,3-dinor-6-keto-$PGF_{1\alpha}$ (PGI_2-M) and 11-dehydro-TXB_2 (TXA_2-M), respectively. The fish diet decreased the 20:4n-6/20:5n-3 ratio in platelet PL from the baseline level of 45:1 to 13:1 ($P < 0.001$), had no effects on platelet aggregation, but significantly decreased platelet TXB_2 production (collagen-stimulated) and TXA_2-M production, while PGI_2-M levels were unaltered. These results indicate that short-term diets which double the usual 20:4n-6 intake using white meat (175–330 g/d) or red meat (275–530 g/d) are not associated with an increased TXA_2 production, but this does not rule out the adverse effects of 20:4n-6 at higher levels in the diet, or for more prolonged periods. Short-term diets containing fish (100–200 g/d with 90–210 mg/d 20:4n-6 and approximately 650–1000 mg/d 20:5n-3) led to significant increases in platelet 20:5n-3 levels and a decrease in the *ex vivo* and systemic TXA_2 production.

Lipids 32, 635–644 (1997).

Eicosanoids derived from arachidonic acid (20:4n-6) are thought to play a role in the pathogenesis of coronary artery disease. The two most powerful vasoactive eicosanoids issuing from the cyclooxygenase pathway are the platelet-derived thromboxane (TXA_2) (1) and prostacyclin (PGI_2), derived from arterial endothelial cells (2). Thromboxane is both a potent pulmonary vasoconstrictor and a procoagulant, whereas PGI_2 is a major endogenous vasodilator and an inhibitor of platelet aggregation (3,4). It is believed that an imbalance between the release of these two mediators could be involved in the pathogenesis of thrombogenesis and atherosclerosis (5).

It has been proposed that the low incidence of myocardial infarction and ischemic heart disease in Greenland Eskimos is due to the high content of long-chain (LC) n-3 polyunsaturated fatty acids (PUFA) in their diet (6,7). The beneficial effects may be due to a decrease in TXA_2 derived from 20:4n-6 and an increase in the 3-series prostanoids which have an attenuated spectrum of biological activity (8). The thromboxane/prostacyclin ratio has subsequently been shown to be reduced in Greenland Eskimos compared with Danes (9).

Since dietary LC n-3 PUFA modify eicosanoid formation from the more dominant precursor fatty acid, 20:4n-6, it has been argued that the ingestion of foods which raise tissue levels of 20:4n-6 will lead to an increased thrombotic potential (10). This view has been based to a large extent on the detrimental findings of two studies, the first of which involved rabbits being injected intravenously with 20:4n-6, resulting in death within 3 min (11). The second was a human study in which four subjects were fed 6 g/d of ethyl arachidonate for a period of 2–3 wk. The threshold concentration of ADP re-

Abbreviations: 20:4n-6, Arachidonic acid; DHA, docosahexaenoic acid (22:6n-3); LA, linoleic acid; LC, long-chain; PAP, platelet adjusted plasma; PEG, polyethylene glycol; PGI_2, prostacyclin; PGI_2-M, 2,3-dinor-6-keto-$PGF_{1\alpha}$; PL, phospholipid; PPP, platelet-poor plasma; PRP, platelet-rich plasma; P/S, polyunsaturated/saturated; PUFA, polyunsaturated fatty acid; TXA_2-M, 11-dehydro-TXB_2; TXA_2, thromboxane A_2; TXB_2, thromboxane B_2.

quired to induce secondary irreversible aggregation of platelet-rich plasma (PRP) dropped significantly in two of the four subjects, indicating increased platelet reactivity (12).

The Western diet is rich in 18:2n-6, containing 10–30 g/d, compared with 1–3 g/d 18:3n-3 (13) and about 50–70 mg/d 20:5n-3 and 100 mg/d docosahexaenoic acid (DHA) (14). The 20:4n-6 intake in the Western diet has been postulated to be between 100–1000 mg/d (15,16). We have reported the 20:4n-6 intake in the Australian diet to be approximately 130 mg/day for adult males and 96 mg/day for adult females (14), based on average national food intake figures. Thus, the relatively high level of n-6 PUFA in the diet, coupled with the body's natural tendency to conserve tissue arachidonic acid, leads to 20:4n-6 being the most abundant 20-carbon PUFA available in tissue membrane phospholipids (PL) for eicosanoid synthesis.

The relative importance of dietary 20:4n-6, compared with dietary linoleic acid, in contributing to tissue 20:4n-6 levels is not fully understood; however, we have shown that short-term diets (1 to 3 wk) rich in foods containing up to 500 mg/day of 20:4n-6 (red meat, tropical seafood, eggs, liver) are associated with significant increases in the plasma levels of 20:4n-6 (17–20). Furthermore, we have recently reported data from a pilot study indicating that such diets are associated with alterations in thromboxane and prostacyclin production (21).

The objectives of this study were to investigate the effect of three diets containing 20:4n-6 (from foods) on serum and platelet PUFA levels, *in vitro* platelet thromboxane production, and *in vivo* whole body production of PGI_2 and TXA_2. The three diets with elevated but constant levels of 20:4n-6 contained low, medium, and high levels of LC n-3 PUFA. Rather than using isolated oils in pharmacological doses, a more realistic dietary approach was used: The three diets all contained the same level of 20:4n-6 (mean of 140 mg/day) which was approximately double the usual consumption level of 20:4n-6 for these particular subjects, whose normal diets were relatively low in meat and eggs, the main source of dietary 20:4n-6. The first diet was rich in white meat which provided little LC n-3 PUFA, the second diet was rich in red meat which provided a similar level of n-3 PUFA to the usual diet, and the third diet was rich in fish which provided approximately 3 g/day of n-3 PUFA.

MATERIALS AND METHODS

Subjects. A total of 29 free-living subjects took part in the three phases of the intervention study (14 males, 15 females), with an age range of 22–52 yr. Subjects were screened for any existing medical condition and requested not to consume garlic, which is known to affect lipid and cholesterol levels and platelet activity (22), or use any form of medication during the study, particularly corticosteroids and nonsteroidal anti-inflammatory drugs such as aspirin, which could interfere with cyclooxygenase activity (23), thus altering platelet function. Subjects were also requested to abstain from extreme exercise and the consumption of vitamin and mineral supplements (particularly vitamin E) during the study and 2 wk prior to the start.

The study consisted of three 3-wk low-fat (<15% energy as fat) dietary intervention phases with a 3-wk washout period between each, at which time subjects returned to their own "baseline or normal" diet. Individual phases consisted of 1 wk of precooked vegetarian food, followed by 2 wk of meat consumption (either white meat, red meat, or fish). Vegetarian meals were precooked for subjects due to their lack of familiarity with vegetarian cooking. Meat was provided raw and cooked by subjects to their own tastes (no added fats) and consumed with vegetables if desired. The white meat consisted of fat-trimmed turkey fillets (<7.2% fat) and turkey roll (1% fat); the red meat consisted of fat-trimmed beef (<2.8% fat) and lamb (<4.2% fat), and the fish was Atlantic salmon (<10% fat) (14). The average intakes were 231 ± 52 g/day of white meat, 351 ± 104 g/day red meat, and 133 ± 32 g/day of fish (Fig. 1). The short duration of each study (2 wk) was largely due to the difficulty that subjects found in maintaining the consumption levels of meat continuously over an extended period of time.

The fish diet was the last carried out, as tissue DHA levels are known to take up to 3 wk to return to pre-dietary intervention levels, whereas other LC PUFA return to normal levels more quickly (24). No other fat sources were allowed and energy percentage as fat was made up to 15% for each individual with olive oil (77% oleic acid, Moro Spanish Olive oil; Conga Foods, Melbourne, Australia) or Brio™ margarine (Brio Foods, Pireas, Greece) containing 61% oleic acid and 13% *trans*-18:1.

The daily energy intake of each subject was determined from pre-intervention study weighed food records, and the dietary 20:4n-6 intake was designated to be proportional to the total energy intake of each subject. The white meat, red meat, and fish stages of the study were thus controlled for 20:4n-6 intake, but with varying levels of LC n-3 PUFA. No LC PUFA were consumed during the vegetarian periods, so that all subjects entered each dietary period from the same background PUFA intake, giving a valuable reference point for the purpose of examining comparative changes on each diet. Also no LC PUFA were available from any dietary source other than the meat or fish during the study periods. Dietary composition was calculated using SODA (System for On-line Dietary Analysis, version 5.0; Computer Models, Cottesloe, WA., Australia) based on Australian food composition data.

Blood collection. Subjects reported to the clinical rooms of the University in the morning, following a 12-h overnight fast on three occasions during each phase of the study. These were at the beginning of each phase, at the end of week one (vegetarian diet), and again at the end of week three, after 2 wk of meat or fish consumption. Weight was recorded to the nearest 0.1 kg. At these times they received dietary counseling and their records of food consumed (by weight) were collected, checked and any relevant changes in diet for the following week explained to them. Subjects were requested to

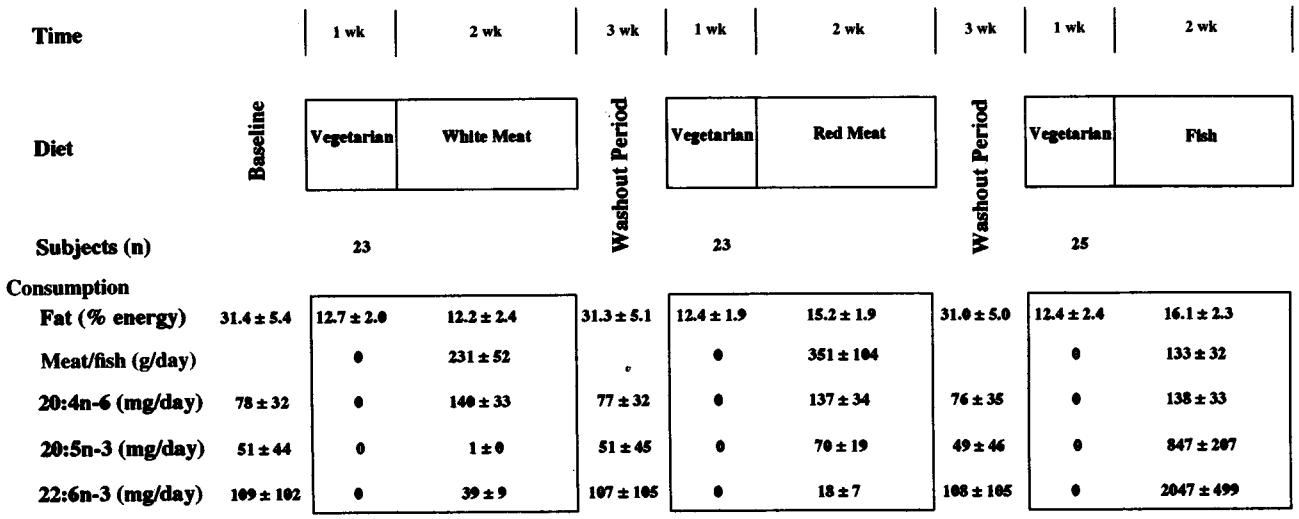

FIG. 1. Experimental design. Three dietary regimes were examined, each consisting of a 1-wk vegetarian diet followed by 2 wk of white meat, red meat, or fish consumption. Each phase was separated by a 3-wk washout period to allow serum phospholipid fatty acid levels to return to baseline. The percentage energy derived from fat in each stage of the study is indicated along with a summary of the amount of meat or fish consumed, with the relevant content of arachidonic acid (20:4n-6), eicosapentaenoic acid (20:5n-3), and docosahexaenoic acid (22:6n-3). Values are mean ± SD.

report any deviations from the dietary protocol and any signs of illness.

Blood was collected following 15 min of quiet relaxation, with minimum stasis. Approximately 34 mL of blood was collected sequentially into a 10-mL plain vacuette (Griener Interpath, Melbourne, Australia), followed by two 5-mL CTAD vacuettes (citric acid, theophylline, adenosine, dipyridamole tubes; Becton Dickinson, Oxford, United Kingdom) pre-warmed to 37°C, and finally three 5-mL sodium citrate vacuettes (Griener Interpath). The serum was removed and frozen at −20°C for later determination of serum fatty acid composition. The blood collected in the three citrate tubes was used for full blood examination and platelet aggregation studies.

Serum PL fatty acid analysis. Lipids were extracted from the serum, and the total PL were separated by thin-layer chromatography and fatty acid methyl esters (FAME) were prepared by saponification in 0.68 M KOH in methanol, followed by methyl esterification with 20% BF_3 in methanol (25). The amounts were quantified using diheptadecanoyl phosphatidylcholine as an internal standard. The FAME were separated by capillary gas chromatography using a 50 m × 0.32 mm i.d. BPX70, WCOT fused-silica capillary column (SGE, Melbourne, Australia) as described previously (26).

Platelet PL fatty acid analysis. Platelets were separated from 10 mL of blood collected in CTAD vacutainers (27) as described by Naughton *et al.* (28), and extracted in 10 mL of 1:1 chloroform/methanol. All platelet separation steps were carried out in polypropylene or silanized glass tubes, and PL fatty acid analysis proceeded as for serum PL fatty acids.

Plasma preparation for platelet aggregation. Platelet-poor plasma (PPP) and PRP were prepared as described previously by Steel *et al.* (29). Platelet aggregation studies required plasma with equal quantities of platelets for each subject, hence requiring concentration adjustment. The platelet-adjusted plasma (PAP) used was obtained by individual dilution of each subject's PRP with their own PPP until a platelet concentration of 220×10^9 platelets/L was achieved. The PAP was then stored at 37°C until the aggregation test was performed, within 2 h of the blood collection.

Platelet aggregation and platelet thromboxane production. Platelet aggregation was determined in PAP using a dual channel, Payton Aggregation Module 300 BD-5 (Payton Scientific Pty. Ltd., Victor Harbour, South Australia). The method used was a turbidimetric method, and aggregation was measured using two different agonists, collagen (Hormon Chemie GMBH, Munich, Germany) and thrombin (Thrombostat, Parke Davies Pty. Ltd., Caringbah, NSW, Australia), both of which initiate a TXA_2 release.

Following platelet aggregation, the supernatant of the aggregated PAP was removed and used for thromboxane determination as outlined by Butcher *et al.* (30). TXB_2 was determined in duplicate in each sample using a radioimmunoassay technique (Scintillation Proximity Assay, SPA, Amersham, Melbourne, Australia) and measured on a liquid scintillation counter. All samples were analyzed as one batch and a pooled serum sample was analyzed five times to determine the intraassay coefficient of variation (mean ± SD, 720.5 ± 8.0 cpm, coefficient of variation 1.1%).

Urine collection. Twenty-four-hour urine samples were collected by subjects, to which was added Indomethacin (Sigma Chemical Co., St. Louis, MO) (50 mg/50 mL urine). Aliquots of 50 mL were stored at −80°C until required for extraction and derivatization.

Prostacyclin measurement. The mean daily excretion of PGI_2-M (2,3-dinor-6-keto-$PGF_{1\alpha}$) derived from 20:4n-6 and

PGI_3-M (Δ^{17}-2,3-dinor-6-keto-$PGF_{1\alpha}$) derived from 20:5n-3 was determined as the methyloxime, pentafluorobenzyl ester, trimethylsilyl ether derivative in 5-mL aliquots of urine spiked with 10 ng of tetradeuterated [19,19,20,20-$^2H_4$] 2,3-dinor-6-keto-$PGF_{1\alpha}$ as an internal standard as described previously (31). The samples were separated using a 12-m, 0.22-mm i.d. BP-1 fused-silica capillary column (SGE, Melbourne, Australia), which interfaced directly with a Hewlett-Packard 5988A single quadrupole mass spectrometer (Palo Alto, CA) as outlined previously (32). The interassay coefficient of variation was 4.2%.

Thromboxane measurement. Quantitative analysis of 11-dehydro-TXB_2 in urine was used for the assessment of *in vivo* thromboxane production (33). A 2-mL aliquot of urine was spiked with 1 ng of tetradeuterated [19,19,20,20-$^2H_4$]-11-dehydro-TXB_2 as an internal standard. Gas chromatography was performed on a Varian 3400 (Palo Alto, CA) operated in splitless mode with a fused-silica capillary column, DB5-MS, 30 m, 0.25 mm i.d., 0.25 mm coating (J&W Scientific, Folsom, CA). The gas chromatograph was interfaced to a Finnigan MAT TSQ 70 triple-stage mass spectrometer (San Jose, CA) operated in NICI mode with methane used as ionization gas. Selected ion monitoring was used to monitor the molecular ion of the pentafluorobenzyl ester trimethylsilyl ether forms of the endogenous metabolite 11-dehydro-TXB_2 and the tetradeuterated [19,19,20,20-$^2H_4$]-11-dehydro-TXB_2 internal standard at *m/z* 511 and *m/z* 515, respectively.

Statistical analysis. We analyzed the results using analysis of variance on data blocks between baseline, vegetarian, and diet period during each study. As sample sizes were approximately equal, the Student's Newman Keul multiple comparison test was applied. All statistical analyses were carried out on a Sun Sparc Station, running Unix, using SAS (Statistical Analysis System, Cary, NC).

RESULTS

One male and one female subject failed to complete the white meat phase of the study, and their results were not recorded; another male only completed the white meat study. One extra female was recruited for the red meat phase, and all subjects completed this phase of the study. One male and two females did not continue with the third phase of the study. Two extra males and three females were recruited to take part in the fish phase of the study. Overall, nine females and 10 males completed all three phases of the study. All subjects remained within a 2-kg weight range during their participation. No statistically significant change occurred in group weight or body mass index in any phase of the study (Table 1). There were no significant differences in baseline levels of PL fatty acids or *in vivo* production of thromboxane or PGI_2 at the start of each study, indicating a return to normal levels during the washout periods.

Fat consumption as a percentage of energy intake on baseline diets was 31% (all figures quoted are for combined male and female results, unless otherwise stated) (Table 2). After 1 wk of vegetarian diet during each of the three diet phases, the fat levels were 12–13% of energy. Following 2 wk on each of the diets, the dietary fat levels were 12, 15, and 16% of energy intake, respectively. The marked fall in the proportion of energy derived from fat on all diets was compensated for by increased carbohydrate consumption.

There was a substantial decrease, relative to baseline, in saturated fat intake during each phase of the study (Table 2). The decrease in monounsaturated fatty acid, relative to baseline during each phase, was more modest owing to the use of olive oil in making up each individual diet to 15% energy as fat. The baseline polyunsaturated/saturated (P/S) ratio in each phase was 0.4, which increased to 0.9 during each of the three vegetarian periods. During the white meat phase, the P/S ratio remained at 0.9, but fell to 0.5 during the red meat phase. The fish was relatively rich in PUFA, and during this phase of the study the dietary P/S ratio increased to 1.3. Cholesterol intake was extremely low on the vegetarian diets relative to baseline ($P < 0.001$). During the white meat and fish phases of the study, cholesterol intakes rose relative to the vegetarian period ($P < 0.001$), but were still well below baseline intakes ($P < 0.001$). During the red meat phase of the study, cholesterol intake returned to baseline levels.

The quantity of meat or fish consumed by each subject and

	Week 3	8,786 ± 1,872	66.7 ± 4.0^{c,f}	15.1 ± 2.1^{c,f}	2.1 ± 2.4	16.1 ± 2.3^{c,f}	3.6 ± 0.5^{c,f}	7.5 ± 1.4^{c}	5.0 ± 0.6^{c,f}	80 ± 22^{c,f}	25.6 ± 7.8^{f}

Values are mean ± SD. Abbreviations: Carbohy. = carbohydrate; Sat. = saturated fatty acids; Mono. = monounsaturated fatty acids; Poly. = polyunsaturated fatty acids. ^{a,b,c}Significantly different to baseline ($^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$). ^{d,e,f}Significantly different to Week 1-vegetarian ($^{d}P < 0.05$, $^{e}P < 0.01$, $^{f}P < 0.001$)

the intake of LC PUFA during the white meat, red meat, and fish dietary periods are shown in Table 3. The amounts consumed daily were 231 ± 52 g of white meat (range 150–270 g white meat for females and 205–330 g white meat for males), 351 ± 104 g of red meat (range 255–400 g red meat for females and 330–500 g red meat for males), 133 ± 32 g of fish (range 90–155 g fish for females and 115–200 g fish for males). The mean 20:4n-6 intake was approximately 77 mg/day during the baseline period, and this almost doubled during the meat and fish diet phases of the study (Table 3). The 20:5n-3 levels of about 50 mg/day on the baseline diet declined significantly on the white meat phase and increased by a factor of 16 in the fish period. The DHA values of about 100 mg/day fell significantly on the meat diets to less than 40 mg/day and increased to about 2050 mg/day on the fish diet.

Significant changes in serum PL fatty acid concentration occurred for only six fatty acids during the study (Table 4). Oleic acid (18:1) levels increased during the vegetarian week of the white and red meat phases, which coincided with the highest consumption period of 18:1 by subjects. After 2 wk on each diet, the 18:1 levels decreased, particularly during the fish phase. Linoleic acid (LA, 18:2n-6) decreased during each vegetarian stage and remained low after two weeks of white meat, red meat or fish consumption. Arachidonic acid increased significantly during the white meat and red meat phases of the study, but decreased during the fish phase.

Eicosapentaenoic acid levels decreased during the vegetarian week of each phase of the study. During the 2 wk of white meat consumption, the level of 20:5n-3 did not change; however, a small but significant increase occurred during the 2 wk of red meat consumption and a large increase occurred during the fish phase of the study. Docosapentaenoic acid (22:5n-3) remained unchanged during the vegetarian week of each phase, but increased during the 2 wk of red meat and fish consumption. DHA (22:6n-3) was only significantly elevated during the fish phase of the study. As anticipated from dietary composition, the serum ratio of 20:4n-6/20:5n-3 changed substantially during the course of the study. During the vegetarian stages, the average ratio was 11:1; this increased to 15:1 on the white meat diet (poor in 20:5n-3) then decreased to 8:1 on red meat and 2:1 on the fish diet.

The changes in platelet fatty acids were relatively minor compared with the serum PL, apart from substantial increases in 20:5n-3 and 22:6n-3 after the fish phase (Table 5). The level of stearic acid (18:0) in the platelet PL decreased significantly during the fish phase of the study ($P < 0.001$), while LA decreased in the final 2 wk of each study. During the white and red meat phases of the study, 20:4n-6 levels remained unchanged, but fell significantly during the fish phase.

TABLE 3
Estimated Daily Intake of Long-Chain Fatty Acids (mg/day) During the Three, Two-Week Periods of Meat and Fish Consumption, Compared with the Mean Baseline Intake Levels Prior to the Study[a]

		Long-chain polyunsaturated fatty acid intake							
		AA[b]		EPA[c]		DPA[d]		DHA[e]

Values are mean ± SD. No change was observed in the concentration of 14:0, 16:0, 16:1, or 18:3n-3 fatty acids.
[a,b,c]Significantly different to baseline ([a]$P < 0.05$, [b]$P < 0.01$, [c]$P < 0.001$).
[d,e,f]Significantly different to week 1—vegetarian ([d]$P < 0.05$, [e]$P < 0.01$, [f]$P < 0.001$).

During each vegetarian period, 20:5n-3 levels decreased significantly; however, the 20:5n-3 level increased significantly during the red meat and fish phases. Platelet levels of 22:6n-3 decreased during the red meat phase and doubled during the fish phase of the study. No significant change was detected in the platelet PL ratio of 20:4n-6/20:5n-3 during the white or red meat diets. However, the fish diet resulted in a decrease from 45:1 (baseline diet) to 13:1.

There were no significant changes in platelet aggregation (data not shown) on any of the studies. However, when all baseline data for the three studies were grouped and compared with the grouped vegetarian data, a significant but unexplained increase in aggregation due to collagen was observed after 1 wk of low-fat vegetarian diet relative to baseline (baseline 64.0% ± 2.4%, vegetarian 71.0% ± 2.3%, $P < 0.01$).

Using collagen as an agonist (Table 6), the *ex vivo* platelet TXB_2 production increased during the vegetarian period of the white meat study ($P < 0.05$) and returned to baseline following 2 wk of white meat consumption ($P < 0.05$). During the vegetarian weeks of the white meat and fish studies, the

Values are mean ± SD.

thrombin-stimulated platelets showed an increased TXB_2 production ($P < 0.01$ and $P < 0.05$, respectively). This decreased during the 2 wk of fish consumption ($P < 0.05$), but remained elevated on the white meat diet.

The daily urinary excretion of PGI_2-M decreased during the 1-wk vegetarian period of each study, reaching significance in the white meat ($P < 0.001$) and fish studies ($P < 0.01$) and remaining depressed, relative to baseline values, during the 2 wk of white meat ($P < 0.001$) and fish consumption ($P < 0.01$) (Table 7). No significant change in PGI_2 output was recorded during the 2 wk of meat or fish consumption relative to the first-week low-fat vegetarian diet. Prostacyclin (PGI_3), derived from the n-3 PUFA 20:5n-3, was detected in most subjects following 2 wk of fish consumption only, and reached a mean value 12 ± 9 ng/day.

The daily urinary excretion of TXA_2-M showed large interindividual variation, with no significant changes during the vegetarian week of each study. No effect of white or red meat consumption was evident, but a significant reduction occurred during the 2 wk of fish consumption ($P < 0.05$) relative to the vegetarian diet.

DISCUSSION

In the Western diet, the main dietary PUFA is linoleic acid, and this fatty acid is almost certainly the major source of the 20:4n-6 which is found in high proportions in most cell membranes of the body (34). High intakes of fatty fish or fish oil rich in LC n-3 PUFA are known to increase membrane PL levels of these LC n-3 PUFA, with such diets often leading to simultaneous reductions in the 20:4n-6 levels in the membranes. These changes have been associated with beneficial effects on thrombosis tendency, including reduced TXA_2 production, reduced platelet aggregation, and lowered plasma triglyceride levels (35).

We have been interested in the converse situation, that is, what are the consequences of ingesting diets containing 20:4n-6 (21,30). In the early 1960s Mohrhauer and Holman (36) showed that on a gram for gram basis, dietary 20:4n-6 led to substantially higher tissue 20:4n-6 levels than dietary LA. The purpose of the present study was to examine the effects of the ingestion of a constant dietary level of 20:4n-6 combined with varying levels of LC n-3 PUFA (supplied from meat or fish) on serum and platelet PL 20:4n-6 levels and subsequent conversion to vasoactive eicosanoids in studies of two weeks' duration. By using white meat, red meat, and fish, we were able to supply a constant level of dietary 20:4n-6 at double the usual intake for these subjects and a varying LC n-3 PUFA intake (from very low to very high).

The meat diets were associated with approximately 20% increases in the serum PL 20:4n-6 concentration and little or no change in n-3 PUFA levels; however, there were no changes in the platelet 20:4n-6 levels on these diets in the short-term period of this study. In contrast, the fish diet led to very large increases in 20:5n-3 and 22:6n-3 in both plasma and platelet PL and to significant decreases in 20:4n-6 levels in both tissues. An obvious explanation for the changes in the platelet lipids on the fish diet (but not on the meat diets) was the increase in the dietary intake of n-3 PUFA by about 3 g/day compared with the increase in 20:4n-6 of only 60–70 mg/day on the meat diets.

There were no effects from any of these diets on *ex vivo* platelet aggregation. This is not surprising since the platelet PL 20:4n-6 on the fish diet was still 12 times the 20:5n-3 level, compared with Eskimos, where the levels of 20:4n-6 and 20:5n-3 in platelet lipids are about the same (37).

However, the fish diet was associated with a significant reduction ($P < 0.05$) in *ex vivo* TXB_2 production from thrombin-stimulated platelets and in the principal urinary metabolite of thromboxane (11-dehydro-TXB_2, TXA_2-M). This decrease in TXA_2-M daily excretion, following the 2 wk of fish consumption, coincided with a decrease in platelet PL 20:4n-6, an increase in 20:5n-3 and 22:6n-3, and a change in the 20:4n-6/20:5n-3 ratio in platelet PL from 68:1 (vegetarian diet) to 13:1. These changes could account for the 20% decrease in TXA_2 production by a number of mechanisms, firstly, replacement of 20:4n-6 in PL by LC n-3 PUFA, effectively lowering the amount of substrate for TXA_2 production

(38); secondly, inactivation of cyclooxygenase by LC n-3 PUFA (36); finally, release of 20:5n-3 from platelet PL, which competes with 20:4n-6 for access to cyclooxygenase and produces an alternative form of thromboxane (TXA_3) (39). Decreases in TXA_2 following fish consumption have been observed in other studies. Knapp and FitzGerald (40), found a 29% reduction in TXA_2 production, measured as the urinary metabolite 2,3-dinor-TXB_2, following 50 mL/day of fish oil for 4 wk. A small amount of TXA_3 was detected (~14% of the total thromboxane level). Ferretti *et al.* (41) observed a 38% reduction in TXA_2 production, measured as the urinary metabolite, 11-dehydro-TXB_2, following 10 wk of fish oil consumption (15 g/day). A small quantity of the TXA_3 metabolite was also detected, but not quantified. In the 2 wk of fish consumption in the present study, no TXA_3 products were detected, possibly owing to the lower level of 20:5n-3 consumed (~847 mg/day), compared with ~9 g/day and 4.5 g/day in the above two studies, respectively. Like many other studies involving fish oil consumption, the intake of LC n-3 PUFA the above two studies is at a pharmacological level and has little resemblance to normal human nutrition. It is likely that TXA_3 is not normally produced in humans consuming a modern Western diet even when modest amounts of fish are consumed, as in the 2-wk fish diet of the present study. White and red meat consumption did not result in a substantial change in platelet 20:4n-6/20:5n-3 ratio or TXA_2 production, even though both these diets significantly increased the 20:4n-6 concentration of the plasma PL. Presumably the low intake of 20:4n-6 and the short time frame of the study contributed to the failure to alter platelet 20:4n-6 levels. However the study was designed to test the impact of high 20:4n-6 intake from foods, in this case specifically meats. The limiting factors proved to be the actual physical quantity of meat that subjects could comfortably consume on a daily basis and the period of time that they could maintain this level of consumption.

The decrease in PGI_2-M recorded during the low-fat vegetarian period of each study is consistent with observations by Nordoy *et al.* of decreased prostacyclin production on low-fat diets (42), the suggested reason being that fatty acids (saturates in particular) stimulate PGI_2 production by endothelial cells. An *in vitro* study by Zhang *et al.* (43) showed stearic acid to increase PGI_2 production by endothelial cells in culture medium, but this increase was associated with morphological signs of cellular damage and reduced viability in culture. No further changes in PGI_2-M production were observed after the 2 wk of meat or fish diets. Previous studies have shown conflicting effects of LC n-3 PUFA on *in vivo* PGI_2 production. Mann *et al.* (32) showed a decreased level of urinary PGI_2-M in rats following 2 wk of dietary supplementation with 20:5n-3, and Ferretti *et al.* (31,41), in a study involving the feeding of 15g/day of fish oil to human subjects, found a 20% decrease in urinary PGI_2-M. In other studies, no change in urinary PGI_2-M was observed when fish oil or fish was fed to human subjects (38,44,45). Prakash *et al.* (45) found a decrease in TXA_2-M in subjects fed a similar diet to this study, containing 450 g/day of salmon (rich in 20:4n-6 and LC n-3 PUFA). In two other human studies involving fish consumption (46,47), urinary PGI_2-M levels were increased. However, it should be noted that in these two studies the level of 20:4n-6 contained in the fish consumed was high (~250 mg/day and ~380 mg/day, respectively). In the present study, a small amount of PGI_3-M (~4% of total prostacyclin) derived from 20:5n-3 was measured in the urine following 2 wk of fish consumption. Knapp and FitzGerald (40), feeding 50 mL/day of fish oil for 4 wk, also found an increase in the PGI_3-M level (from zero to ~15% of the total prostacyclin production).

In conclusion, it can be stated that under the circumstances of this study, there was no increase in TXA_2 production on diets containing 20:4n-6 and relatively low levels of n-3 PUFA (white and red meat), but there was a decrease on a fish diet (100–200 g/day), containing 90–210 mg/day 20:4n-6 and approximately 3 g of LC n-3 PUFA. However, this does not rule out the adverse effects of 20:4n-6 at higher levels in the diet or for more prolonged periods. The LC n-3 PUFA from fish had a beneficial effect on platelet reactivity by lowering *in vivo* TXA_2 production without significantly affecting PGI_2 production; however, the maintenance of PGI_2 levels on fish diets may be dependent on the simultaneous consumption of 20:4n-6, which is relatively high in salmon (14) compared with other sources such as white or red meat, and certainly supplies more 20:4n-6 than is present in fish oil feeding studies. White and red meat consumption within the ranges used in this study does not appear to change prostacyclin production; however, the low-fat diets did decrease prostacyclin production, and future studies will have to take this phenomenon into account.

ACKNOWLEDGMENTS

This project was funded by a grant from the Meat Research Corporation (Sydney, Australia) and in part by DFG grant We681/7-1 (Munich, Germany). The technical assistance of Tony Anderson and Irmgard Papperitz and statistical advice of Michelle Balding are gratefully acknowledged.

ABSTRACT: *In vivo* ^{13}C magnetic resonance spectroscopy (MRS) was applied noninvasively to analyze the fatty acid composition of adipose tissue in 21 full-term newborn infants and 6 mothers. In order to assess the effects of gestational and postnatal age on adipose tissue composition, we studied preterm infants at birth, term infants at the ages of 6 wk and at 6 mon. We also investigated the influence of maternal diet on infant adipose tissue composition by studying the breast-fed infants of women who maintained either an omnivore or a vegan diet. Significant differences were observed in adipose tissue composition of neonates compared with their mothers. Neonates had more saturated and less unsaturated fatty acids than their mothers ($P < 0.01$). We also observed changes in adipose tissue composition with maturity. From birth to 6 wk of age ^{13}C MR spectra showed a significant increase in the amount of unsaturated fatty acids, particularly polyunsaturated fatty acids ($P < 0.01$). Similarly, differences were seen as a result of gestational age. Preterm infants had relatively fewer unsaturated fatty acids than full-term infants. A greater proportion of these unsaturated fatty acids were polyunsaturated. Our results demonstrate that ^{13}C MRS can be utilized to assess noninvasively neonatal adipose tissue lipid composition and to monitor the effects of developmental changes due to gestational age and oral feeding.
Lipids 32, 645–651 (1997).

Infancy is characterized by rapid growth and development. Neonatal adipose tissue fatty acids serve not only as an important energy reserve during this period but also as a source of lipid precursors for membrane development of organs such as the liver and brain (1–3). Preterm and low-birth-weight neonates have been shown to have considerably smaller reserves of adipose tissues, sometimes as little as 10% of that found in term neonates (2). The overall amount of fat the neonate carries appears to be important, and these small reserves may result in retarded growth, reduced ability to maintain body temperature, and impaired neurodevelopment (4). In addition, it has been suggested that the type of fatty acids available is of particular significance to membrane growth and the adipose tissue stores of polyunsaturated fatty acids may be essential for brain development (3).

Neonatal nutrition is thought to have an important influence on certain diseases in adult life, including cardiovascular disease, non-insulin dependent diabetes mellitus, and obesity (5,6). These studies have focused on the effect of birth weight. However, it is known that the fatty acid composition of adipose tissue in adults is an independent risk factor for cardiovascular disease (7). This raises the question of whether the type of fatty acids present in the neonatal adipose also affects adult disease development.

Examination of the fatty acid composition of subcutaneous adipose tissue of infants has so far required tissue samples obtained by biopsy or at postmortem for *in vitro* analysis by gas–liquid chromatography (GLC) (8–14). It has therefore not been possible to perform serial, longitudinal studies of adipose tissue composition of healthy infants. A noninvasive technique would permit the investigation of the relationship between neonatal nutrition, adipose tissue composition, and subsequent growth and development.

Recently magnetic resonance spectroscopy (MRS) has been applied to the study of lipids in humans (15–18) and animals (19–21). Although individual fatty acids cannot be identified, Moonen *et al.* (15) have shown that from an *in vivo* ^{13}C MR spectrum of human adipose tissue, it is possible to determine the quantities of saturated and unsaturated fatty acids present (15). Beckmann *et al.* (16) used ^{13}C MRS to show differences in the adipose tissue profile of subjects after 6 mon dietary change, and we have previously shown that ^{13}C MRS can demonstrate long-term dietary-dependent differences in adipose tissue composition (17).

The objectives of this study were to noninvasively assess, by ^{13}C MRS, differences in the adipose tissue composition of healthy full-term newborn infants and their mothers. Further, we determined the influence of gestational age and the effect of oral feeding on adipose tissue composition of neonates.

MATERIALS AND METHODS

Volunteer assessment. Permission for this study was obtained from the Ethics Committee of the Royal Postgraduate Medical School, Hammersmith Hospital, London (No. 93/4237). Healthy full-term infants (n = 21, 12 males, 9 females), with a mean gestational age of 38.7 ± 0.3 wk (± SEM) (range 37–42 wk) and a mean birth weight of 3.3 ± 0.2 kg (range 2.0–5.1 kg), were studied as soon as possible after birth (mean study day after birth 1.8 ± 0.4, range 0–7 d). The mothers (all omnivores) of six of the infants were also studied on the same day.

Ten infants (4 male, 6 female) had a further examination at the age of 6 wk (mean age 6.2 ± 0.5 wk, range 4–10 wk), eight of whom had received breast milk and two were formula fed. Two of these infants (both male) were reexamined at the age of 6 mon. In addition, three vegan infants (all female, mean age 6.7 mon) and their mothers were studied. All of the 6-mon-old infants had been wholly breast-fed by their mothers. Infants were partially weaned to a vegan or omnivore diet at the time of the study.

Spectra were also obtained from six preterm infants (all female) with a mean gestational age of 33.8 ± 0.5 wk (32–36 wk) and birth weight of 2.0 ± 0.1 kg (1.7–2.6 kg). One preterm baby (gestational age 26 wk, birth weight 1.0 kg, weight at examination 1.9 kg) who had been exclusively fed by total parenteral nutrition (TPN) was studied at the age of 5 wk.

^{13}C MRS. In vivo ^{13}C MR data were obtained at 1.5 T on a Picker prototype system. Spectra were collected from the adipose tissue of the left thigh from the mother and from the upper thigh and buttocks of the neonates. An enveloping saddle transmitter coil and a surface receiver coil (14 or 6 cm) were used. Shimming was performed on the proton water signal in the preterm infants, but in the full-term infants and their mothers, shimming was possible directly on the ^{13}C lipid signals. Each examination lasted approximately 15 min and no sedation was required as infants were studied during natural sleep. During each examination infants were observed with MRS-compatible ECG and pulse oximetry monitors.

Coupled ^{13}C MR spectra of adipose tissue were acquired using a 90° pulse. In initial studies, T_1 and signal height ratio measurements were obtained from adults and neonates (22). Spectra for quantitative analysis were obtained with eight acquisitions at TR 30 s. Because of low signal-to-noise (S/N) ratio, spectra from the preterm infants were also obtained at a TR 300 ms with 256 acquisitions. The spectra were then analyzed using a correction factor to overcome partial saturation effects. This factor was obtained from the ^{13}C MR spectra of full-term infants by measuring the peak areas of several spectra acquired at different repetition times (TR 300 ms and TR 30 s) and calculating the change in the spectra. The factor obtained from the full-term infants was then applied to the spectra obtained from the preterm infants at TR 300 ms for them to be analyzed quantitatively.

Data analysis. Spectral analyses were carried out using a modified Microcal Origin software package (Microcal Software, Inc.) in combination with biochemical prior knowledge, since standard commercially available software could not easily be used. The free induction decays were zero filled to 4 K prior to Fourier transform, and no line broadening was used. The *in vivo* ^{13}C MRS examination introduces some intrinsic difficulties, which need to be considered during data analysis. The S/N can often be limited in infant subjects. Furthermore, the ^{1}H-^{13}C long-range spin-spin couplings (more than one bond apart) are similar to the resonance half-linewidths and cannot be resolved at the low magnetic field strength used, complicating the spectral lineshape. We found therefore that the Gaussian lineshape given by the equation

$$G_i = \frac{A_i}{a_i \times \sqrt{\pi/2}} \times \exp\left(\frac{-2 \times (\nu - \nu_i)^2}{a_i^2} \right) \quad [1]$$

(where A_i is the area of the resonance, a_i the half-linewidth, ν the spectral frequency and ν_i the resonance frequency of the Gaussian i) described the experimental lineshapes much more closely than the Lorentzian shape. In addition, incorporation of biochemical prior knowledge of the lipid resonances into the spectral analysis was found to be advantageous, especially in the analysis of spectra from infant subjects. In particular, use of prior knowledge decreased the noise-related variability of the analysis and increased the overall reliability of the results (23–26). All analyses included a linear baseline $c_0 + c_i\nu$.

^{13}C MR spectra from 98 adult volunteers were pooled and the carbonyl and unsaturated resonances analyzed using one Gaussian component for each resonance. The pooled data showed that the relative chemical shifts of the resonances were unchanged from person to person. Therefore, all the analyses for the current data were performed by first separately analyzing the carbonyl resonance (at around 172 ppm) and then the unsaturated lipid resonances (from 110 to 129 ppm) keeping the resonance frequencies fixed relative to the carbonyl chemical shift (–46.8 and –48.6 ppm from the carbonyl resonance frequency for the mono- and polyunsaturated and polyunsaturated resonances, respectively). By examining the spectra from all of the adults and from the nine infants who had spectra with sufficient S/N ratio, we were able to obtain a reliable individual estimation of the half-linewidths. The relative chemical shifts of the resonances in the spectra from the nine infant subjects were the same as those obtained for the pooled adult data set. However, the resonances in the spectra from the infant subjects were somewhat broader and less well resolved than the corresponding resonances in the spectra from the adult volunteers. Therefore, based on the analyses of the spectra with good S/N ratio from the nine infants, average values for the resonance half-linewidths were calculated and used in the analysis of all other spectra from infants (19.9 Hz for the carbonyl, 19.1 Hz and 19.5 Hz for the mono- and polyunsaturated and polyunsaturated resonance, respectively). Inclusion of this kind of prior knowledge guaranteed unequivocal analysis and resulted in calculated spectra that closely resembled the experimental data (Figs. 1 and 2).

Total fat analysis. Total unsaturated and saturated fatty acids were calculated (Method A) as previously described

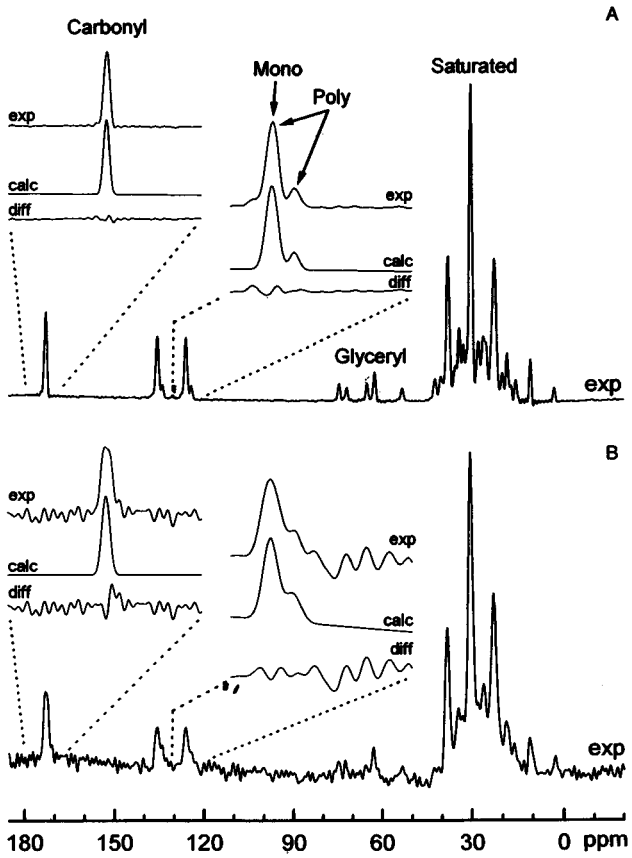

FIG. 1. *In vivo* ^{13}C magnetic resonance spectra of adipose tissue from a (A) mother and her (B) full-term neonate (TR = 30 s). Resonances arising from the carbonyl, unsaturated, glyceryl, and saturated regions of triglycerides may be observed. Assignments: carbonyl carbons 172.1 ppm; carbons in the monounsaturated (mono) and polyunsaturated (poly) positions (–**C**H=**C**H– and –***C***H=CH–CH$_2$–CH=***C***H–) 134.9 and 125.4 ppm; polyunsaturated carbons only (–CH=***C***H–CH$_2$–***C***H=CH–) 133.4 and 124.2 ppm; carbons from glycerol backbone 60–70 ppm; carbons in the saturated position (–***C***H$_2$– or –***C***H$_3$) 10–40 ppm. The results of the lineshape-fitting analysis illustrating the experimental (exp), calculated (calc), and difference (diff) spectra for the carbonyl and unsaturated resonances are also shown (for more details see the Materials and Methods section).

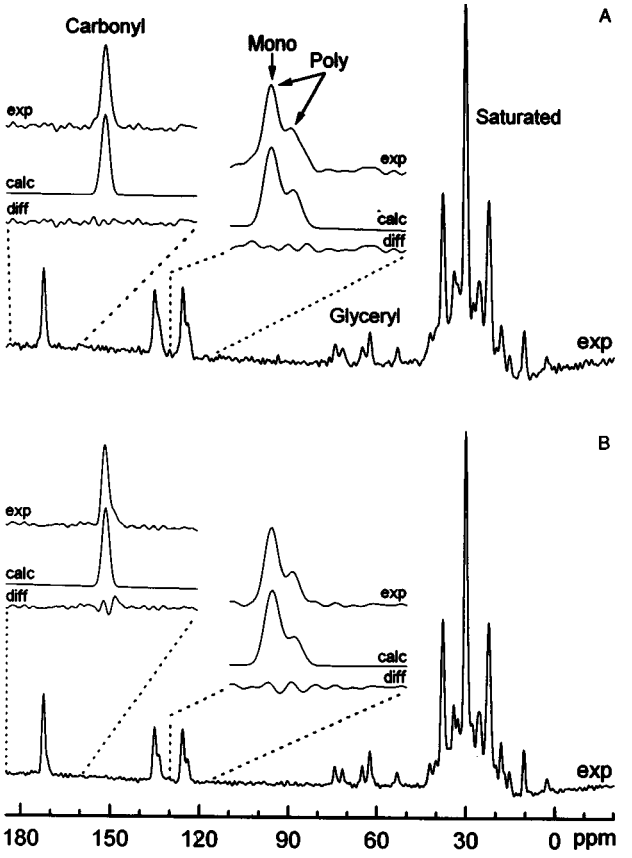

FIG. 2. ^{13}C magnetic resonance spectra from the adipose tissue of 6-mon-old infants breast-fed by (A) vegan and (B) omnivore mothers. For a full assignment, description, and abbreviations, see Figure 1.

(15,16). This method assumes that linoleic acid is the major polyunsaturated fatty acid in adipose tissue. However, this fatty acid is not nearly so prominent in infant adipose tissue as in adults (8–14) and for this reason the method of percentage carbon analysis (Method B) was also used (17,20,22). Both methods are described briefly below.

Total fat analysis by Method A: This method allows the calculation of total levels of polyunsaturated, monounsaturated, and saturated fatty acids (15), allowing direct comparison with literature values obtained by GLC.

$$\%\ \text{polyunsaturated} = \frac{\left(I_p + I_p\right)}{2I_{\text{C=O}}} \times 100 \qquad [2]$$

$$\%\ \text{monounsaturated} = \frac{\left(I_{M+P} + I_{M+P}\right) - \left(I_P + I_P\right)}{2I_{\text{C=O}}} \times 100 \qquad [3]$$

$$\%\ \text{saturated} = 100 - (\%\ \text{polyunsaturated} + \%\ \text{monounsaturated}) \qquad [4]$$

where $I_{C=O}$ = intensity of carbonyl peak (172.1 ppm); I_{M+P} = intensity of monounsaturated (M) and polyunsaturated (P) coupled resonances (134.9 and 125.4 ppm); I_P = intensity of polyunsaturated coupled resonances (133.4 and 124.2 ppm).

Percentage fatty acid carbon analysis by Method B: This method is based on absolute data, makes no assumptions about the composition of the tissue under study, and overcomes the problems of analyzing the unsaturated region of the ^{13}C MR spectra. Percentages of carbons in saturated (found in both saturated and unsaturated fatty acid chains) and unsaturated (found only in unsaturated fatty acid chains) positions in the fatty acid chain are calculated from integrals of three regions of the ^{13}C spectrum: carbonyl groups at 165–175 ppm; unsaturated fatty acid carbons at 120–140 ppm; and saturated fatty acid carbons at 10–45 ppm. This method involved the summing of integrated areas of the carbonyl, unsaturated, and saturated regions of the spectrum to provide a total fatty acid area:

$$\%\ \text{total fatty acid carbons}\ (A) = I_{\text{carbonyl}} + I_{\text{unsaturated}} + I_{\text{saturated}} \qquad [5]$$

$$\%\ \text{unsaturated fatty acid carbons}\ (B) = \frac{I_{\text{unsaturated}}}{A} \times 100 \qquad [6]$$

$$\% \text{ saturated fatty acid carbons} = 100 - B \quad [7]$$

The unsaturated region of the ^{13}C MR spectrum has two pairs of resonances: (i) the larger peaks (I_{M+P}) at 134.9 and 125.4 ppm arise from carbons in the monounsaturated and polyunsaturated positions of the fatty acid chains (–**C**H=**C**H– and –**C**H=CH–CH_2–CH=**C**H–); (ii) the smaller peaks (I_P) at 133.4 and 124.2 ppm arise from carbons in the polyunsaturated positions of the fatty acid chain (–CH=**C**H–CH_2–**C**H=CH–). The proportion of fatty acid carbons that were polyunsaturated or monounsaturated may be determined from the following equations:

$$\% \text{ polyunsaturated fatty acid carbons} = \frac{I_P + I_P}{(I_P + I_P) + (I_{M+P} + I_{M+P})} \times B \quad [8]$$

$$\% \text{ monounsaturated fatty acid carbons} = B - \% \text{ polyunsaturated} \quad [9]$$

Statistical analysis. Differences between the term, preterm, and adult groups were examined using Student's unpaired *t*-test. Differences between the term infants examined at birth, 6 wk and 6 mon later were tested using the Student's paired *t*-test. All results presented are expressed as mean ± SEM.

RESULTS

Representative ^{13}C MR spectra obtained *in vivo* from the adipose tissue of a full-term infant at birth and his mother are shown in Figure 1. Separate resonances arising from carbon atoms from different regions of the triglyceride chains can be observed in both spectra and include: carbonyl (–**C**=O), unsaturated (–**C**=**C**–), glyceryl (–**C**H_2– and –**C**H–), and saturated fatty acid carbons (–**C**H_2– and –**C**H_3). There are clear differences in the relative intensity of saturated and unsaturated fatty acids. Full-term infants at birth had significantly more saturated fatty acids than their mothers [58.4 ± 1.7 vs. 17.9 ± 2.9%, $P < 0.01$] (Method A, see Table 1) and conversely fewer unsaturated fatty acids [41.6 ± 1.7 vs. 82.1 ± 2.9%, $P < 0.01$]. By 6 wk of age, spectra from these infants had changed, showing increases in unsaturated fatty acids [59.6 ± 1.4 vs. 41.6 ± 1.7%, $P < 0.01$], though not to the level found in their mothers.

TABLE 1
Fatty Acid Composition of Adipose Tissue of Mothers, Preterm Infants, and Full-Term Infants at Birth and After 6-wk Development, Analysis Using Method A[a]

	Preterm ($n = 6$)	Full-term at birth ($n = 21$)	6-wk-old infants ($n = 10$)	Mothers ($n = 6$)
Unsaturated (%)	38.9 ± 1.9	41.6 ± 1.7	59.6 ± 1.4[b]	82.1 ± 2.9[a]
Saturated (%)	61.1 ± 1.9	58.4 ± 1.7	40.4 ± 1.4[b]	17.9 ± 2.9[a]

[a]Mean ± SEM. [a]$P < 0.01$, level of significance between mothers and full-term infants at birth. [b]$P < 0.05$, level of significance between full-term infants at birth and 6 wk later.

By expressing the fatty acid content of adipose tissue as percentage fatty acid carbons (Table 2), similar differences can again be observed. This method allows quantification of poly- and monounsaturated fatty acids without making assumptions as to the type of fatty acids present (17). Saturated and unsaturated fatty acid carbons were significantly different in full-term infants compared with their mothers. Lower levels of both polyunsaturated and monounsaturated fatty acid carbons were observed in full-term infants compared with their mothers. The spectra from full-term infants at 6 wk showed an increase in unsaturated fatty acid carbons (infant at birth: 7.5 ± 0.2 vs. 6-wk-old infant: 8.5 ± 0.3%), becoming closer in appearance to that of their mothers. Two infants had a further examination at the age of 6 mon. No significant differences were found between the adipose tissue composition of the infants at the age of 6 wk vs. 6 mon (unsaturated, 6 wk: 8.5 ± 0.3 vs. 6 mon: 8.7 ± 0.8%). However, the adipose tissue of the infants at 6 mon was still significantly different from their mothers with lower levels of unsaturated fatty acid carbons.

Preterm infants had slightly higher relative levels of saturated fatty acid carbons and lower unsaturated fatty acid carbons than full-term infants. When the signal from unsaturated fatty acid carbons was further analyzed for the relative levels of mono- and polyunsaturated fatty acids, preterm infants had lower relative levels of monounsaturated fatty acid carbons than their full-term counterparts (Table 2). Higher levels of polyunsaturated fatty acid carbons were found in the adipose

TABLE 2
Percentage Fatty Acid Carbons Found in the Adipose Tissue of Mothers, Preterm Infants and Full-Term Infants at Birth and After 6 wk Development, Analysis Using Method B[a]

	Preterm ($n = 6$)	Full-term at birth ($n = 21$)	6-wk-old infants ($n = 10$)	Mothers ($n = 6$)
Unsaturated (%)	5.9 ± 0.6[c]	7.5 ± 0.2	8.5 ± 0.3[b]	10.5 ± 0.3[a]
Saturated (%)	93.7 ± 0.6	92.4 ± 0.2	91.5 ± 0.3	89.5 ± 0.3
Polyunsaturated (%)[d]	2.4 ± 0.3	2.1 ± 0.1	2.3 ± 0.2	2.7 ± 0.3
Monounsaturated (%)[e]	3.5 ± 0.3[c]	5.4 ± 0.2	6.1 ± 0.3[b]	7.8 ± 0.2[a]

[a]Mean ± SEM. [a]$P < 0.01$, level of significance between mothers and full-term infants at birth. [b]$P < 0.05$, level of significance between full-term infants at birth and at 6 wk. [c]$P < 0.01$ level of significance between full-term and preterm infants at birth. [d]Polyunsaturated refers to carbons in –CH=***C***H–CH_2–***C***H=CH– positions. [e]Monounsaturated refers to carbons in –***C***H=***C***H and –***C***H=CH–CH_2–CH=***C***H– positions.

TABLE 3
Comparison of Adipose Tissue Composition of 6-mon-old Infants Breast-Fed by Vegan and Omnivore Mothers, Analysis Using Method B

	Vegan infants (n = 3)	Omnivore infants (n = 2)
Unsaturated (%)	11.0 ± 0.3	8.7 ± 0.8
Saturated (%)	89.0 ± 0.3	91.3 ± 0.8
Polyunsaturated (%)	4.3 ± 0.4	2.5 ± 0.4
Monounsaturated (%)	6.7 ± 0.1	6.2 ± 0.4

	Vegan infants (n = 3)	Vegan mothers (n = 3)
Unsaturated (%)	11.0 ± 0.3	12.1 ± 0.2
Saturated (%)	89.0 ± 0.3	87.9 ± 0.2
Polyunsaturated (%)	4.3 ± 0.4	4.3 ± 0.1
Monounsaturated (%)	6.7 ± 0.1[a]	7.8 ± 0.2

[a] $P < 0.01$, level of significance between vegan infants and their mothers.

tissue of the preterm compared to the term infants, although this did not reach the level of significance. The adipose tissue fatty acid composition of the preterm infant receiving TPN closely resembled that of the TPN formula (results not shown).

Representative spectra obtained from the adipose tissue of vegan and omnivore infants at 6 mon are shown in Figure 2. The adipose tissue composition of infants breast-fed by vegan mothers were shown to have higher levels of unsaturated fatty acid carbons in their adipose tissue than infants fed by omnivore mothers [11.0 ± 0.3 vs. 8.7 ± 0.8%] (see Table 3).The vegan infants also had higher levels of polyunsaturated fatty acids than the omnivore infants [4.3 ± 0.4 vs 2.5 ± 0.4%]. No significant differences were found in the polyunsaturated fatty acid composition of adipose tissue composition between the vegan mothers and their infants (Table 4).

DISCUSSION

There is a paucity of information regarding the effects of maternal and postnatal nutrition on neonatal adipose tissue composition and its association with development. This arises from a lack of methods for the assessment of neonatal body composition other than invasive procedures such as biopsy. Until now, investigating noninvasively the effect of diet on adipose tissue composition in healthy infants has not been possible, so that detailed longitudinal studies have not yet been performed. This preliminary study shows that natural abundance ^{13}C MRS allows the noninvasive and repeated measurement of the fatty acid composition of adipose tissue of newborn infants. Using ^{13}C MRS, we showed differences between newborn infants and mothers and showed the influence of gestational age and postnatal maturity on adipose tissue composition of newborn infants.

This is the first study of *in vivo* ^{13}C MRS in newborn infants. No comparative data are therefore available. However, our data may be compared with *in vitro* GLC analysis of tissue samples from preterm and full-term neonates. Published values for the fatty acid composition of adipose tissue in both preterm (saturated 37.9–57.8%, unsaturated 42.0–55.7%) and term infants (saturated 50.8–57.6%, unsaturated 42.8–49.2%) show a large variation (8–14). This probably reflects variability in patient population and methodology (8–14). Our measurements are similar to the range given in the GLC literature, suggesting that the ^{13}C MRS measurements reflect the composition of neonatal adipose tissue.

We have observed clear differences in adipose tissue fatty acid composition between mothers and full-term newborn infants. At birth, newborn infants had significantly more saturated and correspondingly fewer unsaturated fatty acids than their mothers. These differences may arise from the fact that during fetal life glucose is the major substrate for *de novo* synthesis of fatty acids, leading mainly to the production of saturated fatty acids. Polyunsaturated fatty acids predominantly arise directly from maternal sources across the placenta. The higher levels of polyunsaturated fatty acids found in the mother provide the necessary gradient for these essential fatty acids to be transported to the developing fetus (10). This gradient is clearly maintained throughout the gestational period, and the magnitude of this gradient may determine the final level of polyunsaturated fatty acid in the neonate. This appears to suggest that the levels of polyunsaturated fatty acids in the maternal adipose tissue may determine the final levels of these fatty acids in newborn babies. Our preliminary results in the study of vegan mothers and their newborn infants suggest that this may be the case. Further work is underway to determine the relationship between maternal adipose tissue, diet, and neonatal adipose tissue composition.

Marked changes were observed in the ^{13}C MR spectra of the infants who were studied again after 6 wk. The proportion of saturated fatty acids had decreased and that of unsaturated fatty acids increased, resulting in spectra similar to those obtained from their mothers. These changes predominantly reflect the effects of oral feeding on adipose tissue composition. Previous GLC studies have suggested that the fatty acid composition of neonatal adipose tissue changes rapidly during postnatal development and is particularly influenced by milk fat composition (8–14). The adipose tissue composition of the 6-wk-old infants had not altered significantly at the time of the repeated examination at the age of 6 mon. This would suggest that growth and postnatal development had little effect on adipose tissue composition during this period. This finding is in agreement with previous GLC studies which showed little change in the fatty acid composition of adipose tissue in milk-fed infants beyond the age of 1 mon (9,11–13).

Gestational age is known to have a profound effect on the composition of adipose tissue (2,9,10,13). This is clearly confirmed in this study. We found significant differences in the

^{13}C MR spectra of preterm and full-term newborn infants. Since all these infants were examined immediately following birth, the differences observed arise from gestational age differences rather than postnatal external factors such as diet. Preterm infants had more saturated and fewer unsaturated fatty acids than full-term infants. Also, the proportion of polyunsaturated and monounsaturated fatty acids differed. These findings are similar to those previously reported on samples of adipose tissue from infants of differing maturity (2,9,10,13). Accretion of polyunsaturated fatty acids during the third trimester of pregnancy is particularly rapid (2). Previous studies have suggested that during the last trimester of pregnancy there is a 12-fold increase in adipose tissue stores, while total body weight increases only 3-fold. It is thought that only a few additional weeks of intrauterine development will result in the different fatty acid composition of adipose tissue seen between the preterm and term neonates (2). These differences can be clearly observed by *in vivo* ^{13}C MRS.

Preliminary data on infants fed by vegan mothers compared to infants fed by omnivore mothers show a clear trend. The adipose tissue composition of infants directly reflects that of their mothers, with the vegan infants having 70% more polyunsaturated fatty acid carbons than the omnivore infants. Although the consequences of essential fatty acid deficiency in formula-fed infants are well documented, less is known about the effects of very high levels of long-chain polyunsaturated fatty acids in the infant diet. The long-term effects for vegan infants having such high levels of polyunsaturated fatty acids in their diet and adipose tissue are unknown. It may be important to measure the dietary intake of antioxidants in these infants to ensure that rates of lipid peroxidation are not excessively high. Another related problem could be an excessively high n-6/n-3 ratio; competition between n-6 and n-3 long-chain polyunsaturated fatty acids may result in insufficient n-3 fatty acids in the infants of vegan mothers.

The results of this study show that *in vivo* ^{13}C MRS can be used to examine the effects of diet on adipose tissue composition and allows the possibility of using noninvasive methods to study changes due to maturity and to different feeding strategies.

ABSTRACT: The thermotropic phase behavior of lipids extracted either *in vivo* from inner forearm (SCLE) or plantar callus (PC) was investigated by differential scanning calorimetry and small angle X-ray diffraction. PC composition was chromatographically modified (MPC) by eliminating the more polar lipids in order to evaluate their role. Analysis of composition confirms the potential use of PC as a source of stratum corneum lipids. MPC and SCLE exhibit similar differential scanning calorimetry (DSC) profiles with a main transition around 50°C attributed to the solid-to-liquid phase transition of the ceramides. The absence of a transition around 50°C for PC suggests the possible perturbation of ceramide packing by the significantly high proportion of phospholipids. X-ray data suggest a high miscibility of sebum components in stratum corneum lipids with possible modification of chain packing. The MPC patterns show a lipid phase separation which underscores the role of polar lipids in cholesterol/free fatty acids/sterol esters/ceramides structural cohesion.
Lipids 32, 653–660 (1997).

The stratum corneum (SC) controls the permeability of human skin and protects the organism against water loss and cutaneous penetration of deleterious environmental agents (1,2). Transport across sebaceous lipids which are widespread at the skin surface and in the SC is the rate-limiting step in the percutaneous absorption process. In this respect, the intercellular lipid pathway represents the major route of transport across the SC. Keratinocytes, the most abundant cells of the epidermis, synthesize the major structural components of the SC in a programmed differentiation process regulated in time and space (3). The SC (10- to 20-μm thick) is composed of many layers of flat cornified cells filled with keratin separated by a unique and complex mixture of lipids (4). These lipids have been analyzed and shown to vary with location, age, sex, season, and pathological state (5,6). Furthermore, the lipids in the epidermis present a composition gradient from the inner part of the body to the surface that is linked to the differentiation process. Lipids are released from the lamellar bodies during differentiation, and early studies have shown a shift from polar to neutral lipids during cornification. Lipids from adult SC are mainly composed of polar and nonpolar lipids, including phospholipids, cholesterol-3-sulfate, cholesterol, glycosylceramides, ceramides, and sterol esters. These lipids display a local organization, in particular due to ceramide 1, a 30-carbon ω-hydroxy acid amide linked to a sphingosine base bearing an ester-linked linoleic acid on the ω-hydroxy acid, covalently linked to the corneocyte envelope. Extracted intercellular lipids should present a different organization from the native state since they should exclude ceramide 1. Sebaceous lipids, widespread at the skin surface, are mainly composed of triglycerides (TG), wax esters, squalene, and some free fatty acids (FFA).

The thermotropic phase behavior and structural parameters of lipids constituting the intercellular cement of human SC have been a subject of investigation over the last decade. Such studies based on differential scanning calorimetry (DSC), infrared spectroscopy, or X-ray diffraction analysis can indeed provide important insight into the function of these lipids and their role in the interactions of the SC with foreign chemicals (7–13). The specimens used in these experiments consisted of either sheets or solvent-extracted lipids of SC isolated from plastic surgery or human cadaver skin. Other studies focused on reconstructed epidermis (14) or model membrane systems approximating the SC composition (15,16). There have been no reports involving the analysis of *in vivo* extracted human skin lipids.

We have recently proposed a nonirritating solvent system for the *in vivo* extraction of human SC lipids and developed a high-resolution method of lipid analysis by high-performance thin-layer chromatography (HPTLC) (17). This method allows extraction of lipids from the upper layers of the SC together with the sebum film lipids of the skin surface. Thus the method gives access to the lipids first encountered by topically applied molecules. The present study focuses on the organization of the extracted lipids which differs in nature from the native state. The ultimate aim of the work is to understand

the thermotropic behavior of human skin lipids in relation to their composition.

In the present paper, thermotropic transitions and structural characteristics of lipids from two distinct human sources, *in vivo* extracted SC (inner forearm) and plantar callus (PC) were investigated by DSC and X-ray diffraction. PC lipid composition was modified by a chromatographic method in order to study the relative importance of the various components. The results are discussed as a function of the molecular composition of the specimens.

MATERIALS AND METHODS

In vivo *extraction of SC lipids.* This study was conducted in the springtime in healthy volunteers free of dermatological diseases and with untanned skin (Caucasian males, $n = 11$, mean age 32.5 ± 7.5). Six neighboring zones of the inner forearm were chosen. Prior to extraction, the surface of each zone was stripped once with a 22-mm diameter adhesive disk, D-Squame (Cuderm Co., Dallas, TX) after application of a constant pressure (180 g per cm^2) and a constant time of 30 s. A 10-cm glass tube open at both ends, with an area of 3.14 cm^2, was pressed on the skin and filled with 5 mL of a nonirritating solvent to extract upper-layer SC lipids. The solvent used was cyclohexane/ethanol (2:8, vol/vol) as previously described (17). After 1 min of contact and gentle manual shaking, the solvent was transferred to a glass tube. The *in vivo* extraction was done twice and followed by two similar extractions with cyclohexane/ethanol (5:5, vol/vol). The SC lipid extracts (SCLE) were combined and dried under nitrogen.

Extraction of PC. Pooled PC specimens were collected from a chiropodist. After visual inspection for hair or nail contamination, a 10-g sample of callus was extracted three times with 100 mL hexane/methanol (2:3, vol/vol) under sonication in an ultrasonic bath (15 min,160 watts; Branson, Danbury, CT), filtered through a 0.45 µm HV filter (Millipore, Saint-Quentin, France), concentrated under vacuum to dryness, dispersed in a minimum of water, and freeze-dried to constant weight. This extract was called "PC."

Modified PC lipids mixture. The more polar lipid class, i.e., the phospholipids and some ceramides, were eliminated from the PC mixture by silica chromatography as follows: 110 mg of PC was solubilized in 102 mL of chloroform/methanol (95:5, vol/vol) sonicated for 10 min and divided into 6 aliquots of 17 mL. Each aliquot was purified on a 1 g Sep-Pack silica micro column (Millipore), previously conditioned with chloroform/methanol (95:5, vol/vol). For each fraction, the column was washed with 5 mL of chloroform/methanol (95:5, vol/vol) then washed twice with 5 mL of hexane. All the eluted solutions were pooled, dried under nitrogen, and stored at −20°C; 18.8 mg of product called modified plantar callus extract MPC, was obtained.

Lipid analysis. Lipid contents of the three pools SCLE, PC, and MPC were analyzed by HPTLC-automated multiple development (AMD) as recently described (17) except for TG and FFA which were separated and quantified by HPTLC. For TG and FFA analysis, a four-step elution was carried out: once with toluene, followed by three steps with hexane/diethyl ether/formic acid (80:20:0.4, by vol). Lipids were dissolved in cyclohexane/ethanol (35:65, vol/vol) (SCLE) or in hexane/methanol (40:60, vol/vol) (PC, MPC). Five microliters were automatically applied on HPTLC plate. After migration, plates were scanned at 450 nm (TLC 2 scanner, cats3 software; Camag, Basel, Switzerland) after visualization by spraying with 10% (wt/vol) cupric sulfate pentahydrate in 8% (vol/vol) *o*-phosphoric acid and heating for 10 min at 110°C for all lipids except for TG and FFA which were heated 30 min at 150°C (17). The limits of detection and lower point of calibration (in parentheses) were as follows: phospholipids 0.10 (0.2) µg, glycosylceramides 0.09 (0.1) µg, cholesterol-3-sulfate 0.10 (0.1) µg, ceramides 0.20 (0.2) µg, cholesterol 0.10 (0.1) µg, TG 10 ng (0.1 µg), FFA 1 ng (0.1 µg), wax esters 0.09 (0.1) µg, sterol esters 0.10 (0.1) µg, squalene 0.18 (0.2) µg.

DSC. The thermal behavior of lipid samples was studied with a DSC 4 apparatus (Perkin-Elmer, Norwalk, CT) from 5 to 60, 65, or 80°C, depending on the samples, at heating and cooling rates of +5°C/min and −5°C/min, respectively. All experiments were carried out in hermetically sealed aluminum pans. The lipids (from 2 to 3.5 mg dry weight) were first deposited in the pans in 50 µl of a solution of ethanol/cyclohexane (65:35, vol/vol) for SCLE, and methanol/hexane (30:20, vol/vol) for PC and MPC. The solvent was then removed by gentle evaporation under nitrogen before freeze-drying for 12 h. Hydration was performed by adding pure water directly in the pans before sealing to obtain a final water content of 60% by weight. The closed DSC vessels were stored for 3 d at 4°C until analysis.

X-ray diffraction. All experiments were performed on the D24 line of the DCI Synchrotron source at LURE (Orsay, France) by using the initial setup of P. Vachette and C. Bourgaux. The camera produces a highly collimated beam with a cross section nearly equal to 0.4×1 mm^2 at the sample position. The wavelength of the radiation was 1.49 Å. Data were collected by means of a 1024 channel Ar/CO_2- or Xe-filled linear detector. Cylindrical vacuum chambers equipped with capton or mylar windows were placed in the beam pathway to limit X-ray absorption by air. The sample-to-detector distance was set to either 28 or 142 cm for wide-angle or small-angle analysis, respectively. The diffraction patterns were normalized with respect to synchrotron-beam decay and acquisition times. The diffraction band observed at a position close to $q = 0.4$ $Å^{-1}$ is related to the capton window of the vacuum tube placed just after the sampleholder. Calibrations were performed by using tristearin with a repeat distance of 45 Å (18). All the experiments were performed in duplicate using independent samples of each lipid source.

Thin glass capillaries (GLAS, Müller, Berlin, Germany) were used as sample cells. The lipids were first introduced in solution in the same organic solvents as those used for DSC experiments. Solvents were removed under nitrogen flow followed by 12 h of freeze-drying. Final lipid dry weights of ap-

proximately 5 mg were deposited in the capillaries. The required amounts of water to obtain a rate of hydration of 60% by weight were directly added to the sample cells by successive low-speed centrifugations (not exceeding 1000 rpm). The capillaries were then sealed under argon to avoid both water loss and sample oxidation and the lipid–water mixtures were placed in a thermostated bath at 40°C for 1 h. Samples were stored at 4°C until X-ray measurements.

For measurements, the capillaries were placed in a specially designed thermal controller holder developed by G. Keller *et al*. (19). Samples were heated by means of an electric wire. Temperature was measured by a thermocouple introduced near the sample cell and regulated by the use of both the Peltier effect for cooling and the Joule effect for heating. The samples were equilibrated for 5 min at fixed temperatures at which the diffraction patterns were recorded. Between the successive temperature steps, the samples were heated at a rate of 1°C/min.

The scattering intensities are plotted as a function of q which is linked to the scattering angle θ and the wavelength λ by the equation $q = 4\pi \sin\theta/\lambda$. The Bragg law gives the distance d of the repeating units ($n\lambda = 2d \sin\theta$), q being $2\pi/d$ and n an integer.

RESULTS

Lipid composition. Table 1 reports the HPTLC–AMD comparative analysis of three samples: SC lipid extracts originating from inner forearm (SCLE), PC, and MPC, respectively.

SCLE contains ceramides and cholesterol in addition to a few phospholipids and sterol derivatives, i.e., the characteristic lipids of SC as well as squalene, wax esters, and TG which are recognized as the major constituents of sebum (4,5,8,17). Moreover, the TG and FFA contents are in agreement with those previously reported for face origin (4). It is worth noting that the sebum contamination is not negligible, although inner forearm is known to be almost exempt from sebaceous units, and sebum secretion at this site is low (20).

The composition of PC shows only SC lipids and is close to Melnik's published results except that the phospholipid content in our sample is higher probably due to the chiropodist source (21). The absence of sebum components is in agreement with the anatomical origin of this sample. Also, the results indicate that PC is naturally devoid of TG. With respect to the SCLE sample, it follows that these lipids are mostly due to sebum components in the *in vivo* extracted sample.

MPC was prepared from PC by eliminating the more polar compounds, phospholipids, and some of the ceramides. This is explained by the fact that the resolution of the flash chromatographic method does not currently allow the discriminating separation of these two classes of compounds.

DSC profiles. Figure 1, curves a–c, shows the differential calorimetric scans of hydrated SCLE, PC, and MPC, respectively. DSC scans are rather noisy owing to extraction and loss of the native organization, but peak occurrence is not doubtful since a correlation to X-ray recordings as a function of temperature is observed. The phase transitions of the three samples occur over a broad temperature range. SCLE (Fig. 1, curve a) and MPC (Fig. 1, curve c) undergo two low-energy endothermic transitions, a first one in the 20–35°C range and a predominant one in the 40–60°C range, while PC (Fig. 1,

[a]SCLE: stratum corneum lipids extracted *in vivo* on the inner forearm of male volunteers.
[b]PC, plantar callus lipid extract.
[c]MPC, modified PC extract. Each lipid is expressed as the percentage of total lipid extract (wt%).
[d]n.d., not detected.
[e]Trace, detected but under the lowest limit of linearity (see Ref. 17).

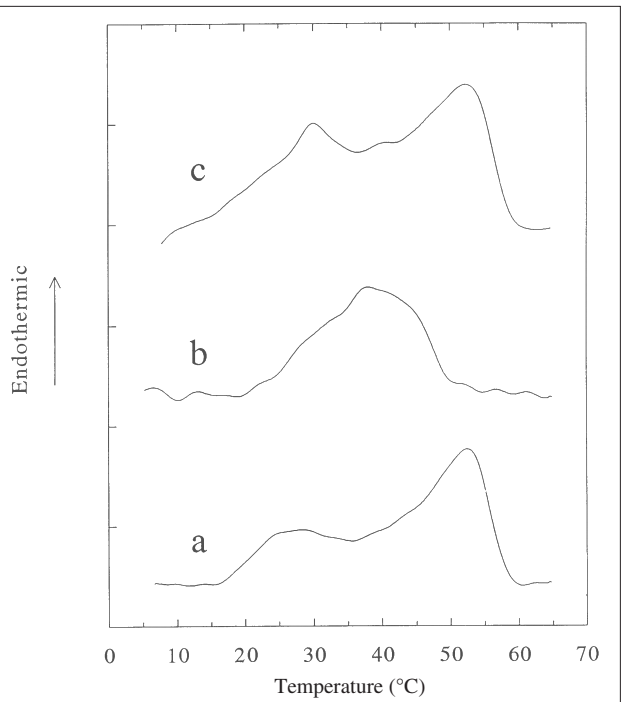

FIG. 1. Differential scanning calorimetry (DSC) thermograms of (a) *in vivo* extracted stratum corneum lipids (stratum corneum lipid extract), (b) plantar callus, (c) modified plantar callus. The samples were hydrated at 60% (by weight), and scans were performed with a heating rate of 5°C/min. After heating at 65°C, cooling at 5°C, and keeping the samples at this temperature for 3 d, reheating led to the same DSC profiles, indicating the reversibility of the endothermic transitions.

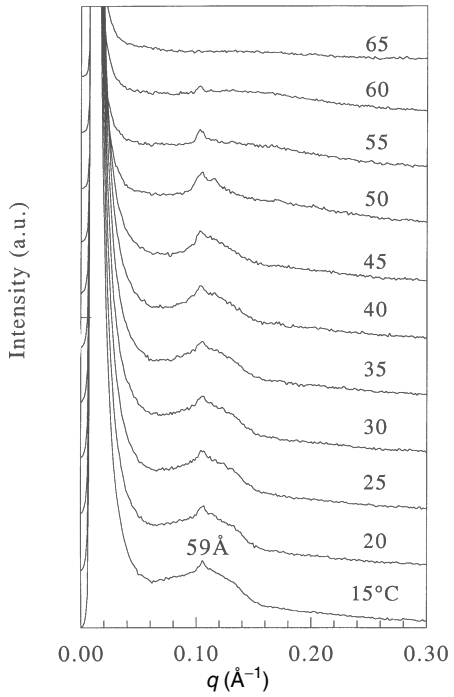

FIG. 2. Small-angle X-ray diffraction patterns of hydrated (60% by weight) *in vivo* extracted stratum corneum lipids (stratum corneum lipid extract) as a function of temperature. Sample heating was performed at 1°C/min. X-ray patterns were recorded at fixed temperatures, every 5°C, after a 5-min equilibrium time. The resolved characteristic distance is reported on the first pattern. The intensities are reported in arbitrary units by using the same scale for each pattern.

curve b) apparently shows only one endotherm over the 25–50°C range. On cooling of the three samples, only one exotherm was observed which corresponds to the principal transition. After 3 d at 4°C, all the transitions were observed again on heating, making the system reversible with a presumably long equilibrium setting time.

X-ray diffraction. The scattering curves recorded as a function of temperature are shown in Figures 2–4. For SCLE and PC the broad and relatively weak diffraction features are related to the presence of a very complex mixture composed of nine classes of lipids (Table 1). For SCLE (Fig. 2) at temperatures below 50°C, a broad scattering band is observed on top of which a main diffraction peak is located at q = 0.106 Å^{-1}. The corresponding repeat distance is 59 Å. As the sample is heated, the scattering signal first progressively disappears between 45 and 55°C while the main diffraction peak is still observed at 60°C. At 65°C all diffraction bands have disappeared.

For PC (Fig. 3), a main diffraction peak appears at q = 0.066 Å^{-1} (distance of 95 Å) with probably its second-order at q = 0.133 Å^{-1}. A shoulder on the right side of the peak is also present at q = 0.08 Å^{-1}. In the 20–35°C temperature range, both peaks at 0.066 and 0.133 Å^{-1} disappear and only the shoulder remains. This shoulder is progressively replaced above 45°C by a broad diffraction peak at q = 0.06 Å^{-1} (105 Å), the intensity of which increases from 40 to 60°C. At 70°C, the remaining diffraction peak has almost totally vanished.

For MPC (Fig. 4A) five diffraction peaks were principally observed at low temperature. The peaks at q = 0.048 Å^{-1} and 0.096 Å^{-1} correspond to the first and second orders of a repeat distance of 129 Å. The peaks at q = 0.188 Å^{-1} and 0.375 Å^{-1} are related to the same Bragg spacing of 33.5 Å. The fifth peak is detected at q = 0.149 Å^{-1} (43 Å). In addition, another diffraction band can be seen at very small angles but is not resolved since it is mainly superimposed with the rings of the direct beam. The evolution of the different diffraction peaks is visualized as a function of temperature in Figure 4B. In the 15–40°C range, the peaks corresponding to periods of 129 Å and 43 Å, respectively, show similar slight increases in intensity. This very likely implies that the peak at d = 43 Å mainly corresponds to the third order of the main repeat distance of 129 Å. From 40 to 50°C, the peak at d = 129 Å progressively decreases in intensity and disappears above 50°C. In contrast, the intensity of the peak at 43 Å significantly increases. This strongly suggests that in the 40–65°C temperature range, the lamellar structure of period 129 Å is disappearing while a new distinct lipid organization (peak at 43 Å) is emerging.

DISCUSSION

There are several published reports on the X-ray determination of the structure of the human SC isolated from either trypsinized plastic surgery specimens or, more recently, from

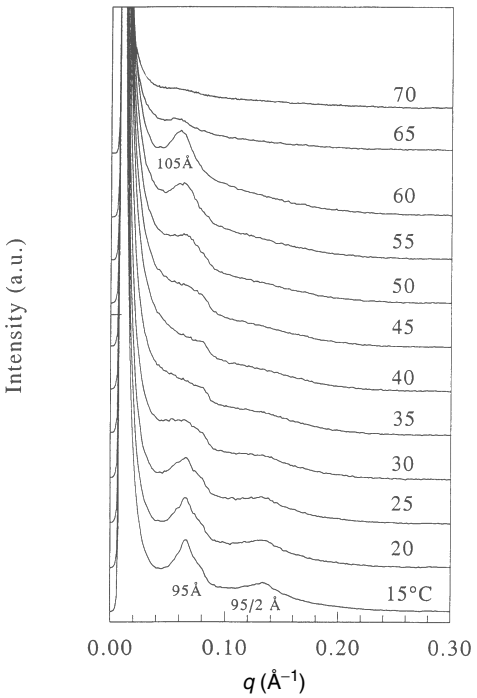

FIG. 3. Small-angle X-ray diffraction patterns of hydrated (60% by weight) plantar callus lipids as a function of temperature. See Figure 2 for experimental details.

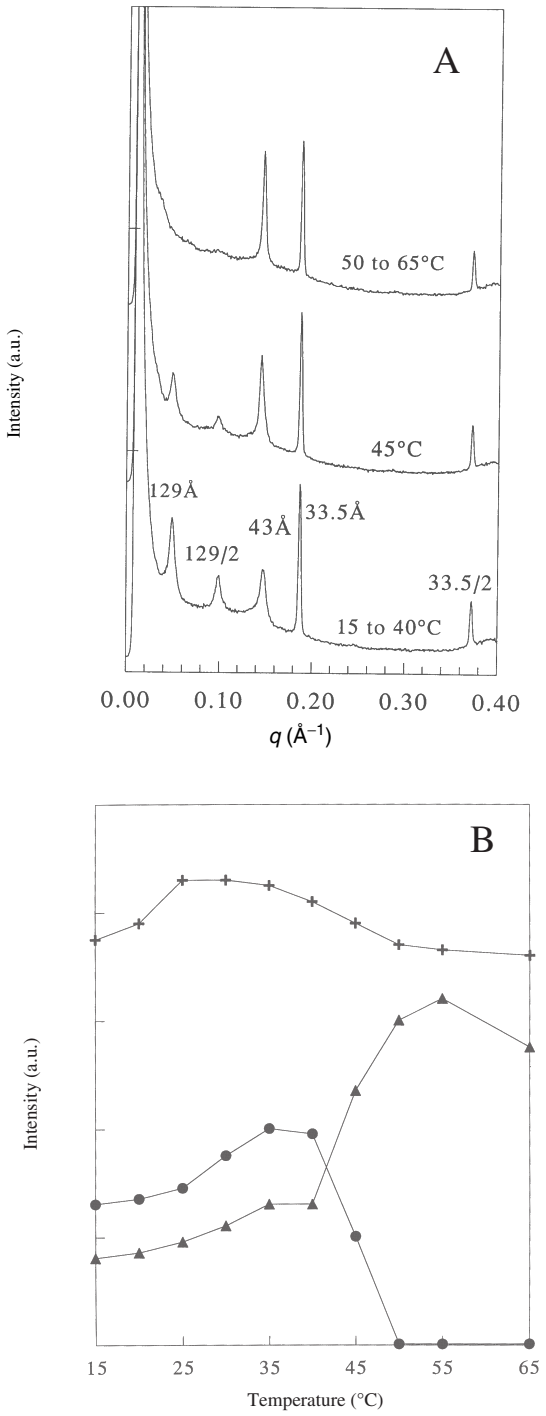

FIG. 4. A) Small-angle X-ray diffraction patterns of hydrated (60% by weight) modified plantar callus lipid extract (MPC) as a function of temperature. The sample was prepared by eliminating the more polar lipids from plantar callus. See Figure 2 for experimental details. (B) Variations of the scattered intensity of hydrated MPC as a function of temperature for the different diffraction peaks observed at $q = 0.048$ Å^{-1} ($d = 129$ Å; ●), $q = 0.148$ Å^{-1} ($d = 42$ Å; ▲) and $q = 0.188$ Å^{-1} ($d = 33.5$ Å; ◆).

dermatomed skin of patients with lamellar ichthyosis (9,10,12,22). Entire sheets were examined with or without lipid extraction (mainly with chloroform/methanol mixtures) in order to study the influence of the different compartments (lipids and corneocytes) in SC organization. DSC studies on similar specimens have also been reported (7–9).

The present study focused on the thermal and structural behavior of the main components of the lipids between corneocyte layers. These lipids are indeed known to modulate the skin barrier properties. First, extractions were performed either *in vivo* (SCLE) or from PC, which is an abundant source of SC. Second, the PC sample was modified in order to gain further information on the role of the different constituents in the SC structure.

Analysis of SCLE lipids shows that this sample is similar in composition to that of SC lipid extracts reported in the literature, providing that the sebum contaminants are not taken into account (4,5,17,21). In this respect, lipid analysis confirms that most of the TG found in SCLE originate from sebum. In contrast, for PC and MPC, the high proportion of phospholipids found in the first sample and the elimination of the more polar lipids from the second one lead to compositions which do not completely reflect human SC extract, despite its usually noted variability. Nevertheless, comparison of SCLE, PC, and MPC should provide information about the effect of sebum, as SCLE is contaminated while PC and MPC are not, and about the effect of phospholipid proportions on the structural properties of the extracted intercorneocyte lipids.

The DSC recording presented for SCLE is in agreement with previously published findings on SC lipids of human origin (7,8,10). Nevertheless, only one high-energy transition has been found around 55°C in SCLE while in native SC, two transitions are found at 65 and 75°C, respectively. In fact, the second transition was attributed to the nonextractable lipids of SC since they are linked to the proteins of the corneocyte membrane (7,8,10). Lowering of the main transition temperature to 55°C instead of the usually reported value of 65°C may be explained by the difference of the extraction methods. The procedures commonly described consist in incubation of entire sheets of SC in organic solvent such that the recovered extracts are claimed to contain the totality of the extractible lipids. In the case of *in vivo* extraction, the solvent used may reach the first intercellular layers of the SC, whose composition may differ from that of the deeper layers (23). MPC and SCLE lipid mixtures exhibit similar thermal behaviors in particular showing a negligible influence of sebum up to 44% contamination. This can be related to the previous results obtained with addition of 1% of sebum (8). The main transition observed around 40–60°C for SCLE and MPC can be ascribed to the solid-to-liquid phase transition of ceramides (24). For PC, the absence of an endothermic transition near 50°C coincides with the tripling of the phospholipid content in relation to SCLE. This suggests that a high proportion of phospholipids may affect ceramide packing. In addition, the significant width of the PC endotherm raises the possibility that the main transition observed with the other two samples (SCLE, Fig. 1 curve a ; MPC, Fig. 1 curve c) may also exist for PC (Fig. 1 curve b) but would be shifted toward lower temperatures, because of the high phospholipid content. Thus,

both transitions observed for SCLE and MPC would merge in the case of PC. The low-energy endotherm (20–35°C) characterizing the SCLE and MPC samples has already been attributed to the orthorhombic to hexagonal transition of the lipid chain packing (8,25,26). In the case of PC, Figure 1 shows that this transition is also observed.

The results of the small-angle X-ray diffraction analysis reveal the role of the individual lipid classes in the structural order. The asymmetry of the diffraction bands found below 20°C for SCLE (Fig. 2) and PC (Fig. 3) may indicate the probable existence of more than one single-phase arrangement. However, no significant lipid segregation is observed. In particular, no visible sebum phase separation appears. The structure of PC, for which a second-order Bragg spacing is detected, probably related to a lamellar structure, appears more organized than SCLE. This can be related to sebum components in SCLE that also contribute to diffraction peak spreading and that decrease the main repeat distance from 95 to 59 Å. Sebum compounds can therefore be incorporated to a high extent in the extracted skin lipids, possibly by inducing lipid chain interpenetration. One can speculate that a similar phenomenon may occur in SC. According to this hypothesis, modification of lateral chain packing should be involved and should directly influence the permeation properties of the skin. MPC patterns show a lipid phase separation, i.e., the coexistence of a lamellar structure of large period (129 Å) very likely governed by ceramides, cholesterol (33.5 Å), and a third structure with a Bragg spacing of 43 Å, presumably owing to fatty acids which present such typical repeat distances (27). Similarly, phase separation has already been demonstrated for cholesterol/ceramide mixtures (27–29). These results taken together underscore the strong contribution of polar lipids to the cohesion of the SC extracted lipid structure. Indeed, it has been recently shown that mixtures of cholesterol and ceramides form lamellar arrangements without cholesterol segregation when equimolar proportions are used (30). Moreover, considering that the polar lipids eliminated from PC mainly include phospholipids (Table 1), these last should also play an important role in cholesterol insertion and interact with the ceramide matrix to modify the period of their lamellar structure from 129 Å (MPC) to 95 Å (PC). This supports the hypothesis, already suggested by DSC experiments, that phospholipids can shift the main endotherm to lower temperatures by affecting ceramide packing.

Comparison of the DSC and X-ray analyses shows that disappearance or modification of the lamellar structures occurs at the temperatures corresponding to the offset of the main transition observed in DSC: 60°C for SCLE and MPC, and 50°C for PC. In particular, results concerning SCLE agree with data previously reported for SC collected by scraping (22), confirming that the *in vivo* extracted SCLE constitutes a reliable SC model. Interestingly, regardless of the extracted pool, the lipid organization, probably governed by the ceramides, is preserved below 35°C (Figs. 2,4). Consequently, the secondary thermal transition depicted at low temperature apparently does not affect the period of the lamellae. In contrast, the wide-angle X-ray diffraction patterns recorded as a function of temperature show that the offset of the low energetic transition (approximately 40°C) coincides with the loss of the chain packing order. Indeed, the short spacing observed at 4.15 Å (q = 1.514 Å^{-1}) progressively disappears with heating from 15 to 35°C and vanishes at 40°C. Figure 5 illustrates the behavior for PC. It is worth noting that the X-ray data support the hypothesis mentioned above for PC that there exist two effective thermal events, similar to SCLE and MPC. The first event corresponds to the fusion of the lipid chains in the 20–35°C range, and the second predominant one leads to the disappearance of the principal lamellar distance of 95 Å in the 40–50°C range. In addition, the X-ray diffraction pattern in Figure 3 shows the formation at 50°C of a new molecular organization with a characteristic distance of 105 Å which disappears above 65°C. However, no thermal event is recorded in this temperature range by DSC. Such a phase transition may result in the sum of exothermal and endothermal events such that no signal is detected in this temperature range. This might also be explained by the different thermal treatments (heating rates, equilibrium times at fixed temperatures) used for DSC and X-ray analyses, respectively, wherein DSC conditions may be too fast to allow the formation of this transient structure with a layer spacing of 105 Å.

In conclusion, the innovation of the present work consists in the *in vivo* extraction of the lipids from the superficial lay-

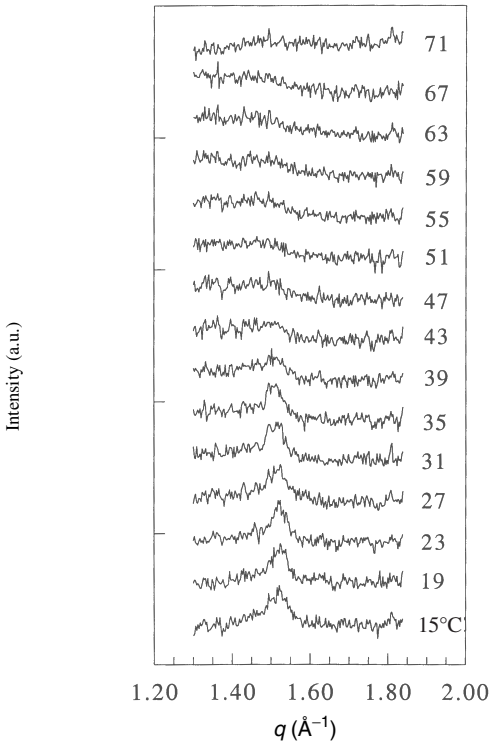

FIG. 5. Wide-angle X-ray diffraction patterns of hydrated (60% by weight) plantar callus lipids as a function of temperature. Sample heating was performed at 1°C/min. X-ray patterns were recorded at fixed temperatures, every 4°C after a 5-min equilibrium time. The intensities are reported in arbitrary units by using the same scale for each pattern.

ers of human SC and a combination of quantitative chemical analysis, DSC, and X-ray diffraction in order to elucidate the structural properties of these lipids in their hydrated state in relation to their nature and degree of association. Composition analysis shows that the use of nonirritating solvents results in extraction of high amounts of sebum contaminants, i.e., wax esters, TG, and squalene, together with the actual intercorneocyte lipids, mainly ceramides and cholesterol derivatives. In contrast, plantar callus lipid extract does not show sebum contamination. Both samples are characterized by a unique molecular arrangement governed by ceramides and which is presumably lamellar, indicating that sebum components are miscible with SC lipids by inducing chain interpenetration. The elimination of phospholipids from the PC extract leads to a lipid phase separation that demonstrates the essential role of polar lipids in ensuring a cooperative molecular arrangement of the cholesterol/FFA/sterol esters/ceramides mixture. PC should represent an easily available source to constitute a reliable model for superficial SC lipid extract without sebum contamination, providing phospholipid content is controlled.

Our data have interesting implications regarding the interactions of topically applied molecules with skin. Since sebaceous lipids constitute nearly half of the *in vivo* extract, a molecule applied on the skin has an equal probability of encountering sebum and/or SC lipids. The high miscibility between sebum and intercorneocyte lipids raises the possibility of *in vivo* contamination of SC superficial layers by sebum. This may be particularly relevant when considering that the probable entanglement of the lipids constituting the SC caused by sebum could enhance the permeability of the SC layer. Thus, the understanding of skin penetration of a molecule in the outer SC layers should involve the study of the interactions of this molecule not only with sebum and SC lipids considered separately but also with a mixture of both. In addition, the skin penetration of a pharmacological compound is governed by its affinity for sebum and/or SC lipids, as a function of the anatomical site of delivery. Comparison of our results with the literature led us to conclude that MPC is indeed the only mixture that contains the long periodicity (130 Å) lamellar phase, very characteristic of the native SC lipid organization. Moreover, the possibility evoked in this work of differentiating lipid phases by controlling the amount of phospholipids may make it possible to explore fine interactions between guest molecules (e.g., drugs, penetration enhancers, excipients) and the different SC components. Our findings also raise the question of the influence of exogenous topically applied lipids on the SC structural order. To this end, experiments on the SC thermotropic phase behavior will be carried out in the presence or absence of sebum using various model compounds.

ACKNOWLEDGMENTS

This work was partially supported by the French Ministry of Industry (agreement 94 2 926020). We thank Dr. C. Grabielle-Madelmont as well as Dr. C. Bourgaux for helpful advice in DSC and X-ray diffraction experiments, respectively.

The Relationship Between the Structure of Monoalkyl Branched Saturated Triacylglycerols and Some Physical Properties

Leif Svensson[a,*], Ulf Hansson[a], Salo Gronowitz[b], and Tomas Klingstedt[b,1]

[a]Karlshamns Sweden AB, S-374 82 Karlshamn, Sweden, and [b]Organic Chemistry 1, Chemical Center, University of Lund, Lund, Sweden

ABSTRACT: Three different physical properties, the gel point ("solidification point"), the refractive index and the density, were determined and related to the structure of the branched triacylglycerols. A four-factor central composite face-centered design was constructed where the four variables were the length of the main chain, the branching position, the length of the side chain, and the number of branched fatty acyl groups attached to the glycerol backbone. Second-order models were calculated in which the three physical properties were related to the structure. Four additional branched triacylglycerols were analyzed in order to confirm the validity of each model. Contour plots are shown in order to visualize the prediction equations which were obtained.

Lipids 32, 661–666 (1997).

Triacylglycerols containing branched fatty acids occur sparingly in nature. They are known components of, e.g., human sebum (1,2) and adipose tissue of lambs (3–5). At least in human sebum, the branched fatty acids occur more frequently in the 2-position than in the 1- and 3-positions (1). One important property of the branched triacylglycerols in human sebum seems to be its porosity for water vapor (6). Branched fatty acids also have been found in milk (7). The crystal structures of both branched saturated fatty acids and triacylglycerols have been described in the literature (8). Furthermore, esters between branched fatty acids and polyols, often others than glycerol, have found use in, e.g., lubricants, owing to excellent lubricity, stability toward oxidation, and low-temperature properties (9,10).

The physical properties of branched triacylglycerols have been investigated previously by Aydin *et al*. (11), who synthesized both the 1-monoacylglycerols and the homotriacylglycerols of nine different α-monoalkyl branched saturated fatty acids. The physical properties investigated were the refractive index (at 20°C), the dielectric constant, and the dipole moment.

[1]Present address: Astra-Draco AB, Box 34, S-221 00 Lund, Sweden.

Abbreviation: ANOVA, analysis of variance.

However, no other systematic investigation has been carried out relating the physical properties of triacylglycerols containing monoalkyl branched saturated fatty acyl groups to their structure. In the present study the gel point ("solidification point"), the refractive index (at 60°C), and the density are related to the structure of such triacylglycerols. A chemometrical approach was applied to the problem resulting in a four-factor central composite face-centered design. The aim has been to cover all possible triglyceride structures with "normal" chain lengths (main chain between 6 and 18 carbons). This approach has required the syntheses of a number of new compounds (12). In the case of the gel point, any polymorphic properties which the triacylglycerols may have were not taken into consideration.

MATERIALS AND METHODS

Materials. All triacylglycerols have been synthesized (12). The objective has been to obtain high purities in order to minimize the effects of impurities on, e.g., the nucleation. The purity of the triacylglycerols was found to be >98% by gas–liquid chromatography and/or high-performance liquid chromatography. All compounds synthesized are racemic.

Measurements. The gel points were determined on a Bohlin VOR Rheometer (Lund, Sweden) used in the oscillation mode. The samples were placed between a cone and a plate with diameters of 25 mm and a gap size of 0.15 mm. The gap was adjusted at 0°C for the samples with high gel points (>−10°C) and at −25°C for the samples with low gel points (<−10°C). The torsion bar used had a torque constant of 92.3 gcm. The samples were subjected to an oscillation (frequency 0.500 s^{-1}) in autostrain mode. This means that the strain was adjusted according to the measured torque in such a way that increased torque leads to a decrease in strain. The strain amplitude varied between 0.002 and 0.2. The measurements were performed in a standard low-temperature cell cooled by liquid nitrogen. The samples were cooled from −10 to −100°C (10 to −10°C for the triacylglycerols with high gel points) with a temperature gradient of −0.5°C/15 s. The results were recorded every 6 s.

The gel points were determined by means of the tangent to the sharply increasing storage modulus (G′). This indicates an increase in the elastic component of the sample. The results are strongly dependent on the temperature gradient chosen, owing to the fact that the triacylglycerols show different polymorphic behavior and nucleation rates. This method of determining the gel point is a modification of the method of Bohlin *et al.* (13).

The gel points of the triacylglycerols with very high gel points (>10°C) were determined simply by agitating 2 g of the triacylglycerol contained in a small bottle with a thermometer using the same frequency as in the rheometer. The samples were cooled by the surrounding air and when necessary with an ice-water mixture. The cooling was carried out in such a way as to achieve the same gradient as with the rheometer (–2°C/min).

Both methods of determining the gel point ("solidification point") described above have in common that any polymorphic properties, if present, are not considered. This should be taken into account when looking at the results. One of the triacylglycerols in the present study, which had a gel point of 10°C, was a liquid at room temperature for more than 1 wk before crystallizing. As is the case with all methods concerning crystallization and melting (e.g., differential scanning calorimetry and rheology), the results depend on the exact method used and how the results are evaluated.

The refractive indices were determined at 60°C with an Abbé refractometer (Carl Zeiss, Jena, Germany), model A.

The densities were determined at 60°C with an Anton Paar Precision density meter (Instrument AB Lambda, Sollentuna, Sweden), OMA 02C.

Experimental design. The structures of the monoalkyl branched saturated triacylglycerols were chosen according to a four-factor central composite design. The four factors are the length of the main chain (X_1), the branching position (X_2), the length of the side chain (X_3), and the number of branched fatty acyl groups attached to the glycerol (X_4). As can be seen in Table 1, the different levels of variable X_2 are defined as functions of variable X_1. In a similar way, the levels of variable X_3 are defined as functions of variables X_1 and X_2. This is due to the fact that, in the case of the branching position, level +1 represents a carbon atom near the end of the main chain. Depending on the length of the main chain, the number of the carbon atom to which the branch is affixed will vary. In the same way, the length of the branch has an upper limit. If this limit is passed, the branch has become the main chain. In the case of the branching position, level +1 has been chosen as a position two carbons away from the end of the main chain to be able to vary the length of the branch.

TABLE 1
Factor Levels of the Experimental Design

	Level		
Factor	–1	0	+1
Length of main chain (X_1)	6	12	18
Branching position (X_2)	2	$X_1/2$	$X_1 - 2$
Length of side chain (X_3)	0	$(X_1 - X_2 + 1)/2$	$X_1 - X_2$
Number of branched acyl groups (X_4)	1	2	3

The complete experimental design, including four control substances, is shown in Table 2. As can be seen, the axial points have been placed 1 unit away from the center instead of the ideal distance of 2 units. This variant of the central composite design is called central composite face-centered design.

The straight chain acid (which is present when there are fewer than three branched fatty acids present in the triacylglycerol) has been chosen to be dodecanoic acid for the axial and center points and hexanoic or octadecanoic acid (half of each) for the remaining triacylglycerols (this is also the way the straight chain acid would have been chosen if the length of the straight chain had been treated as a fifth variable in a fractional factorial design). This way of designing the experiment is based on the idea that the branched fatty acid to a great extent determines the behavior of the entire triacylglycerol.

Statistical analyses. The evaluation of the results was made with the help of the software MODDE for Windows, version 3.0 (Umetri AB, Umeå, Sweden). All measurements were done in a randomized order. Measurements in the center point of the design were repeated twice. MODDE uses multiple linear regression to calculate a prediction equation for each response:

$$Y_p = b_0 + b_1X_1 + b_2X_2 + b_3X_3 + b_4X_4 + b_{12}X_1X_2 + b_{13}X_1X_3 + b_{14}X_1X_4 + b_{23}X_2X_3 + b_{24}X_2X_4 + b_{34}X_3X_4 + b_{11}X_1^2 + b_{22}X_2^2 + b_{33}X_3^2 + b_{44}X_4^2 \quad [1]$$

The estimated coefficients are then rejected or retained depending on their probability. The test is performed at a significance level of $\alpha = 0.05$. The significant coefficients are then reestimated to give the final prediction equation. Outliers, identified by normal probability plots of the residuals (14), are excluded from the multiple linear regression. The fact that a compound has been identified as an outlier means that it does not fit into the mathematical description of a particular physical property. It does not mean that the measurements are incorrect or that the wrong substance has been synthesized. The subject has been described in a recent review article (15).

RESULTS AND DISCUSSION

Gel point. The coefficients of the final prediction equation of the gel point are shown in Table 3 with the corresponding probabilities and 95% confidence intervals. Four triacylglycerols have been identified as outliers (by the technique of normal probability plots) and are consequently excluded from the regression calculations. The four compounds are the triacylglycerols with hexanoyl groups in two positions and a branched fatty acyl group in the remaining position (all marked in Table 4). The two control triacylglycerols with deviating gel points both have two stearoyl groups attached to the glycerol. This could explain why their gel points are high compared to their predicted values (in contrast to the other

Control triacylglycerols				
1-Hexanoyl-2,3-bis(6-propyldodecanoyl)-glycerol	0	0	−0.2	0
1-Octadecanoyl-2,3-bis(6-propyldodecanoyl)-glycerol	0	0	−0.2	0
1,2-Didodecanoyl-3-(16-methyloctadecanoyl)-glycerol	+1	+1	−1	−1
1,2-Dioctadecanoyl-3-(6-propyldodecanoyl)-glycerol	0	0	−0.2	−1

[a]This compound was not synthesized in sufficient amounts to perform measurements.

outliers which have short main chains and correspondingly low gel points). The resulting equation is:

$$Y_{p,\text{ gel point}} = -57 + 23\,X_1 - 1.0\,X_2 - 30\,X_4 + 20\,X_1X_4 + 48\,X_2^2 + 16\,X_4^2 \quad [2]$$

The length of the side chain (X_3) is the only factor which does not have an influence on the response. Figure 1 shows a contour plot of the response surface for triacylglycerols having three branched fatty acyl groups attached to the glycerol skeleton. The response surfaces for the other types of triacylglycerols (having one or two branched fatty acids) have the same appearance. It can be seen that the lowest gel points are obtained when the branch is situated on the middle of the main chain. This result is analogous to a previous investigation on the branched fatty acids themselves (16).

The observed and the predicted gel points are compared in Table 4. An analysis of variance (ANOVA) scheme is shown in Table 5. The coefficient of multiple determination is R^2 = 0.961.

Refractive index (60°C). Four compounds have been identified as outliers, three of which are the same as for the gel point prediction equation. All outliers are marked in Table 4. The calculated response function (the parameters of which

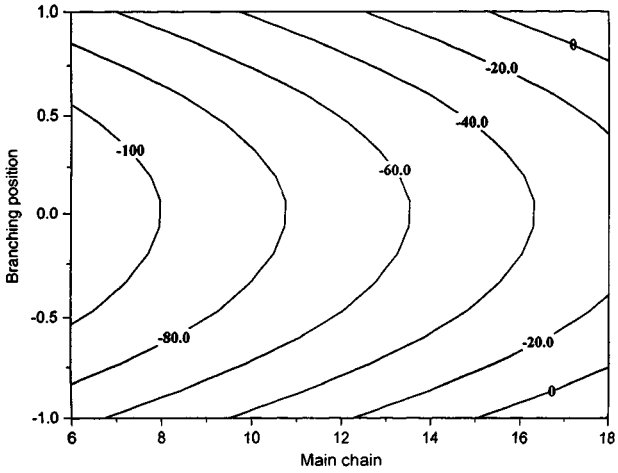

FIG. 1. Contour plot showing the gel point as a function of the structure for monoalkyl branched saturated homotriacylglycerols. The length of the main chain (X_1) is given as the number of carbons (6 to 18) while the branching position (X_2) is given as coded values (−1 to +1).

[a]Values are given with 95% confidence intervals. [b]The probability that a coefficient is equal to zero.

can also be found in Table 3 together with 95% confidence intervals and values of probability) is:

$$Y_{p,\text{ refractive index (60°C)}} = 1.4432 + 0.0046\ X_1 + 0.0003\ X_2 + 0.0010\ X_3 - 0.0018\ X_4 - 0.0018\ X_1X_2 + 0.0038\ X_1X_4 - 0.0014\ X_2X_3 + 0.0025\ X_3X_4 \quad [3]$$

All four factors are important to the response, which means that two factors must be set to a fixed value in order to make a contour plot possible. Since the branching position is the least important factor, it has been set to $X_2 = 0$, i.e., a branching in the middle of the main chain. In this way it is possible to visualize the response function (Fig. 2). Also in this case the homotriacylglycerols have been chosen for the figure. One conclusion is that the longer the main chain the higher the refractive index. This is also similar to the properties of the branched fatty acids themselves (16). The observed and the predicted values are compared in Table 4. An ANOVA scheme is shown in Table 5. The coefficient of multiple determination is $R^2 = 0.950$.

Density (60°C). In addition to the three compounds for which the density could not be measured, two more triacylglycerols were excluded from the regression calculations (Table 4). The obtained prediction equation is:

$$Y_{p,\text{ density (60°C)}} = 0.8906 - 0.0145\ X_1 + 0.0108\ X_2 - 0.0090\ X_3 + 0.0012\ X_4 - 0.0189\ X_1X_4 \quad [4]$$

As in the refractive index case, it is not possible to show the response function in a single picture. All four factors are important. Just to give the reader some idea of the appearance of the response surfaces, one of them is shown in Figure 3. This picture of the homotriacylglycerols demonstrates the decreasing effect of a longer side chain and the increasing ef-

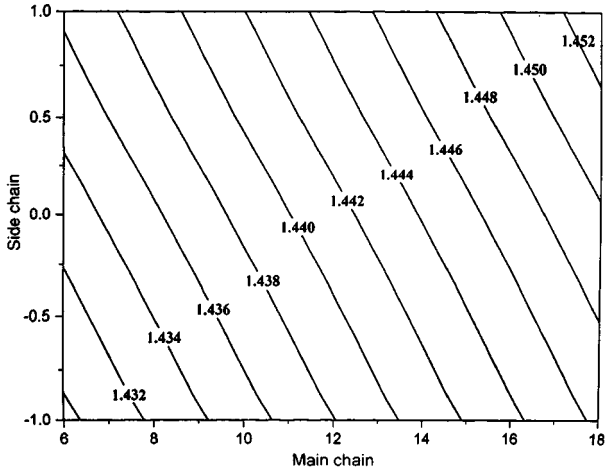

FIG. 2. Contour plot showing the refractive index (at 60°C) as a function of the structure for monoalkyl branched saturated homotriacylglycerols. The length of the main chain (X_1) is given as the number of carbons (6 to 18), and the length of the side chain (X_3) is given as coded values (−1 to +1). In this plot the branching position is set to a medium position ($X_2 = 0$).

fect of a branch far out on the main chain. A longer main chain gives a higher density only when there are two or three branched fatty acyl groups attached to the glycerol. The ANOVA scheme is shown in Table 5. The coefficient of multiple determination is $R^2 = 0.900$. The density prediction equation is the least accurate of the three prediction equations.

ABSTRACT: A number of triacylglycerols with branched acyl groups were prepared *via* 1,2-isopropylidene glycerol for the purpose of studying three different physical properties: gel point, refractive index, and density. The monoacid triacylglycerols were prepared either *via* the corresponding acids or the acyl chlorides.
Lipids 32, 667–673 (1997).

Monoalkyl branched saturated triacylglycerols possess physical properties very different from triacylglycerols with straight-chain acyl groups (1,2). Aydin *et al.* (1) have synthesized both the 1-monoacylglycerols and the monoacid triacylglycerols of nine different α-monoalkyl branched fatty acids and measured several different physical properties of these compounds.

In order to investigate the relation between the structure of the monoalkyl branched saturated triacylglycerols and their physical properties, a four-factor central composite design was constructed. The four factors are the length of the main chain, the length of the side chain, the branching position, and the number of branched acyl groups attached to the glycerol backbone. The first three structure variables are related to branched acyl groups, whereas the fourth variable defines the triacylglycerol. This design requires 25 different triacylglycerols to be prepared. The result of this investigation is given in the accompanying paper (3).

MATERIALS AND METHODS

^{1}H nuclear magnetic resonance (NMR) spectra were recorded on a Varian XL-300 spectrometer (Palo Alto, CA). In the interpretation of ^{1}H NMR spectra, *s* is used for singlet, *d* for doublet, *t* for triplet, *qu* for quartet, *qv* for quintet, *sex,* for sextet, and *oct* for octuplet. The infrared spectrometer used was a Perkin Elmer Model 298 (Norwalk, CT). Mass spectra were recorded on a Finnigan 4021 (San Jose, CA) and a Jeol JMS-Sx 1200 spectrometer (Tokyo, Japan). Gas chromatograms were obtained by using Varian gas chromatograph models 1400 and 3300. Glass columns (length 2.0 m, i.d. 2 mm) were used with 10% SP-2340 on Chromosorb 100/120 and 3% OV 101 on Gas. Chrom. Q 100/120. High-performance liquid chromatography (HPLC) separations were performed by using equipment containing Gilson pump 305 (Gilson Medical Electronics, Middleton, WI), a Dynamex RP C 18 preparative column (250 × 2.0 cm) (Rainin Instrument Co., Woburn, MA), and a Gilson IR detector 131. Reactions which needed to be performed under anhydrous conditions were run in dry vessels under nitrogen. All acid chlorides were prepared from the corresponding acids (4) and an excess of oxalyl chloride (5). Pyridine was dried and purified by distillation from barium oxide. Glycerol was freshly distilled, dichloromethane was distilled from phosphorus pentoxide, methoxymethanol was distilled from molecular sieves (4 Å), and toluene was distilled from sodium wire and benzophenone.

General procedure for the preparation of 1-acyl-2,3-isopropylidene glycerol (Procedure A). A three-necked flask equipped with condenser with drying tube, dropping funnel, and magnetic bar was surrounded with an ice-water bath and flushed with nitrogen. Isopropylidene glycerol (1.25 equiv.) and pyridine (1.25 equiv.) were dissolved in toluene (4.30 mL/mmol of acid chloride). At 0°C, the acid chloride (1.00 equiv.) was added dropwise, and when the addition was complete the cooling bath was removed and the reaction mixture was stirred under nitrogen at room temperature for 20 h. The solution was washed with water, sodium carbonate solution, and water; dried over magnesium sulfate; evaporated; and chromatographed on neutral alumina (100 g/0.1 mol of acylisopropylidene glycerol) using toluene as the eluant. Toluene was evaporated and the residue dried *in vacuo* (2 mm Hg) at 60°C for 4–5 h.

General procedure for the preparation of triacylglycerols (Procedure B). A three-necked flask equipped with reflux condenser with drying tube and magnetic bar was flushed

with nitrogen, after which the flask was charged with methoxymethanol (3.0 mL/mmol of acylisopropylidene glycerol). Under stirring, boric acid (16 equiv.) was added and the mixture heated to 100°C and stirred for about 3 h. By thin-layer chromatography, it was confirmed that the starting material was consumed and by GC that no isomerization had occurred. After cooling, the reaction mixture was poured onto ice and water, and ice-cooled dichloromethane was added. Upon shaking vigorously, the boric acid precipitated and was filtered off, and the precipitate was washed twice with ice-cooled dichloromethane. The combined organic phases were washed with ice-cooled water, dried with sodium sulfate under magnetic stirring for 2 h, and evaporated at room temperature. The residue was dissolved in dichloromethane (3.7 mL/mmol of 1-acylglycerol) and cooled to 0°C. Under stirring, pyridine was added, whereupon the appropriate acyl chloride was added dropwise. After removing the cooling bath, the reaction mixture was stirred under nitrogen for 72 h and then poured into water. The phases were separated and the organic phase washed with water, dried over magnesium sulfate, evaporated, and flash chromatographed on silica gel.

General procedure to the preparation of monoacid triacylglycerols (Procedure C). The acid (169 mmol), glycerol (47 mmol), and 4-toluenesulfonic acid (3 mmol) were dissolved in toluene (40 mL). The reaction mixture was stirred at 180°C for 40 h. After cooling, diethyl ether was added (20 mL), and the solution was washed twice with saturated sodium carbonate solution and twice with water whereupon it was dried over magnesium sulfate. The crude product was purified by column chromatography on neutral alumina.

(Procedure D). A dried, nitrogen-filled flask was charged with glycerol (1.00 g, 10.7 mmol) and pyridine (3.90 mL, 48.1 mmol) in dichloromethane (80 mL), and the solution was cooled to 0°C. Under stirring, 16-methyloctadecanoyl chloride (15.2 g, 48.1 mmol) was added. After removing the ice bath, the reaction mixture was stirred at room temperature for 3 d and water (75 mL) was added. The phases were separated and the organic phase washed twice with water and dried over magnesium sulfate. The crude product was flash chromatographed on silica.

1-Hexanoyl-2,3-isopropylidene glycerol (**1**) (6,7) was prepared according to procedure A from 1,2-isopropylidene glycerol (6.60 g, 50.0 mmol), pyridine (3.95 g, 50.0 mmol), toluene (172 mL), and hexanoyl chloride (5.06 g, 40.0 mmol). Evaporation and distillation (72–78°C/0.3 mm Hg) gave **1** (6.30 g, 71%).

1-(2-Methylhexanoyl)-2,3-isopropylidene glycerol (**2**) was prepared according to procedure A from 1,2-isopropylidene glycerol (6.35 g, 48.1 mmol), pyridine (3.87 mL, 48.1 mmol) and 2-methylhexanoyl chloride (5.70 g, 38.5 mmol) in dry toluene (140 mL). After workup, **2** (5.0 g, 53%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3)=, 1.15 (*d*, 3H, CH_3), 1.29 (*m*, 4H, CH_2), 1.36 (*s*, 3H, iso-CH_3), 1.43 (*s*, 3H, iso-CH_3), 1.60 (*m*, 2H, CH_2), 2.47 (*m*, 2H, CH_2), 3.74 (*oct*, 1H), 4.10 (*m*, 3H), 4.30 (*m*, 1H). Mass spectrometry (MS) electron ionization (EI) *m/e* (rel. int.) 229 (88) M − 15, 113 (40), 101 (100), 85 (73), 69 (50), 57 (38), 43 (60).

1-(4-Methylhexanoyl)-2,3-isopropylidene glycerol (**3**) was prepared according to procedure A from 1,2-isopropylidene glycerol (8.87 g, 67.2 mmol), pyridine (5.41 mL, 67.2 mmol), and 4-methylhexanoyl chloride in dry toluene (190 mL). After workup, **3** (77.9 g, 60%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.87 (*t*, 3H, CH_3), 0.86 (*d*, 3H, CH_3), 1.37 (*s*, 3H, iso-CH_3), 1.40 (*m*, 5H, CH_2, C*H*), 1.44 (*s*, 3H, iso-CH_3), 2.35 (*m*, 2H, CH_2), 3.74 (*qu*, 1H), 4.12 (*m*, 3H), 4.32 (*oct*, 1H). MS (EI) *m/e* (rel. int.) 229 (6) M − 15, 113 (8), 101 (17), 95 (13), 57(23), 43 (100).

1-(4-Ethylhexanoyl)-2,3-isopropylidene glycerol (**4**) was prepared according to procedure A from 1,2-isopropylidene glycerol (2.6 g, 19.4 mmol), pyridine (1.52 mL, 19.0 mmol), and 4-ethylhexanoyl chloride (2.3 g, 14.4 mmol) in dry toluene (100 mL). After workup, **4** (3.4 g, 94%) was obtained.

1-(2-Butylhexanoyl)-2,3-isopropylidene glycerol (**5**) was prepared according to procedure A from 1,2-isopropylidene glycerol (7.67 g, 58.1 mmol), pyridine (4.68 mL, 58.1 mmol), and 2-butylhexanoyl chloride (8.83 g, 46.5 mmol). After workup, **5** (9.8 g, 66%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 6H, CH_3), 1.26 (*m*, 8H, CH_2), 1.37 (*s*, 3H, iso-CH_3), 1.43 (*s*, 3H, iso-CH_3), 1.46 (*m*, 2H, CH_2), 1.59 (*m*, 2H, CH_2), 2.40 (*m*, 1H, C*H*), 3.74 (*qu*, 1H), 4.07 (*qu*, 1H), 4.14 (*d*, 2H), 3.41 (*qv*, 1H). MS (EI) *m/e* (rel. int.) 271 (7) M − 15, 101 (22), 71 (28), 57 (42), 43 (100).

1-Dodecanoyl-2,3-isopropylidene glycerol (**6**) (7) was prepared according to procedure A from 1,2-isopropylidene glycerol (4.2 g, 31 mmol), pyridine (2.5 mL, 31.0 mmol), and dodecanoyl chloride (5.45 g, 25.0 mmol) in dry toluene (125 mL). After workup, **6** (4.7 g, 60%) was obtained.

1-(6-Propyldodecanoyl)-2,3-isopropylidene glycerol (**7**) was prepared according to procedure A from 1,2-isopropylidene glycerol (3.30 g, 25.0 mmol), pyridine (1.98 g, 25.0 mmol), toluene (86 mL), and 6-propyldodecanoyl chloride (5.21 g, 20.0 mmol). Evaporation and drying gave **7** (4.63 g, 65.0%). ^{1}H NMR ($CDCl_3$) δ 0.88 (*m*, 6H, CH_3), 1.25 (*m*, 19H, CH_2, C*H*), 1.37 (*s*, 3H, iso-CH_3), 1.44 (*s*, 3H, iso-CH_3), 1.61 (*m*, 2H, CH_2), 2.35 (*t*, 2H, CH_2), 3.74 (*qu*, 1H), 4.10 (*m*, 3H), 4.32 (*m*, 1H). MS (EI) *m/e* (rel. int.) 341 (100) M − 15, 299 (15), 255 (11), 213 (11), 180 (23), 129 (44), 101 (51), 57 (24), 43 (18).

1-Octanoyl-2,3-isopropylidene-glycerol (**8**) (7) was prepared according to procedure A from 1,2-isopropylidene glycerol (5.29 g, 40.1 mmol), pyridine (3.17 mL, 40.1 mmol), toluene (160 mL), and octadecanoyl chloride (9.62 g, 32.0 mmol). Evaporation and drying gave **8** (7.64 g, 60%).

1-(2-Methyloctadecanoyl)-2,3-isopropylidene glycerol (**9**) was prepared according to procedure A from isopropylidene glycerol (5.5 g, 42.0 mmol), pyridine (3.4 mL, 42.0 mmol), and 2-methyloctadecanoyl chloride (10.6 g, 33.6 mmol) in dry toluene (168 mL). After workup, **9** (10.7 g, 77%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3), 1.15 (*d*, 3H, CH_3), 1.25 (*s*, 28H, CH_2), 1.37 (*s*, 3H, iso-CH_3), 1.44 (*s*, 3H, iso-CH_3), 1.65 (*m*, 2H, CH_2), 2.47 (*sex*, 1H, C*H*), 3.70 (*oct*,

1H), 4.10 (*m*, 3H), 4.30 (*qv*, 1H). MS (EI) *m/e* (rel. int.) 397 (7) M – 15, 185 (6), 143 (8), 57 (47), 43 (100).

1-(16-Methyloctadecanoyl)-2,3-isopropylidene glycerol (**10**) was prepared according to procedure A from 1,2-isopropylidene glycerol (0.88 g, 6.63 mmol), pyridine (0.54 mL, 6.63 mmol), toluene (23 mL), and 16-methyloctadecanoyl chloride (1.68 g, 5.30 mmol). Evaporation and drying gave **10** (1.70 g, 76.0%).

1-(16-Ethyloctadecanoyl)-2,3-isopropylidene-glycerol (**11**) was prepared according to procedure A from 1,2-isopropylidene glycerol (5.29 g, 40.1 mmol), pyridine (3.17 mL, 40.1 mmol), and 16-ethylhexanoyl chloride (10.6 g, 32.0 mmol) in dry toluene (160 mL). After workup, **11** (8.3 g, 61%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.83 (*t*, 6H, CH_3), 1.25 (*m*, 33H, CH_2, CH), 1.37 (*s*, 3H, iso-CH_3), 1.44 (*s*, 3H, iso-CH_3), 1.62 (*m*, 2H, CH_2), 2.34 (*t*, 2H, CH_2), 3.74 (*qu*, 1H), 4.12 (*m*, 3H), 4.32 (*oct*, 1H). MS (EI) *m/e* (rel. int.) 411 (5) M – 15, 185 (3), 171 (5), 129 (10), 101 (27), 57 (35), 43 (100).

1-(2-Hexadecyloctadecanoyl)-2,3-isopropylidene glycerol (**12**) was prepared according to procedure A from 1,2-isopropylidene glycerol (3.25 g, 24.6 mmol), pyridine (1.98 mL, 24.6 mmol), and 2-hexadecyloctadecanoyl chloride (10.3 g, 19.7 mmol) in toluene (72 mL). After workup toluene as the eluent was changed for pentane/ether (88:12), and **12** (7.8 g, 64%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.80 (*t*, 6H, CH_3), 1.25 (*m*, 56H, CH_2), 1.37 (*s*, 3H, iso-CH_3), 1.43 (*s*, 3H, CH_3), 2.37 (*m*, 1H, C*H*), 3.70 (*qu*, 1H), 4.07 (*qu*, 2H), 4.13 (*d*, 2H), 4.31 (*qv*, 1H). MS (EI) *m/e* (rel. int.) 607 (82) M – 15, 564 (7), 340 (10), 137 (20), 97 (37), 81 (47), 69 (100), 57 (58), 43 (42).

1-(4-Methylhexanoyl)-2,3-dihexanoyl glycerol (**13**) was prepared from procedure B from 1-(4-methylhexanoyl)-2,3-isopropylidene glycerol (**3**) (7.80 g, 32.0 mmol), pyridine (12.3 g, 153 mmol), and hexanoyl chloride (20.6 g, 153 mmol). After flash chromatography (ethyl acetate/petroleum ether, 1:9) and HPLC (acetonitrile) **13** (4.30 g, 34%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*m*, 12H, CH_3), 1.31 (*m*, 10H, CH_2), 1.62 (*m*, 6H, CH_2), 2.32 (*m*, 7H, CH_2, C*H*), 4.15 (*qu*, 2H), 4.30 (*qu*, 2H), 5.27 (*m*, 1H). MS (EI) *m/e* (rel. int.) 285 (12) M – 115, 271 (24), 113 (38), 99 (100), 71 (23), 43 (24). Calc. for $C_{22}H_{40}O_6$: C 65.96; H 10.07; MW 400.54. Found: C 66.7; H 10.2.

1-(2-Butylhexanoyl)-2,3-dihexanoyl glycerol (**14**) was prepared according to procedure B from 1-(2-butylhexanoyl)-2,3-isopropylidene glycerol (**5**) (8.0 g, 28.0 mmol), pyridine (5.55 mL, 68.8 mmol), and hexanoyl chloride (18.0 g, 134 mmol). After flash chromatography (ethyl acetate/petroleum ether, 7.5:92.5) and HPLC (acetonitrile), **14** (7.2 g, 60%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.89 (*m*, 12H, CH_3), 1.29 (*m*, 18H, CH_2), 1.62 (*m*, 8H, CH_2), 2.31 (*m*, 5H, CH_2, C*H*), 4.14 (*oct*, 2H), 4.32 (*oct*, 2H), 5.27 (*m*, 1H). 1-(4-Ethylhexanoyl)-2,3-dioctadecanoyl glycerol (**26**) was prepared according to procedure B from 1-(4-ethylhexanoyl)-2,3-isopropylidene glycerol (**4**) (3.40 g, 13.3 mmol), pyridine (2.70 mL, 34.1 mmol), and octadecanoyl chloride (10.2 g, 33.8 mmol). After flash chromatography (ethyl acetate/heptane, 7:93) and HPLC (methanol/ethyl acetate/2-propanol, 70:20:10), **26** (3.21 g, 32%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.86 (*m*, 12H, CH_3), 1.25 (*s*, 60H, CH_2), 1.59 (*m*, 7H, CH_2, C*H*), 2.30 (*m*, 6H, CH_2), 4.14 (*qu*, 2H), 4.30 (*qu*, 2H), 5.30 (*m*, 1H). Calc. for $C_{47}H_{90}O_6$: C 75.14; H 12.08; MW 751.19. Found: C 74.9; H 12.5; $(M + NH_4)^+$ 768.

1-Dodecanoyl-2,3-di-2-pentyldodecanoyl glycerol (**27**) was prepared according to procedure B from 1-dodecanoyl-2,3-isopropylidene glycerol (**6**) (4.08 g, 13.0 mmol), pyridine (2.54 mL, 31.5 mmol), and 2-pentyldodecanoyl chloride (9.09 g, 31.5 mmol). After flash chromatography (ethyl acetate/pentane, 7:92) and HPLC (methanol/ethyl acetate, 65:35), **27** (4.05 g, 40%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 15H, CH_3), 1.25 (*s*, 60H, CH_2), 1.59 (*m*, 10H, CH_2), 2.29 (*t*, 2H, CH_2), 2.32 (*m*, 2H, C*H*), 4.12 (*oct*, 2H), 4.32 (*oct*, 2H), 5.28 (*m*, 1H). Calc. for $C_{49}H_{94}O_6$: C 75.52; H 12.16; MW 779.43: Found: C 76.1; H 11.9; $(M + NH_4)^+$ 796.

1-Octadecanoyl-2,3-di-6-propyldodecanoyl glycerol (**28**) was prepared according to procedure B from 1-octadecanoyl-2,3-isopropylidene glycerol (**8**) (5.17 g, 13 mmol), pyridine (2.54 mL, 31.5 mmol), and 6-propyldodecanoyl chloride (8.02 g, 31.5 mmol). After flash chromatography (ethyl acetate/pentane, 7:93) and HPLC (methanol/ethyl acetate/2-propanol, 70:20:10), **28** (4.73 g, 45%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.87 (*m*, 15H, CH_3), 1.25 (*s*, 64H, CH_2), 1.60 (*m*, 8H, CH_2, C*H*), 2.32 (*t,t,t*, 6H, CH_2), 4.14 (*qu*, 2H), 4.30 (*qu*, 2H), 5.30 (*m*, 1H). Calc. for $C_{51}H_{98}O_6$: C 75.87; H 12.24; MW 807.29. Found: C 76.3; H 11.3; $(M + NH_4)^+$ 824.

1-Dodecanoyl-2,3-di-6-hexyldodecanoyl glycerol (**29**) was prepared according to procedure B from 1-dodecanoyl-2,3-isopropylidene glycerol (**6**) (4.24 g, 13.5 mmol), pyridine (3.20 g, 40.5 mmol), and 6-hexyldodecanoyl chloride (12.28 g, 40.50 mmol). After flash chromatography (heptane/ethyl acetate, 88:12) and HPLC (acetonitrile/ethyl acetate/dichloromethane, 73:23:4), **29** (5.44 g, 50%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 15H, CH_3), 1.25 (*s*, 64H, CH_2), 1.59 (*m*, 8H, CH_2, C*H*), 2.32 (*t,t,t*, 6H, CH_2), 4.14 (*qu*, 2H), 4.30 (*qu*,

2H), 5.25 (*m*, 1H). Calc. for $C_{51}H_{98}O_6$: C 75.87; H 12.24; MW 807.29. Found: 76.7; H 12.4; $(M + NH_4)^+$ 824.

1-(6-Propyldodecanoyl)-2,3-dioctadecanoyl glycerol (**30**) was prepared according to procedure B from 1-(6-propyldodecanoyl-2,3-isopropylidene glycerol (**7**) (4.00 g, 11.2 mmol), pyridine (3.13 g, 39.2 mmol), and octanoyl chloride (11.86 g, 39.20 mmol). After flash chromatography (heptane/ethyl acetate, 88:12), **30** (4.75 g, 50.0%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.82 (*m*, 12H, C*H*$_3$), 1.25 (*s*, 74H, C*H*$_2$), 1.61 (*m*, 7H, C*H*$_2$, C*H*), 2.30 (*t,t*, 6H, C*H*$_2$), 4.14 (*qu*, 2H), 4.30 (*qu*, 2H), 5.30 (*m*, 1H). Calc. for $C_{54}H_{104}O_6$: C 76.37; H 12.34; MW 849.37. Found: C 76.6; H 12.6; $(M + NH_4)^+$ 866.

1-(16-Methyloctadecanoyl)-2,3-dioctadecanoyl glycerol (**31**) was prepared according to procedure B from 1-(16-methyloctadecanoyl)-2,3-isopropylidene glycerol (**10**) (1.70 g, 4.00 mmol), pyridine (1.16 mL, 14.8 mmol), and octadecanoyl chloride (4.47 g, 14.8 mmol). After flash chromatography (ether/pentane, 1:1) and HPLC (chloroform/acetonitrile/2-propanol, 54:44:2), **31** was obtained with m.p. 56.5–58.0°C. ^{1}H NMR ($CDCl_3$) δ 0.83 (*m*, 12H, C*H*$_3$), 1.25 (83H, C*H*$_2$, C*H*) 1.57 (*m*, 6H, C*H*$_2$), 2.31 (*m*, 6H, C*H*$_2$), 4.15 (*qv*, 2H, OC*H*H), 4.22 (*qv*, 2H, OCH*H*), 5.27 (*m*, 1H, OC*H*). Peak matching on $(M + NH_4)^+$. Calc. for $C_{58}H_{116}NO_6$: 922.8803. Found: 922.8834.

1-(2-Hexadecyloctadecanoyl)-2,3-dioctadecanoyl glycerol (**32**) was prepared according to procedure B from 1-(2-hexadecyloctadecanoyl)-2,3-isopropylidene glycerol (**12**) (4.40 g, 7.10 mmol), pyridine (3.20 mL, 39.5 mmol), and octadecanoyl chloride (11.9 g, 39.5 mmol). After flash chromatography (pentane/diethyl ether, 90:10) and HPLC (acetonitrile/dichloromethane, 70:30), **32** (4.70 g, 59.0%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 12H, C*H*$_3$), 1.25 (*s*, 112H, C*H*$_2$), 1.60 (*m*, 8H, C*H*$_2$), 2.30 (*t,t*, 4H, C*H*$_2$), 2.32 (*m*, 1H, C*H*), 4.14 (*oct*, 2H), 4.31 (*hept*, 2H), 5.30 (*m*, 1H). Calc. for $C_{73}H_{142}O_6$: C 78.57; H 12.38; MW 1115.88. Found: C 79.1; H 13.1; $(M + NH_4)^+$ 1132.

Tris(2-methylhexanoyl) glycerol (**33**) was prepared according to procedure C from 2-hexanoic acid (21.0 g, 169 mmol), glycerol (4.30 g, 47.0 mmol), and 4-toluenesulfonic acid in toluene (40 mL). After workup and chromatography (petroleum ether/diethyl ether, 95:5), **33** (6.7 g, 34%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 9H, C*H*$_3$), 1.14 (*d*, 9H, C*H*), 1.28 (*m*, 12H, C*H*$_2$), 1.64 (*m*, 6H, C*H*$_2$), 2.44 (*m*, 3H, C*H*), 4.14 (*m*, 2H, C*H*H), 4.32 (*m*, 2H, CH*H*), 5.30 (*m*, 1H, C*H*). MS peak matching on $(M + NH_4)^+$. Calc. for $C_{24}H_{46}NO_6$: 446. Found 446.

Tris(4-methylhexanoyl) glycerol (**34**) was prepared according to procedure C from 4-methylhexanoic acid (15.6 g, 120 mmol), glycerol (3.1 g, 34 mmol), and 4-toluenesulfonic acid (0.5 g, 3.0 mmol) in toluene (40 mL). Workup after a reaction time of 130 h and chromatography (petroleum ether/diethyl ether, 95:5) gave **34** (6.3 g, 44%). ^{1}H NMR ($CDCl_3$) δ 0.88 (*m*, 18H, C*H*$_3$), 1.35 (*m*, 9H, C*H*$_2$, C*H*), 1.65 (*m*, 6H, CH$_2$), 2.30 (*m*, 6H, C*H*$_2$), 4.16 (*qu*, 2H), 4.30 (*qu*, 2H), 5.30 (*m*, 1H). Calc. for $C_{24}H_{44}O_6$: C 67.25; H 10.35; MW 428.59. Found: C 68.1; H 10.4; $(M + NH_4)^+$ 446.

Tris(4-ethylhexanoyl) glycerol (**35**) was prepared according to procedure D from glycerol (2.10 g, 22.4 mmol), pyridine (8.10 mL, 101 mmol), and 4-ethylhexanoyl chloride (16.4 g, 101 mmol) in dichloromethane (150 mL). After workup and flash chromatography (ethyl acetate/petroleum ether), **35** (1.5 g, 14%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.85 (*t*, 18H, C*H*$_3$), 1.27 (*m*, 9H, C*H*$_2$, C*H*), 1.60 (*m*, 6H, C*H*$_2$), 2.30 (*m*, 6H, C*H*$_2$), 4.15 (*qu*, 2H), 4.30 (*qu*, 2H), 5.30 (m, 1H). Calc. for $C_{27}H_{50}O_6$: C 68.90; H 10.71; MW 470.67. Found: C 68.7; H 10.6; $(M + NH_4)^+$ 488.

Tris(2-butylhexanoyl) glycerol (**36**) (1) was prepared according to procedure C from 2-butylhexanoic acid (15.0 g, 87.0 mmol), glycerol (2.2 g, 24 mmol), and 4-toluenesulfonic acid (0.5 g, 3.0 mmol) in toluene (40 mL). Workup after a reaction time of 130 h and chromatography (petroleum ether/diethyl ether, 95:5) gave **36** (3.8 g, 30%). ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 18H, C*H*$_3$), 1.25 (*m*, 24H, C*H*$_2$), 1.45 (*m*, 6H, C*H*$_2$), 1.60 (*m*, 6H, C*H*$_2$), 2.33 (*m*, 3H, C*H*), 4.10 (*qu*, 2H), 4.35 (*qu*, 2H), 5.28 (*m*, 1H).

Tris(6-propyldodecanoyl) glycerol (**37**) was prepared according to procedure D from glycerol (1.20 g, 13.0 mmol), pyridine (4.80 m, 58.5 mmol), and 6-propyldodecanoyl chloride (15.2 g, 58.5 mmol) in dichloromethane (80 mL). After workup and flash chromatography (ethyl acetate/petroleum ether), **37** (6.5 g, 65%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t,t*, 18H, C*H*$_3$), 1.23 (*m*, 54H, C*H*$_2$), 1.59 (*m*, 9H, C*H*$_2$), 2.32 (*t,t*, C*H*$_2$), 4.14 (*qu*, 2H), 4.30 (*qu*, 2H), 5.30 (*m*, 1H). Calc. for $C_{48}H_{92}O_6$: C 75.34; H 12.27; MW 765.22. Found: C 76.0; H 12.1; $(M + NH_4)^+$ 782.

Tris(2-methyloctadecanoyl) glycerol (**38**) was prepared according to procedure D from glycerol (0.8 g, 86 mmol), pyridine (3.10 mL, 38.5 mmol), and 2-methyloctadecanoyl chloride (12.2 g, 38.5 mmol) in dichloromethane (80 mL). After workup and flash chromatography (ethyl acetate/petroleum ether), **38** (3.8 g, 47%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 9H, C*H*$_3$), 1.14 (*d,d*, 9H, C*H*$_3$), 1.26 (*s*, 84H, C*H*$_2$), 1.63 (*m*, 6H, C*H*$_2$), 2.43 (*sex*, 3H, C*H*), 4.13 (*m*, 2H), 4.32 (*m*, 2H), 5.30 (*m*, 1H). Calc. for $C_{60}H_{116}O_6$: C 77.19; H 12.53; MW 933.53. Found: C 77.4; H 12.8; $(M + NH_4)^+$ 950.

Tris(16-methyloctadecanoyl) glycerol (**39**) was prepared according to procedure D from glycerol (1.0 g, 10.7 mmol), pyridine (3.90 g, 48.1 mmol), and 16-methyloctadecanoyl chloride (15.2 g, 48.1 mmol) in dichloromethane (80 mL). After workup and flash chromatography (ethyl acetate/petroleum ether), **39** (4.9 g, 49%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.84 (*d*, 9H, C*H*$_3$), 0.85 (*t*, 9H, C*H*$_3$), 1.25 (*s*, 78H, C*H*$_2$), 1.61 (*m*, 9H, C*H*$_2$, C*H*), 2.31 (*t,t*, 6H, C*H*$_2$), 4.14 (*qu*, 2H), 4.30 (*qu*, 2H), 5.27 (*m*, 1H). Calc. for $C_{60}H_{116}O_6$: C 77.19; H 12.53; MW 933.53. Found: C 77.1; H 12.5; $(M + NH_4)^+$ 950.

Tris(16-ethyloctadecanoyl) glycerol (**40**) was prepared according to procedure D from glycerol (1.10 g, 1.09 mmol), pyridine (0.34 mL, 4.24 mmol), and 16-ethyloctadecanoyl chloride (1.40 g, 4.24 mmol) in dichloromethane (7.0 mL). After work up and flash chromatography, **40** (0.54 g, 51.0%) was obtained. ^{1}H NMR ($CDCl_3$) δ 0.83 (*t*, 18H, C*H*$_3$), 1.26 (*s*, 84H, C*H*$_2$), 1.27 (*t*, 3H, C*H*), 1.61 (*m*, 6H, C*H*$_2$), 2.31

(*t*, 5H, CH_2), 2.32 (*t*, 2H, CH_2), 4.15 (*qu*, 2H), 4.29 (*qu*, 2H), 5.27 (*m*, 1H). Calc. for $C_{63}H_{122}O_6$: C 77.55; H 12.61; MW 975.61. Found: C 78.3; H 12.8; $(M + NH_4)^+$ 992.

RESULTS AND DISCUSSION

The racemic 1-acyl-2,3-isopropylidene glycerols (**1–13**) were prepared from the appropriate acyl chloride and 1,2-isopropylidene glycerol in pyridine and toluene (7). The presence of pyridine prevents migration of the sensitive isopropylidene ketal (8). Deprotection of the isopropylidene group into the monoacylglycerols can be accomplished by a number of acidic procedures, but since monoacylglycerols are readily isomerized by acid, alkali and heat, the reaction conditions are very important. Deprotection without any acyl migration has been achieved with dimethyl boron bromide at –50°C (9). We chose the less expensive method using boric acid in 2-methoxyethanol at 100°C, which also worked satisfactorily (10). The monoacylglycerols were acylated immediately in the manner described above in order to avoid isomerization. The triacylglycerols so obtained (**14–32**) are given in Scheme 1. The monoacid triacylglycerols (**33–40**) in Scheme 2 were prepared either from glycerol and acyl chloride in pyridine and toluene or in an acid-catalyzed reaction between glycerol and the branched acid in toluene (1).

ACKNOWLEDGMENTS

This work was financially supported by a grant from Karlshamns AB's Research Foundation. The authors are also grateful to Ecaterina Temciuc for preparing one of the triacylglycerols.

COMMUNICATION

A New Lipid from an Australian Marine Sponge, *Callyspongia* sp.

Sylvia Urban and Robert J. Capon*

School of Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia

ABSTRACT: A specimen of the sponge *Callyspongia* sp. collected off the coast of New South Wales, Australia, has yielded the novel lipid (6*Z*,9*Z*,12*Z*,15*Z*)-1,6,9,12,15-octadecapenten-3-one, together with (4*Z*,7*Z*,10*Z*,13*Z*)-4,7,10,13-hexadecatetraenoic acid.

Lipids 32, 675–677 (1997).

Marine organisms are an established source of novel secondary metabolites and are increasingly recognized as a source of unusual lipids. In this context, a number of novel polyunsaturated fatty acids have been isolated and reported to possess interesting biological properties [enzyme inhibitory (1), ichthyotoxic (2), allelopathic (3–5), antibiotic (6), etc.]. For example, the acetylenic fatty acid (**1**) from Pacific Ocean and Caribbean Sea collections of the red alga *Liagora farinosa* (7) has been described as a potent inhibitor of bee venom-derived phospholipase A_2 (100% inhibition; 5.7 mM) (1), while the allelopathic fatty acid (6*Z*,9*Z*,12*Z*,15*Z*)-6,9,12,15-octadecatetraenoic acid (**2**) was isolated from the commercially available edible marine brown alga *Cladosiphon okamuranus* (5). The polyunsaturated fatty acid (4*Z*,7*Z*,10*Z*,13*Z*)-4,7,10,13-hexadecatetraenoic acid (**3**) first reported from the alga *Scenedesmus obiliquas* (8) was reisolated from a Japanese freshwater chlorophyte *Pediastrum* sp. (9) at which time it was shown to inhibit the development of starfish embryos. A closely related polyunsaturated fatty acid methyl ester (**4**) has since been reported from a Japanese soft coral *Xenia* sp. (10). Sponges have also been a source of structurally unusual acetogenins, such as debromorenierin-1 (**5**) from an Italian marine sponge, *Reniera fulva* (11).

In this report we describe the isolation, characterization, and identification of a new lipid, (6*Z*,9*Z*,12*Z*,15*Z*)-1,6,9,12,15-octadecapenten-3-one (**6**), as well as the previously reported polyunsaturated fatty acid, (4*Z*,7*Z*,10*Z*,13*Z*)-4,7,10,13-hexadecatetraenoic acid (**3**), from an Australian sponge, *Callyspongia* sp.

EXPERIMENTAL PROCEDURES

General. All solvents were redistilled before use. Rapid silica filtrations were performed by using Kieselgel 60 silica. Ultraviolet (UV) absorption spectra (λ_{max}) were obtained on a Varian Superscan 3 UV/visible (UV/vis) spectrophotometer (Palo Alto, CA), while infrared (IR) spectra (ν_{max}) were obtained on either a Perkin-Elmer 983G or Perkin-Elmer 1600 Fourier transform infrared spectrometer (Norwalk, CT). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra, as well as two-dimensional NMR experiments, were performed on a Varian Unity 300 spectrometer in the solvents indicated, with spectra referenced to residual ^1H signals in deuterated solvents. Low- and high-resolution electron impact (EI) mass spectra were recorded on either a V.G. Micromass 7070F (Cheshire, England) or a Jeol AX-505H mass spectrometer (Tokyo, Japan), with chemical ionization (CI) mass spectra being recorded on the latter instrument. High-pressure liquid chromatography (HPLC) was performed by means of an ISCO 2350 solvent delivery system (Lincoln, NE) equipped with a Rheodyne injector, Waters 401 differential refractometer (Milford, MA), and Spectra Physics 200 programmable UV/vis wavelength detector (San Jose, CA), and recorded on a Data Acquisition Plotting and Analysis (DAPA) (Perth, Australia) package operating on an Ipex 286PC unit under DOS 5.0 (Melbourne, Australia).

Analytical capillary GC was performed on a Hewlett-Packard 5890 gas chromatograph (Wilmington, DE) equipped and recorded on a data acquisition package (Turbochrom 4; San Jose, CA) operating on a Digital DEC PC under DOS 6.2. The column used was a BP-1 (15 m by 0.22 mm and film thickness 0.25 mm). GC EI mass spectrometry (MS) was carried out on a Jeol AX-505H mass spectrometer equipped with the above column using the following temperature program: 40°C (2 min), followed by ramping at 10°C/min to 270°C (5 min), carrier gas flow 2–3 mL/min, injector temperature 250°C, detector temperature 350°C.

Collection, extraction, and isolation. A specimen of a *Callyspongia* sp. (class Demospongiae: order Haplosclerida: family Callyspongiidae) (12 g extracted dry weight) (Museum of Victoria registry number F77031) was collected by SCUBA (−12 m) off Durras, New South Wales, Australia

(35°40.1′S 150°18.5′E). This sponge exhibits a massive-bulbous growth form. Color in life is pale lilac-mauve and beige when preserved in ethanol. The texture is compressible-spongy yet fibrous and reasonably tough to tear. Oscules are scattered, conspicuous, and often raised with a distinct lip. The sponge surface is transparent with fiber reticulation visible at the surface, optically smooth, but minutely conulose. Structural megascleres are vestigial fusiform oxeas with telescoped ends of dimensions 85–115 µm × 2.5 µm. The peripheral skeleton or ectosome is a tangential isodictyal reticulation of primary multispicular, secondary bispicular and tertiary unispicular fibers with choaonosomal primary fibers occasionally protruding in support of surface conules. The choanosomal skeleton exhibits a wide-spaced isodictyal reticulation of primary fibers 50–75 µm in width, cored by 10–20 oxeas and connecting secondary fibers cored by 2–5 oxeas, with unispicular tertiary fibers becoming more common in the subectosomal region. Spongin is light. Collagen in the mesohyl is abundant and scattered lightly with single interstitial spicules arranged isodictyally.

The fresh sponge was diced, steeped in ethanol, and stored in the dark at –20°C. The crude ethanol extract of this sponge was concentrated under reduced pressure and the CH_2Cl_2-soluble portion subjected to rapid silica filtration [20% stepwise elution from petroleum spirits (60–80°C) to EtOAc] followed by normal-phase HPLC (2.0 mL/min, 20% EtOAc/petroleum spirits, Phenomenex Spherex 5 µ Si 250 × 10 mm column; Torrance, CA) to yield (6*Z*,9*Z*,12*Z*,15*Z*)-1,6,9,12,15-octadecapenten-3-one (**6**) (7 mg, 0.05%) and (4*Z*,7*Z*,10*Z*,13*Z*)-4,7,10,13-hexadecatetraenoic acid (**3**) (4 mg, 0.03%).

RESULTS AND DISCUSSION

The crude ethanol extract of a specimen of *Callyspongia* sp. collected by SCUBA off the coast of New South Wales, Australia, was concentrated and subjected to the purification procedure as outlined in the Experimental Procedures section to yield two lipid-soluble compounds, (6*Z*,9*Z*,12*Z*,15*Z*)1,6,9,12,15-octadecapenten-3-one (**6**) and (4*Z*,7*Z*, 10*Z*,13*Z*)4,7,10,13-hexadecatetraenoic acid (**3**).

Compound (**6**) was isolated by HPLC as a stable, colorless oil, and its purity confirmed by GC analysis. Although the EI mass spectrum of (**6**) revealed only a very weak molecular ion (<1%), CI mass spectral analysis established the molecular formula ($C_{18}H_{26}O$, Δmmu − 1.1) to require six degrees of unsaturation.

The presence of a conjugated ketone functionality was supported by an IR absorption (1697 cm^{-1}) and a characteristic ^{13}C NMR resonance (200.1, s). Further examination of the ^1H and ^{13}C NMR data for (**6**) revealed the presence of an isolated terminal double bond [^1H: δ 6.36 (*dd, J* = 11.0, 17.6 Hz), 6.22 (*dd, J* = 1.3, 17.6 Hz) and 5.83 (*dd, J* = 1.3, 11.0 Hz); ^{13}C: 128.1 (*t*) and 136.5 (*d*) ppm], four 1,2-disubstituted double bonds [^1H: δ 5.38 (*bm*); ^{13}C: 132.0 (*d*), 129.0 (*d*), 128.6 (*d*), 128.3 (*d*), 128.3 (*d*), 128.0 (*d*), 127.8 (*d*), 126.9 (*d*) ppm] and three bisallylic methylenes [^1H: δ 2.83 (*bm*, 6H)]. These latter observations together with resonances for a primary methyl group β to a double bond [^1H: δ 0.97 (*bt*)] established the C_6 to C_{18} structure fragment. Furthermore, the deshielded ^{13}C NMR chemical shifts for the bisallylic [^{13}C: 25.5 (*t*) and 25.6 (2*t*) ppm] and allylic [^{13}C: 21.7 (*t*) and 20.6 (*t*) ppm] methylene carbons were supportive of an all *Z* geometry (12–14). Detailed examination of the COSY NMR data provided correlations (see Fig. 1) to support the complete struc-

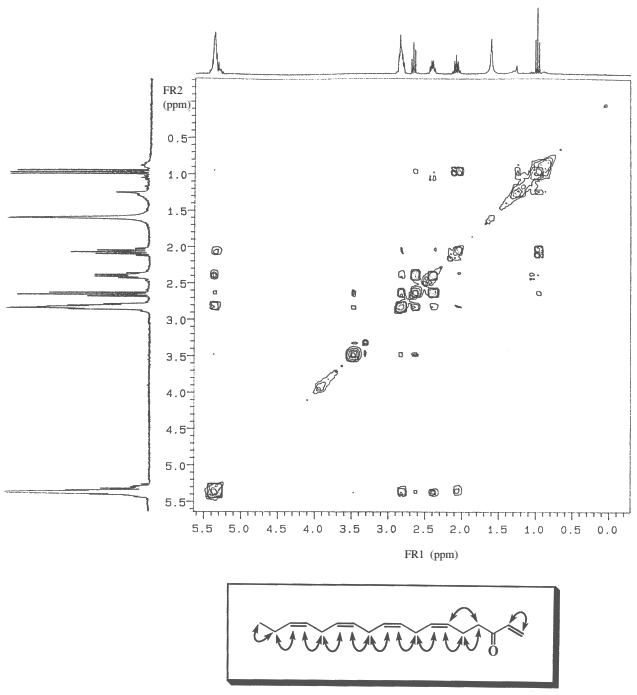

FIG. 1. Selected COSY NMR correlations for (**6**).

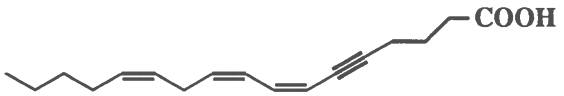
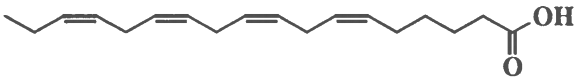
ture as shown, while diagnostic ions were observed in the EI and CI mass spectra (*m/z* 203 and 189).

Compound (**3**) was isolated by HPLC as an unstable, colorless oil, and its purity confirmed by GC analysis. The ^{1}H NMR, IR, and mass spectral data for (**3**) were found to be consistent with that reported for (4*Z*,7*Z*,10*Z*,13*Z*)4,7,10,13-hexadecatetraenoic acid (10,15,16).

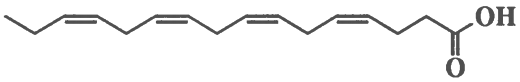
Although the ecological role of the new lipid (6*Z*,9*Z*,12*Z*,15*Z*)-1,6,9,12,15-octadecapenten-3-one (**6**) or the known polyunsaturated fatty acid (4*Z*,7*Z*,10*Z*,13*Z*)4,7,10,13-hexadecatetraenoic acid (**3**) cannot be defined, it is possible to speculate. Filter-feeding organisms such as sponges are susceptible to overgrowth and as with the alga mentioned earlier in this report polyunsaturated lipids such as (**3**) may afford a level of chemical defense and/or the capacity to overgrow adjacent organisms (Scheme 1).



(**1**)

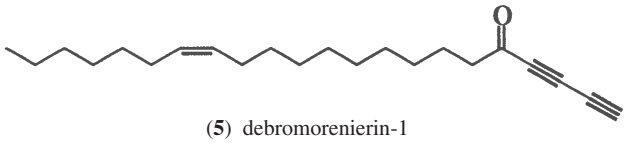


(**2**) (6*Z*,9*Z*,12*Z*,15*Z*)-6,9,12,15-octadecatetraenoic acid

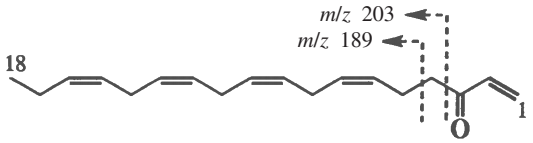


(**3**) (4*Z*,7*Z*,10*Z*,13*Z*)-4,7,10,13-hexadecatetraenoic acid

(**4**)



(**5**) debromorenierin-1



(**6**) (6*Z*,9*Z*,12*Z*,15*Z*)-1,6,9,12,15-octadecapenten-3-one

Gas–Liquid Chromatographic Properties of Positional Isomers of Methyl Thia, Selena, and Tellura Laurate Analogs

Marcel S.F. Lie Ken Jie*, O. Bakare, Y.K. Cheung, and S.H. Chau

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong

ABSTRACT: Gas–liquid chromatographic analyses of three complete series of synthetic positional isomers of methyl thia, selena, and tellura laurate analogs were carried on a nonpolar (SE-30) and a polar (SP-2330) stationary phase. The average ECL (equivalent chain length) values of the thia, selena, and tellura laurate on SE-30 stationary phase were 13.8, 14.8, and 15.7, respectively, while on SP-2330 the average values for the same series were 17.1, 19.0, and 19.1, respectively. Positional isomers with the heteroatom at the 2-position exhibited the lowest ECL values, while those with the heteroatom at the ω-1 position gave the highest ECL values and were readily separated from the other positional isomers of the same series of analogs by this technique.

Lipids 32, 679–681 (1997).

Corey *et al.* (1) have synthesized 7-thia-arachidonic acid, which has been found to be a potent irreversible inhibitor of leukotriene (also known as lipoxin) biosynthesis. This observation suggests a possible means of control of inflammatory diseases caused by an overproduction of leukotrienes in the human body (2). In the field of fatty acid chemistry, only a small number of long-chain fatty acids containing a sulfur atom have been synthesized in order to study their chemical, physical, or biological properties (3–6). Pascal *et al.* (7,8) have prepared the 9- and 10-thiastearic acid isomers and have reported on the inhibitory effects of these fatty acid analogs on cyclopropanoid fatty acid biosynthesis and on the growth of a protozoan species, *Crithidia fasciculata*. Buist's group (9) has been engaged in the study of the metabolism of thiastearic acids by yeast cells, *Saccharomyces cerevisiae*, and have noted a highly chemo-, regio-, and stereoselective introduction of a (*Z*)-olefinic bond into such sulfur-containing fatty acid analogs. Recently the inhibition of protozoan cyclopropane fatty acid synthetase by phosphatidylethanolamines containing thia fatty acid moieties has been reported (10). Metabolism of 3-thia fatty acids in rat liver and other tissues has also been investigated (11).

Fatty acids containing a selenium or tellurium atom are not found in nature. A study of some synthetic selena-alkanoic acids has been reported by Schwarz and Fredga (12), which shows that such selena analogs prevent dietary liver necrosis in rats. Results of the antimicrobial action of selena-alkanoic acids against *Streptococcus pyogenes* show that the reactivity is more effective in the C_{14} acid type than the corresponding C_{15} or C_{16} selena homologs. The position of the selenium atom in the alkyl chain also appears to affect the antimicrobial potency of such derivatives (13). Radioactive-labeled selena fatty acids have been used as myocardial imaging agents (14–16). Success has been achieved with fatty acids containing radioactive ^{125}I and nonradioactive Te atoms as imaging agent, which provide a rapid and pronounced myocardial uptake agent with the advantage of prolonging the myocardial retention and lowering the *in vivo* deiodination periods (17).

In view of these important developments in the chemistry and biochemistry of long-chain fatty acids containing a heteroatom, we have synthesized complete series of thia (18), selena, and tellura (19) fatty acid esters to study their nuclear magnetic resonance spectroscopic and mass spectral properties (20). In this paper we report the gas–liquid chromatographic properties of the entire series of positional isomers of methyl thia, selena, and tellura laurate analogs:

$CH_3(CH_2)_n$-*X*-$(CH_2)_mCOOCH_3$, where $n + m = 9$ and *X* = S, Se, or Te.

MATERIALS AND METHODS

The syntheses of methyl thia, selena, and tellura laurate isomers have been described elsewhere (18,19). Gas chromatographic analysis was carried out on a Hewlett-Packard (model 5890) (Hewlett Packard Inc., Palo Alto, CA) gas chromatograph fitted with a 25-m glass column (0.3 mm diameter, 0.33 μm film thickness, SE-30 stationary phase) or 30-m glass column (0.25 mm diameter, 0.20 μm film thickness, SP-2330 stationary phase). Helium (2 mL flow) was used as the carrier gas at an isothermal column temperature (170°C for SE-30 or 140°C for SP-2330) with a flame-ionization detector. External methyl fatty esters (methyl laurate, myristate, palmitate, and stearate) were used as reference compounds and the ECL (equivalent chain length) (21) values were calculated accordingly.

Abbreviation: ECL, equivalent chain length.

RESULTS AND DISCUSSION

The results of the gas–liquid chromatographic properties of the positional isomers of methyl thia, selena, and tellura laurate on nonpolar (SE-30) and polar (SP-2330) stationary phases are presented as their ECL values in Table 1. In general, nonpolar stationary phases, such as SE-30, separate compounds according to their molecular weights. The heavier the molecular mass, the longer the retention time. The replacement of a methylene group in the alkyl chain of methyl laurate by either a sulfur, selenium, or tellurium atom increases the molecular weight of the parent fatty ester (methyl laurate) substantially. It would therefore be reasonable to expect a large increase in the retention time for the thia, selena, and tellura analogs as compared to the parent methyl ester (methyl laurate). This change in the retention times was reflected by the high ECL values obtained on the nonpolar stationary phases for these three series of analogs. However, the actual ECL values of these analogs did not reflect a substantial proportional increase of anticipated retention time. Bearing in mind that the atomic mass of a tellurium atom is *ca.* 1.6-fold heavier than a selenium atom, which in turn is *ca.* 2.5-fold heavier than a sulfur atom, while the latter is *ca.* 2.3 times heavier than the mass of a methylene group in methyl laurate, it would be expected from a substance like methyl tellura laurate to give an estimated ECL value of at least 11.0 + 9.1 = 20.1. The value of 9.1 was obtained by dividing the atomic mass of tellurium (average value 127.60) by the mass of a methylene group (14.0) to give a quotient of 9.1. By adding this value to the theoretically remaining value of the retention time of a methyl laurate less one methylene group (i.e., being replaced by a hetero atom, leaves an ECL value = 11.0). However, from the results of the study of the methyl tellura laurate isomers, the highest ECL value obtained (methyl 11-tellura laurate) was 16.3 on SE-30 stationary phase. Similarly, the ECL values of the selena and tellura laurates series were in relative terms lower than the estimated ECL values based on the large molecular weights of the parent fatty ester by substitution of one methylene group by a sulfur or selenium atom. The average ECL values of methyl thia, selena, and tellura laurate analogs were 13.8, 14.8, and 15.7, respectively.

The chromatographic results on the SE-30 stationary phase also showed that the farther the position of the hetero atom is from the methyl ester function, the longer the retention time of the positional isomer on the column. Thus, the 2-positional isomers exhibited the lowest ECL values in each series, while the ECL value of the ω-1 isomers (*viz.* 11-thia, 11-selena, and 11-tellura isomers) furnished the highest ECL values. The low ECL values of the 2-positional isomers were considered to be attributed to the results of the conjugative electronic effects involving the lone pair of electrons of the hetero atom (sulfur, selenium, or tellurium) and the polarizable nature of the C=O bond of the ester function. With the position of the hetero atom becoming increasingly remotely positioned from the ester function, the retention times of the positional isomers of heteroatomic fatty esters increased gradually and reached a maximum value for the 11-isomers in each series.

The results on the polar stationary phase (SP-2330) were of interest, as the result of the conjugative electronic effects involving the lone pair of electrons of the hetero atom (sulfur, selenium, or tellurium) also furnished the lowest ECL value for the 2-positional isomer in each of the series studied. While the selena isomers (average ECL value = 19.0) exhibited a marked increase in retention time over the thia isomers (average ECL value = 17.1), the difference in ECL value of the tellura isomers (average ECL value = 19.1) was very similar to those exhibited by the selena isomers. There appeared to be hardly a difference in polarity between a tellura and a selena analog, despite their differences in atomic mass, when the analysis was conducted on the polar SP-2330 stationary phase. Separation of methyl selena and tellura isomers would therefore be difficult, if not impossible, on a polar stationary phase.

We conclude from this study that separation and possible identification of some of the positional isomers of methyl thia, selena, and tellura laurate isomers by gas–liquid chromatographic analysis is feasible using a combination of polar and nonpolar stationary phases.

TABLE 1
Results (equivalent chain length values) of the Gas–Liquid Chromatographic Analyses of Positional Isomers of Methyl Thia, Selena, and Tellura Laurate Analogs on SE-30 and SP-2330 Stationary Phases[a]

ARTICLE

Low Fat–Monounsaturated Rich Diets Containing High-Oleic Peanuts Improve Serum Lipoprotein Profiles[1]

Dawn J. O'Byrne, David A. Knauft[2], and Rachel B. Shireman*

Department of Food Science and Human Nutrition, and the Department of Agronomy, University of Florida, Gainesville, Florida 32611

ABSTRACT: Postmenopausal hypercholesterolemic women are at risk for cardiovascular disease and are encouraged to follow low-fat (LF) (≤30% energy) diets. However, these diets may have undesirable effects on high density lipoprotein cholesterol (HDL-C), apolipoprotein A-I (apo A-I) and triglycerides, whereas diets high in monounsaturated fats do not. Twenty postmenopausal hypercholesterolemic women previously consuming high-fat diets (34% energy) were placed on a low fat–monounsaturated rich diet (LFMR: 26%, 14% energy, respectively) for 6 mon. Sixteen women already eating LF diets (24% energy) were also followed to monitor variations in serum lipids due to seasonal variations. Twenty-five women successfully completed the study (LFMR = 12, LF = 13). Serum cholesterol decreased 10% (264 to 238 mg/dL, $P \leq 0.01$) and low density lipoprotein cholesterol (LDL-C) decreased 12% (182 to 161 mg/dL, $P \leq 0.01$) in the LFMR group, but did not change in the LF group. The reduction in serum cholesterol in the LFMR group was greater than estimated by predictive formulas. Serum triglycerides and apo A-I did not change in the LFMR group. A modest decrease in HDL-C, HDL_3-C, and apolipoprotein B (apo B) occurred in both groups, but only the LFMR group showed a trend toward beneficial changes in LDL-C/HDL-C and apo A-I/apo B ratios. Overall, the LFMR diet was well tolerated and resulted in an improved serum lipid and apolipoprotein profile. *Lipids 32*, 687–695 (1997).

Coronary heart disease (CHD) is the leading cause of death for women over the age of 40 yr (1). The incidence of CHD in women is low prior to menopause; however, after the onset of menopause, it increases to approximately that of men. In the United States, the mean total serum cholesterol for women prior to age 45 is 200–215 mg/dL (5.12–5.56 mmol/L) but rises to 240–260 mg/dL (6.20–6.72 mmol/L) between the ages of 45–54 (2). Currently, the initial treatment for hypercholesterolemia is the Step 1 diet (≤30% energy from fat, ≤10% energy from saturated fat, ≤300 mg cholesterol/d), which generally results in significant reductions in CHD risk factors such as serum cholesterol, low density cholesterol (LDL-C), and apolipoprotein B (apo B). However, low-fat (LF) diets often reduce high density lipoprotein cholesterol (HDL-C) and apolipoprotein A-I (apo A-I), and elevate serum triglycerides (3–5). These changes in the serum profile may be particularly detrimental for women, since serum levels of HDL-C, triglycerides, and the ratio of apo A-I/apo B may be more important in defining the risk of heart disease in this population (6–8). In contrast, diets low in saturated fatty acids (SFA) but high in monounsaturated fatty acids (MUFA) have resulted in reductions in serum cholesterol and LDL-C concentrations without adversely affecting HDL-C, apo A-I, or triglycerides (9–12). Most of the high MUFA diets studied to date, however, are also high in overall fat content (35–40% energy), and are therefore not recommended for treating hypercholesterolemia. Short-term (3–4 wk) controlled studies using diets moderate in fat but relatively high in MUFA have lowered serum cholesterol and LDL-C, but have had inconsistent effects on HDL-C and apo A-I in hypercholesterolemic men and women (13–16). At the time the present study was initiated, it could not be assumed that similar effects would be achieved in a free-living population. Furthermore, it was unclear if postmenopausal women are responsive to dietary treatment, or if diet modification may adversely alter the serum lipid profile. No long-term intervention study using a LF diet rich in MUFA has been conducted exclusively on postmenopausal women.

Most experimental diets have used olive oil, canola oil, or high-oleic sunflower oil as the source of MUFA, but it is also feasible to use nuts containing high amounts of oleic acid (17–19). A high-oleic acid peanut cultivar has been developed at the University of Florida in which 76–80% of the lipid content is MUFA (20), approximately 60–70% more oleic acid than most peanut cultivars. There are several advantages of using the high-oleic peanut as the MUFA source. The low lysine/arginine ratio of peanuts may promote serum cholesterol reduction and other physiological changes which

protect against atherosclerosis (21,22). Frequent consumption of nuts, including peanuts, has been associated with a lower incidence of CHD (23). Peanuts are widely accepted, versatile, and convenient to eat, which may enhance long-term compliance to this LF diet in a free-living population.

The purpose of this study was to determine if a LF diet rich in MUFA from high-oleic peanuts would result in an improved serum lipid and apolipoprotein profile in free-living postmenopausal hypercholesterolemic women.

SUBJECTS AND METHODS

Design. This study was designed to be a 6-mon diet intervention using free-living hypercholesterolemic postmenopausal women who switched from a typical American diet to a LF–monounsaturated rich diet (LFMR). Results were compared to a cohort. Serum lipids and apolipoproteins, body composition, health status, physical activity, and diet composition were measured before initiation of the study and after 6 mon of the diets. The University of Florida Institutional Review Board approved the screening and experimental protocol for this study.

Subjects. Healthy postmenopausal women (50–65 yr of age) with elevated serum cholesterol (220–300 mg/dL; 5.68–7.76 mmol/L) were recruited from the region. To minimize the probability of genetic hyperlipidemia or secondary hyperlipidemias, prospective subjects were eliminated for the following reasons: family history of premature death from heart disease coupled with a serum cholesterol >300 mg/dL (7.76 mmol/L); obesity; serum triglyceride >200 mg/dL; endocrine disorders; hypertension (>140/90 mm Hg); cigarette smoking; consumption of >3 alcoholic beverages per day; hormone replacement therapy; and taking medications that alter blood lipids. Over 350 potential participants were interviewed, and 36 met the criteria to participate in the study. Subjects were unpaid volunteers who gave informed consent to participate in the study. All vitamin/mineral supplements were discontinued 3 mon prior to initiation of the study.

Twenty women who habitually consumed a typical American diet (34% fat, 11% SFA) were assigned to the LFMR diet. It was desirable to have a cohort to control for the seasonal variation in serum lipids and lipoproteins, which has been reported in some long-term studies (24,25). However, having a cohort continue on a high-fat diet posed an ethical dilemma; allowing hypercholesterolemic women to continue eating high-fat diets during a long-term study would continue placing the group at risk for CHD and would be comparable to denying necessary medical treatment. As an alternative, the cohort was constituted from the other 16 hypercholesterolemic women; they were already following self-selected LF diets (LF:20–30% fat, <10% SFA, <300 mg cholesterol). The LF cohort group was instructed to continue following their LF diet. Eight women from the LFMR group and three women from the LF group were unable to complete the study due to injury, illness, schedule conflicts, or noncompliance with the study protocol. The results of the subjects who successfully completed the study are reported (LF = 13, LFMR = 12).

Diets. All participants were taught how to weigh, measure, and record all foods and beverages consumed. Participants completed Seven-Day Diet Records prior to the initiation of the study, and the energy level for weight maintenance was determined by computer analysis (Professional Dietitian, Wellsource, Clackamas, OR) of each subject's baseline diet record. This database contains the nutrient content of approximately 3000 foods and beverages. Information was obtained from the United States Department of Agriculture (USDA) Handbook 8 series (26–33), USDA Handbook 456 (34), Pennington and Church (35), and manufacturers. The nutrient database was expanded by D.J. O'Byrne to include specific processed foods and information on the dietary fiber content of frequently eaten foods (26–33, 36–38, manufacturers' information).

A registered dietitian instructed all participants on their diet protocols. Because subjects were free-living, Daily Eating Plans were given to provide standard guidelines for food selections that would conform to the energy requirements and diet assignment. The LF and LFMR diets had energy distributions of <30% fat, 50–60% carbohydrate, and 15–20% protein. Dietary SFA was restricted to <10% energy, and dietary cholesterol was limited to <300 mg/d. Monounsaturated fat constituted between 50–60% of the fat in the LFMR diet; the main source was high-oleic peanuts. Subjects assigned to the LFMR diet received prepackaged daily rations of dry-roasted high-oleic peanuts. Depending upon energy requirements, LFMR subjects consumed 35–68 g peanuts per day. The peanuts replaced an average of 1 oz (28 g) of cooked lean meat and 3–4 servings of oil or margarine (equivalent of 15–20 g of fat) in the diet.

All participants received educational materials and monthly nutrition/cooking classes to ensure compliance with assigned diets. Subjects were asked to record their food and beverage intake for seven consecutive days each month of the study and to maintain their weight and activity level. Compliance was determined by monthly telephone conversations and evaluation of subject's body weight and Seven-Day Diet Records. A detailed nutrient analysis of each subject's initial and final Seven-Day Diet Record was performed by computer.

Physical measurements. The following measurements were made on each subject prior to the beginning of the diet period and at the end of the 6-mon dietary period: weight, body mass index (BMI) (39), and percentage body fat based on the skinfold thickness of seven anatomical sites (40). Subjects completed a questionnaire on physical activity prior to initiation of the diet and after completion of the study. Weight was measured monthly.

Laboratory methods. Blood samples were drawn after a 12-h fast. Subjects refrained from vigorous exercise and alcohol consumption for 24 h prior to donating blood. Three blood samples were obtained from each subject at 1-wk intervals prior to the beginning of the study and again after 6 mon of dietary treatment. Serum lipid concentrations were measured in triplicate from each sample using microplate methods (41) with reagents from enzymatic kits (Stanbio Enzymatic Triglycerides Procedure No. 2000, Stanbio Enzymatic Cholesterol Procedure No. 1010, and Stanbio Enzymatic HDL-Cho-

lesterol Procedure No. 0599; Stanbio, Houston, TX). Reference sera were included in each assay (Fischer Diagnostics, Orangeburg, NJ). Serum HDL_3 was isolated from total HDL by precipitation with 1.5 M $MgCl_2$ in aqueous 1% dextran sulfate as described by Patsch *et al.* (42). The concentration of HDL_3-C was determined in a similar manner as HDL-C (Stanbio Enzymatic HDL-Cholesterol Procedure No. 0599), except that the dilution correction factor used to take into account the precipitating reagents was 1.21 rather than 1.1. Serum HDL_2-C was calculated by subtracting the concentration of HDL_3-C from HDL-C. The concentration of LDL-C was calculated by the Friedewald formula (43). Freshly isolated serum from each subject was flushed with nitrogen and stored at −70°F (−57°C) until used for apolipoprotein analysis at the end of the study. The serum concentrations of apo A-I, A-II, and B were measured in triplicate from one blood sample taken from each subject prior to initiation of the study and after 6 mon of following the diet. Serum concentrations were determined by a microplate method (41) using turbidimetric test kit reagents and standards (Boehringer Mannheim Biochemica, Indianapolis, IN).

Statistical analysis. Preliminary measurements of serum cholesterol were made on volunteers for the study. Forty-three of 75 prospective subjects had mean serum cholesterol concentrations between 5.68–7.76 mmol/L. Of this group, the mean concentration was 6.55 mmol/L and the sample variance was 10.04 mmol/L. This study was designed to detect a change in serum cholesterol of at least 10% of the sample mean (approximately 0.655 mmol/L). The sample size for each group was calculated using the following formula: $n = 2\sigma^2 [(z_\alpha + z_\beta)^2/\Delta^2]$ (44). In this formula, n = number of subjects in each group; σ^2 = estimated sample variance; $z_\alpha = 1.64$, which corresponds to a one-sided test with $\alpha = 0.05$; $z_\beta = 1.28$, which corresponds with the power = 0.9; and Δ = anticipated change in serum cholesterol. Using the above formula, it was determined that at least 10 subjects were needed in each group in order to have a sufficient sample size. Results are expressed as the mean ± standard deviation. Because subjects were not randomly assigned to the diet groups, Levene's Test for Variance Homogeneity (45) was performed to determine if the sample distribution was similar in both groups. The significance level was set at $P = 0.05$. The Levene's Test showed significant variance for several dietary factors, and log transformations were performed on these data. For variables that had similar sample distribution, an analysis of variance with repeated measures was used to test for significant differences "within" and "between" the two groups ($P = 0.05$). If a significant interaction was detected, a follow-up *t*-test was conducted. A nonparametric test (46) was used on variables in which data transformation did not successfully reduce the sample variance. Analyses were performed using the Statistical Analysis System software (SAS Institute, Inc., Cary, NC).

Correlations between the mean change in variables selected *a priori* were performed to assess the impact of specific dietary components on serum lipids and apolipoproteins and to identify potential confounding factors. These statistical analyses were performed using Microsoft Excel® 4.0 (Microsoft Corporation, Redmond, WA) statistical program.

RESULTS

Diets. Subjects following the LFMR diet tolerated the daily ration of peanuts without difficulties. Initially, some subjects complained of gastrointestinal bloating and cramping, but this subsided with increased fluid intake and consumption of peanuts throughout the day rather than at one time.

The LF and LFMR diets were designed to maintain weight and meet the subjects' nutritional requirements. Dietary energy level was intended to be the same as baseline, but subjects in both groups reduced energy intake (Time Effect, $P \leq 0.01$) by approximately 812–1011 kJ (Table 1). An examination of diet records showed that subjects in each group

began selecting specific food items that were lower in fat and energy than foods eaten at baseline. This may have accounted for the slight decrease in energy intake. The final diets of all subjects provided at least 75% of the Recommended Dietary Allowance for major vitamins and minerals (data not shown). The LFMR group altered their diet to meet the experimental guidelines by increasing %MUFA ($P \leq 0.01$) and lowering %fat ($P \leq 0.01$), %SFA ($P \leq 0.01$), % polyunsaturated fatty acids (PUFA) ($P \leq 0.05$), and cholesterol ($P \leq 0.01$). Subjects in the LF group were already following LF diets at the beginning of the study; thus their baseline diets were significantly different from the LFMR group. The LF group participated in nutrition and cooking classes with the LFMR subjects, which may have inadvertently influenced LF subjects to further restrict %fat ($P \leq 0.01$), %SFA ($P \leq 0.01$), %PUFA ($P \leq 0.05$), and dietary cholesterol ($P \leq 0.01$). Because dietary fat was reduced in both groups, the proportion of energy derived from protein and carbohydrates increased (time effects, $P \leq 0.01$). However, the LF group consistently consumed a diet higher in percentage protein and percentage carbohydrate (Group Effects, $P \leq 0.01$). Dietary fiber increased in both groups, but this was only significant for the LFMR group ($P \leq 0.01$).

The most notable difference between the LF and LFMR diets was the MUFA and fatty acid composition of the diet. Subjects in the LFMR group increased dietary MUFA and ate more than twice the proportion of energy as MUFA compared to the LF group. Fatty acid ratios were similar in the LF and LFMR groups at baseline and did not change in the LF group (Table 2). In contrast, the following dietary fatty acid ratios were reduced ($P \leq 0.01$) in the LFMR group: SFA/MUFA, SFA/UFA, PUFA/MUFA, SFA/fat, and PUFA/fat. The MUFA/fat ratio increased significantly ($P \leq 0.01$) so that LFMR subjects were consuming more than half of all dietary fat as MUFA.

Baseline diets contained similar ratios of lysine to arginine (Table 2). Even though the LF group ate more protein, the ratio of lysine to arginine did not change. Because peanuts are high in arginine, the LFMR diet resulted in a significantly lower lysine/arginine ratio ($P \leq 0.01$).

Physical measurements. Figure 1 shows the monthly weight of subjects. There was a trend toward weight loss during the last month of the study, but the LFMR group experienced a gradual and continuous trend toward weight loss during the entire study. After following the LFMR diet for 6 mon, subjects lost approximately 3 kg ($P \leq 0.01$) while the LF group maintained their weight (Table 3). Four of the LFMR subjects experienced weight loss in excess of 3.6 kg. Reported physical activity did not change in either group (data not shown). The subjects who lost the most weight expressed difficulty in consuming all the required food. When their data were eliminated from the group mean, the mean weight loss for the LFMR group was only 2.1 kg. As a consequence of the weight loss, BMI decreased ($P \leq 0.01$) and body fat was slightly lower in the LFMR group.

Serum lipid and apolipoprotein profile. The baseline serum lipid concentrations for cholesterol, LDL-C, and cholesterol ratios (Table 4) were higher in the LFMR group compared to the LF group. After 6 mon of following the LFMR diet, serum cholesterol and LDL-C fell by approximately 10% and 12%,

[a]Mean ± standard deviation. The mean concentration is the average value of three fasting serum samples; each sample was measured in triplicate. Lipid ratios are calculated from mean serum lipid concentrations.
*$P \leq 0.05$, **$P \leq 0.01$.
[b]Significant ANOVA interaction between diet and time; group means that are statistically significant have different letter superscripts.
[c]Time effect, ANOVA. Total-C/HDL-C = ratio of serum total cholesterol to serum high density lipoprotein cholesterol. LDL-C/HDL-C = ratio of serum low density lipoprotein cholesterol to serum high density lipoprotein cholesterol. See Table 1 for other abbreviations.

respectively ($P \leq 0.01$), and triglyceride levels were stable. Serum cholesterol and LDL-C did not change in the LF group, but triglycerides rose by 14% ($P = 0.056$). Both groups experienced a 4 mg/dL (0.10 mmol/L) decrease in HDL-C (time effect, $P \leq 0.01$). This modest reduction was due to changes in the cholesterol content of the HDL_3 subfraction (time effect, $P \leq 0.01$). The ratios of total cholesterol/HDL-C and LDL-C/HDL-C increased in the LF group ($P \leq 0.05$, $P = 0.058$, respectively) but were lowered by 0.05–0.11 in the LFMR group.

A reduction in serum apo A-I (time effect, $P \leq 0.01$) and apo B concentrations (time effect, $P \leq 0.05$) occurred in both groups (Table 5). Although results from the analysis of variance indicated an effect of time on the concentration of apo A-I, this was primarily due to the 13% decrease in serum values in the LF group ($P \leq 0.01$). In contrast, the LFMR group experienced a small but nonsignificant reduction in apo A-I concentration. Apo B concentrations were lowered to a similar extent in both groups, and the final mean values were within the normal range of 0.60–1.00 g/L. As a result of the changes in apo A-I and apo B concentrations, the ratio of apo A-I/apo B increased slightly in the LFMR group but decreased in the LF group.

DISCUSSION

The LFMR diet resulted in significant reductions in serum cholesterol and LDL-C. These results are in line with short-term studies in which controlled LF diets relatively high in MUFA reduced serum cholesterol by 7–15% and LDL–C by 11–16% in hyperlipidemic males and females (13–15). A seasonal effect on these variables was discounted since the LF group had no reduction in serum cholesterol or LDL-C. Our study demonstrates that free-living postmenopausal women are responsive to diet therapy, and that the LFMR diets elicit reductions in serum cholesterol levels similar to more controlled diets.

The hypocholesterolemic effects of the LFMR diet were underestimated by established predictive equations (47–50). These equations estimated a 3.4–4.0% decrease in serum cholesterol compared to the 10% reduction observed. Yet, when applied to the LF group, these formulas accurately predicted

TABLE 5
Concentrations of Serum Apolipoproteins in Subjects Before and After Following the LF and LFMR Diets (for 6 mon)[a]

	LF (n = 13)		LFMR (n = 12)	
	Before	After	Before	After
Apo A-I (g/L)[b,**]	1.90 ± 0.28	1.62 ± 0.28	1.70 ± 0.24	1.60 ± 0.37
Apo A-II (g/L)	0.48 ± 0.08	0.46 ± 0.12	0.43 ± 0.11	0.42 ± 0.09
Apo B (g/L)[b,*]	1.09 ± 0.18	0.98 ± 0.25	1.08 ± 0.16	0.99 ± 0.17
Apo A-I/Apo B	1.81 ± 0.53	1.75 ± 0.50	1.59 ± 0.26	1.61 ± 0.24

[a]Mean ± standard deviation. The mean concentration of each apolipoprotein was determined on a fasting serum sample and measured in triplicate. *$P \leq 0.05$, **$P \leq 0.01$.
[b]Time effect, ANOVA. Apo = apolipoprotein. See Table 1 for other abbreviations.

the reduction in serum cholesterol (1.8% vs. 1.4–1.5%, respectively). It is important to point out that the predictive equations account only for the influence of dietary cholesterol, SFA, and PUFA on serum cholesterol. Other components of the LFMR diet may have had an additional impact on serum cholesterol. Significant correlations were detected in the LFMR group between the change in serum cholesterol and changes in the amount of carbohydrate (r = –0.842, $P < 0.05$), % fat (r = 0.619, $P < 0.05$), amount of protein (r = –0.603, $P < 0.05$), and MUFA/fat (r = –0.572, P = 0.055). These correlations are largely consistent with the known cholesterol-lowering effects of a LF diet and of replacing SFA with MUFA. Additional factors such as the arginine, phytosterol, and fiber content of the LFMR diet were also analyzed to determine their possible influence on serum cholesterol. The low lysine/arginine ratio of the LFMR diet was expected to promote cholesterol-lowering, but the change in this ratio was not correlated with changes in serum cholesterol (r = –0.195) or LDL-cholesterol (r = –0.085). Phytosterols have been shown to lower serum cholesterol levels, presumably by inhibiting cholesterol absorption (51,52). The phytosterol content of foods has not been thoroughly studied; therefore, the nutrient database used in this study does not contain sufficient information to provide more than a crude approximation of the amount of phytosterols in subjects' diets. Based on information available, the phytosterol content of the LFMR diet appeared to increase (71 ± 42 vs. 147 ± 29 mg/d, $P < 0.001$), whereas the amount in the LF diet did not change (55 ± 40 vs. 41 ± 16 mg/d). It is doubtful whether the small increase in phytosterols influenced serum levels in the LFMR group, since other studies have shown the addition of 500–3400 mg/d of phytosterols is required to elicit significant reductions in serum cholesterol and LDL-C (51,52). Furthermore, no correlation was found between the change in dietary phytosterol content and the change in serum total cholesterol (r = –0.251) and LDL-C (r = 0.199) in the LFMR group. The fiber content in the LFMR diet also increased from 11 to 22 g/d. Peanuts contributed 2.4–4.5 g of dietary fiber to the LFMR diet, but <0.2 g was soluble fiber (38). Dietary fiber has been found to lower serum cholesterol when consumed in excess of 49 g/d as part of a LF diet, or when diets have been supplemented with 12–45 g of purified soluble fiber (53,54). The modest increase in dietary fiber in the LFMR diet did not correlate with changes in serum cholesterol (r = –0.365).

Participants in the study were free-living and as a consequence, food intake could not be strictly controlled. Both groups lowered energy intake below their baseline diets. The reduced energy intake by the LFMR group might account for their weight loss. It is interesting to note that both groups had similar reductions in energy intake, but only the LFMR group lost weight. Serum lipids can be influenced by weight loss, and a significant correlation was seen between changes in weight and cholesterol in the pooled data (r = 0.483). When the LFMR group was analyzed separately, no significant correlations were found between the changes in serum cholesterol and changes in weight (r = 0.545), even though final weights ranged from +2.0 to −5.5 kg of baseline. The influence of weight on serum cholesterol should not be dismissed entirely since the correlation was approaching statistical significance, but of more clinical relevance is the lack of significant correlation between changes in weight and serum LDL-C in the LFMR group (r = 0.397). Nevertheless, it is possible that an interaction between the LFMR diet and weight loss elicited the hypocholesterolemic effects. A linear regression was performed on the pooled data of both groups, and no interaction was found between the LFMR diet and weight change (P = 0.839). The main effect of the LFMR diet on changes in serum total cholesterol was significant (P = 0.045), but the effect of weight change was not (P = 0.185). With the relatively small sample size in this study, it is difficult to separate out the potentially confounding effects of modest weight loss, and it is possible that changes in weight had a slight effect.

Long-term consumption of the LFMR diet resulted in apo B levels within the normal range. Of interest in our experiment was the trend toward lower apo B values even in the LF group. Since the LFMR and LF groups reduced dietary fat, SFA, and cholesterol, the influence of diet modifications probably explains the similar changes in apo B, but seasonal variations cannot be ruled out.

The high MUFA content of the LFMR diet was expected to prevent an increase in serum triglycerides and a decrease in HDL-C and apo A-I, when total dietary fat and saturated fat were reduced. Serum triglycerides and apo A-I did remain stable in the LFMR group, but were adversely affected in the LF group. This suggests that the MUFA content of the LFMR diet attenuated the changes in serum triglycerides and apo A-I that are usually associated with LF-high carbohydrate diets.

This was also evidenced by the slight increase in apo A-I/apo B ratios in the LFMR group, in contrast to the downward trend in the LF group. The modest reduction in HDL-C after the LFMR diet is consistent with that reported for short-term controlled studies of LF diets containing 14–16% MUFA (13–16). It was expected that subjects would consume 16–19% MUFA, but the calculated content of the LFMR diet was only 14%. This was due to inconsistent consumption of canola and olive oils, and overall restriction of dietary fat. One study has shown that a LF diet containing approximately 17% MUFA from olive oil prevented reductions in HDL-C (15). If the LFMR subjects had consumed a higher proportion of MUFA, HDL-C levels might have been spared. Although a reduction in HDL-C is not desirable, this change was a reflection of the lower cholesterol concentration in the HDL_3 subfraction, rather than HDL_2. Epidemiological and clinical data indicate that the inverse relationship seen between HDL-C and premature atherosclerosis is stronger for HDL_2-C than for HDL_3-C (55,56). Because the concentrations of HDL_2-C and apo A-I did not change and the ratio of LDL-C/HDL-C showed a beneficial downward trend, the protective role of HDL was probably not compromised by the LFMR diet.

In summary, the LFMR diet was well tolerated and the high-oleic peanuts were easily incorporated into each subject's daily diet. This diet resulted in significant reductions in serum cholesterol and LDL-C and a trend toward improved lipid and apolipoprotein ratios. The hypocholesterolemic effects of the LFMR diet were greater than expected by predictive equations, which suggests that the use of high-oleic peanuts as the primary source of MUFA may be more advantageous than typical high-oleic oils or other vegetable oils. Furthermore, serum triglycerides, HDL_2-C, and apo A-I were not adversely affected by the LFMR diet. This study documents that free-living postmenopausal women can achieve improved serum lipid and apolipoprotein levels on self-selected LF diets high in MUFA.

ACKNOWLEDGMENTS

We extend our appreciation to the volunteers who participated in the study with such wonderful enthusiasm and diligence. The authors gratefully acknowledge Ronald Randles, Kristine Steible, Joseph Bloom, and James McClave for their assistance with the statistical analysis of the data. The high-oleic peanuts were generously supplied by the Department of Agronomy, University of Florida (Gainesville, FL). This study was supported in part by a grant from the American Dietetic Association Sports and Cardiovascular Nutritionist Practice Group and by special funding from the Institute of Food and Agricultural Sciences, University of Florida. Florida Agricultural Experiment Station Journal Series No. R-05281.

ABSTRACT: The effects of n-3 fatty acid supplementation in the form of fresh fish, fish oil, and docosahexaenoic acid (DHA) oil on the fatty acid composition of plasma lipid fractions, and platelets and erythrocyte membranes of young healthy male students were examined. Altogether 59 subjects (aged 19–32 yr, body mass index 16.8–31.3 kg/m^2) were randomized into the following diet groups: (i) control group; (ii) fish diet group eating fish meals five times per week [0.38 ± 0.04 g eicosapentaenoic acid (EPA) and 0.67 ± 0.09 g DHA per day]; (iii) DHA oil group taking algae-derived DHA oil capsules (1.68 g/d DHA in triglyceride form); and (iv) fish oil group (1.33 g EPA and 0.95 g DHA/d as free fatty acids) for 14 wk. The fatty acid composition of plasma lipids, platelets, and erythrocyte membranes was analyzed by gas chromatography. The subjects kept 4-d food records four times during the study to estimate the intake of nutrients. In the fish diet, in DHA oil, and in fish oil groups, the amounts of n-3 fatty acids increased and those of n-6 fatty acids decreased significantly in plasma lipid fractions and in platelets and erythrocyte membranes. A positive relationship was shown between the total n-3 polyunsaturated fatty acids (PUFA) and EPA and DHA intake and the increase in total n-3 PUFA and EPA and DHA in all lipid fractions analyzed. DHA was preferentially incorporated into phospholipid (PL) and triglyceride (TG) and there was very little uptake in cholesterol ester (CE), while EPA was preferentially incorporated into PL and CE. The proportion of EPA in plasma lipids and platelets and erythrocyte membranes increased also by DHA supplementation, and the proportion of linoleic acid increased in platelets and erythrocyte membranes in the DHA oil group as well. These results suggest retroconversion of DHA to EPA and that DHA also interferes with linoleic acid metabolism.

Lipids 32, 697–705 (1997).

Recent studies have demonstrated that increased intake of polyunsaturated fatty acids (PUFA) of the n-3 series, in particular eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), may have a favorable effect on serum lipids (1–3), platelet aggregability (4–6), and bleeding time (4) and thus could lead to a reduced risk of atherosclerotic vascular disease and thrombotic complications. Long-term consumption of fish leads to the increased incorporation of n-3 fatty acids into plasma lipids, erythrocytes, and platelets (7,8). After fish oil supplementation, increased content of EPA and DHA has been measured in plasma lipids (6,8–10) and platelet (11,12) and erythrocyte membranes (13,14) with the simultaneous decrease of arachidonic acid and docosatetraenoic acid content, but less is known about the effect of DHA supplementation alone. DHA is a major n-3 fatty acid of most fish, yet most commercial fish oils contain more EPA than DHA (15). The aim of the present study was to examine the long-term effects of the supplementation of three different sources of EPA and DHA on the incorporation of fatty acids in plasma lipids, erythrocyte membranes, and platelets in healthy young men. In particular, interest was focused on the effects of DHA-rich oil (without EPA), which has been shown to have a comparable hypotriglyceridemic effect with fish diet and fish oil supplementation (16).

SUBJECTS AND METHODS

Subjects. Altogether 59 healthy male students aged 19–32 yr participated in this study. Body mass index (BMI) ranged from 16.8 to 31.3 kg/m^2. One subject in the control and one in the fish diet group were excluded because of high plasma triglyceride (TG) levels (>2.5 mmol/L). One subject did not follow the fish diet and was excluded. One subject in the fish oil group was excluded because of low platelet counts in the beginning of the study ($35 \cdot 10^9$/L). Three subjects (one in the control, one in the fish diet, and one in the DHA oil group) missed the analysis of fatty acid composition. Thus, the final analysis included 52 subjects. In addition, erythrocyte sam-

Abbreviations: BMI, body mass index; CE, cholesterol ester; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; MUFA, monounsaturated fatty acids; PL, phospholipid; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TG, triglyceride.

ples from 13 subjects—7 in the control, 1 in the fish diet, 3 in the DHA oil, and 2 in the fish oil groups—and a platelet sample from 1 subject in the control group were discarded because of contamination during sample preparation.

Study design. The present study was part of a study to investigate the long-term effects of moderate amounts of n-3 fatty acids in different forms on plasma lipids and was carried out at the Department of Physiology, University of Kuopio (Kuopio, Finland). Detailed description of the study has been described elsewhere (16). The protocol was approved by the Ethics Committee of the University of Kuopio. The subjects were randomly allocated into one of the four diet groups: (i) control group; (ii) fish diet group; (iii) DHA oil group, and (iv) fish oil group. The subjects started the study stepwise with 2-wk intervals in three groups. The study period was 14 wk. The subjects visited the research unit four times: at baseline and after 4 wk, 9 wk, and 14 wk. Height was measured at baseline only and weight at every visit. Blood samples for laboratory measurements were taken at every visit after 12 h fasting.

Experimental diets and oil supplements. Subjects in the control group were asked to maintain their normal dietary habits and physical activities constant throughout the study. Subjects in the fish diet group consumed their fish meal at the University Restaurant every working day five times per week. The number of fish meals actually eaten was 4.3 ± 0.5 times per week which produced 0.38 g EPA, 0.08 g docosapentaenoic acid, and 0.67 g DHA per day. Fish used for meals were rainbow trout *(Oncorhynchus mykis),* Balting herring *(Clupea harengus),* and vendace *(Coregonus albula)*. Samples of cooked fish meals were taken every day. Meals containing same-fish species were pooled, and the fatty acid compositions of fish meals were analyzed. In the fish diet group, the intake of fish, except at the University Restaurant, was on an average 14 g/d, supplying 0.05 g EPA and 0.15 g DHA per day according to food records. The subjects in the DHA oil group took eight algae-derived DHA oil capsules/d (Martek Biosciences Corporation, Columbia, MD) supplying 210 mg DHA per capsule (1.68 g/d) in TG form. DHA oil capsules did not contain EPA or docosapentaenoic acid. Fish oil supplement (Bio-Marin, Pharma Nord ApS, Vojens, Denmark) provided 166 mg EPA, 19 mg docosapentaenoic acid, and 119 mg DHA per capsule (1.33, 0.15, and 0.95 g/d, respectively) as free fatty acids. Compliance was assessed by asking for the return of the unused capsules. Except for the oil supplement, the subjects in the DHA oil and fish oil groups were asked to maintain their normal food habits. Dietary fish intake in the DHA oil and fish oil groups during the study was 32 g and 26 g, respectively. At baseline, there were no significant differences in the dietary intake of arachidonic acid among the study groups (ranged from 0.14 to 0.22 g/d). Subjects in the fish oil group received 59 mg/d arachidonic acid from fish oil supplement.

Dietary records. Each participant kept a 4-d food record, using household measures, over three weekdays and one weekend day in the beginning of the study, and three times during the study. Food records were checked by a nutritionist. The intake of nutrients was calculated using the Micro-Nutrica dietary analysis program, based on the database of the Finnish Social Insurance Institute (17). In the results on the nutrient intake, data for each group are given at baseline (4 d) and for the whole study period based on the mean of 12-d food records.

Analysis of fatty acid composition of plasma lipids, platelets, and erythrocyte membranes. Blood samples for laboratory analyses were taken into EDTA-containing vacuum tubes after 12 h fasting. Plasma was separated by centrifugation and stored at −70°C until analyzed. In the analysis of the fatty acid composition of plasma lipids, samples were extracted with chloroform/methanol (2:1, vol/vol) (18), and the lipid fractions were separated by solid-phase extraction with an aminopropyl column (19). For fatty acid analysis of platelets and erythrocyte membranes, the blood samples were rotated at low speed (120 × *g* for 10 min at 4°C) to separate platelet-rich plasma. The platelets were separated by centrifugation at 2,000 × *g* for 15 min at 4°C and then washed with Tris-HCl buffer (pH 7.6, 172 mmol/L). Erythrocytes were washed with the same buffer and hemolyzed in the same diluted buffer (11 mmol/L). Erythrocyte membranes were prepared by centrifugation at 20,000 × *g* for 20 min at 4°C. Both platelet and erythrocyte membrane sediments were suspended in the Tris-HCl buffer (172 mmol/L) and stored at −80°C until analyzed. Lipids were extracted with chloroform/methanol and transmethylated with 14% boron trifluoride in methanol at +100°C for 1 h. Fatty acid methyl esters were analyzed with gas chromatography (HP 5890 Series II; Hewlett-Packard Company, Waldbronn, Germany) equipped with an HP-FFAP capillary column. The molar percentage proportions of fatty acids were calculated.

Statistical methods. Statistical analyses were carried out with the use of SPSS-PC (SPSS, Chicago, IL). The Kruskall-Wallis test was used to compare the between-group differences in the fatty acid composition values at baseline, and within group the changes in the fatty acid composition values from baseline to 14 wk. When the analysis indicated significant change ($P < 0.05$), the Mann-Whitney U-test was used to compare the values of the study groups to those of the control group.

RESULTS

The baseline characteristics of the subjects and the nutrient composition of the diets at baseline are presented in Table 1. Age, height, weight, and BMI were comparable among the study groups. There were no significant differences among the diet groups in the nutrient intake values based on the 4-d food record at baseline compared with those based on the 12-d food record during the study (three 4-d food records combined), except the intakes of total fat and monounsaturated fatty acids (MUFA) in the fish oil group which increased from 30.9 ± 5.7 to 33.7 ± 4.9% and from 11.0 ± 2.3 to 12.5 ± 2.5% of total energy, respectively, $P < 0.01$ in both. In addition, the intake of vitamin D decreased from 5.5 ± 2.6 to 3.9 ± 1.0 μg/d in the control group and increased from 5.1 ± 3.2

to 9.2 ± 1.8 μg/d in the fish diet group ($P < 0.05$ and $P < 0.01$, respectively).

Fatty acid composition. The fatty acid composition of plasma TG, cholesterol esters (CE) and phospholipids (PL), and platelets and erythrocyte membranes at baseline are shown in Tables 2–6, as well as the changes in the fatty acid values during 14 wk. The baseline levels of fatty acids in the plasma lipid fractions, erythrocyte membranes, and platelets did not differ among the diet groups.

No significant changes were observed in the fatty acid composition of the control group in either plasma lipids, platelets, or erythrocyte membranes during the study period.

Fatty acid composition of plasma lipids. In the fish diet, in DHA oil and fish oil groups, the amount of n-3 fatty acids increased significantly in TG, CE, and PL, and the amount of n-6 fatty acids decreased significantly in PL when compared with those of the control group. In the fish diet group, the proportions of dihomo-γ-linolenic acid in CE and PL and that of

arachidonic acid in PL decreased significantly. The DHA oil-supplemented subjects had significantly decreased values of γ-linolenic acid in CE and lower values of dihomo-γ-linolenic, arachidonic and docosapentaenoic acids in PL. Compared with the control group, the fish oil-supplemented subjects had significant increases in the proportions of docosapentaenoic acid in TG and PL and arachidonic acid in CE, and decreases in the proportions of γ-linolenic and dihomo-γ-linolenic acids in CE and oleic, linoleic, dihomo-γ-linolenic, and docosatetraenoic acids in PL (Tables 2–4, Fig. 1).

Quantitative amounts of EPA and DHA in plasma lipids. Quantitative amounts of EPA and DHA in plasma lipid fractions are presented in Tables 2–4. The 14-wk fish diet elevated most of the quantitative amounts of EPA in PL and CE and the amount of DHA in PL and TG. After DHA oil supplementation, the quantitative amount of DHA in plasma

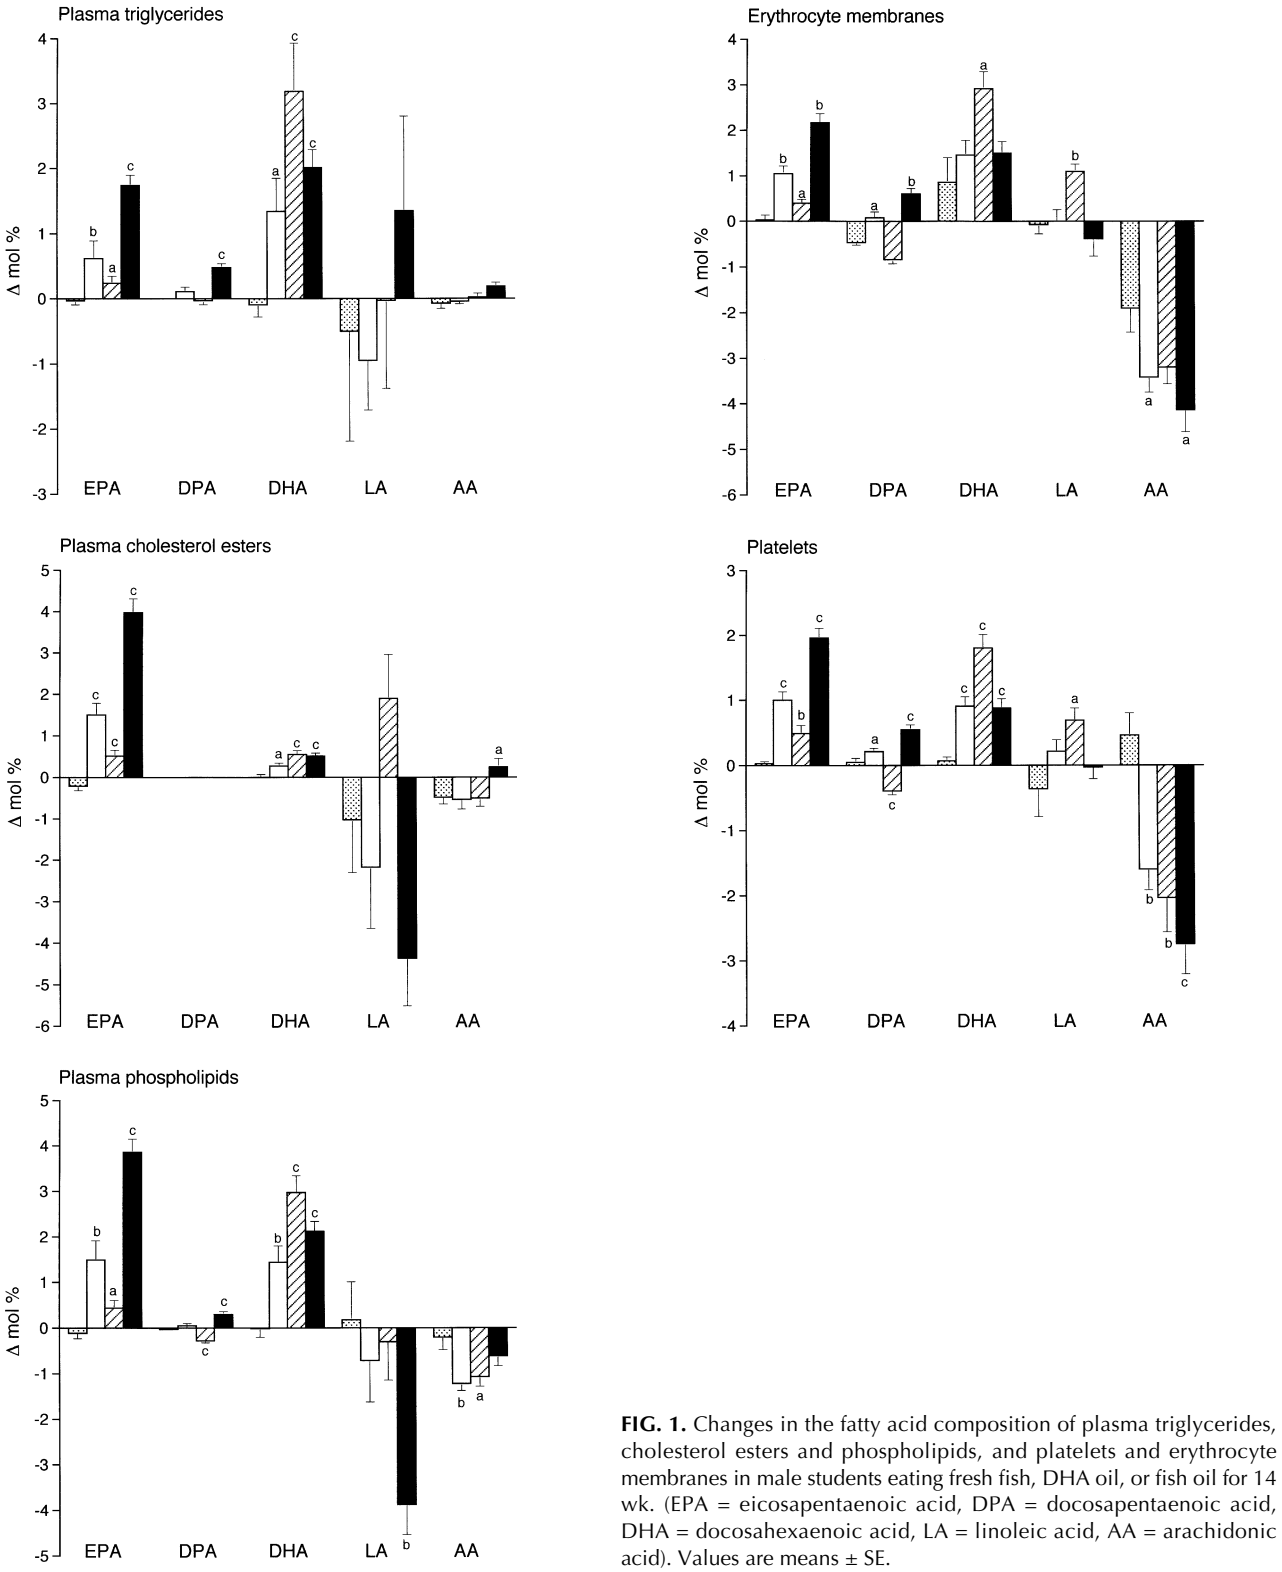

FIG. 1. Changes in the fatty acid composition of plasma triglycerides, cholesterol esters and phospholipids, and platelets and erythrocyte membranes in male students eating fresh fish, DHA oil, or fish oil for 14 wk. (EPA = eicosapentaenoic acid, DPA = docosapentaenoic acid, DHA = docosahexaenoic acid, LA = linoleic acid, AA = arachidonic acid). Values are means ± SE.

lipids increased more than that of EPA, and this increase was greatest in PL and TG. Fish oil supplementation induced the most marked increase of EPA in PL and CE, whereas the increase of DHA was most evident in PL and TG. Figure 2 indicates the relationship between the intake of EPA and DHA and their levels in plasma PL. The same relationship applies to plasma TG, and platelets and erythrocytes membranes, as well (data not shown). Also the dose-response curves calculated on the basis of the results are shown in Figure 2. It should be noted that there are small amounts of EPA and

[a]At baseline and the changes after 14 wk among the study groups. Values are means ± SD. Superscript letters a, b, c are significantly different from control group, $P < 0.05$, $P < 0.01$, $P < 0.001$, respectively. See Table 1 for abbreviations.

DHA derived from α-linolenic acid. Therefore, concentrations of EPA and DHA are clearly measurable even with zero dietary intake of these fatty acids. It seems that the response curves of EPA and DHA are steepest with low intakes of EPA and DHA, and the response curves follow logarithmic equations: the higher the intake the lower the proportional increase in concentration (Fig. 2).

Fatty acid composition of platelets. In platelets, the proportions of EPA and DHA were substantially increased mainly at the expense of arachidonic acid and docosatetraenoic acid in the fish diet, DHA oil, and fish oil groups (Table 5, Fig. 1). Also the proportion of docosapentaenoic acid increased in the fish diet and fish oil groups but was decreased by DHA oil supplementation. Both in the fish diet and fish oil groups the total proportion of MUFA and in the fish oil group the proportion of oleic acid increased significantly. In contrast to other groups, the proportion of linoleic acid increased in the DHA oil group.

Fatty acid composition of erythrocyte membranes. The proportions of EPA in erythrocyte membranes increased in the fish diet, DHA oil, and fish oil groups. The increase of DHA was statistically significant only in the DHA oil group (Table 6, Fig. 1). In the fish diet group, the proportions of arachidonic and docosatetraenoic acids were significantly decreased compared with those of the control group. The DHA oil group had a significantly increased proportion of linoleic acid and decreased proportion of docosatetraenoic acid. In the fish oil group, the proportion of docosapentaenoic acid increased and the proportions of dihomo-γ-linolenic, arachidonic, and docosatetraenoic acids decreased when compared with the control group.

The proportions of EPA and DHA in plasma PL correlated with those in platelets and erythrocyte membranes both at baseline (r = 0.50–0.72, $P < 0.001$ for EPA; and 0.52–0.65, $P = 0.001$ or less for DHA) and after 14 wk (r = 0.83–0.89; $P < 0.001$ and r = 0.40–0.78; $P = 0.015$ or less, respectively)

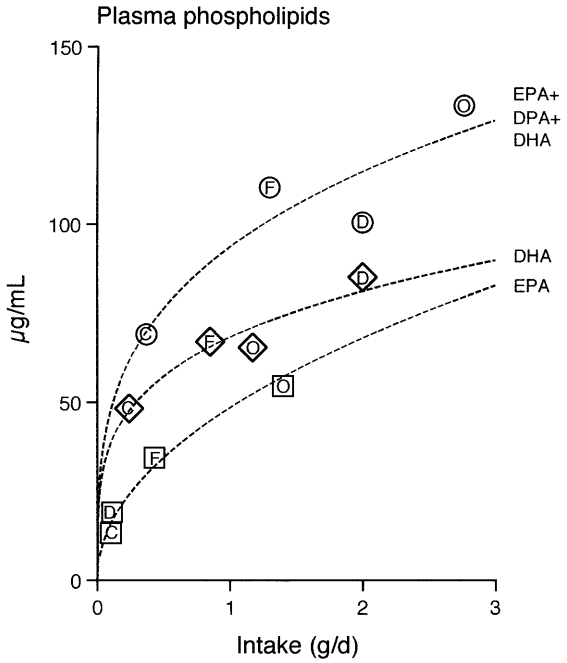

FIG. 2. Relationship between the total intakes (g/d) of EPA, DPA, and DHA (supplementation + dietary intake) and the concentrations in plasma phospholipids (μg/mL). C = control group, F = fish diet group, D = DHA oil group, O = fish oil group. See Figure 1 for other abbreviations.

among the study groups (study subjects pooled together). Correlations between the changes in the levels of EPA in plasma PL with those of EPA in erythrocyte membranes and platelets were $r = 0.91$, $P < 0.001$ and $r = 0.86$, $P < 0.001$, and the corresponding correlations between the levels of DHA were $r = 0.70$, $P < 0.001$ and $r = 0.77$, $P < 0.001$.

DISCUSSION

Fatty acid composition of the diet has a major impact on the fatty acid compositions in plasma lipids, platelets and erythrocyte membranes, but these fractions differ in their response to increased EPA and DHA intakes, as also shown in the present study when examining the effects of n-3 fatty acid supplementation, in the form of fresh fish, fish oil, and DHA oil, on the fatty acid composition of plasma lipid fractions, and platelets and erythrocyte membranes of young healthy male students. In the fish diet and fish oil groups, EPA was preferentially incorporated in plasma CE and PL, as shown in earlier studies, too (13,20,21). In contrast, the increase of DHA was greatest in plasma PL and TG in these groups, whereas only a small increase of DHA was seen in CE. This may be caused by the greater specificity of lecithin-cholesterol acyltransferase (LCAT) to EPA compared with DHA (21). Correlations between the fish intake of Finns (31 g/d in women and 37 g/d in men, respectively) and EPA content of serum CE ($r = 0.60$) and PL ($r = 0.52$) as well as in TG ($r = 0.36$), as reported by Nikkari and coworkers (22), support our results.

EPA and DHA levels in plasma PL have been used as an indicator of fish intake (23,24). Our study subjects were male students habitually consuming diets relatively low in fish products (26–35 g/d). The variability of EPA in plasma PL has been explained by habitual fish consumption, but fish consumption explains a lower proportion of variability in DHA in plasma lipids (25,26). Svensson and coworkers (27) found fourfold higher EPA and twofold higher DHA content of serum phosphatidylcholine in men who consumed fatty fish at an average of 1046 g/wk compared with men who did not consume fish at all. The proportions of both EPA and DHA correlated significantly with fish intake. In the present study, the increase of EPA in plasma PL was about 1.7 times greater compared with that of DHA in the fish diet and fish oil groups. The reason for this could be a more efficient liberation of DHA from chylomicrons (28), leaving more EPA in chylomicron remnants and thereby making more EPA available for PL synthesis in liver.

In addition, the data reported here suggest that the proportions of EPA in platelets reflect well the habitual fish intake over a long term. EPA in platelets (wt%), but not DHA, has been reported to correlate with habitual fish consumption (26). However, in our study the effect of increased DHA intake was seen in platelets, and the change correlated strongly with that of plasma PL. Thus, it is possible that DHA also reflects fish intake, but its less steep dose-response curve compared to EPA makes it more difficult to find strong correlations especially when intakes are estimated from questionnaires. In the fish oil group, the changes in the proportions of EPA and DHA in platelets and erythrocytes were similar as observed after 6-wk cod liver oil supplementation (29), but the change in the proportion of DHA in erythrocytes was greater in the present study. This stresses the importance of the duration of supplementation when erythrocytes are examined.

Our results indicate that the response curves are steepest with low intakes of EPA and DHA (Fig. 2). This view is supported by the results of Bønaa and coworkers (25) comparing plasma PL fatty acids and habitual fish intake, and also by the dose-response study with four different fish intake levels (30). In a dose-response study, the increase of EPA + DHA intake from 3 to 6 g/d caused a very modest increase in their amount in plasma PL compared with the effect of increasing the intake from 1.5 to 3 g/d (31), showing only a weak effect of very high doses. Thus, it seems that the dose-response curves for both EPA and DHA follow logarithmic equations. DHA intake alone does not increase the total amount of n-3 fatty acids as much as the combination of EPA, docosapentaenoic acid, and DHA. In addition, the results of the fish oil group suggest that the high amount of EPA in this product (EPA to DHA ratio 1.4) decreases the effect of DHA when compared with the fish diet group (EPA to DHA ratio 0.6). These results indicate that the relationship between the intake of EPA and DHA and their amounts in plasma and membranes is dependent on the ratio of these fatty acids in the diet, and a reliable equation cannot be calculated on the basis of these results. To apply plasma or membrane EPA and DHA levels for the estimation of fish intake, dose-responses should be determined

using different fish intake levels, and dose-responses for other n-3 fatty acid products should be determined separately.

Interestingly, DHA oil supplementation caused an increase in the proportion of EPA both in plasma lipid fractions and in platelets and erythrocyte membranes, although DHA oil did not contain EPA at all, and the intake of EPA from habitual diet was on average only 0.09 ± 0.04 g/d during the study. This gives evidence of retroconversion of dietary DHA to EPA. Retroconversion of DHA to EPA takes place in peroxisomes by Δ4 enoyl reductase and Δ3, Δ2 enoyl CoA isomerase enzymes (32,33). Retroconversion of DHA to EPA has also been documented in some human (13) and animal studies (34–37), and also *in vitro* (33,37,38). In these studies the increase of docosapentaenoic acid has also been noticed. Docosapentaenoic acid could be a result of a saturation of the DHA or a chain elongation of EPA or both (32,33). However, in the present study the amount of docosapentaenoic acid was unchanged in plasma TG; it decreased in plasma PL, and in platelets and erythrocyte membranes it decreased as much as EPA increased. The decrease of docosapentaenoic acid has also been reported in a short-term study by von Schacky *et al.* (8) in plasma and platelet PL in humans after high DHA ingestion. The decrease of docosapentaenoic acid in the DHA oil group may indicate that the increase of EPA after DHA supplementation is not caused solely by retroconversion but could be a consequence of decreased elongation of EPA as well.

In our fish diet group, a reduced level of arachidonic acid in plasma PL, platelets, and erythrocyte membranes was noticed compared with the control group. Earlier studies have demonstrated that fish consumption decreases the concentration of n-6 PUFA in plasma (26,39), and a negative correlation between fish intake and the proportion of arachidonic acid in serum lipids has been observed (40,41). Eskimos who have a diet high in n-3 fatty acids have low levels of arachidonic acid in serum lipids (7,42). Siess *et al.* (5) reported a considerably reduced arachidonic acid proportion in platelet PL after consumption of a mackerel diet with high doses of EPA (7–11 g/day for 8 d), but also an unchanged proportion of arachidonic acid in plasma (10,32) and platelet PL (10) has been reported. It has been speculated that an unaltered arachidonic acid proportion could be a consequence of transforming linoleic acid to arachidonic acid (40), and the reduced level of arachidonic acid in platelets, but not in serum PL or total serum lipids, could be due to a direct competition between arachidonic acid and n-3 fatty acids for acylation into PL (33).

An interesting finding in our study after DHA supplementation was that the proportion of linoleic acid increased in platelets and erythrocyte membranes and remained unchanged in plasma fractions. DHA has been noticed to decrease Δ6 desaturase activity in rats (43) and to inhibit Δ6 desaturase *in vitro* (44). Our results support these findings and suggest that the transformation of linoleic acid to its metabolites is decreased by DHA. In addition to this step, Δ6 desaturation is also involved in the pathway of DHA from docosapentaenoic acid *via* 24:5n-3 and 24:6n-3. Thus it is possible that the inhibition of this desaturase contributes to the observed increase of the proportion of EPA and linoleic acid and decrease of that of docosapentaenoic acid after DHA supplementation.

In conclusion, fish diet and fish oil supplementation increased the proportions of n-3 fatty acids in plasma lipids, platelets, and erythrocyte membranes. The most striking differences in the distribution of EPA and DHA were seen in plasma CE with preferential incorporation of EPA and in plasma TG with preferential incorporation of DHA. DHA supplementation increased also the proportion of EPA, but in contrast to fish diet and fish oil supplementation, the proportion of docosapentaenoic acid remained unchanged or even decreased in fractions analyzed. Another special aspect of DHA supplementation was the increased proportion of linoleic acid in platelets and erythrocytes. These results indicate that there are marked differences in the effects of EPA and DHA on the composition of plasma and membrane lipids.

Heneicosapentaenoate (21:5n-3): Its Incorporation into Lipids and Its Effects on Arachidonic Acid and Eicosanoid Synthesis

L.N. Larsen[a], K. Høvik[a], J. Bremer[a,*], K.H. Holm[b], F. Myhren[c], and B. Børretzen[c]

[a]Institute of Medical Biochemistry, University of Oslo, Blindern, 0317 Oslo, Norway, [b]SINTEF-Oslo, Blindern, 0314 Oslo, Norway, and [c]Norsk Hydro a.s. Research Centre, N-3901 Porsgrunn, Norway

ABSTRACT: 6,9,12,15,18-Heneicosapentaenoic acid (21:5n-3) (HPA), present in small amounts in fish oils, has been prepared by chemical elongation of eicosapentaenoic acid (EPA) and its biological properties compared with EPA and docosahexaenoic acid (DHA). All the double bonds of HPA are displaced one carbon away from the carboxyl group when compared to EPA. HPA is incorporated into phospholipids and into triacylglycerol in cell culture to a similar extent as EPA and DHA. HPA is a stronger inhibitor of the conversion of α-linoleic acid and dihomo-γ-linolenic acid to arachidonic acid (AA) in hepatoma cells than are EPA, DHA, and AA. HPA is a poor substrate for prostaglandin H synthase and for 5-lipoxygenase, but it inactivates prostaglandin H synthase as rapidly as do AA, EPA, and DHA. HPA inhibits thromboxane synthesis in isolated platelets as efficiently as EPA. EPA, HPA, and DHA are all weak inducers of acyl-CoA oxidase in hepatoma cells. Therefore, since fish oils contain only small amounts of HPA, it is unlikely that this fatty acid is of particular significance for the biological effects of these oils, possibly with the exception that it is a strong inhibitor of AA synthesis.
Lipids 32, 707–714 (1997).

Fish oils are known to contain very long n-3 polyunsaturated fatty acids, mainly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Small amounts of a third, 21-carbon chain length, n-3 polyunsaturated fatty acid, heneicosapentaenoic acid (HPA), has also been identified (1). The origin of this fatty acid is uncertain, but α-oxidation and decarboxylation of 7,10,13,16,19-docosapentaenoic acid (22:5n-3) have been suggested (2). Chemically it is an EPA elongated with one carbon in the carboxyl end. This elongation places the first double bond in the Δ6 position, which is different from that of both EPA (Δ5) and DHA (Δ4). This acid therefore is interesting both because it is found in nature and because it can be used to study the significance of the position of the double bonds in n-3 fatty acids.

The contribution of HPA to the biological effects of fish oils is unknown. Only in one study has synthetic HPA been shown to be a poor substrate of 5-lipoxygenase (3). Considering the many biological effects of fish oil and of its EPA and DHA, we found it of general interest to compare the biological properties of HPA with those of the more abundant EPA and DHA. In the present study, we have tested this fatty acid for its incorporation into phospholipids and triglycerides; we have also compared the effects of EPA, HPA, and DHA as substrates and inhibitors of PGH-synthase and 5-lipoxygenase, which initiate the synthesis of prostaglandins, thromboxane, and leukotrienes. We also have studied the effects of HPA on the conversion of linoleic acid (18:2n-6) to arachidonic acid (AA) in hepatoma cells. The first, rate-limiting enzyme in this conversion is Δ6 desaturase. In all the experiments, EPA and DHA have been included for comparison.

MATERIALS

[1-^{14}C] AA (50–60 mCi/mmol) and [1-^{14}C] linoleic acid (50 mCi/mmol) were obtained from Amersham Laboratories (Buckinghamshire, England). [1-^{14}C]Dihomo-γ-linolenic acid (40–60 mCi/mmol) was from New England Nuclear (Boston, MA). AA and other polyunsaturated fatty acids as well as reduced glutathione, hydroquinone, prostaglandin (PG)-/leukotriene standards, phenylmethylsulfonyl fluoride, trypsin inhibitor Type II-S: Soybean, ATP, and Tris were all purchased from Sigma (St. Louis, MO). EPA and docosapentaenoic acid were gifts from Norsk Hydro (Porsgrunn, Norway). 2,7-Dichlorofluorescein diacetate was from Eastman Kodak Company (Rochester, NY). Picofluor^{TM} 40 was obtained from Packard Instrument Company, Inc. (Groningen, The Netherlands). Dulbecco's minimum essential medium w 74500 mg/L, McCoys 5A medium, Ham's F10 medium, glucose, sodium pyruvate, ultroser and gentamicin, anti- PPLO (a concentrated preparation of the antibiotic Tylocine, used against pleuropneumonia-like organisms), fungizone, penicillin, and streptomycin were from Gibco (Grand Island, NY). Plastic culture dishes and bottles were obtained from Costar (Cambridge, United Kingdom).

Synthesis of all-cis-*6,9,12,15,18-heneicosapentaenoic acid* (Scheme 1).

General. All reactions, workup included, were carried out in the dark under nitrogen. The reactions were monitored by thin-layer chromatography; the following systems were used as eluent: ethyl acetate/hexane 1:4 (**I**), 1:6 (**II**), 4:96 (**III**), 1:1 containing 0.5% acetic acid (**IV**), and hexane saturated with acetonitrile (**V**). All standard reagents used were either from Fluka (Buchs, Switzerland) or Janssen (Acros Chimica, Grel, Belgium), the solvents were from Fluka or Merck (Darmstadt, Germany). Generally, solvents were removed at 10 mm Hg and finally under high vacuum for ≥2 h. Alcohol-free diazomethane was generated in a Mini Diazald Apparatus from Aldrich (Milwaukee, WI).

all-cis-*5,8,11,14,17-Eicosapentaenoyl chloride* (**2**). Oxalyl chloride (2.0 mL, 27 mmol) was added to a stirred benzene solution of *all-cis*-5,8,11,14,17-EPA (2.75 g, 9.1 mmol) kept at 20°C. After 1 h 30 min, volatile material was removed at reduced pressure. The evaporation was repeated twice with more anhydrous benzene (2 × 10 mL). The acid chloride **2**, obtained as a straw-colored oil, was dissolved in dry ether (16 mL) and used without purification in the next step.

all-cis-*Diazo-6,9,12,15,18-heneicosapentaen-2-one* (**3**)(Ref. 4). A solution of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (7.7 g, 35 mmol) in ether (70 mL) was added to a mixture of potassium hydroxide (4.2 g), water (7 mL), 2-(2-ethoxyethoxy) ethanol (22 mL) and ether (14 mL) kept at 65°C within 35 min. Additional ether (16 mL) was used as rinse. The ether was condensed and collected at −78°C, and the resulting etheral solution of diazomethane was quickly filtered through a wad of cotton.

The etheral solution of the acid chloride **2**, cooled to −5–0°C, was added within 1 min to a vigorously stirred solution of diazomethane (approximately 25 mmol) in ether (approximately 100 mL) kept on an ice bath. Dry ether (2 × 4 mL) was used as rinse. A brisk evolution of gas lasted for 10 min. After 20 min all volatile material was removed at 200–10 mm Hg and ≤0°C to give 2.88 g of crude product. Excess diazomethane was conveniently destroyed by means of a gas washing flask (with fritted disc) containing a small amount of acetic acid connected between the reaction flask and the pump.

Purification by flash chromatography (pyridine-treated silica 180 mL, ethyl acetate/hexane 1:9 800 mL, 1:6 200 mL; approximate elution volume 360–830 mL) afforded 2.60 g (88% from **1**) bright orange-colored diazoketone **3**. Infrared (IR); 3013, 2104, 1646 cm^{-1}.

Methyl all-cis-*6,9,12,15,18-heneicosapentaenoate* (**4**)(Refs. 5,6). A solution of silver benzoate (120 mg, 0.52 mmol) in triethylamine was added to a stirred solution of diazoketone **3** (2.0 g, 6.13 mmol) in dry methanol (10 mL) kept at room temperature within 1 h. The reaction was quenched by the addition of hydrochloric acid (1 N, 0.6 mL) and the solvents removed at room temperature under reduced pressure. The residue was partitioned between hexane (30 mL) and hydrochloric acid (1 N, 6 mL). The organic phase was washed with aqueous sodium bicarbonate (10%, 6 mL) and worked up to give 1.96 g crude ester. Purification by flash chromatography (silica 200 mL; ethyl acetate in hexane 2% 400 mL, 3% 600 mL, 4% 400 mL; approximate elution volume 320–770 mL) afforded 1.81 g (89%) of methyl ester **4** as a colorless oil. IR; 3013, 1742 cm^{-1}.

all-cis-*6,9,12,15,18-Heneicosapentaenoic acid* (**5**). The methyl ester **4** (1.70 g, 5.14 mmol) was saponified with guanidine hydrochloride (1.72 g, 18 mmol) and lithium hydroxide monohydrate (504 mg, 12 mmol) in 80% ethanol (20 mL) at room temperature. After 6 h the reaction mixture was washed twice with hexane (2 × 10 mL). The hexane fractions were washed successively with brine (5 mL) that was added with stirring to the reaction mixture, followed by hydrochloric acid (1 N, 30 mL). The free fatty acid was extracted with hexane (40 + 2 × 20 mL) and evaporated to give 1.46 g (90%) of the product **5** as a slightly flaxen oil. IR; 3013, 1709 cm^{-1}. ^1H nuclear magnetic resonance (NMR) (300 MHz, $CDCl_3$); δ; 0.98 (3H, *t*, CH_3), 1.45 (2H, *m*, CH_2), 1.65 (2H, *m*, CH_2), 2.1 (4H, *m*, CH_2-C=), 2.37 (2H, *t*, CH_2-CO), 2.82 (8H, *m*, =C-CH_2-C=), 5.35 (10H, *m*, CH=CH). ^{13}C NMR (75 MHz, $CDCl_3$); δ; 179.92 (CO), 131.89, 129.43, 128.42, 128.18, 128.09, 127.98, 127.91, 127.08, 127.74, 126.88 (C=C), 33.83, 28.85, 26.71, 25.51, 25.41, 24.14, 20.43 (CH_2), 14.14(CH_3).

The conversion of EPA to HPA by this procedure was performed with an all-over yield of approximately 70%.

Cell culture. 7800 C1 Morris hepatoma cells were cultivated mainly as described by Richardson *et al.* (7). They were grown

to confluence in Ham's F 10 medium supplemented with 10% horse serum and 3% calf serum. The medium was supplemented with penicillin (50 U/mL), streptomycin (50 µg/mL), fungizone (2.5 µg/mL), and anti-PPLO (60 µg/mL), and changed every 48 h. The cells were harvested in 1–2 mL phosphate-buffered saline (PBS) by using a rubber policeman.

Rat hepatocytes were prepared from male Wistar rats (350 g), obtained from Møllegaard Breeding Center (Ejby, Denmark). After barbiturate anesthesia, liver parenchymal cells were isolated as described by Berry and Friend (8) with modifications according to Seglen (9). The hepatocytes were plated in 6 × 15 mm culture dishes overnight in DME medium containing HEPES (20 mM), Ultroser G (2%), and gentamicin (50 µg/mL) at a cell density of approximately 2 million cells/dish (1–1.5 mg cell protein) in a volume of 6 mL. The cells were incubated at 37°C in 5% CO_2 and 95% air for 18–20 h before use.

Mouse peritoneal macrophages were isolated mainly as described by Stuart (10) and cultivated in McCoys 5A medium, containing 20 µM fatty acid and 1% fetal calf serum, for 3–18 h.

ASSAY METHODS

Isolation of phospholipids and triacylglycerol. Lipids were extracted from harvested cells twice with butanol (1 mL butanol per 2 mL water phase)(11). L-α-Phosphatidylcholine-di-heptadecanoyl (44 µg) was added as internal standard. The butanol was evaporated under a stream of nitrogen, and the residues were dissolved in chloroform containing 1 mg of butylated hydroxytoluene as antioxidant. Each sample was then subjected to anion-exchange chromatography on bonded-phase columns (12), to yield triacylglycerol and phospholipid fractions.

Gas chromatography of fatty acids. Fatty acids were transmethylated (13) and separated by capillary gas chromatography on a 50 m × 0.22 mm BP1-polyimide coated fused-silica capillary column, film thickness 0.25 µm (SGE M9 column; S.G.E. International, Ringwood, Victoria, Australia) using a Shimadzu GC-14A model gas chromatograph (Tokyo, Japan), fitted with a 3390 A Hewlett-Packard integrator (Palo Alto, CA). Helium at 2.5 kg/cm^2 was used as carrier gas, and the split/splitless injector was used in the split mode with a ratio of 60:1. After sample injection, the temperature was initially held for 5 min at 140°C, then programmed to increase with 4°/min to 250°C and held there for 30–45 min. Amounts of fatty acids were calculated by using the internal standard method and previously determined response factors.

Conversion of 1-^{14}C linoleic- and 1-^{14}C dihomo-γ-linolenic acid. Confluent 7800 C_1 Morris hepatoma cells in 6-cm (diameter) dishes were incubated with [1-^{14}C]linoleic acid (50 µM) and inhibitory fatty acids (50 µM) for 18 h. Cells were then washed with PBS and harvested in 2 mL PBS. The lipids were extracted and methylated as described in the paragraph on gas chromatography and run on high-performance liquid chromatography (HPLC) (model SP 8800 with a Spectra 100 variable wavelength detector and a Raytest Ramona 5 LS liquid-scintillation counter with a 1.0 mL flow cell on line; Spectra-physics). The dry residues were dissolved in 0.2 mL 80% acetonitrile and injected on a 4.6 × 250 mm column containing 5 µm Supelco RP-18 (Bellefonte, PA). Linoleic acid (and dihomo-γ-linolenic acid) was separated from AA by running 80% acetonitrile for 30 min, with a flow rate of 2 mL/minute.

The inhibition of the Δ5 desaturation step was assayed by incubation of hepatoma cells with [1-^{14}C]dihomo-γ-linolenic acid instead of linoleic acid as above. The incubation time was 4 h.

The Δ6 desaturation step was assayed in isolated rat liver microsomes as described by Christiansen *et al.* (14). Microsomal protein (1.0 mg) was incubated for 15 min at 37°C with 25 µM [1-^{14}C]linoleic acid, with or without inhibitory fatty acid (25 µM). The incubation was stopped by addition of 1.0 mL of 15% KOH in methanol followed by heating at 65°C for 45 min. The samples were acidified with 6.0 N HCl and extracted with 3.0 mL of hexane. The hexane was evaporated under nitrogen and the residues were dissolved in 1.0 mL benzene. To methylate the fatty acids, 1.0 mL of methanol-HCl was added to extracted lipids dissolved in 1 mL of benzene and left for 30 min in a water bath at 37°C using capped tubes. The methylated fatty acids were extracted with 2.0 mL of hexane and assayed on HPLC as above.

PGH-synthase. Sheep seminal vesicles were obtained from a local slaughterhouse and stored at −70°C. Microsomal prostaglandin synthase was prepared as described by Egan *et al.* (15). The crude enzyme was stored in small batches at −70°C in 0.1 M potassium phosphate buffer (pH 7.5) (40 mg protein/mL). The enzyme was diluted 1:1 with 0.4% Triton X-100 before use.

Assay by oxygen consumption was recorded with a Clark oxygen electrode (MSE Scientific Instrument, Crawley, Sussex, England) in 0.1 M Tris buffer (2 mL, pH 8) with 0.33 mM glutathione and 0.5 mM phenol at 30°C. Reaction was started by addition of either fatty acid or enzyme (63 µg protein). Oxygen concentration in the buffer in equilibrium with air was assumed to be 221 nmoles O_2/mL at 30°C (16). Based on the stoichiometric reaction of 2 moles of O_2 per mole of fatty acid, the amount of fatty acid consumed during the reaction was calculated.

Assay by cosubstrate oxidation was based on the oxidation of leuco-dichlorofluorescein as reducing cosubstrate in the conversion of AA to PGH_2 as previously described (17).

Thromboxane B_2 production. Human blood platelets were isolated from volunteers essentially as described by Lagarde *et al.* (18). The volunteers had not taken any drugs for at least 10 d. AA (final concentration 10 µM) was used as an inducer of thromboxane production (19), and the reaction was stopped by centrifugation. Thromboxane B_2 produced was measured with an enzyme immunoassay kit (Cayman Chemical, Ann Arbor, MI) (20).

5-Lipoxygenase. RBL-1 cells were grown in suspension culture essentially as described by Kulczycki *et al.* (21). Cells were harvested and 5-lipoxygenase isolated as described by Haurand and Flohe (22). 5-Lipoxygenase activity was measured as oxygen consumption, monitored by a Clark oxygen electrode as described for cyclooxygenase.

The oxygraph chamber (2 mL) contained 8 mM ATP, 3 mM $CaCl_2$, 3 mM reduced glutathione, 50 mM Tris (pH 7.5) and enzyme (5×10^7 cell equivalents). Fatty acid was added as substrate (100 µM final concentration), and oxygen consump-

tion was followed for 2–3 min. The initial reaction rate was estimated from the initial slope of the oxygraph curve.

After incubations with [1-^{14}C] AA, analysis by reversed-phase HPLC (see later) showed formation of 5-hydroxyeicosatetraenoic acid (5-HETE) and 5,12-dihydroxyeicosatetraenoic acid (5,12-diHETE). No PGH-synthase products were detected.

5-Lipoxygenase products. The 5-lipoxygenase (2.5×10^6 cell equivalents) was incubated as above (22) with 20 µM [1-^{14}C]AA at 37°C and with or without 50 µM DHA, EPA, or HPA to study their inhibitory effects on conversion of radioactive AA. The reaction was stopped after 10 s by adding 500 µL acetone + two drops of HCOOH. The reaction products were extracted with $CHCl_3$. The chloroform was evaporated under a stream of N_2, and the dry residues were stored at –20°C until analyzed by reversed-phase HPLC.

The dry residues were dissolved in 0.1 mL of methanol/water (3:1, vol/vol)(see below), and injected on a 4.6×250 mm column containing 5 µm Supelco RP-18. (HPLC system, see earlier mention). Separation was achieved by running a 30-min linear gradient from 75 to 100% methanol (25–0% water containing 0.1% acetic acid, adjusted to pH 5.4 with ammonia) at a flow rate of 1 mL/min. EDTA was added to the eluent at 1 mM concentration. Unlabeled standards (10 µg), added to the samples, were detected at 236 nm (23). The retention time of 5,12-diHETE was 6–7 min, 5-HETE/5-hydroperoxyeicosatetraenoic acid (5-HPETE), 14–15 min, and AA, 24–25 min. To separate PGH-synthase products, a gradient from 60 to 100% methanol was used. Ultraviolet absorption at 206 nm was recorded. The ratio of eluent to scintillation fluid was set at 1:7 (vol/vol).

Other assays. Palmitoyl-CoA oxidase activity was measured essentially as described by Small *et al.* (24) with minor modifications (25). Protein was measured by the method of Lowry (26). Cellular DNA was measured according to Labarca and Paigen (27).

Statistics. Ordinary one-way analysis of variance (ANOVA) was performed and separate *P* values were calculated by Student's *t*-test.

RESULTS

Incorporation into phospholipids and triglycerides. Long-chain n-3 fatty acids normally are found in the phospholipids. We have studied the incorporation of HPA, compared to EPA and DHA, into hepatocyte phospholipids and triglycerides. Neither HPA, EPA, nor DHA had any observable toxic effects on the hepatocytes under the conditions used (fatty acid/albumin ratio, approximately 2.5:1).

Table 1 shows that the amounts of incorporated EPA, DHA, and HPA are similar. Under the conditions used, the incorporation is higher in triglycerides than in the phospholipids. A decrease of the oleic acid (18:1n-9) and linoleic acid (18:2n-6) content is observed in the phospholipids, whereas only oleic acid is decreased in the triglycerides after the treatment. Analyzing the changes in oleic acid content in phospholipids and triglycerides with the ANOVA test gave a *P* value of 0.0002 for oleic acid in phospholipids and 0.0001 in triglycerides which showed that the variation among column means was significantly greater than expected by chance. Also the variation in 18:2n-6 in phospholipids after treatment with fatty acids was significant with a *P* value of 0.0001. The other fatty acids are not significantly changed ($P > 0.05$). Also in 7800 C1 hepatoma cells (not shown), HPA was incorporated to a similar extent as DHA, while EPA was less incorporated. In hepatoma cells, all three fatty acids were incorporated mainly at the expense of AA (20:4n-6).

Other experiments showed that HPA, EPA, and DHA also are incorporated to a similar extent into mouse peritoneal macrophage-phospholipids (not shown).

Effect on linoleic acid conversion to AA. Feeding fish oils decreases the Δ6 desaturation of linoleic acid and its conversion to AA (14). Table 2 shows that HPA decreases the conversion of both linoleic acid and dihomo-γ-linolenic acid to AA even more than EPA and DHA in hepatoma cells. ANOVA test gave very

TABLE 2
Inhibition of Δ6 and Δ5 Desaturase Activity by 20:4n-6, 20:5n-3, 21:5n-3, and 22:6n-3[a]

Inhibitor	Microsomes 18:2 ⇒ 18:3[b]	Hepatoma cells 20:3 ⇒ 20:4	18:2 ⇒ 20:4[c]
Control	8.2 ± 0.6	10.2 ± 0.6	13.3 ± 0.5
20:4	7.6 ± 0.8[a]	4.9 ± 0.1**[bb]	6.1 ± 0.5**[bb]
20:5	5.6 ± 0.1*	4.9 ± 0.4**[b]	3.1 ± 0.4**[b]
21:5	6.7 ± 1.0	3.3 ± 0.3**	1.4 ± 0.4**
22:6	6.6 ± 0.4[a]	6.7 ± 0.7*[bb]	2.8 ± 0.1**[b]

[a]The enzyme activity of Δ6-desaturase (18:2 ⇒ 18:3) was measured in isolated rat microsomes, as γ-linolenic acid produced [percentage of added [1-^{14}C]-linoleic acid (18:2n-6)]. The activity of Δ5 desaturase (20:3 ⇒ 20:4) was measured in hepatoma cells as arachidonic acid (20:4n-6) produced (percentage of incorporated [1-^{14}C]-dihomo-γ-linolenic acid (20:3n-6)). The conversion of 18:2n-6 to 20:4n-6 was measured in hepatoma cells as arachidonic acid produced—percentage of incorporated [1-^{14}C]-linoleic acid (see Assay Methods section). The uptake of linoleic acid or dihomo-γ-linolenic acid into the cell lipids was not changed by the added unlabeled fatty acids. Each value is the mean of three replicates ± SD; *$P < 0.005$, **$P < 0.001$ vs. control; a: $P < 0.01$ vs. 20:5. b: $P < 0.005$, bb: $P < 0.001$ vs. 21:5.
[b]Percentage of 18:2 added to the reaction mixture.
[c]Percentage of substrate taken up by the cells.

significant *P* values for all three columns. In three different experiments on the conversion of linoleic acid to AA, we observed increased accumulation of dihomo-γ-linolenic acid in the hepatoma cells incubated with inhibiting n-3 fatty acids. This accumulation was most pronounced with HPA, but accurate quantification was not possible. The conversion of dihomo-γ-linolenic acid involves only Δ5 desaturase. The Δ6 desaturase cannot be assayed separately in intact cells because of subsequent elongation and Δ5 desaturation. The effect on this step therefore was measured in isolated microsomes (Table 2, column 1). In this assay, HPA showed only insignificant inhibition. Only EPA gave a moderate but significant inhibition compared to control.

PGH-synthase. PGH-synthase has two enzyme activities: cyclooxygenase which consumes two moles of O_2 per mole AA, and a peroxidase which reduces a perhydroxy group into a hydroxyl group with concomitant oxidation of a reducing cosubstrate. We have measured these two enzyme activities by two separate methods. The activity of the cyclooxygenase part was measured as O_2 consumption. Table 3 shows that EPA is only half as good a substrate as AA. DHA and HPA are poor substrates. We obtained an almost identical relative substrate specificity by using the spectrophotometric assay of cosubstrate oxidation (not shown).

Figure 1A shows that EPA, HPA, and DHA are weak competing substrates/inhibitors of cyclooxygenase, when added concomitant with AA (ANOVA: $P = 0.0001$). However, when the enzyme is preincubated with these fatty acids for 30 s under the same conditions before AA is added, EPA inactivates the enzyme almost completely. HPA, DHA, and AA were weaker as inactivators (Fig. 1B). An ANOVA test showed that the variations among the means were significantly greater than expected by chance with a *P* value of 0.0001.

In the absence of reducing cosubstrate, the inactivation is much more rapid (28). Figure 2 shows that as little as 1 μM AA gave about 50% inactivation of the enzyme after 30 s. HPA, EPA, and DHA gave an even stronger inactivation than did AA. ANOVA test showed that a significant inhibition was obtained, giving a P value of 0.001.

Figure 3 shows how HPA, EPA, and DHA inhibited thromboxane production in isolated human blood platelets in five experiments, calculated as percentage of the formation with AA alone. This was confirmed by a *P* value of 0.0001 by the ANOVA test. All the n-3 fatty acids inhibited in every experiment, but the amounts of thromboxane B_2 formed with AA alone varied from one individual to the other in the range 324–1460 pmoles thromboxane B_2 (3×10^8 platelets).

TABLE 3
Substrate Specificity of Cyclooxygenase and 5-Lipoxygenase[a]

Fatty acid	Cyclooxygenase[b] 30 μM	Cyclooxygenase[b] 60 μM	5-Lipoxygenase[b] 100 μM
20:4	439.6 ± 26.7	563.9 ± 33.5	134–141
20:5	109.5 ± 2.5***	260.2 ± 29.4***	149–145
21:5	27.1 ± 7***	26.6 ± 0	8–7
22:6	28.3 ± 3	42.8 ± 5.4	24

[a]The cyclooxygenase-catalyzed reaction (crude prostaglandin H-synthase) was started by adding fatty acid to a final concentration of 30 or 60 μM, and the oxygen consumption was monitored for 2 min (see Assay Methods section). The results are presented as mean of three replicates ± SD. Crude 5-lipoxygenase (5×10^7 cell equivalents) was incubated as described in the materials and Assay Methods sections. Each of the two replicates is presented in the table. ***$P < 0.001$ vs. 20:4.
[b]O_2 uptake (nmole/min).

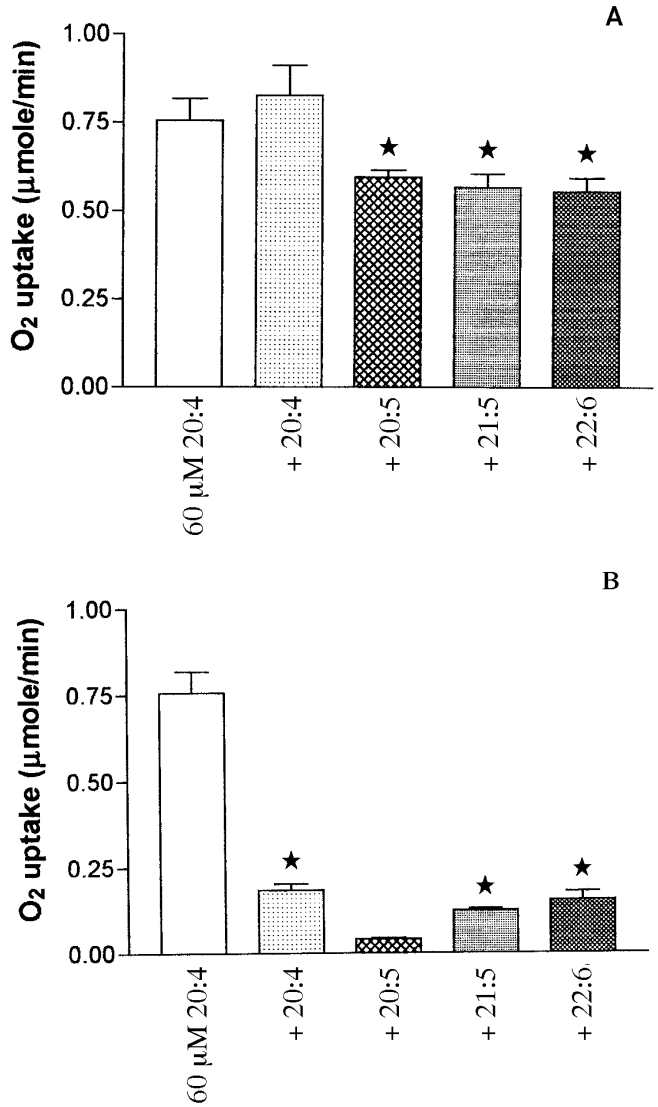

FIG. 1. n-3 Fatty acids as inhibitors/competing substrates of cyclooxygenase, measured as oxygen uptake. Reaction conditions were the same as in Table 2, using crude PGH-synthase as enzyme. A: Arachidonic acid (AA) (20:4n-6) [final concentration (conc.): 60 µM] and n-3 fatty acid (or extra AA), final concentration: 30 µM, were added simultaneously, and initial reaction rate was measured. *: $P < 0.05$ vs. control. B: Cyclooxygenase was preincubated without or with AA or n-3 fatty acid (30 µM, final conc.), 30 s before the addition of AA (final conc.: 60 µM) and measurement of reaction rate; *$P < 0.05$ vs. 20:5. Each bar represents the mean of three replicates ± SD.

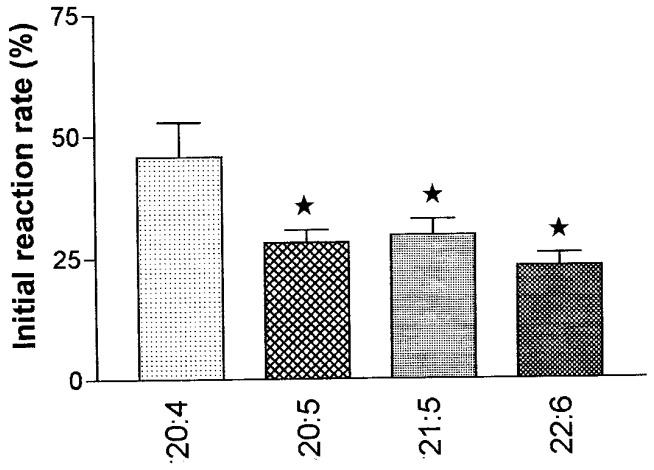

FIG. 2. n-3 Fatty acids and AA as inactivators of PGH-synthase, measured as oxidation of reducing cosubstrate. Crude PGH-synthase (25 µg protein) in 1 mL 0.1 M Tris (pH 8.0) was incubated with 1 µM (final conc.) AA or n-3 fatty acid. After 30 s, AA (final conc. 20 µM), leuco dichlorofluorescein diacetate (1DCF) (final conc. 20 µM) and phenol (final conc. 0.4 mM) were added. Each bar indicates the mean of three replicates ± SD. Results are presented as percentage of the initial change in o.d. at 502 nm with 20 µM (final conc.) AA as substrate. *$P < 0.01$ vs. 20:4. See Figure 1 for abbreviation.

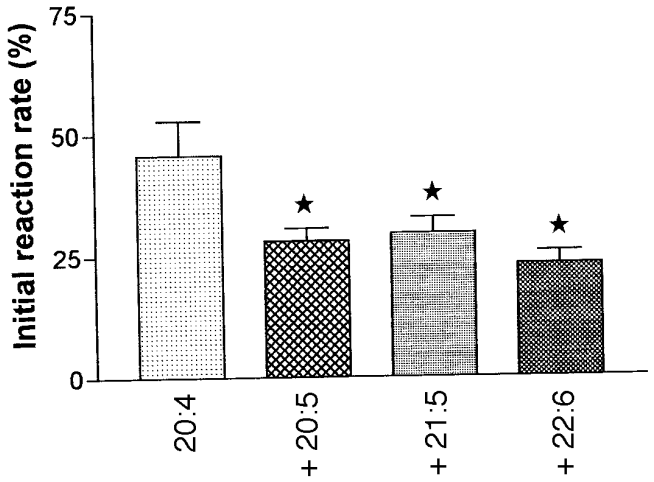

FIG. 3. Inhibition of thromboxane B_2 (TxB_2) production in isolated human blood platelets by preincubation with n-3 polyunsaturated fatty acids. For inhibition studies, 10 µM (final conc.) eicosapentaenoic acid (EPA) (20:5), heneicosapentaenoic acid (HPA) (21:5), or docosahexaenoic acid (DHA) (22:6) were added to the platelet suspension 30 s before addition of AA (final conc.: 10 µM). After 4 min incubation, the production of TxB_2 was estimated by enzyme immunoassay (see assay procedure). In each experiment the amount of TxB_2 produced with AA alone as substrate is set at 100%. Inhibition of TxB_2 production is calculated as percentage of TxB_2 produced with AA. [2–62 pmole TxB_2 was measured in (unstimulated) control platelets (3×10^8)]. Each bar represents the mean of five experiments ± SD. *$P < 0.01$, **$P < 0.001$ vs. 20:4. See Figure 1 for other abbreviation.

5-Lipoxygenase. Table 3 shows, as previously reported (3,29–31), that EPA and AA are about equal as substrates for 5-lipoxygenase, while HPA, like DHA, is a poor substrate. Like PGH-synthase, 5-lipoxygenase is an autoinactivating enzyme (32). We therefore tested whether EPA, HPA, DHA, and AA inactivate 5-lipoxygenase. All these fatty acids inactivated the enzyme only to a moderate extent, both when 5-HETE + 5-HPETE and 5,12-diHETE were measured (not shown).

Induction of acyl-CoA oxidase. Figure 4 shows that acyl-CoA oxidase activity increases threefold in hepatoma cells

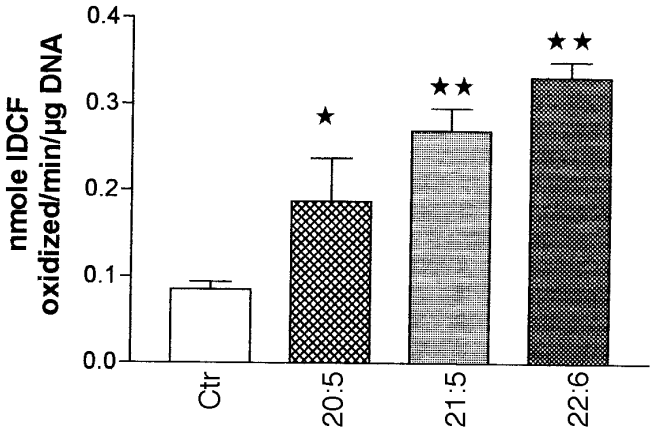

FIG. 4. EPA (20:5), HPA (21:5), and DHA (22:6) as inducers of acyl-CoA oxidase in 7800 C1 hepatoma cells. Confluent hepatoma cells were grown with 80 µM (final conc.) n-3 fatty acids in the medium for 3 d, and the acyl-CoA oxidase was measured with palmitoyl-CoA as substrate (see assay methods). The results are presented as mean of three replicates ± SD. Enzyme activity is expressed as nmoles of oxidized leuco-dichlorofluorescein diacetate (IDCF) per minute and per µg DNA; $^{*}P < 0.05$, $^{**}P < 0.001$ vs. control. See Figures 2 and 3 for abbreviations.

grown for 3 d with 80 µM DHA in the medium. The ANOVA test gave a P value of 0.0001. Student's t-test showed that DHA is a stronger inductor of acyl-CoA oxidase than EPA and HPA ($P < 0.05$), but these acids are all weak inducers compared, e.g., with 3-thia fatty acids (25).

DISCUSSION

Biological effects of fish oils are usually ascribed to their content of EPA and DHA which reduce the content of AA in phospholipids, both by direct incorporation and by inhibition of its synthesis. Since PG and leukotrienes are formed mainly from AA liberated from phospholipids, n-3 fatty acids presumably influence the formation of PG and leukotrienes by inhibiting AA synthesis, by substituting for AA in the phospholipids, and by competing with AA as substrates or inactivators in prostanoid formation.

In the present study we have therefore compared HPA, EPA, and DHA as inhibitors of AA synthesis, as precursors of (phospho)lipids, and as substrates and/or inhibitors of PGH synthase and 5-lipoxygenase, which are key enzymes in the formation of eicosanoids. Previously, HPA has been included only in a study on the substrate specificity of 5-lipoxygenase (3). Our experiments can be seen as a study on the specificity of the different enzyme systems with regard to chain length and position and number of double bonds of the fatty acids. The incorporation of EPA, HPA, and DHA into phospholipids and triglycerides shows that the involved enzymes exhibit low specificity with regard to these fatty acids. They are incorporated equally well, mainly at the expense of oleic acid in hepatocytes. In hepatoma cells they are incorporated at the expense of AA. Our most striking observation is that HPA gave a 90% inhibition of AA synthesis from linoleic acid, whereas AA gave only 50% inhibition, and EPA and DHA showed effects between these.

During conversion of linoleic acid to AA, an increase in dihomo-γ-linolenic acid was observed on the HPLC chromatograms when HPA was used as inhibitor, compared to the other fatty acids (not shown). This indicates that the activity of Δ5 desaturase was inhibited. Analyzing the inhibition of the separate desaturase activities (admittedly under nonidentical conditions), in this conversion of linoleic acid to AA, showed that HPA inhibited Δ5 desaturase strongest whereas EPA was the most potent, but relatively weak inhibitor of the microsomal conversion of linoleic acid to γ-linolenic acid. HPA inhibited the conversion of linoleic acid to AA more efficiently than the desaturation of dihomo-γ-linolenic acid (Table 2, columns 2 and 3). It is a possibility therefore that HPA also inhibits the activity of the elongase which catalyzes the elongation of 18:3 to 20:3. From the results obtained, it looks as if Δ5 desaturase is the main inhibition site for HPA on the conversion of linoleic acid to AA. It is paradoxical that HPA, a fatty acid with a Δ6-double bond, seems more inhibitory on the Δ5 desaturase than AA and EPA which have the first double bond in the Δ5 position. In this connection it is interesting that petroselinic acid (Δ6 monounsaturated octadecaenoic acid) in feeding experiments decreases the level of AA in liver (33), again suggesting an inhibition by the Δ6 double bond on the conversion of linoleic acid.

In yeast, a Δ9 double bond is significant in an inhibition of the Δ9 desaturase (34). Both oxygen uptake and oxidation of reducing cosubstrate show that the PGH-synthase has a high specificity for AA.

According to Evans and Sprecher (35), hydrogen is removed from C_{10} by 12-lipoxygenase and from C_{13} by cyclooxygenase but only in fatty acids where the hydrogen is located at the center of a 1,4-*cis,cis*-pentadiene or a 1,4-pentadiyne system. Hydrogen is removed from C_7 by 5-lipoxygenase. Both AA and EPA have this configuration at C_7 and C_{13}.

However, the introduction of one more double bond in the n-3 position reduces the ability of EPA to be a substrate for PGH-synthase, but not for 5-lipoxygenase. Elongation with one more carbon at the carboxyl end moves the removable hydrogen to the 11- and 14-positions. This combined with the n-3 double bond almost abolished the ability of the acid to be a substrate both for PGH-synthase and for 5-lipoxygenase. Further elongation to DHA made little difference.

However, the preincubation studies on PGH-synthase showed less specificity in the ability of the fatty acids to inactivate this suicidal enzyme. This inactivating effect may be the explanation for the ability of all the n-3 fatty acids to inhibit thromboxane synthesis in platelets (in preincubation experiments). This may contribute to the antithrombotic effect of EPA and DHA, and this effect is probably also shared by HPA.

A discrepancy between the ability to act as substrates and to act as inhibitors is observed also with 5-lipoxygenase. There is evidently a high specificity for chain length and position of double bonds in the reaction. However, all the n-3 fatty acids inhibited the conversion of [1-^{14}C]AA to a simi-

lar extent, suggesting that AA and the n-3 fatty acids all have a similar affinity for the enzyme.

Conclusion. In phospholipid synthesis, the enzymes do not distinguish well between EPA, HPA, and DHA. In AA synthesis, an elongation of EPA to HPA increases the inhibition of the Δ5 desaturase. The ability to act as substrate for PGH-synthase and 5-lipoxygenase is nearly abolished, but the ability to inactivate PGH-synthase is preserved.

Characterization of an HL-60 Cell Variant Resistant to the Antineoplastic Ether Lipid 1-*O*-Octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine

George W. Small[1], Jay C. Strum[2], and Larry W. Daniel*

Department of Biochemistry, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, North Carolina 27157-1016

ABSTRACT: A resistant cell line (HL-60R) was selected by incubating HL-60 cells with increasing concentrations of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) and used to examine the mechanism of resistance to the antineoplastic ether-linked lipid. The HL-60R cells exhibited a >10-fold increase in resistance when measured by [^{3}H]-thymidine incorporation in comparison to the HL-60 cell line. ET-18-OCH_3 binding occurred at 4°C and was not saturable at the concentrations tested (1–100 μM), indicating that the binding was receptor-independent. At 4°C, association of ET-18-OCH_3 was low for each cell line. At 37°C, uptake in the HL-60 cells was approximately 5-fold greater in comparison to HL-60R cells at each concentration tested. However, when the cellular content of ET-18-OCH_3 was equal, both cell lines experienced similar declines in cell growth. Cellular incorporation of ether lipid was determined using serum-free media and in the presence of serum albumin or lipoproteins. Reduced uptake by the resistant cell line was observed only in the presence of albumin. A greater proportion of ether lipid could be removed from prelabeled HL-60R cells than from HL-60 cells, by an albumin wash procedure, indicating an increased rate of internalization and retention by the sensitive cell line. ET-18-OCH_3 uptake in the HL-60 cell line was also more sensitive to treatment with endocytic (chloroquine, monensin) or metabolic (NaF, KCN) inhibitors. These results suggest that uptake is the principal determinant influencing sensitivity of the resistant cell line and consists of receptor-independent binding followed by internalization. Differential uptake requires the presence of serum albumin and is dependent on the energy-dependent endocytosis of the ether lipid.

Lipids 32, 715–723 (1997).

The ether lipid 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) is structurally similar to the biologically active lipid, platelet-activating factor (1-*O*-alkyl-2-acetyl-*sn*-glycerol-3-phosphocholine). ET-18-OCH_3 has minimal platelet-activating factor activity (1,2). However, it has selective antineoplastic activity both *in vitro* and *in vivo* [for reviews see: (3–5)]. The sensitivity of neoplastic cells to ET-18-OCH_3 is variable and the factors governing susceptibility toward the ether lipids are presently unknown.

Several mechanisms have been proposed that could influence cell sensitivity. These include effects on proliferative signal transduction (6–8) and phospholipid metabolism (9–11). Several studies have demonstrated the ability of ET-18-OCH_3 to inhibit protein kinase C *in vitro* (12–14) and to interfere with protein kinase C-mediated cellular responses (15–17). A recent study by Boggs *et al.* (18) examining the effect of ET-18-OCH_3 on lipid metabolism has reported that the inhibition of phosphatidylcholine synthesis by ET-18-OCH_3 can be overcome by supplementation with lysophosphatidylcholine, thereby overriding the cytotoxic but not the cytostatic activity of ET-18-OCH_3. Therefore, inhibition of phosphatidylcholine synthesis by ET-18-OCH_3 may not be sufficient to account for the full activity exhibited by this compound. The possibility that ET-18-OCH_3 is itself metabolized and serves as a precursor for active metabolites has also been suggested (19). However, more recent studies indicate that ET-18-OCH_3 is resistant to metabolic breakdown (20,21).

Two reports provide evidence that cellular lipid composition may be a contributing factor influencing cell sensitivity toward ET-18-OCH_3. Chabot *et al.* (11) found that increases in the endogenous ether lipid content of K-562 cells by supplementation of culture media with 1-*O*-hexadecyl-*sn*-glycerol sensitizes this cell line to subsequent treatment by ET-18-OCH_3. Similarly, Diomede *et al*. (22) found that an increase in the cholesterol content of HL-60 cells reduced ether lipid uptake and sensitivity.

Cellular uptake represents the initial mechanism which could influence sensitivity (23). Bazill and Dexter (24) suggested that uptake may be influenced by endocytic inhibitors. However, these results are not invariably observed. Fleer *et al.* (25) report little correlation between sensitivity and the rate of uptake of an ether lipid analog (hexadecylphosphocholine) among six different cell lines. Other studies found

no effect of endocytic or metabolic inhibitors on ether lipid uptake (25–27). Consequently, the significance and mechanism of ET-18-OCH_3 uptake remain unclear.

The human leukemic cell line HL-60 is relatively sensitive (28,29) to ET-18-OCH_3. In this study, we report the development and characterization of a resistant variant (HL-60R). The HL-60R subline was developed to investigate potential mechanisms which may confer resistance to ET-18-OCH_3 and to avoid complications that may arise owing to comparisons among different cell lines.

MATERIALS AND METHODS

Materials. HL-60 cells were obtained from the American Type Culture Collection (Rockville, MD). Fetal bovine serum (FBS), RPMI 1640, glutamine, and penicillin/streptomycin were from Gibco (Grand Island, NY). ET-18-OCH_3 was a gift from Medmark Pharma, GmbH (Munich, Germany). 1-*O*-[9,10-^{3}H]octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine ([^{3}H]ET-18-OCH_3, 56 Ci/mmol) was synthesized as previously described (21). 1-(octadecylthio)-2-methoxy-*rac*-glycero-3-phosphocholine and *N*-[3-(octadecylthio)-2-methoxyprop-1-yl]-*rac-N,N*-dimethyl-*N*-(γ-hydroxypropyl) ammonium were provided by Dr. Claude Piantadosi, University of North Carolina (Chapel Hill, NC). ET-18-OCH_3 and related derivatives (10 mg/mL) were stored in ethanol. Chloroquine (100 mM) was prepared fresh in water. Monensin (4 mg/mL) was prepared fresh in ethanol. Sodium fluoride and all solvents were from Fisher Scientific (Fair Lawn, NJ). Silica G thin-layer plates were from Analtech (Newark, NJ). Lipid standards were from Serdary Research Laboratories (Port Huron, MI). [^{3}H]inulin, [^{3}H]thymidine, and Ecolume were from ICN Radiochemicals (Irvine, CA). En^{3}Hance was from New England Nuclear Research Products (Boston, MA). All other reagents were from Sigma (St. Louis, MO).

Cell culture. HL-60 cells were maintained at 37°C in a humidified 5% CO_2 atmosphere in RPMI 1640 supplemented with 10% FBS, 50 U/mL penicillin, 50 μg/mL streptomycin, and 2 mM glutamine. Cell viability was determined by trypan blue exclusion, and cell cytotoxicity was measured by [^{3}H]thymidine incorporation as described (30). The resistant cell line was removed from selection media a minimum of 1 wk prior to experiments.

Lipid analysis and ET-18-OCH_3 metabolism analysis. Lipid extraction was performed on 1–5 × 10^7 cells using a modified Bligh and Dyer procedure (31). Phospholipid mass was determined by the method of Rouser *et al.* (32). Cholesterol content was assessed with the procedure of Rudel and Morris (33). Phospholipid species were fractionated by thin-layer chromatography using Silica Gel G plates in a chloroform/methanol/acetic acid/H_2O (50:25:8:2, by vol) solvent system. Neutral lipids were resolved in a hexane/diethyl ether/formic acid (90:60:4, by vol) system. Phospholipid and neutral lipid species were identified by co-migration with known standards and visualized with iodine vapor. The subclass composition of phosphatidylethanolamine and phosphatidylcholine was determined by high-performance liquid chromatography as described by Chabot *et al.* (11).

For metabolic studies, 5 × 10^7 cells were labeled with 1 μM [^{3}H]ET-18-OCH_3 (0.9 μCi/mL) for 24 h prior to lipid extraction. Cells were then centrifuged at 1200 × *g* and washed three times with phosphate-buffered saline prior to lipid extraction. Radioactive metabolites were separated by thin-layer chromatography as described above. En^{3}Hance was used to visualize radioactive metabolites by autoradiography. Radioactive bands were then scraped into scintillation vials containing 200 mL water. Samples were measured by liquid scintillation counting in 3 mL Ecolume.

ET-18-OCH_3 uptake. The amount of ET-18-OCH_3 uptake is defined and expressed as the amount of cell-associated ET-18-OCH_3 relative to the total cellular phospholipid content (mol%). Unless otherwise indicated, 2 μM ET-18-OCH_3 was used for uptake studies, and incubations were conducted at 37°C for 4 h in 10% FBS. Viability remained above 90% and was not reduced by treatment with ether lipid or inhibitors during this time. ET-18-OCH_3 (10 mg/mL) and radiolabeled ET-18-OCH_3 were dried under nitrogen and resuspended in culture media 1 h prior to use, to obtain a final concentration of 2 μM at 0.1 μCi/mL. Any inhibitors to be used were then added. Cells (1 × 10^7/mL) were added per mL of the assay mixture. In order to determine the amount of cell-associated ET-18-OCH_3, 1-mL aliquots were transferred to Eppendorf centrifuge tubes and centrifuged at 3000 rpm for 2 min in an Eppendorf 5415 C centrifuge (Hamburg, Germany). Cell pellets were washed twice in phosphate-buffered saline (pH 7.4). Samples were then digested overnight in 50 μL 1 M NaOH at room temperature; 50 μL 1 M HCL was added and radioactivity was measured by liquid scintillation counting. For binding experiments, the incubation time was reduced to 1 h in order to maintain cell viability at the higher concentrations, and cells were incubated at 4°C to prevent internalization of ET-18-OCH_3. For experiments under serum-free conditions, it was necessary to reduce the concentration of ET-18-OCH_3 to 0.5 μM to prevent cell lysis. For determination of surface-bound vs. internalized ET-18-OCH_3, cells were prelabeled with ET-18-OCH_3 for 4 h. HL-60 cells were incubated with 1 μM, and HL-60R were incubated with 3 μM ET-18-OCH_3 in order to achieve comparable levels of ether lipid in each cell type. Cells were then pelleted and resuspended in an equal volume of RPMI containing 2.5 mg/mL bovine serum albumin for the times indicated and harvested as described above. This procedure is reported to remove ET-18-OCH_3 from the external surface of the plasma membrane, and the radioactivity remaining represents the amount of internalized ET-18-OCH_3 (34,35).

Lipoproteins. Low density lipoproteins (LDL) and high density lipoproteins (HDL) were purified from human plasma by sequential flotation ultracentrifugation (36) then dialyzed against phosphate-buffered saline. Initially, [^{3}H]ET-18-OCH_3 was added to the isolated LDL and HDL fractions. Labeled HDL and LDL were then repurified by gel filtration chromatography to remove any unbound ET-18-OCH_3. However,

ET-18-OCH_3 absorption to lipoproteins was quantitative, and this repurification step was eliminated in subsequent preparations. LDL, HDL, and albumin concentrations were adjusted to approximate the concentrations found under normal culture conditions of 10% FBS. For uptake experiments, the final concentration of LDL was 22 μg/mL, 5 μg/mL for HDL, 2.5 mg/mL albumin, and 2 μM for ET-18-OCH_3 in RPMI.

Pinocytosis. [^{3}H]inulin was used as a marker for fluid phase endocytosis (37), and experiments were conducted under the same conditions used for ET-18-OCH_3 uptake except for the use of [^{3}H]inulin as a radiotracer. Prior to use, [^{3}H]inulin was purified to remove low molecular weight contaminants by size exclusion column chromatography using a Bio-gel P-10 (70 × 100 mm) column (Bio-Rad, Melville, NY). Pinocytosis was assayed using a final concentration of 2 μM inulin.

RESULTS

Establishment of drug resistance. The HL-60 cell line was cultured at an initial concentration of 0.8 μM ET-18-OCH_3. Cell density was measured every 2 d and the concentration of ET-18-OCH_3 was increased in increments of 0.3 μM when cell growth was observed. After a 3-mon selection process, a resistant variant (HL-60R) was established. The HL-60R cell line was continuously maintained in 4 μM ET-18-OCH_3 (2-fold higher than the ID_{50} for the HL-60 cell line). The level of resistance in the resistant variant was estimated from ID_{50} values derived from [^{3}H]thymidine incorporation studies. The HL-60R cell line exhibited a >10-fold level of increased resistance to ET-18-OCH_3 with respect to the parental HL-60 cell line (Fig. 1). The HL-60R cell line was also resistant to a thioether derivative, 1-(octadecylthio)-2-methoxy-*rac*-glycero-3-phosphocholine but not the nonphosphorus derivative, *N*-[3-(octadecylthio)-2-methoxyprop-1-yl]-*rac*-*N,N*-dimethyl-*N*-(γ-hydroxypropyl) ammonium. The HL-60R cell line was stable and could be removed from selection media for at least 4 mon and still retain its resistance to ET-18-OCH_3. Six subclones were selected from colonies grown in soft agar from the HL-60R cell line. Characterization of each subclone according to its growth rate or in its sensitivity, metabolism, or uptake to ET-18-OCH_3 did not reveal any differences in comparison to the original HL-60R cell line (data not shown). The original HL-60R cell line therefore appeared to be a homogeneous population and was used for subsequent experiments.

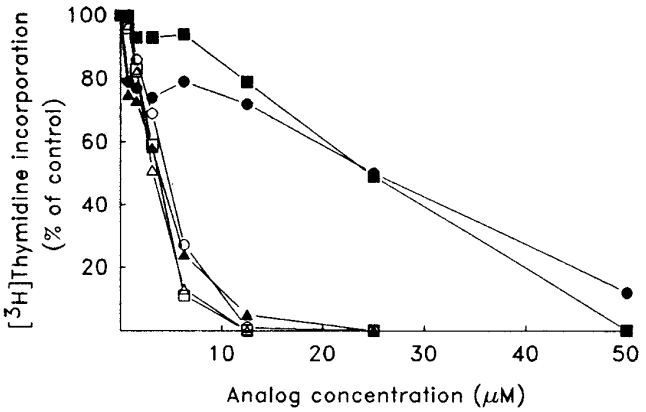

FIG. 1. Effect of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OCH_3) and related analogs on [^{3}H]thymidine incorporation in the HL-60 (open symbols) and HL-60R (closed symbols) cell lines. Cells were incubated at the indicated concentrations of ET-18-OCH_3 (○,●), 1-*S*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (□,■), or 1-*S*-octadecyl-2-*O*-methyl-*rac*-glycero-3-(*N,N*-dimethylamino) propanol (△,△) for 48 h. [^{3}H]thymidine was then added, and cells were incubated for an additional 8 h. Cells were harvested and radioactivity determined as described (30). Values are presented as a percentage of control values (untreated cells) and are the means of triplicates, SD < 10%. Results shown are one of three similar experiments.

Lipid composition analysis. A comparison of the relative amounts of major phospholipid species or subclass composition (diacyl, alkylacyl, alkenylacyl) of phosphatidylcholine and phosphatidylethanolamine did not reveal significant differences between the two cell lines (data not shown). Cholesterol content was assessed and was slightly reduced in the HL-60R cell line (33.8 ± 2.7 nmoles/10^7 cells, n = 4) cells compared to the HL-60 cell line (43.2 ± 4.0 nmoles/10^7 cells, n = 4). This was reflected in a comparable reduction in total phospholipid content in HL-60R cells (119 ± 11.3 nmoles/10^7 cells, n = 4) compared with the HL-60 cells (143 ± 13.9 nmoles/10^7 cells, n = 4). Consequently, a ratio of phospholipid to cholesterol remained essentially the same for HL-60 (3.31) and HL-60R (3.52).

Metabolism of ET-18-OCH_3. The ability to degrade ET-18-OCH_3 was relatively low for both cell lines. Analysis by thin-layer chromatography showed some increase in the neutral lipid and phospholipid fractions of HL-60R cells within 24 h of incubation. However, the bulk of ET-18-OCH_3 remained in its original form (>90%), and further analysis of metabolites was not undertaken. This is in agreement with previous studies reporting low levels of metabolism for ET-18-OCH_3 (20,21).

Binding and uptake of ET-18-OCH_3. Binding of ET-18-OCH_3 was assayed in the HL-60 cell line in order to determine if ET-18-OCH_3 binding is receptor-mediated. Association of the ether lipid with HL-60 cells remained linear with respect to concentration in the range tested (1–100 μM). These results suggested that binding was not receptor-mediated and was more likely occurring by nonspecific absorption to the plasma membrane (data not shown).

Binding and uptake were subsequently examined in both cell lines during a 6-h period (Fig. 2). At 4°C, ET-18-OCH_3 binding was low and remained relatively unchanged during the time course. Binding equilibrium therefore appeared to be established by the earliest sampling time at 1 h. No difference in binding between the two cell lines was observed. At 37°C, ET-18-OCH_3 uptake increased throughout the duration of the experiment in both cell lines. Under these conditions, a difference in the rate of uptake between the two cell lines was

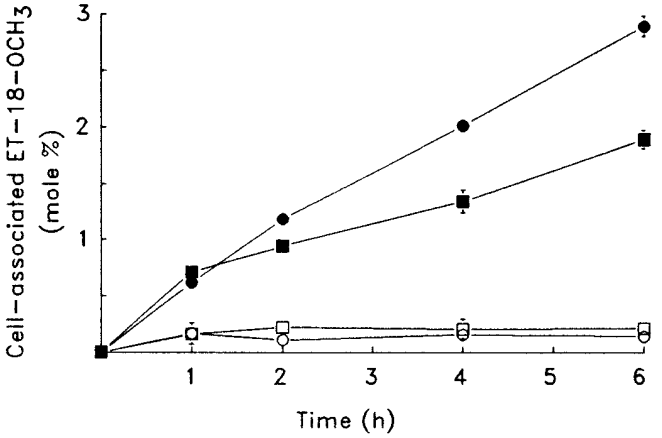

FIG. 2. Time-dependent incorporation of ET-18-OCH_3 in the HL-60 (○,●) and HL-60R (□,■) cell lines. 5×10^5 cells/mL were incubated in presence of 2 μM ET-18-OCH_3 plus 0.1 μCi/mL [^{3}H]ET-18-OCH_3 in 10% fetal bovine serum at 4°C (open symbols) or 37°C (closed symbols). At the indicated times, cell-associated ET-18-OCH_3 was determined as described in the Materials and Methods section and is expressed as the amount of cell-associated ET-18-OCH_3 relative to cellular phospholipid content (mol%). Results are expressed as the means of triplicate samples ± SD and are one of three similar experiments. See Figure 1 for abbreviation.

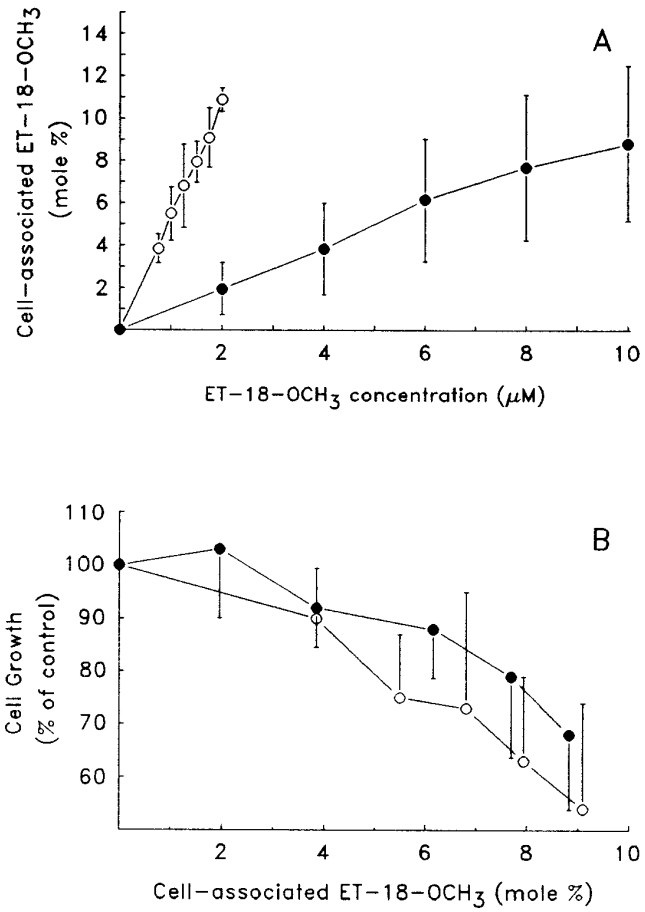

FIG. 3. Long-term uptake of ET-18-OCH_3 and its effect on cell growth in the HL-60 and HL-60R cell lines. (A) Concentration-dependent uptake of ET-18-OCH_3, (B) ET-18-OCH_3 content vs. growth inhibition. The HL-60 (○) and HL-60R (●) cell lines were cultured at an initial density of 5×10^5 cells/mL at the indicated concentrations of ET-18-OCH_3 for 48 h. ET-18-OCH_3 uptake was then determined as described in the Materials and Methods section, and viable cell counts were measured by trypan blue exclusion. Cell growth is represented as a percentage of control values (untreated cells). ET-18-OCH_3 uptake is represented as a mol% of the total phospholipid content. Results are expressed as the means ± SD of five experiments performed in triplicate. See Figure 1 for abbreviation.

observed and clearly evident by 4 h. At this time, uptake was reduced in the HL-60R cell line by approximately 65% relative to the HL-60 cell line. A correlation between uptake and sensitivity was indicated by these results. However, no equilibrium was evident within this time period, and a more detailed examination of ET-18-OCH_3 uptake was therefore undertaken.

ET-18-OCH_3 content and cell growth. ET-18-OCH_3 uptake was next examined in the two cell lines during 2-d incubations at multiple concentrations of ET-18-OCH_3. At the end of the incubation time, ET-18-OCH_3 content was assessed and compared to effects on cell growth. From these results, the extended incubation time increased the differences in uptake previously seen. The difference in uptake between the two cell lines at a given concentration was approximately 5-fold (Fig. 3A). Comparison of ET-18-OCH_3 content vs. cell growth (Fig. 3B) demonstrated similar declines in cell growth in both cell lines. These results indicate that reduced uptake was responsible for the resistance observed in the HL-60R variant since the growth of both cell lines deceased when the ET-18-OCH_3 content was comparable.

Role of serum in ET-18-OCH_3 uptake. The uptake of ET-18-OCH_3 under serum-free conditions or in the presence of individual serum components was next examined. Under serum-free conditions, uptake was considerably higher and 2 μM ET-18-OCH_3 resulted in reduced cell viability. Therefore, 0.5 μM was subsequently used during these experiments. Uptake was equal between the two cell lines in the absence of serum, and uptake was no longer temperature-dependent (Table 1). These results indicated a requirement for serum in mediating the differential uptake of ET-18-OCH_3 in the HL-60 and HL-60R cell lines. Therefore, the uptake of ET-18-OCH_3 in the presence of individual serum components was investigated.

Substantial uptake of ET-18-OCH_3 in association with LDL or HDL could be seen and was not reduced in the HL-60R cell line (Fig. 4). The comparable uptake of ET-18-OCH_3/LDL suggested the two cells lines possessed equal abilities in receptor-mediated endocytosis. These results further indicate that lipoproteins may contribute to the total uptake of ET-18-OCH_3 but do not appear responsible for the difference in uptake seen between the HL-60 and HL-60R cell lines. In these experiments, the final concentration of LDL was 22 μg/mL or 5 μg/mL for HDL, and 2 μM ET-18-OCH_3. In the presence of complete serum, 2 μM ET-18-OCH_3 is distributed among several serum components (38). Consequently, the ET-18-OCH_3 content of LDL and HDL is higher

TABLE 1
Cellular Association of ET-18-OCH_3 Under Serum-Free Conditions[a]

Temperature	HL-60 Uptake (mol%)	HL-60R Uptake (mol%)
4°C	4.49 ± 0.561	5.66 ± 0.277
37°C	5.18 ± 0.223	6.09 ± 0.771
% Reduction	13%	7%

[a]The association of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycerol-3-phosphocholine (ET-18-OCH_3) (0.5 μM) with the HL-60 or HL-60R cell lines was measured in the absence of serum either at 37°C or at 4°C for 1 h using 5×10^5 cells/mL as described in the Materials and Methods section. Results are expressed as the amount of ET-18-OCH_3 associated with cells relative to total phospholipid content (mol%). Results are presented as the means of triplicate samples ± SD and representative of three experiments.

in these experiments in comparison to the fraction of 2 μM ET-18-OCH_3 normally associated with these lipoproteins in complete serum. Therefore the contribution of these lipoproteins in ET-18-OCH_3 uptake is likely to be exaggerated under these conditions. Reduced uptake by the HL-60R cell line was observed only when albumin or serum was present (Fig. 4).

Albumin appeared important in mediating differential uptake, and ET-18-OCH_3 uptake was consequently measured in the presence of increasing concentrations of albumin (1–10 mg/mL). Uptake was effectively reduced by increasing albumin concentration and was lower in the HL-60R cell line in comparison to the HL-60 cell line at all concentrations tested. Increasing the concentration of albumin presumably alters the partitioning equilibrium thereby increasing the back exchange of ET-18-OCH_3 from cells to albumin. Consequently, whether an ET-18-OCH_3/albumin complex was binding could not be determined from this experiment. However, the nonsaturability of ET-18-OCH_3 binding at increasing ether lipid concentration at 4°C discounts this possibility.

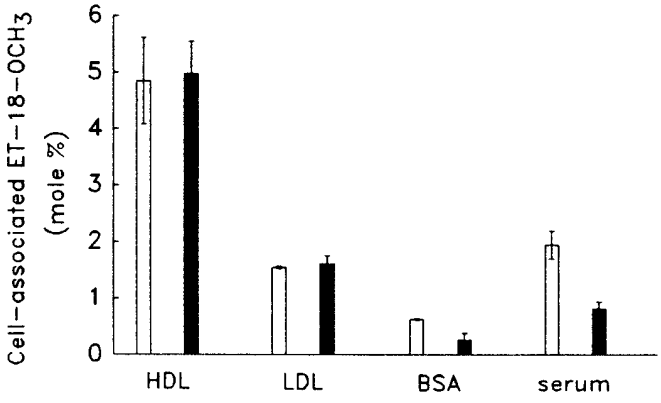

FIG. 4. ET-18-OCH_3 uptake in the presence of individual serum components. Uptake in the HL-60 (open bars) or HL-60R (closed bars) cell lines was measured in the presence of 5 μg/mL high density lipoprotein (HDL), 22 μg/mL low density lipoprotein (LDL), 2.5 mg/mL bovine serum albumin, or 10% fetal bovine serum plus 2 μM ET-18-OCH_3. ET-18-OCH_3 uptake was determined as described in the Materials and Methods section and is expressed as the amount of cell-associated ET-18-OCH_3 relative to cellular phospholipid content (mol%). Results are expressed as the means of triplicate samples ± SD and are one of three similar experiments. BSA, bovine serum albumin. See Figure 1 for other abbreviation.

To confirm that the cellular association of ET-18-OCH_3 was rate-limiting and not dissociation of ET-18-OCH_3 from albumin, uptake was measured as a function of increasing cell density (1 to 20×10^5/mL). Increasing cell density should increase the frequency of ET-18-OCH_3/cell interactions and enhance uptake if binding is rate-limiting. Increasing cell density should not affect uptake if dissociation from albumin is rate-limiting. ET-18-OCH_3 uptake in the presence of albumin was indeed proportional to cell number and similar results were obtained using 10% FBS (data not shown). Based on these results, albumin appears to serve as a reservoir from which ET-18-OCH_3 can rapidly transfer to the cell membrane.

Inhibition of ET-18-OCH_3 uptake. Bazill and Dexter (24) have shown that endocytosis may represent at least one component of ET-18-OCH_3 uptake and may distinguish ET-18-OCH_3-sensitive cells from more resistant cell lines. Therefore, we examined the proportion of uptake attributed to endocytosis in each of our cell lines through the use of the endocytic inhibitors, chloroquine (39,40) and monensin (41) or the metabolic inhibitors, NaF and KCN. The HL-60 cell line was most sensitive to treatment with these agents, and ET-18-OCH_3 uptake was reduced in response to all the compounds tested (data not shown). Monensin was the most effective inhibitor tested, and reductions in uptake were observed in both cell lines. However, the HL-60 cell line was most affected by monensin treatment. The lowest concentration of monensin (12.5 μM) reduced the level of uptake in the HL-60 cell line to a level comparable to untreated HL-60R cells. Further reductions in ET-18-OCH_3 uptake were not observed above 50 μM monensin.

Assessment of internal vs. external ET-18-OCH_3. The results obtained with the inhibitors above suggested that an endocytic mechanism was an important feature in distinguishing ET-18-OCH_3-sensitive from -resistant cell lines. These results were further supported by experiments measuring internalized ET-18-OCH_3 following removal of externally bound ether lipid. In these experiments, cells were incubated for 4 h in 1 μM (HL-60) or 3 μM ET-18-OCH_3 (HL-60R) in order to obtain approximately equal amounts of ET-18-OCH_3 in either cell line. The ET-18-OCH_3 bound to the outer surface of the plasma membrane was then removed by washing cells with RPMI + 2.5 mg/mL bovine serum albumin, and the amount remaining represented internalized ET-18-OCH_3. At 4°C, this procedure resulted in removal of approximately 46% of the ET-18-OCH_3 in HL-60R but only 12% from HL-60 cells (Fig. 5). At 37°C, a gradual loss of ET-18-OCH_3 over 2 h could be observed and appeared comparable between the two cell lines. This decline resulted in nearly complete elimination of cell-associated ET-18-OCH_3 in the HL-60R cell line by the end of the incubation.

Pinocytic uptake. Fluid phase endocytosis was measured using [^{3}H]inulin as a marker to obtain a general measure of endocytic activity in either cell line. Both cell lines endocytosed this compound in a time-dependent manner (Fig. 6). However, reduced uptake was not observed in the resistant

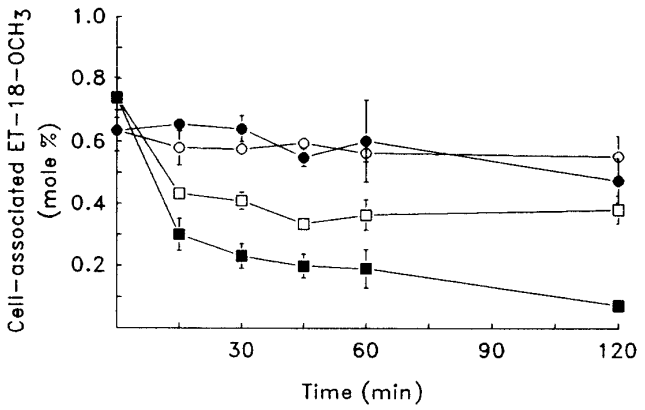

FIG. 5. Removal of externally bound ET-18-OCH_3 from HL-60 (○,●) and HL-60R (□,■) cells which were prelabeled by incubation for 4 h with 1 μM or 3 μM ET-18-OCH_3, respectively. This procedure provided comparable levels of ET-18-OCH_3 between the two cell lines. Cells were pelleted then resuspended (5×10^5/mL) in media containing 2.5 mg/mL bovine serum albumin and incubated at 4°C (open symbols) or 37°C (closed symbols). One-mL aliquots were sampled at the indicated times. Cell-associated ET-18-OCH_3 was determined as described in the Materials and Methods section and is expressed as the amount of cell-associated ET-18-OCH_3 relative to cellular phospholipid content (mol%). Results are expressed as the means of triplicate samples ± SD and are one of three similar experiments. See Figure 1 for abbreviation.

cell line. Similar results have been observed by Sleight and Abanto (34) who have reported that there was little agreement between the pinocytic rate of uptake of horseradish peroxidase and the differences observed in the uptake of lipids among different cell lines. Fluid-phase pinocytosis occurs at a lower magnitude in comparison to substances which can bind to the surface of a cell. The uptake of endocytic markers absorbed to the plasma membrane can be 100 to 1000 times the rate of uptake of a fluid phase endocytic marker (42).

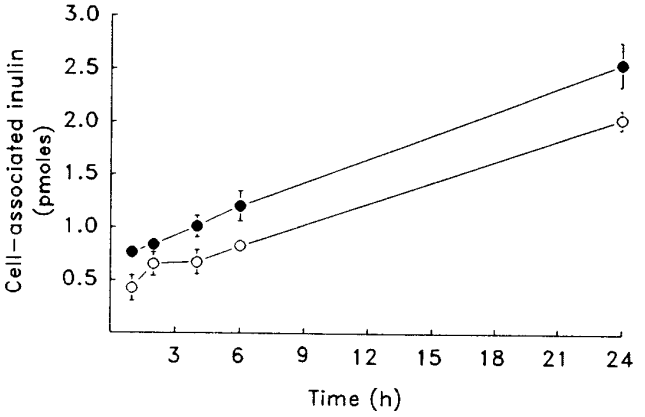

FIG. 6. Time-dependent uptake of [^{3}H]inulin in the HL-60 (○) and HL-60R (●) cell lines. 5×10^5 cells/mL were incubated in the presence of 2 μM inulin (0.5 μCi/nmole) in culture media at 37°C for the indicated times. Inulin uptake was then measured as described in the Materials and Methods section. Results are expressed as pmoles of cell-associated inulin per 5×10^5 cells. Results are the means of triplicate samples ± SD and are one of three similar experiments.

Therefore, measurements of fluid-phase endocytosis may be limited in revealing differences in absorptive endocytosis.

DISCUSSION

In this study, we report the development and characterization of an HL-60 variant (HL-60R) displaying increased resistance to the antineoplastic ether lipid, ET-18-OCH_3. Reduced uptake of ET-18-OCH_3 by the HL-60R cell line was observed during incubations up to 6 h. Long-term incubations (2 d) enhanced these differences. A comparison of ET-18-OCH_3 content and cell growth revealed that both cell lines experienced similar declines in cell growth when the ET-18-OCH_3 content between the two cell lines was equal. This result provided evidence that uptake was the primary difference determining ET-18-OCH_3 sensitivity between these two cell lines.

Binding of ET-18-OCH_3 to HL-60 cells was concentration-dependent and was not saturable in the range tested (1–100 μM). This lack of saturability indicates that ET-18-OCH_3 does not bind through a specific receptor interaction. It remains possible that this compound could be absorbed into the plasma membrane and subsequently interact with a transport protein. However, the existence of a phosphatidylcholine or lysophospholipid transporter accessible to the external plasma membrane has not been established. In addition, the sensitivity of ET-18-OCH_3 uptake to multiple inhibitors in our studies argues against this possibility.

Kelley *et al.* (27) examined uptake under serum-free conditions in the L1210 cell line and concluded that uptake occurred by passive diffusion since uptake could not be reduced by endocytic or metabolic inhibitors. We examined uptake under serum-free conditions using the HL-60 and HL-60R variant as well. These results were at marked contrast with those observed in the presence of serum. Uptake was no longer reduced in the resistant cell line or temperature-dependent. These results suggested that uptake under serum-free conditions was not representative of physiological conditions and is instead, perhaps, a measure of ET-18-OCH_3 partitioning between the media and cells. Passive diffusion did not appear to be responsible for the differential uptake of ET-18-OCH_3 in our cell model since uptake responded to endocytic and metabolic inhibitors. In addition, diffusion as a predominant mechanism of ET-18-OCH_3 uptake seems unlikely since transbilayer movement of lysophosphatidylcholine is reported to be extremely low owing to the polar headgroup of this compound (43).

A study by Bazill and Dexter (24) demonstrated that ET-18-OCH_3 uptake could be reduced by endocytic or metabolic inhibitors in the murine myelomonocytic leukemic WEHI-3B cell line and in the multipotential nonleukemic FDCP-mix A4 cell line. They concluded that endocytosis is the principal determinant distinguishing sensitive cell lines from more resistant cell lines. In a related study, Storch and Munder (26) also reported reduced uptake in a fibrosarcoma-resistant cell line but were unable to suppress uptake using NaF as a metabolic inhibitor. The discrepancy between this study and the work

of Bazill and Dexter (24) suggests that NaF-sensitive endocytosis of ET-18-OCH_3 may be a cell type-specific phenomenon. Our results support an active, endocytic uptake of ET-18-OCH_3 as the determining factor between the sensitive and resistant cell lines. Treatment of HL-60 cells with endocytic inhibitors, chloroquine or monensin, or the metabolic inhibitors, NaF or KCN, suppressed ET-18-OCH_3 uptake. The resistant cell line was less sensitive to these treatments. Monensin was most effective, and inhibition of ET-18-OCH_3 uptake was examined as a function of increasing monensin concentration. At the lowest concentration tested (12.5 μM), uptake in the HL-60 cell line was reduced to approximately the level of uptake seen in untreated HL-60R cells. Further reductions in uptake were not observed above 50 μM monensin, but the level of uptake did not approach zero even after accounting for binding based on data obtained at 4°C. This remaining level of cell-associated ET-18-OCH_3 was equivalent in the HL-60 and HL-60R cell lines. This residual level could represent either an additional mechanism of uptake not inhibitable by monensin, or an enhanced level of ether lipid binding at 37°C due to increased membrane fluidity at the higher temperature. If spontaneous insertion of ET-18-OCH_3 is temperature-dependent, then binding at 37°C could represent a significant component of total uptake under short incubation times. The effects of inhibitors would be underestimated under these conditions and may partly explain the conflicting results from different studies. In addition, multiple endocytic pathways have been described which respond differently to various inhibitory agents (44–46). ET-18-OCH_3 may enter a cell by any endocytic process. Which pathway predominates is likely to vary among different cell types, and consequently, cell responses to different types of inhibitory compounds may also differ.

The presence of serum was required in order to see differential uptake between the HL-60 and HL-60R cell lines. Therefore, some constituent within serum mediated ET-18-OCH_3 interaction with the cell and uptake was therefore examined in the presence of individual serum components. Lipoproteins are known to transport lipids to cells and were therefore considered as potential carriers of ET-18-OCH_3. Uptake of ET-18-OCH_3 in the presence of both LDL and HDL readily occurred. However, reduced uptake by the resistant cell line was not seen. Both cell lines appeared equal in their capacity of receptor-mediated endocytosis of LDL. Studies characterizing the partitioning of ET-18-OCH_3 among serum components indicate that the majority of ET-18-OCH_3 associates with serum albumin (27,38). Our results are consistent with these observations and suggest serum albumin plays an important role in ET-18-OCH_3 uptake. Uptake of ET-18-OCH_3 in the presence of albumin obeyed the same relationship seen with serum. In the presence of albumin, ET-18-OCH_3 was reduced in the resistant variant in comparison to the HL-60 cell line. Removal of externally bound ET-18-OCH_3 by an albumin wash procedure from prelabeled cells was used as an alternative approach to confirm that differences in endocytosis existed between the HL-60 and HL-60R cell lines. A greater proportion of ether lipid could be removed from the HL-60R cell line, indicating the resistant cell line had internalized less ET-18-OCH_3.

Cell lines that exhibit a multidrug-resistant phenotype commonly have enhanced endocytic rates (47,48). Such cells may consequently have increased sensitivity toward ET-18-OCH_3. Therefore, this compound could provide an alternative treatment for neoplastic cells which are refractory toward other antineoplastic agents. Alternatively, multidrug-resistant cells may also have a higher efflux rate of ET-18-OCH_3 which could result in lower accumulation and resistance to growth inhibition. ET-18-OCH_3 has also shown promise in bone marrow purging experiments (49,50). Our results suggest that the use of individual serum components could increase the efficacy or alter the cellular selectivity of this procedure. The use of specific serum components could be used to exploit individual differences among neoplastic cells.

ACKNOWLEDGMENTS

This work was supported in part by grant CA-48995 from the National Institutes of Health. J.C.S. was supported by the Signal Transduction Mechanisms and Cell Function Training Program (CA-09422). We used the Membrane Lipid and Tissue Culture Core Laboratories of the Comprehensive Cancer Center of Wake Forest University (supported by CA-12197). We thank Shelby Puckett for performing thymidine incorporation experiments, Dianne Greene for high-performance liquid chromatography analysis of benzoate derivatives, and Dr. Tom Thuren for assistance with purification of lipoproteins.

Conjugated Linoleic Acid Modulation of Phorbol Ester-Induced Events in Murine Keratinocytes

Kai-Li Liu and Martha A. Belury*

Department of Foods and Nutrition, Purdue University, West Lafayette, Indiana 47906

ABSTRACT: Recent work in our lab has shown that the chemoprotective fatty acid, conjugated linoleic acid (CLA), inhibits phorbol ester skin tumor promotion in mice. Because little is known about the deposition of CLA into tissues as well as its biological activity, this study compared the incorporation and biological activity of CLA to linoleic acid (LA; 18:2, *c*9,*c*12) and arachidonic acid (AA; 20:4 *c*5,*c*8,*c*11,*c*14) in cultured keratinocytes. When keratinocytes (HEL-30) were grown in media containing ^{14}C-CLA for various periods, more than 50% of the ^{14}C-CLA was incorporated into cellular lipids by 9 h. The distribution of CLA in phospholipid classes was similar to LA. Approximately 50% of ^{14}C-LA and ^{14}C-CLA were incorporated into phosphatidylcholine (PC), while the remainder was taken up by phosphatidylethanolamine (PE) and phosphatidylserine/phosphatidylinositol (PS/PI). In contrast, ^{14}C-AA was more equitably distributed into PC, PE, or PS/PI (27, 30, or 38%, respectively). When keratinocytes were prelabeled with radiolabeled fatty acids, phorbol ester-induced release of ^{14}C-CLA was 1.5 times higher than ^{14}C-LA and ^{14}C-AA. However, ^{14}C-prostaglandin E (PGE) release in ^{14}C-CLA prelabeled cultures was 6 and 13 times lower than cultures treated with ^{14}C-LA and ^{14}C-AA, respectively. Moreover, the ability of nonradiolabeled CLA to support ornithine decarboxylase activity, a hallmark event of tumor promotion, was significantly lower than in LA- and AA-treated cultures. These studies suggest that CLA inhibits skin tumor promotion, in part, through a PGE-dependent mechanism.

Lipids 32, 725–730 (1997).

The term "conjugated linoleic acid (CLA;18:2)" refers to a group of positional and geometric isomeric products derived from the essential fatty acid, linoleic acid (LA; 18:2; *c*9,*c*12). The double bonds of CLA can be at the 9, 11 or 10, 12 positions and in *cis* and/or *trans* spatial configurations. In foods, the principal dietary sources of CLA are cooked meats and pasteurized milk and cheese products (1). While CLA is a polyunsaturated fatty acid found naturally in the food supply, its conjugated dienoic double-bond nature lends unique pluripotent chemopreventive effects in rat mammary (2,3) and colon carcinogenesis (4) as well as mouse forestomach (5) and skin carcinogenesis (6,7). Presently, the physiological and biochemical mechanisms of CLA chemoprotection in multiple tissues are poorly understood (8).

Recently our lab found that dietary CLA inhibited phorbol ester-induced tumor promotion in the mouse skin multistage carcinogenesis model (7). This model of carcinogenesis allows for the stages of initiation, promotion, and progression to be operationally separated (9). In this study, a semipurified diet containing no CLA was fed to mice during initiation with dimethylbenz(a)anthracene. After carcinogen initiation, mice were switched to one of four experimental diets containing incremental levels of CLA from 0.0 to 1.5% (by weight of diets), and mice were topically promoted with the phorbol ester, 12-*O*-tetradecanoylphorbol-13-acetate (TPA). These studies clearly demonstrated that, by 25 wk, dietary CLA inhibited TPA-induced tumor promotion in a manner that was independent of a previously established antiinitiator activity (6,7).

Topical application of TPA to mouse skin results in a variety of morphological and biochemical changes in epidermis, including increased prostaglandin (PG) synthesis, induction of ornithine decarboxylase (ODC) and phospholipase activities, interaction with protein kinase C (PKC) and PKC-dependent gene expression (*via* TPA-responsive elements) as well as papilloma formation (10,11). Over the past few years, the roles of polyunsaturated fatty acids [such as LA, arachidonic acid (AA; 20:4, *c*5,*c*8,*c*11,*c*14) and eicosapentaenoate (20:5, *c*5,*c*8,*c*11,*c*14,*c*17] in mouse skin tumor promotion by TPA have been elucidated (12–14). These studies demonstrated that the multistage skin tumorigenesis model displays a lack of response to n-3 dietary fatty acids and a tumor-inhibiting response to LA (reviewed in Ref. 15). In contrast, other studies have demonstrated n-3 fatty acids inhibit carcinogenesis while the n-6 fatty acid, LA, enhances tumorigenesis in rodent mammary and colon cancers. Compared to the effects of n-3 and n-6 fatty acids, CLA appears to lack organ specificity for its chemopreventive properties. Studies thus far have demonstrated CLA inhibits tumorigenesis in mammary, forestomach, and colon and skin models of carcinogenesis (15).

Abbreviations: AA, arachidonic acid; BSA, bovine serum albumin; CLA, conjugated linoleic acid; LA, linoleic acid; ODC, ornithine decarboxylase; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PGE, prostaglandin E; PI, phosphatidylinositol; PS, phosphatidylserine; TLC, thin-layer chromatography; TPA, 12-*O*-tetradecanoylphorbol-13-acetate.

Because CLA appears to have such unique pluripotent chemoprotective effects, we are interested in elucidating the ability of CLA to be deposited into tissues and exhibit subsequent biological activity in the regulation of cellular processes associated with lipid homeostasis and tumor promotion. Because LA can serve as the precursor to CLA in nonenzymatic conversion in foods or be converted to AA *via* desaturation and elongation enzymatic conversion in the liver *in vivo* (16), the goal of the present study was to compare the incorporation and biological activity of each of these fatty acids in keratinocytes. In these studies, the keratinocyte cell line HEL-30 was prelabeled with LA, CLA, or AA, then treated with the tumor promoter, TPA, to induce prostaglandin E (PGE) synthesis and ODC activity, two events strongly linked with skin tumor promotion.

MATERIALS AND METHODS

Chemicals. TPA was purchased form LC Laboratories (Woburn, MA) and diluted in acetone. Radiolabeled (1-^{14}C)-LA, (1-^{14}C)-CLA (specific activities, 55 mCi/mmol) were obtained from American Radiolabeled Chemical Inc. (St. Louis, MO). (1-^{14}C)-AA (specific activity, 56 mCi/mmol) was purchased from Moraver Biochemical Inc. (Brea, CA) and (1-^{14}C) ornithine hydrochloride (specific activities, 50–62 mCi/mmol) from Amersham Life Science (Arlington, IL). Nonradiolabeled fatty acids were purchased from Nu-Chek-Prep (Elysian, MN), and the approximate isomeric composition of CLA (98% pure) was 41.2% *c*9,*t*11- and *t*9,*c*11-CLA, 44.1% *t*10,*c*12-CLA, 9.4% *c*10,*c*12, 1.3% *t*9,*t*11, *t*10,*t*12-CLA, 1.1% *c*9,*c*11-CLA, 0.7% LA, and 2.2% unidentified compound. Standards for triglycerides and phospholipids [phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylserine (PS)] were purchased from Sigma Chemical Company (St. Louis, MO) and authentic PGE_2 standard from Cayman Chemical Co. (Ann Arbor, MI). DC-Alufolien Kiesegel 60 F_{254} thin-layer chromatography (TLC) plates were purchased from EM Separation Technology (Gibbtown, NJ).

Cell culture. The murine epidermal cell line HEL-30 (17) (passage levels between 30 and 40) was maintained in Hanks' Balanced Salt Solution containing vitamin and amino acid mixtures supplemented with 100 Units/mL penicillin and 100 µg/mL streptomycin as well as 5% fetal bovine serum. Cultures were incubated at 37°C in a humidified atmosphere of air/CO_2 95:5 (mol%). For experiments, cells were plated at densities of 4×10^5 per 35-mm dish or 6×10^5 per 60-mm dish. The growth medium was a complete medium with serum, and the cultures were incubated until 90% confluence was reached.

Cellular uptake of ^{14}C-fatty acid. After cells were confluent, cultures (35-mm dishes) were labeled with 0.1 µCi/mL ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA mixed with serum-free media containing 0.1% bovine serum albumin (BSA). At various time points (0–24 h), the labeled media were aspirated from dishes, and cells were rinsed with phosphate-buffered saline (PBS), scraped into methanol (1.0 mL), and counted by liquid scintillation.

Analysis of ^{14}C-fatty acid distribution among phospholipid and triglyceride lipid fractions. Media containing ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA 0.1 µCi/mL were added to confluent cultures which were then incubated for 12 h. The medium was aspirated from dishes, and cultures were washed once with PBS and frozen (−70°C). Thawed cells were scraped into methanol (1.0 mL) and dishes rinsed by methanol (1.0 mL). Lipids were extracted by adding chloroform and 2 M KCl (3:1). Extracts were dried under nitrogen and resuspended in 150 µL chloroform/methanol (2:1, vol/vol). Phospholipid and triglyceride fractions were separated by normal-phase TLC (chloroform/methanol/acetic acid; 65:45:4, by vol) (13). Bands which comigrated with PC, PS/PI, PE, and triglyceride authentic standards were identified by iodine vapors and scraped from plates into vials for counting by liquid scintillation.

TPA-stimulated fatty acid release and PGE synthesis. Confluent cultures were prelabeled with ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA at 0.2 µCi per mL of serum-free media with 0.1% BSA. After 12 h incubation, the labeled medium was removed, and cells were washed once with PBS. Acetone (1 µg/mL) or TPA (1.6 µM) was added to media that were then held for 3 h, at which time an aliquot of the medium was quantitated by liquid scintillation. The medium was collected and acidified (pH 3.0) with 1 N HCl, and eicosanoids were extracted twice by ethyl acetate. Eicosanoid extracts were dried under nitrogen, redissolved in ethyl acetate, and applied onto normal-phase TLC plates. Prostaglandins were separated with the organic phase of ethyl acetate/isooctane/glacial acetic acid/water (55:25:10:50, by vol) (13). Iodine vapors were used to identify the position of PGE_2 compared with authentic standards, and the band which comigrated with PGE_2 standard was cut from plates and counted by liquid scintillation.

Ornithine decarboxylase activity. Cells were grown in serum-rich media until confluent. The medium was changed to serum-free medium with 0.1% BSA containing unlabeled LA, CLA, or AA (5 µg/mL medium) for 12 h followed by treatment with serum-free media with 0.1% BSA containing acetone (1 µL/mL) or TPA (1.6 µM) for 6 h; cultures were then washed once with cold PBS and frozen at −70°C until analyses were performed (13). Cells were scraped into ODC buffer containing sodium-potassium phosphate, pyridoxal phosphate, sodium ethylenediaminetetraacetic acid, and dithiothreiotol and homogenized. Homogenates were centrifuged at $12{,}000 \times g$, and 500 µL supernatant was used to determine the ODC activity as we have described previously (14). Protein values of cell homogenates were determined by Coomassie blue reaction (Bio-Rad, Hercules, CA), and ODC activity was expressed as nmol $^{14}CO_2$ released per mg protein per h.

Statistical analysis. Data were analyzed by one-way ANOVA and the Student's *t*-test ($\alpha = 0.05$) with Minitab Statistical Software (Minitab Inc., State College, PA).

RESULTS

Incorporation of ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA into total cellular lipids. Confluent HEL-30 keratinocytes exhibited maximal cellular uptake of fatty acids after 9 h incubation (Fig. 1). There was not a significant change after 6, 9, 12, 15, and 24 h incubation for any of these fatty acids ($P > 0.05$). More than 80% of total ^{14}C-LA and ^{14}C-AA were incorporated into HEL-30 cells after 12 h incubation, but only 70% of total ^{14}C-CLA was taken up by HEL-30 cells by that same time.

^{14}C-fatty acid distribution among phospholipids and triglycerides. Membrane phospholipid fatty acids serve as the substrate pool for eicosanoid metabolism. Therefore, it was important to compare the extent of fatty acid incorporation into phospholipid classes and triglycerides. Approximately 95% ^{14}C-fatty acids were incorporated into total phospholipids and nearly 5% ^{14}C-fatty acids into triglycerides (Fig. 2). In addition, LA, CLA, and AA were distributed differently among the phospholipid classes. Of the phospholipid-associated fatty acids, 54% of ^{14}C-LA was incorporated into PC, and 23 and 20% were in PS/PI or PE. ^{14}C-CLA demonstrated similar patterns of incorporation into PC, PS/PI, and PE (55, 27, and 14%, respectively). In contrast, ^{14}C-AA was more evenly incorporated into PC, PS/PI, and PE (27, 30, and 38%, respectively).

TPA-stimulated fatty acid release and PGE synthesis. Numerous previous studies have demonstrated that the AA-derived PGE_2 modulates tumor promotion-associated events such as ODC activity, vascular permeability, and hyperplasia (9,10). One of the rate-limiting steps of AA conversion to PGE_2 is the supply of free AA released from phospholipids. TPA-induced free ^{14}C-fatty acid release and PGE synthesis

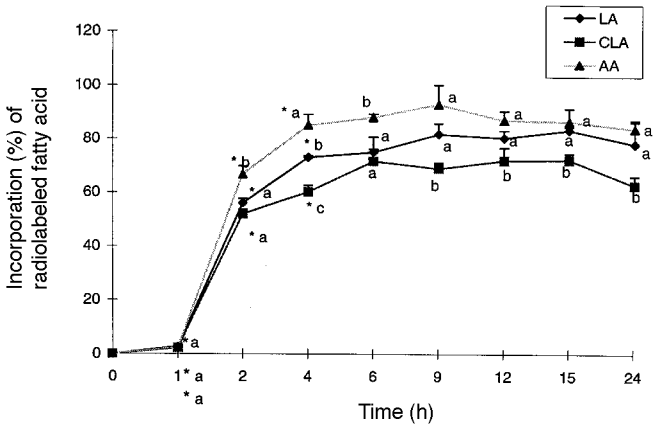

FIG. 1. The percentage of ^{14}C-LA (linoleic acid), ^{14}C-CLA (conjugated linoleic acid), or ^{14}C-AA (arachidonic acid) incorporated into total cellular lipids of HEL-30 keratinocytes. After the removal of media, cells were scraped into methanol and counted by liquid scintillation. Each time point per dish ($n = 3$) represents the mean of percentage incorporation of radiolabeled fatty acid ± SEM from three independent experiments. An asterisk (*) indicates a significant difference between means of each time point and 12 h ($P < 0.05$). Within the same time point, different letters represent a significant difference ($P < 0.05$).

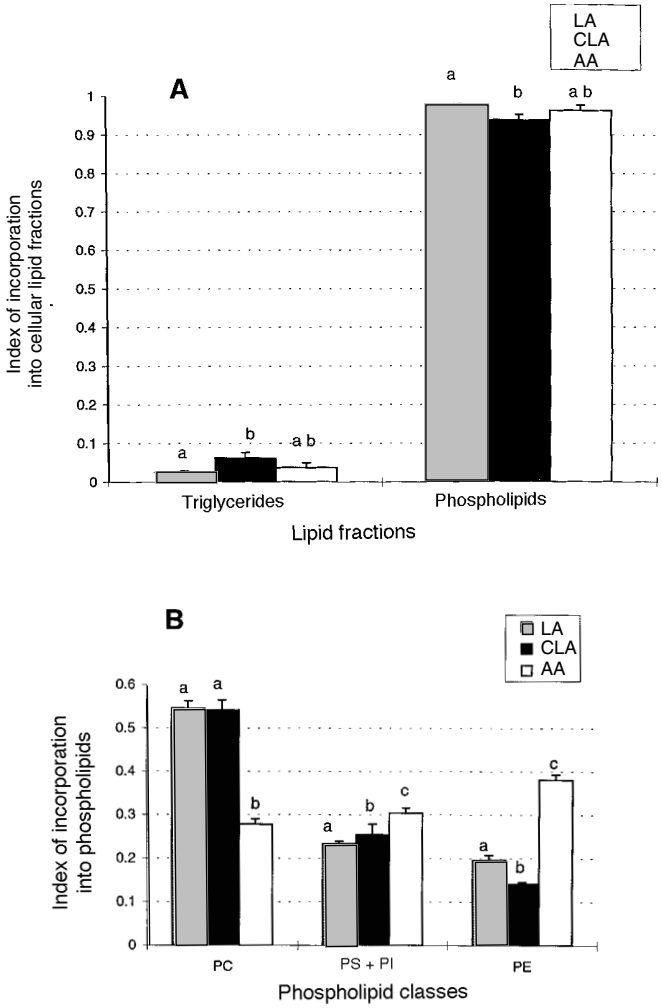

FIG. 2. ^{14}C-Fatty acid distribution among cellular phospholipids and triglycerides of HEL-30 cells. (A) Keratinocyte cultures were prelabeled with 0.1 μCi/mL ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA and incubated for 12 h. Phospholipids and triglycerides were separated by thin-layer chromatography (TLC) and counted. (B) Phospholipid classes were separated by TLC and data represent mean index of incorporation of total cellular lipid fractions from at least three independent experiments containing triplicate samples ($n = 3$). Within the same lipid fraction, the bar not sharing the same letter was significantly different ($P < 0.05$); PC, phosphatidylcholine; PS, phosphatidylserine; PI, phosphatidylinositol; PE, phosphatidylethanolamine. See Figure 1 for other abbreviations.

were significantly greater than acetone treatment. TPA-induced release of ^{14}C-fatty acid could be ranked in decreasing order (^{14}C-CLA > ^{14}C-AA ≅ ^{14}C-LA) (Fig. 3). TPA-induced PGE_2 synthesis in ^{14}C-AA pretreated group was two times higher than in ^{14}C-LA pretreated group and more than five times higher than in ^{14}C-CLA pretreated group (Fig. 4).

ODC activity. In order to determine the ability of CLA to support TPA-induced cell proliferation, ODC activity was measured in keratinocytes pretreated with fatty acid then treated with TPA. TPA-induction of ODC activity was significantly higher than acetone ($P < 0.05$) in all fatty acid-treated groups (Fig. 5). However TPA-induced ODC activity was sig-

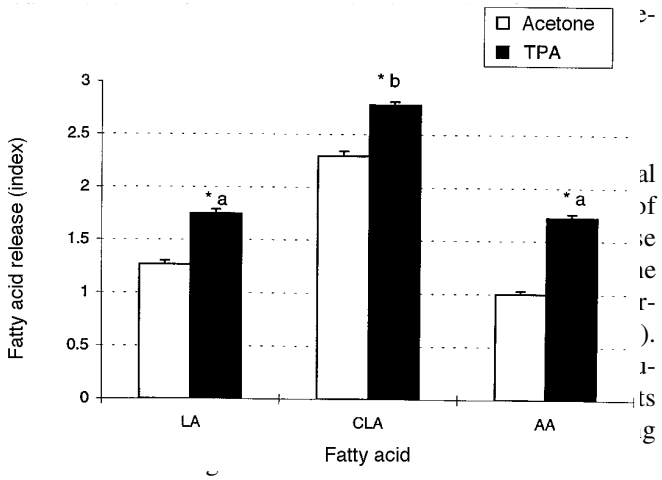

FIG. 3. 12-*O*-tetradecanoylphorbol-13-acetate (TPA)-stimulated fatty acid release. Cultures were labeled with 0.2 μCi/mL ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA. After 12 h, cultures were changed to the media containing acetone or TPA and then incubated 3 h. Radiolabeled fatty acid release was measured in an aliquot of media and counted by liquid scintillation. An index of 1.00 was used for cultures prelabeled with ^{14}C-AA and then treated with acetone. Data represent the mean of radiolabeled fatty acid release index ± SEM from two independent experiments containing triplicate samples. Within the cultures prelabeled with same ^{14}C-fatty acid, an asterisk (*) indicates a significant difference between means of TPA treatment and acetone treatment ($P < 0.05$). Within the cultures treated with TPA, the bar not with a different letter was significantly different ($P < 0.05$). See Figure 1 for other abbreviations.

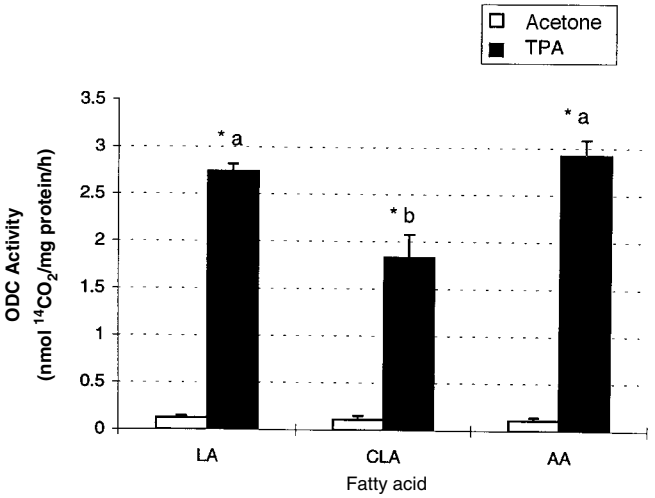

FIG. 5. Effects of LA, CLA, and AA on TPA-induced ornithine decarboxylase (ODC) activity. Confluent keratinocyte cultures were grown in serum-free media containing LA, CLA, or AA for 12 h followed by treatment with acetone or TPA for 6 h. Data represent the mean of ODC activity ± SEM from two independent experiments containing four samples. Within the cultures grown with fatty acid, an asterisk (*) indicates a significant difference between means of TPA treatment and acetone treatment ($P < 0.05$). Within the TPA-treated cultures, the bar not sharing the same letter indicates a significant difference ($P < 0.05$). See Figures 1 and 3 for other abbreviations.

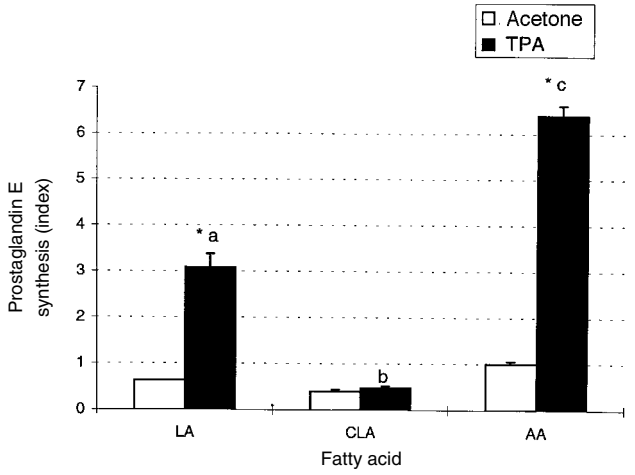

FIG. 4. TPA-stimulated prostaglandin E (PGE) synthesis. Cultures were labeled with 0.2 μCi/mL ^{14}C-LA, ^{14}C-CLA, or ^{14}C-AA. After 12 h, cultures were changed to the media containing acetone or TPA and then incubated 3 h. Radiolabeled prostaglandins were extracted from media and PGE was separated by TLC and counted by liquid scintillation. An index of 1.00 was used for cultures prelabeled with ^{14}C-AA and then treated with acetone. Data represent the mean of radiolabeled PGE synthesis index ± SEM from two independent experiments containing triplicate samples. Within the cultures prelabeled with same ^{14}C-fatty acid, an asterisk (*) indicates a significant difference between means of TPA treatment and acetone treatment ($P < 0.05$). Within the cultures treated with TPA, the bar not sharing the same letter was significantly different ($P < 0.05$). See Figures 1, 2, and 3 for abbreviations.

Exogenous CLA was incorporated into cellular lipids in a manner similar to LA and AA. However, of the phospholipid-associated fatty acids, LA and CLA were preferentially incorporated into PC while the AA was more evenly distributed into PC, PS/PI, and PE. These data are similar to previous findings showing LA and AA distribution in primary epidermal cells (13). Because it is thought that the TPA-induced cytosolic phospholipase A_2 shows preference for PC compared with other phospholipids (18,19), the predominance of LA and CLA in PC is important. However, more recent evidence suggests that this form of cytosolic phospholipase A_2 may also prefer AA-containing PC over other PC containing other fatty acids at the *sn*-2 position (i.e., LA or CLA) (19). These data are notable since we found that TPA treatment was associated with elevated levels of CLA in the media compared with LA and AA. However, there was also a higher amount of free CLA in the acetone (control) media. These data may be reflective of slightly lower incorporation of ^{14}C-CLA and/or higher turnover of CLA-containing phospholipids. The significance of elevated CLA in media of both TPA- and non-TPA (acetone)-treated cultures deserves further attention.

A large body of evidence suggests that eicosanoids play an important role in carcinogenesis and particularly in TPA-induced ODC activity and skin tumor promotion (20). In particular, AA-derived eicosanoids enhance tumor promotion-associated events in mouse skin. Previous studies demonstrated that the inhibition of TPA-induced prostaglandin synthesis reduced ODC activity which may be completely reversed by topical treatment with AA-derived PGE_2 prior to

TPA application (11). Furthermore, TPA-induced PGE_2 synthesis and ODC activity in cultures pretreated with AA were higher compared with LA (13). The tumor promoter, TPA, may stimulate epidermal cells to synthesize PGE by increasing phospholipase A_2 activity and/or inducing PGE synthase activity (20). While the CLA release induced by TPA treatment was elevated, TPA-induced PGE synthesis was low. These data support the hypothesis that dietary CLA inhibits tumor promoter-related events in keratinocytes *via* a PGE-mediated mechanism.

The action of free CLA in cells is still unknown. However, we have shown that CLA may act as a substrate of Δ6 desaturase in a manner similar to LA (21). These data may explain our findings showing a slight amount of an eicosanoid product that comigrated with PGE in our TLC solvent system. The significance of elongated/desaturated products and/or the interaction of CLA as an inhibitor of eicosanoid enzymes such as prostaglandin synthases is not presently understood.

In multistage mouse skin carcinogenesis, TPA-induced promotion is associated with increased ODC activity (9). Increasing basal levels of ODC activity result in the synthesis of polyamines which are thought to be required for stabilizing increased DNA synthesis involved with hyperproliferative cells and tumor promotion (22–24). That CLA supported lower levels of TPA-induced ODC activity than AA or LA suggests CLA is less able to support hyperproliferation induced by TPA.

These data suggest that the antipromoter activity of CLA is dependent, in part, on inhibition of TPA-induced PGE synthesis. Because dietary lipids are a complex mixture of fatty acids, further studies are needed to determine the extent that CLA competes with nonconjugated lipids that are known to modulate carcinogenesis, such LA and AA.

ABSTRACT: Several years ago, it was established that the Δ15 *trans* isomer of α-linolenic acid is converted *in vivo* into fatty acids containing 20 and 22 carbons (geometrical isomers of eicosapentaenoic and docosahexaenoic acids). The present study focused on the *in vitro* Δ6 desaturation, the first step of the biosynthesis of the n-3 long-chain polyunsaturated fatty acids from 18:3n-3. For that purpose, rat liver microsomes were prepared and incubated with radiolabeled 18:3 Δ9*cis*,12*cis*,15*cis* (18:3*c,c,c*) or 18:3 Δ9*cis*,12*cis*,15*trans* (18:3*c,c,t*) under desaturation conditions. The data show that 18:3*c,c,t* is converted at a lower rate compared with α-linolenic acid. The product of conversion of 18:3*c,c,t* may be 18:4 Δ6*cis*, 9*cis*, 12*cis*, 15*trans* resulting from a Δ6 desaturation of the *trans* substrate. Moreover, the conversion of radiolabeled 18:3*c,c,t* was strongly decreased by the presence of 18:3*c,c,c* (up to 48%) while the 18:3*c,c,t* only slightly decreased the conversion of radiolabeled 18:3*c,c,c*. Thus, the desaturation enzyme presented a higher affinity for the native all-*cis* n-3 substrate.
Lipids 32, 731–735 (1997).

Heat treatments of vegetable oils induce the formation of geometrical isomers of essential polyunsaturated fatty acids (PUFA) (1,2). Linoleic acid (18:2 Δ9*cis*, 12*cis*) is mainly isomerized into 18:2 Δ9*cis*, 12*trans* and 18:2 Δ9*trans*, 12*cis* while α-linolenic acid (18:3 Δ9*cis*, 12*cis*, 15*cis*, 18:3*c,c,c*) is transformed mainly into 18:3 Δ9*trans*, 12*cis*, 15*cis* (18:3*t,c,c*) and 18:3 Δ9*cis*, 12*cis*, 15 *trans* (18:3*c,c,t*). Di-*trans* isomers also are obtained at high temperatures (above 200°C), and very little isomerization takes place at the Δ12 position of α-linolenic acid (1,2). Some years ago, it was demonstrated that the 18:3*c,c,t* isomer is the metabolic precursor of geometrical isomers of eicosapentaenoic and docosahexaenoic acids, with a *trans* double bond at the Δ17 and Δ19 positions, respectively (3). This suggests that 18:3*c,c,t* can be desaturated and elongated in rat tissues. The resulting long-chain n-3 *trans* isomers are incorporated in all tissues from rats (4) and have been recently reported in human platelets (5). Moreover, the *trans* C_{20} and C_{22} PUFA have specific physiological effects, as suggested by studies on human platelet aggregation (6,7) or rat electroretinography (4). On the other hand, it has been well established that the transformation of C_{18} PUFA into C_{20} and C_{22} long-chain metabolites is regulated at the first step of the desaturation–elongation process which is the Δ6 desaturation (8). Furthermore, a previous study has shown that a diet rich in *trans* isomers of α-linolenic acid (heated linseed oil) alters the biosynthesis of arachidonic acid at the Δ5 desaturation step (9). This suggests that an interference between the n-6 and *trans* n-3 fatty acid metabolism may exist. Alteration of the Δ6 desaturation of α-linolenic acid itself also was observed when the animals received a diet containing a purified *trans* isomer fraction (10).

However, the conversion of the 18:3*c,c,t* isomer had not yet been studied. The present investigation reports the *in vitro* conversion of 18:3*c,c,t* in microsomal fractions from livers of rats fed a fat-free diet.

MATERIALS AND METHODS

Fatty acids. The 18:3*c,c,c* fatty acids were purchased from Sigma Chemical Company (L'Isle d'Abeau, France) and NEN (Les Ulis, France) in unlabeled and [1-^{14}C]-radiolabeled (specific activity = 52.5 mCi · mmol^{-1}) forms, respectively. Unlabeled and labeled (specific activity = 51.5 mCi · mmol^{-1}) 18:3*c,c,t* was obtained by total synthesis as previously reported (11). Each radiolabeled 18:3 fatty acid was diluted in ethanol with the corresponding unlabeled compound in order to obtain a specific activity of 10 mCi · mmole^{-1}. Coenzymes and other biochemicals were purchased from Sigma (St. Louis, MO).

To identify the product of desaturation of 18:3*c,c,t*, a mixture of mono-*trans* isomers of 18:4n-3 fatty acid was prepared as follows. About 50 g of black currant seed oil (SIO, Saint Laurent Blangy, France) was saponified and the fatty acids were transformed into methyl esters, using sulfuric acid in methanol (0.45% by vol). The fatty acid methyl esters (FAME) (including about 3% of 18:4) were submitted to a urea adduction (1:3, w/w). After extraction by hexane, the

Abbreviations: CPS, counts per second; FAME, fatty acid methyl esters; FID, flame-ionization detector; GC, gas chromatography; HPLC, high-performance liquid chromatography; I/S, inhibitor/substrate; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography.

FAME were fractionated by reversed-phase high-performance liquid chromatography (HPLC). Briefly, a Nucleosil C18 (25 cm × 10 mm i.d.) column (Shandon, Eragny, France) and a Waters R410 refractometer (Milford, MA) were used. The mobile phase was a mixture of acetonitrile and acetone (9:1, vol/vol) at a flow rate of 4 mL · min^{-1}. The purified 18:4n-3 FAME was isomerized using nitrous acid (12). Briefly, 20 mg of 18:4 FAME were heated at 40°C for 5 min in the presence of 200 µL of sodium nitrite and 130 µL of nitric acid. After the addition of water, the FAME were extracted with hexane. The *trans* FAME were then fractionated using silver nitrate thin-layer chromatography (TLC) (2). After elution with a mixture of diethyl ether and methanol (9:1, vol/vol), the plates were sprayed with a solution of 2′,7′–dichlorofluorescein in ethanol (2% by vol) and viewed under ultraviolet light. The spot corresponding to the mono-*trans* isomers (R_f = 0.31) was scraped off and extracted from the silica gel according to the method of Hill *et al.* (13), slightly modified (3). This fraction containing the mixture of the four mono-*trans* isomers was added to the samples before HPLC separation in order to collect the appropriate fraction before counting.

Preparation of microsomes and incubations. Wistar weaning male rats (IFFA CREDO, L'Arbresle, France) were fed a fat-free diet for 3 wk. After an overnight fasting period, they were sacrified by cervical dislocation. Livers were quickly excised and liver microsomes were prepared as previously described (14). Briefly, about 3.5 g of each liver was homogenized in sucrose and phosphate buffer (pH 7.4). The homogenate was then centrifuged for 20 min at 13,000 × *g*. The supernatant was centrifuged for 60 min at 100,000 × *g*. The pellet was then resuspended into saccharose–phosphate buffer and cytosol. Microsomal proteins were quantified according to Layne (15).

Microsomal suspensions containing 5 mg protein were immediately incubated with different levels (range 20–120 nmoles) of [1-^{14}C]-18:3*c,c,c* or -18:3*c,c,t*. The incubations were carried out at 37°C for 15 min, as previously described (10), with the following modifications. Each incubation medium contained 72 mM phosphate buffer, 4.8 mM $MgCl_2$, 0.5 mM CoA, 3.8 mM ATP, 0.5 mM NADPH, 0.8 mM NADH, and 0.5 mM reduced glutathione, in a final volume of 2 mL. The reciprocal interaction between both 18:3 fatty acids was also studied, using a radiolabeled substrate (60 nmoles) and its corresponding unlabeled isomer (20–60 nmoles).

Analysis of the products of conversion. The reactions were stopped by addition of a mixture of chloroform and methanol (2:1, vol/vol). After evaporation to dryness of the chloroform phase, the fatty acids were transesterified according to Morrison and Smith (16). The FAME were then extracted with hexane and fractionated using reversed-phase HPLC according to Narce *et al.* (17). Briefly, a Hibar Lichrocart superspher RP-18 (25 cm × 4 mm i.d.) column (Merck, Darmstadt, Germany) and a Waters R401 refractometer were used. The mobile phase was a mixture of acetonitrile and water (95:5, vol/vol) at a flow rate of 1 mL · min^{-1}. The unlabeled mixture of 18:3*c,c,c* and 18:3n-3 or 18:3*c,c,t* and 18:4 mono-*trans* isomers was added to each sample in order to collect the radioactive fractions which contain the remaining substrate (18:3 *cis* or *trans*) and the subsequent metabolite (18:4 *cis* or *trans*). Each collected fraction was then transferred into a scintillation vial, and Ultima Gold (Packard, Groningen, The Netherlands) scintillation cocktail was added. The radioactivity was assessed using a 1900 TR Tricarb liquid scintillator (Packard). The distribution between substrate and product (percentage of conversion) allows the calculation of the amount of substrate transformed.

*Identification of the metabolite of the conversion of Δ18:3 9*cis*, 12*cis*, 15*trans*.* In order to identify the desaturation product of 18:3*c,c,t*, incubations were performed using 0.83 µCi of radiolabeled 18:3*c,c,t* or 18:3*c,c,c* for each incubation (total: 50 µCi). After 30 min of incubation, the reaction was stopped, and the FAME were prepared as described above and pooled. They were then fractionated by HPLC as described above and then analyzed by TLC. The FAME were separated on silica gel plates (Merck) impregnated with a solution of silver nitrate in acetonitrile. After elution with diethyl ether, the plates were scanned using a Berthold (Elancourt, France) LB 2852 scanner in order to detect the radioactive products. Unlabeled standard FAME (18:3*c,c,t* and 18:4 mono-*trans* isomers) were detected under ultraviolet light after spraying the same plates with a solution of 2′,7′ dichlorofluorescein.

The FAME were also analyzed on a Hewlett-Packard 5890 series II gas chromatograph (Palo Alto, CA), equipped with a split injector and a fused Stabilwax wide-bore silica column (60 m × 0.53 mm i.d., film thickness: 0.50 µm; Restek, Evry, France). The column was connected to a flame-ionization detector (FID) and to a radio-gas chromatography-(GC)-detector (GC ram; Lablogic, Sheffield, United Kingdom). The output flow from the column was split between the FID and the radio-GC-detector. Of the effluent from the column, 90% was oxidized through copper oxide to transform labeled fatty acids into $^{14}CO_2$. The radioactivity was determined by counting $^{14}CO_2$ after mixing it with a mixture of argon and methane (9:1). The remaining 10% of effluent was used for the FID. The data were computed using the Laura software (Lablogic, Sheffield, United Kingdom).

RESULTS AND DISCUSSION

In the present work, we have studied the conversion of one of the main *trans* isomers of α-linolenic acid, which is formed during heat processing of oils. We have also compared its conversion to that of 18:3*c,c,c*, using the enzymatic desaturation system present in rat liver microsomes. In these experimental conditions, the metabolite of 18:3 is 18:4, whereas the latter do not accumulate in an *in vivo* situation.

The effects of the substrate level on the conversion by the microsomal preparation are presented in Table 1. The Δ6 desaturation rate of 18:3*c,c,c* increased rapidly up to the 60 nmoles of substrate level (3.30 nmoles of conversion product). That is the saturating substrate level, as shown by the plateau observed between 60 and 120 nmoles of substrate concentration. On the other hand, the conversion of the 18:3*c,c,t* isomer is lower than that of its *cis* homolog (1.8 vs. 3.3 nmoles with

60 nmoles substrate), and it did not reach a plateau. This suggests that the saturating substrate concentration may be higher for the *trans* vs. the *cis* 18:3 fatty acid in our experimental conditions.

In similar conditions, it has been demonstrated that the 18:3*c,c,c* (α-linolenic acid) is desaturated at the Δ6 position into 18:4 Δ6*cis*, 9*cis*, 12*cis*, 15*cis* (stearidonic acid). However, the metabolic product of the 18:3*c,c,t* by microsomal incubations under the present experimental conditions still remained to be totally identified. Unfortunately, the bioconver-

See Table 1 for other abbreviations.

sion of this *trans* PUFA is low, and the quantity of the metabolite was not sufficient to purify and identify this fatty acid using classical chemical methods (18). As a consequence, we have identified this product by the procedures described in the Materials and Methods section. First, the radiolabeled 18:3*c,c,t* and its metabolite were separated by $AgNO_3$–TLC (R_f = 0.79 and R_f = 0.69, respectively). Unlabeled 18:3*c,c,t* and the mixture of 18:4 mono-*trans* isomers were also eluted as standards on the same plates. The mixture of isolated mono-*trans* isomers of 18:4n-3 presented the same R_f (0.68) as the unknown metabolite. This suggests that (i) it was not an elongation product as a molecule containing three double bonds would have had a similar R_f as the 18:3*c,c,t* precursor and (ii) it is a molecule containing four ethylenic bonds, one of them being in *trans* configuration. Additionally, the radio-GC-detection allowed us to see two labeled compounds (Fig. 1) for the FAME from liver microsomes incubated either in the presence of [1-^{14}C]-18:3 Δ9*cis*, 12*cis*, 15*trans* or in the presence of [1-^{14}C]-linolenic acid. The second peak was not detected when 18:3*c,c,t* was analyzed under similar conditions (data not shown). These two peaks presented the same retention time as 18:3 and 18:4, respectively. Together, these data (HPLC, TLC, GC) clearly indicate that the Δ15 *trans* isomer of linolenic acid is desaturated into a 18:4 *trans* fatty acid. Unfortunately, the amount of the metabolite formed was not sufficient to identify the position of the new double bond by techniques such as GC–mass spectrometry analysis of the dimethyl oxazoline derivatives (19). However, previous data suggested that it cannot be a Δ5 double bond as the metabolite of 18:3*c,c,t*, the 20:5 Δ5*cis*, 8*cis*, 11*cis*, 14*cis*, 17*trans* requires a Δ6 desaturation of 18:3*c,c,t* before an elongation and Δ5 desaturation (3).

The reciprocal interaction in the *in vitro* conversion of both 18:3 fatty acids is presented in Table 2. The 18:3*c,c,c* decreased the conversion of 18:3*c,c,t*. This decrease was more than 36% at an inhibitor/substrate (I/S) ratio of 1:3, reaching a maximum value of 48% at an I/S ratio of 2:3. On the other hand, the *trans* isomer slightly decreased the Δ6 desaturation of 18:3*c,c,c*. This effect ranged from 7 to 22% as the I/S ratio increased from 1:3 to 1. There was therefore a preferential desaturation of the 18:3*c,c,c*. These results suggest that the affinity of the enzyme is greater for the all-*cis* molecule as compared to the *trans* one.

These *in vitro* data have to be confirmed in cellular structures using hepatocytes in culture and *in vivo* experiments. These experiments will allow a better understanding of the metabolic pathway of such unusual fatty acids.

Increased Hepatic β-Oxidation of Docosahexaenoic Acid, Elongation of Eicosapentaenoic Acid, and Acylation of Lysophosphatidate in Rats Fed a Docosahexaenoic Acid-Enriched Diet

Ayako Kanazawa*, Yuri Shirota, and Kenshiro Fujimoto

Department of Applied Biological Chemistry, Faculty of Agriculture, Tohoku University, Sendai 981, Japan

ABSTRACT: Rats were fed a diet supplemented with corn oil (n-3 deficient), soy oil, or a mixture containing 8% 22:6n-3 ethyl ester for 6 wk. The hepatic capacities for the β-oxidation and synthesis of 22:6n-3, in addition to the acylation of lysophosphatidate, were tested *in vitro*. In rats that were fed a 22:6n-3-enriched diet, both the β-oxidation of 22:6n-3 and elongation of 20:5n-3 were enhanced compared to those in rats fed the other diets. Acylation of lysophosphatidate was also enhanced in rats fed a 22:6n-3-enriched diet, while the rate of dephosphorylation of phosphatidate was not changed. The amount of 22:6n-3 in the liver was much less than that consumed in a docosahexaenoic acid-enriched diet. These results suggest that a significant amount of dietary 22:6n-3 was degraded *via* β-oxidation, and that a portion of the retroconverted 20:5n-3 was recycled for the synthesis of 22:6n-3. The recycling of 20:5n-3 might contribute to the low level of 22:6n-3 in rats fed an n-3-deficient diet.

Lipids 32, 737–744 (1997).

Docosahexaenoic acid (DHA, 22:6n-3) in biomembranes is known to be essential for maintaining visual function in monkeys (1,2) and for improving the learning ability of rats (3,4). A prolonged depletion of n-3 fatty acid has been associated with neurological disturbance in a 6-yr-old girl (5). Maintaining the level of 22:6n-3 in biomembranes seems to be important for normal neurological function. It has been suggested that dietary 22:6n-3 is incorporated intact into brain phospholipid (PL) (6), while 18:3n-3 is converted to 22:6n-3 in the liver and then incorporated into brain PL (7). We previously reported that the fatty acid composition of cerebral cortical gray matter was slightly affected by the continuous intake of 22:6n-3 in rats after weaning, although this dietary effect was more distinct in the suckling period (8). We suggested that dietary 22:6n-3 mainly accumulated in the liver after weaning when liver growth accelerated. Furthermore, Anderson and Connor (9) reported that most of the radioactivity of labeled 22:6n-3 was found in the liver of the suckling rat 30 min after injection into the jugular vein, although the radioactivity in the liver was considerably lower in rats that had been functionally hepatectomized. With regard to the metabolism of 22:6n-3, the rates of both its synthesis and degradation seem to be slow and respond to the intake of only a small amount of n-3 fatty acid, considering that 22:5n-3, but not 22:6n-3, accumulates in various cells when they are incubated with 18:3n-3 (10–12), and that a low level of 22:6n-3 is maintained in the rat liver and brain after treatment with an n-3-deficient diet for several generations (13,14). The continuous intake of 22:6n-3 influences the rate of 22:6n-3 metabolism in organs, especially in the liver, which is an important organ for lipid metabolism and storage. The administration of 22:6n-3 (0.3 or 1.0 mL/d) to rats for 14 d induces an increase in β-oxidation and reduces Δ-5 and Δ-6 desaturations of n-6 fatty acid in hepatocytes but does not affect the formation of 22:6n-3 from 20:5n-3 (15). In addition, hepatic peroxisomal β-oxidation is enhanced by the administration of a large amount of 22:6n-3 (500–1500 mg/d) for 10 d in rats, while mitochondrial β-oxidation is not (16). In the present study, the effect of the continuous intake of 22:6n-3 on its own metabolism was tested in rats that were fed a lower level of 22:6n-3 (120–150 mg/d) for a longer period (6 wk) than in previous studies (15,16). Assays were performed when the fatty acid compositions reached a steady state in organs of rats fed different fats. The replacement of fatty acids requires at least 2 wk in livers and longer in the other organs of rats after their diet is changed (14). β-Oxidation of 22:6n-3, synthesis of 22:6n-3, and acylation of lysophosphatidate (LPA) with 22:6n-3 were tested *in vitro* to evaluate the effectiveness of the continuous intake of 22:6n-3 in maintaining 22:6n-3 levels in organs.

MATERIALS AND METHODS

Animals. Male 4-wk-old Sprague-Dawley Rats (Funabashi Farm, Funabashi, Chiba, Japan) were fed 20–25 g/d of a semipurified diet containing 7% fat (17). Table 1 shows the fatty

Abbreviations: BSA, bovine serum albumin; DHA, docosahexaenoic acid; HPLC, high-performance liquid chromatography; LCPUFA, long-chain polyunsaturated fatty acid; LPA, lysophosphatidate; PA, phosphatidate; PAP, phosphatidate phosphohydrolase; PL, phospholipid; TBARS, thiobarbituric acid reactive substance; TG, triglyceride; TLC, thin-layer chromatography.

acid compositions of the dietary fats. After the 6-wk feeding period, the rats were fasted for 15 h and decapitated under diethyl ether anesthesia. Blood was collected in a vial containing heparin, and livers were removed after perfusion with saline, frozen in liquid N_2, and stored at –80°C until use. The procedure used in this study complied with the guide of our institute for the care and use of laboratory animals.

Materials. Radiolabeled fatty acids (1.90–2.15 GBq/mmol) were obtained from New England Nuclear (Boston, MA) and diluted with unlabeled fatty acids (Funakoshi, Tokyo, Japan). 1-Palmitoylglycero-3-phosphate and phosphatidate (PA) were obtained from Funakoshi. Defatted bovine serum albumin (BSA) and malonyl-CoA were obtained from Sigma (St. Louis, MO). Other chemicals were purchased from Wako Pure Chemical (Osaka, Japan).

Ketone body determination. Plasma acetoacetate and 3-hydroxybutyrate levels were measured colorimetrically (18) using a commercial kit (Sanwa Chemical, Nagoya, Aichi, Japan).

Malonyl-CoA determination. The assay was performed basically according to the procedure described by Demoz *et al*. (19). The liver was homogenized in 5% sulfosalicylic acid containing 50 mM dithiothreitol, and centrifuged at 700 × *g* for 10 min. An aliquot of the supernatant was filtered through a 45-µm filter and applied to a high-performance liquid chromatography (HPLC) system (Japan Spectroscopic, Tokyo, Japan) fitted with a LiChrosorb RP-18 column (5-µm particle size, 4 × 250 mm; Merck, Darmstadt, Germany). The solvent contained 6% (vol/vol) methanol in 100 mM sodium dihydrogen phosphate and 75 mM sodium acetate adjusted to pH 4.7, and was delivered at a rate of 1.5 mL/min. Peaks were monitored at 254 nm with a spectrophotometric detector, and the concentration of malonyl-CoA was calculated from the peak area by comparison to a standard curve.

Preparation of homogenates. The liver was homogenized in 0.25 M sucrose and 2 mM $MgCl_2$/3 mM Tris-HCl buffer solution (pH 7.4) and centrifuged at 700 × *g* for 5 min. The supernatant was used for the enzyme assays. The protein content of the supernatant was measured using a Bio-Rad DC protein assay kit (Bio-Rad, Hercules, CA). To assess subcellular densities in the homogenate solution, the activities of catalase (20), cytochrome c oxidase (21), and NADPH cytochrome c reductase (22) were measured as markers for peroxisomes, mitochondria, and microsomes, respectively.

β-Oxidation rate. The oxidation of fatty acids to acetate was measured by a modification of the procedure described by Singh *et al*. (23). A final volume of 250 µL of 50 mM Tris-HCl buffer solution (pH 8.0) contained 37.5 µmol KCl, 0.5 µmol $MgCl_2$, 0.5 µmol oxaloacetate, 1.25 µmol ATP, 0.125 µmol dithiothreitol, 50 nmol NAD, 50 nmol L-carnitine, 15 nmol FAD, 15 nmol $CoANa_3$,10 nmol [1-^{14}C]18:1n-9 or [1-^{14}C]18:2 (70 Bq/nmol), and 0.5 mg BSA. The reaction was started by adding homogenate solution (135–155 µg protein) and stopped after incubation at 37°C for 3 min by adding 0.5 mL of 1 M KOH. The reaction mixture was heated at 60°C for 1 h to hydrolyze acyl-CoA and acyl-carnitine, and acidified with 50 µL of concentrated HCl. After removing fatty acid by the extraction procedure of Folch *et al*. (24), the aqueous phase was transferred to a scintillation vial containing scintillation fluid, and counted in a liquid scintillation analyzer (model 1900 TR; Packard Instrument, Meriden, CT). When [1-^{14}C]20:5n-3 or [1-^{14}C]22:6n-3 (120 or 100 Bq/nmol) was used as a substrate, 25 nmol NADPH was added to the reaction mixture without oxaloacetate. A blank assay was performed using boiled homogenates.

DHA synthesis. The synthesis of 22:6n-3 from 20:5n-3 was measured as previously reported, with minor modifications (25). A final volume of 500 µL of 50 mM potassium phosphate buffer solution (pH 7.4) contained 75 µmol KCl, 2.5 µmol ATP, 2.5 µmol $MgCl_2$, 0.75 µmol glutathione reduced form, 0.625 µmol NADH, 0.625 µmol NADPH, 0.15 µmol $CoANa_3$, 0.15 µmol malonyl-CoA, 50 nmol [1-^{14}C]20:5n-3 (35 Bq/nmol), 0.5 mg BSA, and 0.5 mg Triton WR1339. The reaction was carried out at 37°C for 10 min after adding homogenate solution (1.2–1.4 mg protein) and stopped by adding 1 mL of 10% (wt/vol) KOH/ethanol. Butylated hydroxytoluene was added as an antioxidant and [1-^{14}C]18:0 (250 Bq/tube) was added as an internal standard, and the mixture was heated at 70°C for 60 min. After removing unsaponifiable lipids using petroleum ether, 1 mL of 6 M HCl and 1 mL of KCl-saturated solution were added to the mixture, and the fatty acids were extracted from the acidified mixture with petroleum ether. The fatty acids were analyzed with an HPLC system (Gilson Medical Electronics, Middleton, WI) fitted with two LiChrosorb RP-18 columns (5-µm particle size, 4 × 250 mm; Merck) in series. The fatty acids were eluted with 10% (vol/vol) aqueous methanol containing 0.1% (vol/vol) phosphoric acid at 1 mL/min, and monitored at 210 nm with a spectrophotometric detector, coupled in series to a Ramona radioactivity detector. Peaks were identified by comparing the retention times to those of fatty acid standards (Nippon Suisan Kaisha, Tokyo, Japan). A blank assay was performed using boiled homogenates.

Acyl-CoA synthetase. Activation of [1-^{14}C]18:2 (22 Bq/nmol) or [1-^{14}C]22:6n-3 (26 Bq/nmol) was assayed according to the procedure described by Reddy and Bazan (26).

Acylation of LPA. A final volume of 250 µL of 100 mM

Others	3.2	4.4	7.8

[a]Fatty acid ethyl esters prepared from marine fish oil (Maruha Co.,Tokyo, Japan), in which docosahexaenoic acid (DHA) ethyl ester was concentrated up to a level of 60%, were added to corn oil at a ratio of 15:85 (w/w). n.d., not detected.

potassium phosphate buffer solution (pH 7.4) contained 0.625 μmol ATP, 0.5 μmol $MgCl_2$, 0.125 μmol dithiothreitol, 50 nmol $CoANa_3$, 40 nmol 1-palmitoylglycero-3-phosphate, 5 nmol [1-^{14}C]18:1n-9, 18:2n-6 or 22:6n-3 (150–170 Bq/nmol), 0.2 mg BSA, and 25 μg Triton X-100. The reaction was performed at 37°C for 1–3 min after adding homogenate solution (135–155 μg protein) and stopped by adding 2 mL of chloroform/methanol (1:1, vol/vol) containing 0.1 M HCl. Carrier phosphatidate (PA) and butylated hydroxytoluene were added, and the lipids were extracted according to the procedure described by Kanoh and Åkesson (27) and applied to high-performance thin-layer chromatography (TLC) plates (28). The PA on a Silica Gel 60 aluminum plate (Merck) viewed under iodine vapor was cut out, transferred to a scintillation vial containing scintillation fluid, and counted in a liquid scintillation analyzer. A blank assay was performed without 1-palmitoylglycero-3-phosphate.

Phosphatidate phosphohydrolase (PAP). Dephosphorylation of PA was assayed in the presence of $MgCl_2$ according to the procedure described by Surette *et al.* (29).

Fatty acid analysis. Liver and plasma lipids were extracted by the method of Folch *et al*. (24) and developed on a Silica Gel 60 TLC plate containing a fluorescent indicator (Merck) with *n*-hexane/ethyl ether/formic acid (80:30:1, by vol). The triglyceride (TG) and PL bands on the TLC plates were scraped into tubes and heated at 70°C for 3 h in acetyl chloride/methanol (1:9, vol/vol) with 17:0 as an internal standard. Fatty acid methyl esters were extracted with *n*-hexane. Fatty acid methyl esters were analyzed by gas chromatography as previously described (30).

Thiobarbituric acid reactive substances (TBARS). TBARS were measured by the method of Ohkawa *et al*. (31).

Statistical analysis. Differences between groups were evaluated by the Mann-Whitney U-test when the *P* value in the Kruskal-Wallis test was less than 0.05.

RESULTS

There were no differences among the groups in either the body weight or the liver weight when the rats were sacrificed. The body weights (g) and liver weights (g), ± SD, were as follows: 372.8 ± 8.6 and 14.2 ± 2.3 in the corn group; 360.4 ± 15.8 and 11.9 ± 1.3 in the soy group; 368.6 ± 14.5 and 12.7 ± 0.9 in the DHA group, respectively.

In the rats fed a commercial chow, the rate of β-oxidation of [1-^{14}C]18:2n-6 by homogenate prepared from a frozen piece of liver was about 70% of that by homogenate prepared from a piece kept at 4°C overnight in 0.25 M sucrose and 2 mM $MgCl_2$/3 mM Tris-HCl buffer solution (pH7.4), as shown in Figure 1. However, depression in β-oxidation of [1-^{14}C]20:5n-3 in a frozen piece was much less than that of [1-^{14}C]18:2n-6, and the formation of acid-soluble product from [1-^{14}C]22:6n-3 in 5 min was not depressed (data not shown).

Table 2 shows parameters which reflect hepatic β-oxidation in the three dietary groups. No differences were observed among the dietary groups in the levels of plasma acetoacetate and 3-hydroxybutyrate, which are excreted from the liver as final products of mitochondrial β-oxidation. Liver malonyl-CoA levels were almost the same in the three groups. No differences were observed in the activities of cytochrome c oxidase and catalase, which indirectly reflect mitochondrial and peroxisomal densities in liver homogenates, respectively. Although no differences were observed among the groups in the amounts of acid-soluble products from [1-^{14}C]18:1n-9 and [1-^{14}C]18:2n-6, the amount of product from [1-^{14}C]22:6n-3 was significantly higher in the DHA group than in the other two groups ($P < 0.05$). In addition, the product from [1-^{14}C]20:5n-3 was formed at a slightly higher rate in the DHA group, but the differences between the groups were not statistically significant ($P = 0.05$). When BSA in the reaction mixture was replaced with Triton X-100 at a level of 0.1%, which suppresses mitochondrial β-oxidation much more than it does peroxisomal β-oxidation (32), the formation of acid-soluble product from both [1-^{14}C]20:5n-3 and [1-^{14}C]22:6n-3 was highest in the DHA groups (data not shown).

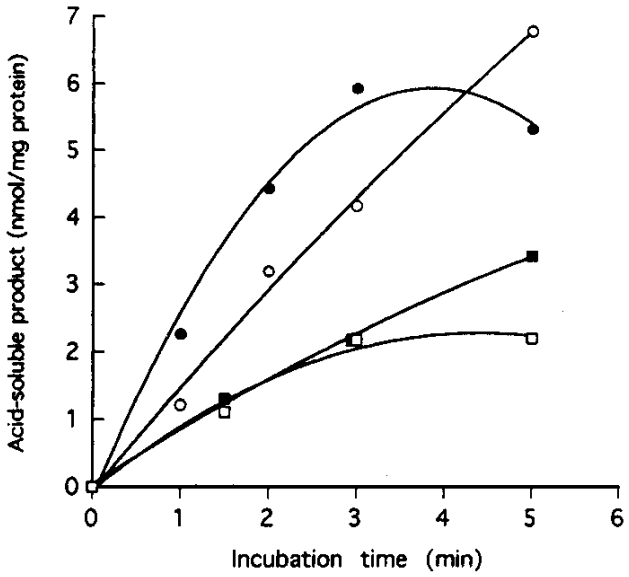

FIG. 1. The formation of acid-soluble product from [1-^{14}C]18:2n-6 and [1-^{14}C]20:5n-3 by a liver homogenate prepared from a frozen piece or a fresh piece of liver. A lobe of liver obtained from a 9-wk-old rat that had been fed a commercial diet was cut into two pieces. One piece was frozen (open symbols) and the other was kept at 4°C overnight in a buffer containing 0.25 M sucrose (closed symbols). ○,●, [1-^{14}C] 18:2n-6; □, ■, [1-^{14}C]20:5n-3.

The specific activity of NADPH cytochrome c reductase (nmol/min/mg protein) as a marker of microsomes was almost the same in the three groups: 36.6 ± 6.3 in the corn group; 36.5 ± 4.8 in the soy group; 33.0 ± 5.8 in the DHA group.

Figure 2 shows an HPLC chromatogram of 22:6n-3 synthesis from 20:5n-3 by liver homogenates of a rat fed soy oil. Two radioactive peaks, which represent elongation and desaturation products from 20:5n-3, were detected, and the radioactivity of endogenous stearic acid (18:0) was almost equal to that at baseline in the absence of [1-^{14}C]18:0 as an

[1-^{14}C]22:6n-3 (nmol/min/mg protein)	0.47 ± 0.13[a]	0.45 ± 0.13[a]	0.65 ± 0.07[b]

[a]Values (means ± SD of five rats) with different superscript letters (a,b) are significantly different ($P < 0.05$). For abbreviation see Table 1.

internal standard (Fig. 2B). As shown in Table 3, the amounts of both 22:5n-3 and 22:6n-3 formed from 20:5n-3 were significantly higher in the DHA group than in the other two groups ($P < 0.05$). Rats in the DHA group showed a greater capacity for 22:6n-3 synthesis, mainly owing to the enhanced chain elongation of 20:5n-3. The synthesis of 22:6n-3 from 22:5n-3 seemed to be almost the same in the three dietary groups, considering that there were no differences in the ratio of 22:6n-3 to 22:5n-3 among the groups.

The effect of dietary fat on the acylation of 1-palmitoylglycero-3-phosphate is shown in Table 4. Acyl-CoA was formed from either 18:2n-6 or 22:6n-3 at a similar rate in the three groups by homogenates, as well as microsomal and mitochondrial fractions (data not shown). The rate of the incorporation of either 18:1n-9 or 18:2n-6 into the PA fraction was higher in the DHA group than in the other two groups ($P < 0.05$), and the intake of 22:6n-3 in the DHA group was more rapid than that in the soy group ($P < 0.05$). The specific activity of acylation of LPA appeared to be higher in the DHA group; however, no differences were observed in the specific activity of PAP, which is a key enzyme in TG synthesis.

The concentrations of the major fatty acids in liver TG and PL are shown in Tables 5 and 6, respectively. Long-chain polyunsaturated fatty acids (LCPUFA) were abundant in the PL fraction. In the DHA group, a considerable amount of 22:6n-3 was detected in both TG and PL, and the 22:6n-3 levels in both fractions were highest in this group. In the corn and soy groups, only a very low level of 22:6n-3 in TG was detected. The 20:4n-6 level in TG was highest in the corn group; however, no differences were observed among the groups in PL. The levels of both 20:5n-3 and 22:5n-3 in TG were highest in the DHA group. No differences were observed among the groups in the 20:5n-3 level in PL; however, the level of 22:5n-3 in PL was significantly lower in the corn group than in the other two groups. The amounts of 22:6n-3 in the plasma and in the liver were highest in the DHA group (Fig. 3). In addition, there were no differences among the

groups with respect to the TBARS value (nmol/g liver), which reflects the level of the secondary product of lipid peroxidation (33): 44.3 ± 3.7 in the corn group; 50.6 ± 4.0 in the soy group; 50.9 ± 3.5 in the DHA group.

DISCUSSION

In this study, the effects of dietary n-3 LCPUFA on fatty acid oxidation were not clear, except for that on the β-oxidation of 22:6n-3. The hepatic capacity for ketogenesis might be almost the same in the three dietary groups, as suggested by the results of tests for plasma ketone bodies, in addition to cytochrome c oxidase and catalase activities (Table 2). Furthermore, the level of malonyl-CoA, which is an inhibitor of the translocation of fatty acyl residues to mitochondria (34), was also the same in the three groups. These results suggest that a low-fat diet over a longer period than has been used in previous studies (15,16,29,35–38) does not produce a remarkable change in the capacity for hepatic ketogenesis. Dietary n-3 LCPUFA is known to increase the capacity for hepatic fatty acid oxidation; however, this effect is not clear in rats fed a diet containing less than 15% fat, and enzyme activities related to β-oxidation often depend on the duration of feeding (36).

No differences were observed among the groups in the rate of the formation of acid-soluble product from either [1-^{14}C]18:1 or 18:2. These values might reflect the initial rate of β-oxidation, i.e., the rate of the normal cycle of β-oxidation. The measurement of radioactive acid-soluble product formed from [1-^{14}C]fatty acid depends on the initial one or two cycles of β-oxidation. The rate of the formation of acid-soluble product from 22:6n-3 was significantly higher in the

22:6n-3	1.41 ± 0.05[a]	3.45 ± 0.56[b]	5.24 ± 0.57[c]

[a]Values (means ± SD of five rats) with different superscript letters (a–c) are significantly different ($P < 0.05$). For abbreviation see Table 1.

DHA group than in the other groups in the presence of NADPH ($P < 0.05$), while little product was formed from either 20:5n-3 or 22:6n-3 in the absence of NADPH (data not shown). The β-oxidation of fatty acids which have a Δ-4 double bond requires 2,4-dienoyl-CoA reductase (39) and proceeds beyond a double bond positioned at either an even- or an odd-numbered carbon atom as a result of the addition of NADPH or a NADPH-generating substrate (40–42). This result suggests that the activity of 2,4-dienoyl-CoA reductase was relatively increased in rats fed a DHA-enriched diet. Bergseth *et al*. (43) reported that 2,4-dienoyl-CoA reductase activity in rat hepatocytes was higher in a fish oil-fed group than in a soya oil-fed group, although there was no difference in the rate of the production of ketone bodies from 22:6n-3 between groups fed the same amounts of soy and fish oils. Willumsen *et al*. (38) reported that a single dose of 20:5n-3 ethyl ester, but not 22:6n-3, enhanced mitochondrial 2,4-dienoyl-CoA reductase. The amount of acid-soluble product from 20:5n-3 was slightly higher in the DHA group than in the other two groups ($P = 0.05$), and 20:5n-3 was found at only a low level (less than 1.5 μmol/g liver) in TG and PL combined, as shown in Tables 5 and 6. These results suggest that the β-oxidation of n-3 LCPUFA was more active in the DHA group than in the other groups and that a significant amount of 22:6n-3 was completely degraded in the DHA group.

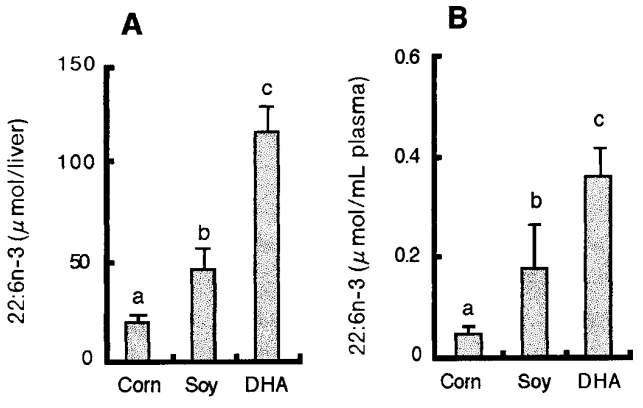

FIG. 3. The 22:6n-3 levels in liver (A) and plasma (B). Each bar represents the amount of 22:6n-3 in the combined triglyceride and phospholipid fractions (mean ± SD of five rats). Bars with different superscript letters (a–c) are significantly different ($P < 0.05$). DHA: docosahexaenoic acid.

Schlenk *et al*. (44) reported that a considerable amount of retroconverted 20:5n-3 was chain-elongated in the liver to 22:5n-3, the carboxyl group of which showed much lower radioactivity than those of 20:5n-3 and 22:6n-3, when rats were fed [U-^{14}C]22:6n-3. In rat hepatocytes, chain elongation of retroconverted 20:5n-3 is observed during prolonged incubation with [4,5-^{3}H]22:6n-3 (45). In this study, the chain elongation of 20:5n-3 *in vitro* was most active in the DHA group, and the amount of 22:6n-3 formed was also significantly higher in the DHA group than in the other dietary groups ($P < 0.05$) (Table 4). This result appears to be inconsistent with the finding of Grønn *et al*. (15), who reported that the synthesis of 22:6n-3 from 20:5n-3 in rat hepatocytes was not affected by the intake of n-3 LCPUFA. However, it should be noted that the source of a two-carbon unit for the chain elongation of 20:5n-3 in hepatocytes is limited to endogenous malonyl-CoA. The chain elongation of 20:5n-3 certainly may have been affected by the amount of substrate acid in the liver, which was most abundant in the DHA group, as shown in Tables 5 and 6. However, the 20:5n-3 levels in the livers of rats fed diets with different 18:2n-6/18:3n-3 ratios did not affect the synthesis of 22:5n-3 or 22:6n-3 from 20:5n-3 in our previous *in vitro* study with a crude microsomal fraction, which included peroxisomes (46). In rats fed a DHA-enriched diet, the chain elongation of 20:5n-3 might be stimulated by the enhanced chain shortening of 22:6n-3.

PA is an intermediate in glycerolipid synthesis, and is mainly produced from 1-acylglycerophosphate with microsomal fractions (47). Berge *et al*. (36) reported that the production of PA and/or LPA from glycerophosphate in either mitochondrial or microsomal fractions was higher in rats fed fish oil than in rats fed soy oil. We also found that the acylation of

LPA was more active in rats fed a DHA-enriched diet (Table 4); however, the elevated activity of PA synthesis did not seem to affect TG synthesis, considering that the PAP activity and the presumed concentration of TG calculated from the amount of total fatty acid (data not shown) were almost the same in all of the groups. Compared to a fat containing 18:3n-3 and/or 18:2n-6, a DHA-enriched fat did not have a distinct effect on TG synthesis. However, Marsh *et al*. (48) observed decreases in hepatic activities of PAP, TG hydrolase, and diacylglycerol hydrolase in rats fed fish oil compared to rats fed a commercial chow.

The amount of 22:6n-3 accumulated in the liver (*ca*. 40 mg) was much less than that consumed in a DHA-enriched diet, even though fatty acid ethyl esters are absorbed less than TG in rats (49). Fatty acid ethyl esters appear to be well absorbed in humans (50,51); however, the intake of n-3 LCPUFA ethyl esters is not routine for healthy subjects, and the amount ingested is generally limited. In addition, it should be noted that the lipid transfer protein activity in rats (52) is quite different from that in humans (53). The present study suggests that a considerable proportion of dietary 22:6n-3, in addition to 22:6n-3 released from glycerolipids, is degraded, while 22:6n-3 might be continually incorporated into newly synthesized glycerolipid at a steady low rate. These results suggest that an excess amount of 22:6n-3 is degraded when rats are fed a large amount of 22:6n-3, and an essential level of 22:6n-3 is maintained when rats are fed only a trace amount of n-3 fatty acid. The reconstitution of 22:5n-3 from retroconverted 20:5n-3 might have contributed to the lack of a complete disappearance of 22:6n-3 in biomembranes.

ACKNOWLEDGMENTS

This work received financial support from the Food Science Institute Foundation (Ryoshoku Kenkyukai, Japan). DHA-enriched fatty acid ethyl esters were provided by Maruha Co. We gratefully acknowledge the assistance of Atsuko Nanjo.

Faculty of Pharmaceutical Sciences, Nagoya City University, Nagoya 467, Japan

ABSTRACT: Preliminary experiments have shown that a diet containing 10% rapeseed oil (low-erucic acid) markedly shortens the survival time of stroke-prone spontaneously hypertensive (SHRSP) rats under 1% NaCl loading as compared with diets containing perilla oil or soybean oil. High-oleate safflower oil and high-oleate sunflower oil were found to have survival time-shortening activities comparable to that of rapeseed oil; olive oil had slightly less activity. A mixture was made of soybean oil, perilla oil, and triolein partially purified from high-oleate sunflower oil to adjust the fatty acid composition to that of rapeseed oil. The survival time of this triolein/mixed oil group was between those of the rapeseed oil and soybean oil groups. When 1% NaCl was replaced with tap water, the survival time was prolonged by ~80%. Under these conditions, the rapeseed oil and evening primrose oil shortened the survival time by ~40% as compared with n-3 fatty acid-rich perilla and fish oil; lard, soybean oil, and safflower oil with relatively high n-6/n-3 ratios shortened the survival time by roughly 10%. The observed unusual survival time-shortening activities of some vegetable oils (rapeseed, high-oleate safflower, high-oleate sunflower, olive, and evening primrose oil) may not be due to their unique fatty acid compositions, but these results suggest that these vegetable oils contain factor(s) which are detrimental to SHRSP rats.

Lipids 32, 745–751 (1997).

The stroke-prone spontaneously hypertensive (SHRSP) strain of rats develops the highest blood pressure among the commonly available rat strains and dies frequently of apoplexy particularly when NaCl is loaded. The dietary risk factors for this animal model are known to be low-protein and high-salt which are also suggested for human apoplexy. Although the genetic differences between the SHRSP strain and normotensive control strain (WKY) have not been fully defined, this animal model has been used widely for studies on essential hypertension, apoplexy, atherosclerosis, and age-related mental disorders.

Perilla seed oil from beefsteak plant *(Perilla frutescens)* has a fatty acid composition similar to that of linseed oil (~15% linoleic and ~60% α-linolenic acid) and is relatively common in east Asian countries. This oil has been shown to lengthen survival time of Donryu rats (a conventional strain) by ~10% (1) and those of SHRSP rats by ~15% (2) as compared with safflower oil (70% linoleic and <1% α-linolenic acid). We hypothesized that the observed beneficial effects of perilla oil on animal models of chronic diseases of the elderly (3) were due to its very low n-6/n-3 ratio. Rapeseed oil (~26% linoleic and ~8% α-linolenic acid) would be expected to have comparable beneficial effects because of its relatively low n-6/n-3 ratio and high oleate content. Low-erucic acid rapeseed oil, however, was found instead to shorten the survival time of SHRSP rats by >40% compared with soybean oil and perilla oil under 1% NaCl loading as drinking water (4).

Historically, a rapeseed strain containing both much smaller amounts of thyrotoxic sulfur compounds and erucic acid was selected, which was found to exhibit significantly less thyrotoxicity as expected. Later, however, the double-low rapeseed oil was reported to induce myocardial necrosis in a strain of the rat (5). After extensive studies, the incidence of myocardial necrosis was ascribed to the unique fatty acid composition of the rapeseed oil. A positive correlation with oleic and α-linolenic acid and a negative correlation with saturated fatty acids were proposed (6), and the necrosis was reproduced with a mixture consisting of soybean oil and triolein (7). Thus, the safety of double-low rapeseed oil for human use appears to have been established earlier as summarized by Dupont *et al.* (8).

However, the positive and negative correlations reported for myocardial necrosis (6) do not appear to apply to the observed shortening of survival time by these oils when fed to SHRSP rats (4), because perilla oil with similar proportions of saturated fatty acids and a greater proportion of α-linolenic acid than rapeseed oil extended the survival time of SHRSP rats significantly. The purpose of these studies was to examine if the survival time-shortening activity is due to the unique fatty acid composition of rapeseed oil, and if such an activity is seen in the absence of NaCl loading.

EXPERIMENTAL PROCEDURES

Diets and animals. A conventional basal diet containing 3.0% (w/w) oil (CE2; Clea Japan Co., Ltd., Tokyo, Japan) was made of fish meal, soybean meal, defatted powdered milk, wheat flour, corn, wheat bran, alfalfa meal, a vitamin mixture,

Abbreviation: SHRSP, Stroke-prone spontaneously hypertensive rat strain.

and a mineral mixture. This basal diet and test oil (fat) were mixed at a weight ratio of 9 to 1. The final oil content was 12.7 wt% (29 energy percentage). Fat and oils commercially available for human use were used, except for high-erucic rapeseed oil which was not for human use; rapeseed oil (low-erucic), soybean oil, safflower oil (high-linoleate), high-oleate safflower oil, high-oleate sunflower oil, perilla oil, evening primrose oil, lard, triolein (from high-oleate sunflower oil), fish oil, and their mixtures. The vitamin E content (total tocopherol) of the basal diet was 26 mg/90 g diet, and those of fats and oils (per 10 g) were 51 mg (fish oil), 18 mg (perilla oil), 6.4 mg (safflower oil), and 2.4 mg (olive oil).

Dietary pellets containing supplemented fats or oils were prepared by Clea Japan Co., Ltd., except for the fish oil diet which was prepared in our own laboratory and contained about 40% water as compared with the pelleted diets containing 8% water. Diets with peroxide values below 10 meq/kg were served. The food in the cage was replaced every day in the case of fish oil diet, and every two days in other diets, in order to keep the peroxide values of the ingested diets below 100 meq/kg. Rats were kept in an air-conditioned room, and the temperature was kept at 23±3°C.

Genetically SHRSP rats were kindly provided by Dr. Y. Suzuki (Professor, Kinki University School of Medicine, Osaka, Japan), and those with high systolic blood pressures were mated to maintain the strain. Blood pressure was measured using equipment from Ueda Manufacturing Co., Ltd., Tokyo, Japan (Model UR5000). Litters were distributed to different dietary groups as far as possible. In preliminary experiments, the number of rats in each group was ~6, and it was increased to >10/group for confirmatory experiments. Rats were weaned to the conventional diet (CE2) at 3 wk of age, and the test diets were given from 4 wk of age. Diet and tap water or 1% NaCl solution were given *ad libitum.* The fatty acid compositions of the diets, determined as methyl esters by gas–liquid chromatography, are shown in Table 1.

Fractionation of rapeseed oil components. In efforts to separate presumed survival time-shortening factor(s) in rapeseed oil, rapeseed oil (low-erucic) was mixed with 2 vol of acetone or ethanol, the mixture was cooled to −70°C, left overnight, and the precipitate was filtered off. After evaporation of the solvent, the residue (*ca.* 0.5% of rapeseed oil as acetone-soluble and 0.7% as ethanol-soluble) was dissolved in soybean oil at a 5-fold concentration (in 1:5 the amount of the treated rapeseed oil) (acetone- or ethanol-soluble in Table 2). A methanol-soluble fraction (0.6% of oil) was obtained by treating the oil at room temperature (methanol-soluble). Saponification of the oil was performed by a conventional method, and the unsaponifiable fraction (0.33% of oil) was dissolved in soybean oil at a 2.5-fold concentration (unsaponifiable fraction). The oil (5.8 kg) dissolved in 9.5 L of hexane and 0.5 L of diethyl ether was mixed with 1 kg of silicic acid (Merck, Darmstadt, Germany). The mixture was stirred overnight, and 5.22 kg of oil was recovered from the hexane/diethyl ether fraction (silicic acid-treated).

Statistical analysis. Statistical analyses of the survival times were performed by Log-Rank and Wilcoxon's test using a computer program (9), "Statistics Made Visual™" (SAS Institute Inc., Cary, NC).

RESULTS

Effect of oils on survival time of SHRSP rats under 1% NaCl loading. At first, we tried to answer the question whether the unique fatty acid composition of the rapeseed oil is responsible for the shortening of survival time of SHRSP rats. In Experiment 1 (Table 3), a mixed oil with a fatty acid composition similar to that of rapeseed oil was prepared by mixing

[a]A conventional diet containing 3% oil (90 g) was mixed with 10 g of lard, oil or oil mixtures, and typical fatty acid composition of the diets is shown in weight percentage. Some variations in fatty acid compositions were noted among the lots of oils used. Fatty acid composition of triolein/soybean oil/perilla oil diet used in Experiment 5 was not presented but was very similar to that of rapeseed oil. Unsaturated fatty acids with 20- and 22-carbon chains in the diets supplemented with vegetable oils were originated mainly from fish meat in the basal diet and partly from unidentified components of the oils.

[b]Diet supplemented with a mixture of 75% high-oleate safflower oil, 12.5% safflower oil, and 12.5% perilla oil.

[c]Not detectable or trace amounts.

[a]Litters of SHRSP rats (male) were distributed among different dietary groups and the test diets were fed from 4 wk of age. See Table 2 for other abbreviations.

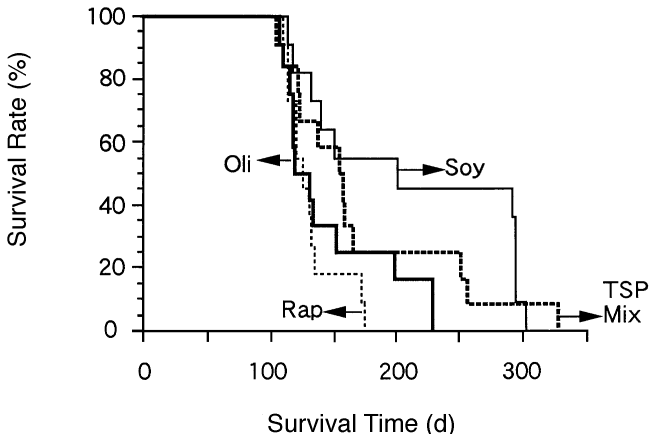

FIG. 1. Effect of vegetable oils on survival rate of stroke-prone spontaneously hypertensive (SHRSP) rats in the presence of 1% NaCl loading. A conventional basal diet containing 3% oil and test oil were mixed at a weight ratio of 9:1, and pelleted diet was fed to SHRSP rats from 4 wk of age. NaCl solution (1%) was given *ad libitum* as drinking water. Rapeseed oil (Rap, $n = 11$), olive oil (Oli, $n = 12$), soybean oil (Soy, $n = 11$), and triolein/soybean oil/perilla oil mixture (TSP Mix, $n = 12$) were examined. See Experiment 5 in Table 2 for detail of statistical analyses.

high-oleate safflower oil (75%), perilla oil (12.5%), and safflower oil (12.5%). The mixed oil was found to shorten the survival time by 45% compared to soybean oil similar to rapeseed oil. Earlier, we noted that perilla oil enhanced and safflower oil shortened the survival time of SHRSP rats by ~10% (1,2) compared with soybean oil. We suspected that the high-oleate safflower oil in the mixed oil was mainly responsible for the survival time-shortening activity of the mixed oil, since the high-oleate safflower oil was found to shorten the survival time similarly to the rapeseed oil (Experiment 2, Table 3). High-oleic sunflower oil was as effective as rapeseed oil, and high-erucic rapeseed oil reduced the survival time even more (Experiment 3). All the high-oleate vegetable oils examined (Experiments 1–3) were found to reduce the life expectancy of SHRSP rats.

When soybean oil and commercially available triolein, prepared from high-oleate sunflower oil, were mixed to adjust the oleate content to that of rapeseed oil, the linoleate content (32%) and α-linolenate content (3%) were slightly different from those of rapeseed oil (26% linoleate and 8% α-linolenate). The survival time of the triolein/soybean oil group was between those of the rapeseed oil and soybean oil groups (Experiment 4). The survival time of the safflower oil group was significantly less than that of the soybean oil group, as reported earlier (2). Because the number of animals was relatively small in Experiment 4, a similar experiment was performed using increased numbers of animals in Experiment 5 to test a triolein/soybean oil/perilla oil mixture. The survival times relative to that of soybean oil group (100) were 78% (triolein/soybean oil/perilla oil group), 72% (olive oil group), and 61% (rapeseed oil group) (Fig.1). The triolein/soybean oil/perilla oil mixture had almost the same fatty acid composition as that of rapeseed oil, but the survival time of this group tended to be longer than that of the rapeseed oil group, although the difference was not statistically significant.

In Experiment 5, the systolic blood pressure and pulse rate were measured at 4 and 8 wk of age and no significant differences among the dietary groups were detected (Table 4).

Effect of lard, vegetable oils, and a docosahexaenoic acid-rich fish oil on survival time of SHRSP rats in the absence of 1% NaCl loading. The survival times increased approximately by 80% when 1% NaCl solution was replaced with tap water. However, the survival time of the rapeseed oil group remained less, i.e., 61% of the soybean oil group (Experiment 6 in Table 5, Fig.2). Fatty acid composition of the evening primrose oil was much different from that of high-oleate vegetable oils (Table 1), but the survival time of this group was almost the same as that of the rapeseed oil group. The survival times of the perilla oil group and fish oil group were longer than that of the soybean oil group by 7 and 9%, respectively, but these differences were not statistically significant. In a similar experiment (Experiment 7), lard and safflower oil were found not to have such a marked survival time-shortening activity as observed with rapeseed oil, evening primrose oil, and other high-oleate vegetable oils (Table 3). Again, n-3 fatty acid-rich oils (fish oil and perilla oil) were beneficial for the survival of SHRSP rats as compared with lard and all other vegetable oils examined. The docosahexaenoate-rich fish oil, supplemented with soybean oil to meet the requirement for linoleate, gave the highest survival time.

Some attempts to separate the presumed survival time-shortening factor. Several fractions were prepared from rapeseed oil and tested to see if survival factor(s) could be removed

or isolated from the oil. Rapeseed oil was treated overnight at −70°C with acetone or ethanol, and the soluble fractions were mixed with soybean oil at a 5-fold concentration (in 1:5 the amount of the treated rapeseed oil). These fractions (acetone-soluble and ethanol-soluble in Table 2) did not shorten the survival time significantly. Similarly, methanol extracts of rapeseed oil (methanol-soluble), obtained at a room temperature, did not exhibit the survival time-shortening activity. Unsaponifiable materials from rapeseed oil were mixed with soybean oil at a 2.5-fold concentration (unsaponifiable fraction), and were found not to exhibit the activity.

Rapeseed oil (5.8 kg) in 9.5 L of hexane and 0.5 L of diethyl ether were mixed with 1 kg of silicic acid. The mixture was stirred overnight, and 5.22 kg of oil was recovered in the hexane/diethyl ether layer (silicic acid-treated). The survival time-shortening activity could not be removed. These experiments suggest that the survival time-shortening factor in rapeseed oil is relatively lipophilic, nonpolar in nature, and is closely associated with the triacylglycerols of the oil.

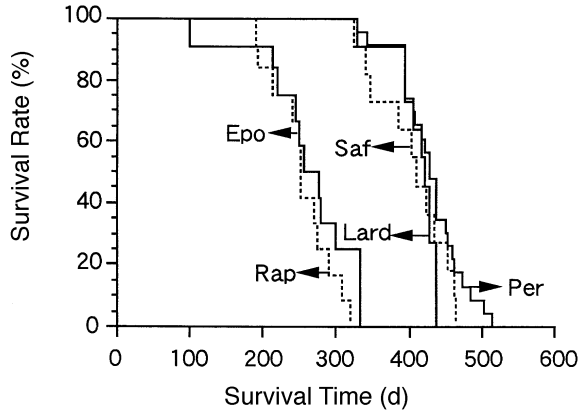

FIG. 2. Effect of vegetable oils on survival rate of stroke-prone spontaneously hypertensive (SHRSP) rats in the absence of 1% NaCl loading. A conventional basal diet containing 3% oil and test oil (lard) were mixed at a weight ratio of 9:1, and pelleted diet was fed to SHRSP rats from 4 wk of age, except for fish oil/soybean oil diet which was prepared in our laboratory (see text for details). Rapeseed oil (Rap, $n = 12$), evening primrose oil (Epo, $n = 12$), safflower oil (Saf, $n = 11$), perilla oil (Per, $n = 23$), or lard (Lard, $n = 11$) were examined. Tap water was given *ad libitum* as drinking water. See Table 4 for details of statistical analyses.

DISCUSSION

The survival time-shortening activity (4) was found not to be confined to rapeseed oil; high-oleate safflower oil, high-oleate sunflower oil, evening primrose oil, and olive oil exhibited comparable activities. Oleate esters have been implicated in certain disease conditions such as atherosclerotic plaques where cholesterol oleate accumulated as the major molecular species (10). However, in this case a high-oleate content itself does not appear to be crucial for this animal model because lard and a microbial oil containing 36–39% oleic acid were relatively safe, while evening primrose oil, containing only 13% oleic acid, was detrimental (Ref. 4 and Table 5). The survival time of the group fed a triolein/soybean oil mixture with an oleate content similar to that of rapeseed oil was between those fed soybean oil and rapeseed oil (Experiment 4 in Table 3). Similarly, the survival time of the group fed the triolein/soybean oil/perilla oil mixture, with a fatty acid composition very similar to that of rapeseed oil, was also found to be between those fed soybean oil and rapeseed oil, although the difference between the mixed oil group and rapeseed oil group was not statistically significant (Experiment 5 in

Table 3). Based on these results, it appears unlikely that the observed survival time-shortening activity is due to the unique fatty acid compositions of these oils. However, it should be noted that the triolein used to make up the two mixed oils was derived from high-oleate sunflower oil. If we presume that rapeseed oil and the other high-oleate vegetable oils contain detrimental factor(s) for SHRSP rats, then the factor(s) may have partially carried over from these oils through the purification steps.

Minor components other than triacylglycerol in high-oleic acid vegetable oils, such as olive oil and high-oleate safflower oil, have been implicated in a number of studies. A high-oleate safflower oil was shown to suppress mammary and colorectal carcinogenesis compared to high-linoleate safflower oil (11), whereas both olive oil and safflower oil were reported to stimulate colorectal carcinogenesis in contrast to perilla oil (12,13). Various preparations of olive oil are known to differ in their contents of minor components and the one used by Onogi *et al.* (12) might have contained a larger quantity of minor components which stimulated carcinogenesis, e.g., β-carotene which was recently shown in clinical trials to increase the incidence of certain types of cancers (14). In fact, olive oil had been shown earlier to suppress colon carcinogenesis (15).

If physiologically active minor components are present in some vegetable oils, they are lipophilic in nature and could affect the central nervous functions after being delivered to the brain through the blood brain barrier. In fact, we found unusual behavioral patterns in rapeseed oil-fed mice as compared with those fed several other kinds of vegetable oils. The phenomena could not be accounted for simply by the differences in the fatty acid compositions, or ratio of linoleate to α-linolenate (16). We have no evidence so far for the interpretation that the presumed survival time-shortening factor also affected the behavior of mice. However, some of the results of behavioral studies in rodents fed different vegetable oils are apparently inconsistent among different laboratories (17–19). The vegetable oils with significant survival-time shortening activities were fed to animals in some behavioral studies: rapeseed oil (18,20–22) and olive oil (17). Apparent discrepancies reported for the effects of vegetable oils on behavior of rodents may have originated, at least in part, from differences in minor components other than fatty acids in the oils.

Compared to Danish people, the incidence of thrombotic diseases in native Greenlanders (Inuit) was less than one-tenth, but that of apoplexy was slightly higher (23,24). Therefore, a long-term ingestion of large amounts of fish oil was suspected to be a risk factor for apoplexy. However, this has not been confirmed by epidemiologic studies (25); although n-3 fatty acid supplementation lengthens bleeding time, there is no evidence to suggest that it causes clinically significant bleeding episodes (25). Consistently, our present (Table 5) and previous studies (2,26) have shown that long-term feedings of fish oil and perilla oil at 10 w/w% of diet were beneficial for the suppression of the development of apoplexy in SHRSP rats.

Rapeseed oil (double-low) has been recently evaluated for possible nutritional benefits associated with its relatively low n-6/n-3 ratio, high-oleate content, and low level of saturated fatty acids. In fact, dietary rapeseed oil and olive oil resulted in decreased n-6 fatty acids with concomitant increases in oleic and n-3 fatty acids, which proved to be very effective for the secondary prevention of coronary heart disease (27). However, the observed beneficial effect of the combination of rapeseed oil and olive oil on coronary heart disease is interpreted to be due to their relatively low linoleic acid contents and n-6/n-3 ratios (28). We need to solve the problem of the survival-time shortening activity observed in SHRSP rats before advising people to consume a large amount of rapeseed oil and olive oil. At present, we need to evaluate carefully the potential merits and problems of high-oleate vegetable oils, including rapeseed oil, in human nutrition.

Oral Acetylsalicylic Acid Induces Biliary Cholesterol Secretion in the Rat

William F. Prigge* and Roger L. Gebhard

Department of Medicine, VA Medical Center, Minneapolis, Minnesota 55417, and University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT: Several agents can alter biliary cholesterol secretion, critical for cholesterol excretion and gallstone formation. Although salicylate effects on bile formation and gallstones have been studied, biliary lipid secretion has not been measured during oral aspirin treatment. We examined whether oral acetylsalicylic acid affects bile lipid secretion. Three groups of young rats were fed chow for 3 wk. Two of the groups then received aspirin at either 1.67 or 3.33 g/kg diet for 4 d. Serum, hepatic, and bile lipids were measured, as were enzymes of cholesterol synthesis and esterification. With oral aspirin, bile cholesterol secretion increased by 42% and hepatic cholesteryl ester content decreased by 40%. Serum cholesterol and hepatic free cholesterol did not change. To evaluate mechanisms of the cholesterol hypersecretion, hypothyroid animals fed low-fat or fish oil diets and repleted with triiodothyronine were also studied. Aspirin stimulated cholesterol secretion to a degree similar to triiodothyronine. An additive response was seen in fish oil-fed rats. Aspirin did not appear to have a primary action on 3-hydroxy-3-methylglutaryl-CoA reductase or acyl CoA:cholesterol acyltransferase activities, and had no direct effect on esterification of cholesterol by isolated hepatocytes. Aspirin may directly increase cholesterol transport into bile or have cell membrane effects which alter cholesterol transport. It remains to be determined whether the observed alterations in bile cholesterol secretion are specific to the rat or also apply to humans. *Lipids 32*, 753–758 (1997).

Several drugs can influence bile flow and bile lipid secretion. Substances which alter biliary cholesterol secretion usually have a more general impact on cholesterol metabolism, particularly cholesterol synthesis. Inhibitors of 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase block the regulatory enzyme of cholesterol synthesis (1). In humans given the reductase inhibitor lovastatin, cholesterol synthesis and cholesterol secretion into bile were reduced (2,3). In the rat, lovastatin also acutely reduced bile cholesterol (4). However, reductase inhibitors given long-term also induce the amount of hepatic enzyme protein, especially in rats (1). Thus, rats withdrawn from inhibitor increased cholesterol synthesis fivefold and bile sterol secretion threefold (1).

Abbreviations: ACAT, acyl CoA:cholesterol acyltransferase; ASA, acetylsalicylic acid; FO, fish oil; HMG-CoA, 3-hydroxy-3-methylglutaryl CoA; LF, low-fat diet; SA, salicylic acid; T3, triiodothyronine.

Bile cholesterol secretion was also increased by progesterone, an inhibitor of cholesterol esterification *via* acyl CoA:cholesterol acyltransferase (ACAT), and by diosgenin, which impairs cholesterol absorption, increases synthesis, and reduces esterification (4,5). Thyroid hormone has many actions on cholesterol metabolism (6–8). Bile flow and cholesterol secretion were reduced in hypothyroid rats, while triiodothyronine (T3) repletion rapidly caused hypersecretion (7,8). Increased hepatic HMG-CoA reductase activity followed bile cholesterol hypersecretion.

In rats, dietary fish oil lowered serum cholesterol and increased bile cholesterol secretion (9–11). The extent of increase varied with experimental conditions. Secretion increased 50% from an acute bile fistula, and 400% from chronic bile-diverted animals. Fish oil (FO) n-3 fatty acids inhibit very low density lipoprotein formation (12) and increase low density lipoprotein receptor activity (13), actions which could increase bile cholesterol secretion.

Some organic anions excreted into bile also affect bile lipid secretion. Iodipamide, ampicillin, and bilirubin reduced bile lecithin and cholesterol secretion in rats to 25% of basal, without altering bile salt output (14,15). The former two agents also increased bile flow. The action of bilirubin on lipid secretion was seen only when conjugated bilirubin was transported into bile (16).

Infusion of sodium salicylate (SA) or lysine acetylsalicylate (ASA) increased bile flow in dogs and monkeys (17–19). Bile salt secretion did not change in dogs given the salicylates (17,19), but lecithin and cholesterol secretion fell markedly in those given lysine ASA (19). Bile lipid secretion was not altered in monkeys infused with sodium SA (18). As a cyclooxygenase inhibitor, ASA has been suggested to inhibit cholesterol crystal nucleation in gallbladder bile. Sodium ASA treatment did not alter bile cholesterol saturation index in humans (20), but bile lipid secretion was not measured. In rat studies, we report that chronic oral ASA stimulates bile cholesterol secretion and, to a lesser extent, secretion of lecithin and bile salt.

MATERIALS AND METHODS

Male Sprague-Dawley rats weighing 75–100 g were fed a low-fat diet (LF) prepared from ground stock rodent chow of

Ralston Purina (St. Louis, MO) as previously described (21). Animals were divided into three groups and fed LF for 3–4 wk. Group one served as control, while groups two and three received 1.67 g/kg and 3.33 g/kg ASA admixed into LF fed for 4 d prior to sacrifice. These animals were given regular water and were maintained in a light-reversed room (dark 0700–1900 h; light 1900–0700 h).

At time of study, animals were weighed and anesthetized with sodium pentobarbital (Nembutal) 60 mg/kg i.p. The bile duct was then cannulated with PE-10 tubing and bile was collected for 2 h, weighed to determine volume, and frozen. Animals were then exsanguinated and the serum was frozen. The liver was removed, rinsed in iced saline, blotted, and weighed. A 1-g sample was promptly homogenized in 11 mL iced 0.25 M sucrose using a Polytron with 10 mm probe at setting 3–4 for 5 s. Homogenate samples were aliquoted for protein analysis and lipid extraction. Remaining homogenate was used to prepare microsomes. Microsomal HMG-CoA reductase activity was measured as described (7). Microsomal ACAT activity was measured using endogenous cholesterol, as we have reported for kidney, with incubation time reduced to 5 min (22).

Total and free cholesterol of liver homogenates and microsomes, and total cholesterol of bile and serum were extracted and quantified by gas–liquid chromatography (GLC) as described (7). Total bile acids were measured using the methods of Talalay (23). Bile lecithin was measured using the PL Kit-K from Nippon-Shoji Kaisha, Ltd. (Osaka, Japan) (24). Protein was determined by the method of Lowry *et al.* (25). Bile was directly transesterified, and liver homogenate phospholipids were extracted and transesterified. Fatty acid methyl esters of the phospholipids were measured by capillary GLC (21).

Serum and bile SA levels were determined by GLC of the methyl derivative. A 0.2-mL sample of serum or bile was saturated with 80 mg NaCl in a 10×75 mm culture tube. An internal standard of 2 μg 13:0 fatty acid and 50 μg of the antioxidant butylated hydroxytoluene in 0.1-mL MeOH was then added, followed by 15 μL of 7 M H_3PO_4 and 1 mL diethyl ether. Tubes were capped, vortexed, and centrifuged. The ether phase was transferred to a conical vial. Ether was removed with nitrogen and traces of water with anhydrous ethanol. Residue was dissolved in 100 μL of 10% methanol in diethyl ether and methylated by addition of diazomethane at −70°C. GLC analysis was performed as described for fatty acid methyl esters (21). Diazomethane was prepared using a glassware kit and the precursor *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide from Aldrich (Milwaukee, WI).

In a second experiment, similar rats were fed LF diet or LF supplemented with 10% (w/w) fish oil (FO). Cholesterol was added to LF to compensate for cholesterol present in FO, so that both diets contained 0.1 mg cholesterol per kcal (21). These rats were made hypothyroid by adding methimazole 0.025% to drinking water (7). Four days prior to study, each diet group was further divided into four groups: one group remained hypothyroid, a second group received 200 μg T3 per 100 g body weight i.p. 48 h prior to study (7), a third group had ASA added to the diet at 1.67 g/kg, and the fourth group received ASA diet plus T3.

Additional animals were prepared to study effects of ASA and SA on esterification of cell membrane free cholesterol. Isolated liver cells, from animals fed LF alone or LF containing 1.67 g/kg ASA, were prepared using 0.5 mM EGTA (26,27). Yields were 400×10^6 hepatocytes per liver and viability was 90%. Cells were diluted to 5.5×10^6/mL and preincubated for 90 min at 4°C to label membranes with 1 μCi [^{3}H] cholesterol/mL (22.5 Ci/mmol), added as a 1 μCi/μL ethanol solution. Cells were centrifuged and resuspended in unlabeled media. One-mL aliquots of cell suspension were placed in 25-mL polycarbonate Erlenmeyer flasks containing 4 mL media continuously gassed with (95%O_2-5%CO_2), with or without 100 μg/mL ASA or 77 μg/mL SA. Cells were incubated for 4 h at 37°C, and lipids were extracted and fractionated (22). [^{3}H]cholesterol esters were measured as the fraction of total [^{3}H] cholesterol.

This project was approved by the Animal Use Subcommittee of the Minneapolis VA Medical Center (Minneapolis, MN). All animals were handled in accordance with all applicable local and federal regulations concerning laboratory animals.

Statistics. Values reported are mean ± SD. Student's unpaired *t*-test was used to calculate significance.

RESULTS

Table 1 shows weight, bile lipid secretion rate, serum and liver cholesterol level, and activities of HMG-CoA reductase and ACAT in control and ASA-fed euthyroid animals. No significant differences were seen for body or liver weights, serum cholesterol, or bile flow between ASA-treated and control animals. Bile cholesterol secretion, however, was significantly higher for animals given ASA, while biliary secretion of phospholipid and bile salts increased only modestly. Bile cholesterol saturation index did not change significantly in either ASA-fed groups.

No significant changes occurred in the fatty acid composition of whole liver or bile phospholipids as a result of ASA treatment (data not shown). Total cholesterol content of liver homogenate was similar for all groups, but ASA treatment decreased hepatic cholesterol ester content significantly to 60% that of control animals. Microsomal total and ester cholesterol contents were significantly reduced by the high ASA dose. Consistent with this finding, HMG-CoA reductase activity was significantly elevated above control values in the high ASA dose animals. ACAT activity was unaffected.

To exclude a direct effect of ASA on measured HMG-CoA reductase or ACAT activity, enzyme activities were assayed with added ASA in ethanol or sodium SA in water. At concentrations between 3 and 100 μg/mL, no effect on measured enzyme activity was produced by these compounds (Table 2). Serum salicylic acid levels in high- and low-dose ASA-fed animals averaged 81 and 45 μg/mL, respectively, while bile contained 16 and 12 μg/mL. These serum values are within the human therapeutic range.

TABLE 1
Effect of Acetylsalicylic Acid (ASA) on Parameters Measured in the Rat[a]

Parameter	Low-fat diet (LF) (n = 10)	LF + ASA 1.67 (g/kg) (n = 11)	LF + ASA 3.33 (g/kg) (n = 10)
Animal weight (g)	231 ± 23	236 ± 13	224 ± 11
Liver weight (g)	10.0 ± 1.0	9.7 ± 1.3	9.1 ± 0.7
Serum cholesterol (mM)	2.19 ± 0.37	2.14 ± 0.24	2.15 ± 0.13
Bile			
Flow (mL/kg/h)	4.56 ± 0.94	4.71 ± 0.77	4.68 ± 0.77
Cholesterol (μmol/kg/h)	2.79 ± 0.61	4.02 ± 1.27*	3.91 ± 1.39*
Phosphatidylcholine (μmol/kg/h)	17.9 ± 3.6	21.8 ± 5.2	23.7 ± 5.1*
Total bile acids (μmol/kg/h)	116 ± 42	153 ± 34*	142 ± 26
Saturation index	0.67 ± 0.11	0.70 ± 0.12	0.74 ± 0.13
Liver cholesterol			
Whole: total	31.1 ± 2.5	29.5 ± 2.3	29.7 ± 1.9
ester	3.6 ± 1.2	2.1 ± 1.5*	2.2 ± 1.2*
Microsomal: total	49.7 ± 5.3	48.5 ± 7.6	43.7 ± 6.1*

HMG-CoA reductase	199 ± 67	268 ± 90	368 ± 137*
ACAT (pmol/mg protein/min)	542 ± 83	499 ± 116	513 ± 171

[a]Values are means ± SD. HMG, 3-hydroxy-3-methylglutaryl. ACAT, acyl-CoA:cholesterol acyltransferase. *Difference between LF and LF + ASA, $P < 0.05$.

A second group of experimental animals was prepared in order to evaluate effects of ASA on biliary lipid secretion changes which we have shown to be associated with dietary FO and T3 status (7,21). Results are shown in Figure 1. Bile cholesterol secretion in hypothyroid rats fed LF or FO, rats repleted with T3, rats given oral ASA, and rats given the combination of T3 repletion plus ASA are shown. There was no difference between LF or FO diet for bile cholesterol secretion by hypothyroid animals. Thyroid hormone repletion significantly increased biliary cholesterol secretion in both diet groups, as previously shown (7,21). Bile cholesterol secretion also increased, to an extent equivalent to that seen with T3, in hypothyroid animals receiving only low-dose dietary ASA. In fact, the ASA effect in FO-fed rats was greater than the T3 effect in LF rats. The combination of T3 repletion plus dietary ASA was similar to that of either agent alone in the LF group. However in FO-fed rats, T3 repletion plus ASA treatment had an additive effect on biliary cholesterol secretion.

As seen for euthyroid rats, microsomal HMG-CoA reductase activity increased in both groups of hypothyroid rats given ASA. HMG-CoA reductase activity was slightly lower in hypothyroid LF than in FO animals, but values nearly doubled in all animals given ASA alone, or T3 plus ASA in combination (Table 3). In these hypothyroid animal studies, elevated baseline serum cholesterol values decreased with all interventions. Serum cholesterol levels of hypothyroid animals on either diet were 2.4 mM. Values fell significantly to 1.7 mM following either ASA feeding, T3 repletion, or the combination of T3 plus ASA. Serum SA levels in hypothyroid animals were less than half the values seen in euthyroid rats, reflecting reduced diet consumption by hypothyroid animals.

Cholesterol esterification was studied in isolated hepatocyte preparations from a third group of LF or LF plus ASA-fed animals. Cholesterol esters formed by hepatocytes prelabeled with [^{3}H] cholesterol and then incubated in media alone or media containing ASA or SA are shown in Table 4. Presence of ASA or SA had no direct effect on cholesterol esterification by hepatocytes of animals fed either diet. However, ASA prefeeding significantly increased hepatocyte cholesterol ester formation above that of control LF diet.

TABLE 2
Enzyme Activity in Control Rat Hepatic Microsomes Incubated with and without ASA and Salicylic Acid (SA)[a]

Drug addition	HMG-CoA reductase (as percentage of 0 addition)	ACAT (as percentage of 0 addition)
ASA (μg/mL)		
0	100	100
3	101	94
10	95	93
30	94	93
100	99	98
NaSA (μg/mL)		
3	93	87
10	93	99
30	96	101
100	95	102

[a]HMG-CoA reductase and ACAT assays were performed without (0) or with (3, 10, 30, 100 μg/mL) addition of salicylates directly to the reaction mixture. No direct effect seen. See Table 1 for other abbreviations.

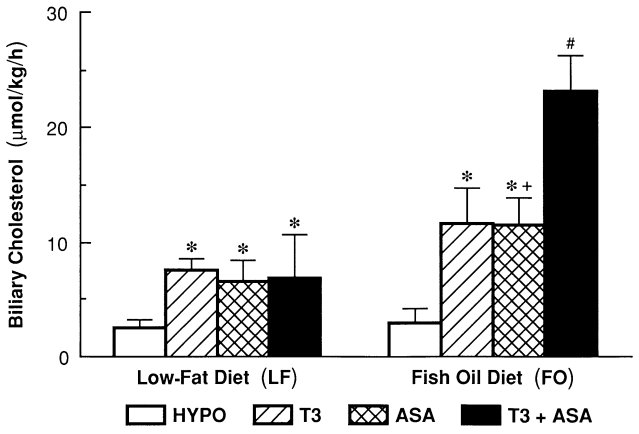

FIG. 1. Hypothyroid rats consuming LF or FO diet were administered triiodothyronine (T3), acetylsalicylic acid (ASA), or T3 plus ASA. Biliary cholesterol secretion was measured in control hypothyroid animals on each diet, and after each intervention. * Values different from LF and FO, $P < 0.05$. + Values, different from LF given T3, $P < 0.05$. # Values different from all other groups, $P < 0.05$.

TABLE 3
HMG-CoA Reductase Activity in Hypothyroid Rats and Hypothyroid Rats Given ASA or ASA + T3 (animals shown in Fig. 1)[a]

Animal diets	Low-fat diet (LF)	Fish-oil diet (FO)
Treatment	Liver microsomal HMG-CoA reductase (pmol/mg protein/min)	
Hypo	183 ± 122 ($n = 6$)	328 ± 37 ($n = 6$)
Hypo + ASA	560 ± 28* ($n = 2$)	549 ± 35* ($n = 2$)
Hypo + ASA + T3	617 ± 280* ($n = 2$)	587 ± 49* ($n = 2$)

[a]Values are means ± SD. * = Different from Hypo alone, $P < 0.05$. T3, triiodothyronine. See Table 1 for other abbreviations.

DISCUSSION

Under most conditions, bile cholesterol and phospholipid secretion are coupled to bile acid secretion (28–30). The mechanism(s) for this linkage are uncertain. It is also postulated that a specific intracellular free cholesterol pool is available for biliary secretion: a pool which can be expanded by synthesis or reduced by ester formation, with concomitant bile secretion change (4,5,31).

Previous studies have evaluated effects of intravenous salicylates on bile and bile lipid secretion. Salicylate infusion produced choleresis and reduced phospholipid and cholesterol secretion into bile (19). It was postulated that dilution of bile acids impaired their ability to extract phospholipid and cholesterol from canalicular membranes. However, the acute intravenous infusion model has limited experimental applicability for studying salicylate effects.

Oral aspirin and salicylates also have been studied to a limited extent in regard to gallstone formation. Aspirin appeared to prevent gallstones in prairie dogs fed a lithogenic diet (32). In humans, 600 mg sodium ASA four times daily, alone or with chenodeoxycholate, produced no ASA-specific change in bile cholesterol saturation index (20). Low-dose oral ASA also did not alter bile saturation index in obese subjects losing weight (33). However, bile lipid secretion was not measured in these studies.

The current studies show increased bile cholesterol secretion in young rats given oral ASA, at blood levels typical for human ASA use. In spite of the fact that bile cholesterol secretion was augmented by ASA treatment, bile cholesterol saturation index did not change significantly. This resulted from the fact that phospholipid and bile acid secretion also increased after ASA treatment, though to a lesser extent than cholesterol secretion. Previous studies also showed no effect of ASA on saturation index (20,33).

Consistent with the augmented bile cholesterol secretion were the observations that HMG-CoA reductase activity increased at high ASA dose, and the finding of diminished hepatic cholesterol esters in ASA-treated rats. Reductase activity usually reflects cholesterol synthesis. Since phospholipid and bile acid secretion also increased during ASA treatment, it seems unlikely that ASA had a primary effect on cholesterol synthesis. We also failed to find direct effects of ASA or SA on reductase or ACAT activity. It seems likely that the increased cholesterol secretion in ASA-treated rats leads to the diminished microsomal cholesterol and whole liver cholesterol ester content and the increased cholesterol synthesis. This is consistent with prior evidence for a hepatocyte free cholesterol pool which metabolically interrelates cholesterol synthesis, biliary secretion, and esterification (4,5,31).

In the second set of experiments, ASA augmented bile lipid secretion by LF-fed hypothyroid rats to the same extent as thyroid hormone repletion (7,8,21). Further cholesterol hypersecretion was seen after ASA treatment of hypothyroid

TABLE 4
Effect of ASA and Salicylic Acid (SA) on Cholesterol Ester Formation from Hepatocyte Membranes Pre-labeled with [3H]Cholesterol[a]

Animal diets	LF			LF + ASA 1.67 (g/kg)	
Hepatocytes (cultures)	Control ($n = 12$)	ASA 100 μg/mL ($n = 11$)	SA 77 μg/mL ($n = 10$)	Control ($n = 12$)	ASA 100 μg/mL ($n = 8$)
Percentage ester*	1.40 ± 0.35	1.39 ± 0.31	1.29 ± 0.25	4.29 ± 2.05[a]	3.56 ± 2.69[b]

[a]Expressed as percentage of total cell [^{3}H]cholesterol, following 4 h incubation at 37°C. Values are mean ± SD. a = Difference between LF control and ASA-fed, $P < 0.01$. b = Difference between LF control/ASA incubated and ASA-fed/ASA-incubated, $P < 0.02$. TABLE 5
Effects of Aspirin upon Hepatic Cholesterol Metabolism in the Rat Are Not Dependent upon the Surgical Intervention (2-h) (for bile drainage)[a]

Treatment	HMG-CoA reductase (pmol/mg protein/min) Microsomal	Hepatic cholesterol ester (μmol/g protein) Whole	Microsomal
LF unoperated ($n = 4$)	273 ± 39	9.2 ± 1.7	7.7 ± 0.8
LF operated/drained ($n = 5$)	234 ± 95	9.3 ± 3.2	6.9 ± 0.9
LF + ASA unoperated ($n = 5$)	487 ± 67*	3.3 ± 0.4*	2.7 ± 0.4*
LF + ASA operated/drained ($n = 5$)	456 ± 105*	2.7 ± 0.3*	1.9 ± 0.2*

[a]This separate group of animals was fed LF diet or LF plus 3 d of ASA. Animals then underwent surgery and bile drainage or had livers removed without surgery. Surgical intervention did not affect the results of ASA treatment. Values are mean ± SD. * = Significantly different from comparable animals not receiving ASA, $P < 0.05$. See Tables 1 and 3 for abbreviations.

rats on FO diet. An exaggerated response in FO-fed rats has been previously reported after T3 treatment (21), and was again seen in the current study. Because of variability in responses of the six FO hypothyroid animals given T3, augmentation above the secretion rate seen in LF rats given T3 did not reach statistical significance. The bile cholesterol response to co-administration of T3 plus ASA to hypothyroid rats suggests that the two mechanisms are not identical, since augmented cholesterol secretion was synergistic in FO-fed but not in LF-fed rats.

The mechanism for the observed ASA actions on bile lipid secretion is not clear. Aspirin is an organic acid which is absorbed, deacetylated to SA, and carried by albumin in blood. Its principal excretory route is renal, but we were able to detect SA in bile. Certain organic anions cause choleresis in association with reduced cholesterol and phospholipid secretion (14,15). We found no effect of ASA on bile flow rate, as opposed to reports of choleresis without change in bile lipid secretion after intravenous infusion of ASA or SA. Thus, the oral ASA effects are not typical of organic anion effects.

Anti-inflammatory effects of aspirin might account for the results observed. Laparotomy with bile duct cannulation and drainage is a traditional method for studying bile secretion in the rat. The surgical intervention could cause cytokine-mediated cholestasis during 2 h of collection, an action prevented by ASA treatment. Since bile collection could only be measured by drainage, we could not test this thesis directly. As shown in Table 5, we found no difference in hepatic HMG-CoA reductase activity or cholesterol ester content in chow-fed rats when measured immediately at time of sacrifice or 2 h after laparotomy and bile drainage. Consistent with findings in Table 1, however, ASA pre-fed rats had higher levels of reductase activity and reduced levels of cholesterol ester content, whether operated or unoperated. Bile cholesterol secretion, of course, could not be measured in unoperated animals. Reductase activity and ester content, two measurements associated with increased bile cholesterol secretion, were unaffected by the surgical procedure. This suggests that ASA's effect was not merely to prevent a cytokine-mediated artifact of this model.

The isolated hepatocyte study found increased esterification of cell membrane [^{3}H] cholesterol in animals fed ASA, but not as a result of hepatocyte incubation with ASA during 4-h culture. These experiments, coupled with absence of ACAT change, suggest that the bile cholesterol hypersecretion did not result from impaired esterification. It is likely that bile lipid secretion differs in isolated hepatocytes compared to intact liver. The increased ester formation observed in cells isolated from ASA-treated rats might have resulted from their state of cholesterol and ester depletion (Table 1), coupled with cessation of the biliary cholesterol hypersecretion after cell isolation.

It is possible that ASA might alter hepatocyte membrane composition or function (34). Hepatic inulin clearance was not altered in the i.v. sodium SA study (18), suggesting that SA does not alter liver permeability. However, altered cellular membrane lipid transport is possibile. Thus, ASA might facilitate cholesterol (and phospholipid) transfer from one pool to another, or influence transport of lipid vesicles to the canalicular membrane (35). The similarity of ASA effect to that of T3 suggests this possibility, as do the synergistic effects observed for ASA with treatments by FO and T3—agents which also affect membrane composition.

ASA is a cyclooxygenase inhibitor. Altered prostaglandin metabolism may have been intermediary in the bile lipid hypersecretion. Since unsaturated fatty acids, such as n-3 fatty acids, are substrates for cyclooxygenase, lipoxygenases and other oxygenase enzymes, prostaglandins or other eicosanoids may be a link to explain the synergism seen in FO-fed hypothyroid animals. This possibility warrants further evaluation. It also remains to be seen whether ASA-altered bile lipid secretion is specific to the young rat or occurs in other species, including humans.

γ-Linolenic Acid-Containing Diet Attenuates Bleomycin-Induced Lung Fibrosis in Hamsters

[a]Department of Dermatology, School of Medicine, [b]Anatomy and Cell Biology, School of Veterinary Medicine, and [c]Department of Molecular Bio-sciences, Division of Pharmacology and Toxicology, School of Veterinary Medicine, University of California-Davis, Davis, California 95616

ABSTRACT: Although bleomycin (BLM), an antineoplastic drug, is used in the treatment of a variety of tumors, the mechanism(s) that contribute to its induced lung injury and fibrosis are not fully elucidated. Since alterations in the levels of certain fatty acid metabolites have been associated with BLM-induced lung injury, we tested the effects of dietary γ-linolenic acid (GLA)-containing evening primrose oil on BLM-induced morphological alterations in the hamster lung, the marked elevation of tissue hydroxyproline (a marker for collagen synthesis), and elevated generation of arachidonic acid metabolites (marker of inflammatory mediators). Our data revealed that after 14 d of dietary GLA-containing oil (i) BLM-induced elevation of lung hydroxyproline was suppressed ($P < 0.05$), (ii) the marked BLM-induced elevation of lung leukotriene B_4 (LTB_4) (a marker of polymorphonuclear generation of proinflammatory LTB_4) was significantly suppressed ($P < 0.05$). The decrease in LTB_4 was accompanied by marked elevations ($P < 0.05$) of lung prostaglandin E_1 (PGE_1) and 15-hydroxyeicosatrienoic acid (15-HETrE), both with known antiinflammatory properties. Taken together, data from these studies suggest that dietary GLA-containing oil contributes to tissue elevation of PGE_1 and 15-HETrE, which *in vivo* may attenuate lung inflammation and fibrosis.
Lipids 32, 759–767 (1997).

Bleomycin (BLM), a mixture of cytotoxic glycopeptides, is used widely as an antineoplastic drug in the treatment of lymphoma, testicular and squamous cell tumors (1), since it has minimal hematopoietic toxicity or immunosuppressive activity. However, this therapy is often complicated by a dose-dependent induction of interstitial pneumonitis that progresses into interstitial pulmonary fibrosis (2), thus, limiting its long-term use. Although the pathogenic mechanisms that contribute to the development of BLM-induced lung injury and fibrosis are not fully elucidated, the search for antifibrotic agents persists in order to prevent the development of lung fibrosis.

The intratracheal instillation of BLM into rodents has been reported to induce fibrosis similar to that seen in humans (3,4); thus, these animals have formed useful models for investigating the biochemical mechanisms of the pulmonary fibrosis. Evidence of the involvement of inflammatory cells and their mediators in BLM-induced pulmonary fibrosis has been reported (5). The pathogenesis of the induced inflammation is characterized initially by edema, hemorrhage, and cellular infiltrates containing predominantly polymorphonuclear (PMN) (6,7) in the vascular, interstitial, and alveolar spaces of the lung. Since neutrophils are known to elaborate potent inflammatory eicosanoids particularly leukotriene (LTB_4), which is generated from arachidonic acid (AA), the possibility exists that eicosanoid mediators may contribute, at least in part, to the initial inflammatory response and ultimately to the pulmonary fibrosis. The reported alterations of prostaglandins and leukotrienes in certain lung disorders (8–10) suggest that these AA metabolites may be pivotal in the early pathogenic phases of lung injury. Additionally, BLM has been reported to induce the generation of reactive oxygen species (11). The increase and the availability of these reactive oxygen species have been associated with increased biosynthesis of prostaglandins (PG) (12). Also interesting, PG and related AA metabolites have been reported to modulate the growth and function of fibroblasts responsible for collagen synthesis (13,14). Taken together, the regulation of excessive generation of inflammatory eicosanoids seems pivotal in the suppression of BLM-induced lung injury. Thus, the need to evolve a therapeutic strategy with minimal side effects seems prudent.

There is a heightened interest that the dietary intake of certain polyunsaturated fatty acids (PUFA) contained in fish oil and/or in vegetable oils may function *in vivo* to alleviate inflammatory disorders. The initial excitement was that dietary PUFA of the n-3 series—α-linolenic acid (18.3n-3), eicosapentaenoic acid (EPA) (20:5n-3) and docosahexaenoic acid (DHA) (22.6 n-3)—could modulate a variety of chronic in-

Abbreviations: AA, arachidonic acid; BLM, bleomycin; B/S, basal-saline; CO, corn oil; DHA, docosahexaenoic acid; DGLA, dihomo-γ-linolenic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; 15-HETrE, 15-hydroxyeicosatrienoic acid; 13-HODE, 13-hydroxy-9,11-octadecadienoic acid; LA, linoleic acid; LTB_4, leukotriene B_4; ODS, octadecylsilyl; PC, phophatidylcholine; PE, phosphatidylethanolamine; PG, prostaglandin; PMN, polymorphonuclear; PUFA, polyunsaturated fatty acid; RP-HPLC, reverse-phase high-performance liquid chromatography; TLC, thin-layer chromatography.

flammatory diseases. These reports prompted investigations into clarifying the basis of the effects of the dietary intake of fish oil (15–18).

Similarly, the PUFA of the n-6 series, particularly γ-linolenic acid (GLA) (18:3n-6), which is a constituent of evening primrose oil and borage oil, have also generated excitement because of reports of the clinical improvement of patients with atopic eczema (a chronic and pruritic inflammatory skin disorder) after oral administration of evening primrose oil (19,20). The ingested GLA is elongated *in vivo to* dihomo-γ-linoleic acid (DGLA), a substrate for PGE_1. This prostanoid has been reported to exert a variety of effects, including antiinflammatory properties. In a recent clinical study, continuous external administration of GLA-containing oil to injured patients promoted DGLA incorporation into red cell phospholipids without increasing AA (21). The short-term continuous enteral feeding of GLA and/or EPA-containing oil attenuated endoxin-induced acute lung injury in pigs and rats (22). It has also been reported that supplementation of human diet with GLA-containing oil (borage oil) suppressed the ability of isolated normal neutrophils to generate LTB_4. Furthermore, the clinical efficacy of dietary GLA-containing oils in patients with rheumatoid arthritis has been reported (23–25).

Based on these promising findings, we reasoned that dietary GLA-containing oil (evening primrose oil) may suppress BLM-induced lung inflammation/interstitial pulmonary fibrosis. This possibility is based on the premise that dietary GLA will be elongated *in vivo* to DGLA which in turn is metabolized into two antiiflammatory metabolites: PGE_1 and 15-HETrE. To test this hypothesis, we supplemented the diet of the BLM-treated hamsters with GLA-containing evening primrose oil in order to determine its effect on: (i) lung eicosanoids and (ii) BLM-induced interstitial pulmonary fibrosis. The abnormality induced by intratracheal instillation of a single bolus of BLM to hamsters has been characterized to initiate interstitial pneumonitis which progresses to fibrosis.

MATERIALS AND METHODS

Animals. Male golden Syrian hamsters (weighing 80–100 g) were obtained from Simonsen Inc. (Gilroy, CA). The animals were housed in groups of 3–4 hamsters per cage in facilities approved by the American Association for the Accreditation of Laboratory Animal Care of the University of California, Davis. The facility provided filtered air, a constant temperature and humidity, and a 12-h/12-h light/dark cycle. The hamsters were initially maintained on Rodent Laboratory Chow 500 (Purina Mills, Inc., St. Louis, MO) with access to water *ad libidum*. The animals were allowed 1 wk to acclimatize to local conditions prior to dietary and treatment modifications.

Study design. The animals were randomly divided into four groups of 14 animals each. There were two control groups: (A) those who received basal-saline diet plus corn oil (B/S + CO) and (B) those who received basal-saline diet plus evening primrose oil (B/S + EPO). There were two experimental hamster groups: (C) those who received basal-saline diet plus BLM plus corn oil (B/S + BLM + CO), and (D) those who received basal-saline diet plus BLM plus EPO simultaneously (B/S + BLM + EPO). The composition of the basal diet is shown in Table 1. The fatty acid composition of the dietary oils is shown in Table 2.

TABLE 1
Composition of the Basal Diet

Constituents	Amount (g/100 g dry wt)
Oil[a]	10
Casein (vitamin-free)[b]	24
L-Cystine[b]	0.3
Glucose[b]	33
Corn starch[b]	20
Cellulose[c]	3
DL-Methionine	2
Mineral mix[d]	4
Vitamin mix[e]	4

[a]The oils added were CO (10% corn oil) and EPO (10% evening primrose oil). Corn oil was purchased from ICN Nutritional Biochemicals (Cleveland, OH). Evening primrose oil was a generous gift from Sid Tracy (Traco Labs, Champaign, IL).
[b]Source: ICN.
[c]Alphacel nonnutritive bulk (ICN).
[d]Custom hamster mineral mix, ICN catalog number 960200 (g/kg diet mix): $CaCO_3$, 298; $CaHPO_4 \cdot 2H_2O$, 74; $CuSO_4 \cdot 5H_2O$, 0.03; $MgSO_4 \cdot 7H_2O$, 107; $MnSO_4 \cdot H_2O$, 4.9; KI, 0.8; K_2HPO_4, 321; NaCl, 166; $ZnCl_2$, 0.5; ferric citrate, 27.3; NaF, 0.05; $CoCl_2$, 0.06; Na_2SeO_3, 0.025; $CrK(SO_4)_2 \cdot 12H_2O$, 0.5.
[e]ICN vitamin diet fortification mix provided the following (mg/kg) except as noted: vitamin A acetate, 20,000 IU/kg; vitamin D_2, 3000 IU/kg; pyridoxine-HCl, 22; α-tocopherol, 100 IU/kg; menadione, 5; biotin, 5; choline chloride, 3000; folic acid, 3; inositol, 150; niacin, 100; calcium pantothenate, 66; riboflavin, 22; thiamine-HCl, 30; vitamin B_{12}, 30; ascorbic acid, 900.

Treatment of animals. The experimental animals were placed under pentobarbital anesthesia (75–85 mg/kg) and received intratracheally one dose of BLM sulfate dissolved in saline (7.5 U/5 mL/kg body weight) as previously described (26). The control animals received the same volume of sterile isotonic saline. Fourteen days after the intratracheal administration of BLM and dietary feedings, the animals were euthanized by an overdose with phenobarbital (90–120 mg/kg) given intraperitoneally.

For biochemical determinations, the lungs were perfused *in situ* from the right side of the heart with ice-cold isotonic saline. The lung lobes were dissected free of nonparenchyma tissue, rinsed in ice-cold saline to wash off the blood, and immediately frozen in liquid nitrogen. The frozen lungs were stored at −80°C until they were processed for: tissue fatty acids in lung phospholipids, endogenous levels of lung cyclooxygenase/lipoxygenase products, and endogenous levels of tissue hydroxyproline.

Analyses of tissue lipids. The frozen lung tissue was thawed, minced, and homogenized in saline. A portion of the homogenate was acidified to pH 3.0 and then passed through ODS (C_{18}) silica columns (Sep-Pak silica cartridge; Waters

TABLE 2
Fatty Acid Composition of Dietary Oils[a]

	Fatty acid (%)	
Fatty acid	Corn oil	Evening primrose oil
16:0	10.5	6.3
16:1n-7	0.1	trace
18:0	1.8	1.8
18:1n-9	27.3	6.5
18:2n-6	60.2	75.4
18:3n-6	0.1	10.0

[a]Details of transmethylation and preparations of fatty acid methyl esters are described in the Materials and Methods section. The number after "n" indicates the number of carbon atoms from the methyl end of the acyl chain to the nearest double bond. Values are expressed as percentage of total fatty acids for corn oil (100%), evening primrose oil (100%). Only major fatty acids were computed.

Chromatography Division, Milford, MA). Briefly, a 6-mL Sep-Pak column was initially preconditioned by passage of 6 mL of methanol (MeOH), followed by 6 mL of H_2O, and then the acidified lung homogenate was applied to the preconditioned column. An initial percolation of petroleum ether onto the column eluted the neutral lipids. This fraction was not processsed further. Next, the polar phospholipids were eluted with 25% MeOH in water, and finally, the PG/leukotrienes/hydroxy fatty acids were eluted together with 100% MeOH. The fraction which contained the mixture of PG, leukotrienes, and hydroxy acids was collected and dried under a stream of N_2 gas. The residue was resuspended in a minimal amount of chloroform/MeOH (2:1, vol/vol), and aliquots were used for determination of the eicosanoids. Radioactive prostanoid was used to determine recovery from the Sep-Pak column. Recovery of ^{14}C-PGE$_2$ is approximately 80–90%.

Identification of the cyclooxygenase products. A portion of the MeOH fraction from the Sep-Pak column was transferred into a reaction vial and dried under N_2 gas. To the dry residue was added 100 µL of *p*-bromophenacyl bromide and 2 µL of *N,N*-diisopropylethylamine (27), and the mixture was incubated for 2 h at room temperature. Authentic PG standards—PGE$_2$, PGE$_{2\infty}$, PGD$_2$, and PGE$_1$—were similarly treated with the same chemical reagents as described above. After incubations, the reaction mixtures were extracted sequentially with ethyl acetate, citrate buffer, and phosphate buffer. The ethyl acetate fraction was dried under N_2 gas and the residue reconstituted in acetonitrile/H_2O (1:1, vol/vol). The resulting *p*-bromophenacyl bromide esters of the PG were separated on a C_{18}-Ultrasphere ODS, 5-µm reverse-phase high-performance liquid chromatography (RP-HPLC) column (25 cm × 4.6 µm, i.d.) (Beckman, Berkeley, CA). The products were eluted isocratically, using a mobile phase of acetonitrile/H_2O (1:1, vol/vol) at a flow rate of 2 mL/min. The absorbance of eluted compounds at 254 nm was automatically recorded using a Beckman System Gold Model 168 detector. Quantitation was determined by comparison with authentic standards.

Identification of lipoxygenase products. Another portion from the MeOH fraction (which contained lipoxygenase products) was dried under N_2 gas and then resuspended in ethanol. An aliquot was injected into the Beckman Ultrasphere 5 µm ODS (RP-HPLC) column as previously described (28). The mobile phase, consisting of MeOH/water/acetic acid (70:30:0.01, by vol) was run first at a flow rate of 0.8 mL/min from 0–10 min, and then increased to 1.8 mL/min for 10–60 min. The separated lipoxygenase products were monitored by characteristic wavelength absorbances on two channels: Channel A was monitored mainly for the leukotrienes at 270 nm (0–20 min) and for the hydroxy fatty acids at 234 nm (20–60 min). Channel B was monitored at 280 nm (0–60 min) for any novel metabolites. Quantitations were as described above, using known amounts of authentic standards.

Identification of lung phospholipid fatty acids. The polar phospholipid fraction eluted with 25% MeOH from the Sep-Pak was dried under N_2 gas and then applied to thin-layer chromatographic (TLC) plates coated with Silica Gel G (0.25-mm thickness) (Merck, Darmstadt, Germany). The plates were developed in the solvent system: chloroform/MeOH/acetic acid/water (50:37.5:3.5:2, by vol) (28). The phospholipids on the TLC plates were visualized under ultraviolet light after spraying with 0.2% 2′, 7′-dichlorofluorescein in ethanol. The TLC bands that correlated with total phospholipids were scraped and eluted with chloroform/MeOH (2:1, vol/vol). An internal standard, heptadecanoate, was added to the mixture and then dried. The fatty acids in the total phospholipids were transmethylated in 6% methanolic HCl, and the resulting fatty acid methyl esters were separated and quantitated in a Shimadzu model GC-17A gas chromatograph (Pleasanton, CA) equipped with a DB-225 fused-silica capillary column (50% cyanopropylphenyl, 0.15-mm film thickness) 30 m × 0.25 mm i.d. (J&W Scientific, Rancho Cordova, CA). Hydrogen (36 cm/s) was used as the carrier gas. The oven was run isothermally at 200°C, and detection of the fatty acid methyl esters was performed with a flame-ionization detector.

Assay for lung hydroxyproline. Hydroxyproline was assayed as previously described (29). Briefly, after thawing and homogenizing the lung tissue, 1.0 mL aliquots of the homogenate were transferred into a tube and precipitated with 0.25 mL of 50% cold trichloroacetic acid. The samples were thoroughly mixed with trichloroacetic acid, placed on ice for 10 min, and then centrifuged at 1500 × *g* for 20 min. The recovered supernatant from each sample was discarded, and each precipitate hydrolyzed overnight in 2 mL of 6 N HCl at 100°C. The concentration of hydroxyproline was measured for each sample by the method of Woessner (30).

Histopathology. Histological studies were performed as previously described (29) on 2 to 4 randomly assigned animals from each treatment group. Briefly, animals were first anesthetized and exsanguinated by transecting the descending aorta. After opening the thoracic cavity, the heart of each animal was tied at its base to isolate the pulmonary vasculature. The trachea was cannulated, and the lungs were fixed by airway instillation with a cacodylate-buffered, glutaraldehyde, paraformaldehyde fixative (440 mosm, pH 7.4) at 30 cm of H_2O pressure. Lungs were fixed for at least 2 h and then the left, right cranial, and right caudal lobes were cut in at

least two sagittal slabs. Stratified sampling provided the best estimate of total lung structure (31). Each slab was dehydrated in 95% ethanol and embedded in paraffin. Sections of each lobe were cut and stained with hematoxylin and eosin for general histopathology and sirius red, which is specific for collagen (32). A lesion was defined as thickening of intralveolar septa due to edematous swelling, the presence of interstitial inflammatory cells, fibrosis, hyperplastic epithelial cells, or airway inflammatory cells.

Statistical analysis. Data were subjected to one-way-analysis of variance. For comparison among the dietary groups [control (CO or EPO) BLM-treated/CO and BLM-treated/EPO], the software Microsoft Office (Excel 5.1) was used. The upper limit of significance chosen was $P < 0.05$. Values in the text are means + standard error (SEM). The biochemical data were expressed on a per lung basis (33) to avoid the artifactual lowering of the values in BLM-treated animals due to presence of proteins of extrapulmonary origin.

RESULTS

GLA-Containing diet attenuates BLM-induced morphological alteration of normal hamster lung. Representative photomicrographs of lungs from hamsters in: (A) control (B/S + EPO), (B) BLM-treated (B/S + BLM + CO), and (C) BLM-treated, GLA-containing EPO-fed (B/S + BLM + EPO) hamster lungs are shown in Figure 1. Lungs from control hamsters (B/S + CO) and (B/S + EPO) showed normal acini with their interalveolar septa and a lack of alveolar inflammatory cells. Lungs from B/S diet plus BLM plus CO-treated hamsters (B/S + BLM + CO) show moderate focal to severe diffuse lung lesions. Lesions of moderate severity were proximal acinar in location and were comprised of septal thickening associated with alveolar and interstitial mononuclear cell inflammation. More severe lesions showed focal fibrotic consolidation and diffuse interstitial and alveolar mononuclear cell inflammation. In contrast, lung from hamsters that received B/S diet plus BLM plus EPO (B/S + BLM + EPO) showed mild multifocal septal thickening and inflammation in proximal acini. These lesions comprised a very small percentage of this lung.

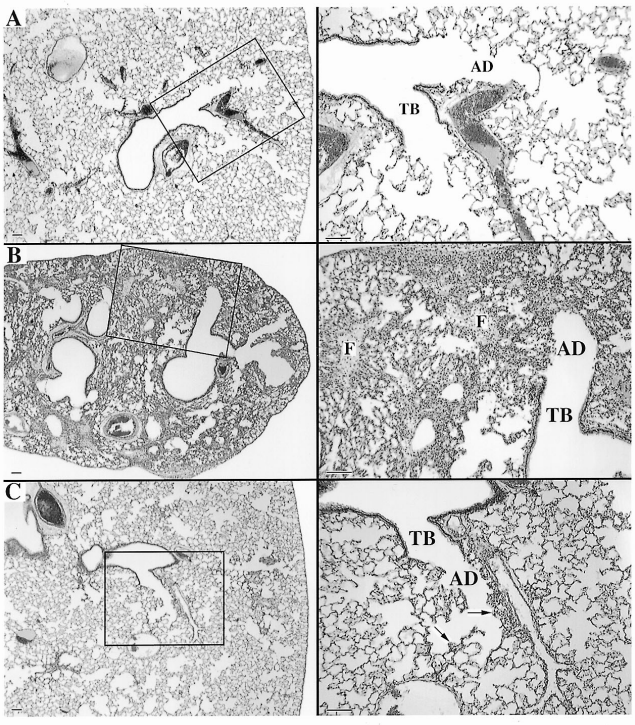

FIG. 1. Effect of γ-linolenic acid (GLA)-containing diet on altered morphologic changes in bleomycin-induced lung fibrosis. Representative photomicrographs of hamster lungs from: (A) control basal/saline (B/S) + evening primrose oil (EPO), (B) bleomycin (BLM)-treated plus corn oil (CO)-fed (B/S + BLM + CO), and (C), BLM-treated plus GLA-containing EPO-fed (B/S + BLM + EPO). The micrographs on the right are inserts (rectangles) of the lower magnification micrographs to the left. TB (representing the terminal bronchiole) and AD (representing the alveolar duct) are indicated in the magnified rectangular inserts. The bars (= 100 μm) are located horizontally on the lower left corner of the inserts. Note the normal acini in "A" with thin interalveolar septa and the absence of alveolar inflammatory cells. In contrast, in B, note the presence of fibrotic face (F) and the abundant alveolar and interstitial inflammatory cells. In C, note the mild interstitial inflammatory lesions (arrows) present in proximal acini.

*GLA-containing diet suppresses (*in vivo*) levels of (BLM)-induced lung hydroxyproline.* Lung collagen (an index of pulmonary fibrosis) was estimated by measuring tissue content of hydroxyproline. The data in Figure 2 revealed that intratracheal instillation of one dose of BLM (7.5 V/kg body weight) induced a marked increase (approximately twofold) in lung hydroxyproline after 14 d, when compared to the two control dietary groups: B/S + CO and B/S + EPO. Feeding of GLA-containing EPO-diet to the BLM-treated animals significantly suppressed (approximately 40%) the BLM-induced elevation of lung hydroxyproline. This GLA-suppressive effect is statistically significant ($P < 0.05$).

Effect of GLA-containing diet on total and individual lung phospholipid PUFA fatty acids. The distribution of PUFA in lung total and individual phospholipids after supplementation of hamster diet with EPO is shown in Table 3. The results in Table 3A revealed significant increases in endogenous DGLA (20:3n-6), the elongation product of GLA (18:3n-6), in all the lung total phospholipids of both the control animals and the experimental animals fed GLA-containing evening primrose oil. Moderate increases in AA (20:4n-6) were evident in all the animals when diets were supplemented with EPO. However, the examination of the distribution of PUFA in the two major lung phospholipids—phosphatidylcholine (PC) and phosphatidylethanolamine (PE)—shown in Table 3B and 3C revealed a striking difference in tissue AA. The data presented represent the mol% of the PUFA in PC or PE, respectively. For instance, lungs of all the animals fed EPO-supplemented diet (rich in GLA) had significantly elevated levels of DGLA in the PC when compared to PE, the level of PE being barely detectable. In contrast, the lung AA was significantly higher in PE than in PC particularly in the B/S + CO animal

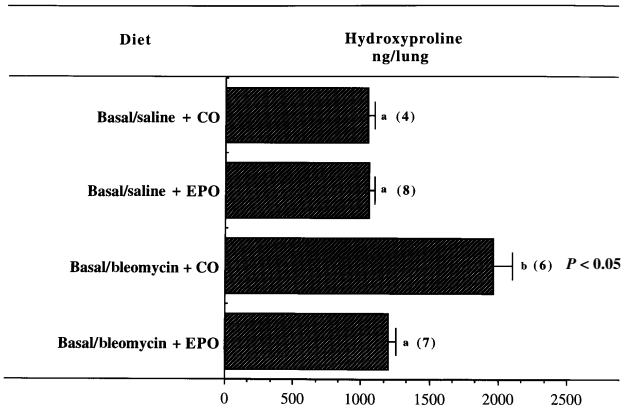

FIG. 2. GLA-containing diet suppressed BLM-induced elevation of lung hydroxyproline. Lungs were removed and homogenized in ice-cold saline from the hamsters in dietary groups: (i) B/S + CO, (ii) B/S + EPO, (iii) B/S + BLM + CO, (iv) B/S + BLM + EPO. BLM (7.5 U/6 mL/kg) was instilled intratracheally into each animal. Hydroxyproline was assayed as described in the Materials and Methods section. Values are means ± SEM. BLM-treated animals fed GLA-containing EPO (BS + BLM + EPO) significantly ($P < 0.05$) suppressed BLM-induced elevation of hydroxyproline when compared to similar animals fed CO (B/S + BLM + CO). The number of animals (*n*) in each group is shown in parentheses. Values not sharing a common superscript letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

group. The reason for the elevated AA in PE relative to PC is presently unclear. This possibility remains to be further elucidated. It appears that these two important C_{20} carbon PUFA (DGLA and AA) are preferentially incorporated into these two major phospholipids. Furthermore, because of inadequate sample size, it was not possible to generate PUFA values for 18:2n-6 and 20:4n-6, in PE, hence, the samples from six animals were pooled and analyzed, and no SEM are shown on Table 3C.

Effect of GLA-containing diet on in vivo *generation of lung prostaglandins.* Since the lung as well as the infiltrating leukocytes are likely to generate PG in the lung, we examined the effects of GLA-supplemented diet on this profile. PGE_1, a cyclooxygenase metabolite of DGLA, was approximately sevenfold higher in the control EPO-fed animals when compared to the control CO-fed animals, which generated only moderate amounts of PGE_1, as shown in Figure 3. However, when BLM-treated animals were fed EPO, the tissue level of PGE_1 in the BLM-treated group was fivefold higher than in the CO-fed animals (Fig. 3). Thus, dietary supplementation with EPO resulted in increased lung levels of PGE_1 in both the control, EPO-fed, and the EPO-fed BLM-treated animals.

The generation of PGE_2 and $PGF_{2\infty}$, metabolites of AA, was high among all the groups of animals, as shown in Table 4, indicating a high level of AA in this tissue, presumably owing to increased release of AA by phospholipase A_2 activity. This hydrolytic activity was not investigated in this study. Interestingly, the generation of $PGF_{2\alpha}$ in EPO-fed animals was elevated when compared to normal CO-fed animals. The significance of this alteration is at present unclear.

Effect of GLA-containing diet on in vivo *generation of lung monohydroxy fatty acids.* The possibility that another potent antiinflammatory hydroxy fatty acid from dietary GLA may be generated in the EPO-fed animals prompted us to examine the lung homogenates for this 15-lipoxygenase metabolite. In control EPO-fed animals, and EPO-fed BLM-treated animals, the tissue levels of 15-hydroxyeicosatrienoic acid (15-HETrE), a metabolite of DGLA, were elevated when compared to CO-fed animals as shown in Figure 4. Interestingly, the marked increase in 15-HETrE in these two animal groups paralleled corresponding increases in 13-hydroxy-

[a]Values are expressed as mol% of phospholipid fatty acids in each phospholipid fraction and represent means ± SEM ($n = 6$). Values not sharing a common superscript letter are significantly different ($P < 0.05$). See footnote to Table 1 for key to diet abbreviation. "Trace" indicates trace (< 0.1) or undetectable amounts of fatty acids; CO, corn oil.

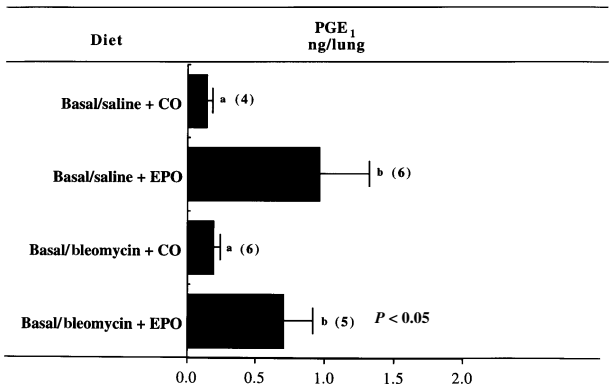

FIG. 3. Effect of dietary GLA-containing EPO on lung prostaglandins. Lungs from the animals in the four dietary groups were removed and homogenized as stated in Figure 2. The homogenates were acidified, percolated through Sep-Pak, and used for prostaglandin determination as described in the Materials and Methods section. Data represent marked generation of prostaglandin E_1 (PGE_1) in animals fed GLA-containing EPO. Results are means ± SEM from the number of animals (*n*) indicated in parentheses. See Figure 1 for other abbreviations, and Figure 2 for explanation of superscript letters.

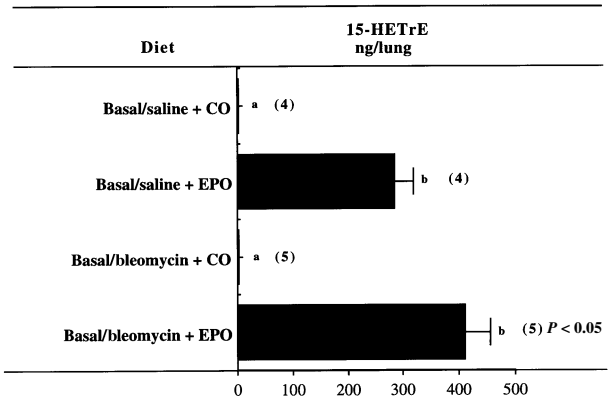

FIG. 4. Effect of dietary GLA-containing EPO on lung monohydroxy fatty acids. Lungs from the animals in the four dietary groups were removed, homogenized, and percolated through Sep-Pak as described in legend of Figure 3. Data represent marked generation of 15-hydroxyeicosatrienoic acid in animals fed GLA-containing evening primrose oil. Results are means ± SEM, with the number of animals (*n*) indicated in parentheses. See Figure 1 for other abbreviations, and Figure 2 for explanation of superscript letters.

9,11-octadecadienoic acid (13-HODE). It appears from these data that elevated tissue GLA/DGLA and/or elevated 15-HETrE may modulate the generation of 13-HODE.

Analyses of the MeOH eluent from Sep-Pak on HPLC also revealed the major hydroxy fatty acid contents from linoleic acid (LA), AA, and DGLA, respectively, as shown in Table 5. The most abundant hydroxy fatty acids in the normal CO-fed hamster lung include: 13-hydroxyoctadecadienoic acid, a metabolite of LA, and 15-HeTrE, a metabolite of AA.

GLA-containing diet suppressed in vivo *generation of BLM-induced LTB_4 in the lung.* To determine whether the intratracheal instillation of BLM into hamster lung resulted in an alteration of lung LTB_4 (a proinflammatory metabolite from AA), aliquots from the Sep-Pak column containing lipoxygenase products were subjected to fractionation on HPLC as described in the Materials and Methods section. The tissue level of LTB_4 was markedly elevated, approximately twofold in BLM-treated, CO-fed animals when compared to the two controls, as shown in Figure 5. Feeding GLA-containing EPO to the BLM-treated animals significantly ($P < 0.05$) suppressed BLM-induced lung generation of LTB_4.

DISCUSSION

Pulmonary toxicity of BLM, with the initial pneumonitis progressing to fibrosis, has been a major obstacle in the successful clinical use of this otherwise effective antineoplastic agent (2). Its wide spectrum of antitumor activity and its minimal cytotoxic effects on bone marrow justify the continued exploration of compounds that could minimize BLM-induced lung toxicity without compromising its antineoplastic efficacy.

Data from these studies revealed that supplementation of

TABLE 4
Effect of Dietary γ-Linolenic Acid-Containing EPO on Lung Prostaglandins (PG)[a]

Diets	PGE_2 (ng/mg protein)	$PGF_{2\alpha}$ (ng/mg protein)
Basal/saline + CO	317.1 ± 115.4	4.7 ± 0.4

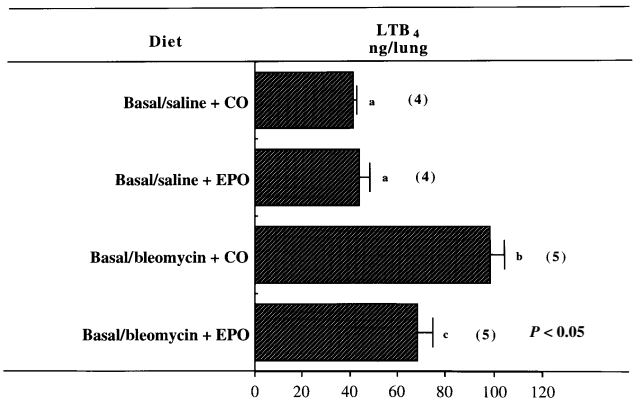

FIG. 5. GLA-containing diet suppressed *in vivo* generation of BLM-induced leukotriene B_4 in the lung. Lungs from the animals in the four dietary groups were removed, homogenized, and percolated through Sep-Pak as described in the legend for Figure 3. Animals fed GLA-containing EPO (BS + BLM + EPO) significantly ($P < 0.05$) suppressed BLM-induced generation of LTB_4 in the lung. Results are means ± SEM, with the number of animals (*n*) indicated in parentheses. See Figure 1 for other abbreviations, and Figure 2 for explanation of superscript letters.

hamster diet with EPO resulted in an elevation of DGLA (an elongation metabolite of GLA) in lung phospholipids (Table 3, A/B). This increase paralleled the elevation in the lung of two major metabolites of DGLA: (i) PGE_1 (a cyclooxygenase product of DGLA) (Fig. 3) and (ii) 15-HETrE (a 15-lipoxygenase product of DGLA) (Fig. 4). The transformation of DGLA into PGE_1 has been reported in a variety of tissues and cells (34–36). Functionally, PGE_1 has been reported to exert biological and pharmacological effects in a variety of systems. For instance, PGE_1 is linked to adenyl cyclase *via* its cell membrane receptor (37) where it increases the cyclase activity in platelets (38) and in fibroblasts (39). In fibroblasts, PGE_1 is reported to induce calcium influx through the plasma membrane (40), whereas in platelets PGE_1 inhibits intracellular calcium mobilization (41) as well as the effects of activated protein kinase C (42,43). The above reports suggest a mechanism whereby endogenous PGE_1 (presumably enhanced by its *in vivo* precursor, DGLA) may regulate function through its interactions with protein kinase C.

GLA/DGLA, as well as 15-HETrE (their 15-lipoxygenase metabolite), have been implicated in biological and pharmacological functions in a variety of systems. For instance, supplementation of guinea pig or human diet with GLA-containing oils resulted in marked elevation of DGLA in the tissue. Both guinea pig and human epidermis contains a very active elongase that catalyzes the conversion of precursor GLA into DGLA (44). *In vitro*, the DGLA is metabolized by epidermal cyclooxygenase into PGE_1, and by epidermal 15-lipoxygenase into 15-HETrE (45). *In vivo*, when guinea pig diet was supplemented with GLA-containing oil, 15-HETrE was generated in the epidermis (46). Additionally, when human diet was supplemented with GLA-containing capsules, a significant amount of DGLA was found in the phospholipids of the PMN. The elevation of DGLA in the phospholipids paralleled the decreased capacity of isolated PMN to biosynthesize LTB_4 *in vitro* (47). These observations are consistent with the *in vitro* inhibition of AA transformation into LTB_4 by 15-HETrE (45,48,49).

Taken together, GLA/DGLA, including their major cyclooxygenase metabolite (PGE_1) and its 15-lipoxygenase metabolite (15-HETrE), are potent modulators of cellular functions. Thus, it is reasonable to expect that the dietary intake of GLA-containing oil could generate both metabolites *in vivo*, which in turn can modulate the pathophysiological conditions of BLM-induced interstitial pulmonary fibrosis. Data derived from these studies are consistent with the stated speculations. The animals whose diets were supplemented with GLA-containing EPO generated elevated levels of PGE_1 and 15-HETrE when compared to control animals whose diet was supplemented with CO. Interestingly, the generation of these metabolites in BLM-treated animals correlated with the suppression of LTB_4 (a proinflammatory metabolite generated from AA). In a recent report, the constitutive activation of 5-lipoxygenase (the enzyme that catalyzes the generation of LTB_4 and peptido LTC_4 from AA) was demonstrated in the lungs of patients with idiopathic pulmonary fibrosis (50). Lung homogenates from the idiopathic pulmonary fibrosis patients contained 15-fold more LTB_4 than homogenates from nonfibrotic lungs. Our data are consistent with the elevation of LTB_4 in this report. Our data further revealed the suppression of lung hydroxyproline (a marker for collagen accumulation) after the dietary intake of GLA-containing EPO. Interestingly, leukotrienes have been reported to exert direct effects on fibroblasts and mesenchymal cells, where they stimulate fibroblast proliferation (51) and collagen synthesis (52). These *in vivo* possibilities imply that the dietary intake of highly purified GLA-containing oil or sufficient intake of constituent PUFA of these oils may serve as a fitting adjunct with negligible side effects for alleviating BLM-induced lung inflammation and fibrosis.

Oleanolic Acid and Ursolic Acid Stabilize Liposomal Membranes

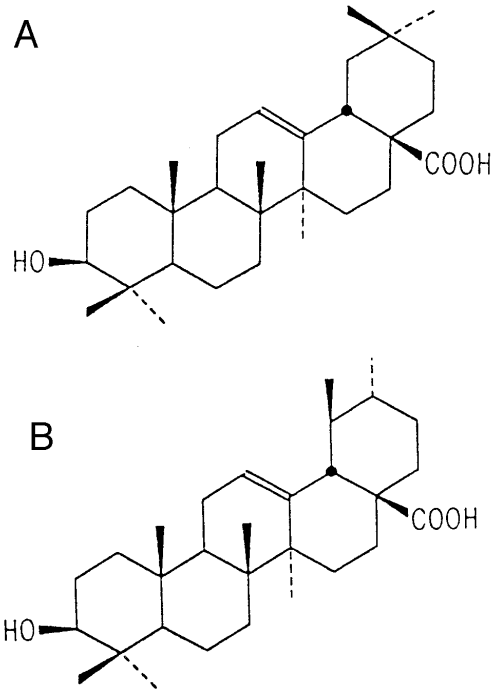
College of Pharmacy, Pusan National University, Pusan, 609-735, Republic of Korea

ABSTRACT: The effects of oleanolic acid (OA) and ursolic acid (UA) on the fluidity and stability of dipalmitoyl phosphatidylcholine (DPPC) liposomal membrane were monitored by measuring the fluorescence polarization of 1,6-diphenyl-1,3,5-hexatriene labeled in the liposomal membrane and the leakage of calcein from the probe-encapsulated liposomes. The experiments with the liposomes made of DPPC and OA or UA showed that OA and UA exhibited a moderate fluidity-modulating effect for the liquid-crystalline liposomal membrane, and a strong condensing effect for both crystalline and liquid-crystalline liposomal membranes. Their effects were comparable to those of cholesterol. These results suggest that their fluidity-modulating and condensing effects might have some implications in their biological functions.

Lipids 32, 769–773 (1997).

Oleanolic acid (OA) (Scheme 1A) and ursolic acid (UA) (Scheme 1B) are pentacyclic triterpene acids which are widely distributed in plants, and their derivatives are aglycones of many naturally occurring saponins (1). UA is also the main component of protective wax-like coatings of many fruits (2). Pentacyclic triterpene acids may possibly enhance the mechanical barrier functions of cell membranes in plants.

Cholesterol (Cho) is well known to enhance the mechanical barrier function of cell membranes in animals (3,4). Plant sterols are also expected to play such a role in plants. The function of Cho in biological membranes is understood on the basis of the studies on its effects on phospholipid liposomal membranes (5–7). In the crystalline state of the phospholipids below the phase transition temperature (T_m), Cho tends to increase the disorder of phospholipid molecules, particularly in the hydrocarbon chain (fluidizing effect), and in the liquid-crystalline state above T_m, cholesterol tightly assembles the molecules of phospholipids in bilayers and the membrane is less fluid and permeable to small hydrophilic molecules and ions (condensing effect) (8,9). In brief, cholesterol has fluidity-modulating and condensing effects for cell membranes. These properties of Cho are inherently related to its stucture:



SCHEME 1

a multicyclic, rigid planar structure, a hydrophilic 3β-hydroxyl group, and a hydrophobic side chain. It is worthwhile to note that OA and UA also have a multicyclic, rigid planar structure and a 3β-hydroxyl group, and are expected to have similar properties as Cho.

Recently, it has been reported that OA and UA have interesting biological activities such as antiangiogenetic activity (10) and cancer cell-differentiating activity (11). It has also been indicated that many cells have an absolute growth requirement for exogeneous sterol, and there exists an important link between sterol and cell growth (3). It has also been suggested that changes in growth behavior and differentiation of a variety of cell types are associated with alterations in plasma membrane fluidity (12,13). In consequence, studies on the effects of OA and UA on the fluidity and stabilization of biological membranes would be necessary for understanding the mechanisms of many biological activities of OA and UA.

Abbreviations: Cho, cholesterol; DPH, 1,6-diphenyl-1,3,5-hexatriene; DPPC, dipalmitoyl phosphatidylcholine; OA, oleanolic acid; UA, ursolic acid.

In this report, we describe the effects of OA and UA on the fluidity and stabilization of liposomes composed of dipalmitoyl phosphatidylcholine (DPPC) by measuring the fluorescence polarization of the 1,6-diphenyl-1,3,5-hexatriene (DPH) (7) labeled in the liposomal membrane and the release of calcein entrapped in liposomes (14). Their effects were compared with those of Cho.

MATERIALS AND METHODS

Chemicals. OA, UA, DPPC, DPH, calcein, and Cho were purchased from Sigma Chemical Co. (St. Louis, MO), and used without further purification. All other reagents were of reagent grade.

Preparation of liposomes. The mixture of DPPC and various amounts of OA, UA, or Cho was dissolved in 2 mL of $CHCl_3$ and reduced to dryness by rotary evaporation, forming a film on the inside of a round-bottomed flask. The small unilamellar liposomes were prepared by suspending the film in 5 mL of 10 mM Tris buffer (pH 7.4) and sonicated for 30 min at 50°C above the T_m of DPPC.

The incorporation of DPH into the liposomal membrane was carried out by adding an aliquot of 1 mM stock solution of DPH in DMSO to make it 2×10^{-6} mM. The mixture was vigorously vortexed and employed for measurements of the fluorescence polarization of DPH. The final concentration of DPPC in liposomes was adjusted to 0.33 mM.

For the preparation of calcein-entrapped liposomes, 5 mL of 10 mM Tris buffer (pH 7.4) containing 50 mM calcein was added to the lipid film, and the mixture was sonicated as described previously. Calcein-entrapped liposomes were separated from free calcein by passing through a Sephadex G-50 column with Tris buffer as the eluent at 10°C. The concentration of DPPC was determined by Stewart method (7) and adjusted to 30 μM by the buffer.

Measurement of the membrane fluidity. The sample was excited by vertically polarized light (358 nm), and intensities of emission (430 nm) were measured through polarizers oriented parallel to the plane of excitation (*Ih*) and perpendicular to the plane of excitation (*Iv*). The fluorescence polarization value (*P*) of DPH labeled in the liposomal membranes was calculated by Equation 1,

$$P = (Ih - Iv \times \mathrm{G})/(Ih + Iv \times \mathrm{G}) \quad [1]$$

where the correction factor *G* was *Ih*/*Iv*. The *P* value was employed as a parameter of fluidity of the membrane.

Measurement of liposomal stability. Calcein is a water-soluble, self-quenching fluorescent compound, and the measurement of fluorescing calcein released from liposomes entrapping high concentrations of this compound was employed for the indication of the leakage of the content of the liposomes (14).

Keeping the calcein-entrapped liposomes at 25 or 42°C with circulating water bath, the fluorescence (*F*) was measured at excitation and emission wavelengths of 482 and 512 nm, respectively. The percentage of the calcein leakage from liposomes was calculated by Equation 2,

$$\text{calcein leakage [\%]} = 100 \times (F - F_o)/(F_t - F_o) \quad [2]$$

where F is the fluorescence intensity at time t, F_o the initial fluorescence intensity, and F_t denotes the fluorescence intensity when the liposomes were completely disrupted by addition of 10% Triton X-100 solution.

The fluorescence measurements were carried out with a Perkin-Elmer luminescence spectrophotometer model LS-5 (Norwalk, CT), provided with a thermostatic cell holder. The samples were degassed by nitrogen before the measurement.

RESULTS AND DISCUSSION

The results of the measurements of the fluorescence polarization values of the DPH labeled in the liposomal membranes made of the lipid mixture of DPPC and OA, UA, or Cho are shown in Figure 1. They show that the values decreased gradually as the temperature increased and decreased abruptly near the T_m of the liposomal membrane from crystalline to liquid-crystalline state as usual cases. The midpoint of the abrupt changes which were shown as sigmoidal curves was taken as T_m. It was 40°C for DPPC liposomes, which was slightly lower than the referred value, 41°C (7).

The addition of the additives to DPPC did not affect the *P* values at 10 mol% content of the additives or slightly lower the values at higher content of the additives at temperatures below T_m. Their differences from the control were not significant. In crystal phase, Cho has been known to increase chain flexibility by inhibiting good packing of the fatty acyl chains. However, the results of the experiments showed that the fluidizing effects of OA, UA, and Cho on the DPPC liposomal membrane in crystalline state are insignificant or not great enough to be detected by this method. On the other hand, it was clearly shown that the addition of the additives to DPPC significantly increased the *P* values in the liquid-crystalline state, and these effects are highly dose-dependent. This means that the addition of OA, UA, or Cho to the DPPC decreases the fluidity of the liposomal membrane in proportion to its concentration in liquid-crystalline state. No significant difference between the activities of OA and UA was observed. This is understandable considering the extreme similarity of structures of these two compounds. However, they were less effective than Cho.

The presence of the rigid multicyclic frame of OA, UA, and Cho restricts the flexing motion of neighboring fatty acyl chain region in the liquid-crystalline phase and reduces the fluidity. OA and UA were less effective in decreasing the fluidity than Cho at the 20 mol% or more content level, although OA and UA have a bulkier multicyclic planar structure than Cho. This suggests that not only the multicyclic planar structure of these additives but also the hydrophobic tail of Cho should be important moieties in inducing fluidity-modulating effects of these compounds on the liposomal membranes. The hydrophobic tail of Cho might be fitted better into the lipid

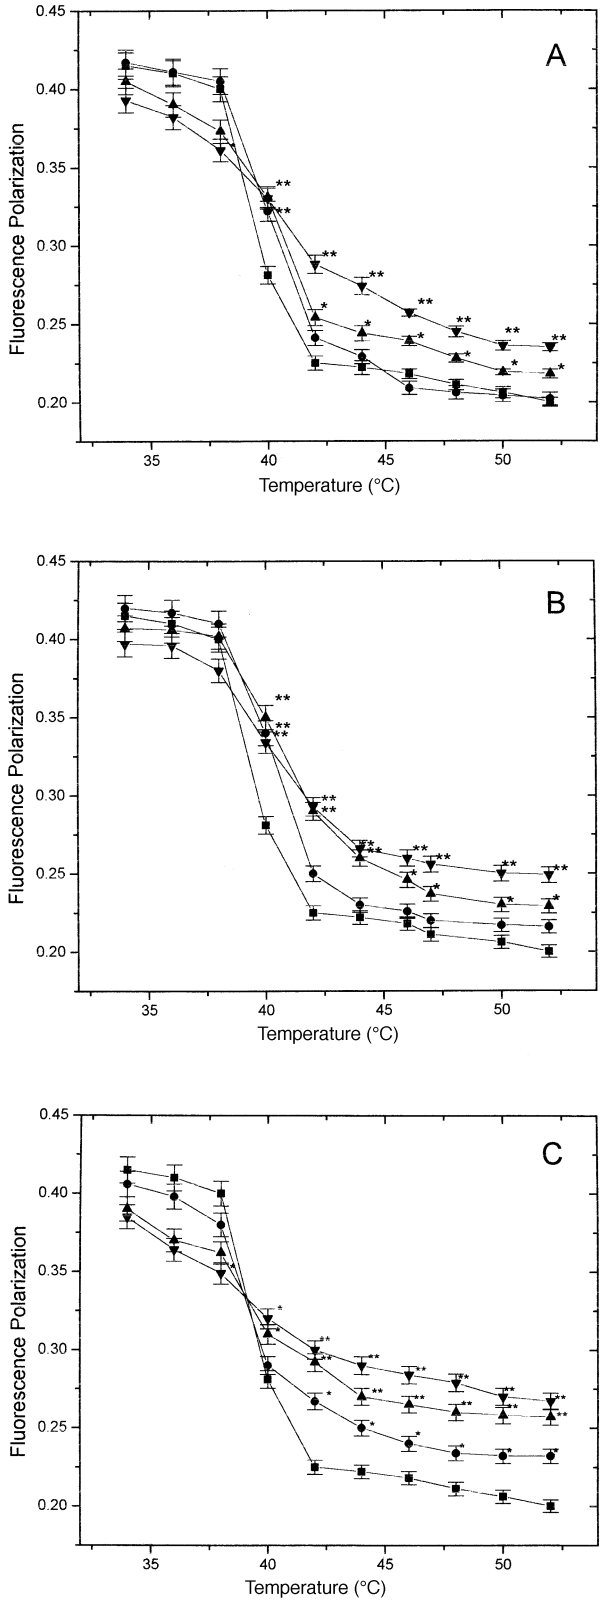

FIG. 1. Fluorescence polarization value of 1,6-diphenyl-1,3,5-hexatriene labeled in the dipalmitoyl phosphatidylcholine (DPPC)-additive liposomal membrane. Each point represents the mean of five replicate measurements ± SE. ■ DPPC, ● DPPC and 10 mol% additive, ▲ DPPC and 20 mol% additive, ▼ DPPC and 30 mol% additive. bilayer, which eventually induces more effective fluidity modulation than OA and UA.

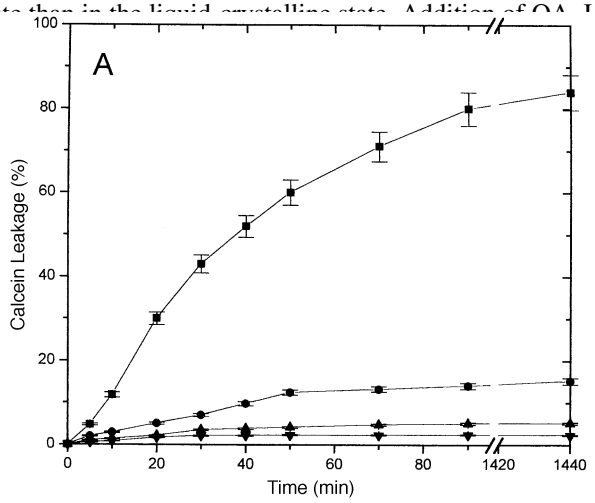
The T_m of the DPPC liposomes did not shift significantly by addition of the additives. However, the temperature range of the phase transition became broader on addition of the additives. This means that the incorporation of the additives into the lipid bilayer of the liposomal membrane reduces the size of the cooperative unit of the phase transition and induces the initiation of the phase transition at lower temperature and the completion of the transition at higher temperature. It has been reported that the presence of more than 30 mol% Cho in DPPC liposomes abolished completely the phase transition peak on the differential scanning thermogram (4). This was ascertained in this experiment. As the content of Cho in the lipid reached 20 mol%, the transition became less evident, and in the presence of 30 mol% Cho, the P value decreased monotonously with increasing temperature, and the T_m was not observed. However, even in the presence of 30 mol% OA or UA in the lipid, the phase transitions were clearly observed.

The results of the measurements of the leakage of calcein at 25 and 42°C from the liposomes made of DPPC and the additives are shown in Figures 2 and 3. They show that OA, UA, and Cho have strong membrane-stabilizing effects for the liposomes. While the liposomes made of DPPC alone were quite unstable, releasing nearly 80% of calcein from the liposomes on standing for 1 h at 25°C, the addition of OA, UA, or Cho to DPPC drastically decreased the leakage of calcein. However significant differences among the effects of these three compounds were not observed within the time period examined in this experiment at 25°C. Their membrane-stabilizing activities were also dose-dependent; the addition of 10 mol% OA, UA, or Cho considerably decreased the leakage and 20 mol% or more OA, UA, or Cho decreased the leakage of calcein nearly down to less than 3% on standing for 2 h at 25°C. These states persisted longer than 24 h.

The liposomes prepared by sonication in this experiment were prestressed fragile vesicles and had a strong tendency to fuse or break. There also existed an osmotic imbalance between the internal and external solutions of the vesicles, and then water would flow down its chemical potential gradient, causing the vesicles to swell and eventually break, so leaking their contents. Although the T_m of the DPPC liposomes did not shift significantly by addition of Cho, OA or UA, the phase transition pattern was greatly perturbed by the presence of these additives. Consequently, some relation of the membrane-stabilizing effects of these additives with their effects on the phase transition could not be excluded.

The experiments on the leakage of calcein at 42°C showed that the liposomes made of DPPC alone showed approximately 70% leakage of calcein on standing for 1 h at 42°C. More leakage at 25°C than at 42°C indicates that the lipid bilayer in liquid-crystalline state is less permeable than the lipid bilayer in crystalline state in spite of the more vigorous motion of molecules and the liquid-crystalline state of the lipid at higher temperature. This indicates that there exist more defects or vacancies in the liposomal bilayer in the crystalline

state than in the liquid-crystalline state. Addition of OA, UA



sudden increase in the leakage of calcein was observed in the leakage experiments at 42°C. This should be the time re-

Cho has been well known to have a condensing effect in liquid-crystalline state of the lipids. The results of this study show that OA, UA, and Cho have a strong condensing effect for the liposomal membrane not only in the liquid-crystalline state but also in the crystalline state. The results also show that although Cho was more effective in decreasing the fluidity of liquid-crystalline liposomal membrane than OA and UA, the latter two compounds showed membrane-stabilizing effects comparable to or more than the former. This means that the fluidity modulation is not the determining factor in condensing and stabilizing the liposomal membranes. Possibly, the proper orientation of the palisade molecule in the lipid bilayers might be important for fluidity modulation, while the random distribution of multicycle planar molecules is for the condensing effect.

ABSTRACT: A simple and efficient method for the synthesis of taurine- and glycine-conjugated bile acids is described. The condensation reaction was achieved by the simple mixing of unconjugated bile acid (1.0 eq.), taurine (2.0 eq.) (or glycinate ester), diethyl phosphorocyanidate (1.2 eq.) in the presence of triethylamine at room temperature for 30–60 min. Sample clean-up was effected by the use of a prepacked Sep-Pak C_{18} cartridge for reversed-phase solid extraction or by direct recrystallization, yielding the desired taurine and glycine conjugates in 89–93 and 92–96% isolated yields, respectively.
Lipids 32, 775–778 (1997).

Bile acids, synthesized from cholesterol in the liver, exist in biological fluids both in the free form at the C24 carboxylic group and, primarily, as their *N*-acyl conjugated forms with taurine or glycine (1).

In continuation of a program of synthesis of potential bile acid metabolites, a need for a supply of taurine and glycine conjugates of various bile acids as authentic reference standards prompted us to examine literature preparations of the amidated bile acids, of which there are several. Those include azide (2), mixed carbonic-carboxylic acid anhydride (2–5), activated ester (6), and carbodiimide (7) methods in peptide syntheses. In particular, the mixed carbonic-carboxylic acid anhydride method introduced by Lack *et al.* (3) and then improved by Tserng *et al.* (4), using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) as a coupling reagent, has now been widely employed for preparing amidated bile acids (8,9), because of its good yield. However, the EEDQ method still has several drawbacks and problems: it is laborious, time-consuming, requires drastic reaction conditions and complicated sample workups. These aspects are undesirable, particularly for small-scale preparation of amidated bile acids.

Abbreviations: CA, cholic (3α,7α,12α-trihydroxy-5β-cholan-24-oic) acid; CDCA, chenodeoxycholic (3α,7α-dihydroxy-5β-cholan-24-oic) acid; DCA, deoxycholic (3α,12α-dihydroxy-5β-cholan-24-oic) acid; DEPC, diethyl phosphorocyanidate; DMF, dimethylformamide; EEDQ, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline; GCA, glycocholic acid; IR, infrared; LCA, lithocholic (3α-hydroxy-5β-cholan-24-oic) acid; ^{1}H NMR, proton nuclear magnetic resonance; TLC, thin-layer chromatography; UDCA, ursodeoxycholic (3α,7β-dihydroxy-5β-cholan-24-oic) acid.

Recently, Tohma *et al.* (10) have reported the use of diethyl phosphorocyanidate (DEPC) as an alternative coupling reagent for preparing some amidated bile acids. The method seems to be useful, but a limited number of bile acids were examined, and detailed reaction conditions and workup procedures remain unreported. We now present an improved method for the preparation of taurine- and glycine-conjugated bile acids (Table 1), using DEPC as a coupling reagent, which proceeds rapidly under mild conditions and affords a pure amidated product isolated in a good yield without requiring complicated workup and tedious column chromatographic purification steps, in contrast to previous procedures.

EXPERIMENTAL PROCEDURES

Materials and reagents. Each m.p. was determined on an electric micro hot stage and are uncorrected. Infrared (IR) spectra were obtained on a Perkin-Elmer 1600 Series Fourier transform IR spectrometer (Norwalk, CT) as KBr pellets. Proton nuclear magnetic resonance (^{1}H NMR) spectra were obtained on a Jeol FX-90Q instrument (Tokyo, Japan) at 90 MHz, with CD_3OD containing 0.1% Me_4Si as the solvent; chemical shifts are expressed in δ (ppm) relative to Me_4Si.

Lithocholic (LCA), deoxycholic (DCA), and cholic (CA) acids were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Chenodeoxycholic (CDCA) and ursodeoxycholic (UDCA) acids were kindly donated by Tokyo Tanabe Co. (Tokyo, Japan). Peptide coupling reagent, DEPC, was supplied by Wako Pure Industries Ltd., and glycine methyl ester hydrochloride, taurine, and triethylamine (Et_3N) were supplied by Nacalai Tesque, Inc. (Kyoto, Japan). All other reagents and solvents were of analytical reagent grade.

Prepacked octadecyl-bonded (C_{18}) silica cartridges for reversed-phase solid extraction, Sep-Pak plus tC_{18} (sorbent weight, 400 mg) and Sep-Pak Vac tC_{18} (sorbent weight, 5 g) were from Waters Associates (Milford, MA). They were washed with 4 mL (or 50 mL) MeOH and 8 mL (or 100 mL) distilled water prior to use.

Thin-layer chromatography (TLC). Analytical TLC was performed on precoated silica gel $60F_{254}$ plates (20 cm × 20 cm, 0.25-mm layer thickness; Merck, Darmstadt, Germany). For the developing solvents, *n*-propyl alcohol/CH_3COOH/water (100:7:6, by vol) and EtOAc/*n*-hexane/CH_3COOH (50:50:1,

[b]Obtained as a potassium salt. Abbreviations: CA, cholic acid; CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; GCA, glycocholic acid; GCDCA, glycochenodeoxycholic acid; GDCA, glycodeoxycholic acid; GLCA, glycolithocholic acid; GUDCA, glycoursodeoxycholic acid; LCA, lithocholic acid; TCA, taurocholic acid; TCDCA, taurochenodeoxycholic acid; TDCA, taurodeoxycholic acid; TLCA, taurolithocholic acid; TUDCA, tauroursodeoxycholic acid; UDCA, ursodeoxycholic acid.

by vol) mixtures were employed for taurine and glycine conjugates, respectively. The spots were detected with 10% phosphomolybdic acid in methanol and heating at 110°C.

Gas–liquid chromatography. A Shimadzu GC-14A gas chromatograph equipped with a flame-ionization detector (Tokyo, Japan) was used. It was fitted with an Ultra ALLOY-1 (HT) (Koriyama, Japan) stainless-steel capillary column (15 m × 0.25 mm i.d.) coated with a film (0.25 μm) of chemically bonded and crosslinked dimethylsiloxane and operated under the following conditions: carrier gas (helium) flow rate, 0.7 mL/min; helium linear velocity, 15.9 m/min; splitting ratio, 50:1; injector temperature, 330°C; detector temperature, 350°C; column temperature, 320°C (isothermal). Simultaneous analysis of unconjugated and glycine-conjugated bile acids was carried out as their methyl ester-trimethylsilyl ether derivatives as described previously (11).

Recovery and reproducibility tests by solid-phase extraction. Sample solutions for recovery and reproducibility tests by Sep-Pak C_{18} cartridges were prepared as follows: Known amounts (50, 70, and 80 mg) of glycocholic acid (GCA) were dissolved in phosphate buffer (pH 7.5) and adjusted to 1% solution. Each solution was applied to a preconditioned Sep-Pak plus tC_{18} cartridge and washed with 2 mL of water. GCA was then eluted with 2 mL of EtOH. In each of three experiments, approximately equal amounts (38, 38, and 39 mg; mean, 38 mg) of GCA were recovered.

General procedure for the synthesis of taurine-conjugated bile acid sodium salts (method A). To a magnetically stirred solution of an unconjugated bile acid (0.25 mmol) in dry dimethylformamide (DMF; 1 mL) were added successively powdered taurine (0.5 mmol), DEPC (0.3 mmol), and anhydrous Et_3N (0.4 mL), and the resulting suspension was stirred at room temperature for 60 min (the reaction was monitored by TLC). The reaction mixture was adjusted to pH 12–14 with 1 M NaOH and then to pH 7–8 with 10% HCl. The solution was diluted with water (9 mL), passed through a preconditioned Sep-PakVac tC_{18} cartridge, and eluted successively with water (20 mL), 25% EtOH (20 mL), and EtOH (25 mL). The last fraction, which contains the desired taurine conjugate sodium salt was evaporated to dryness under a nitrogen stream, and the residue was recrystallized from an appropriate solvent.

General procedure for the synthesis of glycine-conjugated bile acids (method B). To a magnetically stirred solution of an unconjugated bile acid (0.25 mmol) in dry DMF (1 mL) were added successively glycine methyl ester hydrochloride (0.5 mmol), DEPC (0.3 mmol), and Et_3N (0.4 mL), and the resulting suspension was stirred at room temperature for 30 min. The reaction product was extracted with EtOAc, and the combined extracts were washed with water, dried with Drierite, and evaporated to dryness. The residue was then refluxed for 30 min in 5% methanolic KOH (5 mL). Most of the solvent was evaporated under reduced pressure, and the hydrolysis product was dissolved in water (5 mL) and acidified with 5% H_2SO_4 with stirring. The precipitated solid was filtered, washed with water, and dried to give the crude glycine conjugate, which was recrystallized from an appropriate solvent. Otherwise, the KOH hydrolysis product was subjected directly to a Sep-Pak C_{18} cartridge as described above, and the desired glycine conjugate was obtained as a potassium salt.

Taurolithocholic acid sodium salt. Obtained from LCA in 89% yield; m.p., 204–208°C (MeOH-Et_2O) [(lit. m.p., 199–201°C (4)]. IR ν_{max} cm^{-1}: 3304 (OH), 1652 (C=O), 1558 (CONH), 1217, 1046 (SO_3). ^1H NMR δ:0.66 (3H, *s*, 18-Me), 0.93 (3H, *s*, 19-Me), 0.93 (3H, *d*, *J* = 5.4 Hz, 21-Me), 2.96 (2H, *t*, *J* = 5.4 Hz, $CH_2CH_2SO_3Na$), 3.62 (2H, *t*, *J* = 6.3 Hz, $CH_2CH_2SO_3Na$).

Taurodeoxycholic acid sodium salt. Obtained from DCA in 93% yield; m.p., 169–173°C (EtOAc-aq. MeOH) [(lit. m.p., 172–173°C (4)]. IR ν_{max} cm^{-1}: 3406 (OH), 1650 (C=O), 1549 (CONH), 1214, 1043 (SO_3). ^1H NMR δ: 0.69 (3H, *s*, 18-Me), 0.92 (3H, *s*, 19-Me), 0.93 (3H, *d*, *J* = 5.4 Hz, 21-Me), 2.98 (2H, *t*, *J* = 5.4 Hz, $CH_2CH_2SO_3Na$), 3.61 (2H, *t*, *J* = 6.3 Hz, $CH_2CH_2SO_3Na$).

Taurochenodeoxycholic acid sodium salt. Obtained from CDCA in 92% yield; m.p., 177–179°C (EtOH-EtOAc) [(lit. m.p., 182–184°C (4)]. IR ν_{max} cm^{-1}: 3412 (OH), 1654 (C=O), 1551 (CONH), 1221, 1052 (SO_3). ^1H NMR δ: 0.66 (3H, *s*, 18-Me), 0.91 (3H, *s*, 19-Me), 0.94 (3H, *d*, *J* = 4.5 Hz, 21-Me), 2.99 (2H, *t*, *J* = 5.4 Hz, $CH_2CH_2SO_3Na$), 3.60 (2H, *t*, *J* = 6.3Hz, $CH_2CH_2SO_3Na$).

Tauroursodeoxycholic acid sodium salt. Obtained from UDCA in 90% yield; m.p., 201–204°C (EtOH-EtOAc) [(lit. m.p., 200–204°C (4)]. IR ν_{max} cm^{-1}: 3387 (OH), 1654 (C=O), 1550 (CONH), 1223, 1054 (SO_3). ^1H NMR δ: 0.68 (3H, *s*, 18-Me), 0.95 (3H, *s*, 19-Me), 0.94 (3H, *d*, *J* = 5.4 Hz, 21-Me), 2.99 (2H, *t*, *J* = 5.4 Hz, $CH_2CH_2SO_3Na$), 3.61 (2H, *t*, *J* = 6.3 Hz, $CH_2CH_2SO_3Na$).

Taurocholic acid sodium salt. Obtained from CA in 93% yield; m.p., 181–184°C (EtOH-EtOAc) [(lit. m.p., 182–184°C (4)]. IR ν_{max} cm^{-1}: 3416 (OH), 1649 (C=O), 1549 (CONH), 1197, 1042 (SO_3). ^1H NMR δ: 0.70 (3H, *s*, 18-Me), 0.91 (3H, *s*, 19-Me), 1.01 (3H, *d*, *J* = 5.4 Hz, 21-Me), 2.98 (2H, *t*, *J* = 6.3 Hz, $CH_2CH_2SO_3Na$), 3.59 (2H, *t*, *J* = 7.2 Hz, $CH_2CH_2SO_3Na$).

Glycolithocholic acid. Obtained from LCA in 92% yield; m.p., 183–185°C (aq. EtOH) [lit. m.p., 184–186°C (1)]. IR ν_{max} cm^{-1}: 3285 (OH), 1611, 1735 (C=O), 1568 (CONH). ^1H NMR δ: 0.64 (3H, *s*, 18-Me), 0.91 (3H, *s*, 19-Me), 0.92 (3H, *d*, J = 5.4 Hz, 21-Me), 2.59 (1H, *brm*, 3 β-H), 3.97 (2H, *d*, *J* = 4.5 Hz, $NHCH_2COOH$), 6.55 (1H, *t*, *J* = 4.5 Hz, $NHCH_2COOH$).

Glycodeoxycholic acid (GDCA). Obtained from DCA in 96% yield; m.p., 191–193°C (aq. EtOH) [lit. m.p., 191–192°C (4)]. IR ν_{max} cm^{-1}: 3348 (OH), 1631, 1722 (C=O), 1531 (CONH). ^1H NMR δ: 0.67 (3H, *s*, 18-Me), 0.90 (3H, *s*, 19-Me), 0.99 (3H, *d*, *J* = 5.4 Hz, 21-Me), 3.97 (2H, *d*, *J* = 4.5 Hz, $NHCH_2COOH$), 6.68 (1H, *t*, *J* = 4.5 Hz, $NHCH_2COOH$).

Glycochenodeoxycholic acid (GCDCA) potassium salt. Obtained as the potassium salt from CDCA in 93% yield; m.p., 155–163°C (MeOH-Et_2O). IR ν_{max} cm^{-1}: 3412 (OH), 1655, 1733 (C=O), 1545 (CONH). ^1H NMR δ: 0.66 (3H, *s*, 18-Me), 0.90 (3H, *s*, 19-Me), 0.93 (3H, *d*, *J* = 5.4 Hz, 21-Me), 2.50 (1H, *brm* 3 β-H), 3.99 (2H, *d*, *J* = 4.5 Hz, $NHCH_2COOH$), 6.42 (1H, *t*, *J* = 4.5 Hz, $NHCH_2COOH$).

Glycoursodeoxycholic acid. Obtained from UDCA in 95% yield; m.p., 220–223°C (aq. EtOH) [lit. m.p., 228°C (4)]. IR ν_{max} cm^{-1}: 3343 (OH), 1633, 1723 (C=O), 1557 (CONH). ^1H NMR δ: 0.67 (3H, *s*, 18-Me), 0.93 (3H, *s*, 19-Me), 0.94 (3H, *d*, *J* = 6.3 Hz, 21-Me), 3.92 (2H, *d*, *J* = 5.4 Hz, $NHCH_2COOH$), 7.03 (1H, *t*, *J* = 4.5 Hz, $NHCH_2COOH$).

GCA. Obtained from CA in 92% yield; m.p., 143–145°C (aq. EtOH) [lit. m.p., 140–142°C (4)]. IR ν_{max} cm^{-1}: 3376 (OH), 1642, 1734 (C=O), 1560 (CONH). ^1H NMR δ: 0.68 (3H, *s*, 18-Me), 0.88 (3H, *s*, 19-Me), 1.00 (3H, *d*, *J* = 5.4 Hz, 21-Me), 3.96 (2H, *d*, *J* = 4.5Hz, $NHCH_2COOH$), 6.82 (1H, *t*, *J* = 4.5 Hz, $NHCH_2COOH$).

RESULTS AND DISCUSSION

Conventionally, condensation of a carboxylic group at C-24 in 5β-cholanoic acids with an amino group in taurine or glycinate ester has been attained by means of a mixed carbonic-carboxylic acid anhydride method in the presence of EEDQ as a coupling reagent and Et_3N as a catalyst (3,4,8,9). Our improved method reported here is the application of an alternative peptide coupling reagent, DEPC, for the amide bond formation (12). The amidation reaction involves the formation of intermediary acyl phosphates as carboxyl-activated compounds by interaction of carboxylic acids with DEPC in the presence of Et_3N in DMF and subsequent coupling with amines to give the desired amides.

Our initial effort was directed to determining optimal reaction conditions using DCA as a representative substrate. The yield of GDCA in the reaction product was determined as the methyl ester-trimethylsilyl ether derivative by capillary gas–liquid chromatography (11). The amidation reaction proceeded nearly quantitatively within 30 min by mixing DCA (1.0 eq.), glycinate ester (2.0 eq.), DEPC (1.2 eq.), and Et_3N (catalytic amount) in DMF at room temperature. The reaction is simple, clean, and rapid under the mild conditions and no undesirable by-products were formed . On the basis of the exploratory experiment, remaining unconjugated bile acids (LCA, CDCA, UDCA, and CA) were subjected to a similar amidation with glycinate ester (method B) and powdered taurine (method A) in the presence of DEPC to afford the corresponding glycine and taurine conjugates, respectively. All the reaction products showed a single spot on TLC.

Since the free acid forms of taurine-conjugated bile acids are extremely hygroscopic (4), they were converted to the sodium salts by treatment with NaOH after the amidation reaction (method A). To isolate the sodium salts of taurine conjugates as crystalline products, the reaction mixtures diluted with water were loaded on Sep-Pak C_{18} cartridges for reversed-phase solid extraction (13–15). The cartridges were washed successively with water and 20% aqueous EtOH to remove excess reagents, contaminants, and inorganic salts. Elution with EtOH gave the crystalline sodium salts of the desired taurine conjugates (taurolithocholic acid, taurochenodeoxycholic acid, tauroursodeoxycholic acid, taurodeoxycholic acid, and taurocholic acid) in excellent yield (89–93%) after recrystallization.

The use of a disposable C_{18} cartridge for solid extraction is therefore effective for rapid and easy purification of such polar and hydrophilic compounds, compared to a conventional adsorption chromatography on SiO_2 which is time-consuming, tedious, and needs large quantities of eluting solvent. A preliminary experiment for recovery and reproducibility tests by

a Sep-Pak C_{18} cartridge also revealed that nearly constant quantities of GCA are always retained on a Sep-Pak plus tC_{18} cartridge as described in the Experimental Procedures section: the approximate maximal retention capacity of bile acids is *ca.* 10%, relative to the sorbent mass of a Sep-Pak C_{18} used.

On the other hand, glycine-conjugated bile acids (glycolithocholic acid, glycochenodeoxycholic acid, glycoursodeoxycholic acid, glycodeoxycholic acid, and GCA) were isolated and purified as follows (method B): alkaline hydrolysis of the amidated bile acid methyl esters by treatment with methanolic KOH, followed by acidification with H_2SO_4, yielded the corresponding free acids. Direct recrystallization afforded analytically pure samples of the glycine conjugates of bile acids in high yield (92–96%). In the case of GCDCA, the alkaline hydrolyzed product of glycinated CDCA methyl ester was directly applied to a Sep-Pak C_{18} cartridge without acidification and obtained as the crystalline potassium salt, because the free acid was hard to crystallize (3).

In conclusion, this paper described a facile and efficient synthesis of biologically important taurine- and glycine-conjugated bile acids. The method may be utilized to prepare other uncommon amidated bile acids as reference compounds in relatively small-scale.

ACKNOWLEDGMENT

We are grateful to Tokyo Tanabe Co., Ltd. for a generous supply of CDCA and UDCA.

A Synthesis of 4-Hydroxy-2-*trans*-nonenal and 4-(^{3}H) 4-Hydroxy-2-*trans*-nonenal

Animesh Chandra and Satish K. Srivastava*

Department of Human Biological Chemistry and Genetics, The University of Texas Medical Branch, Galveston, Texas 77555-0647

ABSTRACT: 4-Hydroxy-2-*trans*-nonenal, the most abundant and toxic unsaturated aldehyde generated during membrane lipid peroxidation, was synthesized starting from fumaraldehyde dimethyl acetal. In the first step of the synthesis, the fumaraldehyde dimethyl acetal was partially hydrolyzed using amberlyst catalyst to obtain the monoacetal. The 4-hydroxy-2-*trans*-nonenal was synthesized by the Grignard reaction of the fumaraldehyde monoacetal with 1-bromopentane. 4-Hydroxy-2-*trans*-nonenal, obtained as its dimethylacetal, was oxidized to its corresponding 4-keto derivative using pyridinium chlorochromate buffered with sodium acetate as the oxidizing agent. 4-(^{3}H) 4-Hydroxy-2-*trans*-nonenal was obtained in one step by the sodium borotriteride reduction of the 4-keto derivative.
Lipids 32, 779–782 (1997).

Oxidative stress in biological systems, besides oxidizing proteins, results in the oxidation of the membrane lipids leading to an autocatalytic chain reaction of lipid peroxidation and formation of toxic unsaturated aldehydes (1). These metastable products of lipid peroxidation thus potentiate and spread oxidative damage initiated by the local and transient free radical events (1,2). Of the wide variety of aldehydes produced as a result of lipid peroxidation, 4-hydroxy-2-*trans*-nonenal (HNE) is by far the most abundant and cytotoxic (3). It belongs to a class of α-β unsaturated aldehydes which are generated by β-scission of alkoxyl radicals of n-6-polyunsaturated fatty acids such as linoleic or arachidonic acid (1,2). The extreme cytotoxicity of HNE is manifested in its diverse biological effects such as stimulation of neutrophil chemotaxis (1,4) and inhibition of several enzymes such as protein kinase-C, adenylate cyclase, and glyceraldehyde-3-phosphate dehydrogenase (5). Higher concentrations of HNE (40 to 60 μM) have genotoxic effects leading to sister chromatid exchange, micronuclei formation, and DNA fragmentation (6,7). At concentrations >100 μM, HNE and related aldehydes cause lethal toxicity by inhibiting glycolytic enzymes, mitochondrial respiration, and DNA and protein synthesis (1,8,9).

HNE can readily form Michael adducts with nucleophilic sulfhydryls or histidyl residue or form a Schiff base with primary amino groups of proteins (10–13). In recent years much effort has been directed to identifying the metabolic products of HNE and understanding its detoxification processes (1). The methods used for quantification of HNE in biological tissues are based mostly on high-performance liquid chromatography (HPLC) analysis of 2,3-dinitrofluorobenzene or 2,4-dinitrophenyl hydrazine derivatives of HNE (14). One method involves the use of 1,3-cyclohexanedione which gives a fluorescent dihydroacridine derivative, which can then be separated by HPLC (15). HNE has also been quantified by gas chromatography–mass spectrometry of the silyl derivative of its pentafluorobenzyl oxime (16). A major drawback of estimating HNE in biological samples by derivatization is the possible generation of HNE during the process of derivatization owing to autoxidation of polyunsaturated fatty acids (PUFA) or the breakdown of other oxidation products, thereby resulting in an overestimation of what was produced by the tissue (1). In this regard it would be useful to study HNE metabolism using a radiolabeled precursor since this would provide opportunity for quantification and identification of the metabolites.

The present methods available for synthesis of radiolabeled HNE are cumbersome. In one method, hexenal is reacted with 1,3-bis(methylthio)allyl-lithium in tetrahydrofuran at −75°C to give 3-bis(methylthio)-1-nonene-4-ol which is then converted to HNE by mercuric chloride. The overall yield is 47%. Radiolabeled HNE has been synthesized by using radiolabeled hexenal (17). HNE can also be synthesized by the reaction of the Grignard compound of propynal diacetal with hexanal to yield 4-hydroxy-2-nonynal diethyl acetal. The carbon-carbon triple bond is reduced to the double bond by the use of $LiAlH_4$ at low temperature (20°C). The diethyl acetal thus obtained is then hydrolyzed to HNE under mildly acidic conditions. When the tritiated analog of $LiAlH_4$ is used, tritiated HNE can be obtained. The yield of HNE is 53% by this method (Stephens, R.J., personal communication). A simple method of obtaining tritiated HNE is by sodium borotriteride reduction of the 4-keto derivative. However, a

Abbreviations: HNE, 4-hydroxy-2-*trans*-nonenal; HPLC, high-performance liquid chromatography; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

practical problem in developing this kind of synthesis is the difficulty in oxidizing the 4-OH group to yield the corresponding 4-keto derivative. One unpublished report obtained the 4-keto-derivative by oxidation with activated dimethylsulfoxide; however, this reaction has to be carried out at –70°C and takes almost 8 h for completion (18,19). We have developed a relatively simple method for substituting the 4H of HNE with tritium by the oxidation of the 4-OH group of the dimethyl acetal of HNE, to give the corresponding α-β unsaturated ketone, followed by reduction with sodium borotriteride. In this communication we report a synthesis of HNE and 4-(^{3}H) HNE starting from fumaraldehyde dimethyl acetal.

EXPERIMENTAL PROCEDURES

Amberlyst-15 ion-exchange resin, fumaraldehyde dimethyl acetal, pyridinium chlorochromate, chromic acid on anion exchange resin, 2,3-dichloro-4,5-dimethoxy benzoquinone, sodium acetate, 1-bromopentane, magnesium metal, dichloromethane (anhydrous), ether (anhydrous), and sodium carbonate were purchased from Aldrich Chemical Company (Milwaukee, WI). Sodium borohydride, sodium sulfate (anhydrous), ammonium chloride, acetone (HPLC grade) were from Fisher Scientific (Fairtown, NJ). Sodium borotriteride was purchased from DuPont NEN (Boston, MA).

^{1}H spectra were recorded on a 270 MHz Jeol (Peabody, MA) Gx 270 and ^{13}C spectra on a 68 MHz Jeol apparatus, in ς units downfield from the internal standard Me_4Si.

All yields were calculated in percentage (moles) of the product obtained, relative to the number of moles of the starting parent compound.

Nonradiolabeled HNE was synthesized from fumaraldehyde dimethyl acetal which was partially hydrolyzed to give the monoacetal using amberlyst-15 catalyst. The monoacetal was then reacted with 1-bromopentane, in a Grignard synthesis, which yielded HNE as its dimethyl acetal (20) (Scheme 1). HNE obtained as its dimethyl acetal was oxidized to its 4-keto derivative using pyridinium chlorochromate buffered with sodium acetate. The formation of the ketone proved especially tedious owing to the susceptibility of the HNE dimethyl acetal to acid hydrolysis even under mildly acidic conditions. The ketone, which is the oxidized product, once formed reverted easily to HNE and other degradation products (products not identified) upon exposure to moisture and higher temperature. A number of conventional oxidizing agents for the specific oxidation of allylic alcohols, as documented in the literature, were tried. However, most of the methods failed to yield the desired α-β unsaturated ketone. Pyridinium chlorochromate buffered with sodium acetate (1:1.2, w/w) was found to be the oxidizing agent of choice, and yielded the corresponding α-β unsaturated ketone (21) (Scheme 2). These results are summarized in Table 1. Other oxidizing agents led to the hydrolysis of the acetal to yield the aldehyde (HNE) as the major product, as determined by thin-layer chromatography (TLC). Although the synthesis of other 4-hydroxyalkenals is not reported, most of them can be synthesized by modification of the same general method described here, using the appropriate bromoalkane in the Grignard reaction.

Synthesis of fumaraldehyde monodimethyl acetal. The monoacetal **2** was obtained by the partial acid hydrolysis of the fumaraldehyde dimethyl acetal, using amberlyst-15 catalyst. In a typical reaction, 325 mL of acetone was stirred with 2.4 mL water and 3.26 g of amberlyst catalyst. To this mixture, 14.16 g (80 mmol) of the diacetal was added quickly in one portion, at room temperature. Stirring was continued for 6 min, after which the reaction mixture was filtered through a bed of anhydrous sodium carbonate. The solvent was distilled off under vacuum to yield fumaraldehyde monodimethyl acetal, a yellow oil (yield 8.4 g, 80%). The compound was found to be pure by observance of a single spot on TLC (2% methanol–dichloromethane), and by nuclear magnetic resonance (NMR). ^{1}H NMR ($CDCl_3$) ς (ppm) = 9.6 (*d*; 1H, –C*H*O), 6.7 (*dd*; 1H, CH = CH–CHO), 6.3 (*dd*; 1H, –C*H* = CH), 5.1 [*d*; 1H C*H*–$(OCH_3)_2$], 3.4 [*s*, 6H –$(OCH_3)_2$].

*Synthesis of dimethyl acetal of 4-hydroxy-2-*trans*-nonenal.* Magnesium pellets (2.8 g, 116.8 mmol) were added to 10 mL of dry ether. A few drops of 1-bromopentane were added, and the flask was gently heated until the reaction started. If no re-

The Results of the Buffering of Pyridinium Chlorochromate with Sodium Acetate, Yielding the Corresponding α-β Unsaturated Ketone[a]

Oxidizing agent	Ratio of oxidizing agent to dimethyl acetal of HNE	Solvent and dilution	Reaction condition	Major product	4-Keto derivative of HNE
1. DDQ-dioxane	2 mol eq.	Dioxane 10 mg/mL	Stirred and refluxed for 6 h	HNE >90%	Not detected
2. Chromic acid on anionic exchange resin	3.5 g/mmole	Ether 5 mg/mL	Refluxed for 1 h	HNE >90%	<5% by HPLC
3. Activated manganese oxide	10:1 w/w	Hexane 10 mg/mL	Stirred at RT for 24 h	No reaction	
4. Pyridinium chlorochromate	1.5 millieq.	Dry methylene	Stirred at RT for 2 h	HNE >90%	Not detected
5. Pyridinium chlorochromate buffered with 1:1.12 w/w sodium acetate	1.5 millieq.	Dry methylene chloride 5 mg/mL	Stirred at RT for 30 min	Ketone 90% yield	90% yield

[a]DDQ, 2,3-dichloro-4,5-dimethoxy benzoquinone; HNE, 4-hydroxy-2-*trans*-nonenal; HPLC, high-performance liquid chromatography; RT, room temperature.

action was observed after heating, a crystal of iodine was added and the flask heated again, which was usually sufficient to initiate the formation of the Grignard reagent. Dry ether (150 mL) was then added to the reaction mixture followed by dropwise addition of the remaining amount of 1-bromopentane (13.2 g, 87.6 mmol) dissolved in 30 mL of dry ether. The reaction mixture was mildly heated so as to maintain gentle reflux for 30 min. At this stage, the mixture turned dark, as the formation of Grignard reagent proceeded to completion (Scheme 1). The reaction mixture was then cooled to 0°C by ice bath, and the monoacetal (9.5 g, 73 mmol), dissolved in 50 mL of dry ether, was added dropwise with constant stirring. When all of the monoacetal had been added, the stirring was continued for an additional 30 min at 0°C. Thereafter, the reaction was quenched with 75 mL of a saturated solution of ammonium chloride. It was extracted three times with ether, dried over anhydrous sodium sulfate, and the solvent was distilled off to give a brownish oil, the dimethyl acetal of 4-hydroxy-2-*trans*-nonenal. The crude compound was purified further by silica gel column chromatography in 3% methanol–dichloromethane. The purified compound moved as a single spot on TLC in 3% methanol–dichloromethane (yield 10.6 g, 72%). HNE can be obtaind by the acid hydrolysis (in 2.3% H_2SO_4) of the dimethyl acetal whenever required. The hydrolysis is complete in 1 h at room temperature. ^{1}H NMR ($CDCl_3$) ς (ppm) = 0.9 (3H, C*H*$_3$–CH$_2$), 1.2 (5H, C*H*$_2$–CH$_2$–C*H*–), 1.5 (2H, C*H*$_2$–CH$_2$–OH), 1.8 (1H, C*H*$_2$–C*H*–OH), 4.0 (*m*; 1H, C*H*–OH) 4.7 (*d*; 1H, C*H*–O), 5.6 (*dd*; 1H, CHOH–C*H*=CH), 5.9 (*dd*; 1H, C*H*=CH–CH(OCH$_3$)$_2$). ^{13}C NMR ($CDCl_3$) ς (ppm) = 14 (1C; *C*H$_3$–CH$_2$) 22–39 (4C; CH$_3$–*C*H$_2$–*C*H$_2$–*C*H$_2$–*C*H$_2$), 53 (2C; –(O*C*H$_3$)$_2$), 72 (1C, *C*H–OH), 103 (1C –*C*H–O) 126–138 (2C; *C*H=*C*H).

*Synthesis of 4-keto derivative of 4-hydroxy-2-*trans*-nonenal.* Pyridinium chlorochromate (800 mg, 3.71 mmol) was stirred with 1:1.12 w/w equivalent of sodium acetate, in 40 mL of dry methylene chloride. The dimethyl acetal of HNE (500 mg, 2.45 mmol) was dissolved in 10 mL of dry methylene chloride and added in one portion. The stirring was continued at room temperature for an additional 30 min, and the progress of the reaction was monitored by TLC, in 2% methanol–dichloromethane. At this stage the reaction mixture turned brownish due to the deposition of the reduced oxidizing agent. The reaction mixture was diluted with 250 mL (5 vol) of dry ether, the solvent was decanted, and the solid residue extracted three times with ether. The combined organic layer was filtered through a tight gauze of cotton, and the solvent was evaporated at reduced pressure. The ketone obtained was further purified by preparative TLC in 2% methanol–dichloromethane (yield 440 mg, 90%). The compound was found to be pure since it moved as a single spot on TLC (2% methanol–dichloromethane). ^{1}H NMR ($CDCl_3$) ς (ppm) = 1.0 (3H, C*H*$_3$–CH$_2$), 1.2–2 (6H, CH$_3$–C*H*$_2$–C*H*$_2$–C*H*$_2$), 2.5 (2H, C*H*$_2$–C = O), 3.5 (*s*; 6H, (COCH$_3$)$_2$), 6.0 (*dd*; 1H, CH=C*H*–CH) 6.3 (*dd*; 1H, O=C*H*–CH), 7.3 (*d*; 1H, CH–O) ^{13}C NMR ($CDCl_3$) ς (ppm) = 14 (1C, *C*H$_3$), 20–40 (4C, CH$_3$–*C*H$_2$–*C*H$_2$–*C*H$_2$–*C*H$_2$)$_m$ 102–110 (2C, *C*H=*C*H), 140 (1C, *C*H–O), 158, (1C, *C*=O).

*Preparation of 4-(^{3}H) 4-hydroxy-2-*trans*-nonenal.* The keto derivative (10 mg, 0.05 mmol) was suspended in 5 mL of absolute ethanol, 5 mCi (100–1000 mCi/mole) of sodium borotriteride was added, and the mixture was stirred for 2 h. Nonradiolabeled $NaBH_4$ (7.6 mg, 0.2 mmol) was then added and the stirring was continued for 2 h. The solvent was evaporated in a rotary evaporator and the reaction was quenched with 50 mL of acidified water (pH 2.0) to decompose the unreacted $NaBH_4$, extracted three times with methylene chloride, dried over anhydrous sodium sulfate, and the methylene chloride distilled off under vacuum. The crude compound thus obtained was purified by HPLC (yield 6 mg, 60%) as described below and eluted as a single peak (purity was 99%).

Purification of 4(^{3}H)-HNE by HPLC. The crude radiolabeled HNE was purified on a Rainin (Rainin Instrument, Woburn, MA) C_{18} ODS reverse-phase MicroSorb-MV col-

umn (4.6 mm × 25 cm) pre-equilibrated with 3% methanol (Solvent A), using a gradient with 50% methanol (Solvent B). The gradient was programmed such that B reached 100% in 30 min and was held at 100% for an additional 20 min, whereafter A reached 100% in 5 min. The absorbance was monitored at 224 nm. HNE eluted as a sharp peak at a retention time of 42 min. The radioactivity peak was found to coincide with this peak.

Determination of the specific activity. The concentration of HNE in the solution was calculated by determining the absorbance at 224 nm using a Gilford Response Spectrophotometer (Corning Laboratory Sciences, Oberlin, OH) and an extinction coefficient of 13,750 M^{-1} cm^{-1}. An aliquot of the solution was used for the quantification of radioactivity using a Beckman liquid scintillation counter model LS 1801 (Fullerton, CA). The purified 4(^{3}H) HNE had a specific activity of 10 mCi/mmole and a purity of approximately 99%.

RESULTS AND DISCUSSION

This method provides a simple synthesis for obtaining both HNE and 4-(^{3}H) HNE, starting from fumaraldehyde dimethyl acetal. The oxidation of HNE dimethyl acetal to its 4-keto derivative is conveniently achieved by oxidation with pyridinium chlorochromate buffered with sodium acetate. The ketone obtained thereby is reduced with sodium borotriteride to yield the 4-(^{3}H)-HNE. The oxidation reaction is performed at room temperature, is complete in 30 min, and results in high yields of the ketone (90%). Pyridinium chlorochromate alone failed to yield the desired compound resulting in the hydrolysis of the acid-labile acetal groups, and had to be buffered with sodium acetate 1:1.2 w/w. Although we tried other oxidizing agents, they did not yield the desired compound or gave a poor yield, and generally resulted in the hydrolysis of the acetal groups (Table 1).

Chromogenic Assay for Phospholipase D from *Streptomyces chromofuscus*: Application to the Evaluation of Substrate Analogs

Paul J. Hergenrother, Michelle K. Haas, and Stephen F. Martin*

Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712

ABSTRACT: A rapid and convenient chromogenic assay for phospholipase D from *Streptomyces chromofuscus* (PLD_{Sc}) has been developed that converts the choline generated from the enzyme-catalyzed hydrolysis of phospholipids into a chromogenic dye. By quenching the reaction with EDTA at defined times, an initial rate curve is produced from which a k_{cat} and K_m can be readily derived. This assay has been applied to the biological evaluation of several substrate analogs, all of which appear to be activators rather than substrates or inhibitors of this enzyme. Performing the assay in 96-well microtiter plates allows for the easy screening of potential effectors of this enzyme. *Lipids 32,* 783–788 (1997).

Enzymes of the phospholipase D (PLD) class catalyze the hydrolysis of phosphatidylcholine (PC) to give phosphatidic acid (PA) and choline (Scheme 1). The intense interest in these enzymes is due to the discovery that the products of the PLD reaction *in vivo* serve as secondary messengers in the signal transduction cascade (1). Cellular PA can be converted to diacylglycerol (DAG) through the action of a PA phosphohydrolase (2), and the DAG that is produced then activates protein kinase C (3). The prolonged production of DAG through this PLD-mediated pathway represents an alternative to the rapid burst of DAG that is produced directly from the hydrolysis of phospholipids by phosphatidylinositol-specific phospholipases C (4). Moreover, there is evidence that PA directly activates a PA-dependent and DAG-independent protein kinase, which suggests a direct role for PLD in cellular signaling *via* protein kinases (5). Compounds that are specific activators and inhibitors of PLD would be extremely valuable as tools to probe the cellular function of this enzyme. 2,3-Diphosphoglycerate, a compound which possesses structural similarity to PLD product PA, is a competitive inhibitor of PLD (6). Although aminoglycoside antibiotics (7) and a chymotrypsin inhibitor (8) have been shown to inhibit PLD activity *in vivo*, the antibiotics lack specificity toward PLD alone, and the latter inhibitor does not appear to interact directly with PLD.

The cloning and purification of mammalian phospholipases D have proven difficult, whereas several PLD of bacterial origin have been cloned and isolated (9). These prokaryotic PLD have been accorded a greater significance owing to a recent report that compared the primary structures of PLD from numerous sources and found that bacterial and eukaryotic PLD have significant sequence similarity with one another (10). In addition, PLD isolated from various *Streptomyces* sources have been investigated in light of the observation that in the presence of an alcohol acceptor these PLD will catalyze a transphosphatidylation (11), a reaction that is synthetically useful (12). Of the bacterial PLD, the enzyme from *Streptomyces chromofuscus* (PLD_{Sc}) is one of the best characterized (13). This enzyme has been shown to be calcium-

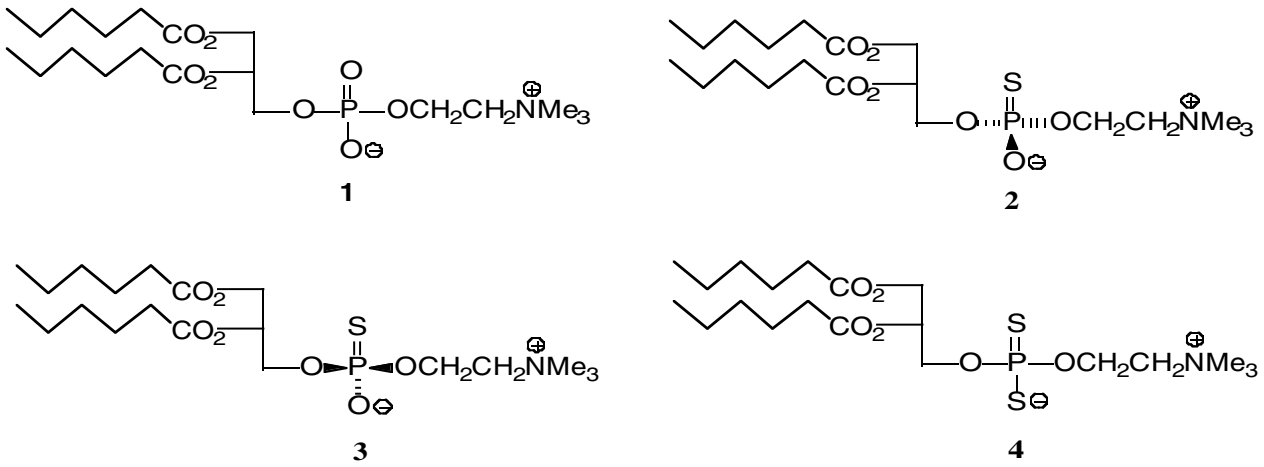

SCHEME 2

dependent and to possess a hydrophobic site that is distinct from its catalytic site (13). This bacterial PLD has been used as a model system for the mammalian enzyme (6), and compounds that activate or inhibit PLD_{Sc} may be useful for *in vivo* studies on mammalian systems. Analogs of the PC substrate **1** (Scheme 2) have been synthesized in which a single nonbridging phosphoryl oxygen has been replaced with sulfur, giving the R_p isomer **2** and the S_p isomer **3**; and in which both oxygens have been substituted by sulfur atoms, providing the dithioate compound **4** (14). We report an initial step toward deriving a structure–activity relationship for PLD_{Sc} using the substrate analogs **2**, **3**, and **4**.

To study the effects of various compounds on PLD_{Sc} activity, a sensitive assay was required that would utilize only small quantities of the substrate analogs. PLD assays using radiometric techniques (6) or safarine-based systems (15) have been reported, but these are too cumbersome for efficient screening of substrate analogs. Likewise, a chromogenic assay utilizing the substrate phosphatidyl-*p*-nitrophenol (16) was unattractive because of the concern that this compound did not adequately resemble the natural PLD substrate. Therefore, a known assay method for PLD_{Sc} that was based on the conversion of choline to a chromogenic dye through the action of choline oxidase, peroxidase, phenol, and 4-aminoantipyrine (17) was modified to a 96-well plate format to minimize the time and amounts of reagents required. We have recently described a variation of this assay (18) that was utilized to evaluate site-specific mutants of PC-preferring phospholipase C from *Bacillus cereus* (19).

MATERIALS AND METHODS

Enzymes. PLD from *S. chromofuscus* (P-8023), choline oxidase (C-5896), and peroxidase (P-8250) were obtained from Sigma Chemical Co. (St. Louis, MO).

Organic compounds. 1,2-Dihexanoyl-*sn*-glycero-3-phosphocholine was obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). 1-(2-Pyridylazo)-2-naphthol (PAN) was purchased from Aldrich Chemical Co. (Milwaukee, WI).

Substrate analogs. Substrate analogs were synthesized as described in Reference 14.

Assay of PLD—overview. Assays were carried out in 96-well microtiter plates that were maintained at 37°C using a constant-temperature water bath. A 50-µL solution of PLD_{Sc} in 100 mM Tris, pH = 8.0, with bovine serum albumin at 0.5 mg/mL was added to a 100-µL solution of the 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine substrate **1** in 50 mM Tris with 36 mM calcium chloride so that the final concentration of Tris was 67 mM, pH = 8.0. The final concentration of $CaCl_2$ was 24 mM and the final volume was 150 µL. The final concentration of PLD_{Sc} was 10.6 units/mL (3.5 units/150 µL reaction volume). The substrate concentrations typically ranged from 0.08 mM to 3.0 mM. After allowing the PLD_{Sc} reactions to progress for a defined time, the reactions were quenched with 75 µL of 0.1 M EDTA (pH = 8.0), followed by the addition of the chromogenic solution. The EDTA solution was added such that the final EDTA concentration was 25 mM. Quenching was performed at 20 s intervals to obtain points from $t = 0$ to $t = 100$ s. The chromogenic solution was added in a 75-µL volume and contained choline oxidase, phenol, 4-aminoantipyrine, and peroxidase in 60 mM Tris at pH = 8.0. This solution was added so that the final concentration of choline oxidase was 1.1 units/mL, phenol was 0.067 mg/mL, 4-aminoantipyrine was 0.1 mg/mL, and peroxidase was 3.5 units/mL. The increase in absorbance at 490 nm with time was monitored by a microplate reader (Bio-Tek Instruments EL311s; Winooski, VT) and found to come to an end point at $t = 60$ min.

Assay of PLD_{Sc}—detailed protocol. Table 1 shows the times at which the reagents in a typical assay were added. To prepare the microtiter plates for the assay, 50 µL of 0.1 M Tris at pH = 8.0 was added to the wells of a 96-well microtiter plate. A 50-µl aliquot of 3*x* substrate in water was then added, where *x* was the desired final concentration. Columns on the plate were used for the different substrate concentrations, and the rows represented the various times. The plate was then incubated in a 37°C bath for 10 min. After this equilibration to 37°C, 50 µL of the PLD_{Sc} solution (also pre-equilibrated to

TABLE 1
Time at Which Reagents Are Added in the PLD_{Sc} Assay[a]

Row on the 96-well microplate	Add PLD_{Sc} at time (s)	Add EDTA at time (s)	Time elapsed in PLD_{Sc} reaction (s)
5	10	110	100
4	20	100	80
3	30	90	60
2	40	80	40
1	50	70	20

[a]Assays were performed at 37°C in 96-well microtiter plates. Rows on the plates were used for the various assay times, with the plate columns representing different substrate concentrations. After the last addition of EDTA, the chromogenic solution (see the Materials and Methods section) was added to all wells of the plate. Row 6 was generally used as a blank, with EDTA being added before PLD_{Sc}. Abbreviation: PLD_{Sc}, phospholipase D from *Streptomyces chromofuscus.*

37°C) was added to the plate *via* a multichannel pipettor according to Table 1. Multichannel pipettors were used for all additions so that the hydrolysis reactions for each of the different substrate concentrations began and ended at exactly the same time. Mixing was achieved by pipetting 50 µL of the reaction mixture two times with the multichannel pipettor. As outlined in Table 1, the PLD_{Sc} reactions were quenched with 75 µL of 0.1 M EDTA at various times, which gave points in 20 s intervals from 20 to 100 s. Addition of EDTA was followed immediately by addition of 75 µL of the chromogenic solution. A blank in which the EDTA was added before the PLD_{Sc} solution was performed for each substrate concentration. The plate was then covered and incubated for 1 h at 37°C, at which time it was read at 490 nm. After subtracting the blank from each substrate concentration, conversion of absorbance at 490 nm to µmols choline was performed *via* the slope of the calibration curve shown in Figure 1. The slopes

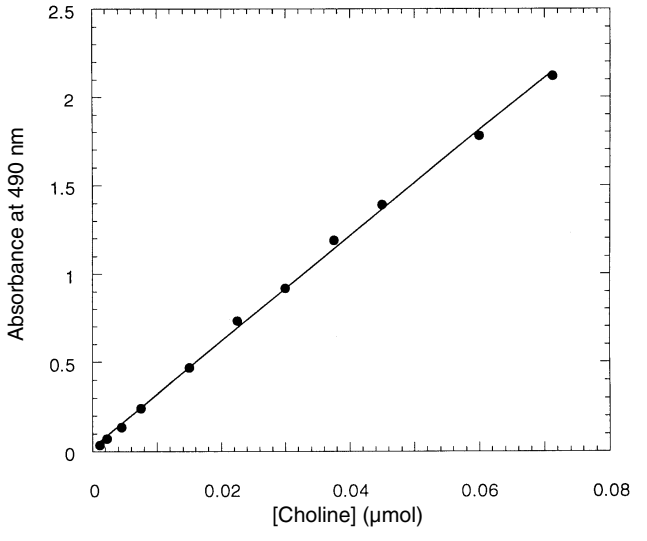

FIG. 1. Calibration curve for the phospholipase D from *Streptomyces chromofuscus* assay. Data points were generated by subjecting choline to the enzymatic reactions of the assay in microtiter plates at 37°C. The slope of this plot was used to convert absorbance at 490 nm to µmoles of choline produced.

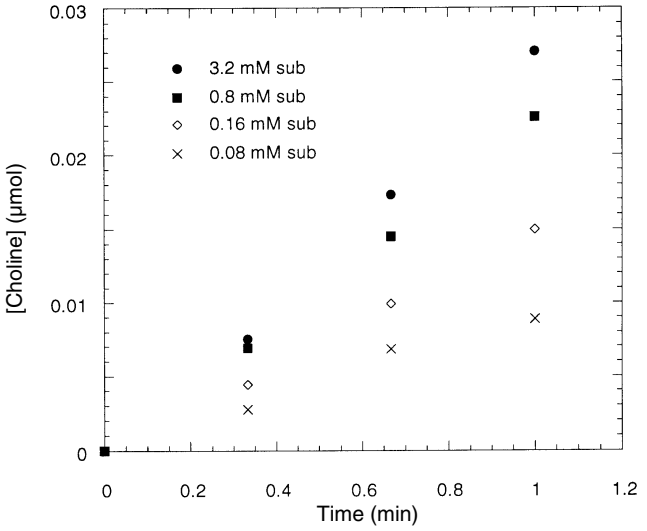

FIG. 2. Example of a plot used to obtain initial velocity values in the phospholipase D from *Streptomyces chromofuscus* assay. The slopes, in µmol/min, were taken from the linear portion of the graph.

of the resulting µmols of choline vs. time graphs (Fig. 2), which were generally linear through the 100-s point, were then plotted vs. substrate concentration as shown in Figures 3–5.

Values of K_m and V_{max} for the PLD_{Sc}-catalyzed hydrolysis of the PC substrate **1** were determined by a nonlinear least squares fit of the observed initial velocities (v) to Equation 1,

$$v = V_{max}\cdot[S]/(K_m + [S]) \quad [1]$$

using the KaleidaGraph curve-fitting program (Synergy Software, Reading, PA).

Assays of **2–4** *as potential substrates of* PLD_{Sc}. To determine whether compounds **2–4** were substrates for PLD_{Sc}, the

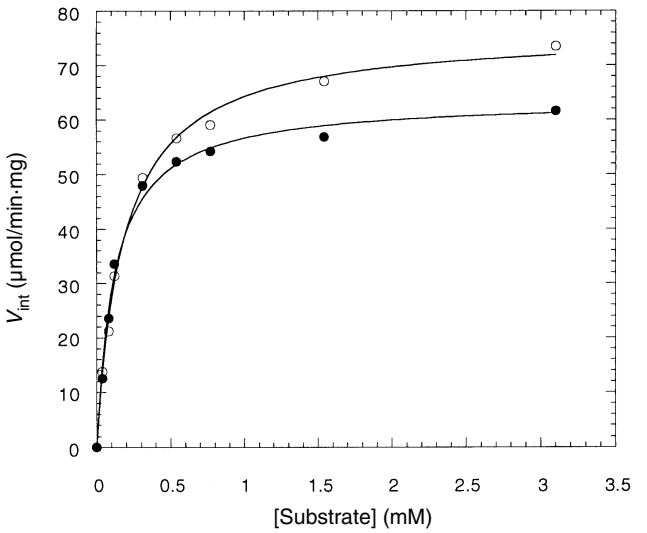

FIG. 3. Initial velocity (V_{int}) vs. substrate graph for the dihexanoylphosphatidylcholine **1** (●), and for **1** in the presence of compound **2** the R_p isomer of **1**, at 0.3 mM (○).

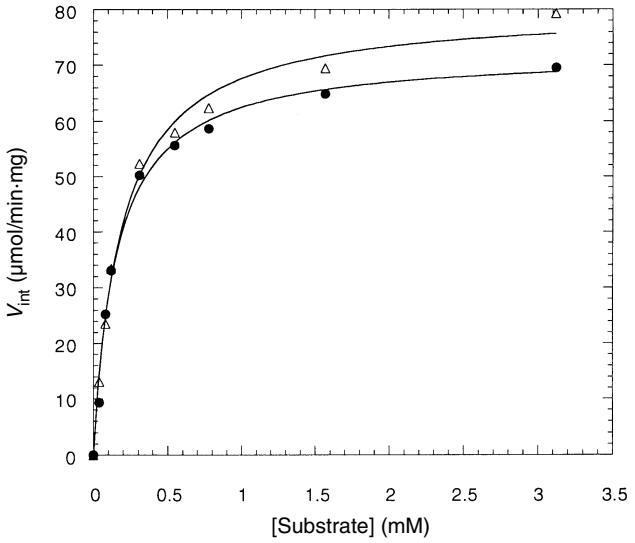

FIG. 4. V_{int} vs. substrate graph for the dihexanoylphosphatidylcholine **1** (●), and for **1** in the presence of compound **3** the S_p isomer of **1**, at 0.3 mM (△). See Figure 3 for abbreviation.

assay was performed as described above substituting these compounds for the substrate. Owing to the hydrophobic nature of the substrate analogs, the solutions containing the compounds were sonicated for 5 min prior to use to completely disperse the compounds. The concentrations at which the compounds were tested ranged from 0.03–0.7 mM for **2** and **3**, and 0.05 to 0.2 mM for **4**. Assays with **2**–**4** were allowed to proceed for as long as 4 min before quenching with EDTA, and no appreciable change in absorbance at 490 nm was measured over the blank.

Assays of **1** *in the presence of* **2**–**4** *and Triton X-100.* The effects of substrate analogs **2**–**4** and Triton X-100 on the

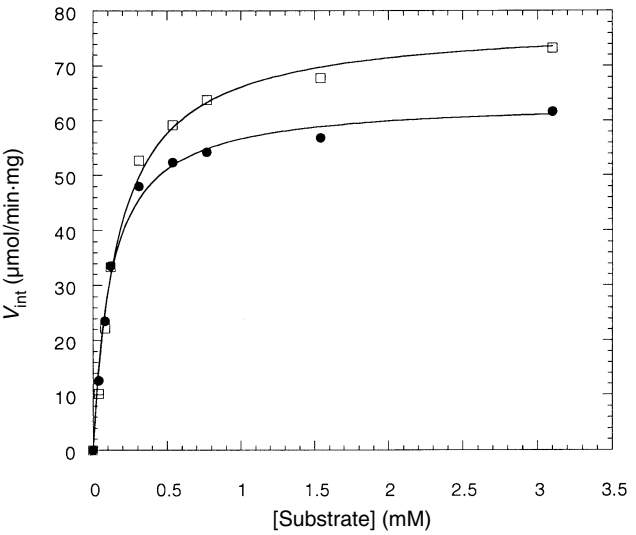

FIG. 5. V_{int} vs. substrate graph for the dihexanoylphosphatidylcholine **1** (●), and for **1** in the presence of compound **4** the dithioate compound of **1**, at 0.10 mM (□). See Figure 3 for abbreviation.

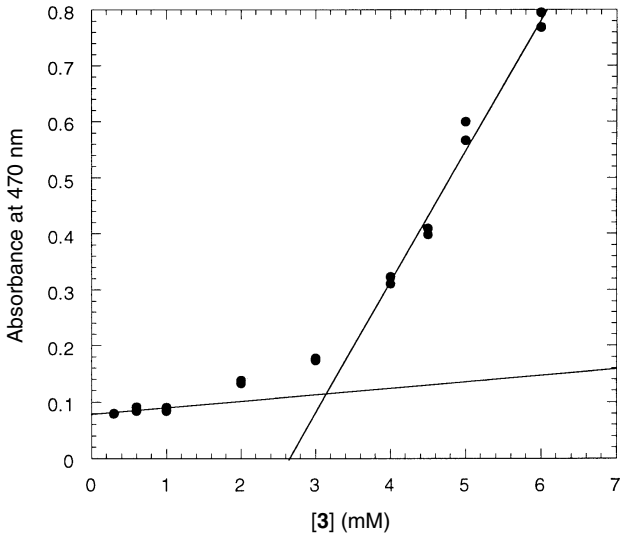

FIG. 6. Example of the graph used to determine the critical micelle concentration for compound **3**, the S_p isomer of dihexanoylphosphatidylcholine. Assays were performed in duplicate as described in the Materials and Methods section, and the critical micelle concentration was taken as the substrate concentration where the two lines intersected.

PLD_{Sc}-catalyzed hydrolysis of **1** were determined by performing the coupled chromogenic assay in the presence of varying concentrations of these compounds. The assays in the presence of **2**–**4** or Triton X-100 were performed by adding the substance in varying concentrations to the Tris buffer containing the PLD_{Sc} substrate **1**. Owing to the hydrophobic nature of the substrate analogs, these solutions were sonicated for 5 min prior to use. The assays were then performed as described above. The substrate analogues were tested in concentrations ranging from 0.1 to 0.3 mM for **2** and **3**, and 0.05 to 0.1 mM for **4**. The effect of Triton X-100 on the PLD_{Sc} reaction was studied at concentrations ranging from 0.03 to 0.2 mM of Triton X-100. The calibration curve shown in Figure 1 was obtained in the presence and absence of 0.2 mM **4** to control for any effects that these compounds may have on the enzymatic reactions converting choline to the chromogenic dye. The calibration curves were found to be identical in the presence and absence of **4** (data not shown).

Assays to determine critical micelle concentrations (CMC). Assays to determine the CMC for phospholipids **1**–**4** were run in duplicate on three different occasions. The assay was conducted in 96-well microtiter plates and is a modification of a known CMC assay based on the solubilization of the dye PAN (20). Varying concentrations of phospholipids **1**–**4** were made up to a total volume of 500 µL in H_2O. To each concentration was added 50 µL of a 1.6 mM PAN solution in pentane, at which point the pentane was allowed to evaporate and the color developed with an end point at 20 min. After 20 min, 200 µL of the solution was transferred to a 96-well microtiter plate and the absorbance was read at 470 nm. The absorbances obtained were graphed vs. substrate concentration and the CMC were calculated as described in Reference 20 and as shown in Figure 6.

RESULTS

Choline can be converted through the action of choline oxidase, peroxidase, phenol, and 4-aminoantipyrine into a chromogenic dye which has a strong absorbance at 490 nm (17). Addition of these reagents after quenching of the enzyme allows for formation of the dye, which is complete in 1 h. By quenching the calcium-dependent PLD_{Sc} reaction with EDTA at times from 20 to 100 s, a rate vs. time curve is obtained (Fig. 2). By following the assay plan shown in Table 1, an entire assay at eight different substrate concentrations can be performed in approximately 2 min. Conversion of absorbance at 490 nm to μmoles choline was performed *via* the calibration curve that was produced by subjecting choline to the enzymatic reactions of the assay (Fig. 1). The slopes (μmol/min·mg) of the rate vs. time plots (Fig. 2) were then graphed vs. substrate concentration as depicted in Figures 3–5. The kinetic parameters V_{max} and K_m were determined from a nonlinear least squares fit of the data to the Michaelis-Menton equation (Equation 1), and k_{cat} values were calculated using a molecular weight of 50,000 for PLD_{Sc} (13). The assay was typically performed with a PLD_{Sc} concentration of 10.6 units/mL; however, concentrations ranging from 2.65 to 21.6 units/mL were also used to confirm the linearity of the assay. The k_{cat} for PLD_{Sc} was $69 \pm 2\ s^{-1}$, with $K_m = 0.12 \pm 0.01$ mM. These kinetic parameters were alternatively obtained *via* the equation describing the Lineweaver-Burk transformation of the data. This analysis yielded a k_{cat} of $56 \pm 9\ s^{-1}$, and a K_m of 0.13 ± 0.04 mM.

Table 2 summarizes the kinetic data obtained for PLD_{Sc} with the PC substrate **1** and with the sulfur-containing analogs **2**–**4**. After it was found that compounds **2**–**4** were not substrates for PLD_{Sc}, they were tested for activation or inhibition of the enzyme. Figures 3–5 show the effect of the substrate analogs **2**–**4** on the PLD_{Sc} reaction. It is clear by comparing Figure 5 with Figures 3 and 4 that activation of PLD_{Sc} occurs at lower concentrations for **4** than for **2** and **3**. When **2** and **3** were tested at 0.1 mM, the activation of PLD_{Sc} was negligible (data not shown).

TABLE 2
Kinetic Parameters for Various Phosphatidylcholine Compounds in the PLD_{Sc} Assay[a]

Compound	k_{cat} (s^{-1})	K_m (mM)
1	69 ± 2	0.14 ± 0.02
2	No activity	No activity
3	No activity	No activity
4	No activity	No activity

[a]Assays were performed at 37°C in 96-well microtiter plates as described in the Materials and Methods section. The values of k_{cat} and K_m were determined from the nonlinear least squares fit of the initial velocities, *v*, to the equation, $v = V_{max} \cdot [S]/(K_m + [S])$, using the KaleidaGraph curve-fitting program. The k_{cat} values were calculated using a molecular weight of 50,000. Points for compounds **2**–**4** were taken out to 4 min, with no change in the absorbance at 490 nm over the blank detected. Abbreviations: **1**, 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine substrate; **2**, R_p isomer of **1**; **3**, S_p isomer of **1**; **4**, dithioate compound of **1**.

CMC data (determined by measuring the amount of PAN solubilized as a function of phospholipid concentration) for compounds **1**–**4** with the 96-well microtiter plate PAN assay are as follows: **1**, 8.1 ± 0.6; **2**, 3.1± 0.2; **3**, 1.9 ± 0.5; and **4**, not available. This assay is displayed graphically in Figure 6, for phospholipid **3**. Of the four phospholipids, only compound **1** had its CMC determined previously. The CMC of **1** was found to be 11.1 mM by nuclear magnetic resonance methods (21), and this value differs from the 8.1 mM determined using the dye inclusion assay; however, these differences are relatively small and not surprising given the disparate nature of these two techniques. Compound **4** was insoluble at concentrations above 0.2 mM, and it did not show any appreciable change in the absorbance at 470 nm when analyzed in the PAN assay from 0.01–0.2 mM.

DISCUSSION

The rapid screening of stimulators/inhibitors of an enzyme requires an assay that will minimize the quantities of reagents required. This is especially important when using small organic compounds that require several synthetic steps to produce and enzymes that are costly or not commercially available. Assays performed in a 96-well plate format are ideally suited for such analysis because the small sample volume and the matrix format allow for rapid evaluation of the effect of selected organic molecules upon enzymatic activity. The present assay fulfills this objective and should find use not only for the screening of potential inhibitors of PLD_{Sc} but also for the determination of kinetic parameters for any site-directed mutants of the enzyme that may be produced in future studies of mechanisms.

Certain phospholipases have been shown to hydrolyze specifically one isomer of phosphorothioate analogs of phospholipids. For example, phospholipase A_2 from various sources is specific for the R_p isomer of these PC analogs (22–24). Conversely, the PC-preferring phospholipase C from *Bacillus cereus* specifically catalyzes the hydrolysis of the S_p thio isomer **3** of PC, whereas the R_p compound **2** is a potent inhibitor (14). Similarly, the PLD from cabbage was also found to be specific for the S_p isomer of thiophosphorylcholine (24). From the data presented in Table 2, it is obvious that neither the S_p nor R_p thiophosphates **3** and **2**, or dithio compound **4** are substrates for PLD_{Sc} under the conditions employed for the assay. This result suggests that both of the nonbridging phosphoryl oxygen atoms of the PC substrate are required for recognition and catalytic processing by PLD_{Sc}.

Close inspection of Figures 3–5 indicates that PLD_{Sc} is inhibited slightly by the substrate analogs **2**–**4** at low substrate concentrations but activated at higher substrate concentrations. This finding is similar to the effect upon PLD_{Sc} of Triton X-100, which caused inhibition at low substrate concentrations but activation at higher concentrations (13). The effect of Triton X-100 has been reproduced using this 96-well plate assay with the same results (data not shown). It has been suggested that PLD_{Sc} possesses a hydrophobic pocket that is

distinct from its active site, and activation of PLD_{Sc} by hydrophobic molecules has been described (13). The activation of PLD_{Sc} by hydrophobic compounds **2–4** is consistent with these results. Because many phospholipases are known to have increased activity in micellar systems (25), the assays studying the effect of **2–4** on the processing of **1** were carried out below the CMC of these compounds. Nevertheless, it is possible that the activation of PLD_{Sc} in the presence of **2–4** is due to pre-micellar aggregation of the lipids. Therefore, while it can be confidently concluded that **2–4** are not inhibitors of PLD_{Sc}, the mechanism of activation by these compounds remains uncertain.

A convenient assay for determining the kinetic parameters for PLD_{Sc} has been developed that is based on the conversion of choline to a chromogenic dye in 96-well plates. This assay has been applied to evaluate the phosphorothioate analogs **2–4** of PC, and it was found that these compounds are not substrates for the enzyme. Indeed these phospholipid analogs activate PLD_{Sc} at high substrate concentrations, with the more hydrophobic dithiophosphate analog **4** giving the most activation. In addition, a simple assay for the determination of CMC has been modified to fit a 96-well plate format, and this assay has been used to establish previously unknown CMC for **2–4**.

Structural Characterization of a "Signature" Phosphatidylethanolamine as the Major 10-Hydroxy Stearic Acid-Containing Lipid of *Cryptosporidium parvum* Oocysts

David P. Schrum[a,*], Srinivas Alugupalli[a], Sean T. Kelly[a], David C. White[b,c], and Ronald Fayer[d]

[a]Microbial Insights, Inc., Rockford, Tennessee, [b]Center for Environmental Biotechnology, University of Tennessee, Knoxville, Tennessee, [c]Environmental Science Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, and [d]USDA, ARS, LPSI, Parasite Immunology Laboratory, Beltsville, Maryland

ABSTRACT: A 10-hydroxy stearic acid-containing lipid from *Cryptosporidium parvum* was purified by thin-layer chromatography and analyzed by infrared spectroscopy, fast-atom bombardment mass spectrometry, ^{1}H and ^{31}P nuclear magnetic resonance spectroscopy, and was identified as phosphatidylethanolamine.
Lipids 32, 789–793 (1997).

Detection and removal of potentially pathogenic and nonculturable microorganisms are major problems in the water industry. Particularly alarming are the protozoal cysts of *Giardia* and oocysts of *Cryptosporidium* which are nonculturable with standard bacterial techniques, and are responsible for diarrhea worldwide (1,2). *Cryptosporidium parvum* is an important and serious pathogen because it infects a wide range of mammalian hosts and patients with acquired immune deficiency syndromes (3). The current methods available to detect oocysts of *C. parvum* in water are currently unsatisfactory (4).

The chemical analysis of oocysts based on lipids may provide a useful method for the sensitive and rapid detection of *C. parvum* (White, D.C., Alugupalli, S., Schrum, D.P., Kelly, S.T., Sikka, M.K., Fayer, R., and Kaneshiro, E.S., unpublished data). The importance of this type of chemical analysis to compare the lipid compositions of the *C. parvum* and Madin-Darby bovine kidney cells has previously been reported (3). In our recent studies, we have shown that the lipid analysis could differentiate between *C. parvum* and *C. muris* (White, D.C., Alugupalli, S., Schrum, D.P., Kelly, S.T., Sikka, M.K., Fayer, R., and Kaneshiro, E.S., unpublished data). The present study was undertaken in order to chemically characterize the ester-linked native form of 10-OH 18:0 in *C. parvum*.

Abbreviations: FAB, fast-atom bombardment; GC/MS, gas chromatography/mass spectrometry; NMR, nuclear magnetic resonance; PE, phosphatidylethanolamine; TLC, thin-layer chromatography; TMS, trimethyl silylation.

MATERIALS AND METHODS

Chemicals. All reagents were of analytical grade. *N,O*-Bis trimethylsilyl trifluoroacetamide, acetyl chloride, pyridine, and phospholipase A_2 (*Crotalus adamanteus* venom) were purchased from Sigma (St. Louis, MO). The standards 3-hydroxy tridecanoic acid and 6-hydroxy stearic acid were purchased from Matreya (Pleasant Gap, PA). The solvents hexane, chloroform, methanol, diethyl ether, and methylene chloride were also used.

Parasites. Oocysts of *C. parvum* used in this study were purified from calf feces as discussed previously (White, D.C., Alugupalli, S., Schrum, D.P., Kelly, S.T., Sikka, M.K., Fayer, R., and Kaneshiro, E.S., unpublished data).

Lipid extraction. Oocysts of *C. parvum* were extracted in a modified single-phase solvent system which included phosphate buffer (White, D.C., Alugupalli, S., Schrum, D.P., Kelly, S.T., Sikka, M.K., Fayer, R., and Kaneshiro, E.S., unpublished data; 5,6), at room temperature in chloroform/methanol/potassium phosphate buffer (50 mM, pH 7.4) (1:2:0.8, by vol) for 3 h. Chloroform and nanopure completely deionized, filtered water (1:1, vol/vol) were then added to cause a phase separation. The organic phase was then collected and dried under a stream of N_2 at 37°C.

Purification of lipids. The total lipid extract was dissolved in chloroform (~0.5 mL) and separated using a silicic acid column (10-cm column length, 0.5-cm inner diameter, 100–200 mesh silicic acid particle size) eluted with 5 mL of chloroform, 5 mL acetone, and 5 mL of methanol to elute neutral, glyco-, and phospholipids, respectively (7). Eluates were analyzed by silica-coated thin-layer chromatography (TLC) plates developed with chloroform/methanol/water (30:8:1, by vol). Sugar-containing compounds were visualized by spraying the plates with α-naphthol and heating at 110°C. Phospray reagent (Supelco, Bellefonte, PA) was used for revealing phosphorus-containing compounds, and ninhydrin reagent was used to reveal the presence of amino-containing species. Each individual lipid fraction was also ana-

lyzed for its fatty acid content. Final purification of the hydroxy fatty acid-containing lipid was achieved by reapplying the hydroxylated fatty acid-rich fractions on preparative TLC plates.

Selective phospholipase A_2 hydrolysis of phosphatidylethanolamine (PE) (8,9). Lyophilized phospholipase A_2 (250 units) was dissolved in 1 mL of 0.5 M Tris buffer with 0.4 M $CaCl_2$, at a pH of 7.5. A 300-µL aliquot of this solution was added to 0.4 mg of PE purified from *C. parvum* dissolved in 500 µL diethyl ether and shaken vigorously at 25°C for 20 min. The ether layer was removed, and the aqueous phase was washed with diethyl ether (2 × 1 mL). The ether washings were combined with the original ether layer, washed once with water (1 mL), collected, and dried under a stream of N_2 at 37°C. The fatty acids were subjected to acid methanolysis [1 M methanolic HCl (1 mL), 80°C, 30 min] and the hydroxy fatty acid methyl esters were separated, subjected to trimethyl silylation (TMS) and analyzed by gas chromatography/mass spectrometry (GC/MS) as previously described (10).

Other analytical techniques: (i) Characterization of the fatty acyl substituents. The acetone-eluted fraction from the silicic acid column was subjected to both mild and strong acid methanolysis as described previously (10). Fatty acid methyl esters were analyzed by GC/MS after the separation of hydroxy fatty acid methyl esters from nonhydroxylated compounds. The former class of fatty acid methyl esters was subjected to TMS derivatization prior to GC/MS analysis as described previously (White, D.C., Alugupalli, S., Schrum, D.P., Kelly, S.T., Sikka, M.K., Fayer, R., and Kaneshiro, E.S., unpublished data; 10).

(ii) Spectroscopy and spectrometry. Infrared spectra of samples were collected on a Bio-Rad FTS-60A Stepscan Interferometer (Bio-Rad Laboratories, Cambridge, MA) and measured as a thin film on NaCl plates.

^1H and ^{31}P nuclear magnetic resonance (NMR) spectra were obtained in $CDCl_3$ or $CDCl_3/CD_3OD$ (2:1, vol/vol) at 40°C on a modified NT360 NMR spectrometer (Nicolet, Madison, WI), operating at frequencies of 360.007 and 145.74 MHz, respectively.

Fast-atom bombardment (FAB) mass spectra were recorded with a ZAB-EQ (VG Analytical, Manchester, United Kingdom). Samples were dissolved in $CHCl_3$, and 1 µL was mixed on the probe tip with a matrix consisting of thioglycerol and 1% trifluoracetic acid. FAB was generated by an 8 keV xenon atom beam.

GC/MS was performed on a Trio-1 (VG Mass Lab) coupled to a Hewlett-Packard model 5890 gas chromatograph (Palo Alto, CA). Chromatographic separations were carried out on a fused-silica capillary column [30 m × 0.32 mm (inner diameter)] coated with cross-linked HP-1. Splitless injections were performed with a Hewlett-Packard model 7673 autosampler; the split valve was opened 1 min after injection. The carrier gas, helium, was used at an inlet pressure of 0.75 bar. The column temperature was programmed from 120 to 290°C, at 20°C/min; both the injector and the interface (between GC and MS) temperatures were kept at 280°C. The ionization was performed at 70 eV. The ion source temperature was 220°C in the electron impact mode. Hydroxy fatty acid methyl esters were identified and quantified as described previously (10).

RESULTS

Mass spectra. The electron impact mass spectrum of the TMS derivatized methyl ester ether (Me/TMS) of 10-OH 18:0 exhibited the characteristic fragments at *m/z* 215 (cleavage between C_9 and C_{10}), at *m/z* 273 (cleavage between C_{10} and C_{11}), and the molecular-specific ion at *m/z* 371 (M – loss of CH_3) (Fig. 1). Hydrolysis under both mild and strong conditions indicated that the 10-OH 18:0 is found mainly as ester-linked to the purified lipid.

Furthermore, the selective hydrolysis of PE purified from *C. parvum* with phospholipase A_2 indicated that 10-OH 18:O is located only on the *sn*-2 position as analyzed by GC/MS (data not shown).

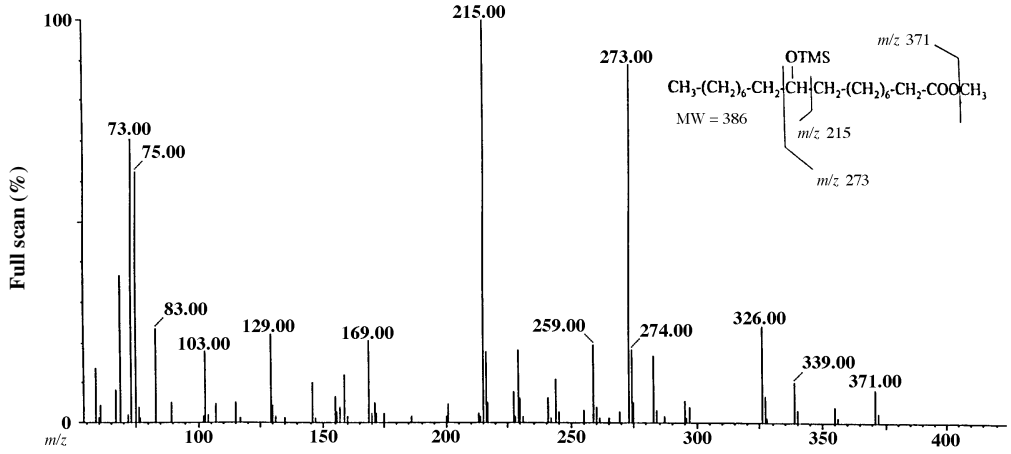

FIG. 1. Electron impact mass spectrum of the Me/trimethyl silylation (TMS)-derivatized 10-OH 18:0 found in *Cryptosporidium parvum*; MW, molecular weight.

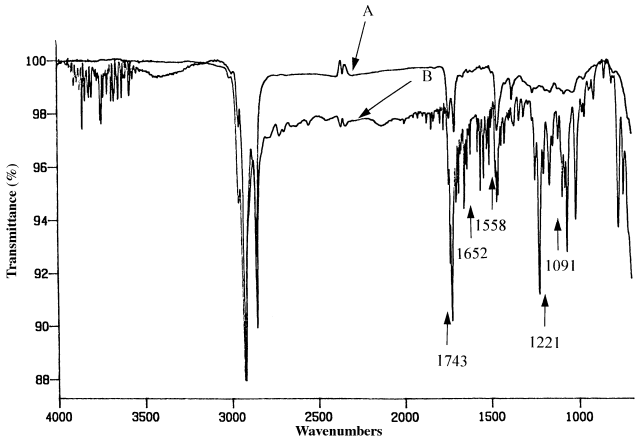

FIG. 2. Infrared spectrum of the purified phosphatidylethanolamine of *C. parvum* (marked A) and that of authentic phosphatidylethanolamine (PE) (marked B). The arrows indicate characteristic absorption bands typifying PE. See Figure 1 for abbreviation.

Fractionation of the total lipid extract by column chromatography followed by preparative TLC of the acetone-eluted fraction allowed the purification of the three lipids. The major lipid purified by preparative TLC was ninhydrin positive and phospray positive with the chromatographic mobility in one-dimension of authentic PE. This component lipid containing the ester-linked 10-OH 18:0 was also shown to be similar to authentic PE from its infrared, FAB/MS, ^{1}H NMR, and ^{31}P NMR spectra.

Figure 2 displays the infrared spectra of the major isolated lipid, which exhibited characteristic PE absorption bands at 1221 and 1091 cm^{-1} indicative for PO_2^-, 1652 and 1558 cm^{-1} indicative for NH_3^+ bands, 1743 cm^{-1} indicative of C=O bands, and 2850, 2920, and 2955 cm^{-1} characteristic of the aliphatic CH_3 and CH_2 stretching regions (between 2800 and 3000 cm^{-1}) (11). The positive FAB mass spectra of the native lipid (Fig. 3) showed the quasimolecular ion at *m/z* 664, confirming the PE structure and the presence of hydroxylated fatty acid substituents. The presence of ion at *m/z* 299 suggests that the lipid is acylated with hydroxylated stearic acid (12,13). Further confirmation of the lipid was also verified by ^{1}H and ^{31}P NMR to establish the configuration and the nature of the lipid (data not shown) (14).

DISCUSSION

The occurrence of 10-OH 18:0 in *Cryptosporidium* (White, D.C., Alugupalli, S., Schrum, D.P., Kelly, S.T., Sikka, M.K., Fayer, R., and Kaneshiro, E.S., unpublished data) led us to investigate the complex native form of this fatty acid in *C. parvum*. Comparision of the mild and strong methanolysis products has shown that 10-OH 18:0 occur in their native form mainly as an ester-linked lipid. Three lipids containing ester-linked 10-OH 18:0 were noted in the present study; however, the emphasis was placed mainly on the major lipid for structural characterization and molecular weight determinations. To the best of our knowledge, the present study is the first report of the presence of a 10-OH 18:0-containing lipid in *C. parvum*. The analysis reported herein shows that the extremely unusual fatty acid, 10-OH 18:0 which was previously reported in *Mycobacterium tuberculosis* lipids (15), is present in the PE of oocysts of *C. parvum* maintained under conditions where they retain infectivity for BALB/c neonatal mice.

ACKNOWLEDGMENTS

We thank S.J. Upton of Kansas State University for gifts of *C. parvum* oocysts, the National Water Research Institute with grants WQI 699 524 94 "Quantitative detection of injured or nonculturable microorganisms by signature biomarker analysis," HRA 699-517-B-94 "Risk reduction in drinking water distributor systems by on-line monitoring of pathogen ecology for quantitative evaluation of mitigation procedures" for supporting initial phases of this work, and Microbial Insights, Inc. for continuing support. The authors thank Albert A. Tuinman and Anna G. Edwards, University of Tennessee (Knoxville, TN), for helping with spectrometry and spectroscopic interpretations and Monica Sikka for excellent technical assistance.

ARTICLE

Recombinant Antibody Fragments That Detect Enoyl Acyl Carrier Protein Reductase in *Brassica napus*

Angelika Ziegler[a,*], Sybil M. Macintosh[a], Lesley Torrance[a], William Simon[b], and Antony R. Slabas[b]

[a]Scottish Crop Research Institute, Invergowrie, Dundee, DD2 5DA, United Kingdom, and [b]Department of Biological Sciences, University of Durham, Durham, DH1 3LE, United Kingdom

ABSTRACT: Purified *Brassica napus* enoyl acyl carrier protein reductase (ENR) was used to select specific antibodies from a library of antibody fragments, single-chain F_v (scF_v), displayed on filamentous phage. Analysis of the selected clones by *Bst*NI fingerprinting and nucleotide sequencing showed that the scF_v were derived from three different human V_H germline genes. The binding specificities were confirmed by Western blots and ELISA. The scF_v preparations reacted with *B. napus* ENR, but not with β-keto reductase, nor enoyl reductase from *Escherichia coli*. Analysis of fragments generated by CNBr treatment indicates that the scF_v 3.13 recognizes an epitope located within the N-terminal 80 amino acids of the enzyme molecule. The scF_v were used to detect ENR directly in extracts of *B. napus* seeds.
Lipids 32, 805–809 (1997).

Lipids have many cellular roles: they provide structural components of membranes, anchor proteins to membranes, are involved in cell signaling and frost tolerance, and provide the correct biochemical environment for essential acylation and desaturation reactions (see Ref. 1 for review). From a commercial viewpoint, the ability of seeds to accumulate lipids as major storage compounds has been the main driving force in this area of research, together with the problems for the industry caused by large variation in fatty acids which occurs naturally in storage triglycerides. A detailed understanding of lipid biochemistry is an important prerequisite in any attempt to manipulate lipid composition. Although the basic pathways of lipid biosynthesis are now understood, the metabolic processes involved are very complex. Enoyl acyl carrier protein reductase (ENR) is part of the type II, dissociable, fatty acid synthetase system and catalyzes the NAD(P)H-dependent reduction of *trans*-Δ2-enoyl acyl carrier protein, an essential step in the *de novo* fatty acid biosynthesis. The activity of ENR increases continually throughout the lipid deposition phase in maturing seeds of oilseed rape *Brassica napus*. The native *B. napus* NADH-specific ENR has been purified and was shown to be a tetramer, consisting of subunits with a molecular mass of about 34 kDa. *Brassica napus* is an allo-tetraploid species containing two pairs of related ENR genes from its parents, *B. oleracea* and *B. campestris* (2). Sequence polymorphism between the parental ENR gene copies is minimal (2). Four isoenzymes of the enzyme have been identified by two-dimensional electrophoresis (3); they are present at different levels in the tissue. Isoforms II and IV are the most abundant in both leaf protein extract and seed material. *Brassica napus* ENR has been cloned and overexpressed in *Escherichia coli* (2). The crystal structure of an ENR-NAD complex has been solved at 1.9 Å resolution (4).

Studies on localization and quantification of ENR in plant tissues and purification of isoenzymes would be facilitated by the ready availability of specific antibody preparations. Polyclonal antisera have been raised against ENR, but the supply of affinity purified material is limited (5).

Large combinatorial phage display libraries have been produced, and a range of recombinant immune reagents with diverse specificities were isolated from such libraries (see Ref. 6 for review). The reagents are produced quickly without the need to immunize experimental animals, and the single-chain F_v genes can be genetically fused to reporter molecules or peptide tags for detection and affinity purification (7,8). Once an antibody fragment is selected from the library, the nucleotide sequences of the light- and heavy-chain variable regions are available for use in studies on plant biochemistry and metabolic processes by expressing the scF_v in plants. This paper describes the production and properties of scF_v specific for ENR by recombinant DNA techniques, and their use in detection of ENR in *B. napus* seeds.

EXPERIMENTAL PROCEDURES

Selection of ENR-specific scF_v from the phage antibody library. The Medical Research Council, United Kingdom (MRC) human synthetic scF_v library (9) was used for the selection of scF_v. In this library rearranged V_H genes were combined with a single Vλ3 chain in the phagemid pHEN. An amber mutation between the sequences encoding the scF_v and pIII means that strains of *E. coli,* that do not suppress the amber stop codon, secrete soluble scF_v (7). The scF_v have a

Abbreviations: AP, Alkaline phosphatase; ECR, *Escherichia coli* enoyl reductase; ENR, enoyl acyl carrier protein reductase from *Brassica napus;* β-KR, β-keto reductase; PBS, phosphate-buffered saline; scF_v, single-chain F_v.

14-residue peptide (myc-tag) attached to the C-terminus which provides a means of detection and purification of soluble scF_v, using myc-tag specific monoclonal antibody 9E10 (10).

The library stock was amplified, and particles were rescued by superinfection with helper phage M13VCS (Stratagene), which supplies the viral genes to permit packaging of the phagemid DNA and the display of the scF_v-pIII fusion proteins on the surface of the phage particles.

For each round of selection, immunotubes (Nunc) were coated by incubation with a preparation of *B. napus* ENR at 60 μg/mL in 50 mM sodium carbonate buffer, pH 9.6, overnight at room temperature (approximately 22°C). The tubes were then rinsed with phosphate-buffered saline (PBS) and blocked with 2% nonfat dried milk (Marvel; Premier Beverages, Stafford, United Kingdom) in PBS. Phage preparations containing approximately 10^{12} colony-forming units were added to the tubes and incubated for 2 h at room temperature. After extensive washing, by rinsing the tubes 20 times with PBS containing 0.1% Tween 20 (BDH Laboratory Supplies, Merck Ltd., United Kingdom) and 20 times with PBS, bound phage was eluted with 100 mM trimethylamine, neutralized, and then used to infect *E. coli* TG-1 cells (suppressor strain). Phage particles were rescued by superinfection with helper phage M13VCS.

After the third round of selection, phage were rescued from single colonies of *E. coli* TG-1 by superinfection with helper phage. The resulting phage particles were collected by polyethylene glycol precipitation from the culture medium and tested by ELISA on antigen-coated plates.

Phage ELISA. Microtiter plates were coated with 10 μg/mL ENR, bovine serum albumin, cellulase, or macerozyme and incubated with phage preparations and then with polyclonal anti-M13 alkaline phosphatase (AP) conjugate (11). Bound AP was assayed by its reaction with *p*-nitrophenyl phosphate (Sigma, St. Louis, MO).

Soluble scF_v. Soluble scF_v were produced by inducing cultures of infected *E. coli* HB2151 (nonsuppressor strain) overnight at 25°C with 1 mM isopropyl-β-D-thiogalactopyranoside (Promega, Madison, WI) (7). Periplasmic extracts containing the scF_v were made from cell pellets by osmotic shock. Bacterial culture supernatant, containing secreted scF_v, was used directly in ELISA and Western blotting. Expression of the scF_v was verified using dot blots.

Sequencing of clones. Different clones, identified by their banding pattern in *Bst*NI fingerprinting (13), were sequenced by the dideoxy method using a USB sequencing kit and sequenase. The sequences were analyzed using GCG (14) and V BASE (15).

Western blot. Soluble scF_v were used in Western blots to detect ENR. One μg of the purified ENR was loaded per lane on SDS-polyacrylamide gels. *Brassica napus* extracts were made by grinding 30 seeds (approximately 35 d after flowering) in 2 mL of buffer (50 mM Tris-HCl, pH 6.8, 1 mM DTT, 0.1% Triton X-100) and centrifuging for 5 min. Twenty μL of the supernatant was loaded per lane. The seeds came from *B. napus* Jet Neuf and Dawson Park.

Related enzyme β-keto reductase (β-KR) (0.5 μg) from oilseed rape, the second reductase involved in fatty acid synthesis, and *E. coli* enoyl reductase (ECR) (0.34 μg) were used as control antigens. The samples were electrophoresed in a 12.5% polyacrylamide gel (16) and electroblotted onto nitrocellulose filters (17). The filters were blocked in 5% nonfat dried milk and the scF_v added. Incubation was for 4 h with gentle shaking at room temperature. After washing, the bound scF_v was detected with a mixture of the mouse monoclonal antibody 9E10 and an antimouse AP conjugate (Sigma). Enzyme substrate was 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium (Sigma). Rabbit polyclonal antiserum raised against ENR (5) was used at a dilution of 1:4000, followed by antirabbit AP conjugate (Sigma).

Protein dot blots. ScF_v preparations from bacterial supernatant or periplasmic extracts were spotted directly onto nitrocellulose filters (Schleicher and Schuell, Dassel, Germany) and air dried. The filters were blocked in 5% nonfat dried milk, and a mixture of mouse monoclonal antibody 9E10 and antimouse AP conjugate was added. Incubation was for 2 h with gentle shaking at room temperature. The enzyme substrate was 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium.

scF_v ELISA. Soluble scF_v preparations were tested in ELISA, either as periplasmic extracts or as bacterial culture supernatants. Microtiter plates were coated with ENR or control antigens (10 μg/mL in carbonate coating buffer) by incubation overnight at 4°C and then rinsed and blocked with 2% nonfat drid milk (Marvel) in PBS. The scF_v were mixed with the antibody 9E10 and added to the wells. After 3 h at room temperature, the plates were rinsed and incubated with antimouse AP conjugate (Sigma) followed by substrate.

Relative binding affinity. The method by Dyson *et al.* (18) was used. Dilutions of ENR were incubated with the phage-antibody preparation in solution until equilibrium was reached (18 h at 4°C). The amount of unbound phage remaining in solution was determined by adsorption on an ELISA plate coated with the substrate ENR. The adsorbed phage were then eluted from the solid phase and titered. The titer represents a value proportional to the free phage in the solution when the reactants are at equilibrium.

Epitope mapping. Purified ENR was digested with CNBr (19), the digest was separated by C_{18} reverse-phase high-performance liquid chromatography (20), and the fractions were spotted (2 nmole/spot) onto a polyvinylidene difluoride-based membrane (21). After wetting with methanol, the membrane was probed with scF_v as described for the Western blots.

RESULTS

Selection of scF_v. The numbers of input and output phage for each round of selection are shown in Table 1. The enrichment for specific binders is indicated by the increasing number of output phages after each consecutive round of selection.

After three rounds of selection and enrichment, 10 out of 14 individual clones tested exhibited binding specificities for

TABLE 1
Titers of Phage (cfu/mL) Obtained During Successive Rounds of Selection on Enoyl Acyl Carrier Protein Reductase

Selection round	Phage input	Phage output
1	5×10^{12}	1.56×10^{4}
2	4×10^{12}	1.2×10^{5}
3	5×10^{12}	1.9×10^{6}

ENR in phage ELISA (code names were 3.1, 3.2, 3.4, 3.7, 3.9, 3.10, 3.11, 3.12, 3.13, and 3.14). The DNA from these clones were subjected to *Bst*NI fingerprinting. This revealed two unique banding patterns (data not shown), suggesting that the V_H chain of the scF_v originated from different germline genes. This was confirmed by sequencing, which showed three groups of sequences, originating from different germline genes. The alignment of amino acid sequences from the scF_v in the three groups is shown in Figure 1. The heavy-chain families were compared with sequences in the V BASE sequence directory (15). ScF_v 3.13 belonged to human V_H 1 locus 1-02; the others belong to either V_H 3 locus DP 45 (3.2, 3.7, and 3.9) or locus DP 49 (3.1, 3.4, 3.10, 3.11, and 3.12).

ELISA. ELISA experiments using phage antibody were performed to identify binders obtained from the library by selection on antigen-coated tubes (Table 2). The absorbance values ($A_{405\ nm}$) range from 0.376 to 1.599. However, it is unlikely that the absorbance values obtained in the phage ELISA reflect the true binding affinity, since the number of phages harvested from small-scale *E. coli* cultures and the number of antibody fragments displayed on the surface of each phage particle vary. Soluble scF_v were produced by expression in the nonsuppressor strain HB2151 from the clones which gave high absorbance values in phage ELISA. Culture supernatants were tested for expression of scF_v using protein dot blots.

Four clones, 3.2, 3.7, 3.9 and 3.12, which reacted with ENR as phage antibodies, failed to react in ELISA when expressed as soluble scF_v. The positive results with these clones in phage ELISA may be due to the amplified detection of the phage by the anti-M13-AP conjugate, since the phage carries

[b]Helper phage only.

about 2700 copies of its major coat protein pVIII against which the polyclonal antiserum would be mainly directed (9). The binding of the soluble scF_v to ENR was shown to be highly specific. No cross-reaction was detected when ECR or β-KR was used at 10 μg/mL to coat ELISA plates (Table 3).

Moreover, we found that the soluble scF_v preparations of the recombinant antibodies 3.10 and 3.13 remained active for at least 6 mon, and the bacterial culture supernatants were functional in ELISA at dilutions of up to 1:100 (data not shown).

Western blotting. Soluble scF_v 3.1, 3.4, 3.10, and 3.13 reacted in immunoblots with SDS-treated purified preparations of ENR. The binding properties of scF_v 3.10 and 3.13 were further investigated; between 0.3 and 1 μg of each ENR, β-KR or ECR, and also crude extracts of *B. napus* seeds in Laemmli sample buffer (20 μL per lane) were tested. Neither scF_v 3.10 nor scF_v 3.13 reacted with β-KR or ECR in the immunoblots (Fig. 2A and data not shown for scF_v 3.10), but detected purified plant ENR and ENR in *B. napus* seed extracts. The additional bands detected in the purified ENR sample are most likely degradation products. When polyclonal antiserum raised against ENR was used to probe an immunoblot, the additional bands in the purified ENR sample were also present (Fig. 2B). The presence of β-KR and ECR was verified by Coomassie-staining of the gel (for ECR) or probing with polyclonal antiserum raised to β-KR. Bands detected had the appropriate molecular mass of about 28 kDa (Fig. 3).

Affinity. The binding affinity of scF_v 3.13 anti-ENR antibody was measured using the method of Dyson *et al.* (18). This method allows the determination of relative dissocia-

TABLE 3
Absorbance Values ($A_{405\ nm}$) Obtained in PTA-ELISA of Soluble scF_v Fragments Against ENR, ECR, and β-KR[a]

tion constants (K_d^{Rel}) between filamentous phage carrying fusions to the coat protein pIII and substrate (ENR) in solution. We determined K_d^{Rel} for scF_v 3.13 as 1.6×10^{-8} M. This value represents a moderate affinity, and is commonly found for scF_v from primary phage repertoires (22).

Epitope mapping. Purified ENR was digested with CNBr, the digest was separated by C_{18} reverse-phase high-performance liquid chromatography, and the fractions were spotted onto polyvinylidene difluoride-based membrane and probed with scF_v 3.13. Only one of the fractions in the dot blot reacted with scF_v 3.13 (data not shown). The amino acid sequence of this fraction was determined, and the epitope was deduced to be within the 80 amino acids of the N-terminus of the ENR molecule.

DISCUSSION

The results show that a set of scF_v specific for ENR were obtained from a phage display library of antibody variable regions after only three rounds of selection. The length of the CDR 3 of the heavy chain of the different anti-ENR scF_v ranged from 5 to 11 amino acids, thus covering the range possible with the MRC human synthetic scF_v library, where the heavy chain CDR 3 was designed to consist of 4 to 12 amino acids (9).

The binding properties of two of the scF_v, 3.10 and 3.13, were studied in more detail. The scF_v were highly specific. They reacted with ENR in ELISA and immunoblotting tests, but not with β-KR which belongs to the same biosynthetic pathway and which shares 25% sequence identity with ENR (23), or ECR.

The scF_v 3.13 epitope was located within the N-terminal 80 amino acids of the ENR molecule. The antigenic index calculated according to Jameson and Wolf (14) indicates that the N-terminus of ENR is antigenic (index >1.0 for nine amino acids at the N-terminus), whereas a similar plot for the N-terminus of β-KR gave values of only –0.45 to 0.45 for the first six amino acids. These data together with the experimental finding suggest that the epitope recognized by scF_v 3.13 is at the mobile N-terminus of the ENR molecule.

Within the N-terminal 80 amino acids of ENR, only two amino acid differences have been detected by Kater *et al.* (2) between the amino acid sequence deduced from nucleotide sequencing data and sequence data determined by direct peptide sequencing of purified ENR protein, reflecting minor sequence polymorphism between the parental ENR genes. The results from Southern blots also suggest a very high degree of sequence homology between the two ENR genes found in members of the Cruciferae family (2). It is therefore highly likely that scF_v 3.13 will react with all isoforms of the enzyme, and it may be useful in affinity purification of the

isoenzymes.

In this paper we have demonstrated the selection from a phage display library of scF_v binding to the plant enzyme ENR. The scF_v will be used in studies to facilitate the understanding of plant lipid biosynthesis and its regulation. The expression of the anti-ENR scF_v genes in transgenic plants may provide a useful alternative to antisense approaches to study and influence biosynthetic pathways during lipid biosynthesis. ScF_v present an attractive tool for intracellular immunomodulation of plants. Plants transformed with antibody genes have been shown to express functional proteins in the cytosol (24,25), and the antibodies can be successfully targeted to specific plant organs, e.g., roots (26) or seeds (12).

Use of Cyclodextrin to Deliver Lipids and to Modulate Apolipoprotein B-100 Production in HepG2 Cells

Michael R. Peluso and Joseph L. Dixon*

Department of Food Science and Human Nutrition, University of Missouri, Columbia, Missouri 65211

ABSTRACT: 2-Hydroxypropyl-β-cyclodextrin (cyclodextrin), cyclodextrin-solubilized oleate, and cyclodextrin-solubilized cholesterol were used to modulate proteolysis and secretion of newly-synthesized apolipoprotein B-100 (apoB) in HepG2 cells. Following cyclodextrin and lipid treatments, cells were pulse-labeled with [^{3}H] leucine, and quantitative immunoprecipitation was used to measure apoB synthesis, apoB secreted into the medium, and the cellular content of undegraded apoB that was not secreted. Three-hour treatment with cyclodextrin-solubilized oleate (0.2 mM) increased secreted apoB from 4% (control cells) to 32% and cellular undegraded apoB from 15% (control cells) to 64% of apoB synthesized, which is consistent with earlier studies using bovine serum albumin to complex exogenous oleate. Prolonged daily (4 d or more) administration of 0.5% (3.5 mM) cyclodextrin with medium containing 10% fetal bovine serum increased the secretion of nascent apoB from 5–10% (control) to 17–28% and cellular undegraded apoB from 15–20% (control) to 25–31% of apoB synthesized, respectively. Subsequent administration of cyclodextrin-solubilized cholesterol (10–40 μg) for only 3 h reversed the cyclodextrin-mediated increase in apoB secretion. The application of 0.5% cyclodextrin to HepG2 cells can rapidly (within minutes) stimulate cholesterol efflux, and transiently (over a 1–2 d period) increase cholesterol synthesis. In the current studies, the cyclodextrin-mediated increase in cholesterol synthesis was not concurrent with the increase in apoB secretion. However, prolonged (15 d) administration of cyclodextrin was shown to increase the cellular free cholesterol concentration by 25–41%, reduce the cellular triglyceride concentration by 59%, and increase apoB secretion 3- to 4-fold, without affecting the cellular cholesteryl ester concentration. In comparison, 14-d treatment with cyclodextrin-solubilized cholesterol (20 μg/mL) followed by 1-d equilibration without cholesterol was shown to increase the cellular free cholesterol and cholesteryl ester concentrations by 76% and 10-fold, respectively, although apoB secretion was not affected. It is hypothesized that chronic daily administration of 0.5% cyclodextrin increased the cellular cholesterol concentration and flux in discrete putative regulatory compartments, which "shielded" nascent apoB from rapid proteolysis and facilitated apoB secretion. In conclusion, cyclodextrin was used independently and in combination with cholesterol or oleate to modulate apoB proteolysis and secretion. We speculate that subcellular changes in cholesterol concentration and flux may modulate apoB production in HepG2 cells.

Lipids 32, 811–823 (1997).

The primary function of very low density lipoprotein (VLDL) is transport of newly-synthesized triglyceride from liver to peripheral tissues. In the capillary beds, plasma VLDL are converted to cholesteryl ester-enriched triglyceride-poor low density lipoprotein (LDL) (1,2). Elevated plasma LDL and apolipoprotein B-100 (apoB) concentrations are primary risk factors for the development of atherosclerosis and coronary heart disease (3–5). Many of the chronic hyperlipoproteinemias associated with atherosclerosis result from hepatic overproduction of apoB-lipoproteins, predominantly VLDL (6–12). However, the mechanisms regulating hepatic apoB-lipoprotein secretion, and specific roles played by cholesterol (CH) metabolism, are not completely understood.

ApoB-100 is synthesized in hepatocytes as a 550 kD glycosylated protein (13–15) that cotranslationally associates with the membrane of the endoplasmic reticulum (ER) (16–19). Complete translocation of nascent apoB across the ER membrane into the ER lumen and apoB transport in the secretory pathway require the complexation of lipid substrates with apoB at the lumenal side of the ER (17,20). An increase in triglyceride synthesis has generally been considered to be a potent stimulus of apoB-lipoprotein assembly and secretion (21–23). However, roles played by the ER CH content, CH biosynthesis, the cellular cholesteryl ester concentration, and CH flux across the liver have not been clearly demonstrated. Some studies have suggested that the hepatocellular cholesteryl ester concentration is an important regulator of apoB-lipoprotein secretion (24–28); whereas, others have indicated no effect of cholesteryl ester on apoB production (29,30). The rate of association of lipid substrates with nascent apoB and the rate of translocation of apoB-lipoprotein particles across the ER membrane into the ER lumen determine whether nascent apoB will be transported in the secretory pathway or proteolytically degraded shortly after translation (31–36). Secretion of apoB-lipoprotein is depen-

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; apoB, apolipoprotein B-100; BSA, bovine serum albumin; cyclodextrin or CD, 2-hydroxypropyl-β-cyclodextrin; CH, cholesterol; ER, endoplasmic reticulum; FBS, fetal bovine serum; HDL, high density lipoprotein; HMG-CoA, β-hydroxy-β-methylglutaryl CoA; LDL, low density lipoprotein; MTP, microsomal triglyceride transfer protein; OA, oleate; PBS, phosphate-buffered saline; VLDL, very low density lipoprotein.

dent upon the expression of microsomal triglyceride transfer protein (MTP) (37–39), which has been suggested to transport both triglyceride and cholesteryl ester from the cytosolic surface of the ER into the ER lumen (40). Recently, MTP has been shown to associate with nascent apoB during early stages of apoB-lipoprotein assembly in cultured HepG2 cells (41).

The human hepatoblastoma cell line HepG2 is commonly utilized as a model system for studying hepatic lipoprotein production (42,43). These cells retain a variety of liver-specific functions, including synthesis of apoB and secretion of apoB-lipoproteins (44–48). Investigation of the association between CH metabolism and apoB-lipoprotein secretion requires independent modulation of cellular CH metabolism. Exogenous CH is commonly administered to cultured hepatocytes through the addition of liposomes, lipoproteins, or a CH-ethanolic solution to the culture medium. However, liposomes and lipoproteins can alter the cellular content of lipids other than CH, and lipoproteins enter the cell mainly through highly-regulated receptor-mediated processes that limit the efficiency of cellular CH uptake. Since ethanol has been shown to independently affect apoB metabolism (49,50), it is an undesirable choice to solubilize CH for apoB studies.

In the current study, 2-hydroxypropyl-β-cyclodextrin [cyclodextrin (CD)] was used as a research tool to study apoB production in HepG2 cells. Cyclodextrin is a water-soluble oligosaccharide consisting of a cyclic hydroxypropyl-substituted backbone of seven α-1,4-D-glucopyranose units (51). The hydrophobic interior cavity forms an inclusion complex with CH (52) that greatly increases CH solubility (53). The current study measured the effect of prolonged chronic treatment with 0.5% (3.5 mM) CD on rapid apoB proteolysis in classical pulse-chase experiments that used [^{3}H] leucine to label newly synthesized apoB. CD was also used to deliver CH and to increase the cellular CH concentration. Finally, we demonstrated the use of CD-solubilized oleate (OA), instead of bovine serum albumin (BSA)-solubilized OA, to reduce apoB proteolysis and to increase apoB secretion. The results may provide a foundation for additional cell culture studies that examine the effects of changes in hepatic subcellular lipid concentrations and flux on apoB-lipoprotein production.

MATERIALS AND METHODS

Materials. L [4,5-^{3}H] Leucine (5 mCi/mL, 131 Ci/mmol) and [2-^{14}C] Na-acetate (200 μCi/mL, 56 mCi/mmol) were purchased from Amersham Corporation (Arlington Heights, IL). 2-Hydroxypropyl-β-cyclodextrin (avg. molar substitution = 0.6, avg. MW = 1380) was purchased from Aldrich Chemical Co. (Milwaukee, WI). CH, Na OA, tissue culture-grade collagen, fetal bovine serum (FBS), and protein assay kit #P5656 were obtained from Sigma Chemical Co. (St. Louis, MO). Eagle's minimal essential medium, nonessential amino acids, Na pyruvate, penicillin, and streptomycin were purchased from Gibco BRL Life Technologies (Grand Island, NY). Leucine-free medium was generated from a minimum essential medium select-amine kit (Gibco catalog #300-9050AV). Leupeptin and pepstatin were obtained from Peninsula Laboratories, Inc. (Belmont, CA). Protein A-sepharose CL-4B beads were from Pharmacia LKB Biotechnology, Inc. (Alameda, CA). Polyclonal anti-human apoB antibody was raised in a rabbit. Sheep antihuman albumin was purchased from Harlan Bioproducts for Science, Inc. (Indianapolis, IN). Other chemicals and reagents were of the highest purity available.

Culturing of HepG2 cells. HepG2 cells were seeded into Falcon tissue culture plates (9.6 cm^2/well) or dishes (60 mm diameter) pre-coated with collagen. Cells were grown in humidified air containing 5% CO_2 at 37°C. Cells were incubated in either complete growth medium (Eagle's minimum essential medium with: 10 mM HEPES, 0.1 mM nonessential amino acids, 1 mM Na pyruvate, 10% FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin), serum-free medium (SFM) (complete medium without 10% FBS), or serum-free leucine-free medium (SFLFM) (used for the pulse-labeling periods only). Unless noted, fresh medium was administered every 48 h. Cells were subjected to various treatment protocols as described in the figure legends and tables.

Preparation and application of CD, CD-solubilized OA, and CD-solubilized CH solutions. CD was dissolved with stirring in phosphate-buffered saline (PBS), generally at a concentration of 2 g/10 mL (20%, wt/vol). The appropriate amount of CH or Na OA was dissolved with stirring into the CD solutions under a gentle stream of N_2. Dissolution of OA was rapid at room temperature; however, solubilization of CH required warming to 40–50°C for 10–15 min. Solutions were passed through a 0.2-μm filter (Sterile Acrodisc; Gelman Sciences, Ann Arbor, MI) and stored at 6–8°C prior to use. To incubation medium that had been pre-applied to the cells, aliquots of CD and CD-solubilized lipid solutions were added to give the concentrations of CD, CH, and OA indicated in the figure legends and tables. Generally, there was a 40-fold dilution of the CD and CD-solubilized lipid solutions at the time of administration to the cells. The dilution step was immediately followed by incubation on a rocking platform at 37°C for a minimum of 60 min.

Pulse-labeling of HepG2 cells, collection of cells and medium, and immunoprecipitation of apoB and albumin. Following treatments described in the figure legends and tables, cells were washed twice with warm PBS and administered serum-free, leucine-free labeling medium containing 100 μCi [^{3}H] leucine per mL for 10 min. Labeling medium was removed, cells were washed twice with warm PBS, and chased with serum-free medium for either 10 min to measure [^{3}H] apoB and [^{3}H] albumin synthesis or for as much as 190 min to measure the cellular content of undegraded [^{3}H] apoB, as well as the secretion of [^{3}H] apoB and [^{3}H] albumin. Medium was collected into microtubes on crushed ice containing 59 μL (per mL of medium) of a protease inhibitor cocktail comprising 1 μL of 1 M benzamidine-HCl, 10 μL of 0.5 M Na_2-EDTA (pH 8.4), 10 μL of 1 M HEPES (pH 9), 3 μL of 287 mM phenylmethylsulfonyl fluoride (in ethanol), and 35 μL of aprotinin (100 kallikrien-inactivating units/mL). Cells were washed twice with cold PBS and collected with a plastic cell

scraper into microtubes with ice-cold pH 8 lysis buffer (generally 1 mL) comprised of: 50 mM Tris, 150 mM NaCl, 5 mM Na_2EDTA, 62.5 mM sucrose, 12.1 mM Na-deoxycholate, 0.5% Triton X-100, leupeptin (50 μg/mL), pepstatin A (50 μg/mL), and the protease inhibitor cocktail described above (59 μL/mL). Lysed cells were incubated on a rocking platform at 6–8°C overnight, and cell lysates were fractionated into a soluble cell extract and an insoluble cell pellet by centrifugation at 12,000 × *g* and 6–8°C for 20 min. An aliquot of each cell extract (generally 75 μL) was taken for quantification of soluble cell protein. Aliquots of cell extract and medium samples were taken for immunoprecipitation of apoB and albumin as previously described (54). In brief, aliquots of cell extracts and medium were combined with excess rabbit antihuman apoB antiserum, or with excess sheep antihuman albumin antiserum. ApoB and albumin were immunoprecipitated and eluted from protein A-sepharose CL-4B beads into electrophoresis sample buffer. An aliquot of each eluted immunoprecipitate was dispersed in 5 mL of Packard Ultima Gold liquid scintillation cocktail (Packard Instrument Co., Meriden, CT) and total [^{3}H] was counted on a Packard Tri-Carb 1500 liquid scintillation analyzer (Packard Instruments, Downers Grove, IL). Protein in a 15-μL aliquot of each eluted immunoprecipitate was separated by SDS-PAGE (3–15% gradient). Developed gels were incubated for 20 min at room temperature in Autofluor (National Diagnostics, Inc., Manville, NJ), dried, and exposed to Kodak X-OMAT XAR-2 film (Sigma catalog # F-5763). The [^{3}H] apoB and [^{3}H] albumin bands were quantified on an Ultroscan XL enhanced laser densitometer (Pharmacia LKB Biotechnology, Bromma, Sweden). Total [^{3}H] apoB and [^{3}H] albumin per sample were calculated from the percentage of total immunoprecipitable [^{3}H] that was present in the [^{3}H] apoB or [^{3}H] albumin band of each autoradiograph.

Incorporation of [^{14}C] acetate into CH. For the experiment depicted in Tables 3 and 4, cells were chased with 2.5 mL of serum-free medium containing 5 μCi [^{14}C] acetate. At the termination of the chase period, medium and cells were collected as described above. Aliquots (1 mL) of medium and cell extracts were frozen at −80°C and lyophilized to reduce the aqueous volume. Medium, cell extract, and cell pellet samples were suspended in 200 μL of H_2O, and lipids were extracted by the method of Folch (55) as modified by Bligh and Dyer (56). Washed extracts were evaporated to dryness under N_2 and redissolved in 200 μL $CHCl_3$/MeOH (2:1, vol/vol). Aliquots (50 μL) of each lipid extract were spotted onto 20 cm × 20 cm silica gel 60 thin-layer chromatography plastic-backed plates (E. Merck, Darmstadt, Germany). A CH/cholesteryl OA standard was spotted in each sample lane, as well as in two independent lanes per plate. Chromatograms were developed with hexane/diethyl ether/glacial acetic acid (80:20:1, by vol). CH and cholesteryl ester were visualized with I_2 vapor, and the silica gel containing the bands was scraped with a razor blade into scintillation vials. Samples were dispersed in 5 mL of scintillation cocktail, and the incorporation of [^{14}C] acetate into CH and total cholesteryl ester was quantified by liquid scintillation counting.

Analysis of CH, total cholesteryl ester, and total triglyceride mass. In the experiment depicted in Figure 4, cells for lipid analysis were treated in parallel to those treated for pulse-labeling and immunoprecipitation of apoB. The cells were collected in a lysis buffer as previously described, and a 75-μL aliquot of each cell lysate was taken for protein quantification. Neutral lipids in the remainder of each cell lysate were extracted by the method of Folch (55) as modified by Bligh and Dyer (56). Extracts were dried under N_2 and re-extracted with three 500-μL volumes of hexane. Hexane extracts were dried under N_2 and redissolved in 500 μL of isooctane/ tetrahydrofuran (99:1). Samples (20 μL) were loaded onto a 5-μm silica column (4.6 mm diameter × 10 cm; Phase Separations, Norwalk, CT; cat. #S5W) attached to a Varian 9012 high-pressure liquid chromatograph (Varian Associates, Inc., Walnut Creek, CA). CH, total cholesteryl ester (as cholesteryl OA), and total triglyceride (as triolein) bands were resolved and eluted with a three-solvent gradient (isooctane:tetrahydrofuran/acetone:methylene-Cl/isopropanol:H_2O), and measured with an evaporative light-scattering detector (Sedere #Sedex 55; Richard Scientific, Novato, CA). Lipid mass was quantified from external standard curves.

Cell protein and [^{3}H] protein analysis. Aliquots of cell extracts (75 μL) or medium (150 μL) were combined with 15 μL of Na cholate solution (10 mg/mL) and 15 μL of 100% trichloroacetic acid per 75 μL aliquot. Samples were mixed, and protein was precipitated at 6–8°C for 60 min. Samples were centrifuged at 10,000 × *g* for 5 min, and pellets were washed with 500 μL of 12% trichloroacetic acid. Samples were recentrifuged and washed pellets were dissolved in 30 μL of 0.7 N NaOH plus 20 μL of 10% Na dodecylsulfate. The sample volume was brought up to 500 μL with a warm (pH 7.2) 50-mM KH_2PO_4 solution. Aliquots were taken for cell protein quantification by the method of Lowry (57), using BSA as a standard. Immunoprecipitable [^{3}H] protein was measured by liquid scintillation analysis as previously described.

Statistical analysis. Data were analyzed on SAS, using a one-way analysis of variance. Statistical significance for each model was set at $P < 0.05$. Treatment means were separated with Fisher's LSD test ($P < 0.05$).

RESULTS

Administration of CD-solubilized OA. Earlier pulse-chase studies in HepG2 cells showed that short-term treatment with 0.8 mM OA (complexed to 1.5% BSA) stimulated apoB intracellular transport, decreased apoB proteolysis, and increased apoB secretion (54). Other studies have demonstrated a BSA-dependent reduction in apoB synthesis (58) and secretion (59) that may confound the effects of OA. In the experiment depicted in Table 1, monolayers of HepG2 cells were pretreated for 1 h, as well as during the 2-h pulse-chase period, with either serum-free medium (Control), serum-free

TABLE 1
CD-Solubilized Oleate (OA) Rapidly Suppresses the Intracellular Degradation of Nascent ApoB[a]

		[^{3}H] ApoB				[^{3}H] Albumin	
Treatment	Cell protein (mg/well)	Synthesis [dpm ($\times 10^{-5}$)/ mg cell protein]	Undegraded in cell (% of synthesis)	Secreted (% of synthesis)	Cellular degradation (% of synthesis)	Synthesis [dpm ($\times 10^{-5}$)/ mg cell protein)	Secreted (% of synthesis)
Control	0.57 ± 0.15	7.1 ± 1.2^b	15.5 ± 1.4^c	4.5 ± 1.0^c	80.0 ± 1.1^b	27.9 ± 5.8	74.3 ± 4.4^c
CD	0.70 ± 0.02	6.4 ± 0.7^{b,c}	15.3 ± 0.6^c	4.2 ± 0.1^c	80.5 ± 0.5^b	29.3 ± 0.5	82.5 ± 5.9^c

[a]HepG2 cells (70% confluent) were treated for 1 h in 1 mL of serum-free medium (SFM) containing one of the following additions: none (control), 1.5 mg (0.15% wt/vol) cyclodextrin (CD), or 61 μg Na oleate (0.2 mM) solubilized with 0.15% CD (OA + CD). All cells were pulsed for 10 min with 100 μCi [^{3}H] leucine in 1 mL of serum-free, leucine-free medium containing the additions described above. Cells from each treatment were chased in 1 mL of SFM (containing additions as above) for either 10 min to measure apoB and albumin synthesis or 100 min to measure the cellular content of undegraded apolipoprotein B-100 (apoB), as well as the secretion of nascent apoB and albumin. Cellular degradation of nascent apoB was calculated as the difference between apoB synthesis and the sum of cellular undegraded apoB and apoB secreted to the medium. Protocols are further described in the Materials and Methods section. Number of wells (*n*) each treatment: Control (*n* = 12), CD (*n* = 6), OA + CD (*n* = 12).
[b,c]Each value represents the mean ± SD. Values down a column with different letter superscripts are statistically different from each other at *P* (model) < 0.05.

medium containing 0.15% (wt/vol) CD (CD), or serum-free medium containing 0.2 mM OA solubilized with 0.15% CD (OA + CD). Albumin synthesis and secretion in this and other experiments were measured as a general control for protein synthesis and secretion. The data show that 0.15% CD alone had no effect on apoB or albumin synthesis and secretion. Administration of CD-solubilized OA modestly reduced apoB synthesis. However, the cellular content of undegraded apoB and apoB secretion was increased 4-fold and 7-fold, respectively. Albumin synthesis was not affected by CD-solubilized OA, although albumin secretion was modestly increased by 24%. The marked reduction in total apoB degradation exceeded that previously reported in HepG2 cells when 1.5% BSA was used to solubilize 0.8 mM OA (54). These results demonstrate the utility of CD as a vehicle for the delivery of OA to cells in tissue culture.

Independent effects of CD on apoB proteolysis and secretion. In the experiment depicted in Table 2, HepG2 cells were incubated for 4 d with 2 mL of complete growth medium (+10% FBS) containing either 0 (control), 0.5, 1, or 1.5% (wt/vol) CD. Medium was removed and fresh medium was applied every 24 h. CD treatment had no effect on either apoB or albumin synthesis. However, secretion of nascent apoB was nearly doubled as the CD concentration was increased from 0 to 0.5%. Although, there was no further significant increase in apoB secretion at higher CD concentrations, there was a CD dose-dependent increase in the cellular content of undegraded apoB.

Although hepatic CH synthesis has been suggested as a modulator of apoB-lipoprotein secretion *in vivo* (60), this has not been confirmed in most studies using cultured cells. In the experiment depicted in Table 3 and Table 4, the effects of both 1- and 4-d CD treatment on apoB production and the effect of CD treatment on the incorporation of [^{14}C] acetate into CH and cholesteryl ester were measured. Table 3 shows that secretion of nascent apoB was increased 2.4-fold in the CD (4-d) group, but only by 82% in the CD (1-d) group. The concentration of newly synthesized apoB remaining undegraded in cells was increased by an average of 20% in both CD-treated groups. Although the increase was not statistically significant in this particular experiment, a similar increase following treatment with 0.5% CD was consistently observed in

TABLE 2
Four-Day CD Treatment Increases the Cellular Content of Undegraded ApoB and Stimulates ApoB Secretion[a]

		[^{3}H] ApoB				[^{3}H] Albumin

[a]HepG2 cells were treated for 4 d in 2 mL of complete growth medium (+10% fetal bovine serum) containing either 0 mg (control), 10 mg (0.5% wt/vol CD), 20 mg (1.0% CD), or 30 mg (1.5% CD) CD. Fresh medium was administered every 24 h. After 4 d, cells (100% confluent) were further treated for 1 h in 1 mL of serum-free medium containing 0 (control), 0.5, 1.0, or 1.5% CD. All cells were pulsed for 10 min with 100 μCi [^{3}H] leucine in 1 mL of serum-free, leucine-free medium containing the additions described above. Triplicate wells of cells from each treatment were chased in 1 mL of serum-free medium (containing additions as above) for either 10 min to measure apoB and albumin synthesis or 100 min to measure the cellular content of undegraded apoB, as well as the secretion of nascent apoB and albumin. Cellular degradation of nascent apoB was calculated as described in Table 1. Protocols are further described in the Materials and Methods section. See Table 1 for abbreviations.
[b,c,d,e] Each value represents the mean ± SD (*n* = 3, *n* = 6 for cell protein). Values down a column with different letter superscripts are statistically different from each other at *P* (model) < 0.05.

[a]HepG2 cells in 60-mm diameter dishes were treated in 5 mL of complete growth medium (+10% fetal bovine serum) without (control) or with 0.5% (wt/vol) CD. In control and CD (4-d) incubations, 5 mL of fresh medium was administered to cells every 24 h over the 4-d period. In CD (1-d) incubations, 5 mL of fresh medium without CD was administered to cells every 24 h during the first 3 d. During the subsequent 24 h, cells were administered 5 mL of fresh medium containing 0.5% CD four times (at 0, 4, 8, and 12 h into the 24-h period). Thus, 5 mL of fresh medium containing 0.5% (3.5 mM) CD was applied four times to both CD-treated groups during either a 1-d or 4-d period. After 4 d, cells were further incubated for 1 h in 2.5 mL of serum-free medium either without (control) or with 0.5% CD (both CD groups). All cells were pulsed for 10 min with 250 μCi [^{3}H] leucine in 2.5 mL of serum-free, leucine-free medium without or with 0.5% CD. Triplicate dishes of cells from each treatment were chased in 2.5 mL of serum-free medium without or with 0.5% CD for either 10 min to measure apoB and albumin synthesis or 100 min to measure the cellular content of undegraded apoB, as well as the secretion of nascent apoB and albumin. Cellular degradation of nascent apoB was calculated as described in Table 1. In dishes of cells chased for 100 min, 5 μCi [^{14}C] acetate was administered with the chase medium to measure CH biosynthesis. These latter results are provided in Table 4. Protocols are further described in the Materials and Methods section. See Table 1 for abbreviations.

[b,c]Each value represents the mean ± SD (n = 3, n = 6 for cell protein). Values down a column with different letter superscripts are statistically different from each other at P (model) < 0.05.

other experiments. Table 4 shows that the incorporation of [^{14}C] acetate into CH was not elevated after 4 d of daily CD administration, and the incorporation of [^{14}C] acetate into CH was only slightly elevated after 1 d of multiple CD applications. This is consistent with a transient (over a 1–2 d period) CD-mediated increase in the incorporation of [^{14}C] acetate into CH that we have observed (Peluso, M.R., and Dixon, J.L., unpublished data). After both 1- and 4-d CD treatments, the incorporation of [^{14}C] acetate into cholesteryl ester was reduced (Table 4). Therefore, the CD-mediated increase in apoB secretion did not occur in parallel with an increase in CH synthesis from acetate or an increase in the esterification of newly synthesized CH. Cyclodextrin did increase movement of nascent CH to the medium (Table 4). The increase in [^{14}C] CH appearing in the medium could have resulted from efflux to CD and from increased incorporation into secreted apoB-lipoprotein.

Comparison of the effects of CD and CD-solubilized OA on apoB production. In Figure 1, HepG2 cells were either untreated in complete growth medium (C), treated with 0.5% (3.5 mM) CD for 4 d in complete growth medium (CD), or treated with 0.15 mM OA solubilized with 0.5% CD in serum-free medium for 3 h (OA). The gel data show that the reduction in apoB degradation by OA was due to a combination of a 3.6-fold increase in cellular undegraded apoB and a 2.8-fold increase in apoB secretion. In contrast, the reduction in apoB degradation by CD was primarily due to a 2.3-fold increase in apoB secretion. Undegraded apoB was increased by only 25% in CD-treated cells. These CD-mediated effects were similar to those shown in Table 2 and Table 3.

In Table 5, to test whether the effects of 4-d CD and short-term OA treatments on apoB secretion were additive, cells treated for 4 d in complete growth medium with 0.5% CD were further treated for 3 h with graded concentrations of CD-solubilized OA (0–0.2 mM). As previously demonstrated, CD reduced apoB proteolysis and increased apoB secretion. The administration of CD-solubilized OA further reduced apoB proteolysis, but apoB secretion was not further increased during 100 min of chase. The gel data provided in Figure 2 illustrate a 70% net increase in cellular undegraded apoB as the OA concentration was increased from 0 to 0.2 mM.

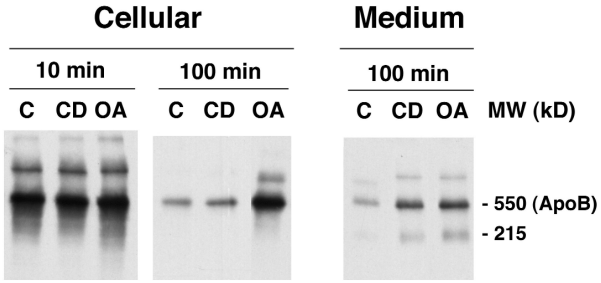

FIG. 1. Comparison of the effect of 3-h oleate (OA) and 4-d cyclodextrin (CD) treatments on apolipoprotein B-100 (apoB) production. HepG2 cells were cultured in 2 mL of complete growth medium (+10% fetal bovine serum). One group of cells was cultured for 4 d as a control (C). A second group was treated for 4 d with daily application of 0.5% (wt/vol) CD (CD). A third group was cultured for 4 d with complete medium and subsequently treated for 1 h prior to pulse-labeling with 1 mL of serum-free medium containing 0.15 mM oleate (OA) solubilized with 0.5% CD. The C and CD groups were similarly treated with 1 mL of serum-free medium without (C) or with 0.5% CD for 1 h prior to pulse-labeling. All cells were pulsed for 10 min with 100 μCi [^{3}H] leucine and triplicate wells from each group were chased for either 10 min or 100 min as previously described. ApoB was immunoprecipitated and quantified by scintillation counting, SDS-PAGE, and fluorography as described in the Materials and Methods section. The figure shows the gel data from one representative sample per treatment. In the C, CD, and OA groups, respectively: [^{3}H] apoB synthesis (cellular apoB at 10 min) averaged 6.2 ± 0.4 ($\times 10^5$), 6.3 ± 0.8 ($\times 10^5$), and 7.7 ± 0.4 ($\times 10^5$) dpm/mg cell protein; the cellular content of undegraded [^{3}H] apoB (cellular apoB at 100 min) averaged 1.1 ± 0.1 ($\times 10^5$), 1.4 ± 0.1 ($\times 10^5$), and 4.9 ± 0.6 ($\times 10^5$) dpm/mg cell protein; and [^{3}H] apoB secreted (medium apoB at 100 min) averaged 0.6 ± 0.2 ($\times 10^5$), 1.4 ± 0.2 ($\times 10^5$), and 2.1 ± 0.3 ($\times 10^5$) dpm/mg cell protein. Each value represents the mean ± SD (n = 3).

TABLE 4
Reduced Degradation of Nascent ApoB in CD-Treated Cells Is Not Accompanied by an Increase in Cholesterol Synthesis from [^{14}C] Acetate[a]

Treatment	[^{14}C] Cholesterol		[^{14}C] Cholesteryl ester	
	Cell	Medium	Cell	Medium
	[dpm ($\times 10^{-3}$)/mg cell protein]		[dpm ($\times 10^{-3}$)/mg cell protein]	
Control	77.2 ± 11.0[c]	3.0 ± 0.2[c]	5.93 ± 0.67[b]	0.28 ± 0.10[b]
CD (1-d)	94.9 ± 4.1[b]	8.3 ± 0.1[b]	2.72 ± 0.27[d]	0.13 ± 0.03[c]
CD (4-d)	85.8 ± 0.1[bc]	8.9 ± 0.6[b]	3.83 ± 0.04[c]	0.11 ± 0.01[c]

[a]HepG2 cells in 60-mm diameter dishes were treated and subjected to pulse-chase protocols as described in Table 3. The incorporation of [^{14}C] acetate (5 µCi/dish) into cellular CH and newly-synthesized CH appearing in the medium was measured over the 100 min chase period. Protocols are further described in the Materials and Methods section. See Table 1 for abbreviations.
[b,c,d]Each value represents the mean ± SD (n = 3). Values down a column with different letter superscripts are statistically different from each other at P (model) < 0.05.

Administration of CD-solubilized CH. The previous experiments have shown that CD can modestly reduce apoB proteolysis and markedly increase apoB secretion, possibly by modulating some aspect of CH metabolism related to CD-mediated CH efflux. To further examine a potential role for cellular CH in apoB-lipoprotein production, the effects of the administration of CD-solubilized CH with the culture medium were measured. In Table 6, HepG2 cells were treated for 4 d in complete growth medium either without (control) or with 0.5% (3.5 mM) CD. CD-treated cells were further treated for 3 h with graded concentrations of CD-solubilized CH (0–40 µg CH). Cyclodextrin-solubilized CH rapidly attenuated the increase in apoB secretion induced by 4-d CD treatment. Indeed, the administration of 20 µg CH decreased apoB secretion to one-third of that induced by CD. Higher doses of exogenous CH had no additional effect. With the application of CD-solubilized CH, albumin secretion was decreased by a maximum of only 20% . This latter result indicated that general inhibition of protein secretion was not the primary cause of the 67% reduction in apoB secretion with the administration of CD-solubilized CH.

In Figure 3, HepG2 cells were either untreated in complete growth medium (control), treated with 0.5% (3.5 mM) CD for 4 d, or treated with 7.5 µg/mL of CD-solubilized CH per d for 3 d followed by multiple applications of 0.5% CD alone for 1 d (CH + CD). Figure 3A shows that in the CD group, there was an increase in cellular undegraded apoB at 70 min, but not at 130 or 190 min of chase. This suggested a transient reduction in apoB proteolysis with CD treatment. Treatment with CD-solubilized CH followed by multiple applications of 0.5% CD alone increased cellular undegraded apoB at 70 and 130 min, but not at 190 min of chase. This suggested a more prolonged transient reduction in apoB proteolysis in cells pretreated with CH. Consistent with previous experiments, daily administration of 0.5% CD for 4 d markedly increased apoB secretion (Fig. 3B). ApoB secretion at 130 and 190 min of chase was 25% higher in CH-treated cells (CH + CD) than in cells treated with CD alone (CD). The results suggest that this specific pretreatment with CD-solubilized CH enhanced the CD-mediated increase in apoB production.

Prolonged treatment with CD and CD-solubilized CH: relationship of changes in cellular neutral lipid concentrations to apoB proteolysis and secretion. In Figure 4, Table 7, HepG2 cells were treated either with 0.5% CD throughout a 15-d period (0.5% CD group), or with CD at concentrations that included a progressive increase from 0.25 to 1% after cells were transferred into 6-well plates (0.25–1% CD group). The latter protocol was implemented to avoid a potentially toxic loss of CH from a small cell mass to a relatively high concentration of CD (1%). An additional group was treated with a constant concentration of CD-solubilized CH (20 µg/mL) for 14 d and subsequently for 1 d with 1% CD alone (CH group). The latter 1 d was simply an equilibration period that was not designed to greatly increase cellular CH efflux or modify cellular CH concentrations. Figure 4A shows that

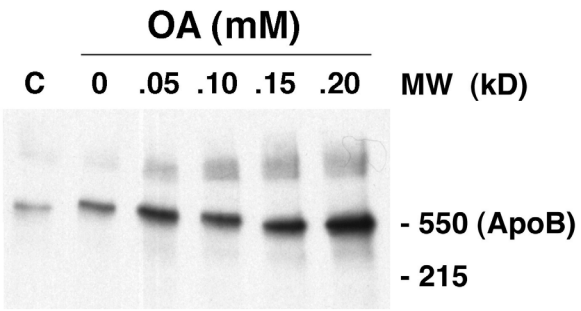

FIG. 2. OA causes a dose-dependent increase in cellular undegraded ApoB in 4-d CD-treated cells. HepG2 cells were treated and subjected to pulse-chase protocols as described in Table 5. ApoB was immunoprecipitated and quantified by scintillation counting, SDS-PAGE, and fluorography as described in the Materials and Methods section. The gel data from one representative sample per treatment is shown. There was a dose-responsive increase in the net cellular content of undegraded apoB at 100 min of chase as the OA concentration was increased from 0 to 0.2 mM. The net cellular content of undegraded [^{3}H] apoB averaged 1.2 ± 0.1 ($\times 10^5$), 1.7 ± 0.2 ($\times 10^5$), 2.2 ± 0.2 ($\times 10^5$), 2.1 ± 0.2 ($\times 10^5$), 2.5 ± 0.1 ($\times 10^5$), and 2.9 ± 0.5 ($\times 10^5$) dpm/mg cell protein in the control (C) and 0, 0.05, 0.10, 0.15, and 0.20 mM OA groups, respectively. Each value represents the mean ± SD (n = 3). See Figure 1 for abbreviations.

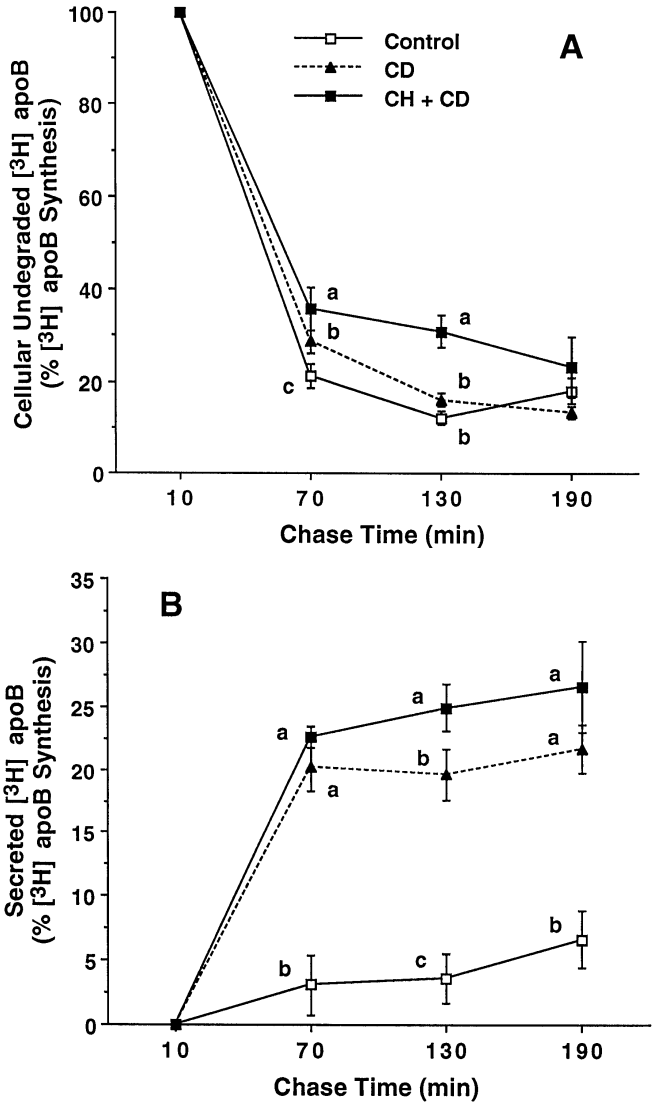

FIG. 3. Three-day pretreatment with CD-solubilized CH, followed by 1 d of multiple CD applications suppresses apoB proteolysis and increases apoB secretion. HepG2 cells were treated for 3 d in 2 mL complete growth medium (+10% fetal bovine serum) containing one of the following additions: none (control), 10 mg (0.5% wt/vol) CD (CD), or 15 µg CH solubilized with 0.5% CD (CH + CD). Fresh medium was administered every 24 h. Cells were further incubated for 20 h in 2 mL complete medium without (control) or with 0.5% CD (CD and CH + CD groups), plus an additional 4 h in 1 mL serum-free medium without or with 0.5% CD. To increase cellular CH efflux in both CD-treated groups during this latter 4 h, fresh medium was administered three times at 1-h intervals beginning at the onset of the period. All cells (70% confluent) were pulsed for 10 min with 100 µCi [^{3}H] leucine in 1 mL serum-free, leucine-free medium without or with 0.5% CD. Triplicate wells of cells from each treatment group were chased in 1 mL serum-free medium without or with 0.5% CD for either 10 min to measure apoB synthesis or 70, 130, or 190 min to measure the cellular content of undegraded apoB (Panel A) and secreted apoB (Panel B). Protocols are further described in the Materials and Methods section. The synthesis of [^{3}H] apoB averaged 7.6 ± 1.0 $(\times 10^5)^b$, 10.2 ± 0.4 $(\times 10^5)^a$, and 8.2 ± 0.2 $(\times 10^5)^b$ dpm/mg cell protein in the control, CD, and CH + CD groups, respectively. Each data point represents the mean ± SD (n = 3). ^{a,b,c}At each time point during the chase period, data points with different letter denotations are statistically different from each other at P (model) < 0.05. See Figure 1 for other abbreviations.

the cellular free CH and cholesteryl ester concentrations were 76% and 10-fold higher, respectively, in CH-treated cells than in control cells. Interestingly, the cellular free CH concentration was 25 and 41% higher in the 0.5% CD and 0.25–1% CD groups, respectively, than in the control group. This occurred without an effect of CD on the cellular cholesteryl ester concentration. The cellular triglyceride concentration was an average of 59% lower after 15 d of CD treatment. Fourteen-day treatment with 20 µg CH/mL (followed by 1-d equilibration) had no effect on apoB or cell protein synthesis (see Fig. legend), proteolysis, or secretion (Fig. 4B and 4C). Following 15-d CD treatment, [^{3}H] apoB and [^{3}H] protein synthesis (per mg cell protein) were increased by an average of 32 and 11%, respectively. Similarly, the concentrations of [^{3}H] apoB and [^{3}H] protein remaining undegraded in cells at the end of the 90-min chase period were increased by an average of 34 and 17%, respectively. In contrast, there was a 2.8-fold and 3.7-fold increase in [^{3}H] apoB secretion in the 0.5% CD and 0.25–1% CD groups, respectively (Fig. 4B). Indeed, the relative percentage of newly synthesized apoB that was secreted increased from 8% in the control group to 18% in the 0.5% CD group to 23% in the 0.25–1% CD group. The results suggest that prolonged chronic CD treatment modestly increased the cellular free CH concentration, markedly increased the assembly of cellular triglyceride with nascent apoB, and markedly increased transport of apoB through the secretory pathway.

DISCUSSION

The effects of CD, CD-solubilized OA, and CD-solubilized CH on apoB production were measured in HepG2 cells. The experiments were designed to alter cellular CH metabolism, modify apoB secretion, suggest a discrete role for cellular CH in apoB-lipoprotein production, and compare the apparent effects of CH to the more established effects of triglyceride. Prolonged chronic treatment with CD was found to decrease intracellular apoB proteolysis and increase apoB secretion. The reduction in apoB proteolysis was proportional to the concentration of CD applied with the incubation medium from 0–1.5% (0–10.5 mM) CD. ApoB secretion approached the maximum (25–30% of apoB synthesized) with 0.5% (3.5 mM) CD.

The utilization of CD-solubilized OA provided insight to the competitive mechanisms regulating apoB proteolysis and secretion. For example, OA was a more potent inhibitor of rapid apoB proteolysis than CD. It has been suggested that OA rescues nascent apoB from rapid proteolysis and increases apoB secretion mainly through an increase in triglyceride synthesis (22,23,34,61). The observations that CD-solubilized OA reduced apoB proteolysis from near 70% (control) to less than 10% of apoB synthesized, and that apoB secretion during a 100-min chase period never exceeded 32% of apoB synthesized, indicated that a process other than inhibition of rapid apoB proteolysis was required for efficient apoB-lipoprotein secretion. Previous studies have shown that

TABLE 5
The Cellular Content of Undegraded ApoB in 4-D CD-Treated Cells Is Rapidly Enhanced by CD-Solubilized Oleate[a]

[a]HepG2 cells were treated for 4 d in 2 mL of complete growth medium (+10% fetal bovine serum) without (control) or with 0.5% (wt/vol) CD. Fresh medium was administered every 24 h. Cells (90% confluent) were further treated for 1 h in 1 mL of serum-free medium without (control) or with 0.5% CD. The incubation medium for the CD groups contained either 0, 0.05, 0.10, 0.15, or 0.20 mM oleate (OA) solubilized with 0.5% CD. All cells were pulsed for 10 min with 100 μCi [^{3}H] leucine in 1 mL of serum-free, leucine-free medium containing the same additions described for the 1-h treatment period. Triplicate wells of cells from each treatment were chased in 1 mL of serum-free medium (containing additions as above) for either 10 min to measure apoB and albumin synthesis or 100 min to measure the cellular content of undegraded apoB, as well as the secretion of nascent apoB and albumin. Cellular degradation of nascent apoB was calculated as described in Table 1. Protocols are further described in the Materials and Methods section. See Table 1 for abbreviations.
[b,c,d]Each value represents the mean ± SD (n = 3, n = 6 for cell protein). Values down a column with different letter superscripts are statistically different from each other at P (model) < 0.05.

small HDL-sized apoB-lipoprotein particles can be retained by HepG2 cells (62), and that sufficient lipid incorporation into nascent apoB at the ER is required for the formation of mature lipoprotein particles that are secreted (19). Rapid uptake of CD-solubilized OA and subsequent incorporation of the fatty acid into triglyceride near the site of apoB synthesis could have induced a large percentage of nascent apoB molecules to form into HDL-sized progenitor apoB-lipoprotein particles that were neither secreted nor degraded during the 100-min chase period. The results support the hypothesis that HepG2 cells have a limited capacity to complex triglyceride with small apoB-lipoprotein particles at the second step in the secretory pathway (17,63).

Triglyceride-facilitated transport of nascent apoB in the secretory pathway has been suggested to rescue apoB from proteolysis during OA administration (34). The mechanism by which prolonged CD treatment decreased apoB proteolysis and increased apoB secretion may have been different. *In vivo*, an increase in hepatic CH synthesis has been associated with increased VLDL production (60). However, CH synthesis was not increased when the CD-mediated decrease in apoB proteolysis and increase in apoB secretion were measured. Figure 4 showed that a marked increase in the cellular free and esterified CH concentrations after a 2-wk treatment with CD-solubilized CH did not affect apoB proteolysis or secretion. In 15-d CD-treated cells, a 25–41% increase in the

[a]HepG2 cells were treated for 4 d in 2 mL of complete growth medium (+10% fetal bovine serum) without (control) or with 0.5% (wt/vol) CD. Fresh medium was administered every 24 h. Cells (90% confluent) were further treated for 1 h in 1 mL of serum-free medium without (control) or with 0.5% CD. The incubation medium for the CD groups contained either 0, 10, 20, 30, or 40 μg CH solubilized with 0.5% CD. All cells were pulsed for 10 min with 100 μCi [^{3}H] leucine in 1 mL of serum-free, leucine-free medium containing the same additions described for the 1-h treatment period. Triplicate wells of cells from each treatment were chased in 1 mL of serum-free medium (containing additions as above) for either 10 min to measure apoB and albumin synthesis or 100 min to measure the cellular content of undegraded apoB, as well as the secretion of nascent apoB and albumin. Cellular degradation of nascent apoB was calculated as described in Table 1. Protocols are further described in the Materials and Methods section. See Table 1 for abbreviations.
[b,c,d,e]Each value represents the mean ± SD (n = 3, n = 6 for cell protein). Values down a column with different letter superscripts are statistically different from each other at P (model) < 0.05.

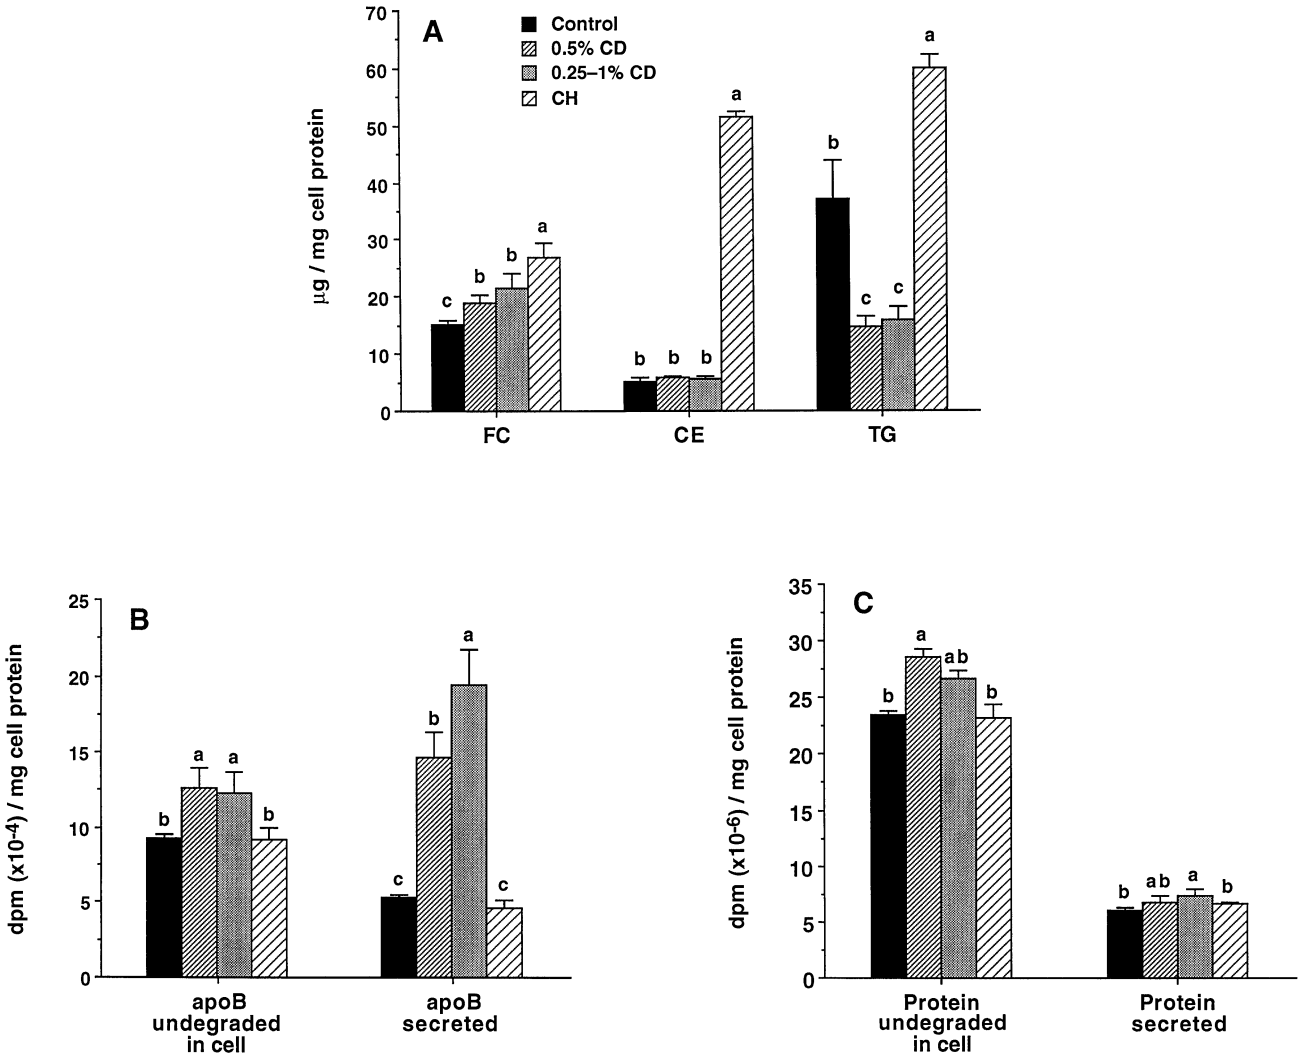

FIG. 4. Effect of 2-wk treatment with CD or CD-solubilized CH on cellular neutral lipid concentrations and apoB and cell protein degradation and secretion. HepG2 cells were cultured in 75-cm^2 flasks for 8 d with complete growth medium (+10% fetal bovine serum) (CM). During this period on d 1, 3, 5, and 7, cells were administered 10 mL CM plus either no addition (control), 0.5% (wt/vol) CD, or 200 µg CH complexed to 0.5% CD. On d 9, 4 separate groups of cells were seeded into 6-well tissue culture plates (9.6 cm^2/well, 1×10^5 cells/well) from the control (1 group), CD-treated (2 groups), and CH-treated (1 group) flasks. The four groups were further treated for 48 h (days 9–10) in 2 mL CM containing either no addition (control), 0.5% CD, 0.25% CD, or 40 µg CH (0.5% CD). Cells were cultured for five additional days (day 11–15) in 1.25 mL CM with the daily treatments indicated (see Table 7). Treatments were reapplied every 24 h (day 11–15). On d 16 (control cells 100% confluent), triplicate wells of cells from each group were collected for lipid analysis. Remaining cells were further treated as indicated for 1 h in 1 mL serum-free medium (SFM). Media were removed, and cells were pulsed for 10 min with 90 µCi [^{3}H] leucine in 1 mL serum-free, leucine-free medium (SFLFM) containing the indicated treatments. Triplicate wells of cells from each group were chased in 1 mL SFM containing the indicated treatments for either 10 min (to measure apoB and protein synthesis) or 90 min (to measure cellular undegraded and secreted apoB and protein). Cells were collected in lysis buffer, and cellular neutral lipids (Panel A), [^{3}H] apoB (Panel B), trichloroacetic acid (TCA)-precipitable [^{3}H] protein (Panel C), and TCA-precipitable cell protein were quantified as described in the Materials and Methods section. Cell protein averaged 1.19 ± 0.12^a, 0.91 ± 0.07^c, 0.88 ± 0.07^c, and 1.02 ± 0.04^b mg/well in the control, 0.5% CD, 0.25–1% CD, and CH groups, respectively ($n = 9$ each). Panel A: FC = free CH, CE = cholesteryl ester, TG = triglyceride. Panel B: [^{3}H] apoB synthesis averaged 62.6 ± 4.7 $(\times 10^4)^c$, 79.6 ± 12.3 $(\times 10^4)^{a,b}$, 86.4 ± 9.0 $(\times 10^4)^a$, and 66.3 ± 2.0 $(\times 10^4)^{b,c}$ dpm/mg cell protein in the control, 0.5% CD, 0.25–1.0% CD, and CH groups, respectively. Panel C: [^{3}H] protein synthesis averaged 34.5 ± 2.2 $(\times 10^6)^b$, 39.5 ± 2.7 $(\times 10^6)^a$, 37.1 ± 1.7 $(\times 10^6)^{a,b}$, and 35.7 ± 0.6 $(\times 10^6)^b$ dpm/mg cell protein in the control, 0.5% CD, 0.25–1.0% CD, and CH groups, respectively. Each bar in the figure represents the mean ± SD ($n = 3$). ^{a,b,c} Values with different letter denotations are statistically different from each other at P (model) < 0.05.

TABLE 7
Treatments Applied[a]

Treatment Group	days 9–10 (48 h)	day 11 (24 h)	day 12 (24 h)	day 13–14 (24 h × 2)	day 15 (24 h)	day 16 (1 h)	day 16 (10 min)	day 16 (10 or 90 min)
Control	CM	CM	CM	CM	CM	SFM	SFLFM	SFM
0.5% CD	0.5% CD	0.5% CD	0.5% CD	0.5% CD	0.5% CD	0.5% CD	0.5% CD	0.5% CD
0.25–1% CD	0.25% CD	0.5% CD	0.75% CD	1% CD	1% CD	1% CD	1% CD	1% CD
CH	40 μg CH	25 μg CH	25 μg CH	25 μg CH	1% CD	1% CD	1% CD	1% CD

[a]SFLFM, serum-free, leucine-free medium; CM, complete growth medium. See Table 1 for other abbreviations.

cellular free CH concentration was associated with a 25% reduction in apoB proteolysis, a 59% reduction in cellular triglyceride concentration, and a 3- to 4-fold increase in apoB secretion. Therefore, rather than a total cellular CH increase, we speculate that an increase in the CH concentration in discrete subcellular CH pools may have influenced apoB proteolysis and secretion in CD-treated HepG2 cells.

One possible mechanism responsible for the CD-mediated increase in apoB production may involve increased CH concentration in an apoB-associated ER regulatory pool. A putative ER regulatory pool of cholesterol modulates both LDL receptor activity and CH biosynthesis by controlling proteolytic release of sterol regulatory element-binding protein-1 (64). In the current studies, chronic and repeated CD-mediated CH efflux could have increased ER CH near the origin of and adjacent to the apoB secretory pathway, without greatly affecting the cellular total CH concentration. An increase in CH concentration in a specific regulatory pool could have "shielded" ER membrane-associated nascent apoB from rapid proteolysis, which is believed to be initiated by a putative ER protease (65).

A second possible mechanism for the CD-mediated increase in apoB production may involve increased CH transport through the putative ER regulatory pool to the plasma membrane. CD can stimulate efflux of newly-synthesized CH (Table 4), as well as CH from cells prelabeled with [^{3}H] CH (66,67). Although the pathway for CH trafficking from ER to plasma membrane diverges from that taken by secretory or integral membrane proteins, it is believed that both pathways have a common origin at the ER (68,69). We suggest that HepG2 cells adapted to chronic CD administration with increased CH flux through the nascent apoB-associated CH pool, which facilitated apoB-lipoprotein secretion. The concept of increased ER-to-plasma membrane CH flux in cells chronically treated with CD is supported by the reversal in CD-stimulated apoB secretion following the administration (and influx) of CD-solubilized cholesterol (Table 6). A CD-mediated increase in cellular LDL-CH uptake could also have contributed CH for increased flux through a regulatory (nascent apoB) pool. Indeed, LDL receptor activity has been shown to be elevated in HepG2 cells treated with 2.86 mM CD for 24 h (70). Increased LDL-cholesterol uptake would explain the observation that CH synthesis was not increased after 4 d of CD treatment in the presence of FBS (Table 4), despite daily removal of CD-solubilized cellular CH with each change of culture medium. Future studies will attempt to measure ER-to-plasma membrane cholesterol flux during chronic CD administration.

The administration of 3.5 mM CD for 4 d had minimal effects on cell culture growth. However, the application of higher CD concentrations for 4 d (Table 2) or repeated application of 3.5 mM CD for 15 d (Fig. 4) modestly attenuated culture growth. HepG2 cells have an absolute requirement for CH to maintain a normal growth rate (71). The administration of CD rapidly stimulates CH efflux, and cell protein synthesis may be transiently reduced when cells are exposed to a high dose of CD relative to the cell mass (Peluso, M.R., and Dixon, J.L., unpublished data).

In summary, treatment of HepG2 cells with CD-solubilized OA (0.2 mM) markedly reduced apoB proteolysis and markedly increased apoB secretion; thus, CD may be used instead of BSA to deliver exogenous OA to cultured cells. Chronic daily treatment of HepG2 cells with 0.5% (3.5 mM) CD modestly increased the cellular free CH concentration, modestly reduced apoB proteolysis, markedly reduced the cellular triglyceride concentration, and markedly increased apoB secretion. The administration of CD-solubilized CH increased the cellular free and esterified CH concentrations, but apoB production was not directly affected by the increase in cellular cholesterol. The use of CD as a research tool to modulate cellular CH metabolism may assist model formation to more clearly define mechanisms involved with disorders of hepatic CH metabolism linked with overproduction of apoB-lipoprotein.

ACKNOWLEDGMENTS

Thanks to Dan Stoops for quantification of lipid mass. We also wish to thank Dr. Norman Javitt for bringing the concept of cholesterol delivery to cultured cells with 2-hydroxypropyl-β-cyclodextrin to our attention. This study was presented in part at the Experimental Biology 95 meeting (Atlanta, GA); April 1995, Abstract #4458. This work was supported by Grant HL-47586 to Joseph L. Dixon from the National Heart, Lung, and Blood Institute, National Institute of Health. Contribution from the Missouri Agricultural Experiment Station, Journal Series Number 12,560.

Capillary Supercritical Fluid Chromatography–Atmospheric Pressure Chemical Ionization Mass Spectrometry of γ- and α-Linolenic Acid Containing Triacylglycerols in Berry Oils

Pekka Manninen* and Päivi Laakso

Department of Biochemistry and Food Chemistry, University of Turku, FIN-20014 Turku, Finland

ABSTRACT: The effect of the γ-linolenic acid (18:3n-6) residue on the elution of triacylglycerols on a 25% cyanopropyl-25% phenyl-50% methylpolysiloxane stationary phase was confirmed by using capillary supercritical fluid chromatography–atmospheric pressure chemical ionization mass spectrometry [cSFC–(APCI)MS]. The general elution rule on this stationary phase is that triacylglycerols having the same ACN + 2*n* value coeluted (ACN = acyl carbon number and *n* = combined number of double bonds in the acyl chains). The different effect of γ- and α-linolenic acid residues on the retention of triacylglycerols and the use of cSFC–(APCI)MS allowed the study of the number of different linolenic acid residue isomer combinations in triacylglycerols with an identical ACN and degree of unsaturation. Stearidonic acid (18:4n-3) residue was found to have a similar effect on the retention behavior of triacylglycerols as that of γ-linolenic acid residue. The abundance of the $[M - RCOO]^+$ ion, formed by the loss of one fatty acid moiety of a triacylglycerol, was found to be clearly higher in the case of γ-isomer of the linolenic acid than that of α-isomer in the identical regiospecific position. This indicates that the distance of the double bonds from the glycerol backbone in the acyl chain affects the stability of a triacylglycerol molecule in the (APCI)MS system. The triacylglycerol composition and the fatty acid combinations of triacylglycerols were found to be almost identical in black currant (*Ribes nigrum*) and alpine currant (*R. alpinum*) seed oils.

Lipids 32, 825–831 (1997).

The γ-isomer of linolenic acid (18:3n-6) should be regarded as an n-6 essential fatty acid having a notable role in health and disease as reviewed by Horrobin (1). Therefore, the analysis of triacylglycerols of edible oils containing γ-linolenic acid residues has a great importance and interest (2). Recently, the separation of triacylglycerols containing γ-linolenic and α-linolenic acid (18:3n-3) residues by using capillary supercritical fluid chromatography (cSFC) has been reported (3). The unique feature of cSFC in the separation of triacylglycerols on a 25% cyanopropyl-25% phenyl-50% methylpolysiloxane stationary phase is the order of the elution, which follows the rule of increasing ACN + 2*n* value, where ACN is the acyl carbon number and *n* is the combined number of double bonds in the acyl chains (4,5). The elution rule together with the effect of γ-linolenic acid residue on the retention resulted in an interesting elution pattern as the triacylglycerol containing the γ-isomer of linolenic acid eluted in a separate peak before that containing the α-isomer or no linolenic acid residues (3). The reported separation of the triacylglycerols of black currant and alpine currant seed oils provided, however, only limited information on the molecular species compositions, since a flame-ionization detector (FID) was used for detection.

The differentiation of linolenic acid isomers in mass spectrometric analysis of triacylglycerol mixtures requires chromatographic separation of the isomers, since both of them produce similar ions. Recently, a method for combining cSFC with atmospheric pressure chemical ionization mass spectrometry [(APCI)MS] for analyzing triacylglycerols in berry oils has been reported to achieve more detailed information about the molecular species (5). The method provided information on both the molecular weights and the possible fatty acid combinations of triacylglycerols. (APCI)MS also has been successfully utilized in combination with liquid chromatographic (LC) separation of triacylglycerols (6–9). Capillary SFC on a cyanopropyl stationary phase allows a different kind of approach for the analysis of triacylglycerols compared with LC, where the elution order in reversed-phase LC is according to increasing ACN – 2*n* values (10) or according to increasing degree of unsaturation, as in silver-ion LC (9,11). This may result in an advantage in the interpretation of cSFC–(APCI)MS spectra of triacylglycerols over those of LC–(APCI)MS mass spectra.

In this study, cSFC–(APCI)MS was applied to the analysis of triacylglycerols of black currant and alpine currant seed oils. Reliable information was achieved on the molecular weight species, as well as on the identities of the molecular associations of fatty acid residues in triacylglycerols. In addition, the ionization of linolenic acid residue isomers is briefly discussed.

EXPERIMENTAL PROCEDURES

Materials. The reference compounds 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol (*sn*-18:1n-9-18:3n-6-18:1n-9) and 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol (*sn*-18:1n-9-18:3n-3-

18:1n-9) (custom-synthesized by Larodan, Malmö, Sweden) were diluted in *n*-hexane (Rathburn Chemicals Ltd., Walkerburn, Scotland) to a concentration of approximately 0.5 mg mL^{-1}. Black currant (*Ribes nigrum*) and alpine currant (*R. alpinum*) seed oil were extracted by supercritical carbon dioxide at Flavex (Rehlingen, Germany) in a production and a pilot plant, respectively. The oils were stored under nitrogen below 0°C, and diluted 10 mg in 1 mL of dichloromethane (Rathburn) before chromatography.

Methods. Supercritical fluid chromatographic separations were obtained on a Lee Scientific Series 600 supercritical fluid chromatograph (Dionex, Salt Lake City, UT) combined with a Finnigan MAT TSQ-700 triple quadrupole mass spectrometer (Finnigan MAT, San Jose, CA) using an LC–APCI interface (Finnigan MAT). The interfacing method is described in detail elsewhere (5). A pneumatic and electrically controlled Valco switching valve (Valco Instruments, Inc., Houston, TX) with an internal loop size of 1.0 µL was used for timed/dynamic split injection. The timed split loop open time was 2.0 s. Two 10 m × 50 µm i.d. SB-Cyanopropyl-25 (25% cyanopropyl–25% phenyl–50% methylpolysiloxane; Dionex) columns combined in series with a zero dead volume butt connector (SGE, Austin, TX) were used for the chromatographic separations. Frit restrictors (30 cm × 50 µm i.d.; Dionex) were installed both after the analytical column and at the dynamic split outlet. Separations were performed at a constant temperature of 135°C with a linear density ramp from 0.16 g mL^{-1} at a rate of 0.010 g mL^{-1} min^{-1} to 0.62 g mL^{-1}. SFC-grade CO_2 (Scott Specialty Gases, Plumsteadville, PA) was used as a carrier fluid with a column flow rate of 0.18 mL min^{-1} measured with propane at the initial conditions of the chromatographic program with FID. The mass spectrometer was operated in a full scan mode using quadrupole 1 for scanning; quadrupoles 2 and 3 were operated in *rf*-only mode. Positively charged ions with *m/z* values 450–1000 were scanned with a scan time of 0.7 s. The corona needle current was set at 5.0 µA. Tuning of the mass spectrometer is described elsewhere (5). The APCI gases (N_2) during the cSFC–(APCI)MS operation were preheated by placing the Teflon gas-tube coils between the SFC oven outer wall and the oven cover. The sheath gas pressure was 1 bar, and the auxiliary gas flow rate was 5 mL min^{-1}. The APCI vaporizer temperature was kept at 425°C and the APCI capillary at 200°C. Methanol was used as a reactant ion solvent vapor, and introduced into the APCI source by leading the sheath gas flow through a 200-mL solvent bottle containing 50 mL of methanol (gradient grade; Merck, Darmstadt, Germany) so that the inlet tube was just beyond the solvent surface. The reactant ion solvent container was kept at ambient temperature.

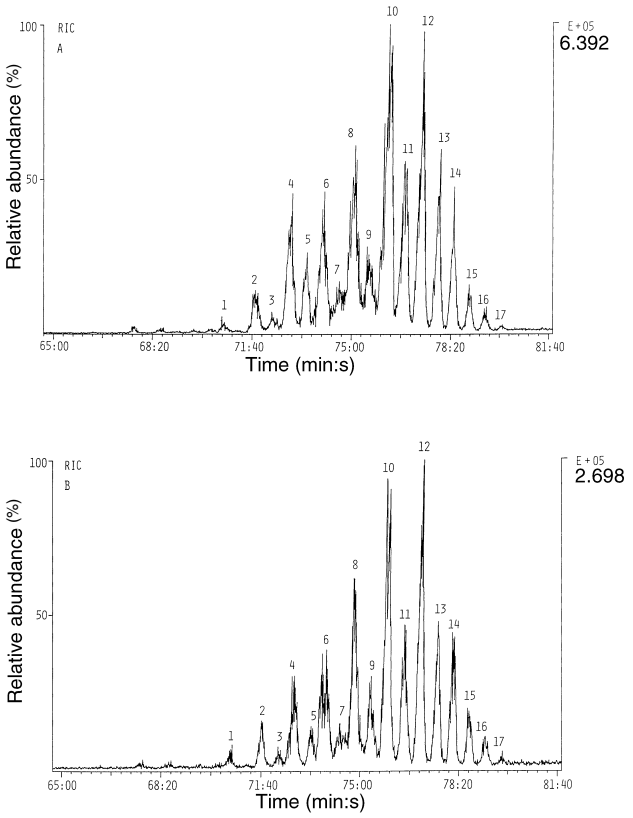

FIG. 1. The reconstructed ion chromatograms (RIC) of (A) black currant, and (B) alpine currant seed oil triacylglycerols obtained on capillary supercritical fluid chromatography–atmospheric pressure chemical ionization mass spectrometry (no smoothing was used in the chromatograms).

RESULTS AND DISCUSSION

The reconstructed cSFC–(APCI)MS ion chromatograms of black currant and alpine currant seed oil triacylglycerols separated on a 25% cyanopropyl-25% phenyl-50% methylpolysiloxane stationary phase are shown in Figure 1. The resolution was equal to or better than that on the same stationary phase reported earlier in the case of cSFC–FID (3). Methanol was used as a reactant ion solvent, which was previously shown to produce abundant $[M + H]^+$ and $[M - RCOO]^+$ ions from triacylglycerols (5). The $[M + H]^+$ ions provided the molecular weight information, whereas the $[M - RCOO]^+$ ions, formed by a loss of one fatty acid residue from a triacylglycerol, provided information on the possible fatty acid combinations of a molecule. Occasionally, $[M + 18]^+$ ions having low abundances were formed, but had no use in interpretation of the mass spectra in this study.

The effect of γ-linolenic acid residue on the elution of triacylglycerols on a 25% cyanopropyl–25% phenyl–50% methylpolysiloxane stationary phase in cSFC–FID has been demonstrated by a baseline separation of triacylglycerols *sn*-18:1n-9-18:3n-6-18:1n-9 and *sn*-18:1n-9-18:3n-3-18:1n-9 by Manninen *et al.* (3). The triacylglycerol containing the γ-linolenic acid residue eluted first, and the other containing the α-linolenic acid residue eluted with the same retention as those 54:5 triacylglycerols containing no linolenic acid residues. The detection with FID, however, could not provide information on the coeluting compounds. Therefore, no direct judgment could be made as to whether there were tri-

acylglycerols containing more than one γ-linolenic acid residue present in the studied oils or not.

The presence of isomeric triacylglycerols (equal number of acyl carbons and double bonds) was studied by plotting the cSFC–(APCI)MS ion chromatograms of the $[M + H]^+$ ions. For example, triacylglycerol 54:9 (*m/z* 873.8) eluted in four separate peaks (Fig. 2). Figure 3 shows, as an example, the mass spectra of the chromatographic peak numbers 14 and 15 in black currant seed oil. In addition, the mass spectral data extracted from peak numbers 13–16 are listed in Table 1. The mass spectra of triacylglycerols exhibited only abundant $[M + H]^+$ ions and $[M - RCOO]^+$ ions. The *m/z* values of the $[M + H]^+$ ions defined the molecular weight species of triacylglycerols present in the peaks: *m/z* 873.8 corresponded to the triacylglycerol 54:9, and *m/z* 875.8 corresponded to 54:8 in peak 14 (Fig. 3B). Peak 15 consisted of triacylglycerols 54:10 (*m/z* 871.9) and 54:9 (Fig. 3D). The presence of $[M - RCOO]^+$ ions in the mass spectra provided information on the possible fatty acid constituents of a triacylglycerol, as indicated in Figure 3A and C. Triacylglycerols eluting in the same chromatographic peak may yield the same fragment ions, which makes the interpretation of the spectra more complicated. The most probable fatty acid combination for triacylglycerol 54:9 in black currant seed oil is 18:3/18:3/18:3, where 18:3 is either α- or γ-linolenic acid moiety, according to the fatty acid analysis. In addition, fatty acid combinations 18:1/18:4/18:4 and 18:2/18:3/18:4 are also possible. The mass spectrum of each of the peaks 13–16 exhibited the fragment ion *m/z* 595.6 corresponding to the loss of one linolenic acid moiety from the molecule. Therefore, triacylglycerol 54:9 may represent the combination 18:3/18:3/18:3 in each of the four peaks. On the other hand, no loss of oleic acid from 54:9 (*m/z* 591.5) was found; thus, the combination 18:1/18:4/18:4 does not exist in black currant seed oil. In addition to the ion *m/z* 595.6, the mass spectra of peaks 14 and 15 provided ions corresponding to the loss of one linoleic acid (*m/z* 593.5) and one stearidonic acid (*m/z* 597.5) from the triacylglycerol 54:9 (Fig. 3). In peak 15,

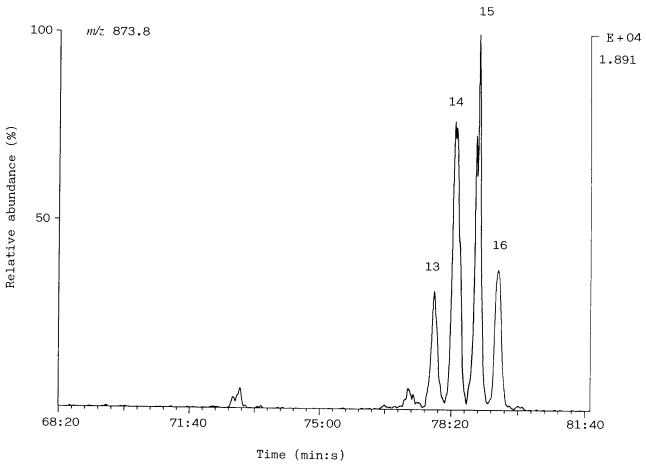

FIG. 2. The ion chromatogram of the molecular ion ($[M + H]^+$) of triacylglycerol 54:9 in black currant seed oil (7-point smoothing used in the ion chromatogram).

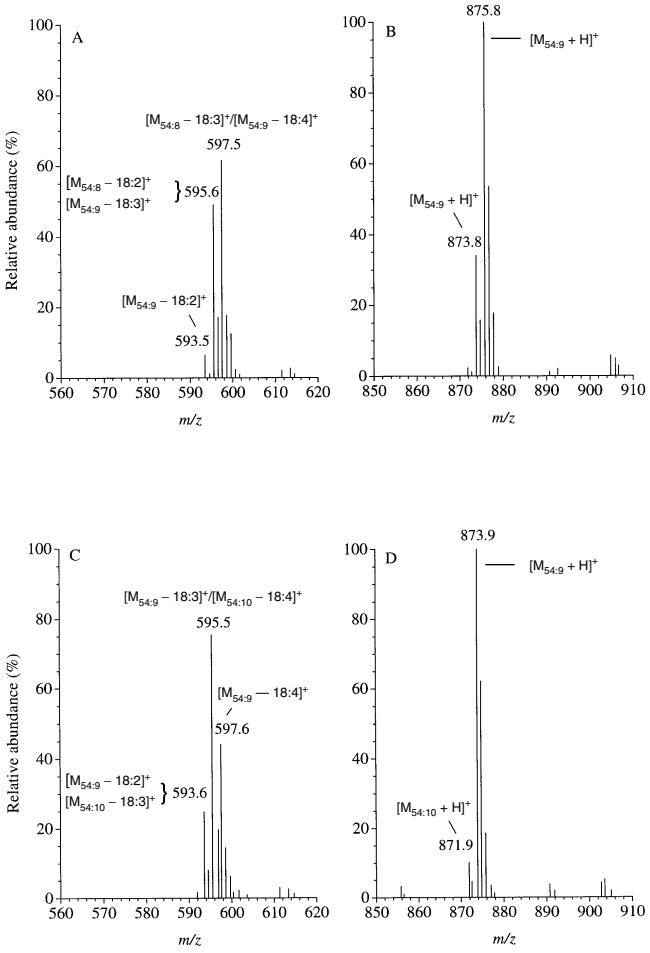

FIG. 3. The mass spectra of the chromatographic peak numbers 14 and 15 in black currant seed oil: (A) the $[M - RCOO]^+$-ion region of peak 14, (B) the $[M + H]^+$-ion region of peak 14, (C) the $[M - RCOO]^+$-ion region of peak 15, and (D) the $[M + H]^+$-ion region of peak 15. Peak numbers refer to those presented in Figure 1A and 2 and in Table 1.

the ion *m/z* 597.6 is produced only from 54:9 by the loss of a stearidonic acid. In addition, only a small portion of the abundances of ions *m/z* 593.6 and 595.5 were formed by the loss of linolenic acid and stearidonic acid from the triacylglycerol 54:10. According to these data, 54:9 in peak 15 is a mixture of 18:3/18:3/18:3 and 18:2/18:3/18:4. Peak 14 consists most probably of the same fatty acid combinations of 54:9, although a large portion of the ion abundances of *m/z* 595.6 and *m/z* 597.5 corresponded to the loss of fatty acid constituents from triacylglycerol 54:8. Tri-acylglycerol 54:9 in peak 16 yielded only one fragment ion (*m/z* 595.6) corresponding to the loss of linolenic acid moiety (Table 1). Furthermore, this peak was found to elute with the same retention time as 18:3n-3/18:3n-3/18:3n-3 in seed oils analyzed earlier (3–5). The molecular associations of fatty acid residues representing triacylglycerol 54:9 were judged based both on the mass spectral data and on the retention properties of triacylglycerols on the SB-Cyanopropyl column. In addition, comparison of the retention times and elution orders of triacylglycerols analyzed earlier with capillary SFC–(APCI)MS (5) with those of black currant

seed oil was useful. Thus, the most probable fatty acid combinations of the triacylglycerol 54:9 in the four peaks were: 18:3n-3/18:3n-3/18:3n-3 in peak 16, 18:3n-3/18:3n-3/18:3n-6 and 18:2/18:3n-3/18:4 in peak 15, 18:3n-3/18:3n-6/18:3n-6 and 18:2/18:3n-6/18:4 in peak 14, and 18:3n-6/18:3n-6/18:3n-6 in peak 13. The effect of ^{13}C and ^{18}O isotopes has to be taken into account in the interpretation of the mass spectra; the abundance of the fragment having a given *m/z* value will be slightly overstated owing to contributions of the molecule two *m/z* units lower containing two ^{13}C isotopes or one ^{18}O isotope.

Black currant and alpine currant seed oil contained small proportions of stearidonic acid (18:4n-3), approximately 4.4 and 3.2%, respectively (3). No ions corresponding to the loss of stearidonic acid were found in any of the mass spectra of the chromatographic peaks representing triacylglycerols containing only the α-isomer of linolenic acid or no linolenic acid residues (Table 1). However, stearidonic acid residue was found, for example, in the peak representing triacylglycerol 54:6 (peak number 9 in Table 1), having the possible fatty acid compositions 18:1/18:2/18:3n-6 and 18:1/18:1/18:4. In addition, triacylglycerol 54:10 as an example was found to be present in such a peak (peak number 15 in Table 1, Fig. 3C and D), which in principle should contain three γ-linolenic acid residues according to the retention order. However, the only possible fatty acid combination for triacylglycerol 54:10 in this peak was found to be 18:3n-6/18:3n-6/18:4. These kinds of observations led to the assumption that stearidonic acid residues similarly affected the retention of triacylglycerols as γ-linolenic acid residue did. The same phenomenon also has been found in silver-ion LC (9).

The fatty acid combinations of black currant and alpine currant seed oil triacylglycerols presented in Tables 1 and 2, respectively, were judged on the basis that γ-linolenic and stearidonic acid residues have a similar effect on the retention of triacylglycerols. The comparison of these two tables revealed that both seed oils are very much alike in the molecular composition as well as in the fatty acid combinations of the triacylglycerols. This study confirmed the tentative identification of the separated molecular species, by both the acyl carbon number and number of double bonds in the acyl chains, of these oils analyzed previously by cSFC–FID (3). In addition, the use of (APCI)MS for detection made it possible to identify coeluting components based on the presence of the $[M + H]^+$ ions in the mass spectra. Furthermore, (APCI)MS provided information on the fatty acid residues, which was not available with SFC–FID. Both black currant and alpine currant seed oil also contained small relative amounts of triacylglycerols with 56 acyl carbons. However, their fatty acid combinations could not be concluded in this study, since they coeluted with much more abundant triacylglycerols with 54 acyl carbons and, thus, produced too low an abundance of the fragment ions to be recognized with certainty. This was already seen in the earlier study of cloudberry and sea buckthorn seed oil (5).

The proportion of triacylglycerols in both of the oils was roughly estimated according to the relation of the abundances of $[M + H]^+$ ions of each triacylglycerol (Table 3). This al-

17	54:10	993	0.3	686	0.5

lowed the comparison of the relative amounts of the corresponding triacylglycerols in the two oils studied. It should be noted, however, that the abundance of both $[M + H]^+$ and $[M - RCOO]^+$ ions has been reported to depend on the regioisomeric position of the fatty acid residues as well as on the acyl chain length and the number of double bonds of the fatty acid residues (5). Byrdwell *et al.* (8) summed the abundances of $[M + H]^+$ and $[M - RCOO]^+$ ions for quantitation purposes. This kind of approach was not considered valuable in the present study, since in several cases a single $[M - RCOO]^+$ ion was a fragment of more than one triacylglycerol. The proportions of the coeluting triacylglycerols in both of the oils resembled those reported by Manninen *et al.* (4) in the case of cSFC–FID. The proportions of triacylglycerols having a high degree of unsaturation were slightly overemphasized in cSFC–(APCI)MS, whereas the molecular discrimination in cSFC–FID at this relatively narrow ACN range has been reported to be insignificant (3). In addition, the combined proportions of isomeric triacylglycerols calculated according to the data in Table 3 were comparable to those reported in the case of direct probe mass spectrometry of black currant and alpine currant seed oil (3). According to the Tables 1–3, the proportion of triacylglycerols containing no γ-linolenic acid or stearidonic acid residues was approximately 61% in black currant seed oil and 67% in alpine currant seed oil. This was quite an expected result, since the relative amount of γ-linolenic acid and stearidonic acid measured as methyl esters is reported to be higher in black currant seed oil (3). The presence of triacylglycerols containing two γ-linolenic acid residues in black currant seed oil has been reported earlier (9,12,13). These kinds of triacylglycerols were also present in alpine currant seed oil. However, the proportion of molecules containing more than one γ-linolenic acid residue was relatively low in both oils studied.

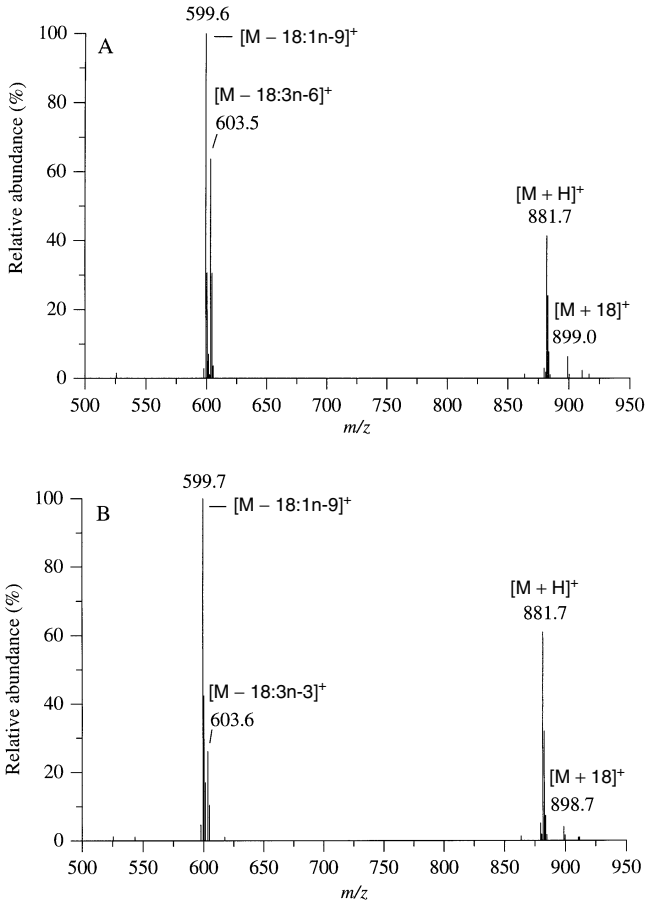

FIG. 4. The mass spectra of triacylglycerols (A) *sn*-18:1n-9-18:3n-6-18:1n-9, and (B) *sn*-18:1n-9-18:3n-3-18:1n-9.

The baseline separation of a two-component mixture of triacylglycerols *sn*-18:1n-9-18:3n-6-18:1n-9 and *sn*-18:1n-9-18:3n-3-18:1n-9 by cSFC–(APCI)MS resulted in differences in the abundances of the molecular ion $[M + H]^+$ and the $[M - RCOO]^+$ ion, produced from a loss of the linolenic acid residue, in the mass spectra (Fig. 4). The abundance of the $[M - 18:3n-3]^+$ ion was lower than that of $[M - 18:3n-6]^+$ ion, whereas the abundance of the $[M + H]^+$ ion was higher. This indicated that, together with the other factors affecting ion abundances mentioned above, the distance of the double bonds from the glycerol skeleton has an effect on the molecule stability in (APCI)MS. The proximity of the double bonds to the head of the acyl chain makes the chain a better leaving group.

The sensitivity of the cSFC–(APCI)MS method was better than that of the corresponding cSFC–FID method as the sample concentration required in cSFC–(APCI)MS was approximately four times less. The data obtained on the triacylglycerols with the used method provided valuable information on the molecular species, such as molecular weight and the molecular association of the fatty acids, which is not available with any other chromatographic detection method. The quantitative analysis of triacylglycerols with cSFC–(APCI)MS, however, will probably require separation of individual triacylglycerols, since the factors affecting the fragmentation of a molecule are very complex.

Characterization of Polar and Nonpolar Seed Lipid Classes from Highly Saturated Fatty Acid Sunflower Mutants

Rosario Álvarez-Ortega, Sara Cantisán, Enrique Martínez-Force, and Rafael Garcés*

Instituto de la Grasa, CSIC, Sevilla, Spain

ABSTRACT: The seed lipids from five sunflower mutants, two with high palmitic acid contents, one of them in high oleic background, and three with high stearic acid contents, have been characterized. All lipid classes of these mutant seeds have increased saturated fatty acid content although triacylglycerols had the highest levels. The increase in saturated fatty acids was mainly at the expense of oleic acid while linoleic acid levels remained unchanged. No difference between mutants and standard sunflower lines used as controls was found in minor fatty acids: linolenic, arachidic, and behenic. In the high-palmitic mutants palmitoleic acid (16:1n-7) and some palmitolinoleic acid (16:2n-7, 16:2n-4) also appeared. Phosphatidylinositol, the lipid with the highest palmitic acid content in controls, also had the highest content of palmitic or stearic acids, depending on the mutant type, suggesting that saturated fatty acids are needed for its physiological function. Positional analysis showed that mutant oils have very low content of saturated fatty acids in the *sn*-2 position of triacylglycerols, between the content of olive oil and cocoa butter.

Lipids 32, 833–837 (1997).

There is currently a controversy over the health effects of semi-solid fats used in margarine and related products. Because most vegetable oils used by industries are liquid at room temperature, they must be modified by hydrogenation (1) or transesterification and then usually fractionated. Hydrogenation produces *trans* and positional isomers of fatty acids that, it has been suggested, may be related to heart disease (2,3). Transesterification increases the saturated content at position *sn*-2 of triacylglycerols, thus increasing its atherogenic effect (4). Vegetable fats, like cocoa butter, with high saturated fatty acid content but almost exclusively at positions *sn*-(1 + 3) of triacylglycerols, seem to be at least neutral on serum lipids in humans (5,6). To avoid the problems associated with chemically modified fats, a highly saturated fatty acid fat with the typical plant triacylglycerols structure should be available to the food industry.

On the other hand, a general problem found by researchers that want to study the effect of one specific fatty acid on health is the lack of a complete set of oils differing in the content of only one major fatty acid and with the same triacylglycerols structure. Oils with different fatty acid compositions from a single source could be very helpful for this purpose. In a previous mutagenesis program several sunflower mutants with either high stearic acid or palmitic acid content in normal or high oleic acid background were selected (7,8). In this work we have characterized the lipids from these mutants.

MATERIALS AND METHODS

Plant material and growth conditions. Sunflower (*Helianthus annuus* L.) seeds from the mutant lines CAS-3, CAS-4, CAS-8, with high stearic acid content, and CAS-5, CAS-12, with high palmitic acid content (7,8) were used in this work. The control seeds were from the public lines RHA-274, with normal fatty acid content, and HA-OL9 (9) derived from Pervenets (10), with high oleic acid content. Plants were cultivated in growth chambers at 25/15°C (day/night), 16-h photoperiod, and 300 μE m^{-2} s^{-1} light intensity. Seeds for analysis were harvested 35 d after flowering and processed immediately. Three replicates were made for each experiment; a different capitulum was taken and analyzed independently for each replicate.

Lipid extraction and separation. Seeds were peeled, and then about 500 mg were ground in a screw-cap glass tube (10 × 13 mm) with a pestle and sand. Total lipids were extracted (11) and separated into triacylglycerols, diacylglycerols, and polar lipids fractions on thin-layer chromatography (TLC) silica gel plates, thickness 0.25 mm, developed with hexane/ethyl ether/ formic acid (75:25:1, by vol). The polar lipids were separated on TLC silica gel plates developed with chloroform/methanol/acetic acid/H_2O (85:15:10:3.5, by vol) or $(NH_4)_2SO_4$-impregnated silica gel plates (12) developed with acetone/benzene/H_2O (90:30:10, by vol). Individual polar lipids were identified by comparison with known standards. TLC plates were partially covered with a glass plate and exposed to iodine vapors; unexposed lipid fractions were scraped off the plates and eluted from silica with chloroform/methanol (1:2, vol/vol).

Lipase hydrolysis. For triacylglycerols fatty acid positional analysis, 10 mg of purified triacylglycerols were hydrolyzed with 2 mg pancreatic lipase (13) in 1 mL of 1 M Tris buffer pH 8, with 0.1 mL $CaCl_2$ (22%) and 0.25 mL deoxycholate (0.1%). After approximately 60% of the triacylglycerols were

hydrolyzed (1–2 min), the reaction was stopped by adding 0.5 mL of 6 N HCl. The lipids were extracted with 1.5 mL ethyl ether three times. The reaction products were separated by TLC as already indicated. The free fatty acids and *sn*-2-monoacylglycerols bands, representing, respectively, the positions 1 + 3 and 2 of triacylglycerols, were scraped off the plate and transmethylated. The procedure was checked by comparing the fatty acid composition of the original triacylglycerols and those remaining after the partial hydrolysis.

Lipid analysis. Fatty acid methyl esters were obtained from the isolated lipids (14) by heating the samples at 80°C for 1 h in a 3-mL solution of methanol/toluene/H_2SO_4 (88:10:2, by vol). After cooling, 1 mL of heptane was added and mixed. The fatty acid methyl esters were recovered from the upper phase, then separated and quantified using a Hewlett-Packard 5890A gas chromatograph (Palo Alto, CA) with a Supelco SP-2380 capillary column (30-m length; 0.32-mm i.d.; 0.20-µm film thickness) of fused silica (Bellefonte, PA). Hydrogen was used as carrier gas. The fatty acids were identified by comparison with known standards. Unusual fatty acids (16:1 and 16:2) were identified by gas–liquid chromatography–mass spectrometry of their picolinyl esters, using electron impact ionization at 70 eV (15,16).

RESULTS

The fatty acid composition of seed lipids from the five sunflower mutants and the two control lines is shown in Table 1. The controls were RHA-274, with normal fatty acid composition, and the high oleic acid line HA-OL9, with a very low level of linoleic acid (Table 1, Part A). The palmitic acid content of the control lines was 5–7% in total and neutral lipids

[a]SD < 2.5% of mean value. [b]— = <0.2%.

and around 12% in polar lipids, while the content of stearic acid was 4–5% in all lipids. Linoleic acid was the main component of RHA-274, followed by oleic acid. In contrast, oleic acid represented 77–88% in the different lipids of HA-OL9. Linolenic, arachidic, and behenic acids were minor components of these lines. Two types of sunflower mutants were studied: two lines with high palmitic acid content in normal (CAS-5) and high oleic acid (CAS-12) backgrounds, respectively (Table 1, Part B), and three lines with high stearic acid content (CAS-3, CAS-4 and CAS-8) in normal background (Table 1, Part C).

The high palmitic acid mutants contained, in the total seed lipids, five times (30%) the palmitic acid normally found in control lines (Table 1, Part B). The highest increase was observed in triacylglycerols which represent approximately 94% of seed lipids (17). The palmitic acid content of polar lipids and diacylglycerols also increased, particularly the polar lipids of CAS-5 (27%). In both mutants palmitic acid increased mainly at the expense of oleic acid. The percentage of linoleic acid, however, remained almost unchanged in the different lipids of CAS-5 and increased in those of CAS-12 compared with RHA-274 and HA-OL9, respectively. Palmitoleic acid (identified as 16:1n-7), which only occurred in trace amounts in the control lines (Table 1, Part A), was present in the high palmitic mutants, mainly in triacylglycerols (4.6–7.6%). Palmitolinoleic acid (identified as 16:2n-7, 16:2n-4), which is not normally found in sunflower seed lipids, was present in these mutants in minor amounts. The other minor fatty acid components remained unchanged.

The stearic acid mutants can be divided into two types depending on the stearic acid level in total seed lipids (Table 1, Part C): one with 26% (CAS-3) and two with 12% (CAS-4 and CAS-8). The stearic acid content increased in all lipids of these mutants compared with the controls. As in the high palmitic mutants, the higher increase of stearic acid was observed in triacylglycerols (five times the value of control line RHA-274 in the case of CAS-3 and 2.5 times in the case of the other two mutants). In CAS-3 and CAS-4 the increase in stearic acid was mainly at the expense of oleic acid and, to a minor extent, of linoleic acid. In CAS-8 linolenic acid occurred at the expense of oleic acid. No changes were observed in the minor fatty acids.

Because of the very different fatty acid composition of these mutant lines it was possible to study the specificity of fatty acids for the different polar lipids. Table 2 shows the fatty acid composition of main polar lipids from control and mutant lines. The minor fatty acids have not been considered, as no differences were found either within the mutants or between these and the control lines. Phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, monogalactosyldiglyceride, and digalactosyldiglyceride were present as the main components of the polar lipid fraction of all lines containing high levels of linoleic acid (RHA-274, CAS-5, CAS-3, CAS-4 and CAS-8). Interestingly, phosphatidylcholine was almost absent from the lines containing high levels of oleic acid (HA-OL9 and CAS-12) and thus no reliable fatty acid analysis could be done. Monogalactosyldiglyceride and digalactosyldiglyceride had about 2–4% of linolenic acid in all cases (data not shown).

All polar lipids from the mutants had increased palmitic (Table 2, Part B) or stearic (Table 2, Part C) acids compared with the corresponding control lines (Table 2, Part A). Nevertheless, the relative contents of these acids depended on the mutant phenotype. As a general rule an increase of palmitic or stearic acid in any lipid was accompanied by some decrease of, respectively, stearic or palmitic acid, thus increasing the total saturated fatty acid content and changing the

palmitic/stearic ratio. A special behavior was observed in phosphatidylinositol. In all mutant lines it had the highest saturated fatty acid content, more than in the control lines, in which it was already high. In the case of the high palmitic mutants 16:0 increased to up to 40%, while stearic acid decreased to 3%. In the high stearic mutants there was a very high content of stearic acid, 41% in CAS-3 or 26–27% in CAS-4 and CAS-8, accompanied by a decrease in the palmitic acid content to 16%. Interestingly, the total saturated acid content in phosphatidylinositol remained fairly constant (approximately 45%) in the different lines, with the exception of the high oleic line HA-OL9 (27.6%) and the very high stearic line CAS-3 (57.4%). In the former, at least 7.4% saturated fatty acids must be at *sn*-2 position of phosphatidylinositol.

The nutritional quality of an oil is determined by its fatty acid composition as well as by the distribution of these fatty acids in triacylglycerols. Table 3 shows the positional analysis of triacylglycerols from control and mutant sunflower seeds. All sunflower lines had very low saturated fatty acid contents in the *sn*-2 position of triacylglycerols. Even in the case of the mutants with high palmitic or stearic acid content, these acids were located almost exclusively at the *sn*-(1 + 3) position. The only important fatty acids found in the *sn*-2 position were oleic and linoleic acids. As expected, in control and mutant lines with normal background, oleic acid was almost evenly distributed while linoleic acid was the main fatty acid at the *sn*-2 position. In the high oleic lines, this position was occupied almost exclusively by oleic acid (over 92%). The behavior of 16:1 in the high palmitic mutants, CAS-5 and CAS-12, was different from that of 18:1 despite the fact that both acids are Δ9 monounsaturated. This acid was mainly located at *sn*-(1 + 3) position, although it was also present in the *sn*-2 position.

DISCUSSION

The mutant sunflower lines presented here contained high levels of saturated fatty acids in the seed oil (up to 30–35%) without undesirable rearrangements in the biosynthetic pathway (Table 1). This is important, as the mutants can be used to develop commercial sunflower lines with high agronomic value. Sometimes, in using mutagenic or molecular biological techniques to modify seed fatty acid composition, some unpredictable responses have been found. For instance, mutant soybean lines with increased contents of palmitic or stearic acids (18) also produced increased levels of linolenic acid, which reduce oil stability. Transgenic canola (19) obtained using anti-mRNA construct to block stearate desaturation, thus raising the stearic acid content in the seeds, also showed increased levels of the products of stearate elongation—arachidic, behenic, and lignoceric acids (10%)—and induced linolenic acid biosynthesis (rising to 23%).

The saturated fatty acids increased in all lipid classes, mainly at the expense of oleic acid, while maintaining or even increasing linoleic acid content. The fatty acid composition of polar lipids seems to be fully compatible with the functioning of biological membranes during seed formation. The fatty acid composition seems to be critical in phosphatidylinositol. This lipid always contained high levels of saturated acids (approximately 45%, except in one case). In the normal and high oleic lines palmitic acid was the main saturated fatty acid. In the high palmitic and high stearic lines the increase of the corresponding saturated fatty acid occurred at the expense of the other. These results suggest that molecular species containing one saturated and one unsaturated acid are needed to fulfill the specific functions of phosphatidylinositol and also that the requirements should not be strict, as palmitic can be a substitute for stearic acid in CAS-3 and linoleic for oleic acid in CAS-12. Phosphatidylcholine, the main polar lipid in sunflower seed and substrate of the oleate desaturase, was practically absent from high oleic lines. By taking into account that oleoyl-phosphatidylcholine desaturase activity could not be detected in developing high oleic sunflower seeds (20), the results suggest that the availability of phosphatidylcholine was modified in the high oleic mutant. The 16:1 formation in high palmitic mutants must be due to the stearate desaturase activity inside the plastid over palmitoyl-acyl carrier protein as a substrate (21). This acid was shown to occur in all lipids of the high palmitic CAS-5 and CAS-12 lines, mainly at *sn*-(1 + 3) position of triacylglycerols. Outside the plastid, 16:1 could be desaturated to 16:2. This acid occurred in CAS-5 but not in CAS-12, thus suggesting the action of the oleoyl-phosphatidylcholine desaturase. These mutants will allow the study of polar lipid functions in seed (phosphatidylcholine in high oleic mutants or phosphatidylinositol in highly saturated fatty acid mutants) and their specificity for fatty acid composition. The different behavior of palmitoleic and oleic acids in triacylglycerols positional analysis (Table 3) shows that the specificity of the sunflower *sn*-2-glycerol-acyltransferase depends not only on the unsaturation degree but also on the chain length.

The most important quality of the oils of these mutants is that the saturated fatty acids are excluded from the *sn*-2 position of triacylglycerols (Table 3), like most vegetable oils. Fatty acids at this position are preferentially absorbed through the intestinal wall (22) while those liberated by lipase hydrolysis from positions *sn*-(1 + 3), particularly saturated fatty acids, may be excreted. Several mechanisms have been proposed to explain the preferred excretion of saturated free fatty acids, including the formation of insoluble calcium/magnesium salts or acid–calcium soap complexes (23). This is important because there is controversy about the biologic effects of the different fats. Cocoa butter contains high levels of both stearic (35%) and palmitic (25%) acids but these, as would be expected, are almost exclusively located at positions *sn*-(1 + 3). In contrast, an animal fat, namely lard, also contains high levels of palmitic (27%) and stearic (16%) acids, but at position *sn*-2 it contains 65% and 4%, respectively. Palm oil, on the other hand, contains high levels of palmitic acid (46%) and around 23% palmitic acid at position *sn*-2 (6). The impaired absorption of saturated fatty acids could explain the neutral effect of cocoa butter on serum lipids in humans (5). Interestingly, the rearrangement by interesterification of palm oil and lard increased and decreased, respectively, the negative biologic effects of these products on rats (6). The studies on the effects of the intake of saturated fatty acids have been carried out using native or interesterified fats as already indicated. Until now, no natural fat with high stearic acid content almost exclusively in positions *sn*-(1 + 3) has been available. By using oils from mutants CAS-5 and CAS-3, the effects of palmitic acid vs. stearic acid could be studied in a high linoleic background. The effects of palmitic acid in high linoleic or high oleic lines could be determined using oils from mutants CAS-5 and CAS-12. A high stearic acid line with high oleic background is being developed and could be added to these studies.

Lipids and Ultrastructure of *Thraustochytrium* sp. ATCC 26185

J.D. Weete*, H. Kim, S.R. Gandhi, Y. Wang, and R. Dute

Department of Botany and Microbiology, Alabama Agricultural Experiment Station, Auburn University, Auburn, Alabama 36849

ABSTRACT: As a representative of a genus with species considered to be potential commercial producers of the nutritionally important polyunsaturated fatty acid docosahexaenoic acid (DHA), *Thraustochytrium* sp. ATCC 26185 was investigated to determine its potential for DHA production and lipid composition. Cells from liquid shake cultures contained 32% (w/w) lipid, 18% of which was nonsaponifiable lipid. The major saturated fatty acids (14:0 and 16:0) comprised up to 59% of the total fatty acids, and DHA was up to 25% after 6 d incubation. Squalene represented 63% of the nonsaponifiable lipid, and cholesterol composed 41% of the total sterols. The phospholipids expected for eucaryotic microbes were detected with phosphatidylcholine as the major phospholipid at 76% of the total. The ultrastructure of this species was similar to other *Thraustochytrium* species except that the cells did not have surface scales and they contained unusual membrane-like structures that appeared to be associated with oil formation.
Lipids 32, 839–845 (1997).

The genus *Thraustochytrium* contains unicellular, zoospore-producing species of historic uncertain taxonomic affinity that have been isolated mainly from coastal marine environments (1,2). However, the thraustochytrids recently have been placed in the stramenopila phylum Labyrinthulomycota (3).

Thraustochytrium species have attracted recent interest because they produce the polyunsaturated fatty acid docosahexaenoic acid [22:6 (4,7,10,13,16,19); DHA] (4,5), which is one of the n-3 fatty acids, along with eicosapentaenoic acid [20:5 (5,8,11,14,17)], believed to provide the health benefits associated with the consumption of certain marine fish and oils therefrom (6). DHA accumulates in the membranes of nervous, visual, and reproductive tissues (7), and is believed to be particularly important in infant nutrition (8). Since the DHA content of fish oil is variable and may not be a satisfactory long-term source of this fatty acid, and fish oil contains arachidonic acid [20:4 (5,8,11,14)] as well as eicosapentaenoic acid, alternate economic sources of this fatty acid have been sought. *Thraustochytrium* may represent such a source of DHA (4,5,9–11).

In spite of the attention given to this genus with respect to DHA production, to our knowledge other major components (e.g., sterols, phospholipids) of the lipid from these organisms have not been reported previously. Therefore, in this communication we are reporting the lipid composition of *Thraustochytrium* sp. ATCC 26185. In addition, we have observed in cells of this species the presence of unusual membrane-like structures that appear to be associated with lipid formation.

MATERIALS AND METHODS

Source of the fungus and culture conditions. Unless noted otherwise, *Thraustochytrium* sp. ATCC 26185 was cultured in 250-mL Erlenmeyer flasks containing 100 mL of the following medium at 28°C, in low intensity fluorescent light alternated diurnally with darkness, and rotary shaking at 120 rpm: 2% (wt/vol) glucose, 0.3% (wt/vol), yeast extract, and 1% (vol/vol) mineral salts solution (12) in reconstituted sea water. Inoculations were made with 5 mL of a 6-d culture grown as described above. Cells were harvested by centrifugation at $2,000 \times g$ for 25 min, washed once with 100 mL of cold reconstituted sea water, dried by lyophilization overnight, and stored at −20°C prior to extraction. Cells that separated into pellets and a floating layer when centrifuged were combined prior to drying, storage, and analysis.

Lipid extraction and estimation of total acyl lipid. Total lipid was extracted from dry cells (*ca*. 25 mg) using the procedure of Bligh and Dyer (13) that was modified according to Kates (14), but with twice the solvent volume to cell dry weight ratio as that recommended by the latter. All extraction and subsequent manipulations of the samples were conducted at low-light intensity. The amount of lipid extracted from the cells was determined gravimetrically. For monitoring changes over the course of culture development, the amount of total acyl lipid was calculated from gas chromatographic data when the methyl ester derivatives of the fatty acid methyl esters (FAME) were prepared directly from the cells after adding 23:0 as an internal standard fatty acid (see below).

Thin-layer chromatography (TLC). Individual neutral lipids were separated from polar lipids by TLC on glass plates (20 cm × 20 cm) coated with a 250-μm layer of silica gel 60

Abbreviations: DHA, docosahexaenoic acid; FAME, fatty acid methyl esters; GLC, gas–liquid chromatography; MS, mass spectrometry; ^{31}P NMR, pulsed nuclear magnetic resonance; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography; TMS, trimethylsilyl.

(Whatman, Maidstone, NJ). The plates were developed twice in hexane/diethyl ether/acetic acid (79:20:4, by vol), and unless the lipids were to be recovered for further analysis, the individual lipid classes were visualized in iodine vapor. For the recovery of individual lipid classes, silica gel was removed from the plates and washed with chloroform/methanol (2:1, vol/vol). Individual phospholipid classes were separated by TLC as described above except that the plates were developed in chloroform/acetone/methanol/acetic acid/water (30:40:10:10:5, by vol). Lipid classes were identified by comparison of their R_f values with those of corresponding lipid standards (Nu-Chek-Prep, Elysian, MN).

Sample derivatization and gas–liquid chromatographic analysis (GLC). For the preparation of methyl ester derivatives of the total fatty acids, a portion of total lipid (*ca.* 5 mg) was heated with 3.0 mL of methanolic-HCl at 80°C for 1 h, and FAME were then extracted with hexane (14). In the cases where the total fatty acids were derivatized directly without extraction of the lipid, 1.5 mL methanolic base (Supelco, Inc., Bellefonte, PA) was added to about 20 mg dry cells, the mixture was heated at 70°C for 15 min, and the FAME were then recovered as before. The FAME were analyzed by gas chromatography as described previously (15), except that the gas chromatograph (Varian 3300, Palo Alto, CA) was equipped with a 30 m × 0.25 µm fused silica capillary column coated with DB-225 (50% cyanopropyl methyl 50% phenyl silicone) (J&W Scientific, Folsom, CA). Injector and detector temperatures were 250°C, and the oven temperature was programmed from 140 to 160°C at 2°C/min, 160 to 180°C at 10°C/min, and 180 to 220°C at 1°C/ min. FAME were identified by comparison of their retention times relative to methyl tricosanoate (23:0) with those of authentic standards obtained from Nu-Chek-Prep, and they were quantified by the internal standard method using 23:0 as the standard.

To obtain the nonsaponifiable lipid, a portion of the total lipid (*ca.* 200 mg) was heated for 2.5 h in 8 mL of 95% ethanol containing 0.8 mL of 33% (wt/vol) KOH (14). The nonsaponifiable lipids were removed from the hydrolysate by washing it three times with 5 mL of hexane. The combined hexane washes were washed twice with 5 mL 3% KOH, twice with 5 mL H_2O, and then brought to dryness under a stream of nitrogen gas. The amount of nonsaponifiable lipid was determined gravimetrically.

Sterols in the nonsaponifiable fraction were analyzed by gas chromatography as their trimethylsilyl ether (TMS) derivatives. Steryl-TMS derivatives were prepared by heating a portion (*ca.* 20 mg) of the nonsaponifiable lipid obtained as described above with 1 mL bis(TMS) trifluroacetamide (99:1, vol/vol) trimethylchlorosilane (Supelco Inc., Bellefonte, PA) at 70°C for 25 min. The solvent was evaporated under nitrogen gas, and the samples were diluted with hexane prior to analysis by GLC. The gas chromatograph (Hewlett-Packard model 5710, Palo Alto, CA) was equipped with a 25-m fused silica DB-5 column (Applied Science Laboratories, State College, PA). Injector and detector temperatures were 300°C and the oven temperature was 280°C isothermal. Sterols were quantitated using the TMS derivative of 5-dihydrocholesterol as the external standard.

GLC–mass spectrometry (MS). GLC–MS analysis of total sterols was performed using a VG 70E (Manchester, England) high-resolution mass spectrometer linked to a Varian 3700 gas chromatograph equipped with a 25-m DB-5 fused silica capillary column as the sample inlet, and operated in the electron impact mode at 70 eV with the source temperature at 200°C.

Pulsed nuclear magnetic resonance (^{31}P NMR) analysis of phospholipids. About 60 mg of total lipid was dissolved in 25 mL chloroform and washed with 25 mL of the K^+/Na^+ salt of EDTA in separatory funnel by shaking vigorously at 30-min intervals over 4 h. The K^+/Na^+ EDTA salt (0.2 M, pH 6.0) solution was prepared according to Seijo *et al.* (16). Emulsions formed during the washing process were disrupted by the addition of KCl (*ca.* 2 g). The lower chloroform phase containing the lipid was collected, and the solvent evaporated under nitrogen gas. The lipid obtained after washing was dissolved in 0.5 mL of chloroform (reagent grade) containing 5% benzene-d_6 and 3.1 mg of trimethylphosphate as an internal reference followed by the addition of 0.25 mL methanol (reagent grade) containing 0.2 M aqueous Cs-EDTA at pH 6.0. The solution was mixed by vortexing, filtered through a 0.2 µm Acrodisc nylon filter (Gelman Sci., Ann Arbor, MI), and then transferred to a 5-mm NMR tube (Wilmad Glass Co., Buena, NJ). ^{31}P NMR analysis was conducted using a Bruker 250 AM system (Karlsruhe, Germany) operated at 101.3 MHz. Cs-EDTA phospholipid NMR reagent was prepared according to Meneses and Glonek (17).

Electron microscopy. Cell pellets were preserved in a 1:1 (vol/vol) mixture of growth medium and fixative (glutaraldehyde in sodium cacodylate buffer) such that the final concentrations were 2% glutaraldehyde in 0.05 M buffer (pH 7.0). The duration of fixation was 4 h, the first 30 min at room temperature, and the remainder of the time at 4°C. This was followed by one wash of the cells in growth medium and 0.1 M buffer (1:1, vol/vol) and two washes in 0.05 M buffer. All buffer washes were at 4°C. Postfixation was carried out in cold OsO_4 (1%) in 0.05 M buffer for 3 h. Following washes in cold buffer and then distilled water, pellets were embedded in 2% agar and, when necessary, diced into 1-mm cubes. Cells were then stained en bloc in 0.5% aqueous uranyl acetate for 2 h at 4°C, dehydrated in an ethanol/propylene oxide series, and embedded in Spurr's resin (18). Ultrathin sections (65 nm) were made, mounted on nickel grids, and stained further with uranyl acetate and lead citrate. Specimens were viewed with a Zeiss 10 transmission electron microscope (Thornwood, NY) at 60 kV.

RESULTS AND DISCUSSION

Growth and lipid content. Biomass production of *Thraustochytrium* sp. in shake flask culture increased linearly over the first 4 d of incubation and peaked at 7.5 g/L at 7 d after inoculation. The solvent extractable lipid content of cells cul-

tured under these conditions for 6 d was 32% of the cell dry weight, 18% of which was nonsaponifiable lipid. When grown under the same conditions, but without basal salts in the medium, biomass was reduced by 52%, lipid content by 14%, and nonsaponifiable lipids by 68% compared to cultures grown with the basal salts. Bajpai *et al*. (5) found that *T. aureum* (ATCC 34304) produced up to 25% lipid while Kendrick and Ratledge (19) reported that the same strain of *T. aureum*, and *T. roseum*, produced only 10 and 0.5% total lipid, respectively.

Thraustochytrium species have been reported to be responsive to light (20). When grown in yeast extract/glucose medium containing basal salts with low-intensity diurnal, fluorescent light, the cultures were a pale yellow color. The cultures of *Thraustochytrium* sp. grown in the light (538 lux) were orange. Also, cultures from the light had almost twofold more biomass than cultures incubated for 6 d in the dark, but there was essentially no difference in the total lipid or the relative proportion of DHA (data not shown).

The total fatty acid profile of *Thraustochytrium* sp. was characterized by the following: (i) relatively high saturated fatty acid content (14:0, 15 to 19%; 16:0, 32.0 to 41%), (ii) very low proportions of 18 and 20 carbon fatty acids, and (iii) high 22 carbon chain length polyunsaturated fatty acid (PUFA) content and DHA being the predominant PUFA at 25 to 32% of the total fatty acids over the 13-d growth period. Since there was little change in the proportion of fatty acids over the 13-d growth period, the fatty acid composition of cells from 6-d-old cultures in Table 1 is considered to be representative. In such cultures, the relative amounts of DHA in the polar lipid and triacylglycerols were similar (data not given).

[a]18:2, 20:1, 20:2, 22:1, 22:2, and 22:3 were not detected.

Shaw (21) recognized that the more primitive fungi, including those taxa now classified as stramenopiles and no longer considered to be fungi, possess both the n-3 and n-6 pathways of PUFA biosynthesis which are both operational in *Thraustochytrium* sp. DHA is the apparent end product of the n-3 pathway, and 22:5 (4,7,10,13,16) appears to be the end product of the n-6 pathway. Previously, a 22:5 with unspecified double-bond location (4) and 22:5 n-3 (19) have been reported for *T. aureum*. The two isomers of 22:5 can be separated by GLC, and the retention time of an authentic 22:5n-6 standard matched that from *Thraustochytrium* sp. Also, its identity as a 22:5 pentaene has been confirmed by GLC–MS (data not shown). Eucaryotic microbes generally are not known to produce n-6 PUFA beyond 20 carbon atoms and four double bonds (22,23).

Squalene and sterols. The identity of squalene as the major component of the nonsaponifiable fraction (Table 2) was confirmed by comparison of GLC retention times of the sample and an authentic standard, and by GLC–MS. The mass spectrum of this compound was similar to that of a squalene standard with a molecular ion at *m/z* 410. Squalene is not known to typically accumulate in such high amounts in fungal cells, i.e., 35 mg squalene per g dry weight of cells; however, it was a major component of lipid from *Rhizopus arrhizus* grown in liquid shake culture (24).

Sterols represented 38% of the nonsaponifiable lipid. At least 13 substances detected in *Thraustochytrium* sp. by GLC are believed to be sterols. The major sterol was cholesterol at 41% of the total sterols (Table 2). The mass spectrum of this compound matched that of a standard TMS derivative of cholesterol and was consistent with previously published spectra of this sterol (25).

The component representing 7.6% of the total sterols had a molecular ion at *m/z* 470, suggesting that it was a C_{28} diene, and a fragmentation pattern shown in Table 2. Based on the prominent $M^+ - 129$ fragment, the nuclear double bond is believed to be at the C-5(6) position, and the second double bond in the side chain, probably the C_{22} rather than C-24(28) position since fragments at *m/z* 296 or 386 were not detected (see below). An additional C_{28} diene was detected at 1.5% of the total sterols with double bonds in the C-5(6) and C-24(28) positions. The latter double-bond assignment is based on the presence of strong fragment ions at *m/z* 296 and 386 (25).

The molecular ion at *m/z* 484 for the sterol representing 21% of the total sterols suggested that this sterol is a C_{29} diene. The GLC retention time and mass spectrum were similar to that of the TMS derivative of an authentic 24-ethylcholesta-5,22-dienol standard, and the mass spectrum was similar to a previously published mass spectrum of the TMS derivative of this sterol (25).

The component representing 12% of the total had a molecular ion of *m/z* 482, suggesting that it is a C_{29} triene. The mass spectrum of this sterol had several major fragment ions anal-

TABLE 2
Squalene and Sterols of *Thraustochytrium* sp. ATCC 26185

Component	Major fragment ions (*m/z*)	Relative percentage[a] (%)
Squalene	410 (M^+)	62.6 —
Sterols		
Cholest-5-enol (cholesterol)	458 (M^+), 368, 353, 329, 255, 129 (100%)	15.1 (41.3)
24-Methyl-cholesta-5,22-dienol (7-dihydroergosterol)	470 (M^+), 380, 365 351, 341, 325, 255 129 69 (100%)	2.8 (7.6)
24-Methyl-cholesta-5,24 (28)-dienol (24-methylene Cholesterol)	470 (M^+) 386, 380, 365, 343, 341, 296, 281, 129 (100%)	0.5 (1.5)
24-Ethyl-cholesta-5,22-dienol	484 (M^+), 394, 379, 355 ($M^+ - 129$), 351 255, 213, 129, 83	4.5 (12.4)
24-Ethyl-cholesta-5,7,22-trienol	482 (M^+), 392, 394, 377 (100%) 351, 253	8.5 (20.7)
Unknowns (8)		6.0 (16.5)

[a]Values are the percentage of total nonsaponifiable fraction; those in parentheses are percentage of total sterols.

ogous to those of the TMS derivative of ergosterol ($C_{28}\Delta^{5,7,22}$) (25) except with 14 higher mass units. For example, *m/z* 377 is analogous to *m/z* 363 in the mass spectrum of ergosterol, *m/z* 351 (100%) analogous to *m/z* 337, and *m/z* 392 to *m/z* 378. Therefore, in the absence of *m/z* 296 and 386, which are indicative of a C-24(28) double bond, this sterol may be the C_{29} analogue of ergosterol, i.e., 24-ethyl-cholesta-5,7,22-trienol. This sterol, described as 7-dehydrostigmasterol, has been detected in the soil amoeba *Acanthamoeba* (26).

The sterol composition of several other *Thraustochytrium* species *(T. roseum, T. striatium, T. virsugence,* and *T. aureum)* was very similar to that of *Thraustochytrium* sp. (data not given).

Phylogenetically primitive, eucaryotic microorganisms vary considerably in the dominant sterol both within and between the various major taxa (15,27). Ergosterol, which is considered to be the "fungal sterol" (28), is characteristically absent from the stramenopila such as Oomycota and Hypochytridiomycota where dominant sterols are cholesterol and/or Δ^5 C_{28} and/or Δ^5 C_{29} sterols with or without double bonds in other positions (28–30). Otherwise, there seems to be no apparent pattern to sterol distributions among these taxa except that fucosterol [24-ethyl-cholesta-5, 24(28E)-dienol] seems to be found in the Oomycota as well as phaeophycean algae (27).

Phospholipids. Phospholipid represented about 8% of the total lipid of *Thraustochytrium* sp. cells from 6-d cultures. The major phospholipid was phosphatidylcholine (PC) at 76% of the total phospholipids (Table 3). Other phospholipids detected were phosphatidylethanolamine (PE) (2%), phosphatidylglycerol (1%), and diphosphatidylglycerol (4%). Lysophosphatidylcholine and phosphatidylinositol were not resolved by ^{31}P NMR in this study, but collectively represented 17% of the total. The presence of both of these phospholipids was confirmed by TLC (data not shown). Phosphatidic acid was not detected in cells cultured in yeast extract/glucose medium with mineral salts, but it was a minor component of cells grown in other media. PC and PE are the most common eucaryotic microbial phospholipids but vary widely in relative proportions between species (23). It is unusual, but not unknown, for PC to be in such high relative amounts and PE to be in such low amounts.

Ultrastructure. Thraustochytrium sp. cells were heterogeneous in size and appearance, with diameters ranging from about 6 to 21 µm, and the cytoplasm appeared granular or filled with multiple oil globules. Cells collected at 6 d after inoculation were multinucleate, spherical unicells (Fig. 1A and B). Up to nine nuclear profiles were observed in a given thin section of a single cell. The presence of condensed chromosomes and spindle fibers in some sections indicated that some of the cells were undergoing mitosis when fixed, and light microscope observations indicated that such coenocytes eventually released smaller cells (data not shown).

Many, but not all, subcellular features of this species were similar to those observed previously for other species of this genus with numerous mitochondrial profiles containing tubular cristae (1,32) (Fig. 1 A and C). Each nucleus was associ-

TABLE 3
Phospholipids of *Thraustochytrium* sp. ATCC 12685

Phospholipid	Chemical shift[a] (ppm)	Relative percentage (%)[b]
Phosphatidylcholine	–0.84	76.2 ± 0.1
Lysophosphatidylcholine + phosphatidylinositol	–0.35	16.9 ± 2.5
Phosphatidylethanolamine	0.08	2.3 ± 0.6
Phosphatidylglycerol	0.54	1.3 ± 0.8
Diphosphatidylglycerol	0.22	3.7 ± 0.7

[a]Chemical shift values are calculated relative to that for phosphatidylcholine assigned the average value of –0.84. Amounts of individual phospholipids were determined using the internal standard Triphenylphosphate.
[b]Values are the averages of two analyses plus/minus the standard deviation.

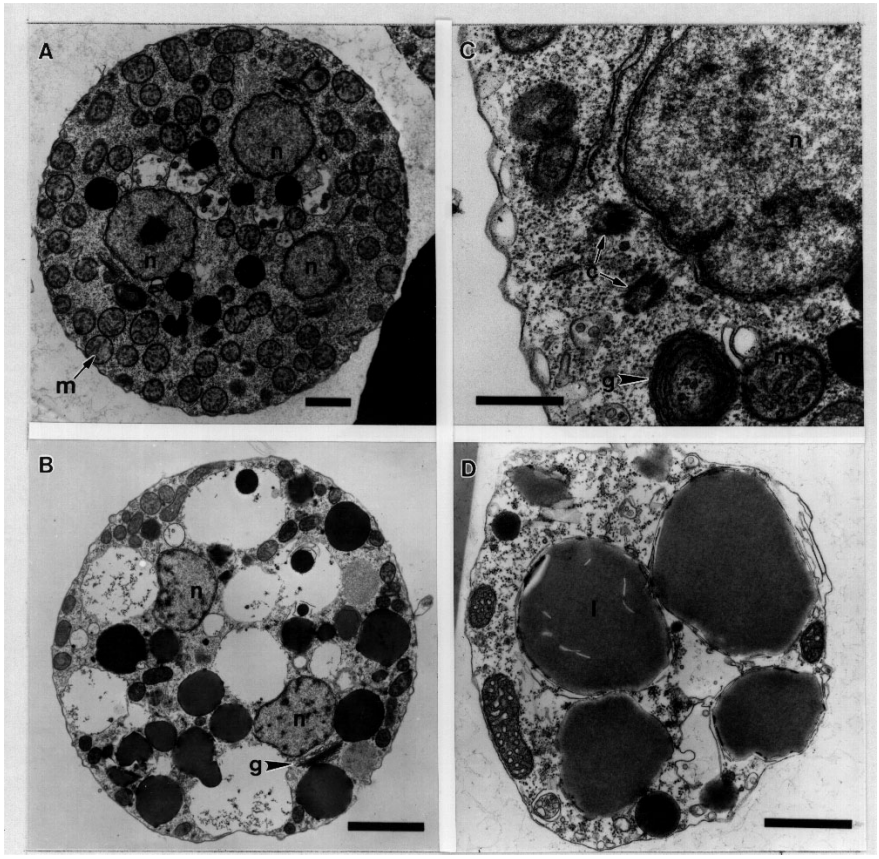

FIG. 1. Transmission electron micrographs of *Thraustochytrium* sp. ATCC 26185 cells. The cells are multinucleate (n, panels A and B) and also contain mitochondria (m) with tubular cristae, Golgi bodies (g), and centrioles © (panels B and C). Prominent lipid bodies (1, panel D) exist in all cells. Bar = 1 μm in panels A and D, 2 μm in panel B, 0.5 μm in panel C.

ated with centrioles (Fig. 1C) and Golgi bodies (Fig. 1 B and C). Species of *Thraustochytrium* are known to form rhizoids or ectoplasmic nets from organelle complexes known as sagenogenetosomes (1,32), but the cells of this species exhibited no rhizoids either in liquid medium or when cultured on semisolid agar medium. Also, the cells were naked with neither cell walls nor scales covering the plasma membrane. This latter observation is of interest in that Goldstein *et al*. (31) observed that the plasma membrane of *T. aureum* was covered by a wall consisting of "tangentially arranged laminations." Darley *et al*. (33) showed that the wall of an unnamed *Thraustochytrium* species consisted of circular scales manufactured within the Golgi apparatus, and that the composition of the scales differed from those of the closely related *Schizochytrium aggregatum*. It is possible , although unlikely, that scales were present in *Thraustochytrium* sp. but were detached during centrifugation to harvest the cells. Experiments are underway to examine this possibility.

Consistent with the results of lipid analyses described above, the cells contained numerous cytoplasmic bodies (Fig. 1D) which have been confirmed as lipid bodies by staining with Sudan Black B. These lipid bodies were associated with branched, hollow membrane-like structures that appeared crystalline in their angularity (Fig. 2A). These structures seemed to be associated with lipid synthesis and deposition (Fig. 2A) and, with continued lipid deposition, they became internalized within the lipid bodies (Fig. 2B). Detailed sectional views (Fig. 2C) indicated that the boundary layer of these structures was not a true unit membrane. Instead, it appeared as electron-opaque lines less than one-half the thickness of the plasma membrane. As the structures became internalized during lipid body enlargement, their boundaries became indistinct (Fig. 2D) which seemed to be followed by loss of the internalized structures (Fig. 1D).

The presence of lipid bodies (or osmiophilic droplets) in *Thraustochytrium* and related genera has been observed by light (20,34) and transmission electron (1,31) microscopy. However, until now, no mention has been made of the membrane-like structures in species of this genus. Whether they are unique to the organism of this study is not known, but they are found consistently in cells cultured in different media and fixed at different times during the growth cycle.

ACKNOWLEDGMENTS

This work is a result of research sponsored, in part, by the National Oceanic and Atmosphere Administration (NOAA), the U.S. Depart-

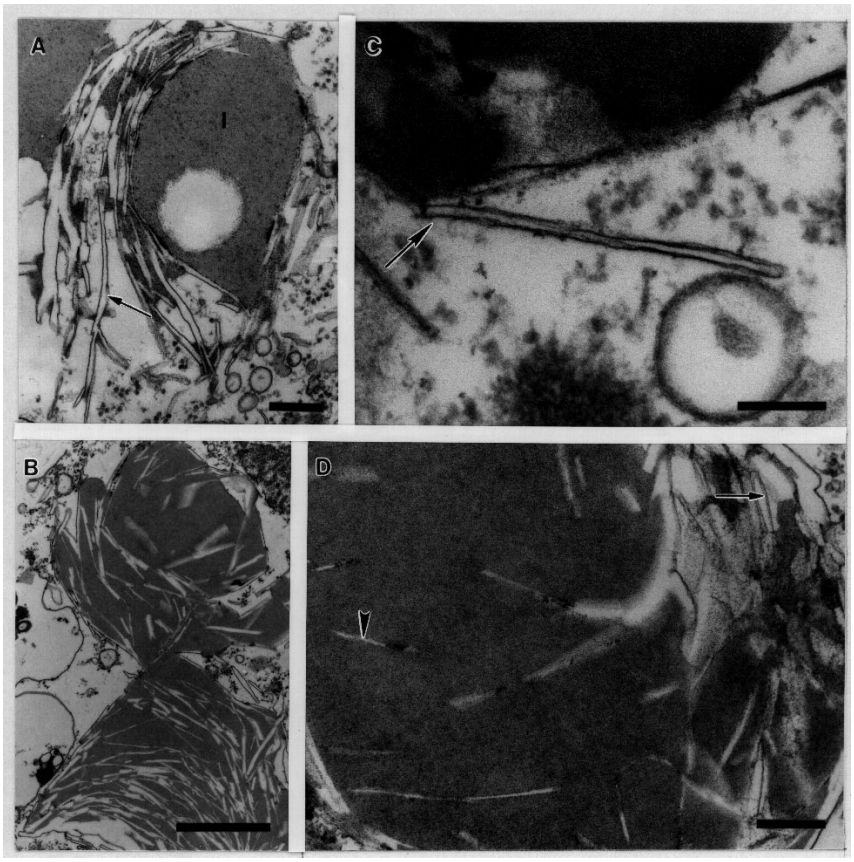

FIG. 2. Micrographs of lipid bodies (l) from cells of *Thraustochytrium* sp. 26185. Branching, hollow structures are associated with lipid synthesis (arrow, panel A) and become internalized as lipid deposition continues (panel B). The boundaries of these structures are not unit membranes (arrow, panel C) and disappear with internalization (arrow, panel D). Bar = 0.2 μm in panels A and D, 1 μm in panel B, 0.1 μm in panel C.

ABSTRACT: The nephrotic syndrome is associated with disturbances in plasma lipid pattern and metabolism. However, the reason for these perturbations is poorly understood. In the present study, we have investigated hepatic triglyceride metabolism in puromycin aminonucleoside-induced nephrotic syndrome in rats. Nephrotic rats displayed a 70% increase in hepatic triglyceride levels compared to controls (16.9 ± 1.6 vs. 9.8 ± 0.6 μmol/g liver; means ± SEM, $P < 0.01$). The capacity for hepatic mitochondrial β-oxidation of fatty acids was substantially elevated (80%). This was associated with a rise in the liver content of the fatty acid carrier carnitine (1.24 ± 0.06 vs. 0.85 ± 0.07 μmol/g dry weight, $P < 0.05$). A positive correlation between the levels of acetylcarnitine and acetyl-CoA was found in normal as well as in nephrotic rats, implying that carnitine plays an important role as an acetyl group acceptor in the liver under normo- and hyperlipidemic conditions. Changes in carnitine levels seem to be tightly coupled to the rate of fatty acid oxidation. There was a significant elevation in the activity of phosphatidate phosphohydrolase (E.C. 3.1.3.4) in liver microsomes from nephrotic rats (1.07 ± 0.09 vs. 0.81 ± 0.04 nmol/min·mg protein, $P < 0.02$). Hepatic very low density lipoprotein (VLDL)–triglyceride secretion rate was 18% higher in nephrotic rats than in controls. The results demonstrate a deranged hepatic triglyceride metabolism in nephrosis, with an increased hepatic triglyceride biosynthesis, a sizable accumulation of hepatic triglycerides, and only a modest increase in VLDL triglyceride secretion. In addition, mitochondrial β-oxidation of fatty acids was enhanced, associated with an increased availability of carnitine.
Lipids 32, 847–852 (1997).

Nephrotic syndrome is a condition associated with profound disturbances in lipid and lipoprotein metabolism (1–4). In addition to its clinical implications related to premature atherosclerosis, coronary heart disease and progressive renal failure (5–7), this condition provides a useful tool to investigate the regulation of hepatic lipid metabolism in a deranged state.

It has previously been suggested that hepatic triglyceride biosynthesis is enhanced in nephrosis, based on the observation that the incorporation of fatty acids into neutral lipids is increased in liver slices from nephrotic rats (8). This is of particular interest because growing evidence points to the overall importance of triglyceride availability for hepatic lipoprotein secretion (9,10). It is generally believed that under normal conditions the rate of triglyceride biosynthesis is governed by the activities of the enzymes involved in this pathway, especially phosphatidate phosphohydrolase and by the availability of fatty acid substrates (11). The latter is in turn affected by the rate of fatty acid oxidation. We have shown that β-oxidation stimulating agents reduced hepatic and plasma triglyceride levels and hepatic triglyceride output in nephrotic and normal rats (12,13), indicating that modulation of fatty acid oxidation influences triglyceride metabolism also in the nephrotic state. However, the impact of nephrosis on hepatic fatty acid oxidation has received scant attention.

The oxidation of long-chain fatty acids is known to be dependent on carnitine for their transport across the inner mitochondrial membrane, which is impermeable to CoA derivatives. It has been shown that adequate carnitine concentrations in the liver are necessary for intact mitochondrial fatty acid oxidation and ketogenesis (14). Furthermore, treatment with carnitine ameliorated alcohol-induced hepatic steatosis (15,16), suggesting that carnitine availability could influence hepatic triglyceride metabolism, and at least under some conditions be a limiting factor. However, the possible impact of nephrosis or other hyperlipidemic conditions on carnitine metabolism has not been previously addressed.

In the present work, we have studied regulatory aspects of hepatic triglyceride biosynthesis and fatty acid catabolism in experimental nephrotic syndrome. We present evidence that the liver capacity for fatty acid oxidation is elevated in nephrotic syndrome and that increased carnitine availability may contribute to this effect. Furthermore, triglyceride bio-

Abbreviations: CPT, carnitine palmitoyltransferase; PAN, puromycin aminonucleoside; PAP, phosphatidate phosphohydrolase; VLDL, very low density lipoprotein.

synthesis was enhanced in nephrosis, associated with an increased phosphatidate phosphohydrolase (PAP) activity.

EXPERIMENTAL PROCEDURES

Male rats of the Sprague-Dawley strain weighing 200–250 g were housed in metal cages and maintained on a 12-h light–dark cycle with the light period between 6 a.m. and 6 p.m. The animals were allowed to move freely in the cages and had free access to standard chow and water. Rats used for the determination of very low density lipoprotein (VLDL)–triglyceride secretion were fasted overnight to avoid interference from chylomicrons. All other experiments were carried out in the nonfasting state. The study was approved by the ethics committee for animal experiments in Stockholm.

Nephrosis was induced by a single intraperitoneal injection of puromycin aminonucleoside (PAN) (Sigma Chemical Co., St. Louis, MO) in a dose of 100 mg/kg body weight. One week after the injection, rats were transferred to individual metabolic cages, and urine was collected for 24 h. Plasma and urine albumin concentrations were measured by an immunonephelometric method using rat albumin antibodies (Nordic Immunology, Tilburg, The Netherlands). Nephrosis was confirmed by the presence of hyperlipidemia, low plasma albumin, and urine albumin loss exceeding 250 mg/24 h. In order to ensure a well-established nephrotic syndrome and to avoid possible direct effects of PAN (17), all experiments were performed at least 6 d after PAN injection. Except for the time-course study, the rats were killed 11–13 d after PAN injection. In the time-course study four subgroups of PAN-treated rats were killed 6, 9, 12, and 14 d after the injection.

On the day of sacrifice, blood sampling was performed by open heart puncture under neuroleptic anesthesia with fentanyl + fluanisone (Hypnorm®; Janssen Pharmaceutica, Beerse, Belgium) aided by the muscle relaxant diazepam (Stesolid®; Dumex Ltd., Copenhagen, Denmark). Collection of plasma and liver tissue samples was carried out between 9 and 11 a.m.

Plasma triglyceride and cholesterol levels were determined using enzymatic procedures (18; Cholesterol CHOD-PAP method BM/Hitachi 917 System Pack [kit insert], 1994 edition; Boehringer Mannheim GmbH, Mannheim, Germany. Triglycerides GPO-PAP Boehringer Mannheim Systems [kit insert], 1995 edition; Boehringer Mannheim GmbH Diagnostica, Mannheim, Germany). Triglyceride and cholesterol concentrations also were measured in a total lipid extract of a 20% liver homogenate. Lipid extraction was done using 20 vol of chloroform/methanol (2:1, vol/vol).

A portion of liver tissue was rapidly frozen in liquid nitrogen, freeze-dried, dissected free of connective tissue and blood, powdered, and precipitated with 0.5 mmol/L perchloric acid in 1 mmol/L Na_2EDTA and neutralized with 2.1 mol/L $KHCO_3$. Total acid-soluble carnitine, free carnitine, acetylcarnitine, and acetyl-CoA were assayed in the supernatant by enzymatic radioisotopic methods (19–21). Short-chain acylcarnitine was calculated as the difference between total acid-soluble and free carnitine.

Livers from individual rats were homogenized, and subcellular fractionation yielding mitochondrial, microsomal, and cytosolic fractions was carried out as described in detail elsewhere (22,23). Cytosolic and microsomal PAP activities were determined by measuring the conversion of ^{14}C phosphatidate into diglycerides (24). Mitochondrial β-oxidation was measured in short-term incubations as the conversion of [1-^{14}C] fatty acids in palmitoyl-CoA or palmitoylcarnitine into acid-soluble radioactive products (25). When palmitoyl-CoA was used as the substrate for oxidation, carnitine was added to the assay mixture (25). Protein concentration was measured by the Lowry procedure using bovine serum albumin as standard (26).

VLDL–triglyceride secretion rate was estimated using Triton WR 1339 (Sigma Chemical Co., St. Louis, MO) as previously described (27,28). In brief, 1 mL of a 20% solution of Triton WR 1339 (Sigma Chemical Co.) in 0.9% NaCl was intravenously injected, and blood samples were drawn hourly for 3 h after the injection. Plasma triglycerides were measured as above, and the entry rate of triglycerides into the circulation (mmol/L/h) was calculated. Data were evaluated by Student's *t*-test and linear regression analysis.

RESULTS

Induction of nephrosis by PAN resulted in a marked increase in triglyceride content in the liver (72%) while cholesterol levels remained unchanged (Table 1). Consequently, the hepatic triglyceride/cholesterol ratio increased significantly (Table 1), indicating that nephrosis primarily resulted in a derangement of hepatic triglyceride metabolism. It is well known that fatty acid β-oxidation affects the availability of fatty acids for esterification and triglyceride formation. β-Oxidation was therefore measured in the hepatic mitochondrial fraction using two substrates in parallel, palmitoyl-CoA or palmitoylcarnitine. Palmitoyl-CoA is dependent for its transport into the mitochondria on the enzyme carnitine palmitoyltransferase while this is not the case for palmitoylcarnitine. As shown in Figure 1, the mitochondrial β-oxidation activity, as measured by the formation of acid-soluble products, was increased from both substrates in livers from nephrotic rats

TABLE 1
Hepatic Lipid Levels in Nephrotic Rats and Normal Controls[a]

	Control	Nephrotic
Triglycerides (μmol/g liver)	9.8 ± 0.6	16.9 ± 1.6[b]
Cholesterol (μmol/g liver)	9.5 ± 0.2	10.1 ± 0.3
Triglyceride/cholesterol ratio	1.03 ± 0.06	1.65 ± 0.15[b]

[a]Values are means ± SEM for seven nephrotic rats and five controls.
[b]$P < 0.01$. Rats were killed 12–13 d after puromycin aminonucleoside (PAN) injection.

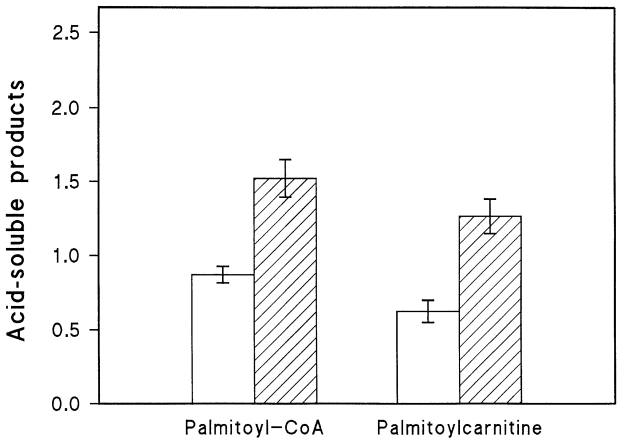

FIG. 1. Effect of nephrosis on mitochondrial β-oxidation of fatty acids. Fatty acid β-oxidation was measured as the formation of acid-soluble products (nmol/min·mg protein) from ^{14}C palmitoyl-CoA or palmitoylcarnitine. Hatched bars represent nephrotic rats (n = 7) and open bars represent normal controls (n = 4). The rats were sacrificed 12–13 d after puromycin aminonucleoside injection. Values are means ± SEM, $P <$ 0.005, with both substrates.

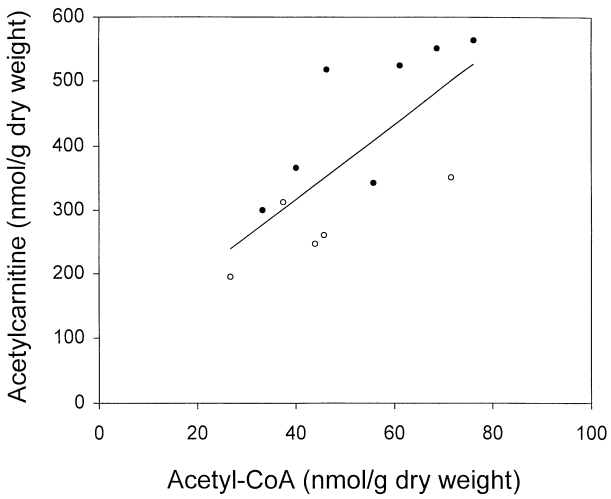

FIG. 2. Relationship between the content of acetylcarnitine and acetyl-CoA in the liver. Data are from the experiment described in Table 2. The regression line for all values (drawn) is [acetylcarnitine] = 5.8[acetyl-CoA] + 84, r = 0.72, $P < 0.01$. The regression lines were for nephrotic rats (●) [acetylcarnitine] = 5.6[acetyl-CoA] + 146, r = 0.78 and for controls (○) [acetylcarnitine] = 2.9[acetyl-CoA] + 141, r = 0.81, respectively.

compared to control rats (87 and 74%, respectively). These results indicated an increased capacity for fatty acid oxidation in the nephrotic state. To further investigate the role of the fatty acid carrier carnitine in β-oxidation of fatty acids, hepatic carnitine content was measured and, as shown in Table 2, total carnitine levels were significantly increased in nephrotic rats compared to controls. Both the free and acylated forms of carnitine were increased in nephrosis. In both experimental groups, the short-chain acylcarnitine pool consisted almost exclusively of acetylcarnitine (Table 2). Under normal conditions, acetylcarnitine is of importance as an acetyl group acceptor in muscle tissue. It was therefore of interest that hepatic acetylcarnitine and acetyl-CoA levels were positively correlated ($P < 0.01$) (Fig. 2) in both normal and nephrotic rats, indicating that the acetyl group acceptor function of carnitine is important in the liver, also in the presence of a massive derangement of hepatic triglyceride metabolism.

The aforementioned experiments were performed in the presence of established hyperlipidemia, 12–13 d after the induction of nephrosis. However, it has been shown that fatty acid synthesis changes over time after the induction of nephrosis (17). It was therefore of interest to study whether this was also the case for fatty acid oxidation. For this purpose, groups of nephrotic rats were sacrificed at different times following the induction of nephrosis. As shown in Figure 3, a slight increase in fatty acid oxidation was already observed 6 d after induction. The capacity for fatty acid oxidation increased over time, and a peak was reached at day 12.

TABLE 2
Hepatic Carnitine and Acetyl-CoA Levels in Nephrotic Rats and Normal Controls[a]

	Control	Nephrotic
Carnitine (μmol/g dry weight)		
Total acid-soluble	0.85 ± 0.07	1.24 ± 0.06[b]
free	0.52 ± 0.08	0.77 ± 0.05[b]
short-chain acyl	0.33 ± 0.03	0.47 ± 0.03[b]
acetyl	0.27 ± 0.03	0.45 ± 0.04[b]
Acetyl-CoA (μmol/g dry weight)	0.045 ± 0.007	0.054 ± 0.006

[a]Values are means ± SEM for seven nephrotic rats and five controls.
[b]$P < 0.05$. Rats were killed 12–13 d after PAN injection. See Table 1 for abbreviation.

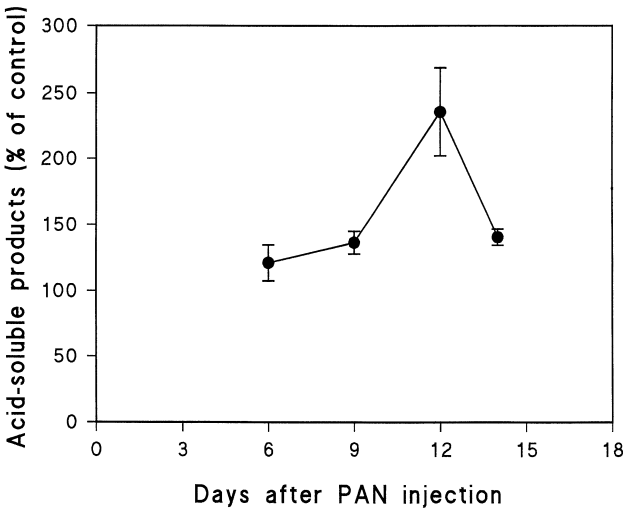

FIG. 3. Effect of nephrosis on mitochondrial β-oxidation of fatty acids: a time-course study. Fatty acid β-oxidation was measured as the formation of acid-soluble products from ^{14}C palmitoylcarnitine. Three nephrotic rats and three controls were used each day except for day 6 when there were only two rats in the nephrotic group, and day 12 with two rats in the control group. The values given for each day represent mean and range. PAN, puromycin aminonucleoside.

TABLE 3
A Time-Course Study of the Effect of Nephrosis on Hepatic Carnitine Levels[a]

	Total acid-soluble carnitine (μmol/g dry weight)			
Days after PAN injection	6	9	12	14
Control rats	0.98	0.85	0.78	1.01
	0.81	0.71	0.74	0.82
	0.70	1.01		0.95
Mean	0.83	0.86	0.76	0.93
Nephrotic rats	1.29	1.91	2.11	1.05
	1.50	2.39	1.08	0.98
		1.38	1.01	1.12
Mean	1.40	1.89	1.40	1.05

[a]Data are from the same experiment as in Figure 3. Individual values for the nephrotic rats and normal controls are given ($n = 11$ in each group). Pooled values from day 6 to day 12 were 1.60 ± 0.17 for nephrotic rats and 0.83 ± 0.05 for controls, means ± SEM, $P < 0.001$. See Table 1 for abbreviation.

TABLE 4
Effect of Nephrosis on Phosphatidate Phosphohydrolase (PAP) Activity[a]

PAP activity (nmol/min·mg protein)	Control	Nephrotic
Cytosolic	0.18 ± 0.01	0.21 ± 0.02
Microsomal	0.81 ± 0.04	1.07 ± 0.09[b]

[a]Combined results from four experiments are shown. Values are means ± SEM for 23 nephrotic rats and 21 controls.
[b]$P < 0.02$. Rats were killed 11–13 d after PAN injection. See Table 1 for other abbreviation.

Consequently, the difference between nephrotic and control rats decreased rapidly. Interestingly, the same temporal pattern was observed using either palmitoylcarnitine (Fig. 3) or palmitoyl-CoA (not shown) as substrates. The increase in palmitoylcarnitine and palmitoyl CoA levels on day 12, about twofold, was in excellent agreement with the results in Figure 1.

Hepatic carnitine levels also showed pronounced changes over time in nephrotic rats with the highest levels reached around day nine (Table 3). Except for day 14, hepatic carnitine was consistently higher in nephrotic rats compared to controls. A significant difference in carnitine levels between the two groups was observed when values from rats killed on days 6 to 12 were pooled (1.60 ± 0.17 vs. 0.83 ± 0.05, $P < 0.001$). Changes in either free carnitine or acetylcarnitine levels followed the same pattern as total carnitine (not shown).

Since triglycerides are known to play an important role in VLDL synthesis and secretion (9,10,29,30), we examined whether hepatic VLDL–triglyceride secretion was altered in nephrotic rats. For this purpose, a group of rats was fasted overnight to avoid interference from chylomicrons and intravenously injected with Triton WR 1339, which blocks the action of lipoprotein lipase on triglyceride-rich lipoproteins (27). The accumulation of plasma triglycerides under these conditions, reflecting the entry rate of newly synthesized VLDL triglycerides, was found to be 18% higher in nephrotic rats than in controls (5.3 ± 0.4 vs. 4.5 ± 0.2 mmol/L/h, $n = 6$, $P < 0.05$), well in line with earlier observations (31). This modest increase was in contrast with the severe elevations of plasma triglyceride levels (19.8 ± 3.2 vs. 1.0 ± 0.06 mmol/L, means ± SEM for 13 nephrotic rats and 11 controls, $P < 0.001$).

In addition to the availability of fatty acids, hepatic triglyceride biosynthesis is influenced by the enzyme activities, including the key enzyme PAP (11). As shown in Table 4, microsomal PAP activity was elevated by 32% in the nephrotic animals, while the cytosolic activity of this enzyme was not affected.

DISCUSSION

A major novel finding in the present work was the increased capacity for hepatic fatty acid oxidation in nephrotic rats. This increase may be mediated through several mechanisms. It has been reported that plasma free fatty acid levels are transiently elevated after the induction of nephrosis (17). Higher plasma free fatty acid levels might result in an increased hepatic fatty acid uptake and initiate adaptive mechanisms to cope with this increased load, i.e., increases in fatty acid oxidation and/or esterification. Thus, increased availability of fatty acids could be a common basis for the increases observed in fatty acid oxidation and triglyceride biosynthesis. Also, the severe hypertriglyceridemia along with a significant accumulation of triglycerides in the liver might trigger compensatory mechanisms, resulting in changes in the partitioning between oxidation and esterification. Whatever the underlying mechanisms, the results obtained are clearly compatible with an increase in fatty acid utilization in nephrotic animals. Furthermore, the degree of increase in fatty acid oxidation was similar utilizing either palmitoyl CoA or palmitoylcarnitine as substrates, arguing against the possibility that the carnitine palmitoyltransferase I (CPT I)-dependent transport of palmitoyl CoA was limiting under these conditions.

In view of the crucial role of carnitine in fatty acid transport through the mitochondrial membrane for subsequent oxidation, it is clearly interesting that hepatic levels of carnitine were increased in nephrotic rats. This finding is consistent with earlier observations that conditions known to stimulate ketogenesis such as starvation and poorly controlled diabetes are associated with increased hepatic carnitine levels (14). However, the nature of this association is unclear. Carnitine is a substrate for CPT I, the enzyme generally believed to be a primary site for the regulation of fatty acid oxidation. Thus, the increase in hepatic carnitine levels might lead to a greater carnitine availability *in vivo* for CPT I and consequently enhanced fatty acid oxidation. Also, there is evidence that carnitine might reduce the sensitivity of CPT I to inhibition by malonyl-CoA which is a major regulator of this enzyme activity (32). It should, however, be pointed out that the increase in the capacity for fatty acid oxidation also can be mediated by effects on other regulatory enzymes in the β-oxidation cycle.

Acetylcarnitine levels in the liver increased in nephrotic rats (Table 2), compatible with increased fatty acid oxidation. It is well-established that the pools of acetylcarnitine and acetyl-CoA are in close relationship, mediated through the action of carnitine acetyltransferase. By this mechanism, intramitochondrially generated acetyl groups bound to CoA can be transferred to carnitine. Acetylcarnitine is then transported across the mitochondrial membrane, making available free CoA intramitochondrially for fatty acid β-oxidation, oxidation of pyruvate, and degradation of branched-chain amino acids (33). Since the pool of tissue carnitine is considerably larger than that of CoA, carnitine can serve as an important acetyl group acceptor (33), a role that has been clearly demonstrated in skeletal muscle during exercise (34,35). In the present study, we were able to demonstrate a statistically significant correlation between acetylcarnitine and acetyl-CoA, indicating that carnitine acts as a buffering substance adjusting the acetyl-CoA/CoA ratio also in the liver. Interestingly, this novel finding was observed in both normal and nephrotic rats.

In nephrotic rats, hepatic triglyceride content as well as VLDL–triglyceride secretion increased, implying enhanced triglyceride biosynthesis in nephrosis. These results are in accordance with the earlier findings that hepatic synthesis of neutral lipids from ^{3}H-palmitate in liver slices from nephrotic rats is increased (8). Interestingly, the increase in VLDL–triglyceride secretion was moderate compared to the substantial accumulation of triglycerides in the liver. These findings are compatible with a compartmentalization of triglycerides into different metabolic pools in the liver. It has been suggested that hepatic triglycerides occur in two pools, a cytoplasmic storage pool and a microsomal secretory pool involved in VLDL formation (9,36,37). However, the interrelationship between the two pools and the mechanisms by which newly synthesized triglycerides are channeled into these pools are poorly understood. Although the present data indicate that both the storage and the secretory pools are increased in nephrosis, a large proportion of newly synthesized triglycerides was apparently retained in the liver.

In nephrotic rats, the increases found in hepatic content and secretion of triglycerides were accompanied by a higher activity of microsomal PAP. PAP, which catalyzes the dephosphorylation of phosphatidic acid to diacylglycerol, is believed to play a prominent role in controlling triglyceride biosynthesis (reviewed in Ref. 38). PAP activity is also present in the cytosol (38,39). It has been suggested that the cytosolic enzyme represents an inactive reserve that is activated when it is translocated onto the endoplasmic reticulum (38). This translocation is promoted by long-chain fatty acids (38). Our observation of an increased microsomal PAP activity suggests that induction of this enzyme activity might contribute to an enhanced triglyceride biosynthesis in nephrosis, and raises the possibility that increased triglyceride biosynthesis may be due to increased availability of the substrate, fatty acids, as well as regulation on the enzyme level. The effects on PAP might, however, be secondary to changes in the availability of fatty acids. Indeed, several hepatic enzyme activities involved in fatty acid synthesis are reported to be elevated, at least transiently after the induction of nephrosis (17), suggesting enhanced fatty acid synthesis. However, primary effects of nephrosis on triglyceride-synthesizing enzymes cannot be excluded. It should be emphasized that there was a discrepancy between the substantial increase in liver triglyceride levels and the slight increase in PAP activity. It seems therefore unlikely that the relatively modest increase in PAP activity in nephrosis can explain the increase in hepatic triglyceride levels. However, as seen from our findings on carnitine and fatty acid oxidation, nephrosis represents a dynamic condition, and an accumulation of triglycerides in the liver after the induction of nephrosis could down-regulate the enzyme activity, thus counteracting more marked initial effects. Such an inhibition of hepatic PAP activity by accumulated lipids has been suggested to occur in chronic alcohol feeding (40).

To summarize, the data presented indicate that the liver capacity for mitochondrial fatty acid oxidation is increased in nephrotic syndrome. This increase might, in part, be mediated through increased carnitine availability. Further, the role of carnitine as an acetyl group acceptor/CoA regenerator in the liver seems to be preserved in nephrotic syndrome in spite of the severe disturbances observed in hepatic lipid metabolism in this condition. The results further suggest that hepatic triglyceride biosynthesis is enhanced in nephrosis, and that this is, in part, mediated through PAP. Moreover, the increase in triglyceride biosynthesis led to a retention of triglycerides in the liver and a disproportionately slight increase in VLDL–triglyceride secretion. These findings suggest that the mechanisms that normally regulate the partitioning of triglycerides between storage and secretion pools are disturbed in the nephrotic syndrome. The precise nature of this disturbance is not known and warrants further studies.

ACKNOWLEDGMENTS

The authors are grateful to Gunvor Nilsson, Gunnel Zeisig, and Agneta Laveskog for excellent technical assistance. ABSTRACT: The effects of conjugated linoleic acid (CLA) on body composition were investigated. ICR mice were fed a control diet containing 5.5% corn oil or a CLA-supplemented diet (5.0% corn oil plus 0.5% CLA). Mice fed CLA-supplemented diet exhibited 57% and 60% lower body fat and 5% and 14% increased lean body mass relative to controls ($P < 0.05$). Total carnitine palmitoyltransferase activity was increased by dietary CLA supplementation in both fat pad and skeletal muscle; the differences were significant for fat pad of fed mice and skeletal muscle of fasted mice. In cultured 3T3-L1 adipocytes CLA treatment (1×10^{-4} M) significantly reduced heparin-releasable lipoprotein lipase activity (–66%) and the intracellular concentrations of triacylglyceride (–8%) and glycerol (–15%), but significantly increased free glycerol in the culture medium (+22%) compared to control ($P < 0.05$). The effects of CLA on body composition appear to be due in part to reduced fat deposition and increased lipolysis in adipocytes, possibly coupled with enhanced fatty acid oxidation in both muscle cells and adipocytes. *Lipids 32,* 853–858 (1997).

CLA is the acronym for a group of positional and geometric isomers of conjugated dienoic derivatives of linoleic acid. They were identified as comprising an anticarcinogenic principal present in grilled ground beef and other food sources, especially dairy products (1–3). Synthetically prepared CLA inhibited carcinogen-induced neoplasia in several animal models (2,4,5) and reduced development of atherosclerosis in rabbits (6) and hamsters (7). CLA reduced tissue arachidonic acid levels and protected against the catabolic effects of endotoxin administration in mice, rats, and chickens without adversely affecting immune function (8,9). Recently it was established that CLA is a growth factor for young rats in that it enhanced body mass and feed efficiency (10). We now report the effects of CLA on body composition in mice.

Abbreviations: CLA, conjugated linoleic acid; CPT, carnitine palmitoyltransferase; DMEM, Dulbecco's modified Eagle's medium; LPL, lipoprotein lipase.

METHODS AND PROCEDURES

Materials. Linoleic acid was purchased from Nu-Chek-Prep Corporation (Elysian, MN); triolein, [9,10-^{3}H(N)], (specific activity 12 Ci/mmol) from American Radiolabeled Chemicals Incorporated (St. Louis, MO); and [1-^{14}C]linoleic acid (specific activity 55 mCi/mmol) from Amersham Life Science (Arlington Heights, IL). CLA was prepared as described (1).

Animals and body composition analyses. Weanling male ICR mice (experiment 1), 6-wk-old female (experiment 2) ICR mice, 6-wk-old male ICR mice [carnitine palmitoyltransferase (CPT) assay], feed ingredients (except for CLA), and semi-purified diet (TD94060, 99% basal mix) (Table 1) were purchased from Harlan Sprague-Dawley (Madison, WI). Diet was stored at –20°C until use. Mice were housed in a windowless room with a 12-h light-dark cycle in strict accordance to guidelines established by the Research Animal Resources Center of University of Wisconsin–Madison. Diet was fed *ad libitum*, freshly provided every day (experiment 1) or three times per week (experiment 2). After a 5-d adaptation period mice were randomly separated into groups and fed either control diet (5.5% corn oil) or CLA-containing diet

TABLE 1
Diet Composition[a]

Ingredients	Treatment	
	Control (g/kg)	CLA (g/kg)
Sucrose	481	481
Casein, "Vitamin-Free" Test	210	210
Corn starch	150	150
DL-Methionine	3	3
Corn oil	55	50
CLA	0	5
Cellulose	50	50
Mineral mix, AIN-76	35	35
Vitamin mix, AIN-76A	10	10
Calcium carbonate	4	4
Choline bitartrate	2	2
Ethoxyquin	0.1	0.1

[a]In experiment 2, diet was prepared as described in Reference 37, which contained the same amount of ingredients except 495 g sucrose and 200 g casein per kg diet, without additional calcium carbonate. CLA, conjugated linoleic acid.

(5.0% corn oil plus 0.5% CLA). For body composition analyses, animals were sacrificed, gut contents were removed (to obtain empty carcass weight), and the carcasses frozen at −20°C. Frozen carcasses were chopped, ground, and freeze-dried to determine water content. Total nitrogen was analyzed by the Kjeldahl method (11). Carcass fat content was measured by extraction with diethyl ether overnight using a Soxhlet apparatus. Total ash content was determined by incineration (500–600°C, overnight).

Cell culture. 3T3-L1 preadipocytes were purchased from American Type Culture Collection (Rockville, MD) and cultured as described (12). Briefly, 3T3-L1 preadipocytes were grown to confluence at 37°C in Dulbecco's modified Eagle's medium (DMEM) containing 10% calf serum. At 2-d post-confluence (designated day 0) cell differentiation was induced with a mixture of methylisobutylxanthin (0.5 mM), dexamethasone (0.25 µM), and insulin (1 µg/mL) in DMEM containing 10% fetal bovine serum. On day 2 this medium was replaced with medium containing 10% fetal bovine serum and insulin only. On day 4 and thereafter the medium consisted of DMEM plus 10% fetal bovine serum only; this medium was subsequently replaced with fresh medium at 2-d intervals.

Fatty acid–albumin complexes were prepared as described (13) with slight modifications and added to culture media 48 h prior to cell harvest. CLA (10 µmol) or linoleic acid (10 µmol), dissolved in 0.1 M KOH, was added to 10 µmol bovine serum albumin solution in phosphate-buffered saline and incubated overnight at 4°C. The pH and volume were adjusted, respectively, to 7.2 and 5.0 mL (before filter sterilization) before use. Final concentrations of linoleic acid and CLA were 100 µM except as indicated for the dose–response experiment. All dishes including control had final concentration of 100 µM albumin.

Cell viability was tested using a number of parameters, as follows. The activities of citrate cleavage enzyme (14) and fatty acid synthetase (15) were determined. In addition 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (Sigma Chemical Co., St. Louis, MO) was used as described (16). Briefly, cells were cultured in a 96-well plate and treated with fatty acid–albumin complexes for 48 h as described above. After rinsing, cells were incubated with 50 µL of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (5 mg/mL) in DMEM at 37°C for 4 h. Medium was then removed and 200 µL of dimethyl sulfoxide added to each well to dissolve formazan crystals before quantifying at 570 nm with a Microplate Reader Model MR600 (Dynatech Industries, Inc., Alexandria, VA).

Free and esterified glycerol were determined using a Sigma Diagnostic Kit. Heparin-releasable lipoprotein lipase (LPL) activity (E.C. 3.1.1.34, 10 U heparin/mL media for 1 h at 37°C) was measured as described (17). Recovery of free fatty acid was estimated at 71% by using [^{14}C]linoleic acid. Protein was determined as described (18).

CPT (E.C. 2.3.1.23) assay. Mice were fed CLA-supplemented or control diet for 1 wk. Half the mice in each group were then fasted overnight prior to sacrifice by cervical dislocation. Epididymal fat pad, skeletal muscle (hind leg), and liver were removed. Tissues were then homogenized in 3 vol (wt/vol) of 0.25 M sucrose, 1 mM EDTA, 10 mM Tris HCl, pH 7.4 at 4°C. Homogenates were centrifuged (700 × *g* for 10 min); supernatant fluid was again centrifuged (12,000 × *g* for 15 min). Pellets (mitochondrial fraction) were washed and stored at −70°C after resuspension in 70 mM sucrose, 220 mM mannitol, 2 mM HEPES buffer, pH 7.4 and 1 mM EDTA. Total CPT activity was assayed by measuring the initial rates of CoASH formation (19).

Statistical analyses. Data in Figures 1 and 2 and Tables 2 and 3 were analyzed using the "2 independent sample *t*-test." Feed intake per cage was determined every day for experiment 1 (two mice per cage) or at 2–3-d intervals for experiment 2 (one mouse per cage). Feed intake data shown in Figures 1 and 2 are calculated under the assumption that in experiment 1 each mouse acted independently, and in experiment 2 mice consumed an equal amount of feed on each of the days constituting the feeding period. Two-way analysis of variance were performed on data (treatments and experiments) for Figure 3, Table 4, and the carcass protein analyses described in the Results section. Of major interest here are the comparisons among the treatments; these were computed using the Statistics Analysis System (SAS Users' Guide: Statistics, SAS Institute Inc., Cary, NC) with the General Linear Mean procedure and Least Square Means option. If the interaction between treatment and experiment was significant, this interaction was then used as the error term in the Least Square Means analysis.

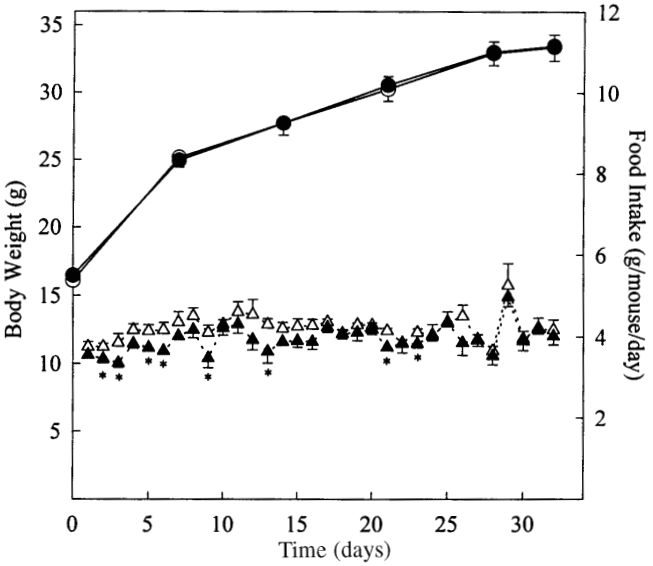

FIG. 1. Body weight (circle) and feed intake (triangle) from male mice fed control or conjugated linoleic acid (CLA)-supplemented diet (experiment 1). Four-week-old male mice were fed either control (open) or CLA (filled)-supplemented diet (0.5% of diet) for 32 d. Body weights ($n = 8$) and feed intake were subjected to *t*-test (*$P < 0.05$). Numbers are mean ± SE.

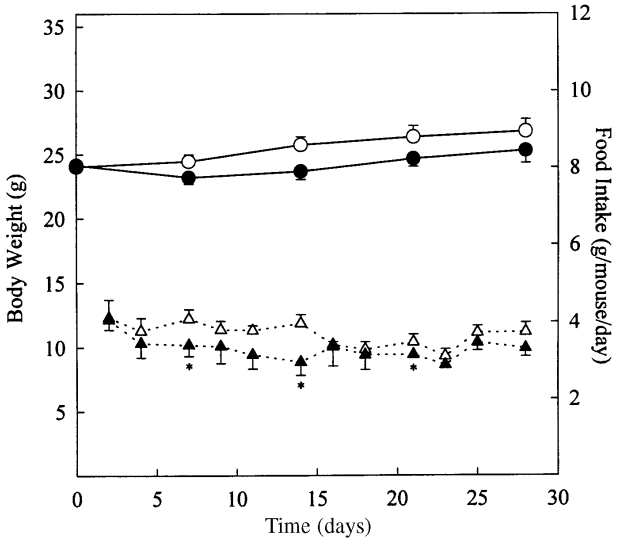

FIG. 2. Body weight (circle) and feed intake (triangle) from female mice fed control or CLA-supplemented diet (experiment 2). Seven-week-old female mice were fed either control (open) or CLA (filled) supplemented diet (0.5% of diet) for 28 d. Body weights and feed intake were subjected to *t*-test (*$P < 0.05$). Numbers are mean ± SE ($n = 6$). See Figure 1 for abbreviation.

RESULTS

Figure 1 shows that male mice fed CLA-supplemented diet exhibited body weights that were indistinguishable from controls. By contrast, the data of Figure 2 indicate that female mice fed CLA appeared to exhibit slightly reduced body weight relative to controls, although the apparent reduction was not statistically significant. In both studies (Figs. 1 and 2) *ad libitum* feed intake for the CLA-fed animals appeared to be reduced at some experimental time points. We have previously shown that small differences in feed intake do not affect body composition (20).

Table 2 shows the effect of CLA supplementation on body composition in these animals. Relative to their respective controls, the percentage body fat in CLA-fed mice was reduced by 57% (males) and 60% (females). Hence, despite similar body weights (Figs. 1 and 2), dietary CLA supplementation resulted in significantly less body fat (Table 2).

By contrast, the percentages of whole body protein and carcass water were significantly enhanced for CLA-fed mice in both experiments (Table 2). Because of the relatively small numbers of animals studied it is not possible to conclude from these data alone that CLA induced a significant increase in whole body protein accretion (whole body protein mass for controls and CLA-fed groups, respectively, were 5.7 and 6.0 g in experiment 1 and 4.4 and 4.6 g in experiment 2; in neither case was the difference significant). However, to date we have conducted 10 such mouse CLA feeding trials, only two of which are reported here in Figures 1 and 2 and Table 2. An analysis of the combined data from these 10 studies indicates that mice fed CLA-supplemented diets do in fact exhibit increased whole body protein relative to controls ($P = 0.0401$).

The mechanism of action of body composition changes is of considerable importance. Accordingly we studied the effect of CLA on total CPT, which is rate-limiting for fatty acid β-oxidation (Table 3). CPT activity was increased by dietary CLA supplementation in both fat pad and skeletal muscle; the differences were significant for fat pad of fed mice, and skeletal muscle of fasted mice. Liver CPT activity was not affected by CLA feeding.

Another key enzyme in lipid metabolism is adipocyte LPL, which hydrolyzes free fatty acids from circulating triacylglyceride; the fatty acids are then taken up by the adipocytes and re-esterified. We utilized 3T3-L1 adipocytes to measure LPL as well as fat mobilization. The amount of CLA added to the cell culture media was based on our determination that the mean CLA content of sera from rats fed diet supplemented with 0.5% CLA for 14 or 28 d is 72 μM (range 23–120 μM).

The data of Figure 3 show that supplementing the culture medium of fully differentiated 3T3-L1 adipocytes with CLA (but not linoleic acid) significantly reduced LPL activity. The inhibitory effect was linear between 20 and 200 μM CLA (Fig. 4). The data indicate a threshold below 20 μM where inhibition is not observed; the apparent enhancement at 5 μM CLA is not understood and requires further study. In separate experiments to determine cell viability we found that incubating 3T3-L1 adipocytes for 2 d with 5 to 200 μM CLA or linoleic acid did not change cell viability as measured using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (data not shown). We also found that incubating 3T3-L1 adipocytes for 2–3 d with CLA under similar conditions did not reduce citrate cleavage enzyme or fatty acid synthetase ac-

TABLE 2
CLA-Induced Changes in Body Composition[a]

Experiment		ECW (g)[b]	Fat (%)	Protein (%)	Water (%)	Ash (%)
1	Control	32.4 ± 1.1	10.13 ± 1.17	17.76 ± 0.30	66.3 ± 0.8	3.08 ± 0.14
	CLA	32.2 ± 0.8	4.34 ± 0.40[f]	18.58 ± 0.14[d]	70.9 ± 0.4[e]	3.24 ± 0.05[c]
2	Control	25.0 ± 0.9	18.68 ± 3.08	17.67 ± 0.61	58.3 ± 2.2	3.67 ± 0.15

[a]Study duration was 32 d (experiment 1) and 28 d (experiment 2). Reported values are means ± SE ($n = 6$ to 8).
[b]Empty carcass weight.
[c–f]Indicates CLA-fed mice are different from control, where [c]$P < 0.05$, [d]$P < 0.01$, [e]$P < 0.001$, and [f]$P < 0.0001$. For other abbreviation, see Table 1.

TABLE 3
Total Carnitine Palmitoyltransferase Activity in Fat Pad, Muscle, and Liver[a]

	Carnitine palmitoyltransferase (nmol[b]/min/mg protein)		
	Fat pad	Muscle	Liver
Fasted			
Control	15.9 ± 1.7	16.8 ± 2.5	16.7 ± 1.6
CLA	18.4 ± 1.9	25.9 ± 2.1[c]	17.7 ± 1.3
Fed			
Control	14.7 ± 2.1	11.7 ± 1.2	5.3 ± 0.9
CLA	22.4 ± 1.4[c]	14.3 ± 1.7	5.3 ± 0.6

[a]Mice were fed control or CLA-supplemented diet (0.5%) for 1 wk. Reported values are means ± SE (n = 6).
[b]nmols *l*-carnitine exchange (Ref. 23).
[c]$P < 0.05$ compared to control. For abbreviation, see Table 1.

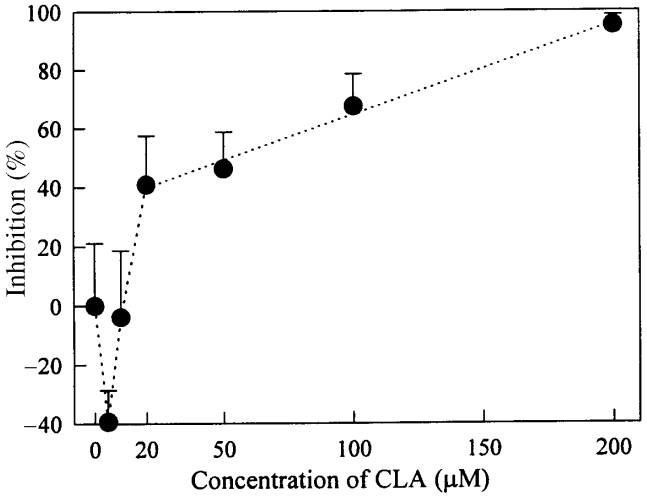

FIG. 4. Effect of CLA dose on LPL activity in 3T3-L1 adipocytes. Reported values are means ± SE of 3–4 culture dishes normalized against control. The r^2 is 0.9901 for the data between 20 and 200 μM CLA. For abbreviations, see Figures 1 and 3.

tivities (data not shown). Finally, there were no CLA- or linoleic acid-induced differences in total protein or heparin-released protein from the cells. Hence, the CLA effect reported here appears to be specific and not due to toxicity.

Table 4 shows the amount of esterified and free glycerol within the cells, and the free glycerol in the culture medium. The findings are consistent with Figures 3 and 4 in that CLA treatment resulted in a significant reduction in intracellular triacylglyceride (determined as esterified glycerol). However, the significant increase in free glycerol in the media indicates that CLA may have stimulated lipolysis as well. Linoleic acid also appears to have stimulated lipolysis in these cells, which is consistent with the findings of Takada *et al.* (21) that body fat was modestly reduced in rats fed gamma-linolenic acid (a metabolite of linoleic acid).

DISCUSSION

The data of Table 2 establish that mice fed CLA-supplemented diets exhibited significant changes in body composition relative to controls. This observation should be considered with regard to effects on the adipocyte (the principal site of fat storage) and the skeletal muscle cell (the principal site of fat oxidation).

The study described in Table 3 was conducted with tissues from control and CLA-fed mice. The findings are consistent with the interpretation that feeding mice a diet supplemented with CLA enhances fatty acid β-oxidation in skeletal muscle and fat pad, but not liver. These data (Table 3) may also explain at least in part our previous report (6) that rabbits fed CLA-supplemented diet exhibited reduced serum triglyceride levels.

The experiments described in Figures 3 and 4 and Table 4, which were conducted with 3T3-L1 adipocytes, indicate that CLA treatment reduced LPL activity while apparently enhancing lipolysis. If we assume that the *in vitro* experiments

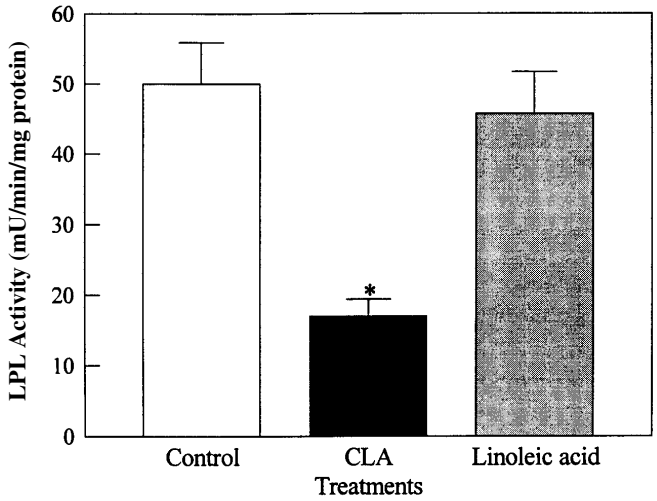

FIG. 3. CLA inhibits lipoprotein lipase (LPL) activity in 3T3-L1 adipocytes. Reported values are means ± SE (n = 15–17, collected from four independent experiments). *$P < 0.05$. See Figure 1 for abbreviation.

TABLE 4
Esterified and Free Glycerol in Cell Sonicates, and Free Glycerol in Culture Medium from Control and CLA-Treated 3T3-L1 Adipocytes[a]

	Percentage of control		
	Control	CLA	Linoleic acid
Esterified glycerol in cell	100[a]	91.7± 6.4[b]	117.1 ± 8.0[c]
Free glycerol in cell	100[a]	84.9 ± 7.2[b]	107.4 ± 5.9[a]
Free glycerol in culture medium	100[a]	122.0 ± 12.9[b]	106.6 ± 2.2[b]

[a]Cells were treated with 100 μM of CLA or linoleic acid for 48 h before assay. The means are for 10 independent experiments, normalized against their respective controls. Data (2–6 dishes per treatment in each experiment) were analyzed as log value with a two-way analysis of variance using fatty acid (as treatments) and experiment. If the interaction between treatment and experiment was significant, this interaction was used as the error term. Means with different superscript letters are significantly different ($P < 0.05$). For abbreviation, see Table 1.

with 3T3-L1 adipocytes (Figs. 3, 4, Table 4) reflect *in vivo* physiological changes, then these data taken together with the data of Table 3 appear to provide a framework for partially understanding the reduction in body fat that is evident in the data of Table 2. It should be noted that the data of Figures 3 and 4 and Table 4 support our very recent findings (22) that adipocytes isolated from rats fed CLA exhibited increased hormone-sensitive lipase activity and enhanced norepinephrine-induced lipolysis.

A possible explanation for the apparent enhancement of lean body mass (Table 2 and accompanying discussion of whole body protein accretion in the Results section) is less clear. This may be related to our previous reports that CLA protects against the catabolic effects of immune stimulation (8,9), which is modulated by prostaglandin E_2 and mediated by interleukin-1 and tumor necrosis factor-α, both of which are linked to obesity (23–26). It is also possible that CLA affects pathways induced by anabolic hormones, perhaps in conjunction with an adaptive response by skeletal muscle necessitated by increased lipid substrate for β-oxidation. Further investigation is required.

There appear to be parallels between the effects of CLA reported and discussed herein and the reported effects of dietary fish oil. Like CLA, fish oil is reported to reduce fat pad size (27, but also see 28), prevent cachexia and body weight loss following immune stimulation (29,30), and reduce tissue arachidonic acid levels (31,32). The omega-3 fatty acids of fish oil modulate numerous biological and physiological effects that are linked to tumor necrosis factor-α, interleukin-1, and the eicosanoid pathways (30,33), indicating that the effects of CLA may also involve eicosanoid mechanism(s).

The isomers of CLA may be metabolized to one or more biologically active products which exert biological effect. For example CLA-derived eicosanoids could regulate the synthesis of arachidonic acid metabolites like prostaglandin E_2. Alternatively, CLA-derived eicosanoids might exhibit biological activity in their own right. These possibilities are at this time speculation, but they are also the focus of considerable ongoing research (8,9,34–36). Understanding the biochemical mechanism(s) of action of CLA will be crucial to fully utilizing the potential of this class of fatty acids in animal husbandry and human application.

ACKNOWLEDGMENTS

We thank Drs. Richard Atkinson, Charles Elson, and Nancy Block for helpful critique in preparing this manuscript. We thank Professor E. Nordheim for assistance with statistical analysis. This research was supported in part by research grants from Kraft Foods Inc., the National Livestock and Meat Board, and gift funds administered through the University of Wisconsin–Madison Food Research Institute. Three of the authors (MWP, MEC, YP) are inventors of CLA-use patents assigned to the Wisconsin Alumni Research Foundation (WARF).

ABSTRACT: The dose-dependent effects of dietary eritadenine on the metabolism of linoleic acid and on the plasma cholesterol concentration were investigated to clarify the mechanism of the hypocholesterolemic action of eritadenine in rats. Rats were fed control or eritadenine-supplemented (2 to 20 mg/kg) diets for 14 d. Eritadenine supplementation significantly decreased both the plasma cholesterol concentration and the 20:4n-6/18:2n-6 ratio of liver microsomal and plasma phosphatidylcholine (PC) in a dose-dependent manner. Eritadenine was also found to decrease the activity of Δ6 desaturase in liver microsomes; there was significant correlation between the Δ6–desaturase activity and the 20:4n-6/18:2n-6 ratio in the PC of liver microsomes ($r = 0.989$, $P < 0.001$) or plasma ($r = 0.986$, $P < 0.001$). Certain plasma PC molecular species, as represented by 16:0-18:2, were increased by eritadenine in a dose-dependent manner, and certain plasma PC molecular species, as represented by 18:0-20:4, were conversely decreased by eritadenine. There was a significant correlation between the plasma total cholesterol concentration and the proportion of the sum of plasma PC molecular species which contain 18:1 or 18:2 in the *sn*-2 position. These results support the idea that the suppression of linoleic acid metabolism by eritadenine might be associated with the hypocholesterolemic action of eritadenine.
Lipids 32, 859–866 (1997).

Eritadenine [2(*R*),3(*R*)-dihydroxy- 4-(9-adenyl)-butyric acid] is known to be a hypocholesterolemic factor of the edible mushroom *Lentinus edodes* (Shiitake in Japanese) (1,2). The mechanism underlying the hypocholesterolemic action of the compound is not yet fully elucidated. Recently, we found that eritadenine decreases the ratio of phosphatidylcholine (PC) to phosphatidylethanolamine (PE) in rat liver microsomes through the depression of PE *N*-methylation (3,4), and that the compound suppresses the metabolism of linoleic acid into arachidonic acid, thereby leading to modifications of liver microsomal and plasma PC molecular species (5,6). It is reasonable to deduce that the decreased PC/PE ratio of liver microsomes may be associated with the hypocholesterolemic action of eritadenine, since there was a significant correlation between the PC/PE ratio and plasma cholesterol concentrations (3,4). However, it is still unclear whether the suppression of linoleic acid metabolism also participates in the hypocholesterolemic action of eritadenine. The mechanism of the suppression of linoleic acid metabolism by eritadenine is also unclear.

In this study, therefore, the dose-dependent effects of dietary eritadenine on various variables concerning lipid metabolism were investigated to clarify the relationship between the suppression of linoleic acid metabolism and the hypocholesterolemic action of eritadenine in rats.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Linoleic acid (1.7 GBq/mmol) was obtained from New England Nuclear (Boston, MA). Unlabeled linoleic acid and other biochemicals were provided by Sigma (St. Louis, MO) and Wako Pure Chemical (Osaka, Japan). All other chemicals were purchased from Wako and were of analytical grade. Eritadenine was isolated from dried *L. edodes* mushroom according to the method of Tokita *et al.* (7), and the purity of eritadenine used was at least 95% when assayed by thin-layer chromatography (TLC) (8).

Animals. Forty-eight male 5-wk-old rats of the Wistar strain were received at 90–100 g body weight from Japan SLC (Hamamatsu, Japan). The rats were individually housed in hanging stainless-steel wire cages kept in an isolated room at a controlled temperature (23–25°C) and humidity (40–60%). Lights were maintained on a 12-h cycle (light on from 0600 to 1800 h). For 5 or 6 d, rats were fed the powdered laboratory stock diet, which resembled the control diet described below except that sucrose and lactose were replaced by starch, and 2 g/kg diet of choline chloride was added. Then they were divided into six groups of eight rats each with similar mean weights (~123 g) and allowed free access to the experimental diets and water for 14 d. The experimental plan was approved by the Laboratory Animal Care Committee of the Faculty of Agriculture, Shizuoka University (Shizuoka, Japan).

Abbreviations: GLC, gas–liquid chromatography; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; PC, phosphatidylcholine; PE, phosphatidylethanolamine; TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

Diets. Six diets, control and eritadenine-supplemented (five levels) diets, were utilized in this study. The control diet consisted of the following (g/kg): casein (Nacalai tesque, Kyoto, Japan), 250; corn starch (Fuji-seifun, Shimizu, Japan), 450; sucrose (Fuji-seito, Shimizu, Japan), 200; corn oil (Honen, Tokyo, Japan), 50; AIN-76 mineral mixture (Oriental Yeast, Tokyo, Japan), 35; AIN-76 vitamin mixture (Oriental), 10; choline chloride (Wako), 4; and lactose (Wako), 1. Eritadenine was fully mixed with lactose and added to the diet at levels of 2, 4, 6, 10, and 20 mg/kg diet at the expense of lactose. The fatty acid composition of corn oil used was as follows (wt%): 16:0, 12.2; 18:0, 1.8; 18:1, 32.8; 18:2n-6, 51.4; and 18:3n-3, 1.6.

Tissue collection and fractionation. At the end of the feeding period, nonfasted rats were killed by decapitation under light anesthesia with diethyl ether between 1100 and 1200 h. Plasma was separated from heparinized whole blood by centrifugation at 2000 × *g* for 20 min at 4°C. An aliquot of the plasma was stored at 4°C until subsequent analyses for plasma lipid concentrations, and the residual plasma was stored at −80°C until analyses for phospholipids. After collection of blood, the whole liver was quickly removed, rinsed in ice-cold saline, blotted on filter paper, and weighed. The liver was homogenized in four volumes (vol/wt) of an ice-cold 10 mM Tris-HCl buffer (pH 7.4) containing 0.15 M KCl, a modified solution of Nguyen *et al.* (9). An aliquot (12 mL) of the homogenate was centrifuged at 10,000 × *g* for 12 min at 4°C, and the resultant supernatants were further centrifuged at 105,000 × *g* for 60 min at 4°C to obtain the microsomal fraction as a precipitate. The microsomes obtained were resuspended in the homogenizing buffer and stored at −80°C until analyses for phospholipids and enzyme activity. Another aliquot (2 mL) of the liver homogenate was stored at −30°C until analyses for liver lipid concentrations.

Lipid analysis. The plasma concentrations of total cholesterol, high density lipoprotein (HDL) cholesterol, free cholesterol, triglycerides, and phospholipids were measured enzymatically with kits (Cholesterol C-Test, HDL Cholesterol-Test, Free Cholesterol C-Test, Triglyceride G-Test, and Phospholipid B-Test, respectively; Wako). The difference between total cholesterol and HDL cholesterol or free cholesterol was assumed to be very low density lipoprotein (VLDL) + low density lipoprotein (LDL) cholesterol or esterified cholesterol, respectively. The total lipids of liver homogenate, liver microsomes, and plasma were extracted by the method of Folch *et al.* (10). The cholesterol, triglycerides, and phospholipids in the extract of liver homogenate were measured according to Zak (11), Fletcher (12), and Bartlett (13), respectively. For the determination of phospholipid class composition, the phospholipids in the extract of liver microsomes were separated into each class by TLC on silica gel 60 (E. Merck, Darmstadt, Germany) using chloroform/methanol/water (65:25:4, by vol) as a developing solvent. The bands of each phospholipid class were visualized in iodine vapor, scraped off the plate, and analyzed directly for inorganic phosphorus (13). For the determinations of fatty acid and molecular species composition, PC was likewise separated by TLC from liver microsomes and plasma, visualized with dichlorofluorescein, scraped off the plate, and extracted with chloroform/methanol (1:2, vol/vol). An aliquot of PC was treated with 14% (w/w) BF_3/methanol reagent (Wako), and fatty acid methyl esters formed were analyzed by gas–liquid chromatography (GLC) on a Model GC-17A (Shimadzu, Kyoto, Japan), equipped with a TC-FFAP capillary column (0.25 mm × 30 m; GL Sciences, Tokyo, Japan). Another aliquot of PC was converted to diacylglycerol benzoates according to the method of Blank *et al.* (14). The diacylglycerol benzoates were analyzed by high-performance liquid chromatography (HPLC) on a Model LC-6A system (Shimadzu), equipped with an ODS column (4.6 × 250 mm, Lichrosorb RP-18; E. Merck), essentially according to the method of Blank *et al.* (14). Since some peaks consisted of two molecular species, the ratio of two molecular species was determined by GLC. A representative chromatogram of PC molecular species by HPLC was shown previously (5).

Enzyme assay. The activity of Δ6 desaturase in liver microsomes was measured essentially according to the method of Svensson (15). The reaction mixture (total 1.5 mL) consisted of 75 mM phosphate buffer (pH 7.0), 0.15 M KCl, 0.25 M sucrose, 0.5 mM nicotinamide, 5.5 mM $MgCl_2$, 5 mM ATP, 1.5 mM glutathione, 0.5 mM CoA, 1 mM NADH, 67 μM [1-^{14}C]linoleic acid (56 MBq/mmol), and liver microsomes (*ca.* 3 mg). After preincubation for 10 min at 37°C, the reaction was started by adding NADH, and the reaction mixture was further incubated for 20 min at 37°C in a test tube of wide bore (16 mm) under reciprocal shaking (120 cycle/min). The reaction was stopped by adding 1 mL of methanol containing 10% KOH (wt/vol). After saponification and subsequent acidification, fatty acids were extracted with petroleum ether. The extracted fatty acids, together with carrier fatty acids (linoleic acid and γ-linolenic acid), were methylated with BF_3/methanol reagent. The fatty acid methyl esters were separated by HPLC. The effluents of the peaks of γ-linolenic acid and linoleic acid were collected, and the radioactivity was counted by liquid scintillation counter. Protein was measured according to Lowry *et al.* (16) using bovine serum albumin as a standard.

Statistical analysis. Data were expressed as mean ± SEM for eight rats. Data were analyzed by one-way analysis of variance, and the differences between means were tested using Duncan's multiple range test (17) when the *F* value was significant. Simple correlation between variables was calculated by linear regression analysis using mean values. A *P* value of 0.05 or less was considered significant.

RESULTS

Effects on growth, food intake, liver weight, and liver lipid concentrations. There was no significant difference in the body weight gain and food intake of animals among the six groups (Table 1). Relative liver weights were not affected by eritadenine supplementation except for the highest dose. Eritadenine did not affect the concentration of cholesterol in the liver. Eritadenine tended to decrease the hepatic concentra-

[a]Values are mean ± SEM for eight rats. Values in a row with different superscript letters (b–e) are significantly different at $P < 0.05$.

tion of triglycerides and inversely to increase the concentration of phospholipids in a dose-dependent manner.

Effects on plasma lipids and liver microsomal phospholipids. Figure 1 shows the effects of dietary eritadenine on plasma lipid concentrations. The plasma total cholesterol concentration was significantly decreased by eritadenine supplementation in a dose-dependent manner, accompanying decreases in VLDL + LDL cholesterol, HDL cholesterol, and esterified cholesterol. The plasma phospholipid concentration was also significantly decreased by eritadenine in a dose-dependent manner, whereas the plasma triglyceride concentration was unaffected by eritadenine. As a whole, the maximal effect of eritadenine on plasma lipids was attained at an eritadenine level of 6 mg/kg diet.

Figure 2 shows the effects of dietary eritadenine on the concentration and proportion of phospholipids in liver microsomes. The concentration of PC was not affected by eritadenine supplementation, whereas the concentration of PE increased in response to eritadenine and reached a plateau at an eritadenine level of 10 mg/kg diet. The concentration of total phospholipids was slightly, but significantly, increased by eritadenine supplementation. The proportion of PC or PE to the total phospholipids was decreased or increased, respectively, by eritadenine supplementation in a dose-dependent manner. Consequently, the PC/PE ratio was also decreased by eritadenine in a dose-dependent manner.

Effects on fatty acid and molecular species composition of PC. Figure 3 shows the effects of dietary eritadenine on the proportion of selected fatty acids (linoleic and arachidonic acid) and their ratio in liver microsomal and plasma PC. The proportion of linoleic acid in liver microsomal PC was significantly increased by eritadenine supplementation in a dose-dependent manner, whereas the proportion of arachidonic acid was significantly decreased by eritadenine. Consequently, the ratio of arachidonic to linoleic acid was significantly decreased by eritadenine in a dose-dependent manner. The effects of eritadenine on linoleic and arachidonic acid in plasma PC were quite similar to those in liver microsomal PC. There was a significantly positive correlation in the ratio of 20:4n-6/18:2n-6 between liver microsomal PC and plasma PC ($r = 0.999$, $P < 0.001$). Furthermore, there was a significantly positive correlation between the 20:4n-6/18:2n-6 ratio and plasma total cholesterol concentrations ($r = 0.990$, $P < 0.001$). The minimal dose of eritadenine to bring about the maximal effect was 10 (for linoleic and arachidonic acid) or 6 (for the ratio of arachidonic to linoleic acid) mg/kg diet. The effects of eritadenine on the other fatty acids of PC were smaller than those on these two fatty acids (data not shown).

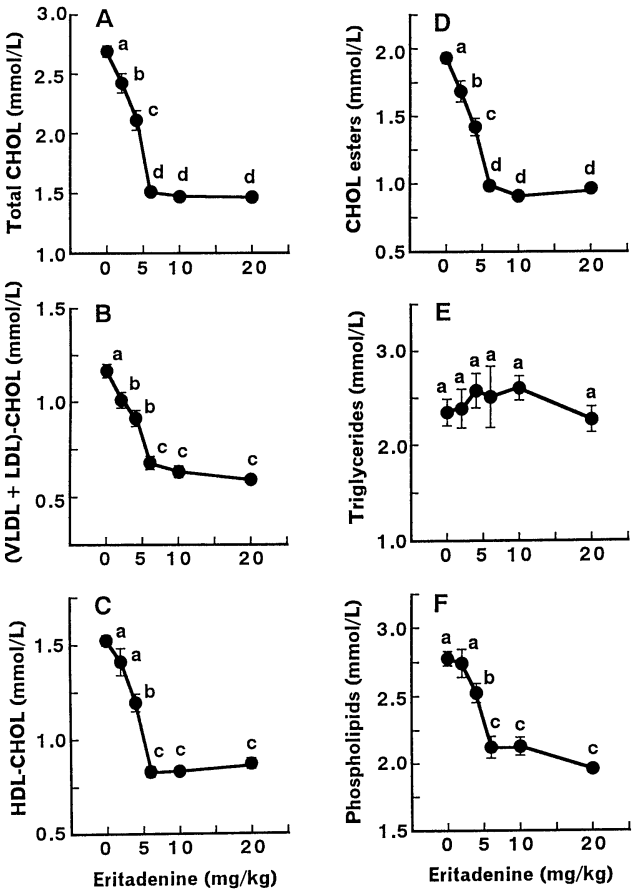

FIG. 1. Dose-dependent effects of dietary eritadenine on the plasma concentration of total cholesterol (A), VLDL + LDL cholesterol (B), HDL cholesterol (C), cholesterol esters (D), triglycerides (E), and phospholipids (F) in rats. The circle and its bar represent mean and SEM, respectively, for eight rats. Values with different letters are significantly different at $P < 0.05$. Abbreviations: CHOL, cholesterol; VLDL, very low density lipoprotein; LDL, low density lipoprotein.

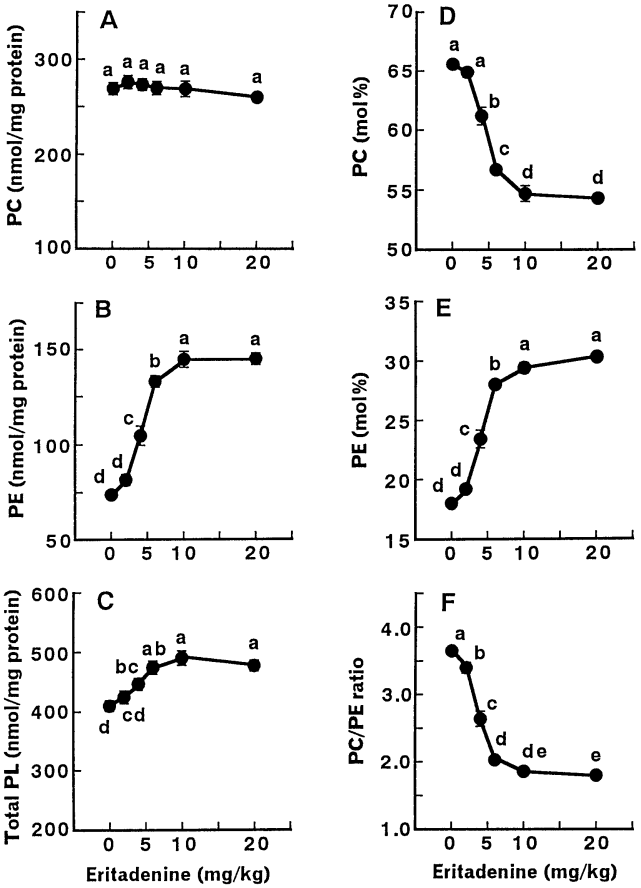

FIG. 2. Dose-dependent effects of dietary eritadenine on the concentration of phosphatidylcholine (A), phosphatidylethanolamine (B), and total phospholipids (C), the proportion of phosphatidylcholine (D) and phosphatidylethanolamine (E), and on the ratio of phosphatidylcholine to phosphatidylethanolamine (F) in liver microsomes of rats. The circle and its bar represent mean and SEM, respectively, for eight rats. Values with different letters are significantly different at $P < 0.05$. Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipids.

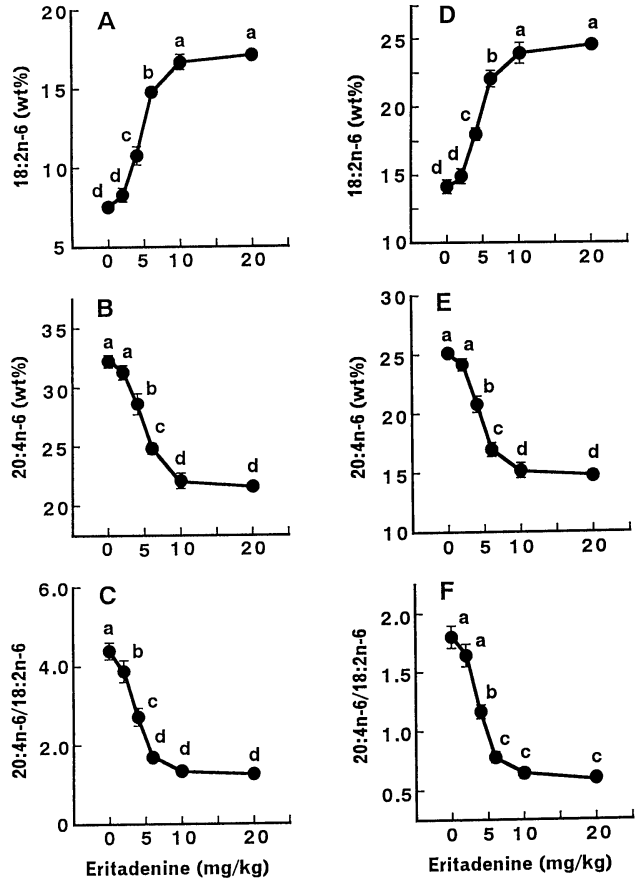

FIG. 3. Dose-dependent effects of dietary eritadenine on the proportion of linoleic acid, arachidonic acid, and the ratio of arachidonic to linoleic acid in liver microsomal phosphatidylcholine (A,B,C) and plasma phosphatidylcholine (D,E,F). The circle and its bar represent mean and SEM, respectively, for eight rats. Values with different letters are significantly different at $P < 0.05$.

Table 2 shows the effect of eritadenine on the molecular species composition of plasma PC. The proportion of 16:0-18:1 or three molecular species containing 18:2 in the *sn*-2 position increased in response to eritadenine supplementation in a dose-dependent manner and had a significantly negative correlation with plasma total cholesterol concentrations. On the contrary, the proportion of each molecular species containing 20:4, 22:5, or 22:6 decreased in response to eritadenine supplementation and had a significantly positive correlation with plasma total cholesterol concentrations. Of three PC molecular species containing 18:2 in the *sn*-2 position, the extent of increase in 16:0-18:2 was apparently greater than that of increase in the other molecular species. In contrast, the extent of decrease in 18:0-20:4 was greater than that of increase in 16:0-20:4 or 18:1-20:4. Similarly, eritadenine affected the molecular species composition of liver microsomal PC (data not shown); there were significantly positive correlations in the proportion of 16:0-18:2 or 18:0-20:4 between liver microsomal PC and plasma PC ($r = 0.996$, $P < 0.001$; $r = 0.998$, $P < 0.001$, respectively). There was a significantly negative correlation between the plasma total cholesterol concentration and the sum of the proportion of plasma PC molecular species containing 18:1 or 18:2 in the *sn*-2 position (Fig. 4).

Effect on Δ6-desaturase activity. Figure 5 shows the effect of dietary eritadenine on the activity of Δ6 desaturase in liver microsomes. The enzyme activity was found to be largely decreased by eritadenine supplementation in a dose-dependent manner. At the highest dose level (20 mg/kg), the enzyme activity was decreased to 28.8% of the value of eritadenine-unsupplemented control group. There was a significantly positive correlation between the Δ6-desaturase activity and the 20:4n-6/18:2n-6 ratio in liver microsomal PC ($r = 0.989$, $P < 0.001$). Further, the activity of Δ6 desaturase had a significantly positive correlation with the PC/PE ratio of liver microsomes (Fig. 6). In addition, there were correlations between the enzyme activity and the concentration (nmol/mg protein) of PE ($r = -0.977$, $P < 0.001$), the proportion (mol%)

[a]Values are mean ± SEM for eight rats in mol%. [b]Correlation coefficient with plasma total cholesterol concentration. [c]Fatty acids in the *sn*-1 and *sn*-2 positions of phosphatidylcholine are indicated at the left and right side, respectively. Values in a row with different superscript letters (d–i) are significantly different at $P < 0.05$. *,**,***Significant at $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively.

of PE ($r = -0.979$, $P < 0.001$), or the proportion of PC ($r = 0.968$, $P < 0.01$) in liver microsomes. However, there was no significant correlation between the enzyme activity and PC concentration in liver microsomes ($r = 0.515$, $P > 0.1$).

DISCUSSION

Effect of eritadenine on linoleic acid metabolism. The present study demonstrated that dietary eritadenine increases the proportion of linoleic acid and conversely decreases the proportion of arachidonic acid in liver microsomal and plasma PC in a dose-dependent manner (Fig. 3). These results can be taken to indicate that eritadenine suppresses the metabolic conversion of linoleic acid into arachidonic acid in rats. In support of this, the activity of Δ6 desaturase in liver microsomes, the rate-limiting enzyme in the metabolism of linoleic acid (18), was found to be largely depressed by eritadenine in a dose-dependent manner (Fig. 5). Furthermore, a significantly positive correlation could be detected between the Δ6-desaturase activity and the 20:4n-6/18:2n-6 ratio in liver microsomal PC. Thus, it is reasonable to conclude that eritadenine suppresses the metabolism of linoleic acid mainly by decreasing the activity of Δ6 desaturase. Leikin and Brenner (19–21) have shown that the activity of Δ6 or Δ5 desaturase was influenced by the composition of liver microsomal membrane constituents, such as PC/PE ratio or PC/cholesterol ratio, in rats. She *et al.* (22) also have shown that there was a significant correlation between the concentration of PC and the activity of Δ6 desaturase in rat liver microsomes which

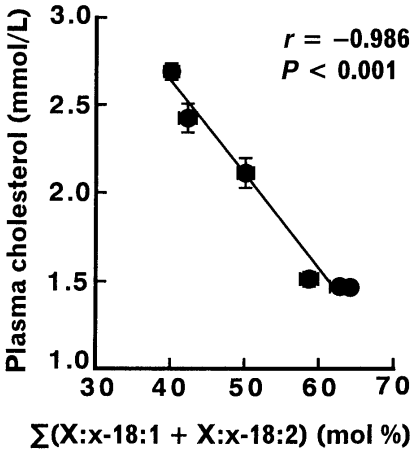

FIG. 4. Correlation between the plasma total cholesterol concentration and the proportion of certain plasma phosphatidylcholine molecular species in rats fed six experimental diets. The circle and its bar represent mean and SEM, respectively, for eight rats. Abbreviation: ∑(X:x-18:1 + X:x-18:2), the sum of phosphatidylcholine molecular species which contain 18:1 or 18:2 in the *sn*-2 position, where X:x denotes fatty acids in the *sn*-1 position (i.e., 16:0, 18:0, or 18:1).

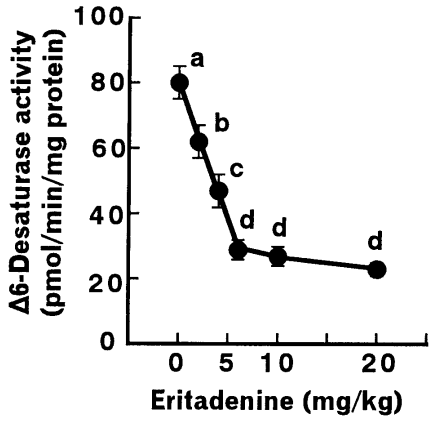

FIG. 5. Dose-dependent effect of dietary eritadenine on the activity of Δ6 desaturase in liver microsomes of rats. The circle and its bar represent mean and SEM, respectively, for eight rats. Values with different letters are significantly different at $P < 0.05$.

were treated with phospholipase C *in vitro* to hydrolyze membrane phospholipids for different times. Furthermore, Leikin and Shinitzky (23) have demonstrated that the Δ6 desaturase, which was isolated from rat liver microsomes by high hydrostatic pressure, has an associated lipid surrounding of PC and cholesterol at an approximately 4:1 mole ratio. These findings suggest that the activity of Δ6 desaturase in liver microsomes can be regulated by microsomal phospholipid composition. One of the most striking effects of eritadenine on microsomal phospholipids is an increase in PE concentration and a resultant decrease in the PC/PE ratio (Fig. 2). Therefore, it is reasonable to deduce that eritadenine may decrease the Δ6-desaturase activity, at least in part, through alteration of liver microsomal phospholipid profile. Indeed, the present study could demonstrate that Δ6-desaturase activity correlates with the PC/PE ratio (Fig. 6) or other variables, but not with PC concentration. These results suggest that the increase in PE or the resultant decrease in the proportion of PC, rather than PC concentration itself, might be associated with the eritadenine-induced decrease in Δ6-desaturase activity. At present, it is unclear whether the decrease in Δ6-desaturase activity is accompanied by a decrease in the enzyme mass.

The modification of fatty acid profile in liver microsomal PC caused by eritadenine is considered to reflect the fatty acid profile of plasma PC mainly through the secretion of lipoproteins from the liver into the blood circulation, although plasma PC can be metabolized by lecithin:cholesterol acyltransferase. In support of this, there was a highly significant correlation in the ratio of 20:4n-6/18:2n-6 between liver microsomal PC and plasma PC. This was also the case for the PC molecular species profile. Thus, it is likely that the alteration of liver microsomal phospholipid class profile, as represented by a decrease in the PC/PE ratio, is a cause of the suppressed activity of Δ6 desaturase and thereby finally modifies the fatty acid and molecular species profiles of plasma PC in rats fed eritadenine.

Relationship between linoleic acid metabolism and plasma cholesterol. Earlier reports have shown that eritadenine neither inhibits cholesterogenesis in the liver of rats (24–26) nor stimulates steroid excretion into feces (27). It has also been shown that the clearance rate of plasma cholesterol was faster in eritadenine-treated rats than in control rats (24–26). On the other hand, a slight suppression of hepatic secretion of plasma lipoproteins by eritadenine was observed (28). Eritadenine increases the requirement for dietary choline, since it depresses PC biosynthesis *via* PE *N*-methylation pathway (4). Hence, depressed lipoprotein secretion from the liver and resultant fat accumulation in the liver due to PC deficiency are brought about when adequate amounts of choline are not included in the diet. When the diet contained an adequate amount of choline chloride (8 g/kg diet), the secretion of triglycerides and cholesterol in a form of VLDL, as measured after Triton WR-1339 injection, was not impaired in eritadenine-fed rats compared with control rats (Sugiyama, K., and Yamakawa, A., unpublished data). This suggests that the essential hypocholesterolemic action of eritadenine cannot be ascribed to the depressed secretion of triglyceride-rich lipoproteins from the liver. In support of this, Vance *et al.* (29) have shown that 3-deazaadenosine, another adenosine analog which can depress PC biosynthesis *via* the PE *N*-methylation pathway, did not affect the secretion of apoproteins and PC from cultured rat hepatocytes even though the cellular PC/PE ratio was significantly decreased. Taken together, these results suggest that eritadenine may exert its hypocholesterolemic action mainly through the enhanced uptake of plasma lipoprotein cholesterol by tissues. In addition to the hypocholesterolemic action, the increase in linoleic acid or the decrease in arachidonic acid due to the suppression of linoleic acid metabolism is another noticeable metabolic change caused by eritadenine. Therefore, it seems reasonable to consider that the suppression of linoleic acid metabolism also may be associated with the hypocholesterolemic action of eritadenine. Actually, in the present study, there was a significant correlation between the 20:4n-6/18:2n-6 ratio and plasma total cholesterol concentrations. It is established that dietary linoleic acid, compared with saturated fatty acids, lowers plasma total and LDL cholesterol in humans (30). It has been shown that dietary linoleic acid enhances the clearance rate of LDL in humans (31) and raises receptor-mediated uptake of LDL in rabbits (32) and hamsters (33), indicating that one of the mechanisms of the hypocholesterolemic action of linoleic acid is enhanced uptake of plasma LDL by tissues. In contrast, the hypocholesterolemic action of dietary linoleic acid in rats appears to be relatively weak (34,35). With regard to this, it is worthwhile to note that in humans the activity of Δ6 desaturation is lower than that in some animal species, including rats (36). Reflecting this, the proportion of linoleic acid is higher than arachidonic acid in plasma PC of humans (37), while the proportion of arachidonic acid is higher than linoleic acid in plasma PC of rats (38). Moreover, some hypocholesterolemic substances, such as PE (39) and soybean protein (38,40), have been shown to suppress the metabolism of linoleic acid and consequently increase the proportion of linoleic acid in plasma PC or phospholipids in rats. Thus, it is likely that in rats the sup-

pression of linoleic acid metabolism is one of the most effective means to elevate the proportion of linoleic acid in plasma PC and to lower the plasma cholesterol concentration.

It is confirmed that certain lipoproteins, e.g., LDL, are taken up whole by tissues *via* receptor-mediated mechanism (41). At present, it is not known whether eritadenine enhances the activity of lipoprotein receptors. As for the hypocholesterolemic action of polyunsaturated fats (linoleic acid), it was postulated that increased fluidity of LDL receptor membranes due to incorporation of polyunsaturated fatty acid may participate in enhanced LDL apoprotein B catabolism in cynomolgus monkeys fed linoleic acid-rich fats (42). Since eritadenine increased the proportion of linoleic acid in liver microsomal phospholipids, the possibility that eritadenine also may increase the proportion of linoleic acid in lipoprotein receptor membrane phospholipids, and thereby may enhance the receptor activity, cannot be ruled out. In addition to lipoprotein receptor activity, the molecular species of plasma lipoprotein PC can affect the uptake rate of lipoprotein. Kadowaki *et al.* (43) have demonstrated that the uptake of reconstituted HDL cholesterol by perfused rat livers was largely influenced by the PC molecular species used for the reconstitution of HDL. They showed that the uptake of cholesteryl oleate of reconstituted HDL by the liver was most stimulated by 16:0-18:2 PC of five PC molecular species tested (16:0-18:2, 16:1-16:1, 18:0-18:2, 18:1-16:0, and 20:1-20:1). These results were explained in terms of different susceptibility of lipoprotein PC molecular species toward hepatic lipase, since the hydrolysis of HDL phospholipids by hepatic lipase is necessary for the subsequent uptake of HDL constituents (44). Indeed, 16:0-18:2 PC incorporated into the reconstituted HDL was most hydrolyzed by hepatic lipase *in vitro* (43). The uptake of the remnants of chylomicron (45) and VLDL (46) was also suggested to be mediated by hepatic lipase. These findings suggest that the phospholipid molecular species composition of plasma lipoproteins may participate in the regulation of plasma cholesterol concentration *via* the uptake process of plasma lipoproteins by the liver. Unlike the model experiments, it is not known whether some hypo- or hypercholesterolemic substances in the diet exert their action actually through such a mechanism. However, it seems reasonable to deduce that dietary eritadenine-induced alteration of plasma PC molecular species profile may be associated with the hypocholesterolemic action of eritadenine, since one of the most prominent changes in plasma PC molecular species caused by eritadenine is an increase in 16:0-18:2 PC.

The correlation analysis showed that most of the molecular species containing 18:1 or 18:2 in the *sn*-2 position and all of the molecular species containing 20:4, 22:5, or 22:6 have significant negative and positive correlations with plasma total cholesterol concentrations, respectively (Table 2). These results, however, must be carefully interpreted, since the correlation does not necessarily indicate the cause–effect relationship. For instance, it has been shown that dietary supplementation with 22:6n-3 increases the proportion of 22:6n-3 and 20:5n-3 in plasma PC with concomitant decrease in plasma cholesterol concentration in rats (47), indicating that plasma PC molecular species containing 22:6 or 20:5 is not necessarily associated with hypercholesterolemia. Nonetheless, plasma PC molecular species may be roughly and conveniently divided into two groups in relation to the plasma cholesterol concentration; one group consists of those molecular species containing 18:1 or 18:2 in the *sn*-2 position, and another group consists of those containing 20:4, 22:5, or 22:6. The fact that there was a significantly negative correlation between the plasma total cholesterol concentration and the proportion of plasma PC molecular species containing 18:1 or 18:2 in the *sn*-2 position (Fig. 4) appears to support that suppressed metabolism of linoleic acid (and probably 18:1) leads to reduction of plasma cholesterol, at least in part, through increases in certain plasma PC molecular species containing 18:2 and 18:1. However, the detailed mechanism remains to be further elucidated.

Effect of Trifluoperazine on Certain Arterial Wall Lipid-Metabolizing Enzymes Inducing Atherosclerosis in Rhesus Monkeys

A. Mohindroo and P. Ahluwalia*

Department of Biochemistry, Panjab University, Chandigarh, India 160014

ABSTRACT: The effect of trifluoperazine (TFP) was investigated on arterial wall lipid-metabolizing enzymes like acyl-CoA:cholesterol acyltransferase (ACAT) and cholesterol ester hydrolase (CEH) in rhesus monkeys. The activity was determined in aortic wall homogenates obtained from rhesus monkeys fed an atherogenic diet coupled with intramuscular injections of adrenaline and TFP. Although TFP had no significant effect on serum cholesterol and triglycerides, it decreased significantly the formation of atherosclerotic lesions by decreasing the esterification of cholesterol, by inhibiting ACAT and enhancing its utilization by activating CEH. Hence, the preventive effect of TFP on the development of atherosclerosis in rhesus monkeys is mediated through its ability to influence the activities of arterial wall lipid-metabolizing enzymes like ACAT and CEH.

Lipids 32, 867–872 (1997).

Atherosclerosis is one of the major causes of death in both developed and underdeveloped countries. This slowly progressive disease begins in childhood and does not become manifest until middle age or later (1). In both man and experimental animals, the most striking feature of this disease is its focal topography. Although classified as a systemic disorder, it does not occur randomly but rather at specific, so-called lesion-prone sites that differ structurally and functionally from nonlesion-prone sites. These lesion-prone areas are characterized by increased permeability of the endothelium to plasma proteins, such as albumin, fibrinogen, and low density lipoprotein-cholesterol. In animals challenged with a diet high in fat and cholesterol, these sites also show a marked increase in intimal cholesterol accumulation (2). Rhesus monkeys are potentially the most useful animal models to study atherosclerosis, as they are phylogenetically close to humans, develop arterial lesions similar to those seen in people, and develop changes in their lipoprotein profiles in response to a cholesterol-containing diet as observed in humans (3,4).

In experimental animals as well as humans, the metabolic activity of the arterial wall constitutes an approach for evaluating the pathogenesis of atherosclerosis (5). The arterial wall and its main structural component, the smooth muscle cell, are metabolically active tissue; hence it is anticipated that most enzymes characteristic of living matter are to be found in this tissue and that their activities are affected by changes in the microenvironment (6). Many membrane-active compounds known to inhibit transition from bilayer to micellar domains within membranes, such as chloroquine, 17-β estradiol and chlorpromazine, can suppress the formation of atheromatous lesions by changing the microenvironment of the arterial wall (7–9). In addition, a number of antiproliferative and antiinflammatory drugs, affecting the cellular, lipid and fibrous components of the lesion, prevent the formation of atherosclerotic lesions without reducing the serum lipid levels (10). Similarly, trifluoperazine (TFP), an antipsychotic drug belonging to the phenothiazine class of compounds and a potent inhibitor of calmodulin and protein kinase C, also acted as a preventive agent against cholesterol-induced experimental atherogenesis in rabbits without affecting the serum lipid profile because of its capacity to interact with cellular membrane phospholipids, leading to an alteration in membrane organization (11–13).

A literature survey showed that little work has been reported using TFP as an antiatherosclerotic agent especially in the arterial wall tissue of rhesus monkeys. In the present work, we studied the effects in atherogenic rhesus monkeys of TFP on their lipids and lipoproteins profile, and on the activities of acyl-CoA:cholesterol acyl transferase (ACAT) and cholesterol ester hydrolase (CEH), two important lipid-metabolizing enzymes of the arterial wall (14,15), which are important in the onset of atherosclerosis.

MATERIALS AND METHODS

Eighteen healthy tuberculosis-negative, adult male rhesus monkeys, 4–5 kg in weight, were acclimatized in the animal house for a period of 2 mon before starting the experiment. The animals were fed a normal diet (wheat flour) and fruits. Water was provided *ad libitum*. A course of broad-spectrum antibiotic (streptomycin; Indian Drugs and Pharmaceuticals Ltd. Rishikesh, India) and a deworming agent (Numental sus-

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; CEH, cholesterol ester hydrolase; TFP, trifluoperazine.

pension, Searle, Mumbai, India) were given to each animal during the acclimatization period.

After 2 mon, the animals were divided into three groups of six monkeys each, selected on the basis of matching body weight and basal serum lipid profiles, and daily were given the following for 8 mon: Group I (control): normal diet (200 g wheat flour containing 11.8% protein, 1.5% fat, 71.2% carbohydrates, 1.2% fiber, 1.5% minerals) + 15 g butter (containing 81% fat, 2.5% minerals). Group II: atherogenic diet (200 g wheat flour, 15 g butter, and 1 g cholesterol) along with intramuscular adrenaline (250 µg/animal) (Bengal Immunity Ltd., Calcutta, India), to enhance the production of atheromatous lesions. Group III: atherogenic diet, intramuscular adrenaline (as in Group II), and intramuscular TFP (1 mg/animal, or 10 µM in blood) (Espazine, Mumbai, India).

In all groups, the following investigations were performed at 0 d, 4 mon, and 8 mon: (i) clinical: The general condition, body weight, and blood pressure of each monkey were monitored; (ii) biochemical: The extent of induced hypercholesterolemia and hyperlipidemia was monitored by measuring serum total cholesterol and triglyceride by the methods of Zak and of Gottfried and Rosenberg, respectively (16,17). The major lipoprotein fractions, low density and high density lipoproteins, were separated by a single, discontinuous, density-gradient ultracentrifugation (Beckman Instruments, Nyon, Switzerland) in a vertical rotor according to the method of Chung *et al.* (18).

For all lipid and lipoprotein assays, blood was drawn from the femoral vein of overnight-fasted monkeys. For obtaining plasma, 0.1% EDTA (Sigma Laboratories, Wadala, Mumbai, India) was added to the blood collection tubes, and lipoprotein fractions were separated immediately by ultracentrifugation (TV-865). The animals were fully conscious when blood pressure was measured and when blood was drawn from the femoral vein.

For enzyme assays, the animals were killed by an intravenous injection of sodium pentothal. The thoraco-abdominal cavity was opened, and the aorta of each animal was removed. Homogenates of aortic tissues were prepared by the method of Stein *et al.* (19). The aorta was excised and rinsed in ice-cold KCl-Tris buffer. The aortas were carefully freed of any adventitial tissue, finely minced, and homogenized with 10 vol KCl-Tris buffer for 1 min. The homogenate was centrifuged at 1000 rpm for 2 min, the supernatant decanted, and the sediment resuspended in 5 vol of KCl-Tris. It was rehomogenized for 1 min and recentrifuged under the same conditions. The combined supernatants, termed aortic homogenate, were used as the enzyme source.

The activities of ACAT and CEH were determined at both the lesion site and the normal site adjacent to the lesion in aortas of all the animals at the termination of the experiment (i.e., 8 mon). All the estimations were carried out in cold conditions, and enzyme activities were assayed on the same day of sacrifice.

ACAT (E.C. 2.3.1.26). Arterial wall ACAT activity was assayed in aortic homogenates by determining the amount of incorporation of oleate (Sigma) into cholesterol ester in the presence of ATP and CoA. The method was adapted from Balasubramaniam *et al.* (20). The incubation mixture, having a final volume of 0.2 mL, contained 0.1 M potassium phosphate buffer, pH 7.4, 2 mM ATP, 4 mM $MgCl_2$, 0.2 mM CoA, 2 mM dithiothreitol, human albumin (1.2 mg/assay), and 20 µg cholesterol in 2 µL acetone (all solvents from Sigma). The reaction was initiated with the addition of 0.1 M oleate. The solution was incubated for 20 min at 37°C, and the reaction was stopped by adding chloroform/methanol (2:1, vol/vol). The cholesteryl esters were isolated by thin-layer chromatography by the method of Yao and Rastetter (21), using silica gel H (Sigma). The plates were developed in the following three solvent systems: Solvent I: benzene/diethyl ether/ethanol/acetic acid (60:40:1:0.05, by vol); Solvent II: hexane/diethyl ether (94:6, vol/vol); Solvent III: hexane alone.

After drying, the plates were placed in an iodine chamber. Spots of cholesterol ester were scraped off and eluted with different concentrations of chloroform/methanol. The cholesterol was then measured by the method of Zak (16).

CEH (E.C. 3.1.1.13). The modified method of Brecher *et al.* (22) was used to determine the activity of CEH in aortic tissue by measuring the amount of cholesterol ester hydrolyzed. Cholesterol ester, dissolved in 50 µL acetone, was used as a substrate and injected directly into the aortic homogenate mixture, which was then incubated for 60 min at 37°C. Then 10 mL chloroform/methanol (2:1, vol/vol) was added to terminate the reaction. The cholesterol and cholesterol esters were separated by thin-layer chromatography by the method of Yao and Rastetter (21), as described above.

Histopathological studies. At the termination of the experiment, i.e., after 8 mon of atherogenic diet administration along with intramuscular injections of adrenaline and TFP, the aortas were taken for histopathological studies. The aortas of each animal was cut at its origin, removed together with its large branches, and fixed in buffered 10% formol saline. The aorta was split open longitudinally and stained with freshly prepared Sudan IV solution for the identification of atherosclerotic lesions (23).

Two-way analysis of variance was carried out to compare all three groups, including the control. For further comparison of test groups with the control, Bonferroni *t*-test statistics were applied; in these, the population variance is estimated by the mean square error of the analysis of variance. These statistics were performed only for those parameters for which the *F*-value was found to be significant.

RESULTS AND DISCUSSION

In the present study TFP was used as an antiatherogenic agent (24). TFP was administered to the rhesus monkeys at a level of 1 mg/animal/d along with an atherogenic diet and adrenaline, which induces hypertension that is associated with an increase in vascular smooth muscle cell (SMC) mass and abnormal growth of arterial media, similar to that observed in atherosclerosis.

[b]Values in parentheses represent percentage change with respect to zero day.

During the experiment, all animals maintained good health and remained active, and no significant changes were observed in the blood pressure or amount of diet and water intake (Table 1).

TFP seemed to have no significant inhibitory effect on serum lipids, as the level of total cholesterol and triglycerides decreased by only 2.7 and 2.75%, respectively, from that of Group II (animals having atherosclerotic lesions). These parameters showed a highly significant increase, by 180 and 37%, respectively, compared to that of control animals (Group I) similar to that of Group II (Table 2). The administration of TFP did not affect the plasma low density lipoprotein– and high density lipoprotein–cholesterol, as their levels remained almost similar to the atherosclerotic group (Group II) (Table 3).

During histopathological examination of Group II animals, extensive sudanophilic staining, indicating fatty streak formation, was observed (Fig. 1), and two animals of this group showed the formation of fibrous plaque (Fig. 2). In contrast, the aortas of Group III animals (TFP-treated) showed scanty sudanophilic fatty streak formation (Fig. 3). The frequency of atheromatous plaques was significantly less in Group III than Group II (Table 4). These observations clearly indicate that TFP can prevent the formation of fatty streaks leading to atherosclerosis in the aorta of rhesus monkeys.

The change in specific activities of ACAT and CEH was also studied by the *in vitro* addition of 0, 10, 25, 50, 75, and 100 μM of TFP to the aortic homogenates of normal rhesus monkeys. With increasing concentrations of TFP, a significant decrease in the specific activity of ACAT and a nominal

increase in specific activity of CEH were observed (Table 5).

ACAT is the primary enzyme responsible for the esterification of cholesterol in all animal cells and is involved in its absorption, very low density lipoprotein secretion, and the formation of lipid-filled macrophages and SMC (14). In the present work, *in vitro* addition of TFP inhibited ACAT activity significantly in the normal aortic tissue (Table 5), maybe by affecting the biophysical properties of cell membrane owing to changes in the membrane–lipid fluidity as reported by Bell and Hubert (9). Moreover, Mehta and Kaul (25) reported that *in vitro* addition of TFP at a concentration of 25 μM inhibited the accumulation of free and esterified cholesterol in the SMC, by inhibiting ACAT activity in hypercholesterolemic conditions.

The activities of ACAT and CEH were determined in aortic homogenates of hypercholesterolemic rhesus monkeys, both at the normal (adjacent to the lesion) site and the lesion site. The *in vivo* administration of TFP significantly decreased the specific activity of ACAT at both the normal and the lesion sites, by 70 and 64%, respectively, as compared to the atherogenic group (Group II) (Table 6). ACAT is responsible for the esterification and storage of cholesterol in the macrophage, and it was hypothesized that the inhibition of arterial wall ACAT might prevent the formation of macro-

phage-enriched fatty streaks and the development of clinically significant fibrous plaque (14), as observed in the present work. This antiatherosclerotic effect of TFP, achieved in the absence of cholesterol lowering, seemed to be in contrast to the reports in literature with other ACAT inhibitors such as CL 277082 (26) and cyclandelate (27), which were marked by reduced plasma cholesterol levels in rabbits along with a reduction in total aortic cholesterol content. Another ACAT inhibitor, U-73482, elevated high density lipoprotein-cholesterol in a dose-related fashion in rats (28).

In contrast to these reports, and in accordance with present observations, Bocan *et al*. (14) showed that the inhibition of ACAT within the arterial wall by specific inhibitors like CI-976 could result in the inhibition of atherosclerotic lesion progression and enhance regression without lowering cholesterol. Although TFP had no significant lowering effect on serum cholesterol and triglycerides in the present work, it did reduce the production of lesions and fatty streaks in aortas. These observations may be due to its inhibitory effect on ACAT activity.

The administration of TFP to Group III animals significantly increased the activity of CEH, by 12 and 53%, respectively, at both the normal and the lesion sites, as compared to Group II (atherosclerotic animals); whereas, compared to normal animals (Group I), the activity level was still higher, by 21%, at the lesion site (Table 7). Thus, TFP seemed to protect

the aortic tissue from excess deposition of cholesterol esters by increasing the aortic wall CEH activity, thereby increasing the release of free cholesterol from the macrophages. These cells are involved in the formation of foam cells in atherosclerosis, a disease characterized by a marked increase in the content of cholesterol esters in the arterial wall owing either to a deficiency of CEH or low CEH activity (29,30). Thus, an increase in the activity of CEH seemed to be beneficial for the prevention of deposition of cholesterol esters in the atherosclerotic lesions.

The foregoing observations suggested that TFP reduced the production of fatty streaks in the aortic tissue by decreasing the esterification of cholesterol through inhibition of inhibiting ACAT and enhanced activation of CEH.

ABSTRACT: Competitive inhibitors of 3-hydroxy-3-methylglutaryl-CoA reductase improve hypercholesterolemia. However, reports about the effects of these agents on bile acid synthesis, the metabolic pathway of cholesterol, are conflicting. We studied the short-term effect of one of these agents, pravastatin, on bile acid synthesis. Six male volunteers were given 40 mg of pravastatin. Plasma mevalonate level (which reflects cholesterol synthesis) and 7α-hydroxy-4-cholesten-3-one level (which reflects bile acid synthesis) were measured every 2 h for 8 h. These plasma levels were compared to those of the same volunteers without pravastatin. Plasma mevalonate level after 2 h was lower than control (3.0 ± 1.1 ng/mL vs. 6.7 ± 2.5, mean ± SD; $P < 0.05$). This decrease continued for 8 h (2.5 ± 0.8 vs. 5.2 ± 1.5; $P < 0.05$). On the other hand, plasma 7α-hydroxy-4-cholesten-3-one level did not change until after 6 h; then at 8 h it was lower than control (15.7 ± 11.8 ng/mL vs. 24.7 ± 16.9; $P < 0.05$). According to three-way layout analysis of variance, mevalonate level was influenced by both pravastatin treatment ($P < 0.01$) and time-course ($P < 0.01$). On the other hand, the 7α-hydroxy-4-cholesten-3-one level was affected by both individual difference ($P < 0.01$) and time course ($P < 0.01$), but pravastatin treatment did not influence this compound. This indicates that bile acid synthesis was not influenced by pravastatin, although cholesterol synthesis was inhibited. The short-term inhibition of cholesterol synthesis did not affect bile acid synthesis.

Lipids 32, 873–878 (1997).

Cholesterol homeostasis in humans is maintained by two input pathways (dietary absorption and *de novo* synthesis) and two output pathways in liver (direct secretion to bile and conversion to bile acids) (1). The rate-limiting step in cholesterol synthesis is conversion of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) into mevalonate (MVA) by HMG-CoA reductase (E.C. 1.1.1.34) (2,3). On the other hand, the first and rate-limiting step in the neutral pathway of bile acid synthesis is catalyzed by cholesterol 7α-hydroxylase (E.C. 1.14.13.7) (4,5). It is well-known that the activities of these two key enzymes change in parallel in the normal physiological state (1).

Competitive inhibitors of HMG-CoA reductase, such as lovastatin, simvastatin and pravastatin, are widely used for treatment of hypercholesterolemia (6). Many investigators have studied the effects of HMG-CoA reductase inhibitors on bile acid synthesis or bile acid secretion in different systems, including animals (7–10), patients with hyperlipidemia (11–13), biliary drainage (14), gallstone (15), and normal subjects (16,17). However, their results were conflicting: bile acid synthesis or bile acid secretion was decreased (7,14, 16,18), increased (15), or unchanged (8–13,17).

In previous studies, we reported convenient and noninvasive indices for the activity of HMG-CoA reductase (19) and cholesterol 7α-hydroxylase (20). Plasma level of MVA, the index of HMG-CoA reductase activity, has sufficient sensitivity to detect the circadian rhythm of cholesterol synthesis (21–23). The plasma level of 7α-hydroxy-4-cholesten-3-one (7α-3one), the index of cholesterol 7α-hydroxylase activity, also has enough sensitivity to detect the circadian rhythm of bile acid synthesis (20). This result indicates that they are useful for monitoring short-term changes. In this study, we report the effect of pravastatin, one of the HMG-CoA reductase inhibitors, on bile acid synthesis in humans under normal physiological conditions, using these indices.

MATERIALS AND METHODS

Chemicals. Heptadeutero-mevalonolactone (MVL-d_7) and heptadeutero-7α-3one (7α-3one-d_7) were prepared as described previously (19,20). Solid-phase column cartridges (Bond Elut SAX, Bond Elut C18, Bond Elut CN, and Bond Elut SI) were purchased from Varian (Harbor City, CA). Dimethylethylsilylimidazole (DMESI) was purchased from Tokyo Kasei Kogyo (Tokyo, Japan). Solvents and other reagents were analytical reagent grade.

Abbreviations: ANOVA, analysis of variance; DMESI, dimethylethylsilylimidazole; GC–MS, gas chromatography–mass spectrometry; HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA; 7α-3one, 7α-hydroxy-4-cholesten-3-one; MVA, mevalonate.

Subjects. Six healthy normal male volunteers, aged 20 to 30 yr, were studied. All subjects were free of hyperlipidemia, renal dysfunction, and hepatic impairment. Informed consent was obtained from each volunteer prior to the study, which conforms to the ethical guidelines of the 1975 Declaration of Helsinki.

Sample collection. The volunteers consumed nothing but water from 5:30 p.m. on the day before study until the end of the study in order to avoid enterohepatic circulation of bile acids. They took 40 mg of pravastatin sodium orally immediately after venous blood was collected at 9:30 a.m. Thereafter, venous blood was sampled every 2 h for 8 h. The collected blood was heparinized and immediately centrifuged at 1000 $\times g$ for 15 min, 1 mL of plasma was used at once for the determination of lipoprotein fractions, and the residual plasma was stored at −20°C until analyzed. All volunteers were used as controls (without administration of pravastatin) more than 7 d before commencement of this study.

Cholesterol and lipoproteins in blood. Plasma total and free cholesterol were measured by enzymatic method (24). Plasma low density lipoprotein and very low density lipoprotein were determined by the method of Burstein (25).

Plasma levels of pravastatin. Plasma levels of pravastatin sodium and its major metabolite, 3-hydroxy-pravastatin, were determined by gas chromatography–mass spectrometry (GC–MS) (26).

Plasma levels of MVA. The plasma level of MVA, an index of the activity of HMG-CoA reductase, was determined by the method described previously (19). In brief, 8 ng of MVL-d_7 was added to 500 μL of plasma as an internal standard. MVA in plasma was extracted and purified by serial solid-phase extractions, using Bond Elut SAX, Bond Elut C18, and Bond Elut CN cartridges. The extract was derivatized with benzylamine followed by DMESI. The resulting mevalonylbenzylamide derivative was determined by GC–MS.

Plasma levels of 7α-3one. The plasma level of 7α-3one, an index of cholesterol 7α-hydroxylase activity, also was determined according to the method described previously (20). A 7-ng aliquot of 7α-3one-d_7 was added to 200 μL of plasma as an internal standard. Then, 7α-3one was extracted from plasma by salting-out extraction and was purified by serial solid-phase extractions using Bond Elut C18 and Bond Elut SI cartridges. The extract was treated with *O*-methylhydroxylamine hydrochloride, then with DMESI. The resulting methyloxime–dimethylethylsilyl ether derivative was quantified by GC–MS.

Statistical analysis. The diurnal changes of plasma MVA and 7α-3one in controls were evaluated by Friedman's test. At each time point after administration of pravastatin, the plasma MVA, 7α-3one, and plasma lipids were compared with those levels at the same time point in controls by the paired *t*-test. The relative concentrations of MVA and 7α-3one were calculated as follows: relative concentration = level at each time/level at 0 h × 100 (%). The degree of influence of changes in relative concentration was evaluated by three-way layout analysis of variance (ANOVA). Time-course change (diurnal rhythm), pravastatin treatment, and individual difference were used as the parameters in this analysis. Probability less than 0.05 was defined as statistical significance.

RESULTS

Plasma concentration of pravastatin and its metabolite. As shown in Figure 1, levels of pravastatin sodium and its 3-hydroxy metabolite reached their maximum at 2 h after oral administration of pravastatin (69.7 ± 41.9 ng/mL and 26.7 ± 14.6 ng/mL, mean ± SD, respectively). They then decreased gradually until 8 h (6.8 ± 2.5 ng/mL and 1.1 ± 0.5 ng/mL).

Changes of plasma lipids. Table 1 shows the changes of total cholesterol, free cholesterol, low density lipoprotein and very low density lipoprotein levels with and without pravastatin. Cholesterol levels and lipoprotein levels after pravastatin administration were not found to be different from controls at the same time point.

Plasma levels of MVA. The diurnal changes of plasma MVA level with and without pravastatin are shown in Figure 2. MVA level in controls showed diurnal variation by Friedman's test ($P < 0.05$), whereas plasma MVA level at 2 h after pravastatin administration had fallen to 3.0 ± 1.1 ng/mL, significantly lower than controls (6.7 ± 2.5 ng/mL, $P < 0.05$). This decrease continued for 8 h (2.5 ± 0.8 ng/mL vs. 5.3 ± 1.5 ng/mL, $P < 0.05$).

Plasma levels of 7α-3one. Figure 3 shows the diurnal changes of 7α-3one levels with and without pravastatin. The plasma level of 7α-3one in controls did not exhibit diurnal variation, and the level after pravastatin administration was

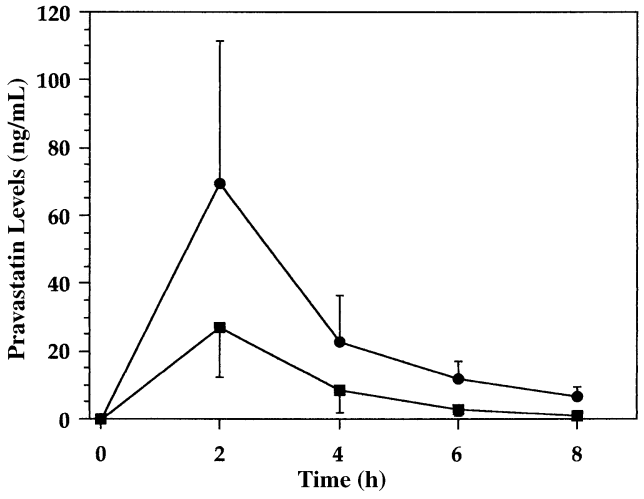

FIG. 1. Plasma levels of pravastatin sodium and its major metabolite determined by gas chromatography–mass spectrometry (GC–MS) after oral administration of 40 mg of pravastatin sodium to six volunteers. The levels of these compounds reached maximum at 2 h after administration, then decreased; ●: pravastatin sodium, ■: metabolite. Error bars express mean ± SD.

TABLE 1
Changes in Total Cholesterol, Free Cholesterol, Low Density Lipoprotein, and Very Low Density Lipoprotein After a Single Dose of Pravastatin[a]

Time	T-Cho (mg/dL)		F-Cho (mg/dL)		LDL (mg/dL)		VLDL (mg/dL)	
(h)	Control	Pravastatin	Control	Pravastatin	Control	Pravastatin	Control	Pravastatin
0	177.0 ± 26.9	182.7 ± 30.6	44.2 ± 7.3	50.6 ± 7.9	413.3 ± 130.1	400.8 ± 172.3	104.9 ± 71.1	120.4 ± 63.9
2	185.9 ± 29.5	182.9 ± 30.6	39.9 ± 13.5	48.3 ± 8.5	423.6 ± 154.3	395.7 ± 162.2	122.3 ± 68.5	107.2 ± 57.6
4	183.6 ± 37.5	179.5 ± 31.3	44.0 ± 7.4	46.9 ± 8.2	432.0 ± 153.4	386.1 ± 162.5	116.8 ± 67.2	106.2 ± 54.7
6	184.2 ± 24.6	178.4 ± 33.5	44.2 ± 6.8	47.5 ± 8.6	416.7 ± 136.6	392.0 ± 159.0	125.3 ± 77.8	111.4 ± 60.3
8	179.4 ± 27.5	180.8 ± 32.9	45.7 ± 6.4	48.9 ± 8.7	418.7 ± 151.6	395.2 ± 166.3	126.2 ± 73.3	120.6 ± 74.5

[a]Each value represents mean ± SD. T-Cho, total cholesterol; F-Cho, free cholesterol; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

not significantly different from the control until 6 h. However, the plasma level of 7α-3one at 8 h after pravastatin administration was significantly lower than controls (15.7 ± 11.8 ng/mL vs. 24.7 ± 16.9 ng/mL, $P < 0.05$).

Relative concentration of MVA and 7α-3one. The changes in relative concentration of MVA and 7α-3one are shown in Table 2. These relative concentrations of each index were evaluated by ANOVA (Table 3). Individual difference, the pravastatin treatment, and time-course change were used as the factors of this analysis. Pravastatin treatment and time course were significant factors for the change of MVA levels ($P < 0.01$). On the other hand, pravastatin treatment did not affect the levels of 7α-3one, while individual difference and time course were significant factors for the change of 7α-3one levels ($P < 0.01$).

DISCUSSION

Pravastatin and the other HMG-CoA reductase inhibitors are used widely for the treatment of hyperlipidemia. According to pharmacokinetic studies, the plasma levels of pravastatin and its metabolites reach their maximal level at 1 h after oral administration (27). In this study, the levels of pravastatin and its metabolite reached maximal level at 2 h, although we did not measure those levels at 1 h after administration. Cholesterol and plasma lipoproteins showed no significant change. These results suggest that cholesterol homeostasis does not change within 8 h after administration of pravastatin.

We measured plasma levels of MVA and 7α-3one to evaluate the single-dose effect of pravastatin on cholesterol and bile acid synthesis. We and other authors have reported that plasma levels of MVA and 7α-3one are indices of cholesterol synthesis (19,21–23,28–31) and bile acid synthesis (20,32, 33), respectively. These plasma indices can be used to monitor short-term serial change of cholesterol and bile acid synthesis.

First, we observed the diurnal variation of plasma MVA and 7α-3one levels in controls. The MVA level showed a diurnal rhythm as previously reported (21–23). On the other hand, the 7α-3one level in controls did not show diurnal change. According to our previous results, however, 7α-3one level had a circadian rhythm in healthy volunteers (20). The discrepancy between these results might be due to the entero-

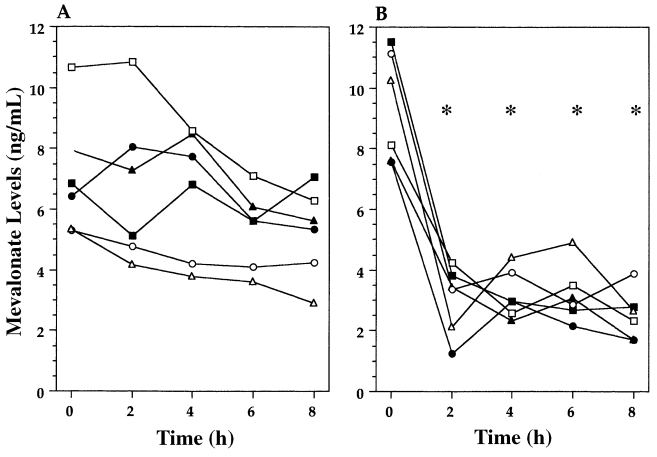

FIG. 2. Diurnal changes of plasma mevalonate (MVA) levels determined by GC–MS without (A), and with pravastatin (B). Plasma samples were collected from six healthy volunteers every 2 h for 8 h. Diurnal change was observed in controls by Friedman's test ($P < 0.05$). Plasma MVA levels after pravastatin (B) were significantly lower from 2 h to 8 h than in controls (A) by paired *t*-test ($P < 0.05$). *Significant difference ($P < 0.05$). See Figure 1 for abbreviation.

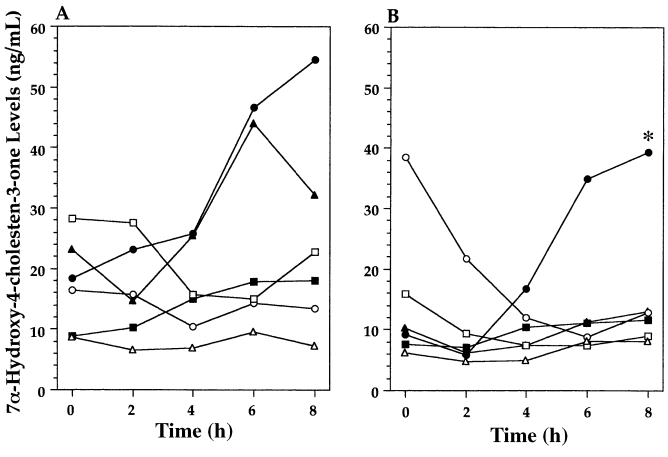

FIG. 3. Diurnal changes of plasma 7α-3one levels determined by GC–MS without (A), and with pravastatin (B). Plasma samples were collected from six healthy volunteers every 2 h for 8 h. Diurnal variation was not observed in the control. Plasma 7α-3one level at 8 h after pravastatin administration was significantly lower than in controls (A) by paired *t*-test ($P < 0.05$). *Significant difference ($P < 0.05$). See Figure 1 for abbreviation.

TABLE 2
Changes in Relative Concentration of Mevalonate and 7α-Hydroxy-4-cholesten-3-one After a Single Dose of Pravastatin[a]

Time	Mevalonate (%)		7α-Hydroxy-4-cholesten-3-one (%)	
(h)	Control	Pravastatin	Control	Pravastatin
0	100.0 ± 0.0	100.0 ± 0.0	100.0 ± 0.0	100.0 ± 0.0
2	93.4 ± 16.8	32.9 ± 12.6	95.9 ± 21.5	68.2 ± 13.0
4	92.8 ± 17.4	34.4 ± 5.8	103.1 ± 41.0	91.5 ± 52.6
6	76.1 ± 7.4	34.9 ± 9.3	149.2 ± 70.7	139.7 ± 115.9
8	74.9 ± 16.1	26.4 ± 4.3	147.5 ± 80.1	154.9 ± 129.2

[a]Each value represents mean ± SD. Relative concentrations of mevalonate and 7α-hydroxy-4-cholesten-3-one were calculated as follows: relative concentration = levels at each time/levels at 0 h × 100 (%).

hepatic circulation of bile acid. In the previous study, volunteers took food three times in 24 h. In contrast, the volunteers in this study did not take any food except water during the study, because food intake causes the enterohepatic circulation of bile acids, which is one of the most important regulators of bile acid synthesis (34,35).

Scoppola *et al.* (31) reported plasma MVA levels after a single dose of simvastatin. The MVA level was depressed to 30–40% of baseline levels within 2 h (31). In our study, plasma MVA levels after pravastatin administration were significantly lower than control at the same time point from 2 to 8 h. We observed that MVA levels decrease to about 30% of basal level within 2 h after pravastatin. Furthermore, the change of MVA levels was evaluated by ANOVA, according to which the change of MVA level is dependent on both pravastatin treatment and time course. The result of Scoppola *et al.* (31) and our results suggest that the activity of HMG-CoA reductase was inhibited by the single dose of HMG-CoA reductase inhibitors *in vivo.* In a long-term study for administration of pravastatin, however, it has been reported that HMG-CoA reductase activity was increased (15,36). In those reports, the activities of HMG-CoA reductase were assayed after separation of the microsomal fractions from liver tissue (15,36). This inhibitor is water-soluble, and then may move into the cytosol fraction during the preparation of the microsomal fraction. Therefore, the enzyme activity of the resulting microsomal fractions probably does not reflect the *in vivo* situation.

It remains unclear whether newly synthesized or preformed cholesterol is used as substrate of bile acid synthesis dominantly. All reports on the effects of lovastatin indicate that this agent decreased bile acid synthesis or its concentration in bile (7,8,14,16,18). Vlahcevic *et al.* (7) and Björkhem (8) reported cholesterol 7α-hydroxylase activity was significantly decreased when rats were treated with lovastatin. In tracer kinetic studies (16,18), this inhibitor also reduced bile acid synthesis in healthy human volunteers. Furthermore, when patients with external bile fistula were given a single dose of lovastatin, their bile acid concentration in bile was markedly decreased (14). On the other hand, most studies on the other reductase inhibitors, such as pravastatin and simvastatin, reported that most of the bile acids are synthesized from preformed (i.e., plasma) cholesterol (9–13,17). Scheibner *et al.* (9,10) treated both rats and hamsters with pravastatin, and concluded that bile acids were synthesized mostly from preformed (i.e., plasma) cholesterol. Patients with hyperlipidemia have been treated with simvastatin (11) or pravastatin (12,13) for more than 4 wk. Neither simvastatin nor pravastatin affected bile acid concentration in bile or feces (11–13). However, Okamoto *et al.* (15) assayed both cholesterol 7α-hydroxylase activity and serum levels of 7α-hydroxycholesterol in patients with cholesterol gallstone. The serum level of 7α-hydroxycholesterol as well as 7α-3one has been shown to be an index of cholesterol 7α-hydroxylase activity (15,19). It was reported that both the enzyme activity and serum level of 7α-hydroxycholesterol were significantly increased by administration of pravastatin for more than 1 wk (15). In the present study, plasma 7α-3one level was not influenced by pravastatin treatment but influenced by individual difference and diurnal change according to ANOVA. Our results support most of the publications concerning the effects of pravastatin and simvastatin on bile acid synthesis.

In conclusion, cholesterol synthesis was inhibited more than 8 h after oral administration of pravastatin. On the other hand, a single dose of pravastatin did not affect bile acid synthesis. These results suggest that most of the bile acid was

ABSTRACT: Cholesterol and α-tocopherol oxidations were studied in brain subcellular fractions isolated from cerebral hemispheres of 4-month-old, male Fischer 344 rats. The fractions were suspended in buffered media (pH 7.4, 37°C) and oxidized by adding (i) ferrous iron (Fe^{2+}) with or without ascorbate or (ii) peroxynitrite (an endogenous oxidant produced by the reaction of superoxide and nitric oxide). Treatment of subcellular fractions with Fe^{2+} in the presence or absence of ascorbate produced primarily 7-keto- and 7-hydroxy-cholesterols and small amounts of 5α,6α-epoxycholesterol. Since brain contains high levels of ascorbate, any release of iron could result in oxysterol formation. Peroxynitrite oxidized α-tocopherol but not cholesterol. Hence, the toxicity of peroxynitrite or nitric oxide could not be due to cytotoxic oxysterols. When synaptosomes were incubated for 5 min in the presence of 0.5 to 2 μM Fe^{2+} and ascorbate, α-tocopherol was oxidized while cholesterol remained unchanged. Thus, α-tocopherol is functioning as an antioxidant, protecting cholesterol. Diethylenetriaminepentaacetic acid blocked production of oxysterols, whereas citrate, ADP and EDTA did not. A significant percentage of mitochondrial cholesterol was oxidized by treatment with Fe^{2+} and ascorbate. Hence, mitochondrial membrane properties dependent on cholesterol could be particularly susceptible to oxidation. The oxysterols formed were retained within the membranes of synaptosomes and mitochondria. The 7-oxysterols produced are known to be inhibitors of membrane enzymes and also can modify membrane permeability. Hence, oxysterols may play an important role in brain tissue damage during oxidative stress.
Lipids 32, 879–886 (1997).

Biological membrane components such as cholesterol and phospholipids are known to undergo peroxidation which can result in structural and functional damage within the membrane. The oxidation of cholesterol gives rise to numerous products under a large variety of conditions (1). Hydroperoxy-, oxy-, and hydroxy-cholesterols are known to be formed during the oxidation of cholesterol. The majority of the oxidation products of cholesterol are known to be biologically active as cytotoxic, atherogenic, mutagenic, carcinogenic, or enzyme inhibitory substances (2). One of the goals of the current study was to obtain information on the types of oxysterols formed and their rates of formation when brain subcellular fractions were subjected to oxidative stress.

Vitamin E is the major lipid-soluble antioxidant in biological membranes. Some of our studies probed the mechanism of protection of membrane components such as cholesterol by vitamin E. If membrane vitamin E concentrations are not sufficient to provide adequate antioxidant protection, cholesterol within the membrane could be oxidized, producing various oxygenated derivatives of cholesterol. Therefore, studies relating the consumption of tocopherol with oxidation of cholesterol are important. This can be done conveniently under *in vitro* conditions by incubating brain subcellular fractions with endogenous or exogenous oxidants. Using this technique, we have previously studied the oxidation of vitamin E in subcellular fractions from brain (3). Endogenous oxidizing agents that were tested include hydrogen peroxide, lipid peroxides, or a mixture of ferrous iron (Fe^{2+}) and ascorbic acid. In addition, oxidations induced by peroxynitrite (formed from nitric oxide, a neurotransmitter, and superoxide, an oxygen radical formed during many biological reactions) are also of neurochemical interest. In this study we have investigated the oxidation of synaptosomal and mitochondrial cholesterol and α-tocopherol with Fe^{2+}, or a mixture of Fe^{2+} and ascorbic acid, or peroxynitrite. Our data can be used in selecting the appropriate oxysterol and in vitro conditions for studies of alterations of brain membrane function induced by the specific oxysterol.

EXPERIMENTAL PROCEDURES

Chemicals. All chemicals used were of reagent-grade purity from standard sources. Solvents for chromatography were high-performance liquid chromatography grade from Burdick and Jackson Laboratories, Inc. (Muskegon, MI). The hydroxy- or keto-cholesterols were obtained from Sigma Chemicals (St. Louis, MO), or Research Plus Inc. (Bayonne, NJ). Regisil with 1% trimethylchlorosilane was used for silylation of the cholesterol derivatives and was purchased from Regis

Abbreviations: DTPA, diethylenetriaminepentaacetic acid; TMCS, trimethylchlorosilane; trivial names of sterols: cholest-5-ene-3β,7α-diol = 7α-hydroxycholesterol; cholest-5-ene-3β,7β-diol = 7β-hydroxycholesterol; 3β-hydroxycholest-5-ene-7-one = 7-ketocholesterol; 5,6,α-epoxy-5α-cholestan-3β-ol = 5α,6α-epoxycholesterol.

Technologies Inc. (Morton Grove, IL). Other special chemicals were purchased from the following sources: α-tocopherol and α-tocopherolquinone from Kodak Laboratory Chemicals (Rochester, NY) and Ficoll (Type 400) from Sigma Chemicals. Absolute ethanol was obtained from Midwest Solvents Company (Pekin, IL) and was redistilled prior to use. Ferrous sulfate heptahydrate (Sigma Chemicals) was used as the source of Fe^{2+}. Most of the reagent-grade chemicals were from Sigma Chemicals.

Biochemical assays. All experiments were repeated and confirmed with brain samples from different sets of animals on separate days. The concentrations of total proteins were determined by the Lowry technique as modified by Markwell *et al*. (4).

Chromatography of cholesterol and cholesterol oxidation products. Details of the initial treatment of the samples for analysis have already been published (5). Briefly, 2 mL ethanol containing 0.025% (wt/vol) butylated hydroxytoluene and 0.1 ml of 30% (wt/vol) ascorbic acid were pipetted into tubes containing samples for tocopherol analyses. The mixture was heated at 60°C for 30 min after the addition of 1 mL of 10% potassium hydroxide solution. Tubes were cooled, and 2 mL of water was added followed by 2 mL of hexane containing 0.025% (wt/vol) butylated hydroxytoluene. Tocopherol, cholesterol, and their oxidation products were extracted into the hexane phase by vortexing for one minute. A portion of the hexane extract was used for tocopherol assays by reverse-phase liquid chromatography with electrochemical detection (5).

The second portion of the hexane extract was used for cholesterol and oxysterol determinations (6). After evaporation of the solvent, trimethylsilyl ether derivatives of the sterols were prepared and analyzed by gas–liquid chromatography equipped with a flame-ionization detector and a capillary column under the following conditions: DB1 column, 30 m × 0.32 mm, film thickness 0.25 μm; temperature programming—oven temperature initial 50°C, initial time 3 min, program rate 30°C per min, final value 290°C, second program rate 1°C per min, final temperature 300°C and keep at 300°C for 5 min. Under these conditions, the observed retention times (in minutes) of the various sterols were as follows: cholestane (internal standard) = 14.83; cholesterol = 17.33; 7α-hydroxycholesterol = 17.02, 7β-hydroxycholesterol = 18.3, 5α,6α-epoxycholesterol = 18.75, and 7-ketocholesterol = 20.63.

Preparation of subcellular fractions from rat brain. Four-month-old, male Fischer 344 rats (Harlan Sprague Dawley, Indianapolis, IN) were used. The subcellular fractions were isolated from cerebral hemispheres by standard centrifugation methods (7). Ficoll, obtained commercially, was further purified by dialyzing a 40% (wt/vol) aqueous solution against water for 3 h. The final Ficoll concentration was estimated by using a graph relating density and concentration. Brain tissue was homogenized in 10 vol of ice-cold isolation medium containing 0.32 M sucrose, 10 mM HEPES, and 1 mM EDTA at pH 7.4, using a glass-glass homogenizer. The homogenate was centrifuged at 1300 × *g* for 3 min and the supernatant saved. The pellet was resuspended in 10 mL of the isolation medium, rehomogenized, and centrifuged at 1300 × *g* for 3 min. The pooled supernatants were centrifuged at 17,000 × *g* for 10 min to get the crude mitochondrial fraction. The resulting pellet was resuspended in 15 mL of isolation medium. Half of this suspension was layered over 11 mL of 7.5% (wt/vol) Ficoll medium which had been layered over 11 mL of 10% (wt/vol) Ficoll medium. The tubes were centrifuged in a Beckman SW 28 rotor (Fullerton, CA) at 99,000 × *g* for 45 min. The fraction at the interface between the two Ficoll solutions was removed, diluted 1:5 with isolation medium, and centrifuged for 10 min at 17,000 × *g* to isolate the synaptosomes. The purity of the fractions was tested by electron microscopy and also by estimating the activities of the marker enzymes. The activity of the Na-K-ATPase (marker for synaptosomes) was usually enriched two- to threefold in synaptosomes compared with the crude homogenate (8). Mitochondria sedimented at the bottom of the gradient and were washed once and used. The activity of the mitochondrial marker enzyme succinate dehydrogenase was enriched eight- to tenfold in the mitochondria compared with crude homogenate.

Oxidants used in the study. Most of the experiments were done using Fe^{2+} alone or in combination with ascorbate as the oxidizing agent.

Peroxynitrite was used as the oxidant in a few experiments. The compound was prepared by the method of Keith and Powell (9). Briefly, a mixture of sodium nitrite and hydrogen peroxide was acidified with hydrochloric acid, and almost immediately sodium hydroxide was added to neutralize the acid and to make the solution alkaline. The excess hydrogen peroxide was destroyed by passing the solution through manganese dioxide. The solution was then frozen. A darker yellow solution enriched in peroxynitrite separated out, was removed, and used in all experiments. The peroxynitrite concentration was estimated using an extinction coefficient of 1670 per M per cm at 302 nm (10). The peroxynitrite solution prepared was very basic. When larger volumes of peroxynitrite were added, the excess base was partially neutralized on the day of the experiment. Under these conditions, the peroxynitrite solution is stable for 2–3 h. The concentration of peroxynitrite was rechecked after partial neutralization.

Protocol for incubations. Synaptosomes were incubated in a medium (pH 7.4) simulating extracellular fluids or plasma and contained: 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, and 10 mM glucose. HEPES (10 mM) was also added for additional buffering capacity. Mitochondria were incubated in a medium containing 25 mM HEPES and 125 mM KCl. Usually subcellular fractions containing 250 μg of protein per mL of incubation media (total volume of 3 mL) were used. The oxidant concentrations and the times of incubation were varied and are given in the figure legends. After incubation of the subcellular fraction with the oxidizing agent, the tubes were placed on ice. The reaction mixture was then centrifuged for 15 min

at 17,000 rpm in a Sorvall SS 34 rotor (Sorvall Inc., Newton, CT) (35,000 × *g*) to sediment the subcellular fractions which were then analyzed for various components. When synaptosomes were incubated with a mixture of Fe^{2+} and ascorbate, more than 99% of the ascorbate was observed to have been consumed during the incubation.

Experiments with chelating agents. In these experiments, chelators were added to the buffered medium containing the synaptosomes. The following endogenous and exogenous chelators were added to all samples (final concentration = 250 μM): ADP, citrate, EDTA, and diethylenetriaminepentaacetic acid (DTPA). The samples were then treated with Fe^{+2} with or without ascorbate, incubated, and processed as described above.

Reductions with sodium borohydride. The method of Carpenter *et al*. (11) was followed. After incubation, the synaptosomal samples were saponified, extracted with hexane, and the extract was evaporated to dryness. Powdered sodium borohydride (100 mg) was added to the residue (on ice) followed by 3 mL of a mixture of methanol and diethyl ether (1:1). The solution was left overnight at room temperature in the dark. During the next morning, 2 mL of 0.5 M HCl was added, and the mixture was extracted two times with 2 mL of diethyl ether. The combined ether extracts were scrubbed with 2 mL of water, the solvent was evaporated off, and the residue was derivatized for oxysterol assays.

RESULTS

Incubation of subcellular fractions for prolonged periods of time with or without oxidants could be expected to result in damage to membranes and to release membrane components such as cholesterol into the medium. Therefore, cholesterol and oxysterols were determined in the incubation medium after the *in vitro* treatments. This was done by analyzing 1 mL of the supernatant for cholesterol and oxysterols as described in the Experimental Procedures section. We selected synaptosomes for this experiment since synaptosomes contain large amounts of cholesterol, and therefore, releases of small amounts of cholesterol into the medium would be measurable. It was found that less than 1% of total cholesterol was released. This small percentage of cholesterol found in the medium may have been due to the trapping of membranes during the removal of supernatant. Oxysterols were not detectable in the supernatant.

Since hydroperoxides may be produced during oxygen radical attack, an experiment was conducted to study the effect of reduction of oxysterols with sodium borohydride. In this experiment, synaptosomes were incubated with a mixture of 25 μM concentrations of Fe^{2+} and ascorbic acid for 3 h, and the samples were processed for oxysterols after borohydride reduction as described in the Experimental Procedures section. The results are given in Table 1. As expected, almost all (99%) of the 7-ketocholesterol was converted to the corresponding hydroxycholesterol. The oxidized samples did not show any new peaks after the borohydride treatment. Since no new hydroxycholesterols were observed, it can be concluded that hydroperoxide formation in positions other than 7 did not occur during incubations with Fe^{2+} and ascorbate. Similar results were also obtained with 50 or 100 μM concentrations of Fe^{2+} and ascorbate.

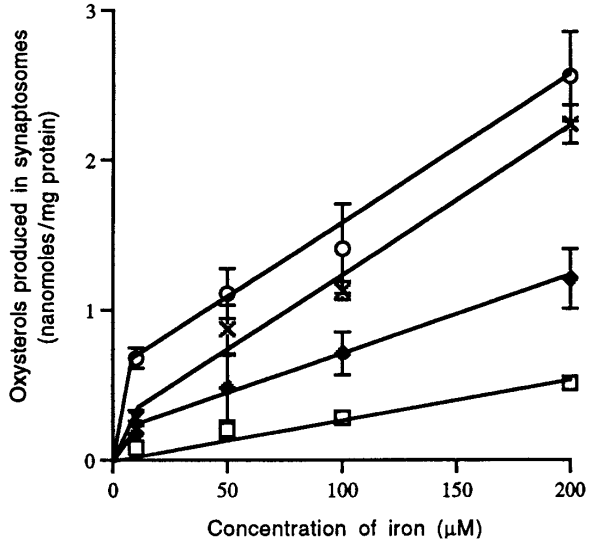
The effect of incubating synaptosomes with varying concentrations of Fe^{2+} with or without ascorbate upon the production of oxysterols was examined. As shown in Figure 1, the production of oxysterols upon incubations with Fe^{2+} increased nearly linearly with metal concentration. It is possible that ascorbate or other chelators are released into the medium and are causing oxidation in the presence of Fe^{2+} added. Therefore, accumulation of oxysterols would be expected to be directly related to Fe^{2+} concentration. This is not the case with production of oxysterols when synaptosomes are incubated with mixtures of Fe^{2+} and ascorbate. As shown in Figure 1, the formation of oxysterols tend to reach a plateau level as the concentration of the oxidants is increased beyond 100 μM.

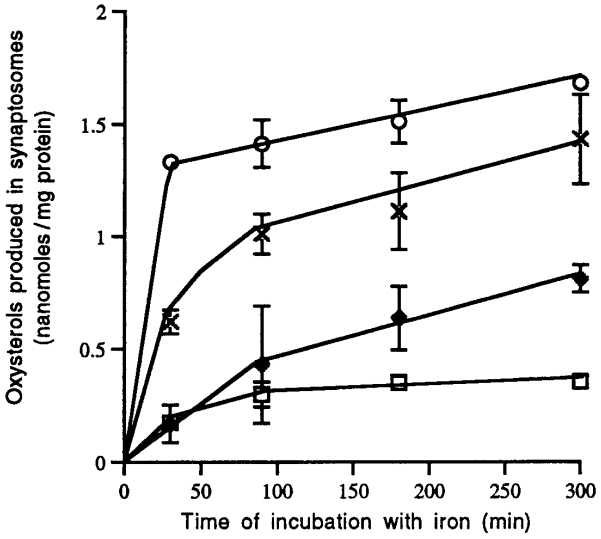
The rate of production of oxysterols when synaptosomes were incubated with Fe^{2+} with or without ascorbate is shown in Figure 2. Cholesterol oxidation does take place in the presence of Fe^{2+} alone. Since synaptosomes contain high concentrations of ascorbate, it is possible that the ascorbate is leaking out and is reacting with the added Fe^{2+} to produce the radical(s) that cause oxidation of cholesterol. Compared with treatments with Fe^{2+}, the production of oxysterols increased about fourfold when synaptosomes were incubated with both Fe^{2+} and ascorbate (Fig. 2). In both cases, there is an initial rapid phase of formation of the oxysterols which is followed

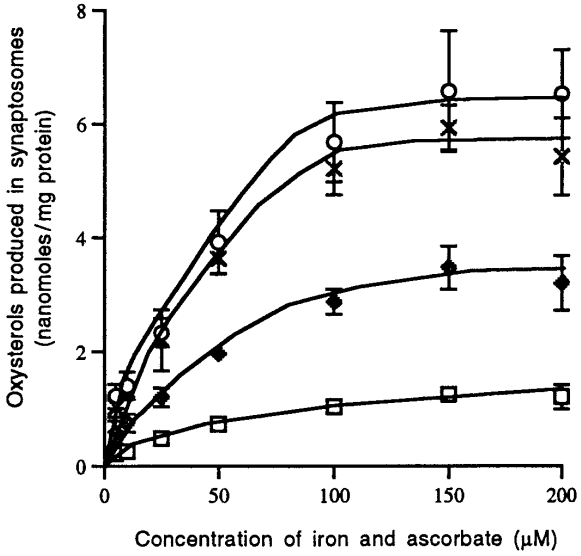
TABLE 1
The Effect of Sodium Borohydride Treatment upon the Estimated Concentrations of Oxysterols After Synaptosomes Were Incubated with a Mixture of Ferrous Iron and Ascorbate[a]

Sample type	7α-Hydroxy cholesterol	7β-Hydroxy cholesterol	5α,6α,Epoxy cholesterol	7-Ketocholesterol
Oxidized	1.82 ± 0.04*	3.36 ± 0.10	0.76 ± 0.02	3.1 ± 0.09
Oxidized and treated with borohydride	1.85 ± 0.28	6.34 ± 0.44	0.85 ± 0.08	n.d.**

[a]Samples of synaptosomes (750 μg protein in 3 mL) were oxidized by incubation at 37°C with a mixture of 25 μM ferrous salt and 25 μM ascorbate. After centrifugation, oxysterols in the pellets were determined by capillary gas chromatography. The borohydride (100 mg per tube) was added to the dried hexane extract as described in the Experimental Procedures section. *All units are nanomoles per mg protein. Mean ± SD (n = 3). **None detected.







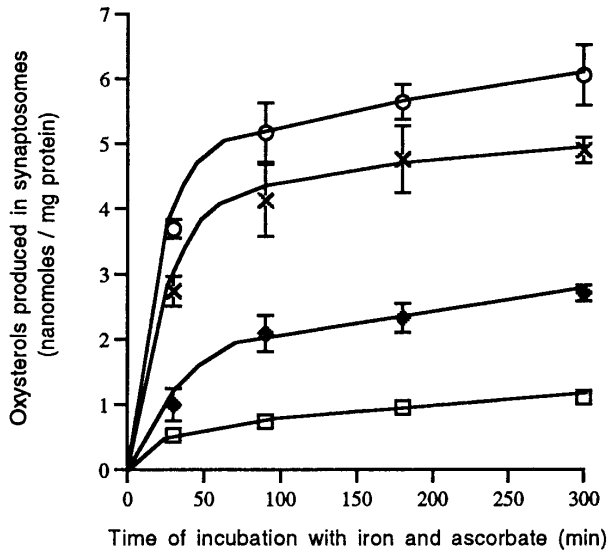


FIG. 1. The influence of concentration of Fe^{2+} or a mixture of Fe^{2+} and ascorbate upon the production of oxysterols in synaptosomes. Synaptosomes were isolated from the cerebral hemispheres of 4-month-old, male Fischer rats. They were incubated with Fe^{2+} in the presence or absence of ascorbate in a medium containing 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, HEPES (10 mM) and 10 mM glucose at pH 7.4. After the incubation, the synaptosomes were separated by centrifugation and then assayed for oxysterols by gas–liquid chromatography. Cholesterol derivatives: ○, 7-keto-; X, 7β-hydroxy-; ◆, 7α-hydroxy-; □, 5α-, 6α-epoxy-.

FIG. 2. The rate of production of oxysterols from synaptosomes incubated with Fe^{2+} or a mixture of Fe^{2+} and ascorbate (100 μM). Synaptosomes were isolated from the cerebral hemispheres of 4-month-old, male Fischer rats. They were incubated with Fe^{2+} with or without ascorbate in a medium containing 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, HEPES (10 mM) and 10 mM glucose at pH 7.4. After incubation, the synaptosomes were separated by centrifugation and then assayed for oxysterols by gas–liquid chromatography. Cholesterol derivatives: ○, 7-keto-; X, 7β-hydroxy-; ◆, 7α-hydroxy-; □, 5α-, 6α-epoxy-.

by a much slower phase. Hydroxyl radical production from Fe^{2+}/ascorbate mixtures is fast. It is possible that the rapid phase is due to the release of radicals by all the available Fe^{2+} and ascorbate and that the slower phase may be due to the slow leaking of ascorbate which then forms oxygen radicals in the presence of iron present on the outside.

The rate of change in cholesterol and tocopherol concentrations during the incubations of synaptosomes with Fe^{2+} alone or Fe^{2+} plus ascorbate are shown in Figure 3. Even at the first sampling time of 30 min, most of the α-tocopherol had been consumed and only a small percentage of cholesterol was oxidized. The initial phase of oxidation was examined in more detail in the next experiment. Synaptosomes were incubated for a very short time (5 min) with low concentrations of Fe^{2+} and ascorbate. The goal was to reduce the oxidative stress on the synaptosomes so that the antioxidant

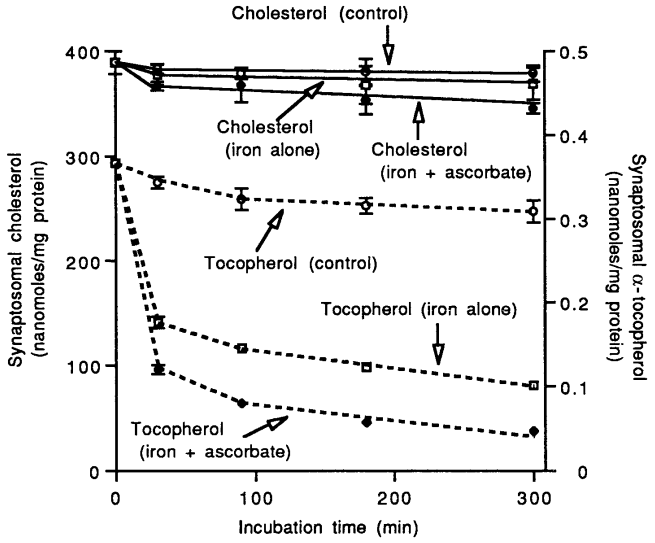

FIG. 3. The changes in concentrations of cholesterol and α-tocopherol when synaptosomes were incubated with Fe^{2+} alone or a mixture of Fe^{2+} plus ascorbate (100 μM). Synaptosomes were isolated from the cerebral hemispheres of 4-month-old, male Fischer rats. They were incubated with the oxidant in a medium containing 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, HEPES (10 mM), and 10 mM glucose at pH 7.4. After incubation, the synaptosomes were separated by centrifugation and then assayed for cholesterol by gas–liquid chromatography or α-tocopherol by high-performance liquid chromatography.

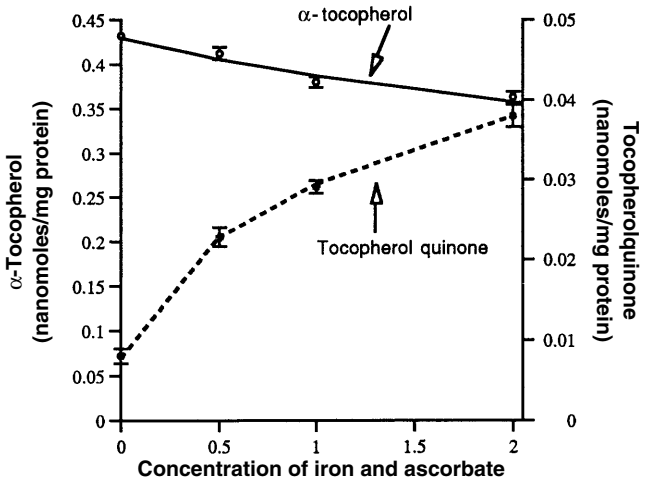

FIG. 4. Oxidation of α-tocopherol and production of tocopherolquinone when synaptosomes were incubated with low concentrations of Fe^{2+} and ascorbate for a short incubation time of 5 min. Synaptosomes were isolated from the cerebral hemispheres of 4-month-old, male Fischer rats. They were incubated with the oxidant in a medium containing 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, HEPES (10 mM), and 10 mM glucose at pH 7.4. After incubation, the synaptosomes were separated by filtration and assayed for tocopherol and quinone by high-performance liquid chromatography.

activity of α-tocopherol could be demonstrated. The results are shown in Figure 4. Tocopherol was oxidized, and α-tocopherolquinone was produced at all concentrations of Fe^{2+} and ascorbate. Throughout this experiment, the concentrations of cholesterol remained unchanged within limits of experimental error, and oxysterol production was not observed. Therefore, α-tocopherol is indeed acting as an antioxidant in the membrane and is preventing the oxidation of cholesterol. It should be noted that the amount of α-tocopherol oxidized is much smaller than that of cholesterol. The efficiency of α-tocopherol as an antioxidant depends upon its ability to break free radical chains. Thus the amount of α-tocopherol needed for antioxidant protection of cholesterol would be expected to be quite small.

The influence of chelators upon the oxidation of cholesterol was studied next. Two endogenous (ADP and citrate) and two exogenous (EDTA and DTPA) compounds were used in this experiment. The amounts of 7β-hydroxycholesterol formed when synaptosomes were incubated with chelators and Fe^{+2} in the presence or absence of ascorbate are shown in Figure 5. [We chose to follow the production of 7β-hydroxycholesterol since it is one of the two main products formed and also because the sensitivity of detection of this compound is much higher than that of 7-ketocholesterol (6).] DTPA was able to completely block the production of oxysterols during oxidations induced by Fe^{+2} or Fe^{+2} and ascorbate. This may be due to the ability of DTPA to prevent the recycling of iron between the oxidized and reduced forms and to prevent the oxidative reactions driven by ascorbate and ferrous iron as observed by Burkitt and Gilbert (12).

The effect of addition of peroxynitrite to synaptosomes was tested. It was found that peroxynitrite in concentrations as high as 15 mM did not cause any declines in cholesterol or production of oxysterols. Therefore, the toxicity of peroxynitrite (and of nitric oxide, indirectly) can not be attributed to the cytotoxicity of oxysterols.

The oxidation of mitochondrial cholesterol was examined next. Mitochondria were incubated with Fe^{2+} with or without ascorbate. The changes in α-tocopherol and cholesterol concentrations during these incubations are shown in Figure 6. It can be seen that a substantial proportion of mitochondrial cholesterol is oxidized. Hence, the oxidation of mitochondrial cholesterol can be monitored reliably by measuring the decline in cholesterol concentration. This is in contrast to oxidation of synaptosomal cholesterol which cannot be followed accurately by estimating the small percentage decrease in cholesterol concentration during oxidation.

The effect of increasing the concentrations of Fe^{2+} and ascorbate upon the production of oxysterols in mitochondria was also studied. The results given in Figure 7 show that the primary products were 7-keto-, 7-hydroxy-, 5α,6α-epoxycholesterols. Thus, the oxysterols produced during oxidations of mitochondria and synaptosomes were identical in structure.

DISCUSSION

A mixture of Fe^{2+} and ascorbate was selected as oxidizing agent for three reasons. First, this mixture is known to be a

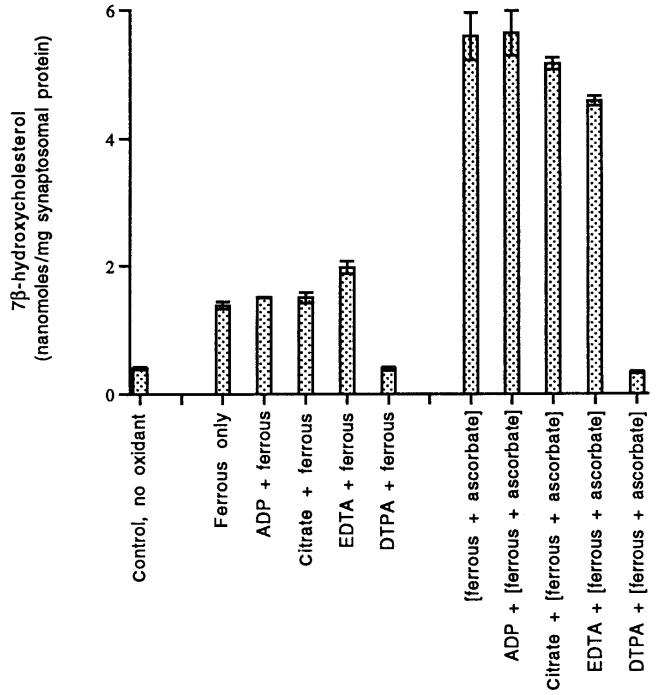

FIG. 5. The effect of addition of chelators upon the production of 7β-hydroxycholesterol when synaptosomes were oxidized with either Fe^{2+} or Fe^{2+} and ascorbate. Synaptosomes were isolated from the cerebral hemispheres of 4-month-old, male Fischer 344 rats. They were incubated in the presence of Fe^{2+} with or without ascorbate (100 μM each) in a medium containing 135 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM sodium phosphate, HEPES (10 mM) and 10 mM glucose at pH 7.4. The chelators used were ADP, citrate, EDTA and diethylenetriaminepentaacetic acid (DTPA) at 250 μM final concentrations. After the incubation, the synaptosomes were separated by centrifugation and then assayed for oxysterols by gas–liquid chromatography.

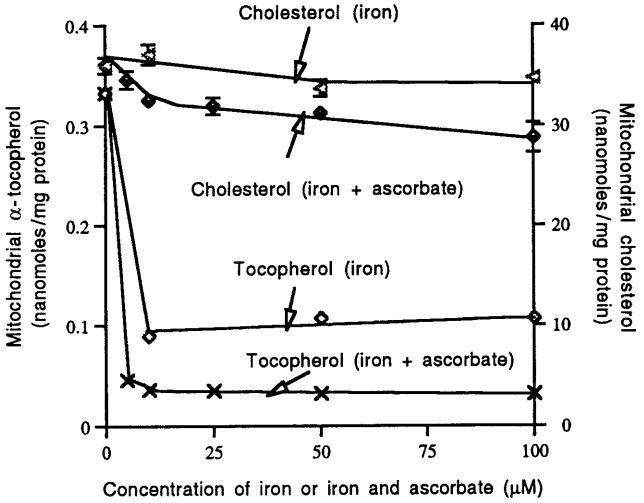

FIG. 6. Oxidation of cholesterol and α-tocopherol in mitochondria incubated with varying concentrations of a mixture of Fe^{2+} in the presence or absence of ascorbate. Mitochondria were isolated from the cerebral hemispheres of 4-month-old, male Fischer 344 rats. They were incubated for 3 h with mixtures of Fe^{2+} and ascorbate in a medium containing 25 mM HEPES and 125 mM KCl at pH 7.4. After incubation, the mitochondria were sedimented and then assayed for cholesterol by gas–liquid chromatography and for α-tocopherol by high-performance liquid chromatography.

powerful oxidizing agent. Second, the brain is characterized by high concentrations of ascorbic acid (13). High concentrations of ascorbate are present in the extracellular fluid in brain as shown by the fact that the cerebrospinal fluid concentrations of ascorbate are about two to three times that in blood plasma. Third, several areas of the brain such as the basal ganglia are known to contain high levels of iron (see review by Vatassery (14)). It also should be kept in mind that the hydroxyl radicals produced are extremely reactive and will react with the nearest membrane components from both synaptosomes and mitochondria. For example, the plasma membrane surrounding the synaptosomes will be expected to undergo oxidation, and other membranous organelles such as mitochondria within the synaptosomes may not be attacked.

The mechanism of oxidation of cholesterol and tocopherol by Fe^{2+} and ascorbate is quite complex. Hydroxyl radicals produced can abstract a hydrogen and form carbon-centered radicals that react with oxygen making peroxy derivatives. After reviewing the chemistry of oxidation of cholesterol, Lijana *et al.* (15) stated that the 7-hydroperoxide derivative is an initial product of oxidation. Gutteridge and Halliwell (16) have proposed that hydroperoxides will be formed during preparation of cell fractions and that radicals derived from the hydroperoxides will make major contributions to oxidation of membrane components. Any of these radicals could be involved in the oxidation of cholesterol and α-tocopherol.

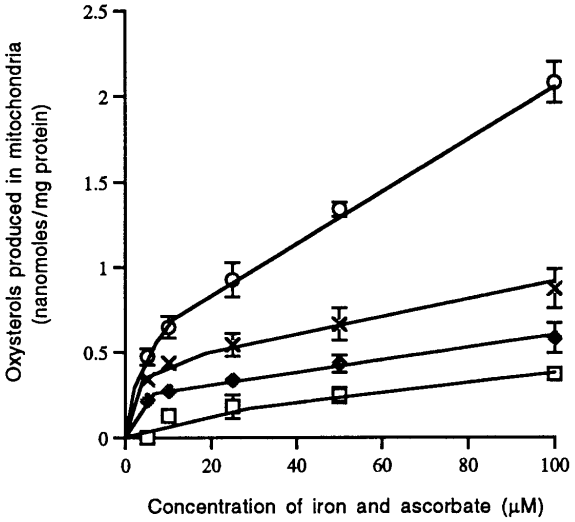

FIG. 7. Production of oxysterols when mitochondria were incubated with varying concentrations of Fe^{2+} and ascorbate. Mitochondria were isolated from the cerebral hemispheres of 4-month-old, male Fischer 344 rats. They were incubated for 3 h with mixtures of iron and ascorbate in a medium containing 25 mM HEPES and 125 mM KCl at pH 7.4. After incubation, the mitochondria were sedimented and then assayed for oxysterols by gas–liquid chromatography. Few, if any, studies have examined oxysterol production in brain. However, many investigations on the oxidation of cholesterol in lipoproteins have been reported in the literature. Hydroperoxycholesterols are produced during these oxidations. These compounds are very unstable and will decompose to the hydroxy compounds even during storage of the samples in the refrigerator (personal communication: Dr. Jon Teng, Department of Human Biological Chemistry and Genetics, The University of Texas Medical Branch, Galveston, TX). Therefore, investigators like Carpenter *et al*. (11) extract the lipids from the samples and then treat the extract with sodium borohydride to reduce the hydroperoxides to the hydroxyl derivatives. However, sodium borohydride also reduces aldehydes and ketones to the corresponding alcohols. The results of our studies in Table 1 show that the 7-ketocholesterol was reduced to the alcohol during the borohydride treatment. Furthermore, since only 7-hydroxycholesterols were formed, the data also show that hydroperoxide substitutions in positions other than 7 did not take place during attack by hydroxyl radicals. The procedure used in this report does not include a borohydride reduction step during sample preparation. Hence, we have been able to collect data on the formation of 7-ketocholesterol.

The observation that low micromolar concentrations (about 10 μM) of Fe^{2+} in the incubation medium can cause oxidation of synaptosomal cholesterol (Fig. 1) is of special interest. As mentioned above, the concentration of ascorbate is high in the extracellular fluid of the brain. Therefore, oxygen radicals would be expected to be produced whenever Fe^{2+} is available. This suggests that the release of small amounts of iron into the extracellular environment could cause formation of cytotoxic oxysterols within membranes. Our data show that a substantial proportion of mitochondrial cholesterol undergoes oxidation (Fig. 6). Since the intracellular concentration of ascorbate is quite high in the brain, mitochondrial membrane functions dependent on cholesterol will be especially subject to change during intracellular release of iron under normal or pathological conditions. The production of oxysterols within mitochondrial membranes also could have additional deleterious effects.

Comparisons of oxidation of α-tocopherol and cholesterol in both synaptosomes (Figures 3 and 4) and mitochondria (Fig. 6) show that α-tocopherol is oxidized before cholesterol oxidation begins. In fact, when peroxynitrite is the oxidant, all of the α-tocopherol is oxidized, whereas cholesterol remains unoxidized. This confirms our previous observation that membrane cholesterol is indeed quite resistant to oxidation when compared with tocopherol (17). This is to be expected since vitamin E is involved with antioxidant protection of membrane components such as cholesterol.

Smith and colleagues (18,19), who have been pioneers in the investigation of oxidation products of cholesterol, have examined the presence of oxysterols in brain samples. They found that cholesterol derivatives with hydroxylated side chains are found in the brain. For example, they demonstrated that 24-hydroxycholesterol was synthesized from cholesterol in rat brain samples (18). Later, these authors found that this oxysterol was synthesized and metabolized in the brain (19). We did not find evidence for the formation of 24-hydroxycholesterol during treatment with Fe^{2+} or a mixture of Fe^{2+} and ascorbate. It is possible that very small quantities of this oxysterol may have been formed and our method of assay was not sensitive enough to detect this compound.

Oxidation of membrane cholesterol by mixtures of Fe^{2+} and ascorbate primarily resulted in the oxidation of the 7-position of cholesterol. The reaction products observed were mostly 7α- and 7β-hydroxycholesterols, as well as 7-ketocholesterol. We did find that smaller amounts of the 5,6-epoxide of cholesterol were formed, suggesting that the 5,6 double bond is also vulnerable to oxidation by hydroxyl radicals. These oxidation products are characteristic for autoxidation of cholesterol as pointed out by Smith (1). Sevanian and McLeod (20) have studied the oxidation of cholesterol in liposomes by hydroxyl radicals. They also found that 5,6α-epoxide, as well as 7keto- and 7β-hydroxycholesterols, were formed. Our data show that peroxidative reactions involving cholesterol within the brain are similar to those found in other tissues and *in vitro* conditions.

Some data are available in the literature on the biological properties of 7-oxysterols. The potential biological functions of the oxysterols may involve interactions with and modulation of membrane enzymes rather than cytosolic enzymes or receptors. In one study it was found that incubation of rat hepatocytes in primary culture with 7β-hydroxycholesterol resulted in the inhibition of gap junctional communication between cells (21). Theunissen *et al*. (22) found that the 7-oxy derivatives of cholesterol decreased the permeability of liposomes to glucose, and the authors attribute this to a direct effect upon membrane structural properties. Kandutsch *et al.* (23) have reported that 7-ketocholesterol is a potent inhibitor of cholesterol synthesis. Thus, the 7-oxysterols may play a role in altering membrane function and membrane enzyme activities.

Several studies have shown that some oxysterols are much more potent than cholesterol itself in inhibiting the uptake of cholesterol into fibroblasts and presumably other cells mediated by the low density lipoprotein receptor (24). Goldstein and Brown (24) suggested that the higher potency of oxysterols may be due to the fact that they are more water-soluble than cholesterol and thus will be able to diffuse out into the cytosol. We did not find that any of the oxysterols produced by the *in vitro* oxidation of the synaptosomal membranes diffused into the incubation medium. In other words, the oxysterols produced by the reaction of cholesterol with oxygen radicals remained within the membranes for a few hours during the incubations. This is a significant amount of time during which the oxysterols produced could have an effect upon membrane properties.

In summary, when synaptosomes or mitochondria from brain are treated with a hydroxyl radical-generating system, cholesterol is oxygenated primarily in the 7 position with smaller amounts of 5,6-epoxide also being formed. A sub-

stantial percentage of cholesterol in mitochondria is oxidized under these conditions. The oxysterols produced remain within the membrane for significant periods of time (as long as 5 h, the time of incubation). The formation of oxysterols during oxidative stress could be an especially important factor in altering mitochondrial function. Among the various chelators tested, only DTPA was able to block oxysterol production. The 7-oxysterols are known to alter membrane properties such as permeability and enzyme activities and may play a role in normal brain function. More importantly the possibility that since these oxysterols are known to be cytotoxic, they could cause degeneration of the brain during oxidative stress associated with pathological conditions such as Parkinson's disease and Alzheimer's disease.

Absorption of Dietary Cholesterol Oxidation Products and Incorporation into Rat Lymph Chylomicrons

D.F. Vine, K.D. Croft, L.J. Beilin, and J.C.L. Mamo*

University of Western Australia, Department of Medicine, Royal Perth Hospital, Perth Western Australia 6000, Australia

ABSTRACT: Cholesterol oxidation products (oxysterols) induce macrophage lipid loading and accumulate in early arterial fatty streaks. The origin of lesion oxysterols has not been elucidated. The absorption of oxysterols from the diet and transport to the arterial wall by postprandial lipoprotein remnants may be a significant source. This study aimed to investigate the extent of oxysterol absorption and the effect on chylomicron composition. Cholesterol was heat-treated, causing 30% oxidation; the major oxidation products were 7β-hydroxycholesterol, 7-ketocholesterol, 5α,6α-epoxycholesterol, and 5β,6β-epoxycholesterol. Conscious lymph-cannulated rats were given a bolus gastric infusion of 50 mg oxidized cholesterol or 50 mg purified cholesterol in a vehicle of triglyceride. In the rats given the oxidized cholesterol, 6% of the oxysterol load was absorbed and incorporated into lymph chylomicrons. Rats given pure cholesterol had no increase in oxysterols above baseline levels. The incorporation of oxysterols into lymph chylomicrons differed over time with 7β-hydroxycholesterol, having peak absorption at 3 h, followed by 7-ketocholesterol at 4 h and 5α,6α-epoxycholesterol at 5 h. The absorption of oxysterols in animals given the oxidized cholesterol gastric infusate was associated with lymph chylomicron compositional changes at 2–4 h. The oxidized cholesterol-treated group had a twofold increase in the cholesterol (890 ± 84 μg vs. 440 ± 83 μg at 3 h) and triglyceride content (19.76 ± 3.4 μg vs. 8.49 ± 3.8 μg at 3 h). This led to a doubling of chylomicron size over this postprandial period, with particles having a mean diameter of 294 nm in the oxidized cholesterol-treated animals, compared to 179 nm in the purified cholesterol group. In conclusion, dietary oxysterols appear to influence postprandial lipoprotein particle size and composition. These changes may have effects on the clearance of chylomicrons from plasma, arterial delivery of oxysterols, and possible deposition in arterial lesions.

Lipids 32, 887–893 (1997).

Atherogenesis is characterized by the deposition of cholesterol and oxysterols in the wall of arterial vessels (1–3). The origin of lesion cholesterol is accepted to be derived from circulating lipoproteins, in particular low density lipoprotein (LDL). Unabated uptake by monocyte-derived macrophages of oxidatively modified LDL *via* scavenger receptors may be one source of oxysterols found in arterial lesions (4). It is thought that when delivery of lipoproteins exceeds catabolism, LDL trapped within the subendothelial space undergoes oxidative modification by cells of the arterial wall and serves as a substrate for macrophages (5,6). Alternatively, LDL may be oxidatively modified by macrophages themselves (7,8).

Cholesterol and oxysterols in arterial lesions also may be derived from chylomicrons, which are intestinally derived lipoproteins responsible for the transport of dietary lipid from the intestine to the plasma (9). Circulating chylomicrons undergo conversion to the cholesterol-rich chylomicron remnants by the action of endothelial lipoprotein lipases (9). Chylomicron remnants are delivered efficiently to the arterial wall and are selectively retained by fatty lesions (10,11). Furthermore, chylomicron remnants are avidly degraded by macrophages, and *in vitro* this leads to lipid loading (12). Feeding of cholesterol oxidation products to rabbits leads to arterial wall damage and lipid deposition (13,14), whereas purified cholesterol does not, despite persistent hypercholesterolemia. These observations, combined with several gastric gavage and venous infusion studies of oxidized cholesterol products (15–18), have led to the suggestion that atherosclerosis associated with cholesterol consumption actually reflects the level of cholesterol oxidation products in the diet rather than the amount of native cholesterol alone (19).

In man, the consumption of oxidatively modified lipids has increased, following advances in food processing, the development of convenience foods, and extended shelf-life products. However in a recent review, Smith (20) highlighted the paucity of studies investigating oxysterol absorption from the diet, metabolism, transfer among lipoproteins in blood, and assimilation into various tissues. The need for further studies and the plausible relationship between dietary oxysterols and the oxysterol content of lesions led to this study which was to investigate the absorption and incorporation of oxysterols into nascent lymph chylomicrons.

MATERIALS AND METHODS

Materials. Cholesterol (99% purity) and triolein (99%) were purchased from Sigma (St. Louis, MO). Cholesterol was de-

termined colorimetrically (Trace Scientific, catalog no: TR 13015, Melbourne, Australia). Triglycerides were measured colorimetrically (Wako, Osaka, Japan). Bis(trimethylsilyl)-trifluoracetamide (BSTFA) was purchased from Sigma. Other reagents were from Ajax (Auburn, NSW, Australia).

Preparation of gastric lipid infusions. Purified cholesterol was prepared by recrystallization of cholesterol (Sigma) from ethanol. Gas chromatography–mass spectrometry (GC–MS) analysis showed 99.9% purity. Oxidized cholesterol was prepared by heating cholesterol at 135°C for 10 h (21). GC–MS analysis of the oxidized cholesterol is shown in Table 1. The pure and heat-treated cholesterol (50 mg) were dissolved in 1 mL of chloroform then combined with 600 mg of triolein (99.9% Sigma). The solvent was evaporated under a constant stream of nitrogen in a water bath maintained at 37°C. GC–MS analysis of the purified cholesterol emulsion showed 99.9% purity.

Chylomicron isolation. Wistar rats (300 g) were anesthetized with phenobarbital (0.05 mg/kg) and the superior mesenteric lymph duct cannulated (22). In addition the duodenum was cannulated by a gastrostomy as described previously (22). Postoperatively the rats were placed in individual restraining cages with free access to water and were infused with 0.15 M NaCl through the gastric cannula at 1.5 mL/h. The animals were allowed to recover for 18 h and lymph was collected 2 h before administration of the cholesterol emulsion (50 mg purified or oxidized cholesterol) *via* the duodenal cannula. The animal model used in this study has provided a useful means to assess intestinal lipid absorption; however, the potential impact of short-term restraint on this process is presently unknown. At 30 min after giving the animals the cholesterol emulsion, infusion of saline was continued at 1.0 mL/h. Lymph was collected into tubes containing 5 mM EDTA every hour for 24 h. The lymph collected was centrifuged at 3000 rpm for 10 min to remove cells, cholesterol and triglyceride were determined, and the lymph was flushed with nitrogen and stored at 4°C for up to 48 h for GC–MS analysis. Chylomicron size and count rate were determined using an automated particle sizer (Brookhaven Industries Pty. Ltd., New York, NY).

Oxysterol analysis and quantification. Lymph oxysterols were determined using a quantitative GC–MS method in selective ion monitoring (SIM) as reported by Mori *et al*. (23). Briefly, to 500 µL of lymph in a glass tube, 2 mL of 1 M KOH/methanol and 1 µg 5α-cholestane (internal standard, 10 µg/mL in ethyl acetate) were added. The tube was flushed with N_2 and heated at 45°C for 60 min protected from light. To the saponified lymph, 4 mL of double-distilled H_2O was added, and lipids were extracted twice with diethyl ether (1 mL). The lipid extract was dried under N_2 and then derivatized with BSTFA (50 µL) and pyridine (50 µL) by heating samples at 60°C for 20 min under N_2. Samples were reconstituted after evaporation with N_2 with 1% BSTFA in heptane (50 µL) for GC–MS analysis. A Hewlett-Packard HP 5890 gas chromatograph coupled with an HP 5970 Series mass-selective detector and an HP chemstation (Palo Alto, CA), using G1034C MS chemstation software (Rockville, MD), were used. Oxysterols were resolved on an HP-1 crosslinked methyl silicone column (12 m × 0.2 mm, 0.33 mm film thickness; Hewlett-Packard), using helium as the carrier gas with an inlet pressure of 30 kPa. The mass spectrometer was operated in the electron impact mode (70 eV) and SIM was used. Four characteristic identifying ions were used for each oxysterol in SIM mode. To quantify the oxysterols calibration curves, measuring peak area vs. response of the oxysterol and the internal standard 5α-cholestane were used. Peak identification was confirmed by relative retention time and total ion mass and mass spectra comparison with external standards, as well as with the HP MS Chemstation NBS Mass Spectral Data Library of compounds to give >99% match.

Statistical analysis. The differences in lipid measurements in lymph at different time points were determined using Student's *t*-test. Area under the curve analysis also was used to determine differences in total lipid absorption. A random effect repeated measures model using PROC MIXED in SAS was used to determine relationships between oxysterol, triglyceride, and cholesterol content and particle size of chylomicrons.

TABLE 1
The Cholesterol Oxidation Products of Autoxidized Cholesterol[a]

Sterol	Weight (%) Mean ± SEM
Cholesterol	69.28 ± 4.31
Oxysterols	30.72 ± 1.54
7β-Hydroxycholesterol	6.96 ± 0.74
5α,6α-Epoxycholesterol	4.83 ± 0.52
5β,6β-Epoxycholesterol	4.83 ± 0.52
7-Ketocholesterol	8.62 ± 1.21
6β-Hydroxycholesterol	0.99 ± 0.05
Cholest-4-ene-3-one	0.43 ± 0.01
4,6-Cholestadiene-3-one	1.47 ± 0.05

Unknowns	1.56 ± 0.05
	100.00

[a]Cholesterol was autoxidized by heating at 135°C for 10 h.

RESULTS

The oxysterol profile following heating of cholesterol at 135°C for 10 h is given in Table 1. Of the total sterol mass, approximately 30% underwent oxidation. The major cholesterol oxidation products were the 7β-hydroxycholesterol, 7-ketocholesterol, 5α,6α-epoxycholesterol, and 5β,6β-epoxycholesterol with small amounts of other oxidation products. Only 1.5% of total oxysterols could not be identified.

The appearance of oxysterols in lymph chylomicrons was quantified in rats given 50 mg of oxidized cholesterol or purified cholesterol. Note that total lymph flow was not affected by the infusion of vehicle (49.05 ± 4.70 mL), oxysterols (50.06 ± 6.07 mL), or purified cholesterol (46.59 ± 5.12 mL). In the fasted state and prior to lipid infusion, rats showed

basal levels of 7β-hydroxycholesterol in the lymph. The mean preinfusion basal production of 7β-hydroxycholesterol was similar for purified and oxidized cholesterol-treated rats, that is, 937.68 ± 218.74 ng and 988.12 ± 260.41 ng, respectively (mean ± SEM). On giving triglyceride vehicle alone, there was no difference in lymph 7β-hydroxycholesterol levels (979 ± 257.70 ng) or any other detectable oxysterols, indicating that the basal level of secretion was not artifactual. Moreover, rats given purified cholesterol showed similar levels of lymph 7β-hydroxycholesterol pre- and postlipid infusion. In contrast, rats given oxidized cholesterol showed significant absorption and incorporation of oxysterols into lymph chylomicrons. The mass of cholesterol oxidation products incorporated into nascent lymph chylomicrons, expressed as a percentage of the oral load provided, was 6.27 ± 1.06%, i.e., 0.94 mg (mass in lymph)/15 mg (oral oxysterol load) percentage. The major oxysterols quantitated in lymph were 7β-hydroxycholesterol, 5α,6α-epoxycholesterol, and 7-ketocholesterol. However the 5β,6β-epoxycholesterol was not detected in the lymph although it formed a component of the heat-treated cholesterol. Of the oxysterols absorbed, there was no difference in the total mass of individual oxysterols in lymph with a mean 7β-hydroxycholesterol mass of 276.81 ± 64.07 μg, 5α,6α-epoxycholesterol 133.23 ± 19.48 μg and, 7-ketocholesterol 251.65 ± 52.72 μg. In addition, when the lymph mass of specific oxysterols was expressed as a fraction of the quantity in the infusate, there appeared to be no difference in the incorporation of oxysterols into chylomicrons. The percentage absorption of 7β-hydroxycholesterol was 7.91 ± 1.84%, 5α,6α-epoxycholesterol 5.47 ± 0.8%, and 7-ketocholesterol 5.81 ± 1.23%. The peak absorption of oxysterols appeared to differ, with 7β-hydroxycholesterol, 7-ketocholesterol, and 5α,6α-epoxycholesterol peaking at 3 h, 4 h, and 5 h, respectively (Fig. 1).

In order to compare oxysterol incorporation into lymph with that of unoxidized cholesterol, it was necessary to correct for basal or endogenous production. To achieve this, a basal mass of cholesterol in lymph (calculated as cholesterol secretion per hour before giving lipid × 12 h) was subtracted from the mass of cholesterol in lymph, following lipid delivery. On this basis, we calculated that the secretion of unoxidized cholesterol into lymph chylomicrons of rats given pure cholesterol had an efficiency of approximately 12% or threefold higher than the secretion of oxysterols in rats given autoxidized cholesterol.

Rats given cholesterol oxidation products secreted similar amounts of unoxidized cholesterol to rats given purified cholesterol, following lipid infusion, despite being given significantly less (30%) unoxidized cholesterol. The secretion of unoxidized cholesterol was 7.21 ± 1.12 mg (mean ± SEM) in rats given purified cholesterol and 6.51 ± 1.56 mg in rats given oxidized cholesterol; however, the mass of cholesterol infused in the pure-fed group was 50 mg, and in the oxidized-fed group 35 mg. Therefore, in order to achieve similar lymphatic secretion of cholesterol, the efficiency of cholesterol absorption in rats given oxidized cholesterol products would have needed to have been greater than in rats given pure cholesterol alone.

While the total mass of cholesterol secreted did not differ significantly between groups, there were substantial differences in the pattern of cholesterol secretion. The peak level of unoxidized cholesterol in rats given oxidized cholesterol appeared to be earlier than for rats given purified cholesterol (4 h and 6 h, respectively). At 1–3 h after gastric infusion, the oxidized cholesterol-treated animals had greater lymph cholesterol secretion of cholesterol compared to rats receiving pure cholesterol, and at 3 h, secretion was more than twofold different (890 ± 84 μg vs. 440 ± 83 μg cholesterol, respectively, $P = 0.0036$) (Fig. 2). In fact, the cholesterol content of

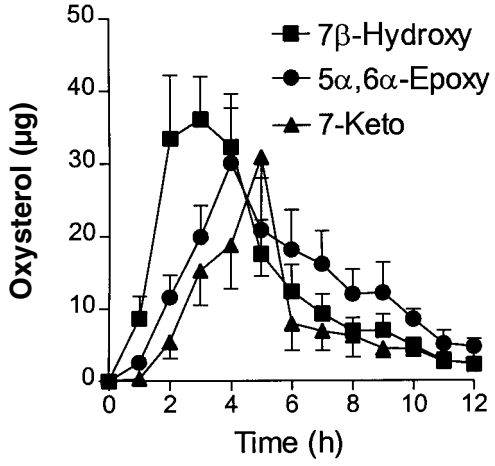

FIG. 1. The lymphatic absorption of the oxidized cholesterol products 7β-hydroxycholesterol, 5α,6α-epoxycholesterol, and 7-ketocholesterol in rats given an oxidized cholesterol emulsion *via* a gastric cannula. Values are the mean ± SEM of six rats. Lymph oxysterols were analyzed and quantitated using calibration curves with GC–MS in selective ion monitoring mode.

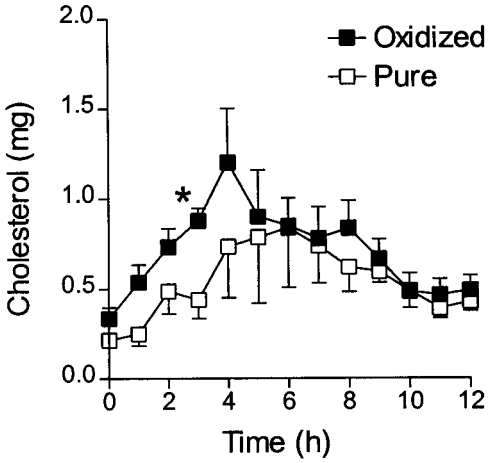

FIG. 2. The lymphatic absorption of cholesterol in lymph cannulated animals given oxidized and purified cholesterol emulsions by gastric infusion. Values are expressed as the mean ± SEM for six rats. Student's *t*-test was used at each time point; $^*P < 0.05$.

chylomicrons was found to be significantly associated with the incorporation of oxysterols ($P = 0.0008$).

The inclusion of oxysterols in dietary lipid altered the rate of lymphatic triglyceride release, although the total triglyceride secreted was not affected (oxidized cholesterol and purified cholesterol treated groups, 247.56 ± 42.76 mg and 190.98 ± 35.03 mg, respectively). Figure 3 shows that rats given oxysterols had a maximal triglyceride secretion rate of 29 mg/h at 4 h after infusion compared to 18 mg/h at 7 h after infusion for the purified cholesterol group. Overall triglyceride secretion was shown to be dependent on total oxysterol levels in the chylomicrons ($P = 0.0026$). Triglyceride secretion following absorption of the lipid load was on average twofold greater for oxysterol-treated animals at 2, 3, and 4 h compared to those given purified cholesterol. For example, the triglyceride content of the lymph in the oxidized and purified cholesterol treated groups at 3 h was 19.76 ± 3.38 mg vs. 8.49 ± 3.83 mg ($P = 0.0401$).

Triglyceride forms the bulk component of lymph chylomicrons, and hence, to a large extent, determines chylomicron particle size. The kinetics in plasma and arterial uptake of chylomicrons is regulated by size, and so the mean diameter of lymph chylomicrons was determined. Figure 4, shows that following lipid delivery, chylomicron size increased in oxysterol-treated and in native cholesterol-fed rats. However, chylomicrons isolated from oxysterol-fed rats were found to be significantly larger at 2–4 h following gastric infusion, compared to chylomicrons isolated from rats provided with pure cholesterol alone. The largest chylomicron fraction isolated from oxysterol-treated rats 3 h postprandially had a mean of 294 ± 17 nm, representing a 2.5-fold increase in size above baseline. In contrast, chylomicrons isolated from rats given pure cholesterol only attained a mean diameter of 179 ± 17 nm ($P = 0.0008$). Although triglyceride secretion increased in rats given oxidized cholesterol, the greater particle size at 2–4 h postlipid infusion was also dependent on the increased level of oxysterols ($P = 0.0001$).

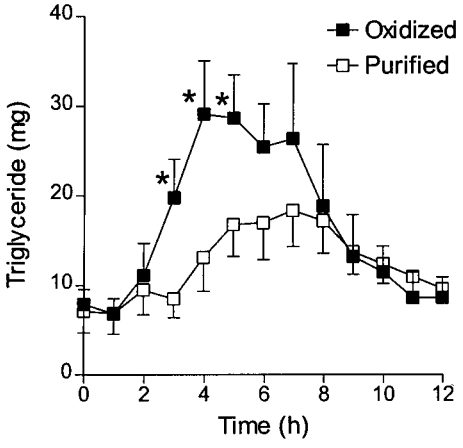

FIG. 3. The absorption of triglyceride in the lymph of animals given oxidized and purified emulsions. The lymphatic duct was cannulated in rats, and cholesterol emulsions were administered *via* a gastric cannula. Values are the mean ± SEM for six rats. Student's *t*-test was used at each time point, $*P < 0.05$.

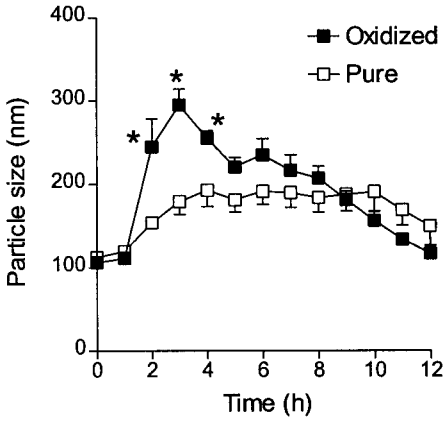

FIG. 4. The particle size of lymph chylomicrons in the oxidized and purified cholesterol-treated animals. Particle size of the lymph chylomicrons was determined using an automated particle sizer after collection of lymph every hour. Values are the mean ± SEM of six rats, $*P < 0.05$.

DISCUSSION

Oxysterols have been implicated in the onset and progression of atherosclerosis, based on observations of their proatherogenicity (20,24,25). Indeed, oxidized cholesterol products have been shown to have greater atherogenicity than native cholesterol, as evidenced by arterial damage and development of arterial lesions (15–19). The accumulation of oxysterols in atherosclerotic lesions suggests they are involved in the disease process (1–3). Oxidatively modified LDL, which is rich in oxysterols (23), has been considered the primary cause of endothelial damage (26,27) and a source of arterial macrophage cholesterol loading, which leads to the development of arterial fatty streaks (8,29,30). Alternatively, dietary oxysterols, found primarily in cholesterol-rich processed foods, might be preferentially transported to the arterial wall by postprandial lipoproteins and also may be a source of lesion oxysterols. This is plausible, given that postprandial chylomicron remnants are avidly taken up and retained by the arterial wall *in vivo* (10,11) and induce lipid loading in macrophages *in vitro* (12). However, there is a paucity of data with respect to oxysterol absorption from the intestine, secretion into circulation, and assimilation in tissues. The aims of this study were both to determine the extent of dietary oxysterol incorporation into lymphatic chylomicrons, and to compare the efficiency of lymphatic secretion with native cholesterol.

Autoxidized cholesterol products were generated following heating of pure cholesterol at 135°C for 10 h. The oxysterols produced were found to be qualitatively similar to those found in common cholesterol-rich food products (31) and mixed diets (32), with significant amounts of 7β-hydroxycholesterol, 5α,6α-epoxycholesterol, 5β,6β-epoxycholesterol, and 7-ketocholesterol. Approximately 30% of the cholesterol was oxidized following heating, and we were able

to identify 98% of the oxidation products. The oxysterol content of cholesterol-rich processed foods such as egg, milk and cheese powders, and other processed foods such as biscuits in the ppm is well established (20,31). The extensive use of egg and milk powders in a myriad of processed products suggests that ingestion of oxysterols from the diet is significant. Indeed Emanuel *et al*. (33) reported an increase in postprandial plasma levels of oxysterols after giving patients dried egg powder containing ~230 ppm oxysterols. Cholesterol oxidation products may form a small but potentially significant amount of total lipid intake.

In rats, we found substantial incorporation of dietary oxysterols in lymph chylomicrons. However, there were significant differences in the type of oxysterols absorbed, the patterns of lymphatic release, lymphatic secretion of other dietary lipids, chylomicron size, and chylomicron composition. Secretion of oxysterols into lymph would be dependent on the sum of absorption, processing, and packaging within the enterocyte. This study did not enable us to distinguish among these three processes, but rather provides us with an overview of the consequence of dietary oxysterol delivery.

Oxysterols have the potential to bind to "carrier" proteins such as albumin in addition to lipoproteins. However, following isolation of the lymph chylomicron fraction by ultracentrifugation, we found no detectable oxysterols in the infranatant. It would seem unlikely, therefore, that dietary oxysterols were delivered *via* the portal system in the absence of lipoprotein transport. Consistent with this, several groups have shown that dietary oxysterols were found exclusively associated with the triglyceride-rich lipoprotein fraction in plasma (33,34). It is likely that oxysterols not associated with lymph chylomicrons were excreted, although this was not specifically determined in this study.

Of the four major cholesterol oxidation products infused, only three appeared in lymph. We were unable to detect 5β,6β-epoxycholesterol in chylomicrons. The selective appearance or exclusion of oxysterols suggests either absorbance across intestinal epithelial cells differed with isomeric forms of cholesterol oxidation products or, alternatively, differential processing occurs within the enterocyte. Bile acids are necessary for efficient absorption of hydrophobic sterols, presumably including oxysterols. It is unlikely that 5β,6β-epoxycholesterol fails to form micelles with bile; hence, we would suggest that 5β,6β-epoxycholesterol either is degraded in intestinal epithelial cells, or simply not incorporated into chylomicrons.

The appearance of oxysterols in lymph chylomicrons differed quantitatively and qualitatively from native cholesterol. Expressed as a percentage of the dose administered, the incorporation of oxysterols into lymph chylomicrons was less than for native cholesterol, even after allowing for basal cholesterol production. There are several possible explanations for these observations. Absorption of lipids would be a finite process; so perhaps uptake was saturated under our infusate regimen. Consistent with this suggestion is the observation that, despite a smaller dose of native cholesterol in the oxysterol-fed rats, secretion of native cholesterol in oxysterol-fed rats was the same as in those given cholesterol alone. Alternatively, absorption of oxysterols may simply be less efficient, representing competition for, or a decrease in, the rates of esterification, as the primary form of cholesterol secreted in chylomicrons is esterified (35). However, it has been reported that the majority of oxysterols in lymph chylomicrons are nonesterified (36). From an alternative perspective, if absorption of oxysterols was similar or indeed greater than native cholesterol, lower rates of secretion would be a consequence of decreased incorporation into chylomicrons. Although this seems unlikely, the absence of 5β,6β-epoxycholesterol from lymph chylomicrons would be consistent with this possibility.

In a similar study Osada and colleagues (35) investigated oxysterol absorption in lymph-cannulated rats. There were several observations in that study which differed from the present report. Osada *et al.* found that the appearance of oxysterols in lymph was linear 24 h after administration of the diet, whereas in this study incorporation of oxysterol in lymph chylomicrons peaked 3–5 h after lipid delivery and returned to baseline levels at approximately 12 h. In addition, Osada and co-workers found that approximately 30% of the oxysterol load appeared in lymph chylomicrons which is significantly greater than the 6% absorption of oxysterols observed in this report. The differences between the two studies might be explained in the nature of the gastric infusates. Firstly, Osada *et al*. delivered a greater mass of oxysterols relative to pure cholesterol (88% vs. 30% of total sterol load, respectively). The lipid emulsion was also dissolved in sodium taurocholate, a bile acid salt, which may have aided emulsification and absorption. Consistent with this possibility is that, in the absence of exogenous emulsifying agents, the postprandial lipemic response following a lipid load in rats and in man normally displays "bell-shaped" kinetics (36). Nevertheless, both reports demonstrate that oxysterols can be delivered into circulation associated with chylomicrons.

The presence of oxysterols in the infusate enhanced the chylomicron triglyceride secretion rate into lymph 2–4 h postpresentation of the lipid load. This is a surprising observation which may have reflected increased absorption of triolein and/or increased esterification of monoglyceride within the enterocyte. A greater rate of triglyceride release was not compensatory to decreased cholesterol incorporation, which was also enhanced in oxysterol-treated rats. Furthermore, the increase in chylomicron triglyceride and cholesterol content in oxidized cholesterol-fed rats was not a consequence of greater chylomicron biosynthesis because particle number remained constant. Rather, chylomicrons isolated from oxysterol-fed rats were substantially larger than those isolated from rats given pure cholesterol alone. The clearance from plasma of larger chylomicrons is quite different from smaller chylomicrons (37); however, the impact of oxysterols on this process remains to be investigated.

When clearance of chylomicrons is delayed such as in type III hyperlipoproteinemia (38), familial hypercholesterolemia (39), or in secondary disease states such as diabetes (40),

there is an increased frequency of atherogenesis. A reduced clearance from plasma is thought to result in increased arterial delivery and retention of postprandial lipoproteins (11). Oxysterols may affect the metabolism of chylomicrons in plasma, including interaction with lipoprotein lipases and uptake of chylomicron remnants by high-affinity mechansims. Redgrave *et al*. (41) have shown that the apolipoprotein complement of chylomicrons is significantly altered by the cholesterol content on the surface of the lipoprotein molecule. Similarly chylomicrons containing oxysterols may alter the apolipoprotein complement, in turn affecting their metabolism. Mortimer *et al*. (42) showed 7β-hydroxycholesterol incorporation into chylomicrons impaired the clearance of cholesterol ester, an indicator of remnant uptake. Oxysterols incubated with macrophages also stimulate sterol accumulation in macrophages (43). Oxysterols also might exacerbate the atherogenicity of postprandial remnants. Chylomicron remnants serve as excellent substrates for arterial macrophages and can induce foam cell formation (10–12). Indeed, lipid-laden macrophages isolated from early human atheroma contain mainly 7β-hydroxycholesterol (1), and advanced lesions contain a number of oxysterols which we have shown to be secreted into lymph associated with chylomicrons, including 7β-hydroxycholesterol, 7-ketocholesterol, and 5α,6α-epoxycholesterol (1–3). It is plausible that the inclusion of oxysterols into lymph chylomicrons delays their clearance from plasma with the consequence of increasing exposure and delivery of lipid to the arterial wall. We can conclude from this study that oxysterols in atherosclerotic tissue might, in part, be derived from dietary sources.

Refeeding Varying Fatty Acid and Cholesterol Diets Alters Phospholipids in Rat Intestinal Brush Border Membrane

M. Keelan, M.T. Clandinin, and A.B.R. Thomson*

Nutrition and Metabolism Research Group, Division of Gastroenterology, Department of Medicine, University of Alberta, Edmonton, T6G 2C2, Canada

ABSTRACT: Refeeding a diet initially given shortly after weaning results in a different adaptive change in the *in vitro* intestinal uptake of sugars and lipids than if the diet is given for the first time at a later age. This study was undertaken in rats to test the hypothesis that changes in nutrient uptake associated with refeeding diets containing beef tallow (S), beef tallow plus 1% cholesterol (Sc), fish oil (F), or fish oil plus cholesterol (Fc) are associated with changes in the brush border membrane (BBM) phospholipids and phospholipid fatty acids. Weanling Sprague-Dawley rats were fed *ad libitum* one of the four diets. At 35 d of age (about 2 wk after weaning), the rats were maintained on either the same diet used at weaning, or were switched to one of the other semisynthetic diets which were then fed for a further 7 wk. At week nine (2 + 7) the rats were either continued on the same diet or were switched back to the original diet for 2 wk (2 + 7 + 2). The groups of animals which were compared included SSSc vs. ScSSc; ScScS vs. SScS; FFFc vs. FcFFc; and FcFcF vs. FFcF. Refeeding S, Sc, F, or Fc had no effect on food consumption or on body weight gain. Refeeding Fc resulted in increased ileal BBM total phospholipids, whereas rechallenge with F resulted in a decline in the jejunal BBM ratio of phospholipid/cholesterol. Refeeding Sc resulted in a decrease in the ileal BBM phosphatidylcholine (PC). In rats rechallenged with Fc, there was increased ileal BBM sphingomyelin (SM), increased ileal BBM phosphatidylethanolamine (PE), decreased ileal BBM PC/PE, and an increased ileal BBM SM/PC. Refeeding had no effect on the fatty acyl constituents of the jejunal or ileal BBM PC or PE. These results suggest that there are late effects of the early introduction of dietary cholesterol on intestinal BBM phospholipid content and composition that may contribute to the previously reported changes in intestinal nutrient absorption.
Lipids 32, 895–901 (1997).

Nutrient absorption by the intestine is subject to adaptation (1). For example, there is increased absorption of nutrients in animals with streptozotocin diabetes, or in the remaining intestine following intestinal resection; in contrast there is reduced absorption of nutrients following abdominal irradiation, with aging, or with the chronic feeding of ethanol (2,3). Alterations in intestinal absorption are associated with changes in the amount and/or type of brush border membrane (BBM) phospholipids of the BBM (4–9). These BBM lipid changes may be associated with alterations in enterocyte microsomal phosphatidylethanolamine (PE) methyltransferase activity, or with changes in BBM or enterocyte microsomal activity of PE methyltransferase (10). Alterations in dietary fat unsaturation alter the intestinal transport of nutrient as well as the fatty acid composition of the BBM phospholipids (11,12).

Refeeding a diet initially given to a rat shortly after weaning results in different adaptive changes in the *in vitro* intestinal uptake of glucose, fatty acids, and cholesterol than if the diet is given for the first time at a later age (13). These transport changes are not explained by differences in the animals' food intake, body weight gain, or intestinal morphology. The signal for critical period programming may be the ratio of dietary carbohydrate to protein (14), polyunsaturated to saturated fatty acids (15,16), or long-chain polyunsaturated fatty acids to saturated fatty acids (17,18). Adding cholesterol to a low-fat diet alters the late effects of early nutrition (13,19). The addition of cholesterol to a high-fat diet also influences the adaptive response of the intestine when fed early or later in life (20).

Our studies using a diet feeding program involving diets enriched with saturated fatty acids or n-3 rich oils, with or without cholesterol supplementation, have shown that such treatments are associated with alterations in the intestinal transport of sugars and lipids (20). For example, refeeding a diet supplemented with cholesterol is associated with an increase in galactose, fatty acid, and cholesterol uptake as compared with feeding a cholesterol-supplemented diet for the first time later in life. Accordingly, the present study was undertaken in rats to test the hypothesis that previously reported alterations in the intestinal transport of sugars and lipids associated with refeeding diets containing saturated beef tallow (S), beef tallow plus 1% cholesterol (Sc), polyunsaturated fish oil (F), or fish oil plus 1% cholesterol (Fc) are associated with changes in BBM phospholipids and phospholipid fatty acids.

METHODS AND MATERIALS

Diet sequences. The guiding principles for the care and use of laboratory animals, approved by the Canadian Federation of Biological Societies and by the Council of the American Physiological Society, were carefully observed in the conduct of this study. Weanling female Sprague-Dawley rats were purchased commercially and housed with *ad libitum* access to water and food. There were 8–10 animals in each group. Pairs of rats were housed at a temperature of 21°C, with 12 h of light and 12 h of darkness. Weanling animals were fed isocaloric semisynthetic diets containing either saturated beef tallow or polyunsaturated fish oil, with or without added cholesterol (1.0%). The four diet groups are abbreviated as: S, Sc, F, or Fc. At 35 d of age (2 wk after weaning), the rats were maintained on either the same diet used at weaning, or were switched to one of the other diets which were then fed for a further 7 wk (Table 1). At week nine (2 + 7), the rats were continued either on the same diet, or were switched back to the original diet for 2 wk (2 + 7 + 2). Eight groups of animals were compared as follows: SSSc vs. ScSSc; ScScS vs. SScS; FFFc vs. FcFFc; and FcFcF vs. FFcF.

Composition of the diets. The protein content of the semisynthetic diets was 27%, and the carbohydrate content was 40.7% (starch 20% and glucose 20.7%). The diets contained 20% (w/w) fat of either a high or a low polyunsaturated-to-saturated fatty acid ratio. The proportions of polyunsaturated, monounsaturated, and saturated fatty acids are shown (Table 2). Cholesterol was added to either the S or to the F diet to give a concentration of 1%. These diets were nutritionally adequate, providing for all known essential nutrient requirements [ingredient and concentration (g/kg diet), respectively]: fat, 200; starch, 200; casein, 270; glucose, 207.65; nonnutritive fiber, 50; vitamin mix, 10; mineral mix, 50.85; L-methionine, 2.5; choline, 2.75; inositol, 6.25, where A.O.A.C. vitamin mix (Teklad Test Diets, Madison, WI) provided the following per kilogram of complete diet: 20,000 IU of vitamin A; 2,000 IU of vitamin D; 100 mg of vitamin E; 5 mg of menadione; 5 mg of thiamine-HCl; 8 mg of riboflavin; 40 mg of pyridoxine-HCl; 40 mg of niacin; 40 mg of pantothenic acid; 2,000 mg of choline, 100 mg of myoinositol; 100 mg of *p*-aminobenzoic acid; 0.4 mg of biotin; 2 mg of folic acid, and 30 mg of vitamin B_{12}; and Bernhart Tomarelli mineral mix (General Biochemicals, Chagrin Falls, OH) was modified to provide 77.5 mg of Mn^{2+} and 0.06 mg Se^{2+} per kilogram of complete diet. The diets containing the added 1% cholesterol were designated as Sc or Fc.

Food consumption was determined twice weekly. The animals were weighed at the beginning of the study, and weekly thereafter. At study termination, the animals were anesthetized by the injection of sodium pentobarbital (800 mg/kg body weight). Intestinal weights were determined when the BBM were prepared for lipid analysis, as described below.

BBM preparation and analysis. Jejunal and ileal BBM were prepared from mucosal scrapings by homogenization, $CaC1_2$ precipitation, differential centrifugation, and density gradient centrifugation. The details of this methodology have

Safflower oil	20 g	20 g
Fish oil	—	100 g

[a]For diets containing cholesterol, 1% cholesterol was added. No 22:1 was present in the diet; n.d., not detected.

been published (4,21). Protein was determined according to the method of Lowry *et al*. (22). The BBM markers that were assayed included sucrase (23) and alkaline phosphatase (24). In addition, Na^+K^+-ATPase (25), NADPH cytochrome C reductase (26), β-glucuronidase (27), and DNA (28,29) were assayed as markers of basolateral membrane, microsomes, lysosomal membranes, and nuclear material, respectively. The activities of these various enzymes are linear with respect to the amount of membrane protein added to the assay system. All assays of enzyme activities were performed at substrate concentrations that yield maximal activity rate values.

Lipid extractions of the isolated BBM were carried out immediately after preparation, according to a modification of the methods of Bowyer and King (30) and Folch *et al*. (31). Free cholesterol and cholesterol esters were determined enzymatically from lipid extracts (32). The total phospholipid content was assayed from lipid extracts (33), and the phospholipid composition was assayed by thin-layer chromatography (34).

Lipid extraction and analysis of phospholipid fatty acid composition. The final BBM preparation was suspended in the supernatant, and aliquots were taken for immediate lipid extraction according to a modification (30) of the method of Folch *et al*. (31). Ethoxyquin was used as an antioxidant. Lipid extracts were dried under nitrogen at 50°C, reconstituted in chloroform, and spotted onto silica gel H thin-layer chromatography plates (20 × 20 cm, 250 μ thickness; Analtech, Newark, DE). The plates were developed in chloroform/methanol/2-propanol/triethylamine/deionized water (60:18:50:26:14, by vol) to separate the individual phospholipids. The phospholipid spots were visualized with 0.03% (wt/vol) 2′,7′-dichlorofluorescein in 0.01 M NaOH under ultraviolet light. Phosphatidylcholine (PC) and PE spots were scraped into tubes for transesterification of the fatty acid components using 14% boron trifluoride in methanol (Sigma, St. Louis, MO), as described previously (35). A known amount of nonadecane was used as the internal standard. Phospholipids were refluxed with boron trifluoride in methanol/hexane (1.5:2.0, vol/vol) for 50 min at 90–100°C. Deionized water (1.0 mL) was added to the tubes, which were then allowed to stand 90 min before being centrifuged at 600 × *g* for 10 min. The upper hexane layer was transferred to 1.6 mL vials and evaporated to dryness under nitrogen at 60°C. Additional hexane was added to each vial, then again evaporated to dryness. At this stage, samples could be stored at −80°C until later analysis.

Fatty acid methyl esters were analyzed by automated glass capillary gas–liquid chromatography on the Varian model 600 gas chromatograph interfaced with the Varian Vista 402 data system (Varian Instruments, Georgetown, Ontario, Canada), using a fluid silica BP20 capillary column (25 m × 0.25 mm i.d.; Varian) (36). Fatty acid methyl esters were quantitated using flame-ionization detectors. The column was an open tubular glass capillary column (18 m × 0.25 mm i.d.) coated with SP1000/grade AA). Helium was used as a carrier gas at a flow rate of 1.8 mL/min and with an inlet pressure of 80 kPa. The inlet splitter was set at 4 to 1. Samples were injected at 175°C, and after 3 min in the oven the temperature was increased at a rate of 2°C/min for 20 min, and chromatography was complete after 50 min. Fatty acid methyl esters were identified with known standards and by the method of equivalent chain length (37).

Statistics. The results are expressed as mean ± SEM. To determine the effect of dietary rechallenge ("critical period programming"), *t*-tests were performed between the following groups: ScSSc vs. SSSc; SScS vs. ScScS; FcFFc vs. FFFc; and FFcF vs. FcFcF. A statistically significant difference was accepted as $P < 0.05$.

RESULTS

Animals. Refeeding with diets enriched with S, Sc, F, or Fc had no effect on the animals' food consumption or body weight gain (data not shown).

BBM enzyme activity. The BBM invertase activity was enriched 18-fold, and BBM alkaline phosphatase activity was enriched sevenfold, as compared with homogenates (data not shown). No difference in enrichment was noted among the eight diet groups.

Rechallenge with S was associated with an increase in the ileal BBM ratio of alkaline phosphatase/invertase, as compared with animals fed Sc for 9 wk and then fed S for 2 wk (SScS vs. ScScS; 2.1 ± 0.5 vs. 1.0 ± 0.2, respectively, $P < 0.05$, Table 3). Refeeding with Fc resulted in an increased jejunal BBM activity of alkaline phosphatase (FcFFc vs. FFFc; 2058 ± 216 vs. 1304 ± 223, $P < 0.05$), whereas rechallenge with F resulted in a decline in the jejunal BBM activity of alkaline phosphatase (FFcF vs. FcFcF; 1342 ± 178 vs. 2544 ± 465, $P < 0.05$).

BBM lipids. There was no diet effect on BBM cholesterol, but refeeding Fc resulted in increased ($P < 0.05$) ileal BBM total phospholipids (FcFFc vs. FFFc), and rechallenge with F resulted in a decline in the jejunal BBM ratio of phospholipid/cholesterol (FFcF vs. FcFcF) (Table 4).

Refeeding Sc resulted in a decrease in the ileal BBM PC (ScSSc vs. SSSc; 78 ± 11 vs. 176 ± 46, $P < 0.05$, Table 5). In rats rechallenged with Fc, there was an increase in ileal BBM sphingomyelin (FcFFc vs. FFFc; 188 ± 35 vs. 83 ± 14, $P < 0.05$), and PE (195 ± 22 vs. 121 ± 12, $P < 0.05$). There was a corresponding decrease in the ratio of PC/PE (0.5 ± 0.1 vs. 1.0 ± 0.1, $P < 0.05$), as well as an increase in the ratio of sphingomyelin/PC (1.3 ± 0.3 vs. 0.6 ± 0.1, $P < 0.01$).

The major fatty acids in BBM PC and PE were 18:0, 18:2n-6, 16:0, 18:1n-9, and 20:4n-6 (Table 6). Refeeding with different dietary lipids had no effect on the fatty acyl constituents of the jejunal or ileal BBM PC or PE.

DISCUSSION

The intestinal adaptive response to dietary rechallenge depends upon the presence of cholesterol: refeeding S or F has no effect on BBM phospholipids, whereas rechallenge with

See Table 1 for other abbreviations.

Sc or Fc results in modifications of BBM phospholipids (Table 5). Dietary rechallenge with Fc enhances jejunal BBM alkaline phosphatase activity as compared with animals fed only F and later challenged with Fc. The reverse was also true: dietary rechallenge with F reduced jejunal BBM alkaline phosphatase activity as compared with animals fed Fc and later challenged with F. Ileal BBM total phospholipids are increased in animals rechallenged with Fc, and reduced when rechallenged with F, owing to changes in sphingomyelin and PE content. Although the expected changes in BBM fatty acid composition are observed with feeding fish oil vs. saturated fatty acids, the presence or absence of cholesterol in the diet does not alter BBM phospholipid fatty acid composition with dietary rechallenge. This observation is consistent with the results of previous studies in which BBM cholesterol content appears to be relatively resistant to modification in a variety of models of intestinal adaptation (4–6,38). Thus, cholesterol must be present in the diet for the rechallenge effect on BBM phospholipids to be observed.

The same feeding program used in this study is associated with alterations in intestinal transport (20). In most previous studies of intestinal adaptation of dietary lipid alterations, the modified uptake of nutrients is associated with changes in the BBM phospholipid fatty acid composition (39–41). While diet rechallenge was associated with changes in BBM phospholipids, this was seen only in the ileum and only when cholesterol was present. Since rechallenge with S or F also results in adaptations of nutrient uptake in the jejunum, there must be some mechanism other than BBM phospholipids to explain the changes in uptake. Other factors considered were BBM phospholipid fatty acids (Tables 6–9), food intake, and body weight gain, but these were also not explanations.

Furthermore, the lack of clear association of BBM lipid compositional changes and BBM nutrient transport indicates that there must be a diet-associated mechanism other than villus morphology, crypt cell production rate, enterocyte turnover time, or distribution of transporters along the villus (42). A possible explanation for the lack of expected association between transport and BBM lipid compositional changes in response to alterations in dietary lipids would be to recognize the heterogeneity of distribution of transporters along the villus, with most transport occurring in the upper third of the villus (42), and with variations in BBM phospholipids along the villus (43,44). In this study, we measured phospholipids and fatty acyl constituents in BBM from enterocytes pooled from along the villus. It is possible that there were diet-associated alterations in BBM lipids in only a portion of the enterocytes from along the villus, and that by measuring fatty acids and phospholipids from the homogenate rather than from portions along the villus, we were unable to detect a membrane compositional change in a portion of cells that was responsible for altered nutrient uptake. This possibility is supported by the finding that the activity of enterocyte microsomal membrane fatty acid and phospholipid metabolic enzymes varies along the villus, as does the enterocyte microsomal membrane composition of fatty acids and phospholipids (Keelan, M., Clandinin, M.T., and Thomson, A.B.R., 1997, unpublished observations). Finally, it has been recognized recently that protein-mediated processes as well as passive permeation participate in the BBM uptake of lipids (45,46), so that diet-associated alterations in lipid uptake may be due only in part to changes in BBM lipids, lipophilic properties, and therefore passive permeation.

Facile and General Method for Preparation of (*E*)-4-Hydroxy-2-alkenals

Kazuhiro Sugamoto*, Yoh-ichi Matsushita, and Takanao Matsui

Faculty of Engineering, Miyazaki University, Miyazaki 889-21, Japan

ABSTRACT: A facile one-pot synthesis of (*E*)-4-hydroxy-2-alkenals such as (*E*)-4-hydroxy-2-nonenal, (*E*)-4-hydroxy-2-heptenal, and (*E*)-4-hydroxy-2-hexenal was achieved from the corresponding (2*E*,4*E*)-2,4-alkadienals by reduction–oxygenation with molecular oxygen and triethylsilane in the presence of cobalt(II) porphyrin as a catalyst followed by treatment with trimethylphosphite.

Lipids 32, 903–905 (1997).

Lipid peroxidation in biological systems produces many degradation products, including (*E*)-4-hydroxy-2-alkenals, which exhibit biological activity including cytotoxicity and genotoxicity (1,2). (*E*)-4-Hydroxy-2-nonenal (HNE) and (*E*)-4-hydroxy-2-hexenal (HHE) are major aldehydes derived from n-6 and n-3 unsaturated fatty acids, respectively. The synthesis of pure (*E*)-4-hydroxy-2-alkenals is required to study their biological behaviors. Consequently several synthetic efforts have been published (3–8).

Recently, we found that α,β,γ,δ-unsaturated carbonyl compounds were converted into γ-hydroxy-α,β-unsaturated carbonyl compounds regioselectively using cobalt(II) porphyrin-catalyzed reduction–oxygenation followed by reduction *in situ* (9). Using this method, we describe herein a facile and general method for a one-pot preparation of (*E*)-4-hydroxy-2-alkenals from (2*E*,4*E*)-2,4-alkadienals.

MATERIALS AND METHODS

Materials. (2*E*,4*E*)-2,4-Nonadienal, (2*E*,4*E*)-2,4-heptadienal, and (2*E*,4*E*)-2,4-hexadienal were purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan) and freshly distilled under reduced pressure. 2-Propanol and dichloromethane (Wako Pure Chemical Industries, Ltd., Osaka, Japan) were distilled from calcium hydride. Trimethylphosphite was purchased from Wako Pure Chemical Industries, Ltd. Triethylsilane and chlorotriethylsilane were purchased from Shin-Etsu Chemical Co., Ltd. (Tokyo, Japan). 2-Propan(ol-d), lithium aluminum deuteride, and [5,10,15,20-tetraphenylporphinato)cobalt(II) (abbreviated as Co(tpp)] were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI). {[5,10,15,20-Tetrakis(2,6-dichlorophenyl)porphinato]cobalt(II) (abbreviated as Co(tdcpp)} was prepared from commercially available 5,10,15,20-tetrakis(2,6-dichlorophenyl)porphine (Tokyo Kasei Kogyo Co., Ltd., Tokyo, Japan) by the insertion of cobalt ion using a method described in the literature (10). Triethyldeuterosilane was obtained by the reaction of chlorotriethylsilane with lithium aluminum deuteride according to a described method (11). Column chromatography was carried out using BW-300 purchased from Fuji Silysia Co., Ltd. (Aichi, Japan).

Typical procedure for synthesis of HNE. To a dichloromethane solution (5 mL) of (2*E*,4*E*)-2,4-nonadienal (277 mg, 2 mmol) and Co(tdcpp) (1.9 mg, 0.002 mmol) in a 50-mL Kjeldahl flask equipped with a three-way stopcock were added 5 mL of 2-propanol. The atmosphere in the flask was replaced with oxygen by bubbling into the solution for 5 min and then an oxygen balloon was attached to the flask through the three-way stopcock. After triethylsilane (0.35 mL, 2.2 mmol) was added to the solution at 28°C, the mixture was stirred at 28°C for 3 h, followed by treatment with trimethylphosphite (0.3 mL, 2.6 mmol) at 0°C for 2 h at room temperature. After the solvent was removed under reduced pressure, the residue was purified by silica gel column chromatography with *n*-hexane/ethyl acetate (16:1–4:1, vol/vol) to afford oily HNE (180 mg, 57.7%).

Synthesis of (E)*-4-hydroxy-2-[5-$^2H_1$]nonenal.* (*E*)-4-Hydroxy-2-[5-$^2H_1$]nonenal ([^{2}H]HNE) was prepared in 62.4% yield by the same procedure as described above except that triethyldeuterosilane and 2-propan(ol-d) were used instead of triethylsilane and 2-propanol.

Derivatization to 2,4-dinitrophenylhydrazone. To a solution of HNE (156 mg, 1 mmol) in 2 mL of ethanol were added 20 mL of 2,4-dinitrophenylhydrazine reagent, prepared from 2,4-dinitrophenylhydrazine (2 g), 98% H_2SO_4 (5 mL), H_2O (15 mL), and ethanol (20 mL). The mixture was stirred for 30 min at room temperature, and then the orange precipitate was collected by filtration followed by washing with 10 mL of 50% aqueous ethanol. The precipitate was then dried *in vacuo* to give 2,4-dinitrophenylhydrazone in a quantitative yield.

Abbreviations: Co(tdcpp), [5,10,15,20-tetrakis(2,6-dichlorophenyl)porphinato]cobalt(II); Co(tpp), (5,10,15,20-tetraphenylporphinato)cobalt(II); EI-MS, electron ionization-mass spectrometry; HHE, (*E*)-4-hydroxy-2-hexenal; [^{2}H]HNE, (*E*)-4-hydroxy-2-[5-$^2H_1$]nonenal; HNE, (*E*)-4-hydroxy-2-nonenal; NMR, nuclear magnetic resonance.

Spectral analyses. ^{1}H (250 MHz) and ^{13}C (63 MHz) nuclear magnetic resonance (NMR) spectra were recorded on a Bruker AC-250P (Rheinstetten, Germany) in $CDCl_3$ with tetramethylsilane ($\delta = 0.00$) as an internal standard. Infrared (IR) spectra were measured in $CHCl_3$ with a Hitachi IR 270-30 (Tokyo, Japan) spectrometer. Electron ionization–mass spectrometry (EI–MS) was effected on a Hitachi M-2000AM mass spectrometer operating at 70 eV. Melting points were measured using a Yanako MP-500D (Kyoto, Japan).

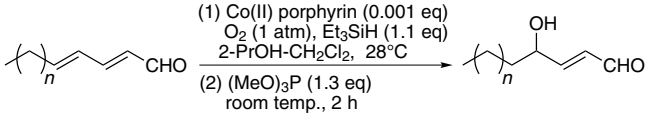
RESULTS AND DISCUSSION

Gardner *et al.* (8) reported a two-step synthesis of HNE starting from 3(*Z*)-nonenal. This method described a facile and efficient synthesis of HNE in comparison with previously described procedures (3–7). Recently, we found that α,β,γ,δ-unsaturated carbonyl compounds were converted into γ-hydroxy-α,β-unsaturated carbonyl compounds regioselectively using a cobalt(II) porphyrin-catalyzed reduction–oxygenation followed by reduction *in situ* (9). We expected that various (*E*)-4-hydroxy-2-alkenals could be synthesized in one pot from commercially available (2*E*,4*E*)-2,4-alkadienals by reduction–oxygenation. In practice, (2*E*,4*E*)-2,4-alkadienals were made to react with catalytic amounts of cobalt(II) porphyrin (0.001 eq) and triethylsilane (1.1 eq) under 1 atm of oxygen followed by treatment of trimethylphosphite (1.3 eq) in one pot (Scheme 1). The results are summarized in Table 1. When Co(tpp) was used as the catalyst, yields of (*E*)-4-hydroxy-2-alkenals were low (Entries 1–3), because the Co(tpp) had decomposed within 1 h, before reaction was complete. In contrast, when Co(tdcpp) was used instead of Co(tpp), (*E*)-4-hydroxy-2-alkenals were obtained in good yields (Entries 4–6), since the Co(tdcpp) was stable for several hours under the given reaction conditions.



SCHEME 1

Labeled HNE is important for pharmacodynamic and metabolic studies. Bravais *et al.* (12) have already reported synthesis of tritium- and deuterium-labeled (*E*)-4-hydroxy-2-nonenal-diethylacetal, but this method required a multistep procedure. Therefore, we tried one-pot synthesis of the labeled HNE using a Co(tdcpp)-catalyzed reduction–oxygenation. (2*E*,4*E*)-2,4-Nonadienal was allowed to react with oxygen and triethyldeuterosilane and 2-propan(ol-d) under conditions as already described, to give the deuterium-labeled HNE after purification by column chromatography (Scheme 2). The product showed the following ^{1}H NMR chemical shifts: ppm (δ), and (multiplicity, coupling constant in Hz, number of protons, and carbon assignments): 4.44 (*ddd*, *J* = 1.5, 5.0, 6.4 Hz, 1H, C-4), 6.31 (*ddd*, *J* = 1.5, 7.9, and 15.6 Hz, 1H, C-2), 6.83 (*dd*, *J* = 5.0 and 15.6 Hz, 1H, C-3), 9.58 (*d*, *J* = 7.9 Hz, 1H, C-1). Its 2,4-DNPH derivative showed molecular ion (*m/z*,

Lipase-Catalyzed Monoesterification of 1-*O*-Hexadecylglycerol in Organic Solvents

Laura E. Bertello, María Laura Salto, and Rosa M. de Lederkremer*

CIHIDECAR, Departamento de Química Orgánica, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Buenos Aires, Argentina

ABSTRACT: A simple method is presented to esterify 1-*O*-hexadecyl-*rac*-glycerol using lipases in different organic solvents. The following fatty acids were used: $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, and $C_{18:2}$. Monoesterification was achieved by using a limiting amount of the fatty acid. Both the 1-*O*-hexadecyl-3-*O*-acylglycerol and the 2-*O*-acylglycerol were obtained in a total yield of 75% and a ratio of 7:1 in dichloromethane after 3 d. Chromatographic data for the monoesters, useful for the identification of the natural products, are given (gas–liquid chromatography, thin-layer chromatography, reverse-phase thin-layer chromatography). The structure was confirmed by a chemical synthesis of 1-*O*-hexadecyl-2-*O*-hexadecanoylglycerol. The 3-*O*-glyceride was also formed by acyl migration, as the minor component. The monoesters were separated by column chromatography and characterized by ^1H and ^{13}C nuclear magnetic resonance spectra.

Lipids 32, 907–911 (1997).

Glyceryl ether lipids of the 1-*O*-alkyl-2-*O*-acylglycerol type were described as components of free or protein-linked glycosylphosphatidylinositols (GPI) (1). In particular, 1-*O*-hexadecyl-2-*O*-hexadecanoylglycerol was identified in GPI of epimastigote forms of *Trypanosoma cruzi* (2), in the GPI anchor of the 1G7-antigen of metacyclic forms of *T. cruzi* (3), and in the sialic acid acceptor mucins of this parasite (4). Interestingly, in the latter, the 1-*O*-alkyl-2-*O*-acylglycerol was mostly replaced by ceramide when epimastigotes differentiate to the infective metacyclic forms.

On the other hand, structural analysis of the phosphatidylinositol lipid class in *T. cruzi* epimastigotes showed that the alkylacyl species is more abundant than the diacylglycerol lipids. Hexadecylglycerol was esterified with the $C_{18:1}$ and $C_{18:2}$ fatty acids, identified by gas–liquid chromatography (GLC)–mass spectrometry (5). In the infective trypomastigote forms of *T. cruzi,* hexadecylglycerol esterified with the $C_{18:0}$ fatty acid was detected by *in vivo* incorporation of [^3H] palmitic acid (6).

Abbreviations: GLC, gas–liquid chromatography; NMR, nuclear magnetic resonance; RPTLC, reverse-phase thin-layer chromatography; TFA, trifluoroacetic acid; TLC, thin-layer chromatography.

In connection with our studies on the structure of GPI, standards of alkylacylglycerols were required for capillary GLC and thin-layer chromatography (TLC) analyses.

Lipases in organic solvents have been widely used for the synthesis or hydrolysis of fatty acid esters (7,8). Enzymatic esterification of 1-*O*-octadecyl-*rac*-glycerol with oleic acid in the presence of organic solvents using the lipase from *Candida cylindracea* was investigated. A considerable proportion of the diester was obtained when an excess of oleic acid was used (9). Diesterification of 1-*O*-alkyl-*sn*-glycerols with eicosapentaenoic acid and docosahexaenoic acid, respectively, by lipase was reported (10).

In the present work, 1-*O*-hexadecyl-*rac*-glycerol was esterified with $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, and $C_{18:2}$ by using the nonregiospecific lipase from *C. cylindracea* (11) or the lipase from *Pseudomonas* sp. (7). A limiting amount of fatty acid was used in order to obtain monoesterification of the hexadecylglycerol. Furthermore, the monopalmitoyl derivatives were chemically synthesized and characterized by the nuclear magnetic resonance (NMR) spectra.

MATERIALS AND METHODS

Materials. Lipases from *C. cylindracea* (new name, *C. rugosa*) Type VII (Sigma, St. Louis, MO) and from *Pseudomonas* sp. Type XIII (Sigma) were used. All chemicals were of analytical grade. An incubator shaker (New Brunswick Science INNOVA 4000, Edison, NJ) at 200 rpm was used.

Analytical methods. TLC was performed using silica-gel 60 (Merck, Darmstadt, Germany) with the following solvent systems: (i) hexane/ethyl acetate (4:1, vol/vol); (ii) toluene/ethyl acetate (20:1, vol/vol). Reverse-phase TLC (RPTLC) was performed on RP-18 F_{254s} (Merck) using chloroform/methanol/water (40:100:3, by vol) as solvent. Compounds were detected by spraying the plates with 10% H_2SO_4/0.04 M $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$/3 mM $Ce(SO_4)_2$ and heating to 200°C.

The lipids as trimethylsilyl derivatives were analyzed with a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) with a flame-ionization detector and nitrogen as the carrier gas. An HP-1 capillary column (12 m × 0.22 mm) was used.

[a]2-*O*-$C_{14:0}$ = 2-*O*-myristoyl-1-*O*-hexadecylglycerol, etc.
[b]Gas–liquid chromatography (GLC) of the trimethylsilyl derivatives using an HP-1 capillary column (0.2 mm × 12 m). The oven temperature program was 245°C (1 min) to 255°C at 3°C/min and to 320°C at 9°C/min. Retention time, rt.
[c]Thin-layer chromatography (TLC) on silica gel 60 (Merck, Darmstadt, Germany) using the solvent system hexane/ethyl acetate (4:1, vol/vol). Not detected, n.d.
[d]Reverse-phase thin-layer chromatography (RPTLC) on RP-18 F254s (Merck) using the solvent chloroform/ethanol/water (40:100:3, by vol).

The temperature was maintained at 245°C for 1 min, and then increased to 255°C at 3°C/min and then to 320°C at 9°C/min. Quantitative analyses were performed using 5-α-cholestane as internal standard. Aliquots of the reaction products were taken to dryness with a nitrogen stream, and trimethylsilylation was performed with 20–50 µL of Sylon HTP (Supelco, Bellefonte, PA) by heating at 70°C for 10 min.

The products were characterized by their ^{1}H and ^{13}C NMR spectra using a Bruker AC200 spectrometer (Karlsruhe, Germany.

Column purification of the alkylacyl products. The products of the reaction were purified by column chromatography on Unisil (200–325 mesh; Clarkson Chemical Co., South Williamsport, PA), eluting with hexane/ethyl acetate (9:1, vol/vol). The purification was monitored by TLC.

*Esterification of 1-*O*-hexadecylglycerol.* A suspension of 0.1 mmol of 1-*O*-hexadecyl-*rac*-glycerol, 0.05 mmol of myristic, palmitic, stearic, oleic and linoleic acid, respectively, and 1 mg of lipase from *C. cylindracea* or from *Pseudomonas* sp. in 2 mL of organic solvent was stirred at 37°C. The progress of the reaction was monitored by TLC and GLC. For chromatographic data, see Table 1.

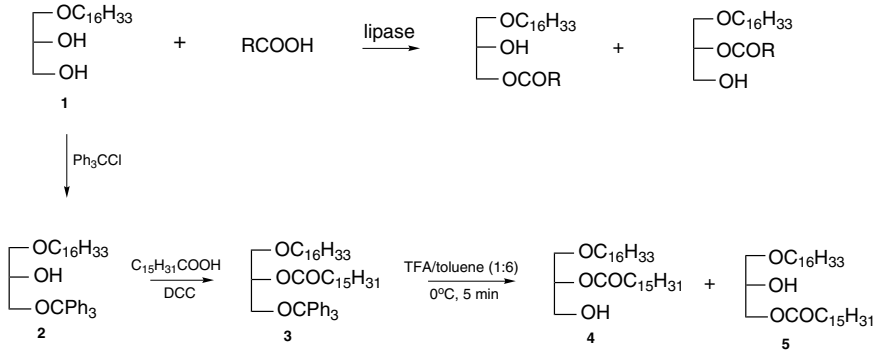
Determination of the optimal temperature. To a solution of 0.05 mmol of 1-*O*-hexadecylglycerol, 0.025 mmol of palmitic acid, and 0.01 mmol of 5-α-cholestane as internal standard in 1 mL of toluene were added 35 units of the lipase from *Pseudomonas* sp., and the mixture was stirred at different temperatures. The reaction progress was monitored by TLC and GLC.

Determination of the optimal solvent. To a solution of 0.05 mmol of 1-*O*-hexadecylglycerol, 0.025 mmol of palmitic acid, and 0.01 mmol of 5-α-cholestane in 1 mL of different solvents were added 35 units of the lipase from *Pseudomonas* sp., and the mixture was stirred at 33°C. The reaction progress was monitored by GLC.

*Chemical synthesis of 1-*O*-hexadecyl-2-*O*-hexadecanoylglycerol (**4**) and 1-*O*-hexadecyl-3-*O*-hexadecanoylglycerol (**5**) (Scheme 1).* A solution of 1-*O*-hexadecylglycerol (**1**) (95 mg, 0.3 mmol), trityl chloride (0.33 mmol), triethylamine (0.45 mmol), and 4-*N*,*N*-dimethylaminopyridine (0.01 mmol) in dichloromethane (2 mL) was stirred overnight at room temperature. The solution was poured into ice water and extracted with dichloromethane. The organic extract was washed with water and dried with sodium sulfate.

After removal of the solvent, compound **2** crystallized from ethanol (yield 161 mg, 96%) and was recrystallized from the same solvent, m.p. 48–49°C, R_f = 0.46 (Solvent ii). The starting material, 1-*O*-hexadecylglycerol, did not move with this solvent. ^{1}H NMR ($CDCl_3$): δ 7.45 (*m*, 6H, aromatic), 7.25 (*m*, 9H, aromatic), 3.95 (*m*, 1H, –C*H*OH–), 3.59–3.41 (*m*, 4H, –CH_2–O–CH_2–), 3.21 (*d*, *J* = 4.7 Hz, 2H, –CH_2OCPh$_3$), 2.42 (*d*, *J* = 4.7 Hz, O*H*, disappears on deuteration). ^{13}C NMR ($CDCl_3$): δ 143.99, 128.77, 127.88, 127.11 (C_6H_5), 86.75 (O*C*Ph$_3$), 72.14, 71.74 (*C*H, O*C*H$_2$R), 69.96 (*C*H$_2$O), 64.75 (*C*H$_2$OCPh$_3$); the alkyl carbons are not listed.

For the acylation, a solution of compound **2** (28 mg, 0.05 mmol), palmitic acid (0.055 mmol), 1,3-dicyclohexylcarbodiimide (0.055 mmol), 4-*N*,*N*-dimethylaminopyridine (0.055 mmol) in 1 mL dichloromethane was allowed to stand overnight at room temperature. The *N*,*N*-dicyclohexylurea was filtered, and the filtrate was washed with water and evaporated to a syrup which was purified by column chromatogra-



SCHEME 1

phy to afford compound **3**, R_f = 0.8 (solvent ii); yield 32 mg (83%). ^{1}H NMR ($CDCl_3$): δ 7.45 (*m*, 6H, aromatic), 7.3 (*m*, 9H, aromatic), 5.22 (*m*, 1H, –C*H*OCOR), 3.61 (*m*, 2H, –CH_2–O–CH_2–), 3.44–3.27 (–O–CH_2–CH_2–), 3.24 (*d*, *J* = 4.7 Hz, 2H, CH_2OCPh$_3$). ^{13}C NMR ($CDCl_3$): δ 143.94, 128.75, 127.82, 127.05 (C_6H_5), 86.75 (O*C*Ph$_3$), 71.73, 71.60 (*C*H, O*C*H_2R), 69.56 (*C*H_2O), 62.73 (*C*H_2OCPh$_3$).

Several methods were tried for detritylation in an attempt to minimize intramolecular acyl migration (12). Best results were obtained by treating tritylated compound **3** with a solution of trifluoroacetic acid (TFA) in toluene (1:6, vol/vol) for 5 min at 0°C. After this time, TLC (solvent i) showed no starting material and two spots, R_f 0.5 (major) and 0.63 (minor) corresponding to the 2-*O* and 3-*O* acyl derivatives, respectively. The latter probably formed in the detritylation step. The reaction was diluted with toluene and evaporated to dryness *in vacuo* at room temperature, with several additions of toluene. The ratio of 1-*O*-hexadecyl-2-*O*-hexadecanoyl-glycerol (**4**) and 1-*O*-hexadecyl-3-*O*-hexadecanoylglycerol (**5**) was established by capillary GLC. The products were separated by column chromatography and characterized by ^{1}H and ^{13}C NMR. For **4**, ^{1}H NMR ($CDCl_3$): δ 5.04–4.95 (*m*, 1H, –C*H*OCO–), 3.81 (*d*, *J* = 4.5 Hz, 2H, CH_2–OCH_2–), 3.65 (*dd*, *J* = 10.6 Hz, *J* = 4.8 Hz, 1H, –CH–CH_2OH), 3.58 (*dd*, *J* = 10.6 Hz, *J* = 5.1 Hz, 1H, –CH–CH_2OH), 3.45 (*t*, *J* = 6.6 Hz, 2H, OCH_2–CH_2), 2.35 (*t*, *J* = 7.35 Hz, 2H, –CH_2–COO–). ^{13}C NMR ($CDCl_3$): δ 173.70 (*C*=O), 72.88 (*C*H), 71.93 (O*C*H_2–R), 70.00 (*C*H_2O), 63.03 (*C*H_2OH). For **5**, ^{1}H NMR ($CDCl_3$): δ 4.21 (*dd*, *J* = 11.5 Hz, *J* = 4.8 Hz, 1H, –CH–CH_2OCO–), 4.12 (*dd*, *J* = 11.5 Hz, *J* = 5.0 Hz, 1H, –CH–CH_2OCO–), 4.07–3.95 (*m*, 1H, –C*H*OH–), 3.55–3.38 (*m*, 4H, –CH_2–OCH_2). ^{13}C NMR ($CDCl_3$): δ 174.00 (*C*=O), 71.80, 71.42 (*C*H, O*C*H_2R), 68.93 (*C*H_2O), 65.44 (*C*H_2OCO).

RESULTS AND DISCUSSION

*Enzymatic esterification of 1-*O*-hexadecyl-*rac*-glycerol.* Esterification of 1-*O*-hexadecyl-*rac*-glycerol with a limited amount of the $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, and $C_{18:2}$ fatty acid afforded the monoesters (Scheme 1). Aliquots of the mixtures were analyzed by GLC after trimethylsilylation, using a short capillary column (12 m), under conditions which gave a good separation for the 2-*O*-acyl and 3-*O*-acyl derivatives of each molecular species (Table 1). The absence of the 2,3-di-*O*-acyl derivative was checked by TLC.

The enzymes of *C. cylindracea* or *Pseudomonas* sp. gave the 3-*O*-acyl isomer as the main product together with the 2-*O*-acyl derivative. The products could be separated by Unisil column chromatography, and the alkylglycerol, which was used in excess, could be recovered and recycled. Racemic alkylglycerol was used instead of active compound because of cost. Furthermore, the optically active compounds were not necessary to compare the chromatographic data and characterize the natural acyl derivatives of 1-*O*-alkyl-*sn*-glycerol, for they behave the same under these chromatographic conditions. The positional isomers were identified by comparison with the products obtained by chemical synthesis. The isomers were differentiated by TLC; the 3-*O*-acyl derivative always showed a higher R_f value than the 2-*O*-acyl-1-*O*-alkylglycerol, and the homologous compounds of each type were not separated. In contrast, RPTLC did not differentiate positional isomers but could be used for the separation of the compounds obtained by esterification with homologous fatty acids. Unsaturated derivatives were better characterized by the difference shown by RPTLC before and after catalytic hydrogenation. Chromatographic data are listed in Table 1.

Alkyl monoacylglycerols from the glycoinositol phospholipid membrane anchor of bovine erythrocyte acetylcholinesterase were analyzed as trimethylsilyl ethers by GLC, but no data are given for the retention times of individual species (13).

Effect of the solvent in the lipase synthesis of monohexadecanoyl derivatives of hexadecylglycerol. The esterification of 1-*O*-hexadecylglycerol with palmitic acid was performed at 33°C using the lipase from *Pseudomonas* sp. in toluene, in dichloromethane, and in diisopropylether. The reaction was followed by GLC for several days (Fig. 1). The enzyme was able to esterify the substrate in all three solvents, but was most effective in dichloromethane (yield 75%).

In contrast to our results, esterification of 1-*O*-octadecyl-*rac*-glycerol with oleic acid, catalyzed by porcine pancreatic lipase, does not take place in dichloromethane (9). However, our data agree with those results when using ether as solvent, which extensively inhibited esterification. On the other hand, the enzyme from *C. cylindracea* was able to catalyze the esterification of 2-chloro and 2-methoxy propionic acid with 1-butanol in chloroform (14), and the lipase from *Mucor miehei* was active for the synthesis of propyl myristate in another chlorinated solvent, trichloroethane (15).

As recommended for glycerol esterification (8), the reac-

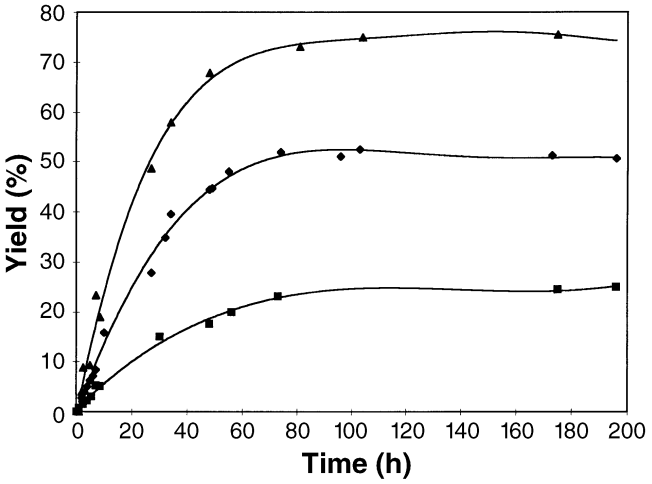


FIG. 1. Effect of solvent in the total yield of monopalmitoyl derivatives of 1-*O*-hexadecylglycerol. Esterification was catalyzed by the lipase from *Pseudomonas* sp. at 33°C. The solvents used were: methylene chloride (▲), toluene (◆), and diisopropylether (■).

tion was also effective in hexane, as shown by TLC, but quantification of the reaction was limited by the low solubility of the substrate. A mixture of the 2- and 3-monoglycerides was obtained in a ratio of 1:4; 1:5, and 1:7 in diisopropylether, toluene, and dichloromethane, respectively, after 72 h, as determined by GLC following trimethylsilylation of an aliquot of the reaction mixture.

Effect of reaction temperature. Figure 2 shows the effect of the reaction temperature on the esterification catalyzed by the *Pseudomonas* lipase in toluene. The rate of the reaction increased with temperature, with a maximum at 55°C. The effect was the same in the other solvents (not shown). In agreement, it was reported that esterification of glycerol with ethyl stearate in acetronile using the lipase from *C. antarctica* increased with temperature, with 60–80°C being the optimal range (16).

*Chemical synthesis of 1-*O*-hexadecyl-2-*O*-hexadecanoyl-rac-glycerol (***4***) and 1-*O*-hexadecyl-3-*O*-hexadecanoyl-rac-glycerol (***5***).* The title compounds were prepared according to Scheme 1, starting from 1-*O*-hexadecyl-*rac*-glycerol. The primary alcohol was selectively protected by tritylation with tritylchloride in triethylamine and 4-*N,N*-dimethylaminopyridine (17). After 18 h no starting material was detected by TLC, and the trityl derivative showed $R_f = 0.46$ (solvent ii). Compound **2** crystallized from ethanol in 96% yield. After recrystallization from the same solvent, it had a m.p. of 48–49°C and was characterized by NMR spectroscopy.

Acylation of **2** was performed with palmitic acid in the presence of 1,3-dicyclohexylcarbodiimide and 4-*N,N*-dimethylaminopyridine, at room temperature (18), affording **3** as an amorphous product with $R_f = 0.80$ (solvent ii) in 83% yield. Enzymatic acylation of compound **2** was not effective with any of the lipases used in this study, probably owing to steric hindrance by the bulky trityl group.

Several methods for the detritylation of compound **3** were tried to minimize acyl migration, a phenomenon well-known in the preparation of 2-monoglycerides (12). A better yield of 1-*O*-hexadecyl-2-*O*-hexadecanoylglycerol (R_f = 0.5, solvent i) was obtained by treating compound **3** with TFA in toluene (1:6, vol/vol) at 0°C. Complete detritylation was obtained after 5 min; however, GLC analysis of an aliquot after trimethylsilylation showed compound **4** and its position isomer **5** in a molar ratio of 2:1. Separation was achieved by column chromatography in a cold room.

Each individual alkylacylglycerol showed a characteristic ^{1}H NMR spectrum for the protons of the glyceryl backbone.

1-*O*-Hexadecyl-2-*O*-hexadecanoyl-*sn*-glycerol has been synthesized by another method, starting from 3-*O*-benzyl-*sn*-glycerol (19). The chemical shifts, which were only reported for position 2 of the glycerol moiety [δ_H 4.99 (*m*) and δ_C 72.91], are similar with those found in the present work for compound **4**.

1-*O*-Hexadecyl-3-*O*-hexadecanoylglycerol has been isolated from a soft coral (20). The NMR data are also in good agreement with our results for compound **5**, although the authors did not assign the ^{13}C NMR signals.

In conclusion, monoesterification of alkylglycerol catalyzed by lipases is a simple method which yields the 2-*O*-acyl and 3-*O*-acyl derivatives in a good total yield. A combination of chromatographic analyses can be used for the identification of the different monoacylalkylglycerols. The 3-*O*-acylglyceride is usually detected together with the natural 2-*O*-acyl derivative as a result of acyl migration.

The monoesters were also obtained by a high-yield chemical method, not previously described for these compounds.

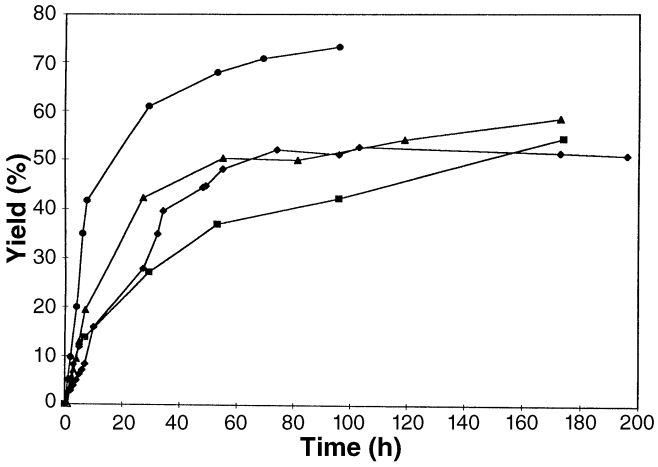

FIG. 2. Effect of reaction temperature in the total yield of monopalmitoyl derivatives of 1-*O*-hexadecylglycerol. Esterification was catalyzed by the lipase from *Pseudomonas* sp. in toluene. The temperatures used were: 25°C (■), 33°C (◆), 45°C (▲), and 55°C (●).

ARTICLE

Effects of Oxidative Stress on Glycerolipid Acyl Turnover in Rat Hepatocytes

Julio Girón-Calle, Patricia C. Schmid, and Harald H.O. Schmid*

The Hormel Institute, University of Minnesota, Austin, Minnesota

ABSTRACT: Lipid peroxidation was induced in freshly isolated rat hepatocytes by incubation in the presence of Fe^{3+}, resulting in accumulation of thiobarbituric acid reactive substances. Analysis of lipid classes revealed that the levels and fatty acid compositions of the two major phospholipids, phosphatidylcholine (PC) and phosphatidylethanolamine (PE), remained unchanged but the levels of triacylglycerols (TAG) were significantly reduced, and some of their polyunsaturated fatty acids were selectively lost as the result of oxidant treatment. Acyl turnover in PC and PE as determined by ^{18}O incorporation from $H_2{}^{18}O$-containing media remained largely unchanged during oxidant treatment, while some increased turnover of the saturated fatty acids in TAG was observed. We hypothesize that constitutive recycling of membrane phospholipids rather than selective *in situ* repair eliminates peroxidized species of PC and PE. TAG could serve as an expendable fatty acid reserve, providing a limited but very dynamic pool of polyunsaturated fatty acids for the resynthesis of phospholipids.
Lipids 32, 917–923 (1997).

Polyunsaturated fatty acids are readily peroxidized by a free radical-driven, autocatalyzed chain reaction (1). In biological systems, lipid peroxidation is kept to a minimum by antioxidants such as tocopherol, ascorbic acid and ubiquinone which break the chain reaction by scavenging free radicals (2,3), and by antioxidant enzymes such as superoxide dismutase, catalase, and glutathione peroxidase which inactivate lipid peroxides and reactive oxygen species (4,5). Despite the presence of antioxidant defense systems, a certain extent of peroxidation of the polyunsaturated fatty acids of membrane phospholipids is likely to occur *in vivo*, resulting in the generation of hydroperoxides as primary products. It has been proposed that the combined activities of phospholipase A_2 and acyl-CoA:lysophospholipid acyl transferase could serve as a membrane repair system by selectively removing the peroxidized acyl groups and reacylating the resulting lysophospholipids. Peroxidized fatty acids would be reduced by glutathione peroxidase to hydroxy fatty acids which, in turn, are substrates for degradation *via* β-oxidation (6–9). This hypothesis is based primarily on observations that phospholipase A_2 activity is stimulated by oxidative stress (10–13) and that peroxidized phospholipids are preferentially hydrolyzed by phospholipase A_2 in model membranes (14–16). The proposed reacylation of lysophospholipids that are generated through enhanced phospholipase A_2 activity has received less attention. In order to accomplish repair by this mechanism, enhanced deacylation should be accompanied by enhanced reacylation. However, because phospholipid turnover is a complex process that involves both *de novo* synthesis and remodeling by deacylation–reacylation, oxidative stress may have selective effects on these processes. For example, treatment of endothelial cells with linoleic acid hydroperoxide resulted in enhanced phosphatidylinositol synthesis, as measured by incorporation of both labeled fatty acids and inositol, whereas phosphatidylcholine (PC) synthesis was significantly reduced (17). Also, hydrogen peroxide was found to inhibit reacylation of arachidonic acid into phospholipids of alveolar macrophages (18), and phospholipid reacylation was inhibited in neuronal membranes by lipid hydroperoxides (19). In other radiolabel experiments, enhanced incorporation of exogenous [9,12-^{3}H]oleic acid into phosphatidylethanolamine (PE) was found in *tert*-butylhydroperoxide-treated erythrocytes, whereas its incorporation into PC was inhibited (20).

We have used the incorporation of ^{18}O from $H_2{}^{18}O$-containing media into glycerolipid acyl groups as a measure of acyl turnover in intact cells (21–25). In rat hepatocytes, acyl turnover was high, especially in triacylglycerols (TAG) (20% of total TAG per hour) but also in glycerophospholipids where it involved both *de novo* synthesis and remodeling by deacylation–reacylation at similar rates. We suggested that these two processes are regulated together and are linked to intracellular transfer and degradation (24,25). If all membrane lipids are continually replaced through synthesis, transport and degradation, any peroxidized fatty acids would become substrates for glutathione peroxidase during their normal turnover cycles, thus obviating the need for any specific repair mechanism. However, synthesis and remodeling could be selectively enhanced under oxidative stress.

In the present study, we have used the ^{18}O-technique to determine the effects of oxidative stress on glycerolipid acyl turnover in rat hepatocytes. We have found that acyl turnover

Abbreviations: NEFA, nonesterified fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; TAG, triacylglycerol(s); TBARS, thiobarbituric acid-reactive substances.

remains essentially unchanged during peroxidative treatment and that TAG are selectively depleted of their polyunsaturated fatty acids. Our results suggest that membrane repair occurs by a process based on recycling rather than on selective deacylation–reacylation of peroxidized phospholipids *in situ*.

MATERIALS AND METHODS

Materials. Male Sprague-Dawley rats, 200–350 g, were obtained from Sasco, Inc. (Omaha, NE). $H_2{}^{18}O$, 95% enrichment, was from Isotec, Inc. (Miamisburg, OH). Tetramethoxypropane, diheptadecanoylPC, diheptadecanoylPE, and $FeCl_3$ were from Sigma (St. Louis, MO). Heptadecanoic acid and triheptadecanoylglycerol were from Nu-Chek-Prep (Elysian, MN). Gas chromatography–mass spectrometry was carried out on a Hewlett-Packard 5890 series gas chromatograph (Palo Alto, CA) with a 5972 mass-selective detector and automatic injection system.

Hepatocyte preparation and incubation. Hepatocytes were obtained by perfusion of the liver with collagenase (26) using nonfasted rats as previously described (24). Viability was assessed by determination of trypan blue exclusion (24) and/or lactate dehydrogenase leakage (27), and was always found to be above 85%. Hepatocytes were resuspended in Krebs-Ringer/HEPES buffer pH 7.4 (1.5 mM Ca^{2+}) with 10 mM glucose and no bovine serum albumin at a density of 4×10^6 cells/mL. Cells were incubated for up to 90 min in 15-mm diameter glass vials (0.2 mL incubates) at 37°C with gentle swirling in an atmosphere of 95:5, O_2/CO_2. For experiments of ^{18}O incorporation, the incubation medium contained 40% $H_2{}^{18}O$. In the cases in which lipid peroxidation was induced, $FeCl_3$ (to a final concentration of 93 μM) was added from a freshly prepared concentrated solution at the start of incubations. Thiobarbituric acid reactive substances (TBARS) were determined in aliquots of total incubation media according to Huber *et al.* (28), and were expressed as nmol of malondialdehyde equivalents, using tetramethoxypropane as standard. In this procedure, boiling of samples is avoided in order to prevent interference of products derived from sugars (28). After incubation, the cell suspensions were transferred to ice-cold glass tubes, and the cells were sedimented by centrifugation at low speed. Lipids were extracted immediately from the cell pellets (29) using solvents containing 0.01% butylated hydroxytoluene. Lipid phosphorus was determined in aliquots according to Bartlett (30).

Separation of lipid classes and preparation of fatty acid methyl esters. Lipid classes were obtained by preparative thin-layer chromatography on layers of Silica Gel H, 20 × 20 cm. Plates were viewed under ultraviolet light after spraying with 2′,7′-dichlorofluorescein (0.1% wt/vol in ethanol), and fractions were scraped off. For preparation of PC and PE chromatograms were developed with chloroform/methanol/ammonium hydroxide/water (65:35:5:1, by vol), and the phospholipids were eluted from the adsorbent with chloroform/methanol/water (30:50:20, by vol). Nonesterified fatty acids (NEFA) methyl esters and TAG were obtained by thin-layer chromatography of aliquots in which NEFA had been methylated with diazomethane (31). Hexane/diethyl ether/glacial acetic acid (80:20:1, by vol) was used as developing system and diethyl ether for elution. Methyl esters of esterified fatty acids in PC, PE, and TAG were prepared by transesterification in 0.2 N NaOH/methanol (45°C, 1 h).

Fatty acid composition and ^{18}O excess. Fatty acid methyl esters were analyzed, and ^{18}O excess was determined by gas chromatography–mass spectrometry using a Hewlett-Packard HP5MS 30 m × 0.25 mm column. DiheptadecanoylPE, diheptadecanoylPC, triheptadecanoylglycerol, and heptadecanoic acid were added to the original lipid extracts as internal standards. The methyl ester preparations were divided into two aliquots. One of them was hydrogenated and used for determination of ^{18}O excess in the resulting 16:0, 18:0, 20:0, and 22:0 methyl esters by gas chromatography–mass spectrometry as described (22–24), using the McLafferty rearrangement ion (*m/z* 74 and *m/z* 76). Unlabeled hepatocyte preparations were processed and used to correct for the natural abundance of *m/z* 76 (about 1% of *m/z* 74). The second aliquot was not hydrogenated and was used for determination of ^{18}O excess in palmitic (16:0) and stearic (18:0) acid methyl esters. Catalytic hydrogenation of unsaturated fatty acids is required to achieve accurate measurement of ^{18}O excess (22–24). Thus, ^{18}O excess is given on figures and tables for the methyl esters of palmitic and stearic acids analyzed in nonhydrogenated samples, and for the methyl esters of C_{20} and C_{22} fatty acids analyzed in hydrogenated samples, representing mostly arachidonic (20:4) and docosapentaenoic (22:5) plus docosahexaenoic (22:6) acids, respectively. Additionally, ^{18}O excess in the methyl esters of oleic plus linoleic acids was obtained by calculating the difference between the values for the methyl ester of stearic acid (18:0) in hydrogenated and nonhydrogenated samples. This second, nonhydrogenated aliquot also was used for determination of fatty acid composition using total ion detection. All experiments were carried out in duplicate and were well reproducible. In all figures, high and low values are superimposed on the bar graphs representing averages.

RESULTS

Effects of oxidative stress on lipid class and fatty acid composition. Lipid peroxidation was induced in isolated rat hepatocytes by incubation in the presence of 93 μM Fe^{3+}. This led to accumulation of TBARS, which include malondialdehyde and other secondary products of lipid peroxidation (32) (Fig. 1). The lipid-soluble antioxidant, butylated hydroxytoluene completely inhibited TBARS generation caused by Fe^{3+}. Although TBARS accumulated faster during the first 20 min of oxidant treatment, accumulation continued throughout the 90-min incubation, indicating that lipid peroxidative decomposition went on during the entire time period. Viability of control and oxidant-treated cells remained relatively high, declining by about 8% from 85–90% at the beginning of the incubations. Hence, assays were performed on cells incubated in the presence or absence of Fe^{3+} for 45 and 90 min.

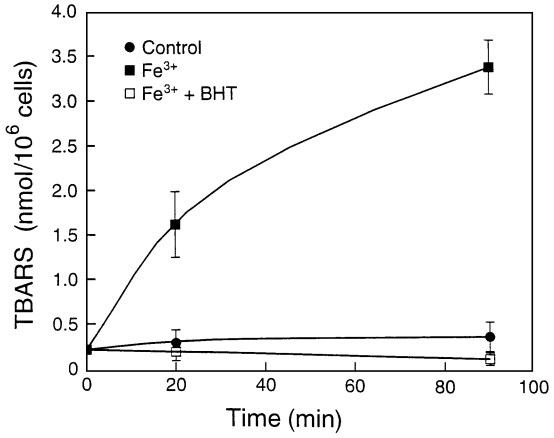

FIG. 1. Thiobarbituric acid-reactive substances (TBARS) accumulation during incubation of hepatocytes with no addition, addition of 93 μM Fe^{3+}, and addition of 93 μM Fe^{3+} plus 2 mM butylated hydroxytoluene (BHT). Cells were preincubated for 5 min with or without BHT before addition of Fe^{3+}. TBARS were determined in 50 μL aliquots taken from the incubations as described in the Materials and Methods section. Averages and standard deviation of three different incubations are shown.

In spite of the detectable lipid peroxidation (TBARS accumulation) as the result of treatment with Fe^{3+} (Fig. 1), the cells did not exhibit any measurable loss of polyunsaturated fatty acids (Table 1).

When the major classes of glycerolipids were isolated and analyzed separately, the results summarized in Table 2 were obtained. Oxidant treatment had little or no effect on the levels of PC and PE, based on total lipid phosphorus, but caused a significant reduction of TAG. Both control and oxidant-treated cells showed a decline in total phospholipid of 5 and 10% as determined by phosphorus analysis of aliquots after 45 and 90 min of incubation, respectively. This was probably as a result of a decrease in intact cell numbers and/or losses of membranes due to blebbing (33). As illustrated in Figure 2, there were only minor changes in the constituent fatty acids of PC and PE, but there was a selective loss of polyunsaturated fatty acids in TAG after 90 min of oxidant treatment.

[a]Fatty acid methyl esters were prepared by transesterification in 0.2 N NaOH/MeOH and analyzed by gas chromatography using 17:0 as internal standard. Minor fatty acids, together representing less than 5% of the total (16:1, 20:3n-6, and 20:5n-3), were not routinely determined. Data represent averages of duplicate incubations (see figures for typical variability of data).

As shown in Figure 3, oxidant treatment for 90 min also reduced the levels of NEFA by 60 to 80%, whereas 45 min of oxidant treatment had essentially no effect. As observed previously (24), rat hepatocytes contain very low levels of NEFA (9 nmol/μmol lipid phosphorus), consisting almost entirely of palmitic, stearic and oleic acids, and they do not contain measurable amounts of polyunsaturated fatty acids.

Effects of oxidative stress on glycerolipid acyl turnover. Incorporation of ^{18}O from $H_2{}^{18}O$-containing media into glycerolipid acyl groups was used as a measure of acyl turnover. Control cells exhibited acyl turnover similar to that observed previously under the same conditions (24,25). ^{18}O incorporation into all acyl groups increased linearly during incubation except for a small decline in cells incubated for 90 min with Fe^{3+} (Fig. 4). In PC (Fig. 5), ^{18}O-incorporation was linear for

[a]Before and after incubation for 45 and 90 min in the absence or presence of 93 μM Fe^{3+}. Lipid classes were separated by preparative thin-layer chromatography and fatty acid methyl esters prepared as described in the Materials and Methods section. 17:0 Internal standards for each lipid class were used. Averages of duplicate incubations are shown. LP: lipid phosphorus.

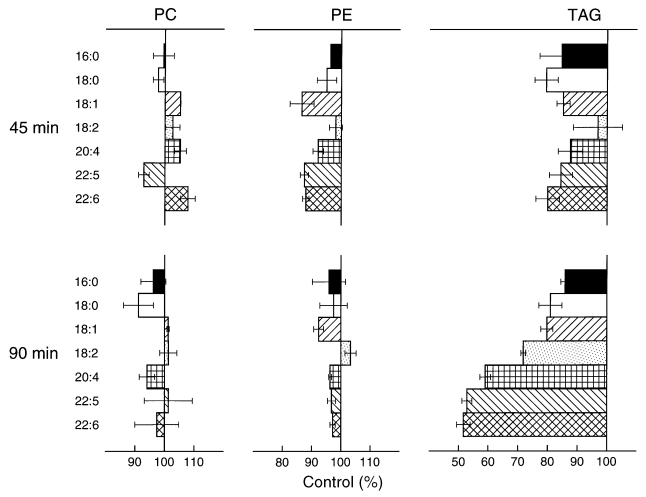

FIG. 2. Effect of Fe^{3+} treatment on the fatty acid composition of the major lipid classes. Fatty acid compositions were determined in phosphatidylcholine (PC), phosphatidylethanolanine (PE), and triacylglycerols (TAG) of hepatocytes incubated for 45 and 90 min in the presence or absence of 93 μM Fe^{3+}. Fatty acids were calculated as nmol of fatty acid per mol of total lipid phosphorus (Table 2), and their composition in the peroxidized hepatocytes was then expressed as percentage of their composition in control cells incubated for the same time periods. Averages of duplicate incubations are represented. High and low values are superimposed.

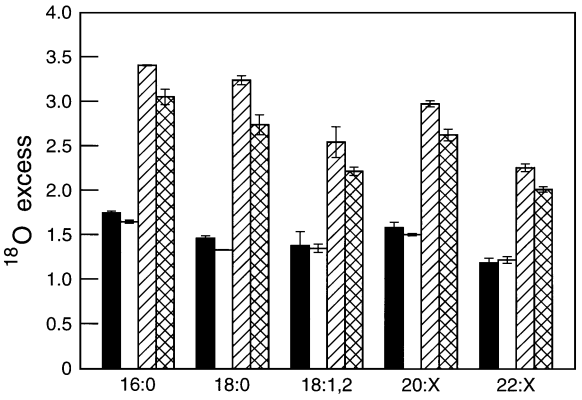

FIG. 4. Incorporation of ^{18}O from $H_2{}^{18}O$ into hepatocyte total fatty acids. Lipids were extracted from hepatocytes incubated for 45 and 90 min in media containing 40% $H_2{}^{18}O$ in the presence and absence of 93 μM Fe^{3+}. Atom percentage excess of ^{18}O was determined by gas chromatography–mass spectroscopy of fatty acid methyl esters as described in the Materials and Methods section. Averages of duplicate incubations are represented, including high and low values. Closed box, 45-min control; open box, 45-min Fe^{3+}; diagonal striped box, 90 min control; cross-hatched box, 90 min Fe3+.

90 min and proceeded at 1.3 atom percentage excess per hour for 16:0 and 18:0, 1.1% for 18:1 plus 18:2, 1.75% for 20:4, and 0.4% for the C_{22} fatty acids. The data for PE were similar except that incorporation was lower in 20:4 (0.8%) but higher in the C_{22} fatty acids (1.1%). Perhaps most importantly, oxidative stress for 45 and 90 min had no measurable effect on the rates of acyl turnover of these two major classes of glycerophospholipids. As observed previously (24), acyl turnover was higher in TAG than in either PC or PE, especially with respect to the long-chain polyunsaturated C_{20} and C_{22} fatty acids of which arachidonic acid (20:4n-6) and docosahexaenoic acid (22:6n-3) are the major representatives. Oxidant treatment resulted in increased turnover of 16:0 and 18:0 in TAG but had no effect on ^{18}O incorporation into NEFA (data not shown).

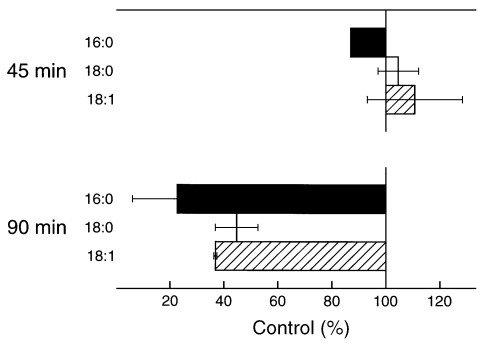

FIG. 3. Effect of Fe^{3+} treatment on nonesterified fatty acids. Methyl esters of nonesterified fatty acids were obtained by reaction with diazomethane and isolated by preparative thin-layer chromatography from lipid extracts of hepatocytes incubated for 45 and 90 min in the presence and absence of 93 μM Fe^{3+}. In using heptadecanoic acid as internal standard, fatty acid composition was calculated as nmol of fatty acid per mol of total lipid phosphorus, and the values for peroxidized hepatocytes were then expressed as percentage of those for control cells incubated for same time controls. Averages of duplicate incubations are represented, including high and low values.

Table 3 summarizes ^{18}O incorporation (calculated from data of the 45-min incubations) for the three major classes of glycerolipids. By taking into account the concentration of $H_2{}^{18}O$ in the media (40%) and the loss of one fatty acid oxygen upon reacylation, acyl turnover rates can be estimated from atom percentage excess of ^{18}O by multiplying these data by a factor of 5 (22–24). Thus, acyl turnover in hepatocyte PC and PE proceeded at up to 10% per hour. Perhaps most importantly, turnover of polyunsaturated fatty acids was extremely high in TAG, i.e., ~40% per hour for C_{20} and ~20% per hour for C_{22} fatty acids (Table 3). Even though these fatty acids are relatively minor components of TAG (Table 2), they are continuously recycled and may therefore become readily available for phospholipid synthesis and remodeling.

DISCUSSION

We have induced oxidative stress in isolated rat hepatocytes by incubating them in the presence of Fe^{3+}. Iron propagates lipid peroxidation by catalyzing the decomposition of preexisting lipid hydroperoxides to form alkyl and peroxyl radicals (34), and also may play a role as initiator of lipid peroxidation (35). The use of Fe^{3+} to induce lipid peroxidation in hepatocytes is well documented, especially when used as the Fe^{3+}/ADP complex (36–38). However, we observed that ADP

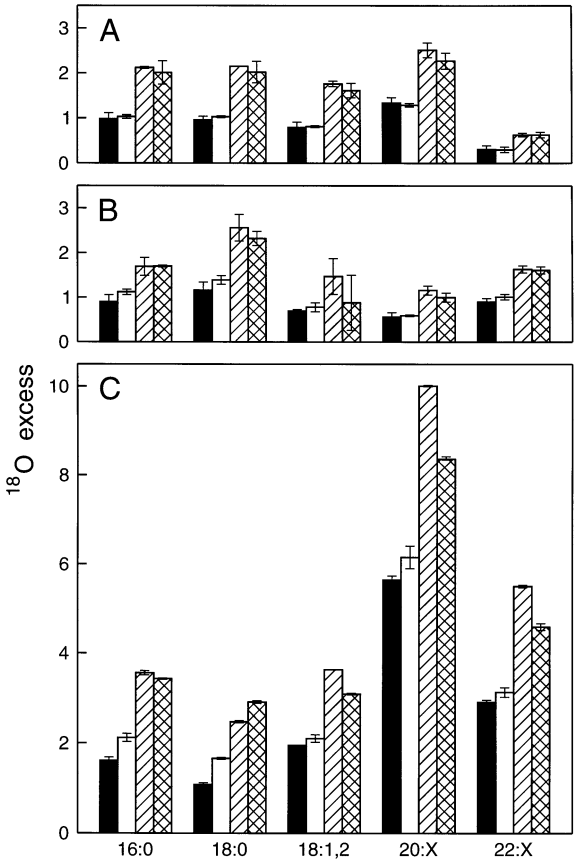

FIG. 5. Incorporation of ^{18}O from $H_2{}^{18}O$ into constituent fatty acids of the major lipid classes. Lipids were extracted from hepatocytes incubated for 45 and 90 min in media containing 40% $H_2{}^{18}O$, in the presence and absence of 93 μM Fe^{3+}. PC (panel A), PE (panel B), and TAG (panel C) were isolated by preparative thin-layer chromatography and ^{18}O excess was determined by gas chromatography–mass spectrometry of fatty acid methyl esters as described in the Materials and Methods section. Averages of duplicate incubations are represented, including high and low values. Closed box, 45 min control; open box, 45 min Fe^{3+}; diagonal striped box, 90 min control; cross-hatched box, 90 min Fe^{3+}.

itself caused important lipid metabolic alterations, independent of oxidative stress (39). Hence, we have used Fe^{3+} alone which caused nonlethal lipid peroxidation as indicated by the accumulation of TBARS (Fig. 1). This oxidative stress did not affect the amounts, acyl compositions, and acyl turnover rates of the major glycerophospholipids, PC and PE. In contrast, the amounts of TAG were reduced, concomitant with a selective loss of their polyunsaturated fatty acids. Assuming that lipid peroxidation affects both phospholipids and TAG, we propose that the selective losses of polyunsaturated fatty acids from TAG, which might be considered an expendable fatty acid pool, are used to maintain the structurally and functionally important glycerophospholipids. Lipolytic release of arachidonate from TAG and its incorporation into glycerophospholipids have been demonstrated in cultured human leukemia (HL-60) cells (40). Pacifici *et al.* (17) speculated that TAG could sustain membrane turnover in endothelial cells treated with a lipid hydroperoxide by providing diacylglycerol for phospholipid synthesis. Utilization of polyunsaturated fatty acid from the TAG pools could satisfy immediate, short-term needs, and TAG is the only source of such fatty acids in cultured cells. Supply of polyunsaturated fatty acid to cells *in vivo* occurs through the blood supply.

The membrane phospholipids of hepatocytes and other nucleated cells exist in a dynamic equilibrium involving *de novo* synthesis, remodeling by deacylation–reacylation, intracellular transfer, and degradation. We have shown that this process involves the turnover of substantial portions (>10% per hour) of the major glycerophospholipids (21–25). Hence, peroxidatively modified acyl groups would be hydrolyzed readily during normal glycerolipid turnover. Our present data support the view that this constitutive acyl turnover of glycerophospholipids has a major role in protecting cell membranes from lipid peroxidation. A preferential hydrolysis of peroxidized acyl groups by phospholipase A_2 (14–16) could be part of this process by making it more likely for peroxidized phospholipids to be recycled, without causing measurable increases in the overall rates of turnover. The lysophospholipids generated by this mechanism could be removed by lysophospholipase activity rather than being substrates for enhanced reacylation. Lysophospholipases are widely distributed in rat liver and other tissues, exhibit broad substrate specificity, and are thus able to prevent the accumulation of lysophospholipids (41). We have not found any evidence of the proposed *in situ* repair or of a nonspecific, general increase of acyl turnover, which also might be a possible response to peroxidative stress. It will be of interest to examine the effects of oxidant
