FIG. 1. Effect of caffeine on triacylglycerol content during 3T3-F442A cell differentiation. Confluent 3T3-F442A cells were induced to differentiate by 20 nM insulin on day 0. Open bars: insulin alone. Black bars: insulin plus 500 μM caffeine. Results are expressed as the mean ± SD of two independent experiments, each performed in duplicate.

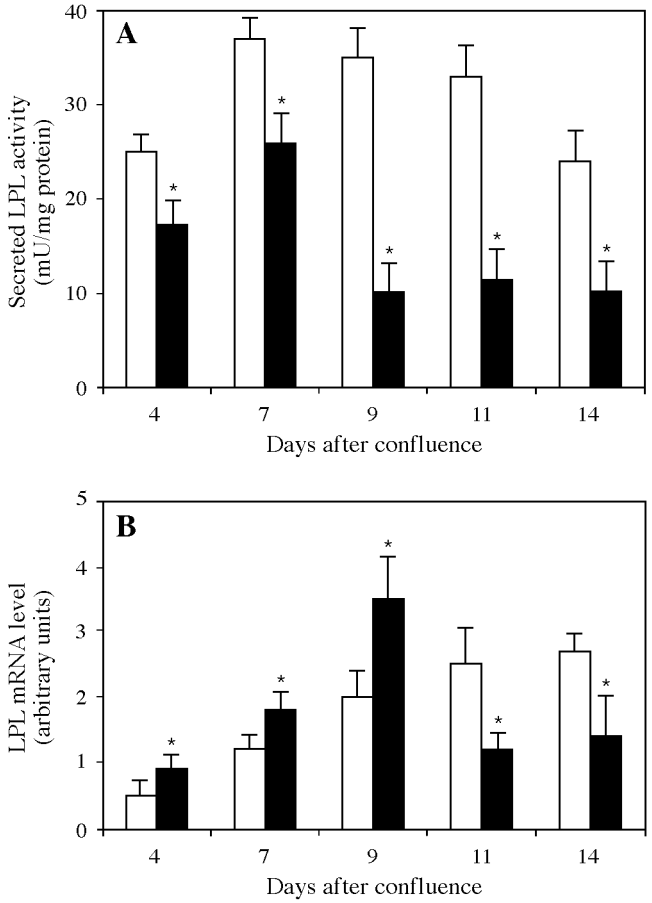

FIG. 2. Time course of the effect of caffeine on lipoprotein lipase (LPL) gene expression during 3T3-F442A cell differentiation. Confluent cells were exposed to 20 nM insulin to stimulate differentiation. Caffeine (500 μM) was added on day 0. (A) Secreted LPL activity was measured at the time indicated, as described in the Experimental Procedures section. The asterisks indicate values that differed significantly by at least $P < 0.05$ (treated cells vs. control). (B) Lipoprotein lipase mRNA level. Total mRNA was extracted and analyzed by Northern blotting as described in the Experimental Procedures section. The results are expressed as amount of LPL mRNA after correcting for the 28S rRNA signal and expressed in arbitrary units. Results are the mean ± SD of two independent experiments performed in duplicate. Open bars: insulin-treated cells. Black bars: insulin plus 500 μM caffeine-treated cells. The asterisks indicate values that differed significantly by at least $P < 0.05$ (treated cells vs. control).

remained low at day 14 (Fig. 2B). These effects of caffeine are dose-dependent, with a maximal effect from 0.5 mM caffeine (not shown).

Since caffeine did not affect either the triacylglycerol content or the morphological changes, it is unlikely that it accelerates the adipocyte differentiation process. Our observations support the idea that the caffeine effect is different at different levels of differentiation. To determine whether there was any relationship between the growth status of the culture and the action of caffeine, we determined the expression of LPL mRNA in 3T3-F442A preadipocytes and differentiated 3T3-F442A adipocytes at various times from 2 to 12 d after the onset of differentiation by insulin (Fig. 3A). At the very beginning of differentiation (days 0 to 5), caffeine exposure for 9 d stimulates induction of LPL mRNA and, in contrast, the presence of caffeine in the medium of differentiating cells inhibits the further induction of LPL mRNA by about 50% when added for 9 d at day 12. Therefore, during the differentiation process the caffeine effect is the sum of various effects on a number of important but unknown phases in adipocyte differentiation resulting in the level of LPL expression observed.

A possible cellular target of caffeine is the phosphodiesterase enzymes which hydrolyze cyclic nucleotide monophosphates. We therefore performed experiments by treating cells for 9 d with theophylline, another phosphodiesterase inhibitor (16). Theophylline exhibited the same pattern of action as caffeine (Fig. 3B). These findings suggest that the cAMP pathway is involved in the regulation of LPL gene expression. The action of caffeine and theophylline was therefore compared to that of cAMP on this regulation in fully differentiated cells (Fig. 4). When 3T3-F442A cells were incubated for 48 h with the cAMP analog, dibutyryl cAMP (db-cAMP), LPL mRNA levels decreased twofold, but this inhibition was transient, reaching baseline values within 7 d after addition of dibutyryl cAMP, in contrast with the effects of caffeine and theophylline, which remained potent after 7 d.

DISCUSSION

When confluent preadipocytes were incubated in the presence of insulin, they were induced to differentiate and accumulate triacylglycerol (14). Maximal differentiation was achieved after 11 d of insulin treatment. LPL has been shown to be one of the early genes induced during this process (15). Our results confirm this early induction, since maximal activity was found after 7 d (Fig. 1). In contrast, the cellular LPL mRNA level continued to increase after 11 d, suggesting a decrease in translational efficiency. This might be an indirect effect *via*

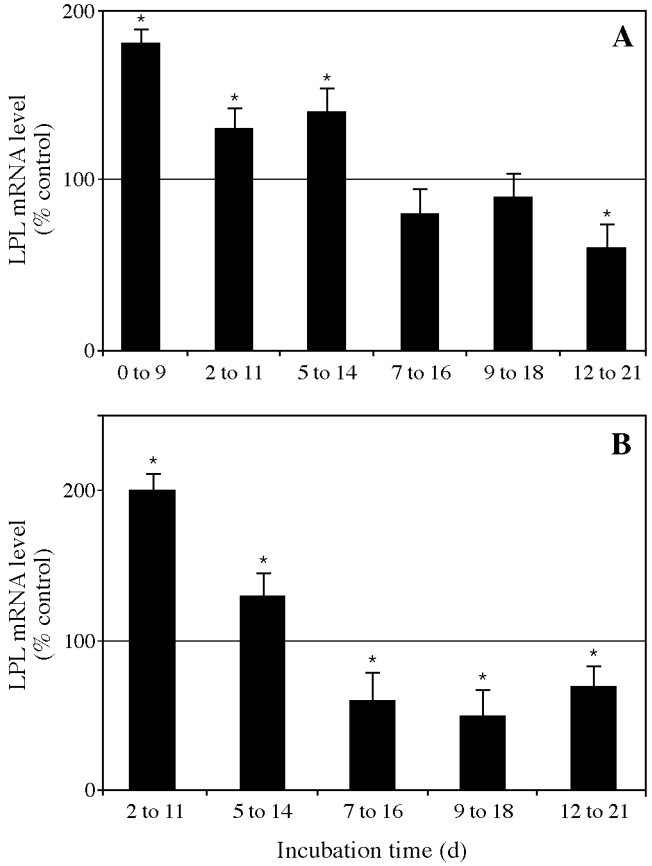

FIG. 3. Effect of chronic exposure of 3T3-F442A cells to caffeine and theophylline on adipose differentiation. 3T3-F442A cells cultured in defined medium with 20 nM insulin were exposed to caffeine (500 μM) (A) or theophylline ($7 \cdot 10^{-4}$ M) (B) for 9 d at different times after the onset of differentiation. Control cells were incubated for the same time with vehicle alone. LPL mRNA determination was performed as in Figure 2B. Results correspond to the ratio of LPL mRNA level in caffeine- or theophylline-treated cells compared to the corresponding control cells. Results are the mean ± SD of two independent experiments performed in duplicate.The asterisks indicate values that differed significantly by at least $P < 0.05$ (treated cells vs. control). For abbreviation see Figure 2.

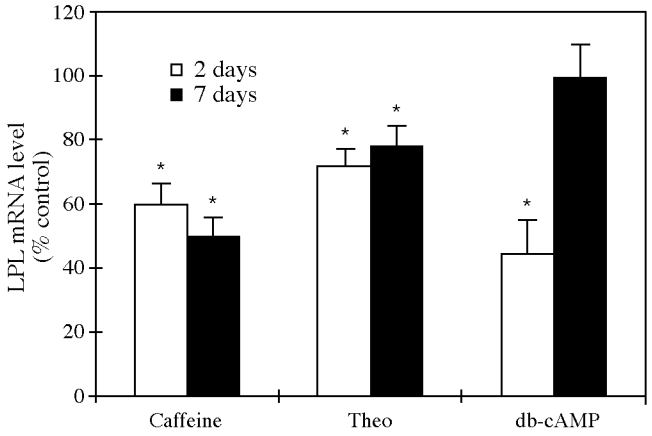

FIG. 4. Inhibitory effect of intracellular dibutyryl cyclic AMP (db-cAMP) level on steady-state of LPL mRNA level. Fully differentiated 3T3-F442A adipocytes were incubated in the presence of 500 μM caffeine, 70 μM theophylline (Theo), 10 μM db-cAMP, or vehicle alone (control) for 48 h or 7 d. LPL mRNA was determined as in Figure 2B. Data obtained by densitometric scanning were corrected for differences in RNA loading by using the 28S rRNA signal and expressed as a percentage of control. Results are the mean ± SD of two experiments in duplicate The asterisks indicate values that differed significantly by at least $P < 0.05$ (treated cells vs. control). For abbreviations see Figure 2

induction of other transactivators such as peroxysome proliferator-activated receptors or CAAT enhancer binding protein family members (21).

The addition of caffeine to the culture medium markedly decreased the secretion of LPL activity in both 3T3-F442A cells, undergoing adipocyte differentiation (Fig. 2), and in fully differentiated cells (Fig. 4). The main action of caffeine is to block cAMP degradation by inhibiting phosphodiesterase activity (16). It was therefore not surprising to observe that the caffeine effect can be mimicked by theophylline, another phosphodiesterase inhibitor, or by dibutyryl cAMP itself (Fig. 4). Our results are in agreement with the suggestion that inhibition of LPL activity induced by epinephrine is due to increased cellular cAMP (10). In fully differentiated 3T3-F442A cells, cAMP regulates the transcription of several major adipose genes, but acts solely as an antilipogenic agent since it does not elicit any loss in adipose characteristics (22). In addition, during differentiation of these cells, cAMP does not affect the morphological changes characteristic of the differentiation process (23).

There are still a number of uncertainties concerning the actual role of the cAMP/protein kinase A (PKA) pathway in LPL gene expression (10,24). In our experimental data, we demonstrated a clear biphasic effect of caffeine on LPL mRNA level, i.e., a marked increase when the drug is provided during the differentiation process and a decrease when the drug is added when adipocytes reached maturity. Since LPL activity is decreased in both conditions, this suggests that, in 3T3-F442A cells, LPL is regulated by cAMP at both transcriptional and post-transcriptional levels at least during the differentiation process. In addition, we cannot exclude that LPL mRNA turnover could be regulated. A post-transcriptional inhibition of LPL mRNA translation has been observed in epinephrine-treated 3T3-F442A cells as well as mature 3T3 L_1 cells (25), and this effect has been related to the first 50 (1601–1650) nucleotides of the 3' untranslated region of the messenger (11).

The situation concerning mature adipocytes is reminiscent of that observed in adipose tissue of rats fasted overnight, a condition of very high cellular cAMP content (7). After fasting, the majority of LPL is located in a highly inactive form in rough endoplasmic reticulum. Only mature, fully glycosylated LPL can be secreted from adipocytes (26). In addition, dimerization of LPL is essential for activity (6), and a study in 3T3-F442A cells demonstrated that LPL became a dimer after core glycosylation and transfer to the Golgi apparatus (27).

Our results suggest that caffeine stimulates LPL gene transcription at the onset of adipocyte differentiation and decreases LPL gene transcription in mature adipocytes. In addi-

tion, the inhibitory effect of caffeine might start very soon in the differentiation process since it was more potent when caffeine was added for 9 d after day 2 than when it was added for 9 d at later stages (compare Figs. 2B and 3A). Caffeine is supposed to exert its action *via* an increase in cAMP level. A variety of genes induced by cAMP share a conserved motif in their transcriptional control sequence, referred to as the cAMP response element (CRE). Such a sequence has been described in the rat LPL promoter (28), where CRE binds the CRE-binding protein CREB which is directly phosphorylated by PKA (29). Phosphorylation of CREB stimulates the transcriptional activity of several genes. This effect is mediated through the interaction with the ubiquitous P300/CBP (CREB-binding protein) coactivator family (29,30). The inhibitory effect of the cAMP/PKA pathway might occur *via* two pathways, i.e., a direct inhibitory effect of cyclic AMP response element modulator, a negative counterpart of the CREB family, or an indirect effect, buffering the P300/CBP family members which decreases the transcriptional efficiency of the genes requiring P300/CBP, such as fos/jun (31).

Other mechanisms may also be involved in the action of caffeine. Mobilization of Ca^{2+} ions from the sarcoplasmic reticulum compartment by caffeine has been described in myocardial cells (32). The actual physiological significance of the mechanisms of action of caffeine on LPL gene expression and their impact on the various levels of regulation appear quite complex and therefore require further investigation.

Tocotrienols Inhibit the Growth of Human Breast Cancer Cells Irrespective of Estrogen Receptor Status

Kalanithi Nesaretnam*, Ruth Stephen, Ray Dils, and Philippa Darbre

Division of Cell and Molecular Biology, School of Animal and Microbial Sciences, The University of Reading, Whiteknights, Reading RG6 6AJ, England

ABSTRACT: Potential antiproliferative effects of tocotrienols, the major vitamin E component in palm oil, were investigated on the growth of both estrogen-responsive (ER+) MCF7 human breast cancer cells and estrogen-unresponsive (ER–) MDA-MB-231 human breast cancer cells, and effects were compared with those of α-tocopherol (αT). The tocotrienol-rich fraction (TRF) of palm oil inhibited growth of MCF7 cells in both the presence and absence of estradiol with a nonlinear dose-response but such that complete suppression of growth was achieved at 8 μg/mL. MDA-MB-231 cells were also inhibited by TRF but with a linear dose-response such that 20 μg/mL TRF was needed for complete growth suppression. Separation of the TRF into individual tocotrienols revealed that all fractions could inhibit growth of both ER+ and ER– cells and of ER+ cells in both the presence and absence of estradiol. However, the γ- and δ-fractions were the most inhibitory. Complete inhibition of MCF7 cell growth was achieved at 6 μg/mL of γ-tocotrienol/δ-tocotrienol ($\gamma T_3/\delta T_3$) in the absence of estradiol and 10 μg/mL of δT_3 in the presence of estradiol, whereas complete suppression of MDA-MB-231 cell growth was not achieved even at concentrations of 10 μg/mL of δT_3. By contrast to these inhibitory effects of tocotrienols, αT had no inhibitory effect on MCF7 cell growth in either the presence or the absence of estradiol, nor on MDA-MB-231 cell growth. These results confirm studies using other sublines of human breast cancer cells and demonstrate that tocotrienols can exert direct inhibitory effects on the growth of breast cancer cells. In searching for the mechanism of inhibition, studies of the effects of TRF on estrogen-regulated pS2 gene expression in MCF7 cells showed that tocotrienols do not act *via* an estrogen receptor-mediated pathway and must therefore act differently from estrogen antagonists. Furthermore, tocotrienols did not increase levels of growth-inhibitory insulin-like growth factor binding proteins (IGFBP) in MCF7 cells, implying also a different mechanism from that proposed for retinoic acid inhibition of estrogen-responsive breast cancer cell growth. Inhibition of the growth of breast cancer cells by tocotrienols could have important clinical implications not only because tocotrienols are able to inhibit the growth of both ER+ and ER– phenotypes but also because ER+ cells could be growth-inhibited in the presence as well as in the absence of estradiol. Future clinical applications of TRF could come from potential growth suppression of ER+ breast cancer cells otherwise resistant to growth inhibition by antiestrogens and retinoic acid.

Lipids 33, 461–469 (1998).

Tocopherols and tocotrienols, collectively known as vitamin E, are lipid-soluble compounds that are often present as natural components in vegetable oils. Structurally, these compounds are similar, except that tocotrienols have an unsaturated side chain with three double bonds whereas the tocopherols have a fully saturated side chain (1). In their function as antioxidants, they are important for the protection of unsaturated lipids against peroxidation, particularly in biomembranes (2), by a mechanism resulting mainly from their ability to donate phenolic hydrogens to lipid-free radicals (3–5). Whereas the vitamin E fraction of most common vegetable oils contains mainly tocopherols, palm oil is a rich source of tocotrienols, with refined palm oil containing 133 mg α-tocopherol (αT), 130 mg α-tocotrienol (αT_3), 204 mg γ-tocotrienol (γT_3), and 45 mg δ-tocotrienol (δT_3) per kg of oil (6).

Experimental studies both *in vitro* and *in vivo* have suggested that tocotrienols may possess anticancer properties (7,8). Unlike many other fats and oils, palm oil does not enhance the yield of chemically-induced mammary tumors when fed to rats at high levels (20% w/w fat) in a semipurified diet (9–11). Evidence that this effect is related to the vitamin E fraction of the palm oil [tocotrienol-rich fraction (TRF)] was shown in our recent study (12) where chemically-induced mammary tumors were more numerous in rats fed vitamin E-free palm oil than in those animals fed palm oil containing vitamin E. Furthermore, addition of the vitamin E fraction of palm oil to a corn oil diet increased the median latency period and reduced both tumor incidence and tumor yield in a dose-dependent manner (12).

This inhibitory action of tocotrienols on breast tumor growth *in vivo* could result either from direct effects on the growth of the tumor cells themselves or from indirect sys-

temic interactions. Studies on the growth of MDA-MB-435 human breast cancer cells *in vitro* have demonstrated that the TRF of palm oil can inhibit directly the growth of these cells whereas αT did not have any such effect (13). However, the MDA-MB-435 cells lack estrogen receptors, and estrogen is known to play an important role in the growth of many breast cancer cells *in vivo* (14,15) and *in vitro* (16,17). Thus, the work presented here extends these cell culture studies to compare the effects of tocotrienols on the growth of human breast cancer cells which possess estrogen receptors and which are estrogen-responsive for growth with those cells which lack estrogen receptors.

Growth of the ER+ MCF7 human breast cancer cell line is regulated *in vitro* by estrogens (16,18) and offers a suitable model system in which to study the effects of tocotrienols. Separate sublines of MCF7 cells show different sensitivities to estrogen for growth, but the MCF7McGrath subline (19) is so dependent on estrogen for growth that it is unable to proliferate to any large extent in the absence of estrogen (16). However, recent studies have shown that growth of these cells is regulated also by complex interactions with growth factors of which one major mitogenic component would appear to be the insulin-like growth factors (IGF) (17,20). Growth regulation by the IGF system is itself complex since there are two ligands (IGFI and IGFII), two receptors (IGFIR and IGFIIR), and at least six high-affinity extracellular binding proteins (IGFBP 1-6) (21), and it would appear that estrogen can alter the expression of several of these components in breast cancer cells including IGFII (22), IGFIR (23), and IGFBP (24). Growth inhibitory effects in estrogen-responsive human breast cancer cells could thus result either from a direct antagonism of estrogen action at the estrogen receptor level (25) as found for antiestrogens such as tamoxifen and ICI 182,780 (26,27) or from interactions in growth factor pathways such as changing levels of IGFBP (28). The work presented here describes the effects of the TRF of palm oil and of individual tocotrienols on the growth of estrogen-responsive MCF7McGrath human breast cancer cells, on pS2 gene expression as a molecular marker of estrogen action (29), and on levels of secreted IGFBP.

MATERIALS AND METHODS

Materials. Plastic tissue culture dishes, growth media, and fetal calf serum (FCS) were all purchased from Gibco BRL (Paisley, Scotland). Zaponin and isoton were purchased from Coulter Electronics (Harpenden, England). Hybond membranes were bought from Amersham International (Amersham, England). 17-β-Estradiol was purchased from Steraloids (Croydon, England). The TRF and individual αT_3, γT_3, and δT_3 fractions were obtained from the Palm Oil Research Institute of Malaysia (PORIM). The αT was obtained from Sigma Chemical Company (Croydon, England) at a purity of approximately 95%.

Isolation of TRF and individual tocotrienols. Extraction of the TRF from palm oil has been described by Sundram and Gapor (30). In brief, palm oil fatty acid distillate was converted into methyl esters by esterification. The methyl esters were then removed by distillation, leaving a vitamin E concentrate. This was further concentrated by crystallization and passed through an ion-exchange column to give 60–70% pure vitamin E. Further purification was achieved by washing and then drying the concentrate followed by a second molecular distillation stage. The final purity of the vitamin E preparation, TRF, was 95–99%, its composition being (w/w) αT 32%, αT_3 25%, γT_3 29%, and δT_3 14%.

Individual tocotrienols were separated by thin-layer chromatography and further chromatographed repeatedly until a purity of about 90% (highest available) was obtained.

Culture of stock cells. The MCF7 McGrath human breast cancer cells were kindly provided by Dr. K. Osborne at passage number 390 (19). Stock cells were grown as monolayer cultures in Dulbecco's modified Eagle's medium (DMEM) supplemented with 5% FCS, 10^{-8} M estradiol, and 10 μg/mL insulin in a humidified atmosphere of 10% carbon dioxide in air at 37°C. 17-β-Estradiol was dissolved in ethanol and diluted 1:10,000 in culture medium. Insulin was dissolved in 6 mM HCl and diluted 1:1,000 in culture medium. MDA-MB-231 human breast cancer cells were obtained from the American Tissue Culture Collection (Manassas, VA). Stock cells were grown as for MCF7 cells but with the omission of estradiol and insulin. Cells were subcultured at weekly intervals by suspension with 0.06% trypsin/0.02% EDTA (pH 7.3).

Cell growth experiments. Cells were suspended from stock plates by treatment with phenol red-free 0.06% trypsin/0.02% EDTA (pH 7.3), added to an equal volume of phenol red-free RPMI1640 medium containing 5% dextran-charcoal treated FCS (DCFCS) (31), and counted on a hemacytometer. Cells were then added to the required volume of phenol red-free RPMI1640 medium containing 5% DCFCS at a concentration of 0.2×10^5 cells/mL and plated in monolayer in 0.5-mL aliquots into 24-well plastic tissue culture dishes. After 24 h, the medium was changed to phenol red-free RPMI1640 medium with 5% DCFCS supplemented with the appropriate concentrations of TRF, αT, individual tocotrienol fractions, with or without estradiol. Both TRF and αT were dissolved in dimethyl sulfoxide, estradiol in ethanol, and all were diluted 1:10,000 in culture medium. Control cultures contained the same volume of dimethyl sulfoxide or ethanol vehicle alone. The culture medium was changed routinely every 3–4 d.

Cell counting. Cells were washed rigorously *in situ* with phosphate-buffered saline (PBS) in order to wash off non-adherent dead cells and were then lysed in 0.5 mL 0.01 M HEPES buffer/1.5 mM $MgCl_2$ plus 2 drops of zaponin solution for 5 min. The nuclei released were counted in isoton on a Coulter counter. All cell counts were carried out in triplicate on triplicate dishes and results calculated as the mean ± standard error. *P* values were determined using Student's *t*-test for two-samples assuming unequal variance [by standard software packages Minitab and Microsoft Excel (Microsoft Corp., Redmond, WA)]. Viability of adherent cells was determined using the standard try-

pan blue dye exclusion assay technique and performing cell counts on a hemacytometer.

RNA analysis by Northern blotting. Cells were plated onto 9-cm plastic tissue culture dishes in 16-mL aliquots of phenol red-free RPMI1640 medium with 5% DCFCS. After 24 h, the medium was changed to phenol red-free RPMI1640 medium containing 5% DCFCS with or without 10^{-8} M estradiol or 8 μg/mL TRF. After a further 6 d, cells were washed *in situ* with PBS, harvested into ice-cold PBS using a rubber policeman and pelleted by centrifugation. Whole cell RNA was prepared by the guanidinium cesium chloride method (32). Aliquots of RNA (20 μg) were subjected to electrophoresis in 1.5% agarose-formaldehyde gels (32). RNA was transferred onto Hybond-N membrane and hybridized to ^{32}P-labeled cDNA probes for pS2 and 36B4 exactly as described previously (29). The pS2 DNA probe was a 300-base pair P*st*1 fragment from pS2 cDNA (29). The 36B4 DNA probe was a 220-base pair P*st*1 fragment which acted as a control since 36B4 mRNA is not regulated by estrogen (33).

Western ligand blotting of IGFBP. Cells were plated onto 3.5-cm plastic tissue culture dishes in 2.5-mL aliquots of phenol red-free RPMI1640 medium supplemented with 5% DCFCS. After 24 h, the medium was changed to phenol red-free RPMI1640 medium with 5% DCFCS and supplemented with 10^{-8} M estradiol or with 6 μg/mL of αT, αT_3, γT_3, or δT_3 as required. After a further 6 d, the medium was changed to serum-free medium: cells were washed three times with phenol red-free RPMI1640 medium and incubated in 0.5 mL of serum-free medium per dish (phenol red-free RPMI1640 medium with 15 mM HEPES buffer, 0.25% bovine serum albumin, and any supplements of estradiol or vitamin E as above) for a further 24 h. Medium conditioned by the cells was collected, cellular material removed by centrifugation, and medium stored at −70°C. Cells remaining on each dish were counted as described above.

Aliquots of the conditioned media were run on polyacrylamide gel electrophoresis, loading into each well the volume of conditioned medium equivalent to 10^5 cells. Aliquots of conditioned media were each mixed with an equal volume of gel sample buffer (26 mM Tris-HCl (pH 6.8), 2% sodium dodecyl sulfate (SDS), 10% glycerol, 0.01% bromophenol blue), heated to 100°C for 2 min, and proteins separated by 15% polyacrylamide-SDS gel electrophoresis. Proteins were transferred onto Hybond-C extra membrane by semidry Western blotting in 48 mM Tris, 39 mM glycine, 1.3 mM SDS, 20% methanol. Western blots were hybridized to ^{125}I-IGFI as described by Hossenlopp and coworkers (34). ^{125}I-IGFI was prepared by the iodogen method (35).

RESULTS

Effect of TRF and αT on cell growth. Initial experiments were designed to determine the effect of TRF on the growth of MCF7McGrath human breast cancer cells. Figure 1A shows

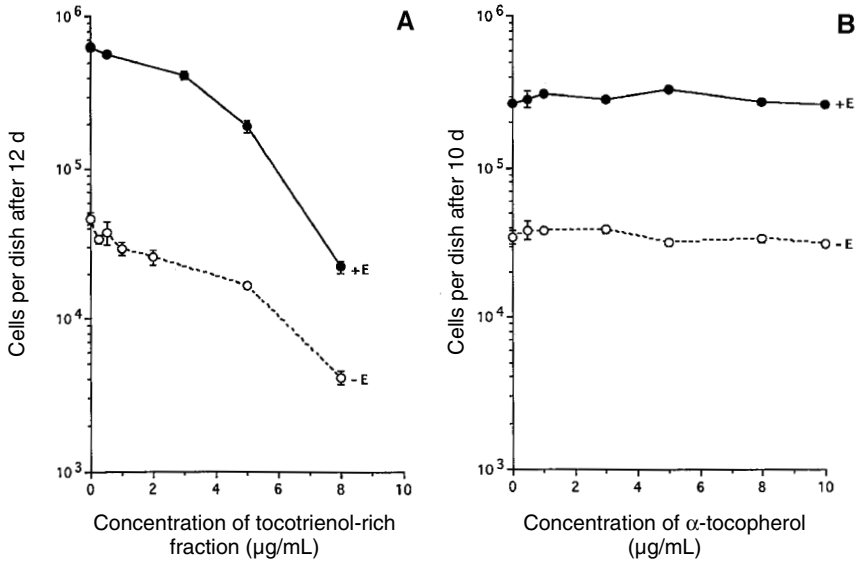

FIG. 1. Effect of the tocotrienol-rich fraction (TRF) of palm oil (A) or α-tocopherol (B) on regulation of the growth of estrogen-responsive ER+ MCF7McGrath human breast cancer cells in monolayer culture. Cells were grown for (A) 12 d or (B) 10 d in 24-well dishes in RPMI1640 medium lacking phenol red but containing 5% dextran-charcoal treated fetal calf serum (DCFCS) and increasing concentrations of either TRF or α-tocopherol (αT) in either the absence (open circles and dotted lines) or presence (closed circles and solid lines) of 10^{-8} M estradiol. Plating densities of the cells were (A) $1.34 \pm 0.01 \times 10^4$ cells per dish for the experiment in the absence of estradiol, and $2.41 \pm 0.08 \times 10^4$ cells per dish for the experiment in the presence of estradiol; (B) $0.43 \pm 0.02 \times 10^4$ cells per dish for the experiment in the absence of estradiol, and $0.64 \pm 0.01 \times 10^4$ cells per dish for the experiment in the presence of estradiol. Error bars represent the standard error of triplicate dishes. Where no bars are seen, the error was too low for visual display.

that TRF inhibited the growth of these estrogen-responsive cells both in the absence and in the presence of estradiol, and in a dose-dependent manner. On its own, TRF inhibited cell growth at concentrations of 0.5 μg/mL ($P = 0.031$), 1 μg/mL ($P = 0.04$), 2 μg/mL ($P = 0.027$), 5 μg/mL ($P = 0.018$), and 8 μg/mL ($P = 0.009$). At 8 μg/mL TRF, cell numbers at 12 d fell below the plating density of the cells ($P = 0.002$). In the presence of 10^{-8} M estradiol, TRF was also able to inhibit cell growth at concentrations of 0.5 μg/mL ($P = 0.04$), 3 μg/mL ($P = 0.01$), 5 μg/mL ($P = 0.002$), and 8 μg/mL ($P = 0.005$), but cell numbers remained above plating density in all cases. In contrast to these results with TRF, Figure 1B shows that αT had no effect on growth of MCF7McGrath human breast cancer cells at any concentration tested from 0.5–10.0 μg/mL in either the absence or in the presence of 10^{-8} M estradiol (after 10 d at 10 μg/mL αT, in the absence of estradiol $P = 0.421$ and in the presence of estradiol $P = 0.535$).

These results are in line with previous studies using ER– MDA-MB-435 human breast cancer cells (13) where cell growth was similarly shown to be inhibited by TRF but not by αT. However, since these previous studies were based on different cell biological criteria, control experiments were repeated here using ER– MDA-MB-231 human breast cancer cells for direct comparison. Figure 2A shows that after 10 d, TRF inhibited cell growth at concentrations of 2 μg/mL ($P = 0.003$), 5 μg/mL ($P = 0.002$), 8 μg/mL ($P = 0.001$) and 10 μg/mL ($P = 0.0001$) but in all cases cell growth remained substantial and cell numbers well above plating density. However, at 20 μg/mL, TRF was able to inhibit MDA-MB-231 cell growth and reduce cell numbers below plating density ($P = 0.057$) (data not shown). In contrast, αT had no effect on growth of MDA-MB-231 cells at any concentration up to 10 μg/mL (Fig. 2B) or indeed even at 20 μg/mL (data not shown).

Effect of individual tocotrienols on cell growth. Further experiments studied the effects on cell growth of individual tocotrienol fractions (α-, γ-, and δ-) in order to determine which of the fractions were effective or most effective in inhibiting the cell growth. These results are shown in Figures 3 and 4. For MCF7McGrath cells, γT_3 and δT_3 were the most effective of the fractions at inhibiting cell growth in the absence of estradiol (Fig. 3) and did so in a dose-dependent manner after both 7 and 14 d in culture. Already after 7 d, γT_3 showed highly significant inhibitory effects at concentrations from 4 μg/mL ($P = 0.001$) to 6 μg/mL ($P = 0.002$). At 6 μg/mL γT_3, cell growth was completely suppressed with cell numbers even falling below the plating density ($0.130 \pm 0.086 \times 10^5$ cells on day 0; $0.057 \pm 0.002 \times 10^5$ cells on day 7; $0.021 \pm 0.076 \times 10^5$ cells on day 14). δT_3 also inhibited cell growth after 7 d at concentrations from 4 μg/mL ($P = 0.03$) to 6 μg/mL ($P = 0.007$). Again, at 6 μg/mL δT_3, cell growth was completely suppressed with cell numbers even falling below the plating density ($0.078 \pm 0.005 \times 10^5$ cells on day 0; $0.069 \pm 0.046 \times 10^5$ cells on day 7; $0.040 \pm 0.014 \times 10^5$ cells on day 14). αT_3 had no inhibitory effect on growth of MCF7McGrath cells after 7 d in culture (at 4 μg/mL $P = 0.569$; at 5 μg/mL $P = 0.482$; at 6 μg/mL $P = 0.249$) and had only a small inhibitory effect after 14 d in culture at concentrations of 5 μg/mL ($P = 0.038$) and 6 μg/mL ($P = 0.022$).

In the presence of estradiol, MCF7McGrath cell growth was inhibited most strongly by δT_3 (Fig. 3) (after 14 d, *P* val-

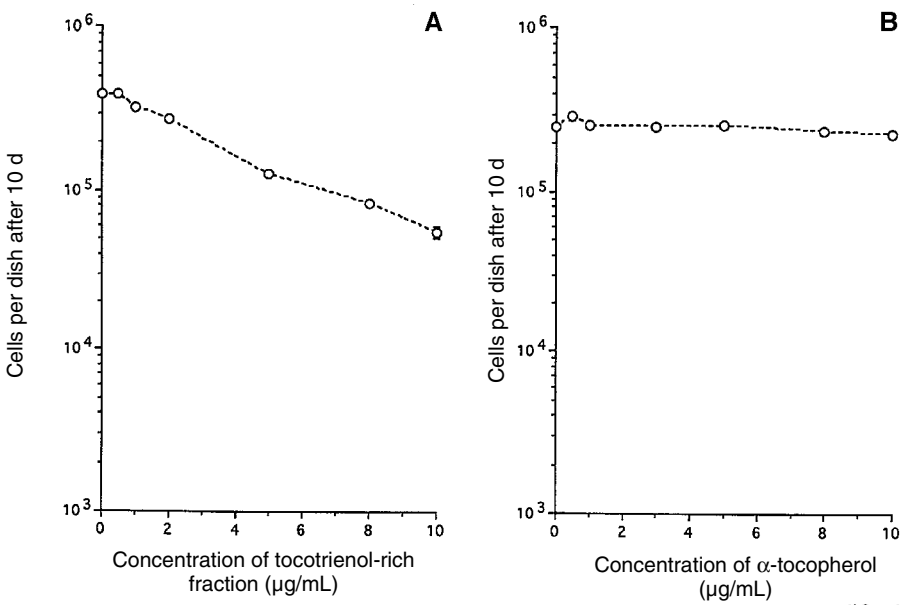

FIG. 2. Effect of the tocotrienol-rich fraction (TRF) of (A) palm oil or (B) αT on regulation of the growth of estrogen-insensitive ER– MDA-MB-231 human breast cancer cells in monolayer culture. Cells were grown for 10 d in 24-well dishes in RPMI1640 medium lacking phenol red but containing 5% DCFCS and increasing concentrations of either TRF or αT in the absence of estradiol. Cells were plated together in one experiment for A and B at a density of $1.05 \pm 0.19 \times 10^4$ cells per dish. Error bars represent the standard error of triplicate dishes. Where no bars are seen, the error was too low for visual display. See Figure 1 for abbreviations.

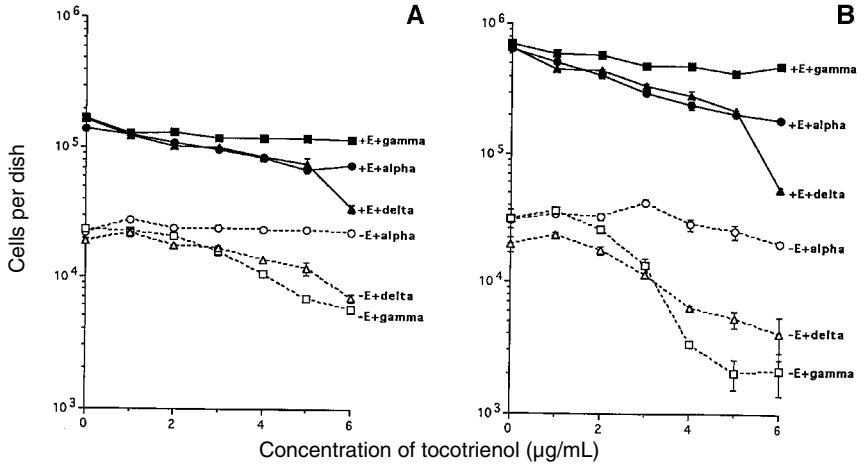

FIG. 3. Effect of individual tocotrienols on regulation of the growth of estrogen-responsive ER+ MCF7McGrath human breast cancer cells in monolayer culture. Cells were grown for (A) 7 or (B) 14 d in 24-well dishes in RPMI1640 medium lacking phenol red but containing 5% DCFCS and increasing concentrations of α-tocotrienol (αT_3) (●,○), γ-tocotrienol (γT_3) (■,□), or δ-tocotrienol (δT_3) (▲,△) in either the absence of estradiol (–E) (open symbols, dotted lines) or the presence of 10^{-8} M estradiol (+E) (closed symbols, solid lines). Cells were plated at a density of $1.06 \pm 0.08 \times 10^4$ cells per dish for the –E + αT_3 experiment, of $1.30 \pm 0.08 \times 10^4$ cells per dish for the –E + γT_3 experiment, of $0.78 \pm 0.05 \times 10^4$ cells per dish for the –E + δT_3 experiment, and of $2.44 \pm 0.21 \times 10^4$ cells per dish for the entire +E experiment with αT_3, γT_3, and δT_3. Error bars represent the standard error of triplicate dishes. Where no bars are seen, the error was too low for visual display.

ues were 1 μg/mL $P = 0.009$; 2 μg/mL to 6 μg/mL $P < 0.001$). At a concentration of 10 μg/mL (data not shown), all three fractions could inhibit cell growth after 7 d (αT_3 by 63%, γT_3 by 32%, δT_3 by >100%) and after 14 d (αT_3 by 61%, γT_3 by 14%; δT_3 by >100%). At 10 μg/mL, δT_3 reduced cell numbers below plating density ($P = 0.008$ after 7 d; $P = 0.001$ after 14 d).

Parallel comparisons using ER– MDA-MB-231 cells showed that cell growth could be inhibited by all three tocotrienol fractions but most markedly by the δT_3 (Fig. 4). However, even at concentrations of 10 μg/mL (data not shown), cell numbers did not fall below plating density.

Cell viability. Where cell numbers in monolayer culture fell below plating density implying cell death, trypan blue vi-

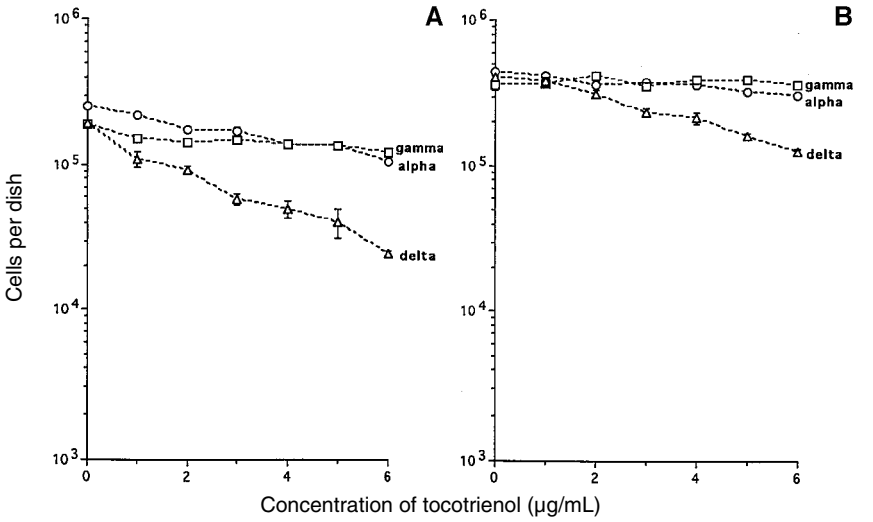

FIG. 4. Effect of individual tocotrienols on regulation of the growth of estrogen-insensitive ER– MDA-MB-231 human breast cancer cells in monolayer culture. Cells were grown for (A) 7 or (B) 14 d in 24-well dishes in RPMI1640 medium lacking phenol red but containing 5% DCFCS and increasing concentrations of αT_3 (●,○), γT_3 (■,□), or δT_3 (▲,△) in the absence of estradiol. Cells were plated together for the entire experiment at a density of $0.99 \pm 0.08 \times 10^4$ cells per dish. Error bars represent the standard error of triplicate dishes. Where no bars are seen, the error was too low for visual display. See Figure 1 for abbreviation.

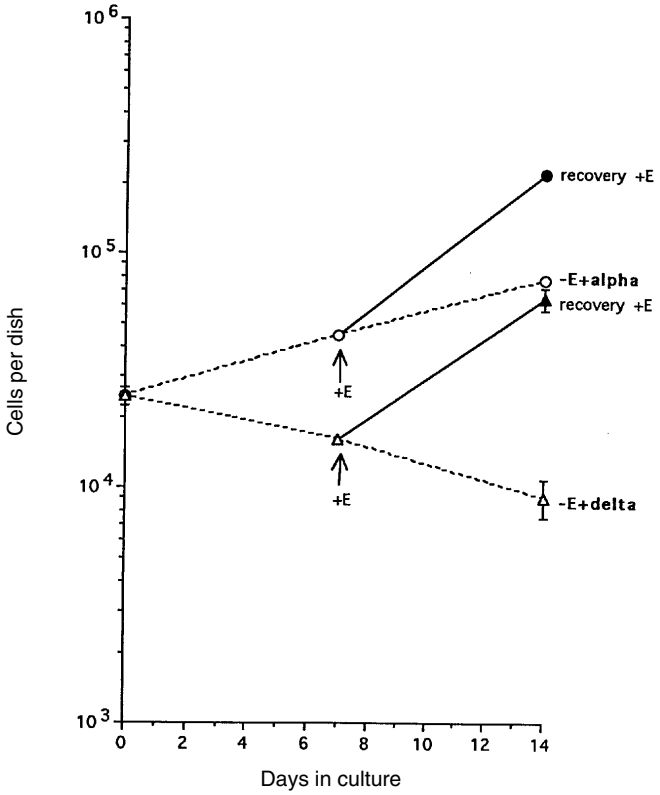

FIG. 5. Recovery of MCF7McGrath cell growth following a 7-d exposure to αT_3 or δT_3. MCF7McGrath human breast cancer cells were grown in monolayer culture for 14 d in 24-well dishes in RPMI1640 medium lacking both phenol red and estradiol but containing 5% DCFCS and either 6 μg/mL αT_3 (–E + alpha) (open circles, dotted lines) or 6 μg/mL δT_3 (–E + delta) (open triangles, dotted lines). Parallel dishes of cells were grown as above for 7 d but then for a further 7 d in RPMI1640 medium with 5% DCFCS and 10^{-8} M estradiol without tocotrienol (solid circle, solid line for 7 d with αT_3, 7 d recovery with estradiol; solid triangle, solid line for 7 d with δT_3, 7 d recovery with estradiol). Error bars represent the standard error of triplicate dishes. Where no bars are seen, the error was too low for visual display. See Figure 1 for abbreviation.

ability counts were carried out in order to ascertain the viability of remaining adherent cells. MCF7McGrath human breast cancer cells grown without estradiol but with 10 μg/mL TRF showed a viability count of 98.8 ± 1.2% for cells remaining attached to the dish after 12 d (cf. Fig. 1A). Growth of MCF7 cells with 6 μg/mL of individual tocotrienol fractions in the absence of estradiol (cf. Fig. 3) gave viability counts after 7 d of 91.9 ± 2.4% for αT_3, 89.1 ± 1.3% for γT_3, 94.3 ± 3.1% for δT_3, and after 14 d of 78.4 ± 4.1% for αT_3, 72.0 ± 2.7% for γT_3, 73.9 ± 3.9% for δT_3. To test further for the viability of remaining adherent cells, a recovery experiment was performed in which cells were grown for 7 d with 6 μg/mL of either αT_3 or δT_3 followed by a further 7-d recovery period with estradiol. The results shown in Figure 5 demonstrate that cells exposed for 7 d to tocotrienol were subsequently still capable of regrowth in monolayer culture when tocotrienol was removed and estradiol added back.

Regulation of pS2 mRNA. In order to investigate any estrogen antagonist properties of TRF, effects of TRF were studied on pS2 mRNA levels. pS2 is an estrogen-regulated gene whose expression can be inhibited at the estrogen receptor level by antiestrogens and estrogen antagonists (29). At the concentrations tested, TRF (8 μg/mL) did not reduce the levels of pS2 mRNA either in the presence or in the absence of estradiol (Fig. 6). 36B4 mRNA is not regulated by estrogen, and levels of this mRNA are given to control for unequal loading of RNA samples. When comparisons were made of relative levels of pS2 mRNA to 36B4 mRNA, TRF was found to have no effect on pS2 mRNA levels either in the presence or in the absence of estradiol.

Regulation of IGFBP. Levels of IGFBP have also been shown to be altered by estrogen in estrogen-responsive human breast cancer cells, and this may have a functional role in growth regulation (24). Results given in Figure 7 show that IGFBP2 (32 kDa) and IGFBP4 (24 kDa) are the two major binding proteins secreted from MCF7McGrath cells, as reported previously (36). Levels of these IGFBP were not increased by γT_3 or δT_3.

DISCUSSION

The ability of the TRF of palm oil to inhibit mammary carcinogenesis in animal studies (5–12) is of potential importance for cancer prevention and treatment, but the mechanism remains unresolved even to the extent of knowing whether the action is directly on the tumor cells or indirectly *via* systemic interactions. The results of this study demonstrate that the TRF of palm oil can inhibit the growth of estrogen-responsive MCF7McGrath as well as estrogen-insensitive MDA-MB-231 human breast cancer cells *in vitro* and furthermore that MCF7 cell growth can be inhibited by TRF irrespective of the presence or absence of estradiol. These data confirm other recent studies using other sublines of ER– (13,37) and ER+ (38–40) breast cancer cells and suggest that the inhibition of tumor growth found *in vivo* could result, at least in part, from direct inhibitory effects on the growth of the cancer cells.

Comparison between growth of MCF7 and MDA cells shows that the inhibitory growth responses to tocotrienols differ in the two cell lines. Growth of MDA-MB-231 cells gave an inhibitory response which was linear with respect to increasing concentrations of tocotrienol whereas the MCF7 cell response was nonlinear. Thus, tocotrienols have greater inhibitory effects at low concentration on the MDA cells but at higher concentrations on the MCF7 cells. The 10-d growth of MDA cells (Fig. 2) could be suppressed by one doubling (3.96×10^5 to 1.98×10^5 cells/dish) by 3 μg/mL TRF, whereas 12-d growth of MCF7 cells (Fig. 1) in the presence of estradiol required 4 μg/mL TRF for suppression by one doubling (6.29×10^5 to 3.15×10^5 cells/dish). However, complete suppression of growth was achieved at lower concentration of TRF for the MCF7 cells. The growth of the MCF7 cells showed 100% growth inhibition with 8 μg/mL of TRF irrespective of the presence of estradiol, whereas the MDA cells

showed only 44% growth inhibition at this concentration, requiring 20 μg/mL TRF for 100% growth inhibition. Separation of the TRF into individual tocotrienols α-, γ- and δ- revealed that the γ- and δ-fractions were the most inhibitory to breast cancer cell growth and again showed the same differences in response in the two cell lines. The 7-d growth of MDA-MB-231 cells (Fig. 4A) could be suppressed by one doubling (1.95×10^5 to 0.98×10^5 cells/dish) by 2 μg/mL δT_3, whereas 7-d growth of MCF7 cells (Fig. 3A) in the presence of estradiol needed 5 μg/mL δT_3 for suppression by one doubling (1.66×10^5 to 0.83×10^5 cells/dish). However, complete suppression of MCF7 cell growth was achieved at concentrations of 6 μg/mL $\gamma T_3/\delta_3$ in the absence of estradiol and at 10 μg/mL δT_3 in the presence of estradiol, whereas for MDA-MB-231 cell growth complete suppression of growth was never achieved even at 10 μg/mL concentrations of the most inhibitory δT_3 component.

It is interesting that TRF (8 μg/mL) and $\gamma T_3/\delta T_3$ (6 μg/mL) could inhibit MCF7McGrath cell growth such that cell numbers were decreased below the plating density since this implies cell death. It would now be interesting therefore to determine whether tocotrienols can induce apoptotic pathways in the ER+ cells, as has already been described in breast cancer cells for hormone ablation (41), antiestrogen treatment (42,43), antagonism of IGF pathways (44), and administration of other cytotoxic agents (45,46).

Although it is often stated that αT is the most active form of vitamin E in inhibiting growth of cells (47), none of the breast cancer cells showed any sensitivity to αT in either these or other (13,39) studies. This emphasizes the importance of tocotrienols to growth inhibition of breast cancer cells. The reasons for the high sensitivity of breast cancer cells to tocotrienols are unknown but could relate either to permeability of the breast epithelial cell membrane to tocotrienols or to metabolism of tocotrienol within the breast cells (13). Alternatively, there may prove to be a pathway important specifically for breast cancer cell proliferation which is highly sensitive to tocotrienols. Inhibition of smooth muscle cell proliferation by vitamin E has been suggested to occur through alteration of protein kinase C activity (47) which could result from the antioxidant properties of vitamin E (48). Tocotrienols have been reported to affect lipid parameters, in particular linoleic acid metabolism (49), and it is known that linoleic acid plays a role in mammary epithelial cell growth and differentiation (50; unpublished personal data). Within estrogen-responsive breast cancer cells, another potential pathway of growth inhibition could be through antagonism of estrogen action, in a mechanism analogous to that characterized for growth inhibition by antiestrogens (25–27). Estrogen is known to act *via* an intracellular receptor protein which functions as a ligand-activated transcription factor (25), and it is now well established that the partial antiestrogen tamoxifen can act by interfering with transcriptional activation by the estrogen receptor and that the pure antiestrogens ICI 164,384 and ICI 182,780 can act by preventing dimerization and DNA binding of estrogen receptors (26,27). The TRF of

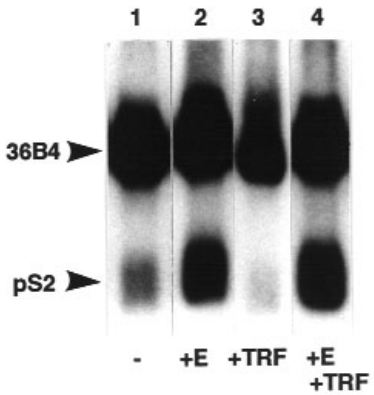

FIG. 6. Effect of the tocotrienol-rich fraction (TRF) of palm oil on expression of pS2 mRNA in MCF7McGrath human breast cancer cells. Northern blot of whole cell RNA from cells grown for 6 d in monolayer culture with 5% DCFCS alone (–) (track 1), with 10^{-8} M estradiol (+E) (track 2), with 8 μg/mL TRF (+TRF) (track 3) or with both 10^{-8} M estradiol and 8 μg/mL TRF (+E + TRF) (track 4). The blot was probed for expression of the estrogen-regulated pS2 mRNA and also a control non-estrogen-regulated 36B4 mRNA to control for any unequal RNA loadings. Positions of the mRNA are indicated by arrows. See Figure 1 for other abbreviation.

palm oil was clearly able, in the present studies, to inhibit growth of the MCF7McGrath cells in the presence of estrogen. In the absence of estrogen, TRF could also have acted to antagonize the action of residual estrogen in the cell or estrogen memory effects (51). However, TRF appeared to be unable to alter expression of the estrogen-regulated pS2 gene in MCF7McGrath cells, which is a well-established marker of estrogen receptor-mediated action (29) (Fig. 6). Furthermore, if TRF were acting on cell growth in the absence of estrogen to inhibit residual estrogen effects, it would be expected that TRF would act in a concentration-dependent manner such that lower levels of TRF would be needed to inhibit growth in the absence than in the presence of estrogen. Clearly this was not the case since inhibition of MCF7McGrath cell growth was found to require similar concentrations of TRF in the absence and in the presence of estrogen. The overall evidence would suggest therefore that tocotrienols do not act by an estrogen receptor-mediated mechanism.

An alternative mechanism for growth inhibition by TRF could relate to IGFBP (Fig. 7). Recent reports have emphasized the importance not only of estrogen but also of the insulin-like growth factors in breast cancer cell growth (20). IGFBP can influence the interaction between IGF and their receptors and so play an important role in mediating IGF regulation of breast cancer cell growth (20). It is thus possible that TRF could inhibit breast cancer cell growth by increasing production of inhibitory IGFBP in an analogous mechanism to that proposed for growth inhibition by retinoic acid in breast cancer cells (52). The growth inhibitory γT3 and δT3, however, did not appear to increase levels of IGFBP in these studies.

Inhibition of the growth of breast cancer cells by tocotrienols could have important clinical implications not only

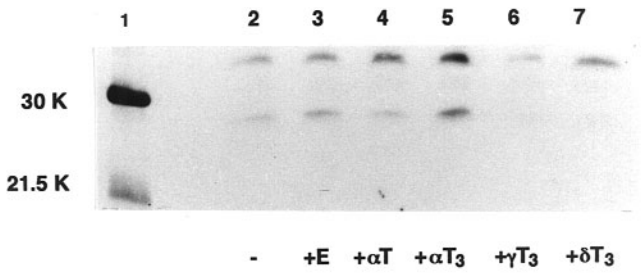

FIG. 7. Effect of individual tocotrienols on the secretion of insulin-like growth factor binding protein (IGFBP) from MCF7McGrath human breast cancer cells. Western ^{125}I-IGFI ligand blot of cells grown for 6 d in monolayer culture in RPMI1640 medium with 5% DCFCS alone (–) (track 2), with 10^{-8} M estradiol (+E) (track 3), with 6 μg/mL +αT (track 4), with 6 μg/mL αT_3 (track 5), with 6 μg/mL γT_3 (track 6), or with 6 μg/mL δT_3 (track 7). Positions of ^{14}C-labeled protein molecular weight markers are given in track 1 and sizes in kDa are indicated on the left-hand side. In tracks 2–7, the upper band corresponds to IGFBP2 (32 KDa) and the lower band to IGFBP4 (24 KDa) as reported previously (36). See Figure 1 for other abbreviation.

because tocotrienols are able to inhibit the growth of both ER+ and ER– phenotypes but also because estrogen-responsive cells could be inhibited in the presence as well as in the absence of estrogen. Unfortunately the molecular mechanism of the growth inhibition remains unknown and will need further work to elucidate. However, from a clinical perspective, it will also be of interest to determine whether breast cancer cells can develop resistance to this pathway of growth inhibition by TRF. A major problem in the therapy of breast cancer results from the ability of the tumor cells to develop resistance (14,15) to growth inhibition by estrogen withdrawal (53), antiestrogen administration (54), and retinoic acid (55). It will be very important to determine whether growth inhibition by TRF is also subject to development of resistance or not. Tocotrienols could offer an alternative clinical approach to growth suppression of breast cancer cells resistant to other regimes of therapy.

ACKNOWLEDGMENTS

This study was supported financially by the Malaysian government (KN). TRF and individual tocotrienols were all kindly supplied by PORIM. We thank Professor Pierre Chambon (Centre National de la Recherche Scientifique, Strasbourg, France) for providing the pS2 and 36B4 cDNAs. We thank Eileen Hales, Rita Gordon, Elizabeth Pontin, and John Taylor for technical assistance and research support services.

ABSTRACT: The influence of dietary supplementation with 20:4n-6 on uptake and turnover of deuterium-labeled linoleic acid (18:2n-6[d_2]) in human plasma lipids and the synthesis of desaturated and elongated n-6 fatty acids from 18:2n-6[d_2] were investigated in six adult male subjects. The subjects were fed either a high-arachidonic acid (HIAA) diet containing 1.7 g/d or a low-AA (LOAA) diet containing 0.21 g/d of AA for 50 d. Each subject was then dosed with about 3.5 g of 18:2n-6[d_2] as the triglyceride (TG) at 8:00 A.M., 12:00, and 5:00 P.M. The total 18:2n-6[d_2] fed to each subject was about 10.4 g and is approximately equal to one-half of the daily intake of 18:2n-6 in a typical U.S. male diet. Nine blood samples were drawn over a 96-h period. Methyl esters of plasma total lipid (TL), TG, phospholipid, and cholesterol ester were analyzed by gas chromatography–mass spectroscopy. Dietary 20:4n-6 supplementation did not affect uptake of 18:2n-6[d_2] in plasma lipid classes over the 4-d study period nor the estimated half-life of 24–36 h for 18:2n-6[d_2]. The percentages of major deuterium-labeled desaturation and elongation products in plasma TL, as a percentage of total deuterated fatty acids, were 1.35 and 1.34% 18:3n-6[d_2]; 0.53 and 0.50% 20:2n-6[d_2]; 1.80 and 0.92% 20:3n-6[d_2] and 3.13 and 1.51% 20:4n-6[d_2] for the LOAA and HIAA diet groups, respectively. Trace amounts (<0.1%) of the 22:4n-6[d_2] and 22:5n-6[d_2] metabolites were present. Plasma TL concentration data for both 20:3n-6[d_2] and 20:4n-6[d_2] were 48% lower ($P < 0.05$) in samples from the HIAA diet group than in samples from the LOAA diet group. For a normal adult male consuming a typical U.S. diet, the estimated accumulation in plasma TL of 20:4n-6 synthesized from 20 g/d (68 mmole) of 18:2n-6 is 677 mg/d (2.13 mmole). Dietary supplementation with 1.5 g/d of 20:4n-6 reduced accumulation of 20:4n-6 synthesized from 20 g/d of 18:2n-6 to about 326 mg/d (1.03 mmole).

Lipids 33, 471–480 (1998).

The effect of dietary arachidonic acid (AA) (20:4n-6) on linoleic acid (18:2n-6) metabolism is of interest because of their precursor–product relationship and the biological importance of these two fatty acids. Eicosanoids produced from 20:4n-6 are involved in the regulation of a variety of important physiological functions (1,2). Constriction of arterial vessels, increased platelet aggregation, and decreased bleeding times are examples of effects associated with 20:4n-6 that may have a negative impact on cardiovascular disease and strokes. There is also some concern that a diet might become prothrombotic if the n-6/n-3 balance is disrupted by a diet rich in 20:4n-6 (1,3). An early study involving humans reported that feeding 6 g/d of 20:4n-6 ethyl esters produced a potentially adverse increase in platelet sensitivity to the aggregation agent ADP (4). A recent study that used diets supplemented with 1.5 g/d of 20:4n-6 for 50 d found no effect on bleeding time or platelet aggregation (5) and a general lack of significant physiological effects due to dietary 20:4n-6 supplementation (5–8). For example, no effect was observed on immune response, apoprotein, serum triglyceride, total cholesterol, or lipoprotein levels (6,7). A large increase in the 20:4n-6 content of plasma, but not platelet, phospholipids (PL) (6) and a large increase in the eicosanoid metabolites of urine samples (8) were observed.

Metabolism of 18:2n-6 and 20:4n-6 has been studied individually in animal models, but studies that have examined the influence of dietary 20:4n-6 on the metabolism of 18:2n-6 are limited to animal and *in vitro* studies. Dietary 20:4n-6 substantially increases the 20:4n-6 content of animal tissue and human plasma PL at the expense of 18:2n-6 (6,9,10). Adding 20:4n-6 to rat liver microsome preparations did not depress desaturation *in vitro* of 18:2n-6 to 18:3n-6 (11). However, addition of 20:4n-6 to kidney cells slightly depressed 6-desaturase activity (12). Addition of 20:4n-6 to cultured cells increased conversion of 18:2n-6 to 20:4n-6 in several, but not all, cell lines (13,14). Stable isotope tracer methods have been used to show that dietary 18:3n-6, 20:3n-6, and 20:4n-6 reduced the synthesis of 20:4n-6 from 18:2n-6 in rats fed low-fat diets (15). Isotope tracer methods have not been used in humans to investigate whether dietary 20:4n-6 inhibits desaturation and elongation of 18:2n-6 or influences the uptake and disappearance of 18:2n-6 into lipid classes. The objective of this study was to investigate if supplementation of a typical U.S. diet with dietary 20:4n-6 has an influence on the synthesis, acyltransferase selectivity, uptake, and turnover of n-6[d_2] fatty acids in adult male subjects fed tracer doses of deuterium-labeled linoleic acid (18:2n-6[d_2]).

EXPERIMENTAL PROCEDURES

Study design. Six Caucasian male subjects between the ages of 20 and 39 yr were housed in a metabolic ward. Medical histories, physical examinations, and clinical blood profile data indicated that the subjects were in good health and had no history of congenital ailments. The subjects' height/weight ratios, blood pressures, fasting serum cholesterol, and triglyceride concentrations were within normal ranges. Body weights, fasting serum total cholesterol, and total lipid (TL) concentrations are summarized in Table 1. Institutional ethical approval was obtained for the study protocol from the Agricultural Research Service's Human Studies Institutional Review Committee and the University of California at Davis, Human Subjects Committee. Informed consent was obtained from each subject before initiation of the study.

The subjects were provided diets that contained 1.7 g/d of 20:4n-6 [high AA (HIAA)] or 0.21 g/d of 20:4n-6 [low AA (LOAA)]. ARASCO oil (3 g/d), provided by Martek Bioscience Corp. (Columbia, MD), was added as the source of 20:4n-6 in the HIAA. An equal amount of high oleic safflower oil (3 g/d) was added to the LOAA. The subjects were fed these diets for 50 d prior to the deuterated 18:2n-6[d_2] isotope experiment. As shown in Table 2, the fatty acid compositions of the diets were similar except for 20:4n-6. The 20:4n-6 content of the total dietary fat was 0.2% (LOAA) and 2.0% (HIAA). The ARASCO oil contained 0.025% tocopherol and 0.025% ascorbyl palmitate as antioxidants. The peroxide value was 0.4 meq/kg. Analysis by gas chromatography (GC), GC–mass spectrometry (MS), and thin-layer chromatography (TLC) detected only traces of oxidation products. The fatty acid composition of the ARASCO oil (wt%) was: 0.5, 14:0; 0.2, 15:0; 11.1, 16:0; 0.5, 17:0; 10.6, 18:0; 8.7, 9*c*-18:1; 0.2, 11*c*-18:1; 6.5, 18:2n-6; 3.8, 18:3n-6; 0.9, 20:0; 0.4, 20:1n-9; 0.6, 20:2n-6; 0.6, 5,11,14-20:3; 2.5, 20:3n-6; 49.7, 20:4n-6; 1.6, 22:0; 1.2, 24:0; and 0.2%, 22:4n-6. Detailed information on the study design and diet compositions has been described previously (16).

All meals were prepared from weighed food portions and their consumption monitored. Duplicate meals were collected and analyzed for fatty acid composition. Values for total fat, protein, and carbohydrate were obtained by analysis of diet composites and were similar to calculated values based on food composition data in U.S. Department of Agriculture Handbook 8 (17). No significant changes in the subjects' weights were observed during the controlled diet period, indicating a stable energy balance.

Preparation of deuterated trilinoleylglycerol. A 100-g triglyceride (TG) sample containing *cis*-9,*cis*-12-octadecadienoic-12,13-d_2 acid (18:2n-6[d_2]) was prepared directly from *Crepis alpina* oil as described previously (18). The *C. alpina* oil contained 76% crepenynic acid, which is an "enyne" 18-carbon fatty acid with a *cis* double bond at the 9 position and a triple bond at the 12 position. The triple bond of crepenynic acid was reduced to a dideuterio-olefinic bond with Lindlar catalysis and deuterium gas. The TG product was purified by silica gel chromatography and contained 86% *cis*-9,*cis*-12-octadecadienoic acid, 3.5% *cis*,*trans*-octadecadienoic acid isomers, 5% oleic acid, 1% stearic acid, 4% palmitic acid, and 0.5% myristic acid. Residual crepenynic acid was not detected by GC or MS methods at a detection limit of 0.005%. The isotopic purity of the 18:2n-6[d_2] was 79% d_2, 4% d_1, 17% d_0.

Stable isotope study. After a 12-h overnight fast, about 5 g of TG containing 3.5 g of 18:2n-6[d_2] was mixed with 100 g of no-fat yogurt and fed to each subject at 8:00 A.M., 12:00, and 5:00 P.M. as part of their meals. The subjects were pro-

TABLE 2
Fatty Acid Composition of Diets

Fatty acid	LOAA (g/d)	HIAA (g/d)	Difference (g/d)

Unknown	1.3	2.0	–0.7
Total weight	84.4	86.2	+1.8

[a]Diets: 2800 total calories; 27.1–27.8 energy percentage (en%) total fat, 15 en% protein, 57 en% carbohydrate. For abbreviations see Table 1.

vided a fat-free snack at 8:00 P.M.. The total weight of deuterated 18:2n-6[d_2] fed to each subject was about 10.4 g and replaced about 10 g of total fat containing 2 g of 18:2n-6 in the diets consumed on the day of the study. The total amount of deuterated 18:2n-6[d_2] fed per kg of body weight is given in Table 1 for each subject. A multiple dose procedure was used to maintain a relatively constant concentration of 18:2n-6[d_2] in plasma lipids over an 8-h time period in order to enhance the amount of n-6 desaturated and elongated fatty acid products synthesized from 18:2n-6[d_2]. Blood samples (*ca.* 14 mL each) were collected by venipuncture at 0, 4, 8, 12, 24, 36, 48, 72, and 96 h.

Analysis of plasma lipid fatty acids. Plasma TL were extracted with 2:1 chloroform/methanol (19). Preparative TLC was used to isolate TG, cholesterol ester (CE), and PL from plasma lipids (20,21). Known weights of triheptadecanoin, cholesteryl heptadecanoate, and diheptadecanyl-*sn*-phosphatidylcholine (Applied Science, State College, PA) were added as internal standards to the TL extract. The 17:0 internal standard data were used to calculate the concentrations (μg/mL) of deuterated and nondeuterated fatty acids in the plasma lipid classes. Methyl esters of the isolated lipid classes were prepared by heating the samples with a 5% HCl-methanol solution (22).

Plasma lipid methyl esters were analyzed by GC–MS methods. The Hewlett-Packard gas chromatograph (model 5890; Palo Alto, CA) was equipped with a Supelcowax 10 fused-silica column (30 m × 0.25 mm; Supelco Inc., Bellefonte, PA) and temperature-programmed from 165 to 265°C at 5°C/min with a 20-min final hold. The mass spectrometer used was a Hewlett-Packard model 5988A quadrupole mass spectrometer system and was operated in a positive chemical ionization mode with isobutane as the ionization reagent. The GC–MS methodology utilized selected ion monitoring of the appropriate ion masses for the fatty acid in each GC peak. The areas for each of the ion masses monitored were obtained by integration of the peaks. The specific operating conditions and computer-assisted storage and processing of the MS data have been described previously (23,24).

Weight data for isotope-labeled and nonlabeled fatty methyl ester derivatives of the plasma lipid samples were calculated from the known weight of 17:0 added as an internal standard prior to conversion of the lipid classes to their methyl esters. Response factors were determined by analysis of standard mixtures containing weighed amounts of pure fatty methyl esters purchased from Nu-Chek-Prep Inc. (Elysian, MN) and Applied Science. The accuracy of the GC–MS data was determined by adding known weights of 18:2n-9[d_2], 20:3n-6[d_2], and 20:4n-6[d_2] to TG, PL, and CE samples isolated from plasma samples drawn from other study subjects who had not been fed 18:2n-6[d_2]. The weight for each of the deuterated fatty esters added was equal to about 0.57% of the total unlabeled fatty acids in the samples. Standard deviations were based on three replicate analyses. The range for the standard deviations for the deuterated fatty acids added to TG, PL, and CE was 0.005 to 0.008%.

Statistical analysis and calculations. Data were analyzed with the SAS-PC statistical software package from Statistical Analysis System Institute, (Cary NC). A two-tailed, unpaired *t*-test was used to test for significant differences between data from subjects fed the LOAA and HIAA diets (25).

The time-course curves, obtained by plotting the deuterated fatty acid data for the nine samples collected between 0 and 96 h, were used to calculate a total area value for the concentrations (μg/mL plasma) of the deuterated fatty acids and their metabolites, as described previously (26,27). The μg/mL total area data were converted to μg/mL/g of 18:2n-6[d_2] fed and corrected for small differences in the amounts of 18:2n-6[d_2] fed to the subjects. The total area values were used to calculate the relative concentrations of 18:2n-6[d_2] and the dideuterated n-6 fatty acid products in plasma lipids. The percentage of 18:2n-6[d_2] converted to 20:4n-6[d_2] was calculated by dividing the μg/mL/g 20:4n-6[d_2] area values by the area values for 18:2n-6[d_2]. Percentage enrichment was calculated by dividing the deuterated fatty acid μg/mL data by the sum of the unlabeled plus deuterated fatty acid g/mL data.

RESULTS

Plasma lipid composition. The fatty acid compositions of plasma lipid classes from the six subjects used in this study are summarized in Table 3. The plasma data for this subset of subjects are similar to the data for the entire study group of 10 subjects (6). Plasma TG samples from the three subjects receiving the AA-supplemented diet, contained 2.1% AA compared to 1.0% AA for the LOAA diet subjects. The possibility of less conversion of 18:2n-6 to 20:4n-6 is suggested by the higher percentage of 18:2n-6 (20.9 vs. 22.5%) in the plasma TG of the HIAA diet group. As expected, the percentage of 20:4n-6 in plasma PL from the HIAA diet group was higher than for the LOAA diet subjects (15.7 vs. 11.6%). The CE fraction for samples from subjects fed the HIAA diet was higher (14.8 vs. 8.0%) in 20:4n-6 and 5.1% lower in 18:2n-6 than for CE from subjects fed the LOAA diet. The increases in 20:4n-6 percentages of PL and CE were compensated for by a decrease in 18:2n-6 and 18:1n-9 percentages.

Uptake and turnover. The percentages of 18:2n-6[d_2] in the total 18:2n-6 of plasma TG, PL, and CE samples collected over 96 h are plotted in Figure 1. The curves represent the average of data from three subjects and are nearly identical. There were no significant differences between the percentage enrichment time-course curves for individual subjects within and across diet groups. The variation for percentage enrichments in the plasma TG 4-, 8-, and 12-h samples for the LOAA and HIAA diet groups is due to the differences in absorption and clearance of chylomicron TG by individual subjects. The differences (see Table 3) between the 18:2n-6 and 20:4n-6 composition of the plasma lipid classes for subjects fed the LOAA and HIAA diets did not affect the 18:2n-6[d_2] percentage enrichment data. These results show that dietary 20:4n-6 supplementation did not influence uptake and turnover of 18:2n-6[d_2] in plasma TL, TG, PL, and CE. Max-

[a]Values as %, mean, n = 3, ± standard deviation. TG, triacylglycerol; PL, phospholipid; CE, cholesterol ester; TL, total lipids. For other abbreviations see Table 1. Boldface type indicates data for fatty acids that were the most influenced by diet.

imum concentrations of 18:2n-6[d_2] occurred 12 h after the first dose and 4 h after the last dose of 18:2n-6[d_2] was fed. The half-life for 18:2n-6[d_2] in TL was between 24 and 36 h.

The average recovery of 18:2n-6[d_2] as a percentage of the total dose fed was 17% (range 10–27%). Percentage recovery was calculated from the sum of the 18:2n-6[d_2] concentrations in the 4- to 12-h plasma TL sample and a total plasma volume equal to 40 mL plasma per kg of body weight. Percentage recovery was directly related to plasma TG concentration. The lower percentage recoveries were observed for subjects with lower TG concentrations, and this relationship is likely related to plasma TG clearance rates. These percentage recovery data are only approximate because the sampling times were not frequent enough to ensure that samples containing the maximal enrichment of 18:2n-6[d_2] were collected. Variation in the percentage recovery data was not related to the 20:4n-6 content of the diet or the concentrations of 18:2n-6[d_2] and n-6[d_2] fatty acid metabolites that accumulated in plasma PL and CE.

The time-course curves shown in Figure 2 provide a comparison of percentage enrichment data and concentration (μg/mL of plasma) data for 20:4n-6[d_2] in plasma TL. The percentage enrichment of 20:4n-6[d_2] in the 36- to 96-h samples from the LOAA diet group were about 85% higher than for the same time samples from the HIAA diet group. Isotopic dilution by endogenous 20:4n-6 is responsible for the difference between the percentage enrichment and μg/mL data. The area concentrations for 20:4n-6[d_2] in total plasma of the

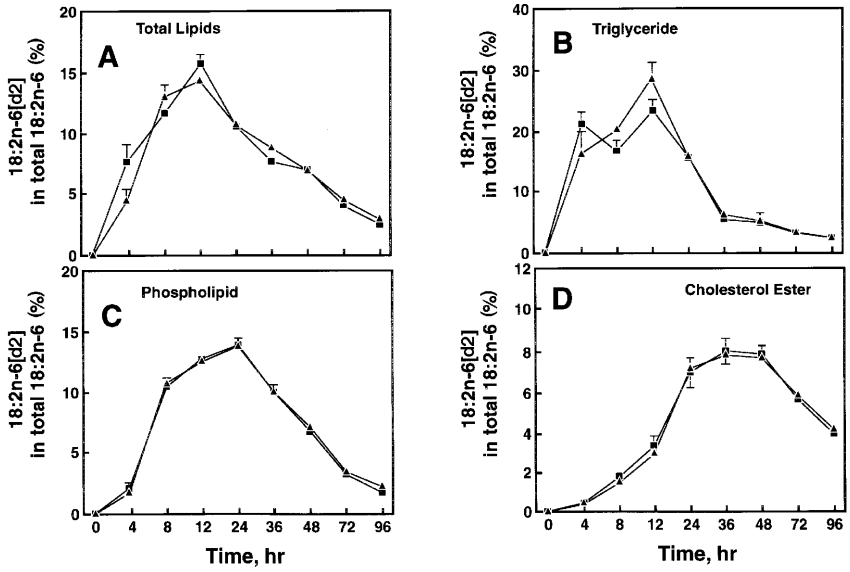

FIG. 1. Time-course curves for percentage enrichment of 18:2n-6[d_2] in plasma lipid classes of subjects from high arachidonic acid (HIAA) and low arachidonic acid (LOAA) diet groups. Each point is the average of data from three subjects. The error bars represent standard errors. Error bars are not shown when less than width of the symbols.

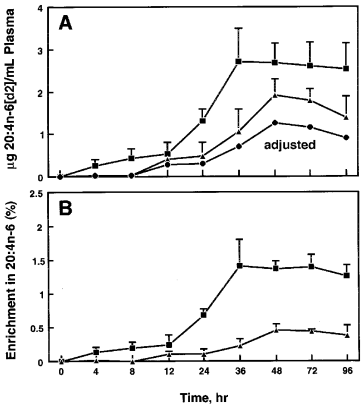

FIG. 2. Time-course curves for percentage enrichment and concentration of 20:4n-6 in plasma total lipid of subjects from LOAA (■) and HIAA (▲) diet groups Each point is the average of data from three subjects. The error bars represent standard errors. The curve labeled "adjusted" (●) represents HIAA diet group data adjusted to compensate for differences in plasma total lipid concentrations for subjects from the two diet groups. See Figure 1 for abbreviations.

LOAA diet group subjects were 35% higher than for subjects in the HIAA diet group. For the HIAA subjects, the μg/mL data underestimate the effect of the dietary 20:4n-6 supplementation on depression of 20:4n-6[d_2] accumulation because TL concentrations for the subjects in the HIAA group averaged 35% higher than for the LOAA diet group. The curve labeled "adjusted" represents the HIAA diet group data that were adjusted to compensate for differences in the plasma TL concentrations for subjects from the two diet groups. The difference in the concentration time-course curves provides a better estimate for the effect of dietary 20:4n-6 on 20:4n-6[d_2] accumulation than percentage enrichment data since the μg/mL data are independent of exogenous 20:4n-6.

The results in Figure 2 show that dietary 20:4n-6 supplementation depressed 20:4n-6[d_2] levels in plasma TL. The curve shapes for the percentage enrichment and the μg/mL plasma lipid curves are similar and show that uptake and turnover of 20:4n-6[d_2] in plasma TL were not significantly affected by dietary 20:4n-6 supplementation. The decrease in 20:4n-6[d_2] concentration between 48 and 96 h was small and indicates that there was conservation of 20:4n-6[d_2]. Maximal concentrations of 20:4n-6[d_2] occurred at 36 to 48 h after the first dose and 28 to 40 h after the last dose of 18:2n-6[d_2] was fed.

Data are summarized in Table 4 for plasma TG, PL, and CE samples that contained the maximal concentrations and maximal percentage enrichments for 18:2n-6[d_2] and its three major fatty acid metabolites. Both the percentage enrichment data in Table 4 for 18:2n-6[d_2] and the time-course data in Figure 1 were similar for subjects within the same diet group and between diet groups. The variability for the maximal concentration (μg/mL) data for all of the deuterium-labeled fatty acids was closely related to the variability in lipid class concentrations of the subjects. Overall, the maximal percentage enrichment for the 18:3n-6[d_2] was the least consistent. The 18:3n-6[d_2] percentage enrichment data for TG samples were

[a]A range for the sample time (h) indicates that maximum concentration of the deuterium-labeled fatty acids occurred at different times.
[b]% = mean % enrichment (n = 3) ± standard deviation.** LOAA vs. HIAA data significantly different at $P < 0.05$; * significant difference at $P < 0.1$.
[c]Concentration data for TL do not equal total for TG, PL, and CE because data are for samples collected at different times. For abbreviations see Tables 1 and 3.

significantly lower (19.8 vs. 29.3%) for the HIAA diet group compared to the LOAA group subjects. Enrichment data for 20:4n-6[d_2] was significantly lower in TL, TG, PL, and CE samples from the HIAA diet group than for the LOAA group.

The major elongation and desaturation products of 18:2n-6[d_2] are 20:2n-6[d_2], 18:3n-6[d_2], 20:3n-6[d_2], and 20:4n-6[d_2]. These labeled fatty acids could be measured with an accuracy of ± 10% or better when they were present at 0.4 μg/mL or higher. The concentrations of 22:4n-6[d_2] and 22:5n-6[d_2] were generally about 10-fold lower (0.04 μg/mL), and the relative analytical error was about ±20%. The amount of 22:3n-6[d_2] in these samples was very small and could only be qualitatively measured. Dideuterated 24-carbon fatty acid products were not detected.

Acyltransferase selectivity. The distribution of n-6[d_2] fatty acid metabolites among the three major plasma lipid classes (TG, PL, and CE) is shown in Figure 3**,** where data are presented as area concentration per gram of 18:2n-6[d_2] fed (μg/mL/g 18:2n-6[d_2] fed). Note that these data do not compensate for differences between plasma lipid concentrations of individual subjects and should not be used to estimate the percentage of n-6[d_2] fatty acids synthesized from 18:2n-6[d_2]. The concentration data shown in Figure 3 are useful for determining the relative differences in the selectivity for incorporation of each n-6[d_2] fatty acid metabolite into individual plasma lipid classes.

The relative distribution patterns for the n-6[d_2] fatty acids in TG, PL, and CE are similar for subjects fed the LOAA and HIAA diets except for 20:4n-6[d_2]. These data in Figure 3 show that 18:3n-6[d_2] was selectively incorporated into TG and almost totally excluded from PL; 20:3n-6[d_2] was selectively incorporated into PL compared with TG and CE; incorporation of 20:4n-6[d_2] into PL and CE was much greater than for TG; and 20:2n-6[d_2] was selectively incorporated into TG and PL relative to CE. Comparison of the LOAA and HIAA 20:4n-6[d_2] data suggests that the lower concentration of 20:4n-6[d_2] in CE for subjects fed the HIAA diet was compensated for by a higher concentration of 20:4n-6[d_2] in TG. The selectivity of PL and CE for 20:3n-6 and 20:4n-6 is similar to the selectivity observed when subjects were fed a pulse dose of 20:3n-6[d_2] (28).

The distribution patterns for n-6[d_2] fatty acids in plasma PL were similar for the LOAA and HIAA diet groups. The CE n-6[d_2] fatty acid data for the two diet groups were also not different. These results show that dietary 20:4n-6 supplementation had little influence on the selectivity of PL and lecithin:cholesterol acyltransferase (LCAT) for these n-6 fatty acids. The patterns for the TG data for subjects from the LOAA and HIAA diet groups suggest that dietary 20:4n-6 may have inhibited incorporation of n-6[d_2] fatty acid metabolites into PL and CE.

Desaturation and elongation. The n-6[d_2] fatty acid products in plasma TL, TG, PL, and CE are plotted in Figure 4 as a percentage of the total deuterated fatty acids. The percentages were calculated from time-course curve μg/mL total area data. The percentage 18:2n-6[d_2] (not shown) was >90% of

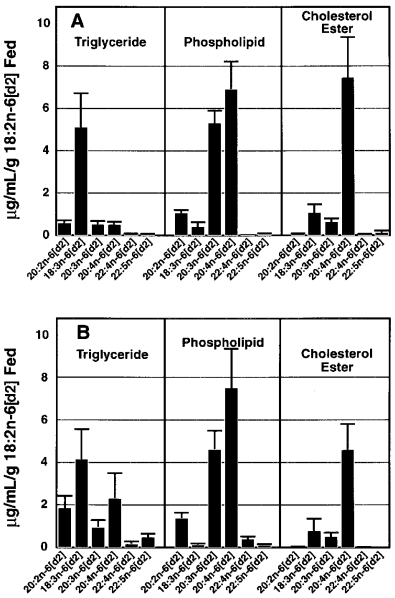

FIG. 3. Area concentrations for deuterated n-6 fatty acid metabolites in plasma triglyceride, phospholipid, and cholesterol ester of subjects fed LOAA (A) and HIAA (B) diets. Each bar is the average of data from three subjects. The error bars represent standard deviations. Data plotted are for the total areas under the time-course curves per mL of plasma per g of 18:2n-6[d_2] fed. For abbreviations see Figure 1.

the total [d_2] fatty acids in all plasma lipid classes. The percentage data in Figure 4 compensate for the differences in plasma lipid concentration between the two groups of subjects, and the metabolite data can be directly compared. Unlike the concentration data in Figure 3, these percentage data cannot be used to compare enzyme selectivity because the percentages are normalized values calculated from the total deuterated fatty acids in a specific lipid class.

The small percentage values for the n-6[d_2] fatty acids present in plasma lipids suggest that the amounts of these fatty acids synthesized over the 4-d study period were small. The sum for all the n-6[d_2] fatty acid percentages was less than 10% of the 10.4 g of 18:2n-6[d_2] fed per subject. These results show dietary 20:4n-6 supplementation depressed the percentage 18:3n-6[d_2] in TG by 65% ($P < 0.07$), 20:3n-6[d_2] in PL by 26% ($P < 0.1$), and 20:4n-6[d_2] in CE by 52% ($P < 0.14$). In plasma TL from subjects fed the HIAA diet, the percentage of 20:3n-6[d_2] was reduced by 48% ($P < 0.005$), and 20:4n-6[d_2]

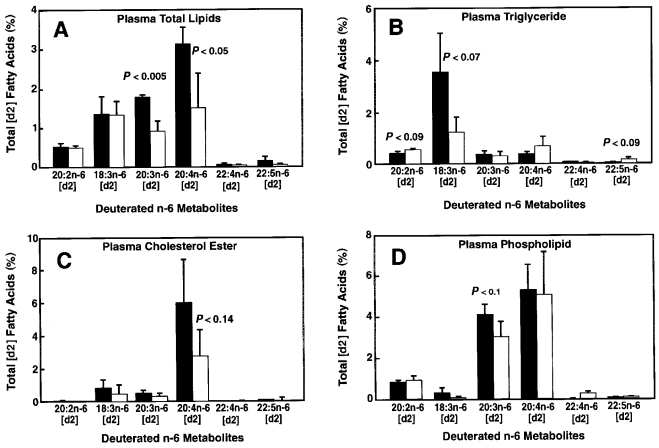

FIG. 4. Percentage of n-6 fatty acid elongation and desaturation products of 18:2n-6[d_2] in plasma lipid classes of subjects from LOAA (■) and HIAA (□) diet groups. Each bar is the average of data from three subjects. The error bars represent standard deviations. Percentage data are calculated from total-area-under-the-time-course curve concentration data. See Figure 1 for abbreviations.

was reduced by 52% ($P < 0.05\%$). The total plasma lipid data show that accumulation of 20:3n-6[d_2] in the LOAA diet group was 0.88% higher than in the HIAA diet group (1.80 vs. 0.92%) over the 4-d study period. Accumulation of 20:4n-6[d_2] was 1.62% higher in the LOAA diet group than in the HIAA group (3.13 vs. 1.51%) and represents a 52% depression of 20:3n-6 and 20:4n-6 accumulation by the 1.5 g/d of 20:4n-6 added to the HIAA diet. Thus the percentage data in Figure 4 show a 52% reduction in 20:4n-6[d_2] accumulation. This result should and does agree well with the 58% reduction in 20:4n-6[d_2] concentration calculated from the μg/mL area data in Figure 2 after adjusting the data for differences in plasma lipid concentrations.

DISCUSSION

Uptake and turnover. The curves for percentage enrichment of 18:2n-6[d_2] in the major lipid classes of plasma (Fig. 1) are evidence that the 7.5-fold (1.5 g/d) higher content of 20:4n-6 in the LOAA and HIAA diets did not measurably affect the mechanisms responsible for uptake and turnover of 18:2n-6. The curve shapes in Figure 2 for percentage enrichment and concentration of 20:4n-6[d_2] in plasma TL were similar and indicate that supplementation with 20:4n-6 may have slightly increased 20:4n-6[d_2] turnover rates. Maximal incorporation of 20:4n-6[d_2] occurred 36–48 h after the first dose of 18:2n-6[d_2] (also see Table 4). Subtraction of the 4 h required for absorption indicates that 32 to 44 h is the approximate time required for maximal accumulation of the 20:4n-6[d_2] synthesized from 18:2n-6[d_2]. The concentrations of 20:4n-6[d_2] in the 48-, 72-, and 96-h samples were not greatly different, suggesting turnover of 20:4n-6[d_2] was slow. These results from human subjects suggest that 20:4n-6 is conserved by recycling and are consistent with the results from rats fed 18:2n-6[d_2] (29).

However, when 20:4n-6[d_2] was fed to other subjects in these same diet groups, the estimated half-life for 20:4n-6[d_2] in plasma TL and PL was 36 to 44 h compared to 24–36 h for 18:2n-6[d_2] (30). Also, in the 20:4n-6[d_2] study, the percentage enrichment time-course curves for the total lipid and PL declined from a maximum at 8 and 12 h respectively, and dietary 20:4n-6 supplementation had no significant effect on turnover. The results from the 20:4n-6[d_2] study suggest that 20:4n-6 is not conserved more strongly than 18:2n-6 and that turnover of 20:4n-6 is not significantly slower than for 18:2n-6. The implication is that in the 18:2n-6[d_2] study, the synthesis of 20:4n-6[d_2] from 18:2n-6[d_2] rather than incorporation is largely responsible for the plateau in 20:4n-6[d_2] that occurred between 36 and 96 h. In effect, accumulation of 20:4n-6[d_2] was approximately equal to disappearance of 20:4n-6[d_2]. These results suggest that 20:4n-6[d_2] synthesis was regulated to replace loss of 20:4n-6[d_2].

The approximately threefold lower 20:4n-6[d_2] percentage enrichment in plasma TL from the HIAA diet group subjects was less than expected based on the ratio of 20:4n-6 in the diets. The predicted difference for percentage enrichment is about 17-fold for the following reasons. Isotopic dilution from exogenous 20:4n-6 should have reduced the percentage enrichment of 20:4n-6[d_2] for the HIAA diet group by 8.5-fold (0.21 vs. 1.7 g/d), and the concentration of 20:4n-6[d_2]

in plasma TL was about 50% lower. The lower-than-predicted difference in the percentage enrichment data suggests that accumulation of exogenous 20:4n-6 was restricted compared with accumulation of 20:4n-6[d_2] synthesized from 18:2n-6[d_2]. The threefold difference between the 20:4n-6[d_2] percentage enrichment data correlated well with the threefold difference for percentage 20:4n-6 in plasma total lipid composition data (Table 3). This correlation also suggests that accumulation of dietary 20:4n-6 was restricted in subjects from the HIAA diet group.

Acyltransferase selectivity. The n-6[d_2] fatty acid metabolite data in Figure 3 show a large difference between the concentrations of the various n-6[d_2] fatty acid metabolites incorporated into the three major plasma lipid classes. These differences are related to fatty acid chain length, number of double bonds, and double bond position. Since both 18:3n-6 and 20:3n-6 have three double bonds located at the same position relative to the terminal methyl group, chain length is the structural difference responsible for the preferential incorporation of 18:3n-6[d_2] into TG and the preferential incorporation of 20:3n-6[d_2] into PL. The concentrations of 20:3n-6[d_2] and 20:4n-6[d_2] in PL were similar. These results suggest that the additional double bond at the 5-carbon position in 20:4n-6 has little effect on PL acyltransferase selectivity. The 5-*cis* double bond is the only difference between the structure of these two fatty acids, and it is likely responsible for the preferential incorporation of 20:4n-6[d_2] into CE relative to 20:3n-6[d_2]. Exclusion of 20:2n-6[d_2] from CE is of interest because LCAT is highly selective for 18:2n-6[d_2], and the only structure difference between these two fatty acids is chain length. Comparison of the distribution pattern for 20:4n-6[d_2] in plasma TG, PL, and CE from subjects fed the LOAA and HIAA diets suggests that the transfer of 20:4n-6[d_2] to CE from PL by LCAT was partially diverted into TG.

Desaturation and elongation. The n-6[d_2] fatty acid (Table 4) precursors of 20:4n-6[d_2] are synthesized from 18:2n-6[d_2] by the following sequence: 6-desaturation → chain elongation → 5-desaturation. The maximal concentration for deuterated 18:3n-6 and 20:3n-6 in plasma lipid classes was low, which is consistent with 6-desaturase as the rate-limiting step. Qualitatively, these results with male subjects indicate that accumulation of 20:4n-6 synthesized from 18:2n-6 in humans is much lower than in rats and mice. The times for maximal incorporation (Table 4) show distinct differences for the times required to accumulate the various labeled fatty acid metabolites in TG, PL, and CE. The time required for synthesis and incorporation of 20:3n-6[d_2] and 20:4n-6[d_2] into PL and CE is approximately 36 h since maximal incorporation of 18:2n-6[d_2] occurred at 12 h and maximal incorporation of 20:n-4 occurred at 48 h.

The HIAA diet group percentage enrichment data for several n-6[d_2] fatty acid metabolites are significantly lower than data for the LOAA group. However, much of the difference is due to the greater isotopic dilution by the higher percentage of unlabeled 20:4n-6 (Table 3) in plasma lipids from the HIAA subjects rather than from reduced conversion of 18:2n-6[d_2] to n-6[d_2] metabolites. These results illustrate that percentage enrichment data must be interpreted cautiously. These single-point data do not provide a valid quantitative estimate of the amount of 18:2n-6[d_2] converted to these intermediates because the times for maximal incorporation of the individual fatty acids are different and subject-dependent. Also note that the data in Table 4 for total plasma lipid should not be compared with the sums for the individual lipid class data because the time of maximal incorporation for the various metabolites occurs at different times.

In contrast to the percentage enrichment data in Table 4 for single time-point samples, the percentage data in Figure 4 represent a weighted contribution of all samples collected over the 4-d study period. The influences of differences between plasma lipid class concentration (see Table 3) and the unlabeled fatty acid contents of the lipid classes are removed by normalizing the total deuterated fatty acid μg/mL data to a 100% basis. However, differences between percentage values still represent differences in the concentrations. Thus, conversion of the μg/mL deuterated fatty acid data to relative percentage provides a useful approach to estimate the percentage of 18:2n-6[d_2] fed that was converted to 20:4n-6[d_2] and incorporated into plasma lipids. The percentage data for 18:3n-6[d_2] and 20:2n-6[d_2] in plasma total lipids show that total accumulation of these fatty acids was nearly identical and indicate that δ-6 desaturation and elongation were not influenced by dietary 20:4n-6. These results are consistent with rat liver microsome *in vitro* results that showed exogenous 20:4n-6 and 20:5n-3 did not depress desaturation of 18:2n-6 to 18:3n-6 (11). The percentage data for PL, CE, and TL are consistent with the conclusion that the HIAA diet significantly depressed accumulation of 20:3n-6[d_2] and 20:4n-6[d_2] synthesized from 18:2n-6[d_2].

Estimate of 20:4n-6 synthesis. The following calculations assume that the 20:4n-6[d_2] incorporated into plasma TL reflects 20:4n-6[d_2] synthesis and that turnover rates for 18:2n-6 and 20:4n-6 are similar. This last assumption is supported by results from other subjects in these same diet groups that were fed 20:4n-6[d_2] (30). For the purpose of this estimate, the first step is to use the percentage of 18:2n-6[d_2] converted to 20:4n-6[d_2] over the 4-d study period to calculate the mg/d of 20:4n-6 synthesized per g of 18:2n-6. For subjects fed the LOAA diet, the percentage conversion of 18:2n-6[d_2] to 20:4n-6[d_2] was 3.13 ± 0.44% (Fig. 4) of the 18:2n-6[d_2] in total plasma lipid. A conversion of 3.13% indicates 325 mg of 20:4n-6[d_2] was synthesized from the 10.4 g of 18:2n-6[d_2] fed over the 4-d study period, or 31.3 mg of 20:4n-6[d_2] per g of 18:2n-6[d_2] fed. By extrapolation, the accumulation of 20:4n-6 synthesized from the 20 g/d of 18:2n-6 in the LOAA diet is equal to 626 mg/d. Similar calculations based on 1.51 ± 0.89% conversion of 18:2n-6[d_2] for the subjects fed the HIAA diet indicate accumulation of 302 mg/d of 20:4n-6 synthesized from 18:2n-6.

Results for subjects fed the LOAA diet suggest that accumulation of 20:4n-6 synthesized from 18:2n-6 is 2–3 times higher than the 20:4n-6 content of typical U.S. diets and that

relatively little dietary 20:4n-6 is necessary to meet requirements. These estimates based on the accumulation of 20:4n-6 synthesized from 18:2n-6 are consistent with estimates based on studies of vegetarians and the postulate that the requirement for 20:4n-6 is approximately 500 mg/d (31). The 324 mg/d difference for the amount of 20:4n-6 synthesized from 20 g/d of 18:2n-6 represents a 52% reduction in total 20:4n-6 accumulation by subjects fed the HIAA diet. This 52% reduction is similar to the 58% depression based on the 20:4n-6[d_2] area concentration data shown in Figure 2**.** These estimates for 20:4n-6 synthesis compare well with an estimate of 440 mg/d based on data from an earlier 2-d study using a single dose of deuterated 18:2n-6 (27).

Results presented here for the metabolism part of this AA study show that a relatively large increase in dietary 20:4n-6 intake had little effect on uptake and turnover, acyltransferase selectivity, and the accumulation of 18:3n-6[d_2] and 20:2n-6[d_2] synthesized from 18:2n-6[d_2]. These metabolic results are consistent with the lack of significant effects from the clinical part of this study (5–7) and with the lack of toxicity effects in rats fed about 1.2 g of 20:4n-6/d/kg body weight for 90 d (32). The only significant physiological effect observed was an increase in the urinary metabolites of thromboxane and prostaglandin I_2 when diets were supplemented with 20:4n-6 (8). The only significant metabolic effect of 20:4n-6 supplementation was the depression (about 50%) in plasma TL of the deuterated 20:3n-6 and 20:4n-6 synthesized from 18:2n-6[d_2]. This depression was less than expected based on the 8.5-fold difference in the 20:4n-6 ratio in the diets and was inversely related to the approximately twofold increase in the 20:4n-6 content of plasma PL. The inhibition of 20:4n-6 accumulation was in marked contrast with the sevenfold stimulation of 20:4n-6[d_2] synthesis from 20:3n-6[d_2] (28). Overall, these results show that moderate fluctuation in dietary 20:4n-6 intake would not be expected to have a major effect on n-6 fatty acid metabolism.

Effects of the Ratio of Polyunsaturated and Monounsaturated Fatty Acid to Saturated Fatty Acid on Rat Plasma and Liver Lipid Concentrations

Nai Wen Chang[a,*] and Po Chao Huang[b]

Departments of Biochemistry, [a]China Medical College, Taichung, Taiwan, Republic of China, and [b]College of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

ABSTRACT: The effects of dietary monounsaturated fatty acid (MUFA) and polyunsaturated fatty acid + MUFA/saturated fatty acid (PUFA + MUFA/SFA) ratio on plasma and liver lipid concentrations were studied. In experiment I, when rats were fed with 40% fat (energy%, PUFA/SFA ratio 1.0) and 1% (w/w) cholesterol (C) diets for 21 d, a large amount of MUFA (28.1 energy%, PUFA + MUFA/SFA = 5.7) in the diet was found to increase the plasma total C, triacylglycerol (TAG), and phospholipid (PL) as compared with the low-MUFA diet (7.0 energy%, PUFA + MUFA/SFA = 1.4). The plasma very low density lipoprotein (VLDL)-C, VLDL-TAG, VLDL-PL, and low density lipoprotein (LDL)-C increased significantly in the high-MUFA diet group, but high density lipoprotein (HDL)-C did not change significantly. The high-MUFA diet resulted in greater accumulation of liver C but lesser accumulation of TAG. In experiment II, when dietary SFA was fixed at a certain level (13.2 energy%; PUFA + MUFA/SFA = 2.0), rats given a larger amount of MUFA (23.1 energy%; PUFA/MUFA = 0.2; MUFA/SFA = 1.8) showed higher plasma and liver C levels than did the low-MUFA diet (7.7 energy%; PUFA/MUFA = 2.5; MUFA/SFA = 0.6). When PUFA was fixed at a certain level (24.4 energy%), there was not a significant difference in the plasma C level between the high- and low-MUFA dietary groups (PUFA + MUFA/SFA = 4.8 and 8.4), but the higher PUFA + MUFA/SFA diet, which was high in MUFA/SFA ratio, significantly decreased the plasma HDL-C and TAG levels. However, when MUFA content was fixed at a certain level (16.4 energy%), no significant difference was observed between the two groups with different PUFA/SFA ratios of 0.2 and 4.1, but liver C level was raised in the higher PUFA/SFA diet. It appears that the PUFA/SFA ratio alone is unsuitable to predict the change of plasma C level, because a large amount of dietary MUFA may lead to an increase of plasma and liver lipids in rats. It seems that the prerequisites for keeping low plasma and liver C are (i) low MUFA/SFA ratio, (ii) high PUFA/MUFA ratio, and (iii) PUFA + MUFA/SFA ratio not to exceed 2.

Lipids 33, 481–487 (1998).

Among the dietary factors which can affect the plasma cholesterol (C) level, the amount of dietary C and the amount and the degree of saturation of fatty acids are perhaps more important than the others (1,2). A significant relationship between dietary fat, plasma lipid levels, and coronary heart disease is reported by many epidemiologists worldwide (3–7). During the last three decades many investigators have reported that polyunsaturated fatty acids (PUFA) decrease and saturated fatty acids (SFA) increase the plasma total C and low density lipoprotein (LDL)-C levels in humans (8–11) as well as in animals (12–16). However, monounsaturated fatty acids (MUFA), such as oleic acid, were once considered to have no effect on plasma C levels (17). Hence, the PUFA/SFA ratio has frequently been used in predicting the cholesterolemic effect of dietary fat. Diets with higher PUFA/SFA ratios were found to have stronger hypocholesterolemic effect than those with lower PUFA/SFA ratios (8–18).

However, since 1985, studies by Mattson and Grundy (19) and Grundy (20) and some other investigators (21–23) have reported that when MUFA-rich safflower oil or olive oil is supplemented to the diet or replaced by SFA, serum C and LDL-C levels decrease but high density lipoprotein (HDL)-C level does not show any decrease in human subjects. Therefore, it seems that MUFA may be better than PUFA in preventing or treating atherosclerosis (19–23). Sirtori *et al*. (24) reported that olive oil diet does not appear to reduce the plasma total C level in the same way as corn oil diet in high-risk patients. Becker *et al.* (25) also found that a MUFA-rich diet does not affect the plasma total C, triacylglycerol (TAG), LDL-C, and HDL-C levels when compared with an SFA-rich diet in normolipidemic men. Ginsburg *et al*. (26) concluded that a decrease in the plasma total C level in human subjects during consumption of the MUFA diet occurs in response to the removal of SFA from the diet. A meta-analysis of 27 trial studies, carried out by Mensink and Katan (27), showed that the replacement of carbohydrates by MUFA results in a negative but nonsignificant coefficient on the plasma total C and LDL-C concentrations. Perez-Jimenez *et al*. (28) studied lipoprotein concentrations in normolipidemic males consuming two high-fat diets, similar in their fatty acid composition but prepared using two different plant oils: virgin olive oil

and refined high-MUFA sunflower oil. When the two MUFA diets were compared, significantly higher concentrations of total C and LDL-C were noted with the consumption of the olive oil-rich diet.

In the present study, we emphasized the effect of the PUFA + MUFA/SFA ratio of the dietary fat, as well as the PUFA/SFA ratio, on plasma and liver lipid levels in rats. In experiment I, two oil mixtures of different fatty acid saturation, with the same PUFA/SFA ratio of 1.0 but a different PUFA + MUFA/SFA ratio of 1.4 or 5.7, were given to separate groups of rats. In experiment II, PUFA, MUFA, or SFA of the dietary fat was fixed at a certain level for each of three pairs of rat groups, respectively, and then the PUFA + MUFA/SFA ratio was changed as described in the Materials and Methods section for the three pairs of rat groups. The effects of these test diets on the plasma and liver lipid concentrations were studied.

MATERIALS AND METHODS

Animals. In experiment I, 30 male Wistar rats (Laboratory Animal Center, College of Medicine, National Taiwan University, Taipei, Taiwan), each weighing about 200 g, were used for the study. The rats were divided into two groups of 12 rats in each on the basis of their weight. On day 7, 14, and 21, four rats in each group were sacrificed. The remaining six rats were used as a control group (day 0); they were fed with commercially available rat chow (Rodent laboratory chow 5001; Purina Co., St. Louis, MO) and were sacrificed before the experiment. Rats were housed individually in stainless steel, wire-bottomed cages and were given a diet and water *ad libitum* during the different dietary periods. The food consumption per group and the individual body weights were measured every 2 d.

In experiment II, 36 male Wistar rats, each weighing about 160 g, were divided into six groups of six rats each. The test diets in this study were fed to the rats for a period of 21 d.

Diet and feeding protocol. Each group was fed the same basic, semisynthetic powdered diet which differed only in its fatty acid content. The experimental diet contained (w/w): 1% C, 4% salt mixture (AIN-76, ICN Biomedicals Inc., Costa Mesa, CA), 1% vitamin mixture (AIN76, ICN), 3% methyl cellulose, 20% casein, 51% cornstarch, and 20% fat. The different fat mixtures were prepared with various ratios of soybean oil, coconut oil, palm oil, sunflower oil, and olive oil as shown in Tables 1 and 2. Each diet supplied 15% of total energy as protein, 45% as carbohydrate, and 40% as fat. In experiment I, both diet 1 and diet 2 had PUFA/SFA ratios of 1.0, but diet 1 had a PUFA + MUFA/SFA ratio of 1.4 and diet 2 had a PUFA + MUFA/SFA ratio of 5.7 (Table 1). In experiment II, the first two diets (diet 1 and diet 2) had approximately the same amount of PUFA, but diet 1 had a PUFA + MUFA/SFA ratio of 4.8 and diet 2 had a PUFA + MUFA/SFA ratio of 8.4. The next two diets (diet 3 and diet 4) had the same MUFA level, but the PUFA + MUFA/SFA ratios were 1.0 and 7.6, respectively. The last two diets (diet 5 and diet 6) had the same SFA level, therefore, the same PUFA + MUFA/SFA ratio (2.0), but the MUFA/SFA ratios were 1.8 and 0.6, respectively (Table 2).

TABLE 1
Fatty Acid Composition of Oil Used in Test Diets in Experiment I

Fatty acids	Diet 1[a] (%)	Diet 2[b] (%)
6:0	0.1	—[c]
8:0	2.0	—
10:0	2.0	—
12:0	15.6	—
14:0	7.1	0.2
16:0	10.8	11.2
18:0	3.6	3.5
Subtotal[d]	41.2 (16.5)	14.9 (6.0)
16:1	0.1	0.6
18:1	17.3	69.7
Subtotal[d]	17.4 (7.0)	70.3 (28.1)
18:2	36.5	13.4
18:3	4.9	1.4
Subtotal[d]	41.4 (16.6)	14.8 (6.0)
PUFA/SFA ratio	1.0	1.0
MUFA/SFA ratio	0.4	4.7
PUFA/MUFA ratio	2.4	0.2
PUFA + MUFA/SFA ratio	1.4	5.7

[a]Diet 1 (low MUFA diet): 68.5% soybean oil + 31.5% coconut oil.
[b]Diet 2 (high MUFA diet): 12.3% soybean oil + 87.7% olive oil.
[c]—, not detectable.
[d]Each value in the parentheses is the energy%. PUFA, polyunsaturated fatty acids; MUFA, monounsaturated fatty acids; SFA, saturated fatty acids.

The pattern of fatty acids of these mixed oils (soybean oil, coconut oil, palm oil, sunflower oil, and olive oil) was analyzed by high-performance liquid chromatography (29) for verification of correct PUFA/SFA and PUFA + MUFA/SFA ratios.

Sample collection and analysis. Fasting blood samples were taken by decapitating rats on days 0, 7, 14, and 21 in experiment I or on day 21 in experiment II. The plasma (1 mg EDTA/mL) was stored at 4°C before analysis. Liver was excised, weighed, and frozen until analysis. Feces were pooled from a group during the last 3 d of the experimental period and then dried at 75°C to a constant weight, ground into a fine powder, and stored in a vacuum desiccator.

In experiment I, plasma very low density lipoprotein (VLDL), LDL, and HDL were obtained with ultracentrifugation at density 1.006, 1.063, and 1.21 g/mL, respectively. In experiment II, plasma HDL-C level was determined by a commercial kit that uses a precipitation-enzymatic method (Boehringer Mannheim Co., Meylan, France). Total plasma and liver lipids were determined by the method of sulfophospho-vanillin reaction (30). Plasma and lipoprotein C and TAG were determined by a commercial kit enzymatic method (Boehringer Mannheim Co.). Plasma and lipoprotein phospholipid (PL) were determined by using bioMérieux (Marcy-l'Etoile, France) enzyme kit.

Liver TAG was determined by the method of Soloni (31).

[a]Diet 1: 100% soybean oil; Diet 2: 100% sunflower oil; Diet 3: 100% palm oil; Diet 4: 26% olive oil + 74% sunflower oil; Diet 5: 53% palm oil + 47% olive oil; Diet 6: 21% coconut oil + 79% soybean oil.
b—, not detectable.
[c]Each value in the parentheses is the energy%. For abbreviations see Table 1.

Liver PL was analyzed by the method of Stewart (32). Liver C was determined by the method of Abell *et al.* (33).

Feces were extracted with petroleum ether (1:10, wt/vol) and filtered. The neutral steroid content of the filtrate was determined by the method of Abell *et al.* (33). Another portion of feces was extracted with alcohol (1:5, wt/vol), and then alcohol was evaporated. The residue was suspended in petroleum ether (1:2.5, wt/vol), shaken, centrifuged, and the liquid phase was discarded. The remaining precipitate was analyzed for the acid steroid content by the method of Weber (34).

Statistical analysis. The data between two groups were compared by analysis of variance (ANOVA). Student's *t*-test was used whenever a statistically significant difference between the two groups was shown by ANOVA. All data are presented in tables and figures as mean ±SD.

RESULTS

In experiment I, the growth of rats in both groups was not different in each of the experimental periods. Figure 1 shows the plasma total C, TAG, and PL contents at the end of the feeding period. It is clear that when the PUFA/SFA ratio was fixed at 1.0, with 1% C supplement, the high PUFA + MUFA/SFA ratio (5.7, diet 2) showed significantly higher plasma total C,

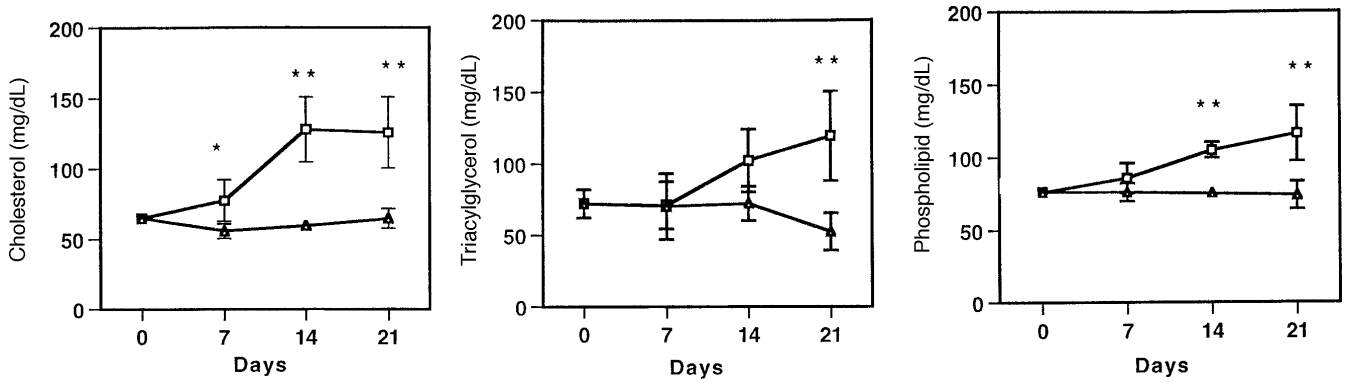

FIG. 1. Changes in the concentrations of plasma lipids during the different feeding periods in experiment I. Diet 1 (△): PUFA + MUFA/SFA = 1.4; Diet 2 (□): PUFA + MUFA/SFA = 5.7. Asterisks indicate significant difference from diet 1 period by the Student's *t*-test (*$P < 0.05$; **$P < 0.01$). Results are shown as mean ± SD ($n = 4$). PUFA, polyunsaturated fatty acids; MUFA, monounsaturated fatty acids; SFA, saturated fatty acids.

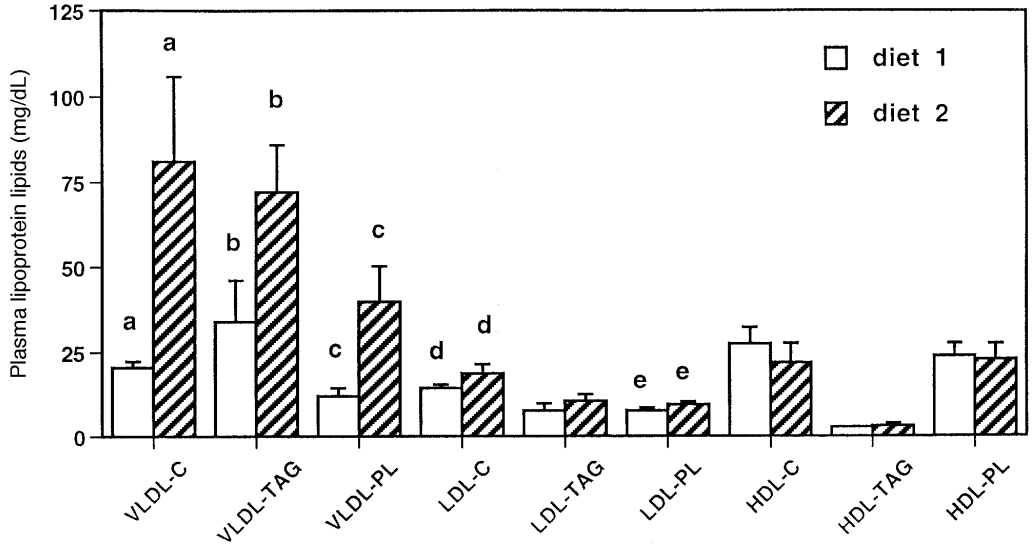

FIG. 2. Changes in the concentrations of plasma lipoprotein lipids after the 21-d feeding periods in experiment I. Diet 1: PUFA + MUFA/SFA = 1.4; Diet 2: PUFA + MUFA/SFA = 5.7. Matching letters (a–e) indicate a significant difference between mean values by Student's *t*-test (a–c, $P < 0.01$; d,e, $P < 0.05$). Each bar represents the mean ± SD ($n = 6$). Abbreviations: C, cholesterol; TAG, triacylglycerol; PL, phospholipid; VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein. For other abbreviations see Figure 1.

TAG, and PL than the lower PUFA + MUFA/SFA ratio (1.4, diet 1) during the last period of the experiment ($P < 0.01$). Figure 2 shows that plasma VLDL lipids were significantly higher in the high-MUFA group (diet 2) ($P < 0.01$), whereas the effect was less in HDL lipids. At the same time, high MUFA (diet 2) significantly increased the LDL-C and LDL-PL contents after the 21-d feeding periods ($P < 0.05$). In addition, as shown in Figure 3, liver C, TAG, and PL contents increased in both low- and high-MUFA diets. The high-MUFA diet resulted in greater accumulation of liver C but lesser accumulation of TAG.

In experiment II, the effects of different PUFA + MUFA/SFA, MUFA/SFA, or PUFA/MUFA ratios on the plasma lipid contents are shown in Table 3. When PUFA was fixed at a certain level, the difference in plasma total C and PL levels between the two dietary groups (PUFA + MUFA/SFA = 4.8 and 8.4) was not significant, but the higher PUFA + MUFA/SFA diet, which was high in MUFA/SFA ratio, showed a significant decrease in the plasma HDL-C and TAG. When SFA was fixed at a certain level, a high-MUFA diet (diet 5, PUFA/MUFA = 0.2) showed a significant increase in plasma total C, TAG, PL, and total lipid ($P < 0.01$) as compared with the low-MUFA diet (diet 6, PUFA/MUFA = 2.5). But when MUFA was fixed at a certain level, no significant difference was observed between the two groups with different PUFA/SFA ratios of 0.2 and 4.1 ($P > 0.05$). As shown in Table 4, when either MUFA or SFA was fixed at a certain level, rats given higher ratios of MUFA/SFA (diet 4

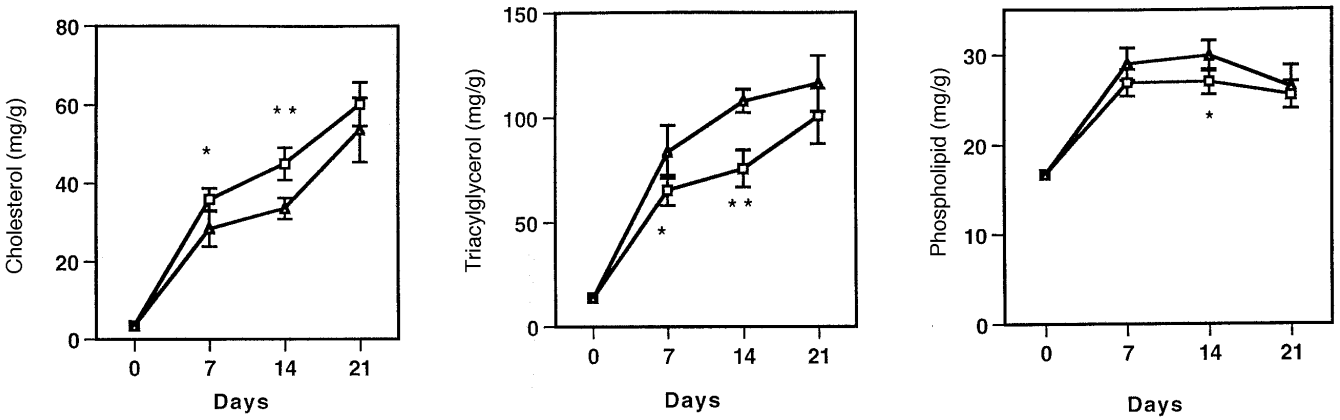

FIG. 3. Changes in concentrations of liver lipids during the different feeding periods in experiment I. Diet 1 (△): PUFA + MUFA/SFA = 1.4; Diet 2 (□): PUFA + MUFA/SFA = 5.7. Asterisks indicate significant difference from diet 1 period by the Student's *t*-test (*$P < 0.05$; **$P < 0.01$). Results are shown as mean ± SD ($n = 4$). For abbreviations see Figure 1.

PUFA/MUFA ratio	2.7	2.2	0.3	1.2	0.2	2.5
PUFA + MUFA/SFA ratio	4.8	8.4	1.0	7.6	2.0	2.0

[a]Diets are described in Table 2. HDL, high density lipoprotein. For other abbreviations see Table 1. Matched superscripts (a–f) indicate a significant difference between mean values (a, $P < 0.05$; b–f, $P < 0.01$) by Student's *t*-test. Results are shown as mean ± SD ($n = 6$ in all groups).

and diet 5) showed significantly higher liver C levels ($P < 0.05$). However, when PUFA was fixed at a certain level, liver lipids were not found to differ significantly in both groups which had different PUFA + MUFA/SFA ratios (4.8 and 8.4). The liver TAG level was not found to differ significantly among each dietary group in experiment II.

Fecal neutral and acidic steroids of the rats in experiment II are shown in Table 5. The results showed that when MUFA was fixed at a certain level, the high SFA group (diet 3, 19.6 energy%) excreted more neutral and acidic steroids, whereas, when PUFA or SFA was fixed at a certain level, a high-MUFA diet showed higher fecal neutral and acidic steroids.

DISCUSSION

By keeping the PUFA/SFA ratio of dietary fat at 1.0, we observed that higher dietary MUFA increased plasma total C, TAG, and PL levels (Fig. 1), as well as liver total C content (Fig. 3) in rats. The hypocholesterolemic effect of MUFA was not observed. The plasma lipids of the VLDL fraction were also increased in high-MUFA diet (Fig. 2). Even when PUFA or SFA was fixed at a certain level, rats given higher ratios of MUFA/SFA showed higher C levels (Table 3). It seems that the PUFA/SFA ratio alone is unsuitable to predict the change of plasma C level, because the MUFA tends to increase plasma C level under our experimental conditions.

In this study, we did not observe the hypocholesterolemic effect of a high-MUFA diet in rats as reported by Grundy and his associate (19,20). When PUFA/SFA was fixed at 1.0, we found that the high-MUFA diet (PUFA, 6; MUFA, 28; SFA, 6 energy%; PUFA + MUFA/SFA = 5.7) increased both plasma and liver C contents in rats as compared with the low-MUFA diet (PUFA, 17; MUFA, 7; SFA, 17 energy%; PUFA + MUFA/SFA = 1.4) in experiment I. Grundy (20) suggested that a liquid diet rich in MUFA (PUFA, 8; MUFA, 28; SFA, 4 energy%; PUFA/SFA = 2.0; PUFA + MUFA/SFA = 9.0) appeared to be at least as effective in lowering plasma C in humans as compared with the high-SFA diet (PUFA, 7; MUFA, 8; SFA, 25 energy%; PUFA/SFA = 0.28; PUFA + MUFA/SFA = 0.6). In another study, Mattson and Grundy (19) reported that, as compared with the high-SFA diet (PUFA, 4; MUFA, 16; SFA, 20 energy%; PUFA/SFA = 0.2; PUFA + MUFA/SFA = 1), the high-MUFA diet (PUFA, 7; MUFA, 29; SFA, 3 energy%; PUFA/SFA = 2.3; PUFA + MUFA/SFA = 12) lowered plasma LDL-C in normotriglyceridemic patients, but did not lower the plasma total C level in hypertriglyceridemic pa-

TABLE 5
Fecal Neutral and Acidic Steroids of Rats in Experiment II

Groups	Sample number	Feces dry weight (g/d/rat)	Neutral steroids (mg/d/rat)	Acidic steroids (mg/d/rat)
PUFA fixed[a]				
Diet 1	6	1.40	46.90	2.86
Diet 2	6	1.34	53.87	5.44
MUFA fixed[a]				
Diet 3	6	1.76	57.23	7.32
Diet 4	6	1.48	38.86	2.69
SFA fixed[a]				
Diet 5	6	1.50	57.75	3.81
Diet 6	6	1.39	52.04	2.99

[a]Diet 1: PUFA + MUFA/SFA = 4.8, PUFA/MUFA = 2.7; Diet 2: PUFA + MUFA/SFA = 8.4, PUFA/MUFA = 2.2; Diet 3: PUFA + MUFA/SFA = 1.0, PUFA/MUFA = 0.3; Diet 4: PUFA + MUFA/SFA = 7.6, PUFA/MUFA = 1.2; Diet 5: MUFA/SFA = 1.8, PUFA/MUFA = 0.2; Diet 6: MUFA/SFA = 0.6, PUFA/MUFA = 2.5. For abbreviations see Table 1.

tients. It might be the effect of a low SFA content rather than the high MUFA content of the safflower oil diet (high-MUFA diet), when compared to the high-SFA diet (coconut oil or palm oil) which induced higher plasma C levels. In addition, the high-MUFA diet used by Mattson and Grundy (19) had a very high PUFA + MUFA/SFA ratio of 9 or 12, but our diets of high PUFA + MUFA/SFA ratio (5.7, 7.6, or 8.4) did not lower plasma and liver C in experiments I and II. To exclude the effect of changing the amount of PUFA, MUFA, and SFA at the same time, we fixed the amount of PUFA, MUFA, or SFA when comparing a set of two test diets (experiment II) and found that plasma and liver C levels were raised in higher MUFA/SFA diets (Tables 3 and 4). With human subjects, we reported previously that when the dietary PUFA/SFA ratio was fixed at 1.0, those subjects given a diet with a PUFA + MUFA/SFA ratio of 4.5 showed significantly higher plasma TAG, VLDL-TAG, LDL-TAG, and LDL-C levels than those subjects given a diet with a PUFA + MUFA/SFA ratio of 1.5 (35).

We have observed repeatedly in rat experiments that when the PUFA/SFA ratio was fixed at 1.0, diets rich in MUFA resulted in greater accumulation of liver C (Fig. 3). Similar results were also obtained by Peifer *et al*. (36), Beynen (37), Bulur *et al*. (38), and Spady and Dietschy (39). It is worthwhile to notice that when the amount of SFA was fixed at a certain level, the higher ratio of PUFA/MUFA (diet 6, PUFA/MUFA = 2.5, MUFA/SFA = 0.6) lowered plasma total C, TAG, and PL and liver C (Tables 3 and 4), and when the amount of MUFA was fixed at a certain level (16.4 energy%), the high-PUFA diet (diet 4, PUFA + MUFA/SFA = 7.6, PUFA/MUFA = 1.2, MUFA/SFA = 3.5) resulted in the same plasma C level but higher liver C level than did the high-SFA diet (diet 3, PUFA + MUFA/SFA = 1.0, PUFA/MUFA = 0.3, MUFA/SFA = 0.8) (this experiment was repeated twice). The reason that diet 4, which is high in PUFA, resulted in increased liver C may be its high MUFA/SFA ratio, unlike diet 6 or diet 3. It seems that the prerequisites for keeping low plasma and liver C are (i) low MUFA/SFA ratio, (ii) high PUFA/MUFA ratio, and (iii) PUFA + MUFA/SFA ratio not to exceed 2.

When the amount of PUFA was fixed at a higher level (24.4 energy%, diet 1 and diet 2), the plasma and liver lipids were less affected by changing the amounts of SFA and MUFA.

The present study indicated that a large amount of dietary MUFA supplemented with 1% C may raise plasma and liver C levels in rats, and the PUFA + MUFA/SFA ratio, if not to exceed 2, may be more suitable to predict the change of plasma lipids than the PUFA/SFA ratio.

Lipid-Lowering Effects of WAY-121,898, an Inhibitor of Pancreatic Cholesteryl Ester Hydrolase

Brian R. Krause[a,*], Drago R. Sliskovic[b], Maureen Anderson[a], and Reynold Homan[a]

[a]Department of Vascular & Cardiac Diseases and [b]Medicinal Chemistry, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, Michigan 48105

ABSTRACT: WAY-121,898 is an inhibitor of pancreatic cholesteryl ester hydrolase (pCEH). After confirming its *in vitro* potency and relative lack of a major effect on acyl-CoA:cholesterol acyltransferase (ACAT), it was found that this compound lowers plasma cholesterol in cholesterol-fed, but not chow-fed, rats. Measures of liver cholesteryl ester content and the direct determination of cholesterol absorption (lymph–fistula model) show that inhibition of cholesterol absorption is at least one mechanism for the observed cholesterol lowering. However, WAY-121,898 was also active when administered parenterally to cholesterol-fed rats, and in cholesterol-fed hamsters cholesterol-lowering occurred with oral dosing despite no change in cholesterol absorption, suggesting other modes of action possibly relating to inhibition of liver CEH. Combination treatment in cholesterol-fed rats with the ACAT inhibitor CI-976 resulted in a greater-than-additive reduction in plasma cholesterol, implying that both pCEH and ACAT may play a role in cholesterol absorption in this species. In rabbits, WAY-121,898 prevented the rise in plasma cholesterol due to the feeding of cholesteryl ester but not in rabbits fed (free) cholesterol. In guinea pigs, the compound induced an increase in adrenal cholesteryl ester mass. Taken together, the overall profile in these animal models suggests that WAY-121,898 inhibits more than just the intestinal (lumenal) pCEH, and that the role of this enzyme in cholesterol metabolism may be different within and across species, the former depending upon the dietary cholesterol load. *Lipids 33,* 489–498 (1998).

Pancreatic, bile acid-dependent cholesteryl ester hydrolase (pCEH, E.C. 3.1.1.13) is secreted into the small intestine where it catalyzes the hydrolysis of dietary cholesteryl esters and other acylated lipids. However, several observations suggest that the role of pCEH extends beyond that of simply hydrolyzing dietary lipids. Immunolocalization of pCEH within intestinal cells has been demonstrated (1), and cultured CaCo-2 cells bind and internalize pCEH (2,3), suggesting an extralumenal site of action for the enzyme. Cholesterol absorption and/or cholesterol esterifying activity in the intestine are decreased in pancreatic fistula rats (4,5), pancreatectomized rats, (6), and in rats perfused with pancreatic fluid previously treated with antibody to pCEH (7). In addition, isolated enterocytes from common bile duct-cannulated rats exhibit a marked decrease in the ability to esterify cholesterol, which can be restored by the addition of pCEH (8). It has been proposed based on these and other experiments that pCEH, in addition to its role in lipid hydrolysis, may catalyze cholesteryl ester formation after uptake of the enzyme into the mucosal cells (1,8–11). Data support a role for pCEH in the uptake of both unesterified cholesterol (3,11) and cholesteryl ester into intestinal cells, the latter independent of ester hydrolysis (12). Thus, pCEH may be involved at several steps or sites during cholesterol absorption (i.e., cholesteryl ester hydrolysis, cholesteryl ester synthesis, uptake of unesterified and esterified cholesterol).

If the above putative functions of pCEH are correct, it suggests that pharmacologic inhibition of this enzyme might lead to inhibition of cholesterol absorption and thereby a reduction in plasma cholesterol concentration. Indeed, preliminary evidence suggests that WAY-121,898, a novel carbamate, potently and selectively inhibits pCEH *in vitro* and inhibits cholesterol absorption *in vivo* in rats, dogs, and quail (13–16). The purpose of the present study was to confirm the preliminary observations in rats (i.e., efficacy and mechanism of action), and to extend these findings by determining the activity of WAY-121,898 in other possibly more relevant animal models in which more plasma cholesterol is transported in low density lipoprotein (LDL). In addition, since rat liver can also synthesize and possibly secrete a bile salt-dependent CEH (17,18), it was of interest to compare oral and parenteral routes of administration of WAY-121,898. Finally, we determined whether co-administration with CI-976, an inhibitor of acyl-CoA:cholesterol acyltransferase (ACAT) (19,20), would result in additive effects with regard to plasma cholesterol reduction. Intestinal ACAT has also been strongly implicated in the esterification of dietary cholesterol (21,22). Overall, the results suggest fundamental species differences in the response to WAY-121,898 and the possible existence of extra-intestinal sites of action. Moreover, it seems likely that both pCEH and ACAT may play a role in cholesterol absorption in rats.

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; IC_{50}, concentration required to inhibit enzyme activity 50%; LDL-C, low density lipoprotein-cholesterol; MES, 2-[*N*-morpholino] ethanesulfonic acid; pCEH, pancreatic cholesteryl ester hydrolase; SC, subcutaneous.

MATERIALS AND METHODS

Both compounds (WAY-121,898 and CI-976) were synthesized in the Department of Chemistry, Parke-Davis Pharmaceutical Division. The spectral data for WAY-121,898 (i.e., nuclear magnetic resonance, mass spectrum, CHN analysis) were consistent with the proposed structure (13). The *in vitro* inhibitory effects of WAY-121,898 on pCEH activity were assessed by using the porcine enzyme (0.0025 U/mL final concentration; Calbiochem, La Jolla, CA). The substrate was a micellized lipid suspension composed of [^{3}H]cholesteryl oleate (2 μCi/mL), 1 mM lysophosphatidylcholine, 40 mM cholate, and 0.01 mM cholesteryl oleate dispersed in a buffer of 150 mM NaCl, 1 mM EDTA and 20 mM 2-(*N*-morpholino) ethanesulfonic acid, pH 6.0. The substrate was prepared by combining aliquots of 100 mM sodium cholate in chloroform/methanol (2:1, vol/vol), 100 mM lysophosphatidylcholine in chloroform/methanol (2:1, vol/vol), 1 mM cholesteryl oleate (in chloroform), and a volume of [^{3}H]cholesteryl oleate. Solvents were removed by evaporation under a stream of N_2. The dried lipids were resuspended in the appropriate volume of buffer to yield the desired final concentrations of lipids. The pCEH (32.7 IU/mg) was dissolved at a concentration of 0.1 mg/mL in the same buffer as that used for substrate. A more dilute lipase solution (0.15 μg/mL) was used for the assay. The assay was performed at room temperature. Five microliters of the test compound, dissolved in ethanol at a concentration 40-fold greater than the final desired test concentration, was added to individual wells of a 96-well plate. The assay wells without test compound received the same volume of ethanol alone. One hundred microliters of carboxyester lipase (0.15 μg/mL) was added to each well. The assay reaction was begun by the addition of 100 μL of substrate and stopped 10 min later by the addition of 20 μL of 1 N HCl. For quantitation of the substrate and lipolytic products, the contents of each well were transferred to glass high-performance liquid chromatography autosampler vials (12 × 32 mm) and combined with 0.6 mL of ethyl acetate/acetone (2:1, vol/vol). The vials were capped, vortexed twice, and lightly centrifuged for 5 min. The organic phase was transferred to clean autosampler vials and dried under a stream of nitrogen followed by vacuum dessication for at least 1 h. The dried extracts were dissolved in 50 μL of dioxane and then further diluted with 150 μL of isooctane. The [^{3}H]-labeled lipids were then quantitated by high-performance liquid chromatography as previously described (23). The possible effect of WAY-121,898 on microsomal ACAT activity was also determined by using the assay of Field and Salome (24) with livers from cholesterol-fed rats, as described previously (20). In these assays dimethylsulfoxide was used as the drug vehicle, and the concentration required to inhibit enzyme activity 50% (IC_{50}) was calculated (Dose-Effect Analysis with Microcomputers, Chou and Chou, BIOSOFT Software, Cambridge, United Kingdom).

Male, Sprague-Dawley rats (200–225 g, Charles River, Portage, MI) were fed either normal chow or chow supplemented with 0.5% cholic acid, 5.5% peanut oil, and varying amounts of cholesterol (0 to 1.5%). Golden Syrian hamsters (males, 90–110 g) were fed normal chow or chow containing cholesterol (0.06%) and hydrogenated coconut oil (10%) (25). Hartley guinea pigs (males, 450–500 g) were fed normal chow, and New Zealand white rabbits (males, 1.6–1.8 kg) were fed chow supplemented with 5% corn oil and either 0.5% cholesterol or 0.87% cholesteryl oleate (both containing 0.5% sterol). In all experiments, the drugs (WAY-121,898 or CI-976) were mixed into the diet to provide the indicated doses, unless otherwise stated. In one experiment a comparison was made between oral (gavage and diet-admix) and parenteral (subcutaneous, SC) drug administration. The vehicle for oral gavage was carboxymethylcellulose (CMC, 1.5%) and Tween 20 (0.2%) in water. SC dosing utilized an ethanol/PEG-200 (10:90, vol/vol) vehicle. Drugs and diets were initiated at the same time and continued for 1 wk (cholesterol-fed rats), 2 wk (chow-fed animals, cholesterol-fed hamsters), or 5 wk (cholesterol-fed rabbits). Plasma lipids and liver cholesteryl esters were measured by standard methods described previously (20).

Although liver cholesteryl ester content correlates well with measures of cholesterol absorption (26), cholesterol absorption was measured directly in rats by determining the rate of appearance of cholesterol and cholesteryl esters into mesenteric lymph after a single bolus of drug into a duodenal cannula (20). A lipid emulsion was then infused, which was prepared by dissolving 200 mg of cholesterol and 250 mg of egg phosphatidylcholine in chloroform. After removal of the chloroform by evaporation under N_2 and vacuum, 5 g safflower oil, 100 mg sodium taurocholate, and 100 mL of saline were added and the entire mixture was emulsified by sonication. The rate of infusion into the duodenum was 2.5 mL/h. In hamsters the dual-isotope method of Turley *et al.* (26) was used to measure cholesterol absorption, with the following modifications. Telezol (tiletamine/zolazepam, 40 mg/kg) was used as anesthetic instead of ether, and intravenous injections were into the jugular vein instead of the femoral. In this experiment the hamsters were fed a chow diet supplemented with 0.2% cholesterol and 10% hydrogenated coconut oil. Intralipid (Kabi Pharmacia Inc., Clayton, NC) was used as the intravenous (IV) vehicle for injection of the [^{3}H] cholesterol, and medium-chain triglyceride oil (Mead Johnson Nutritionals, Evansville, IN) was used as a vehicle to orally dose the [^{14}C] cholesterol, as described (26). Percentage cholesterol absorption was calculated from the percentages of the oral [^{14}C] and intravenous [^{3}H] doses remaining in plasma 72 h after isotope administration.

RESULTS

WAY-121,898 inhibited rat liver ACAT and porcine pCEH with IC_{50} values of 47 μM and 650 nM, respectively (Fig. 1). Thus, this compound was at least 70-fold more potent against pCEH compared to ACAT based upon these assays. With regard to the ACAT inhibitor used in this study, CI-976, we have shown that the IC_{50} for ACAT inhibition using rat liver

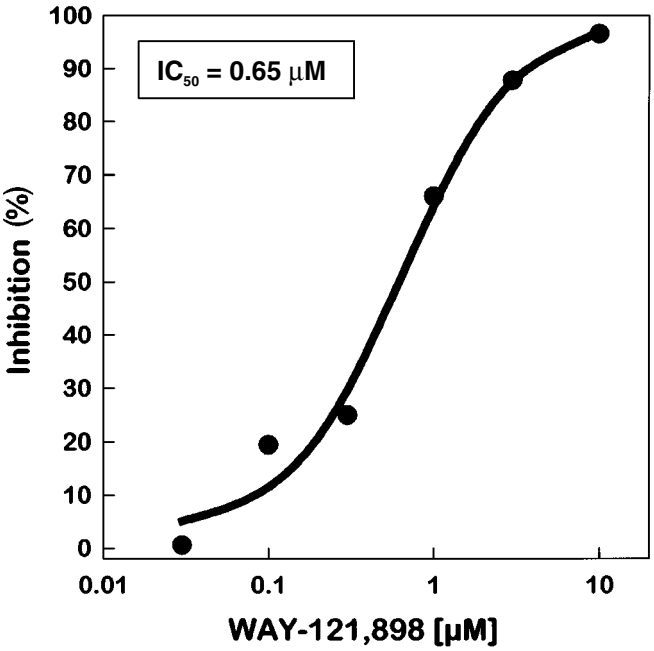

FIG. 1. Inhibition curve for WAY-121,898 against porcine pancreatic cholesteryl ester hydrolase (pCEH). Each point represents the mean of triplicate determinations. The concentration required to inhibit enyzme activity 50% (IC_{50}) is indicated.

microsomes is 180 nM, and this compound has no effect on pCEH up to 100 μM (20). CI-976 also inhibits the rabbit (20) and hamster (25,26) ACAT enzyme. Clark *et al.* (27) have also reported that WAY-121,898 not only lacks significant inhibitory activity against ACAT but also does not inhibit other serine hydrolases, including pancreatic triglyceride lipase.

In our laboratory WAY-121,898 was first evaluated in normal, chow-fed animals using diet-admix drug administration. Plasma total cholesterol concentrations were unchanged in rats at doses of 50, 100, and 200 mg/kg, but plasma triglycerides were significantly decreased (at 50 and 100 mg/kg). Liver cholesteryl esters decreased at the highest dose (Table 1). In a separate experiment (data not shown), we used oral gavage and an olive oil vehicle rather than diet-admix. Again, plasma cholesterol was unchanged, and plasma triglycerides were reduced 27, 49, and 55% at doses of 25, 50, and 100 mg/kg, respectively. Thus, in chow-fed rats, efficacy with respect to triglyceride-lowering was improved with the oil vehicle, but cholesterol-lowering was still not observed. In chow-fed hamsters, in contrast to rats, WAY-121,898 lowered plasma cholesterol by 20 and 31% at 10 and 30 mg/kg (diet-admix). Plasma triglycerides remained unchanged while liver cholesteryl esters tended to decrease in all dose groups, with significance reached at the intermediate dose of 30 mg/kg. Other modes of drug administration (gavage using different vehicles) were not evaluated in chow-fed hamsters.

Since both ACAT and pCEH have been implicated as playing a role in the absorption of exogenous (dietary) cholesterol, it was of interest to determine whether inhibitors of these enzymes would prevent diet-induced hypercholesterolemia, and furthermore, at what level of dietary cholesterol optimal efficacy would be observed. To this end, groups of rats were fed varying amounts of cholesterol and dosed orally with the drugs for 2 wk (50 mg/kg). Plasma cholesterol in controls increased steadily from about 50 mg/dL (chow alone) to almost 300 mg/dL in both experiments (from 1 to 1.5% dietary cholesterol, Table 2). Both drugs failed again to alter plasma cholesterol in the absence of added cholesterol, but they blunted the rise in plasma cholesterol with increases in dietary cholesterol load. However, with WAY-121,898, efficacy (percentage changes compared to controls) plateaued at 0.4% dietary cholesterol (about a 50% reduction), whereas with CI-976 efficacy continually increased with increasing dietary (and plasma) cholesterol up to about 70%.

Based upon the foregoing results in cholesterol-fed rats, further experiments were conducted with WAY-121,898 using 0.4% cholesterol to examine changes in the mode of drug administration and in the drug route. By using this amount of dietary cholesterol, gavage administration with an aqueous suspension vehicle was less effective than diet-admix for lowering plasma cholesterol (Fig. 2). Plasma triglyceride levels were unchanged, and gavage with an oil vehicle did not improve efficacy (data not shown). In the same experiment, plasma cholesterol was also reduced when WAY-121,898 was administered subcutaneously. In fact, at 50 mg/kg, cholesterol-lowering using the SC route (–39%) exceeded that for the oral route (–19%, –11%).

Since both CI-976 and WAY-121,898 appeared to affect diet-induced hypercholesterolemia, combination treatment using both drugs in the same animals was attempted using 0.4% dietary cholesterol. At a dose of approximately 25 mg/kg, CI-976 and WAY-121,898 reduced plasma cholesterol by 27 and 10%, respectively, but the combination resulted in a 46% reduction (Fig. 3).

In order to study the mechanism of action of WAY-121,898, rats were fitted with duodenal and mesenteric lymph cannulas to measure lymphatic cholesteryl ester output during active lipid absorption. After a single oral dose of WAY-121,898 (30 mg/kg), the rise in cholesteryl ester output was blunted significantly, whereas the output of triglycerides was unaffected (Fig. 4). Lymphatic unesterified cholesterol, which was a small percentage of the total, was unaffected by drug treatment (data not shown).

It was next determined whether WAY-121,898, like CI-976 (26), is efficacious in hamsters, an animal species with more LDL-cholesterol (LDL-C) compared to the rat. After chronic drug treatment (10 d) with WAY-121,898, the animals were injected IV with [^{3}H] cholesterol and then orally gavaged with [^{14}C]cholesterol. Percentage cholesterol absorption was 45% in controls, and unaffected by WAY-121,898 at doses of 30 and 100 mg/kg (Table 3). In a second experiment, even a dose of 200 mg/kg failed to affect cholesterol absorption (data not shown). Despite this apparent lack of effect on cholesterol absorption, however, plasma cholesterol and liver cholesteryl ester concentrations were reduced in cholesterol-fed hamsters. Plasma triglycerides were unchanged.

Previously it was reported that cholesterol derived from cholesteryl ester is preferentially absorbed over free cholesterol in rabbits, and that an inhibitor of pCEH (cellulose sulfate) can inhibit cholesterol absorption in rabbits (28). To confirm these data, WAY-121,898 was dosed orally (gavage, CMC suspension) to rabbits fed chow supplemented with corn oil and either cholesterol or cholesteryl oleate for 5 wk. Plasma cholesterol increased 17-fold upon feeding cholesterol, and 15-fold with cholesteryl oleate (Fig. 5). WAY-121,898 had no effect on plasma cholesterol in cholesterol-fed rabbits, but significantly decreased plasma cholesterol by 42% in rabbits fed the cholesteryl oleate. There were no drug-

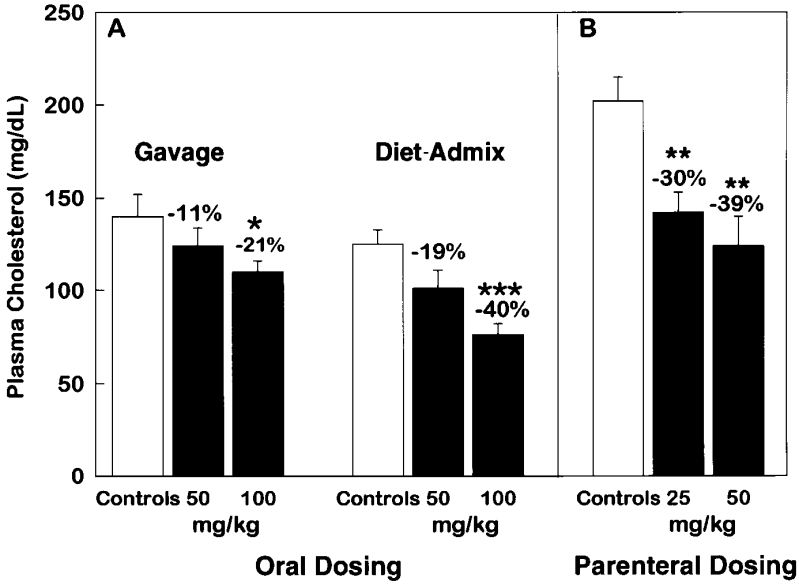

FIG. 2. Reductions in plasma cholesterol by WAY-121,898 in cholesterol-fed rats. The drug was administered either orally (A, gavage and diet-admix) or by daily subcutaneous injection (B, parenteral dosing) in rats fed chow supplemented with peanut oil, cholic acid, and cholesterol (0.4%) for 1 wk. Numbers above the drug-treated groups (closed bars) are percentage changes from control (open bars). *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$.

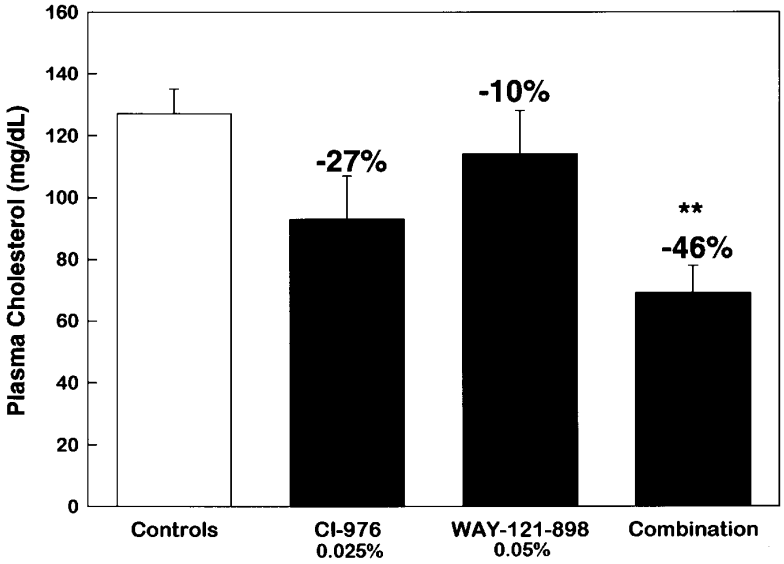

FIG. 3. Effect of CI-976 (acyl-CoA: cholesterol acyltransferase inhibitor) and WAY-121,898 (pancreatic cholesteryl ester hydrolase inhibitor) singly and in combination on plasma cholesterol in cholesterol-fed rats. The compounds were administered by diet-admix (0.025%) to rats receiving 0.04% dietary cholesterol for 1 wk. Numbers above the drug-treated groups (closed bars) are the percentage changes from control (open bars). $^{**}P < 0.01$.

induced changes in liver total, free or cholesteryl ester concentrations in any group (data not shown).

To address the specificity of WAY-121,898 and its possible extraintestinal sites of action, we evaluated the compound in guinea pigs for changes in adrenal cholesteryl ester mass. The adrenal gland contains a well-described microsomal CEH (29), and the guinea pig has been used in many studies evaluating the potential adrenal toxicity of xenobiotics (30–32). Although WAY-121,898 reduced plasma cholesterol by 16% under these conditions, it produced a significant increase in adrenal cholesteryl ester mass (Fig. 6).

DISCUSSION

The present study represents an attempt to use an *in vivo* pharmacologic approach toward understanding the possible role(s) of pCEH in cholesterol absorption. This was made possible by the disclosure of a potent and relatively selective inhibitor of pCEH, WAY-121,898 (13). In our routine screens (porcine pCEH and rat liver ACAT), this compound was approximately 70-fold more potent against pCEH compared to ACAT. We did not examine activities against pCEH from other species in the present study. Our IC_{50} value for WAY-121,898 against porcine pCEH (650 nM) is somewhat higher than that reported by the group at Wyeth-Ayerst for the bovine enzyme (200 nM) (13), yet lower than the value found by Gallo *et al.* (33) for rat pCEH (2 μM, or 24-fold higher than rat ACAT IC_{50}). *In vitro* data are lacking for inhibition of pCEH from hamster or rabbit pancreas (i.e., other species used for *in vivo* efficacy). This should be considered when interpreting the *in vivo* data. However, it has been established that there is a high degree of homology at the primary sequence level for pCEH across species (34). Moreover, WAY-121,898 clearly inhibited the absorption of cholesteryl esters in rabbits, and unlike CI-976 (25), it lowered plasma cholesterol in cholesterol-fed hamsters. These *in vivo* data suggest that the compound inhibits rabbit and hamster pCEH. Lastly, it should be noted that we did not determine the activity of WAY-121,898 against ACAT from species other than rat. It seems unlikely that WAY-121,898 would lack significant inhibitory activity against rat ACAT (27) yet be a potent inhibitor of hamster and rabbit ACAT since it did not lower plasma cholesterol in cholesterol-fed rabbits as would be expected of an ACAT inhibitor. Nonetheless, direct proof that WAY-121,898 lacks activity against rabbit or hamster ACAT would require further *in vitro* evaluation.

Besides taking advantage of the discovery of WAY-121,898, we also utilized a potent and specific ACAT inhibitor, CI-976 (19), for comparative purposes in our study. CI-976 inhibits ACAT (or ACAT "subtypes") in both endocrine and lipoprotein-producing tissues, although it is somewhat more potent in the latter (20,35). It has been shown to inhibit cholesterol absorption in cholesterol-fed rats (20) and hamsters (25,26). Based upon our observations using WAY-121,898 (pCEH inhibitor) and CI-976 (ACAT inhibitor), we have arrived at several conclusions. First, since WAY-121,898 did not lower plasma cholesterol in normal, chow-fed rats, it is tempting to conclude that pCEH is not involved in the reabsorption of biliary (endogenous) cholesterol. However, CI-976 (20) and other ACAT inhibitors (36) are also not hypocholesterolemic in chow-fed rats. Therefore, the current pharmacologic approach suggests at least three possibili-

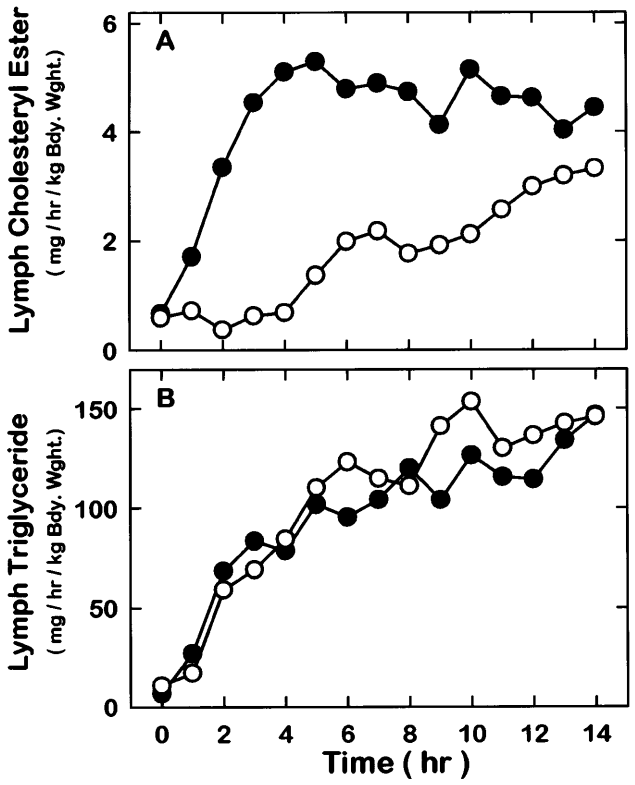

FIG. 4. Effect of a single dose of WAY-121,898 on the lymphatic output (transport) of cholesteryl esters (A) and triglycerides (B) in rats with a mesenteric lymph fistula. After collecting basal lymph for 2 h the compound (○) or vehicle alone (●) was injected directly into the duodenum *via* a cannula, and lymph was collected hourly. Each point represents the mean of two animals.

ties: (i) very little cholesterol esterification is occurring in chow-fed rats in lipoprotein-producing organs, (ii) another enzyme besides ACAT or pCEH (or ACAT subtype not sensitive to CI-976) is catalyzing intestinal esterification of biliary cholesterol, or (iii) the compounds are not potent enough to answer the question as to which enzyme is important. The fact that cholesterol absorption is normal in both pCEH knockout mice (37) and ACAT knockout mice (35) seems to support the first two possibilities. However, the disrupted gene in the ACAT knockout was originally cloned from macrophages, and more recent ACAT inhibitors with improved bioavailability lower plasma cholesterol in chow-fed rats (38). So it is possible that another ACAT-related protein or ACAT subtype exists in the intestine of these animals which catalyzes the formation of cholesteryl esters in chow-fed rats. The modest reduction (30%) in plasma triglycerides in chow-fed rats with WAY-121,898 is an unexpected finding. The lymph–fistula data would argue against an effect on triglyceride absorption, as would the report that WAY-121,898 does not inhibit pancreatic triglyceride lipase *in vitro* (27). Thus, one would have to postulate that inhibition of the bile salt-dependent CEH in the liver might alter hepatic triglyceride metabolism. Clearly, further experiments are also required to support this hypothesis.

Another finding in this study is that inhibition of pCEH by WAY-121,898 inhibits the absorption of exogenous cholesterol in rats. This was demonstrated directly using the rat lymph–fistula model, coupled with experiments in which diet-induced hypercholesterolemia was inhibited by drug treatment. These data therefore confirm the preliminary reports that WAY-121,898 is efficacious in rats fed cholesterol, and that its mechanism of action includes inhibition of cholesterol absorption (13,15,16). They are also consistent with reports of other pCEH inhibitors that inhibit cholesterol absorption in rats (39–44) and are unlikely due to a unique side effect in rats treated with WAY-121,898. However, these observations are at variance with the mouse pCEH knockout data (37), and thus suggest major species differences. Efficacy with WAY-121,898 was maximal at a dietary cholesterol load of 0.4%, but with CI-976 efficacy continued to improve with increases in dietary cholesterol. One interpretation of this observation may be that at high levels of dietary cholesterol in the rat (i.e., >0.5%) esterification may be driven more by ACAT than by pCEH, as first suggested by Heider *et al.* (45) based on rabbit experiments. At a dietary cholesterol load of 0.4%, it could be postulated that both enzymes play a role in cholesterol absorption since an additive effect was observed with WAY-121,898 and CI-976 in combination in the cholesterol-fed rat model. Interestingly, Bhat and Brockman (12) have previously suggested a role for both pCEH and ACAT in cholesterol absorption based upon experiments with rat intestinal sacs (12). Our *in vivo* rat data using both inhibitors in combination seems to support their hypothesis that pCEH catalyzes the "flip-flop" of cholesterol, *via* the ester,

TABLE 3
Efficacy of WAY-121,898 in Cholesterol-Fed Hamsters[a]

	Group

Liver cholesteryl esters (mg/g)	8.7 ± 0.9	7.9 ± 0.9	5.1 ± 1.0*

[a]Values are the mean ± SEM (n = 6/group); *$P < 0.05$.

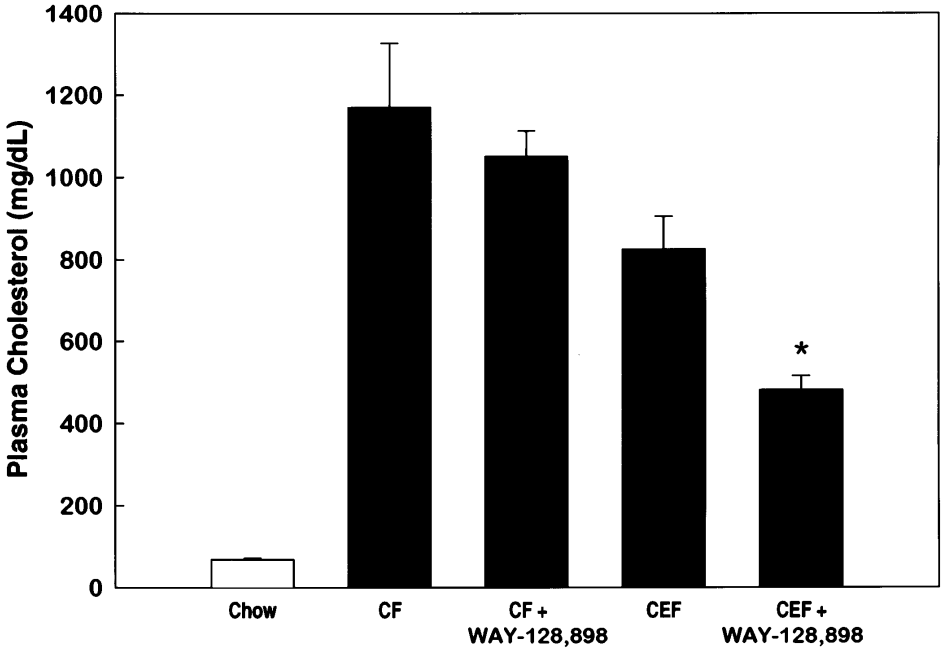

FIG. 5. Effect of WAY-121,898 on plasma cholesterol in rabbits fed either cholesterol (CF) or cholesteryl ester (CEF). *$P < 0.05$ vs. CEF controls.

across the villus membrane into the intestinal cell where ACAT catalyzes reesterification.

The effects of WAY-121,898 were distinctly different in the hamster compared to the rat. Unlike the rat, we observed cholesterol-lowering in animals on a chow diet (100 mg/kg), and the cholesterol-lowering in animals fed cholesterol was not due to inhibition of cholesterol absorption. Although CI-976 does not lower plasma cholesterol in chow-fed hamsters (25), other ACAT inhibitors are active (46), so under these conditions both ACAT and pCEH may play a role in cholesterol absorption. In cholesterol-fed hamsters, ACAT inhibitors, including CI-976, lower plasma cholesterol in part by inhibiting cholesterol absorption (25,26). Therefore, ACAT and not pCEH may mediate cholesterol esterification in the intestine of cholesterol-fed hamsters. The efficacy due to WAY-121,898 could be due to inhibition of liver CEH or CEH in plasma which has been shown to modify lipoprotein composition and structure (47). Such changes could alter lipoprotein clearance. We favor this possibility since liver cholesteryl ester concentrations were actually decreased in hamsters by WAY-121,898 rather than increased as would be expected by inhibiting liver CEH. Such a mechanism also may pertain to the efficacy we observed after parenteral dosing in cholesterol-fed rats.

In contrast to cholesterol-fed rats and hamsters, we observed no change in plasma cholesterol after WAY-121,898 treatment in cholesterol-fed rabbits, suggesting that the putative mechanisms discussed above whereby CEH might alter plasma cholesterol are not operative in this species. This lack of hypocholesterolemic activity in cholesterol-fed rabbits, which is in marked contrast to the potent effects observed with CI-976 and other ACAT inhibitors (45,48), could be due in part to the fact that rabbit liver contains no detectable CEH activity or mRNA, and intestinal CEH in rabbits is low and variable (49). Likewise, Field (22) could find no evidence for an intestinally-derived CEH in rabbit intestine. Thus, there seems to be a distinct difference between rats and rabbits with regard to responses to WAY-121,898, and not surprisingly the bulk of the data in the literature supporting a role for pCEH is largely derived from the rat. Although pCEH seems to play no role in cholesterol absorption in rabbits, WAY-121,898 did appear to inhibit the hydrolysis and subsequent absorption of dietary cholesteryl ester. Inhibition of cholesteryl ester absorption was also inhibited in pCEH knockout mice (37), and it seems reasonable to suggest that inhibition of ester hydrolysis by WAY-121,898 would likely be observed in other species as well. For example, a suicide inhibitor of pCEH inhibits cholesteryl ester absorption, or more properly, the absorption of cholesterol derived from dietary cholesteryl ester, in rats (50). Thus, it now seems indisputable that pCEH plays a primary role in the absorption of cholesteryl esters.

Although WAY-121,898 showed no adverse effects in our animal experiments, we did observe an increase in adrenal cholesteryl ester content after drug treatment in chow-fed guinea pigs. This suggests to us that the drug reached the adrenal gland to inhibit cholesteryl ester hydrolysis. Whether this would ultimately result in adrenal dysfunction is unknown, but mobilization of stored esters could theoretically be compromised with drug treatment. Despite this finding, it has been reported that this compound reduces the cholesterol

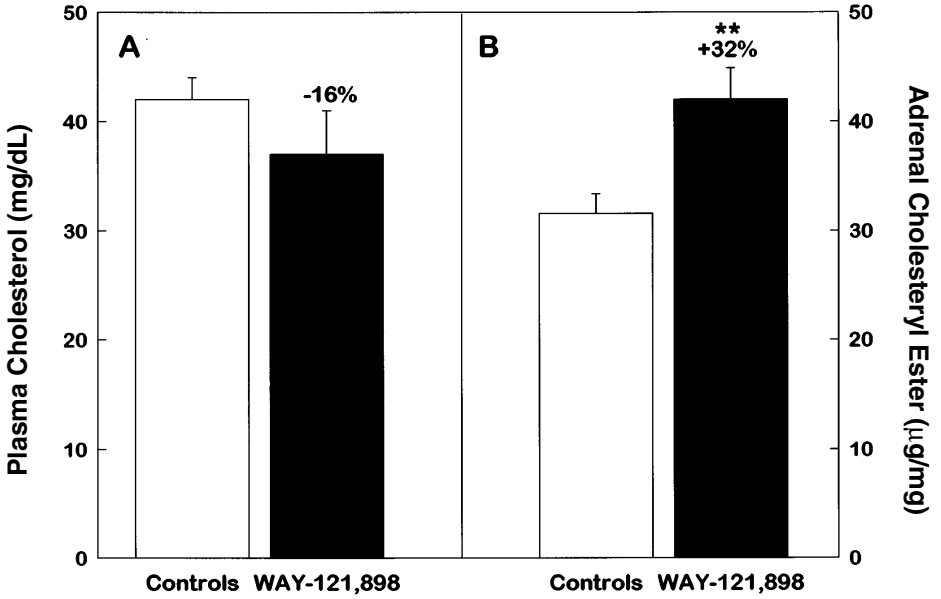

FIG. 6. Effect of WAY-121,898 (100 mg/kg) on plasma cholesterol (A) and adrenal cholesteryl esters (B) in chow-fed guinea pigs. The compound was dosed by daily (A.M.) oral gavage for 2 wk using an oleic acid vehicle. The numbers above the drug-treated groups (solid bars) are the percentage changes from controls (open bars). $^{**}P < 01$.

content, presumably cholesteryl esters, of the aorta in cholesterol-fed quail (16). Such differences between tissues may be due to differences in drug uptake or to differences between the CEH enzymes in these tissues. Regardless, these observations again underscore the variety of responses to WAY-121,898 across species, and point to the need for further clarification of the role(s) of pCEH in cholesterol metabolism.

Suppression of Hypercholesterolemia in Hepatoma-Bearing Rats by Cabbage Extract and Its Component, *S*-Methyl-L-Cysteine Sulfoxide

Wataru Komatsu, Yutaka Miura, and Kazumi Yagasaki*

Department of Applied Biological Science, Tokyo Noko University, Tokyo 183-8509, Japan

ABSTRACT: The effect of cabbage extract on cholesterol metabolism was studied in Donryu rats subcutaneously implanted with an ascites hepatoma cell line (AH109A). The hepatoma-bearing rats exhibited hypercholesterolemia induced by increasing cholesterogenesis in the host liver and decreasing steroid excretion into feces. The cabbage extract intake or administration reduced serum cholesterol level and enhanced fecal bile acid excretion and cholesterol 7α-hydroxylase activity, the rate-limiting enzyme of bile acid biosynthesis, in the microsomal fraction of the liver. Furthermore, *S*-methyl-L-cysteine sulfoxide, a component of cabbage, could mimic the effect of cabbage extract when orally administered. These results suggest that cabbage suppresses hypercholesterolemia responding to hepatoma growth by upregulating cholesterol catabolism and that *S*-methyl-L-cysteine sulfoxide in cabbage is one of the factors suppressing hypercholesterolemia in the hepatoma-bearing rats.
Lipids 33, 499–503 (1998).

Many dietary factors have been shown to influence serum cholesterol (Ch) levels. Rats have been used as an experimental animal in many studies on Ch metabolism. However, it has generally been necessary to use a high dose of Ch plus cholic acid (1,2) in order to induce exogenous hypercholesterolemia. Another approach in the rat has been to induce the development of solid hepatomas (3). In humans and animals, hepatoma induces abnormal serum lipid metabolism, particularly an increase in serum total Ch (T-Ch) levels (3–5). We have reported that rats subcutaneously implanted with an ascites hepatoma cell line of AH109A show a slight decrease in high density lipoprotein (HDL)-Ch and an enormous increase in the very low density lipoprotein plus low density lipoprotein (VLDL + LDL)-Ch, which result in endogenous hypercholesterolemia (6) and hypertriglyceridemia (7,8) during growth of the hepatoma. The hepatoma-induced hypercholesterolemia is shown to be induced by an increased cholesterogenesis in the host liver and a decreased steroid excretion into feces (7).

Abbreviations: C, casein; Ch, cholesterol; Ch 7α-H, cholesterol 7α-hydroxylase; FA, fatty acids; HDL, high density lipoprotein; LDL, low density lipoprotein; NEFA, nonesterified fatty acid; SMCS, *S*-methyl-L-cysteine sulfoxide; T-Ch, total cholesterol; TG, triglyceride; VLDL, very low density lipoprotein.

In general, vegetable diets were reported to have a hypolipidemic activity (9,10), and cabbage was reported to have a positive influence on the cholesterol metabolism by decreasing an atherogenicity index [(T-Ch) − (HDL-Ch)/HDL-Ch] (11). In the present study, we examined the effect of cabbage extract treatment on endogenous hypercholesterolemia and Ch metabolism in hepatoma-bearing rats.

EXPERIMENTAL PROCEDURES

Animals and diets. Male Donryu rats (4 w of age) were obtained from NRC Haruna (Gunma, Japan). They were kept on a stock pellet diet (CE-2; CLEA Japan, Tokyo, Japan) for 4 d and on a 20% casein diet (20C) containing 5% corn oil (12) for another 7 (experiment 1) or 10 (experiment 2) d in an air-conditioned room with an 8:00 A.M. to 8:00 P.M. light cycle. Cabbage was obtained from a local market in Fuchu, Tokyo, and cabbage extract was prepared as follows. Washed cabbage was put into a juicer, centrifuged, and then filtered through a Toyo No. 2 filter paper (Advantec Toyo Co., Tokyo, Japan) to obtain cabbage extract. The extract was given to rats either by addition of its freeze-dried sample to the 20C diet at 1.3% in experiment 1, or oral administration in experiment 2. In experiment 1, rats were divided into three groups of similar body weight; two of the groups received a subcutaneous implantation of 5×10^5 AH109A cells (ascites hepatoma cell line, obtained from Institute of Development, Aging and Cancer, Tohoku University, Sendai, Japan) suspended in phosphate-buffered saline to produce solid tumor in the back, as described previously (6). Rats of each of these groups were given either 20C or 20C supplemented with 1.3% freeze-dried cabbage extract. Animals of the third group received a subcutaneous sham injection of phosphate-buffered saline alone instead of AH109A as the normal control and were given the 20C. In experiment 2, rats were divided into three groups of similar body weight, and all received an implantation of AH109A. All the animals were given the 20C for another 14 d. One group was orally administered the cabbage extract (1 mL/100 g body weight/d), and another one with an aqueous solution of *S*-methyl-L-cysteine sulfoxide (SMCS, obtained from Research Organics Inc., Cleveland, OH; 25 mg/mL/100 g body weight/d). The control group was given distilled water (1 mL/100 g body weight/d) alone. All the administrations

were conducted once a day at 9:00 A.M. for 14 d. The content of SMCS was reported to be 590 mg/100 g in cabbage (13). Thus, the dose of 25 mg/100 g body weight/d is calculated to be approximately equivalent to that of 1.3% freeze-dried cabbage extract diet intake per day or 1 mL/100 g body weight/d of the cabbage extract. The animals were deprived of their diets at 9:00 A.M. on the scheduled days but allowed free access to water until decapitation 4 h later. Blood was collected and left to clot at room temperature for 2–4 h to obtain serum. The liver and hepatoma were quickly removed, washed with cold 0.9% NaCl, blotted on filter paper, weighed, and provided for various analyses.

Lipid analyses. Total lipids were extracted according to the procedure of Folch *et al.* (14) from the liver. After aliquots of the chloroform phase had been dried, Ch (15) and TG (16) concentrations were determined as described (17). Serum lipoproteins were separated into VLDL + LDL and HDL fractions by the precipitation method (6). The total Ch of unfractionated serum (T-Ch) and HDL (HDL-Ch) was enzymatically determined with a commercial kit (Wako Pure Chemical Industries, Osaka, Japan), and the difference between T-Ch and HDL-Ch was regarded as (VLDL + LDL)-Ch.

Hepatic lipid syntheses. Total fatty acids (FA) and Ch syntheses were measured using liver slices (100–120 mg) and 37 kBq/μmol/assay of [1-^{14}C]acetic acid (2.04 GBq/mmol; Amersham International, Buckinghamshire, United Kingdom) as described previously (7,18).

Fecal steroid excretion. Feces were collected for 2 d before sacrifice (days 12–14). Neutral sterols and bile acids were extracted according to the method of Yamanaka *et al.* (19), then enzymatically determined with commercial kits (Wako Pure Chemical Industries) as described previously (7,20).

Microsomal cholesterol 7α-hydroxylase (Ch 7α-H) activity. Liver samples weighing 2 g were homogenized in 0.1 M phosphate buffer (pH 7.4), and microsomal fractions were obtained by ultracentrifugation in a Hitachi RP83T rotor (Tokyo, Japan) at 40,000 rpm for 1 h at 4°C. Aliquots of the microsomal fractions were incubated for 40 min in 0.1 M phosphate buffer (pH 7.4) containing 111 kBq/0.2 μmol/assay of [7α-^{3}H(N)]Ch (814 GBq/mmol; NEN Research Products, Boston, MA), and the enzyme activity was evaluated by counting [^{3}H]water as described previously (21).

Statistical analysis. Data were analyzed by a one-way analysis of variance (ANOVA). When F values were significant ($P < 0.05$), differences were inspected by Duncan's multiple-range test.

RESULTS

In experiment 1, the effect of cabbage extract on the Ch metabolism was first examined in AH109A-bearing rats treated by supplementation of a freeze-dried cabbage extract to a 20C diet. As shown in Table 1, body weight gain, food intake, and liver weight were significantly reduced by bearing solid hepatoma, but the cabbage extract intake had no significant effects on these parameters and hepatoma weight (the hepatoma group vs. the hepatoma + cabbage group), except for liver weight that was decreased by the extract. The hepatic TG level was reduced in the hepatoma-bearing rats, whereas the

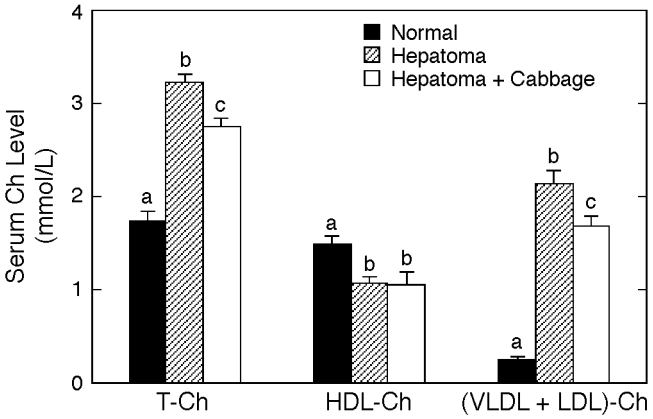

FIG. 1. Effect of cabbage extract on serum cholesterol (Ch) levels in hepatoma-bearing rats. Each value represents the mean of six rats. Vertical bars indicate standard errors. When the F value was significant at $P < 0.05$, the means were inspected by Duncan's multiple-range test. [a,b,c]Values not sharing a common letter are significantly different. T-Ch, total cholesterol; HDL, high density lipoprotein; VLDL, very low density lipoprotein; LDL, low density lipoprotein.

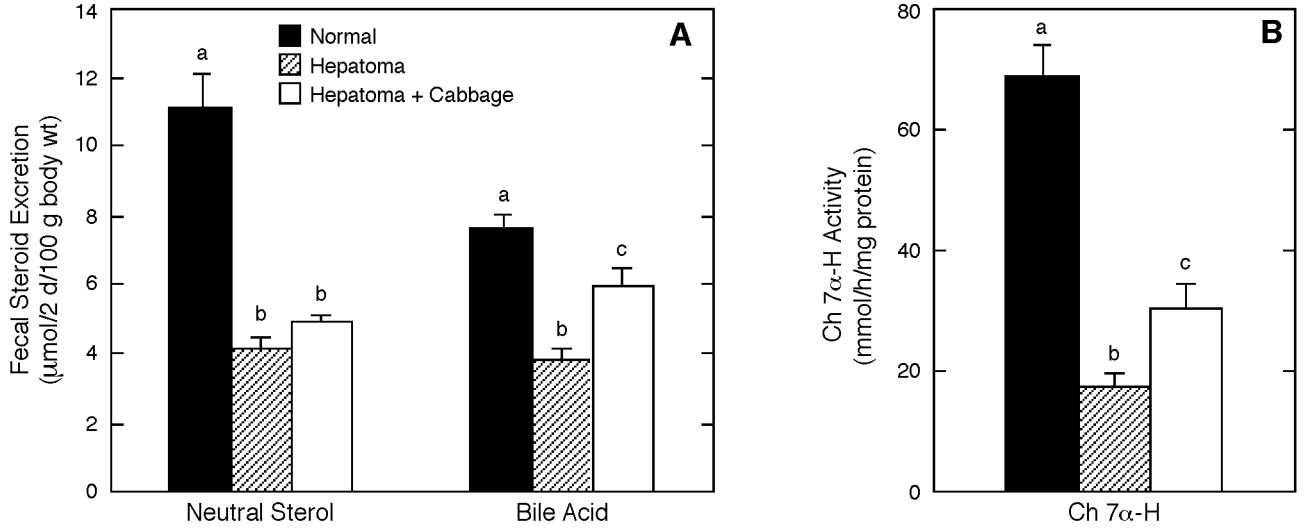

FIG. 2. Effect of cabbage extract on fecal steroid excretion (A) and microsomal cholesterol 7α-hydroxylase (Ch 7α-H) activity (B) in hepatoma-bearing rats. Each value represents the mean of six rats. Vertical bars indicate standard errors. When the *F* value was significant at $P < 0.05$, the means were inspected by Duncan's multiple-range test. [a,b,c]Values not sharing a common letter are significantly different.

hepatic Ch was unchanged by bearing hepatoma. Cabbage extract exerted no influences on these two parameters. Changes in serum Ch levels are illustrated in Figure 1. Both T-Ch and (VLDL + LDL)-Ch levels were significantly increased by bearing hepatoma, and these elevations in the hepatoma-bearing rats were suppressed by the cabbage extract intake. The HDL-Ch level was significantly decreased in the hepatoma-bearing rats, but no change was observed between the hepatoma and the hepatoma + cabbage groups. Table 1 also shows the hepatic FA and Ch syntheses by liver slices. No significant changes were seen in FA synthesis among the three groups, while the Ch synthesis was significantly enhanced in the hepatoma-bearing rats. However, the cabbage extract intake did not affect the Ch synthesis. Fecal steroid excretion and Ch 7α-H activity in the microsomal fraction of the host liver are shown in Figure 2. The excretion of neutral sterols and bile acids into feces, as well as the Ch 7α-H activity, the rate-limiting enzyme of bile acid biosynthesis, were reduced by bearing hepatoma, and reductions in bile acid excretion and the enzyme activity were partially restored by the intake of cabbage extract.

Since SMCS, a component of cabbage, was reported to reduce the serum Ch level in Ch-loaded rats (22,23), we next investigated its effect on Ch metabolism in the hepatoma-bearing rats. In this experiment, the cabbage extract and SMCS solution were administered orally, because a slight (though not significant) reduction in food intake was observed in feeding the cabbage extract-supplemented diet in experiment 1 (as seen in Table 1). As shown in Table 2, body weight gain, food intake, liver and hepatoma weights, and hepatic Ch level were unchanged among these three groups. The hepatic TG level was significantly elevated in rats receiving SMCS compared with the other two groups. The serum Ch levels are illustrated in Figure 3. It was confirmed that the serum T-Ch and (VLDL + LDL)-Ch levels were reduced in cabbage extract-administered rats (the hepatoma + cabbage group) when compared with con-

trol rats (the hepatoma group), and similar reduction was observed in the SMCS-administered rats (the hepatoma + SMCS group). The hepatic FA and Ch syntheses were not affected by either the cabbage extract or SMCS administration (Table 2), while fecal bile acid excretion and Ch 7α-H activity in liver microsome were significantly enhanced in both the cabbage extract- and SMCS-administered rats (Fig. 4).

DISCUSSION

The present study investigated the effect of cabbage extract treatment on serum Ch and Ch metabolism in rats with hepatoma. The serum T-Ch level in the hepatoma-bearing state is significantly higher than that in the normal state (6–8). Results of this work show that the cabbage extract treatment significantly decreased this elevated serum T-Ch level, and that the decrease was due to significant reduction of the (VLDL + LDL)-Ch level in hepatoma-bearing rats. Treating the hepatoma-bearing rats with cabbage extract could stimulate the fecal excretion of bile acids and the microsomal activity of Ch 7α-H. The hypocholesterolemic action of cabbage extract may be due, at least in part, to a stimulation of bile acid excretion, and this stimulation may be the result of an increased Ch 7α-H activity in the liver microsomal fraction. The component(s) in cabbage which has the hypocholesterolemic activity in the hepatoma-bearing state is unknown. SMCS, which was identified by Morris and Thompson (24) as a constituent of a number of species of Cruciferae plants such as cabbage, cauliflower and broccoli, was reported to suppress hypercholesterolemia in Ch-loaded rats (22,23). So, we compared the actions of SMCS with those of cabbage extract in hepatoma-bearing rats. Results demonstrated that the effects of SMCS mimicked those of the cabbage extract in serum Ch, fecal bile acid excretion, and Ch 7α-H activity. These results suggest that SMCS is one component in cabbage which suppresses hypercholesterolemia in the hepatoma-bearing rats. Mechanism by which SMCS stimulates Ch 7α-H activity is unclear at present. SMCS has been recently reported to reduce serum Ch level in alloxan-induced diabetic rats (25). Thus, SMCS is suggested to be a strong hypocholesterolemic agent in endogenous hypercholesterolemic models as well as Ch-loaded, exogenous hypercholesterolemic ones.

In conclusion, cabbage extract has a hypocholesterolemic activity in hepatoma-bearing rats, and SMCS is one of the chemical entities in cabbage. The mechanism by which

[a,b]Values not sharing a common letter are significantly different. See Figures 2 and 3 for abbreviations.

SMCS stimulates Ch 7α-H activity is unknown, and further studies are needed.

ABSTRACT: Human erythrocytes in the circulation undergo dynamic oxidative damage involving membrane lipid peroxidation and protein aggregation during aging. The present study was undertaken to determine the effect of n-3 fatty acid supplementation on lipid peroxidation and protein aggregation in the circulation and also the *in vitro* susceptibility of rat erythrocyte membranes to oxidative damage. Wistar male rats were fed a diet containing n-6 fatty acid-rich safflower oil or n-3 fatty acid-rich fish oil with an equal amount of vitamin E for 6 wk. n-3 Fatty acid content in erythrocyte membranes of rats fed fish oil was significantly higher than that of rats fed safflower oil. The degree of membrane lipid peroxidation and protein aggregation of rats fed fish oil was not significantly higher than that of rats fed safflower oil when the amounts of phospholipid hydroperoxides, thiobarbituric acid-reactive substances, and detergent-insoluble protein aggregates were measured. When isolated erythrocytes were oxidized under aerobic conditions in the presence of Fe(III), the degree of membrane lipid peroxidation of erythrocytes from rats fed fish oil was increased to a greater extent than that of rats fed safflower oil, whereas the degree of membrane protein aggregation of both groups was increased in a similar extent. Hence, n-3 fatty acid supplementation did not affect lipid peroxidation and protein aggregation in membranes of circulating rat erythrocytes, and the supplementation increased the susceptibility of isolated erythrocytes to lipid peroxidation, but not to protein aggregation, under the aerobic conditions. If a sufficient amount of vitamin E is supplied, n-3 fatty acid supplementation may give no undesirable oxidative effects on rat erythrocytes in the circulation.
Lipids 33, 505–512 (1998).

Fish oils which contain high amounts of the n-3 fatty acids, eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), have been suggested to decrease the risk of developing cardiovascular diseases and cancer (1). Epidemiological studies have shown an apparent beneficial effect of fish intake in reducing mortality from heart disease (2). On supplementation of n-3 fatty acids, arachidonic acid (20:4n-6) in phospholipids of cell membranes in various tissues of animals is replaced by these n-3 fatty acids (3,4).

Fish oils containing highly unsaturated n-3 fatty acids are readily susceptible to autoxidation under aerobic conditions (5). Glavind *et al*. (6) have reported that lipid peroxides appear in the plaque of human atheroma and that the degree of atheroma correlates with the extent of lipid peroxidation of the plaque. Since those initial observations, lipid peroxidation products have been considered to be related to various disorders in humans including atherosclerosis, diabetes, burn injury, and retinopathy (7). In relation to possible undesirable effects of fish oil intake, several studies have been done. Studies on human urine (8,9) and plasma (10–14) have shown that levels of lipid peroxidation products were slightly increased in persons eating a diet with high fish oil content. Studies on experimental animals have shown a decrease in tissue vitamin E content (15–17) and an increase in *in vitro* susceptibility to lipid peroxidation of tissues on n-3 fatty acid supplementation (15–22).

Our previous studies have shown that human erythrocytes in the circulation undergo dynamic oxidative damages including membrane lipid peroxidation (23) and protein aggregation (24) during aging. Membrane protein aggregation leads to aggregation of cell surface carbohydrate chains of band 3 glycoprotein resulting in recognition by anti-band 3 autoantibody (25). This process may be related to clearance of oxidatively damaged senescent erythrocytes by macrophages (26). It is important to elucidate whether the increased unsaturation of fatty acids in erythrocyte membranes makes them more susceptible to lipid peroxidation and protein aggregation in the circulation, and whether lipid peroxidation precedes induction of protein aggregation. The present study was undertaken to determine the effect of n-3 fatty acid supplementation on lipid peroxidation and protein aggregation of rat erythrocyte membranes in the circulation, and to clarify whether protein aggregation results from lipid peroxidation.

Abbreviations: BHT, butylated hydroxytoluene; $C_{12}E_8$, octaethylene glycol *n*-dodecyl monoether; DPBS, Dulbecco's phosphate-buffered saline; DPBS(–), Ca^{2+}- and Mg^{2+}-free DPBS; HPLC, high-performance liquid chromatography; PCOOH, phosphatidylcholine hydroperoxide; PEOOH, phosphatidylethanolamine hydroperoxide; SDS-PAGE, SDS-polyacrylamide gel electrophoresis; TBA, thiobarbituric acid; TBARS, TBA-reactive substance.

It was found that n-3 fatty acid supplementation did not affect lipid peroxidation and protein aggregation of rat erythrocyte membranes in the circulation. The supplementation increased the susceptibility of isolated erythrocytes to lipid peroxidation but produced little change in the susceptibility to protein aggregation under aerobic conditions.

MATERIALS AND METHODS

Materials. ADP was obtained from Oriental Yeast Company (Tokyo, Japan). Phosphatidylcholine (egg yolk) and phosphatidylethanolamine (egg yolk) were obtained from Nippon Fats and Oils Liposome Company (Tokyo, Japan). Phosphatidylcholine hydroperoxide (PCOOH) and phosphatidylethanolamine hydroperoxide (PEOOH) were prepared just before use according to the method previously described (27). Peroxide values of PCOOH and PEOOH were estimated to be 1380–1680 and 770–840 neq/mg, respectively. Cytochrome c and luminol were purchased from Sigma Chemical Company (St. Louis, MO) and Wako Pure Chemical Industries (Osaka, Japan), respectively. Thiobarbituric acid (TBA) and Silica gel 60 for thin-layer chromatography were obtained from Merck (Darmstadt, Germany). Phenylmethylsulfonyl fluoride and diisopropyl fluorophosphate were obtained from Sigma. Octaethylene glycol *n*-dodecyl monoether ($C_{12}E_8$) was from Nikko Chemical Company (Tokyo, Japan).

Animals and diets. Sixteen 4-wk-old Wistar male rats weighing 50–70 g were supplied by Japan Laboratory Animals Inc. (Tokyo, Japan). Four animals were housed together in a stainless steel cage in a room of controlled temperature at 23 ± 1°C, humidity at 55 ± 5%, and lighting of 12 h dark–light cycle. The animals were allowed free access to food. The animals were fed a normal solid diet, Clea rodent diet CE-2 containing 4.5% soybean oil and 7.0 mg% vitamin E (Clea Japan Corp., Tokyo, Japan) during 1 wk for acclimatization. Rats were divided into two groups of eight animals each, and each group was fed a diet with safflower oil or with fish oil for 6 wk. Weights of rats after feeding were 350–450 g. A powdered diet with AIN-76 composition, in which corn oil was replaced by cornstarch, and whose vitamin E content was 4.56 mg% (Oriental Yeast Company), was stored at 4°C before use. Safflower oil and fish oil with the fatty acid composition shown in Table 1 were stored at –20°C before use. Each oil contained 32.5 mg% vitamin E. Peroxide and acid values of safflower oil were 1.1 neq/mg and 0.2, respectively, and those of fish oil were 1.2 neq/mg and 0.2, respectively. Diets for feeding were freshly prepared every day by uniformly mixing 427.5 g of the powdered AIN-76 diet, 22.5 g of each oil (5% by weight), and 62.5 mL of deionized water. The overall content of vitamin E in both diets was equal at 5.93 mg% dried solid.

Erythrocyte preparation. At the end of the feeding period, eight rats of each diet group (six for lipid and protein aggregate analysis and two for vitamin E analysis) were anesthetized with an air/diethyl ether mixture, and blood (10–12 mL) was collected over citrate-phosphate-dextrose by cardiac puncture. Blood was immediately centrifuged at 320 × *g* and 4°C for 10 min to remove plasma and buffy coats. Erythrocytes were washed four times by centrifugation at 650 × *g* and 4°C for 5 min with Ca^{2+}- and Mg^{2+}-free Dulbecco's phosphate-buffered saline (DPBS) to make a cell pellet.

In vitro *oxidation of isolated rat erythrocytes*. Oxidation of erythrocytes was carried out according to the method previously described (28). Five milliliters of an erythrocyte suspension in DPBS (40% hematocrit) was mixed with an equal volume of a solution of an iron catalyst ADP/Fe(III) (a mixture of 3.4 mM ADP and 0.2 mM $FeCl_3$ in isotonic saline) and incubated under aerobic conditions at 37°C for 90 min. The cells were pelleted by centrifugation, washed twice with DPBS(–) and twice with isotonic saline to make a cell pellet.

Determination of hemoglobin. To 10 μL of the erythrocyte pellet was added 3.0 mL of water, and the lysate was centrifuged at 9,600 × *g* for 20 min. Absorbance of the supernatant at 523 nm was measured, and the hemoglobin concentration was calculated using a molecular extinction coefficient of 7,880 and a molecular weight of 64,000 (28).

Determination of vitamin E. Vitamin E contents of erythrocytes from two rats of each diet group were determined by high-performance liquid chromatography (HPLC) according to the method previously described (29). The amount of vitamin E in the sample was estimated by comparing the peak area with those of the calibration curve of the standard *dl*-α-tocopherol. Vitamin E content in erythrocytes was expressed per g hemoglobin.

Fatty acid composition of phospholipids of erythrocyte membranes. Erythrocytes were lysed and extracted with chloroform/methanol (2:1, vol/vol). The phospholipid fraction on silica gel thin-layer chromatography was methylated with 3% hydrochloric acid/methanol and analyzed by gas chromatography using an Hitachi G-5000 gas chromatograph (Tokyo, Japan) equipped with a fused-silica capillary column DB-225 (0.25 mm i.d. × 30 m) (J&W Scientific Company, Inc., Folsom, CA) and a flame-ionization detector with helium as a carrier gas.

Lipid peroxidation products in erythrocyte membranes. To 1.0 mL of the erythrocyte pellet, 1.0 mL of water was added and the mixture was left for 15 min. To the lysate, 11 mL of 2-propanol was added and the mixture was shaken occasionally for 1 h, after which 7 mL of chloroform was added to the mixture and shaken occasionally for another hour. The organic layer (18 mL) was collected by centrifugation at 1,500 × *g* for 15 min, filtered through a glass wool column, and 17 mL was isolated (30). The layer was divided into two 8-mL fractions. Both fractions were evaporated at below 30°C to dryness for determination of PEOOH, PCOOH, and TBA-reactive substances (TBARS). The amounts of lipid peroxidation products were expressed per g hemoglobin.

PEOOH and PCOOH. Contents of PCOOH and PEOOH in the lipid fraction of erythrocyte membranes were determined by a HPLC-chemiluminescence method (27,31). The lipid fraction was dissolved in 5.0 mL of chloroform/

methanol (2:1, vol/vol) and washed twice with 1 mL of 0.05 M KCl to obtain 3.5 mL of the organic layer. A 3.0-mL portion of the organic layer was evaporated to dryness at below 30°C and redissolved in 50 μL of chloroform/methanol (1:9, vol/vol). A 40-μL portion of this extract was analyzed. The amounts (neq) of PCOOH and PEOOH were determined by comparing their peak areas with a calibration curve of the peak areas of the standard solutions of PCOOH and PEOOH (0–100 neq).

TBARS. TBARS in the lipid fraction of erythrocyte membranes were determined according to the method previously described with added butylated hydroxytoluene (BHT) and in the absence and presence of EDTA (23,32). The lipid fraction of membranes was suspended in 0.9 mL of water for analysis.

Protein aggregates in erythrocyte membranes. $C_{12}E_8$-insoluble protein aggregates in erythrocyte membranes were isolated according to the method previously described (24,33). The amounts of protein in erythrocyte membranes and isolated aggregates were determined by the Lowry method (34). SDS-polyacrylamide gel electrophoresis (SDS-PAGE) of SDS-solubilized aggregates was done by the method of Laemmli (35) using 10% polyacrylamide gel under reducing conditions. The gel was stained by Coomassie brilliant blue R-250.

Statistical analysis. Data were analyzed by the Student's *t*-test.

[a]Expressed as percentages (w/w) of total fatty acids present. Abbreviations: UI, unsaturation index (sum of percentages of individual fatty acids × number of double bonds); PI, peroxidizability index (sum of percentages of individual fatty acids × number of active methylenes); MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

RESULTS

Two groups of Wistar male rats were fed a diet with 5% safflower oil or 5% fish oil for 6 wk. Fatty acid compositions of safflower and fish oils are shown in Table 1. As expected, safflower oil was rich in n-6 fatty acids (n-6 total: 78.0%, and n-3 total: 0.3%) and fish oil was rich in n-3 fatty acids (n-6 total: 1.3%, and n-3 total, 26.5%). While the unsaturation index (the sum of the percentages of individual fatty acids × number of double bonds) of the fish oil was equal to that of the safflower oil, the peroxidizability index, (the sum of the percentages of individual fatty acids × number of active methylenes) of the fish oil was higher than that of safflower oil, indicating that fish oil may be more readily peroxidized. Both diets contained an equal amount (5.93 mg% dried diet) of vitamin E; the safflower oil diet had 1.5 mg vitamin E/g polyunsaturated fatty acids and the fish oil diet had 4.3 mg vitamin E/g polyunsaturated fatty acids. Erythrocytes were isolated from each of six rats of both rat groups. Fatty acid compositions of phospholipids of erythrocyte membranes of both rat groups were determined (Table 2). It was found that phospholipids of erythrocytes of rats fed safflower oil contained higher amounts (39.0%) of n-6 fatty acids than those of rats fed fish oil (13.0%), and those of rats fed fish oil contained higher amounts (22.3%) of n-3 fatty acids than those of rats fed safflower oil (1.9%). Both the unsaturation index and the peroxidizability index of the erythrocyte membrane phospholipids from rats fed a diet containing fish oil were higher than those from rats fed a diet containing safflower oil. Vitamin E content of erythrocytes was estimated to be 12% lower in two rats fed fish oil (10.3 and 10.5 μg/g hemoglobin) than in two rats fed safflower oil (11.6 and 12.0 μg/g hemoglobin).

Contents of phospholipid hydroperoxides, PCOOH and PEOOH, in erythrocyte membranes of both rat groups were determined by an HPLC-chemiluminescence method (27,31). Representative HPLC chromatograms are shown in Figure 1A. When the mean content of these phospholipid hydroperoxides of six rats of both the groups were compared (Fig. 2A), no significant differences between two groups were observed. Concentrations of PCOOH and PEOOH of both rat groups were lower than 0.7 nmol/g hemoglobin. The TBARS in erythrocyte membranes of both rat groups were estimated. TBA assay of Ohkawa's procedure at pH 3.5 was performed in the presence of BHT in order to prevent lipid peroxidation while heating under the acidic assay conditions (23,32). It has been claimed that the TBA assay in the presence of EDTA reflects exclusively malonaldehyde derivatives that liberate malonaldehyde under the assay conditions, and that the assay in the absence of EDTA reflects not only malonaldehyde derivatives but also the derivatives of alka-2,4-dienals and alk-2-enals (32,36). Representative absorption spectra of the TBA assay mixtures of erythrocyte membranes shown in Figure 3A indicate that absorption spectra from both rat groups were similar to that of standard TBA red pigment without disturbing colored pigments. When the mean values of contents of TBARS of six rats of two rat groups were compared (Fig.

[a]Expressed as percentages (w/w) of total fatty acids present.
[b]Values are means for six rats.
[c]Significance of difference by Student's *t*-test between data for safflower oil- and fish oil-fed rats. For abbreviations see Table 1.

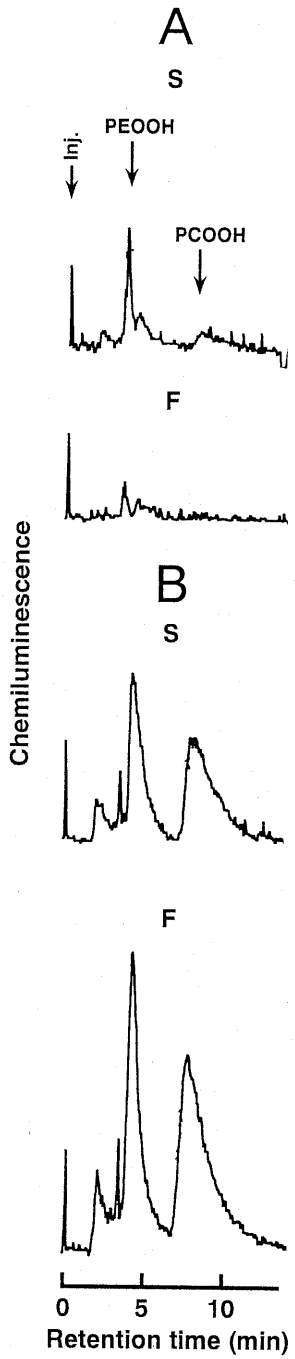

FIG. 1. Representative chromatograms of high-performance liquid chromatography-chemiluminescence assay of phosphatidylcholine hydroperoxide (PCOOH) and phosphatidylethanolamine hydroperoxide (PEOOH) in rat erythrocyte membranes. (A) Membranes of erythrocytes of a rat fed a diet containing safflower oil (S) or fish oil (F); (B) membranes of erythrocytes of a rat fed a diet containing S or F which were oxidized *in vitro* with ADP/Fe(III) at 37°C for 90 min.

4A), no significant differences between the groups were observed. Contents of the substances in the presence of EDTA of both rat groups were estimated to be about 2 nmol/g hemoglobin, and those of the substances in the absence of EDTA of both rat groups were estimated to be much higher at 35 nmol/g hemoglobin. Hence, erythrocyte membranes of rats fed fish oil did not show enhanced lipid peroxidation in the circulation as compared to rats fed safflower oil.

Membrane protein aggregates insoluble in detergent $C_{12}E_8$, whose presence indicates oxidative damage to erythrocyte membranes (24,33), were obtained from erythrocytes of both rat groups. The aggregates were solubilized with SDS, and their protein contents were measured (Fig. 5A). Contents of the aggregates of erythrocytes from rats fed fish oil were similar to those from rats fed safflower oil. SDS-PAGE of the aggregates from both rat groups revealed a similar pattern (Fig. 6A). Erythrocyte membranes of rats fed fish oil did not exhibit increased oxidative protein aggregation in the circulation when compared to the membranes of rats fed safflower oil.

Erythrocytes from the two rat groups were oxidized *in vitro* at 37°C for 90 min in the presence of ADP/Fe(III) (28) under aerobic conditions. Figure 1B shows representative HPLC chromatograms of PCOOH and PEOOH, and Fig-

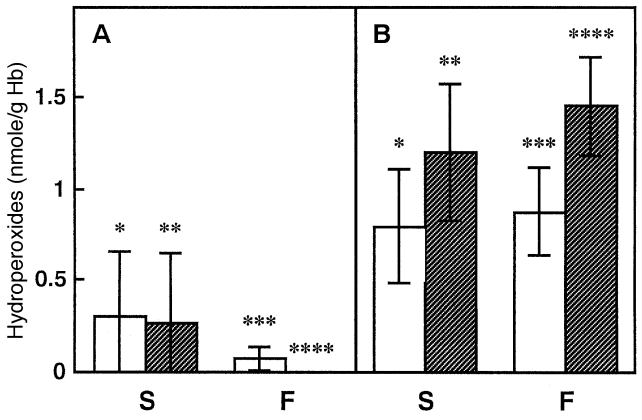

FIG. 2. Contents of PCOOH (striped bars) and PEOOH (open bars) in rat erythrocyte membranes. (A) Membranes of erythrocytes of rats fed a diet containing S or F. (B) Membranes of erythrocytes of rats fed a diet containing S or F which were oxidized *in vitro* with ADP/Fe(III) at 37°C for 90 min. Mean values ± SD for six rats are given. $*P < 0.01$; $**P < 0.02$; $***P < 0.001$; $****P < 0.001$. Hb, hemoglobin; for other abbreviations see Figure 1.

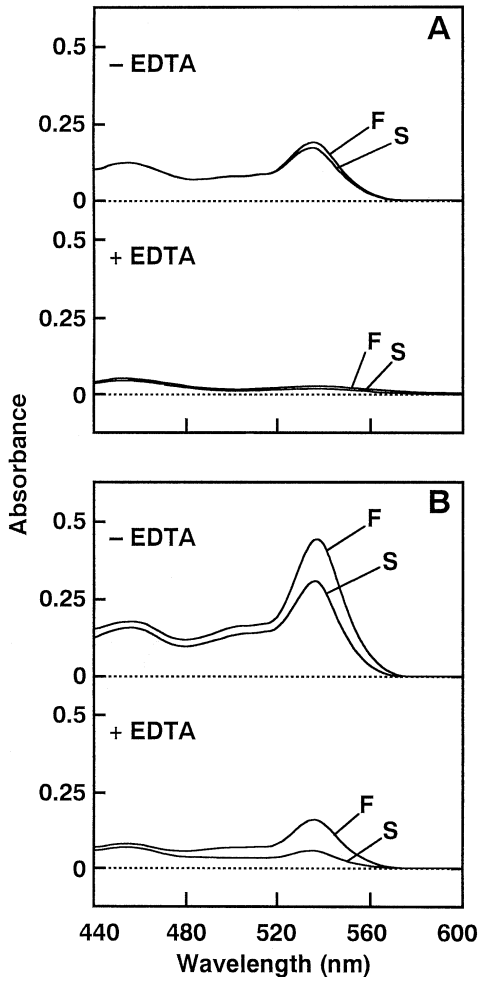

FIG. 3. Representative absorption spectra of thiobarbituric acid (TBA) reaction mixtures with and without EDTA of rat erythrocyte membranes. (A) Membranes of erythrocytes of a rat fed a diet containing S or F; (B) membranes of erythrocytes of a rat fed a diet containing S or F which was oxidized *in vitro* with ADP/Fe(III) at 37°C for 90 min. For abbreviations see Figure 1.

ure 2B shows the concentrations of PCOOH and PEOOH from six rats of both rat groups. The hydroperoxide levels of both rat groups were extensively increased by the *in-vitro* aerobic oxidation, and the degree of the increase of the group fed fish oil was higher than that fed safflower oil. Figure 3B shows representative absorption spectra of the TBA reaction mixtures, and Figure 4B shows the mean levels of TBARS of six rats of both groups. The levels of TBARS in the presence and absence of EDTA of both groups were increased by oxidation, and the levels of the rat group fed fish oil were increased more. The TBARS of the rat group fed fish oil were increased over that of the safflower-fed group twofold in the assay without EDTA and fivefold in the assay with EDTA. The results indicate that fish oil supplementation caused enhanced *in vitro* susceptibility to lipid peroxidation of erythrocyte membranes. $C_{12}E_8$-insoluble membrane protein aggregates were obtained from erythrocytes of both rat groups oxidized *in vitro*. The amount of aggregates from both rat groups was increased by the oxidation, and the increased levels of the rat group fed fish oil was similar to those of the rat group fed safflower oil (Fig. 5B). SDS-PAGE of the aggregates from both rat groups revealed a similar pattern (Fig. 6B). Erythrocyte membrane proteins of both rat groups were similarly aggregated by the *in vitro* oxidation, and the degree of aggregation did not correspond to the degree of lipid peroxidation of membrane.

DISCUSSION

Wistar rats were fed a diet containing safflower oil or fish oil with an equal amount of vitamin E, which was carefully prepared to prevent lipid peroxidation before feeding. n-3 Fatty acid content of isolated erythrocyte membranes of rats fed fish oil was significantly higher than that of rats fed safflower

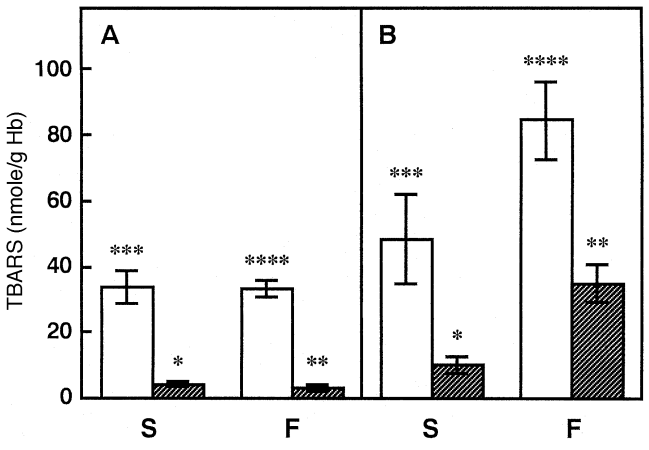

FIG. 4. Contents of TBA-reactive substances (TBARS) in the TBA assay with (striped bars) and without EDTA (open bars) of rat erythrocyte membranes. (A) Membranes of erythrocytes of a rat fed a diet containing S or F; (B) membranes of erythrocytes of a rat fed a diet containing S or F which was oxidized *in vitro* with ADP/Fe(III) at 37°C for 90 min. oil. When lipid peroxidation products, phospholipid hydroperoxides, and TBARS of isolated erythrocyte membranes were determined, the degree of membrane lipid peroxidation of isolated erythrocytes with high n-3 fatty acid content was similar to that of erythrocytes with low n-3 fatty acid content. In the studies on TBARS, great attention was paid to prevent lipid peroxidation under the aerobic conditions of the assay. The assay was always conducted in the presence of antioxidant BHT (32,36), and a modified Ohkawa's method at pH 3.5 with and without EDTA (23,32) was employed. In this study, it is conceivable that water-soluble TBARS in membranes may be released into plasma while in the circulation or into the medium during the isolation of membranes, and such losses could not be determined. However, it seems unlikely that a large amount of water-soluble TBARS was released from membranes because a substantial amount of TBARS in the erythrocyte membranes oxidized *in vitro* stayed in the membranes (Figs. 3B and 4B). Vitamin E in membranes of erythrocytes with high n-3 fatty acid content was slightly decreased when compared with that of erythrocytes with low n-3 fatty acid content, indicating that vitamin E was consumed to prevent lipid peroxidation of n-3 fatty acids during the circulation, as has been suggested in earlier studies (15–22). It was found in this study that the amount of vitamin E supplemented was high enough to prevent lipid peroxidation of erythrocyte membranes in the circulation. The degree of membrane protein aggregation, as assessed by detergent $C_{12}E_8$-insoluble aggregates (24,33) and SDS-PAGE of the aggregates, was similar between erythrocytes with high and low n-3 fatty acid contents. Hence, fish oil supplementation that caused high n-3 fatty acid content in erythrocyte membranes did not cause increased lipid peroxidation and protein aggregation while in the circulation. The results indicate that n-3 fatty acid supplementation did not increase the oxidative damage of circulating rat erythrocyte membranes, which may be reasonably explained by the fact that the oxygen pressure in the rat vasculature is lower than atmospheric. A sufficient supply of vitamin E prevents oxidative damage to erythrocytes with high n-3 fatty acid content in the circulation.

The degree of membrane lipid peroxidation of erythrocytes with high n-3 fatty acid content was increased under aerobic conditions with Fe(III) ion to a higher extent than that of erythrocytes with low n-3 fatty acid content, indicating that the n-3 fatty acid supplementation increased the susceptibility of erythrocyte membranes to lipid peroxidation under aer-

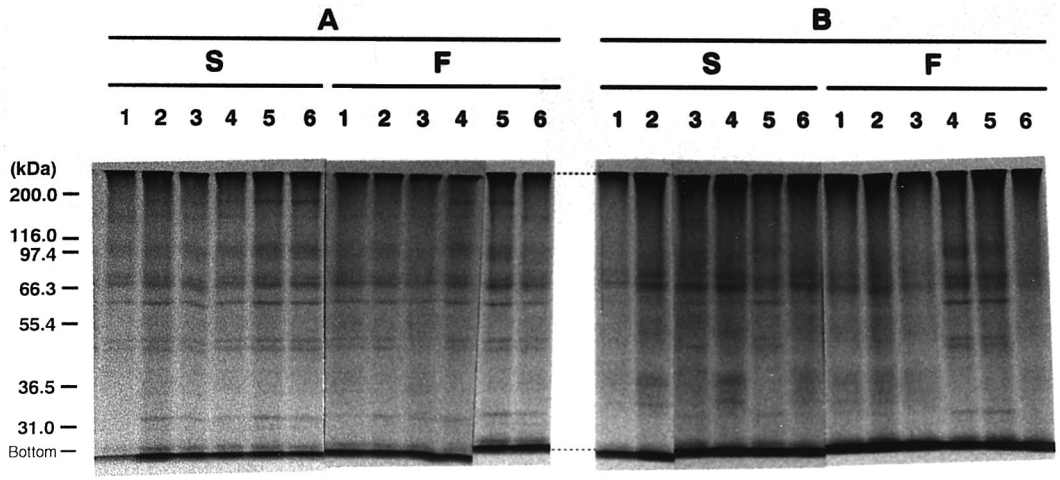

FIG. 6. SDS-polyacrylamide gel electrophoresis of detergent-insoluble protein aggregates in rat erythrocyte membrane. (A) Membranes of erythrocytes of rats fed a diet containing S or F; (B) membranes of erythrocytes of rats fed a diet containing S or F which were oxidized *in vitro* with ADP/Fe(III) at 37°C for 90 min. All the aggregates of six rats of each group were electrophoresed. Bands were visualized by staining with Coomassie brilliant blue R-250. Protein molecular-weight-marker (Iwaki Glass Corporation, Chiba, Japan) was used for indication of the protein positions of molecular weight. For abbreviations see Figure 1.

obic conditions. The amount of vitamin E present in membranes under these conditions may be too small to prevent oxidation of membranes with high n-3 fatty acid content. The increased susceptibility to lipid peroxidation, which was tested under the artificial aerobic conditions, does not reflect the circulation conditions of the erythrocytes *in vivo.* The degree of membrane protein aggregation of erythrocytes with high vs. low n-3 fatty acid content was increased to a similar extent by the *in vitro* oxidation, indicating that oxidative membrane protein aggregation did not correspond to lipid peroxidation, and that lipid peroxidation was not a causative factor for membrane protein aggregation.

Several studies suggesting undesirable effect of dietary n-3 fatty acid intake for humans have appeared. Measurement of human urinary and plasma levels of lipid peroxidation products in relation to increased n-3 fatty acid intake has been carried out. Daily urinary TBARS levels in humans fed a diet containing n-3 fatty acids for 40–50 d are slightly increased (8,9), but the same authors suggested the increase was caused by the lipid peroxidation products formed in food before its consumption (8). The present authors have shown in previous studies that human urinary TBARS levels of each subject eating regular Japanese food exhibited a 1.5–3-fold variation daily and 2–3-fold variation within a day (37), suggesting that the urinary TBARS level is not a good index for lipid peroxidation studies of the whole human body. Several reports show that high intakes of n-3 fatty acids led to increased human plasma TBARS and lipid hydroperoxide levels (10–14). However, in most of these studies (10,11,13) the TBA assay was carried out without addition of BHT, and TBARS could be produced during the aerobic assay procedures. Furthermore, TBARS in serum or plasma are usually very low and could not yet be identified (38). Hackett *et al*. (39) strongly argued that the TBA asssay of plasma is not reliable. By contrast, Kinsella (40) has suggested that intake of n-3 fatty acid preparations which contain vitamin E should not exert any deleterious effects *via* peroxidation when adequate levels of vitamin E are consumed (40).

Studies on experimental animals supplemented with n-3 fatty acids have shown a decrease in vitamin E content and an increased susceptibility to *in-vitro* lipid peroxidation of tissues (15–22). Supplementation of herring oil to rats increased TBARS levels in liver microsomes and susceptibility to *in vitro* lipid peroxidation (19). Supplementation of menhaden oil to rats increased TBARS levels in heart and liver and their susceptibility to *in vitro* lipid peroxidation (20). In most of these previous studies (19–21), the TBA assay was carried out without addition of any antioxidants, and there is a possibility that artifactual lipid peroxidation took place during the assay under aerobic conditions.

In conclusion, n-3 fatty acid supplementation did not affect lipid peroxidation and protein aggregation in rat erythrocyte membrane and may not enhance dynamic oxidative damages of the cells. It is likely that if a sufficient amount of vitamin E is supplied, n-3 fatty acid supplementation does not bring about undesirable effects in relation to lipid peroxidation.

Modification of Milk Formula to Enhance Accretion of Long-Chain n-6 and n-3 Polyunsaturated Fatty Acids in Artificially Reared Infant Rats

Yu-Yan Yeh[a,*], Shaw-Mei Yeh[a], and Eric L. Lien[b]

[a]Department of Nutrition, The Pennsylvania State University, University Park, Pennsylvania 16802, and [b]Wyeth Nutritionals International, Philadelphia, Pennsylvania 19101

ABSTRACT: Artificially reared infant rats were used to determine the effects of long-chain polyunsaturated fatty acid (LCPUFA) supplementation on blood and tissue concentrations of arachidonic acid (AA) and docosahexaenoic acid (DHA). Beginning at 7 d of age, infant rats were fed for 10 d with rat milk formulas supplemented with AA at 0, 0.5 and 1.0%, or supplemented with DHA at 0, 0.5 and 1.0% of total fatty acid. The supplementation of AA increased accretion of the fatty acid in tissue and blood phospholipids with a maximum increase of 9% in brain, 15% in liver, 25% in erythrocytes, and 43% in plasma above the values of unsupplemented infant rats. Rat milk formula containing 1.0% of AA had no added benefits over that containing 0.5% of AA. The supplementation of DHA increased phospholipid DHA by a maximum of 24% in brain, 87% in liver, 54% in erythrocytes, and 360% in plasma above the unsupplemented control. The increase in tissue and blood DHA was concentration-dependent on formula fatty acid. Brain phosphatidylcholine and phosphatidylethanolamine were similarly enriched with AA and DHA by supplementation of the corresponding fatty acids. In general the observed increase of AA was accompanied by a decrease in 16:0, 18:1n-9, and/or 18:2n-6, whereas the increased DHA was associated with a reduction of 18:1n-9, 18:2n-6, and/or 20:4n-6. Clearly, infant rats were more responsive to DHA than AA supplementation, suggesting a great potential of dietary manipulation to alter tissue DHA concentrations. However, the supplementation of DHA significantly decreased tissue and blood AA/DHA ratios (wt%/wt%), whereas there was little or no change in the ratio by AA supplementation. Although the physiological implications of the levels of AA and DHA, and AA/DHA ratios achieved under the present experimental conditions are not readily known, the findings suggest that artificial rearing could provide a suitable model to investigate LCPUFA requirements using various sources of AA and DHA in rats.

Lipids 33, 513–520 (1998).

Long-chain polyunsaturated fatty acids (LCPUFA), especially arachidonic acid (AA, 20:4 n-6) and docosahexaenoic acid (DHA, 22:6n-3) are found in high concentrations in neural tissues and retina (1–3). Although precise functions of LCPUFA are not completely understood, AA and DHA are currently considered essential for growth, development, and maturation of fetuses and infants (4–6). In addition, inadequate DHA level has been associated with impaired visual acuity, learning ability, and neural functions (7–11). Thus, adequate provision of LCPUFA and their precursors to ensure optimal growth and development of infants is obviously critical (6,12).

Human milk, which contains various concentrations of AA and DHA, is the preferred source of LCPUFA (13). Most infant formulas, on the other hand, are devoid of AA and DHA (13), but do contain linoleic acid (LA, 18:2n-6) and α-linolenic acid (LN, 18:3n-3), the precursors of LCPUFA (14). Preterm infants fed commercially available formulas had AA and DHA concentrations in plasma and erythrocytes that were lower than those of breast-fed counterparts (5,15,16). Similar relationships between infant formula feeding and blood LCPUFA levels were noted in full-term infants. Term infants fed conventional formulas were unable to maintain concentrations of blood AA and DHA seen in breast-fed infants during postnatal development (5,15,17–19). Coincident with the difference in plasma and erythrocyte DHA levels, the formula-fed infants had poorer visual acuity, slower information processing ability, and impaired neural functions compared to breast-fed infants (8–12). In an attempt to promote accretion of LCPUFA, DHA in the form of fish oil or LN in vegetable oil has been supplemented to infant formulas (16,18–22). Fish oil added to formula increased DHA in plasma and erythrocytes to a level comparable to that of breast feeding (16,21). Vegetable oil (e.g., soybean oil and canola oil) rich in LN also increased DHA levels in plasma and erythrocytes (10,18,22), and the extent of the increase was inversely related to LA/LN ratios in the diet (14,23). However, the maximum level of DHA achieved by dietary LN fell short of that observed in infants fed fish oil-supplemented formula or breast milk (20,23). Interestingly, the supplementation of DHA or LN in formulas has been shown to improve visual acuity and

Abbreviations: AA, arachidonic acid; AR, artificial rearing; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; LA, linoleic acid; LN, α-linolenic acid; LCPUFA, long-chain polyunsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; RMF, rat milk formula.

neural functions to various degrees (10,12,19), although such benefits were not observed in other studies (22,24,25). It should be stressed that fish oil supplementation resulted in a reduction of AA in blood which was accompanied by growth retardation of preterm infants (26). Nonetheless, when fish oil high in DHA but low in eicosapentaenoic acid (EPA, 20:5n-3) was used in formula supplementation, no such adverse effects on blood AA concentration and growth were observed (9,16).

Despite these observations there are concerns about the usefulness of fish oil to provide DHA for infants because of the potential deleterious effect of EPA (3). EPA may compete with AA for production of different series of prostaglandins and leukotrienes leading to metabolic abnormalities (27). The present study was therefore undertaken to test the use of microbial oils rich in either AA or DHA but devoid of EPA as sources of LCPUFA for infant rats. To this end, an artificial rearing (AR) model of infant rats was used throughout the study. The postnatal brain growth spurt in rats corresponds to the rapid growth of human brain during the perinatal period (28). Thus, the AR infant rats provide a useful model to study brain metabolism and development of preterm infants. One of the major advantages of the AR model is the precise control of quantity and composition of milk formula provided to each pup (29). Moreover, the model has been proven suitable for studying metabolic consequences or nutrient requirements of neonates by altering the composition and amount of milk (29–31). The results demonstrated that supplementation of AA and DHA was effective in enriching the respective fatty acids in blood and tissue phospholipids.

MATERIALS AND METHODS

Animals and artificial rearing. Pathogen-free pregnant Sprague-Dawley rats at 14 d of gestation were purchased from Harlan Sprague-Dawley (Indianapolis, IN) and housed in individual plastic containers. They were fed *ad libitum* a nonpurified diet (Purina Rat Chow, Ralston Purina, St. Louis, MO) and had access to water at all times. For each study, newborns from four pregnant rats were delivered naturally, culled to 10 pups per dam within 12 h of birth, and were nourished by their dams until the beginning of AR. At 7 d of age, one to two weight-matched rat pups from each litter were assigned to one of three AR groups. In Study 1, the pups were fed rat milk formulas (RMF) that contained 0, 0.5, or 1.0% AA as total fatty acids by weight. In Study 2, the pups received RMF which contained 0, 0.5, or 1.0% DHA. Ten of the remaining pups comparable to those in the AR groups were assigned to one of the four dams. They were suckled by the dam throughout the lactating period and were used as models for growth rates. For artificial feeding, infant rats were anesthetized with diethyl ether for 90 s in a chamber for the purpose of permanent placement of intragastric cannulas using the nonsurgical technique of Hall (32). The cannulas were connected to plastic syringes on an infusion pump for automatic feeding for 15 min each hour (30). All pups were weighed daily, and AR care was provided, including antiseptic dressing, cleansing of the perianal area, and stimulation to eliminate (30). The daily milk intake of artificially reared rats was adjusted to match the growth rate of the mother-reared pups. The animal protocol was reviewed and approved by The Pennsylvania State University Animal Care and Use Committee.

RMF. RMF were prepared essentially according to the method of Auestad *et al*. (33). The formulas were modified from RMS-2A formula and were composed of carbohydrate, protein, fat, vitamins, and minerals that closely resembled those of rat milk (33). All formulas contained 11.8% fat (w/w) consisting of fat from milk formula base (3.4%), medium-chain triglyceride (2.0%), and corn oil (microbial oil + corn oil = 6.4%) (30). Microbial oils (Martek Bioscience, Columbia, MD) provided sources of n-6 and n-3 LCPUFA. Microbial oil A (triglyceride oil produced by *Mortierella alpina*) contained 17.7% AA, 16.3% 16:0, 15.1% 18:0, 23.4% 18:1n-9, 11.5% 18:2n-6, and small percentages of other fatty acids, but no DHA and EPA. Microbial oil B (triglyceride oil produced by *Crypthecodinium cohnii*) contained 41.9% DHA, 15.5% 14:0, 19.1% 16:0, 13.8% 18:1n-9, and small percentages of other fatty acids, but no AA and EPA. In Study 1, microbial oil A was added at the expense of corn oil to make RMF variations in AA concentrations of 0, 0.5, or 1.0%. Microbial oil B was used in Study 2 to prepare formulas containing 0, 0.5, or 1.0% DHA. All RMF were degassed with nitrogen and allocated for storage at −20°C. The formulas were rehomogenized daily before feeding.

Lipid extraction and fatty acid analysis. Infant rats were artificially fed for 10 d. At 17 d of age, the pups were anesthetized with pentobarbital (Anpro Pharmaceutical, Arcadia, CA) (5 mg/100 g body weight) for collection of blood by cardiac puncture. Livers and brains were excised, rinsed in 0.9% NaCl, blot-dried on filter paper, frozen in liquid nitrogen, and then stored at −80°C for subsequent lipid analysis. Plasma and erythrocytes were prepared by centrifugation and wash procedures described previously (34).

For analyses of fatty acids, lipid extracts were prepared from plasma, erythrocytes, brain, and liver according to the extraction procedures of Folch *et al.* (35), using chloroform/methanol (2:1, vol/vol) containing 50 μg butylated hydroxytoluene as the antioxidant. Lipid extracts were then subjected to thin-layer chromatographic separation of lipid classes using silica G plates and a hexane/ethyl ether/acetic acid (80:20:1, by vol) solvent (36). The phospholipid band remaining at the origin of the plate was scraped into an ampule for transmethylation by using 12% boron trifluoride in methanol (wt/vol) (37). The methylated fatty acids were analyzed by gas chromatography (Model 5980 Series II; Hewlett-Packard, Palo Alto, CA) equipped with an SP-2330 fused-silica capillary column (30 m × 0.25 mm i.d., 20 μm film; Supelco, Bellefonte, PA) and a flame-ionization detector. The gas chromatographic conditions were the same as those described elsewhere (38). For fatty acid analysis of phospholipid species, the lipid extracts were separated into phosphatidylcholine (PC) and phosphatidylethanolamine (PE) by thin-layer chromatography using silica G plates and a solvent mixture of chloro-

form/methanol/petroleum ether (bp 35–60°C)/acetic acid /boric acid (40:20:30:10:1.8; vol/vol/vol/vol/wt) as described in a previous study (39). The isolated individual phospholipids were transmethylated and analyzed by gas chromatography (38). Fatty acid proportions were expressed as wt% of total fatty acid. The absolute content of individual fatty acids was measured by the addition of free heptadecanoic acid as an internal standard prior to transmethylation (34).

Statistical analysis. Data are expressed as means ± SD. The significant difference in comparing three dietary treatments was analyzed by one-way analysis of variance. Tukey's pairwise comparisons (40) using Minitab Statistical software (Minitab, State College, PA) was applied to determine where the difference existed.

RESULTS

Artificially reared infant rats grew at the same rate as the mother-reared counterparts. At the onset of the artificial feeding on day 7 of life, mean body weight for three groups of infant rats fed AA- supplemented formulas were 15.5 ± 1.0 g, 16.0 ± 1.1 g, and 15.7 ± 1.0 g compared with 15.3 ± 0.8 g for mother-reared offspring. After 10 d of feeding (i.e., at 17 d of age) the mean body weights of 28.7 ± 1.7 g, 29.0 ± 0.8 g, and 29.1 ± 2.0 g were not different from 29.6 ± 1.4 g of the mother-reared infant rats with the same age. Similarly, there was no difference in body weight between a mother-reared and artificially reared infant rats before and after the feeding of DHA-supplemented formulas.

Fatty acid analyses of RMF revealed that the actual weight percentage of AA (i.e., 0, 0.46, and 0.93%) and DHA (i.e., 0, 0.51, and 0.94%) in the formulas were close to the targeted levels of 0, 0.5, and 1.0% (Table 1). There was no difference in other fatty acids among the three formulas supplemented with DHA. Similarly, the wt% of other fatty acids were maintained constant except stearic acid (18:0) in the AA-supplemented formulas. All formulas contained medium-chain fatty acids (i.e., 8:0 and 10:0), although they were lower in DHA-supplemented than AA-supplemented formulas. Overall, the unsupplemented formulas contained major fatty acids, except 18:3n-3, similar to those of rat milk from various sources compiled by Auestad *et al*. (33). The absence of 18:3n-3 in the present formulas was designed to minimize the contribution of n-3 LCPUFA by endogenous synthesis.

The first series of experiments determined the effects of AA supplementation on blood and tissue fatty acid composition of phospholipids. As shown in Table 2, AA supplemented at 0.5 and 1.0% increased AA equally in plasma by 35–43% above the level of unsupplemented formula. The increases were accompanied by a lower weight percentage of 16:0 and 18:1n-9 than that of unsupplemented. The concentrations of DHA in plasma were not altered by AA supplementation. The AA supplementation also enriched the AA level in erythrocytes by 20–25% as compared with control unsupplemented infant rats, but lowered the weight percentages of 16:0, 18:0, and 18:1n-9. The erythrocyte DHA level was higher in supplemented than unsupplemented animals.

In the brain, the weight percentage of AA in phospholipids was 9% higher in the AA-supplemented groups at either 0.5 or 1.0% AA than in the unsupplemented group (Table 3). There were slight, but significant reductions in DHA by the two levels of AA supplementation. The weight percentages of 18:2n-6, 22:4n-6, and 22:5n-6 were lower in 0.5% AA-supplemented than in unsupplemented infant rats. All other brain fatty acids remained unchanged. The weight percentages of AA in liver phospholipids of infant rats fed supplemented formulas (both at 0.5 and 1.0%) were 10–15% higher than the control (Table 3). AA supplementation had no effect on weight percentage of liver DHA or other fatty acids. Brain PE contained markedly higher concentrations of AA and DHA than PC (Table 4). AA supplementation increased AA accretion in both phospholipid species with greater percentages increases in PC (i.e., 21–25% above the control) than those in PE (i.e., 5–8% above the control). The AA supplementation did not alter weight percentages of brain DHA, 16:0, 18:0, and 18:1n-9, but lowered 18:2n-6 and increased 22:4n-6 and 22:5n-6 in PC. In PE, the increase in weight percentage of AA was accompanied by a reduction in 16:0 and 18:0 when the

22:5n-6	—	—	—	1.7 ± 0.2[a]	2.3 ± 0.3[b]	2.3 ± 0.5[b]
22:6n-3	2.3 ± 0.5	2.8 ± 0.8	2.4 ± 0.3	4.5 ± 0.4[a]	6.2 ± 1.0[b]	6.4 ± 1.1[b]
AA/DHA	3.3 ± 0.8[a]	3.7 ± 1.0[a,b]	4.4 ± 0.7[b]	4.0 ± 0.2	3.6 ± 0.5	3.6 ± 0.5

[a]Values (wt%) are means ± SD for four samples. Fatty acids included only major saturated and unsaturated (n-9, n-6, and n-3) species, and hence did not add up to 100%. Values for plasma or erythrocyte with different superscript roman letters in the same row are significantly different at $P < 0.05$. For abbreviations see Table 1.

formula was supplemented with 1.0% AA. The weight percentage of DHA was not affected, but the weight percentages of 22:4n-6 and 22:5n-6 were slightly increased by the AA supplementation. Consequent to the AA supplementation, AA/DHA ratios were increased in plasma and brain total phospholipids but were not changed in erythrocyte and liver total phospholipids or in brain PC and PE (Tables 2–4).

In the second series of experiments, RMF supplemented with DHA were fed to artificially reared infant rats. The supplementation of DHA markedly increased accretion of DHA in plasma phospholipids to 2.7–4.6-fold of the unsupplemented level (Table 5). The increase in DHA was accompanied by reduction of 18:0 (4–10 wt%), 18:1n-9 (13–16 wt%), and 16:0 (11 wt% only at high DHA-supplemented group). The weight percentage of plasma AA was not affected by the supplementation. Erythrocyte DHA levels were 27–54% higher in infant rats fed formula supplemented with DHA than the control (Table 5). There was a concomitant reduction in weight percentages of 18:2n-6 (5–8%) and AA (7–13%). No other fatty acids were affected by the DHA supplementation.

The supplementation of DHA also enhanced the accretion of DHA in tissue phospholipids. In the brain, weight percentages of DHA of the supplemented animals were 20–24% higher than those of unsupplemented counterparts (Table 6). Brain AA, 16:0, 18:0, and 18:2n-6 levels were not changed by DHA supplementation, but there were significant decreases in weight percentages of 18:1n-9 and 22:4n-6. Liver phospholipid DHA levels were highly enriched by the DHA supplementation (Table 6). In the supplemented groups, weight percentages of DHA were 45–81% higher than those of unsupplemented infant rats. On the other hand, the weight percentages of 18:1n-9 and 18:2n-6 were lower in the supplemented than in the unsupplemented group. There were no differences in AA, 16:0, and 18:0 among the groups. A similar trend of changes in fatty acid composition of brain PC and PE was noted. In PC, DHA supplementation increased weight percentages of DHA by 17–33% with little changes in the other fatty acids (Table 7). The enrichment of DHA in PE was more pronounced than in PC and was accompanied by slight but significant reduction in 18:1n-9, 18:2n-6, AA and 22:4n-6.

The supplementation of DHA in formulas reduced AA/DHA ratios in blood and tissues. This reduction resulted from increased DHA together with either decreased or unchanged AA. The most pronounced decrease in the ratio was seen in plasma, followed by erythrocyte phospholipids. The ratios decreased from 8:1 in the control to 3:1 and 2:1 in the supplemented groups in plasma, and from 6:1 in the control

AA/DHA	3.2 ± 0.2	3.4 ± 0.5	3.4 ± 0.5	1.0 ± 0.1	1.0 ± 0.1	1.0 ± 0.1

[a]Values (wt%) are means ± SD for four samples. Fatty acids included only major saturated and unsaturated (n-9, n-6, and n-3) species, and hence did not add up to 100%. Values for each phospholipid with different superscript roman letters in the same row are significantly different at $P < 0.05$. For abbreviations see Table 1.

to 4:1 and 3:1 in the supplemented infant rats in erythrocytes (Table 5). The ratios in the liver decreased from the unsupplemented 4:1 to 3:1 and 2:1 in the supplemented groups (Table 6). There was slight but significant reduction of the ratios in brain total phospholipids, PC, and PE (Tables 6 and 7).

The increased weight percentages of AA and DHA in tissue and blood resulting from the supplementation of the corresponding AA and DHA in milk formulas led to significant changes in the absolute amounts of the fatty acids. In infant rats who received unsupplemented formula, absolute amount of total fatty acids in phospholipids of plasma was 1.03 ± 0.86 mg/mL, of erythrocytes 0.52 ± 0.05 mg/mL, of brain 9.03 ± 0.57 mg/g, and of liver 2.97 ± 0.33 mg/g. The concentrations were not altered in those fed formulas supplemented with either AA or DHA.

DISCUSSION

Long-chain polyunsaturated fatty acids, especially DHA, have been suggested as conditionally essential and should be provided to infants (41,42). Although infants are capable of desaturation and elongation of LN and LA to form DHA and AA, respectively (14,43), the synthesis may not be sufficient to meet AA and DHA requirements during the rapid phase of growth and development in infants (20,23,43). Supplementation of DHA in formula has been proven effective in enriching and maintaining DHA levels in the circulation to levels that are achieved by breast-feeding (16,19–21). More importantly, the supplementation of DHA improved visual function to a greater extent than LN supplementation in preterm infants (44,45). However, the effectiveness of LN supplementation in improving visual acuity is controversial. Makrides *et al.* (46) and Jorgensen *et al.* (11) have independently demonstrated that infants fed formulas with LN levels as high as or higher than human milk had lower visual acuity than that of breast-fed counterparts. To the contrary, most recent studies of Auestad *et al.* (22) and Innis *et al.* (24,25) showed that there was no difference in visual acuity in infants fed either breast milk or formula containing LN. Clearly, the benefits of n-6 and n-3 fatty acid supplementation require further investigation. In this context, it is pertinent to point out that supplementation of DHA from various sources has been extensively investigated in human infants (12,16,18,22), and newborn animals (30,47–49). The present study was designed to evaluate the potential use of Microbial oil A, rich in AA but devoid of DHA and EPA, and Microbial oil B, rich in DHA but devoid of AA and EPA, to enrich LCPUFA in infant rats.

The results clearly demonstrated that supplementation of

18:2n-6	1.7 ± 0.1	1.8 ± 0.1	1.7 ± 0.1	16.8 ± 0.9a	15.4 ± 1.5^{a,b}	14.3 ± 0.7^{b}
20:4n-6	12.2 ± 0.6	13.3 ± 0.9	13.3 ± 0.6	16.0 ± 0.5	16.3 ± 1.2	17.3 ± 1.5
22:4n-6	0.2 ± 0.01^{a}	0.2 ± 0.01^{b}	0.1 ± 0.1^{b}	0.8 ± 0.01	0.7 ± 0.1	0.9 ± 0.2
22:5n-6	1.2 ± 0.03	1.2 ± 0.1	1.2 ± 0.01	0.9 ± 0.3	1.2 ± 0.4	1.1 ± 0.8
22:6n-3	8.8 ± 0.9^{a}	10.6 ± 0.7^{b}	10.9 ± 0.8^{b}	4.2 ± 0.1^{a}	6.1 ± 0.1^{b}	7.6 ± 1.0^{c}
AA/DHA	1.4 ± 0.1^{a}	1.3 ± 0.02^{b}	1.2 ± 0.1^{b}	3.9 ± 0.2^{a}	2.7 ± 0.2^{b}	2.3 ± 0.4^{b}

[a]Values (wt%) are means ± SD for four samples. Fatty acids included only major saturated and unsaturated (n-9, n-6, and n-3) species, and hence did not add up to 100%. Values for each tissue with different superscript roman letters in the same row are significantly different at $P < 0.05$. For abbreviations see Table 1.

AA increased accretion of the fatty acid in total phospholipids of plasma, erythrocytes, brain and liver (Tables 2, 3). Similar increases in brain PE and PC were observed (Table 4). The extent of increase of AA, however, was relatively small, ranging from ≤9% for brain, ≤15% for liver, ≤25% for erythrocytes, to ≤43% for plasma above the values of the infant rats fed unsupplemented formula. Furthermore, an increase in AA content from 0.5 to 1.0% in milk formulas did not further increase tissue and blood accretion of AA. The increase of AA in most cases was accompanied by a decrease in 18:2n-6, 18:1n-9, and/or 16:0. DHA provided in milk formulas was effective in enriching the fatty acid in the circulation and tissues (Tables 5–7), and the extent of the increase above the control was greater than that of AA enrichment. Phospholipid DHA was increased up to 360% in plasma, 87% in liver, 54% in erythrocytes, and 24% in brain above that of the unsupplemented group. There was a concomitant reduction of 18:1n-9, 18:2n-6, and/or 20:4n-6 associated with these changes. Moreover, the accretion of DHA increased with increasing DHA content in milk formulas in almost all tissue and blood phospholipids. The reason for the different degree of enrichment between AA and DHA is not known. Contrary to LA and LN, both AA and DHA are not readily oxidized for energy (7). Instead, they are mostly esterified to glycerolipids (50). Therefore, the competition between β-oxidation and incorporation into complex lipids may not explain the difference. It is possible that phospholipids in various blood components and tissues are initially saturated with AA more than DHA, and the degree of saturation may determine the incorporation of LCPUFA into phospholipids. This notion is supported by the facts that weight percentages of AA are higher than weight percentages of DHA in plasma, erythrocytes, brain, and liver of unsupplemented infant rats. Thus, the data indicate that infant rats are more responsive to dietary supplementation of DHA than AA, suggesting a great potential of dietary manipulation to alter tissue DHA concentrations.

Coinciding with the disproportionate incorporation of dietary AA and DHA into tissues and blood, DHA supplementation significantly decreased the ratio of AA/DHA, whereas there was little or no change in the ratio by AA supplementation. Although the beneficial effects of DHA enrichment on retinal and neural functions have been widely recognized (7–9), the consequences of the decrease in AA/DHA ratio resulting from DHA supplementation is not known. It is reasonable to hypothesize that a decrease in the ratio may be deleterious to infant growth as has been shown by Carlson

TABLE 7
Fatty Acids of Brain Phosphatidylcholine and Phosphatidylethanolamine in Infant Rats Fed Formulas Supplemented with DHA[a]

	Phosphatidylcholine[a]			Phosphatidylethanolamine[a]		
Fatty acid	0% DHA	0.5% DHA	1.0% DHA	0% DHA	0.5% DHA	1.0% DHA
16:0	60.2 ± 0.1^{a}	61.2 ± 0.4^{b}	59.7 ± 0.6^{b,c}	7.7 ± 0.3	7.8 ± 0.2	7.4 ± 0.4
18:0	10.0 ± 0.2	9.8 ± 0.4	9.5 ± 0.7	28.2 ± 0.7	27.6 ± 0.6	27.9 ± 1.0
18:1n-9	17.7 ± 0.3^{a}	17.3 ± 0.2^{a,b}	16.9 ± 0.6^{b}	7.9 ± 0.5^{a}	7.5 ± 1.0^{a,b}	6.6 ± 0.5^{b}
18:2n-6	1.6 ± 0.1^{a}	1.4 ± 0.01^{b}	1.6 ± 0.1^{a,b}	1.8 ± 0.5^{a}	1.7 ± 0.7^{a}	1.0 ± 0.1^{b}
20:4n-6	3.7 ± 0.1^{a}	3.4 ± 0.1^{b}	4.3 ± 0.6^{c}	24.0 ± 0.4^{a}	22.9 ± 0.4^{b}	22.5 ± 0.6^{b}
22:4n-6	0.3 ± 0.01	0.3 ± 0.02	0.3 ± 0.1	6.9 ± 0.1^{a}	6.4 ± 0.3^{b}	6.4 ± 0.1^{b}
22:5n-6	0.5 ± 0.1	0.5 ± 0.1	0.4 ± 0.1	2.1 ± 0.1	2.2 ± 0.1	2.1 ± 0.1
22:6n-3	1.2 ± 0.6^{a}	1.4 ± 0.6^{b}	1.6 ± 0.6^{c}	18.7 ± 1.2^{a}	21.9 ± 1.2^{b}	24.0 ± 1.5^{c}
AA/DHA	3.1 ± 0.1^{a}	2.4 ± 0.1^{b}	2.7 ± 0.2^{b}	1.3 ± 0.1^{a}	1.1 ± 0.1^{b}	0.9 ± 0.1^{c}

[a]Values (wt%) are means ± SD for four samples. Fatty acids included only major saturated and unsaturated (n-9, n-6, and n-3) species, and hence did not add up to 100%. Values for each phospholipid with different superscript roman letters in the same row are significantly different at $P < 0.05$. For abbreviations see Table 1.

et al. (26), who found that preterm infants fed formula supplemented with fish oil had increased DHA and decreased AA levels of plasma and erythrocytes which were accompanied by poor growth. Therefore, any attempt to increase accretion of LCPUFA must take into consideration the balance between n-3 and n-6 fatty acids. Whether this can be achieved by simultaneous supplementation of AA and DHA is currently under investigation.

It is worth noting that, although supplementation of DHA consistently enriched the fatty acids in blood and tissues, the degree of enrichment of DHA in plasma and erythrocytes was markedly higher than that of brain total phospholipids, PE, and PC. If one examines the adequacy of DHA accretion in brain, the levels of fatty acid determined in plasma or erythrocytes may not serve as a completely accurate index. This notion is in agreement with a recent suggestion by Innis (41) that AA and DHA in circulating lipids are not a good index of organ LCPUFA status. Since circulating lipid, especially erythrocyte phospholipid AA and DHA, has been widely used to reflect LCPUFA status in infants (41,51,52), further studies to establish the validity for use of erythrocyte lipids are warranted.

Despite the significant increase in accretion of AA and DHA in brain phospholipids, it is not known whether the levels achieved under the present experimental conditions are adequate for growth and development since optimal concentrations of LCPUFA have not been established (7). The requirements of AA and DHA for infants, estimated from either milk fatty acid composition or infant blood lipid profile, have been suggested but none has been agreed on (7). The present study shows that an AR system using AA and DHA derived from microbial sources for supplementation may provide a useful model to establish LCPUFA requirements for infants.

ABSTRACT: The effects of conjugated linoleic acid (CLA) on the levels of chemical mediators in peritoneal exudate cells, spleen and lung, and the concentration of immunoglobulins in mesenteric lymph node and splenic lymphocytes and in serum were examined in rats. After feeding diets containing either 0 (control), 0.5 or 1.0% CLA for 3 wk, there was a trend toward a reduction in the release of leukotriene B_4 (LTB_4) from the exudate cells in response to the dietary CLA levels. However, CLA did not appear to affect the release of histamine. A similar dose-response pattern also was observed in splenic LTB_4, lung LTC_4 and serum prostaglandin E_2 levels, and the differences in these indices between the control and 1.0% CLA groups were all statistically significant. The reduction by CLA of the proportions of n-6 polyunsaturated fatty acids in peritoneal exudate cells and splenic lymphocyte total lipids seems to be responsible at least in part for the reduced eicosanoid levels. Splenic levels of immunoglobulin A (IgA), IgG, and IgM increased while those of IgE decreased significantly in animals fed the 1.0% CLA diet. This was reflected in the serum levels of immunoglobulins. The levels of IgA, IgG, and IgM in mesenteric lymph node lymphocytes increased in a dose-dependent manner, while IgE was reduced in those fed the higher CLA intake. However, no differences were seen in the proportion of T-lymphocyte subsets of mesenteric lymph node. These results support the view that CLA mitigates the food-induced allergic reaction.
Lipids 33, 521–527 (1998).

Conjugated linoleic acid (conjugated derivatives of linoleic acid, CLA) exerts diverse physiological effects most of which are favorable to human health. A range of studies has shown a marked alleviating effect of CLA on mammary carcinogenesis (1–4). The mechanism underlying this effect is not yet well understood (5), but continued intake of CLA is not necessarily required for suppression of carcinogenesis (6,7). When considering the diverse effects of CLA, it is reasonable that eicosanoids are involved in the mechanism. The influence of CLA on the metabolic processes leading from linoleic acid to arachidonic acid and, hence, eicosanoids appears to be related to their desirable effects, since CLA tended to reduce the tissue level of prostaglandin E_2 (PGE_2), a putative candidate for a cancer-promoting effect of dietary n-6 polyunsaturated fatty acids (PUFA) (8). In addition, there is a possibility that CLA itself serves as substrate of enzymatic systems for eicosanoid production, as it is shown to undergo desaturation and elongation similar to linoleic acid (9), although it is unknown whether these metabolites could be converted to eicosanoids.

Since the food allergic reaction can readily be modified by the type of dietary PUFA, either n-6 or n-3 (10,11), it is interesting to know if CLA could modify it. The clinical symptom of food allergy is induced by the production of chemical mediators such as histamine and leukotriene (LT) and PG triggered by allergen-specific immunoglobulin (Ig)E (12,13). Our previous studies showed a reduction by CLA of the serum PGE_2 level (8), which is one of the typical chemical mediators in the allergic reaction (12,13). In this context, Belury and Kempa-Steczko (14) showed that CLA reduces the proportion of linoleic acid dose-dependently in hepatic phospholipid and suggested this may result in modified arachidonate-derived eicosanoid production by extrahepatic tissues. More recently, Wong *et al*. (15) reported that CLA modulates certain aspects of the immune defense such as lymphocyte proliferation in mice, although the effect was not always reproduced possibly because of the dependence on the duration of the feeding period. In the present study, we measured the production of chemical mediators and the level of Ig in rats fed different levels of CLA, either 0.5 or 1.0%.

MATERIALS AND METHODS

Preparation of CLA. CLA was prepared according to the method described by Ip *et al*. (16). In brief, 50 g of linoleic acid, purity >99% (Sigma Chemical Co., St. Louis, MO) was dissolved in 290 g of ethylene glycol containing 15 g of NaOH and heated at 180°C for 2 h under nitrogen. After cooling to room temperature, the content was adjusted to pH 4 and extracted with *n*-hexane. The hexane layer was washed with 5% NaCl, dehydrated with 3-A molecular sieves (Nacalai

Abbreviations: CLA, conjugated linoleic acid; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; LT, leukotriene; MLN, mesenteric lymph node; PEC, peritoneal exudate cells; PG, prostaglandin; POD, peroxidase; PUFA, polyunsaturated fatty acid.

Tesqu, Kyoto, Japan) and dried in a rotary evaporator under nitrogen. The purity of CLA was measured by gas–liquid chromatography (Shimadzu GC-17A, Kyoto, Japan) using a Supelcowax 10 column (0.32 mm × 60 m, film thickness, 0.25 μm; Supelco Inc., Bellefonte, PA). Column temperature was raised from 150 to 220°C at a rate of 4°C/min. The identification of peaks was carried out by the equivalent chain length method (17) and gas chromatography–mass spectrometry (Jeol Auto MS 50, Tokyo, Japan). The purity of CLA preparation was 80.7% with the following composition in percentage: 9*c*,11*t*/9*t*,11*c*, 29.8; 10*t*,12*c*, 29.6; 9*c*,11*c*, 1.3; 10*c*,12*c*, 1.4; 9*t*,11*t*/10*t*,12*t*, 18.6; linoleic acid, 5.6; and others, 13.7.

Animals and diets. The animal experiment adhered to the Kyushu University guidelines for the care and use of laboratory animals. Male, 4-wk-old Sprague-Dawley rats were obtained from Japan Charles River (Atsugi, Japan) and housed individually in a room with controlled temperature and light (20–23°C and lights on 0800–2000 h). After acclimation for 4 d, rats were divided into three groups of 10 rats which were given free access to the experimental diets. The diets were prepared according to the recommendation of the American Institute of Nutrition (AIN-93G diet) (18). The basal diet contained the following ingredients, in g/100 g diet: cornstarch 39.8; casein, 20.0; dextrinized cornstarch, 13.2; sucrose, 10.0; soybean oil, 7.0; AIN-93 mineral mixture, 3.5; AIN-93 vitamin mixture, 1.0; L-cystine, 0.3; choline bitartrate, 0.25; cellulose, 5.0; *tert*-butylhydroquinone, 0.002; and either linoleic acid, 1.0; linoleic acid (Control) and CLA, 0.5 and 0.5; or CLA, 1.0. Thus, LA or CLA was added at the expense of soybean oil in the AIN-93G diet. The fatty acid composition calculated from the composition of individual oils is given in Table 1. Body weight and food intake were recorded every other day. After 3 wk of feeding, five rats were used for collection of the exudate cells and the remaining five rats for other analyses. Blood was withdrawn from the abdominal aorta under light diethyl ether anesthesia and tissues were immediately excised.

Preparation of peritoneal exudate cells (PEC). The method described by Matsuo *et al.* (19) was adopted for the preparation of PEC. Tyrode buffer, consisting of 137 mM NaCl, 2.7 mM KCl, 0.4 mM $NaH_2PO_4 \cdot 2H_2O$, 1 mM $MgCl_2 \cdot 6H_2O$, 12 mM $NaHCO_3$, 1.8 mM $CaCl_2 \cdot 2H_2O$, 5.6 mM D-glucose and 0.1% bovine serum fraction V (Boehringer Mannheim GmbH, Mannheim, Germany), pH 7.4, was injected into the rat peritoneal cavity (6 mL/100 g body weight), and the abdomen was gently massaged for 2 min. Then, the cavity was opened, and the buffer containing PEC was recovered with a plastic pipet. The fluid was centrifuged at 200 × *g* for 5 min at 4°C. The supernatant was discarded and the cell pellet was resuspended in Tyrode buffer.

TABLE 1
Fatty Acid Composition of Dietary Fat[a]

	Group		
Fatty acid	Control	0.5% CLA	1.0% CLA
16:0	9.1	9.0	9.0
18:0	3.2	3.42	3.2
18:1	20.4	20.3	20.1
CLA	—	6.4	12.9
18:2	59.7	53.6	47.4
18:3	7.5	7.5	7.4

[a]Fatty acid composition was calculated from the composition of individual component fats, soybean oil, linoleic acid, and conjugated linoleic acid (CLA).

Measurement of leukotriene B_4 (LTB_4) and histamine. LTB_4 was measured as described elsewhere (20–22). PEC (2×10^6 cells) were suspended in Tyrode buffer containing 5 mM calcium ionophore A23187 (Sigma Chemical Co.). After incubating for 20 min at 37°C, 50 mL of the acetonitrile/methanol mixture (6:5, vol/vol) and 50 ng of PGB_2 (Sigma Chemical Co.), as the internal standard, were added. The mixture was kept at −20°C for 30 min and then centrifuged at 1,000 × *g* for 10 min. The supernatant was filtered through a 4-GV 0.22 μm filter (Millipore Corp., Tokyo, Japan). LTB_4 was measured by reversed-phase high-performance liquid chromatography (HPLC) (SCL-10A; Shimadzu Co., Kyoto, Japan) equipped with an ODS-A column (150 × 6.0 mm, 5 μL particle size; YMC, Kyoto, Japan). A mixture of acetonitrile/methanol/water (30:25:45, by vol) containing 5 mM CH_3COONH_4 and 1 mM disodium EDTA, pH 5.6, was used as a mobile phase with a flow rate of 1.1 mL/min. LTB_4 and PGB_2 were detected by absorbance at 280 nm (SPD-10A; Shimadzu Co.). Quantitation of LTB_4 was achieved by comparing the peak area of LTB_4 with that of PGB_2. Histamine content in the culture supernatant was measured fluorometrically (19,23). The intracellular content of histamine also was measured after disrupting the cells by sonication.

Preparation of spleen and mesenteric lymph node (MLN) lymphocytes. Spleen and MLN were excised immediately after withdrawing blood from the aorta, and the tissues were immersed in RPMI 1640 medium (Nissui Pharmaceutical Co., Tokyo, Japan) (24,25). The lymphocytes were rinsed three times with the RPMI 1640 medium and filtered to remove tissue scum. To remove fibroblasts, cell suspension was incubated for 30 min at 37°C. Then, 5 mL of the resulting cell suspension was layered on 4 mL of Lympholyte-Rat (Cedarlane, Hornby, Canada) and centrifuged at 1,500 × *g* for 30 min. The lymphocyte band at the interface was recovered, and the cells were rinsed again. The lymphocytes were cultured in 10% fetal bovine serum (Intergen, Purchase, NY) in RPMI 1640 medium at a cell density of 2.5×10^6 cells/mL with or without 2.5 μg/mL of lipopolysaccharide (Bacto lipopolysaccharide B, *Escherichia coli* 026:B6; Difco Laboratories, Detroit, MI). After incubation at 37°C for 24 and 72 h, the concentrations of IgA, IgG, IgM, and IgE were measured by an enzyme-linked immunosorbent assay (ELISA) (26).

T-cell population analysis. Spleen and MLN lymphocytes were analyzed as $CD4^+$- and $CD8^+$-cells by using fluorescein-labeled mouse anti-CD4 (W3/25, mouse IgG1) or phycoerythrin-labeled mouse anti-CD8 (MRC OX-8, mouse IgG1) (both from Serotec Ltd., Kidlington, Oxford, United King-

dom) (23,25). The stained lymphocytes were fixed with 2% paraformaldehyde and analyzed with the EPICS Profile II flowcytometer (Coulter Electronics Ltd., Luto, United Kingdom).

Measurement of serum and culture supernatant Ig by ELISA. Measurements of total Ig were executed using sandwich ELISA methods (24,25). Goat anti-rat IgE, rabbit anti-rat IgG (Fab')2, goat anti-rat IgM (all from Biosoft, Paris, France), and mouse anti-rat IgA (Zymed Lab, San Francisco, CA) were used to fix respective Ig. These antibodies were diluted 1,000 times with 50 mM carbonate-bicarbonate buffer (pH 9.6), and each well of 96-well plates was treated with 100 µL of the solution for 1 h (2 h for IgA) at 37°C. After blocking with 300 µL of the blocking solution overnight at 4°C, each well was treated with 100 µL of the diluted serum or culture supernatant for 1 h (2 h for IgA) at 37°C. Bound IgA was detected by reacting stepwise with 100 µL of peroxidase (POD)-conjugated rabbit anti-rat IgA (1,000 times dilution; Zymed) at 37°C for 2 h, IgG with 100 µL of POD-conjugated rabbit anti-rat IgG (Fab')2 (2,000 times dilution; Cappel, West Chester, PA), and IgM with 100 µL of POD-conjugated goat anti-rat IgM (1,000 times dilution, Cappel) at 37°C for 1 h. Wells were rinsed three times with Tween 20 in phosphate-buffered saline between each step. After incubation at 37°C for 15 min with 100 µL of 1.5% oxalic acid, absorbance at 415 nm was measured with an MPR-A4i ELISA reader (Tosoh, Tokyo, Japan). The bound IgE was detected by reacting with biotin-conjugated mouse anti-rat IgE (2,000 times dilution; Betyl, Montgomery, TX) followed by POD-conjugated avidin (5,000 times dilution, Zymed Lab) at 37°C for 1 h.

Statistical analysis. Data were analyzed by one-way analysis of variance followed by Duncan's new multiple-range test to identify significant differences (27). Values in the text are means ± SE.

RESULTS

Growth performance and tissue weight. As shown in Table 2, there was no difference in food intake and growth of rats for 3 wk among the groups. Thus, the feed efficiency also was comparable among the groups (mean values 0.41 to 0.42). Among tissues weighed, there was a tendency of increasing liver weight and decreasing perirenal adipose tissue weight by dietary CLA and the difference between the linoleic acid and 1.0% CLA groups was significant.

Release of chemical mediators from PEC. PEC isolated from rats fed linoleic acid or CLA were incubated with or without calcium ionophore A23187, and the concentrations of histamine and LTB_4 were measured in the medium. The content of histamine in the cells also was measured to estimate the cellular histamine contents. As shown in Figure 1, the effect of CLA on the release of histamine in PEC was diverse, and there was no significant difference in any of the parameters measured. However, the amounts of histamine stored in the cells tended to decrease with an increasing dietary level of CLA. There was a trend toward a reduction in

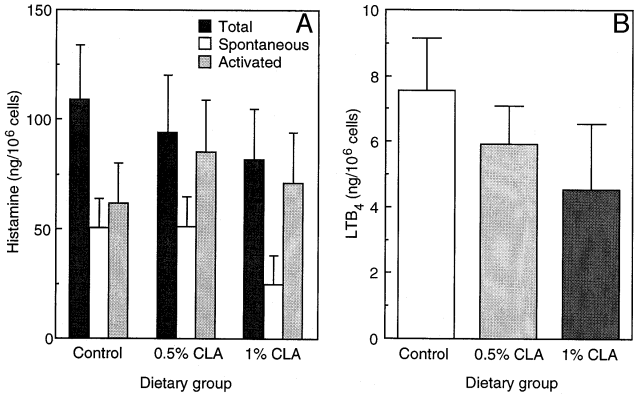

FIG. 1. Effect of dietary conjugated linoleic acid (CLA) on histamine content and release (A) and leukotriene B_4 (LTB_4) release (B) in rat peritoneal exudate cells. Means ± SE of five rats. Histamine release was measured in the presence and absence of calcium ionophore A23187. Total, total amounts of histamine in the cells; Spontaneous, the amount of histamine released during incubation without calcium ionophore A23187; Activated, the amount of histamine which was released from the cells when treated with A23187.

LTB_4 release in response to the dietary level of CLA, but the difference was not significant.

Tissue eicosanoid levels. The effect of CLA on LTB_4 and LTC_4 levels of spleen and lung is shown in Figures 2 and 3, respectively. CLA dose-dependently reduced the level of splenic LTB_4, and the difference between the control and 1% CLA groups was significant. No effect of CLA on the splenic LTC_4 level was observed. However, the concentration of LTC_4 in lung was reduced significantly by CLA even at the 0.5% dietary level. A trend of the dose-dependent reduction of LTB_4 also was observed, but the difference was not significant. The results of the levels of spleen and serum PGE_2 are summarized in Figure 4. CLA significantly reduced the concentration of serum PGE_2, while there was no effect of CLA on the splenic level of PGE_2.

Fatty acid compositions of PEC and splenic lymphocyte lipids. The PUFA composition of PEC and spleen lympho-

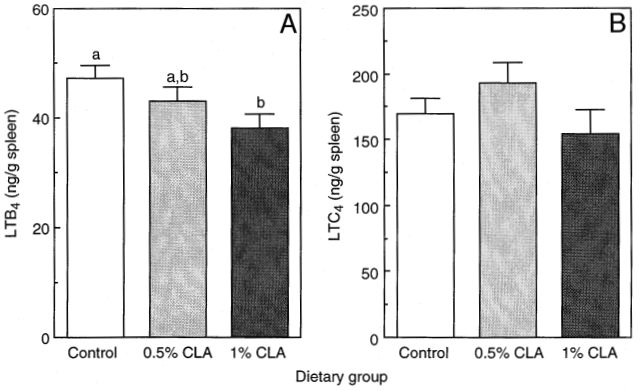

FIG. 2. Effect of dietary CLA on the concentration of splenic (A) LTB_4 and (B) leukotriene C_4 (LTC_4). Mean ± SE of five rats. Values without a common letter are significantly different at $P < 0.05$. For abbreviations see Figure 1.

TABLE 2
Effects of CLA on Growth and Tissue Weights of Rats[a]

Parameter	Group		
	Control	0.5% CLA	1.0% CLA
Initial body weight (g)	102 ± 1	101 ± 1	102 ± 1
Final body weight (g)	170 ± 2	166 ± 3	162 ± 4
Food intake (g/day)	19.1 ± 0.2	18.9 ± 0.3	18.6 ± 0.3
Tissue weight (g/100 g body weight)			
Liver	4.17 ± 0.09[a]	4.11 ± 0.09[a,b]	4.54 ± 0.07[b]
Kidney	0.85 ± 0.03	0.86 ± 0.03	0.87 ± 0.05
Perirenal adipose tissue	1.41 ± 0.07[a]	1.09 ± 0.09[a,b]	0.97 ± 0.14[b]
Heart	0.40 ± 0.02	0.34 ± 0.04	0.34 ± 0.04
Lung	0.48 ± 0.02	0.52 ± 0.02	0.49 ± 0.01
Spleen	0.22 ± 0.01	0.22 ± 0.01	0.25 ± 0.02
Brain	0.66 ± 0.02	0.70 ± 0.01	0.70 ± 0.01
Testis	0.96 ± 0.04	0.87 ± 0.10	1.00 ± 0.03

[a]Mean ± SE of 5 rats. Control group received 1.0% linoleic acid; 0.5% CLA group, 0.5% each of linoleic and CLA; and 1.0% CLA group, 1.0% CLA, respectively. Values without a common superscript letter (a,b) are significantly different at $P < 0.05$. For abbreviation see Table 1.

cyte total lipids is shown in Table 3. There was a dose-dependent reduction by dietary CLA of all n-6 PUFA, 18:2, 20:3, 20:4 and 22:4 in PEC lipids, while there was no difference in the proportion of n-3 PUFA, 22:6 among the groups. A clearer change in these n-6 PUFA was shown in splenic lymphocyte total lipids, and the reduction of 20:4n-6 was significant on a 1.0% CLA diet. Docosahexaenoic acid also tended to decrease with dietary CLA. The decreasing trend of all PUFA in CLA-fed rats was mainly attributable to a moderate increase in major saturated fatty acids, and oleic acid tended to decrease similar to PUFA (data not shown).

Serum thiobarbituric acid value. The concentration of thiobarbituric acid-reactive substance in serum was not modified by dietary CLA, and the values were within 4.1 to 5.5 ng/mL serum in all groups of rats.

Serum Ig levels. As shown in Figure 5, CLA increased the concentration of IgA, IgG and IgM, while decreasing that of IgE in serum. The difference between the control and 1.0% CLA groups was significant in these Ig.

Ig levels in spleen and MLN lymphocytes. Table 4 shows the Ig levels in the medium of rat spleen and MLN lymphocytes cultured for 72 h with or without lipopolysaccharide. Irrespective of the presence or absence of lipopolysaccharide, CLA showed no detectable effects on the Ig levels in spleen lymphocytes except for those of IgM after incubation with lipopolysaccharide, where CLA increased it in a dose-dependent manner. Under the similar situation, CLA increased the concentration of IgA, IgG, and IgM in MLN lymphocytes. The magnitude of the increase was particularly marked at the dietary CLA level of 1.0%. In contrast, there was a significant reduction of the IgE level when the cells from rats fed a 1% CLA diet were incubated with lipopolysaccharide in comparison with the control. A similar response to CLA also was observed even when these cells were incubated for 24 h (data not shown).

Subsets of MLN lymphocytes. The proportion of T-lymphocyte populations of MLN was analyzed as $CD4^+$ and $CD8^+$ subsets. There were no effects of CLA on their relative proportions ($CD4^+/CD8^+$ ratio; 2.6 ± 0.3, 2.4 ± 0.2, and 2.8 ± 0.1 for the control, 0.5% CLA, and 1.0% CLA, respectively).

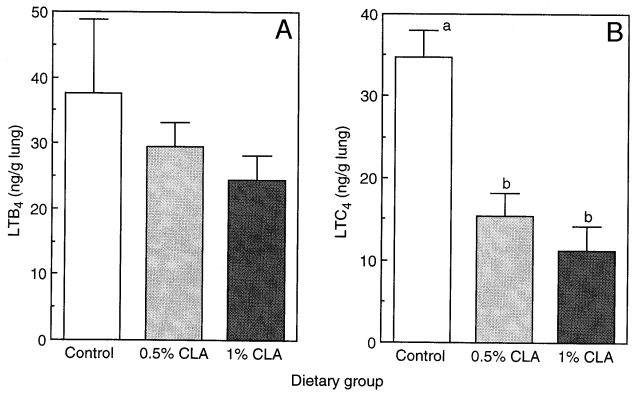

FIG. 3. Effect of dietary CLA on the concentration of lung (A) LTB_4 and (B) LTC_4. Mean ± SE of five rats. Values without a common letter are significantly different at $P < 0.05$. For abbreviations see Figures 1 and 2.

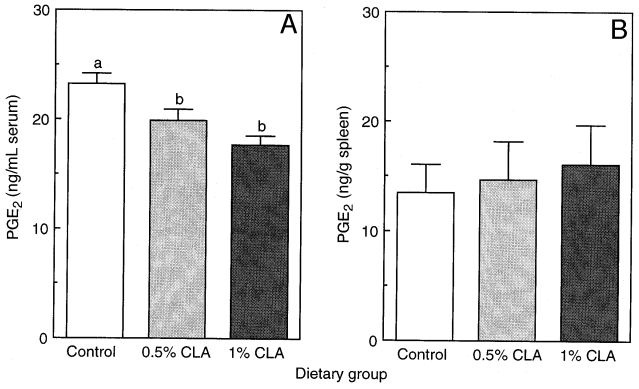

FIG. 4. Effect of dietary CLA on the concentration of (A) serum and (B) spleen prostaglandin E_2 (PGE_2). Mean ± SE of five rats. Values without a common letter are significantly different at $P < 0.05$. For other abbreviation see Figure 1.

Values without a common superscript letter (a,b) are significantly different at $P < 0.05$; n.d., not detected. For other abbreviation see Table 1.

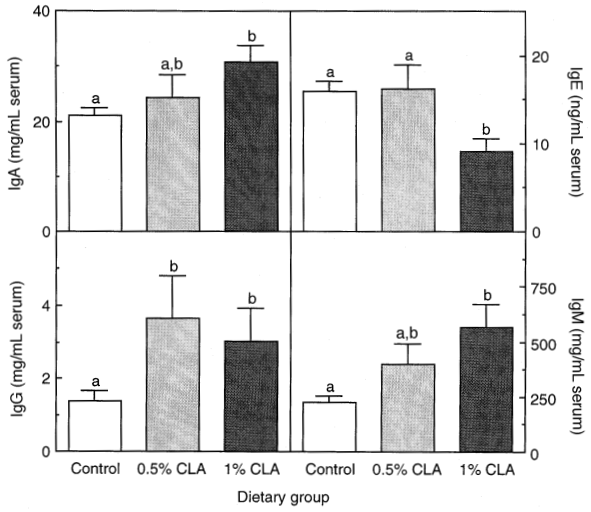

FIG. 5. Effect of dietary CLA on the concentration of serum immunoglobulins (Ig). Mean ± SE of five rats. Values without a common lettter (a,b) are significantly different at $P < 0.05$. For abbreviation see Figure 1.

DISCUSSION

The pathway from linoleate to arachidonate and then eicosanoids is crucial to a range of metabolic diseases (28,29). Food allergy is one such disorder, and it is known that some eicosanoids are involved as chemical mediators in the manifestation of clinical symptoms of hypersensitivity (12,13). The inhibitors of LT production have now been clinically adopted (30,31). However, less is known of the effect that food components exert on this process. Although several food components have been shown to reduce eicosanoid production *in vitro*, in most cases it is practically unsatisfactory because of the limited efficacy (21,22). The results of the present study showed that CLA effectively controlled the production of LTB_4, LTC_4, and PGE_2. CLA significantly reduced LTC_4 production in the lung but not in the spleen. A similar tissue-specific reduction of LTC_4 was observed in rats given sesamin and α-tocopherol simultaneously, while in the spleen LTB_4 but not LTC_4 was reduced (21,22). These observations suggest a complex interaction between dietary fat and antioxidants in the LT-producing system.

Numbers of animal studies showed that dietary PUFA effectively modify the production of eicosanoids, and there is an interaction between n-6 and n-3 PUFA (32). PUFA of the n-3 family suppress the production of eicosanoids from arachidonic acid and exert a substantial suppressing effect on carcinogenesis in breast and colon (33,34). However, the anticarcinogenic effect of n-3 PUFA is far less than that of CLA (2–4). Eicosanoid production is known to be dependent on

TABLE 4
Effects of CLA on the Immunoglobulin Production in Splenic and Mesenteric Lymph Node Lymphocytes of Rats[a]

Immunoglobulin	Without lipopolysaccharide			With lipopolysaccharide		
	Control	0.5% CLA	1% CLA	Control	0.5% CLA	1% CLA
Spleen (ng/mL)						
IgA	3.75 ± 1.23	4.83 ± 0.99	3.78 ± 0.96	9.74 ± 2.45	13.6 ± 3.27	8.30 ± 2.50

Mesenteric lymph node (ng/mL)						
IgA	1.65 ± 0.13[a]	4.78 ± 1.77[b]	5.05 ± 0.10[b]	2.91 ± 0.23[A]	8.72 ± 0.90[B]	22.3 ± 0.7[C]
IgG	n.d.	3.08 ± 0.69[a]	28.1 ± 4.38[b]	n.d.	4.64 ± 0.11[A]	31.9 ± 4.1[B]
IgM	1.86 ± 0.34[a]	4.74 ± 0.50[a]	96.6 ± 13.4[b]	2.85 ± 0.44[A]	6.36 ± 0.48[B]	122 ± 9[C]
IgE	3.81 ± 0.32	4.02 ± 0.33	3.64 ± 0.47	4.81 ± 0.17[A]	4.52 ± 0.29[A]	3.74 ± 0.21[B]

[a]Means ± SE of five rats. Values without a common superscript letter (A,B,C,a,b,c) are significantly different at $P < 0.05$. The lymphocytes were incubated with or without lipopolysaccharide for 72 h, and the concentration of immunoglobulins (Ig) in the supernatant was measured; n.d., not detected.

the substrate availability (35). CLA reduced the proportion of n-6 PUFA including arachidonic acid in the immune cells as observed in the liver and other tissues (8,14). Because of the limited availability of PEC samples for fatty acid analysis, they were analyzed as two pooled samples from two and three rats each. Though the number of analysis may not permit us to draw a definite conclusion, it seems likely that fatty acid composition of PEC also responded similarly as in spleen lymphocytes. This reduction was at least responsible for the reduced production of LT and PG in these cells. CLA may affect metabolic interconversion of fatty acids in the liver that may ultimately result in modified fatty acid composition and arachidonate-derived eicosanoid production in extrahepatic tissue (14). However, more direct participation of the metabolites of CLA cannot be ruled out (9,36). Therefore, the present study added possible usefulness of CLA for controlling the allergic reaction caused by food. Since the effect of CLA on Ig production differed between MLN lymphocytes and spleen lymphocytes, the analysis of the fatty acid composition of the former cells may provide a clue to understanding the mechanism of action.

In contrast to the eicosanoid production, the level of histamine released from PEC, which reflects the mast cell degranulation by a receptor-independent pathway, apparently was not modified by CLA and more directly the fatty acid composition of membrane phospholipids. Engels *et al*. (37) observed that the type of dietary fats and thus the change in the fatty acid composition of mast cell phospholipids did not influence the cell degranulation process. CLA is reported to be incorporated into triglyceride more preferably than phospholipids in tumor cells (7). Thus, CLA may not substantially influence the fatty acid composition of membrane phospholipids and hence, the structure and function of the membrane. In such a situation, the degranulation of the mast cells may not be modified largely.

An interesting observation is that CLA regulates the Ig production class specifically. Food allergy reaction is initiated by the production of allergen-specific IgE (12,13). IgA, in contrast, serves as an antiallergic factor by interfering with the intestinal absorption of allergen, and IgG also works as an antiallergic factor through the competition with binding of allergen to the receptor on the surface of the target cells such as mast cells and basophiles (12,13). CLA increased the production of IgA and IgG, while reducing that of IgE in lymphocytes, in particular MLN lymphocytes irrespective of the presence or absence of lipopolysaccharide, a cell activator. The response of splenic lymphocytes to CLA was less clear except for a slight but significant increase in IgM after lipopolysaccharide activation. However, the response pattern similar to MLN lymphocytes was observed in serum, indicating that CLA can modify the Ig levels preferably even on a whole-body basis. Bile acids (24) and unsaturated fatty acids (25) also regulate antibody production class specifically, but in a manner contrasted from that of CLA. These compounds may promote the allergic response through an increase in IgE production and a reduction in IgA and IgG production. It is plausible that the production of IgE and of IgA and IgG are at least reciprocally regulated. Thus, in addition to the favorable effect on the eicosanoid production, CLA was expected to mitigate the food allergic reaction.

The amounts of CLA ingested by rats of the present study corresponded to approximately 30 and 60 mg/100 g body weight for 0.5 and 1.0% CLA diets, respectively. These amounts were pharmacological when extrapolated to human, 18 and 36 g/60 kg body weight/day. However, as in the case of weight reduction in man, approximately 3 g/d for 2 to 3 mon, a prolonged ingestion may produce a favorable effect even at a lower dose. A long-term trial with a lower dietary level of CLA merits further study.

In conclusion, CLA produced a situation favorable for mitigation of food allergic reaction. Since the effect was seen at a dietary level as low as 0.5 or 1.0%, it is likely that CLA can strongly regulate multiple metabolic processes. Thus, the clinical application of CLA is warranted. Studies with immunized animals will provide more direct information regarding this issue.

METHOD

Simultaneous Quantitation of Ceramides and 1,2-Diacylglycerol in Tissues by Iatroscan Thin-Layer Chromatography–Flame-Ionization Detection

Kenji Okumura*, Kazunori Hayashi, Itsuro Morishima, Kichiro Murase, Hideo Matsui, Yukio Toki, and Takayuki Ito

Second Department of Internal Medicine, Nagoya University School of Medicine, Nagoya 466, Japan

ABSTRACT: Ceramides and 1,2-diacylglycerol have been demonstrated in intracellular signaling pathways. A method of simultaneous mass determination of ceramides and 1,2-diacylglycerol in tissues was developed using the Iatroscan which combines thin layer chromatography and flame ionization detection (TLC/FID) techniques. Because of relatively low amounts of these components in tissues, the fraction of nonpolar lipids, which included ceramides and glycerides, was eluted with chloroform/acetone mixture (3:1, vol/vol) through a silicic acid column to eliminate the polar phospholipids. Development of Chromarods was carried out using three solvent systems in a four-step development technique. The relationship of the peak area ratio to weight ratio compared with cholesteryl acetate added as an internal standard was linear. The amount of ceramides increased with incubation of rat heart homogenate and human erythrocyte membranes in the presence of sphingomyelinase (E.C. 3.1.4.12). The Iatroscan TLC/FID system provided a quick and reliable assessment of ceramides and 1,2-diacylglycerol.

Lipids 33, 529–532 (1998).

Ceramides and 1,2-diacylglycerol (DAG) are involved in numerous important biological processes (1–3). The activation of protein kinase C, induced by 1,2-DAG, plays an important role in transmembrane signaling systems. Ceramide generation, resulting chiefly from sphingomyelin hydrolysis, constitutes a signal transduction pathway that mediates cytokines and tumor necrosis factor-α (4,5). Ceramide production has been reported to induce NF-κB, a stress response transcription factor (6). The ultimate effects of the stimulation of the sphingomyelin pathway are the induction of cell differentiation and apoptotic death (7). Sphingolipid metabolites involving ceramides inhibit the activity of protein kinase C (8). Therefore, 1,2-DAG, a physiological endogenous activator of protein kinase C, may oppose this ceramide-related action.

Abbreviations: 1,2-DAG, 1,2-diacylglycerol; FID, flame-ionization detection; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography.

The Iatroscan combines the resolution efficacy of thin-layer chromatography (TLC) with the possibility of quantification by flame-ionization detection (FID) (9). We report here the simultaneous quantitation of 1,2-DAG and ceramides from rat heart with the use of the Iatroscan in a study of the significance of the two lipids in the myocardium. The quantitation of 1,2-DAG using the TLC/FID procedure was reported by us (10) and others (11,12). For the quantitative measurement of tissue ceramides, radiolabeled sphingomyelin (13) and diglyceride kinase (14) are usually utilized. Derivatives from ceramides have been determined by high-performance liquid chromatography (HPLC) (15) and gas-liquid chromatography (16). Direct measurements of ceramides and 1,2-DAG by HPLC (17) and TLC (18) have recently been reported.

MATERIALS AND METHODS

Materials. Ceramides (type III, type IV, *N*-palmitoyl-D-sphingosine, and *N*-lignocerol-DL-dihydrosphingosine), 1,2-dioleoyl-*rac*-glycerol (diolein), triolein, oleic acid, cardiolipin from bovine heart, and sphingomyelinase (E.C. 3.1.4.12) from *Bacillus cereus* were purchased from the Sigma Chemical Co. (St. Louis, MO). Cholesteryl acetate, cholesterol, and butylated hydroxytoluene were obtained from Wako Chemical Co. (Osaka, Japan). All other chemicals were of analytical reagent grade. Male Sprague-Dawley rats weighing approximately 300 g were used in the experiments unless otherwise mentioned (Nihon SLC Inc., Hamamatsu, Japan).

Instrumentation. Sample analyses were carried out with the Iatroscan MK-5 TLC/FID analyzer (Iatron Lab. Inc., Tokyo, Japan) under the following conditions: flow rate of hydrogen, 160 mL/min; flow rate of air, 2000 mL/min; scan speed, 30 s/scan. Silica-gel, 75 μm precoated thin-layer rods (Chromarods-SIII; Iatron Inc.) were used in sets of 10. Peak areas were calculated using a potentiometric recorder (Chromatocorder 12; System Instruments, Tokyo, Japan) connected to the analog output of the Iatroscan.

Lipid extraction. Animals were anesthetized with sodium pentobarbital (50 mg/kg, intraperitoneally). Heart was rapidly

excised and washed thoroughly with cold saline and then frozen immediately in liquid nitrogen and lyophilized. The lyophilized tissue samples corresponding to 12–14 mg were homogenized, in 5 mL of a chilled chloroform/methanol mixture (2:1, vol/vol) containing 0.01% butylated hydroxytoluene as an antioxidant and cholesteryl acetate (0.08 mg per tube) as an internal standard, with a motor-driven glass–glass homogenizer kept in ice. The homogenate was chilled on ice 30 min and then filtered through a paper filter (Type 1; Toyo Roshi Inc., Tokyo, Japan). The filtrate was evaporated to dryness under a stream of nitrogen at 40°C. The dry residue was dissolved in 1000 µL of a chloroform/acetone mixture (3:1, vol/vol) and applied to 0.5-mL silicic acid (minus 350 mesh size; Bio-Rad, Richmond, CA) column (20 mm × 5.5 mm) equilibrated with chloroform. Ceramides, neutral lipids, and free fatty acids were eluted with 6 mL of the chloroform/acetone mixture. The elution with this solvent mixture has been reported to result in the effective resolution of ceramide components (19,20). The eluate was concentrated under a nitrogen stream at 40°C and then dissolved in 20 µL chloroform.

Chromarod development and scanning. One microliter of the lipid extracts was applied carefully to the Chromarods with a Hamilton syringe. The first development was carried out in a solvent system of chloroform/methanol/H_2O (57:12:0.6, by vol) until the solvent front had migrated approximately 2.5 cm. The rods were air-dried at room temperature for 10 min and then subjected to the second development in 1,2-dichloroethane/chloroform/acetic acid (46:6:0.05, by vol) until the solvent front had migrated approximately 9 cm. The second development was repeated (third development). The fourth development was carried out in *n*-hexane/diethyl ether/acetic acid (98:1:1, by vol) until the solvent front had migrated approximately 11.5 cm. The Chromarods were then dried at 50°C and scanned in the Iatroscan MK-5. Each sample was analyzed with three Chromarods, and the results were averaged.

The action of sphingomyelinase. We determined the production of ceramides in the homogenate from rat heart and human erythrocyte membranes in the presence of sphingomyelinase. The fresh tissue from rat heart was homogenized with glass-Teflon™ homogenizer in the reaction buffer. Erythrocytes were washed with ice-cold phosphate-buffered saline and disrupted by freezing and thawing in lysis buffer containing 20 mM Tris-HCl, pH 7.5. The lysate was centrifuged for 30 min at 20,000 × *g* at 4°C. The resulting pellet (membrane fraction) was washed five times in lysis buffer. The heart homogenate and erythrocyte membrane preparation were incubated at 37°C in reaction buffer containing 100 mM Tris-HCl, pH 7.5, 5 mM $MgCl_2$, 0.1% Triton X-100 (final volume, 200 µL), and neutral and magnesium-dependent sphingomyelinase from *Bacillus cereus* (final 300 mU/mL). The reaction was stopped by the addition of 5 mL of the chloroform/methanol mixture (2:1, vol/vol) containing hydroxytoluene and choles-teryl acetate, and lipids were extracted as mentioned above.

RESULTS AND DISCUSSION

In the present study, most of the phospholipids including cardiolipin were excluded in the more nonpolar lipid components separated by silicic acid column chromatography; see TLC separation (Fig. 1). This polar separation on a silicic acid column was necessary to avoid overloading the Chromarods.

The four-time development procedure using three kinds of solvent systems described in the Materials and Methods section resolved a standard mixture of ceramides, 1,2-diolein, cholesteryl acetate, cholesterol, triolein, and oleic acid (Fig. 2A). Figure 2B shows an Iatroscan TLC/FID chromatogram of rat heart neutral lipids. The four kinds of ceramides, which differed in stereospecificity (D- and L-forms) and in hydroxy and nonhydroxy fatty acids, were not resolved in this system. This was determined by spiking the rat heart homogenate neutral lipid fraction with ceramide type III and type IV, palmitoyl-D-sphingosine and lignocerol-DL-dihydrosphingosine and by observing no resolution of the ceramide peak.

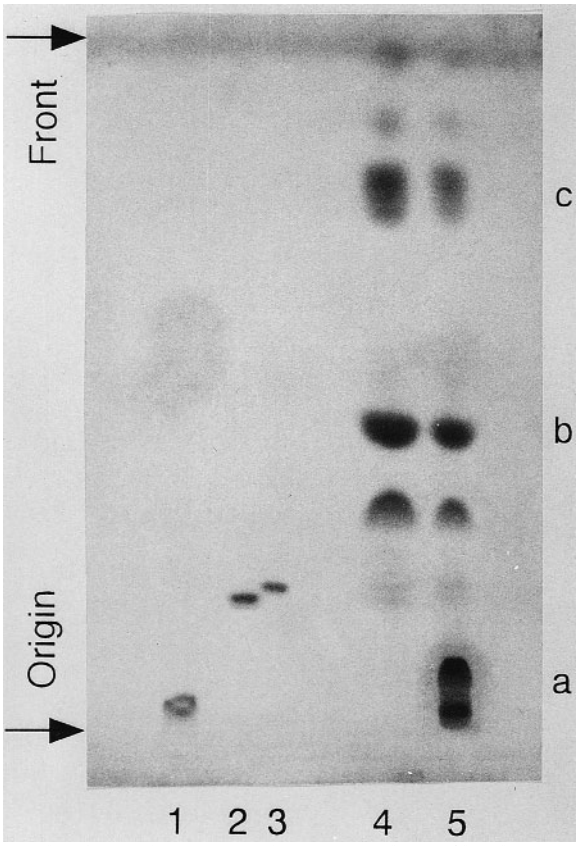

FIG. 1. Thin-layer chromatography (TLC) analysis of lipids. (1) Cardiolipin, (2) ceramides (type IV), (3) ceramides (type III), (4) nonpolar fraction separated by a silicic acid column with chloroform/acetone (3:1, vol/vol) from rat heart, (5) crude lipid extracts from rat heart. TLC was performed on silica gel plates (20 cm × 20 cm, Kieselgel 60 F_{254} from Merck, Darmstadt, Germany). The first development was in chloroform/methanol/H_2O (57:12:0.6, by vol) to 5 cm; the second development was in 1,2-dichloroethane/chloroform/acetic acid (46:6:0.05, by vol) to 14 cm. Spots were visualized by spraying the plates with 40% sulfuric acid and heating at 150°C for 30 min. (a) Phospholipids, (b) cholesterol, (c) triglycerides.

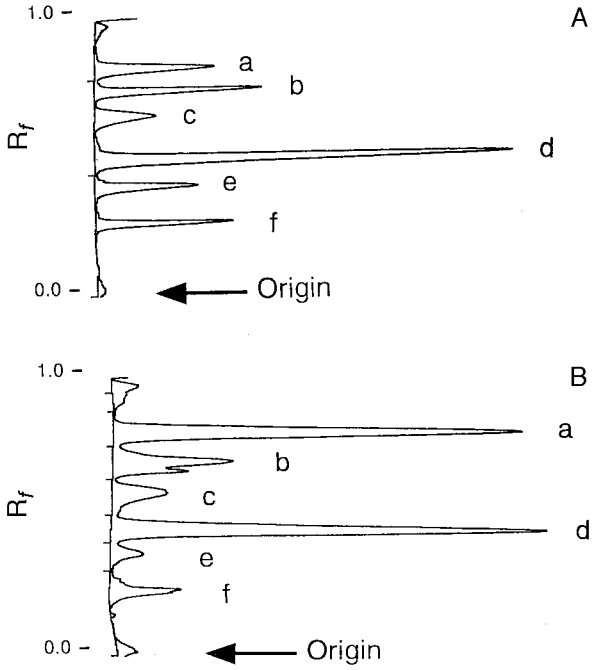

FIG. 2. (A) TLC–flame-ionization detection (FID) separation of the standard lipids. The peaks are as follows: a, cholesteryl acetate; b, triolein; c, oleic acid; d, cholesterol; e, 1,2-diolein; f, ceramides (type III). (B) TLC/FID separation of a tissue sample from a rat heart. The peaks are as follows: a, cholesteryl acetate as an internal standard; b, triglycerides; c, fatty acids; d, cholesterol; e, 1,2-DAG; f, ceramides. 1,2-DAG, 1,2-diacylglycerol; for other abbreviation see Figure 1.

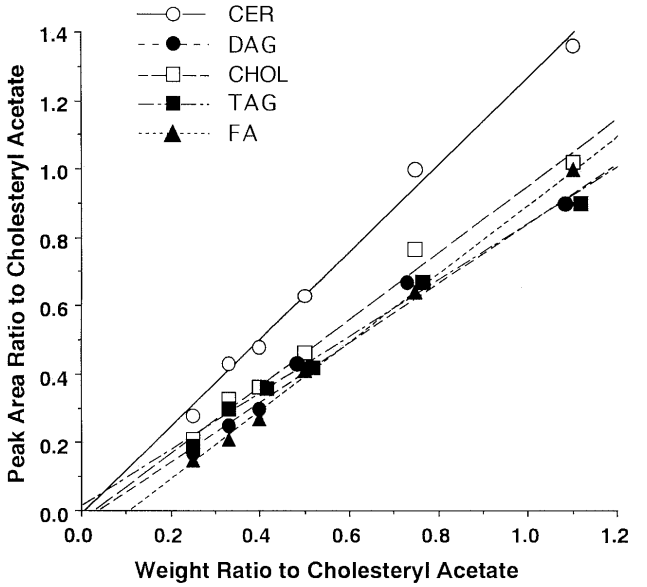

FIG. 3. Calibration curves. These lines indicate the relationship between the weight ratios and the peak area ratios of ceramides (CER), 1,2-diolein (DAG), cholesterol (CHOL), triolein (TAG), and oleic acid (FA) compared to cholesteryl acetate by the FID response. Data represent mean values from duplicate samples.

The recovery of type III ceramides, 1,2-diolein, cholesterol, and triolein by the extraction involving the silicic acid column was determined by comparing the response to cholesteryl acetate. The ratio of these compounds to cholesteryl acetate was 90.4 ± 6.9, 112.8 ± 12.9, 105.8 ± 8.7, and 110.2 ± 3.4%, respectively (n = 6, mean ± SD). The intraassay coefficient of variation was 7.7, 11.5, 8.2, and 3.1%, respectively.

Standard solutions were prepared for all the lipid classes, and the area response was calculated relative to cholesteryl acetate, chosen as the internal standard. The peak area ratios to cholesteryl acetate were compared with the weight ratios to cholesteryl acetate and are shown in Figure 3. The calculated regression equations yielded $y = 1.275x - 0.011$ and $y = 0.876x - 0.033$ for ceramides and 1,2-DAG, respectively. The relationship of the peak area ratio to weight ratio compared with cholesteryl acetate was linear.

With the Iatroscan TLC/FID procedure, it was found that the ceramides and 1,2-DAG contents in the rat hearts amounted to 0.759 ± 0.038 μg/mg dry weight and 0.384 ± 0.059 μg/mg dry weight (n = 6, mean ± SD), respectively, corresponding to 0.173 ± 0.009 and 0.0875 ± 0.0134 μg/mg wet weight, respectively. The value of 1,2-DAG was similar to our previous finding (10), and the value of ceramides was consistent with the content in rat liver (21). The ratio of ceramide content to 1,2-DAG was twice the level found in skeletal muscle in which a diglyceride kinase assay was used (22). This discrepancy may be attributed to differences in tissues or methods.

To examine the effect of sphingomyelinase on the amount of ceramides and 1,2-DAG, the heart homogenate and erythrocyte membranes were incubated in the presence of sphingomyelinase for 60 min. The homogenate of rat heart in Tris buffer contained a 10-fold amount of ceramides compared with the values of tissues frozen by liquid nitrogen even before incubation, probably due to production of ceramides in the buffer by the homogenization procedure. Incubation in the presence of sphingomyelinase produced increased ceramide levels at 30 min, but the concentration decreased at 45 and 60 min. This would suggest a further degradation of the ceramides produced and the exhaustion of sphingomyelin as a source (Fig. 4). This was consistent with the fact that sphingomyelin, which was estimated using the TLC/FID procedure (23), had almost disappeared (data not shown). Exposure to sphingomyelinase generated a large amount of ceramides in the erythrocyte membrane preparations, similar to those observed in the rat heart homogenate (Fig. 4). The ceramide levels reached a sixfold increase at 45 min. The 1,2-DAG levels also increased despite a lack of change in the cholesterol levels.

Ceramides, which were first discovered in brain tissue, have recently been identified as a putative cellular messenger (1), as has 1,2-DAG (3). The intense interest in these lipids makes a quantitative and simultaneous determination of their levels in cells and tissues desirable. Radiolabeled precursors, followed by lipid extraction and TLC separation, have been used for this purpose but have not provided quantitative data, and care must be taken regarding the choice of the labeled precursor (13). Alternatively, the mass determination of ceramides and 1,2-DAG using diglyceride kinase as described by Preiss *et al.* (14) has frequently been achieved. However, the method involves several procedures such as lipid extrac-

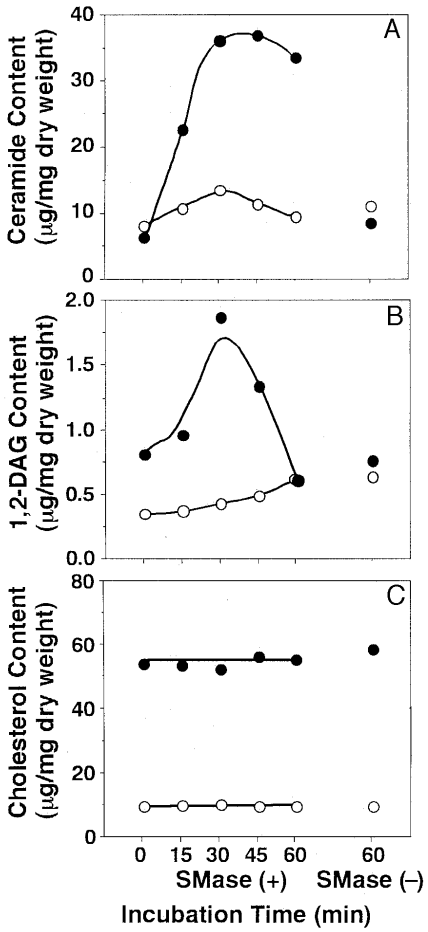

FIG. 4. Changes in ceramides (A), 1,2-DAG (B), and cholesterol (C) in homogenates from rat heart (○) and erythrocyte membranes (●) in the presence and absence of sphingomyelinase (SMase) from *Bacillus cereus* (300 mU/mL). Data represent mean values from duplicate samples. The experiment was performed twice with similar results. For abbreviation see Figure 2.

tion, labeling with radioactive phosphate by the enzyme, reextraction, separation by TLC, and quantitation of radioactivity. The Iatroscan TLC/FID system provided a quick and reliable mass assay of ceramides and 1,2-DAG in animal tissues. Although it is of interest to determine the sources of ceramides and 1,2-DAG, a mass assay is not helpful in this respect.

A Gas Chromatographic–Mass Spectrometric Method Using a PoraPLOT Column for the Detection of Hydroperoxide Lyase in *Chlorella pyrenoidosa*

Alberto Nuñez*, Thomas A. Foglia, and George J. Piazza

ERRC, ARS, USDA, Wyndmoor, Pennsylvania 19038

ABSTRACT: A gas chromatographic–mass spectrometric (GC–MS) method using a PoraPLOT Q column was developed for the analysis and identification of the volatile products produced by the action of hydroperoxide lyase (HPLS) upon 13-hydroperoxylinoleic or 13-hydroperoxylinolenic acids. The developed procedure required no derivatization, was not affected by the presence of water, did not require cryogenic conditions to be maintained during injection, and allowed for the quantitation of most products. An acetone powder preparation of *Chlorella pyrenoidosa* cells was triturated with borate buffer pH = 8.0, and the mixture centrifuged at 12,000 × *g*. The supernatant and pellet were assayed for HPLS activity by GC–MS analysis of the volatile products given by linoleic acid hydroperoxide. The data showed that the majority of HPLS activity resides in the pellet fraction, and that the primary volatile component was pentane, with smaller amounts of 2-(*Z*)-pentene and 1-pentene being produced. The fact that HPLS activity resides in the water-insoluble fraction of the acetone powder suggests that HPLS from *Chlorella* is a membrane-associated enzyme. This investigation also determined that a spectrophotometric assay using alcohol dehydrogenase for measuring HPLS activity was not specific, but measured enzymatic activity other than HPLS.

Lipids 33, 533–538 (1998).

Membrane-associated enzyme fatty acid hydroperoxide lyase (HPLS) cleaves linolenic or linoleic acid hydroperoxy derivatives **1** and **2**, respectively. HPLS from higher plants cleaves at the C–C bond adjacent to the hydroperoxide function that is proximal to the carboxy carbon to produce C_{12} oxo-aldehyde **3** and hexanal **4**, and hexenals **6** and **8** (Scheme 1). In crude systems the corresponding reduced hexanol **5** or hexenols **7** and **9** often are detected. HPLS derived from algae, mushroom, and grass cleaves fatty acid hydroperoxides at the C–C bond adjacent to the hydroperoxide function distal to the carboxyl carbon to form C_{13} oxo-aldehyde **10** and a C_5 fragment that varies with enzyme source (1). For example, HPLS from the microalga *Chlorella* will produce pentane **11** and 2-(*Z*)-pentene **14** (2), whereas HPLS from the blue-green microalga *Oscillatoria* and from grass produces pentanol, **12**, and 1-pentene-3-ol, **13** (3,4). Whereas HPLS in higher plants is membrane-associated, HPLS in *Chlorella* and *Oscillatoria* is reported to be water-soluble (2–4).

Although most studies involving HPLS are directed toward an understanding of lipid metabolism and the physiological role of HPLS products, there are also potential industrial uses for this enzyme. For example, the short-chain volatile products from the above reactions are major contributors to the characteristic fresh odor of many green-leaf plants and fruits that are of importance to the fragrance and flavor industry. On the other hand, the long-chain HPLS products, oxo-carboxylic acids, can be oxidized to dicarboxylic acids and used to produce polyamides similar to nylon 13,13.

Recently, we reported a procedure for immobilizing HPLS that was isolated from a partially purified aqueous extract of *Chlorella* (5). HPLS activity was assayed by a published method using **2** as substrate (6). This method is based on the ability of aldehyde **10** to serve as a substrate for yeast alcohol dehydrogenase (ADH) and thereby cause the oxidation of the ADH cofactor NADH. By following the oxidation of NADH spectrophotometrically, a crude or a partially purified enzyme extract could be assayed for HPLS activity. Doubts, however, arose about the actual presence of *Chlorella* HPLS when the expected oxo-carboxylic acid product **10** could not be identified. Accordingly, an alternative method was devised for the identification, isolation, and quantification of the volatile short-chain oxidation products formed from **2** by HPLS.

There are several prior reports concerning the analysis of short-chain HPLS oxidation products. One method measured volatile aldehydes by high-performance liquid chromatographic (HPLC) analysis of their 2,4-dinitrophenylhydrazone derivatives (7). Identification of the short-chain HPLS reaction products directly has been achieved by GC analysis of headspace volatiles, while the semivolatile products required solvent extraction (2–4,7–9). GC analysis was done with columns that separated the products based on their polarity. Accordingly, reported polar and apolar volatile products such as those expected from HPLS cleavage (Scheme 1) were poorly resolved.

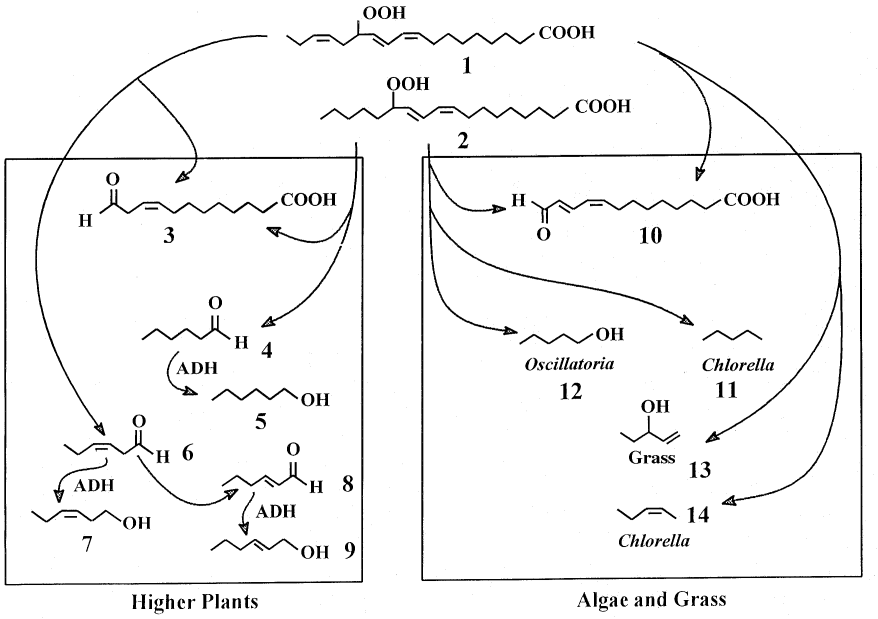


SCHEME 1

In this study, a GC–MS method using a porous polymer column (PoraPLOT Q) was evaluated for its ability to separate standard compounds of different polarity and volatility that are expected from the action of HPLS on hydroperoxides **1** or **2**. The main advantage of this column is that compounds are separated primarily by size, rather than polarity or boiling point. Accordingly, both polar and apolar HPLS volatile oxidation products were resolved. After determining optimal conditions for separating the expected products, the method was used to assay HPLS activity in water-soluble and insoluble protein fractions from *Chlorella pyrenoidosa*.

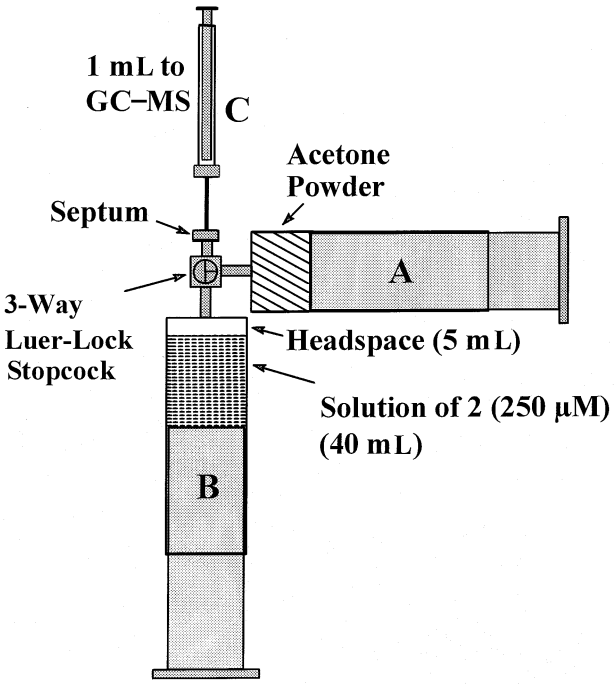
MATERIALS AND METHODS

Chemicals and materials. Soybean lipoxygenase Type 1-B, linoleic acid, ADH, and NADH were purchased from Sigma Chemical (St. Louis, MO). Water was purified to a resistance of 18 MΩ-cm using a Barnstead (Dubuque, IA) NANOpure system. Pentane, 1-pentene, pentanol, 1-hexene,1-penten-3-ol, hexanal, 2-(*E*)-hexenal, and hexanol were purchased from Aldrich Chemical (Milwaukee, WI). All other reagents were of the highest purity available. Hydroperoxide **2** was produced as described previously (5). *Chlorella* cells were disrupted using cold acetone to give an acetone powder as reported previously (10).

Enzyme extraction and purification. Water-soluble enzymes were extracted and partially purified from the acetone powder as reported earlier (5). Further purification and molecular weight estimation of the partially purified enzyme extract was done with a Sephadex G-75 column (2.5 × 48 cm) eluted with potassium phosphate 50 mM (pH 7.0), collecting 2.8-mL fractions. The molecular weight standards (Sigma) were: aprotin (6.5 kDa), cytochrome c (12.4 kDa), carbonic anhydrase (29 kDa), albumin (66 kDa), and blue dextran (2,000 kDa).

Headspace analysis. Typically, 4 g of acetone powder obtained from *Chlorella* cells was mixed with 20 mL 0.2 M borate buffer (pH 8.0) and centrifuged at 12,000 × *g*. The supernatant was removed, and the pellet was resuspended and centrifuged (12,000 × *g*) five additional times. The pellet was divided equally, and each portion was suspended in 20 mL of buffer. One portion was boiled for 10 min to give the control preparation. The fraction to be assayed for HPLS activity was loaded into a 60-mL gas syringe and connected to a closed three-way Luer-lock stopcock (syringe A on Scheme 2). A 40-mL aliquot of an aqueous solution of **2** (250 μM) was loaded into a second 60-mL gas syringe (syringe B on Scheme 2), leaving a headspace of 5 mL. Before allowing the contents of both syringes to mix, a 10-μL aliquot of hexane in methanol (1.5 μL hexane/mL methanol) was added through the septum on the three-way stopcock (see Scheme 2) as an internal standard. The contents of syringe A were dispensed into syringe B through the stopcock, and the mixture was allowed to stand for 30 min at room temperature. Afterward, 1 mL of gas headspace was removed by syringe through the septum and manually injected into the GC–MS. After analysis, 2 mL of hexane was added to the reaction mixture for extraction of less volatile products, and 1 μL of the organic layer was injected into the GC–MS.

GC–MS of volatiles. Analysis of headspace volatiles was performed with a Hewlett-Packard (HP, San Fernando, CA) 5890 Series II Plus GC equipped with an HP 5972 Series mass detector set to scan from *m/z* 35 to *m/z* 400 at 1.2 scans per second and a PoraPLOT Q column coated with styrene-divinylbenzene polymer (25 m × 0.32 mm × 8 μm) (Chrompack, Raritan, NJ). The following oven temperature profile was used to elute the products: 50 (3 min) to 160°C (5 min)



SCHEME 2

at 15°C/min; to a final temperature of 250°C (5 min) at 15°C/min. All injections were splitless with the injector and detector set at 250°C, using He as carrier gas at 1 mL/min. For GC–MS analyses of the products in the hexane layer the oven temperature profile was: 180 (10 min) to 250°C (5 min) at 15°C/min.

*Isolation and analysis of **10***. Semipreparative purification of the C_{13}-oxo carboxylic acid methyl ester was done on a Waters (Milford, MA) LC Module 1 HPLC equipped with a Lichrosorb 5 μ Diol Column (25 × 1 cm) from Phenomenex (Torrance, CA) using a linear gradient of hexane/0.5% isopropanol to hexane/2% isopropanol (30 min). Detection of products was made with a Waters 996 Photodio Array Detector set to monitor at 276 and 233 nm and a Varex MK III Light Scattering Detector from Alltech Associates (Deerfield, IL). The fractions with absorption at 276 nm were collected and analyzed by GC–MS: column HP-5MS (30 m × 0.25 mm); 80 (5 min) to 230°C (10 min) at 10°C/min. The ^{1}H nuclear magnetic resonance (NMR) spectra of the products were obtained using a Varian (Palo Alto, CA) Unity + 400 MHz NMR instrument.

RESULTS AND DISCUSSION

GC–MS assay. One unique property of the porous polymer column used in this study is its ability to separate polar and apolar products. Separation of C_1 to C_7 compounds is accomplished with little or no influence of compound polarity; compounds are separated primarily on the basis of size. However, column elution temperatures are much higher than the boiling points of the volatiles and because of this, products in the C_3–C_5 range are trapped on the column head even at a 50°C column temperature. Accordingly, multiple injections of large sample volumes can be made without compromising compound resolution until the minimum sensitivity of the instrument is reached, approximately 10^{-10} g of sample. Figure 1

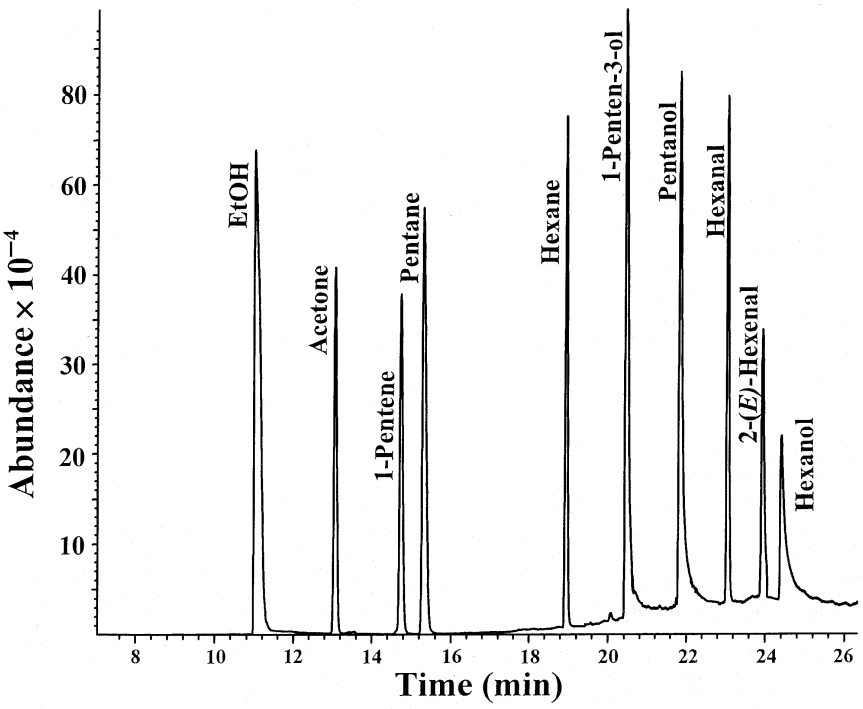


FIG. 1. Gas chromatography–mass spectrometry (GC–MS) of the headspace volatiles in a standard mixture (see the Results and Discussion section) using a PoraPLOT Q column with a temperature program described in the Materials and Methods section.

shows a chromatogram for a headspace injection of a mixture of standard compounds similar to the short-chain products expected from the oxidation of **1** or **2** with HPLS. Because the standards had different volatilities, the standards were injected by taking different amounts of headspace from three separate sample vials in order to obtain similar peak sizes. In the first vial 1 μL of acetone, ethanol, 1-pentene, pentane, and hexane were dissolved in 1 mL methanol. From the headspace of this vial was taken 100 μL for injection. The second vial contained 1 μL of pure 1-penten-3-ol, hexanal, and 2-(*E*)-hexanal, and 200 μL of the headspace was taken for injection from this vial. The third vial contained 1 μL of pure 1-pentanol and 1-hexanol, and 400 μL of the headspace was injected. Peak shape and retention times of the standards from consecutive injections of the three mixtures were identical to those obtained from a single injection of the same volume of each vial. Acetone and ethanol were included because traces were present in the acetone powder and partially purified enzyme extracts. Among the compounds injected, pentanol and hexanol were the more difficult to detect because they tend to elute as broad peaks at low concentration. For the same reason, the resolution of 2-(*E*)-hexenal and 2-(*E*)-hexenol also was poor.

Previous work (2) identified pentane as the major volatile product from the action of *Chlorella* HPLS on **2** by comparison of its retention time with a standard. In that study an active alumina column was used for GC headspace analysis. This column gave effective separation of light hydrocarbons (C_1–C_5), whereas large hydrocarbons or polar material eluted only with difficulty. Because water interacts strongly with alumina columns, precautions need to be taken with regard to the water content of samples to avoid variations in eluate retention times. In another study (3), pentanol was the only short-chain product reported from the reaction of *Oscillatoria* HPLS with **2**. In that study a Carbowax 20M column was used for the detection of pentanol. Other GC analyses of volatiles from grass and germinating soybean seedling HPLS cleavage of **2** also used polar or intermediate polarity columns (4,8). These latter columns, however, require a minimum operating temperature of at least 40°C, but at this temperature apolar short hydrocarbon fragments, such as pentane, are not retained. More recently Salch *et al.* (9) used an HP-5MS low-polarity GC column with a mass detector for the detection of pentane and 2-(*Z*)-penten-1-ol and 1-penten-3-ol. This column can elute both polar and apolar compounds, but we found that ethanol and pentane were not resolved even when cryogenic conditions were used. Also, injection of large sample amounts required cryogenic cooling to avoid peak broadening. As Figure 1 shows, a PoraPLOT column can resolve the mixture of polar and apolar C_5 and C_6 volatile products such as those expected from the interaction of HPLS with **1** or **2** with no need for subambient or cryogenic cooling when large volumes are injected. An added benefit of the column is that it is not affected by water or oxygen, which allows for direct injection of aqueous headspace samples.

By using the air-tight system described in the Materials and Methods section, shown in Scheme 2, the headspace of an active HPLS acetone powder, a heat-treated powder control, and the supernatant from a buffer wash of the active powder were assayed for HPLS activity using the PoraPLOT Q column. Injection of the headspace from the active acetone powder reaction, with hexane as internal standard, showed the presence of three peaks with retention times and mass spectra that corresponded to pentane, 2-(*Z*)-pentene, and 1-pentene (Fig. 2A and inset). Pentane yields were between 5

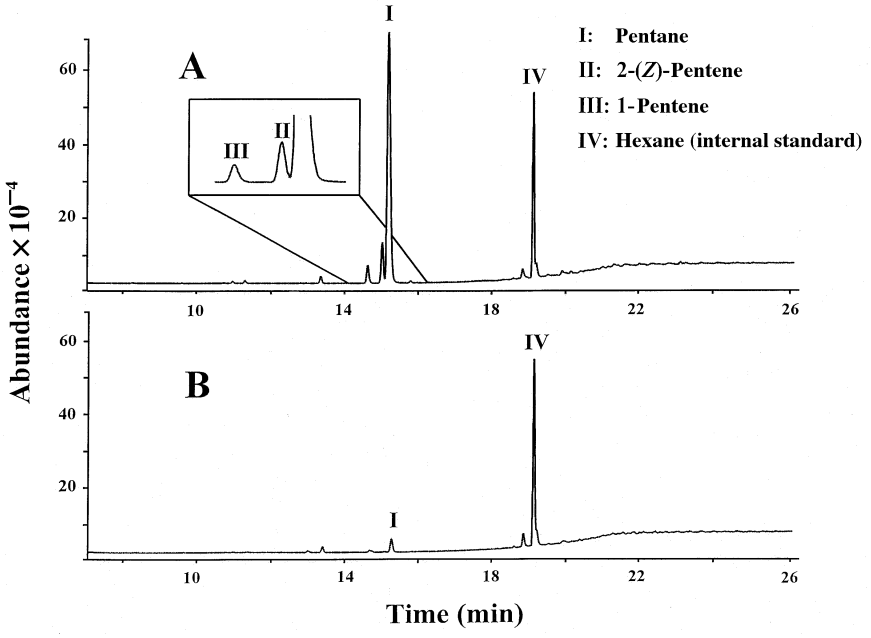

FIG. 2. (A) GC–MS of the headspace volatiles from the reaction of 40 mL of **2** (250 μM) with 2 g of hydroperoxide lyase-active acetone powder from *Chlorella pyrenoidosa*; (B) control reaction. For structure of **2** see Scheme 1; for abbreviation see Figure 1.

and 10%. Although detectable amounts of pentane also are present in the heat-treated powder control (Fig. 1B) and the buffer-washed supernatant (data not shown), the control levels of pentane were always below 3% of the amount found using the HPLS-active acetone powder. In our product analysis the presence of 2-(*Z*)-pentene could be attributed to small amounts of **1** contaminating **2**. However, the source of the 1-pentene is unclear. 2-(*Z*)-Pentene and a third unidentified product that was presumed to be 2-(*E*)-pentene were detected previously in *Chlorella* HPLS reactions when the substrate was **1** (2). Our analysis of the headspace showed that no *E*-isomer was formed.

To determine whether less volatile and more polar alcohols or aldehydes were produced, the reaction mixture was extracted with hexane, and 1 μL of the hexane phase was injected in the GC–MS. No alcohol products were detected. Although small amounts of hexanal were found in the product mixtures, this compound also was detected in the control and is presumed to be formed by nonenzymatic degradation of **2**.

Additional confirmation for the presence of the products resulting from HPLS activity in the acetone powder pellet was obtained by semipreparative HPLC isolation of the nonvolatile products of the reaction. The latter were extracted from the aqueous phase with ether and then methylated. A collected HPLC fraction with ultraviolet absorption at 276 nm gave a single peak by GC–MS with the following mass spectrum: 238 $[M]^+$; 207 $[M - CH_3O]^+$; 206 $[M - CH_3OH]^+$; 188 $[M - H_2O - CH_3OH]^+$; 178; 149; 121; 119; 109; 95; $[CH_2CH{=}CHCH{=}CHCHO]^+$; 81 $[CH{=}CHCH{=}CHCHO]^+$; 68; and 55. This spectrum corresponds to the published spectrum of **10** (2,3,9,11). ^{1}H NMR of the same fraction furnished the following chemical shifts in ppm. In parentheses are the number of protons, multiplicity, coupling constants, and carbon assignments: δ = 9.60 (1H, *d,* $J_{12,13}$ = 7.90 Hz, C13); 6.15 (1H, *dd,* $J_{11,12}$ = 15.2 Hz, C12); δ = 7.43 (1H, *ddd,* $J_{10,11}$ =11.53 Hz, $J_{9,11}$ = 0.92 Hz, C11), δ = 6.26 (1H, *ddt,* $J_{9,10}$ = 10.80 Hz, $J_{8,10}$ = 0.55 Hz, C10); δ = 5.98 (1H, *dt,* $J_{8,9}$ = 7.87 Hz, C9); δ = 3.70 (3H, *s,* ester methyl); δ = 2.30 (4H, *m*, C2,8); δ = 1.62 (2H, *m*, C3); δ = 1.45 (2H, *m*, C7); δ = 1.34 (6H, *m*, C4–6). These data match the spectrum recently reported by Salch *et al.* (9) for 13-oxo-9-(*Z*), 11-(*E*)-tridecadienoic acid.

A recent report showed that under anaerobic conditions lipoxygenase can cause the cleavage of **1** to produce **10** and a mixture of 2-(*Z*)-penten-1-ol and 1-pentene-3-ol. However, no pentane was found in this reaction (9). In our studies with *Chlorella,* pentane was the major volatile detected from the acetone powder pellet. Whether the reaction was conducted under an atmosphere of oxygen or nitrogen, no difference in the products was observed (results not shown). These data suggest that HPLS activity is the major route to the oxo-product **10** and pentane.

Spectrophotometric assay. HPLS activity has been monitored spectrophotometrically at 234 nm by following the loss of the conjugated diene chromophore of **2** or the increase at 280 nm when oxo-acid **10** is the main product. To improve the specificity of this assay a linked assay has been devised that couples ADH to HPLS. ADH reduces the aldehydes produced by HPLS to alcohols and in the process oxidizes NADH. Thus HPLS activity can be followed by the decrease in absorption at 340 nm (6). We reported earlier that a partially purified water-soluble protein fraction derived from the supernatant of *C. pyrenoidosa* and *fusca* gave the expected decrease in absorption at 234 nm and the decrease at 340 nm when **2** and ADH/NADH were present (5,7). However, a more careful examination of the ADH/NADH assay revealed that the reaction of the water-soluble protein fraction with **2** and NADH has the same kinetic profile in the presence or absence of ADH. Because only traces of the ADH/NADH-reduced alcohol derivative of **10** can be detected in organic extracts of this reaction and because the level of volatile organics is comparable to the background levels in heat-treated controls, these results indicate that the spectrophotometric assay was detecting an enzyme activity that was not HPLS. These results were obtained even after further purification of the water soluble extract from *C. pyrenoidosa* by DEAE Sepharose CL-6B columns and gel filtration, where the major protein present had a molecular weight of 46 kDa and maximal activity at pH 6.5, properties similar to those reported previously for HPLS from *C. pyrenoidosa* and *Oscillatoria* (2,3).

In conclusion, the use of GC–MS with a PoraPLOT Q column allowed the development of a method that requires no derivatization, was not affected by the presence of water, did not require cryogenic conditions to be maintained during injection, and allowed for the quantitation of most of the expected volatile products from the action of HPLS upon **1** or **2**. Moreover, the data obtained by using this method show that HPLS resides in the water-insoluble fraction obtained from *C. pyrenoidosa* acetone powder. HPLS activity in an aqueous extract of *C. pyrenoidosa* acetone powder could not be confirmed by the ADH/NADH assay, and the nature of the products arising from the degradation of **2** by enzymatic activity in the aqueous is under study.

ABSTRACT: Pigs were fed a commercial conjugated linoleic acid (CLA) mixture, prepared by alkali isomerization of sunflower oil, at 2% of the basal diet, from 61.5 to 106 kg live weight, and were compared to pigs fed the same basal diet with 2% added sunflower oil. The total lipids from liver, heart, inner back fat, and omental fat of pigs fed the CLA diet were analyzed for the incorporation of CLA isomers into all the tissue lipid classes. A total of 10 lipid classes were isolated by three-directional thin-layer chromatography and analyzed by gas chromatography (GC) on long capillary columns and by silver-ion high-performance liquid chromatography (Ag^+-HPLC); cholesterol was determined spectrophotometrically. Only trace amounts (<0.1%; by GC) of the 9,11-18:2 *cis/trans* and *trans,trans* isomers were observed in pigs fed the control diet. Ten and twelve CLA isomers in the diet and in pig tissue lipids were separated by GC and Ag^+- HPLC, respectively. The relative concentration of all the CLA isomers in the different lipid classes ranged from 1 to 6% of the total fatty acids. The four major *cis/trans* isomers (18.9% 11 *cis*,13 *trans*-18:2; 26.3% 10 *trans*,12 *cis*-18:2; 20.4% 9 *cis*,11 *trans*-18:2; and 16.1% 8 *trans*,10 *cis*-18:2) constituted 82% of the total CLA isomers in the dietary CLA mixture, and smaller amounts of the corresponding *cis,cis* (7.4%) and *trans,trans* (10.1%) isomers were present. The distribution of CLA isomers in inner back fat and in omental fat of the pigs was similar to that found in the diet. The liver triacylglycerols (TAG), free fatty acids (FFA), and cholesteryl esters showed a similar pattern to that found in the diet. The major liver phospholipids showed a marked increase of 9 *cis*,11 *trans*-18:2, ranging from 36 to 54%, compared to that present in the diet. However, liver diphosphatidylglycerol (DPG) showed a high incorporation of the 11 *cis*,13 *trans*-18:2 isomer (43%). All heart lipid classes, except TAG, showed a high content of 11 *cis*,13 *trans*-18:2, which was in marked contrast to results in the liver. The relative proportion of 11 *cis*,13 *trans*-18:2 ranged from 30% in the FFA to 77% in DPG. The second major isomer in all heart lipids was 9 *cis*,11 *trans*-18:2. In both liver and heart lipids the relative proportions of both 10 *trans*,12 *cis*-18:2 and 8 *trans*,10 *cis*-18:2 were significantly lower compared to that found in the diet. The FFA in liver and heart showed the highest content of *trans,trans* isomers (31 to 36%) among all the lipid classes. The preferential accumulation of the 11 *cis*,13 *trans*-18:2 into cardiac lipids, and in particular the major phospholipid in the inner mitochondrial membrane, DPG, in both heart and liver, appears unique and may be of concern. The levels of 11 *cis*,13 *trans*-18:2 naturally found in foods have not been established.
Lipids 33, 549–558 (1998).

Interest in conjugated linoleic acid (CLA) has increased in the past decade as a result of reports of several health benefits related to its consumption. CLA has been reported to protect against cancer (1–8) and atherosclerosis (9,10). In addition, CLA has been reported to decrease body fat while increasing muscle (11,12) and bone mass (13). However, commercial CLA preparations are mixtures of several positional and geometric isomers of conjugated octadecadienoic (18:2) acid. Not all the isomers in these mixtures have been resolved chromatographically, and the active isomer(s) has (have) not been identified. It has been assumed that 9 *cis*,11 *trans*-18:2 is the active isomer, because it is the major isomer present in milk, dairy products and meats (14–18). A recent epidemiological study in Finland, which appears to support this assumption,

Abbreviations: CE, cholesteryl ester; *cis/trans*, refers to the group of CLA isomers, or a specific positional isomer, having either a *cis/trans* or a *trans,cis* configuration; CLA, conjugated linoleic acid; DMOX, 4,4-dimethyloxazoline; DPG, diphosphatidylglycerol (cardiolipin); FAME, fatty acid methyl esters; FFA, free fatty acids; GC, gas chromatography; GC-DD-FTIR, -direct deposition-Fourier transform infrared; GC-EIMS, -electron ionization mass spectrometry; HPLC, high-performance liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; SM, sphingomyelin; TAG, triacylglycerol; TLC, thin-layer chromatography.

found a significant inverse gradient between milk intake and incidence of breast cancer in 4,697 initially cancer-free women over a 25-yr follow-up period (19).

A number of studies reported the presence of CLA isomers in human adipose tissue (20,21), bile (22), blood (15,23–25), and milk (15). CLA isomers were incorporated into both tissue total neutral lipids (5,7,26,27) and total phospholipids (1,2,5,7,26–28), as well as cancer tissue (2) of animals fed CLA diets. Only one recent study presented the content of CLA isomers in the different liver phospholipids of rats fed CLA (28). An accurate assessment of CLA content has so far been prevented, firstly, because acid-catalyzed methylation procedures, which may isomerize the conjugated *cis/trans* to *trans,trans* 18:2 isomers (29), were used in the analysis of CLA isomers (1,2,5,7,16,18,20,26,28); secondly, by the lack of chromatographic methods to separate all the individual CLA isomers. We have just reported a silver-ion high-performance liquid chromatography (Ag^+-HPLC) method which clearly separated for the first time four isomers—11 *cis*,13 *trans*-18:2, 8 *trans*,10 *cis*-18:2, 9 *cis*,11 *trans*-18:2, and 10 *trans*,12 *cis*-18:2—that were found in a commercial CLA preparation, plus the corresponding four *cis,cis* and four *trans,trans* isomers (30, and references cited therein).

In the present communication, we report for the first time the distribution of CLA isomers in the tissues of pigs fed a commercial CLA mixture at 2% of the diet. The CLA isomers were separated by both gas chromatography (GC) and Ag^+-HPLC as their fatty acid methyl esters (FAME). The identity of major CLA isomers was confirmed by GC-direct deposition (DD)-Fourier transform infrared (FTIR) spectroscopy and GC-electron ionization mass spectrometry (EIMS). Adipose lipids generally showed the same distribution of the isomers fed. Liver phospholipids showed an increase of 9 *cis*,11 *trans*-18:2 isomer, while in heart phospholipids an increase of 11 *cis*,13 *trans*-18:2 isomer was found. Diphosphatidylglycerol (DPG) in both liver and heart lipids showed a uniquely characteristic incorporation of 11 *cis*,13 *trans*-18:2.

MATERIALS AND METHODS

Animals and tissues. Pigs (Landrace boar by Landrace × Large White sow) were fed a basal diet (barley, wheat, soybean meal, and canola meal) supplemented with either 2% added sunflower oil or a CLA mixture (Natural Lipids Ltd., Hovdebygda, Norway), from 61.5 to 106 kg live weight, as described elsewhere (12). The CLA content of the commercial product was 55.4% of the total FAME, and the distribution of CLA isomers is included in Table 2 (see below). The total fat content of the diet, which included the 2% added test oil, was 3.2% on a dry matter basis. Eight pigs from each diet were selected for total lipid analysis. At time of slaughter, liver, heart, inner back fat, and omental fat were removed, and portions were immediately frozen and maintained at −70°C until analyzed.

Separation of lipid classes and preparation of FAME. Liver and heart tissues were pulverized at dry ice temperature (31), and the total lipids were extracted with chloroform/methanol (1:1, vol/vol). All the lipid classes were separated on thin-layer plates by three-directional thin-layer chromatography (TLC) using silica gel H plates (32). For each tissue, two TLC plates were used to separate 3-mg portions of total lipids each, to ensure sufficient material was available for analysis of the minor lipid classes. To each isolated lipid class (combined from the two TLC plates), a known amount of methyl heptadecanoate (17:0) was added as an internal standard to permit quantitation of the lipids. The lipid classes, in the presence of silica gel, were methylated using sodium methoxide (Supelco, Inc., Bellefonte, PA) for 15 min at 50°C to avoid isomerization of CLA isomers (29), except free fatty acids (FFA) and sphingomyelin (SM); FFA were methylated with diazomethane (33) and SM (because of *N*-acyl fatty acids) with 5% anhydrous HCl/methanol (w/w) for 1 h at 80°C (34). The resultant FAME were purified by TLC using hexane/diethyl ether/acetic acid (85:15:1, by vol) before analysis by GC and Ag^+-HPLC. Back fat and omental fat were methylated directly with sodium methoxide, and the resultant FAME were purified by TLC. Cholesterol was determined spectrophotometrically as described previously (35).

GC. The total FAME of each individual lipid class from the pig tissues investigated were analyzed by GC (model 5890; Hewlett-Packard, Palo Alto, CA), equipped with a flame-ionization detector. A CP-Sil 88 fused-silica capillary column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Chrompack, Bridgewater, NJ) was used, and H_2 was the carrier gas at a split ratio of 1:15 (29). The column was operated at 150°C for 2 min, then temperature-programmed at 1°C/min to 200°C, followed by a second temperature program at 5°C/min to 215°C, and finally held for 20 min at 215°C; the total run time was 75 min.

HPLC. The total FAME mixtures were separated on a ChromSpher 5 Lipids (4.6 mm i.d. × 25 cm stainless steel; 5-μm particle size) silver-impregnated column (Chrompack), as described recently (30). The mobile phase was 0.1% acetonitrile in hexane, prepared fresh each day. The column was operated isocratically at room temperature for 1 h prior to the initial injection of the day. The flow rate of the mobile phase was 1.1 mL/min, and detection was by ultraviolet at 233 nm. If the HPLC column required regeneration, it was flushed with 1% acetonitrile for 4 h, followed by 1 h with 0.1% acetonitrile. The FAME of each lipid class from all eight pigs were combined for the HPLC analyses. Duplicate HPLC analyses were performed but they were identical, and therefore, no standard errors were calculated. The limited data derived in this study suggest that the response of the different CLA isomers measured at 233 nm was accurate relative to one another. There was generally good agreement in the relative distribution of CLA isomers between GC and Ag^+-HPLC results.

Derivatives of 4,4-dimethyloxazoline (DMOX). Total tissue FAME were hydrolyzed to their FFA using 1 N KOH in 95% ethanol (33). The FFA were placed into a 1-mL screw cap reaction tube with a Teflon liner, and a threefold excess

of 2-amino-2-methyl-1-propanol was added. After purging with argon, the reaction vial was heated for 0.5 h at 170°C. The DMOX derivative was then partitioned into petroleum ether as described previously (36). The reaction product was finally taken up in a minimal amount of isooctane for subsequent GC-EIMS and GC-DD-FTIR analyses.

GC-EIMS and GC-DD-FTIR. The equipment and operating conditions used for the GC-EIMS (37) and GC-DD-FTIR (30,38) are given elsewhere. For GC-EIMS, a 100-m CP-Sil 88 column was used, whereas a 50-m CP-Sil 88 column was used for the GC-DD-FTIR work.

RESULTS

Lipid class composition. The inclusion of CLA in the diet of pigs, fed from 61.5 to 106 kg live weight, did not significantly alter the liver and heart lipid class composition, except for cardiac triacylglycerol (TAG) (Table 1). Heart TAG in pigs fed CLA showed a decrease which was not significant because of the large animal-to-animal variation. Characteristic differences evident between liver and heart lipids were related to the content of phosphatidylcholine (PC), diphosphatidylglycerol (DPG), FFA, and cholesteryl ester (CE). PC, FFA, and CE were lower, and DPG was higher in heart compared to liver lipids (Table 1). There were no diet effects on the total free cholesterol and CE content in liver and heart lipids. The heart contained less free and esterified cholesterol compared to the liver (Table 1).

Separation of CLA isomers by GC. The fatty acid composition of liver, heart, inner back fat, and omental fat lipids was determined by GC using a long capillary column (100 m) with a polar liquid phase (CP-Sil 88), as demonstrated previously for milk analysis (29). The CLA region of the GC chromatogram that is bracketed between linoleic (18:2n-6) and arachidonic (20:4n-6) acids is presented (Figs. 1 and 2) in order to show the position of CLA isomers in relation to neighboring FAME present in tissue lipids. The CLA diet (Fig. 1A) and selected tissue lipid classes of pigs fed CLA (Fig. 1B–D and Fig. 2A–D) are shown. On this GC column, all the CLA isomers eluted between linolenic acid (18:3n-3) and 20:2n-6, a relatively clear region in the GC chromatogram of tissue FAME, with two exceptions. A small (<0.1%) unidentified peak marked "x" (Figs. 1A and 2A) was observed in the GC chromatograms of all lipid classes of pigs fed the control diets, and was also found in the dietary commercial CLA oil. Therefore, minor peak "x" was presumably a combination of an unknown non-CLA and CLA isomer; peak "x" was not included in Table 2. In addition, 21:0, found only in SM, coeluted with the 8 *cis*,10 *cis*-18:2 peak. The GC column was used to separate the *cis/trans* CLA isomers into four peaks in the order: 9 *cis*,11 *trans*-18:2 plus 8 *trans*,10 *cis*-18:2 (tailing peak); a minor component tentatively identified as 9 *trans*,11 *cis*-18:2; 11 *cis*,13 *trans*-18:2; and 10 *trans*,12 *cis*-18:2. The three major *cis/trans* peaks were identified by GC-DD-FTIR and GC-EIMS as their DMOX derivatives. The minor *cis/trans* peak was identified as 9 *trans*,11 *cis*-18:2 based on comparison with the 9 *cis*,11 *trans*-18:2 commercial standard mixture from Matraya Inc. (Pleasant Gap, PA), which contained trace amounts the 9 *trans*,11 *cis*-18:2 isomer (21). The *cis,cis* CLA isomers also separated into four peaks (Figs. 1 and 2). The *cis,cis* configuration was established by GC-DD-FTIR, and the molecular weight was established by GC-EIMS as the DMOX derivative. The elution order of the positional *cis,cis* CLA isomers by GC (8,10; 9,11; 10,12; and 11,13) was determined by comparison with Ag^+-HPLC results (*vide infra*) and found to be the opposite of the latter. The *trans,trans* CLA isomers separated into two peaks: 11 *trans*,13 *trans*-18:2; and 8 *trans*,10 *trans*-18:2, 9 *trans*,11 *trans*-18:2 plus 10 *trans*,12 *trans*-18:2. The *trans,trans* configuration was confirmed by GC-DD-FTIR and the molecular weight and double-bond positions by GC-EIMS.

Separation of CLA isomers by Ag^+-HPLC. The Ag^+-HPLC method, just developed (30), was applied to the separation of FAME CLA isomers in the diet (Fig. 1A') and pig tissue lipid classes (Fig. 1B'–D', and Fig. 2A'–D'). Ultraviolet detection at 233 nm selectively identified FAME with a conjugated double-bond system. Ag^+-HPLC was used to separate the *cis/trans* CLA isomers into four major peaks in the order: 11 *cis*,13 *trans*-18:2, 10 *trans*,12 *cis*-18:2, 9 *cis*,11 *trans*-18:2, and 8 *trans*,10 *cis*-18:2; see Figures 1 and 2. The structures of all four *cis/trans* CLA isomers were identified by GC-DD-FTIR and GC-EIMS as their DMOX derivatives, and by comparison with known standards (30). The *trans,trans* CLA isomers eluted first from the silver ion column. The structures of four *trans,trans* isomers were established by comparison to known and/or standard mixtures of CLA isomers (30); see Figures 1 and 2. Based on the absorption at 233 nm, there were another four unidentified peaks of FAME in this region, including the shoulder on 8 *trans*,10 *trans*-18:2. Infrared and

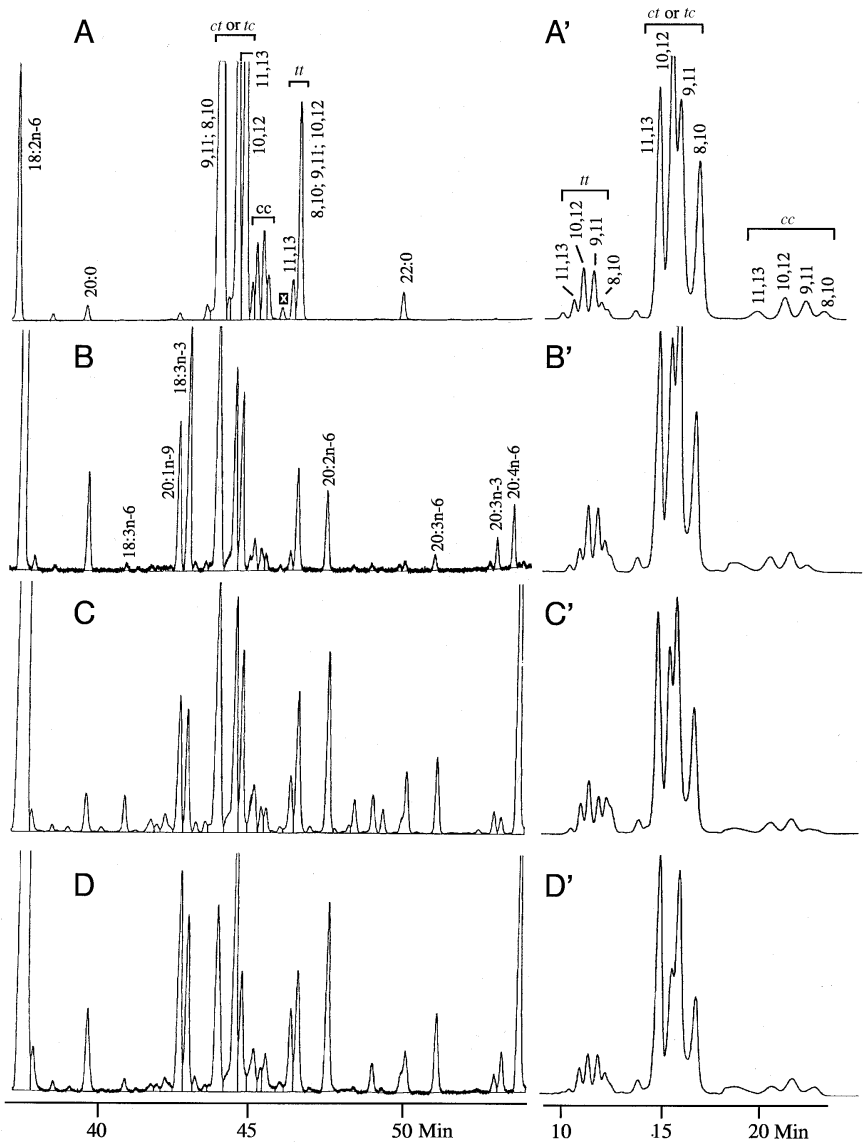

FIG. 1. Partial profiles obtained by gas chromatography (GC) (A to D) and silver-ion high-performance liquid chromatography (Ag^+-HPLC) (A' to D') of the conjugated linoleic acid (CLA) mixture fed to pigs (A,A'), and of CLA isomers found in selected tissues of pigs fed the CLA diet: omental fat (B,B'), liver triacylglycerols (TAG) (C,C'), and heart TAG (D,D'). The GC region selected was between linoleic (18:2n-6) and arachidonic (20:4n-6) acids. All known fatty acids and CLA isomers were labeled; "x" is an unknown in the GC chromatogram which was also found in the chromatograms of both the dietary CLA mixture and the tissues of pigs fed the control and CLA diets. The letters *c* and *t* refer to the *cis* and *trans* CLA isomers. The elution order of the cis,cis CLA isomers is: 8,10-, 9,11-, 10,12-, and 11,13-18:2.

mass spectral confirmation of these isomers is in progress. In the *cis,cis* region four peaks were separated which eluted in the same order as those of the *trans,trans* and *cis/trans* CLA isomers (30) (Figs. 1 and 2).

There may be slight differences in the distribution of CLA isomers between the GC and the Ag^+-HPLC chromatograms in Figures 1 and 2. There were two reasons for this difference. (i) One of eight available GC chromatograms was selected for display (Figs. 1 and 2) and may not reflect the average distribution, whereas for the Ag^+-HPLC, only a single chromatogram was available after the FAME for the same lipid class from all eight pigs on the CLA diet were combined. (ii) Other still unidentified minor components or metabolites of these complex mixtures may also be eluting in the CLA region of the Ag^+-HPLC chromatogram.

CLA content in pig tissues fed the control diet. Pigs fed the control diet showed relatively small peaks (<0.1%) corresponding in retention time to 9 *cis*,11 *trans*-18:2, 9 *trans*,11 *trans*-18:2, and unknown "x" on the GC chromatogram (chromatogram not shown). CLA isomers in tissues from control

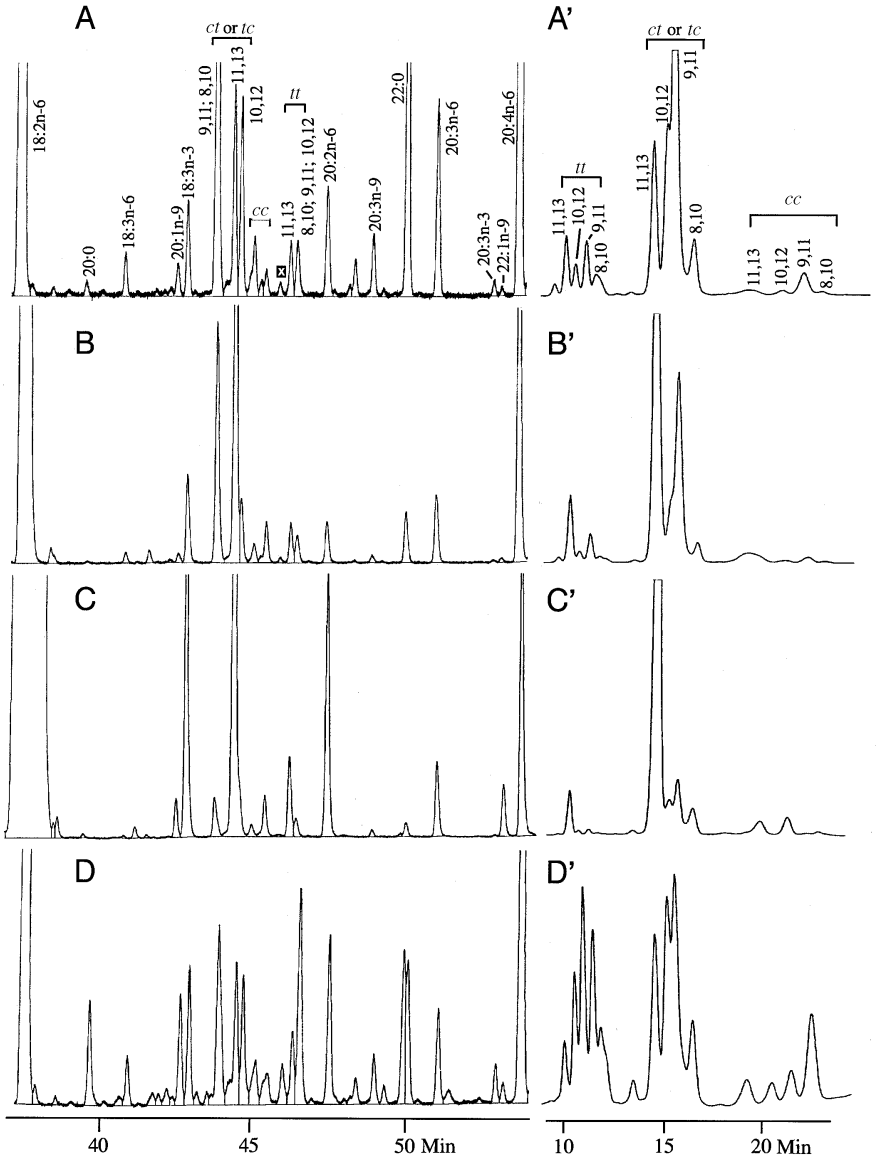

FIG. 2. Partial GC (A to D) and Ag^+-HPLC (A' to D') chromatograms of selected liver and heart lipid classes of pigs fed the CLA diet: liver phosphatidylcholine (PC) (A,A'), heart PC (B,B'), heart diphosphatidylglycerol (DPG) (C,C'), and liver free fatty acids (FFA) (D,D'). For other abbreviations see Figure 1.

animals were only confirmed by their relative retention time on GC. The concentrations of the CLA isomers in the lipids of pigs fed the control diet were too low under our experimental conditions to be detected by ultraviolet at 233 nm after Ag^+-HPLC separation.

CLA isomeric distribution in the diet and adipose tissue. The CLA preparation, included at 2% by weight in the diet, contained 81.7% *cis/trans* CLA isomers, based on Ag^+-HPLC analyses. The reported values are expressed as percentages of total CLA content. The relative concentrations of the four *cis/trans* CLA isomers were found by Ag^+-HPLC to be: 18.9% 11 *cis*,13 *trans*-18:2; 26.3% 10 *trans*,12 *cis*-18:2; 20.4% 9 *cis*,11 *trans*-18:2; and 16.1% 8 *trans*,10 *cis*-18:2. The GC results of the diet are included in Table 2. The total *trans,trans* and *cis,cis* CLA contents were 10.1 and 7.4%, respectively. The inner back fat and omental fat (Figs. 1B and 1B') showed a similar distribution of CLA isomers as that found in the dietary CLA oil.

Total CLA content in tissue lipid classes. The total CLA content in all the tissue lipid classes is shown in Table 2 (last column). The total CLA content was highest in liver TAG (6%) and lowest in liver SM (1%). Back fat showed a higher accumulation of total CLA than omental fat (Table 2). The major phospholipids, PC and PE (phosphatidylethanolamine), incorporated between 2.8 and 5.8% of total CLA. The remaining phospholipids incorporated between 1.5 and 4% of total CLA. DPG, which is a major phospholipid in inner mitochondrial membranes of liver and heart, accumulated about

[a]The identification of the major CLA isomers was confirmed by spectroscopic analyses and comparison with Ag^+-HPLC. The peak between 11*c*,13*c*-18:2 and 11*t*,13*t*-18:2, labeled "x" in Figures 1A and 2A, was not included because it was also present in controls.
[b]For abbreviations see Table 1.
[c]Percentage of total CLA isomers in the total fatty acid methyl ester composition of each lipid class.
[d]Values are means ± SD (n = 8).
[e]The concentration of 8*c*,10*c*-18:2 could not be quantitated in the SM fraction using this GC column because this CLA isomer coeluted with 21:0 present in SM.

2% of total CLA. The highest relative content of *trans,trans* CLA isomers was found in the FFA fraction (Table 2); see liver FFA chromatogram (Figs. 2D and 2D').

Relative CLA isomeric distribution in liver lipids. The distribution and standard deviation (SD) data for CLA isomers determined by GC are presented in Table 2. The relative composition of CLA isomers in liver lipids is summarized graphically in Figure 3 in order to compare it to that present in the dietary CLA oil used. The sum of 9 *cis*,11 *trans*-18:2 and 8 *trans*,10 *cis*-18:2 was increased in liver PC and PE and decreased in DPG, SM, and FFA. The neutral lipids (TAG and CE) and the minor phospholipids (phosphatidylserine and phosphatidylinositol) showed no selectivity in the incorporation of these two CLA isomers compared to the diet. No further conclusions could be made on these data because these two CLA isomers were not separated by GC. To evaluate the effects of each of these two individual isomers, see the Ag^+-HPLC results (Fig. 4). On the other hand, 11 *cis*,13 *trans*-18:2 accumulated in DPG, where its relative concentration increased to 40%, compared to about 20% in the CLA oil. The 10 *trans*,12 *cis*-18:2 isomer was relatively low in all liver lipids compared to its level in the diet. The content of the four

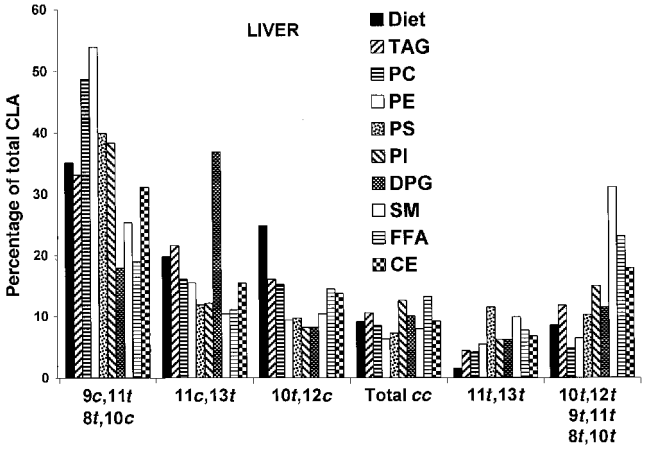

FIG. 3. Quantitative comparison of CLA isomeric distributions determined by GC for the different liver lipid classes that had been previously isolated by thin-layer chromatography (TLC). Relative amounts (*y* axis) are expressed as percentages of total CLA. The CLA isomers are shown (*x* axis) in the GC elution sequence. Total *cc* represents the total of four minor *cis,cis* CLA isomers. The distribution of the CLA isomers in the diet is included for comparison. PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol; SM, sphingomyelin; CE, cholesteryl ester. For other abbreviations see Figures 1 and 2.

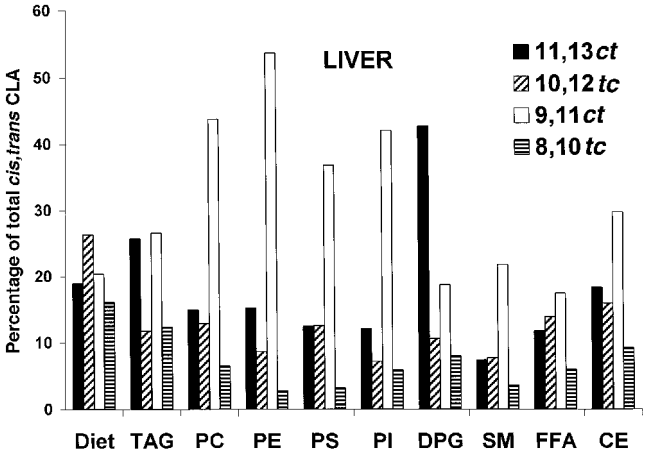

FIG. 4. Quantitative comparison of the four major *cis/trans* CLA isomers in the different liver lipid classes and the diet determined by Ag^+-HPLC. Relative amounts (*y* axis) are expressed as percentage of total *cis/trans* CLA isomers. The distribution of the *cis/trans* CLA isomers in the diet are included for comparison. For abbreviations see Figures 1–3.

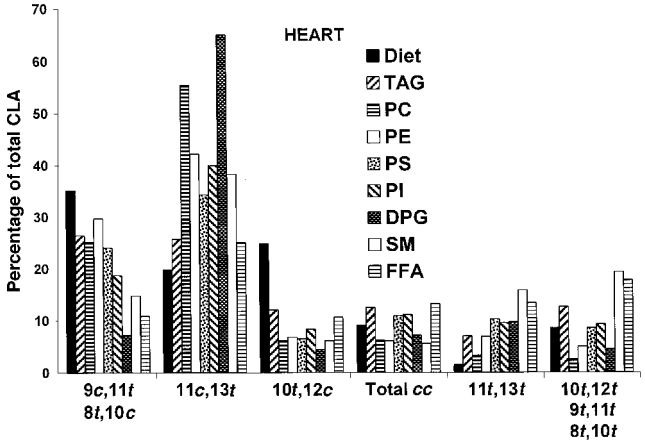

FIG. 5. Quantitative comparison of CLA isomeric distribution determined by GC for the different heart lipid classes that were previously isolated by TLC. For abbreviations see Figures 1–3.

cis,cis CLA isomers was low in liver lipids. Their total concentrations were combined for presentation in Figure 3. The *trans,trans* isomers appeared to accumulate in liver lipids: 11 *trans*,13 *trans*-18:2 into phosphatidylserine and SM, and the mixture of the three *trans,trans* CLA (10,12-, 9,11-, and 8,10-18:2) isomers into SM, FFA, and CE (Fig. 3). The increase of *trans,trans* CLA isomers in SM was due to the acid (HCl/methanol) methylation (29) required to hydrolyze the *N*-acyl fatty acids.

The distribution of the major *cis/trans* CLA isomers in all the liver lipid classes, identified by Ag^+-HPLC, is presented in Figure 4. The results indicate that 9 *cis*,11 *trans*-18:2 was the major isomer in all liver lipids, except DPG, which showed a marked increase in 11 *cis*,13 *trans*-18:2. Furthermore, most liver lipid classes showed markedly lower levels of 8 *trans*,10 *cis*-18:2, and in some lipid classes lower levels 10 *trans*, 12 *cis*-18:2 compared to the distribution found in the CLA diet.

Relative CLA isomeric distribution in heart lipids. Contrary to the liver lipids, the heart showed a high content of the 11 *cis*,13 *trans*-18:2 CLA isomer in all lipid classes, except TAG, as determined by both GC (Fig. 5) and Ag^+-HPLC (Fig. 6). The accumulation was highest in cardiac DPG, in which the relative concentration of the 11 *cis*,13 *trans*-18:2 isomer reached 77% of the total CLA (HPLC results). The second major isomer in heart lipids was 9 *cis*,11 *trans*-18:2. The heart lipids showed much lower levels of 8 *trans*,10 *cis*-18:2 and 10 *trans*,12 *cis*-18:2 compared to those found in the CLA diet (Fig. 6). The content of the *cis,cis* CLA isomers was not increased in the heart (Fig. 5), whereas the *trans,trans* CLA isomers appeared to accumulate relative to the CLA diet, especially in heart FFA (Fig. 5). Again the *trans,trans* content in the SM fractions should be viewed with caution because SM had to be methylated with HCl/methanol (29).

DISCUSSION

Improved separation of CLA isomers. By using optimal conditions, the long polar GC capillary column (100 m SP-Sil 88) separated 10 peaks attributed to CLA (Figs. 1 and 2). Some isomers coeluted, and their complete assignments were not possible, even using GC-DD-FTIR and GC-EIMS. However, identification of the CLA isomers became possible after the development of a new Ag^+-HPLC method (30). Ag^+-HPLC was used to separate *trans,trans*, *cis/trans*, and *cis,cis* CLA positional isomers found in the diet and pig tissues (Figs. 1 and 2). The CLA isomers were identified by comparison to known CLA mixtures and by GC-DD-FTIR and GC-EIMS as their DMOX derivatives (30). Some GC assignments were also confirmed by spiking the samples with known CLA standards. A systematic comparison of the relative intensities of the CLA isomers in the Ag^+-HPLC and GC chromatograms permitted the identification of the isomers resolved by GC. A good example was the one for heart lipids in which the

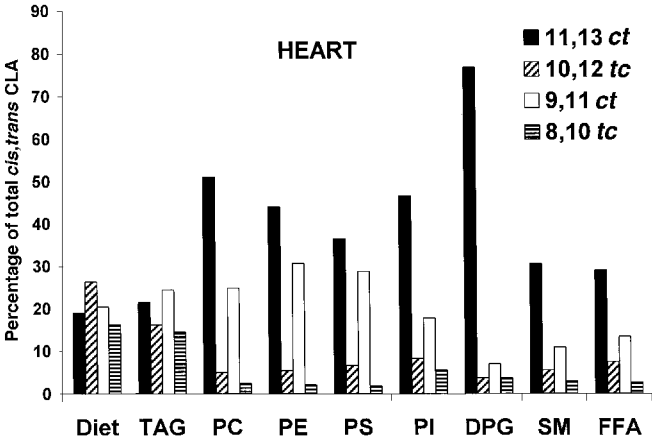

FIG. 6. Quantitative comparison of the four major *cis/trans* CLA isomers in the different heart lipid classes and the diet determined by Ag^+-HPLC. For abbreviations see Figures 1–3.

trans,trans, *cis/trans*, and *cis,cis* 11,13-18:2 were the major CLA isomers in both the Ag^+-HPLC (Fig. 2B') and GC (Fig. 2B) chromatograms.

Previous studies reporting the CLA content in animal tissues have not adequately resolved the CLA isomers, which is now possible using the Ag^+-HPLC method (30). The literature results were presented as 9 *cis*,11 *trans*-18:2 (1,2), total CLA (5,39), or total CLA in total neutral lipids and total phospholipids without (7,26) or with (27,28) some isomer identification. In one study the distribution of CLA isomers in the liver lipid classes was reported (28). Furthermore, in many studies, acid-catalyzed methylation procedures were used (1,2,5,7,13,16,18,20,26,28) to prepare FAME for GC analysis, which generally increased the content of *trans,trans* CLA isomers due to double-bond isomerization (29). That left much of the data on CLA incorporation difficult to interpret other than a general knowledge of total CLA levels. For example, Sugano *et al.* (28), who recently reported the CLA distribution in liver lipid classes of rats fed a 1% CLA preparation for 2 wk, methylated the isolated lipid classes with BF_3/methanol, which significantly increased the *trans,trans* CLA content in all lipid classes. Therefore, the reported CLA composition likely included artifacts: (i) the *trans,trans* isomers were reported as the major isomer in DPG (or cardiolipin), phosphatidylserine, phosphatidylinositol, and PE (28), and (ii) we suspect that one CLA isomer, 9 *cis*,11 *cis*-18:2, was mislabeled in liver DPG (Ref. 28, Fig. 2E). Based on our data (Fig. 2 C and C'), it is presumably 11 *cis*,13 *trans*-18:2. However, as noted earlier, the incorporation of total CLA isomers into hepatic phospholipids, which in their study ranged from 0.8 to 4.5% (28), was generally similar in magnitude to that found in pig liver phospholipids (1.0 to 3.2%, Table 2).

Distributions of CLA isomers into pig tissue lipids. This is the first report showing the accurate separation of CLA isomers found in individual tissue lipid classes from test animals fed CLA. Work is still in progress on the identification of CLA metabolites in pig tissues, and hence was not included in this publication. The total CLA content in pig tissue lipids ranged from 1 to 6%, depending on the tissue and lipid class (Table 2). Generally, the CLA content was higher in the neutral lipids such as TAG, CE, and FFA (3–6%) than in phospholipids such as SM and DPG (1–2%). However, the changes in tissue CLA incorporation appeared to have had no effect on the quantitative lipid class composition in the liver and heart of pigs fed this CLA mixture, except possibly cardiac TAG (Table 1).

Our results indicate that the relative absorption of all the CLA isomers was similar, since there was generally no difference between the distribution of CLA isomers in the commercial CLA preparation fed to pigs and in inner back fat, omental fat, liver TAG, and heart TAG. Sugano *et al.* (28) measured the lymphatic recovery and CLA isomeric composition of the lymph fluid in the rat and found that total CLA was absorbed less (~55%) than linoleic acid (70–80%). However, the composition data included a high *trans,trans* content, presumably generated during methylation with BF_3/methanol. By ignoring their *trans,trans* content in the dietary emulsion and the lymph fluid, the relative distribution of the remaining CLA isomers was similar before and after absorption, which is consistent with our results. The feeding of CLA was reported to decrease subcutaneous fat and increase lean meat (11,12). However, this physiological change was not accompanied by any change in the distribution of CLA isomers in the inner back fat (subcutaneous fat).

Liver and heart each showed a uniquely characteristic distribution of CLA isomers even though both tissues received a generally similar CLA distribution, as evidenced by their respective TAG composition. The reason for the observed differences in relative accumulation of the different CLA isomers in the tissues lipid classes is not clear. The tissue fatty acid composition is a dynamic system constantly receiving, metabolizing, oxidizing, and incorporating dietary fatty acids. The accumulation of 11 *cis*,13 *trans*-18:2 could be due to slower metabolism of this isomer or preferential incorporation. On the other hand, the low content of both 10 *trans*,12 *cis*-18:2 and 8 *trans*,10 *cis*-18:2 could be due to rapid metabolism or selective discrimination. Metabolites of CLA isomers were shown to occur in animal tissues (40,41). In fact, Sébédio *et al.* (42) found that 10,12-18:2 was metabolized to 8,12,14-20:3 and 5,8,12,14-20:4 in essential fatty acid-deficient rats. This would indicate that 10 *trans*,12 *cis*-18:2 was metabolized.

The contents of FFA in both liver and heart lipids were less than 3 and 1%, respectively (Table 1). However, in the FFA fractions, the relative concentrations of the *trans,trans* CLA isomers were more than 30% of the total CLA isomers (Fig. 2D') compared to 10% in the diet. These results suggest that the *trans,trans* CLA isomers were metabolized more slowly than the corresponding *cis/trans* CLA isomers. This result is similar to that observed when rats were fed a diet rich in erucic acid, which accumulated in the cardiac FFA fraction (31). This was partially due to the slower rate of metabolism of erucic acid compared to other fatty acids (43).

Significance of the unique distribution of CLA isomers into pig tissue lipids. The information available to date does not permit drawing a definitive conclusion regarding the favorable or adverse biological activity of any of the CLA isomers. To our knowledge, there are no studies in which individual synthetic CLA isomers have been evaluated in biological systems. The only study in which a natural extract (from fried ground beef) was used exhibited anticarcinogenic properties (44).

If 9 *cis*,11 *trans*-18:2 is assumed to be the active CLA isomer, then the incorporation/accumulation of the 11 *cis*,13 *trans*-18:2 CLA isomer into heart phospholipids, and particularly DPG in both heart and liver, could be viewed with concern. DPG is found principally in the inner mitochondrial membrane and is intrinsically involved in many of the enzymes of bioenergetics of mitochondria; see reviews (45,46). The incorporation of 11 *cis*,13 *trans*-18:2 into mitochondrial DPG could adversely affect the activity of key enzymes in mitochondrial energetics, because DPG is firmly imbedded in

many of these enzymes (45). A marked decrease in the linoleic acid content of inner mitochondrial DPG could also affect enzyme activity. In fact, Sugano *et al.* (28) showed that feeding CLA to rats produced a significant decrease of linoleic acid from 69.6 to 54.7% in liver DPG. However, we did not find a change in the content of linoleic acid in pig liver (control 75% vs. CLA 73%) or heart (control 85% vs. CLA 86%) DPG fed the CLA diet (the complete fatty acid composition will be published elsewhere). We also did not find any gross pathological abnormalities in this pig study (12). It should be noted that specific mitochondrial functions have not yet been evaluated.

The large epidemiological study conducted in Finland (19) indirectly supports the conclusion that 9 *cis*,11 *trans*-18:2 is the active isomer, because this is the major CLA isomer in milk. We have reexamined milk and dairy products using the new Ag^+-HPLC method (30) and confirmed that 9 *cis*,11 *trans*-18:2 is the major CLA isomer in milk (Sehat, N., private communication). Based on this assumption, it might be prudent to revise commercial CLA preparations to exclude the 11 *cis*,13 *trans*-18:2 CLA isomer as a major component.

On the other hand, if we assume that 9 *cis*,11 *trans*-18:2 is not the only active isomer in CLA preparations, then the incorporation of 11 *cis*,13 *trans*-18:2 into cardiac and DPG lipids (this study), and/or the desaturation and elongation of 10 *trans*,12 *cis*-18:2 in essential fatty acid-deficient rats (42), could be viewed as beneficial. Certainly many of the feeding trials, which included several CLA isomers, have also shown anticarcinogenic (1–8) and other beneficial responses (9–13). Pariza *et al.* (47) reported that 9 *cis*,11 *trans*-18:2 was metabolized to 11 *cis*,13 *trans*-20:2, and the latter exhibited similar biological activity to that of CLA isomeric mixtures. This is most interesting, since the configuration of 11 *cis*,13 *trans*-20:2 from the carboxyl group to the conjugated system is identical to that of 11 *cis*,13 *trans*-18:2.

There is a definite need for further feeding studies using pure CLA isomers to clarify these issues.

Dietary Docosahexaenoic Acid and Immunocompetence in Young Healthy Men

D.S. Kelley*, P.C. Taylor, G.J. Nelson, and B.E. Mackey

USDA, ARS, Western Human Nutrition Research Center,
and Western Regional Research Center, Presidio of San Francisco, California

ABSTRACT: The purpose of this study was to examine the effect of dietary docosahexaenoic acid (DHA), in the absence of eicosapentaenoic acid, on human immune response (IR). A 120-d study with 11 healthy men was conducted at the Metabolic Research Unit of the Western Human Nutrition Research Center. Four subjects (control group) were fed the stabilization or basal diet (15, 30, and 55% energy from protein, fat, and carbohydrate, respectively) throughout the study; the remaining seven subjects (DHA group) were fed the basal diet for the first 30 d, followed by 6 g DHA/d for the next 90 d. DHA replaced an equivalent amount of linoleic acid; the two diets were comparable in their total fat and all other nutrients. Both diets were supplemented with 20 mg d-α-tocopherol acetate per day. Indices of IR were examined on study day 22, 30, 78, 85, 106, and 113. Addition of DHA at moderately high levels did not alter the proliferation of peripheral blood mononuclear cells cultured with phytohemagglutinin or concanavalin A, or the delayed hypersensitivity skin response. Also, additional DHA did not alter the number of T cells producing interleukin 2 (IL2), the ratio between the helper/suppressor T cells in circulation, or the serum concentrations of immunoglobulin G, C3, and interleukin 2 receptor (IL2R). DHA supplementation, however, caused a significant ($P = 0.0001$) decrease in the number of circulating white blood cells which was mainly due to a decrease in the number of circulating granulocytes. The number of lymphocytes in peripheral circulation was not affected by Dietary DHA enrichment, but the percentage of lymphocytes in white blood cells increased because of a reduction in granulocyte numbers. None of these indices was changed in the control group. Our results show that when total fat intake is low and held constant, DHA consumption does not inhibit many of the lymphocyte functions which have been reported to be inhibited by fish oil consumption.
Lipids 33, 559–566 (1998).

Both the amount and type of dietary fat modulate human immune response (IR). A reduction in total fat intake enhances several indices of IR, and the converse occurs with an increase in dietary fat (1–4). A moderate increase in the consumption of the n-6 polyunsaturated fatty acids (PUFA), linoleic acid (LA), or arachidonic acid did not lower the human IR when total fat intake was maintained constant (1,2,5). But n-6 PUFA lowered human IR when its addition to the diet caused an increase in the total fat intake (4). The addition of n-3 PUFA from fish oil or flaxseed oil also reduced several aspects of the human IR (6–19). Since total fat intake was not kept constant in most of these studies, it is difficult to determine if the decline in IR was due to the amount or the type of fat, or a combination of the two factors. Because fish oils cause a decrease in IR, their use has been explored in the management of autoimmune disorders (20–24).

Fish oils contain a variable mixture of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), along with many other fatty acids, cholesterol, heavy metals, and chlorinated hydrocarbons. It is not known if the decline in IR caused by the fish oils is due to EPA, DHA, both, or some other factors. Purified esters of EPA lowered several aspects of the IR in humans (13,14,19). *In vitro* studies conducted with human (25) and rat lymphocytes (26) and *in vivo* studies in rats (27) showed that DHA esters/salts also inhibit immune cell functions. Until recently, purified DHA was not available for human use, and no studies regarding its effects on human IR have been done. Studies with DHA are important, because it is the major n-3 fatty acid in tissues, and the body tends to conserve it over EPA. Such studies are now possible with the availability of DHASCO^{TM} oil (a gift from Martex Corporation, Columbia, MD), which contains 40% DHA as natural triacylglycerol.

The purpose of this study was to examine the effect of a moderately high intake (6 g/d) of DHA (in the absence of EPA) on human immunocompetence, while dietary fat was held constant. To avoid increased oxidative stress from the consumption of DHA, 20 mg d-α-tocopherol acetate was added to the diets daily. We examined the effect of feeding DHASCO^{TM} oil (15 g/d) for 83 d on several indices of immune status [complete and differential blood cell count, lymphocyte phenotypic analysis and *in vitro* proliferation, serum immunoglobulin G (IgG), C3, and interleukin 2 receptor (IL2R)] in healthy men. In previous studies with dietary fish oil these indices were found to be altered.

Abbreviations: Bq, Becquerel; CD, cluster designation; Con A, concanavalin A; CTL, cytotoxic T; DHA, docosahexaenoic acid; DTH, delayed type hypersensitivity skin response; EPA, eicosapentaenoic acid; IL, interleukin; IR, immune response; LA, linoleic acid; LTB_4, leukotriene B_4; PBMNC, peripheral blood mononuclear cells; PHA, phytohemagglutinin; PMN, polymorphonuclear leukocytes; PUFA, polyunsaturated fatty acid; WBC, white blood cell.

MATERIALS AND METHODS

Subjects and study design. The study protocol was approved by the Human use committees of the University of California at Davis, and the USDA committee (Houston, TX). Twelve healthy men were selected for the study after a physical and clinical examination by a licenced physician. The study lasted for 120 d (April 1 to July 29, 1996) although no immunological tests were conducted after d 113, because of other scheduled procedures. Subjects lived at the Metabolic Research Unit of the Western Human Nutrition Research Center for the duration of the study, except when going for daily walks (2 × 2 miles) or other scheduled outings. They consumed only those foods prepared by the staff of the Metabolic Research Unit, and were under constant supervision. Subjects were divided into two groups: a control group of four was fed the stabilization or basal diet for all 120 d of the study; the remaining eight subjects (DHA group) were fed the basal diet for the first 30 d of the study and a DHA-supplemented diet for the last 90 d. One subject from the DHA group did not complete the study; hence, data from only seven subjects were evaluated to determine the effects of DHA on IR.

Both diets were intended to provide 15, 30, and 55% energy from protein, fat, and carbohydrates, respectively. As shown in Table 1, the analyzed compositions of each of the two diets were not different from one another or from the planned values. Diets composed of natural foods, except DHA and vitamin E, were fed in a 5-d rotating menu, comprising three meals and a post-dinner snack. Body weights of the subjects were maintained within 2% of their initial weights throughout the study, by adjusting their energy intake if necessary. For the DHA-supplemented group, 15 g of DHASCO^{TM} oil was incorporated by replacing an equivalent amount of safflower oil; all other foods were identical between the two diets. The DHASCO^{TM} oil, purified from an alga, contains 40% DHA as triacylglycerol. It also contains 12:0 (3.8%), 14:0 (13.5), 16:0 (11.5%), 18:0 (1.2%), 18:1n-9 (27.9), and the balance as minor components. The main effect of incorporating 15 g DHASCO^{TM} oil by replacing an equivalent amount of safflower oil was to replace 6 g linoleic acid (LA) with the same amount of DHA. The DHASCO^{TM} oil was kept in sealed containers at –20°C, and all open bottles were flushed with nitrogen before returning to the refrigerator. It was served only in cold foods such as yogurt, dips, or salads. Thus, the chances of DHA oxidation were minimized. Dietary composites from each of the 5-d menus for both diets were analyzed for macronutrients. The micronutrient content of the diets was calculated using USDA Handbook 8 (28); all nutrients were at or above the recommended dietary allowances and were not different between the two diets. Diets contained about one recommended dietary allowance of vitamin E from natural foods (calculated using values from USDA Handbook 8) and were supplemented with an additional 20 mg/d of d-α-tocopherol acetate (Bronson Pharmaceutical, St. Louis, MO).

TABLE 1
Nutrient Composition of Experimental Diets[a]

	Energy %	
Nutrient	DHA diet	Control diet
Protein	15.2 ± 1.3	14.6 ± 1.2
Carbohydrate	53.9 ± 6.0	56.4 ± 6.8
Fat, total	30.9 ± 4.3	29.0 ± 3.8
Saturated	8.9 ± 0.9	8.1 ± 0.9
Monounsaturated	9.2 ± 0.7	9.2 ± 0.8
n-6 Polyunsaturated	6.5 ± 0.8	8.5 ± 0.7
n-3 Polyunsaturated	2.8 ± 0.1	1.1 ± 0.1
Trans	1.9 ± 0.3	2.1 ± 0.3
P/S ratio	1.2	1.1
Cholesterol (mg/d)	360	360

[a]Data shown are the mean ± SD of five dietary composites from five different menu days. Polyunsaturated/saturated (P/S) ratio and cholesterol levels are calculated and not analyzed; hence, SD is not shown for these variables. DHA, docosahexaenoic acid.

Laboratory procedures. Blood samples were collected between 7: 00 and 8:00 A.M. after an overnight fast on study days 22, 30, 78, 85, 106, and 113, by antecubital venipuncture into evacuated tubes containing heparin for cell culture experiments, EDTA for blood cell count and phenotypic analysis, and no anticoagulant for preparation of sera.

Blood cell count and lymphocyte phenotypic analysis. For each blood draw, a complete and differential cell count was performed by using a Serono Baker Automated system (model 9000 diff; Allentown, PA). Phenotypic analysis for B (CD19+), T (CD3+), helper (CD3+, CD4+), suppressor (CD3+, CD8+), natural killer (CD3-,CD16+, 56+), and cytotoxic T (CTL; CD3+, CD16+, 56+) cells was done by using Becton-Dickinson FACStar flow cytometer (San Jose, CA) as previously reported (5). The numbers of lymphocytes producing IL2 were also determined with the flow cytometer, using instructions and reagents provided by Becton-Dickinson. The lymphocytes were activated by mixing 500 μL of whole blood with 500 μL RPMI-1640, containing 10 μg brefeldin A, 25 ng phorbol 12-myristate 13-acetate, and 1 μg ionomycin. An unstimulated tube containing only blood and brefeldin was used as a control. The tubes were incubated at 37°C in 5% CO_2 for 4 h. The T-cell surface antigen (CD3+) was stained for 30 min with R-phycoerythrin-Cyanin5-CD3 monoclonal antibody. The cells were incubated for 10 min in Facs Lysing Solution to lyse the red cells. The cells were then centrifuged and resuspended in Facs Permeabilizing Solution. After a 10-min incubation period, 2 mL of phosphate buffered saline was added, the cells centrifuged, and the supernatant discarded. The pellet was stained with fluorescent-conjugated intracellular IL2 monoclonal antibody and incubated for 30 min. The cells were washed once with phosphate buffered saline and resuspended in 1% paraformaldehyde. The number of IL2-producing cells was analyzed with a flow cytometer with gating on the CD3+ cells.

Proliferation of peripheral blood mononuclear cells (PBMNC). PBMNC were isolated using Histopaque-1077 as previously reported (5,6) and cultured in RPMI-1640 containing 10% autologous serum. One hundred microliters of the culture medium containing 1×10^5 PBMNC were inoculated

in each well of a 96-well flat-bottom culture plate. An additional 100 μL of the culture medium with or without the mitogens was added to each well. The mitogens used were phytohemagglutinin (PHA) and concanavalin A (Con A). Both PHA and Con A were used at three concentrations; final concentrations (mg/L) in the culture media were 2.5, 5, and 10. PBMNC were cultured for a total of 72 h; [^{3}H] thymidine, 37 K becquerel (Bq), in 50 μL, was added to each well during the last 24 h. PBMNC were collected on filter strips, and the radioactivity was determined using a Packard β-gas counter. [^{3}H] thymidine incorporation into cellular DNA (Bq/1000 cells) was used as the index of PBMNC proliferation.

Delayed type hypersensitivity (DTH) skin response and the serum IgG, C3, and IL2R. DTH response to seven recall antigens was assayed by intradermally injecting 0.1 mL of each antigen solution into the forearm. The antigens used were tuberculin purified-protein derivative (1 international test unit), mumps (4 complement-fixing test units), tetanus toxoid (1:100, vol/vol dilution of a solution containing 4 flocculation units/0.5 mL), candida (1:100, vol/vol dilution), trichophyton (1:30, vol/vol dilution), streptokinase streptase (100 KU/L), and coccidioidin (bioequivalent to U.S. reference coccidioidin 1:100, provided by the Office of Biologics, Food and Drug Administration, Washington, DC). The antigens were diluted with a diluent containing, per liter, 3 mL normal human serum and 9 g sodium chloride. Tuberculin purified-protein derivative, mumps, and tetanus toxoid were supplied by Connaught Laboratories Inc. (Swiftwater, PA). Candida (Dermatophyton O), trichophyton, and the antigen diluent were obtained from Hollister Stier (Spokane, WA). Streptokinase streptase and coccidioidin were purchased from Behringwereke A.G. (Marburg/Lahn, Germany, and Berkeley Biologicals (Berkeley, CA), respectively. Response to these antigens was determined by measuring mean induration diameters (mm) at 48 h after injections. Induration diameters with less than 4 mm were scored negative. Data are reported as the mean sum of induration diameters for all positive responses (induration score) and the number of positive responses to the seven antigens (antigen score).

Serum IgG and C3 concentrations were determined using a nephelometer as previously reported (6). Serum IL2R was quantified by using an ELISA kit purchased from Immunotech (Westbrook, ME).

Data analysis. For both dietary groups, two determinations of IR were made at the end of stabilization, middle, and end of the intervention periods (d 23, 30, 78, 85, 106, and 113). Means of the two measurements are shown in the Results section. A repeated measure of analysis of variance model was used to determine the effects of DHA on the indices of IR tested. A univariate, split-plot approach was taken using SAS PROC MIXED (29). Contrasts were constructed for comparisons among the stabilization and intervention periods, and in cases for which responses were linear, the control and DHA group slopes were compared. Changes in the parameters examined are considered significant for $P < 0.05$ unless otherwise stated.

RESULTS

The mean ± SEM for age (yr), weight (kg), and body mass index (kg/m^2) for subjects in DHA group ($n = 7$) and control group ($n = 4$) were 33.1 ± 1.8, 78.6 ± 4.2, 23.7 ± 0.8, and 33.3 ± 3.1, 74.7 ± 4.2, 23.1 ± 1.1, respectively. None of these physical characteristics was different between the two groups.

The average daily energy intake for all subjects was 11.7 MJ (2800 Kcal), and was not different between the two groups. The total fat intake was also similar between the two groups. Fatty acid composition of the two diets is shown in Table 2. Fatty acids other than DHA, linoleate, laurate, and myristate were not different between the two diets. The DHA diet contained 6.5 wt% of DHA, while the control diet contained less than 0.1% of it. Since DHA was incorporated by replacing equivalent amount of LA, the control diet contained 6.7% more LA than the DHA diet. The laurate and myristate contents of the DHA diet were approximately twice their levels in the basal diet, but they were still only 1.3 and 4.3% of the total fatty acids, respectively.

Effect of DHA on circulating white blood cells (WBC). The number of total circulating WBC, along with their differentiation into granulocytes or polymorphonuclear leukocytes (PMN), monocytes, lymphocytes, and various subsets of lymphocytes is shown in Table 3. This table shows that in the DHA group the number of circulating total WBC decreased by 10%, from the end of stabilization period (day 30) to the end of the intervention period (day 113). This decrease in WBC numbers was statistically significant ($P = 0.0001$). The decrease in WBC in the DHA group was primarily due to a decrease in the number of PMN, which were reduced by 21% ($P = 0.0001$). The decrease in the number of circulating PMN

NK (CD3-, 16+, 56+)[1]	0.25 ± 0.04	0.24 ± 0.04	0.25 ± 0.13	0.20 ± 0.07
CTL (CD3+,16+, 56+)[1]	0.06 ± 0.01	0.06 ± 0.01	0.05 ± 0.01	0.06 ± 0.01

[a]WBC, white blood cells; PMN, polymorphonuclear leukocytes; CD, cluster designation; NK, natural killers; and CTL, cytotoxic T. Data shown are mean ± SEM for the number of subjects shown. Study day 30 and 113 correspond to the end of stabilization and intervention dietary periods, respectively. Although data are shown only for the end of the stabilization and intervention periods, data from study days 22,30,78,85,106, and 113 were all used to determine dietary effects using repeated measures of analysis of variance (ANOVA). Superscript(*) indicates significant change with DHA feeding (P = 0.0001), and superscript 1 indicates cell number × 10^{-9}/L blood. NK, See Table 1 for other abbreviations.

was also evident if these cells were expressed as percentage of the total WBC. The temporal changes in the number of circulating WBC and PMN for both the control and DHA groups are shown in Figure 1. This figure shows that the reduction in WBC and PMN numbers in the DHA group was evident within 50 d of DHA supplementation.

Table 3 also shows that the number of monocytes in the DHA group also decreased; however, it did not reach statistical significance. The number of total WBC, PMN, and monocytes in the control group, and that of lymphocytes in both groups remained unchanged throughout the study. The percentage of lymphocytes in the DHA group was increased (P = 0.0001) with DHA supplementation, because of the reduction in granulocytes in this group. DHA supplementation did not affect the number of B, total T, helper T, suppressor T, helper/suppressor ratio, CTL, or natural killer cells in circulation. The number of T cells producing IL2 was about 40% in both groups, and was not changed by DHA supplementation.

Effect of DHA feeding on PBMNC proliferation. Table 4 contains data regarding the proliferation of PBMNC cultured with three different concentrations of PHA and Con A. At the suboptimal concentration of PHA (2.5 mg/L), proliferation in both groups was higher at day 113, compared to the corresponding values at day 30. However this increase was not statistically significant and was not due to DHA intake. At this PHA concentration, PBMNC proliferation values at study day 78 for the DHA and control groups were 10.7 ± 1.4, and 9.2 ± 1.6, respectively, and were not different from the corresponding values at study day 30 (Table 4). PBMNC proliferation did not change at PHA concentration of 5 or 10 mg/L, or at any of the concentrations of Con A, throughout the study.

Effect of DHA on DTH skin response and serum concentrations of IgG, C3, and IL2R. Table 5 contains the data for both the groups regarding the immune indices listed above. Both the induration and antigen scores on day 113 were lower than at day 30 in both groups; however, none of these de-

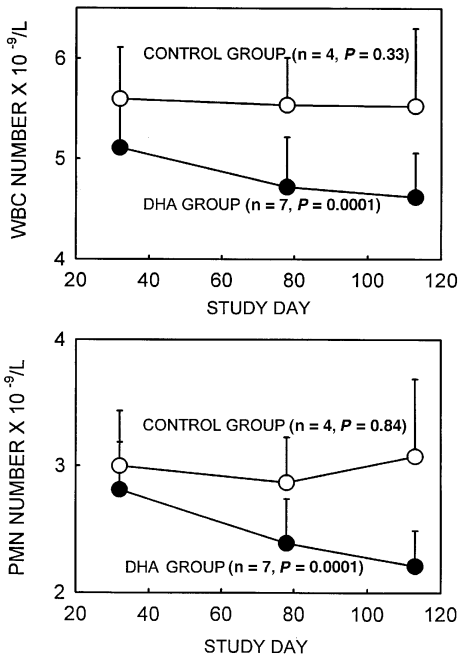

FIG. 1. Docosahexaenoic acid (DHA) feeding decreases the number of circulating white blood cells (WBC) and polymorphonuclear leukocytes (PMN). Data shown are the mean ± SEM for the number of subjects shown. The P values shown were obtained by analysis of variance.

TABLE 4
DHA Feeding Does Not Alter the Proliferation (Bq/1,000 cells) of PBMNC Cultured with Mitogens[a]

	DHA group (n = 7)		Control group (n = 4)	
Mitogen (mg/L)	Study day 30	Study day 113	Study day 30	Study day 113
PHA, 2.5	10.20 ± 0.97	13.61 ± 1.09	8.80 ± 1.00	12.56 ± 0.98
PHA, 5	13.65 ± 0.82	14.26 ± 0.83	13.37 ± 0.70	14.29 ± 1.11
PHA, 10	13.90 ± 0.92	14.47 ± 0.74	13.63 ± 0.75	15.20 ± 0.74
Con A, 2.5	6.24 ± 0.35	6.13 ± 0.45	5.55 ± 1.02	5.36 ± 0.76
Con A, 5	8.70 ± 0.43	8.52 ± 0.47	7.72 ± 0.89	7.95 ± 0.67
Con A, 10	10.08 ± 0.48	9.43 ± 0.46	9.04 ± 0.76	8.66 ± 0.95

[a]Data shown are mean ± SEM for the number of subjects shown for each group. Study days 30 and 113 correspond to the end of stabilization and intervention dietary periods, respectively. PHA, phytohemagglutinin; Con A, concanavalin A; Bq, becquerel; and PBMNC, peripheral blood mononuclear cells. None of these variables was altered by DHA supplementation as determined by repeated measures of ANOVA using data from study days 22, 30, 78, 85, 106, and 133. See Tables 1 and 3 for other abbreviations.

creases was statistically significant, and could not be attributed to DHA feeding. These changes were primarily due to a reduction in response to tetanus antigen. At day 30, six of the subjects in the DHA group tested positive for this antigen, with an induration (mean ± SEM) of 12.7 ± 2.4 mm. However, at day 113, only three of the subjects tested positive for this antigen in the DHA group, with an induration of 9.5 ± 0.5 mm. In the control group, all four subjects tested positive for tetanus on day 30, with an induration of 12.2 ± 2.4 mm. Only three subjects in the control group tested positive on day 113, with an induration of 8.0 ± 1.5 mm. It is possible that dietary enrichment or enrichment with DHA reduced the induration due to tetanus; however, because not all subjects responded to this antigen, we did not have adequate power to test the significance of the reduction in this response. Serum levels of IgG, C3, and IL2R were not affected by either diet (Table 5).

DISCUSSION

We examined if supplementation of diets with DHA triacylglycerol would lower human IR, as previously reported with fish oil supplementation. In contrast to most of the previous studies with fish oils, we maintained total fat intake constant, supplemented DHA in the absence of dietary EPA, and ensured adequate vitamin E intake by additional supplementation of d-α-tocopherol acetate at 20 mg/d. All these factors are important in evaluating the effects of n-3 PUFA on human IR.

Dietary DHA enrichment did not lower lymphocyte proliferation or the DTH skin response in the present study unlike results reported in a number of human studies in which fish oils or purified EPA were added to the diets without adjustment for the extra fat intake (8–14). There was no change in the number of lymphocytes producing IL2 or in the ratios between helper and suppressor T cells, as reported by others using EPA (8,13). Neither did DHA feeding alter the serum levels of IgG, C3, and IL2R. We believe the low and constant fat content of our experimental diets is the most likely reason why DHA did not inhibit the indices of IR as previously found by others with fish oils or EPA. It is likely that in studies with fish oils the increase in both total fat and n-3 PUFA contributed to the inhibition of IR.

Fish oils also contain EPA, which inhibits IR in humans (13,14,19), and it may be a more potent inhibitor than DHA. About 9% of the dietary DHA is retroconverted to EPA in humans (30,31). DHA supplementation raised its concentration from 1.8 to 8.1 wt% of plasma fatty acids, and that of plasma EPA from 0.38 to 3.39 wt% in the subjects included in our current study (32). Whether this amount of EPA is adequate to inhibit IR, or it is metabolized differently from the dietary

TABLE 5
DHA Feeding Does Not Alter DTH Response, and Serum Concentrations of IgG, C3, IL2R[a]

	DHA group (n = 7)		Control group (n = 4)	
	Study day30	Study day 113	Study day 30	Study day 113
Induration (mm)	39.4 ± 4.6	33.4 ± 6.4	35.1 ± 4.2	23.8 ± 1.3
Antigen Score	3.2 ± 0.4	3.0 ± 0.4	3.0 ± 0.4	2.5 ± 0.6
IgG (μmol)	86.0 ± 8.4	91.6 ± 8.4	85.1 ± 3.7	93.0 ± 8.2
C3 (μmol)	9.9 ± 0.4	9.8 ± 0.4	11.4 ± 1.5	11.8 ± 0.9
IL2R (nmol)	188.0 ± 17.1	189.3 ± 17.5	170.4 ± 15.3	195.1 ± 45.6

[a]DTH, delayed type hypersensitivity skin response; IgG, immunoglobulin G; C3, complement fraction 3; IL2R, interleukin 2 receptor. Data shown are mean ± SEM for the number of subjects shown for each group. Study days 30 and 113 correspond to the end of stabilization and intervention dietary periods, respectively. Antigen score refers to the number of antigens tested positive at 48 h after the application of 7 recall antigens. None of the variables was altered by DHA supplementation. See Table 1 for other abbreviation.

EPA is unknown. With the exception of a decrease in arachidonic acid, the plasma concentration of other fatty acids was not changed with DHA feeding (32). The modest increase in vitamin E intake in our study may also have prevented the inhibition of IR by DHA, as others (15) have shown that very high doses of α-tocopherol (200 mg/d) can overcome the inhibition of IR caused by fish oils (15 g/d). The amount of DHA in our study is comparable to the total of EPA and DHA provided from 15 g of fish oil; however, we provided only 10% of the vitamin E provided by these workers.

Which of the three factors (total fat, EPA, vitamin E) discussed above is more important cannot be answered from our study design. Regardless of the mechanisms involved, our results show that if total fat intake is maintained constant, a moderately high intake of DHA as triacylglycerol does not inhibit several indices of human IR that have previously been reported to be inhibited by fish oils, purified EPA, or flaxseed oil.

Our results do show a significant decrease in the number of circulating PMN in the subjects fed the DHA-containing diet. We are aware of only one human study with n-3 fatty acids where such effects have been reported in abstract form (33). Results from our current study regarding the number of circulating PMN contrast our recent findings with arachidonic acid feeding (5), where we found significant increase in their number in peripheral blood in the group fed arachidonic acid-containing diet. These opposing effects of DHA and arachidonic acid on the number of circulating PMN are consistent with their many other opposing effects on several physiological functions. The concept of dietary fats affecting the formation or maturation of WBC is relatively new and poorly understood. However, there are reports showing the inhibition of tumor development in animals fed diets supplemented with n-3 fatty acids (34,35). Results from a recent study by other investigators (36) showed that the number of colony-forming units–granulocyte macrophage in the bone marrow increased twofold in rats fed diets containing DHA, compared to the corresponding numbers in the rats fed a control or n-6 PUFA diet. If all of these colony-forming units attained maturation and their release into blood was proportional to their numbers in the marrow, then the number of PMN and monocytes should be higher in the blood of DHA-fed rats than those in the control or n-6 PUFA diet-fed rats. Unfortunately, these workers did not perform blood cell counts. The decrease in the number of PMN in drawn blood as seen in our study and the increase in the colony-forming units in the bone marrow of rats seem inconsistent; however, these two results become consistent if DHA blocks the migration of these cells from bone marrow to blood or increases their margination in the circulation. Of course, the differences could be simply due to species differences, but still it is important that future studies in this area monitor both colony-forming units in bone marrow and the number of granulocytes and monocytes in blood.

Colony-forming units are the precursors of both monocytes and PMN, yet we found significant decrease in the number of circulating PMN only. A close look at our data in Table 3 suggests that the number of circulating monocytes also decreased in the subjects fed the DHA-containing diet, but this decrease did not attain statistical significance. We may not be able to detect the change in the number of circulating monocytes, because of their relatively small numbers compared with PMN numbers. Results from the rat study suggest that this is the most likely explanation for our results with PMN and monocytes. However, other explanations such as the effect of DHA on PMN proliferative and storage pools, their apoptosis and egress from bone marrow could also explain our results. The number of lymphocytes, which are derived from a different progenitor cell than the PMN and monocytes, was not affected by DHA feeding. Actually, lymphocytes as a percentage of WBC increased because of the decrease in PMN count. Thus, it seems that DHA effect was specific for granulocytes or for granulocyte-monocytes.

The number of circulating PMN is influenced by a number of hormones, growth factors, toxins, and cytokines. We are not sure of the mechanisms by which DHA caused the decrease in the number of circulating PMN. We did monitor the concentrations of cortisol, T3, and T4 in the sera of our study subjects (not shown); none of these hormones changed in both groups during the study. Feeding diets containing fish oil to healthy subjects decreased leukotriene B_4 (LTB_4) production by isolated neutrophils and monocytes (12), and LTB_4 is known to enhance neutrophil chemotaxis and diapedesis (37). It is possible that increased intake of DHA reduced LTB_4 production in our study, which may have mediated the decrease in the number of circulating PMN.

It is possible that some of the effects observed in this study were due to a reduction in LA intake rather than the increase in DHA intake. The intake of LA was decreased by about 7 g/d in the high DHA diet compared to the basal diet. The subjects on the high DHA diet were still receiving more than 20 g/d LA, an amount that will flood the fatty acid metabolic acid pathways and is well above any known requirements for LA. The plasma LA content in the basal and high DHA diets fed subjects was 39 and 36%, respectively. The difference between the two groups was not statistically significant. The basal diet contained less than 50 mg DHA per day, and the high DHA diet had 6 g/d. Thus, it is unlikely that any of the changes in immune functions were due to a 20% reduction in LA intake. These were most likely the result of increase in DHA intake.

Although the PMN counts decreased by 21%, the residual counts were still within the clinically normal ranges. The subjects fed the high DHA diet did not show an increase in the rate of infections or any other health problems. The risk for infections may increase, if the subjects had a marginal PMN count prior to DHA supplementation, or if a high amount of DHA was consumed for an extended period of time. DHA may also inhibit other aspects of human IR, if it is added to diets high in total fat or low in n-6 PUFA and/or antioxidant nutrients. These questions need to be addressed in future studies. Until more information is available, people supplementing their diets with DHA should have a periodic evaluation of their immune status.

ACKNOWLEDGMENTS

The authors are appreciative of the support provided by the dietary and nursing staff of the Metabolic Research Unit in conducting this study. We also thank the volunteers who participated in the study, the Bioanalytical laboratory for sample processing, and the Martex Corporation for donating the DHASCO™ oil.

The Metabolism and n-6/n-3 Ratio of Essential Fatty Acids in Rats: Effect of Dietary Arachidonic Acid and a Mixture of Sesame Lignans (sesamin and episesamin)

Rumi Umeda-Sawada*, Megumi Ogawa, and Osamu Igarashi

Institute of Environmental Science for Human Life, Ochanomizu University, Tokyo 112, Japan

ABSTRACT: In this study, we examined the effect of dietary arachidonic acid (AA) and sesame lignans on the content and n-6/n-3 ratio of polyunsaturated fatty acid (PUFA) in rat liver and the concentrations of triglyceride (TG) and ketone bodies in serum. For 4 wk, rats were fed two types of dietary oils: (i) the control oil diet groups (CO and COS): soybean oil/perilla oil = 5:1, and (ii) the AA-rich oil group (AO and AOS): AA ethyl esters/palm oil/perilla oil = 2:2:1, with (COS and AOS) or without (CO and AO) 0.5% (w/w) of sesame lignans. Dietary AA and sesame lignans significantly affected hepatic PUFA metabolism. AA content and n-6/n-3 ratio in the liver were significantly increased in the AO group, despite the dietary total of n-6 PUFA being the same in all groups, while AOS diet reduced AA content and n-6/n-3 ratio to a level similar to the CO and COS groups. These results suggest that (i) dietary AA considerably affects the hepatic profile and n-6/n-3 ratio of PUFA, and (ii) dietary sesame lignans reduce AA content and n-6/n-3 ratio in the liver. In the AO group, the concentration of acetoacetate was significantly increased, but the ratio of β-hydroxybutyrate/acetoacetate was decreased. On the other hand, the AO diet increased the concentration of TG in serum by almost twofold as compared to other groups. However, the AOS diet significantly reduced serum TG level as compared to the AO group. In addition, the AOS diet significantly increased the acetoacetate level, but reduced the β-hydroxybutyrate/acetoacetate ratio. These results suggest that dietary sesame lignans promote ketogenesis and reduce PUFA esterification into TG. This study resulted in two findings: (i) sesame lignans inhibited extreme changes of the n-6/n-3 ratio by reducing hepatic PUFA content, and (ii) the reduction of hepatic PUFA content may have occurred because of the effects of sesame lignans on PUFA degradation (oxidation) and esterification.

Lipids 33, 567–572 (1998).

Sesame lignans (sesamin and episesamin) are compounds found in sesame seeds and sesame seed oil. They have multiple biological functions such as antioxidative activity (1,2), anticarcinogenicity (2), antihypertensive effect (3,4) in rats, and alleviation of hepatic injury caused by alcohol or carbon tetrachloride (5) in mice. Sesame lignans also affect lipid metabolism, inhibit cholesterol absorption from the intestine, reduce 3-hydroxy-3-methyl-glutaryl CoA reductase activity in liver microsomes (6,7), and affect the incorporation of linoleic acid into lipid subfractions (8) in rats. They also increase the content of dihomo-γ-linolenic acid (DGLA) by the inhibition of Δ5 desaturase activity in the *Mortierella alpina* fungus and rat liver microsomes (9,10). In human studies, it has been reported that sesame lignans have hypocholesterolemic effects (11).

In our previous studies, we reported that sesame lignans inhibited Δ5 desaturation from DGLA (n-6) to arachidonic acid (AA, n-6), but not from 20:4n-3 to eicosapentaenoic acid (EPA, n-3) in cultured rat hepatocytes (12) and *in vivo* (13). We also found that sesame lignans increased the content of n-6 fatty acids, especially AA, but decreased the content of n-3 fatty acids, especially EPA, in rat liver, when EPA-rich diet was given (13). Consequently, the n-6/n-3 ratio *in vivo* was significantly reduced in the EPA-rich group but returned to almost the original level when administered with sesame lignans (13). This is because EPA and AA compete for incorporation into triglyceride (TG) and phospholipid (14), and a decrease in EPA content may lead to an increase in AA content in the liver. Both EPA and AA are polyunsaturated fatty acids (PUFA) and precursors of eicosanoids, but some functions of eicosanoids from EPA and AA are competitive (15). In addition, epidemiological and clinical studies have shown that the n-6/n-3 PUFA ratio in plasma is associated with the frequency of thrombosis occurring (16,17). Therefore we can assume that the ratio of n-6/n-3 *in vivo* is important.

AA is one of the major PUFA in cell membrane phospholipids and also the precursors of eicosanoids such as 2 series' prostaglandin and 4 series' leukotriene, which have various functions including regulation of the immune system. AA is maintained at a constant level in normal condition *in vivo*. It was recently shown that breast milk contains AA which contributes to infant development (18), and there are several studies about AA in milk formula. Moreover, additional studies reported on the effects of dietary AA in humans (19).

This study is a part of a study examining the effect of dietary sesame lignans on hepatic PUFA metabolism and the

n-6/n-3 ratio of essential fatty acid *in vivo*. In this report, we will focus on the effect of dietary AA and sesame lignans on fatty acid metabolism compared to that of EPA and sesame lignans which we reported in our past study (13). To investigate the effect of dietary AA and sesame lignans on PUFA metabolism in rats, the content of PUFA in the liver was determined and the n-6/n-3 ratio of PUFA was also examined. Furthermore, to study effects of dietary AA and sesame lignans on the hepatic metabolism of PUFA with respect to their oxidation and secretion as TG, the concentration levels of serum TG and ketone bodies were determined.

[a]Values are expressed as percentage of weight. AA, arachidonic acid; CO, control oil diet; COS, CO + sesame lignans; AO, AA-rich oil diet; AOS, AO + sesame lignans.

MATERIALS AND METHODS

Materials. Sesame lignans (a mixture of sesamin and episesamin, 47:53, w/w) prepared from refined sesame seed oil and purified by the method of Fukuda *et al*. (20) were kindly donated by Suntory Ltd. (Osaka, Japan). AA ethyl esters (purity > 99%) were also donated by Suntory Ltd. Soybean oil and palm oil were provided by Ajinomoto Co., Inc. (Tokyo, Japan). Perilla oil was provided by Ohta Oil Co. (Okazaki, Japan).

Animals and diets. All experiments were approved by the Animal Experimentation Ethics Commitee of Ochanomizu University. Three-week-old male Wistar rats were purchased from Nippon Clea Co. (Tokyo, Japan). The rats were initially fed on a commercial diet (CE-2; Nippon Clea Co.) for 1 wk. The animals, weighing an average of 98 g, were then divided into four groups of six animals each. They were housed individually in an air-conditioned room at 23 ± 1°C with a 12-h light–dark cycle and were given experimental diets (15 g/d, 1–7 d; 20 g/d, 8–17 d; 25 g/d, 18–28 d) and water *ad libitum* for 4 wk. The basal diet prepared according to the standards given by the American Institute of Nutrition (AIN) (21) was provided by Eisai Co. (Tokyo, Japan), containing the following percentage of ingredients according to weight: casein, 20; glucose, 25; sucrose, 25; cornstarch, 15; filter paper, 5; AIN mineral mixture, 3.5; AIN vitamin mixture, 1; choline bitartate, 0.2; DL-methionine, 0.3. The test diets were prepared by mixing 5% (w/w) experimental oil mixtures with the basal diet. These oil mixtures were prepared: (i) the control oil diet groups (CO and COS): soybean oil/perilla oil = 5:1 and (ii) AA-rich oil groups (AO and AOS): AA ethyl esters/palm oil/perilla oil = 2:2:1. Each of the two diets was then split into two groups: with (COS and AOS) or without (CO and AO) 0.5% (w/w) of sesame lignans. The percentage of AA in AO and AOS diets is the same as that of EPA in the EPA-rich oil group in our previous study (13). The level of total n-6 PUFA is the same in all groups. The fatty acid compositions of these dietary oils are shown in Table 1.

Lipid analyses. Lipids were extracted from the livers of the rats by the method of Folch *et al*. (22). TG extracted from the liver was separated by thin-layer chromatography by the method of Skipski *et al*. (23). Margaric acid (17:0), as an internal standard, was added to the lipid extracts which was then methylated using HCl-methanol by the method mentioned in our previous paper (24) to measure the content of fatty acids in tissues. The fatty acid methyl esters were then measured by gas–liquid chromatography (Perkin-Elmer AutoSystemGC, Palo Alto, CA) on a Rascot Silliar 5CP capillary column (0.25 mm × 50 m; Nihon Chromato Works Ltd., Tokyo, Japan) as described previously (24). The TG in serum was measured by a commercial kit (Wako Pure Chemical Industries., Ltd., Osaka, Japan). Acetoacetate and β-hydroxybutyrate (HOB) in serum were measured enzymatically by another commercial kit (ketone test SANWA; Sanwa kagaku kenkyusho Co., Ltd., Nagoya, Japan).

Statistical analysis. All values are expressed as means ± SD. Significance of the difference between dietary treatments ($P < 0.05$) was determined by analysis of variance (ANOVA). Interaction between dietary AA and sesame lignans was investigated by two-way factorial ANOVA. Analyses were performed using a StatView (system 4.02) computer package (Abacus Concepts, Inc., Berkeley, CA).

RESULTS

PUFA content in the liver. Table 2 shows the effect of dietary AA and sesame lignans on PUFA contents in the liver. The AO diet significantly increased AA (20:4n-6) content, showing that a relatively large amount of external AA has been incorporated into the liver. However, the AOS diet reduced AA content to a level similar to the CO and COS groups. The COS diet increased DGLA (20:3n-6) level while the AO and AOS diets significantly increased 22:4n-6 level. The AO diet also significantly increased total n-6 PUFA content, despite dietary n-6 PUFA levels being the same in all groups. On the other hand, the AOS diet reduced total n-6 PUFA content to a level similar to the CO and COS groups. EPA (20:5n-3) content was reduced by the COS, AO, and AOS diets. EPA content in the CO, AO, and AOS groups was lower than that in the CO group. No significant differences were observed in 18:3n-3 content between the CO and AO groups, despite the difference in dietary 18:3n-3 level in the two diets. The AO and AOS diets reduced docosahexaenoic acid (22:6n-3) content. The n-6/n-3 ratio in the CO group was 2.69 (Table 1), but after dietary treatment, the ratio increased slightly to 3.78. A similar result was also obseved in the COS group. On the other hand, the n-6/n-3 ratio in the AO group was increased by over twofold, from 3.62 to 7.58 while the n-6/n-3 ratio in

[a]Results are expressed as μmol/g tissue and are means ± SD (n = 6). The significance of differences between the dietary treatments was analyzed by analysis of variance. Mean values with different superscript letters within a given row are significantly different ($P < 0.05$). PUFA, polyunsaturated fatty acids. See Table 1 for other abbreviations.

the AOS group significantly reduced to 5.95, which is a level similar to the CO and COS groups.

Below are the results of two-way factorial ANOVA. AA content was significantly affected by both dietary AA ($P < 0.0001$) and sesame lignans ($P = 0.001$), and the interactional effect of dietary AA and sesame lignans was significant ($P = 0.0002$). Total n-6 PUFA was also significantly affected by both dietary AA ($P = 0.0432$) and sesame lignans ($P = 0.0001$), and the interactional effect of dietary AA and sesame lignans was significant ($P = 0.0134$). The n-6/n-3 PUFA ratio was significantly affected by dietary AA ($P < 0.0001$), and the interactional effect of dietary AA and sesame lignans was significant ($P = 0.0157$).

PUFA composition of liver TG. Table 3 shows PUFA composition of TG fraction in the liver. The AO diet significantly increased the proportion of AA (20:4n-6). However, the AOS diet reduced the proportion of AA level. By using the two-way factorial ANOVA, the proportion of AA was significantly affected by dietary AA ($P < 0.0001$), and the interactional effect of dietary AA and sesame lignans was significant ($P = 0.0002$).

Concentrations of serum TG. Table 4 shows the effect of dietary AA and sesame lignans on the concentration of serum TG. The AO diet significantly increased a level of TG. However, the AOS diet reduced it to a level similar to the CO and COS groups. As for the results of two-way factorial ANOVA, serum TG level was significantly affected by both dietary AA ($P = 0.0006$) and sesame lignans ($P = 0.0002$).

Concentrations of ketone bodies. Table 5 shows the effect of dietary AA and sesame lignans on the concentration of ketone bodies (acetoacetate and HOB) in blood. The COS and AOS diets slightly increased the total of ketone bodies as compared to the CO diet. The COS, AO, and AOS diets also increased acetoacetate concentration as compared to the CO diet, and an extreme increase was seen in the COS and AOS groups. On the contrary, the COS, AO, and AOS diets re-

duced HOB, especially in the COS and AOS groups. The ratio of HOB/acetoacetate was reduced by the COS, AO, and AOS diets, particularly by the COS and AOS diets.

Below are the results of two-way factorial ANOVA. Total of ketone bodies was significantly affected by dietary sesame lignans ($P = 0.0029$). Acetoacetate was significantly affected by dietary sesame lignans ($P < 0.0001$), and the interactional effect of dietary AA and sesame lignans was significant ($P = 0.0274$). HOB was significantly affected by dietary sesame lignans ($P < 0.0001$), and the interactional effect of dietary AA and sesame lignans was significant ($P = 0.0262$). The ratio of HOB/acetoacetate was significantly affected by both dietary AA ($P < 0.0001$) and sesame lignans ($P < 0.0001$), and the interactional effect of dietary AA and sesame lignans was significant ($P < 0.0001$).

DISCUSSION

This study is a part of our investigation into the effect of dietary sesame lignans on hepatic PUFA metabolism and n-6/n-3 ratio of PUFA *in vivo*. The aim of this study was to investigate the effect of dietary AA and sesame lignans on PUFA metabolism and the ratio of n-6/n-3 PUFA in rat. In this study, we examined the effect of AA and sesame lignans on the content and n-6/n-3 ratio of PUFA in rat liver, the concentrations of TG, and ketone bodies in serum.

Dietary AA and sesame lignans significantly affected hepatic PUFA metabolism. The contents of sesamin and episesamin in the liver in the COS and AOS groups were less than 1 μg/g liver (data not shown). AA content and n-6/n-3 ratio in the liver were significantly increased in the AO group, despite the total of dietary n-6 PUFA being the same in all groups (Table 2). This result suggested that hepatic n-6/n-3 ratio was affected not only by the n-6/n-3 ratio in dietary oil but also by the PUFA profile in the diet. However, AOS diet reduced AA content and n-6/n-3 ratio to a level similar to the CO and COS groups (Table 2). These results suggest that (i) dietary AA considerably changes the hepatic PUFA profile and n-6/n-3 ratio and (ii) dietary sesame lignans reduce AA content and n-6/n-3 ratio in the liver. In addition, two-way factorial ANOVA showed significant interactional effect of dietary AA and sesame lignans on AA content and n-6/n-3 ratio in the liver. In our past study (13), we examined the dietary effects of EPA and sesame lignans. We found that (i) dietary EPA significantly increased EPA content and reduced n-6/n-3 ratio in the liver and (ii) dietary sesame lignans reduced EPA content and increased n-6/n-3 ratio. Similar results were observed in our present study. From the results of the two studies, we might consider that sesame lignans inhibit extreme changes of n-6/n-3 ratio and function to bring it close to the appropriate n-6/n-3 ratio *in vivo*. We assumed that sesame lignans maintain the appropriate n-6/n-3 ratio, not only from a decrease by n-3 fatty acid-rich diet but also from an increase by n-6 fatty acid-rich diet. This regulating effect is especially significant on the excess of EPA and AA, which are the intermediate metabolites of PUFA and precursors of eicosanoids.

We have already confirmed that sesame lignans reduce the contents of EPA in the liver (13), but have no effect on intestinal absorption of EPA and AA (25). Moreover, we can also consider that sesame lignans do not accelerate PUFA transportation into the peripheral tissues, because the peripheral tissue PUFA content was not increased by dietary sesame lignans (13,25). Consequently, it is probable that sesame lignans alter hepatic PUFA metabolism.

Free fatty acids are activated to acyl-CoA in the liver, and then (i) esterified into TG and phospholipid or (ii) changed *via* acetyl-CoA to CO_2 and H_2O by β-oxidation or (iii) changed to ketone bodies. Ketone bodies, which are the degraded products of free fatty acid in liver, are the general term for acetone, acetoacetate, and HOB. They are used as an energy source, substituting for glucose. If abnormal metabolism occurs, excess ketone bodies will be produced and released into blood and urine, finally leading to ketoacidosis. Ketone bodies in the blood are in the form of acetoacetate and HOB. Acetoacetate and HOB can be interconverted with each other through the function of HOB dehydrogenase. From our

former results, we can consider that sesame lignans alter plasma fatty acids by enhancing fatty acid degradation system. If sesame lignans really accelerated this system, ketogenesis rates should be promoted. In this study, we examined the concentration of ketone bodies in the rats' blood so as to investigate the relationship between dietary sesame lignans and the capacity for fatty acid degradation.

Although total ketone body concentration was slightly increased in the COS and AOS groups, the changes were small (Table 5). This might be because the rats used in this study were normal, and the total ketone bodies in blood was kept at a normal level. In the AO group, the concentration of acetoacetate was significantly increased, but HOB/acetoacetate ratio decreased (Table 5). On the other hand, the concentration of TG in serum increased by almost twofold in the AO group as compared to the other groups (Table 4). However, the AOS diet significantly reduced the serum TG level as compared to the AO group (Table 4). In addition, the AOS diet significantly increased the acetoacetate level but reduced the HOB/acetoacetate ratio (Table 5). The two-way factorial ANOVA showed significant interactional effects between dietary AA and sesame lignans which affects the levels of acetoacetate and HOB and the HOB/acetoacetate ratio. Also, AA composition of liver TG was affected by dietary sesame lignans (Table 3).

Several studies have demonstrated that fibric acid derivatives such as clofibrate and bezafibrate enhance peroxisomal β-oxidation which is responsible for the increased production of ketone bodies in rat livers (26–28). It has also been reported that dietary fenofibrate, one of the fibric acid derivatives, increased hepatic ketogenesis but decreased secretion of TG (29). Furthermore, it has also been demonstrated that the ratio of HOB/acetoacetate is decreased by clofibrate (30) and fenofibrate (29). Esterification of fatty acids into TG depends on the level of fatty acid in tissues. Moreover, this fatty acid level affects ketogenesis. Therefore, it is considered that fibric acid derivatives regulated ketogenesis and esterification of fatty acid into TG.

The results of our present study suggest that the effect of sesame lignans on the hepatic PUFA metabolism might be similar to that of fibric acid derivatives. It also suggests that (i) a large amount of AA is incorporated into the liver by dietary AA, thus stimulating the esterification into TG and slightly promoting ketogenesis, but (ii) dietary sesame lignans promote ketogenesis and reduce PUFA esterification into TG. As a result, we may conclude that sesame lignans affect hepatic metabolism of PUFA between PUFA degradation (oxidation) and esterification.

This study yields two important findings: (i) sesame lignans inhibited extreme changes of n-6/n-3 ratio by reducing hepatic PUFA content, and brought it close to the appropriate n-6/n-3 ratio *in vivo,* and (ii) the reduction of hepatic PUFA content may have occurred because sesame lignans acted at some point between PUFA degradation (oxidation) and esterification. At present, several studies are in process concerning the appropriate n-6/n-3 ratio *in vivo*. However, it is difficult to regulate the n-6/n-3 ratio by the intake of various dietary oils because by using supplements and health foods there is a risk of excessive intake of n-6 or n-3 fatty acids, such as AA or EPA. Therefore, it is valuable to find that sesame lignans have a stabilizing effect on the balance of n-6/n-3 *in vivo*.

Psyllium, Not Pectin or Guar Gum, Alters Lipoprotein and Biliary Bile Acid Composition and Fecal Sterol Excretion in the Hamster

Elke A. Trautwein*, Dörte Rieckhoff, Angelika Kunath-Rau, and Helmut F. Erbersdobler

Institute of Human Nutrition and Food Science, University of Kiel, 24105 Kiel, Germany

ABSTRACT: Different soluble dietary fibers known to alter cholesterol metabolism were fed to golden Syrian hamsters, and their specific impact on lipoproteins, biliary bile acid profile, and fecal sterol excretion was evaluated. Semipurified diets containing 20% fat; 0.12% cholesterol; and 8% of psyllium (PSY); high (hePE) and low (lePE) esterified pectin; or high (hvGG) and low (lvGG) viscous guar gum were fed for 5 wk. Compared to control, PSY caused a significant reduction in plasma cholesterol (2.9 ± 0.5 vs. 5.5 ± 0.5 mmol/L), whereas hePE, lePE, hvGG, or lvGG had no apparent effect on plasma lipids. Hepatic total and esterified cholesterol were substantially decreased with PSY, pectin and guar gum, whereby PSY produced the most pronounced effect. Distinctive changes existed in the bile acid profile related to the different fibers. In contrast to pectin and guar gum, PSY caused a significant increase in the cholate:chenodeoxycholate and the glycine:taurine conjugation ratio. Pectin and guar gum did not alter daily fecal neutral sterol excretion while PSY caused a 90% increase due to a higher fecal output. Daily fecal bile acid excretion and total fecal bile acid concentration were significantly increased by PSY, whereas hePE, lePE, hvGG, and lvGG revealed no or only minor effects. Taken together, the disparate hypocholesterolemic effects of PSY, pectin, and guar gum on cholesterol and bile acid metabolism in the hamster are possibly related to different physicochemical properties, e.g., viscosity and susceptibility to fermentation, affecting the fiber-mediated action in the intestine.

Lipids 33, 573–582 (1998).

Water-soluble fiber sources such as psyllium (PSY), pectin (PE), and guar gum (GG) have been shown to exert a cholesterol-lowering effect in humans and in different experimental animals (1,2). Although recent studies have attempted to elucidate the primary mechanism(s) responsible for the cholesterol-lowering effect, distinct actions of specific fibers have not been completely defined (3–9). Suggested mechanisms by which dietary soluble fibers lower cholesterol include an interruption of the enterohepatic circulation of bile acids, with an enhanced fecal excretion stimulating bile acid synthesis, a decrease in cholesterol absorption, or the production of volatile fatty acids, e.g., propionic acid in the cecum inhibiting hepatic cholesterol synthesis.

In a series of studies using the guinea pig as a model, Fernandez *et al*. (4–6) showed that the hypocholesterolemic action by different types of fiber is greatly influenced by the level of dietary cholesterol. For instance, PE had a substantial cholesterol-lowering effect with a high cholesterol diet and a more moderate effect with low dietary cholesterol. In contrast, GG was more effective with low rather than high dietary cholesterol, whereas PSY revealed similar hypocholesterolemic effects with either low- or high-cholesterol diets. Recently, Fernandez (1) has shown that different primary mechanisms specific to each type of fiber seem responsible for the observed effects of PSY, PE, or GG. Whereas PE and PSY stimulated hepatic cholesterol 7α-hydroxylase activity, the key enzyme in bile acid synthesis, GG had no effect. PE reduced cholesterol absorption independent from dietary cholesterol, GG did so only with high dietary cholesterol, whereas PSY did not affect cholesterol absorption (1). Studies with rats have shown that PSY and PE caused an increase in the bile acid pool size, altered bile acid composition, and increased cholesterol 7α-hydroxylase activity (10,11).

In previous studies with Syrian hamsters, a commonly used animal model because of similarities with human cholesterol and bile acid metabolism (12–14), we have found contrasting effects of PE, GG, and PSY when hamsters were fed a lithogenic diet high in dietary cholesterol (0.4%). Whereas PSY significantly reduced plasma, hepatic, and biliary lipids mainly by increasing the fecal excretion of bile acids, PE and GG demonstrated only minor effects in that hamster study (15).

The present study was designed to further compare the lipid-lowering effectiveness of PE, GG, and PSY using a moderate level of dietary cholesterol (0.12%) and to elucidate whether physicochemical properties such as viscosity and degree of esterification (DE) affect the hypolipidemic capacity of PE and GG. Therefore, two types of GG, a high and low

Abbreviations: ANOVA, analysis of variance; DE, degree of esterification; EC, esterified cholesterol; FC, free cholesterol; GG, guar gum; HDL, high density lipoprotein; hePE, high-esterified pectin; HPLC, high-performance liquid chromatography; hvGG, high viscous guar gum; LDL, low density lipoprotein; lePE, low-esterified pectin; lvGG, low viscous guar gum; PE, pectin; PL, phospholipid; PSY, psyllium; TC plasma total cholesterol; TG, plasma triacylglycerols; VLDL, very low density lipoprotein.

viscous GG, and two varieties of PE differing in DE and viscosity were tested.

MATERIALS AND METHODS

***Animals*.** Male golden Syrian hamsters (SASCO, Omaha, NE) weighing 62 ± 2 g were randomly assigned to six diet groups (n = 10 per group). Hamsters were housed in groups of 3–4 per cage in a temperature-controlled environment under a 12-h light–dark cycle (lights on 1800 h) with free access to water and semipurified diets. All experimental protocols and procedures were approved by the Animal Care and Use Committee at the University of Kiel, Germany.

Diets and feeding procedures. Hamsters were fed semipurified diets containing 20% fat, 0.12% dietary cholesterol, and 10% cellulose to ensure normal bowel function and to prevent the lethal enteritis "wet tail." Diets were fed for 5 wk. The basal composition of the diets was, in g/kg dry weight: casein 200, wheat starch 288, glucose 150, cellulose 100, fat 200, mineral mix 46, vitamin mix 12, cholesterol 1.2, choline chloride 3. The dietary fat blend (in g/kg: palm stearin 88, olive oil 48, butter 40, sunflower oil 24) resembled the typical German fat intake with a polyunsaturated/saturated ratio of 0.32. The compositions of the Ausman-Hayes mineral mix (F8530 BioServ, Frenchtown, NJ) and the Hayes-Cathcart vitamin mix were detailed previously (16). In the fiber-supplemented diets, 8% supplements of the tested dietary fiber sources were added at the expense of wheat starch. The dietary fiber sources were PSY husks, two varieties of PE, a high-esterified pectin (hePE) with a DE of 69%, and a low-esterified pectin (lePE) with a DE of 34% and two types of GG, a high viscous (hvGG) and a low viscous guar gum (lvGG). The viscosities of the GG measured in 1% solutions were 6014 mPa·s for hvGG and 22 mPa·s for lvGG. The viscosities of the PE measured in 2% solutions were 71 mPa·s for hePE and 185 mPa·s for lePE. All viscosities were measured in preheated solutions (85°C for 10 min) at 25°C with increasing shear rates using a Bohlin Rheometer (Bohlin Instruments, Mühlacker, Germany). PSY was kindly supplied by Kellogg Company (Battle Creek, MI) and hePE, lePE, hvGG, and lvGG by Danisco Ingredients (Grindsted Division, Quickborn, Germany). Hamsters were given free access to food, and the actual food consumption was recorded daily. Body weights were monitored on a weekly basis.

Necropsy. After 5 wk, hamsters were housed individually in wire-bottomed cages and fasted overnight (18 h) and then exsanguinated under anesthesia using a gaseous mixture of CO_2/O_2 (50:50). Blood samples were drawn into EDTA-wetted syringes by cardiac puncture and the liver was excised, blotted, and weighed. A portion of the liver was removed and frozen for hepatic cholesterol analysis. Immediately after removal of the intact cecum, the pH of the cecal contents was measured using a spear-tip pH electrode. The total contents were then collected by gentle finger-stripping of the cecum, weighed, homogenized, and deep-frozen in liquid nitrogen. Gallbladder bile was aspirated, weighed, and analyzed for biliary lipids and bile acid composition.

Plasma lipid and lipoprotein analysis. Blood samples from six hamsters were drawn upon arrival (baseline) to establish basal plasma lipids randomly and from all hamsters (n = 10 per diet) after 5 wk. Plasma was separated immediately by centrifugation at 5,000 × g for 10 min. Plasma total cholesterol (TC) and triacylglycerol (TG) concentrations were determined by enzymatic assays (Sigma kit #352 and #336, respectively; Sigma Chemicals, Deisenhofen, Germany). Plasma lipoproteins (n = 5–6 hamsters per diet) were isolated by sequential ultracentrifugation (17) by using a L7-65 ultracentrifuge and a 50.4 Ti rotor (Beckman Instruments, Munich, Germany) and plasma pooled from two hamsters. A preservative solution (final concentration in plasma: 1 mM benzamidine, 0.04% EDTA, 0.005% gentamycin sulfate, 0.05% NaN_3) was added to protect lipoproteins from enzymatic degradation. Three fractions were isolated based on the following densities: very low density lipoprotein (VLDL) (d < 1.006 kg/L), low density lipoprotein (LDL) (1.006 < d < 1.055 kg/L), high density lipoprotein (HDL) (1.055 < d < 1.21 kg/L). With the exception of VLDL, lipoprotein fractions were dialyzed against 0.15 mol/L NaCl, 0.04% EDTA, and 0.05% NaN_3 at 4°C for 24–36 h. TC, free cholesterol (FC), TG, and phospholipid (PL) concentrations were determined using enzymatic assays (#352 for TC and #336 for TG; Sigma Chemicals and Wako Free Cholesterol C kit for FC and Wako Phospholipid B kit for PL, Wako Chemicals, Düsseldorf, Germany). Protein concentration was determined by a modification of the Lowry procedure (18). To verify the density cut-points and to check for cross-contaminations, LDL and HDL apolipoproteins were separated by gradient SDS-polyacrylamide gel electrophoresis (4–20%), and stained with Coomassie Brilliant Blue. No traces of apolipoprotein $apoB_{100}$ could be detected in the HDL fractions (data not shown).

Hepatic cholesterol analysis. Cholesterol concentrations were analyzed after extraction with chloroform/methanol following the procedure described in detail previously (19). TC was determined enzymatically (using Sigma kit #352) and FC was analyzed using high-performance liquid chromatography (HPLC). Esterified cholesterol (EC) concentrations were calculated as the difference between TC and FC.

Bile analysis. Gallbladder bile lipids were isolated using a modified Folch extraction (20). Biliary cholesterol and PL were determined enzymatically in an aliquot of the chloroform phase (Wako Free Cholesterol C kit for biliary cholesterol and Wako Phospholipid B kit for PL, Wako Chemicals). Biliary bile acids were analyzed in an aliquot of the methanol/KCl phase as taurine and glycine conjugated bile acids using an isocratic HPLC method as previously described in detail (19). Total bile acid concentration was calculated as the sum of individual bile acids (taurine and glycine conjugates of cholate, chenodeoxycholate, deoxycholate, and lithocholate) as measured by HPLC.

Determination of fecal neutral sterols and bile acids. Fecal samples were collected over a 3-d period during wk 4 from six randomly selected hamsters per diet group to measure fecal bile acid and neutral sterol excretion. Fecal sterols were

analyzed in an oven-dried fecal sample using a modification of the method of Suckling *et al.* (21) as previously detailed (19). Neutral sterols were determined by gas chromatography as described in detail previously (22). Fecal total bile acids were determined according to the micro method described by Czubayko *et al.* (23) with some minor modifications. Bile acids were methylated using methanolic-HCL (Supelco, Deisenhofen, Germany) prior to conversion to their trimethylsilyl ethers using Sylon HTP (Supelco). The trimethylsilyl derivatives were evaporated under nitrogen and resuspended in *n*-decane (Sigma Chemicals) and centrifuged for 10 min to settle the precipitates. A 1-µL sample was injected. Bile acids were separated and quantified by gas chromatography using a capillary column (DB1, 30 m, 0.25 mm i.d. and 0.25 µm film thickness; J&W Scientific, Mainz, Germany). The column was operated at 200°C hold for 1 min and then gradually increased to 220, 240, and 280°C. Injector temperature and detector were set at 280°C. Helium was used as carrier gas at a flow rate of 150 kPa. Bile acid standards included 5β-cholanic acid (internal standard), ursodeoxycholic acid, lithocholic acid, deoxycholic acid, cholic acid, chenodeoxycholic acid, hyodeoxycholic acid (all from Sigma Chemicals), and 5β-cholanic acid-3α-ol and 5β-cholanic acid-3α-7α-diol-12-one (Steraloids, Wilton, NH).

The daily cholesterol intake was calculated based on data of the daily food intake during wk 4. Daily cholesterol intake in µmol/d was as follows: control, 20.7; hePE, 22.5; lePE, 22.5; hvGG, 22.5; lvGG, 24.0; and PSY, 25.8. The apparent neutral sterol absorption was calculated as: dietary cholesterol intake per day − fecal excretion of neutral sterols (µmol/d). The total sterol balance was calculated as dietary cholesterol intake per day − [fecal excretion of neutral sterols (µmol/d) + fecal excretion of bile acids (µmol/d)].

Statistical analysis. Statistical differences were calculated using a one-way analysis of variance (ANOVA). When significant *F* ratios were found, individual means were further compared by the Bonferroni-Dunn *post-hoc* test utilizing the SuperANOVA statistical software package (Version 1.11; Abacus Concepts Inc., Berkeley, CA). Differences were considered significant at $P < 0.05$. Results were expressed as means ± SD.

RESULTS

Body weight gain and cecal weight. Food consumption, final body weights, and weight gain were not affected by the supplementation of PE and GG. Total body weight gain was significantly lower in PSY-fed hamsters compared to all other diet groups (Table 1). Weights of the cecum, the cecal wall, and the cecal content were significantly higher in PSY-fed hamsters (+211, +150, and +270%, respectively, compared to control) compared to hamsters fed the control or PE- and GG-enriched diets. Cecal pH was not significantly altered in hamsters fed the PE-, GG-, or PSY-enriched diets, suggesting no acidic conditions possibly because the hamsters were fasted for 18 h and therefore no active fermentation took place (Table 1).

Plasma lipids and lipoproteins. After 5 wk, TC concentrations were significantly lower in PSY-fed hamsters compared to all other diets (Fig. 1). TG concentrations were decreased significantly by 42% in PSY-fed hamsters compared to control (Fig. 1). No significant differences in TC and TG were observed between the control and hePE, lePE, hvGG, and lvGG diets although TC was 10% reduced by hePE. PSY significantly decreased VLDL-, LDL-, and HDL-cholesterol by 75, 47, and 38%, respectively. Whereas lePE, hvGG, and lvGG had no effect, hePE decreased VLDL-, LDL-, and HDL-cholesterol by 20, 22, and 28%, compared to control, but these reductions did not reach the level of significance (Table 2). The LDL/HDL ratio was not altered by any of the different dietary fibers.

PSY significantly affected the composition of VLDL and LDL (Table 3). In the VLDL fraction, significantly higher relative percentages of TG and lower percentages of FC and EC and PL were found. In the LDL fraction, the relative percentages of EC and PL were significantly decreased by 21 and

[a]Values are mean ± SD, $n = 10$ per diet; hePE, high-esterified pectin; lePE, low-esterified pectin; hvGG, high viscous guar gum; lvGG, low viscous guar gum.
[b]In a column, means with different superscripts are significantly different ($P < 0.05$) using one-way analysis of variance (ANOVA) and the Bonferroni/Dunn test.
[c]Hamsters received 25 g food (25 g wet weight = 13.9 g dry weight).

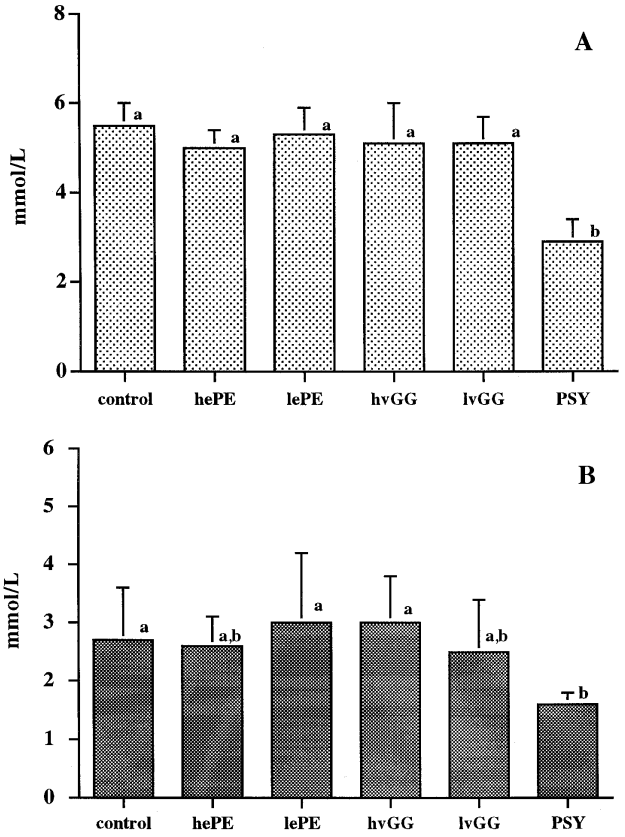

FIG. 1. Plasma (A) total cholesterol and (B) triacylglycerol concentrations of hamsters fed diets containing 8% supplements of different pectins, guar gums, or PSY. Values are mean ± SD (n = 10 per diet). Bars with different letters were significantly different ($P < 0.05$) using one-way analysis of variance (ANOVA) and the Bonferroni-Dunn test. hePE, high-esterified pectin; lePE, low-esterified pectin; hvGG, high viscous guar gum; lvGG, low visous guar gum; PSY, psyllium.

23%, respectively, while the percentages of TG and protein were significantly increased with PSY (Table 3).

Hepatic cholesterol accumulation. Liver weights of hamsters fed the PE- and GG-supplemented diets did not differ significantly compared to control. In contrast, liver weights of PSY-fed hamsters were significantly lower compared to all other diets (Table 4). A significant reduction of hepatic TC and EC occurred with hePE, lePE, hvGG, lvGG and PSY, whereby PSY caused the most pronounced effects. Whereas hePE and hvGG reduced TC by 29 and 23%, respectively, PSY caused a 89% decrease in hepatic TC. In contrast, only minor reductions of 10–20% in hepatic TC were found with lePE and lvGG. Hepatic FC concentrations did not differ between hamsters fed hePE, lePE, hvGG, and lvGG compared to control while PSY produced a significant decrease in FC compared to other diets. Whereas in livers from PSY-fed hamsters, EC accounted for only 31% of TC, 88–91% of total hepatic cholesterol was present in the form of cholesteryl esters in hamsters fed the control or PE- and GG-supplemented diets (Table 4).

Biliary lipids. The molar percentage of biliary cholesterol was significantly reduced by 57% in hamsters fed PSY (2.3 ± 0.4 mol% in controls vs. 1.0 ± 0.2 mol% with PSY). HePE and hvGG caused a modest but insignificant decrease (–17%) while lePE and lvGG had no effect (data not shown). PSY and, to a lesser extent, hvGG produced a significant increase (+7 and +3%, respectively) in the molar percentages of biliary bile acids (88.4 ± 1.1, 90.4 ± 1.8, and 94.0 ± 1.2 mol% in control, PSY-, and hvGG-fed hamsters, respectively).

Bile acid profile. Changes in the bile acid profile of gallbladder bile were distinctive for each dietary fiber (Table 5). The most evident changes were seen in the relative percentages of taurochenodeoxycholic and glycocholic acid. All dietary fibers except lvGG significantly reduced taurochenodeoxycholic acid although by a different extent, and PSY also caused a decrease in glycochenodeoxycholic acid. In fact, cheno conjugates were decreased by 68% with PSY. The relative percentage of glycocholic acid was significantly expanded from 40% in control to 55% in PSY-fed hamsters, while this bile acid was not significantly affected by hePE, lePE, hvGG, and lvGG (Table 5). As a result of the observed changes in the bile acid profile, the cholate/chenodeoxycholate ratio was dramatically increased from 2.1 ± 0.3 in control hamsters to 7.2 ± 0.8 with PSY feeding. In contrast, PE and GG had no substan-

[a]Values are mean ± SD, n = 5–6 per diet; EC, esterified cholesterol; FC, free cholesterol; TG, plasma triacylglycerols; PL, phospholipids. See Tables 1 and 2 for other abbrevations.
[b]In a column, means with different superscripts are significantly different ($P < 0.05$) using one-way ANOVA and the Bonferroni/Dunn test.

tial effects on this ratio (Fig. 2). While GG and PSY decreased the percentage of taurodeoxycholic acid, glycodeoxycholic acid was significantly increased by PSY and PE but not by GG (Table 5). In control hamsters, 36% of bile acids were conjugated with taurine, while PSY, hePE, lePE, and hvGG decreased taurine conjugation. Again, PSY had the most pronounced effect leading to a reduction in taurine conjugated bile acids of more than 50%. As a result, the glycine/taurine conjugation ratio was 2.8 times higher in gallbladder bile from PSY-fed compared to control hamsters (Fig. 2). HePE, lePE, and hvGG also expanded this ratio, but this increase was not statistically significant.

[c]TCA, taurocholic acid; GCA, glycocholic acid; TCDCA, taurochenodeoxycholic acid; GCDCA, glycochenodeoxycholic acid; TDCA, taurodeoxycholic acid; GDCA, glycodeoxycholic acid. Taurolithocholic and glycolithocholic acids were only present in traces (<1% of total bile acids). See Table 1 for other abbreviations.

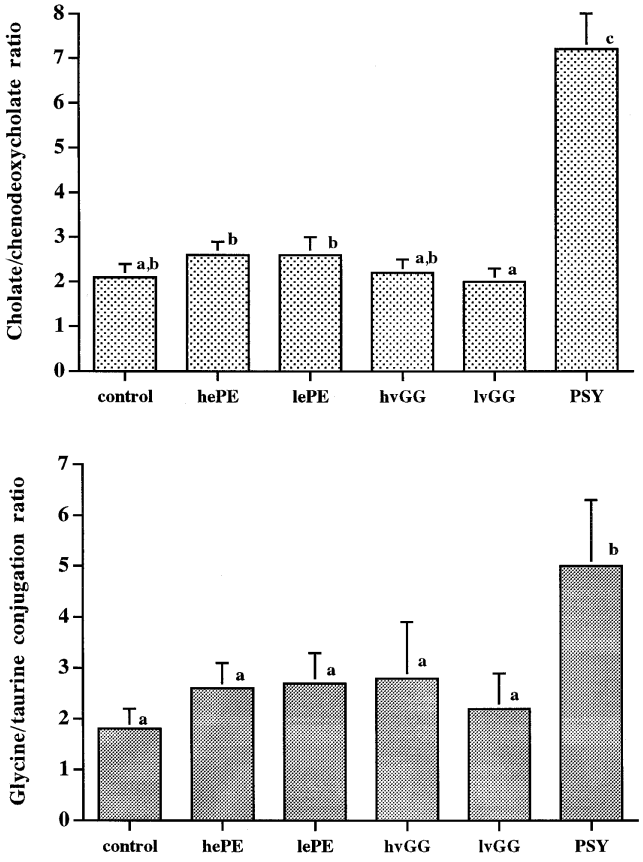

FIG. 2. Cholic acid/chenodeoxycholic acid ratio and glycine/taurine conjugation ratio in gallbladder bile of hamsters fed diets containing 8% supplements of different pectins, guar gums, or PSY. Values are mean ± SD ($n = 10$ per diet). Bars with different letters were significantly different ($P < 0.05$) using one-way ANOVA and the Bonferroni-Dunn test. See Figure 1 for abbreviations.

Fecal excretion of neutral sterols and bile acids. The daily fecal weight was significantly increased by 138% in PSY-fed hamsters compared to all other diets. In contrast, hePE, lePE, hvGG, and lvGG had only a modest effect on fecal weight (Table 6). The moisture content of the fecal samples was not different. Fecal neutral sterol excretion expressed per gram feces was not different between diet groups (Table 6). However, the daily excretion of neutral sterols was significantly higher in PSY-fed hamsters compared to all other diets owing to the higher fecal output. The bulk of neutral sterols was composed of coprostanol and cholesterol whereas other sterols were only present in small concentrations (Table 6). The fecal concentration of cholesterol was three times higher in PSY-fed hamsters compared to controls while coprostanol was decreased by 55%, suggesting a diminished intestinal breakdown of cholesterol. In contrast, PE and GG revealed no striking changes in the fecal neutral sterol profile.

Fecal total bile acid concentration (expressed per gram feces dry weight) was significantly increased in PSY-fed hamsters compared to all other diets (Table 7). PE and GG had no effect on the fecal bile acid concentration. Daily fecal bile acid excretion was more than four times higher in PSY-fed compared to control hamsters. HePE and hvGG caused a slight but not significant increase, whereas lePE and lvGG had no effect on daily fecal bile acid excretion (Table 7). Distinct changes in the excretion of individual bile acids were apparent (Table 7). There was a significant increase in deoxycholic acid with PSY while lePE, hvGG, and lvGG seemed to reduce the excretion of deoxycholic acid compared to fecal samples of control hamsters. The excretion of lithocholic acid was lower with all fiber supplements compared to control, but this effect was only significant with lePE and lvGG. Other observed differences were a greater excretion of 12-ketolithocholic acid in hamsters fed the fiber supplements compared to controls. However, owing to the large variation, these increases were not significant. In addition, substantial changes in the bile acid excretion profile existed when expressed as percentage of total bile acids. Again, PSY caused the most pronounced alterations. There was a significant decrease in the percentage of lithocholic acid from 41 ± 6% in control to 18 ± 2% in PSY-fed hamsters. In contrast, the percentage of deoxycholic acid was increased from 30 ± 5% in controls to

[a]All values are mean ± SD, $n = 6$ per diet.
[b]In a column, means with different superscripts are significantly different ($P < 0.05$) using one-way ANOVA and the Bonferroni/Dunn test.
[c]CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; hyo-DCA, hyodeoxycholic acid (5β-cholanic acid-3α,6α-diol); 12-keto-LCA, 12-ketolithocholic acid (5β-cholanic acid-3α-ol-12-one); LCA, lithocholic acid; UDCA, ursodeoxycholic acid. See Table 1 for other abbreviations.

66 ± 6% with PSY while hePE had no effect and lePE, hvGG, and lvGG caused a slight decrease. Other changes were a significantly lower percentage of hyodeoxycholic acid with PSY and a higher percentage of 12-ketolithocholic acid with PE and GG.

Taking into account the daily cholesterol intake during wk 4, the apparent neutral sterol (cholesterol) absorption was obviously moderately depressed by PSY (Fig. 3). The calculated total sterol balance was +9.5 μmol/d in controls and was not altered by PE and GG, while a negative balance (–2.4 μmol/d) was found in hamsters fed PSY (Fig. 3).

DISCUSSION

Although the cholesterol-lowering effect of PE, GG, and PSY is well established in experimental animals and human subjects, the mechanism(s) involved remain to be elucidated (1,24). Physicochemical properties such as viscosity, fermentability, or binding capacity of bile acids have received much attention and are thought to affect the hypocholesterolemic action of soluble fibers though the supporting evidence is inconsistent. Particularly, the putative action of the fibers in the small intestine may play a major role in regulating cholesterol and bile acid metabolism by altering absorption of dietary or biliary cholesterol and reabsorption of circulating bile acids.

In the present study the effects of PE, GG, and PSY on lipoproteins, bile acid profile, and particularly on fecal sterol excretion were further investigated utilizing the hamster, which is a common model to study diet-induced hypocholesterolemic effects (12–14). In previous studies with hamsters fed 0.4% dietary cholesterol, PSY significantly lowered plasma lipids by increasing the fecal excretion of bile acids, whereas PE and GG failed to demonstrate a distinct lipid-lowering effect (15,25). To exclude that an excessive dietary cholesterol intake could possibly overwhelm possible fiber-mediated effects because the amount of dietary cholesterol clearly affects the metabolic response of different fibers (1),

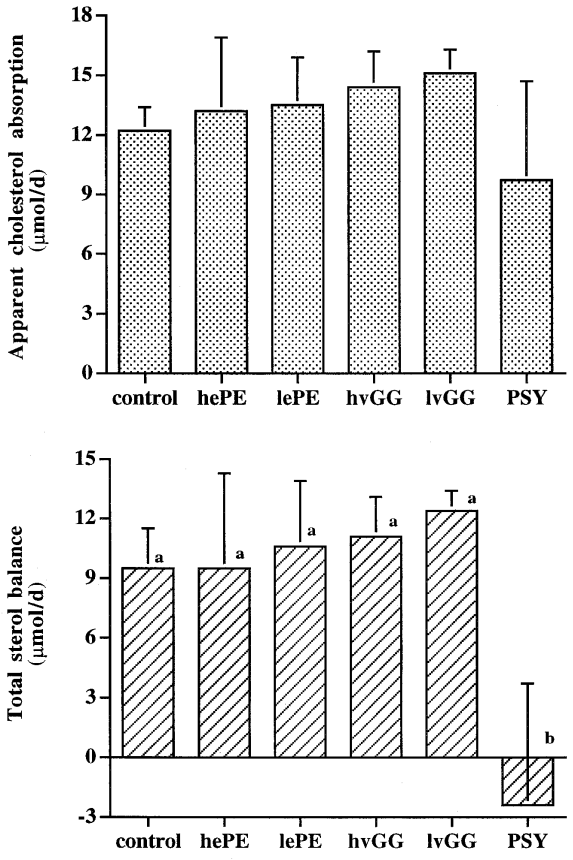

FIG. 3. Apparent cholesterol excretion (μmol/d) and total sterol balance (μmol/d) in hamsters fed diets containing 8% supplements of different pectins, guar gums, or PSY. Values are mean ± SD ($n = 6$ per diet). Bars with different letters were significantly different ($P < 0.05$) using one-way ANOVA and the Bonferroni-Dunn test. Apparent cholesterol absorption = cholesterol intake (μmol/d) – fecal excretion of neutral sterols (μmol/d). Cholesterol intake (μmol/d) was: control, 20.7; hePE, lePE and hvGG, 22.5; lvGG, 24.0 and PSY, 25.8. Total sterol balance = cholesterol intake (μmol/d) – [fecal excretion of neutral sterols (μmol/d) + fecal excretion of bile acids (μmol/d)]. See Figure 1 for abbreviations.

in the present study, diets containing a moderate level of dietary cholesterol (0.12%) were applied.

Again, 8% PSY significantly altered lipoprotein and bile acid metabolism, while the different types of PE (hePE and lePE) and GG (hvGG and lvGG) produced no substantial lipid-lowering effect. This lack of a potent hypocholesterolemic action of PE and GG could possibly be related to several aspects. First, adding these highly fermentable fibers to a diet already rich in nonfermentable cellulose (10%) could have resulted in a dilution of the expected effects of either PE or GG in the intestine, although this assumption seems rather unlikely because PSY caused a significant hypolipidemic effect with changes in lipoprotein and bile acid composition and excretion.

Second, it seems plausible that PE and GG were partially hydrolyzed, diminishing their physicochemical properties and attenuating their hypocholesterolemic potential. In fact, PE and GG are both highly fermentable and are usually almost completely degraded. Evidently, PSY is less rapidly and only partially fermented, whereas PE and possibly GG completely disappear in the human gut (28). Normally, the fermentation of soluble fibers is subject of the colonic microflora and takes place in the cecum and colon. Possibly, because of the distinctive digestive tract of the hamster (e.g., cheek pouches, pregastric and gastric pouch), a pregastric fermentation of PE and GG could have occurred (26,27). Therefore, it seems possible that GG and PE, but apparently not PSY, were already hydrolyzed and sufficiently degraded in the rumen-like forestomach. The action of PSY seems not to be impaired by pregastric fermentation, indicating that PSY, PE and GG differ in their physicochemical properties, e.g., in their fermentation capacity. These differences in the fermentative breakdown seem to relate to their hypocholesterolemic potential and could explain the disparate response on cholesterol metabolism of PSY vs. PE and GG in hamsters. However, the forestomach microflora is poorly defined, and the known bacterial populations do not hydrolyze PE or GG (29). Also, residence time of digested food in the forestomach seems rather short, reducing the effectiveness of a pregastric fermentation (30). Taken together, a pregastric fermentation of PE and GG seems speculative unless part of the colonic microflora has settled in the pregastric pouch because of the known coprophagy. To clearly prove this hypothesis, fermentation end products (short-chain fatty acids or lactic acid) need to be analyzed in the forestomach contents. Whereas PSY clearly expanded the intestinal volume (increase in the cecal content), PE and GG revealed no effect on cecal weight, further supporting the theory of a pregastric breakdown.

A third explanation for the lack of effect could be that 8% PE and GG, unlike 8% PSY, might not have been efficient enough to produce changes in lipoprotein or bile acid metabolism although studies using rats and guinea pigs have clearly demonstrated lipid-lowering effects with similar or even lower doses of PE and GG (3,5,6,31). In contrast, previous hamster studies have also shown more equivocal effects of PE and GG on cholesterol metabolism (32,33).

The lipid-lowering potential of PE and GG has been attributed to physicochemical properties such as degree of esterification and/or viscosity (27,34). In line with previous findings (34), hePE was somewhat more effective in lowering plasma cholesterol than lePE (−10 vs. −4%) even though the viscosity of hePE was lower compared with lePE (71 vs. 184 mPa·s). However, the two types of GG which differed in their viscosity (6014 and 22 mPa·s) did not reveal different effects on lipoproteins, bile acid profile, and sterol excretion. A previous hamster study also could not demonstrate a consistent effect of different viscosities on the lipid-lowering action of GG (27). Therefore, the present data do not clarify the impact of the degree of esterification or viscosity on the hypocholesterolemic effect of PE and GG.

PSY impressively reduced the plasma cholesterol and TG, which is in line with previous findings from studies with various animal models including the hamster (5,7,8,35,36). PSY not only caused a 75% reduction in plasma VLDL-cholesterol but also affected the composition of VLDL and LDL by decreasing the relative EC content and increasing the relative proportion of TG which has also been shown previously (4). These compositional changes could possibly indicate a modified production of VLDL and conversion to LDL particles, suggesting that the hypocholesterolemic effect of PSY occurs at multiple metabolic sites including the regulation of lipoprotein synthesis and catabolism as demonstrated previously (1,4).

Increased excretion of bile acids and neutral sterols due to impaired reabsorption of bile acids and diminished cholesterol absorption is thought to be the major determinant for the cholesterol-lowering action of soluble fibers. In fact, PSY accelerated bile acid removal, resulting in a 348% increase in daily bile acid excretion mainly as deoxycholic acid. Reportedly, PSY does not bind bile acids *in vitro* (35). However, our data clearly demonstrate that bile acid excretion is significantly enhanced by PSY. Although the physicochemical mechanisms involved are not fully understood, it is likely that, during the enteric gelation of PSY bile acids and preferentially taurine conjugated bile acids were entrapped. PSY also expanded daily total neutral sterol excretion (89% increase) which may indicate increased losses of endogenous cholesterol or an inhibition of cholesterol absorption. It was found that PE and GG inhibited cholesterol absorption especially in animals fed high-cholesterol diets (1) whereas PSY had no effect on cholesterol absorption (1,8,37). However, the present data suggest that cholesterol absorption was moderately inhibited by PSY. The entrapment of bile acids within the viscous matrix formed in the intestinal lumen could possibly disturb micelle formation, leading to a diminished cholesterol absorption. In humans, PSY has been shown to decrease cholesterol absorption efficiency (38). The calculated total sterol balance was markedly altered with PSY mainly owing to the increase in bile acid excretion. The positive sterol balance in control hamsters (+9.5 μmol/d) was shifted toward a negative balance in PSY-fed hamsters (−2.4 μmol/d), suggesting stimulated bile acid synthesis. Indeed, a PSY-induced up-regulation of the hepatic 7α-hydroxylase ac-

tivity, the key enzyme in bile acid synthesis, has recently been demonstrated in rats, hamsters, and guinea pigs (1,7,11). Subsequently, there is an increased demand for FC in the liver which can be attained by raising the hepatic *de novo* synthesis of cholesterol *via* stimulation of the HMG-CoA reductase activity or by stimulating the liver uptake of lipoprotein cholesterol by up-regulating the LDL-receptor activity. All of these alterations have been documented after PSY supplementation (1,7,9,11).

Another point to consider is the significant changes in the circulating bile acid profile induced by PSY and, to a minor degree, by hePE and lePE. PSY produced a predominant cholate profile with a 40% increase in glycocholate while taurochenodeoxycholate and glycochenodeoxycholate were decreased by 86 and 57%, respectively. As a result, the cholate/cheno ratio increased from 2.1 in controls to 7.2 in PSY-fed hamsters. In addition, PSY also increased the glycine/taurine conjugation ratio by impressively expanding the pool of glycine conjugated bile acids. Recirculating bile acids are known as potent inhibitors of hepatic bile acid synthesis by down-regulating cholesterol 7α-hydroxylase activity dependent on their hydrophobicity. Since chenodeoxycholate is more hydrophobic than cholate, a cheno-rich bile acid profile will inhibit bile acid synthesis more than a predominant cholate profile. The PSY-induced changes in the bile acid profile reflect a reduced hydrophobicity and an increase in hydrophilic bile acids (cholate). Moreover, PSY seems to remove selectively taurine conjugated bile acids (mostly taurocheno). As suggested, the composition of individual bile acids may be more important than the total concentration of the recirculating bile acid pool in regulating bile acid and cholesterol synthesis (39). Therefore, both the qualitative changes (decrease in chenodeoxycholate with concomitant reduction in hydrophobicity) and the quantitative changes (increased fecal bile acid excretion) in the bile acid pool produced by PSY favored a stimulation of bile acid synthesis. Taken together, these findings are consistent with the hypothesis of previous studies (11,36), demonstrating that PSY influences cholesterol and bile acid metabolism by affecting the enterohepatic circulation of the bile acid pool.

In summary, the present disparate findings further emphasize that the cholesterol-lowering action of PE, GG, and PSY results from distinct mechanisms specific to each fiber. In particular, the action of soluble fibers in the intestine, i.e., alterations of enterohepatic circulation of bile acids and changes in composition of the bile acid pool seem to play the major role in regulating cholesterol metabolism. The disparate effects of PSY, PE, and GG found in the present study are possibly related to different physicochemical properties of these fibers affecting intestinal viscosity and susceptibility to fermentation (especially in the forestomach) and therefore the fiber-mediated action in the intestine. Both increased fecal bile acid excretion and changes in bile acid profile produced by PSY seem to be the most important determinants of stimulating hepatic bile acid synthesis which is most likely the major mechanism through which PSY lowers cholesterol.

ACKNOWLEDGMENTS

ABSTRACT: The effect of dietary cyanidin 3-*O*-β-D-glucoside (C3G), a typical anthocyanin pigment, on the generation of thiobarbituric acid reactive substances (TBARS) during serum formation *ex vivo* and susceptibility of serum to further lipid peroxidation was studied in rats. Rats were fed a diet containing C3G (2 g/kg) for 14 d. Feeding C3G resulted in a significant decrease in generation of TBARS during serum formation. The serum from the C3G-fed group showed a significantly lower susceptibility to further lipid peroxidation provoked by 2,2′-azobis(2-amidinopropane)hydrochloride or Cu^{2+} than that of the control group. No significant differences were observed in serum phospholipid, triglyceride, esterified cholesterol, and free fatty acid concentrations between the control and the C3G-fed groups. Concentrations of endogenous antioxidants remaining in the serum after blood coagulation were not affected by the C3G feeding. These results demonstrate that feeding C3G increases the *ex vivo* oxidation resistance of the serum without affecting serum endogenous antioxidant levels, and reduces the TBARS generated during serum formation without changing the concentrations of serum lipids.

Lipids 33, 583–588 (1998).

The production of active oxygen species, such as hydroxyl radicals, superoxide anion radicals, and singlet oxygen and other radicals, is believed to be involved in carcinogenesis, mutagenesis, aging, and atherosclerosis (1–6). Endogenous antioxidants are presumed to protect cells against active oxygen species (1,5–9), and there is an increasing interest in the *in vivo* protective function of natural antioxidants contained in dietary plants (10–12). We previously reported that edible beans have antioxidative activity *in vitro* (13), although these food items had not been recognized previously as having antioxidant activity. Among the beans tested, the antioxidant activity of colored pea beans (*Phaseolus vulgaris* L.) was remarkable, suggesting that pigments contained in the seed coat had a potential role as dietary antioxidants. Three anthocyanin pigments, pelargonidin 3-*O*-β-D-glucoside, cyanidin 3-*O*-β-D-glucoside (C3G) and delphinidin 3-*O*-β-D-glucoside (D3G), were isolated from red and black beans (*P. vulgaris* L.), and identified as antioxidants *in vitro* (14–16). Among the isolated pigments, C3G (Scheme 1) had significant antioxidant activity (15) and scavenging activity against hydroxyl radicals and superoxide *in vitro* (16). Therefore, it seemed possible that C3G may also act as a potent antioxidant *in vivo*.

Recently, the "French paradox," a low incidence of coronary heart disease and atherosclerosis despite eating a high-fat diet, has been suggested to relate to phenolic compounds contained in red wine. These may act as *in vivo* inhibitors of low density lipoprotein (LDL) oxidation (17–20). Red wine contains a large amount of anthocyanins, such as D3G, petunidin 3-*O*-β-D-glucoside, malvidin 3-*O*-β-D-glucoside and C3G derived from grape skin (21,22), indicating that these anthocyanin pigments may also exert an inhibitory effect upon the oxidation of LDL.

C3G is widely distributed in the human diet through crops, beans, fruits, vegetables and red wines (23), suggesting that humans can ingest considerable amounts of C3G from plant-based diets daily. In general, anthocyanin pigments are stable in acidic conditions, but are unstable and rapidly broken down in neutral conditions (24). Due to this instability at neutral pH, anthocyanins have not been recognized as antioxidants (24). However, we have recently demonstrated in *in vitro* studies that C3G has antioxidant activity (15) and the capacity to scavenge hydroxyl radicals and superoxide under physiological conditions (16). There have been no prior studies as to whether feeding C3G could improve the *in vivo* antioxidant status of animals. In addition, it has not been clarified in animals whether C3G is effectively absorbed or accumulated in tissues.

Abbreviations: AAPH, 2,2′-azobis(2-amidinopropane)hydrochloride; C3G, cyanidin 3-*O*-β-D-glucoside; D3G, delphinidin 3-*O*-β-D-glucoside; GSH, reduced glutathione; LDL, low density lipoprotein; TBARS, thiobarbituric acid reactive substance.

In the present study, we evaluated the effect of C3G, which is an anthocyanin with antioxidant activity, *ex vivo* lipid peroxidation, and oxidation resistance of liver and serum in rats.

MATERIALS AND METHODS

Chemicals. 2,2′-Azobis(2-amidinopropane) hydrochloride (AAPH), ascorbic acid, and reduced glutathione (GSH) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). α-Tocopherol was obtained from Eisai Co. (Tokyo, Japan). C3G (purity: more than 95%) was purified using the commercial food coloring material (San Red No. 5F; San-Ei Gen F.F.I., Inc., Osaka, Japan) derived from violet corn (*Zea mays* L.) using previously described high-performance liquid chromatography (25). The structure and purity were confirmed by ^{1}H and ^{13}C nuclear magnetic resonance, fast atom bombardment mass spectra, ultraviolet–visible infrared spectra before use.

Animals and diets. Five-week-old male Wistar rats (~105 g; Japan SLC Inc., Hamamatsu, Japan) were used and housed individually in stainless-steel wire-mesh cages at 23 ± 0.3°C with a 12-h light cycle. Rats were allowed free access to water and a semipurified diet. All animals were fed the control diet containing (wt%): casein, 25; mineral mixture (AIN93G-MX) (26), 3.5; vitamin mixture (AIN93-VX) (26), 1; choline chloride, 0.2; corn oil, 5; cellulose powder, 4; and the remainder carbohydrate (sucrose/starch = 1:2) for 7 d before the experiment. C3G (2 g/kg diet) was added in place of sucrose. Rats were maintained in accordance with the Guidelines for Animal Experimentation of Nagoya University.

Experimental design and tissue preparation. Ten rats were divided into two groups and fed the control diet (control group) or the control diet containing 0.2% C3G (C3G group) for 14 d. After 14 d of feeding, the rats were killed by decapitation. After the collected blood had sat at room temperature for 5 min for coagulation, the serum was obtained by centrifugation at 1,600 × *g* for 15 min at 4°C. The separation of serum was finished within 30 min. The serum was immediately stored at −80°C until assayed. The liver was rapidly excised after being perfused with physiological saline. The liver was kept at −80°C until assayed. These conditions were standardized for all the animals.

Measurement of oxidation resistance of the serum. The serum was oxidized at 37°C by incubation with AAPH or $CuSO_4$ (27,28). The final concentrations of AAPH and $CuSO_4$ were 25 mM and 500 μM, respectively. During incubation, aliquots were taken at specific intervals, and lipid peroxidation was stopped by the addition of butylated hydroxytoluene at a final concentration of 60 μM. The degree of oxidation was immediately measured by the thiobarbituric acid reactive substances (TBARS) assay (29). The measurement of oxidation resistance of the serum was performed within 1 wk after killing the rats.

Measurement of oxidation resistance of liver homogenate. Frozen liver (0.5 g) was homogenized in 20 vol of 20 mM phosphate buffer (pH 7.4) using a Potter-Elvehejm homogenizer, and the homogenate was oxidized at 37°C by incubation with AAPH (final concentration, 5 mM). During incubation, aliquots were taken at specific intervals, and butylated hydroxytoluene was added to them at the final concentration of 60 μM. The degree of oxidation was immediately measured by TBARS assay (30). The measurement of oxidation resistance of the liver was performed within 1 wk after killing the rats.

Measurement of protein concentration of liver homogenate. The protein concentration of the liver homogenate was determined using a BCA Protein Assay Kit (Pierce, Rockford, IL).

Measurement of antioxidants. The α-tocopherol concentration in the serum was measured by high-performance liquid chromatography according to the method of Ueda and Igarashi (31). The ascorbic acid concentration in the serum was measured according to the method of Yamamoto *et al.* (32). The GSH concentration in the serum was measured using a commercial assay kit (GSH-400; Oxis International, Inc., Portland, OR). The serum uric acid concentration was measured using a commercial assay kit (Uric acid B-Test Wako; Wako Pure Chemical Industries, Ltd.) by the colorimetric method of Kabasakalian *et al.* (33). Serum antioxidant concentrations were measured within 1 mon after killing the rats.

Measurement of serum lipids. Serum phospholipid (34), triglyceride (35), total cholesterol (36), and free cholesterol (36) were measured by enzymatic assay with commercial assay kits (Phospholipid C-test, triglyceride G-test, Cholesterol E-test, Free cholesterol E-test, respectively; Wako Pure Chemical Industries, Ltd.). Serum esterified cholesterol concentrations were calculated by subtracting the concentration of free cholesterol from that of the total cholesterol. Serum free fatty acid was measured by a colorimetric method with a commercial assay kit (NEFA-test; Wako Pure Chemical Industries, Ltd.) (37). Serum lipid concentrations were measured within 1 mon after killing the rats.

Statistical analysis. All results were expressed as the means ± SE. Data were compared using Student's *t*-test. Probability values < 0.05 were considered significant.

RESULTS

Effect of dietary C3G on body weight gain, food intake, and liver weight. Body weight gain after 14 d, food intake, and liver weight of the rats in the C3G group were not significantly different from those in the control group (data not shown), suggesting that feeding C3G did not cause serious toxicity in rats.

Effect of dietary C3G on serum TBARS concentration and the susceptibility of the serum to lipid peroxidation. Figure 1A shows the concentration of TBARS generated during formation of serum from rats in the control and C3G groups. The serum TBARS concentration was slightly but significantly lower in the C3G group (82% of the control group) than in the control group. Figure 1B and C show the time course of

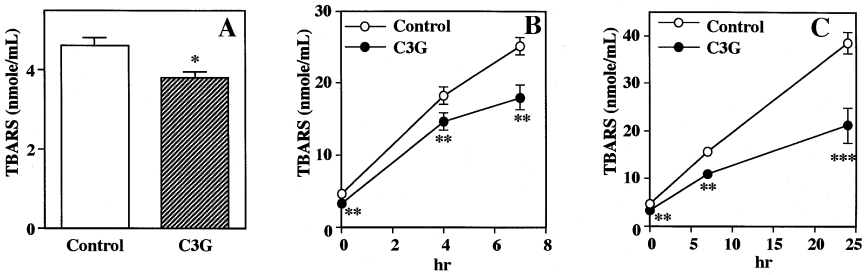

FIG. 1. Effect of cyanidin 3-*O*-β-D-glucoside (C3G) feeding on the serum thiobarbituric acid reactive substance (TBARS) concentration (A) and the susceptibility of the serum to lipid peroxidation induced by 2,2′-azobis(2-amidinopropane)hydrochloride (AAPH) (B) or $CuSO_4$ (C) in rats. The serum from the control or C3G group was incubated at 37°C with AAPH (25 mM) or $CuSO_4$ (500 μM). During the incubation at specified intervals, the TBARS concentration in the medium was measured. Values are means ± SE for five rats. *Significantly different ($P < 0.05$) from the control value. **Significantly different ($P < 0.05$) from the control value at the respective incubation times. ***Significantly different ($P < 0.01$) from the control value at the respective incubation times.

TBARS generation in serum exposed to AAPH or $CuSO_4$. The serum obtained from the C3G group showed significantly less oxidation compared with that from the control group throughout the 7-h incubation when the lipid peroxidation was induced by AAPH (Fig. 1B). In the presence of $CuSO_4$, lipid peroxidation of the serum from the C3G group was also inhibited by 67 and 52% after 7- and 24-h incubation, respectively, compared with that from the control group (Fig. 1C).

Effect of dietary C3G on serum lipid concentrations. The serum lipid concentrations in the control and C3G groups are shown in Table 1. No significant difference was observed for the phospholipid, triglyceride, esterified cholesterol, and free fatty acid concentrations between the control and the C3G groups. Total and free cholesterol concentrations in the C3G group were significantly lower than those in the control group.

Effect of dietary C3G on serum antioxidant concentrations. Serum antioxidant concentrations of the rats in the control or C3G groups are shown in Table 2. No significant differences between the sera from control and C3G groups were observed in the concentrations of α-tocopherol, GSH, ascorbic acid, and uric acid.

Effect of dietary C3G on liver protein, TBARS concentration, and the susceptibility of liver homogenate to lipid peroxidation. The liver protein concentrations in rats from the control and C3G groups were 148.6 ± 5.1, 153.1 ± 5.9 mg/g wet weight, respectively, which were not significantly different. The TBARS generated in the liver homogenates from the control or C3G groups are shown in Figure 2A. No significant difference in the TBARS concentration was observed between the control and C3G groups in the liver. Figure 2B shows the time course of TBARS generation of the liver homogenate exposed to AAPH. The susceptibility of liver to lipid peroxidation was not affected by the C3G feeding when the lipid peroxidation was induced in liver homogenate by AAPH.

DISCUSSION

Recently, the antioxidant activity of phenolic phytochemicals has been widely investigated (38–40). However, anthocyanins, which are included in the phenolic phytochemicals, are unstable in neutral conditions, and therefore we believe that anthocyanins would not have antioxidant activity. We have demonstrated in an *in vitro* study that C3G has both antioxidant activity (15) and the capacity for scavenging hydroxyl radicals and superoxide (16). C3G is one of the most prevalent anthocyanins in a plant-based daily diet, but the *in vivo* effectiveness has been uncertain. Therefore, we tried to determine whether C3G ingested by animals would act as an antioxidant *in vivo*.

In this study, the concentration of TBARS generated during serum formation was significantly lower in the C3G group than in the control group, and C3G feeding resulted in a significant resistance of the serum against further lipid peroxidation induced by AAPH or Cu^{2+}. The reduction in the serum TBARS concentration and the increase in the oxidation resistance of the serum observed in the C3G group are not due to

TABLE 1
Effect of Cyanidin 3-*O*-β-D-glucoside (C3G) Feeding on the Serum Lipids in Rats[a]

Group	Triglyceride (mg/100 mL)	Phospholipid (mg/100 mL)	Cholesterol (mg/100 mL)			Free fatty acid (meq/100 mL)
			Total	Free	Esterified	
Control	121.8 ± 6.9	276.5 ± 6.3	107.6 ± 3.9	28.0 ± 2.0	79.6 ± 4.1	0.30 ± 0.03
C3G	109.0 ± 6.9	259.8 ± 6.8	90.6 ± 2.9*	19.4 ± 1.1*	71.2 ± 2.0	0.34 ± 0.03

[a]Values are means ± SE for five rats. *Significantly different ($P < 0.01$) from the control value.

TABLE 2
Effect of C3G Feeding on the Serum Antioxidants Concentrations in Rats[a]

Group	α-Tocopherol (μg/mL)	Ascorbic acid (μg/mL)	GSH (μg/mL)	Uric acid (μg/mL)
Control	18.6 ± 0.9	5.0 ± 0.3	52.2 ± 2.3	16.0 ± 0.1
C3G	17.9 ± 0.9	5.9 ± 0.5	50.6 ± 2.4	15.0 ± 0.1

[a]Values are means ± SE for five rats. See Table 1 for abbreviation.

the decrease in serum lipids such as phospholipids, triglycerides, and free fatty acids. Frei *et al*. (27) reported that the esterified cholesterol fraction was very sensitive to oxidation induced by AAPH in human plasma. In this study, the serum concentration of esterified cholesterol was not affected at all by C3G feeding. These results indicate that dietary C3G reduces the generation of TBARS during serum formation and increases the oxidation resistance of the serum without changing the serum lipid concentrations.

The effect of red wine consumption on the susceptibility of plasma and LDL to *ex vivo* lipid peroxidation has been reported (20,41). Fuhrman (41) reported that the total polyphenols in the plasma LDL fraction were elevated fourfold after 2 wk of red wine consumption in humans, and the elevation was associated with a significant decrease in LDL susceptibility to lipid peroxidation. Red wine contains a large amount of anthocyanins such as C3G (21,22), indicating that the pigments may contribute to the inhibitory effect on oxidation of LDL. The measurement of C3G and related compounds in the serum and lipoproteins is not routinely available, but further studies are in progress to accomplish this.

The serum contains an array of antioxidants, such as ascorbic acid, α-tocopherol, uric acid, and GSH. These antioxidants decrease the rate of lipid peroxidation during the activation of platelets when blood clots to form serum. In this study, no significant differences between the control and the C3G groups were observed in the concentrations of these physiological antioxidants left in serum, suggesting that C3G feeding did not affect the concentrations of serum antioxidants in rat plasma prior to blood coagulation. Nardini *et al*. (42) reported that the α-tocopherol concentration in the plasma and lipoproteins was significantly higher in rats fed caffeic acid compared to that in the control rats, and the purported antioxidant action of caffeic acid *in vivo* may be related to both its direct antioxidant properties as well as the sparing effect on α-tocopherol. The antioxidant action of C3G, however, seems to be due to a direct antioxidant effect, since a sparing effect on endogenous antioxidants was not apparent.

In contrast to the findings in rat serum, TBARS generation during homogenation of liver concentration and the susceptibility of the liver homogenate to lipid peroxidation were not affected by C3G feeding in rats. The liver ascorbic acid, α-tocopherol, and glutathione concentrations were also not affected by C3G feeding. Because the liver contains a sufficient amount of antioxidants (for example, liver in the C3G group rats had ascorbic acid; 172.2 ± 7.1 μg/g liver, α-tocopherol; 47.6 ± 2.6 μg/g liver, and GSH; 1.8 ± 0.1 mg/g liver) and antioxidative enzymes (glutathione peroxidase, catalase, superoxide dismutase, etc.), it may be difficult to modulate the liver antioxidant capacity by C3G feeding. It is also possible that unmetabolized C3G is not present in rat liver and thus could not influence lipid peroxiation there.

Anthocyanin pigments are widely distributed in the human diet through seeds, fruits, and vegetables. Red wine also contains anthocyanins derived from grape skin. Therefore, humans ingest significant amounts of anthocyanin pigments from a plant-based diet. In the present study, we have demonstrated for the first time that oral administration of C3G is associated with antioxidant activity in rats. We have recently reported that C3G was able to react with peroxyl radicals, and then converted itself to the oxidation products, 4,6-dihydroxy-2-*O*-β-D-glucosyl-3-oxo-2,3-dihydrobenzofuran and protocatechuic acid (25). Protocatechuic acid can also scavenge free radicals, suggesting that C3G would produce another radical scavenger by the reaction of C3G with biological radicals *in vivo*. Further studies are under way to demonstrate that these oxidation reactions of C3G occur *in vivo*, and to find evidence for the oxidized metabolites or C3G in animals.

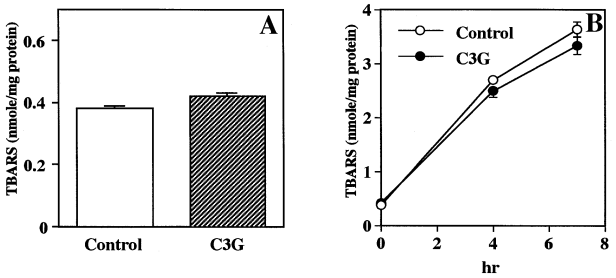

FIG. 2. Effect of cyanidin C3G feeding on the liver TBARS concentration (A) and the susceptibility of the liver homogenate to lipid peroxidation induced by AAPH (B) in rats. The liver homogenate that was obtained from the control or C3G group was incubated at 37°C with AAPH (5 mM). During the incubation at specified intervals, the TBARS concentration in the medium was measured. Values are means ± SE for five rats. See Figure 1 for abbreviations.

ACKNOWLEDGMENTS

This study was supported by a Program for Promotion of Basic Research Activities for Innovative Biosciences. The authors would like to thank Takahito Ichi, San-Ei Gen F.F.I. Inc., Toru Niwa and Tatsuya Uraji, Nikken Fine Chemicals Co., Ltd. for providing the food coloring material and purifying C3G.

[a]Noda Institute for Scientific Research, Chiba 278, Japan, and [b]National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Ibaraki 305, Japan

ABSTRACT: The protective effect of a vitamin E analog, phosphatidylchromanol [1,2-diacyl-*sn*-glycero-3-phospho-2′-(hydroxyethyl)-2′,5′,7′,8′-tetramethyl-6′-hydroxychroman; PCh], against oxidative hemolysis of human erythrocytes was examined and was compared with those of vitamin E (α-tocopherol) and 2,2,5,7,8-pentamethyl-6-chromanol (PMC). These three compounds at 50 μM protected the erythrocytes from hemolysis, when erythrocyte suspension (10%, vol/vol) was incubated with a water-soluble radical generator, 2,2′-azobis(2-amidinopropane)-dihydrochloride (75 mM). When erythrocyte suspension was oxidized after pretreatment with these compounds (50 μM) for 30 min followed by washing, PCh protected about 54% of erythrocytes from the hemolysis, while α-tocopherol protected only about 16% of the cells and PMC did not show any protective effect. During preincubation, α-tocopherol, PMC, and PCh were incorporated into the cells at the concentration of 12.6, 3.7, and 16.3 nmol/mg protein, respectively. Moreover, PCh was found in the ghost membrane fraction at a 20% higher level than α-tocopherol, and no PMC was detected in this fraction. These results indicate that phosphatidyl group in PCh acts as an excellent carrier of chromanol moiety into cells as well as an anchor within membranes more efficiently than phytyl group in α-tocopherol. PMC seems to be slightly anchored within membranes because of the lack of hydrophobic side chain. The excellent antihemolytic activity of PCh is likely to be caused by its accumulation within erythrocyte membranes.
Lipids 33, 589–595 (1998).

Increasing evidence suggests that free radical-induced oxidative damages lead to various pathological events including coronary heart disease, cancer, and aging (1). In particular, lipid peroxidation in biological membranes has attracted much attention in relation to the deterioration of membrane structure and impairment of enzymatic functions (2). Much interest exists in the possibility that antioxidants reduce the risk of such degenerative diseases by inhibiting free radical-induced oxidative damage (3). Therefore, several studies have examined both natural and synthetic antioxidants for the inhibition of lipid peroxidation in membrane systems.

In phospholipid bilayers of biomembranes, the primary defense against free radical-induced oxidative damages involves vitamin E (α-tocopherol) (4,5), and the presence of specific binding sites for α-tocopherol in erythrocyte membranes was demonstrated (6,7). α-Tocopherol consists of two structural domains. One is a chromanol group, responsible for radical scavenging ability, and the other is phytyl side chain, which is required for anchoring the chromanol group within phospholipid bilayers (8). It has been accepted that the phytyl side chain of α-tocopherol facilitates the incorporation of α-tocopherol into biomembranes and arranges its chromanol group on a suitable site for scavenging chain-carrying lipid peroxyl radicals in phospholipid bilayers (9,10). Thus, the phytyl side chain of α-tocopherol has an important role in its antioxidant activity in the membranes.

In previous papers, we described a new synthetic vitamin E analog, phosphatidylchromanol [1,2-diacyl-*sn*-glycero-3-phospho-2′-(hydroxyethyl)-2′,5′,7′8′-tetramethyl-6′-hydroxychroman (PCh), Scheme 1], which contains phosphatidyl moiety as the substitute for phytyl chain (11). Its antioxidant abilities in bulk oils and phospholipid bilayers were also examined by comparing them with those of α-tocopherol and 2,2,5,7,8-pentamethyl-6-chromanol (PMC) (11–14). PCh is expected to act as an effectively protective reagent against oxidative cellular injury, because phosphatidyl group seems to possess high affinity for cellular phospholipid bilayers and has been actually regarded as a suitable and nontoxic carrier of pharmaceuticals into cells (15). The aim of this study is to elucidate the action of PCh as a protective reagent against oxidative damages mediated by lipid peroxidation in biomembranes.

Free radical-induced deterioration of erythrocyte membranes and resulting hemolysis serve as a good model for studying the oxidative damage in biomembranes (16–26). It

has been well studied that free radicals attack erythrocyte membranes to induce peroxidation of lipids and proteins and eventually cause hemolysis (18–23). Therefore, the oxidative hemolysis of erythrocytes induced by free radicals is a well-defined model to estimate the antioxidative action of α-tocopherol and its analogs in biomembranes. In the present study, human erythrocytes were oxidized by a water-soluble radical generator, and the protective effect of PCh on the lipid peroxidation and hemolysis was investigated and was compared with those of α-tocopherol and PMC.

MATERIALS AND METHODS

Chemicals. 2,2′-Azobis(2-amidinopropane)-dihydrochloride (AAPH) and 3,5-di-*tert*-butyl-4-hydroxytoluene (BHT) were obtained from Wako Pure Chemical Co. (Osaka, Japan). *dl*-α-Tocopherol and PMC were obtained from Eisai Co. (Tokyo, Japan). Probucol [4,4′-(isopropylidenedithio)bis(2,6-di-*tert*-butylphenol)] was from Sigma Chemical Co. (St. Louis, MO). All other chemicals used were of reagent grade. PCh was synthesized enzymatically from 2,5,7,8-tetramethyl-6-hydroxy-2-(hydroxyethyl)chroman and phosphatidylcholine and purified as described previously (11).

Preparation of human blood plasma and erythrocytes. Blood was taken from healthy volunteers and then was put into tubes containing EDTA, disodium salt (1 mg/mL). Plasma and erythrocytes were separated by centrifugation at 1000 × *g* for 20 min at 4°C. Erythrocytes were washed three times with 5 vol of the phosphate buffered saline (PBS). The buffy coat was carefully removed with each wash. At the last washing, the cells were centrifuged exactly at 1000 × *g* for 20 min to obtain packed cells with a constant volume.

Assay for oxidative hemolysis. Oxidative hemolysis of erythrocytes was performed as reported by Miki *et al.* (22) with a slight modification. Washed erythrocytes (0.5 mL) were suspended in 4 vol of PBS. Antioxidants, except for PCh, were added to the cell suspension as ethanol solution. The final ethanol concentration in the suspension was less than 0.5% (vol/vol), which had no effect on erythrocytes. Since PCh was only slightly soluble in ethanol, it was dispersed in PBS with a vortex mixer for 1 min followed by ultrasonic irradiation with an ultrasonicator (Model B1210J-DTH; Branson, Tokyo, Japan) for 30 s and then added to the erythrocyte suspension. After preincubation of this suspension at 37°C for 5 min, 2.5 mL of 150 mM AAPH dissolved in PBS was added to the suspension. Oxidation was carried out in the dark at 37°C under air with continuous shaking. When erythrocytes were oxidized after pretreatment with antioxidants, washed erythrocytes (1 mL) were suspended in 9 vol of PBS. Then antioxidant was added at the concentration of 50 μM in the suspension. After preincubation of this suspension at 37°C for 30 min, erythrocytes were washed three times with 10 mL of PBS. Washed erythrocytes were oxidized by the same aforementioned procedure. In both cases, oxidation was carried out in the dark at 37°C under air with continuous shaking. At specific intervals, the reaction mixture (0.1 mL) was withdrawn, diluted with 4 vol of PBS, and centrifuged (2000 × *g* for 5 min). The absorption of the supernatant at 540 nm was measured (absorption A). Similarly, the reaction mixture (0.1 mL) was treated with 4 vol of 0.1% Triton X-100 solution to yield complete hemolysis, and the absorption of the supernatant after centrifugation was measured at 540 nm (absorption B). Percentage hemolysis was calculated from the ratio of the readings, (absorption A/absorption B) × 100.

Oxidation of ghost membranes. Ghost membranes were prepared from erythrocytes by the method of Dodge *et al.* (27), after 25 mL of erythrocyte suspension (10%, vol/vol) was preincubated with each antioxidant (50 μM) at 37°C for 30 min, followed by washing three times with PBS (25 mL). The phospholipid concentration in the ghost membrane was calculated from the phosphorus content according to the method of Bartlett (28). Ghost membranes were suspended in PBS containing 0.5 mM diethylenetriaminepentaacetic acid (DTPA) at the concentration of 1 mM. The ghost membrane suspension (0.5 mL) was preincubated at 37°C for 5 min. Oxidation was initiated by adding 80 mM AAPH (0.5 mL) dissolved in PBS containing 0.5 mM DTPA. The reaction mixture was incubated at 37°C with continuous shaking in the dark. After 4 h of incubation, the reaction mixture (0.1 mL) was withdrawn and 0.1 mL of 10 mM BHT in ethanol was added. The lipids were extracted three times by the method of Bligh and Dyer (29). The lipid portion was evaporated with nitrogen gas, and the residue was dissolved in the mixture of methanol and water (95:5, vol/vol, 0.1 mL) for high-performance liquid chromatographic (HPLC) analysis of phospholipid hydroperoxides (PL-OOH) (30). Sample (10 μL) was injected into an octylsilyl column (TSK gel OCTYL-80Ts column, 6 × 150 mm; TOSOH, Tokyo Japan) and eluted with methanol/water (92.5:7.5, vol/vol). The hydroperoxides were

detected by ultraviolet absorption at 235 nm. The concentration of PL-OOH was calculated from the standard curve of phosphatidylcholine hydroperoxides. Standard phosphatidylcholine hydroperoxides were prepared as described previously (30).

Determination of antioxidants in erythrocytes and ghost membranes. After preincubation of 15 mL of erythrocyte suspension (10%, vol/vol) with each antioxidant (50 μM) for 30 min at 37°C, erythrocytes were washed three times with PBS (15 mL) and centrifuged at 1000 × *g* for 20 min. Then a hexane/ethanol mixture (4:1, vol/vol, 4 mL) containing 25 μM BHT and water (2 mL) was added to washed erythrocytes (0.5 mL). They were mixed with a vortex mixer for 30 s and were sonicated for 1 min followed by centrifugation at 1500 × *g* for 5 min. Hexane layers obtained from repeated extraction for three times were collected and evaporated with nitrogen gas. The residue was dissolved in the mixture of acetonitrile and chloroform (6:4, vol/vol, 0.1 mL) for the analysis of α-tocopherol, or in *n*-hexane (0.1 mL) for the analysis of PMC and PCh. α-Tocopherol was quantified by HPLC on an octylsilyl column (TSK gel OCTYL 80Ts, 4.6 × 100 mm; TOSOH) with acetonitrile/water (99:1, vol/vol) as an eluent at a flow rate of 1.2 mL/min. PMC was determined by HPLC on an aminopropylsilyl column [YMC Pack A-612(NH_2), 4.6 × 100 mm; Yamamura Chemical Laboratories, Kyoto, Japan] with hexane/isopropanol (99:1, vol/vol) as an eluent at a flow rate of 1.0 mL/min. For HPLC analysis of PCh, an aminopropylsilyl silica column (Shim-Pack FLC-NH_2, 4.6 × 50 mm; Shimadzu Co., Kyoto, Japan) was used with hexane/isopropanol/10% phosphoric acid (70:30:0.5, by vol) as an eluent at a flow rate of 2.0 mL/min. In each determination, the eluent was monitored fluorometrically at an excitation wavelength of 298 nm and an emission wavelength of 325 nm using a Shimadzu RF-10A (Shimadzu Co.). The respective concentration was calculated from the standard curve of the authentic compounds.

Measurement of protein. Protein was determined by the method of Bradford (31) using bovine serum albumin as a standard.

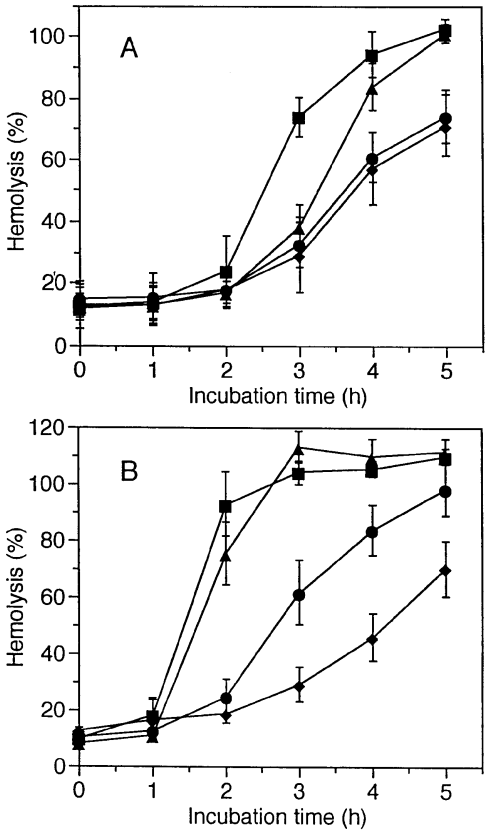

FIG. 1. Effect of coincubation (A) and preincubation (B) of erythrocyte suspension with α-tocopherol, 2,2,5,7,8-pentamethyl-6-chromanol (PMC), or 1,2-diacyl-*sn*-glycero-3-phospho-2′-(hydroxyethyl)-2′,5′,7′,8′-tetramethyl-6′-hydroxychroman (PCh) on 2,2′-azobis(2-amidinopropane)-dihydrochloride (AAPH)-induced oxidative hemolysis of erythrocytes. (A) Erythrocyte suspension (10%, vol/vol) in phosphate buffered saline (PBS) (pH 7.4) was incubated with AAPH (75 mM) and α-tocopherol or α-tocopherol analogs (50 μM). (B) Erythrocyte suspension (10%, vol/vol) in PBS (pH 7.4) was preincubated with α-tocopherol or α-tocopherol analog (50 μM) for 30 min followed by washing three times. After washing, the suspension was incubated with AAPH (75 mM). Each point represents the mean ± the standard deviation of three separate experiments. (■), No addition; (●), α-tocopherol; (▲), PMC; (◆), PCh.

RESULTS

Effects of antioxidants on free radical-induced hemolysis of human erythrocytes. Oxidative hemolysis was induced by a water-soluble azo compound, AAPH. Incubation of erythrocyte suspension with 75 mM AAPH at 37°C resulted in time-dependent hemolysis with an induction period (Fig. 1). In order to estimate the antihemolytic potency of α-tocopherol, PMC and PCh, erythrocyte suspensions were coincubated with each compound (50 μM) and AAPH (75 mM). α-Tocopherol and PMC were added to erythrocyte suspension as ethanol solution, while PCh was added as aqueous dispersion in PBS. These compounds retarded the occurrence of hemolysis and suppressed its percentage (Fig. 1A, coincubation experiment). α-Tocopherol and PCh exhibited nearly the same inhibitory effects and were more efficient than PMC. In a separate experiment, erythrocyte suspension was oxidized after pretreatment with each compound for 30 min, followed by washing three times to avoid the interference by unincorporated antioxidants (preincubation experiment). In this case, PMC had no protective effect (Fig. 1B). In contrast to PMC, α-tocopherol and PCh protected against hemolysis significantly even after pretreatment followed by washing. It should be noted that PCh was much more effective than α-tocopherol in suppressing the hemolysis of erythrocytes in the preincubation experiment, although little difference was observed between the two compounds in the coincubation experiment.

In addition to α-tocopherol analogs, we investigated the protective effects of BHT and probucol on oxidative hemolysis of erythrocytes in the preincubation experiment (Fig. 2). When preincubation was carried out in the absence of antioxidant, most of the erythrocytes were subjected to lysis after

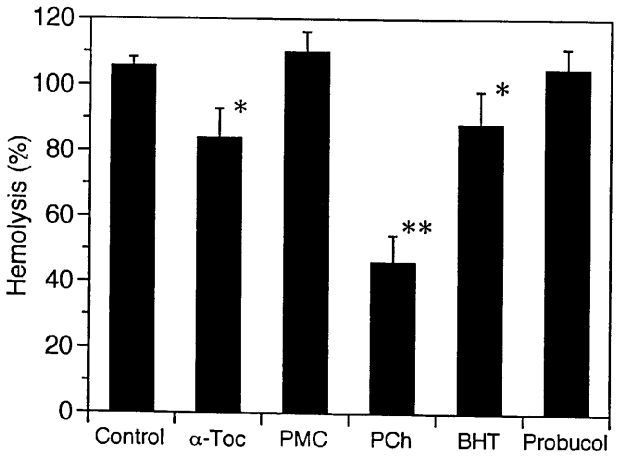

FIG. 2. Effect of preincubation of erythrocyte suspension with α-tocopherol, PMC, PCh, BHT, or probucol on AAPH-induced oxidative hemolysis of erythrocytes. Erythrocyte suspension (10%, vol/vol) in PBS (pH 7.4) was preincubated with each antioxidant (50 μM) for 30 min followed by washing three times. After washing, the suspension was incubated with AAPH (75 mM) for 4 h. Bars represent the mean ± the standard deviation of three separate experiments. Asterisks indicate significant differences between control and antioxidant treatment: *, $P < 0.05$; **, $P < 0.01$. See Figure 1 for abbreviations.

incubation with AAPH (75 mM) for 4 h (control experiment). Probucol showed no significant protection similar to PMC, while α-tocopherol and BHT lowered the hemolysis to 83.8 ± 9.0% and 88.1 ± 9.8%, respectively. PCh exhibited a remarkable resistance to hemolysis, and the percentage of hemolysis was 46.0 ± 8.3%.

Incorporation of α-tocopherol, PMC, and PCh into human erythrocytes and their ghost membranes. In order to clarify the reason for the marked difference in antihemolytic potency among the three α-tocopherol analogs, the amounts of α-tocopherol and its analogs incorporated into erythrocytes and those accumulated within ghost membrane were measured after incubation for 30 min at 37°C (Table 1). Endogenous α-tocopherol was found at the level of 0.2 and 2.7 nmol/mg protein in erythrocytes and erythrocyte membrane fraction, respectively. The presence of endogenous α-tocopherol is likely to cause the induction period which was observed when erythrocytes without treatment of any antioxidants were exposed to AAPH (Fig. 1). When erythrocytes were incubated with α-tocopherol, PMC, or PCh at 50 μM, these compounds were incorporated into the cells at the concentration of 12.6 ± 0.7, 3.7 ± 0.2, and 16.3 ± 0.5 nmol/mg protein, respectively. In ghost membranes, PMC was not found, although α-tocopherol and PCh were found at 84.4 ± 6.2 and 101.0 ± 2.3 nmol/mg protein, respectively.

Effect of concentration of PCh in the pretreatment medium and pretreatment time on its antihemolytic activity. In order to study the antihemolytic action of PCh, the relationship between the concentration of PCh in the preincubation medium and its inhibitory effect against the hemolysis of erythrocyte was examined. The protective effect was increased with the

TABLE 1
Incorporation of α-Tocopherol Analogs into Erythrocytes[a]

	Concentration of antioxidant (nmol/mg protein)			
	Erythrocytes		Ghost membrane fraction	
Analog				
No addition		(0.19 ± 0.01)[b]		(2.68 ± 0.09)
α-Tocopherol	12.6 ± 0.7		84.4 ± 6.2	
PMC	3.7 ± 0.2	(0.21 ± 0.07)	n.d.[c]	(2.62 ± 0.10)
PCh	16.3 ± 0.5	(0.22 ± 0.03)	101.0 ± 2.3	(2.74 ± 0.13)

[a]Each value represents the mean ± the standard deviation of triplicate analyses.
[b]Values in parentheses are the concentration of endogenous α-tocopherol.
[c]Not detected. PMC, 2,2,5,7,8-pentamethyl-6-chromanol; PCh, 1,2-diacyl-*sn*-glycero-3-phospho-2′-(hydroxyethyl)-2′,5′,7′,8′-tetramethyl-6′-hydroxychroman.

elevation of the concentration up to 50 μM, reaching a plateau above 50 μM (Fig. 3A). The protective effect of PCh was enhanced with the increase of pretreatment time for up to 30 min, reaching a plateau for more than 30 min (Fig. 3B). Thus,

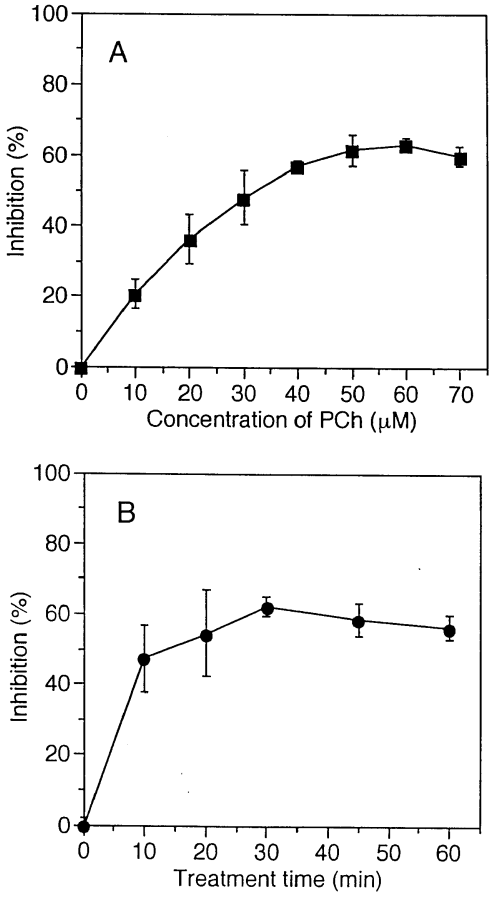

FIG. 3. Effect of the concentration (A) and the pretreatment time (B) of PCh on the protection of AAPH-induced oxidative hemolysis of erythrocytes. (A) Erythrocyte suspension (10%, vol/vol) in PBS (pH 7.4) was preincubated with PCh for 30 min followed by washing three times. (B) Erythrocyte suspension (10%, vol/vol) in PBS (pH 7.4) was incubated with PCh (50 μM) for specific time followed by washing three times. In both cases the suspension was incubated with AAPH (75 mM) for 4 h. Each point represents the mean ± the standard deviation of three separate experiments. See Figure 1 for abbreviations.

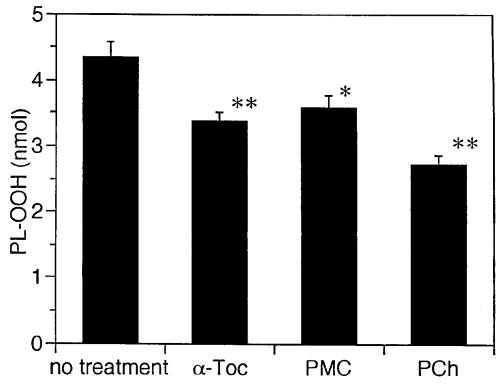

FIG. 4. AAPH-induced oxidation of α-tocopherol analog-pretreated ghost membranes. Erythrocyte suspension (10%, vol/vol) in PBS (pH 7.4) was preincubated with α-tocopherol, PMC, or PCh (50 μM) for 30 min, followed by washing three times, and then the ghost membranes were prepared by the method of Dodge *et al.* (27). The suspension of ghost membranes containing 0.5 μmol of phospholipids was incubated with AAPH (75 mM) for 4 h. Bars represent the mean ± the standard deviation of three separate experiments. Asterisks indicate significant differences between no treatment and α-tocopherol analog treatment: *, $P < 0.05$; **, $P < 0.01$. See Figure 1 for abbreviations.

an optimal concentration and an optimal time in the pretreatment of PCh appeared in the inhibition of oxidative hemolysis.

Oxidation of ghost membrane prepared from α-tocopherol-, PMC-, or PCh-pretreated erythrocytes. The ghost membranes prepared from erythrocytes after preincubation with each compound for 30 min were subjected to the oxidation initiated by AAPH. PL-OOH were accumulated as the primary products of ghost membrane peroxidation as shown in Figure 4. A lower amount of PL-OOH was accumulated in the pretreated ghost membranes. The membranes pretreated with PCh accumulated a lower amount of PL-OOH, as compared with those pretreated with α-tocopherol and PMC. This indicates that the resistance of erythrocyte membranes to free radical-induced lipid peroxidation was enhanced by the pretreatment of erythrocytes with α-tocopherol and α-tocopherol analogs, particularly PCh.

DISCUSSION

The above results show that PCh acts as a potent protector against oxidative cell injury in human erythrocytes and that its protective effect is superior to those of α-tocopherol and PMC. α-Tocopherol, PMC, and PCh are homologs of 2,5,7,8-tetramethyl-6-chromanol with phytyl side chain, methyl group, and phosphatidyl group, at the 2-position, respectively (Scheme 1). Although their structures are identical except for the substituents at the 2-position, their antioxidant effects seem to be much different from one another in a heterogeneous system because of their inherent physical properties.

We have reported that α-tocopherol, PMC, and PCh gave almost the same peroxyl radical-scavenging activity in homogeneous solution (11). On the other hand, α-tocopherol showed the longest induction period among the three compounds in phosphatidylcholine liposomes, probably owing to their different location in phospholipid bilayers (11,13,14), in which we have proposed that chromanol moiety in PCh is located at the interface between aqueous phase and lipid bilayers (13), analogous with the polar head group of phospholipids. It is reasonable that the difference in their antioxidant activities is, at least in part, derived from location and mobility of each analog in phospholipid bilayers. However, in intact cells the incorporation and retention of antioxidant within cellular membranes are also important factors in its activity. PCh is expected to possess high affinity for cellular membranes because of its nature as phospholipid that is a major component of cellular membrane bilayers. Therefore, this study is focused on the action of PCh in cellular membranes as compared with those of α-tocopherol and PMC.

The order of antihemolytic activity of the three compounds in the preincubation experiment appeared to be correlated with their amounts incorporated into erythrocytes. The local concentrations of α-tocopherol and PCh in erythrocytes were much higher than that of PMC (Table 1), indicating that α-tocopherol and PCh are effectively incorporated into erythrocytes. PMC could hardly be retained within the ghost membrane fraction in spite of the incorporation into the cells to some extent (32,33). These results indicate that phytyl chain and phosphatidyl moiety can act as an anchor to retain a chromanol moiety within membranes. α-Tocopherol and PCh incorporated into the membranes should play a role in preventing hemolysis by protecting the oxidation of membrane lipids. In fact, we found that the ghost membranes prepared from erythrocytes pretreated with α-tocopherol analogs elevated the resistance to free radical-induced lipid peroxidation (Fig. 4).

The existence of the α-tocopherol selective uptake system in red blood cells has been reported (6,7). Kaneko *et al.* (34) demonstrated that α-tocopherol was well incorporated into cultured cell because of the high affinity of its phytyl group with cell membranes. The fact that PCh was found in a higher amount than α-tocopherol in pretreated erythrocytes and their ghost membranes indicates that the affinity of phosphatidyl group with cell membranes is higher than that of phytyl group. Shuto *et al.* (15) reported that nucleoside analogs containing a phosphatidyl residue possess a high affinity for cell membranes, resulting in the penetration into cells. Furthermore, a phosphatidyl derivative of genipin, which is a water-soluble compound having some pharmacological activities, was found to exhibit the enhanced cytotoxicity in spite of the weak cytotoxicity of genipin itself (35). Therefore, it is concluded that a phosphatidyl group in PCh acts as an excellent carrier and anchor of chromanol group in erythrocyte membranes.

After the treatment of erythrocytes with α-tocopherol and PCh for 30 min, the concentrations of α-tocopherol and PCh reached similar levels, which were 66 and 74 times in the cells, and 31 and 37 times in the ghost membranes greater than endogenous α-tocopherol concentration, respectively (Table 1). However the inhibition of AAPH-induced hemoly-

sis by the treatment with PCh was much greater than that by the treatment with α-tocopherol (Figs. 1 and 2). Thus, the marked difference in antihemolyic potency between α-tocopherol and PCh cannot be fully explained by their cellular concentrations. Free radicals generated from AAPH are known to attack erythrocyte membranes from the outside to induce lipid peroxidation in membrane phospholipids (18–23). The chromanol moiety of PCh seems to be located at the interface of the membrane and scavenges aqueous radicals rather than lipophilic radicals efficiently, while α-tocopherol mainly scavenges chain-carrying lipid peroxyl radicals in the hydrophobic region of membranes (13,14). The ability of PCh in scavenging aqueous radicals seems to be of great advantage to suppress their attacks on erythrocyte membranes and resulting in hemolysis.

Enormous amounts, as compared to endogenous α-tocopherol, of α-tocopherol and PCh incorporated into ghost (Table 1) did not result in efficient inhibition of AAPH-induced formation of PL-OOH (Fig. 4) but prevented efficient hemolysis (Fig. 1 and 2). However, it might be possible that the exogenous antioxidant prevents not only lipid peroxidation but also protein oxidation that was also observed in AAPH-induced oxidation of ghost membranes (18,22), resulting in effective prevention of hemolysis (Figs. 1 and 2).

Although PMC was incorporated into erythrocytes to some extent, it was not retained in ghost membrane fraction (Table 1). PMC can not be anchored because of the lack of long chain and may be transferred freely without orientation in the membrane (9,35,36); hence it may penetrate into cytosol easily. No inhibition on the oxidative hemolysis by PMC appears to be due to inability to be retained within the membranes. Niki *et al.* (32) reported that the mobility of PMC was quite high within and between liposomal membranes. Furthermore, they have shown that the antioxidant activity of chromanols was elevated with decreasing length of side chain in the oxidation of plasma low density lipoprotein (36). Thus, PMC, having no long side chain, can transfer easily from erythrocytes to outside of cells, resulting in less effective oxidative hemolysis of human erythrocytes.

The efficiency of antioxidants in the heterogeneous phase is determined by not only their radical-scavenging activity but also their physical properties, such as local concentration and mobility in the microenvironment (36). The present results obtained from antihemolytic activity suggest that the ability both to be incorporated into the cells and to be retained within the membranes should be involved in the factors responsible for the action of antioxidant in biomembranes. It is clear that phosphatidyl moiety makes an antioxidant molecule easier to be inserted into cellular membranes. Phosphatidyl derivatives may be promising compounds in the prevention or cure of cellular oxidative damage-related diseases.

ABSTRACT: We have reported that the peroxyl radicals derived from methyl eicosapentaenoate (20:5n-3) are more polar than those from methyl linoleate (18:2n-6) since the former peroxyl radicals have at least two molecules of oxygen in a molecule while the latter peroxyl radical has one. This lowers the oxidizability for 20:5n-3 in aqueous Triton X-100 micelles by enhancing the termination reaction rate for peroxyl radicals and by reducing the rate of propagation since there may be more polar peroxyl radicals derived from 20:5n-3 at the surface than within the micelle core. In this study, we measured the effect of three antioxidants, di-*tert*-butyl-4-methylphenol (BHT), 2,2,5,7,8-pentamethyl-6-chromanol (PMC) and 2-carboxy-2,5,7,8-tetramethyl-6-chromanol (Trolox), on the oxidation of lipids in aqueous micelle. Antioxidants give a clear induction period during oxidation of 18:2n-6 initiated with a water-soluble radical initiator, and its induction length decreases in the order of BHT > PMC > Trolox. This is consistent with the proposed location of three antioxidants: being in the core of micelle, at the surface, or in aqueous phase, respectively. However, BHT does not inhibit the oxidation of 20:5n-3 efficiently, and its rate of oxidation is slower than that observed in the oxidation of 18:2n-6, supporting the idea that polar peroxyl radicals derived from 20:5n-3 are preferentially located at the surface of the micelle. Similar results were obtained when oxidation was initiated with a lipid-soluble radical initiator except antioxidants had lesser effect on the oxidation rate of 20:5n-3.
Lipids 33, 597–600 (1998).

The oxidizability of polyunsaturated fatty acids in homogeneous solution is known to be dependent on the number of bisallylic positions available for oxidation (1–4). In contrast, the oxidizability of polyunsaturated fatty acids in aqueous micelles is reported to decrease with an increasing number of bisallylic sites (5,6). We have confirmed this interesting observation by comparing the oxidation kinetics of methyl eicosapentaenoate (20:5n-3) and methyl linoleate (18:2n-6) in both homogeneous solution and aqueous micelles (7). It has been suggested that the peroxyl radicals derived from 20:5n-3 are more polar than those from 18:2n-6 since the former peroxyl radicals contain two molecules of absorbed oxygen while the latter peroxyl radicals have one (7). Therefore, we hypothesized that the polar peroxyl radicals derived from 20:5n-3 are likely to diffuse from the core to the micelle surface, and this lowers the oxidizability for 20:5n-3 in aqueous micelles by enhancing the termination reaction rate for polar peroxyl radicals derived from 20:5n-3 and by reducing the rate of propagation since there is less oxidizable 20:5n-3 at the surface than the micelle core.

To obtain additional evidence to support this hypothesis, we have measured the effects of antioxidants on the oxidation of 20:5n-3 and 18:2n-6 in aqueous micelles. We have chosen 2,6-di-*tert*-butyl-4-methylphenol (BHT), 2,2,5,7,8-pentamethyl-6-chromanol (PMC), and carboxy-2,5,7,8-tetramethyl-6-chromanol (Trolox) as antioxidants for comparison since it is reported that BHT preferentially locates in the core of micelle (8,9), PMC resides at the micelle surface (10), and Trolox remains essentially in aqueous phase (11). BHT, PMC, and Trolox can trap two molecules of peroxyl radical per molecule (12), and the rate constants for H-atom abstraction of these antioxidants by peroxyl radicals are 1.4×10^4, 3.8×10^6, and 1.1×10^6 $M^{-1}s^{-1}$, respectively (13), indicating that BHT has the lowest activity as measured in homogeneous solution.

Figure 1 shows the rate of oxygen uptake during oxidation of 2 mM 18:2n-6 (or 20:5n-3) initiated with the water-soluble radical initiator, 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH; 4 mM), in the presence or absence of 5 μM antioxidant (BHT, PMC, or Trolox) in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 under aerobic conditions at 37°C. The micelles were prepared as follows: Appropriate amounts of 18:2n-6 (or 20:5n-3) in benzene (and, if necessary, appropriate amounts of antioxidants and/or lipid-soluble initiator) were placed in a glass flask. The solvent was removed on a water aspirator and then on a vacuum pump fol-

Abbreviations: 18:2n-6, methyl linoleate; 20:5n-3, methyl eicosapentaenoate; AAPH, 2,2′-azobis(2-amidinopropane)dihydrochloride; AMVN, 2,2′-azobis(2,4-dimethylvaleronitrile); BHT, 2,6-di-*tert*-butyl-4-methylphenol; PMC, 2,2,5,7,8-pentamethyl-6-chromanol; Trolox, 2-carboxy-2,5,7,8-tetramethyl-6-chromanol.

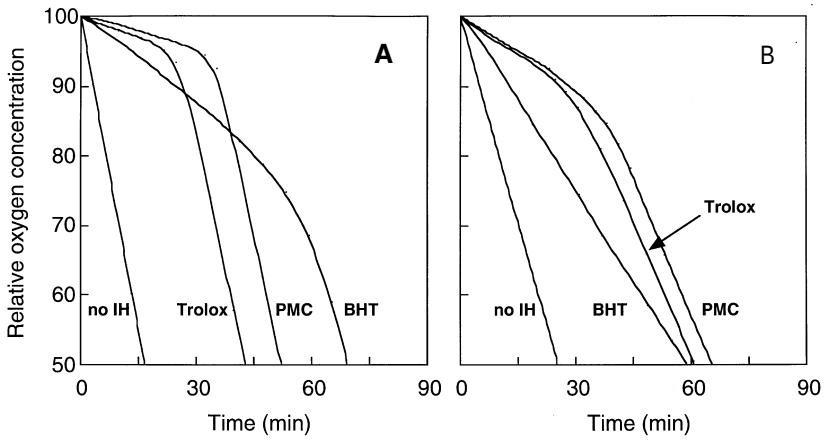

FIG. 1. Aerobic oxidation of 2 mM (A) 18:2n-6 and (B) 20:5n-3 initiated with 4 mM water-soluble 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH) in the absence [no inhibitor (IH)] or presence of 5 μM antioxidants in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 at 37°C. Reproducibility was excellent in at least two independent measurements. PMC, 2,2,5,7,8-pentamethyl-6-chromanol; BHT, 2,6-di-*tert*-butyl-4-methylphenol; Trolox, 2-carboxy-2,5,7,8-tetramethyl-6-chromanol.

lowed by the addition of 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100. If necessary, AAPH was added to the flask. Reaction mixtures were shaken vigorously, were transferred to a reaction vessel, and oxygen concentrations within micellar suspension were monitored using an oxygen electrode.

The rate of oxygen uptake during the oxidation of 18:2n-6 in the absence of antioxidants was greater than that for 20:5n-3 under equivalent conditions (Fig. 1), and this is consistent with our previous observation (7). The addition of antioxidants to 18:2n-6 micelle retarded the rate of oxygen uptake. After the consumption of antioxidant (data not shown), the rate of oxygen uptake was similar to that observed in the absence of antioxidant; the period of inhibited oxidation is called the induction period. It is noteworthy that all antioxidants gave a clear induction period. The length of induction period produced by the addition of test antioxidants decreased in the order of BHT > PMC > Trolox. This order is consistent with the reported preferential location of the three antioxidants, BHT within the micelle core (8,9), PMC at the surface of micelle (10), and Trolox in aqueous phase (11), suggesting that Trolox trapped peroxyl radicals produced by the water-soluble radical initiator while BHT scavenged only peroxyl radicals which migrated into the micelle core. The decay of antioxidants during the induction period was measured using a reversed-phase high-performance liquid chromatograph equipped with an electrochemical detector. The results are summarized in Figure 2 where 2

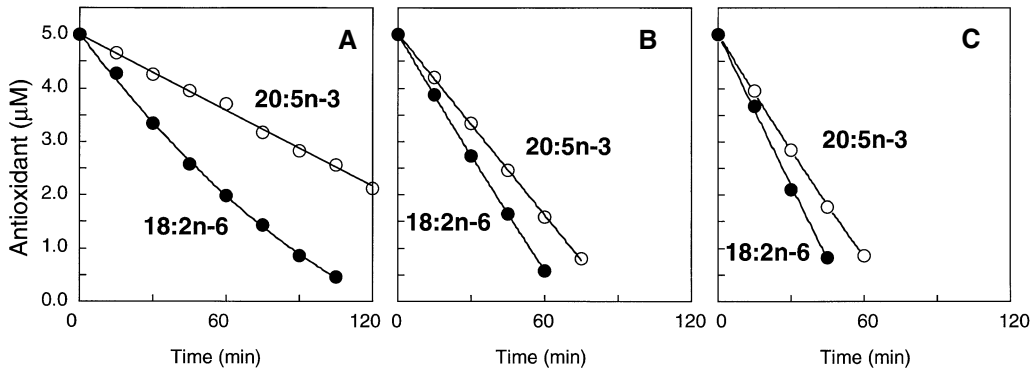

FIG. 2. Consumption of antioxidants during the aerobic oxidation of 2 mM 18:2n-6 (●) or 20:5n-3 (○) initiated with 2 mM water-soluble AAPH in the presence or absence of 5 μM antioxidants in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 at 37°C. (A) BHT and (B) PMC were measured by a reversed-phase high-performance liquid chromatograph equipped with an electrochemical detector (700 mV) using an octylsilyl column (5 μm, 4.6 × 150 mm; Wako, Osaka, Japan) with 50 mM $NaClO_4$ in methanol/water (4:1, vol/vol) as the mobile phase (0.8 mL/min). (C) Trolox was measured in the same system except using 50 mM $NaClO_4$ in methanol/water (1:1, vol/vol) as the mobile phase. Reproducibility was excellent in at least two independent measurements. See Figure 1 for abbreviations.

mM AAPH was used instead of 4 mM in Figure 1 to retard the relative consumption of antioxidants. The rate of disappearance of antioxidants during the oxidation of 18:2n-6 in aqueous micelle decreased in the order of BHT > PMC > Trolox. This again is consistent with the presumed distribution of antioxidants within micelles.

On the other hand, BHT did little to inhibit the oxidation of 20:5n-3 in aqueous micelles while Trolox and PMC were more efficient (Fig. 1). Thus, as expected, the rate of disappearance of BHT during the oxidation of 20:5n-3 was much smaller than that observed for 18:2n-6 oxidation. These results strongly suggest that polar peroxyl radicals derived from 20:5n-3 are not located within the micelle core where BHT resides, but rather are at the surface of the micelle which was suggested in a previous kinetic study (7).

It is important to demonstrate that the three antioxidants used in this study were of good quality. Table 1 gives the kinetic parameters of the three antioxidants measured during aerobic oxidation of 150 mM 18:2n-6 in acetonitrile initiated with 2 mM 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN), a lipid-soluble radical initiator, in the presence or absence of 20 μM antioxidants at 37°C; the induction period; the rate of oxidation during induction period; and rate of propagation measured as the rate of oxidation after the complete consumption of antioxidants. BHT, PMC, Trolox, and α-tocopherol gave essentially the same induction period as previously reported (12). Values for rate of propagation were nearly equivalent under the experimental conditions, indicating an absence of contamination. Values for rate of oxidation during induction period for PMC, Trolox, and α-tocopherol were similar and about 20 times less than that for BHT as was previously observed (13).

Figure 3 shows the rate of oxygen uptake during the aerobic oxidation of 2 mM 18:2n-6 and 20:5n-3 initiated with 2 mM AMVN, a lipid-soluble radical initiator, in the presence or absence of 2 μM antioxidant (BHT, PMC, or Trolox) in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 at 37°C. The rate of oxygen uptake during oxidation of 18:2n-6 in the absence of antioxidant was much faster than that for 20:5n-3 at similar conditions, which is consistent with our previous data (7). BHT within the micelle core inhibited the oxidation of 18:2n-6 in aqueous micelles initiated with the lipid-soluble radical initiator but it did not efficiently suppress the oxidation of 20:5n-3 in aqueous micelles. As a consequence, the rate of BHT consumption observed in 18:2n-6 oxidation was much greater than that observed in 20:5n-3 oxidation as shown in Figure 4, where 4 μM antioxidants are used instead of 2 μM in Figure 3 to retard the relative consumption of antioxidants. In contrast, PMC located at the surface of the micelle inhibited oxidation of both 18:2n-3 and 20:5n-3 in aqueous micelles and gave a clear induction period although the inhibition of 20:5n-3 oxidation was less

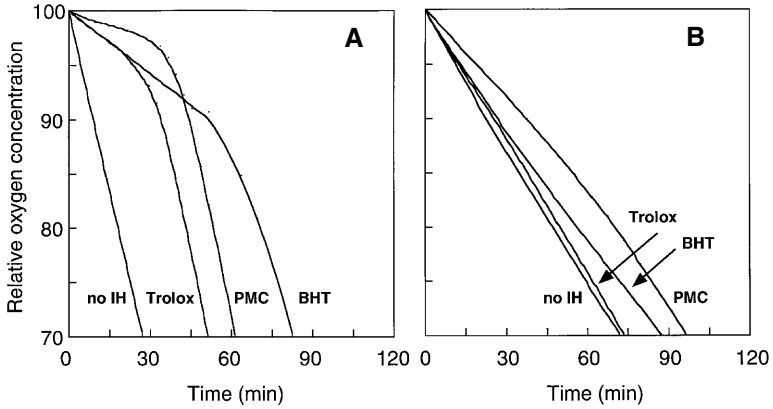

FIG. 3. Aerobic oxidation of 2 mM (A) 18:2n-6 and (B) 20:5n-3 initiated with 2 mM lipid-soluble 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) in the absence (no IH) or presence of 2 μM antioxidants in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 at 37°C. Reproducibility was excellent in at least two independent measurements. See Figure 1 for abbreviations.

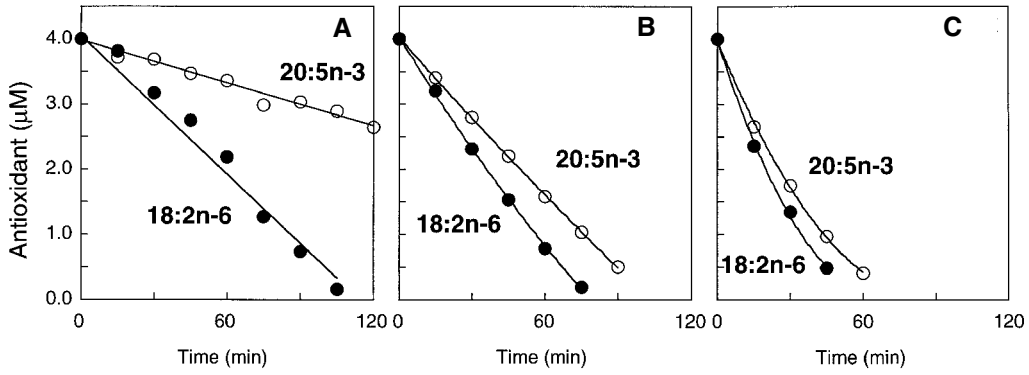

FIG. 4. Consumption of antioxidants during the aerobic oxidation of 2 mM 18:2n-6 (●) or 20:5n-3 (○) initiated with 2 mM lipid-soluble AMVN in the presence or absence of 4 μM antioxidants in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 at 37°C. Antioxidants were measured as described in Figure 3. Reproducibility was excellent in at least two independent measurements. See Figure 2 for abbreviation.

clear. These results again support the view that polar peroxyl radicals formed from 20:5n-3 should relocate to the surface of the micelle rather than stay within the micelle core.

It is interesting that Trolox was consumed at a greater rate than was BHT (Fig. 4) despite that AMVN is expected to be located in the micelle. The peroxyl radicals produced from AMVN are low molecular weight compounds containing two polar function groups, cyano and peroxyl groups. Therefore, they are likely to be polar enough to migrate to the aqueous interface where Trolox is active.

In summary, we have demonstrated that the polar peroxyl radicals derived from 20:5n-3 should be located at the surface of the micelle by comparing the effects of three different antioxidants which have different site reactivities in aqueous micelles. Migration of the polar peroxyl radicals derived from 20:5n-3 to the surface of the micelle should lower the oxidizability for 20:5n-3 by enhancing the termination reaction rate for polar peroxyl radicals and by reducing the rate of propagation since there is less oxidizable 20:5n-3 at the surface than in the micelle core.

ACKNOWLEDGMENTS

We thank Dr. W.C. Dunlap for his valuable comments and Eisai Co. for the supply of PMC and α-tocopherol. This work was supported by Grants-in-Aid for Scientific Research from the Ministries of Education, Science and Culture, and Health and Welfare of Japan.

Partial Purification and Characterization of Sphingosine *N*-Acyltransferase (ceramide synthase) from Bovine Liver Mitochondrion-Rich Fraction

Hiroshi Shimeno*, Shinji Soeda, Masahiko Sakamoto, Takeshi Kouchi, Takashi Kowakame, and Taro Kihara

Department of Biochemistry, Faculty of Pharmaceutical Sciences, Fukuoka University, Fukuoka 814-0180, Japan

ABSTRACT: Sphingosine *N*-acyltransferase (ceramide synthase, E.C. 2.3.1.24) was solubilized from bovine liver mitochondrion-rich fraction with *n*-octyl β-D-thioglucoside as the detergent and partially purified by sequential chromatography on columns of DE-32, shingosine affinity, and Sepharose CL-6B. The partially purified preparation migrated on SDS-polyacrylamide gel electrophoresis as two major protein bands of 62 and 72 kDa. The molecular mass of the enzyme estimated by gel filtration was 240–260 kDa, suggesting that the partially purified enzyme is present in a subunit form or simply has an aggregative nature. The specific activity of the final preparation for the condensation of sphingosine with stearoyl-CoA increased by 98.7-fold compared with the starting material. The optimal pH value for the ceramide synthesis was 7.5. The partially purified enzyme had an apparent K_m of 146 μM and a V_{max} of 11.1 nmol/min/mg protein for stearoyl-CoA. The K_m and V_{max} values toward sphingosine were 171 μM and 11.3 nmol/min/mg protein, respectively. Interestingly, sphinganine was also a good substrate for this enzyme, and the K_m and V_{max} values were 144 μM and 8.5 nmol/min/mg protein, respectively.

Lipids 33, 601–605 (1998).

Ceramide biosynthesis begins by the formation of sphinganine (dihydrosphingosine) from serine and palmitoyl-CoA. Addition of a fatty acyl chain to sphinganine yields dihydroceramide, which appears to precede the introduction of the 4,5-*trans*-double bond of sphingosine. These steps have been shown to take place at the cytosolic surfaces of the endoplasmic reticulum (1,2). However, there is also evidence for ceramide biosynthesis by the direct condensation of sphingosine with fatty acyl-CoA. This system has been studied with microsomes from rodent brain and liver (3–5). One of the important unresolved issues in ceramide synthesis therefore concerns whether the sphingosine and sphinganine *N*-acyltransferases both are identical and located only in microsomes. Another pathway involves the condensation of sphingosine with free fatty acid catalyzed by the reverse reaction of the lysosomal ceramidase that hydrolyzes ceramide to sphingosine and free fatty acid (6,7). Thus, the enzymic mechanism for ceramide synthesis is still poorly understood, largely because of the resistance to solubilization and the labile enzyme activity.

We became interested in the ceramide synthase activity in the mitochondrial fraction, because the enzyme activity was enriched in the mitochondria of mouse brain (4). Our recent study (8) confirmed that the specific activity (2.6 ± 0.18 U/mg protein) of mitochondrial fraction from bovine brain was 1.6 times that of the microsomal fraction. Here we report the partial purification and characterization of a sphingosine *N*-acyltransferase from bovine liver mitochondrial fraction. This study suggests that the sphingosine *N*-acyltransferase also catalyzes *N*-acylation of sphinganine and participates in ceramide synthesis in this organelle.

MATERIALS AND METHODS

Materials. The following materials were commercially obtained: D-sphingosine, DL-erythro-dihydrosphingosine (sphinganine), fatty acyl-CoA, aprotinin, 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate (CHAPS), and concanavalin A (Con A) from Sigma Chemical Co. (St. Louis, MO); leupeptin and antipain from Peptide Institute (Osaka, Japan); *n*-octyl β-D-thioglucoside (OTG), phenylmethanesulfonyl fluoride (PMSF), 3,3′-diaminobenzidine tetrahydrochloride, Triton X-100, horseradish peroxidase, and celite from Wako Pure Chemical Co. (Osaka, Japan); DE-32 from Whatman (Maidstone, England); and Sepharose CL-6B from Pharmacia Biotech (Uppsala, Sweden).

Preparation of sphingosine-coated celite. Sphingosine affinity column material was prepared according to the method of Boulanger *et al.* (9). Briefly, 20 mg of sphingosine in 20 mL chloroform was mixed with 10 g dried celite, and the solvent was evaporated at 37°C under a nitrogen stream. The lipid matrix was treated with 10 vol 100 mM Tris-HCl buffer (pH 7.4)/1% glycine at room temperature overnight. The sphingosine celite was washed with cold buffer B prior to use as the column material.

Subcellular fractionation. Fresh bovine liver was obtained from a local slaughterhouse and immediately rinsed with cold

Abbreviations: CHAPS, 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate; Con A, concanavalin A; OTG, *n*-octyl β-D-thioglucoside; PMSF, phenylmethanesulfonyl fluoride.

saline. The tissue (1 kg) was cut into pieces and homogenized in 5 vol 20 mM Tris-HCl buffer (pH 7.4)/0.15 M NaCl/0.25 M sucrose (buffer A). After centrifugation at 1,000 × *g* for 10 min, the precipitate was removed, and the supernatant was centrifuged at 5,000 × *g* for 20 min. The precipitate was suspended with 5 vol buffer A, and the suspension was centrifuged again at 5,500 × *g* for 15 min. The resulting precipitate was collected and used as the mitochondrial fraction.

Solubilization and purification of ceramide synthase. All steps were performed at 4°C. (i) Solubilization of ceramide synthase: the mitochondrial pellet was suspended in 10 vol of buffer A containing 2 μg/mL antipain, 20 μg/mL aprotinin, 5 μg/mL leupeptin, 2 mM EDTA, 2 mM PMSF, and 50 mM OTG. The suspension was stirred for 2 h and then centrifuged at 10,000 × *g* for 45 min. To the precipitate was added 5 vol the same buffer, and the suspension was stirred for 1 h and centrifuged. These supernatants were combined and dialyzed against 20 mM Tris-HCl buffer (pH 7.8) for 16 h. (ii) DE-32 chromatography: the dialysate was applied to a column (5 × 20 cm) of DE-32, preequilibrated with 20 mM Tris-HCl buffer (pH 7.8). The proteins were eluted with a linear gradient of NaCl in the Tris buffer from 0 to 1.25 M at a flow rate of 42 mL/h (fraction volume, 9 mL/tube). The active fractions (tube No. 80-115) were collected and concentrated on a PM-10 membrane (Amicon Co., Beverly, MA). The concentrate was dialyzed against 20 mM Tris-HCl buffer (pH 7.4)/0.15 M NaCl (buffer B) for 16 h. (iii) Sphingosine affinity column chromatography: the dialysate was applied to a column of sphingosine-coated celite (1.6 × 10 cm), preequilibrated with buffer B. After washing the column with buffer B, the adsorbed proteins were eluted with a linear gradient of KI in buffer B from 0 to 1.5 M at a flow rate of 18 mL/h (fraction volume, 2 mL/tube). The highest enzyme activity was eluted at 0.45 M KI. The active fractions (tube No. 16-20) were collected and concentrated on a PM-10 membrane. The concentrate was dialyzed against buffer B for 16 h. (iv) Gel filtration on Sepharose CL-6B: the dialysate was applied to a column (1.6 × 40 cm) of Sepharose CL-6B, preequilibrated with buffer B containing 1 mM OTG/10% glycerol. The proteins were eluted with the same buffer at a flow rate of 13 mL/h (fraction volume, 2 mL/tube). The active fractions were collected and enzymatically characterized.

Assay of ceramide synthase. Ceramide synthase activity was determined as described previously (8). Briefly, D-sphingosine (800 nmol) in 100 μL of 20 mM Tris-HCl buffer (pH 7.4)/0.1% Tween 20 and stearoyl CoA (400 nmol) in 100 μL of 20 mM Tris-HCl buffer (pH 7.4) were placed in a 12 × 100 mm screw-cap test tube. The suspension was further diluted with the Tris buffer to a final volume of 450 μL. The enzyme reaction was started by adding 200 μL of enzyme solution plus 100 μL of liposome suspension (170–200 μg lipids). The liposomes were prepared by using the lipids derived from the mitochondrial membrane. The addition of liposome preparation increased the specific activity of solubilized ceramide synthase by 2.3-fold (8). After incubation at 37°C for 90 min, the enzyme reaction was terminated by adding 3 mL of chloroform/methanol (2:1, vol/vol). The mixture was shaken and centrifuged. A 2-mL portion of the lower layer was withdrawn and mixed with chloroform/methanol (2:1, vol/vol) and 10% (wt/vol) ammonium sulfate (1 mL each). The mixture was shaken and centrifuged. The lower layer was withdrawn and evaporated to dryness. The dried sample was allowed to react at 65°C for 15 min with benzoyl chloride and pyridine. The benzoylated ceramide was detected by high-performance liquid chromatography on a silica column with 10% 2-propanol in *n*-hexane as mobile phase.

Determination of protein. Protein concentration was determined by the method of Lowry *et al*. (10), using bovine serum albumin as reference.

Gel electrophoresis and sugar chain staining. Samples were analyzed by electrophoresis on a 12% SDS-polyacrylamide gel under unreducing conditions (11). The separated proteins were stained with Coomassie Brilliant Blue R. For the sugar chain staining (12), proteins were transferred from the gel to a nitrocellulose membrane, using a semidry electroblot system (Sartoblot; Sartorius Co., Göttingen, Germany). The membrane was incubated at 25°C for 10 min with 2% bovine serum albumin in 50 mM Tris-HCl buffer (pH 7.4)/0.2 M NaCl and subsequently for 30 min with 50 μg/mL Con A in the Tris buffer. After washing, the membrane was further incubated for 30 min with 50 μg/mL peroxidase in the Tris buffer. After washing, peroxidase reaction was carried out at 25°C with 0.06% 3,3′-diaminobenzidine tetrahydrochloride and 0.01% H_2O_2 in the Tris buffer.

Enzyme unit. One unit (U) was defined as the amount of enzyme which forms 1 nmol of stearoylsphingosine per min at 37°C.

RESULTS AND DISCUSSION

Solubilization of enzyme activity. Prior to purification experiments, we examined the effects of various detergents on the solubilization of ceramide synthase activity from the mitochondrial fraction (Fig. 1). Although Triton X-100 most effectively solubilized the mitochondrial proteins, it inhibited the enzyme activity in a concentration-dependent manner. CHAPS was at least a better detergent than Triton X-100 for solubilization of the mitochondrial proteins. However, the solubilized enzyme activity was very low (0.03 U/mg protein at 50 mM CHAPS). OTG was able to solubilize ceramide synthase (0.15 U/mg protein at 50 mM OTG) without solubilization of a large bulk of the mitochondrial proteins. Evidence in endoplasmic reticulum suggests that ceramide synthesis occurs on the cytoplasmic face (12). OTG might solubilize effectively the ceramide synthase that associates weakly with the outer side of the membranes. From these results, we used 50 mM OTG upon the solubilization of ceramide synthase. The buffered detergent also contained the following protease inhibitors: antipain, aprotinin, leupeptin, EDTA, and PMSF. As shown in Figure 2, these protease inhibitors greatly effected the stability of solubilized enzyme activity.

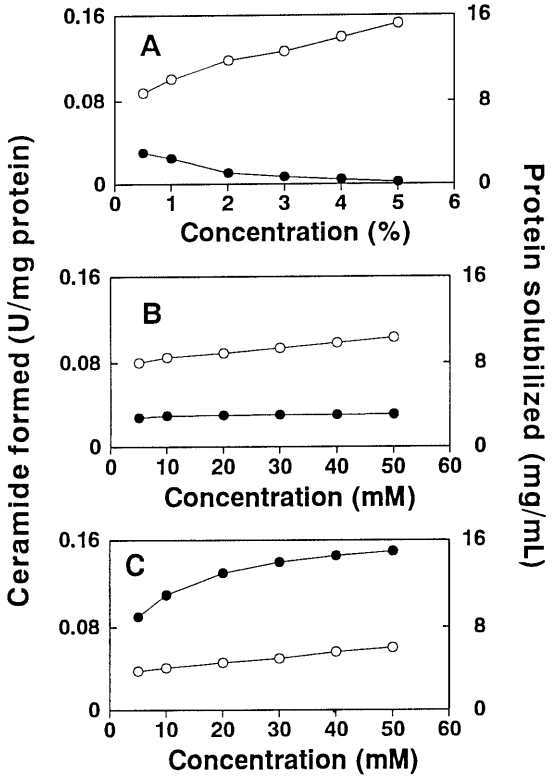

FIG. 1. Effects of various detergents on the solubilization of ceramide synthase activity from bovine liver mitochondria. Mitochondrial pellet was suspended in 10 vol buffer containing various concentrations of (A) Triton X-100, (B) CHAPS, or (C) OTG. The suspension was stirred at 4°C for 2 h, and then centrifuged at 10,000 × *g* for 45 min. The protein concentration (○) and ceramide synthase activity (●) were determined as described in the Materials and Methods section. The data represent the mean of duplicate experiments.

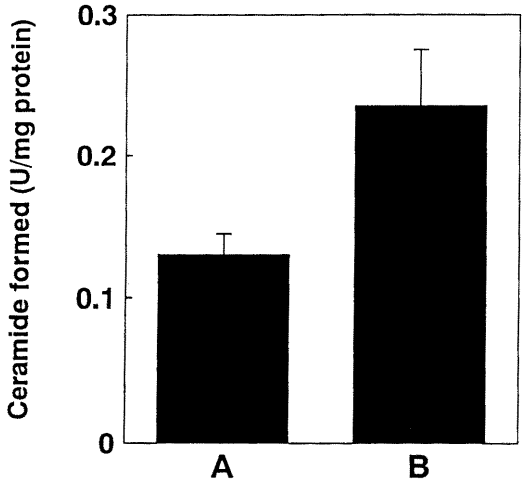

FIG. 2. Effects of protease inhibitors on the stability of the ceramide synthase activity solubilized from the mitochondrial pellet. Ceramide synthase was solubilized with (A) buffered *n*-octyl β-D-thioglucoside (OTG) alone (A) or (B) buffered OTG containing antipain, aprotinin, leupeptin, EDTA, and phenylmethanesulfonyl fluoride. After centrifugation, the enzyme activity was determined as described in the Materials and Methods section. Each bar represents the mean ± SD of triplicate experiments.

Enzyme purification. Table 1 summarizes the results of a typical purification of ceramide synthase from bovine liver mitochondrion-rich fraction. Buffered OTG containing the protease inhibitors solubilized the enzyme activity with yield of 82.7%. The OTG extract was next applied to a DE-32 column. At this stage, the enzyme was purified 10.5-fold from the starting mitochondria with yield of 67.4%. The enzyme fraction was subsequently bound to a sphingosine-celite column and eluted by increasing KI gradient from 0 to 1.5 M (Fig. 3). The eluate exhibited a 75.3-fold increase in the specific activity. The column was able to be used several times for the purification of this enzyme. Gel filtration on Sepharose CL-6B yielded two peaks of ceramide synthase activity (Fig. 4). One minor activity appeared as the initial pass-through fraction, while the other major activity was estimated in fractions having the molecular masses of 240–260 kDa. The latter active fraction was collected and concentrated. The final enzyme preparation did not contain the affinity column material, celite, and had a specific activity of 14.8 U/mg protein and a 98.7-fold purification. The low purification factor

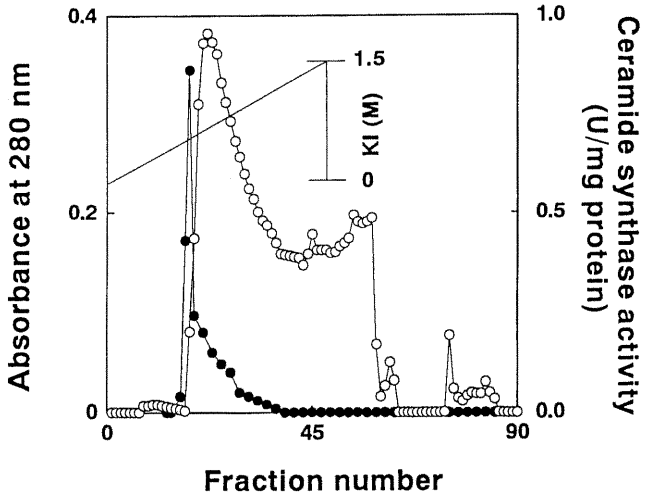

FIG. 3. Sphingosine affinity column chromatography. Column procedures were as described in the Materials and Methods section. ○, absorbance at 280 nm; ●, enzyme activity.

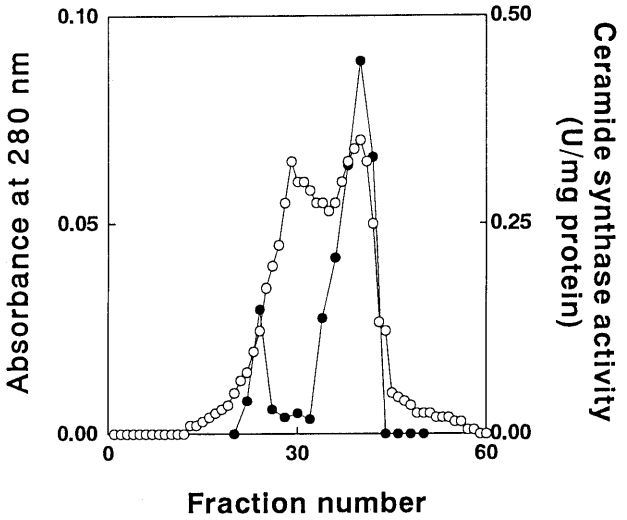

FIG. 4. Sepharose CL-6B chromatography. Column procedures were as described in the Materials and Methods section. ○, absorbance at 280 nm; ●, enzyme activity.

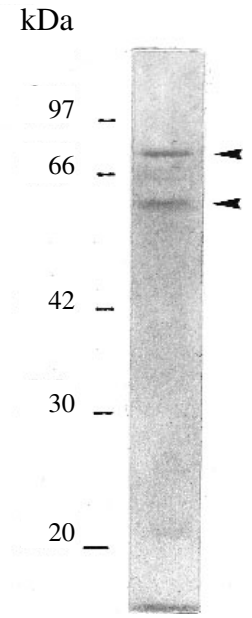

FIG. 5. Molecular mass determination of the purified enzyme on SDS-polyacrylamide gel electrophoresis. About 5 μg of the final preparation was applied on a 12% gel as described in the Materials and Methods section. Molecular mass markers: 97 kDa, phosphorylase b; 66 kDa, bovine serum albumin; 42 kDa, aldolase; 30 kDa, carbonic anhydrase; and 20 kDa, soybean trypsin inhibitor.

may be partly caused by the labile enzyme activity. Although the ceramide synthase activity was higher in the presence of liposomes, we failed to keep the enzyme activity stable at low temperatures. An additional method is needed for stabilizing the enzyme activity.

Physicochemical properties of the partially purified enzyme. Analysis of the enzyme preparation on 12% SDS-polyacrylamide gel electrophoresis under unreducing conditions revealed two major protein bands of 62 kDa and 72 kDa (Fig. 5). To assess whether these proteins have oligosaccharide chains, they were transferred to a nitrocellulose sheet and detected by the Con A-peroxidase method (12). The two protein bands were bound to Con A and stained by peroxidase reaction. A minor band of 69 kDa was also observed (data not shown). The different molecular mass of this enzyme, determined on gel filtration (Fig. 4) and on SDS-polyacrylamide gel electrophoresis (Fig. 5), suggests that the ceramide synthase was present in the buffer solution as a subunit form, or simply in aggregated form with these proteins. Such a high-molecular-weight nature of the enzyme has been observed in gel filtration of the preparation solubilized from rat liver microsomes (5).

Substrate specificity and other enzymic properties of the partially purified enzyme. The influence of pH on the ceramide synthase activity was examined, using sphingosine and stearoyl-Co A as substrates. As shown in Figure 6, the enzyme activity was maximal at pH 7.5: more than 70% of the maximal activity was obtained over the pH range 7.0–8.0. Substrate specificity of the partially purified enzyme was also determined with various acyl (C_6–C_{22})-CoA and sphingosine or with stearoyl-CoA and sphinganine as substrates (Table 2). CoA esters having regular chain (C_{16}–C_{18}) were good substrates. Very long chain (C_{22}) or short chain (C_6–C_{12}) decreased the function as substrate. The observed substrate specificity is adequate, when considering the majority of stearoyl- and palmitoyl-chains in naturally occurring ceramides. The partially purified enzyme could form dihydroceramide with stearoyl-CoA and sphinganine as substrates. The K_m values determined for sphingosine and sphinganine were almost identical (171 and 144 μM). However, when the latter substrate was utilized, the putative dihydroceramide dehydrogenase present in the mitochondria still awaits definitive enzymological characterization. There is also some evidence for ceramide synthesis by reversal of ceramidase (6,7). The partially purified enzyme had no ceramidase activity at pH 4.5,

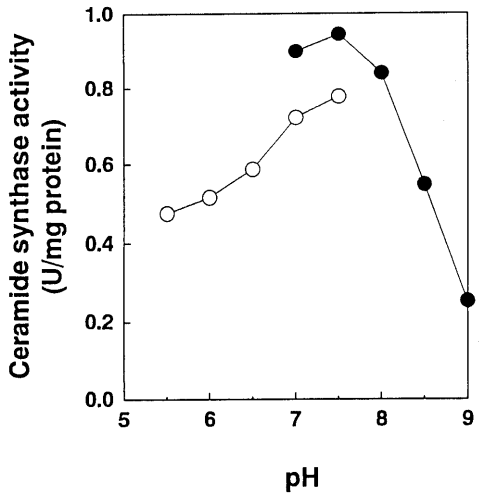

FIG. 6. Effect of pH on the purified enzyme activity. Enzyme activity was determined using stearoyl-CoA and sphingosine as substrates. Buffers used: ○, phosphate buffer; ●, Tris-HCl buffer. The data represent the mean of duplicate experiments.

TABLE 2
Substrate Specificity of the Purified Ceramide Synthase[a]

Substrate	Kinetic parameter		
	K_m (μM)	V_{max} (U)	V_{max}/K_m
Sphingosine (500 μM) plus			
Hexanoyl-Co A [$C_{6:0}$]	522	1.88	0.0036
Lauroyl-Co A [$C_{12:0}$]	358	1.75	0.0049
Palmitoyl-Co A [$C_{16:0}$]	141	7.68	0.0545
Stearoyl-Co A [$C_{18:0}$]	146	11.11	0.0761
Behenoyl-Co A [$C_{22:0}$]	299	2.53	0.0085
Oleoyl-Co A [$C_{18:1}$]	180	7.25	0.0403
Stearoyl-Co A (500 μM) plus			
Sphingosine	171	11.33	0.0663
Sphinganine	144	8.54	0.0593

[a]Enzyme activity was determined as described in the Materials and Methods section, using various concentrations (10–800 μM) of substrates. Kinetic parameters were obtained from Lineweaver-Burk plot analyses. K_m and V_{max} were calculated from the plot *x* and *y* intercepts, respectively. The data represent the mean of duplicate experiments.

when examined using stearoylsphingosine as substrate (data not shown). Thus, the partially purified enzyme may participate in the mitochondrial ceramide (dihydroceramide) synthesis. To better understand the mechanism of ceramide synthesis, purification of the mitochondrial enzyme to a homogeneous state and also the purification of ceramide synthase from the microsomal fraction are needed.

The next step following ceramide formation is the biosynthesis of sphingomyelin (13) or glucosylceramide (14) in Golgi compartments. The transportation mechanism of ceramide is not known at present. Saposin D is a candidate for the ceramide-transporting protein, because of its ability to form a complex with ceramide (15). However, saposins A–D are mainly localized in lysosomes and activate the degradation of several sphingolipids by acid hydrolases (for review, see Refs. 16 and 17). Recently, we purified a ceramide-binding protein from bovine brain cytosol fraction, whose N-terminal amino acid sequence was completely different from those of saposins A–D (Kihara, T., Soeda, S., and Shimeno, H., unpublished work). If the novel binding protein present in cytosol acts as a ceramide transporter, the pathway that ceramide is directly synthesized from sphingosine and acyl-CoA on the mitochondrial compartments and followed by the transportation to another compartment to form glycosphingolipids or to function as a lipid mediator of signal transduction (18,19) will be acceptable. We are currently examining the physiological function of the ceramide-binding protein.

N-Stearoyl-phosphatidylserine: Synthesis and Role in Divalent-cation-induced Aggregation and Fusion

Margarita Morillo, M. Luisa Sagristá*, and M. Africa de Madariaga

Department of Biochemistry and Molecular Biology, Faculty of Chemistry, University of Barcelona, 08028 Barcelona, Spain

ABSTRACT: *N*-Acylphosphatidylserines have been isolated from intact and injured tissues, but the participation of such acidic phospholipids in membrane aggregation and fusion has not been demonstrated. We have synthesized *N*-stearoylphosphatidylserine (NSPS) and examined divalent-cation-induced aggregation of NSPS-liposomes, which leads to membrane destabilization and fusion. The purified lipid was characterized by its chromatographic and spectroscopic (infrared and ^{1}H nuclear magnetic resonance) properties and by its chemical degradation pattern. Aggregation of unilamellar NSPS-liposomes was studied as a function of calcium and magnesium concentration. The ability of calcium and magnesium to induce vesicle aggregation is higher for phosphatidylserine (PS)-liposomes (threshold concentration 1.5 mM for calcium and 4.6 mM for magnesium) than for NSPS-liposomes (threshold concentration 2.8 mM for calcium and 6.6 mM for magnesium). The irreversibility of the aggregation reactions after adding EDTA suggests that vesicle fusion might occur in the presence of calcium and magnesium. Preliminary studies, based on mixing of both lipid and internal aqueous contents, show that fusion rather than aggregation of NSPS-liposomes occurs in the presence of calcium ions. The tendency of NSPS-liposomes to aggregate at higher cation concentrations than PS-liposomes suggests that *N*-acylation of phosphatidylserine protects the membrane against degenerative damage caused by aggregation and fusion.
Lipids 33, 607–616 (1998).

Amide-linked fatty acids occur in nature mainly in sphingolipids as part of their ceramide (*N*-acylsphingosine) backbone. In contrast, the primary amino groups of glycerophospholipids, such as phosphatidylethanolamine (PE) and phosphatidylserine (PS), are not usually *N*-acylated. Nevertheless, *N*-acylphosphatidylethanolamines (NAPE) were originally detected in wheat flour (1), and the occurrence of these phospholipids as natural constituents is now well established. Their presence has been demonstrated in microorganisms (2–4), in cotyledons of cottonseeds (5), in higher plants (6,7), in fish brain and spinal cord (8), in the granular cells from pig epidermis (9), in dog brain (10), in bovine erythrocytes (11), in degenerating baby hamster kidney cells (12), in infarcted canine myocardium (13), and in ischemic brain of immature rats after decapitation (14). Moreover, *N*-acylphosphatidylserines (NAPS) have been identified in sheep erythrocytes (15), in the central nervous system of freshwater fish (8), and in bovine brain (16). It has also been reported that NAPS accumulate in the bacterium *Rhodopseudomonas sphaeroides* when it is grown in 20 mM Tris (17–19), but Schmid *et al*. (20) established the identity of this lipid as phosphatidyl-Tris rather than NAPS.

Both NAPE and NAPS are negatively charged lipids with one more hydrophobic chain than the more common glycerophospholipids. *N*-Acyl phospholipids are found only in measurable amounts in mammalian tissues in normal physiological conditions. However, they can accumulate under conditions of degenerative change involving disintegration or digestion of membranes, although their natural occurrence never surpasses 20% of the total phospholipid content. This can occur as the result of normal metabolism, e.g., as in the granular cells of the epidermis (12,21) and, possibly, in certain populations of erythrocytes (22) or as the result of ischemic injury (8,16), infarction (13), cancer (23), or other pathological conditions (22). Since *N*-acyl derivatives may appear only after cell death, when degenerative changes begin (14), they may be detected only in small amounts, if at all, in healthy cells. Nevertheless, in some pathological conditions there are measurable amounts of such derivatives before death.

More recently, Hansen *et al*. (24,25) have shown the dose-dependent glutamate-induced formation of NAPE and *N*-acyl-ethanolamines (NAE) mediated by the *N*-methyl-D-aspartate receptor in primary cultures of mouse neocortical neurons. Because primary cultures of cerebral cortical neurons provide a sensitive and well-characterized *in vitro* model for investigation of the excitotoxic action of amino acids such as glutamate, the authors suggest that NAPE and NAE are formed during neuronal death, that these compounds may be a defense mechanism after the exposure of the neurons to glutamate, and that these compounds may be used as markers of neurotoxicity. Furthermore, the formation of NAE by injured neurons may induce apoptosis in neigh-

boring neurons, which reduces the impact of a local neuronal injury within the brain.

Different biological properties have been attributed to NAPE, to NAPS, and to their alkylacyl analogs. The effect of the two *N*-acylated phospholipids on the activity of delipidated and solubilized lysosomal glucocerebrosidase, a lipid-requiring enzyme, is opposite (26,27). NAPE was reported (22) to lower serum triacylglycerols in rats made hyperlipidemic through oral administration of Triton WR-1339. 1-Alkyl-2-acyl-glycerophospho(*N*-acyl)PE show antineoplastic activity (28). 1-Alkyl- and 1-acyl-2-acetyl-glycerophospho(*N*-acetyl)PE act as inhibitors of the platelet-activating factor (1-alkyl-2-acetyl-glycerophosphocholine) (22).

It has been postulated that NAPE protect the membrane by stabilizing the lipid bilayer and by maintaining cell compartmentalization following tissue damage (22). This premise is based on data from animal systems that demonstrate the accumulation of NAPE only in degenerative conditions (13,14) and from biophysical studies of aqueous dispersions of NAPE, which indicate that these lipids stabilize a bilayer conformation where nonlamellar phases would otherwise be favored (22,29,30). Nevertheless, we have also established the influence of NAPE on the fusion properties of phospholipidic vesicles used as models of biomembranes (31).

Although *N*-acylation converts nonbilayer unsaturated PE into a bilayer lipid, the addition of Ca^{2+} can reverse the bilayer-stabilizing effect. Thus, NAPE may be involved in membrane fusion, induced by Ca^{2+}, responsible for the disruption of the sarcolemma. This hypothesis is corroborated by the following findings: (i) the discovery of a calcium-dependent acyl-transferase in membrane cells (32,33), (ii) the presence of *N*-acylated glycerophospholipids in heart cells after myocardial infarct (13), and (iii) the proposal by Post and co-workers (34,35) that cellular degradation in myocardial infarct could be the result of an increase in intracellular Ca^{2+} due to ischemia.

Even though NAPSs have been isolated from natural sources and prepared *via* semisynthetic procedures, there are no published data on the participation of such acidic phospholipids in membrane processes like permeability and fusion. The present paper deals with the synthesis and characterization of the *N*-stearoyl derivative of PS (NSPS) and examines the calcium- and magnesium-induced aggregation of NSPS-liposomes, which leads to fusion. Our results suggest that *N*-acylation of PS protects the membrane against damage by aggregation and fusion, since it eliminates the free fatty acids that destabilize membrane structure and since NSPS-liposomes have been found to aggregate at higher cation concentrations than PS-liposomes.

MATERIALS AND METHODS

Chemicals. Egg lecithin (65%; Merck A.G., Darmstadt, Germany) for synthesis was purified by aluminum oxide column chromatography and thin-layer chromatography (TLC) before use. L-Serine and stearoyl chloride, used in the synthesis of PS and NAPS respectively, and dipalmitoyl PS, used as standard for analytical TLC, were purchased from Sigma Chemical Co. (St. Louis, MO). The fluorophore-labeled phospholipids, *N*-(7-nitro-2,1,3-benzoxadiazol-4-yl)-PE (NBD-PE) and *N*-(lissamine Rhodamine B sulfonyl)-PE (Rh-PE) were obtained from Avanti Polar Lipids (Birmingham, AL). $TbCl_3 \cdot 6H_2O$ and dipicolinic acid (DPA), used in the mixing assay for the aqueous content, were from Ventron (Seymour, Stockport, England) and Sigma, respectively. All other reagents were of analytical grade. Water was twice-distilled (Millipore systems), and all organic solvents were redistilled before use.

Preswollen CM-cellulose (CM 52, sodium form; Whatman, Maidstone, England), used to purify PS, was suspended in methanol and decanted several times to remove small fibers before use. Columns were packed as described by Rouser (36) for DEAE-cellulose, and were provided with a glass wool plug and some glass beads on top of the bed in order to avoid disturbance of the adsorbent during solvent changes. Before applying the lipids, methanol was removed by eluting with 3 bed volumes of chloroform/methanol (1:1, vol/vol) and 7 bed volumes of chloroform. The lipid was applied to the column dissolved in chloroform (≤50 mg lipid/mL) with a maximal amount of 5 mg lipid/mL of bed volume. The column was eluted with 3, 20, 3, 3, and 9 bed volumes of chloroform/methanol (vol/vol) 1:0, 4:1, 7:3, 3:2, and 1:1, respectively. The flow rate was 0.48 mL/min. The column was reused after washing with 10, 3, and 7 bed volumes of methanol, chloroform/methanol (1:1, vol/vol) and chloroform, respectively.

Analytical TLC was performed on layers of silica gel G (Sil G-25) purchased from Macherey-Nagel Düren (Düren, Germany). Preparative TLC was carried out on 1-mm thick layers prepared with silica gel H obtained from Merck (TLC-Kieselgel 60H, 15 μm). Samples were made visible with iodine, by spraying with ninhydrin or ammonium molybdate in H_2SO_4 or by charring.

Enzymes. Streptomyces species phospholipase D (E.C. 3.1.4.4.) Class VII was purchased from Sigma.

Synthesis of PS. PS was obtained by PC transphosphatidylation with *Streptomyces* sp. phospholipase D (37) in the presence of L-serine. Peroxide-free diethyl ether (4.32 mL) was added to 100 mg of dry PC and the mixture was sonicated (50 W for 1 min). Enzyme (70.3 U) and 2.6 g of L-serine were introduced into the reaction vessel, dissolved in 7.3 mL of 0.2 M acetate buffer pH 5.6 (40 mM $CaCl_2$), and the sonicated PC/diethyl ether solution plus 3 additional mL of diethyl ether were added. The reaction vessel was deaerated with N_2. The reaction was carried out at 30 ± 1°C under continuous stirring; the extent of the transphosphatidylation reaction was checked by TLC (Table 1, solvent systems 1 and 2) at different times. After 6 h, the reaction was stopped by the addition of 14.6 mL of 0.1 M EDTA pH 5.6 and the mixture was stirred for 10 min. Diethyl ether was removed under vacuum and PS was extracted, first with a mixture of 14.6 mL of $CHCl_3$/MeOH (2:1, vol/vol) and then with 1.46 mL of water. The lower layer was collected and further extracted three

[a]Adsorbent: Silica gel G (Merck).
[b]Solvent systems: 1, chloroform/methanol/acetic acid/water (50:25:7:3, by vol); 2, chloroform/methanol/ammonium hydroxide (28%) (50:25:6); 3,chloroform/methanol/water (65:25:4); 4, chloroform/methanol/ammonium hydroxide (28%) (65:25:5); 5, chloroform/methanol/acetone/acetic acid/water (50:20:10:10:5); 6, hexane/diethyl ether/formic acid (40:10:1); 7, chloroform/methanol/ammonium hydroxide (28%) (40:10:1). The data represent the mean ± SD of at least five determinations. PC, phosphatidylcholine; PS, phosphatidylserine.

times with 14.7 mL of $CHCl_3$. The combined organic extracts were concentrated in a vacuum evaporator. PS was redissolved in $CHCl_3$ and dried by anhydrous Na_2SO_4. The product was purified by CM-cellulose column chromatography and checked by ^1H nuclear magnetic resonance (NMR) and infrared (IR). Lipid concentrations were determined by phosphorus analysis (38).

Synthesis of NSPS. NAPS have been synthesized elsewhere by acylation of bovine brain PS with fatty acid imidazolide (16) in 45% yield, after purification with TLC. The yields of their synthesis with fatty acid anhydride (18,19) were about 5% after purification by silicic acid column chromatography. The synthesis using the carbonyldiimidazole derivative of oleic acid (20) yielded 56% of NAPS after purification by TLC. Finally, NSPS has been synthesized by reacting PS with stearoyl chloride, analogous to NAPE synthesis (3), but the purification procedures and yields were not reported.

In the present study, PS was converted to NSPS following essentially the method proposed by Dawson *et al*. (6) for NAPE synthesis. Stearoyl chloride (0.157 mmol) and Et_3N (0.158 mL), used as catalyst, were added to 48 mg of PS dissolved in 19 mL of ethanol-free $CHCl_3$. The reaction mixture was deaerated under N_2 and stirred for 90 min. The reaction was stopped by addition of 5% HCl to hydrolyze the remaining stearoyl chloride. The triethylammonium chloride formed was removed by six washes in water, and the organic phase was dried by anhydrous Na_2SO_4. NSPS was purified by preparative TLC on silica gel H using first $CHCl_3$/MeOH/NH_3 (28%) (Table 1, solvent system 4) and then hexane/diethyl ether/formic acid (Table 1, solvent system 6) as eluents. The product was extracted from the adsorbent with $CHCl_3$/MeOH/H_2O (10:21:10). Chloroform and water were added to the eluate to give a final ratio of 20:21:20, and the lower layer was removed and dried. The amide bond was detected by IR and ^1H NMR. Gas–liquid chromatography (GLC) was used to confirm the incorporation of the third fatty acid chain.

IR spectra. These were obtained from a film of lipid chloroform solutions (approximately 5 mg/mL) on KCl crystals by using a Perkin-Elmer 687 IR spectrophotometer. All spectra were recorded at room temperature against a KCl crystal reference.

NMR spectra. ^1H NMR (200 MHz) spectra were recorded on a Varian XL-200 spectrometer operating in the Fourier transform mode. Samples (15–25 mg lipid/mL) were measured in 5 mm o.d. sample tubes at room temperature. Typically, 200–300 scans were averaged. $CDCl_3$ was used as solvent and for field frequency locking purposes. Chemical shifts are expressed in parts per million (ppm) downfield from tetramethylsilane, which was used as the internal standard.

Fatty acids analysis. Fatty acids were converted into fatty acid methyl esters (FAME) and analyzed by GLC on a Perkin-Elmer 990 gas chromatograph equipped with a flame-ionization detector. Data were obtained with a 2 m × 2 mm i.d. column packed with 15% polymeric ethylene glycol succinate as stationary phase on Chromosorb W (100–120 mesh; Johns-Manville, Denver, CO). Helium at 30 mL/min was used as carrier gas. Injector, column, and detector temperatures were, respectively, 230, 188, and 250°C. Samples were applied as hexane solutions.

Preparation of liposomes. Liposomes were prepared by a classical method. NSPS was dissolved in $CHCl_3$, and the solvent was evaporated under a stream of nitrogen gas to deposit a lipid film on the wall of a glass test tube. Final traces of residual solvent were removed under vacuum for 12 h. Multilamellar vesicles were prepared by vortexing the dried lipid film (0.5 mg/mL) with 20 mM Tris-HCl buffer (pH 7.4) containing 100 mM NaCl and 0.1 mM EDTA. Small unilamellar vesicles were prepared by sonication of the phospholipid suspensions for 20 min (with intervening periods of 30 s every 90 s) in a Braun Labsonic 2000 probe sonifier equipped with a 9.5-mm probe, operating at 48 W. During sonication the suspension was kept at 45°C under a nitrogen stream. Titanium particles and possible undispersed lipids were removed by centrifugation. It was verified by TLC that the lipid did not suffer degradation due to sonication. Before use, the liposome dispersion was passed through a 0.45 μm filter.

Assay of vesicle aggregation. Vesicle aggregation was monitored by continuous measurements of the turbidity of the liposome suspensions at 400 nm for 2 min. The optical density changes were monitored with a Hewlett-Packard 8540A ultraviolet/visible spectrophotometer equipped with a Peltier temperature control cell and continuous stirring. The NSPS concentration for the aggregation assay was 0.05 mg/mL.

Measurements were performed at 20°C before and after the addition of small aliquots of concentrated calcium and magnesium salt solutions to the liposome suspensions. In order to avoid initial bubbling problems or the formation of large vesicles, we report the increments of absorbance after 20 s of cation addition. The threshold concentrations (c_t) for the aggregation process were calculated as described by Ohki (39).

Light-scattering measurements. The size distribution of unilamellar phospholipid vesicles, with or without added divalent ions, was analyzed by dynamic light scattering using a PCS41 optics unit (Malvern Autosizer IIc) and a 5-mW He-Ne laser (Spectra Physics) at an excitation wavelength of 633 nm. The data were collected with a Malvern 7032N 72 data channel correlator, and the mean hydrodynamic diameter was calculated from a cumulant analysis of the intensity autocorrelation function. The possible reversibility of the aggregation reaction was verified by adding EDTA to the aggregated vesicles at six times the concentration of divalent ions and measuring the size again after 2 min of incubation.

Assay of vesicle fusion. The fusion of vesicles induced by calcium ions was measured by monitoring the mixing of the lipid and mixing of the internal aqueous contents using fluorescent probes.

Lipid mixing was measured, using a modification of the fluorescence resonance energy transfer assay of Struck *et al.* (40), to show the fusion of liposomal membranes. Two populations of small unilamellar NSPS vesicles were prepared: one with NBD-PE and Rh-PE at 1 and 0.5 mole%, respectively, with respect to the total lipid at the membrane (0.05 mg/mL) and the other without fluorescent probes. The fluorescence-labeled liposomes and a ninefold excess of unlabeled vesicles were mixed at 20°C to study the dilution of the fluorescent lipids by continuous monitoring of the decrease in energy transfer from NBD-PE to Rh-PE using a Kontron SFM 25 spectrofluorimeter at excitation and emission wavelengths of 440 and 536 nm, respectively. Maximal fluorescence was determined using reference liposomes containing 0.1% NBD-PE and 0.05% Rh-PE. Measurements were performed at 20°C for 2 min after the addition of small aliquots of a concentrated $CaCl_2$ solution to the liposome suspensions. Light-scattering controls were performed using unlabeled vesicles. The percentage of maximal fluorescence was calculated as:

$$\% \text{ maximal fluorescence} = \frac{\frac{F_t - S_t}{F_T - S_T} - \frac{F_0 - S_0}{F_T - S_T}}{\frac{R_t - S_t}{R_T - S_T} - \frac{F_0 - S_0}{F_T - S_T}} \times 100 \qquad [1]$$

where F_t = fluorescence intensity at time t; F_0 = fluorescence intensity at zero time; F_T = fluorescence intensity in the presence of 0.7% of Triton X-100. R and S represent the same measurements for reference liposomes and light-scattering controls, respectively (41).

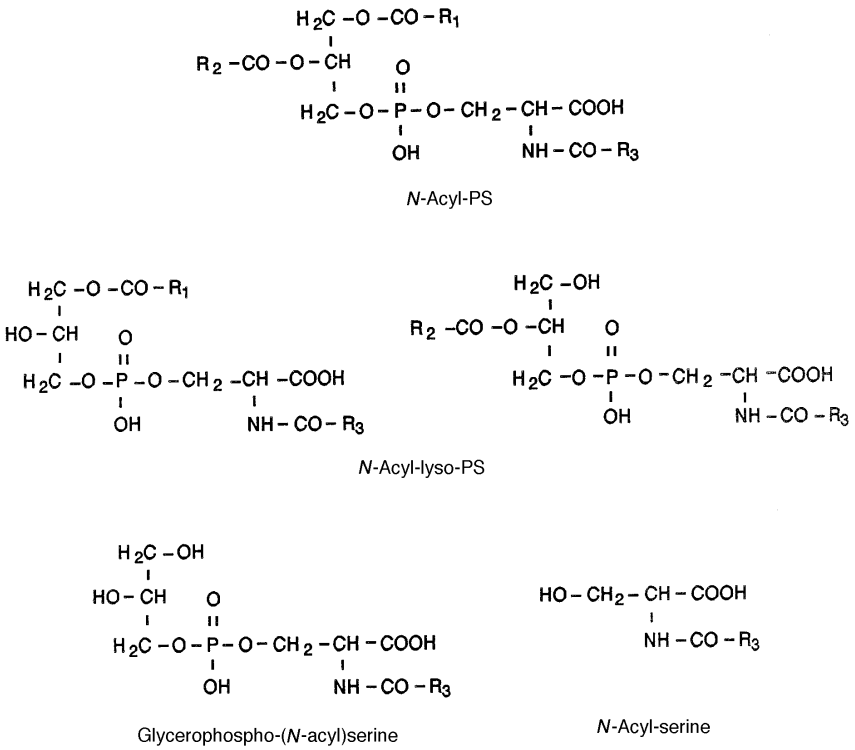
A modification of the method of Nir *et al.* (42) was used for mixing assay for the aqueous contents. Three populations of unilamellar vesicles (0.05 mg lipid/mL) were prepared in the following solutions: (i) 10 mM $TbCl_3 \cdot 6H_2O$/100 mM nitrilotriacetic acid/20 mM Tris-HCl buffer (pH 7.4), (ii) 100 mM DPA/20 mM NaCl/20 mM Tris-HCl buffer (pH 7.4) and (iii) 5 mM $TbCl_3 \cdot 6H_2O$/50 mM nitrilotriacetic acid/50 mM DPA/10 mM NaCl/20 mM Tris-HCl buffer (pH 7.4). After vesicle preparation, nonentrapped material was separated by gel filtration of 0.4 mL of the liposomal suspension on a Sephadex G-50 (Pharmacia Biotech, Uppsala, Sweden) column (200 × 10 mm) previously equilibrated with 100 mM NaCl/0.75 mM EDTA/20 mM Tris-HCl buffer (pH 7.4). Liposomes were eluted by the solution used in the equilibration process, and 1.6 mL of liposomes free of nonentrapped material was collected. $TbCl_3$ and DPA vesicles were mixed in a 1:1 molar ratio at a final lipid concentration of 0.05 mg/mL for the fusion assay in a 100 mM NaCl/20 mM Tris-HCl buffer (pH 7.4). Fluorescence measures were performed at 20°C for 2 min after the addition of small aliquots of a concentrated $CaCl_2$ salt solution to the liposome suspensions in a Kontron SFM 25 spectrofluorimeter at an excitation wavelength of 276 nm. The emission fluorescence was measured at 545 nm using a 530 cut-off filter to eliminate the contribution of light scattering. The value for 100% fusion was determined using the reference liposomes prepared with solution (iii). Light-scattering controls were performed using unlabeled vesicles. The percentage of fusion was calculated in the same way as for the lipid mixing assay.

Negative stain electron microscopy. Control NSPS liposomes were prepared in 20 mM Tris-HCl buffer (pH 7.4) containing 100 mM NaCl and 0.1 mM EDTA. To check the fusion of NSPS liposomes, an aliquot of control liposomes was incubated with Ca^{2+} (3 mM) for 2 min and then with EDTA (16 mM) for 1 h. Vesicle fusion was monitored by negative stain electron microscopy of liposome suspensions before and after the addition of calcium and EDTA. A drop of the liposome suspension was placed on a copper grid (400 mesh) for 90 s. Then buffer and liposome excess were drawn off and quickly replaced by a drop of 2% ammonium molybdate solution (pH 7.4). Finally, after 30 s the bulk of the heavy metal solution was also drawn off. Thoroughly dry grids were examined in a Hitachi MT-600 electron microscope at an acceleration of 75 kV.

RESULTS

Synthesis and characterization of NSPS. *N*-Acylserine phospholipids occur as derivatives of 1,2-diacylglycerol and exhibit the configuration indicated in Scheme 1. Sequential degradation of these phospholipids can produce *N*-acylserine lysophospholipids, glycerophospho-(*N*-acyl)serine and *N*-acylserine. Thus, the synthesis of *N*-acylserine phospholipids can be accomplished by converting PC to PS through a transphosphatidylation reaction and by acylation of serine phospholipids with fatty acyl chloride.

The conversion of PC to PS by *Streptomyces* sp. phospholipase D proceeded with 87% yield. Crude PS was found to contain the by-product phosphatidic acid and PC, and was thus purified by TLC. Purified PS was obtained in 49.5%



SCHEME 1

yield and was identified by TLC (Table 1), by IR (Fig. 1) and ^{1}H NMR (Table 2). The IR and NMR spectra were identical to those reported in the literature (15,22,43). The analysis of purified PS by GLC showed that the fatty acid composition of PS and PC was the same (Table 3). This result indicates that the enzyme does not prefer any particular molecular species of PC during the transphosphatidylation process.

Synthesis of NSPS proceeded with 82% yield. NSPS was checked by TLC (Table 1), IR (Fig. 1), NMR (Table 2), and GLC (Table 3). The increase in stearic acid for NSPS, as revealed by FAME analysis, is consistent with the molar ratio 1:2 for the excess stearic acid/total fatty acids in PS, indicating that fatty acids at the *sn*-1 and *sn*-2 positions of the NSPS are the same as in PS and that the excess stearic acid corresponds to the third acyl chain incorporated owing to the acylation process. Although the IR spectrum of NSPS was similar to that of PS, the strong absorption bands at 1660 cm^{-1} (C=O stretch of the secondary amide), 1530 cm^{-1} (NH deformation), and 3380 cm^{-1} (NH stretch) indicated the presence of an amide bond in the molecule.

NSPS was obtained in 39% yield after purification by preparative TLC on silica gel H plates, using two solvent systems as indicated in the Materials and Methods section. Crude NSPS was contaminated by a considerable amount of stearic acid, since stearoyl chloride was used in excess in the acylation reaction, and by some remaining PS. The purification step using chloroform/methanol/ammonium hydroxide (28%) (65:25:5) as solvent system eliminates all PS, but NSPS still contained small amounts of stearic acid since the spots were lengthened and there was a slight overlap. Stearic acid was

[a]Spectra were obtained from lipids dissolved in deuteriochloroform to a final concentration of approximately 10–15 mg lipid/mL and required 200 transients. ^{1}H NMR spectra were acquired by using a Geminis-200 spectrometer operating at 200 MHz in the Fourier transform mode at room temperature. Chemical shift values are expressed in parts per million (ppm) relative to tetramethylsilane at 0 ppm. The underlined values correspond to the characteristic shifts of each lipid. For abbreviations see Table 1.

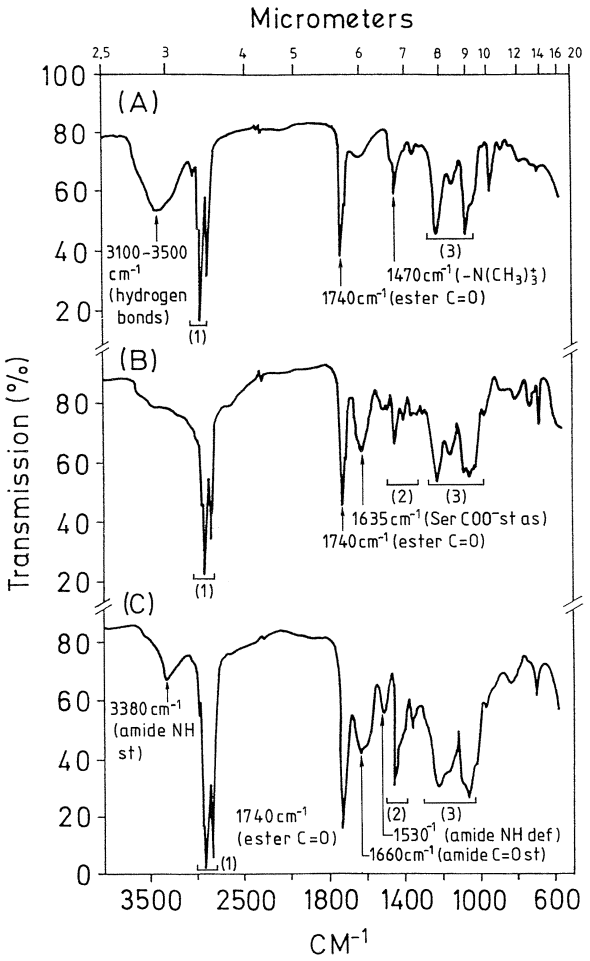

FIG. 1. Infrared spectra of phosphatidylcholine (A), phosphatidylserine (PS) (B), and *N*-stearoylphosphatidylserine (NSPS) (C). General absorption bands: (i) 2750–2950 cm^{-1} (CH stretching of CH_2); (ii) 1370–1450 cm^{-1} (CH bending of CH_3); (iii) 1090–1240 cm^{-1} [$(RO)_2(OH)P=O$ and $(RO)_2PO_2^-$ stretching].

eliminated by another TLC run using hexane/diethyl ether/formic acid (40:10:1) as eluent.

The NSPS IR spectrum was similar to that found in the literature for NAPS isolated from sheep erythrocytes (15) and bovine brain (16), or prepared by chemical acylation of palmitoyl-oleoyl-PS (20,22). Chemical shift data for the ^1H NMR spectrum of NSPS are summarized in Table 2 and are consistent with those found in the literature for *N*-oleoyl-(palmitoyloleoyl)PS (20,22).

Calcium- and magnesium-induced vesicle aggregation. Aggregation of NSPS-liposomes was studied in the presence of the divalent cations calcium and magnesium (Fig. 2). In the simplest interpretation, the initial rate of change in the optical density (increments of absorbance 20s after cation addition) of the liposome solutions measures the rate of aggregation of two vesicles. The sigmoidal plots, obtained when the turbidity changes of NSPS-liposomes 20s after cation addition were plotted vs. increasing concentrations of the two divalent ions, show clear differences in the ability of these cations to induce aggregation of NSPS-liposomes. For concentrations below 6 mM, calcium was found to be more effective than magnesium in inducing NSPS-liposomes' aggregation, but above 6 mM magnesium was more effective. The effectiveness of both cations is higher for PS-liposomes (threshold concentration 1.5 mM for calcium and 4.6 mM for magnesium) than for NSPS-liposomes (threshold concentration 2.8 mM for calcium and 6.6 mM for magnesium), suggesting that *N*-acylation of PS protects the membrane against aggregation during any degenerative process.

The calcium-threshold concentrations for aggregation of PS (1.5 mM) and NSPS (2.8 mM) are of physiological relevance since the cytosolic level of calcium in unexcited cells (typically 0.1–0.2 μM) is several orders of magnitude lower than the concentration in the extracellular medium or in the sarcoplasmic reticulum. However, this level can be raised

TABLE 3
Percentage of the Total Fatty Acids Content

Sample	Percentage of the total fatty acids[a]				
	$C_{16:0}$	$C_{18:0}$	$C_{18:1}$	$C_{18:2}$	Others
PC	35.8 ± 0.8	12.5 ± 0.9	30.2 ± 0.2	19.1 ± 1.0	2.4 ± 0.2
PS	36.1 ± 1.1	12.1 ± 0.2	30.5 ± 0.6	18.6 ± 1.5	2.7 ± 0.2
NSPS	24.5 ± 0.1	41.2 ± 1.2	19.8 ± 2.2	12.6 ± 0.6	1.9 ± 0.1

[a]Fatty acid contents were determined by gas–liquid chromatography (GLC) of the fatty acid methyl esters produced *via* transmethylation. Data represent the mean ± SD of at least three determinations. GLC was performed on a Perkin-Elmer 990 gas chromatograph equipped with flame-ionization detector. Data were obtained with a 2 m × 2 mm i.d. column packed with 15% polymeric ethylene glycol succinate as stationary phase on Chromosorb W (100-120 mesh). Helium at 30 mL/min was used as carrier gas. Injector, column, and detector temperatures were, respectively, 230, 188, and 250°C. Samples were applied as hexane solutions. For abbreviations see Table 1.

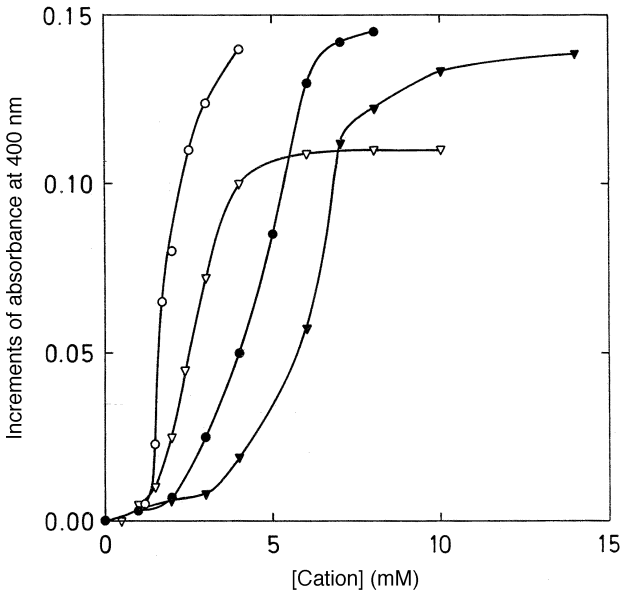

FIG. 2. Influence of calcium and magnesium concentrations on the aggregation state of NSPS-liposomes. Turbidity changes were plotted vs. $[Ca^{2+}]$ (○,▽) and $[Mg^{2+}]$ (●,▼). The phospholipid vesicle concentration was 0.05 mg/mL of 20 mM Tris-HCl buffer (pH 7.4), containing 100 mM NaCl and 0.1 mM EDTA. Measurements were performed at 20°C. (○,●) PS control, and (▽,▼) NSPS. For abbreviations see Figure 1.

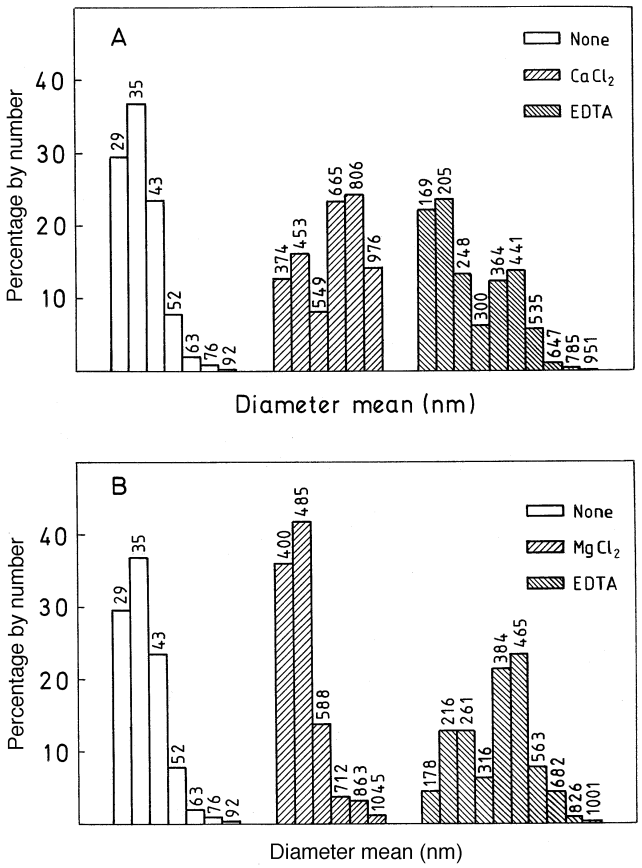

FIG. 3. Effect of calcium and magnesium on NSPS-liposome size. The state of aggregation of NSPS liposomes was monitored by photon correlation spectroscopy in the presence of 3 mM calcium (A) and 6 mM magnesium (B). Vesicle diameter was measured before and after addition of divalent cation. The reversibility of the aggregation reaction was followed by vesicle size analysis after EDTA addition, at six times the concentration of divalent ions, to the aggregated vesicles. For abbreviation see Figure 1.

abruptly by transiently opening calcium channels in the plasma membrane or an intracellular membrane, following ischemia under conditions of degenerative change involving disintegration and/or digestion of membranes. In this way, *N*-acylation of PS would delay aggregation and fusion processes due to cytosolic calcium increase.

Particle size analysis and aggregation irreversibility. The state of aggregation of unilamellar NSPS-liposomes induced by the divalent cations calcium and magnesium was also monitored by photon correlation spectroscopy. The results are summarized in Figure 3. The initial size of NSPS-liposomes prepared by sonication was in the range of 29–43 nm, but the particle size increases in the presence of both cations. After addition of EDTA to the aggregated vesicles only partial reversibility of NSPS-liposomes' aggregation occurred, since the liposomes did not return to the initial size, indicating that divalent ions induce the formation of irreversible aggregates. The irreversibility of the aggregation reactions after adding EDTA suggests that vesicle fusion might occur in the presence of either cation. Systematic aggregation and fusion studies using different NAPS liposomes are now in progress.

Calcium-induced NSPS-liposome fusion. Preliminary studies, based on mixing analysis for both lipid and internal aqueous contents (Fig. 4), show that fusion rather than aggregation of NSPS-liposomes occurs in the presence of calcium ions. Figure 4A shows the percentage of fusion of NSPS-liposomes following lipid mixing after the addition of various Ca^{2+} concentrations (1, 2, 3, and 4 mM). The increase in lipid mixing depended on calcium concentration in the medium. Mixing was inappreciable when 1 mM calcium was used, whereas the extent of lipid mixing was of 60, 75, and 90% 2 min after the addition of 2, 3, and 4 mM of calcium, respectively.

The results obtained when the mixing of the internal aqueous content was monitored are shown in Figure 4B. Aqueous mixing was also a function of calcium concentration, but at the same calcium concentration the extent of fusion measured following mixing of aqueous contents was always lower than the extent of fusion measured by lipid mixing; the mixing of aqueous contents was less than 10% with 2 mM calcium.

The increase in fusion with increasing calcium concentration in the medium correlates well with the calcium-induced aggregation shown by turbidimetric assays. The lower mixing for the internal aqueous content can be explained in two ways. First, in lipid mixing measurements there may be a contribution of fusion and semifusion processes. On the other hand, the lower internal aqueous contents mixing can be explained by a loss of fluorescence due to the leakage of encapsulated Tb-DPA complex into the EDTA-containing medium.

To confirm the fusion of NSPS-liposomes, transmission electron micrographs were obtained before and after the correlative incubation of control liposomes with 3 mM calcium and 16 mM EDTA. The increase in the size of the vesicles incubated with the divalent cation (Fig. 5) again demonstrates the calcium-induced fusion of NSPS-liposomes.

DISCUSSION

Membrane fusion is a key event in the functioning of a living organism. Thus, membrane fusion occurs in a very specific and highly controlled fashion, and specific modulators determine when and where membrane fusion occurs. Membrane fusion is an extremely complex process, and many primary and secondary factors are involved in its induction and regulation. A large number of different fusogenic lipids have been proposed to be specifically involved in membrane fusion. The presence of significant amounts of type II nonbilayer-preferring lipids in any biomembrane, and the fact that their phase preference can be triggered and membrane fusion induced by biological fusion factors, strongly suggest a central role for type II nonbilayer-preferring lipids in biomembrane fusion (44).

NAPS have been isolated from normal tissues (8,15,16); but it is not possible to rule out their formation postmortem, like NAPE (14). Although we have shown the participation of the parent compounds NAPE in membrane processes, like permeability and fusion (29,31), there are no published re-

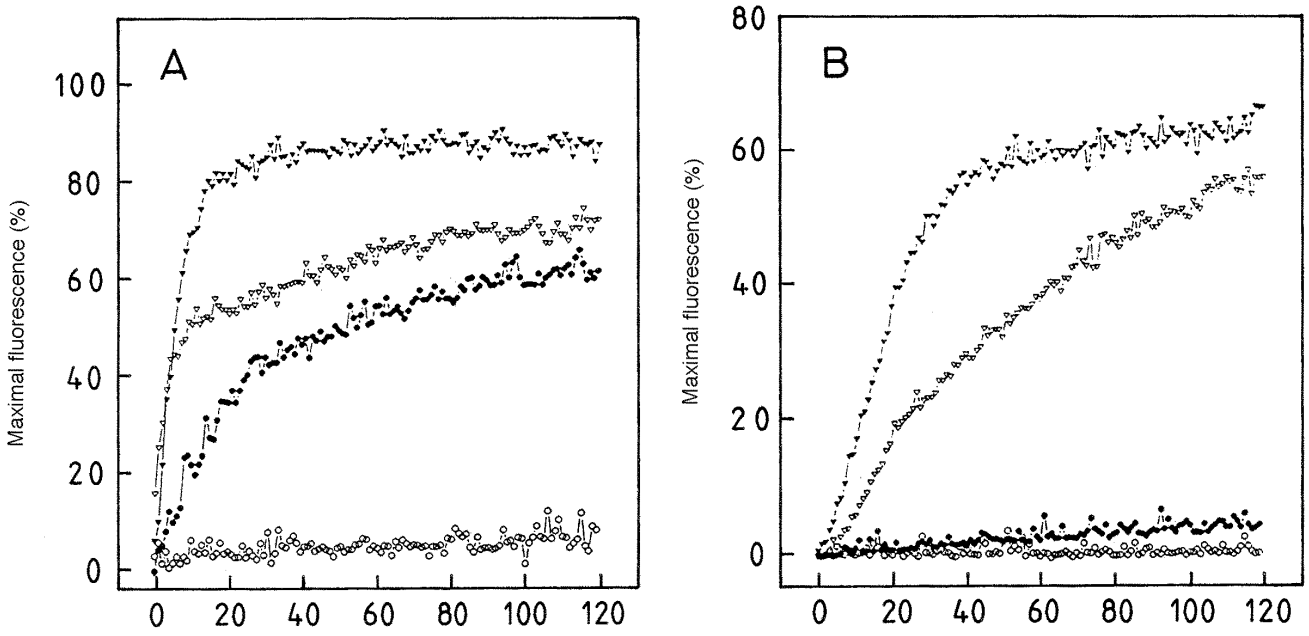

FIG. 4. Ca^{2+}-induced fusion of NSPS small unilamellar vesicles. (A) Lipid mixing; (B) internal aqueous contents mixing. Ca^{2+} [1 mM (○), 2 mM (●), 3 mM (▽), and 4 mM (▼)] was added at $t = 0$ to a vesicle suspension of 0.05 mg lipid/mL. Fluorescence measures were done at 20°C. The percentage of maximal fluorescence at 536 nm (A) and at 545 nm (B) was calculated as described in the Materials and Methods section. For abbreviation see Figure 1.

sults on the participation of NAPS in such processes. Nevertheless, the group of Casal (45) has shown differences in the phase behavior between the parent compound *N*-methylated phosphatidylserine and PS, and they have indicated that *N*-methyl-phosphatidylserine is also unusual in its interactions with metal ions, but results on this latter aspect have not been published. We have synthesized NSPS to examine divalent cation-induced aggregation of NSPS-liposomes as a previous step for membrane fusion. The conversion of egg transphosphatidylated PS to NSPS proceeded with 82% yield and, after purification by preparative TLC on silica gel H plates using two solvent systems, NSPS was obtained in 39% yield.

The purified NSPS was characterized by its chromatographic and spectroscopic (IR and ^1H NMR) properties and by chemical degradation. Although the IR spectrum of NSPS was similar to that of PS, the strong absorption bands at 1660 cm^{-1} (C=O stretch of the secondary amide), 1530 cm^{-1} (NH deformation), and 3280 cm^{-1} (NH stretch) were indicative of the presence of an amide bond in the molecule. Besides this, the NSPS IR spectrum was similar to that found in the literature for the NAPS isolated from sheep erythrocytes (15) and bovine brain (16), or prepared by chemical acylation of palmitoyl-oleoyl-PS (20,22). In addition, chemical shift data obtained from the ^1H NMR spectrum of NSPS are consistent with those found in the literature for *N*-oleoyl(palmitoyloleoyl)PS (20,22). On the other hand, the increase in stearic acid for NSPS with respect to egg transphosphatidylated PS, found by FAME analysis, agrees with the incorporation of

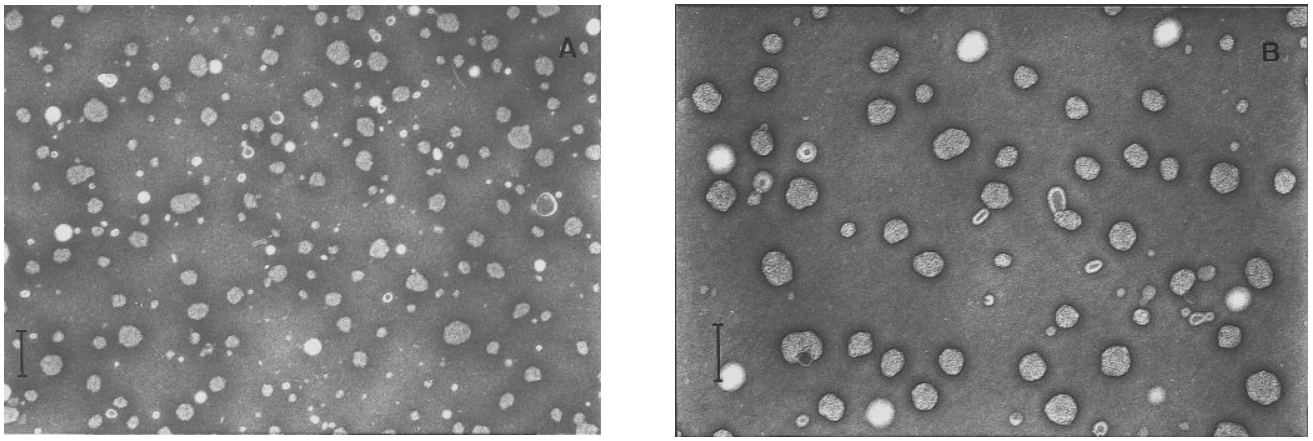

FIG. 5. Transmision electron micrographs of NSPS vesicles before (A) and after (B) their incubation with calcium (3 mM) for 2 min and then with EDTA (16 mM) for 1 h. Bar: 100 nm (A) and 400 nm (B).

this fatty acid in the third chain by the acylation process. These results indicate that the synthesized molecules are indeed NSPS.

The aggregation of NSPS-liposomes was studied in the presence of calcium and magnesium. Clear differences were found in the effectiveness of these cations in inducing aggregation of NSPS-liposomes. The threshold concentrations of these divalent ions were 2.8 mM for Ca^{2+} and 6.6 mM for Mg^{2+}; thus Mg^{2+} is much less potent than Ca^{2+} in inducing aggregation of NSPS-liposomes. The analysis of NSPS-liposomes by photon correlation spectroscopy shows a size increase in the presence of divalent cations calcium and magnesium, which agrees with the aggregation process observed turbidimetrically. The fact that the liposomes do not return to their initial size, after addition of EDTA to the aggregated vesicles, indicates that the divalent cations induce the formation of irreversible aggregates and suggests that vesicle fusion rather than mere aggregation might occur. Vesicle fusion was demonstrated by transmission electron microscopy and by the experiments showing both lipid and aqueous contents mixing when calcium cations were added to NSPS-liposomes. Nevertheless, the comparison of the results of photon correlation spectroscopy and those of lipid and internal aqueous contents mixing shows that not all aggregates led to fused vesicles. The addition of EDTA to the aggregated vesicles removes the higher aggregates, but all the remaining ones are still larger than the initial liposomes, indicating that the size of liposomes does not return to the initial value. On the other hand, the extension of fusion 2 min after calcium 3 mM addition is lower than 60%.

The calcium threshold concentration obtained by us for the aggregation of egg transphosphatidylated PS-liposomes is similar to that reported for aggregation (46) and fusion (47) in 0.1 M NaCl of unilamellar bovine brain PS vesicles. This indicates that the PS headgroup is responsible for aggregation and fusion and, thus, our PS constitutes a good tool to study the physiological consequences of PS acylation. The threshold concentrations of calcium and magnesium ions for aggregation of PS-liposomes were 1.5 mM and 4.6 mM, respectively, indicating that Ca^{2+} binds to PS more strongly than Mg^{2+}. This difference in the threshold concentrations correlates well with the results reported for the interaction of calcium and magnesium with bovine brain PS (48,49).

The effectiveness of calcium and magnesium cations in inducing vesicle aggregation and fusion is higher for PS-liposomes than for NSPS-liposomes. Since we have studied the effect of calcium and magnesium on the aggregation and fusion properties of only one type of NAPS, it may be too early to speculate on the effect of such acidic phospholipids on membrane processes. However, it is likely that *N*-acylation of PS provides a double protective effect against degerative damage of membranes through aggregation and fusion mechanisms, since *N*-acylation decreases the sensitivity of PS to calcium and magnesium ions and removes free fatty acids, which have fusogenic properties. This result is consistent with the postulated protective role for N-acyl derivatives of PE (2,29,30), since, like *N*-acyl deriv atives of PE, NSPS helps to stabilize a bilayer conformation under conditions in which fusion may be favored. Moreover, this postulated protective effect is consistent with the defense mechanism postulated by Hansen *et al*. (24,25) for the synthesis of NAPE related to the neuronal death induced by the exposure of cultured cerebral cortical neurons to glutamate.

ABSTRACT: The major alkenes of the haptophytes *Isochrysis galbana* (strain CCAP 927/14) and *Emiliania huxleyi* (strains CCAP 920/2 and VAN 556) have been identified by nuclear magnetic resonance spectroscopy and by mass spectrometric analysis of their dimethyl disulfide adducts. The dominant alkene in *I. galbana* is (22*Z*)-1,22-hentriacontadiene, with 1,24-hentriacontadiene and 1,24-tritriacontadiene present in much lower abundance; (22*Z*)-1,22-hentriacontadiene also occurs in *E. huxleyi* (strain CCAP 920/2), together with (2*Z*,22*Z*)-2,22-hentriacontadiene (the major hydrocarbon) and (3*Z*,22*Z*)-3,22-hentriacontadiene. Minor abundances of 2,24-hentriacontadiene and 2,24-tritriacontadiene are also present in this strain. In contrast, the dominant alkene in *E. huxleyi* (strain VAN 556) is (15*E*,22*E*)-1,16,23-heptatriacontatriene with the related alkatriene 1,15,22-octatriacontatriene also present and (22*Z*)-1,22-hentriacontadiene occurring as a minor component. From structural relationships (15*E*,22*E*)-1,15,22-heptatriacontatriene is proposed to derive from the same biosynthetic pathway as that of the characteristic C_{37} alkenones which occur in both *E. huxleyi* and *I. galbana*. The C_{31} and C_{33} dienes likely derive from chain extension and decarboxylation of (*Z*)-9-octadecenoic acid or (*Z*)-7-hexadecenoic acid, using a pathway analogous to that elucidated previously in the chlorophyte *Botryococcus braunii*. Therefore, long-chain dienes and trienes, which can co-occur in haptophytes, may have distinct biosynthetic pathways.
Lipids 33, 617–625 (1998).

The Haptophyta (= Prymnesiophyta) are a distinct phylum of photosynthetic eucaryotes found throughout the oceans and in certain fresh waters (1). They constitute a high proportion of marine biomass, certain species forming enormous blooms observable from space (1). The characteristic C_{37} alkenones observed in certain species, such as *Emiliania huxleyi*, are typically amongst the most abundant lipids of Quaternary marine sediments (2), and the relative abundances of the components with different degrees of unsaturation are used as a paleo-sea surface temperature proxy (U^{k}_{37} and $U^{k'}_{37}$) (3,4). Haptophytes can also contain significant abundances of C_{31} and C_{33} alkadienes in addition to C_{37} and C_{38} alkatrienes (5–7). However, the diene components have not been reported in those marine sediments where alkenones occur in high abundance and the C_{37} and C_{38} hydrocarbons may or may not be present (2). Indeed, in a study of the Black Sea, C_{31} dienes were abundant in surface particulates but disappeared with depth and were absent from the bottom sediment. In the same sediments the alkenones were in high abundance and a C_{37} and a C_{38} triene were still present (8).

Although the positions of the double bonds in haptophyte alkenones are known and their stereochemistry has been established as *trans* (9), the long-chain alkenes have not been characterized. Therefore, as part of a wider investigation into the reasons for the differing labilities of long-chain lipids to biodegradation, we have fully elucidated the structures of the major haptophyte alkenes.

EXPERIMENTAL PROCEDURES

Culture conditions. Isochrysis galbana (CCAP 927/14) was cultured in artificial seawater medium (F/2). *Emiliania huxleyi* strains CCAP 920/2 and VAN 556 were cultured in filtered (0.6 μm) pasteurized seawater. All cultures were kept under continuous aeration and light and were harvested at stationary phase after confirmation that the cultures were axenic.

Hydrocarbon isolation. Freeze-dried cells (5–10 g) were extracted using ultrasonication in 2:1 dichloromethane/methanol, the solvent being removed by rotary evaporation. The hydrocarbon fraction was isolated from the extract using silica gel column chromatography (~5 g silica) and eluting with hexane (5 column volumes). The fraction was purified further by silica gel thin-layer chromatography (TLC; R_f = 0.95–1.0), developing with hexane.

Gas chromatography (GC). GC was carried out using a Carlo Erba 5300 instrument equipped with a polysiloxane

capillary GC column (CP Sil 5CB, 50 m, 0.12 µm film, 0.32 mm i.d.; Chrompack, The Netherlands), using hydrogen as carrier gas. The temperature program was 40 (isothermal 2 min)–250°C at 12°C min^{-1}, 250–300°C at 4°C min^{-1} (isothermal 30 min). Dimethyl disulfide adducts were analyzed under similar conditions, utilizing an HT-5 GC capillary column (25 m, 0.1 µm film, 0.32 mm i.d.; SGE, Victoria, Australia); the temperature program was 40 (isothermal 2 min)–250°C at 12° min^{-1}, 250–370°C at 4° min^{-1} (isothermal 30 min). Quantitation of the alkenes was undertaken using flame-ionization detection with *n*-tricosane (99%; Sigma, Dorset, United Kingdom) as internal standard.

GC–mass spectrometry (GC–MS). GC–MS of the hydrocarbon fractions was undertaken in electron impact (EI) mode (70 eV, scan time 1 s; *m/z* 50 to 750) using a Finnigan MAT 4500 instrument and helium as carrier gas. GC conditions were as above.

Nuclear magnetic resonance (NMR) spectroscopy. NMR analyses were carried out on a Jeol GX400 spectrometer operating at 400 MHz for ^1H and 100 MHz for ^{13}C. Samples were analyzed in deuterochloroform and the resulting free induction decays were processed with the Jeol processing program SpecNMR using a Gaussian window function (GF = 0.5, BF = –0.2 for ^1H and GF = 2.0, BF = –0.3 for ^{13}C). In some cases the free induction decay was zero-filled four times to 131,072 data points and a Gaussian window applied for resolution enhancement (GF = 1.0, BF = –1.5). Spectra were referenced to the solvent (7.26 ppm for ^1H and 77.0 ppm for ^{13}C).

Formation of dimethyl disulfide (DMDS) adducts. Aliquots of total hydrocarbon fractions were adducted following the method of Carlson *et al.* (10). In brief, samples dissolved in hexane (0.2 mL) were added to DMDS (0.2 mL) and a solution of iodine in diethyl ether (6 mg in 0.1 mL). After 12 h at 40°C, sodium thiosulfate (5% aqueous; 1 mL) was added and the adducts extracted into hexane.

Catalytic hydrogenation. An aliquot of the *I. galbana* (CCAP 927/14) hydrocarbon fraction dissolved in hexane (5 mL) was hydrogenated over PtO_2 (1 mg), 2 h, at 20°C. After filtration the product was analyzed by GC and GC–MS. An aliquot was coinjected with a standard C_5 to C_{40} *n*-alkane mix (CP-6A; PolyScience, Evanston, IL).

Diimide reduction. To the hydrocarbon fraction of *E. huxleyi* (VAN 556) in diethyl ether (1 mL) was added a methanol solution of copper sulfate (0.04 mg in 0.4 mL) followed by hydrazine hydrate (0.05 mL). The reaction mixture was left open to the air and stirred at room temperature (1 h) prior to being quenched by addition of water (5 mL). The hydrocarbon products were recovered by extraction with diethyl ether (2 × 5 mL). The combined extracts were dried ($MgSO_4$) and the solvent removed by rotary evaporation. The product was purified by flash chromatography using hexane as eluant, analyzed by GC–MS, and then adducted with DMDS before analysis by GC–MS.

Standard compounds. Authentic alkene standards for NMR comparisons were obtained from either the Aldrich Chemical Company (Dorset, UK) [(*E*)-2-heptene, (*E*)-3-heptene, (*Z*)-3-heptene, (*E*)-7-tetradecene, (*Z*)-9-heneicosene, 1-heptadecene] or Lancaster Synthesis Ltd. (Lancashire, UK) [(*Z*)-2-heptene].

RESULTS AND DISCUSSION

Isochrysis galbana *(CCAP 927/14).* The hydrocarbons of *I. galbana* (CCAP 927/14) are dominated by a single component (Table 1; Fig. 1), assigned by GC–MS as a C_{31} diene (M^+ at *m/z* 432; 10% of base peak intensity). Three minor components, two C_{31} dienes and a C_{33} diene, are also present (Table 1).

The ^1H NMR spectrum of the major diene displays an intense signal at 1.25 ppm as a result of aliphatic CH_2 groups and a terminal alkyl methyl group at 0.88 ppm. Three characteristic mutually coupling vinylic resonances are observed at 5.81 ppm (1-H, *ddt*, *J* = 10.3, 17.1, and 6.6 Hz), 4.99 ppm (1-H, *ddt,* *J* = 17.1, 2.2, 1.7 Hz), and 4.92 ppm (1-H, *ddt,* *J* = 10.3, 2.2, 1.2 Hz) representing a terminal double bond, which are in accord with those recorded for the terminal double bond in 1-heptadecene (Table 2). Another set of vinylic resonances integrating for two hydrogens is observed at 5.35 ppm. The highly second-order nature of this multiplet is characteristic of a disubstituted double bond flanked by similar hydrocarbon groups representing an AA′XX′X″X‴ system. Comparison of the appearance of the chemical shift with that observed in (*Z*)-9-heneicosene and (*E*)-7-tetradecene (Fig. 2) clearly indicates that the double bond has *cis* stereochemistry (Table 3) and confirms a previous report indicating that the vinylic hydrogens in such molecules are deshielded in the *cis* relative to the *trans* isomer (11). Spectral analysis of the vinylic hydrogens in the highly second-order AA′XX′X″X‴system possessing either a *cis* or a *trans* double bond was simulated using the computer program Laocoön (12). In the case of the *cis* isomer, the splitting pattern was reproduced using $^3J_{A,A'}$ = 11.0 Hz, $^3J_{A,XX'}$ and $^3J_{A',X''X'''}$ = 6.1 Hz, $^4J_{A,X''X'''}$ and $^4J_{A',XX'}$ = –1.2 Hz and $^2J_{X,X'}$ and $^2J_{X'',X'''}$ = 12.0 Hz (sign not determined). In the case of the *trans* iso-

[a]Trace component (<0.01 mg/g dry weight alga).

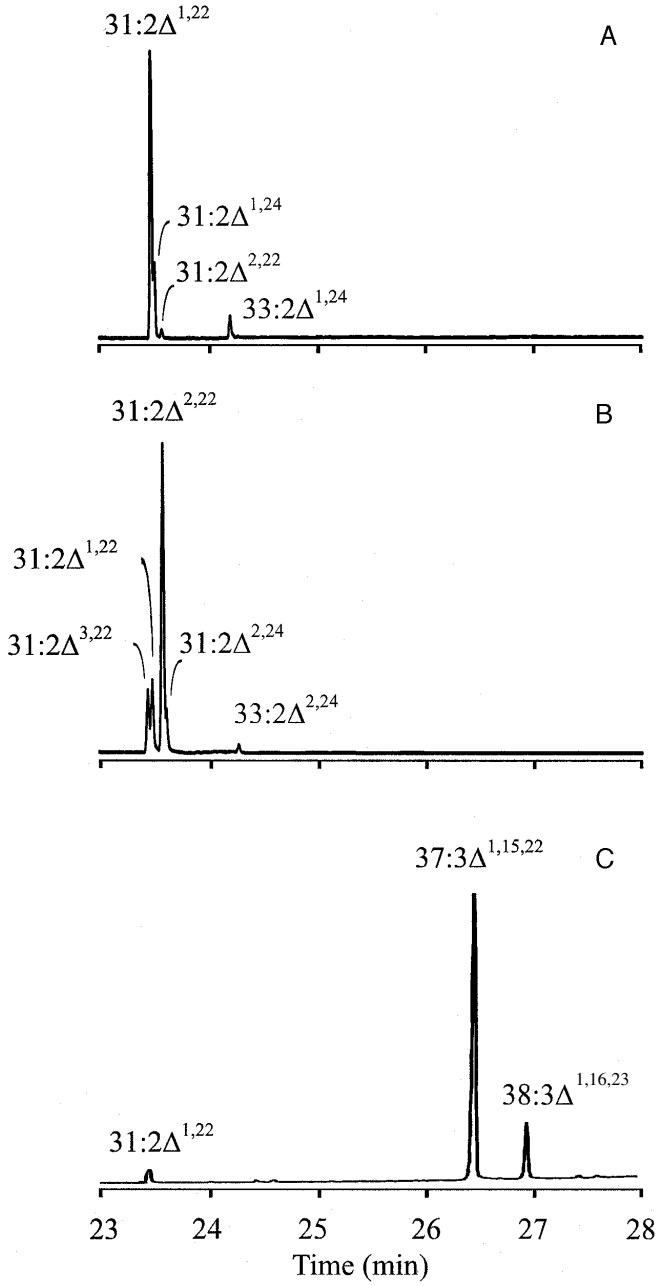

FIG. 1. Gas chromatograms of hydrocarbon fractions isolated from (A) *Isochrysis galbana* (CCAP 927/14), (B) *Emiliania huxleyi* (CCAP 920/2), (C) *E. huxleyi* (VAN 556).

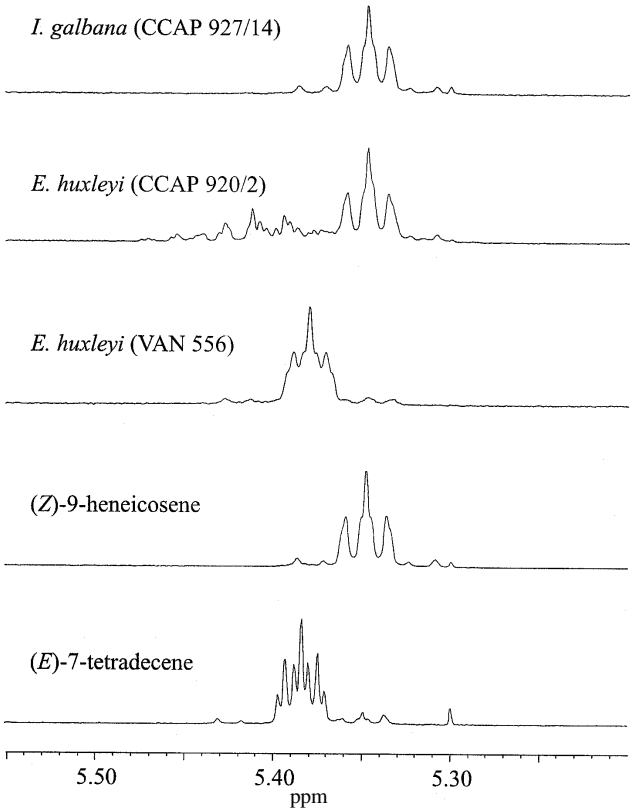

FIG. 2. Partial ^{1}H nuclear magnetic resonance (NMR) spectra comparing the mid-chain vinylic resonances in hydrocarbons from *Isochrysis galbana* and *Emiliania huxleyi* and in two alkene standards.

mer, the splitting pattern was reproduced using similar values to those for the *cis* isomer but increasing $^{3}J_{A,A'}$ to 16 Hz and $^{4}J_{A,X''X'''}$ and $^{4}J_{A',XX'}$ to −1.4 Hz. Comparison of the allylic hydrogen resonances in 1-heptadecene, (*Z*)-9-heneicosene, and (*E*)-7-tetradecene (Fig. 3) reveals differences in splitting patterns and in chemical shifts. Of particular note is a deshielding effect of the double bond in the order *trans* < *cis* < terminal (Table 4). The allylic hydrogen resonances in the *I. galbana* diene clearly comprise a composite arising from allylics next to a terminal double bond and a *cis*-substituted double bond in the middle of a long hydrocarbon chain (Table 4; Fig. 3).

Comparison of the sp^2 hybridized resonances in the ^{13}C NMR spectra of the diene with those in (*Z*)-9-heneicosene, (*E*)-7-tetradecene, and 1-heptadecene clearly confirms the presence of the terminal double bond (resonances at 114.1 and 139.3 ppm) and the *cis*-substituted double bond (resonance at 129.9 ppm) (Table 5). As observed for the midchain vinylic hydrogens in the ^{1}H NMR spectra, a *cis*-substituted double bond in such molecules also has a small but significant deshielding effect on the ^{13}C chemical shift of the mid-chain vinylic carbons.

The presence of the terminal double bond is confirmed and the position of the *cis* double bond identified as at C-22 from the mass spectrum of the DMDS adduct (Table 6, Fig. 4A, and Scheme 1, the fragmentation scheme for DMDS adducts of haptophyte alkadienes) with diagnostic ions at *m/z* 620 (M^+) and also at *m/z* 61 (A^+), 173 (D^+), 399 [$(C - 48)^+$; i.e., $C - CH_3SH$] and 465 [$(B - 94)^+$; i.e., B-DMDS] (*c.f.* reference 10) giving the structure of the major component as (22*Z*)-1,22-hentriacontadiene (Scheme 2A). The double bonds of the minor C_{31} component (Table 1) are at C-1 and C-24, characteristic ions being *m/z* 620 (M^+), 61 (A^+), 145 (D^+), 465 [$(B - 94)^+$] and 427 [$(C - 48)^+$] (Table 6). Likewise, the double bond positions in the minor C_{33} diene (Table 1) are also at C-1 and C-24, characteristic ions being *m/z* 648 (M^+), 61 (A^+), 173 (D^+), 493 [$(B - 94)^+$] and 427 [$(C - 48)^+$]

[a]Relative signs of coupling constants given.

(Table 6). A mass spectrum of the DMDS adduct of the smallest C_{31} diene was not recorded.

The straight-chain nature of the C_{31} dienes was confirmed by hydrogenating an aliquot of the *I. galbana* hydrocarbon fraction. GC–MS analysis of the product reveals two products, the major product being *n*-hentriacontane and the minor product, *n*-tritriacontane, as confirmed by coinjection with an *n*-alkane standard mixture.

Emiliania huxleyi *(CCAP 920/2).* The hydrocarbon composition of *E. huxleyi* (CCAP 920/2) comprises four C_{31} dienes and a single C_{33} diene (Table 1; Fig. 1).

Initial ^{1}H NMR analysis of the hydrocarbon fraction indicates aliphatic moieties with an intense resonance at 1.25 ppm (CH_2 groups) and a terminal alkyl methyl at 0.88 ppm along with the presence of a vinylic methyl group at 1.60 ppm in the major isomer and hence a C-2 double bond. This is accompanied by the characteristic second-order multiplet for the two vinylic hydrogens of a *cis*-substituted double bond (5.35 ppm) in the middle of the hydrocarbon chain as observed in the major *I. galbana* diene. Partially overlapping this multiplet is an extremely complicated series of resonances arising from the hydrogens attached to the C-2 double bond. Comparison of the chemical shifts and splitting patterns of these hydrogens and the vinylic methyl group with those in (*Z*)-2-heptene and (*E*)-2-heptene indicates that the C-2 double bond is also *cis* (Table 2). Thus, the terminal vinylic methyl group appears at 1.60 ppm in the diene, which agrees with that observed in (*Z*)-2-heptene but is significantly different from that of 1.63 ppm observed in (*E*)-2-heptene. Furthermore, the splitting pattern observed for the vinylic methyl is

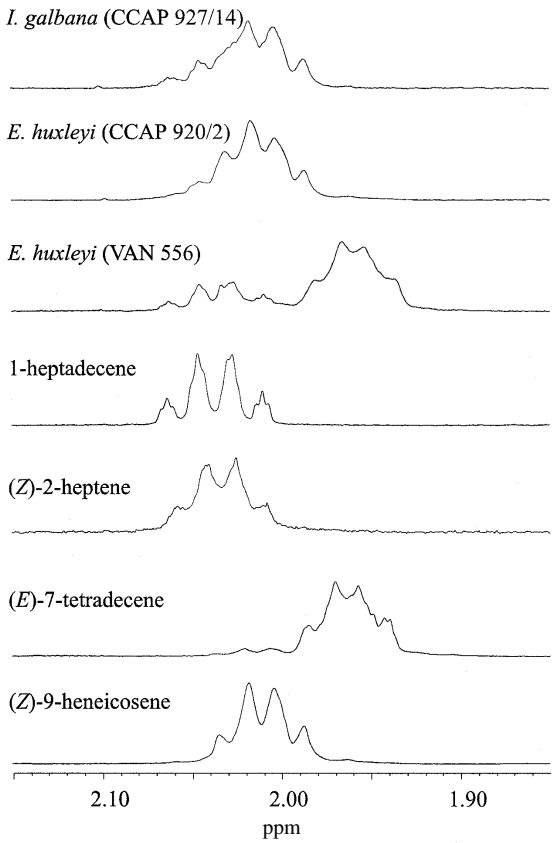

FIG. 3. Partial ^{1}H NMR spectra comparing the allylic resonances (excluding methyl groups) in haptophyte hydrocarbons and in four alkene standards. For abbreviations see Figure 2.

almost identical to that in (*Z*)-2-heptene but is completely different from that in (*E*)-2-heptene (Table 4). To interpret the complicated splitting patterns associated with the hydrogens on the C-2 double bond, we carried out decoupling experiments on both the diene and (*Z*)-2-heptene (Fig. 5). Irradiation of the vinylic methyl collapses 2-H basically into a doublet (*J ca.* 11 Hz) and 3-H into a doublet of triplets (*J ca.* 11 and 7 Hz), although for the diene the doublet of triplets is partially obscured by the midchain vinylics. In both cases a strong second-order roofing effect is observed. Similarly, irradiation of the allylic hydrogens collapses 2-H into a doublet of quartets (*J ca.* 11 and 7 Hz), and 3-H into a doublet of quartets (*J ca.* 11 and 1 Hz), both sets of multiplets again showing a strong second-order roofing effect. Simulation of the appearance of the vinylic hydrogens and vinylic methyl using the program Laocoön (12) not only confirmed the preceding interpretations but also allowed a more realistic estimation of the allylic coupling constants. Furthermore, the simulation revealed a long-range five-bond coupling from 1-H_3 to 4-H_2 (Tables 2 and 4). The appearance of the allylic hydrogens is in agreement with a composite of signals derived from the allylics next to the midchain double bond, as in (*Z*)-9-heneicosene, and those next to the C-2 double bond, as in (*Z*)-2-heptene, albeit with a slight shielding effect (Fig. 3).

In addition to those resonances associated with the major isomer, a set of multiplets associated with one of the minor components and characteristic of a terminal double bond as observed in *I. galbana*, is also clearly present.

The ^{1}H NMR data (Tables 2 and 3) indicate therefore that the major *E. huxleyi* (CCAP 920/2) diene contains two *cis*-substituted double bonds, one at C-2 and the other somewhere in the middle of the chain. One of the minor dienes possesses a terminal double bond.

These conclusions are supported by ^{13}C NMR studies. The C-2 and C-3 chemical shifts (123.6 and 130.9 ppm) in the major diene were compared with those recorded for (*Z*)-2-heptene and (*E*)-2-heptene (Table 5). Excellent agreement was obtained between the diene and (*Z*)-2-heptene, with small but significant differences in chemical shift being observed for (*E*)-2-heptene. Weaker signals attributable to a terminal double bond in one of the minor dienes are clearly observable at 114.1 and 139.3 ppm.

Compound	Chemical shift, δ (ppm)
(22*Z*)-1,22-Hentriacontadiene	114.1, C-1 139.3, C-2 129.9, C-22 and C-23
(2*Z*,22*Z*)-2,22-Hentriacontadiene	123.6, C-2 130.9, C-3 129.9, C-22 and C-23
(15*E*,22*E*)-1,15,22-Heptatriacontatriene	114.1, C-1 139.3, C-2 130.3 and 130.4, C-15, C-16, C-22 and C-23
1-Heptadecene	114.1, C-1 139.3, C-2
(*Z*)-9-Heneicosene	129.9, C-9 and C-10
(*E*)-7-Tetradecene	130.4, C-7 and C-8
(*Z*)-2-Heptene	123.6, C-2 130.9, C-3
(*E*)-2-Heptene	124.6, C-2 131.7, C-3

The mass spectra of the DMDS adducts indicate that the major C_{31} diene and two of the minor C_{31} isomers have a double bond at C-22, with ions at *m/z* 173 (D^+) and 399 [$(C - 48)^+$] (Table 6). The position of the second double bond in the major isomer is confirmed as C-2 from ion *m/z* 75 (A^+) and as C-1 in one of the minor C_{31} isomers from ion *m/z* 61 (A^+) (Tables 1 and 6). Thus, the major C_{31} diene in *E. huxleyi* (CCAP 920/2) is (2*Z*,22*Z*)-2,22-hentriacontadiene (Scheme 2B) and the second-most abundant is (22*Z*)-1,22-hentriacontadiene, identical to the major component in *I. galbana* (Table 1, Fig. 1 and Scheme 2A). The adduct mass spectrum of the third-most abundant C_{31} diene possesses an ion at *m/z* 89 $(A)^+$, indicating a double bond at C-3. The least abundant C_{31} diene has double bonds in the C-2 and C-24 positions, indicated by ions *m/z* 75 (A^+), 145 (D^+), 451 [$(B - 94)^+$] and 427 [$(C - 48)^+$] (Table 6), as has the C_{33} alkadiene indicated by ions *m/z* 75 (A^+) , 173 (D^+), 479 [$(B - 94)^+$] and 427 [$(C - 48)^+$] (Table 6).

Following the GC–MS studies of the DMDS adducts, we re-analyzed the ^1H NMR spectrum of the hydrocarbon fraction with a view to confirming the structure of 3,22-hentriacontadiene and determining the geometry of the C-3 double bond. Comparison of a minor triplet at 0.952 ppm (J = 7.6 Hz), representing 1-H_3, with those in (*Z*)-3-heptene and (*E*)-3-heptene, indicates *cis* stereochemistry as the result of a subtle difference in chemical shift. In (*Z*)-3-heptene this is at 0.955 (*t, J* = 7.5 Hz) and in (*E*)-3-heptene at 0.963 (*t, J* = 7.5 Hz). Therefore, this isomer is (3*Z*,22*Z*)-3,22-hentriacontadiene (Scheme 2C).

Emiliania huxleyi *(VAN 556).* The alkene distribution of *E. huxleyi* (VAN 556) is dominated by a C_{37} triene (Table 1, Fig. 1) together with lesser abundances of a C_{38} triene and a C_{31} diene (Table 1). The ^1H NMR spectrum of the triene displays an intense resonance at 1.25 ppm (CH_2 groups), a terminal alkyl methyl at 0.88 ppm, and illustrates the presence of a terminal double bond with resonances at 4.92, 4.99, and

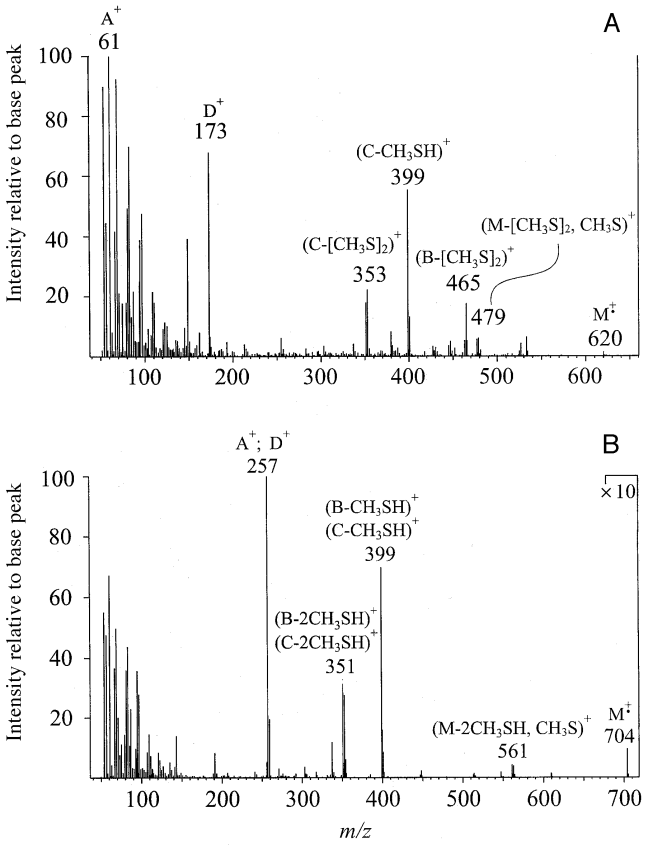

FIG. 4. Mass spectra of dimethyl disulfide (DMDS) adducts of (A) (22*Z*)-1,22-hentriacontadiene from *I. galbana* (CCAP 927/14) and (B) (15*E*,22*E*)-1,15,22-heptatriacontadiene from diimide reduction of major C_{37} triene in *E. huxleyi* (VAN 556). For abbreviations see Figure 1, Scheme 1, and Tables 6, 7.

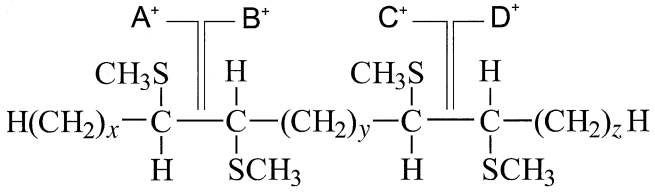
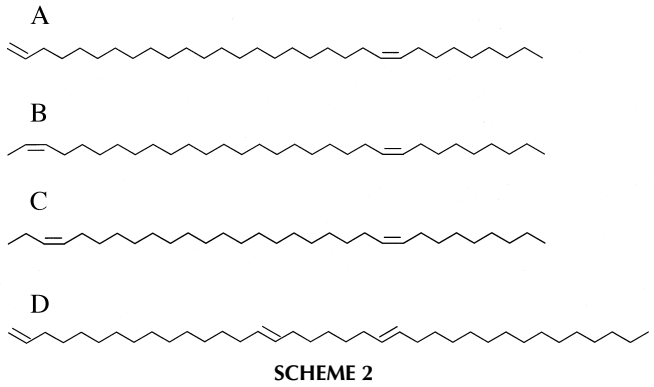
5.81 ppm (Table 2). A second-order multiplet, representing four hydrogens and hence two double bonds in the middle of the hydrocarbon chain, is observed at 5.38 ppm. The chemical shift is in accord with a *trans* double bond (Table 3), although a clear comparison of the splitting pattern with that observed for the vinylic hydrogens in (*E*)-7-tetradecene was not immediately obvious. Zero-filling of the free induction decays and application of a window function for resolution enhancement produced a significantly improved splitting pattern comparable with that seen in (*E*)-7-tetradecene and markedly different fron that derived from (*Z*)-9-heneicosene processed in the same manner (Fig. 6).

The *trans* nature of the internal double bonds was confirmed by analyzing the chemical shifts of the allylic hydrogens. Separate multiplets were observed for the hydrogens allylic to the terminal double bond (2.03 ppm), as observed in 1-heptadecene, and for those allylic to the internal double bonds (1.96 ppm), as observed in (*E*)-7-tetradecene (Fig. 3).



SCHEME 1



SCHEME 2

^{13}C NMR chemical shifts for the sp^2 hybridized carbons (Table 5) also accord with a terminal double bond (114.1 and 139.3 ppm) and two midchain *trans* double bonds (130. 3 and 130.4 ppm).

Although the DMDS-adducted C_{37} triene can be observed by high-temperature GC–MS, the instability of the high-mass fragment ions (>*m/z* 655) did not allow the molecular ion or

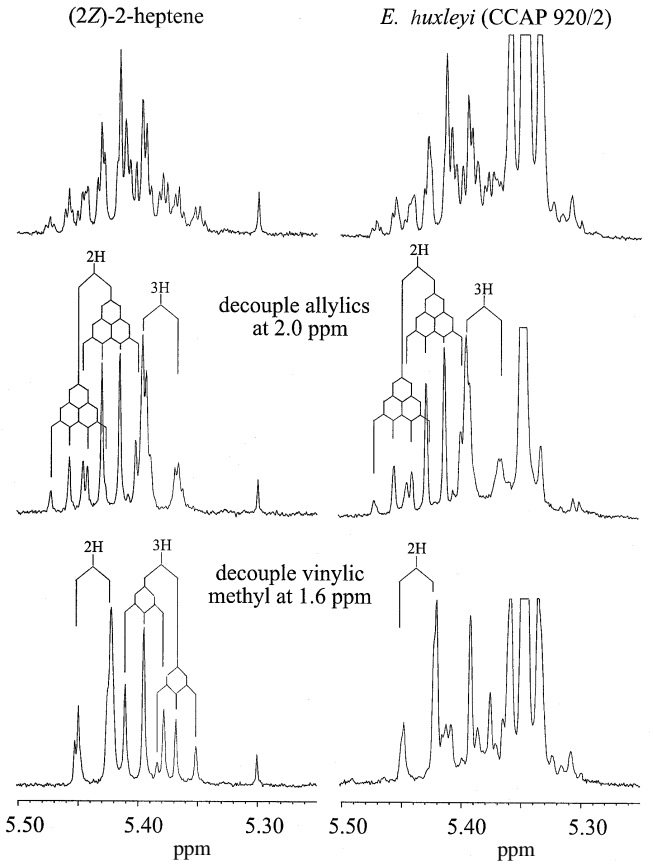


FIG. 5. Partial ^1H NMR spectra and decoupled spectra comparing the vinylic resonances in the *E. huxleyi* (CCAP 920/2) hydrocarbons with those in (*Z*)-2-heptene. For abbreviations see Figure 2.

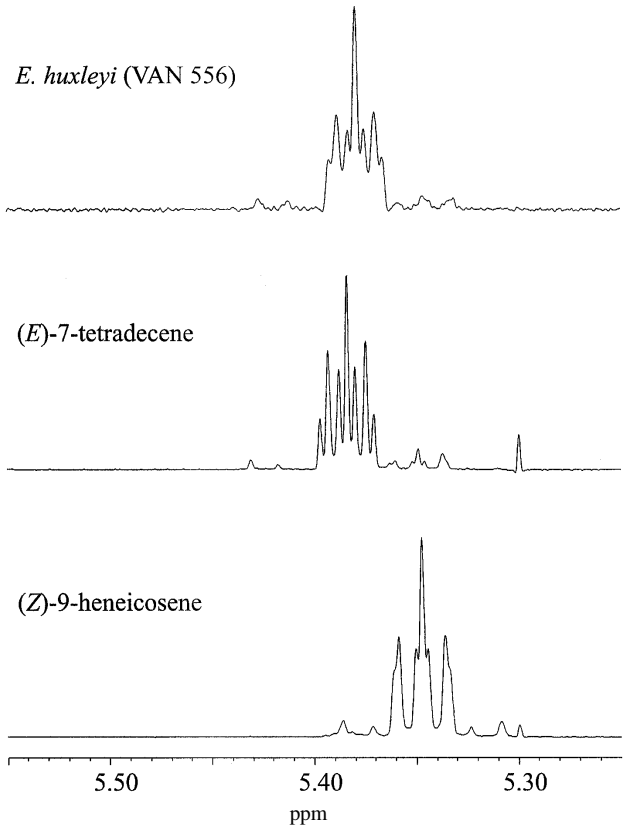

FIG. 6. Partial resolution-enhanced ^{1}H NMR spectra comparing the vinylic resonances in the *E. huxleyi* (VAN 556) hydrocarbons with those in two alkene standards. For abbreviations see Figure 2.

certain key fragment ions to be observed. Therefore, the sample was examined by desorption chemical ionization using ammonia as collision gas, giving a pseudo-molecular ion at *m/z* 814 (MNH_4^+) corresponding to a molecular weight for the DMDS-adducted C_{37} alkatriene of 796 Da.

An aliquot of the hydrocarbon fraction was reduced with diimide (13–15) in order to assign the positions of the internal double bonds, an approach used successfully in the structural elucidation of the acyclic triterpenoid botryococcene (16). Although the reduction is not entirely chemoselective, the product mixture comprises predominantly hydrocarbons derived from terminal double bond reduction. The reduced mixture was subsequently adducted with DMDS and analyzed by GC–MS. The major adducted diene has a spectrum with principal fragment ions at *m/z* 704 (M^+), 257(A^+) and (D^+), 351 [$(B - 96)^+$; i.e., $B - 2CH_3SH$] and [$(C - 96)^+$], 399 [$(B - 48)^+$] and [$(C - 48)^+$] (Table 7; Fig. 4B) indicating a C_{37} alkadiene with double bonds located symmetrically at C-15 and C-22, giving the structure of the major triene as (15*E*,22*E*)-1,15,22-heptatriacontatriene (Scheme 2D). This approach also showed the internal double bond positions of the reduced C_{38} alkatriene to be at C-15 and C-22 (Table 7). It is likely that the geometry of the double bonds in this component is *trans*, by analogy with the C_{37} alkatriene.

The minor C_{31} diene component is (22*Z*)-1,22-hentriacontadiene, assigned by retention time comparison with the component derived from *I. galbana* and from mass spectral interpretation of the fragmentation of the DMDS adduct.

Biosynthetic relationships. The *cis* geometry and the n-9 (ω9) position of unsaturation in the most abundant dienes (Table 1) is strong evidence that these lipids derive from (*Z*)-9-octadecenoic acid (oleic acid), followed by chain elongation and decarboxylation, as has been elucidated for the chlorophyte alga *Botryococcus braunii* (17). The diene isomers with n-7 (ω7) unsaturation may derive from elongation and decarboxylation of (*Z*)-7-hexadecenoic acid, though such a pathway is still to be demonstrated.

In contrast, the positions and geometry of nonterminal unsaturation in the C_{37} triene (and by analogy the C_{38} triene) correspond to those in the C_{37} (and C_{38}) haptophyte alkadienone (6), so these components likely share a common biosynthesis. The full details of such a pathway are still unknown and should be determined. However, whatever this pathway may be, it is highly probable that in haptophytes the long-chain alkatrienes and the co-occurring alkadienes have distinct biosynthetic pathways.

ABSTRACT: The fatty acid composition of a *Pseudomonas* sp. *(Alteromonas)* and its host, the dinoflagellate *Ostreopsis lenticularis,* vectors in ciguatera fish poisoning, has been studied. The major fatty acids in *O. lenticularis* were 16:0, 20:5n-3, and 22:6n-3, but 18:2n-6, 18:3n-3, and 18:n-3 were also identified. In contrast to other dinoflagellates, 18:5n-3 was not detected in *O. lenticularis*. Even-chain fatty acids such as 9-16:1, 11-18:1, and 13-20:1 predominated in the *Pseudomonas* sp. from *O. lenticularis,* but 16–20% of (*E*)-11-methyl-12-octadecenoic acid was also identified. The chirality of the latter was confirmed by total synthesis (28% overall yield) starting from oxacyclotridecan-2-one. The fatty acid compositions of two other *Pseudomonas* species, from the palytoxin-producing zoanthids *Palythoa mamillosa* and *P. caribdea,* were also studied and were similar to that of the *Pseudomonas* sp. from *O. lenticularis*. The possibility of using some of these fatty acids as chemotaxonomic lipids in identifying marine animals that consume toxic dinoflagellates or zoanthids is discussed.
Lipids 33, 627–632 (1998).

Ostreopsis lenticularis (Dinophyceae) Fukuyo 1981 is a toxic benthic dinoflagellate partially responsible for the production of ciguatoxins directly related to ciguatera fish poisoning (1). Of the different bacterial flora (e.g., *Agrobacterium*, *Alcaligenes*, *Pseudomonas*, and *Vibrio*) associated with *O. lenticularis*, bacteria from the genus *Pseudomonas* (*Alteromonas)* were required for the development of toxicity in cultured *Ostreopsis* (2). Palytoxin, one of the most potent nonprotein toxins known, is produced by the zoanthids *Palythoa caribdea* and *P. mamillosa* (3,4). Palytoxin hemolytic activity has been detected in extracts of the dinoflagellates *O. lenticularis*, *Gambierdiscus toxicus*, and *Prorocentrum concavum,* as well as in bacteria associated with *O. lenticularis* grown in pure culture (5). Similarly, palytoxin hemolytic activity was detected in extracts of bacteria from the genus *Pseudomonas* isolated from the Caribbean zoanthids *P. caribdea* and *P. mamillosa* (6). There is no report in the literature on the fatty acid composition of *O. lenticularis* nor that of its most important symbiont, the unusual bacterium *Pseudomonas* sp. (2). Therefore, herein we report the fatty acid composition of both *O. lenticularis* and its associated bacterium *Pseudomonas* sp. In addition, we report the fatty acid composition of two other bacterial strains, isolated from the palytoxin producing *Palythoa* species *P. caribdea* and *P. mamillosa*, which we demonstrate share a similar fatty acid profile as the *Pseudomonas* sp. from *O. lenticularis*. This fatty acid analysis is important since the idea of using specific signature fatty acids for monitoring toxic dinoflagellate blooms, such as the ones implicated in ciguatera fish poisoning, is quite attractive.

The fatty acid composition of several toxic dinoflagellates, such as *Gymnodinium catenatum*, has been reported before (7,8). The principal fatty acids in dinoflagellates are considered to be 16:0, 20:5n-3, and 22:6n-3, followed by 14:0, 16:1n-7, and 18:2n-6. In addition, a rare 18:5n-3 fatty acid, considered by many as a characteristic fatty acid of dinoflagellates, has also been reported (7).

MATERIALS AND METHODS

General experimental procedures. Fatty acid methyl esters were analyzed using a gas chromatograph equipped with a fused silica nonpolar capillary column (30 m × 0.32 mm i.d.) containing either methyl silicone (SE-54; Supelco Inc., Bellefonte, PA) or poly(dimethylsiloxane) (SPB-1; Supelco Inc.) with He as carrier gas. Analyses were performed using the following conditions: initial temperature, 130°C; rate of increase, 3°C/min; final temperature, 260°C. Samples were also analyzed by gas chromatography–mass spectrometry (GC/MS) at 70 eV equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane crosslinked with 5% phenyl methylpolysiloxane. High-

resolution mass spectral data were recorded in a VG AutoSpec high-resolution mass spectrometer.

Culturing of O. lenticularis. *Ostreopsis lenticularis* Fukuyo 1981 was isolated from the coastal waters of southwest Puerto Rico in November of 1989 and has been kept in continuous clonal culture since that time (1). Erd-Schrieber (ES) medium was used for the maintenance of these cultures (9). Clonal cultures of *O. lenticularis* were established by carefully passing individual cells isolated from the surfaces of field-sampled macroalgae through a series of filtered seawater washes using sterile Pasteur pipettes and depression slides. After four cell washings, an individual cell was placed in a test tube with 5 mL of sterile seawater and 25% ES medium. After approximately 3 wk, the dinoflagellate cells were microscopically checked and transferred to 25 mL of sterile seawater and 50% ES media. Following an additional 3 wk, these cultures were transferred to 100 mL of seawater and 100% ES media. The process of increasing volume was then gradually continued until the desired volume for maintaining the clonal culture was reached. For maintenance purposes, these cultures were continuously transferred to fresh media after 15 to 20 d of growth. Dinoflagellates, harvested from their respective suspensions by filtration (glass fiber filters; Gelman, Fisher Scientific, Cayey, Puerto Rico), were also extracted in distilled methanol and the extracts subsequently evaluated for their toxicity in white Swiss mice using reported procedures (10).

Isolation and identification of associated bacteria. Sterile samples of the harvested dinoflagellate cell suspensions were serially diluted and streaked on Zobell agar plates for aerobic incubation at 23–25°C. Zobell blood agar was used for the growth of fastidious bacteria in aerobic and anaerobic conditions. Isolates were identified at least to generic level (11,12). Characterization was done by routine biochemical and antibiotic tests modified for marine bacteria. The API 20E system (Analytab Products, Plainview, NY) was also used for characterization, as recommended by MacDonell *et al.* (13) for marine isolates. The microorganism associated with the toxicity was identified as a *Pseudomonas* sp. (10).

Palythoa *associated bacteria.* Zoanthid species *P. caribdea* and *P. mamillosa* were sampled on shallow reef flats at La Parguera, on the southwest coast of Puerto Rico. Samples for bacteriological analyses were obtained aseptically in the field using sterile bags and gloves. Zoanthid samples were returned to the laboratory, cleaned of foreign material, rinsed with sterile artificial water (calcium and magnesium free), and homogenized. Homogenized samples were serially diluted, streaked on marine agar (Difco, Fisher Scientific) enriched with 0.1% starch (MA+), and incubated aerobically at 27°C. Colony isolation was started after 48 h of incubation and isolates stored on MA+ slants for subsequent identification. Isolated marine bacteria obtained from zoanthid homogenates were identified to genus and when possible to species using standard biochemical tests in conjunction with Gram and flagellar stains, motility, antibiotic susceptibility, and the API 20E system as described above (11–13). Both *P. caribdea* and *P. mamillosa* shared associated bacterial strains from the genus *Pseudomonas* sp. Analysis of the *Palythoa*-like hemolytic activity of extracts from both of these associated bacterial strains indicated that they produced palytoxin when grown in pure culture in the absence of their *Palythoa* hosts.

The presence of toxic, hemolytic activity in the extracts of cultured zoanthid-associated bacterial flora was detected using a hemolysis neutralization assay (14). Extracts were tested for their hemolytic activity in microtiter Elisa plates preblocked with sterile filtered 1% bovine serum albumin in a phosphate buffered saline solution. Plates inoculated with white Swiss mice red cells in the presence and absence of extracts being tested were covered and incubated at 37°C for 6 h. Results of the hemolysis assay were assessed visually.

Fatty acid isolation. The biomass thus obtained from either *O. lenticularis* (300–600 mg) and the *Pseudomonas* bacterial strains (100–120 mg) was separated by centrifugation of the cultured liquid (6000 r.p.m. for 20 min), and the lipids were extracted with chloroform/methanol (1:1, vol/vol) affording 30–50 mg of total lipids, which were methylated with 1.0 M HCl in methanol, resulting in typically 3–5 mg of fatty acid methyl esters.

Permanganate/periodate oxidation. A stock oxidant solution of sodium metaperiodate (10 mM) and $KMnO_4$ (2.5 mM) in H_2O was prepared. This solution (1 mL) together with 1 mL K_2CO_3 solution (180 mM) was added to the methyl esters (1 mg) in *t*-butanol (2 mL), and the mixture was shaken thoroughly at room temperature for 1 h. At the end of this time, the reaction mixture was acidified with one drop of concentrated H_2SO_4, and excess oxidant was destroyed with $NaHSO_3$. The reaction mixture was extracted thoroughly with ether (3×4 mL), the organic layer was dried over Na_2SO_4, and the ether removed in a stream of N_2. The acids thus obtained were methylated with 1.0 M HCl/MeOH for GC analysis.

2-Methyldodecanedioic acid dimethyl ester. GC/MS *m/z* (relative intensity) M^+ 272(0.1), 241(3), 227(1), 213(9), 199(7), 185(12), 167(6), 153(10), 126(10), 112(36), 98(34), 88(100), 83(23), 74(24), 69(36), 57(25), 55(63).

3-Methyloxacyclotridecan-2-one. To a solution of oxacyclotridecan-2-one (1.10 g, 5.6 mmol) in 10 mL of tetrahydrofuran at −78°C was added dropwise a solution of lithium diisopropylamide (LDA) (5.8 mmol) in 5 mL of tetrahydrofuran prepared from diisopropylamine (0.8 mL, 5.8 mmol) and *n*-butyllithium (1.2 mL, 5.8 mmol) in hexane. After the mixture was stirred at −78°C for 20 min, methyl iodide (0.35 mL, 5.6 mmol) was added, and the reaction mixture was stirred at −78°C for 2 h. The reaction mixture was quenched with a saturated NH_4Cl solution (20 mL), and extracted with benzene (3×30 mL). The organic phase was successively washed with a 0.1 M HCl solution (1×10 mL), a saturated $NaHCO_3$ solution (1×30 mL), a saturated NaCl solution (1×50 mL), and finally dried over Na_2SO_4. After rotoevaporation, 0.95 g (79% yield) of a colorless oil was obtained. Infrared (IR) (neat) υ_{max} 2927, 2861, 1724, 1465, 1350, 1230, 1169, 1057 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz) δ 4.28 (1H, *m*, H-13), 4.01 (1H, *m*, H-13), 2.51 (1H, *m*, H-3), 1.62 (4H, *m*, CH_2),

1.28–1.40 (14H, *m*, CH_2), 1.13 (3H, *d, J* = 6.9 Hz, CH_3); ^{13}C nuclear magnetic resonance (NMR) ($CDCl_3$, 75 MHz) δ 177.0 (*s*, C-2), 64.4 (*t*, C-13), 39.7 (*d*, C-3), 33.7 (*t*), 27.5 (*t*, C-12), 26.5 (*t*), 26.5 (*t*), 25.5 (*t*), 25.2 (*t*), 24.8 (*t*), 24.1 (*t*), 17.6 (*q*, CH_3); GC/MS *m/z* (relative intensity) M^+ 212(4), 194(4), 166(2), 151(3), 139(9), 138(17), 126(7), 112(17), 110(16), 98(33), 97(35), 83(61), 74(85), 69(62), 55(100); high-resolution mass spectrometry calcd for $C_{13}H_{24}O_2$ 212.1776, found 212.1769.

12-Hydroxy-2-methyldodecanal. To 3-methyloxacyclotridecan-2-one (0.56 g, 2.6 mmol), in 20 mL dry toluene at −78°C, and under N_2, 3 mL diisobutylaluminum hydride (1.0 M, 3 mmol) was slowly added over a 10-min period. The reaction mixture was stirred at −78°C for 2 h, subsequently quenched with a saturated NH_4Cl solution, and finally stirred for 1 h at room temperature. After this time the reaction mixture was filtered under vacuum, and washed with excess ether. The organic washings were evaporated *in vacuo* to give 12-hydroxy-2-methyldodecanal (0.48 g, 2.2 mmol) for an 85% yield. IR (neat) υ_{max} 3600–3100 (OH), 2940, 2856, 2724, 1728 (CHO), 1468, 1168, 1060 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz) δ 9.61 (1H, *d, J* = 2 Hz, CHO), 3.60 (2H, *t, J* = 6.6 Hz, H-12), 2.30 (1H, *m*, H-2), 1.67–1.51 (4H, *m*, CH_2), 1.40–1.20 (15H, *m*, CH_2), 1.07 (3H, *d, J* = 6.9 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 205.8 (*s*, C-1), 63.0 (*t*, C-12), 46.3 (*d*, C-2), 32.8 (*t*), 30.6 (*t*), 29.5 (*t*), 29.5 (*t*), 29.4 (*t*), 26.9 (*t*), 25.7 (*t*), 13.3 (*q*, CH_3); GC/MS *m/z* (relative intensity) M^+ 214(1), 172(1), 138(2), 125(1), 111(4), 97(14), 83(21), 69(31), 58(100), 55(58).

(Z)- and (E)-11-methyl-12-octadecen-1-ol. To a stirred suspension of 1-hexyltriphenylphosphonium bromide (0.41 g, 0.96 mmol) in 10 mL tetrahydrofuran was added 0.4 mL of *n*-butyllithium (2.5 M, 0.96 mmol) in hexane at 0°C over 10 min. The reaction mixture was stirred for an additional 10 min at 0°C before adding dropwise 12-hydroxy-2-methyldodecanal (0.20 g, 0.95 mmol) in 5 mL dry tetrahydrofuran. After 2 h, the reaction was quenched with a saturated NH_4Cl solution (15 mL), and the reaction mixture was extracted with ether (3 × 50 mL). The organic phase was washed with a saturated NaCl solution (1 × 20 mL), dried over $MgSO_4$, and concentrated *in vacuo*. The crude product was purified through silica gel column chromatography eluting with hexane/ether (8:2, vol/vol), which finally afforded 0.18 g (69% yield) of a 9:1 ratio of (*Z*)- and (*E*)-11-methyl-12-octadecen-1-ol as a colorless oil. Spectral data for the (*Z*) isomer is presented below. IR (neat) υ_{max} 3600–3150 (OH), 2999, 2951, 2920, 2850, 1466, 1383, 1067, 725 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz) δ 5.29 (1H, *m, J_{cis}* = 11 Hz, H-13), 5.09 (1H, *brt*, J_{cis} = 11 Hz, H-12), 3.63 (2H, *t, J* = 6.5 Hz, H-1), 2.40 (1H, *m*, H-11), 2.00 (2H, *m*, H-14), 1.54 (2H, *m*, H-2), 1.40–1.20 (20H, *m*, CH_2), 0.90 (3H, *d, J* = 6.6 Hz, CH_3), 0.89 (3H, *brt, J* = 6.8 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 136.4 (*d*, C-12), 128.3 (*d*, C-13), 63.0 (*t*, C-1), 37.6 (*t*), 32.8 (*t*), 31.6 (*d*, C-11), 31.5 (*t*), 29.8 (*t*), 29.6 (*t*), 29.4 (*t*), 27.5 (*t*), 27.4 (*t*), 25.7 (*t*), 22.5 (*t*), 21.4 (*q*, C-19), 14.0 (*q*, C-18); GC/MS *m/z* (relative intensity) M^+ 282(15), 264(1), 250(1), 183(5), 165(5), 140(28), 125(28), 109(21), 97(30), 95(33), 83(61), 69(98), 67(38), 57(45), 55(100).

(Z)- and (E)-11-methyl-12-octadecenoic acid. To a solution of 11-methyl-12-octadecen-1-ol (0.11 g, 0.39 mmol) in 5 mL of dry dimethyl formamide was added a solution of pyridinium dichromate (1.56 g, 4.15 mmol) in 2 mL of dry dimethyl formamide. The reaction mixture was stirred at room temperature for 20 h, poured into 50 mL of H_2O, and extracted with ether (3 × 70 mL). The ethereal layers were combined and washed with a solution of NH_4Cl (30 mL), dried over $MgSO_4$, and concentrated *in vacuo*. The resulting oil was purified by column chromatography eluting first with hexane/ether (8:2, vol/vol) and finally with ether to give 0.07 g (62%) of a 9:1 mixture of (*Z*)- and (*E*)-11-methyl-12-octadecenoic acid. Spectral data for the (*Z*) isomer is presented below. IR (neat) υ_{max} 3003, 2965, 2923, 2851, 1714, 1461, 1258, 1101, 1017 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz) δ 5.34–5.24 (1H, *m, J_{cis}* = 10.5 Hz, H-13), 5.10 (1H, *brt, J_{cis}* = 10.5 Hz, H-12), 2.40 (1H, *m*, H-11), 2.34 (2H, *t, J* = 7.5 Hz, H-2), 2.00 (2H, *m*, H-14), 1.62 (2H, *m*, H-3), 1.29–1.20 (20H, *m*, CH_2), 0.90 (3H, *d, J* = 6.6 Hz, CH_3), 0.86 (3H, *brt, J* = 6.8 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 178.3 (*s*, C-1), 136.3 (*d*, C-12), 128.2 (*d*, C-13), 37.4 (*t*), 33.7 (*d*, C-11), 31.5 (*t*), 31.4 (*t*), 29.7 (*t*), 29.6 (*t*), 29.5 (*t*), 29.4 (*t*), 29.3 (*t*), 29.1 (*t*), 28.9 (*t*), 27.4 (*t*), 27.3 (*t*), 24.6 (*t*), 22.4 (*q*, C-19), 13.9 (*q*, C-18); GC/MS *m/z* (relative intensity) M^+ 296(4), 264(1), 197(3), 179(6), 140(19), 125(20), 112(9), 97(24), 95(11), 83(48), 69(92), 67(22), 57(37), 55(100).

RESULTS

Fatty acid composition of O. lenticularis. The fatty acid composition of *O. lenticularis*, as well as that of its associated *Pseudomonas* sp., is presented in Table 1. Fatty acids accounted for 2–3% of the extracted biomass. As expected, the major fatty acids in *O. lenticularis* were 16:0, 20:5n-3, and 22:6n-3, which accounted for more than 50% of its fatty acid composition. Considerable amounts (23%) of the polyunsaturated fatty acids 18:2n-6, 18:3n-3 and 18:4n-3 were also identified. In contrast to other dinoflagellates (7), the fatty acid 18:5n-3 was not detected in *O. lenticularis*. More than 99% of the fatty acids from *O. lenticularis* were even-chain fatty acids.

Fatty acid composition of Pseudomonas *sp*. Even-chain monounsaturated fatty acids predominated in the *Pseudomonas* sp. from *O. lenticularis* (Table 1). For example, the biosynthetically related monounsaturated fatty acids 9-16:1, 11-18:1, and 13-20:1 accounted for more than 54% of the total fatty acids from this strain. The (*Z*)-11-octadecenoic acid was the most abundant monounsaturated fatty acid (40%), but small amounts of (*E*)-11-octadecenoic acid were also identified. These acids were characterized as methyl esters by GC/MS, and the double-bond positions were determined by dimethyl disulfide derivatization (15), as well as by $KMnO_4/NaIO_4$ oxidation.

The unusual methyl-branched fatty acid 11-methyl-12-oc-

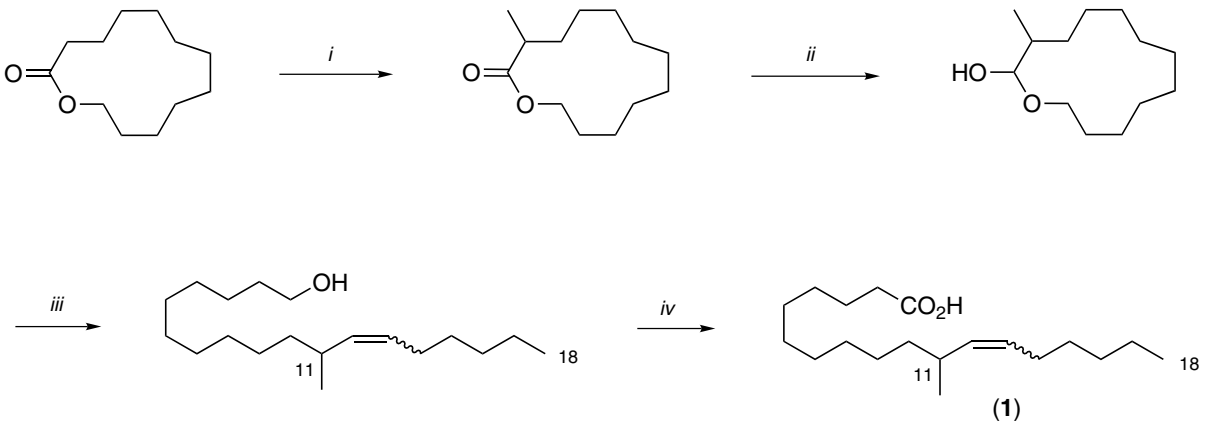
[a]Isolated from *O. lenticularis*.
[b]Isolated from *P. mamillosa*. Traces of 13-18:1 and 19:0 were also detected.
[c]Isolated from *P. caribdea*. Traces of 11-16:1 was also detected.

tadecenoic acid (**1**, Scheme 1) was also identified in the *Pseudomonas* sp. from *O. lenticularis* by a combination of GC retention times of the methyl ester [equivalent chain length (ECl) = 18.06], MS, catalytic hydrogenation, and dimethyl disulfide derivatization as we previously described for this same acid from a *Vibrio* bacterium (16). In this work, the double-bond position at C-12 in **1** was further confirmed by $KMnO_4/NaIO_4$ oxidation followed by esterification. Methyl 11-methyl-12-octadecenoate cleaved under these conditions, and after esterification, to 2-methyldodecanedioic acid dimethyl ester and methyl hexanoate. The mass spectrum of 2-methyldodecanedioic acid dimethyl ester also confirmed the methyl substitution at C-11 in **1**, since it displayed a base peak at *m/z* 88 (McLafferty rearrangement), resulting from an ad-



Reagents and conditions: *(i)* LDA, CH_3I, THF, –78°C (79%); *(ii)* DIBAL-H, toluene, –78°C, (85%); *(iii)* $Br^-Ph_3P^+(CH_2)_5CH_3$, *n*-BuLi, THF, 0°C (69%); *(iv)* PDC, DMF, rt (62%).

SCHEME 1

ditional 2-methyl substitution in one of the α carbons of the fragmentation product.

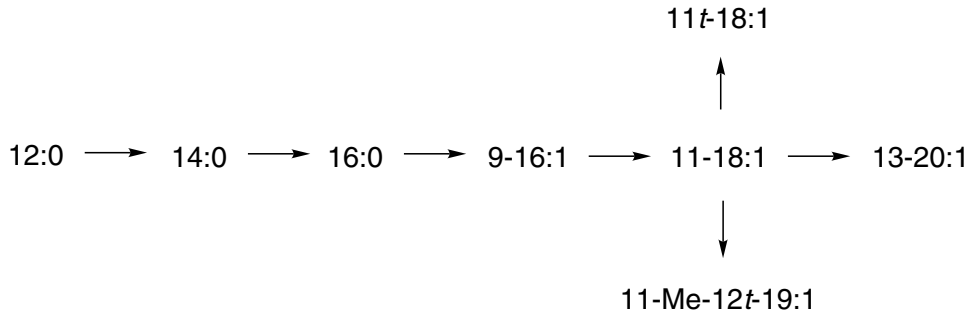
While all of the above data confirm 11-methyl-12-octadecenoic acid (**1**) as the most probable structure, the double-bond stereochemistry, i.e., *Z* or *E*, still needed to be determined. The 11-methyl-12-octadecenoic acid (**1**) was initially reported in *Byrsocarpus coccineus* seed oil (17), and more recently in *Mycobacterium fallax* (18), and in a *Vibrio alginolyticus* (16). In the aforementioned bacteria, the C-12 double-bond stereochemistry was not defined, but in *B. coccineus* it was determined as *E* (17). In order to unequivocally determine the double-bond stereochemistry in our 11-methyl-12-octadecenoic acid (**1**), as well as to establish reference ECL values for the methyl esters of the *Z* and *E* isomers of **1**, we undertook the first total synthesis of 11-methyl-12-octadecenoic acid (**1**, Scheme 1). Our synthetic scheme, which is probably the shortest possible for this compound (four steps), was planned to afford the *Z* isomer as the main product, but enough *E* isomer should be formed so as to permit careful GC/MS studies. The synthesis started with commercially available oxacyclotridecan-2-one, which was α-methylated with lithium diisopropylamide and methyl iodide in a 79% yield. Reduction of 3-methyloxacyclotridecan-2-one with diisobutylaluminum hydride in toluene at −78°C afforded, in an 85% yield, initially a lactol which opened to 12-hydroxy-2-methyldodecanal. The aldehyde was subsequently coupled, in a Wittig reaction, with 1-hexyltriphenylphosphonium bromide and *n*-butyllithium, affording (*Z*)- and (*E*)-11-methyl-12-octadecen-1-ol in a 9:1 ratio, respectively. Final oxidation with pyridinium dichromate, in dimethyl formamide, afforded a mixture of (*Z*) and (*E*)-11-methyl-12-octadecenoic acid (**1**) in a 62% yield. The methyl esters of **1** were then prepared for comparative GC studies. Careful nonpolar capillary GC coinjection of synthetic methyl (*Z*)-11-methyl-12-octadecenoate (ECL = 17.92) and methyl (*E*)-11-methyl-12-octadecenoate (ECL = 18.06) with the fatty acid methyl ester mixture from the bacterium *Pseudomonas* sp. established the natural acid as (*E*)-11-methyl-12-octadecenoic acid. It is interesting to point out that methyl (*Z*)-11-methyl-12-octadecenoate elutes before methyl octadecanoate (18:0) in nonpolar capillary GC. These retention times are important for future reference inasmuch as fatty acid methyl ester analyses are frequently used, as an aid, in bacterial identification.

Fatty acid composition of bacteria from Palythoa. The fatty acid composition of two unusual strains of *Pseudomonas* sp., isolated from the zoanthids *P. mamillosa* and *P. caribdea* is also presented in Table 1. Fatty acids from these *Pseudomonas* species also accounted for 2–3% of the extracted biomass. The fatty acid composition of *P. caribdea* has been reported (19). A striking similarity in the fatty acid composition of these two strains to the *Pseudomonas* sp. from *O. lenticularis* was observed. In the two *Pseudomonas* from *Palythoa,* the monounsaturated fatty acids 9-16:1, 11-18:1, and 13-20:1 were also particularly abundant (64–58%), while the saturated fatty acids 14:0, 16:0, and 18:0 accounted for another significant amount (14–22%) of the total fatty acid composition. The only significant difference between these two *Pseudomonas* strains is that the bacterium from *P. caribdea* had more 12:0 and less 18:0, as well as some 9,12-18:2, as compared to the *Pseudomonas* sp. from *P. mamillosa.* (Table 1). A very interesting finding is that both strains also contained (*E*)-11-methyl-12-octadecenoic acid (16–22%), which was characterized as we described above.

DISCUSSION

There are several important considerations that can be drawn from this study. One interesting conclusion is that *Pseudomonas* associated with toxin-producing marine organisms, such as *O. lenticularis* and *Palythoa*, seem to have a similar fatty acid profile, with a fatty acid biochemistry centered around (*Z*)-11-octadecenoic acid (Scheme 2). The first total synthesis of 11-methyl-12-octadecenoic acid, a key fatty acid in these bacteria, was also accomplished. GC retention times of methyl (*Z*)- and (*E*)-11-methyl-12-octadecenoate are presented as reference for further literature comparisons. The fatty acid profile of *O. lenticularis*, important vector in ciguatera fish poisoning in this area of the Caribbean, is also presented for the first time. While, in general, *O. lenticularis* has a similar fatty acid composition comparable to most toxic dinoflagellates, it is devoid of the polyunsaturated fatty acid 18:5n-3.

The (*E*)-11-methyl-12-octadecenoic acid probably originated, in these *Pseudomonas*, from 11-octadecenoic acid, *via S*-adenosylmethionine methylation, as was demonstrated before for *M. fallax* (18). Likewise, the presence of (*E*)-11-oc-



SCHEME 2

tadecenoic acid in these bacteria is probably the result of a *cis-trans* isomerization (20). Whether (*Z*)-11-octadecenoic acid or (*E*)-11-octadecenoic acid, or both, are precursors to (*E*)-11-methyl-12-octadecenoic acid is still a matter of speculation.

Some caution, however, should be taken concerning the identification of the bacterial strains associated with *O. lenticularis* and the two *Palythoa* species. The conventional microbiological techniques employed are frequently imprecise when used to identify marine bacteria. As noted in the Results section, the three strains examined in this study were found to be from the genus *Pseudomonas*. The precise identification of these strains requires further genetic analyses, and such studies are now in progress. Irrespective of this, all three strains produced toxic material when grown in pure culture and have the same signature fatty acids.

Whether we can use a simple fatty acid methyl ester analysis to verify the transmission of toxins from *O. lenticularis* to ciguatoxic fish remains to be seen. Perhaps, and even more important, is the possibility of using some of these fatty acids as biomarkers for toxicity in marine microalgae and bacteria. We have presented here a basis for such a comparison, but direct identification of some signature fatty acids, such as (*E*)-11-methyl-12-octadecenoic acid, in ciguatoxic fish still remains to be done. One particular problem is the small amounts of *O. lenticularis*, and its symbiotic bacteria, in fish. Work is in progress elucidating the fatty acids of toxin-producing bacteria in the marine environment.

Epoxidation Reactions of Unsaturated Fatty Esters with Potassium Peroxomonosulfate

Marcel S.F. Lie Ken Jie* and Mohammed Khysar Pasha

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong

ABSTRACT: Epoxidation of the double bond in methyl oleate, octadec-11*E*-en-9-ynoate, ricinoleate (12-hydroxy-octadec-9*Z*-enoate), *iso*-ricinoleate (9-hydroxy-octadec-12*Z*-enoate), and 12-oxo-octadec-9*Z*-enoate with potassium peroxomonosulfate (oxone, 2 $KHSO_5.KHSO_4.K_2SO_4$) in the presence of trifluoroacetone or methyl pyruvate gave the corresponding monoepoxy derivatives. Reaction of Oxone® with methyl linoleate and octadeca-9*Z*,11*E*-dienoate furnished the corresponding diepoxystearate derivative. Methyl 9,12-dioxo-octadec-10*Z*-enoate was obtained when a C_{18} furanoid fatty ester (methyl 9,12-epoxy-9,11-octadecadienoate) was treated with Oxone®. The yield of these reactions was very high (85–99%), and the epoxy derivatives were readily isolated by solvent extraction. The products were identified by spectroscopic methods.
Lipids 33, 633–637 (1998).

Various oxidants, such as *m*-chloroperoxybenzoic acid (*m*-CPBA), magnesium monoperoxyphthalate hexahydrate (MMPP) and urea-hydrogen peroxide (UHP), are used to oxidize olefinic compounds to the corresponding epoxy derivatives (1–5). *m*-CPBA is the epoxidizing agent most often used in fatty acid chemistry. However, due to the shock-sensitive and explosive nature of *m*-CPBA during transportation, this reagent is now shipped in about 60–70% concentration in the presence of *m*-chlorobenzoic acid and water, which act as stabilizers. Another drawback of using *m*-CPBA for the epoxidation of unsaturated fatty esters is the need to remove *m*-chlorobenzoic acid and excess *m*-CPBA by washing with dilute sodium sulfite solution. During the washing of the reaction product mixture with sodium sulfite, the mixing of the various phases causes an emulsion to be formed, which requires long standing time for the organic layer to be clearly separated from the aqueous solution. In view of this practical problem, we decided to investigate the use of potassium peroxomonosulfate (Oxone®, DuPont Corp.; 2 $KHSO_5.KHSO_4.K_2SO_4$) as an epoxidation reagent instead. Oxone® generates dioxiranes *in situ* in the presence of ketones (such as acetone, trifluoroacetone, and methyl pyruvate). Dioxiranes are reported to be powerful epoxidation species with high reactivity toward both electron-rich and electron-deficient olefins (6,7).

In this report we present the results of the epoxidation of a number of mono- and diunsaturated fatty esters and unsaturated oxygenated fatty esters by dioxiranes generated *in situ* (Scheme 1).

Abbreviations: COSY, homonuclear correlation spectroscopy; IR, infrared; *m*-CPBA, *m*-chloroperoxybenzoic acid; MMPP, magnesium monoperoxyphthalate, hexahydrate; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography; TMS, tetramethylsilane.

MATERIALS AND METHODS

Thin-layer chromatography (TLC) was performed on microscope glass slides coated with silica gel G (*ca.* 0.1 mm thick), and a mixture of *n*-hexane/diethyl ether in various proportions was used as the developer. Components on the micro-plates were viewed by exposing them to iodine vapor. Column chromatographic separation was performed on silica gel (Merck, Darmstadt, Germany; type 60, 230–400 mesh ASTM) as the adsorbent and by gradient elution with a mixture of *n*-hexane/diethyl ether as the mobile phase. Infrared (IR) spectra were recorded on a Bio-Rad (Hercules, CA) FTS-7 FT-IR spectrometer. Samples were run as neat films on KBr discs. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier-transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) (0.2–0.3 mM) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS ($\delta_{TMS} = 0$ ppm).

Methyl oleate (**1**) and methyl linoleate (**3**) were purchased from Aldrich Chemical Co. (Milwaukee, WI). Methyl octadeca-9*Z*,11*E*-dienoate (**5**) and methyl octadec-11*E*-en-9-ynoate (**7**) were synthesized according to procedures described elsewhere (8,9). Methyl ricinoleate (methyl 12-hydroxy-octadec-9*Z*-enoate, **9**) and methyl *iso*-ricinoleate (methyl 9-hydroxy-octadec-12*Z*-enoate, **11**) were isolated from *Ricinus communis* (castor) and *Wrightia tinctoria* seed oils, respectively (10). Methyl 12-oxo-octadec-9*Z*-enoate (**13**) and 2,5-disubstituted furanoid fatty ester (**15**) were synthesized as described elsewhere (11). Potassium peroxymonosulfate (Oxone®) was purchased from Aldrich Chemical Co.

*Epoxidation of methyl oleate (**1**), methyl linoleate (**3**), methyl octadeca-9Z,11*E*-dienoate (**5**) and methyl octadec-11*E*-en-9-ynoate (**7**), as exemplified by compound **5** with potassium peroxymonosulfate in the presence of trifluoroacetone (Scheme 1).* A mixture of methyl octadeca-9*Z*,11*E*-dienoate (**5**, 0.1 g, 0.34 mmol), acetonitrile (3 mL), and aqueous disodium EDTA (Na_2EDTA) solution (2 mL, 4×10^{-4} M) was stirred for 2 min at room temperature. The reaction mixture was cooled to 0–5°C, and trifluoroacetone (0.2 mL) was added *via* a precooled syringe. Sodium hydrogencarbonate (0.13 g, 1.54 mmol) and Oxone® (0.31 g, 0.5 mmol) were then added and the reaction mixture was stirred for 1.5 h at 0–5°C. Water (50 mL) was added and the reaction mixture was extracted with diethyl ether (3×50 mL). The ethereal extract was washed with water (20 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated to give methyl 9,10*Z*;11,12*E*-diepoxystearate (**6**, 0.11g, 99%). Infrared (IR) (neat): 1740 (*s*, ester C=O, str.), 1463 (*m*), 1436 (*m*), 1198 (*m*), 1172 (*m*, C-O-C), 898 (*m*, *E*-epoxy ring), and 835 (*w*, *Z*-epoxy ring) cm^{-1}; ^1H (NMR) ($CDCl_3$, δ_H) 0.88 (*t*, $J = 6.7$ Hz, 3H, C*H*$_3$), 1.26–1.63 (*m*, 22H, C*H*$_2$), 2.31 (*t*, $J = 7.5$ Hz, 3H, 2-*H*$_2$), 2.64–2.77 (*m*, 2H, 9-*H* and 12-*H*), $J_{9,10} = 4.1$ Hz), 2.87–3.03 (*m*, 2H, 10-*H* and 11-*H*, $J_{11,12} = 2.1$ Hz), and 3.66 (*s*, 3H, COOC*H*$_3$); ^{13}C NMR ($CDCl_3$, δ_C) 14.06 (C-18), 22.56 (C-17), 24.88 (C-3), 25.85/25.89 (C-14) , 26.70 (C-7), 28.07, 28.58, 29.01, 29.06, 29.08, 29.13, 29.17, 29.22, 31.58/31.64 (C-13), 31.72 (C-16), 34.05 (C-2), 51.48 (COO*C*H$_3$), 54.76, 55.42, 55.62, 55.66, 56.36, 56.60, 57.75 (C-9, C-10, C-11, C-12, epoxy carbons) and 174.30 (C-1).

*Methyl 9,10-Z-epoxystearate (**2**) from methyl oleate (**1**).* Yield: 99%; IR (neat): 1740 (*s*, ester C=O, str.), 1196 (*m*) and 1171 (*m*, C-O-C) cm^{-1}; ^1H NMR ($CDCl_3$, δ_H) 0.88 (*t*, $J = 6.5$ Hz, 3H, C*H*$_3$), 1.21–1.65 (*m*, 26H, C*H*$_2$), 2.31 (*t*, $J = 7.5$ Hz, 2H, 2-*H*$_2$), 2.88 (*m*, 2H, 9-*H* and 10-*H*), and 3.66 (*s*, 3H, COOC*H*$_3$); ^{13}C NMR ($CDCl_3$, δ_C) 14.11 (C-18), 22.69 C-17), 24.92 (C-3), 26.58 (C-12), 26.63 (C-7), 27.82 (C-8), 27.86 (C-11), 29.05 (C-4), 29.20, 29.24, 29.36, 29.56, 29.58, 31.88 (C-16) , 34.08 (C-2), 51.44 (COO*C*H$_3$), 57.19/57.24 (C-9, C-10) and 174.25 (C-1).

*Methyl 11,12-*E*-epoxy-octadec-9-ynoate (**8**) from methyl octadec-11*E*-en-9-ynoate (**7**).* Yield: 85%; IR (neat) 2250 (*m*, C=C), 1740 (*s*, C=O, str.) and 890 (*m*, epoxy ring) cm^{-1}; ^1H NMR ($CDCl_3$, δ_H) 0.88 (*t*, $J = 7.0$ Hz, 3H, C*H*$_3$), 1.29–1.64 (*m*, 20H, C*H*$_2$), 2.19 (*t*, $J = 6.8$ Hz, 2H, 8-*H*$_2$), 2.30 (*t*, $J = 7.4$ Hz, 2H, 2-*H*$_2$), 3.01 (*m*, 1H, 12-*H*), 3.07 (*d*, $J = 17$ Hz, 1H, 11-*H*) and 3.66 (s, 3H, COOC*H*$_3$); ^{13}C NMR ($CDCl_3$, d_C) 14.06 (C-18), 18.71 (C-8), 22.57 (C-17), 24.89 (C-3), 25.64 (C-14), 28.32, 28.62, 28.76, 28.99, 29.03, 31.72 (C-16), 34.03 (C-2), 45.73 (C-11, confirmed by C-H COSY), 51.43 (COO*C*H$_3$), 60.60 (C-12, confirmed by C-H COSY), 76.75 (C-10, confirmed by long-range C-H COSY), 84.48 (C-9, confirmed by long-range C-H COSY) and 174.18 (C-1).

*Reaction of methyl octadeca-9Z,11*E*-dienoate (**5**) with* m*-CPBA (Scheme 2).* A mixture of compound **5** (0.16 g, 0.544 mmol), dichloromethane (10 mL), *m*-CPBA (0.15 g, 0.85 mmol) was stirred for 1 h. Dichloromethane (50 mL) was then added and the reaction mixture was washed with aqueous sodium sulfite solution (5%, 3×10 mL). The organic extract was washed with water (20 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated and silica column chromatographic separation (using a mixture *n*-hexane/diethyl ether, 95:5, vol/vol as eluent) of the residue gave a mixture (90% total yield) of methyl 9,10-*Z*-epoxy-octadec-11*E*-enoate (**17**) and methyl 11,12-*E*-epoxy-octadec-9*Z*-enoate (**18**). Spectral analysis was conducted on the mixture of compounds **17** and **18**. IR (neat): 1741 (*s*, C=O, str.), 1457 and 1436 cm^{-1}. ^1H-NMR ($CDCl_3$, δ_H) 0.88 (*t*, $J = 7.0$ Hz, 3H,

CH_3), 1.18–1.64 (*m*, 20H, CH_2), 2.07 (*q*, *J* = 6.7 Hz, 2H, 13-*H*$_2$ of **17**), 2.20 (*m*, 2H, 8-*H*$_2$ of **18**), 2.30 (*t*, *J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.81 (*tt*, *J* = 27 Hz, 1H, 12-*H* of **18**), 3.04 (*m*, 1H, 9-*H* of **17** and 12-*H* of **18**), 3.34 (*m*, 10-*H* of **17** and 11-*H* of **18**), 3.66 (*s*, 3H, $COOCH_3$), 5.04 (*t*, *J* = 9.0 Hz, 1H, 10-*H* of **17**), 5.30 (*t*, *J* = 6.5 Hz, 1H, 11-*H* of **17**), 5.70 (*tt*, *J* = 7.7 Hz, 1H, 9-*H* of **18**) and 5.92 (*tt*, *J* = 6.9 Hz, 1H, 12-*H* of **17**); ^{13}C NMR ($CDCl_3$, δ_C) 14.01 (C-18), 22.54 (C-17), 24.83 (C-13), 26.22, 27.86 (C-8 of **18**), 28.71, 28.90, 28.95, 28.99, 29.04, 29.09, 29.16, 31.62/31.69 (C-16), 32.51 (C-13 of **17**), 33.98 (C-2), 51.36 ($COOCH_3$), 54.35 (C-12 of **18**), 57.12 (C-9 of **17**), 58.71(C-10 of **17**), 60.11 (C-11 of **18**), 123.96 (C-11 of **17**), 127.14 (C-10 of **18**), 136.19 (C-9 of **18**), 138.02 (C-12 of **17**) and 174.17 (C-1).

*Preparation of methyl 11,12-*E*-epoxy-octadec-9*Z*-enoate (**18**).* A mixture of methyl 11,12-*E*-epoxy-octadec-9-ynoate (1.2 g, 3.89 mmol, obtained by epoxidation of methyl octadec-11*E*-en-9-ynoate (methyl santalbate) as described elsewhere (9), Lindlar catalyst (15 mg) and ethyl acetate (10 mL) were shaken with hydrogen (90 mL of hydrogen was taken up in 4 h). The solvent was evaporated under reduced pressure, water (25 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 50 mL). The ethereal layer was dried over sodium sulfate. The filtrate was evaporated, and column chromatographic separation of the residue using a mixture of *n*-hexane and diethyl ether (9:1, vol/vol as eluent) afforded methyl 11,12-*E*-epoxy-octadec-9*Z*-enoate (**18**, 90%). IR (neat) 1740 (*s*, C=O,str.), 1456 and 1435 cm^{-1}. ^{1}H-NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 6.0 Hz, 3H, CH_3), 1.20–1.64 (*m*, 20H, CH_2), 2.20 (*m*, 2H, 8-*H*$_2$), 2.31 (*t*, *J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.81 (*m*, 1H, 12-*H*), 3.34 (*dd*, $J_{11,12}$ = 1.4 Hz, 1H, 11-*H*), 3.67 (*s*, 3H, $COOCH_3$), 5.04 (*t*, *J* = 9.0 Hz, 1H, 10-*H*) and 5.66 (*tt*, *J* = 7.7 Hz, 1H, 9-*H*); ^{13}C NMR ($CDCl_3$, δ_C) 14.06 (C-18), 22.57 (C-17), 24.91 (C-3), 25.91 (C-14), 27.69 (C-8), 28.98, 29.07, 29.10, 29.53, 31.75 (C-16), 32.08 (C-13), 34.07 (C-2), 51.46 ($COOCH_3$), 54.45 (C-11, confirmed by C-H COSY), 60.21 (C-12, confirmed by C-H COSY), 127.17 (C-10, confirmed by C-H COSY), 136.32 (C-9, confirmed by C-H COSY) and 174.33 (C-1).

*Reaction of Oxone® in the presence of methyl pyruvate with methyl 12-hydroxy-octadec-9Z-enoate (**9**), methyl 9-hydroxy-octadec-12Z-enoate (**11**), methyl 12-oxo-octadec-9Z-enoate (**13**) and methyl 9,12-epoxy-octadeca-9,11-dienoate (**15**), as exemplified by the epoxidation reaction of compound **13**.* A mixture of methyl 12-oxo-octadec-9*Z*-enoate (**13**, 0.2 g, 0.65 mmol), acetonitrile (6 mL), aqueous Na_2EDTA solution (4 mL, 4×10^{-4} M), and methyl pyruvate (0.66 g, 0.65 mmol) was stirred for 2 min at room temperature. Sodium hydrogencarbonate (0.26 g, 3.1 mmol) and Oxone® (0.61 g, 0.99 mmol) were added, and the reaction mixture was stirred for 45 min. Water (50 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 50 mL). The organic layer was washed with water (20 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated to give methyl 9,10-*Z*-epoxy-12-oxostearate (**14**, 0.2 g, 95%). IR (neat): 1740 (*s*, ester C=O, str.), 1717 (*s*, C=O str.) and 1173 cm^{-1}. ^{1}H NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 7.0 Hz, 3H, CH_3), 1.20–1.60 (*m*, 20H, CH_2), 2.31 (*t*, *J* = 7.4 Hz, 2H, 2-*H*$_2$), 2.47 (t, *J* = 7.3 Hz, 2H, 13-*H*$_2$), 2.60–2.66 (*dd*, *J* = 5.3 Hz, 2H, 11-*H*$_2$), 2.98 (*m*, 1H, 9-*H*), 3.28 (m, 1H, 10-*H*) and 3.66 (*s*, 3H, $COOCH_3$); ^{13}C NMR ($CDCl_3$, δ_C) 14.03 (C-18), 22.49 (C-17), 23.55 (C-14), 24.88 (C-3), 26.40 (C-7), 27.97 (C-8), 28.83, 29.00, 29.14, 29.26, 31.58 (C-16), 34.03 (C-2), 41.61 (C-11, confirmed by C-H COSY), 43.33 (C-13), 51.46 ($COOCH_3$), 52.33 (C-10), 56.49 (C-9), 174.23 (C-1) and 208.48 (C-12).

*Methyl 9,10-Z-epoxy-12-hydroxystearate (**10**) from methyl ricinoleate (**9**).* Yield: 90%; IR (neat): 3449 (*s*, OH), 1740 (*s*, C=O, str.), 1460 (*m*), 1437 (*m*), 1201 (*m*) and 1174 (*m*) cm^{-1}; ^{1}H NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 6.6 Hz, 3H, CH_3), 1.21–1.83 (*m*, 20H, CH_2), 2.31 (*t, J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.92 (*m*, 1H, 9-*H*), 3.14 (*m*, 1H, 10-*H*), 3.66 (*s*, 3H, $COOCH_3$) and 3.87 (*m*, 1H, C*H*OH); ^{13}C NMR ($CDCl_3$, δ_C) 14.09 (C-18), 22.63 (C-17), 24.89 (C-3), 25.55/25.63 (C-14), 26.42 (C-7), 27.91 (C-8), 28.04, 29.02, 29.17, 29.30, 29.32, 31.84 (C-16), 34.05 (C-2), 34.84/35.24 (C-11), 37.46/37.82 (C-13), 51.46 ($COOCH_3$), 54.55/55.38 (C-10), 56.37/57.19 (C-9), 69.97/70.78 (C-12) and 174.29 (C-1).

*Methyl 12,13-Z-epoxy-9-hydroxystearate (**12**) from methyl* iso-*ricinoleate (**11**).* Yield: 90%; IR (neat) 3454 (*s*, OH), 1739 (*s*, C=O, str.), 1462, 1437, 1251 cm^{-1}; ^{1}H NMR ($CDCl_3$, δ_H) 0.90 (*t*, *J* = 6.9 Hz, 3H, CH_3), 1.20–1.76 (*m*, 24H, CH_2), 2.00 (O-*H*, D_2O exchangeable), 2.30 (*t, J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.95 (*m*, 2H, 12-*H* and 13-*H*), 3.60 (*m*,1H, C*H*OH) and 3.66 (*s*, 3H, $COOCH_3$); ^{13}C NMR ($CDCl_3$, δ_C) 14.03 (C-18), 22.64 (C-17), 24.31 (C-11), 24.94 (C-3), 25.69/26.29 (C-7), 27.81 (C-14), 29.09, 29.25, 29.48, 31.74/31.99 (C-16), 34.11 (C-2), 37.54 (C-8, C-10), 51.49 ($COOCH_3$), 57.17/57.36 (C-12), 57.48/57.88 (C-13), 71.13/71.54 (C-9) and 174.32 (C-1) as supported by data from Tulloch and Mazurek (12).

*Methyl 9,12-dioxo-octadec-10Z-enoate (**16**) from methyl 9,12-epoxy-octadeca-9,11-dienoate (**15**).* Yield: 90%; IR (neat): 1736 (*s*, C=O, ester, str.), 1700 (*s*, C=O, oxo, str.), 1609 (*m*), 1437 (*m*) and 1395 (*m*) cm^{-1}. ^{1}H NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 6.8 Hz, 3H, CH_3), 1.29–1.32 (*m*, 12H, CH_2), 1.74–1.81 (*m*, 6H, CH_2), 2.29 (*t*, *J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.53 (*t*, *J* = 7.1 Hz, 4H, 8-*H*$_2$ and 13-*H*$_2$), 3.66 (*s*, 3H, $COOCH_3$) and 6.31 (*s*, 2H, 10-*H* and 11-*H*); ^{13}C NMR ($CDCl_3$, δ_C) 14.04 (C-18), 22.49 (C-17), 23.39, 23.49 (C-7, C-14), 24.88 (C-3), 28.79, 28.89, 28.93, 29.03, 31.60 (C-16), 34.04 (C-2), 42.48, 42.60 (C-8, C-13), 51.44 ($COOCH_3$), 135.56, 135.79 (C-10, C-11), 174.24 (C-1), 203.03 and 203.07 (C-9 and C-12). Similar data were reported elsewhere (3).

RESULTS AND DISCUSSION

Treatment of the various unsaturated fatty esters with Oxone® in the presence of either trifluoroacetone or methyl pyruvate afforded the corresponding epoxides in very high yields as summarized in Scheme 1. The NMR spectral properties of

methyl 9,10-*Z*-epoxystearate (**2**) and those of methyl 9,10-*Z*;12,13-*Z*-diepoxystearate (**4**) from methyl oleate and methyl linoleate, respectively, were similar to those reported in the literature (2,13). From the results of the ^{13}C NMR analysis of the products, it was apparent from the shifts of the epoxy carbon nuclei that the reaction of oxone with methyl linoleate was not stereoselective. Seven signals (in the region of δ_C 54.19–56.99) instead of four were found in the spectrum for the shifts of the epoxy carbon atoms. It was possible to differentiate the signals for the C-10/C-12 epoxy carbon nuclei from those originating from the C-9/C-13 epoxy carbon atoms by the C-H COSY technique.

Epoxidation of the conjugated 9-*Z*,11-*E*-diene ester (compound **5**) with *m*-CPBA gave a mixture of mono-epoxy olefinic esters (compounds **17** and **18**, see Scheme 2) only. Compounds **17** and **18** could not be further epoxidized by *m*-CPBA. However, when the same substrate (compound **5**) was reacted with Oxone® in trifluoroacetone, both double bonds in the substrate were readily epoxidized to give the corresponding *Z,E*-epoxy derivative (**6**) in almost quantitative yield. Compound **6** comprised a mixture of stereoisomers as reflected by the seven signals arising from the shifts of the epoxy carbon atoms (C-9, C-10, C-11, and C-12) which appeared at δ_C 54.76–57.75. In an effort to identify the various carbon chemical shifts of the mixture of compounds **17** and **18**, it was necessary to synthesize one of these positional isomers. Compound **18** was prepared by semihydrogenation of methyl 11,12-*E*-epoxy-octadec-9-ynoate, which was obtained by *m*-CPBA epoxidation of methyl santalbate as reported elsewhere (14). By comparing the results of the shifts of the critical carbon atoms in the ^{13}C NMR spectrum of compound **18**, it was possible to identify many of the carbon signals arising from compounds **17** and those belonging to compound **18**.

The reactions involving methyl ricinoleate (**9**) , *iso*-ricinoleate (**11**), and methyl 12-oxo-octadec-9*Z*-enoate (**13**) with Oxone® were carried out in the presence of methyl pyruvate instead of trifluoroacetone. Reactions with Oxone® in methyl pyruvate were as effective and high yielding as those observed when conducted in the presence of trifluoroacetone. Methyl ricinoleate (**9**) reacted with Oxone® to give methyl 9,10-*Z*-epoxy-12-hydroxystearate (**10**). Of great interest was the reaction of methyl *iso*-ricinoleate (**11**) with Oxone® in methyl pyruvate. This reaction gave exclusively the corresponding epoxy-hydroxystearate derivative (**12**), which was identified by the IR absorption at 3454 cm^{-1} for the stretching vibration of the O-H group, the shifts of the epoxy protons at δ_H 2.95 (12-H and 13-H), and from the shifts of the carbon nuclei at δ_C 57.17/57.36 (C-12) and 57.48/57.88 (C-13). Unlike the reaction of methyl *iso*-ricinoleate with *m*-CPBA, the reaction with Oxone® in the presence of methyl pyruvate did not give rise to the frequently reported tetrahydrofuranyl derivative (methyl 9,12-epoxy-13-hydroxystearate). In the reaction of methyl *iso*-ricinoleate with *m*-CPBA, the hydroxy group acts as a nucleophile in an intramolecular cyclization reaction involving the dimethylene interrupted hydroxy-epoxy intermediate (1,15). The latter reaction is catalyzed by the presence of a weak acid (chlorobenzoic acid) which is found in *m*-CPBA (as a stabilizer or by-product). While in the case of Oxone® with methyl pyruvate, the presence of sodium hydrogencarbonate prevents the epoxy group from being protonated and thus preventing the cyclisation reaction to occur as observed in the case of *m*-CPBA.

Reaction of methyl 12-oxo-octadec-9*Z*-enoate (**13**) with Oxone® furnished the corresponding epoxy-oxo derivative (**14**), which was confirmed by the spectral data. By using C-H COSY technique, the shift of the C-11 carbon atom was shown to correspond to the signal at δ_C 41.61. This value was erroneously assigned in an earlier study by us when the same substrate was epoxidized with *m*-CPBA under concomitant ultrasonic irradiation (15). Ring-opening reaction of a C_{18} 2,5-disubstituted furanoid fatty ester (compound **15**) with Oxone® furnished methyl 9,12-dioxo-octadec-10*Z*-enoate (**16**) in 90% yield. The *Z*-configuration of the double bond was confirmed from the following physical data: a singlet at δ_H 6.31 (2H, 10-*H*, 11-*H*) and carbon shifts at δ_C 135.56, 135.79 (C-10, C-11).

It can be concluded from the above results that Oxone® is a stronger epoxidizing agent than *m*-CPBA. Oxone® in the presence of trifluoroacetone or methyl pyruvate converts all double bonds into the corresponding epoxides including conjugated diene systems and in the case of methyl *iso*-ricinoleate (a dimethylene interrupted hydroxy-olefin ester) epoxidation with Oxone® yields exclusively the corresponding epoxy-hydroxy derivative. Furthermore, the isolation of the epoxy derivatives from reactions involving Oxone® is a facile procedure resulting in high product yield.

Callyspongynes A and B: New Polyacetylenic Lipids from a Southern Australian Marine Sponge, *Callyspongia* sp.

Francis Rooney and Robert J. Capon*

School of Chemistry, The University of Melbourne, Parkville, Victoria 3052, Australia

ABSTRACT: A *Callyspongia* sp. collected by SCUBA off Barwon Heads, Australia, has afforded two new polyacetylenic lipids, callyspongynes A and B, the structures of which were assigned by spectroscopic analysis and chemical derivatization. *Lipids 33*, 639–642 (1998).

Polyacetylenic lipids represent a class of natural product common to marine sponges, with many examples reported in recent years of this structure class varying in chain length, degrees of unsaturation, and biological activity (antimicrobial, antitumor, antifungal, and antiviral). Sponge genera known to feature polyacetylenic lipids include *Petrosia* (1–8), *Cribrochalina* (9–12), *Tetrosia* (13), *Xestospongia* (14,15), *Siphonochalina* (16), *Reniera* (17), *Haliclona* (18), and *Callyspongia* (19). This latter observation together with our recent experience in isolating novel lipids from a southern Australian *Callyspongia* sp. (20) prompted an investigation of the lipid content of another *Callyspongia* sp. in our collection. This report describes the results of a chemical analysis of a *Callyspongia* sp. collected by SCUBA at ~30 m depth off Barwon Heads (Victoria, Australia).

EXPERIMENTAL PROCEDURES

All solvents were redistilled before use. Rapid silica filtrations were carried out using Kieselgel 60 silica gel loaded into a sintered glass funnel and eluted under low vacuum. Solid phase extraction was carried out using Alltech Maxiclean silica 900 mg cartridges (Alltech Corp., Deerfield, IL) attached to luer lock syringes. High-performance liquid chromatography (HPLC) was performed on an ISCO 2350 solvent delivery system (ISCO Corp., Lincoln, NE) equipped with a rheodyne injector, Waters 401 differential refractometer and Spectra Physics 200 programmable UV/VIS wavelength detector, and recorded on either Chart V3.2 data collection package using an AD Instruments Mac Lab/2E operating on an Apple Macintosh LC; or a Data Acquisition Plotting and Analysis (DAPA) package operating on an Ipex 286PC unit under DOS 5.0. Thin-layer chromatography was carried out on Machery-Nagel Duren Alugram Sil G/UV_{254} plates and visualized by both short (254 nm)- and long (365 nm)-wavelength ultraviolet light, as well as spraying with 5% vanillin in H_2SO_4/H_2O (50% wt/vol) and heating at 100°C for 2–5 min. Chiroptical measurements $[\alpha]_D$ were obtained on a Jasco DIP-1000 digital polarimeter in a 100 mm × 2 mm cell. Infrared (IR) spectra were acquired on a Perkin-Elmer 1600 Fourier transform IR spectrophotometer. Nuclear magnetic resonance (NMR) experiments were performed on either a Varian Inova 400, Varian Unity 300, or a Varian Unity plus 400 spectrometer in the solvents indicated, with ^1H NMR referenced to residual solvent resonances and ^{13}C NMR to carbon resonances.

Electrospray ionization (ESI) (1:1 acetonitrile/water matrix) mass spectra were acquired on a Micromass Quattro II mass spectrometer at the cone voltages indicated. Electron impact ionization (EI) (70 eV) mass spectra were acquired on a JEOL ax-505H mass spectrometer. High-resolution ESI (1:1 acetonitrile/water matrix) mass measurements were recorded on a Bruker BioApex 47E FT mass spectrometer at a cone voltage of 100 kV. Gas chromatography/mass spectrometry (MS) analysis was performed on a Hewlett-Packard 5890 gas chromatograph with mass selective detector MSD HP 5970 MS and a split/splitless injector for capillary columns, using a fused-silica column, 25 m × 0.2 mm HP–5 (cross-linked 25% phenylmethyl silicone, 0.33 mm film thickness).

Collection, extraction, and isolation. A marine sponge *Callyspongia* sp. (class Demonspongia: order Haplosclerida: family Callyspongidae) (32.5 g) was collected by SCUBA (–30 m) off Barwon Heads. The sponge was diced, steeped in ethanol, and stored at –18°C until required, and a voucher specimen (registry number F77048) deposited with the Museum of Victoria. The decanted ethanol extract was concentrated *in vacuo* and partitioned into CH_2Cl_2-, methanol-, and H_2O-soluble fractions. The CH_2Cl_2-soluble fraction was further partitioned with CH_3CN, and the CH_3CN-soluble material fractionated by rapid silica filtration (10% stepwise gradient from hexane to ethyl acetate) followed by HPLC (2 mL/min elution with 15% ethyl acetate/hexane through a Phenomenex 5 μ silica 250 × 10 mm column) (Phenomenex, Torrance, CA) to yield a mixture of callyspongynes (24 mg, 0.074%) as a colorless oil. $[\alpha]_D$–3.9° (c = 0.24 $CHCl_3$); EIMS (70 eV) mass spectrum *m/z* 492 (1%, minor homolog),

Abbreviations: EI, electron impact ionization; EIMS, electron impact mass spectrometry; ESI, electrospray ionization; HPLC, high-performance liquid chromatography; IR, infrared; MS, mass spectrometry; MTPA, α-methoxy-α-(trifluoromethyl)phenylacetic acid; NMR, nuclear magnetic resonance.

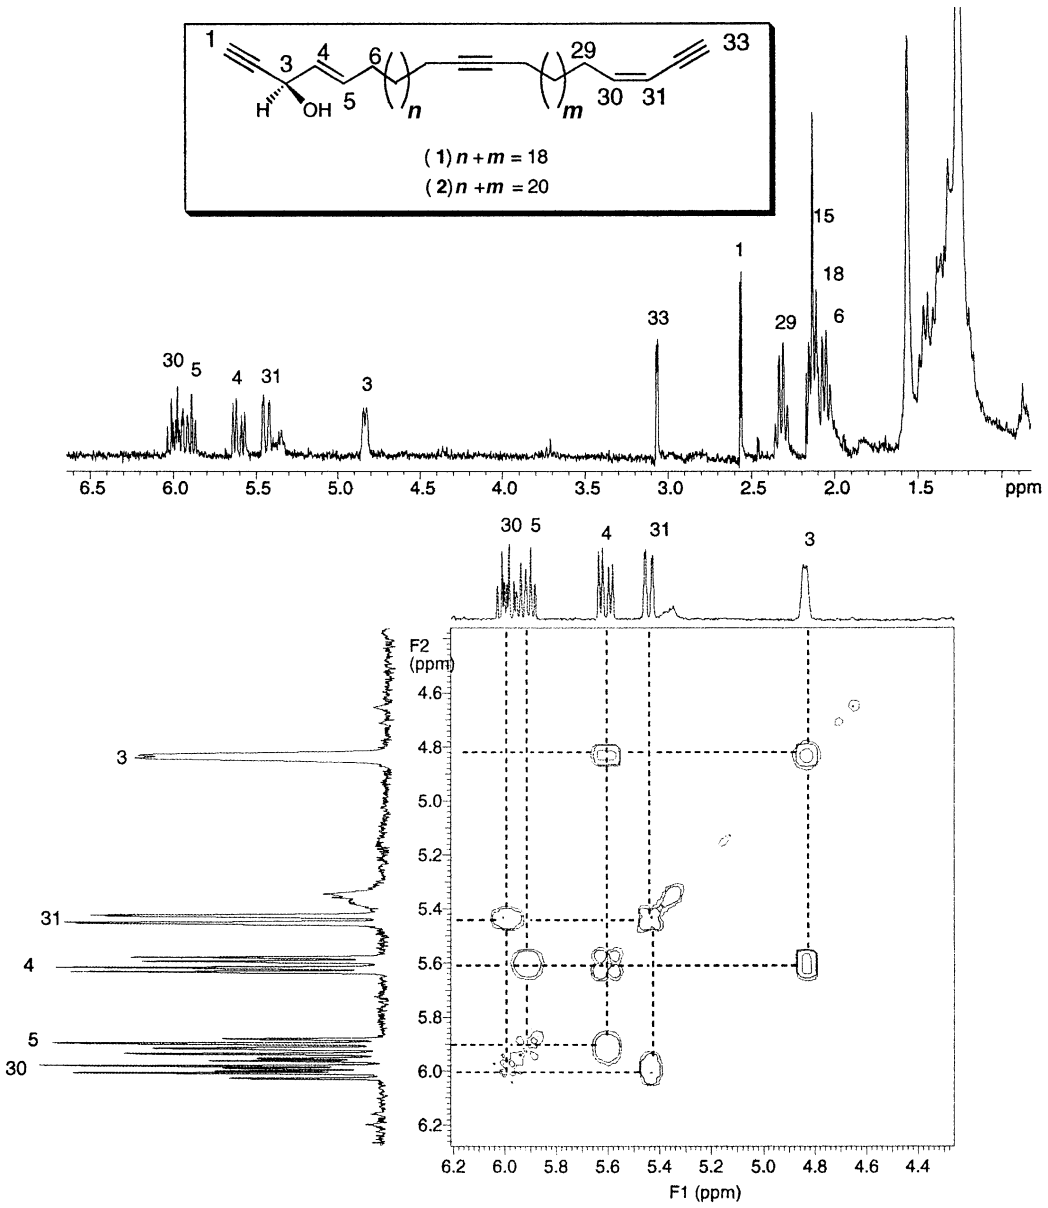

FIG. 1. ^{1}H ($CDCl_3$, 400 MHz) and an expansion of the selected homonuclear correlation spectroscopy nuclear magnetic resonance spectra of callyspongynes.

464 (4%, major homolog), 446(1), 421 (2), 381 (1), 279 (2), 252(5), 187 (10), 173 (15), 95 (56), 54 (100); high-resolution EIMS *m/z* 464.4035 ($C_{33}H_{52}O$ requires 464.4021); ESI (+) *m/z* 493 (minor homolog, M + H), 465 (major homolog, M + H); IR (film) ν_{max} 3300, 2900 cm^{-1}; ^{1}H, ^{13}C and two-dimensional NMR see Table 1.

Derivatization. A solution of dicyclohexylcarbodiimide (1.5 eq in 15 mL of dry CH_2Cl_2) was added to a solution of callyspongynes (1 eq, 9 mg in 0.5 mL of dry CH_2Cl_2) containing 4-dimethylaminopyridine (1 mg) and either (*R*)- or (*S*)-α-methoxy-α-(trifluoromethyl)phenylacetic acid (MTPA) (1.5 eq, 3.5 mg), and the solution was stirred for 16 h at 25°C. The reaction product obtained from standard aqueous workup was purified by HPLC (2 mL/min elution with 15% ethyl acetate/ hexane through a Phenomenex 5 µ silica 250 × 10 mm column) to yield the (*R*)-MTPA (6 mg, 66%) and (*S*)-MTPA (7 mg, 77%) esters, respectively. Selected Δδ(*S-R*) ^{1}H NMR shifts for the Mosher esters are shown in Figure 2.

RESULTS AND DISCUSSION

Solvent partitioning of the ethanol extract of the *Callyspongia* sp. followed by rapid silica filtration and silica HPLC yielded a mixture of callyspongynes as optically active colorless oil. Examination of the NMR data (see Fig. 1) revealed resonances consistent with a secondary alcohol [^{1}H: δ 4.84 (*dd*); ^{13}C: 62.8 (*d*) ppm], as well as a disubstituted [^{13}C: (80.2) (2*s*) ppm] and two monosubstituted acetylenes [^{1}H: δ

2.56 (*d*); ^{13}C: 74.0 (*d*) and 83.3 (*s*) ppm; and ^{1}H: δ 3.06 (*dd*); ^{13}C: 80.3 (*d*) and 81.1 (*s*) ppm]. These observations were further substantiated by IR absorptions (3300 and 2900 cm^{-1}). The NMR data also established the presence of *cis* [^{1}H: δ 5.99 and δ 5.44 J_{cis} = 10.6 Hz; ^{13}C: 146.2 (*d*) and 107.2 (*d*) ppm] and *trans* [^{1}H: δ 5.60 and δ 5.90 J_{trans} = 15.1 Hz; ^{13}C: 128.0 (*d*) and 134.7 (*d*) ppm] 1,2-disubstituted double bonds. Analysis of the two-dimensional NMR data (Table 1 and Fig. 1) established the terminal structure fragments and positioned the remaining acetylenic functionality within an unbranched carbon chain. ESI MS revealed the presence of two homologs, an observation confirmed by both direct insertion and gas chromatography EI MS. High-resolution EIMS provided experimental evidence for the molecular formula of the major component callyspongyne A (**1**) ($C_{33}H_{52}O$), and by comparison defined a molecular formula for the minor homolog callyspongyne B (**2**) ($C_{35}H_{56}O$). Repeated efforts to analyze fragmentation patterns and employ tandem mass spectrometry techniques failed to unambiguously position the disubstituted acetylenic unit along the carbon chain (Fig. 2).

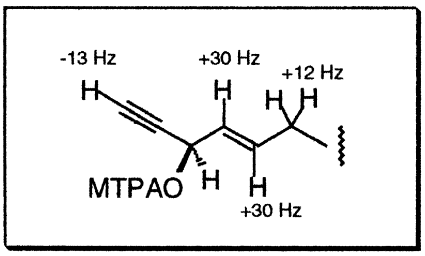

FIG. 2. ^{1}H nuclear magnetic resonance (NMR) Δδ (*S*-*R*) Mosher ester analysis. MTPA, methoxy-α-(trifluoromethyl)phenyl-acetic acid.

Application of the advanced Mosher method (21) for assignment of absolute stereochemistry required preparation of the diastereomeric MTPA esters of the callyspongyne mixture, and comparison of the resulting NMR spectra. The Δδ values as depicted in Figure 2 were diagnostic for a 3*R* absolute stereochemistry. This assignment of absolute stereochemistry to the callyspongynes when considered in conjunction with the experimentally measured -ve optical rotation was consistent with the absolute stereochemistry assigned to acetylenic lipids possessing a common C1 to C7 subunit reported from other marine sponges (1–5).

Although callyspongynes A and B (**1** and **2**) incorporate terminal acetylenic functionalities common to other polyacetylenic lipids from marine sponges, the isolated "central" acetylenic functionality is uncommon. The ecological role of such novel unsaturated lipids in marine sponges remains unknown, although in at least one instance it has been speculated that they serve as chemical defense agents to both the sponge itself and to predatory nudibranches (8).

ACKNOWLEDGMENTS

The assistance of L. Goudie in specimen collection and taxonomic classification is greatly appreciated. The Australian Research Council funded this research.

ARTICLE

Comparative Effects of α- and γ-Linolenic Acids on Rat Liver Fatty Acid Oxidation

Tamotsu Kumamoto[1] and Takashi Ide*

Laboratory of Nutrition Biochemistry, National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Tsukuba Science City 305, Japan

ABSTRACT: It has been reported that both n-3 and n-6 octadecatrienoic acids can increase hepatic fatty acid oxidation activity. It remains unclear, however, whether different enzymes in fatty acid oxidation show a similar response to n-3 and n-6 octadecatrienoic acids. The activity of hepatic fatty acid oxidation enzymes in rats fed an oil mixture rich in α-linolenic acid (18:3n-3) and borage oil rich in γ-linolenic acid (18:3n-6) was therefore compared to that in rats fed an oil mixture rich in linoleic acid (18:2n-6) and a saturated fat (palm oil) in this study. Linseed oil served as the source of 18:3n-3 for the oil mixture rich in this octadecatrienoic acid and contained 30.6% 18:3n-3 but not 18:3n-6. Borage oil contained 25.7% 18:3n-6 and 4.5% 18:3n-3. Groups of seven rats each were fed diets containing 15% various fats for 15 d. The oxidation rate of palmitoyl-CoA in the peroxisomes was higher in rats fed a fat mixture rich in 18:3n-3 (3.03 nmol/min/mg protein) and borage oil (2.89 nmol/min/mg protein) than in rats fed palm oil (2.08 nmol/min/mg protein) and a fat mixture rich in 18:2n-6 (2.15 nmol/min/mg protein). The mitochondrial palmitoyl-CoA oxidation rate was highest in rats fed a fat mixture rich in 18:3n-3 (1.93 nmol/min/mg protein), but no significant differences in this parameter were seen among the other groups (1.25–1.46 nmol/min/mg protein). Compared to palm oil and fat mixtures rich in 18:2n-6, a fat mixture rich in 18:3n-3 and borage oil significantly increased the hepatic activity of carnitine palmitoyltransferase and acyl-CoA oxidase. Compared to palm oil and a fat mixture rich in 18:2n-6, a fat mixture rich in 18:3n-3, but not fats rich in 18:3n-6, significantly decreased 3-hydroxyacyl-CoA dehydrogenase activity. Compared to palm oil and a fat mixture rich in 18:2n-6, borage oil profoundly decreased mitochondrial acyl-CoA dehydrogenase activity, but a fat mixture rich in 18:3n-3 increased it. 2,4-Dienoyl-CoA reductase activity was significantly lower in rats fed palm oil than in other groups. Compared to other fats, borage oil significantly increased Δ^3,Δ^2-enoyl-CoA isomerase activity. Activity was also significantly higher in rats fed 18:2n-6 oil than in those fed palm oil. It was confirmed that both dietary 18:3n-6 and 18:3n-3 increased fatty acid oxidation activity in the liver. These two dietary octadecatrienoic acids differ considerably, however, in how they affect individual fatty acid oxidation enzymes.

Lipids 33, 647–654 (1998).

*To whom correspondence should be addressed at Laboratory of Nutrition Biochemistry, National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, 2-1-2 Kannondai, Tsukuba Science City 305, Japan. E-mail: idetaka@nfri.affrc.go.jp

We demonstrated previously that dietary fats rich in n-3 octadecatrienoic acid (α-linolenic acid) increased the fatty acid oxidation rate through both the mitochondrial and peroxisomal pathways in liver homogenates in rats (1,2). We also showed that dietary α-linolenic acid increased the hepatic activity of enzymes in the β-oxidation pathway, including carnitine palmitoyltransferase, acyl-CoA dehydrogenase, acyl-CoA oxidase, enoyl-CoA hydratase, 3-ketoacyl-CoA thiolase, Δ^3,Δ^2-enoyl-CoA isomerase, and 2,4-dienoyl-CoA reductase, but unexpectedly decreased 3-hydroxyacyl-CoA dehydrogenase activity. Fish oil containing very long-chain n-3 polyunsaturated fatty acids has been amply demonstrated to increase the mitochondrial (3,4) and peroxisomal (4–7) fatty acid oxidation rate in rat liver. It is thus plausible that various n-3 polyunsaturated fatty acids can increase hepatic fatty acid oxidation in the rat. By contrast, we (1,2) previously showed that a dietary fat rich in 18:2n-6 (safflower oil) only slightly but inconsistently increased hepatic mitochondrial and peroxisomal fatty acid oxidation activity. Takada *et al*. (8), however, demonstrated that a dietary fat (of fungal origin) rich in γ-linolenic acid (18:3n-6) significantly increased the peroxisomal fatty acid oxidation rate and carnitine palmitoyltransferase activity in rat liver. Thus, it is plausible that both n-3 and n-6 octadecatrienoic acids can increase hepatic fatty acid oxidation activity. It remains unclear, however, whether different enzymes in fatty acid oxidation show a similar response to n-3 and n-6 octadecatrienoic acids. We therefore compared the effect of dietary α- and γ-linolenic acids on the activity of different hepatic fatty acid oxidation enzymes using linseed and borage oils as the sources of these linolenic acids in the rat.

MATERIALS AND METHODS

Materials. [1-^{14}C]Palmitic acid was purchased from Amersham International (Bucks, United Kingdom). [1-^{14}C]Palmitoyl-CoA and nonradiolabeled palmitoyl- and linoleyl-CoA were prepared according to the method of Kawaguchi *et al*. (9). Acetyl-CoA was prepared by acylating CoA with acetic anhydride, acetoacetyl-CoA with diketene, and crotonyl-CoA with crotonic anhydride. Sorboyl-CoA, *trans*-2-octenoyl-CoA, and *trans*-3-hexenoyl-CoA were prepared using the mixed anhydride method (10). Malonyl-CoA was purchased

from Sigma Chemical Co. (St. Louis, MO). Bovine serum albumin fraction V (essential fatty acid-free) was purchased from Boehringer Mannheim GmbH (Mannheim, Germany). Linseed oil rich in α-linolenic acid was purchased from Nakarai Tesque (Kyoto, Japan). Palm and safflower oils were the gift of Nisshin Oil Co. (Tokyo, Japan). Borage oil rich in γ-linolenic acid was donated by Nippon Synthetic Chemical Industry Co. (Osaka, Japan).

Animals and diets. Male Sprague-Dawley rats obtained from Charles River Japan (Kanagawa, Japan) were housed individually in animal cages in a room with controlled temperature (20–22°C), humidity (55–65%), and lighting (light on from 07:00 to 19:00 h), and fed a commercial nonpurified diet (Type NMF; Oriental Yeast Co., Tokyo, Japan). Fat content of the nonpurified diet was 5.2% and its fatty acid composition was (in wt%): 16:0, 14.8; 16:1n-7, 2.1; 18:0, 2.7; 18:1n-9, 22.2; 18:2n-6, 44.5; 18:3n-6, 0.1; 18:3n-3, 6.2; 20:4n-6, 1.1; 20:5n-3, 3.0; 22:4n-6, 0.1; 22:5n-6, 0.2; 22:5n-3, 0.4; 22:6n-3, 2.7. After 7 d of acclimatization, rats were fed purified experimental diets. The composition of the experimental diet was (in wt%): fat, 15; casein, 20; cornstarch, 15; sucrose, 43; cellulose, 2; mineral mixture (11), 3.5; vitamin mixture (11), 1; DL-methionine, 0.3; and choline bitartrate, 0.2. Animals were fed a diet containing palm oil; a fat mixture (18:2 oil) composed of palm and safflower oils (12:88, w/w); another fat mixture (18:3n-3 oil) composed of linseed, palm, and safflower oils; and tripalmitin (54:39:2:5, by wt), and borage oil for 15 d. The composition of polyunsaturated fatty acid was the sole variable, and the total polyunsaturated fatty acid content was the same in fat mixtures rich in 18:2n-6 or 18:3n-3 and a fat rich in 18:3n-6 (borage oil) (Table 1). We followed our institute's guidelines in laboratory animal care and use.

Enzyme assays. At the termination of the experimental period, rats were anesthetized lightly using diethylether and bled from the abdominal aorta, and livers were quickly excised. About 3 g each of liver was homogenized with 7 vol of 0.25 M sucrose and centrifuged at 500 × *g* for 10 min. The supernatant was recentrifuged at 9000 × *g* for 10 min to isolate mitochondria. The mitochondrial fraction was washed twice with 0.25 M sucrose containing 1 mM EDTA and 3 mM Tris-HCl (pH 7.0) and finally suspended in the same medium to give a protein concentration of 20–25 mg/mL. Mitochondrial and peroxisomal fatty acid oxidation rates were measured using a 500 × *g* supernatant fraction of liver homogenates, with [1-^{14}C]palmitoyl-CoA (0.2 mM) as a substrate, according to the method of Mannaerts *et al*. (12) as detailed elsewhere (1). The supernatant fraction of liver homogenates obtained after centrifugation at 500 × *g* for 10 min was used to measure fatty acid oxidation enzyme activity except in the case of acyl-CoA dehydrogenase (E.C. 1.3.99.3). Because acyl-CoA dehydrogenase is primarily a mitochondrial enzyme (13) and the assay using the 500 × *g* supernatant fraction as an enzyme source gave an extremely high blank value, this enzyme was assayed in an isolated mitochondrial fraction as an enzyme source. Carnitine palmitoyltransferase (E.C. 2.3.1.21) activity was measured using both the 500 × *g* supernatant and mitochondrial fractions. Carnitine palmitoyltransferase, acyl-CoA dehydrogenase, and acyl-CoA oxidase (E.C. 1.3.3.6) activities were measured according to the methods of Markwell *et al*. (14), Dommes and Kunau (15), and Hashimoto *et al*. (16) using palmitoyl-CoA as a substrate. Enoyl-CoA hydratase (E.C. 4.2.1.17) activity, using crotonyl-CoA and *trans*-2-octenoyl-CoA substrates (17), and 3-hydroxyacyl-CoA dehydrogenase (E.C. 1.1.1.35)(18) activity using acetoacetyl-CoA substrate were analyzed according to the method of Osumi and Hashimoto (17). Sorboyl-CoA for 2,4-dienoyl-CoA reductase (E.C. 1.3.1.34) (19) and *trans*-3-hexenoyl-CoA for Δ^3,Δ^2-enoyl-CoA isomerase (E.C. 5.3.3.8) (20) were used as substrates in assaying activity. The activity of succinate dehydrogenase (E.C. 1.3.99.1) (21), a marker enzyme for mitochondria, was measured in both the 500 × *g* supernatant and mitochondrial fraction to calculate mitochondrial recovery from the 500 × *g* supernatant (1). The activities of fatty acid synthetase (22), malic enzyme (E.C. 1.1.1.40) (23), glucose 6-phosphate dehydrogenase (E.C. 1.1.1.49) (24), and pyruvate kinase (E.C. 2.7.1.40) (25) were measured using a 9000 × *g* supernatant fraction of liver homogenate as an enzyme source as detailed elsewhere (1,2,26). Mitochondrial and peroxisomal oxidation rates of fatty acid were measured using nonfreeze-thawed enzyme preparations on the day rats were sacrificed. Other enzymes were assayed in enzyme preparations that had been stored at –40°C up to 10 d.

Lipid analysis. Commercial enzyme kits obtained from Wako Pure Chemical (Osaka, Japan) were used in assaying serum concentrations of cholesterol (Cholesterol C-test Wako) and free fatty acid (NEFA C-test Wako). Serum and liver lipids were extracted and purified (27). Triacylglycerol and phospholipid contents in the lipid extract were determined as described elsewhere (28,29). Cholesterol content in the liver lipid extract was analyzed enzymatically as detailed elsewhere (29). Triacylglycerol and phospholipid in the liver lipid extract were separated by thin-layer chromatography, and the fatty acid composition of these lipid molecules was determined using gas–liquid chromatography (28).

TABLE 1
Fatty Acid Composition of Dietary Fats

Fatty acids (wt%)	Palm oil	18:2n-6 Oil[a]	18:3n-3 Oil[b] (fat mixture)	Borage oil
16:0	45.3	11.6	11.6	10.7
16:1n-7	0.1	—	—	0.4
18:0	4.4	2.7	2.7	3.4
18:1n-9	39.1	16.1	16.4	16.5
18:2n-6	9.4	69.1	38.6	38.7
18:3n-6	—	—	—	25.7
18:3n-3	0.3	0.2	30.6	4.5
Total PUFA[c]	9.7	69.3	69.2	68.9

[a]Mixture of palm and safflower oils (12:88, w/w).
[b]Mixture of linseed, palm, and safflower oils, and tripalmitin (54:39:2:5, by wt).
[c]PUFA, polyunsaturated fatty acids.

Statistical analysis. The examination of significant differences of means with a pooled estimate of variance was established according to the methods of Snedecor and Cochran (30) for one-way classifications as detailed elsewhere (31).

RESULTS

There were no significant differences in average food intake and growth among the groups of rats fed different dietary fats (Table 2). Liver weight was significantly lower in rats fed 18:2n-6 oil than in those fed palm and borage oils. But no significant difference in this parameter was detected between rats fed 18:2n-6 oil and 18:3n-3 oil.

Effect of dietary α- and γ-linolenic acids on hepatic palmitoyl-CoA oxidation rate and fatty acid oxidation enzyme activity. Owing to the considerable differences detected in liver weight among groups, the effect of dietary fats on hepatic enzyme was estimated comparing both specific (nmol/min/mg protein) and total (μmol/min/100 g body weight) activity. Although only the value for specific activity is presented in each table and figure, similar results regarding the effect of α- and γ-linolenic acids on enzyme activity were confirmed when it was expressed as total activity. Compared to palm and 18:2n-6 oils, an oil mixture rich in α-linolenic acid and borage oil rich in γ-linolenic acid significantly increased specific and total activities of hepatic peroxisomal palmitoyl-CoA oxidation rate (Fig. 1), carnitine palmitoyltransferase, and acyl-CoA oxidase activity (Table 3). Compared to palm and 18:2n-6 oil, 18:3n-3 oil significantly increased specific and total activities of mitochondrial acyl-CoA dehydrogenase, whereas borage oil greatly decreased them. By contrast, dietary α-linolenic acid greatly reduced 3-hydroxyacyl-CoA dehydrogenase activity, but borage oil left it unchanged. Mitochondrial oxidation rate was significantly higher in rats fed 18:3n-3 oil than in the other groups regardless of the way the value was expressed. Compared to other fats, borage oil failed to increase the specific and total activities in the mitochondrial fatty acid oxidation rate, however. Enoyl-CoA hydratase and 3-ketoacyl-CoA thiolase activities were highest in rats fed 18:3n-3 oil, but one-way analysis of variance showed no significant difference in the specific and total enzyme activities among groups. 2,4-Dienoyl-CoA reductase activity was significantly lower in rats fed palm oil than in other groups. Compared to other fats, borage oil significantly increased Δ^3,Δ^2-enoyl-CoA isomerase activity. Activity was also significantly higher in rats fed 18:2n-6 oil than in those fed palm oil.

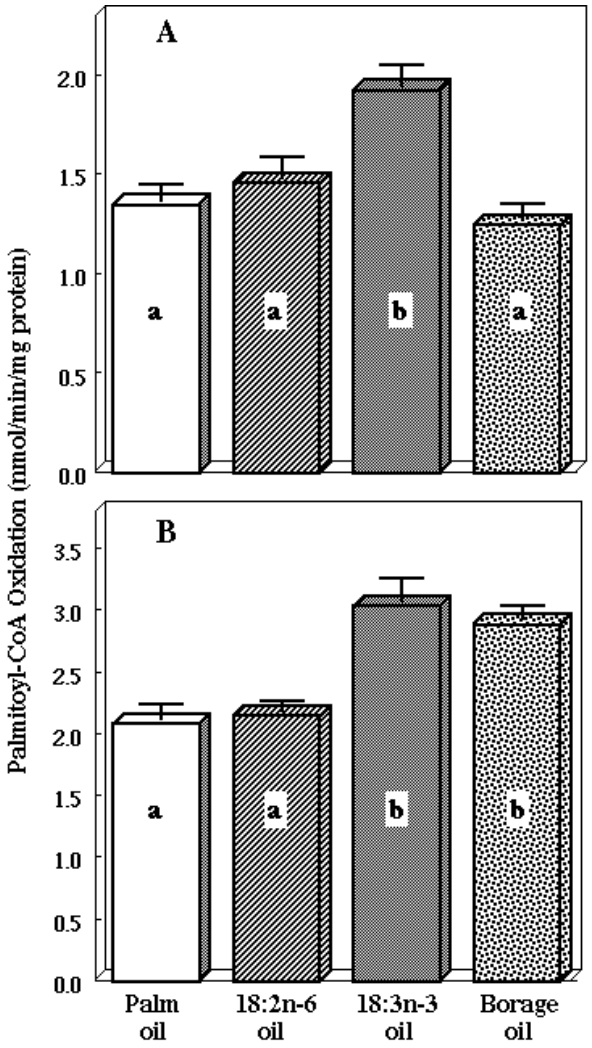

FIG. 1. Effect of α- and γ-linolenic acids on palmitoyl-CoA oxidation in rat liver homogenate. Values are means ± SE of seven determinations made on separate animals. a, b: Values with unlike letters differ significantly at $P < 0.05$. (A) Mitochondrial β-oxidation; analysis of variance (ANOVA), F value = 13.9 ($P < 0.01$). (B) Peroxisomal β-oxidation; ANOVA, F value = 11.0 ($P < 0.01$).

TABLE 2
Growth Parameters and Liver Weight of Rats Fed Various Fats

	Dietary fat[a]				ANOVA[b]

Acyl-CoA oxidase[b]	3.00 ± 0.13^{f}	2.89 ± 0.06^{f}	4.53 ± 0.18^{g}	4.10 ± 0.26^{g}	21.9	$P < 0.01$
Enoyl-CoA hydratase						
Crotonyl-CoA substrate	3070 ± 114	3258 ± 191	3895 ± 206	3372 ± 366	1.88	N.S.
t-2-Octenoyl-CoA substrate	1499 ± 82	1491 ± 57	1721 ± 95	1474 ± 121	1.49	N.S.
3-Hydroxyacyl-CoA dehydrogenase[c]	180 ± 17^{g}	212 ± 14^{g}	54.3 ± 3.1^{f}	192 ± 12^{g}	35.6	$P < 0.01$
3-Ketoacyl-CoA thiolase[c]	90.1 ± 5.7	87.4 ± 5.8	106 ± 13	84.4 ± 4.3	1.62	N.S.
2,4-Dienoyl-CoA reductase[d]	5.02 ± 0.36^{f}	7.02 ± 0.52^{g}	9.98 ± 1.22^{g}	8.95 ± 0.42^{g}	7.74	$P < 0.01$
Δ^3,Δ^2-Enoyl-CoA isomerase[e]	31.0 ± 1.6^{f}	39.2 ± 1.6^{g}	35.4 ± 0.7^{f,g}	43.0 ± 2.0^{h}	11.1	$P < 0.01$

[a]Values are means ± SE (7 rats/group). Carnitine palmitoyltransferase activity was measured using both 500 × *g* supernatant and mitochondrial fractions as enzyme sources. Acyl-CoA dehydrogenase activity was measured using a mitochondrial fraction as an enzyme source. Activity of other enzymes was assayed using a 500 × *g* supernatant as an enzyme source.
[b]Palmitoyl-CoA was used as substrate.
[c]Acetoacetyl-CoA was used as substrate.
[d]Sorboyl-CoA was used as substrate.
[e]*trans*-3-Hexenoyl-CoA was used as substrate. Values with unlike roman superscript letters (f–g) differ significantly at $P < 0.05$. For abbreviations see Table 2.

Effect of dietary α- and γ-linolenic acid on enzyme activity in fatty acid synthesis. Although differences were not always significant, activity of enzymes in fatty acid synthesis was higher in rats fed palm oil than in those fed various polyunsaturated fats (Fig. 2). Activity was comparable, however, among rats fed different polyunsaturated fats, with some exceptions.

Effect of dietary α- and γ-linolenic acid on serum and hepatic lipid levels. Compared to palm oil, dietary fats rich in polyunsaturated fatty acid reduced serum triacylglycerol concentration (Table 4). The extent of reduction was exaggerated in rats fed fats rich in α- or γ-linolenic acids. Although no significant difference among groups was detected, serum cholesterol concentration tended to be lower in rats fed 18:3n-3 oil and borage oil than in those fed palm and safflower oils. Serum phospholipid concentrations were comparable among rats fed polyunsaturated fats and were significantly lower than in rats fed palm oil. Serum free fatty acid concentrations were also lower in rats fed polyunsaturated fats than in those fed palm oil, and the greatest decrease was detected with borage oil. Hepatic triacylglycerol concentrations were the same among rats fed various polyunsaturated fats and were significantly lower than in rats fed palm oil. Hepatic cholesterol concentration in rats fed borage oil was the lowest among groups and was significantly less than in those fed palm and 18:2n-6 oils. Compared to palm and 18:2n-6 oils, 18:3n-3 oil also reduced this parameter, and the difference between rats fed 18:2n-6 oil became statistically significant. Hepatic phospholipid concentrations were significantly higher in rats fed 18:2n-6 and 18:3n-3 oils than in those fed palm and borage oils.

Effect of dietary α- and γ-linolenic acid on liver lipid fatty acid composition. Compared to palm oil, dietary polyunsaturated fats increased the proportion of polyunsaturated fatty acids in triacylglycerol and phospholipid (Table 5). As phospholipid is a major component of biomembranes, unsaturation of this lipid molecule should remain constant to maintain the fluidity of biological membranes under the different nutri-

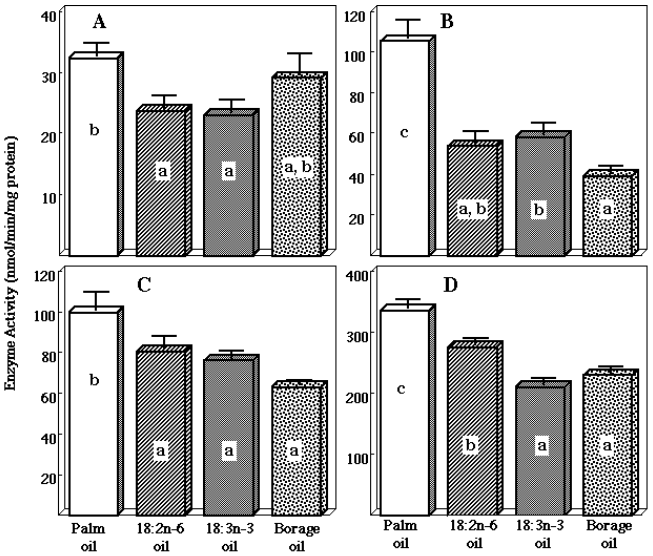

FIG. 2. Effect of α- and γ-linolenic acids on enzyme activity in fatty acid synthesis in the rat liver. [a]Values are means ± SE of seven rats.
[b]For abbreviations see Table 2. Values with unlike roman superscript letters (c–e) differ significantly at $P < 0.05$.

tional conditions. Although only a limited amount of polyunsaturated fatty acids is available in the diet containing palm oil, in the present study, hepatic phospholipid but not triacylglycerol retained considerable amounts of polyunsaturated fatty acids. Therefore, the extent of the increase in the proportion of polyunsaturated fatty acids attributable to dietary polyunsaturated fats was exaggerated in the hepatic triacylglycerol fraction compared to the phospholipid fraction. Even though borage oil contained considerable amounts of γ-linolenic acid, this fatty acid represented only a minor proportion both in triacylglycerol and phospholipid. Compared to fat mixtures rich in linoleic acid, dietary fats rich in γ-linolenic acid did not increase the sum of n-6 fatty acid concentrations in these lipid fractions. A dietary fat rich in α-linolenic acid increased the proportion of n-3 fatty acid (α-linolenic acid) in triacylglycerol and eicosapentaenoic and docosahexaenoic acids in phospholipid at the expense of n-6 fatty acid.

DISCUSSION

We previously demonstrated that, compared to saturated fats (palm and coconut oils) and safflower oil, perilla and linseed oils rich in a-linolenic acid (63% α-linolenic acid for perilla oil and 56% for linseed oil) increased mitochondrial and peroxisomal fatty oxidation rates in the rat liver (1,2). We also showed that, compared to safflower and palm oils, perilla and linseed oils increased the hepatic activity of various enzymes

[a]Values are means ± SE of seven rats.
[b]For abbreviations see Tables 1 and 2. Values with unlike roman superscript letters (d–g) differ significantly at $P < 0.05$. Comparisons were made between groups of rats fed different fats within fatty acid type.

in the β-oxidation pathway, including carnitine palmitoyltransferase, acyl-CoA dehydrogenase, acyl-CoA oxidase, enoyl-CoA hydratase, 3-ketoacyl-CoA thiolase, 2,4-dienoyl-CoA reductase, and Δ^3,Δ^2-enoyl-CoA isomerase, but unexpectedly decreased 3-hydroxyacyl-CoA dehydrogenase activity. A fat mixture composed of safflower and perilla oils containing α-linolenic acid at a level as low as 20% still effectively increased the mitochondrial and peroxisomal fatty acid oxidation rate and the activity of certain enzymes in the fatty acid oxidation pathway (2). This result was essentially confirmed in the present study in rats fed a fat mixture containing 30% α-linolenic acid from linseed oil.

Takada *et al*. (8) demonstrated that, compared to soybean oil, mold oil originating from a *Mucor circinelloides* and rich in n-6 octadecatrienoic acid (γ-linolenic acid) increased the peroxisomal fatty acid oxidation rate and carnitine palmitoyltransferase activity in the rat liver. The present study demonstrated that, compared to palm oil and a fat mixture rich in linoleic acid, a plant-originated oil rich in γ-linolenic acid (borage oil) also effectively increased the activity. It is therefore conceivable that dietary γ-linolenic acid, like α-linolenic acid, has a physiological activity to enhance hepatic β-oxidation in the rat liver. The present study, however, indicated that differences existed between n-3 and n-6 octadecatrienoic acids in the physiological activity affecting hepatic β-oxidation enzyme. Accordingly, dietary fat rich in α-linolenic acid enhanced both the mitochondrial and peroxisomal fatty acid oxidation rate whereas fat rich in γ-linolenic acid enhanced the peroxisomal, but not the mitochondrial, fatty acid oxidation rate. Our present study confirmed our previous finding (2) that dietary α-linolenic acid reduced 3-hydroxyacyl-CoA dehydrogenase activity in the rat liver. Borage oil rich in γ-linolenic acid, however, did not reduce this enzyme activity in the present study. In addition, α-linolenic acid enhanced mitochondrial acyl-CoA dehydrogenase activity, but borage oil profoundly reduced it.

Acyl-CoA oxidase is presumed to regulate peroxisomal fatty oxidation (13). Consistent with this assumption, an increase of peroxisomal palmitoyl-CoA oxidation by dietary fats rich in γ- and α-linolenic acids was associated with increased acyl-CoA oxidase activity in the liver homogenate. Carnitine palmitoyltransferase is regarded as a key enzyme regulating mitochondrial fatty acid oxidation (13,32). Even though dietary γ-linolenic acid, like α-linolenic acid, increased carnitine palmitoyltransferase activity, it did not increase the mitochondrial palmitoyl-CoA oxidation rate in the liver homogenate. There are two carnitine palmitoyltransferases in mitochondria, one in the outer mitochondrial membrane (carnitine palmitoyltransferase I) and the other in the inner mitochondrial membrane (carnitine palmitoyltransferase II). Freezing-thawing of mitochondria inactivates carnitine palmitoyltransferase I but not transferase II (32), meaning that the transferase activity we measured spectrophotomerically using a freeze-thawed 500 × *g* supernatant or mitochondrial fraction most likely represents transferase II activity (32). We previously demonstrated (1) that, compared to palm and safflower oils, perilla oil rich in α-linolenic acid increased both the carnitine palmitoyltransferase activity measured spectrophotomerically using freeze-thawed enzyme preparations (mitochondria and a 500 × *g* supernatant) and the activity measured radiochemically using intact mitochondria, which represents carnitine palmitoyltransferase I activity. We did not measure carnitine palmitoyltransferase I activity using intact mitochondria in our present study, so it is possible that dietary γ-linolenic acid increased carnitine palmitoyltransferase II but not I activity in the liver, thus failing to enhance the mitochondrial fatty acid oxidation rate. The determination of the transferase I activity using intact mitochondria as an enzyme source in rats fed γ-linolenic acid is therefore required to clarify this point.

Our present study confirmed the previous observation (2) that dietary α-linolenic acid decreased 3-hydroxyacyl-CoA dehydrogenase activity even though this polyunsaturated fatty acid increased both the mitochondrial and peroxisomal palmitoyl-CoA oxidation rates in liver homogenates. Several enzyme molecules possess 3-hydroxyacyl-CoA dehydrogenase activity in the rat liver (18,33,34). Some evidence (2) indicates that mitochondrial 3-hydroxyacyl-CoA dehydrogenase specific to short-chain acyl-CoA is the enzyme responsible for the reduction by dietary α-linolenic acid of 3-hydroxyacyl-CoA dehydrogenase activity in the rat liver. Dietary γ-linolenic acid did not reduce 3-hydroxyacyl-CoA dehydrogenase activity, but did decrease mitochondrial acyl-CoA dehydrogenase activity measured with palmitoyl-CoA and linoleoyl-CoA substrates in the present study. This reduced enzyme activity may account for the failure of dietary γ-linolenic acid to increase the mitochondrial β-oxidation rate in the rat liver despite the fact that this dietary fat increased carnitine palmitoyltransferase activity. Six distinct acyl-CoA dehydrogenase species differing in substrate specificity have been isolated and characterized (35,36). Four catalyze the first step of the mitochondrial β-oxidation cycle for fatty acids with different chain lengths. These correspond to short-, medium-, long-, and very long-chain acyl-CoA dehydrogenases. The remaining species are involved in oxidizing branched-chain amino acids. We used long-chain fatty acyl-CoA substrates in our present study to measure acyl-CoA dehydrogenase activity in mitochondria, so it is at least probable that dietary γ-linolenic acid reduced the activity of acyl-CoA dehydrogenase species specific to a long-chain acyl-CoA substrate. It is also possible, however, that dietary γ-linolenic acid affects the activity of both long chain acyl-CoA dehydrogenase and of other acyl-CoA dehydrogenase species in the rat liver. Acyl-CoA dehydrogenase activity will have to be measured using a variety of acyl-CoA substrates differing in chain length to clarify this point in future studies.

The degradation of unsaturated fatty acids *via* the β-oxidation pathway to yield acetyl-CoA requires the involvement of auxiliary enzymes (2,4-dienoyl-CoA reductase and Δ^3,Δ^2-enoyl-CoA isomerase) in addition to those required for the β-oxidation of saturated fatty acids (13,37). It is therefore rea-

sonable to expect that dietary polyunsaturated fatty acids increase the activity of these enzymes. In fact, compared to palm oil, various polyunsaturated fats significantly increased hepatic activity of these enzymes in the present study except for one occasion (Δ^3,Δ^2-enoyl-CoA isomerase in rats fed 18:3n-3 oil).

The role of the peroxisome proliferator-activated receptor (PPAR), a member of the nuclear receptor superfamily, in regulating lipid metabolism has been well demonstrated (38–40). After activation, PPAR is heterodimerized with retinoid × receptor (RXR), a member of another nuclear receptor superfamily, binds to peroxisome proliferator response element (PPRE) of a target gene, and modifies its expression. Various types of PPAR (α, γ_1, γ_2, and δ) have been identified in rodents and humans. PPARα is highly expressed in liver and may play a crucial role in regulating lipid metabolism in this tissue. So far, PPRE has been identified as the promoter of genes of various peroxisomal and mitochondrial fatty acid oxidation enzymes including acyl-CoA oxidase, peroxisomal bifunctional enzyme, medium chain acyl-CoA dehydrogenase and 3-hydroxy-3-methylglutaryl-CoA synthase, and it has been demonstrated that the expression of these genes is under the control of PPAR. Göttlicher *et al*. (41) and Keller *et al*. (42) have demonstrated that natural fatty acids are activators of PPAR to induce gene expression. These studies demonstrated that polyunsaturated fatty acids activate PPAR more than do saturated and monounsaturated fatty acids. More recent studies (43,44) indicate that fatty acids and eicosanoids are ligands of PPAR to induce its DNA binding and expression of target genes. It is therefore plausible that PPAR-mediated effects may account for dietary α- and γ-linolenic acids having different effects on only some of the hepatic fatty acid oxidation enzymes. It has been reported, however, that various polyunsaturated fatty acids including linoleic, α-linolenic, γ-linolenic, arachidonic, eicosapentaenoic, and docosahexaenoic acids are equally effective in activating PPAR, despite the fact that dietary linoleic, α-linolenic, and γ-linolenic acids differ considerably in how they affect hepatic fatty acid oxidation rate and fatty oxidation enzymes in our present and previous studies (1,2). Present knowledge concerning the PPAR signaling pathway therefore does not necessarily explain the data obtained with rats fed various polyunsaturated fat diets.

Evidence supports the assumption that fatty acid synthesis and oxidation rates in the liver are inversely regulated under different nutritional and pathological conditions (45–48). We previously demonstrated, however, that dietary α-linolenic acid, compared to linoleic acid, did not affect enzyme activity in the hepatic fatty acid synthetic pathway even though this octadecatrienoic acid increased mitochondrial and peroxisomal fatty acid oxidation (1,2). Compared to fat mixtures rich in linoleic acid, borage oil rich in γ-linolenic acid and a fat mixture rich in α-linolenic acid increased fatty acid oxidation activity in the liver but were essentially ineffective in modulating enzyme activity in fatty acid synthesis. It is therefore reasonable to assume that enzymes in fatty acid oxidation and synthesis are not necessarily reciprocally regulated in rats fed different fats.

In conclusion, we have shown that dietary α-linolenic acid induced hepatic β-oxidation activity in both peroxisomal and mitochondrial pathways, and dietary γ-linolenic acid in the form of borage oil increased peroxisomal but not mitochondrial β-oxidation activity. The effects of dietary α- and γ-linolenic acids on hepatic enzyme activities in the β-oxidation pathway were also found to differ considerably from one other.

Free Fatty Acid Fractions from Some Vegetable Oils Exhibit Reduced Survival Time-Shortening Activity in Stroke-Prone Spontaneously Hypertensive Rats

Makoto Miyazaki, Min-Zhao Huang, Naoya Takemura, Shiro Watanabe*, and Harumi Okuyama

Department of Biological Chemistry, Faculty of Pharmaceutical Sciences, Nagoya City University, Nagoya 467-8603, Japan

ABSTRACT: Previously, we demonstrated that several vegetable oils that included low-erucic rapeseed oil markedly shortened the survival time (by ~40%) of stroke-prone spontaneously hypertensive (SHRSP) rats as compared with perilla oil, soybean oil, and fish oil. We considered that a factor other than fatty acids is toxic to SHRSP rats, because the survival time-shortening activity could not be accounted for by the fatty acid compositions of these oils. In fact, a free fatty acid (FFA) fraction derived from lipase-treated rapeseed oil was found to be essentially devoid of such activity. A high-oleate safflower oil/safflower oil/perilla oil mixture exhibited a survival time-shortening activity comparable to that of rapeseed oil, but the activity of this mixed oil was also reduced by lipase treatment. A partially hydrogenated soybean oil shortened the survival time by ~40%, but a FFA fraction derived from lipase-treated partially hydrogenated soybean oil shortened it by 13% compared with soybean oil. Fatty acid compositions of the rapeseed oil and a FFA fraction derived from lipase-treated rapeseed oil were similar, but those of hepatic phospholipids of rats fed the oil and FFA were slightly but significantly different. These results support the interpretation that the survival time-shortening activity exhibited by some vegetable oils is due to minor components other than fatty acids, and that an active component(s) were produced in or contaminated soybean oil during the partial hydrogenation processes.

Lipids 33, 655–661 (1998).

Perilla seed oil and fish oil rich in n-3 fatty acids have beneficial effects on animals used as models of chronic diseases of the elderly (1). Perilla oil prolonged the survival time of Donryu rats (a conventional strain) and stroke-prone spontaneously hypertensive (SHRSP) rats (a model of human stroke) by ~10 and ~15%, respectively, compared with safflower oil (2,3). The observed beneficial effects of these oils were attributed to their low n-6/n-3 ratios. Rapeseed oil (low-erucic) had been assumed to be beneficial for chronic diseases because of its relatively high oleate and α-linolenate, and low linoleate contents. Dietary rapeseed (low erucic) and olive oils were very effective for the secondary prevention of coronary heart disease (4). Unexpectedly, however, rapeseed oil shortened the survival time of SHRSP rats (by 40%) compared with soybean, safflower, perilla and fish oils (5–7).

Although an old-type rapeseed contained very high amounts of erucic acid and thyrotoxic sulfur compounds, oil made from a newly developed strain of rapeseed (double-low) contains much lower amounts of these compounds. However, Vles *et al*. (8) reported that even the double-low rapeseed oil induced myocardial necrosis in Sprague-Dawley rats. Subsequently, the incidence of myocardial necrosis was attributed to the unique fatty acid composition of double-low rapeseed oil because the incidence was positively correlated with oleic and α-linolenic acids and negatively correlated with saturated fatty acids (9). In regard to survival time-shortening activity, the positive and negative correlations observed for myocardial necrosis were not applicable because perilla oil, which prolonged the survival time of SHRSP rats, contained a similar proportion of saturated fatty acids and a higher proportion of α-linolenic acid than rapeseed oil (6).

The survival time-shortening activity was not restricted to rapeseed oil; other high-oleate vegetable oils such as high-oleate safflower, high-oleate sunflower, and olive oils were also active in this respect. A high-oleate content by itself was not responsible for the survival-time shortening activity because lard and a microbial oil containing 36-39% oleic acid were relatively safe in this animal model, and evening primrose oil containing as little as 15% oleic acid exhibited activity similar to that of the oils which reduced longevity. Therefore, the observed survival time-shortening activities of these vegetable oils could not be accounted for by their unique fatty acid compositions. We postulated the presence in these oils of a factor(s) that are toxic to SHRSP rats (6). Here, we report that FFA fractions derived from some of these oils had a lower survival time-shortening activity, which may help in identifying and developing the means to eliminate the active component(s).

MATERIALS AND METHODS

Diets and animals. A conventional basal diet containing 2.7% (w/w) oil (CE-2; Clea Japan Co., Ltd., Tokyo, Japan) was made of fish meal, soybean meal, defatted powdered milk,

Abbreviations: FFA, free fatty acids; SHRSP, a strain of stroke-prone spontaneously hypertensive rats; SPF, specific pathogen-free; TLC, thin-layer chromatography.

wheat flour, corn, wheat bran, alfalfa meal, a vitamin mixture, and a mineral mixture. This basal diet was mixed with a vegetable oil or a derived free fatty acid (FFA) fraction in a 9:1 weight ratio. The final oil content was 12.7 wt% (29 energy %). The following vegetable oils, commercially available for human use, were used; rapeseed (low-erucic), soybean, safflower (high-linoleate), high-oleate safflower, perilla, sesame, and partially hydrogenated soybean (melting point: 30°C) oils. The source for the preparation of oleic acid ethyl ester (Wako Pure Chemical Industry, Osaka, Japan) is unclear. The fatty acid composition of the diets is shown in Table 1. Diets supplemented with these oils were kept at 4°C for less than 1 mon. Diets were replaced every 2 d to keep the peroxide values of the fed diets below 100 meq/kg.

A conventional strain of SHRSP rats, which were kindly provided by Dr. T. Suzuki (Kinki University School of Medicine, Osaka, Japan), was used in the experiment shown in Figure 1 and a specific pathogen-free (SPF) strain of SHRSP rats, which were purchased from Seack Yoshitomi Co. (Fukuoka, Japan), was used in other experiments. Blood pressure was measured every 2 wk using a photoelectric tail-cuff procedure after prewarming the rats at 35°C for 5 min in a thermostatic cage (Model UR5000; Ueda Manufacturing Co. Ltd., Tokyo, Japan). Male littermates were, as far as possible, equally distributed in different dietary groups. Rats were weaned to the conventional diet (CE-2) at 3 wk of age, and the test diets were given from 4 wk of age. The diet and 1% NaCl solution were given *ad libitum*. In the experiment shown in Figure 1, rats were kept in an air-conditioned room at 23 ± 3°C. In other experiments, rats were kept in a room specified for SPF animals; temperature and humidity were 23 ± 2°C and at 50 ± 2%, respectively.

Lipase and detergent treatment of vegetable oils. Vegetable oils and a partially hydrogenated soybean oil were dissolved at 4°C in polyvinyl alcohol solution (4.5 L) containing 1.8% polyvinyl alcohol 117 and 0.2% polyvinyl alcohol 205 (kindly provided by Kuraray Co., Ltd., Osaka, Japan). Sucrose fatty acid ester (2%) was used only for the preparation of detergent-treated hydrogenated soybean oil without added lipase (Experiment 3, Table 3). Then 0.1 M phosphate buffer, pH 8.0 (3 L), with or without 0.1% (wt/vol) Lipase AY 30 (90,000 I.U./3 g/3 L; Amano, Nagoya, Japan), was added and the mixture was stirred at room temperature or 35°C for 1 wk. Triacylglycerols in rapeseed oil, partially hydrogenated soybean oil, and a mixture of high-oleate safflower oil/safflower oil/perilla oil were hydrolyzed to FFA in 90.6, 86.3, and 91.7% of the total ester bonds, respectively. After the reaction, hexane (7.5 L) and NaCl (3 kg) were added, the hexane layer was separated, and the solvent was evaporated under reduced pressure to obtain FFA fractions or detergent-treated oils.

Lipid analysis. SHRSP rats ($n = 6$) in the rapeseed oil, soybean oil or partially hydrogenated soybean oil group were used for lipid analysis after 60 d of feeding. The SHRSP rats were anesthetized with pentobarbital (Nembutal, 50 mg/kg, i.p.; Dainabot, Osaka, Japan) after fasting for 18 h. Blood samples were collected from an abdominal vein using a syringe containing 3.8% (wt/vol) sodium citrate, and plasma was prepared by low-speed centrifugation. The thoracic aorta was excised, and the attached fat tissues were removed with the aid of a microscope. Samples were kept frozen at −80°C until lipid analysis. The total lipids were extracted from the samples according to the method of Bligh and Dyer (10), and triacylglycerols and phospholipids were separated by silica

[a]Fatty acids are designated by the number of carbons; the number of double bonds, and the position of the first double bond numbered from the methyl terminus is indicated as n-3 or n-6, and *cis* or *trans* isomers are designated as *c* or *t*.
[b]Ninety grams of conventional diet that contained 2.7% oil was mixed with 10 g of oil or of free fatty acids (FFA) fraction from lipase-treated oils.
[c]Oleic acid ethyl ester/soybean oil/.perilla oil mixture was prepared by mixing oleic acid ethyl ester (57.2%), soybean oil (27.8%), and perilla oil (14.8%).
[d]See Materials and Methods section for the preparation of FFA fractions from lipase-treated oils.
[e]This mixed oil consisted of high-oleate safflower (75%), safflower (12.5%), and perilla oils (12.5%).
[f]n.d., not detected.

gel thin-layer chromatography (TLC). Petroleum ether/diethyl ether/acetic acid (80:30:1, by vol) was used as the developing solvent. Spots were located under a ultraviolet light after plates were sprayed with 0.005% (wt/vol) primuline solution (Nacalai Tesque Co., Kyoto, Japan) and the lipids were extracted from the adsorbent using Bligh and Dyer mixture. Fatty acids were analyzed as methyl esters by gas–liquid chromatography on a capillary column coated with DB-225 (0.2 mm, 30 m length; J&W Scientific, Folsom, CA), using heptadecanoic acid as an internal standard. Column temperature was programmed from 165 to 205°C at a rate of 3°C/min, then to 210°C at a rate of 1°C/min, and then to 222°C at a rate of 0.5°C/min. Injector and detector temperatures were both 250°C. The *trans*- and *cis*-18:1 contents were determined using $AgNO_3$–TLC in conjunction with gas–liquid chromatography. The $AgNO_3$-TLC analyses were performed on precoated silica gel TLC plates that had been immersed in a 10% (wt/vol) solution of $AgNO_3$ in acetonitrile, dried horizontally, and activated at 110°C for 1 h. The plates were developed with 0.75% ethanol in chloroform. The lipid bands were sprayed with primuline solution and then identified under an ultraviolet UV light. The separated fractions were scraped off the plate, and the lipids were extracted with chloroform/hexane (1:1, vol/vol) and analyzed by gas–liquid chromatography (7,11).

Statistical analysis. Data are presented as means ± SD. Statistical analysis of the survival time data was performed by log-rank and Wilcoxon signed rank method (a nonparametric method) using a computer program JMP 3.0, Statistic Made Visual (SAS Institute, Cray, NC). Statistical analysis of other data was performed by analysis of variance using Bonferroni's multiple comparison or repeated measures analysis of variance (Stat View J-4.11; Abacus Concepts Inc., Berkeley, CA).

RESULTS

Effect of oils and derived FFA fractions on survival time of SHRSP rats. Rats in all groups grew normally, and there were no differences in average body weights (data not shown) and systolic blood pressures (Fig. 1) among the rats in the rapeseed oil, soybean oil, and partially hydrogenated soybean oil groups and rats fed the FFA derived from lipase-treated rapeseed oil up to 13 wk of age. Rapeseed oil shortened the survival time of SHRSP rats by 35% compared to soybean oil (Fig. 2). In contrast, the FFA fraction derived from lipase-treated rapeseed oil did not exhibit such a survival time-shortening activity, although fatty acid compositions were not altered significantly by the lipase-treatment (Table 1). Partially hydrogenated soybean oil was as detrimental as rapeseed oil (Experiment 1, Table 2, and Fig. 2). When a triolein/soybean oil/perilla oil mixture with the same fatty acid composition as that of rapeseed oil was fed to SHRSP rats, the survival time of this mixed oil group was between those of the rapeseed oil and soybean oil groups (6). Similarly, the survival time of the oleic acid ethyl ester/soybean oil/perilla oil mixture group was between the rapeseed oil and soybean oil groups (Experiment 1, Table 1).

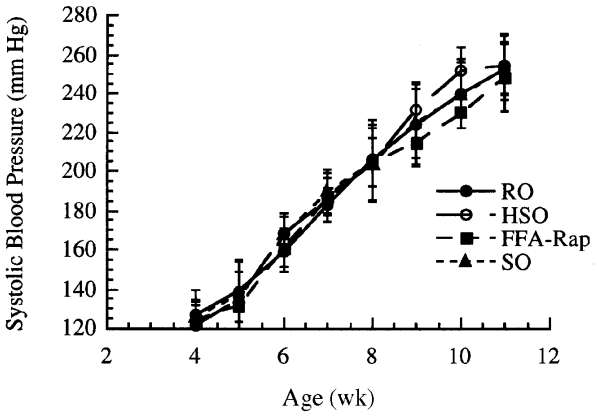

FIG. 1. Systolic blood pressure of stroke-prone spontaneously hypertensive (SHRSP) specific pathogen-free (SPF) rats under 1% NaCl loading. A diet containing 10% (w/w) rapeseed oil (RO), hydrogenated soybean oil (HSO), soybean oil (SO), or a FFA fraction derived from lipase-treated rapeseed oil (FFA-Rap) was fed to SHRSP rats from 4 wk of age. The differences among the dietary groups were not significant in the repeated measures ANOVA.

To minimize the standard deviation among experiments, we changed in subsequent experiments from using a conventional strain of SHRSP rats kept in a temperature-controlled room to SPF SHRSP rats kept in temperature, humidity, and light-controlled conditions. The difference in the mean survival times between the rapeseed oil and soybean oil groups was smaller in SPF SHRSP (Experiment 2, Table 2) than in the conventional SHRSP rats (Experiments 1, Table 2); the former had a higher blood pressure (~40 mm Hg) and appeared to be more sensitive to dietary conditions (e.g., 1%

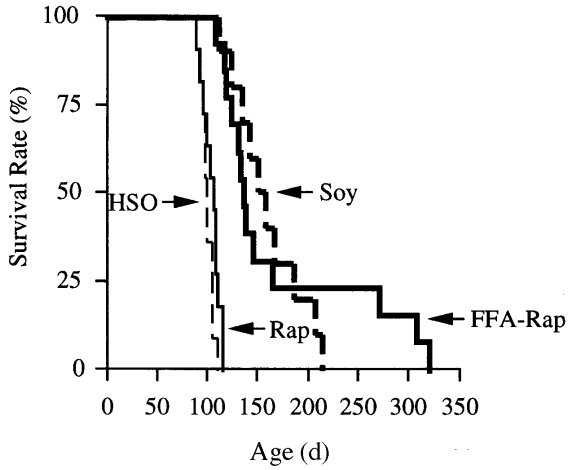

FIG. 2. Survival time-shortening activities of some vegetable oils and a free fatty acid (FFA) derived from lipase-treated rapeseed oil. Diets supplemented with different oils were fed to SHRSP rats (conventional) from 4 wk of age. NaCl solution (1%) was given *ad libitum* as drinking water. Partially hydrogenated soybean oil (HSO, $n = 11$), rapeseed oil (Rap, $n = 11$), soybean oil (Soy, $n = 10$), and a FFA derived from lipase-treated rapeseed oil (FFA-Rap, $n = 11$) were examined. Results of statistical analysis were presented in Experiment 1, Table 2. For other abbreviations see Figure 2.

[a]SPF, specific pathogen-free; SHRSP, stroke-prone spontaneously hypertensive rats.

NaCl loading). Despite the differences in substrains of SHRSP and in animal care conditions, a statistically significant difference was observed in the mean survival times between the soybean oil and rapeseed oil groups. Previously, we noted that a mixed oil (75% high-oleate safflower oil, 12.5% perilla oil, and 12.5% safflower oil) with a fatty acid composition similar to that of rapeseed oil shortened the survival time by 45% compared to soybean oil (6). A FFA fraction obtained by lipase treatment of the same mixture was essentially devoid of the survival time-shortening activity (Experiment 2, Table 2). The survival times of sesame oil and soybean oil groups were similar but tended to be shorter than that of rats fed the FFA fraction derived from a lipase-treated mixed oil (Experiment 2, Table 2, and Fig. 3). Previously, we noted that both hydrogenated soybean and rapeseed oils had survival time-shortening activities comparable to that of rapeseed oil (7). The FFA fraction derived from lipase-treated hydrogenated soybean oil prolonged the survival time compared with rapeseed oil. However, the survival time of rats fed the FFA fraction derived from lipase-treated hydrogenated soybean oil was significantly shorter than that of rats fed the FFA fraction derived from lipase-treated mixed oil (Experiment 2, Table 2).

The lipase treatment used for the preparation of FFA fractions involves both lipase and detergent action. The subsequent experiments (Experiment 3, Table 2) examined whether detergent treatment without added lipase removes the presumed survival time-shortening factor. Rapeseed and partially hydrogenated soybean oils were treated with detergents in the absence of lipase. The detergent treatment alone did not reduce the survival time-shortening activity of the oils (Experiment 3, Table 2).

Effect of oils and derived FFA fractions on tissue lipid composition. Lipid contents in plasma, aorta, liver, and heart were determined for the rats fed the rapeseed oil, FFA derived from lipase-treated rapeseed oil, partially hydrogenated soybean oil, or soybean oil. No significant difference was observed in the contents of plasma cholesterol, plasma triacylglycerols, plasma phospholipids, aortic cholesterol, aortic

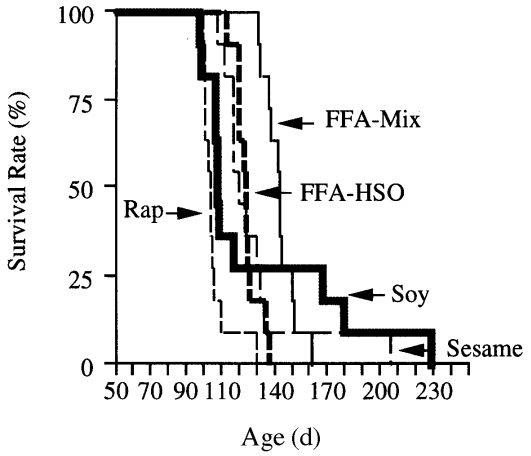

FIG. 3. Survival time-shortening activities of some vegetable oils and FFA fractions derived from lipase-treated oils. Rapeseed oil (Rap, n = 11), soybean oil (Soy, n = 11), sesame oil (Sesame, n = 11), a FFA derived from lipase-treated partially hydrogenated soybean oil (FFA-HSO, n = 11), and a FFA derived from lipase-treated mixed oil (FFA-Mix, n-11) were fed to SHRSP rats (SPF). Results of statistical analysis were presented in Experiment 2, Table 2. For other abbreviations see Figure 1.

phospholipids, liver phospholipids, liver neutral lipids, heart phospholipids, and heart neutral lipids among the four dietary groups (data not shown). The fatty acid compositions of tissue phospholipids are shown in Tables 3 and 4. *Trans* fatty acids were found in significant amounts only in the hydrogenated soybean oil group, and the compositions of other fatty acids in tissue phospholipids were affected relatively little by these diets. Interestingly, in plasma phospholipids and hepatic phospholipids, the proportion of arachidonic acid was significantly higher in the group fed the FFA derived from lipase-treated rapeseed oil than in the group fed the rapeseed oil (Tables 3 and 4). In contrast, no significant differences in fatty acid compositions among the four dietary groups were observed in the aortic phospholipids and triacylglycerols of all tissues examined (data not shown).

DISCUSSION

No survival time-shortening activity was observed in the FFA fractions from lipase-treated rapeseed oil (Fig. 1 and Experiment 1, Table 2) and mixed oil having a fatty acid composition similar to that of rapeseed oil (Experiment 2, Table 2). The chemical forms of the oils were different, e.g., triacylglycerol vs. free fatty acid, but fatty acid compositions were similar. Triacylglycerols are absorbed as 2-monoacylglycerols and FFA after pancreatic lipase hydrolysis, and the absorption rate of FFA is known to be higher than that of triacylglycerols (12). In the present experiments, no statistical differences were observed in tissue lipid contents and growth rates between the groups fed oils and those fed the FFA fractions derived from the lipase-treated oils. Our interpretation is that the presumed toxic factor(s) in these oils were inactivated by the lipase or they were hydrolyzed to a more hydrophilic compound(s) that remained in the detergent layer, or both. Lipase action was probably involved to obtain FFA fractions essentially devoid of survival time-shortening activity, because the activity was not diminished by treating oils with detergent-containing buffer without lipase.

The presumed toxic factor(s) in rapeseed oil could not be

eliminated or inactivated by partial hydrogenation (7). Unexpectedly, partially hydrogenated soybean oil exhibited a survival time-shortening activity similar to rapeseed oil, suggesting that a toxic factor(s) are generated in or contaminate partially hydrogenated soybean oil during the process of production (Fig. 1 and Ref. 7). The survival time of rats fed the FFA fraction derived from lipase-treated partially hydrogenated soybean oil was significantly shorter than that of rats fed the FFA fraction derived from a mixture of high-oleate safflower oil/safflower oil/perilla oil (Table 2), suggesting that *trans* fatty acids may be partially responsible for the survival time-shortening activity. The lipase treatment was also effective for the preparation of FFA fraction from hydrogenated oils (Table 2).

Several other studies have shown or suggested the existence of minor components other than triacylglycerol in rapeseed oil. Among sulfur compounds, isothiocyanates and oxazolidinethione do not appear to be responsible for the survival time-shortening activity, because butyl isothiocyanate (8 mg/kg of soybean oil), phenethyl isothiocyanate (1 mg/kg), and allyl isothiocyanate (1 mg/kg) did not shorten the survival time at concentrations comparable to those in rapeseed oil (5). Rapeseed oil has a significantly higher phytosterol content than soybean oil (13). However, unsaponifiable compounds from rapeseed oil did not exhibit survival time-shortening activity and no significant amounts of phytosterols were found in tissue lipids (data not shown). We suggest that the toxic factor(s), if any, are different from those described above and are sensitive to lipase action.

Mean survival time of experimental animals has not been a common endpoint for the determination of the safety or nutritional adequacy of fats and oils. By using this measure, we raised a question on the safety of some of the common oils and oil products in human nutrition, although the applicability of the results to human nutrition is entirely unknown. Besides shortened survival time, we observed accelerated renal injury in SHRSP rats fed rapeseed oil and partially hydrogenated oil (Miyazaki, M., Watanabe, S., Oikawa, T., Morazumi, K., Fuzinami, T., and Okuyama, H., unpublished data). Other groups have also raised questions on the safety of some common vegetable oils using different endpoints; for example, increased mortality after injection of iron into piglets fed a rapeseed oil-supplemented, tocopherol-restricted diet (14), and reduced platelet counts in piglets fed rapeseed oil- or high-oleate vegetable oil-supplemented diets (15,16). The problem of myocardial necrosis reported in rapeseed oil-fed Sprague-Dawley rats remains unresolved (8,9). The lipase-treatment and successful preparation of FFA fraction essentially devoid of survival time-shortening activity of the original oils described in this paper may help in solving these unresolved problems raised by other laboratories.

Docosahexaenoic Acid Does Not Affect Aggression of Normal Volunteers Under Nonstressful Conditions. A Randomized, Placebo-Controlled, Double-Blind Study

Tomohito Hamazaki[a,*], Shigeki Sawazaki[a], Yoko Nagao[b], Toyomi Kuwamori[c], Kazunaga Yazawa[d], Yutaka Mizushima[a], and Masashi Kobayashi[a]

ABSTRACT: We previously found that docosahexaenoic acid (DHA) intake prevents aggression enhancement at times of mental stress. In the present study we investigated changes in aggression under nonstressful conditions. Forty-six students of two universities took either DHA-rich fish oil capsules containing 1.5 g DHA (DHA group: 13 males and 9 females) or control oil capsules containing 97% soybean oil plus 3% of another fish oil (control group: 11 males and 13 females) for 3 mon in a double-blind fashion. At the start and end of the study they took an aggression-estimating test (P-F Study) without a stressor component. DHA (5.9 to 8.5%, $P < 0.001$) and eicosapentaenoic acid (0.7 to 1.5%, $P < 0.001$) increased in red blood cell phospholipids in the DHA group, while linoleic acid increased slightly (8.3 to 9.1%, $P < 0.002$) in the soybean oil control group. In the control group, measured aggression levels decreased from 34.8 to 29.4% ($P < 0.005$), whereas they remained stable in the DHA group (33.5 to 33.8%). The intergroup differences (–5.4 vs. 0.3%) were marginally significant ($P \leq 0.05$). Aggression levels were stable in the DHA group whether there was stressor (as previously shown) or not. This effect of DHA appears to be interesting, considering the reported association between a low intake of n-3 fatty acids and depression.
Lipids 33, 663–667 (1998).

Several epidemiological studies (1,2) have suggested that a higher intake of fish appears to be associated with a lower incidence of coronary heart disease. Dietary intervention with fatty fish (3) or α-linolenic acid (4), one of the n-3 fatty acids, has also reduced the total mortality in secondary prevention trials. In the intervention trial with fish (3), reduction in death rates was attributed to a decreased incidence of fatal arrhythmia, because fatal myocardial infarctions were significantly reduced in the fish-eating group compared with the nonfish-eating group, although the total incidence of myocardial infarction was similar between the two groups.

A recent intervention trial with n-3 long-chain fatty acids in survivors of coronary heart disease found that the standard deviation of all normal RR intervals in 24-h Holter recordings significantly increased in an n-3 fatty acid group compared with controls ingesting olive oil capsules (5). This finding is important because an increase in parasympathetic tone reflected by an increased standard deviation of RR intervals is associated with a higher ventricular fibrillation threshold and fewer episodes of ventricular fibrillation (6). Indeed, Sellmayer *et al.* (7) have successfully reduced ventricular premature complexes with fish oil in a placebo-controlled double-blind study. However, there have been few mechanistic studies on antiarrhythmic effects of fish (8,9). Taking into account that hostility may be a significant risk factor for CHD and arrhythmia (10), it is important to investigate whether fish oils might modulate hostility or aggression.

Hibbeln and Salem (11) have proposed an interesting hypothesis about n-3 fatty acids and depression. They have suggested that societies consuming large amounts of n-3 fatty acids appear to have low rates of major depression, and postulated that docosahexaenoic acid (DHA), one of the long-chain n-3 fatty acids, may reduce the development of depression. Consequently, the study of psychological effects of n-3 fatty acids has become rather important.

In our previous study (12) using university students as subjects, we showed that administration of DHA-rich fish oil prevented enhancement of aggression at times of mental stress. To investigate the effect of DHA on aggression further, we conducted a similar study under nonstressful conditions. In the present study we carefully chose the timing of psychological testing to avoid the confounding influence of any academic examinations.

SUBJECTS AND METHODS

Subjects. The purpose and plan of the present study was explained to two classes of university students to recruit volunteers; one was a fourth-year class at Toyama Medical and Pharmaceutical University and the other was a third-year class at Kogakkan University. Fifty-nine nonsmoking students of

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; RBC, red blood cells.

Toyama Medical and Pharmaceutical University [21–30 yr of age (median 22), 16 males and 15 females] and Kogakkan University (20–22 yr of age, 14 males and 14 females) volunteered to enter two parallel trials. None of the subjects had participated in the previous study (12). They were in good health as determined by history and physical examinations conducted by physicians 3 mon before the trial. They did not suffer from any chronic illness including alcoholism and were not taking any medicines regularly. They were allocated to either the control or the DHA group in a double-blind manner; randomization was stratified according to site and sex (Table 1). Written informed consent was obtained from each subject, and the study was approved by the Pharmacy and Therapeutics Committee (a subcommittee of the ethics committee) of Toyama Medical and Pharmaceutical University.

Study design. The design of the present study was very similar to our previous one (12). The present study was performed in the two universities on the same protocol. All subjects were asked to maintain their body weights and physical activity levels and to consume their habitual diets during the study. They were instructed to take 10 capsules per day containing DHA-rich fish oil (for the DHA group, 1.5 g DHA/day) or control oil (the control group) for 13 wk. Three or four capsules were taken after each meal. Each capsule contained 300 mg of oil with 0.3% α-tocopherol. The fish oil used for the DHA group contained 49% DHA and 7% eicosapentaenoic acid (EPA) and was essentially odorless. The control oil was a mixture of 97% soybean oil and 3% of another fish oil (concentrated sardine oil containing 32% EPA and 16% DHA) that had been only partially deodorized. The detailed fatty acid composition of the oils is shown elsewhere (13).

At the starting point of the study and at the end (13 wk afterward), subjects were asked to come to their own universities in the early morning without having breakfast and to refrain from drinking alcoholic beverages during the previous day. Blood was taken from fasting subjects. After breakfast they were asked to take psychological tests and to complete a food frequency questionnaire for the previous 4 wk. At the end of the study they were also asked to guess what their capsules had contained. Of 22 control subjects, 10 said they were receiving control capsules, 6 said DHA capsules, and 6 were unsure. Of 20 subjects taking DHA capsules, 7 thought they were taking control capsules, 9 thought DHA, and 4 were unsure. Thus 45% of subjects in each group had correctly surmised their treatment group.

TABLE 1
The Number of Subjects at the Start and the Exclusion of Subjects[a]

	Control group				DHA group			
	Toyama		Kogakkan		Toyama		Kogakkan	
Exclusion step	M	F	M	F	M	F	M	F
Subjects at randomization	8	8	7	7	8	7	7	7
Dropouts[b]			–2	–1				–2
Significant body weight changes (|Δ| > 3 kg)			–1 (+3.5 kg)				–1 (+4 kg)	
Insufficient capsule intake (<70%)	–1			–1				–1
Decrease in red blood cell DHA (applied to DHA group only)[c]					–1	–2		
Final number	7	8	4	5	7	5	6	4

[a]The exclusion was performed before the double-blind code was broken. M, male; F, female; DHA, docosahexaenoic acid.
[b]Four of the five dropouts were due to personal reasons and the other (control male) was due to intolerance to capsules (gastrointestinal disorder).
[c]The exclusion at this step was performed without knowing the results of psychological tests after the double-blind code was broken.

The major difference between the present study and the previous one was timing. The present study started in July (during summer vacation) and ended in October in the same school year. The two check points were carefully chosen so that no important exams were scheduled within 30 d from any check points at either university.

Psychological tests. Two tests were employed. One was P-F Study, originally developed by Rosenzweig (14). We used the adult form of a Japanese version (15). This test consisted of 24 pictures illustrating frustration. Subjects were asked to look at those pictures and describe their first reactions (replies) with a couple of sentences. The frequency of appearance of their reactions to others was calculated as extraggression (%). The other test was a Japanese version (16) of Cook and Medley hostility scale (17). This test consisted of 87 questions, 50 of which were selected for measurement of hostility. Rating of these two tests was blindly done by three testers independently throughout the study. On rare occasions of discrepancy in ratings of P-F Study among the three testers, they discussed their scorings so as to reach a consensus.

Fatty acid analysis. The fatty acid composition of the total phospholipid fraction of red blood cells (RBC) was determined as described previously (18) with slight modification. Briefly, packed RBC from EDTA-anticoagulated blood were washed twice with saline. Total lipids were extracted by the method of Folch *et al.* (19). The total phospholipid fraction was separated by thin-layer chromatography, and its fatty acid composition was analyzed by gas chromatography after transmethylation (20).

Food analysis. Food intake was calculated, from two sets of food frequency questionnaires completed at the start and end of the study, with our own software. This software was a program of Kishokun (a food questionnaire program, Kan'ei-shuppan, Okayama, Japan) modified for local use.

Exclusion of subjects. According to the exclusion criteria determined prior to the trial (<70% capsule intake, and >3 kg changes in body weights), some subjects were excluded before the double-blind code was broken except for the exclusion step based on the DHA concentration of RBC (Table 1). Some subjects in the DHA group whose DHA concentration did not increase after capsule administration were excluded (Table 1). This step was performed by investigators who did not know the results of P-F Study and Cook and Medley hostility scale and applied to the DHA group only, after the code was broken and the DHA concentration of RBC was available.

Statistical analysis. Data are expressed as mean ± SD. Statview (Japanese version 4.5; Abacus Concepts, Berkeley, CA) was used for statistical analysis. A paired *t*-test was used for intragroup comparisons of the end and start of the study. Intergroup differences (the differences between intragroup differences of the two groups) were analyzed by an unpaired *t*-test. Site effect-adjusted *P*-values were calculated by two-way analysis of variance with the following two factors: sites and capsules. Baseline values of the two groups were compared by using an unpaired *t*-test. Differences with $P < 0.05$ were considered significant.

RESULTS

One subject in the control group complained of gastrointestinal disorder and dropped out before the study was completed. Subjects who completed the study complained of no serious adverse effects of capsules, and could not infer the kind of their own capsules more correctly than by chance. Excluded subjects are listed in Table 1.

Changes in the fatty acid composition of the total phospholipid fraction of RBC are shown in Table 2. In the control group, linoleic acid increased; the increase was small but statistically significant. In the DHA group, DHA and EPA increased over time, whereas arachidonic acid decreased.

Averaged daily intakes of fatty acids from food are shown in Table 3. There were no significant differences between the two groups at the start.

Changes in Cook and Medley hostility scale were not significant in either the control group (33.3 ± 11.4 to 31.9 ± 10.2%, $n = 24$) or the DHA group (38.8 ± 13.4 to 37.5 ± 16.2%, $n = 22$). This was true in both universities (data not shown).

TABLE 2
Changes (mol%) in the Fatty Acid Composition of the Total Phospholipid Fraction of Red Blood Cells (mean ± SD)[a]

	Control group ($n = 22$)[b]		DHA group ($n = 22$)	
Fatty acid	Start	End	Start	End
16:0	23.3 ± 2.5	23.2 ± 2.5	22.6 ± 2.8	22.3 ± 1.5
18:0	14.9 ± 1.0	14.9 ± 1.3	14.8 ± 1.1	14.6 ± 0.8
18:1	11.6 ± 0.8	12.0 ± 1.1	12.0 ± 1.0	12.2 ± 1.1
18:2	8.3 ± 0.7	9.0 ± 0.9[c,e]	8.5 ± 0.8	8.3 ± 0.9
20:4	9.5 ± 1.0	9.1 ± 1.9	9.4 ± 1.0	8.8 ± 0.6[c,f]
20:5	0.77 ± 0.27	0.66 ± 0.23	0.71 ± 0.19	1.35 ± 0.36[d,f]
22:6 (DHA)	4.8 ± 1.0	4.6 ± 1.1	4.8 ± 0.9	7.0 ± 1.0[d,f]

[a]Basically, there were no marked differences between the two universities, therefore data from the two universities were combined. There were no significant differences between the two groups at baseline.
[b]Two blood samples from Kogakkan University were lost during transportation.
[c]Significantly different from baseline, $P < 0.001$.
[d]Significantly different from baseline, $P < 1 \times 10^{-9}$; however, *P* was theoretically null for DHA, since subjects with decreased DHA contents were excluded beforehand.
[e]Intragroup differences were significantly different from the other group; $P < 0.001$.
[f]Intragroup differences were significantly different from the other group; $P < 0.001$. For abbreviation see Table 1.

Changes in extraggression (P-F Study) are shown in Table 4. Extraggression significantly decreased over time in the control group at both Toyama and Kogakkan, whereas it remained stable in the DHA group. The intergroup differences were significant ($P < 0.05$) by two-way analysis of variance; however, an unpaired *t*-test showed a tendency toward decreased extraggression in the control group compared with the DHA group ($P = 0.05$).

DISCUSSION

Recently, suggestions of a relationship between low n-3 fatty acid intake and increased incidence of depression (11) have been further strengthened by the findings of Adams *et al.* (21) that the ratio of RBC phospholipid arachidonic acid to EPA correlates significantly with severity of depression. Interestingly, our previous study (12) suggested an aggression-stabilizing effect of DHA administration under the stress of university examinations. This effect might prevent students from experiencing wider variances of mental reactions to stressful events and thus from mental exhaustion. This effect may also be applicable to prevention of arrhythmia. As described in the introduction, it has been suggested that the intake of n-3 fatty acids prevents life-threatening arrhythmias. Aggressive behaviors are associated with decreased parasympathetic nervous system activity, which is linked with decreased brain serotonin function (10). Also, parasympathetic tone is important for prevention of ventricular fibrillation (6). Consequently, if DHA administration stabilizes the brain serotonergic function as postulated by authors of previous studies (11,12,22), this effect may contribute to the antiarrhythmic effects of fish oils.

Extraggression in the control group was significantly lower at the end of the study. This finding was contrary to our previous study (12), in which controls exhibited increased extraggression over time. The major difference between the two studies consists in the absence of extremely important exams 7–10 d after the last psychological tests in the present study. Consequently, the presence or absence of mental stress may have contributed to the radically different result. In general, the presence of a stressor increases the degree of aggression (23,24). Actually, hostility (the Multiple Affect Adjective Checklist) and aggression (the Adjective Rating Form) scales of nondrinkers were higher than those of moderate drinkers when subjects were not provoked, whereas, after provocation, both scales increased in the two groups, and those of moderate drinkers became higher than for nondrinkers (24). Thus, it is possible that the results obtained from the psychological testing methods without stressor as performed in the present study were different from the previous results (12). The results of the present study therefore do not necessarily contradict our previous finding that DHA reduced aggression in a normal population under significant stress.

We chose identical control capsules with those used before (12) to facilitate the comparison of the two studies. In the previous study (12) the control oil did not change the fatty acid composition of the total plasma phospholipid fraction, but

TABLE 3
Averaged Daily Intakes of Lipids and Energy (mean ± SD)[a]

Item	Control group (n = 24)		DHA group (n = 22)	
	Start	End	Start	End
		g/d		
Total lipids	66.9 ± 35.7	57.3 ± 20.1	67.5 ± 25.1	55.7 ± 21.2[b]
Linoleic acid (18:2)	12.8 ± 6.8	12.9 ± 5.1	11.5 ± 4.4	10.1 ± 4.6
EPA (20:5)	0.088 ± 0.099	0.144 ± 0.098[c]	0.107 ± 0.102	0.319 ± 0.111[d]
DHA (22:6)	0.022 ± 0.024	0.043 ± 0.024[d]	0.026 ± 0.025	1.529 ± 0.028[d]
Linoleic acid/total lipids	0.20 ± 0.04	0.22 ± 0.05	0.18 ± 0.05	0.18 ± 0.04
		kJ/d		
Total energy	9.19 ± 3.92	8.34 ± 3.23	8.07 ± 1.97	7.25 ± 2.00

[a]Lipid and energy intakes were assessed by food frequency questionnaires at the start and end of the study. There were no significant differences between the two sites; therefore, data were combined. Food intake of the last 4 wk was requested at each check point. Data at the end of the study contain lipids from capsules. There were no significant differences in any data between the two groups at the start.
[b]Significantly different from baseline, $P < 0.005$.
[c]Significantly different from baseline, $P < 0.002$.
[d]Significantly different from baseline, $P < 0.001$. EPA, eicosapentaenoic acid, for other abbreviations see Table 2.

RBC fatty acids were not measured. In that study, extraggression increased in the control group under stressful conditions. However, in the present study (Table 2), linoleic acid concentrations in the RBC phospholipid fraction increased over time in the control group, but plasma fatty acids were not measured. Although the daily intake of linoleic acid did not increase in the control group even after taking capsule lipids into consideration, the ratio of the intakes of linoleic acid to total lipids tended to increase from 0.20 to 0.22 (Table 3, P = 0.08). This increment might partly explain the changes in linoleic acid in control RBC.

We did not anticipate any changes in extraggression in the control group. We carefully planned the timing of psychological testing. The study started at the beginning of summer vacation of the universities, and ended at the middle of the semester that was more than 1 mon away from any important exams. Therefore, stress levels for students appeared alike between the two check points. At least it is highly unlikely that students felt less stress at the end of the study. Then, why did measured extraggression decrease in the control group? It is possible that habituation to testing could account for such a decline, but this would not explain the failure of a drop in measured extraggression in the DHA group.

If we look at intergroup changes instead of intragroup differences, we may ask the following question: Is there any possibility that a difference in extraggression between the two groups was merely a chance finding? The intergroup differences in extraggression were not significant either in Toyama subgroup alone or in Kogakkan (Table 4). Besides, the plain sum of the two subgroups without consideration of the site effect showed only a marginally significant difference (P = 0.05) by unpaired t-test. Considering the number of comparison tests, the intergroup difference in extraggression may be a chance finding. Finally, we found at the end of our study that 45% of each treatment group had correctly identified their assignment but it is not possible to determine whether this could have further biased the testing result. Consequently, it is prudent to treat the intragroup changes in extraggression cautiously in the control group. The results of the Cook and Medley hostility scale partly support the null hypothesis about changes in extraggression.

In conclusion, the administration of DHA does not change extraggression in university students in the absence of mental stress related to examinations. Whether these findings would be applicable to patients undergoing the stress of a life-threatening disease such as myocardial infarction will be determined with further study.

TABLE 4
Changes in Extraggression After 3 mon of Capsule Administration (mean ± SD)

	Start	End	Intragroup difference
Toyama subgroup			
Control (n = 15)	33.5 ± 7.7	30.2 ± 10.6[a]	−3.3 ± 5.9

Effect of the Degree of Hydrogenation of Dietary Fish Oil on the *trans* Fatty Acid Content and Enzymatic Activity of Rat Hepatic Microsomes

Nora Morgado, Angélica Galleguillos, Julio Sanhueza, Argelia Garrido, Susana Nieto, and Alfonso Valenzuela*

Laboratorio de Lípidos y Antioxidantes, Instituto de Nutricion y Tecnologia de los Alimentos (INTA), Universidad de Chile, Santiago, Chile

ABSTRACT: The degree of fat hydrogenation and the *trans* fatty acid content of the diet affect the fatty acid composition of membranes, and the amount and the activity of some membrane enzymes. We describe the effects of four isocaloric diets containing either sunflower oil (SO, 0% *trans*), fish oil (FO, 0.5% *trans*), partially hydrogenated fish oil (PHFO, 30% *trans*), or highly hydrogenated fish oil (HHFO, 3.6% *trans*) as fat sources on the lipid composition and the *trans* fatty acid content of rat hepatic microsomes. We also describe the effect of these diets on the cytochrome P-450 content and on the aminopyrine *N*-demethylase, aniline hydroxylase, and UDP-glucuronyl transferase microsomal activities. Cytochrome P-450 content was dependent on the degree of unsaturation of the diet, being higher for the FO-containing diet and lower for the HHFO diet. Aminopyrine *N*-demethylase activity also correlated with the degree of unsaturation of the diet as did the cytochrome P-450 content did (FO > SO > PHFO > HHFO). Aniline hydroxylase activity appeared to be independent of the degree of unsaturation of the dietary fat, but correlated with the *trans* fatty acid content of the diet, which was also reflected in the *trans* content of the microsomal membranes. UDP-glucuronyl transferase activity was higher for the FO-containing diet than for the SO diet, showing intermediate values after the PHFO and HHFO diets.

Lipids 33, 669–673 (1998).

It has been proposed that several membrane functions are dependent on the lipid composition of the membrane (1,2), and that dietary fat intake can modify, to some extent, the composition and the biochemical activity of cellular membranes (3,4). The cytochrome P-450 hepatic microsomal mixed-function oxidase system (MFOS) plays a vital role in the biotransformation of a wide variety of drugs and foreign compounds and of some endogenous substances such as steroids and eicosanoids (5). The MFOS components are membrane-bound molecules, and the microsomal lipid environment, which is readily influenced by different dietary fatty acids, plays an important role in the enzyme regulation of the system (6,7).

Partially hydrogenated and highly hydrogenated vegetable and marine oils (mainly fish oil) are widely used for the preparation of margarines and shortenings for human foods and animal feed (8). Hydrogenation provides oils better stability against oxidation and facilitates mixture with other food components (9). However, this chemical process forms variable and, under some conditions, high amounts of positional and/or geometric *trans* fatty acids isomers (10). The biological effects of *trans* fatty acids have been a matter of controversy (11,12), and concerns about their consumption and biological effects arose from the "unnatural" origin of these isomeric fatty acids (13). Partially hydrogenated fish oil (PHFO) and highly hydrogenated fish oil (HHFO) are widely used in some South American and European countries for the manufacture of cheap margarines and industrial fats, and as components of diverse food items. The complex fatty acid composition of fish oils (FO) (more than 20 different n-11, n-9, n-7, n-6, and n-3 fatty acids can be identified) allows the formation of a great variety of *trans* isomers, especially when the oil is subjected to partial hydrogenation (14).

As biochemical information concerning the effects of PHFO and HHFO and the role of *trans* fatty acid isomers on the activity of MFOS components is scarce, we studied in the rat the effect of a synthetic diet containing these hydrogenated products as the fat source on the fatty acid composition of hepatic microsomal membranes, on the cytochrome P-450 content of these membranes, and on the activity of some enzymes related to MFOS. Results are compared to the effect of a vegetable oil and of a nonhydrogenated FO.

MATERIALS AND METHODS

Materials. Components of the synthetic diet were purchased at the local market. Commercial sunflower (SO), refined FO (sardine oil), PHFO, and HHFO (both prepared from sardine oil) were provided by Watts Alimentos (Santiago, Chile). Solvents and salts were purchased from Merck Chile (Santiago, Chile). Fatty acid standards (*cis* and *trans*) for gas chromatography and reagents for fatty acid methyl ester prepara-

Abbreviations: FO, fish oil; HHFO, highly hydrogenated fish oil; MFOS, mixed-function oxidase system; MUFA, monounsaturated fatty acids; PHFO, partially hydrogenated fish oil; PUFA, polyunsaturated fatty acids; SAFA, saturated fatty acids; SO, sunflower oil.

tion and for enzyme assays were obtained from Sigma Chemicals (St. Louis, MO).

Methods. Peroxide value, the cholesterol content, the unsaponifiable matter, the free acidity, the melting point, and the iodine value of the oils were assessed according to AOAC Official methods (15). Isocaloric (16 kJ/g) synthetic diets were prepared according to Saito *et al*. (16) with some minor modifications. The total fat content was always 15.5% w/w: 0.5% w/w was provided by SO to avoid essential fatty acid deficiency, and the remaining 15% was either SO, FO, PHFO, or HHFO. Four groups ($n = 8$) of 70 day-old male Wistar rats (Biocronogen, Santiago, Chile) weighing 200–230 g and previously fed with the standard laboratory chow were separated in individual cages and fed with one of the four experimental diets for 40 d. Animals were maintained under light/dark cycles of 12 h and with water *ad libitum*. Animal weight and diet consumption were determined daily and registered. No significant changes were observed in the weight gain and in the diet consumption when the different experimental groups were compared. At the end of each experimental period, animals were sacrificed by cervical dislocation, and hepatic microsomes were prepared by ultracentrifugation according to Lake (17). Purity of microsomal preparation was determined assessing glucose-6-phosphatase activity (E.C. 3.1.3.9) according to Gierow and Jergil (18). The treatment and the managing of animals were approved by INTA's Review Board.

Microsomal lipids were extracted with methanol/chloroform (2:1, vol/vol) according to Bligh and Dyer (19). Microsomal cytochrome P-450 content was assessed as described by Omura and Sato (20). Aminopyrine *N*-demethylase cytochrome P-450 associated activity was measured through the reagent of Nash (21), and aniline hydroxylase-cytochrome P-450 associated activity was assessed through the formation of *p*-aminophenol according to Lake (17). UDP-glucuronyl transferase activity (E.C. 2.4.1.108) was assayed according to the method of Dannenberg and Zakim (22).

Total *trans* fatty acid content of the different oils used for the diets' formulations was assessed by infrared spectroscopy according to AOCS method Cd 14-61 (23). Gas chromatography of microsomal fatty acids (*cis* and *trans*) was performed in a Hewlett-Packard 5890 series II Plus gas chromatograph (Palo Alto, CA) with split injector and flame-ionization detector, and using an SP-2560 (Supelco, Inc., Bellefonte, PA) capillary column (100 m × 0.25 mm i.d.). The column temperature was raised from 140 to 240°C at 2°C/min and then was maintained at 240°C for 20 min. The injector temperature was 240°C, and the detector temperature was 260°C. Hydrogen was used as carrier gas.

Statistical analysis. Results are expressed as mean ± SD. Statistical significance of differences between mean values was assessed by analysis of variance coupled with Duncan's multiple-range test at the 5% level of significance (24).

RESULTS

Table 1 shows the chemical and physical characterization of the oils used for the diet preparation. The low peroxide value, unsaponifiable matter, and free acidity of the four oils guarantee their quality as suitable fats for the study. As the cholesterol content of the four oils was very different due to their origin and/or processing (no cholesterol for vegetable oil, high cholesterol for FO, and intermediate values for PHFO and HHFO due to hydrogenation), its content was adjusted in each oil to that of FO to avoid metabolic differences due to the sterol. The melting point of each oil correlated with the degree of hydrogenation, low for SO and FO and high for HHFO. The iodine value also agrees with the degree of hydrogenation of the oils being high for FO due to its high polyunsaturation, and low for HHFO. As expected, SO and FO showed low content of *trans* fatty acids. HHFO, as a result of the drastic reduction of its unsaturation due the strong hydrogenation, also showed a low *trans* content. However, for PHFO, 30% of the total fatty acids contained *trans* unsaturations.

Table 2 shows the *cis* and *trans* fatty acid isomers that can be identified under our experimental conditions in the microsomal membranes after the different dietary fats. For diets containing PHFO and HHFO, there were increases in the content of saturated (SAFA) and monounsaturated (MUFA) fatty acids of microsomal membranes when compared to the SO and FO diets. However, feeding rats with PHFO and HHFO reduced the content of polyunsaturated fatty acids (PUFA) of microsomes. The *trans* fatty acid content of microsomal membranes of the dietary groups fed different diets showed some differences. While membranes from rats fed SO, FO, and HHFO showed very low content of *trans* isomers, membranes from animals fed with PHFO showed a significantly higher amount of isomeric fatty acids. *Trans* fatty acids present in the PHFO-containing diet were incorporated into microsomal membranes. As the biological behavior of *trans* fatty acids has been compared to the behavior of SAFA (25), in Table 2 are also presented the SAFA + *trans* content of microsomal membranes and the ratio MUFA + PUFA/SAFA + *trans*. There was a decrease in the microsomal unsaturated

fatty acids/SAFA ratio as a consequence of feeding animals the PHFO- and the HHFO-containing diets.

The cytochrome P-450 content of microsomal membranes (Fig. 1A) showed good correlation with the degree of unsaturation of the oils used for the diets preparation (i.e., iodine value, Table 1), a higher content of the hemoprotein corresponding to the FO-containing diet and a lower content to the HHFO diet. The cytochrome P-450 content of microsomal membranes from rats fed the SO- and PHFO-containing diets, which had relatively similar iodine values, was the same. Figure 1 also shows the activity of two cytochrome P-450 dependent membrane-bound enzymes (aminopyrine *N*-demethylase, Fig. 1B, and aniline hydroxylase, Fig. 1C), and the activity of an enzyme not associated with cytochrome P-450 (UDP-glucuronyl transferase, Fig. 1D) in response to the different oil-containing diets. Aminopyrine *N*-demethylase activity agreed, as did the cytochrome P-450 content, with the degree of unsaturation of the diet, showing a higher activity for FO and a lower activity for HHFO, and exhibiting intermediate values for SO and PHFO diets. However, when the effect of the different diets on the aniline hydroxylase activity was analyzed, different results were obtained. The activity of this enzyme showed no correlation with the degree of unsaturation of the oils, but was associated with the *trans* fatty acid composition of microsomal membranes. The most important difference in the microsomal membrane fatty acid composition was observed for the PHFO diet, i.e., the higher *trans* content and the lower MUFA + PUFA/SAFA + *trans* ratio. Aniline hydroxylase activity was significantly higher in microsomes from rats fed the PHFO diet when compared to the other oil-containing diets assayed. UDP-glucuronyl transferase activity showed significant differences when the effect of the SO diet and that of the FO diet were compared. The activity of the enzyme after the PHFO and HHFO diets showed intermediate values when compared to the activity after the SO or the FO diet, (Fig. 1D).

DISCUSSION

It has been demonstrated that variation in dietary fatty acids produces corresponding variations in the fatty acid composition of phospholipids of the microsomal membranes (26) and, thus, alters the membrane structure and fluidity, resulting in changes in the activity of MFOS enzymes (5). Our results confirmed these observations, but we also demonstrated that isomeric *trans* fatty acid content of diets is reflected in the *trans* fatty acid composition of microsomes. As communicated by Saito and Yamagushi (7), we also observed that the

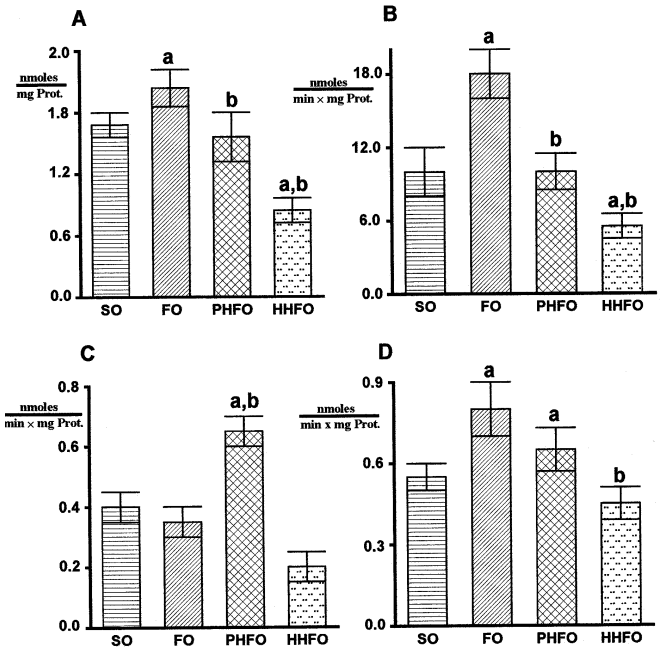

FIG. 1. Effect of sunflower oil (SO)-, fish oil (FO)-, partially hydrogenated fish oil (PHFO)-, and highly hydrogenated fish oil (HHFO)-containing diets on the cytochrome P-450 content (A), and on the aminopyrine *N*-demethylase (B), aniline hydroxylase (C), and UDP-glucuronyl transferase (D) activities of rat hepatic microsomes. Results represent the mean ± SD for $n = 8$ samples. a: difference from SO-containing diet, $P < 0.05$. b: difference from FO-containing diet, $P < 0.05$.

FO-containing diet increased the cytochrome P-450 content and the aminopyrine *N*-demethylase activity. In addition to these observations, we have also demonstrated a correlation between the degree of unsaturation of the diet and the cytochrome P-450 content, and the aminopyrine demethylase activity of microsomal membranes. Saito and Yamagushi (7) observed that the aniline hydroxylase activity of hepatic microsomes remains unchanged after feeding rats with diets containing lard, soybean oil, or sardine oil as the fat source. Diets were different in their degree of unsaturation, but all contained low amounts of *trans* fatty acids. In our experimental design, results demonstrated that this is also valid for the SO-, FO-, and HHFO-containing diets. However, we observed a high microsomal activity for aniline hydroxylase after the PHFO containing diet. If we discard the effect of the degree of unsaturation of the diet on the activity of the enzyme, which appears to be valid for the SO-, FO- and HHFO-containing diets, it can be inferred that the high *trans* content of the PHFO containing diet, which is also reflected in the higher *trans* composition of microsomes from animals fed the PHFO diet, may be affecting the aniline hydroxylase activity. Saito and Yamagushi (7) did not analyze the fatty acid composition of microsomal membranes.

On the other hand, Yang *et al.* (27) observed that a 5% FO-containing diet significantly increased the activity and the amount of UDP-glucuronyl transferase when compared to corn oil, showing correlation between the activity of the enzyme, the fat content of the diet, and the degree of unsaturation of the fat. Our results show significant differences for the UDP-glucuronyl transferase activity with the different diets assayed. The activity of the enzyme is reduced by reducing the degree of unsaturation of the diet. The activity of the enzyme with the FO diet is higher than the activity assayed after the SO diet, a result which is similar to that of Yang *et al.* (27) when comparing the effect of FO with corn oil which, such as SO, is less unsaturated than FO. However, these authors did not assay the effect of hydrogenated fats on the activity of the enzyme. According to their observation on the effect of the degree of dietary fat unsaturation on the UDP-glucuronyl transferase activity, a reduction should be expected in the activity of the enzyme after the PHFO- and the HHFO-containing diets when compared to the FO diet. Our results confirmed this assumption for the HHFO diet but not for the PHFO diet. Therefore, it can be inferred that other dietary factors and/or membrane components, different than the lipid composition of the diet and/or the fatty acid composition of the microsomal membranes, may be regulating the microsomal UDP-glucuronyl transferase activity. The total amount of sterols (cholesterol plus cholesterol-hydrogenated products) consumed by the animals may be a matter of concern. To our knowledge, the effect of partial or high hydrogenation of FO on its cholesterol content has not been studied. As diets were supplemented with cholesterol up to the amount contained in unhydrogenated FO, we cannot disregard possible effects of the cholesterol-hydrogenated products on the enzymatic parameters assayed.

Cyclic Fatty Acid Monomers from Dietary Heated Fats Affect Rat Liver Enzyme Activity

Courdjo Lamboni[a], Jean-Louis Sébédio[b], and Edward G. Perkins[c,*]

[a]Faculté des Sciences, Département de Biochimie/Nutrition Université du Bénin, Lomé, Togo, [b]I.N.R.A, Station de Recherches sur la Qualité des Aliments de l'Homme, 21034 Dijon Cédex, France, and [c]Burnsides Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT: This study was conducted to investigate the effects of dietary cyclic fatty acid monomers (CFAM), contained in heated fat from a commercial deep-fat frying operation, on rat liver enzyme activity. A partially hydrogenated soybean oil (PHSBO) used 7 d (7-DH) for frying foodstuffs, or 0.15% methylated CFAM diets was fed to male weanling rats in comparison to a control group fed a nonheated PHSBO (NH) diet in a 10-wk experiment. All diets were isocaloric with 15% fat. Animals fed either CFAM or 7-DH diets showed increased hepatic content of cytochrome (cyt.) b_5 and P_{450} and increased activity of (E.C. 1.6.2.4) NADPH-cyt. P_{450} reductase in comparison to the control rats. In addition, the activities of (E.C. 2.3.1.21) carnitine palmitoyltransferase-I and (E.C. 1.1.1.42) isocitrate dehydrogenase were significantly decreased when compared to that of rats fed the NH diet. A significantly depressed activity of (E.C. 1.1.1.49) glucose 6-phosphate dehydrogenase was also observed for these animals compared to the control rats fed NH diet. Moreover, liver and microsomal proteins were significantly increased when CFAM or 7-DH diets were fed to animals in comparison to controls while liver glycogen was decreased significantly in experimental groups of rats. The results obtained in this study indicate that the CFAM in the diet from either synthetic sources or used fats increase the activity of liver enzyme systems that detoxify them.

Lipids 33, 675–681 (1998).

Numerous studies in the literature have indicated that when dietary fats are heated at high temperatures, such as in deep frying, harmful substances are formed (1–4). Among the toxic compounds generated from the deep-fat frying process are carbonyl, cyclic monomer, and dimer derivatives (5,6). Other studies have reported that fats obtained from restaurants and those prepared during frying experiments are not significantly damaged by heating during normal use unless they are abused (7–10).

However, it has been generally accepted that nutritionally harmful materials are present in the oxidized or polymeric portions of heated fats. Iwaoka and Perkins (11) showed that when small quantities (about 1%) of purified methyl ω-(2-alkyl cyclohexyl) carboxylic acids (CFAME) were fed to rats with low-level protein diets (8–10% casein), the CFAME decreased weight gains and feed consumption in these animals compared to controls. Liver enlargement with accumulation of lipid was detected in animals fed 0.15% CFAME in their diets. In addition, there are reports in the literature that toxic compounds formed during deep-fat frying may cause deleterious effects on rats when ingested through heated fats (12–14). The complete isolation and purification of cyclic fatty acid monomers (CFAM) were accomplished by Rojo and Perkins (15,16) as well as Sébédio *et al.* (17).

Even though previous studies have focused on isolating compounds that are generated in fats upon deep frying and feeding them to rats to determine their fate (13,18), little attention has been paid to studying the effects of cyclic compounds contained in heated fats from a commercial deep-frying operation on liver enzyme activity when such fats are fed to rats. Therefore, the present study focused on determining the effects of CFAM present in partially hydrogenated soybean oil (PHSBO) commercially used for 7 d on (7-DH) for frying foodstuffs as well as a diet which contained hydrogenated CFAM methyl esters on rat liver enzyme activity.

MATERIALS AND METHODS

Animals, diets, and procedures. Male Sprague-Dawley weanling rats (50–60 g) were purchased from Harlan Sprague-Dawley Inc. (Indianapolis, IN) and were maintained on the standard Harlan Teklab 7001 4% mouse rat diet for 1 wk in steel wire-mesh cages. All animals (10 animals in each group) were then assigned into three groups: a control group of rats [nonheated (NH)] fed a diet containing nonheated PHSBO and two experimental groups fed diets containing either PHSBO used 7 d for frying foodstuffs (7-DH) or CFAME. The animals were randomly assigned as previously described (19). Animals were sacrificed by decapitation with a guillotine after a 12-h fast. The following procedures were employed: protein determination according to Lowry *et al.* (20); total liver lipid extraction according to Folch *et al.* (21); liver glycogen measurement according to Lo *et al.* (22) modified

[a]From Harlan Teklad (Madison, WI). NH = Control group of rats fed diet containing nonheated partially hydrogenated soybean oil (PHSBO); 7-DH = group of rats fed diet containing PHSBO used 7 d for frying foodstuffs; CFAM = group of rats fed diet containing cyclic fatty acid monomers.

by Lamboni (23); liver mitochondria and microsomes were prepared according to Lake (24); microsomal cytochrome (cyt.) b_5 and P_{450} contents and NADPH-cyt. P_{450} reductase activity were carried out according to Lake (24); carnitine palmitoyltransferase-I (Cpt-I) activity according to McGarry *et al.* (25); glucose 6-phosphate dehydrogenase activity in the $31{,}000 \times g$ supernatant fluid by the use of a Sigma Kit (Sigma Co., St. Louis, MO); and isocitrate dehydrogenase (ICDH) activity in the liver homogenate by the use of a Sigma Kit. The experimental groups of rats (CFAM and 7-DH) had free access to food and tap water as did their controls fed the NH diet.

The CFAM used in the present feeding study were prepared from linseed oil by heating, urea fractionation of the corresponding methyl esters, hydrogenation, and preparative high-performance liquid chromatography (15).

The isolation and determination of CFAM from the used oil were carried out according to the procedure described by Rojo and Perkins (15) as well as by Sébédio *et al.* (17). The CFAM were determined in the PHSBO sample that had been used 7 d for frying foodstuffs. After hydrogenation of the corresponding methyl esters with platinum oxide as catalyst and urea fractionation, the fraction not forming urea adducts was isolated. This fraction is a polar fraction and contained the CFAME materials. An aliquot of 250 µL of phenanthrene solution (0.50 mg/mL) was added to the fraction containing the CFAME as an internal standard. A Hewlett-Packard 5890 (Palo Alto, CA) gas–liquid chromatograph was used with 24 psi H_2 as carrier gas. The column used for the analysis was a CPSIL 88 column (60 m × 0.25 mm × 0.20 µm (Chrompack Inc., Raritan, NJ), and the conditions were as follows: 160°C (0), increased by 2°C/min to 220°C.

The composition of the fats fed as part of the diets was as previously shown (19, Table 1). The diet composition fed to animals for the 10-wk duration of the experiment is described in Table 1. In the present study the animals were fed a fiber-free diet; it has been reported that such diets can increase the toxic effects of a variety of compounds.

Statistical analysis of data. Data were analyzed by analysis of variance for a completely randomized design using the StatView statistical software package (StatView SE + Graphics; 1988 Abacus Concepts, Inc., Berkeley, CA). When *F* tests detected significance ($P < 0.05$), pairwise comparisons of means among groups were performed by Fisher's protected least significant difference.

RESULTS

Feed efficiency, weight gain. In comparison with the control group of rats, the feed efficiency (Table 2) of animals fed a 0.15% CFAME diet did not show any significant difference. However, three rats in the group fed the CFAM diet exhibited considerable hair loss and showed signs of dermatitis. The rats fed the 7-DH diet did not show any significant difference in feed efficiency compared to controls or to the CFAME diet group of rats. When rats were fed CFAM or 7-DH diets, their weight gains were not significantly different from the control group of animals fed NH diet (Table 2).

CFAME. The PHSBO used 7-DH contained 0.16% by weight of CFAM. Gas–liquid chromatography indicated that

TABLE 2
Several Parameters of Control and Experimental Rats[a]

	Group		
Item	NH	7-DH	CFAM
Weight (g)	273.24 ± 25.81	257.23 ± 18.4	270.07 ± 25.18
Feed efficiency (g gain/g feed)	0.234 ± 0.001	0.238 ± 0.001	0.239 ± 0.002
Liver weight/body weight ratio (mg/g)	3.21 ± 0.04	3.2 ± 0.06	3.23 ± 0.04
Liver protein (mg/g)	235.89 ± 22.46	479.13 ± 16.12[b]	460 ± 15.22[b]
Microsomal protein (mg/g)	30.39 ± 1.10	60.40 ± 1.23[b]	63.15 ± 1.34[b]
Liver lipid (mg/g)	57.73 ± 1.58	70.80 ± 1.27[b]	70.17 ± 1.00[b]
Lipid/protein ratio	1.06 ± 0.11	0.60 ± 0.02[b]	0.62 ± 0.02[b]
Liver glycogen (mg/g)	10.65 ± 0.66	6.77 ± 0.40[b]	6.75 ± 0.64[b]

[a]Values are means ± SEM. NH = control group of rats fed diet containing nonheated partially hydrogenated soybean oil (PHSBO) ($n = 10$). 7-DH = group of rats fed diet containing PHSBO used 7 d for frying foodstuffs ($n = 11$). CFAM = group of rats fed 0.15% cyclic fatty acid monomers diet ($n = 11$).
[b]$P < 0.0001$ when compared to the control animals fed NH diet.

the pattern of cyclic compounds present in the 7-DH was the same as that identified earlier (Rojo and Perkins 1987) with the aid of gas chromatography–mass spectrometry. The retention times of the isomers comprising the mixture of CFAME in the 7-DH were identical to that in the standard CFAME profiles (26).

Lipid, protein, and glycogen. Rats fed 0.15% CFAME or 7-DH diets (Table 2) showed significant increases ($P < 0.0001$) in liver lipid content compared to the control animals. In addition, small fat droplet infiltration in liver cells was extensive in the group of rats fed CFAME diet while only a few (3,4) of the livers of rats fed the 7-DH diet showed the same condition by microscopy.

The protein content of the microsomal fractions (Table 2) increased significantly ($P < 0.0001$) in rats fed the 0.15% CFAME diet as well as those fed the 7-DH diet compared to the control animals. There was no significant difference in microsomal protein when the CFAM diet group of rats was compared to that of the 7-DH group.

The liver glycogen (Table 2) measured in both experimental groups (CFAME and 7-DH) was significantly decreased ($P < 0.0001$) compared to control animals. No significant difference was found in liver glycogen content in either the 7-DH or CFAME group of rats.

Microsomal cyt. b_5 and P_{450}. The contents of microsomal cyt. b_5 and P_{450} (Table 3) were significantly increased ($P < 0.0001$) in rats fed the 0.15% CFAME diet as well as those fed the 7-DH diet compared to control animals fed the NH diet. No significant difference was noticed for the microsomal cyt. contents when the CFAME diet group of rats was compared to those fed the 7-DH diet.

TABLE 3
Hepatic Microsomal Cytochromes Contents of Control and Experimental Rats[a]

Item	Group		
	NH	7-DH	CFAM
Cytochrome b_5 content	0.37 ± 0.01	0.84 ± 0.04[b]	0.73 ± 0.06[b]
Cytochrome P_{450} content (nmol/mg micr. protein)	1.03 ± 0.03	1.97 ± 0.08[b]	1.86 ± 0.11[b]

[a]Values are means ± SEM; micr. = microsomal. NH = control group of rats fed diet containing nonheated partially hydrogenated soybean oil (PHSBO), ($n = 8$). 7-DH = group of rats fed diet containing PHSBO used 7 d for frying foodstuffs ($n = 11$). CFAM = group of rats fed 0.15% cyclic fatty acid monomers diet ($n = 11$).
[b]$P < 0.0001$ when compared to the control animals fed NH diet.

Enzymatic activities. (i) NADPH-cyt. P_{450} reductase. The activities of the P_{450} mixed function oxidase enzyme measured in liver microsomes of rats fed either the CFAME or 7-DH diets were significantly increased ($P < 0.0001$) compared to the control group of rats fed the NH diet. The increased activity observed for animals fed the CFAME diet was significantly different ($P < 0.05$) from that measured for the group of rats fed the 7-DH diet (Fig. 1).

(ii) CPT-I. The CPT-I activity measured for rats fed either

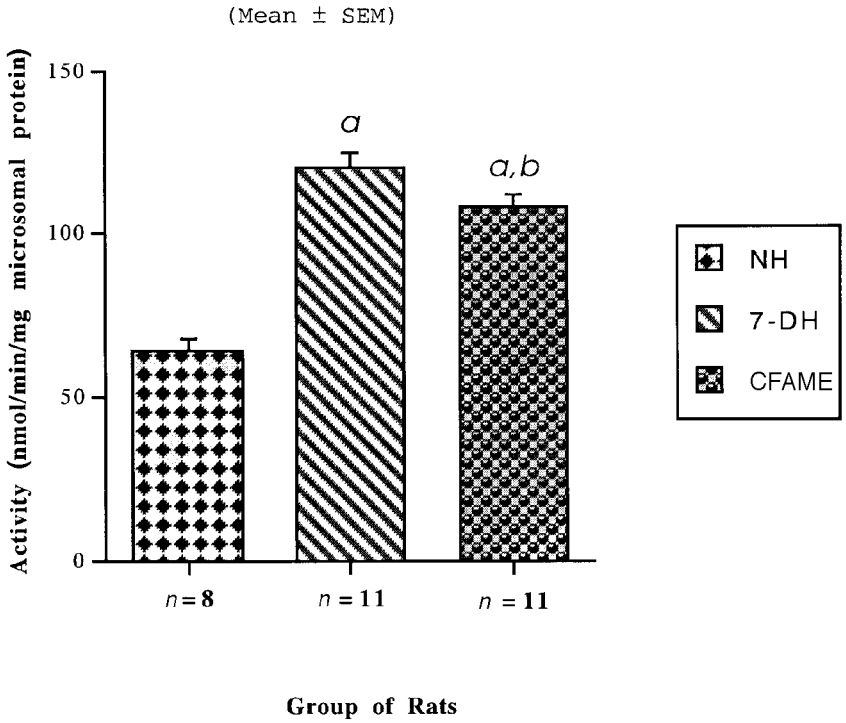

FIG. 1. NADPH-cytochrome P_{450} reductase activity in liver microsomes of rats fed NH, 7-DH, and CFAME diets. NH = group of rats fed diet containing nonheated partially hydrogenated soybean oil (PHSBO). 7-DH = group of rats fed diet containing PHSBO used 7 d for frying foodstuffs. CFAME = group of rats fed diet containing cyclic fatty acid monomer methyl esters. [a]$P < 0.0001$ when compared to the control group of rats fed NH diet. [b]$P < 0.05$ when compared to NH.

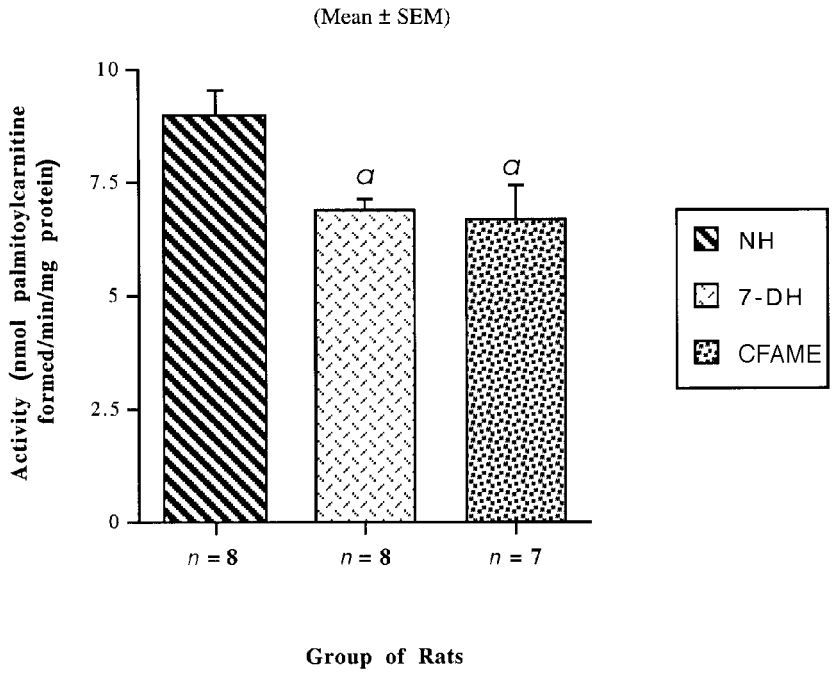

FIG. 2. Carnitine palmitoyltransferase-I activity in liver mitochondria of rats fed NH, 7-DH, and CFAME diets. $^{a}P < 0.01$ when compared to the control group of rats fed NH diet. See Figure 1 for abbreviations.

CFAM or 7-DH diets was significantly decreased ($P < 0.01$) compared to the control group of rats fed the NH diet. The activity of the CFAM group of rats was not significantly different from that measured for the 7-DH diet group of rats (Fig. 2).

(iii) ICDH. The activity of ICDH was significantly decreased ($P < 0.05$) in liver homogenates when rats were fed either CFAM or 7-DH diets in comparison to the control group of rats fed NH diet (Fig. 3). There was no significant difference in the CFAM diet group of rats compared to the 7-DH diet group.

(iv) Glucose 6-phosphate dehydrogenase. The activity of D-glucose 6-phosphate:NADP-oxidoreductase measured in

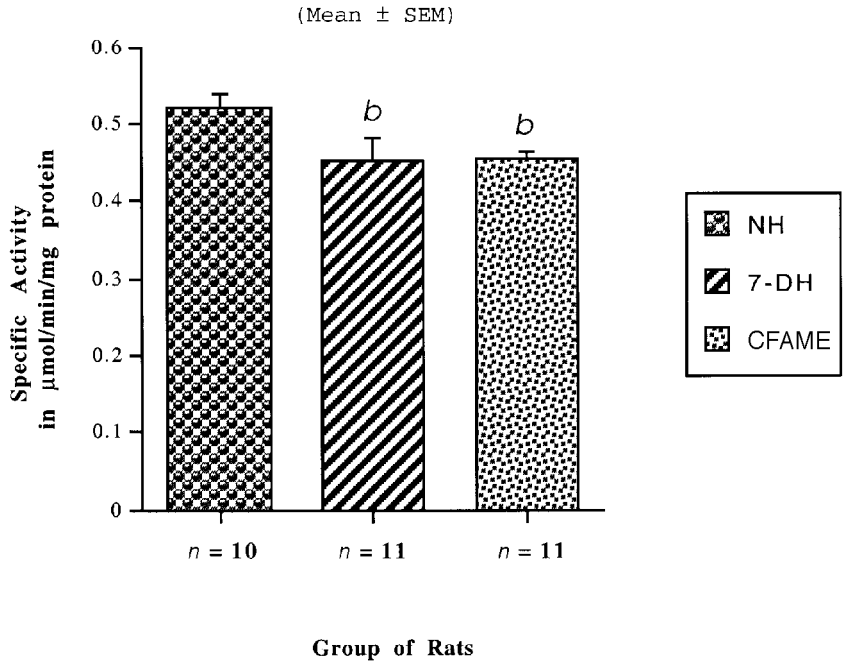

FIG. 3. Isocitrate dehydrogenase activity in liver of rats fed NH, 7-DH, and CFAME diets. $^{b}P < 0.05$ when compared to the control group of rats fed NH diet. See Figure 1 for abbreviations.

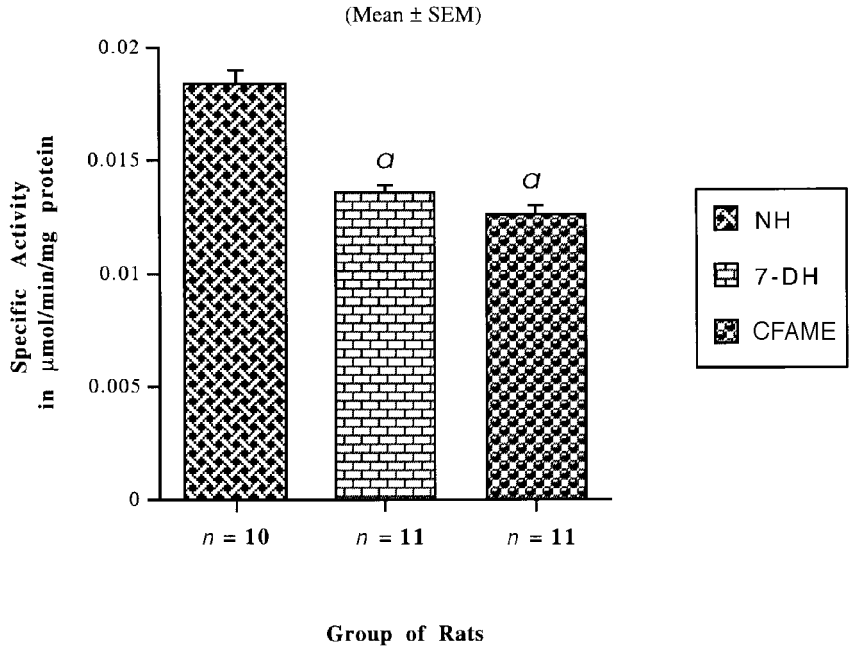

FIG. 4. Glucose 6-phosphate dehydrogenase activity in liver of rats fed NH, 7-DH, and CFAME diets. $^{a}P < 0.0001$ when compared to the control group of rats fed NH diet. See Figure 1 for abbreviations.

the liver of rats fed either CFAME or 7-DH diets showed in each case significantly depressed activity ($P < 0.0001$) compared to the control group of rats fed NH diet (Fig. 4). There was no significant difference when the CFAME diet group of rats was compared to that fed the 7-DH diet.

DISCUSSION

Lamboni and Perkins (19) reported that rats fed the 7-DH diet grew at a slightly slower rate than those fed CFAME. This may be due to the oxidation products generated in the oil upon heating since the CFAM group of rats grew less than control animals but more than the group of rats fed 7-DH diet. The liver weight/body weight ratio was increased in the group of animals fed either CFAM or 7-DH diets. The difference was not significant but did suggest an increase in liver size of those animals fed either CFAME or 7-DH diets. It can be inferred that the used fat contained products that could be attributed in part to CFAM which may have induced an increased liver weight. Indeed, by feeding rats an approximate amount of CFAM as was present in the used oil, similar increases in liver weights were observed. The significantly ($P < 0.0001$) increased liver protein in groups CFAM and 7-DH compared to the control rats fed the NH diet suggests that less protein was being used for somatic growth and more retained in the liver of those animals. This increase of protein in liver of rats fed either CFAM or 7-DH diets may be a response of the body to cope with the adverse metabolic effects of CFAM contained in the used PHSBO diet. The increased content of microsomal protein, discussed previously, suggests an increased rate of protein synthesis to aid in the increased participation of the mixed-function oxidase enzymes involved in xenobiotic detoxification. In addition, it has been reported that there is liver damage in animals fed either CFAME or 7-DH diets compared to the control group of rats (26). This liver damage observed may contribute to the high protein level measured for those animals in liver and microsomal fractions.

Furthermore, the lipid/protein ratio (Table 2) of animals fed either CFAME or 7-DH diets clearly confirmed the large amount of protein being retained or produced compared to that of lipid in liver tissue of the same group of rats. The microsomal cyt. P_{450} and b_5 contents (Table 3) of rats fed either CFAM or 7-DH diets were significantly increased ($P < 0.0001$) in each case compared to control animals fed NH diet. This clearly demonstrates the effects (elevated levels of detoxifying enzymes) of the components generated in the 7-DH oil as well as that of CFAM. Besides the increased content of liver microsomal cyt. P_{450}, the activity of NADPH-cyt. P_{450} reductase was also significantly increased ($P < 0.0001$) in rats fed either CFAM or 7-DH diets compared to the control animals. This suggests an active detoxification in the liver of compounds such as CFAM ingested either in the diet or those generated along with other compounds in the 7-DH oil during the deep-frying process. The decreased NADPH-cyt. P_{450} reductase activity of the CFAM diet-fed rats was compared to those fed the 7-DH diet (Fig. 1). The data clearly suggested that compounds other than CFAM also were generated in the used oil and that they exerted their effects in conjunction with the CFAM. This could explain the highest activity measured for animals fed the 7-DH diet in comparison to those fed the CFAM diet. In addition, these results showed an

apparent dose response of the toxic compounds suggesting that liver microsomal content of cyt. b_5 or P_{450} is dependent upon the concentration of the components generated in the oil during heating (19). The reductase is known to receive electrons from NADPH through FAD and FMN. This suggests that NADPH was being used during the detoxification process by the P_{450} mixed-function enzyme. Indeed, the activity of glucose-6-phosphate dehydrogenase measured in the liver $31{,}000 \times g$ supernatant fluid was significantly depressed ($P < 0.0001$) when rats were fed either CFAM or 7-DH diets in comparison to the control group of rats fed the NH diet (Fig. 4). These results indicate that large amounts of NADPH were being produced and that the excess of the reducing equivalent NADPH inhibited the activity of the enzyme discussed previously (19).

The decreased activity of CPT-I measured in rats fed either CFAM or 7-DH diets in comparison to the control animals fed the NH diet (Fig. 2) is compatible with the possibility that less long-chain fatty acids were being degraded *via* the mitochondrial β-oxidation pathway and more fatty acids were being incorporated into triglycerides.

The highly significant decrease in liver glycogen (Table 2), which was measured when rats were fed either CFAM diet or 7-DH diet, suggests increased glycolytic activity, leading to the formation of pyruvate which would subsequently be converted to acetyl-CoA *via* the pyruvate dehydrogenase complex enzyme in the mitochondrial matrix. The acetyl-CoA formed could undergo oxidative degradation through the tricarboxylic acid (TCA) cycle or might be utilized for the biosynthesis of long-chain fatty acids such as palmitic acid *via* fatty acid synthase.

The decreased activity of ICDH, which was measured when rats were fed either CFAM or 7-DH diets (Fig. 3), suggests an impairment of TCA cycle enzyme activity in the presence of CFAM and supports our previous finding (19). If the TCA cycle is impaired, acetyl CoA oxidation would be impaired. It could therefore be inferred that cyclic compounds and other oxidation products which were generated in the fat during the commercial deep-frying process were in part responsible for the impairment of ICDH in the mitochondrial TCA cycle.

Heated fats exert generalized nutritional toxic effects on rat morphology and physiology and these mechanisms are not yet completely understood. Siess *et al.* (27) reported an increased activity of NADPH-cyt. P-450 reductase in female Wistar rats fed for 4 wk a semisynthetic diet containing different quantities of cyclic monomers isolated from linseed oil. In a related study of oil/olestra blends, heated soybean oil was used. No statistical differences were found in the physiological responses to the heated or unheated oil (28).

Magnesium Silicate Treatment of Dietary Heated Fats: Effects on Rat Liver Enzyme Activity

Edward G. Perkins[a,*] and Courdjo Lamboni[b]

[a]Burnsides Research Laboratory, Department of Food Science and Human Nutrition, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801, and [b]Faculté des Sciences, Département de Biochimie/Nutrition, Université du Bénin, Lomé, Togo

ABSTRACT: In an effort to reduce the deleterious nutritional effects of oxidation products generated in heated fats, a partially hydrogenated soybean oil (PHSBO) used 7 d (7-DH) for frying foodstuffs was obtained from a commercial deep-fat frying operation. The used fat was treated with magnesium silicate (T-7DH). Isocaloric diets containing 15% of either 7-DH or T-7-DH fats were prepared and fed to male weanling rats for 10 wk in a pair-feeding experiment and compared to control rats fed nonheated PHSBO (NH). Animals fed the 7-DH diet showed higher liver enzyme cytochrome b_5 and P_{450} activity than the T-7DH diet compared to the NH group, suggesting a positive effect of the treatment. These results suggested the presence of lower amounts of harmful compounds in the diet containing the heated used oil which had been treated with the active adsorbent.

Lipids 33, 683–687 (1998).

Fried foods taste good and appeal to most people in our twentieth-century society and are readily available through fast-food restaurants. Numerous studies state that dietary heated fats contain harmful substances (1–4) that may cause deleterious effects when fed to laboratory animals. Previously, Crampton *et al.* (5) reported that the primary cause of the lowered nutritive value of diets containing thermally polymerized linseed oil was the presence of one or more dimeric fatty acid radicals which are in some way inimical to the well-being of the animals fed such fats. Moreover, their deleterious effects could well be aggravated since they were produced at the expense of unsaturated fatty acids.

Other studies (6–8) have reported adverse biological effects of heated and oxidized fats such as enlargement or fatty necrosis of liver, retarded growth, hair loss and dermatitis when such fats were fed to rats.

Although it has been generally accepted that growth-depressing and other nutritionally harmful materials are present in the oxidized or polymeric portion of heated fats, none of the studies focused on a direct way to alleviate the deleterious effect of heated edible oils observed when such fats are fed to laboratory animals. The present study will focus on treating heated fats with the aid of an active filter aid and compare its effects on rat liver enzyme activity with those of the non-treated used oil. The heated fat, a partially hydrogenated soybean oil (PHSBO) used 7 d (7-DH) for frying foodstuffs, was obtained from a commercial restaurant deep-fat frying operation. The composition of the heated oils has previously appeared (8). The activities of the following enzymes were investigated: NADPH-cytochrome (cyt.) P450 reductase, carnitine palmitoyltransferase (CPT), isocitrate dehydrogenase (ICDH), and glucose 6-phosphate dehydrogenase

MATERIALS AND METHODS

Animals, diets, and procedures. Male weanling Sprague-Dawley rats (50–60 g) from Harlan Sprague-Dawley Inc. (Indianapolis, IN) were housed in steel wire-mesh cages and maintained on a standard chow diet for 1 wk. All animals were then assigned into three groups: a control group (NH) fed a diet containing nonheated PHSBO and two experimental groups fed diets containing either PHSBO used 7 d for frying foodstuffs (7-DH) or 7-DH treated one time with 10% magnesium silicate (T-7DH). Animals were assigned to cages by complete randomization (wherein cage locations are assigned at random) as described by Lamboni (8) Animals of the experimental groups were pair-fed (wherein the control animal was fed only the amount consumed by the experimental animal. There was therefore a 1-d time lag in their corresponding diets for 10 wk of the experiment). The composition of the diets fed to the rats is described in Table 1.

The following procedures and determinations were carried out: protein determination according to Lowry *et al.* (9); total liver lipid according to Folch *et al.* (10); liver glycogen according to Lo *et al.* (11) as modified by Lamboni (12); microsomal cyt. b_5 and P_{450} contents and NADPH-cyt. P_{450} reductase activity according to Lake (13); CPT-I activity according to McGarry *et al.* (14); glucose 6-phosphate dehydrogenase activity in the 31,000 × *g* supernatant fluid by the use of a Sigma Kit (Sigma Chemical Co., St. Louis, MO); ICDH activity in the liver homogenate by the use of a Sigma Kit.

[a]From Harlan Teklad (Madison, WI).
[b]From Solka-Floc (James River Corporation, Berlin, NH). NH, control group of rats fed diet containing nonheated partially hydrogenated soybean oil (PHSBO); 7-DH, group of rats fed diet containing PHSBO used 7 d for frying foodstuffs; T-7DH, group of rats fed diet containing 7-DH oil treated with magnesium silicate.

The treatment of the used heated fat was done by adding 10% magnesium silicate to the hot fat (150°C) while stirring and then filtering under vacuum through No. 42 Whatman filter paper (Maidstone, England). Gel permeation chromatography was performed to check the amount of polymers removed from the treated used oil (T-7DH) in comparison to the nontreated 7-DH oil. This assay was performed on the oils fed to animals by using a Waters (Milford, MA) 501 high-performance liquid chromatography pump, a Waters 410 differential refractometer, and a series of size-exclusion columns (two columns of Ultrastyragel 500A, 30 cm, Part # 10571, Waters; and two columns # H10 XH0066 with G1000 HXL, 30 cm; Supelco, Inc., Bellefonte, PA). Tetrahydrofuran was used as mobile phase, and the rate was 0.7 mL/min while the pressure was 1.5×10^3 psi.

Statistical analysis of data. Analysis of variance for a completely randomized design was carried out using the StatView statistical software package (StatView SE + Graphics; 1988 Abacus Concepts, Inc., Berkeley, CA). When significant ($P < 0.05$) F-tests were detected, pairwise comparisons of mean among groups were performed by Fisher's protected least significant difference.

RESULTS

Gel permeation chromatography of the oils. The analysis of the oils fed to rats showed that the nonheated (NH) PHSBO contained 100% triglycerides and no polymers. In contrast, the 7 d used oil had more polymers (about 9.9%) while the 7 d used oil which was treated with a synthetic magnesium silicate showed a lower polymer content (about 4%).

Weight gain, feed efficiency, liver weight/body weight ratio. The results in Table 2 indicate that rats fed 7-DH diet did not show any significant difference in feed efficiency among groups. Animals fed the 7-DH diet, however, lost hair and showed signs of dermatitis. The hair loss seen in the T-7DH group was evidenced by some hair deposited under individual cages of those animals.

A significant ($P < 0.05$) increase in the liver weight/body weight ratio for animals fed the 7-DH diet (Table 2) compared to rats fed the control NH diet was noted. There was no significant difference between the 7-DH and the T-7DH groups in terms of liver weight/body weight ratio.

Protein, lipid, glycogen. Animals fed the 7-DH diet showed an increased ($P < 0.0001$) liver protein content compared to those fed the NH diet (Table 2). The increase observed when animals were fed the T-7DH diet was significantly different ($P < 0.001$) from that of control rats.

After 10 wk of pair-feeding rats with their respective diets, the liver microsomal protein content significantly increased in the 7-DH rats ($P < 0.0001$) while no significant difference was observed in those fed the T-7DH diet compared to those fed the NH diet (Table 2). When the nontreated oil diet group of animals was compared to those on the treated diet, the increase observed in the former group was significantly ($P < 0.0001$) different.

The liver lipid content of animals fed the 7-DH or T-7DH diets was significantly increased ($P < 0.0001$) compared to the control group. The liver lipid content of rats pair-fed the 7-DH diet was significantly increased ($P < 0.01$) compared to those pair-fed with the treated oil diet (T-7DH).

Rats pair-fed the 7-DH diet showed that the 15% 7-DH diet induced the lowest lipid/protein ratio ($P < 0.01$) although

TABLE 2
Several Parameters of Control and Experimental Rats in a Pair-Feeding Experiment[a]

	Group		
Item	NH	7-DH	T-7DH
Feed efficiency (gram gain/gram feed)	0.232 ± 0.004	0.232 ± 0.003	0.232 ± 0.005
Liver weight/body weight ratio (mg/g)	2.75 ± 0.05	2.95 ± 0.02[b]	2.894 ± 0.06
Liver protein (mg/g)	392.65 ± 7.44	593.22 ± 17.50[a]	487.09 ± 25.84[c]
Microsomal protein (mg/g)	30.51 ± 1.01	56.47 ± 1.55[a]	30.60 ± 1.32[f]
Liver lipid (mg/g)	63.88 ± 1.69	79.66 ± 1.86[a]	72.86 ± 2.07[c,e]
Lipid/protein ratio	0.98 ± 0.02	0.81 ± 0.04[d]	0.92 ± 0.05

[a]Values are means ± SEM and $n = 10$ for each group. [a]$P < 0.0001$ when compared to the control animals fed NH diet. [b]$P < 0.05$ when compared to the control group. [c]$P < 0.001$ when compared to the control animals. [d]$P < 0.01$ when compared to the control rats. [e]$P < 0.01$ when T-7DH is compared to 7-DH diet group. [f]$P < 0.0001$ when T-7DH is compared to the 7-DH diet group of rats. See Table 1 for abbreviations.

TABLE 3
Hepatic Microsomal Cytochromes Content of Control and Experimental Rats in a Pair-Feeding Experiment[a]

Item	Group		
	NH	7-DH	T-7DH
Cytochrome b_5 content (nmol/mg micr. protein)	0.46 ± 0.02	0.75 ± 0.08[a]	0.49 ± 0.03[b,c]
Cytochrome P_{450} content (nmol/mg micr. protein)	1.04 ± 0.03	1.68 ± 0.08[a]	1.15 ± 0.06[b,c]

[a]Values are means ± SEM and $n = 10$ for each group; micr. = microsomal. [a]$P < 0.0001$ when compared to the control animals fed NH diet. [b]Nonsignificant when compared to the control NH. [c]$P < 0.0001$ when T-7DH is compared to the 7-DH diet group of rats. See Table 1 for abbreviations.

there was not any significant decrease in the T-7DH group compared to the controls (Table 2).

In another pair-feeding experiment, decreased liver glycogen of animals fed the 7-DH diet was significantly different ($P < 0.0001$) from the control animals while the significance level was at $P < 0.01$ for the T-7DH group (Table 2). The liver glycogen of the T-7DH group of rats was different ($P < 0.01$) than that of the 7-DH group.

Microsomal cyt. b_5 and P_{450}. Rats pair-fed the 7-DH diet showed a highly significant increase ($P < 0.0001$) in the cyt. b_5 compared to the control group of rats fed the NH diet while the difference observed for the T-7DH group of animals was not statistically significant (Table 3). The value for the treated oil group compared to the untreated oil was significantly decreased ($P < 0.0001$).

Liver microsomal cyt. P_{450} content for the group of rats fed the 15% 7-DH diet was greatly increased ($P < 0.0001$) compared to the control group pair-fed a 15% NH diet. It was also increased ($P < 0.0001$) when compared to the T-7DH group of animals (Table 3).

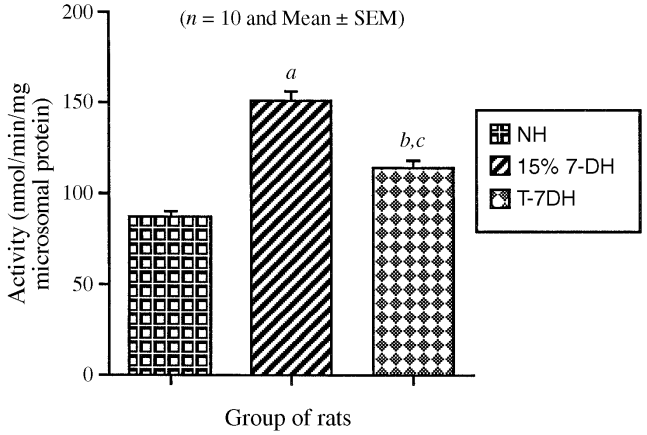

FIG. 1. NADPH-cytochrome P_{450} reductase activity in liver microsomes of rats fed NH, 7-DH, and T-7DH diets. NH = control group of rats fed diet containing nonheated partially hydrogenated soybean oil (PHSBO); 7-DH = group of rats fed diet containing PHSBO used 7 d for frying foodstuffs; T-7DH = group of rats fed diet containing 7-DH oil treated with magnesium silicate. [a]$P < 0.0001$ when compared to the control group of rats fed NH diet; [b]$P < 0.01$ when compared to NH; [c]$P < 0.0001$ when compared to 7-DH group of rats.

NADPH-cyt. P_{450} reductase. The NADPH-cyt. P_{450} reductase of rats fed the experimental diets showed an increased level of activity compared to the control group. The increase was significant at $P < 0.0001$ for the 15% 7-DH diet group of rats and at $P < 0.01$ when the used oil had been treated with magnesium silicate (Fig. 1). The activity of the 7-DH diet group of animals was higher than that of the T-7DH group ($P < 0.0001$).

CPT-I. A significant decreased activity ($P < 0.01$) of CPT-I was noted when rats were pair-fed the 7-DH diet in comparison with the control animals. Feeding the T-7DH diet to rats did not result in any statistically significant difference compared to the control group of rats (Fig. 2). The lower activity of CPT-I observed for the 7-DH diet group of rats was not significantly different from those fed the T-7DH diet.

ICDH. Decreased activity of the ICDH was observed when rats were pair fed the 15% 7-DH diet, and the results were significantly different ($P < 0.05$) from the control animals. Feeding 15% of the T-7DH diet to rats did not result in any significant difference with the control group of rats (Fig. 3). No significant difference was noted when the 7-DH diet group of rats was compared to the group of rats fed the T-7DH.

Glucose 6-phosphate dehydrogenase. The activity of D-glucose 6-phosphate:NADP-oxidoreductase measured in the liver of rats fed the 7-DH diet was depressed compared with a control group of rats fed the NH diet ($P < 0.0001$). Rats fed

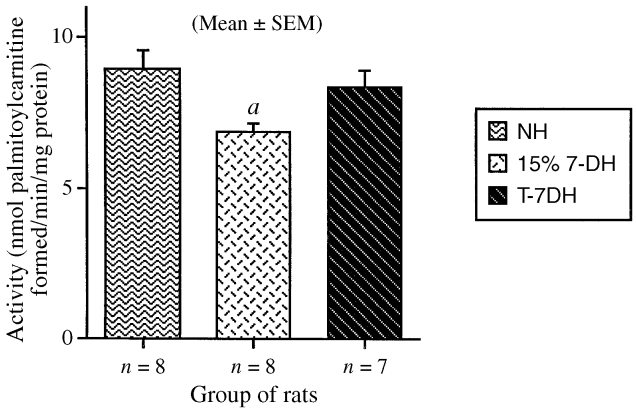

FIG. 2. Carnitine palmitoyltransferase-I activity in liver mitochondria of rats fed NH, 7-DH, and T-7DH diets. [a]$P < 0.01$ when compared to the control group of rats fed NH diet. See Figure 1 for abbreviations.

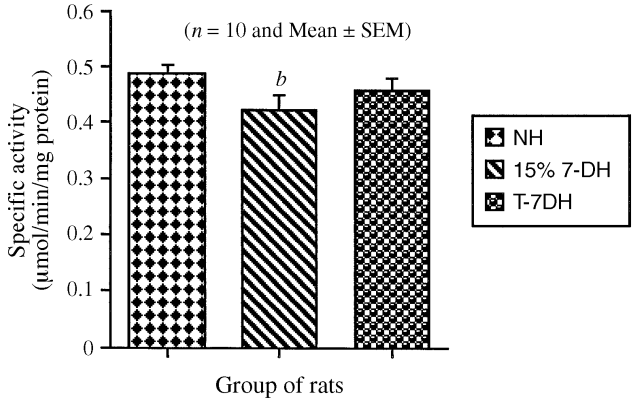

FIG. 3. Isocitrate dehydrogenase activity in liver of rats fed NH, 7-DH, and T-7DH diets. $^{b}P < 0.05$ when compared to the control group of rats fed NH diet. See Figure 1 for abbreviations.

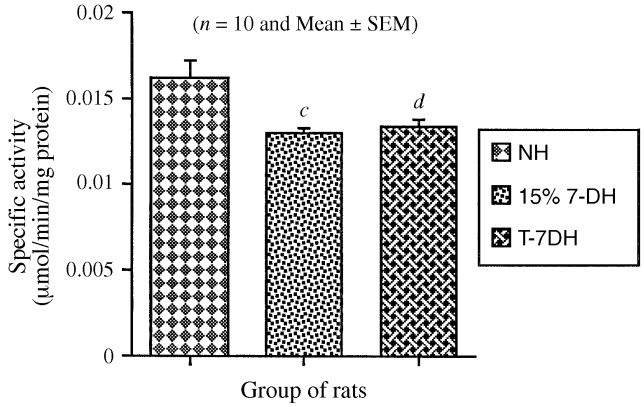

FIG. 4. Glucose 6-phosphate dehydrogenase activity in liver of rats fed NH, 7-DH, and T-7DH diets. $^{c}P < 0.001$ when compared to the control group of rats fed NH diet. $^{d}P < 0.01$ when compared to the control. See Figure 1 for abbreviations.

the T-7DH diet also had significantly depressed activity compared to controls ($P < 0.01$) (Fig. 4).

DISCUSSION

The results of the present study indicated that fats heated at deep-frying temperatures contain levels of lipid oxidation products and polymeric compounds which were decreased by treatment with a synthetic filter aid. When diets containing such treated fats were fed to rats, the results showed that such treatment decreased the deleterious nutritional effects shown by the untreated heated fats. Oils used for deep frying as well as the compounds generated in used oils caused a generalized increase in the content and activity of the liver detoxification enzymes when ingested. Significance at $P < 0.05$ for the group of rats fed the nontreated heated PHSBO (7-DH group) in comparison to the control (NH) group was noted. The nontreated oil group of rats developed enlarged livers while the treated oil group did not. Treatment of the used oil with a synthetic filter aid had a positive effect on improving the nutritional parameters of the oil when fed to rats. In addition, the nonsignificant increased liver protein (Table 2) measured for the treated oil diet group of rats compared to the control animals was highly significant when the untreated oil diet was fed. This further confirms that the deleterious effects of oxidation products and the positive effects of the treatment of the 7 d used oil decreased the amount of such oxidation products from the used oil. The increase in liver protein observed for the 7-DH diet group of rats may be a way of coping with the adverse metabolic effects of heated fats (14). Although the liver lipid content was significantly increased in both experimental groups of rats, the increase was less in the T-7DH group of animals than the group fed the 7-DH diet, suggesting again that the treatment had an effect in reducing the accumulation of lipid in the liver. The lipid/protein ratio measured in this study for all groups confirms this.

In addition to the positive effects of the treatment assigned to the used oil, the cyt. b_5 and P_{450} contents (Table 3) of the group of rats fed the T-7DH increased less than the significant increase in the 7-DH diet group of animals compared to the control NH. This further suggests that some of the components generated in the used oil had been reduced by the magnesium silicate treatment of the used oil and thus decreased its toxic effects. Therefore, less cyt. P_{450} had been formed in the liver microsomes of the T-7DH diet group of rats due to less toxic substrates leading to a less extensive detoxification process involving the enzyme NADPH-cyt. P_{450} reductase, with activity proportional to the content of cyt. P_{450} of the microsomal fraction (Fig. 1). Cyt. b_5 acts as an electron donor to cyt. P_{450} and is reduced either by NADPH-cyt. P_{450} reductase or by another microsome-bound flavoprotein NADH-cyt. b_5 reductase which is specific for NADH (15,16).

The activity of CPT-I (Fig. 2) in animals fed the treated oil diet suggests a better oxidation of long-chain fatty acids than when the used oil was not treated with synthetic magnesium silicate as indicated by the significant decreased activity of CPT-I in the 7-DH group. A possible accumulation of fatty acids into triglycerides and phospholipids for the group of rats fed the 7-DH diet could be an explanation for the fatty livers reported in the literature when such heated fats were fed to laboratory animals. The liver glycogen content of animals fed the 7-DH diet was significantly decreased (Table 2), suggesting an increased glycolytic activity with subsequent formation of more acetyl-CoA than that of the T-7DH diet group.

The statistically nonsignificant decreased activity (Fig. 3) of ICDH of animals fed the T-7DH diet compared to the control group contrasted with the statistically significant decrease in the nontreated 7-DH diet group, suggesting that there might be recovery of the impairment of the enzyme in the treated group. The treatment of used oil might be responsible for the positive effects on recovering the ICDH activity. Previously, Yoshioka *et al.* (17) reported a decreased activity of succinate dehydrogenase when rats were fed autoxidized safflower oils, and they attributed this impairment to the high carbonyl value detected in the oils.

Even though significant depressed activity of glucose 6-phosphate dehydrogenase was measured in both experimental groups of rats compared to the control group (Fig. 4), the activity in the T-7DH group was less than that of the untreated 7-DH group. This suggests less production of NADPH in the 7-DH group through the pentose phosphate pathway when it is necessary for fatty acid synthesis and for the P_{450} mixed-function oxidase system. This is supported by the increased activity of the NADPH-cyt. P_{450} reductase (Fig. 1). Reduced synthesis of fatty acid in the treated oil group of rats could explain the fact that there was no fatty liver in the T-7DH diet group of rats while it was noted in the group of rats fed the nontreated oil diet (7-DH group). The highly increased activity of NADPH-cyt. P_{450} reductase measured for the 7-DH group of rats confirms the increased utilization of NADPH to cope with the high level of toxic compounds ingested by rats when they are fed such fats. Treatment of the used oil removed a portion of the toxic components generated during the heating process of the oil by adsorption and thus alleviated the level of toxicity of the fat.

Protective Effects of Lemon Flavonoids on Oxidative Stress in Diabetic Rats

Yoshiaki Miyake[a,*], Kanefumi Yamamoto[a], Nobuko Tsujihara[b], and Toshihiko Osawa[c]

[a]Central Research Laboratory of Pokka Corporation, Ltd., Aichi, 481-8515, [b]College of Nagoya Women's University, Nagoya 467, and [c]Laboratory of Food Biodynamics, Nagoya University Graduate School of Bioagricultural Sciences, Chikusa, Nagoya 464-8601, Japan

ABSTRACT: The effects of lemon flavonoids, as crude flavonoids prepared from lemon juice, were investigated in diabetic rats. The oxidative stress of eriocitrin (eriodictyol 7-*O*-β-rutinoside) and hesperidin (hesperetin 7-*O*-β-rutinoside) on streptozotocin-induced diabetic rats was investigated. Diabetic rats were given a diet which contained 0.2% crude flavonoids, 0.2% eriocitrin, and 0.2% hesperidin. After the 28-d feeding period, the concentration of the thiobarbituric acid- reactive substance in the serum, liver, and kidney of diabetic rats administered crude flavonoids, eriocitrin, and hesperidin significantly decreased as compared with that of the diabetic group. The levels of 8-hydroxydeoxyguanosine, which is exchanged from deoxyguanosine owing to oxidative stress, in the urine of diabetic rats administered eriocitrin and hesperidin significantly decreased as compared with that of the diabetic rat group. Crude flavonoids, eriocitrin, and hesperidin suppressed the oxidative stress in the diabetic rats. These results demonstrated that dietary lemon flavonoids of eriocitrin and hesperidin play a role as antioxidant *in vivo*.

Lipids 33, 689–695 (1998).

Flavonoid compounds are widespread in the plant kingdom and are present in citrus fruits. Flavonoids in citrus fruits, known as bioflavonoids or vitamin P, exhibit beneficial effects on capillary permeability and fragility. These compounds have been investigated regarding their physiological function such as anti-inflammatory, anticarcinogenic, and antitumor activities (1–3). We have isolated antioxidative flavonoid glycosides from lemon fruit and identified eriocitrin (eriodictyol 7-*O*-β-rutinoside) of the flavanone glycoside (4), and 6,8-di-*C*-β-glucosyldiosmin and 6-*C*-β-glucosyldiosmin of the *C*-glucosylflavones (5). The flavonoid content in lemon fruit was analyzed; and hesperidin (hesperetin 7-*O*-β-rutinoside), also known as vitamin P, and eriocitrin were abundantly found. Eriocitrin had stronger antioxidative activity than the other citrus flavonoid compounds and was abundantly present in lemon and lime fruits, although hesperidin is widely distributed the among citrus fruits (6).

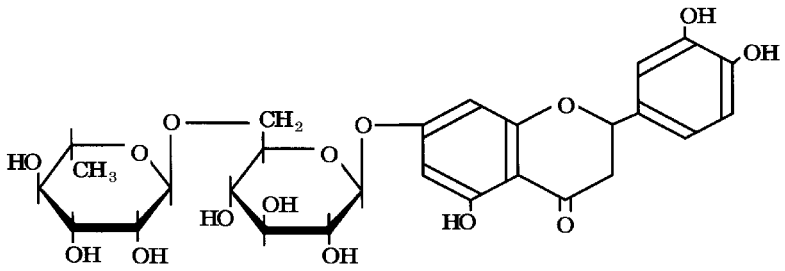
Abbreviations: CAT, catalase; CF, crude flavonoids; GSH, reduced gluthathione; GSH-Px, glutathione peroxidase; GST, glutathione *S*-transferase; 8-OHdG, 8-hydroxydeoxyguanosine; SOD, superoxide dismutase; STZ, streptozotocin; TBARS, thiobarbituric acid-reactive substances.

Much attention has been focused on the involvement of oxidative stress of active oxygen and free radicals in aging and disease. The active oxygen species have been proposed as the attacking agents on polyunsaturated fatty acids in cell membranes. Lipid peroxidation is suspected to be strongly associated with aging and carcinogenesis (7). Antioxidants in food are expected to prevent diseases caused by oxidative stress (8,9). It is important to determine how antioxidants in food are metabolized *in vivo* and how antioxidant metabolites function *in vivo*. We had reported the metabolic pathway of eriocitrin by human intestinal bacteria for the exploration of antioxidative mechanism of eriocitrin *in vivo* (10). Oxidative modification of various proteins and lipids in plasma is found in diabetes (11). Diabetes mellitus is associated with increased lipid peroxidation, which may contribute to long-term tissue damage and increased oxidative stress as assessed by plasma hydroperoxides. Oxidative stress is an early state in the disease pathology and may contribute to the development of complications (12). Investigation of the pathophysiology of the secondary complications of diabetes is increasingly focusing on the role of oxidative stress in its initiation and progression (13). There is now ample evidence supporting the involvement of reactive oxygen species in this disease.

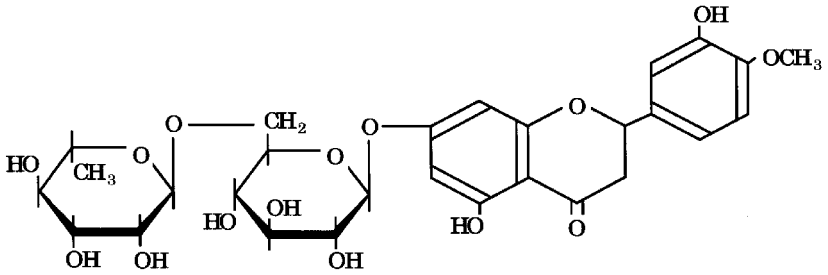
In this study, we examined whether dietary lemon flavonoids suppress oxidative stress *in vivo*, and determined whether these compounds are useful in the prevention of diabetic complications caused by oxidative stress. Oxidative stress was induced in rats using streptozocin (STZ), which is toxic to β-cells and is widely used for the induction of experimental diabetes mellitus (14). The protective effects of the lemon flavonoids eriocitrin and hesperidin, as well as crude flavonoids (CF) prepared from lemon juice, on oxidative stress were then determined.

EXPERIMENTAL PROCEDURES

Materials and chemicals. CF were prepared from lemon juice (4). This was applied to a Cosmosil 75C 18-OPN ODS column (Nacalai Tesque, Inc., Kyoto, Japan), which was washed with water and successively eluted with 100% methanol. The eluate was concentrated under reduced pressure and lyophilized. The lyophilized powder containing CF was examined for flavonoid glycosides content by high-performance



eriocitrin (eriodictyol 7-*O*-β-rutinoside)



hesperidin (hesperetin 7-*O*-β-rutinoside)

SCHEME 1

liquid chromatography according to the method of Miyake *et al.* (6). The CF (1.00 g) contained eriocitrin (385 mg), hesperidin (182 mg), 6,8-di-*C*-β-glucosyldiosmin (72.2 mg), narirutin (25.0 mg), and diosmin (22.0 mg). Eriocitrin was prepared from lemon peel extract (4), and the purity was greater than 99.0% as determined by high-performance liquid chromatography. Hesperidin was obtained as a reagent-grade chemical from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). The chemical structures of eriocitrin and hesperidin are shown in Scheme 1.

Animals and diets. Five-week-old male Wistar strain rats (Japan SLC, Ltd., Hamamatsu, Japan) were individually housed in stainless-steel cages with screen bottoms. The animals were kept under controlled conditions with a 12-h light/dark cycle (0800–2000 light) and at 22–24°C. All rats were fed commercial CE-2 pellets (Crea Japan, Ltd., Tokyo, Japan) and water *ad libitum*. Diabetes was induced in ether-anesthetized rats by the administration of STZ (60 mg/kg) as a freshly prepared solution (50 mg/mL) in saline *via* intraperitoneal injection. Diabetic rats were fed on CE-2 pellets and water *ad libitum* for 48 h after the administration of STZ. The increase of glucose content in urine of diabetic rats was checked by a commercial glucose kit (TES-Tape, Shionogi Pharmaceutical Company, Ltd., Tokyo, Japan). Three additional groups of diabetic rats were fed water *ad libitum* and CE-2 pellets containing CF, eriocitrin, or hesperidin for 28 d.

This experiment was carried out with five groups of five rats. The control group was the nondiabetic rat group (C), which had not received STZ. Diabetic rats were randomly assigned to four groups of five animals: a diabetic group fed CE-2 pellets (D); a diabetic group fed CE-2 pellets containing 0.2% CF (S+CF); a diabetic group fed CE-2 pellets containing 0.2% eriocitrin (D+ERI); and a diabetic group fed CE-2 pellets containing 0.2% hesperidin (D+HES). The feeds were prepared by mixing CE-2 pellets with the powder of CF, eriocitrin, and hesperidin. The food intake (g) of individual rats was measured daily. Body weight of the rats was measured weekly.

Tissue collection and processing. After 27 d on diet, rats were placed in individual metabolic cages in order to collect urine for 24 h. The collected urine was used to determine 8-hydroxydeoxyguanosine (8-OHdG).

After feeding the rats for 27 d, they were fasted for 10 h. On day 28 the rats were then anesthetized with ether, blood was collected into tubes by cardiac puncture, and the livers and kidneys were removed and stored at −80°C. Liver and kidney tissues were homogenized twice in 10 vol of 50 mM sodium phosphate buffer (pH 7.4) at 4°C for 15 s. The homogenate was filtered through cheesecloth, and the filtrate was centrifuged at 1,900 × *g* for 5 min. The supernatant was used for various measurements. Blood was centrifuged at 1,900 × *g* for 10 min to obtain serum.

The serum, the supernatant of homogenized liver and kidney, and the urine of rats were stored at −80°C and processed for biochemical measurements within 2 wk.

Measurement of thiobarbituric acid-reactive substances (TBARS). The serum TBARS concentration was determined by the method of Yagi (15) and is expressed as nmol of malondialdehyde per mL of blood. The liver and kidney TBARS concentrations were measured by the method of Uchiyama

and Mihara (16) using a homogenate prepared by homogenizing 1 g of frozen rat liver and kidney (a section from the main lobe) with 9 mL of 1.15% KCl.

Determination of 8-OHdG. Rat urine was centrifuged at 1,900 × *g* and the precipitate was removed. The content of 8-OHdG in the urine was measured using the 8-OHdG enzyme-linked immunosorbent assay kit (Japan Institute for Control Aging, Fukuroi City, Japan) (17,18). Creatinine content in the urine was measured using commercial kits (Wako Pure Chemical Industries, Ltd.) (19).

Measurement of antioxidative enzyme activities and glutathione. The supernatants of homogenized liver and kidney were analyzed for their antioxidant enzyme activities and content of glutathione. Superoxide dismutase (SOD) activity was measured by the xanthine/xanthine oxidase/nitro-blue tetrazolium system (20), and the catalase (CAT) activity was measured by a spectrophotometric method, following a decrease in absorbance at 240 nm and 25°C, due to hydrogen peroxide decomposition (21). Glutathione peroxidase (GSH-Px) activity was measured using the procedures of Lawrence and Burk (22) with *t*-butyl hydroperoxide as the substrate, following the decrease in absorbance of NADPH at 340 nm. Glutathione *S*-transferase (GST) activity was assayed by measuring the conjugation of reduced glutathione (GSH) with 1-chloro-2,4-dinitrobenzene (23). The content of GSH was measured by an enzymatic method (24). Protein content was measured using a commercial protein assay kit (Bio-Rad Protein Assay, Bio-Rad Laboratories, Richmond, CA).

Lipid analyses. Total cholesterol and triglyceride in the serum were enzymatically measured using commercial kits (cholesterol E-test and triglyceride E-test, respectively; Wako Pure Chemical Industries, Ltd.).

Statistical analyses. All values were expressed as mean ± S.E. ($n = 5$). The data for each of the five groups were statistically analyzed by Duncan's multiple-range test, and significant differences in the means were $P < 0.05$.

RESULTS AND DISCUSSION

General features of diabetic animals. As shown in Figure 1, the growth rate of the STZ-induced diabetic rat group (D) was slower than that of the nondiabetic rat group (C), as indicated by the smaller body weight increase during the 28-d period. The growth curves of the diabetic rat groups administered lemon flavonoids as CF, eriocitrin, and hesperidin (D+CF, D+ERI, and D+HES) also showed a slower growth rate than that of the nondiabetic rat group (C). The average food intake of the diabetic rat groups (D, D+CF, D+ERI, and D+HES) in 1 d was greater than that of the nondiabetic rat group (C). As shown in Table 1, the volume of urine and the glucose level in serum and urine of the diabetic rat groups (D, D+CF, D+ERI, and D+HES) were higher than those for the nondiabetic rat group (C). The decrease in body weight gain, the increase in food intake, the high volume of urine, and the high glucose levels in blood and urine for the STZ-induced diabetic rats are typical symptoms of diabetes (25). There was no improvement in these symptoms for the diabetic rats after the administration of lemon flavonoids such as the CF, eriocitrin, and hesperidin.

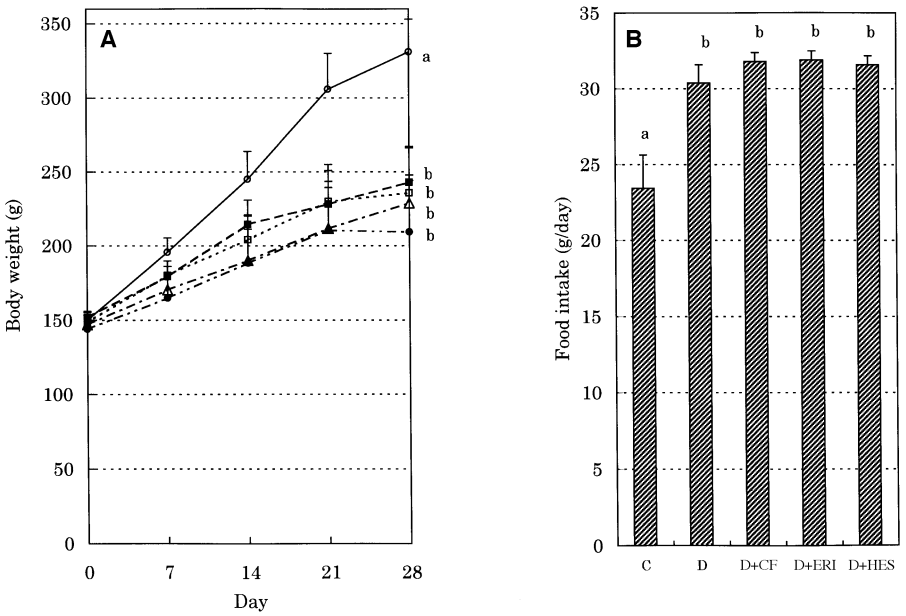


FIG. 1. Effect of dietary lemon flavonoids on body weight gain (A) and food intake (B) of diabetic rats. Diet groups (A) were: nondiabetic group (○; C), diabetic group (●, D), diabetic group administered crude flavonoids (△; D+CF), diabetic group administered eriocitrin (□; D+ERI), diabetic group administered hesperidin (■, D+HES). Values are means ± SEM of five rats per group. Lines or bars that do not share a common lowercase letter are significantly different at $P < 0.05$.

TABLE 1
Effect of Lemon Flavonoids on Liver, Kidney, Serum, and Urine of Diabetic Rats[a]

	Rat groups				
	C	D	D+CF	D+ERI	D+HES
Liver weight (% body weight)	3.95 ± 0.18[a]	5.30 ± 0.50[b]	5.42 ± 0.18[b]	5.19 ± 0.33[b]	5.08 ± 0.47[b]
Kidney weight (% body weight)	0.68 ± 0.02[a]	1.29 ± 0.13[b]	1.16 ± 0.05[b,c]	1.09 ± 0.03[c]	1.14 ± 0.10[b,c]
In serum (mL/100 mL)					
Glucose	170.6 ± 10.8[a]	532.9 ± 60.5[b]	609.3 ± 75.4[b]	521.1 ± 46.2[b]	559.7 ± 75.4[b]
Total cholesterol	42.6 ± 5.29[a]	81.8 ± 25.7[b]	77.6 ± 14.3[b]	74.8 ± 7.03[b]	79.7 ± 15.5[b]
Triglyceride	36.1 ± 3.96[a]	247 ± 77.3[b]	202 ± 45.7[b]	142 ± 71.7[b]	143 ± 34.7[b]
In urine					
Glucose (mL/100 mL)	0.07 ± 0.03[a]	10.92 ± 1.40[b]	9.81 ± 1.64[b]	11.09 ± 1.37[b]	9.47 ± 1.07[b]
Volume (mL/24 h)	10.6 ± 2.4[a]	136.7 ± 17.5[b]	151.0 ± 24.3[b]	114.3 ± 57.3[b]	115.0 ± 20.6[b]

[a]Values are means ± SEM of five rats per group. Values within the same row that do not share a common superscript roman letter are significantly different at $P < 0.05$. Abbreviations: C, nondiabetic group; D, diabetic group; D+CF, diabetic group administered crude flavonoids, (CF); D+ERI, diabetic group administered eriocitrin; D+HES, diabetic group administered hesperidin.

The liver and kidney weights (% body weight) for the diabetic rat group (D) were higher than those of the nondiabetic rat group (C) because of the hypertrophy of the liver and kidney caused by the STZ induction (Table 1). These are typical symptoms of diabetic rats (25). The kidney weights for the diabetic rat groups administered CF (D+CF) and hesperidin (D+HES) were not different from those of the diabetic rat group (D). However, kidney weights for rats fed eriocitrin (D+ERI) were significantly lower than for the diabetic rat group (D) ($P < 0.05$). The eriocitrin of lemon flavonoids may play an important role for improvement of the hypertrophy of the kidney in the diabetic rats. With respect to the liver weights, there were no differences among the diabetic rat groups. The levels of triglyceride and total cholesterol in the serum of the diabetic rats had been reported to be greatly elevated (25). The level of triglyceride in the serum of the diabetic rat groups administered lemon flavonoids (D+ERI and D+HES) was lower than in the diabetic rat group (D) but there was no significant difference ($P < 0.05$). Hesperidin decreases the triglyceride in the blood of rats fed fat (26). Eriocitrin and hesperidin may suppress the triglyceride in the blood of diabetic rats. There was no difference among the diabetic rat groups in the level of total cholesterol in serum.

TBARS levels of liver, kidney, and serum. The changes in the TBARS of the liver, kidney, and serum of diabetic rats after the administration of the lemon flavonoids are summarized in Figure 2. There was a significant increase in the TBARS of the liver, kidney, and serum in the diabetic rat group (D) compared to the control group. However, the TBARS levels of the liver, kidney, and serum in the diabetic rat groups administered lemon flavonoids (D+CF, D+ERI, and D+HES) were significantly decreased compared to the TBARS of the diabetic rat group (D). The increase of malondialdehyde, caused by lipid peroxidation, in tissue and blood of STZ-induced diabetic rats has been previously reported (13,27). The increased levels of TBARS, the reactive substance of malondialdehyde and TBA, resulted in increased levels of oxygen free radicals which attacked the polyunsaturated fatty acids in cell membranes and caused lipid peroxidation. STZ can also give rise to oxygen free radicals because of the increase in blood glucose levels in diabetes (14). An amino-carbonyl reaction, the so-called Maillard reaction, occurs *in vivo* as well as *in vitro* and is associated with the chronic complications of diabetes mellitus and aging in human beings (28). In particular, long-lived proteins such as lens crystallins, collagens, and hemoglobin may react with reducing sugars thus undergoing dehydration, rearrangement, cleavage, and polymerization reactions to produce advanced glycation end products (13,28). Lemon flavonoids of the CF, eriocitrin, and hesperidin affected the suppression of lipid oxidation in the liver, kidney, and serum. We postulated that these flavonoids play a role as free radical scavengers *in vivo* and prevent the development of complications associated with diabetes.

Determination of 8-OHdG in rat urine. Lipid peroxidation may play an important role in carcinogenesis, and there is speculation that oxidative damage can occur in DNA during the peroxidative breakdown of the membranes' polyunsaturated fatty acids (8). It is reported that mutation in mitochondrial DNA is caused by oxygen radicals and hydroxy radicals that oxidize 2′-deoxyguanosine to 8-OHdG (29). In STZ-induced diabetic rats, STZ stimulated H_2O_2 generation and caused DNA fragmentation (30). Since 8-OHdG has continued to serve as a good biomarker for the estimation of oxidative damage in DNA, we determined 8-OHdG in the urine of diabetic rats using the monoclonal antibody against 8-OHdG (17,18). The levels of total 8-OHdG over 24 h in the urine of diabetic rats and of 8-OHdG relative to creatinine content in the urine are shown in Figure 3. There was a significant increase of 8-OHdG in the urine of the diabetic rat group (D) compared to the control group. However, the level of 8-OHdG in the urine of the diabetic rat groups administered eriocitrin (D+ERI) and hesperidin (D+HES) significantly decreased compared to 8-OHdG of the diabetic rat group (D). The diabetic rat group administered the lemon CF (D+CF) did not have a significant decrease, but showed a tendency to decrease. The effects on total 8-OHdG for 24 h and 8-OHdG relative to creatinine content were almost the same. CF, eriocitrin, and hesperidin suppressed the generation 8-OHdG in the urine of the diabetic rats. This result suggests that the di-

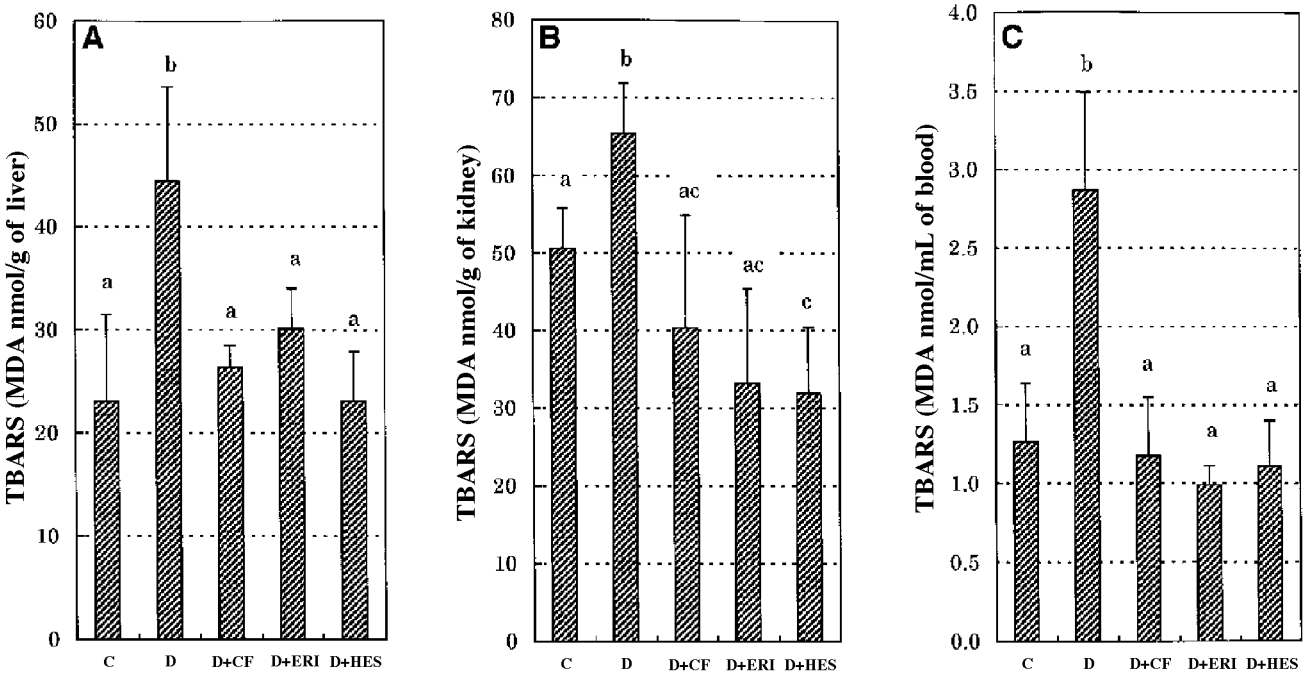

FIG. 2. Effect of lemon flavonoids on liver (A), kidney (B), and serum (C) thiobarbituric acid-reactive substances (TBARS) of diabetic rats, measured in terms of malondialdehyde. etary lemon flavonoids eriocitrin and hesperidin play a role in scavenging the free radicals generated by oxidative stress *in vivo*.

Influence of antioxidative enzyme activities. A considerable body of clinical and experimental evidence suggests the involvement of free radical-mediated oxidative processes in the pathogenesis of diabetic complications (13). The increase in the production of free radicals can result from the hyperglycemia-induced enhancement in glucose autoxidation, pro-

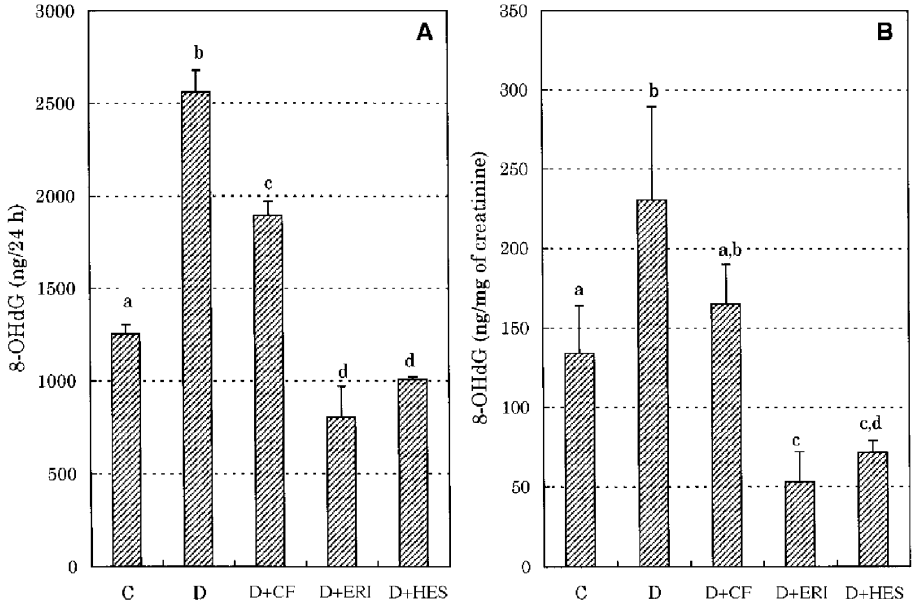

FIG. 3. Effect of lemon flavonoids on the total 8-hydroxydeoxyguanosine (8-OHdG) levels in a 24-h period (ng/24 h) (A) and on the content of 8-OHdG relative to the content of creatinine (ng/mg of creatinine) (B) in the urine of diabetic rats. Values are means ± SEM of five rats per group. Values within the same panel that do not share a common lowercase letter are significantly different at $P < 0.05$. tein glycation, and subsequent oxidative degradation of glycated protein (28). The glutathione antioxidant system plays a fundamental role in cellular defense against reactive free radicals and other oxidant species (31). It consists of GSH and an array of functionally related enzymes. If the diabetic state is associated with a generalized increase in tissue oxidative stress, it may be reflected in changes of the tissue glutathione antioxidant system. The activities of the antioxidative enzymes SOD, CAT, GST, and GSH-Px in diabetic rats fed CF, eriocitrin, and hesperidin are shown in Table 2. The activities of SOD and GST in the liver and that of SOD and CAT in the kidney were not different among the rat groups. The activity of GSH-Px in the liver and kidney and of GST in kidney for the diabetic rat groups administered lemon flavonoids (D+CF, D+ERI, and D+HES) increased when compared with the non-diabetic rat group (C) and the diabetic rat group (D). GSH-Px and GST work together with GSH during the decomposition of hydrogen peroxide or other organic hydroperoxides (31). The lemon flavonoids eriocitrin and hesperidin may function to increase the concentration of these enzymes as well as the antioxidative activity *in vivo*. The activities of CAT and the content of GSH in the liver for the diabetic rat group (D) decreased when compared with the nondiabetic rat group (C). However, the activities for the diabetic rat groups administered lemon flavonoids (D+CF, D+ERI, and D+HES) were higher than for the diabetic rats (D). The content of GSH consumed by oxidative stress in the diabetic rats suggests that administration of the lemon flavonoids afforded an improvement.

CF in lemon fruit contained many compounds such as flavonoids and phenolic compounds. Eriocitrin and hesperidin, present in CF of lemon, had a strong suppressing effect on oxidative stress as evidenced by decreased levels of TBARS and 8-OHdG in tissues of diabetic rats. These results suggest that dietary lemon flavonoids eriocitrin and hesperidin may play a role in preventing the development of diabetes and be useful in preventing diseases caused by oxidative stress.

Distribution of α- and γ-Tocopherols in Atlantic Salmon *(Salmo salar)* Tissues[1]

Monina P.M. Parazo[a], Santosh P. Lall[b,2], John D. Castell[b,3], and Robert G. Ackman[a,*]

[a]Canadian Institute of Fisheries Technology, DalTech, Dalhousie University, Halifax, Nova Scotia B3J 2X4, and [b]Department of Fisheries and Oceans, Halifax, Nova Scotia B3J 2S7, Canada

ABSTRACT: Groups of Atlantic salmon parr (mean initial weight 9.5 g) were fed three diets, the first containing no tocopherol supplement, the others supplemented with either all-*rac*-α-tocopherol (A-T) or RRR-γ-tocopherol (G-T). Tocopherol concentrations in the liver, serum, testes, kidney, brain, gill, muscle, and perivisceral fat were measured after 36 wk. Despite a higher dietary intake of G-T, compared to A-T, deposition of γ-tocopherol (γT) was less efficient than of α-tocopherol (αT) in most tissues except in the perivisceral fat, an adipose tissue. In fish fed the G-T diet, the γT/αT ratio was highest in the perivisceral fat and lowest in the liver, indicating that the liver is the most discriminatory organ for retaining αT as compared to γT, and the perivisceral fat is more suitable for the storage of γT. A negative correlation ($P < 0.01$) was observed between the γT/αT ratio and the corresponding tissue phospholipid content, suggesting that γT is less efficiently deposited compared to αT in the phospholipid-rich membranes which are presumed to be the functional site for lipid antioxidants *in vivo*. During restricted intake of αT, the liver and muscle exhibited the greatest reduction of this tocopherol among the tissues analyzed. The presence of minimal αT in the muscle from fish fed the tocopherol-unsupplemented diet led to greater susceptibility to lipid peroxidation after frozen storage than was the case for muscle containing higher concentrations of either αT or γT. However, both αT and γT were effective stabilizers of salmon muscle lipids during frozen storage.

Lipids 33, 697–704 (1998).

Tocopherols are powerful *in vivo* antioxidants which are intimately associated with lipids of cell membranes and are postulated to exert wide-ranging effects on aging, cancer, arthritis, platelet aggregation, and prostaglandin synthesis (1,2). Natural plant tocopherols include alpha (αT), beta (βT), gamma (γT), and delta (δT) forms, but αT is widely believed to be the most biologically efficacious form of vitamin E in animals. In humans consuming diets abundant in both αT and γT, tissues are preferentially enriched with αT rather than γT (3), and the reasons for the discrepancy of incorporation in animal tissues of these two most abundant plant tocopherols have been actively researched. In studies on rats, intestinal absorption rates and tissue uptake after absorption for the two tocopherols were reportedly similar, but γT disappeared faster than αT from the tissues after 24 h through a once-obscure mechanism (4,5). In normal human subjects, αT and γT are similarly absorbed at the intestinal level, yet mechanisms involving the action of a hepatic αT-binding protein result in the reduction of plasma γT concentration by 24 h (6). However, while the existence of the αT-binding protein in the hepatocyte (7,8) may explain the greater prevalence of circulating αT, it does not fully account for why γT, once it has reached the tissues, is not retained to the same degree as αT. Behrens and Madere (9) inferred that although γT is able to reach the different organ tissues in the rat, it is unable to bind to membrane structures with as high an affinity as αT, suggesting that molecular specificity at the site of antioxidant activity in the tissues may well be one of the crucial factors.

The hypothesized functional site of tocopherols in the cell lies within the lipid components of cell membranes (10). The phytyl chain facilitates incorporation and retention of tocopherols in membranes, with the hydroxy group optimally positioned for scavenging free radicals (11). Recently, fluorescence spectroscopy techniques provided evidence that αT is wholly embedded within the phospholipid-rich membrane bilayer with the chromanol head oriented toward the polar interfacial region (10,12). In highly active biological cells, αT concentrates in the membranous components where it inhibits peroxidative damage to the unsaturated lipids within the membrane bilayer (13). Cell membranes are complex structures, and specificity for incorporation of different forms of related compounds is no doubt rigorously controlled. It is therefore provocative to speculate that biodiscrimination for αT and γT may exist at the level of incorporation within cell membrane lipids rather than merely from the total tissue lipid pool. Marine fish phospholipids are characterized by a high (35–45%) amount of long-chain polyunsaturated fatty acids, particularly docosahexaenoic acid (14). Although αT is the

Abbreviations: A-T, all-*rac*-α-tocopherol-supplemented diet; G-T, RRR-γ-tocopherol-supplemented diet; 5-NS, 5-doxylstearate; 16-NS, 16-doxylstearate; TBARS, 2-thiobarbituric acid-reactive substances; no-T, non-tocopherol-supplemented diet; αT, α-tocopherol; γT, γ-tocopherol.

major tocopherol found in lipids of marine fish (15), our recent data verified that γT can be deposited along with αT in Atlantic salmon (*Salmo salar*) muscle lipids (16,17). A feasible approach to gaining insight into this matter of membrane distribution of tocopherols is to relate the proportions of the γT to the αT to the tissue phospholipid content in different salmon organs. We presumed that if discrimination between incorporation of these tocopherols in the membrane lipid bilayer does not occur, the γT/αT ratio would remain similar in various tissues despite varying phospholipid contents.

Diets for cultured Atlantic salmon are usually supplemented with tocopherol, solely in the αT form. Other than *in vivo* antioxidant-related functions, membrane-bound αT reduces postmortem lipid oxidation in fish products by stabilizing membrane lipids (16,18,19). In rainbow trout, adequate tocopherol intake improved the sensory quality of the fillets (20), thus affecting the quality, and ultimately the marketability, of the fish product.

The objectives of this experiment were to compare the deposition of dietary all-*rac*-α-tocopherol and RRR-γ-tocopherol in various tissues of Atlantic salmon in relation to tissue phospholipid content, and to examine the pattern of tocopherol depletion in tissues during restricted intake of these two tocopherols. Another objective was to determine if dietary γT deposited in the muscle functions similarly to αT in providing oxidative stability to the muscle after frozen storage at –40°C for 6 mon.

TABLE 1
Composition of the Test Diets[a]

Feed ingredient	Amount (w/w%)
Casein	32.5
Gelatin	4.0
Herring meal	12.0
Krill meal	3.0
Dextrin	11.0
Starch[b]	11.5
Celufil	3.7
Amino acid mix[c]	0.7
Vitamin mixture[d]	2.5
Mineral mixture[e]	5.0
Herring oil[f]	14.0

[a]Tocopherol contents by analysis were 6 mg αT/kg for the nontocopherol-supplemented diet (no-T), 36 mg αT/kg for the all-*rac*-α-tocopherol-supplemented diet (A-T), and 15 mg αT/kg + 78 mg γT/kg for the RRR-γ-tocopherol-supplemented diet (G-T).
[b]Contains 8% cornstarch and 3.5% pregelatinized starch.
[c]Supplied 0.5% DL-methionine and 0.2% L-phenylalanine.
[d]Supplied vitamins at the following levels (IU or mg/kg diet): vitamin A, 8000 IU; vitamin D_3, 3000 IU; vitamin K, 40; thiamin, 50; riboflavin, 70; *d*-calcium pantothenate, 200; *d*-biotin, 1.5; folic acid, 20; vitamin B_{12}, 0.15; niacin, 300; pyridoxine, 30; inositol, 500; ascorbic acid, 50; choline chloride, 5000.
[e]Supplied minerals at the following levels (mg element/kg diet): manganese, 40; iron, 50; copper, 15; zinc, 100; magnesium, 398; iodine, 5; cobalt, 15; sodium, 985; fluorine, 4.5; phosphorus, 2900; potassium, 2500.
[f]To the weighed herring oil (14 w/w% of the diet), 0.015% of tocopherol supplement was added to the A-T diet (DL-α-tocopherol) and G-T diet (D-γ-tocopherol) prior to incorporation of the oil with the dry ingredients. In the no-T diet, Celufil (US Biochemicals, Cleveland, OH) replaced tocopherol.

MATERIALS AND METHODS

Fish and diets. Atlantic salmon parr (9.5 g average initial weight) were randomly distributed into tanks (50 fish/tank) containing 200 L fresh water maintained at 2 L/min flow rate and an average temperature of 16 ± 2°C. The photoperiod was automatically set at 12 h of light. Feeding to satiety during the lighted period was done by hand twice daily except on weekends when fish were fed only once per day.

The formulations of the three semipurified diets were the same except for tocopherol supplementation as shown in Table 1. All-*rac*-α-tocopherol was obtained from US Biochemical Corporation (Cleveland, OH) and RRR-γ-tocopherol from Sigma (St. Louis, MO). Test diets were steam-pelleted in a laboratory pellet mill (California Pellet Mill, San Francisco, CA) and stored in sealed plastic containers at –35°C. Feed rations sufficient for about 7 d were thawed at one time. The test diets had similar moisture (8%), protein (43%), and lipid (15%) contents.

After 36 wk on the experimental diets, six fish were randomly selected from each treatment, stunned with a blow to the head, and then weighed. Blood was collected using heparinized vials (Becton-Dickinson, Rutherford, NJ) and centrifuged for 5 min to separate the serum for collection. The liver, brain, gill, kidney, and portions of the white muscle and perivisceral fat (an adipose tissue surrounding the gastrointestinal tract) were then rapidly excised and weighed. Precocious maturation was observed in more than 90% of the males sampled at 36 wk, and testes from these mature individuals were also collected for lipid and tocopherol analyses. Since individual organ weights were occasionally too small for tocopherol analysis, tissue samples from two individuals in the same treatment were combined for each replicate analysis.

Lipid extraction and tocopherol analyses. Immediately after excision and weighing, the tissues were transferred to a test tube containing 18 mL hexane/isopropanol (3:2, vol/vol), homogenized, and extracted for total lipids following the method of Hara and Radin (21).

Total lipid extracts were quantitatively dissolved in hexane and tocopherol contents of the diets, and tissues were determined by high-performance liquid chromatography with fluorescence detection following the AOCS method (22). The high-performance liquid chromatography system consisted of a Partisil 5 μm column (11 cm × 4.7 mm; Whatman, Clifton, NJ) equipped with a guard column, a Waters (Milford, MA) U6K Injector, a Waters 6000A Solvent Delivery System, a Waters 420 AC Fluorescence Detector with 280 excitation and 338 nm emission filters, and a Perkin-Elmer (Norwalk, CT) LCI-100 Laboratory Computing Integrator. The isocratic mobile phase was hexane/isopropanol (99.5:0.5, vol/vol) at 1.5 mL/min flow rate. Peaks were identified by comparing retention times with those of authentic αT and γT standards or by coinjecting the tocopherol standard with the lipid sample. Quantitation was achieved by reading sample peak areas against linear regression lines plotted for standard solutions of the tocopherols.

Analysis of lipid composition. The percentage composition of tissue lipids from fish fed the supplemented diet (G-T) was determined using a TH-10 Mark III TLC/FID Iatroscan (thin-layer chromatography with flame-ionization detection; Iatron Laboratories, Tokyo; Canadian Agent Scientific Products and Equipment, Rexdale, Ontario, Canada) attached to an SP-4200 computing integrator. The lipid sample was spotted onto silica gel-coated quartz rods (Chromarods SIII) and developed in a solvent system consisting of hexane/chloroform/isopropanol/formic acid (80:14:1:0.2, by vol) for 50 min. The analytical conditions for quantitation of lipid classes followed the method of Parrish and Ackman (23). Standards used for identification and quantitation of lipid class peaks in the sample were tripalmitin, cholesterol, 1,2-dipalmitoyl-3-phosphatidylcholine, cholesteryl palmitate (Serdary Research Laboratories, London, Ontario, Canada), and palmitic acid (Nu-Chek-Prep, Elysian, MN). Standard curves for each lipid type were plotted by chromatographing known quantities of the standards in the same solvent system and on the same rods as those used for tissue lipid samples.

Oxidative susceptibility of the muscle. The oxidative susceptibility of the muscle was determined by the 2-thiobarbituric acid-reactive substances (TBARS) test according to Woyewoda *et al.* (24) using 1,1,3,3-tetraethoxypropane (Sigma, St. Louis, MO) to make up the malonaldehyde standard solution. Intact muscle samples from six fish were stored for 6 mon at −40°C prior to the TBARS test. At the end of 6 mon, tocopherol levels in the muscle samples were not remeasured since drastic decreases in tocopherols were not expected under this storage condition. Ackman and Timmins (25) reported that no dramatic decreases in αT content of smoked salmon fillets occurred within 12 wk of storage at −10°C. Since the storage temperature in this new experiment was lower and the muscles were not exposed to treatments (e.g., brining and smoking) which would potentially degrade tocopherols, the content of the muscles should not significantly differ from the values determined prior to storage.

Statistical analysis. Differences in means of tissue lipid content and TBARS values were determined by one-way analysis of variance and Tukey's test, and the relationship between tissue tocopherol and phospholipid content was determined by regression analysis using Systat 5.2 (Evanston, IL).

RESULTS AND DISCUSSION

No unexplained fish mortalities or gross pathological symptoms were observed during the feeding trial. After 36 wk, the average weight of fish was 85 g, and no remarkable differences in specific growth rate were observed between dietary treatments.

Table 2 shows the lipid contents of various tissues of Atlantic salmon after 36 wk on the experimental diets, and Table 3 shows that lipid class composition of the tissues from the fish fed the G-T diet. There were no significant differences in lipid content of the tissues of fish from the different dietary treatments except in the perivisceral fat. Fish used in this experiment were judged lean at sacrifice, considering the low lipid content of white muscle tissue. Salmon do not deposit much fat in fresh water but do so after smolting into salt water when dietary fat can be raised to 27–29% of the diet, resulting in over 16% fat in market fish.

TABLE 2
Lipid Contents[a] (%) of Tissues, Wet Weight, in Atlantic Salmon Fed no-T, A-T, or G-T Diets

	Diet group		
Tissue	no-T	A-T	G-T
Brain	7.8 ± 0.2	7.9 ± 0.3	7.3 ± 0.1
Gill	14.8 ± 1.3	14.4 ± 0.5	13.4 ± 0.3
Kidney	6.3 ± 0.6	6.2 ± 0.5	7.0 ± 0.5
Liver	3.0 ± 0.4	3.9 ± 0.9	2.9 ± 0.2
Muscle	1.7 ± 0.1	1.5 ± 0	1.6 ± 0.0
Perivisceral fat	92.1 ± 0.2[b]	95.5 ± 0.4[c]	92.7 ± 1.0[b,c]
Serum (mg/mL)	18.4 ± 0.9	18.2 ± 1.3	18.9 ± 1.8
Testes	2.1 ± 0.3	1.9 ± 0.3	2.1 ± 0.8

[a]The no-T and G-T diets contained some α-tocopherol derived from the dietary ingredients. Mean ± SEM followed by different superscripts (b,c) within one row are significantly different ($P < 0.05$), $n = 2$ or 3; each n is a pooled sample from two fish. See Table 1 for abbreviations.

Phospholipids, sterols, and triacylglycerols were the major components in all tissues. The perivisceral fat contained small amounts of phospholipids and extremely high levels of triacylglycerols, a characteristic of its function as major tissue depot for lipid reserves. The gill lipids exhibited a large proportion of triacylglycerol probably originating from fatty supportive tissues of the gill arch.

Comparative tissue distribution of αT and γT. Despite a 100% higher dietary concentration of γT compared to αT (Table 1), the tissue γT content of the G-T_{fed} fish were lower than αT in tissues from the all-*rac*-α-tocopherol supplemented diet (A-T)-fed fish in the liver, serum, kidney and testes, whereas no difference was seen in the brain tissue (Fig. 1). Muscle and gill γT contents were slightly higher than those of αT although this difference was less pronounced than the proportions of the dietary tocopherol concentrations. Only the perivisceral fat γT concentration greatly exceeded (almost

TABLE 3
Composition of Lipids (%) from Tissues of Atlantic Salmon Fed the γ-Tocopherol Diet[a]

	Lipid class		
Tissue	Triacylglycerol	Sterol	Phospholipid
Brain[b]	2.4 ± 0.5	19.4 ± 0.3	77.2 ± 0.2
Gill	90.8 ± 1.5	1.7 ± 0.4	8.4 ± 1.1
Kidney	61.9 ± 2.8	4.8 ± 0.2	33.3 ± 2.7
Liver	18.6 ± 4.0	6.6 ± 0.9	74.8 ± 3.2
Muscle	35.1 ± 2.1	3.7 ± 0.7	62.2 ± 2.0
Perivisceral fat	98.7 ± 0.2	0.4 ± 0	0.9 ± 0.2
Serum	39.2 ± 1.9[c]	8.3 ± 0.1	52.5 ± 2.0
Testes	7.5 ± 1.3	17.7 ± 0.2	74.8 ± 1.2

[a]Values are mean ± SD of 2–3 lipid extracts.
[b]The brain contained 1.3% free fatty acids, a value higher than in other samples.
[c]Includes both sterol esters and triacylglycerols.

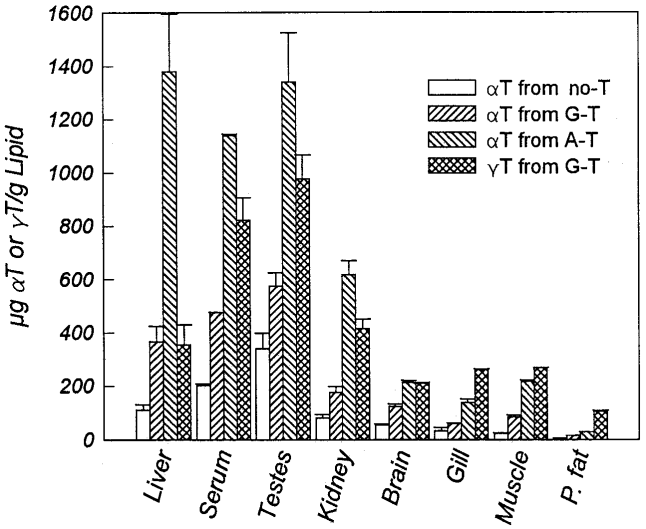

FIG. 1. Concentrations (μg/g lipid) of tocopherols in selected tissues of fish fed no supplemental tocopherol (No-T), or supplemented with α-tocopherol (A-T), or supplemented with γ-tocopherol containing a small proportion of alpha (G-T), after 36 wk. P. fat, perivisceral fat.

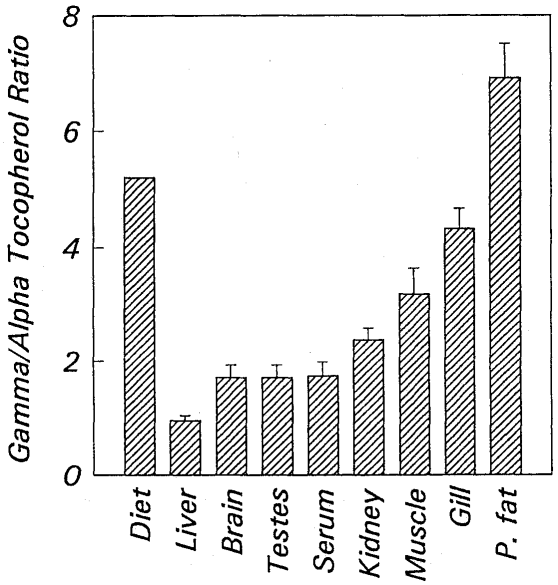

FIG. 2. Ratio of γT/αT in the G-T diet and in selected tissues of the fish fed the G-T diet for 36 wk. See Figure 1 for abbreviations.

400%) that of αT in the corresponding tissue of the (A-T)-fed fish. It is thus apparent that γT is preferentially stored in the adipose tissue, and its accumulation in the total lipids of critical tissues in Atlantic salmon is inferior to that of αT. This difference in tissue distribution of αT and γT is interesting because previous reports have shown that adipose tissue tocopherol constitutes little more than an inactive reserve of this compound. In humans, more than 90% of adipose tissue tocopherols is largely dissolved in the lipid droplet within the cell rather than in the surrounding membrane and therefore unavailable for immediate use (26). Furthermore, adipose αT is not rapidly released back into the bloodstream after αT supplementation in humans is halted (27). In guinea pigs, Machlin *et al.* (28) also found that adipose tissue tocopherol is not readily available for maintaining plasma tocopherol levels and preventing signs of vitamin E deficiency, thereby having no immediate nutritional value and simply representing a tissue depot with slow turnover rate. In a similar context, it is likely that γT stored in the adipose tissue of Atlantic salmon is biochemically inactive as opposed to αT found in the critical tissues.

In fish fed the G-T diet containing primarily γT and minimal αT, different tissues had varying affinities for the two tocopherols (Fig. 1). The γT/αT ratio (Fig. 2) was lowest in the liver, highest in the perivisceral fat, and the other tissues exhibited intermediate values. These results emphasized the importance of the liver in selecting αT over γT in Atlantic salmon. Similarly the fact that the γT/αT ratio was higher in the perivisceral fat than in the diet indicated preferential storage of γT in the depot organ as opposed to αT which distributed largely within critical tissues. The perivisceral fat is mostly triacylglycerol that would derive both fatty acids and tocopherols from the circulating chylomicrons (8). The gills are also rich in triacylglycerols and they have the next-highest ratio (Fig. 2). Other body sites may acquire their lipids from very low density lipoprotein after the discrimination process screens out and excretes tocopherols other than alpha. The relationship between the γT/αT ratio and tissue phospholipid content showed a trend of decreasing ratio with increasing tissue phospholipid content (Fig. 3). A greater accumulation of αT compared to γT in phospholipid-rich tissues suggests that preference for αT over γT in Atlantic salmon tissues appears to be governed at the level of incorporation in the lipid bilayer of membrane structures. The difference in their incorporation at sites close to the phospholipids in cell membranes may impact heavily on their *in vivo* antioxidant activities.

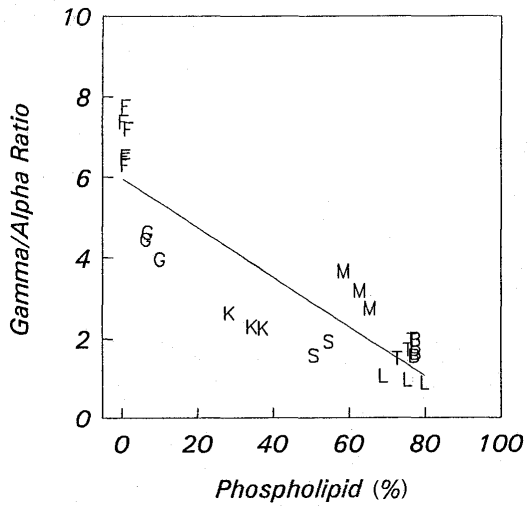

FIG. 3. Correlation between γT/αT ratio and phospholipid contents (%) from tissues of fish fed the G-T diet for 36 wk (r^2 = 0.77; n = 26; P < 0.01); B (brain), G (gill), F (perivisceral fat), K (kidney), L (liver), M (muscle), S (serum), T (testes). See Figure 1 for other abbreviations.

Erickson *et al*. (29) found that the αT concentration in milk was at least three times higher in the lipid of the fat globule membrane than in the lipid inside the fat globule. During lipid oxidation, tocopherol associated with the membrane was lost more rapidly than that found inside the fat globule, implying its greater role in determining the oxidative stability of milk. Correspondingly, the distribution of αT within the lipid bilayer of cell membranes is now well established. Krishnamurthy and Bieri (30) and Gruger and Tappel (13) were some of the early investigators who observed that tocopherols in active biological cells concentrate largely in phospholipid-rich cellular regions, e.g., mitochondria and microsomal fractions. Buttris and Diplock (31) also verified that the inner and outer mitochondrial and microsomal membrane sections were the major tocopherol-containing sites, implying the specific localization of tocopherols in membrane regions particularly liable to oxidative attack. In 1989, Gomez-Fernandez *et al.* (12) used fluorescence spectroscopy techniques to determine the position of tocopherol within phospholipid vesicles based on tocopherol's intrinsic fluorescence and the quenching action of membrane probes, e.g., 5-doxylstearate (5-NS), 16-doxylstearate (16-NS), and acrylamide. Acrylamide, a water-soluble quencher with very low capacity to penetrate the phospholipid bilayer was inefficient in quenching αT located in the fluid membrane. On the other hand, 5-NS and 16-NS, probes known to be located at a graded series of depths from the surface of the bilayer, were both effective, 5-NS more than 16-NS, in quenching the fluorescence of αT. It is thus clear that αT lies embedded within the phospholipid bilayer with its chromanol head located near the polar region of the membrane. Fukuzawa *et al.* (10) further clarified that no interaction takes place between the hydroxyl group in the chromanol head of αT and the polar interfacial region, indicating that the hydrophobic chromanol head is poorly exposed at the surface. No analogous studies were done for γT. Since γT has one methyl group less than αT in the chromanol head, it is highly probable that molecular discrimination of incorporation in membrane lipid bilayers exists between the two tocopherols due to their different steric structures in the chromanol region. The presence of more methyl substituents in the chromanol region should increase lipophilic properties, thereby making αT the more soluble tocopherol in lipid substrates (32). Interestingly, a recent report showed α-tocotrienol as a more potent scavenger of peroxyl radicals in liposomes compared to αT, presumably due to a difference in vitamin E-membrane interactions conferred by the hydrocarbon tails (33). Unsaturation in the tail of αT gives rise to an altered three-dimensional molecular structure in α-tocotrienol which may profoundly affect the orientation and organization of membrane phospholipids and result in different antioxidant potencies between the two vitamin forms (33).

The scatter of the points in Figure 3 strongly suggests the involvement of other mechanisms of biodiscrimination between γT and αT which take place at the cellular level in response to the diverse metabolic functions of various tissues. For instance, Ackman and Cormier (15) found that metabolically active dark muscle in cod was richer in αT than the white muscle tissue, since confirmed for Atlantic salmon (34). In this new experiment, the liver and testes exhibited similar proportions of tissue phospholipids, but the γT/αT ratios differed by about 75% (Fig. 2). Also, the muscle showed a higher γT/αT ratio (*ca*. 3) than would have been expected from the relatively high phospholipid content, possibly due to γT deposition in neutral lipid of adipocytes attached to connective tissue (35,36), as well as the redirection of essential αT from muscle phospholipids into phospholipids of other and more critical tissues. Hamre and Lie (34) suggest that each organ may have unique combinations of mechanisms by which they take up lipids and tocopherols from plasma.

As already pointed out (7,8), another discriminatory mechanism relates to the existence of an αT-specific factor, which is reportedly present in the rat, but not yet studied in fish. Catignani and Bieri (37) were the first to report the presence of a tocopherol-binding protein in rat liver which was specific for, but not necessarily limited to, αT since α-tocotrienol and γT also exhibited minimal competitive effects. The protein, a 30 kDa αT-binding protein, exists uniquely to the hepatocyte in the rat, and regulates plasma tocopherol concentration by preferentially incorporating the αT into nascent very low density lipoproteins (8). Another αT-binding protein of molecular mass 14.2 kDa was also recently identified and suspected to be responsible for the intracellular transport and distribution of αT in all tissues including the liver (38). Although the existence of a 30 kDa αT-binding protein in fish liver has not yet been verified, our data suggest that an analogous protein exists in Atlantic salmon liver since this organ appeared to be the most biased tissue for accumulating αT.

The interrelationships between tissue phospholipids, αT-specific protein factor, or other mechanisms which collectively result in biodiscrimination between αT and γT distribution in Atlantic salmon tissues require further investigation. Nevertheless, the greater accumulation of γT in adipose tissue compared to αT, and the negative correlation obtained between γT/αT and tissue phospholipid content suggest that inferior structural compatibility of γT in the phospholipid-rich membrane bilayer, compared to that of αT, may partly explain the distribution pattern of the two tocopherols in Atlantic salmon tissues.

Tissue αT distribution. The tissue lipid tocopherol content from all fish groups after 36 wk on the experimental diets is shown in Figure 1. The nontocopherol supplemented diet (no-T)-fed fish showed the lowest amounts of αT in lipids of all tissues examined, while the (G-T)-fed fish exhibited only somewhat higher tissue αT content. The (A-T)-fed fish exhibited the highest αT content in all tissues analyzed.

To establish which of the tissues of Atlantic salmon were prone to lose tocopherol during restricted intake of this compound, the ratios of tocopherol content of the (A-T)- and (no-T)-fed fish (calculated as [αT content of A-T]/[αT content of no-T]) were determined for each of the tissues examined (Fig. 4). These ratios reflect the magnitude of tocopherol loss in the tissues of the no-T-fed fish. After a period of low

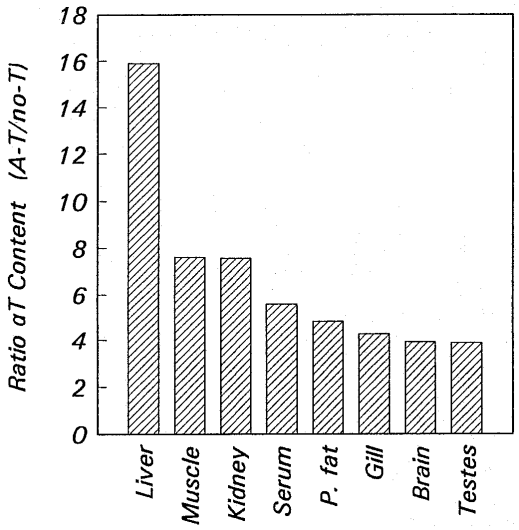

FIG. 4. Ratios of tissue αT concentrations in tissues of the (A-T)- and (no-T)-fed fish after 36 wk. See Figure 1 for abbreviations.

tocopherol intake and almost 900% weight gain, the (no-T)-fed fish still retained appreciable quantities of tocopherol in certain tissues such as the testes. The brain is another tissue that tenaciously retained tocopherol during the period of low tocopherol intake in Atlantic salmon (Fig. 4). Clearly, the different tissues of Atlantic salmon have variable ability for retention and deposition of tocopherols during a period of restricted intake of this compound. The liver showed the greatest disparities, indicating its function as a major depot organ for tocopherol which is likely mobilized during periods of deprivation (Fig. 4), a result similar to that obtained by Cowey *et al.* (39) in rainbow trout. Although the muscle showed moderate loss of tocopherol (Fig. 4), it accounts for at least 50% of the fish weight, and therefore lost greater actual amounts of tocopherol compared to the liver. Cowey *et al.* (40) suggested the possibility that tocopherol is translocated from the muscle of rainbow trout to other more critical organs during the deprivation periods. This also applies to Atlantic salmon in this experiment where drastic decreases in liver and muscle tocopherols probably reflect transport into the developing testes from the precocious males, since the testes exhibited the highest concentration of tocopherol among the tissues of the (no-T)-fed fish, and the least margin of difference in tocopherol concentration among the tissues of the (no-T)- and (A-T)-fed fish (Fig. 4). Lie *et al.* (41) reported a similar scenario for female Atlantic salmon where a net transport of tocopherol from peripheral tissues to the gonads occurred during vitellogenesis, thus protecting the reproductive organ from critical tocopherol deficiency status at the expense of the other organs.

The pattern of tissue tocopherol depletion observed in Atlantic salmon follows that generally observed for other animal models. In rats, significant amounts of tocopherol loss from the liver occurred when dietary intake of this compound was minimal (42). In contrast, tocopherol stores in the nervous system tissues and brains of rats and dogs declined slowly during restricted intake (43,44). Bieri (42) speculated that the kinetics of tissue tocopherol depletion in rats may be affected by the respective amounts of labile and bound tocopherol present in the particular organ.

Oxidative susceptibility of the muscle. In Atlantic salmon, the liver and muscle exhibited drastic decreases in tocopherol concentrations during restricted intake of this compound, implying mobilization of their tocopherol stores toward other and more critical tissues. As the muscle constitutes the consumable portion of the fish, tocopherol loss from this organ may adversely affect the postmortem quality of the resultant fish flesh product. Salmon farming is an international and intensively competitive industry where quality has only comparatively recently superseded maximal growth as a major concern (45,46).

Sigurgisladottir *et al.* (16) reported that with experimental Atlantic salmon fillets containing more γT than αT, TBARS values were lower after a forced oxidation test than for fillets containing only a smaller amount of αT. In this new experiment, the presence of minimal αT in the muscle from fish fed the no-T diet exposed the tissue to significantly greater susceptibility to lipid peroxidation after frozen storage at –40°C for 6 mon than was the case for muscle containing higher concentrations of either αT or γT (Fig. 5). Muscle samples from the G-T treatment exhibited tissue αT levels that were closer to the no-T rather than to those from the A-T treatments, yet the muscle TBARS values were significantly better than that of the no-T treatment and corresponded more closely with those of the A-T treatments. Thus, the significant drop in oxidative susceptibility of the G-T muscle samples compared to the control was most likely due to the presence of γT. The results of this experiment confirm the reports of Sigurgisladottir *et al.* (16,17) that γT improves the oxidative stability of Atlantic salmon muscle.

Frozen storage of natural fish muscle does not halt natural biochemical processes such as loss of αT content and of its protective effect on lipids. There are, however, seasonal effects, probably linked to sexual maturity or food availability, that can at times lead to very rapid loss of αT and consequent rancidity even in a lean species such as sole (47). Our view that storage of muscle samples for 6 mon at –40°C would not

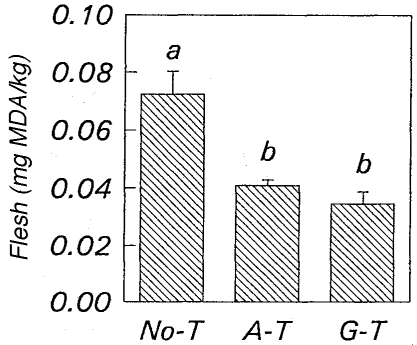

FIG. 5. Thiobarbituric acid-reactive substances in salmon fillets from the different dietary treatments expressed as mg malonaldehyde (MDA)/kg flesh. See Figure 1 for abbreviations.

lead to an excessive reduction in αT or γT may have been optimistic. A recent study of artificially fed caged Atlantic mackerel *Scomber scombrus* (48) mentioned a storage study of frozen salmon muscle (−30°C) that did show an increase in TBARS over 6 mon (details not available). Unfortunately the authors of this study on mackerel enriched in γT appear to have carried out the storage on homogenized muscle samples, thus maximizing exposure to oxygen in this notoriously oxidation-sensitive species (49). Our earlier frozen storage study (25) on smoked mackerel and salmon was carried out on intact muscle tissue, as was the procedure here. The composition of farmed salmon muscle differs in one important aspect from the muscle composition of our experimental fish. Farmed salmon muscle usually contains two pigments, astaxanthin and canthaxanthin (50). The former is the basis of the natural color of wild Atlantic salmon. Like carotene itself, such carotenoids can protect highly unsaturated fatty acids against oxidation, and carotene operates effectively in conjunction with αT (51).

The protective effects of dietary αT on maintaining the oxidative quality of fish flesh products have already been demonstrated for species such as rainbow trout and channel catfish (18,20). O'Keefe and Noble (18) reported reduced oxidative rancidity of frozen stored (−10°C) channel catfish fed 100 mg αT/kg diet or higher concentrations, and suggested that longer storage periods may require higher concentrations of dietary tocopherol (up to 400 mg/kg diet) to maintain acceptable fillet quality. The critical dietary αT levels which afford oxidative stability to the resultant fillets may relate to the quality of dietary lipids, since a diet containing a high n-3 polyunsaturated fatty acids content and a low tocopherol content resulted in rancid flavor development in Atlantic salmon fillets (19).

Most of the above-published results dealt with αT as the dietary ingredient. Except for Sigurgisladottir *et al.* (16,17) and Hamre and Lie (34), there appear to be no previous reports on the deposition of other tocopherols in salmon muscle, particularly of γT and its potential role in preserving the oxidative quality of fish-food products. This study confirms that dietary intakes of either αT or γT by Atlantic salmon were effective in maintaining the oxidative stability of the muscle tissue. Moreover, the low level of αT in the diet of the (G-T)-fed fish appeared to be adequate for the health of growing fish of this size. The no-T diet contained only half as much αT, derived from the marine animal products in the diet, and the fish fed this diet showed no adverse effects despite the inclusion of highly unsaturated fatty acids in the diet.

ABSTRACT: The production of B-ring and side-chain oxysterols was evaluated in meat from chickens fed diets differing by the kind of oil or fat added. The effect of supplementary levels of natural antioxidants, as α-tocopherol and β-carotene, on the meat cholesterol oxidative stability was also studied. Lard, sunflower and olive oil were used as dietary fat. Raw and cooked meats were analyzed for oxysterols, and cholesterol was also quantified. Oxysterol analyses were carried out by combining the use of solid-phase extraction, thin-layer chromatography, capillary gas chromatography, and capillary gas chromatography–mass spectrometry. Oxysterols were detected within the 0.1–0.5 μg/g range in raw meat. Cooking increased the oxysterol content of the meat, and levels as high as 5 μg/g muscle tissue were observed. B-Ring oxysterols were mainly produced: the α- and the β-epoxycholesterols, the 7α- and 7β-hydroxycholesterols, and the 7-ketocholesterol. The results showed that the meat from the chickens fed the olive oil-based diet containing α-tocopherol at 200 mg/kg of diet presented the best cholesterol oxidative stability. A positive effect could not be found for dietary β-carotene administered at levels of 15 and 50 mg/kg of diet. Furthermore, a significant decrease in the tissue cholesterol content was observed with the olive and the sunflower oil-based diets.

Lipids 33, 705–713 (1998).

Food oxidation affects the quality and the safety of the human diet by generating compounds having biological activities that could adversely affect health (1–3). Unsaturated lipids are particularly susceptible to oxidation, and the mechanism has been thoroughly studied and well documented in the literature (4). Lipid oxidation is responsible for quality deterioration of muscle foods and results in the formation of lipid hydroperoxides which decompose into secondary products such as aldehydes, alcohols, ketones, and short-chain carboxylic acids (5–7). Cholesterol is also prone to oxidation, producing a wide variety of cholesterol oxides, termed oxysterols (8). Cholesterol oxidation may proceed by the same mechanisms described for lipid oxidation or can be initiated by free radicals generated during lipid oxidation (8).

Oxidized lipids and cholesterol oxides are implicated in the enhancement of atherosclerosis (9,10). Oxysterols are well absorbed from the diet and are transferred into cholesterol-rich lipoproteins such as very low density lipoproteins, low density lipoproteins (LDL), and chylomicrons (11,12). Oxysterols have been detected in LDL and in atheromatous plaque (13,14). They can modify cell membrane fluidity and permeability and inhibit cholesterol biosynthesis by suppressing hydroxy methyl glutaryl-CoA reductase activity. They also are cytotoxic, immunosuppressant and affect the production of prostacyclin by endothelial cells, cause apoptosis, and inhibit cellular cholesterol efflux (15–17). All these deleterious effects support the hypothesis that oxysterols are involved in atherosclerosis (9,15).

A variety of cholesterol oxides have been detected in cholesterol-rich foods, such as spray-dried egg powder, meat and meat products (18,19). Storage, cooking, and processing procedures increase the oxysterol level in foods as a result of increased cholesterol and lipid oxidation (18,19). One way to increase the oxidative stability of lipids and cholesterol in foods is to increase the amounts of natural antioxidants such as α-tocopherol (vitamin E) or β-carotene in the diet. Feeding diets supplemented with α-tocopherol to animals like chickens, cows, and pigs resulted in vitamin accumulation in the animal muscle (20,21) and better oxidative stability under prooxidative conditions such as storage and cooking (20,21). Meat from pigs and calves fed such diets had reduced cholesterol oxidation when stored or cooked (22,23).

Few reports about antioxidant effects of β-carotene-supplemented diets have been published. The results were not so convincing as those reported for α-tocopherol, and a lack of protective action of β-carotene has been reported (24). In the present work, broiler chickens were fed one of four diets supplemented with various amounts of α-tocopherol and β-carotene. Lard (rich in saturated fatty acids), sunflower oil (rich in 18:2n-6 and 18:3n-3), and olive oil (rich in 18:1n-9)

Abbreviations: cGC, capillary gas chromatography; α-epoxide, 5,6α-epoxy-5α-cholestan-3β-ol; β-epoxide, 5,6β-epoxy-5β-cholestan-3β-ol; 7α-hydroxycholesterol, cholest-5-ene-3β-7α-diol; 7β-hydroxycholesterol, cholest-5-ene-3β,7β-diol; 20α-hydroxycholesterol, cholest-5-en-3β,20-diol; 25-hydroxycholesterol, cholest-5-en-3β,25-diol; 7-ketocholesterol, 3β-hydroxycholest-5-en-7-one; LDL, low density lipoprotein; triol, 5α-cholestane-3β,5,6β-triol.

were used as dietary fat. The study was focused on cholesterol oxidation and levels in raw and cooked broiler meat and evaluated the extent to which these parameters were affected by the dietary natural antioxidants and the unsaturation of the dietary fat. Interest in this meat arises from the increasing production of poultry in the United States, Asia, and Europe (25). The results of this study relate directly to the quality and the safety of poultry meat.

MATERIALS AND METHODS

Animals. Four experiments were carried out. For each experiment, 280 eight-day-old female broiler chicks of the Ross strain were used. They were placed in 24 flat-deck cages of 1 square meter each. The chicks were raised according to routine practices in terms of light and temperature. Except for the first experiment, each experiment lasted 6 wk and consisted of three dietary treatments, differing by the fat type included in the basal diet and by the amount of antioxidant supplemented (Table 1). At the end of each experiment, the chickens were slaughtered and legs were separated, vacuum packed, and stored at −20ºC until needed for processing. Analyses were performed within 2 mon. Thighs were thawed and processed for cholesterol and oxysterol analyses. The composition of the basal diet was maize (50.56%), soybean meal (39.58%), fat (6.00%), calcium carbonate (1.00%), dicalcium phosphate (2.00%), salt (0.40%), DL-methionine (0.16%), vitamins and minerals (0.40%).

Meat cooking. Broiler thighs were cooked in polyethylene bags. Samples were placed in a water bath at 85ºC until the inside temperature reached 80ºC (50 min). Samples were immediately processed for cholesterol and cholesterol oxides analyses after cooking.

Cholesterol oxides determination. Raw and cooked meat from the four experiments were analyzed for the following cholesterol oxides: cholest-5-ene-3β,7α-diol (7α-hydroxycholesterol), cholest-5-ene-3β,7β-diol (7β-hydroxycholesterol), 3β-hydroxycholest-5-en-7-one (7-ketocholesterol), 5,6α-epoxy-5α-cholestan-3β-ol (α-epoxycholesterol), 5,6β-epoxy-5β-cholestan-3β-ol (β-epoxycholesterol), cholest-5-en-3β,20-diol (20α-hydroxycholesterol), 5α-cholestane-3β,5,6β-triol (triol), and cholest-5-en-3β,25-diol (25-hydroxycholesterol) using a method developed by García-Regueiro and Maraschiello (26). 19-Hydroxycholesterol (5-cholestene-3β-19-diol) (50 µg), used as the internal standard, and butylated hydroxytoluene (BHT) (0.002%) were added to 20 g of meat prior to extraction. Lipid extraction was carried out according to the procedure of Folch *et al*. (27). The total extract (~1 g) was successively passed through silica and Florisil® columns (Varian Associates, Palo Alto, CA) of 10 g. Thin-layer chromatography permitted further purification of cholesterol oxides and their separation from cholesterol. The detection, identification, and quantification of oxysterols as trimethylsilyl ether derivatives were performed by using capillary gas chromatography (cGC) in the solvent-venting mode with flame ionization detection as described earlier (26). A fused-silica open tubular capillary column (30 m × 0.25 mm i.d.) coated with 5% phenylmethylsilicone and with a film depth of 0.25 µm (J&W Scientific, Folsom, CA) was used. An initial column temperature of 220°C was programmed at a rate of 5°C/min to 310ºC, which was held for 25 min (26). Peaks were identified by using relative retention times (Table 2). Oxysterols detected by cGC were confirmed by using cGC–mass spectrometry in the single-ion monitoring mode (26). Table 2 lists the major abundant ions characterizing trimethylsilylether-oxysterol derivatives and the characteristic ions chosen for selected ion monitoring.

Check on the production of artifactual cholesterol oxides. To 20 g of meat sample was added 20 mg of cholesterol, which was nearly twice the cholesterol content initially present. This sample and another of 20 mg of cholesterol alone were subjected to the entire procedure, with 50 µg of 19-hydroxycholesterol being added as internal standard to both samples prior to extraction. This experiment was to determine artifactual oxysterol production during sample processing.

Cholesterol determination. Fat (50 mg) extracted from meat by the procedure of Folch *et al.* (27) was saponified for cholesterol determination as described earlier (28). The cGC procedure was modified; the column is described in the preceding paragraph. Helium was the carrier gas at a head pressure of 2.0 bar. The initial column temperature of 240ºC was programmed at a rate of 12.5ºC/min to 310ºC, which was held for 4 min. Solvent-venting injection was used (28). Cholesterol was determined in raw and cooked meat with 5α-cholestane as the internal standard.

Statistics. Within each dietary group and for each experi-

[a]Relative retention time (RRT) = (retention time of solute)/(retention time of 19-hydroxy cholesterol).
[b]Ions chosen for identity confirmation by mass spectrometry are bold and underlined.
[c]Capillary gas chromatographic retention time of 19-hydroxycholesterol was 18.09 ± 0.27 min (mean ± relative standard deviation), calculated from seven consecutive manual injections. Abbreviations: 7α-Hydroxycholesterol, cholest-5-ene-3β,7α-diol; 7β-hydroxycholesterol, cholest-5-ene-3β,7β-diol; β-epoxycholesterol, 5,6β-epoxy-5β-cholestan-3β-ol; α-epoxycholesterol, 5,6α-epoxy-5α-cholestan-3β-ol; 20α-hydroxycholesterol, cholest-5-en-3β,20-diol; triol, 5α-cholestane-3β,5,6β-triol; 25-hydroxycholesterol, cholest-5-en-3β,25-diol; 7-ketocholesterol, 3β-hydroxycholest-5-en-7-one.

ment, each determination was carried out on independent samples of raw and cooked meat. A least-squares analysis using the GLM (General Linear Models) from SAS (29) was carried out including the dietary treatment and the nature of the sample (raw or cooked) as fixed effects. Correlation analysis were performed with the CORR procedure from SAS (29).

RESULTS

The thigh samples from the four experiments were analyzed for B-ring (7α-hydroxycholesterol, 7β-hydroxycholesterol, α-epoxycholesterol, β-epoxycholesterol, cholestanetriol, 7-ketocholesterol) and side-chain cholesterol oxides (20α-hydroxycholesterol, 25-hydroxycholesterol) and cholesterol itself.

Cholesterol oxides in raw broiler meat. Tables 3 to 6 show the cholesterol oxide content in raw meat for the four experiments and their respective three dietary treatments (basal, basal plus α-tocopherol, basal plus β-carotene). Cholesterol oxides resulting from the B-ring oxidation of cholesterol were the main products, i.e., 7-hydroxyisomers, epoxyisomers and 7-ketocholesterol. Total oxysterol concentrations within the range of 0.1 μg/g muscle tissue were quantified. Cholesterol oxides were not detected in all samples, as shown in Table 7. Low concentrations (<0.1 μg/g) of 20α-hydroxycholesterol were detected in a limited number of raw-meat samples from the sunflower oil experiment. Triol and 25-hydroxycholesterol were not detected (Tables 3–7). There were no significant differences in total oxysterol concentrations in raw meat between each dietary treatment in spite of an obvious decrease shown by the dietary group supplemented with α-tocopherol within each experiment (Tables 3–6). The groups fed α-tocopherol also showed a decrease in the frequency of the oxysterol occurrence (Table 7). When the results obtained from all the control groups were compared, the muscle from the experiment with sunflower oil contained significantly higher amounts of oxysterols than the muscle from experiments with lard and sunflower oil (Table 8). This was also observed for the groups fed α-tocopherol. The groups supplemented with β-carotene had no significant differences between them (Table 8). In conclusion, total amounts of oxysterols reported were lower than 0.5 μg/g, and the ratio of total amount of oxysterol to cholesterol ranged from 0.003 to 0.10% (Table 8).

Cholesterol oxides in cooked broiler meat. When cooked and raw meats were analyzed and compared, a marked increase in the cholesterol oxides content was noted for each experiment and for each dietary treatment (Tables 3–6). The production of B-ring cholesterol oxides contributed to the overall oxysterol increase. This result is reflected in Table 9

[a]Broiler chickens were fed a diet containing lard. Basal: broilers only fed the basal diet. Basal + α-tocopherol: broilers fed the basal diet supplemented with 200 mg α-tocopherol/kg of diet. Basal + β-carotene: broilers fed the basal diet supplemented with 50 mg β-carotene/kg of diet. For each dietary treatment $n = 12$ for raw and $n = 8$ for cooked meat.
[b]See footnote *b* in Table 3 for statistical treatment and abbreviations. Different superscript roman letters (a,b) indicate significant differences ($P < 0.05$).

which presents the sum of the α- and β-epoxycholesterol, the sum of the 7α- and 7β-hydroxycholesterol, and the sum of the three C7-oxysterols for raw and cooked meat. Triol was detected in some cooked samples at mean values lower than 0.1 μg/g (Tables 3, 4, 6, and 7). Some cholesterol oxides were detected in all of the samples analyzed, particularly in the experiment with sunflower oil (Table 7). In some cases, the 20α-hydroxycholesterol and the 25-hydroxycholesterol were detected but only in a couple of samples from the groups fed the basal diet and those supplemented with β-carotene (Tables 4, 5, and 7). The experiment with sunflower oil generally yielded the highest values for total oxysterol content (4.62 for the basal group and 4.63 μg/g for the β-carotene-supplemented group; see Table 5). In the experiments with lard and sunflower oil, the dietary groups supplemented with α-tocopherol had significantly less cholesterol oxidation (Tables 4,5). The groups fed the basal diet and the groups supplemented with β-carotene did not differ significantly (Tables 3–6). No significant differences were detected between the dietary treatments with olive oil. In summary, cooked meat had an increased ratio of oxysterol to cholesterol when compared with raw meat. When the experiments were compared, the diet supplemented with sunflower oil yielded significantly higher total amounts of oxysterols than the three other experiments (Table 8). Dietary α-tocopherol reduced the total oxysterols and the ratio of total oxysterol to cholesterol (Table 8).

Oxidation ratios. In raw meat, the 7α-isomer was the predominant alcohol and the β-epoxide was the predominant epoxide (Tables 3–6). In cooked meat, the β-epoxide and the 7β-hydroxycholesterol were the predominant isomers as shown in Table 9. 7α-Hydroxycholesterol predominated only in a few cases (Table 9).

The production of artifactual oxysterols. As described earlier, our procedure permits the detection of oxysterol concentrations at the ng/g level (26). No oxysterol peaks were detected at the respective relative retention times when cholesterol-spiked samples were analyzed by cGC. The absence of artifactual oxysterols was confirmed by cGC–mass spectrometry in the single-ion monitoring mode, meaning that artifactual oxysterols, if present, could be generated at levels below the sensitivity range of the procedure and would minimally

contribute to the overestimation of results. Furthermore, the amounts of cholesterol oxides obtained in raw meat agreed with those reported by Zubillaga and Maerker (30). Artifact production was minimized by taking strict precautions such as using butylated hydroxytoluene (0.002%) during the extraction procedure, avoiding elevated temperatures (>40°C) during sample handling, and storing at low temperatures for very short periods. The Folch extracts were stored at –40°C for less than 48 h. After the solid-phase extraction step, the purified extract is unstable and more susceptible to oxidation due to the loss of BHT during the solid-phase extraction. The purified extract obtained after this extraction was stored overnight at –40°C.

Cholesterol in raw and cooked meat. The cholesterol levels in raw and cooked meat are listed in the Table 8. Within each experiment, cholesterol concentrations in raw meat did not significantly differ between dietary treatments. On the other hand, raw meat in the experiments with sunflower and olive oil gave a significantly reduced cholesterol content when compared with the experiment using lard (Table 8). Values ranging from 63.31 to 65.20 mg/100 g of muscle tissue and from 60.99 to 70.83 mg/100 g of muscle tissue were measured for the two experiments with lard. Cholesterol values from 55.00 to 57.48 mg/100 g of muscle tissue and from 49.10 to 51.10 mg/100 g of muscle tissue were measured for the experiments with sunflower and olive oils, respectively.

[a]Results (LS mean ± SE) are expressed in mg/100 g tissue for cholesterol and in µg/g for total oxysterols. Ox/chol, total oxysterols/cholesterol, expressed in percentages.
[b]For experimental parameters and abbreviations, see Tables 2–6. Different superscript roman letters (a,b,c) indicate significant differences between columns ($P < 0.05$).

These results showed that dietary unsaturated oils decreased tissue cholesterol levels. The increase in the cholesterol content of cooked meat could be explained by the loss of moisture (Table 8, lines 3 and 4; Ref. 18).

DISCUSSION

Oxidation can occur in the A and B cholesterol rings and also in the cholesterol side chain (8). In this study, B-ring cholesterol oxides, i.e., the 7α- and 7β-hydroxycholesterol, the 7-ketocholesterol, and the α- and the β-epoxide, were the main ones detected in raw and cooked meat. The presence of these oxysterols in raw meat at low concentrations and low frequency might result from mild lipid oxidation occurring during the period between slaughter and the vacuum packaging of thigh samples. Monahan *et al*. (22) also observed minimal cholesterol oxidation in raw pork stored at −20ºC. Lipid oxidation was reported not to be totally inhibited at −20ºC, and the storage of chicken thigh meat at −20ºC during 150 d minimally increased thiobarbituric acid values (22,31). The oxidation process principally affects the polyunsaturated fatty acids of the muscle membrane phospholipids (32). In raw meat, initiation can be caused by generation of hydroxyl radicals (·OH) or a myoglobin-derived radical (5,6,33). This latter compound is the major catalyst of lipid oxidation in raw chicken meat (31). Autoxidation of oxymyoglobin occurs at −20ºC (34). The generation of alkoxy and peroxy radicals from lipid hydroperoxides in the presence of ferrous and ferric ions can lead to the formation of 7α- and 7β-cholesterol hydroperoxides (35,36). The C7-oxysterols detected in raw meat could be the result of the thermal decomposition of cholesterol hydroperoxides in the gas chromatograph system (37). The predominance of 7α-hydroxycholesterol in raw meat is not consistent with radical-mediated cholesterol oxidation, suggesting another origin. The predominance of 7α-hydroxycholesterol over its β-isomer was reported earlier (8,38). Cooking increases lipid oxidation, which leads to the formation of characteristic flavors (7). This study showed that cooking increased the concentration of oxysterols by a factor of 10 compared with raw meat. B-Ring cholesterol oxides were produced in essentially all the samples (Table 7). An increase in cholesterol oxide production is likely the consequence of accelerated lipid oxidation (23). At high temperatures, the 7α- and the 7β-cholesterol hydroperoxides resulting from radical attack on cholesterol decompose into their respective alcohols and, by dehydration, yield the 7-ketocholesterol. Recently, Nielsen *et al.* (39) showed that 7-ketocholesterol can also be produced by free radical-induced dehydrogenation of the 7-alcohols. The 7α-cholesterol hydroperoxide epimerizes to the quasi-equatorial substituent at high temperatures (40). Epimerization of the 7α-hydroxycholesterol to the 7β–derivative is also possible (8). The predominance of the 7β-isomer observed in the majority of the cases (Table 9) accounts for radical-mediated cholesterol oxidation (8). Cholesterol epoxidation was marked by β-stereoselectivity (Table 9). The increased epoxidation could be ex-

plained by exposing cholesterol to increasing amounts of H_2O_2 and lipid hydroperoxides, as evidenced by α/β epoxide ratios ranging from 1:3 to 1:10 and favoring the β-isomer (Table 9 and Refs. 35,41,42). β-Epoxycholesterol is more labile than its α isomer, and that could account for some reduced ratios at high temperature and acidic pH (Table 8) (42,43). Sevanian and McLeod (35) suggested that the attack on cholesterol by peroxyl radical, originated from the polyunsaturated fatty acids of phospholipids, involves preferentially the β-face (35). Moreover, the cholesterol hydroperoxides are cholesterol-epoxidizing agents (44). The hydration of both epoxides gives the triol which was detected in only a few samples in this study (8).

Diet influences the composition of the muscle membrane fatty acids (20). Lin *et al.* (20) reported that neutral lipids are more affected than polar ones and that the ratio of unsaturated to saturated membrane fatty acids increased with dietary fat unsaturation. Cholesterol oxidation increases with the unsaturation of liposomal membrane fatty acids (35). Different dietary fat unsaturation had no effect on cholesterol oxidative stability in raw meat (Table 8). On the other hand, in cooked meat the highest production of oxysterols in the sunflower oil-based diet is probably caused by an higher proportion of polyunsaturated fatty acids in the muscle membrane. The lower unsaturation of lard and olive oil could account for less cholesterol oxidation observed in meat from those groups (Table 8). Lin *et al.* (20) reported that meat from broiler chickens fed olive oil had a better oxidative stability during refrigerated and frozen storage. This was related to the accumulation in muscle tissue of oleic acid, which is less susceptible to oxidation.

Although differences in the effects of natural antioxidants were not significant in raw meat, the groups supplemented with α-tocopherol showed reduced amounts of cholesterol oxides in cooked meat, suggesting a protective effect (Table 8 and Refs. 20,21). Supplemental α-tocopherol increased the lipid oxidative stability and, as a consequence, reduced the production of oxysterols during cooking. In the sunflower oil-based diet, in spite of the beneficial action of the α-tocopherol, the production of cholesterol oxides remained high during cooking and was comparable to the levels detected for the control groups on the lard- and olive oil-based diets (Table 8). The high unsaturation level of the sunflower oil diet reduced the antioxidative action of the α-tocopherol administered at 200 mg/kg of diet. Besides a low extent of unsaturation, olive oil also contains polyphenols that are potent antioxidants (45). The possible presence of these molecules in muscle tissues could have contributed to the better cholesterol oxidative stability observed for the three dietary groups fed the olive oil (Tables 6 and 8).

In raw meat, the groups supplemented with β-carotene showed similar and sometimes higher oxysterols values when compared with their respective control group, indicating no protective action against cholesterol oxidation or possibly a prooxidant effect (Tables 3–6). Increasing the levels of supplemental β-carotene also did not influence the total oxysterol levels in cooked meat (Table 8). King *et al.* (24) also observed the lack of effect of supplemental β-carotene and found that it was not as well absorbed as α-tocopherol and acted as a prooxidant at 25 mg/kg of diet, as indicated by thiobarbituric acid-reactive substance values in nonheated meat, but not in heated meat. No studies on the effects of dietary β-carotene on cholesterol oxidation have been reported in the literature. Another finding from this study is that the unsaturation grade of the diet significantly decreases the cholesterol levels in the muscle tissues, the lowest levels being achieved with the olive oil-based diet (Table 8). The administration of α-tocopherol and β-carotene did not influence the cholesterol levels within each dietary group.

In conclusion, the present study demonstrated that cooking increased the content of B-ring oxysterols in broiler meat to concentrations as high as 5 μg/g. Cholesterol oxidation was greatly influenced by dietary fat unsaturation. A decrease in the cholesterol content of muscle tissue was also observed when the broilers were fed diets containing unsaturated fats. The dietary administration of α-tocopherol at 200 mg/kg of

diet increased the cholesterol oxidative stability, whereas β-carotene at 15 and 50 mg/kg of diet did not manifest any protective effect. Oxysterols have been shown to be absorbed from the diet and accumulate in LDL and could contribute to the atherogenic properties of oxidized LDL (9–11,46). In the United States, studies have estimated a mean intake of 20 g of poultry meat per day and a consumption of 216 g of cooked red meat per day for heavy meat consumers (47,48). The present work shows that a meat less likely to generate oxysterols during cooking was obtained by the combined use of dietary olive oil and α-tocopherol in poultry feed. Decreased dietary ingestion of oxysterols may reduce their accumulation in human LDL and limit their possible pathological action on the arterial wall (49).

ACKNOWLEDGMENTS

This work was carried out within the framework of the European concerted action DIET-OX (AIR project No. PL 921577): Dietary Treatment and Oxidative Stability of Muscles and Meat Products. Nutritive Value, Sensory Quality and Safety. C. Maraschiello was holder of an EC AIR grant (AIR1-CT-94-5025). We are grateful to Drs. Pere Gou and Luis Guerrero for their advice on the statistical analysis.

ABSTRACT: The antioxidant effects of α- and γ-tocopherols were evaluated in a model system based on the autooxidation of purified sunflower oil (p-SFO) triacylglycerols at 55°C for 7 d. Both tocopherols were found to cause more than 90% reduction in peroxide value when present at concentrations >20 ppm. α-Tocopherol was a better antioxidant than γ-tocopherol at concentrations ≤40 ppm but a worse antioxidant at concentrations >200 ppm. Neither α- nor γ-tocopherol showed a prooxidant effect at concentrations as high as 2000 ppm. The amount of tocopherols consumed during the course of oxidation was positively correlated to the initial concentration of tocopherols, and the correlation was stronger for α- than for γ-tocopherol. This correlation suggested that, besides reactions with peroxyl radicals, destruction of tocopherols may be attributed to unknown side reactions. Addition of $FeSO_4$, as a prooxidant, caused a 12% increase in the peroxide value of p-SFO in the absence of tocopherols. When tocopherols were added together with $FeSO_4$, some increase in peroxide value was observed for samples containing 200, 600 or 1000 ppm of α- but not γ-tocopherol. The addition of $FeSO_4$, however, caused an increase in the amount of α- and γ-tocopherols destroyed and led to stronger positive correlations between the amount of tocopherols destroyed during oxidation and initial concentration of tocopherols. No synergistic or antagonistic interaction was observed when α- and γ-tocopherols were added together to autooxidizing p-SFO.
Lipids 33, 715–722 (1998).

Lipid oxidation is one of the most detrimental quality parameters for lipids rich in polyunsaturated fatty acids (PUFA). Vegetable oils have different susceptibilities to oxidative degradation due to differences in fatty acid composition and in their contents of known and unknown antioxidant/prooxidant components. α- and γ-Tocopherols are the major natural antioxidants in most vegetable oils acting, *via* numerous biochemical and biophysical mechanisms, as efficient scavengers of active oxygen species and free radicals (1). Although it is well accepted that tocopherols act as antioxidants mainly by inhibiting free radical propagation *via* donation of phenolic hydrogens to peroxyl radicals, the absolute and relative antioxidant potency of the different tocopherols varies depending on temperature, composition of lipids, concentration of tocols used, and experimental setup (1–3).

The chemical structures of α-tocopherol (5,7,8-trimethyl tocol) and γ-tocopherol (7,8-dimethyl tocol) support a hydrogen-donating power in the order α > γ (1,4), but a reversed order (γ > α) of antioxidant activity was obtained when the two tocopherols were compared in various lipid systems (2,5–11). The relatively low potency of α-tocopherol, compared to γ-tocopherol, was attributed to possible participation of its tocopheroxyl radical in a number of propagative reactions (reviewed in Ref. 1). We tested the effects of α- and γ-tocopherols (at concentrations of 0–2000 ppm) on the development of peroxides in purified sunflower oil (SFO) and rapeseed oil (RSO) (containing no tocopherols, no iron or copper, and no pigments) after incubation at 55°C for 1–7 d, but neither tocopherol showed any prooxidant effect even at the very high concentrations used (12). These experiments suggested that α-tocopherol is not a prooxidant *per se* but may act as a prooxidant synergist (or co-prooxidant) when present at high concentrations together with known prooxidants such as transition metal ions, lipid peroxides, or other oxidizing agents.

In this paper, we report results from an investigation on the antioxidant activities of α- and γ-tocopherols against peroxidation of purified sunflower oil (p-SFO) triacylglycerols. p-SFO, free from anti- and prooxidant species that would influence the results of tocopherol action, was used because it is a rich source of the highly oxidizing linoleic (*cis*-9, *cis*-12-octadecadienoic) acid and was prepared by alumina column chromatography of commercial SFO. The effects of 1–2000 ppm of α- and γ-tocopherols on the stability of p-SFO were investigated using peroxide value (PV) measurements. Selected α- and γ-tocopherol concentrations (200, 600, and 1000 ppm) were used to study the effects of inclusion of ferrous sulfate on the antioxidant performance of the two tocols. Differences in antioxidant potency between individually added α- and γ-tocopherols and their mixtures were also investigated.

Abbreviations: BHT, butylated hydroxytoluene; HOSO, high-oleic sunflower oil; HPLC, high-performance liquid chromatography; HPSEC, high-performance size exclusive chromatography; PF, protection factor; p-HOSO, purified high-oleic sunflower oil; p-RSO, purified rapeseed oil; p-SFO, purified sunflower oil; PUFA, polyunsaturated fatty acids; PV, peroxide value; RSO, rapeseed oil; SFO, sunflower oil; TO•, tocopheroxyl radical.

MATERIALS AND METHODS

Materials and reagents. A commercial sample of SFO was used for the study of effects of tocopherols. A sample of high-oleic sunflower oil (HOSO), obtained as a gift from Dr. Maha Misbah (Unilever Research, Vlaardingen, The Netherlands), and a commercial sample of RSO were used, together with SFO, for an intercomparison study on the effects of oil purification on its stability. The fatty acid composition, calculated iodine values, and α- and γ-tocopherol levels of these oils are described in Table 1. Alumina used for column chromatography (neutral Al_2O_3, 70–120 mesh, Art. 1077) and tocopherol standards (isomer kit, Art. 15496) were purchased from Merck (Darmstadt, Germany). According to the manufacturer, the tocopherols were from the *d*-form (RRR) and were 95% pure [by high-performance liquid chromatography (HPLC)]. Sea sand and ferrous sulfate heptahydrate ($FeSO_4 \cdot 7H_2O$) were from Sigma Chemical Co. (St. Louis, MO). All other solvents and chemicals, of reagent grade or better quality, were obtained from local suppliers and were used without further purification.

Oil purification. SFO, HOSO, and RSO were purified from antioxidants and from trace metals and other prooxidants *via* adsorption chromatography to yield p-SFO, purified HOSO (p-HOSO), and purified RSO (p-RSO) triacylglycerol fractions. A glass column (40 × 2.5 cm i.d.), plugged with glass wool, was packed with 250 g of alumina (activated at 100°C for 8 h and then at 200°C for 12 h) suspended in *n*-hexane, capped with sea sand, and conditioned by prewashing with 200 mL of *n*-hexane. The oil (100 mL) was dissolved in an equal volume of hexane and passed through the column, which was then washed with 200 mL of *n*-hexane. The chromatographic column was wrapped with aluminium foil to prevent light-induced oxidations during the purification process, and triacylglycerols were collected in an aluminum foil-wrapped flask. Analysis of the purified oils by thin-layer chromatography (Merck precoated silica gel 60 thin-layer chromatographic plates, 0.25 mm layer thickness and chloroform/diethyl ether; 90:10, vol/vol) showed that they are composed mainly of triacylglycerols together with minor amounts of sterol esters (results not shown). The purified oils were found to contain undetectable amounts of tocopherols (HPLC, <0.5 ppm), peroxides (FeSCN colorimetric, <0.6 mequiv O_2/kg oil) and iron and copper (atomic absorption spectroscopy, <0.01 and <0.001 ppm, respectively). The method is especially easy and fast (1 h) and gives a good recovery (*ca.* 80%) of triacylglycerols that are practically free of all minor components except for sterol esters.

TABLE 1
Fatty Acid Composition, Calculated Iodine Values, and Tocopherol Levels of the Oils Used in This Study

	Sunflower oil (SFO)	Rapeseed oil (RSO)	High-oleic sunflower oil (HOSO)
Fatty acids (relative wt%)[a]			
Palmitic (16:0)	6.4	5.2	4.0
Stearic (18:0)	4.1	2.0	2.3
Oleic (18:1)	25.2	60.8	81.5
Linoleic (18:2)	62.7	22.4	10.1
Linolenic (18:3)	0.1	6.9	0.1
Others[b]	1.5	2.7	2.0
Calculated iodine value[c]	130.5	109.1	87.8
Tocopherol levels (ppm)[d]			
α-Tocopherol	526	224	445
γ-Tocopherol	7	341	20

[a]Fatty acids were analyzed as methyl ester derivatives by gas chromatography: column, NB-351 (25 m × 0.32 mm i.d., 0.2 mm film, Nordion Ltd., Helsinki, Finland), column temperature: 160°C (2 min), 4°C/min, 240°C (5 min); injector temperature: 240°C; and flame ionization detector temperature: 260°C.
[b]Other minor fatty acids include: 14:0, 16:1, 20:0, 20:1, 22:0, 22:1, 24:0, and 24:1.
[c]Iodine values were calculated according to the following AOCS (13) formula: iodine value = % 18:1 × 0.860 + % 18:2 × 1.732 + % 18:3 × 2.616.
[d]Tocopherols were analyzed by high-performance liquid chromatography as explained in the Materials and Methods section.

Autooxidation experiments and stability measurements. Different oxidation experiments were performed. First the stabilities of samples of SFO, HOSO, RSO and their purified triacylglycerol fractions (p-SFO, p-HOSO and p-RSO, respectively) were compared. Thereafter, p-SFO was chosen for the following experiments: (i) studies of antioxidant effects of α- and γ-tocopherols at 1, 2, 4, 7, 20, 40, 70, 100, 200, 400, 700, 1000, 1500, and 2000 ppm levels, (ii) the effects of inclusion of 50 ppm of ferrous ion on the antioxidant performance of α- and γ-tocopherols used at 200, 600, and 1000 ppm levels, and (iii) the differences in the antioxidant effect between individual tocopherols and of mixtures thereof. Ferrous sulfate was added to the purified oils as solution in ethanol, and ethanol was later removed by evaporation under vacuum. Tocopherols were added to the oil-containing vials (*vide infra*) as solutions in hexane, and hexane was evaporated under a stream of nitrogen.

Portions of oil samples (*ca.* 1 g) were oxidized in 6-mL borosilicate glass vials (40 × 22 mm; Chromacol Ltd., London, United Kingdom) at 55°C in a thermostated oven in the dark. Vials were taken from the oven and cooled in a dessicator before samples were taken for analysis. Experiments were performed twice, and each sample was incubated and analyzed in duplicate. The stability of the oxidized samples was evaluated by measuring PV by a modified ferric thiocyanate method (14). The protection factor (PF) was calculated for different α- and γ-tocopherol concentrations as follows:

$$PF = (PV_{control} - PV_{sample})/PV_{control} \quad [1]$$

Analysis of residual tocopherols. The amount of residual α- and γ-tocopherols in thermooxidized oils was quantified by HPLC analysis on a Hibar pre-packed LiChrosorb NH_2 column (25 cm × 4 mm i.d., particle size 5 mm; Merck). The mobile phase was *n*-heptane/methyl *tert*-butyl ether/tetrahydrofuran/methanol (79:20:1:0.1, by vol) at a flow rate of 1.0 mL/min. The system consisted of an HPLC pump (Pharmacia

LKB Biotechnology, Uppsala, Sweden), a 10-μL injection loop, and a Merck F-1050 fluorescence spectrophotometer. The peaks were detected at an excitation wavelength of 295 nm and an emission wavelength of 320 nm. Peaks were recorded and integrated using the JCL 6000 chromatography data system (Jones Chromatography, Mid-Glamorgan, United Kingdom) and the amounts of α- and γ-tocopherols were quantified against references used as external standards.

Analysis of the polymerized materials. To study the effects of α- and γ-tocopherols on polymerization of the oils after removal from the oven, the vials were allowed to stay in a dark cupboard for 4 wk. Then dimers and polymers were analyzed by high-performance size exclusion chromatography (HPSEC) essentially as described by Hopia *et al.* (15). Specifically, portions of the oxidized oils were dissolved in tetrahydrofuran to a concentration of *ca.* 20 mg/mL and analyzed in an HPSEC system consisting of an HPLC pump (Pharmacia LKB Biotechnology), a Rheodyne injector fitted with a 20-μL sample loop (Cotati, CA), and a Waters refractive index detector (Waters Associates, Milford, MA) thermostated to 35°C. The separation was performed on two (100- and 50-Å) columns (PLGEL 30 × 0.8 cm i.d.; Polymers Laboratories Inc., Amherst, MA) connected in series. The mobile phase was HPLC-grade tetrahydrofuran (Merck) stabilized with 0.025% butylated hydroxytoluene (BHT) and was used at a flow rate of 0.8 mL/min. Peaks were recorded and integrated using the JCL 6000 chromatography data system, and quantitation of each lipid class was based on peak areas assuming equal detector response.

Statistical analysis. Differences between different treatments were evaluated statistically by an analysis of variance procedure, the general linear model supported by the statistical analysis system (16). Statements in the text referred to as significant apply to a 5% significance level.

RESULTS AND DISCUSSION

The model system. To understand certain mechanistic parts of the lipid oxidation process, one should use simple predictive model systems. Under specified conditions, these models should be able to provide the user with a reasonable prediction of a specific problem. Important factors to be considered and perhaps controlled include: (i) relative levels and chemical nature of substrates, anti- and prooxidants, synergists and physicochemical modifiers (17), (ii) temperature, which acts directly by affecting rates of different reactions or indirectly by affecting relative solubility of various reactants, and (iii) oxygen tension as determined by surface-to-volume ratio and by solubility, which is influenced by temperature and viscosity of the reaction mixture.

Purified triacylglycerols are the most valid models to study oxidation of vegetable oils (18). Purified triacylglycerol fractions must be prepared from vegetable oils to provide the natural complexity of fatty acid distribution and to the eliminate anti- and prooxidant species normally present in the oils. Apart from having a similar fatty acid composition, purified triacylglycerols also exhibit a viscosity approximately similar to that of their oils of origin. The other important factors to be considered in autooxidation models are the reaction temperature and the dimensions of the reaction vessel. A temperature of 55°C was used to minimize thermal decomposition of hydroperoxides (19). The borosilicate glass vials used as reaction vessels enabled fair oxidation of control oils and were easy to use owing to their small size and their disposable nature.

Before the start of the actual experiments, the oxidative stabilities of p-SFO, p-RSO and p-HOSO triacylglycerols were compared to those of their unpurified precursors. Results on PV measurements after incubation of the six oils at 55°C for 7 d (Fig. 1) indicated that both the fatty acid composition (Table 1) and the nonglyceride components are important for oil stability. The importance of the degree of fatty acid unsaturation in the stability of these oils is obvious when comparing p-SFO, p-RSO, and p-HOSO triacylglycerols. The great difference in stability between the nonpurified oils and their purified fractions emphasizes the importance of nontriacylglycerol constituents as natural oxidation inhibitors in vegetable oils. Tocopherols are generally accepted as the major natural antioxidants in plant oils although other phenolic compounds, which may be more potent as antioxidants, are present in some oils, e.g., olive (20) and sesame (21).

p-SFO was chosen as a model substrate for this study for two main reasons: (i) SFO is one of the important sources of dietary linoleic acid, and results to be gained on its stabilization may find some nutritional applications; and (ii) owing to its higher iodine value (Table 1), p-SFO is much more susceptible to oxidation than p-RSO and p-HOSO (Fig. 1) and may therefore serve as a potential illustrative substrate for studies on structure–activity relationships among tocopherols.

Effects of α- and γ-tocopherols on peroxidation of p-SFO. Figure 2 shows a plot of the PF against the concentration (1–2000 ppm) of α- and γ-tocopherols in p-SFO. Results indicate that both α- and γ-tocopherols acted as very efficient antioxidants and almost completely inhibited the peroxida-

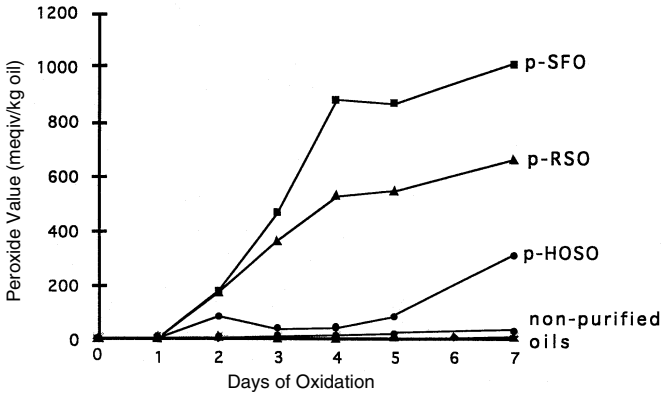

FIG. 1. The oxidative stability of purified (p-SFO, p-RSO, and p-HOSO) and nonpurified (SFO, RSO, and HOSO) sunflower, rapeseed and high-oleic sunflower oils, respectively. (For details on purification, see the Materials and Methods section.)

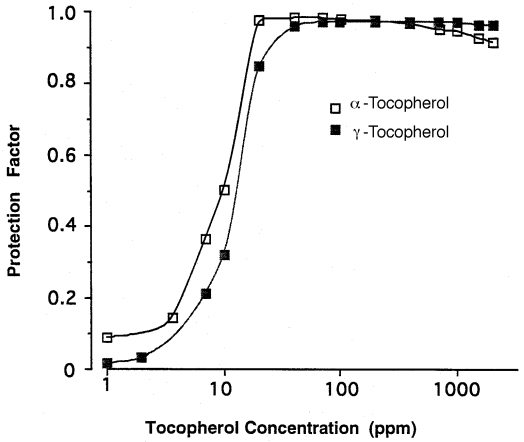

FIG. 2. Effects of adding α- and γ-tocopherols on the stability of p-SFO. Oil samples containing 1–2000 ppm of α- or γ-tocopherol were incubated in the dark at 55°C for 7 d. Peroxide values were measured, and a protection factor was calculated as explained in the Materials and Methods section. α-Tocopherol is significantly more effective than γ-tocopherol in the concentration range 1–20 ppm, and γ-tocopherol is significantly more effective than α-tocopherol in the concentration range 1000-–2000 ppm ($P < 0.05$). For abbreviation see Figure 1.

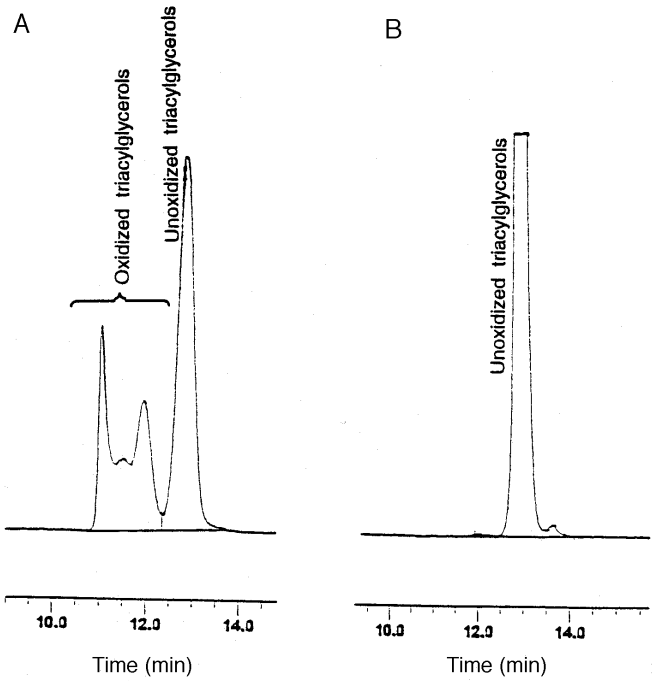

FIG. 3. Typical parts of high-performance size exclusion chromatograms showing formation of polymers, dimers, and oligomers in (A) control samples of p-SFO and (B) samples of p-SFO containing 500, 1000, or 2000 ppm of either α- or γ-tocopherols, upon incubation at 55°C for 7 d and then at room temperature for 4 wk. For abbreviation see Figure 1.

tion of p-SFO during the 7 d of oxidation when present at concentrations above 20 ppm (PF ≈ 1.00). These results are in accordance with previous findings that concentrations as low as 11 ppm of γ-tocopherol in p-RSO were enough to cause a marked inhibition of peroxide and secondary product formation (18). Further details on the differences between α- and γ-tocopherols can be summerized as follows: (i) α-tocopherol was significantly more effective than γ-tocopherol at low concentrations (1–20 ppm), (ii) both tocopherols were equally effective within the concentration range 40–200 ppm, and (iii) γ-tocopherol was sightly more effective than α-tocopherol at concentrations greater than 200 ppm and the difference became significant at concentrations higher than 1000 ppm.

The most interesting finding from this experiment is, however, the absence of any prooxidant effect for either α- or γ-tocopherols even at the very high concentrations used. Several investigators demonstrated that tocopherols (particularly α-tocopherol) act as prooxidants when present in high concentrations in autooxidizing lipids (e.g., 9, 22–24). Huang *et al.* (22), using stripped corn oil as substrate, and Terao and Matsushita (23), using methyl linoleate as substrate, described the prooxidant effect they observed for high concentrations of α-tocopherol as an "initial" prooxidant effect that was not observed at later stages of oxidation. To check if a prooxidant effect becomes evident after a longer period of oxidation, samples containing 500, 1000, and 2000 ppm tocopherols were stored in a dark cupboard for 4 wk after the 7 d of incubation in the oven. Analysis of dimers and polymers by HPSEC showed no signs of polymerization in samples containing either α- or γ-tocopherols, although the controls contained *ca.* 55% total dimers and polymers (Fig. 3). In conclusion, both α- and γ-tocopherols were very efficient inhibitors of PUFA peroxidation in the dark at 55°C for 7 d and afterward at room temperature for 4 wk, even when present at very high concentrations. That this conclusion is in contradiction with previous reports (9,22–24) may be attributed to differences in experimental conditions, interpretation of results, and possibly the absence of a standardized definition of a prooxidant.

Antioxidant effects of α- and γ-tocopherols in absence and presence of ferrous ions. The role of transition metal ions (such as as iron, copper, cobalt, nickel, manganese, etc.) in catalyzing peroxidation reactions in fats and oils is well documented (25–27) despite lack of precise knowledge of the mechanism(s) involved. In this experiment, PV of p-SFO controls containing 50 ppm of ferrous were *ca.* 12% higher than those of controls without this salt (PV ≈ 1200 mequiv/kg oil).

Figure 4A shows the PV of samples of p-SFO containing 200, 600, and 1000 ppm of α- and γ-tocopherols upon oxidation for 7 d in the presence or absence of 50 ppm of ferrous ions. γ-Tocopherol was slightly less effective as an antioxidant than α-tocopherol at 200 ppm but was significantly more effective at higher concentrations, in agreement with results from the previous experiment (Fig. 2). In addition, PV for samples containing α-tocopherol were significantly higher, in the order 200 < 600 < 1000 ppm, whereas differences in PV between samples containing 200, 600, or 1000 ppm of γ-tocopherol were minor. The presence of iron caused a significant enhancement of the perooxidation of p-SFO containing 600 or 1000 ppm of α-tocopherol and a very minor increase in the PV of p-SFO containing γ-tocopherol. The presence of ferrous sulfate significantly enhanced the rates of losses of both tocopherols (Fig. 4B), and the losses were much greater

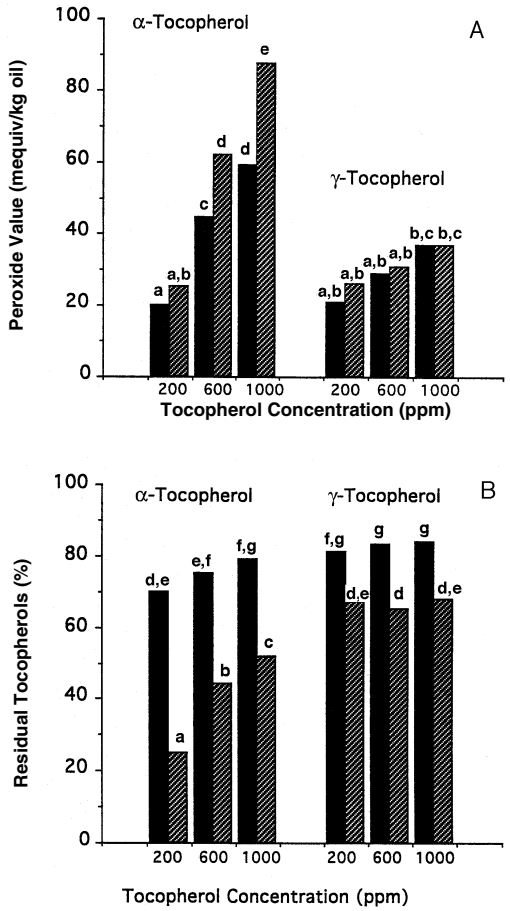

FIG. 4. Effects of concentration of added α- or γ-tocopherols (200, 600, or 1000 ppm) on (A) the peroxidation of p-SFO and (B) the consumption of tocopherols in the absence (solid bar) and presence (hatched bar) of of 50 ppm of ferrous ions as $FeSO_4 \cdot 7H_2O$. Bars marked by different letters (a–g) are significantly different ($P < 0.05$).

for α- than for γ-tocopherol. Data presented in Figure 5 clearly demonstrate that the amounts of tocopherols consumed have high positive correlations with the initial concentrations of tocopherols added. The correlations for both α- and γ-tocopherols were much higher in the presence of ferrous ($y = 29.86 + 0.470\ x$, $R^2 = 0.981$; and $y = 2.22 + 0.326\ x$, $R^2 = 0.998$ for α- and γ-tocopherols, respectively) than in its absence ($y = 11.61 + 0.211\ x$, $R^2 = 0.981$; and $y = 6.85 + 0.157\ x$, $R^2 = 0.991$ for α- and γ-tocopherols, respectively). Despite these iron-induced differences in peroxide formation and tocopherol consumption, both α- and γ-tocopherols were still very efficient antioxidants even when present at 1000 ppm in the presence of 50 ppm of ferrous ions.

The difference in antioxidant activity between α- and γ-tocopherols can be explained by considering the theory of "Antioxidant Strength and Efficiency" as explained and used by Marinova and Yanishlieva (28). The finding that α-tocopherol was consumed more quickly than γ-tocopherol (Fig. 4B) is in agreement with difference in redox potentials (+0.273, and +0.348 V, respectively, Ref. 29) which implies that α-tocopherol is a stronger hydrogen-donor and is more vulnerable to oxidation than γ-tocopherol. Hence, α-tocopherol can participate easily in side reactions (reactions other than those with peroxyl radicals) which might have negative effects on the lipid peroxidation rate at certain time points. Participation of α-tocopherol in side reactions makes it a less efficient antioxidant than its γ-homolog. The high positive correlations between the initial amount of tocopherols in the oxidized oils and the rates of tocopherol consumption (Fig. 5) support the assumption that tocopherols are consumed not only in antioxidation reactions but also in first-order side reactions, the rates of which are much greater for α- than for γ-tocopherols. Data showing a decrease in the effectiveness of α-tocopherol with

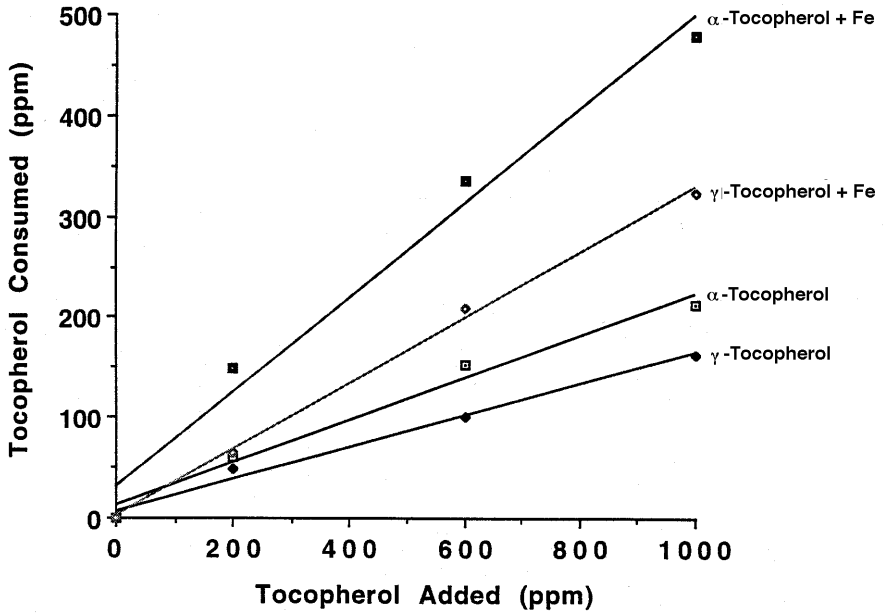

FIG. 5. Correlation between the concentration of added α- or γ-tocopherols (200, 600, or 1000 ppm) and the amount of tocopherols consumed in the absence and presence of ferrous sulfate heptahydrate.

increasing concentrations due to side reactions were also obtained and discussed by Yanishlieva and Marinova (30).

An evaluation of the importance of side reactions for α- and γ-tocopherol antioxidant activity can be achieved by considering the lipid oxidation reactions in samples containing or lacking these antioxidants (see Scheme 1, a theoretical representation of major oxidation pathways in systems composed of PUFA and tocopherols). When high tocopherol concentrations are still available, reactions given by Equations 2 and 9 will dominate over those given by Equations 3 and 5, resulting in inhibition of PUFA oxidation. The slight decrease in antioxidant efficiency observed for high α-tocopherol concentrations (1000–2000 ppm) is not yet explainable. It was suggested (see literature review in Ref. 1) that this effect is due to reactions 7 and 8 of tocopheroxyl radicals (TO·) with unperoxidized lipids and their hydroperoxides, respectively. Studies on the kinetics of the abstraction of hydrogen by the TO· from fatty acids or from lipid hydroperoxides showed that these reactions have significantly very low rates (in the order of some 10^{-1} $M^{-1}s^{-1}$) compared to reaction of α-tocopherol with peroxyl radicals (in the order of some 10^5–10^6 $M^{-1}s^{-1}$) and TO· coupling reactions (Eq. 13 of Scheme 1) (see literature review in Ref. 1). The availability of residual tocopherols at these points of oxidation provides further evidence that the previously mentioned mechanism cannot explain the decrease in antioxidant activity at high concentrations of α-tocopherol. This interpretation implies that a net prooxidant effect on the oxidation of PUFA will not be observed until all the tocopherol is consumed (Eqs. 8 and 10 of Scheme 1). The high positive correlation between tocopherol consumption and initial tocopherol concentration (Fig. 5) may be attributed to self-oxidation and formation of some prooxidant species by reaction with oxygen (10). It has been reported by Doba *et al.* (31) that oxygen reacts very slowly with TO·, and they suggested that oxygen has no effect of α-TO· decay. However, the relevance of the reaction of α-TO· radical with oxygen in our model cannot be evaluated and requires further investigations.

The relative importance of different tocopherol-consuming reactions seem to be affected markedly by their structure and concentration, degree of fatty acid unsaturation, availability of oxygen and its diffusion kinetics, temperature and presence of other antioxidants or prooxidants (e.g., metal salts). Although the presence of $FeSO_4$ did not cause the tocopherols to show any prooxidant effect in our model system, its inclusion enhanced the rate of peroxidation in samples containing higher concentrations of α-tocopherol and led to a very rapid consumption of both α- and γ-tocopherols. Many reviews (32–36) were published on the prooxidant effects of iron and other transition metal traces on PUFA peroxidation, but interactions between metals and tocopherols are not yet precisely understood. According to these reviews, low-valency-state metals are more effective prooxidants owing to either or both of following mechanisms: (i) they can generate, *via* formation of metal-oxygen transition complexes, active oxygen species (e.g., $O_2{\cdot}^-$ and $HO_2{\cdot}$):

$$O_2 + M^{n+} \rightarrow [M^{(n+1)+} \text{----} O_2) \rightarrow O_2{\cdot}^- + M^{(n+1)+} \quad [15]$$

(ii) they can generate radicals *via* degradation of hydroperoxides by Fenton and Fenton-like reactions:

$$AOOH + M^{n+} \rightarrow AO{\cdot} + OH^- + M^{(n+1)+} \quad [16]$$

$$LOOH + M^{n+} \rightarrow LO{\cdot} + OH^- + M^{(n+1)+} \quad [17]$$

It was previously suggested that free radical species generated by these reactions can destroy the tocopherols:

$$M^{n+1} + O_2{\cdot}^- + TOH \rightarrow TO{\cdot} + HO_2{\cdot} + M^{n+} \quad [18]$$

Moreover, tocopherols and TO· are able to reduce metal ions to lower state valences which will recycle reactions 15–17 (37–39):

$$TOH + M^{(n+1)+} \rightarrow TO{\cdot} + H^+ + Mn^{n+} \quad [19]$$

$$TO{\cdot} + M^{(n+1)+} \rightarrow TO^+ + Mn^{n+} \quad [20]$$

Reactions 19 and 20 may be responsible, at least in part, for the enhanced tocopherol destruction observed in this study. A comparison of the prooxidant effects of $FeSO_4$ and hemoglobin showed that organic forms of iron may be more active than inorganic forms as prooxidants (40). The prooxidant effects of trace metal ions are determined by their electronic configuration, valency state, and type of associated ligands (27). Thus, the form in which trace metal ions occur in vegetable oils and the mechanism by which they propagate oils' oxidation in the presence and absence of tocopherols and other minor constituents are important areas for further research.

Mixed vs. individual addition of α- and γ-tocopherols. Because vegetable oils contain a mixture of natural α- and γ-to-

Initiation	TOH + initiator → TO·	[2]

SCHEME 1

copherols, one of the aims of this study was to investigate whether α- and γ-tocopherols will synergize or antagonize each other's effect when present in mixtures. The effects of mixing α- and γ-tocopherols on the stability of p-SFO were tested in a Latin-square design using combinations of 100, 300, and 500 ppm levels of each tocopherol (Table 2). Similar to the results obtained in the previous experiments, addition of α- and γ-tocopherols in mixtures to p-SFO triacylglycerols significantly inhibited their rate of peroxidation (PV = 16.4–57.4 mequiv O_2/kg oil, Table 2) compared to the controls (PV = 1004 mequiv O_2/kg oil). Figure 6A compares the protective effects of mixtures containing 100, 300, or 500 ppm concentrations of each tocol with those containing 200, 600, or 1000 ppm levels of either tocol alone. The mixture containing 100 ppm of α-tocopherol together with 100 ppm of γ-tocopherol was also more effective than 200 ppm of either α- or γ-tocopherol alone. The stability of mixtures containing 300 or 500 ppm of each tocol was intermediate between those containing γ-tocopherol alone or α-tocopherol alone at 600 or 1000 ppm levels, respectively. These results (Fig. 6A) also show that the mixture containing 100 ppm of α-tocopherol and 100 ppm of γ-tocopherol had the highest antioxidant activity among all other mixtures, and that higher concentrations of the mixed tocopherols are less effective in inhibiting peroxide formation than mixtures containing lower concentrations of mixed tocopherols. This finding suggests possible synergism between α- and γ-tocopherols when they are present at relatively low concentrations. Buttner (41) showed quite elegantly that antioxidants with large differences in redox potentials (e.g., α-tocopherol and ascorbate) show a pecking order, or hierarchy, for free radical reactions. Omura (42) showed that the BHT and butylated hydroxyanisole pair act synergistically because BHT can regenerate butylated hydroxyanisole from its radicals. Determination of residual tocopherols (Fig. 6B) showed that, although α-tocopherol was consumed more quickly than γ-tocopherol, γ-tocopherol co-oxidized with its α-homolog and that complete consumption of α-tocopherol was not a prerequiste for the oxidation of γ-tocopherol. Percentage losses of α-tocopherol were slightly higher in mixtures than in samples containing this tocol alone, and an opposite trend was observed for γ-tocopherol (Fig. 6B). This effect was, however, not enough to qualify α-tocopherol to act as a strong regenerator of its γ-homolog. Obviously, the hierarchy in the case of α- and γ-tocopherols is not significant to allow the type of synergism that was observed for BHT and BHA.

TABLE 2
Effect of Mixing Tocopherols on Peroxide Value[a] of p-SFO After 7 d of Oxidation

γ-Tocopherol concentration (ppm)	α-Tocopherol concentration (ppm)		
	100	300	500
100	16.4	30.4	38.1
300	28.1	35.4	51.1
500	28.2	46.8	57.4

[a]Expressed in milliequivalents O_2/kg oil. For abbreviation see Table 1.

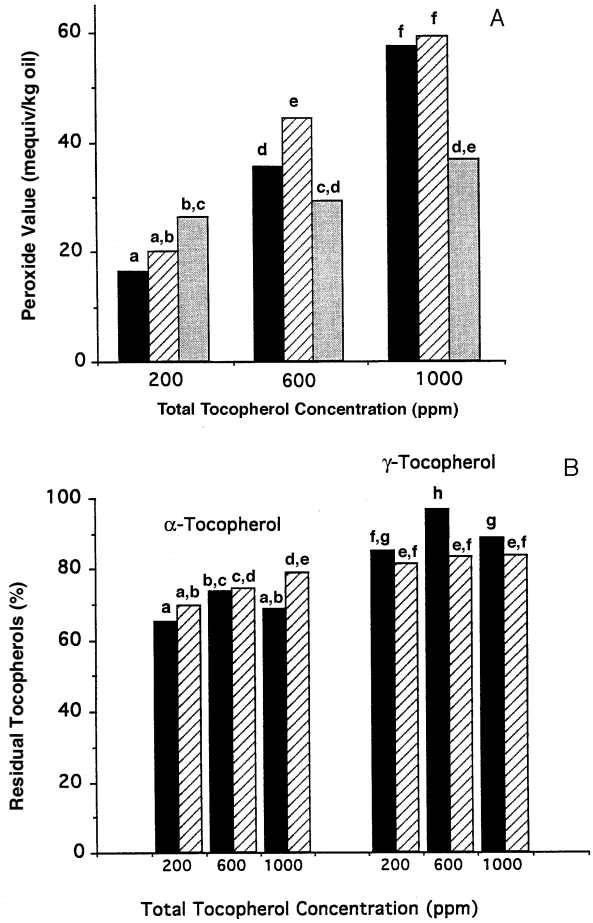

FIG. 6. Comparison between the effects of (A) mixed (solid bar) vs. individually added α-tocopherol (hatched bar) or γ-tocopherols (shaded bar) on peroxidation of p-SFO triacylglycerols; (B) mixed (solid bar) vs. individually added α- or γ-tocopherol (hatched bar) on residual tocopherols during the peroxidation of p-SFO. Bars marked by different letters (a–g) are significantly different ($P < 0.05$).

In conclusion the work conducted in this study revealed that γ-tocopherol is a more efficient antioxidant than α-tocopherol possibly because of the latter's ability to participate in reactions other than those with peroxyl radicals, especially in the presence of trace metal ions. It was further found that α- and γ-tocopherols may synergize each other when present in concentrations less than 200 ppm but not when present at higher concentrations. Interestingly, no prooxidant effect was observed for α-tocopherol at all concentrations tested (1–2000 ppm) and in the presence of ferrous ions. Work is in progress to study the differences between α- and γ-tocopherols in influencing the molecular nature of hydroperoxides and their degradation products using methyl linoleate model system.

ACKNOWLEDGMENTS

Maria Dolores Fuster thanks the Spanish Ministry of Education and Science (Madrid) for a 3-mon scholarship to conduct this research in Uppsala. From Unilever Research Laboratorium (Vlaardingen, The Netherlands), we thank Dr. Maha Misbah for a kind gift of HOSO

and Dr. C. W. van Oosten for suggesting alumina column chromatography for the preparation of purified natural triacylglycerols.

Tanacetum (*Chrysanthemum*) *corymbosum* Seed Oil—A Rich Source of a Novel Conjugated Acetylenic Acid

Nanzad Tsevegsuren[a], William W. Christie[b,*], and Dorothy Lösel[a]

[a]Department of Animal and Plant Sciences, University of Sheffield, Sheffield S10 2TN, United Kingdom, and [b]Scottish Crop Research Institute, Invergowrie, Dundee DD2 5DA, Scotland, United Kingdom

ABSTRACT: A new conjugated *trans,trans*-diunsaturated acetylenic acid (17%), found for the first time in nature as a main component of the seed oil of *Tanacetum (Chrysanthemum) corymbosum*, was shown to be octadeca-8*t*,10*t*-dien-12-ynoic acid. Another already known naturally occurring acetylenic acid, crepenynic acid (10%), was found also in the seed oil. The structure of this new unusual fatty acid was confirmed by chromatographic (thin-layer chromatography, gas chromatography, high-performance liquid chromatography) and spectroscopic (infrared, ultraviolet, mass spectrometry) methods by using different chemical derivatizations (deuteration, preparation of picolinyl ester, dimethyloxazoline, and maleic anhydride adduct).
Lipids 33, 723–727 (1998).

Seed oils of a large number of species of Asteraceae have been studied previously and found to contain a range of unusual fatty acids, e.g., Δ3 *trans* (1), Δ5 *cis* (2), Δ6 *cis* (3), conjugated (4,5), acetylenic (6,7), epoxy (8,9) and hydroxy (10) acids, and these have been reviewed elsewhere (11–14). *Tanacetum (Chrysanthemum)*, a genus of the Asteraceae, is less studied with respect to the fatty acid composition of the seed oils. Useful representatives of the genus *Chrysanthemum* are known. *Chrysanthemum parthenium* (feverfew) is an ornamental medicinal herb, believed to be antiseptic and used as an antidote, aperient, carminative, sedative, and vermifuge for hysteria and parturition. *Chrysanthemum cinerarifolium* (pyrethrum or Dalmatian insect flower) is cultivated for the dried inflorescences, which are used in the manufacture of insecticides and parasiticides (15). *Chrysanthemum coronarium* (16) has been reported to contain epoxy (vernolic and coronaric) acids as seed oil components.

In continuation of our exploration of the potential of less common oil seeds, fatty acids from seeds of *Tanacetum corymbosum*, an ornamental plant growing in Germany, were investigated by means of chromatographic and spectroscopic methods. Two unusual fatty acids were identified.

EXPERIMENTAL PROCEDURES

Seeds. Seeds of *T. (Chrysanthemum) corymbosum* were a generous gift of the Botanic Gardens (University of Münster, Münster, Germany).

Extraction of seed oil. The ground seeds were extracted at room temperature by grinding with a mortar and pestle in petroleum ether (boiling range, 40–60°C) containing 0.001% butylated hydroxytoluene (BHT).

Preparation of fatty acid methyl esters (FAME). Mixed FAME were prepared by transesterification of the seed oil with 2.0 M sodium methoxide in methanol (17).

Deuteration. Methyl esters of unsaturated fatty acids were subjected to deuteration with deuterium gas and Wilkinson's catalyst (18,19). The methyl ester (up to 2 mg) and Wilkinson's catalyst (5 mg) in dioxane (1 mL) were degassed with helium in a tube fitted with a Teflon-lined septum. The vessel was purged with 5 vol of deuterium with constant stirring and then was left with an atmosphere of deuterium at 60°C for 2 h. The solvent was removed in a stream of nitrogen, and the deuterated ester was obtained by adsorption chromatography on a small column of Florisil™ (0.5 g; Sigma Chemical Co., Poole, United Kingdom), eluted with hexane/acetone (96:4, vol/vol). It was converted to the picolinyl ester for analysis by gas chromatography–mass spectrometry (GC–MS).

Preparation of picolinyl esters. The free acids (1 mg), prepared by hydrolysis with 0.1 M ethanolic potassium hydroxide, were converted to the acid chlorides by reaction with oxalyl chloride (0.5 mL) at ambient temperature overnight. Excess reagent was removed in a stream of nitrogen, and the product reacted immediately with a solution (0.5 mL) of 3-hydroxymethylpyridine in dichloromethane [20 mg/mL; stored over beads of molecular sieve—type 4A (Fisher Scientific, Loughborough, United Kingdom)]. After 1 h at ambient temperature, the solvent was evaporated, the product taken up in isohexane (5 mL), and washed with water (2 × 2 mL). The hexane solution was dried over anhydrous sodium sulfate; then the solvent was evaporated. The product was dis-

Abbreviations: BHT, butylated hydroxytoluene; DMOX, 4,4-*N,N*-dimethyloxazoline; ECL, equivalent chain length; FAME, fatty acid methyl ester; FTIR, Fourier transform infrared spectroscopy; GC–MS, gas chromatography–mass spectrometry; GLC, gas–liquid chromatography; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography; UV, ultraviolet spectroscopy.

solved in isohexane containing BHT (50 ppm) for analysis by GC–MS.

Preparation of dimethyloxazoline (DMOX) derivatives. DMOX derivatives were prepared by heating the free acid with 2-amino-2-methyl-1-propanol at 180°C for 2 h (20).

Preparation of maleic anhydride adduct. The mixed FAME (14 mg) of *T. corymbosum* were added to maleic anhydride (20 mg) in toluene and refluxed under nitrogen for 2 h. The solvent was removed by vacuum evaporation, and the residue was dissolved in *n*-hexane, washed with distilled water, and dried with anhydrous sodium sulfate (21).

Thin-layer chromatography (TLC). To obtain additional information on unusual components in oils, analytical TLC of oils and of FAME was carried out on a 0.25-mm layer of Silica gel G (Merck, Darmstadt, Germany), using a solvent system of *n*-hexane/diethyl ether [70:30, vol/vol (oil) or 80:20, vol/vol (FAME)]. Spots were visualized by spraying with phosphomolybdic acid (5% in ethanol) and heating at 100°C.

Capillary gas–liquid chromatography (GLC). Capillary GLC analysis of FAME was carried out using a Perkin-Elmer 8310 Gas Chromatograph equipped with a flame-ionization detector and a 30 m × 0.25 mm DB 23 capillary column (J&W Scientific, Folsom, CA) under the following conditions. The oven temperature was programmed to increase from 160 to 230°C at 2°C/min, and held at this point for 5 min before cooling down again to 160°C. The split/splitless injector temperature was 250°C, and the flame-ionization detector temperature was 270°C. Hydrogen was the carrier gas at a flow rate of 1.0 mL/min (head pressure 180 kPa H_2). Split injection was used with a split ratio of 50:1. Components were quantified by electronic integration. Identification of FAME was confirmed by comparison of equivalent chain lengths (ECL) with those of standards or of FAME from previously known seed oils.

GC–MS. The derivatives were submitted to GC–MS with a Hewlett-Packard 5890 Series II plus gas chromatograph (Palo Alto, CA) attached to an HP model 5989 MS Engine. The latter was used in the electron impact mode at 70 eV with a source temperature of 250°C. The GC was fitted with on-column injection. For picolinyl ester and DMOX derivatives, a capillary column of fused silica coated with Supelcowax 10^{TM} (25 m × 0.25 mm, 0.25 μm film; Supelco UK, Poole, United Kingdom) was used. After holding the temperature at 80°C for 3 min, the oven temperature was increased by temperature-programming at 20°C/min to 180°C, then at 2°C/min to 280°C, where it was held for 15 min. Helium was the carrier gas at a constant flow rate of 1 mL/min, maintained by electronic pressure control.

High-performance liquid chromatography (HPLC). An HPLC instrument was used that consisted of a Philips (Cambridge, United Kingdom) PU 4100 Gradient Pumping System, Philips PU 4026 Refractive Index Detector, Rheodyne 7125 Injector, and Gilson 201 Fraction Collector. Preparative separations of FAME (100–200 μg in 10 μL) were carried out on two Shandon Hypersil C_{18} columns (250 × 4 mm, 5 micron particles; Phase Separations Ltd., Macclesfield, United Kingdom) connected in series at ambient temperature. Methanol/water (90:10, vol/vol) at a flow rate of 1.0 mL/min was used as the mobile phase (22).

Ultraviolet (UV) absorption spectroscopy. UV spectra were determined from solutions of the seed oil in *n*-hexane, using a Philips UNICAM PU 8720 UV/VIS Scanning Spectrophotometer, with a focusing attachment, to confirm the presence of any conjugated fatty acids.

Fourier transform infrared spectroscopy (FTIR). FTIR spectra were determined from oil films on sodium chloride cells using a Perkin-Elmer PARAGON 1000 FTIR spectrometer (Beaconsfield, United Kingdom) with a focusing attachment to check the presence of any unusual (*trans* unsaturated or oxygenated) fatty acids.

RESULTS AND DISCUSSION

Extraction of the seeds of *T. corymbosum* with petroleum ether yielded 16.7% oil. TLC of the seed oil and of the mixed FAME did not reveal any oxygenated fatty acids. The fatty acid composition of the seed oil and the chromatographic sep-

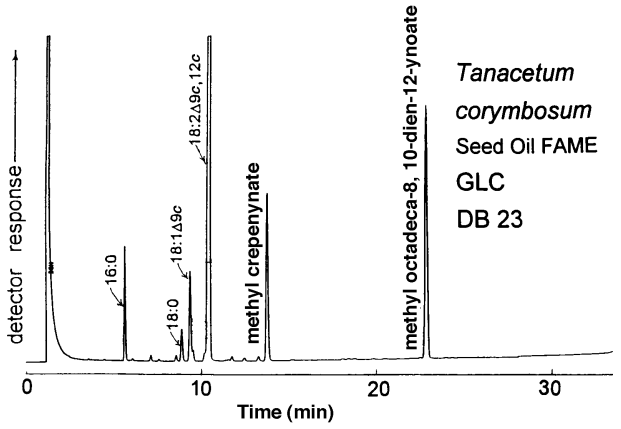

FIG. 1. Gas–liquid chromatogram (GLC) of total fatty acids of *Tanacetum corymbosum* seed oil separated on a DB 23 column (J&W Scientific, Folsom, CA) as their methyl esters.

aration characteristics on a DB 23 capillary column are presented in Table 1.

As can be seen from Table 1, GLC analysis of the methyl esters of mixed fatty acids of *T. corymbosum* seed oil revealed two unusual components along with more common fatty acids. The first unusual component (10.1%) had an ECL value of 20.20 on the DB 23 column. The second fatty ester (17.8%) had an ECL of 23.63. GLC separation of the FAME of *T. corymbosum* seed oil is illustrated in Figure 1. Tentative identification of the proposed methyl crepenynate in *T. corymbosum* seed oil was based on the appearance of a single peak, following coinjection into GLC with *Crepis sibirica* seed oil FAME, known to contain crepenynic acid, and this was subsequently confirmed by GC–MS.

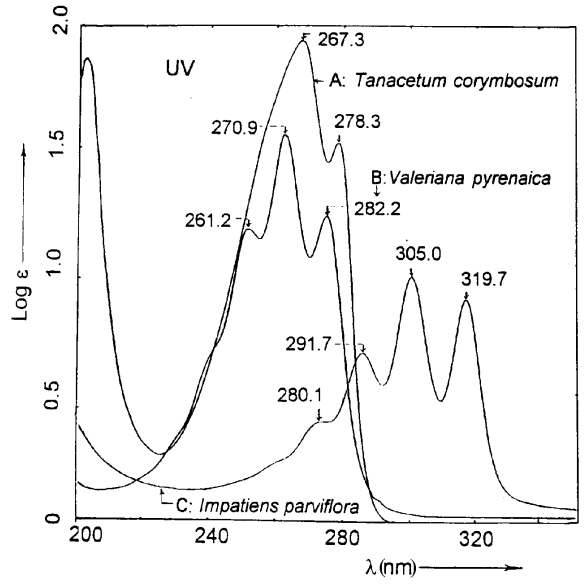

FIG. 2. Ultraviolet (UV) spectra of the seed oils. A: *T. corymbosum* (λ_{max} = 267.3; 278.3 nm), B: *Valeriana pyrenaica* (λ_{max} = 261.2; 270.9; 282.2 nm) and C: *Impatiens parviflora* (λ_{max} = 280.1; 291.7; 305.0; 319.7 nm). See Figure 1 for other abbreviation.

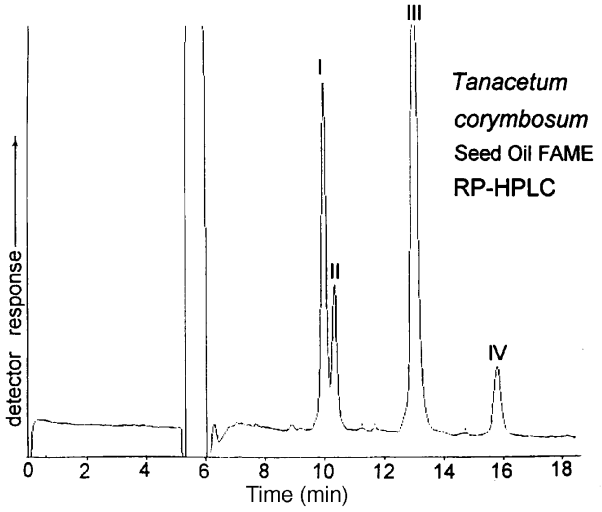

FIG. 3. Separation of the mixed fatty acid methyl esters of *T. corymbosum* seed oil by reversed-phase high-performance liquid chromatography (RP-HPLC) on two columns of Shandon Hypersil C_{18} (Phase Separations Ltd., Macclesfield, United Kingdom) connected in series. I–IV, Fractions I–IV.

The FTIR spectrum of the *T. corymbosum* seed oil exhibited characteristically strong *trans* absorption at 983.3 cm^{-1}, which is indicative of a conjugated *trans* double-bond group (23,24). The UV spectrum of the oil showed two maxima at 267.3 and 278.3 nm which were also characteristic of a conjugated *trans,trans* diunsaturated acetylenic acid (5,25,26), in comparison with those of *Valeriana pyrenaica* and *Impatiens parviflora* seed oils known to contain α-eleostearic and α-parinaric acids, respectively (Fig. 2).

The presence of the conjugated *trans,trans* unsaturation in the unknown ester was further indicated by the fact that the GLC peak of this compound only decreased strongly (more than 50%) after reaction of the mixed FAME of *T. corymbosum* seed oil with maleic anhydride, indicating that the unknown fatty acid had formed a maleic anhydride adduct by the Diels-Alder reaction. The UV spectrum of the compound after reaction with maleic anhydride was changed markedly, giving two new strong maxima at 241.1 and 248.1 nm.

Preparative separation of mixed methyl esters by reversed-phase HPLC gave four fractions (Fig. 3), and the composition of each was determined by GLC on a DB 23 column. The unknown ester was enriched in Fraction I with a content of 91% (Table 2). Fraction II consisted mainly of methyl crepenynate (66.1%) in addition to the unknown ester (25.9%). Fraction III contained only methyl linoleate. The main constituents of Fraction IV were methyl oleate (77.3%) and *cis*-vaccenate (9.6%). The unknown ester from Fraction I was deuterated for study by GC–MS.

The structures of the two unusual fatty acids were determined by MS of various derivatives. The mass spectrum of the methyl ester of the component believed to be crepenynate gave a molecular ion at *m/z* = 292 and several abundant fragments closely resembling those published for this fatty acid. The mass spectra of methyl esters did not provide a fragmen-

tation pattern suitable for characterization of structure because of the ionization of double and triple bonds, resulting in their migration (27). However, the picolinyl ester and DMOX derivatives of this fatty acid had spectra identical to that of authentic crepenynate with ions diagnostic for the positions of the double and triple bonds (28).

The second methyl ester gave a molecular ion at *m/z* = 290. The mass spectra of the picolinyl ester and DMOX derivatives of this acid are illustrated in Figure 4A and 4B. The former has the expected molecular ion at *m/z* = 367. There is a gap of 76 amu between *m/z* = 220 and 296, equivalent to C_6H_4, but this does not indicate precisely where each double and triple bond is located, other than between carbons 8 to 13. The mass spectrum of the DMOX derivative has the expected molecular ion at *m/z* = 329, and it is evident that the conjugated system lies somewhere between carbons 7 and 13, but the exact position cannot be fixed definitively. Indeed, it could be argued from the gap of 12 amu between *m/z* = 168 and 180 that the first double bond is in position 7. It seems possible that the high temperature required to prepare the DMOX derivative may have caused isomerization.

As none of the derivatives of the unknown gave mass spectra which were interpretable unequivocally in terms of the positions of the double and triple bonds, the methyl ester was subjected to deuteration with Wilkinson's catalyst and converted to the picolinyl ester for analysis by MS. The spectrum is illustrated in Figure 4C. The molecular ion is at *m/z* = 383 as expected. A series follows of ions 14 amu apart, representing cleavage at successive methylene groups to *m/z* = 312. The next ion is at *m/z* = 296, a loss of 16 amu or CD_2, and there is a similar gap to *m/z* = 280. The next series of ions at *m/z* = 265, 250, 235, and 220 are 15 amu apart, equivalent to a loss of CHD. The remaining ions are 14 amu apart. The ions 15 amu apart illustrate where single bonds were present in the original molecule, i.e., positions 8 and 10, while those 16 amu apart locate the triple bond, i.e., position 12.

Together with the spectroscopic evidence, the data confirmed that the unknown was octadeca-8*t*,10*t*-dien-12-ynoic acid, which has not been reported in nature. It seems plausible that crepenynic acid (octadeca-9*c*-en-12-ynoate), which was also identified in the oil, is an intermediate in the biosynthesis of the new acid, but little appears to be known of the biosynthesis of conjugated fatty acids.

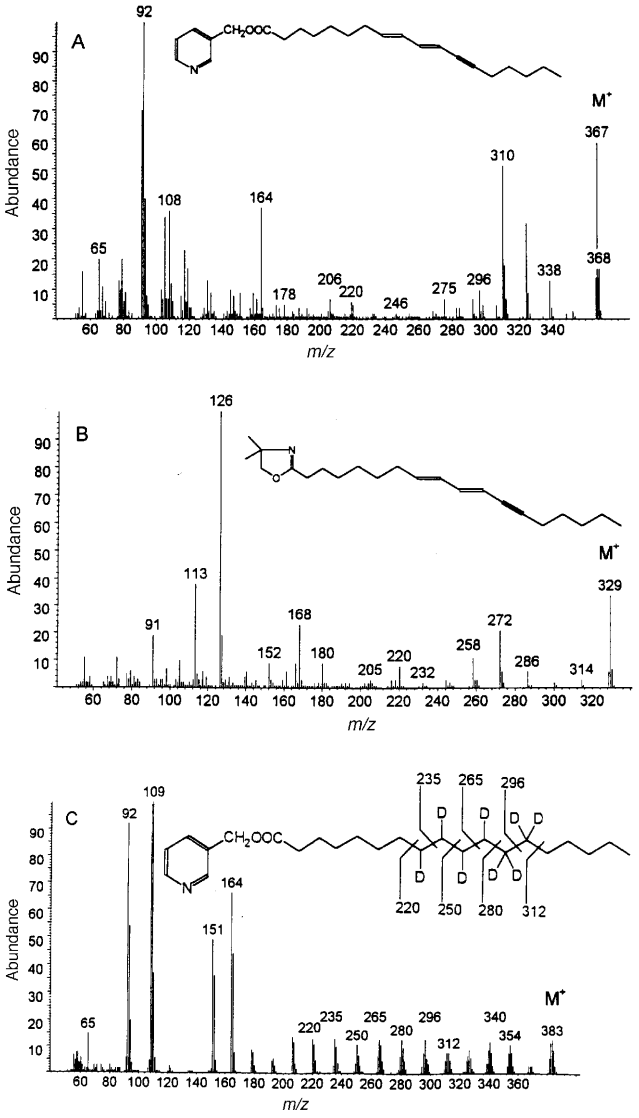

FIG. 4. The mass spectrum of different derivatives of octadeca-8,10-dien-12-ynoic acid of *T. corymbosum* seed oil. A: the picolinyl ester, B: the 4,4-*N,N*-dimethyloxazoline derivative, C: the picolinyl ester of deuterated octadeca-8,10-dien-12-ynoic acid. See Figure 1 for other abbreviation.

ACKNOWLEDGMENTS

N. Tsevegsuren thanks the Royal Society, London, for a research fellowship, during which this work was carried out. The authors are indebted to H. Vogt, H. Brockmann, and H. Voss from the Botanical Garden (University of Münster, Münster, Germany) for the gift of seed samples and to P.R. Keen and P. Dewsbury of Department of Animal and Plant Sciences (University of Sheffield, United Kingdom) for their assistance in GLC and HPLC separations. The authors wish to thank Prof. E. Haslam, R. Hansen, and W. Simon from De-

partment of Chemistry, University of Sheffield, for providing GC–MS (methyl esters), IR and UV spectra; Honorary Research Professor F.D. Gunstone and Dr. G. Dobson from Scottish Crop Research Institute (Invergowrie, Dundee, Scotland) for giving useful advice; and G.W. Robertson for providing the mass spectra. The Scottish Office Agriculture, Environment and Fisheries Department provided funding for WWC.

Fullerene Lipids: Synthesis of Dialkyl 1,2-[6,6]-Methano-[60]-fullerene Dicarboxylate Derivatives

Marcel S.F. Lie Ken Jie* and Sunny Wai-Hung Cheung

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: Reaction of C_{60} fullerene with dialkyl bromomalonate (where the alkyl groups consist of short-, medium-, and long-saturated chains or unsaturated long chains) in the presence of sodium hydride gives [6,6]-bridged mono-adducts of methanofullerene. The spectroscopic properties of such fullerenoid lipids are reported.

Lipids 33, 729–732 (1998).

The reactivity and chemical derivatization of fullerenes have drawn keen and continuous attention after discovery of a method for bulk production (1). A large range of functionalized fullerenes has been prepared for material and pharmaceutical applications (2–6). For instance, methanofullerene derivatives bearing the salts of carboxylic acids possess inhibitory activity against human immunodeficiency virus protease (7,8). The biological activity of water-soluble fullerenes has also been explored, with results showing structural dependence of DNA cleavage, cytotoxicity, and enzyme inhibitory activities including human immunodeficiency virus-protease inhibition (9). However, limited attention has been given to the functionalization of fullerene with groups containing long-chain ester functions. The synthesis of a C_{60} fullerene containing three fatty acids was described by Murakami *et al*. (10), who studied the multibilayer structure and the electronic properties of this compound. Bingel (11) reported the synthesis of diethyl methanofullerene dicarboxylate by Michael addition of a stabilized α-halocarbanion to fullerenes followed by intramolecular subsitution of the halogen.

In this paper we describe the synthesis of various dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate derivatives containing saturated and unsaturated alkyl groups (compounds **1**–**14**), which are novel lipid molecules with an extraordinary large nonpolar spherical carbon cage unit (the buckminsterfullerene system) and two ester functions with protruding alkyl chains of varying chain lengths (saturated and unsaturated) (Scheme 1). The synthesis of compound **7**, containing a C_{18} alkyl chain, was recently reported (12).

MATERIALS AND METHODS

Infrared (IR) spectra were recorded on a Bio-Rad (Richmond, CA) FTS-7 FT-IR spectrometer. Samples were run as mulls or neat films on KBr discs. Ultraviolet spectra were recorded on a Hewlett-Packard Diode Array Spectrophotometer, model 8452A (Hewlett-Packard, Palo Alto, CA). Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) with tetramethylsilane as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from tetramethylsilane ($\delta_{TMS} = 0$ ppm). Mass spectral analyses were carried out on Finnigan MAT-LCQ [atmospheric pressure chemical ionization (APCI)] (Finnigan Corp., San Jose, CA). Microanalyses were performed by Butterworth Laboratories Ltd. (Middlesex, United Kingdom).

Bromomalonic acid was prepared from malonic acid by the procedure described by Yankwich and Stivers (13). Diethyl bromomalonate was prepared from diethyl malonate as described elsewhere (14). *n*-Butanol, *n*-hexanol, *n*-octanol, *n*-nonanol, *n*-decanol, *n*-octadecanol, 10-undecen-1-ol, methyl

oleate, and linoleate were purchased from Aldrich Chemical Co. (Milwaukee, WI). Octadec-6-enoic acid and erucic acid [22:1(13*c*)] were isolated from carrot and rapeseed oil, respectively. Octadec-6-ynoic, octadec-9-ynoic, and docos-13-ynoic acids were prepared by bromination–dehydrobromination reaction of the corresponding olefinic esters as described elsewhere (15). The unsaturated and long-chain alcohols were prepared by lithium aluminum hydride reduction from the corresponding fatty acids or methyl esters. C_{60} fullerene was purchased from Lancaster Synthesis Ltd. (Eastgate, Lancashire LA3 3DY, United Kingdom) or from Materials and Electrochemical Research Corp. (Tucson, AZ).

General method for the preparation of dialkyl bromomalonate intermediates as exemplified by the synthesis of distearyl bromomalonate. A solution of dicyclohexylcarbodiimide (0.47 g, 2.3 mmol) in dichloromethane (10 mL) was added to a mixture of bromomalonic acid (0.2 g, 1.1 mmol), 1-octadecanol (0.53 g, 2.0 mmol), and dichloromethane (10 mL) over a period of 1 h at room temperature. The reaction mixture was stirred for 16 h and then filtered. The precipitate collected on the filter paper was washed with *n*-hexane (20 mL). The combined organic solution was evaporated under reduced pressure. The residue was chromatographed on a silica gel (30 g) column using a mixture of *n*-hexane/diethyl ether (95:5, vol/vol) to give distearyl bromomalonate (0.5 g, 59%).

*General method for the preparation of dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate derivatives as exemplified by the synthesis of distearyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (**7**).* A mixture of distearyl bromomalonate (0.28 g, 0.4 mmol), sodium hydride (0.98 g, 2.1 mmol), and toluene (10 mL) was stirred at room temperature for 10 min. A solution of C_{60} fullerene (150 mg, 0.21 mmol) in toluene (110 mL) was added, and the reaction mixture was stirred for 16 h at room temperature. The color of the reaction mixture changed from purple to wine red. Water (50 mL) was added and the reaction mixture was extracted with chloroform (2×30 mL). The combined organic extract was washed with water (30 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated under reduced pressure. The residue was stirred with diethyl ether (50 mL), and precipitate (unreacted C_{60} fullerene, 41 mg) was filtered. The filtrate was evaporated under reduced pressure and the residue was dissolved in toluene (3 mL). The toluene solution was loaded onto a silica gel (30 g) column in *n*-hexane. The column was eluted with a mixture of toluene/*n*-hexane 1:9 vol/vol (100 mL) to remove traces of C_{60} fullerene (purple band). The polar wine-red colored product was subsequently eluted with a mixture of diethyl ether/*n*-hexane (0.5:99.5, vol/vol) (500 mL) to give distearyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (104 mg, 69% yield based on reacted fullerene).

*Selected spectroscopic and mass spectral data of the synthesized compounds **1**, **2**, **7**, **11**, and **13**. (i) Diethyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (**1**)*: λ_{max} (CH_2Cl_2) 252, 318 nm; IR (mull, cm^{-1}): 2983, 2929, 2855, 1748, 1463, 1442, 1429, 1296, 1265, 1238, 1096, 528; ^1H NMR ($CDCl_3$, δ_H, J/Hz) 1.49 (*t*, *J* = 7.1, 6H, CH_3), 4.57 (*q*, *J* = 7.1, 4H); ^{13}C NMR ($CDCl_3$, δ_C) 14.25 (CH_3), 53.43 (methano bridge), 63.42 ($COOCH_2$), 71.60 (C_{60}-sp^3 C), 139.04, 140.95, 141.92, 142.22, 142.99, 143.02, 143.08, 143.89, 144.62, 144.69, 144.89, 145.19, 145.26, 145.24 (C_{60}-sp^2 C), 163.61 (C=O); mass spectral analysis (APCI): *m/z* 879.1 (M^+); microanalysis: found C, 90.76, H, 1.42 ($C_{67}H_{10}O_4$, calcd. *(ii) Dibutyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (**2**)*: λ_{max} (CH_2Cl_2) 254, 286, 326 nm; IR (mull, cm^{-1}): 2962, 2929, 2868, 1745, 1462, 1429, 1266, 1233, 1206, 1186, 1177, 1063, 755, 527; ^1H NMR ($CDCl_3$, δ_H, J/Hz) 1.01 (*t, J* = 7.5, 6H, CH_3), 1.48–1.58 (*m*, 4H, CH_2), 1.79–1.88 (*m*, 4H, CH_2), 4.50 (*t, J* = 6.6, 4H, $COOCH_2$-); ^{13}C NMR ($CDCl_3$, δ_C) 13.69 (CH_3), 19.16 (CH_2CH_3), 30.54 ($CH_2CH_2CH_3$), 52.36 (methano bridge), 67.19 ($COOCH_2$), 71.65 (C_{60}-sp^3 C), 139.01, 140.95, 141.91, 142.21, 142.89, 143.01, 143.08, 143.88, 144.61, 144.68, 144.88, 145.18, 145.26, 145.35 (C_{60}-sp^2 C), 163.71 (C=O); mass spectral analysis (APCI): *m/z* 935.1 (M^+); microanalysis: found C, 91.22, H, 1.93 ($C_{71}H_{18}O_4$, calcd. C, 90.17, H, 2.14).

*(iii) Distearyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (**7**)*: λ_{max} (CH_2Cl_2) 254, 288, 326 nm; IR (neat, cm^{-1}): 2969, 2922, 2851, 1746, 1463, 1428, 1266, 1233, 1205, 755, 526; ^1H NMR ($CDCl_3$, δ_H, J/Hz) 0.88 (*t, J* = 6.7, 6H, CH_3), 1.25-1.59 (*m*, 60H, CH_2), 1.84 (quintet, *J* = 7 Hz, 4H, $COOCH_2CH_2$), 4.49 (*t, J* = 6.5, 4H, $COOCH_2$); ^{13}C NMR ($CDCl_3$, δ_C) 14.15 (CH_3), 22.72, 26.03, 28.62, 29.27, 29.39, 29.65, 29.70, 29.75, 31.95 (CH_2), 52.47 (methano bridge), 67.50 ($COOCH_2$), 71.70 (C_{60}-sp^3 C), 139.00, 140.96, 141.93, 142.22, 143.00, 143.02, 143.09, 143.89, 144.61, 144.70, 144.89, 145.19, 145.27, 145.40 (C_{60}-sp^2 C), 163.73 (C=O); mass spectral analysis (APCI): *m/z* 1327.5 (M^+); microanalysis: found C, 86.91, H, 4.64 ($C_{99}H_{74}O_4$, calcd. C, 89.56, H, 5.62).

*(iv) Dilinoleyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (**11**)*: λ_{max} (CH_2Cl_2) 258, 280, 326 nm; IR (cm^{-1}): 3007, 2925, 2853, 1748, 1558, 1507, 1540, 1232, 1092, 754, 526; ^1H NMR ($CDCl_3$, δ_H, J/Hz) 0.89 (*t, J* = 6.8, 6H, CH_3), 1.29–1.37 (*m*, 64H, CH_2), 1.84 (quintet, *J* = 7 Hz, 4H, CH_2), 2.01–2.08 (*m*, 8H, CH_2), 2.77 (*t, J* = 6.0, 4H, CH_2), 4.49 (*t, J* = 6.6, 4H, $COOCH_2$), 5.34–5.37 (*m*, 8H, olefin); ^{13}C NMR ($CDCl_3$, δ_C) 14.11 (CH_3), 22.59, 25.66, 26.00, 27.23, 28.60, 29.23, 29.28, 29.36, 29.55, 29.70, 31.54 (CH_2), 52.44 (methano bridge), 67.45 ($COOCH_2$), 71.68 (C_{60}-sp^3 C), 127.90, 128.08, 130.02, 130.23 (CH=CH of linoleyl), 138.99, 140.94, 141.91, 142.20, 142.99, 143.01, 143.09, 143.88, 144.60, 144.65, 144.69, 144.88, 145.18, 145.26, 145.37 (C_{60}-sp^2 C), 163.69 (C=O); mass spectral analysis (APCI): *m/z* 1319.3 (M^+); microanalysis: found C, 90.40, H, 5.18 ($C_{99}H_{66}O_4$, calcd. C, 90.11, H, 5.04).

*(v) Di-9-octadecynyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate (**13**)*: λ_{max} (CH_2Cl_2) 254, 294, 324 nm; IR (cm^{-1}): 2953, 2927, 1746, 1463, 1428, 1266, 1233, 1205, 1186, 1114, 711, 526; ^1H NMR ($CDCl_3$, δ_H, J/Hz) 0.88 (*t, J* = 6.7, 6H, CH_3), 1.27–1.49 (*m*, 44H, CH_2), 1.84 (quintet, *J* = 7 Hz, 4H, CH_2), 2.13 (*t, J* = 7.9, 8H, C≡C-CH_2), 4.49 (*t, J* = 6.6, 4H,

$COOCH_2$); ^{13}C NMR ($CDCl_3$, δ_C) 14.15 (CH_3), 18.77, 18.79 ($C\equiv C\text{-}CH_2$), 22.68, 25.91, 28.59, 28.90, 29.00, 29.15, 29.19, 29.24, 31.86 (CH_2), 52.42 (methano bridge), 67.43 ($COOCH_2$), 71.66 (C_{60}-sp^3 C), 80.08, 80.37 (C≡C acetylene), 138.98, 140.94, 141.90, 142.20, 142.98, 143.00, 143.08, 143.87, 144.59, 144.64, 144.67, 144.87, 145.16, 145.25, 145.36 (C_{60}-sp^2 C), 163.67 (C=O), mass spectral analysis (APCI): *m/z* 1319.5 (M^+); microanalysis: found C, 88.87, H, 4.99 ($C_{99}H_{66}O_4$, calcd. C, 90.11, H, 5.04).

DISCUSSION

The cyclopropanation of C_{60} fullerene by reaction with bromomalonates in the presence of an auxiliary base is a reliable method of fullerene functionalization. This approach allows the exclusive formation of [6.6]-bridged adducts to be formed. By controlling the reaction time and the amount of bromomalonate, mono adducts can be obtained. However, it is also possible to form higher adducts (bis up to hexakis) with a stereochemically defined addition pattern using template activation with 9,10-dimethylanthracene (11,16–19).

In the synthesis of the dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate derivatives (compounds **1–14**), the procedure described by Bingel (11) was adopted with a slight modification. Instead of treating dialkyl malonates with bromine to form the dialkyl bromomalonates, it was essential to prepare bromomalonic acid first and then esterify the latter with saturated or unsaturated fatty alcohols to yield the corresponding dialkyl bromomalonates (61% average yield). This approach ensured that the alkyl chains containing unsaturated centers would not be brominated when unsaturated dialkyl malonates were used as substrates.

C_{60} fullerene was then treated with the respective dialkyl bromomalonates in the presence of sodium hydride at room temperature in toluene to give the requisite dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate derivatives (35–69% yield, based on reacted C_{60} fullerene). While our work was in progress, a recent publication described a similar reaction for the preparation of compounds **1** and **7** by the direct treatment of C_{60} fullerene with malonate in the presence of CBr_4 and diazabicyclo[5.4.0]undec-7-ene (12).

The diethyl (**1**), dibutyl (**2**), dihexyl (**3**), and dinonyl (**5**) 1,2-[6,6]-methano-[60]-fullerene dicarboxylates are dark-brown solids with very high melting points (>240, 210–211, 177–179, and 153–159°C, respectively). The dioctyl and the longer chain saturated and unsaturated dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylate analogs (compounds **4**, **6–14**) are viscous liquids which cannot be crystallized from organic solvents. C_{60} fullerene is very insoluble in common organic solvents such as acetone, diethyl ether and tetrahydrofuran, but the dialkyl 1,2-[6,6]-methano-[60]-fullerene dicarboxylates are readily soluble in diethyl ether and chlorinated solvents. Such a difference in the solubility between C_{60} fullerene and the functionalized fullerene molecule facilitated the isolation and purification of the requisite products from the reaction mixture. It was necessary to remove as much of the unreacted C_{60} fullerene as possible prior to purification of the requisite product by column chromatography. The mass spectral analysis (APCI technique) gave the exact molecular mass unit (M^+) for the various products. However, we were unable to recrystallize the products isolated by column chromatography before submission to microanalysis. Some of the results from the microanalysis were slightly off the mark, which reflected the possible presence of some impurities (unreacted C_{60} fullerene).

The ^1H and ^{13}C NMR spectral analyses of these compounds (**1–14**) were conducted in solutions of deuteriochloroform. The proton shift of the methylene group adjacent to the carboxylate function appeared in the region of δ_H 4.49–4.57. The shifts of the remaining protons of the alkyl chain were characteristic and comparable to those observed in the alkyl chain of fatty esters or fatty alcohols.

The ^{13}C NMR spectral analysis of the products showed 14–15 signals for the sp^2 carbon nuclei of the fullerene cage (region of δ_C 138–145). The signal at δ_C 71 (2 carbon equivalent, sp^3 carbons) was due to the shifts of the carbon atoms at the junction of the [6,6]-fused rings of the fullerene and to which the cyclopropane system is attached. The shift of the carbon of the methano bridge of the cyclopropane ring appeared at about δ_C 52 . The presence of the carboxylate groups was evident from the signals at δ_C 163. The shifts of the remaining carbon atoms (methylenic, olefinic, and acetylenic) were found in their respective chemical shift regions. From these results we are able to show that long- and short-chain, saturated and unsaturated dialkyl malonate derivatives of C_{60} fullerene can be successfully synthesized.

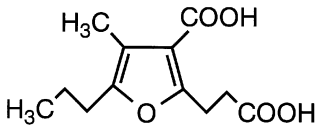
ABSTRACT: To obtain a specific antiserum for use in enzyme-linked immunosorbent assay (ELISA) of 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid (CMPF), we prepared a hapten-carrier conjugate in which the CMPF hapten was linked to a carrier protein through the 5-(1-hydrazopropyl) group. The antisera raised against this antigen in guinea pigs had excellent specificity for CMPF, showing little cross-reactivity with closely related compounds and no significant cross-reactivities with other furan compounds. The results indicated that a specific antiserum to CMPF could be produced by an antigen whose CMPF moiety is linked to a carrier protein through a position remote from the inherent functional groups. A standard curve of CMPF by ELISA using a chemiluminescence system showed a high sensitivity and a linearity in the range of 5–100 ng/mL.
Lipids 33, 733–736 (1998).

The furan fatty acids first shown in fish by Glass *et al.* (1,2) were later detected in extremely small quantities in a variety of animals (3,4), and, to a lesser extent, in plant sources (5) and marine bacteria (6). In human feeding experiments, the correlation of furan fatty acid intake with urofuranic acid excretion (7) suggested that the furan fatty acids might be degraded to urofuranic acids (4). Binding of many acidic drugs and hormones to serum albumin is decreased in patients with renal failure (8–11). A number of endogenous ligand substances in uremic serum inhibit the binding of drugs to serum proteins (12–16). In particular, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid (CMPF) (Scheme 1) in an endogenous, ligand is tightly bound to serum protein (17,18) and, therefore, the concentration of CMPF in uremic plasma is not significantly decreased by hemodialysis (19). Recently, it was suggested that CMPF inhibits transport of thyroxine into hepatocytes in uremia (20), inhibits the active uptake of thyroxine into anterior pituitary cells (21), and enhances drug inhibition of thyroxine binding in serum (22). Analysis of CMPF has previously been performed by gas chromatographic (23), and gas chromatographic–mass spectrometric techniques (24), as well as by high-performance liquid chromatography (19) but these methods require sample preparation and can be inconvenient for routine screening of many samples. Therefore, we have tried to develop a sensitive enzyme-linked immunosorbent assay (ELISA) for CMPF.



SCHEME 1

In the present study, we prepared CMPF–protein conjugate as an immunogen used for the production of a specific antiserum and an assay antigen, toward the development of a sensitive ELISA for CMPF by chemiluminescence system .

EXPERIMENTAL PROCEDURES

Reagents. 2,2-Dimethyl-1,3-dioxane-4,6-dione was purchased from Kodak Company (Rochester, NY). Bovine serum albumin (BSA) Fr. VI and ovalbumin (OVA) were from Sigma Chemical Co. (St. Louis, MO). Silica gel 60 G and 60 HF_{254} were supplied by Merck (Darmstadt, Germany). Anti-guinea pig IgG antibody-alkaline phosphatase conjugate was obtained from Chemicon International Inc. (Temecula, CA) and Lumiphos 530 {containing 4-methyl-4(3-phosphatephenyl)spiro[1,2-dioxetane-3,2′-adamantane] disodium salt (3.3×10^{-4} M), magnesium chloride (8.0×10^{-4} M), cetyltrimethylammonium bromide (1.13×10^{-3} M), and fluorescein surfactant (5.6×10^{-5} M) in 2-amino-2-methyl-1-propanol buffer (0.75 M, pH 9.6)} from Wako Pure Chemicals (Osaka, Japan). Other general reagents of analytical

Abbreviations: BSA, bovine serum albumin; CMF, 3-carboxy-4-methyl-2-furanpropanoic acid; CMEF, 3-carboxy-4-methyl-5-(1-propenyl)-2-furanpropanoic acid; CMFM, 3-carboxy-4-methyl-5-(1-oxopropyl)-2-furanpropanoic acid methyl ester; CMHF, 3-carboxy-4-methyl-5-(1-hydroxypropyl)-2-furanpropanoic acid; CMOF, 3-carboxy-4-methyl-5-(1-oxopropyl)-2-furanpropanoic acid; CMPF, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid; CMPM, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid methyl ester; CMZF, 3-carboxy-4-methyl-5-(1-hydrazopropyl)-2-furanpropanoic acid; ELISA, enzyme-linked immunosorbent assay; IR, infra red; NMR, nuclear magnetic resonance; OVA, ovalbumin; PBS, 0.1 M sodium phosphate-buffered saline (pH7.2); UV, ultraviolet.

grade were obtained from Nakarai Tesque (Kyoto, Japan). CMPF, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid methyl ester (CMPM), 3-carboxy-4-methyl-5-(1-hydroxypropyl)-2-furanpropanoic acid (CMHF), 3-carboxy-4-methyl-5-(1-propenyl)-2-furanpropanoic acid (CMEF), 3-carboxy-4-methyl-5-(1-oxopropyl)-2-furanpropanoic acid methyl ester (CMFM), and 3-carboxy-4-methyl-2-furanpropanoic acid (CMF) used for the examination of cross-reactivities of anti-CMPF antiserum were prepared according to the methods of Pfordt *et al*. (25) in our laboratory.

Spectroscopic analyses of furan propanoic acids. Ultraviolet (UV) spectra of methanol solutions were taken on a Hitachi U3200 spectrophotometer (Tokyo, Japan) and infrared (IR) spectra on Shimadzu spectrometer IR-406 (Tokyo, Japan). Proton nuclear magnetic resonance (^{1}H NMR) spectra were obtained on a JEOL JNMF X-100 (Tokyo, Japan).

*Synthesis of hapten: 3-Carboxy-4-methyl-5-(1-oxopropyl)-2-furan propanoic acid, CMOF (**2**).* To a solution of CMFM (**1**; 500 mg) in methanol (10 mL) was added 1 M sodium hydroxide (5.0 mL), and the mixture was allowed to stand at room temperature for 12 h. The reaction mixture was concentrated to 3.0 mL; to this was added 2 M hydrochloric acid (5.0 mL), and the resulting solution was extracted with chloroform (3 × 20 mL), washed with water (25 mL), dried over anhydrous sodium sulfate, and then the resulting solution was evaporated to dryness under reduced pressure. The residue was purified by preparative thin-layer chromatography on silica gel 60 HF_{254} plates using chloroform/methanol (5:1, vol/vol) as a solvent. The product (R_f = 0.1) was eluted with chloroform/methanol/water (20:10:1, by vol) to give CMOF (**2,** 300 mg) as a colorless amorphous substance. UV (λ_{max} 275 nm). ^{1}H NMR (acetone-d_6) δ: 2.78 (2H, *m*, CH_2CH_2COOH), 3.36 (2H, *m*, CH_2CH_2COOH). IR ν_{max} cm^{-1}: 1710 (aliphatic COOH), 1690 (olefinic COOH).

*3-Carboxy-4-methyl-5-(1-hydrazopropyl)-2-furanpropanoic acid, CMZF (**3**).* To a solution of CMOF (**2**, 100 mg) in methanol (3.0 mL) was added hydrazine hydride (100 mg) and this was allowed to stand at room temperature for 2 h. The resulting solution was evaporated to dryness under reduced pressure, the residue was purified by preparative thin-layer chromatography on silica gel 60 HF_{254} to give CMZF (**3**, 40 mg) as an oily product. UV (λ_{max} 278 nm). ^{1}H NMR (dimethylsulfoxide-d_6) δ:1.92 (3H, s ,4-CH_3), 2.55 (2H, m, CH_2CH_2COOH), 3.55 (2H, m, CH_2CH_2COOH). IR ν_{max} cm^{-1}: 1710 (aliphatic COOH), 1690 (olefinic COOH).

Preparation of antigens: *CMZF–BSA conjugate (**4a**).* To a solution of BSA (50 mg) in 0.2 M phosphate buffer (pH 6.8, 5.0 mL) were added CMZF (**3**, 30 mg) in methanol (0.5 mL) and 2 wt% aqueous glutaraldehyde (0.5 mL), and the reaction mixture was stirred at 4°C overnight.

The resulting solution was dialyzed against water (3 × 2 L) and then lyophilized to give CMZF-BSA conjugate (**4a**, 38 mg). Measurement of UV absorbance at 285 nm in aqueous solution of the hapten, BSA, and the conjugate revealed that 23 moles of CMZF (**3**) were coupled to each mole of BSA.

*CMZF–OVA conjugate (**4b**).* To a solution of OVA (5 mg) in 0.1 M phosphate buffer (pH 6.8, 1.0 mL) were added CMZF (**3**, 3 mg) in methanol (0.15 mL) and 2 wt% aqueous glutaraldehyde (50 μL). The procedure that followed was carried out as described above to obtain a solution of CMZF-OVA conjugate (**4b**, 4 mg).

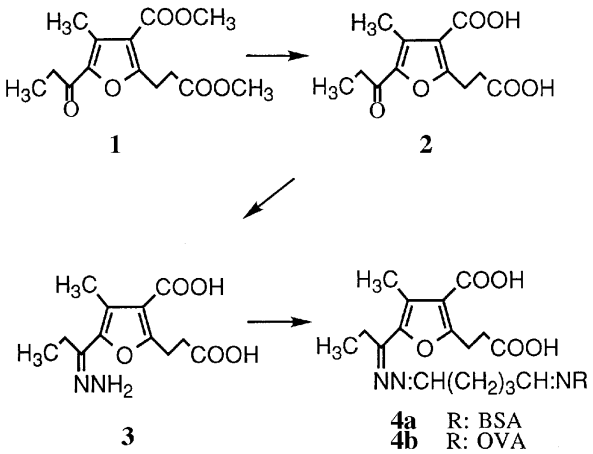
Immunization. Three male guinea pigs were used for immunization. CMZF–BSA conjugate (0.5 mg) was dissolved in sterile isotonic saline (0.25 mL) and emulsified with Freund's complete adjuvant (0.25 mL). This emulsion was injected at multiple sites over the scapulae and in the back. This procedure was repeated at intervals of 2 wk for 2 mon and then once a month. The guinea pigs were bled 10 d after the booster injection. The sera were separated by centrifugation at 800 × *g* for 20 min and stored at −80°C.

ELISA. Fifty microliters of CMZF–OVA conjugate (1 μg/mL) in 0.1 M sodium phosphate-buffered saline (pH 7.2) (PBS) was added to each well of a 96-well microtiter plate (Sumilon MS-K, Sumitomo Bakelite Co., Tokyo, Japan) and incubated at room temperature for 3 h. Unbound conjugate was removed from the plate with four washes of PBS containing 0.5 wt% Tween 20 (PBS/Tween). To block the unoccupied solid phase to minimize nonspecific binding, 0.1 wt% casein solution in PBS (PBS/casein, 0.22 mL) was added, and the mixture was incubated at room temperature for 2 h. The wells were washed with PBS/Tween (4 × 0.22 mL) and 50 μL of a 2000-fold diluted antiserum with PBS/casein was incubated with a standard solution of CMPF (0–200 ng/mL) in PBS (50 μL) at 4°C overnight. The solution was removed and the wells were washed as before. Anti-guinea pig IgG antibody-alkaline phosphatase (1:5000 dilution, 50 μL) was added to each well, and the plate was incubated at room temperature for 1 h. Unbound antibody–enzyme conjugate in solution was removed, and each well was washed as before. Lumiphos 530 (60 μL) was added to each well, and the light counts were measured by a Luminous CT-9000D microplate reader (Dia-itoron Co., Ltd.).

Specificity. The cross-reactivities were examined by calculating the ratio of the quantity of CMPF to the quantity of related compounds corresponding to 50% inhibition of solid phase antigen binding to the antiserum.

RESULTS AND DISCUSSION

To prepare an immunogen for the production of a specific antiserum to CMPF, we synthesized a CMPF hapten which could be coupled to a carrier protein without affecting the functional groups of CMPF, which are important antigen determinants in the CMPF molecule. The starting material, 2,2-dimethyl-1,3-dioxane-4,6-dione, was transformed into a methyl ester (**1**) in four steps (25). Next, as indicated in Scheme 2, upon treatment with sodium hydroxide, CMFM (**1**) was hydrolyzed to furnish the dicarboxylic acid (**2**). Condensation of CMOF (**2**) with hydrazine produced the hydrazone derivative (**3**). Linking of CMZF (**3**) to BSA and OVA was accomplished using glutaraldehyde as a cross-linking reagent. We have therefore successfully prepared CMZF-protein con-



SCHEME 2

jugates (**4a** and **4b**) with intact functional groups in CMPF. The UV spectra of two hapten–protein conjugates and two proteins demonstrate that a sufficient number of hapten molecules were attached to each protein.

Three immunized guinea pigs yielded antisera exhibiting binding activity to CMPF. High binding activity of CMPF was present in all antisera 5 mon after the primary immunization. Titers were determined by measuring the ability of diluted antiserum to bind 50% of solid phase antigen. The typical standard curve of CMPF was constructed with a 2000-fold diluted antiserum with PBS/casein using a solid phase antigen. Chemiluminescence intensity was measured while the concentrations of competing CMPF were varied from 0–200 ng/mL. The binding inhibition curve for quantitation was obtained at 5–100 ng/mL as shown in Figure 1. The detection limit of CMPF by ELISA using chemiluminescence system was 10-fold higher than that by ELISA using colorimetric system (data not shown).

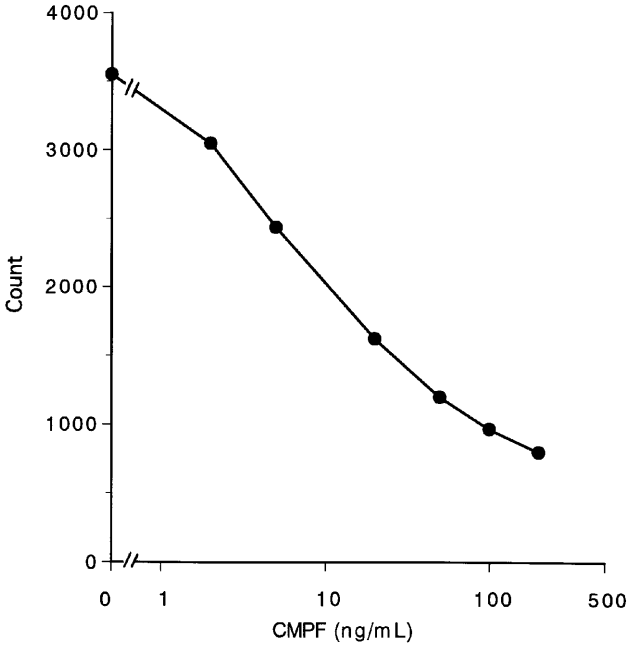


FIG. 1. Typical standard curve of 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid (CMPF) by enzyme-linked immunosorbent assay using chemiluminescence system.

TABLE 1
Cross-reactivity (%) of Anti-CMPF Antiserum with Compounds Related to CMPF[a]

Compound	Cross-reactivity
CMPF	100
CMEF	31.2
CMHF	15.2
CMF	8.7
CMFM	<0.01
CMPM	<0.01
Furfuryl acetate	<0.01
Tetrahydrofurfuryl acrylate	<0.01
3-Indoleacetic acid	<0.01
2-Furanoic acid	<0.01
2-Methyl furan	<0.01

[a]CMPF, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid; CMEF, 3-carboxy-4-methyl-5-(1-propenyl)-2-furanpropanoic acid; CMHF, 3-carboxy-4-methyl-5-(1-hydroxypropyl)-2-furanpropanoic acid; CMF, 3-carboxy-4-methyl-2-furanpropanoic acid; CMFM, 3-carboxy-4-methyl-5-(1-oxopropyl) 2-furanpropanoic acid methyl ester; CMPM, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid methyl ester.

The cross-reactivity of antiserum to CMPF analogs was calculated by the method of Abraham (26). Table 1 indicates that the antiserum is highly specific for CMPF. The antiserum raised against the CMZF–BSA conjugate exhibited 31.2% of cross-reactivity with CMEF and 15.2% of cross-reactivity with CMHF. The cross-reactivities of CMEF and CMHF were due to the close similarity of the structures of these compounds to CMPF by the use of the 1-oxopropyl group for coupling to carrier protein. The antiserum showed low cross-reactivity with CMF (8.7%), indicating that the antiserum also recognizes the 5-side chain. Furthermore, the antiserum exhibited no significant cross-reactivities with CMFM (<0.01%) and other furan compounds (<0.01%). The antibody particularly recognizes functional groups of CMPF remote from the 1-oxopropyl group which is linked to the carrier. The antiserum strongly discriminates CMPM from CMPF. It is generally accepted that conjugation of an antigenic carrier through positions on a hapten distal to their functional groups would elicit antibodies of greater specificity than those raised by conjugation through the carboxyl acids as the inherent functional group in CMPF. Our results demonstrated that the antiserum was highly specific to CMPF with minimal cross-reactivity to the closely related urofuran compounds.

The utilization of this sensitive ELISA for determination of CMPF in biological fluids will be the subject of a future communication.

9-Hydroxy-traumatin, A New Metabolite of the Lipoxygenase Pathway

Harold W. Gardner

Bioactive Research, National Center for Agricultural Utilization Research, ARS, USDA, Peoria, Illinois 61604

ABSTRACT: 9-Hydroxy-traumatin, 9-hydroxy-12-oxo-10*E*-dodecenoic acid, was isolated as a product of 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid as catalyzed by enzyme preparations of both soybean and alfalfa seedlings. This suggested that 9*Z*-traumatin, 12-oxo-9*Z*-dodecenoic acid, was being converted into 9-hydroxy-traumatin in an analogous manner to the previously identified enzymic conversion of 3*Z*-nonenal and 3*Z*-hexenal into 4-hydroxy-2*E*-nonenal and 4-hydroxy-2*E*-hexenal, respectively. Other metabolites of 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid were similar for both soybean and alfalfa seedling preparations, and they are briefly described.
Lipids 33, 745–749 (1998).

A plant wound-healing hormone, traumatic acid (2*E*-dodecenedioic acid), was identified almost 50 years ago (1). It is certain that this compound arises from 12-oxo-9*Z*-dodecenoic acid (9*Z*-traumatin) through the hydroperoxide lyase chain cleavage of either 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13*S*-HPODE) or 13*S*-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid into a six-carbon aldehyde and 9*Z*-traumatin followed by aldehyde oxidation and double-bond rearrangement of the latter [see reviews on the hydroperoxide lyase pathway (2–4)]. More recently, the wound-healing properties of 12-oxo-10*E*-dodecenoic acid (10*E*-traumatin) were reported (5).

This author is unaware of any report of an in-chain hydroxylated form of 9*Z*- or 10*E*-traumatin as a product of the lipoxygenase pathway. In this work, 9-hydroxy-12-oxo-10*E*-dodecenoic acid (9-hydroxy-traumatin) was identified as a product of 13*S*-HPODE metabolism by both alfalfa and soybean seedlings.

MATERIALS AND METHODS

Enzyme preparations and reaction conditions. Two grams of seeds, either soybeans (*Glycine max* cv Williams) or alfalfa (*Medicago sativa*), were germinated on moistened Kimpac (Kimberly-Clark, Corp., Neenah, WI) for 3 d at room temperature. The washed seedlings were Polytron-homogenized for 30 s in 20 mL 50 mM Na phosphate buffer (pH 7.0) with or without 0.5% Triton X-100. The homogenates were centrifuged at 8,000 × *g* for 15 min. The floating oleosome layer was removed by aspiration. A final concentration of 1 mM 13*S*-HPODE served as a substrate and was added as a 4% solution in methanol. Although the supernatant solution was used "as is" in some experiments, the yield of 9-hydroxy-traumatin was very low under these conditions. The yield improved after the enzyme solution was diluted 10-fold with 50 mM phosphate buffer (pH 7.0), and all results presented here utilized the 10-fold diluted supernatant solutions (total reaction volume of 20 mL). After addition of 13*S*-HPODE, the reaction was permitted to proceed for 20 min at 25°C with magnetic stirring. A larger-scale experiment (150 mg 13*S*-HPODE substrate) was completed essentially as a scaled-up version of the smaller incubations. That is, a 10-fold diluted supernatant prepared from soybean seedlings was incubated with 1 mM 13*S*-HPODE in 50 mM phosphate buffer (pH 7.0) for 20 min at 25°C with magnetic stirring (total reaction volume of 480 mL). All reactions were terminated by adjusting the pH to 4.0 with 1 M oxalic acid, and extracting with a 3-fold volume of $CHCl_3$/MeOH (2:1, vol/vol). The preparation of 13*S*-HPODE was described previously (6).

Preparation of derivatives and thin-layer chromatography (TLC) isolation. The extracted products were methyl-esterified by a short exposure (*ca.* 15 s) to CH_2N_2 in diethyl ether/MeOH (9:1, vol/vol). A short exposure to CH_2N_2 was important to minimize side reactions often observed with aldehydes [see review (6)].

For direct analysis of the total reaction mixture by gas chromatography–mass spectrometry (GC–MS), the solvent was removed from the methyl esters and trimethylsilyloxy ethers (OTMSi) were prepared as described (6). In certain experiments the product methyl esters (equivalent to 1 mg of 13*S*-HPODE originally added as substrate) were first treated with $SnCl_2$ to reduce residual 13*S*-HPODE to the corresponding hydroxyl derivative, and this reduction was followed by the preparation of OTMSi derivatives. For reduction, a quantity of 3.8 mg $SnCl_2 \cdot 2H_2O$ (Aldrich Chemical, St. Louis, MO) in 0.64 mL pyridine/MeOH (1:1, vol/vol) was added for a 1 h reaction time. Pyridine was an essential ingredient in the re-

Abbreviations: EIMS, Electron impact-mass spectrum; GC–MS, gas chromatography–mass spectrometry; ^{1}H NMR, proton nuclear magnetic resonance spectrometry; 13*S*-HPODE, 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid; 9-hydroxy-traumatin, 9-hydroxy-12-oxo-10*E*-dodecenoic acid; OTMSi, trimethylsilyloxy ether; TLC, thin-layer chromatography; traumatic acid, 2*E*-dodecendioic acid; 9*Z*-traumatin, 12-oxo-9*Z*-dodecenoic acid; 10*E*-traumatin, 12-oxo-10*E*-dodecenoic acid.

duction in order to minimize acid-catalyzed reactions caused by $SnCl_2$. Reduction products were extracted by adding a 3-fold volume of $CHCl_3/H_2O$ (2:1, vol/vol) followed by washing the $CHCl_3$ layer twice with H_2O.

For purification of methyl 9-hydroxy-traumatin, the technique of "chemical" chromatography was utilized. First, the methyl-esterified product mixture was separated by TLC using Silica Gel 60 F_{254} precoated plates from Merck (20 cm × 20 cm × 0.25 mm) and diethyl ether/hexane (7:3, vol/vol) as developing solvent. GC–MS monitoring revealed that the methyl 9-hydroxy-traumatin migrated as a partially pure substance between $R_f = 0.2$ and 0.4. The silica scraped from this portion of the plate was extracted with ethyl acetate, and the solvent was evaporated with a stream of N_2. Next, the dried sample was silylated with OTMSi reagent, and then separated by TLC using hexane/diethyl ether (7:3, vol/vol). Methyl 9-OTMSi-traumatin was detected as an ultraviolet-absorbing band at $R_f = 0.38$, and this derivative was extracted from the scrapings by ethyl acetate giving pure methyl 9-OTMSi-traumatin as assessed by GC–MS and proton nuclear magnetic resonance (^{1}H NMR).

Spectral methods. GC–MS was accomplished with a Hewlett-Packard Model 5890 (Palo Alto, CA) gas chromatograph interfaced with a Model 5971 mass selective detector operating at 70 eV. The capillary column used was a Hewlett-Packard HP-5MS cross-linked 5% phenyl methyl silicone, 0.25 mm × 30 m, film thickness 0.25 µm. The methyl-esterified–OTMSi derivatives were separated by temperature programming from 160 to 260°C at a rate of 5°C/min then held at 260°C for 10 min (He flow rate = 0.67 mL/min).

Methyl 9-OTMSi-traumatin (in $CDCl_3$ solution) was examined by ^{1}H NMR utilizing a Bruker model ARX-400 spectrometer (400 MHz) (Karlsruhe, Germany).

RESULTS AND DISCUSSION

When either a soybean or alfalfa supernatant preparation was used "as is" to catalyze the transformation of 13*S*-HPODE, only a trace amount of 9-hydroxy-traumatin (methyl ester, 9-OTMSi ether) was observed by GC–MS. However, after a 10-fold dilution of the seedling extracts, methyl 9-OTMSi-traumatin was readily analyzed. One of two possibilities for the reduced amount of 9-hydroxy-traumatin produced by the undiluted preparation was the facile reaction of 9-hydroxy-traumatin with protein sulfhydryl and amino groups in the relatively concentrated enzyme solution. Another was the possibility of artifact production from the relatively larger amount of unreacted 13*S*-HPODE extracted from the diluted reaction mixture. To eliminate this latter possibility, residual 13*S*-HPODE was reduced in a portion of the product mixture with $SnCl_2$ in MeOH/pyridine (pyridine was included to suppress acid-catalyzed reactions), and this mixture was compared with the unreduced product (Fig. 1). There was little difference in the relative abundance of 9-hydroxy-traumatin in the two samples (based on ion abundance); the slightly smaller amount in the reduced sample could easily be attributed to additional sample handling. As seen in Figure 1, the principal products observed as arising from free-radical decomposition of 13*S*-HPODE were isomeric 13-oxo-9,11-tridecadienoic acid and 13-oxo-9,11-octadecadienoic acid. Authentic metabolites, not due to free-radical decomposition of 13*S*-HPODE, were also tentatively identified by their electron impact mass spectra (EIMS) compared with the literature. Most of these metabolites have been described in soybean before (7,11,12,16,17–20), with the exception of 9-hydroxy-traumatin and one isomeric epoxyhydroxyoctadecenoic acid. However, the latter compound, 11,12-epoxy-13-hydroxy-9-

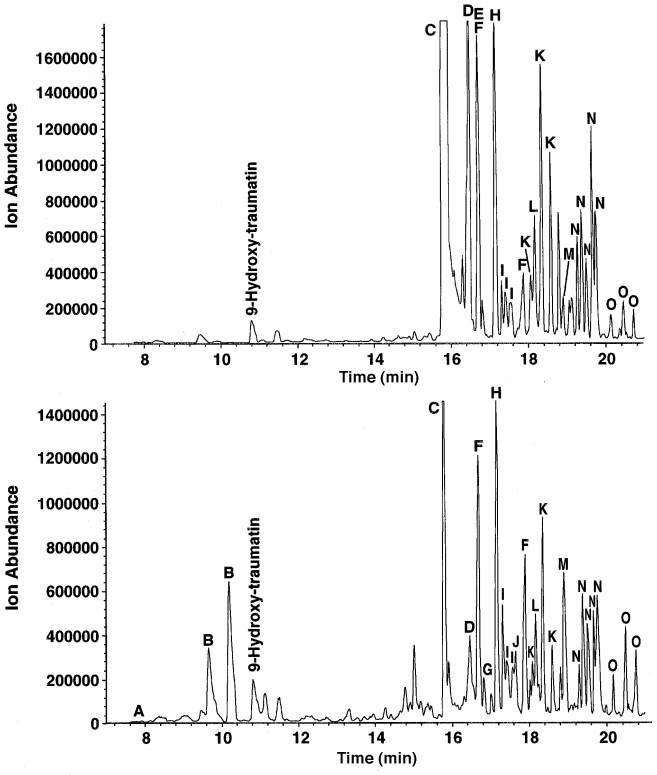

FIG. 1. Gas chromatography–mass spectrometry (GC–MS) analysis of 9-hydroxy-traumatin and other metabolites of 13*S*-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13S-HPODE) (as methyl esters/trimethylsilyloxy ethers) as produced by a soybean seedling preparation (10-fold diluted supernatant). Top: residual hydroperoxides reduced by $SnCl_2$ before analysis; bottom: unreacted 13*S*-HPODE was not reduced before analysis. Tentative identification was from literature mass spectra as follows (as methyl esters/trimethylsilyloxy ethers): A, traumatin (7); B, 13-oxo-9,11-tridecadienoic acid (9*Z*,11*E* and 9*E*,11*E* isomers) (8); 9-hydroxy-traumatin (this report); C, 13-hydroxy-9*Z*,11*E*-octadecadienoic acid (9); D, 9-hydroxy-10*E*,12*Z*-octadecadienoic acid (9); E, 13-hydroxy-9*E*,11*E*-octadecadienoic acid [spectrum the same as C (9)]; F, 13-oxo-9,11-octadecadienoic acid (9*Z*,11*E* or 9*E*,11*E*) (10); G, 9-oxo-10,12-octadecadienoic acid (10); H, 12,13-epoxy-11-hydroxy-9-octadecenoic acid (11); I, overlapping peaks of isomeric H and 9,10-epoxy-11-hydroxy-12-octadecenoic acid (11,12); J, 11,12-epoxy-13-hydroxy-9-octadecenoic acid (13); K, isomeric 9,10-epoxy-13-hydroxy-11-octadecenoic acid (14); L, 12,13-epoxy-9-hydroxy-10-octadecenoic acid (15); M, 12,13-epoxy-9-oxo-10-octadecenoic acid and 9,10-epoxy-13-oxo-11-octadecenoic acid (Gardner, H.W., unpublished data); N, isomeric 9,10,13-trihydroxy-11-octadecenoic acid, 9,12,13-trihydroxy-10-octadecenoic acid, and 11,12,13-trihydroxy-9-octadecenoic acid (16); O, isomeric dihydroxyoxooctadecenoic acid (16).

octadecenoic acid, has been identified as a product of *Vicia faba* peroxygenase/epoxygenase (21). Isomeric oxodihydroxyoctadecenoic acids and trihydroxyoctadecenoic acids are presumed to arise from epoxide hydrolase (22) action on epoxyoxooctadecenoic acids and epoxyhydroxyoctadecenoic acids, respectively. The positional isomers of epoxyhydroxyoctadecenoic acid and epoxyoxooctadecenoic acids observed by their mass spectra indicated a mixed reaction mechanism of: (i) alkoxyl radical rearrangement (23) (e.g., the 13-hydroperoxide gives rise to 12,13-epoxides) and (ii) peroxygenase oxidation of double bonds (19,21) of either hydroxyoctadecadienoic acid or oxooctadecadienoic acid (e.g., the 13-hydroperoxide affords 11,12-epoxides and/or 9,10-epoxides from epoxidation of the 9- and 11-double bonds). The epoxyoxooctadecenoic acids were ascertained to be both 12,13- and 9,10-epoxides by treatment with BF_3–MeOH followed by GC–MS of their methoxy-OTMSi derivatives as described previously (23). The products observed as a result of 13*S*-HPODE metabolism by alfalfa seedling extracts were remarkably similar to soybean, the only observable difference being the relative abundance of metabolites (data not shown). No evidence could be found for the previously reported γ-ketol (24). Also not detected in the product mixtures of either soybean or alfalfa seedlings were ketols from allene oxide synthase-catalyzed reactions. It is known from previous work that expression of allene oxide synthase in soybean seedlings is comparatively low (25).

When control extracts were incubated without added 13*S*-HPODE, it was interesting to find traces of 9-hydroxy-traumatin present. Based on the abundance of the principal fragment ion (*m/z* 157), the controls had at least 12-fold less 9-hydroxy-traumatin present at the expected GC retention time (Fig. 2). In one control 9-hydroxy-traumatin was not detected (data not shown). According to the literature (e.g., Ref. 7), the activity of hydroperoxide lyase, the enzyme that cleaves 13*S*-HPODE into 9*Z*-traumatin and hexanal, is improved by detergent. However, when seedlings were homogenized with 0.5% Triton X-100 in buffer, the production of 9-hydroxy-traumatin was not significantly increased, compared to the preparation without detergent (data not shown).

9-Hydroxy-traumatin was easily isolated by a two-step TLC procedure affording about 0.3 mg from a mixture obtained from a reaction using 150 mg 13*S*-HPODE catalyzed by a soybean seedling preparation. The first step involved TLC isolation of the methyl-esterified mixture, including 9-hydroxy-traumatin (methyl ester), using diethyl ether/hexane (7:3, vol/vol). After derivatization by OTMSi reagent, the chromatographic properties of methyl 9-OTMSi-traumatin were changed considerably from the other components of the mixture, permitting facile TLC isolation by hexane/diethyl ether (7:3, vol/vol). Since it is highly unlikely that the chromatographic properties of coeluting compounds would be identical after a specific derivatization, we have found this method of "chemical chromatography" to be useful. Depending on the functional groups present on the compound of interest, a variety of other reagents, such as $NaBH_4$ reduction, chromic acid oxidation etc., has been utilized in other research.

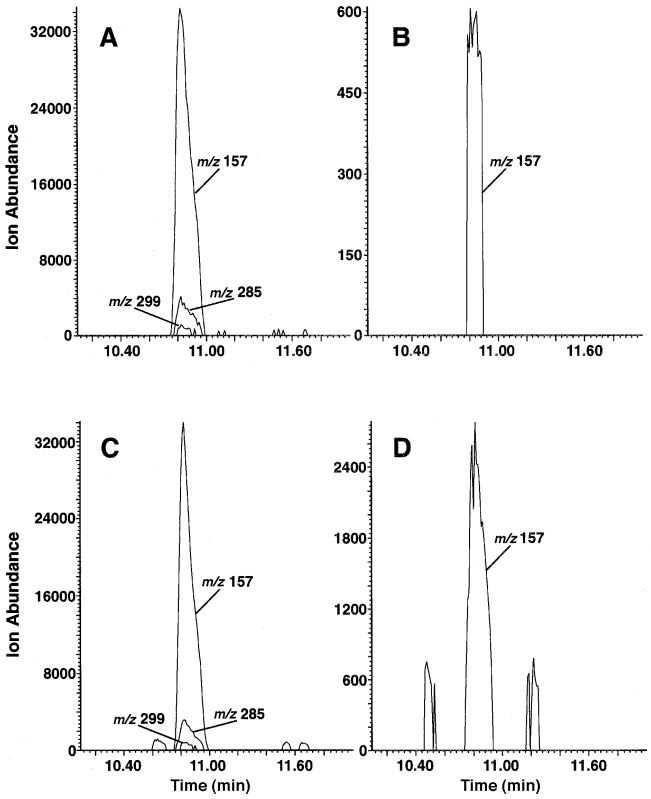

FIG. 2. GC–MS ion chromatograms (*m/z* 157 [M – $(CH_2)_7COOMe]^+$, 285 [M – CHO]$^+$, and 299 [M – Me]$^+$) showing the elution of 9-hydroxy-traumatin (as methyl ester/trimethylsilyloxy ether) with ion abundances illustrated. All treatments utilized supernatant preparations diluted 10-fold with buffer. Panel A, soybean seedling preparation treated with 1 mM 13*S*-HPODE; panel B, soybean supernatant preparation control without 13*S*-HPODE; panel C, alfalfa seedling preparation treated with 1 mM 13*S*-HPODE; panel D, alfalfa supernatant preparation control without 13*S*-HPODE. For abbreviations see Figure 1.

The methyl 9-OTMSi-traumatin isolated by "chemical chromatography" was examined by ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.109 (9H, *m*, H-9-OTMSi), 1.30 and 1.60 (12H, *m*, H-3 to H-8), 2.29 (2H, *t*, H-2), 3.66 (3H, *s*, H-OMe), 4.35 (1H, *dt*, H-9), 6.25 (1H, *ddd*, $J_{9,11}$ = 1.6 Hz, $J_{11,12}$ = 8 Hz, $J_{10,11}$ = 15.5 Hz, H-11), 6.78 (1H, *dd*, $J_{9,10}$ = 4.5 Hz, $J_{10,11}$ = 15.5 Hz, H-10), 9.56 (1H, *d*, $J_{11,12}$ = 8 Hz, H-12). The coupling, $J_{10,11}$ = 15.5 Hz, proved that the double bond was 10*E*.

The methyl ester/OTMSi derivative of 9-hydroxy-traumatin gave the following EIMS *m/z* (rel. int.): 314 [M]$^+$ (0.3), 299 [M – Me]$^+$ (2), 285 [M – CHO]$^+$ (10), 270 [M – CHO –Me]$^+$ (2), 267 [M – MeOH – Me]$^+$ (2), 230 (4), 157 [M –$(CH_2)_7COOMe]^+$ (100), 129 (17), 73 [trimethylsilyl]$^+$ (91). The OTMSi derivative was subjected to $NaBH_4$ reduction in MeOH followed by treatment with OTMSi reagent affording the bis OTMSi derivative with the following EIMS *m/z* (rel. int.): 373 [M – Me]$^+$ (0.7), 357 [M – MeO]$^+$ (2), 298 [M –TMSiOH]$^+$ (2), 285 [M – $CH_2OTMSi]^+$ (12), 259 [M –CH=$CHCH_2OTMSi]^+$ (3), 231 [M – $(CH_2)_7COOMe]^+$ (89), 147 (23), 73 [trimethylsilyl]$^+$

(100). The preceding $NaBH_4$-reduction product was further treated with H_2 and Pd on $CaCO_3$ catalyst in MeOH for 1 h. The hydrogenated product was treated with OTMSi reagent and subjected to EIMS *m/z* (rel. int.): 359 $[M - MeO]^+$ (0.7), 333 $[M - MeOH - Me]^+$ (2), 259 $[M - (CH_2)_3OTMSi]^+$ (56), 233 $[M - (CH_2)_7COOMe]^+$ (14), 143 $[M - (CH_2)_7COOMe - TMSiOH]^+$ (100), 73 $[trimethylsilyl]^+$ (68). In summary, the ^1H NMR data combined with GC–MS of various derivatives left little doubt that the original compound was 9-hydroxy-traumatin.

Although the pathway of 9-hydroxy-traumatin was not directly demonstrated, it is likely that 9*Z*-traumatin, the hydroperoxide lyase-catalyzed product, is the precursor. Conclusive proof must await the direct testing of 9*Z*-traumatin as a substrate. Because 9*Z*-traumatin readily isomerizes in most plant extracts into 10*E*-traumatin, it would be desirable to develop a synthetic method to produce the substrate of interest.

The oxidation is proposed to occur in a manner analogous to the conversion of 3*Z*-nonenal and 3*Z*-hexenal into 4-hydroxy-2*E*-nonenal and 4-hydroxy-2*E*-hexenal, respectively (Fig. 3). In the conversion of 3*Z*-nonenal to 4-hydroxy-2*E*-nonenal, the first step is oxygenation of 3*Z*-nonenal to 4-hydroperoxy-2*E*-nonenal by lipoxygenase (and possibly 3*Z*-alkenal oxygenase) (26,27). Although the oxidation of 3*Z*-nonenal is an n-6 oxidation typical of the reactions completed at alkaline pH values by soybean lipoxygenase-1 with its normal polyunsaturated fatty acid substrates, at neutral pH values soybean lipoxygenase-2 and -3, as well as lipoxygenase-1, are capable of using the carboxylic end of the molecule as a signal to oxygenate at C-9 (4). The second step involves a dual pathway, whereby, the 4-hydroperoxide is reduced to the 4-hydroxide by hydroperoxide-dependent peroxygenase. In the process of reduction, this enzyme also utilizes the oxidation potential of the hydroperoxide to oxidize 3*Z*-nonenal to 3,4-epoxynonanal, which undergoes rearrangement into a second molecule of 4-hydroxy-2*E*-nonenal (28). Examination of the stereochemistry of the 4-hydroxyl of 4-hydroxy-2*E*-nonenal showed that the product was nearly racemic (26,28), probably because of the dual nature of the biosynthetic pathway. However, it was shown that the first product, 4*S*-hydroperoxy-2*E*-nonenal, could be formed in fairly high chiral purity by oxidizing 3*Z*-nonenal with purified soybean lipoxygenase isozymes (26). The stereoconfiguration of the 9-hydroxyl of 9-hydroxy-traumatin was not examined in this study because it was not expected to be instructive considering the crude enzyme preparations utilized. Such preparations would

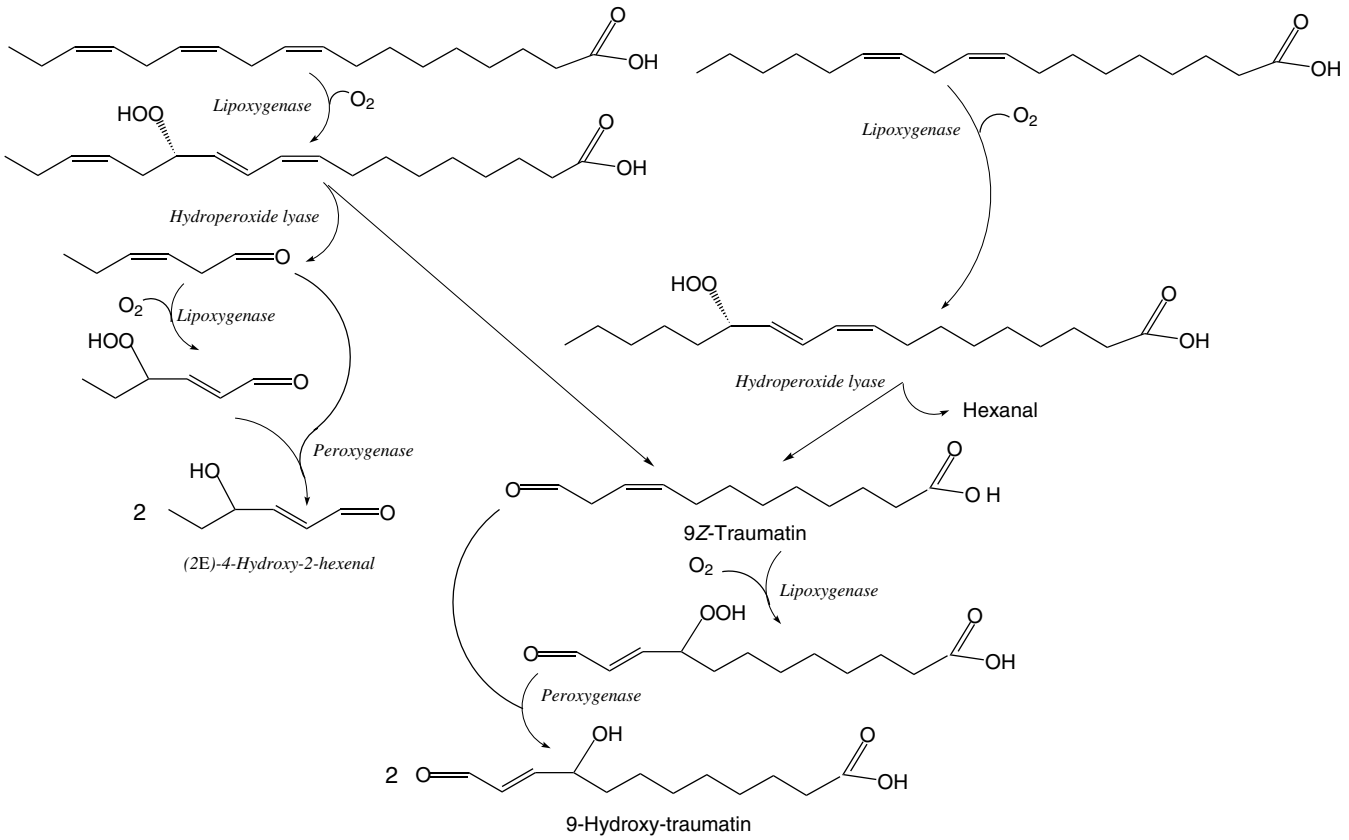

FIG. 3. Proposed reaction scheme of 9-hydroxy-traumatin biosynthesis from 9*Z*-traumatin, compared with known pathways in the formation of analogous hydroxylated aldehydes (not shown is the formation of 4-hydroxy-2*E*-nonenal from 3*Z*-nonenal originating from hydroperoxide lyase cleavage of the 9-hydroperoxide of linoleic acid). Peroxygenase performs a dual function of reducing the hydroperoxides formed from 9*Z*-traumatin, 3*Z*-hexenal or 3*Z*-nonenal, as well as epoxidizing a second molecule of 9*Z*-traumatin, 3*Z*-hexenal or 3*Z*-nonenal affording 9,10-epoxy-12-oxododecanoic acid, 3,4-epoxyhexanal or 3,4-epoxynonanal, respectively, which subsequently rearrange into a second molecule of hydroxylated product (28).

be expected to be composed of enzymes catalyzing the dual pathway, that is, oxygenase(s) and hydroperoxide-dependent peroxygenase.

The question of physiological significance is most interesting. Certainly, the oxidation product of 10*E*-traumatin, traumatic acid, as well as 10*E*-traumatin itself, have plant wound-healing properties. Currently, the physiological effect of 9-hydroxy-traumatin is unknown, but this compound should be a reactive molecule similar to its analog, 4-hydroxy-2-nonenal, which is known to have multiple effects on organisms, including responses known to be indicative of lipid signals (29–31).

Rate Constants for Quenching Singlet Oxygen and Activities for Inhibiting Lipid Peroxidation of Carotenoids and α-Tocopherol in Liposomes

Kenji Fukuzawa[a,*], Yasuki Inokami[a], Akira Tokumura[a], Junji Terao[b], and Asahi Suzuki[c]

[a]Faculty of Pharmaceutical Sciences and Departments of [b]Nutrition, School of Medicine, and [c]Chemical Science and Technology, Tokushima University, Tokushima, Japan

ABSTRACT: The $^1O_2$ quenching rate constants (k_Q) of α-tocopherol (α-Toc) and carotenoids such as β-carotene, astaxanthin, canthaxanthin, and lycopene in liposomes were determined in light of the localization of their active sites in membranes and the micropolarity of the membrane regions, and compared with those in ethanol solution. The activities of α-Toc and carotenoids in inhibiting $^1O_2$-dependent lipid peroxidation (reciprocal of the concentration required for 50% inhibition of lipid peroxidation: $[IC_{50}]^{-1}$) were also measured in liposomes and ethanol solution and compared with their k_Q values. The k_Q and $[IC_{50}]^{-1}$ values were also compared in two photosensitizing systems containing Rose bengal (RB) and pyrenedodecanoic acid (PDA), respectively, which generate $^1O_2$ at different sites in membranes. The k_Q values of α-Toc were 2.9×10^8 $M^{-1}s^{-1}$ in ethanol solution and 1.4×10^7 $M^{-1}s^{-1}$ (RB system) or 2.5×10^6 $M^{-1}s^{-1}$ (PDA system) in liposomes. The relative $[IC_{50}]^{-1}$ value of α-Toc in liposomes was also five times higher in the RB system than in the PDA-system. In consideration of the local concentration of the OH-group of α-Toc in membranes, the k_Q value of α-Toc in liposomes was recalculated as 3.3×10^6 $M^{-1}s^{-1}$ in both the RB and PDA systems. The k_Q values of all the carotenoids tested in two photosensitizing systems were almost the same. The k_Q value of α-Toc in liposomes was 88 times less than in ethanol solution, but those of carotenoids in liposomes were 600–1200 times less than those in ethanol solution. The $[IC_{50}]^{-1}$ value of α-Toc in liposomes was 19 times less than that in ethanol solution, whereas those of carotenoids in liposomes were 60–170 times less those in ethanol solution. There were no great differences (less than twice) in the k_Q and $[IC_{50}]^{-1}$ values of any carotenoids. The k_Q values of all carotenoids were 40–80 times higher than that of α-Toc in ethanol solution but only six times higher that of α-Toc in liposomes. The $[IC_{50}]^{-1}$ values of carotenoid were also higher than that of α-Toc in ethanol solution than in liposomes, and these correlated well with the k_Q values.

Lipids 33, 751–756 (1998).

α-Tocopherol (α-Toc) and carotenoids have recently been implicated in the prevention of or protection against serious human health disorders such as cancer and heart disease. These effects have been attributed in part to their antioxidant properties.

Singlet oxygen ($^1O_2$) has aroused much interest as a biological oxidant. It is generated in a variety of biological systems and by photosensitization by the absorption of light. Many studies have shown that α-Toc and carotenoids scavenge $^1O_2$, but in most of these studies a homogeneous solution such as ethanol (EtOH), not membranes, has been used (1–6). It is important to know the antioxidant properties and activities of the compounds on $^1O_2$ in membranes, because these compounds are located in membranes in biological systems. Recently, we reported the kinetics and dynamics of $^1O_2$ scavenging by α-Toc in liposomes (7,8). Here we examined the $^1O_2$-scavenging rate constants (k_Q values) of carotenoids such as β-carotene (β-Car), astaxanthin, canthaxanthin, and lycopene in model membranes using phosphatidylcholine liposomes and compared them with that of α-Toc. $^1O_2$ was site specifically generated in liposomes by photosensitization with two photosensitizers; water-soluble Rose bengal (RB), which generates $^1O_2$ at the membrane surface, and lipid soluble pyrenedodecanoic acid (PDA), which becomes located in an inner region of the membranes where $^1O_2$ is generated. We also measured the inhibitory activities of carotenoids and α-Toc on $^1O_2$-dependent peroxidation of egg yolk phosphatidylcholine in liposomes and EtOH solution and compared the results with their k_Q values. Their antioxidant dynamics and kinetics in membranes were interpreted based on our results with respect to the membrane localizations of the antioxidants and the local concentrations and mobilities of their active moieties in the membranes.

MATERIALS AND METHODS

Materials. α-Toc was a gift from Eisai Co. (Tokyo, Japan). Astaxanthin and canthaxanthin were kindly provided by

Abbreviations: BHT, butylhydroxytoluene; β-Car, β-carotene; DMPC, dimyristoylphosphatidylcholine; DPBF, 1,3-diphenyl-isobenzofuran; egg PC, egg phosphatidylcholine; EP, endoperoxide; HEPES, *N*-2-hydroxyethylpiperazine-*N*′-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid; HPLC, high-performance liquid chromatography; IC_{50}, concentration at which 50% inhibition occurs; k_Q, rate constant for quenching $^1O_2$; $^1O_2$, singlet oxygen; PC-OOH, phosphatidylchline hydroperoxide; PDA, 12-(1-pyrene) dodecanoic acid; RB, Rose bengal; SA, stearylamine; α-Toc, α-tocopherol.

Hoffman-La Roche, Basel, Switzerland. β-Car was purchased from Sigma Chemical Co. (St. Louis, MO). Lycopene was supplied by Kagome Co. (Tochigi, Japan). Butylhydroxytoluene (BHT), 12-(1-pyrene)-dodecanoic acid (PDA), stearylamine (SA), and *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) were obtained from Wako Pure Chemical Industries (Tokyo, Japan). Dimyristoylphosphatidylcholine (DMPC) and egg yolk phosphatidylcholine (egg PC) were products of Nippon Oil and Fats Co. (Tokyo, Japan). The fatty acid composition (mol%) of egg PC was 33.1 palmitate, 1.2 palmitoleate, 11.6 stearate, 30.0 oleate, 15.5 linoleate, 3.3 arachidonate, and 5.3 docosahexaenoate. Diethylenetriaminepentaacetic acid (DTPA) was from Nakalai Tesque Co. (Kyoto, Japan). RB was from Kanto Chemicals (Tokyo, Japan) and 1,3-diphenyl-isobenzofuran (DPBF) was from Tokyo Chemical Co., Tokyo. All other reagents were of analytical grade.

Preparation of liposomes and photosensitized oxidation. Liposomes were prepared as described previously (7). For studies on PDA-sensitized photooxidation, a solution of α-Toc, carotenoids, DMPC or egg PC in chloroform with or without SA, and PDA was evaporated with a stream of nitrogen under reduced pressure. For measurement of the rate constant of $^1O_2$ scavenging, a solution of DPBF in EtOH was further added to the resulting thin film, which was then re-evaporated. The thin film was dispersed in 10 mM HEPES buffer (pH 7.0) containing 0.5 mM DTPA in a vortex mixer and ultrasonicated in a Bransonic bath (Yamato, Tokyo, Japan) at 40°C for 2 min (positively charged liposomes) or 20 min (neutrally charged liposomes). For studies on RB-sensitized photooxidation, a solution of RB in HEPES buffer (pH 7.0) was added to the dispersed sample before sonication. The liposome suspension was placed at a distance of 4 cm from a 85-W halogen-tungsten lamp (Toshiba JD 100W 110V 85WN-E) and photoirradiated at 1564 lumen at 37°C.

Calculation of the $^1O_2$ scavenging rate constants (k_Q) *of carotenoids and α-Toc.* The k_Q values were determined by the method of Young *et al.* (9) by measuring the inhibition by carotenoids or α-Toc of photooxidation of DPBF, a specific $^1O_2$ trap. To exclude the participation of the lipid radical chain reaction, we used DMPC liposomes which are in a liquid crystalline state at 37°C. $^1O_2$ was generated at the membrane surface using RB in SA-DMPC liposomes, because negatively charged RB interacts at the membrane surface of these positively charged liposomes (8). PDA generated $^1O_2$ in the inner region of the membrane irrespective of the membrane charge (7). The calculated values of k_Q in DMPC liposomes were revised taking account of the local concentrations of reactants, all of which were assumed to be present in membranes.

Quantitation of hydroperoxides of egg PC (PC-OOH). The rate of lipid peroxidation was measured by quantitating PC-OOH formation, which was followed by HPLC with a ultraviolet-detector at 234 nm (10). After incubation, 20 μL of the reaction mixture was subjected to HPLC in a Hitachi L-6000 apparatus. A reversed-phase column (YMC-Pack A-212 C8; Yamamura Chemical Lab., 6 × 150 mm) was used and developed with methanol/H_2O/triethylamine (95:5:0.01, by vol) at a rate of 1 mL/min.

RESULTS AND DISCUSSION

Values for the rate constants (k_Q) of α-Toc and carotenoids for scavenging $^1O_2$ in DMPC liposomes and EtOH solution were measured by the technique of Young *et al.* (9) using Equations 1 and 2:

$$S_0/S_{\alpha\text{-}T} = 1 + (k_Q/k_d)\,[\alpha\text{-Toc}] \quad [1]$$

$$S_0/S_{Car} = 1 + (k_Q/k_d)\,[Car] \quad [2]$$

where S_0 and $S_{\alpha\text{-T}}$ or S_{Car} denote the slopes of first-order plots of disappearance of DPBF in the absence and presence of α-Toc or carotenoids. [Car] refers to the concentration of all carotenoids. The rate of deactivation of $^1O_2$ (k_d) is the rate constant for natural decay of $^1O_2$ to $^3O_2$. The k_d value of $^1O_2$ in liposomes has not yet been determined. We used the k_d values in EtOH solution (8.3×10^4 s^{-1}) (11) and *tert*-BuOH (3.0×10^4 s^{-1}) (12) for the RB system and PDA system, respectively, because $^1O_2$ is generated at a polar membrane surface in the RB system and a hydrophobic membrane inner region in the PDA system. The micropolarity of the environment around the OH-groups of α-Toc in liposomes close to the membrane surface was inferred to be equal to that in EtOH (13), in which the dielectric constant is higher than that in *tert*-BuOH. Table 1 shows the k_Q values for carotenoids and α-Toc in EtOH solution and liposomes. β-Car, astaxanthin, and canthaxanthin showed similar k_Q values. The k_Q of lycopene obtained in the photoirradiation systems (data not shown) was about 10 times less than that reported in the system using endoperoxides (EP) such as 3,3′-(1,4-naphthylidene)dipropionate (4), which is known to generate only $^1O_2$. Lycopene would be unstable on exposure to light. The k_Q values of carotenoids in liposomes in the RB system were recalculated using the k_d value in *tert*-BuOH, and were almost the same as those in the PDA system (Table 1). The active site of β-Car, which is at the center of the conjugated polyene chain, is reported to be localized in the hydrophobic region (14,15) where $^1O_2$ is also highly localized irrespective of its generation site because of its higher solubility in the hydrophobic region than in the polar region (16), resulting in similar k_Q values of carotenoids calculated using the k_d value in *tert*-BuOH in either photosensitizing system.

The k_Q values in liposome membranes were revised taking account of the concentrations of reactants in membranes. Their concentrations in liposome membranes were 242 (SA-DMPC liposomes) and 266 (DMPC liposomes) times those in the bulk phase, as calculated from the volume of membranes assuming that the volume of one DMPC molecule is 1253 Å^3 (17). The revised k_Q values are shown in Table 1.

The inhibitory effects of carotenoids and α-Toc on $^1O_2$-dependent lipid peroxidation in EtOH solution and liposomes were compared. The rate of PC-OOH formation was higher

TABLE 1
Rate Constants (k_Q) of α-Toc, Carotenoids and BHT for Scavenging $^1O_2$ Generated with RB, PDA, and EP in EtOH Solution and Liposomes[a]

BHT	8.2×10^6			3.4×10^{6c}	9.7×10^7	3.5×10^7	1.4×10^{5e}				5.9×10^4

[a]The concentrations of carotenoids, α-Toc, and BHT were 2.5–15 μM, 25–100 μM, and 0.1–3 mM, respectively. The concentrations of DPBF, RB, and PDA were 250, 5, and 250 μM, respectively. The concentrations of other reactants in the liposome systems were 5 mM DMPC with or without 0.5 mM SA, and 10 mM HEPES buffer (pH 7.0) containing 0.5 mM DTPA. The EtOH solution and liposomes were photoirradiated for ~30 s, in RB system and ~8 min in PDA system at 37°C.
[b]Reference 4.
[c]Reference 5.
[d]Values calculated using the k_d value in EtOH (8.3×10^4 s^{-1}).
[e]Values calculated using the k_d value in *tert*-BuOH (3.0×10^4 s^{-1}).
[f]Values in liposomes revised considering that the local concentrations of reactants were 242 times higher than in the bulk phase in the RB system (SA-DMPC liposomes).
[g]Values in liposomes revised considering that the local concentrations of reactants were 266 times higher than in the bulk phase in the PDA system (DMPC liposomes).
[h]Averaged values of revised values for RB and PDA except the value of α-Toc.
[i]k_Q of α-Toc = k_Q (RB) × 4/34 × 100/50 or k_Q (PDA) × 20/34 × 100/50.
[j]k_Q (liposomes: EP) = k_Q (EtOH: EP) × k_Q (liposomes: Average)/ k_Q (EtOH: Averaged). Abbreviations: α-Toc, α-tocopherol; BHT, butyl hydroxytoluene; RB, Rose bengal; PDA, 12-(1-pyrene) dodecanoic acid; EP, endoperoxide; β-car, β-carotene; DPBF, 1,3-diphenyl-isobenzofuran; DMPC, dimyristoyl-phosphatidylcholine; SA, stearylamine; HEPES, *N*-2-hydroxyethylpiperazone-*N*′-2-ethanesulfonic acid; DTPA, diethylene triaminepentaacetic acid; k_Q, rate constant for quenching $^1O_2$.

in liposomes than in EtOH solution (data not shown) as reported previously (7). α-Toc and carotenoids inhibited the formation of egg PC-OOH by photoirradiation in a concentration dependent manner. Their concentrations for 50% inhibition of the initial rate of lipid peroxidation (IC_{50}) were measured in EtOH solution and liposomes. Table 2 shows the activities of the compounds for inhibiting $^1O_2$-dependent lipid peroxidation as reciprocals of IC_{50} value: $[IC_{50}]^{-1}$. Higher $[IC_{50}]^{-1}$ values indicate higher antioxidant activity. β-Car, astaxanthin, and canthaxanthin showed similar $[IC_{50}]^{-1}$ values. The order of lipid peroxidation-inhibiting activities was: all carotenoids examined > α-Toc > BHT in both EtOH solution and liposomes. These values were well correlated with the order of their k_Q values. The $[IC_{50}]^{-1}$ value of lycopene (data not shown) was about 10-fold less than those of other carotenoids, like its k_Q value, possibly because of its lability to light.

TABLE 2
Activities of α-Toc, Carotenoids, and BHT for Inhibiting Lipid Peroxidation Induced by $^1O_2$ Generated with RB and PDA in EtOH Solution and Liposomes[a]

	$[IC_{50}]^{-1}$ (10^3 M^{-1})				
	EtOH	Liposomes			
	RB system	RB system		PDA system	
		Apparent	Rev.[b]	Apparent	Rev.[c]
α-Toc	13.5	172	0.71	196	0.74
β-Car	83.3	333	1.38	1477	5.6
Canthaxanthin	236	333	1.38	2933	11.0
Astaxanthin	238	476	1.97	2960	11.1
BHT	0.063	4.5	0.019	6.9	0.026

[a]The concentrations of carotenoids, α-Toc, and BHT were 0.1–50 μM, 0.5–200 μM, and 0.025–50 mM, respectively. The concentrations of RB and PDA were 5 and 250 μM, respectively. The concentrations of other reactants in the liposome systems were 5 mM PC with or without 0.5 mM SA, and 10 mM HEPES buffer (pH 7.0) containing 0.5 mM DTPA. The EtOH solution and liposomes were photoirradiated for ~60 and ~6 min, respectively, in RB system, and ~180 min in PDA system at 37°C.
[b]Revised values in SA-egg liposomes calculated assuming that the concentration of antioxidants in the membrane phase was 242 times that in the bulk water phase.
[c]Revised values in egg liposomes calculated assuming that the concentration of antioxidants in the membrane phase was 266 times that in the bulk water phase. egg PC, egg phosphatidylcholine; IC_{50}, concentration at which 50% inhibition occurs; for other abbreviations see Table 1.

TABLE 3
Ratios of the k_Q Values and the Relative Activities for Inhibiting Lipid Peroxidation in the RB System to Those in the PDA System in EtOH Solution and Liposomes

	RB system/PDA system		
	Ratio of k_Q value		Ratio of activity for inhibiting lipid peroxidation[a]
	EtOH	Liposomes	Liposomes
α-Toc	1.7	5.6	5.4
β-Car	1.3	1.2	1.4
Canthaxanthin	0.93	1.1	0.71
Astaxanthin	1.1	1.0	1.0

[a]Activity relative to that of astaxanthin: $[IC_{50}]^{-1}/[IC_{50}]^{-1}$(astaxanthin). For abbreviations see Tables 1 and 2.

Table 3 shows the ratios of the k_Q values in the RB system to those in the PDA system for α-Toc and carotenoids and their relative activities for inhibiting lipid peroxidation in EtOH solution and liposomes. There was little difference in the k_Q values in the RB system and PDA system in EtOH solution. But in liposomes, the k_Q value for α-Toc in the RB system was about five times greater than that in the PDA system, although the k_Q values for carotenoids were almost the same in the two photosensitizing systems. The relative activity of α-Toc in inhibiting lipid peroxidation in liposomes in the RB system was also five times greater than that in the PDA system but there was no appreciable difference in the activities of carotenoids for inhibiting lipid peroxidation in the RB system and PDA system. These results were well correlated with results on the k_Q values in the RB and PDA systems. The OH-groups of α-Toc are mainly localized in the region close to the membrane surface (18–22), so their concentration in this region, where $^1O_2$ is generated by RB, is higher than their concentration postulated by assuming that they are uniformly distributed in the membrane. This would explain the relatively higher k_Q value in the RB system (1.4×10^7 $M^{-1}s^{-1}$). On the contrary, PDA generates $^1O_2$ in the hydrophobic region where the concentration of the OH-groups of α-Toc is lower than that postulated as described above, resulting in relatively lower k_Q values in the PDA system ($2.5 \times 10^6 M^{-1}s^{-1}$). Takahashi *et al.* (19) reported that α-Toc scavenges lipid radicals close to the membrane surface more effectively than those in deep regions of the bilayer membrane and also effectively scavenges radicals attacking from outside the membranes. On the contrary, the quenching sites of carotenoids are localized in the hydrophobic region (14,15) where the concentration of $^1O_2$ is also high irrespective of its generation site, because $^1O_2$ is more soluble in the hydrophobic region than in the polar region (16). Thus, the k_Q values of all carotenoids were similar irrespective of the photosensitizer.

The k_Q value of α-Toc in liposomes was recalculated as 3.3×10^6 $M^{-1}s^{-1}$ in both the RB and PDA systems from Equation 3 in consideration of the local concentrations of the OH-groups of α-Toc in membranes, which were assumed to be about 0, 50, and 50% in the polar zone (10 Å), hydrogen belt (4 Å), and hydrophobic core (20 Å) of DMPC liposomes, respectively (18–22).

$$S_0/S_{\alpha\text{-T}} = 1 + (k_Q/k_d)\ [\text{OH-group of } \alpha\text{-Toc}] \quad [3]$$

where $[\text{-OH group of } \alpha\text{-Toc}]_{RB} = [\alpha\text{-Toc}] \cdot [(10 + 4 + 20)/4] \cdot [50/100]$ and $[\text{-OH group of } \alpha\text{-Toc}]_{PDA} = [\alpha\text{-Toc}] \cdot [(10 + 4 + 20)/20] \cdot [50/100]$. The recalculated k_Q values for α-Toc may be similar in the RB and PDA systems, because the OH-groups of α-Toc in the region closed to the membrane surface are supposed to have higher reactivity but lower mobility than those in the inner membrane region from consideration of the findings (i) that the k_Q value of α-Toc in homogeneous solution is higher in solvents with higher dielectric constants (7,18) and (ii) that the chromanol moiety of α-Toc is near the membrane surface and its mobility is restricted, possibly by hydrogen bonding of its OH-groups with ester carbonyl moieties of membrane PC (18, 23).

The revised k_Q values in liposomes for α-Toc and carotenoids were 88 and 600–1200 times lower, respectively, than those in EtOH solution (Table 4). The lower k_Q values in liposomes than in EtOH solution may have been due to the lower diffusion rates of reactants in membranes than in EtOH solution and to their lateral diffusion in membranes but their three-dimensional diffusion in EtOH solution.

The k_Q values of carotenoids were about 40–80 times that of α-Toc in EtOH solution, but only six times that of α-Toc in liposomes (Table 4). The mobilities of carotenoids would be suppressed more than that of α-Toc in membranes, resulting in greater decreases in their k_Q values than that of α-Toc in liposomes than in EtOH solution. The $[IC_{50}]^{-1}$ values for carotenoids were also decreased more than that for α-Toc in liposomes than in EtOH solution (Table 5), consistent with results on their k_Q values. The membrane structure may inhibit the interaction of $^1O_2$ with carotenoids more strongly than with α-Toc and BHT, resulting in greater reduction in k_Q and $[IC_{50}]^{-1}$ values for carotenoids than for α-Toc and BHT in the membrane system.

The order of the ratios of $[IC_{50}]^{-1}$ values in liposomes to those in EtOH solution, that is, $[IC_{50}]^{-1}$ (liposomes)/$[IC_{50}]^{-1}$ (EtOH), was BHT (radical scavenger) > α-Toc (radical scavenger and $^1O_2$ quencher) > carotenoids ($^1O_2$ quencher) (Table 5). Some radical-type active oxygens generated by the minor reaction (Type I action) of RB photoirradiation would participate in the progress of lipid peroxidation more in liposomes

than in EtOH solution, because PC molecules are ordered and packed in membranes that are suitable for progression of the radical chain reaction.

Since photoirradiation systems are reported to generate small amounts of active oxygens other than $^1O_2$, we attempted to estimate the liposomal k_Q values of α-Toc and carotenoids in the EP system, which generates only $^1O_2$. The k_Q values for α-Toc and carotenoids have been measured by the EP method in EtOH solution (4,5) but not in liposomes because EP is heat-labile and so cannot be used in the liposome system. We estimated the liposomal k_Q values in the EP system using the reported k_Q value in EtOH solution in the EP system (4,5) from Equation 4,

$$k_Q\ (\text{liposome: EP}) = k_Q(\text{EtOH: EP}) \times \frac{k_Q\ (\text{liposome: Average})}{k_Q\ (\text{EtOH: Average})} \quad [4]$$

where k_Q (EtOH: EP) is the reported k_Q value in EtOH solution in the EP system (4,5), and k_Q (liposome: Average) and k_Q (EtOH: Average) are the averaged k_Q values obtained by photoirradiation with RB and PDA in liposomes and EtOH solution, respectively, except that we took the k_Q (liposome: Average) for α-Toc as $3.3 \times 10^6\ M^{-1}s^{-1}$(Table1). The estimated k_Q values in liposomes in the EP system shown in Table 1 were about 90 (α-Toc) and 600–1200 (carotenoids) times less than those in EtOH solution.

The k_Q values for quenching $^1O_2$ in membranes of α-Toc and carotenoids and their activities for inhibiting $^1O_2$-dependent lipid peroxidation obtained in this study reflect their antioxidant properties in biological systems better than those in homogeneous solution. Considerations of the antioxidant properties and functions of α-Toc and carotenoids suggest that their physicochemical behaviors in membranes may be particularly important.

We show for the first time that the following factors are important in influencing the k_Q and $[IC_{50}]^{-1}$ values of α-Toc and carotenoids in membranes: (i) the concentrations of antioxidants, which are concentrated in membranes, (ii) the membrane localizations of active groups of antioxidants and their local concentrations in membranes, (iii) the solubility and generation site of $^1O_2$ in membranes, depending on the localization of photosensitizers in the surface or inner region, and (iv) the mobility of antioxidants in membranes, which is lower than that in EtOH solution.

Dietary Oxidized Cholesterol Modulates Cholesterol Metabolism and Linoleic Acid Desaturation in Rats Fed High-Cholesterol Diets

[a]Laboratory of Science of Bioproducts, Hirosaki University, Faculty of Agriculture, Hirosaki 036, Japan, and [b]Laboratory of Food Science, Kyushu University, School of Agriculture, Fukuoka 812-01, Japan

ABSTRACT: The interactive effect of high dietary levels of oxidized cholesterol on exogenous cholesterol and linoleic acid metabolism was examined in male 4-wk-old Sprague-Dawley rats given high-cholesterol diets. The rats were pair-fed purified diets free of or containing either 0.5% cholesterol alone or both 0.5% cholesterol and 0.5% oxidized cholesterol mixture (containing 93% oxidized cholesterol) for 3 wk. Hepatic 3-hydroxy-3-methylglutaryl CoA reductase activity was reduced in rats given cholesterol alone or both cholesterol and oxidized cholesterol. However, hepatic cholesterol 7α-hydroxylase activity was lowered only when rats were given both cholesterol and oxidized cholesterol, although dietary cholesterol increased this activity. Reflecting this effect, acidic steroid excretion was lowest among the groups of rats given cholesterol and oxidized cholesterol. On the other hand, the activity of hepatic Δ6 desaturase, a key enzyme in the metabolism of linoleic acid to arachidonic acid, was increased in rats given both cholesterol and oxidized cholesterol, although dietary cholesterol alone lowered its activity. As a result, the Δ6 desaturation index, 20:3n-6 + 20:4n-6/18:2n-6, in liver and serum phospholipids tended to be higher in the group fed both cholesterol and oxidized cholesterol than in the one fed cholesterol alone. Thus, dietary oxidized cholesterol significantly modulated exogenous cholesterol metabolism and promoted linoleic acid desaturation even when it was given at high levels together with a high cholesterol diet.

Lipids 33, 757–764 (1998).

Recently, it has been shown that endogenous oxidized cholest-5-en-3β-ol (cholesterol derivatives) are formed during oxidative modification of low density lipoprotein (1–3). Some of these may be sources of oxidized cholesterol in the walls of arteries, because oxidized low density lipoprotein is taken up by macrophages *via* scavenger receptors. Many oxidized cholesterol derivatives are biologically deleterious agents potentially influencing vital physiological and biochemical processes. There is evidence from *in vivo* studies that oxidized cholesterol exhibits toxic actions (4). On the other hand, cholesterol in various common foods is also susceptible to reactions with oxygen under mild conditions, yielding a wide range of oxidation products in high levels during processing and storing of foods. In fact, high levels of oxidized cholesterol have been detected in various processed foods such as egg (total level of oxidized cholesterol, 1.3–4151 μg/g), dairy (0.19–1037 μg/g), meat (0.6–4878 μg/g), marine fish (5.2–287 μg/g) and miscellaneous processed (1.1–147.8 μg/g) products (5). Therefore, oxidized cholesterol in tissues could be partly exogenously absorbed from the diet. Peng *et al.* (6) assumed that the rate of absorption of oxidized cholesterols is not significantly different from that of cholesterol. We also observed that approximately 30% of oxidized cholesterol was absorbed into lymph when oxidized cholesterol was orally administered in rats (7). In addition, numerous studies showed that oxidized sterols influence specific key enzymes in cholesterol and fatty acid metabolism in *in vitro* bioassay (4). On the other hand, we observed dietary oxidized cholesterol disturbed growth and modulated cholesterol and fatty acid metabolism in *in vivo* studies (8,9).

Thus, dietary oxidized cholesterol appears to specifically modify various parameters of lipid metabolism, although dietary cholesterol also affects cholesterol and linoleic acid metabolism. Notwithstanding the significance of deleterious activities of oxidized cholesterol derivatives, only limited information concerning the interactive effect of dietary oxidized cholesterol on exogenous cholesterol and linoleic acid metabolism *in vivo* is available, particularly during consumption of large amounts of it. Therefore, we sought to know how high dietary levels of oxidized cholesterol modulate exogenous cholesterol and linoleic acid metabolism in rats fed high-cholesterol diet, because commonly consumed foods contain oxidized cholesterol along with unoxidized cholesterol.

MATERIALS AND METHODS

Chemicals. 3-Hydroxy-3-methyl[1-^{14}C]glutaryl-coenzyme A (HMG-CoA; 55 mCi) was purchased from Amersham Inter-

*To whom correspondence should be addressed at Laboratory of Science of Bioproducts, Faculty of Agriculture, Hirosaki University, 3 Bunkyocho, Hirosaki 036, Japan. E-mail: kyoichi@cc.hirosaki_u.ac.ip

Abbreviations: Chol, 0.5% cholesterol added; cholesterol, cholest-5-en-3β-ol; Chol-free, cholesterol-free; Chol + OxChol, both 0.5% cholesterol and 0.5% oxidized cholesterol-added; HDL, high density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; 7β-hydroxycholesterol, cholest-5-en-3β, 7β-diol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; TBARS, thiobarbituric acid-reactive substances.

national, plc, (Buckinghamshire, United Kingdom). [1-^{14}C]Linoleic acid (53 mCi/mmol) and [4-^{14}C] cholesterol (51 mCi/mmol) were produced by New England Nuclear, (Boston, MA), and purified by thin-layer chromatography as described previously (9) prior to use.

Animals and diets. Twenty-four male Sprague-Dawley rats (4-wk old), purchased from Seiwa Experimental Animals (Fukuoka, Japan) and housed individually in stainless steel mesh cages, were given a nonpurified diet (type NMF; Oriental Yeast Co., Tokyo, Japan) and acclimated for 4 d in an air-conditioned room with controlled temperature and reversed light and dark cycle (20–23°C and lights on 1700 to 0500). Rats were then divided into three groups of six rats each; one group was fed a cholesterol-free diet (Chol-free group), the second was fed a diet with 0.5% added cholesterol alone, (Chol group) and the third was fed a diet with a mixture of both 0.5% cholesterol and 0.5% oxidized cholesterol mixture (Chol + Ox Chol group). Diets were prepared according to the recommendations of the American Institute of Nutrition (10), and contained by weight percentage: casein, 20; safflower oil (Rinoru Oil Co., Nagoya, Japan), 5; mineral mixture (AIN76), 3.5; vitamin mixture (AIN76), 1.0; choline bitartrate, 0.2; DL-methionine, 0.3; cellulose, 5.0; cornstarch, 15; sodium cholate, 0.25; and sucrose to 100. Cholesterol (0.5%) or both cholesterol (0.5%) and oxidized cholesterol mixture (0.5%) were added at the expense of sucrose. An oxidized cholesterol mixture was prepared from pure cholesterol by heating as described previously (9). The preparation contained by weight percentage: cholesterol, 8.2; cholest-5-en-3β,7α-diol, 5.5; cholest-5-en-3β,7β-diol, 18.2; 5,6α-epoxy-5α-cholestan-3β-ol, 2.9; 5,6β-epoxy-5β-cholestan-3β-ol, 9.0; 5α-cholestan-3β,5,6β-triol, 5.7; 3β-hydroxycholest-5-en-7-one, 22.0; cholest-5-en-3β,25-diol, 3.8; and unknown oxidized sterols, 23.5. Experimental diets were prepared weekly, packed in a pouch containing an oxygen adsorbent and stored at 4°C to avoid peroxidation. Diets were changed every day, and body weight and food intake were recorded daily. The Chol-free and Chol groups were given diets at the level consumed by the Chol + Ox Chol group because dietary oxidized cholesterol caused a significant reduction in food intake. After 3 wk, rats were killed by decapitation at 1000 for the measurement of liver enzyme activities and serum and liver lipids. The liver was excised immediately, frozen with liquid nitrogen, and kept at −80°C until analyzed. Blood serum was prepared by centrifugation after allowing blood to clot at room temperature. Feces were collected for 2 d, beginning 10 d before killing, and lyophilized.

Analyses. The activities of HMG-CoA reductase, cholesterol 7α-hydroxylase, and Δ6 desaturase of liver microsomes were measured according to the procedure reported previously (9). The concentration of microsomal protein was determined by the method of Lowry *et al*. (11). Total liver and serum lipids were extracted by method of Folch *et al*. (12) and analyzed for the concentrations of cholesterol, triglyceride, and phospholipids (13). Serum high density lipoprotein (HDL)-cholesterol was measured using a commercially available kit (HDL C-test, Wako Pure Chemicals, Osaka, Japan). Liver and blood lipoperoxides were also analyzed by the methods of Yagi (14) and Ohkawa *et al.* (15) as thiobarbituric acid-reactive substances (TBARS), although complete lipoperoxide values were not always shown by this method. The fatty acid compositions of liver and serum phospholipids were analyzed as their methyl esters by gas–liquid chromatography (Shimadzu gas chromatograph GC-8APF, Kyoto, Japan) on 10% Silar 10C column (3 mm × 2 m) after phosphatidylcholine (PC) and phosphatidylethanoleamine (PE) were separated by thin-layer chromatography (16) and derivatized. The concentration and composition of acidic steroids excreted in feces were also analyzed by gas–liquid chromatography using a 3% AN-600 column (3 mm × 2 m) as described previously (17). The concentrations of oxidized cholesterol in liver, serum, and feces were quantified by capillary gas–liquid chromatography (Shimadzu gas chromatograph GC-14A) using ULBON HR-1 column (0.25 mm × 50 m, liquid phase thickness, 25 μm; Shinwa Chemical Industries, Ltd., Kyoto, Japan) under the conditions described previously (18).

Statistical analysis. Data were expressed as mean ± SE of six animals. The exact nature of the differences ($P < 0.05$) among the groups was determined by Duncan's new multiple-range test (19).

RESULTS

Growth parameters and liver weight. No statistically significant differences among groups were observed in body weight gain according to the type of diet (Table 1). However, the relative liver weight at the time of killing was significantly higher in the Chol group than in the Chol-free or Chol + Ox Chol group.

Concentrations of liver and serum lipids. The concentration of liver cholesterol was significantly lower in the Chol + Ox Chol group than in the Chol group, although its level was significantly higher than that of Chol-free group (Table 2). The liver triglyceride level in the Chol + Ox Chol group significantly decreased compared to the Chol group, and its level tended to be lower than for the Chol-free group. Contrary to these effects, the concentration of liver phospholipids was significantly higher in the Chol + Ox Chol group than in the Chol group, although its level was comparable to that of Chol-free group. Reflecting such modulation, the cholesterol/phospholipid ratio in the Chol + Ox Chol group (1.85 ± 0.13) was significantly lower than in the Chol group (3.78 ± 0.19), although the ratio was significantly higher than for the Chol-free group (0.34 ± 0.07).

On the other hand, the diet containing both cholesterol and oxidized cholesterol, as compared to cholesterol alone, significantly lowered the concentration of serum cholesterol (Table 3). Moreover, the concentration of serum HDL-cholesterol was significantly lowered in both the Chol and the Chol + Ox Chol groups compared with the Chol-free group, and its level tended to be lower in the Chol + Ox Chol group

TABLE 1
Effects of Dietary Oxidized Cholesterol on Growth Parameters in the Rats Given High-Cholesterol Diet[a]

Groups	Initial body wt (g)	Weight gain (g/10 d)	Food intake (g/d)	Liver weight (g/100 g body weight)
Chol-free	113 ± 1	158 ± 8	18.1 ± 0.6	5.41 ± 0.21[b]
Chol	113 ± 1	171 ± 2	18.4 ± 0.2	6.93 ± 0.09[c]
Chol + Ox Chol	113 ± 1	162 ± 1	17.9 ± 0.3	5.80 ± 0.07[b]

[a]Data are presented as mean ± SE for six rats in each group.
[b,c]Values without a common superscript letter are significantly different at $P < 0.05$. Abbreviations: Chol-free, cholesterol-free diet; Chol, 0.5% cholesterol diet; Chol + Ox Chol, both 0.5% cholesterol and 0.5% oxidized cholesterol diet.

TABLE 2
Effect of Dietary Oxidized Cholesterol on Liver Lipid Concentrations in the Rats Given High-Cholesterol Diets[a]

Groups	Total cholesterol (mg/g)	Triglyceride (mg/g)	Phospholipid (mg/g)
Chol-free	5.68 ± 0.81[b]	68.2 ± 10.6[b,c]	16.8 ± 0.4[c]
Chol	57.8 ± 2.1[d]	76.6 ± 11.3[c]	15.3 ± 0.4[b]
Chol + Ox Chol	32.3 ± 2.2[c]	43.9 ± 3.8[b]	17.5 ± 0.2[c]

[a]Data are presented as mean ± SE for six rats in each group.
[b–d]Values without a common superscript letter are significantly different at $P < 0.05$. For abbreviations see Table 1.

TABLE 3
Effect of Dietary Oxidized Cholesterol on Serum Lipid Concentrations in the Rats Given High-Cholesterol Diets[a]

Groups	Total cholesterol (mg/dL)	HDL-cholesterol (mg/dL)	Triglyceride (mg/dL)	Phospholipid (mg/dL)
Chol-free	97.7 ± 5.2[c]	62.5 ± 1.5[d]	154 ± 21	111 ± 8
Chol	194 ± 12[d]	47.2 ± 4.1[b]	146 ± 25	92.6 ± 12.2
Chol + Ox Chol	142 ± 14[d]	39.1 ± 2.6[b]	126 ± 5	84.2 ± 10.1

[a]Data are presented as mean ± SE for six rats in each group.
[b–d]Values without a common superscript letter are significantly different at $P < 0.05$. For abbreviations see Table 1.

than the Chol group. However, the HDL-cholesterol/total cholesterol ratio was same for the Chol + Ox Chol and the Chol groups (Chol-free, 64 ± 3; Chol, 24 ± 3; Chol + Ox Chol 28 ± 2%). Although a significant difference was not observed in the concentrations of serum triglyceride and phospholipids, the concentrations in the Chol + Ox Chol group tended to be lower than in both the Chol-free and Chol groups.

Key enzyme activities of liver microsomes. Figure 1 shows the specific activities of HMG-CoA reductase, cholesterol 7α-hydroxylase, and Δ6 desaturase of liver microsomes. The HMG-CoA reductase activities in both the Chol and Chol + Ox Chol groups were significantly lower than that in Chol-free group; however, there was no difference between the Chol and the Chol + Ox Chol groups, although the activity tended to be lower in the Chol + Ox Chol group than in the Chol group. The cholesterol 7α-hydroxylase activity was significantly higher in both the Chol and the Chol + Ox Chol groups than in the Chol-free group; however, the activity in Chol + Ox Chol group was significantly lower than in the Chol group. On the other hand, the Δ6 desaturase activity in the Chol or the Chol + Ox Chol group was significantly decreased compared to the Chol-free group; however, the activity in the Chol + Ox Chol group was significantly higher than in the Chol group.

Fatty acid profiles of liver. Table 4 shows the fatty acid compositions of liver phospholipids. Dietary cholesterol significantly increased the proportion of palmitoleic, oleic, dihomo-γ-linolenic, and linoleic acids and decreased those of stearic acid in PC and PE. Arachidonic acid in PE rather increased while decreasing in PC; docosahexaenoic acid in PE was not significantly altered while decreasing in PC. Reflecting the modulation in the fatty acid composition, the ratio of Δ6 desaturation index (20:3n-6 + 20:4 n-6)/18:2 n-6 was sig-

[b–d]Values without a common superscript letter are significantly different at $P < 0.05$. For abbreviations see Table 1.

nificantly decreased in the Chol group compared to the Chol-free group. Contrary to this observations, the reduction of the ratio was moderate when the rats were given both cholesterol and oxidized cholesterol because the effect on the proportions of these fatty acids was small. Therefore, the index was higher in the Chol + Ox Chol group than in the Chol group, particularly in PC. A similar tendency was also observed in liver PE and serum PC fatty acid compositions.

Contents of oxidized cholesterols in liver and serum. Table 5 shows the concentration of major oxidized cholesterol derivatives in the liver and serum. Dietary oxidized cholesterol elevated cholesterol derivative levels in liver. Cholest-5-en-3β, 7α-diol; 5,6α-epoxy-5α-cholestan-3β-ol and 5,6β-epoxy-5β-cholestan-3β-ol; 5α-cholestan-3β,5,6β-triol; and 3β-hydroxycholest-5-en-7-one were detected only in the Chol + Ox Chol group, whereas cholest-5-en-3β,7β-diol was detected

TABLE 5
Effect of Dietary Cholesterol on Sterol Composition of Liver in the Rats Given High-Cholesterol Diets[a]

Component	Group		
	Chol-free	Chol	Chol + Ox Chol

[a]Data are presented as mean ± SE for six rats in each group.
[b]Composed of more than 20 components including oxidized cholesterols and plant sterols and their metabolites.
[c]Composed of more than five unknown components.
[d–f]Values without a common superscript letter are significantly different at $P < 0.05$. For abbreviations see Table 1.

even in the rats given no oxidized cholesterol. In addition, the concentration of cholest-5-en-3β,7β-diol in the Chol group was higher than that in the Chol-free group. The same changes were also observed in serum, although the level of cholest-5-en-3β,7β-diol was same level between the Chol-free and the Chol groups.

Fecal steroid excretion. Table 6 summarizes between groups data for composition of fecal steroids. Although the weight of dried feces was comparable between groups, the fecal excretion of neutral steroids in the Chol + Ox Chol group was the highest among the three groups. The excretion of cholesterol and unknown neutral steroids was significantly higher in the Chol + Ox Chol group than the Chol group. The concentration of coprostanol in feces of the Chol + Ox Chol group was higher than other two groups.

In contrast, dietary oxidized cholesterol significantly lowered the excretion of acidic sterols, the value in the Chol + Ox Chol group being lower than in both the Chol and Chol-free groups. The composition of acidic sterols was also modified by dietary oxidized cholesterol, and the ratio of secondary to primary bile acids (deoxycholic acid/cholic acid and lithocholic acid/chenodeoxycholic acid) in the Chol + Ox Chol group was significantly increased compared to that observed in the rats fed the cholesterol-only supplement.

TBARS value of blood and liver. Figure 2 shows the concentrations of blood and liver lipoperoxides measured as TBARS. The TBARS values of blood and liver significantly increased after feeding the diet containing both cholesterol and oxidized cholesterol compared to either the cholesterol-free diet, or that which cholesterol alone was added. The value of the Chol group was lower than that of the Chol-free group although this difference was not statistically significant.

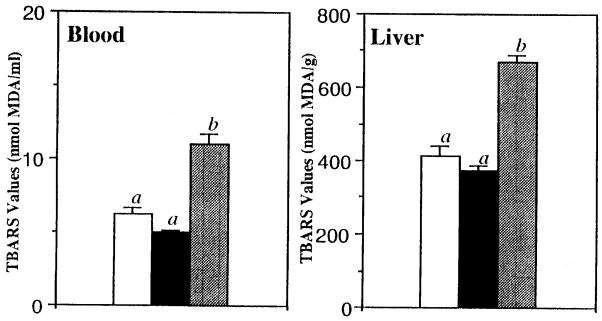

FIG. 2. Effect of dietary oxidized cholesterol on blood and liver thiobarbituric acid-reactive substances (TBARS) values in rats given high cholesterol diets. Values are presented as mean ± SE for six rats in each group. Values without the same letter are significantly different at $P < 0.05$. MDA, malondialdehyde. For abbreviations see Figure 1.

DISCUSSION

Our previous observations indicated that dietary oxidized cholesterol modulates some parameters of lipid components and metabolism accompanying aging (8,9). The present study also showed that high dietary levels of oxidized cholesterol disturbed exogenous cholesterol metabolism and modified various parameters of lipid metabolism when rats were fed high-cholesterol diets.

Relative liver weight in the Chol + Ox Chol group was significantly lower compared to the Chol group, although food intake and weight gain of rats were not different due to the paired-feeding protocol. In addition, the color of the livers of rats fed oxidized cholesterol (dark-red) was different from that of the rats of other groups (Chol-free group, bright-red; Chol group, whitish-red). We previously observed that dietary oxidized cholesterol increased hepatic glutamic pyruvic transaminase levels (9). Thus, dietary oxidized cholesterol may exert deleterious effects against hepatic function, as various oxidized cholesterol derivatives exhibit toxic action in bioassay (4). However, more detailed studies on this toxic effect of dietary oxidized cholesterol on hepatic function are required because whether the *in vitro* toxic property of oxidized cholesterol is the same or similar to the effect *in vivo* has not yet been determined.

The concentration of liver cholesterol in the Chol + Ox Chol group was significantly decreased compared to the Chol group. Moreover, the same tendency was shown in serum cholesterol level. These depressive effects on cholesterol of liver and serum may be due to the large excretion of cholesterol in feces. In fact, we observed that oxidized cholesterol inhibited the absorption of cholesterol from the intestines in a previous study (20). In addition, the reduction of sterol biosynthesis may also affect the concentration of liver cholesterol, as reduction of the hepatic HMG-CoA reductase activity was observed when rats were fed diets containing either both cholesterol and oxidized cholesterol or cholesterol alone. Various oxidized cholesterol derivatives have been shown to be potent inhibitors of sterol biosynthesis *in vitro* (21,22). In the limited information about *in vivo* studies, Erikson *et al*. (23) observed that HMG-CoA reductase activity was inhibited by perfusion of the liver with cholest-5-en-3β, 25diol. Vargas *et al.* (24) also reported that hepatic HMG-CoA reductase activity in laying hens was suppressed by feeding an oxidized cholesterol mixture. These observations were consistent with the present results.

Despite dietary cholesterol increasing cholesterol 7α-hydroxylase activity, this enzyme was inhibited by dietary oxidized cholesterol, although this activity may partly be lowered by the promotion of cholesterol excretion in feces. The hydroxylase activity has also been shown to be inhibited by oxidized cholesterol in an other *in vivo* study (25). Therefore, this inhibitory action may be partly caused by the competitive inhibition of cholesterol binding to liver microsomal cytochrome P-450 by oxidized sterols as suggested by Böstrom (25). The decrease of the hydroxylase activity by dietary oxidized cholesterol may be associated with the reduction in fecal acidic steroids excretion. The change in composition of fecal acidic steroids also indicates a differential effect of oxidized cholesterol on enzymes involved in bile acid conversion as reported previously (26,27). Moreover, oxidized cholesterol can be converted to unusual acidic *steroids* by intestinal bacteria, yielding oxidized cholesterol derivatives with increased toxicity. In fact, there was an increase in the ratio of secondary to primary bile acids in the rats fed oxidized cholesterol. This modulation might be a factor in colon cancer because deoxycholic and lithocholic acids are known to have potent promoter properties (28,29).

On the other hand, the hepatic Δ6 desaturase activity was significantly higher in the Chol + Ox Chol group than in the Chol group, although the Δ6 desaturase activity was suppressed by dietary cholesterol as reported previously (30). These results were consistent with the observation of Hochgraf *et al*. (31), although they gave oxidized linoleic acid to rats. As a result, the desaturation index of linoleic acid expressed as the ratio of (20:3n-6 + 20:4n-6/18:2n-6) in the Chol + Ox Chol group tended to increase in liver PC, PE, and serum PC compared to the Chol group. This modulation may be caused by increased fluidity of hepatic microsomes accompanying a decreased cholesterol/phospholipid ratio as Hochgraf *et al*. reported (31).

Thus, oxidized cholesterol modulated key enzymes in the metabolism of cholesterol as well as polyunsaturated fatty acids in liver microsomes. Unesterified oxidized cholesterol derivatives may exert various deleterious actions on hepatic lipid metabolism shortly after being incorporated into the cells as demonstrated by Brown and Goldstein (32), although it is generally believed that cells acquire exogenous cholesterol by two mechanisms, diffusional transfer (33) and receptor-mediated endocytosis (32).

Dietary oxidized cholesterol influenced the levels of triglyceride and phospholipid in the liver and serum. The same tendency was observed in plasma but not in liver of chicks given oxidized cholesterol (34). On the other hand, the concentration of liver cholesterol ester was lower in the rats given both cholesterol and oxidized cholesterol than in those given cholesterol alone, although these data were not shown. Some *in vitro* studies (35,36) found that oxidized cholesterol derivatives stimulated the fatty acyl-CoA:cholesterol acyltransferase activity in cultured cells and isolated microsomes. However, this did not occur in microsomes from bovine adrenal cortex and murine macrophage-like cells (37,38). The apparent inhibition of acyl-CoA:cholesterol acyltransferase activity by dietary oxidized cholesterol may be observed in this experimental condition because the enzyme in our experiment was saturated with sterol substrate as Smith and Johnson suggested (4), although our result was consistent with the latter.

The TBARS value of blood and liver was higher in Chol + Ox Chol group than in the other two groups. Although the interaction of oxidized cholesterol derivatives such as hydroperoxycholesterols with the TBA reagent cannot be excluded, it is possible that oxidized sterols stimulate the formation of free radicals in the tissues leading to reaction with coexisting fatty acids to form TBARS.

In conclusion, the present results demonstrated diverse effects of a high dietary level of oxidized cholesterol on exogenous cholesterol and linoleic acid desaturation when rats were fed a high-cholesterol diet. Emanuel *et al*. (39) reported that oxidized cholesterol derived from foodstuffs elevated oxidized cholesterol levels in human plasma. These oxidized cholesterol derivatives may have deleterious effects on lipid

metabolism, as observed in the present study. Our experimental conditions may not necessarily reflect usual diets because the level of oxidized cholesterol in the experimental diet was very high compared to a natural diet. Therefore, further studies are needed to confirm the current results under more physiological conditions. However, these observations help elucidate how high dietary levels of oxidized cholesterol modulate exogenous cholesterol metabolism and linoleic acid desaturation when high-consuming a cholesterol diet.

The Cholesterol-Lowering Effect of Guar Gum in Rats Is Not Accompanied by an Interruption of Bile Acid Cycling

Marie-Laure Favier[a], Pierre-Etienne Bost[b], Christian Demigné[a,*], and Christian Rémésy[a]

[a]Laboratoire des Maladies Métaboliques et Micronutriments, I.N.R.A. de Clermont-Ferrand/Theix, 63122 St-Genès-Champanelle, France, and [b]Rhône-Poulenc, 92400 Courbevoie, France

ABSTRACT: A viscous hydrocolloid (guar gum, GG; 2.5% of the diet) or a steroid sequestrant (cholestyramine; 0.5% of the diet) was included in semipurified diets containing 0.2% cholesterol to compare the cholesterol-lowering effects of each agent in rats. In the present model, GG significantly lowered plasma cholesterol (–25%), especially in the density < 1.040 kg/L fraction, whereas cholestyramine was less potent. Bile acid fecal excretion significantly increased only in rats fed cholestyramine, similar to the cecal bile acid pool; the biliary bile acid secretion was accelerated by GG, but not their fecal excretion, whereas GG effectively enhanced neutral sterol excretion. As a result, the total steroid balance (+13 μmol/d in the control) was shifted toward negative values in rats fed the GG or cholestyramine diets (–27 or –50 μmol/d, respectively). Both agents induced liver 3-hydroxy-3-methylglutaryl-CoA reductase, but cholestyramine was more potent than GG in this respect. The present data suggest that, at a relative low dose in the diet, GG may be more effective than cholestyramine in lowering plasma cholesterol by impairing cholesterol absorption and by accelerating the small intestine/liver cycling of bile acids, which is interestingly, accompanied by reduction of bile acid concentration in the large intestine.
Lipids 33, 765–771 (1998).

Several studies have indicated that the dietary intake of nonstarch polysaccharides can lower circulating cholesterol levels in humans as well as in experimental animals (1–3). Various compounds have been documented: cereal brans, gums, resistant starch, or compounds displaying sequestrant properties such as cholestyramine (a resin) or β-cyclodextrin (4–7). Guar gum (GG) has been shown to be particularly effective as a cholesterol-lowering agent: in the small intestine this neutral galactomannan has the capacity to form gels which may trap organic materials such as bile acids or sterols (8). GG, a hydrocolloid, is not markedly digested in the upper part of the digestive tract, but is extensively broken down in the large intestine by the host microflora, yielding short-chain fatty acids (SCFA) that are soon absorbed.

The cholesterol-lowering effect of fermentable carbohydrates may be explained by various mechanisms: (i) impairment of cholesterol absorption in the small intestine, (ii) binding of bile acids by hydrocolloids, with subsequent interruption of the enterohepatic bile acid cycling and increased fecal steroid excretion (9–11), (iii) impairment of the passive reabsorption of bile acids in the large intestine by insolubilizing these compounds (luminal pH acidification, entrapping to various insoluble structures, bacterial dehydroxylation into apolar metabolites), and (iv) production of specific metabolic effects, especially in the liver on lipid metabolism.

Previous investigations have established that the cholesterol-lowering effect of dietary fibers depends on their capacity to accelerate the fecal excretion of steroids and on their fermentability (12). The question was raised whether hydrocolloids such as GG could act, to some extent, as steroid sequestrants in the digestive tract. Both GG and cholestyramine produce greater fecal sterol excretion (13) and, in human subjects, increase bile acid synthesis (14). But in contrast to cholestyramine, GG is devoid of ion-exchange capacity and, in some experiments, hydrocolloids and cholestyramine showed contrasting effects on bile acid excretion (15).

The aim of the present work was to examine whether GG exerts effects different from those of cholestyramine on the enterohepatic bile acids cycling and on the control of plasma cholesterol and liver metabolism.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (IFFA-CREDO, l'Arbresle, France) weighing approximately 150 g were fed for 21 d semipurified diets distributed as a moistened powder. The control diet contained the following (in g/kg diet): casein (L. François, Paris, France), 150; corn oil, 100; cholesterol, 2; wheat starch, 678; mineral and vitamin mixes (Usine d'Alimentation Rationnelle, Villemoisson/Orge, France), 60 and 10, respectively (Table 1). The first experimental group contained 25 g of GG/kg diet at the expense of wheat starch, and

Abbreviations: GG, guar gum; HDL, high density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA; SCFA, short-chain fatty acid.

TABLE 1
Composition (g/kg) of the Experimental Diets

Diet group	Control	Guar gum	Cholestyramine
Wheat starch	678	653	673
Casein	150	150	150
Corn oil	100	100	100
Cholesterol	2	2	2
Guar gum	0	25	0
Cholestyramine	0	0	5
Mineral mixture	60	60	60
Vitamin mixture	10	10	10

the second contained 5 g cholestyramine/kg diet. GG flour (Meyproguar) of high MW ($\approx 2 \times 10^6$) was purchased from Meyhall (Kreuzlingen, Switzerland). Two animals were housed per cage and maintained in temperature-controlled rooms (22°C), with the dark period from 2000 to 0800 h. Rats were maintained and handled according to the recommendations of the Institutional Ethics Committee (Clermont-Ferrand University). The body weight of rats was recorded every 48 h during the experimental period; food intake and fecal excretion were recorded over three 2-d periods throughout the last 10 d.

Sampling procedures. Rats were killed at the end of the dark period, at which time cecal fermentations are still very active. They were anesthetized with sodium pentobarbital (40 mg/kg) and maintained at 37°C. An abdominal incision was made, and blood (1 mL) was drawn from both the portal vein and the abdominal aorta. The blood of each animal was placed in plastic tube containing heparin and centrifuged at $10,000 \times g$, for 5 min. After centrifugation, plasma was removed and kept at +4°C for lipid and lipoprotein analysis. After blood sampling, the cecal content was removed and weighed; two samples of it were transferred to microfuge tubes and immediately frozen at −20°C.

The small intestine was clamped at the pylorus and the ileal-cecal junction, removed, stripped of mesentery and fat, and weighed. The small intestine was halved to facilitate handling, and the content of each section was emptied into a preweighed tube by finger stripping and then frozen at −20°C. A portion of liver was freeze-clamped and stored at −80°C for the measurement of liver lipids. Two grams of liver were homogenized in 4 mL of an ice-cold buffer 1 (50 mmol/L Tris-hydrochloride, 250 mmol/L sucrose, 50 mmol/L EDTA, 2 mmol/L dithiothreitol, and 2 μmol/L leupeptin, pH 7.2) with a Potter-Elvejhem homogenizer (Braun, Melsungen, Germany) at moderate speed. The homogenate was first centrifuged at $10,000 \times g$ (15 min, 4°C); the resulting supernatant was then centrifuged at $100,000 \times g$ (60 min, 4°C). Pellets were resuspended in 2 mL of chilled buffer 1. The centrifugation procedure was repeated, and the resulting pellets were homogenized in 1 mL of buffer 2 (sucrose, 100 mmol/L; KCL, 50 mmol/L; K phosphate, 40 mmol/L; EDTA, 30 mmol/L; dithiothreitol, 1 mmol/L; pH, 7.2). The microsomal preparation was stored at −80°C until measurement of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase activity. The microsomal content of proteins was determined using the Pierce BCA reagent kit (Interchim, Montluçon, France).

Surgical procedure. In a separate series of anesthetized rats, a mid-line laparotomy was performed and the bile duct was exposed and ligated distally. The bile duct was then catheterized with a PE10 polyethylene catheter (Biotrol, Paris, France), and bile was allowed to drain for 30 min and then collected for two 30-min periods into preweighed vials cooled on ice. Bile volume was determined gravimetrically.

Analytical procedures. SCFA concentrations were measured by gas–liquid chromatography after ethanolic extraction of samples on supernatants ($8,000 \times g$, 5 min at 4°C) of cecal content. Bile acid analysis was conducted either directly on bile, or from cecal content, small intestine content or feces extracted by a two-step procedure. For this purpose, 1-vol sample was first dispersed in 10 vol of ethanolic KOH (0.5 M) using a Polytron disintegrator (Lucerne, Switzerland) and extracted at 70°C for 2 h, then 1 vol of this suspension (typically 2.5 mL) was redispersed in 4 vol of ethanolic KOH and reextracted at 70°C for 2 h. Bile acids were quantified using the reaction catalyzed by the 3-(α-hydroxysteroid dehydrogenase (E.C. 1.1.1.50; Sigma, St. Louis, MO). Sterol analysis was conducted by gas–liquid chromatography. Neutral steroids were extracted three times with 1 mL of hexane from a 100-μL aliquot of the alkaline ethanolic extract. After addition of 5-α-cholestane as an internal standard, the solvent was evaporated under a stream of N_2 and the residue dissolved in hexane. Portions (0.5 μL) of this extract were injected into a gas chromatograph (Delsi 330, Paris, France) equipped with a 12 m × 0.25 mm (i.d.) fused-silica capillary column (BP10; SGE, Villeneuve-St.-Georges, France) and a flame-ionization detector. Helium was used as a carrier gas, and the sterols were separated isothermally at 260°C. Sterols were calculated from the peak areas relative to the peak area of the internal standard. Triglycerides (Biotrol, Paris, France) and total cholesterol (BioMérieux, Charbonnières-les-Bains, France) were determined in plasma and bile (only cholesterol) by enzymatic procedures.

Plasma lipoproteins were separated on a density gradient by preparative ultracentrifugation (16), in a TST 41.14 swinging-bucket rotor (Kontron, Zürich, Switzerland) at $100,000 \times g$ for 36 h (15°C). Because of low level of plasma low density lipoprotein and the partial overlapping of high density lipoprotein (HDL)1 and HDL2 fractions in rats, only two fractions were considered: the fraction of density < 1.040 kg/L (chiefly triglyceride-rich lipoproteins, together with some low density lipoprotein) and the fraction of density > 1.040 kg/L (HDL). The cholesterol content of each fraction was determined by the method described above. Liver triglyceride and cholesterol were extracted and analyzed as described by Mazur *et al.* (17), and a control serum (Biotrol-33 Plus) serving as the control of analysis accuracy was treated similar to samples.

Enzyme activities. The activity of HMG-CoA reductase (E.C. 1.1.1.34) was determined on microsomal fractions as described by Wilce and Kroone (18). Labeled mevalonolac-

tone was separated from unreacted HMG-CoA by column chromatography using AG1-X8 resin (200–400 mesh, formate form; BioRad, Paris, France). Specific radioactivity of the enzyme was expressed in pmole of [3-^{14}C]HMG-CoA transformed in [^{14}C]mevalonolactone per min per mg of microsomal protein, after correcting for recovery of [^{3}H]mevalonolactone from the column.

Calculation and data analysis. The cecal pool was calculated as: cecal concentration (mmol/L) × cecal content volume (mL). Values are given as the means ± SEM and, where appropriate, significance of difference ($P < 0.05$) between mean values was determined by analysis of variance coupled with the student Newman-Keuls' Test.

RESULTS

Effects of diets on body weight, cecal development, cecal pH, and cecal fermentations. As indicated in Table 2, there were no significant differences in body weight between control rats and rats fed 2.5% GG or 0.5% cholestyramine.The cecal weight was significantly enhanced in rats fed the GG diet (+72%) with a similar increase of cecal wall weight. Only the GG diet caused an acidification of the cecal content (pH 6.60 compared to 7.00 for control rats). Rats fed the GG diet had cecal SCFA concentration of 135 mmol/L, compared to about 90 mmol/L for rats adapted to the control or the cholestyramine diet. Similarly, the total SCFA pool was significantly enhanced only in rats fed GG diet (+178% compared to the control); futhermore, there was a higher molar proportion of propionate in rats fed GG (38%, vs. 24 and 29% for the control and cholestyramine-fed rats, respectively).

Effects of diets on biliary secretion and fecal excretion of acidic and neutral sterols. As shown in Table 3, the biliary flow was higher (not significantly) in rats fed the GG diet than in the control rats, and the biliary bile acid secretion was significantly enhanced only in rats fed GG (+36% above the control values). Futhermore there was a significant increase in biliary cholesterol excretion (+60% above the control values) in rats fed GG diets and a slight increase with rats fed a cholestyramine diet. The bile acid content of small intestines in rats fed GG and cholestyramine diets was slightly higher than in the control rat (about +35%). The cecal pool of bile

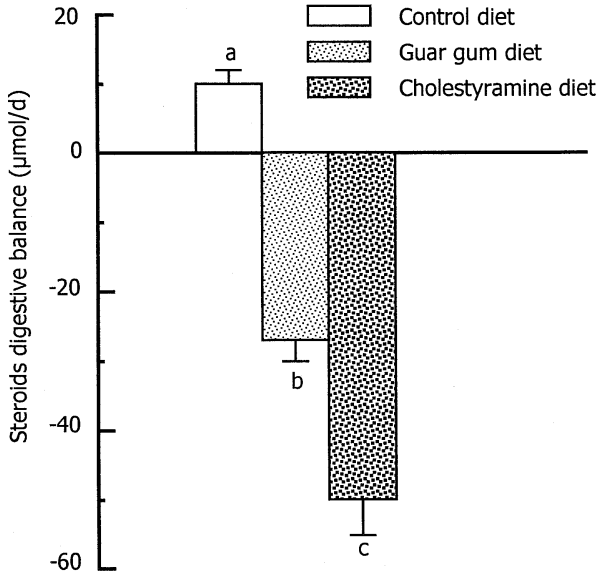

FIG. 1. The steroid balance is referred to as: cholesterol intake – total steroids excretion. Each value is the mean ± SEM, $n = 10$. Bars not sharing a common letter are significantly different ($P < 0.05$).

acids in rats adapted to the GG diet was similar to that found in control rats (14.8 µmol); but it was significantly increased in rats fed the cholestyramine diet (18 µmol). There was a substantial excretion of sterols (chiefly coprostanol) amounting to 61 µmol/d in the control diet, 123 µmol/d in the GG diet, and 106 µmol/d in the cholestyramine diet. Coprostanol excretion was significantly enhanced in rats fed the GG and cholestyramine diets (87 and 71 µmol/d, respectively, vs. 39 µmol/d for the control diet). Taking into account the daily cholesterol intake (116–131 µmol/d), it appears that the sterol net absorption was markedly lowered by GG and cholestyramine (8 and 11 µmol/d, respectively, vs. 55 µmol/d for the control); as a result, the apparent cholesterol digestibility was reduced (6 and 9% for GG and cholestyramine diets, respectively, compared to 47% for the control diet). Fecal bile acid excretion was enhanced only with the cholestyramine diet (+45% compared to the control diet). Furthermore, total steroid excretion was significantly enhanced with GG and cholestyramine diets (+53 and +62%, respectively). The total steroid balance (Fig. 1) was +13 µmol/d in the control diet;

TABLE 2
Effects of the Diets on the Final Body Weight and Cecal Digestive Parameters[a]

Diet group	Control	Guar gum	Cholestyramine
Final body weight (g)	323 ± 10	307 ± 6	322 ± 7
Cecal weight (g)	2.24 ± 0.16^{a}	3.77 ± 0.32^{b}	2.71 ± 0.18^{a}
Cecal wall weight (g)	0.63 ± 0.01^{a}	0.85 ± 0.03^{b}	0.69 ± 0.05^{a}
Cecal pH	7.00 ± 0.07^{a}	6.60 ± 0.03^{b}	7.11 ± 0.06^{a}
Cecal SCFA concentration (mM)	91 ± 7^{a}	135 ± 9^{b}	88 ± 6^{a}
Cecal SCFA pool (µmol)	114 ± 6^{a}	318 ± 10^{b}	118 ± 5^{a}
Molar ratio of cecal SCFA (acetate/propionate/butyrate)	(62:24:12)	(46:38:16)	(62:29:10)

[a]Each value is the mean ± SEM, $n = 10$. Values within a row that are not followed by a common superscript letter are significantly different ($P < 0.05$). SCFA, short-chain fatty acid.

TABLE 3
Effects of the Diets on Bile and Intestinal Bile Acid Concentration, and on the Fecal Excretion of Steroids[a]

Diet group	Control	Guar gum	Cholestyramine
Bile			
Bile flow (mL/h)	1.06 ± 0.08[a]	1.26 ± 0.32[a]	0.95 ± 0.12[a]

Total steroids (μmol/d)	103 ± 8[a]	158 ± 12[b]	167 ± 13[b]
Cholesterol intake[c] – neutral sterol excretion (μmol/d)	55 ± 3[a]	8 ± 5[b]	11 ± 3[b]

[a]Each value is the mean ± SEM, $n = 10$. Values within a row that are not followed by a common superscript letter are significantly different ($P < 0.05$).
[b]The cecal bile acid pool (μmol) was calculated: [bile acid] × cecal content, namely the difference between total cecal weight and the cecal wall weight.
[c]Cholesterol intake was (in μmol/d): 116 ± 3 (control), 131 ± 5 (guar gum), and 117 ± 6 (cholestyramine).

whereas it was negative for GG and cholestyramine diets (–27 and –50 μmol/d, respectively).

Effects of diets on plasma and liver lipids concentration and HMG-CoA reductase activity. As shown in Table 4, the plasma cholesterol concentration was significantly decreased in rats fed the GG and cholestyramine diets compared to control rats (–25 and –13%, respectively); there was no significant triglyceride-lowering effect. In rats fed the control diet (0.2% of cholesterol), the major part of plasma cholesterol was found in the density < 1.040 kg/L (Fig. 2). GG effectively lowered cholesterol in this fraction (–51%), but cholestyramine was less effective (–30%). The cholesterol of density > 1.040 kg/L fraction was not significantly modified by any of the diet conditions. Furthermore GG and cholestyramine diets decreased cholesterol concentration in the liver. HMG-CoA reductase activity significantly increased with the GG and cholestyramine diets (+86 and +339% vs. the control, respectively). Liver triglycerides were not significantly affected.

DISCUSSION

Numerous studies have demonstrated that soluble fibers like GG exert a cholesterol-lowering effect in human or animal models (19,20) when there is a substantial dietary supply of cholesterol ranging from 0.2 to 1% (21,22). Similarly, in this present study by using 0.2% cholesterol diets, GG significantly lowered plasma cholesterol concentration (–25%), but cholestyramine was apparently less effective (–13%). The cholesterol-lowering effect of GG is probably connected to its ability to elevate the viscosity in the small intestine lumen (2,23), which results in a decreased intraluminal mixing or increased thickness of the unstirred water layer (2,13). Such changes would affect cholesterol absorption, hence neutral sterol excretion. Bile acid-binding capacity is questionable for GG since it is devoid of suitable polar groups ($–NH_3^+$, $–COOCa^+$) and of polysaccharidic cavity (or helical structure) to include steroids; nevertheless, some data *in vitro* sug-

TABLE 4
Effects of the Diets on Lipid Metabolism Parameters[a]

Diet group	Control	Guar gum	Cholestyramine
Plasma			
Cholesterol (mM)	1.94 ± 0.06[c]	1.45 ± 0.05[a]	1.69 ± 0.04[b]
Triglyceride (mM)	2.25 ± 0.36[b]	1.94 ± 0.21[b]	1.49 ± 0.19[a]
Liver			
Cholesterol (mg/g liver)	5.6 ± 0.5[b]	3.6 ± 0.5[a]	3.1 ± 0.4[a]
Triglyceride (mg/g liver)	10.0 ± 1.2	8.3 ± 0.5	8.9 ± 1.5
Microsomal HMG-CoA reductase (pmol/min·mg protein)	20 ± 2[a]	37 ± 5[b]	85 ± 7[c]

[a]Each value is the mean ± SEM, $n = 10$. Values within a row that are not followed by a common superscript letter are significantly different ($p < 0.05$). HMG-CoA, 3-hydroxy-3-methylglutaryl-CoA.

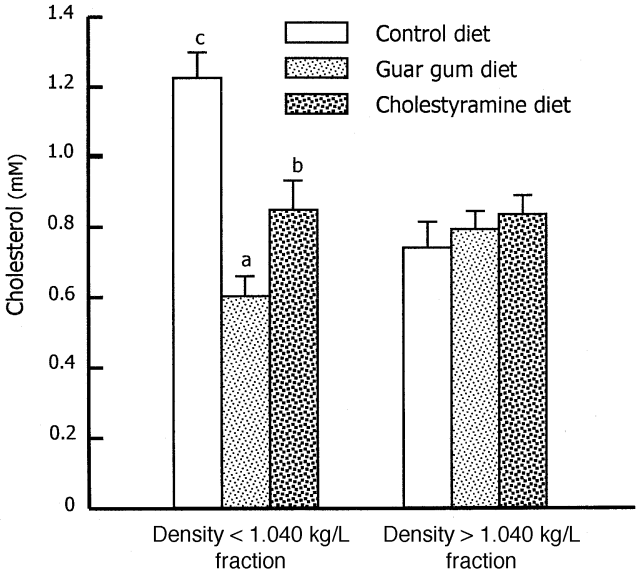

FIG. 2. Changes in cholesterol concentration of lipoprotein fractions, in control rats and rats adapted to guar gum or cholestyramines. Each value is a mean ± SEM of three pools of rat plasma representing 10 animals per pool. The fractions with a density lower than 1.040 kg/L correspond chiefly to triglyceride-rich lipoproteins, with a minor contribution of low density lipoprotein. The fractions with a density higher than 1.040 kg/L correspond essentially to high density lipoprotein. Bars not sharing a common letter are significantly different ($P < 0.05$).

gest that this capacity does exist for GG (14). On the other hand, bile-acid binding by cholestyramine is effective (24), but it binds a relatively small portion of trihydroxy bile acids which dissociate to varying extents from the sequestrants in the terminal ileum (25).

Notably in this study, fecal bile acid excretion did not significantly increase in rats fed the GG diet, although their biliary secretion (+36%) did increase, which is contrary to reports, particularly in hamster or guinea pig models, indicating that bile acid excretion is more responsive to dietary hydrocolloids than sterol excretion (15,21). The fact that fecal bile acid excretion was not elevated by GG probably reflects a lower availability of exogenous cholesterol, since GG apparently lowers cholesterol absorption.

GG diets also may increase both biliary secretion and intestinal bile acid pools (26–28). In the present experiments, the cecal bile acid pool was not enlarged in rats fed the GG diet, compared to fiber-free control rats, in spite of a higher rate of hepatic secretion. With higher levels of GG in the diet (5% or higher), this cecal pool was significantly increased, even if the fecal bile acid excretion was marginally increased (22). More efficient bile acid recovery in the small intestine is needed. Bile acid recovery and biosynthetic pathways are coordinately regulated and could be responsive to the size of the bile acid pool in enterohepatic circulation (29). Some data support the view that ileal bile acid transport could be increased with dietary fermentable carbohydrates (22,30). The mechanisms involved in this adaptive response could be either the hypertrophy of the ileal mucosa, along with an elongation of small intestine (31,32) affording higher capacity of reabsorption or upregulation of the ileal transporter, which is activated by cholic acid (33). The fact that an intestinal bile acid pool increase elicited by GG represents an effective stimulus is unproven. The large intestine also contains a noticeable bile acid pool (22) of which most is insolubilized due to several factors (acidic luminal pH, high Ca concentration, binding on microorganisms) and the remainder is reabsorbed by a passive (but relatively efficient) process. With its effectiveness depending on its capacity to impair bile acid reabsorption from the large bowel along with small intestine reabsorption (34), cholestyramine increases the bile acid cecal pool and the fecal excretion rate, greater than the control.

In control rats, dietary cholesterol drastically subdued HMG-CoA reductase basal activity, but GG and cholestyramine significantly activated this enzyme. Although the activation was greated with cholestyramine than with GG, cholestyramine was less effectively hypocholesterolemic in the present model. In rats adapted to 0.3% cholesterol diets, hepatic cholesterolgenesis could be reactivated in pectin- or psyllium-fed rats (35). Acceleration of the enterohepatic cycling of bile acids with GG may tend to counteract HMG-CoA reductase activation (36), which could explain more-effective cholesterol-lowering with GG than with cholestyramine even though the fecal excretion of bile acids was lower with GG than with cholestyramine. Another difference between GG and cholestyramine is that GG is broken down to SCFA by the large intestine microflora. In fact, with the relatively low GG level used in the present experiment, it seems unlikely that SCFA make a major contribution to liver metabolism, although some specific effects of propionate on lipid metabolism have been proposed (37). Also, soluble fibers such as those in GG tend to limit the postprandial increase of insulin (38,39), which is an important factor in the regulation of HMG-CoA reductase activity (40).

In conclusion, it appears that, in the present rat model fed low-cholesterol diets, a moderate percentage of GG (2.5%) may be more effective than 0.5% cholestyramine to lower plasma cholesterol. The fact that GG mainly affects the cholesterol digestive balance and lowers bile acid availability in the large intestine is enlightening by suggesting that an accelerated bile acid transfer from the ileum to the large intestine is not the unique mechanism whereby fibers stimulate bile acid secretion by the liver, in parallel to activation of cholesterol 7α-hydroxylase. Accordingly, Pandak *et al.* (41) postulated the existence of a factor likely to downregulate the liver cholesterol 7α-hydroxylase (possibly an intestinal peptide) that would be secreted or absorbed from the intestine in the presence of bile acids; whether fibers could interfere with such a process awaits further investigation. Also, this study suggests that bile acid reabsorption may be increased along with enlargement of the intestinal pool, even in the presence of viscous compound such as GG; it is still unproven if this reflects enhanced passive reabsorption along the small intestine or some upregulation of ileal transport. Bile acids are considered as potential initiators of colonocyte proliferation

(42,43), and some concerns have been raised about the risk of increasing bile acid transfer into the colon for the purpose of plasma cholesterol-lowering, especially with high-fat diets. In this respect, moderate concentrations of GG seem interesting because they combine effective cholesterol-lowering and limited transfer of bile acids into the colon. Nevertheless, even if this transfer were to be increased, fermentable hydrocolloids would also elicit processes in the large intestine (acidification, adsorption, *in situ* reabsorption) which tend to maintain luminal bile acids at a low level.

ABSTRACT: Sphingomyelin (SM) and cholesterol (Chol) are major surface lipid constituents of plasma lipoproteins. We investigated the effects of SM and Chol on the plasma clearance of lipid emulsions as a model for lipoprotein particles in rats. The presence of Chol facilitated the removal of emulsion particles from plasma, whereas SM delayed particle removal. Preinjection of lactoferrin, an inhibitor of the apolipoprotein E (apoE) receptor, revealed that the differences in clearance of emulsions were due to the differences in affinity for the apoE receptor. Measurement of apolipoprotein binding suggested that the balance of apoE and apoC (apoC-II and apoC-III) bound to emulsions caused the difference in plasma clearance of emulsion particles. That is to say, SM in the emulsion surface decreased binding of apoE, which led to a longer circulation of emulsion particles in plasma. Chol, on the other hand, decreased the ratio of apoC to apoE, which may have promoted emulsion uptake through the apoE receptor. We also examined *in vitro* lipolysis using immobilized lipoprotein lipase (LPL) in a heparin affinity column. Lipolysis rates were significantly reduced by the incorporation of SM into the emulsion surface, but not by the incorporation of Chol, indicating that SM in the lipoprotein surface is an important lipid component regulating LPL-mediated lipolysis. Our results suggest that the presence of SM and Chol in the lipoprotein surface plays an important role in the circulation behavior and LPL-mediated lipolysis of lipid emulsions through their effect on the selectivity of plasma protein binding.
Lipids 33, 773–779 (1998).

Lipid emulsions composed of triacylglycerol (TG) and phosphatidylcholine (PC) have been routinely used in parenteral nutrition for almost 30 yr. Recently, lipid emulsions were used as drug carriers in drug delivery systems (1). For example, the delivery of prostaglandin E_1 in injectable lipid emulsions has been proven, and is commercially available (2,3). However, it is likely that this type of emulsion is rapidly metabolized by lipoprotein lipase (LPL) and is readily taken up by the liver after intravenous injection. Because the release of drugs in blood is considered to depend on both the lipolysis of TG and the clearance of the particles from plasma, control of these metabolic processes is necessary in order to improve lipid emulsions as injectable drug carriers.

Emulsion droplets have a size and lipid composition similar to chylomicrons and have also been used as models for plasma lipoproteins. The metabolism of protein-free lipid emulsions in rats is comparable to that of chylomicrons (4,5). On entering the plasma, lipid emulsions rapidly acquire apolipoproteins, such as apoA-I, C-II and E, from circulating lipoproteins. It is thought that apoC-II is an activator of LPL, and apoE is necessary for recognition by lipoprotein receptors. On the other hand, an inhibitory effect on hepatic uptake through apoE-specific receptors by apoC-I, C-II, and C-III has been reported (6–11). The metabolism of lipid emulsions can be affected by the selective binding of these apolipoprotein to lipid particles.

Within a blood compartment, TG-rich lipoproteins are converted into remnants through the hydrolysis of TG by LPL (12). These remnants are subsequently taken up by the liver, although hepatic removal appears to be accomplished by several overlapping mechanisms (13). Lipolysis of TG in chylomicrons produces cholesterol (Chol)-enriched remnant particles (14). Presumably, the amount of Chol in the lipoprotein surface is an important factor influencing the metabolism of lipoproteins. In addition, differences in sphingomyelin (SM) content among plasma lipoproteins (15–19) may affect both lipolysis by LPL at endothelial sites and recognition by lipoprotein receptors. However, minimal information is available on the physiological role of SM in lipoprotein metabolism. We assume that the lipid composition of lipoproteins or lipid emulsions plays a crucial role in the metabolism of the particles. In other words, it must be possible to regulate both the clearance from plasma and triolein (TO) lipolysis of artificial lipid emulsions by modulating the lipid composition of an emulsion surface.

Experimental emulsions often contain liposome-like particles (20), which may affect the metabolism of emulsions. In this study, we prepared isolated emulsions without liposomes and evaluated the effects of Chol and SM in the emulsion surface on the lipolysis and clearance from plasma in rats. The selectivity of apolipoprotein binding was estimated, and its

relevance to plasma clearance is discussed in this paper. These results are useful both for the deeper understanding of lipoprotein metabolism and for the development of improved lipid-emulsion drug carriers.

EXPERIMENTAL PROCEDURES

Materials. Egg yolk PC was kindly provided by Asahi Kasei Co. (Tokyo, Japan). The purity (over 99.5%) was determined by thin-layer chromatography. Egg yolk SM, Chol, and TO were obtained from Sigma Chemical Co. (St. Louis, MO) and were used without purification. Fatty acid-free bovine serum albumin and sodium heparin were obtained from Sigma. Cholesteryl 1-pyrenedecanoate was purchased from Molecular Probes Inc. (Eugene, OR). Bovine lactoferrin was purchased from Wako Pure Chemicals (Kyoto, Japan). Heparin affinity columns (HiTrap® Heparin, 1 mL) were obtained by Pharmacia Biotech (Uppsala, Sweden).

Preparation of emulsions. We prepared lipid emulsions by the method described previously (20) using a high-pressure emulsifier (Nanomizer; Nanomizer Inc., Tokyo, Japan). Briefly, PC, Chol, SM and a fluorescent probe, cholesteryl 1-pyrenedecanoate, were mixed in chloroform. After evaporation of the solvent, the mixture was dried in a vacuum, resuspended in 30 mL of buffer [10 mM Tris-HCl, 150 mM NaCl, 1 mM EDTA, and 0.01% (wt/vol) NaN_3] and successively emulsified [under a pressure of 1000 kg/cm^2 for 6 min, at 60°C for TO–PC, TO–PC/SM (2:1) emulsions; 15 min, at 30°C for TO–PC/Chol (3:2) emulsions]. After removing contaminating vesicles by ultracentrifugation, homogeneous emulsion particles were obtained. We confirmed the complete separation of emulsion particles from vesicles by ^{31}P nuclear magnetic resonance spectra in the presence of praseodymium as described previously (20). All types of emulsion particles were characterized by determining their particles size and lipid composition. The weight-averaged particle size of each emulsion was 110 ± 20 nm as determined from quasi-elastic light-scattering measurements (Photal LPA-3000/3100; Otsuka Electronic Co., Osaka, Japan). Phospholipid concentration was determined by the phosphorus assay according to the method of Bartlett (21). SM concentration was determined by thin-layer chromatography. The concentration of Chol was determined using enzymatic assay kits free cholesterol E-test Wako obtained from Wako Pure Chemicals. As a result, we confirmed that the surface lipid composition of isolated emulsions was the same as the surface lipid composition of starting lipid mixtures.

In vivo *experiments.* Emulsions were labeled with a fluorescent probe, cholesteryl 1-pyrenedecanoate, in phosphate-buffered saline (8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 136.9 mM NaCl, 2.7 mM KCl, pH 7.4). The probe to TO molar ratio was 1:500. Male Wistar rats (Shimizu Laboratory Supplies Co., Ltd.) weighing approximately 200 ± 20 g were fasted overnight. Rats were anesthetized with sodium pentobarbital (Nembutal; Abbott Laboratories, Chicago, IL), and fluorescence-labeled emulsions were injected into the exposed femoral vein as a bolus of 25-μmol emulsion TO (*ca.* 22 mg TO) in 0.5 mL irrespective of emulsion composition and size. Blood samples of 250 μL were collected from the carotid vein at different time points and immediately centrifuged to separate the plasma. To remove the proteins in plasma, 600 μL of chloroform/methanol 1:1 (vol/vol) was added to 100 μL of each plasma sample. The fluorescence intensity of the solvent phase was measured by an Hitachi (Tokyo, Japan) F-4500 spectrofluorometer. Plasma emulsion concentration was calibrated by the fluorescence intensity of known concentration of emulsions. TO concentration in plasma was determined through enzymatic assay by the TG-G test Wako (Wako Pure Chemicals). The plasma clearances of emulsion particles and emulsion TO were simulated with a mono-exponential curve-fitting program. The initial concentration at time zero was estimated by extrapolating from the fitting curve. The concentration of emulsion particles and emulsion TO remaining in plasma were represented as a percentage of the initial blood concentration. The plasma clearances obtained by fluorescence probe and enzymatic assay were consistent with those measured using radiolabeled glycerol tri[1-^{14}C]oleate and 1, 2-^{3}H-cholesteryl hexadecylether (results not shown).

Apolipoprotein binding. Binding amounts of apoC-II, C-III, and E to lipid emulsions were determined by the ultracentrifugation method as described previously (22). Human plasma was centrifuged for 1.5 h at 27,000 rpm in a Beckman (Fullerton, CA) SW 28 rotor to remove the chylomicron-containing top fraction. Emulsions were incubated with chylomicron-free plasma for 20 min at 37°C. The final concentration of emulsion TO was 3.2 mM, which corresponded to the initial emulsion concentration in plasma immediately after the injection in *in vivo* experiments. The mixtures were ultracentrifuged for 20 min at 32,000 rpm in a Beckman SW 50.1 rotor. The equilibrium concentration of apolipoprotein in the bottom fraction was determined in single radical immunodiffusion assay plates, purchased from Dai-ichi Pure Chemicals (Tokyo, Japan). The amounts of apoC-II, C-III, and E binding were calculated from the difference between the apolipoprotein concentration before and after ultracentrifugation.

Lipolysis assay with heparin affinity column. Purified bovine milk LPL suspended in 3.8 M ammonium sulfate, 0.02 M Tris-HCl, pH 8.0, was purchased from Sigma Chemical Co. LPL solution was prepared according to the previously described methods (23). LPL was immobilized in a heparin affinity column. Emulsions (final concentration of TO was 1 mM) in 3 mL of Tris-HCl buffer [4% fatty acid-free bovine serum albumin, 180 mM Tris-HCl, 100 mM NaCl, 1 mM EDTA, 0.01% (wt/vol) NaN_3, pH 8.5] containing 30 vol% of human plasma were circulated through the affinity column (1.65 μg, LPL) at 1.2 mL/min using a peristaltic pump. The temperature was kept constant at 37°C by a thermostat. Free fatty acids (FFA) released during circulation were measured at the indicated times by the enzymatic colorimetric reagent, NEFA C (Wako Pure Chemicals).

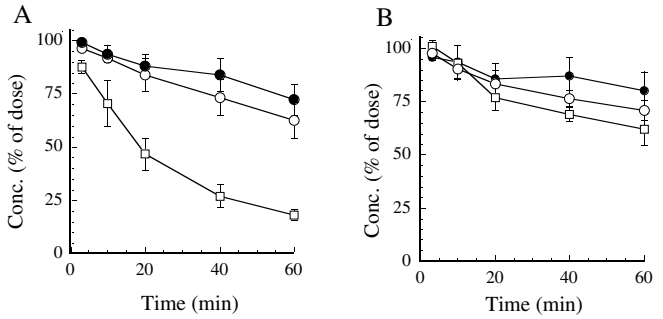

FIG. 1. Plasma clearance of lipid emulsions in rats without (A) or with (B) preinjection of lactoferrin. ○, triolein (TO)–phosphatidylcholine (PC) (control); ●, TO–PC/sphingomyelin (SM) (2:1 molar ratio); □, TO–PC/cholesterol (Chol) (3:2) emulsions. Concentration of emulsion particles is represented as percentage of dose. Initial concentration at time zero was estimated by extrapolating from a fitting curve. Data represent the mean ± SD of five or six rats.

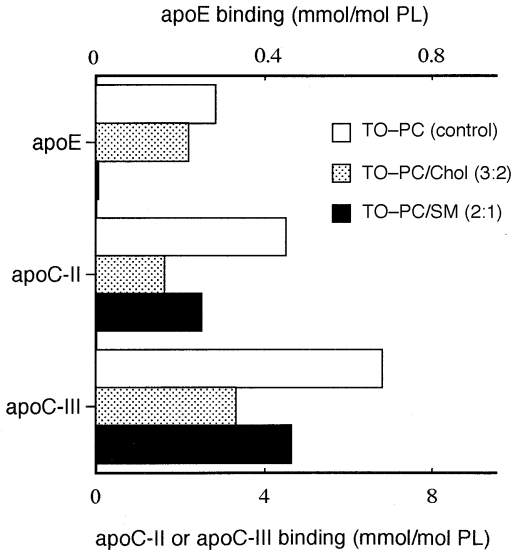

FIG. 2. Effects of SM and Chol on apolipoprotein (apo) binding to emulsions. Open bar, TO–PC (control); dotted bar, TO–PC/Chol (3:2 molar ratio); closed bar, TO–PC/SM (2:1) emulsions. Experiments on two separate preparations were performed in duplicate, each giving similar results. PL, phospholipids. See Figure 1 for other abbreviations.

RESULTS

Effect of Chol and SM on plasma clearance of emulsion particles. Figure 1A shows plasma clearance after injection of fluorescence-labeled emulsions. We prepared three types of labeled emulsions: TO/PC (control); TO–PC/Chol (molar ratio, 3:2); and TO–PC/SM (2:1). Approximately 60% of the injected control emulsions was detected in the plasma 1 h after injection. TO–PC/Chol emulsions disappeared more rapidly than the control emulsions, with only 20% of the injected emulsions remaining after 1 h. In contrast, the removal of emulsion particles was delayed when SM was incorporated into the surface. Two hours after emulsion injection, 25.1 ± 3.9 and 51.0 ± 5.9% of TO–PC and TO–PC/SM (2:1) emulsions remained in plasma, respectively. SM has a significant effect on emulsion clearance.

To elucidate the difference in plasma clearances caused by Chol or SM in the emulsion surface, we investigated the effects of lactoferrin (70 mg/kg rat) on emulsion removal from plasma. In previous studies, lactoferrin was shown to selectively block the apoE-mediated uptake of chylomicrons and very low density lipoproteins in rats (24–26). This lactoferrin effect has been attributed to an arginine/lysine-rich sequence at position 25-31 that resembles the binding site (amino acids 142–148) of apoE (27). Figure 1B shows plasma clearance of injected emulsions with preinjection of lactoferrin 1 min prior to emulsion injection. The presence of lactoferrin had little effect on the clearance of control emulsions, while the clearance of TO–PC/Chol emulsions was delayed effectively. Also, the presence of lactoferrin had almost no effect on the clearance of TO–PC/SM emulsions. Thus, all types of emulsions were removed from plasma at similar rates in the presence of lactoferrin.

Apolipoprotein binding to lipid emulsions. In artificial lipid emulsions as well as in TG-rich lipoproteins, the binding of exchangeable apolipoprotein to the surface of lipid particles plays a crucial role in their metabolism. To investigate the effect of the lipid composition of the emulsion surface on the binding behavior of apolipoprotein, we examined the binding of apoC-II, C-III, and E to the three emulsion types

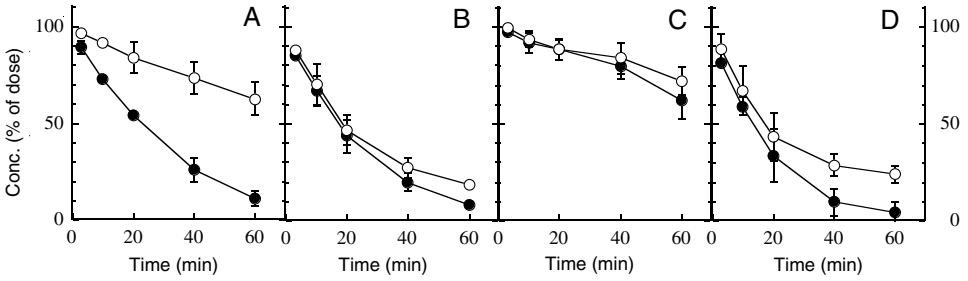

FIG. 3. Plasma clearance of emulsion particles and emulsion TO. ○, Emulsion particle concentration of injected dose as determined by fluorescence measurement. ●, TO concentration of injected dose determined by enzymatic assay. Initial concentrations at time zero of emulsion particles and emulsion TO were estimated by extrapolating from a fitting curve. (A) TO–PC (control); (B) TO–PC/Chol (3:2); (C) TO–PC/SM (2:1), (D): TO–PC (diameter is 200 nm) emulsions. Data represent the mean ± SD of five or six rats. See Figure 1 for abbreviations.

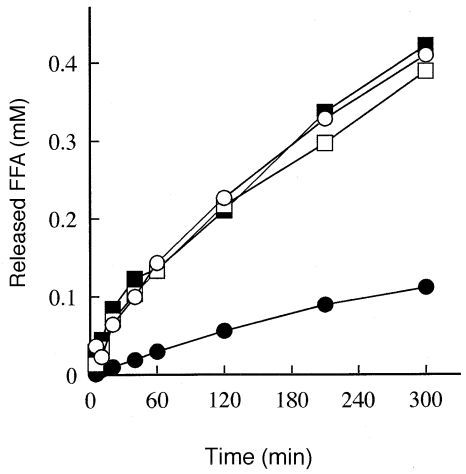

FIG. 4. Released free fatty acid (FFA) during lipolysis with lipoprotein lipase (LPL) in heparin affinity column. ○, TO–PC (control); ●, TO–PC/SM (2:1, molar ratio); □, TO–PC/Chol (3:2). ■, TO–PC (diameter is 200 nm) emulsions. The mixtures of plasma and emulsions in Tris buffer were circulated through the immobilized LPL attached with columns. Temperature was 37°C. TO concentration of lipid emulsions was 1 mM. Each value is a mean of duplicated determinations. See Figure 1 for other abbreviations.

in human serum. Figure 2 shows the effect of Chol and SM on the amount of apolipoprotein binding per surface phospholipid. Incorporation of SM into the emulsion surface drastically reduced the amount of apoE binding, while only a slight decrease was observed in the case of Chol incorporation. On the other hand, the amounts of apoC-II binding to TO–PC/Chol and TO–PC/SM emulsions were about one-third and one-half of the control values, respectively. We also found that the binding behavior of apoC-III was similar to that of apoC-II, with Chol reducing the binding of apoC more effectively than SM.

Plasma clearance of emulsion TO. In metabolic processes of lipid emulsions, the emulsion core, namely TO, is hydrolyzed by LPL on endothelial cells. We investigated the plasma clearance of core TO as well as that of emulsion particles (Fig. 3). Emulsion TO was removed from plasma by two processes: (i) the lipolysis of TO at the endothelial surface of capillaries, and (ii) the uptake of emulsion particles by the organs. Consequently, the difference between TO and emulsion particle concentration corresponds to the fraction of lipolysis *in vivo*. For control emulsions, TO in cores disappeared from plasma faster than the emulsion particles, indicating a significant degree of TO lipolysis in plasma. For TO–PC/Chol (3:2) and TO–PC/SM (2:1) emulsions, the small difference in clearance of emulsion particles and TO indicates minimal hydrolysis of emulsion TO by LPL. The rapid uptake of emulsion particles affects the lipolysis of emulsion TO. To determine the relationship between the clearance of emulsion particles and the amount of lipolysis *in vivo*, we examined the metabolism of large emulsion particles (diameter: 200 nm) composed of TO and PC in rats. As shown in Figure 3D, large emulsion particles were removed from plasma as rapidly as TO–PC/Chol (3:2) emulsions, and TO lipolysis was reduced to a level similar to TO–PC/Chol (3:2) emulsions.

Lipolysis in vitro. We measured FFA released during circulation of emulsions through immobilized LPL in a heparin affinity column. This lipolysis assay has the advantage of excluding the effects of particle-uptake by the organs as occurs *in vivo*, and allows the comparison of LPL activity with different emulsions. Figure 4 shows the time course of FFA released during lipolysis with LPL in a heparin affinity column. TO–PC/Chol (3:2) emulsions and large emulsion particles were hydrolyzed at rates similar to control emulsions, although both emulsions had low susceptibility to LPL *in vivo*. In contrast, as shown in Figure 4, lipolysis was negligible in TO–PC/SM (2:1) emulsions. This suggests that the key component in the lipoprotein surface regulating lipolysis was not Chol but SM. The presence of Chol is a determinant of early liver-uptake (Fig. 1), but has little influence on LPL activity (Fig. 4).

DISCUSSION

Phospholipid liposomes coexist with emulsion particles in commercially produced lipid emulsions and sonicated emulsions composed of TG and PC (28–32). We have shown the coexistence of liposomes and emulsion particles on the basis of a monolayer/bilayer equilibrium (33). To evaluate the emulsion kinetics in rats, it is necessary to separate excess liposomes completely, otherwise, coexisting liposomes may distort the clearance of emulsions through association with apolipoprotein or by other mechanisms. We prepared isolated lipid emulsions by ultracentrifugation and confirmed the absence of liposomes by the nuclear magnetic resonance method. As shown in Figure 1A, about 60% of the injected TO–PC (control) emulsions remained in rat plasma at 1 h after injection, which is compatible with results reported by Redgrave *et al.* (34) using isolated emulsions without liposomes.

We discovered that surface Chol promotes the removal of emulsions from plasma, while SM delays clearance of emulsions. In addition, the removal of TO–SM emulsions was slower than that of TO–PC/SM (2:1) emulsions (two hours after injection, 57.1 ± 9.4% of TO–SM emulsions remained in plasma.). Lipid emulsions in blood are mainly subject to uptake by the reticuloendothelial system and by apoE-recognizing receptors. Lactoferrin inhibits the apoE-mediated interaction of lipoproteins *in vivo* (24–26). Figure 1B suggests that the difference in emulsion removal (Fig. 1A) is due to the difference in the affinity with the apoE-mediated receptor. In fact, SM in the emulsion surface inhibited apoE binding to emulsions (Fig. 2) and delayed emulsion uptake by the liver. On the other hand, Chol in the emulsion surface decreased the ratio of apoC to apoE on the emulsions (Fig. 2) and promoted apoE-mediated uptake. The ratio of apoE to apoC correlated better with lipoprotein uptake than the absolute apoE content (13). Chol-containing emulsions are cleared from plasma rapidly because of a decrease in the inhibition effect of apoC on the apoE function. SM and Chol are lipid components regulating

the circulation time of emulsion particles in plasma through their effect on the selectivity of apolipoprotein binding.

Apolipoprotein are thought to interact surface PC layers with nestled helices. Apolipoprotein binding is likely to be reduced by the increase in the order of phospholipid layer. We proposed that either SM or Chol increases the order of emulsion surface and thereby reduces the total apolipoprotein binding to the lipid surface. The mechanism of the modulation of apolipoprotein binding in Chol- or SM-containing emulsions remains to be fully clarified. We have, however, obtained data indicating that the binding of apoC-II is regulated predominantly by the acyl chain order of surface lipids, whereas surface properties other than the acyl chain order may be important for the binding of apoE (Saito, H., and Arimoto, I., unpublished data). These differences in binding behavior may lead to differentials binding to emulsions depending upon the incorporation of Chol or SM.

Within a blood compartment, TG-rich lipoproteins are converted into remnants through the hydrolysis of core TG by LPL, and concomitantly become enriched in Chol at the lipoprotein surface (14). These remnants are subsequently taken up by the liver, although the precise mechanism of recognition is still unclear. Our results suggest that Chol enrichment resulting from TG hydrolysis reduces the binding of apoC to chylomicrons and leads to a rapid uptake through the apoE receptor and a termination of lipolysis by LPL. In addition, it may be possible that chylomicrons are metabolized and taken up by the liver more rapidly than very low density lipoproteins because the former contain little SM at the particle surface. Our results reveal physiologically significant evidence that the circulation behavior of lipoprotein particles is regulated by the lipid composition in the lipoprotein surface.

Emulsion TG is hydrolyzed by LPL located at the surface of the capillary endothelium before the lipid particles are taken up by organs. Lipolysis of lipid emulsions *in vivo* has been evaluated by the difference between the clearance of TO and emulsion particles (34,35) and by considering the competition between lipolysis and organ uptake. That is to say, if the uptake of the particles by organs is very rapid, LPL at endothelial sites will be unable to fully hydrolyze emulsion TG because the concentration of LPL substrate in plasma is decreasing too quickly.

As shown in Figure 3, the concentration of particles and TO of TO–PC/Chol (3:2) emulsions decreased concurrently in rat plasma. But it seems that Chol does not inhibit enzymatic activity; it promotes the removal of particles from plasma, resulting in a reduced amount of lipolysis. In fact, large emulsion particles which were removed rapidly from plasma appeared to show a low level of lipolysis (Fig. 3). To examine this in detail, LPL activity was determined in experimental conditions under which emulsion particles were circulating at all times without removal. As shown in Figure 4, we measured the lipolysis of different emulsions by using immobilized LPL in a heparin affinity column. This revealed that TO–PC/Chol (3:2) emulsions and large emulsions (diameter: 200 nm) were hydrolyzed at rates similar to the control emulsions. This supports the hypothesis that lipid particles which are rapidly removed from plasma are lipolyzed only to a limited extent *in vivo*. We also found that only SM-containing emulsions inhibited LPL susceptibility (Fig. 4). This is consistent with data in Figure 1 showing that SM decreased the lipolysis of TO despite the lengthy circulation of emulsion particles in the blood. From these results, it was concluded that SM is an important factor in regulating LPL activity in lipoprotein metabolism. On the contrary, Chol, which is a major component of plasma lipoproteins, was subject to enzymatic reaction in almost the same pattern as the control (Fig. 4). This is consistent with results showing that kinetic parameters of the LPL reaction were not affected by the addition of Chol (22).

ApoC-II is a well-known activator of LPL (36,37), and apoC-III exhibits an inhibitory effect upon LPL-mediated lipolysis (36). In these studies, however, apoC-III interfered with apoC-II in the activation of LPL only when the apoC-III concentration was extremely high compared with the physiological concentration (36). In addition, Wang *et al.* (38) have reported that apoC-II concentration is neither a determining factor in the *in vivo* hydrolysis of TG-rich lipoproteins nor a factor in the expression of hypertriglyceridemia. Also, very little apoC-II is required to maximally activate LPL (23,36, 39). The decrease in apoC binding by Chol and SM, therefore, is thought to have minimal influence on the LPL-mediated lipolysis. We recently showed that the inhibition of TO lipolysis by SM is attributed both to low affinity for, and reduced catalytic activity of, LPL on emulsion particles containing the phospholipid (23). Our results suggest that the content of Chol or SM in the plasma lipoprotein surface plays different roles in the regulation of clearance from plasma and the susceptibility to LPL in lipoprotein metabolism.

Emulsions of defined composition and metabolic behavior are of value not only to mimic plasma lipoproteins, but also to be vehicles for the delivery of lipophilic drugs to targeted organs. We found that emulsions containing SM were less susceptible to LPL and were very slow to be taken up by the liver after intravenous injection. Emulsions containing SM may, therefore, be appropriate carriers of lipophilic drugs which must circulate in the blood for a long time without hydrolysis of the core lipid. Chol-containing emulsions, on the other hand, would be useful for the rapid accumulation of lipophilic drugs in organs (mainly liver).

ABSTRACT: In studies of bovine plasma lipoproteins, apolipoprotein E (apoE) was not found associated with α-lipoproteins isolated over a broad range of densities. However, studies of cerebrospinal fluid (CSF) lipoproteins from other mammals have shown that apoE is a major apolipoprotein associated with high density lipoprotein, a fact that prompted us to determine if this were also the case in bovine CSF. CSF samples were obtained from animals with a surgically implanted catheter. Most analyzed samples were obtained from cows at various stages of the postpartum period; however, a few samples also were obtained at term or during pregnancy. Analyses of isolated ultracentrifugal fractions by polyacrylamide gel electrophoresis revealed the presence of two apo, with the expected molecular weights for apoE and apoA-I. By using both matrix-assisted laser desorption mass spectrometry and microsequencing techniques, we demonstrated that these apo are indeed apoE and apoA-I.

Lipids 33, 781–786 (1998).

The Shores (1) were the first to report on a novel apolipoprotein (apo) enriched in arginine amino acids and associated with very low density lipoproteins (hydrated densities less than 1.006 g/mL) in both humans and cholesterol-fed rabbits (2). They referred to this protein as the "arginine-rich protein." Subsequently, Swaney *et al.* (3), in their studies of lipoproteins, reported that a similar protein with a molecular weight of 35,000 was present on rat high density lipoprotein (HDL) (hydrated densities between 1.063 and 1.21 g/mL). This protein has since been designated apoE. In a variety of mammals, apoE is associated with α-lipoproteins, particularly those having hydrated densities within the low density lipoprotein (LDL) (hydrated densities between 1.020 and 1.063 g/mL) density range. This occurs when the ultracentrifugally isolated LDL is electrophoretically heterogeneous, i.e., the fractions contain both α- and β-lipoproteins (4–9). In most cases (8–11), the protein moiety of these α-lipoproteins contains apoA-I as the major apo, and apoE is one of the minor apo. Notable exceptions are rat α-migrating LDL which can be heavily enriched in apoE (12). By contrast, bovine α-LDL do not contain any discernible amounts of this apo (10).

With the onset of lactation, the concentration of cholesterol in bovine plasma can increase rapidly within 2 wk from 50 to over 300 mg/dL (13,14), due exclusively to changes in the levels of the main carrier of cholesterol, α-lipoproteins (10,15), with roughly 30% having hydrated densities between 1.020 and 1.063 g/mL (10). These α-lipoproteins, being elevated in concentrations throughout a wide range in density, have proven suitable for detailed characterization (10). When separated on a density gradient, compositional differences in the fractions were observed in both the lipid and protein moieties, but a protein corresponding in molecular weight to apoE was not detected in any of the fractions (10). Cordle *et al.* (16) also were unable to detect apoE in their studies of bovine plasma lipoproteins. However, an apo having a molecular weight between 36,000 and 40,000 was found associated with triacylglycerol-rich lipoproteins which are present in low concentrations in bovine plasma (17,18). To detect this protein the lipoproteins had to be isolated from large plasma volumes (17,18). Grummer *et al.* (18) in their studies proposed this protein to be apoE. Subsequent to these studies, two groups have published the sequence for bovine apoE based on analyses of hepatic cDNA (19,20).

In contrast to plasma where apoA-I is the major apo associated with HDL, Roheim *et al.* (21) in their studies of cerebrospinal fluid (CSF) HDL found that both apoE and apoA-I were the predominant apo. Pitas *et al.* (22) later reported apoE to be associated with lipoproteins within the HDL density range, primarily HDL_2 (hydrated densities between 1.090 and 1.121 g/mL) in canine CSF and HDL_3 (hydrated densities between 1.121 and 1.21 g/mL) in human CSF.

MATERIALS AND METHODS

Two sets of CSF samples were obtained from nine cows, which were part of the research herd at the experimental station of Texas A&M in Beeville, Texas. The initial set was obtained from six crossbred (*Bos taurus* × *B. indicus*; 1/2 Angus

× 1/4 Brahman × 1/4 Hereford), first-calf heifers 28–30 mon of age. Heifers in various stages of the peripartum and postpartum periods were maintained in lots measuring 25 × 9 m and fed hay and concentrate to maintain late pregnant and lactating females in excellent body condition (23). The second set consisted of CSF obtained postpartum (between 11 and 53 d) from three pluriparous crossbred (Brahman × Hereford, F_1) cows, 8 to 10 yr of age, and maintained as described above. Twelve samples, six from each of two cows, were drawn on different days, and four samples were obtained from a third cow on four other days.

Sampling and preparation of CSF. Indwelling third ventricle cannulae were installed surgically with animals under halothane anesthesia as previously described (24). Samples were taken with a tuberculin syringe before, during, and after parturition as determined by the experimental protocol. Sampling intervals ranged from 1 min to 6 h. Aseptic technique was employed at all times. A solution (50 μL) containing EDTA (37.2 g/L) and the oxytocinase inhibitor, phenanthroline (1 g/L), was added to each collection vial. Vials were then turned upside down, allowing the fluid to run off and residual fluid to dry on the walls. Samples were immediately placed on ice, within 30 min frozen at −70°C until assayed, and then sent to the University of California at Los Angeles (Los Angeles, CA) where they were centrifuged in a tabletop centrifuge for 15 min. The recovered volumes varied from 0.5 to 2.0 mL. Two pools were formed from samples in the initial set to obtain baseline lipid data on whole CSF as well as ultracentrifugally isolated lipoproteins. Pools consisted of samples drawn either at parturition or between the 17th and 21st day postpartum. In the case of a sixth cow, from which three samples were obtained (in the third trimester, at parturition and at 5 d of postpartum), only ultracentrifugal isolation of CSF lipoproteins was done, as was the case for samples received in the second set.

Enzymatic analyses of CSF lipids. Concentrations of cholesterol and triacylglycerol in CSF samples were measured at 490 nm using a Vmax Microplate Reader (Molecular Devices Corp., Sunnyvale, CA). Triacylglycerol analyses were done by mixing 600 μL of Sigma enzymatic reagent (Sigma Chemical Co., St. Louis, MO) with 100 μL of samples or diluted standards of 10- and 20-fold to concentrations of 20 and 10 mg/dL, respectively. Cholesterol analyses were done by mixing 600 μL of an enzymatic reagent, prepared as described by Puppione and Charugundla (25), with 40 μL of sample. Standards were diluted 16-fold to a concentration of 12.5 mg/dL. Measured volumes were dispensed into 1.0-mL tubes using a Cavro 190 IQ pipetter/dispenser (Cavro Scientific Instruments, Sunnyvale, CA). Following incubation at 37°C, 175 μL aliquots of the solution were dispensed in triplicate into 96 "Flat bottom" well plates (Costar, Cambridge, MA) that were then read in the plate reader. From the absorbance values of the standards, the concentrations were calculated on an IBM PS/2 computer using software from Molecular Devices. The dispensing of the incubated enzymatic solutions was done with a Biomek 2000 (Beckman Instruments, Fullerton, CA).

Isolation of CSF lipoproteins. The density of the CSF samples was raised to 1.21 g/mL by mixing a concentrated NaBr solution (density = 1.316 g/mL) in the proportions of 1 part sample to 2 parts NaBr solution. Total volume in each tube consisted of 6 mL of this mixture and 2 mL of a NaBr solution having a density of 1.21 g/mL. Lipoproteins were isolated using a 50 Ti Beckman rotor (Beckman Instruments). Ultracentrifugation was done at 40,000 rpm for 24 to 30 h and at 16°C. The top 0.5 to 1.0 mL was recovered from each tube. All salt solutions used for ultracentrifugation contained Na_2EDTA (0.04%), NaN_3 (0.05%), and Gentamycin (0.005%). The densities of salt solutions, prepared according to Lindgren (26), and of the infranates were measured at 26°C using a DMA 02D Mettler/Paar Densitometer (Graz, Austria) to an accuracy of ± 0.0002 g/mL.

Electrophoretic analyses. Centricon-10 concentrators (Amicon, Inc., Beverly, MA) were used both to concentrate the lipoproteins to approximately eightfold over concentrations in the CSF and to reduce the salt concentration with 0.196 molal NaCl as solvent. Apolipoproteins were separated on 12.5% polyacrylamide minigels with 1% sodium dodecyl sulfate in the buffer, prepared as described by Weber and Osborne (27) modifying the procedures of Laemmli (28). Human apo A-I, carbonic anhydrase, ovalbumin, and albumin were run as standards. Gels were stained with Coomassie Brilliant Blue R-250, destained with an aqueous methanolic (45% MeOH) containing 10% acetic acid, and dehydrated in a Model 583 gel dryer (BioRad, Richmond, CA) after remaining in water overnight. Then scans were taken with a Color One Scanner (Apple Computer, Inc., Cupertino, CA).

Microsequencing of CSF apo. Proteins were resolved on a 12.5% polyacrylamide gel (Bio-Rad Mini Protean) and stained with Amido Black 10B (29). After destaining, the bands were excised from the gel with a razor blade and prepared for trypsin digestion according to Jenö *et al.* (30). The gel slices were prepared for trypsin digestion by preincubation in three solutions for short periods: twice for 15 min in 40% aqueous *n*-propanol; twice for 15 min in 50% aqueous acetonitrile, 50 mM triethylammonium bicarbonate (pH 8.5); and for 1 min in 50 mM triethylammonium bicarbonate (pH 8.5). Then 50 μL of the same buffer containing 1 μg of trypsin was added and the digestion proceeded overnight at 37°C . After removing the supernatant, the gel slices were extracted twice with 0.1% aqueous trifluoroacetic acid at 55°C. The pooled supernatants and extracts were resolved by reversed-phase high-performance liquid chromatography (Hewlett-Packard 1090L, Palo Alto, CA) as described by Fischer *et al.* (29). The absorbance of column fractions (*ca.* 100 μL) was measured at 210 nm, and major fractions were analyzed by matrix-assisted laser desorption mass spectrometry (MALD–MS) (32) on a Bruker Reflex time-of-flight mass spectrometer (Karlsruhe, Germany) in the reflector mode as described in detail elsewhere (31). By using an automated PE Procise 494 Protein Sequencer (Applied Biosystems, Foster City, CA) (32), chemical sequence analyses of selected peptide fraction were carried out.

RESULTS

Lipid concentrations in bovine CSF. To analyze for CSF lipids, two separate pools were prepared using samples obtained at parturition and postpartum (days 17–21). Cholesterol levels, which were low for both pools, were twofold higher during the postpartum period (11 ± 0.04 μg/mL) than at parturition (5 ± 0.17 μg/mL). Triacylglycerols were not detected in these pools.

CSF apo distribution. Lipoproteins were isolated ultracentrifugally from bovine CSF at a density of 1.21 g/mL. Analyses of isolated fractions by SDS-polyacrylamide gel electrophoresis (PAGE) revealed two apo in all of the 15 samples which were obtained 2 wk or longer postpartum. One of the apo comigrated with human apoA-I (MW 28,000) (Fig. 1). The other apo with mobility intermediate to ovalbumin and carbonic anhydrase was calculated to have a molecular weight of 38,000 and was seen as a doublet, suggesting that this protein had undergone posttranslational glycosylation similar to what has been described for human apoE (33). The 38 K apo was not always observed when samples obtained around the peripartum period were analyzed. As can be seen from Figure 1, the amount of protein observed for the 11th day postpartum was lower than at the other times. But in other cases (data not shown) in which the 28 K apo was clearly seen, the 38 K apo was either absent or present in low amounts. In the only cow from which CSF was drawn during pregnancy and at term, no detectable amounts of the 38 K band were detected during pregnancy and a faint band was observed at term. The 38 K apo band also was not detected when lipoproteins from a pool of three CSF samples obtained at parturition from three cows were analyzed.

Sequencing of the major apo in bovine CSF. Two procedures were used separately to identify the two apo in bovine CSF. Initially, the apo were separated by PAGE, and the two bands noted above were excised from the gel. Following incubation with trypsin, as described in the Materials and Methods section, tryptic fragments were separated by high-performance liquid chromatography. Molecule masses of major fractions were determined by MALD-MS which revealed the presence of tryptic fragments predicted to be derived from bovine apoE and bovine apoA-1. To confirm this assignment, three of the apoE fragments were chemically sequenced and found to be in agreement with published data derived from cDNA analysis (19,20). Tryptic digestion of bovine apoA-I yielded seven fragments, and sequence data were obtained on two of these. These data are summarized in Tables 1 and 2.

DISCUSSION

Studies of various mammals have shown that the major site of synthesis of apoE is the liver (35–39), with additional synthesis occurring in extrahepatic tissue, including the brain (35–39). Brzozowska *et al.* (20) found this also to be true for the bovine. In addition to the brain, other extrahepatic sites of synthesis were the small intestine, lung, kidney, and mammary gland (20). Recently Ndikum-Moffor *et al.* (40) identified the corpus luteum as site of bovine synthesis of both apoE and apoA-I.

The extent to which apoE and apoA-I participate in lipid homeostasis in the CSF remains to be demonstrated. Concentration of CSF lipids is quite low, contrary to that in plasma. Pitas *et al.* (22) reported that the cholesterol value range was 2.1–6.6 μg/mL in human CSF and had mean values of 9–10 μg/mL in canine CSF. In our study of bovine CSF, the cholesterol concentrations were comparable to canine levels during the postpartum period and intermediate to human values at parturition.

Because apoE had not been detected in association with HDL in bovine plasma, we wanted to determine whether lipoproteins containing apoE could be isolated from bovine CSF. Analyses by PAGE revealed a 38,000 molecular weight

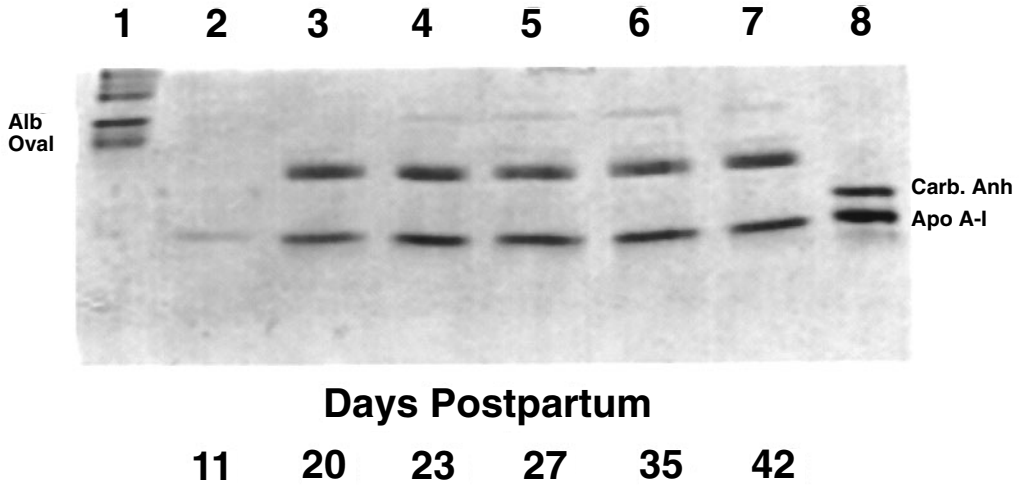

FIG. 1. Distribution of bovine cerebrospinal fluid (CSF) apolipoproteins in ultracentrifugally isolated fractions. Standards are in lanes 1 and 8. Distributions for fractions isolated from postpartum CSF are in lanes 2 through 7. Days postpartum are listed at the bottom of the various lanes; apo, apolipoprotein.

protein. We then utilized MALD-MS and microsequencing techniques, basing our analyses on published sequences obtained from analysis of cDNA, to identify both apoE and apoA-I. Prior to our studies, there were other reports on the presence of apoE in bovine CSF. Using commercially available bovine CSF as a source of lipoproteins for studying the development of nerve cells, Bellosta *et al.* (41) reported that PAGE analysis revealed a protein band that the authors identified as being apoE, presumably based on its mobility. In a postmortem study of bovine CSF lipoproteins, Jones *et al.* (42) and Hochstrasser *et al.* (43), using two-dimensional gels, found apoE to be elevated in animals afflicted with bovine spongiform encephalopathy. In our study of live normal cows, we were able to observe apoE by PAGE after the lipoproteins had been isolated ultracentrifugally and concentrated approximately eightfold.

Our strategy for the characterization of the bovine CSF apo on ultracentrifugally isolated lipoproteins included the determination by MALD-MS of molecule masses of tryptic fragments, which were matched to the masses of hypothetical tryptic fragments that can be generated from bovine apoA-I and apoE. For selected fragments, we also determined the amino acid sequence by automated Edman degradation. Both sets of data were found to be in excellent agreement, allowing identification of these apo.

Microsequencing techniques also were used by Ndikum-Moffor *et al.* (40) to identify apoE and apoA-I secreted by explant cultures of bovine corpus luteal slices. In their study, they found that apoE mRNA was expressed only during days 2 and 3 of the estrous cycle, but apoA-I mRNA levels did not vary throughout the cycle. During pregnancy, these authors (40) found that apoA-I mRNA was expressed, with higher levels toward the later stages. ApoE mRNA, however, was not expressed during pregnancy. In our study, most of the PAGE analyses were done on samples obtained 2 wk or later postpartum. However, in the few samples obtained during the peripartum period, apoA-I was always observed, but not apoE. Because the brain is considered to be the synthesis site of the apoE associated with CSF lipoproteins, hormonal changes taking place following the delivery of the calf might influence the synthesis of apoE in the brain of the cow. Supraphysiological doses of estrogen were given to rodents to understand how hormonal changes might be affecting apoE and influencing its possible role in the development of Alzheimer's disease (44,45). The brains of rats and mice were found to respond to 17-β estradiol by increasing the synthesis of both apoE and the corresponding mRNA (44,45). It is yet undetermined if physiological hormonal changes in cows are affecting levels of CSF lipoproteins containing apoE.

ABSTRACT: The effects of estivation on the phospholipid-specific fatty acid composition of mitochondrial membranes in the hepatopancreas of the terrestrial snail *Cepaea nemoralis* were investigated. The fatty acid composition of all phospholipids was significantly altered in snails estivating for 6 wk, indicating that substantial remodeling occurs. The most profound changes occurred in cardiolipin (CL). CL of estivating snails was 13-fold more saturated, contained 9-fold more monoenes, and had 45% fewer polyenes than in active snails. These differences were due, in part, to a reduction in linoleic acid (18:2n-6) content of CL from estivators. As in mammals, CL of active snails appears to preferentially incorporate 18:2n-6, which accounts for 60% of the acyl chains in this phospholipid. This proportion was reduced by 50% in estivators. Changes in the fatty acyl content of other phospholipids of estivating snails included increased monoenes in phosphatidylethanolamine (PE) and phosphatidylinositol, reduced ratios of n-3/n-6 polyenes in PE and phosphatidylcholine (PC), and an increased n-3/n-6 ratio in phosphatidylserine (PS). Arachidonic acid (20:4n-6) levels were reduced in PS but increased in CL and PC. Taken together, these alterations to fatty acid composition are consistent with decreased biological activity of membrane-related processes which occur in conjunction with the reduction of mitochondrial aerobic metabolism observed during estivation.

Lipids 33, 787–793 (1998).

Depression of basal metabolic rate is a common physiological strategy, allowing organisms to prolong the duration of their tolerance of suboptimal environmental conditions (1,2). Profound metabolic rate depression occurs during hibernation, torpor, and estivation. Suppression of mitochondrial respiration is a key component of strategies to reduce basal metabolic rate. Indeed, in hibernating ground squirrels, electron transfer is inhibited by 70 to 80% at the site of ubiquinol/cytochrome c_1, and adjustments of mitochondrial membrane composition are implicated in the mediation of this reduction (3). Changes to mitochondrial membrane composition have been studied in mammalian hibernators (4). However, hibernation and torpor are characterized by reductions in both metabolic rate and body temperature, and thus it is difficult to attribute changes of membrane phospholipid composition to either of these parameters. Several authors have attempted to overcome the confounding effects of temperature and metabolic rate reduction by comparing membrane compositional changes in active and quiescent overwintering animals (5,6), thus controlling for responses induced by lowered temperature. Nonetheless, interspecies differences still remain. Estivation, however, provides a superior model for studies of this nature. It typically occurs during environmental drought as a means to avoid desiccation (1). Metabolic rate reduction occurs in the absence of temperature change or significant cellular water loss. The extent of metabolic depression in estivators is at least as great as that observed during hibernation and torpor. Estivating terrestrial snails, for example, typically undergo a metabolic rate reduction of 85% (2).

As the functional mileu of the electron transport chain and many of the transporters and channels associated with oxidative phosphorylation, the mitochondrial membranes represent a potentially powerful site for the regulation of metabolism. Mitochondrial membranes are composed principally of proteins and phospholipids, and the function of many of the proteins associated with the membranes is responsive to, and in many cases dependent upon, surrounding phospholipids (7,8). Altering the composition of associated phospholipids can effect large changes in protein function (7). Modifications to the phospholipid environment include substitution of one phospholipid species for another, and/or modification of the acyl chains of particular phospholipids. Previously, we demonstrated that changes in the absolute and proportional amounts of individual phospholipids were altered in estivating snails. Here, we present results which indicate that a phospholipid-specific fatty acid remodeling occurs in mitochondrial membranes which is consistent with reduced rates of metabolic functions during estivation.

MATERIALS AND METHODS

Experimental animals. Several *Cepaea nemoralis* were collected in early summer, kept in terraria in the laboratory for *ca.* 6 wk, and fed a diet of "iceberg" lettuce. A group of these snails was removed to a dry terrarium, and food was withheld to induce estivation which lasted for 6 wk.

Mitochondrial isolation. Hepatopancreas from active or estivating snails was excised and immersed in 10 vol of mitochondrial isolation buffer (100 mM sucrose, 20 mM Hepes),

Abbreviations: CL, cardiolipin; H_{II}, inverse hexagonal phase; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol.

0.5% bovine serum albumin (BSA), pH 7.5), and homogenized by three passes with a Potter-Elvehjem homogenizer (Fisher Scientific Ltd., Whitby, Ontario, Canada). Homogenates were centrifuged at $150 \times g$ for 10 min and the pellet discarded. The remaining supernatant was centrifuged at $5000 \times g$ for 10 min, and the pellet "washed" by repeating this step twice. This procedure consistently gave a recovery of *ca.* 85% of mitochondria (9).

Purity of the mitochondrial preparation and recovery of mitochondria did not differ significantly ($P > 0.05$) between active and estivating snails based on the distribution of cytochrome c oxidase (mitochondrial marker), peroxidase (peroxisomal marker), and the proportional content of the phospholipid sphingomyelin (used to mark nonmitochondrial membranes, including nuclear membrane, endoplasmic reticulum, and lysosomal and plasma membranes). Recoveries of total cytochrome oxidase activities in the "mitochondrial fraction" of active and estivating snails were 82.4 ± 5.1 and 88.8 ± 4.0% ($n = 4$), respectively. Only 3.5 ± 1.0% of total peroxidase activity was recovered in the mitochondrial fraction of active snails, and 3.8 ± 0.8% ($n = 4$) in estivating snails. The proportional content of sphingomyelin in the mitochondrial fraction was 2.4 ± 1.5% ($n = 7$) in active snails and 4.2 ± 1.5% ($n = 8$) in estivators.

Total mitochondrial lipids were extracted by the method of Bligh and Dyer (10). Phospholipids were separated from neutral lipids and each other by thin-layer chromatography and methylated, as in Holub and Skeaff (11). Bands were visualized by using dichlorofluorescein. There were no band overlaps. An internal standard (17:0) was added to the phospholipid fatty acids prior to methylation. Individual fatty acids from each phospholipid fraction were separated and identified by gas chromatography using a reversed-phase DB-225 fused silica column (J&W Scientific, Folsom, CA) as described by Glémet and Ballantyne (12).

A small sample (1 g) of the diet (lettuce) was homogenized in 50 mM imidazole buffer using three 10-s bursts with a Polytron PT10 unit (Kinematica GmbH, Luzern, Switzerland). Lipid extraction of the homogenate was as above. Individual fatty acids were separated and quantified as above.

Chemicals. Chemicals were obtained from the Sigma Chemical Co. (St. Louis, MO) or Fisher Scientific Ltd. and were of the highest purity available. The fatty acid standard was obtained from Nu-Chek Prep Inc. (Elysian, MN) and was augmented by the addition of a menhaden extract.

Statistical analysis. Proportional phospholipid fatty acid compositional data were arcsine transformed where necessary to normalize the data and were compared by using Student's *t*-tests. *P*-values were adjusted (based on the number of tests made and degrees of freedom) to compensate for the use of multiple *t*-tests in comparing the fatty acid compositions of each phospholipid from active and estivating snails (13).

RESULTS

The snail diet (lettuce) was composed primarily of three fatty acids, 16:0, 18:2n-6 and 18:3n-3, which combine to account for 83% of total fatty acids (Table 1). 18:2n-6 was the most abundant fatty acid in lettuce, at almost 42% of total. Lettuce contained a large proportion (64%) of 18-carbon fatty acids, a lower proportion (29%) of 16-carbon fatty acids, and trace amounts of 14, 20, 22 and 24-carbon fatty acids.

Phospholipids from hepatopancreas mitochondria of active snails contained lower proportions (47%) of 18-carbon fatty acids than dietary lettuce, and greater proportions of their elongation products, especially 20-carbon fatty acids (37%). Some of the most common fatty acids in hepatopancreas mitochondrial phospholipids of active snails are 18:2n-6 (18%), 18:3n-3 (8%), and 20:4n-6 (18%) (Table 2).

The fatty acid composition of mitochondrial phospholipids was altered dramatically in estivating snails (Table 2). The proportion of 18:2n-6, 18:3n-3, and 18:4n-3 decreased by 60,

[a]Values are presented as means ± SE; n.d. = not detectable.
[b]Significantly different from active values, $\alpha = 0.0034$.
[c]Unsaturation index = $\sum m_i \cdot n_i$; where m_i is the mole percentage and n_i is the number of C–C double bonds in fatty acid "i".
[d]Mean chain length = $\sum f_i \cdot c_i$; where f_i is the mole fraction and c_i is the number of carbon atoms in fatty acid "i".

61, and 63%, respectively, in hepatopancreas mitochondria of estivating snails. 18-carbon fatty acids constituted only 30% of total fatty acids in estivators, compared with 47% in active snails (see above). These changes were offset by greater proportions of shorter chain fatty acids (14- and 16-carbons) and longer chain (22-carbons) fatty acids, which increased from 10 to 18% and from 5 to 9%, respectively. The phospholipid fatty acids of estivating snails contained significantly more monoenes and fewer polyenes. The reduced polyene content of mitochondrial membranes from estivators resulted primarily from a lower content of n-3 fatty acids, the proportional occurrence of which was reduced by 51%.

The greatest differences between the fatty acid composition of active and estivating snail mitochondria occur in the major constituent phospholipids of the mitochondrial membranes [phosphatidylcholine ((PC), phosphatidylethanolamine (PE) and cardiolipin (CL), which constitute 37.7, 35.2, and 11.4% of total phospholipids in mitochondria from the hepatopancreas of active snails (14)]. Perhaps the most profound alterations of fatty acid composition occurred in CL (Table 3). A 50% reduction in 18:2n-6 content was observed in CL which, in combination with a 57% decrease in 18:3n-3, accounted for a 55% decrease in the total polyene content of CL from estivating, compared to active, snails. While polyene levels decreased, saturated fatty acids increased 13-fold, and monoenes increased 9-fold. This resulted in a 33% reduction in CL unsaturation index.

Unsaturation index was not altered during estivation in any other phospholipid species. However, in PE, the proportion of monoenes increased 48%, due in part to an almost fourfold increase in 16:1 content (Table 4). Membranes of estivators contained 43% fewer n-3 polyenes, largely due to significant reductions in 18-carbon n-3 fatty acids. This resulted in a lowering, by 43%, of the n-3/n-6 ratio in estivating snail mitochondria.

[a–d]See Table 2 for footnotes.

No statistically significant changes to proportions of saturates, monoenes, or polyenes were observed in any other phospholipids. However, PC showed a similar decrease (51%) in n-3 fatty acid content in estivators (Table 5). This occurred primarily through significant reductions to 18:3n-3, 18:4n-3, and 20:3n-3 contents during estivation. The n-3/n-6 ratio of PC from estivating snails was thus decreased by 56%.

PC was the only phospholipid to show a change in average fatty acid chain length between experimental groups. PC from mitochondria of estivating snails contained longer fatty acyl chains on average than in active snails.

The n-3/n-6 polyene ratio appeared to be 4.5-fold greater in phosphatidylserine from estivating snails (Table 6), though a relatively large standard error made this statistically insignificant at $\alpha = 0.0034$. The altered value of the n-3/n-6 ratio was largely due to a statistically significant 50% decrease in 20:4n-6 and a concomitant, but not significant, 2.6-fold increase in 18:3n-3.

In phosphatidylinositol (PI), only 20:1 and 16:1 content were altered in estivators (Table 7). Proportions of both increased, which was reflected in a doubling of the proportion of monoenes in PI, though this was also not significant at $\alpha = 0.0034$.

Arachidonic acid (20:4n-6) was present in trace amounts in lettuce (Table 1), but occurred as a major constituent fatty acid of all phospholipids, except for CL, where it accounted for less than 4% of total fatty acids in active snails. 20:4n-6 was enriched 70% in PC during estivation, while PS 20:4n-6 content decreased by 52%.

DISCUSSION

The phospholipid composition of mitochondrial membranes from *C. nemoralis* hepatopancreas is dramatically altered during estivation. Many aspects of this remodeling indicate a reduced biological activity of the mitochondrion during estivation, when metabolic rate is reduced to about 15% of normal

(1,2). These changes are consistent with the inhibition of certain mitochondrial membrane-bound proteins, a stabilizing of the bilayer, and a reduced propensity toward hexagonal phase formation.

Perhaps the most dramatic changes to constituent fatty acids occurred in CL, a unique phospholipid which typically is found exclusively in the mitochondrial inner membrane (7). CL is found in close association with certain mitochondrial proteins, including the mono-, di-, and tricarboxylate carriers, and also carnitinepalmitoyl translocase, cytochrome c oxidase, ADP/ATP exchanger, and phosphate transporter (7). Many of these proteins do not function, or function submaximally, in its absence. In many cases, the ability of CL to stimulate protein function is dependent upon its fatty acyl composition (7,15,16). For example, several studies have demonstrated a specific requirement of the respiratory chain enzyme cytochrome c oxidase for CL with 18:2n-6 acyl chains. In rats fed diets deficient in 18:2n-6, which results in CL 18:2n-6 being replaced with other fatty acids (17), mitochondrial function (18), and cytochrome c oxidase activity (15) are both decreased by as much as 50%. This loss of activity has been shown to result directly from the presence of 18:2n-6-deficient CL, as activity can be fully recovered when delipidated cytochrome c oxidase is reconstituted with 18:2n-6/18:2n-6 CL (15). In estivating *Cepaea*, cytochrome c oxidase activity is reduced by 85% (14). This could be mediated in part by the significant reduction of CL 18:2n-6 content. As in mammals, *Cepaea* CL was particularly enriched in 18:2n-6, which accounted for 60% of all fatty acids in CL of active snails. The 18:2n-6 content of CL from estivating *Cepaea* decreased by 50%. A similar decrease in CL 18:2n-6 content in rats fed an 18:2n-6-deficient diet results in a 26% decrease in cytochrome c oxidase activity (15), suggesting that, during estivation, the reduced 18:2n-6 content of CL may play a role in

the observed reduction of cytochrome c oxidase activity. The activities of other CL-requiring mitochondrial membrane proteins which have specific interactions with 18:2n-6 acyl chains (7,15,16) may be similarly suppressed.

The altered fatty acyl composition of CL changes the molecular geometry of this phospholipid, and thus its functional properties in the membrane (19,20). CL of estivating snails was threefold more saturated, contained ninefold more monoenes, and had 45% fewer polyenes than that of active snails. Thus, the unsaturation index of CL from estivating snails was 33% reduced from control values. The more highly saturated CL found in estivating snails effects changes in the molecular geometry of CL which decrease its propensity to form nonlamellar structures, like the inverse hexagonal (H_{II}) phase (19,20). H_{II} phase-favoring phospholipids affect the structure and physical properties of membranes (8,21–23). These, in turn, can modulate the function of specific membrane proteins (24), an interaction illustrated by the requirement of a minimal proportion of hexagonal phase-preferring lipids for proper function of membrane-bound proteins, like rhodopsin in the visual system (25).

Other modifications to mitochondrial membrane composition during estivation also suggest greater bilayer stability. The mitochondrial membranes of estivating snails are characterized by an increased proportion of monoenes in PE. They also contain lower proportions of the H_{II} phase-preferring phospholipids, PE and CL (14). The other major constituent of mitochondrial membranes, PC, shows an increased average acyl chain length. Taken together, these changes suggest that membrane remodeling during estivation selects against H_{II} phase-preferring phospholipids, resulting in the adoption of a more stable lamellar phase in the phospholipid bilayer of estivators. H_{II} phase-preferring phospholipids are known to be important in a number of biological functions which are key to anabolic and catabolic processes, including trafficking of membrane fragments and proteins, fusion, and mitochondrial contact sites (8,24,26–29). The compositional changes which lower the tendency for formation of nonbilayer structures in mitochondrial membranes appear to be related to the depressed metabolism, and therefore reduced rates of these processes in estivating *Cepaea*.

Other aspects of the phospholipid compositions of mitochondria from estivatings snails are typical of those observed in association with reduced metabolic rates. The proportional content of monoenes in CL, PE, and PI was greater in estivating snails, due to the replacement of polyenes, like 18:2n-6 and 18:3n-3, with 16:1 and 18:1. Similarly, increased proportions of phospholipid monoenes have been shown to correlate strongly with reduced metabolic rates in other organisms (30,31). The specific mechanism underlying this correlation remains unknown, and the effects of phospholipid incorporation of monoenes are complicated. While modeling studies indicate that greater incorporation of monoenes in the *sn*-1 position can induce looser packing arrangements (32), dimonoenoic phospholipids are better able to form highly ordered phases than di-polyenoic phospholipids (22). Thus, the neighboring fatty acyl chain will determine how increased monounsaturation affects phospholipid properties. The impact of increased monoene incorporation in PE, PI, and CL on membrane bilayer stability is, therefore, uncertain without positional information. The reported association between monoenes and metabolic rate in various systems is, however, an interesting phenomenon that warrants further investigation.

The n-3/n-6 ratio of membrane phospholipid fatty acids was reduced in estivating snails, primarily due to decreased proportions of 18:3n-3 and 18:4n-3 in PE and PC. Similarly, lower proportional contents of n-3 polyenes are characteristic of the mitochondrial membranes of animals with lower metabolic rates (30,31). This has been demonstrated allometrically in mammals (31) and through comparisons of reptiles with mammals (30). In contrast, higher levels of n-3 polyunsaturated fatty acids are associated with superior recovery from postischemia reperfusion in rat heart (33), when oxygen levels may be expected to be abnormally high. Thus, the significance of phospholipid n-3 content may be related to the cellular oxygen concentrations which characterize different metabolic rates and physiological states. Lower relative levels of n-3 polyenes in estivating snails thus appear to be related to the metabolic rate reduction in these animals.

Changes in phospholipid fatty acid composition induced by estivation may not be attributable solely to the effects of elongation or desaturation. Mitochondria of estivating snails contain fewer phospholipids than those of active animals. These phospholipids do not appear to be lost from the cell (14). This suggests that phospholipids may be removed from the mitochondria and sequestered elsewhere in the cell (14). We have observed that a significant reduction in total mitochondrial phospholipid content occurs during estivation. Preferential removal of specific phospholipid or fatty acid species from the membrane thus provides a mechanism for altering phospholipid-specific fatty acid composition which is independent of elongating and desaturating processes.

In summary, the dramatic changes in phospholipid-specific fatty acid composition demonstrated here are consistent with profound reductions in the rates of membrane-associated processes during estivation. These results also suggest that estivating snails are a valuable model for studies of the relationship between metabolic rate and mitochondrial membrane composition. The results of this study should be extended to vertebrate estivators and to investigations of the functional properties of mitochondrial and cellular membranes during estivation.

Changes in Tissue Polyunsaturated Fatty Acids with Age, in Spontaneously Hypertensive Rats

Marie-Claire Delachambre, Michel Narce*, Philippe Asdrubal, and Jean-Pierre Poisson

Unité de Nutrition Cellulaire et Métabolique, Faculté des Sciences Mirande, Université de Bourgogne, 21011 Dijon Cedex, France

ABSTRACT: The relationship between the biosynthesis of long-chain fatty acids and their distribution in the key organs of hypertension is of considerable interest because of their role in the production of vasoactive eicosanoids and their effects on membrane properties. The present study analyzed the fatty acid compositions of the total lipids in the kidney, aorta, heart, and hepatocytes of 1-, 3-, and 6-mon-old spontaneously hypertensive rats (SHR) and their normotensive controls, Wistar Kyoto rats (WKY) by capillary gas chromatography . The major changes concerned the polyunsaturated fatty acids (PUFA). The percentage of arachidonic acid (AA) was significantly greater in the 1-mon-old SHR kidney than in the WKY kidney, but it was lower at 3 and 6 mon. The percentage of eicosapentaenoic acid was very low in the SHR kidney. The results for the aorta were similar, with marked decreases in 18:2n-6 and 18:3n-3 in SHR aged 1 and 6 mon. Despite a higher proportion of 18:2n-6 and AA at 6 mon, there was no major change in the SHR heart lipids. The fatty acid spectrum in the liver provides additional evidence for the previously reported inhibition of desaturase activities in SHR. Thus, this study shows that the PUFA composition is modified differently in different tissues in SHR, and this may be related to the pathogenesis of hypertension in these animals.

Lipids 33, 795–801 (1998).

Both humans and animals suffering from genetic hypertension have abnormal fatty acid metabolism (1–7). The synthesis of polyunsaturated fatty acids (PUFA) in the liver of spontaneously hypertensive rats (SHR) differs significantly from that of normotensive Wistar Kyoto (WKY) rats, depending on the age of the animals and the pathogenesis of hypertension (7–9). The activities of liver microsomal desaturases, which are key enzymes in PUFA synthesis, are greatly reduced, and this becomes more severe once the rats are hypertensive (after 3 mon of age) than during the prehypertensive period. These abnormalities may be linked to the altered membrane properties and functions that occur in hypertension (3,10,11), as membrane viscosity can be affected by small changes in fatty acid composition (12). Ollerenshaw *et al.* (13) showed that the erythrocyte membranes of patients with essential hypertension have a reduced linoleic acid (LA) content, while the arachidonic acid (AA) and oleic acid contents are above normal in subjects consuming similar diets.

Abnormalities of fatty acid metabolism may have implications for the local synthesis of eicosanoids, which depends greatly on the availability of C_{20} PUFA precursors (dihomo-γ-linolenic acid, DGLA, 20:3n-6; AA, 20:4n-6; eicosapentaenoic acid, EPA, 20:5n-3), arriving *via* the circulation. Their release from membrane phospholipids (PL) is the rate-limiting step in the synthesis of vasoactive eicosanoids involved in the regulation of blood pressure. These include thromboxane A_2, derived from AA, which is a powerful vasoconstrictor; prostaglandin E_2 and prostaglandin I_2, derived from the same precursor, which have the opposite effect; and prostaglandin E_1, derived from DGLA (14–18).

Consequently, the relationship between changes in liver PUFA synthesis and the PUFA status of organs in SHR involved in the pathology of hypertension has to be considered. The present work examines the distribution of PUFA in several tissues involved in hypertension, the heart (19), kidney (20–22) and thoracic aorta (23,24), as well as in the isolated hepatocytes of SHR and WKY rats. Measurements were made on rats aged 1, 3, and 6 mon to detect changes linked to the pathogenesis of hypertension (before 3 mon of age) and the blood pressure.

MATERIALS AND METHODS

Male SHR and WKY normotensive rats aged 3 or 11 wk were purchased from Iffa Credo (Domaine des Oncins, L'Arbresle, France), and fed *ad libitum* on a commercial standard diet (Souriffarat, UAR, Villemoisson Sur Orge, France; weight in g/kg pellets: protein 210; carbohydrate 535; fat 40; cellulose 45; moisture content 115; ash 55; minerals 27.8; vitamins: retinol 16,000 IU/kg, cholecalciferol 2,000 IU/kg, vitamin E 500 mg/kg; fatty acid composition of fat (% wt/wt of total): palmitic acid, 16:0: 10.1; palmitoleic acid, 16:1n-7: 0.9; stearic acid, 18:0: 2.7; oleic acid, 18:1n-9: 26.9; LA, 18:2n-6: 49.2; linolenic acid, 18:3n-3: 0.2; others: 10.0) and given tap water *ad libitum*. The schedule was 12 h dark/12 h light.

The systolic blood pressure of prewarmed, conscious rats was measured before killing, using a tail pulse transducer (M+M Electronic Inc., Basel-Müncheenstein, Switzerland).

Abbreviations: AA, arachidonic acid; DGLA, dihomo-γ-linolenic acid; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; LA, linoleic acid; PL, phospholipids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; SHR, spontaneously hypertensive rat; WKY, Wistar Kyoto.

Blood pressure was determined for each animal by taking the average of five measurements.

Groups of four animals from each strain aged 1, 3, and 6 mon were anesthetized with sodium pentobarbital (Sanofi, Paris, France). Hepatocytes were prepared by the method of Seglen (25) and suspended in Krebs-Henseleit bicarbonate buffer containing 1% fatty acid-free bovine serum albumin. Hearts, kidneys, and thoracic aortas were quickly removed, weighed and frozen. They and the isolated hepatocytes were stored at −80°C until analysis. They were cut into thin slices, homogenized in 15 mL chloroform/methanol (2:1, vol/vol). Total lipids were extracted by the method of Folch *et al.* (26), saponified, and methylated by heating in 14% boron trifluoride in methanol at 80°C for 20 min (27). Fatty acid methyl esters were then extracted with 2 mL isooctane, separated by gas–liquid chromatography (Packard, model 417 gas–liquid chromatograph equipped with a flame–ionization detector and a 30-m capillary glass column coated with Carbowax 20M), and identified by their relative retention times (fatty acid standards: gas–liquid chromatography model mixture reference standards; Nu-Chek-Prep, Elysian, MN). Results (mole %) were expressed as arithmetic means with standard errors (mean ± SE) for each group.

Statistical significance of differences between means was assessed using the Student's *t* test. Values were considered significant when $P < 0.05$ and very significant when $P < 0.01$.

RESULTS

Systolic blood pressure. SHR blood pressures (mm Hg) were significantly higher (135 ± 4 at 1 mon, 221 ± 8 at 3 mon, and 232 ± 10 at 6 mon) than those of WKY at all three ages studied: 107 ± 6 (1 mon), 141 ± 7 (3 mon), and 146 ± 8 (6 mon). Blood pressure became abnormally high in SHR at the age of 2 mon (about 150 mm Hg). Hypertension was definitively established at the age of 3 mon (221 ± 8 mm Hg) and remained more or less constant thereafter.

Fatty acid composition of kidney total lipids. The fatty acid composition of the kidney total lipids is shown in Table 1. At each age, changes were seen between the SHR and WKY groups. At 1 mon of age, kidneys from the SHR had lower amounts of 18:2n-6 (16.5 vs. 18.3 mole %), 18:3n-3 (0.35 vs. 0.66 mole %), and less 20:5n-3 (0.50 vs. 0.77 mole %) compared to the WKY rats, but higher levels of 20:4n-6 (26.6 vs. 20.4 mole %). The 3 mon-old SHR had a higher concentration of LA (18.1 vs. 16.0 mole %) than the WKY rats, but there was no significant difference in their AA contents. The 3-mon-old SHR had significantly lower levels of 22:5n-3 (docosapentaenoic acid, DPA) than the WKY kidneys (0.43 vs. 0.53 mole %), but interestingly there were no differences in the levels of docosahexaenoic acid (DHA, 22:6n-3) in these tissues at this age. The 6 mon-old SHR had lower concentrations of AA (21.2 vs. 26.0 mole %), 22:5n-6 (0.15 vs. 0.48 mole %), EPA (0.15 vs. 0.75 mole %), DPA (0.36 vs. 0.82 mole %), and DHA (1.78 vs. 3.41 mole %) than WKY rats of the same age. SHR had significantly more 18:0 (8.8 vs. 7.2 mole %) than the WKY at the age of 1 mon, less 18:0 at the age of 3 mon, and significantly more 16:0 (23.2 vs. 20.0 mole %) and 18:1n-9 (15.8 vs. 12.6 mole %) than WKY at 6 mon.

The PUFA/saturated fatty acid (SFA) ratio decreased in SHR with age, while it increased in WKY. The 18:2n-6 concentration tended to increase with age in SHR, whereas 20:4n-6 decreased. The corresponding fatty acids of the n-3 family changed similarly. With respect to WKY rats, 20:4n-6

TABLE 1
Fatty Acid Composition of Kidney Total Lipids[a]

	1 mon		3 mon		6 mon	
Fatty acid	WKY	SHR	WKY	SHR	WKY	SHR
16:0	25.59 ± 1.08	24.30 ± 0.57	22.20 ± 0.25	22.25 ± 0.33	20.03 ± 0.34	23.17 ± 0.42[c]

PUFA/SFA	1.37	1.50	1.46	1.45	1.66	1.24

[a]Values (mol %) are given as mean values ± SEM for four rats.
[b,c]Significantly different from the value for the WKY control group at $P < 0.05$, $P < 0.01$, respectively. Abbreviations: WKY, Wistar Kyoto; SHR, spontaneously hypertensive rat; SFA, total saturated fatty acids; PUFA, total polyunsaturated fatty acids.

was higher and 18:2n-6 lower in 3-mon-old than in younger rats, and the opposite occurred in the 6-mon-old rats.

Fatty acid composition of aorta total lipids. The fatty acid composition of aorta total lipids is shown in Table 2. The most important changes in the fatty acid composition in this tissue concerned LA, AA, and EPA. There was a highly significant decrease in LA (to 13.1) and in EPA and a slight increase in AA in 1-mon-old SHR as compared to WKY. By the time the rats had reached 3 mon 20:4n-6 was significantly elevated (3.6%) in SHR, while adrenic acid (22:4n-6) and DHA were only slightly higher in SHR than in WKY. Six-mon-old SHR had significantly lower LA (22.7%) and 18:3n-3 (1.1%) than WKY (30.0 and 1.5%) and slightly higher AA. The SHR had significantly more 16:1n-7 (5.8%) and 18:1n-9 (22.3%) at 1 mon than did WKY (4.1 and 19.9%), but they had significantly less 18:1n-9 (27.4%) at the age of 3 mon than did WKY (32.2%). The SHR had significantly more 16:0 and 16:1n-7 (24.8 and 9.9%) than WKY (21.3, 8.0%) at 6 mon.

The PUFA/SFA ratio increased greatly at the age of 6 mon in both strains. In relation to age, the fatty acid profiles for both strains were similar, in spite of a smaller increase in 18:1n-9 in SHR at 3 mon than in WKY, and a smaller increase in 18:2n-6 at 6 mon. The fatty acid profile of 6-mon-old WKY was very different from that of SHR and of the younger WKY rats.

Fatty acid composition of heart total lipids. The fatty acid composition of heart total lipids is shown in Table 3. Levels of 18:3n-3, 20:5n-3 and 22:6n-3 were similar in the SHR and WKY groups at all time periods studied. Levels of the n-6 fatty acids showed no major difference between these two groups at 1 and 3 mon of age except that SHR aged 3 mon had significantly lower 22:5n-6 and 22:5n-3 than WKY. By 6 mon of age, 20:4n-6 and the C_{22} fatty acids were significantly higher in the SHR, compared to the WKY group. In contrast, the levels of the 20:2n-6 and 20:3n-6 fatty acids were markedly reduced in this tissue from the SHR group.

The PUFA/SFA ratio increased in SHR with age. With respect to the effect of age, the amounts of 18:2n-6 were significantly lower and those of 22:6n-3 significantly higher in 6 mon-old WKY than in 1- and 3-mon-old rats. Stearic acid tended to increase with age, while 18:1n-9 remained unchanged. SHR had a similar profile, except that 20:4n-6 was higher at 6 mon than at the two other ages.

Fatty acid composition of hepatocyte total lipids. The fatty acid composition of hepatocyte total lipids is shown in Table 4. In this tissue, the major changes in the fatty acid levels between SHR and WKY groups were observed at the age of 3 mon, whereas there was no significant difference between 1 mon-old SHR and WKY for any of the fatty acids. At 3 mon of age, the SHR showed marked increases in the levels of 18:2n-6 (23.8 vs. 18.0 mole %), 18:3n-3 (0.8 vs. 0.4 mole %), and 22:6n-3 (7.5 vs. 6.5 mole %) compared to the WKY hepatocytes. In contrast, levels of 20:4n-6 (16.4 vs. 22.8 mole %) and its precursor fatty acid, 20:3n-6 (0.5 vs. 0.8 mole %), were lower in this group compared to the WKY animals. Hepatocytes from 3 mon-old SHR had significantly lower 16:0 (23.5 vs. 25.7 mole %) and 18:0 (8.8 vs. 13.3 mole %) than WKY, but more 18:1n-9 (13.5 vs. 7.3 mole %).

The PUFA/SFA ratio was higher in 3- and 6-mon old SHR than in WKY. Most of the differences in the fatty acid profiles of the two strains affected 18:2n-6 and 20:4n-6. LA was much higher and 20:4n-6 lower in 3-mon-old SHR than in WKY. The amount of 18:2n-6 increased regularly with age in WKY, while that of 20:4n-6 decreased. There was also a sharp decrease in 18:0 and a sharp increase in 18:1n-9 in 3-mon-old SHR.

Changes in the distribution of C_{20} PUFA and their C_{18} precursors in WKY and SHR organs. Considering changes in C_{20}

and C_{18} PUFA profiles in WKY and SHR organs, LA in aorta and kidney of SHR (1 and 6 mon) was lower than in WKY. It was higher in the SHR heart (6 mon), hepatocyte (1 and 3 mon) and kidney (3 mon). The AA was usually higher in the SHR aorta and heart (at 6 mon) than in WKY. It was higher in the SHR kidney during the prehypertensive period (1 mon), but the amounts in the kidney and hepatocytes of adult SHR were similar to or less than those in WKY. Linolenic acid was also lower in SHR than in WKY during the prehypertensive period (1 mon), particularly in the SHR aorta and kidney, but it was markedly higher in the SHR hepatocytes (3 mon). EPA was quite often lower in SHR organs than in WKY, particularly in the SHR aorta (1 mon), kidney (1 and 6 mon), and hepatocytes (6 mon).

DISCUSSION

The proportions of fatty acids which are associated with membrane structure or which may be involved in the regulation of blood pressure (such as 18:2n-6, 20:3n-6, 20:4n-6 and 20:5n-3) were altered in SHR animals, compared to the levels of these fatty acids observed in tissues from the WKY group. These alterations do not reflect different nutritional status, as we did not observe differences in food consumption between WKY and SHR groups during the experiment. Similarly, no significant body weight difference appeared between the two groups of rats during the entire experiment, as shown in our previous studies (7,8).

The kidney cannot convert 18:2n-6 to 18:3n-6 in either normotensive or hypertensive rats (28), so that the precursors of series 1 and 2 prostaglandins (20:3n-6 and 20:4n-6) need to be provided *via* the circulation from the liver, the major site of fatty acid desaturation and elongation. The high content of 20:4n-6 in the kidneys of 1-mon-old SHR suggests that this fatty acid, or its Δ6 desaturated precursor, is highly incorporated. Alternatively, substantially less AA may be released by phospholipases A_2 and C in SHR. Okamoto *et al.* (22) showed that the AA content of the phospholipids (PL) increases with aging in SHR. Our findings on the fatty acid composition of total lipids in the kidney do not reflect such change, as the amount of AA was lower in SHR than in WKY aged 3 and 6 mon. This apparent difference may be explained by the results of Murthy *et al.* (29), who showed that PL acyltransferase activity is lower in the SHR kidney than in WKY, suggesting greater acylation of PUFA to the triglycerides rather than the PL fraction. However, our results agree with our previous results (7,8) showing that more arachidonate is synthesized by hepatocytes in 1-mon-old SHR than in WKY and that liver microsomal n-6 Δ6 and Δ5 activities decrease in SHR with age.

The kidney of SHR also contains less 20:5n-3 at all ages from 1 mon to 6 mon. At 1 mon, the higher proportion of AA in SHR kidney might contribute to an increase of the ratio n-6/n-3 PUFA. In spite of a conversion into vasodilatory eicosanoid (prostaglandin I_2), AA is a precursor for eicosanoids with potent vasoconstrictor effects, like thromboxane A_2 and isoprostanes, while DGLA and EPA are the precursors of the vasodilators prostaglandins E_1 and I_3 but not of any known vasoconstrictors. Consequently, the SHR kidney seems to contain a higher proportion of one type of eicosanoid precursor (AA) during the prehypertensive period (before 3 mon) and lower proportions of vasodilator precursors of other eicosanoids (DGLA and EPA) when there is hypertension (after 3 mon). DGLA could also inhibit the conversion of AA to vasoactive leukotrienes *via* its 15-hydroxy derivative (30). On the other hand, several experiments have shown that the capacity to synthesize vasodilator prostaglandins in SHR was impaired *in vivo* (31) and that SHR do not produce more prostaglandin I_2 than WKY rats (32). Consequently, PUFA could be involved in blood pressure regulation indirectly or even independently of the prostanoid system, *via* their influence on the biosynthesis of diradylglycerols and phospatidic acid, key intracellular messengers involved in the mediation of agonist-induced vascular smooth muscle cell contraction (33). Thus, an imbalance in the distribution of PUFA in the kidney of 1-mon-old SHR might contribute to the development and to the maintenance of hypertension in these rats. On the other hand, the lower level of DPA observed in SHR kidney at 3 mon of age is not followed by a decrease of its DHA metabolite, suggesting that the Δ4 desaturation system is not altered. Nevertheless, the significant fall in proportion of DPA observed in 6-mon-old SHR was associated with a subsequent fall of DHA.

Although the proportion of AA in the mesenteric vessels of SHR is lower than in controls (34), the fraction of AA in the SHR aorta is higher than in controls at 1 and 3 mon. These results are similar to those for the kidney and indicate that the SHR aorta has the potential to synthesize more cyclooxygenase products than the aorta of age-matched WKY or may undergo changes in the incorporation of PUFA in the *sn*-2 position of membrane phospholipids. This is in agreement with previous data showing an increased synthesis of AA metabolites by SHR aortic vascular segments *in vitro* taken from rats that had been hypertensive for 2–3 mon (35). The sharp decreases in the proportions of LA and α-linolenic acid in the SHR aorta at 1 and 6 mon of age are in agreement with the results of Dominiczak *et al.* (11) in cultured vascular smooth muscle cells from the stroke-prone SHR. The change may contribute to the reduced membrane fluidity of vascular smooth muscle in hypertensive rats (11).

Relatively little information is available on the effect of hypertension on PUFA metabolism in the heart. Lipid alterations, like PL deficiency and lower mass of associated fatty acids, have been reported for newborn SHR heart myocytes (36), suggesting that intrinsic factors, probably genetically determined, are active in the first few days of life in the absence of any neurohumoral regulation or hemodynamic stress. The present study shows that these alterations seem to disappear after weaning, as the heart proportions of 18:2n-6, 20:4n-6, 20:3n-6, and 20:5n-3 in SHR and WKY were similar at the ages of 1 and 3 mon. Nevertheless, the proportions of 18:2n-6 and 20:4n-6 were higher in 6-mon-old SHR than in WKY. It has been reported that cardiac performances were more impaired with age in hypertensive rats than in age-matched normotensive animals, and that young SHR exhibited normal or greater cardiac performances than WKY (37). The decreased cardiac performance with age might be related to changes in membrane lipid composition, which could have a number of effects on receptor function, transport proteins, electrolyte balance, eicosanoid production, enzyme activities, mitochondrial respiration, and/or other membrane-associated processes. The lower cytoplasmic fatty acid-binding proteins in the SHR heart (38) could contribute to an alteration in heart PL turnover, leading to the storage of n-6 PUFA.

We have previously reported that the Δ6 and Δ5 desaturase activities in the liver microsomes of 3-mon-old SHR are inhibited (9). The results from the present study support these obser-

vations, with higher liver 18:2n-6 and lower liver 20:4n-6 proportions in 1- and 3-mon-old SHR than in their homologous WKY. But the transformation of radiolabeled linoleate by isolated hepatocytes does not correlate with these results (7); it was consistently higher in hepatocytes from SHR than in those from WKY aged 1 mon, and similar in hepatocytes from rats aged 3 and 6 mon. These discrepancies suggest that the cellular metabolism of newly formed AA is altered. These changes were associated with elevated 18:3n-3 in 3-mon-old SHR, which may influence the balance between n-3 and n-6 essential fatty acids metabolism in the SHR liver, as the conversion of 18:2n-6 to 20:4n-6 is known to be inhibited by 18:3n-3 (39,40).

In conclusion, these results show that the PUFA composition of the organs and tissues involved in hypertension, like the kidney, heart and aorta, is influenced by local factors, which change with the age of the animal, and does not solely reflect their provision *via* the circulation. The different fatty acid proportions in the SHR organs and tissues studied may alter tissue function, the range of the prostaglandins being produced, and the synthesis of key intracellular messengers. Nevertheless, the changes observed in fatty acid composition of total lipids can result partially from changes in lipid class composition across the studied tissues, and in that way, such data can only be interpreted with caution. It is now necessary to investigate the fatty acid profiles of lipid classes—particularly of different types of PL—and how these changes can influence the PUFA cascade. In particular, the synthesis of the vasodilatory epoxyeicosatrienoic acids, recently demonstrated in smooth muscle (41), heart (42) and kidney (43), may be of significance in hypertension. Whether dietary PUFA might correct local imbalances and be useful for treating hypertension is worthy of further study.

ABSTRACT: The identity of a previously unrecognized conjugated linoleic acid (CLA) isomer, 7 *trans*, 9 *cis*-octadecadienoic acid (18:2) was confirmed in milk, cheese, beef, human milk, and human adipose tissue. The 7 *trans*, 9 *cis*-18:2 isomer was resolved chromatographically as the methyl ester by silver ion–high-performance liquid chromatography (Ag^+–HPLC); it eluted after the major 9 *cis*, 11 *trans*-18:2 isomer (rumenic acid) in the natural products analyzed. In the biological matrices investigated by Ag^+–HPLC, the 7 *trans*, 9 *cis*-18:2 peak was generally due to the most abundant minor CLA isomer, ranging in concentration from 3 to 16% of total CLA. By gas chromatography (GC) with long polar capillary columns, the methyl ester of 7 *trans*, 9 *cis*-18:2 was shown to elute near the leading edge of the major 9 *cis*, 11 *trans*-18:2 peak, while the 4,4-dimethyloxazoline (DMOX) derivative permitted partial resolution of these two CLA isomers. The DMOX derivative of this new CLA isomer was analyzed by gas chromatography–electron ionization mass spectrometry (GC–EIMS). The double bond positions were at Δ7 and Δ9 as indicated by the characteristic mass spectral fragment ions at *m/z* 168, 180, 194, and 206, and their allylic cleavages at *m/z* 154 and 234. The *cis*/*trans* double-bond configuration was established by GC–direct deposition–Fourier transform infrared as evidenced from the doublet at 988 and 949 cm^{-1} and absorptions at 3020 and 3002 cm^{-1}. The 7 *trans*, 9 *cis*-18:2 configuration was established by GC–EIMS for the DMOX derivative of the natural products examined, and by comparison to a similar product obtained from treatment of a mixture of methyl 8-hydroxy- and 11-hydroxyoctadec-9 *cis* enoates with BF_3 in methanol.

Lipids 33, 803–809 (1998).

The major conjugated linoleic acid (CLA) isomer present in cow milk (1–9), human milk (10,11), cheese (2,3,5,12–16), beef (17), and human adipose tissue (18,19) was reported to be 9 *cis*, 11 *trans*-octadecadienoic acid (18:2), or rumenic acid. CLA is a collective term referring to all conjugated geometric and positional isomers of 18:2. Parodi (1) determined the major 9 *cis*, 11 *trans*-18:2 isomer in milk by a combination of gas chromatography (GC) and argentation thin-layer chromatography, partial hydrazine reduction, and ozonolysis. In addition to the 9 *cis*, 11 *trans*-18:2, Ha *et al.* (2) reported seven more CLA isomers (10 *cis*, 12 *trans*-18:2; 10 *trans*, 12 *cis*-18:2; 11 *cis*, 13 *cis*-18:2; 9 *cis*, 11 *cis*-18:2; 10 *cis*, 12 *cis*-18:2; and 9 *trans*, 11 *trans*-18:2/10 *trans*, 12 *trans*-18:2) in cheese based on comparing equivalent chain length data with published results (20), and GC–chemical ionization mass spectrometry of the fatty acid methyl esters (FAME). Recently, Lavillonnière *et al.* (16) identified five additional minor CLA isomers in cheese (8 *cis*, 10 *trans*-18:2; 8 *cis*, 10 *cis*-18:2; 8 *trans*, 10 *trans*-18:2; 11 *trans*, 13 *trans*-18:2; and 11?,13?-18:2). They partially reduced the CLA mixture with hydrazine, isolated the resulting monounsaturated fatty acids by silver nitrate thin-layer chromatography and identified the fatty acids by gas chromatography–electron ionization mass spectrometry (GC–EIMS) as their 4,4-dimethyloxazoline (DMOX) derivatives. These authors also evaluated the total CLA mixture by GC–EIMS.

In the past decade, unequivocal identification of CLA isomers was very limited for the following reasons. Firstly, in almost all reports, the identifications of GC peaks were solely based on comparing observed GC retention times with those of ill-defined commercial CLA mixtures, without independent confirmation of provisional assignments by chemical or spectroscopic methods. Secondly, acid-catalyzed methylation procedures, which were reported to increase *trans*,*trans* CLA isomers (8), were not avoided. Thirdly, even with 100-m GC capillary columns, the resolution of all the CLA isomers has not been achieved (16,21). Therefore, other confirmatory techniques were necessary to identify CLA isomers. Diagnostic ions in the EI mass spectra observed for a mixture of the 4-phenyl-1,2,4-triazoline-3,5-dione adducts (22) were suc-

Abbreviations: Ag^+–HPLC, silver ion–high-performance liquid chromatography; *cis/trans,* refers to all the CLA isomers having either a *cis,trans* or a *trans,cis* configuration; CLA, conjugated linoleic acid; DMOX, 4,4-dimethyloxazoline; FAME, fatty acid methyl esters; GC–DD–FTIR, gas chromatography–direct deposition–Fourier transform infrared; GC–EIMS, gas chromatography–electron ionization mass spectrometry.

cessfully used to identify double-bond positions in CLA mixtures. GC–EIMS with selected ion monitoring was used to suggest the presence of different CLA isomers in an unresolved mixture of four 4-methyl-1,2,4-triazoline-3,5-dione adducts of CLA (23). Full mass scan data allowed the identification of individual isomers in conjugated fatty acid mixtures resolved by GC of 4-methyl-1,2,4-triazoline-3,5-dione derivatives (24). Reconstructed ion profiles of the isomer-specific ions for CLA DMOX were used to distinguish between the signals of different CLA isomers in the present study. This permitted the determination of double-bond positions for partially resolved CLA isomers. Recently, we modified a silver ion–high-performance liquid chromatography (Ag^+–HPLC) method by Adlof *et al.* (25). For the first time, using the modified method, we separated 12 geometric and positional CLA isomers found in a commercial mixture (15). This proved to be an essential complementary chromatographic technique for the identification of CLA isomers.

In the present communication, a newly identified CLA isomer found in milk, cheese, beef, human milk, and adipose tissue matrices was resolved as the FAME derivative by Ag^+–HPLC, and as the DMOX derivative by GC. This CLA isomer was identified as 7 *trans*, 9 *cis*-18:2 by GC–EIMS and GC-direct deposition-Fourier transform infrared (GC–DD–FTIR) spectroscopy. The *trans*,*cis* geometry was established by GC–EIMS for the DMOX derivative of the natural products examined, and by comparison with a known 7 *trans*, 9 *cis*-18:2 product.

MATERIALS AND METHODS

A mixture of CLA isomers was purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Several pure CLA isomers were obtained as their free fatty acids from Matreya Inc. (Pleasant Gap, PA). Acetonitrile and hexane were ultraviolet grade. Other solvents were distilled-in-glass quality. 2-Amino-2-methyl-1-propanol (95%) was purchased from Aldrich Chemical Company, Inc. (Milwaukee, WI). A 10% solution of trimethylsilyldiazomethane (TMS-DAM) in hexane was obtained from TCI America (Portland, OR). Anhydrous $NaOCH_3$/methanol was purchased from Supelco, Inc. (Bellefonte, PA). Cow milk was available from a previous study (9). Cheese and beef products were purchased locally. The biological specimens were human subcutaneous adipose tissues. They were a gift from Dr. H.J. Boehles (Johann-Wolfgang-Goethe University Clinic, Frankfurt, Germany) and were obtained from a group of male and female children, aged 1–13 yr, with inguinal hernia. Human milk was a gift from Dr. G. Jahreis (Friedrich Schiller University, Jena, Germany).

Lipid extraction. Milk lipids were extracted using a modified Folch procedure as described previously (8). Cheese was extracted with diethyl ether/petroleum ether (1:1) after homogenization with ethyl alcohol in the presence of potassium oxalate. The total cheese lipids were then dried over anhydrous Na_2SO_4. Beef lipids were extracted with chloroform/methanol as described previously (26). Human adipose tissue was extracted as described previously (19).

Preparation of FAME. The total lipids from milk, cheese, beef, and human adipose tissue (20–70 mg) were methylated using anhydrous $NaOCH_3$/methanol (15). The FAME were analyzed directly by GC and Ag^+–HPLC. The free fatty acids were methylated with a 10% trimethylsilyldiazomethane as described previously (15,27).

Ag^+–HPLC. The HPLC equipment and conditions were the same as described previously (15). A ChromSpher 5 Lipids semipreparative (10 mm i.d. × 250 mm stainless steel; 5 µm particle size) and an analytical (4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size) silver impregnated columns were used (Chrompack, Bridgewater, NJ). The mobile phase was 0.1% acetonitrile in hexane and was operated isocrati-

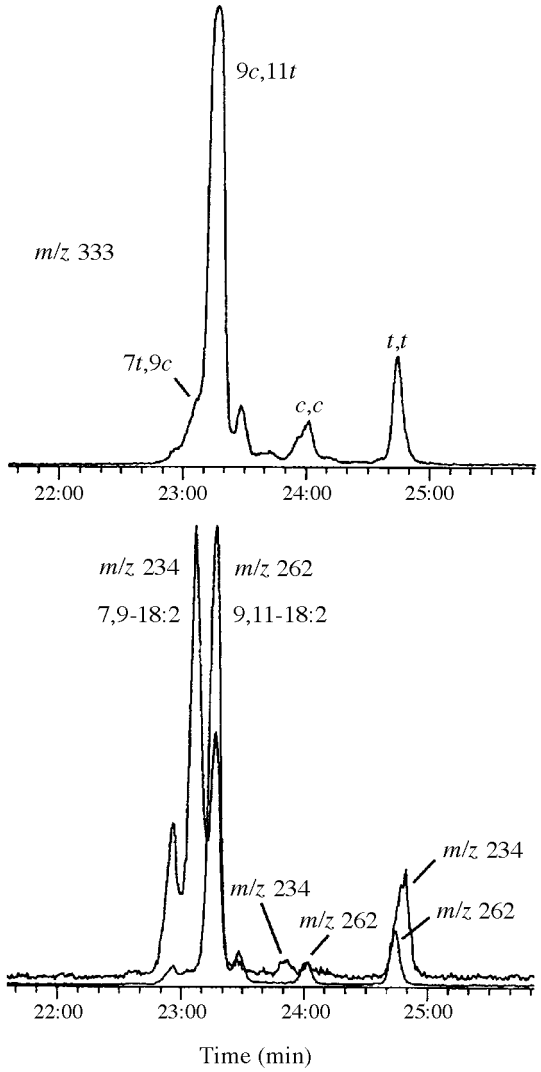

FIG. 1. Partial gas chromatography–electron ionization mass spectrometry (GC–EIMS) chromatogram of conjugated fatty acid 4,4-dimethyloxazoline (DMOX) derivatives from human adipose tissue showing the reconstructed ion profiles for *m/z* 333 (top); and *m/z* 234 and 262 (bottom). In the *cis*/*trans* region, the first two peaks (*m/z* 234) were due to 7 *cis*, 9 *trans*-18:2, 7 *trans*, 9 *cis*-18:2, respectively, and the third one (*m/z* 262) was due to 9 *cis*, 11 *trans*-18:2.

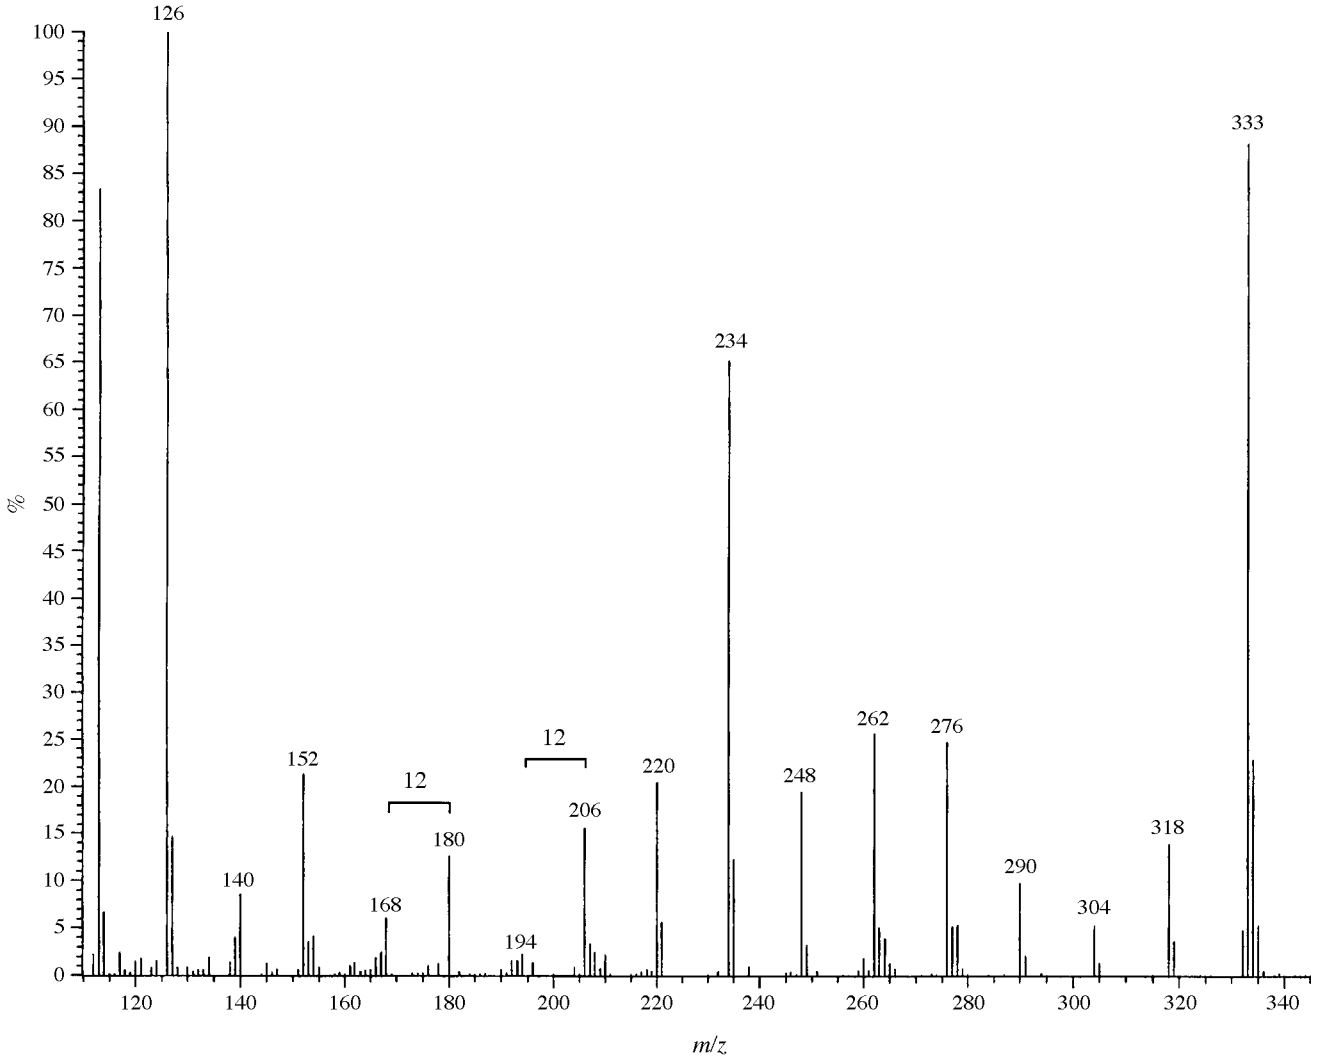

FIG. 2. GC–EIMS spectrum of the DMOX derivative of 7 *trans*, 9 *cis*-18:2 from cow milk. For abbreviations see Figure 1.

cally. The flow rates were 4.0 mL/min and 1.0 mL/min, for the semipreparative and analytical columns, respectively. Detection was at 233 nm.

DMOX derivatives. DMOX derivatives were prepared as described previously (15,28,29).

Instrumentation. The GC (8), GC–EIMS (15,28), and GC–DD–FTIR (30) instruments and conditions were given previously.

RESULTS AND DISCUSSION

The *m/z* 333 GC–EIMS ion profile for the DMOX derivatives of fatty acids from human adipose tissue (Fig. 1 top) showed the presence of a small peak emerging just ahead of that of the major 9 *cis*, 11 *trans*-18:2 isomer. A similar *m/z* 333 GC-EIMS ion profile was observed for the fatty acid DMOX derivatives of all other natural matrices investigated. The mass spectrum for this new peak is shown in Figure 2 for cow milk. The EI mass spectrum of the new compound exhibited an abundant molecular ion at *m/z* 333, characteristic of 18:2 DMOX derivatives. An abundant ion at *m/z* 126, followed by a homologous series of ions separated by gaps of 14 mass units, with intervals of 12 mass units found between *m/z* 168 (C6) and 180 (C7), and between *m/z* 194 (C8) and 206 (C9), indicated the presence of two double bonds at Δ7 and Δ9. In addition, the mass spectrum showed two favorable allylic cleavage ions at *m/z* 154 and 234, supporting a 7,9-18:2 structure. The abundant ion at *m/z* 152 is due to an anomaly (31), which remains unexplained. The reconstructed ion profile for the characteristic allylic ion *m/z* 234 showed two peaks due to 7,9-18:2 isomers that eluted before the one at *m/z* 262 for the 9 *cis*, 11 *trans*-18:2 isomer in Fig. 1 (bottom). The possible geometric configuration of the two 7,9-18:2 isomers will be discussed below. These results demonstrated that the first two eluting peaks (*m/z* 234) did not arise from the adjacent major 9 *cis*, 11 *trans*-18:2 isomer (*m/z* 262). Techniques, such as GC equivalent chain length (2), and partial hydrazine reduction followed by GC separation of the resultant 18:1 iso-

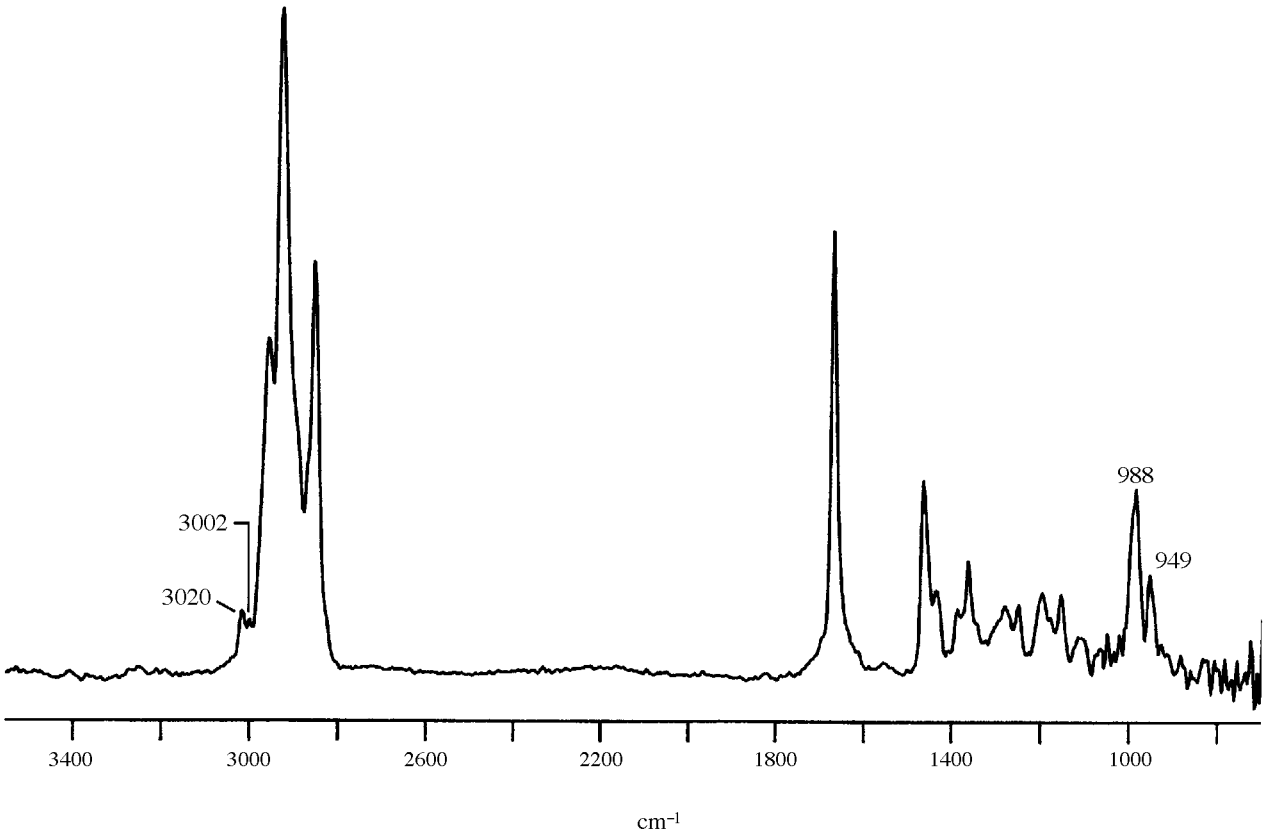

FIG. 3. Gas chromatography–direct deposition–Fourier transform infrared (GC–DD–FTIR) spectrum of 7 *trans,* 9 *cis*-18:2 DMOX derivative from cheese. For other abbreviation see Figure 1.

meric mixtures (16), did not identify the 7,9-18:2 isomer in cheese. A possible reason for the latter is that the 7 *trans*-18:1 FAME coeluted with the 6 and 8 *trans*-18:1 FAME, and the 7 *trans*-18:1 DMOX coeluted with the 9 *trans*-18:1 DMOX, even on long polar capillary columns (32).

The geometric configuration of the 7,9-18:2 DMOX derivatives was established by GC–DD–FTIR, as shown for cheese in Figure 3. The observed IR spectrum exhibited the characteristic doublet for conjugated *cis*/*trans* dienes at 988 and 949 cm^{-1} and absorptions at 3020 and 3002 cm^{-1} (19,33). The IR spectrum of 7,9-18:2 was similar to that of 9 *cis*, 11 *trans*-18:2. However, FTIR was not able to distinguish between a *cis*,*trans* or a *trans*,*cis* configuration.

Ag^+–HPLC was shown to separate the different *trans*,*trans*, *cis*/*trans*, and *cis*,*cis* CLA isomers of 8,10-18:2, 9,11-18:2, 10,12-18:2, and 11,13-18:2 (15), and is shown for comparison in Figure 4 (top). The 7,9-18:2 isomer in the natural matrices investigated was clearly separated by Ag^+–HPLC, eluting in the *cis*/*trans* region after the major 9 *cis*, 11 *trans*-18:2 peak, and was generally the most abundant of the minor CLA positional isomers. Figure 4 shows typical Ag^+–HPLC separations for cow milk, cheese, beef, and human adipose tissue and human milk. The relative elution position of this peak is consistent with a *cis*/*trans* configuration found by IR for this compound. To demonstrate that this peak was not due only to the 8 *trans*, 10 *cis*-18:2 isomer (Fig. 4, top), which eluted at about the same retention volume as that of the *cis*/*trans* 7,9-18:2 peak (Fig. 4, bottom five chromatograms), a representative cheese sample was fractionated as FAME by semipreparative Ag^+–HPLC. The fraction enriched in the *cis*/*trans* 7,9-18:2 isomer was further analyzed as the DMOX derivative by GC–EIMS. The results obtained were similar to those shown in Figures 1 and 2, thus confirming the double bond positions of this new isomer. The difference in retention time between the 8 *trans*, 10 *cis*-18:2 and *trans*/*cis* 7,9-18:2 was also demonstrated chromatographically by coinjecting increasing amounts of a commercial CLA mixture (Fig. 5A) added to a beef fat extract (Fig. 5B). With increased amounts of the commercial CLA mixture, the 8 *trans*, 10 *cis*-18:2 emerged as the more abundant and before the 7,9-18:2 CLA isomer in the coinjected mixture (Fig. 5, bottom). These data do not indicate the presence or absence of the 8 *trans*, 10 *cis*-18:2 isomer in the natural products investigated.

The absolute configuration of the 7,9-18:2 isomer was established by using two methods. The DMOX derivatives of geometric CLA isomers were separated by GC (19); the 9 *cis*, 11 *trans*-18:2 eluted before the 9 *trans*, 11 *cis* isomer (19). Based on this evidence, the first of the two *m/z* 234 peaks in Fig. 1 (bottom) was due to 7 *cis*, 9 *trans*-18:2, while the sec-

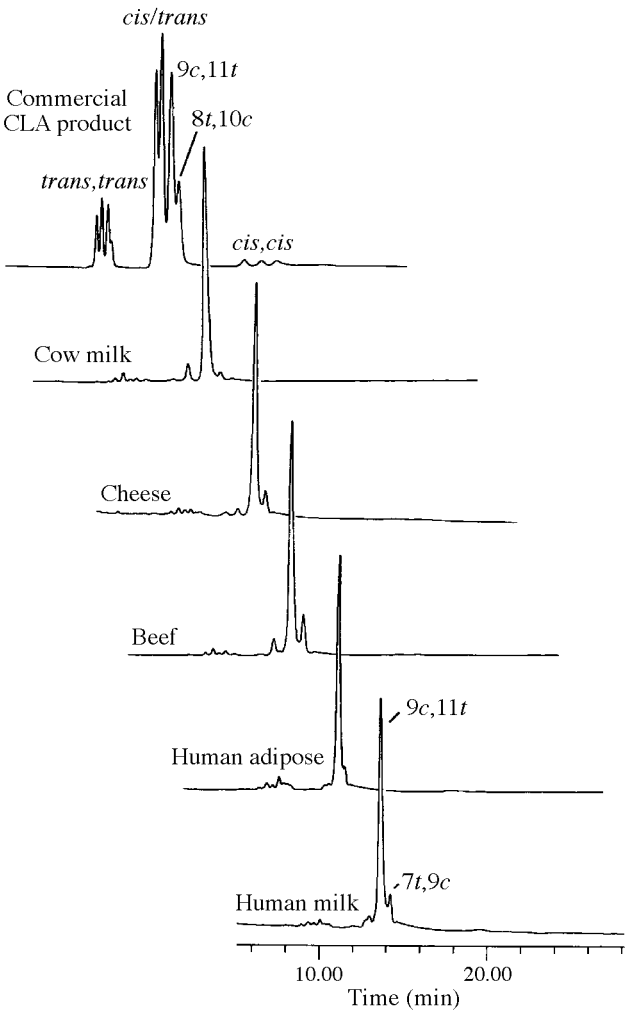

FIG. 4. Silver ion–high-performance liquid chromatography (Ag^+–HPLC) chromatograms of a commercial conjugated linoleic acid (CLA) mixture containing 12 CLA isomers and of cow milk, cheese, beef, human adipose tissue, and human milk. Concentration-dependent variations in resolution were observed between the 9,11-18:2 and the 7,9-18:2 *cis/trans* isomers, but the elution sequence was not altered.

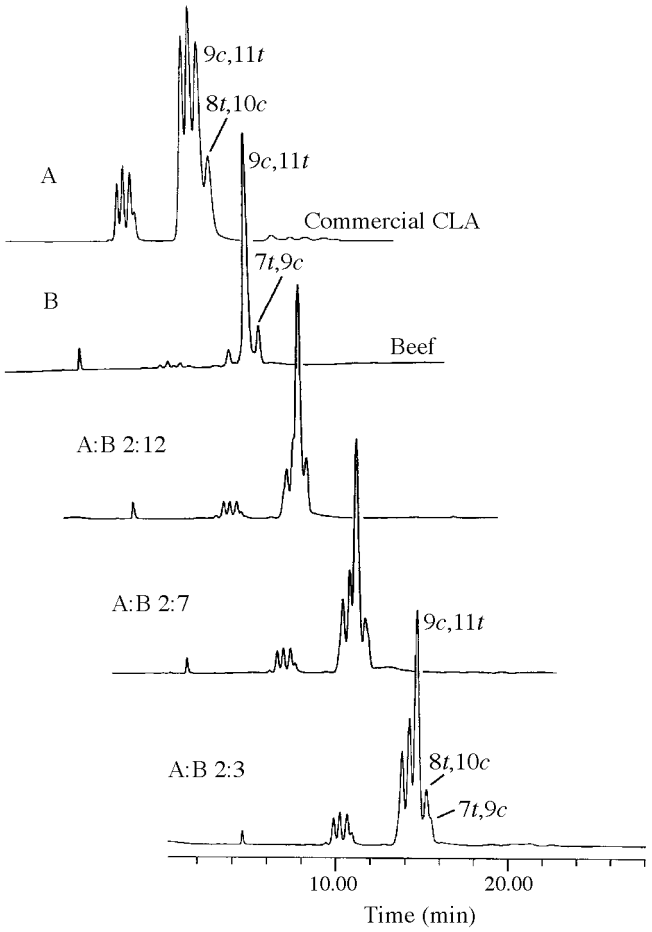

FIG. 5. Ag^+–HPLC chromatographic distinction between the 7 *trans*, 9 *cis*-18:2 isomer found in total beef fat and the 8 *trans*, 10 *cis*-18:2 isomer present in a commercial CLA mixture. Coinjection of these mixtures indicated that 7 *trans*, 9 *cis*-18:2 elutes after 8 *trans*, 10 *cis*-18:2. For abbreviations see Figure 4.

ond, more abundant, peak was due to 7 *trans*, 9 *cis*-18:2. Further independent confirmation was obtained from a mixture of methyl 8-hydroxy- and 11-hydroxyoctadec-9-*cis*-enoates treated with BF_3, as reported previously (28). The products of this reaction included two 7,9-18:2 isomers: 7 *trans*, 9 *cis*-18:2 and 7 *trans*, 9 *trans*-18:2 (28). Analysis of this mixture as DMOX derivatives by GC showed that the 7 *trans*, 9 *cis*-18:2 coeluted with the peak of the new CLA isomer (data not shown), thus establishing its identity. A similar result was also found for the 7 *trans*, 9 *trans*-18:2 (*vide infra*). Ag^+–HPLC did not separate the *cis/trans* geometric isomers.

In addition, Figure 1 is also consistent with the presence of trace levels of 7 *trans*, 9 *trans*-18:2, 7 *cis*, 9 *trans*-18:2, and 7 *cis*, 9 *cis*-18:2, based on the GC–EIMS reconstructed ion profile of the allylic ion *m/z* 234 for the DMOX derivatives of human adipose tissue. This recontructed ion profile permitted the identification of the 7 *trans*, 9 *trans*-18:2 isomer that was not resolved by GC. Furthermore, the last eluting *trans*, *trans* Ag^+–HPLC peak observed for the different specimens investigated had the same retention volume as that of the 7 *trans*, 9 *trans*-18:2 product of the BF_3 reaction with methyl 8-hydroxyoctadec-9-*cis*-enoate. This result was consistent with the presence of a trace of 7 *trans*, 9 *trans*-18:2 in these matrices. The identities of minor CLA isomers will need to be fully confirmed by direct measurements. The relative abundance of the 7 *trans*, 9 *cis*-18:2 isomer in a few select examples of natural products was determined by Ag^+–HPLC (Table 1).

In conclusion, a new CLA isomer was found in milk (cow and human), cheese, beef, and human adipose tissue, and it was generally prominent among the minor CLA isomers ranging in concentration from 3 to 16% of the total CLA isomers. This CLA isomer would therefore also be expected in all ruminants and dairy products, and in humans and animals that consume them. The isomer was shown to be 7 *trans*, 9 *cis*-18:2 based on GC–EIMS, GC–DD–FTIR and Ag^+–HPLC results. These results emphasize the need to use the most polar GC columns available, such as long CP-Sil 88 or

TABLE 1
Amount of 7,9-18:2 FAME Isomer, Relative to Total CLA FAME, in Natural Products as Determined by Ag^+–HPLC[a]

	CLA Isomers (% of total CLA)			
Natural product	9*c*,11*t*	7*t*,9*c*	Other *c*/*t*	Total *t*/*t*
Human milk[b]	79.7–84.0	5.9–9.9	4.3–7.3	3.8–6.4
Cow milk[b]	82.1–86.8	2.8–5.3	4.2–6.2	4.6–6.4
Sheep milk	86.0	6.0	2.7	5.3
Cheese[c]	80.0–83.5	4.6–11.1	1.6–5.8	5.8–9.2
Beef	74.8	15.8	4.8	4.2
Human adipose tissue[b]	83.2–87.4	2.9–5.1	1.8–2.0	6.6–10.5

[b]Ranges obtained for five different samples.
[c]Ranges obtained for five types of cheese.

SP2560 capillary columns, to resolve as many CLA isomers as possible (21). Furthermore, we found it essential to confirm the identity of CLA isomers by GC–EIMS as their DMOX derivatives. Optimal GC conditions (21) allowed the resolution of 7 *trans*, 9 *cis*-18:2 and 9 *cis*, 11 *trans*-18:2 as DMOX derivatives. Erroneous conclusions may result if CLA assignments are solely based on chromatographic retention times. Ag^+–HPLC will become a necessary complementary method for the identification of the different geometric and positional CLA isomers including those present at trace levels (15). The 7 *trans*, 9 *cis*-18:2 isomer in biological matrices and dairy products may arise by desaturation of the 7 *trans*-18:1 as demonstrated by Pollard *et al.* (34).

[a]Division of Medical Cell Biology, Clinical Research Center, Novum, and [b]Metabolism Unit, Center for Metabolism and Endocrinology, Department of Medicine, Karolinska Institutet at Huddinge University Hospital, S-141 86 Huddinge, Sweden

ABSTRACT: The type and amount of lipophilic antioxidants in plasma of hyperlipidemic patients are of great importance since they play a central role in preventing deleterious oxidation of blood lipids and proteins. Isolation and quantitation of lipophilic antioxidants from hyperlipidemic plasma samples meet great obstacles because of increased levels of various intermediary lipid products. This study was designed to develop a rapid and efficient extraction and separation procedure for simultaneous analysis of ubiquinone-9 and -10 as well as α-, δ-, and γ-tocopherol isomers. The levels of ubiquinone-10, α- and γ-tocopherol were analyzed in human plasma samples using high-performance liquid chromatography. Lipid extraction was performed by petroleum ether/methanol/water. After phase separation, ubiquinone was reduced to ubiquinol by sodium borohydride and the lipids were separated on a C18 column. A binary gradient with solvents containing lithium perchlorate was used, and an electrochemical detector was employed for quantitation. This procedure was also efficient for the analysis of antioxidant lipids in samples containing a large number of accumulated and interfering lipid intermediates. Thus, the procedure described here is useful for efficient and rapid quantitation of ubiquinones and tocopherols in human plasma samples, especially those originating from hyperlipidemic patients.
Lipids 33, 811–815 (1998).

Ubiquinone (UQ) is an obligatory constituent of the mitochondrial respiratory chain and, consequently, a well-studied lipid (1). During recent years, an additional function for UQ has been discovered: this lipid in its reduced form (ubiquinol) is the only endogenously synthesized lipid-soluble antioxidant in animal tissues (2). UQ is also found in blood, associated with low and high density lipoproteins (3,4). Since the antioxidant function is dependent on the reduced state of the lipid, an enzymatic mechanism is obviously present both in blood and in various cells for regeneration of the oxidized form (5,6). The blood antioxidant level is important in preventing cholesterol oxidation, preventing damage during reperfusion injury and also in ameliorating inflammation (7,8).

α-Tocopherol, the major lipid-soluble antioxidant present in blood, originates from the diet (9). In contrast to various tissues where ubiquinol is the dominating antioxidant, the concentration of α-tocopherol in the blood is 10 times higher than that of UQ (10). While α-tocopherol inhibits lipid peroxidation by quenching LOO· radicals, ubiquinol has been considered to influence both the initiation and propagation steps (2).

The use of high-performance liquid chromatography (HPLC) has considerably improved the separation and quantitation of UQ in various lipid extracts. Because UQ cannot be subjected to alkaline hydrolysis (11), an efficient extraction procedure was difficult to find since those that are used are time-consuming and cannot be applied to a large number of samples. Various chromatographic procedures have been employed to purify the samples and analyze the amount of UQ by using an ultraviolet (UV) detector to monitor the absorbing carbon-carbon double bonds of the isoprenoid sidechain or the characteristics of the benzoquinone ring (12–14). However, a large number of lipid metabolites, present in hyperlipidemic blood, absorb UV light at low wavelengths and prevent simultaneous quantitation of both UQ and tocopherols. Methods are additionally available which avoid most of these obstacles, such as coupled-column liquid chromatography (15,16), but these are time-consuming and necessitate special equipment.

In this study, we describe a rapid extraction procedure followed by a separation of the reduced UQ and tocopherols by reversed-phase HPLC using a binary gradient. In this system, by using an electrochemical detector, a broad range of lipid soluble antioxidants can be analyzed simultaneously. An additional advantage of the procedure is that the numerous lipid metabolites in the hyperlipidemic blood do not interfere with the quantitation of the antioxidant lipids.

MATERIALS AND METHODS

Chemicals. All solvents used in this study were obtained from Merck (Darmstadt, Germany) and were of HPLC grade. UQ and tocopherols used in the standard mixture or employed as internal standards were obtained from Sigma Chemical (St. Louis, MO). The other chemicals were pro analysis grade (Merck).

Plasma samples. The material examined consisted of 18 hyperlipidemic and 21 control samples. After overnight fasting, venous human blood samples were collected in he-

parinized vacutainers. EDTA-containing tubes were equally efficient. The tubes were centrifuged immediately to prepare plasma, which was stored at −80°C prior to use in the various experiments. No antioxidants were added to the samples.

Lipid extraction. Samples of plasma (0.2 mL) were taken for lipid extraction; and 5-μL internal standards (2 nmol δ-tocopherol and 1 nmol UQ-9) dissolved in chloroform/methanol (2:1, vol/vol), 0.2 mL distilled water, 3.6 mL methanol, and 2.4 mL petroleum ether (boiling point 40–60°C) were added. The samples were vortexed vigorously for 30 s and centrifuged at 800 × *g* for 5 min to obtain phase separation. The upper solvent phase was transferred into another tube and dried under nitrogen.

HPLC analysis. The lipid residue was dissolved in 0.1 mL chloroform/methanol (2:1, vol/vol) and 2 μL 0.5 M sodium borohydride (dissolved in 0.2% NaOH) was added to a final concentration of 10 mM to reduce the UQ. This was required for determination of the total amount of UQ-10 with the electrochemical detector. The sample was vortexed for 5 s and incubated at room temperature for 10 min. Then 20 μL of this mixture was analyzed by HPLC (Shimadzu LC-6A with C-R4A Chromatopac system; Shimadzu, Tokyo, Japan). UQ and tocopherols were separated using a reversed-phase Microsorb C-18 column (3 μm, 4.6 mm × 10 cm; Rainin Instrument Co. Inc., Woburn, MA) (17). The column was protected by using a filter (Rheodyne 0.5 μm × 3 mm, Cotah, CA). A binary gradient was employed with a flow rate of 1.5 mL/min, from the initial 90% methanol/water (9:1, vol/vol) (A solvent) to 100% methanol/2-propanol/*n*-hexane (2:1:1, by vol) (B solvent). Both solvents contained 20 mM lithium perchlorate as an electrolyte and were degassed with helium. During the first 5 min, 90% A and 10% B solvents were employed. Between 5 and 15 min, a linear gradient was applied up to 50% B solvent; between 15 and 23 min, the B concentration was additionally increased to 53%; and between 23 and 26 min, a step gradient was used to reach 100% B concentration. During an additional 4 min, only B solvent was utilized. The levels of UQ and tocopherols were monitored with an electrochemical detector (Shimadzu L-ECD-6A) applying a potential of + 0.7 V vs. Ag/AgCl. The peak areas of compounds were compared to the peak areas of standard compounds with known concentrations. The peak areas were calculated using the computer programme of C-R4A Chromatopac (Shimadzu).

For comparison, UQ was also analyzed in all samples by injecting the lipid extract into the HPLC using a reversed-phase system with a C-18 Hypersil ODS column, (3 μm, 4.6 mm × 6 cm; Hewlett-Packard, Böblingen,Germany) (14). In this system, UQ was detected by UV absorption at 275 nm. The absorbance value of 0.04 AUFS corresponding to the recorder full scale was used for detection. Before injection, ferric chloride (final concentration 0.25 mM) was added to the samples in order to determine the total oxidized UQ-10 pool. A linear gradient was started with 100% methanol/water (9:1, vol/vol) and continued to 100% methanol/2-propanol/*n*-hexane (2:1:1, by vol) during a time course of 15 min.

The recovery studies demonstrated a range of 89–96%. In a separate series, aliquots of the same sample were quantitated at 8–12 different occasions. The recoveries were calculated by using internal standards. The difference between the samples did not exceed 8%.

RESULTS

The concentration of UQ can be determined by HPLC using its UV absorption at 210 nm based on the presence of double bonds. Organic compounds containing double bonds generally exhibit high absorption peaks in the UV region because the electrons in unsaturated bonds are easily excited. Because the carbon-carbon double bonds in the isoprenoid side-chain of UQ are numerous, this method has a high sensitivity. Tocopherols have rather high absorption peaks at this wavelength but other lipophilic compounds have similar retention times. A more specific but less sensitive approach is to use UV detection at 275 nm, which is the absorbance maximum for UQ in the oxidized form. Tocopherols have at this wavelength very low absorption and cannot be quantified. In normal human plasma, UQ-10 could be easily quantitated at this wavelength (Fig. 1A). In various types of hyperlipidemic conditions, however, a large number of additional absorbing peaks appeared on the chromatogram, eliminating the possibility of identification and quantitation of UQ (Fig. 1B).

By using appropriate conditions, as described in the Materials and Methods section, complete isolation and analysis of both tocopherols and UQ could be performed. In this procedure, the lipids were extracted by a mixture of petroleum ether and methanol. After phase separation, the phospholipids were removed, as they partitioned to the methanol phase. The extraction of neutral lipids was complete and rapid. As comparison, the samples were also extracted with prolonged treatment with chloroform/methanol (2:1, vol/vol) and also with ethanol. With all three procedures, the recoveries were identical. It is of utmost importance to use an appropriate concentration of sodium borohydride (Table 1). Low concentrations of the reducing agent were unsufficient to reduce UQ completely, whereas at high concentrations α-tocopherol was markedly degraded. The highest concentrations tested also caused breakdown of UQ. The optimal range was found to be 5–10 mM.

By designing an efficient gradient system and using an electrochemical detector, HPLC separation of a mixture containing standards of δ-, γ-, and α-tocopherols, as well as UQ-9 and UQ-10, resulted in a complete separation of all constituents (Fig 2A). When the same hyperlipidemic plasma as that shown in Fig. 1B was analyzed using an electrochemical detector, the two plasma tocopherols, the γ- and α-forms, were well separated (Fig. 2B). They were also distinguishable from the δ-form which was added as an internal standard. In the same gradient system, UQ-10 was eluted after 22 min, well separated from the internal standard, UQ-9. A very similar HPLC pattern was obtained when a large number of plasma samples originating from patients suffering from different types of hyperlipidemic conditions were investigated.

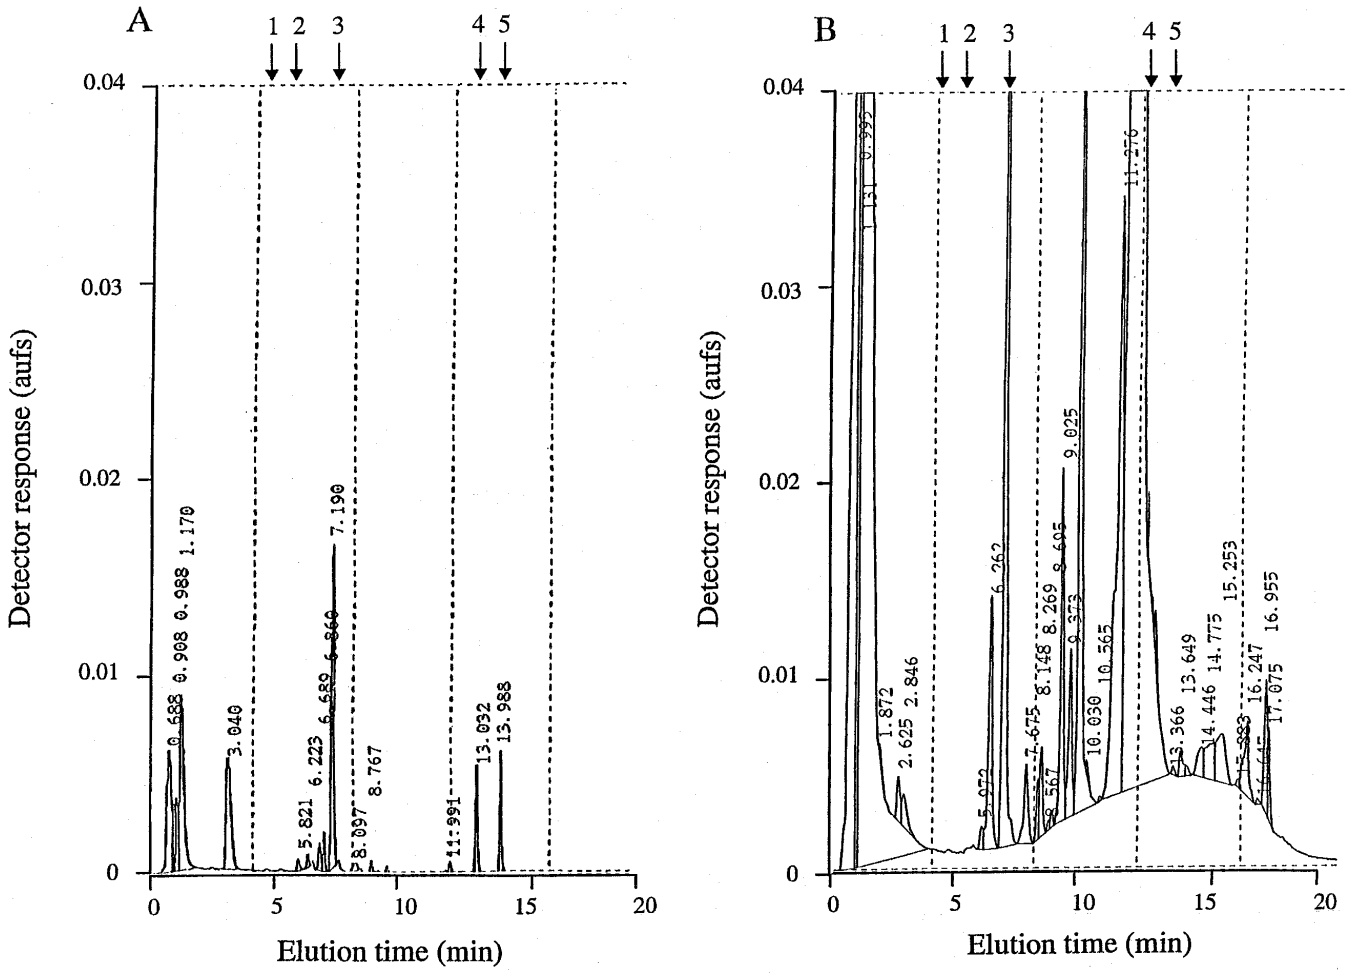

FIG. 1. Analysis of plasma ubiquinone (UQ) with high-performance liquid chromatography using ultraviolet absorption at 275 nm. (A) Normal human plasma. (B) Human plasma from a hyperlipidemic patient. Elution times: 1, δ-tocopherol; 2, γ-tocopherol; 3, α-tocopherol; 4, UQ-9; 5, UQ-10. The individual peaks were identified by comparing the retention times with those of the standards.

Also, normolipidemic plasma samples in this system exhibited a similar pattern as the hyperlipidemic ones but the lipid amounts were lower (Fig. 2C). The reliability of the method employed is demonstrated in Table 2. Analyses of plasma samples from 18 hyperlipidemic patients and 21 control subjects showed that the plasma levels of UQ-10 as well as α- and γ-tocopherols were significantly higher in hyperlipidemic patients compared to control subjects.

10	100	100
100	91	100
200	66	87
500	5	27

DISCUSSION

Recent developments concerning the antioxidant function of UQ have created a considerable interest in the quantitation of this lipid. Because of the low blood levels of UQ and the presence of other components with similar chromatographic properties, UQ isolation and quantitation is still a difficult task. The large number of lipid metabolites which accumulate in human blood in various hyperlipidemic conditions causes interference, not only when UV absorption is used to detect the double bonds but also when the absorbing characteristics of the benzoquinone ring are utilized. However, normal human blood, free from accumulating pathological lipid products, can be studied by using UV detection at 275 nm.

Petroleum ether efficiently extracted the lipids from various blood samples. In the presence of methanol, partition of the solvent phases was obtained providing a simple way of removing the phospholipids. In this way, the sample preparation required less than 10 min. We used sodium borohydride to reduce UQ to ubiquinol, which could be detected with high sensitivity using an electrochemical detector. When fresh samples are analyzed, the degree of reduction in the *in vivo*

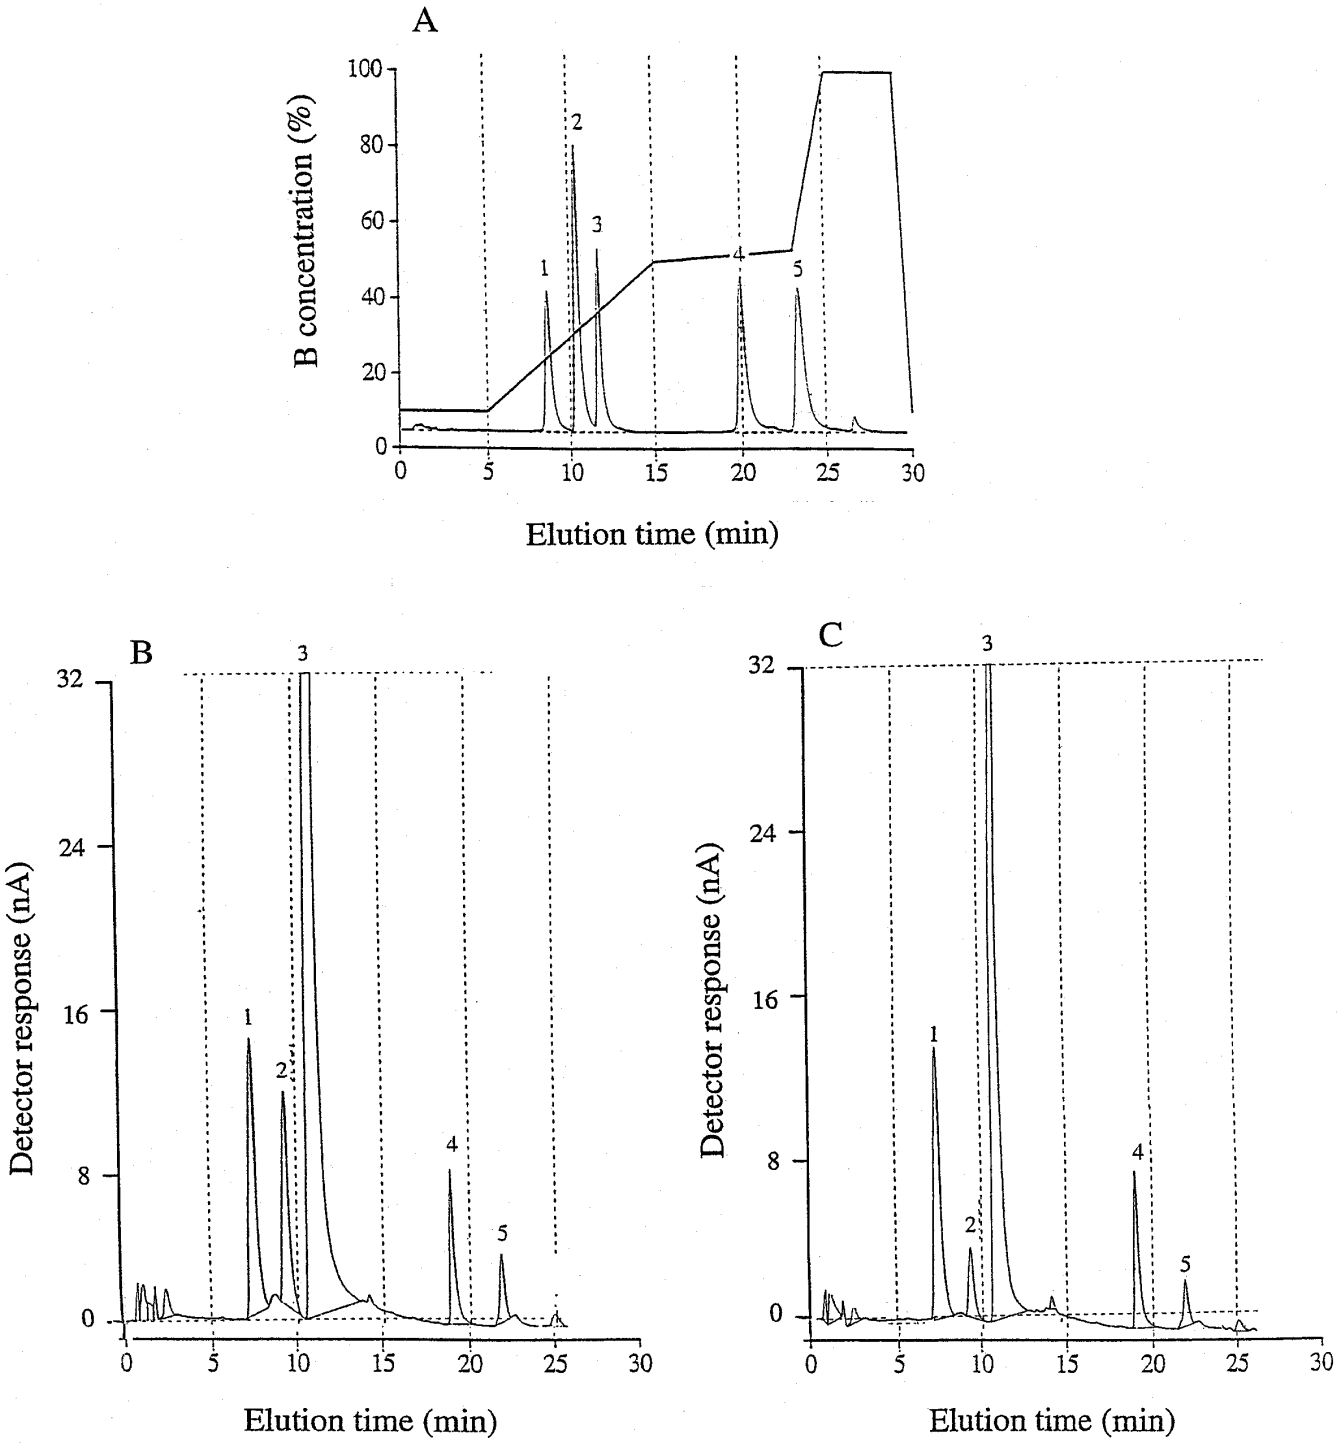

FIG. 2. Separation and quantitation of redox lipids from hyperlipidemic human plasma. The procedure used is described in the Materials and Methods section. The gradient pattern of B solvent [methanol/2-propanol/*n*-hexane (2:1:1, by vol)] is given as a straight line. (A) Separation of standards. (B) Chromatography of lipid extract from plasma sample of a hyperlipidemic patient (also shown in Fig. 1B). Chromatography of a normolipidemic plasma sample. 1, δ-tocopherol; 2, γ-tocopherol; 3, α-tocopherol; 4, UQ-9, 5, UQ-10. For abbreviation see Figure 1.

state can also be investigated. In earlier studies, we found that about 60% of blood UQ is in reduced form. Upon storage, the extent of reduction is decreased (18). The difference between the amounts of ubiquinol, analyzed with and without sodium borohydride treatment, can be used for the calculation of the amount of the oxidized form of UQ. Since only the reduced UQ is effective as an antioxidant, the redox state of this lipid is often of great physiological interest (19,20).

The two main types of redox lipids present in blood are

TABLE 2
Plasma Levels of Lipophilic Antioxidants in Hyperlipidemic Patients and Control Subjects[a]

	Patients	Control subjects
Ubiquinone-10	1.54 ± 0.59	0.75 ± 0.51[b]
α-Tocopherol	69.5 ± 17.3	38.4 ± 11.6[b]
γ-Tocopherol	10.9 ± 6.4	3.3 ± 1.1[b]

[a]The values are given as μmol/L. The results are means ± SD (n = 18 for hyperlipidemic and n = 21 for control plasma samples).
[b]$P < 0.001$ (Student's t-test).

UQ and tocopherols. Certain species possess only one dominant UQ homolog with a specific isoprenoid side-chain length, but in many cases an additional minor component, differing by one isoprene, coexists (21). In the case of tocopherols, the α-form is dominant, but the γ-form is often additionally present. When internal standards, comprising UQ with a different chain length and δ-tocopherol (which is practically absent in animal tissues), were included in the blood sample, the HPLC procedure employed separated all the five components well. The procedure described could be used in various studies to investigate the distribution and function of the two major classes of lipid-soluble antioxidants.

A range of chromatographic separations has previously been employed to remove contaminating lipid intermediates and to allow quantitation of UQ at the wavelength of 210 nm (21). The specificity of measurements, based on the analysis of the benzoquinone ring (275 nm), is considerably higher. This method is less sensitive than that using the absorption at 210 nm, but the relatively low background obtained represents an additional advantage. In this way, detection with an UV detector is a useful procedure in many cases. In blood samples with accumulated lipid intermediates, the utilization of an electrochemical detector is the only practical useful procedure.

Evidence That Commercial Calf and Horse Sera Can Contain Substantial Amounts of *trans*-10,*cis*-12 Conjugated Linoleic Acid

Yeonhwa Park and Michael W. Pariza*

Food Research Institute, University of Wisconsin–Madison, Madison, Wisconsin 53706

ABSTRACT: We analyzed fetal calf, newborn calf, horse, and adult cow sera for conjugated linoleic acid (CLA). All sera samples contained CLA, but the amounts varied. The predominant isomer was *cis*-9,*trans*-11 CLA but some samples appeared to contain substantial amounts of an isomer with the retention time of *trans*-10,*cis*-12 CLA.
Lipids 33, 817–819 (1998).

CLA is the acronym for a class of positional and geometric conjugated dienoic isomers of linoleic acid. The term was coined by Ha *et al.* (1) when they reported biological activity (i.e., anticarcinogenic activity) associated with CLA isolated from grilled ground beef or produced from linoleic acid by base-catalyzed isomerization. Since then, substantial interest has developed in the biochemical actions of CLA and its potential application to foods, feeds, and pharmaceuticals (2).

While numerous isomers have been described in various commercial CLA products (3,4), the major isomer in the diet is *c*-9,*t*-11 CLA (where *c* = *cis* and *t* = *trans*) (5) because dairy products are the major dietary source of CLA, and virtually all the CLA in dairy products is present as the *c*-9,*t*-11 isomer (6). Only small amounts of the *t*-10,*c*-12 CLA isomer are observed in dairy products (7). McGuire *et al.* (8) reported that human milk also contains mostly *c*-9,*t*-11 CLA with only small amounts of the *t*-10,*c*-12 CLA isomer. The *c*-9,*t*-11 CLA is also the major isomer in beef products, but beef consistently appears to contain the *t*-10,*c*-12 CLA isomer as well, in varying levels (5).

Given the prominence of the *c*-9,*t*-11 CLA isomer in the diet and especially in dairy products, this isomer may be the most biologically active form of CLA (5). However, it is important to note that this assumption has not been proved. We are utilizing cultured mammalian cells in our investigation of this issue (9). Since bovine and/or horse sera are commonly added to cell culture media, we undertook an investigation of the natural occurrence of CLA isomers in these products sold for cell culture use.

Abbreviation: CLA, conjugated linoleic acid.

Five lots of fetal calf sera, three lots of newborn calf sera, and three lots of horse sera were purchased from commercial sources (Table 1, footnote *a*). Sera were also obtained from four cows maintained at the Dairy Forage Research Center, University of Wisconsin (UW)–Madison (Madison, WI). The sera were analyzed for CLA as described (5). Briefly, sera samples were extracted with chloroform/methanol (2:1) and methylated with 4% HCl in methanol at 60°C for 20 min. Heating to 60°C, as opposed to 80°C (7), substantially reduces isomerization artifact with this methylation procedure (5; Park, Y., and M. Pariza, unpublished observations). Additionally only trace amounts of the *t*-9,*t*-11 isomer were sometimes detected.

Methyl esters of fatty acids were analyzed with gas chromatography and identified by comparison with CLA standard prepared in this laboratory. The procedure utilizes a Hewlett-Packard 5890 series II (Palo Alto, CA) fitted with a flame-ionization detector and 3396A integrator. A Supelcowax-10 (Supelco, Bellefonte, PA) fused-silica capillary column (60 m × 0.32 mm i.d., 0.25 μm film thickness) was used and oven temperature was programmed from 50 to 185°C, increased 20°C per min, held for 80 min, increased 2°C per min to 225°C, and held for 60–100 min. This method has been validated with individually synthesized authentic CLA isomer standards (10).

The results are shown in Table 1. Total CLA in the commercial fetal and newborn calf sera ranged from 0.181–0.495% of fatty acids, which is in general agreement with the levels of total CLA usually reported for dairy and beef fat (5–8, unpublished observations). The mean total CLA content from the UW–Madison cows was 0.151%. Interestingly, the horse sera samples exhibited substantial variation. Sample 1 contained exceptionally high levels of total CLA whereas samples 2 and 3 were considerably lower (Table 1).

Both the *c*-9,*t*-11 CLA isomer and a peak with the retention time of the *t*-10,*c*-12 CLA isomer were detected in all of the commercial fetal and newborn calf sera, and in horse serum sample 1 (Table 1). In general the putative *t*-10,*c*-12 isomer content in these sera samples appeared to be higher than expected based on dairy fat analyses (5–8, and unpublished observations). By contrast the only isomer detected in the sera of the UW–Madison cows and in horse sera samples 2 and 3 was *c*-9,*t*-11 CLA.

TABLE 1
The *cis*-9,*trans*-11- and Putative *trans*-10,*cis*-12-CLA in Commercial Calf and Horse Sera[a]

	Fatty acid (%)		
	Total CLA	*c*-9,*t*-11-CLA	*t*-10,*c*-12-CLA
Fetal calf sera			
1	0.404	0.331 (82.0)[b]	0.073
2	0.375	0.295 (78.6)	0.080
3	0.495	0.363 (73.4)	0.132
4	0.341	0.256 (75.0)	0.085
5	0.181	0.159 (87.8)	0.022
Newborn calf sera			
1	0.379	0.301 (79.5)	0.078
2	0.224	0.193 (86.2)	0.031
3	0.246	0.212 (86.0)	0.035
Horse sera

3	0.044	0.044 (100)	n.d.
Cow sera[d]	0.151	0.151 (100)	n.d.

[a]Fetal calf sera 1, 2, and 4, newborn calf sera 1 and 2, and horse sera 1 and 3 were purchased from Sigma Chemical Co. (St. Louis, MO). Fetal calf sera 3 and 5, newborn calf serum 3, and horse serum 2 were from Biowhittaker (Walkersville, MD). CLA, conjugated linoleic acid.
[b]Numbers in parentheses are percentages of *cis*-9, *trans*-11-CLA.
[c]n.d., not detected.
[d]Mean from four cows (range 0.137–0.183%) maintained at the University of Wisconsin–Madison Dairy Forage Research Center.

The data of Table 1 beg the question of the source of the putative *t*-10,*c*-12 isomer in the commercial sera samples. It is well documented that linoleic acid is converted to *c*-9,*t*-11 CLA by several species of rumen bacteria (11–16) and by a strain of *Lactobacillus reuteri* isolated from rat colon (17). Verhulst *et al.* (18) reported that *Propionibacterium acnes* converts linoleic acid to *t*-10,*c*-12 CLA, but to what extent this finding pertains to the data of Table 1 is unclear.

Evidence exists for the generation of *c*-9,*t*-11 CLA by mammalian enzymes: a double bond can be introduced into vaccenic acid (*t*-11-octadecenoic acid) by the action of Δ-9 desaturase, to generate *c*-9,*t*-11 CLA (19,20). Also, *c*-9,*t*-11 CLA may be generated *in situ via* carbon-centered free radical oxidation (21). However, to our knowledge there is no known mechanism whereby the *t*-10,*c*-12 CLA isomer might be generated by mammalian enzymes. Moreover, the apparent finding of exceptionally high total CLA and putative *t*-10,*c*-12 CLA in horse serum sample 1 is intriguing in that the horse has a hind-gut fermentation area, where long-chain fatty acid absorption is expected to be minimal.

The commercial bovine sera used in developing the data of Table 1 were from fetal or newborn calves, whereas the UW–Madison cows were adult animals. The horse sera samples in Table 1 likely also came from adult animals (personal communication from the supplier, Sigma Chemical Co., St. Louis, MO). Hence, possibly undefined nutritional and/or physiological factors, as well as age, may be involved in the apparent accumulation of the *t*-10,*c*-12 CLA isomer in sera.

We are currently exploring these possibilities.

ACKNOWLEDGMENTS

The authors thank Drs. Larry Satter and Tilak Dhiman of the UW–Madison Dairy Forage Research Center for providing the adult cow sera samples. This research was supported in part by gift funds administered through the University of Wisconsin–Madison Food Research Institute. Lectin May Contribute to the Atherogenicity of Peanut Oil

David Kritchevsky*, Shirley A. Tepper, and David M. Klurfeld[1]

The Wistar Institute, Philadelphia, Pennsylvania 19104

ABSTRACT: Peanut oil is unexpectedly atherogenic for rats, rabbits, and primates. The lesions it produces are more fibrous than fatty. The mechanism underlying the atherogenicity of peanut oil has been elusive. Randomization of peanut oil reduces significantly its atherogenic properties, but native and randomized peanut oils have similar rates of lipolysis, and rats fed the two oils absorb and transport lipids in a similar fashion. Peanut oil differs from other oils in having a relatively high lectin content, and the randomization process markedly reduces the lectin content as well. The biologically active lectin of peanut oil has an affinity for glycoproteins found specifically on arterial smooth muscle cells. Peanut lectin has been shown to stimulate growth of smooth muscle and pulmonary arterial cells. Vigorous washing of peanut oil reduces its lectin content by 46%. Compared to rabbits fed cholesterol and peanut oil, rabbits fed cholesterol and washed peanut oil exhibited less severe atherosclerosis in the aortic arch (by 9%) and in the thoracic aorta (by 31%). The data suggest that peanut oils' endogenous lectin may contribute significantly to its atherogenic properties.

Lipids 33, 821–823 (1998).

Peanut oil has been shown to be unexpectedly atherogenic when fed to rats (1,2), rabbits (3), or monkeys (4,5) on an atherogenic diet. Peanut oil is more atherogenic than corn oil even when fed as part of a cholesterol-free atherogenic diet (6). Steiner and Dayton (7) found that a diet containing 50–75% ground peanuts was hypercholesterolemic and hyperlipoproteinemic for rabbits, resulting in some aortic sudanophilia. We found that when peanut oil was randomized (autointeresterified) it became significantly less atherogenic for rabbits (8) and vervet monkeys (5). The aortic lesions of the rabbits fed peanut oil contain a relatively small amount of lipid and are characterized by thick, fibromuscular plaques.

The unexpected atherogenicity of peanut oil and its reversal by randomization could not be ascribed to its triglyceride structure since the five principal triglycerides of native (mol%) and randomized (mol%) peanut oil (listed respectively, as follows) contained oleic and linoleic acids almost exclusively (9): OOO (16.3) and OOL (15.9); OLO (11.8) and OOO (13.1); OOL (9.1) and OLL (9.6); POO (8.0) and OLO (7.9); PLO (7.6) and POO (5.3); OLL (6.6) and LOL (4.8) where O = oleic acid; L = linoleic acid; P = palmitic acid. Our recent studies (10) suggest that the presence of palmitic acid at the *sn*-2 position of a triglyceride increases its atherogenic potential, but the principal fatty acids present at the *sn*-2 position of peanut oil are linoleic and oleic. Lipolysis rates of peanut oil, randomized peanut oil, and corn oil are similar (11). Lymphatic absorption of cholesterol is the same in rats fed native or randomized peanut oil (12,13). We began to investigate the possibility that peanut lectin might predispose this oil to become atherogenic. We found that peanut oil had 22% greater lectin-like activity than soybean oil, 129% more than corn oil, and 57% more than randomized peanut oil (14).

MATERIALS AND METHODS

Male, New Zealand White rabbits (8/group), initial weight 3–3.5 kg, were fed a diet containing 92% commercial ration, 6% oil, and 2% cholesterol. This diet was chosen so that results would be comparable to earlier studies (3,8). After 60 d the rabbits were bled under light anesthesia, then killed, and livers and aortas removed. Serum total cholesterol and triglycerides were analyzed using commercial kits (Sigma, St. Louis, MO). Aliquots of liver were homogenized in chloroform/methanol 2:1 (15), and the lipid extract was analyzed for free and total cholesterol (16) and triglycerides (17). Aortas were graded visually on a 0–4 scale (18).

Peanut oil (10 L) was mixed with 5 L of phosphate-buffered saline (pH 7.3) for 2 h then separated by centrifugation. The washed peanut oil (8 L) was mixed with 1.6 L high- purity water for 2 h then separated by centrifugation. Lectins present in the oils were determined as described previously (14) using the method of Lotan *et al.* (19) in which various concentrations of phosphate-buffered saline extracts of the oils are used to agglutinate human erythrocytes. Presence of lectins in the oils was verified by polyacrylamide gel electrophoresis (20). Lectin-like activity (μg/kg) of the oils used was: corn oil, 24.0; peanut oil, 55.0; and washed peanut oil, 29.5.

RESULTS AND DISCUSSION

Necropsy results are given in Table 1. There were no significant differences in any parameter. Effects of the fats on atherosclerosis are presented in Table 2. Severity of aortic arch atherosclerosis in rabbits fed peanut oil was 17% greater than that seen in corn oil and 10% greater than in rabbits fed

washed peanut oil. Severity of atherosclerosis in the thoracic aorta of rabbits fed peanut oil was 36% greater than in those fed corn oil and 44% greater than in those fed washed peanut oil ($P < 0.05$, Mann-Whitney test). The oils used in this experiment were analyzed for lectin-like activity, which in peanut oil was 129% higher than in corn oil and 86% higher than in washed peanut oil. The presence of lectin-like activity provides a rational reason for the atherogenicity of peanut oil. That activity is reduced significantly during the randomization process as is the oil's atherogenicity.

Sanford and Harris-Hooker (21) showed that peanut lectin stimulated growth of smooth muscle and pulmonary arterial cells but not aortic endothelial cells. The structure of peanut lectin has recently been described by Banerjee *et al.* (22). Peanut lectin exhibits a specificity for D-galactose residues and preferentially for the β-D-Gal(1-3)D-Gal-NAC sequence which occurs on arterial smooth muscle cells. Peanut lectin, in the presence of hypercholesterolemia, could enhance proliferation of arterial smooth muscle cells. Testing the effects of peanut lectin added to atherogenic diets containing other oils would be of interest.

ACKNOWLEDGMENTS

We are indebted to Dr. Mark Bieber and Mr. Ted Ziegert of the BestFoods Technical Center for providing the intact and washed peanut oil. Supported, in part, by a Research Career Award (HL-00734) from the National Institutes of Health.

Isolation and Structure of Glucosylceramides from the Starfish *Cosmasterias lurida*

Marta S. Maier*, Anabel Kuriss, and Alicia M. Seldes

Departamento de Química Orgánica, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, 1428 Buenos Aires, Argentina

ABSTRACT: From the water-insoluble lipid fraction of the methylene chloride/methanol extract of the starfish *Cosmasterias lurida,* two new glucosylceramides together with a known glucosylceramide, ophidiacerebroside E, were isolated by chromatographic procedures and characterized by spectroscopic (^{1}H and ^{13}C nuclear magnetic resonance, mass spectrometry) methods. The new compounds were identified as (2*S,* 3*R,* 4*E,* 8*E,* 10*E*)-1-(β-D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxyheptadecanoyl)amino]-9-methyl-4,8,10-octadecatriene (**3**) and (2*S,*3*R,*4*E,*8*E,*10*E*)-1-(β-D-glucopyranosyloxy)-3-hydroxy-2-[(*R*)-2-hydroxyoctadecanoyl)amino]-9-methyl-4,8,10-octadecatriene (**4**). *Lipids 33,* 825–827 (1998).

Among echinoderms, glycosphingolipids and sphingosine derivatives have been isolated from starfish (1,2), sea urchin (3), and sea cucumber (4). To date, the structures which have been elucidated contain a 2-hydroxy fatty acid chain, the doubly unsaturated sphingosine 4,8-sphingadiene as well as the saturated phytosphingosine 4-hydroxysphingosine, and one hexose unit (characteristic of glucosylceramides) or more than one hexose units (characteristic of ceramide oligosaccharides). Five cytotoxic glucosylceramides containing a novel sphingosine base 2-amino-1,3-dihydroxy-9-methyl-4,8,10-octadecatriene were isolated from the starfish *Ophidiaster ophidianus* (5).

As for the constituents of *Cosmasterias lurida* Philippi, a very common starfish collected in cold waters off the Patagonian coast of Argentina, we have described the isolation and the determination of structure of two novel steroidal monoglycoside sulfates (6) and four new sulfated asterosaponins (7). In this paper we report on the isolation and characterization of glucosylceramides from the starfish *C. lurida*.

MATERIALS AND METHODS

Fresh specimens of *C. lurida* were collected at San Antonio Oeste, Río Negro, Argentina, and identified by Dr. Alejandro Tablado from the Museo de Ciencias Naturales "Bernardino Rivadavia," Buenos Aires, Argentina, where a voucher specimen is preserved (No. 31231). The animals (14 specimens, 4 kg wet weight) were kept frozen until worked up. The frozen animals were homogenized in methylene chloride/methanol (1:2, vol/vol) (5 L) and centrifuged. After concentration *in vacuo*, the residue was partitioned between H_2O and ethyl acetate/*n*-buthanol (2:1, vol/vol), and the organic layer was concentrated and chromatographed on a silica gel column using methylene chloride/methanol/water (8:1.3:0.1, by vol) as the eluent followed by recrystallization from methanol to give the crude glucosylceramide mixture CL-1 (125 mg, 0.003%). Normal-phase thin-layer chromatography (TLC) was performed on silica gel F_{254} (Merck, Darmstadt, Germany) with methylene chloride/methanol/ethyl acetate/water (8.5:1.5:2:0.1, by vol). Reversed-phase TLC was performed on C_{18} silica gel 60 F_{254} with methanol. ^{1}H nuclear magnetic resonance (NMR) spectra were recorded in a Bruker AC-200 (Karlsruhe, Germany) spectrometer. Chemical shifts are listed in δ (ppm) relative to tetramethylsilane employed as internal standard. Coupling constants (*J*) are presented in Hz. ^{13}C NMR spectra are full decoupled. Gas chromatography–mass spectrometry (GC–MS) analyses were performed on a VG TRIO-2 (Manchester, United Kingdom) instrument. Fast atom bombardment mass spectra (FABMS) were registered in a VG-ZAB BEQ spectrometer. Preparative high-performance liquid chromatography (HPLC) was carried out in a Micromeritics chromatograph (Norcross, GA) with a solvent delivery system model 750, a Thermo Separation Products refractive index detector (Fremont, CA), and a Phenomenex Ultracarb ODS 20 column (250 × 10 mm, 5μ) (Torrance, CA) eluting with absolute methanol at a flow rate of 3.0 mL/min.

RESULTS AND DISCUSSION

A water-insoluble lipid fraction, which was obtained from the methylene chloride/methanol extract of the starfish *C. lurida,* was treated with organic solvents followed by normal-phase column chromatography to give the fraction CL-1, showing a single spot on normal-phase and three spots on reversed-phase TLC. CL-1 exhibited the characteristic signals of a sphingosine-type glucosylceramide possessing 2-hydroxy fatty acid and β-glucopyranose moieties in the ^{1}H and ^{13}C

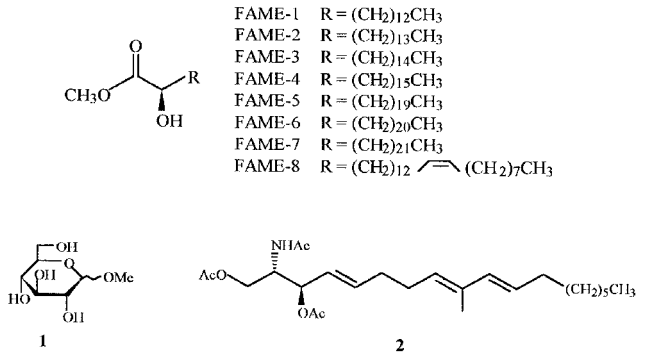
[b]Signals superimposed with the solvent.

NMR spectra (Table 1). Before separation of the mixture CL-1 into individual glucosylceramides, the fatty acid constituents and long-chain base moieties of these molecular species were investigated. CL-1 was methanolized with methanolic hydrochloric acid to yield a mixture of fatty acid methyl esters (FAME) and a mixture of long-chain base (LCB) together with methyl-D-glucopyranoside (8).

The FAME mixture exhibited ^{1}H and ^{13}C NMR signals due to normal 2-hydroxy FAME including a monounsaturated compound. Analysis of the FAME mixture by GC–MS showed the presence of eight compounds (FAME 1–8); they were characterized as methyl (2*R*)-hydroxy-pentadecanoate, -hexadecanoate, -heptadecanoate, -octadecanoate, -docosanoate, -tricosanoate, -tetracosanoate, and -tetracosenoate by comparing their spectral data with those reported (9). The position of the double bond in methyl-(2*R*)-hydroxy-tetracosenoate (FAME-8) was determined by GC–MS analysis of the dimethyl disulfide derivative (10) according to peaks at *m/z* 490 (M^+), 317, and 173. The double bond in FAME-8 was considered to have (*Z*) configuration as indicated by the signal observed at δ 27 ppm in the ^{13}C NMR spectrum of the FAME mixture due to the methylene carbons next to the olefinic carbons (11). Thus, the fatty acid composition of CL-1 was characterized as shown in Scheme 1, by the FAME, methyl-glucopyranoside (**1**), and acetylated LCB (**2**).

Mixture of FAME. ^{1}H NMR ($CDCl_3$): δ 0.87 (*t, J* = 6.3 Hz, 3H, terminal CH_3), 1.25 (*bs*, long chain -CH_2-), 3.77 (*s*, 3H, $COOCH_3$), 4.17 (*m*, 1H, H-2). ^{13}C NMR ($CDCl_3$): δ 14.2 [$(CH_2)_nCH_3$], 27.0 ($CH_2CH{=}CHCH_2$), 52.5 ($COOCH_3$), 70.6 [CH(OH)], 130.0 (CH=CH), 176.0 ($COOCH_3$).

The LCB mixture was acetylated to give the LCB acetate



SCHEME 1

mixture Ac-LCB and analyzed by GC–MS, showing the presence of (2*S*, 3*R*, 4*E*, 8*E*, 10*E*)-2-acetamido-1,3-diacetoxy-9-methyl-4,8,10-octadecatriene (**2**) as the major component (Scheme 1) as determined by comparing MS, ^{1}H NMR, and optical rotation data with those reported for ophidiacerebrosides containing the same base (5).

2-Acetamido-1,3-diacetoxy-9-methyl-4,8,10-octadecatriene (**2**). Gas–liquid chromatography retention time 22.0 min. ^{1}H NMR ($CDCl_3$): δ 0.87 (*t*, *J* = 6.9 Hz, 3H, terminal CH_3), 1.25 [*bs*, 8H, $(CH_2)_4CH_3$)], 1.69 (*s*, 3H, CH_3-19), 1.95 (*s*, 3H, CH_3CO), 2.12 (*s*, 6H, CH_3CO), 4.04 (*dd*, *J* = 12.3, 3.3 Hz, 1H, H-1a), 4.31 (*dd*, *J* = 12.3, 5.2 Hz, 1H, H-1b), 4.41 (*m*, 1H, H-2), 5.30 (*t*, *J* = 7.3 Hz, 1H, H-3), 5.35 (*m*, 2H, H-4, H-8), 5.57 (*dt*, *J* = 15.0, 6.4 Hz, 1H, H-11), 5.75 (*dt*, *J* = 15.3, 6.6 Hz, 1H, H-5), 5.99 (*d*, *J* = 15.0 Hz, 1H, H-10). MS *m/z* = 435 (M^+), 375 (M–60), 336, 256, 243, 144.

CL-1 (90 mg) was separated repeatedly by reversed-phase HPLC into four major fractions **3**–**6** each displaying a single peak on reversed-phase HPLC (Table 2). Fractions **3**, **4,** and **6** revealed single molecular ion peaks in their negative fast atom bombardment mass spectra, but fraction **5** exhibited three molecular ion peaks. Each fraction was methanolized and the FAME analyzed by GC–MS; a single FAME was detected from fractions **3** (FAME-3), **4** (FAME-4) and **6** (FAME-7), and three kinds of FAME were obtained for fraction **5** [FAME-5 (33%), FAME-6 (18%), and FAME-8 (39%)]. In taking the molecular masses of the four fractions and the fatty acid components into account, the LCB component of **3**, **4**, **5**, and **6** must be assigned as 2-amino-1,3-dihydroxy-9-methyl-4,8,10-octadecatriene. Accordingly, only

6 R = $(CH_2)_{21}CH_3$

SCHEME 2

three fractions are homogeneous, and they are assigned to compounds **3**, **4**, and **6** (Scheme 2). As glucosylceramides **3**, **4** and **6** differed only in the chain length of their α-hydroxy fatty acid constituents, they showed the same characteristic ^1H and ^{13}C NMR signals due to C-1–C-11, C-1′, C-2′, C-1″–C-6″ of a 1-*O*-β-glucopyranoside of a (2*S*,3*R*,4*E*,8*E*, 10*E*)-2-amino-1,3-dihydroxy-9-methyl-4,8,10-octadecatriene ceramide possessing a (2*R*)-hydroxy fatty acid (Table 1). The assignment of ^1H NMR signals was determined by ^1H–^1H correlation spectroscopy and ^1H NMR decoupling experiments. The conjugated diene structure was also supported by an ultraviolet band at 225 nm. Glucosylceramides **3** and **4** are new compounds, and compound **6** (ophidiacerebroside E) has been reported previously as a minor component in the starfish *O. ophidianus* (5). The natural occurrence of the ceramide present in glucosylceramide **4** was recently reported as the 1-sulfate derivative from the bryozoan *Watersipora cucullata* (12).

ACKNOWLEDGMENTS

We are most grateful to Dr. Alejandro Tablado (Museo de Ciencias Naturales "Bernardino Rivadavia," Buenos Aires) for the taxonomic identification of *C. lurida*. We also thank UMYMFOR and LANAIS-EMAR (CONICET-FCEN) for spectroscopic analysis and the International Foundation for Science and the Universidad de Buenos Aires for partial financial support.

The Signature 10-Hydroxy Stearic Acid Thought to Correlate with Infectivity in Oocysts of *Cryptosporidium* Species Is an Artifact

Robert S. Burkhalter[a], Carol A. Smith[a], David C. White[a,b,*], Ronald Fayer[c], and Andrew B. White[d]

[a]Center for Environmental Biotechnology, University of Tennessee, Knoxville, Tennessee, [b]Environmental Science Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, [c]USDA, ARS, Livestock and Poultry Sciences Institute, Parasite Immunology Laboratory, Beltsville, Maryland, and [d]Microbial Insights, Inc., Rockford, Tennessee

ABSTRACT: Heating or freezing leads to loss in infectivity of oocysts of *Cryptosporidium parvum* toward neonatal BALB/c mice and is reflected in the profile of the polar lipid fatty acids. Upon loss of infectivity, the ratio of polar lipid to neutral lipid fatty acid decreased and the relative proportions of 18:1n-9 also decreased; proportions of 18:2n-6 and 20:5n-6 increased, whereas the proportions of 16:0 remained constant with freezing. During these investigations, a novel fatty acid, 10-OH 18:0, was discovered in the glycolipid fraction. The identification of a fatty acid unique to species of *Cryptosporidium* was thought to provide a specific biomarker for this organism. *Cryptosporidium* also demonstrated fluctuations in absolute quantities of 10-OH 18:0 with events that lead to loss of infectivity. This led to the presumed correlation of this biomarker with infectious *Cryptosporidium*. The 10-OH 18:0 was putatively localized at the *sn*-2 position of phosphatidylethanolamine. High-performance liquid chromatography/electrospray ionization mass spectrometry revealed that the 10-OH 18:0 existed principally in the free fatty acid form. Herein, we establish that the free fatty acid 10-OH 18:0 was, in actuality, an artifact of the procedures for sample preparation.

Lipids 33, 829–833 (1998).

A major problem in the potable water industry is the detection, identification, and determination of the presence of infectious protozoan parasites. *Cryptosporidium* is of special concern as it is widespread in surface water samples, has extreme resistance to disinfection by chlorine, completes its infectious cycle only in human or mammalian hosts, and is potentially fatal to immunocompromised individuals who become infected (1). Successful methods must be highly sensitive, as the presence of as few as 10–30 oocysts may initiate infections. The method must also be highly specific to *Cryptosporidium*, sufficiently rapid so as to be potentially useful to the water industry, and provide an indication of viability/infectivity. To date, existing methodologies for the detection of *C. parvum* oocysts in drinking water are not satisfactory (2). With the discovery that freezing *C. parvum* oocysts at –70°C, which renders them noninfectious to neonatal BALBC/c mice (3), induced shifts in the polar lipid/neutral lipid ratio, a shift in fatty acid composition, a decrease in cholesterol, and a loss in an unusual fatty acid 10-hydroxy stearic acid (10-OH 18:0) (4), a potentially quantitative biomarker was proposed. Identification of this fatty acid as unique to species of *Cryptosporidium* would provide a signature lipid biomarker (SLB) in complex environmental matrices such as water distribution system biofilms. For this reason, the focus of the assay was shifted to the highly unusual fatty acid, 10-OH 18:0. Previous investigators had shown that the traces of 10-OH 18:0 were localized at the *sn*-2 position of phosphatidylethanolamine (PE) (5). However, the combined efforts of parent/derived fragment ion mass spectrometry and high-performance liquid chromatography/electrospray ionization/mass spectrometry (HPLC/ESI/MS) by R.S. Burkhalter and C.A. Smith revealed that the 10-OH 18:0 existed in the free fatty acid form (6). Free fatty acids are extremely unusual in nature and the potential of 10-OH 18:0 as a unique "signature" was explored. Unfortunately, subsequent experimental evidence revealed the true origin of 10-OH 18:0. The 10-OH 18:0 was found to be an extractable component of the disposable rubber pipette bulbs used during purification and was not found as a lipid component of *Cryptosporidium* oocysts.

MATERIALS AND METHODS

Chemicals. All reagents were of analytical grade. The standards (3-hydroxy eicosanoic acid, 12-hydroxy stearic acid, and 6-hydroxy stearic acid) were purchased from Matreya (Pleasant Gap, PA). Chromatography-grade solvents of chloroform, methanol, acetone, and water were also used (4,5).

Rubber bulbs. Amber rubber bulbs (2-mL, catalog number 14065B; Fisher Scientific Co., Pittsburgh, PA) were utilized with glass pipettes to transfer solutions.

Abbreviations: CID, collision-induced dissociation; FAB, fast ion bombardment; GC, gas chromatography; HPLC/ESI/MS, high-performance liquid chromatography/electrospray ionization/mass spectrometry; PE, phosphatidylethanolamine; 10-OH 18:0, 10-hydroxy stearic acid.

Parasites. Oocysts of *C. parvum* used in this study were purified from calf feces as previously described (4,5).

Lipid extraction. Membrane filter retentates or lyophilized sediments were extracted at room temperature and atmospheric pressure with the one-phase chloroform/methanol/phosphate buffer (50 mM, pH 7.4), 1:2:0.8 by vol, solvent system as previously described (7–9). All solvents were of gas chromatography grade and obtained from Baxter Scientific Products (McGaw Park, IL). All glassware was washed in a 10% (vol/vol) Micro cleaner solution (Baxter Diagnostics, Deerfield, IL), rinsed five times with tap water and then five times in deionized water. The glassware was then heated overnight in a muffle furnace at 450°C. Glass filter loaded samples were extracted in separatory funnels containing the chloroform/methanol/phosphate buffer, 1:2:0.8 single phase extractant 4 h before adding chloroform and deionized water (final solvent ratios, chloroform/methanol/ phosphate buffer/water; 1:1:0.4:0.5 by vol) to form two phases. The organic phase was then collected and dried under a stream of N_2 at 37°C.

Purification of lipids. The total lipid extract was dissolved in chloroform (~ 0.5 mL) and separated using a silicic acid column (10-cm column length, 0.5-cm inner diameter, 100–200 mesh particle size). Each sample was loaded onto the column in a minimal volume of chloroform (100–200 μL) and then eluted in batches with 5 mL of chloroform, 5 mL acetone, and 5 mL of methanol so as to elute neutral, glyco-, and polar lipids, respectively (9). Prepacked silicic acid columns (Burdick and Jackson inert solid phase extraction system #7054G; Muskegon, MI) are also a commercial alternative. Bulk elution of the neutral lipids with chloroform was followed by recovery of the free fatty acids in acetone or glycolipid fraction. For each fraction, the solvent was removed under a stream of nitrogen. The lipids were stored at –20°C until analysis.

HPLC/ESI/MS. The acid 10-OH 18:0 migrates in reverse-phase high-performance liquid chromatography (C-18 Alltech Altima 5 μm particle size, 150 mm in length, 1 mm diameter column; Deerfield, IL) with a mobile phase consisting of methanol/ultrapure water/aqueous ammonia (100:6:1) at a flow rate of 50 μL/min with a retention time of 12–14 min typical of hydroxylated free fatty acids (3-OH 20:0). In contrast, PE elutes at 20–22 min under these conditions. Those components eluting with a retention volume typical of free fatty acids were nebulized into the ESI inlet of either the VG (Micromass Inc., Beverly, MA) Quattro II triple quadrupole mass spectrometer or the Micromass Platform II single quadrupole mass spectrometer. Analyses were performed in the negative mode of ionization so as to promote fragmentation resulting from cleavage of the two-acyl functionalities with charge retention on the free fatty acids formed through acyl cleavage. Initially, elevated cone voltages were utilized so as to promote fatty acyl cleavage from intact phospholipids. However, upon realizing that the biomarker of interest existed in the free fatty acid form, low orifice voltages were utilized so as to promote "soft" ionization. Tuning was performed such that maximum sensitivity was attained while achieving a minimum of unit resolution at a *m/z* value of 300 atomic mass units (a.m.u.) (resolution = 300). For the present study, resolution values of between 750 and 1,000 easily fulfilled this criterion. Narrow mass scans in the continuum mode of data acquisition were performed over a mass range spanning 320 to 270 a.m.u. at a scan rate of 0.4 s with a interscan delay of 0.1 s. Alternatively, selected ion monitoring of mass 299 could be utilized, which provided increased sensitivity. The continuum mode of data acquisition was utilized as this is the only means to obtain "true" signal averaging.

Mass spectral optimization studies found no significant gain in sensitivity upon the addition of organic bases. This is advantageous, as reverse-phase columns are generally not stable at pH values greater than 9. Addition of water to methanol resulted in a slight loss in sensitivity with model synthetic compounds. The initial mobile phase of methanol/water/aqueous ammonia was utilized so as to resolve free fatty acids from PE. As it will be explained later, the establishment that the novel biomarker was indeed present as a free fatty acid and that no PE species were present in the glycolipid fraction lends itself to a variation of the chromatographic conditions. Conversion to a mobile phase consisting of 100% methanol would be more efficient in that the analysis time would be reduced with a slight gain in sensitivity. Tuning in the negative mode of ionization may vary. But for the present study, the voltage applied across the capillary was –2.13 kV, the high voltage lens was set at 0.2 kV, and the initial cone voltage was set at –22 V so as to promote "soft" ionization. The nitrogen drying gas and nebulizing gas flow rates were set at 300 and 25 L/h. respectively. The temperature of the ESI source was set at 120°C. The photomultiplier detector was set to its maximum gain value.

Extracted ion chromatograms at a *m/z* value of 299 were monitored. Ion currents for 299 in the 11–14 min range were diagnostic of 10-OH 18:0 in the free fatty acid form. Ion currents in the range of interest were averaged with background subtraction resulting in a diagnostic mass spectrum.

RESULTS

Evidence that the 10-OH 18:0 is a free fatty acid. As previously stated, earlier investigators found the 10-OH 18:0 localized at the *sn*-2 position of PE (5). However, utilization of the derivative ion scanning of specific parent ion capabilities of the triple quadrupole mass spectrometer in the negative ionization mode did not support this. Examination of those parent ions that result in a fragment ion corresponding to 10-OH 18:0 revealed no parents which could correspond to PE or any possible phospholipid. Secondly, neutral loss mass scans for a neutral loss of 141 of the acetone fraction in the positive mode of ionization revealed that this fraction contained no detectable quantities of PE species. PE was found to be located in the methanol (polar lipid) fraction through neutral loss mass scans. The retention behavior of 10-OH 18:0 on the HPLC/ESI/MS system was described in the experimental section. The acid 10-OH 18:0 was found to coelute in the free fatty acid region (12–14 min) of the chro-

matogram with a synthetic standard of 3-OH 20:0. Elution of the free hydroxylated fatty acids as a class was clearly resolved from PE which eluted as a class at 20–22 minutes. Additional evidence as to the true nature of 10-OH 18:0 was supplied through examination of the ion current for a *m/z* value of 299 at both high and low orifice voltages. At high orifice voltages, the ion current for 10-OH 18:0 was found to be over two orders of magnitude less than at low orifice voltages (1.63×10^8 peak height units at −22 V vs. 8.53×10^5 peak height units for −200 V). With synthetic phospholipids, the −200 V cone voltage was found to maximize the dissociation of the acyl groups of phospholipids resulting in a maximal ion current for the fatty acyl constituents at maximal orifice voltage settings. Lower cone voltages (−22 V) resulted in maximal ion currents for the intact molecular species. This observation provided additional evidence that 10-OH 18:0 existed as an intact molecular species and was not acylated to any phospholipid. The combined evidence of parent ion MS, neutral loss mass scans, HPLC retention behavior, and effects of variation of the orifice voltage clearly established 10-OH 18:0 existed not as an acyl constituent of PE but as a free fatty acid.

Evidence that the free fatty acid is an eighteen-carbon fatty acid with a hydroxyl functionality localized at the 10 position. Theoretically, several fatty acids could produce a *m/z* value of 299 in the negative ion mode of operation. Obviously, any monohydroxylated 18-carbon fatty acid with the hydroxyl group at positions 2–17 would yield a deprotonated molecular ion at 299. Other possibilities include but are not limited to a 17-carbon monoenoic fatty acid with a sulfhydryl (-SH) substituent as well as the polyenoic fatty acid 20:6n-3. Unambiguous assignment of the free fatty acid as 10-OH 18:0 was accomplished through comparison of the parent/derivative ion mass spectrum of 10-OH 18:0 with synthetically available standards (6-OH 18:0 and 12-OH 18:0). The first quadrupole acted as the mass filter, allowing only ions with a *m/z* value of 299 to pass into the second mass analyzer. Collision-induced dissociation (CID) of the parent molecule was accomplished in the hexapole collision chamber between the first and third quadrupoles in the presence of 0.5 Torr of argon at a collision energy of 30 eV. Diagnostic fragments were monitored by scanning the third quadrupole mass analyzer. Hydroxylated fatty acids produced low-energy CID fragment ions which were indicative of hydroxy-substituted fatty acids as a class at a *m/z* value of 281 (loss of H_2O from the hydroxyl moiety) and at a *m/z* value of 253 (loss of formic acid). Nonhydroxylated free fatty acids (palmitic acid) do not undergo any significant fragmentation under similar conditions. The site of the hydroxy functionality was confirmed to be in the 10 position through the examination of two charge-remote fragment ions that overlapped at a *m/z* value of 141 for 10-OH 18:0. The two charge-remote fragmentation processes were confirmed through examination of the daughter ion spectra of two other mid-chain, branched hydroxylated fatty acids, 6-OH and 12-OH 18:0, under identical conditions. Analogous peaks expected and observed for 12-OH 18:0 were at *m/z* values of 113 and 169. For 6-OH 18:0, fragment ions at *m/z* values of 197 and 85 were observed. The nature of the two charge-remote fragmentation events has been discussed (10). However, to summarize, fragmentation of hydroxylated fatty acids under low-energy conditions leads to fragmentation events that are distinct from previously published high-energy CID processes (11). Also, those low-energy CID fragments which are produced are indicative of hydroxylated fatty acids as a class as well as of the site of hydroxysubstitution.

Sources of 10-OH 18:0. The identification of a fatty acid unique to species of *Cryptosporidium* by Schrum *et al.* (5) was critical to the application of this technique toward complex environmental matrices. However, conventional GC/MS methodologies lack the sensitivity necessary for use of this technique as a method capable of detecting an infectious dose of *Cryptosporidium.* It was hoped that through the application of the more sensitive technique of ESI MS, a more sensitive assay might result. Also, through the identification of those endogenous 10-OH 18:0 acylated phospholipids, a great deal of specificity to the assay should be gained. Identification of the 10-OH 18:0 as a free fatty acid as opposed to an acylated component of PE was initially thought to be a fortuitous event as hydroxylated free fatty acids are extremely rare in nature. The free fatty acid nature of the biomarker was subsequently exploited for expeditious recovery and analysis by HPLC/ESI/MS with the expected gains in method sensitivity and specificity.

It was only after many repetitions of this assay that the true origin of 10-OH 18:0 was discovered. Quantities of 10-OH 18:0 extracted from oocysts of *Cryptosporidium* fluctuated wildly. Occasionally, no 10-OH 18:0 was detected from extracted oocysts of *Cryptosporidium*. The random appearance of 10-OH 18:0 in one of our sample blanks was the first indication that this compound was generated through sample handling. The observation of free 10-OH 18:0 in a sample blank was initially thought to have arisen from some interfering contaminant. However, formation of the trimethylsilyl ether adduct of the methyl ester of the sample blank resulted in an analyte possessing chromatographic behavior and a mass spectrum identical to that analyte previously described by Schrum *et al.* (5) as 10-OH 18:0.

An additional benefit of adapting the identification of the target analyte to HPLC/ESI/MS was the decrease in sample handling. This should result in a much more rapid assay with less risk of sample contamination due to the decrease in sample handling. The extraction procedures are simple and straightforward. The method involves the liquid/liquid extraction of organic soluble lipids followed by the class fractionation of neutral, glyco-, and polar lipids over silicic acid columns. The simplicity of the assay eased the efforts to localize the source of contamination once 10-OH 18:0 was realized to be an artifact of sample isolation and preparation.

All organic solvents (methanol, chloroform, acetone) used in the assay were concentrated from an initial volume of 100 mL to a final volume of 100 μL and injected onto the HPLC/ESI/MS system. Only HPLC-grade solvents were used for the extraction and fractionation of samples. All organic solvents were found to contain no 10-OH 18:0. The 10 mL of

phosphate buffer used in the liquid/liquid extraction procedures was extracted by the method of Bligh and Dyer (8), as was 10 mL of Millipore (Milford, MA) water. They, too, were found to contain no 10-OH 18:0. This eliminated the source of contamination as arising from the solvents utilized for extraction and fractionation.

Those soaps and sterilization agents utilized to clean glassware were also examined; 1 mL of Fisherbrand solvent-free concentrator, 1 mL of Fisherbrand vesphenne II, and 1 mL of a 1:1 (vol/vol) mixture of the two were extracted by the method of Bligh and Dyer (8). No 10-OH 18:0 was identified from any of these three samples.

The disposable amber rubber pipette bulbs (Fisherbrand 14 065B) were then examined. A set of five rubber bulbs was extracted, and all were found to contain authentic free acid 10-OH 18:0. This was confirmed through both HPLC/ESI/MS analysis and GC/MS separation and identification of the trimethylsilyl ether adducts of the methyl ester of 10-OH 18:0.

So as to eliminate the possibility that 10-OH 18:0 was also a lipid component of *Cryptosporidium* species as well as the rubber bulb, two samples of 1×10^8 oocysts of *Cryptosporidium* previously found to contain 10-OH 18:0 were extracted. At no time were disposable rubber bulbs utilized. Both sets of experiments were found to contain no detectable quantities of 10-OH 18:0 through HPLC/ESI/MS and GC/MS analysis when disposable rubber bulbs were not used in the manipulations. This established that the target analyte was not an interfering contaminant but an artifact of the sample preparation procedures.

DISCUSSION

The putative occurrence of such an unusual component as 10-OH 18:0 in *Cryptosporidium* (4,5) led us to investigate the complex native form of this fatty acid in *C. parvum*. When the new studies by R.S. Burkhalter and C.A. Smith showed that the 10-OH 18:0 was a free fatty acid and not as an ester in PE (6), it was then realized that the fast atom bombardment (FAB) mass spectrum of PE presented by Schrum *et al.* (5) actually provided no evidence supporting the presence of 10-OH 18:0 as an acyl constituent in PE. This spectrum was obtained under positive ionization conditions, which will not produce fragment ions corresponding to fatty acyl constituents. Positive-ion FAB MS should provide protonated molecular ions and diglyceride ions after loss of the polar head group as a neutral species. FAB MS performed in the negative ion mode of operation would be expected to generate fatty acids with charge retention after acyl cleavage. In short, the fragment ion at 299 in the positive ion FAB mass spectrum of the major PE did not correspond to a fatty acyl constituent 10-OH 18:0. The enzymatic hydrolysis of PE recovered by thin-layer chromatography and subsequent derivatization with electron-withdrawing groups for negative ion detection by GC/MS (6) achieved the sensitivity to detect 10-OH 18:0, but the 10-OH 18:0 was apparently added during the preparation as a contaminant and was not in the PE.

When adaptation of HPLC/ESI/MS techniques revealed 10-OH 18:0 to be a free fatty acid, the putative signature became even more unique. Efforts were focused to characterize the target analyte of interest more completely and to establish lower limits of detection. Difficulty in producing a calibration curve for oocyst number vs. content of 10-OH 18:0 became a major problem. This was rationalized as being due to sample heterogeneity after microscopic examination of the preparations showed the oocysts clumped together and attached to fibers that were in these purified fecal preparations. The clumping increased with storage at 4°C. Difficulty in dispersing the oocysts reproducibly was thought to be the problem. Unfortunately, the random nature of the appearance of the 10-OH 18:0 prevented the appearance of the analyte in a sample blank until many repetitions were performed. Clearly when examining for traces of specific analytes such as found in 10–30 oocysts, comprehensive blank analyses which test for each step of the procedure must be rigorously performed. If repeated controls of lipids from a bacterium known not to contain 10-OH 18:0 had been utilized, the artifact might have been detected earlier.

Lipid biomarkers and Cryptosporidium *oocyst infectivity.* There is reproducible evidence of a correlation between loss of infectivity and oocyst metabolism in *C. parvum*. R. Fayer (personal communication; USDA, ARS, LPSI Parasite Immunology Laboratory, Beltsville, MD) has shown a direct correlation between the loss in amylopectin content of *C. parvum* oocysts and infectivity to BALB/c neonatal mice. There is a greater than threefold decrease in polar lipid fatty acids (PLFA) (from 3.8 to 0.75 pmoles/10^3oocysts) with a shift in patterns (4). With loss of infectivity by freezing there is a striking decrease in the proportion of 18:1n-9*c*, an increase in 18:2n-6 and 20:3n-6 with little change in the proportion of 16:0. During freezing of *C. parvum* oocysts, the phospholipids and cholesterol decrease, polyenoic PLFA accumulate, and polyenoic fatty acids in the polar lipids and neutral lipids increase. Lipid shifts have been shown to be excellent markers for the nutritional/physiological status in bacteria (12). Identification of lipid shifts with infectivity is a tool that will be useful in research studies of infectivity, but overlap in lipid composition with algae and other components of drinking water community requires that the oocytes be highly purified before analysis prior to use as a monitoring system for infectious *Cryptosporidium*. Patterns of PLFA of purified oocysts can used to differentiate between *C. parvum* and the nonhuman pathogens *C. baileyi, C. serpentis*, and *C. muris* (6).

Rumenic Acid: A Proposed Common Name for the Major Conjugated Linoleic Acid Isomer Found in Natural Products

Sir:

At the last American Oil Chemists' Society meeting in Chicago, May 10–13, 1998, there was a formal discussion period after a day-long series of presentations on conjugated linoleic acid (CLA) attended by about 100 participants. One of the topics discussed was the possible naming of the major CLA isomer, *cis*-9, *trans*-11-octadecadienoic acid—found in milk, other dairy products, and meats of ruminant animals—as rumenic acid. The name rumenic acid has been proposed by Peter W. Parodi and is supported by a number of other scientists.

There was extensive debate on this topic. CLA is a mixture of many positional and geometrical isomers of conjugated octadecadienoic acids both in natural products and in commercial preparations. In natural products, the predominant isomer (≥80% of total CLA) is *cis*-9, *trans*-11, whereas in commercial preparations the number and proportion of the isomers can vary widely depending on the conditions of preparation.

The major arguments presented against naming any CLA isomer were: (i) the term CLA has been in common use for nearly two decades; (ii) *cis*-9, *trans*-11 appears also to be formed outside the rumen by desaturation of *trans*-11-18:1; (iii) the active isomer has yet to be identified; (iv) there appears to be evidence that *cis*-9, *trans*-11 isomer may not be the only active CLA isomer, therefore; how shall we name them?

On the other hand, the major arguments for naming *cis*-9, *trans*-11-octadecadienoic acid rumenic acid were: (i) this is the major naturally occurring conjugated fatty acid in milk, other dairy products, and meats from ruminants; (ii) a major natural component can be named regardless of whether any biological activity has been ascribed to it; (iii) the name would avoid the misconception that it is a CLA having a methylene-interrupted double bond system, and (iv) it is an easy name, associated with the major place of origin, and may thus be less confusing.

Additional names were suggested, such as bovinic acid. However, there was agreement that this name did not encompass the broad spectrum of natural products containing *cis*-9, *trans*-11-octadecadienoic acid, for example, from sheep and other ruminants.

There was no complete consensus, but half the participants said they would use the new name in their future publications. We therefore recommend naming *cis*-9, *trans*-11-octadecadienoic acid as rumenic acid.

Analysis of Novel Hydroperoxides and Other Metabolites of Oleic, Linoleic, and Linolenic Acids by Liquid Chromatography–Mass Spectrometry with Ion Trap MS^n

Ernst H. Oliw*, Chao Su, Torun Skogström, and Günther Benthin

Division of Biochemical Pharmacology, Department of Pharmaceutical Biosciences, Uppsala Biomedical Center, Uppsala University, S-751 24 Uppsala, Sweden

ABSTRACT: Linoleate is oxygenated by manganese-lipoxygenase (Mn-LO) to 11*S*-hydroperoxylinoleic acid and 13*R*-hydroperoxyoctadeca-9*Z*,11*E*-dienoic acid, whereas linoleate diol synthase (LDS) converts linoleate sequentially to 8*R*-hydroperoxylinoleate, through an 8-dioxygenase by insertion of molecular oxygen, and to 7*S*,8*S*-dihydroxylinoleate, through a hydroperoxide isomerase by intramolecular oxygen transfer. We have used liquid chromatography–mass spectrometry (LC–MS) with an ion trap mass spectrometer to study the MS^n mass spectra of the main metabolites of oleic, linoleic, α-linolenic and γ-linolenic acids, which are formed by Mn-LO and by LDS. The enzymes were purified from the culture broth (Mn-LO) and mycelium (LDS) of the fungus *Gaeumannomyces graminis*. MS^3 analysis of hydroperoxides and MS^2 analysis of dihydroxy- and monohydroxy metabolites yielded many fragments with information on the position of oxygenated carbons. Mn-LO oxygenated C-11 and C-13 of 18:2n-6, 18:3n-3, and 18:3n-6 in a ratio of ~1:1–3 at high substrate concentrations. 8-Hydroxy-9(10)epoxystearate was identified as a novel metabolite of LDS and oleic acid by LC–MS and by gas chromatography–MS. We conclude that LC–MS with MS^n is a convenient tool for detection and identification of hydroperoxy fatty acids and other metabolites of these enzymes.

Lipids 33, 843–852 (1998).

Mass spectrometry (MS) has been extensively used for analysis of oxygenated metabolites of arachidonic and linoleic acids, which are formed by lipoxygenases, prostaglandin H (PGH) synthases, and cytochromes P450. These metabolites are prostaglandins and thromboxanes, leukotrienes, lipoxins, hydroxyeicosatetraenoic acids (HETE), allene oxide, jasmonic acid, regioisomeric epoxides, vicinal diols, and hydroxy fatty acids (1–3). Mass spectrometric analysis of eicosanoids and lipoxins has mainly been performed by gas chromatography (GC)–MS, which provides structural information and can be used to quantify metabolites in minute amounts (4,5).

GC–MS has some drawbacks. It requires derivatization, and it is not suitable for direct analysis of many labile metabolites, e.g., hydroperoxy fatty acids. In recent years, liquid chromatography (LC)–MS has become a routine method thanks to robust ionization techniques, e.g., electrospray ionization (ESI) or atmospheric pressure chemical ionization (APCI) (4,6). Many fatty acid metabolites have already been studied by LC–MS (4,7–13).

In this report we use LC–MS with MS^n to study the fatty acid metabolites of two unique enzymes: linoleate diol synthase (LDS) with ferriheme (15) and linoleic acid 13*R*-lipoxygenase (Mn-LO) with a manganese metal center (16). These enzymes were isolated from mycelium (LDS) and from the culture broth (Mn-LO) of the "take-all" fungus (*Gaeumannomyces graminis*), which is a devastating pathogen of wheat (14).

LDS converts linoleate sequentially to 8*R*-hydroperoxylinoleate (8-HPODE) through an 8-dioxygenase by insertion of molecular oxygen (17,18) and to 7*S*,8*S*-dihydroxylinoleate (7,8-DiHODE) through a hydroperoxide isomerase by intramolecular oxygen transfer (19,20). LDS will also oxygenate oleic and α-linolenic acids, but not γ-linolenic acid (18). The reaction mechanism of LDS has features in common with PGH synthases, e.g., formation of ferryl intermediates and a tyrosyl radical during catalysis (21).

Mn-LO metabolizes linoleic acid to 11*S*-HPODE and to 13*R*-HPODE (16,22). Its oxygenation mechanism thus differs from iron lipoxygenases (22). Mn-LO will also oxidize α- and γ-linolenic acids but not oleic acid (16). The oxygenation of unsaturated C_{18} fatty acids by Mn-LO and by LDS is summarized in Table 1. These oxylipins have been characterized mainly by GC–MS (16–18,22).

Wheelan *et al*. (8) systematically performed low-energy fast atom bombardment tandem MS^2 of monohydroxy substituted oleic, linoleic, linolenic, and arachidonic acids. ESI and tandem MS have also been used for MS^2 analysis of HETE and dihydroxyeicosatetraenoic acids, epoxyeicosatrienoic acids, and certain hydroperoxides of linoleic and arachidonic acids (7,9–12). Structurally informative and abundant product ions were formed by fragmentation processes, which were influenced by the position of the hydroxy and epoxy groups and by the double bonds.

The first aim of the present study was to evaluate LC–MS with MS^n as a tool for analysis of hydroperoxy-, hydroxy- and dihydroxy-substituted linoleic acids, which are formed by two novel enzymes, Mn-LO and LDS. The interpretation of the mass spectra of the linoleate hydroperoxides was not straightforward without comparison with structurally related compounds. We therefore studied some of the metabolites in deuterated methanol/water and performed a systematic study of different unsaturated C_{18} fatty acid metabolites, which are formed by Mn-LO and LDS. MS^3 spectra of hydroperoxy fatty acids and MS^2 spectra of mono- and dihydroxy fatty acids were found to provide sufficient information for identification.

MATERIALS AND METHODS

Materials. Mn-LO and LDS were purified to homogeneity as described (15,16). The acids 18:1n-9 (99%) and 18:3n-3 (99%) were from Merck (Darmstadt, Germany); 18:2n-6 (99%) and 18:3n-6 (99%) were from Sigma (St. Louis, MO) and Nu-Chek-Prep (Elysian, MN), respectively. The labeled compounds [1-^{14}C]18:2n-6 (55 Ci/mol) and [1-^{14}C]18:1 (55 Ci/mol) were from Amersham Corp. (Amersham, United Kingdom). The compounds 8*R*-HPODE, 8*R*-HODE, and 7*S*,8*S*-DiHODE were prepared and characterized as described (18). Compounds 11*S*-HPODE, 13*R*-HPODE, 13*R*-HPOTrE, 11*S*-HPOTrE(n-6), and 13*R*-HPOTrE(n-6) were prepared from biosynthesis with Mn-LO as described (16,22). Hydroperoxy fatty acids were reduced to alcohols with $NaBH_4$ (16). $C^2H_3O^2H$ (99.5%) and ^2H_2O (99.5%) were from Merck.

Incubations with Mn-LO or LDS. Fatty acids (0.25 mM) were incubated with purified Mn-LO or purified LDS as described (15,16). Radiolabeled fatty acids were used in some experiments. After extractive isolation (without acidification of Mn-LO metabolites) on octadecasilane silica (SepPak/C_{18}; 23), the metabolites were either separated by thin-layer chromatography (18) or directly analyzed by LC–MS with a reversed-phase–high-performance liquid chromatography (RP–HPLC) column.

LC–MS analysis. The pump for HPLC was from Thermo Separation Products (SpectraSYSTEM P2000; San Jose, CA) equipped with a degasser (Uniflow Degasys DG-1310, Tokyo, Japan). The column contained octadecasilane silica (5 μm, 250 × 2 mm or 150 × 2 mm; Kromasil 5 C_{18} 100A, Phenomenex, Torrance, CA) and a guard column (Opti-Gard, 1 mm C_{18}; Optimize Technologies, Oregon City, OR). The RP–HPLC columns were eluted with methanol/water/acetic acid, 80:20:0.01, at 0.2 mL/min. The effluent first passed an ultraviolet detector (Kratos Spectroflow 757, Ramsey, NJ) equipped with an integrator (Merck Hitatchi D-2500, Tokyo, Japan) and then into an ion trap mass spectrometer (LCQ; Finnigan MAT, San Jose, CA), where it was subject to APCI or ESI. The vaporizer temperature for APCI was 450°C. The targets for automatic gain control were usually set at 5×10^7 for full MS and at 1×10^7 for MS^n. For ESI the capillary temperature was usually 230°C. Negative ions were monitored and prostaglandin $F_{1\alpha}$ (Upjohn, Kalamazoo, MI) was used for tuning. Compounds in methanol/water, 1:1, or in deuterated methanol/water were infused into the mass spectrometer with a syringe pump at a rate of 50–100 ng per min (10–20 μL/min).

GC–MS analysis. Capillary GC–MS was performed with an ion trap mass spectrometer (ITS 40, Finnigan) as described (23). Methyl ester, trimethylsilyl ether, and chlorohydrin derivatives were prepared as described (23,24).

RESULTS

General observation and nomenclature. APCI–MS resulted in fragmentation of the hydroperoxides (M) with three strong signals, $[M - 1]^-$, $[M - 19]^-$ and $[M - 17]^-$, which corresponded to the carboxylate anion of the hydroperoxide ($[M - H]^-$), a fragment due to loss of water from the carboxylate anion of the

hydroperoxide ($[M - H - H_2O]^-$), and the carboxylate anion of the corresponding alcohol ($[M - H - O]^-$). The reduction of the hydroperoxide to the alcohol might be due to the high temperature (450°C) of the APCI source. In contrast, ESI–MS usually showed only two of these signals, $[M - 1]^-$ and $[M - 19]^-$. For convenience, the carboxylate anion $[M - 1]^-$ is often designated A^-. This carboxylate anion was subject to MS^2 (or MS/MS) analysis, i.e., A^- was first isolated in the ion trap and then subjected to collision-induced fragmentation, and the full mass spectrum of the daughter ions was recorded. This procedure was designated MS^2 A → full-scan. By analogy, MS^3or (MS/MS/MS) A → B → full-scan designates isolation and collision-induced fragmentation of *m/z* A^-, isolation of one of its daughter ions *m/z* B^-, collision-induced fragmentation of *m/z* B^- and recording of a mass spectrum of the daughter ions of B^-. For hydroperoxides, MS^2 A → full-scan yielded mainly *m/z* $[A - 18]^-$, whereas MS^3 A → [A – 18] → full-scan yielded a mass spectrum usually with many intense ions. Some ions were formed by loss of CO_2 and/or water, whereas other fragments appeared to be formed by cleavage in the vicinity of the oxygenated carbon.

APCI or ESI of mono- and dihydroxy fatty acid metabolites yielded essentially similar results. MS^2 A → full-scan provided sufficient fragmentation for structural identification. All compounds showed loss of water, loss of CO_2, or a combination of the two. The metabolites with an 8-hydroxy group formed a typical ion (*m/z* 157) by α-cleavage of the C-8-C-9-bond with transfer of a proton to the unsaturated side, whereas cleavage of the C-8-C-7 bond was not noticed. 7,8-Dihydroxy metabolites were fragmented both between C-9 and C-8 and between the hydroxyl carbons (C-7 and C-8) with transfer of a proton to the unsaturated side. The bisallylic hydroxy metabolites formed two informative ions containing the carboxy group, which differed by 28 amu. They were apparently due to α-cleavage with proton transfer to the adjacent double bond, and both could be further fragmented by loss of carbon dioxide. Finally, MS^2 A → full-scan of microgram amounts of metabolites sometimes resulted in a mass spectrum with an intense negative ion at *m/z* [A + 1]. This might be due to too high a setting of the automatic gain control target causing "space charge," since reanalysis of smaller amounts of material yielded a mass spectrum without the negative ion at *m/z* [A + 1].

LDS and oleic acid. RP–HPLC and LC analysis of metabolites of 18:1n-9 formed by LDS is shown in Figure 1. The two major metabolites eluted at 9.5 and 10.5 min, respectively. GC–MS analysis of the first eluting compound, marked I, showed it to be 7*S*,8*S*-dihydroxy-9*Z*-octadecenoic acid (7,8-DiHOME). The second eluting metabolite (II) was identified as 8-hydroxy-9(10)epoxystearate (see below). Small amounts of a mixture of 8*R*-hydroperoxy-9*Z*-octadecenoic acid (8-HPOME) and 8*R*-hydroxy-9*Z*-octadecenoic acid (8-HOME) eluted after about 18 min (data not shown) as judged from ESI–MS and MS^2 analysis with signals at *m/z* 313 (100%) and 295 (313 – 18; about 5%) due to 8-HPOME, and *m/z* 297 (30%) due to 8-HOME.

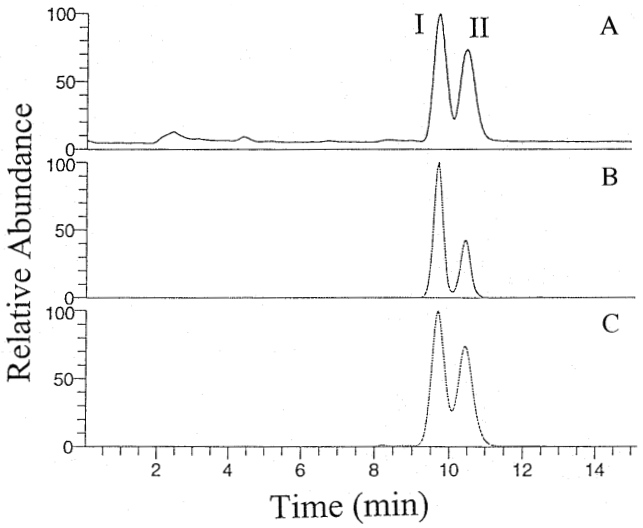

FIG. 1. Liquid chromatography–mass spectrometry (LC–MS) analysis of major metabolites formed by linoleate diol synthase (LDS) and oleic acid. Trace A shows total ion current (TIC), trace B, a mass chromatogram (*m/z* 313) of the carboxylate anion of 7*S*,8*S*-dihydroxy-9*Z*-octadecenoic acid (7,8-DiHOME), and trace C, TIC of MS^2 313 → full-scan. The peak with 7,8-DiHOME is marked I. The peak marked II was found to contain 8-hydroxy-9(10)epoxystearic acid. For explanation of MS^2 see text.

8R-HOME (M_w 298). MS^2 297 → full-scan yielded two strong signals, *m/z* 279 (297 – 18) and 157. The signal at *m/z* 157 is also present in the corresponding mass spectrum of 8-HODE, and it is likely due to $O{=}CH{-}(CH_2)_6{-}COO^-$, which might be formed by α-cleavage between C-8 and C-9 with transfer of a proton to the unsaturated fragment.

7S,8S-DiHOME (M_w 314). MS^2 313 → full-scan showed signals, *inter alia*, at *m/z* 295 (313 – 18), 277 (295 – 18), 251 (295 – 44, loss of CO_2), 233 (251 – 18), 197, 173 [possibly due to $CHO{-}CHOH{-}(CH_2)_5{-}COO^-$ formed by α-cleavage], 155 (173 – 18), 143 [possibly $OCH{-}(CH_2)_5{-}COO^-$], and 137 (155 – 18). This MS^2 spectrum is shown in Figure 2A. The structure of 7,8-DiHOME was confirmed by GC–MS (17).

8-Hydroxy-9(10)epoxystearic acid (M_w 314). MS of this metabolite, marked II (Fig. 1), showed a strong signal at *m/z* 313 (A^-), which suggested a molecular weight of 314. The carboxylate anion at *m/z* 313 shifted to 314 in deuterated methanol/water, which suggested that the metabolite contained one hydroxyl group and possibly an epoxy group. MS^2 313 → full-scan yielded *m/z* 295 (313 – 18), 277 (295 – 18), 187 [possibly $O{=}CH{-}CHOH{-}(CH_2)_6{-}COO^-$ formed by α-cleavage between C-9 and C-10], 171, 157 [possibly $O{=}CH{-}(CH_2)_6{-}COO^-$], and 141 as some of the most intense signals (Fig. 2B). In deuterated methanol/water, MS^2 314 → full-scan yielded signals at *m/z* 296 and 295, 278 and 277, and in the lower mass range *m/z* 188 [possibly $O{=}CH{-}CHO^2H{-}(CH_2)_6{-}COO^-$], 171, 157, 158, and 142. One deuterium atom was thus retained in the large carboxyl-group containing fragment (*m/z* 187) and to some extent in the small fragments (*m/z* 157 and 158).

GC–MS analysis of the trimethylsilyl ether methyl ester derivative yielded a mass spectrum at a C value of 20.5 with

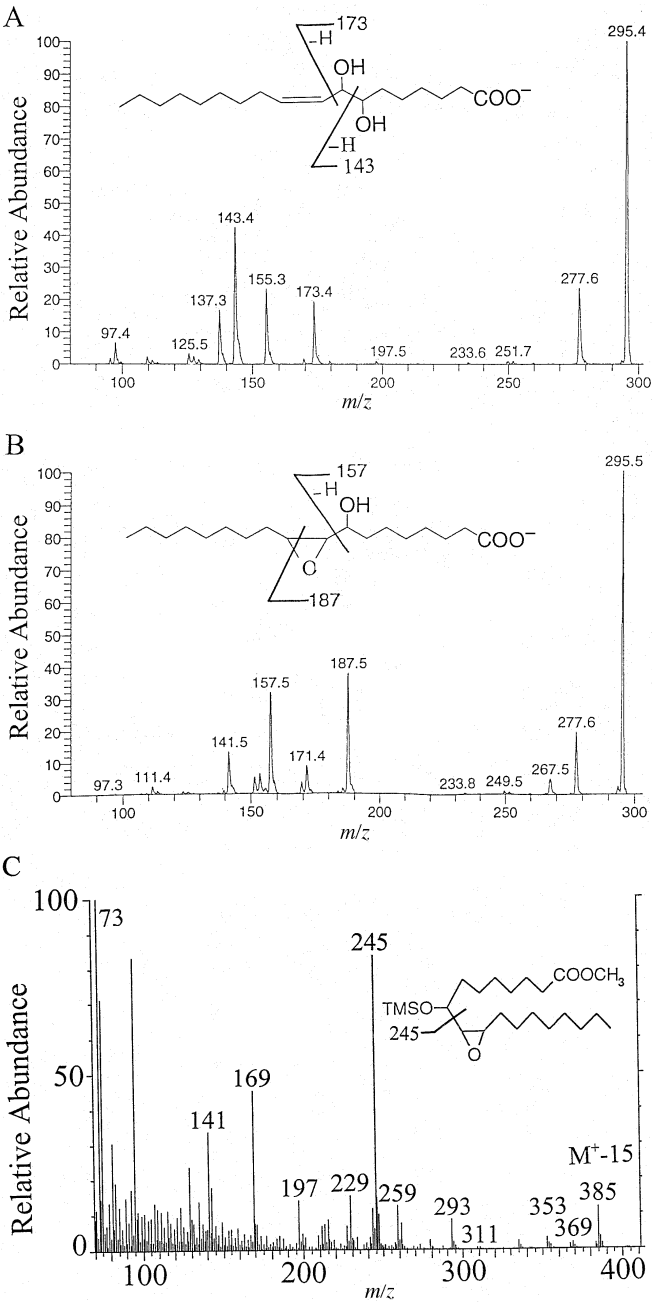

FIG. 2. LC–MS and gas chromatography–mass spectrometry (GC–MS) analysis of the two major LDS metabolites of oleic acid. (A) MS^2 analysis of the carboxylate anion (*m/z* 313) of 7,8-DiHOME (MS^2 313 → full-scan), which is marked I in Figure 1. (B) MS^2 analysis of metabolite II in Figure 1 (MS^2 313 → full-scan). The inset shows the proposed structure of metabolite II, 8-hydroxy-9(10)epoxystearate. (C) GC–MS analysis of the methyl ester trimethylsilyl ether (TMS) derivative of metabolite II with electron impact ionization. The inset shows this derivative of 8-hydroxy-9(10)epoxystearic acid. For other abbreviations see Figure 1.

signals, *inter alia*, at *m/z* 385 ($M^+ - 15$), 369 ($M^+ - 31$), 353, 311 [$M^+ - 89$, loss of $\cdot OSi(CH_3)_3$], 293 (311 – 18), 259, 245 {80%; possibly $[(CH_3)_3Si–O–CH_2–(CH_2)_6–COOCH_3]^+$}, 197, 169 (40%), and in the lower mass range at *m/z* 141, 129, 95, and 73 (base peak). The mass spectrum is shown in Figure 2C. Both the LC–MS and GC–MS analyses were thus consistent with an epoxy alcohol. For further confirmation, chlorohydrin adducts were prepared. The chlorohydrin and methyl ester trimethylsilyl ether derivative of this metabolite yielded two regioisomeric compounds (C value 22.4 and 22.6). Both spectra showed signals, *inter alia*, at *m/z* 245 $\{[(CH_3)_3Si–O–CH_2–(CH_2)_6–COOCH_3]^+\}$, and at 383 [$M^+ -$ 125, possibly loss of HCl and $\cdot OSi(CH_3)_3$], which were consistent with hydroxyl groups at C-8 and either C-9 or C-10 and chlorine at either C-10 or C-9. The LC–MS and GC–MS analysis of the metabolite and the formation of these chlorohydrins suggested that it was an epoxy alcohol, 8-hydroxy-9(10)epoxystearic acid.

LDS and linoleic acid. LDS metabolized linoleic acid to 7,8-DiHODE as the main metabolite and to only small amounts of 8-H(P)ODE as shown in Figure 3. An epoxy alcohol could not be detected. 8-HODE and 8-HPODE eluted

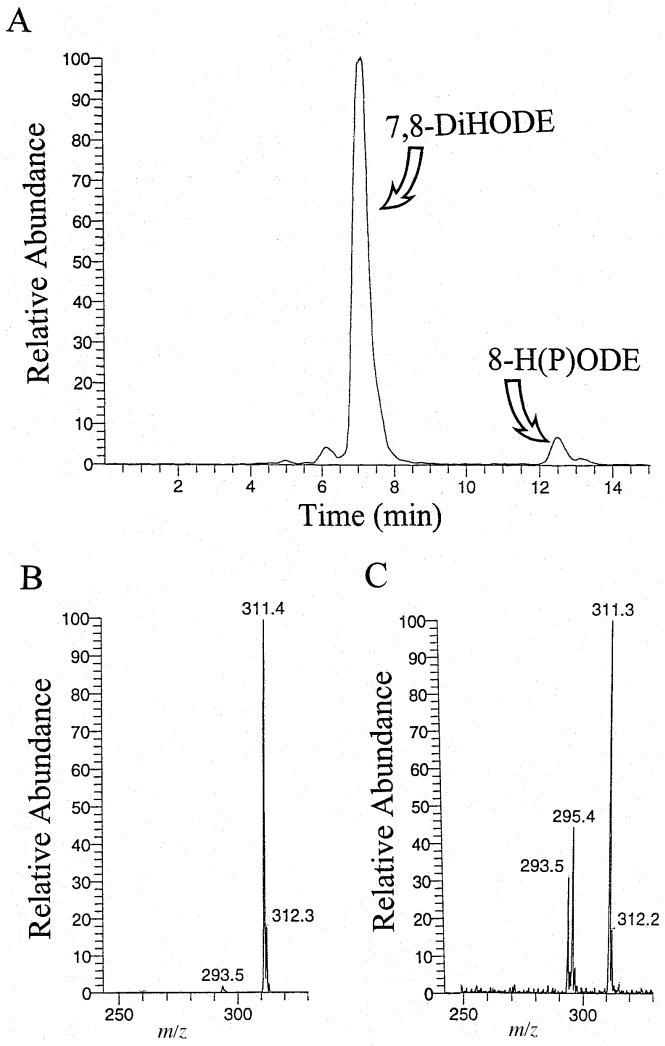

FIG. 3. LC–MS analysis of major metabolites formed by LDS and linoleic acid. (A) Chromatogram with TIC. The peaks containing 7*S*,8*S*-dihydroxy-9*Z*,12*Z*-octadeadienoic acid (7,8-DiHODE) and 8*R*-hydro(pero)xy-9*Z*,12*Z*-octadecadienoic acid [8-H(P)ODE] are marked in the figure. (B) Electrospray–MS (ESI–MS) analysis of the material in the peak marked 7,8-DiHODE. (C) ESI–MS analysis of the material in the peak marked 8-H(P)ODE. See Figure 1 for other abbreviations.

together on RP–HPLC. LC–MS analysis suggested that this peak contained 8-HPODE and 8-HODE in approximately a 3:1 ratio as judged from the intensities of *m/z* 311 and 293 (311 – 18), and of *m/z* 295, respectively (Fig. 3C). We confirmed that ESI–MS analysis of 8-HPODE did not generate a signal at *m/z* 295.

*8*R-*HPODE (M_w 312).* ESI–MS showed a strong signal at *m/z* 311 (A^-) and a weaker signal at *m/z* 293 (311 – 18). MS^2 311 → full-scan yielded *m/z* 293 (311 – 18) and 275 (293 – 18) as main signals. MS^3 311 → 293 → full-scan showed trivial signals due to losses of water, CO_2, and water plus CO_2. The MS^3 spectrum is shown in Figure 4A. Signals were also noted at *m/z* 223 [293 – 70, possibly loss of $CH_3(CH_2)_3CH$], 195 [293 – 98, possibly loss of $CH_3(CH_2)_4CH{=}CH_2$], 183 [293 – 110, possibly loss of $CH_3(CH_2)_4CH{=}CH_2{-}CH$], 171 [unidentified; isobaric with $CH_3{-}C(=O){-}(CH_2)_6{-}COO^-$], 163, 153 (171 – 18), 127 (171 – 44), and 111. Many of these fragments might conceivably be explained by collision-induced dehydration of 8-HPODE to 8-ketolinoleate (*m/z* 293) in the ion trap. MS^2 analysis of 8-ketolinoleate (MS^2 293 → full-scan) will be needed to confirm this. In deuterated methanol/water, ESI–MS showed signals at *m/z* 312 (311 + 1) and 293 (312 – 19, loss of ^2HHO), whereas MS^2 312 → full-scan yielded *m/z* 294 (312 – 18) and a weak signal at 275 (294 – 19), indicating different fragmentation mechanisms in MS and in MS^2.

*8*R-*HODE (M_w 296).* APCI–MS of 8-HODE showed *m/z* 295 (A^-) and weak signals at *m/z* 277 (295 – 18) and 157 [possibly $O{=}CH{-}(CH_2)_6{-}COO^-$], whereas ESI–MS mainly showed signals at *m/z* 295 and 157. MS^2 295 → full-scan yielded strong signals at *m/z* 277, 157, and weak signals at 251 (295 – 44), 182, and 139 (157 – 18). The mass spectrum is shown in Figure 4B.

In deuterated methanol/water, MS^2 296 → full-scan yielded *m/z* 157 and 277 as the main signals, and a weak signal at 252 (296 – 44). These results suggest that deuterium of the hydroxy group was not retained in the fragment *m/z* 157 [*cf.* 8-hydroxy-9(10)epoxystearate above].

7S,8S-DiHODE (M_w 312). The mass spectrum was dominated by *m/z* 311 (A^-), but a signal was also noted at *m/z* 293 (311 – 18). MS^2 311 → full-scan yielded signals at *m/z* 293 (311 – 18), 275 (293 – 18), 173 [possibly due to $OCH{-}CHOH{-}(CH_2)_5{-}COO^-$], 155 (possibly 173 – 18), 143 [possibly $OCH{-}(CH_2)_5{-}COO^-$], and 137 (155 – 18). This MS^2 spectrum is shown in Figure 4C. MS^3 311 → 293 full-scan showed signals, *inter alia*, at *m/z* 275 (293 – 18), 257 (275 – 18; possibly due to loss of water from the carboxyl group), 249 (293 – 44), 177, and 143.

In deuterated methanol/water, MS of 7,8-DiHODE showed signals as expected from a compound with two hydroxyl groups at *m/z* 313, 294 (313 – 19), and 275 (294 – 19). MS^2 313 → full-scan yielded *m/z* 294, 276 (294 – 18), 275 (294 – 19), 174 [possibly $OCH{-}CHO^2H{-}(CH_2)_5{-}COO^-$], and 156 (174 – 18). The intensities of *m/z* 276 and 275 appeared to vary with the collision energy. MS^3 313 → 294 → full-scan yielded *m/z* 276 (294 – 18), 258 (276 – 18), 250 (294 – 44), 177, and 143.

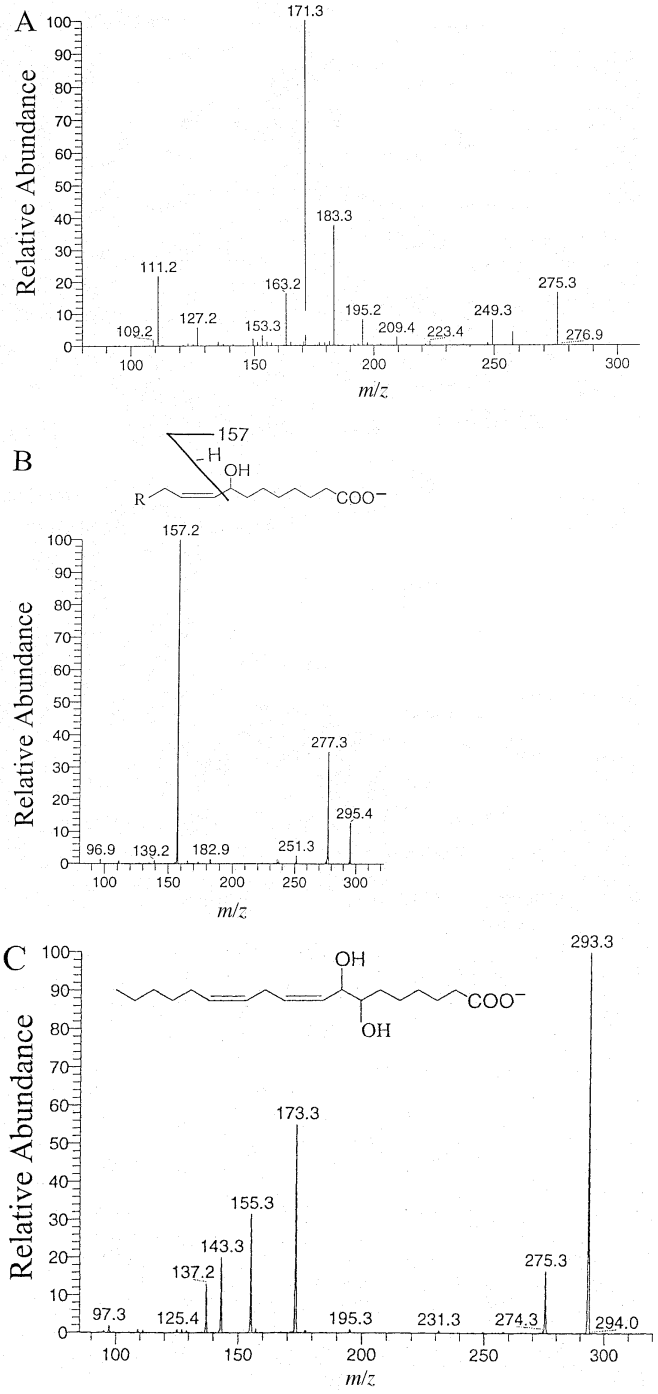

FIG. 4. MS^n of the carboxylate anions of metabolites of LDS and linoleic acid. (A) MS^3 analysis of the carboxylate anion (*m/z* 311) of 8-HPODE (MS^3 311 → 293 → full-scan). (B) MS^2 analysis of the carboxylate anion (*m/z* 295) of 8-HODE (MS^2 295 → full-scan). The inset shows the structural formula of 8-HODE where R designates $CH{=}CH{-}(CH_2)_4CH_3$. (C) MS^2 analysis of the carboxylate anion (*m/z* 311) of 7,8-DiHODE (MS^2 311 → full-scan). For abbreviations see Figures 1 and 3.

LDS and α-linolenic acid. LDS metabolized 18:3n-3 to one major metabolite, 7*S*,8*S*-dihydroxy-9*Z*,12*Z*,15*Z*-octadecatrienoic acid (7,8-DiHOTrE), so efficiently that its pre-

cursor [8*R*-hydroperoxy-9*Z*,12*Z*,15*Z*-octadecatrienoic acid (8-HPOTrE)] could not be detected.

7S,8S-DiHOTrE (M_w 310). MS^2 309 → full-scan showed signals at *m/z* 291 (309 – 18), 273 (291 – 18), 247 (291 – 44), 173 [possibly OCH–CHOH–$(CH_2)_5$–COO^-], 155 (possibly 173 – 18), 143 [possibly OCH–$(CH_2)_5$–COO^-], and 137 (possibly 155 – 18). The MS^2 spectra of 7,8-DiHOME, 7,8-DiHODE, and 7,8-DiHOTrE differed mainly in relative intensities of the main ions in the lower mass range.

Mn-LO. Like many other lipoxygenases, Mn-LO will oxygenate 18:2n-6, 18:3n-3, and 18:3n-6 but not 18:1n-9 (Table 1). Significant amounts of corresponding alcohols could not be detected. Mn-LO can convert the 11*S*-hydroperoxy fatty acids to 13*R*-hydroperoxy fatty acids (22). We will focus on the 11-hydroperoxy metabolites of Mn-LO, since 13*S*-hydroperoxy fatty acid metabolites are well-known products of soybean lipoxygenases and have been studied by MS^2 (8,9,12).

Mn-LO and linoleic acid. The two metabolites, 11*S*-HPODE and 13*R*-HPODE, which are formed from 18:2n-6 by Mn-LO, were separated by RP–HPLC as shown by the inset in Figure 5A. As judged from the total ion current, 11*S*-HPODE and 13*R*-HPODE were formed in a ratio of ~1:3.

11S-HPODE (M_w 312). APCI–MS showed signals at *m/z* 311 (A^-), 295 (possibly due to reduction of 11-HPODE to 11-HODE in the APCI source) and 293 (311 – 18), whereas the corresponding analysis with ESI–MS yielded 311 (base peak) and a strong signal at 293 (311 – 18; Fig. 5A). MS^2 311 → full-scan yielded *m/z* 293 (311 – 18) as the main ion and signals at 267 (311 – 44), 197, and 183 (unidentified) (Fig. 5B). MS^3 311 → 293 → full-scan yielded several fragments as shown in Figure 5C with signals, *inter alia*, at *m/z* 275 (293 – 18), 249 (293 – 44), 233 (293 – 44 – 18), 195 (293 – 98, possibly loss of C12–C18 and a hydrogen), 177 (possibly 195 – 18), 167, 153, 151 (possibly 195 – 44), 141, and 123 (possibly 167 – 44). A few fragments might be visualized as derived from the carboxylate side chain of an 11-keto-linoleic acid intermediate (*m/z* 293) and formed by α-cleavage, e.g., *m/z* 195 by cleavage between C-11 and C-12 with transfer of a proton to the unsaturated C-12. The ion at *m/z* 167 might conceivably be formed by cleavage between C-11 and C-10 with transfer of a proton to C-11.

11S-HODE (M_w 296). APCI–MS showed signals at *m/z* 295 (A^-) and 277 (295 – 18), whereas the latter ion was weak in ESI–MS. MS^2 295 → full-scan yielded many fragments (Fig. 5D). In addition to *m/z* 277 (295 – 18) and 251

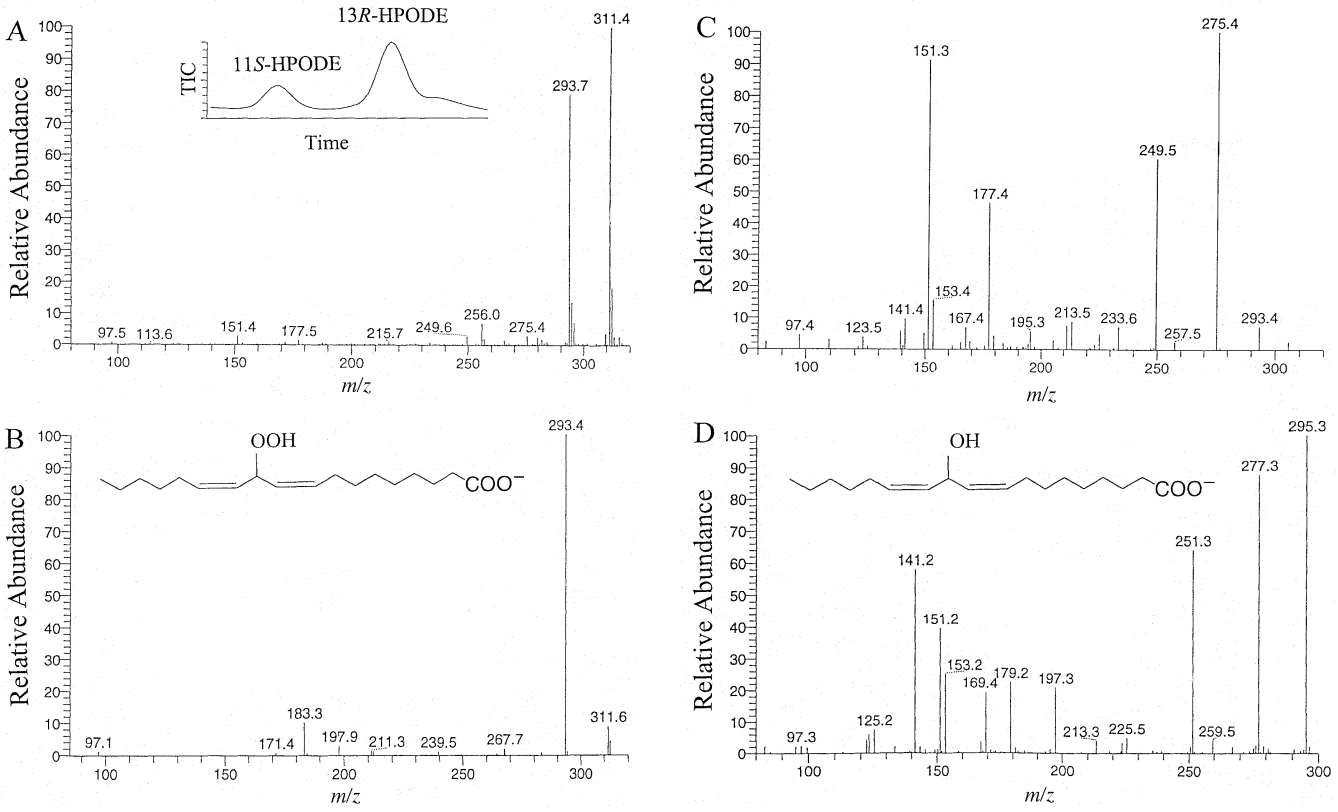

FIG. 5. LC–MS analysis of 11*S*-hydroperoxy-9*Z*,12*Z*-octadecadienoic acid (11*S*-HPODE) and formed by manganese lipoxygenase (Mn-LO). (A) MS of 11-HPODE. The inset shows separation of 11-HPODE and 13-hydroperoxy-9*Z*,11*E*-octadecadienoic acid (13-HPODE) by reversed-phase–high-performance liquid chromatography–mass spectrometry. (B) MS^2 analysis of the carboxylate anion (*m/z* 311) of 11-HPODE (MS^2 311 → full-scan). (C) MS^3 analysis of the carboxylate anion (*m/z* 311) of 11-HPODE (MS^3 311 → 293 → full-scan). (D) MS^2 analysis of the carboxylate anion (*m/z* 293) of 11*S*-hydroxy-9*Z*,12*Z*-octadecadienoic acid (11-HODE) (MS^2 293 → full-scan) with a low collision energy (24%). For other abbreviation see Figure 1.

(295 – 44), signals were noted at 197 [A^- – 98, possibly OCH–CH=CH–$(CH_2)_7COO^-$], 195 (weak, collision energy-dependent signal), 179 (possibly 197 – 18), 171, 153 (possibly 197 – 44), 151, and 141 [unidentified; this signal was also noted in the corresponding mass spectrum of 11-HOTrE(n-6)]. In deuterated methanol/water, ESI–MS of [$^2H_2$]11-HODE yielded *m/z* 296, 252 (296 – 44), and 233 (252 – 19). MS^2 296 → full-scan yielded *m/z* 278 (296 – 18) with a variable and less intense signal at 277 (296 – 19), 252 (296 – 44), 197, 198, 180, 170, 141, and 142.

*13*R-*HPODE (M_w 312).* APCI–MS yielded three strong signals [*m/z* 311 (A^-), 295 and 293], whereas ESI–MS mainly showed the signals at *m/z* 311 and 293. MS^2 311 → full-scan yielded *m/z* 293 (100%), but also intense signals at 267 (311 – 44), 195, and 171. MS^3 311 → 293 → full-scan yielded several strong signals, e.g., *m/z* 275 (293 – 18), 249 (293 – 44), 195, 179, 177, 141, and, in the lower mass range, 113. When 13-HPODE was dissolved in deuterated methanol/water, the MS signal with ESI was obtained at *m/z* 312, as expected, and MS^2 312 → full-scan yielded a signal at *m/z* 293 (loss of ^{2}HHO). ESI–MS^2 spectra of linoleic acid hydroperoxides formed by soybean lipoxygenase (presumably mainly 13*S*-HPODE) has been published (9), and our analysis of 13*R*-HPODE with MS^2 311 → full-scan and MS^3 311 → 293 → full-scan yielded many identical fragments also in the lower mass range.

*13*R-*HODE (M_w 296).* The mass spectrum of 13-HODE was similar to that reported with low-energy fast bombardment tandem MS (8). For a comparison, MS^2 295 (A^-) → full-scan yielded signals, *inter alia*, at *m/z* 277 (A^- – 18), 195 (A^- – 100, possibly due to loss of O=CH–C_5H_{11}), and 179. In deuterated methanol/water, MS^2 296 → full-scan yielded *m/z* 277, 196, 180, and 179. The signal at *m/z* 196 indicated a proton transfer from the hydroxy substituent as reported by Wheelan *et al.* (8).

Mn-LO and α-linolenic acid. The increase in light absorption at 235 nm during incubation of 0.25 mM 18:3n-3 with Mn-LO (0.5 μg) at room temperature is shown in Figure 6A. LC–MS analysis after 1 and 4 min incubation indicated that 11-HPOTrE and 13-HPOTrE were formed in a ratio of ~1:2. 11-Hydroperoxy metabolites will be converted to 13-hydroperoxy metabolites by Mn-LO, and it is therefore essential to have excess of substrate present in order to trap the 11-hydroperoxy intermediate (22).

*11*S-*HPOTrE (M_w 310).* MS^2 309 → full-scan yielded *m/z* 291 (309 – 18; 100%). MS^3 309 → 291 → full-scan yielded many fragments as shown in Figure 6B, e.g., *m/z* 273 (291 – 18), 247 (291 – 44), 211, 203, 195, 165, 177 (195 – 18), 165, 151, 149, and 139.

*11*S-*HOTrE (M_w 294).* MS^2 293 → full-scan yielded strong signals at *m/z* 275 (293 – 18), 249 (293 – 44), 213, 197 [base peak; likely OCH–CH=CH–$(CH_2)_7$–COO^-], 177, and 151 (169 – 18) as shown in Figure 6C. In addition, signals were noted at *m/z* 179 (possibly 197 – 18), 169, 167, and 153 (possibly 197 – 44). Many signals in the lower mass range were also present in the corresponding mass spectrum of 11*S*-HODE.

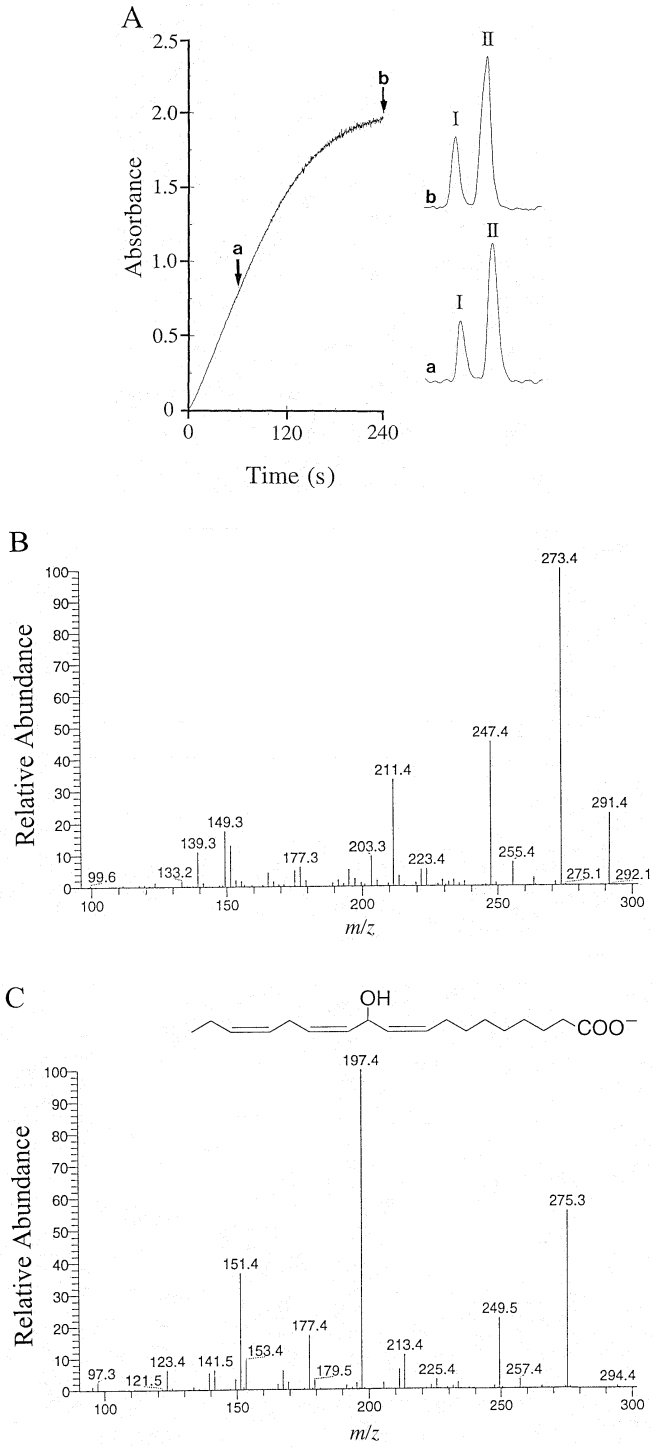

FIG. 6. Metabolism of α-linolenic acid by Mn-LO. (A) Increase in light absorption at 235 nm due to formation of 13-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid (13-HPOTrE) during incubation of Mn-LO and 18:3n-3. The insets show the TIC from LC–MS analysis of 11*Z*-hydroperoxy-9*Z*,12*Z*,15*Z*-octadecatrienoic acid (11-HPOTrE) and 13-HPOTrE formed after 1 and 4 min of incubation (marked a and b). Peak I contains 11-HPOTrE and peak II 13-HPOTrE. (B) MS^3 analysis of the carboxylate anion (*m/z* 309) of 11-*S*-HPOTrE (MS^3 309 → 291 → full-scan). (C) MS^2 analysis of the carboxylate anion (*m/z* 293) of 11-hydroxy-9*Z*,12*Z*,15*Z*-octadecatrienoic acid (MS^2 293 → full-scan). For other abbreviations see Figures 1 and 5.

*13*R-*HPOTrE (M_w 310).* APCI–MS yielded *m/z* 309 (A^-), 293, and 291 (309 – 18). The signal at *m/z* 293 was not noted during ESI–MS. MS^2 309 → full-scan yielded mainly *m/z* 291 (309 – 18), and many weak signals, e.g., 273, 247, 209, and 197, which were in agreement with a MS^2 analysis of 13*S*-HOTrE (9). MS^3 309 → 291 → full-scan yielded strong signals at *m/z* 273 (291 – 18), 262, 247 (291 – 44), 221, and 177.

Mn-LO and γ-linolenic acid. The two Mn-LO metabolites of 18:3n-6 were separated by RP–HPLC and analyzed by LC–MS with ESI. The total ion current indicated that 11-HPOTrE(n-6) and 13-HPOTrE(n-6) were formed in ratio of ~1:1.

*11*S-*HPOTrE(n-6) (M_w 310).* MS^2 309 → full-scan yielded *m/z* 291 (309 – 18; 100%). MS^3 309 → 291 → full-scan yielded many fragments, e.g., *m/z* 273 (291 – 18), 247 (291 – 44), 229 (291 – 44 – 18), 225, 175, 170, 149, 139, and 125. A comparison with the corresponding mass spectrum of 11-HPODE shows that some nontrivial fragments of 11*S*-HPOTrE(n-6) were decreased by 2 amu, e.g., *m/z* 175 and *m/z* 149.

*11*S-*HOTrE(n-6) (M_w 294).* MS^2 293 → full-scan yielded *m/z* 275 (293 – 18), 249 (293 – 44), 231 (293 – 44 – 18), 195 (weak), 177 (possibly 295 – 18), 167, 151 (possibly 195 – 44), 141, and 123 (possibly 167 – 44). The presence of *m/z* 177 and 167 in the MS^2 spectrum of 11-HOTrE(n-6) and *m/z* 179 and 169 in the corresponding mass spectrum of 11-HODE suggests that these fragment pairs contain the carboxylate side chains and are formed by α-cleavage as discussed above.

*13*R-*HPOTrE(n-6) (M_w 310).* MS^2 309 → full-scan yielded *m/z* 291. MS^3 309 → 291 → full-scan yielded signals at *m/z* 273 (291 – 18), 247 (291 – 44), 193, 177, 165, and in the lower mass range 123 and 113.

*13*R-*HOTrE(n-6) (M_w 294).* MS^2 293 → full-scan showed a strong signal at *m/z* 275 (293 – 18) and a weaker signal at 193 [293 – 100, possibly α-cleavage with proton transfer to the unsaturated side chain (9)]. This MS^2 spectrum was similar to that reported for 13*S*-HOTrE(n-6) (9).

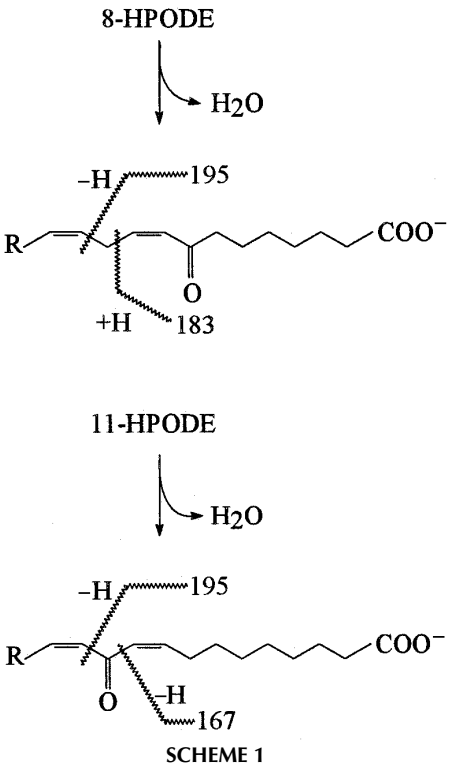
DISCUSSION

The two most well-characterized fatty acid dioxygenases are lipoxygenases of plants and animals and PGH synthases of mammals (1,2). The fungus *G. graminis* contains two unique dioxygenases, which seem to be related to lipoxygenases and to PGH synthases, respectively. Mn-LO oxidizes linoleic, α-linolenic, and γ-linolenic acids at C-11 and at C-13, whereas LDS oxidizes oleic, linoleic, and α-linolenic acids at C-8 to hydroperoxy metabolites, which then can be isomerized by LDS to 7,8-dihydroxy metabolites (Table 1). We report here the LC–MS analysis of these oxylipins and some new observations on the two enzymes.

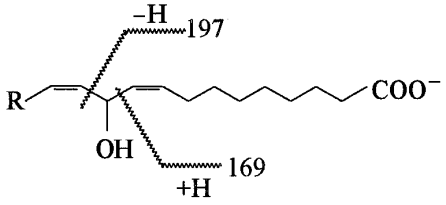
Mn-LO formed hydroperoxides with virtually no formation of the corresponding alcohols. LDS appeared to form only small amounts of 8-hydroxy fatty acids in comparison with 8-hydroperoxy and 7,8-dihydroxy fatty acids. LDS contains heme (16), which might reduce hydroperoxides to alcohols, and formation of significant amounts of 8-hydroxy fatty acids was therefore not unexpected.

LC–MS analysis of the fatty acid hydroperoxides formed by purified Mn-LO and by purified LDS allowed structural identification. MS yielded the carboxylate anion, and MS^2 of the carboxylate anion showed mainly loss of water. However, MS^3 analysis (MS^3 A → [A – 18] → full-scan) yielded an extensive fragmentation, which could be used to identify the 8-, 11-, and 13-hydroperoxy metabolites. For example, 8-HPODE showed characteristic ions with high intensity at *m/z* 183 and 171, 11-HPODE at *m/z* 177 (195 – 18) and 151 (195 – 44), and 13-HPODE at *m/z* 179 and 113. The mechanism of the collision-induced fragmentation of hydroperoxides during MS^3 analysis (MS^3 A → [A – 18] → full-scan) remains to be determined. The structure of the dehydrated hydroperoxide anion (*m/z* $[A - 18]^-$), which is isolated in the ion trap, is unknown, but it might be the anion of the corresponding keto compound. It will therefore be of interest to perform MS^2 analysis (MS^2 A → full-scan) of 8- and 11-ketolinoleate to determine similarities in fragmentation with the MS^3 fragmentation of 11-HPODE and 8-HPODE indicated below [Scheme 1; R designates $CH_3(CH_2)_4$].

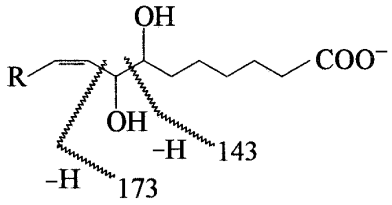
APCI and ESI yielded similar results with the hydroxy and dihydroxy fatty acids, but the hydroperoxides were partly reduced to alcohols during APCI. ESI is a milder ionization technique, and we used ESI for analysis of hydroperoxides. Mn-LO converted 18:2n-6, 18:3n-3, and 18:3n-6 to 11-hydroperoxy and 13-hydroperoxy metabolites. 18:3n-3 is metabolized twice as fast as 18:2n-6, and much faster than



SCHEME 1



SCHEME 2



SCHEME 4

18:3n-6 (16). When the fatty acid substrates are consumed, 11-hydroperoxy metabolites are converted to 13-hydroperoxy metabolites by Mn-LO (22). Under conditions with substrate excess, we found that Mn-LO converted 18:2n-6, 18:3n-3, and 18:3n-6 to 11-hydroperoxy and 13-hydroperoxy fatty acid metabolites in relative amounts (as judged from ion intensities), which ranged from almost 1:1 (18:3n-6) to 1:3 (18:2n-6) as judged from LC–MS analysis.

We also performed LC–MS analysis of the corresponding 8-, 11-, and 13-hydroxy fatty acids. MS^2 analysis (MS^2 A $\rightarrow$ full-scan) yielded characteristic mass spectra, and the structure of many nontrival fragments could be deduced. 13-HODE showed strong signals at *m/z* 195 and 179, whereas 11-HODE showed characteristic ions, *inter alia*, at *m/z* 179 and 169. These ions might be formed by cleavage at either side of C-11 (Scheme 2).

All the 8-hydroxy fatty acids yielded one fragment (*m/z* 157) due to α-cleavage between C-8 and C-9 and transfer of a proton to the unsaturated side chain (Scheme 3).

The 7,8-diols also formed fragments based on (-cleavage between C-8 and C-9 with proton transfer to C-9, e.g., *m/z* 173. Cleavage also occurred between the hydroxyl groups (*m/z* 143) as illustrated by Scheme 4. The analysis of [$^2H_3$]-derivatives supported this fragmentation.

A new finding was that oleic acid was oxidized by LDS to an epoxy alcohol along with 7,8-dihydroxyoleic acid as major metabolites. Recent work on the catalytic mechanism of LDS suggests many similarities with PGH synthases. LDS and PGH synthases will form two ferryl oxygen intermediates and a tyrosyl radical during catalysis as judged from stopped flow experiments and electron paramagnetic resonance spectrometry (2,21). One of these ferryl oxygen intermediates can apparently catalyze two reactions with oleic acid as a substrate, *viz*., hydroxylation at C-7 of 8-HOME to 7,8-dihydroxyoleic acid or epoxidation of the double bond of 8-HOME to 8-hydroxy-9(10)epoxystearic acid. We could not detect epoxidation of any other fatty acids by LDS.

In summary, LC–MS with MS^n was found to be convenient for studies on the metabolism of fatty acids by Mn-LO and LDS. This method may also be valuable for analysis of related metabolites in other biological systems. Biosynthesis of 8-HODE has also been reported by *Laetisaria arvalis*, *Aspergillus nidulans,* and *Leptomitus lacteus* (25–27) and by rat liver micromes (23). 11-HODE and bisallylic HETE are formed from linoleic and arachidonic acids by rat and human hepatic microsomes and by recombinant human cytochromes P450 (23,28–30). LC–ESI–MS with MS^2 and MS^3 options might be useful for analysis of hydroxy and hydroperoxy fatty acids and structurally related metabolites from many different sources.

Characterization of Phospholipase D Activity in Bovine Photoreceptor Membranes

G.A. Salvador and N.M. Giusto*

Instituto de Investigaciones Bioquímicas de Bahía Blanca (INIBIBB),
Universidad Nacional del Sur, CONICET, Buenos Aires, Argentina

ABSTRACT: Phospholipase D (E.C. 3.1.4.4.) was detected in isolated bovine rod outer segments (ROS) and its properties determined. The enzyme activity was assayed using either a sonicated microdispersion of 1,2-diacyl-*sn*-[2^{3}H]glycerol-3-phosphocholine (PC), or [^{14}C]ethanol. Using [^{3}H]PC and ethanol as a substrate, we were able to detect the hydrolytic properties as well as the transphosphatidylation reaction catalyzed by phospholipase D (PLD): formation of [^{3}H]phosphatidic acid and phosphatidylethanol [^{3}H]PtdEt; whereas with [^{14}C]ethanol or [^{3}H]glycerol in the absence of exogenous PC, only transphosphatidylation reactions were detected (formation of [^{14}C]PtdEt or [^{3}H]phosphatidylglycerol, respectively). The use of varying concentrations of [^{3}H]PC and 400 mM of ethanol gave an apparent K_m value for PC of 0.51 mM and a V_{max} value of 111 nmol × h^{-1} × (mg protein)$^{-1}$. The activity was linear up to 60 min of incubation and up to 0.2 mg of protein. The optimal ethanol concentration was determined to be 400 mM, with an apparent K_m of 202 mM and a V_{max} value for ethanol of 125 nmol × h^{-1} × (mg protein)$^{-1}$. A clear pH optimum was observed around 7. PLD activity was increased in the presence of 3-[(3-cholamidopropyl)dimethylammonio]-1-propane-sulfonate or sodium deoxycholate and inhibited with Triton X-100. The enzyme activity was also activated in the presence of Ca^{2+} or Mg^{2+} (1 mM) although these ions were not required for measuring PLD activity. The high specific activity of PLD found in purified ROS compared to the activity found in other subcellular fractions of the bovine retina suggests that this enzymatic activity is native to ROS. The present report is the first evidence of PLD activity associated with photoreceptor ROS.
Lipids 33, 853–860 (1998).

The retinal rod photoreceptor is a highly specialized structure in visual transduction. The outer segment of this cell undergoes dynamical renewal and shedding of the disc membranes (1). While new discs are added at the base of the rod outer segments (ROS), old discs at the apical tip are phagocytized by the retinal pigment epithelium (2,3). The metabolism of lipids in ROS is quite distinct from that of protein, especially when considering their turnover rates. ROS phospholipids are renewed by membrane as well as by molecular replacement (3). This molecular replacement could involve the exchange of entire molecules mediated by exchange proteins from outside the ROS (4), and molecular retailoring such as fatty acid exchange and modification of base groups (5).

A special feature of ROS membranes is their particular lipid composition, very rich in long- and very long chain polyunsaturated fatty acids in their phospholipids (6,7). The metabolism of these ROS phospholipids and their role in the photoreceptor physiology have not yet been clearly defined.

Several enzymatic activities involved in lipid metabolism and molecular retailoring of phospholipids, such as phosphatidate phosphohydrolase (PAPase) (8), phospholipase A_2 (9–13), acyltransferase (14), phospholipase C (15,16), diacylglycerol (DG) kinase and phosphoinositide kinases (17,18) and phosphatidylethanolamine *N*-methyltransferase (19), have been described in ROS.

In view of the dynamic role of phospholipids in membrane function, we decided to study the properties of enzymatic modification to their polar portion in ROS. We speculate that the base exchange enzymes and phospholipase D (PLD) could be responsible for the biological transformation of protein microenvironments, probably regulating membrane function by modification of the polar head group of phospholipids (20).

PLD is the enzyme responsible for the hydrolysis of phosphatidylcholine (PC) which leads to the generation of choline and phosphatidic acid (PA). PA can be further hydrolyzed by phospholipase A_2 to form the proposed second messenger lysophosphatidic acid, or by PAPase to form DG. Both enzymes responsible for the hydrolysis of PLD products have been extensively characterized in ROS (8–13). In the last few years PLD has been implicated in novel signal transduction pathways, as described in eukaryotic cells, and, moreover, PLD is regulated by small G proteins (21,22), protein kinase(s) (23,24), and PLD activation has also been implicated in intracellular traffic of membranes (25,26).

This paper demonstrates the first evidence that PLD activity is present in isolated ROS membranes and determines kinetic parameters of the enzyme as well as other aspects of transphosphatidylation reactions in ROS.

Abbreviations: CHAPS, 3-[(3-Cholamidopropyl)dimethylammonio]-1-propanesulfonate; CMC, critical micelle concentration; DG, diacylglycerol; NaDOC, sodium deoxycholate; PA, phosphatidic acid; PAPase, phosphatidate phosphohydrolase; PC, phosphatidylcholine; PG, phosphatidylglycerol; PLD, phospholipase D; PtdEt, phosphatidylethanol; ROS, rod outer segments; Triton X-100, *t*-octylphenoxypoly ethoxyethanol.

MATERIALS AND METHODS

[2-^{3}H]Glycerol (14.5 Ci/mmol) and [^{14}C]ethanol (4.5 Ci/mol) were supplied by New England Nuclear DuPont (Boston, MA). Phosphatidylethanol (PtdEt) standard was purchased from ICN Biomedicals (Costa Mesa, CA). PLD from cabbage and all other chemicals not specifically mentioned were obtained from Sigma Chemicals (St. Louis, MO).

Isolation of purified ROS. Fresh bovine eyes were obtained from a local abattoir (Trans Link, General Cerri, Argentina) and stored in crushed ice within 10 min of the animal's death. Bovine eyes were dark-adapted for 1–2 h. All subsequent procedures were conducted under dim red light and carried out at 2–4°C. The preparation containing crude ROS was then purified by discontinuous density gradient centrifugation as described by Kühn (27). This procedure gave ROS (band I) retained at the 0.84/1.00 M density interface, broken ROS contaminated with mitochondria and rod inner segments (band II), retained at the 1:00/1.14 M density interface, and a pellet composed of non-ROS membranes. The purity of ROS membrane preparation (band I) was controlled by the ratio of absorbance at 278 and 500 nm after solubilization in a 70 mM potassium phosphate buffer (pH 7) containing 1% of Emulphogene. Values of 2.3 ± 0.2 were typically obtained for this ratio. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (28) was also used to check the purity of the membranes. Even in heavily overloaded gels, rhodopsin consituted 85% of photoreceptor membrane proteins. Thin-layer chromatography of photoreceptor membrane lipids in overloaded plates showed no cardiolipin, suggesting nondetectable contamination with mitochondria. On the other hand, an enrichment in long- and very long chain polyunsaturated fatty acid esterified to dipolyunsaturated molecular species in PC was observed as a characteristic in bovine ROS (6,7). Purity of populations of ROS in particular batches was determined by assaying marker enzyme activities in all fractions of the gradient, as previously described by Roque and Giusto (19). NADPH-cytochrome c reductase (microsomal marker) and cytochrome c oxidase activities were measured in band I, band II, and the pellet of the gradient. The mitochondrial marker enzyme was enriched in band II and pellet, whereas cytochrome c reductase was very low in band I and presented the highest activity in the pellet. These results led us to confirm that band I (purified ROS) was only slightly contaminated by either microsomes or mitochondria (less than 5%).

Preparation of other subcellular fractions. The crude mitochondrial and microsomal fractions were obtained from the remainder of the retinas, which were homogenized in a Potter-Elvehjem homogenizer with 0.32 M sucrose in 50 mM Tris-HCL (pH 7.4) with 1 mM EDTA to a final volume of 10%. Homogenization was performed by 10 up-and-down strokes by means of a motor-driven Teflon pestle. The homogenates were centrifuged at 1,000 × *g* for 15 min and resuspended to produce the crude nuclear pellet. The pooled supernatants were then spun at 11,500 × *g* for 20 min and washed twice to produce a crude mitochondrial pellet. The supernatants were centrifuged at 130,000 × *g* for 45 min to produce microsomes as a pellet and the cytosol as the supernatants.

Preparation of radioactive substrate. The [^{3}H]PC was obtained from bovine retinas. These were incubated for 2 h at 37°C with 10 μCi/retina of [2-^{3}H]glycerol (14.5 Ci/mmol) as previously described (29). Lipids were extracted from the tissue according to Folch *et al.* (30). [^{3}H]PC was isolated by one-dimensional thin-layer chromatography on silica gel H using chloroform/methanol/water (65:25:4, by vol) and eluted therefrom according to Arvidson (31). To assess the purity of [^{3}H]PC, we rechromatographed it by two-dimensional thin-layer chromatography according to the method of Rouser *et al.* (32). Radioactive [^{3}H]PC had a specific activity of 0.1–0.2 Ci/ mol.

Preparation of PtdEt standard. PtdEt standard was prepared from egg lecithin with cabbage PLD, according to a published procedure, with slight modifications (33). The reaction mixture contained 1.3 mM egg PC, 0.1 M sodium acetate buffer, (pH 5.6), 38 mM $CaCl_2$, 0.5 mM sodium dodecyl sulfate, 3 M ethanol, and 300 μg of cabbage PLD, in a total volume of 1 mL. After 2 h of incubation at 30°C, the reaction was stopped with chloroform/methanol (2:1, vol/vol), and the lipids were extracted and processed according to Folch *et al.* (30). Extract was evaporated to dryness under nitrogen, the residue dissolved with chloroform and then applied to a column of 1 g of heat-activated silicic acid. Lipids were eluted with 40 mL of chloroform/methanol (97:3 vol/vol), chloroform/methanol (47:3 vol/vol), chloroform/methanol (22:3 vol/vol), and chloroform/methanol (2:1 vol/vol). PtdEt was present in the following eluates: chloroform/methanol (47:3 vol/vol) and chloroform/methanol (22:3 vol/vol). Our standard preparation showed the same R_f as PtdEt standard from ICN Biomedicals.

Enzyme assay. ROS PLD activity was determined by measuring the formation of [^{3}H]PtdEt and [^{3}H]PA from [^{3}H]PC. [^{3}H]PC was dried under a stream of nitrogen and resuspended in assay buffer; this aqueous microdispersion was sonicated until the solution became clear. The standard incubation mixture contained: 1 mM [^{3}H]PC (0.15 Ci/mol), added as previously described, 40 mM HEPES (pH 6.8), 25 mM KF, 400 mM ethanol, and 200 μg of ROS membrane protein in a total volume of 250 μL. The assay mixture was sonicated, in a sonication bath, for 30 s prior to incubation. The assays were carried out for 60 min at 37°C. Reactions were terminated by the addition of 5 mL of chloroform/methanol (2:1, vol/vol). The lipids were then extracted according to Folch *et al.* (30) and were washed using an upper phase containing 0.1 M sulfuric acid (34). Blanks were prepared identically, except that chloroform/methanol was added to the membranes before adding the substrate. Alternatively, blanks were prepared by using membranes boiled for 5 min and incubated as described above. Both blank preparations yielded similar values of activity (less than 2% of the activity observed in the experimental samples); hence, the first preparation was used on a regular basis.

Transphosphatidylation reactions in ROS were studied by the production of [^{14}C]PtdEt or [^{3}H]phosphatidylglycerol (PG)

using [^{14}C]ethanol or [^{3}H]glycerol as substrate, respectively. The transphosphatidylation assay contained 5 μCi of [^{14}C]ethanol (4.5 Ci/mol) or 5 μCi [^{3}H]glycerol (14.5 Ci/mol) in 40 mM HEPES (pH 6.8), 25 mM KF, 2 mM sodium oleate, and 200 μg of ROS membrane protein in a total volume of 250 μL.

Isolation of lipids. PA and PtdEt were separated by one-dimensional thin-layer chromatography on silica gel H and developed with chloroform/methanol/acetone/acetic acid/water (50:15:15:10:5, by vol), up to 70% of the plate (35). When [^{3}H]PC was used as substrate, the chromatogram was rechromatographed up to the top of the plate using hexane/diethyl ether (70:30, vol/vol) as the developing solvent, to separate the neutral lipids. PG was separated by one-dimensional thin-layer chromatography on silica gel H using chloroform/acetone/methanol/acetic acid/water (50:20:10:10:5, by vol). Lipids were visualized by exposure of chromatograms to iodine vapors, and were then scraped off the plate into vials for counting by liquid scintillation.

Other methods. Radioactivity corresponding to lipids was determined in a liquid scintillation spectrometer after the addition of 0.35 mL of water and 5 mL of 4% Omnifluor in toluene/Triton X-100 (*t*-octylphenoxypoly ethoxyethanol; 4:1, vol/vol).

Proteins were determined according to the method of Bradford (36), and lipid phosphorus by the method of Rouser *et al.* (32).

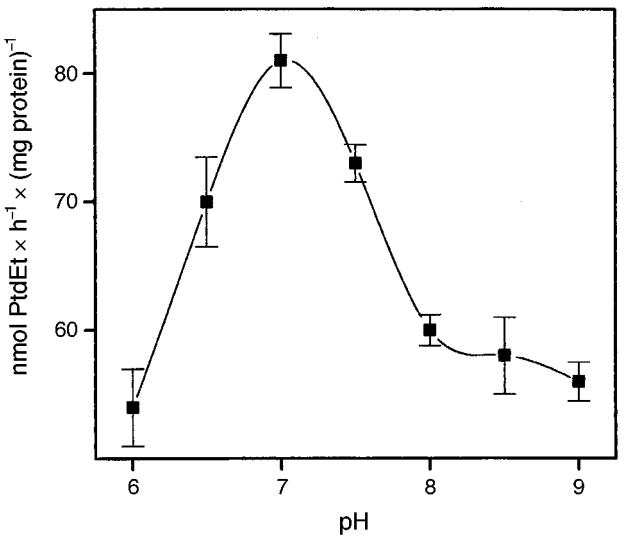

FIG. 1. Rod outer segment (ROS) phospholipase D (PLD) activity as a function of pH. Purified ROS membranes (200 μg) were incubated with 25 mM KF, 1 mM dithiothreitol (DTT), 1 mM [^{3}H]phosphatidylcholine (PC), 3 mM 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfate (CHAPS), 0.2 mM $CaCl_2$, and 400 mM ethanol in the following buffers: 40 mM Tris-maleate (pH 6–7.5); 40 mM Tris-HCl (pH 8–9). The activity is expressed as the mean ± SD of four or five independent samples. Other abbreviation: PtdEt, phosphatidylethanol.

RESULTS

Effect of time and protein concentration on PLD activity. PLD activity was detected in ROS preparations using a sonicated microdispersion of [^{3}H]PC obtained from bovine retinas as decribed above, either in the presence of 400 mM ethanol, or [^{14}C]ethanol or [^{3}H]glycerol without exogenous PC. The production of [^{14}C]PtdEt was protein concentration- and time-dependent, i.e., it was linear up to 60 min of incubation and up to 200 μg of protein in the incubation medium. [^{3}H]PG production was linear up to 200 μg of protein in the reaction mixture.

Effect of pH on PtdEt formation. To determine the optimal pH for PLD activity, ROS membranes were incubated at 37°C for 60 min with 1 mM [^{3}H]PC, 3 mM {3-[(3-cholamidopropyl)dimethylammonio]-1-propane sulfonate} (CHAPS), 1 mM dithiothreitol, 25 mM KF, 0.2 mM $CaCl_2$, and 400 mM ethanol, using different buffers in order to provide a range of pH between 6 and 9 (Fig. 1). Maximal activity was observed around pH 7. However, activity at lower and higher pH value was 50% of the activity observed at the optimal pH.

Effect of Mg^{2+} and Ca^{2+} on ROS PLD activity. To determine whether PLD activity was Mg^{2+}-dependent, ROS membranes were incubated with 1 mM [^{3}H]PC, 25 mM KF, 1 mM dithiothreitol, 3 mM CHAPS, and 400 mM ethanol as a function of Mg^{2+} concentrations (0–8 mM). The controls (0 mM Mg^{2+}) were incubated in the presence of 5 mM EDTA. PtdEt production was maximal at 1 mM of Mg^{2+} (Fig. 2). PA production was less than 15% of the PtdEt generated at every Mg^{2+} concentration assayed. PtdEt and PA production decreased drastically (40% of the production observed at 1 mM Mg^{2+}) at higher concentrations of this ion.

To determine the optimal concentration of Ca^{2+} for PLD activity, ROS membranes were incubated under the conditions decribed above in the presence of increasing concentrations of Ca^{2+} (0–8 mM) (Fig. 2). The controls (0 mM Ca^{2+}) were incubated in the presence of 5 mM EGTA. At 1 mM of Ca^{2+} the highest PA and PtdEt production was detected, and PLD activity was significantly inhibited (30% of the activity observed at 1 mM Ca^{2+}) as the concentration of this ion increased. PA production was less than 10% of PtdEt production at every Ca^{2+} concentration assayed.

Effect of PC concentration on ROS PLD activity. PtdEt formation increased as the PC concentration in the mixture increased. The production of PtdEt was linear up to 1 mM of PC concentration (Fig. 3A). PA generated by PLD activity also increased and was linear up to 1 mM of PC (Fig. 3B). The data obtained from Figures 3A and 3B (PtdEt and PA production) were plotted into a Lineweaver-Burk plot (Fig. 3C). The V_{max} was 111 nmol × h^{-1} × (mg protein)$^{-1}$, and the apparent value of K_m was 0.51 mM.

Effect of ethanol concentration on ROS PLD activity. The effect of varying ethanol concentrations on PtdEt, and PA formation was studied. The optimal ethanol concentration for PtdEt formation was 400 mM. At higher ethanol concentrations, product generation was inhibited. The Lineweaver-Burk plot, constructed with data from the sum of PtdEt and PA, shows an apparent K_m of 202 mM and a V_{max} of 125 nmol × h^{-1} × (mg protein)$^{-1}$.

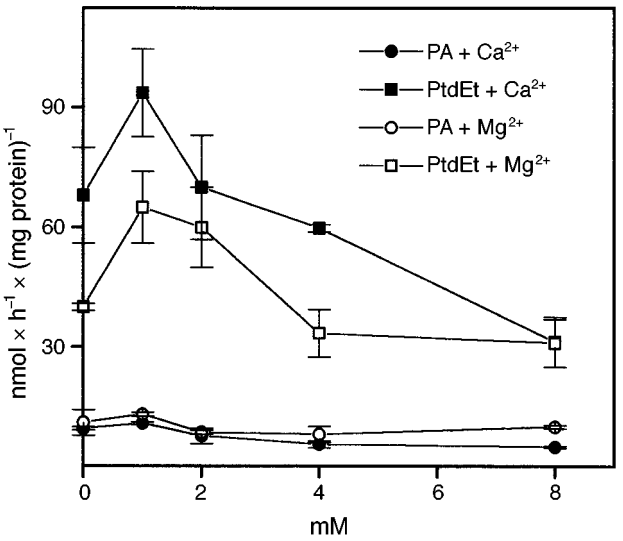

FIG. 2. ROS PLD activity as a function of Mg^{2+} and Ca^{2+} concentrations. Purified ROS membranes (200 µg) were incubated with 25 mM KF, 1 mM DTT, 1 mM [^{3}H]PC, 3 mM CHAPS, and 400 mM ethanol, in the presence of 40 mM HEPES (pH 6.8) and varying concentrations of $MgCl_2$ or $CaCl_2$. The activity is expressed as the mean ± SD of three independent samples. PA, phosphatidic acid; for other abbreviations see Figure 1.

PLD activity in the presence of oleic acid and detergents. The activators employed in this study include Triton X-100, CHAPS, sodium deoxycholate (NaDOC), polyoxyethylenesorbitanmonooleate (Tween 80), and sodium oleate (Fig. 4). Only CHAPS and NaDOC were found to significantly activate PLD from ROS membranes. Maximal stimulation (300% increase) occurred around the critical micelle concentration (CMC) of CHAPS, that is, 5 mM, although an important activation occurred below its CMC (50% increase). When NaDOC was added to the incubation mixture, the maximal stimulation occurred at its CMC (2.5 mM). Tween 80 only stimulated PLD activity at very low detergent concentrations (0.1 mM), whereas Triton X-100 slightly inhibited PLD activity (by 5% with respect to the control) at every concentration assayed.

Sodium oleate has been reported as a possible activator of PLD activity in rat brain (35). For PLD from ROS membranes, the oleic acid concentration required for maximal activation was 2 mM (27% increase). But the stimulation was less pronounced than in the presence of certain detergents (CHAPS and NaDOC) at similar concentrations. (Fig. 4).

When assays were carried out using [^{3}H]PC as substrate, CHAPS, 3 mM (0.2%, wt/vol), was the chosen activator because it producd a 50% increase and because this tensioactive agent is widely used in the study of visual protein systems (37). The maximal activation with CHAPS (300% increase with respect to control) was observed around its CMC.

PLD activity in ROS and retinal fractions. Table 1 shows the specific activities of PLD in fractions obtained by fractionation of crude ROS and retina. Crude ROS, obtained by shaking the retina in a 40% sucrose buffer solution, diluting and centrifuging, were layered onto a discontinuous sucrose

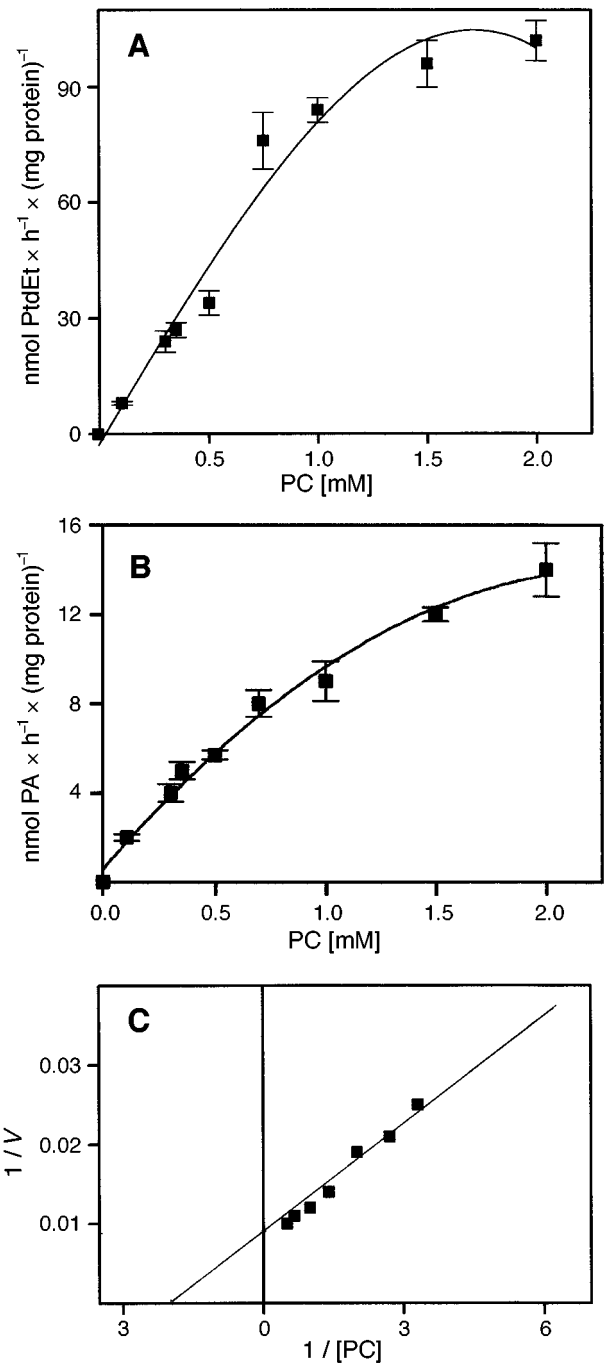

FIG. 3. ROS PLD activity as a function of PC concentration. Purified ROS membranes (200 µg) were incubated in 40 mM HEPES (pH 6.8), 25 mM KF, 1 mM DTT, 3 mM CHAPS, 0.2 mM $CaCl_2$, 400 mM ethanol, and varying concentrations of [^{3}H]PC. (A) PtdEt formation as a function of PC concentration. The activity is expressed as the mean ± SD of four or five independent samples. (B) Effect of PC concentration on PA production. The activity is expressed as the mean ± SD of four or five independent samples. (C) Double reciprocal plot of the data from plots A and B (the sum of PA plus PtdEt) were made according to Lineweaver and Burk to obtain apparent K_m and V_{max} values. For abbreviations see Figures 1 and 2.

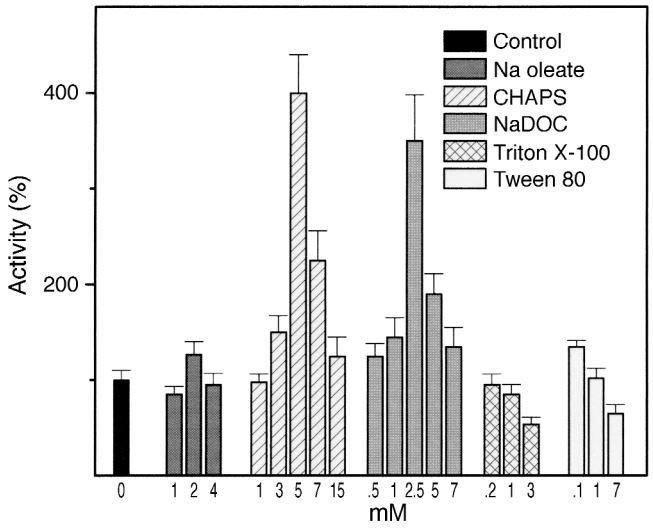

FIG. 4. Effect of detergents and sodium oleate on ROS PLD activity. The reaction mixture contained 200 µg of ROS protein, 40 mM HEPES (pH 6.8), 25 mM KF, 1 mM DTT, 0.2 mM $CaCl_2$, 1 mM [^{3}H]PC, and the indicated concentration of sodium oleate, sodium deoxycholate (NaDOC), CHAPS, *t*-octylphenoxypolyethoxyethanol (Triton X-100), or polyoxyethylenesorbitanmonooleate (Tween 80). The percentage of activity is presented as the mean ± SD of five or six independent samples.

TABLE 1
Phospholipase D Activity in Rod Outer Segment (ROS) Membranes and Retinal Subcellular Fractions[a]

Fraction	nmol PtdEt × h^{-1} × (mg protein)$^{-1}$	Protein (mg)
Band I (0.84/1.00 M interface)	40 ± 5.2	2.54
Band II	29 ± 0.31	0.88
Pellet	27 ± 0.98	3.90
Crude ROS	22 ± 1.9	9.98
Total homogenate	51 ± 6.8	210.00
P_1 (crude nuclei)	22 ± 1.09	92.36
P_2 (crude mitochondria)	35 ± 5.92	19.40
Microsomal	59 ± 6.02	14.23
Cytosolic	25 ± 1.47	65.64

[a]Band I (purified ROS), band II, and pellet of the gradient and retinal subcellular fractions were obtained as described in the Materials and Methods section. In every fraction assay, the reaction mixture contained 200 µg of protein, 40 mM HEPES (pH 6.8), 25 mM KF, 1 mM dithiothreitol, 0.2 mM $CaCl_2$, 1 mM [^{3}H] phosphatidylcholine, 3 mM 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate, and 400 mM ethanol in a total volume of 250 µL. The enzymatic activity is expressed as the mean ± SD of four independent samples. Typical protein content of total homogenate from 10 retinas was 210 mg. PtdEt, phosphatidylethanol.

gradient. Band I, obtained at the 0.84/1.00 M interface, contained purified ROS and showed the highest specific activity of PLD with respect to band II (1.00/1.14 M interface) and pellet. In addition, marker enzyme activities were also assayed in all fractions, with the purpose of determining possible mitochondrial or microsomal contamination of ROS membranes (band I) of the gradient. Whereas the mitochondrial marker enzyme (cytochrome c oxidase) was enriched in band II and pellet [60 and 35 nmol × min^{-1} × (mg protein)$^{-1}$, respectively], the cytochrome c reductase activity (the microsomal marker enzyme) was very low in band I and band II [0.5 and 1 nmol × min^{-1} × (mg protein)$^{-1}$, respectively] and presented the highest activity in the pellet [3.6 nmol × min^{-1} × (mg protein)$^{-1}$]. These results demonstrated that band I (purified ROS) was only slightly contaminated with microsomes or mitochondria (lower than 5%) (19).

Table 1 also shows the specific activities of PLD in crude nuclear fraction (P_1), crude mitochondrial fraction (P_2), microsomal fraction and cytosolic fraction, obtained from the subcellular fraction of the remainder of the retina. The nuclear pellet contained not only a heterogeneous population of nuclei and tissue fragments but also an aggregation of mitochondria, derived from the photoreceptor inner segment, fragmental outer segments, and isolated photoreceptor terminals (pedicle synaptosomes). The crude mitochondrial fraction also contained fragmented photoreceptor outer segments and synaptic pedicles together with many free mitochondria, conventional nerve-ending particles, peroxisomes, lysosomes and occasional bipolar terminals (38). PLD activity was determined with exogenous [^{3}H]PC by measuring [^{3}H]PtdEt and [^{3}H]PA production. The microsomal fraction showed the highest PLD specific activity. The activity found in band I (purified ROS) was as high as 60% of the activity present in microsomes.

DISCUSSION

PLD activity has been described and characterized in a great number of mammalian tissues (39–41). It has also been proposed that such enzymatic activity could be implicated in multiple processes such as membrane intracellular trafficking (21,42), generation of second messengers such as PA, DG and lysophosphatidic acid (20), choline supply for acetylcholine synthesis in rat brain (43) and exocytic hormone release in pancreatic islet cells (44), and participation in events occurring during neutrophil activation (45) and in leukemic cell differentiation (46), among many other cellular events.

The present work demonstrates the presence of PLD activity in isolated ROS from bovine retinas. The activity of PLD observed in ROS [50 nmol × h^{-1} × (mg protein)$^{-1}$] is in agreement with that described for rat brain synaptosome (34). In our ROS membranes, prepared by discontinuous sucrose gradient centrifugation, the activity of PLD was as high as 66% of that found in microsomes. It has been shown that ROS membranes present minimal contamination, with cytochrome c reductase a microsomal marker enzyme (19). This indicates that PLD activity is located in ROS and does not constitute a contamination from other fractions. The majority of contaminants in ROS preparations arise from excessively vigorous homogenization procedures employed too early during the isolation process, with subsequent steps often not able to completely separate ROS from contaminants because of entrapped particles. The method used to obtain our ROS preparations involves gentle homogenization, and the buffer used has moderate ionic strength, thus allowing us to retain the soluble and peripheral protein of the ROS.

We have also established that the optimal pH for PLD activity is 7.0, and this value agrees with the findings of Kanoh *et al.* (40). The presence of ions such as Mg^{2+} and Ca^{2+} stimulates PLD activity. The optimal concentration was 1 mM for both ions. At 1 mM of Ca^{2+}, PtdEt production was increased by 44% with respect to the control (5 mM EGTA). In the presence of 1 mM Mg^{2+}, the activity was increased by 50% with respect to the control (5 mM EDTA). However, enzymatic activity was clearly detected in the absence of these ions [50–60 nmol $\times$ h^{-1} $\times$ (mg protein)$^{-1}$].

When the enzyme was assayed with increasing PC concentrations, the maximal activity was detected at 1 mM PC, the apparent value of K_m for PC being 0.51 mM and the V_{max} being 111 nmol $\times$ h^{-1} $\times$ (mg protein)$^{-1}$. The effect of increasing ethanol concentrations was examined, and the K_m for ethanol was 202 mM (for the sum of PtdEt and PA). V_{max} values, obtained with ethanol [125 nmol $\times$ h^{-1} $\times$ (mg protein)$^{-1}$], are in agreement with the V_{max} values obtained with PC. These values of K_m are similar to those of Kobayashi and Kanfer (35) for synaptosomal brain PLD.

ROS PLD was investigated in the presence of natural or synthetic tensioactive agents, of which the most effective in activating the enzyme were CHAPS and NaDOC. Oleic acid was a poor activator of ROS membrane PLD when [^{3}H]PC was used as a substrate. However, oleic acid is the most effective activator for synaptosomal PLD in rat brains (35). Kanoh *et al.* (40) have studied brain PLD activity from different species (bovine, rat, and rabbit), and they found that PLD activity in bovine brain is poorly detected when enzyme activity is assayed in the presence of oleic acid or Triton X-100. These findings are in accordance with our findings on PLD activation in bovine ROS. Triton X-100, a nonionic detergent, which does not usually break protein–protein interactions, did not affect ROS PLD activity. Stimulation of PLD activity in ROS is very important (300% increase) in the presence of CHAPS, a zwitterionic detergent, or in the presence of NaDOC (250% increase), a bile salt-like anionic detergent that is denaturing and effective at breaking protein–protein interactions. Whether the stimulatory effect of detergents, such as CHAPS and NaDOC, on the PLD activity is due to direct action on the enzyme or on the substrate cannot be distinguished from the present experiments. We also propose that mild perturbations of the membrane at the microenvironment of the enzyme do not interfere with its activity; on the contrary, this effect activates the enzyme.

To study transphosphatidylation reactions, characteristic of most PLD (32), ROS membranes were incubated in the presence of [^{14}C]ethanol or [^{3}H]glycerol in order to obtain [^{14}C]PtdEt or [^{3}H]PG, respectively. [^{14}C]PtdEt production was time- and protein concentration-dependent. These assays were carried out in the presence of oleic acid as activator because in the absence of exogenous PC, oleic acid was effective in allowing measuring of the enzymatic activity.

Base exchange enzymes and PLD have a common characteristic: their capacity to modify the polar portion of phospholipids. Fliesler and Anderson (48) demonstrated the existence of base exchange enzymes in retina, and they suggested their presence in ROS. The presence of both enzyme activities, PLD and base exchange, could play an important role in phospholipid metabolism in vertebrate photoreceptors, as well as in the lipid–protein interactions in ROS membranes.

Bazán *et al.* (49) have suggested that in photoreceptor membranes the pool of PA may arise from phospholipid degradation by a PLD. In addition, PA is the precursor of DG, and this neutral lipid may participate in the fusion of synaptic vesicles to presynaptic membranes during neurotransmission (50). Furthermore, PA breakdown by PAPase has been clearly demonstrated in ROS (6). It is interesting to speculate that PA, produced by PLD, in ROS may be involved in a signal transduction mechanism, and that it could then be hydrolyzed by PAPase to yield DG. DG has been established as an intracellular second messenger, and it has been demonstrated recently that DG is capable of activating a novel characterized ROS protein kinase C isozyme (51).

Fusion mechanisms between disc membranes and plasma membrane have been described in ROS (52), and the implication of several PLD isozymes regulated by small G proteins in the membrane fusion processes (21,42,45,47) is well known. On the other hand, the presence of small G proteins in ROS (53,54) provides a starting point for further studies aimed at understanding the regulation and physiological functions of PLD in photoreceptor membranes.

Lipase Specificity Toward Some Acetylenic and Olefinic Alcohols in the Esterification of Pentanoic and Stearic Acids

Marcel S.F. Lie Ken Jie* and Xun Fu

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong

ABSTRACT: The esterification of five medium- and long-chain acetylenic alcohols (2-nonyn-1-ol, 10-undecyn-1-ol, 6-octadecyn-1-ol, 9-octadecyn-1-ol, and 13-docosyn-1-ol), seven olefinic alcohols (*cis*-3-nonen-1-ol, 10-undecen-1-ol, *cis*-6-octadecen-1-ol, *cis*-9-octadecen-1-ol, *trans*-9-octadecen-1-ol, *trans*-9, *trans*-11-octadecadien-1-ol, *cis*-9,*cis*-12-octadecadien-1-ol), and four short-chain unsaturated alcohols (allyl alcohol, 3-butyn-1-ol, 3-pentyn-1-ol, and *cis*-2-penten-1-ol) with pentanoic or stearic acid in the presence of various lipase preparations was studied. With the exception of 2-nonyn-1-ol, where Lipase AY-30 (*Candida rugosa*) was used as the biocatalyst, the esterification of C_{11}, C_{18}, and C_{22} acetylenic alcohols with pentanoic acid appeared to be generally unaffected by the presence of an acetylenic bond in the alcohol as relatively high yields of the corresponding esters (78–97%) were obtained. However, medium- and long-chain olefinic alcohols were discriminated by Lipase AY-30, Lipolase 100T (*Rhizomucor miehei*), and especially by porcine pancreatic lipase (PPL), when esterification was conducted with pentanoic acid. Esterification of medium- and long-chain acetylenic or olefinic alcohols with a long-chain fatty acid, stearic acid, was very efficient except when Lipase AY-30 and Lipolase 100T were used. Short-chain unsaturated alcohols were much more readily discriminated. 3-Pentyn-1-ol and 3-butyn-1-ol were difficult (<5% yield) to esterify with pentanoic or stearic acid in the presence of Lipase AY-30 and PPL, respectively. Very low yields (<26%) of esters were produced when 3-butyn-1-ol and 3-pentyn-1-ol were reacted with pentanoic or stearic acid, when catalyzed by lipase from *Candida cylindracea*. No reaction took place between 3-butyn-1-ol and stearic acid in the presence of Lipase AY-30. Esterification of short-chain acetylenic and olefinic alcohols was most efficiently achieved with Lipolase 100T (*Rhizomucor miehei*), Lipozyme IM20 (*Rh. miehei*), or Novozyme 435 (*Candida antarctica*) as the biocatalyst.

Lipids 33, 861–867 (1998).

Lipase as a biocatalyst in the esterification of fatty acids and in the hydrolysis of fatty esters has been extensively studied. Lipase specificity toward their substrates is important for metabolic studies, for synthesis of structured lipids, and for the isolation of useful fatty acids. Several review articles have been published detailing the wide variety of enzymes, substrates, and conditions used to accomplish such transformations (1–3), e.g., the lipase from *Brassica napus* L. discriminates against *cis*-4 and *cis*-6 unsaturated fatty acids and also against secondary and tertiary alcohols (4), while the lipase from *Candida parapsilosis* shows a high activity in the presence of esters with long-chain fatty acids and particularly unsaturated fatty acids with a *cis*-9 double bond (5).

The lipase reaction selectivity on the alcohol moiety of esters during hydrolysis and on the discrimination of different types of alcohols during esterification has also been reported. Most of these studies have focused on the chain length of saturated, methyl-branched, aromatic, and cyclic alcohols (6–12). Olefinic fatty alcohols are found in extracts of marine sponges, fish, and plants, e.g. , *cis*-3-nonen-1-ol and *cis*-3, *cis*-6-nonadienol are volatile components detected in watermelon (*Citrillus vulgaris*). These compounds are biosynthetic products derived from linoleic and linolenic acids, respectively (13,14). Long-chain fatty alcohols are synthesized in the brain from the corresponding long-chain fatty acid which is reduced by microsomal aldehyde reductase (15). The accumulation of C_{18} fatty alcohols in human breast cancer cells (MCF-7 cell line) suggests a deviation from the ordinary lipid metabolism in normal breast epithelial cells (16).

Because fatty alcohols are important in biological systems, this work investigated the effects that the unsaturation centers in fatty alcohols have on the alcohols' esterification rates to short- and long-chain fatty acids when various lipases or lipase preparations are used as biocatalysts. We recently reported the effects of the acetylenic bond in long- and medium-chain fatty acids in lipase-catalyzed esterification reactions with *n*-butanol: we showed that different lipases are able to discriminate acetylenic fatty acids according to the position of the triple bond in the alkyl chain of the fatty acid molecule (17).

MATERIALS AND METHODS

Immobilized lipases from *Rhizomucor miehei* (Lipolase 100T and Lipozyme IM 20) and *Candida antarctica* (Novozyme 435) were gifts from Novo Nordisk A/S (Hong Kong). Lipases from *Candida cylindracea* (CCL, type VII, 905 μ/mg) and porcine pancreatic lipase (PPL, type II, 179 μ/mg) were purchased from Sigma Chemical Co. (St. Louis, MO). Lipases from *Pseudomonas cepacia* (PS-D, type I) and *Candida*

Abbreviations: NMR, nuclear magnetic resonance; PPL, porcine pancreatic lipase.

rugosa (Lipase AY-30) were gifts from Amano Pharmaceutical Co. Ltd. (Nagoya, Japan). Allyl alcohol, 3-butyn-1-ol, *cis*-2-penten-1-ol, 3-pentyn-1-ol, *cis*-3-nonen-1-ol, 10-undecen-1-ol, 10-undecenoic acid, methyl 2-nonynoate, pentanoic acid, linoleic acid, oleic acid, and stearic acid were purchased from Aldrich Chemical Co. (Milwaukee, WI). *cis*-6-Octadecenoic and erucic acids were isolated from carrot and rapeseed oil, respectively. *trans*-9, *trans*-11-Octadecadienoic acid was prepared as described elsewhere (18).10-Undecynoic, 6-octadecynoic, 9-octadecynoic, and 13-docosynoic acids were synthesized by bromination–dehydrobromination reaction of the corresponding olefinic fatty acids as described elsewhere (19,20).

2-Nonyn-1-ol, 10-undecyn-1-ol, 6-octadecyn-1-ol, 9-octadecyn-1-ol, 13-docosyn-1-ol, *cis*-9-octadecen-1-ol, *cis*-9,*cis*-12-octadecadien-1-ol, and *trans*-9,*trans*-11-octadecadien-1-ol were obtained by lithium aluminum hydride reduction of the corresponding methyl esters (21). *cis*-6-Octadecen-1-ol was prepared by semihydrogenation of 6-octadecyn-1-ol over Lindlar catalyst (22). *trans*-9-Octadecen-1-ol was obtained by isomerization of *cis*-9-octadecen-1-ol with *p*-toluenesulfinic acid (23).

^{13}C nuclear magnetic resonance (NMR) spectra were obtained using a Bruker Avance DPX_{300} NMR spectrometer (Bruker, Fallanden, Switzerland) with the sample dissolved in deuteriochloroform. Gas–liquid chromatographic analyses were performed on a Hewlett-Packard (Hewlett-Packard Incorp., Palo Alto, CA) model 5890 instrument equipped with a fused silica capillary column coated with Nukol™ (Supelco Inc., Bellefonte, PA) (15 m, 0.53 mm diameter, 0.50 μm film thickness) as stationary phase at a column temperature of 200°C.

General method for the enzymatic esterification of acetylenic and olefinic alcohols as exemplified by the reaction of 9-octadecyn-1-ol with 1-pentanoic acid in the presence of CCL. A mixture of 9-octadecyn-1-ol (25 mg, 0.093 mmol), pentanoic acid (12.3 mg, 0.12 mmol), *n*-hexane (1.2 mL), and *CCL* (25 mg) was stirred at 40°C for 24 h in a glass culture tube. The reaction mixture was centrifuged to remove the lipase, and the *n*-hexane solution was loaded on a silica gel (6.0 g, 230–400 mesh; E. Merck, Darmstadt, Germany) in an *n*-hexane column (12 mm i.d.). The column was eluted with a mixture of *n*-hexane/diethyl ether (95:5 vol/vol, 50 mL). The eluate was evaporated under reduced pressure to give only 9-octadecynyl pentanoate (30 mg, 92%). The product was identified by gas–liquid chromatographic analysis and confirmed by NMR spectroscopic analysis. The results are graphically presented in Figures 1–7. Each bar represents the average percentage yield from at least two determinations. (Note: in the case of the esterification of short-chain alcohols with pentanoic acid, the eluate containing the esters after silica column chromatography was evaporated at atmospheric pressure.) In all other similar experiments, the amount of the respective fatty alcohol used was 25 mg, lipase 25 mg, and the amount of pentanoic or stearic acid was in 30% excess of the molar equivalent of the fatty alcohol.

Competitive enzymatic esterification of C_{18} olefinic alcohols with a mixture of pentanoic and stearic acids in the presence of PPL as exemplified by the reaction involving cis*-6-octadecen-1-ol.* A mixture of *cis*-6-octadecen-1-ol (40 mg, 0.15 mmol), pentanoic acid (15 mg, 0.15 mmol), stearic acid (40 mg, 0.14 mmol), *n*-hexane (1.6 mL), and PPL (30 mg) was stirred at 40°C for 24 h. The mixture of *cis*-6-octadecenyl pentanoate and stearate esters was isolated by column chromatography as described above. The ratio of each component was estimated from the relative intensities observed for the shifts of the C-2 carbon nuclei of the pentanoate and stearate esters in the ^{13}C NMR spectrum. The shift of the C-2 nucleus of *cis*-6-octadecenyl pentanoate appeared at δ_C 34.13, while the shift of the C-2 nucleus of *cis*-6-octadecenyl stearate appeared at δ_C 34.43.

The results of the competitive esterification experiment involving *cis*-6-octadecen-1-ol, *cis*-9-octadecen-1-ol, *trans*-9-octadecen-1-ol, *cis*-9,*cis*-12-octadecadien-1-ol, and *trans*-9,*trans*-11-octadecadien-1-ol are presented in Figure 5.

RESULTS AND DISCUSSION

A total of seven lipase preparations [Lipase AY-30 (*C. rugosa*), Lipolase 100T (*R. miehei*), PPL, CCL, PS-D (*P. cepacia*), Lipozyme IM 20 (*R. miehei*), Novozyme 435 (*C. antarctica*)] were used as biocatalysts in studying the esterification process.

In order to establish a general reaction time for the esterification for the proposed unsaturated alcohols with pentanoic or stearic acid, the esterification of *cis*-9-octadecen-1-ol with pentanoic or stearic acid was first studied over a period of 6, 12, 18, 20, 24, 30, 40, and 50 h using the various lipases. In each case the esterification process showed a gradual increase of ester formation. Generally, esterification of *cis*-9-octadecen-1-ol was more sluggish (about 23% after 12 h) with pentanoic acid than with stearic acid (about 60% after 12 h). However, after 20–24 h of reaction at 40°C, the esterification process reached a steady state. Little or no further esterification was observed when the reaction time was extended from 24–50 h, when a yield of about 95% of each ester was obtained. From this study it was concluded that a 24-h reaction period would be an ideal reaction time to study the esterification of the various acetylenic and olefinic alcohols with pentanoic or stearic acid.

The results of the esterification of acetylenic alcohols with pentanoic acid are given in Figure 1. 2-Nonyn-1-ol [9:1(2*a*)] [Note: The chain length of the alcohol is denoted by the first number, the number following the colon indicates the number of unsaturated center(s) present in the chain, the number within the brackets gives the position of the unsaturated center from the hydroxy function, and the letter (*a* = acetylene, *c* = *cis*, *t* = *trans,* and *e* = ethylenic) describes the type of unsaturated center(s) involved.] was significantly discriminated (43% yield), when Lipase AY-30 was used as the biocatalyst. This observation indicated that the effect of the acetylenic bond on the electronic nature of the hydroxy function seemed to affect the catalytic property of the enzyme. Lipase AY-30

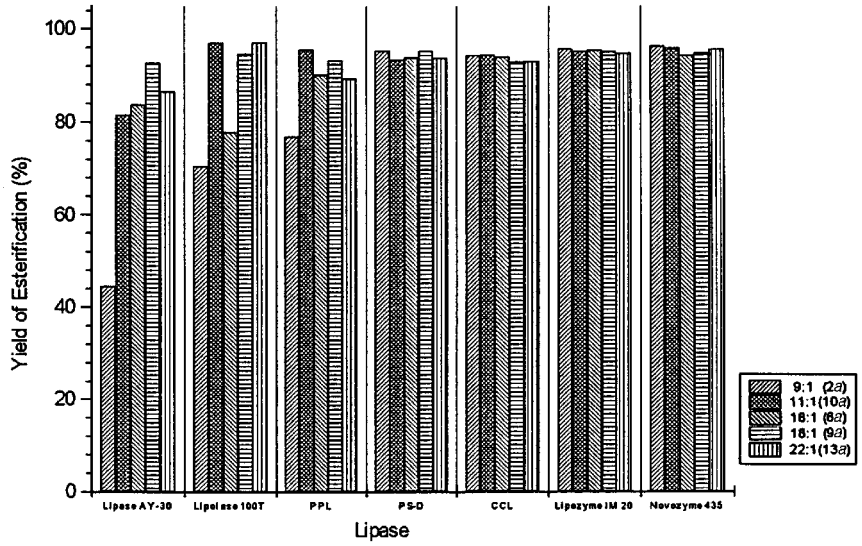

FIG. 1. Esterification yields of acetylenic fatty alcohols with pentanoic acid catalyzed by various lipases after 24 h. *a* = acetylene; PPL, porcine pancreatic lipase, and CCL, *Candida cylindracea* (Sigma Chemical Co., St. Louis, MO); PS-D, *Pseudomonas cepacia*, and Lipase AY-30, *Candida rugosa* (Amano Pharmaceutical Co. Ltd., Nagoya, Japan); Lipolase 100T, Lipozyme IM20, and Novozyme 435 (Novo Nordisk A/S, Hong Kong).

therefore could be considered as sensitive or discriminating against a propargyl system.

The esterification of the C_{11}, C_{18}, and C_{22} acetylenic alcohols with pentanoic acid in the presence of the other lipases appeared to be only slightly affected by the acetylenic bond in the alcohol as relatively high yields (78–97%) of esters were obtained. The presence of an acetylenic bond, irrespective of its position in the alkyl chain of the alcohol, did not seem to interfere significantly with the rate of esterification.

The esterification of seven olefinic alcohols [viz. 9:1(3*c*), 11:1(10*e*), 18:1(6*c*), 18:1(9*c*), 18:1(9*t*), 18:2(9*t*,11*t*), and 18:2(9*c*,12*c*)] with pentanoic acid was investigated next, and the results are shown in Figure 2. In the presence of Lipase AY-30, the esterification of 9:1(3*c*), 11:1(10*e*), and 18:1(9*t*) gave comparatively low yields (28, 40, and 48%, respectively) of the corresponding esters, while the remaining unsaturated C_{18} alcohols were esterified in good yields (60–75%). Lipolase 100T seemed to discriminate the monounsaturated C_{18} fatty alcohols,

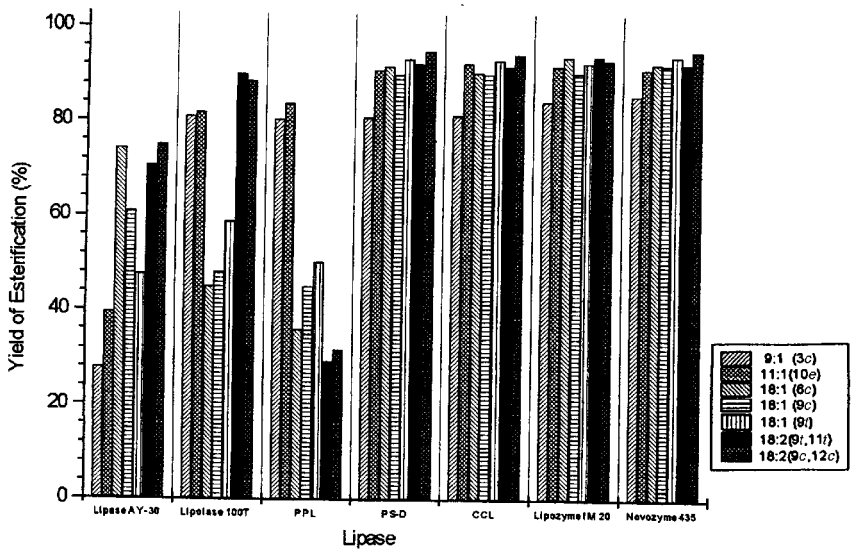

FIG. 2. Esterification yields of olefinic fatty alcohols with pentanoic acid catalyzed by various lipases after 24 h. *c = cis; t = trans; e* = ethylenic. See Figure 1 for other abbreviations and company sources and locations.

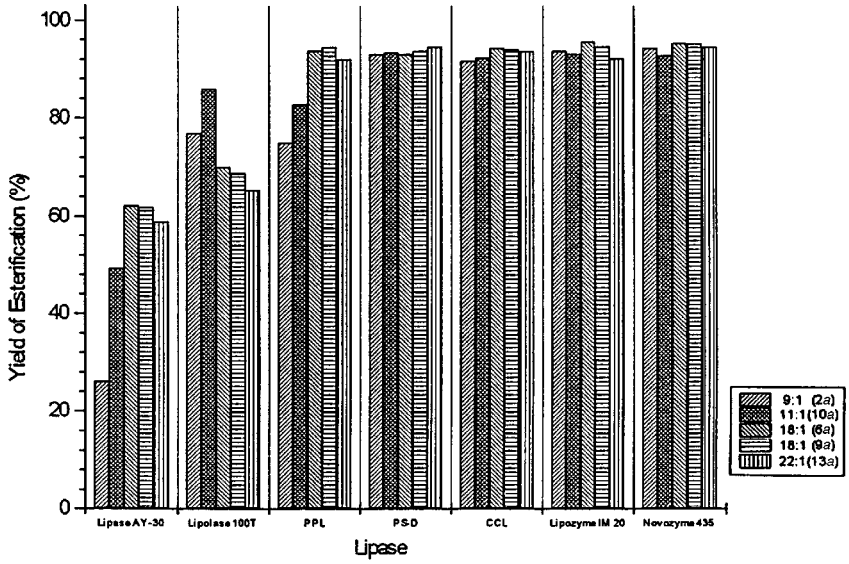

FIG. 3. Esterification yields of acetylenic fatty alcohols with stearic acid catalyzed by various lipases after 24 h. See Figure 1 for abbreviations and company sources.

but not the medium (C_9, C_{11}) and long-chain alcohols (C_{18}) containing two double bonds (methylene-interrupted or conjugated). Of interest was the result of the esterification conducted in the presence of PPL: the medium-chain olefinic alcohols [9:1(3*c*) and 11:1(10*e*)] were readily esterified, but the C_{18} and C_{22} unsaturated alcohols yielded only 29–50% of the corresponding pentanoate esters. Esterification of the olefinic alcohols in the presence of the other lipases furnished high yields of the pentanoate esters (average yield of 93%).

When the same sets of acetylenic and olefinic alcohols were subjected to esterification with stearic instead of pentanoic acid, the yields of the esters obtained were also generally very high (average 93%) for most lipases. Some significant discrimination was observed for Lipase AY-30 and Lipolase 100T: the yields of the stearate esters fluctuated between 26–86% (Fig. 3 and 4).

To further investigate the apparent differences in the ability of PPL to esterify olefinic C_{18} alcohols with short-vs. long-chain fatty acids, a competitive esterification reaction was carried out with each of the following alcohols [18:1(6*c*), 18:1(9*c*), 18:1(9*t*), 18:2(9*t*,11*t*), and 18:2(9*c*,12*c*)] using a mixture of pentanoic and stearic acids. The resulting mixture

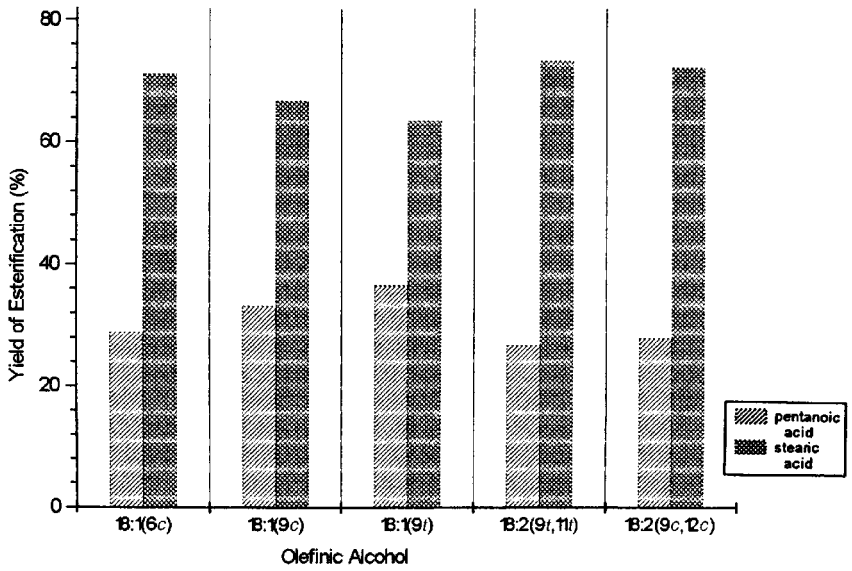

FIG. 5. Comparison of relative yields obtained from porcine pancreatic lipase-catalyzed esterification reaction between pentanoic and stearic acids with long-chain olefinic C_{18} fatty alcohols after 24 h. See Figure 2 for abbreviations.

of pentanoate and stearate esters was isolated by silica column chromatography. The ratio of the pentanoate to stearate esters was estimated from the intensities of the signals arising from the shifts of the C-2 carbon atoms of the ester mixture. The shift of the C-2 nucleus of the pentanoate ester appeared at δ_C 34.13, while the shift of the C-2 nucleus of the stearate ester appeared at δ_C 34.43. The amounts in percentage yield based on the individual fatty acid used are shown in Figure 5. In each case the amount of stearate ester was two- to threefold higher than that of the pentanoate ester. These results confirmed the initial observation that PPL favored the esterification of long-chain fatty acids (e.g., stearic acid) over short-chain fatty acids (e.g. pentanoic acid) with C_{18} olefinic alcohols.

To assess the effects of short-chain unsaturated alcohols on the rate of esterification with pentanoic and stearic acids,

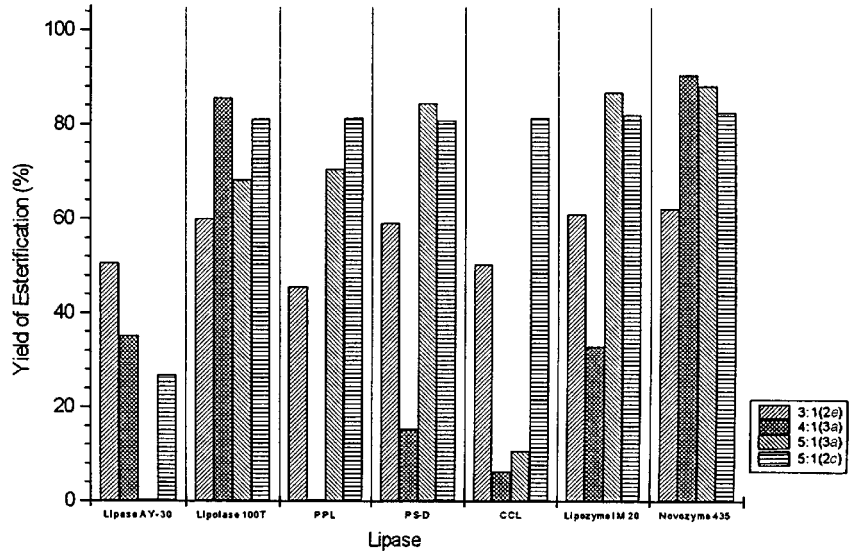

FIG. 6. Esterification yields of short-chain unsaturated alcohols with pentanoic acid catalyzed by various lipases after 24 h. See Figures 1 and 2 for abbreviations and Figure 1 for company sources.

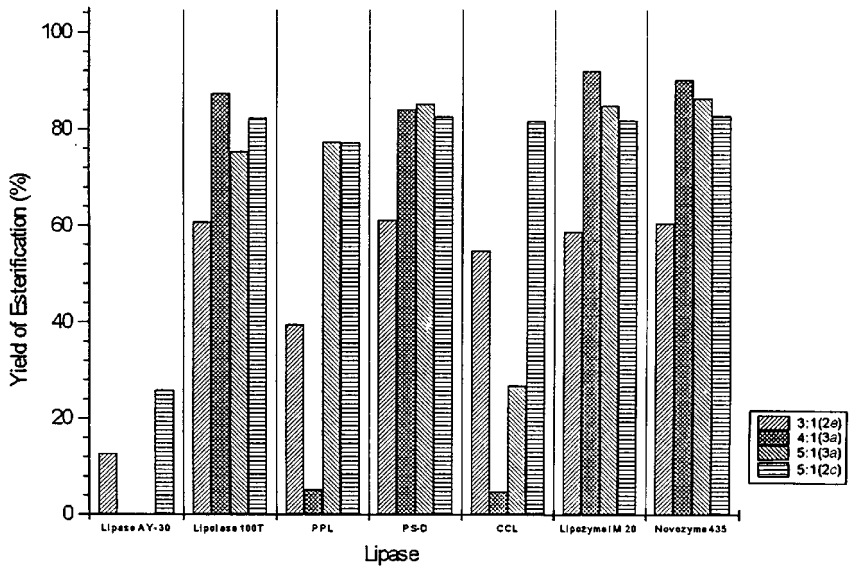

FIG. 7. Esterification yields of short-chain unsaturated alcohols with stearic acid catalyzed by lipases after 24 h. See Figures 1 and 2 for abbreviations and Figure 1 for company sources.

four unsaturated alcohols [3:1(2*e*), 4:1(3*a*), 5:1(3*a*), and 5:1(2*c*)] were selected. The results of the lipase-catalyzed esterification of such short-chain unsaturated alcohols with pentanoic or stearic acid are presented in Figures 6 and 7, respectively. The most striking feature in this study was seen in the case of Lipase AY-30, which was able to esterify 3:1(2*e*), 4:1(3*a*), and 5:1(2*c*) with pentanoic acid in yields varying from 27–51%. However, 5:1(3*a*) was not esterified with pentanoic acid in the presence of Lipase AY-30, and when pentanoic acid was replaced by stearic acid, only 3:1(2*e*) and 5:1(2*c*) were esterified in low yields (13 and 26%, respectively).

When PPL was used as the biocatalyst, 4:1(3*a*) was not esterified with pentanoic acid, and only 5% yield of the ester was obtained when pentanoic acid was replaced by stearic acid in this reaction. Low yields of ester production were found for 4:1(3*a*) and 5:1(3*a*) when CCL lipase was used. The other remaining lipases showed no difficulty in catalyzing the esterification of the short-chain unsaturated alcohols with either pentanoic or stearic acid.

From these results it is difficult to rationalize the precise mechanism involved in the enzymes during the esterification process. However, the data point to the fact that some of the lipases are relatively sensitive to the acetylenic or olefinic bonds, especially where this unsaturation is adjacent to the hydroxy function. Also, PPL appears to behave particularly sensitively toward short-chain fatty acid (pentanoic acid) during the esterification of such substrate with olefinic C_{18} fatty alcohols, probably due to the less well-bound nature of the short-chain fatty acid to the pancreatic lipase as compared to long-chain fatty acids, such as stearic acid.

This study concludes that medium- and long-chain acetylenic and olefinic alcohols are generally readily esterified in the presence of the seven lipase preparations studied, except in the case of PPL which shows discrimination against olefinic long-chain (C_{18}) alcohols. Short-chain (C_3–C_5) acetylenic or olefinic alcohols are best esterified with either pentanoic or stearic acid when catalyzed by Lipolase 100T, Lipozyme IM20, or Novozyme 435.

The Triggering Signal Dictates the Effect of Docosahexaenoic Acid on Lymphocyte Function *in vitro*

Laura J. Jenski[a,*], John M. Scherer[a,b], LaDawn D. Caldwell[a], Victori A. Ney[a], and William Stillwell[a]

ABSTRACT: Docosahexaenoic acid (DHA) is an n-3 fatty acid beneficial to several human conditions including inflammation and autoimmune disease. To better understand the effect of DHA on immunity, we monitored the rise in cytosolic free calcium, interleukin 2 receptor (IL2R) expression, and proliferation of splenic lymphocytes triggered with three different stimuli in the presence or absence of DHA. We found that 10 μg DHA/mL suppressed concanavalin A-induced mitogenesis and the mixed lymphocyte reaction while concurrently enhancing proliferation stimulated with anti-Thy-1 antibodies. Proliferation, as measured by [^{3}H]thymidine incorporation after 2 to 5 d of culture, was affected by DHA, but earlier activation effects such as elevation of cytosolic free calcium and IL2R expression were not altered. These results imply that DHA incorporated into membrane phospholipids differentially affects the activity of distinct membrane-bound receptors and signaling molecules. This result suggests that DHA may be used to modulate immune responses selectively, e.g., to suppress undesired autoimmunity while maintaining protective immunity.
Lipids 33, 869–878 (1998).

There is considerable interest in long-chain n-3 polyunsaturated fatty acids (PUFA) as natural agents to control autoimmunity and destructive inflammatory responses. The two n-3 PUFA of greatest interest are docosahexaenoic acid (DHA, $22{:}6^{\Delta 4,7,10,13,16,19}$) and eicosapentaenoic acid ($20{:}5^{\Delta 5,8,11,14,17}$), best recognized as components of oil from cold-water fish. DHA and eicosapentaenoic acid have similar although not identical activities, including suppression of arachidonic acid (AA, $20{:}4^{\Delta 5,8,11,14}$) metabolism and reduction of cancer growth (1,2). Their effects on immune cell function are puzzling and controversial, however. The predominant, but by no means exclusive, opinion is that they suppress lymphocyte proliferation and macrophage activation (3). The mechanisms of action of n-3 fatty acids are not well understood and may include effects on eicosanoid production, lipid peroxidation, and membrane structure. The influence of DHA on membrane structure is of particular interest to us because membranes are fundamental to all cells and provide an opportunity for DHA (in membranes) to participate in very diverse biological processes.

One likely reason for variable effects of n-3 PUFA on immune cells is the complexity of the immune system itself. The lymphocyte lineage is divided into T and B lymphocytes; T lymphocytes may be further distinguished (subdivided) by the expression of the membrane proteins CD4 and CD8. Lymphocytes may be immature or mature; they may be naïve or memory cells, depending on whether they have been exposed to antigen; and they may be driven by cytokines to distinct differentiation states, such as in the Th1/Th2 paradigm. There is substantial evidence that different cell types have distinct stimulation and costimulation requirements (4–6) and use nonidentical, though perhaps overlapping, signaling pathways (7–9). Thus, the outcome of membrane enrichment with n-3 fatty acids will depend on several variables, including the nature of the target cell, the presence of accessory cells, and the type, magnitude, and multiplicity of stimuli.

To use n-3 PUFA rationally and effectively to improve human health, we need a clearer understanding of their effects on immune function. In this report we focus on the effect of DHA on splenic T lymphocyte proliferation. T lymphocytes play key roles in immunity, orchestrating as well as implementing immune responses. We have chosen DHA for study because it is the longest, most unsaturated fatty acid found in abundance in nature and because of cells' propensity to retain this fatty acid in membrane phospholipids at the expense of n-6 and n-9 fatty acids (10). Membranes enriched in DHA display significant changes in membrane structure and function, including increased permeability and fusibility, formation of putative lipid microdomains, and alterations in membrane proteins (11–16). Because of the importance of the plasma membrane in lymphocyte activation, DHA-induced alterations in membrane structure may modulate lymphocyte function. We predict, furthermore, that DHA will have disparate effects on T cells activated through different membrane-associated receptors. Here we explore the importance of the triggering stimulus (lectin, alloantigen, and monoclonal anti-Thy-1 antibody) on modulation of lymphocyte activation and proliferation by DHA.

Abbreviations: AA, arachidonic acid; BSA, bovine serum albumin; Con A, concanavalin A; DHA, docosahexaenoic acid; FBS, fetal bovine serum; FITC, fluorescein isothiocyanate; IgG, immunoglobulin G; IL2R, interleukin 2 receptor; PUFA, polyunsaturated fatty acid(s).

MATERIALS AND METHODS

Reagents. RPMI 1640 and Hanks' balanced salt solution were purchased from Gibco (Grand Island, NY), fetal bovine serum (FBS) and bovine calf serum were obtained from HyClone Labs (Logan, UT), concanavalin A (Con A) was purchased from Pharmacia (Piscataway, NJ), and all other cell culture reagents were obtained from Sigma Chemical Co. (St. Louis, MO). Anti-CD90 (anti-Thy-1.2; clone 30H12) and anti-CD25 [anti-IL2Rα; clone AMT13; phycoerythrin-labeled and fluorescein isothiocyanate (FITC)-labeled] were bought from Boehringer-Mannheim Biochemicals (Indianapolis, IN), anti-CD90 (anti-Thy-1; clone G7; unlabeled and FITC-labeled) was purchased from PharMingen (San Diego, CA), and anti-rat immunoglobulin G (IgG) (R-3756) was obtained from Sigma Chemical Co. Fluo-3 was obtained from Calbiochem (LaJolla, CA), fatty acids were purchased from Nu-Chek-Prep (Elysian, MN), [methyl-^{3}H]thymidine (2 Ci/mmole) was bought from Amersham Corp. (Arlington Heights, IL), and BetaMax ES scintillation fluid was purchased from ICN Biochemicals (Costa Mesa, CA).

Mice. Young adult BALB/c and C57BL/6 male mice were purchased from Harlan Sprague-Dawley (Indianapolis, IN) and provided standard rodent chow (#5001; Purina, Richmond, IN) and water *ad libitum*. They were used in an approved protocol, housed in the AAALAC-accredited Animal Facility at the Indiana University—Purdue University at Indianapolis School of Science, and euthanized under the guidelines of the 1993 American Veterinary Medical Association Panel on Euthanasia.

Preparation of fatty acid-enriched media. To enrich medium with fatty acids from an ethanolic stock, commercial fatty acids in hexane were evaporated under a stream of nitrogen and then dissolved at levels of 25 to 100 mg/mL ethanol. The fatty acids were added gradually to RPMI 1640 medium supplemented with 100 units penicillin/mL, 100 µg streptomycin/mL, 25 mM HEPES buffer, and 2 mM glutamine ("supplemented RPMI") also containing 50 µM 2-mercaptoethanol and 5% FBS ("complete medium"), with mixing on a stir plate. The control medium received a comparable amount (0.05%) of ethanol vehicle only. The media were sterilized by filtration through 0.22-µm Millipore filters (Milford, MA) and used immediately. Ethanolic fatty acid stocks were covered with foil and stored at −20°C.

In some experiments, DHA-enriched medium was prepared by the method described by Spector and Hoak (17). Briefly, ≤5 mg of DHA in 5 mL hexane was added to Celite (0.1 mmol fatty acid per g Celite) and evaporated to dryness under nitrogen. The dried, DHA-coated Celite was mixed with supplemented RPMI containing 1% (wt/vol) bovine serum albumin (BSA) to produce the desired DHA concentration(s); in experiments shown here, the final DHA concentration was 50 µg/mL of BSA-containing RPMI. DHA was transferred from the Celite to the BSA in the medium by stirring the suspension, protected from light, at room temperature for 30 min. Celite was removed by centrifugation (20 min, $1360 \times g_{max}$, 4°C), and the medium was sterilized by filtration through a 0.22-µm Millipore filter. Medium was covered in foil and stored frozen. FBS and 2-mercaptoethanol were added to make complete medium just prior to use.

Cell cultures. Spleens were teased into single-cell suspensions, cell viability was measured by trypan blue exclusion, and the cells were resuspended at 5×10^6 cells/mL of complete medium (described above). As indicated in the Results section, complete medium was supplemented with DHA or AA, either complexed to BSA or in ethanol. For Con A stimulation, 5×10^5 BALB/c spleen cells/well were cultured in triplicate wells in 96-well flat-bottomed plates with various Con A concentrations in a final volume of 200 µL/well. For anti-Thy-1 stimulation, 5×10^5 BALB/c spleen cells were cultured in triplicate wells with 0 to 25 µg anti-Thy-1 (30H12 or G7) per mL of complete medium. With both Con A and anti-Thy-1 stimuli, the cultures were incubated for 48 h under standard culture conditions (in a 37°C, humidified, 5% CO_2 incubator), and [^{3}H]thymidine (0.5 µCi/well) was present during the last 4 h of incubation. Cultures were harvested onto glass-fiber filters with an automated cell harvester (Cambridge Technology, Watertown, MA), and radioactivity incorporated into DNA and present on the filters was measured by liquid scintillation counting in an LS1801 beta counter (Beckman Instruments, Fullerton, CA).

For primary mixed lymphocyte cultures, single-cell suspensions of C57BL/6 splenocytes were treated with 40 µg mitomycin C/mL for 30 min at 37°C, washed three times in Hanks' balanced salt solution, and resuspended at 5×10^6 cells/mL of complete medium plus DHA complexed to BSA or BSA alone. Five hundred thousand BALB/c responder splenocytes, prepared as described in the paragraph above, were mixed in triplicate wells with an equal number of mitomycin C-treated C57BL/6 stimulator splenocytes in a total volume of 200 µL/well. The plates were incubated for 5 d under standard culture conditions, with 0.5 µCi/well of [^{3}H]thymidine present during the last 24 h of incubation. The cultures were harvested onto filters, and radioactivity present on the filters was measured as described above. For secondary mixed lymphocyte cultures, ~1×10^8 naïve BALB/c splenocytes were cultured with mitomycin C-treated C57BL/6 splenocytes at a ratio of 10:1 in 60 mL of medium (either DHA-enriched or control medium) in two 75-cm^2 stationary flasks for 10 d, at which time the cells were harvested and washed by centrifugation ($500 \times g_{max}$, 10 min) in Hanks' balanced salt solution. The cells were restimulated for 3 d with mitomycin C-treated C57BL/6 splenocytes in 96-well plates as described above. [^{3}H]Thymidine (0.5 µCi/well) was added during the last 24 h of incubation, and radioactivity incorporated into DNA was measured as usual.

Intracellular free calcium. Fluo-3/AM was reconstituted in dimethylsulfoxide to a concentration of 1 µg/µL and stored covered with foil at −20°C. BALB/c spleen cells were cultured at a concentration of 5×10^6 cells/mL for 2 h in control or DHA-supplemented medium. Cells (1×10^6) from culture were resuspended in 1 mL of supplemented RPMI medium without serum, and 5 µL of fluo-3/AM was added to the cells, which were then incubated for 30 min in a humidified 37°C incubator with 5%

CO_2. In some tubes, G7 monoclonal anti-Thy-1 antibodies (4 µg) were added concurrently with the fluo-3/AM. After incubation, the tubes were placed in the sampling station of a Coulter Epics Elite ESP flow cytometer (Miami, FL) and immersed in a beaker containing 37°C water. By using forward and side scatter, a gate was established around the viable lymphocyte population; 525-nm fluorescence emission from the cells was measured for approximately 1 min to obtain baseline readings. Data collection was then paused, either 10 µg of Con A or 11.5 µg of anti-rat IgG (to crosslink cell surface-bound anti-Thy-1 antibodies) was added to the cells to stimulate an increase in intracellular free calcium, and data collection was resumed for an additional 9 min. Baselines were established so that 90% of the cells before stimulation were at or below the baseline. The percentage of cells responding was determined by measuring the percentage of cells above the baseline at 2 min after addition of the stimulus (i.e., at the maximal response).

Interleukin 2 receptor (IL2R) expression. Five million spleen cells contained in 1 mL were placed in each well of a 24-well plate and were incubated under standard culture conditions with 2 µg Con A/mL or 2 µg G7 anti-Thy-1 antibody per mL of control (ethanol alone) or ethanolic DHA-supplemented medium. After 24 h, the cells were harvested by centrifugation (340 × g_{max}, 10 min), resuspended in supplemented RPMI, and counted with a hemocytometer; viability was checked by trypan blue exclusion. One million cells were added to 1 mL of 0.1 M methyl α-D-mannopyranoside in supplemented RPMI containing 15% bovine calf serum and incubated at 4°C for 30 min. The cells were centrifuged at 340 × g_{max} for 5 min, the supernatant was discarded, and 1 mL of a solution containing 2 µg/mL of phycoerythrin- or FITC-labeled anti-CD25 (IL2R α chain) antibody in phosphate buffered saline was added to the pellet. The cells were incubated for 30 min at 4°C and then analyzed by flow cytometry. By using forward and side scatter, gates were set to exclude debris; the percentage of $IL2R^+$ cells was calculated with Immuno 4 software (Coulter Corp.), which compares the fluorescence of stimulated vs. unstimulated spleen cells.

Statistical methods. Student's *t*-test was used to compare two means, and analysis of variance was used for multisample analyses. A probability $P \leq 0.05$ was the criterion for statistical significance, i.e., accepting that measured values were not the same.

RESULTS

DHA suppresses Con A mitogenesis and the mixed lymphocyte reaction. Our objective was to explore the effect of DHA on early activation events and the subsequent proliferation of lymphocytes triggered with qualitatively and quantitatively different stimuli. To establish the DHA dose for subsequent experiments, we measured Con A-stimulated lymphocyte proliferation as a function of DHA concentration in culture medium (Fig. 1A). As anticipated from our previous work (18) and that of other investigators (19,20), DHA inhibited proliferation in a dose-dependent fashion. At 10 µg DHA/mL, lymphoproliferation was ~80% of control (ethanol vehicle only); the inhibition was reproducible and statistically significant but not so severe that proliferation was undetectable. We initially tested DHA delivered bound to BSA; because the

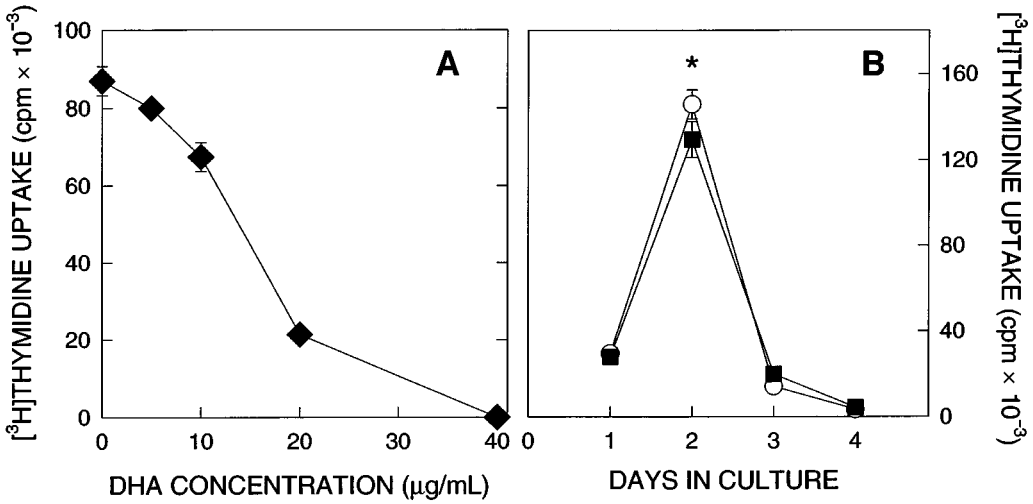

FIG. 1. Docosahexaenoic acid (DHA) decreases concanavalin A (Con A)-stimulated proliferation in a dose-dependent fashion without grossly altering the peak response. (A) Splenocytes (5×10^5 cells/well) were cultured for 2 d with 1.5 µg Con A/mL in medium supplemented with various DHA concentrations (as shown on the abscissa) or in the ethanol vehicle alone. [^{3}H]Thymidine (0.5 µCi/well) was present during the last 4 h of incubation. The data are expressed as means ± SD ($n = 3$); some error bars are smaller than the symbol. (B) Splenocytes (5×10^5 cells/well) were cultured with 2 µg Con A/mL in the presence (■) or absence (○) of 10 µg DHA/mL; there were no medium changes after the cultures were established. Cultures were harvested every day for 4 d, and [^{3}H]thymidine was present for the last 4 h of incubation. The data are expressed as means ± SD ($n = 3$). The asterisk denotes a significant difference between DHA-supplemented and control cultures ($P < 0.05$, analysis of variance).

two fatty acid addition methods produced comparable results, for technical convenience most experiments except mixed lymphocyte reactions were performed with 10 µg DHA/mL, delivered in ethanol. Figure 1B also demonstrates that DHA does not grossly alter the temporal kinetics of Con A-induced mitogenesis. The peak incorporation of [^{3}H]thymidine was on culture day 2, whether the culture contained control medium or medium supplemented with 10 µg DHA/mL. The decreased [^{3}H]thymidine incorporation on days 3 and 4 represents a combination of nutrient exhaustion (the medium is not replenished during the culture period) and normal down-regulation of the response, and thus all subsequent measurements were made on or before the second culture day.

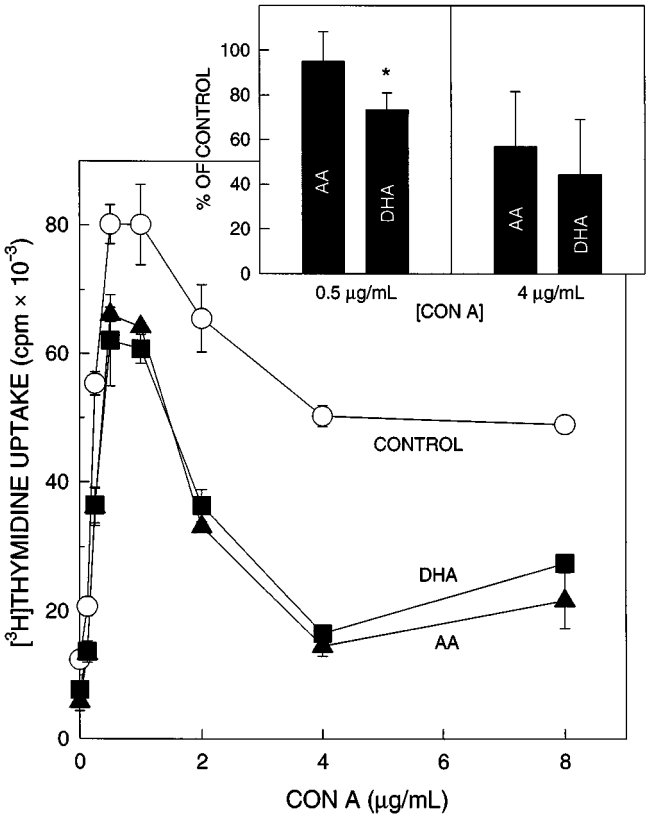

FIG. 2. DHA preferentially inhibits lymphoproliferation triggered by high Con A concentrations. Main figure: Splenocytes (5×10^5 cells/well) were cultured for 2 d in various Con A concentrations without fatty acid addition (○) or with 10 µg/mL of arachidonic acid (AA) (▲) or DHA (■) added in ethanol. [^{3}H]Thymidine (0.5 µCi/well) was added during the last 4 h of incubation, after which the cells were harvested and the incorporated radioactivity was measured by scintillation counting. Each symbol is the mean ± SD of triplicate wells; the graph is one representative experiment from three performed with control, AA- and DHA-supplemented media, and from >20 performed with DHA-supplemented and control media. Inset: The means ± SE of three independent experiments are shown for splenocytes cultured in the presence of 10 µg/mL of DHA or AA. The data are expressed as percentage of control (y-axis) for ease of presentation. Results for two Con A doses, 0.5 and 4.0 µg/mL, are shown to illustrate the greater fatty acid effect at higher Con A concentrations. The asterisk denotes greater inhibition of proliferation by DHA compared to AA ($P < 0.05$, analysis of variance). For abbreviations see Figure 1.

When we explored the inhibitory effect of DHA on cells stimulated with various Con A concentrations (Fig. 2), we observed that inhibition was more pronounced at higher (≥4 µg/mL) than lower (<1 µg /mL) Con A concentrations. In the representative experiment shown in the main portion of Figure 2, the level of proliferation stimulated by 0.5 µg Con A/mL in the presence of DHA was ~78% of control, whereas with 4 µg/mL, proliferation in DHA was ~33% of control. In a series of three experiments, DHA was slightly but significantly more inhibitory than AA (17 and 5% inhibition for DHA vs. AA, respectively; Fig. 2, inset), even though, at 10 µg/mL, the molar concentration of AA (33 µM) exceeded that of DHA (30.5 µM). To further explore this phenomenon, in the following experiments we test two other stimuli, allogeneic cells and monoclonal antibodies to Thy-1. Although the three stimuli may share some signaling pathways, the signals they induce are not identical (21,22).

Figure 3 summarizes results obtained when BALB/c splenocytes were cultured with allogeneic (C57BL/6) splenocytes, inactivated with mitomycin C, in the presence and absence of DHA. The primary response after 5 d of mixed lym-

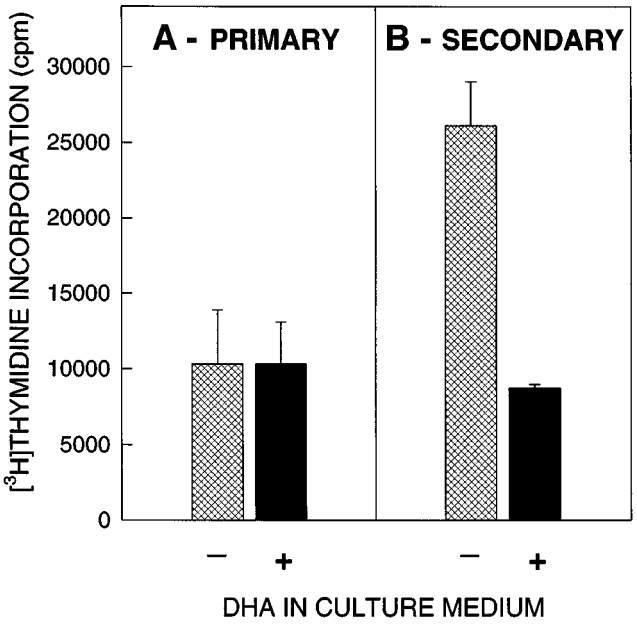

FIG. 3. Secondary mixed lymphocyte reactions are dramatically inhibited by DHA. (A) For the primary response, BALB/c splenocytes (5×10^5 cells/well) were cultured for 5 d with mitomycin C-inactivated C57BL/6 splenocytes (1:1) in microtiter wells with (solid bars) and without (hatched bars) bovine serum albumin-bound DHA at 50 µg/mL; [^{3}H]thymidine (0.5 µCi/well) was added for the last 24 h of incubation. (B) For the secondary response, BALB/c splenocytes were stimulated with mitomycin-inactivated C57BL/6 splenocytes at a ratio of 10:1 for 10 d in 75-cm^2 flasks with and without DHA supplementation, harvested, and restimulated for 3 d with mitomycin C-treated C57BL/6 stimulators as in the primary culture, with (solid bars) and without DHA (hatched). Primary and secondary cultures included unstimulated controls, the cpm of which have been subtracted as background from the cpm shown. The data are presented as means ± SE for 8 (primary response) and 5 (secondary response) experiments. For abbreviation see Figure 1.

phocyte culture was, on average, unaffected by DHA, whereas the secondary response, obtained by culturing splenocytes with stimulators in the presence or absence of DHA for 10 d and then restimulating under the same conditions, was drastically reduced by DHA. In fact, secondary responses in DHA-enriched medium were at the same levels as the primary response, that is, there was no evidence that antigen-specific clones had been expanded. Because of limited cell recovery we did not test secondary cultures established in the opposite medium, i.e., control cells restimulated in DHA-supplemented medium, and so on. DHA-induced suppression of the secondary mixed lymphocyte reaction was much more striking than that observed with Con A mitogenesis. Medium for mixed lymphocyte cultures was prepared with additional BSA (beyond that present in the FBS) to aid in fatty acid delivery, but we adjusted the amount of DHA appropriately; that is, 50 μg DHA/mL of BSA-supplemented medium produced the same inhibition of Con A-stimulated proliferation as 10 μg DHA/mL delivered in ethanol (data not shown). Although there was a small, not unexpected increase in background proliferation associated with the BSA supplement, the main differences between the mixed lymphocyte reaction and the Con A-stimulated mitogenesis were the nature of the stimulus and the duration of culture.

DHA enhances anti-Thy-1-induced proliferation. If culture duration, not the stimulus, were the determining factor in the effect of DHA, then DHA in a 2-d culture stimulated with something other than Con A should produce results similar to those seen for Con A (Fig. 2). We chose, as the alternative stimulus, antibody to Thy-1. Thy-1 is a glycosylphosphatidylinositol-linked glycoprotein implicated in T lymphocyte activation (23), through which signaling is accomplished *via* pathways overlapping with but not identical to those associated with Con A and T cell antigen receptors (21,22,24,25). Figure 4 demonstrates that, unlike Con A, anti-Thy-1-stimulated lymphocyte proliferation is augmented by the presence of DHA. With 3 to 6 μg anti-Thy-1/mL added at the beginning of culture, maximal proliferation was enhanced approximately twofold by DHA. This result was observed for two different anti-Thy-1 antibodies, G7 and 30H12, and in the absence of a crosslinking antibody. 30H12 is generally not stimulatory in the absence of crosslinking anti-IgG, however, DHA did augment the low level of proliferation triggered by 30H12 alone. We have reproduced this finding 10 times, both in BSA-supplemented and BSA-unsupplemented DHA-enriched media. This result also rules out extended culture periods as a critical component of the action of DHA, with the reservation that DHA-mediated suppression, but not enhancement, may require prolonged culture. Thus, we conclude that at least one aspect of the effect of DHA on proliferation is related to the stimulus.

DHA does not affect elevation of cytosolic free calcium or IL2R expression. Because the measure of proliferation, [^{3}H]thymidine incorporation 2 to 5 d after culture initiation, is late with respect to cells' first exposure to DHA, we were interested in monitoring earlier activation events. Our goal was to approximate where along the timeline from receptor occupation to thymidine incorporation (i.e., cell cycling) DHA exerts its influence. Two events were examined, calcium mobilization and IL2R expression, occuring within minutes and hours, respectively, of activation.

Table 1 demonstrates that the presence of DHA does not affect the percentage of splenocytes responding to either Con A or anti-Thy-1 by increasing intracellular free calcium. Approximately one-third to 40% of splenocytes respond to these

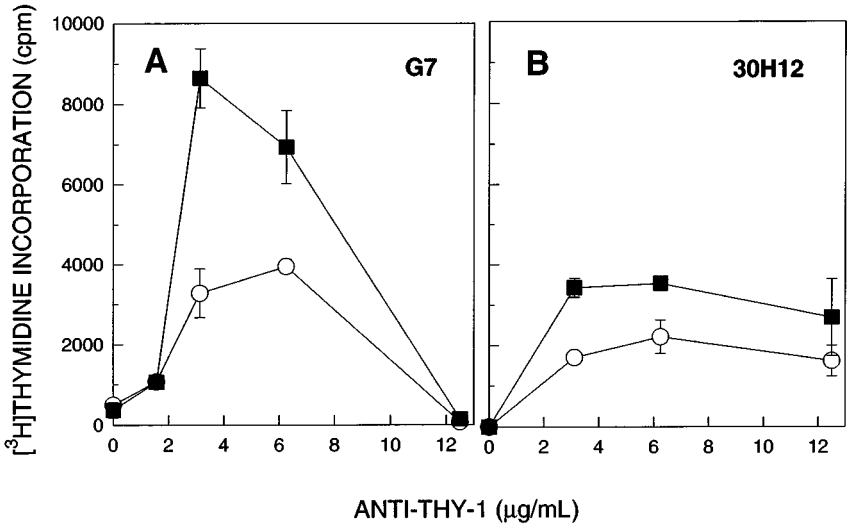

FIG. 4. In contrast to other stimuli, anti-Thy-1 evokes greater lymphoproliferation in the presence of DHA. Splenocytes (5×10^5 cells/well) were cultured in 10 μg DHA/mL (■) or ethanol vehicle alone (○), with various concentrations of monoclonal anti-Thy-1 antibodies G7 (A) or 30H12 (B). A secondary crosslinking anti-IgG was not used in either case. [^{3}H]Thymidine was added for the last 4 h of the 48-h culture period. The data shown are means ± SD for triplicate wells; one representative experiment is shown for each antibody.

TABLE 1
DHA Does Not Alter the Percentage of Lymphocytes That Elevate Calcium in Response to Mitogen[a]

	Calcium-mobilizing cells (%)	
Stimulus	Control	DHA^+
Con A	34.0 ± 3.7	33.4 ± 2.3
Anti-Thy-1	40.5 ± 3.6	39.6 ± 3.7

[a]Fresh splenocytes were incubated for 2 h in docosahexaenoic acid-supplemented (DHA^+) or control medium, washed, and loaded with the calcium-sensitive fluorescent probe fluo-3. The percentage of cells with fluorescence intensity above baseline after mitogen addition [calcium-mobilizing cells (%)] was measured by flow cytometry. For anti-Thy-1 stimulation, the fluo-3-loaded cells were pretreated with the G7 monoclonal anti-Thy-1 antibody, baseline fluorescence was measured, and crosslinking anti-rat IgG was then added to induce calcium mobilization. The percentage of cells responding with calcium mobilization was calculated at the peak of the response, 2 min after stimulus addition. The data are presented as means ± SE for three separate experiments; there were no significant differences between control and DHA^+ cells (Student's *t*-test). Con A, concanavalin A; IgG, immunoglobulin G.

T cell stimuli, consistent with the approximate proportion of T cells in mouse spleen. Table 2 shows that the peak calcium levels (average intensity of fluo-3 fluorescence 2 min after stimulation) were the same and elevated cytosolic free calcium was sustained equivalently (9 min after stimulation) in DHA-supplemented and control groups. The data are presented as ratios of stimulated/baseline to allow compilation of individual experiments. The mean numerical values for sustained fluorescence in anti-Thy-1-stimulated cells with and without DHA were 3.67 and 4.30, respectively, but statistical analysis suggested no significant difference ($P = 0.09$, Student's *t* test). Thus, there is no reason *a priori* to suspect that the effect of DHA on splenocyte proliferation is caused by altered calcium mobilization, an early activation event.

Expression of the IL2R α chain (CD25) is a lymphocyte activation marker detected several hours after cell triggering, but one that is dependent upon early activation events for relevant gene transcription. IL2R expression is not necessarily induced in parallel with other hallmarks of activation, such as elevated cytosolic calcium and IL2 synthesis (26). Thus, IL2R expression is an independent measure of the effects of DHA.

TABLE 2
DHA Does Not Affect the Calcium Levels Achieved in Response to Mitogen[a]

	Peak level		Sustained level	
Stimulus	Control	DHA^+	Control	DHA^+
Con A	6.87 ± 1.09	6.42 ± 0.12 ($P = 0.70$)	5.84 ± 0.46	5.12 ± 0.45 ($P = 0.37$)
Anti-Thy-1	4.57 ± 0.17	4.18 ± 0.43 ($P = 0.44$)	4.30 ± 0.23	3.67 ± 0.16 ($P = 0.09$)

[a]Cells described in Table 1 were analyzed for relative calcium levels (mean fluorescence channel) at baseline, the peak response (2 min after stimulus addition), and sustained response (after 9 min of stimulation). The data are presented as -fold fluo-3 fluorescence increase, i.e., the ratio of mean fluorescence channel after stimulation to mean fluorescence channel of the baseline. Statistical analyses revealed no significant differences between control and DHA+ groups (Student's *t*-test, $n = 3$ separate experiments). For abbreviation see Table 1.

In Table 3 we present the results of experiments in which splenocytes were cultured with Con A or anti-Thy-1 in the presence or absence of DHA. After 24 h, IL2R expression was measured by flow cytometry with fluorescent antibodies to CD25. The data indicate that DHA does not affect IL2R expression on splenocytes stimulated with either Con A or G7. The percentage of $IL2R^+$ cells and the mean channel fluorescence, an indication of surface receptor density, were equivalent in the presence and absence of DHA. Compared to Con A, anti-Thy-1 treatment led to fewer $IL2R^+$ splenocytes, with a lower receptor density per cell (Table 3), and less incorporation of [^{3}H]thymidine (Fig. 4), whereas the percentage of cells mobilizing calcium in response to anti-Thy-1 was greater than for Con A (Table 1), consistent with other reports dissociating intracellular free calcium responses from IL2R expression (26).

DISCUSSION

In this report we demonstrate that the activating stimulus dictates whether DHA has a suppressive or enhancing effect on lymphocyte proliferation. This result may help to reconcile apparently conflicting reports on the action of this fatty acid, and it implies that DHA may be used to modulate immune responses selectively. In addition, the data we show here are consistent with the effect of DHA being expressed late, i.e., during cell cycling, rather than during early activation events.

We entertained two interpretations for the differential effect of DHA on responses to low vs. high Con A doses and to mitogen or alloantigen vs. anti-Thy-1. First, there may be disparate populations responding; second, the stimulus (signaling pathway) may dictate the effect of DHA. These are, however, not mutually exclusive hypotheses; in fact, the disparate responses of various cell types imply differences in signaling. Evidence suggestive of multiple responding cell populations dates back decades ago when it was observed that purified T cell populations responded within a narrow, high Con A dose range, whereas T cells supplemented with adherent splenic or peritoneal exudate cells proliferated at lower Con A doses (27), indicating either multiple populations (the T cell population responding to low Con A doses required accessory cells) or one responding population requiring costimulation when the Con A dose was limiting. Even disease states yield clues for disparate populations responding to different Con A doses; lymphocytes from patients with light atopic dermatitis showed reduced Con A reactivity at low Con A concentrations (28). We have determined that DHA does not significantly alter the proportion of T ($Thy\text{-}1^+$) and B (surface immunoglobulin-positive) cells in unstimulated cultures (18), or the percentage of $CD4^+$ and $CD8^+$ T cells in Con A-stimulated cultures (preliminary data not shown). However, our results in Figure 3 strongly suggest that development of immunologic memory, as modeled by the secondary mixed lymphocyte reaction, is severely decreased by DHA. Naïve and memory T cells are a good example of different responding cell "types" with different signaling requirements. In contrast

TABLE 3
DHA Does Not Affect Interleukin 2 Receptor Expression on Splenocytes[a]

	Positive cells (%)		Mean fluorescence channel	
Stimulus	Control	DHA^+	Control	DHA^+
Con A	49.7 ± 7.7[b]	54.0 ± 6.7[b]	1.04 ± 0.08[c] 3.01[d]	1.08 ± 0.10[c] 2.3[d]
G7	29.1 ± 4.4[b]	28.5 ± 4.1[b]	0.76 (0.75–0.76)[e] 1.68[d]	0.80 (0.76–0.84)[e] 1.52[d]

[a]Splenocytes were stimulated with Con A or G7, or left unstimulated, in the presence (DHA^+) or absence (Control) of DHA. After 24 h, the cells were harvested and stained with FITC- or phycoerythrin-labeled anti-CD25 (to detect interleukin 2 receptor) for 30 min on ice. The viable cell population was gated, and fluorescence intensity was measured with a Coulter Elite ESP flow cytometer. Data from the background (stained, unstimulated cells) and experimental (stained, stimulated cells) were loaded into Coulter's Immuno 4 data analysis software, and the background histogram was automatically subtracted from experimental histograms to produce "Positive cells (%)."
[b]Mean ± SE (n = 3–4 separate experiments).
[c]Mean ± SE (n = 3 separate experiments, phycoerythrin-labeled anti-CD25).
[d]Single experiment, FITC-labeled anti-CD25.
[e]Mean (range), n = 2 separate experiments, phycoerythrin-labeled anti-CD25. There were no significant differences (Student's t-test) between DHA^+ and control groups having multiple samples. For other abbreviations see Table 1.

to memory cells, naïve T cells respond well to Con A, displaying elevated intracellular calcium and proliferation (29), are strictly dependent upon costimulation, especially through CD28/B7-2 interactions (5), and do not use IL12 in place of CD28/B7-2 ligation (30); naïve $CD4^+$ cells are not activated by IL15, and naïve $CD8^+$ T cells require exposure to their specific restricting class I major histocompatibility complex molecule to survive (4).

If memory cells have a lower threshold for activation, as suggested by this evidence, is DHA modulating the magnitude of the signal perceived by lymphocytes? That is, does DHA potentiate responses and thereby deliver superoptimal signals from mitogens and alloantigens, and bring weak signals (anti-Thy-1) into the optimal range? The data do not argue strongly for this interpretation. Neither the Con A dose-response curve (in the 0.25–1.0 μg/mL range) nor the anti-Thy-1 dose-response curve is left-shifted, as one would predict for potentiation. The sizable percentage of cells responding to anti-Thy-1 by elevating cytosolic free calcium or expressing CD25 suggests that anti-Thy-1 is not a weak signal in need of potentiation. Finally, the cells showing the most dramatic difference in DHA inhibition, naïve and memory T cells, have significant physiological differences beyond mere antigen dose preference.

The stimulus dose is not unimportant, however. Lymphocytes are stimulated to proliferate at low Con A concentrations but undergo apoptosis at high Con A concentrations (32). Not unexpectedly, intracellular activation events follow dose-dependent kinetics, e.g., substrates including ERK1, ERK2 and c-jun, are tyrosine-phosphorylated in a Con A dose-dependent fashion (32). Whereas binding of increasing amounts of Con A to the cell surface is a hyperbolic function, the resultant cellular responses are more complicated, i.e., sigmoidal, implying cooperativity (interaction) between receptors and other membrane proteins (33). Con A binds to and sequentially redistributes multiple sets of cell surface receptors, which are distinguished by the Con A concentration required for redistribution (first set, low dose; second set, high dose) (34). Con A receptors are present in small clusters, which bind succinyl-Con A (a dimeric rather than tetrameric form of the lectin) with high affinity, and co-existing large aggregates, which bind Con A with only low affinity (35). Ultimately, at very high Con A concentrations, competition between lectin molecules for the limiting number of surface receptors reduces Con A-induced receptor crosslinking and precludes a proliferative cell response.

What action of DHA may concurrently decrease mitogenesis and alloreactivity and increase responses through Thy-1? Viewing our results from the standpoint of the effect of DHA on membrane structure, we suggest that phospholipids containing DHA may act as annular lipids around membrane receptors, influencing receptor function; or may induce membrane microdomains into which membrane proteins, glycoproteins, and glycolipids may be selectively recruited or excluded. The potential scenario with DHA and Thy-1 is particularly interesting from a membrane structure standpoint. Thy-1 is a glycoprotein found on murine thymocytes and T cells, neurons of several species, fibroblasts, and rat mast cells (36), and is involved in T lymphocyte activation (23), inhibition of neurite outgrowth (37), and mast cell triggering (38). However, Thy-1 is lipid-linked, and therefore its signaling ability must be related to its ability to cluster with appropriate transmembrane proteins. Indeed, Thy-1 is found complexed with a 100 kDa transmembrane protein (39), as well as tyrosine kinases and a tyrosine phosphatase (40–42), in membrane domains poorly soluble in nonionic detergents. One may argue that the detergents used to isolate Thy-1 or the detergent-resistant domains, or the antibodies used to aggregate Thy-1 for cell activation, create an artificial Thy-1/domain association (43,44). However, the observation that most glycosylphosphatidylinositol-linked proteins (in contrast to transmembrane proteins) preferentially partition with certain lipids (cholesterol, sphin-

golipids, saturated fatty acids) during detergent extraction (45,46), implies that these proteins prefer a membrane environment different from other membrane proteins. Furthermore, functional lipid-linked Thy-1 and nonfunctional transmembrane Thy-1 (engineered with the transmembrane and cytoplasmic domains of NCAM-140) are found naturally clustered in distinct domains (47), strongly implying that membrane lipid domain formation may be a key element in regulating Thy-1 function. We have reported that DHA-containing phospholipids interact poorly with cholesterol, inducing the membrane to segregate into DHA-rich/cholesterol-poor and DHA-poor/cholesterol-rich domains (14). Thus, there is good reason to believe that membrane enrichment with DHA will induce lipid microdomain formation that promotes or stabilizes detergent-resistant (cholesterol-rich) domains. We speculate that its lipid anchor will cause Thy-1 to associate preferentially with select (cholesterol-rich) domains induced by DHA, thereby favoring Thy-1's interaction with signaling proteins and enhancing lymphoproliferation.

Much of the confusion surrounding n-3 fatty acids' effects on lymphocytes arises from technical differences in the experiments performed: free vs. esterified fatty acids, cell type, species, stimulus, and assay method. Free fatty acids obliterated the spike of intracellular free calcium (release from intracellular stores) in T cell lines (48,49); but once esterified into phospholipids, fatty acids did not affect intracellular stores but instead depressed the sustained calcium elevation, purportedly by activating the plasma membrane Ca^{2+}-ATPase and enhancing calcium extrusion (50,51). In our experiments, we expect that even the 2-h fatty acid exposure will produce significant esterification of DHA into phosphatidylethanolamine. In the myeloid leukemia T27A, for example, we found esterified DHA present after 2 h at almost one-third of the 24-h (plateau) level (52). Our results with normal mouse splenocytes agree in part with those of Chow *et al.* (50), in that the initial spike of cytosolic free calcium is unaffected by DHA enrichment; we did not, however, observe a depression of sustained calcium levels. These studies also differ with respect to stimuli and monitoring methods. Stimuli included anti-CD3 (49,50), Con A (48) (current study), and anti-Thy-1 (current study); fluorescence methods included flow cytometry (51) (current study), spectrofluorimetry (48–50), and the fluorophores Indo-1 (51), fura-2 (48–50), and fluo-3 (current study). The same argument that experimental differences may lead to different outcomes applies to the measurement of IL2R. Khalfoun *et al.* (19) found increased CD25 expression on phytohemagglutinin-stimulated human lymphocytes cultured *in vitro* for 72 h with DHA, whereas we did not detect such a difference in samples from a different lymphoid tissue of a different species, stimulated with different mitogens, and tested at a much earlier time. Our study is more similar to that of Calder and Newsholme (53), who stimulated rat lymphocytes with Con A for 48 h and found no difference in IL2R expression in the presence and absence of DHA.

Because DHA does not alter cytosolic free calcium elevation or IL2R expression but does affect [^{3}H]thymidine incorporation, it is tempting to speculate that DHA affects cell cycling. Progression through the cell cycle is coordinated with phosphatidylcholine synthesis to allow net phospholipid accumulation during S phase (54); interestingly, the incorporation of excess DHA into phosphatidylcholine instead of its usual phospholipid species, phosphatidylethanolamine, is associated with reduced cell proliferation (52). We have recently reported the apparent block or prolongation of S phase in DHA-treated Con A-activated lymphocytes (18), consistent with reports of n-3 fatty acid inhibition of S phase in cancer cells (55,56). This area is clearly ripe for more extensive study.

Overall, our data suggest that DHA may inhibit or enhance lymphocyte proliferation depending upon the stimulus used to elicit the response. We cannot at this point fully rule out that it is the magnitude of the signal rather than the particular membrane receptor(s) involved that is key to the differential effects of DHA, although, for reasons stated earlier, we favor the disparate membrane receptor theory. The possibility that enrichment of membrane phospholipids with DHA influences the protein and lipid composition of membrane domains associated with cell signaling is a very attractive one. A final consideration is that, although Con A and anti-Thy-1 both target T cells, the T cell subset responding to each stimulus may not be identical. We are currently exploring whether DHA influences the development or maintenance of Th1 and Th2 cells, two functionally disparate T cells thought to have different activation requirements. Armed with more complete information on the effects of DHA on T lymphocytes, we will be in a better position to utilize DHA to control immune responses.

ABSTRACT: We have compared the effects of three different margarines, one based on palm oil (PALM-margarine), one based on partially hydrogenated soybean oil (*TRANS*-margarine) and one with a high content of polyunsaturated fatty acids (PUFA-margarine), on serum lipids in 27 young women. The main purpose of the study was to test if replacement of *trans* fatty acids in margarine by palmitic acid results in unfavorable effects on serum lipids. The sum of saturated fatty acids (12:0, 14:0, 16:0) was 36.3% of total fatty acids in the PALM-diet, the same as the sum of saturated (12:0, 14:0, 16:0) (12.5%) and *trans* (23.1%) fatty acids in the *TRANS*-diet. This sum was 20.7% in the PUFA-diet. The content of oleic acid was 37.9, 35.2, and 38.6%, respectively, in the three diets, whereas linoleic acid amounted to 16, 13.5, and 27.3%, respectively. Total fat provided 30–31% and the test margarines 26% of total energy in all three diets. The subjects consumed each of the diets for 17 d in a Latin-square crossover design. There were no significant differences in total cholesterol, low density lipoprotein (LDL)-cholesterol and apolipoprotein B (apoB) between the *TRANS*- and the PALM-diets. High density lipoprotein (HDL)-cholesterol and apoA-I were significantly higher on the PALM-diet compared to the *TRANS*-diet whereas the ratio of LDL-cholesterol to HDL-cholesterol was lower, although not significantly ($P = 0.077$) on the PALM-diet. Total cholesterol, LDL-cholesterol, and apoB were significantly lower on the PUFA-diet compared to the two other diets. HDL-cholesterol was not different on the PALM- and the PUFA-diets but it was significantly lower on the *TRANS*-diet compared to the PUFA diet. Compared to the PUFA-diet the ratio of LDL- to HDL-cholesterol was higher on both the PALM- and the *TRANS*-diets whereas apoA-I was not different. Triglycerides and lipoprotein (a) were not significantly different among the three diets. We concluded that nutritionally, palmitic acid from palm oil may be a reasonable alternative to *trans* fatty acids from partially hydrogenated soybean oil in margarine if the aim is to avoid *trans* fatty acids. A palm oil-based margarine is, however, less favorable than one based on a more polyunsaturated vegetable oil.

Lipids 33, 879–887 (1998).

Abbreviations: Apo, apolipoprotein; BMI, body mass index; E%, percentage of energy; HDL, high density lipoprotein; LDL, low density lipoprotein; Lp(a), lipoprotein (a); PALM-margarine, a hard zero-*trans* margarine containing 80% palm oil, 11% soybean oil, and 9% rapeseed oil; PHSO, partially hydrogenated soybean oil; PUFA, polyunsaturated fatty acids; PUFA-margarine, a commercial soft highly polyunsaturated margarine consisting of coconut, palm, refined sunflower, and refined rapeseed oils; *TRANS*-margarine, a hard margarine containing a high amount of *trans* fatty acids from PHSO, containing 56% PHSO, 34% refined rapeseed oil, and 10% refined soybean oil.

Partially hydrogenated vegetable oils constitute a major ingredient in margarine production. Such oils contain a number of geometrical (*cis-trans*) and positional isomers of mono- and diunsaturated fatty acids and saturated fatty acids. The content of *trans* unsaturated octadecenoic (C_{18}) fatty acids in margarines varies from 10.7 to 30.1% (1), and margarine is the most important single source of *trans* fatty acids in, for example, the Norwegian diet.

Trans fatty acids from partially hydrogenated vegetable oil increase serum total and low density lipoprotein (LDL) cholesterol (2–9), decrease high density lipoprotein (HDL) cholesterol (4,5), and increase lipoprotein (a) [Lp(a)] (6,9–11) in humans. Replacement of *trans* fatty acids by less atherogenic fatty acids in margarines is therefore desirable.

Palm oil, unlike soybean oil, can be used without hydrogenation to achieve a certain hardness of margarine products because of its semisolid texture at room temperature. Palm oil consists of 50% saturated and 50% unsaturated fatty acids and has a content of 43.8% palmitic acid and 10.6% linoleic acid (12). From the literature it appears that the effects of palmitic acid and palm oil on blood lipids are controversial. Hegsted *et al*. (13) reported that palmitic acid is cholesterol-increasing, but less so than myristic acid. Nestel *et al*. (6) found no difference in total and LDL cholesterol when an elaidic acid-rich diet was compared to one rich in palmitic acid. Ng *et al.* (14) found a palm oil diet not to be hypercholesterolemic in Malaysian volunteers. In a later study Ng *et al.* (15) found that dietary palmitic and oleic acids exert similar effects on serum cholesterol and lipoprotein profiles in normocholesterolemic men and women. Marzuki *et al.* (16) found no significant difference in effect on total, LDL, and HDL cholesterol when palm oil was compared to soybean oil. Choudhury

et al. (17) suggest that $C_{16:0}$ is not always a cholesterol-increasing fatty acid. They found no significant differences between palm olein and olive oil. On the other hand, Temme *et al.* (18) found a significant rise in total serum cholesterol with a diet rich in palmitic acid compared to one rich in oleic acid. One study in primates also indicated that palmitic acid increases total cholesterol (19).

As far as we know, no study has been published where the effects of palm oil on serum lipids have been directly compared to those of partially hydrogenated soybean oil (PHSO). In this study we compared the effects of three test margarines on serum lipids and Lp(a). One margarine with a high content of PHSO (*TRANS*-margarine), one of similar hardness but consisting of 80% palm oil (PALM-margarine), and one high in polyunsaturated fatty acids (PUFA-margarine). The aim of the study was to test whether palmitic acid can replace *trans* fatty acids in margarine without producing unfavorable effects on blood lipids and to see how a palm oil-based margarine compared nutritionally to one high in PUFA.

MATERIALS AND METHODS

Participants and their baseline characteristics. Thirty female home economics students were recruited in a strictly controlled dietary study. Criteria for inclusion were that the participants should be reliable and have a regular meal pattern. One person had been operated on for thyroid cancer (about three-quarters of the gland removed) and one had hypothyroidism. Both were well-regulated on thyroid hormone therapy. Two had a previous diagnosis of thrombosis and one of these had a lack of protein-S. Otherwise all participants were in good health with no history of diabetes, anemia, renal, hepatic or gastrointestinal disturbances, hypertension or intolerance, and all had normal dietary habits. None was taking any medication known to affect serum lipids except for oral contraceptives. We had no screening criteria with regard to smoking habits, age, physical activity, or body weight. All participants were requested to maintain their regular lifestyles and especially their usual extent of physical activities throughout the study. They were asked to abstain from alcohol consumption during the study period. In addition they were asked to report in a diary any deviation from their usual behavior.

Two persons withdrew during the study, and one participant had not fasted before blood sampling and this person also had problems with compliance and was excluded from the study. Thus, data from 27 subjects with a mean age of 27 yr (SD 5.8, yr range 19–42 yr) were evaluated. Seven of the women were taking oral contraceptives and 10 were smokers. Baseline levels of serum lipids and lipoproteins are presented in the Results section.

The average weight of the participants was 77.5 kg (SD 13 kg) ranging from 56.4 to 100 kg, and the body mass index (BMI) ranged from 20 to 36 kg/m^2 (mean 26.5 kg/m^2, SD 4.1 kg/m^2). Four persons had a BMI above 30. Eliminating the data of these four participants from the statistical analysis caused negligible changes in blood parameters except for total serum cholesterol (see below).

The protocol and the objective of the study were explained to the subjects in detail, and they gave their informed consent before entering the study. No payment was given except for free food during the study. The study protocol was approved by the Regional Committee for Ethics in Biomedical Research of Norway.

Habitual diet. The participants filled in a quantitative food frequency questionnaire (20) designed to cover the habitual diet, and each questionnaire was thoroughly checked. The calculated average amount of total fat in the habitual diet was found to be 31% of energy (SD 5.7%). The mean daily intake of saturated fatty acids, monounsaturated fatty acids, and PUFA was 29, 26, and 13.9 g, respectively, and the intake of linoleic and α-linolenic acids was 10.4 and 1.4 g, respectively. The calculated mean intake of cholesterol was 259 mg/d (SD 141 mg/d).

Study design. The study ran from January to March 1996, during periods of 17 d. Studies have demonstrated new stable levels of serum lipids and lipoproteins within 14 d on a controlled diet (21–23). Each person received the three diets in a sequence determined by assignment to one of six possible sequences as directed by a Latin-square design. The participants were fed simultaneously, and all three diets were fed in the three periods. The study was designed as an intraindividual crossover comparison of the effects on blood lipids of the three diets. In this way, variation due to residual effects of the previous diet or to drift of variables over time could be minimized. After the end of the test period, the participants crossed over to the next diet with a wash-out period of 1 wk. During this week the subjects returned to their normal eating habits.

Body weight without heavy clothes was monitored twice a week and read to the nearest 0.1 kg. Body height was measured without shoes and read to the nearest 0.1 cm. BMI was calculated as weight (kg)/height^2 (m)^2. Dietary compliance was checked daily by interview and diaries.

Test margarines. We used three different margarines in our study. We wanted to test a hard zero-*trans* margarine containing palm oil (PALM-margarine) with a hard margarine containing a high amount of *trans* fatty acids from PHSO (*TRANS*-margarine). The PALM-margarine was produced from 80% palm oil, 11% soybean oil and 9% rapeseed oil, and the *TRANS*-margarine from 56% PHSO, 34% refined rapeseed oil and 10% refined soybean oil. The third margarine was a commercial soft highly polyunsaturated margarine consisting of coconut oil, palm oil, refined sunflower oil and refined rapeseed oil (PUFA-margarine). Because of its high content of sunflower oil, this margarine contained more vitamin E than the other two (205 mg/kg vs. 81 and 100 mg/kg in the PALM- and the *TRANS*-margarines, respectively).

The fatty acid compositions of the three margarines are given in the Results section. The margarines were produced by the addition of water, vitamin A, vitamin D, NaCl, aroma (diacetyl, 0.002%), β-carotene as color, and emulsifier (soybean

lecithin, 0.3%). The PALM-margarine contained 16% water, the *TRANS*-margarine 15.7%, and the PUFA-margarine 18%.

Experimental test diets. The three diets were based on a 7-d menu and were calculated by using a computer-based, nutrient calculation program. They were designed to have the same nutrient composition except for the fatty acids and for the tocopherol content. The diets were calculated to contain 15.6 energy percent (E%) protein, 34 E% fat, and 50.4 E% carbohydrate. The fat from the background diet was calculated to supply a minimal amount of 6 E% while the test fat was planned to amount to 28 E%. The fat from the background diet came from meat, fish, dairy products, and cereals. The menu for the three experimental diets contained the same basic food items and differed only in the source of test margarine used for spreading, baking, and cooking. The test fats were also incorporated into the menus in several foods including bread, buns, porridge, and sauces.

Dinner was prepared and served under supervision in a dining room at the college from Monday through Friday. All meals including weekend meals were prepared at school. Supper and breakfast for the next day were sent home. Each Friday, weekend meals were packaged for home consumption. Perishable food was sent in frozen condition. During the controlled feeding periods, no foods other than those in the menu were allowed. If the participants lost weight or were hungry, they were allowed to eat buns with the same fat and energy composition as the rest of the diet. Coffee, tea, and mineral water with artificial sweeteners were allowed *ad libitum*. Initial daily caloric intake for each individual was calculated from estimates of energy requirements based on weight and height (24). Each diet was assigned a color code and an energy level. All foodstuffs were weighed for each individual subject. The subjects were supplied with free food to meet 100% of their mean daily energy requirements. The diet was calculated to contain 89.5 g fat per 10 MJ, of which 74 g derived from the margarines and 16 g from the background diet. The participants were informed before entering the study that they would be given three different types of fat in three different periods and that the type of fat would first be identified after the study.

Chemical analysis. Duplicate portions corresponding to a daily energy intake of 8.5 MJ were taken of the three diets. After homogenization and freeze-drying, the homogenates corresponding to seven consecutive days were pooled into one portion and kept frozen at –20°C until analyzed. The nitrogen content was determined by the Kjeldahl technique. The factor used for conversion of nitrogen content to protein was 6.25. The content of total fat was determined by chloroform–methanol extraction (25). The metabolizable energy content of the diets was determined as described by Andersson *et al.* (26).

For analysis of fatty acid composition, the lipid fractions of the duplicate portions were isolated by Soxhlet extraction of about 5 g of freeze-dried homogenates from each series. The solvent used was diethyl ether, analytical grade, and the extraction time was 4 h. Quantitatively, the lipid recovery was almost the same as extraction with the more polar solvent mixture chloroform–methanol (25). The fatty acids of the respective fat extracts were converted to methyl esters by the BF_3 method (27) and analyzed by gas chromatography as described in an earlier study (9).

The cholesterol content in the test fats and the homogenates was determined on the lipid extract as trimethylsilyl ether derivatives by gas chromatography (28). 5β,3α-Cholestanol was used as internal standard, and the separation between cholesterol, tocopherols, and plant sterols was acceptable on the nonpolar DB-5 capillary column used (30 m × 0.25 mm) (Alltech Associates, Inc., Deerfield, IL).

Blood sampling and analyses. Blood samples were taken after an overnight fast, before breakfast at the end of each period. A second fasting blood sample was taken from nine subjects that prolonged the experimental periods by one day. For these nine subjects the mean of the two values was used. During the start of the first period, baseline samples were taken. Serum was obtained by low-speed centrifugation within 1 h of venipuncture and stored at –70°C until analyzed.

Serum cholesterol and serum triglycerides were measured by enzymatic methods (29,30) using automated analyzer equipment (Hitachi 737; Hitachi Limited, Tokyo, Japan). LDL cholesterol was calculated using the equation of Friedewald *et al.* (31).

Serum HDL cholesterol was measured by an essentially similar enzymatic technique (29) after precipitation of the LDL fraction with dextran sulfate and magnesium chloride (Technicon Reagent T 0.1-2801-56, Tarrytown, NY). Serum apolipoprotein (apo) A-1 (Orion Diagnostika, Espoo, Finland) and serum apoB (Behringwerke Ag, Marburg, Germany) were both quantified immunoturbidimetrically using a seven-point standard curve and an automated enzyme analyzer (Cobas Fara; Hoffman-La Roche, Basel, Switzerland) essentially according to the manufacturer's instructions. Serum Lp(a) was quantified by a commercial kit [TintElize Lp(a); Biopool AB, Umeå, Sweden)] according to the manufacturer's instructions. The coefficients of variation were as follows: total cholesterol, 2%; HDL cholesterol, 5%; triglycerides, 3%; apoA-I, 6.3%; apoB, 5.5%, and Lp(a), 7.7%, at 100 mg/L, and 2.7% at 400 mg/L.

All lipid analyses were performed at the Clinical Chemistry Department and Clinical Research Unit, Ullevaal University Hospital, Oslo, Norway.

Statistical methods. Data were analyzed by repeated-measures analysis of variance for a crossover trial. When the analysis indicated a significant effect of diet ($P < 0.05$), the Bonferroni method was used for a pairwise comparison between the three diet groups. P values <0.05 were considered significant. All P-values are two-tailed. Plasma Lp(a) had a skewed distribution and was log transformed before pairwise comparisons were performed. Correlation coefficients (Pearson) between levels of serum lipids and apo are presented when suitable. Data analysis was performed using the statistical package SPSS 8.0 (SPSS Inc., Chicago, IL).

RESULTS

Dietary compliance. Two persons left the study after the first period because of illness. One participant had not fasted before blood sampling and also had problems with dietary compliance during the last period and was therefore excluded. Thus, of the 30 volunteers who entered the study, 27 completed according to schedule.

Compliance with the diets was judged by direct observation of consumption of weekday dinner, and by evaluation of food diaries. All 27 participants complied well, and only very small deviations from the diet were noted, e.g., one participant left out apples from the menu three times. The fasting body weights were significantly reduced ($P < 0.01$) during the first two periods (mean loss 1.9 and 0.47 kg, respectively). The weight loss was almost entirely confined to the four participants with BMI >30, who lost between 1.7 and 7 kg during the study period. In order to adhere to the "intention to treat" principle, the data from all 27 participants are given, but in addition the data were calculated after omission of the data from the four subjects with BMI >30.

Test diets. The three test margarines and the duplicate portions of the diets were analyzed, and the energy and protein contents were found to be identical in the three diets (Table 1). The energy contribution from fat was analyzed to be 31% in the PALM-diet, 30.1% in the *TRANS*-diet, and 30.4% in the PUFA-diet. This was slightly less than the calculated 34 E%. The PALM-diet contained 79.8 g fat per 10 MJ, the *TRANS*-diet 79.2 g fat, and the PUFA-diet 79.2 g fat per 10 MJ.

All three diets were very low in cholesterol; it was slightly lower in the *TRANS*-diet (67 mg/10 MJ) than in the PALM-diet (103 mg/10 MJ) and PUFA-diet (94 mg/10 MJ). The composition of fatty acids in margarines and duplicate portions of the diets is shown in Table 2. The PALM-diet contained 0.3% *trans* fatty acids, and the *TRANS*-diet 23.1% *trans* fatty acids, corresponding to 7% of energy.

The sum of the cholesterol-increasing saturated fatty acids (12:0, 14:0, and 16:0) in PALM-diet was the same (36%) as the sum of *trans* fatty acids and 12:0, 14:0, and 16:0 in the *TRANS*-diet. The PUFA-margarine had a content of 21% of 14:0–16:0 saturated fatty acids. The E% from 12:0, 14:0, 16:0 and *trans* fatty acids was in PALM-diet, *TRANS*-diet and PUFA-diet, 11, 11 and 6, respectively. The sums of *cis* 18:2 and 18:3 in the PALM-diet and the *TRANS*-diet were identical, 18%.

TABLE 1
Content of Energy and Nutrients of Duplicate Portions of the Test Diets[a]

	PALM-diet	*TRANS*-diet	PUFA-diet
Energy (MJ)	8.40	8.35	8.48
Protein (E%)	17.7	17.1	17.2
Fat (E%)	31.0	30.1	30.4
Carbohydrate (E%)	51.3	52.8	52.4
Cholesterol (mg)	86	56	80

[a]Portions corresponding to an estimated intake of 8.5 MJ/d were analyzed. Abbreviations: PALM-diet, diet using a hard zero-*trans* margarine containing palm oil; *TRANS*-diet, diet using a hard margarine containing a high amount of *trans* fatty acids from partially hydrogenated soybean oil; PUFA-diet, diet using a soft highly polyunsaturated margarine; E%, energy percentage.

Serum lipids and apo. Table 3 shows concentrations of total, LDL, and HDL cholesterol, apoB, apoA-1, and triglycerides at baseline and after the three different test diets. Table 4 shows the mean differences among the three diets and their statistical significance probabilities. Serum total and LDL cholesterol at baseline were higher than expected when compared to those on the experimental diets. This apparant discrepancy could be due to underestimation by the food frequency questionnaire of the fat intake, to the higher relative content of saturated fat and of cholesterol in the habitual diet, and to the fact that the experimental period started shortly after the Christmas holiday season.

There were no significant differences in total cholesterol, LDL cholesterol, and apoB between the *TRANS*- and the PALM-diets. HDL cholesterol and apoA-I were significantly higher on the PALM-diet compared to the *TRANS*-diet, while the ratio of LDL to HDL-cholesterol was lower on the PALM-diet, although this difference failed to reach statistical significance ($P = 0.077$).

Total cholesterol, LDL cholesterol, and apoB were significantly lower on the PUFA-diet compared to the other two diets. HDL cholesterol was not different on the PALM- and the PUFA-diets but was significantly lower on the *TRANS*-diet compared to the PUFA diet. The ratio of LDL to HDL cholesterol was higher on both the PALM- and the *TRANS*-diets compared to the PUFA-diet, although the difference between the PALM- and the PUFA-diets was significant only after exclusion of the four subjects with BMI >30 ($P = 0.063$ for $n = 27$ and 0.001 for $n = 23$). ApoA-I was not different on the PALM- and the *TRANS*-diets compared to the PUFA-diet.

Triglycerides and Lp(a) were not significantly different among the three diets. The Pearson coefficient of correlation between the baseline levels of apoB and LDL was 0.41 ($P = 0.04$) and between apoA and HDL was 0.73 ($P < 0.01$). The Pearson coefficient of correlation between the levels of apoB and LDL on the PALM-diet was 0.48 ($P = 0.01$) and between apoA-I and HDL was 0.86 ($P < 0.01$). The Pearson coefficient of correlation between the levels of apoB and LDL on the *TRANS*-diet was 0.28 ($P = 0.16$) and between apoA-I and HDL was 0.91 ($P < 0.01$). The Pearson coefficient of correlation between the levels of apoB and LDL on the PUFA-diet was 0.49 ($P = 0.01$) and between apoA-I and HDL was 0.87 ($P < 0.01$).

DISCUSSION

In this study we wanted to test whether palm oil could replace PHSO in margarine without causing unfavorable effects on serum lipids. *Trans* fatty acids in the *TRANS*-margarine were replaced by an equal amount of saturated fatty acids, mostly palmitic acid, in the PALM-margarine, and the sum of 12:0, 14:0, and 16:0 saturated fatty acids was equal to the sum of

more favorable ratio of LDL to HDL cholesterol. The results indicate that, from a nutritional point of view, palm oil may be used as a substitute for PHSO in margarine, which could contribute to a reduced content of *trans* fatty acids in food products. As expected, a margarine in which saturated fatty acids corresponding to 20% of total fatty acids were replaced by PUFA (the PUFA-margarine) had more favorable effects on blood lipids than the other two test margarines.

The 27 participants in this study were all young women. The diets were given in random order, and the women went into the study at different points in their menstrual cycles. Yu *et al.* (32) analyzed data from 18 studies, and their results indicate that the total and LDL cholesterol responses to dietary fatty acids for women and men are quite similar with the possible exception of HDL cholesterol. They found that unsaturated fatty acids may increase HDL cholesterol in men but not in women. In relation to our results this may indicate that the difference in HDL cholesterol between the PALM- and the PUFA-diets (Table 4) may have been slightly overestimated compared to what we might have seen if men had been studied. Otherwise, the results presented should be valid for both men and women.

We had no exclusion criteria concerning the BMI. Four individuals had a BMI above 30 but the others were within 85–120% of desirable BMI (≤25). It is difficult to maintain body weight in a metabolic study when BMI is over 30 (strong overweight). Judd *et al.* (8) included only subjects who were within 85–120% of BMI ≤25 in their study. Brussaard *et al.* (22) had six participants in their experiment who lost weight, between 3 and 7 kg. The data from these participants did not affect the conclusions from the experiment. The four participants in our study who were overweight with BMI >30 lost significant weight during the study period, in particular during the first period. Exclusion of these four persons from the calculations resulted in higher total cholesterol on the PALM-diet than on the *TRANS*-diet (mean difference 0.20 mmol/L, P = 0.058). Otherwise the results were not altered.

We did not find any significant difference between the PALM-diet and the *TRANS*-diet on the effect on LDL cholesterol. This result is in accordance with that reported by Nestel

et al. (6). In that study no significant difference in total or in LDL cholesterol was found with an elaidic acid-rich diet (18:1 *trans,* 7 E%) in 27 mildly hypercholesterolemic men compared to a palmitic acid diet. Our PALM-diet, like that of Nestel *et al.*, contained very little myristic acid, which is the most potent cholesterol-increasing fatty acid (14,32–36). Judd *et al*. (8) observed significantly higher total cholesterol and also higher, but not significantly, LDL cholesterol on a saturated fat diet (12:0, 14:0, and 16:0) compared to a high *trans* (6.6 E%) diet. Mensink and Katan (4) found a significant increase in total and LDL cholesterol on a saturated fat diet compared to *trans*-fatty acid diet. The saturated fat diets in both of these two studies contained higher amounts of lauric, myristic, and palmitic acids than the *trans* diets. Wood *et al.* (37) did not find a difference in total or LDL cholesterol between crude palm oil and a *trans* fatty acid-rich margarine. The difference in palmitic acid corresponded approximately to that of *trans* fatty acids in the two diets. The diets differed, however, both in oleic and linoleic acids, and their results (37) therefore cannot be directly compared to ours. Our results indicate that 18:1 *trans* fatty acids have an LDL cholesterol-increasing effect similar to that of palmitic acid.

Hayes and Khosla (38) suggested that the effect of 16:0 may vary depending on the amount of cholesterol in the diet. They suggested that when cholesterol intake was <300 mg/d in normocholesterolemic subjects the serum cholesterol response to dietary palmitic acid was negligible. At intakes of dietary cholesterol >400 mg/d (38), the serum cholesterol increased, probably because of down-regulation of the LDL receptor and probably maximizing very low density lipoprotein secretion. The results from our study indicate, however, that 16:0 is hypercholesterolemic even at cholesterol intake <300 mg/d.

As expected, total and LDL cholesterol were significantly lower on the PUFA-diet than on the PALM-diet. This is in accord with the results of several previous studies (39–41). Wardlaw and Snook (39) compared a diet rich in saturated fatty acids (butter) to corn and sunflower oils. When the intake of saturated fatty acids was reduced, a significant lowering in total and LDL cholesterol was observed. Cox *et al.* (40) studied the effect of butter, coconut oil, and safflower oil on serum lipids. Total and LDL cholesterol were significantly lower on the diet containing safflower oil and coconut oil compared to butter. Abbey *et al.* (41) exchanged saturated fatty acids with MUFA (raw almonds) and also with PUFA (walnuts). On both diets there was a significant reduction in total and LDL cholesterol.

Also compared to the *TRANS*-diet, the PUFA-diet reduced total and LDL cholesterol. This is in accord with the results of previous studies (4,5,42). Wood *et al.* (42) compared butter to hard and soft margarines. Soft margarine reduced total and LDL cholesterols significantly compared to hard margarine (*trans* fatty acids) and butter. In the studies of Mensink and Katan (4) and of Zock and Katan (5) *trans* fatty acids were found to increase total and LDL cholesterols significantly compared to oleic and linoleic acids, respectively.

Several reports indicate that 18:1 *trans* fatty acids decrease HDL cholesterol compared to saturated fat or to oleic acid (4,5,43,44). Also partially hydrogenated fish oil has a similar HDL cholesterol-decreasing effect (9). This HDL cholesterol-lowering effect was also observed in this study in that the lowest HDL cholesterol and apoA-I were observed on the *TRANS*-diet. The higher LDL to HDL cholesterol ratio observed on the *TRANS*-diet was mainly due to this effect on HDL cholesterol. Others have also noted the increasing effect of *trans* fatty acids on the LDL to HDL cholesterol ratio (4,43), which suggests that palm oil may be preferable to PHSO when considering the effects on the LDL/HDL ratio.

As a mechanism for the HDL-reducing effect of *trans* fatty acids, an increase in activity of cholesteryl ester transfer protein has been suggested (45,46). Increased activity of this enzyme may contribute to a rise in LDL cholesterol and a decrease in HDL cholesterol (46).

We found the highest HDL cholesterol on the PALM-diet although the difference between the PALM-diet and the PUFA-diet was not significant. Also others have found that HDL cholesterol may be significantly increased with intake of palmitic acids compared to oleic- or elaidic-rich diets (6,37,47). On the basis of available evidence (48–51), it may be assumed that the combined LDL cholesterol-increasing and HDL cholesterol-lowering effects of *trans* fatty acids contribute to increased risk for coronary heart disease, and it may be prudent to limit the use of partially hydrogenated vegetable oils in margarine production.

In this study we did not find any significant effect of *trans* fatty acids (7 E%) on Lp(a). A number of studies recently demonstrated that *trans* fatty acids increase Lp(a) when fed at a level of 7 E% or more (6,9–11). In an earlier study we also found increased levels of Lp(a) in young men after intake of a diet with PHSO (8.5 E% *trans* fatty acids) or a diet with partially hydrogenated fish oil (8 E% *trans* fatty acids) compared to a butter diet (9). In a smaller recent study the increasing effect on Lp(a) with partially hydrogenated fish oil did not reach significant level, presumably because of lack of power (52). As in the present study only women participated in that study, and it cannot be excluded that the effect of *trans* fatty acids on Lp(a) is more pronounced in men.

In conclusion, the results from our study indicate that, from a nutritional point of view, palm oil may be a reasonable alternative to PHSO in margarine production if the aim is to avoid *trans* fatty acids while maintaining the same degree of hardness. As expected, both margarines based on these oils were found to have less favorable effects on blood lipids than a more PUFA-rich soft margarine.

ACKNOWLEDGMENTS

We gratefully acknowledge the cooperation of the participants in the study. We thank our kitchen staff, especially Knud Detlefsen, Borgny Kirkholt and Siri Damman, for their assistance; Kari Solvoll for help with data handling of the food frequency questionnaires; Anita B. Mathisrud for taking blood samples; and Paula Yli-Jama for the vitamin E analyses. The study was part of the Nordic R&D Program for the Food Industry with financial support from The Nordic Industrial fund and the Norwegian food company Mills DA.

Different Degrees of Moderate Iron Deficiency Modulate Lipid Metabolism of Rats

Gabriele I. Stangl* and Manfred Kirchgessner

Institute of Nutritional Physiology, Technical University, München-Weihenstephan, 85350 Freising, Germany

ABSTRACT: Severe iron deficiency affects lipid metabolism. To investigate whether moderate iron depletion also alters lipid variables—including lipid levels in serum and liver, hepatic lipogenesis, and fatty acid composition indicative of an impaired desaturation—we carried out experiments with rats fed 9, 13, and 18 mg iron/kg diet over a total of 5 wk. The study also included three pair-fed control groups and an *ad libitum* control group, fed with 50 mg iron/kg diet. The iron-depleted rats were classified as iron-deficient on the basis of reduced serum iron, hemoglobin concentration, and hematocrit. All moderately iron-deficient rats had significantly lower cholesterol concentrations in liver and serum lipoproteins than their pair-fed controls. Rats with the lowest dietary iron supply had higher concentrations of hepatic phosphatidylcholine (PC) and phosphatidylethanolamine (PE), lower activities of glucose-6-phosphate dehydrogenase, malic enzyme and fatty acid synthase, and higher triacylglycerol concentrations in serum lipoproteins than the corresponding pair-fed control rats. Moderate iron deficiency also depressed the serum phospholipid level. Moreover, several consistent significant differences in fatty acid composition of hepatic PC and PE occurred within moderate iron deficiency, which indicate impaired desaturation by Δ-9 and Δ-6 desaturases of saturated and essential fatty acids. We conclude that lipid variables, including cholesterol in liver and serum lipoproteins as well as fatty acid desaturation, reflect the gradations of iron status best and can be used as an indicator of the degree of moderate iron deficiency.

Lipids 33, 889–895 (1998).

Iron deficiency is a nutritional problem of worldwide importance, greatly contributing to human and animal morbidity. Experiments with animal models during the past decades have revealed a strong relationship between dietary iron and lipid metabolism. Some investigators have observed lipemia when anemia was produced by iron-deficient diets (1–3). Moreover, hepatic lipogenesis measured by means of ^{14}C-glucose incorporation was altered in livers of severely iron-deficient chicks and rats (2,3), and the fatty acid composition of tissues changed as a result of nutritional iron depletion (4–7). However, within these experiments, the results from one study often contradicted those from another. Many of these reports used either bleeding or diets with a maximum of 6 mg iron/kg to characterize metabolic defects associated with severe iron deficiency. However, moderate iron deficiency is more widespread than severe anemia. Only some single experiments point to the fact that moderate iron depletion also causes hyperlipemia (2), depresses hepatic lipogenesis (2), and increases essential fatty acids in rat tissues (4).

The objectives of the present study were to evaluate the effects of different degrees of moderate dietary iron depletion, by using diets with iron concentrations ranging from 9 to 18 mg iron/kg, on lipid concentrations of serum and lipoproteins, the liver lipid concentrations, the activities of hepatic lipogenic enzymes, and the fatty acid composition of individual liver phospholipids. Several investigations on iron-induced changes in lipogenesis utilized incorporation of labeled glucose into triacylglycerols (3,8), whereas enzymes involved in lipogenesis have been scarcely investigated in view of iron deficiency. One aspect of this study dealt with the effect of moderate iron deficiency on some enzymes involved in lipogenesis.

Many early iron deficiency studies did not take into consideration the fact that animals deficient in micronutrients often reduce voluntary food intake. Iron deficiency is therefore generally combined with an energy deficiency, which has been shown to affect lipid metabolism markedly. To eliminate differences in food intake we assigned iron-adequate pair-fed groups to each iron-deficient group.

MATERIALS AND METHODS

Animals and diets. In this experiment, weaned male specific pathogen-free Sprague-Dawley rats (WIGA GmbH, Sulzfeld, Germany) with an average body weight of 40 ± 2 g were fed diets moderately depleted of iron for 5 wk. For that purpose, the rats were divided into seven groups of 12 each. Three of these groups were made moderately iron-deficient by providing diets containing 9, 13, and 18 mg iron/kg. The iron supplementation of those diets was selected in such a way that disturbances in lipid metabolism were just detectable. The experiment included three pair-fed control groups and an *ad libitum* group, fed with 50 mg iron/kg diet that has been shown

Abbreviations: HDL, high density lipoprotein; PC, phosphatidylcholine; PE, phosphatidylethanolamine (diacyl); VLDL, very low density lipoprotein.

to provide rats with adequate iron (9). The basal diet had 2.6 mg/kg iron and was adjusted to the experimental dietary iron concentrations by supplementation with iron as $FeSO_4 \cdot 7H_2O$. All the other components of the diet remained constant. The composition of the basal semisynthetic diet is given in Table 1. The diet was prepared from natural feedstuffs. All diets were fortified with recommended amounts of vitamins and minerals according to Reeves and coworkers (9). Rats were housed individually in a controlled environment, in Macrolon cages (Becker GmbH, Castrop-Ruxel, Germany) in a room maintained at 24°C with a humidity of 60%. All rats were kept under conditions of controlled lighting with a daily 12-h light/dark cycle and had free access to drinking water (double-distilled water, supplemented with 0.14 g/L sodium chloride to adjust osmolarity to that of tap water). Care and treatment of rats followed recommended guidelines (10). At the end of the experimental period of 5 wk, 12 h after the last feeding, the rats were killed by decapitation after light anesthesia with diethyl ether. Blood for hematological measurements was collected into EDTA-coated vials. Blood for determination of serum iron and lipoproteins was collected into untreated tubes. The liver and brain were promptly excised. Serum and tissue samples were stored at –80°C until analyzed.

Iron analyses. Iron concentration in serum was measured directly by aspirating a dilute solution (1:5) into the flame of the atomic absorption spectrometer. Iron concentration of each sample was calculated from standard curves using various dilutions of an iron standard solution (1000 ± 2 mg/L) from Merck (Darmstadt, Germany). All specimens were analyzed in duplicate. The coefficient of variation for duplicate analyses was typically below 2%.

Hematological measurements. Hematological variables including erythrocyte count, hematocrit, and hemoglobin concentration were determined with a Coulter Counter and a hemoglobinometer (Coulter Electronics GmbH, Krefeld, Germany).

TABLE 1
Composition of Basal Diet[a]

Ingredient	g/kg diet
Casein	200
Cornstarch	328
Sucrose	300
Fiber (cellulose)	30
Soybean oil	50
Coconut oil	30
Vitamin mixture[b]	20
Mineral mixture[c]	40
DL-Methionine	2

[a]Basal diet analyzed had 2.6 mg/kg iron.
[b]Vitamins/kg diet: 4000 IU *all-trans* retinol; 1000 IU cholecalciferol; 150 mg *all-rac*-α-tocopherol; 1.47 mg menadione sodium bisulfite; 5 mg thiamine hydrochloride; 7.20 mg riboflavin; 6 mg pyridoxine hydrochloride; 15 mg Ca pantothenate; 30 mg nicotinic acid; 1.38 g choline chloride; 0.2 mg folic acid; 0.2 mg D-biotin; 25 mg cyanocobalamin; sucrose to 20 g.
[c]Minerals/kg diet: $Na_2HPO_4 \cdot 2H_2O$, 3.15 g; KH_2PO_4, 3.82 g; KCl, 4.77 g; $MgCl_2 \cdot 6H_2O$, 4.24 g; $CaCO_3$, 12.49 g; $NiSO_4 \cdot 6H_2O$, 4.48 mg; $ZnSO_4 \cdot 7H_2O$, 131.9 mg; $CuSO_4 \cdot 7H_2O$, 23.6 mg; $MnSO_4 \cdot 5H_2O$, 30.8 mg; KI, 0.26 mg; $Na_2MoO_4 \cdot 2H_2O$, 0.28 mg; $Na_2SeO_3 \cdot 5H_2O$, 0.50 mg; $CrCl_3 \cdot 6H_2O$, 9.61 mg; NH_4VO_3, 0.23 mg; $Na_2SiO_3 \cdot 5H_2O$, 37.76 mg; H_3BO_3, 2.86 mg; NaF, 2.21 mg; $(CH_3COO)_2Pb \cdot 3H_2O$, 0.73 mg; sucrose to 40 g.

Lipid extraction and analysis. Liver lipids were extracted with a hexane/isopropanol mixture (3:2, vol/vol, containing butylated hydroxytoluene as antioxidant) as described by Hara and Radin (11). Hepatic phospholipids were separated by high-performance liquid chromatography as described by Eder and coworkers (12) and collected with a fraction collector (model 201; Gilson, Villiers le Bel, France). Hepatic phospholipids separated by high-performance liquid chromatography were methylated with boron fluoride/methanol reagent (13). Fatty acid methyl esters were separated by gas chromatography using a Hewlett-Packard HP 5890 gas chromatographic system (Hewlett-Packard, Taufkirchen, Germany), fitted with an automatic on-column injector, a flame ionization detector, and a CP-Sil 88 capillary column (50 m × 0.25 mm internal diameter, film thickness 0.2 μm; Chrompack, Middleburg, The Netherlands). The oven temperature program used was as described by Eder and Kirchgessner (14). The detector temperature was 300°C. Fatty acid methyl esters were identified by comparing their retention times with those of individual purified standards and quantified with heptadecanoic acid methyl ester as internal standard (15). The amounts of individual hepatic phospholipids [phosphatidylcholine (PC) and phosphatidylethanolamine, diacyl (PE)] were calculated by the amount of their bound fatty acids. For measurement of liver total triacylglycerols and total cholesterol, liver lipids were extracted with hexane/isopropanol (3:2, vol/vol) and then dissolved in a chloroform/Triton X-100 mixture (1:1, vol/vol) as described by De Hoff *et al.* (16). After evaporating the chloroform under vacuum, total triacylglycerols and total cholesterol were determined by adding test reagents for fully enzymatic spectrophotometric assay of triacylglycerols (Merck, ref. 14354) and cholesterol (Boehringer, Mannheim, Germany, ref. 816302).

Activities of lipogenic enzymes. Approximately 4 g of liver was homogenized in 10 mL of 0.25 M sucrose solution (in 0.1 M phosphate buffer, pH 7.4) using a Potter-Elvehjem homogenizer. Homogenates were centrifuged (105,000 × *g* for 1 h at 4°C), and the supernatants were used for enzyme assays. All the enzymes were assayed by spectrophotometric methods. Glucose-6-phosphate dehydrogenase (E.C. 1.1.1.49) (17), 6-phosphogluconate dehydrogenase (E.C. 1.1.1.44) (18), and malic enzyme (E.C. 1.1.1.40) (19) were determined by the rate of NADP reduction. In the assay of glucose-6-phosphate dehydrogenase, activity of 6-phosphogluconate dehydrogenase was inhibited by maleimide (17). Fatty acid synthase was determined by the rate of malonyl-CoA-dependent NADPH oxidation (20). Citrate cleavage enzyme (E.C. 4.1.3.8) was determined from NADH oxidation (21).

Serum lipids and lipoproteins. Blood was allowed to clot for at least 30 min before centrifugation. Serum samples were obtained by centrifugation at 4°C for 10 min at 1100 × *g*. Lipoproteins in serum as very low density lipoproteins (VLDL; density < 1.006 kg/L), low density lipoproteins

(LDL; density 1.006–1.063 kg/L) and high density lipoproteins (HDL; density 1.063–1.210 kg/L) were separated by the method of Kupke and Wörz-Zeugner (22) using density gradient ultracentrifugation with a Beckman air-driven ultracentrifuge and an A-100 fixed angle rotor at 100,000 × *g* for 2.5 h (Beckman Instruments, Palo Alto, CA). The adjustment of the density of serum with KBr solution to separate HDL was done according to a method of Terpstra *et al*. (23). According to adjustment of the density of serum, lipoproteins at the top of the tube were aspirated with a Beckman Airfuge Tube Fractionator (Beckman Instruments) and removed. The lipoprotein fractions at the bottom of the tubes were analyzed enzymatically for total cholesterol, triacylglycerols, and phospholipids by using an autoanalyzer (Hitachi 704, Boehringer, Mannheim, Germany) and Boehringer kit reagents.

Statistical analysis. The effect of iron concentration in the diet was evaluated by analysis of variance and compared for statistical significance ($P < 0.05$) by Fisher's multiple range test. All data in the present text are expressed as means ± SD.

RESULTS

Weight gain and iron status. Weight gain, food intake, and iron status of iron-deficient and iron-adequate rats are shown in Table 2. Rats receiving 9 mg iron/kg diet had a lower body weight gain than the corresponding pair-fed controls, and daily food intake was depressed compared to the *ad libitum*-fed control group. Body weight gain and food intake of the groups fed 13 or 18 mg iron/kg diet did not differ from their pair-fed controls and the *ad libitum*-fed group, respectively. All iron-dependent hematological parameters, including hemoglobin concentration, hematocrit, and iron concentration in serum, decreased markedly by week 5 in rats on the iron-deficient diets, demonstrating that the moderate iron deficiency was well developed 5 wk after the experiment started. Iron status did not differ between iron-adequate groups.

Liver lipids. The hepatic triacylglycerol concentration was unaffected by moderate dietary iron depletion (Table 3). The most striking difference in hepatic lipids was a lower cholesterol concentration in iron-deficient rats compared to their corresponding pair-fed controls. Concentrations of phospholipids (PC and PE) were elevated in rats fed 9 mg iron/kg diet compared to all the other groups.

Activities of hepatic lipogenic enzymes. Rats receiving 9 mg iron/kg diet had lower activities of glucose-6-phosphate dehydrogenase, malic enzyme, and fatty acid synthase than their corresponding pair-fed controls, whereas animals supplied with 13 and 18 mg iron/kg diet had enzyme activities near the control values (Table 3). The activities of 6-phosphogluconate dehydrogenase and citrate cleavage enzyme depended primarily on food intake and were reduced in livers of rats with the lowest iron supply and their pair-fed controls relative to all the other groups.

Serum lipids and lipoproteins. Iron deficiency led to considerable alterations in serum lipid and lipoprotein concentrations (Table 4). Rats receiving 9 mg iron/kg diet had a higher concentration of triacylglycerols in serum than their corresponding pair-fed controls. This elevation was primarily due to an increase in VLDL and LDL triacylglycerols, whereas triacylglycerol concentration in HDL remained unchanged. Triacylglycerols in serum and lipoproteins of the other iron-restricted groups and control groups did not differ. Cholesterol concentration in serum varied markedly with the dietary iron intake, and was reduced in all iron-inadequate rats compared to the corresponding pair-fed and *ad libitum* controls. The reduction of serum cholesterol level was caused by reduced VLDL, LDL and HDL cholesterol. Iron-inadequate rats without any reduction in food intake (groups fed 13 and 18 mg iron/kg diet) had a lower phospholipid concentration in serum and the lipoproteins than their pair-fed controls, whereas the phospholipid levels of rats receiving 9 mg iron/kg diet did not differ from their pair-fed controls.

Fatty acid composition of hepatic phospholipids. Iron deficiency influenced considerably the fatty acid composition of individual phospholipids, and the most striking differences were depressed proportions of total and individual monounsaturated fatty acids in PC and PE (Table 5). In agreement with total liver lipids, the proportions of total saturated fatty acids in hepatic PC and PE did not differ between the groups. Iron-deficient rats had higher proportions of 18:2n-6 in hepatic PC and PE than their pair-fed controls, and slightly decreased levels of 20:4n-6 (Table 6). Therefore, the ratio be-

TABLE 2
Body Weight Gain, Food Intake, and Iron Status of Moderate Iron-Deficient Rats and Their Pair-Fed Controls[a,b]

	Group/iron supply[c]						
Parameter	Fe – 9[d]	Fe + PF9[e]	Fe – 13[d]	Fe + PF13[e]	Fe – 18[d]	Fe + PF18[e]	Fe + *ad libitum*

[a]Data are means ± SD, $n = 12$ for each group. See Table 2 for column heading explanations.
[b]Means were compared by Fisher's multiple range test; means not sharing a common superscript roman letter are significantly different at $P < 0.05$.
[c]Fe– means iron-deficient groups, Fe+ means iron-adequate groups, PF means control group pair-fed to the iron-deficient group.
[d]Activities of glucose-6-phosphate dehydrogenase (G6PDH), 6-phosphogluconate dehydrogenase (6PGDH), and malic enzyme (ME) are expressed as nmoles NADP · reduced mg protein^{-1} · min^{-1} at 25°C; activity of citrate cleavage enzyme (CCE) is expressed as nmoles NADH oxidized · mg protein^{-1} · min^{-1} at 25°C; activities of fatty acid synthase (FAS) are expressed as nmoles NADPH oxidized · mg protein^{-1} · min^{-1} at 25°C.

tween 20:4n-6 and 18:2n-6 in PC and PE was markedly decreased by dietary iron deficiency. There were also some iron-induced alterations in n-3 polyunsaturated fatty acids, which showed an increase in most individual n-3 polyunsaturated fatty acids in PC and PE.

DISCUSSION

Since clinical iron deficiency is rarely as severe as can be achieved by feeding laboratory animals a diet maximally depleted of iron, we used diets only moderately depleted in iron in an attempt to mimic the human situation more closely. The alignment of food intake between the deficiency and the control group is necessary to isolate the symptoms of a trace element restriction and to make valid conclusions. In most iron deficiency studies both the iron-deficient and the iron-adequate diets were fed *ad libitum*. We have ascertained that even moderate iron-depleted rats receiving 9 mg iron/kg diet depressed voluntary food intake. The importance of such pair-fed groups consists in the fact that some iron effects would be otherwise over- or underestimated. This was apparent from the present findings showing that the activities of some lipogenic enzymes were reduced in iron-depleted rats compared to the iron-adequate rats fed the diet *ad libitum*, but not when the iron-adequate diet was fed in amounts equal to the depletion group. On the other hand, the triacylglycerol concentration in serum and VLDL of the rats with lowest iron supply was higher than that of their pair-fed controls and equal to that of the *ad libitum*-fed controls.

Excluding the discrepancies in food intake from the pre-

sent findings, it is clear that dietary iron is associated with various aspects of lipid metabolism and that some alterations in lipid variables occur even in moderate iron deficiency. Parameters including hepatic cholesterol, phospholipids and cholesterol in serum and the lipoproteins, and fatty acid composition of hepatic total lipids and individual phospholipids were changed by only a slight iron deficiency. Only the condition of well-developed iron deficiency, with hemoglobin concentrations below 100 g/L, appears to be associated with a depressed capacity for lipid synthesis, as shown by the decreased activity of enzymes associated with lipogenesis and elevated triacylglycerol concentrations in serum and lipoproteins. Also, iron-deficiency anemia provoked by high-fat and high-copper diets, with hemoglobin concentrations about 85 g/L, has been shown to depress enzymes involved in lipogenesis (24).

However, it is difficult to compare the quality and extent of changes in lipid metabolism found in the present iron-deficiency study with those from other experiments because the changeability of lipid parameters also depends on the age, sex, and strain of the rats and the composition of the diets used in the experiment (1,2,25). Our results show hypertriglyceridemia in rats receiving the lowest level of dietary iron. The association of nutritional severe iron deficiency and lipemia has been already recognized by Amine and Hegsted (25) and Lewis and Iammarino (26), who found a rise in the plasma triacylglycerol content of chicks and weanling rats fed iron-deficient diets compared to the controls; the extent of their lipemia was a function of the degree of iron deficiency. However, in contrast to these findings, some authors found lowered triacylglycerols in serum of iron-deficient rats (27,28). A study by Lewis and Iammarino (26) demonstrating reduced activity of lipoprotein lipase suggests that lipemia in iron-deficient rats is due to impaired clearance of blood lipids. However, another report did not confirm a reduction of lipoprotein lipase activity due to iron depletion (3).

The depressed cholesterol level in liver and serum of the iron-depleted rats might be associated with the reduced activities of lipogenic enzymes involved in providing the reduced form of NADP for several pathways of synthesis. This can be supported by early results showing that the rate of lipid synthesis was depressed in iron-deficient rats (2). On the basis of the observed reduction in hepatic cholesterol level we also expected a lower triacylglycerol content in liver. However, hepatic triacylglycerol levels remained nearly unchanged by iron deficiency. The role of iron in mammalian metabolism includes a number of diverse functions which may also be responsible for the observed phenomena. Although there is no evidence for abnormal respiratory function of liver mitochondria in iron-deficient animals (3,29) and for changes in cytochrome oxidase activity (30), decreased carnitine levels observed in iron-deficient rats (31) may contribute to the observed findings. Besides, degeneration of parenchymal liver cells which has been reported in iron-deficient rats (25,32) could also be responsible for the alterations in liver lipid metabolism.

In the current study, few consistent significant differences in fatty acid composition, which indicate impaired desaturation of saturated and essential fatty acids by desaturases, occurred in moderate iron deficiency. This was apparent by the

[a]Data are means ± SD, $n = 12$ for each group. See Table 2 for column heading explanations.
[b]Means were compared by Fisher's multiple range test; means not sharing a common superscript letter are significantly different at $P < 0.05$.
[c]Fe– means iron-deficient groups, Fe+ means iron-adequate groups, PF means control group pair-fed to the iron-deficient group. PUFA, polyunsaturated fatty acids.

accumulation of linoleic and linolenic acid in hepatic individual phospholipids. Iron has been shown to be a structural component of Δ-6 desaturase (33), and the increased levels of linoleic and linolenic acids may be due to a decreased level of the chain elongation and desaturase activities necessary for the synthesis of arachidonic acid and eicosapentaenoic acids, which are essential substrates for the production of endoperoxides and thromboxanes. Iron is also present in the cytochrome and the terminal components of the stearyl CoA desaturase, which converts palmitic to palmitoleic acid and stearic to oleic acid (34). Individual hepatic phospholipids of iron-depleted rats from the present study had lower proportions of palmitoleic and oleic acids and higher proportions of stearic acid. Similar fatty acid alterations as a consequence of iron deficiency have been also found in liver total lipids (4,7,35), brain (36), and intestinal mucosa (4). Moreover, desaturase activity in livers of rats fed low-iron diets was significantly lowered (37). However, the study of Johnson *et al.* (6) did not confirm the requirement for iron in the Δ-9 pathway of fatty acid desaturation.

In conclusion, the current findings point to the fact that moderate nutritional iron depletion alters various aspects of lipid metabolism. Our study revealed that iron restriction first affects the lipid variables including cholesterol in liver and serum and fatty acid desaturation, and last the hepatic lipogenic enzymes and the triacylglycerol content in liver and serum. Therefore, the cholesterol concentration in serum and liver and the alteration in fatty acid composition of hepatic phospholipids best reflect the gradations of iron status and can be used as an indicator of the degree of iron deficiency.

ABSTRACT: Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) were distributed mainly in the *sn*-1,3 positions of seal oil triglyceride and in the *sn*-2 position of squid oil triglyceride. Seal oil-rich or squid oil-rich fats having constant saturated/monounsaturated/polyunsaturated fatty acid (PUFA) and n-6/n-3 PUFA ratios were fed to exogenously hypercholesterolemic rats for 160 d. The control fat contained linoleic acid as the sole PUFA. Before starting the experimental diets, rats were orally treated with high doses of vitamin D for 4 d to accelerate atherogenesis. The percentage of arachidonic acid in phosphatidylcholine and phosphatidylethanolamine of liver, platelets, and aorta was lower in the marine oil groups than in the control group, seal oil being more effective than squid oil. Maximal platelet aggregation induced by collagen was significantly lower in both marine oil groups. Platelet thromboxane (TX) A_2 production induced by collagen or thrombin was markedly reduced by feeding seal or squid oils, the reduction being more pronounced in the seal oil than in the squid oil group. Aortic prostacyclin (PGI_2) production was the same among the three groups. The ratio of the productions of aortic PGI_2 and platelet TXA_2 was significantly higher in the seal oil than in the control group. Although there was no difference in intimal thickness among the three groups, the aortic cholesterol content was significantly lower in the marine oil groups than in the control group. These results showed that the main effects in rats of the different intramolecular distributions of EPA and DHA in dietary fats were on arachidonic acid content in tissue phospholipids and on platelet TXA_2 production.
Lipids 33, 897–904 (1998).

The Greenland Inuit who mainly live on seal have a low incidence of myocardial infarction (1). Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are thought to be responsible for the physiological effects. These n-3 polyunsaturated fatty acids (PUFA) have lowering effects on triglyceride and cholesterol concentrations in plasma, on arachidonic acid content in various tissue phospholipids, and on thromboxane (TX) A_2 production in platelets (2,3). These functions are thought to contribute to the antiatherosclerotic effect of EPA and DHA (2,4). These PUFA are mainly distributed at the 1 and 3 positions in seal oil triglycerides. Several studies showed that differences in the intramolecular distribution of fatty acids in triglycerides may influence physiological functions of the fatty acids (5,6). However, there are few studies on physiological effects of the different intramolecular distributions of EPA and DHA in triglycerides (7,8).

In our previous study, dietary seal oil reduced plasma and liver triglyceride concentrations and arachidonic acid content in liver phospholipids more effectively than fish oil, in which EPA and DHA were located mainly at the *sn*-2 position (8). The ratio of the productions of aortic prostacyclin (PGI_2) and platelet TXA_2 stimulated by thrombin was significantly higher in rats fed seal oil than in those fed fish oil. These results suggest that seal oil may be more effective for suppressing thrombosis and hence atherosclerosis than fish oil.

In the present study, we investigated the effect of long-term feeding (160 d) of seal oil-rich and squid oil-rich oils to exogenously hypercholesterolemic (ExHC) rats, a strain of Sprague-Dawley rats which readily develops hypercholesterolemia on cholesterol feeding (9). EPA and DHA were located mainly at the *sn*-2 position in the squid oil. ExHC rats were orally treated with high doses of vitamin D to accelerate atherogenesis before starting a hypercholesterolemic diet. We previously observed that this treatment induces atherosclerotic lesions and cholesterol accumulation in rat aorta (9). For quantitative estimation of the effects of the structural differences in seal and squid oils, the dietary fats were designed to give constant ratios of saturated and monounsaturated fatty acids, PUFA, and n-6 and n-3 PUFA in these marine oil groups. The control fat contained linoleic acid as the sole PUFA.

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; ExHC, exogenously hypercholesterolemic; HDL, high density lipoprotein; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PGI_2, prostacyclin; PRP, platelet-rich plasma; PUFA, polyunsaturated fatty acids; TBARS, thiobarbituric acid-reactive substances; TX, thromboxane.

MATERIALS AND METHODS

Materials. Squid oil was obtained from the liver of *Todarodes pacificus*. Seal oil was from harp seal. These oils were purified to edible grade. Briefly, these oils dissolved in 5 vol of acetone were cooled to −80°C and the supernatants were concentrated and the obtained lipids were purified with silica gel chromatography. Fatty acid composition of squid and seal oils and the intramolecular distribution of fatty acids are shown in Table 1. EPA and DHA were mainly located at the *sn*-2 position of the triglyceride in squid oil; in contrast, 16:0 and 18:1 were at the *sn*-1,3 positions. In seal oil, EPA and DHA were mainly at the *sn*-1,3 positions and 16:1 and 18:1 were at the *sn*-2 position. Seal and squid oils contained cholesterol at 0.14 and 1.6% and α-tocopherol at 0.031 and 0.23%, respectively.

Safflower and coconut oils were obtained from Nissin Oil Mills Ltd., Tokyo, Japan, and Nacalai Tesque, Kyoto, Japan, respectively.

Animals and diets. ExHC rats originally donated by Takeda Chemical Industries (Osaka, Japan) were bred and maintained at Seac Yoshitomi (Fukuoka, Japan). Seven-week-old male ExHC rats weighing an average of 253 g were housed individually in an air-conditioned room (21–24°C, lights on 800–2000) and given free access to a nonpurified commercial diet (NMF, Oriental Yeast Co., Tokyo, Japan) for a week. The rats were given vitamin D_2 (200,000 IU/kg body weight) orally for four successive days as described previously (9). The vitamin D_2-treated rats were divided into three groups and maintained on a purified diet for 160 d. The experimental diets were prepared according to the recommendation of the American Institute of Nutrition (10) and contained (g/kg) cornstarch 355, casein 200, pregelatinized cornstarch 132, sucrose 100, fat 100, cellulose 50, mineral mixture (AIN-93G-MIX) 35, vitamin mixture (AIN-93-VX) 10, cholesterol 10, L-cystine 3, choline bitartrate 2.5, sodium cholate 2.5, and *tert*-butylhydroquinone 0.014. The mineral and vitamin mixtures were purchased from Nihon Nosan Kogyo (Tokyo, Japan). Dietary fats were designed to have a constant ratio of polyunsaturated/monounsaturated/saturated fatty acids ratio as shown in Table 2. The energy percentage of n-3 PUFA was 2.2 in the diets. The rats in the seal and squid oil groups were fed on average 190 mg/d of n-3 PUFA during the feeding period. Dietary fat in the control group was a mixture of coconut and safflower oils (76.1:23.9 w/w). Dietary fats in the seal and squid oil groups were mixtures of seal, coconut, and safflower oils (24.1:66.9:9.0 by wt) and squid, coconut, and safflower oils (26.1:65.0:8.9 by wt), respectively. Seal and squid oils contributed cholesterol to the diets at 3.4 and 42 mg/100 g diet, respectively. Because cholesterol was added at 1000 mg/100 g diet, the cholesterol contribution of seal and squid oils to lipid metabolism is minimal. The contribution of α-tocopherol from the seal and squid oils ws 0.75 and 6.1 mg/100 g diet, respectively. Rats were given only freshly prepared food each evening to prevent peroxidation of dietary fat. After the rats had been starved for 7 h (700–1400), they were killed under diethyl ether anesthesia by withdrawing blood from the abdominal aorta into a syringe containing 3.8% trisodium citrate.

Tissue preparation for determining atherosclerosis histologically. The entire aorta with its main branches was dissected from each animal and washed with physiological saline. Thoracic aorta between heart junction and right carotid artery was perfused with 20% neutral formalin buffer solution at pH 7.4, and preserved in the same solution before paraffin embedding in the routine manner to prepare 5 μm-thick serial sections. The sections were stained with orcein

and hematoxylin. Intimal thickness was measured by using a Nikon microscope and NIH Image as described (9).

Analytical methods. The triglyceride structure of squid and seal oils was analyzed by a Grignard degradation method as described previously (8). Briefly, triglyceride was reacted with 1 M ethylmagnesium bromide in diethyl ether for 25 s. After the addition of acetic acid to stop the reaction, the reaction mixture was extracted with diethyl ether. After the ether extract was concentrated by evaporating off, it was applied to a silica gel G thin-layer chromatography plate containing 5% boric acid, and the plate was developed with chloroform/acetone (96:4, vol/vol). 2-Monoglyceride and a mixture of 1- and 3-monoglyceride fractions were transmethylated with sulfuric acid/methanol (1:115, vol/vol). Fatty acid methyl esters were analyzed by gas–liquid chromatography on an Omegawax 320 capillary column (Supelco Japan, Tokyo, Japan; 30 m long, 0.25 μm film, 0.32 mm i.d., helium as carrier gas, split ratio of 1:80). Column, injector, and detector temperatures were 190, 250, and 250°C, respectively.

Plasma lipoproteins were prepared by ultracentrifugation as described previously (11). Plasma and lipoprotein lipids were determined by commercially available kits; Cholesterol C Test, Triglyceride G Test, and Phospholipid B Test (Wako Pure Chemicals, Osaka, Japan). Plasma high density lipoprotein (HDL)-cholesterol was determined with HDL-C Daiichi (Daiichi Pure Chemicals, Tokyo, Japan). Serum thiobarbituric acid-reactive substances (TBARS) were measured by LPO-Test (Wako Pure Chemicals). Tissues and thoracic aorta lipids were extracted by the method of Folch *et al.* (12). Cholesterol (13), triglycerides (14), and phospholipids (15) in the liver were analyzed as described previously. After saponification of aortic lipids, cholesterol was derivatized to the trimethylsilyl ether and then quantified by gas–liquid chromatography on a 3% OV-17 (GL Science, Tokyo, Japan) column (3). 5α-Cholestane (Nacalai Tesque) was used as an internal standard. Phosphatidylcholine (PC), phosphatidylethanolamine (PE), and triglyceride in tissues were separated by thin-layer chromatography, and the fatty acid composition was analyzed by gas–liquid chromatography as described above.

Analysis of eicosanoids and platelet aggregation. Approximately 28 mg of abdominal aorta was incubated in Krebs-Henseleit bicarbonate buffer (pH 7.4) at 25°C for 30 min (8), and the concentration of 6-keto-prostaglandin $F_{1\alpha}$, a stable metabolite of PGI_2, was determined with a commercial enzyme immunoassay kit (Cayman Chemical Co., Ann Arbor, MI). Citrated plasma was centrifuged at $160 \times g$ for 10 min to obtain platelet-rich plasma (PRP), and platelet-poor plasma was obtained from the centrifugation of PRP at $1000 \times g$ for 15 min. PRP was stimulated by 10 μg/mL collagen, and platelet aggregation was measured with an automated platelet aggregation analyzer (Aggrecorder II; Kyoto Daiichi Kagaku, Kyoto, Japan) at 37°C. After 5 min, indomethacin (final concentration, 42 μM; Sigma-Aldrich Japan, Tokyo, Japan) was added to stop the production of TXA_2. Citrated blood was stimulated by thrombin (final concentration 1 U/200 μL citrated blood) for 5 min at 37°C, and the reaction was stopped by the addition of indomethacin. TXB_2, a stable metabolite of TXA_2, was measured with a commercial enzyme immunoassay kit (Cayman Chemical).

Statistical analysis. Data were analyzed by Duncan's new multiple-range test (16), and differences were considered significant at $P < 0.05$.

RESULTS

Growth, food intake, and liver weight. Body weights, food intake, and relative liver weights are shown in Table 3. There were no significant differences in body weight gain and food intake. Relative liver weight was significantly higher in the seal oil group than in the squid oil and control groups.

The concentrations of plasma and liver lipids and plasma TBARS. The concentrations of plasma and liver lipids are shown in Table 3. Total cholesterol, triglyceride, and phospholipid concentrations in plasma were significantly lower in the squid and seal oil groups than in the control group. The HDL-cholesterol concentration was significantly lower in the squid oil group than in the control group. The atherogenic index [total cholesterol − HDL-cholesterol)/HDL-cholesterol] in the seal oil group was significantly lower than indices in the other groups. The reduction of cholesterol and triglyceride concentrations in plasma was due to the decrease both in very low density lipoprotein and low density lipoprotein fractions (data not shown). The concentration of TBARS in plasma was significantly higher in the seal oil group than in the control group.

The liver triglyceride concentration was significantly lower in the squid and seal oil groups than in the control group. There were no significant differences in hepatic cholesterol and phospholipid concentrations among the three groups.

TABLE 3
Growth Parameters, Plasma Lipid Concentrations, Atherogenic Indices, and Thiobarbituric Acid-Reactive Substances

	Group		
	Control[a]	Squid oil[a]	Seal oil[a]
Growth parameters			
Initial body weight (g)	253 ± 6	250 ± 4	257 ± 3
Body weight gain (g)	329 ± 9	346 ± 10	354 ± 20
Food intake (g/d)	18.6 ± 0.3	18.9 ± 0.3	19.0 ± 0.4
Relative liver weight (g/100 g body weight)	5.26 ± 0.11[a]	5.22 ± 0.11[a]	5.74 ± 0.18[b]
Plasma lipid concentration			
Total cholesterol (mg/dL)	619 ± 68[a]	368 ± 28[b]	360 ± 46[b]
HDL-cholesterol (mg/dL)	49.8 ± 5.0[a]	33.7 ± 2.4[b]	44.8 ± 4.7[a,b]
Triglyceride (mg/dL)	206 ± 20[a]	112 ± 11[b]	132 ± 18[b]
Phospholipid (mg/dL)	402 ± 37[a]	203 ± 19[b]	228 ± 26[b]
Atherogenic index	11.5 ± 0.7[a]	10.5 ± 1.5[a]	7.21 ± 0.81[b]
Plasma TBARS (nmol/mL)	3.36 ± 0.37[a]	4.21 ± 0.38[a,b]	5.22 ± 0.44[b]
Liver lipid concentration (mg/g)			
Cholesterol	152 ± 7	156 ± 3	161 ± 4
Triglyceride	24.4 ± 1.4[a]	19.2 ± 0.9[b]	18.0 ± 0.4[b]
Phospholipid	22.3 ± 0.3	23.6 ± 0.4	23.8 ± 0.7

[a]Values represent mean ± SE, $n = 8$ rats. Values with different superscript roman letters are significantly different at $P < 0.05$. HDL, high density lipoprotein; atherogenic index: (total cholesterol – HDL-cholesterol)/HDL-cholesterol; TBARS, thiobarbituric acid-reactive substances.

Fatty acid composition in liver, platelets, and aorta. Fatty acid composition of PC and PE was measured in liver, platelets, and aorta (Tables 4–6). The percentage of arachidonic acid in the phospholipids of these tissues was significantly lower in the marine oil groups than in the control group. Seal oil was more effective for lowering the arachidonic acid content than squid oil. Percentages of linoleic acid in the aorta PC and platelet PC and PE were significantly higher in the seal oil group than in the squid oil group. As a result, the desaturation index [(20:4n-6 + 20:3n-6)/18:2n-6] was lower in the marine oil groups than in the control group, seal oil being more effective than squid oil. Percentages of n-3 PUFA in liver PC, aorta PE, and platelet PE were higher in the seal oil group than in the squid oil group. EPA and n-3 docosapentaenoic acid (22:5n-3) in aorta and platelet PE were higher in the seal oil than in the squid oil group.

[a]Mean ± SE, $n = 8$ rats. Values with different superscript roman letters are significantly different at $P < 0.05$. For abbreviations see Tables 2 and 4.

As shown in Table 7, percentages of DHA and EPA in liver triglycerides were significantly lower in the seal oil than in the squid oil group.

Eicosanoid production and platelet aggregation. As shown in Table 8, production of TXA_2 in PRP stimulated by collagen and in citrated blood stimulated by thrombin was much lower in the seal and squid oil groups than in the control group. Seal oil was more effective for lowering TXA_2 production than squid oil. The difference was particularly significant in the stimulation with collagen. Production of PGI_2 was not influenced by the dietary fats. As a result, the ratio PGI_2/TXA_2 was highest in the seal oil group and lowest in the control group. Maximal platelet aggregation by collagen was significantly lower in the squid and seal oil groups than in the control group.

Intimal thickness and cholesterol concentration in aorta. Differences in the thickness of aortic intima were not statistically significant among the three groups (data not shown). Cholesterol content in aorta was significantly lower in the squid and seal oil groups than in the control group (1.91 ± 0.07, 2.06 ± 0.11, and 2.51 ± 0.21 μg/mg aorta in the squid oil, seal oil, and control groups, respectively).

DISCUSSION

We previously reported that triglyceride structures in dietary seal and fish oils were reflected by the structures in chylomicron triglycerides secreted from intestinal cells to lymph (8). EPA and DHA at the *sn*-1,3 positions in seal oil triglyceride were retained at 94 and 92% in lymph triglycerides collected for 3 h after the administration, respectively, and EPA and DHA at the *sn*-2 position in fish oil triglyceride was retained at 62 and 74%, respectively. A similar observation was reported by Christensen and Høy (17). Christensen *et al*. (7) also observed that the removal rate from plasma of radiolabeled cholesterol contained in chylomicrons following seal oil feeding was faster than that after fish oil feeding. In addition, the recovery of radiolabeled palmitic acid from the liver was significantly lower in rats fed seal oil than in animals fed fish oil. They also reported that fatty acids bound to 2-monoglycerides following hydrolysis of chylomicron triglycerides may affect the clearance rate of chylomicrons and chylomicron remnants (18,19). Based on these results, the structural difference of triglycerides of seal and squid oils may affect lipid metabolism differently.

EPA and DHA inhibit Δ6 desaturation of linoleic acid and hence reduce arachidonic acid content in tissue phospholipids (2). In the present study, the effects of feeding seal and squid oils on the arachidonic acid content in several tissue phospholipids differed (Tables 4–6). Although total n-3 PUFA content in the dietary fats was the same in the seal and squid oil groups, feeding of seal oil more effectively reduced the arachidonic acid content in liver, platelets, and aorta phospholipids than squid oil. Desaturation indices in these phospholipids were significantly lower in the seal oil group than in the squid oil group. Therefore, the reduction of arachidonic acid in these phospholipids may be due to the inhibition of Δ6 desaturation. Generally, an increase of n-3 PUFA content in the liver induces the inhibition of Δ6 desaturation of linoleic acid and hence the reduction of arachidonic acid (2). However, although total n-3 PUFA content contained in liver PC was slightly higher in the seal oil group than in the squid oil group, it was not increased in liver PE by feeding with seal oil. In addition, n-3 PUFA content in liver triglycerides of the seal oil group was only half that of the squid oil group. These observations indicate that total n-3 PUFA content in the liver of rats fed seal oil was lower than of those fed squid oil. Therefore, the reduction of arachidonic acid content in the seal oil group may have occurred without an increase of n-3

TABLE 8
Production of Aortic Thromboxane A_2 and Prostacyclin, and Platelet Aggregation[a]

	Group		
	Control	Squid oil	Seal oil
Production of platelet thromboxane A_2 (ng/mL)			
Collagen	492 ± 30[a]	150 ± 14[b]	74.6 ± 4.4[c]
Thrombin	555 ± 38[a]	145 ± 15[b]	101 ± 8[b]
Production of aortic prostacyclin (pg/mg aorta)			
	1019 ± 241	847 ± 264	937 ± 193
Ratio of aortic prostacyclin and platelet thromboxane A_2			
Collagen	2.19 ± 0.54[a]	5.99 ± 1.86[a,b]	10.1 ± 2.67[b]
Thrombin	2.11 ± 0.73[a]	5.77 ± 1.28[a,b]	9.60 ± 2.55[b]
Maximal aggregation (%)			
Collagen	48.4 ± 3.2[a]	40.8 ± 2.3[b]	40.7 ± 0.9[b]

[a]Mean ± SE, $n = 6$–8 rats. Values with different superscript roman letters are significantly different at $P < 0.05$. Prostacyclin and thromboxane A_2 were measured as 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2, respectively. Collagen: final concentration of collagen was 10 μg/mL. Thrombin: final concentration of thrombin was 1 U/200 μL citrated blood. Maximal aggregation: platelet was stimulated by 10 μg/mL collagen.

PUFA content in the liver. It is not evident how the structural differences of the triglycerides may influence Δ6 desaturation of linoleic acid.

An alternative possibility is that the differences in n-3 PUFA composition between dietary seal and squid oils may cause the observed influence on fatty acid composition in the phospholipids. Octadecatetraenoic (18:4n-3) and docosapentaenoic (22:5n-3) acids were higher in the seal oil than in the squid oil (Table 1). However, the effect of these n-3 PUFA on arachidonic acid content in phospholipids has never been reported. Mechanisms for different effects between seal and squid oils on linoleic acid metabolism deserve further investigation.

In our previous study in which seal oil-rich or fish oil-rich diets were fed to rats for 3 wk, the reduction of arachidonic acid content in the seal oil group was observed in liver PC and PE but not in platelet and aorta PC (8). In the present study, the percentage of arachidonic acid was even lower in platelet and aorta PC and PE in the seal oil group than in the squid oil group. The desaturation and elongation of linoleic acid to arachidonic acid are performed mainly in the liver (20) and hence a large portion of arachidonic acid in phospholipids of extrahepatic tissues is supplied from the liver. Christensen and Høy (21) did not observe any influence that was attributable to structural differences in seal and fish oils on the incorporation rate of n-3 PUFA into and the arachidonic acid content of heart and kidney phospholipids of rats fed for 17 d (21). These observations suggest that the influence of the reduction of arachidonic acid in the liver would be slowly transferred to the extrahepatic tissues. Therefore, long-term feeding may be necessary to identify effects of structural differences of seal and squid oils.

The content of n-3 PUFA, in particular EPA and 22:5n-3, in platelet and aorta PE was higher in the seal oil group than in the squid oil group. The increase in EPA occurred in spite of the lower EPA content in dietary seal oil compared with squid oil. Chylomicron triglyceride incorporated from intestinal lymph into the bloodstream is hydrolyzed at *sn*-1 and *sn*-3 positions to free fatty acid and 2-monoglyceride by peripheral lipopotein lipase. A portion of the free fatty acids is incorporated into the peripheral tissues, and the remaining part is taken up by the liver. A portion of the 2-monoglyceride is transformed to 1-monoglyceride and then hydrolyzed to free fatty acid. The remaining portion of the 2-monoglyceride is incorporated into the liver with the chylomicron remnant. It is thought that because of low activity, if any, of the 2-monoglyceride pathway, 2-monoglyceride incorporated into the liver is hydrolyzed to free fatty acid and glycerol and then the fatty acid is partitioned to various lipid fractions. The extent of the partition of free fatty acids and 2-monoglyceride between the peripheral tissues and the liver is not clearly understood. It seems likely that the partition may depend to some extent on the species of fatty acids, in particular, EPA and DHA. Ackman (22) suggested that EPA and DHA at the 1 and 3 positions in fish oil would be incorporated mainly into the peripheral tissues rather than the liver. Our results support this suggestion, because n-3 PUFA, in particular EPA, were preferentially incoporated into aorta and platelets rather than liver in rats fed on seal oil compared to rats fed on squid oil.

Platelet TXA_2 production was effectively suppressed by feeding with either marine oils. In particular, seal oil was more effective than squid oil in reducing TXA_2 production. Thrombin and collagen had similar influences on TXA_2 production, because the correlation coefficient between the production of TXA_2 stimulated by thrombin and collagen was high (r = +0.914). The reduction could be induced by the decrease in arachidonic acid of platelet phospholipids, because a highly positive correlation between platelet TXA_2 production and arachidonic acid content has been reported (2). In the present study, the correlation coefficient between the production of platelet TXA_2 stimulated by thrombin and the arachidonic acid content in platelet PC was high (r = +0.96). We previously reported that, although both EPA and DHA reduced arachidonic acid content in phospholipids of various tissues, DHA was more effective than EPA (4). Our results suggested that DHA, in comparison with EPA, more efficiently suppresses Δ6 desaturation of linoleic acid and competes with arachidonic acid for the *sn*-2 position of phospholipids. However, the relationship between the differences in triglyceride structure and the different effects of EPA and DHA on arachidonic acid content in phospholipids is not known.

In contrast to TXA_2 production, although arachidonic acid content in aorta phospholipids was suppressed by the feeding with marine oils, in particular with seal oil, PGI_2 production was not influenced by the reduction of arachidonic acid. Aortic PGI_2 production is not dependent on arachidonic acid content in aorta phospholipids (2). Saito *et al.* (23) reported that EPA enhanced the production of PGI_2 by activating cyclooxygenase in cultured rat vascular smooth muscle cells. This may explain why the production of PGI_2 was not reduced, although arachidonic acid content in aorta phospholipids was lower in rats fed seal or squid oils. In any event, it is reasonable to think that seal oil is more effective to prevent thrombosis than squid oil, because the PGI_2/TXA_2 ratio was higher in the seal oil group than in the squid oil group.

Atherosclerotic lesions developed in the aortas of ExHC rats treated orally for 180 d with high doses of vitamin D and a high cholesterol/sodium cholate/olive oil diet (9). However, atherosclerotic development was slight in this study compared with the previous observation. Therefore, the effect of squid and seal oils on atherogenesis was not apparent, although the aortic cholesterol content was lower in rats fed seal and squid oils. In our previous study, serum cholesterol concentration increased more than 1000 mg/dL (9), whereas about 600 mg/dL was maximal in the present study. This may be one of the reasons why intimal thickening was slight. The difference of dietary fats likely caused the different effect on the serum cholesterol concentration. Instead of the olive oil, rich in oleic acid, used in the previous study, dietary fat rich in lauric, myristic and palmitic acids was used as a basal fat in the present study. These saturated fatty acids are known to

be hypercholesterolemic in humans and experimental animals (24). It is not clear why saturated fatty acids in our animal model were not hypercholesterolemic compared with olive oil.

In conclusion, the different intramolecular distribution of EPA and DHA in dietary fats mainly affected arachidonic acid content in tissue phospholipids and TXA_2 production in platelets of rats fed for a long time, although the influence on atherosclerosis was not clearly observed. The mechanism for these different effects between seal and squid oils remains to be clarified.

Effects of Dietary Methionine and Cystine on Lipid Metabolism in Hepatoma-Bearing Rats with Hyperlipidemia

Masashi Kawasaki, Ryuhei Funabiki, and Kazumi Yagasaki*

Department of Applied Biological Science, Tokyo Noko University, Tokyo 183-8509, Japan

ABSTRACT: Abnormal lipid metabolism and its restoration by dietary methionine (Met) and cystine (Cys) were studied in Donryu rats subcutaneously implanted with an ascites hepatoma cell line of AH109A. The hepatoma-bearing rats exhibited hyperlipidemia characterized by rises in serum triglyceride and cholesterol levels. Decreased lipoprotein lipase (LPL) activities in epididymal adipose tissue, cardiac muscle, and gastrocnemius as well as increased fatty acid mobilization from adipose tissue were considered to be responsible for the hepatoma-induced hypertriglyceridemia, while increased hepatic cholesterogenesis and decreased steroid excretion into feces were thought to be responsible for the hepatoma-induced hypercholesterolemia. Dietary-supplemented Met or Cys reduced the AH109A-induced hypertriglyceridemia with suppression of fatty acid synthesis in the host liver. Met restored the fall of LPL activities, while Cys did not. Dietary Met or Cys also reduced the hypercholesterolemia with restoration of decreased bile acid excretion into feces. These results suggest that dietary Met or Cys is hypolipidemic in the hepatoma-bearing rats with slight differences in their modes of action.

Lipids 33, 905–911 (1998).

Various cancers developed in, for example, breast and colon affect serum lipoprotein profiles in humans (1,2). Hepatoma also induces abnormal serum lipid metabolism in humans (3,4) and animals (5,6). Rats subcutaneously implanted with an ascites hepatoma cell line of AH109A show hyperlipidemia (7,8) with a notable decrease in high density lipoprotein (HDL) fraction and an enormous increase in the very low density lipoprotein plus low density lipoprotein (VLDL + LDL) fraction (6–8) during growth of the hepatoma. AH109A-bearing rats thus provide us with an endogenously hyperlipidemic animal model that is quite distinct from cholesterol (Ch)-loaded animals that have been widely used as an exogenously hypercholesterolemic model. Dietary-supplemented amino acids such as sulfur amino acids (9) and basic amino acids (10) can reduce the hepatoma-induced hyperlipidemia.

Lipoprotein lipase (LPL) affects not only the catabolism of triglyceride (TG)-rich lipoproteins but also the quantity and quality of HDL (11). LPL activity often decreases in the tumor-bearing state (12). In the present study, we first examined whether tissue LPL activity would be decreased by AH109A implantation. Second, we studied the actions of methionine (Met) and cystine (Cys) on the hyperlipidemia and their modes of action, with special attention to changes in LPL activity. Dietary Met and Cys were found to reduce the hepatoma-induced hyperlipidemia with slight differences in their modes of action.

EXPERIMENTAL PROCEDURES

Materials. Sodium heparin was purchased from Wako Pure Chemical Industries (Osaka, Japan). [Carboxyl-^{14}C]triolein (original specific radioactivity = 4.1 GBq/mmol) was purchased from NEN Research Products (Boston, MA). Insta-Gel was the product of Packard Instrument Co., Inc. (Meriden, CT). [1-^{14}C]Acetic acid (sodium salt, original specific radioactivity = 2.04 GBq/mmol) was purchased from Amersham International plc (Buckinghamshire, United Kingdom). Cholesterol C-test Wako and Total Bile Acid test Wako were purchased from Wako Pure Chemical Industries.

Animals and diets. Male Donryu rats were obtained from NRC Haruna (Gunma, Japan) at 4 wk of age. The animals were individually housed in stainless-steel cages with wire bottoms in an air-conditioned room with a temperature of 22°C, a relative humidity of 60%, and an 8:00 A.M. to 8:00 P.M. light cycle and kept on a stock pellet diet (CE-2; CLEA Japan, Tokyo, Japan), followed by a 20% casein (20C) diet (8). The composition of the 20C diet was as follows: 20% casein, 5% corn oil, 51.3% α-cornstarch, 17% sucrose, 3.5% mineral mixture (AIN 76 composition) (13), 1% vitamin mixture (AIN 76 composition) (13), 0.2% choline bitartrate, and 2% cellulose powder. After preliminary feeding, rats were divided into six or four groups of similar body weights (experiment 1: 152.9 ± 3.3, 154.5 ± 5.6, 154.9 ± 5.6, 154.7 ± 3.9, 153.3 ± 4.7, or 154.6 ± 3.6 g, and experiment 2: 153.9 ± 4.7, 153.9 ± 3.5, 154.1 ± 2.7, or 154.1 ± 3.1 g, mean ± standard error), and the animals received an implantation of 5×10^5

Abbreviations: 20C, 20% casein diet; Ch, cholesterol; Cys, cystine; FA, fatty acid; H, hepatoma-bearing group; HDL, high density lipoprotein; HSL, hormone-sensitive lipase; HTGL, hepatic triglyceride lipase; LDL, low density lipoprotein; Met, methionine; N, normal group; LPL, lipoprotein lipase; NEFA, nonesterified fatty acid; PBS(–), Ca^{2+}, Mg^{2+}-free.phosphate-buffered saline; PL, phospholipid; T-Ch, total cholesterol; TG, triglyceride; TNF, tumor necrosis factor-α; VLDL, very low density lipoprotein.

AH109A cells (provided by SRL, Tokyo, Japan) suspended in Ca^{2+}, Mg^{2+}-free phosphate-buffered saline [PBS(−)] (0.5 mL/rat) in the back to produce a solid hepatoma (hepatoma-bearing group) (6). One group of animals received an injection of PBS(−) alone (0.5 mL/rat) and was designated as the normal group. In experiment 1, all the rats were kept on the 20C diet, and the rats in hepatoma-bearing groups were sacrificed on the 1st, 2nd, 4th, 7th, and 14th d after AH109A implantation, while those of the normal group were sacrificed on the day of PBS(−) injection (d 0). In experiment 2, the hepatoma-bearing rats were fed the 20C diet (control) and the 20C diet supplemented with either 1.2% L-Met or L-Cys for 14 d. Likewise, rats of the normal group were fed the 20C diet for 14 d. Water and each diet were available at all times. Animals were deprived of their diet at 9:00 A.M. on the 14th d but allowed free access to water until killing, which was performed 4 h later by decapitation. Blood was collected and left to clot at room temperature to obtain serum. The liver, epididymal adipose tissue, cardiac muscle, gastrocnemius, and solid hepatoma were quickly removed, washed with cold 0.9% NaCl, and blotted on filter paper. Aliquots of the liver, epididymal adipose tissue, cardiac muscle, and gastrocnemius were frozen in liquid nitrogen and stored at −70°C until analyzed.

Lipid analyses. Total lipids were extracted according to the procedure of Folch *et al*. (14) from the liver and solid hepatoma. After portions of the chloroform phase had been dried under nitrogen, Ch (15), TG (16), and phospholipid (PL) (17) were determined as previously described (7). The serum TG and PL levels were also determined as described above. The serum nonesterified fatty acid (NEFA) level was measured by the method of Kushiro *et al.* (18). The serum lipoproteins were separated into HDL and VLDL + LDL fractions by the precipitation method (6). The total Ch of unfractionated serum (T-Ch) and HDL (HDL-Ch) were determined by an enzymatic method using a Cholesterol C-test Wako, and the difference between T-Ch and HDL-Ch was regarded as (VLDL + LDL)-Ch.

Measurement of tissue lipolytic activities. LPL was extracted from epididymal adipose tissue, cardiac muscle, and gastrocnemius by the method of Noguchi *et al.* (19); the tissues weighing 300 mg were homogenized in 0.2 M Tris-HCl buffer (pH = 8.5) containing 10 U/mL of sodium heparin. Hepatic TG lipase (HTGL) was also extracted from the liver in the same way. Lipase (LPL and HTGL) activities were then estimated as described previously (20,21). Briefly, 0.1 mL of the above-mentioned enzyme source was mixed with 0.1 mL of substrate solution (arabic gum-emulsified Tris-HCl buffer, 0.2 M and pH = 8.0, containing rat serum to supply adequate apolipoprotein C-II as an activator for LPL, and 0.1 M and pH = 8.5 for HTGL) containing 925 Bq (= 55,500 dpm)/μmol/assay of [carboxyl-^{14}C]triolein. The mixture was incubated at 37°C for 1 h, followed by the extraction and counting of hydrolyzed [^{14}C]oleic acid. Hormone-sensitive lipase (HSL) activity in adipose tissue was also determined. From epididymal adipose tissue, HSL was extracted with 2 vol of 0.2 M phosphate buffer (pH = 7.0) by homogenization (22). The enzyme suspension (0.1 mL) previously incubated with 1 M NaCl for 10 min was mixed with 0.1 mL of substrate solution (arabic gum-emulsified 0.2 M phosphate buffer, pH = 7.0) containing 925 Bq/μmol/assay of [carboxyl-^{14}C]triolein and the mixture was incubated at 30°C for 1 h. At the end of the incubation period, hydrolyzed [^{14}C]oleic acid was extracted and radioactivity was counted after adding Insta-Gel. One unit of lipase activity was defined as 1 μmol of fatty acid (FA) released per hour.

Hepatic lipid syntheses. Total FA and Ch syntheses were measured using liver slices (23,24). Liver slices weighing 100–120 mg were placed in 1 mL of Krebs-Ringer phosphate buffer (pH = 7.4) containing 37 KBq/μmol/assay of [1-^{14}C]acetic acid, sodium salt. Each tube was gassed with 100% O_2, stoppered tightly with a screwcap, and incubated at 37°C for 2 h. At the end of the incubation period, 1 mL of 15% ethanolic KOH was added and the mixture was saponified at 75°C for 2 h. Nonsaponifiable lipids were extracted three times with petroleum ether, and digitonin-precipitable sterols were formed, isolated, washed, dissolved in methanol, and counted after addition of a toluene-based scintillator. The residual aqueous layer was acidified to pH = 2 with concentrated HCl, and total FA were extracted three times with petroleum ether. Pooled extracts were then dried under nitrogen, dissolved in chloroform, and washed twice with water. The chloroform layer was quantitatively transferred to a scintillation vial, dried, and counted as mentioned above.

Fecal steroid excretion. Feces were collected for 2 d before killing (days 12–14). Neutral sterols and bile acids were extracted from dried and ground feces after saponification according to the procedure of Yamanaka *et al.* (25). Fecal 3β-hydroxy neutral sterols and 3α-hydroxy bile acids were determined by enzymatic methods (26), using commercial kits as described previously (27).

Statistical analysis. Results were expressed as mean ± standard error. Statistical analysis was carried out by analysis of variance followed by Student's *t*-test, or Duncan's multiple-range test (28).

RESULTS

Experiment 1. Food intake and body weight gain per day after AH109A implantation were almost the same among the five hepatoma-bearing groups (food intakes for groups of the 1st, 2nd, 4th, 7th, and 14th d after AH109A implantation were 19.1 ± 0.9, 18.0 ± 0.8, 18.2 ± 0.8, 18.3 ± 1.1, and 19.3 ± 0.3 g/d, respectively, and body weight gains for those groups were 6.9 ± 0.7, 5.6 ± 0.7, 5.9 ± 0.4, 6.0 ± 0.6, and 6.0 ± 0.2 g/d, respectively). The solid hepatoma started to be palpable on the 5th d after implantation, and the absolute and relative weights on the 14th d were 5.8 ± 1.5 g/rat and 2.5 ± 0.7% of body weight, respectively.

Figure 1 shows the time course of the serum TG and Ch levels after AH109A implantation. Judging from the data obtained on 0, 1, 2, 4, 7, and 14 d after the implantation of AH109A, the serum TG level significantly increased the day

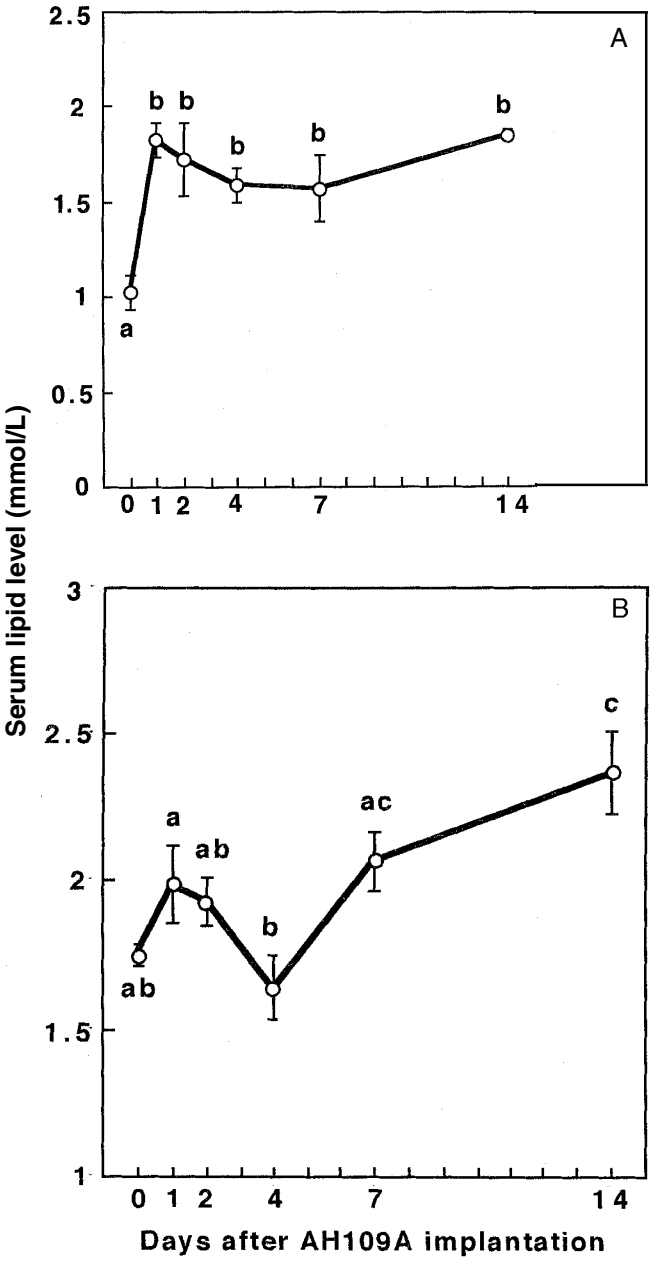

FIG. 1. Changes in the serum A: triglyceride (TG) and B: total cholesterol (T-Ch) levels with days after AH109A (SRL, Tokyo, Japan) implantation. Each value represents the mean of six rats. Vertical bars indicate standard errors. Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test.

following implantation and remained at a high level until the 14th d. The serum T-Ch level fluctuated during the first 7 d but rose significantly on the 14th d.

Figure 2 illustrates changes in the tissue TG lipase (LPL and HTGL) activities with days after AH109A implantation. LPL activity in epididymal adipose tissue decreased significantly the day after AH109A implantation and continued to decrease until the 14th d (10% of the control group). Cardiac muscle and gastrocnemius LPL activities also decreased the day after AH109A implantation and remained at low values until killing. HTGL activity in the liver showed no significant changes during the first week but dropped significantly on the 14th d.

Experiment 2. Table 1 shows food intake, body weight gain, liver and solid hepatoma weights, and lipid contents in the liver and hepatoma 14 d after AH109A implantation. Food intake, body weight gain, and liver weight were reduced by the presence of the hepatoma. Among the hepatoma-bearing groups, no significant changes in these parameters and hepatoma weight were noted. Liver TG content was decreased in the presence of the hepatoma, but the PL and Ch contents were not affected. The liver Ch content was increased by feeding Cys, but liver TG and PL contents and hepatoma lipid contents were not affected by feeding either Met or Cys.

Figure 3 represents changes in the serum lipid levels. As compared with the normal group, the serum TG, T-Ch, (VLDL + LDL)-Ch, PL, and NEFA levels were significantly higher in the hepatoma-bearing group (N vs. H). Conversely, the serum HDL-Ch level was lower in the hepatoma-bearing group than in the normal group (N vs. H). Dietary Met and Cys decreased the serum TG, PL, T-Ch, and (VLDL + LDL)-Ch levels. The HDL-Ch level was significantly increased by dietary Met, but dietary Cys had little effect on the level.

Figure 4 shows LPL activities in various tissues. In epididymal adipose tissue, cardiac muscle and gastrocnemius, these activities were all lower in the hepatoma-bearing group than in the normal group (N vs. H). In hepatoma-bearing groups, dietary Met restored the reduced LPL activity, but Cys did not.

As shown in Table 2, the HTGL activity was decreased in the presence of the hepatoma, while HSL activity was increased by hepatoma implantation. Dietary sulfur amino acids had no effect on these activities.

The lipid (FA and Ch) syntheses by liver slices are also shown in Table 2. Hepatic Ch synthesis was significantly stimulated by AH109A implantation, but FA synthesis was not (N vs. H). Dietary sulfur amino acids had no effect on Ch synthesis, while they suppressed FA synthesis.

As shown in Table 2, dry weight of feces and excretion of both neutral sterols and bile acids were significantly reduced by the presence of the hepatoma (N vs. H). Both dietary Met and Cys enhanced bile acid excretion, while these amino acids had no influence on neutral sterol excretion.

DISCUSSION

The serum TG level quickly increased the day following hepatoma implantation and was almost constant until the 14th d (Fig. 1). In contrast, LPL activity in various tissues rapidly decreased the day following the implantation. In the case of epididymal adipose tissue, LPL activity continued to decrease up to the 14th d (Fig. 2). These findings are not inconsistent with the results described by Damen *et al.* (12) who found a reduction of LPL activity in postheparin plasma in mice bearing a GRSL ascites tumor (a murine leukemia). LPL activity is concerned with serum TG clearance; a reduction of LPL activity is related to an increase in the serum TG level. Thus,

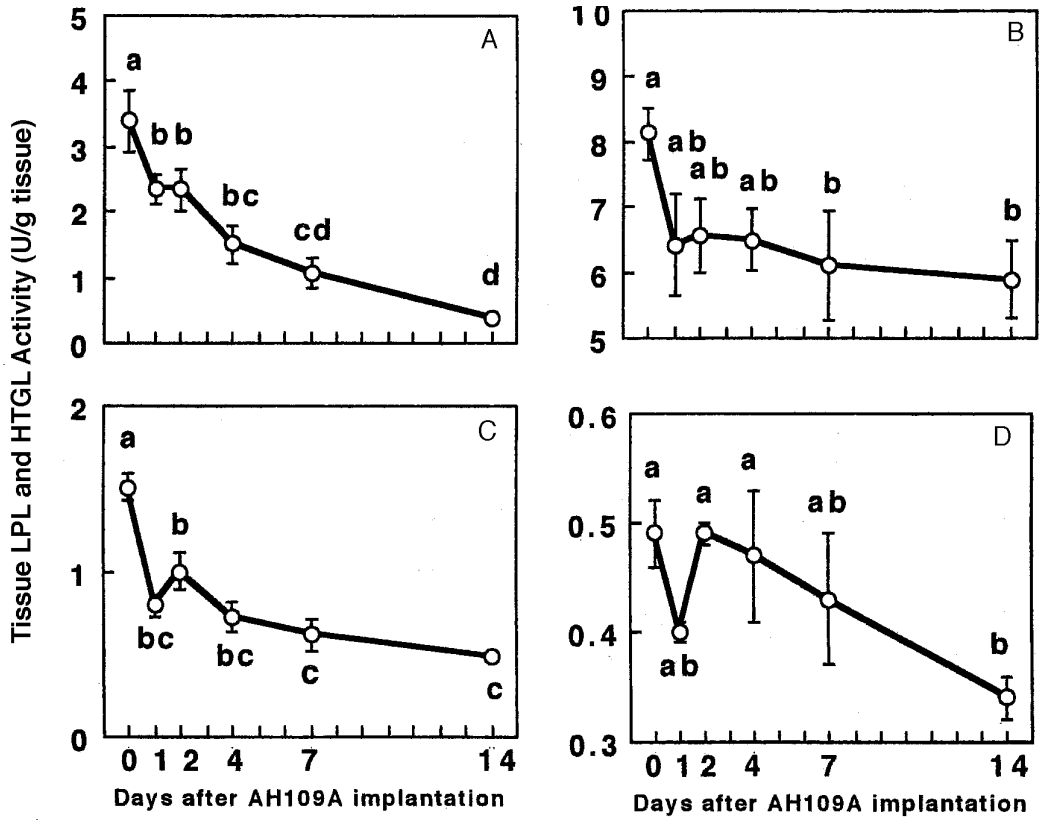

FIG. 2. Changes in tissue lipoprotein lipase (LPL) [A: epididymal adipose tissue (EAT), B: cardiac muscle, and C: gastrocnemius] and hepatic triglyceride lipase (HTGL) (D: liver) activities with time after AH109A implantation. Each value represents the mean of six rats. Vertical bars indicate standard errors. Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test. See Figure 1 for company source.

the reduction of tissue LPL activity is considered to be one cause for the hypertriglyceridemia in AH109A-bearing rats. HSL in adipose tissue (Table 2) and the serum NEFA level (Fig. 3) increased significantly in hepatoma-bearing rats when compared with hepatoma-free (normal) rats. This increased FA mobilization from adipose tissue is thought to be another cause for the hepatoma-induced hypertriglyceridemia, which was reduced by ingestion of either Met- or Cys-fortified diet

TABLE 1
Initial Body Weight, Food Intake, Body Weight Gain, Weights and Lipid Contents of Liver and Hepatoma in Hepatoma-Bearing Rats[a]

	Normal (N)	Hepatoma-bearing (H)		
Measurement	20C	20C	20C + 1.2 Met	20C + 1.2 Cys
Initial body weight (g)	153.9 ± 4.7	153.9 ± 3.5	154.1 ± 2.7	154.1 ± 3.1
Food intake (g/14 d)	267.6 ± 7.0[b]	209.6 ± 7.7	180.9 ± 8.3	192.8 ± 11.5
Body weight gain (g/14 d)	112.8 ± 3.2[b]	84.9 ± 4.9	69.7 ± 6.8	75.8 ± 8.6
Liver weight (g)	12.4 ± 0.6[b]	9.8 ± 0.5	9.1 ± 0.3	9.0 ± 0.6
Hepatoma weight (g)	—	41.3 ± 2.6	37.8 ± 4.4	39.3 ± 2.8
Liver lipid content (μmol/g liver)				
Triglyceride	14.4 ± 2.1[b]	7.2 ± 1.5	5.7 ± 3.2	6.2 ± 2.2
Phospholipid	32.0 ± 0.8	31.5 ± 0.9	34.5 ± 1.0	34.0 ± 0.9

Hepatoma lipid content (μmol/g hepatoma)				
Triglyceride	—	1.7 ± 0.2	1.4 ± 0.2	2.1 ± 0.2
Phospholipid	—	7.4 ± 1.7	8.8 ± 1.4	7.7 ± 1.0
Cholesterol	—	5.7 ± 0.5	5.2 ± 0.3	5.4 ± 0.3

[a]Each value represents the mean ± standard error of six rats. Cys, cystine; Met, methionine; 20C, 20% casein diet.
[b]Significantly different from the hepatoma-bearing-20C diet group at $P < 0.05$ by Student's *t*-test. Values not sharing a common superscript letter (c,d) are significantly different at $P < 0.05$ by Duncan's multiple-range test.

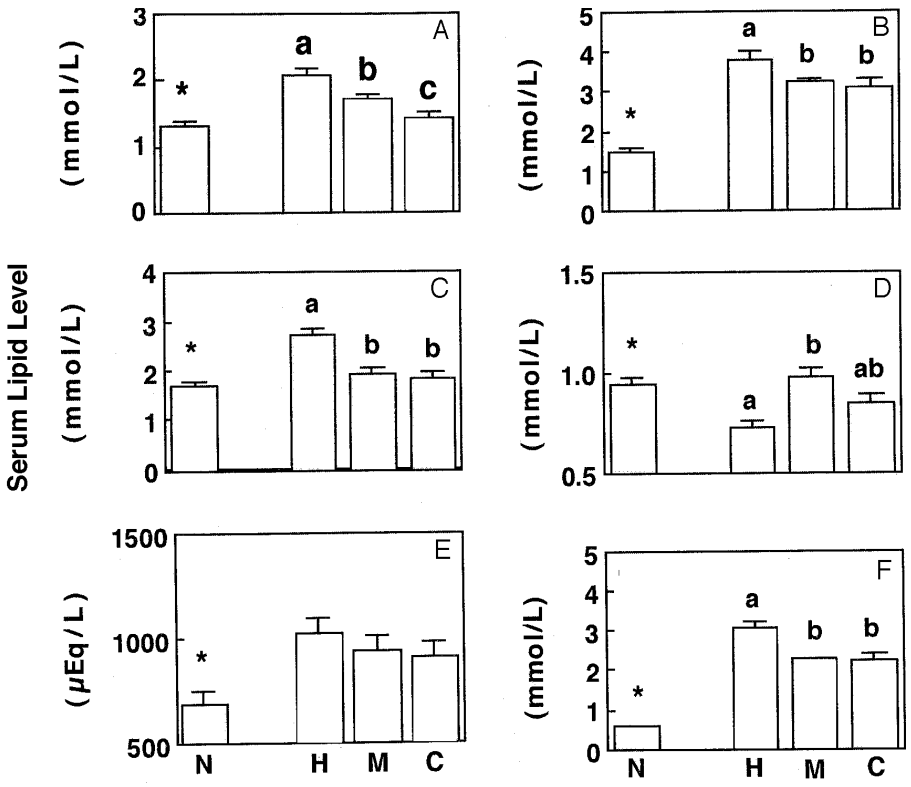

FIG. 3. Effects of dietary additions of either methionine (Met) or cystine (Cys) to a 20% casein diet (20C) on serum lipid levels in hepatoma-bearing rats. Each value represents the mean of six rats. Vertical lines at the top of the bars indicate standard errors. *Significantly different from hepatoma-bearing-20C diet (H) group at $P < 0.05$ by Student's *t*-test. Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test. A: TG, triglyceride; B: T-Ch, total cholesterol; C: PL, phospholipid; D: HDL-Ch, high density lipoprotein-cholesterol; E: NEFA, nonesterified fatty acid; F: (VLDL + LDL)-Ch, (very low density lipoprotein + low density lipoprotein)-cholesterol. N, normal group fed 20C; H, hepatoma-bearing group fed 20C; M, hepatoma-bearing group fed 20C + 1.2Met; C, hepatoma-bearing group fed 20C + 1.2Cys.

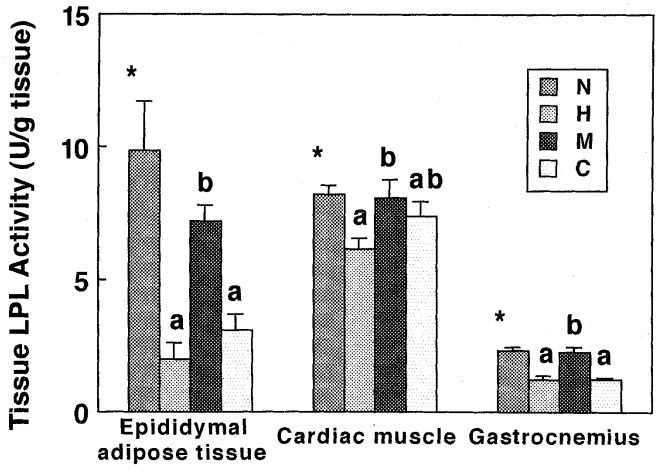

FIG. 4. Effects of dietary additions of either Met or Cys to a 20C on tissue LPL activities in hepatoma-bearing rats. Each value represents the mean of six rats. Vertical lines at the top of the bars indicate standard errors. *Significantly different from hepatoma-bearing-20C diet (H) group at $P < 0.05$ by Student's *t*-test. Values not sharing a common letter are significantly different at $P < 0.05$ by Duncan's multiple-range test. See Figure 3 for abbreviations.

(Fig. 3). Both sulfur amino acids suppressed hepatic FA synthesis in the hepatoma-bearing state (Table 2), but they failed to suppress the increased NEFA level in the serum. Met restored decreased LPL activity in the hepatoma-bearing state to the level of that in the normal state, while Cys did not (Fig. 4). The hypotriglyceridemic effect of Met may therefore be due to a suppression of hepatic FA synthesis and a restoration of decreased LPL activity in various tissues, whereas that of Cys may be due to a suppression of hepatic FA synthesis. Since the hypotriglyceridemic effect of Cys was stronger than that of Met (Fig. 3), a certain powerful mechanism(s), such as an increased FA oxidation in the liver, must operate in the case of Cys.

The hepatoma-induced hypercholesterolemia was characterized by a striking increase in the (VLDL + LDL)-Ch level and a slight but significant decrease in the HDL-Ch level (Fig. 3). An increase in hepatic cholesterolgenesis and a decrease in bile acid excretion into feces (Table 2) are considered to be responsible for the hepatoma-induced hypercholesterolemia. Both Met and Cys succeeded in improving the hypercholesterolemia by reducing the (VLDL + LDL)-Ch level

TABLE 2
Activities of Hepatic Triglyceride Lipase and Hormone-Sensitive Lipase, Hepatic Lipid Syntheses, and Fecal Steroid Excretion in Hepatoma-Bearing Rats[a]

	Normal (N)	Hepatoma-bearing (H)		
Measurement	20C	20C	20C + 1.2Met	20C + 1.2Cys
Hepatic triglyceride lipase activity (U/g tissue)				
Liver	2.4 ± 0.3[b]	1.2 ± 0.1	1.7± 0.2	1.4 ± 0.2
Hormone-sensitive lipase activity (U/g tissue)				
Epididymal adipose tissue	1.2 ± 0.1[b]	1.5 ± 0.1	1.4 ± 0.1	1.3 ± 0.1
Hepatic lipid syntheses (dpm × 10^{-4}/2 h/g liver)				
Fatty acids	9.2 ± 1.7	10.2 ± 2.1[c]	4.6 ± 0.5[d]	4.3 ± 1.0[d]
Cholesterol	3.2 ± 0.3[b]	14.5 ± 3.7	16.7 ± 3.5	12.7 ± 2.4
Fecal dry weight (g/2 d)	1.7 ± 0.2[b]	0.8 ± 0.1	0.8 ± 0.1	0.9 ± 0.1
Steroid excretion (μmol/2 d)				
Neutral sterols	41.1 ± 4.7[b]	14.7 ± 2.1	11.3 ± 1.0	12.7 ± 1.4
Bile acids	26.5 ± 3.0[b]	9.9 ± 1.4[c]	16.4 ± 1.7[d]	17.3 ± 1.3[d]

[a]Each value represents the mean ± standard error of six rats. See Table 1 for other abbreviations.
[b]Significantly different from the hepatoma-bearing-20C diet group at $P < 0.05$ by Student's *t*-test. Values not sharing a common superscript letter (c,d) are significantly different at $P < 0.05$ by Duncan's multiple-range test.

(Fig. 3). The hypocholesterolemic actions of these two sulfur amino acids could be attributed to a restoration of decreased bile acid excretion into feces, like a Cys derivative, *S*-methyl-L-cysteine sulfoxide (29). In addition to these common actions of the two amino acids, Met restored the decreased HDL-Ch level in the hepatoma-bearing state to the normal level (Fig. 3). Since LPL deficiency induced by injecting antibody against LPL is associated with low level of HDL-Ch and occurrence of hypertriglyceridemia (11), the restoration effect of Met on HDL-Ch appears to be related to that on LPL activity in tissues. The restorative effect of Met on LPL activity also seems to contribute toward improvement of the hepatoma-induced hypercholesterolemia, since the hypercholesterolemia itself may be influenced by LPL activity.

LPL is known to be regulated by various factors. Insulin enhances LPL activity and mRNA level (30,31), while tumor necrosis factor-α (TNF) suppresses both (32,33). TNF productivity in resident macrophages from AH109A-bearing rats is found to be much higher than that from normal rats (34). Thus, the cytokine seems to be a factor that affects LPL activity and hence serum lipoprotein profiles, as suggested previously (8). To know how Met restores the decreased LPL activity in the hepatoma-bearing state is also important: suppression of an LPL-inactivating factor(s) like TNF, induction of LPL-activating factor(s) like insulin, or their combination. Further intensive studies are needed to clarify these aspects.

Dietary Proteins Modulate the Effects of Fish Oil on Triglyceridemia in the Rat

Isabelle Demonty[a], Yves Deshaies[b], and Hélène Jacques[a,*]

ABSTRACT: Sprague-Dawley rats were fed purified diets varying in both protein (20%) and lipid (11%) content for 28 d to verify the independent and interactive effects of dietary proteins and lipids on serum and hepatic lipids, and on tissue lipoprotein lipase (LPL) activity in both fasted and postprandial states. These diets consisted of either casein–menhaden oil, casein–coconut oil, soy protein–menhaden oil (SPMO), soy protein–coconut oil, cod protein–menhaden oil, or cod protein–coconut oil. A randomized 3 × 2 factorial design was used. A significant protein–lipid interaction was seen on serum triglyceride levels: menhaden oil, compared with coconut oil, induced a decrease in serum triglyceride levels when combined with soy protein but not when combined with cod protein and casein. The lower serum triglyceride concentrations observed in the SPMO-fed rats could be the result of decreased hepatic triglycerides when soy protein was compared with casein and when menhaden oil was compared with coconut oil. Total LPL activity in the heart was higher in menhaden oil-fed rats than in coconut oil-fed rats in the postprandial state. The higher LPL activity in the heart could, however, explain only 10% of the reduction of serum triglycerides, contributing slightly to the lowering effects of SPMO diet on serum triglycerides. Therefore, the present results indicate that dietary proteins can modulate the effects of fish oil on triglyceridemia in the rat, and that could be mainly related to specific alterations in hepatic lipid concentrations.
Lipids 33, 913–921 (1998).

Fish consumption has been inversely associated with the risk of coronary heart disease (1,2). These correlations with cardiovascular events appear to be mediated by the hypotriglyceridemic and antithrombogenic effects of n-3 polyunsaturated fatty acids present in fish oil (3,4). Plasma triglycerides are reduced by a decrease in hepatic triglyceride synthesis (5), a very low density lipoprotein (VLDL) synthesis (6), and an increase in VLDL and chylomicron degradation by lipoprotein lipase (LPL) (4,7,8).

Abbreviations: CACO, casein-coconut oil; CAMO, casein–menhaden oil; CPCO, cod protein–coconut oil; CPMO, cod protein–menhaden oil; HDL, high density lipoproteins; LDL, low density lipoproteins; LPL, lipoprotein lipase; P/S ratio, polyunsaturated to saturated fatty acid ratio; SPCO, soy protein–coconut oil; SPMO, soy protein–menhaden oil; VLDL, very low density lipoproteins; VLM, *vastus lateralis* muscle.

Dietary proteins also have been shown to influence plasma lipid concentrations. Soy protein compared with casein and other animal proteins reduces plasma cholesterol in animal models (9,10) and in humans (11). Soy protein may also modulate the effects of dietary lipids on cholesterol metabolism. Indeed, when combined with corn oil, a source of n-6 polyunsaturated fatty acids, soy protein enhances the hypocholesterolemic effect of corn oil compared with butter, a source of saturated fatty acids (12). The effects of soy protein on triglyceride levels are less documented. However, since soy protein has been shown to reduce hepatic triglyceride (13) in addition to hepatic cholesterol concentrations, as well as hepatic triglyceride and cholesterol secretion into the blood (14), it may possibly accentuate the hypotriglyceridemic effect of fish oil.

The effects of dietary fish protein (which is a major nutrient in fish) on serum lipids have been compared to those of soy protein and casein. In rats, cod protein may decrease serum cholesterol and triglycerides when compared with casein (15). In rabbits, cod protein was shown to induce lower VLDL triglycerides (16) and higher high density lipoprotein (HDL) cholesterol (16,17) concentrations than casein and soy protein. These latter beneficial effects associated with decreased risk of coronary heart disease were related to increased activity of plasma postheparin LPL activity (18). A previous study in rabbits carried out in our laboratory also demonstrated that, when combined with cod protein, corn oil does not reduce total and HDL cholesterol, as it does when combined with either casein or soy protein (16), indicating that fish protein can interact with dietary lipids to modulate lipidemia. Because previous reports demonstrated that both fish oil (5) and fish protein (16) can reduce serum triglycerides, the determination of the combination of both nutrients possibly accentuating the hypotriglyceridemic response was important. Thus an attempt was made in rabbits to determine if such a combination of soy and cod proteins with fish oil may modulate serum and hepatic lipid concentrations (19). However, when fish oil was combined with either casein, fish protein or soy protein, an increasing effect of fish oil on triglyceridemia occurred, suggesting that the rabbit model we used was not the best animal model for studying the reducing effects of fish oil on triglyceridemia observed in humans (19). The present study was thus undertaken in the rat, which had a

reducing triglyceridemic response to fish oil comparable to that of humans (7,20).

Our working hypothesis was that dietary proteins can modulate the effects of fish oil on lipid metabolism. The aim of this study was to determine the distinct and interactive effects of three dietary proteins, casein, cod protein and soy protein, and of two dietary lipids, menhaden oil and coconut oil, on serum lipid levels. A 9% coconut oil plus 1% corn oil diet was used in the present study for comparison with the literature (5) and with one of our previous experiments (15). To gain insight into the mechanisms by which the diet may influence serum lipids, hepatic lipids and LPL activity in white adipose tissue, skeletal and heart muscles were assessed. Because insulin is a major modulator of lipogenesis and LPL activity, serum insulin levels were also determined.

MATERIALS AND METHODS

Experimental animals. Sprague-Dawley rats (120) (St-Constant, Québec, Canada) initially weighing *ca.* 200 g were housed individually in stainless-steel wire-bottom mesh cages. The temperature (20 ± 2°C) and humidity (45–55%) of the animal room were constant and the rats were kept under a daily inverted light–dark cycle (light: 2000 to 0800). During an adaptation period of 2 d in their new environment, the rats were fed a nonpurified commercial diet (rat chow No. 5075; Charles River Canada, St-Constant). They were then divided into six groups of 20 rats of the same average weights. Purified diets and water were provided once daily on an *ad libitum* basis for a period of 28 d. Food intake was measured daily and body weight was monitored three times a week. At the end of the experimental period, 10 rats of each group were killed by decapitation in the fasted state, and the remaining 10 rats were killed in the fed state. Two rats, one in the fasted state and one in the fed state, were eliminated before statistical analysis because of abnormally low growth rate. This protocol was approved by the animal ethics committee of Université Laval (Québec, Canada).

Purified diets. Powdered purified diets, varying in both protein (20%) and lipid (11%) sources, consisted of either casein–menhaden oil (CAMO), casein–coconut oil (CACO), soy protein–menhaden oil (SPMO), soy protein–coconut oil (SPCO), cod protein–menhaden oil (CPMO), or cod protein–coconut oil (CPCO). The composition of each purified diet is detailed in Table 1. Coconut oil and menhaden oil were supplied by ICN Biomedicals Canada Ltd. (Mississauga, Ontario, Canada), and corn oil was purchased from Mazola (Best Foods Canada, Montréal, Canada). According to manufacturer information, menhaden oil contained 28.2% saturated fatty acids, 23.0% monounsaturated fatty acids, 1.8% linoleic acid, 2.3% arachidonic acid, 16.0% eicosapentaenoic acid, 10.8% docosahexaenoic acid, and 5.23 mg cholesterol/g menhaden oil. Therefore, menhaden oil provided only 0.5 g cholesterol/kg in menhaden oil diets, and we considered this amount as negligible. Coconut oil contained 92.0% saturated fatty acids, mainly from lauric acid (48.5%), 6.5% monounsaturated fatty acids, and 1.5% polyunsaturated fatty acids. α-Tocopherol, butylated hydroxyanisole and butylated hydroxytoluene (ICN Biomedicals Canada Ltd.) were added to the diets as proposed by Fritsche and Johnston (21) to minimize the oxidation of n-3 and n-6 polyunsaturated fatty acids in menhaden oil, and n-6 polyunsaturated fatty acids in corn oil and coconut oil. Cholesterol was supplied by Sigma (Sigma Chemical Co., St. Louis, MO). Highly purified casein (85.8% protein), soybean protein isolate (87.6% protein), cornstarch, cellulose (Alphacel), and rat mineral mixture were purchased from ICN Biomedicals Canada Ltd., and vitamin mix was supplied by Teklad Test Diets (Madison, WI). The cod protein was prepared in our laboratory by freeze-drying cod fillets and diethylether delipidation for 24 h in an industrial Soxhlet-type apparatus (Canadawide Scientific, Montréal, Québec, Canada), rendering a cod protein isolate containing 93.7% protein. The protein content (N × 6.25) of casein, soy protein, and cod protein was assayed by the Kjeldahl method using a Kjeldahl-Foss autoanalyzer (Model 16210; Foss Co., Hillerod, Denmark), and the level of protein in the diets was adjusted at the expense of cornstarch to obtain an isonitrogenous content. The residual lipid content of casein (0.07%), soy protein (0.44%), and cod protein (0.19%) was determined with a Goldfish Lipid Extractor (Model 35001; Labconco Corporation, Kansas City, MO). The energy content of the diets was measured in an automatic adiabatic calorimeter (Model 1241; Parr Instruments, Moline, IL) and was similar in the CAMO (19.6 kJ/g), CACO (19.5 kJ/g), SPMO (19.8 kJ/g), SPCO (19.4 kJ/g), CPMO (19.1 kJ/g), and CPCO (19.1 kJ/g) diets.

At the end of the 28-d experimental period, all rats were food-deprived for 12 h and weighed. Six groups of 10 rats, which were first conditioned to meal eating, were fed for 30 min a meal similar to the experimental diet. These rats were killed by decapitation 2.5 h after the meal. The remaining rats were killed after the 12-h fast.

[a]CACO = casein–coconut oil; CAMO = casein–menhaden oil; SPCO = soy protein–coconut oil; SPMO = soy protein–menhaden oil; CPCO = cod protein–coconut oil; CPMO = cod protein–menhaden oil. BHA, butylated hydroxyanisole; BHT, butylated hydroxytoluene.

Serum, lipoprotein, and hepatic lipid analyses. Blood samples of all rats were collected in a 10-mL tube and centrifuged (2,000 × *g*, 4°C, 15 min) to isolate serum. Total cholesterol and triglycerides were determined by enzymatic methods using CHOD-PAP and triglyceride without free glycerol enzymatic kits provided by Boehringer Mannheim (Laval, Québec, Canada) respectively. HDL cholesterol was measured enzymatically with the CHOD-PAP kit after precipitation of VLDL and low density lipoproteins (LDL) with phosphotungstic acid and magnesium ions as described by Burstein *et al*. (22), using an HDL precipitant solution supplied by Boehringer Mannheim. Total (VLDL + LDL) cholesterol was determined by subtracting HDL cholesterol from total cholesterol.

The livers of fasted rats were removed, weighed, frozen in liquid nitrogen, and stored at −80°C. Hepatic lipids were then extracted by chloroform/methanol (2:1, vol/vol) according to Folch *et al*. (23), and determined enzymatically as described above.

Tissue LPL activity. Epididymal adipose tissue, *vastus lateralis* muscle (VLM), and heart of fasted and fed rats were removed and weighed. Approximately 50 mg from each of these tissues was homogenized in 1 mL of solution using all-glass Duall grinders (Kontes Glass, Vineland, NJ). The homogenization solution for adipose tissue consisted of 0.25 M sucrose, 12 mM deoxycholate, 10 mM tris(hydroxymethyl-aminomethane (Tris)-HCl, and 1 mM EDTA at pH 7.4. The homogenization solution for muscle tissues consisted of 1 M ethylene glycol, 50 mM Tris-HCl, 3 mM deoxycholate, 10 UI/mL heparin, and 5% (vol/vol) aprotinin (Trasylol; Miles Pharmaceuticals, Rexdale, Ontario, Canada) at pH 7.4. The homogenates of epididymal adipose tissue were centrifuged at 12,000 × *g*, 4°C for 20 min. The fraction between the upper fat layer and the bottom sediment was removed and diluted with 4 vol of a dilution solution similar to the homogenization solution but without deoxycholate. Homogenates of VLM and heart, as well as diluted samples of epididymal adipose tissue, were then quickly frozen and stored at −80°C until LPL measurements.

LPL activity was measured in these extracts using a method described by Deshaies *et al*. (24). Samples of 100 µL of tissue homogenates were incubated for 1 h at 28°C with 100 µL of a substrate mixture containing either 0.1 or 2 M NaCl. The substrate consisted of 0.2 M tris(hydroxymethyl)-aminomethane (Tris)-HCl buffer, pH 8.6, containing 10 MBq/L [^{14}C]carboxytriolein, and 2.52 mM cold triolein emulsified in 5% gum arabic, 2% fatty acid-free bovine serum albumin, and 10% human serum as a source of apolipoprotein C-II. After incubation, free oleate released by LPL was separated from intact triolein. Sample radioactivity was then determined. LPL activity was calculated by subtracting lipolytic activity measured in a final NaCl concentration of 1 M (activity not due to LPL) from total lipolytic activity measured in a final NaCl concentration of 0.05 M.

Serum glucose and insulin. Serum insulin was measured by radioimmunoassay as described by Desbuquois and Aurbach (25). Serum glucose was measured with an autoanalyzer (YSI 2700 Select; Yellow Springs, OH).

Statistical analyses. The results are expressed as mean ± standard error of the mean and the significance level is $P \leq 0.05$. Data were subjected to an analysis of variance using the general linear model procedure of the Statistical Analysis System (SAS Institute, Cary, NC), according to a 3 × 2 factorial arrangement used to determine the main protein and lipid effects, as well as interactions among dietary proteins and lipids. When statistically significant protein and lipid effects as well as protein–lipid interactions were detected, Duncan's New-Multiple-Range test was performed to identify differences among diet groups. Data for serum triglycerides and (VLDL + LDL) cholesterol of fasted rats were logarithmically transformed to achieve normality of residues. However, data presented in tables and figures are not transformed.

RESULTS

Food consumption and weight gain. Table 2 shows the mean food intake and body weight gain of rats fed the various diets. At the end of the experimental period, food consumption and weight gain were similar for the six dietary groups of rats sacrificed either in the fasted or in the fed state. Food intake at the last meal was also the same for the six dietary groups.

Serum and hepatic lipids. Mean values of serum total, lipoprotein, and hepatic cholesterol of fasted rats are presented in Table 3. The overall analysis of variance and multiple comparisons are shown in the bottom half of the table. A significant protein effect was seen on total serum cholesterol concentrations, which were lower in rats fed soy protein and cod protein than in those fed casein. The lipid source induced significant effects on total and HDL cholesterol in the fasted state. Coconut oil diets provoked higher levels of total and HDL cholesterol than menhaden oil diets. Casein and cod protein induced higher hepatic cholesterol concentrations

TABLE 2
Food Intake and Weight Gain of Rats Fed the Purified Diets[a]

Dietary group	*n*	Food intake (g/d)	Food intake last meal (g)	Weight gain (g/28 d)
Fasted				
CACO	10	21.3 ± 0.8	—	128 ± 10
CAMO	10	21.4 ± 0.4	—	148 ± 11
SPCO	9	20.6 ± 0.6	—	106 ± 8

L	CO > MO	CO = MO	CO > MO	CO = MO

[a]Values are means ± SEM, n = 9–10 rats per dietary group. VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL-C, high density lipoprotein-cholesterol; ANOVA, analysis of variance. See Table 1 for other abbreviations.
[b]$P < 0.05$ indicates significant protein or lipid effects or their interactions.
[c]Explanation of the symbols: =, no difference among the groups at $P < 0.05$; >, significantly higher than the group with which it is compared at $P < 0.05$; <, significantly lower than the group with which it is compared at $P < 0.05$.

than soy protein. However, hepatic cholesterol was higher in rats fed casein than in those fed cod protein. Neither an independent lipid effect nor a protein–lipid interaction was observed on hepatic cholesterol concentrations.

Table 4 shows the effects of the purified diets on serum and lipoprotein cholesterol of rats in the fed state. Significant protein effects were observed on serum cholesterol. Total, (VLDL + LDL) and HDL cholesterol were higher in the casein-fed rats than in the soy protein-fed rats. Total and HDL cholesterol were also lower after soy protein consumption when compared with cod protein consumption. In contrast to the lipid effect observed in the fasted state, the lipid source induced no significant effect on serum total and lipoprotein cholesterol levels in the postprandial state.

TABLE 4
Total Serum and Lipoprotein Cholesterol Levels of Rats Fed the Purified Diets in the Fed State[a]

Dietary group	Total cholesterol (mmol/L)	(VLDL ± LDL)-C (mmol/L)	HDL-C (mmol/L)
CACO	2.4 ± 0.1	1.4 ± 0.1	1.0 ± 0.1
CAMO	2.4 ± 0.2	1.3 ± 0.2	1.1 ± 0.1
SPCO	2.1 ± 0.1	1.1 ± 0.1	1.0 ± 0.1
SPMO	1.7 ± 0.1	0.9 ± 0.1	0.8 ± 0.0
CPCO	2.2 ± 0.2	1.1 ± 0.1	1.1 ± 0.1
CPMO	2.2 ± 0.2	1.1 ± 0.1	1.1 ± 0.1

L	CO = MO	CO = MO	CO = MO

[a–c]See Table 3 for footnotes.

Serum total triglycerides of rats in the fasted and fed states are presented in Figures 1 and 2, and hepatic triglycerides of rats in the fasted state are shown in Figure 3. As shown in Figures 1 and 2, a significant protein–lipid interaction was observed in the fasted and the fed states: there was a hypotriglyceridemic effect of menhaden oil compared to coconut oil when combined with soy protein but not when combined with either casein or cod protein. The lowest values of serum triglycerides in both the fasted and the fed states were thus observed when rats were fed SPMO. In the fasted state, serum triglyceride concentrations of SPMO-fed rats were lower than those of CACO- and SPCO-fed rats. In the fed state the effects between dietary proteins were more pronounced: when combined with coconut oil, cod protein induced lower serum triglycerides than soy protein, casein being intermediate, and when combined with menhaden oil, soy protein induced lower serum triglycerides than casein and cod protein. Proteins and lipids in the diets had independent effects on hepatic triglyceride concentrations (Fig. 3). Casein and cod protein caused similar triglyceride levels in the liver,

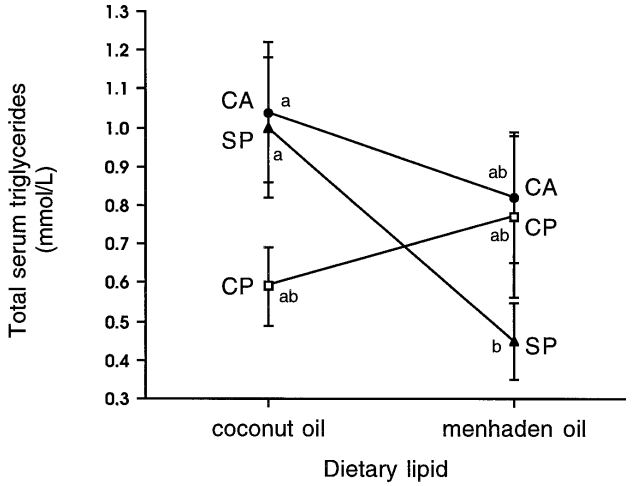

FIG. 1. Interaction between proteins and lipids in the regulation of total serum triglycerides (n = 9–10 rats per dietary group; P = 0.046) of rats fed the purified diets in the fasted state. CA = casein; SP = soy protein; CP = cod protein. Groups bearing different letters were significantly different at $P < 0.05$.

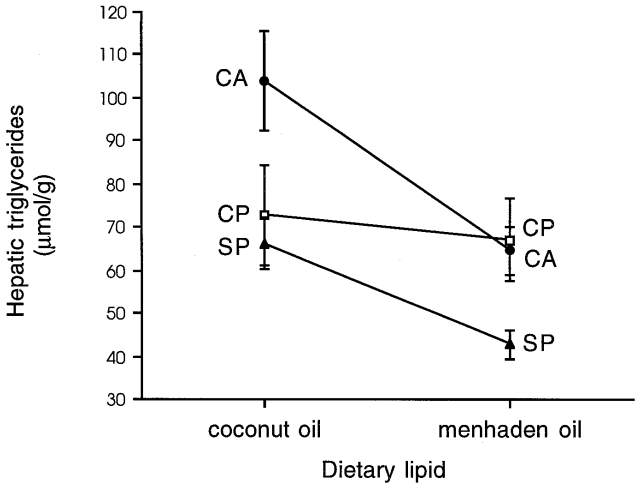

FIG. 3. Main protein and lipid effects on hepatic triglycerides of rats fed the purified diets in the fasted state (n = 9–10 rats per dietary group). P value for protein effect = 0.009, CA > SP, CA = CP, CP = SP; P value for lipid effect = 0.005, CO > MO; P value for protein–lipid interaction = 0.2. See Figure 1 for abbreviations.

but casein induced higher triglyceride concentrations than soy protein. The lipid effect was attributed to a diminution of hepatic triglycerides after menhaden oil compared to coconut oil feeding. Menhaden oil, compared with coconut oil, induced a greater diminution of hepatic triglyceride content when combined with casein (38%) and soy protein (34%) than when combined with cod protein (13%).
