LPL activity. Table 5 shows LPL activity in epididymal adipose tissue, VLM, and heart of fasted and fed rats. In fasted rats, LPL activity in epididymal fat and VLM was modulated by significant protein effects. Total LPL activity in epididymal fat, expressed as µU/tissue, was higher following cod protein consumption than after casein or soy protein feeding. In the VLM, casein feeding induced higher LPL activities than either soy protein or cod protein feeding. No lipid or protein effect and no protein–lipid interaction was observed in the heart in fasted rats. However, in fed rats, the only significant effect was a lipid effect in the heart: LPL activity was higher when coconut oil was replaced by menhaden oil.

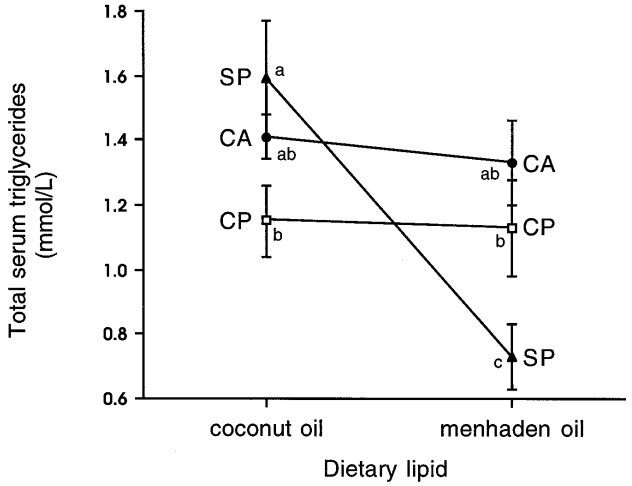

FIG. 2. Interaction between proteins and lipids in the regulation of total serum triglycerides (n = 9–10 rats per dietary group; P = 0.003) of rats fed the purified diets in the fed state. Groups bearing different letters were significantly different at $P < 0.05$. See Figure 1 for abbreviations.

Serum insulin and glucose. Serum insulin and glucose levels of fasted and fed rats are presented in Table 6. No significant effect of diet was observed on serum insulin or glucose levels. Pearson's correlation coefficients between insulin levels and total LPL activity in tissues were also calculated. LPL activity in epididymal adipose tissue was positively correlated with serum insulin levels in the fed state (n = 59, r = 0.38, P = 0.006), but no such correlation was seen in the fasted state (n = 59, r = 0.08, P = 0.58). Variations of insulinemia could explain about 14% (r^2 = 0.14) of variations of LPL activity in this tissue. No significant correlations were seen between LPL activity in VLM of fed rats (n = 59, r = 0.23, P = 0.09) and heart of fasted rats (n = 59, r = –0.23, P = 0.08) and serum insulin levels. Variations of insulinemia could explain only 4% (r^2 = 0.04) of variations of LPL activity in these tissues. There were no correlations between LPL activity in VLM of fasted rats (n = 59, r = –0.07, P = 0.63) and heart of fed rats (n = 59, r = 0.05, P = 0.71) and serum insulin levels.

DISCUSSION

The present study shows that dietary proteins and lipids affected serum cholesterol independently but induced interactive effects on serum triglycerides, resulting in a diminution of serum triglycerides when menhaden oil was combined with soy protein but not with either casein or cod protein. These results emphasize the importance of nutrient interactions in determining plasma lipid profiles and potential risks for cardiovascular disease. It appears from this study that dietary proteins modulate the effects of menhaden oil on serum

triglycerides and that could be related to specific alterations in hepatic cholesterol and triglyceride concentrations. This concept is in good agreement with the results reported by Ikeda *et al*. (26), showing that the effects of dietary lipids on lipid metabolism may be modulated by the origin of dietary proteins in rats. Indeed, in their study, plasma and hepatic triglycerides were lower in hypercholesterolemic rats fed perilla oil (high in α-linolenic acid) than in those fed safflower oil (high in linoleic acid), and these effects were more pronounced with casein than with soy protein.

In the present study, although the fatty acid composition of coconut oil and menhaden oil differs greatly, no significant difference occurred in weight gain between the six dietary groups, either in the fasted or in the fed state. The linoleic acid requirement for growing rats is 1–2% of total calories (27), and the coconut oil and menhaden oil diets provided 1.60 and 1.67% of total calories from linoleic acid, respectively, therefore preventing a deficiency in linoleic acid in our dietary groups. However, the coconut oil diets contained only 0.1 g of α-linolenic acid/kg diet, which is lower than the minimal requirement for adult rats (1.3 g/kg diet) (28), while the menhaden oil diets provided 2 g of α-linolenic acid/kg diet. Nevertheless, a deficiency in α-linolenic acid is characterized in the rat by abnormal electroretinogram and impaired vision, but not by growth retardation, skin lesions, or fatty liver as is observed in linoleic acid deficiency (29). Consequently, the lower α-linolenic acid content of coconut oil diets in comparison with menhaden oil diets did not influence weight gain of rats, and the effects of diets on lipid variables in the present study can be attributed to the origin of dietary proteins and lipids.

The lowering effect of soy protein on serum and hepatic cholesterol we observed when compared with casein is in good accordance with the earlier findings of Hurley *et al.* (15) and Saeki and Kiriyama (30). Choi *et al*. (31) also found lower hepatic cholesterol concentrations after feeding soy protein in comparison with casein, when sardine oil was the

lipid source. The mechanism for the hypocholesterolemic effect of soy protein may involve a reduction in intestinal cholesterol and bile acids (32) absorption, which leads to an increased excretion of neutral steroids and bile acids in feces (32,33), a reduction in hepatic cholesterol concentrations (32), and a rise in the activity of apolipoprotein B/E receptors (32,33). Lower plasma insulin concentrations and insulin/glucagon ratio following soy protein feeding instead of casein feeding (32,33) may be implicated in these effects. However, the exact role of the soy protein constituents in the regulation of lipid metabolism is not clearly defined. Both the essential amino acids and nonessential amino acid components of soy protein may account for its effects on serum and hepatic lipids. One of the postulated mechanisms is that the lower lysine/arginine ratio of soy protein compared with that of casein may influence lipid metabolism by modulating serum concentrations of hormones, such as insulin and glucagon (34), and in turn the activity of specific enzymes involved in the lipolysis or the cholesterol and triglyceride synthesis. Indeed, Sugano *et al*. (35) showed that, in rats, serum glucagon levels increased proportionately with increasing amounts of arginine added to casein.

In the present study, cod protein induced a hypocholesterolemic effect similar to that of soy protein compared with casein in the fasted state. These results are in good agreement with those previously observed in rats (15,36). However, in this study hepatic cholesterol in rats fed cod protein was significantly different, being intermediate to hepatic cholesterol in rats fed casein and soy protein. Other studies in rats showed significantly higher hepatic cholesterol concentrations after cod protein feeding compared with soy protein feeding, but cod protein and casein did not induce statistically different effects in these studies (15,36). As with soy protein, it has been postulated that the lower lysine/arginine ratio of cod protein when compared with casein may have played a role in the hypocholesterolemic effect of cod protein (37). On the other hand, cod protein is rich in essential amino acids, and contains more lysine and methionine than casein and soy protein (38). These differences in amino acid content may be involved in the divergent effects of cod protein in comparison to soy protein and casein on hepatic cholesterol concentrations and other lipid parameters.

The hypotriglyceridemic impact of fish oil consumption is well documented. The n-3 long-chain polyunsaturated fatty acids present in fish oil decreased plasma triglyceride concentrations in a number of clinical (3,4) and rat (5,6,20) studies. Specifically the effects of n-3 polyunsaturated fatty acids appear to be attributed to a reduction of hepatic triglyceride synthesis (5,7) with impairment of VLDL assembly and secretion (6). Also the high polyunsaturated to saturated fatty acid (P/S) ratio of fish oil can contribute to the reduction of plasma triglycerides. Indeed, a diet rich in n-6 polyunsaturated fatty acids with a high P/S ratio (P/S ratio = 1.4) provoked a hypotriglyceridemic effect as compared to a diet rich in saturated fatty acids (P/S ratio = 0.07) (39). However, with the same P/S ratio (P/S ratio = 1.39), a diet rich in n-3 polyunsaturated fatty acids induced significantly lower triglyceride concentrations than a diet rich in n-6 polyunsaturated fatty acids (P/S ratio = 1.4) (39), showing that n-3 polyunsaturated fatty acids lower triglycerides by themselves, and not only by increasing the P/S ratio.

The present results demonstrate for the first time that the effects of fish oil on serum triglycerides can be modulated by dietary proteins. The lowering effect of fish oil on serum triglycerides is observed only when menhaden oil is combined with soy protein and is accompanied by a 34% diminution of hepatic triglyceride concentrations in fasted rats, strongly suggesting that the reducing effect of SPMO on serum triglycerides could be the result of a diminution of hepatic triglyceride synthesis and secretion into the blood. In the presence of coconut oil, soy protein already induced lower hepatic cholesterol and triglyceride concentrations than casein, confirming previous data obtained in rats by Terpstra *et al*. (40) and Hurley *et al*. (15) on hepatic cholesterol and by Iritani *et al*. (13) on hepatic triglycerides. The combination of soy protein plus menhaden oil accentuated the reducing effect of menhaden oil on hepatic triglycerides, suggesting that soy protein has an additive effect with fish oil on hepatic triglycerides, resulting in a greater diminution of serum triglycerides. Notably, the observation that LPL activity in the heart was inversely correlated with serum triglycerides in both fasted ($n = 59$, $r = -0.31$, $P = 0.02$) and fed ($n = 59$, $r = 0.34$, $P = 0.01$) rats suggests a relationship between triglyceride hydrolysis rate in the heart and serum triglyceride levels. However, the increase of LPL activity in the heart when rats were fed menhaden oil could explain only 10% of the diminutions of serum triglyceride levels ($r^2 = 0.096$ and 0.11 for fasted and fed rats, respectively), thereby contributing slightly to the lowering effects of SPMO diet on serum triglycerides. Baltzell *et al*. (7) also observed an increase in heart LPL activity in rats after a diet containing fish oil, compared with a diet containing corn oil, but there was no correlation with plasma triglyceride levels. In this study, no correlations were observed between LPL activity in epididymal fat or VLM and serum triglycerides.

The hypotriglyceridemic effect of fish oil was not reproduced in the fasted and fed states when combined with casein and cod protein. Menhaden oil combined with casein reduced only slightly and not significantly serum triglycerides by 21% in the fasted state and 6% in the fed state, despite a 38% reduction of hepatic triglycerides. These effects could result from a decrease in triglyceride synthesis in the liver without a concomitant reduction in the rate of triglyceride secretion from the liver to the blood. According to Lewis (41), both cholesterol ester and triglyceride hepatic content appear to be important in the regulation of VLDL secretion. Avramoglu *et al*. (42) showed that VLDL secretion correlates better with total mass of cholesterol ester within HepG2 cells than with the mass of intracellular triglycerides, and not only with newly synthetized cholesterol esters but also with stored cholesterol esters. Consequently, it is possible that the unchanged hepatic cholesterol content following menhaden oil compared

to coconut oil in combination with casein could have prevented a reduction of hepatic VLDL triglyceride secretion into the blood and maintained unchanged serum triglyceride concentrations.

The combination of menhaden oil plus cod protein provoked no reducing effect on serum triglycerides in fasted rats. The lack of a hypotriglyceridemic effect of menhaden oil with cod protein could be partly related to the low reducing effect of menhaden oil on hepatic triglycerides (13%) when combined with cod protein. According to Lewis (41), the supply of fatty acids to the liver is dependent not only on dietary fatty acids and *de novo* lipogenesis but also on endogenous free fatty acids released from fat stores in peripheral tissues and by lipolysis of circulating triglyceride-rich lipoproteins. In the present study, higher fasting LPL activity in epididymal fat tissue was shown in rats fed cod protein than in rats fed casein and soy protein. Similarly, higher plasma postheparin fasting LPL activity was observed in rabbits fed cod protein compared with those fed soy protein (18). These facts support the concept that cod protein enhances the supply of fatty acids to the liver from an increased intravascular lipolysis, attenuating the reducing effect of menhaden oil on hepatic VLDL triglyceride assembly and secretion into the blood. Further studies are now necessary to verify the rates of synthesis and secretion of triglycerides from the liver when rats are fed casein, cod protein, and soy protein in the presence of menhaden oil.

In contrast to the interactions outlined above was the lack of a serum insulin and glucose response to the diets. Our inability to detect insulin differences between diets in this study may be partly attributed to the high variability of insulin values in rats fed menhaden oil. Also, in rats, insulinemia reaches a peak in the postprandial state at 30 min to 1 h after the meal, and insulin determination was done in this study at only one time point, 2.5 h after the meal, not allowing under these conditions a complete investigation of insulin response. Thus, fasting and postprandial insulinemia in the present study do not seem to be responsible for the interaction of dietary proteins and lipids on triglyceridemia. A modulation of the hypotriglyceridemic effect of fish oil by dietary proteins through a regulation of LPL activity by plasma insulin levels was not observed in the present study.

In conclusion, the above results show that there are interactions between dietary proteins and lipids in the regulation of serum triglyceride levels in the rat. Indeed, soy protein enhanced the hypotriglyceridemic effect of fish oil, whereas casein and to a greater extent cod protein dampened it. The present results suggest that dietary proteins can modulate the effects of fish oil on serum triglyceride concentrations through hepatic cholesterol and triglyceride concentrations. The role of insulin levels in this modulation is still unclear. Further studies to determine the rates of synthesis and secretion of triglycerides, and the overall response of insulinemia and triglyceridemia by repeated measures in the postprandial state, would be of help to clarify the mechanisms by which dietary proteins modulate the hypotriglyceridemic effect of fish oil.

Carnitine Palmitoyltransferase I, Carnitine Palmitoyltransferase II, and Acyl-CoA Oxidase Activities in Atlantic Salmon (*Salmo salar*)

Livar Frøyland[a,*], Lise Madsen[b], Karen M. Eckhoff[a], Øyvind Lie[a], and Rolf K. Berge[b]

[a]Institute of Nutrition, Directorate of Fisheries, N-5002 Bergen, Norway, and [b]Department of Clinical Biochemistry, University of Bergen, Haukeland Hospital, N-5021 Bergen, Norway

ABSTRACT: Salmon farmers are currently using high-energy feeds containing up to 35% fat; the fish's capability of fully utilizing these high-energy feeds has received little attention. Carnitine is an essential component in the process of mitochondrial fatty acid oxidation and, with the cooperation of two carnitine palmitoyltransferases (CPT-I and CPT-II) and a carnitine acylcarnitine transporter across the inner mitochondrial membrane, acts as a carrier for acyl groups into the mitochondrial matrix where β-oxidation occurs. However, no reports are available differentiating between CPT-I and CPT-II activities in fish. In order to investigate the potential for fatty acid catabolism, the activities of key enzymes involved in fatty acid oxidation were determined in different tissues from farmed Atlantic salmon (*Salmo salar*), i.e., acyl-CoA oxidase (ACO) and CPT-I and CPT-II. Malonyl-CoA was a potent inhibitor of CPT-I activity not only in red muscle but also in liver, white muscle, and heart. By expressing the enzyme activities per wet tissue, the CPT-I activity of white muscle equaled that of the red muscle, both being >> liver. CPT-II dominated in red muscle whereas the liver and white muscle activities were comparable. ACO activity was high in the liver regardless of how the data were calculated. Based on the CPT-II activity and total palmitoyl-L-carnitine oxidation in white muscle, the white muscle might have a profound role in the overall fatty acid oxidation capacity in fish.
Lipids 33, 923–930 (1998).

Fatty acid β-oxidation occurs in two distinct organelles, i.e., peroxisomes and mitochondria. Mitochondria and peroxisomes are vital for sustaining life, but these organelles have evolved with distinct metabolic features. Fatty acid β-oxidation in peroxisomes, like mitochondria, generates acetyl-CoA through successive steps of dehydrogenation, hydration, and thiolytic cleavage. In contrast to mitochondrial β-oxidation, the first dehydrogenation step involves the reduction of O_2 to H_2O_2 by acyl-CoA oxidase, whereas in mitochondria the second dehydrogenation step reduces NAD^+ to NADH (1). The peroxisomal β-oxidation sequence, which is not coupled to a phosphorylating system, is not inhibited by cyanide (1). Mitochondrial β-oxidation of fatty acids is thought to be essentially complete, whereas this seems not to be the case in peroxisomes (2). Mitochondria are more abundant than peroxisomes in most animal cells and under normal conditions oxidize more than 90% of long-chain fatty acids (3).

The processes of lipid catabolism are less well known in fish (4,5), but teleosts, like higher vertebrates, store a considerable proportion of their triacylglycerol (TG) in a discrete abdominal tissue (6) and in adipocytes which are distributed throughout the muscle myosepta (7–9). In addition, a lipase which degrades long-chain TG occurs in red and white muscles of fish (10). During starvation, ketone bodies, but not nonesterified fatty acids, are an important fuel for muscle in elasmobranchs, whereas nonesterified fatty acids, but not ketone bodies, are an important fuel in teleosts (11,12). Both mitochondria and peroxisomes show a broad chain-length specificity of hepatic β-oxidation of fatty acids in fish (13–15). In an Antarctic fish (*Notothenia gibberifrons*) and another teleost (*Myoxocephalus octodecimspinosus*), substrate selectivities were broader for peroxisomal β-oxidation than for mitochondrial β-oxidation and the peroxisomal β-oxidation system could account for up to 30 and 50% of total hepatic β-oxidation, respectively (16,17). In addition to the liver, red muscle (18,19) and heart (20) also possess a high capacity for the oxidation of fatty acids, whereas the kidney and particularly the white muscle (21) have a lower ability to oxidize fatty acids. Atlantic salmon fed L-carnitine revealed a higher capacity to β-oxidize [1-^{14}C]palmitic acid in both liver cubes and isolated hepatocytes (22). The muscle metabolic organization of salmonids undergoes seasonal variation (23), and during cold conditions (24–26) and spawning (27) an enhanced capacity for lipid oxidation occurs.

In general, the amount of fat in the fish feed is continuously rising, and today a normal commercial salmonid feed contains around 30–35% fat. However, no reports exist as to fish handling these high-fat diets and the effect it will have on fat deposition and/or fatty acid catabolism in different tissues. Another important aspect is that in most cases the capacity to β-oxidize fatty acids in different tissues is expressed per gram wet weight

Abbreviations: ACO, acyl-CoA oxidase (E.C. 1.3.3.6); BSA, bovine serum albumin; CPT-I, carnitine palmitoyltransferase I (E.C. 2.3.1.21); CPT-II, carnitine palmitoyltransferase II (E.C. 0.0.0.0); TG, triacylglycerol.

and/or per milligram protein (specific activity). The importance of considering tissue size was emphasized elsewhere (28–31); therefore, we have also presented the data per wet tissue. The aim of the present study was to study key enzymes involved in peroxisomal and mitochondrial β-oxidation in different tissues and to differentiate between carnitine palmitoyltransferase-I (CPT-I) and CPT-II activities in Atlantic salmon.

MATERIALS AND METHODS

Chemicals. [*N*-Me-^{14}C]L-carnitine was purchased from New England Nuclear (Boston, MA). 2′,7′-Dichlorofluorescein diacetate was obtained from Eastman Kodak Company (Rochester, NY). Palmitoyl-CoA, horseradish peroxidase, L-carnitine, and other cofactors were from Sigma Chemical Co. (St. Louis, MO). All other chemicals were of reagent grade and obtained from common commercial sources.

Fish. Five sexually immature adult Atlantic salmon (*Salmo salar*) weighing 4183 ± 687 g (69.6 ± 4.3 cm) were collected from Institute of Marine Research, Matre Aquaculture Research Center, Norway). The fish had been kept in net pens in the sea and fed a standard diet containing 29% lipid (Elite Granulat, T. Skretting A/S, Bergen, Norway). The protocol was approved by the Norwegian State Board of Biological Experiments with Living Animals (Bergen, Norway).

Preparation of tissue homogenates. When fully anesthetized (methomidate), the fish were killed by a blow to the head; and the liver and heart were removed, weighed, and homogenized with an Ultra-Turrax T25 to 20% (wt/vol) in ice-cold sucrose solution containing 0.25 M sucrose in 10 mM HEPES buffer and 1 mM EDTA, pH 7.4. Red muscle was sampled from one side of the fish and dissected free from skin, subdermal lipid, and underlying white muscle. White muscle was sampled on the same side directly below the dorsal fin toward the vertebral column. Red and white muscles were weighed and homogenized as described above. The resulting total homogenates were then centrifuged (1880 × *g* for 10 min at 2°C). The resulting postnuclear fraction (E-fraction) was collected, and some portions were used immediately to determine CPT-I activity. Other aliquots were stored at −80°C until analyzed.

Lipid analysis. Tissue lipids were determined in the E-fractions by enzymatic colorimetric methods. TG and cholesterol were determined according to Technicon Method no. SA4-0324L90 (32) and Technicon Method no. SA4-0305L90 (33) (Technicon Instruments, Tarrytown, NY), respectively. Phospholipids were measured by the method of bioMérieux (Marcy-l'Etoile, France) (34).

Enzyme activities. Fatty acid oxidation was determined in the E-fractions as acid-soluble products using [1-^{14}C]palmitoyl-L-carnitine as substrate (35). All samples were preincubated for 2 min at the different temperatures used before adding the substrate. After incubation for 10 min, oxidation was stopped by addition of 150 µL 1.5 M KOH; 25 µL fatty acid-free bovine serum albumin (BSA) (100 mg/mL) was then added to the suspension in order to bind nonoxidized substrate. Next, 500 µL of 4 M $HClO_4$ was added to precipitate nonoxidized substrates bound to BSA. The total solution was then centrifuged at 1880 × *g* for 10 min at 2°C. Aliquots of 500 µL were assayed for radioactivity.

The rate-limiting enzyme in peroxisomal β-oxidation, acyl-CoA oxidase (ACO) (E.C. 1.3.3.6), was determined according to Small *et al*. (36). Oxidation of 2′,7′-dichlorofluorescein diacetate was monitored by following the increase in A_{502} for 7 min after the samples had been preincubated for 3 min at the different temperatures used. CPT-I (E.C. 2.3.1.21) and CPT-II (E.C. 0.0.0.0) activities were measured essentially as described by Bremer (37). CPT-I is deeply anchored on the outer mitochondrial membrane and loses activity upon exposure to detergents but is stabilized by BSA (38,39). Briefly, the assay medium for CPT-I contained 70 mM KCl, 5 mM KCN, 100 µM palmitoyl-CoA, 10 µL BSA (10 mg/mL), 600 µg tissue protein, and 20 mM HEPES, pH 7.5. The reaction was started with 200 µM [*N*-Me-^{14}C]L-carnitine (1000 dpm/nmol). When included, malonyl-CoA (5 µM) was added to the assay mixture 15 min prior to the start of the reaction. CPT-II, which is localized on the inner surface of the inner mitochondrial membrane, is readily released by a variety of detergents (38,39). Assay conditions for determining CPT-II activity were identical except that BSA was omitted, 0.01% Triton X-100 was included, and the amounts of tissue protein were 400 µg (white muscle), 40 µg (red muscle), and 100 µg (heart and liver). The reaction was stopped with 1 mL 1 N HCL, and water-saturated 1-butanol was added to extract the product, i.e., palmitoyl-[^{14}C]carnitine. Aliquots were assayed for radioactivity on an LKB Wallac 1219 Rackbeta liquid scintillation counter. All enzyme assays were run in duplicate and performed under conditions where product formation was linear with respect to both the time of incubation and the amount of protein. Protein was determined using the Bio-Rad protein kit (Bio-Rad, Richmond, CA).

RESULTS

The fatty acid oxidation capacity and enzyme activities increased in all tissues with increasing assay temperatures but were practically not detectable at 50°C. The reason for this is probably that the organelle membranes had disintegrated, and the enzymes to some extent were denatured.

The mass of the different tissues is given in Table 1. Lipids and protein content of the E-fractions are shown in Table 2.

TABLE 1
Tissue Mass and Percentage of Body Mass[a]

Tissue	Mass (g)	Body mass (%)
Heart	5.1 ± 1.2	0.1
Liver	40.3 ± 8.4	1.0
Red muscle[b]	209 ± 34	5.0
White muscle[b]	2510 ± 412	60.0

[a]Tissue values are means ± SD, $n = 5$.
[b]Red and white muscle mass in Atlantic salmon were derived from the assumption that they occupy 5 and 60% of the total body mass, respectively (Ref. 64).

TABLE 2
Lipids and Protein Content in E-fractions from Various Organs[a]

Organ	Protein (mg/g tissue)	Triacylglycerol (μmol/g tissue)	Cholesterol (μmol/g tissue)	Phospholipids (μmol/g tissue)
Heart	28.7 ± 3.1	3.6 ± 0.8	2.1 ± 0.3	3.7 ± 0.5
Liver	94.4 ± 8.5	5.6 ± 1.4	4.9 ± 0.8	15.4 ± 2.2
Red muscle	20.3 ± 1.5	16.8 ± 5.9	1.4 ± 0.2	3.7 ± 0.4
White muscle	36.1 ± 4.9	16.0 ± 4.8	1.8 ± 0.2	2.1 ± 0.5

[a]All values are means ± SD, $n = 5$.

The amount of TG was high in muscle, whereas the liver contained high levels of cholesterol and especially phospholipids. In addition, the protein content of liver was *ca.* threefold higher than the other tissues.

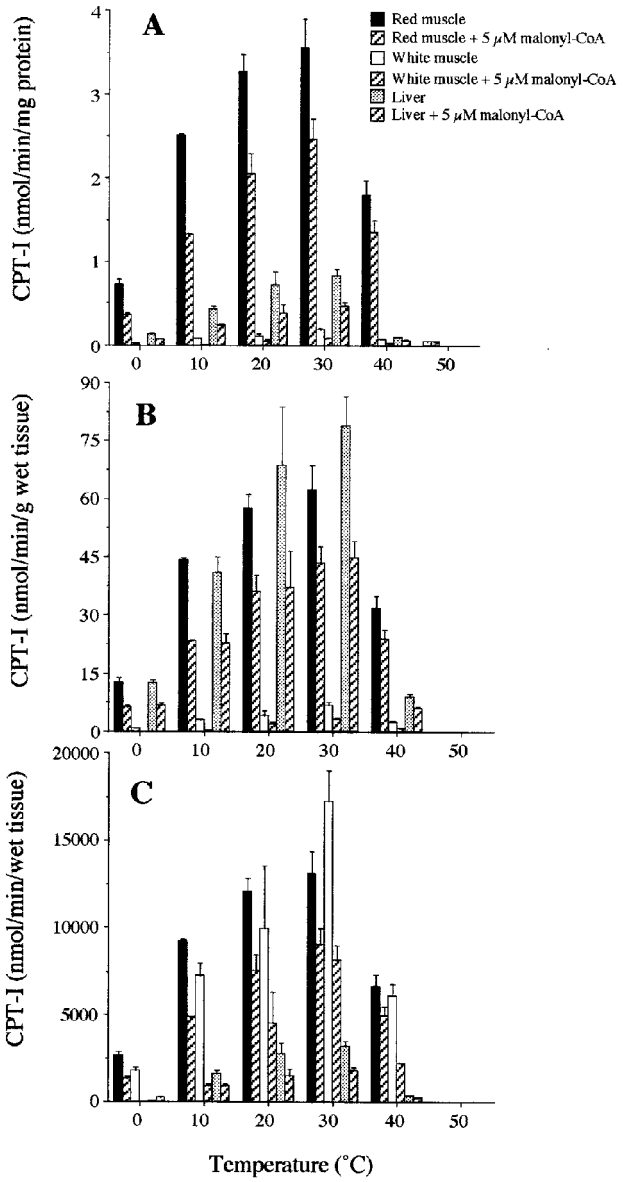

FIG. 1. Activity of carnitine palmitoyltransferase I (CPT-I) in different tissues of Atlantic salmon with varying assay temperatures. The results are expressed per milligram protein (A), per gram wet tissue (B), and per wet tissue (C). The values represent means ± SD ($n = 5$).

Figure 1 shows CPT-I activities in different tissues with varying assay temperatures. In panels A–C the CPT-I activity is expressed as nmol/min/mg protein (specific activity), nmol/min/g wet tissue, and nmol/min/wet tissue, respectively. Increased CPT-I activities with increasing temperature with a maximum at 30°C were observed for all tissues, and CPT-I was malonyl-CoA-sensitive. Above 30°C the enzyme activity declined and at 50°C no enzyme activity could be detected. The order of CPT-I activities in different tissues was red muscle >> liver > white muscle. If the results are calculated as nmol/min/g wet tissue, the CPT-I activity in liver equaled that of red muscle, whereas both were much greater than white muscle (panel B). However, by calculating the enzyme activity as nmol/min/wet tissue, a completely different picture emerged (panel C). The total enzyme activity in white muscle equaled that in red muscle and both were much greater than in liver.

Figures 2 to 4 are presented in the same manner as Figure 1. Figure 2 shows that CPT-II activity dominated in red muscle when expressed as specific activity, and the CPT-II activities in liver and heart were much greater than that of white muscle at all temperatures (panel A). As for CPT-I, the CPT-II activity in liver equaled that of red muscle when calculated as nmol/min/g wet tissue (panel B). The total CPT-II activity dominated in red muscle, whereas no differences were observed in liver and white muscle (panel C). The order of activity of the key enzyme in peroxisomal β-oxidation, i.e., acyl-CoA oxidase (ACO), was liver >> red and white muscle and heart (Fig. 3).

Figure 4 shows the fatty acid oxidation measured as acid-soluble products in E-fractions with palmitoyl-L-carnitine as a substrate. The total oxidation of palmitoyl-L-carnitine was highest in red muscle when calculated as nmol/min/mg protein (panel A) or as nmol/min/wet tissue (panel C). If the data are calculated as nmol/min/g wet tissue, the activities in liver equaled that of red muscle (panel B).

DISCUSSION

The heart, liver, and especially the red muscle, but not white muscle, are generally accepted as the most important tissues involved in fatty acid oxidation in fish (4,5,20).

In the present study we analyzed the rate of key enzymes involved in mitochondrial and peroxisomal β-oxidation of fatty acids in different tissues from Atlantic salmon. Enzyme activities are normally expressed per gram wet mass or per

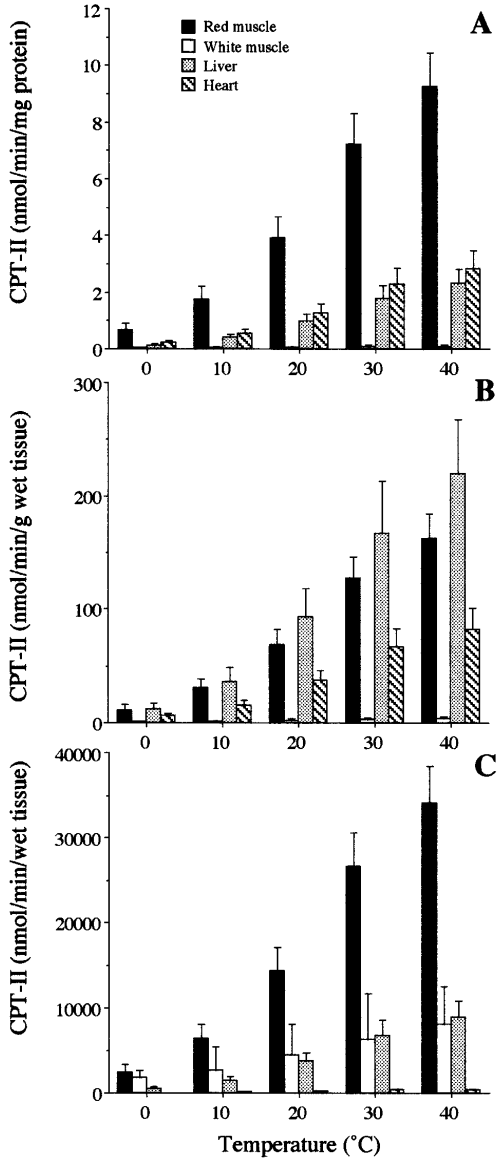

FIG. 2. Activity of carnitine palmitoyltransferase II (CPT-II) in different tissues of Atlantic salmon with varying assay temperatures. The results are expressed per milligram protein (A), per gram wet tissue (B), and per wet tissue (C). The values represent means ± SD (n = 5).

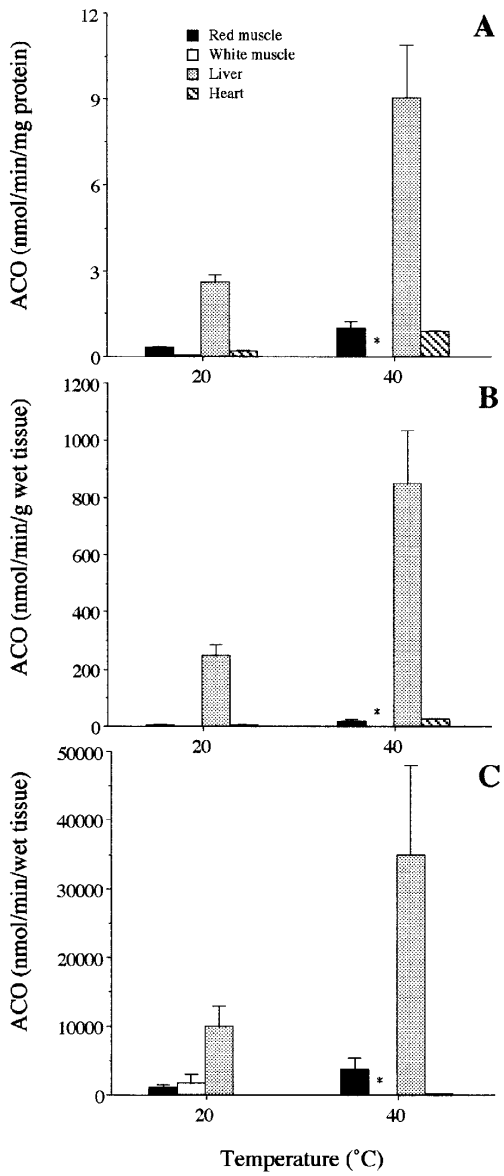

FIG. 3. Activity of acyl-CoA oxidase (ACO) in different tissues of Atlantic salmon with two assay temperatures. The results are expressed per milligram protein (A), per gram wet tissue (B), and per wet tissue (C). The values represent means ± SD (n = 5). *Denotes not determined. The reason for this was that the assay mixture at 40°C became cloudy and led to an unaccounted for unspecific activity.

milligram protein (specific activity), but we have included the rates per wet tissue, i.e., per organ of fish based on the information given in Table 1.

CPT has a wide distribution in the animal kingdom, and the concentration of the enzyme seems to be correlated to the metabolic activity of the animal (40). CPT-I and its sensitivity toward malonyl-CoA, an intermediate in fatty acid synthesis, are believed to regulate hepatic fatty acid oxidation and ketogenesis (41,42). Rodnick and Sidell (43) reported that CPT-I in red muscle of striped bass (*Morone saxatilis*) was malonyl-CoA-sensitive, a fact never before shown in Atlantic salmon. No data differentiating CPT-I and CPT-II activities from any fish have been published. Figure 1 shows that CPT-I was sensitive toward malonyl-CoA in all tissues analyzed, indicating that the fatty acid synthesis and fatty acid oxidation are regulated in the same manner as in mammalian tissues.

The liver contains about three times more protein as the other tissues (Table 2). This is reflected when the enzyme activities of hepatic CPT-I and CPT-II are expressed per gram wet tissue as the hepatic activities equaled that of red muscle (Figs. 1 and 2). In contrast, when hepatic CPT-I and CPT-II activities are expressed per milligram protein or per wet tissue, they do not reach the level of red muscle (Fig. 1).

Another interesting finding was observed when enzyme activities were expressed per wet tissue as the CPT-I activity

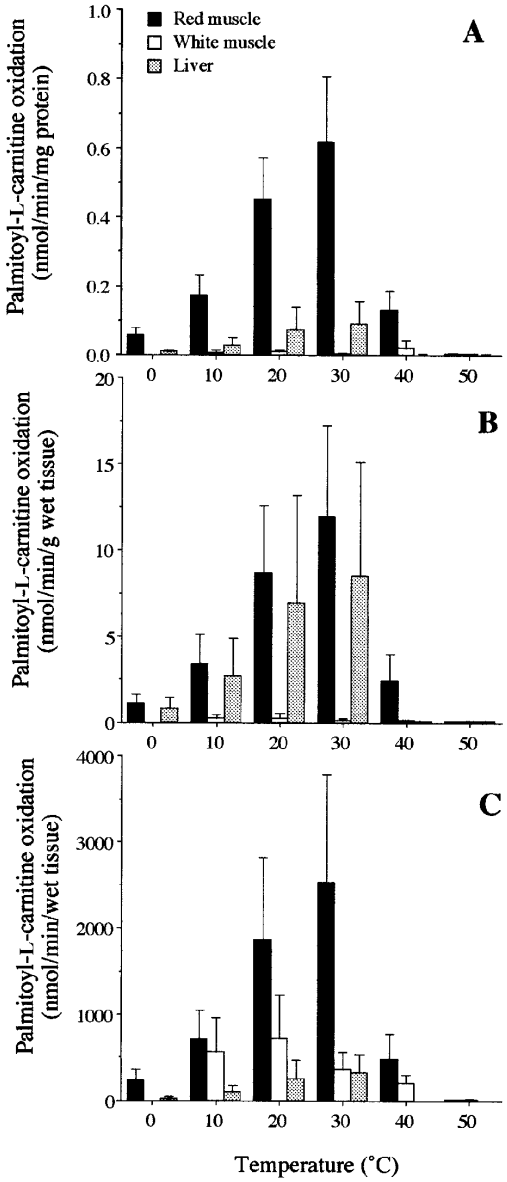

FIG. 4. Oxidation of palmitoyl-L-carnitine in different tissues of Atlantic salmon with varying assay temperatures. The results are expressed per milligram protein (A), per gram wet tissue (B), and per wet tissue (C). The values represent means ± SD (n = 5).

of white muscle was of the same magnitude as for red muscle (Fig. 1), whereas the CPT-II activity was much lower and comparable to the liver (Fig. 2). Importantly, CPT-I and CPT-II activities are found not only in mitochondria but also in other organelles, e.g., peroxisomes and microsomes (44,45). However, the role of CPT-II in other organelles remains uncertain (46,47), whereas mitochondrial CPT-II is involved in the process of β-oxidation, i.e., generates acyl-CoA from acylcarnitines in the mitochondrial matrix (Fig. 5).

By comparing Figure 2 with the oxidation of palmitoyl-L-carnitine (Fig. 4), which must be converted to acyl-CoA by CPT-II before it can undergo β-oxidation (Fig. 5), this study indicates that CPT-II activity in Atlantic salmon reflects the capacity of mitochondrial fatty acid oxidation and involvement of L-carnitine in mitochondrial long-chain fatty acid oxidation. In addition, adding L-carnitine to isolated mitochondria stimulated the oxidation of fatty acids in rainbow trout (*Salmo gairdneri*) (20), and supplementation of L-carnitine to Atlantic salmon led to an increased fatty acid oxidation capacity (22). Furthermore, accelerated growth and reduced body fat were reported for hatchery-reared sea bass (*Dicentrarchus labrax*) (48,49) and African catfish (*Clarias gariepinus*) (50) fed carnitine.

The peroxisomal ACO activity dominated in liver regardless of how the results are expressed. Thus this organ has a high capacity for peroxisomal β-oxidation, whereas red and white muscles seem to possess a limited ACO activity (Fig. 3).

The rate of key enzymes involved in the fatty acid oxidation system and the interpretation of their possible role in the metabolic pathways depend on how the data are expressed (51). After comparing the rate of palmitoyl-L-carnitine oxidation in red muscle from Atlantic salmon with hepatic fatty acid oxidation of palmitoyl-L-carnitine from other species, evidently this tissue possesses a high capacity to oxidize fat (Table 3).

In fish muscle, lipids exist in two forms: neutral lipids (TG) in lipid droplets distributed in cell cytoplasm as local energy stores and polar lipids (phospholipids) serving as major components of the cell membrane. Atlantic salmon stores most of its reserve of lipids (TG) in the muscle instead of the liver (54,55). Histological studies revealed that approximately 40% of white muscle TG was stored in myosepta, whereas the remaining 60% was localized to the perimysium (56–58), which is the connective tissue surrounding a bundle of muscle fibers. Involvement of white muscle in the higher range of sustained cruising speeds of active species was suggested by several authors (59–61). Moreover, the white muscle of pelagic species is functionally and structurally adapted for sustained aerobic activity with relatively abundant mitochondria being preferentially situated close to the source of gas and metabolite exchange (62,63). This is interesting as more than 60% of the total body mass of Atlantic salmon is composed of white muscle (64); thus, the overall metabolic capacities of this tissue might have been underestimated up to now.

Currently, salmon feed usually contains 30–35% fat, but with improving technology the amount of fat in salmon feed will most likely increase to 40–45%. Are salmon capable of metabolizing this added dietary fat? Moreover, how will different fat (oil) sources affect fat deposition vs. catabolism, i.e., storage or energy utilization? Results from a relatively limited number of studies performed on mitochondrial β-oxidation in fish suggest that a substrate preference exists (for review see Ref. 5); thus, the importance of selecting the right fat (oil) source with an optimal fatty acid composition for energy utilization becomes evident.

In conclusion, based on CPT-II activity and palmitoyl-L-carnitine oxidation, Atlantic salmon seem to possess a high capacity to utilize fat as an energy source. Mitochondrial β-

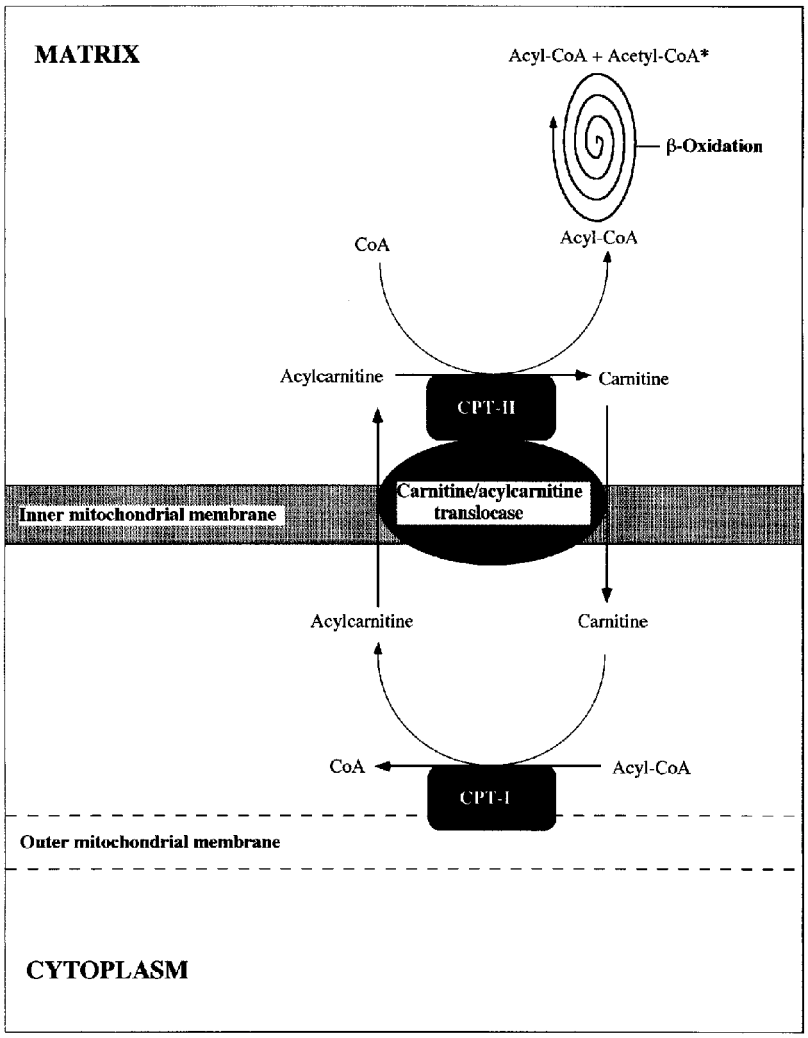

FIG. 5. Schematic presentation of the carnitine-dependent transfer of activated fatty acids (acyl-CoA esters) into mitochondria. CPT-I in the outer mitochondrial membrane converts acyl-CoA to acylcarnitine. This is a necessary step as acyl-CoA esters cannot penetrate the inner mitochondrial membrane. The outer membrane also contains the long-chain acyl-CoA synthetase (not shown). Carnitine/acylcarnitine translocase in the inner mitochondrial membrane exchanges acylcarnitine with carnitine. CPT-II on the inner surface of the inner mitochondrial membrane is responsible for the conversion of acylcarnitine to acyl-CoA. Acyl-CoA enters the β-oxidation sequence and leads to formation of acid-soluble products. *Denotes acid-soluble product. See Figures 1 and 2 for abbreviations.

TABLE 3
The Rate of Palmitoyl-L-Carnitine Oxidation Measured as Acid-Soluble Products in Different Species[a]

Species	Tissue	Palmitoyl-L-carnitine oxidation (nmol/min/mg protein)	Reference
Atlantic salmon	Red muscle	0.45[b]	
Hamster	Liver	0.41	35
Rabbit	Liver	1.47	52
Rat	Liver	0.22	53

[a]Values are expressed as means.
[b]Determined at 20°C, whereas the other values were measured at 30°C.

oxidation dominates in red muscle, but white muscle makes a significant contribution to the overall fatty acid oxidation capacity in fish.

Phospholipid Composition of the Granular Amebocyte from the Horseshoe Crab, *Limulus polyphemus*

Jennifer C. MacPherson[a], James G. Pavlovich[b], and Robert S. Jacobs[a,*]

[a]Marine Science Institute and [b]Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT: The phospholipid composition was determined for the amebocyte of the primitive arthropod *Limulus polyphemus*. The total fatty acid composition of the cells' lipids was analyzed by gas chromatography/mass spectrometry (GC/MS) of fatty acid methyl esters (FAME). The FAME analysis revealed high levels of 20-carbon polyunsaturated fatty acids (PUFA), especially arachidonic (20:4n-6) and eicosapentaenoic (20:5n-3) acids. Almost 20% of the total lipid profile was comprised of dimethyl acetals of 16- to 20-carbon chain lengths, indicative of plasmalogens in the phospholipid pool. Phospholipids, analyzed by high-pressure liquid chromatography, included phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI), sphingomyelin (SPH), and cardiolipin (CL). PE and PC levels predominated at 42.2 and 36.3%, respectively. Smaller amounts of PS (9.0%) and PI (6.2%) were present, as well as low levels of SPH (4.6%), CL (1.6%), and trace amounts of lysophosphatidylcholine. The major phospholipid species, PE, PC, PS and PI, were collected and their molecular species were examined by electrospray–ionization mass spectrometry. The molecular species within the phospholipid classes reflected the high levels of PUFA seen in the total lipid profile. PI was mainly composed of 18:0*a*/20:4. Over half of the PS consisted of 18:0*a*/18:1 and 18:0*a*/20:4. The major PE species were 20:1*p*/20:5, 20:1*p*/20:4, 18:0*p*/20:5, and 18:0*p*/20:4. PC had the largest distribution of molecular species, and its most abundant species were 16:0*e*/20:5, 16:0*e*/20:4, and 16:0*p*/20:4. The presence of 16:0*e*/20:4 is the first documentation of a specific precursor to platelet-activating factor in an invertebrate hemocyte. Note: at the *sn*-1 position: [*a* = 1=*O*-acyl, *e* = 1-*O*-alkylether, and *p* = 1-*O*-alk-1′-enyl (plasmalogen)].
Lipids 33, 931–940 (1998).

The horseshoe crab, *Limulus polyphemus*, serves as a unique model for studying the lipid chemistry of invertebrate blood cells. The majority of lipid analyses in arthropods have involved studies on whole animals, muscle tissue, or specific organs owing to constraints on organism size and the amounts of blood available (2,3). The presence of as many as six circulating blood cells in arthropods further complicates the isolation and analysis of an individual cell type (4). In horseshoe crabs, large quantities of blood are readily available and a single circulating blood-cell type, the granular amebocyte (5), is present. Moreover, *Limulus* is considered to be a living fossil with blood cells regarded as "primordial immunocytes" because they possess functions comparable to those found in vertebrate leukocytes, such as platelets, macrophages, and B- and T-lymphocytes (4). These vertebrate leukocytes are especially active during an immunological challenge brought on by injury or infection. The activation of these blood cells during an immune response is associated with the production of fatty acid metabolites, termed eicosanoids, which are primarily generated from unsaturated 20-carbon polyunsaturated fatty acids (PUFA) cleaved from the cell's phospholipid membrane, notably di-homo-γ-linoleic acid (20:3), arachidonic acid (AA) (20:4), and eicosapentaenoic acid (EPA) (20:5). The presence of these PUFA in specific phospholipid pools in the cell membrane also has been implicated in accelerating membrane fusion (6). The *Limulus* amebocyte produces eicosanoids (7), and its rapid degranulation in the presence of pathogens is well established (8,9). Therefore, a better understanding of the phospholipid composition, as well as the molecular species within each phospholipid class, will provide a framework for interpreting some of the functions of this primitive undifferentiated cell. In these studies, we will report the phospholipid composition of the *Limulus* granular amebocyte.

MATERIALS AND METHODS

Chemicals and materials. The chloroform, methanol, water, hexane, isopropanol, and acetone used to extract, fractionate, and separate lipids were Fisher Scientific high-pressure liquid chromatography (HPLC)-grade (Pittsburgh, PA). The benzene was Fisher A.C.S.-certified grade and the ethanol was 200-proof dehydrated alcohol, U.S.P. punctilious (Quantum

Chemical Co., Anaheim, CA). Phospholipid, cardiolipin (CL), and sphingomyelin (SPH) standards were obtained from Sigma (St. Louis, MO) and Avanti Polar Lipids (Alabaster, AL).

Horseshoe crabs. The horseshoe crabs were purchased from either Marine Biological Laboratories (Woods Hole, MA) or Gulf Specimens (Panacea, FL) and maintained in tanks with fresh, flowing seawater and fed fresh local mussels, *Mytilus galloprovincialis,* collected by university divers from local piers. Blood samples were obtained within 1 wk of the animals' arrival. Animals with a prosoma, the larger anterior portion of the horseshoe crab which is followed by the smaller posterior opisthosoma, of 15–20-cm width were used.

Cell isolation. Prior to blood collection, the animals were cooled at 4°C for at 1 h. The animals were bled *via* cardiac puncture at the prosoma–opisthosomic joint using a sterile 16.5-gauge needle. Aliquots of blood (15 mL) were collected into sterile, silanized 50-mL Pyrex centrifuge tubes containing 10 mL of ice-cold saline (3.0% NaCl, buffered to pH 4.6 with citrate and EDTA) (5). The cells were briefly spun in a clinical centrifuge at room temperature (300 × *g*). The plasma/buffer supernatant was decanted, and the lightly pelleted cells were washed by resuspending in 10 mL of sterile 3% NaCl. Duplicate blood samples were obtained from each animal: one sample was used for fatty acid methyl ester (FAME) analysis and the other was extracted for phospholipid analysis. FAME were prepared directly from freshly isolated amebocytes to expedite analysis of the total lipid.

FAME analysis. The amebocyte's total cellular fatty acids were saponified and derivatized directly by a four-step process (10–12). The blood cells were isolated and washed, as detailed above, and then transferred into a 10-mL Pyrex test tube with a Teflon-lined lid and pelleted in a clinical centrifuge at room temperature (300 × *g*). The supernatant was decanted; the cells were lysed, and the lipids were saponified by adding 2 mL of 3.75 M NaOH/MeOH (50:50, vol/vol) and by heating at 100°C for 30 min. Samples were cooled, and the free fatty acids were methylated with the addition of 3 mL of 6 N HCl/MeOH (65:55, vol/vol) and with heating at 85°C for 10 min. The samples were cooled and 1 mL of hexane/CH_2Cl_2 (50:50, vol/vol) was added. The tubes were inverted end-over-end for 3–5 min. The aqueous layer was removed and 3 mL of 0.3 M NaOH was added. The tubes were inverted end-over-end for 10 min. The upper organic layer was transferred to an amber vial. The samples were placed under nitrogen for either immediate analysis by gas chromatography/mass spectrometry (GC/MS) or stored at −35°C until analyzed.

GC/MS analysis. FAME samples were analyzed on a Hewlett-Packard 5790 gas chromatograph (Palo Alto, CA) coupled to a VG 70SE double-focusing mass spectrometer using a DB-5MS column, 30 m × 0.25 mm i.d. (J&W Scientific, Folsom, CA). A 1-μL aliquot of the FAME sample was injected. The DB-5 column was held at 50°C for 1 min, ramped to 125°C at 18°/min, and then ramped to 255°C at 3°/min. The sample chromatograms were compared to an authentic standard of mixed FAME (PUFA-2) (Matreya Inc., Pleasant Gap, PA) run under the same conditions as the samples. The mass spectra of the dimethyl acetal (DMA) peaks were compared with known spectra National Institute of Standards and Technology (NIST) library.

Lipid extraction and fractionation. The cells for the phospholipid analyses, isolated as described above, were transferred to a 15-mL, silanized Pyrex test tube with a Teflon-lined cap. The cells were pelleted, the supernatant was decanted and then the cells were resuspended in 1 mL of sterile 3% NaCl. The cells were extracted using a modification of Kates (13). A 3.75-mL aliquot of methanol/chloroform (2:1, vol/vol) was added to the cell solution. The samples were vortexed and placed on a rotary shaker for 2 h. The solution was centrifuged in a clinical centrifuge for 5 min, the supernatant was transferred to a new tube, and the pellet was reextracted in 4.75 mL of methanol/chloroform/water (2:1:0.8, by vol). The sample was centrifuged, as before, and the supernatant was pooled with the first extract. A 2.5-mL aliquot each of chloroform and water was added to the pooled extract. The samples were vortexed, centrifuged, and the lower aqueous layer was removed. An equal volume of benzene was added and samples were taken to dryness under N_2. The samples were immediately resuspended in chloroform/MeOH (4:1, vol/vol) and stored under N_2 at −35°C until fractionated.

The samples were dried and resuspended in chloroform before being fractionated on small silica columns in Pasteur pipets using Baker-analyzed 60–200 mesh silica gel (Phillipsburg, NJ). The columns were equilibrated in chloroform. The sample was applied to the column followed by 4 column volumes (8 mL) of chloroform to elute the neutral lipids, 16 column volumes (32 mL) of acetone to elute the glycolipids, and finally 4 column volumes (8 mL) of MeOH to elute the phospholipids and SPH. The fractions were dried down under N_2 and stored at −35°C until analyzed.

HPLC analysis of phospholipid classes. The phospholipid extracts were analyzed using the method developed by Patton *et al*. (14). The lipid classes were separated using a Hitachi 6200A HPLC (San Jose, CA) equipped with two Rainin Silica Microsorb-MV columns (Woburn, MA) in tandem (4.6 i.d. × 150 mm, 5 μm, 100 Å). The columns were preceded by an Upchurch precolumn packed with 30–40 μm PerisorbA (Oak Harbor, WA). The phospholipid peak elution was monitored at 205 nm. The separation was isocratic starting with a flow rate of 0.5 mL/min for the first 60 min and then increased to 0.8 mL/min for the remainder of the run (*ca*. 180 min). The solvent phase was water/1 M phosphate buffer (pH 7.4)/isopropanol/-hexane/EtOH/acetic acid (55:1.2:485:376:100:0.6, by vol). The peaks for each lipid class were collected. CL samples were pooled while phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), and SPH peaks were collected individually for electrospray–ionization/mass spectrometry (ESI/MS) analysis to determine their molecular species. Phosphate does not easily volatilize and therefore interferes with ESI/MS analysis. To avoid problems, samples were briefly taken to dryness under N_2 and reextracted to remove phosphate (13,15).

ESI/MS analysis of molecular species within each phospholipid class. The fatty acid composition of the major phospholipid classes (PE, PC, PS, and PI) was analyzed using a modification of Kim *et al*. (16). The phospholipid classes were separated on a Phenomenex C18 minicolumn (2.0 i.d. × 150 mm, 5 µm, 80Å) preceded by a 30-mm guard column of the same material using a Michrom BioResources UMA HPLC System (Auburn, CA) at a flow rate of 400 µL/m. The samples were separated using a starting solvent phase of 0.5% ammonium hydroxide in water/MeOH/hexane (12:88:0) for 3 min followed by a linear gradient to water/MeOH/hexane (0:18:12) over a 30-min period. The column was maintained at 20–25°C.

The solvent flow was split postcolumn (1:3, vol/vol), and 100 µL of the HPLC effluent was directed into the inlet of an ESI probe of a Fisons VG Platform II single quadrupole mass spectrometer (Micromass Ltd., Altrincham, United Kingdom). The ESI/MS was tuned daily by direct infusion of dipalmitoyl PC (positive-ion mode) or PI (negative-ion mode) (2 µM). The skimmer cone voltage was set during tuning for moderate fragmentation (−60 to −70 V in negative-ion and 40–50 V in positive-ion mode). The mass collection range was set between 100 and 1000 amu for all samples. Sample ions were generated using N_2 nebulization-assisted electrospray with a source temperature maintained at 80°C. All spectra were collected in total scan mode and subjected to background subtraction.

PI and PS samples were analyzed in negative-ion mode. PE and PC peaks were analyzed in both positive- and negative-ion modes. The negative-ion analyses of PE and PC were used to determine the fatty acids associated with the major molecular ions generated in the positive-ion mode. A phospholipid molecular ion can represent one, sometimes two, but rarely all three of the phospholipid subclasses (diacyl, alkylacyl, and alkenacyl). The molecular species of the major peaks were identified through examination of their mass spectra. The remaining molecular species listed were calculated based on the molecular ion and any available fragmentation data from the negative-ion spectra (1). The molecular ion usually represents the entire phospholipid, either $[M + H]^+$ or $[M - H]^-$, depending on the analysis mode, the exception being PC in negative-ion mode that displays a pseudomolecular ion of [M − 15], corresponding to a loss of a methyl group from the choline headgroup (17). Since the phospholipids were separated by class prior to ESI/MS, the headgroup is known and any free fatty acids present in the mass spectra are generated from ester linkages at the *sn*-1 or *sn*-2 position. The FAME/DMA profile in the GC/MS analyses was also used to predict the likely diacyl and alkenylacyl species present in each sample. In the more complicated phospholipid classes, PE and PC, published tables of the three subclasses (diacyl, alkylacyl, and alkenylacyl) were used to help determine the molecular species of the minor peaks (18). In these tables, the molecular ion is calculated based on *sn*-1 and *sn*-2 linkages, as well as the total number of carbons and double bonds present in these positions. Since the double bond in the vinyl linkage of alkylacyl lipids is considered part of the linkage, it is not counted as a double bond in these tables (15,18).

Analysis of smaller phospholipid peaks. The smaller peaks present in the HPLC phospholipid separation (CL and SPH) were screened to identify major species present. The samples were separated by HPLC in a manner similar to the major phospholipid classes. The mass range was set between 100 and 1000 amu, except for CL samples where the range was extended to 2000 amu. These samples were screened in both positive- and negative-ion modes.

RESULTS

GC/MS analysis of FAME. The chromatogram of the FAME revealed that almost half (46%) of the amebocyte fatty acid content consisted of two 20-carbon PUFA, AA, and EPA (Table 1). The next most abundant species were the saturated and monounsaturated 18-carbon fatty acids at 12.9 and 11.6%, respectively. DMA made up nearly 20% of the total lipid. DMA are formed by the acid methanolysis of phospholipids containing vinyl groups in ether linkages. Therefore, the DMA here indicate that a considerable portion of the phospholipids contains ether lipids with alkenyl groups at the *sn*-1 position of the phospholipids. The DMA profile in the amebocyte indicates that eicosene (20:1) was the most com-

[a]Values are the mean ± SEM, $n = 5$. Samples were derived from five separate individuals. Trace levels of fatty acid were considered to be less than 0.1%.
[b]This peak was a mixture of three molecular ions: 294, 310, and 312 amu.
DMA = dimethyl acetal; *i/ai* indicates iso- and anteiso-fatty acids.

TABLE 2
Phospholipid Composition of the *Limulus* Amebocytes[a]

Phospholipid class	Percentage area
Phosphatidylethanolamine	42.2 ± 1.0
Phosphatidylinositol	6.2 ± 0.5
Phosphatidylserine	9.0 ± 0.7
Cardiolipin	1.6 ± 0.5
Phosphatidylcholine	36.3 ± 0.7
Sphingomyelin[b]	4.6 ± 0.5

[a]The percentage area is the mean ± SEM of amebocyte preparations from seven animals.
[b]One of the samples analyzed by electrospray–ionization/mass spectrometry (ESI/MS) contained lysophosphatidylcholine.

mon alkyl chain in ether linkage (9.5%), with lesser amounts of octadecane (18:0) and hexadecane (16:0), 5.9 and 1.4%, respectively.

HPLC analyses of the phospholipid classes. A clean separation existed between the major phospholipid classes. Analysis of the phospholipid fraction revealed a greater proportion of PE (42.2%) than PC (36.2%) (Table 2), followed by lower levels of PS and PI at 9.0 and 6.2%, respectively. SPH (4.6%) and CL (1.6%) were also present in the amebocyte membranes. Lysophosphatidylcholine (LPC) was detected at trace levels in one of the SPH samples.

ESI/MS analyses of the molecular species within the major phospholipid classes. The levels of EPA and AA in the FAME analyses were reflected by the predominance of phospholipid species containing these fatty acids. To distinguish between alkyl and alkenyl linkages at the *sn*-1 position using ESI/MS without prior separation of these subclasses (13) is not possible, as previously stated, but the phospholipid molecular species can still be calculated based on the molecular ion, the headgroup, and any fatty acids that have fragmented from the phospholipid molecule, as seen in the negative-ion spectra. The diacyl and plasmalogen species agreed well with the species of FAME and DMA present in the total lipid (Table 1).

Examination of the negative-ion mass spectra for PI revealed only the molecular ion $[M - H]^-$ (Fig. 1A). To examine the fatty acid profile in the PI class, the sample also was analyzed at higher voltages (–80 to –100 V, data not shown). These spectra indicated 18-carbon *m/z* 281 (18:1) and 283

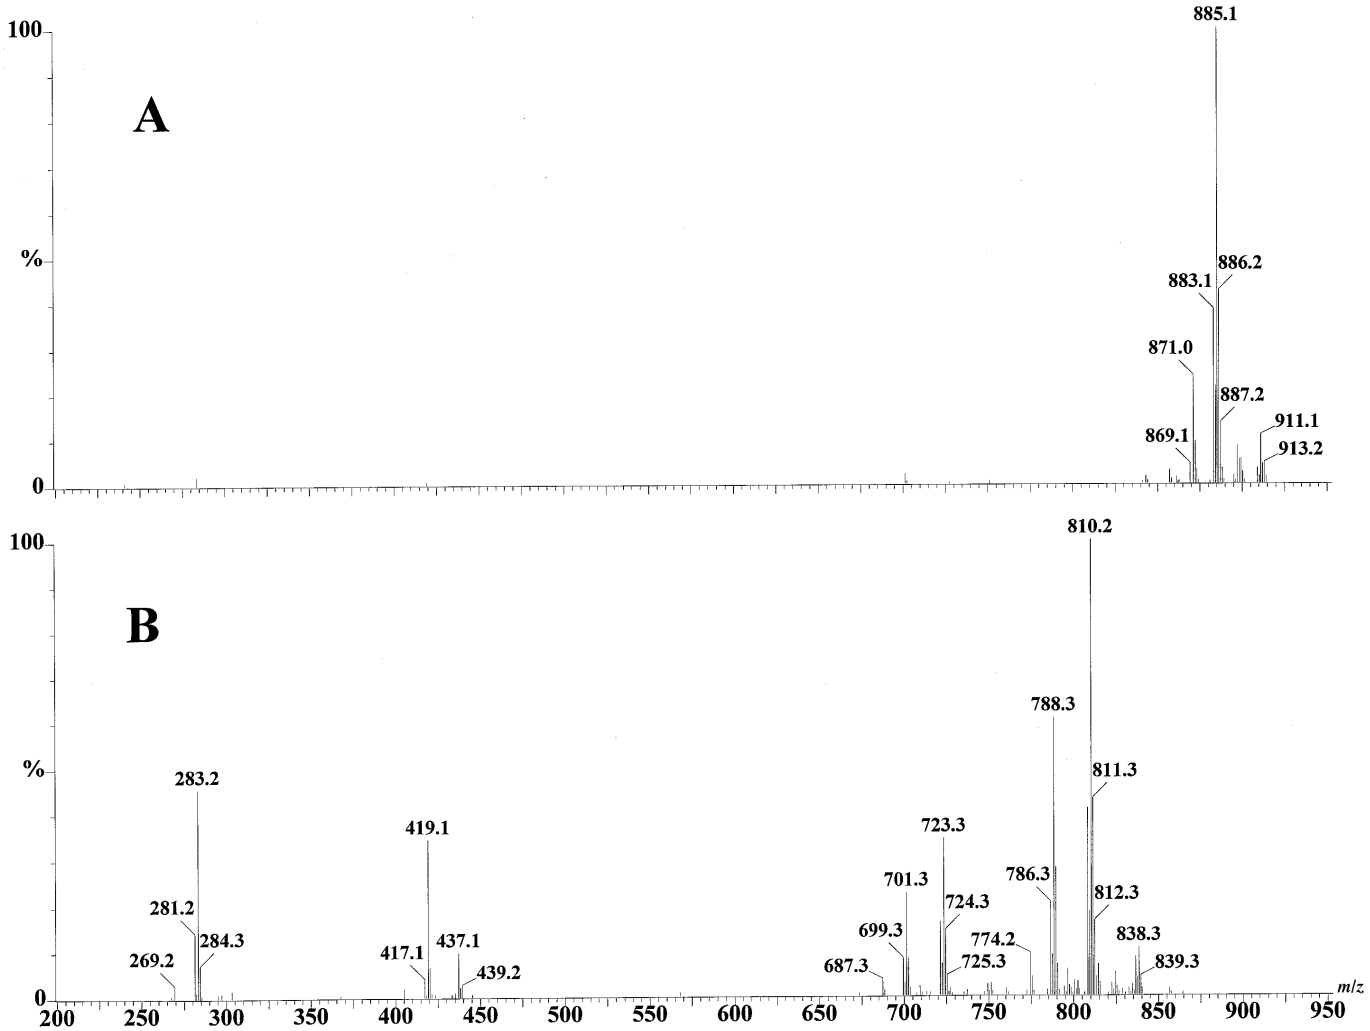

FIG. 1. Electrospray–ionization/mass spectrometry negative-ion mass spectra of the molecular ions and fragments of (A) phosphatidylinositols and (B) phosphatidylserines in the *Limulus* amebocyte.

(18:0), 20-carbon *m/z* 301 (20:5), 303 (20:4), 305 (20:3), 307 (20:2) and 309 (20:1), as well as *m/z* 313 (22:6), 315 (22:5), and 317 (22:4) were present. Greater than half of the PI (52.3%) consisted of a single species, 18:0*a*/20:4 (Table 3), where *a* = 1-*O*-acyl. Almost another quarter of the PI (21.4%) was composed of a mixture of the two species 18:0*a*/20:5 and 18:0*e*/20:4, where *e* = 1-*O*-alkylether. The PS negative-ion mass spectra displayed numerous fragments (Fig. 1B). The molecular ion $[M - H]^-$ was present, as well as ions corresponding to the loss of serine $[M - 88]^-$, and the loss of both serine and fatty acids (*m/z* 417–439) and free fatty acids (*m/z* 281, 283). There were two predominant species of PS, 18:0*a*/20:4 (*m/z* 810) and 18:0*a*/18:1 (*m/z* 788), at 33.8 and 22.7%, respectively (Table 3). The fatty acid composition of PS and PI species indicates that almost 90% of these lipids are diacyl species.

Analysis of the positive-ion mass spectra of the PE revealed the molecular ion $[M + H]^+$ and the loss of ethanolamine from the major species $[M - 142]^+$ (Fig. 2A). The negative-ion mass spectra (Fig. 3A) gave a molecular ion at $[M - H]^-$, as well as free fatty acids at *m/z* 281, 301, and 303. In contrast to the prevalence of diacyl species in the PI and PS fractions of the amebocyte, the PE molecular species consisted of plasmalogen (62%), diacyl (27%), and alkylacyl (11%) phospholipids (Table 4). The chains in the *sn*-1 position of ether lipids are in ether or vinyl ether linkage and are not readily cleaved from the phospholipid backbone during ESI/MS analysis. The general lack of saturated and monounsaturated 16- to 20-carbon free fatty acids in the negative-ion spectra further supports the predominance of ether lipids in this class. The major species were 20:1*p*/20:5 (27.3%) and 20:1*p*/20:4 (13.6%), where *p* = 1-*O*-alk-1′-enyl (plasmalogen). A significant amount of 18:0*p*/20:5 (13.7%) and 18:0*p*/20:4 (4.5%) also existed.

The positive-ion mass spectra for the PC yielded only molecular ions $[M + H]^+$ and the choline headgroup (*m/z* 184) (Fig. 2B). The negative-ion spectra for the PC were quite complicated. The pseudomolecular ion occurred at $[M - 15]$, which is indicative of demethylation of the choline headgroup (17) (Fig. 3B). The other peaks present included the losses of the quaternary nitrogen from the molecular ion (*m/z* 660–720), the loss of quaternary nitrogen and fatty acids (*m/z*

[a]Phospholipid nomenclature from Reference 1. The letter designates the linkage at the *sn*-1 position in the phospholipid. See Tables 2 and 3 for abbreviations.
[b]The percentage composition was based on the average relative intensities of each molecular ion from the analyses of five separate individuals, mean ± SEM.

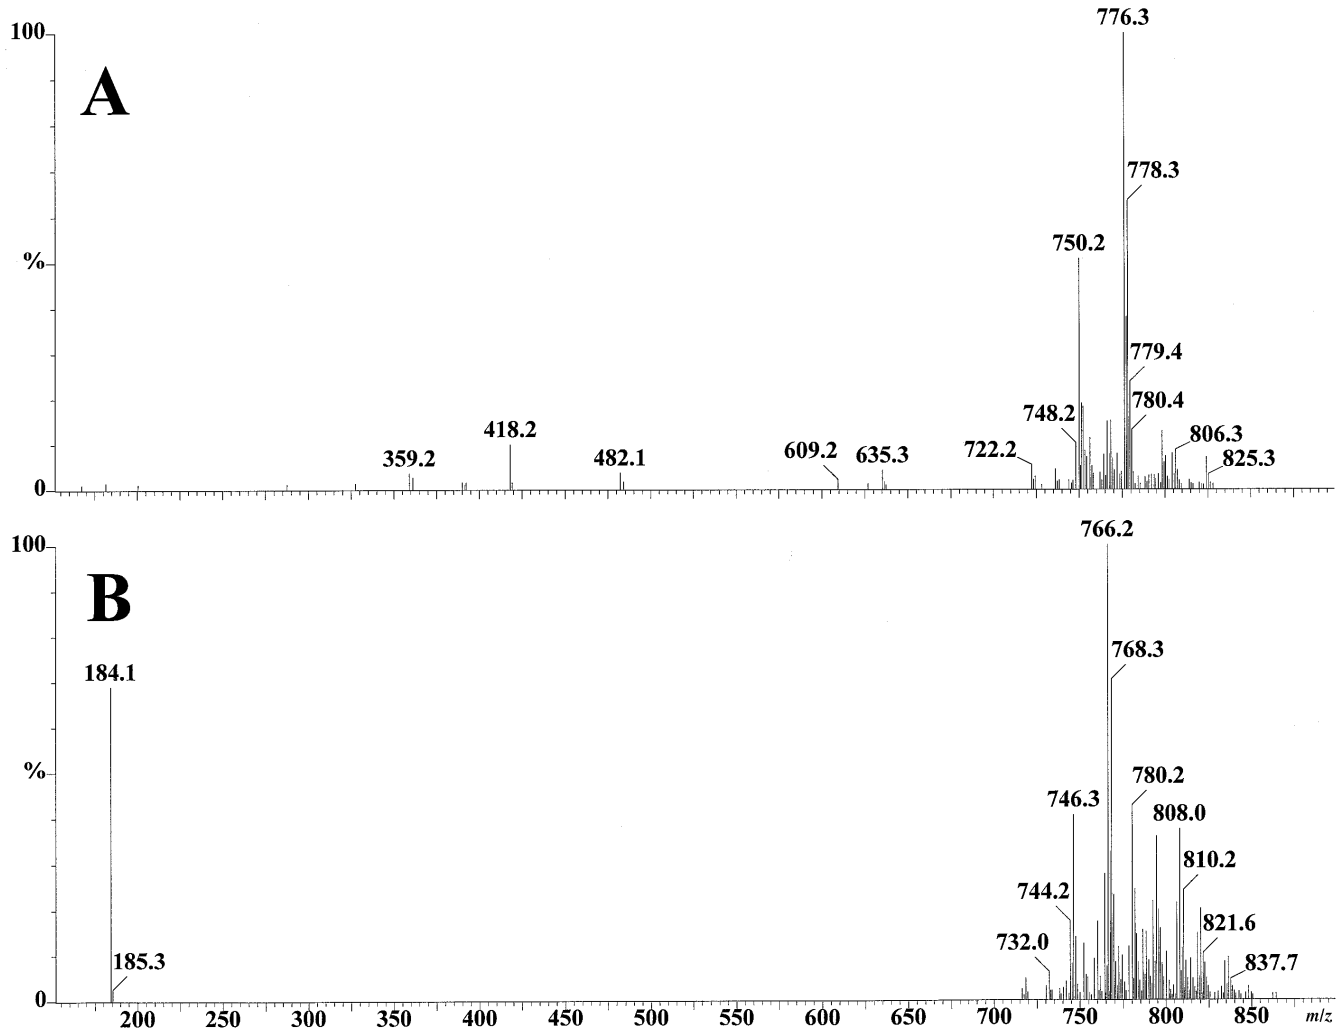

FIG. 2. Electrospray–ionization/mass spectrometry positive-ion mass spectra of the molecular ions and fragments of (A) phosphatidylethanolamines and (B) phosphatidylcholines in the *Limulus* amebocyte.

370–420), as well as the presence of large levels of free fatty acids (*m/z* 255–317). Whereas plasmalogen levels dominated in PE, the levels of the three subclasses in PC were almost evenly distributed. The composition of the PC species consisted of diacyl (39%), alkylacyl (35%), and plasmalogen (26%) phospholipids (Table 5). In comparison to the PE fraction, the presence of detectable 16:0 (*m/z* 255) and large 18:1 (*m/z* 281) in the negative-ion spectra mirrors the higher levels of diacyl phospholipid in the PC fraction. A broad distribution of molecular species was present in PC, but the three major species were a mixture of 16:0*e*/20:5 and 16:0*p*/20:4 (14.4%) and 16:0*e*/20:4 (8.9%).

Screening of CL, SPH, and LPC species. Small peaks in the phospholipid samples (<5%) were screened to identify major species present. The CL fraction was tested in both positive- and negative-ion modes (data not shown). In negative-ion mode, the mass spectra revealed mainly free fatty acids (20:5 > 20:4 ≫ 18:1 > 18:0 = 18:2 > 22:4 > 22:5). The positive-ion spectra showed a cluster of molecular ions in the range of *m/z* 1520–1660. The masses are most likely dipotassiated CL species resulting from the use of potassium phosphate in the HPLC solvent and potassium chloride in the wash buffer used to remove phosphate. The major masses present were *m/z* 1531, 1553, and 1579, indicative of CL with fatty acid mixtures of 18:1, 18:2, 20:4 and 20:5, which correlates with the fatty acid profile seen in the negative-ion mass spectra.

In the positive-ion mode scan of the SPH samples, an extracted ion profile of the choline headgroup, *m/z* 184, demonstrated the presence of six peaks (data not shown). The mass spectra of the five major peaks revealed apparent masses of *m/z* 675, 689, 703, 717 and 731, while the sixth minor peak had an apparent mass of *m/z* 661. Each of these apparent masses had an additional sodiated mass at $[M + 23]^+$. The incremental difference of 14 mass units between each major peak indicates a group of SPH with saturated carbon chains ranging from 13 (*m/z* 661) to 18 (*m/z* 731) carbons. In one of the four SPH samples tested, two minor LPC peaks were detected at *m/z* 496 (16:0 LPC) and *m/z* 524 (18:0 LPC). These LPC peaks displayed the characteristic cleavage of the

choline headgroup at *m/z* 184, the molecular ion $[M + H]^+$, the loss of water $[M - 18]^+$ peak, the addition of sodium $[M + 23]^+$, and the addition of potassium $[M + 38]^+$.

DISCUSSION

Analysis of FAME. At present, very few reports are available on the lipid composition of arthropod blood cells to compare with that of the *Limulus* amebocyte. One report is available for the mixed crab blood cells of *Carcinus meanas* of 20% EPA and 10% AA levels (19). *Limulus* amebocytes demonstrate significant levels of ether lipids. Phospholipids with alkenylether bonds (plasmalogens), and to a lesser extent those with alkylether bonds, are also common components in vertebrate blood cells and are most often found in the PC and PE classes (20,21). Though the levels of ether lipids are modest in mammals, in lower animals they can reach appreciable levels, especially the alkylacyl phospholipids. Horseshoe crabs are arthropods, though more closely related to arachnids than crustaceans. In Sugiara *et al.* (2), the tissues of two arachnids, a spider and a water scorpion, were analyzed, and they contained between 6.7 and 17.9% alkylacyl PC and between 13.7 and 22.7% alkylacyl PE, respectively. A marine prawn contained 7% alkylacyl PC and 7% alkylacyl PE. Alkylacylphospholipids can represent up to 20% of the lipid in marine organisms, and in extreme cases as much as 50–80% (2,3,22). The most commonly reported groups in the *sn*-1 position of ether lipids are 16:0, 16:1, 18:0 and 18:1 (23); however, the DMA profile in the amebocyte indicates that eicosene (20:1) is the most abundant group in ether linkage (9.5%), with lesser amounts of 18:0 (5.9%) and 16:0 (1.4%). The role of eicosene ether lipids is not known, but they have been detected in small amounts at the *sn*-l position in the ether lipids of human erythrocytes, adrenal glands, and placentas (23). We also compared the amebocyte to vertebrate white blood cells with similar functions, i.e., platelets and macrophages.

Analysis of the phospholipid class composition. In comparison to mammalian leukocytes, the PE levels of the amebocyte (42.2%) were about 60% greater than those seen in

[a]Phospholipid nomenclature from Reference 1. The letter designates the linkage at the *sn*-1 position in the phospholipid. See Tables 2 and 3 for abbreviations.
[b]The percentage composition was based on the average relative intensities of each molecular ion from the analyses of five separate individuals, mean ± SEM.

platelets and macrophages (23–29%), whereas PC levels (36.3%) were at the lower end of the range seen in these leukocytes (35–46%) (24–26). The higher PE levels in the amebocyte may reflect differences in immune response between invertebrate and vertebrate lymphocytes. Even though the amebocyte can undergo diapedesis, like the macrophage or neutrophil, to reach the site of injury or counter microbial invasion, it is not phagocytic, and it encapsulates foreign bodies by degranulating and releasing clotting factors and antimicrobial substances (8). When compared to the platelet, the amebocyte can plug the site of injury, but unlike the platelet it degranulates initially allowing clot material to fill the site of injury, followed by continued migration of cells to the site of injury, infiltrating and replacing the clot material. These cells then degranulate, elongate, and serve as basis for the formation of new tissue or even carapace (27). The amebocyte PI (6.2%) and PS (9.0%) levels were roughly comparable to the amounts of PI and PS previously reported in platelets and macrophages, 6–8 and 5–11%, respectively. The amount of SPH present in the amebocyte, ~5%, was apparently low in relation to the range of 9–20% SPH detected in mammalian leukocytes (25,26). The amebocyte's CL levels (1.6%) were in a range similar to that reported in human and guinea pig macrophages (1–2.5%) (20,21).

Analysis of the phospholipid molecular species. The molecular species composition of the amebocyte phospholipids reported here reflects the key role this hemocyte plays in the immune defenses of this organism. Within the phospholipid classes, a number of overall similarities existed between the molecular species distribution of PS and PI in the amebocyte with vertebrate platelets and macrophages. In the human platelet, the predominant diacyl molecular species of PS are 18:0*a*/20:4 (41%) and 18:0*a*/18:1 (37%) (24), but in the mouse macrophage, PS has three major species 16:0*a*/18:1 (41.1%), 18:0*a*/18:1 (19.8%), and 18:0*a*/20:4 (11.1%) (21). The PS profile of the amebocyte was more similar to the platelet than the macrophage with its predominant PS species of 18:0*a*/20:4 (34%) and 18:0*a*/18:1 (23%). The major PI species of the amebocyte was 18:0*a*/20:4 (52.3%), and the level of this molecular species was comparable to the mouse macrophage 18:1*a*/20:4 levels (59.1%), but was lower than the human platelet that is almost three-quarters 18:0*a*/20:4 (71%). The level of 18:0*a*/20:4 PI is an important indicator of signal transduction processes as this PI species can act as a potential source for the biosynthesis of PI-4,5-bisphosphate. After cellular activation, PI-4,5-bisphosphate is hydrolyzed, and the diacylglycerol portion remains in the plasma membrane inner leaflet while inositol 1,4,5-triphosphate (IP_3) is released into the cytosol and stimulates the release of Ca^{2+} from the endoplasmic reticulum, which in turn activates numerous cellular processes (28). The recent detection of a putative IP_3 receptor (29) in the *Limulus* amebocyte reinforces the likelihood that there must be a potential source for IP_3 in the plasma membrane.

The major species of PE seen in the amebocyte differed markedly from those reported in vertebrate cells. Whereas diacyl species dominated in the PE lipid pools of mammalian leukocytes, ether lipids made up almost three-quarters of the amebocyte PE species. The major PE species reported in mammalian leukocytes were 16:0*a*/20:4, 18:0*a*/20:4, 16:0*a*/18:1, and 16:0*a*/18:2 (21,24,26). The predominant *Limulus* PE species, 20:1*p*/20:5 and 20:1*p*/20:4, were unusual with the eicosene (20:1) group in the *sn*-1 position. One earlier report, in the guinea pig macrophage, discussed small amounts of eicosenoic acid, mixed with 18:3, in ester linkage at the *sn*-1 position, but none in ether linkage (26).

Elevated levels of AA and EPA in the *sn*-2 position in plas-

malogen PE were reported in prior analyses of both *Limulus* nerve tissue and photoreceptor membranes (30,31). These levels of AA and EPA are quite significant to cellular functions. Glaser and Gross (6) demonstrated that the speed of membrane fusion is directly related to the amount of plasmalogen PE molecular species with PUFA in the *sn*-2 position, particularly AA. The rate of membrane fusion, using plasmalogen PE vesicles, is doubled when 20:4 is in the *sn*-2 position rather than 18:1. The predominance of PE plasmalogens species containing AA and EPA is likely to play a significant role in the rapid rate of degranulation of the *Limulus* amebocyte during an immune response to pathogens or external injury. With an open coelom, *Limulus* must be able to react quickly to injury or microbial invasion to preclude systemic contamination, and degranulation promotes the release of clotting and antimicrobial proteins (polyphemusins and antilipopolysaccharide factor) from the cell's granules (8). These levels of polyunsaturation may also affect the membrane fluidity of the amebocyte, as *Limulus* inhabits a broad range of habitats, from the continental shelf (~200 m) to shallow bays (≤5 m) where temperature and salinity ranges are quite extreme (2–3°C/32 ppt to +25°C/13 ppt) (32).

The PC species observed in the amebocyte, as with the PS and PI pools, were similar to those seen in mammalian leukocytes. The diacyl PC species that predominated in mammalian leukocytes were 16:0*a*/18:1, 16:0*a*/18:2, 16:0*a*/16:0, and 16:0*e*/20:4 (21,24,26). In *Limulus*, the pattern was similar, except the major species were alkylether and plasmalogens, 16:0*e*/20:5, 16:0*p*/20:4, 16:0*e*/20:4, and 16:0*e*/18:1. As reported for the PE species, high levels of AA and EPA were also detected in the PC fractions of *Limulus* nerve tissue (30%) and photoreceptor membranes (42%) (30,31).

In the present study of the amebocytes, the detection of 16:0*e*/20:4 as major species in the PC phospholipid pool is significant, as it is considered to be a precursor to platelet-activating factor (PAF) (1-*O*-alkyl-2-acetyl-PC) (33). PAF-like lipids were detected in as many as 30 species of invertebrates (2,3), but this is the first documentation of the presence of a specific precursor to PAF in an invertebrate hemocyte. PAF is involved in both signaling and adhesive events between proinflammatory cells and vascular tissues (34). The presence of this potential precursor to PAF is a further indication that signal transduction pathways seen in modern vertebrate cells may also occur in this primitive invertebrate blood cell.

An Efficient Ultrasound-Assisted Zinc Reduction of Fatty Esters Containing Conjugated Enynol and Conjugated Enynone Systems

Marcel S.F. Lie Ken Jie*, Jamal Mustafa, and Mohammed Khysar Pasha

Department of Chemistry, University of Hong Kong, Hong Kong

ABSTRACT: Reduction of methyl 8-hydroxy-11-*E/Z*-octadecen-9-ynoate (**1**) with zinc in either aqueous *n*-propanol or water under concomitant ultrasound irradiation furnished a mixture of methyl 8-hydroxy-9*Z*,11*E*-octadecadienoate (**3a**) and methyl 8-hydroxy-9*Z*,11*Z*-octadecadienoate (**3b**) (96% yield). Reduction of methyl 8-oxo-11-*E/Z*-octadecen-9-ynoate (**2**) under similar conditions gave methyl 8-oxo-10-*Z*-octadecenoate exclusively (**4**, 70%). The latter compound was epoxidized and converted to a C_{18} furanoid fatty ester (**6**, methyl 8,11-epoxy-8,10-octadecadienoate) in 70% yield.
Lipids 33, 941–945 (1998).

Lindlar catalyst is widely used for the semihydrogenation of acetylenic compounds (1,2), but the reduction of conjugated diacetylenes or enynes with this catalyst has produced complex mixtures of dienes and monoenes (2,3). Morris *et al.* (4) reported the use of zinc powder in aqueous organic solutions for the reduction of conjugated enyne fatty esters. However, these reactions require long reaction times (16–43 h) to complete. To improve such reduction reactions, Petrier and Luche (5,6) used Zn-$NiCl_2$ as the catalyst for conjugated systems under concomitant ultrasonic irradiation. This observation prompted us to study the reduction of methyl 8-hydroxy-11-*E/Z*-octadecen-9-ynoate (**1**) and methyl 8-oxo-11-*E/Z*-octadecen-9-ynoate (**2**) with zinc under ultrasound conditions.

MATERIALS AND METHODS

Thin-layer chromatography (TLC) was performed on microscope glass plates coated with silica (*ca.* 0.1 mm thick), and a mixture of *n*-hexane/diethyl ether, 1:1 vol/vol, was used as the developer. Components on the microplates were viewed by exposing them to iodine vapor. Column chromatographic separations were accomplished using silica gel (Merck Art. 7730, type 60, 70–230 mesh; Darmstadt, Germany) as the adsorbent with mixtures of *n*-hexane/diethyl ether as the eluent. Infrared (IR) spectra were measured on a Bio-Rad FTS-7 Fourier-IR spectrometer (Richmond, CA) on neat samples placed between NaCl plates. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier-transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) (0.2–0.3 mM) with tetramethylsilane as the internal reference standard. Chemical shifts are given in δ-value in ppm downfield from tetramethylsilane. Mass spectra were recorded on a Finnigan Mat 95 mass spectrometer (70 eV; Finnigan Mat Corp., San Jose, CA). Ultrasonication was carried out using a 20 kHz (52 W/cm^2) ultrasound horn (Undatim Ultrasonic S.A., Louvain-la-neuve, Belgium).

Methyl santalbate (methyl 11-*E*-octadecen-9-ynoate) was obtained from methyl ricinoleate as reported (7), and methyl 8-hydroxy-11-*E/Z*-octadecen-9-ynoate (**1**) and methyl 8-oxo-11-*E/Z*-octadecen-9-ynoate (**2**) were obtained by oxidation (using selenium dioxide/*tert*-butyl hydroperoxide) of methyl santalbate as described elsewhere (8). Compound **2** could also be obtained from compound **1** by the two-phase chromic acid oxidation procedure (9) in 73% yield.

*Reduction of methyl 8-hydroxy- and 8-oxo-C_{18}-enynoate as exemplified by the reaction of methyl 8-hydroxy-11-*E/Z*-octadecen-9-ynoate (**1**) with zinc under ultrasound.* A mixture of compound **1** (300 mg, 0.98 mmol), zinc powder (30 g), and *n*-propanol/water (40 mL, 1:1, vol/vol) was placed in an air-jacketed glass cell (about 150 mL in volume) and sonicated for 15 min. The internal temperature of the reaction reached about 85°C at the end of the sonication period. The reaction mixture was filtered under suction and the zinc residue was washed with diethyl ether (200 mL). Water (100 mL) was added to the filtrate and the ethereal layer was isolated. The aqueous solution was reextracted with diethyl ether (2 × 50 mL) and the organic extracts were combined. The ethereal extract was washed with water (30 mL) and dried over anhydrous Na_2SO_4. The filtrate was evaporated and the residue was separated by silica column chromatography using a mixture of *n*-hexane/diethyl ether (3:2, vol/vol) to give a mixture of methyl 8-hydroxy-9*Z*,11*E/Z*-octadecadienoate isomers (**3a** and **3b**, 290 mg, 96%) as an oil. Retention factor (R_f) = 0.3 (*n*-hexane/diethyl ether, 1:1, vol/vol, as developer); IR

When water was substituted for aqueous *n*-propanol, compounds **3a** and **3b** were obtained in 70% yield after 25 min of sonication. The geometric isomers (**3a** and **3b**) could not be separated by silver-ion TLC into individual isomers.

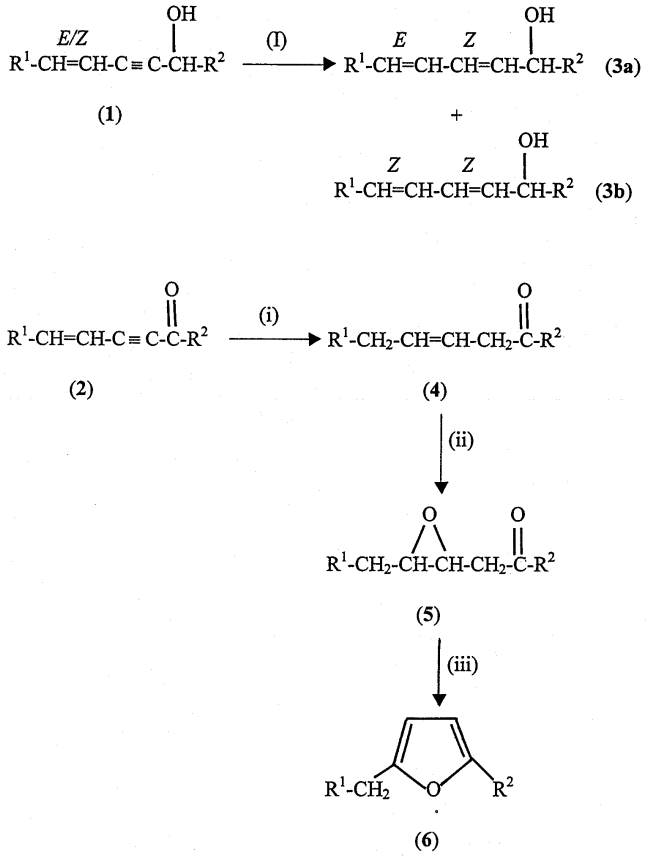
Reaction of methyl 8-oxo-11-*E/Z*-octadecen-9-ynoate (**2**) with zinc under ultrasound furnished methyl 8-oxo-10-*Z*-octadecenoate (**4**, 213 mg, 70%) as an oil. R_f = 0.5 (*n*-hexane/diethyl ether, 1:1, vol/vol, as developer); IR (cm^{-1}): 1739 (C=O, ester stretching), 1717 (C=O, oxo stretching), and 1636; ^1H NMR ($CDCl_3$, δ_H): 0.89 (*t*, 3H, C*H*$_3$), 1.3–1.6 (*m*, 18H, C*H*$_2$), 2.02 (quartet, *J* = 6.7Hz, 2H, 12-*H*), 2.29 (*t, J* = 7.5 Hz, 2H, 2-*H*), 2.43 (*t, J* = 7.4 Hz, 2H, 7-*H*), 3.14 (*d, J* = 6.2 Hz, 2H, 9-*H*), 3.6 (*s*, 3H, COOC*H*$_3$), and 5.59 (*m*, 2H, 10-*H*, 11-*H*); ^{13}C NMR ($CDCl_3$, δ_C): 14.10 (C-18), 22.66 (C-17), 23.55 (C-6), 24.79 (C-3), 27.52 (C-12), 28.83, 28.90, 29.19, 29.25, 29.36, 31.84 (C-16), 33.98 (C-2), 41.71 (C-9), 42.16 (C-7), 51.45 (COO*C*H$_3$), 120.88 (C-10), 133.73 (C-11), 174.16, and 209.05 (C-8); mass spectral analysis (EI, 70 eV), *m/z* (intensity): 310 (M^+, 0.5), 171 (100, base peak), 139 (17), 111 (23), 83 (23) and 69 (14). When the reaction was carried out in water with zinc, the temperature of the reaction rose to 98°C after 15 min of sonication. The yield of compound **4** by this procedure was 60%.

Transformation of compound **4** *to C_{18} furanoid fatty ester (***6***).* A mixture of methyl 8-oxo-10-*Z*-octadecenoate (**4**, 56 mg, 0.18 mmol), *m*-chloroperoxybenzoic acid (57 mg, 0.33 mmol), and dichloromethane (20 mL) was stirred at room temperature for 12 h. An aqueous solution of Na_2SO_3 (10%, 5 mL) was added to the reaction mixture. The organic layer was isolated and successively washed with aqueous $NaHCO_3$ (10%, 5 mL), water (10 mL), and dried over anhydrous Na_2SO_4. The filtrate was evaporated under reduced pressure to give crude methyl 8-oxo-10,11-epoxystearate (**5**, 46 mg) as an oil: R_f = 0.8 (*n*-hexane/diethyl ether, 7:3, vol/vol, as developer), IR (cm^{-1}) 1740, 1710, 1060; ^1H NMR ($CDCl_3$, δ_H): 0.88 (*t*, 3H, C*H*$_3$), 1.2–1.8 (*m*, 20H, C*H*$_2$), 2.30 (*t, J* = 7.0 Hz, 2H, 2-*H*), 2.48 (*t, J* = 7.0 Hz, 2H, 7-*H*), 2.62 (*dd, J* = 6.0 Hz, 2H, 9-*H*), 2.8–3.0 (*m*, 1H, 11-*H*), 3.2–3.4 (*m*, 1H, 10-*H*), and 3.66 (*s*, COOC*H*$_3$); ^{13}C NMR ($CDCl_3$, δ_C): 14.0 (C-18), 22.5 (C-17), 23.6 (C-6), 24.9 (C-16), 26.4 (C-12), 28.0, 28.8, 29.0, 29.1, 29.3, 31.6 (C-16), 34.0 (C-2), 41.7 (C-9), 43.3 (C-7), 51.3 (COO*C*H$_3$), 52.3 (C-10), 56.4 (C-11), 174.1(C-1), and 208.1 (C-8).

A mixture of the crude compound **5** (46 mg), sodium azide (28 mg, 0.43 mmol), ammonium chloride (23 mg), ethanol (5 mL), and water (1 mL) was refluxed for 30 min. Water (5 mL) was added and the cooled reaction mixture was extracted with diethyl ether (2 × 25 mL). The ethereal extract was washed with water (20 mL) and dried over Na_2SO_4. The filtrate was evaporated and the residue was separated by preparative TLC (*n*-hexane/diethyl ether, 4:2, vol/vol, as developer) to give methyl 8,11-epoxy-8,10-octadecadienoate (**6**, 30 mg, 70%) as an oil. R_f = 0.9 (*n*-hexane/diethyl ether, 9:1, vol/vol, as developer); IR (cm^{-1}): 3100, 1741, 1639, 1566, and 1119; ^1H NMR ($CDCl_3$, δ_H): 0.87 (*t*, 3H, C*H*$_3$), 1.2–1.4 (*m*, 12H, C*H*$_2$), 1.6 (*m*, 6H, C*H*$_2$), 2.30 (*t, J* = 7.5 Hz, 2H, 2-*H*), 2.55 (*t, J* = 7.5 Hz, 4H, 7-*H*, 12-H), 3.66 (*s*, 3H, COOC*H*$_3$), and 5.8 (*s*, 2H, furan ring, 9-*H*, 10-*H*); ^{13}C NMR ($CDCl_3$, δ_C): 14.10 (C-18), 22.66 (C-17), 24.86 (C-3), 27.97, 28.08, 28.15, 28.79, 28.88, 29.07, 29.20, 30.32, 31.80 (C-16), 34.06 (C-2), 51.46 (COO*C*H$_3$), 104.80 (C-10), 104.91 (C-9), 154.33 (C-8), 154.71 (C-11), and 174.27 (C-1); mass spectral analysis (EI, 70 eV), *m/z* (intensity): 308 (M^+, 45), 277 (10), 237 (5), 223 (19), 193 (10), 180 (14), 179 (100, base peak), and 149 (18).

RESULTS AND DISCUSSION

The reactions and products from the zinc reduction of methyl 8-hydroxy-11-*E/Z*-octadecen-9-ynoate (**1**) and methyl 8-oxo-11-*E/Z*-octadecen-9-ynoate (**2**) are shown in Scheme 1. The substrates (**1** and **2**) consisted of mixtures of geometric isomers, because these mixtures were not able to be separated into individual isomers by silica column chromatography prior to reduction. Reduction of methyl 8-hydroxy-11-*E/Z*-octadecen-9-ynoate (**1**) with zinc in aqueous propanol (1:1, vol/vol) and under concomitant ultrasonic irradiation furnished a 96% yield of a mixture of methyl 8-hydroxy-9*Z*,11*E*-octadecadienoate (**3a**) and methyl 8-hydroxy-9*Z*,11*Z*-octadecadienoate (**3b**) as a viscous oil in about 1:1 ratio (by comparing the intensities of the signals in the ^{13}C NMR spectrum and integration ratios of the olefinic protons in ^1H NMR spectrum). These isomers could not be separated into individual isomers by silver-ion TLC. The ^1H NMR spectrum of the mixture of isomers showed a total of seven signals in the olefinic region with a multiplet at δ_H 6.29 where an intensity equivalent to the shifts of two protons (total olefinic protons equal to eight) existed. The ^{13}C NMR spectrum also revealed seven signals with the shifts of two carbon nuclei overlapping at δ_C 125.02. The overlapping signals in the ^1H and ^{13}C NMR spectra are connected as evident from the ^1H-^{13}C correlation spectroscopy correlation spectrum (Fig. 1). In view of the fact that the NMR spectra showed eight protons and eight carbons for the olefinic system, the conclusion could be that the reduction of compound **1** produced only two geometric isomers. These isomers were methyl 8-hydroxy-9*Z*,11*E*-octadecadienoate (**3a**) and methyl 8-hydroxy-9*Z*,11*Z*-octadecadienoate (**3b**). The presence of an *E*-double bond in



$R^1 = CH_3(CH_2)_5$; $R^2 = (CH_2)_6COOCH_3$

Reagents and conditions: (i) Zn powder, 50% aqueous *n*-propanol or water, ultrasound 15 min; (ii) *m*-chloroperoxybenzoic acid, CH_2Cl_2, 12 h, 20°C; (iii) NaN_3, NH_4Cl, EtOH, H_2O, reflux, 30 min.

SCHEME 1

position C-11/C-12 of compound **3a** [partial formula: –CH_2–CH=CH–CH=CH–CH(OH)–] was confirmed by the quartet at δ_H 2.09 (13-*H*), which was shown to be correlated to the carbon signal at δ_C 32.86 (*E*-double bond, C-13). Likewise the presence of a *Z*-double bond in position C-11/C-12 of compound **3b** could be confirmed by the quartet at δ_H 2.16, which was correlated to the carbon signal at δ_C 27.45. Similar chemical shift values for methylene-interrupted olefinic fatty esters with *E/Z* configurations have been reported (10). The carbon atom bearing the hydroxyl group gave two signals in the ^{13}C NMR spectrum (δ_C 67.75 and 67.89, C-8), due to the nonstereospecific hydroxylation of C-8 as mentioned elsewhere (8).

The attempt to assign the shifts of the various protons and carbon atoms of the olefinic system of the mixture of compounds **3a** and **3b** unambiguously was difficult. By referring to the chemical shifts of the protons and carbon nuclei of the olefinic system of C_{18} conjugated dienes as described elsewhere (11), we tentatively assigned the signals for olefinic protons and carbon atoms as follows: the signal at δ_H 6.29 (2H, correlated to two overlapping carbons at δ_C 125.02) and the signal at δ_H 6.24 (*m*, 1H, correlated to δ_C 122.94) are due to shifts from 10-*H*/C-10 of compound **3b** and 11-*H*/C-11 of compounds **3a** and **3b** in view of the low-carbon shift values and the high deshielded protons; the signal at δ_H 6.02 (*t, J* = 11Hz, 1H, correlated to δ_C 130.54) is likely due to signals from 12-*H*/C-12 (*E*-double bond) of compound **3a** in view of the high *J* value; the hydroxy at C-8 is expected to induce a strong deshielding effect on the adjacent carbon nuclei, which inferred that the signals at δ_H 5.76 (connected to δ_C 137.46) are most likely the results of the shifts of 9-*H*/C-9 of compound **3b**, and the signals at δ_H 5.52/ δ_C 134.64 to 9-*H*/9-C of compound **3a**; the signal at δ_H 5.39/ δ_C 133.35 is probably due to 12-*H*/C-12 of compound **3b** and the remaining signal at δ_H 5.26/δ_C 131.39 can therefore be assigned to the shifts of 10-*H*/C-10 of compound **3a**. The mass spectral analysis of compounds **3a/3b** showed a molecular ion of $M^+ = 310$, which agrees with the structure of a hydroxy-C_{18} diene methyl ester. The fragment ions at *m/z* = 167 (relative intensity 59%) [due to the cleavage of C-7/C-8] provided evidence of the position of the hydroxy group at C-8. The peak at *m/z* = 165 (36%) is due to the fragment $CH_3(CH_2)_5CH{=}CH{-}CH{=}CH{-}C{\equiv}O^+$, and the peak at *m/z* = 171 (77%) is due to the fragment $^+O{\equiv}C(CH_2)_6COOCH_3$, which are daughter ions supporting the position of the hydroxy group at the C-8 position of the alkyl chain.

Reduction of substrate **1** was also successfully carried out in pure water as the "solvent" medium, despite the fact that the substrate was not soluble in water. The reduction reaction carried out in water gave compound **3a/3b** in 70% yield. This result indicated that reactions of hydrophobic lipid molecules could be successfully accomplished in water under ultrasound (12,13). When the reaction was repeated under similar condition but under nonultrasonic condition, the substrate was recovered.

Reduction of methyl 8-oxo-11-*E/Z*-octadecen-9-ynoate (**2**) furnished an unprecedented methylene-interrupted oxo-ene derivative (**4**, methyl 8-oxo-10*Z*-octadecenoate) as a viscous oil. The presence of a methylene group between the olefinic bond and the oxo function in this compound was evident from the doublet (*J* = 6.2 Hz) at δ_H 3.14 in the ^1H NMR spectrum and from the signal at δ_C 41.71 (C-9) in the ^{13}C NMR spectrum. The spectral data indicated that the olefinic bond was of the *Z*-configuration, as the shift of the carbon atom of the methylene group adjacent to the olefin appeared at δ_C 27.52 (C-12) and also from the shifts of the olefinic carbon atoms at δ_C 120.88 (C-10) and 133.73 (C-11). The IR spectrum showed no evidence of the presence of any *trans*-olefinic bond as no absorption was found in the region of 960 cm^{-1}. The molecular ion $M^+ = 310$ agrees with the structure of compound **4**. The peaks at *m/z* = 171 (100%, base peak) and *m/z* = 139 (17%) are fragments resulting from the cleavage of C-8/C-9. These ion fragments confirmed the position of the oxo group at C-8 of the alkyl chain of the fatty ester.

In order to prove that compound **4** was indeed a methylene-interrupted oxo-ene derivative, the unsaturated center was epoxidized. And if this epoxy system were interrupted by a methylene group from the oxo function, cyclodehydra-

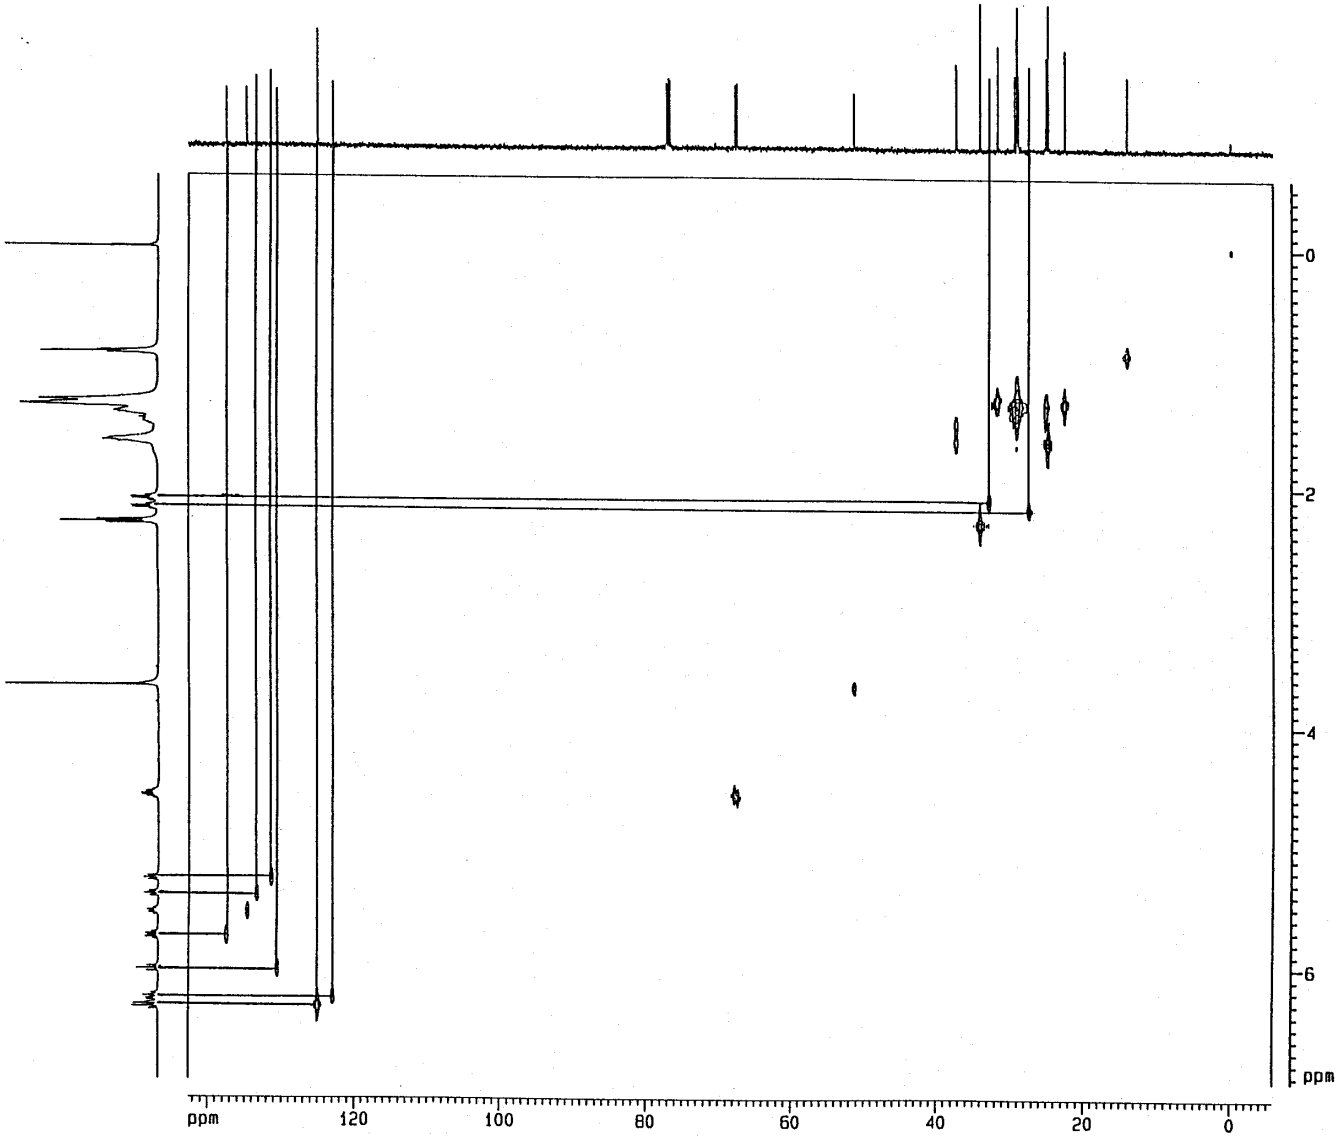


FIG. 1. Proton and carbon-13 nuclear magnetic resonance correlation spectrum of a mixture of compounds **3a** and **3b**.

tion of the epoxy-oxo system would result in the formation of a furanoid fatty ester product (14). Epoxidation of compound **4** furnished the corresponding epoxy derivative **5** as a viscous oil, which, after treatment with sodium azide in ammonium chloride, gave a 2,5-disubstituted C_{18} furanoid fatty ester (**6**, methyl 8,11-epoxy-8,10-octadecadienoate) in 70% yield as a viscous oil. The presence of the furan ring was confirmed by NMR spectroscopic analysis: δ_H 5.8 (furan ring protons) and δ_C 104.80, 104.91, 154.33, and 154.71 for the four furan ring carbon atoms. The position of the furan ring (straddling the C-8 and C-11 carbon atoms of the alkyl chain) was determined from the mass spectral fragmentation pattern, which gave a base peak at *m/z* 179 (100%) and a corresponding fragment ion *m/z* = 223. These ion fragments are characteristic of furanoid fatty esters and arise from the cleavage of the carbon-carbon β to the furan system (9,14). From these results zinc reduction of methyl 8-oxo-11-*E*/*Z*-octadecen-9-ynoate (**2**) was confirmed as furnishing methyl 8-oxo-10-*Z*-octadecenoate (**4**). Unlike the corresponding hydroxy-enynoate (compound **1**), reduction of the oxo-enynoate (compound **2**) appeared to have taken a novel and unexpected route to furnishing a single methylene-interrupted oxo-ene derivative (compound **4**).

These results indicate that zinc reduction of a conjugated oxo-enyne fatty ester furnishes a single methylene-interrupted *Z*-olefinic keto derivative, while a conjugated allylic hydroxy-enyne fatty ester gives a mixture of the corresponding hydroxy-diene isomers.

Models of Antioxidant Protection Against Biological Oxidative Damage

Sir:

Among the many published works describing antioxidant protection against oxidation, there are a few that present enough data to construct a model or simulation model that brings out the relationships between the components that are measured. The research of Eder and Kirchgessner (1) and Allard *et al.* (2) are suitable for simple modeling. The applications and advantages of simple models and simulation models of biological oxidations have been described (3,4). For the research of Eder and Kirchgessner (1), two simple simulation models showing the relationships in the reactions are:

$$\text{TBARS} = \frac{\text{PUFA} \times \text{PEROX}}{\text{TOCOPHEROL} + \text{ANTIOXIDANT}} \quad [1]$$

$$\text{TBARS} = \frac{\text{PUFA} \times \text{PEROX}}{\text{LOG TOCOPHEROL}} \quad [2]$$

These models follow the basic relationship: Products of Peroxidation = Oxidizable Lipids/Antioxidants. TBARS are the thiobarbituric acid-reacting substances given in Table 2 (1). PUFA are the amounts of polyunsaturated fatty acids with three to six double bonds as given in Table 3 (1). PEROX is the peroxidizability of these PUFA. TOCOPHEROL is the amount of total tocopherol given in Table 2 (1). ANTIOXIDANT is the amount of antioxidants in addition to total tocopherol. The researchers present two bases for measuring tocopherol and TBARS, namely, dry matter and total lipid. When values of TBARS that were calculated from the models are compared to the experimental TBARS, there was good agreement. Application of regression analysis of the calculated values of TBARS vs. the experimental measurements of TBARS gives, for the first model using dry matter basis, $r = 0.79$, $P < 0.1$ and, for total lipid basis, $r = 0.89$, $P < 0.02$. Regression analysis for the second model for dry matter basis gives $r = 0.81$, $P < 0.05$ and for total lipid $r = 0.91$, $P < 0.02$.

For the research of Allard *et al.* (2), a simple simulation model giving the interrelationships between measured components is:

$$(\text{ETHANE} + \text{PENTANE}) + \text{TBARS} + \text{PEROXIDE} = \frac{(\text{PUFA} \times \text{PEROX}) + \text{CAROTENE}}{\text{LOG TOCOPHEROL} + \text{ASCORBATE} + \text{Se} \bullet \text{GSHPx}} \quad [3]$$

This model also follows the basic relationship: Products of Peroxidation = Oxidizable Lipids/Antioxidants. The terms TBARS, (PUFA × PEROX), and TOCOPHEROL are as described for the first model presented here and now using the data of Allard *et al.* (2). ETHANE + PENTANE use the combined data for breath ethane and pentane from Table 3 (2). PEROXIDE uses the data on the measurement of lipid peroxides of Table 3. An average of the four measurements (ETHANE + PENTANE) + TBARS + PEROXIDE can be defined as a lipid peroxidation index as indicated in Table 3. ASCORBATE is the amount of ascorbic acid reported in Table 1. Se · GSHPx is the activity of the enzyme selenium-glutathione peroxidase in Table 3 (2). Allard *et al.* (2) discuss some of the relationships in their data. This model uses 17 individual pieces of experimental data in an overall relationship. The lipid peroxidation indices are calculated *via* the model and compared to the indices calculated from the four pieces of experimental data of Table 3. The results are viewed in the format of the study of Allard *et al.* For the groups at week 0; menhaden oil + vitamin E, menhaden oil, olive oil + vitamin E, and olive oil, the percentages of the amounts calculated by the model compared to the amounts of the experimental lipid peroxidation indices are: 105, 110, 100, and 100%, respectively. These results show very good agreement. After the subjects had been fed the supplements for 6 wk, there were significant changes in the n-3 fatty acids and vitamin E. The same model was able to give a good fit to these main experimental data. For the groups at week 6: menhaden oil + vitamin E, menhaden oil, olive oil + vitamin E, and olive oil, the percentages of the amounts calculated by the model compared to the amounts of the experimental lipid peroxidation indices are: 91, 115, 83, and 97%, respectively. These examples of the application of simulation modeling show that modeling can be a valuable addition to many studies.

ARTICLE

Divergent Incorporation of Dietary *trans* Fatty Acids in Different Serum Lipid Fractions

Helvi M. Vidgren[a,*], Anne M. Louheranta[a], Jyrki J. Ågren[a,b], Ursula S. Schwab[a], and Matti I.J. Uusitupa[a]

Departments of [a]Clinical Nutrition and [b]Physiology, University of Kuopio, Kuopio, Finland

ABSTRACT: *Trans* fatty acids may be involved in atherosclerotic vascular diseases. We investigated the incorporation of dietary *trans* fatty acids and oleic acid into the serum triglycerides (TG), cholesterol esters (CE), and phospholipids (PL). Fourteen healthy female volunteers, aged 23.2 ± 3.1 yr (mean ± SD), body mass index 20.8 ± 2.1 kg/m^2 participated in this study. All subjects consumed both a *trans* fatty acid-enriched diet (TRANS diet) and an oleic acid-enriched diet (OLEIC diet) for 4 wk according to a randomized crossover design. Both experimental diet periods were preceded by consumption of a baseline diet for 2 wk which supplied 37% of total energy (E%) as fat: 18 E% from saturated fatty acids (SFA), 12 E% from monounsaturated fatty acids, and 6 E% from polyunsaturated fatty acids. Five E% of the SFA in the baseline diet was replaced by *trans* fatty acids (18:1*t* and 18:2*c,t* + 18:2*t,t,* where *c* is *cis* and *t* is *trans*) in the TRANS diet and by oleic acid (18:1n-9) in the OLEIC diet. After the TRANS diet, the proportions of 18:1*t* and 18:2*t* increased ($P < 0.001$) in all serum lipid fractions analyzed. The increase of 18:1*t* in TG and PL (1.80 ± 0.28 vs. 5.26 ± 1.40; 1.07 ± 0.34 vs. 3.39 ± 0.76 mol% of total fatty acids, respectively) was markedly higher than that in CE (0.44 ± 0.07 vs. 0.92 ± 0.26), whereas that of 18:2*t* was nearly the same in all three fractions. The proportions of palmitic, stearic, arachidonic, and eicosapentaenoic acids in TG, CE, and PL and that of oleic acid in TG and CE were decreased when compared with the baseline value. In contrast, the proportion of palmitoleic acid in TG and PL and that of linoleic acid in PL increased on the TRANS diet. After consumption of the OLEIC diet, the proportion of oleic acid increased in all three lipid fractions analyzed, and the percentage increase was nearly the same in all fractions. In contrast, the proportions of 18:1*t* in TG and PL and 18:2*t* in TG and CE decreased when compared with the baseline value. In conclusion, a moderate increase in dietary *trans* fatty acids resulted in a marked incorporation into serum lipids and decreased the conversion of linoleic acid to its more unsaturated long-chain metabolites. Analysis of 18:1*t* from serum TG and PL seems to reflect reliably the dietary intake of this fatty acid.

Abbreviations: CE, cholesterol ester; E%, total energy percentage; EPA, eicosapentaenoic acid; MUFA, monounsaturated fatty acids; OLEIC diet, oleic acid-enriched diet; PL, phospholipid; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TG, triglyceride; TRANS diet, *trans* fatty acid-enriched diet.

Trans fatty acids are unsaturated fatty acids that are found in the tissues and milk of ruminant animals (1). They are produced by the process of biohydrogenation of dietary polyunsaturated fatty acids (PUFA) in the rumen of ruminant animals (2). Larger amounts of *trans* fatty acids are found in certain types of margarines and shortenings. They are formed when vegetable oils, rich in PUFA, are partially hydrogenated to produce fats with better firmness and plasticity (3). Only small amounts of *trans* fatty acids occur in nature (4); e.g., milk contains 3% (range 2.7–3.4%) *trans* fatty acids of total fat. The predominant *trans* fatty acid in foodstuffs is elaidic acid (18:1Δ9*t*), and 18:1Δ10*t* and 18:1Δ11*t* are predominant isomers in partially hydrogenated oils. With a predominance at position 10, the monounsaturated fatty acids (MUFA) contain *trans* double bonds at positions 6–12. *Cis* double bonds are almost entirely at position 9 (2). Recent studies indicate that *trans* MUFA or hydrogenated fats, when substituted for oleic acid, increase low density lipoprotein and decrease high density lipoprotein cholesterol levels (5,6). In a prospective epidemiological study, a positive relationship was found between 18:1*t* intake and the risk for coronary heart disease (7); and strong positive associations between 25-yr death rates from coronary heart disease and average intake of the 18:1*t* were also reported (8). Methodological difficulties involved in the analysis of *trans* fatty acid isomers in food items have resulted in an inadequate and unreliable database to estimate dietary *trans* fatty acid intake. Analysis of the fatty acid composition of serum lipids is one approach to estimate the dietary intake of *trans* isomers. *Trans* fatty acid isomers were analyzed from serum triglycerides (TG), cholesterol esters (CE) and phospholipids (PL), total plasma, platelets, erythrocytes, and adipose tissue (6,9–13). The incorporation of *trans* fatty acids into all lipid fractions during a moderate dietary *trans* fatty acid intake was determined in animals (14), but not in humans. This study was undertaken to determine the impact of moderate *trans* fatty acid intake on the fatty acid profile of the TG, CE, and PL fractions of serum. Fatty acid profiles were assessed after the consumption of a diet in which part of the saturated fatty acids (SFA) was replaced with 18:1*t* (18:1*t*, *trans*-octadecenoate, elaidic acid) and 18:2*t* (18:2*c,t*, mono-*trans*-octadecadienoate + 18:2*t,t*, *trans*-*trans*-octadecadienoate). These data were compared to the fatty acid pattern of subjects after they consumed a diet in which

TABLE 1
Baseline Characteristics of the Study Subjects[a]

	n = 14
Age (yr)	23.2 ± 3.1
Height (cm)	165.7 ± 6.6
Weight (kg)	57.1 ± 5.6
BMI (kg/m^2)	20.8 ± 2.1
Fasting plasma glucose (mmol/L)	5.0 ± 0.3
Total cholesterol (mmol/L)	4.5 ± 0.5
Total triglycerides (mmol/L)	0.9 ± 0.3

[a]Values are means ± SD. BMI, body mass index.

part of SFA was replaced with 18:1 *cis* (18:1*c*, *cis*-octadecenoate, oleic acid).

SUBJECTS AND METHODS

Subjects. Fourteen healthy female volunteers aged 23.2 ± 3.1 yr (mean ± SD) participated in this study (Table 1). All had normal body weight with the mean body mass index of 20.8 ± 2.1 kg/m^2. Their average fasting plasma glucose was 5.0 ± 0.3 mmol/L, serum total cholesterol 4.5 ± 0.5 mmol/L, and TG 0.9 ± 0.3 mmol/L. Not one subject was taking medication known to affect lipid metabolism, and all had normal liver, kidney, and thyroid functions. Four of the study subjects used low-estrogen oral contraceptives during the study. The subjects were advised to maintain a constant level of physical activity during the study period. Subjects gave their informed consent for the study, and the study protocol was approved by the Ethics Committee of the University of Kuopio (Kuopio, Finland).

Study design. All subjects consumed both a *trans* fatty acid-enriched diet (TRANS diet) and an oleic acid-enriched diet (OLEIC diet) for 4 wk according to a randomized crossover study design. Eight of the subjects were on the TRANS diet during the first dietary period and six were on the OLEIC diet. Both experimental diet periods were preceded by the consumption of a baseline diet for 2 wk. Height, routine hematological measurements, and levels of serum creatinine, thyroxine, and liver enzymes were analyzed at the start of the study. Body weight was measured at 2-wk intervals. Samples for the determination of serum lipids and the fatty acid composition of serum lipid fractions were taken after a 12-h fast in the beginning and at the end of each diet period.

Experimental diets. Baseline diet and both experimental diets supplied 37% of total energy intake (E%) as fat, 48–50 E% as carbohydrates, and 14–16 E% as protein. The calculated fatty acid composition of the baseline diet was 16 E% from SFA, 14 E% from MUFA, and 6 E% from PUFA. During both experimental diet periods, 5 E% of SFA was replaced by either *trans* fatty acids (18:1*t* and 18:2*c,t* + 18:2*t,t*) in the TRANS diet or oleic acid (18:1n-9) in the OLEIC diet. The cholesterol content was *ca.* 300 mg/1000 kcal, and dietary fiber content *ca.* 11 g/1000 kcal in the TRANS and OLEIC diets (Table 2).

During the baseline diet, butter (17–33 g/d), olive oil (14–24 g/d), and sunflower oil (5–9 g/d) were used as main sources of fat. The absolute amounts included in the diet depended on the E% intake. The source of *trans* fatty acids in the TRANS diet was a *trans* fatty acid-enriched margarine (39–72 g/d, mean intake of 18:1*t* 8.25 ± 1.82 g/d and that of 18:2*c,t* + 18:2*t,t* 2.14 ± 0.47 g/d) specially prepared for this

[a]Data are based on a 4-d food record during run-in and washout periods and on a 7-d food record during the TRANS and the OLEIC diets.
[b]The intake of 18:1n-9 + n-7 during the TRANS diet was 13.1% of energy and during the OLEIC diet 17.0% of energy. Values are calculated from the fatty acid analysis of double portions, mean of seven samples.
[c]Includes 18:1*t*, 18:2*c,t*, 18:2*t,t*.
[d]The intake of *trans* fatty acids during the TRANS diet was 5.5% of energy and during the OLEIC diet 1.4% of energy. Values are calculated from the fatty acid analysis of double portions, mean of seven samples. Double portions were not collected during the run-in and washout periods.
[e]Derived from *trans* fatty acid-enriched margarine. —Not available. Values are mean ± SD. MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids.

study. Fatty acid composition of the margarine was as follows: SFA, 16.0% of total fatty acids (palmitic acid 9.6%, stearic acid 5.0%), MUFA, 63.8% (oleic acid 41.4%, 18:1*t* 22.3%), and PUFA, 20.0% (linoleic acid 14.2%, 18:2*c,t* 2.4%, 18:2*t,t* 3%) (Raisio Group, Finland). In addition, a small amount of sunflower oil (0–1 g/d) was also included in the diet. The major source of oleic acid in the OLEIC diet was olive oil (29–51 g/d) (Raisio Group). In addition, sunflower oil (2–5 g/d) was also included in that diet. Except for the *trans* fatty acid-enriched margarine, and olive and sunflower oils, the diets were composed of common Finnish foodstuffs. The subjects received margarines, milk products, oils, and spreads free of charge.

The experimental diets were planned for six levels of energy intake: 1400, 1600, 1800, 2000, 2200, and 2400 kcal (5.9, 6.7, 7.5, 8.4, 9.2, and 10.1 MJ, respectively). The estimation of the energy requirement of the subjects was based on 3-d food records kept before the study. The subjects received both oral and detailed written instructions about the diets, specifying the amounts of individual foodstuffs by the main food groups, and they were asked, whenever possible, to weigh the food items on a digital scale before consumption. To assess dietary compliance, subjects kept 7-d food records (5 weekdays and 2 weekend days) during both experimental diet periods. During the run-in and washout diet periods, 4-d food records (3 weekdays and 1 weekend day) were kept. Nutrient intake was calculated by using the Micro-Nutrica dietary analysis program based on the database of the Finnish Social Insurance Institute. Food composition tables were based on values obtained from Finnish food analyses and values taken from international food composition tables (15). The data regarding *trans* fatty acids and oleic acid were not available in the food composition data. Therefore, two estimates are used in the results: one for *trans* fatty acid intake calculated from the intake of the *trans* fatty acid-enriched margarine, and the other for both *trans* fatty acid and oleic acid intakes calculated combining data from fatty acid analysis of double portions and food records.

Laboratory methods. Enzymatic colorimetric methods were used for the determination of cholesterol and TG from the whole serum (Monotest® Cholesterol and Triglyceride GPO-PAP; Boehringer Mannheim GmbH Diagnostica, Mannheim, Germany) with an automated instrument (Kone Specific Clinical Analyzer; Kone Ltd., Espoo, Finland). The coefficient of variation between the measurements for serum total cholesterol using two different standards was 0.9% and for total TG was 0.9–1.0%. Plasma glucose was analyzed by glucose oxidase method (Glucose Auto & Stat, Model GA-110; Daiichi, Kyoto, Japan).

Analysis of fatty acid composition of serum lipids. After centrifugation of the samples at 3000 rpm at 5°C for 15 min, the plasma was transferred to plastic tubes and stored under nitrogen at −78°C until the time of analysis. The procedure applied to fatty acid analyses was described elsewhere (16). In short, in the fatty acid analysis the serum samples were extracted with chloroform/methanol (2:1, vol/vol), and the lipid fractions were separated by solid-phase extraction with aminopropyl columns. The fatty acids of serum TG, CE, and PL were transmethylated with 14% boron trifluoride in methanol and analyzed by gas chromatograph (HP 5890 Series II; Hewlett-Packard Company, Waldbronn, Germany) equipped with a fused-silica capillary column (100 m, 0.25 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA) for analysis of *trans* fatty acids and with an HP-FFAP capillary column (25 m, 0.20 mm i.d., 0.33 μm film thickness; Hewlett-Packard, Palo Alto, CA) for analysis of other fatty acids. The molar percentage proportions of fatty acids in serum lipid fractions were calculated.

Statistical analysis. The data were analyzed with SPSS-PC (SPSS, Chicago, IL). Before further analysis, normal distribution of the variables was checked with the Kolmogorov-Smirnov test. An analysis of variance for repeated measurements was performed to assess whether there was any carryover effect. A nonparametric Wilcoxon test for paired samples was used to compare the results within diet periods and at the 4-wk time point between the TRANS and the OLEIC diets. All data are expressed as the mean ± SD.

RESULTS

Baseline characteristics of the subjects are presented in Table 1. No significant changes in body mass index occurred during the experimental diet periods (20.8 ± 1.9 vs. 20.6 ± 1.7 kg/m^2, beginning vs. end of the TRANS diet; 20.7 ± 2.0 vs. 20.6 ± 1.8 kg/m^2, beginning vs. end of the OLEIC diet). Serum total cholesterol tended to decrease in the TRANS diet (4.5 ± 0.5 vs. 4.2 ± 0.6 mmol/L, beginning vs. end, $P = 0.059$), whereas serum total TG did not change (0.9 ± 0.3 vs. 0.9 ± 0.3 mmol/L, beginning vs. end). In the OLEIC diet, both total cholesterol (4.8 ± 0.6 vs. 4.1 ± 0.6 mmol/L, $P < 0.001$, beginning vs. end) and total TG (0.9 ± 0.3 vs. 0.8 ± 0.3 mmol/L, $P = 0.020$, beginning vs. end) decreased significantly. The actual compositions of the two experimental diets and the baseline diet during run-in and washout periods are shown in Table 2. The goals of the experimental diets were well achieved. The mean energy intake remained stable during the study. The intake of protein and carbohydrates was similar during the diet periods. The OLEIC diet provided 1.3 E% more fat (nonsignificant) than the TRANS diet. The intake of PUFA was a little lower (nonsignificant) as well as that of palmitic acid ($P < 0.001$) in the TRANS diet compared to that in the OLEIC diet. The cholesterol and fiber contents of the diets were similar.

Fatty acid composition of serum lipids. The fatty acid compositions of serum TG, CE, and PL are presented in Tables 3, 4, and 5, respectively. No significant differences existed in the fatty acid composition of serum lipid fractions at baseline between the diet groups.

After consumption of the TRANS diet, both 18:1*t* and 18:2*t* were incorporated into all serum lipid fractions analyzed. The percentage increase of 18:1*t* in TG and PL was markedly higher than that in CE (197, 236, and 117%, respectively) (Fig. 1), whereas that of 18:2*t* was nearly the same in all three fractions (117, 114, and 94%, respectively).

[a]See Table 3 footnote.

The quantitative distribution of 18:1*t* and 18:2*t* to different serum lipid fractions during TRANS diet is presented in Table 6. The amount of 18:1*t* increased mostly in TG and PL while the greatest increase of 18:2*t* was seen in CE. The ratio of 18:1*t* to 18:2*t* in TRANS diet was about 3.9. After 4 wk on the diet, this ratio was 4.18 ± 1.07 in PL, 2.48 ± 0.30 in TG, and only 0.52 ± 0.19 in CE.

After 4 wk on the TRANS diet, the proportions of palmitic, stearic, and oleic acids in serum TG were decreased when compared with the baseline value (Table 3). The proportions of γ-linolenic, dihomo-γ-linolenic and arachidonic acids from n-6 PUFA and the proportion of eicosapentaenoic acid (EPA) from n-3 PUFA series decreased in TG. In contrast, the proportion of palmitoleic acid in TG increased on the TRANS diet when compared with the baseline value.

Similar changes were also found in the serum CE and PL (Tables 4 and 5) after consumption of the TRANS diet. The proportions of palmitic, stearic, arachidonic, and α-linolenic acids and of EPA decreased in CE and PL. Furthermore, the proportion of dihomo-γ-linolenic acid in CE decreased, and the proportions of palmitoleic and linoleic acids in PL increased on the TRANS diet when compared with the baseline value.

After consumption of the OLEIC diet, the proportion of oleic acid increased in all three lipid fractions analyzed, and the percentage increase was nearly the same in all fractions. In contrast, the proportions of 18:1*t* in TG and PL and 18:2*t* in TG and CE decreased on the OLEIC diet when compared with the baseline value (Fig. 1, Tables 3–5).

The 4-wk TRANS diet elevated most the quantitative amounts of 18:1*t* in PL (10.8 ± 3.3 vs. 32.6 ± 6.1) and TG (10.7 ± 3.4 vs. 31.2 ± 13.4), and the amount of 18:2*t* in CE (8.6 ± 1.2 vs. 16.1 ± 3.7) and TG (5.9 ± 1.8 vs. 12.7 ± 5.3). The OLEIC diet induced the most marked increase of oleic acid in CE (168.6 ± 22.8 vs. 178.7 ± 24.6) and PL (103.1 ±

[a]See Table 3 footnote.

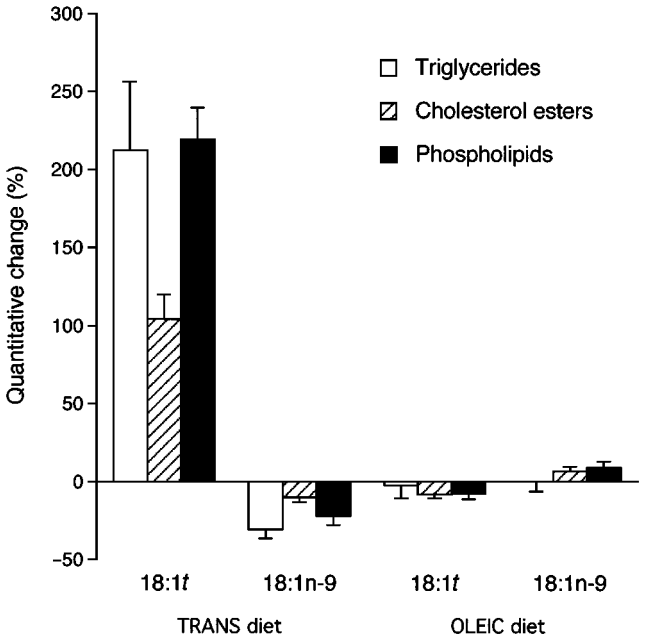

FIG. 1. Percentage changes of quantitative amounts from baseline after consumption of the TRANS and OLEIC diets for 18:1*t* and 18:1n-9, where *t* is *trans.*

16.9 vs. 111.7 ± 20.7). Notably, the average quantitative change of oleic acid in TG was negative (221.2 ± 68.2 vs. 220.2 ± 79.0).

After 4 wk on the OLEIC diet, the proportions of all SFA (myristic, palmitic, and stearic) decreased in TG and CE but only that of myristic acid in PL. In addition, the OLEIC diet led to the decreased proportions of docosahexaenoic acid in TG, linoleic acid and EPA in CE, and EPA and docosapentaenoic acid in PL. In CE an increased proportion of γ-linolenic acid was observed (Tables 3–5).

The proportions of both 18:1*t* and 18:2*t* in all three lipid fractions were higher after the TRANS diet when compared with those after the OLEIC diet. By contrast, the proportion of oleic acid was higher in all three fractions after the OLEIC diet when compared with that after the TRANS diet.

In general, the level of n-3 fatty acids in each of the lipid fractions assessed decreased after the subjects changed from the baseline to TRANS or OLEIC diets. In some cases these differences reached statistical significance.

The value of the sum of n-6 fatty acids (excluding linoleic acid) decreased in all lipid fractions on the TRANS diet compared to the baseline level, while this value remained unchanged on the OLEIC diet. The sums of n-6 fatty acids in CE and PL were lower at the end of the TRANS diet as compared with those at the end of the OLEIC diet. The proportion of dihomo-γ-linolenic acid in all lipid fractions was lower at the end of the TRANS diet when compared with the OLEIC diet.

The proportion of myristic acid in CE was higher and that of stearic acid in PL lower after consumption of the TRANS diet when compared with those at the end of the OLEIC diet. Of MUFA, the proportion of palmitoleic acid in TG and PL was higher after the TRANS diet than after the OLEIC diet. The proportion of linoleic acid in CE was higher, but that of α-linolenic acid lower after the TRANS diet.

DISCUSSION

In the present study the main dietary *trans* fatty acid, 18:1*t,* was preferentially incorporated in serum TG and PL, but to a lesser degree in CE, whereas dietary 18:2*t* induced a similar increase in all serum lipid fractions among young healthy women after 4 wk of moderate dietary intake of *trans* fatty

acids. The increase in the proportion of 18:1*t* was *ca.* threefold in serum TG and PL and twofold in CE. Also quantitative increases of 18:1*t* were highest in serum TG and PL. In contrast, the increase in the proportion of 18:2t was twofold, and quantitative increases were nearly the same in all lipid fractions reflecting identical incorporation of 18:2t in serum TG, CE, and PL.

The intake of *trans* fatty acids during the TRANS diet was *ca.* five times higher (5 E%) than the amount of *trans* fatty acids in the habitual Finnish diet (about 1 E%, that means 1.7 g/person/day and 1.9% of the total fat consumption), the main source (77%) being edible fats (17). Habitual diet includes *ca.* 80% of the dietary *trans* fatty acids as 18:1 isomer and 20% as 18:2 isomers (17). In the present study the *trans* fatty acid-enriched margarine consisted of *ca.* 80% *trans* fatty acid 18:1 isomer and *ca.* 20% *trans* fatty acid 18:2 isomers from all *trans* fatty acids, the proportion identical to the Finnish diet.

In some previous studies the incorporation of dietary *trans* fatty acids was analyzed in total plasma or serum lipids (9,18,19) or in serum TG (10,11,20), CE (12) or PL (11), in platelet PL (10,20), and erythrocytes (21), and in serum TG, CE, and PL in animal study (14). The *trans* fatty acid composition data of serum or plasma TG, CE, and PL of mothers, their infants and children, and estimated dietary *trans* fatty acid intake have been reported (22). In the present study the change from about 1 to 5 E% achieved an increase in the proportion of serum TG and PL and also in CE. The relative levels of incorporation of 18:1*t* into TG, PL, and CE are consistent with the isotope tracer data reported earlier (6). In rabbits, 18:1*t* from diet was incorporated into the fatty acids of serum TG, CE and PL, although the levels of incorporation were considerably under the level of *trans* fatty acid in the diet (14). Mensink and Hornstra (10) reported decreased proportion of 18:1*t* in serum TG from 3.5 ± 0.1 to 2.8 ± 0.1% when habitual intake of total *trans* fatty acids decreased from 4.7 ± 0.3 to 2.1 ± 0.2 E%.

Serum TG tends to reflect the fatty acid composition of the most recent meals, and the variation in the *trans* fatty acids for TG is larger than for other lipid fractions. Nestel and coworkers (18) reported a sevenfold increase in plasma elaidic acid concentration with the *trans* fatty acid diet (7 E%) during 11 wk in 27 mildly hypercholesterolemic men. However, total plasma lipid data are not considered a valid biomarker estimating dietary *trans* fatty acid intake over the long term. In contrast, serum PL reflects the habitual dietary intake over a period of several weeks, and according to the present results it would be one biomarker of dietary *trans* fatty acid intake in the long term. The 18:1*t* to 18:2*t* ratio was also closest to that in diet in PL.

Trans fatty acids behave like SFA, and they are preferentially incorporated into the 1-position in PL replacing SFA. In the present study, after consumption of 5 E% TRANS diet, the proportions of palmitic, stearic, and SFA decreased not only in PL but in TG and CE, as well, which indirectly supports the view of replacements. Oleic acid, but not 18:1*t*, competes with linoleic acid for incorporation into the 2-position of PL. Thus, on the TRANS diet a greater incorporation of linoleic acid into PL would be expected. This was, in fact, observed in our study subjects as in an earlier animal study (14), where after *trans* fatty acid feeding increased the amount of linoleic acid in CE and PL, but was found unchanged in TG when compared to 18:1 *cis* diet.

Our results suggest that *trans* fatty acids may be involved in the metabolism of n-6 fatty acids as a result of a reduced conversion of linoleic acid to its long-chain polyunsaturated metabolites (γ-linolenic, dihomo-γ-linolenic, and arachidonic acids) observed in the subjects fed the TRANS diet. These findings are compatible with inhibition of arachidonic acid formation by *trans* fatty acids as a result of inhibition of desaturase activity (23–27). Another explanation for the reduced proportion of n-6 metabolites is the selective incorporation of linoleic acid into PL. These changes could potentially result in the preservation of an unsaturated *cis* double bond-containing fatty acid in the 2-position of PL favoring lecithin cholesterol acyltransferase activity. In the present study the proportion of arachidonic acid decreased in all lipid fractions. In contrast, Wood and coworkers (19) noticed higher level of arachidonic acid in total serum lipids after *trans* diet (5.5 E% from *trans* fatty acids). This issue still needs to be resolved.

The proportion of n-3 fatty acids tended to decrease after subjects were switched from the baseline to either the TRANS or OLEIC diet. These findings suggest a shift in the fatty acid profile of the diet, and the dramatic alteration of the *trans* or MUFA content of the diet at the expense of n-3 fatty acids will be reflected in the fatty acid profile at all lipid fractions.

The proportion of oleic acid increased significantly in all lipid fractions of our study subjects reflecting good adherence to the OLEIC diet. Fatty acid compositions of serum TG and PL are considered good biomarkers of oleic acid intake because oleic acid predominates in TG (13). Our results support this finding although the percentile increase of oleic acid in all

TABLE 6
Total Serum Cholesterol and Triglycerides (mmol/L) and Quantitative Amounts (μg/mL) of 18:1*t* and 18:2*t* in the Serum Triglycerides, Cholesterol Esters and Phospholipids, and Changes from Baseline After Consumption of the TRANS Diet[a]

[a]See Table 3 footnote.

lipid fractions was relatively small, a finding consistent with previous studies (28). In the present study, the 5 E% increase in oleic acid intake induced a 12–18% increase of oleic acid in lipid fractions. Also Valsta *et al.* (29) reported about 7% increase in the proportion of oleic acid in serum TG, although the dietary intake of oleic acid (from olive oil) increased by 47%. Increased proportions of oleic acid in TG (30) and CE (31) were seen after oleic acid-enriched diets while Sarkkinen and coworkers (32) did not find any increase in the proportion of oleic acid in serum CE, erythrocyte, or platelet membranes when the increase of monoene intake was rather low.

The most plausible explanation for the decrease of 18:1*t* and 18:2*t* in serum lipid fractions after consumption of the OLEIC diet in the present study is the decreased intake since the amount of butter was smaller in the OLEIC diet than the baseline diet. Also the medium-fat milk products of the baseline diet were replaced by low-fat milk products in the OLEIC diet.

In conclusion, a moderate increase in dietary *trans* fatty acids results in a marked incorporation into serum TG and PL, and to a lesser degree in CE. In addition, our results suggest that 5 E% *trans* fatty acids in diet decrease the conversion of linoleic acid to its more unsaturated long-chain metabolites. Analysis of 18:1*t* from serum TG and PL seems to reflect reliably the dietary intake of this fatty acid.

ABSTRACT: Commercial cheese products were analyzed for their composition and content of conjugated linoleic acid (CLA) isomers. The total lipids were extracted from cheese using petroleum ether/diethyl ether and methylated using $NaOCH_3$. The fatty acid methyl esters (FAME) were separated by gas chromatography (GC), using a 100-m polar capillary column, into nine minor peaks besides that of the major rumenic acid, 9*c*,11*t*-octadecadienoic acid (18:2), and were attributed to 19 CLA isomers. By using silver ion–high performance liquid chromatography (Ag^+–HPLC), CLA isomers were resolved into seven *trans,trans* (5–9%), three *cis/trans* (10–13%), and five *cis,cis* (<1%) peaks, totaling 15, in addition to that of the 9*c*,11*t*-18:2 (78–84%). The FAME of total cheese lipids were fractionated by semipreparative Ag^+–HPLC and converted to their 4,4-dimethyloxazoline derivatives after hydrolysis to free fatty acids. The geometrical configuration of the CLA isomers was confirmed by GC–direct deposition–Fourier transform infrared, and their double bond positions were established by GC-electron ionization mass spectrometry. Reconstructed mass spectral ion profiles of the $m + 2$ allylic ion and the $m + 3$ ion (where m is the position of the second double bond in the parent conjugated fatty acid) were used to identify the minor CLA isomers in cheese. Cheese contained 7*t*,9*c*-18:2 and the previously unreported 11*t*,13*c*-18:2 and 12*c*,14*t*-18:2, and their *trans,trans* and *cis,cis* geometric isomers. Minor amounts of 8,10-, and 10,12-18:2 were also found. The predicted elution orders of the different CLA isomers on long polar capillary GC and Ag^+–HPLC columns are also presented.

Lipids 33, 963–971 (1998).

Conjugated linoleic acid (CLA) has been reported to lead to reduced carcinogenesis (1–5) and atherosclerosis (6,7), increased bone mass (8) and muscle mass (9–11), and to have antidiabetic properties (12) in laboratory animals. The term CLA refers to a mixture of positional and geometric conjugated octadecadienoic acid (18:2) isomers. The active isomer has been assumed to be 9*c*,11*t*-18:2 (also called rumenic acid) because it is the major CLA isomer present in milk (13–20), cheese (15,21–27), and meat (14,15,28) from ruminant animals. It is formed as an intermediate in the biohydrogenation of linoleic acid in the rumen (29–31), and possibly by Δ9 desaturation of vaccenic acid (11*t*-18:1) (32).

Besides the major 9*c*,11*t*-18:2 established by Parodi (13), there are a number of minor CLA isomers in cheese and milk. To date, their reported identities and levels remain questionable, because of inadequate chromatographic separations and confirmatory methods used to establish the double bond positions and configurations. Ha *et al.* (21) were the first to report six additional CLA peaks in cheese separated on a 60-m Supelcowax-10 gas chromatographic capillary column. Based on comparisons of gas chromatographic equivalent chain lengths with published data (33), they reported the presence of 10*c*,12*t*-18:2, 10*t*,12*c*-18:2, 11*c*,13*c*-18:2, 9*c*,11*c*-18:2, 10*c*,12*c*-18:2, 9*t*,11*t*-18:2, and 10*t*,12*t*-18:2 as fatty acid methyl esters (FAME) after BF_3 methylation. They determined the molecular weight of the CLA isomers by gas chromatography (GC)–chemical ionization mass spectrometry (MS), but were unable to identify CLA positional isomers by GC–MS using 4-phenyl-1,2,4-triazoline-3,5-dione derivatives. Nevertheless, their BF_3 methylation procedure, GC separation conditions, and equivalent chain length comparisons were subsequently used by many investigators (17,23,24,34), with variation in the methylation catalyst, i.e., HCl (15,22), tetramethylguanidine (25), or $NaOCH_3$ (35). Acid (BF_3 or HCl)-catalyzed methylations (8,15,17,21–24,34) were shown to lead to isomerization of *cis/trans* to *trans,trans* CLA isomers and the formation of methoxy artifacts (19), as well as CLA artifacts from allylic hydroxy fatty acids (36). Acid fat extraction procedures (22,25) may also lead to CLA isomer-

Abbreviations: *c*; *cis*; *cis/trans*, refers to the same positional isomers that have either a *cis,trans* or a *trans,cis* configuration; CLA, conjugated linoleic acid; DMOX, 4,4-dimethyloxazoline; FAME, fatty acid methyl esters; GC–DD–FTIR, gas chromatography–direct deposition–Fourier transform infrared; GC–EIMS, gas chromatography–electron ionization mass spectrometry; HPLC, high performance liquid chromatograph(y); *t, trans*.

ization. On the other hand, base-catalyzed methylation did not isomerize CLA isomers nor produce methoxy artifacts (19). The GC resolution of CLA isomers was improved by using 100-m polar capillary columns under optimal conditions, which resulted in the separation of 10 GC peaks attributed to CLA isomers (19,37).

Recently, Lavillonnière *et al.* (26) reported the identity of five additional minor CLA isomers in cheese (8*c*,10*t*-18:2, 8*c*,10*c*-18:2, 8*t*,10*t*-18:2, 11*t*,13*t*-18:2, and 11?,13?-18:2). They methylated cheese lipids with $NaOCH_3$, then partially reduced the isolated CLA mixture with hydrazine, separated the resultant monounsaturated (18:1) FAME by silver nitrate thin-layer chromatography, and analyzed them by GC. The positional 18:1 isomers were identified as 4,4-dimethyloxazoline (DMOX) derivatives by GC–electron ionization mass spectrometry (GC–EIMS). These authors also evaluated the total CLA DMOX mixture by GC–EIMS.

We have just reported the separation of 12 CLA isomers as their FAME from a commercial CLA mixture by using silver ion high-performance liquid chromatography (Ag^+–HPLC) based on their double-bond geometry (*trans,trans*, *cis/trans,* and *cis,cis*) and position (8,10-, 9,11-, 10,12-, and 11,13-18:2) (27). The Ag^+–HPLC method, together with reconstructed GC–EIMS ion profiles of isomer-specific ions for CLA DMOX derivatives, permitted us to identify the previously unrecognized and abundant minor isomer, 7*t*,9*c*-18:2, in milk, cheese, beef, and human milk and adipose tissue (38).

In the present communication, we report the accurate identification and composition of CLA isomers in cheese, including for the first time the previously unreported 11*t*,13*c*- and 12*c*,14*t*-18:2 isomers. Cheese lipids were fractionated by semipreparative Ag^+–HPLC, and the minor CLA isomers were identified by GC–EIMS and GC–direct deposition-Fourier transform infrared (GC–DD–FTIR) spectrometry.

MATERIALS AND METHODS

A mixture of CLA FAME was purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Pure CLA isomers (9*c*,11*t*-18:2, 10*t*,12*c*-18:2, 9*c*,11*c*-18:2, and 9*t*,11*t*-18:2) were obtained as free fatty acids from Matreya Inc. (Pleasant Gap, PA). Acetonitrile and hexane were ultraviolet grade. Other solvents were distilled-in-glass quality. 2-Amino-2-methyl-1-propanol (95%) was purchased from Aldrich Chemical Company, Inc. (Milwaukee, WI). A 10% solution of trimethylsilyldiazomethane in hexane was obtained from TCI America (Portland, OR). The cheeses were purchased locally.

Lipid extraction. Cheese was extracted using a published procedure (39). Briefly, 20 g cheese, 2 g potassium oxalate, and 100 mL ethyl alcohol were placed in a blender jar and homogenized for 3 min. The jar contents were poured into a 250-mL centrifuge tube, to which 50 mL diethyl ether and 50 mL petroleum ether were added. The contents were mixed well for 0.5 min after each addition of solvent. The mixture was centrifuged at 1700 rpm for 7 min at room temperature. The lower phase was reextracted two more times with 50 mL petroleum ether and diethyl ether (1:1, vol/vol). The combined organic phases were transferred into a 1000-mL separatory funnel containing 500 mL distilled water and 30 mL saturated sodium chloride. The combined organic extract was washed two more times with 100 mL distilled water. Any emulsion formed was broken up by the addition of saturated sodium chloride (2–5 mL), and allowed to stand for 30 min. The combined organic layer was poured through a glass column (2.5 cm × 50 cm) containing a bed of anhydrous sodium sulfate (15 cm). The organic solvent was removed using a rotary evaporator at 37°C and the total lipids were determined gravimetrically.

Preparation of FAME. Free fatty acids of CLA were dissolved in 1 mL of 20% methanol/benzene, placed in a reaction tube fitted with a Teflon-lined screw cap, and reacted with trimethylsilyldiazomethane for 30 min at room temperature (40). Unreacted trimethylsilyldiazomethane was destroyed by adding acetic acid with gentle swirling until the yellow color disappeared. After addition of H_2O (5 mL), 1 mL isooctane was added to extract the FAME which were subsequently dried over Na_2SO_4.

Portions of total lipids from cheese (20–70 mg) were placed into 15-mL reaction tubes fitted with a Teflon-lined screw cap. One milliliter of benzene was added to dissolve the lipids, followed by 4 mL anhydrous $NaOCH_3$. The tubes were flushed with nitrogen, then heated at 50°C for 10 min with occasional shaking. After completion of methylation, 0.2 mL of water was added, and the FAME were extracted with hexane, dried over Na_2SO_4, and analyzed directly by GC and HPLC.

HPLC. The HPLC (Waters 510 solvent delivery system; Waters Associates, Milford, MA) was equipped with an autosampler and 2-mL injection loop for the semipreparatory column and a 200-µL injection loop for the analytical column (Waters 717), an ultraviolet detector (Waters 486 tunable absorbance), a fraction collector (Waters LR 76413), and an operating system (Waters Millennium^{TM} version 2.15.01). Both ChromSpher 5 Lipids semipreparative (10 mm i.d. × 250 mm stainless steel; 5 µm particle size) and an analytical (4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size) silver-impregnated column were used (Chrompack, Bridgewater, NJ). CLA isomers were measured at 233 nm. The mobile phase was 0.1% acetonitrile in hexane and operated isocratically. The solvent flows were 4.0 and 1.0 mL/min, for the semipreparative and analytical columns, respectively. The flow was commenced for 0.5 h prior to sample injection. For solution containing about 20 mg/mL, typical injection volumes were 150–200 µL for the semipreparative column and 5–15 µL for the analytical column. Whenever necessary, the column was restored by flushing with 1% acetonitrile in hexane for 4 h followed by 0.5 h with 0.1% acetonitrile in hexane.

DMOX derivatives. In a reaction tube, 10–20 mg of methyl heptadecanoate (17:0) and *ca.* 1–2 mg of CLA FAME were added, and the mixture was hydrolyzed with 1 N KOH/95% ethanol at 50°C for 30 min. The free fatty acids were extracted with petroleum ether after the reaction was neutral-

ized with HCl. The free fatty acids were added to a screw-cap reaction tube (1 mL) and a threefold excess of 2-amino-2-methyl-1-propanol (w/w) was added. The tube was purged with argon, capped, and heated at 170°C for 0.5 h in an oven. The reaction mixture was transferred into a 250-mL separatory funnel containing 40 mL of petroleum ether and 50 mL of water and shaken vigorously. Saturated NaCl was added to break the emulsion. The aqueous layer was removed, and the petroleum ether was rewashed with water, dried over anhydrous Na_2SO_4 and concentrated to the desired volume under a stream of argon (36).

GC. The cheese FAME were analyzed by GC (model 5890; Hewlett-Packard, Palo Alto, CA) using a fused-silica capillary column (CP-Sil 88; 100 m × 0.25 mm i.d. × 0.2 µm film thickness; Chrompack Inc.). The column was held at 70°C for 4 min after injection, temperature-programmed at 13°C/min to 175°C, held there for 27 min, then temperature-programmed at 4°C/min to 215°C, and held there for 31 min. Hydrogen was the carrier gas, at a split ratio of 20:1.

GC–EIMS. The GC–EIMS was performed using a GC (Hewlett-Packard 5890, series II) coupled to a mass spectrometer (Autospec Q mass spectrometer) and a data system (OPUS 4000; Micromass, Manchester, United Kingdom). The GC–EIMS system utilized version 2.1 BX software. This system was used with a 50-m CP-Sil 88 capillary column described previously (41). The GC–EIMS conditions were: splitless injection with helium sweep restored 1 min after injection; injector and transfer lines' temperature 220°C; oven temperature was 75°C for 1 min after injection, then temperature-programmed 20°C/min to 185°C, held there for 15 min, then temperature-programmed 4°C/min to 220°C, and held there for 45 min.

GC–DD–FTIR. A Bio-Rad (Cambridge, MA) Tracer™ GC–FTIR 60A spectrometer system was used. This system was used with a 50 m CP-Sil 88 capillary column (42).

RESULTS AND DISCUSSION

Fat extraction from cheese. The total fat was extracted from cheese (39). In this method, potassium oxalate served as a grinding agent and formed calcium oxalate, which prevented calcium ions from causing emulsions. The total fat content of 11 commercial cheese products ranged from 14 to 37% (Table 1). For the extraction of fats and oils, acid conditions were avoided because they may lead to isomerization of the *cis/trans* to *trans,trans* CLA isomers. In a previous study (22) preliminary acid digestion may have contributed to the low content of 9*c*,11*t*-18:2, 48–68% (22), instead of 78–84% reported for selected cheese products (Table 1).

Methylation. The total lipids from cheese were methylated using $NaOCH_3$ to avoid any isomerization of conjugated dienes and formation of methoxy and CLA artifacts. Acid-catalyzed methylation using either BF_3, HCl or H_2SO_4 would lead to conversion of *cis/trans* to *trans,trans* CLA isomers. Reducing the temperature during methylation reduced the extent of this conversion (17,23,43), but the methylation, particularly of phospholipids, may not be complete (19). Therefore, to avoid isomerization and incomplete methylation of CLA, $NaOCH_3$ is recommended. If test samples contained significant amounts of free fatty acids, alkali hydrolysis followed by subsequent methylation using tetramethylsilyldiazomethane (40) was carried out and checked by thin-layer chromatography (19), and these steps are recommended. However, neither of these two methods will methylate sphingomyelin, since the *N*-acyl bond is resistant to alkali. In the present cheese study, we ignored the small contribution of CLA from sphingomyelin because its level in cheese was less than 0.1%, and the occurrence of CLA in sphingomyelin is generally the lowest compared to all the other phospholipids (37).

GC. The CLA region of the FAME GC trace for cheese (Fig. 1) was a complex mixture of 10 peaks attributed to many

Expected Gas Chromatographic Elution Order of Positional and Geometric CLA Fatty Acid Methyl Ester, or Dimethyloxazoline, Isomers on a 100 m CP-Sil 88 Capillary Column[a]

cis/trans-18:2[b]	*cis,cis*-18:2[c]	*trans,trans*-18:2[d]
7*c*,9*t*	(7*c*,9*c*)[e]	12*t*,14*t*
(6*t*,8*c*)	8*c*,10*c*	11*t*,13*t*
(8*c*,10*t*)	9*c*,11*c*	10*t*,12*t*
7*t*,9*c*	10*c*,12*c*	9*t*,11*t*
9*c*,11*t*	11*c*,13*c*	8*t*,10*t*
8*t*,10*c*	12*c*,14*c*	7*t*,9*t*
10*c*,12*t*		
9*t*,11*c*		
11*c*,13*t*		
10*t*,12*c*		
12*c*,14*t*		

[a]The elution order was: all the *cis/trans,* followed by all the *cis,cis,* followed by all the *trans,trans* CLA positional isomers. Many CLA isomers overlapped within each geometric group.
[b]The observed elution time of *cis/trans* CLA isomers increased as the Δ value of the *cis* double bond increased in the molecule. For a pair of *cis/trans* isomers in which the *cis* double bond has the same Δ value, the isomer with the lower Δ *trans* value eluted first. Therefore, it followed that for the same positional isomer, the *cis,trans* eluted before the *trans,cis* geometric isomer.
[c]The observed elution time of *cis,cis* CLA isomers increased with increased Δ values.
[d]The observed elution time of *trans,trans* CLA isomers increased with decreased Δ values.
[e]CLA isomers shown in parentheses were predicted. For abbreviations see Table 1.

more unresolved CLA isomers, even with a highly polar 100-m capillary column. The CLA isomers in the gas chromatogram were labeled based on an elution order that was verified recently (19,37,38) as well as in this study; see the predicted elution order in Table 2. Besides the major 9*c*,11*t*-18:2, there were minor peaks in the *cis/trans* region corresponding to 9*t*,11*c*- plus 10*c*,12*t*-18:2; 11*t*,13*c*-18:2; and a mixture of 10*t*,12*c*- plus 12*c*,14*t*-18:2. The 7*t*,9*c*,10*c*,12*c*- and 8*t*,10*c*-18:2 isomers eluted on the leading and the tailing edges of 9*c*,11*t*-18:2, respectively. In the *cis,cis* region (Fig. 1) there was one major peak consisting of a mixture of 7*c*,9*c*-, 8*c*,10*c*-, and 9*c*,11*c*-18:2, followed by a smaller peak due to 10*c*,12*c*-, 11*c*,13*c*-, plus 12*c*,14*c*-18:2. The *trans,trans* region showed four responses attributed to the FAME of 12*t*,14*t*-18:2; 11*t*,13*t*-18:2; a mixture of 10*t*,12*t*-, 9*t*,11*t* plus 8*t*,10*t*-18:2; and 7*t*,9*t*-18:2 (Fig. 1). To separate and confirm the identity of CLA isomers, complementary techniques, such as Ag^+–HPLC, GC–EIMS and GC–DD–FTIR were used.

Ag^+–HPLC. The separation of cheese FAME by Ag^+–HPLC is shown in Figure 2. The elution order observed by Ag^+-HPLC for a commercial mixture of 12 CLA isomers (27), plus those found in natural products (38, and the present study), are listed in Table 3. The main CLA isomer in cheese was 9*c*,11*t*-18:2. To determine the structure of the many minor CLA isomers, FAME were prepared from 1 g of cheese lipids and were fractionated using a semipreparative Ag^+–HPLC column. Five fractions were collected and those containing minor CLA isomers, Fractions 1, 2, 4 and 5, were shown after expanding the *y*-scale in Figure 2. The fractions were subsequently derivatized to DMOX and analyzed by GC–EIMS and GC–DD–FTIR.

GC–EIMS reconstructed ion profiles for DMOX derivatives of conjugated dienes. The fatty acid DMOX mass spectra consisted of a series of even-mass ions separated by 14 mass units due to successive losses of methylene units. A gap of 12 mass units between ions containing n–1 and n carbon atoms indicated the presence of a double bond between carbons n and n + 1 of the parent fatty acid (44). For monounsaturated fatty acids, more abundant peaks occurred due to allylic cleavages on either side of the gap of 12 mass units for ions containing $n - 2$ and $n + 2$ carbons (44). In addition, the $n + 3$ carbons fragment ion occurred in equal abundance to the one containing $n + 2$ carbons; the mechanism of formation of this ion remains unknown (45). Therefore, for conjugated dienes, prominent ions occurred at $n - 2$, $m + 2$ and $m + 3$, where n is the position of the first double bond and m is the position of the second double bond along the parent conjugated fatty acid chain. These three prominent ions were clearly recognizable in previous published spectra of CLA DMOX (27,46,47), and in the series of mass spectra of 12,14-18:2 to 8,10-18:2 isomers found in cheese (Fig. 3).

The characteristic abundant ions with $m + 2$ and $m + 3$ carbons in the GC–EIMS DMOX spectra of CLA isomers were used in this study to identify trace amounts of isomers, because the gap of 12 mass units was often too weak to observe. For example, all the minor CLA isomers in Figure 3, except for the major 9*c*,11*t*-18:2 isomer, were missing one or more of the expected ions of the conjugated system, but the allylic $m + 2$ and the $m + 3$ ions were clearly visible. The prominent ion profiles for the $m + 2$ and $m + 3$ pair of ions due to a spe-

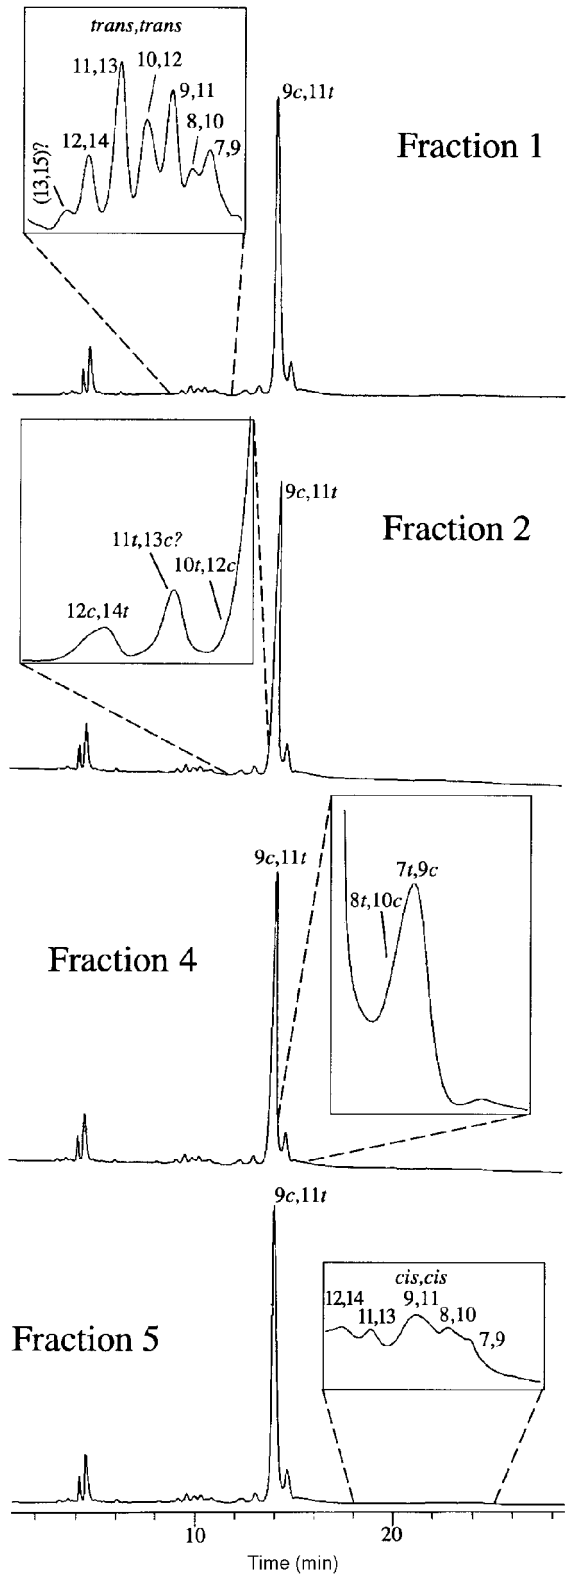

FIG. 2. Silver ion–high performance liquid chromatography (Ag^+–HPLC) profile for a commercial cheese product. Expanded traces are shown for Fractions 1 (A), 2 (B), 4 (C), and 5 (D). These fractions were collected by Ag^+–HPLC for further analysis.

TABLE 3
Elution Order of Positional and Geometric CLA FAME Isomers by (Ag^+–HPLC)[a]

trans,trans-18:2[b]	*cis/trans*-18:2[b,c]	*cis,cis*-18:2[b]
(13*t*,15*t*)d	(13,15 *c/t*)	
12*t*,14*t*	12,14 *c/t*	12*c*,14*c*
11*t*,13*t*	11,13 *c/t*	11*c*,13*c*
10*t*,12*t*	10,12 *c/t*	10*c*,12*c*
9*t*,11*t*	9,11 *c/t*	9*c*,11*c*
8*t*,10*t*	8,10 *c/t*	8c,10*c*
7*t*,9*t*	7,9 *c/t*	7*c*,9*c*

[a]The elution order was: all the *trans,trans,* followed by all the *cis/trans,* followed by all the *cis,cis* CLA positional isomers.
[b]The observed elution time of each group of geometric CLA isomers increased as the Δ values decreased.
[c]For the same positional isomer, the *cis,trans* and the *trans,cis* geometric isomers were not clearly separated under our experimental conditions.
[d]CLA isomers shown in parentheses were not confirmed. For abbreviations see Table 1.

cific CLA isomer were normalized and displayed. If these two ion profiles superimposed, then this GC peak was due to this specific CLA isomer. For nearly coeluting (or coeluting) CLA isomers, the reconstructed ion chromatograms showed a small (or lack of) difference in retention times. This reconstructed ion profile GC-EIMS method allowed the identification of most minor CLA isomers in cheese.

Identification of Ag^+–HPLC fractions. Fraction 1 consisted of a mixture of seven *trans,trans* CLA peaks (Fig. 2), as evidenced by the elution order of geometric CLA isomers previously found by Ag^+–HPLC (27) and verified by GC–DD–FTIR with characteristic =C-H stretching (3016 cm^{-1}) and deformation (990 cm^{-1}) vibrations for *trans,trans* CLA isomers. The GC–EIMS reconstructed ion profile for the molecular ion *m/z* 333 of the DMOX derivative of all CLA isomers is shown in Figure 4A. The total *trans,trans* CLA DMOX mixture exhibited three GC–EIMS peaks using a 50-m CP-Sil 88 capillary column. In using the reconstructed ion profile technique described above, the identify of the first small peak (Fig. 4C) was established as 12*t*,14*t*-18:2 (Fig. 3). The second CLA peak (Fig. 4B) was due to 11*t*,13*t*-18:2 (Fig. 3), and the third one (Fig. 4D) to 9*t*,11*t*-18:2 (Fig. 3). The CLA isomers 8*t*,10*t*- and 10*t*,12*t*-18:2 coeluted with 9*t*,11*t*-18:2 (reconstructed ion profile not shown), while the 7*t*,9*t*-18:2 eluted on the tail of the third peak [see reference (38), Fig. 1 bottom]. The first small peak in the Ag^+–HPLC chromatogram (Fig. 2, Fraction 1) would appear to be 13*t*,15*t*-18:2 based on the Ag^+–HPLC elution order, although this was not confirmed by GC–EIMS.

In Figure 3, GC–EI mass spectra were obtained from different cheese fractions, except the one for 10,12-18:2, because this *trans,trans* isomer coeluted by GC–EIMS with 9*t*,11*t*-18:2 (Fig. 4D), and the corresponding *cis/trans* and *cis,cis* isomers were very weak. However, its identity was confirmed from the reconstructed ion profiles for *m/z* 276 (*m* + 2) and 290 (*m* + 3) in each case. A mass spectrum of 10*t*,12*c*-18:2, shown for comparison in Figure 3, was selected from a previous study on the distribution of CLA isomers in pig lipid classes (37).

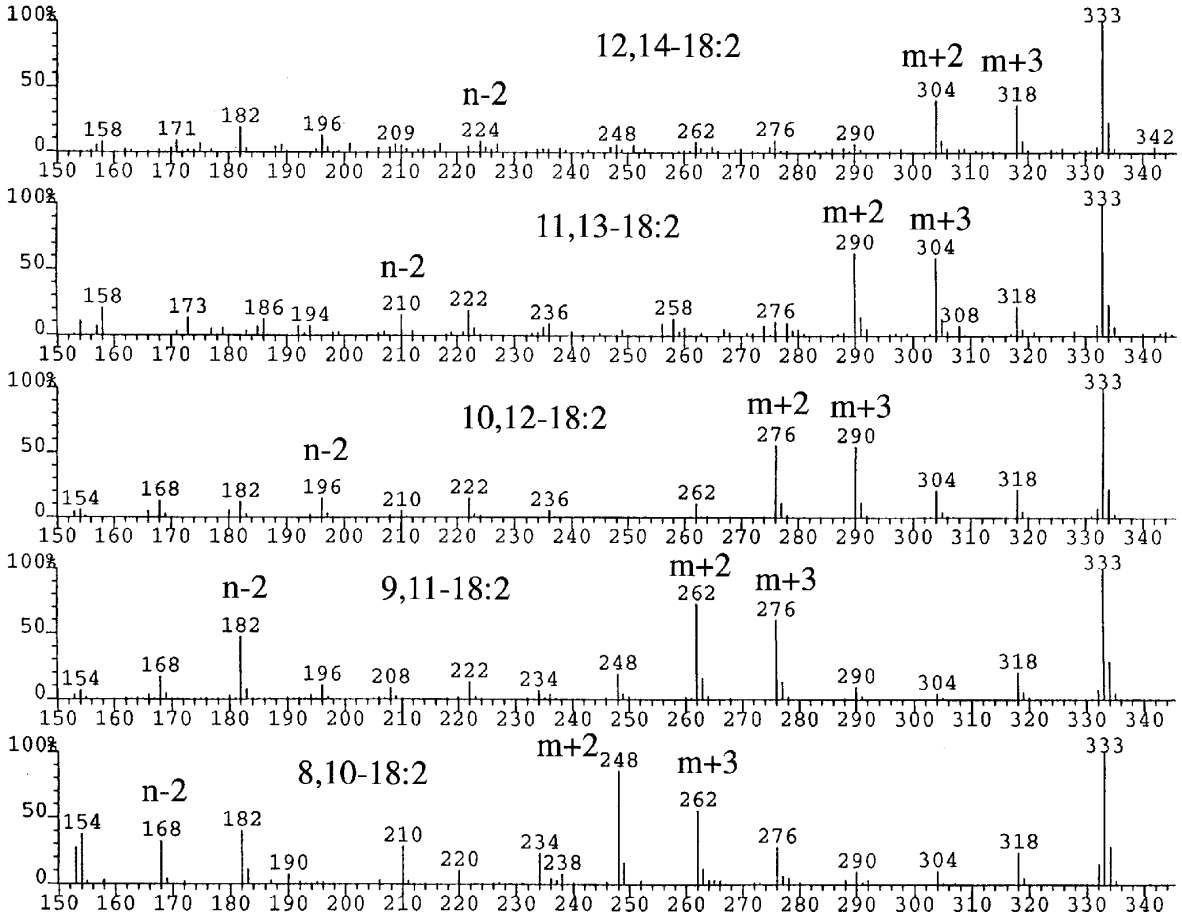

FIG. 3. GC–electron ionization mass spectra of the 4,4-dimethyloxazoline (DMOX) derivatives of 12*t*,14*t*-18:2 (Fraction 1), 11*t*,13*t*-18:2 (Fraction 1), 10*t*,12*c*-18:2 [reference (37), see text], 9c,11*t*-18:2 (Fraction 2), and 8*c*,10*c*-18:2 (Fraction 5). The allylic ions $n-2$ and $m+2$, and the $m+3$ ion are labeled for each of the positional CLA DMOX isomers; the molecular ion was *m/z* 333. For other abbreviations see Figure 1.

Fraction 2 (Fig. 2) showed two minor *cis/trans* CLA peaks eluting before the major 9*c*,11*t*-18:2, whose *cis/trans* geometric configuration was consistent with Ag^+–HPLC and GC–DD–FTIR data. In using the same reconstructed ion profile techniques described for the *trans,trans* CLA isomers, the peaks were shown to be due to 12,14- and 11,13-18:2. The EI mass spectra of the DMOX derivative of the 12,14- and 11,13-18:2 isomer were similar to the corresponding *trans,trans* CLA isomers shown in Figure 3. The geometric configuration of 12,14-18:2 was likely 12*c*,14*t*-18:2 based on the GC elution sequence and because it was possibly derived from biohydrogenation and isomerization of α-linolenic acid in the rumen. The geometric configuration of the 11,13-18:2 isomer in cheese was probably 11*t*,13*c*-18:2 based on the following considerations. On a 100-m CP Sil 88 column (Fig. 1), the 11,13-18:2 isomer in cheese eluted after the 11*c*,13*t*-18:2 isomer previously found in a Nu-Chek-Prep commercial mixture (27,37). In using two Ag^+–HPLC columns in series, the 11,13-18:2 isomer in cheese eluted before the 11*c*,13*t*-18:2 present in the Nu-Chek-Prep commercial mixture when these two lipid mixtures were coinjected (Sehat, N., unpublished data). Therefore, the relative elution sequences of the two *c/t* 11,13-18:2 isomers observed by both Ag^+–HPLC and GC are consistent with the presence of 11*t*,13*c*-18:2 in cheese. On the other hand, the fact that 11*t*,13*c*-18:2 eluted *before* 10*t*,12*c*-18:2 by GC cannot be reconciled with the expected GC elution sequence (Table 2), namely, 10*t*,12*c*-18:2 is expected to elute first, followed by 12*c*,14*t*-18:2 and then by 11*t*,13*c*-18:2. Therefore, the identification of the *c/t* 11,13-18:2 peak in cheese is only tentatively attributed to the 11*t*,13*c*-18:2 isomer. The double-bond configuration of these two *c/t* 11,13-18:2 geometric isomers (after isolation) still needs to be definitively confirmed by such methods as hydrazine reduction and GC separation of the resulting 18:1 fatty acids (26, and references cited therein). Trace amounts of 10*t*,12*c*-18:2 were generally not resolved chromatographically from the major 9*c*,11*t*-18:2 by Ag^+–HPLC because of the large differences in concentration between these two isomers.

Fraction 3 contained the major 9*c*,11*t*-18:2 (Fig. 2), which was not further investigated. Fraction 4 (Fig. 2) contained one *cis/trans* CLA peak. The main isomer under this minor peak

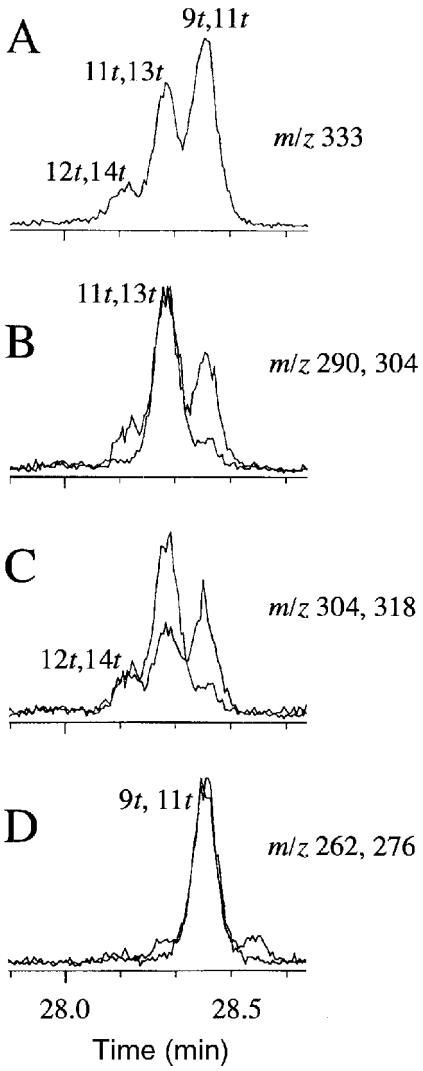

FIG. 4. Reconstructed ion chromatograms for DMOX derivatives of *trans,trans* CLA isomers in Fraction 1 isolated from cheese using Ag^+–HPLC showing the profiles for (A) the molecular ion *m/z* 333; (B) the allylic ion (*m* + 2) and the *m* + 3 ion for 11,13-18:2, (C) 12,14-18:2, and (D) 9,11-18:2. In each case these two ions were normalized for the CLA isomer indicated. For abbreviations see Figures 1–3.

was identified as 7*t*,9*c*-18:2 by GC–EIMS, GC–DD–FTIR and by comparison with partial synthesis, as reported recently (38). In addition to the 7*t*,9*c*-18:2, small amounts of 8*t*,10*c*-18:2 were evident under this peak by GC–EIMS.

Fraction 5 (Fig. 2) contained a mixture of five *cis,cis* CLA peaks as evidenced by their elution on Ag^+–HPLC (Table 3). The more predominant CLA isomers were identified by GC–EIMS as 9*c*,11*c*-18:2 and 8*c*,10*c*-18:2, with minor amounts of 12*c*,14*c*-, 11*c*,13*c*-, and 7*c*,9*c*-18:2. The EI mass spectrum of the DMOX derivative of the 8*c*,10*c*-18:2 isomer is shown in Figure 3. The peak expected for 10*c*,12*c*-18:2 was not observed, probably because it was too weak.

Composition of CLA isomers in cheese. The total CLA content of cheese fats was determined by GC and ranged from 0.4 to 0.8% (Table 1). Based on the separation of CLA isomers by Ag^+–HPLC, the compositions of the various cheese products are reported in Table 1. The concentration of the major 9*c*,11*t*-18:2 ranged from 78 to 84% (as percentage of total CLA) in the cheese products investigated. Among the minor CLA isomers, 7*t*,9*c*-18:2 was the most predominant at about 5 to 12% (containing undetermined small amounts of 8*t*,10*c*-18:2), followed by 11*t*,13*c*-18:2 at about 2%. The presence of 7*t*,9*c*-18:2 in the rumen is expected from Δ9 desaturation of 7*t*-18:1, and to a smaller extent from biohydrogenation and isomerization of γ-linolenic acid, while 12*c*,14*t*-18:2 is from biohydrogenation and isomerization of α-linolenic acid. The remainder was a mixture of total *trans,trans* (5 to 9%) and *cis,cis* (<1%) CLA isomers produced in the complex rumenal fluids.

Alternative methods used to determine CLA isomers in cheese by partial reduction with hydrazine, followed by GC separation of the resultant mixtures of octadecenoic acids (18:1) (26), did not lead to the identification of the 12,14- and 7,9-18:2 isomers. A possible reason for the latter is that 14*t*-18:1 is only partially resolved on polar capillary GC columns from 13*t*-18:1 as DMOX, and even less resolved as FAME (48). Similarly, the 7*t*-18:1 FAME coelutes with 6*t*- and 8*t*-18:1 FAME, while 7*t*-18:1 DMOX coelutes with 9*t*-18:1 DMOX (48).

The 11*t*,13*c*-18:2 isomer was found as a minor CLA component in cheese lipids. On the other hand, the 11*c*,13*t*-18:2 isomer was present at about 22% of total CLA in a commercial CLA mixture (27). The latter isomer, when included in the diet of pigs at the level found in commercial CLA mixtures, preferentially accumulated in heart lipids, particularly in heart and liver diphosphatidylglycerol (37). It would be of interest to investigate if 11*t*,13*c*-18:2 also accumulated in heart lipids and diphosphatidylglycerol, of pigs fed a cheese product containing 11*t*,13*c*-18:2 at about 1% of total CLA.

The availability of Ag^+–HPLC, GC–EIMS, GC–DD–FTIR, and very long polar capillary GC columns has provided the necessary tools to investigate the minor isomers of CLA in cheese products. Combinations of these methods plus reversed-phase HPLC will be required to identify the metabolites of CLA. In addition to 9*c*,11*t*-18:2 and the isomers reported previously by Ha *et al.* (21) and Lavillonniere *et al.* (26), the previously unrecognized isomers 11*t*,13*c*-18:2, 12*c*,14*t*-18:2, the prominent 7*t*,9*c*-18:2 (38), and their *trans,trans*, and *cis,cis* geometric isomers were found in this investigation. On the basis of our observed results in this and previous studies (19,37,38), the elution orders of CLA isomers on Ag^+–HPLC and long polar GC columns were determined (Tables 2 and 3).

ABSTRACT: Long-chain polyunsaturated fatty acids (LCPUFA) are important for normal visual and cortical development. In a previous study of the effects of LCPUFA on cognitive function of term infants at the age of 3 mon, we indicated that infants with evidence of reduced growth parameters at birth and impaired attention control as manifested by a late peak fixation during infant habituation assessment may benefit from LCPUFA supplementation. The aim of this prospective study was to determine whether LCPUFA supplementation and late peak fixation are related to means-end problem-solving ability in these same infants at the age of 9 mon. Term infants (58) were randomized to one of two formulas containing either LCPUFA or no LCPUFA and completed 4 mon of feeding with their formula. Cognitive function was assessed at 3 mon of age by measures of infant habituation. Infants (20 LCPUFA and 20 no-LCPUFA) completed the problem-solving assessment at 9 mon. The no-LCPUFA group had lower scores on both measures of intention and number of solutions, but neither of these differences was significant. Analysis of covariance for the effects of group and peak fixation, covaried with gestation and birth weight, showed that the number of solutions was significantly reduced in the late peak-fixation infants receiving no LCPUFA ($P < 0.02$). Intention scores tended to be reduced in this group ($P < 0.06$). The late peak-fixation infants who received LCPUFA had solution and intention scores similar to early peak-fixation infants receiving LCPUFA or no LCPUFA. These findings suggest that in term infants who have reduced growth parameters at birth and who show evidence of impaired attention control, information processing and problem-solving ability in infancy may be enhanced by LCPUFA supplementation.
Lipids 33, 973–980 (1998).

Observational studies indicate that children who were breast fed are advantaged in cognitive and intellectual development compared to children who were fed formula milk (1–3). The mechanisms that underlie this advantage remain uncertain. Various constituents of human milk including hormones, growth-promoting factors, and nutrients were postulated as factors that may positively influence neural development. However, studies of children who were breast-fed or bottle-fed involve nonrandom assignment to these groups, and factors such as genetic and social-demographic variables, parenting skills, or quality of parent–child interaction may also contribute to differences in cognitive abilities. Attempts to statistically control for the potentially confounding effects of these factors may be inadequate (4–6).

Currently, one hypothesis involves the role of LCPUFA, especially arachidonic acid (AA) and docosahexaenoic acid (DHA), which are considered to have an important role in cellular physiology and are preferentially accreted by the infant brain during the last intrauterine trimester and the first months of life (7,8). Photoreceptor outer segment membranes in the retina contain uniquely high concentrations of DHA, their presence being important for normal photochemical activity of the visual pigment rhodopsin (9). DHA may also influence excitable membrane function by contributing to the modulation of membrane fluidity, particularly at the synapses (10). LCPUFA are present in human milk, but until recently were not available in formulas as it was assumed that they would be synthesized by the infants from the essential C18 fatty acids, n-6 linoleic acid and n-3 α-linolenic acid through elongase and desaturase enzyme systems. Young infants can synthesize AA and DHA (11,12), but low concentrations of AA and DHA in plasma and red cell membranes and low concentrations of DHA in cerebral cortex in formula-fed term and preterm infants compared to infants receiving human milk suggest that these enzyme systems may be inadequate to meet the infants' needs during the first months of life (13–15). The possibility that LCPUFA concentrations remain below optimum owing to metabolic insufficiency suggests that dietary supply of preformed LCPUFA may be important, particularly in infants who are fed formula.

Whether this relative deficiency of LCPUFA in formula-fed term infants, at a critical time of brain growth and development, is functionally relevant remains uncertain. Enhanced visual acuity scores were reported in term infants fed a DHA-supplemented formula compared to infants fed a standard formula, and acuity scores correlated with erythrocyte DHA (16–18). Four-month-old term infants who had received a formula supplemented with DHA and AA performed better in the Brunet-Lézine psychomotor development test compared to infants who were fed an identical formula containing no

LCPUFA supplement (19), although this advantage was not evident at 24 mon (20). However, standard tests of infant psychomotor development such as the Brunet-Lézine test and the Bayley Scales of Infant Development (21), when applied to normal populations in early infancy, provide scores that depend more on perceptual and motor abilities than on cognitive abilities (22). Standard tests of infant development correlate poorly both with scores obtained from the same tests applied in later infancy and with measures of childhood intelligence (23).

New assessments of infant cognitive function that correlate more closely with childhood intelligence were evaluated. Infant habituation, which is described as the decrease in attention to a stimulus over repeated presentations, is now one of the basic tools for studying memory and cognition in infancy (24,25). Studies showed a significant negative relation ship between infant habituation scores and childhood IQ, with infants who habituated with shorter "looking times" achieving higher IQ scores (21,25,26). Although the reported correlations are generally modest and some studies failed to demonstrate a significant relationship between habituation scores and IQ scores (27), measures of infant habituation reflect individual differences in cognitive function that demonstrate some stability throughout childhood (22,25,26,28,29).

Measures of "looking time" during habituation may reflect speed of information processing (25,29,30), and infants who show characteristics of faster processing (i.e., shorter looking times) have faster reaction times (31). Negative correlations between speed of decision-taking and IQ scores in children and adults implicate speed of processing as a component in the development of intelligence (32). Alternatively, "looking time" during habituation may be related to inhibitory processes involved in the control of attention, which was previously identified by differences in the pattern of habituation organization (28,33). Better attention control is characterized by a pattern of the peak fixation (longest fixation) occurring early in the sequence of fixations. Infants who have an early peak fixation may have a shorter looking time because they immediately attend maximally to the stimulus, inhibit attention to other less-salient stimuli, and are quicker to inhibit attention to the stimulus (disengage) when information processing is completed. In contrast, poorer attention control is shown by a pattern of the peak fixation occurring later in the sequence. Infants who have a late peak fixation may have a longer "looking time" because they are slower to pay maximal attention to the stimulus, are more easily distracted by other stimuli due to poorer inhibitory control, and take longer to disengage from the stimulus when processing is completed (28). Pattern of habituation organization was reported to remain stable for several months (34).

We reported on the effects of LCPUFA supplementation on measures of habituation in term infants at age 3 mon who demonstrated either an early or late peak fixation where an early peak fixation was defined as a peak fixation that occurred on the first fixation, and a late peak fixation was defined as a peak fixation that occurred on any fixation other than the first (35). Infants who demonstrated late peak fixations had significantly longer total "looking times" if they received no LCPUFA supplementation in comparison to infants who did receive LCPUFA supplementation. Infants with late peak fixations also had reduced growth parameters at birth compared to infants with early peak fixations. The total "looking times" of infants with early peak fixations were not influenced by LCPUFA supplementation. These data suggested that term infants who have reduced growth parameters at birth and who may have poorer inhibitory control of attention demonstrate less-efficient information processing if they are not supplemented with LCPUFA.

In a prospectively designed study, we studied all infants again at 9 mon of age to determine if LCPUFA supplementation and position of peak fixation at 3 mon were related to problem-solving ability. Infant means-end problem solving is described as the deliberate and planful execution of a sequence of steps to achieve a goal (36). This ability develops rapidly after 6 mon of age when infants begin to solve simple problems such as searching under a cover for a toy (37) or pulling a support to retrieve a toy resting on it (38,39). At 9 mon, infants begin to solve more complex problems which require completion of two intermediate steps to achieve a goal (40). Infant scores on a two-step problem measured at 9 mon correlate positively with childhood vocabulary and IQ scores measured at 3 yr (22,40).

The aims of this prospectively designed study were twofold: (i) to determine whether LCPUFA supplementation influences two-step problem-solving ability at 9 mon; and (ii) to determine whether problem-solving ability at 9 mon is related to early and late peak fixation at 3 mon.

EXPERIMENTAL PROCEDURES

Subjects. The study was conducted on term infants (birth weight 2500–4000 g; gestation 37–42 wk) who were randomized to one of two formulas containing either LCPUFA or no LCPUFA, who completed 4 mon of feeding with their formula, and who demonstrated either an early or a late peak fixation on the habituation assessment undertaken at 3 mon of age. The details of the habituation assessment have been described elsewhere (35). The problem-solving assessment described here was undertaken when infants were 9 mon of age.

Infant formulas. The infant formulas were commercially available (LCPUFA: Aptamil/Milupan (Milupa Ltd., Trowbridge, United Kingdom); no LCPUFA: Aptamil) and were identical apart from the fatty acid composition (Table 1). LCPUFA-supplemented formula was enriched with a fat blend (Milupan) derived from milk fat, vegetable oils, and egg lipids. Infant formulas were supplied as ready-to-feed by Milupa Ltd. Random assignment of infants to their formula was accomplished with a time-balanced randomization table.

Problem-solving assessment. The principles of this procedure have been described and evaluated (37–40). The infant sat on the parent's lap at the end of a table, and problems were presented on a tray (60 × 80 cm). The goal object was a small

toy which was placed on a 22 × 42 cm brown cloth and hidden under a cover, a blue cloth (6 × 6 cm). To familiarize infants with the materials and the procedure, we presented the cloths and toy on the tray individually, allowing two presentations of each object and 20 s for play.

Next, infants received pretests on the component steps of the two-step problem: first they pulled the cloth to retrieve the toy on the far end, and second they searched for the toy after they had seen it hidden under the cover. Infants were allowed 30 s to retrieve the toy and played with the toy for 20 s before receiving the next trial. Four trials were administered on each pretest. Finally, infants received four test trials on the two-step problem. The cloth was positioned 5 cm from the front edge of the tray. When the infant was looking, the toy was set down on the far end of the cloth, and the cover was placed over it. The tray was immediately pushed forward, and infants were allowed 30 s to retrieve the toy. All trials were recorded on videotape. Behavior was scored from the videotapes for evidence of intention. Intentional behavior was defined as behavior aimed at achieving the goal of retrieving the toy, rather than simply playing with the cloth or cover (37,38,40). Information on the problem-solving assessment may be obtained from the first author.

An "intention score" was defined as the total of the scores for each behavior, averaged across the four trials. For the two steps of the problem and three behaviors appropriate to the step, the scores were 0 (no intention), 1 (ambiguous and possible intention), and 2 (clear intention) (see Table 2). The total intention score for the entire problem could range from 0 to 12. Intentional solutions were trials on which each relevant behavior was scored as intentional (1 or 2). All videotapes were scored by one independent, trained observer. As a check on reliability, a second independent observer scored a random sample of 40% of assessments on the two-step task. The interobserver correlation for intention score was $r = .97$, and the proportion of agreements on the identification of intentional solutions was 94%. Because of the high level of reliability, the results were based entirely on the scores of the first observer.

Demographic, nutritional, and anthropometric data. We also obtained information on social class, housing, family size, maternal education, and maternal age. Social class was coded as six categories using the Office of Population Censuses and Surveys Standard Occupational Classification (41) (social class I; social class II; social class III nonmanual; social class III manual; social class IV; social class V and unemployed) and was based on occupation of the income-providing parent, or on the father's occupation if both parents were earning. Housing was coded as rented or owned. Family size was recorded as the number of surviving children in the family unit. Maternal education was recorded as the age when the mother left full-time education.

Mothers and infants were seen by a research nurse before discharge and at 1, 2, and 3 mon during home visits. The volume of formula milk consumed by the infant during the 3 d prior to each home visit was calculated by measuring all residual volumes of milk from the feeds over these periods. Information on the following infant anthropometric measures at birth and at 3 mon was obtained by the research nurse: weight; crown–heel length; occipito-frontal head circumference (OFC); subscapular skinfold; triceps skinfold; and midarm circumference (MAC). The ratio of MAC to OFC at birth, which was shown to detect intrauterine growth retardation in infants born with a birth weight in the "normal range,"

TABLE 2
Criteria for Scoring Behavior for Evidence of Intention on Each Step of the Two-Step Problem

	No intention (0)	Possible intention (1)	Clear intention (2)

Cloth behavior	Play; cover not within reach	Hesitant pulling	Pull cloth
Fixation	Fixate away from cover	Fixate briefly away from cover	Fixate cover continuously
Cover retrieval	Ignore cover	Attempt to grasp	Pick up cover
Cover step			
Cover behavior	Play; cover not removed	Hesitant removal	Remove cover
Fixation	Fixate away from toy	Fixate briefly away from toy	Fixate toy continuously
Toy retrieval	Ignore toy	Attempt to grasp toy	Pick up toy

was calculated as MAC (cm)/OFC (cm) (42–44). Anthropometric measures were not obtained at 9 mon.

Mothers and researchers remained blind to the diet groups throughout the entire study period (i.e., until both the habituation assessment at 3 mon and problem-solving assessment at 9 mon were completed). The study was approved by the Tayside Committee on Medical Research Ethics (Dundee, United Kingdom).

Statistical methods. A sample size of 22 in each group was calculated to detect a difference of one intentional solution on problem-solving with a power of 90% at $P = 0.05$ level. A sample size estimate for the relationship of problem-solving at 9 mon to peak fixation at 3 mon could not be obtained because this relationship had never been studied. Comparisons between diet groups on demographic and nutritional variables were made with the Student's *t*-test for interval measures and chi-square test for categorical measures. Comparisons on anthropometric measures were made with analysis of covariance (ANCOVA) covaried with gestation. The effects of diet and peak fixation on measures of problem-solving were determined with ANCOVA covaried with gestation and birth weight. Interactions between the factors of diet and peak fixation were examined with analyses of simple effects covaried with gestation and birth weight. Additionally, the effect of diet on problem-solving scores at each level of peak fixation was examined with regression analysis. Independent, potentially confounding, variables included in these analyses were gestation, birth weight, gender, and social class. All analyses were run with SPSS Version 6.1.2 for Windows (45). A P value < 0.05 was considered as evidence of a significant difference.

RESULTS

The total enrollment for the habituation and problem-solving assessments was 58 infants (LCPUFA = 27; no-LCPUFA = 31); 18 infants were excluded from the study; 10 failed to complete the habituation assessment (mother failed to attend: LCPUFA = 1; no-LCPUFA = 3; infant became distressed: LCPUFA = 2; no-LCPUFA = 4); 8 failed to complete the problem-solving assessment (mother failed to attend: LCPUFA = 3; no-LCPUFA = 4; data lost through experimenter error: LCPUFA = 1); 40 infants completed both assessments (LCPUFA = 20; no-LCPUFA = 20). The characteristics of the LCPUFA and no-LCPUFA groups are shown in Table 3. The LCPUFA group had a significantly longer ges-

tation than the no-LCPUFA group (6 d), but no significant differences existed on any other demographic and social variables. ANCOVA covaried with gestation showed that the no-LCPUFA group had a significantly greater triceps skinfold at birth ($P < 0.05$), but no other significant anthropometric or formula intake differences were present between the groups. The LCPUFA group had marginally higher scores on both measures of intention and number of intentional solutions (Table 3), but ANCOVA covaried with gestation showed that these differences were not significant.

Analysis of the relationship of 9-mon problem-solving scores of the LCPUFA and no-LCPUFA groups to early and late peak fixation on the 3-mon habituation assessment is shown in Table 4. ANCOVA on number of intentional solutions for the effects of diet and peak fixation, covaried with gestation and birth weight, showed a significant diet × peak fixation interaction ($P < 0.03$). Simple-effects analyses showed that the number of intentional solutions did not differ significantly between the early peak-fixation infants receiving or not receiving LCPUFA ($P = 0.18$). In contrast, the number of intentional solutions was significantly reduced in the late peak-fixation infants receiving no LCPUFA ($P < 0.02$).

This interaction was further examined by separate regression analyses on the number of intentional solutions in the early and late peak-fixation infants. Independent and potentially confounding variables included gestation, birth weight, gender, and social class. In the early peak-fixation infants, none of these variables was significantly related to number of intentional solutions. In the late peak-fixation infants, only diet ($P < 0.05$) and birth weight ($P < 0.05$) were significantly related to the number of intentional solutions. None of the other factors significantly increased the predictive power of the regression equation.

ANCOVA on intention scores for the effects of diet and peak fixation showed no significant main effects, and the diet × peak interaction was not significant ($P = 0.28$). Analysis of simple effects showed that, although intention scores did not differ between the early peak-fixation infants receiving either LCPUFA or no LCPUFA ($P = 0.92$), intention scores tended to be reduced in the late peak-fixation infants receiving no LCPUFA ($P = 0.051$).

DISCUSSION

The infants recruited to this study were randomly assigned to a formula either supplemented or not supplemented with LCPUFA. Infants were assessed at 3 mon of age by infant habituation measures, and analysis of the pattern of habituation identified infants who demonstrated either an early or a late peak fixation. Previously we found that at the age of 3 mon, infants who had a late peak fixation and who received no LCPUFA supplementation had increased total "looking times" in comparison to other groups. We have now demonstrated that at the age of 9 mon, infants with a late peak fixation at age 3 mon and who received no-LCPUFA supplementation had reduced two-step problem-solving ability in comparison to other groups. These findings are important because longer "looking times" on infant habituation and lower scores on infant two-step problem-solving were shown to be related to lower childhood IQ scores (22,29). Although the reported correlations between infant habituation and problem-solving scores and childhood IQ tend to be low and therefore account for a relatively small proportion of the variance in IQ scores (22), our findings suggest that provision of preformed dietary LCPUFA may have implications for the development of childhood intelligence.

Table 4 shows there was variation between the problem-solving scores of the diet and peak-fixation groups that may be related to the small numbers of subjects. However, problem-solving scores in both the LCPUFA and no-LCPUFA early peak-fixation groups and in the LCPUFA late peak-fixation group were within the normal range for 9-mon-old infants (40). The exception was the no-LCPUFA late peak-fixation group in which problem-solving scores were low. We had reported the association between late peak fixation and reduced growth parameters at birth (35). This finding suggests that factors affecting intrauterine growth may also affect the development of neural systems involved in the regulation of habituation and problem-solving. Concentration of DHA in brain tissue increases steadily during fetal development (8), and a positive correlation exists between fetal growth measurements such as weight and head circumference and circulating concentrations of LCPUFA (46). Possibly among these infants with reduced growth parameters and late peak fixations, some were LCPUFA-deficient at birth. If infant cognitive function is influenced by LCPUFA, then this may depend on factors that affect fetal LCPUFA status (e.g., maternal LCPUFA status during pregnancy), as well as the postnatal LCPUFA status of the infant. LCPUFA supplement had no effect on habituation or problem-solving in infants who tended

[b]$P = 0.051$.
[c]$P < 0.05$.

to have normal growth parameters and who had an early peak fixation, which may be explained by some of these infants already being sufficiently endowed with LCPUFA and therefore not benefiting from their LCPUFA supplementation.

The no-LCPUFA formula provided only 0.34% of energy from α-linolenic acid (18:3n-3; ALA) and may have been deficient, but what level is optimal is unclear. Jensen *et al.* (47) showed that the percentage of DHA in erythrocyte phospholipids at age 120 d was significantly higher in infants fed a formula with ALA content constituting 3.24% of the total fatty acids, in comparison to infants fed formulas containing either 0.4, 0.95, or 1.7% ALA among which erythrocyte DHA content did not differ significantly. However, infants receiving formula with the highest level of ALA demonstrated poorer growth at age 120 d (48). The fact that the ALA composition of both LCPUFA and no-LCPUFA formulas in our study was similar suggests that the observed effects on infant cognitive behavior were due to LCPUFA supplementation rather than ALA deficiency.

Examination of problem-solving scores at 9 mon suggests that the benefits of early LCPUFA supplementation to term infants persisted beyond the period they received their supplemented formula. Similar benefits of early LCPUFA supplementation to preterm infants were reported in infants who received LCPUFA-supplemented formula until 2 mon and who showed improved scores on measures of visual attention at 12 mon (49). The absence of differences between the randomized diet groups in formula intake or anthropometric measures at 3 mon suggests that other nutritional factors were unlikely to have contributed to problem-solving ability. We do not have precise data on the timing and nature of solid feeding during the first months of life in these infants, but weaning foods had low-LCPUFA content and were unlikely to have influenced LCPUFA status (50).

How can we explain these effects of LCPUFA on infant cognitive behavior? Developmental psychologists have offered alternative interpretations for differences in looking times during infant habituation that consider processes involved in speed of information processing (25,29,30), inhibitory control of attention (28,33), and arousal or sensitization (51), although it is uncertain whether there are stable individual differences in sensitization that can account for differences in infants' "looking times." One possible explanation for our findings is that accumulation of LCPUFA in cell membranes in the central nervous system results in an increase in the speed at which infants are able to process information. Recently, two other randomized trials reported that DHA-supplemented preterm infants demonstrated shorter "looking times" during the novelty preference phase of the Fagan Test of Infant Intelligence compared to unsupplemented controls (49,52). Although no studies have investigated the relationship between speed of processing and infant problem-solving, infants who are faster at processing information may be more efficient at solving the two-step problem. These infants may more quickly identify the correct method for solving the problem, and more quickly achieve a solution before being distracted or forgetting the final goal.

Alternatively, LCPUFA may influence the development of neural structures involved in the inhibitory control of attention and disengagement or release of attention from a stimulus. Young infants show considerable difficulty at disengaging from one stimulus to orient to another, but disengagement improves substantially after 3 mon (53,54). Development of several cortical structures may be involved in this change, including parietal cortex, prefrontal cortex, and frontal eye fields (55). Improved maturation of these structures in infants who received LCPUFA-supplemented formula may have enhanced their capacity to release attention after sufficient information had been processed, which in turn would reduce their total "looking time" during habituation. Similarly, improved ability at releasing attention may assist infants to switch quickly from manipulating the cloth to manipulating the cover and solve the two-step problem. Evidence exists that development of prefrontal cortex is involved in the ability to solve means-end problems such as searching for a hidden object and reaching around a barrier (56,57), and early LCPUFA supplementation may contribute to prefrontal maturation. Although it is not possible to distinguish between the speed of processing or release of attention hypotheses in our present study, assessments of infant reaction times (31) and disengagement (53) in future research should help to identify the specific effects of LCPUFA on infant cognitive function.

Although this study was conducted on a relatively small number of infants and it remains to be shown whether similar effects can be obtained with a larger sample, the results suggest that term infants who have reduced growth parameters at birth and show evidence of impaired attention control as manifested by a late peak fixation during infant habituation assessment may selectively benefit from LCPUFA supplementation. We speculate that LCPUFA supplementation may enhance more-efficient information processing in these susceptible infants, and the data suggest that the effects persist beyond the period of supplementation. Further larger randomized studies are required to examine the relationship of maternal and infant LCPUFA status to infant cognitive function, to identify the characteristics of those infants who may benefit from LCPUFA supplementation, and to determine the relationship of LCPUFA supplementation to intellectual abilities in later childhood.

ACKNOWLEDGMENTS

The investigators wish to acknowledge the support they received from Milupa Ltd., UK, and to thank Alan Slater and Liz Brown for provision of computer software and advice on the habituation assessment, and Lyn Galbraith, Diana Ciupka, and Andrew Mirrlees for assistance with scoring the habituation and problem-solving assessments.

Tomato Lycopene and Low Density Lipoprotein Oxidation: A Human Dietary Intervention Study

Sanjiv Agarwal and A. Venketeshwer Rao*

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Ontario M5S 3E2, Canada

ABSTRACT: Increase in low density lipoprotein (LDL) oxidation is hypothesized to be causally associated with increasing risk of atherosclerosis and coronary heart disease. In recent epidemiological studies, tissue and serum levels of lycopene, a carotenoid available from tomatoes, have been found to be inversely related to risk of coronary heart disease. A study was undertaken to investigate the effect of dietary supplementation of lycopene on LDL oxidation in 19 healthy human subjects. Dietary lycopene was provided using tomato juice, spaghetti sauce, and tomato oleoresin for a period of 1 wk each. Blood samples were collected at the end of each treatment. Serum lycopene was extracted and measured by high-performance liquid chromatography using an absorbance detector. Serum LDL was isolated by precipitation with buffered heparin, and thiobarbituric acid-reactive substances (TBARS) and conjugated dienes (CD) were measured to estimate LDL oxidation. Both methods, to measure LDL oxidation LDL-TBARS and LDL-CD, were in good agreement with each other. Dietary supplementation of lycopene significantly increased serum lycopene levels by at least twofold. Although there was no change in serum cholesterol levels (total, LDL, or high-density lipoprotein), serum lipid peroxidation and LDL oxidation were significantly decreased. These results may have relevance for decreasing the risk for coronary heart disease.

Lipids 33, 981–984 (1998).

Coronary heart disease is one of the leading causes of death in North America. Epidemiological, clinical, and biochemical studies indicate convincingly that increased serum low density lipoprotein (LDL) cholesterol concentration is associated with increased risk of atherosclerosis (1,2). Oxidative damage to LDL caused by reactive oxygen species may play an important role in the etiology of coronary heart disease (3–5). Antioxidants are believed to slow the progression of atherosclerosis because of their ability to inhibit LDL oxidation (6–9).

In recent epidemiological studies, lycopene levels in serum and adipose tissue were inversely associated with the risk of coronary heart disease (10–13). Lycopene is an antioxidant carotenoid without provitamin-A activity. Tomatoes and tomato products are the main sources of lycopene in the human diet. *In vitro* studies have shown it to be one of the most potent antioxidants (13–15) while epidemiological, animal, and tissue culture studies have indicated its anticarcinogenic potential (for review see Ref. 13). In humans lycopene levels are related to dietary habits and lifestyle (16). The aim of this study was to investigate the effect of dietary supplementation of lycopene on LDL oxidation in healthy human subjects.

MATERIALS AND METHODS

Subjects. Nineteen healthy subjects (10 male and 9 female), age group 25 to 40 yr (average age 29 yr), nonsmokers, not pregnant, and not taking any medication or vitamin supplements, were chosen for this study. Average weight and body mass index of the subjects were 67.6 ± 11.6 kg and 24.0 ± 2.8 kg/m^2, respectively. The subjects maintained their body weight and had no adverse symptoms during the entire study period.

Study design. A randomized, cross-over study design was used. All subjects completed all four treatments including a placebo (0 mg lycopene); 126 g spaghetti sauce (39.2 mg lycopene), provided by Hunt-Wesson Inc., Fullerton, CA; 540 mL tomato juice (50.4 mg lycopene), provided by H.J. Heinz Co. of Toronto, Ontario, Canada; and 1.243 g of 6% lycopene oleoresin from tomatoes (75.0 mg lycopene), provided by LycoRed Natural Product Industries Ltd., Beer-Sheva, Israel, in the form of capsules. Each treatment was for 1 wk with a 1-wk washout phase. Dietary lycopene in the form of tomato products or capsules was consumed once a day with a standardized breakfast consisting of pasta, margarine, grated Parmesan cheese, banana, and BECEL® margarine (Lipton, Toronto, Ontario, Canada) during the treatment period. Test products were consumed as a part of breakfast to standardize the delivery of lycopene. Subjects consumed their regular breakfast during the washout periods. They were advised to avoid consuming tomatoes and tomato products and any other sources of lycopene throughout the study period (treatment and washout phases) and were provided with a list of food products containing tomatoes as a guide. They also main-

Abbreviations: BHT, butylated hydroxytoluene; CD, conjugated dienes; HDL, high-density lipoprotein; LDL, low density lipoprotein; TBARS, thiobarbituric acid-reactive substances.

tained their food records and a symptoms diary during the study period, which were used to check compliance. The study protocol was approved by the Human Ethics Committee of the University of Toronto. Blood samples were collected from overnight fasting subjects at the end of each treatment phase. Serum was separated from fresh blood and stored at −70°C for analysis. All the samples from one subject were analyzed at the same time to avoid the sample-handling variability.

Lycopene analysis. Serum lycopene was extracted using hexane/methylene chloride (5:1) containing 0.015% butylated hydroxytoluene (BHT) and analyzed by high-performance liquid chromatography using Vydac 201HS54 reverse-phase analytical column (The Separations Group, Hesperia, CA) and a mixture of acetonitrile/methanol/methylene chloride/water (7:7:2:0.16, by vol) as mobile phase (16,17). Lycopene was measured as single peak containing *all trans* and *cis* isomers using an absorbance detector set at 470 nm. An external standard of lycopene (Sigma Chemical Co., St. Louis, MO) was used as reference standard. The coefficient of variance was 4.0%.

Serum cholesterol analysis. Serum was analyzed for total cholesterol, triglycerides, and high-density lipoprotein (HDL)-cholesterol after magnesium chloride precipitation using a Technicon CH1000 (Technicon Inc, Tarrytown, NY) with chemical methods of the Lipid Research Clinic (LRC) Project (18). LDL cholesterol was derived using a modification of the Freidewald formula. The precision and accuracy for total cholesterol, triglyceride, and HDL cholesterol measurements were certified by the Centers for Disease Control—National Heart, Lung and Blood Institute (CDC—NHLBI) Lipid Standardization Program. Internal and external quality control procedures were followed (18).

LDL isolation. For LDL oxidation analysis, serum LDL were isolated by precipitation with buffered heparin (19). The LDL precipitate was separated by centrifugation at $1000 \times g$ and resuspended in saline for further analysis. LDL cholesterol contents were estimated enzymatically (20) using Cholesterol Assay Kit (Sigma Chemical Co.). The coefficient of variance was 1.7%.

Malondialdehyde analysis. Malondialdehyde, as a measure of lipid peroxidation, was estimated using the thiobarbituric acid (TBA) reaction. Results are expressed as TBA-reactive substances (TBARS). Freshly thawed serum or freshly prepared LDL samples were incubated with TBA and orthophosphoric acid, in the presence of BHT, for 45 min at 95°C, cooled to room temperature, and extracted with *n*-butanol. Absorbance of the butanol phase was measured at 535 nm (16,21,22). Results were calculated using the extinction coefficient 1.56×10^5 M^{-1}. Serum-TBARS are reported as μmol/L of serum and LDL-TBARS as mmol/mol LDL. The coefficients of variance for serum-TBARS and LDL-TBARS were 2.8 and 5.3%, respectively.

Conjugated diene (CD) analysis. CD analysis was also done to measure lipid peroxidation. Lipids from LDL were extracted by chloroform/methanol (2:1), dried under nitrogen, redissolved in cyclohexane, and analyzed spectrophotometrically at 234 nm using the molar extinction coefficient 2.95×10^4 M^{-1} (23). LDL-CD are reported as mmol/mol LDL. The coefficient of variance was 2.5%.

Statistical analysis. All statistical calculations were performed by using Excel 5.0 (Microsoft Corp., Redmond, WA). *P* values were assessed by analysis of variance, Dunnett's test, two samples paired Student's *t*-test, and Student-Newman-Keuls multiple range test (SAS Institute, Cary, NC). *P* values of <0.05 were considered statistically significant. Results are expressed as mean ± SEM.

RESULTS

Figure 1 shows the effect of dietary lycopene on serum lycopene. Serum lycopene levels increased significantly with daily intakes of 126 g of spaghetti sauce (39.2 mg lycopene), 540 mL of tomato juice (50.4 mg lycopene), or 1.24-g capsule of tomato oleoresin (75 mg lycopene) as a part of breakfast for a period of 1 wk each over the placebo when no lycopene was consumed. The average increase in serum lycopene levels for any treatment over placebo was at least twofold. However, there were no differences in the serum lycopene levels between the different treatments.

Dietary intake of tomato products had no significant effects on either cholesterol (total, LDL, or HDL) or triglycerides. All dietary lycopene treatments significantly lowered serum LDL oxidation over the placebo (Fig. 2). Both LDL-TBARS and LDL-CD decreased significantly with each tomato product. The average decrease over placebo was 25% for LDL-TBARS and 13% LDL-CD for the tomato products treatment. There were no significant differences between

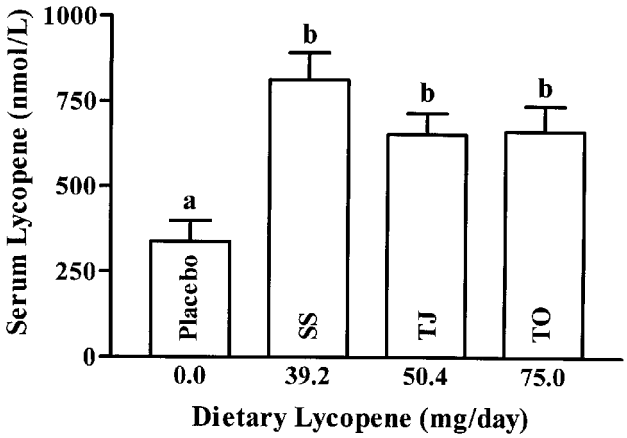

FIG. 1. Effect of dietary lycopene supplementation on serum lycopene concentration. Dietary lycopene was provided to healthy human subjects in the form of spaghetti sauce (SS), tomato juice (TJ), or tomato oleoresin capsules (TO) with a standardized breakfast for a period of 1 wk in a random order. Fasting blood samples were collected at the end of each treatment. Serum lycopene was extracted by hexane/methylene chloride and analyzed by high-performance liquid chromatography (16,17). Results are mean ± SEM. Bars with different letters are statistically significant ($P < 0.05$).

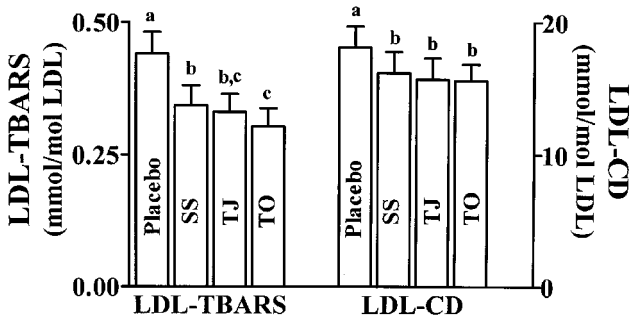

FIG. 2. Effect of dietary lycopene supplementation on serum low density lipoprotein (LDL) oxidation [LDL-thiobarbituric acid-reactive substances (TBARS) and LDL-conjugated dienes (CD)]. Dietary lycopene was provided to healthy human subjects in the form of SS, TJ, or TO with a standardized breakfast for a period of 1 wk in a random order. Fasting blood samples were collected at the end of each treatment. Serum LDL was separated by complexation with heparin. LDL oxidation was measured by spectrophotometric thiobarbituric acid-malondialdehyde and CD assay. Results are mean ± SEM. Bars with different letters are statistically significant ($P < 0.05$). For other abbreviations see Figure 1.

LDL-TBARS and LDL-CD between different sources of lycopene. Both methods of detecting LDL oxidation, LDL-TBARS and LDL-CD, yielded similar results and were highly correlated ($r = 0.89$, $P < 0.05$) with each other. Also LDL-TBARS were significantly correlated ($r = 0.90$, $P < 0.05$) with the serum-TBARS.

DISCUSSION

Our study indicates that human subjects absorb lycopene from traditional sources of processed tomato products including spaghetti sauce and tomato juice as well as from tomato oleoresin. Consuming the tomato products for 1 wk resulted in significantly higher levels of serum lycopene when compared to the placebo. Although no baseline (washout phase) measurements were made, the carryover effect is not important because plasma half-life of lycopene is about 2–3 d (24), and we allowed 1 wk washout during which no tomato products were consumed. Lycopene levels dropped significantly when the subjects consumed lycopene-free diet (16). Moreover, a randomized, cross-over study design provides for a balance in which the order of treatments was assigned to the subjects (25). The consumption of spaghetti sauce, containing much lower amounts of lycopene, resulted in an increase in serum lycopene almost identical to that with tomato oleoresin, which contained a higher lycopene amount, indicating a differential absorption rate for lycopene from different tomato products. These differences can probably be attributed to the differences in food processing. Lycopene from heat-processed tomatoes is more bioavailable than from fresh tomatoes (26).

Intake of tomato products protected the serum LDL cholesterol from oxidative damage and increased the serum lycopene levels. For oxidation analysis, the LDL were separated by precipitation following complexation with heparin at an isoelectric point. The technique was particularly chosen because of its simplicity and rapidity, which avoided artifactual oxidation during processing (27). Moreover, a highly significant correlation between precipitation method and ultracentrifugation or quantitative electrophoresis techniques for plasma LDL analysis had already been established (19,28).

TBARS and CD analyses were used to estimate serum LDL oxidation. Since TBARS assay as a measure of lipid oxidation lacks sensitivity and specificity, we modified the method in this study by using isolated LDL together with BHT during heating and butanol extraction of the pigment. These procedures contributed to increasing specificity and sensitivity of TBARS assay (22). Additional measurement of LDL oxidation was carried out by measuring total serum-TBARS and LDL-CD. The results obtained from these different analyses were in good agreement with each other. Highly significant correlations between LDL-TBARS and serum-TBARS and between LDL-TBARS and LDL-CD, as observed in this study, would further support the validity of using the TBARS test to measure oxidative stress. Our results indicate that both TBARS and CD are good indicators of LDL oxidation. Others reported similar results (29).

Several studies suggest that lipid peroxidation products are cytotoxic and genotoxic and play an important role in the etiology of several degenerative diseases (5–8,30–32). Oxidized LDL is involved in the formation of foam cells that eventually lead to the formation of arterial plaques (5,33), making oxidized LDL a risk factor for coronary heart disease. That the intake of lycopene lowered not only serum lipid peroxidation but also LDL oxidation may have an important physiological relevance in decreasing the risk for coronary heart disease.

In this study, the different tomato products were consumed in one or two servings per day for 1 wk. These consumption levels are easily achievable and are consistent with the current dietary guideline for healthful eating (34,35). Daily consumption of tomato products providing at least 40 mg lycopene was enough to alter LDL oxidation; however, intakes lower than this may also be effective. Future long-term studies should be undertaken in healthy human subjects as well as subjects at risk for coronary heart disease to obtain further information about the role of dietary lycopene in the prevention of the disease.

ACKNOWLEDGMENTS

We thank H.J. Heinz Co. of Canada and Hunt-Wesson Inc., USA for the supply of food products and support of the present work. Technical assistance from Charu Jain, Elena Speciani, and Zeeshan Waseem is deeply appreciated. We also thank Drs. Philip Conelly and David Jenkins for the serum lipid analysis and Dr. Letty Rao for critically reading the manuscript.

Low pH Enhances the Transfer of Carotene from Carrot Juice to Olive Oil

Gillian T. Rich*, Annette Fillery-Travis, and Mary L. Parker

Institute of Food Research, Norwich Research Park, Norwich, NR4 7UA, United Kingdom

ABSTRACT: A current model for carotenoid transport and absorption in the gut proposes an initial solubilization in the oil phase of dietary emulsions followed by incorporation of the carotenoids in mixed bile salt micelles. To assess the relevance of the first stage of this model to what is observed *in vivo* we have examined the transfer of carotene from carrot juice to olive oil. Increased acidity enhanced the transfer from both whole juice and carotene crystals isolated from carrot chromoplasts. The transfer was significantly slower from whole juice. By using exogenous β-carotene and measuring its transfer to oil in the presence and absence of carrot juice we have demonstrated that the inhibition of the transfer in juice arises, at least in part, from soluble juice factors. The inhibition is relieved by a fall in pH, which leads to lowering of the electric potential at the oil/aqueous phase interface and aggregation of carrot tissue including crystalline carotene. Under conditions of low pH, oil droplets adhere to the tissue aggregates, allowing carotene to pass into the oil. Our results provide an explanation for why carotene absorption *in vivo* is depressed by conditions of low gastric acidity.

Lipids 33, 985–992 (1998).

There is evidence that carotenoids in plant foods are important not only as precursors of vitamin A but also for enhancement of cell-mediated immune responses (1,2) and for their antioxidant (3) and anticarcinogenic (4) potential. Therefore, there is interest in their bioavailability from plant foods and the mechanisms by which they are solubilized and transported in the gastrointestinal tract. *In vivo* studies have shown that the absorption of carotenoids from vegetables can be very low. For example, it may be as low as 1–2% from raw carrot (5), but cooking and small particle size usually lead to enhanced absorption (reviewed in Ref. 6).

The carotenoids fall into two classes: the xanthophylls, which have one or two polar groups, and the carotenes, which are completely apolar. The carotenes in plant foods such as carrots and tomatoes are present largely in crystalline form in membrane-bounded organelles, the chromoplasts (7). Given the stability of the crystalline state and the hydrophobicity of the carotenes, there is debate as to how they cross the aqueous phase in the gut for absorption into the body. It has been suggested (8) that they are solubilized in the oil phase of dietary emulsions and then transferred to mixed micelles before absorption into the enterocytes. If this hypothesis is correct, then the bioavailability of carotenes in the diet will be influenced by factors that control the transfer of the carotenes from the plant tissue into the oil phase. The aim of the work reported here was to examine one of these factors, the pH of the aqueous phase, using carrot juice as a source of carotenes.

MATERIALS AND METHODS

Commercially available washed carrots were used and stored at 1–2°C at 98% humidity. Unless otherwise stated, the work reported in this paper was done on carrots which had been stored under these conditions for less than 2 mon. Nylon mesh with a nominal 63 μm hole size was from John Staniar & Co. (Manchester, United Kingdom). β-Carotene (95%) and olive oil (low acidity) were obtained from Sigma-Aldrich (Poole, United Kingdom). Spurr resin for embedding samples for electron microscopy was from Agar Scientific Ltd. (Stansted, United Kingdom). All other reagents were of Analar grade.

Carrots were peeled and the outer cortex juiced with a Moulinex juicer (Type CF1A). The juice was then filtered through one layer of nylon mesh (pore size 63 μm). For experiments using plastid-free juice, the juice was diluted to the required concentration with a solution containing 70 mM NaCl and 1 mM sodium azide and then centrifuged at 27,600 $\times g_{max}$ for 20 min at 4°C. The clear, straw-colored supernatant was used. Protein concentration in the plastid-free juice was measured by Bradford's microprotein assay (9).

A fraction enriched in chromoplast carotene was prepared from the carrot juice by differential centrifugation. A 40% dispersion of juice in 70 mM NaCl plus 1 mM sodium azide was centrifuged at 1300 $\times g_{max}$ for 20 min. The supernatant was recentrifuged at 7200 $\times g_{max}$. A centrifugation at 38,000 $\times g_{max}$ of the resulting supernatant yielded a pellet, the top of which was enriched in carotene crystals. These were washed in 20 vol of a solution that was 70 mM NaCl, 1 mM azide, 55 mM KCl and recentrifuged.

Carotene was measured by a modification of the method of Hart and Scott (10). Since α- and β-carotene are the major carotenoids in raw carrot, constituting 98.1 ± 0.4% (mean and standard deviation) of the total (the residue being 1.9 ± 0.4%

lutein) and α-carotene contributes only 25.0 ± 1.9% to this total (10), no attempt was made to distinguish between the carotenes. An aliquot of juice was vortexed with 1 mL *n*-hexane and 4 mL of tetrahydrofuran (THF)/methanol (MeOH) (1:1, vol/vol) containing 0.1% butylated hydroxytoluene. NaCl (25%) and water were then added to bring the aqueous NaCl concentration and volume to 10% and 1 mL, respectively. After mixing, the carotene extracted into the hexane phase was calculated from the absorbance at 450 nm using a Perkin-Elmer lambda 9 spectrophotometer. Calibration with known amounts of β-carotene gave the effective extinction coefficient, $\varepsilon^{1\ cm} = 0.152$ AU/μg. (Concentration = $A^{450}/(0.152 \times 537 \times V)$ μmoles/mL where V = juice volume in mL).

Transfer of carotene from juice to olive oil was measured in 50-mL, stoppered Quickfit flasks using 30 mL aqueous phase and 6 mL olive oil. The area of the undisturbed oil/water interface was 16 cm^2. The aqueous phase contained the juice at the required concentration, 1 mM sodium azide, and 70 mM NaCl to make up the volume to 30 mL. The mixture was adjusted to the required pH by the addition of HCl or NaOH solutions. It was pre-equilibrated for 20 min at 37°C in a Gallenkamp Plus II incubator with the shaking platform in orbital mode (setting 5.5). The oil was then added and the flasks returned to the shaking incubator. Samples of the oil phase (30–60 μL) were taken at intervals, centrifuged briefly at 10,000 × *g* to remove any entrained aqueous phase and carrot tissue. Carotene was measured by diluting aliquots of the oil (10 to 50 μL) into 1 mL *n*-hexane and measuring the absorbance at 450 nm using a mM extinction coefficient of 137.4 (10) .

In experiments where transfer of exogenous β-carotene was measured, crystalline β-carotene was dispersed in 20 mL oxygen-free water to a concentration of 1.6 to 2.3 mM by sonication using an MSE Soniprep 150 ultrasonic disintegrator (MSE Scientific Instruments, Crawley, Sussex, United Kingdom) and a 9.5-mm probe at maximum power with 16 cycles of 15 s power on, 30 s power off. This gave a β-carotene dispersion, which by light microscopy was shown to have particles of size ranging from ≤0.4 to about 4 μm. The dispersion could be conveniently diluted into the experimental systems.

Carrot juice that had been incubated with oil was examined by light (including polarized light) microscopy. To assess quantitatively the adherence of oil drops to carrot tissue we used a hemacytometer (a calibrated counting chamber of known volume).

For transmission electron microscopy, samples were fixed in 3% glutaraldehyde in 0.05 M cacodylate buffer (pH 7.2) for 3 h then centrifuged and resuspended in buffer three times. The samples were then centrifuged and the sediment mixed with just molten agarose which was quickly cooled in ice. The samples were then chopped into small cubes and postfixed in 1% aqueous osmium tetroxide for 4 h, dehydrated through an ethanol series, transferred to acetone, and then infiltrated and embedded in Spurr resin. Sections approximately 80 nm thick were cut with a diamond knife and collected on copper grids. After sequential staining with uranyl acetate (saturated solution in 50% aqueous ethanol) and lead citrate (11), the sections were examined and photographed in a JEOL 1200EX transmission electron microscope (JEOL, Tokyo, Japan).

The ζ potentials of olive oil droplets dispersed in plastid-free juice were measured with a Rank Brothers Mark II particle microelectrophoresis apparatus (Rank Brothers, Bottisham, Cambridge, United Kingdom) at 22–25°C. Olive oil (200 μL) was dispersed in 8 mL of the aqueous phase (adjusted to the required pH) by vortexing and the resulting emulsion transferred to a rectangular electrophoresis cell for mobility measurements. The ζ potentials were calculated from the Smoluchowski equation (12) with appropriate corrections for temperature variation effects on the dielectric constant and viscosity.

RESULTS

Particle size. Preliminary experiments indicated that, although the amount and rate of carotene transport from carrot tissue into oil was quite variable, one important controlling factor was particle size. Figure 1 shows a typical experiment illustrating the particle size effect. Here, carrot juice was filtered through a 63-μm mesh. The residue on the mesh was washed with a solution of 70 mM sodium chloride + 1 mM sodium azide until the washings were clear and colorless. The washings were combined with the filtrate, and transport of carotene from this mixture to oil was compared with that from the residue dispersed in 70 mM NaCl so that both contained the same concentration of carotene. It is clear that larger particles give less transport, particularly at longer times. To stan-

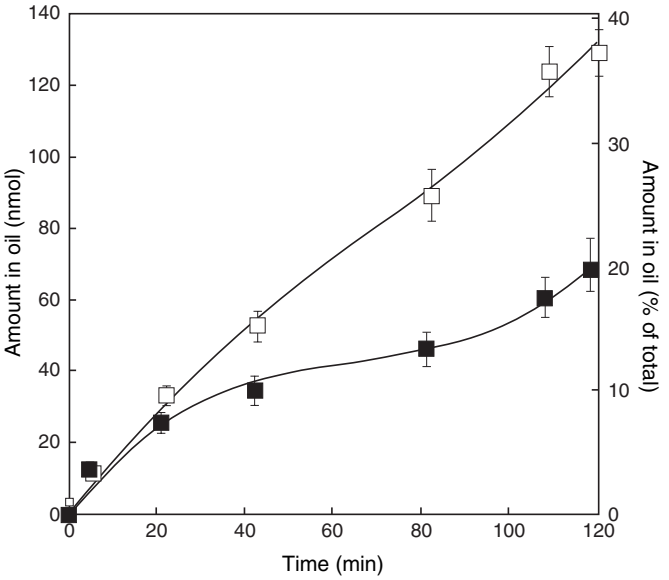

FIG. 1. The effect of particle size on carotene transfer from carrot juice to olive oil. The pH of the aqueous phase was 2.1, and the initial concentration of carotene 11.6 μM. (□) Juice filtered through 63-μm nylon mesh; (■) unfiltered residue from the filtration. The points represent the means of two experiments and the error bars the range of values.

dardize the particle size, subsequent work described in this paper used juice filtered through the 63-μm mesh.

Nature of the filtered juice. Electron microscopy showed that the filtered juice consisted largely of cell contents. There was extensive vesiculation. Some intact chromoplasts were present as well as carotene crystals both free and membrane-bounded. Following the terminology adopted by Ben-Shaul and Naftali (13) who described the ultrastructure of lycopene bodies in tomato chromoplasts, in this paper the following definitions will be used: "carotene crystal," a free crystal from a carrot chromoplast; "carotene body," the native carotene structure in carrot chromoplasts that is membrane-bounded; "chromoplast," the organelle containing the carotene bodies.

Concentration dependence of transport. Transport of carotene depended on the amount of filtered juice in the aqueous phase. Figure 2 shows the results when transport was measured at four different dilutions of the carrot juice. There is an approximately linear relationship between transport and the concentration of carotene (see the insert to Fig. 2).

pH dependence of transport. Low pH enhanced carotene transfer into oil. Figure 3 summarizes the results where transport into the oil was measured at two pH values (pH 2–2.4 and pH 6.2–6.6) after 20 min, and in most cases after 1 h and 2 h. In all these experiments the initial carotene concentration in the aqueous phase was 95 μM. It can be seen from Figure 3 that although low pH invariably leads to enhanced carotene transfer the magnitudes of the effect and the absolute values of carotene transfer are variable.

Reversibility of pH effect on transport. Since low pH could lead to breakdown of some component(s) affecting transport, we explored the reversibility of low pH treatment. Filtered juice mixtures were pre-incubated for 1 h at pH 2 and 6. One of the low pH mixtures was then adjusted to pH 6 and transport measured in this system and compared with transport measured in mixtures that were kept at the same pH as in the pre-incubations. Table 1 shows two representative experiments: the first one on carrots that had been stored for less than 2 mon, and the second one done on carrots that had been stored for more than 4 mon, when our macroscopic and microscopic observations (see below) indicated some changes in the properties of the carrot juice. It is clear from the data for carrots stored for the shorter time that low pH treatment does not affect transport subsequently measured at high pH. However, with the older carrots the effect of lowering the pH in the pre-incubation was irreversible. We have also observed the intermediate situation where there is partial reversal of the effect of low pH pretreatment.

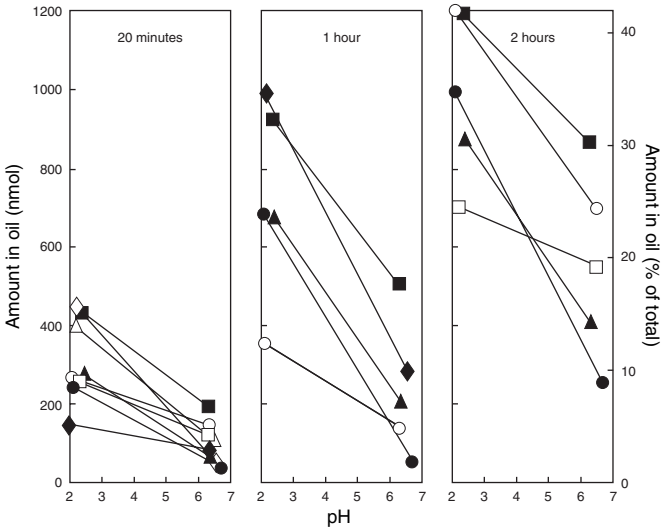

FIG. 3. Summary of carotene transfer from carrot juice to olive oil at low pH (2.03 to 2.37) and high pH (6.27 to 6.70). Each line joins the amount of transfer measured at 20 min, 1 and 2 h at the two pH values from the same batch of juice and does not represent the amount of transfer at any intermediate pH (see Fig. 6). Each experiment is given a different symbol. The initial concentration of carotene in the aqueous phase was 94 μM.

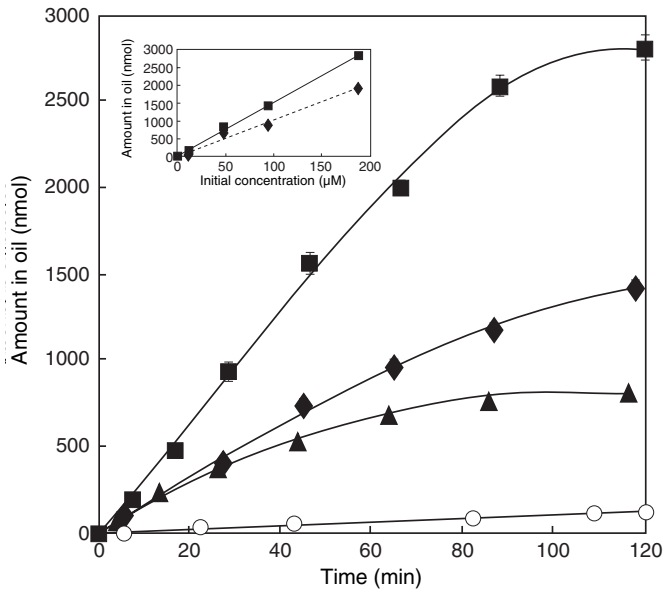

FIG. 2. The effect of concentration of carrot juice on carotene transfer to olive oil, pH 2.1. The initial concentrations of carotene in the aqueous phase were ■ 188, ◆ 94, ▲ 47, and ○ 11.6 μM. The error bars represent the range of amounts transferred measured for two replicates of the experiment. Transfer at the two lower concentrations was measured only once. The insert shows the data plotted as a function of the initial concentration of carotene in the aqueous phase, ■ at 2 h and ◆ at 1 h.

TABLE 1
The Reversibility of the pH Effect on Carotene Transport from Carrot Juice

	Carrots stored less than 2 mon		Carrots stored more than 4 mon	
	% Transferred at 20 min[a]	% Transferred at 60 min[a]	% Transferred at 20 min[b]	% Transferred at 60 min[b]
pH 2.1 throughout	9.2 (0.2)	17.2 (0.9)	10.7 (0.1)	21.8 (1.2)
pH 2.1–pH 6.2	4.9 (0.1)	9.5 (0.2)	11.2 (0.2)	21.7 (0.1)
pH 6.2 throughout	5.6 (0.5)	10.5 (0.7)	5.7 (0.2)	16.9 (0.7)

[a]Mean (range of values) for two replicates where the initial concentration of carotene in the aqueous phase was 95 μM.
[b]Mean (standard deviation) for three replicates where the initial concentration of carotene in the aqueous phase was 63.9 μM.

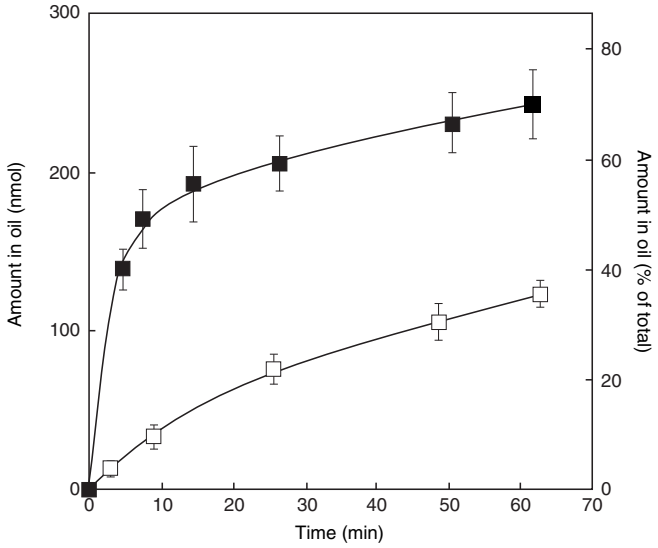

FIG. 4. Carotene transfer from isolated chromoplast measured at pH 2.1 ± 0.1 (■) and pH 6.5 (□). The initial carotene concentration in the aqueous phase was 11.6 μM. The error bars represent the SD in three experiments.

Partitioning of carotene from a fraction enriched in carotene crystals and carotene bodies. Figure 4 shows the rate of uptake of carotene from chromoplast carotene isolated from carrot juice. It is apparent that the partitioning is faster than that observed from carrot juice (compare Fig. 4 with Fig. 1). However, the results resemble those from carrot juice in that the partitioning is pH-dependent, being greater at low pH.

Effect of pH and carrot juice on exogenous β-carotene transport. The studies of transport using isolated chromoplast carotene from carrot showed that the process is inherently pH-sensitive. However, further work showed that the situation with carrot juice is rather more complicated and that there are factors in the carrot tissue that inhibit carotene transport, the inhibition being relieved by lowering the pH. This was shown by the following experiments: we dispersed pure β-carotene in an aqueous phase without juice and measured its rate of transport to oil at pH 2 and 6 (see Fig. 5a). The rate of transport of the β-carotene is independent of pH and significantly faster than endogenous carotene transfer from carrot juice. Then we added exogenous β-carotene at the same concentration to carrot juice and measured the transport of the added β-carotene plus the endogenous carotene and compared this transport to that measured with carrot juice alone. The results of the experiment are shown in Figure 5b. By fitting third-order polynomials to the data and subtracting the curves for endogenous carotene transport from those for exogenous plus endogenous carotene transport we could calculate the effect of the juice on the exogenous β-carotene transport. The calculated data are shown in Figure 5a. It is clear that the exogenous β-carotene transport is slowed by the presence of carrot juice and is enhanced by low pH.

Correlation of carotene transport with ζ potential of the oil. Transfer of carotene from the carrot juice to the oil phase involves penetration through the oil–water interface, which when unmodified is negatively charged (14). Therefore, we considered it likely that the effect of pH on carotene transport could be due to alterations in the electric potential at the

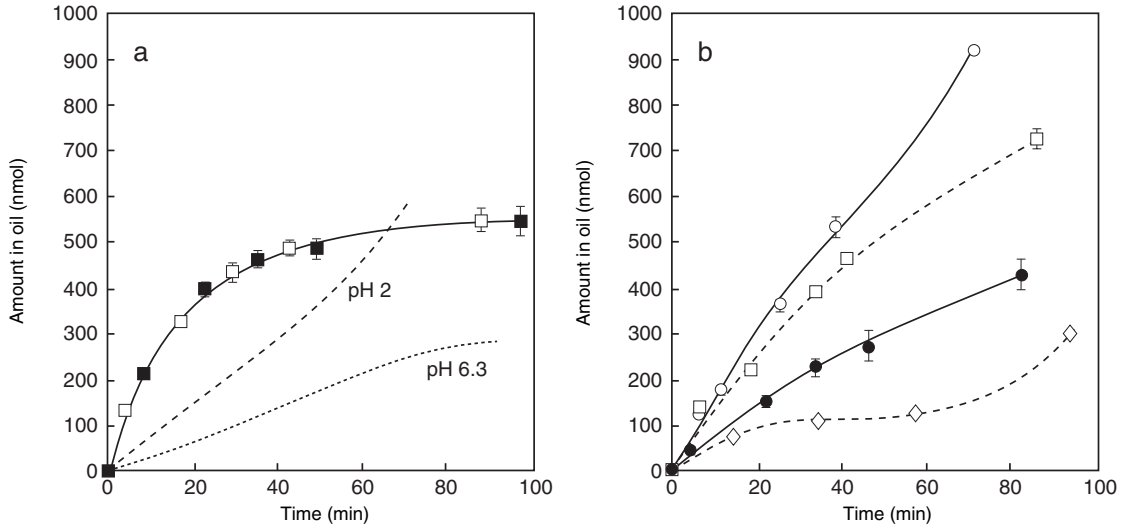

FIG. 5. Inhibition of exogenous β-carotene transfer to olive oil by carrot juice. (a) β-Carotene transfer to oil in the presence and absence of carrot juice. Transfer was measured at pH 2 (□) and pH 6.3 (■) from a solution of 70 mM NaCl, 55 mM KCl, and 1 mM sodium azide containing initially 25.3 μM β-carotene. The dotted lines show the transfer to oil of exogenous β-carotene added to carrot juice at pH 2 and pH 6.3 calculated from the data in b (see text for details). (b) Transfer of exogenous β-carotene and carotene from carrot juice to olive oil at pH 2 and 6.3: solid lines show data when exogenous β-carotene was added to carrot juice and the total amount of β-carotene and endogenous carotene from carrot juice was measured from an aqueous phase containing initially 25.3 μM added β-carotene + 47.5 μM carotene in juice (○) at pH 2, (●) at pH 6.3. The dotted lines show the amount of carotene transfer without added β-carotene (□) at pH 2, (◇)at pH 6.3.

oil/carrot juice mixture interface. A close approximation to the potential at an oil/aqueous phase interface is given by the ζ potential (15). This is the potential at the plane of shear as oil droplets move through the aqueous phase and is related to the electrophoretic mobility (12).

In three batches of carrot juice which were giving similar proportional enhancement of carotene transfer to oil with lowered pH, we measured the amount of transfer after 20 min incubation as a function of pH and the ζ potential of olive oil droplets dispersed in plastid-free juice. Figure 6 shows the results. Here the carotene concentration in the oil at each pH is expressed as a percentage of the concentration measured at pH 2. This normalization procedure obviates the difficulty of variability in the absolute amount of carotene transport between experiments.

Interpretation of the ζ potential against pH curve is complicated since potentially the contribution of changing adsorption at the interface as well as protonation of adsorbed ionizable group at the interface has to be considered. What is significant in the context of carotene transfer to oil is that, although the shapes of the curves of carotene transport as a function of pH, and ζ potential as a function of pH, have similar shape, they cannot be superimposed on the pH axis. Therefore, although it is possible that some soluble component in the carrot juice is important in determining the pH dependence of surface charge at the interface and hence ζ potential, the latter cannot be the only important factor in determining transfer of carotene into the oil phase.

Studies precluding solubilized carotene being the partitioned form of carotene. Plastid-free juice prepared at pH >6 was straw-colored. As the pH was lowered, the yellow color was progressively lost. To quantify this effect we incubated undiluted filtered juice for 20 min over a pH range from 2.42 to 6.20 and then prepared plastid-free juice samples and measured their absorbances at 450 nm. Table 2 shows the results together with the soluble protein concentrations. Both the absorbance and protein concentration fell as the pH was lowered. This loss of soluble protein and carotenoid was largely irreversible: raising the pH of juice incubated at pH 2.42 to 6.32 did not restore the original protein concentration or absorbance value in the plastid-free juice (see Table 2). Since carotene transport is highest at low pH when soluble carotenoid is at its lowest, it seems unlikely that this is the form in which it reaches the oil.

Macroscopic and microscopic observations. Light microscopy showed that the aqueous phases during and after incubations with oil contained oil droplets, some of which had orange crystals located at their surface. It was not possible to tell by light microscopy whether these crystals were actually carotene bodies. Lowering the pH precipitated cellular material containing the crystals (Fig. 7a). This precipitate was invariably present when carotene partitioning was high: for example, when at high pH after low pH treatment the low pH enhancement of transport was not reversed. The precipitate sedimented quite rapidly under $1 \times g$ and could be collected from the bottom of the flask after all the other material had been aspirated away. Entrained in the precipitate were oil droplets (arrows in Fig. 7a) associated with aggregates of cell contents with large amounts of adhering orange crystals (arrowheads). Material in juice at pH >6 sedimented overnight. This material was more diffuse with few aggregates and included many freely floating carotene crystals/bodies (arrowheads in Fig. 7b), which were absent in low pH sediments where carotene crystals were invariably associated with aggregated cellular material. Another distinct difference between low pH sediments and the aqueous phases from which they were prepared was the larger number of oil drops seen at low pH. Using a hemacytometer we found the ratio of the number of oil droplets per milliliter of juice incubated with

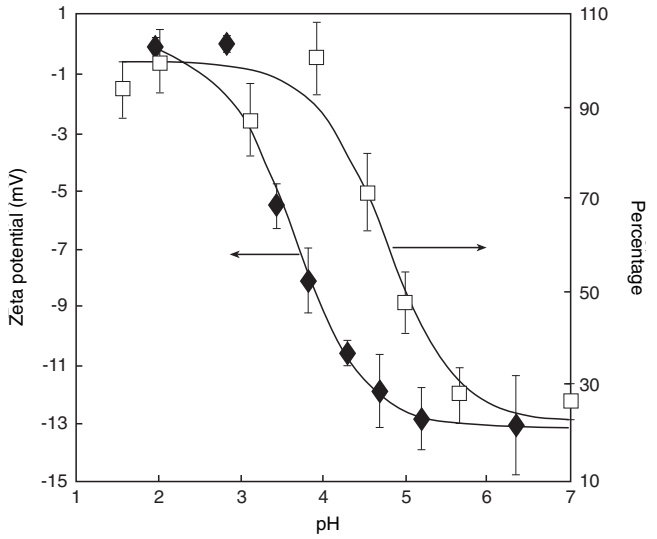

FIG. 6. The ζ potential (left-hand axis) of olive oil droplets dispersed in plastid-free carrot juice as a function of pH (◆). The solid line represents the equation $\zeta = -13.27 \times 10^{pH}/(10^{3.7} + 10^{pH})$ and is the best fit to the data. Also shown (right-hand axis) is the relative amount of carotene transport from carrot juice to olive oil as a function of pH (□). The amount transferred is expressed as a percentage of that measured at pH 2. The solid line is $\% = 100 - (78.06 \times 10^{pH})/(10^{4.8} + 10^{pH})$ and is the best fit to the data. The initial concentration of carotene in the aqueous phase was 94 μM.

TABLE 2
The Protein Concentration and Absorbance of Plastid-Free Juice as a Function of pH[a]

pH	Protein concentration (mg/mL)	$A_{450}{}^{1\ cm}$
6.20	0.73	1.01
5.36	0.40	0.252
4.45	0.094	0.029
3.30	0.044	0.005
2.42	0.034	0.007
2.42 → 6.32[b]	0.097	0.005

[a]Whole juice containing 1 mM sodium azide was incubated for 30 min at 37°C at the indicated pH values. Plastid-free samples were then prepared for protein and absorbance measurements.
[b]Juice incubated at pH 2.42 was adjusted to pH 6.32 and incubated for a further 15 min.

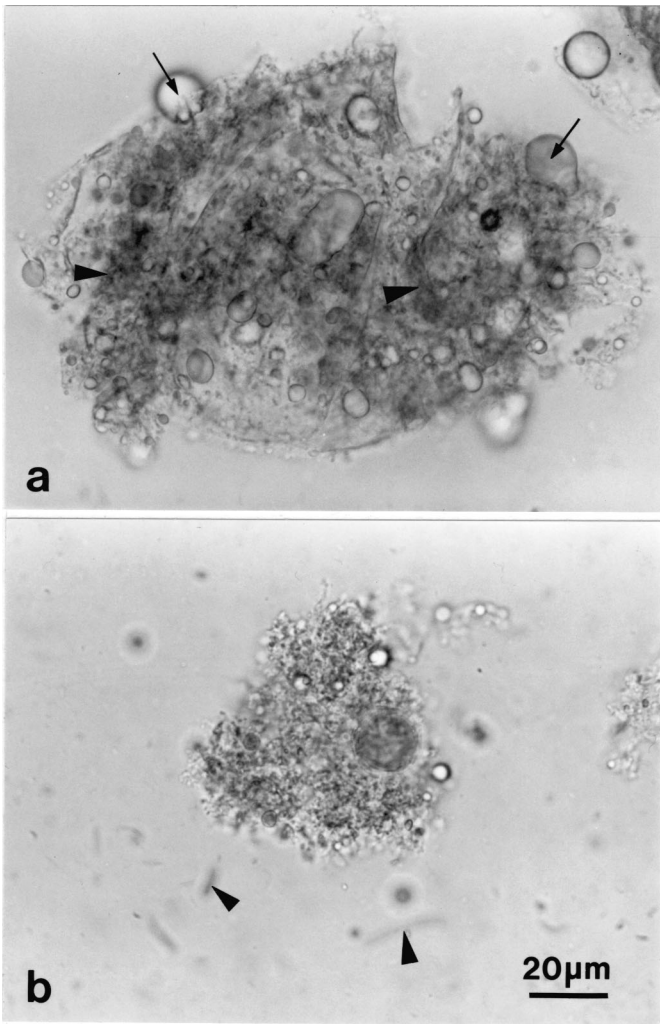

FIG. 7. Light microscopy of carrot juice incubated with olive oil. (a) Typical aggregate of carrot cell material seen at low pH (pH 2) showing entrained oil droplets (arrows) and carotene crystals/bodies (arrowheads). Note the absence of free crystals in the background surrounding the aggregate. (b) A rare aggregate seen at pH 6 surrounded by many free carotene crystals/bodies (arrowheads).

oil at pH 2.16 compared to the number at pH 6.24 was 3.0 ± 0.6. However, when we only counted droplets that were attached to carrot material this ratio rose to 10.0 ± 1.3.

The location of exogenous β-carotene in carrot juice at low and high pH was also examined. At low pH (2.17) the added β-carotene crystals were found entirely on aggregated cell contents. In contrast, at pH 6.32 the β-carotene crystals were uniformly distributed. On the rare aggregates that were present, the density of crystals was no higher than that found floating free. Thus, the location of added β-carotene crystals at different pH values mimics that of the endogenous carotene.

Electron microscopy confirmed and amplified these findings. Sediment from untreated filtered juice (Fig. 8a) appeared very similar to the sediment from filtered juice incubated with oil at pH 6.3 (Fig. 8b). Distinctive features in both were the presence of vesicles less than 1 μm in diameter as well as plastoglobuli and electron-opaque carotene crystals

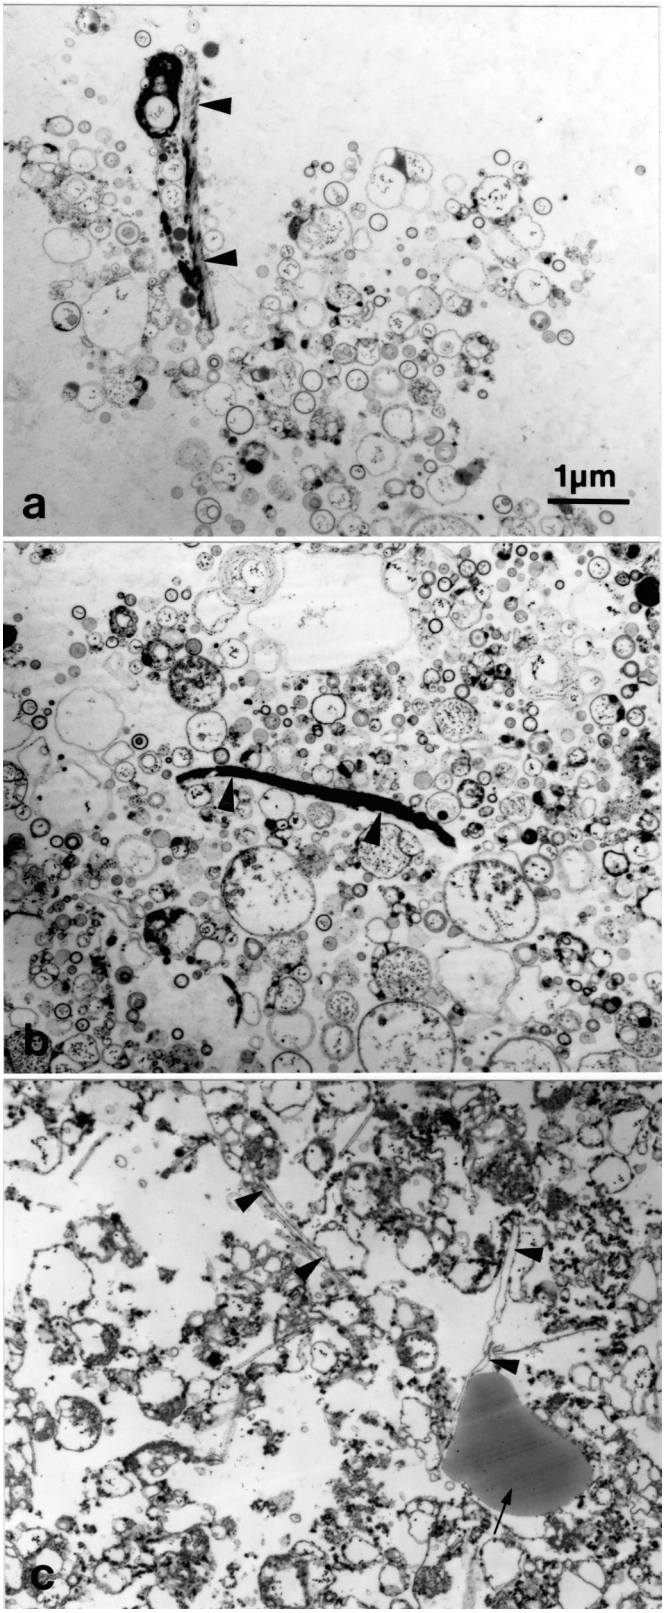

FIG. 8. Transmission electron micrographs of filtered carrot juice. (a) Untreated, (b) incubated with oil at pH 6.3, (c) incubated with oil at pH 2.2. Arrowheads in a and b indicate carotene bodies, and in c, carotene body membranes from which the carotene has been eluted. A distorted oil droplet is arrowed in c.

and carotene bodies (indicated by arrowheads in the figures), which had been released from the chromoplasts. There were no olive oil droplets visible. In contrast, filtered juice incubated with oil at pH 2.2 (Fig. 8c) showed the presence of adhering oil droplets (arrow in figure) and densely staining precipitated material (probably largely protein) concentrated around membranes. There were no electron-opaque carotene crystals, but there were needle-shaped membranous vesicles (indicated by arrowheads) which we have interpreted as carotene body membranes from which the carotene had been extracted by either the incubation with oil or the ethanol dehydration. Oil drops were frequently distorted and lying adjacent to the carotene body membranes.

DISCUSSION

The absorption of lipid-soluble vitamins from the gut is enhanced by acidic conditions (16–18) and by the presence of fat in the diet (19,20). Further, others have shown (21), using omeprazole to suppress gastric acid secretion in human subjects, that after a liquid meal containing fat and β-carotene there is an increased serum concentration of *trans* and *cis* β-carotene at low gastric pH compared to high gastric pH. That there is reduced uptake of β-carotene from consumption of carrot material compared to that when β-carotene is given in purified supplements has been shown in both humans (22) and ferrets (23).

The results presented in this paper suggest that these observations can be explained if an important step for absorption is partition of the carotene into an oil phase. In using either juice or a fraction of juice enriched in carotene, this partition is pH-dependent, being higher at low pH. In using purified β-carotene alone, partition is independent of pH. Further, the rate at which carotene partitions is much higher using β-carotene alone than carotene in carrot juice. However, if carrot juice is added to exogenous β-carotene, the β-carotene partitioning becomes pH-dependent and the rate of partitioning falls at both low and high pH. Our observations by microscopy indicate that the extent of precipitation of aggregated cell contents and the adherence of either carotene crystals/bodies or β-carotene crystals to these aggregates correlate with the amount and rate of transport into the oil.

There is a possibility that carotene in carrot juice could reach the oil phase as a water-soluble carotene–protein complex. Such a complex has been isolated from an enriched chromoplast fraction from carrot tissue (24). However, the low concentration of solubilized carotene and loss of protein in the aqueous phase (especially at low pH) during our experiments argues against solubilized carotene as the partitioned species. In this context it is significant that carotenoids are known to be unstable under acid conditions (25). Furthermore, our spectroscopic and high-performance liquid chromatographic studies (Rich, G.T., Fillery-Travis, A., and Scott, K.J., unpublished data) indicate that the noncrystalline, soluble components in carrot juice contain only trace amounts of carotene.

Our light microscope observations are consistent with the carotene in carrot juice passing directly into the oil phase from either carotene crystals or carotene bodies. We have noticed isolated carotene crystals/bodies adhering to oil–water surfaces. The concentration of crystals and oil droplets on precipitated cell components at low pH therefore provides a mechanism for the low-pH enhancement of carotene transport into the oil. It is a physical process whereby the crystals and oil droplets are brought close together so the carotene can pass through the oil–water interface and dissolve in the oil. The low ζ potential of the oil droplets at low pH aids this process. At pH values approaching neutrality, when the ζ potential is much larger, there will be significant repulsion between the oil droplets and the negatively charged cellular material.

We have shown the importance of particle size in determining carotene transfer into oil. This parallels other studies (5) showing that finely chopped vegetables give higher absorption of β-carotene compared to whole or sliced vegetables. However, organelle structures sequestering the carotene crystals cannot be the only factors in carrot juice inhibiting carotene transfer, because purified β-carotene partitioning is also inhibited by carrot juice. A possible candidate for this inhibitory factor is fiber. For example, various types of dietary fiber reduce the bioavailability of β-carotene in chicks (26). A similar effect has been shown with humans where pectin added to a meal containing purified β-carotene reduced the plasma β-carotene response (27). In general, the effect of high-fiber diets is to increase the fecal excretion of lipids (28) and carotene (29). This has been attributed to high-viscosity conditions limiting the absorption. Raw carrots contain about 2.5% dietary fiber of which 32 to 48% is soluble and includes pectin (30,31). It is possible that this is acting at the oil surface in our experiments inhibiting transfer of carotene into the oil. This idea is consistent with the rapidity with which carotene isolated from carrot juice partitions into the oil compared to the rate when juice is used. A similar effect has been observed by Zhou, Gugger, and Erdmann (32) who showed that ferrets fed carrot chromoplasts had higher serum and tissue carotene concentrations than ferrets fed carrot juice. Both the chromoplast isolation process and our preparation of chromoplast carotene involve washing which would remove soluble fiber. It is also possible that acid conditions cause some degradation of pectin which would contribute to the enhancement of carotene transport at low pH.

Our observations that the pH dependence of partitioning of carotene from carrot juice into oil mimics what is observed *in vivo* for carotene absorption from the gut contents suggest that an important step in chromoplast carotene absorption is solubilization in the gastric oil phase. This first stage is followed by solubilization in mixed bile salt micelles, whose concentration in the duodenum is stimulated by fat in the diet. A number of factors influence the solubility of carotene in mixed micelles (reviewed in Ref. 33). Important in the context of the present work is the observation that below pH 5 the solubility of carotene in mixed micelles decreases with a decrease in pH (34). We have suggested that fiber in carrot

juice inhibits carotene partitioning into oil. Similarly, this putative factor could also inhibit solubilization of carotene in bile salt micelles.

Effects of Feeding *Lunaria* Oil Rich in Nervonic and Erucic Acids on the Fatty Acid Compositions of Sphingomyelins from Erythrocytes, Liver, and Brain of the Quaking Mouse Mutant

Claire Cook[a], Joan Barnett[a], Keith Coupland[b], and John Sargent[a,*]

[a]Department of Biological and Molecular Sciences, University of Stirling, Stirling FK9 4LA, United Kingdom, and [b]Croda Chemicals Ltd., Hull, Humberside, HU6 7PH, United Kingdom

ABSTRACT: Feeding an oil from *Lunaria biennis* rich in 22:1n-9 and 24:1n-9 to homozygous quaking (qk.qk) mice caused a large increase in the percentage of 24:1n-9 and corresponding decreases in the percentage of 24:0 and 22:0 in sphingomyelins from liver, erythrocytes, and milk. Brain sphingomyelin from 2-wk-old qk.qk pups born to qk.qk mothers maintained on the *Lunaria* oil had essentially normal percentage of 24:1n-9 and 18:0, in contrast to pups born to mothers maintained on a control oil rich in 18:1n-9 whose brain sphingomyelin had a markedly reduced percentage of 24:1n-9 and an increased percentage of 18:0. After 2 wk and up to and beyond weaning, the qk.qk pups from *Lunaria*-fed mothers weaned on to the *Lunaria* diet had a markedly decreased percentage of 24:1n-9 in their brain sphingomyelin, accompanied by an increased percentage of 18:0, as compared to heterozygous quaking mice. However, the percentage of 24:1n-9 in brain sphingomyelin in qk.qk pups weaned on to the *Lunaria* diet continued throughout this period (2–8 wk postbirth) to be significantly higher than in qk.qk pups weaned on to the control diet. We conclude that dietary 24:1n-9 influences the fatty acid composition of brain sphingomyelin in qk.qk mice, but only *via* the mother in pre- or early postnatal animals. We further consider that the dietary effects may be elicited mainly in the sphingomyelin of nonmyelinated brain cells, and that the nervonic acid in myelin sphingomyelin may be formed mainly by chain elongation in oligodendrocytes from shorter chain fatty acid precursors.

Lipids 33, 993–1000 (1998).

The "quaking" mouse is a recessive autosomal mutant characterized by deficient myelination of the central nervous system (1). Lipids of the central nervous system of quaking mice have markedly reduced levels of cerebrosides and sulfatides, reduced levels of the major phosphoglycerides, and unaltered levels of sphingomyelin (1–3). Simultaneously, the brain cerebrosides, sulfatides, and sphingomyelin of quaking mice have markedly decreased levels of gadoleic acid (20:1n-9), behenic acid (22:0), lignoceric acid (24:0), and nervonic acid (24:1n-9) (2,4). Brain microsomes from quaking mice have a markedly reduced ability to convert behenyl CoA to lignocerate (5–7), due to a markedly reduced condensing enzyme activity (with both 20:0 and 22:0 CoA as substrates) (8).

Recently the quaking gene was cloned and shown to be a multifunctional gene involved in a specific set of developing tissues to link signal transduction with some aspect of RNA metabolism (9,10). Thus, the abnormalities of brain lipid metabolism in quaking mice, specifically the markedly reduced capacity to form lignoceric and nervonic acid from shorter chain precursors, are but one of a variety of outcomes of the quaking mutation. Nonetheless, the quaking mouse mutation remains a useful model system for investigating aspects of brain lipid metabolism, including influences of dietary-administered fatty acids on the fatty acid compositions of brain sphingolipids. The present study was undertaken to determine the extent to which long-chain monoenoic fatty acids, specifically 22:1n-9 and 24:1n-9, administered in the diet can access the brain of quaking mice and thereby modify the fatty acid composition of brain sphingomyelin.

MATERIALS AND METHODS

Animals and diets. Heterozygous quaking mice (qk.+), i.e., phenotypically normal animals, were purchased from the MRC Radiobiology Unit, Didcot, Oxfordshire, United Kingdom, and maintained on a standard laboratory chow supplied by Special Diet Services, Witham, Essex, United Kingdom. Homozygous quaking mice (qk.qk), i.e., animals expressing the quaking symptom, were bred from the heterozygous stock and weaned directly on to either a control diet or a test diet. These diets were purchased from ICN Biomedicals Ltd., Thame, Oxfordshire, United Kingdom, and consisted of the standard ICN diet AIN-93G (for growth, pregnancy, and lactation of rodents), which contains 7% w/w soy oil, supplemented with a further 3% w/w of either a high-oleic acid sunflower oil to produce the control diet, or an oil extracted from

TABLE 1
Fatty Acid Compositions of the Test and Control Diets[a]

Fatty acid	Control diet	Test diet
16:0	10.8	8.0
16:1n-7	0.6	0.4
18:0	3.5	2.9
18:1n-9	38.8	22.3
18:2n-6	39.3	38.4
18:3n-3	5.4	5.4
20:0	0.8	0.7
20:1n-9	0.8	1.0
22:1n-9	0.0	13.8
24:0	0.0	0.0
24:1n-9	0.0	6.8

[a]Data are expressed as wt% of total fatty acids. The control diet contained 7% soy oil + 3% of a high-oleic acid sunflower oil. The test diet contained 7% soy oil + 3% of an oil from *Lunaria biennis.*

Lunaria biennis to produce the test diet. Both the high-oleic acid sunflower oil and the *Lunaria* oil were supplied by Croda Chemicals, Hull, Humberside, United Kingdom. The test diet differed from the control diet by having a reduced percentage of 18:1n-9 and correspondingly increased percentages of 22:1n-9 and 24:1n-9 in its lipid component (Table 1). Quaking mice pups were weaned, 19 d after birth, randomly on to the two diets, such that the sex ratios of the two groups were the same, and the mice were maintained on the two diets until they reached sexual maturity. A second generation of qk.qk mice was then bred from the first generation of qk.qk females and qk.+ males (as noted by other authors, qk.qk males did not breed successfully with qk.qk females), and the second-generation qk.qk pups were continued on the same diets as their qk.qk mothers. The results presented here for liver and blood are from first-generation mice and for brain and milk from second-generation mice. Groups of animals were sacrificed at times specified in individual Figures and Tables, and samples of brain, liver and heparinized blood were taken for analyses. Erythrocytes were sedimented from blood by centrifugation and washed twice in 0.9% wt/vol NaCl. Samples of liver, brain, and erythrocytes were either processed for analysis immediately, or frozen at −70°C and processed for analysis within weeks, with the same result. Milk was collected from lactating qk.qk mothers by manual expression after anesthetizing them and promoting milk flow by injecting oxytocin.

Lipid extraction and analyses. Total lipids were extracted from samples of brain, liver, erythrocytes, and milk by the method of Folch *et al.* (11). Lipid extracts were stored at –20°C under nitrogen between procedures. Lipid class composition was determined by high-performance thin-layer chromatography (HPTLC) of total lipids on silicic acid, using methyl acetate/propan-2-ol/chloroform/methanol/0.25% w/w aq. KCl (25:19:25:10:9, by vol) as solvent and copper acetate–phosphoric acid as a charring stain, and scanning densitometry performed on a Shimadzu CS-9000 instrument (Tokyo, Japan) (12). Sphingomyelin was routinely isolated from all tissues following mild alkaline transesterification of total lipid, so as to convert *O*-acyl glycerides into fatty acid methyl esters and water-soluble products, while leaving *N*-acyl sphingolipids intact (13). Sphingolipids and fatty acid methyl esters were extracted from the alkaline transesterification reaction medium after adding chloroform and methanol (14), and sphingomyelin isolated by HPTLC in methyl acetate/propan-2-ol/chloroform/methanol/0.25% w/w aq. KCl (25:19:25:10:9, by vol) as solvent. Triacylglycerols and phosphoglycerides (comprising phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol) were isolated from milk total lipid in the same solvent. Individual lipid classes were detected on thin-layer plates by staining with 0.1% 2′,7′-dichlorofluorescein in 97% methanol containing 0.01% (wt/vol) butylated hydroxytoluene, eluted from the plates with chloroform/methanol (2:1, vol/vol) and dried under nitrogen prior to preparing fatty acid methyl esters for gas chromatographic (GC) analyses. Fatty acid methyl esters were prepared from sphingomyelin by reacting with 1% sulfuric acid in methanol for 24 h at 60°C, and from phosphoglycerides and triacylglycerols by reacting with 1% sulfuric acid in methanol for 16 h at 50°C. Fatty acid methyl esters were purified by HPTLC using hexane/diethyl ether/acetic acid (80:20:2, by vol) as solvent and analyzed by capillary GC using a Canberra-Packard 436 instrument (Berkshire, United Kingdom) fitted with a Sil 5CB column (50 m × 0.32 mm; Chrompack, London, United Kingdom) with hydrogen as carrier gas and a thermal gradient from 50 to 260°C (14). Individual fatty acid methyl esters were identified by comparison with authentic standards and by GC–mass spectrometry using a Fisons MD 800 instrument fitted with a DB-5MS column (15 m × 0.25 mm; J&W Scientific, Folsom, CA) with helium as carrier gas.

Statistical analyses. Data are expressed as means ± 1 SD with the total number of individual determinations (each on a separate animal) in parentheses. Significance of difference between dietary treatments was determined by Student's *t*-test.

RESULTS

The diet containing the test oil, which was rich in both erucic acid (22:1n-9) and nervonic acid (24:1n-9), readily altered the fatty acid compositions of sphingomyelin from erythrocytes and liver, as compared to the control diet, which was rich in oleic acid (18:1n-9) (Table 2). In the present study, mice were routinely weaned on to the experimental diets 19 d after birth. Effects of the two diets on liver and erythrocyte sphingomyelin were readily apparent 1 or 2 wk after weaning. The data in Table 2 show the maximal changes that occurred by 8 wk post-birth, i.e., *ca.* 5 wk post-weaning. Erythrocyte sphingomyelin had the same fatty acid composition in nonsymptomatic, qk.+ animals and symptomatic, qk.qk animals fed the control diet, with 22:0, 24:0, and 24:1n-9 being the major fatty acids, accounting for *ca.* 15, 30, and 20%, respectively, of the total fatty acids. The same situation held for livers of qk.+ and qk.qk mice fed the control diet except that 22:0, 24:0, and 24:1n-9 accounted for *ca.* 30, 25, and 15%, respectively, of the total fatty acids. Feeding the *Lunaria* oil rich in 22:1n-9 and 24:1n-9

24:0	26.0 ± 2.8	24.7 ± 3.6[a]	6.5 ± 1.5[b]
24:1n-9	16.2 ± 1.4	14.4 ± 3.2[a]	56.0 ± 2.3[b]

[a]Data are expressed as wt% of total fatty acids and are means ± 1 SD of determinations on three separate animals weaned on to the respective diets and sacrificed 8 wk postbirth. Significant differences ($P < 0.05$) between qk.qk mice fed the control and test diets are indicated by different superscript letters (a,b) in a given row.

markedly affected the fatty acid compositions of sphingomyelin in both erythrocytes and liver of qk.qk mice. In both tissues there was a marked elevation of the percentage of 24:1n-9 and corresponding decreases in the percentage of 22:0 and especially of 24:0. These data establish that the *Lunaria* oil was readily digested and assimilated by the qk.qk mice and exerted a major influence on the fatty acid composition of sphingomyelin in both liver and erythrocytes.

The above experiment was performed on first-generation qk.qk mice, i.e., qk.qk mice born to qk.qk mothers maintained on conventional laboratory chow and then weaned on to the test and control diets and maintained on these diets for the rest of their lives. Analyses of brain sphingomyelin in these mice revealed minor changes only (data not shown). Therefore, maintained on the respective control and test diets, second-generation mice were bred from qk.+ fathers and from qk.qk mothers that had been maintained on the two diets since weaning. The remainder of the experiments were performed on these second-generation mice. Although difficulties were experienced in breeding the mice, no difficulties were experienced in maintaining the weaned mice on either the test or control diets and no mortalities occurred.

Table 3 shows the evolution of sphingolipids in the brains of quaking mice over the 2-mon period following birth; the first sampling time was at 2 wk (5 d before weaning), the earliest time we could reliably identify pups born from first-generation qk.qk females and qk.+ males as being quaking mutants. Normal qk.+ mice fed the control diet had a relatively constant percentage of sphingomyelin, *ca.* 3%, throughout the 8-wk study period. Qk.qk mice fed the control diet had the same percentage sphingomyelin as the qk.+ mice at 2 and 4 wk and only slightly increased percentage of sphingomyelin at 6 and 8 wk. Apart from a slight difference at 2 wk, qk.qk mice fed the test diet had the same percentage sphingomyelin as those fed the control diet. In contrast to the evolution of sphingomyelin, the evolution of both cerebrosides and sulfatides in the 2-mon period postbirth was markedly depressed in qk.qk mice compared to qk.+ mice when both were fed the control diet, and feeding the test diet to the qk.qk mice did not change their depressed levels of brain cerebrosides or sulfatides (Table 3). These findings held for both the hydroxy and nonhydroxy components of both cerebrosides and sulfatides (data not shown).

Figures 1–6 show the evolution of the principal fatty acids in sphingomyelin from the brain lipids of the second-genera-

tion qk.qk mice postbirth. At the earliest sampling period, 2 wk postbirth, the percentage of 16:0 was elevated in qk.qk mice fed the control diet as compared to qk.+ mice fed the control diet (Fig. 1). In qk.qk mice fed the test diet, the level of 16:0 was further elevated compared to qk.qk mice fed the control diet. As sampling progressed through weaning, the levels of 16:0 fell in all cases to reach the same value by *ca.* 5 wk, after which no further change occurred (Fig. 1). Of the total fatty acids in all three groups of mice at 2 wk postbirth, 18:0 accounted for more than 70% with the level of 18:0 in qk.qk mice fed the control diet being higher than in both qk.+ mice fed the control diet and qk.qk fed the test diet (Fig. 2). The level then increased slightly in qk.+ mice fed the control diet, and substantially more so in qk.qk mice fed both the control and test diets which reached the same final level of 18:0 (Fig. 2). The initially low levels of 20:0 in qk.+ fed the control diet were even lower in qk.qk fed the same diet and qk.qk mice fed the test diet (Fig. 3). As the animals progressed through weaning, the level of 20:0 increased in all three groups of animals, more so in the qk.qk mice than the qk.+ mice and especially in qk.qk mice fed the control diet. However, differences between the test and control diets in the qk.qk mice were not significantly different. A much clearer

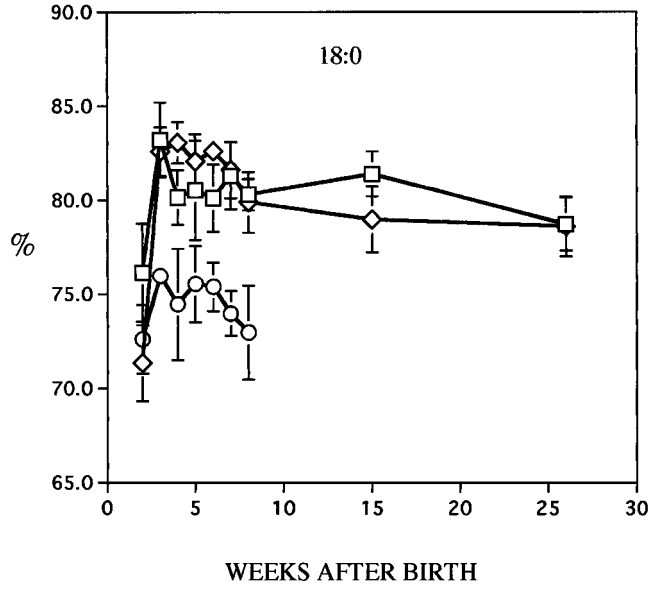

FIG. 2. See Figure 1 for caption details.

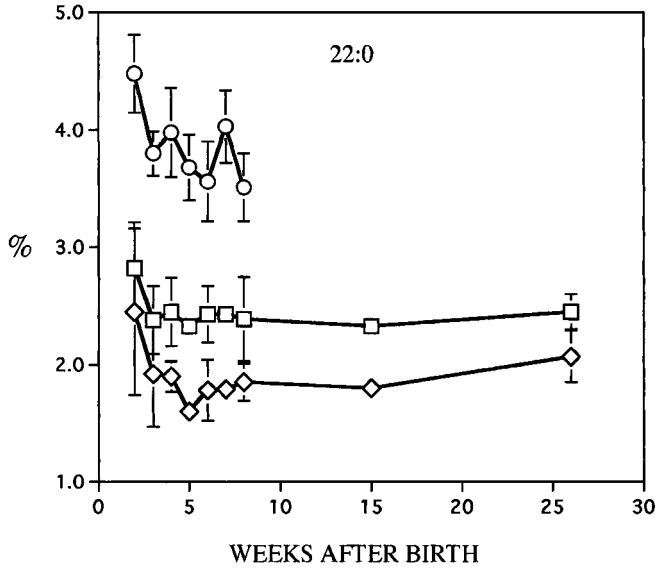

FIG. 4. See Figure 1 for caption details.

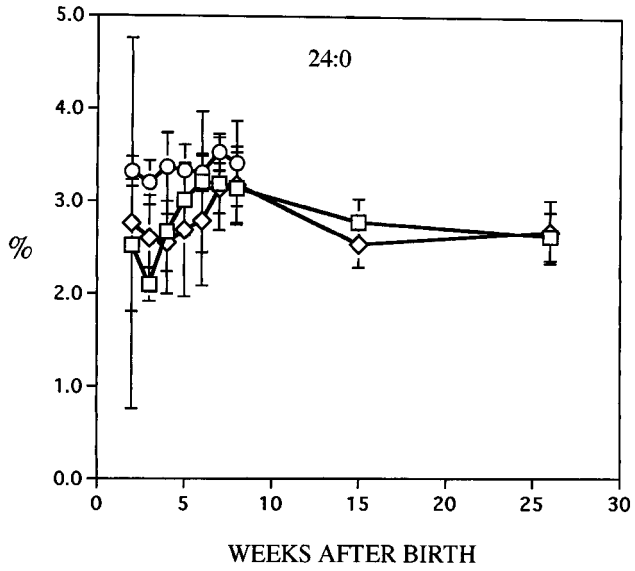

FIG. 5. See Figure 1 for caption details.

picture emerged for 22:0 (Fig. 4) where qk.+ mice fed the control diet had a consistently higher level than qk.qk mice fed the control diet, and these in turn had a consistently higher level of 22:0 than qk.qk mice fed the test diet. Clearly, levels of 22:0 in brain sphingomyelin are depressed in qk.qk mice and further depressed by administering the *Lunaria* oil diet. Levels of 24:0 were also initially depressed in qk.qk mice compared to qk.+ mice (Fig. 5) and, although the levels progressively increased in the qk.qk mice, differences between the test and control diets were not significantly different. Finally, Figure 6 shows that the initial level of 24:1n-9 was the same in qk.qk mice fed the test diet as in qk.+ mice fed the control diet, and substantially higher than in qk.qk mice fed the control diet. Further, while the level of 24:1n-9 rose progressively in qk.+ mice fed the control diet, it fell rapidly in qk.qk mice fed the test diet to reach a level that was consistently significantly ($P < 0.05$) greater than in qk.qk mice fed the control diet (Fig. 6).

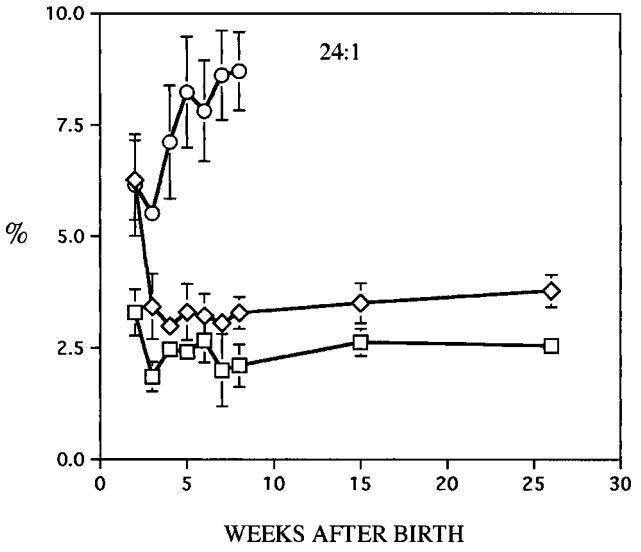

FIG. 6. See Figure 1 for caption details.

Last, because the test diet had clearly influenced brain sphingomyelin fatty acids in qk.qk mice sometime prior to weaning, we investigated the influence of the diet on lactating mothers' milk. Table 4 shows that the test diet markedly increased the level of 24:1n-9 and simultaneously depressed the levels of 22:0 and especially 24:0 in milk sphingomyelin, as compared to the control diet. Lipid class analyses established that 100 g of milk total lipid from qk.qk mice fed the test diet contained 0.6 g of sphingomyelin, 3.1 g of phosphoglycerides, and 87 g of triacylglycerols. The percentages of 24:1n-9 in the total fatty acids of these lipids were 43.9% in sphingomyelin, 0.7% in phosphoglycerides, and 1.6% in triacylglycerols. We conclude that, although sphingomyelin has by far the highest level of 24:1n-9 in the individual milk lipids of qk.qk. mice fed the test diet, the majority of the total 24:1n-9 present in their milk resides in the triacylglycerols.

DISCUSSION

The results of the present study are entirely consistent with previous studies of the quaking mouse mutant. Thus, levels of cerebrosides and sulfatides but not sphingomyelin are markedly reduced in the brain lipid of quaking (qk.qk) as compared to normal (qk.+) mice (1–3; Table 3). Moreover, qk.qk mice have reduced levels of 24:1n-9 in brain sphingomyelin due to a markedly reduced ability to convert C_{20} to C_{22} and C_{24} fatty acids (5–8). This is clearly seen here in the evolution of the fatty acid composition of sphingomyelin in qk.qk mice where, in the 2–8 wk period postbirth, there is a marked elevation in 18:0, and marked depressions of 22:0, 24:0, and especially 24:1n-9 (Figs. 1–6). The quaking gene is now known to be involved in fundamental developmental processes including nerve myelination (9,10), and it would be very surprising if normalization of the nervonic acid content of brain sphingolipids, as was attempted in the present

TABLE 4
Fatty Acid Composition of Milk Sphingomyelin from Quaking Mice Fed the Test and Control Diets[a]

Fatty acid	qk.qk Control diet	qk.qk Test diet
16:0	26.0 ± 1.6	27.1 ± 2.6
18:0	3.4 ± 0.9	2.5 ± 0.7
18:1n-9	5.6 ± 1.8	6.8 ± 3.9
18:2n-6	4.5 ± 1.2	5.4 ± 3.6
20:0	0.7 ± 0.7	0.5 ± 0.5
22:0	8.0 ± 0.5[a]	0.5 ± 0.4[b]
24:0	22.1 ± 2.8[a]	1.2 ± 0.4[b]
24:1n-9	14.1 ± 4.0[a]	43.9 ± 9.2[b]

[a]Data are wt% of total fatty acids in sphingomyelin and are means ± 1 SD for separate milk samples from three individual animals. Significant differences ($P < 0.05$) between control and test diets are indicated by different superscript letters (a,b) in a given row.

study, by itself ameliorated the condition. Nonetheless, the findings here are relevant to understanding the interplay between dietary fatty acids and *de novo* fatty acid biosynthesis in determining the final composition of brain sphingomyelin.

Our results establish that *Lunaria* oil is readily digested and assimilated as evidenced by its marked effects on the fatty acid compositions of sphingomyelins from liver and erythrocytes (Table 2). While the effects were elicited here in quaking (qk.qk) mice, the fatty acid compositions of erythrocyte and liver sphingomyelins of these mice were not significantly different from those of their nonquaking (qk.+) counterparts. Thus, the quaking mutation does not affect the sphingomyelin of extra neural tissue which points to the biosynthesis of C_{24} fatty acids proceeding normally in extra neural tissues including the liver of quaking mice. This is supported by the abundance of 24:0 and 24:1 in milk sphingomyelin from quaking mice fed the control diet (Table 4). Therefore, the results obtained here for liver, erythrocytes, and milk may be directly compared with the various studies already published for the effects of dietary fatty acids in influencing the fatty acid compositions of tissue sphingomyelins in various species and especially the levels of 24:0 and 24:1 in sphingomyelin (15–22). Of these studies, the most definitive is that by Bettger and Blackadar (21) who fed rats 21 different oils, ranging in percentages of 18:1n-9 from 5–78%, 22:1n-9 from 0–23% and 24:1n-9 from 0–1%, and examined the effects of the diets on the ratios of 24:1/24:0 in liver sphingomyelin. These authors determined empirically that the ratio (r) of 24:1n-9/24:0 in rat liver sphingomyelin was determined by the dietary fatty acid composition according to the following relationship:

$$r = 1.88[24{:}1n\text{-}9] - 1.48[24{:}0] + 0.21[22{:}1n\text{-}9] + 0.01[18{:}1n\text{-}9] + 0.26 \quad [1]$$

where the figures in square brackets are the percentage of an individual fatty acid in the dietary oil. This relationship establishes the importance of chain elongation of both 18:1n-9 and 22:1n-9 in determining the final level of 24:1n-9 in liver sphingomyelin, and it equally demonstrates the importance of even small percentages of both 24:1n-9 and 24:0 in establishing the final levels of these fatty acids in liver sphingomyelin.

It is instructive to consider our results in terms of the Bettger and Blackadar (21) relationship. The predicted value of r = 24:1/24:0 for the control diet in this study is 0.65. The measured values of r = 24:1/24:0 for sphingomyelins are 0.59 and 0.62 for erythrocytes and liver, respectively, in qk.+ mice; and 0.75, 0.58, and 0.63 for erythrocytes, liver, and milk, respectively, in qk.qk mice. We conclude that the Bettger and Blackadar (21) relationship holds for sphingomyelins in extra neural tissues of both normal (qk.+) and quaking (qk.qk) mice fed the control diet. We also conclude that, because the control diet has negligible levels of both 24:1n-9 and 24:0, the final levels of these fatty acids in the extra neural sphingomyelins are determined largely by chain elongation reactions operating on shorter-chain fatty acid precursors.

In contrast, the predicted value of r = 24:1/24:0 for the test diet fed to qk.qk mice is 16.16. Here the measured values for sphingomyelins are 4.6, 8.6, and 36.6 for erythrocytes, liver, and milk, respectively. We conclude that the Bettger and Blackadar (21) relationship does not hold for extraneural tissues for the test diet and propose that this reflects (i) the high level of 6.8% of 24:1n-9 in the test diet, and (ii) the probability that such a high dietary input of 24:1n-9 inhibits not only the formation of 24:1n-9 from shorter-chain monoenoic acid precursors but also the formation of 24:0 from shorter-chain saturated acid precursors, because the microsomal fatty acid elongase forming C_{24} from C_{18} and C_{20} precursors does not discriminate between saturated and n-9 monounsaturated substrates (22,23). Thus, the observed substantial deviation of the predicted from the measured value for the test diet is proof of a direct and strong influence of elevated dietary 24:1n-9 in determining the levels of both 24:1n-9 and 24:0 in extra neural sphingolipids in qk.qk mice, not only by direct incorporation into sphingomyelin but probably also by inhibition of the biosynthesis of 24:0 from shorter-chain precursors.

Neither does the Bettger and Blackadar (21) relationship apply to brain for either diet (Table 5). Nonetheless, it is clear that the test diet has consistently increased the ratio of 24:1n-9/24:0 in brain sphingomyelin of qk.qk mice relative to that observed with the control diet. Further, the ratio in 2-wk-old qk.qk mice fed the test diet exceeds that in qk.+ mice fed the control diet. This results mainly from an elevation of 24:1n-9 (Fig. 6) and, to a lesser extent, from a depression of 24:0 (Fig. 5). Clearly, maternally provided 24:1n-9 has substantially influenced brain sphingomyelin in 2-wk-old qk.qk mice. Again we propose that dietary-administered 24:1n-9 is directly incorporated into brain sphingomyelin up to 2 wk postbirth, during which time it also inhibits the biosynthesis in brain of longer-chain fatty acids from shorter-chain precursors, seen here in the depressed levels of 22:0 and 24:0 in brain sphingomyelin of qk.qk mice fed the diet rich in 24:1n-9 at 2-wk postbirth. However, after this time the effects of dietary-administered 24:1n-9 fall off rapidly.

Sphingomyelin in brain is distributed approximately equally between grey matter (nonmyelinated) and white matter (myelinated), whereas cerebrosides and sulfatides are present predominantly in white matter (24). Myelination in mice only becomes extensive from 9–10 d postbirth (2,25). Therefore, the observed effects of the *Lunaria* oil on brain sphingomyelin 2-wk postbirth in qk.qk mice must involve largely nonmyelinated cells. Presumably these cells, mainly neurons and astrocytes, have sphingomyelin that has been influenced

TABLE 5
The Ratios of 24:1n-9/24:0 in Brain Sphingomyelin in the Present Study

	Postbirth (2 wk)	Postbirth (8 wk)	Postbirth (26 wk)
qk.+ Control (predicted 0.65)	1.86	2.56	—
qk.qk Control (predicted 0.65)	1.30	0.67	0.97
qk.qk Test (predicted 16.16)	2.27	1.03	1.41

by the dietary *Lunaria* oil in the present study, by preformed 24:1n-9 delivered from the mother, either *in utero* or after birth during lactation, increasing the percentage of 24:1n-9 by direct incorporation into sphingomyelin and also decreasing the percentage of 20:0, 22:0, and 24:0 in sphingomyelin by further inhibiting the already depressed formation of C_{22} and C_{24} fatty acids from shorter-chain precursors in the quaking mouse brain. Thus, (1-^{14}C)lignoceric acid injected into 15-d-old mice has a specific radioactivity in the total lipid of neurons and astrocytes that is essentially the same as in serum, consistent with its direct incorporation into these cells' sphingolipids (25). However, the specific activity of the injected (1-^{14}C)lignoceric acid in myelin is much less than in serum (26), consistent with C_{24} fatty acids in myelin sphingolipids being biosynthesized extensively if not solely from chain elongation of shorter-chain fatty acids. This is supported by radioactivity from subcutaneously administered (1-^{14}C) stearic acid being readily incorporated into C_{24} fatty acids of mice brain myelin during myelination (27). In contrast, high density serum lipoprotein, whose sphingomyelin contains labeled lignoceric acid, labels the lignoceric acid of brain sphingomyelin of either 20-d-old (rapidly myelinating) or adult (nonmyelinating) rats to only the same very low level (28), i.e., serum lignoceric acid is not incorporated directly into the sphingomyelin of myelin nor, once myelination has been initiated, is it incorporated into the sphingomyelin of neurons or astrocytes. Thus, the marked reduction of the percentage of 24:1n-9 in total brain sphingomyelin observed between 2–8 wk postbirth in the present dietary study reflects the accretion of sphingomyelin resulting from nerve myelination; this myelin-specific sphingomyelin is deficient in 24:1n-9 and elevated in 18:0 and 20:0 due first, to the blockage in converting C_{20} to C_{22} and C_{24} fatty acids in quaking mice brains and second, to the inability of serum 24:1n-9 to contribute to or influence brain sphingomyelin biosynthesis once myelination has been initiated. This presumably reflects development of the blood–brain barrier.

In summary, the results here establish that a dietary oil rich in 22:1n-9 and 24:1n-9 can effectively normalize the level of 24:1n-9 in brain sphingomyelin in the quaking mouse mutant, but only up to 2-wk postbirth. Thereafter, there is a progressive fall in the level of 24:1n-9 in brain sphingomyelin, despite a continuing high dietary input of 24:1n-9. We propose that the positive dietary effect up to 2-wk postbirth is confined largely to neurons and astrocytes, whose sphingomyelin can be biosynthesized from extraneural 24:1n-9 derived from the mother either *in utero* or early postbirth. The present data do not allow us to distinguish between these two possibilities. In contrast, during the 2–8-wk period postbirth, dietary 24:1n-9 is not available to the brain *via* the blood. Rather, the C_{24} fatty acids required for the biosynthesis of sphingomyelin for the rapid phase of myelination in the period starting *ca.* 2 wk postbirth are synthesized, presumably in oligodendrocytes, from C_{18} fatty acids by chain elongation reactions which are defective in quaking mice. Fatty acid chain elongation reactions may only assume true importance within the brain coincident with the initiation of rapid myelination of nerves, closure of the blood–brain barrier, and the imminent removal of maternally derived nutrients as the newborn approaches weaning.

ACKNOWLEDGMENT

We thank Croda Chemicals Ltd., Hull, United Kingdom, for the generous grant that made this research possible.

ABSTRACT: The purpose of the present investigation was to test whether permanent skeletal muscle cells (rat L6 cells) could serve as an *in vitro* model for α-tocopherol (αTocH) biodiscrimination studies. L6 cells were incubated in the presence of high density lipoprotein (HDL), low density lipoprotein (LDL), and very low density lipoprotein (VLDL) labeled in the lipid moiety with either all-*rac*- or *RRR*-[^{14}C]αTocH. These incubations were performed either in the absence or in the presence of exogenously added bovine lipoprotein lipase (LPL) since skeletal muscle is one of the major expression sites of LPL *in vivo*. Time-dependent uptake studies (up to 24 h) in the absence of LPL have shown that equipotent doses of all-*rac*- and *RRR*-[^{14}C]αTocH (1.36:1) led to almost identical accumulation of the tracer, independent of the lipoprotein class used as αTocH carrier. With regard to αTocH donor capacity, it appeared that HDL is the most potent αTocH donor, followed by LDL and VLDL. In the presence of LPL, all-*rac*- and *RRR*-[^{14}C]αTocH uptake was significantly enhanced (between two- and tenfold). Biodiscrimination studies using chiral high-performance liquid chromatographic analysis with radiometric detection of the corresponding methyl ether derivatives on a Chiralcel OD column have demonstrated that the 2*S*-and 2*R*-isomers of αTocH were taken up in a 1:1 ratio by L6 cells independent of the absence or presence of LPL. In addition, we have not observed biodiscrimination between the four 2*R*-isomers, i.e., there was no preferential accumulation of the *RRR*-isomer. These data suggest that L6 cells do not discriminate between different αTocH isomers and that the addition of endogenous LPL significantly enhances the uptake of *RRR*- and all-*rac*-αTocH.
Lipids 33, 1001–1008 (1998).

Synthetic all-*rac*-α-tocopherol (2*RS*-, 4′*RS*-, 8′*RS*-αTocH) is an equimolar mixture of eight different stereoisomers and is used as a vitamin E supplement and as a food additive. The biopotencies of the eight αTocH isomers have been determined in the rat resorption and gestation assay. These data led to the officially established activity ratios of 1:1.36 [synthetic all-*rac*-/*RRR*-α-tocopheryl-acetate (αToc-acetate)] and 1:1.49 (synthetic all-*rac*-αToc-acetate/*RRR*-αTocH). For αToc-acetate relative biopotencies of 100 (*RRR*), 90 (*RRS*), 73 (*RSS*), 57 (*RSR*), 60 (*SSS*), 37 (*SRS*), 31 (*SRR*), and 21% (*SSR*) were established (1). Ingold and colleagues (2) investigated the structural necessities for optimal "biopotency" that give these lipid-soluble phenolic antioxidants Vitamin E activity. The most important determinants were a fully methylated aromatic ring, 2*R*-configuration, and the size of the heterocyclic ring (2).

Dietary vitamin E is taken up by intestinal cells and resecreted in chylomicrons in proportion to the concentration of the naturally occurring tocopherols in the diet (3–5). *In vivo* studies have demonstrated preferential enrichment of very low density lipoproteins (VLDL) with αTocH over γ-tocopherol, a process facilitated by a hepatic αTocH-binding/transfer protein (6–9). Traber *et al.* (3,4) demonstrated that the liver is where the preferential enrichment of newly synthesized VLDL with *RRR*-αTocH occurs. The organs with the highest capabilities for biodiscrimination of αTocH isomers (i.e., uptake of one isomer in excess of the others) are brain (10), adrenal glands (11), and also erythrocytes are capable of pronounced preferential uptake of *RRR*- over all-*rac*-αTocH (11,12). With regard to αTocH-isomer biodiscrimination in the liver, contradictory results were reported: Whereas some authors observed preferential enrichment with 2*R*-isomers (11,12), others demonstrated enrichment with 2*S*-isomers (13). Skeletal muscle—a major storage site of αTocH besides the liver and adipose tissue in the rat (14)—is not able to discriminate between different αTocH isomers (13).

In the fasting state, αTocH is distributed between the VLDL, low and high density lipoprotein (LDL and HDL, respectively) fractions in a 1:1.9:1.4 ratio (15) in humans, but in rats the vast majority of αTocH is transported in the HDL fraction. αTocH uptake by peripheral tissues may occur by different pathways: One of the first steps contributing to tissue supply with αTocH is lipoprotein lipase (LPL)-mediated hydrolysis of triglyceride-rich lipoproteins (16). Second, tissues may acquire LDL-associated αTocH partially *via* the LDL receptor pathway. However, the quantitative importance

Abbreviations: CE, cholesteryl ester; DMEM, Dulbecco's modified Eagle's medium; HDL, high density lipoproteins; HPLC, high-performance liquid chromatography; LDL, low density lipoproteins; LPDS, lipoprotein-deficient serum; LPL, lipoprotein lipase; PBS, phosphate-buffered saline; αToc-acetate, α-tocopheryl-acetate; αTocH, α-tocopherol; αToc-ME, α-tocopheryl-methyl ether; VLDL, very low density lipoproteins.

of this pathway is not entirely clear since Watanabe heritable hyperlipidemic rabbits (lacking functional LDL receptors) have normal tissue αTocH concentrations (17). Finally, αTocH transfer between lipoproteins and tissues might contribute to the maintenance of tissue αTocH levels (17,18).

During the present study we compared the uptake of lipoprotein-associated all-*rac*- and *RRR*-αTocH by rat skeletal muscle myoblasts (L6 cells) in the absence or presence of LPL. HDL, LDL, and VLDL were labeled with either all-*rac*- or *RRR*-[^{14}C]-αTocH, and uptake and biodiscrimination were determined by chiral high-performance liquid chromatography (HPLC) with radiometric detection.

EXPERIMENTAL PROCEDURES

Materials. Methanol, 2-propanol, hexane, and potassium bromide were obtained from Merck (Vienna, Austria). LC-18 reversed-phase HPLC columns were obtained from Supelco (250 × 4.6 mm i.d.; Vienna, Austria) or from Chrompack (200 × 2 mm i.d.; Vienna, Austria). The chiral phase (Chiralcel OD; 250 × 4.6 mm i.d.) used for the separation of 2*R*- and 2*S*-αTocH isomers as their methyl ether derivatives was obtained from P.H. Stehelin Co. (Basel, Switzerland). Ready Safe scintillation cocktail was obtained from Beckman (Vienna, Austria). Synthetic all-*rac*- (specific activity: 2.07 GBq/mmol, radiochemical purity 99.1%, by HPLC) and natural *RRR*-[^{14}C]αToc-acetate (specific activity: 2.07 GBq/mmol, radiochemical purity 99.8%, by HPLC) was prepared following the procedure described in Reference 19. Consumables used during cell culture studies were obtained from BioWhitaker or Costar (Vienna, Austria). Dulbecco's modified Eagle's medium (DMEM) was obtained from Boehringer Ingelheim (Vienna, Austria). PD-10 size exclusion columns were from Pharmacia (Uppsala, Sweden). All other materials were purchased from Merck (Darmstadt, Germany) as analytical grade reagents. L6 cells (permanent rat skeletal muscle myoblasts) were obtained from American Type Culture Collection (Rockville, MD).

Hydrolysis of all-rac- *and* RRR-*αToc-acetate*. Free αTocH was prepared from all-*rac*- and *RRR*-αToc-acetate essentially as described by Mayer and Isler (20). In a conical vial containing 10 mg $LiAlH_4$ in 100 µL dry diethyl ether and a stirrer, 400 µCi (14.8 MBq) all-*rac*-αToc-acetate or 200 µCi (7.4 MBq) *RRR*-αToc-acetate in ether (1000 µL) were added dropwise at room temperature and stirred for 45 min, followed by the addition of moist ether (2 mL) and H_2SO_4 (1 N, 500 µL). The mixture was vortexed and then centrifuged at 3000 rpm. The upper ether layer was removed, and the remaining aqueous layer was extracted three more times. The ether extracts were combined and dried under argon. αTocH yields were ≈ 95–100%. Analysis of the products was performed on an LC-18 column with radiometric detection as described below.

Lipoprotein preparation. Human VLDL, LDL, and apoE-free HDL_3 (termed HDL throughout this report) were prepared by density gradient ultracentrifugation of plasma, obtained from normolipemic donors, in a TL120 tabletop ultracentrifuge (at $r_{av.}$ 350,000 × g) as described in Reference 21 or by vertical single-spin ultracentrifugation (22). Lipoproteins were recovered from the tubes, and excess KBr was removed by size exclusion chromatography on PD-10 columns. Lipoprotein-deficient serum (LPDS) was prepared by standard techniques (23).

Lipoprotein labeling. Lipoproteins were labeled with [^{14}C]αTocH as follows: 1.5 mg HDL-, 0.8 mg LDL-, and 0.08 mg VLDL-protein were labeled with 7.5, 4, and 0.8 µCi *RRR*-αTocH or with 10.2, 5.4, and 1.1 µCi all-*rac*-αTocH by direct syringe-injection of the corresponding tracer dissolved in ethanol (<5.5% of the final volume), followed by dilution with phosphate-buffered saline (PBS) (final volume 2 mL) and incubation at 37°C for 3 h. Free activity was removed on PD-10 size exclusion columns. This labeling procedure resulted in the following specific activities: 13 (all-*rac*-αTocH-HDL), 13 (all-*rac*-αTocH-LDL), 61 (all-*rac*-αTocH-VLDL), 9 (*RRR*-αTocH-HDL), 9 (*RRR*-αTocH-LDL), and 40 (*RRR*-αTocH-VLDL) cpm/ng protein. The intended differences in the specific activities of lipoprotein preparations labeled with either all-*rac*- or *RRR*-αTocH were 1.36 (USP ratio) according to the differences in biopotencies of the corresponding isomer (mixtures).

Isolation of bovine LPL. Bovine LPL was isolated as described (24). Fresh, unpasteurized bovine milk (1 L) was centrifuged (9000 rpm, 4°C, 30 min) to separate cream. The floating cake was discarded, and NaCl was added to a final concentration of 350 mM to the remaining skim milk. After filtration the enzyme was purified by affinity chromatography on heparin- and phenyl-sepharose. The indicated concentrations were added together with the labeled lipoprotein preparations and incubated for the indicated times in DMEM containing 10% (vol/vol) LPDS. LPL activity was measured with a synthetic triglyceride emulsion as described earlier (25).

Analysis of αTocH and αToc-acetate. Reversed-phase HPLC of radio labeled αTocH and αToc-acetate was performed on a Chrompack LC-18 column (200 × 2 mm) with methanol/water (98:2; vol/vol) as the mobile phase (200 µL/min), essentially as described in Reference 26. Radiolabeled compounds were detected with a Radiomatic Flo-One radiometric HPLC detector (Packard-Canberra, Vienna, Austria; channel set at 0–156 keV) which was preceded by an ultraviolet (UV) detector to allow simultaneous detection of labeled and unlabeled compounds. Liquid scintillation fluid flow rate was set to 1 mL/min. The concentration of endogenous αTocH in the lipoprotein preparations used was assessed as described in Reference 27.

Cell culture studies. Rat L6 skeletal muscle myoblasts were seeded in 35-mm multiwell culture plates and cultured under standard conditions (37°C, 5% CO_2, 95% humidity) in DMEM containing fetal calf serum (10% vol/vol), streptomycin (40 mg/mL), and penicillin (40 units/mL). When the cells were 70–80% confluent the monolayers were washed twice with PBS (pH 7.4) and conditioned in fresh DMEM containing LPDS (10%, vol/vol) for 24 h to deplete the intra-

cellular αTocH stores. The cells were then washed again (DMEM, 2×), and the uptake assays were initiated in DMEM containing LPDS and the correspondingly labeled lipoprotein preparation. Lipoproteins were added at concentrations of 50 (HDL), 25 (LDL), and 2.5 (VLDL) μg protein/mL medium, reflecting an approximation of the lipoprotein mass ratios present in plasma of normolipemic donors. Where indicated, the medium was supplemented with bovine LPL (50 μg/mL).

After 2, 6, and 24 h the tissue culture plates were placed on ice, the medium was removed, and the cells were washed twice with ice-cold PBS containing bovine serum albumin (2 mg/mL) followed by another two washes with ice-cold PBS and extracted with hexane/2-propanol (3:2, vol/vol; 1 mL, room temperature, 20 min). The organic extracts were used to analyze uptake and isomer distribution of the αTocH labels. The cellular residue was lysed in NaOH (1 mL, 0.3 N) and the cellular protein content measured according to the method of Lowry *et al.* (28).

Preparation of αToc-methylether derivatives for chiral HPLC. The cellular lipid extracts were dried under argon and converted to the corresponding methyl ether derivatives as described in Reference 20. Briefly, to the dry extracts (kept under argon) 50 μL monoglyme, 25 μL KOH (25%, wt/vol; dropwise addition; vortex after each addition) and 30 μL dimethylsulfate (dropwise addition, vortex after each addition) were added. The incubation mixture was then kept at 50°C for 30 min. The ether phase was removed with nitrogen and to the remaining mixture 100 μL water and 500 μL hexane were added and vortexed for 1 min. To achieve phase separation, the samples were centrifuged at 3000 rpm (4°C, 10 min). The hexane phase was removed, the samples were extracted a second time, and the combined hexane layers containing the αToc-methyl ether (αToc-ME) derivatives were dried under argon and resuspended in 150 μL hexane and analyzed by chiral phase HPLC with radiometric detection as described below.

Chiral phase HPLC of αToc-ME derivatives. αToc-ME derivatives were separated on a 250 × 4.6 mm Chiralcel OD column. This chiral phase separates all-*rac*-αToc-ME derivatives into five peaks, the first peak containing the four 2*S*-isomers and separating the four 2*R*-isomers [*RSS, RRS, RRR,* and *RSR* (29)]. The peak assignment of αToc-ME isomers was based on Reference 29. Forty microliters of the cellular lipid extracts in hexane was injected into the chromatographic system, which consisted of a Waters 510 pump, a Waters 717 plus autosampler, a Packard/Canberra radiometric FlowOne beta detector that was preceded by a Waters 490E programmable multiwavelength ultraviolet-visible detector set at 283 nm to allow simultaneous detection of labeled and unlabeled αToc-ME isomers. The mobile phase was hexane at 1 mL/min, and the scintillation fluid flow was set at 2 mL/min. Total analysis time for isomer separation was 80 min.

RESULTS

Analytical procedures. Prior to lipoprotein labeling, the αToc-acetate labels were converted to the corresponding αTocH tracers as described in the Experimental Procedures section. The αToc-acetate tracers (eluting at 5.6 min under the chromatographic conditions described in the Experimental Procedures section) were converted quantitatively to free αTocH (eluting at 4.8 min) under the conditions described in the Experimental Procedures section (data not shown).

The chiral separation of all-*rac*-αToc-ME derivatives is shown in Figure 1 (A: ultraviolet detection of unlabeled derivatives; B: radiometric detection of [^{14}C]-labeled derivatives). Derivatization and chiral phase HPLC was performed as described in the Experimental Procedures section. The separation of the αToc-ME derivatives results in the occurrence of five peaks, with the first one containing the four 2*S*-isomers (eluting at 25 min) and the remaining four peaks resembling the four 2*R*-isomers which were baseline-separated (29). Peak 1 contained 51.6% (2*S* isoforms) of the total peak

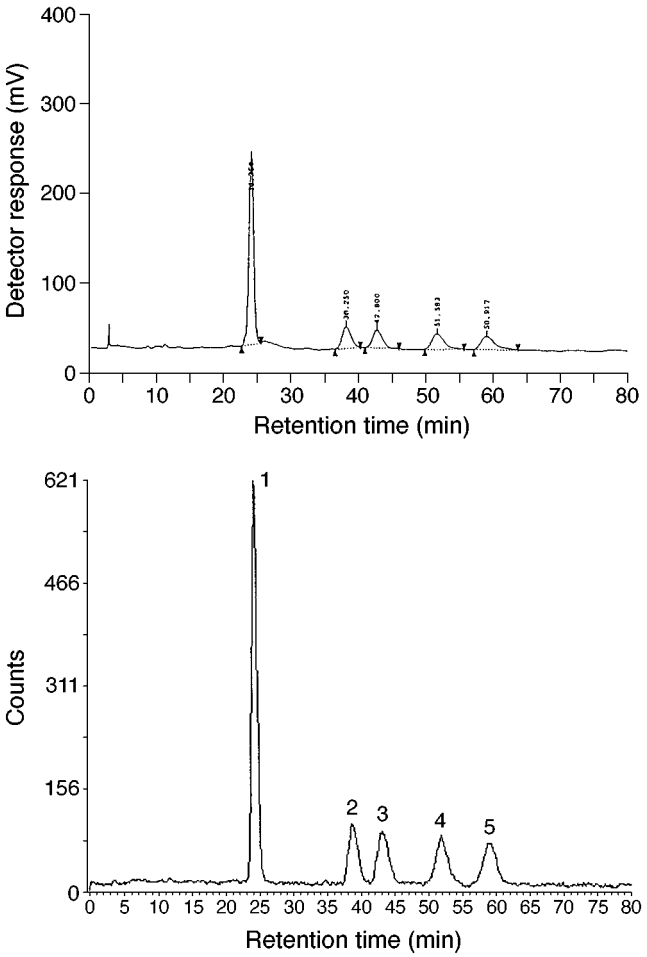

FIG. 1. Chiral high-performance liquid chromatographic separation of α-tocopheryl methyl ester (αToc-ME) derivatives. (A) Unlabeled αToc-ME derivatives (50 ng) and (B) approximately 100,000 cpm of all-*rac*-[^{14}C]αToc-ME derivatives were separated on a Chiracel OD column by the methods described in the Experimental Procedures section. Peak 1 eluted at 25 min and contained the four 2*S*-isomers. The four 2*R*-isomers were separated as follows: peak 2, *RSS,* 38 min; peak 3, *RRS,* 43 min; peak 4, *RRR,* 52 min; and peak 5, *RSR,* 61 min; peak assignment as in Reference 29.

area (or radioactivity) and the remaining four peaks (*RSS*-, *RRS*-, *RRR*- and *RSR*-αToc-ME) contained 12.2, 10.7, 12.6, and 12.8% of the activity as expected for the four 2*R*-αToc-ME isomers. The absolute limit of detection with radiometric detection was approximately 300 cpm/peak corresponding to $\approx 4 \times 10^{-12}$ mol per isomer. Owing to the good miscibility of the mobile phase and the liquid scintillation fluid the ratio was kept as low as possible, i.e., at 1:2 (mobile phase/scintillator). These chromatographic conditions were used to analyze the uptake of all-*rac*- and *RRR*-[^{14}C]αTocH by L6 rat skeletal muscle myoblasts throughout the study described here.

Uptake of HDL-, LDL- and VLDL-associated all-rac- *and* RRR-*[^{14}C]-αTocH by L6 cells in the absence or presence of LPL.* Lipoproteins were labeled with all-*rac*- or *RRR*-[^{14}C]-αTocH as described in the Experimental Procedures section. We intended to label the different lipoprotein classes with all-*rac*- and *RRR*-αTocH in a ratio of 1.36 (to account for the USP ratio of 1:1.36) and achieved differences in the specific activities of 1.4 (HDL and LDL) and a slightly higher value of 1.5 in case of VLDL. This experimental approach (instead of similar specific activities and addition of higher concentrations of the all-*rac*-labeled lipoproteins) was chosen to have equipotent [^{14}C]αTocH concentrations and similar protein and lipid concentrations on the cells. Prior to the uptake experiments, the L6 cells were preincubated in DMEM supplemented with LPDS to deplete the intracellular αTocH pool. The endogenous αTocH content of the lipoprotein preparations used was 1.9 ± 0.2, 3.7 ± 0.1, and 2.5 ± 0.08 nMol/mg total lipoprotein mass for HDL, LDL, and VLDL (mean ± SD, three different preparations), respectively, similar to previously published results (30–32).

The time-dependent uptake of all-*rac*- and *RRR*-[^{14}C]-αTocH labeled HDL, LDL, and VLDL, respectively, in the absence or presence of LPL is shown in Figure 2. From these data it is evident that αTocH concentrations in L6 cells increased in a time-dependent manner and, in the absence of LPL, this increase was more or less linear when HDL and LDL were used as αTocH donors. In case of VLDL, αTocH uptake tended to level off at the 24 h point. The resulting αTocH concentrations in L6 rat skeletal muscle myoblasts were not significantly different when the cells were either incubated in the presence of all-*rac*- or *RRR*-[^{14}C]-αTocH labeled lipoproteins, i.e., equipotent doses of all-*rac*- or *RRR*-αTocH led to a comparable increase of the cellular αTocH content (Fig. 2).

There was, however, a significant difference in the αTocH donor capacity of the different lipoprotein classes used during these experiments. The lipoprotein concentrations chosen during the present study reflect the approximate concentration ratio of VLDL, LDL, and HDL occurring in plasma of normolipemic donors. Although we have not analyzed the mass transfer of unlabeled, endogenous αTocH, the apparent donor capacity for [^{14}C]αTocH appears to be highest for HDL (1.5% of *RRR*- and 1.4% h^{-1} of all-*rac*-[^{14}C]-αTocH), followed by LDL (0.9% of *RRR*- and 0.8% h^{-1} of all-*rac*-[^{14}C]-αTocH) and VLDL (0.4% of *RRR*- and 0.4% h^{-1} of all-*rac*-[^{14}C]-αTocH). The addition of LPL to the cell incubations in the presence of HDL, LDL, or VLDL led to a significant increase of αTocH uptake by L6 myoblasts as compared with experiments performed in the absence of LPL, independent of which lipoprotein class was used as αTocH vehicle (Fig. 2). At the 24 h point, all-*rac*-αTocH uptake in the presence of

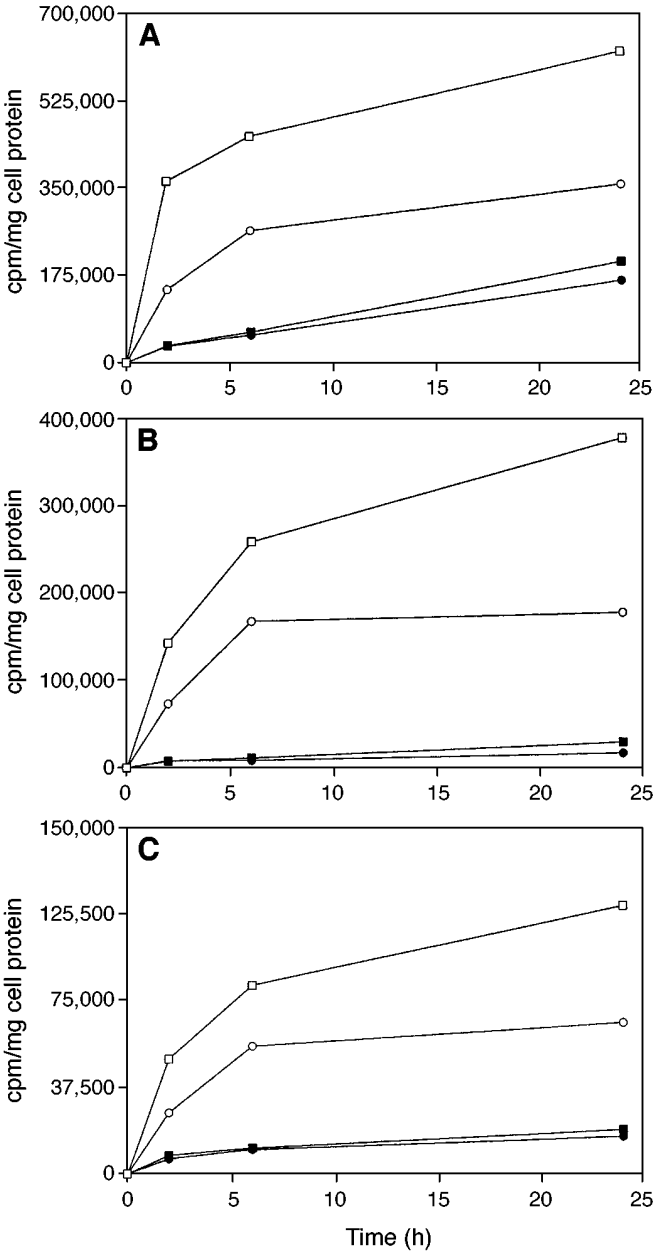

FIG. 2. Time-dependent accumulation of all-*rac*-[^{14}C]α-tocopherol (αTocH) and *RRR*-[^{14}C]αTocH incorporated into high density lipoprotein (HDL), low density lipoprotein (LDL), and very low density lipoprotein (VLDL) in the presence or absence of lipoprotein lipase (LPL). According to the procedures described in the paragraph headed "Cell culture studies," lipoproteins labeled with [^{14}C]all-*rac*- (○,●) or [^{14}C]*RRR*-αTocH (□,■) were added at concentrations of (A) 50 HDL, (B) 25 LDL, and (C) 2.5 VLDL μg protein/mL medium in the absence (●,■) or presence (○,□) of bovine LPL (50 μg/mL) which was added together with the labeled lipoprotein preparations.

TABLE 1
α-Tocopherol (αTocH) Activity Ratios (all-*rac*-:*RRR*-) in L6 Cells After Coincubation with Labeled VLDL, LDL, or HDL in the Absence or Presence of LPL[a]

	Mean αTocH ratios (all-*rac*-:*RRR*-)					
	–LPL			+LPL		
Vehicle	2 h	6 h	24 h	2 h	6 h	24 h
HDL	1.03	1.1	1.23	2.47	1.72	1.74
LDL	0.97	1.32	1.62	1.94	1.54	2.1
VLDL	1.25	1.05	1.17	1.87	1.47	1.75

[a]VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein; LPL, lipoprotein lipase.

LPL (50 µg/mL medium) increased by 3.1-, 11.9-, and 5.7-fold (HDL, LDL, and VLDL, respectively; Fig. 2) whereas *RRR*-αTocH uptake was increased by 2.2-, 9.2-, and 3.8-fold (HDL, LDL, and VLDL; Fig. 2).

Coincubation of L6 cells with all-*rac*- or *RRR*-[^{14}C]-αTocH verified the expectation that equipotent doses of the tracers incorporated into HDL, LDL, or VLDL will lead to comparable (intra)cellular accumulation of the tracers. This assumption is further substantiated by data shown in Table 1 where the cellular all-*rac*-:*RRR*-αTocH ratios are shown. In the absence of LPL the all-*rac*-:RRR-αTocH ratios were between 0.97 and 1.25 except for LDL at the 24 h point, where the ratio was 1.6 (Table 2). However, the situation was different when the cells were incubated with the respective lipoprotein preparations labeled with either all-*rac*- or *RRR*-[^{14}C]αTocH in the presence of LPL. During these experiments the all-*rac*-:*RRR*-αTocH ratios were much higher, i.e., between 1.5 and 2.5. Obviously the addition of LPL resulted in the preferential accumulation of all-*rac*-[^{14}C]-αTocH in L6 cells.

αTocH stereoisomer distribution in L6 cells. In general the αTocH isomer distribution in L6 cells after coincubation with all-*rac*-[^{14}C]αTocH-labeled HDL, LDL, or VLDL in the absence or presence of LPL led to almost similar patterns (Table 2). In line with the results shown in Table 1, we have not observed preferential enrichment of the myoblasts with one of the 2*R*-isoforms; rather, the 2*S*- and 2*R*-isoforms accumulated in a 1:1 ratio (Σ 2*S* = 46.2–52.7% and Σ 2*R* = 47.3–53.8%). This was observed for all the donor–lipoprotein preparations and all time points analyzed during the present study (with the exception of LDL at the 24 h point; 2*S*:2*R* = 0.72). Also within the 2*R*-isomer group we have not observed preferential uptake of one of the isomers. From these data it appears reasonable to conclude that (under the conditions described here) no biodiscrimination of αTocH isomer uptake occurs in L6 cells.

DISCUSSION

We investigated the relative bioavailability of *RRR*-αTocH and all-*rac*-αTocH and the changes in the concentration of the 2*S*- and 2*R*-isomers in permanent rat skeletal muscle myoblasts (L6 cells). To deliver αTocH to these cells we used HDL, LDL, and VLDL in the presence and absence of LPL as donor vehicles. In contrast to the liver and heart (33,34) other organs/tissues (including skeletal muscle) are devoid of αTocH transfer/bind-

[a]Experimental conditions as described in Table 1. For abbreviations see Table 1.

ing protein. Despite the absence of αTocH transfer/binding protein, *in vivo* studies have demonstrated that skeletal muscle acquires *RRR*-αTocH in excess of all-*rac*-αTocH during longer supplementation times (35) as a result of plasma enrichment with the *RRR*-isomer (13,35). In addition this apparent "biodiscrimination" was attributed to different αTocH uptake pathways, i.e., the contribution of chylomicrons (delivering all forms of αTocH) and the other lipoprotein classes (preferentially enriched in *RRR*-αTocH) (35). Our short-term studies with permanent rat myoblasts showed that the L6 cells do not discriminate between different stereoisomers of αTocH, independent of the donor lipoprotein used. We have not observed substantial enrichment of the myoblasts with one of the 2*R*′-isoforms, rather the 2*S*- and 2*R*-isoforms accumulated in a 1:1 ratio independent of the lipoprotein fraction used as αTocH donor (Table 2). From these data it is evident that the myoblasts show no enhancement of the 2*R*-/2*S*-isomer ratio relative to the isomer distribution present in the corresponding donor lipoprotein fractions. These findings are compatible with an *in vivo* study in rats (13), where it was demonstrated that three different types of skeletal muscle did not show an enhanced *RRR*/*SRR* ratio relative to plasma.

During the present study we have obtained evidence (on the basis of transfer rates) that HDL is a more efficient αTocH donor than LDL or VLDL. This is especially noteworthy as the experiments were performed under LPDS conditions where the expression of LDL receptors is upregulated (23). One interpretation is that under "normal" conditions the contribution of HDL to tissue supply with αTocH could be even more pronounced. The higher donor capacity of HDL is in line with findings obtained with permanent hepatocytes where we (31) demonstrated that the transfer of αTocH from HDL was approximately twofold higher than from LDL. The transfer of HDL- and LDL-associated αTocH occurred independent from lipoprotein particle uptake and was regulated by the intracellular cholesterol content (31), compatible with the concept of "selective" uptake as described for HDL cholesteryl esters (CE) (36). This assumption is further substantiated by the finding that the liver and the adrenals—the sites with the highest capacity for selective HDL-lipid uptake (14)—contain the highest αTocH concentrations. In addition, it was shown that interlipoprotein transfer of αTocH occurs with the highest efficacy from labeled HDL particles (18,37). These good αTocH donor properties of HDL might (at least in part) be a result of the high curvature of the particle, an important physical property affecting the efficacy of lipoprotein-independent lipid transfer (38). A different distribution of αTocH between the polar surface and the hydrophobic core in different lipoprotein classes could offer another explanation for this observation (39). Therefore, it appears reasonable to assume that *in vivo* the HDL fraction is an important (and somewhat underestimated) αTocH donor, contributing to the maintenance of αTocH levels in organs and tissues.

Significantly increased αTocH uptake by L6 cells in the presence of LPL was an interesting finding from the present study. *In vivo* studies (40) have demonstrated that the uptake of αTocH in skeletal muscle depends on the level of LPL expression. The enhancement of αTocH uptake in the presence of LPL is most probably due to higher lipolysis rates (41) and, in addition, to the proposed bridging function of the enzyme (40). This bridging function was attributed to the presence of a heparin- and a lipid-binding site in the LPL molecule (42) resulting in increased lipoprotein binding to the surface of a variety of cells (43–45). As a result LPL increases binding (bridging), internalization, and degradation of lipoproteins (46,47) by mechanisms involving the LDL receptor-related protein and the VLDL receptor (48–50). In one of our earlier studies we demonstrated that the addition of exogenous bovine LPL significantly increased selective HDL-CE uptake by mouse peritoneal macrophages (51). The effects of LPL on selective HDL-CE uptake could be attributed to enhanced HDL-particle internalization and a second pool of HDL particles delivering CE without concomitant particle internalization (51). Whether LPL-generated lipolysis products enhance cell permeability [as demonstrated for endothelial layer permeability (52)] remains to be elucidated. Along this line it is noteworthy that αTocH-uptake by skeletal (thigh) muscle of LPL-overexpressing mice was dependent on the level of LPL (over)expression and was highly correlated with the amount of free fatty acids in the tissue (40). A combination of three effects mediated by LPL—enhanced lipoprotein binding, enhanced selective uptake, and enhanced permeability caused by lipolysis products—could ultimately result in increased αTocH uptake as observed in the present study. From the chiral HPLC data shown in Table 2 it is evident that the addition of LPL did not affect the isomer distribution in L6 cells incubated in the presence of all-*rac*-αTocH.

The present study showed that permanent L6 rat myoblasts do not acquire 2*R*-isomers in excess of 2*S*-αTocH isomers, in line with findings obtained *in vivo* (13). From these results one might anticipate that for the treatment of, e.g., muscle myopathies equipotent doses of natural *RRR*- and synthetic all-*rac*-αTocH would be equally effective. In addition we would emphasize L6 cells as a valuable *in vitro* model reflecting comparable αTocH uptake mechanisms as observed for rat and mouse skeletal muscle *in vivo*. We expect verification of our *in vitro* findings during *in vivo* experiments with transgenic mice overexpressing LPL in skeletal and cardiac muscle (40).

Metal-Ion Stimulation and Inhibition of Lysophospholipase D Which Generates Bioactive Lysophosphatidic Acid in Rat Plasma

Akira Tokumura*, Maki Miyake, Osamu Yoshimoto, Mayumi Shimizu, and Kenji Fukuzawa

Faculty of Pharmaceutical Sciences, The University of Tokushima, Tokushima 770-8505, Japan

ABSTRACT: We found that lysophospholipase D (LPLD) in rat plasma prefers unsaturated to saturated lysophosphatidylcholines as substrates, generating a biologically active lipid, lysophosphatidic acid, but it does not hydrolyze diacyl-phospholipids. In this study, this LPLD required a metal ion for activity, Co^{2+} being the most effective, followed in order by Zn^{2+}, Mn^{2+}, and Ni^{2+}. This metal-ion-stimulated LPLD with unique substrate specificity, which has not been described previously, was susceptible to thiol-blocking reagents and serine esterase inhibitors, but not to a histidine-modifying reagent. Consistent with results using thiol-modifying agents, short-chain fatty aldehydes, secondary products of lipid peroxidation, were found to inhibit LPLD. Addition of dibutylhydroxytoluene or butylhydroxyanisole to the plasma increased the activity of this enzyme, probably in a manner independent of its antioxidant activity, since another antioxidant, propyl gallate, was rather inhibitory. These results suggest that rat plasma contains an active LPLD that differs in some properties from other members of the known phospholipase D family detected in animal tissues and body fluids.

Lipids 33, 1009–1015 (1998).

Lysophosphatidic acid (LPA) has the simplest structure of all phospholipids, but has a variety of biological activities (1–3), among which its effect in inducing proliferation received much attention (4). Recent reports on cloning of genes for LPA receptors from various sources (5–7) support the idea that LPA functions as a first messenger through its specific seven transmembrane-spanning proteins (8). LPA was originally identified as a vasoactive principle with platelet-aggregating activity in the incubated serum of rats (9). Later, several groups identified LPA as an active component in serum or ascites, using *in vitro* assay systems with fibroblast cells (10), neuronal cells (11), glioma cells (12), tumor cells (13,14), and oocytes (11). LPA was found to be present at micromolar concentrations in serum, by its chemical measurement after thin-layer chromatography (TLC) separation of lipid extracts of serum (15,16). Two mechanisms participated in the accumulation of LPA in serum or plasma: (i) its release from activated human platelets (15), possibly *via* the action of phospholipase A_2 on phosphatidic acid in membranes of platelets (17) and (ii) lysophospholipase D (LPLD), which hydrolyzes unsaturated lysophosphatidylcholines (LPC) preferentially over saturated LPC in rat plasma (18). We report here some properties of this LPLD. Our results suggest that plasma LPLD is a novel type of LPLD requiring a metal ion for optimal activity.

EXPERIMENTAL PROCEDURES

Materials. 1-[1-^{14}C]Palmitoyl-2-lyso-*sn*-glycero-3-phosphocholine (16:0-LPC, 1.48–2.22 GBq/mmol) was purchased from DuPont-New England Nuclear (Boston, MA). l-Oleoyl-2-lyso-*sn*-glycerol-3-phosphate (18:1-LPA), acetaldehyde, 1,1,3,3-tetramethoxypropane, and *p*-bromophenacyl bromide were purchased from Sigma Chemical Co. (St. Louis, MO). Acrolein was a product of Tokyo Kasei Kogyo Co. (Tokyo, Japan). Propyl gallate and 3-*tert*-butyl-4-hydroxyanisole were from Kanto Chemical Co. (Tokyo, Japan). 2,6-Di-*tert*-butyl-4-hydroxy-methylphenol (BHT), *N*-ethylmaleimide (NEM), *o*-phenanthroline, diisopropyl fluorophosphate (DFP), EGTA, and EDTA were from Wako Pure Chemical Industries (Osaka, Japan). Phenylmethylsulfonyl fluoride (PMSF) and dithio-bis-(2-nitrobenzoic acid) (DTNB) were obtained from Nacalai Tesque (Kyoto, Japan). Other chemicals were reagent grade, and solvents were double-distilled.

Rat plasma. Blood was withdrawn through an abdominal artery from fasting (8–10 h) male Wistar rats (8–11 wk old; Japan SLC, Shizuoka, Japan) anesthetized with sodium pentobarbital (40 mg/kg, i. p.), and immediately mixed with 0.01 vol of heparin solution (final concentration, 2 I.U./mL) in sterilized plastic centrifugation tubes, unless otherwise de-

Abbreviations: BHT, 2,6-di-*tert*-butyl-4-hydroxy-methylphenol; DFP, diisopropyl fluorophosphate; DTNB, dithio-bis-(2-nitrobenzoic acid); LAT, lysolecithin acyltransferase; LCAT, lecithin:cholesterol acyltransferase; LPA, lysophosphatidic acid; LPC, lysophosphatidylcholine; LPLD, lysophospholipase D; NEM, *N*-ethylmaleimide; PC, phosphatidylcholine; PMSF, phenylmethylsulfonyl fluoride; TLC, thin-layer chromatography.

scribed. In some experiments, rat blood was anticoagulated with 0.15 vol of acid–citrate–dextrose solution, EDTA solution (6.7 mg/mL), or EGTA (6.7 mg/mL) solution. Serum was prepared by allowing rat blood to stand in the absence of anticoagulant at 37°C for 1 h and then overnight at 4°C.

Measurement of LPLD activity. The standard procedure for measurement of LPLD activity was as follows: First, rat plasma or serum was mixed with 0.05 vol of a solution of [^{14}C]16:0-LPC in saline containing 0.25% bovine serum albumin. The final concentration of radioactive LPC was 3.5 nmol/mL (0.0074 MBq/mL). Immediately after the addition of [^{14}C]16:0-LPC, a 0.2-mL aliquot of plasma or serum was withdrawn as the 0 h sample. The remaining plasma or serum was incubated at 37°C for 6 h, and 0.2-mL samples were withdrawn after 2, 4, and 6 h and diluted with 2% KCl solution to 2 mL. Lipids were extracted from these diluted samples by the method of Bligh and Dyer (19) after adjusting the samples to pH 2.5 with 1 N HCl, except in experiments on the metal-ion requirement of LPLD, in which lipids were only extracted after 6-h incubation. The lipid extracts were fractionated together with 18:1-LPA (0.1 μmol) as a carrier on a Merck Silica gel 60 TLC plate (Darmstadt, Germany) in a solvent system of chloroform/methanol/20% ammonium hydroxide (60:35:8, by vol). Lipid bands were visualized under an ultraviolet lamp after spraying with a 1-mM solution of *p*-toluidino-2-naphthalenesulfonic acid in 50 mM of Tris-HCl (pH 7.4). Bands of individual phospholipids were scraped off the gel, mixed with 5 mL of Sintisol EX-H (Wako), and counted in a liquid scintillation counter. LPLD and lysolecithin acyltransferase (LAT) activities were calculated from the radioactivities of the bands of the LPA and phosphatidylcholine (PC), respectively, against the sum of the radioactivities of the PC, LPC and LPA bands, and expressed as percentage conversion/h.

In experiments with various agents that modified amino-acid residues of proteins, plasma from heparinized rat blood was preincubated with test reagents at 37°C for 15 min, and then incubated with [^{14}C]16:0-LPC (0.0074 MBq), as described. All test reagents were dissolved in ethanol. The final concentration of ethanol in rat plasma was 1%. In control experiments, the plasma was preincubated with ethanol alone at a final concentration of 1%, followed by the addition of [^{14}C]16:0-LPC.

For experiments with chelators, the plasma obtained from heparinized blood was mixed with 0.05 vol of EDTA solution at final concentrations of 1, 2.5, 5, 10, 20, and 50 mM or *o*-phenanthroline at final concentrations of 0.25, 0.5, and 1 mM or distilled water as a control. The mixtures were then incubated with 0.05 vol of a solution of [^{14}C]LPC for 6 h.

For studies on the metal-ion requirement for LPLD activity, the plasma from heparinized blood was first treated with 0.04 vol of a solution of EDTA, and the pH of the mixture was adjusted to pH 7.4. The plasma was then mixed with 0.01 vol of a solution of $CaCl_2$, $MgCl_2$, $BaCl_2$, $CoCl_2$, $NiCl_2$, $FeCl_3$, $CdCl_2$, $HgCl_2$, $ZnSO_4$, $CuSO_4$, or $MnCl_2$ at final concentrations of 5 or 10 mM or distilled water as a control (EDTA–plasma). The final concentration of EDTA was 5 mM in these experiments. As another control (heparin–plasma), the plasma was mixed with 0.05 vol of distilled water. These samples were then incubated with 0.05 vol of a solution of [^{14}C]LPC for 6 h. In several experiments, the heparinized plasma was mixed with 0.01 vol of a solution of a metal ion such as $CoCl_2$ or $CuSO_4$ without preaddition of EDTA or *o*-phenanthroline. In such cases, control plasma was mixed with 0.01 vol of distilled water.

In experiments with short-chain fatty aldehydes, the plasma (0.9 mL) was first treated with 0.05 mL of [^{14}C]LPC solution and then promptly treated with 0.05 mL of a solution of freshly prepared acetaldehyde or acrolein in saline or saline alone (as a control). Malondialdehyde was generated from 1,1,3,3-tetramethoxypropane as described previously (20). The plasma was mixed with 0.05 mL of [^{14}C]LPC solution and 0.05 mL of a solution of malondialdehyde in 0.1 M sodium phosphate buffer, pH 6.4, or vehicle alone.

The antioxidants used in this study were poorly water-soluble, so desired amounts of these chemicals were dried in tubes, to which the plasma was added directly. The mixtures were then shaken vigorously and incubated with [^{14}C]LPC with or without preaddition of Cu^{2+} or Fe^{3+}.

Statistics. Experimental values are means ± SEM, and differences between the means were compared by unpaired Student's *t*-test. A P value of <0.05 was considered statistically significant.

RESULTS

Cation requirement for LPLD activity. For measurement of LPLD activity, rat plasma was incubated with [^{14}C]16:0-LPC for up to 6 h. As shown in Figure 1, the radioactive LPC was almost linearly decreased with time, concomitant with the in-

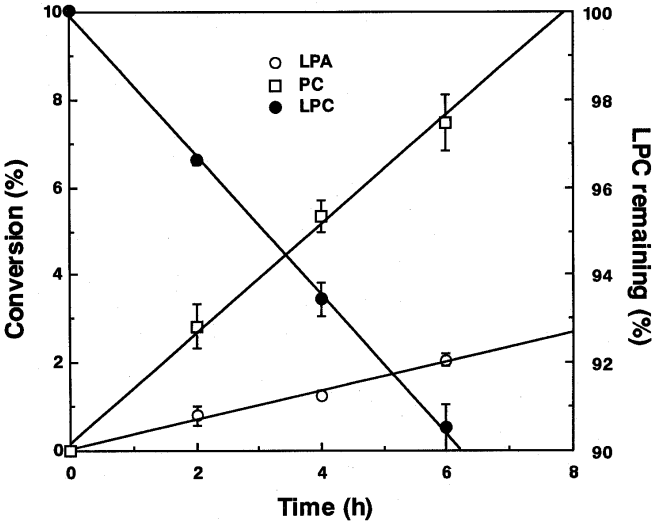

FIG. 1. Metabolic conversions of [^{14}C]lysophosphatidylcholine (LPC) to lysophosphatidic acid (LPA) and phosphatidylcholine (PC) during incubation of rat plasma at 37°C. Values are mean ± SEM of four independent experiments.

creased radioactivities in two bands of PC and carrier LPA during the incubation period. The radioactivity comigrating with carrier LPA is actually due to LPA degraded by the action of LPLD, since this radioactive lipid shows the same chromatographic behavior as that of standard LPA on a TLC plate developed with a mixture of chloroform/methanol/water (65:35:5), chloroform/methanol/28% ammonium hydroxide (65:35:5), or chloroform/methanol/20% ammonium hydroxide (60:35:8). The conversion of LPC to PC would be due to the LAT activity of lecithin:cholesterol acyltransferase (LCAT; E.C. 2.3.1.43), as first demonstrated with human plasma (21). The rates of both reactions occurring during incubation of rat plasma could be calculated from the slopes of the straight lines obtained.

Incubation of the plasma in conditions which prevent bacterial contamination (100 U/mL penicillin + 100 µg/mL streptomycin) does not modify the results described above. Furthermore, we confirmed that incubation of [^{14}C]LPC with heat-denatured plasma (60°C, 1 h) or without plasma at 37°C for 6 h did not lead to its conversion to LPA.

Using this convenient method, we first examined the effect of anticoagulant on the plasma LPLD activity. Because EDTA and EGTA, but not acid–citrate–dextrose, inhibited the LPLD activity (Fig. 2), metal ions may be required for optimal activity. The LPLD activity in the serum was almost the same as that of the heparinized plasma. Next, we examined effect of metal-cation chelators on the LPLD activity of the heparinized plasma. Figure 3A and B shows the concentration-dependent inhibitions of LPLD by additions of EDTA and *o*-phenanthroline, respectively. The transition metal chelator *o*-phenanthroline was more effective than the bivalent cation chelator EDTA. These results suggest that at least one transition metal cation is required for optimal activity of LPLD. Consistent with previous reports on LAT activity of human plasma (22),

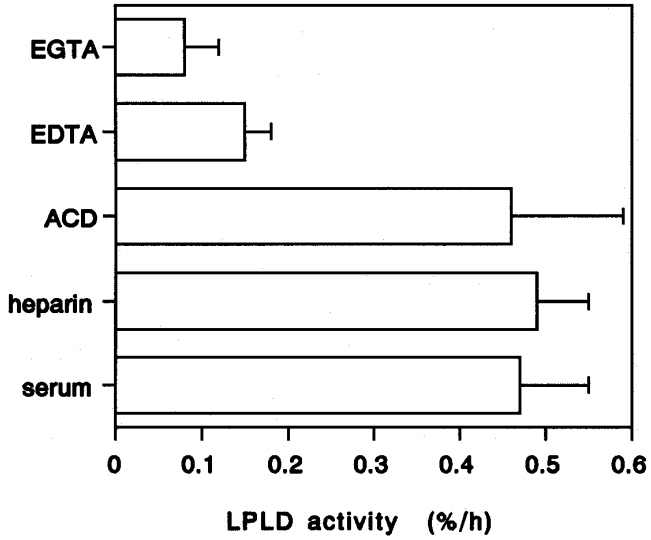

FIG. 2. Effect of anticoagulant on lysophospholipase D (LPLD) activity. Values are mean ± SEM of three independent experiments. ACD, acid–citrate–dextrose.

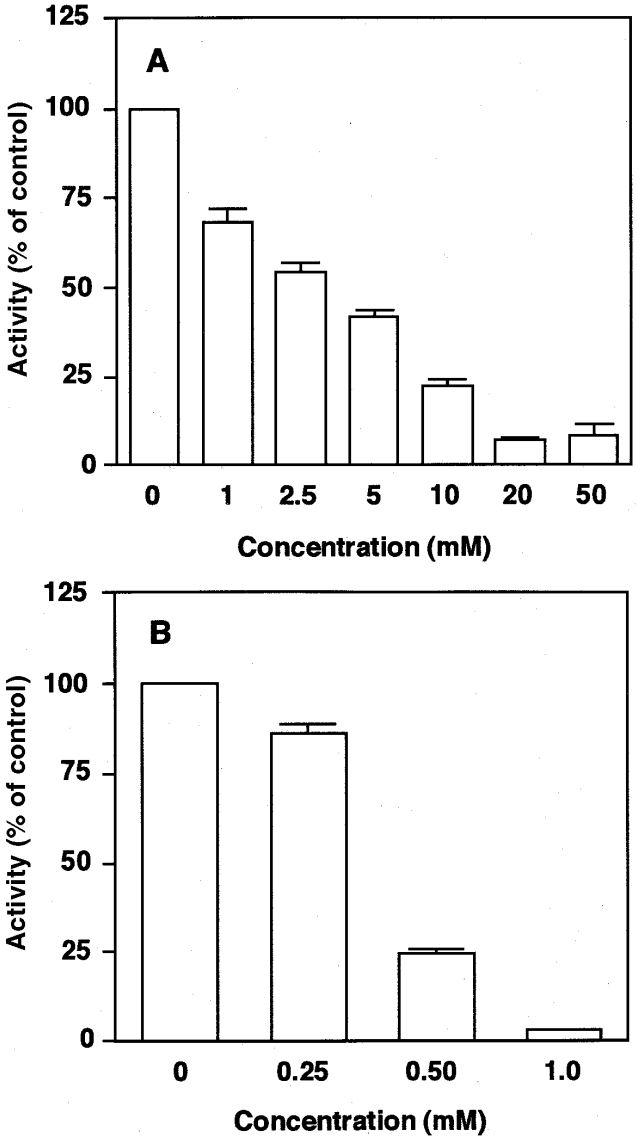

FIG. 3. Effects of EDTA (A) and *o*-phenanthroline (B) on LPLD activity. Values are expressed as percentages of the control (heparinized plasma mixed with 0.15 vol of saline), and shown as mean ± SEM of three independent experiments. See Figure 2 for abbreviation.

LAT activity in rat plasma was insensitive to EDTA (Table 1) and *o*-phenanthroline (data not shown).

To examine the metal-ion requirement of the LPLD in detail, we added various metal ions to plasma pretreated with 5 mM EDTA. Table 1 summarizes the results of these experiments and the effects of metal ions on LAT activity, which could be simultaneously measured with our assay system. LPLD activity was restored to approximately the normal level by addition of 5 mM Mn^{2+}, 5 mM Zn^{2+}, or 10 mM Co^{2+}. Ni^{2+} at 5 mM and Mg^{2+} at 10 mM were less effective, and Ca^{2+}, Ba^{2+}, Fe^{3+} and Cu^{2+} at 5 mM were all inactive. Consistent with a previous finding that LAT in human plasma does not require any metal ion (22), the LAT activity in rat plasma was not stimulated by any metal ion used (Table 1), except for a slight but significant increase in the activity on addition of 5

TABLE 1
Effect of Metal Ions on the Activities of Lysophospholipase D (LPLD) and Lysolecithin Acyltransferase (LAT) in Incubated Rat Plasma[a]

Metal	Concentration (mM)	*n*	Activity (% of control) LPLD	LAT
Heparin–plasma	—		100.0	100.0
EDTA–plasma	—	14	36.8 ± 2.7	102.5 ± 2.0

Zn^{2+}	5	3	90.7 ± 5.9**	74.7 ± 2.6**

[a]Values are mean ± SEM. *$P < 0.05$ vs. EDTA–plasma, **$P < 0.01$ vs. EDTA–plasma.

mM Ni^{2+}. Since the addition of 5 mM Co^{2+} to EDTA-treated plasma resulted in increase in LPLD activity to 1.5-fold that of heparinized plasma without preaddition of EDTA, we examined the concentration-dependent augmentation of the LPLD activity by Co^{2+}: a maximal value of about 2.5-fold higher than the control was attained at concentrations below 1 mM, as shown in Figure 4.

In order to confirm the metal-cation requirement of plasma LPLD, we performed two types of experiments. First, heparinized rat plasma was dialyzed against saline, pH 7.4, at 4°C for 2 d, resulting in reduction of LPLD activity to 17.2 ± 1.6% ($n = 5$) of controls before dialysis. Addition of 2 mM Zn^{2+} after dialysis increased the LPLD activity to 64.8 ± 14.2% ($n = 5$) of the original activity, but supplement of Ca^{2+} was not as effective (29.4 ± 5.6%, $n = 5$). The second experiment was undertaken to examine reversal of EGTA inhibition of LPLD activity by Zn^{2+} or Ca^{2+}. Addition of 2.5 mM Zn^{2+} to rat plasma anticoagulated with EGTA restored the LPLD activity (81.9 ± 9.9% of the activity of heparinized plasma, $n = 4$), but no reactivation was observed upon addition of 2.5 mM Ca^{2+} (0.2 ± 0.2% of the activity of heparinized plasma, $n = 4$).

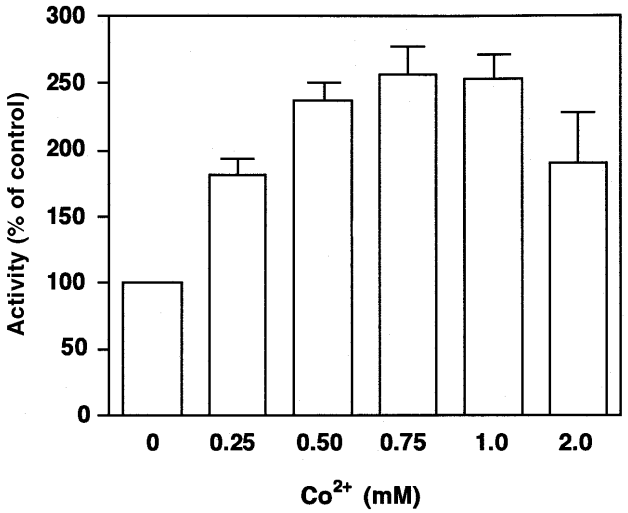

FIG. 4. Potentiation of LPLD activity by cobalt ion. Values are expressed as percentages of the control (heparinized plasma mixed with 0.1 vol of saline) and shown as mean ± SEM of three independent experiments. See Figure 2 for abbreviation.

Effects of short-chain fatty aldehydes and antioxidants on LPLD activity. Several heavy metal ions such as Cu^{2+} induce lipid peroxidation in plasma lipoproteins (23), and short-chain fatty aldehydes, secondary products of lipid peroxidation, inactivate human plasma LCAT (24,25). Therefore, we examined the effects of acetaldehyde, acrolein, and malondialdehyde on the LPLD and LAT activities in rat plasma. As shown in Table 2, both acetaldehyde and acrolein reduced the LPLD activity, whereas a slight increase in the LPLD activity was seen after treatment of the plasma with malondialdehyde. On the other hand, the LAT activity was inhibited by all three aldehydes, consistent with previous results on LCAT in human plasma (25). Acrolein had a stronger inhibitory effect than acetaldehyde on both LPLD and LAT activity.

To confirm that metal-ion-induced lipid peroxidation is involved in the observed inhibitions of LPLD activity by some metal ions, we tested the protective effects of several antioxidants on metal-ion-induced inhibition of LPLD activity. Typical results of this experiment are shown in Figure 5. As expected, incubation of rat plasma with 2 mM of Cu^{2+} resulted in considerable reduction in LPLD activity, and BHT seemed to restore this reduced LPLD activity. However, by increasing the concentration of BHT by 2 mM, the activity increased further, reaching nearly twice the normal level, indicating that the effect of BHT is not related to its activity in preventing lipid peroxidation in the plasma, but rather to its specific stimulatory action on the enzyme. To confirm this idea, we examined the effect of BHT on LPLD activity without preaddition

TABLE 2
Effects of Fatty Aldehydes on LPLD and LAT Activities in Incubated Rat Plasma[a]

Aldehyde	Concentration (mM)	Activity (% of control) LPLD	LAT
Acetaldehyde	5	87.8 ± 1.2**	72.5 ± 11.8
	10	72.5 ± 5.1*	63.9 ± 7.7*
Acrolein	5	72.9 ± 5.1*	48.5 ± 2.0**
	10	65.4 ± 5.7*	37.7 ± 2.8**
Malondialdehyde	5	112.1 ± 6.5	73.7 ± 7.8
	10	116.7 ± 5.2	62.3 ± 5.5*

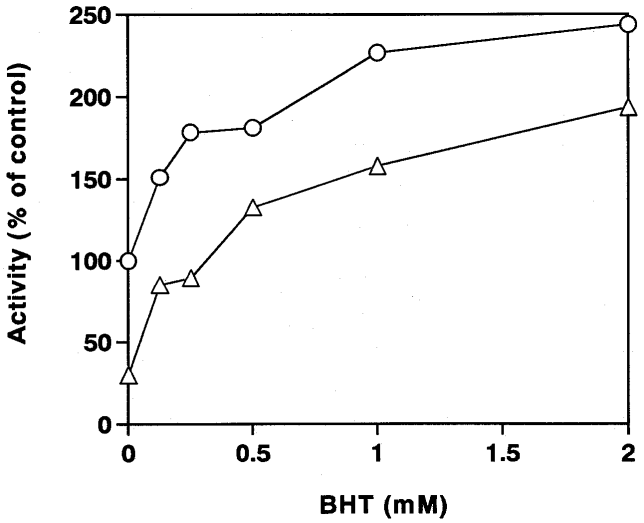

FIG. 5. Effect of butylated hydroxytoluene (BHT) on LPLD activity. Heparinized rat plasma was incubated with various concentrations of BHT in the presence (△) and absence (○) of 2 mM Cu^{2+} for 6 h.

of Cu^{2+}, and found that BHT increased the LPLD activity in a concentration-dependent manner to a similar extent to that observed in the presence of Cu^{2+} (Fig. 5). The above idea was further supported by the results shown in Figure 6, where the effects of three antioxidants at different concentrations on LPLD activity are compared: butylhydroxyanisole increased the LPLD activity to a lesser extent than BHT, and propyl gallate reduced the activity slightly.

Inhibition of LPLD activity by chemicals that modify amino acid residues of proteins. Table 3 shows the inhibitory effects of various compounds that react with specific amino acid residues of proteins on the LPLD activity in rat plasma and on LAT activity for comparison. LPLD was resistant to 1

Small error bars are masked by symbols for mean values. Butylated hydroxytoluene (○), butylhydroxyanisole (△), propyl gallate (□). See Figure 2 for abbreviation.

TABLE 3
Effects of Various Amino Acid-Modifying Agents on LPLD and LAT Activities[a]

Inhibitor	Concentration (mM)	Activity (% of control) LPLD	LAT
pBPB	1	103.4	2.7
PMSF	1	99.0	75.7
	3	83.3	63.7
DFP	1	97.5	53.2
	3	88.0	34.8
	10	40.6	1.5
NEM	3	90.7	64.0
	10	75.9	44.9
DTNB	1	73.6	53.3
	3	72.3	36.5
	10	52.4	5.5

[a]pBPB, *p*-bromophenacyl bromide; DFP, diisopropyl fluorophosphate; NEM, *N*-ethylmaleimide; DTNB, dithio-bis-(2-nitrobenzoic acid). See Table 1 for other abbreviations.

mM *p*-bromophenacyl bromide, unlike LAT in the plasma. Both PMSF and DFP, serine esterase inhibitors, reduced the LPLD activity less than the LAT activity. The results from the effect of serine esterase inhibitors on LAT activity are consistent with previous reports on their effects on rat LCAT (26) and human LAT (22,27). Similar results were obtained with DTNB, a thiol-modifying agent. NEM was less effective than DTNB in inhibiting the LPLD and LAT activities in rat plasma. In this case also, LPLD was more resistant to this thiol-modifying chemical than LAT. These results are consistent with previous results (28).

DISCUSSION

Our previous study (18) showed that 16:0-LPC was the most abundant molecular species in rat plasma (166 ± 9 nmol/mL). Approximately only 2% of the radioactivity of exogenous 16:0-LPC (3.5 nmol/mL) was recovered in LPA during 6-h incubation in the current study as a result of dilution of exogenous 16:0-LPC into large pools of endogenous 16:0-LPC in rat plasma. Based on this assumption, the total amount of 16:0-LPA generated from the endogenous 16:0-LPC during 6-h incubation is estimated to be about 3.7 nmol/mL. If the LPLD activity were not inactivated during further incubation for up to 48 h, 16:0-LPA would amount to 29.6 nmol/mL, which is higher than 17 nmol/mL quantified by gas–liquid chromatography (18). This difference can be explained by a finding that the rate of LPA accumulation was gradually decreased 12 h after incubation of rat plasma at 37°C (Tokumura, A., Miyake, M., Nishioka, Y., Yamano, S., Aono, T., and Fukuzawa, K., unpublished data). Thus, it is likely that our method with radioactive 16:0-LPC could reflect the metabolic conversion of endogenous 16:0-LPC to 16:0-LPA in rat plasma, prompting us to examine some properties of LPLD in rat plasma by this convenient method.

Our results clearly show that LPLD in rat plasma requires a metal ion for optimal activity. Several lipolytic enzymes had Zn^{2+} in their active site: i.e., sphingomyelinase in fetal bovine

serum (29), phospholipase C from *Bacillus cereus* (30), glycosylphosphatidylinositol-specific phospholipase D in plasma (31), and leukotriene A_4 hydrolase in mammalian tissues (32). Therefore, Zn^{2+} is likely to be an endogenous metal ion associated with LPLD. This metal ion may be included in the active center of LPLD, because the reduced activity in the presence of EDTA or EGTA was restored on its addition to the plasma. However, the additional role of stabilization of protein structure by metal ions cannot be completely excluded at this stage.

The LPLD has a relatively broad specific requirement for metal ions, but the strong stimulatory effect of Co^{2+} on LPLD activity in rat plasma is noteworthy. In this context, a broader spectrum of cation requirement (Zn^{2+}, Co^{2+}, Mn^{2+}, Ba^{2+}, Mg^{2+}, and Ca^{2+}) was recently reported for phospholipase D activity in mitochondria isolated from rat small intestine (33), and equipotent stimulations by Co^{2+} and Zn^{2+} were reported for purified leukotriene A_4 hydrolase (32) . Like LPLD in rat plasma, the activity of plasma glycosylphosphatidylinositol-specific phospholipase D reduced by EGTA and *o*-phenanthroline can be restored by several metal ions such as Co^{2+}, Ni^{2+} and Mn^{2+}, although these were less effective than Zn^{2+} (31).

The present investigation showed that Cu^{2+} inhibited LPLD and LAT activities in rat plasma, although the mechanism of their inhibition is unknown. A previous report suggested that several short-chain fatty aldehydes inactivated LCAT in human plasma by reacting with a cysteine residue of the enzyme (25). Consistent with this report, both acrolein and acetaldehyde, secondary products of lipid peroxidation, inhibited LPLD activity, suggesting that an essential cysteine residue is near the active center, as in the case of LCAT. However, the Cu^{2+}-induced inhibition of LPLD activity observed in this study cannot likely be attributed to its induction of lipid peroxidation in rat plasma, since incubation with the antioxidant propyl gallate did not inhibit Cu^{2+}-induced inhibition of the LPLD, and BHT prevented the inhibitory effect of Cu^{2+}, but potentiated LPLD activity in the absence of Cu^{2+}.

As noted above, plasma LPLD may have a cysteine residue(s) with an essential catalytic role, because both DTNB and NEM inhibited the LPLD activity in a concentration-dependent manner. Alternatively, the cysteine residue may have a steric effect near the site of substrate binding, as in the case of LCAT (34), although the susceptibility of the cysteine residue of LPLD in rat plasma to these thiol-modifying reagents was less than that of plasma LAT. Similarly, LPLD activity seems to be less sensitive to serine esterse inhibitors such as DFP and PMSF than LAT activity, although no direct evidence exists of a serine residue located in or near LPLD, as reported for LCAT (35). LPLD does not appear to have a histidine residue that plays a catalytic role, unlike that in LCAT (35).

LPLD in rat plasma differs from intracellular LPLD reported in various mammalian tissues (36–39), in both substrate specificity and cation requirement. The existence in plasma of a phospholipase D with Zn^{2+} in its active site was reported (31), but its metal-ion requirement differs from that of rat plasma LPLD. Furthermore, the enzyme has strict substrate specificity: it hydrolyzes glycosylphosphatidylinositol selectively in *in vitro* conditions (40). In conclusion, the LPLD activity in rat plasma is due to an undescribed metalloenzyme. The biological role of plasma LPLD is to generate LPA with growth factor- and hormone-like activities continuously in the circulating blood and to provide it to various tissues. Thus, modulation of plasma LPLD is an interesting subject for further study. Our results suggest that the accumulation of LPA in blood vessels may be affected by various metal deficiencies, cigarette smoking, and *in vivo* lipid peroxidation in the circulation.

ABSTRACT: The phospholipid composition of rat urinary transitional epithelium (TE) and the fatty acid composition of microsomal, mitochondrial, cytosolic, and plasma membrane (PM) subcellular fractions were investigated. PM marker enzymes and electron microscopy analysis were used to characterize the PM fraction, which showed a distinctive lipid composition compared to the general profile of PM from different sources. The levels of cholesterol and sphingomyelin were not enriched in the PM fraction; on the other hand, the increased amounts of glycosphingolipids and phosphatidylserine, and the decreased level of phosphatidylcholine followed the general features of a PM profile. This differential PM lipid composition may reflect the unique morphology of this mammal TE, consisting of concave plaques with an asymmetrical membrane unit. The distribution of the double bond across the PM indicated a higher unsaturation of the inner relative to the outer part of the PM hemileaflet. In addition, the presence of 20:3n-9 nonessential fatty acid in a normal TE may represent a characteristic fatty acid metabolism of this epithelium.

Lipids 33, 1017–1022 (1998).

The transitional epithelium (TE) covering the innermost surface of the organs of the mammal urinary tracts consists of several layers of cells. The luminal surface of this epithelium has a thick asymmetric plasma membrane (PM) which is in contact with hypertonic urine (1). As a consequence, this epithelium exhibits a strikingly low permeability to water and solutes of small molecular size (2,3). In spite of the relatively large amount of data available on the protein components of this membrane in normal (4–6) or pathological (7,8) conditions, the molecular bases responsible for this lack of permeability remain unknown. Previous reports on the lipid composition of the luminal surface of bladder epithelial cells (9,10) indicated that phosphatidylcholine (PC), phosphatidylethanolamine, phosphatidylinositol, and cerebroside (CB) are the major components of the lipid fraction. Ketterer *et al.* (9) reported the presence of saturated and polyunsaturated fatty acids, mainly n-6 derivatives, and found high levels of one eicosatrienoic acid, an unusual fatty acid for a normal tissue since it is a hallmark of essential fatty acid (EFA) deficiency (11). As far as we know, no further studies on the fatty acid composition of this epithelium have been done. Thus, it is important to know whether the peculiar asymmetry of the PM proteins and lipids (including their fatty acid composition) may play a role in barrier function (12). Urothelial PM possesses the same lipid classes as all biological membranes; however, the ratio among these classes and the molecular species are unique for each membrane. Most lipids are synthesized in the endoplasmic reticulum (ER); consequently, the finding of a particular ratio in each organelle implies that lipid sorting may occur in the traffic route from the biosynthesis site to the final localization. The question is how the interplay between the biosynthetic site and all the processes during the lipid sorting and traffic may result in unique urothelial PM characteristics. Even more interesting is how this interplay is modulated by different cellular conditions. Following this reasoning, we have investigated in this work the lipid and fatty acid composition of microsome (Mic), mitochondrial (Mit), cytosol (Cyt), and PM fractions from rat urinary bladder epithelium as a preliminary approach to understanding the morphological, functional, and biochemical changes of those organelles resulting from dietary lipid manipulation.

MATERIALS AND METHODS

Animals. Sprague-Dawley adult rats of both sexes and weighing 250–350 g were used.

Isolation of TE. TE cells from urinary bladders of 30 rats were obtained using a procedure developed in our laboratory for exfoliating urinary epithelium (13). Histological controls were done in order to ensure that basal membrane remained undamaged and attached to the underlying connective tissue.

Subcellular fractionation and PM purification. The procedure was essentially as described by Stubbs *et al.* (14). Briefly, the cell pellet containing the exfoliated and washed TE was homogenized in 10 mM Tris buffer (pH 7.4) contain-

Abbreviations: CM, crude membranes; Cyt, cytosol; D-BI, double-bond index; EFA, essential fatty acid; ER, endoplasmic reticulum; GSL, glycosphingolipids; Mic, microsome; Mit, mitochondria; PC, phosphatidylcholine; PM, plasma membrane; PS, phosphatidylserine; SPH, sphingomyelin; TE, transitional epithelium.

ing 1 mM each of EDTA and EGTA. The same buffer was used during the entire procedure. After centrifugation at 63,600 × *g* for 30 min, the supernatant was kept as the Cyt fraction, and the pellet was resuspended in the buffer and layered on a support of 1.6 M sucrose (in the same buffer). This two-layer sucrose gradient was centrifuged for 30 min at 10,200 × *g*. The pellet, consisting of nuclear and cell debris, was discarded. The upper layer was then centrifuged at 63,000 × *g* for 15 min. The resulting pellet, or crude membrane (CM), was resuspended in buffer and layered over a discontinuous sucrose density gradient consisting of steps of 1.3, 1.1, and 0.75 M sucrose in buffer. The centrifugations were performed in an SW 25.1 (Beckman) rotor at 26,000 rpm for 2 h. Membranes at each interface, named P1, P2 and P3 from the lower to the higher density, were collected, diluted with 10 vol of buffer, and centrifuged at 10,000 × *g* for 30 min. The purity of the gradient-separated fractions was assayed by determination of enzyme marker activities and subsequent electron microscopy examination.

Electron microscopy procedure. Membrane fractions were prepared as described (15). Briefly, pellets were fixed in 2.5% glutaraldehyde in 0.02 M sodium cacodylate, pH 7.3, and postfixed in osmium tetroxide. Thin sections from three different blocks of each pellet were obtained and stained with uranyl acetate and lead citrate and examined in a Siemens 101 electron microscope.

Membrane enzyme assay. 5′-Nucleotidase (E.C. 3.1.3.5), glucose-6-phosphatase (E.C. 3.1.3.9), succinic-INT-reductase [INT: 2-(*p*-indophenyl)-3(*p*-nitrophenyl)-5-phenyltetrazolium], and thiamine pyrophosphatase were assayed as described by Morre (16). Na-K-ATPase was determined by the procedure of Post and Sen (17). All reagents were purchased from Sigma Chemical Co. (St. Louis, MO).

Phospholipid determination. Total lipids were extracted and fractionated into neutral and acidic lipids as described by Macala *et al.* (18). Phospholipid was measured in lipid extracts by the modified microprocedure of Bartlett (19). For phospholipid class analysis, acidic or neutral phospholipids were fractionated by high-performance thin-layer chromatography, developed, and quantified by densitometry (Shimadzu CS-9000 scanning densitometer) as described by Macala *et al.* (18).

Fatty acid determination. The total lipid fraction was saponified in 10% KOH containing 50% MeOH as described by Bridges and Coniglio (20). Digests were acidified (pH 2.0) with concentrated HCl and extracted three times with petroleum ether. Combined extracts were taken to dryness under N_2 and methylated at 95°C with 3% methanolic HCl. Methyl esters were extracted with petroleum ether and quantitated by gas–liquid chromatography as previously described (21).

RESULTS

Several membrane markers were determined in subcellular fractions of urinary TE. As shown in Table 1, the specific activities of enzymes associated with the PM (5′-nucleotidase, Na-K-ATPase) were enriched in P2 fraction relative to the specific activities of the enzymes in the CM fraction. On the other hand, the specific activities of the enzymes associated with Mit [succinic-INT-reductase, where INT is 2-(*p*-indophenyl)-3(*p*-nitrophenyl)-5-phenyltetrazolium] and Golgi (thiamine pyrophosphatase) were decreased relative to their specific activities in CM fraction. The P2 fraction (PM) was somewhat contaminated with ER as indicated by the specific activity of glucose-6-phosphatase. Overall, the enzymatic profile of P2 as well as the ultrastructural studies (Fig. 1), showing a great profusion of profiles with the characteristic concave plaques of the asymmetric unit membrane of this epithelium (22), were consistent with a luminal PM origin of the TE cells.

Table 2 shows the lipid composition of TE. The cholesterol/phospholipid molar ratio (C/P: 0.64) was similar to that reported for luminal PM of TE (9,10,23). This may represent a characteristic of luminal PM of TE since most PM are enriched in cholesterol with respect to the levels found in the total homogenate. The only report showing a cholesterol/phospholipid (molar ratio) for PM higher than the value reported in this work for total homogenate is that from Stubbs *et al.* (14). The lipid and phospholipid contents (as the percentage of dry weight) were lower in TE than those reported for purified luminal PM (Table 2). Table 3 shows that the major phospholipids of TE were PC, phosphatidylethanolamine, phosphatidylserine, and cerebroside. Table 4 gives the fatty acid composition of total lipids of different subcellular fractions from TE. All fatty acids were identified according to their retention time on gas chromatography, as compared with known pure standards. The major fatty acids in PM were 16:0, 18:0, 18:1, 18:2, 20:3n-9, and 20:4n-6. Intriguingly, the nonessential 20:3n-9

TABLE 1
Specific Activities of Marker Enzymes in Subcellular Fractions of TE[a]

Fraction	CM	P1	P2	P3	Cyt
5′-Nucleotidase	1.4 ± 0.3	3.0 ± 1.1	25.0 ± 4.0	7.0 ± 1.0	7.0 ± 0.9

FA	—	16.9 ± 1.0
C	—	19.2 ± 2.4

[a]Lipid analyses were performed as indicated in the Materials and Methods section. Values represent the average of three experiments ± SEM. SPH, sphingomyelin; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; CB, cerebroside; Sulf, cerebroside sulfatide; FA, fatty acid; C, cholesterol. For other abbreviation see Table 1.

fatty acid appeared in a high proportion (14%) in the Mic fraction. Nervonic acid (24:1n-9) was detected only in CM and PM fractions (results not shown). Our data show that the double-bond index (D-BI) of PM (0.9) was lower than that of the Mic fraction (1.9). Similar differences in the D-BI between both PM and Mic were observed in hepatocyte membranes (24). Major changes in PM relative to Mic fraction were increased values for palmitic (16:0), stearic (18:0), and oleic (18:1) acids and decreases in 20:3n-9 and arachidonic acid (20:4). Accordingly, the ratios 16:0/18:0, 18:0/18:1, and 18:0/20:4 were increased in PM. The Mit showed the lowest D-BI (0.3), whereas the Cyt fraction, containing probably very small vesicles, showed the same value of PM D-BI (0.94).

The introduction of multiple double bonds creates structurally different zones within the bilayer. The structural gradient arising from different concentration of double bonds at different depths of the bilayer membrane may influence membrane function. Thus, it is important to analyze the double-bond profile across the bilayer. Table 5 illustrates the degree of unsaturation along the hydrocarbon chain from C_5 to C_{12}. Clearly, the largest difference between PM and Mic corresponded to the C8 and C11 depths.

TABLE 4
Fatty Acid Composition of Subcellular Fractions from Rat TE[a]

Fatty acid	TH	PM	Mic	CM	Mit	Cyt
16:0	13.8	19.3	1.9	20.7	19.6	19.6
16:1	2.3	3.4	7.3	7.7	n.d.	3.4
18:0	16.7	19.5	7.8	9.0	50.0	20.6
18:1	17.0	21.7	14.7	31.2	21.4	21.0
18:2	1.6	6.0	15.7	14.3	1.6	n.d.
20:1n-9	0.4	1.9	14.3	0.3	n.d.	0.3
20:2n-9	3.7	2.0	n.d.	0.8	n.d.	0.3
20:3n-9	18.0	1.2	14.3	0.7	n.d.	0.3
20:4n-6	11.4	6.3	10.8	1.7	n.d.	14.3
20:4n-3	0.6	3.8	9.4	n.d.	n.d.	2.1
22:1n-9	0.4	3.9	0.8	n.d.	n.d.	0.2
D-BI	1.3	0.9	1.9	0.8	0.3	0.9
$D\text{-}BI_{EFA}/D\text{-}BI_{non\text{-}EFA}$	0.62	1.36	1.4	0.82	0.15	2.48

[a]Cellular fractions were isolated as described in the Materials and Methods section. Only the more representative fatty acids are shown. Values represent percentage of total. The SEM for all values (three separate determinations) were not above 10% of the mean shown. D-BI is the sum of the fraction of each fatty acid times the number of double bonds in that acid. TH, total homogenate; PM, plasma membrane; Mic, microsome; CM, crude membranes; Mit, mitochondria; Cyt, cytosol. For other abbreviation see Table 1.

TABLE 5
Degree of Unsaturation at Different Membrane Depths[a]

Carbon number	5	6	7	8	9	10	11	12
PM	8.6	1.2	1.6	14.3	32.6	0.1	16.4	6.9
Mic	26.0	0.0	4.7	35.4	35.4	3.2	49.7	15.7

[a]Values are the sum of the percentages of each fatty acid from PM and Mic fractions containing a double bond at the carbon indicated. For abbreviations see Table 4.

DISCUSSION

This work reports the fatty acid composition of several subcellular fractions and additional data about phospholipid content of rat urinary bladder TE. It is important to try to relate the striking plasticity and recycling of luminal surface membrane and their discoidal vesicles of TE cells (25,26) to the lipid composition of different membrane compartments. Moreover, luminal PM is part of a complex membranous system where interrelationships among all components may be modulated by different factors. The biology, biochemistry, biophysics, and pathology of this epithelium are particularly interesting. Table 1 summarizes the enzymatic activities of several subcellular fractions from TE, showing that the P2 fraction resembles a PM profile with low enzyme activity of markers other than those in PM organelles, indicating an acceptable degree of purification. This was corroborated by ultrastructural observations (Fig. 1).

Table 2 indicates that total lipid and phospholipid contents (as percentage of dry weight) were lower in TE than those reported for purified luminal PM (4). This is not an unexpected result since loss of soluble Cyt proteins occurs after PM purification.

It is known that PM are typically enriched in cholesterol, sphingomyelin (SPH), and phosphatidylserine (PS), whereas PC is decreased in comparison to those values in ER (27). This implies that cholesterol and SPH are sorted and concentrated together in their pathway to the trans-Golgi and further out (27). Interestingly, this does not seem to be the case for urothelial TE since cholesterol and SPH contents in total TE (37 and 6.5, respectively, Table 3) were about the same as those in PM (40 and 8.5, respectively; Refs. 9,14). Alternatively, the relative lack of concentration at the luminal surface of these two typically PM lipids may also imply a poorly developed ER. If this is the case, PM-like organelles such as Golgi, endocytotic vesicles (endosomes), and the PM itself would be the major components of the total membrane fraction of this epithelium. By contrast, PS content was lower in total TE (7.6%) than that reported for PM (26.3%; Refs. 9,14), in agreement with the general concept that PS is enriched in PM. The high amount of PS in PM may contribute to maintaining the integrity of the rigid plaques of the urinary bladder luminal surface through the interaction of PS with the cytoskeleton (28). It has been shown that anionic phospholipids (i.e., PS) in urothelial membrane greatly increase calcium oxalate–crystal membrane interactions (29). The amount of PC was higher in total TE (59.7%) than in PM (22.0%, Refs. 9,14). This result agrees with the general idea that the enrichment of glycosphingolipids (GSL) at the apical surface is at the expense of PC. GSL content was previously reported (9,13,14); and nervonic acid (24:1n-9), a characteristic compound of monohexosyl GSL (cerebrosides), was detected in Cyt (enriched in Golgi marker enzyme, see Table 1) and PM fractions. The enrichment of GSL and the lack of concentration of SPH in PM fraction would indicate, contrary to the concept on their intracellular traffic to the surface (27), that these two lipids are sorted in different domains. This may represent another particular characteristic of the lipid transport of this mammal's TE.

The high percentage of the nonessential fatty acid 20:3n-9 (Table 4) was not unexpected since an eicosatrienoic acid was first described by Ketterer *et al.* (9,14) in luminal surface of rat urinary bladder epithelium. The presence of this non-EFA in ER (Mic), the site where the acyl desaturase activity is localized, has no explanation at the present time. Nevertheless,

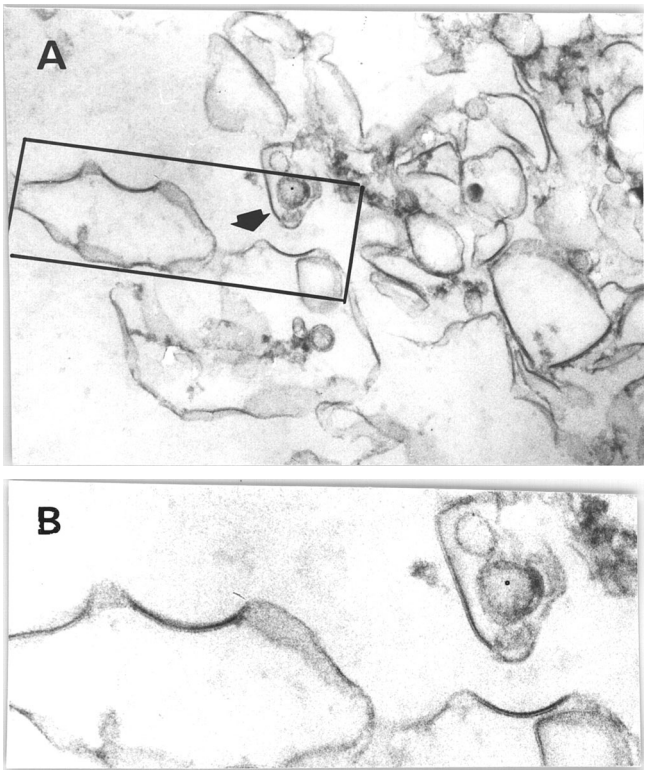

FIG. 1. Both panels correspond to pellets of plasma membrane fraction (P2) from rat urinary transitional epithelium. The subcellular fraction was obtained and prepared for electron microscopy analysis as described in the Materials and Methods section. Typically scalloped membrane profiles showing the thick, asymmetrical plasma membrane (arrow) are seen. (A): 20,000 ×, (B): 60,000 ×.

the accumulation of 20:3n-9 in TE, also described in normal human cartilage (30), may suggest a metabolic shift of the elongation and desaturation enzyme activities to the precursors of the nonessential n-9 fatty acid family (31) in response to a shortage of n-6 EFA precursors. Testing this hypothesis will require further metabolic and dynamic studies. On the other hand, exogenous 20:3n-9 behaves as a down-regulator of certain antimetastatic cell adhesion molecules (E-cadherin and desmoglein) in human epidermoid cells (32).

Contrary to the difference observed in the D-BI of PM and Mic fractions, no significant change in the values of the D-BI_{EFA}/D-$BI_{non\text{-}EFA}$ ratios of those fractions was observed. These assessments emphasize the need to study unsaturation in the cross-sectional direction of the bilayer. The results (Table 5) show that the maximal differences between PM and Mic fractions were localized at the depths of C8 and C11. Table 4 indicates that all fatty acids containing double bonds at C8 and C11 (20:3n-9, 20:4n-6, 20:4n-3, and 20:1n-9) were decreased in the PM fraction relative to those values in Mic fraction. Nevertheless, the fatty acids showing the greatest decline were 20:1n-9 and 20:3n-9. According to the representation in Leger *et al.* (33), the first double bond starting from the methyl group in 20:1n-9 and 20:3 n-9 causes a shortening of one C-C bond; this results in a shift of the double bond in the 11-position from the inner to the outer half of the leaflet defined by the C10 depth. Thus, the decreased amounts of these fatty acids in PM may represent a lesser degree of unsaturation of the outer part of the leaflet with a concomitant higher unsaturation of the inner part, relative to those of the Mic membrane. It is tempting to consider that the different shape of the double-bond distribution in urethelial PM may affect the structural order and function of this membrane, leading to the unique properties and morphology of the urinary luminal surface.

In summary, from the comparison of the phospholipid content of total TE (this report) and PM fraction (14), some evidence is presented that cholesterol, SPH, and GSL do not follow the general concept that they are transported in the same microdomain from the ER to the PM. This also suggests that differential regulatory mechanisms may govern the intracellular traffic of those lipids. The presence of the nonessential 20:3n-9 fatty acid in normal TE is an important point in future metabolic studies of this epithelium. The study of the unsaturation across the membrane from different fractions revealed that plasma membrane C11 depth is different from that of the other fractions, and this may represent important functional consequences for PM. Finally, lipid quantitation of different subcellular membrane fractions may be useful as a complementary approach for future assessments to how compositional distribution may affect or reflect cellular function, particularly compartmental interrelationships within the cell.

Alterations in Heart and Kidney Membrane Phospholipids in Hypertension as Observed by ^{31}P Nuclear Magnetic Resonance

Yuling Chi and Raj K. Gupta*

Department of Physiology and Biophysics, Albert Einstein College of Medicine of Yeshiva University, Bronx, New York 10461

ABSTRACT: Abnormalities of phospholipids in hypertension have previously been described in human erythrocyte, platelet, and plasma lipoproteins. Since the heart and kidney are adversely affected by hypertension, we investigated possible alterations in their membrane phospholipids, which could play a role in the derangement of intracellular ion balance widely observed in hypertension. The phospholipid compositions of heart and kidney from spontaneously hypertensive rats (SHR) and Wistar-Kyoto (WKY) rats were determined by using ^{31}P nuclear magnetic resonance (NMR) spectroscopy. Absolute contents of all phospholipids in hypertensive hearts and kidneys were significantly higher than in normotensive hearts and kidneys. Expressed as a fraction of total phospholipid, cardiolipin (CL) and phosphatidylethanolamine plasmalogen (PEp) were significantly increased in SHR hearts compared to WKY hearts (CL and PEp were 7.95 ± 0.22% and 13.16 ± 0.35% in SHR vs. 7.01 ± 0.20% and 11.19 ± 0.42% in WKY rats, $P \leq 0.05$), but phosphatidylethanolamine (PE) and phosphatidylcholine (PC) were significantly decreased in SHR (PE and PC were 22.46 ± 0.37% and 44.81 ± 0.43% in SHR vs. 24.02 ± 0.44% and 46.01 ± 0.50% in WKY rats, $p \leq 0.05$). In the phospholipids extracted from rat kidneys, the percentage of PE was significantly higher for SHR than for WKY rats (20.37 ± 0.60% vs. 18.43 ± 0.37%, $P \leq 0.05$), while PEp and phosphatidylserine (PS) were significantly lower for SHR (PEp and PS were 10.22 ± 0.36% and 8.42 ± 0.28% in SHRs vs. 11.29 ± 0.36% and 9.71 ± 0.40% in WKY rats, $P \leq 0.05$). The above alterations in phospholipid composition might contribute to the higher oxygen consumption in the hypertensive heart and abnormal intracellular ion concentrations and ion transport in the heart and the kidney in hypertension.

Lipids 33, 1023–1030 (1998)

Abnormalities in phospholipids of erythrocyte membranes from essential hypertensive patients have been reported in the literature (1). Phospholipid composition of human red blood cell membranes for hypertensive patients was different from that for normal individuals, and these differences could be correlated to alterations in Na^+–Li^+ exchange activity across the erythrocyte membrane in hypertension. Altered phospholipids were also found in plasma lipoproteins (2) and in platelet membranes (3) in hypertensive patients. In animal models, abnormal phospholipids have been reported in the jejunal brush-border membranes from spontaneously hypertensive rats (SHR) (4), in left and right ventricles of aorta-constricted rats (5), and in pressure-overload hypertrophied rat hearts (6). Changes in phospholipids in the kidney were also observed during ischemia (7) and other pathological conditions (8). Depletion of dietary magnesium and/or phosphorus also alters membrane lipids (9,10). However, to our knowledge, there are no reports of alterations in phospholipid compositions of heart and kidney membranes in hypertension. Since abnormalities in cardiac and renal functions often are associated with hypertension, we investigated possible alterations in phospholipid compositions of the heart and kidney membranes in hypertension. Alterations in membrane phospholipids in the heart and the kidney might contribute to the abnormal intracellular ion concentrations and ion transport observed in these organs in hypertension.

We utilized the SHR as a model of human hypertension (11) with the Wistar-Kyoto (WKY) rat serving as the normotensive control. The phospholipid compositions of heart and kidneys from SHR and WKY rats were determined by using ^{31}P nuclear magnetic resonance (NMR) spectroscopy. This technique has been successfully used to measure phospholipid composition of biological membranes (1,12–14).

MATERIALS AND METHODS

Materials. Anhydrous methanol (MeOH), deuterated chloroform ($CDCl_3$), and deuterium oxide (99.8% D_2O) were supplied by Aldrich (Milwaukee, WI). Potassium chloride (KCl), chloroform ($CHCl_3$), ethylenediaminetetraacetic acid (EDTA), cardiolipin (CL) sodium salt from bovine heart, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) from frozen egg yolk, phosphatidylserine (PS) sodium salt and sphingomyelin (Sph) from bovine brain, and phosphatidylinositol (PI) ammonium salt from bovine liver were purchased from Sigma Chemical Company (St. Louis, MO).

Phospholipid preparation. Male SHR (250–400 g) were used as hypertensive models. Male WKY rats (250–400 g) were used as the normotensive controls. Pentobarbital anesthesia (65 mg/kg i.p.) was administered; laparotomy was per-

Abbreviations: CL, cardiolipin; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PEp, phosphatidylethanolamine plasmalogen; PI, phosphatidylinositol; PS, phosphatidylserine; SHR, spontaneously hypertensive rat; Sph, sphingomyelin; WKY, Wistar-Kyoto.

formed. Fresh kidneys and hearts were taken out and frozen immediately by using liquid nitrogen or dry ice. Total lipid was extracted by a modification of the methods of Meneses and Glonek (15), and Bligh and Dyer (16). Frozen tissues were weighed and then homogenized, using a homogenizer, in 5 mL of a mixture of chloroform/methanol (2:1) for 2 min. The homogenates were transferred to a flask, and more chloroform/methanol (2:1) mixture was added up to 20 vol per unit tissue wet weight (20 mL/g). The mixture was stirred for 20 min and filtered through a sintered glass funnel. The same volume of solution was used to rinse the residuals through the funnel. The filtrate was mixed with 0.2 times its total volume with 0.74% KCl to remove all nonlipid impurities and allowed to separate overnight. The bottom (chloroform) layer was collected and dried in a rotary evaporator at 30°C (13,15–17). The purified dry phospholipids were suspended in 3 mL of the solvent mixture solution [$CDCl_3$/MeOH (anhydrous)/0.2 M EDTA (in D_2O) = 118:8:3] and used for NMR experiments (1).

NMR measurements. The phospholipid extract was placed in a 10-mm NMR tube and allowed to stand for a few minutes until the aqueous phase had separated. The spinning turbine was adjusted along the NMR tube so that only the chloroform phase was in the region of signal detection. ^{31}P NMR spectra for analyzing phospholipids in the extracts of kidney and heart membranes were obtained at 202.3 MHZ on a Varian VXR-500 NMR spectrometer using a spectral width of 10,000 Hz, 16 K data points, a flip angle of 60° (pulse width, 30 μs), an acquisition time of 0.82 s, a relaxation delay of 4.2 s, and 512 transients, at room temperature. Chemical shifts are referenced to PC set at −0.84 ppm (1,12,13). Each resonance in the ^{31}P NMR spectra of phospholipid extract samples was assigned by spiking the samples with pure known phospholipids (PC, PE, PS, PI, Sph, and CL) purchased from Sigma. Our assignments are generally consistent with those in the literature (1,12,13), although ^{31}P peak positions are in some cases (e.g., PS and Sph) somewhat displaced relative to those published in the literature owing to differences in solvent used. Resonance intensities were measured as peak areas. Relative intensities remained unchanged upon doubling the pulse recycle time, showing that they were unaffected by relaxation times. The areas under the ^{31}P NMR resonances in the spectra of phospholipid extracts were integrated to obtain concentrations that are expressed as absolute concentrations and also as percentage of total phospholipid measured as area under all resonances for the seven major classes of phospholipids. Only half of the area under the CL resonance was included in the concentration and percentage calculations, since this phospholipid contains two phosphorus atoms. The resonance of a methyl phosphonate sample of known concentration was used to quantitate individual phospholipids in extracts as μmol/g wet tissue weight.

Statistical analysis. All data are reported as the mean ± standard error. The statistical significance of the differences between SHR and WKY rats was analyzed by the nonpaired *t*-test. $P \leq 0.05$ was considered significantly different.

RESULTS

Figures 1 and 2 show typical ^{31}P NMR spectra of phospholipids extracted from heart and kidney membranes of SHR and WKY rats. The assignments of the phospholipid resonances are indicated in the spectra and were obtained as described in experimental procedures. Two types of PE are present in heart and kidney membranes, and they can be discriminated by ^{31}P NMR spectroscopy: diacyl PE and alkenylacyl PE (PE plasmalogen, PEp).

As shown in Table 1, the absolute amounts of all the major phospholipid components were significantly higher in extracts from hearts of hypertensive rats than of normotensive rats. The percentages of CL and PEp in total phospholipid were also significantly higher for SHR than for WKY rats (CL and PEp were 7.95 ± 0.22% and 13.16 ± 0.35% in SHR heart membranes vs.7.01 ± 0.20% and 11.19 ± 0.42% in WKY heart membranes, $P \leq 0.05$), but the percentages of PE and PC were significantly lower for SHR than for WKY rats (PE and PC were 22.46 ± 0.37% and 44.81 ± 0.42% in SHR heart membranes vs. 24.02 ± 0.44% and 46.01 ± 0.50% in WKY heart membranes, $P \leq 0.05$).

Table 2 shows data on phospholipids extracted from rat kidneys. As in hearts, the absolute amounts of all ofthe phospholipid components in kidneys were significantly higher in hypertensive rats than in normotensive rats. The percentage of PE in total phospholipid was significantly higher for SHR than for WKY rats (20.37 ± 0.60% in SHR kidney membranes vs. 18.43 ± 0.37% in WKY kidney membranes, $P \leq 0.05$), but the percentages of PEp and PS were significantly lower for SHR than for WKY rats (PEp and PS were 10.22 ± 0.36% and 8.42 ± 0.28% in SHR kidney membranes vs. 11.29 ± 0.36% and 9.71 ± 0.40% in WKY kidney membranes, $P \leq 0.05$).

DISCUSSION

Biological membranes are composed of protein, phospholipid, and cholesterol and are organized as the structural framework for a wide variety of membrane functions including membrane permeability barrier and appropriate environment for the optimal function of transmembrane proteins such as ion channels and ion pumps (18). Phospholipids comprise the predominant chemical components present in the membranes. In heart and kidney the main phospholipid components are PC, PE, PS, PI, Sph, CL. It is well known that phospholipid bilayers are asymmetrical (19). The head groups of the phospholipids PI and PS are negatively charged, and these two anionic phospholipids reside primarily in the inner leaflet of the plasma membrane. PC, PE, and Sph are neutral. PC and Sph are predominantly present in the outer leaflet, whereas PE is predominantly restricted to the inner leaflet. CL contains four fatty acyl chains and a backbone of three glycerol groups chained together by two negatively charged phosphate groups (20,21). In mammalian tissues, CL is almost exclusively localized in mitochondria where it is biosynthesized (22–24). Extensive research on phospholipids suggests that alterations in phospholipid compo-

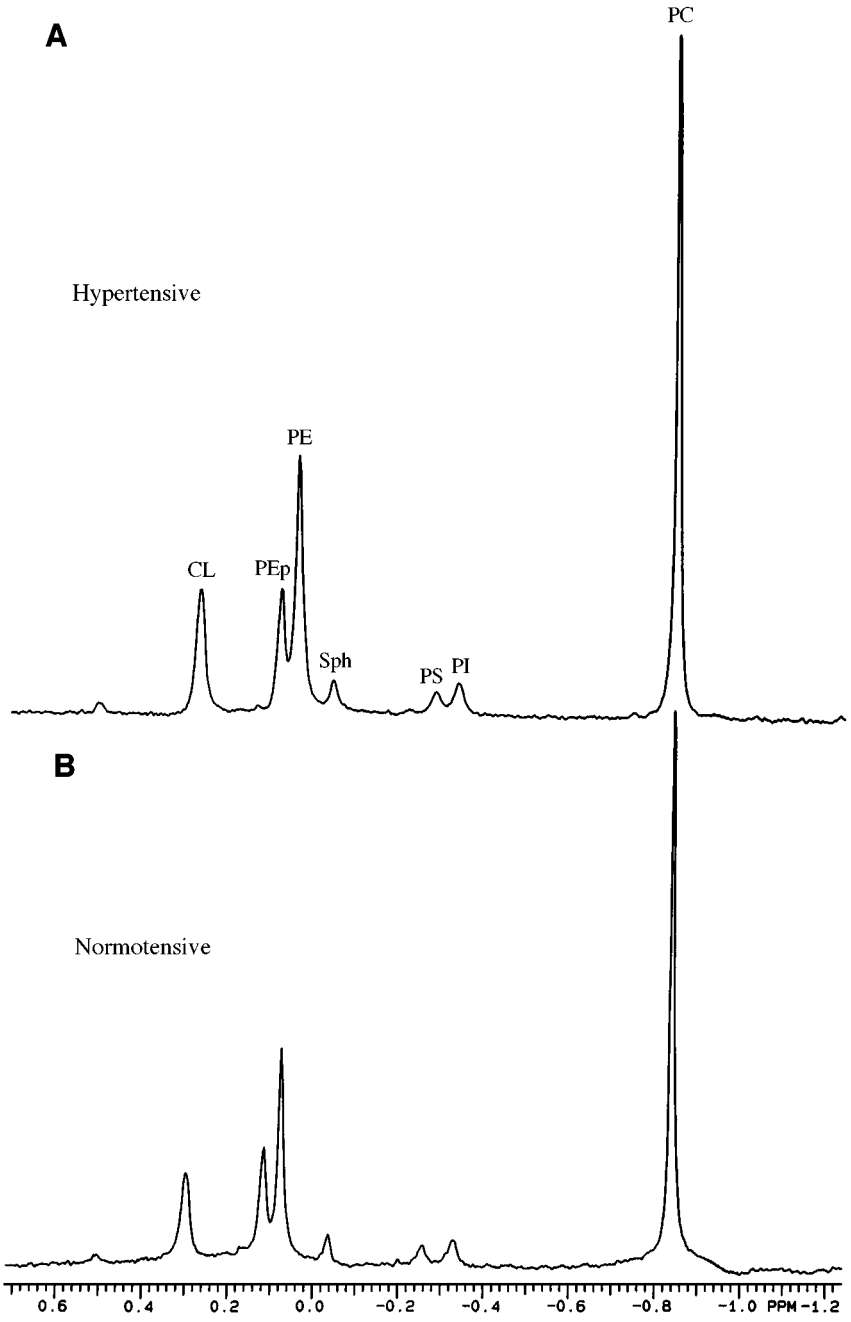

FIG. 1. Comparison of ^{31}P nuclear magnetic resonance (NMR) spectra of phospholipids from a spontaneously hypertensive rat heart (A) and a normotensive rat heart (B). Assignments of various resonances to individual phospholipids are shown. Chemical shifts are referenced to PC set at –0.84 ppm. Vertical scales have been adjusted to take into account small differences in tissue weights. sition may cause significant modification of membrane functions. For example, Lijnen *et al.* (25) reported a significant correlation between total phospholipid content of erythrocyte membranes and the activities of Na^+–Li^+ exchange, Na^+–K^+ cotransport, and Na^+ pump. Engelmann *et al.* (26,27) reported that a change in composition of only 3% of total membrane lipids could cause up to 40% variation in sodium–lithium countertransport activity. They also showed that small changes in membrane PC or Sph (~5% of total phospholipid) resulted in doubling or halving of the rate of Na^+–Li^+ exchange (28). Thus

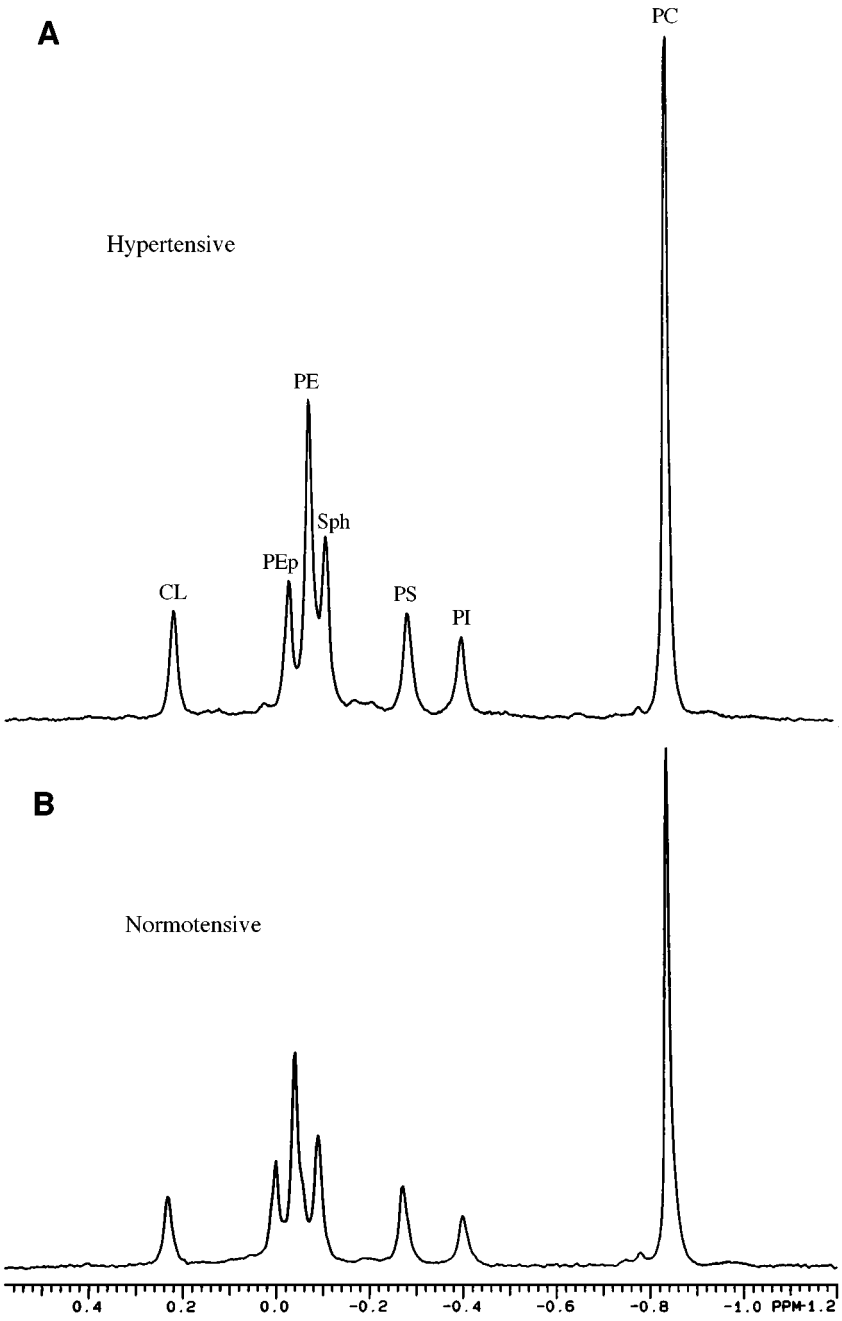

FIG. 2. Comparison of ^{31}P NMR spectra of phospholipids from a spontaneously hypertensive rat kidney (A) and a normotensive rat kidney (B). Vertical scales have been adjusted to take into account small differences in tissue weights. For abbreviations see Figure 1.

small changes in membrane lipids could, in principle, be responsible for significant alterations in ion transport activities.

In this study, the experimental data in Tables 1 and 2 and Figures 1 and 2 show a sizable increase in all of the membrane phospholipid components in the heart and the kidneys from the SHR in comparison to a normotensive rat. Earlier work also showed altered phospholipids in the heart and kidneys under pathological conditions. Foudin *et al.* (29) reported that PE, PEp and PI were significantly increased in heart mitochondria from rats after chronic ethanol administration, which often results in development of refractory hypertension (30–32). Consistent with this, we found that the absolute contents of PE, PEp, and PI from the heart membranes of hypertensive rats were significantly increased. PEp,

expressed as a percentage of total phospholipid, was also significantly increased. Interestingly, we also found that CL, a special dimeric phospholipid with unique structural features, was significantly increased in both absolute content and as a percentage of total phospholipid in hearts from hypertensive rats relative to normotensive controls. It has been suggested that CL participates in movement of Ca^{2+} across the inner mitochondrial membrane (33–35). Increased CL may contribute to alterations in cardiac myocyte calcium homeostasis in hypertension (36). To get an idea of the affinity of Ca^{2+} to CL, we measured the binding constants of Ca^{2+} to CL and other phospholipids. Of all the phospholipids (PC, PE, PS, CL) measured, the interaction of Ca^{2+} and CL was the strongest. The binding constant for Ca^{2+} and CL was measured as 4.32 ± 0.14 mM^{-1}, while the interaction between Ca^{2+} and PC was undetectable ($K_a \leq 0.1$ mM^{-1}). These results are in agreement with the work of others (33). Alterations in fatty acid components of CL may also affect the affinity of CL for Ca^{2+} (37). We have previously reported that the unsaturation and chain length of fatty acids decreased in heart and kidney membrane phospholipids from hypenensive rats (38). These alterations might affect the ability of CL to participate in Ca^{2+} translocation. A decreased percentage of PC in heart membrames from hypertensive rats would also facilitate greater interaction of Ca^{2+} with membranes in hypertensive cardiac cells since an increase in PC inhibits the interaction of Ca^{2+} with liposomes containing PC (33).

Although the binding constant of Ca^{2+} to CL is relatively low in relation to intracellular free Ca^{2+} concentration (~100–200 nM), the total concentration of CL in mitochondrial membrane of ~4 mM (33,35) is over an order of magnitude higher than calcium–CL dissociation constant which would still result in significant binding of Ca^{2+} to CL.

The precise functional role of membrane CL remains unknown. However, it appears absolutely required for maximal mitochondrial cytochrome c oxidase activity (22,39,40) and for mitochondrial carnitine/acylcarnitine translocase activity (41). Creatine kinase and ATP/ADP carrier are also specifically bound to CL in the inner mitochondrial membrane (42–47). Interestingly, increased CL content has been found to correlate width increased cytochrome oxidase activity in rat heart mitochondria (48). Therefore, increased CL in hypertensive heart observed in our study might in part be responsible for increased oxygen consumption in the hypertensive heart reported previously (49–51).

Our results show that absolute concentrations of all of the major phospholipid components are significantly increased in kidney membranes from hypertensive rats. Previous work of our group showed that intracellular free calcium concentration was significantly increased in perfused hypertensive kid-

ney (52). Significantly increased contents of CL, PI, and PS are consistent with the elevated level of free calcium in the hypertensive kidney since Tyson *et al.* (53,54) have demonstrated that CL is one of the most active ionophores for translocating calcium. Also, PS is required to activate protein kinase C, which is involved in calcium translocation; and inositol 1,4,5-trisphosphate, which is derived from a phosphorylated form of PI, mediates calcium mobilization (54,55); and both are increased in the hypertensive kidney.

The bilayer structure of biological membrane as originally proposed by Gortel and Grendel in 1925 is still an attractive way to explain many properties of cell membranes (56). Luzatti and coworkers (57) established that every biological membrane consists of large amounts of nonbilayer lipids next to bilayer-forming lipids. The ability of lipids to adopt nonbilayer structures is believed to be important for membrane fluidity (58). PE is typical nonbilayer-preferring lipid (58). It may regulate the fluidity of membranes (56,58–60) and modify the Ca^{2+} transport processes by enhancing a slow sustained uptake component that strongly depends on temperature (35). An increase in PE content in kidney membranes from SHR would contribute to nonbilayer characteristics in the lipid bilayer. Furthermore, increased CL content, together with increased PE, in kidney membrane from hypertensive rats would lead to more Ca^{2+} sequestered in the mitochondrial membranes as well as more Ca^{2+} translocated into mitochondria.

To our knowledge, this study is the first report in the literature on alterations in phospholipids of the hypertensive heart and kidney, the two organs well known to be adversely affected in essential hypertension. It appears possible that these abnormalities may at least in part account for abnormal ion balance and ion transport observed in hypertensive heart and kidney cells (25–28,51,52,55,61–70).

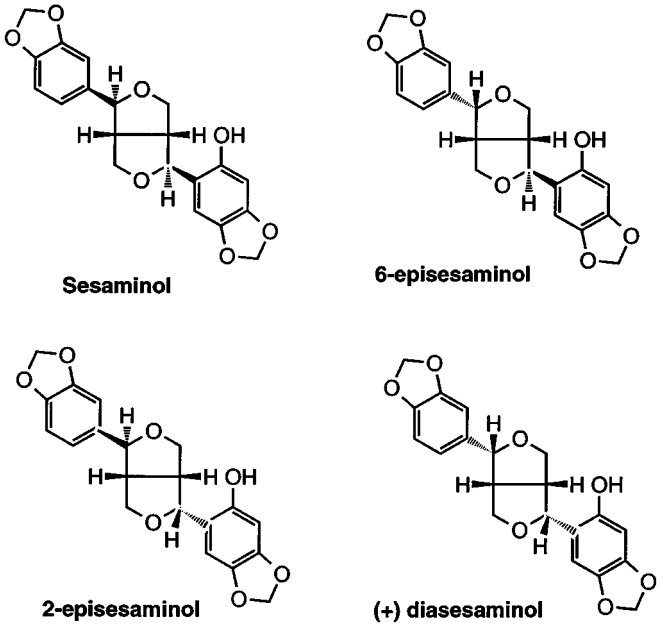
Inhibition of 2,2′-Azobis(2,4-dimethylvaleronitrile)-Induced Lipid Peroxidation by Sesaminols

Myung-Hwa Kang[a], Hirotaka Katsuzaki[b], and Toshihiko Osawa[a,*]

[a]Laboratory of Food and Biodynamics, Nagoya University Graduate School of Bioagricultural Sciences, Nagoya 464-8601, Japan, and [b]Faculty of Bioresources, Mie University, Tsu, Mie 514, Japan

ABSTRACT: We found that sesaminols, a mixture of sesaminol and its stereoisomers, are potent inhibitors of the oxidation of low-density lipoprotein induced by 2,2′-azobis(2,4-dimethylvaleronitrile). Although sesaminols strongly inhibit lipid peroxidation related to their ability to scavenge free radicals, their antioxidant effects have not been investigated. To confirm the involvement of the phenolic moiety in the sesaminol structure in antioxidant activity, sesaminols were reacted with 2,2′-azobis(2,4-dimethylvaleronitrile). The reaction products were isolated by high-performance liquid chromatography and found to have a 1-cyano-1,3-dimethyl-butyl-peroxyl group in their structures. These chemical structures suggest that the sesaminols reacted with the alkylperoxyl radicals to form four major reaction products that are stereoisomers of each other, although the stereochemistry of each isomer has not yet been confirmed. Further instrumental analyses of the reaction products may increase our understanding of the antioxidant activity of sesaminols.
Lipids 33, 1031–1036 (1998).



SCHEME 1

Sesame (*Sesamum indicum* L.) is one of the world's most important oil seed crops. Not only is it a source of edible oil but also the seed itself provides a nutritious food for humans. Sesame seed oil resists oxidative deterioration (1,2). Its remarkable stability is thought to be due to the presence of the endogenous antioxidants sesaminols and sesamol, together with tocopherols (3). Quantification using high-performance liquid chromatography (HPLC) showed that the amount of sesaminols dramatically increased during the manufacturing process, particularly during bleaching; we previously found that sesaminol and three stereoisomers including 2-episesaminol, 6-episesaminol, and (+) diasesaminol (Scheme 1) are produced by intermolecular transformation from sesamolin (3,4), a minor component of sesame oil. Sesamolin is readily converted to sesamol under such conditions as hydrolytic scission at the C_2 position (5). We recently reported the absorption, distribution, and metabolism of sesamolin after having fed it to rats (6). In that study, we found that sesamolin is transformed to sesamol and sesamolinol during absorption from the gastrointestinal tract (6). We suggested therefore that the metabolism of sesamolin differs *in vivo* from that observed *in vitro*. We also found that the chelation of sesaminol with ADP-Fe^{3+}/NADPH inhibits microsome peroxidation (6). Various studies have investigated the therapeutic potential of several synthetic and natural antioxidants as inhibitors of low density lipoprotein (LDL) oxidation (7,8). We found that sesaminol from sesame seed exhibits the strongest antioxidant properties (9–15), and is a potent inhibitor of LDL oxidation induced by $CuSO_4$ or 2,2′-azobis(2-amidinopropane) dihydrochloride *in vitro* (Kang, M.-H., Naito, M., Sakai, K., Uchida, K., and Osawa, T., submitted for publication).

The products formed by the reaction of several natural antioxidants with the peroxyl radical have recently been isolated and identified, and the reaction mechanisms have been studied (16–20). α-Tocopherol is an important natural antioxidant that is present in food as well as in living cells. The reaction products of α-tocopherol with alkylperoxyl radicals have been elucidated, and the antioxidant mechanism of tocopherol has been proposed (16–18). Sugiyama *et al.* (19) reported that

tetrahydrocurcuminoids, which are major metabolites of curcumin, form 3,4-dimethoxybenzoic acid, 3′,4′-dimethoxy acetophenone, and 3-(3,4-dimethoxyphenyl)-propionic acid *via* the reaction of peroxyl radicals generated by thermolysis. The two reaction products of an anthocyanin pigment with 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) were identified as 4,6-dihydroxy-2-*O*-β-D-glucosyl-3-oxo-2,3-dihydrobenzofuran and protocatechuic acid (20). However, the oxidation products of sesaminols with alkylperoxyl radical have not been elucidated.

The present study evaluated the inhibitory effects of sesaminols on the oxidation of LDL induced by AMVN. To investigate the antioxidant mechanism of sesaminols, we identified the oxidation products of sesaminol and its stereoisomers with the alkylperoxyl radicals, generated in the reaction with AMVN, which is an initiator of free radicals.

MATERIALS AND METHODS

Materials. Scum from the commercial refining process for unroasted sesame oil was esterified and extracted as previously reported (3,4). Sesaminol and 2-episesaminol were found and identified as the major products by comparing the results of analysis with data from authentic samples. The ratio of sesaminol/2-episesaminol/6-episesaminol/(+) diasesaminol was found to be 37:41:6:16 by wt. Because these stereoisomers isomerize each other at room temperature (3,4), we used the mixture of sesaminol and its stereoisomers for further experiments. AMVN and acetonitrile were purchased from Wako Pure Chemical (Osaka, Japan). Tetramethylsilane and $CDCl_3$ were purchased from Aldrich Chemical (Milwaukee, WI).

Lipoprotein preparation. LDL (d = 1.019 to 1.063 g/mL) was isolated from the serum of healthy humans by stepwise ultracentrifugation at 150,000 × g for 20 h, followed by extensive dialysis against phosphate-buffered saline containing 0.01% EDTA at 4°C for 48 h. To remove EDTA, LDL was dialyzed against a 2,000-fold vol of phosphate-buffered saline without EDTA for 48 h at 4°C. LDL was sterilized by passage through a 0.22 μm filter and then used within 7 d. Protein concentrations were determined with a bicinchonic acid protein assay kit (Pierce Chemical, Rockford, IL), using bovine serum albumin as the standard.

Oxidation of LDL. The mixture of sesaminol and its stereoisomers was dissolved in dimethyl sulfoxide with sonication. The final content of the solvent (DMSO) was <1%. Sesaminols were added to a tube containing 2 mM AMVN and LDL (0.2 mg protein/mL, diluted with PBS) to a final concentration of 1 μM (21). The tubes were incubated in a thermostatically controlled water bath for the indicated time. The reaction was stopped by the addition of 1 mM EDTA and 10 μM butylated hydroxytoluene. The lipid peroxidation of LDL was evaluated by measuring the formation of 2-thiobarbituric acid-reactive substances (TBARS). TBARS were calculated as malondialdehyde equivalents, using as the standard freshly diluted malondialdehyde bis(dimethyl acetal), i.e., 1,1,3,3-tetraethoxypropane. Malondialdehyde was prepared by hydrolysis of 1,1,3,3-tetraethoxy-propane (Aldrich Chemical) with 1 N HCl (22).

Procedure for reacting sesaminols with AMVN. For the oxidation reaction, a mixture of 10 mM sesaminols and 18 mM AMVN was dissolved in 18 mL oxygen-saturated acetonitrile and incubated in a screw-cap test tube at 37°C in air for 4 h. The oxidation products were separated by reverse-phase HPLC on a Develosil ODS-5 column (4.6 mm i.d. × 250 mm, Nomura Chemical, Aichi, Japan) using MeOH/H_2O (70:30, vol/vol) as the solvent. These were repurified by normal-phase HPLC on a Develosil SI-60-5 column (4.6 mm i.d. × 250 mm, Nomura Chemical) using *n*-hexane/ethyl acetate (70:30, vol/vol) as the solvent. The elution profile was monitored by measuring the absorbance at 280 nm and a flow rate of 2.5 mL/min. The peak area was determined with a *C*-R3A Chromatopac (Shimadzu, Kyoto, Japan).

Spectroscopy. ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on an NMR JNM-EX-270 spectrometer (JEOL, Tokyo, Japan) using $CDCl_3$ as the solvent and tetramethylsilane as the internal standard (tetramethylsilane δ = 0.00). ^{13}C NMR spectra were measured at 67.5 MHz, and ^1H NMR at 270 MHz. Mass spectra were obtained with a gas chromatograph mass spectrometer system (JMS-DX-300, JEOL). Electron impact spectra were obtained with an ionizing energy of 70 eV. The infrared spectra of samples in liquid film were determined with an FT/IR-8300 device (Japan Spectroscopic, Tokyo, Japan). Ultraviolet spectra were determined with a U-best 50 (Japan Spectroscopic). Wavelengths of maximal light absorption and specific rotations were determined using a DIP-370 spectrometer (Japan Spectroscopic).

Statistical analysis. Results are presented as means ± SD. Data were analyzed by Student's *t*-test.

RESULTS AND DISCUSSION

Antioxidant effect of sesaminols. Reactive oxygen species are involved in the oxidative attack on polyunsaturated fatty acids leading to lipid peroxidation of such biological systems as biological membranes (23,24) or lipoproteins (25). The process of lipid peroxidation is thought to be involved in various types of vascular disease. This observation is consistent with the fact that biological membranes as well as lipoproteins contain high concentrations of polyunsaturated fatty acids which are unstable and susceptible to oxidation. Oxidative modification of LDL may be of particular importance in the pathogenesis of atherosclerosis (26). Therefore, agents that protect LDL from oxidation are of interest as possible antiatherogenic agents. The oxidative modification of LDL by transitional metal ions *ex vivo* appears to be prevented by the addition of antioxidants such as vitamin E (27), probucol (28), butylated hydroxytoluene (29), and flavonoids (30). As shown in Figure 1, we evaluated the inhibitory effects of sesaminols in the oxidative modification of LDL induced by AMVN. Sesaminols (1 μM) exhibited a strong antioxidant effect in terms of decreasing TBARS formation. Sesaminols

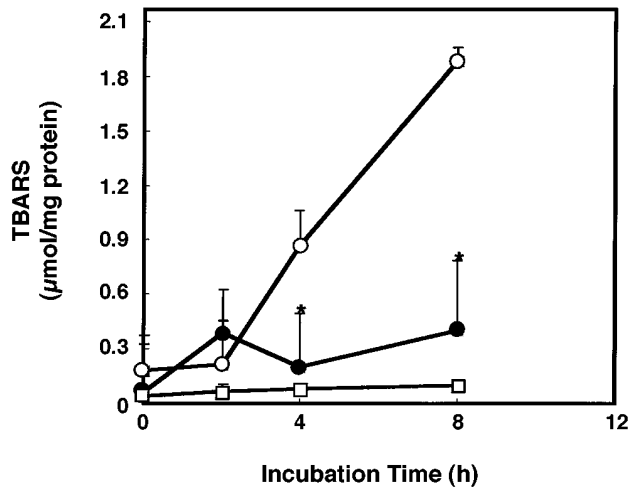

FIG. 1. Time-dependent effect of sesaminols in 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN)-induced low-density lipoprotein (LDL) peroxidation. LDL (0.2 mg protein/mL) was incubated in the absence (native LDL, □) or presence (oxidized LDL, ○) of 2 mM AMVN without or with sesaminols (●) for 2 h at 37°C. The reaction was terminated by the addition of EDTA and butylated hydroxytoluene. Oxidation was monitored by the formation of TBARS. *Significantly different from oxidized-LDL ($P < 0.05$).

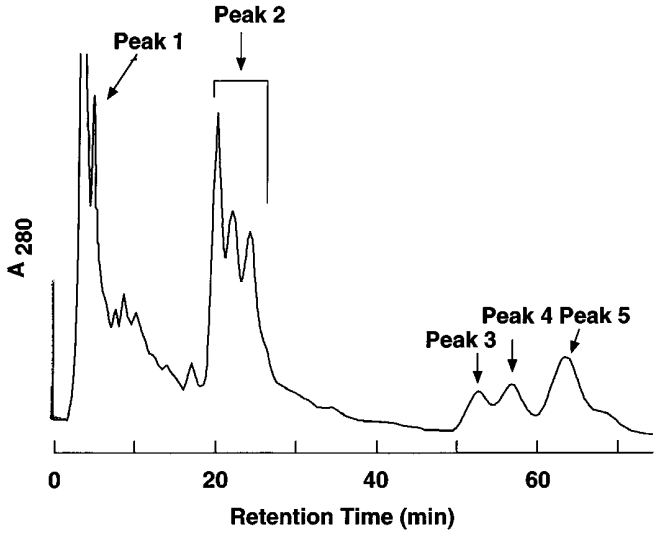

FIG. 2. Representative chromatogram of the high-performance liquid chromatography (HPLC) separation of reaction products of sesaminol and its stereoisomers with AMVN, as determined by absorbance at 280 nm. Sesaminol and its stereoisomers (10 mM) were incubated with AMVN (200 mM) in oxygen-saturated acetonitrile for 4 h at 37°C. An aliquot of the solution was subjected to reverse-phase HPLC on a Develosil ODS-5 column (Nomura Chemical, Aichi, Japan). For abbreviation see Figure 1.

exist as a mixture of sesaminol and its stereoisomers, which are inter-convertible, and we found that there is no significant difference between sesaminol and its stereoisomers in their antioxidant activity. The potent inhibitory effect of sesaminols against lipid peroxidation could be attributed to their ability to scavenge free radicals (3,4).

As suggested by Osawa *et al.* (9,13,19,31,32), dietary antioxidants such as the β-diketone type, including tetrahydrocurcuminoids, curcumin, and eucalyptus leaf waxes must play an important role in protecting against oxidative damages.

Time course of the formation of reaction products. As shown in Figure 2, we isolated five main peaks through HPLC separation. Peaks 1, 3, 4, and 5 increased with incubation time. However, peak 2 decreased gradually with incubation time (Fig. 3) and finally reached a constant peak area. Because the formation of such products reached a maximum after 4 h, we stopped the reaction at 4 h and isolated and identified the reaction products.

Isolation of reaction products. The oxidation products were separated by reverse-phase HPLC using MeOH/H_2O (70:30, vol/vol) as the solvent. Purification of peaks 3, 4, and 5 yielded the following amounts of each product: product 2; 5.9 mg (peak 3); product 3; 7.3 mg (peak 4); and product 4; 14.5 mg (peak 5). Peak 2 was found to be a mixture of sesaminols plus the reaction product, which was further repurified by normal-phase HPLC using *n*-hexane/ethyl acetate (70:30, vol/vol) as the solvent. Pure reaction product or product 1, 12.1 mg (peak 2), was obtained.

Structure determination of the reaction products. Peak 1 was confirmed to contain only the degradation products, because it was found not to possess the sesaminol structure in ^1H NMR spectra. All of the other products named, or products 1–4, which were contained in peaks 2–5, respectively, were confirmed as the adducts of sesaminol structure with AOO$^\bullet$ by NMR and mass spectra. Products 1–4 have essentially the

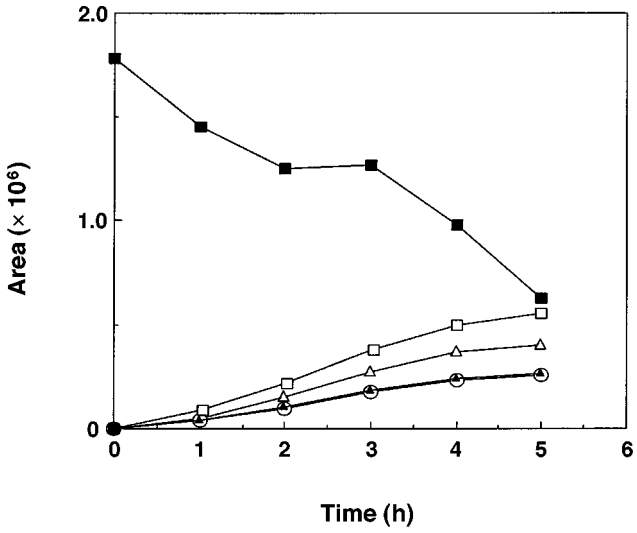

FIG. 3. Time-dependent effect for the oxidation products of sesaminol and its stereoisomers induced by AMVN. Sesaminol and its stereoisomers (10 mM) were incubated with AMVN (200 mM) in oxygen-saturated acetonitrile at 37°C. At the indicated time, aliquots of the solution were subjected to reverse-phase HPLC on a Develosil ODS-5 column [△, peak 1; ■, peak 2 (sesaminol and its stereoisomers plus product); ○, peak 3; ▲, peak 4; □, peak 5]. Peak numbers refer to peaks in Figure 2. For abbreviations see Figures 1 and 2. For manufacturer see Figure 2.

TABLE 1
Summary of the Spectroscopic Analyses of Oxidation Products of Sesaminols[a]

same spectral data except for $[\alpha]^{25}_{D}$ as shown in Table 1. NMR data are summarized in Tables 2 and 3. By comparision with the infrared spectrum of sesaminol, a new absorption was found at 1686 cm^{-1} that was due to the α,β-unsaturated carbonyl. During ^{13}C NMR analysis, the signal of the phenolic carbon at C-2′ of sesaminol (δ 150.7 ppm) shifted to δ 186.6 ppm as a result of the conversion into a carbonyl carbon in the oxidation products. In addition, a large shift in the signal of the C-5′ from δ 140.8 ppm in sesaminol to δ 101.4 ppm in the oxidation products suggested that a 1-cyano-1,3-dimethyl-butyl-peroxyl group derived from AMVN attached to the C-5′ position of sesaminol. Further detailed examination of the ^{1}H NMR and ^{13}C NMR spectra as well as other analyses of the oxidation products using instrumentation suggested that the chemical structures of the four reaction products are essentially the same. As described in the Materials and Methods section, sesaminol and 2-episesaminol exist as the major components in sesame seed oil, and 6-episesaminol and (+) diasesaminol exist as the minor components (3,4). Although it is possible that each of four stereoisomers of sesaminols reacts with AOO$^\bullet$ (the alkoxyl radical generated by AMVN) to produce four stereoisomers which have different stereochemistry at C-5′ and C-1[a] (Scheme 2), only four stereoisomers were found to be produced as the main reaction products. By instrumental analyses, we cannot confirm the stereochemistry of four reaction products; therefore, we can only propose the chemical structure for all of the reaction products without stereochemistry as shown in Scheme 2. This process may represent the antioxidant mechanism of sesaminols with AMVN. The first step may be the abstraction of hydrogen. The resulting sesaminol radicals can then react with the peroxyl radicals. We therefore suggest that sesaminols are chain-breaking antioxidants that react with peroxyl radicals to stop the autoxidation of polyunsaturated fatty acids. Peroxyl radicals are known to be chain-carrying radicals in lipid peroxidation (18). Our group has elucidated the reactions of peroxyl radicals with such phenolic-type antioxidants as tetrahydrocurcurminoids and cyanidin 3-*O*-D-glucoside (19,20). α-Tocopherol is highly reactive with free radicals and reactive oxygen species and forms a variety of products. For example, it traps free radicals generated from such radical initiators as benzoyl peroxide (33), AMVN (17), and *tert*-butyl hydroperoxide (16) and reacts with alkyl and alkoxyl radicals to produce alkylated derivatives (16,17,33–36). Free radical oxidation of α-tocopherol was reported to take place *via* the tocopheroxyl radical as an intermediate (37).

Sesame seed and oil are used for pharmaceutical purposes. These substances are also important in traditional Indian medicine, where sesame oil is used to prepare extracts of herbs and medicinal plants (38). Sesame oil is also believed to be suitable for application to the skin because of its spreading and antioxidant properties (38). Our studies have mainly fo-

cused on the physiological and pharmacological roles of sesaminols because this substance is readily available and is widely used. It is thus important to investigate the inhibitory effects of sesaminols against oxidative damage and its mechanism of action in biological systems. We are now conducting detailed studies on the effects of sesaminols in preventing oxidative damage in an animal model to expand our present findings to clinical applications.

S-Methyl Derivatives from Thiol Compounds by the Pyrolytic Reaction with Trimethylsulfonium Hydroxide

Klaus Vosmann[a], Erika Klein[b], and Nikolaus Weber[b,*]

[a]Institut für Chemie und Physik der Fette, and [b]Institut für Biochemie und Technologie der Fette, H.P. Kaufmann-Institut, BAGKF, D-48147 Münster, Germany

ABSTRACT: Base-catalyzed transesterification of acyl lipids with methanol in the presence of trimethylsulfonium hydroxide (TMSH) is an easy and convenient method for the preparation of fatty acid methyl esters for gas chromatography (GC) analyses. Free fatty acids are converted to fatty acid methyl esters by the pyrolytic reaction with TMSH as well. We have found that lipids and other compounds containing thiol groups are also converted easily to the corresponding methyl sulfides (methyl thioethers) by the pyrolytic reaction with TMSH occurring in the injector of the gas chromatograph. For example, alkane thiols such as dodecane thiol and octadecane thiol are converted to the corresponding alkyl methyl sulfides, whereas bis(methylthio) derivatives are formed from α,ω-alkane dithiols, e.g., 1,8-octanedithiol, and from 2,3-dimercaptopropan-1-ol (dimercaprol). Furthermore, 3β-mercaptocholest-5-ene (thiocholesterol) is converted to 3-methylthiocholest-5-ene by the same reaction. The *S*-methylation reactions which finally lead to the corresponding methylthio derivatives of lipids and other compounds with thiol groups may be of diagnostic value for the structural analysis of such compounds by GC and GC/mass spectrometry.
Lipids 33, 1037–1041 (1998).

Trimethylsulfonium hydroxide (TMSH) is a very useful reagent for the preparation of fatty acid methyl esters for gas chromatography (GC) analysis by base-catalyzed transmethylation of acyl lipids (1–6) or by the pyrolytic decomposition of the TMSH salts of fatty acids in the GC injector (7). Recently, we showed that various lipids having acidic substituents such as amino, amide, or hydroxy groups form *N*- and *O*-methylated derivatives, in varying proportions, by the pyrolytic reaction with TMSH (8–10). Thiol compounds are versatile intermediates for various technical applications such as rubber substitutes (11–14), stabilizers for polyvinyl chloride (15), antioxidants (16,17), lubricant additives (11–13,16,18,19), wetting agents and surface-active chemicals (20,21) as well as coatings (11,18,22). They are also used for the preparation of pharmaceuticals (17,23), cosmetic formulations (17,19,21), insecticides and insect repellents (12,24) as well as compounds with antimicrobial activity (25). Thiols are a further series of compounds having acidic properties which might be converted to the corresponding *S*-methyl derivatives by the pyrolytic reaction with TMSH. This study demonstrates the use of TMSH in the *S*-methylation of lipids and other compounds containing thiol groups for GC and GC/mass spectrometry (MS) analyses.

MATERIALS AND METHODS

Chemicals. Dodecanethiol and octadecanethiol, didodecyl sulfide, 1,8-dimercaptooctane, 2,3-dimercaptopropan-1-ol (dimercaprol; BAL), *threo*-1,4-dimercapto-2,3-butandiol (dithiothreitol, Cleland's reagent), mercaptoacetic acid (thioglycolic acid) as well as its methyl- and 2′-ethylhexyl esters, 3,3′-thiodipropionic acid methyl ester, 2-mercaptopropionic acid (thiolactic acid) and 3-mercaptopropionic acid, *N*-(2-mercaptopropionyl)-glycine (tiopronin), 2-amino-3-mercapto-3-methylbutanoic acid (DL-penicillamine), cholest-5-ene-3β-thiol (thiocholesterol), and 2-ethylhexanol were purchased from Sigma-Aldrich-Fluka (Deisenhofen, Germany). TMSH reagent (0.2 M TMSH in methanol) was a product of Macherey-Nagel (Düren, Germany).

Preparation of standards. Methyl esters of carboxylic acids as well as methyl thioethers were obtained by the reaction of the original compounds having carboxy and/or thiol groups with diazomethane (26). Derivatives with methyl ester and/or methylthio groups were purified by thin-layer chromatography on 0.3 mm Silica Gel H (E. Merck, Darmstadt, Germany) layers using hexane/diethyl ether (99:1, vol/vol) as the solvent system for alkyl methyl sulfides, hexane/diethyl ether (95:5, vol/vol) for cholesteryl methyl sulfide and mercaptoacetic acid derivatives, hexane/diethyl ether (1:1, vol/vol) or diethyl ether for 2,3-dimercaptopropan-1-ol and dithiothreitol as well as their methylthio derivatives.

Derivatization for GC. Under standard conditions, 30–60 μL TMSH reagent was added to 0.4 mg of a compound containing thiol groups (molar ratio TMSH/thiol and/or carboxy equivalents, *ca.* 4:1). The derivatization mixture, 1–2 μL, was directly injected into the gas chromatograph.

GC. GC of compounds containing thiol groups as well as of their derivatives formed by the pyrolytic reaction with TMSH was carried out in a Hewlett-Packard (Böblingen,

Germany) HP-5890 Series II gas chromatograph fitted with a flame-ionization detector. *S*-Methyl derivatives (methyl thioethers) of various thiol compounds were chromatographed on a 0.12 μm DB-23 fused-silica capillary column (Macherey-Nagel), 40 m × 0.18 mm i.d using hydrogen as the carrier gas. *S*-Methyl derivatives of short-chain thiol compounds were separated at 60°C for 5 min, followed by linear programming from 60 to 240°C at 10°C per min. The long-chain alkyl methyl sulfides were separated initially at 200°C for 5 min, followed by linear programming from 200 to 240°C at 10°C per min. The final temperature was kept constant for 20 min. Cholesteryl methyl sulfide was separated isothermally at 270°C on a 0.52 μm HP-1 fused-silica column (Hewlett-Packard), 25 m × 0.32 mm i.d. The split ratio was 1:10; the injector as well as flame-ionization detector temperatures were 280°C. GC peaks were assigned by comparison of their retention times with those of known standards.

GC/MS. GC/MS of methylthio derivatives of compounds containing thiol groups was performed at electron impact mode (70 eV) on a Hewlett-Packard HP-5890 Series II/5989 A gas chromatograph/mass spectrometer as described recently (8,9). The GC instrument was equipped with a 0.23 μm Permabond OV-1 fused-silica capillary column (Macherey-Nagel) 25 m × 0.32 mm i.d. The carrier gas was He at a flow rate of 1.0 mL/min. The column temperature was initially kept at 50 or 70°C for 5 min and then programmed from 50 or 70°C to 240°C at 12°C/min; the final temperature was held for 5 min. Other operating conditions were split/splitless injector in splitless mode (temperature 300°C), interface temperature 280°C, and ion source temperature 200°C.

Structural analysis. GC peaks were assigned by comparison of their retention times and mass spectral data with those of commercial or synthetic standards. Similarly, structural assignments were made for standards containing thiol groups or their methylthio derivatives which were prepared by the reaction with diazomethane. Peaks of *S*-methylated compounds obtained by the pyrolytic reaction with TMSH (7) were assigned a particular structure if ions corresponding to all the important mass fragments were present.

RESULTS AND DISCUSSION

TMSH is involved in two very different types of chemical reactions. The first is as a base catalyst for the mild transesterification of acyl lipids. Commercial TMSH reagent is a 0.2 M methanolic TMSH solution which transmethylates acyl lipids such as triglycerides to the corresponding fatty acid methyl esters at room temperature within a few minutes (1–6). Other functional groups of lipids such as hydroxy, amino, or amide groups do not react under these conditions with TMSH reagent either at room temperature or under reflux conditions (8–10).

The second type of reaction is the pyrolytic reaction of TMSH with various acidic groups of compounds occurring in the injector of the gas chromatograph at high temperatures. Acidic groups of compounds such as carboxylic functions and phenolic hydroxy groups (2,7) were transformed by the pyrolytic reaction of TMSH almost completely to the corresponding *O*-methyl derivatives. In contrast, this reaction leads to partial methylation if less acidic groups are present, as observed for hydroxy, amino, and amide groups (8–10).

Because of the higher acidity of the SH-group, conversion to the corresponding methylthio derivatives by the pyrolytic reaction of thiol compounds with TMSH might be expected to be as high as that of free fatty acids. Therefore, we have reacted various thiol compounds with TMSH reagent at different temperatures and checked the formation of reaction products by thin-layer chromatography. At room temperature incomplete derivatization was found even after 2 h, whereas almost complete *S*-methylation was observed within 30 min in a closed tube at 70°C. For GC derivatization the pyrolytic reaction of TMSH in the GC injector at 280°C was tested for its usefulness in *S*-methylation of various thiol compounds.

$$R - SH \xrightarrow[250°C]{TMSH} R - S - CH_3$$

Under standard conditions, long-chain alkanethiols such as 1-dodecanethiol and 1-octadecanethiol were converted almost completely (>99%) to methyl dodecyl sulfide (methyl dodecyl thioether; *m/z* (rel%) 216 (48), $[M]^+$) and methyl octadecyl sulfide (methyl octadecyl thioether; *m/z* (rel%) 300 (34), $[M]^+$), respectively, as was checked by GC/MS (Table 1). In addition to the molecular ion peaks, the mass spectra of both *S*-methylated derivatives showed typical fragments that were formed by loss of the *S*-methyl group {*m/z* (rel%) 201 (100) $[M - CH_3]^+$ and *m/z* (rel%) 285 (100) $[M - CH_3]^+$, respectively}, while the tendency for the loss of methyl thiol was not strongly pronounced. The fragment *m/z* 61 was formed by α-cleavage of the C-C bond next to the *S*-atom (Table 1). These data agree with those given in the literature (27,28).

Studies concerning the optimal molar ratio between alkyl thiol substrates and TMSH reagent revealed that the ratio of pyrolytic conversion of thiol compounds to the corresponding *S*-methylated products in the presence of TMSH depended on the molar excess of the methylating reagent (Fig. 1). Extensive conversion was reached already at a molar ratio of about 2:1 (TMSH/thiol equivalents). Under these conditions, dodecanethiol was converted to an extent of 96% to methyl dodecylsulfide. In contrast, lipids containing hydroxy, amine, and amide groups were not found to be converted completely to the corresponding *O*-methyl or *N*-methyl derivatives, even if a 20-fold excess of TMSH was used for derivatization (8–10).

In vulcanization, bifunctional thiol compounds such as 1,6-dimercaptohexane and 1,8-dimercaptooctane are used for the formation of polythioethers by addition reaction onto α,ω-diene monomers (12). Under standard conditions (molar ratio TMSH/thiol equivalent = 4:1), the product of the pyrolytic reaction of 1,8-dimercaptooctane with TMSH was 1,8-

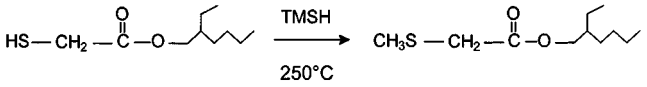
[b]Base peak: *m/z* 57.

bis(methylthio)octane as was checked by gas chromatographic comparison with synthetic standards as well as by GC/MS (Table 1). The dominant fragment peak at *m/z* 61 (base peak) for both compounds is formed by α-cleavage as mentioned above. By using a suboptimal TMSH concentration (molar ratio TMSH/thiol equivalent = 2:1), two reaction products, i.e., 1-mercapto-8-methylthiooctane and 1,8-bis(methylthio)octane, were observed in the gas chromatogram in addition to small proportions of nonderivatized 1,8-dimercaptooctane (data not shown).

$$HS-[CH_2]_8-SH \xrightarrow[250°C]{TMSH} CH_3S-[CH_2]_8-SH + CH_3S-[CH_2]_8-SCH_3$$

Mercaptoacetic acid 2′-ethylhexylester (thioglycolic acid 2′-ethylhexylester) and other mercaptoacetic acid esters are used as stabilizers for polymers (15). Under standard conditions, mercaptoacetic acid 2′-ethylhexylester was *S*-methylated to an extent of (>94%) to the corresponding methyl sulfide by the pyrolytic reaction with TMSH, whereas other possible reaction products such as mercaptoacetic acid methylester and its methylthio derivative as well as 2-ethylhexan-1-ol and its methoxy derivative were not detected by gas chromatographic analysis. These data suggest that the formation of methylthio acetic acid 2′-ethylhexylester is by far the preferred reaction when mercaptoacetic acid 2′-ethylhexylester is reacted with TMSH under pyrolytic conditions.



Retention time of methylthio acetic acid 2′-ethylhexylester was compared with that of a synthetic standard that had been prepared by the reaction of mercaptoacetic acid 2′-ethylhexylester with diazomethane. In addition, the reaction product was analyzed by MS (Table 1). The typical fragmentation of this thioether led to two important fragments at *m/z* 157 and 61 because the ester group stabilizes the positive ions formed by α-cleavage in contrast to other thioethers which do not have further stabilizing groups.

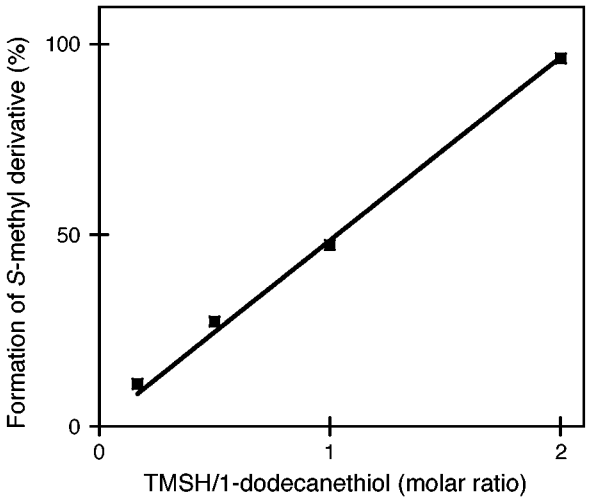


FIG. 1. Formation of methyl dodecyl sulfide (methyl dodecyl thioether) in relation to the molar ratio of trimethylsulfonium hydroxide (TMSH) (values are mean of two determinations).

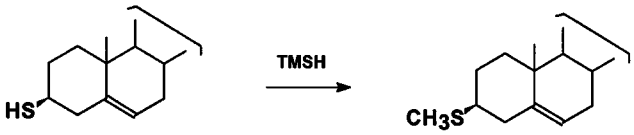
Similar results were obtained for the pyrolytic reaction of mercaptoacetic and mercaptopropionic acids with TMSH. Obviously, these thiol compounds were almost completely (>99%) converted to methylthioacetic acid methyl ester and methylthiopropionic acid methyl ester, respectively, which were compared by GC and GC/MS with the corresponding derivatives prepared by the reaction of mercaptoacetic or mercaptopropionic acids with diazomethane (Table 1).

However, the pyrolytic reaction of compounds having additional amino groups, e.g., penicillamine and tiopronin, mainly led to partially methylated derivatives even in the presence of high molar excess of TMSH. For example, 2-amino-3-mercapto-3-methylbutyric acid (penicillamine) was predominantly derivatized to 2-*N*-methylamino-3-methylthio-3-methylbutyric acid methyl ester {*m/z* (rel%): 191 (0.7; $[M]^+$), 103 (25.4; $[CH_3\text{-}NH\text{-}CH_2\text{-}COOCH_3]^+$), 89 (100; $[(CH_3)_2\text{-}C\text{-}S\text{-}CH_3]^+$}, whereas 2-*N,N*-dimethylamino-3-methylthio-3-methyl-butyric acid methyl ester {*m/z* (rel%): 205 (0.9; $[M]^+$), 116 (100; $[(CH_3)_2N\text{-}CH\text{-}COOCH_3]^+$), 89 (26.9; $[(CH_3)_2C\text{-}S\text{-}CH_3]^+$} was formed in small proportions only. Similarly, *N*-(2-mercaptopropionyl)-glycine (tiopronin) which is used as an antidote against heavy metal poisoning was mainly derivatized to *N*-(2-methylthiopropionyl)-glycine methyl ester {*m/z* (rel%): 191 (9.8; $[M]^+$), 145 (100; $[M - S\text{-}CH_2]^+$), 88 (8.3; $NH\text{-}CH_2\text{-}COOCH_3]^+$), 75 (57.6; $[CH_3\text{-}CH\text{-}S\text{-}CH_3]^+$)}. In addition, small proportions of *N*-methyl-*N*-(2-methylthiopropionyl)-glycine methyl ester {*m/z* (rel%): 205 (9.6; $[M]^+$), 159 (100; $[M - S\text{-}CH_2]^+$), 102 (31.2; $CH_3N\text{-}CH_2\text{-}COOCH_3]^+$), 75 (45.1; $[CH_3\text{-}CH\text{-}S\text{-}CH_3]^+$} were formed. These results agree with our previous observations on the incomplete derivatization by TMSH of lipids containing amino and amide groups (9,10). Therefore, derivatization by the pyrolytic reaction with TMSH of thiol compounds having additional amino or amide groups is not recommended without limitation.

The alkyl sulfides (dialkyl sulfides, alkyl thioethers), prepared from the corresponding thiol compounds, are mainly used as stabilizers and antioxidants for technical products such as polymers and lubricants (15–17). Cleavage of the sulfide (thioether) bond by the pyrolytic reaction with TMSH was not observed for dialkyl sulfides, e.g., didodecyl sulfide, but for 3,3′-thiodipropionic acid methyl ester suggesting an activation of the sulfide bond by the two neighboring β-carboxy groups (data not shown).

2,3-Dimercaptopropan-1-ol (dimercaprol, BAL) is a highly effective antidote against arsenic and heavy metal compounds (23). By using a molar ratio of TMSH/thiol equivalent (≈3:1), dimercaprol was converted almost completely (>96%) to the corresponding 2,3-bis(methylthio)-propan-1-ol as is obvious from GC comparison with synthetic standards and GC/MS studies (Table 1). Typical mass fragments were found at *m/z* 61 (α-cleavage) and 91. However, using a suboptimal molar ratio of 1:1 (TMSH/thiol equivalent) partially *S*-methylated isomers of dimercaprol, i.e., 2-methylthio dimercaprol and 3-methylthio dimercaprol, were detected together with the nonderivatized compound and the 2,3-bis(methylthio) derivative (data not shown). Under the conditions described, *O*-methylation of the hydroxy group of dimercaprol was observed in trace amounts only. Similar results were obtained for dithiothreitol (*threo*-1,4-dimercapto-2,3-butandiol; Table 1).

Cholest-5-ene 3β-thiol (thiocholesterol), i.e., a thioanalog of cholesterol, is used in biochemical studies (29,30). Under standard conditions, more than 90% of cholest-5-ene 3β-thiol was converted to the cholest-5-enyl 3-methyl sulfide (3-methylthiocholest-5-ene) by the pyrolytic reaction with TMSH.



The 3-methylthio derivative was identified by comparison with a synthetic standard as well as by GC/MS. Typical mass fragments are given in Table 1. The mass spectrum is very similar to that of 3-*O*-methylcholesterol. The only difference was observed for the molecular ion at *m/z* 416 instead of *m/z* 400 and the fragment at *m/z* 401 (loss of CH_3 group) instead of *m/z* 385 due to the higher molecular mass of *S* (32 amu) as compared to *O* (16 amu).

In summary, our data show that *S*-methylated derivatives are formed, almost quantitatively, by the pyrolytic reaction of thiol compounds with TMSH in the GC injector, whereas thiol groups react slowly with the TMSH reagent at room temperature. The extent of the formation of *S*-methylated products depends particularly on the molar excess of the TMSH reagent. However, the pyrolytic reaction of compounds containing both thiol and amino groups with TMSH leads to incomplete derivatization of the NH_2 group. The use of TMSH is therefore recommended for the analysis of thiol compounds that do not contain additional amino groups. The

pyrolytic formation of *S*-methyl derivatives with TMSH can be of diagnostic value for the structural analysis of thiol compounds in samples by GC and GC/MS. It is worth noting that long-chain dialkyl sulfides (dialkyl thioethers) are neither cleaved nor converted to the corresponding methylthio derivatives at all.

A Semiautomated Enzymatic Method for Determination of Nonesterified Fatty Acid Concentration in Milk and Plasma

Michael A. Christmass[a,b,*], Leon R. Mitoulas[a], Peter E. Hartmann[a], and Peter G. Arthur[a]

Departments of [a]Biochemistry and [b]Human Movement, The University of Western Australia, Nedlands 6907, Australia

ABSTRACT: An enzymatic assay for the determination of nonesterified fatty acid concentrations in milk and plasma is described. The procedure is semiautomated for use with a plate luminometer or plate spectrophotometer and enables routine batch processing of large numbers of small samples (≤5 μL). Following the activation of nonesterified fatty acids (NEFA) by acyl-CoA synthetase, the current assay utilizes UDP-glucose pyrophosphorylase to link inorganic pyrophosphate to the production of NADH through the reactions catalyzed by phosphoglucomutase and glucose-6-phosphate 1-dehydrogenase. With this assay sequence the formation of NADH from NEFA is complete within 50 min at 37°C. Enzymatic spectrophotometric techniques were unsuitable for NEFA determination in human milk due to the opacity of the sample. The use of the NADH-luciferase system has overcome this problem, allowing the enzymatic determination of NEFA in human milk. Sample collection and treatment procedures for milk and plasma have been developed to prevent enzymatic lipolysis and to limit interference from enzymes present in milk. The recovery of palmitic acid added to milk and plasma samples was 94.9 ± 2.9 and 100 ± 4.5%, respectively. There was no difference (P = 0.13) in plasma NEFA concentrations determined by the current method and a commercially available enzymatic spectrophotometric technique (Wako NEFA-C kit). Plasma NEFA concentrations determined by gas chromatography were 28% higher compared to both the Wako NEFA-C kit and the current method.

Lipids 33, 1043–1049 (1998).

Determination of the nonesterified fatty acid (NEFA) concentration in biological fluids is of importance in a wide variety of clinical and experimental conditions. As a consequence, considerable effort has been applied to the development of accurate methods for NEFA determination that are sufficiently convenient for routine analysis. Techniques for analysis of NEFA include titrimetry with alkali after extraction (1), colorimetry of NEFA-copper or -cobalt soaps (2), and gas chromatography (GC; [3]). Titrimetric and colorimetric methods enable quantification of NEFA, whereas GC also provides identification of individual NEFA. Nevertheless, these methods involve the use of hazardous chemicals and are complex and labor-intensive.

More recently, enzymatic techniques based on the specificity of acyl-CoA synthetase have been established (4). These methods, although unable to identify individual NEFA, do not require extraction of the sample with organic solvents and hence have enabled the development of relatively simple and convenient procedures. However, current enzymatic methods are costly (Wako NEFA-C kit; Wako Pure Chemical Industries Ltd., Osaka, Japan) and have not previously been reported for the determination of NEFA in milk.

A further limitation of enzymatic techniques is the possibility of interference from biologically active substances in the sample. Reducing agents (ascorbic acid, bilirubin) and alkaline phosphatase inhibit enzymatic colorimetric (5) and luminometric (6) methods, respectively. Alternatively, the action of lipases present in the sample may result in overestimation of NEFA concentration (7). Several methods for collection and treatment of samples for NEFA determination have been described (6–9). However, the appropriate method of choice is dependent on the analytical technique, assay sequence, and nature of the sample. In this context, a sample collection and treatment method suitable for enzymatic determination of NEFA concentration in milk has not previously been described.

Our research on (i) the role of NEFA in the control of human milk synthesis and (ii) NEFA metabolism during exercise involves the collection of large numbers (≥600) of small samples (≤5 μL). To facilitate batch processing of these samples, a suitable, semiautomated method was required. Accordingly, we have developed an enzymatic assay which has been linked to plate luminometry to enable the routine determination of NEFA in milk and plasma. In addition, collection and treatment procedures for milk and plasma, suitable for enzymatic determination of NEFA, have been established.

MATERIALS AND METHODS

Subjects. Human milk samples were obtained from volunteers recruited from the Nursing Mothers' Association of Australia (Western Australian Branch). Human plasma was obtained by finger prick from nonfasting volunteers. Volunteers provided written, informed consent and all procedures were approved by

Materials. Bacterial luciferase E.C. 1.14.14.3 (from *Vibrio harveyi*), bovine serum albumin (BSA; essentially fatty acid-free, 0.005%), *n*-caproic acid (6:0, Na salt, 99% pure), *N*-tris[hydroxymethyl]methyl-2-aminoethanesulfonic acid hemisodium salt (TES; free acid, 99.5% pure), 3-[*N*-morpholino] propanesulfonic acid hemisodium salt (MOPS, 99% pure), oleic acid (18:1n-9, Na salt, 95% pure), palmitic acid (16:0, Na salt), and tetradecylaldehyde (80% pure) were obtained from Sigma Chemical Company (Castle Hill, Australia). Dipotassium hydrogen orthophosphate 3-hydrate ($K_2HPO_4 \cdot 3H_2O$, 99.0% pure) and potassium dihydrogen orthophosphate (KH_2PO_4, 99% pure) were obtained from BDH Chemicals (Port Fairy, Australia). Ethylenediaminetetraacetic acid (EDTA, tetra-Na salt, 99% pure), hydrochloric acid (HCl, 31.5% w/w), and sodium hydroxide (NaOH, 97% pure) were obtained from Ajax Chemicals (Sydney, Australia). Acyl-CoA synthetase E.C. 6.2.1.3 (from *Pseudomonas fragi*), adenosine triphosphate (ATP; di-Na salt, 99% pure, from yeast), coenzyme A (CoA; lyophilized free acid, grade 1), dithiothreitol, flavin mononucleotide (FMN, 95% pure), glucose-6-phosphate 1-dehydrogenase E.C. 1.1.1.49 (from *Leuconostoc mesenteroides*), nicotinamide adenine dinucleotide (NAD, 98% pure, from yeast), reduced nicotinamide adenine dinucleotide (NADH, di-Na salt, 98% pure), phosphoglucomutase E.C. 5.4.2.2 (from rabbit muscle), triethanolamine (TEA), uridine-5′-diphosphoglucose (UDP-glc, di-Na salt, 98% pure, from yeast), and uridine-5′-diphosphoglucose pyrophosphorylase E.C. 2.7.7.9 (from beef liver) were obtained from Boehringer Mannheim (North Ryde, Australia). Lauric acid (12:0, A grade, 99.5% pure) was obtained from California Corporation for Biochemical Research (Los Angeles, CA). The Wako NEFA-C kit was obtained from Wako Pure Chemical Industries Ltd. Materials used for GC determination have been listed previously (10).

Assay principles. (i) Nonesterified fatty acids. Following the activation of NEFA by acyl-CoA synthetase (4), the current assay sequence utilizes UDP-glucose pyrophosphorylase, phosphoglucomutase and glucose-6-phosphate 1-dehydrogenase to link inorganic pyrophosphate to the reduction of NAD to NADH as outlined below:

$$\text{ATP} + \text{NEFA} + \text{CoA} \xrightarrow{\text{acyl-CoA synthetase}} \text{acyl}-\text{CoA} + \text{AMP} + \text{PPi} \quad [1]$$

$$\text{PPi} + \text{UDP}-\text{glc} \xrightarrow{\text{UDP-glucose pyrophosphorylase}} \text{glucose-1-phosphate} + \text{UTP} \quad [2]$$

$$\text{glucose-1-phosphate} \xrightarrow{\text{phosphoglucomutase}} \text{glucose-6-phosphate} \quad [3]$$

$$\text{glucose-6-phosphate} + \text{NAD}^+ \xrightarrow{\text{glucose-6-phosphate 1-dehydrogenase}} \text{6-phosphoglucono-}\delta\text{-lactone} + \text{NADH} + \text{H}^+ \quad [4]$$

The amount of NADH present is directly proportional to the concentration of NEFA in this reaction sequence.

(ii) Luminescence detection. The principle of the luminescent method, outlined below, has been described previously (11):

$$\text{NADH} + \text{H}^+ + \text{FMN} \xrightarrow{\text{oxidoreductase}} \text{NAD}^+ + \text{FMNH}_2 \quad [5]$$

$$\text{FMNH}_2 + \text{RCHO} + \text{O}_2 \xrightarrow{\text{bacterial luciferase}} \text{FMN} + \text{RCOOH} + \text{H}_2\text{O} + \text{light} \quad [6]$$

This process is metabolite-independent and involves the kinetic measurement of NADH. The amount of light output measured is directly proportional to the NADH present.

The technique of luminescence detection (11) has been modified and semiautomated for the measurement of lactose, galactose, β-hydroxybutyrate, and D-lactate (12) with the ML2250 Microtiter Plate Luminometer (Dynatech Laboratories, Chantilly, VA). In the current study, this technique (12) has been adapted for the determination of NEFA in milk and plasma.

Methods. (i) Sample collection and treatment. Milk samples were collected from mothers at the Department of Biochemistry, The University of Western Australia. Mothers expressed a small amount of milk (<1 mL) before and after each breast feed. Subsamples (250 µL) for NEFA determination were taken immediately and 400 mM EDTA (20 µL) was added according to Chappell *et al.* (13). Samples were frozen at −80°C until required for assay. Prior to assay, milk samples were thawed and then incubated at 80°C in a water bath for 5 min. Following incubation, samples were sonicated (Branson Sonifer B-12; Branson Ultrasonics Corp., Danbury, CT) for 20 s and a subsample (50 µL) was acid-denatured. The method of acid denaturation was modified from Kather and Weiland (6) and involved the addition of 1 M HCl (50 µL) to the 50 µL subsample which was mixed and left to stand at room temperature for 1 min. Samples were neutralized with an equal volume of 1 M NaOH in 100 mM TES.

Finger-prick blood samples were collected in heparinized hematocrit tubes (Chase Instruments, Glen Falls, VT) and centrifuged (H.I. Clements, North Ryde, Australia) for 5 min at $8000 \times g$. Plasma was treated at collection according to a modification of the acid denaturation procedure used for milk. Five microliters of plasma was added to the same volume of 200 mM HCl, mixed, and allowed to stand for 1 min at room temperature. The sample was neutralized by addition of an equal volume of 200 mM NaOH in 100 mM TES and stored at −80°C until required for assay. For GC analysis plasma was obtained from the Blood Transfusion Service of Western Australia.

(ii) Working solutions: reagents. Assay reagent: ATP (4 mM), $MgCl_2$ (10 mM), CoA (30 mM in 25 mM MOPS buffer, pH 5), UDP-glc (3 mM), NAD^+ (8.5 mM), acyl-CoA synthetase (1.2 U/mL), UDP-glucose pyrophosphorylase (0.8 U/mL in 50 mM TEA and 200 µM dithiothreitol), phosphoglucomutase (13.4 U/mL), glucose-6-phosphate 1-dehydro-

genase (6 U/ml), Triton X-100 (0.03%, vol/vol) in 100 mM TEA, pH 8.4. Control reagent: assay reagent excluding acyl-CoA synthetase. Components for the assay/control reagent (except phosphoglucomutase, glucose-6-phosphate 1-dehydrogenase) were stored as stock solutions and were stable for at least 3 mon at −80°C. The complete assay and control reagents were aliquoted and stored at −80°C and were stable for 1 mon. The bioluminescent reagent was prepared according to Thompson *et al.* (12): potassium phosphate (100 mM), BSA (1.6%), EDTA (4 mM), FMN (8 μM), tetradecylaldehyde (0.1%), and bacterial luciferase (0.4 mg/mL) in TES (300 mM, pH 6.8) was aliquoted and stored at −80°C and was stable for at least 4 mon (13). Reagents for the Wako NEFA-C kit were prepared according to manufacturers' instructions. Reagents prepared for modification of the Wako NEFA-C kit have been outlined previously (14).

(ii) Working solutions: standards. A 1 mM NEFA standard was prepared by adding 16:0 to a heated solution of 4% BSA and 0.1% Triton X-100 (50°C). This solution was briefly sonicated and diluted with the BSA/Triton solution to prepare individual standards (range 0–500 μM) which were stored at −20°C. Standards for the Wako NEFA-C kit were prepared according to manufacturers' instructions.

Procedures. Standards were heated to 37°C and vortexed. Two microliters (plasma) and 5 μL (milk) of each standard, sample, blank, and quality control were pipetted in triplicate into a 96-well V-bottom microtiter plate (Flow Laboratories, McLean, VA). Two or 5 μL of either assay or control reagent was added to each well. The plate was mixed (Denley Welltech Wellmixx2, Cytosystems, Castle Hill, Australia), sealed (plate sealer, ICN Biomedicals, Aurora, CA), and incubated at 37°C for 60 min. The procedure for plate luminometry was modified from Thompson *et al.* (12). The reaction was stopped with the addition of 200 μL NaOH (20 mM). Five-microliter aliquots from each well were transferred to a Microlite® 96-well flat-bottom plate (Dynatech Laboratories), diluted with 150 μL NaOH (10 mM), and reacted with 15 μL of bioluminescent reagent in a ML2250 Microtiter Plate Luminometer (Dynatech Laboratories). The luminometer was programmed for a 5-s delay after addition of the bioluminescent reagent which was followed by a 5-s read period. The peak and integrated light response during the read period were automatically calculated. The sample concentration was determined by calculation relative to a standard curve.

The current method for plasma was adapted for use with a plate spectrophotometer (Titertek Multiskan® MCC/340 plate reader; Flow Laboratories) according to the following modifications: 50 μL of each sample, standard, blank, and quality control was plated in duplicate and 50 μL of either assay or control reagent was added to each well. Following incubation, 50 μL of double-deionized water was added to each well and absorbance was measured at 340 nm on the plate spectrophotometer.

Samples were analyzed using the Wako NEFA-C kit according to either manufacturers' instructions or Johnson and Peters (14) using a plate spectrophotometer (Titertek Multiskan®). Assay procedures for NEFA analysis by GC have been previously described (10). Briefly, lipids were extracted from plasma into methanol/chloroform (1:1, vol/vol) with internal standard (heptadecanoic acid). Lipid extracts, evaporated to dryness under N_2 at 40°C, were dissolved in hexane/*tert*-butyl methyl ether (200:3, vol/vol). Nonesterified fatty acids were separated (porasil silica column) and evaporated to dryness under N_2. Dried NEFA samples were methylated by the addition of H_2SO_4 in methanol and incubated at room temperature for 40 min. Methyl esters were extracted into hexane and evaporated to dryness under N_2. Toluene containing internal standard (methyl pentadecanoic acid) was added and methyl esters were separated and quantified by GC at 150°C [(Shimadzu GC-8A (Kyoto, Japan), glass column, 2 m length and 2.6 mm internal diameter packed with 10% SP-2340 on 100/120 Chromosorb (Supelco, Bellefonte, PA)].

Statistics. Paired and unpaired *t*-tests were used to determine the significance of differences between plasma sample collection and treatment procedures and differences in NEFA concentrations determined between methods. Statistical analysis was performed using Statview SE + Graphics® (Abacus Concepts, Inc., Berkeley, CA). All results presented are means ± SE unless stated otherwise.

RESULTS AND DISCUSSION

Our aim was to develop an assay for determination of NEFA concentration in large numbers (≥600) of small (≤5 μL) human milk and plasma samples. An appropriate technique was required to enable routine processing of these samples. In this context the current method has been developed as a semiautomated procedure utilizing either a Microtiter plate luminometer or a Titertek multiscan plate spectrophotometer and 96-well microtiter plates.

Standards. To avoid underestimation of NEFA concentration, standards were prepared with 4% BSA based on the method of Miles *et al.* (15). Light responses increased linearly for 16:0 standards over the range 0–500 μM ($r = 0.998$) and showed close agreement with known concentrations of NADH ($P < 0.001$, $r = 0.999$; $y = -5.06 \times 10^{-3} + 0.978x$, y = NADH, x = 16:0). The plate spectrophotometric procedure showed a linear increase in absorbance for 16:0 standards across the range 0–500 μM ($r = 0.999$). Standards were stable for approximately 1 mon at −20°C.

Sample collection and treatment. (i) Milk. Chemical colorimetric (16,17) and GC (18,19) methods are predominantly used to determine NEFA concentration in milk. These methods are costly, labor-intensive, and require relatively large sample volumes (13). The development of enzymatic spectrophotometric (4) and luminometric procedures (6) for NEFA determination in plasma has overcome many of these problems. Determination of NEFA requires sample treatment to prevent lipolysis during storage and analysis. However, enzymatic determination of NEFA in milk requires additional sample treatment to limit interference from enzymes present in milk.

In vitro enzymatic lipolysis due to lipases in milk can be prevented by the addition of EDTA to milk samples at collection (13). Accordingly, NEFA concentration in samples collected without EDTA increased by 102 ± 28% during 60 min at room temperature (361 ± 17 to 714 ± 64 μM, $n = 5$; $P < 0.001$) whereas samples collected with EDTA increased by 5 ± 5% (361 ± 17 to 375 ± 3 μM, $n = 5$; $P = 0.81$). Production of NADH beyond the incubation period (drift) was observed in milk samples collected with EDTA. This outcome is likely to be a consequence of thioesterase II (20) as well as nondivalent cation-dependent lipases present in milk (13). This drift was abolished by incorporating an incubation step (80°C for 5 min) and acid denaturation after the addition of EDTA during treatment of milk samples.

(ii) Plasma. Heparin is known to activate plasma lipoprotein lipase (21), however, collection of blood samples in heparinized containers is often desirable to prevent clot formation. Despite the potential for *in vitro* enzymatic lipolysis (7), available literature reveals a lack of consistency in the approach to limit this effect (9,22). The efficacy of acid denaturation to prevent enzymatic lipolysis in plasma samples collected with heparinized tubes was examined in the current study. Duplicate plasma samples were either acid-denatured immediately upon collection and stored at −80°C or stored at −80°C and diluted with water prior to assay. Immediate acid denaturation resulted in lower values (17.1 ± 8.5%) for plasma NEFA when compared to samples untreated before storage ($P = 0.059$; $n = 9$). There was no difference when samples were untreated before storage and either acid-denatured or diluted with water prior to assay ($P = 0.979$; $n = 4$). These findings indicate that plasma collected in heparinized containers should be acid-denatured immediately at collection.

The potential for variation in sample final pH following treatment with acid and base during acid denaturation can result in chemical hydrolysis of plasma triacylglycerol and hence overestimation of NEFA concentration. When plasma samples (5 μL) were acid-denatured with HCl (1 M) and NaOH (1 M) according to Kather and Weiland (6), a large range for plasma sample final pH (5–9) was observed. Hydrochloric acid (1 M; 1:1, vol/vol) added to the sample (pH 0–1) and allowed to stand at room temperature for 0–4 min had no effect on NEFA concentration ($P = 0.521$; $n = 4$). However, alkaline conditions are known to cause saponification of triacylglycerol. Duplicate plasma samples were acid-denatured and NaOH was added to the sample/HCl mixture resulting in either an alkaline (range, 9–13) or a neutral pH. Plasma NEFA concentrations were higher in alkaline compared to neutral pH samples immediately following sample treatment ($P = 0.015$; 91 ± 29 μM neutral, 333 ± 53 μM alkaline) and after 60 min at room temperature ($P = 0.001$; 124 ± 33 μM neutral, 539 ± 40 μM alkaline). There was no change in NEFA levels across the 60 min at room temperature in neutral pH samples ($P = 0.203$). In contrast, a 67 ± 14% increase in NEFA was observed during the same period in alkaline samples ($P = 0.009$). Alkaline final pH following plasma sample treatment with acid and base has been avoided by reducing the HCl and NaOH concentrations from 1 M to 200 mM and including a TES buffer (100 mM, pH 7) with the NaOH.

Reagent. All enzymatic methods for determination of NEFA require activation by acyl-CoA synthetase (4). Following this initial reaction, the current assay sequence differs from existing enzymatic methods (4–6,15,23,24) by utilizing UDP-glucose pyrophosphorylase to convert inorganic pyrophosphate to glucose-1-phosphate in the presence of UDP-glc. Glucose-1-phosphate is linked to the production of NADH by way of the reactions catalyzed by phosphoglucomutase and glucose-6-phosphate 1-dehydrogenase. The control reagent (assay reagent excluding acyl-CoA synthetase) was used to account for the presence of glucose-1-phosphate, glucose-6-phosphate, and inorganic pyrophosphate in milk (<5%) and plasma (≤10%).

This assay sequence has enabled a reduction in completion time compared to previous luminometric methods (6). The formation of NADH from NEFA in a 500 μM 16:0 standard and in samples of milk and plasma was complete within 50 min at 37°C and was stable from 60–120 min (Fig. 1). Furthermore, changes in absorbances from a 500 μM 16:0 standard and a human plasma sample showed a similar response for the plate spectrophotometric method (Fig. 1). Accordingly, an incubation period of 60 min at 37°C for both methods was chosen to ensure complete formation of NADH. The concentrations of acyl-CoA synthetase and UDP-glucose pyrophosphorylase, the rate-limiting enzymes for the assay sequence, were optimized for these incubation conditions and to reduce background reagent contamination.

The reactions involved in luminescence detection can be affected by several components present in either the reagent mixture or the sample. Inhibition or stimulation of the light

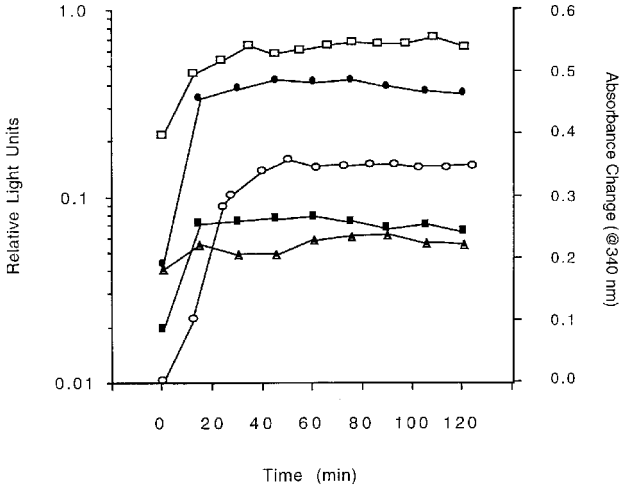

FIG. 1. Time course of nonesterified fatty acid (NEFA) conversion from a 500 μM 16:0 (●) standard and from samples of (▲) human milk and (■) plasma (plate luminometric method, closed symbols; plate spectrophotometric method, open symbols). NADH from NEFA is converted to relative light units as described in the Materials and Methods section of the text. Values are means of duplicate determinations.

TABLE 1
Effect of Reagent and Sample Components on Light Response

Component	Dilution factor[a]	
	10% change[b]	50% change[b]
Milk	65.9	11.5
Plasma	111	4.4
Reagent	520	92.9

[a]Final dilution factor for component in the luminometer well which provided either a 10 or 50% change in relative light units.
[b]Light response normally present in diluted luminescent reagent was taken as 100%.

response by these components was minimized by the high final dilution (1428-fold in the luminometer well) of the reaction mixture. The effects of specific components on the light response are outlined in Table 1.

We found enzymatic spectrophotometric techniques unsuitable for NEFA determination in whole milk and milk whey fractions owing to the opacity of the sample. This problem has been overcome by the use of the NADH-luciferase system. In addition, the combination of the current assay sequence with this system resulted in considerably lower reagent costs when compared to a commercially available spectrophotometric method (Wako NEFA-C kit).

Validation. Recovery, precision, and sensitivity. The recovery of a range of NEFA added to different milk and plasma samples, the interassay variation, and the detection limit (defined as three times the standard deviation of the mean blank) and sensitivity (defined as the detection limit concentration in the luminometer well volume) for the luminometric and spectrophotometric assays are listed in Table 2.

Method comparisons. Human plasma NEFA concentrations determined by the plate luminometric method and the plate spectrophotometric procedure were highly correlated ($r = 0.985$; $P < 0.02$) and showed close agreement ($P = 0.53$; Fig. 2). The plate luminometric method was also compared to a commercially available spectrophotometric method (Wako NEFA-C kit) and a modification of this method for use with 10-µL sample volumes (14). The concentration of NEFA in human plasma samples determined by the Wako NEFA-C kit and the plate luminometric method were highly correlated ($r = 0.998$; $P < 0.001$) and differed by less than 6% ($P = 0.13$; Fig. 2). In contrast, NEFA concentrations determined by the method of Johnson and Peters (14), although highly correlated with the plate luminometric method ($r = 0.989$; $P < 0.001$), were approximately 50% lower ($P = 0.01$; Fig. 2). This difference was found to be due to the effect of sample treatment procedures. Specifically, NEFA concentrations in untreated plasma were lower compared to both acid-denatured ($P = 0.009$) and water-diluted ($P = 0.04$) plasma although all treatments were highly correlated ($P < 0.001$, $r = 0.998$, $y = 11.6 + 1.51x$, y = water-diluted, x = untreated; $P < 0.001$, $r = 0.975$, $y = 112.5 + 1.41x$, y = acid-denatured, x = untreated).

Considerable differences in NEFA concentrations have been reported for blood samples collected under similar conditions, in unrelated studies, when determined by either GC (25) or enzymatic methods (22). When plasma samples were subjected to parallel analysis, we found NEFA concentrations in plasma measured by GC were highly correlated with those determined by the Wako NEFA-C kit and the plate luminometric method ($r = 0.986$, $P < 0.02$; and $r = 0.992$, $P < 0.01$, respectively). However, values derived from GC were 28% higher when compared to those determined by the enzymatic methods ($P = 0.02$, Wako NEFA-C kit; $P = 0.03$, plate luminometry; Fig. 2). These results support the findings of previous direct comparisons between GC and enzymatic methods (26,27). Differences in NEFA–protein interactions between standards and samples have been avoided by the inclusion of albumin with standards (15). This discrepancy is therefore not entirely due to the analytical behavior of the standards. Alternatively, the lower values determined by enzymatic methods compared to GC may be explained by the inability of acyl-CoA synthetase to activate fatty acids tightly bound to albumin (28) or those containing more than 20 carbon atoms (5). As a consequence of the difference in NEFA levels determined by enzymatic procedures when compared to GC, the method of determination should be taken into account when comparing values reported in the literature.

TABLE 2
Recovery of Known Concentrations of NEFA Added to Human Milk and Plasma, the Interassay Variation, and the Detection Limit and the Sensitivity of the Plate Luminometric and Spectrophotometric Methods

NEFA	Recovery (%)	Interassay variation (%)	Detection limit (µM)[a]	Sensitivity (nM)[b]
6:0[c]	97.5 ± 1.52 $n = 8$	7.4 $n = 5$	8.0 ± 0.6 $n = 8$	5.6 ± 0.4 $n = 8$
12:0[c]	96.4 ± 1.64 $n = 8$			
16:0[c]	94.9 ± 0.91 $n = 10$			
18:1n-9[c]	97.4 ± 2.55 $n = 7$			
16:0[d]	100 ± 4.50 $n = 8$	6.8 $n = 7$	9.0 ± 1.7 $n = 10$	2.6 ± 0.5 $n = 10$
16:0[e]	95.8 ± 1.80 $n = 6$	4.9 $n = 5$	13.2 ± 2.7 $n = 5$	4393 ± 916 $n = 5$

Obesity as a Risk Factor for Certain Types of Cancer[1]

K.K. Carroll*

Centre for Human Nutrition, Department of Biochemistry, The University of Western Ontario, London, N6A 5C1, Canada

A survey of body weight, smoking, and cancer mortality involving 750,000 Americans over the period from 1959 to 1972 showed a 33% increase in cancer deaths for men and a 55% increase for women whose body weight was more than 40% above average. Overweight men had significantly higher rates of colorectal cancer, whereas women had higher rates of cancers of the breast, cervix, endometrium, gallbladder and biliary passages, ovary, and uterus (1). It should be noted, however, that being overweight is not necessarily synonymous with obesity (2).

Other more recent studies, such as the Danish record-linkage study (3), have provided additional evidence of an association between obesity and cancer (4–6). This is a matter for concern because of the high incidence of obesity in many countries and because of the increasing incidence of obesity in many parts of the world (5–15).

The aim of this review is to summarize information on obesity in relation to cancer at the various sites for which there is evidence of a positive association.

ENDOMETRIAL CANCER

The link between obesity and endometrial cancer is well-established (4,16–18), particularly for postmenopausal women (19). The association has been observed in both case–control and follow-up studies and in many cases was confined to very obese women (18). The relationship is stronger in older women (19–21). A positive association between endometrial cancer and upper body fat, as measured by waist-to-hip ratio or waist-to-thigh ratio, has been observed in some studies (22–24), but not in others (25). In some cases, this positive association disappeared after adjustment for body mass index (BMI) (26–28).

The association between obesity and endometrial cancer probably has a hormonal basis. Endometrial epithelial cells are stimulated by elevated estrogen levels; and this stimulation, unopposed by progesterone, is thought to be conducive to development of cancer (29,30). Obese women have higher levels of serum estrone and estradiol (27,28,31), presumably as a result of the production of estrogen in adipose tissue by aromatization of androstenedione (32). Obese women also have decreased levels of sex hormone-binding globulin, thus increasing the amount of bioavailable estrogen (32–34).

Steroid measurements in urine collected from women in a cohort study provided further evidence in favor of the hypothesis that unopposed estrogen is a risk factor for endometrial cancer (35). In a recent case–control study, high circulating levels of androstenedione were associated with increased risk of endometrial cancer in both pre- and postmenopausal women, but high levels of estrone and estradiol were only associated with increased risk in postmenopausal women (36). In premenopausal women, obesity may influence endometrial cancer through its tendency to cause amenorrhea and luteal phase progesterone deficiency (21).

BREAST CANCER

A number of studies have shown that obesity increases the risk of breast cancer in postmenopausal women (4,5,17, 37–43). In contrast, a meta-analysis showed a modest inverse association between BMI and premenopausal breast cancer (44). An inverse association between adiposity and breast cancer has also been observed in a number of other studies (43). This may not apply in all cases, however, since a study of women in seven different countries showed that incidence of breast cancer in premenopausal women increased with body mass in low- and moderate-risk countries but decreased with increasing body mass in high-risk countries. In postmenopausal women, the rates increased with body mass in all risk groups (45,46). Cohort studies have been less supportive of the positive correlation between body mass and breast cancer in postmenopausal women than case–control studies (39,41; but see 42).

Breast cancer may also be influenced by the distribution of body fat. An increase in central adiposity has been reported to increase the risk of postmenopausal breast cancer, independent of relative weight, particularly when there is a family history of breast cancer (41). Breast cancer patients were also found to have more visceral fat compared to subcutaneous fat than controls, as measured by computed tomography (47).

Breast cancer risk was not found to be related to body fat distribution in women under 45 yr of age (48). In agreement with earlier studies, Swanson *et al.* (48) found an inverse correlation between body weight and breast cancer in young

[1]This paper was prepared as one of the background documents for the WHO Consultation on Obesity (Geneva, Switzerland, 3-5 June 1997). For further details, please see the report of the Consultation, Obesity: preventing and managing the global epidemic (WHO/NUT/NCD/97.2).

Abbreviation: BMI, body mass index.

women. It was concluded that this probably can not be explained by increased frequency of anovulatory cycles or by detection bias (45).

Adult weight gain has consistently been associated with increased risk of breast cancer, even in cohort studies that showed no association between baseline relative weight and subsequent risk of breast cancer (17,43). In most studies, increased body mass was associated with poorer survival and increased likelihood of recurrence, and adverse outcomes were more pronounced among postmenopausal women and women with less advanced disease (41,49,50). In this connection, it is of interest that most women gain weight during the menopause (51). Weight loss has been associated with reduced risk in some studies but not in others (17,43,52).

Breast cancer, like endometrial cancer, is strongly influenced by hormonal factors, and the differing effects of adiposity on pre- and postmenopausal breast cancer may be explainable on the basis of differences in steroid hormone metabolism (41). Before the menopause, the ovaries are the main source of estrogen, whereas after the menopause production from the ovaries decreases and the estrogen produced in adipose tissue by aromatization of androstenedione assumes greater importance, particularly in obese individuals (53,54). Other factors, such as increased levels of androstenedione and decreased levels of sex hormone-binding globulin, may enhance the risk of breast cancer as well as endometrial cancer after the menopause.

In a recent brief communication, Potischman *et al.* (55) reported that serum total estradiol levels decreased with increasing BMI in premenopausal women, whereas they increased in postmenopausal women. This could be a reason for the differing relationships between obesity and breast cancer in premenopausal compared to postmenopausal women. They suggested that the lower levels of estrogen in obese premenopausal women may be due to uptake by adipocytes and a higher metabolic clearance rate. Gerber (56) suggested, on the other hand, that high estrogen levels may be a cause of leanness in premenopausal women. This idea was based on the observation of an inverse relationship between BMI and high density lipoprotein cholesterol levels in premenopausal women. It was suggested that stimulation of hepatic lipoprotein lipase by estrogen results in high low density lipoprotein cholesterol and lower serum triglycerides, leading to lower BMI.

Breast cancer normally originates in mammary epithelial tissue (57) and the adipose tissue of the mammary gland may have a particularly important influence on the epithelial tissue because of their close association with one another (58). This influence may be exerted through estrogens produced in the adipose tissue or through other fat-soluble compounds, such as eicosanoids formed from polyunsaturated fatty acids present in the lipids of adipose tissue (59). An experiment showed a positive correlation between the fat content of the mammary gland in rats on different diets and the number of mammary tumors induced by 7,12-dimethylbenz(a)anthracene in rats on those diets (60). The possibility that mammary gland mass is positively associated with risk of breast cancer has been discussed by Trichopoulos and Lipman (61).

Hyperinsulinemia related to obesity and insulin resistance may pose a risk for breast cancer (62,63). In a case–control study, serum levels of C-peptide, a marker of hyperinsulinemia, were significantly higher in patients with early breast cancer compared to controls, but the study indicated that hyperinsulinemia with insulin resistance was a risk factor for breast cancer independent of general adiposity or body fat distribution (64).

PROSTATE CANCER

Obesity does not appear to be an important risk factor for prostate cancer (4). Although some cohort studies have shown a positive association with overweight, others have not, nor have most case–control studies (65). In a recent report on a large cohort of Swedish construction workers, various aspects of body size, including adult weight and BMI, were positively associated with prostate cancer, and the risk was more strongly related to mortality than to incidence (66). A high BMI may be due to greater muscle mass rather than adipose tissue, and a prospective study in Japanese-American men showed a positive association between prostate cancer and muscle area, but not fat area (67). In fact, obese men with prostate cancer have been reported to have a better prognosis than those with more normal weight (68). This could be related to inhibition of prostate cancer growth and metastasis by increased endogenous estrogen and decreased endogenous testosterone, associated with obesity.

PANCREATIC CANCER

A positive association between body weight or obesity and pancreatic cancer has been reported in some studies but not others (3,69). It has been suggested that effects of obesity on pancreatic cancer may be mediated through sex hormones, since the pancreas contains sex hormone receptors and the anti-estrogen, tamoxifen, inhibits the growth of pancreatic tumors (69).

COLORECTAL CANCER

Although the relationship of BMI to colon cancer has been investigated rather extensively, there does not appear to be a clear consensus (4,70,71). Obese men have been reported to be at higher risk, whereas obese women are not (5). In contrast, the authors of a recent report on a large cohort study in Denmark concluded that the least obese men had the highest risk of colon cancer (72). In the Framingham study, obesity in men combined with low serum cholesterol was associated with four times greater risk compared to people with average values (73). Other studies indicated that obesity in adolescence or early adulthood poses a risk of colon cancer for men (71,74,75).

A report on Harvard alumni provided evidence that higher

levels of Quetelet's index were associated with higher colon cancer risk only among those who were less active (76). The results of a recent large case–control study by Slattery *et al.* (77) also indicated that a large BMI was more strongly associated with increased risk of colon cancer in individuals who were physically inactive and had a high energy intake. There was some evidence that men may be at higher risk than women, especially older women, as a result of an unfavorable energy balance.

In other recent studies, higher BMI was related to higher risk of adenomas in the distal colon in both men and women (78,79). This relationship was stronger for larger adenomas. It was also observed that waist circumference and waist-to-hip ratio are positively related to higher risk of large colon adenomas or cancer in men (78). Slattery *et al.* (77) reported that those at greatest risk of colon cancer had the most unfavorable energy balance, were physically inactive, had high energy intakes and large BMI.

Insulin is a growth factor for colonic mucosal cells and a mitogen for colonic carcinoma cells *in vitro,* and insulin or related growth factors may mediate the influence of obesity on colon cancer (80). Men have a greater tendency than women to accumulate fat tissue in the abdomen, and this is associated with higher insulin levels, which could help to account for the stronger association between obesity and colon cancer in men (80).

Although cancers of the colon and rectum are frequently considered together as colorectal cancer, the rectum differs from the colon in a number of respects (70). Colon cancer and rectal cancer should therefore probably be considered separately in relation to factors that affect them. In a study of Seventh-Day Adventists, a 25% excess in body weight was associated with increased rectal cancer in both men and women, but with increased colon cancer in men only (81). Whereas BMI was positively correlated with higher risk of colonic adenomas in both men and women, it was not apparently related to rectal adenomas in women (78,79).

RENAL CELL CANCER

Renal cell cancer has been consistently associated with overweight and obesity (4,82). The results of case–control studies and a large multicenter study indicated that body weight has a stronger impact on renal cell cancer in women than on men, and in the multicenter study, rate of weight change appeared to be an independent risk factor for women (82). The stronger association in women suggests a role for increased levels of endogenous estrogens (4). These may affect renal cell proliferation and growth by means of receptors present in renal cells or through paracrine growth factors (82).

CANCER AT OTHER SITES

In the large American study cited in the introduction, obese women had higher rates of cancer at a number of sites other than those discussed above (1). The Danish record-linkage study of obese subjects also showed increased incidence of cancer at some additional sites, including the esophagus, liver, and ovary (3). The excess cancers of the esophagus and liver may have been related to higher alcohol intake in the obese cohort. Obese women tend to have more anovulatory cycles, which might affect their susceptibility to ovarian cancer (3). The risk of epithelial ovarian cancer has been observed to decrease with increasing numbers of full-term pregnancies (83). One of the more surprising observations in the Danish study was an excess of brain cancer in the year following discharge from hospital, for which there was no good explanation (3).

SUMMARY AND CONCLUSIONS

In conclusion, obesity has been associated with increased risk for a number of different types of cancer. The evidence has been most consistent for endometrial cancer, breast cancer in postmenopausal women, and renal cell cancer. More variable results have been reported for colorectal, prostate and pancreatic cancer.

Possible mechanisms by which obesity may influence cancer risk include alteration in hormonal patterns, including sex hormones and insulin, and factors such as the distribution of body fat and changes in adiposity at different ages. The increasing prevalence of obesity in many parts of the world emphasizes the importance of learning more about the relationship between obesity and cancer and the mechanisms involved in their interaction.

ARTICLE

A Pathway for Biosynthesis of Divinyl Ether Fatty Acids in Green Leaves

Mats Hamberg*

Department of Medical Biochemistry and Biophysics, Division of Physiological Chemistry II, Karolinska Institutet, S-171 77 Stockholm, Sweden

ABSTRACT: [1-^{14}C]α-Linolenic acid was incubated with a particulate fraction of homogenate of leaves of the meadow buttercup (*Ranunculus acris* L.). The main product was a divinyl ether fatty acid, which was identified as 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid. Addition of glutathione peroxidase and reduced glutathione to incubations of α-linolenic acid almost completely suppressed formation of the divinyl ether acid and resulted in the appearance of 13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid as the main product. This result, together with the finding that 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid served as an efficient precursor of the divinyl ether fatty acid, indicated that divinyl ether biosynthesis in leaves of *R. acris* occurred by a two-step pathway involving an ω6-lipoxygenase and a divinyl ether synthase. Incubations of isomeric hydroperoxides derived from α-linolenic and linoleic acids with the enzyme preparation from *R. acris* showed that 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid was transformed into the divinyl ether 12-[1′(*Z*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid. In contrast, neither the 9(*S*)-hydroperoxides of linoleic or α-linolenic acids nor the 13(*R*)-hydroperoxide of α-linolenic acid served as precursors of divinyl ethers.

Lipids 33, 1061–1071 (1998).

Fatty acid hydroperoxides are generated in higher plants by lipoxygenase-catalyzed dioxygenation of linoleic and α-linolenic acids. Further metabolism of α-linolenic acid 13(*S*)-hydroperoxide catalyzed by allene oxide synthase, allene oxide cyclase, reductase, and β-oxidation enzymes results in the formation of 12-oxo-10,15(*Z*)-phytodienoic acid (12-oxo-PDA) and jasmonic acid (1,2). This pathway is of biological importance in plants because it produces compounds which are involved in defense reactions against insects and other phytopathogens (3), in mechanical responses such as tendril coiling (4), and in pollen development (5). Other pathways of hydroperoxide metabolism in higher plants result in the formation of fatty acid epoxides and epoxy alcohols (6,7), short-chain aldehydes (8), and divinyl ethers (9). The last-mentioned family of compounds includes colneleic and colnelenic acids {9-[1′(*E*),3′(*Z*)-nonadienyloxy]-8(*E*)-nonenoic acid and 9-[1′(*E*),3′(*Z*),6′(*Z*)-nonatrienyloxy]-8(*E*)-nonenoic acid, respectively}, which are generated from the 9(*S*)-hydroperoxide derivatives of linoleic acid and α-linolenic acid, respectively, in potato tubers (9) and tomato roots (10). Etheroleic and etherolenic acids {12-[1′(*E*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid and 12-[1′(*E*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid, respectively} constitute another set of divinyl ether fatty acids, which are produced from the 13(*S*)-hydroperoxides of linoleic acid and α-linolenic acids, respectively, in bulbs of garlic (11). In addition, small amounts of divinyl ethers have been isolated from marine algae. Thus, divinyl ethers biogenetically related to 6,9,12,15-octadecatetraenoic acid, 5,8,11,14,17-eicosapentaenoic acid, and α-linolenic acid have been obtained from the brown alga *Laminaria sinclairii* (12), whereas the red alga *Polyneura latissima* was found to contain a divinyl ether, polyneuric acid, related to the 9(*S*)-hydroperoxide derivative of arachidonic acid (13).

Divinyl ethers of higher plants have been generated in various nonphotosynthetic tissues and have not been detected in preparations of green leaves (10,14). Colneleic acid has been reported to be a potent inhibitor of potato lipoxygenase (15); however, so far no specific biological function has been ascribed to colneleic acid or other divinyl ethers. The present study is concerned with a pathway for biosynthesis of divinyl ether fatty acids in green leaves of certain plants.

EXPERIMENTAL PROCEDURES

Plant materials. Specimens of the meadow buttercup (*Ranunculus acris* L.) and other plants used in this study were collected in June–September 1998 at a large number of locations outside Stockholm.

Abbreviations and trivial names: 9-H(P)OD, 9-hydro(pero)xy-10(*E*),12(*Z*)-octadecadienoic acid; 9-H(P)OT, 9-hydro(pero)xy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid; 12-oxo-PDA, 12-oxo-10,15(*Z*)-phytodienoic acid; 13-H(P)OD, 13-hydro(pero)xy-9(*Z*),11(*E*)-octadecadienoic acid; 13-H(P)OT, 13-hydro(pero)xy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid; colneleic acid, 9-[1′(*E*),3′(*Z*)-nonadienyloxy]-8(*E*)-nonenoic acid; colnelenic acid, 9-[1′(*E*),3′(*Z*),6′(*Z*)-nonatrienyloxy]-8(*E*)-nonenoic acid; etheroleic acid, 12-[1′(*E*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; etherolenic acid, 12-[1′(*E*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; FT-IR, Fourier transform infrared; GC–MS, gas chromatography–mass spectrometry; GLC, gas–liquid chromatography; GSH, glutathione (reduced form); GSH-px, glutathione peroxidase; NMR, nuclear magnetic resonance; RP-HPLC, reversed-phase high-performance liquid chromatography; SP-HPLC, straight-phase high-performance liquid chromatography; SPE, solid-phase extraction; UV, ultraviolet.

Fatty acids and fatty acid hydro(pero)xides. Linoleic and α-linolenic acids were purchased from Nu-Chek-Prep (Elysian, MN). [1-^{14}C]α-Linolenic acid (DuPont NEN, Boston, MA) was mixed with unlabeled material and purified by SiO_2 chromatography to afford a specimen having a specific radioactivity of 4.0 kBq/μmol. 9(*S*)-Hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid [9(*S*)-HPOT] and 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid [13(*S*)-HPOT] were prepared by incubation of α-linolenic acid with tomato lipoxygenase (16) and soybean lipoxygenase (17), respectively. 9(*S*)-Hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HPOD] and 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD] were obtained in an analogous way from linoleic acid. 13(*R*)-HPOT was prepared by incubation of α-linolenic acid with manganese lipoxygenase followed by isolation by reversed-phase high-performance liquid chromatography (RP-HPLC) (18). Hydroxy fatty acids were prepared from the corresponding hydroperoxides by reduction with sodium borohydride in methanol. 12-Oxo-PDA and its 10,11,15,16-tetrahydro derivative were prepared as described (19).

Divinyl ether fatty acids. Colneleic and colnelenic acids were prepared by incubation of 9(*S*)-HPOD and 9(*S*)-HPOT, respectively, with the 9300 × *g* supernatant fraction of homogenate of potato tuber followed by purification by RP-HPLC (20). Etheroleic and etherolenic acids were obtained by incubations of 13(*S*)-HPOD and 13(*S*)-HPOT, respectively, with whole homogenates of bulbs of garlic (*Allium sativum* L.) followed by isolation by RP-HPLC (11,21).

Enzyme preparations. Leaves of *R. acris* were minced and homogenized at 0°C in 0.1 M potassium phosphate buffer pH 6.7 (1:5, vol/wt) using an Ultra-Turrax. The homogenate was filtered through gauze, and the filtrate (protein, 3.8 mg/mL) was centrifuged for 15 min at 1100 × *g*. Further centrifugation of the supernatant (protein, 2.7 mg/mL) for 60 min at 105,000 × *g* provided a particulate fraction and a particle-free supernatant (protein, 1.6 mg/mL). The particulate fractions obtained by centrifugations at 1100 × *g* and 105,000 × *g* were resuspended in volumes of phosphate buffer equal to those of the corresponding supernatants (protein in 1100 × *g* sediment fraction, 1.1 mg/mL; protein in 105,000 × *g* particulate fraction, 0.7 mg/mL). Most of the incubations were carried out using the 105,000 × *g* particulate fraction; however, in large-scale preparations, use was also made of the 1100 × *g* particulate fraction which contained appreciable divinyl ether synthase activity. Although fresh leaves of *R. acris* were used for most of the experiments, it was also possible to use leaves which had been shock-frozen in liquid nitrogen and subsequently stored at −80°C. Glutathione peroxidase (GSH-px) and reduced glutathione (GSH) were purchased from Sigma Chemical Co. (St. Louis, MO).

Chemical methods. Catalytic hydrogenation, reduction with sodium borohydride, and oxidative ozonolysis were performed as described (18,22). Short-chain fragments formed upon oxidative ozonolysis were identified by gas chromatography–mass spectrometry (GC–MS) analysis. Configurational determination of hydroxy acids and 12-oxo-PDA were carried out by gas–liquid chromatography (GLC) analysis of diastereomeric (−)-menthoxycarbonyl derivatives (22,19).

Chromatographic and instrumental methods. Analytical RP–HPLC was performed with a column of Nucleosil 100-5 C_{18} (250 × 4.6 mm) purchased from Macherey-Nagel (Düren, Germany). The solvent systems used were mixtures of acetonitrile/water/acetic acid in the proportions 50:50:0.02, by vol (system A), 60:40:0.02, by vol (system B), and 70:30:0.02, by vol (system C). For straight-phase high-performance chromatography (SP–HPLC), a column of Nucleosil 50-5 (250 × 4.0 mm) and a solvent system of ethyl acetate/hexane (8:992, vol/vol) were used. The absorbance (210 nm) and radioactivity of HPLC effluents were determined on-line using a Spectromonitor III ultraviolet (UV) detector (Laboratory Data Control, Riviera Beach, FL) and a liquid scintillation counter (IN/US Systems, Tampa, FL), respectively. GLC was performed with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm). Helium at a flow rate of 25 cm/s was used as the carrier gas. Retention times found on GLC were converted into C-values as described (23). GC-MS was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. UV spectra were recorded with a Hitachi (Tokyo, Japan) model U-2000 UV/VIS spectrophotometer. Fourier transform infrared (FT-IR) spectrometry was carried out using a Perkin-Elmer (Norwalk, CT) model 1650 FT-IR spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded on a JEOL JNM-EX270 instrument. Deuteriochloroform containing 0.03% tetramethylsilane was used as the solvent. Radioactivity was determined with a Packard Tri-Carb model 4450 liquid scintillation counter (Packard Instruments, Downers Grove, IL).

Incubations and treatments. [1-^{14}C]α-Linolenic acid (300 μM) or hydroperoxides (200 or 300 μM as indicated) were stirred with enzyme preparation (2–10 mL) at 23°C for 20 min. The mixtures were acidified to pH 4 and rapidly extracted with 2 vol of diethyl ether. Material obtained after evaporation of the solvent was dissolved in 3 mL of 2-propanol/chloroform (1:2, vol/vol) and subjected to solid-phase extraction (SPE) using an aminopropyl column (0.5 g; Supelco, Bellefonte, PA). After rinsing with 5 mL of the same solvent mixture, acidic components were eluted with 10 mL of diethyl ether/acetic acid (98:2, vol/vol) (*cf.* Ref. 24). The material obtained was subjected to RP-radio-HPLC using solvent systems A and C.

Preparation of compound **4**. Batches of 5–10 mg of crystalline compound **4** were prepared in the following way. Leaves of *R. acris* (24 g) were homogenized in potassium phosphate buffer (120 mL), and the fractions sedimenting at 1100 × *g* and 105,000 × *g* were collected. They were suspended and homogenized in buffer (130 and 120 mL, respectively) and separately stirred at 23°C for 30 min with unlabeled 13(*S*)-HPOT (300 μM). The incubation mixtures were

pooled, acidified to pH 4, and extracted with diethyl ether. The residue remaining after evaporation of the solvent was dissolved in 12 mL of 2-propanol/chloroform (1:2, vol/vol) and subjected to SPE (4 columns) as described above. The material obtained was dissolved in HPLC mobile phase (6 mL) and aliquots of 1 mL were subjected to semipreparative RP-HPLC using a column of Nucleosil C_{18} 100-7 (250 × 10 mm) and solvent system B at a flow rate of 5 mL/min. This procedure afforded 10–12 mg of pure Compound **4** (yield from 13(*S*)-HPOT, 45–54%). Crystallization from hexane at –25°C afforded white crystals, m.p. 49–50°C.

RESULTS

Isolation of oxidation products of α-linolenic acid. [1-^{14}C]α-Linolenic acid (300 μM) was stirred at 23°C for 20 min with a suspension (10 mL) of the 105,000 × *g* particle fraction of a homogenate of *R. acris*. Material obtained following extraction with diethyl ether and preliminary purification by SPE was subjected to RP-HPLC radiochromatography. As seen in Figure 1, a major labeled compound (compound **4**; 77% of the recovered radioactivity) as well as three minor compounds (compounds **1–3**; 4, 1, and 2%, respectively, of the recovered radioactivity) appeared. A small peak (9%) due to residual unconverted α-linolenic acid was also observed. Larger amounts of compound **4** needed for identification were prepared as described in the Experimental Procedures section. Compound **4** obtained in this way was a crystalline solid melting at 49–50°C. The methyl ester prepared by means of diazomethane was a colorless oil which solidified on cooling and remelted at 25°C. When an aliquot of compound **4** was placed on a hot plate and heated above its melting point, a distinct odor of cut apple became apparent, probably due to cleavage of the divinyl ether structure and liberation of 3-hexenal.

Identification of compound **4**. Compound **4** showed strong UV absorption with λ_{max} (EtOH) = 267 nm (ε = 41,200) (Fig. 2, Table 1). The fact that the absorption band was smooth with no sign of splitting excluded the possibility of a conjugated triene chromophore but was in agreement with, e.g., a conjugated dienone or a bathochromically shifted diene. The FT-IR spectrum (film) of the methyl ester of compound **4** is given in Figure 3. Bands were observed at 1740

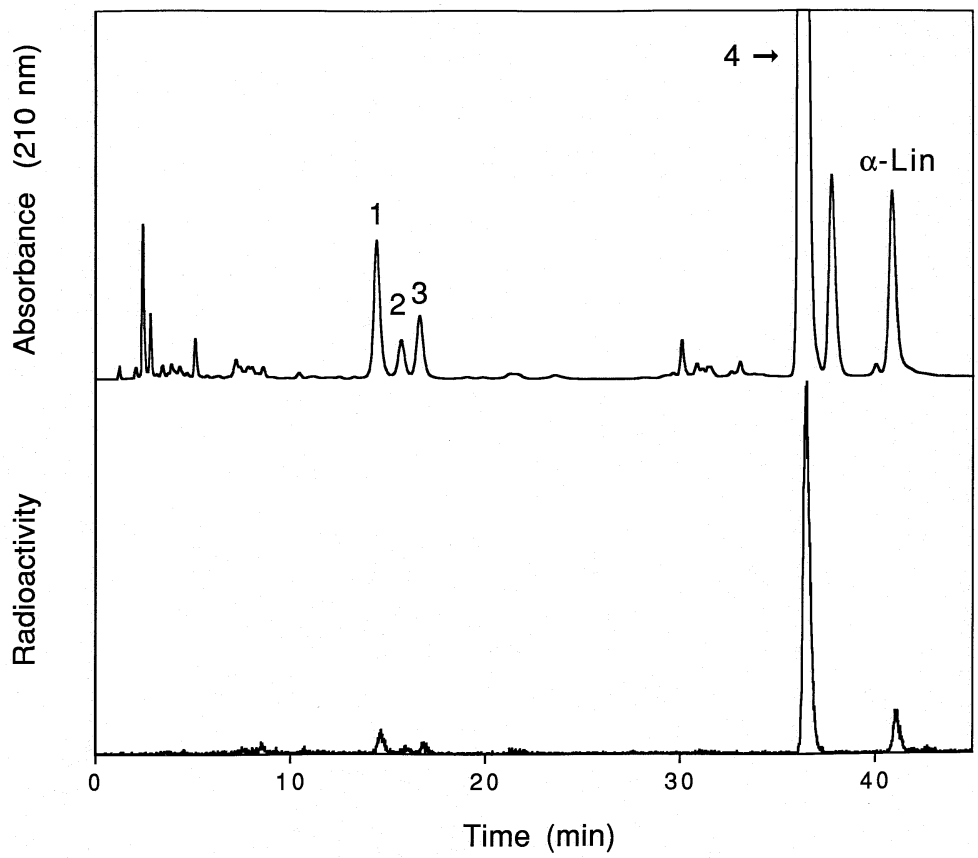

FIG. 1. Analysis by reversed-phase-radio-high-performance liquid chromatography of reaction product obtained following incubation of [1-^{14}C]α-linolenic acid (300 μM) with the 105,000 × *g* particulate fraction of homogenate of *Ranunculus acris*. The column was eluted at a flow rate of 1.5 mL/min with solvent system A (0–25 min) followed by solvent system C (25–45 min). Peak 1, compound **1**; peak 2, compound **2**; peak 3, compound **3**; peak 4, compound **4**; α-Lin, α-linolenic acid. The peak of ultraviolet absorption appearing between compound **4** and α-linolenic acid was due to 2,6-di-*tert*-butyl-4-methylphenol (BHT), an antioxidant present at a level of 10 ppm in the diethyl ether used.

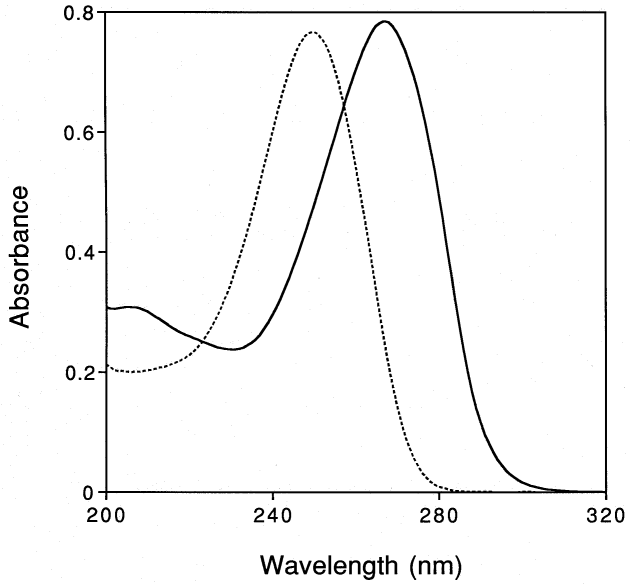

FIG. 2. Ultraviolet spectra of compound **4** (solid line) and compound **6** (dashed line). Solvent, 99.5% ethanol.

TABLE 1
Ultraviolet and Chromatographic Data of Divinyl Ethers[a]

Compound	λ_{max}[b] (nm)	Retention volume[c] (mL)	C-value[d]
Compound **6**	250	20.8	18.83
Compound **4**	267	27.2	19.74
Etheroleic acid	250	21.4	19.33
Etherolenic acid	268	25.8	19.74[e]
Colneleic acid	250	25.5	19.41
Colnelenic acid	253	30.2	19.45[e]

[a]Abbreviations/trivial names: compound **6**, 12-[1′(*Z*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; compound **4**, 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; etheroleic acid, 12-[1′(*E*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; etherolenic acid, 12-[1′(*E*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; colneleic acid, 9-[1′(*E*),3′(*Z*)-nonadienyloxy]-8(*E*)-nonenoic acid; colnelenic acid, 9-[1′(*E*),3′(*Z*),6′(*Z*)-nonatrienyloxy]-8(*E*)-nonenoic acid.
[b]Ultraviolet spectra were recorded on the free acids dissolved in 99.5% ethanol.
[c]Straight-phase high-performance liquid chromatography was performed on the methyl esters using a column of Nucleosil 50-5 and a solvent system of ethyl acetate/hexane (8:992) at a flow rate of 1.0 mL/min. The detector was set at 250 nm.
[d]Gas–liquid chromatography was performed on the methyl esters using a methyl silicone capillary column (25 m) at 230°C.
[e]Partial degradation on the capillary column.

(ester C=O), 1646 (C=C), 1595 (C=C), 1165 (C–O–C), and 911 cm^{-1} (*trans*-substituted vinyl ether). The mass spectrum of the methyl ester of compound **4** showed prominent ions at *m/z* 306 (26%; M^+), 277 (2; $M^+ - 29$; loss of $\cdot C_2H_5$), 275 (3; $M^+ - 31$; loss of $\cdot OCH_3$), 245 [4; $M^+ - (29 + 32)$], 217 (3), 199 (3), 163 [10; $M^+ - 143$; loss of $\cdot(CH_2)_6$-$COOCH_3$], 149 (25), 131 (27), 107 (31), 81 (100), and 55 (98). Proof for the presence of four double bonds in compound **4** was provided by the mass spectrum of the derivative formed upon catalytic hydrogenation of the methyl ester of compound **4**. The molecular ion of this derivative was shifted to *m/z* 314 (0.1%) and the ion due to loss of $\cdot OCH_3$ appeared at *m/z* 283 (2%). Further ions were observed at *m/z* 229 (18%; $M^+ - 85$; loss of $\cdot(CH_2)_5$-CH_3), 214 (15, $M^+ - 100$; loss of OHC-$(CH_2)_4$-CH_3); 197 [49; $M^+ - (85 + 32)$], 143 {27; $[(CH_2)_6$-$COOCH_3]^+$}, 129 {11; $[(CH_2)_5$-$COOCH_3]^+$}, 97 {31; $[(CH_2)_4$-$CH{=}C{=}O]^+$}, 87 {59; $[(CH_2)_2$-$COOCH_3]^+$}, 74 {69; $[CH_2{=}C(OH)$-$OCH_3]^{\cdot+}$}, and 55 (100). Oxidative ozonolysis performed on the methyl ester of compound **4** produced monomethyl nonanedioate as

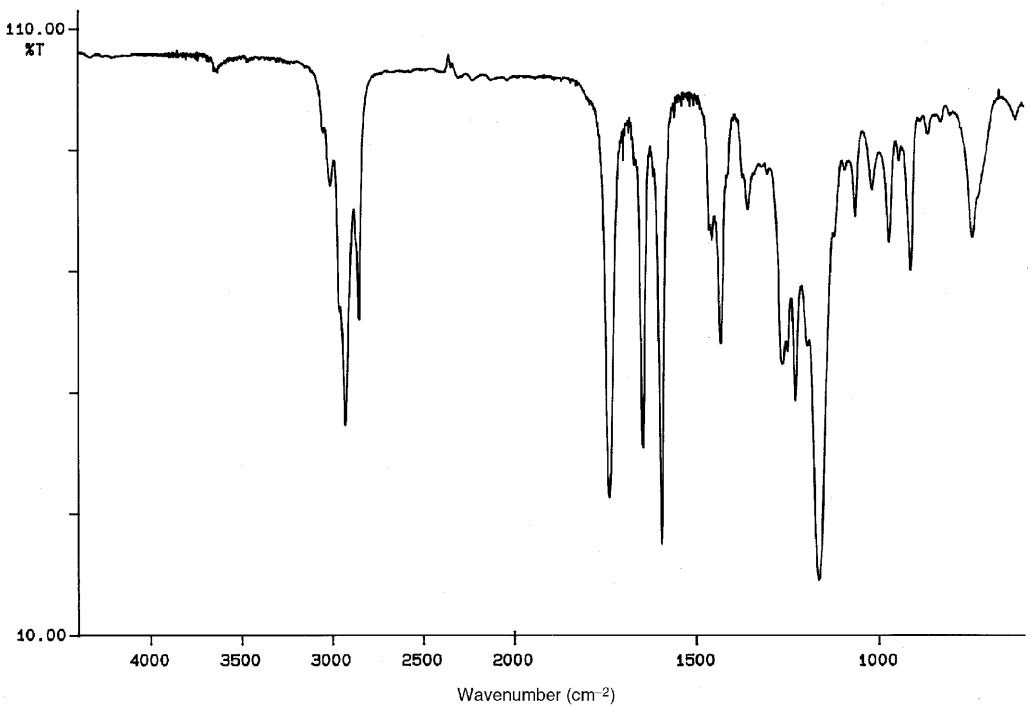

FIG. 3. Fourier transform infrared spectrum (film) of the methyl ester of compound **4**.

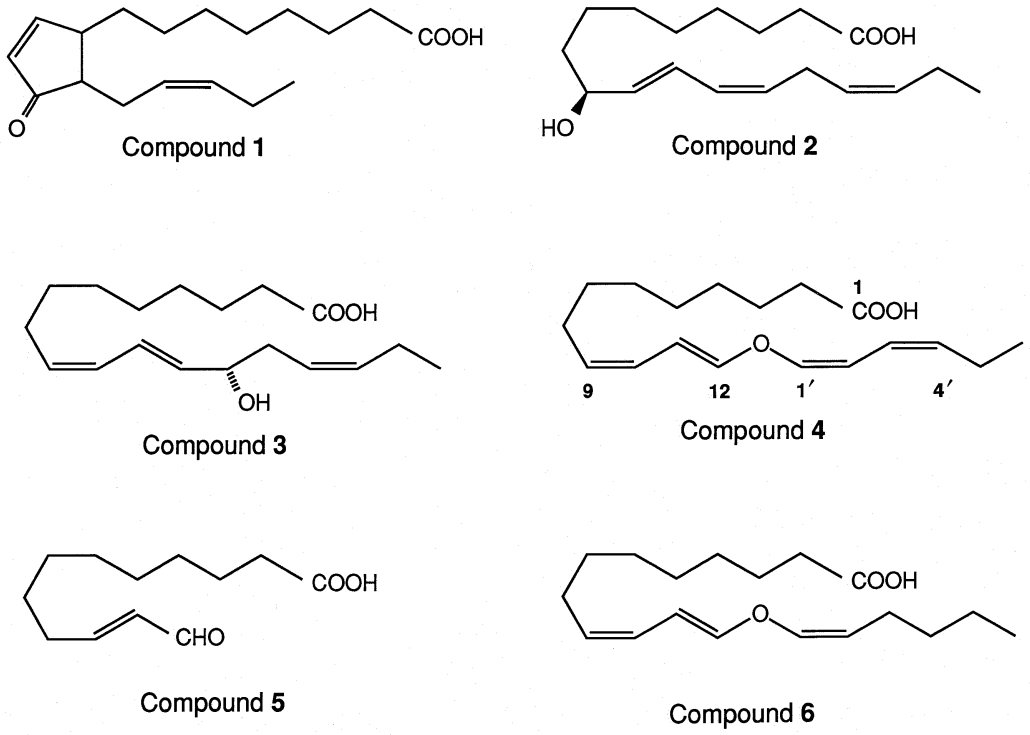
the major nonvolatile fragment. The data mentioned indicated that compound **4** possessed a tetraunsaturated ether structure located in a position corresponding to carbons 9–16 of the parent fatty acid. Support for the presence of such a partial structure was provided by an experiment in which compound **4** (400 μg) in acetone (7.5 mL) was treated with 20% hydrochloric acid (2.5 mL) at 23°C for 1 h (*cf.* Ref. 11). The product was subjected to RP-radio-HPLC using solvent system A. A major peak of radioactivity appeared (compound **5**; 8.3–9.1 mL effluent). Compound **5** was identified as 12-oxo-10-dodecenoic acid by its UV spectrum, which showed λ_{max} (EtOH) = 220 nm, and by its mass spectrum (methyl ester), which showed prominent ions at *m/z* 194 (5%; $M^+ - 32$; loss of CH_3OH), 166 (4), 149 (4), 123 (8), 112 (12), 98 (65), 83 (42), 74 (43), and 55 (100). Oxidative ozonolysis performed on the methyl ester of **5** produced monomethyl decanedioate, thus localizing the double bond to the Δ^{10} position. Identification of the acid hydrolysis product **5** as 12-oxo-10-dodecenoic acid confirmed the presence in compound **4** of an unsaturated ether structure with its oxygen attached to C-12 (Scheme 1). NMR spectroscopy was used to determine the geometrical configurations of the double bonds. Eight groups of signals due to the eight olefinic protons of compound **4** were observed (Fig. 4A and Table 2). Correlation of the signals with the different protons was achieved by spin-spin decoupling experiments and by using the NMR spectrum of methyl colneleate (Fig. 4C) as a reference (15,25). The signals centered at 5.30 and 5.84 ppm were due to the protons at C-9 and C-10, respectively, whereas the signals centered at 6.32 and 5.41 ppm were due to the protons at C-3′ and C-4′, respectively. As shown by the values of $J_{9,10}$ and $J_{3',4'}$ (10.6 and 11.1 Hz, respectively), both the Δ^9 and $\Delta^{3'}$ double bonds had the *Z* geometrical configuration. Earlier work on divinyl ether fatty acids (11–13,15,21,25) and on other vinyl ether compounds, such as ethyl propenyl ether (26), have shown that the coupling constants of protons across *Z* and *E* vinyl ether double bonds have values of 6–7 and 11–12 Hz, respectively. As seen in Table 2, $J_{11,12}$ determined for the signals of the vinylic protons at C-11 (6.05 ppm) and C-12 (6.58 ppm) was 11.9 Hz, thus demonstrating that the Δ^{11} double bond had the *E* configuration. In the same way, the coupling constant of the protons of the $\Delta^{1'}$ double bond (signals centered at 6.20 and 5.50 ppm) had the value 6.2 Hz. This showed that the $\Delta^{1'}$ double bond had the *Z* geometrical configuration. On the basis of the data presented, compound **4** was identified as 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid (Scheme 1). This compound had previously been isolated from *L. sinclairii*, a brown alga (12). The spectral data of compound **4** (Figs. 2–4, Table 2) were almost identical to those of the algal divinyl ether, although the value of the extinction coefficient at 267 nm found in the present work (ε 41,200) was considerably higher than that previously reported (ε 30,000) (12). Furthermore, compound **4** was structurally closely related to etherolenic acid (11), differing from this compound only with respect to the geometrical configuration of the double bond introduced in the divinyl ether synthase reaction [1′(*Z*) in compound **4**, 1′(*E*) in etherolenic acid].

Identification of 12-oxo-PDA. The UV spectrum of compound **1** showed λ_{max} (EtOH) = 220 nm (ε = 12,500), and the mass spectrum of the methyl ester showed prominent ions at



SCHEME 1

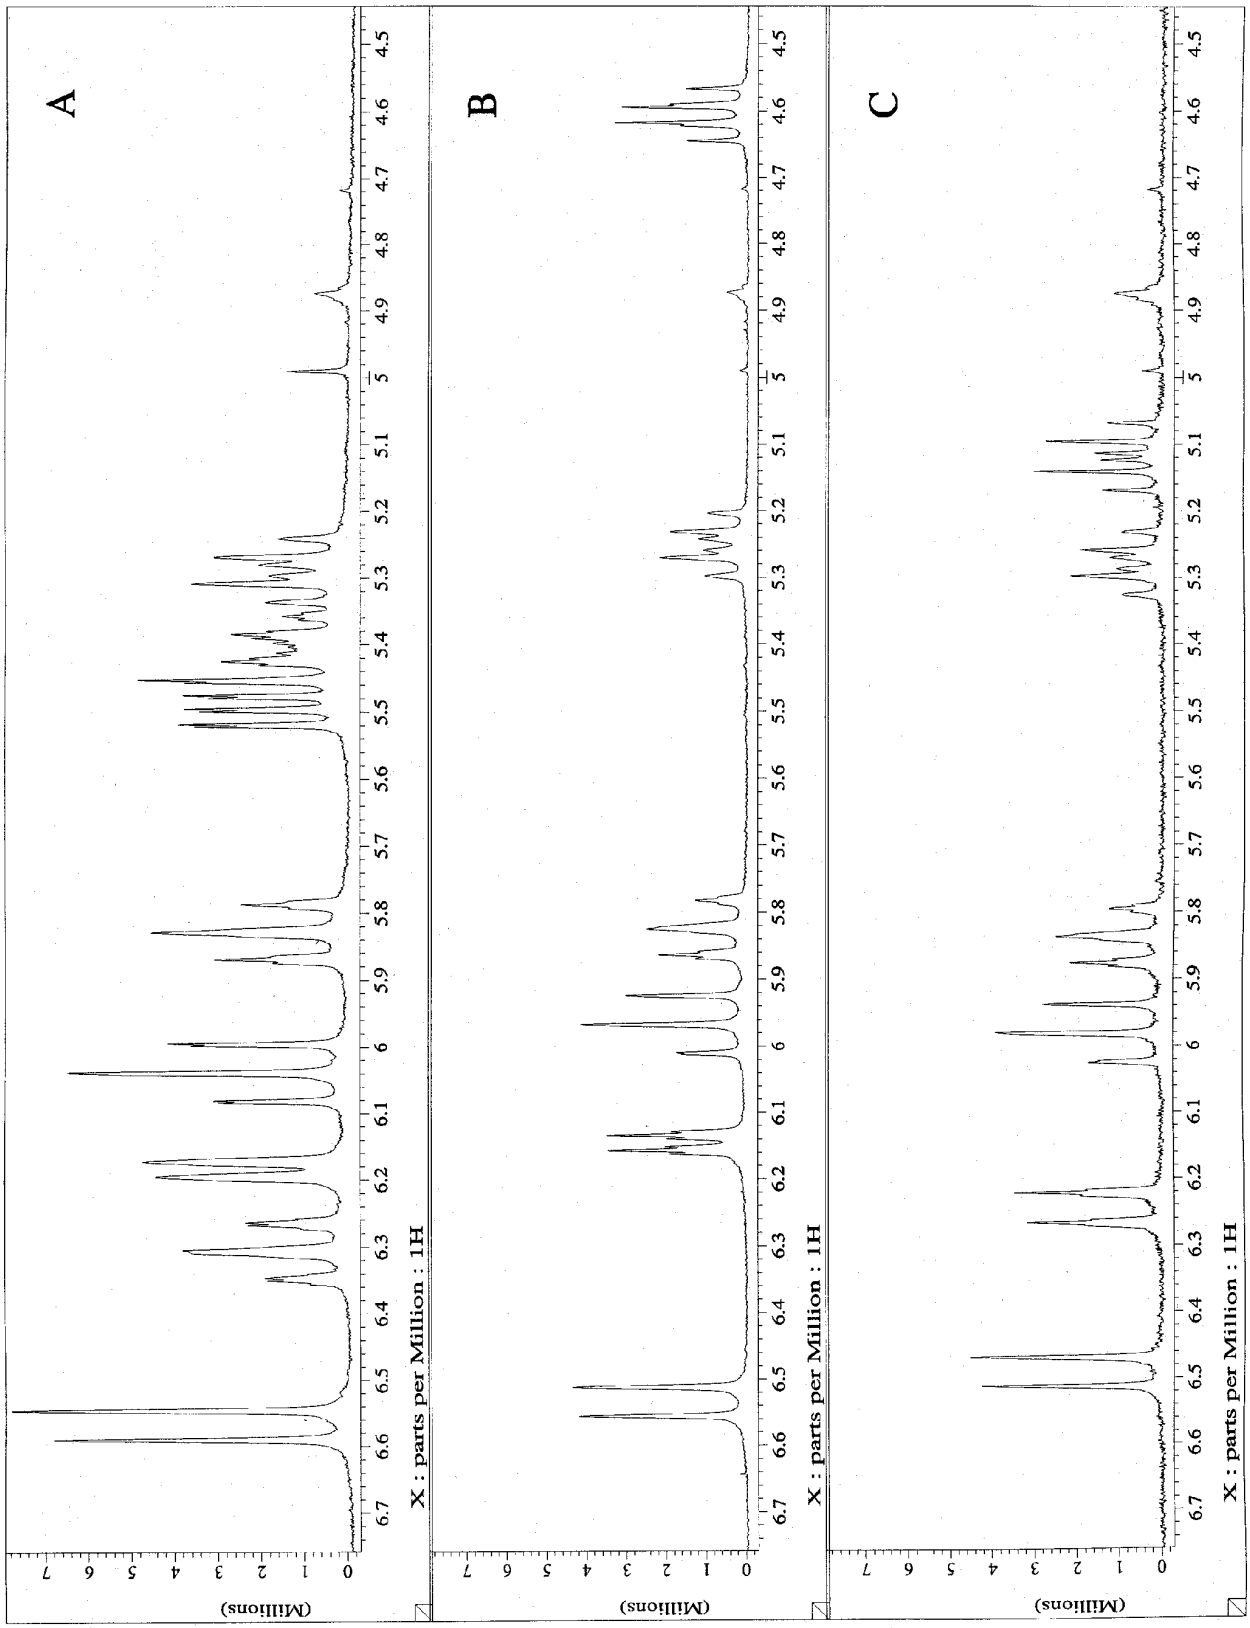


FIG. 4. Partial nuclear magnetic resonance spectra of the methyl esters of compound **4** (A), compound **6** (B), and of methyl colneleate (C). The region δ 4.5–6.7 ppm containing signals due to the olefinic protons are shown. Solvent, deuteriochloroform.

[a]Proton nuclear magnetic resonance spectra were recorded at 270 MHz in $CDCl_3$ with tetramethylsilane as internal chemical shift reference.

m/z 306 (15%; M^+), 275 (16; $M^+ - 31$; loss of $\cdot OCH_3$), 238 (18; $M^+ - 68$; β-cleavage with loss of C_5H_8); 206 [11; $M^+ - (68 + 32)$], 177 [19; $M^+ - 129$; loss of $\cdot(CH_2)_5$-$COOCH_3$], 163 [32; $M^+ - 143$; loss of $\cdot(CH_2)_6$-$COOCH_3$], 149 [25; $M^+ - 157$; loss of $\cdot(CH_2)_7$-$COOCH_3$], 109 (53), 107 (54), 95 (96), 82 (54), and 55 (100). These spectral data were identical to those of authentic 12-oxo-PDA. The identity of compound **1** with 12-oxo-PDA was confirmed by the findings that compound **1** and authentic 12-oxo-PDA cochromatographed on RP-HPLC (solvent system A; effluent volume, 21.6 mL) and on GLC (methyl ester; C-value, 20.11), and that catalytic hydrogenation performed on **1** produced 10,11,15,16-tetrahydro-12-oxo-PDA.

Identification of hydroxy acids. Compounds **2** and **3** were identified as 9(*S*)-hydroxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid [9(*S*)-HOT] and 13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid [13(*S*)-HOT], respectively, by UV spectrometry, mass spectrometry (methyl ester–trimethylsilyl ether derivatives), and by their chromatographic behavior on RP-HPLC and GLC. The authentic compounds were used as references.

Incubation in the presence of GSH-px. [1-^{14}C]α-Linolenic acid (300 μM) was stirred at 23°C for 20 min with a suspension of the 105,000 × *g* particulate fraction in the presence of GSH-px (8 units/mL) and GSH (2 mM). Analysis of the product by RP-radio-HPLC showed the presence of a main peak of radioactivity, i.e., compound **3** (90%), and a minor peak due to compound **4** (2%). Although the extent of oxygenation of α-linolenic acid (92%) was close to that found in a control incubation carried out in the absence of GSH-px and GSH (93%), it was apparent that inclusion of GSH-px/GSH resulted in strong inhibition of the formation of compound **4** and a correspondingly increased formation of compound **3**.

*Incubation of 13(*S*)-HPOT*. [1-^{14}C]13(*S*)-HPOT (200 μM) was stirred with a suspension of the 105,000 × *g* particulate fraction at 23°C for 20 min, and the product was analyzed by RP-radio-HPLC. A main peak of radioactivity comigrating with compound **4** (85%) appeared. Examination of this material by UV spectroscopy and GC–MS (methyl ester) gave results identical to those found for compound **4** biosynthesized from α-linolenic acid (see above). This experiment thus showed that 13(*S*)-HPOT served as an efficient precursor of compound **4** and, together with the results of the incubation carried out in the presence of GSH-px (see above), indicated that biosynthesis of **4** from α-linolenic acid occurred by a two-step pathway involving 13(*S*)-HPOT as a free intermediate.

*Incubation of 13(*S*)-HPOD and structure of compound* **6**. Incubation of [1-^{14}C]13(*S*)-HPOD (200 μM) as described above led to the formation of a major radioactive product, i.e., compound **6** (61% of the recovered radioactivity). Peaks due to 13(*S*)-HPOD remaining nonconverted (27%) and 13(*S*)-HOD (7%) were also observed. The UV spectrum of **6** showed λ_{max} (EtOH) = 250 nm (Fig. 2, Table 1), and the mass spectrum of its methyl ester showed prominent ions at *m/z* 308 (39%; M^+), 277 (3; $M^+ - 31$; loss of $\cdot OCH_3$), 251 (4; $M^+ - 57$; loss of $\cdot(CH_2)_3$-CH_3), 219 [3; $M^+ - (57 + 32)$], 177 (16), 165 [21; $M^+ - 143$; loss of $\cdot(CH_2)_6$-$COOCH_3$], 159 (15), 135 (26), 81 (63), 67 (79), and 55 (100). Catalytic hydrogenation of **6** produced a derivative identical to that formed from **4** upon hydrogenation (see above). Oxidative ozonolysis performed on the methyl ester of **6** yielded monomethyl nonanedioate as the main product. The data mentioned indicated the presence in **6** of a triunsaturated ether partial structure located

[a]Fresh leaves (3 g) were minced and homogenized in 0.1 M potassium phosphate buffer pH 6.7. Ten milliliters of the filtered homogenate were stirred at 23°C for 20 min with 300 μM [1-^{14}C]α-linolenic acid. The product obtained by extraction with diethyl ether and solid-phase extraction was subjected to reversed-phase-radio-high-performance liquid chromatography using the conditions given in the legend to Figure 1.
[b]The percentages of the recovered radioactivity associated with compound **4** and 12-oxo-PDA are given.
[c]Mixture of compound **4** and an unknown isomer as described in the text.

with its oxygen attached to C-12. NMR spectroscopy showed six groups of signals due to olefinic protons (Fig. 4B, Table 2). The protons at the Δ^9 double bonds gave rise to signals at 5.27 and 5.84 ppm. The value of $J_{9,10}$ (10.6 Hz) demonstrated that this double bond had the *Z* geometrical configuration. Signals at 5.98 and 6.55 ppm were due to the protons at the Δ^{11} double bond. The observed $J_{11,12}$ (11.8 Hz) was in agreement with a vinyl ether double bond having the *E* configuration. In the same way, the $\Delta^{1'}$ double bond was assigned the *Z* configuration based on the value of $J_{1',2'}$ (6.2 Hz) calculated from the signals at 4.62 and 6.16 ppm (protons at C-2′ and C-1′, respectively). The NMR spectrum of the methyl ester of compound **6** was closely similar to that earlier reported for the methyl ester of synthetic 8(*Z*)-colneleic acid (15). On the basis of the results described, **6** was assigned the structure 12-[1′(*Z*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid, a new member of the oxylipin family of compounds.

*Incubations of 9(*S*)-HPOD, 9(*S*)-HPOT, and 13(*R*)-HPOT*. The hydroperoxides [1-^{14}C]9(*S*)-HPOD, [1-^{14}C]9(*S*)-HPOT, and [1-^{14}C]13(*R*)-HPOT (200 μM) were stirred with the enzyme preparation, and the products were analyzed by RP-radio-HPLC. In each case, a main peak of radioactivity appeared corresponding to unchanged hydroperoxide. In addition, a small peak due to the corresponding hydroxy acid (11–13% as compared to the hydroperoxide) was also observed. Compounds having the same polarity as divinyl ether fatty acids were undetectable.

Biosynthesis of divinyl ethers in other plants. Whole homogenates of leaves of 26 plants were incubated with [1-^{14}C]α-linolenic acid, and the product profiles were determined by RP-radio-HPLC (*cf.* Fig. 1). As seen in Table 3, formation of compound **4** was observed in leaves of *R. acris*, *R. repens*, *R. polyanthemos*, *R. peltatus*, and *R. lingua* but not in any of the other 21 plants tested. Interestingly, leaves of *R. peltatus* and *R. lingua*, two aquatic plants, produced compound **4** as well as another, slightly less polar compound. This compound appeared to be an isomer of compound **4** as suggested by its UV spectrum, which showed λ_{max} (EtOH) = 267 nm, and its mass spectrum (methyl ester), which was similar to but not identical to that of the methyl ester of compound **4**. Work is in progress to determine the full structure of this isomer.

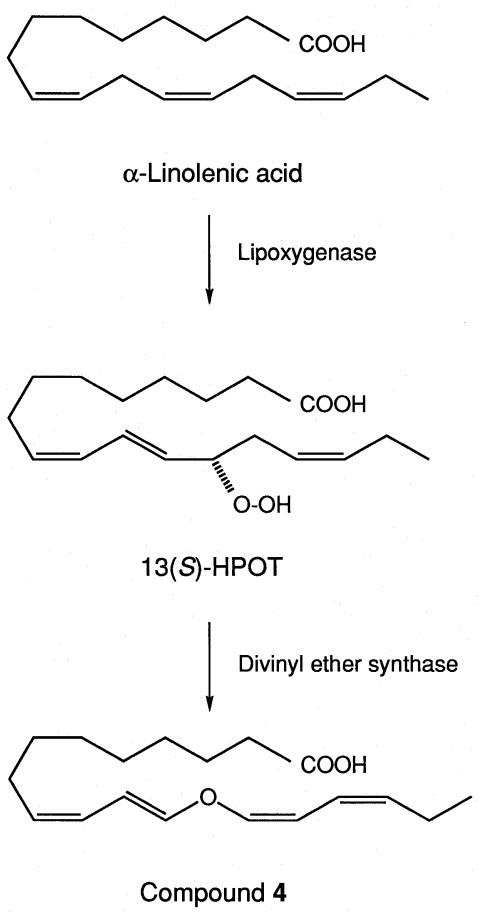
Chromatographic separation of divinyl ether fatty acids. For analytical purposes, it was of interest to examine the chromatographic separation of regio- and stereoisomeric divinyl ethers. As expected, RP-HPLC readily separated compounds **4** and **6** (effluent volumes, 34.2 and 46.2 mL, respectively, using solvent system B). On the other hand, RP-HPLC did not allow separation of compounds **4** or **6** from their corresponding 1′(*E*) isomers (etherolenic and etheroleic acids). SP-HPLC was useful for separation of the methyl esters of the three groups of C_{18} divinyl ethers fatty acids presently known. As seen in Table 1, within each group, the trienoic ester was easily separated from the corresponding tetraenoic ester. The three trienoates as well as the three tetraenoates were also separable; however, the separation between the trienoate methyl colneleate and the tetraenoate methyl etherolenate was small. Also GLC was useful for identification of the divinyl ethers, although the methyl esters of compound **4** and etherolenic acid were inseparable (Table 1). In fact, apart from separation by SP-HPLC, the only reliable way of distinguishing compound **4** and etherolenic acid was by NMR.

DISCUSSION

Compound **4** was isolated in crystalline form as a product of metabolism of α-linolenic acid in a preparation of leaves of the meadow buttercup (*R. acris* L.). By means of spectral and

chemical methods, the structure assigned to compound **4** was 12-[1′(*Z*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid. This compound had previously been isolated from a brown alga, *L. sinclairii* and characterized in form of its methyl ester derivative (12). Formation of compound **4** in *R. acris* occurred by a two-step process involving the hydroperoxide 13(*S*)-HPOT as an intermediate (Scheme 2). The enzymes involved, i.e., ω6-lipoxygenase and divinyl ether synthase, were both particle-bound. Linoleic acid 13(*S*)-hydroperoxide was metabolized analogously to 13(*S*)-HPOT and produced compound **6**. The transformation catalyzed by divinyl ether synthase of *R. acris* proceeded in a regio- and stereospecific way as judged by the finding that neither the 9-hydroperoxides of linoleic or α-linolenic acids nor the 13(*R*)-hydroperoxide of α-linolenic acid was convertible into divinyl ethers. As would be expected, 11(*S*)-hydroperoxy-7(*Z*),9(*E*),13(*Z*)-hexadecatrienoic acid, an ω6 hydroperoxide having the "*S*" absolute configuration, was efficiently converted by the enzyme to provide the dinor homolog of compound **4** (data not shown).

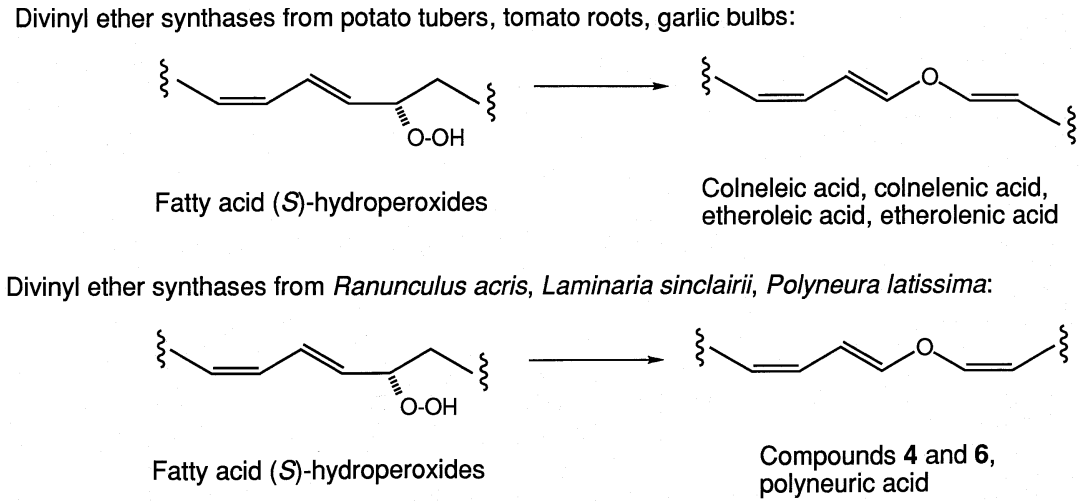
Profiles of oxylipins formed in fresh leaves were determined by incubation of [1-^{14}C]α-linolenic acid with leaf whole homogenates followed by analysis of the products by RP-radio-HPLC. The radio-HPLC method, which allowed separation of *inter alia* α- and γ-ketols, 12-oxo-PDA, and epoxyoctadecadienoates and of regioisomeric hydroxy-, hydroperoxy-, and oxooctadecatrienoates, appeared to be advantageous to the radio-thin-layer chromatography method recently described (10). By means of the RP-radio-HPLC technique, biosynthesis of compound **4** was consistently observed in leaves of plants belonging to the genus *Ranunculus*, family *Ranunculaceae* (Table 3). It was also noted that most of the plants were capable of biosynthesis of 12-oxo-PDA, thus giving support to the notion that compounds produced by the allene oxide synthase/allene oxide cyclase pathway are of general importance in plants (27,28).



SCHEME 2

In previous work, colneleic acid was isolated as a product of enzymatic dehydration of 9(*S*)-HPOD in preparations of potato tuber (9) and tomato roots (10). Isotopic studies of the conversion showed that one of the two hydroperoxide oxygens of the parent hydroperoxide was retained in the product (29), and that the *pro-R* hydrogen at C-8 of the hydroperoxide was selectively eliminated during formation of the Δ^8 double bond (20). Proposed intermediates in the conversion are an epoxide carbocation (20,29) or an oxonium ion, formed in a Bayer-Villiger-type reaction (15). Another divinyl ether, etheroleic acid, was recently obtained by incubation of 13(*S*)-HPOD with a membrane-bound divinyl ether synthase from bulbs of garlic (11,21). Etheroleic and colneleic acids may be regarded as regioisomers having identical configurations of their double bond systems, i.e., *Z,E* for the conjugated diene retained from the parent hydroperoxide, and *E* for the double bond introduced in the divinyl ether synthase reaction. Enzymatic dehydration catalyzed by extracts of potato and garlic also took place with α-linolenic acid 9- and 13-hydroperoxides, respectively. Thus, 9(*S*)-HPOT was converted into colnelenic acid by potato tuber (25), and 13(*S*)-HPOT was converted into etherolenic acid by preparations of garlic (11). These transformations appeared to proceed analogously to those of the corresponding linoleic acid hydroperoxides and involved introduction of a vinyl ether double bond having the *E* geometrical configuration (Scheme 3). Biosynthesis of compounds **6** and **4** from 13(*S*)-HPOD and 13(*S*)-HPOT, respectively, also proceeded with retention of the positions and configurations of the *Z,E*-conjugated double bonds of the parent hydroperoxides; however, in this case the newly introduced double bond ($\Delta^{1'}$) had the *Z* rather than the *E* geometrical configuration (Scheme 3). Introduction of a vinyl ether double bond having the *Z* configuration was similarly involved in the proposed biosynthesis of divinyl ethers from fatty acid hydroperoxides in marine algae (12,13).

Divinyl ether fatty acids emerge as a growing and interesting family of compounds produced by enzymatic dehydration of fatty acid hydroperoxides. The present study demonstrates that divinyl ethers can be produced in green leaves of certain higher plants. This makes it of interest to explore whether divinyl ethers, like jasmonic acid and other oxylipins of the allene oxide synthase–allene oxide cyclase pathway, are involved as mediators in defense reactions against pathogens or in other physiological or pathological processes in plants.



SCHEME 3

ACKNOWLEDGMENTS

Mrs. G. Hamberg is thanked for expert technical assistance and for collection and identification of the plant materials used. The author is greatly indebted to Prof. Per-Erik Jansson and Mr. Reine Eserstam (Clinical Research Center, Huddinge University Hospital, Stockholm) for their help with the NMR analyses. This work was supported by the Swedish Medical Research Council (Proj. No. 03X-5170) and by Vesical Co. (Stockholm).

ABSTRACT: This work shows that fucosterol, Δ^5-avenasterol, and similar ethylidene-side chain sterols can undergo acid-catalyzed isomerization to give a mixture of five isomers. Four isomers formed from fucosterol were analyzed, using gas chromatography–mass spectrometry, and were characterized as Δ^5-avenasterol, two $\Delta^{5,23}$-stigmastadienols, and $\Delta^{5,24(25)}$-stigmastadienol. When the unsaponifiables fraction from oat oil was subjected to acid hydrolysis, the two $\Delta^{5,23}$-stigmastadienol isomers and $\Delta^{5,24(25)}$-stigmastadienol were detected while fucosterol coeluted with sitosterol. Interisomerization of ethylidene-side chain sterols represents a limitation to the use of the acid hydrolysis method in the determination of sterols in food and other plant materials rich in these sterols, e.g., oat lipids.
Lipids 33, 1073–1077 (1998).

Currently, the analysis of phytosterol content in foods is of interest because of their cholesterol-lowering properties (1). Plant sterols can be found in four forms: free sterols, sterol esters of fatty or phenolic acids, sterylglycosides, and acylated sterylglycosides (2,3). The major dietary sources for phytosterols are vegetable oils (4) and cereals (2). Although methodology for the analysis of sterols in oils is well established (5), methods for the analysis of sterols in cereals are yet to be developed and validated (6).

Campesterol, stigmasterol, sitosterol, and Δ^5-avenasterol (Table 1) are the most widespread phytosterols in plant foods. Analysis of the free and esterified forms of these sterols is possible by gas chromatography (GC) or by high-performance liquid chromatography after alkaline hydrolysis of whole foods or their lipid extracts (7), whereas analysis of these sterols in glycosylated forms requires hydrolysis of the glycosidic bonds (6,7). Furthermore, sterols may also be bound, together with other lipids, to the carbohydrate matrix of the cereal which makes them unavailable for straight extraction with lipophilic solvents. Thus, hydrolysis may also be needed to release starch-bound lipids including sterols (8). Jonker *et al.* (9) recommended the use of acid hydrolysis for the breakdown of the glycosidic bonds, but acid hydrolysis was previously reported to decompose labile sterol glycosides, namely Δ^5- and Δ^7-avenasterolglycosides in oats (7).

During our work on the analysis of oat sterols, we found that the conditions of strong acid and high temperature caused a marked decrease in the amounts of Δ^5-avenasterol and the emergence of an unknown peak (Määtä, K., Lampi, A., Petterson, J., Fogelfors, B.M., Piironen, V., and Kamal-Eldin, A., submitted for publication). In this paper, we investigate the effect of acid hydrolysis on fucosterol and other commercially available sterols (i.e., campesterol, stigmasterol, and sitosterol) (Table 1). We also study the nature of the degradation products resulting from fucosterol and compare them to those generated from Δ^5-avenasterol present in oat kernel unsaponifiables.

EXPERIMENTAL PROCEDURES

Materials. Lipids were extracted from oat kernels in a Soxhlet apparatus using *n*-hexane. Reference sterols were obtained from the following sources: sitosterol (Research Plus Inc., Bayonne and Denville, NJ), campesterol (C-5157), stigmasterol (S-2424), and fucosterol (F-5379) from Sigma Chemical Co. (St. Louis, MO). Cholestane (C-8003, Sigma) was used as a reference standard in GC analyses. Tri-Sil®, the reagent used to derivatize the sterols to trimethylsilyl ethers (TMS ethers), was purchased from Pierce Chemical Co. (Rockford, IL). All other solvents and reagents used were of analytical grade (E. Merck, Darmstadt, Germany) and were used without further purification.

Preparation of the sterol samples. Oat lipids were saponified by reaction with saturated aqueous KOH/ethanol (1:8, vol/vol) at 85°C for 10 min, and the unsaponifiables were extracted with cyclohexane and deionized water. The unsaponifiables obtained from oat lipids and different sterol standards (*viz.,* fucosterol, sitosterol, campesterol, and stigmasterol) were

TABLE 1
Trivial and Systematic Names of Sterols Mentioned in the Text

Trivial name	Systematic name
Campesterol	Δ^5-24α-methyl-cholesten-3β-ol
Stigmasterol	$\Delta^{5,E\text{-}22}$-24α-ethyl-cholestadien-3β-ol
Sitosterol	Δ^5-24α-ethyl-cholesten-3β-ol
Fucosterol	Δ^5-24*Z*-ethylidene-cholestadien-3β-ol
Δ^5-Avenasterol	Δ^5-24*E*-ethylidene-cholestadien-3β-ol
Δ^7-Avenasterol	Δ^7-24*E*-ethylidene-cholestadien-3β-ol

Abbreviations: GC–MS, gas chromatography–mass spectrometry; RRT, relative retention time; TMS, trimethylsilyl.

analyzed for their sterol contents by GC with and without acid hydrolysis. Cholestane was added as a reference standard in amounts approximately equal to those of the sterol in the samples. Acid hydrolysis was performed by a modification of the AOAC method (8) using 6 M HCl for 30 min at 80°C, and sterols were then extracted with cyclohexane/diethylether (1:1, vol/vol) (Toivo, J., unpublished). Most of the solvents were evaporated at 40°C by a rotary evaporator, and sterols were dissolved in chloroform, transferred to glass-stoppered tubes, and stored at –20°C until further analysis.

Derivatization. TMS ether derivatives of the sterols were prepared by adding 100–120 μL of the Tri-Sil reagent to sterols (50–200 μg) in glass-stoppered tubes. After shaking to dissolve the sterols in the reagent, the tubes were heated at 60°C for 45 min. Excess reagent was then removed under nitrogen, and the residue was dissolved in hexane.

GC and GC–mass spectrometry (MS). Analysis of sterol TMS derivatives was performed using a DB-5ms fused-silica capillary column (5% phenyl-methylpolysiloxane, 30 m × 0.25 mm i.d. and 0.25 μm film thickness; J&W Scientific, Folsom, CA) fitted in an HP 5890 II series gas chromatograph (Hewlett-Packard, Avondale, PA) fitted with a flame-ionization detector, a splitless injector, and an autosampler (7673; Hewlett-Packard). The separation was performed under the following temperature program: 70°C (1 min), 25°C/min, 275°C (21 min). The injector and detector temperatures were 250 and 330°C, respectively, and the helium (carrier gas) was used at an inlet pressure of 18 psi. Peaks were recorded and peak areas were computed using a GyncoSoft version 5.3 software (Gynkotek GmbH, Germering, Germany).

GC–MS was performed on an HP 5890 series II gas chromatograph coupled to a TRIO-1000 mass spectrometer with a LAB-BASE™ data system (version R2.10; Fisons Instruments, VG MASSLAB, Manchester, United Kingdom). The separation was performed on the same column as above under the following temperature program: 70°C (1 min), 25°C/min, 245°C (1 min), 3°C/min, 275°C (20 min). Helium was used as a carrier gas at an inlet pressure of 12 psi. Electron ionization (EI) mass spectra (*m/z* 100–500) were obtained at a scan rate of 10 scans/min, a 70 eV ionization energy, 280°C interface temperature, and 200°C ion source temperature.

RESULTS AND DISCUSSION

Kesselmeier *et al.* (7) showed that Δ^5- and Δ^7-avenasterols present in oat lipids are destroyed by acid hydrolysis. Figure 1 presents gas chromatograms of the unsaponifiable fractions of oat lipids analyzed, in this study, with and without acid hydrolysis. Samples analyzed before acid hydrolyis showed peaks for campesterol, stigmasterol, sitosterol, Δ^5-avenasterol, and Δ^7-avenasterol. The chromatogram of samples analyzed after acid hydrolysis showed a significant reduction in the level of Δ^5-avenasterol accompanied by the emergence of a number of unknown peaks. Tisconia and Bertini (10) previously reported that a remarkable change in the contents of Δ^5-avenasterol occurred in olive oil during bleaching and that the effect was magnified by increasing the level of bleaching earth. Touche *et al.* (11) made similar observations for bleached coconut oil, where about 50% of Δ^5-avenasterol was destroyed. In both studies, the decrease in Δ^5-avenasterol content was accompanied by the appearance of some unidentified components, one of which was then identified as its geometrical isomer, fucosterol.

The unknown peaks in acid-hydrolyzed oat unsaponifiables (Fig. 1) had retention times and mass spectra similar to the isomerization products of fucosterol (Fig. 2). The two sterols eluting in the double peak before sitosterol in Figures 1 and 2 [isomers a and b, relative retention times (RRT) 1.70 and 1.71, respectively] as well as the last isomer (RRT = 1.85) had the same retention times and mass spectra as those resulting from fucosterol (*vide infra*). However, fucosterol coeluted with sitosterol (as judged by injection of standards) under the chromatographic conditions used. The presence of fucosterol in the acid-hydrolyzed oat unsaponifiables was confirmed by the detection of the ions at *m/z* 296 and *m/z* 386 in the mass spectrum of a mixed sitosterol/fucosterol peak (RRT = 1.75) and their absence in the unhydrolyzed oat unsaponifiables (Fig. 3).

Commercially available campesterol, stigmasterol, and sitosterol were subjected to acid hydrolysis and analyzed by GC–MS. Results showed that acid hydrolysis had no effect on these sterols since chromatograms of untreated and acid-treated sterols were similar (data not shown). Owing to the lack of a commercial standard of Δ^5-avenasterol, its geometrical isomer fucosterol was used for acid hydrolysis. The GC–MS chromatogram of the TMS derivatives of acid-treated fucosterol (Fig. 2) showed that fucosterol was partially transformed into Δ^5-avenasterol and three other peaks. Examination of the mass spectra of all five peaks (Fig. 4) revealed that all peaks have similar molecular masses (484 for TMS derivatives), suggesting that they are all isomers. Acid-catalyzed isomerization of fucosterol can be expected to affect only the side chain double bond since it is generally known that the sterol Δ^5 double bond is insensitive to acids, in contrast to Δ^7 double bonds which isomerize to Δ^8- under acid conditions (Parish, E.J., personal communication). The mass spectra of fucosterol (RRT = 1.75, relative to cholestane which elutes at 16.7 min) and Δ^5-avenasterol (RRT = 1.79) are nearly identical and are similar to the mass spectrum of Δ^5-avenasterol presented elsewhere (Määtä, K., Lampi, A., Petterson, J. Fogelfors, B.M., Piironen, V., and Kamal-Eldin, A., submitted for publication). The characteristic ions in these spectra are the *m/z* 386 due to McLafferty-type cleavage of the C22-C23 bond together with a one-hydrogen transfer from C-20 (12) and the ion at *m/z* 296 (386 – trimethylsilanol). The spectrum of the last isomer (RRT = 1.85) is similar to those of fucosterol and Δ^5-avenasterol and may be attributed to $\Delta^{5,24(25)}$-stigmastadienol (13). The mass spectra of the two compounds eluting in the double peak (RRT 1.70 and 1.71) just before sitosterol (RRT = 1.76) are nearly identical and suggest a $\Delta^{5,23}$ structure based on the assignment of the characteristic peak at *m/z* 283 to an allylic cleavage of the C20-C22 bond coupled with loss of the silanol group (12,14). The assignment of a $\Delta^{5,23}$ to these compounds may

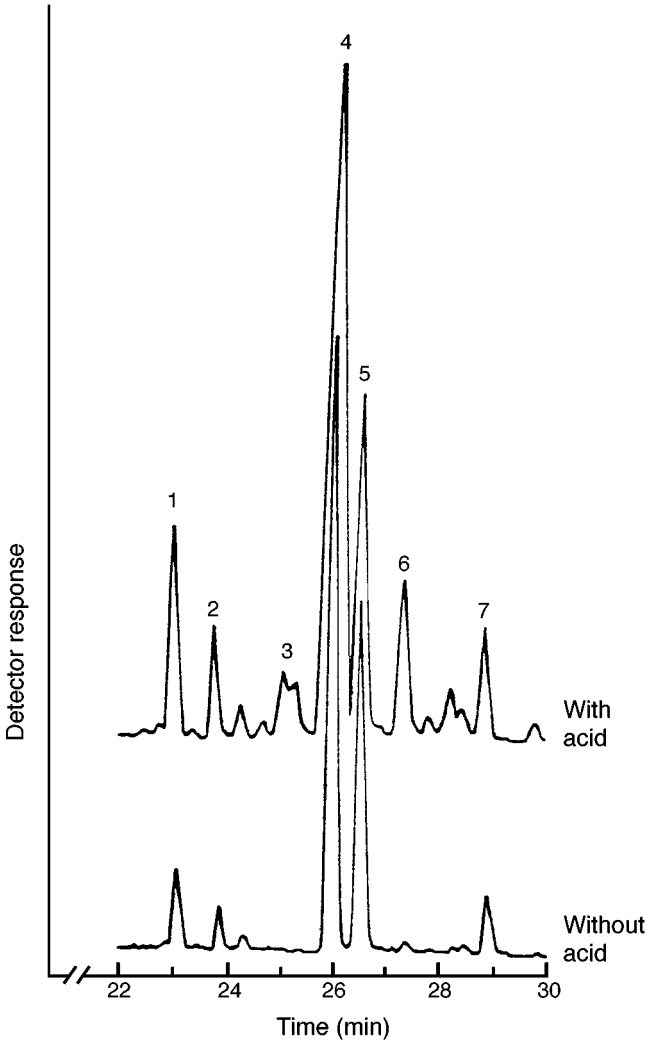

FIG. 1. Gas chromatography–mass spectrometry chromatogram of sterol extracts obtained from oat lipids with and without acid hydrolysis. Peaks: (1) campesterol, (2) stigmasterol, (3) unknowns, (4) sitosterol + fucosterol (with acid) and only sitosterol (without acid), (5) Δ^5-avenasterol, (6) unknown sterol having similar mass spectrum as Δ^5-avenasterol, and (7) Δ^7-avenasterol.

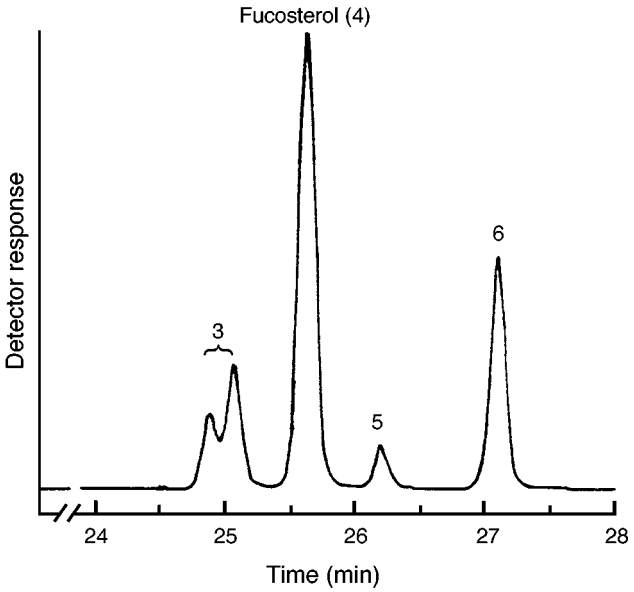

FIG. 2. Gas chromatography–mass spectrometry chromatogram showing acid-catalyzed isomerization products of fucosterol. Peaks: (3) sterols (a) and (b), (4) fucosterol, (5) Δ^5-avenasterol, and (6) sterol (c) or $\Delta^{5,24(25)}$-stigmastadienol. For identifications of (a), (b), and (c) see Figure 4.

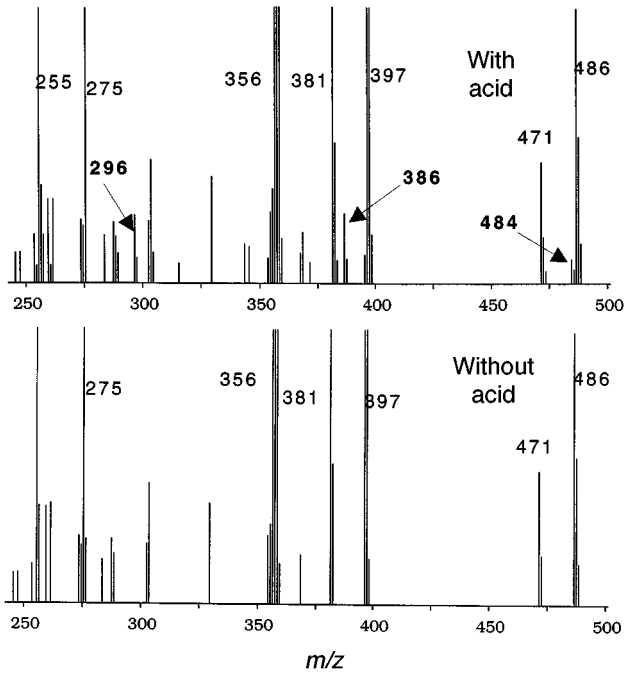

FIG. 3. Magnified part (*m/z* 250–500) of the mass spectra of peak 4 in the sterol extract from oat lipids with and without acid hydrolysis (see Figure 1). Peaks at *m/z* 296, 386, and 484 (upper panel) are typical for fucosterol and their intensities can be compared to the peak at *m/z* 471 (M-15, relative abundance to an *m/z* 129 base peak = 3.4%), one of the typical peaks for sitosterol

be argued since this structure has been reported not to occur naturally. This structure is supported by knowledge related to carbonium ion stabilities and by mass fragmentation patterns. Two other structural possibilities, *viz.* $\Delta^{25(27)}$ and $\Delta^{28(29)}$, were ruled out since an ion at *m/z* 290 (due to allylic cleavage at the C23-C24 bond together with loss of the silanol group) was absent in their mass spectra.

The isomerization of fucosterol, and probably other ethylidene-side chain sterols, can be explained by considering the stability of the carbonium ion resulting from reactions of acids with alkenes. It is known that the stability of carbonium ions determines the relative reactivities of different alkenes toward acids. The side chain double bond in these sterols is labile owing to the possibility of formation of a stable tertiary carbonium ion, whereas the double bond in stigmasterol is stable toward acid hydrolysis possibly because of a relatively

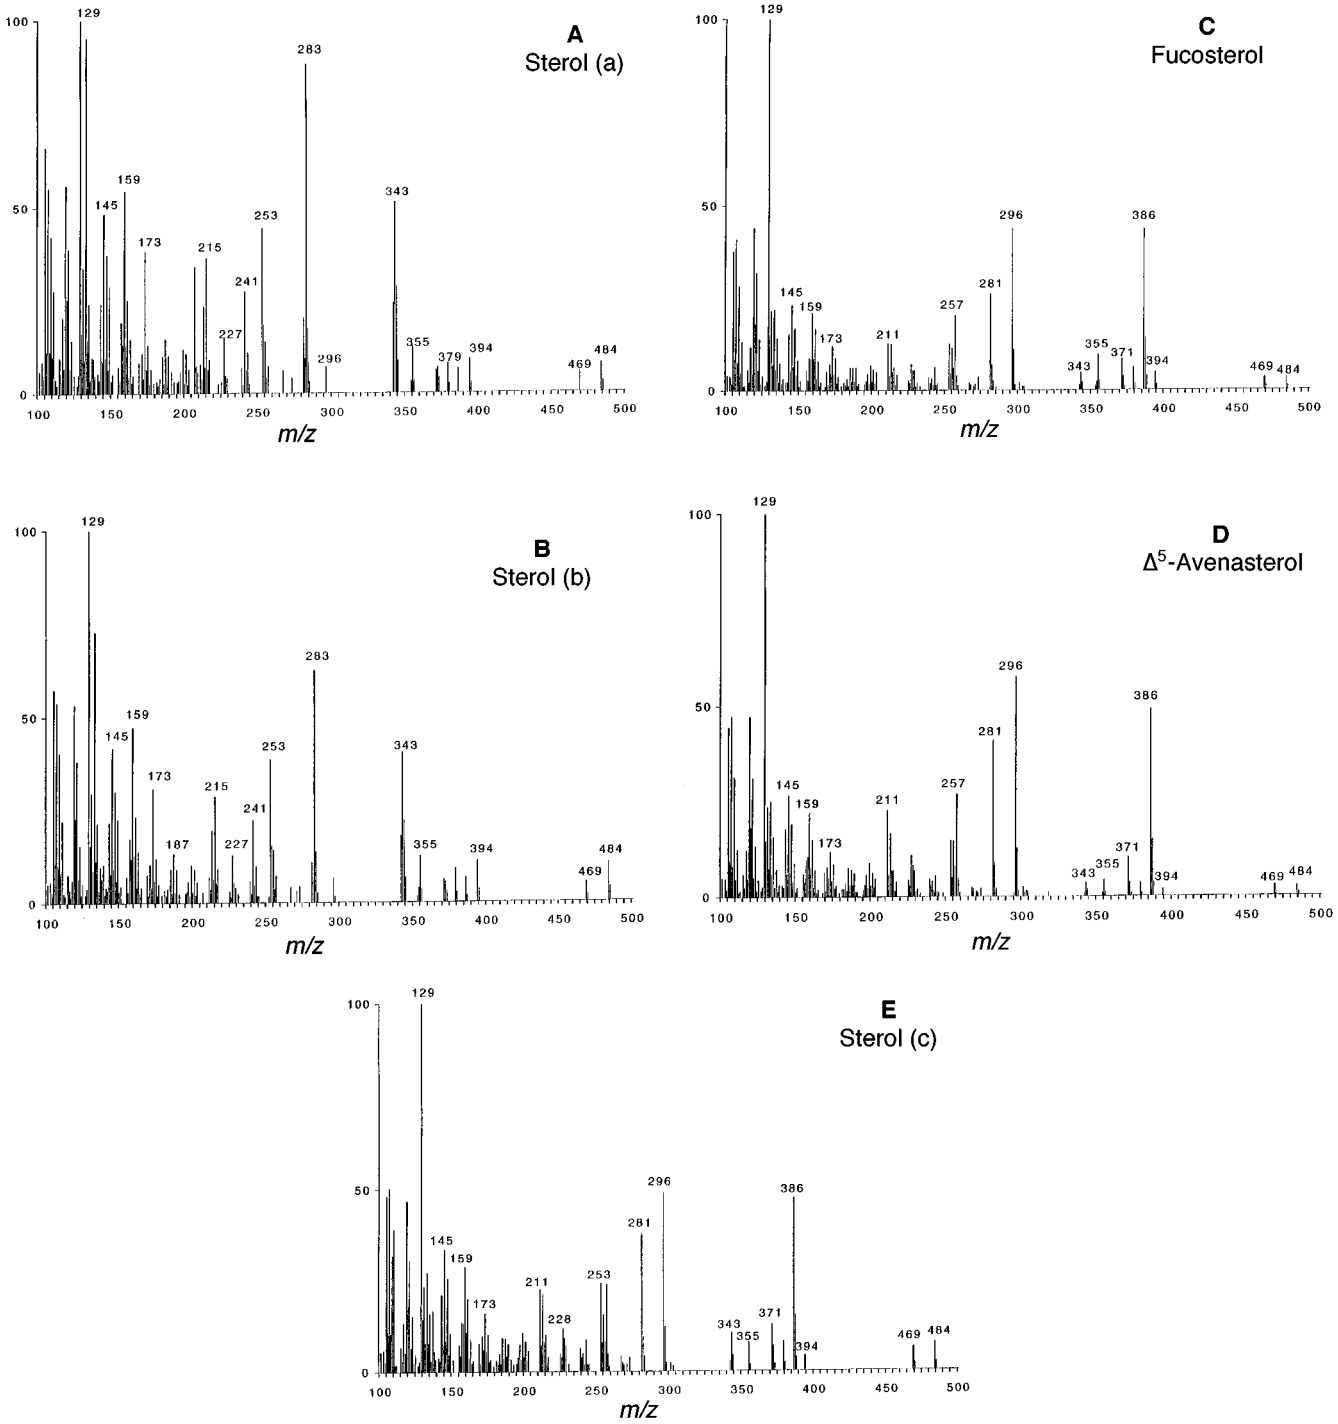

FIG. 4. Mass spectra of the isomerization products of fucosterol. See chromatogram in Figure 2 for peak positions.

lower stability of the secondary carbonium ion resulting in that case. The stability of the carbonium ions determines not only the reactivity of double bonds toward acids but also the type of products resulting from the return of the carbonium ion to an alkene *via* the loss of the acidic proton. After the carbonium ion is formed, it can lose a proton to produce a number of possible isomeric alkenes, the more highly substituted alkenes being the most preferable products (15). Application of this basic notation to the fucosterol/Δ^5-avenasterol case (Fig. 5) explains the findings obtained in this study.

The isomerization of Δ^5-avenasterol and other ethylidene-side chain sterols needs to be considered when analyzing sterol levels in foods derived from plants and other plant products. Fortunately, these sterols are abundant only in a few foods (e.g., oats) which restricts the analytical problem only to those foods. Ways to overcome this problem, including the

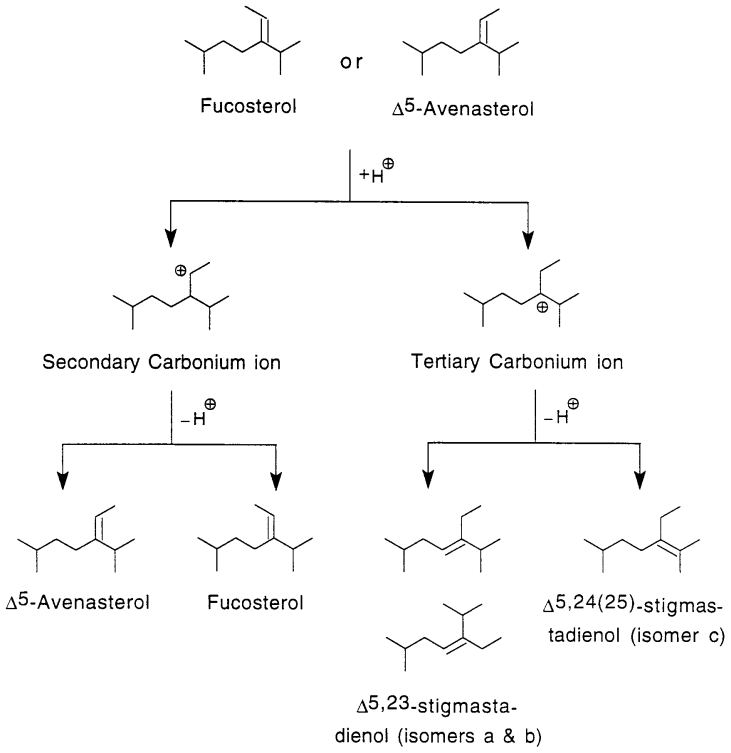

FIG. 5. Representation of the hypothetical acid-catalyzed isomerization of fucosterol and Δ^5-avenasterol.

enzymatic hydrolysis suggested by Kesselmeier *et al.* (7) need to be investigated, and alternative or complementary analytical methods need to be developed and validated.

Surface Pressure-Dependent Cross-Modulation of Sphingomyelinase and Phospholipase A_2 in Monolayers

María Laura Fanani and Bruno Maggio*

Departamento de Química Biológica - CIQUIBIC, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, CC 61, 5000 Córdoba, Argentina

ABSTRACT: We investigated the ways in which phospholipase A_2 and sphingomyelinase are mutually modulated at lipid interfaces. The activity of one enzyme is affected by its own reaction products and by substrates and products of the other enzyme; all this depends differently on the lateral surface pressure. Ceramide inhibits both the sphingomyelinase activity rate and the extent of degradation, and decreases the lag time at all surface pressures. Dilauroyl- and dipalmitoylphosphatidylcholine, the substrates of phospholipase A_2 (PLA_2), do not affect sphingomyelinase activity. The products of PLA_2, palmitic acid and lysopalmitoylphosphatidylcholine, strongly enhance and shift to high surface pressures the activity optimum and the cut-off point of sphingomyelinase. Palmitic acid also shifts to high surface pressures the cut-off point of PLA_2 activity. Sphingomyelin strongly inhibits PLA_2 at surface pressures above 5 mN/m, while ceramide shifts the cut-off point and the activity optimum to high surface pressures. The sphingolipids increase the lag time of PLA_2 at low surface pressures. Both phosphohydrolytic pathways involve different levels of control on precatalytic steps and on the rate of activity that appear independent on specific alterations of molecular packing and surface potential. The mutual lipid-mediated interfacial modulation between both phosphohydrolytic pathways indicates that phospholipid degradation may be self-amplified or dampened depending on subtle changes of surface pressure and composition.
Lipids 33, 1079–1087 (1998).

Lipid substrates organized in well-controlled simple model membrane systems have been invaluable for unraveling on a molecular basis the generic surface determinants of lipolytic activity in relation to the physical properties of the lipid substrate. Lipid monolayers in particular, the model on which the very concept of a lipid bilayer as the basic constitutive structure of biomembranes was derived, clearly demonstrated that the activity of several phospholipases from different sources is markedly affected by both the long-range physical state and the fine intermolecular organization of the lipid interface (1,2). The unique possibility of lipid monolayers maintaining a control and precise knowledge of several surface parameters in real time during a catalytic reaction showed that, besides the influence of structural defects and curvature (3–5), the lateral surface pressure and electrostatic interfacial potential (6,7) can markedly affect the activity of phospholipase A_2 (PLA_2), phosphatidylinositol-specific and nonspecific phospholipase C, and sphingomyelinase (Sphmase) (8–14). Despite the fact that phosphohydrolytic enzymes constitute a very heterogeneous group of proteins, all activities studied to date have revealed a profound dependence on a few fundamental supramolecular surface parameters of the lipid interface on which they act (1–9,13–15). This is extremely important because it means that biophysical studies in model systems, usually requiring relatively large amounts of well-purified enzymes and lipids, can provide valuable information using readily available secretory or bacterial phosphohydrolytic enzymes when the aim is, as in the present work, to understand the general basic physicochemical parameters regulating these activities.

On the other hand, several lipid mediators and biomodulators of membrane function can either be common intermediates or participate indirectly as parent or derived compounds that relate different signaling pathways (16–19). Several of these lipids cause profound local and long-range effects on the molecular organization and overall topology of the membrane interface (5,20) that can markedly affect lipolytic activity (2,5,10,21). Nonsubstrate lipids such as gangliosides, neutral glycosphingolipids, ceramide (Cer), sphingosine, and semisynthetic derivatives of sphingosine in mixed phospholipid monolayers, unilamellar vesicles, and micelles can modulate the activity of PLA_2 and phospholipase C (2,7,21–26). Recent studies indicate that lipid mediators such as diacylglycerols and Cer, formed by *Bacillus cereus* phospholipase C and Sphmase degradation of bilayer vesicles, affect markedly and in different manners the membrane topology, stability, and susceptibility to bilayer recombination (27,28).

Abbreviations: Cer, ceramide (*N*-stearoylsphingosine); Cer*P*Cho, brain sphingomyelin; dlPC, (didodecanoyl-*sn*-glycero-3-phosphocholine); dpPC, (dihexadecanoyl-*sn*-glycero-3-phosphocholine); llPC, lysolauroylphosphatidylcholine, (1-lauroyl-2-hydroxy-*sn*-glycero-3-phosphocholine); lpPC, lysopalmitoylphosphatidylcholine, (1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine); PLA_2, porcine pancreatic phospholipase A_2 (E.C. 3.1.1.4); Sphmase, sphingomyelinase, *Bacillus cereus* sphingomyelin phosphodiesterase (E.C. 3.1.4.12).

In previous work we showed that it is possible to follow the degradation of brain sphingomyelin (Cer*P*Cho) to Cer by *B. cereus* Sphmase using lipid monolayers to precisely control the intermolecular organization of the interface while the catalytic reaction is taking place (10). An independent study with a bacterial Sphmase from *Staphylococcus aureus* (11) published almost simultaneously to ours also showed that this is a valid technique. These results are in general agreement regarding the use of the technique, the catalytic rate and presence of lag time, while the surface pressure dependence of the activity of the two bacterial Sphmases reveals some differences (10,11).

We showed that the activities of *B. cereus* Sphmase and porcine pancreatic PLA_2 can be mutually modulated by the presence of their respective substrates and products (10). The importance of this finding resides mostly in that it clearly indicated under well-controlled molecular organization and in real time that the rate of phospholipid degradation by one enzymatic pathway contains information that can be sensed by, transduced to, and markedly modulate the catalytic rate of another pathway with which no common intermediates are shared (10). In continuation of our studies and with the objectives of understanding the generic biophysical determinants of the mutual modulation of both enzymes under well-controlled molecular conditions, within the context given at the beginning of this section, we investigated the possible dependence of the lipid-mediated changes of enzymatic activities on the lateral surface pressure and on whether these could be correlated to alterations of the lipid organization according to film composition and surface pressure. The results obtained provide evidence, at least from this simplified model system, which supports the concept of a surface-regulated interfacial "cross-talk" between Sphmase- and PLA_2-catalyzed pathways which selectively depends on which lipid intermediate of either pathway is present. In addition, the mutual modulation is controlled dramatically by the lateral surface pressure and in different manners depending on the surface composition; the lipids participating in both pathways affect differently the rate of activity, the lag time, or the extent of the catalytic reactions mediated by Sphmase and PLA_2, but the effects are independent of molecular packing expansion–condensation, or alterations of the local electrostatic dipole potential caused by specific lipid–lipid interactions.

EXPERIMENTAL PROCEDURES

Porcine pancreatic PLA_2 and *B. cereus* Sphmase were from Sigma-Aldrich, Inc. (St. Louis, MO). Didodecanoyl-*sn*-glycero-3-phosphocholine (dlPC), dihexadecanoyl-*sn*-glycero-3-phosphocholine (dpPC), palmitic acid, 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (lpPC), Cer*P*Cho, and Cer were from Avanti Polar Lipids (Alabaster, AL). Organic solvents and chemicals were of the highest purity available, inorganic salts were roasted at 400°C, and water was double-distilled in an all-glass apparatus. Absence of surface-active impurities in aqueous solution and spreading solvents was controlled as described (28,29). Details of the equipment used were given elsewhere (30): a specially designed thermostated circular Teflon-coated trough with two adjacent compartments separated from each other by shallow and narrow slits. Monolayers of pure or mixed lipids (containing, unless otherwise stated, 10 mol% of a nonsubstrate lipid) were prepared as described previously at the desired surface pressure (10), which was kept constant by an automatic surface barostat (31). An aliquot of a concentrated enzyme solution was injected into the subphase (final concentration for Sphmase and PLA_2 was 83 and 105 ng protein/mL buffer, respectively) of the reaction compartment (18 mL, 17 cm^2 of surface area) under continuous stirring with a miniature Teflon-coated rod. The adjacent compartment served as a monolayer reservoir that automatically supplied lipid to the surface of the reaction compartment in order to maintain constant the surface pressure during the enzymatic reaction. The time course of the reaction was followed at 25 ± 1°C by the decrease of surface area as a function of time (10). The rates of enzymatic activities reported in the ordinate of the figures and in Table 1 are calculated as the number of lipid molecules degraded per minute per unit of surface area as reported elsewhere (1,7,10,11,22–25) and correspond to the slope of the linear portion of the time-course curves (Fig. 1) obtained in duplicate or triplicate for the different systems studied. The lag time (1) is taken by extrapolation of the linear part of the curve of phospholipid degradation as a function of time

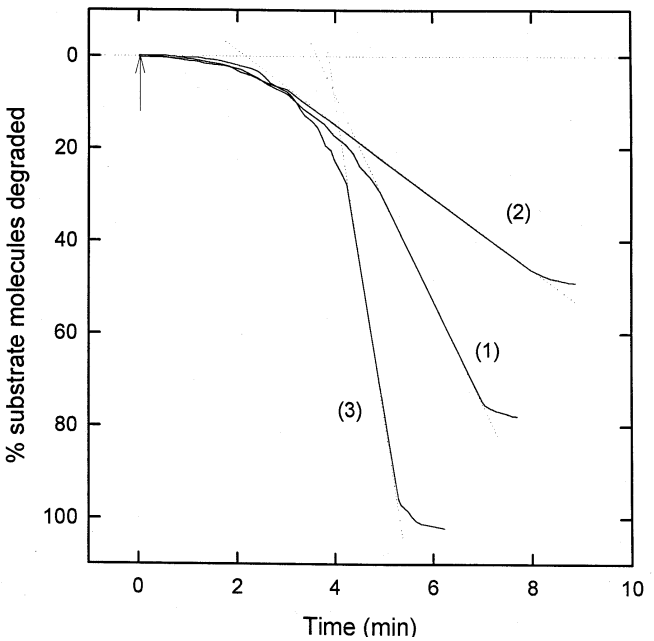

FIG. 1. Sphingomyelinase, *Bacillus cereus* sphingomyelin phosphodiesterase (E.C. 3.1.4.12) (Sphmase) activity against mixed lipid monolayers. Representative real time experiments of the degradation by Sphmase of a lipid monolayer of pure brain sphingomyelin (Cer*P*Cho) at 15 mN/m (curve 1), Cer*P*Cho/ceramide (Cer) (9:1) at 15 mN/m (curve 2), and Cer*P*Cho/palm (9:1) at 20 mN/m (curve 3) are shown. The arrow represents injection of 83 ng/mL Sphmase (final concentration) in the subphase.

TABLE 1
Comparison Between the Deviation from Ideality of the Molecular Parameters and Enzymatic Activities and Lag Times in Mixed Monolayers[a]

		10 mN/m				20 mN/m			
Enzyme	Lipid mixture (9:1)	Percentage deviation of mean molecular area	Percentage deviation of surface potential/ molecule	Enzymatic activity (mol/min·cm^2) $\times 10^{-13}$ ± SEM	Lag time (min)	Percentage deviation of mean molecular area	Percentage deviation of surface potential/ molecule	Enzymatic activity (mol/min·cm^2) $\times 10^{-13}$ ± SEM	Lag time (min)

[a]The table shows the percentage deviation from the ideal behavior of the mean molecular area and surface potential/molecule and the porcine pancreatic phospholipase A_2 (PLA_2) or sphingomyelinase, *Bacillus cereus* sphingomyelin phosphodiesterase (E.C. 3.1.4.12) (Sphmase) activities and lag times in mixed monolayers of didodecanoyl-*sn*-glycerol-3-phosphocholine (dlPC) or brain sphingomyelin (Cer*P*Cho) with 10 mol% of the nonsubstrate lipid indicated at 10 and 20 mN/m. Similar lack of correlation of molecular packing or surface potential/molecule with the rate of enzyme activity or lag times was found at other surface pressures; Cer, ceramide; lpPC, 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine.
[b]These mixed lipid monolayers at 20 mN/m are above the surface pressure cut-off point for PLA_2.

(Fig. 1) to the abscissa at zero substrate degradation (10). The number of molecules is obtained from the known area per molecule at each surface pressure, using the respective lipid surface pressure–area compression isotherm for each mixture (data not shown). The extent of degradation is expressed as the percentage of substrate molecules hydrolyzed at the end of the reaction (Fig. 1), with respect to those initially present on the surface of the reaction compartment. The halting of the reaction occurs at different times for the different mixtures and surface pressures employed, and the final extent of degradation is independent of the reaction rate.

For PLA_2 we used dlPC as substrate (7,22). Its degradation produces lysolauroylphosphatidylcholine (llPC) and lauric acid, both of which are immediately desorbed from the monolayer into the subphase, resulting in a true zero-order kinetic regime when pure substrate is continuously supplied from the monolayer reservoir (1,22, 23). In the case of Sphmase, the hydrolysis of Cer*P*Cho produces Cer which remains in the monolayer. Because of the marked difference between the molecular area of Cer*P*Cho and Cer, the catalytic activity can be measured by the decrease of monolayer area at a specified surface pressure (10,11). The portion of linear decrease of area as a function of time represents a pseudo zero-order kinetics (10,22,23). After this, the velocity of the enzymatic reaction gradually decreases to zero due to the increased mole fraction of product remaining at the interface.

RESULTS

In order to properly determine the rate of degradation of Cer*P*Cho and dlPC by Sphmase or PLA_2, respectively, in lipid monolayers containing 10 mol% of other lipids, it is necessary to know the possible alteration of the molecular packing areas due to lipid–lipid interactions. To this end, we carried out surface pressure– and surface potential–area isotherms at 25 ± 1°C for mixed films of Cer*P*Cho with 10 mol% of Cer, dlPC, lpPC and palmitic acid, as well as of dlPC with 10 mol% of palmitic acid, lpPC, Cer, and Cer*P*Cho. Table 1 shows the percentage deviations from the ideal mixing behavior for the mean molecular area and mean surface potential per unit of molecular surface density of these films [usually denominated surface potential/molecule (30)] at two different representative surface pressures together with the rate of activity of Sphmase or PLA_2 and the lag time, at the indicated film composition and surface pressure. The deviations in mean molecular area were taken into account for the calculation of the number of molecules of Cer*P*Cho or dlPC degraded by the respective enzymes acting on each mixed film (22). All the films studied showed small deviations of the mean molecular area, while relatively low negative deviations of the surface potential per molecule were observed in some of the films. In any case, in spite of similar or different behavior regarding the alteration of molecular parameters, the activation or inhibition of the rate of enzymatic activities, or variation of the lag times, showed no consistent correlation (i.e., always increases or decreases enzyme activity or lag times for molecular expansions or condensations, or depolarizations or hyperpolarizations) with changes of intermolecular packing or alterations of the surface electrostatic potential per molecule across the interface (Table 1).

Activity of Sphmase against mixed monolayers: *(i) Effect of Cer.* At all surface pressures studied, and in all the films, after a time that depends on the surface pressure and on the film composition, the reaction reaches a constant rate of degradation (pseudo zero-order kinetic regime); after this it decreases

gradually to zero (see Fig. 1) owing to the increasing proportion of product remaining at the interface (10). The existence of the linear pseudo zero-order regime indicates that the enzymatic catalysis is proceeding in temporary steady state in the film due to the initial substrate excess with respect to the enzyme at the interface. The rate of activity is altered by the presence of Cer, the product of the Sphmase reaction. The inhibition exerted by the initial presence of Cer that was described before at 15 mN/m (10) was also found over the whole range of surface pressures studied (Fig. 2A). The inhibition is less marked at surface pressures beyond 18 mN/m largely because the very Sphmase activity against a pure film of Cer*P*Cho decreases dramatically at 18 mN/m and above (10). In films containing Cer, the lag time consistently remains slightly shorter than that found against pure Cer*P*Cho (between surface pressures of 5 and 20 mN/m), and it does not show the dramatic increase above 18 mN/m (Fig. 2B). Cer decreases the extent of degradation of Cer*P*Cho by Sphmase over the whole range of surface pressure studied (Fig. 2C). The initial presence of product stops the reaction at a lower ratio of Cer/Cer*P*Cho than that necessary to end the reaction against a pure film of Cer*P*Cho. A defined threshold of relative proportions for the action of Cer appears to be present. Similar results were obtained in films containing 10 or 5 mol% of Cer; with proportions of 2.5 mol% or less, Cer induces no alteration of the lag time or the rate of activity compared to a film of pure Cer*P*-Cho, an effect of Cer exerted directly at the interface and not on the enzyme in the bulk subphase (10).

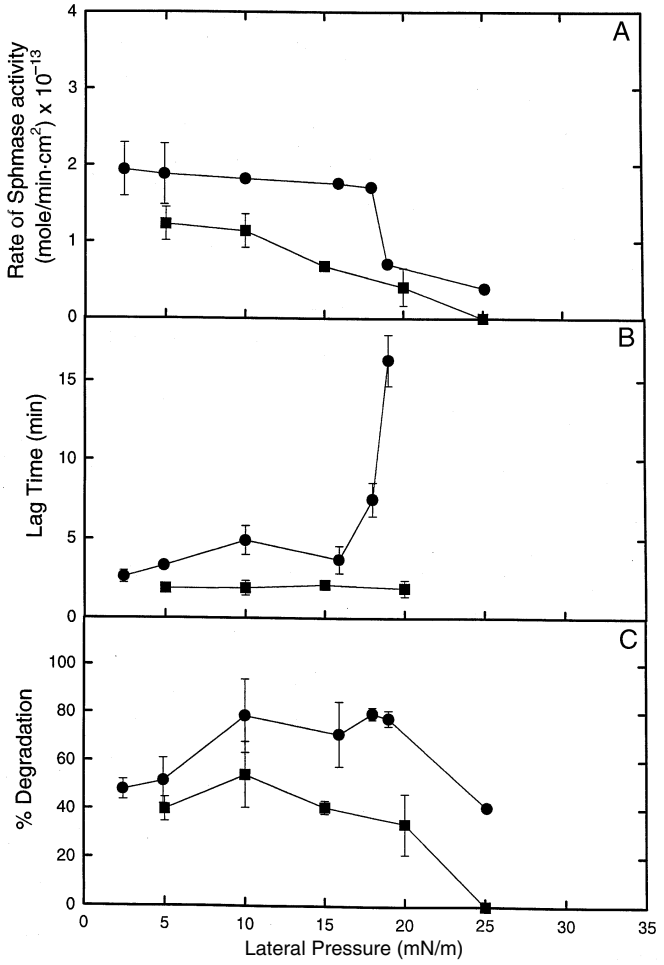

FIG. 2. Surface pressure dependence of sphingomyelinase activity against monolayers containing Cer. The rate of sphingomyelinase activity (A), lag time (B), and percentage substrate degradation (C) against monolayers of pure Cer*P*Cho (●) and Cer*P*Cho/Cer (9:1) (■) are shown at different constant surface pressures. The results are average values ± SEM; where no error bars can be seen these are within the size of the point. See Figure 1 for abbreviations.

(ii) Effect of substrates and products of PLA$_2$. We previously reported that dlPC or dpPC, substrates of PLA$_2$, had no significant influence on the Sphmase activity at 15 mN/m when present at a mole fraction of 0.1 in mixed monolayers with Cer*P*Cho (10). Figure 3 shows that this is generally the case also at all the other surface pressures studied. For simplicity, only the results for dpPC are shown in Figure 3 since the effects of dlPC on Sphmase activity were generally similar. Experiments using mixed films of Cer*P*Cho with the products of degradation of dlPC cannot be done because the short-chain products lauric acid and llPC desorb immediately from the interface into the subphase. Because of this and since, different from dlPC, the products of degradation of dpPC, namely palmitic acid and lpPC, remain at the interface where we performed the experiments with the latter lipids.

Figure 3A shows that both palmitic acid and lpPC have a similar influence on the pattern of surface pressure dependence of Sphmase activity, compared to that found for pure Cer*P*Cho at surface pressures below 15 mN/m (although the dependence on pressure is similar, palmitic acid is actually inhibitory of the activity by about 50–70% over the range 5–15 mN/m while lpPC has no significant effect). At 18 mN/m and above, either palmitic acid or lpPC strongly enhances the hydrolysis of Cer*P*Cho by Sphmase exhibiting a peak of activation at 20 mN/m. Also, either lipid markedly shifts to higher values the cut-off surface pressure point for activity. As mentioned before (10), an equimolar mixture of lpPC and palmitic acid has no significant effect on the activity of Sphmase over the whole range of surface pressure studied (data not shown).

The lag times for the Sphmase reaction against the mixed films with palmitic acid or lpPC are similar over the range of surface pressures studied (Fig. 3B). Again, both products of the reaction catalyzed by PLA$_2$ abolished the lag-time increase of the Sphmase reaction observed in films of pure Cer*P*Cho above 18 mN/m. This is similar to the effect of Cer, but this lipid inhibits the Sphmase activity while the products derived from the PLA$_2$ hydrolysis activate Sphmase. The extent of degradation of Cer*P*Cho in films containing lpPC or palmitic acid reaches about 80–100% over the surface pressure range where the enhanced activation in these films is observed (beyond 18 mN/m).

Activity of PLA$_2$ against mixed monolayers: *(i) Effect of palmitic acid and lpPC.* The variation of the PLA$_2$ activity with the surface pressure is similar to that reported previously

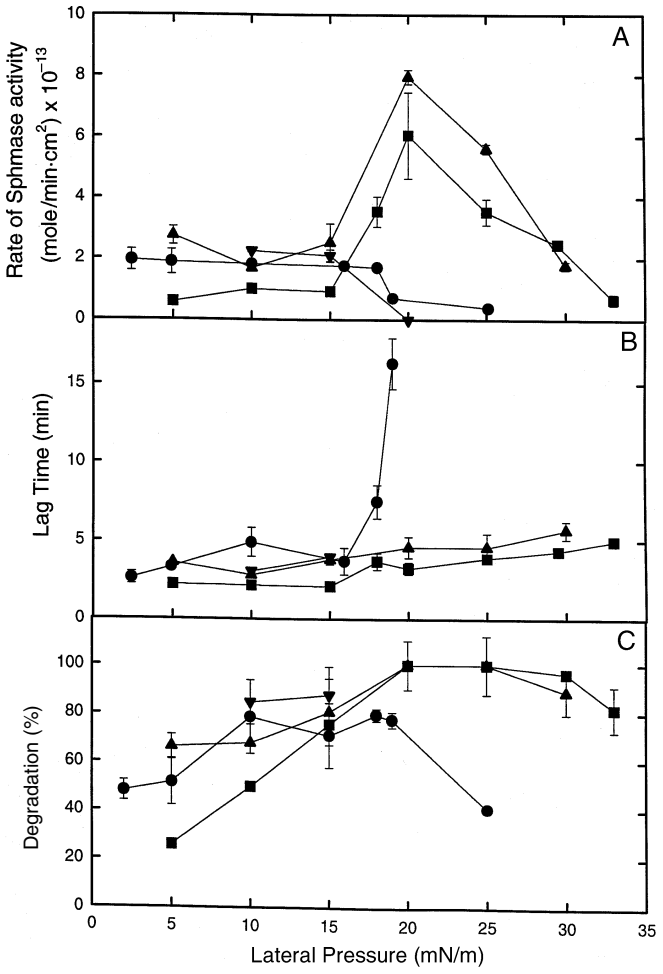

FIG. 3. Surface pressure dependence of sphingomyelinase activity against monolayers containing substrates and product of porcine pancreatic phospholipase A_2 (E.C. 3.1.1.4) (PLA_2). The rate of sphingomyelinase activity (A), lag time (B) and percentage substrate degradation (C) against monolayers of pure Cer*P*Cho (●), Cer*P*Cho/palmitic acid (9:1) (■), Cer*P*Cho/1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (lpPC) (9:1) (▲), and Cer*P*Cho/dihexadecanoyl-*sn*-glycerol-3-phosphocholine (9:1) (▼) are shown at different constant surface pressures. The results are average values ± SEM; where no error bars can be seen these are within the size of the point. See Figure 1 for other abbreviation.

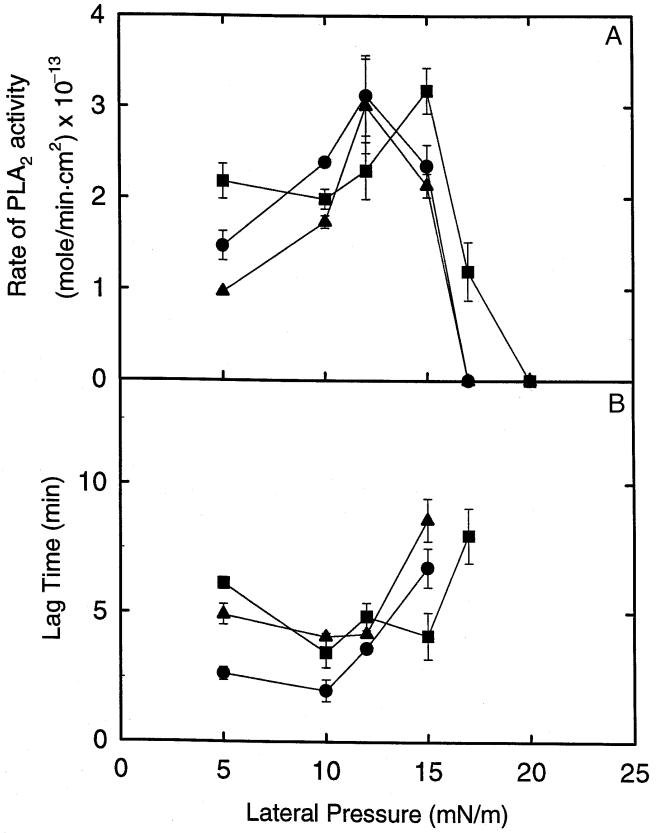

FIG. 4. Surface pressure dependence of PLA_2 activity against monolayers containing its own reaction products. The rate of PLA_2 activity (A) and lag time (B) against monolayers of pure didodecanoyl-*sn*-glycero-3-phosphocholine (dlPC) (●), dlPC/palmitic acid (9:1) (■), and dlPC/lpPC (9:1) (▲) are shown at different constant surface pressures. The results are average values ± SEM; where no error bars can be seen these are within the size of the point. See Figure 3 for other abbreviations.

(23,24). The pattern of variation is not altered significantly by the presence of 10 mol% of lpPC in the mixed film with dlPC (Fig. 4), except for a small inhibition at surface pressures below 12 mN/m. In mixed monolayers with palmitic acid, the optimal surface pressure for activity is slightly shifted from 12 to 15 mN/m, and the enzyme exhibits enhanced hydrolytic activity at high surface pressures; also, the cut-off pressure point for activity shifts from 17 to 20 mN/m (Fig. 4A). The pattern of dependence of the reaction lag time on the surface pressure (Fig. 4B) is generally similar; the lag times tend to be increased in films containing palmitic acid or lpPC at surface pressures below 12 mN/m, and the changes are not significant above this pressure. The products of hydrolysis of dlPC by PLA_2 immediately desorb from the interface, and the reaction in all film exhibits zero-order kinetics (22–24); thus, in all cases the degradation can reach 100% and comparisons of the extent of substrate degradation for different films are not possible.

(ii) Effect of substrate and product of Sphmase. The presence of Cer*P*Cho or Cer at 10 mol% in mixed films with dlPC induces marked changes in the surface pressure dependence of the PLA_2 activity (Fig. 5A). Cer*P*Cho markedly inhibits the PLA_2 activity except at the lowest surface pressure used in our study (5 mN/m). On the other hand, the presence of Cer induces slight decreases of PLA_2 activity at surface pressures below 15 mN/m but shifts the cut-off pressure point for activity well above 20 mN/m. The lag times in the mixed films with Cer*P*Cho are not significantly different except at 5 mN/m where the latency period is more than twice the value observed in the pure film of dlPC. The presence of Cer induces longer lag times at surface pressures below 12 mN/m and shifts the marked increase of the lag time to above 15 mN/m (Fig. 5B).

DISCUSSION

As stated in the introductory section, our objectives were to investigate, under well-controlled conditions of intermolecu-

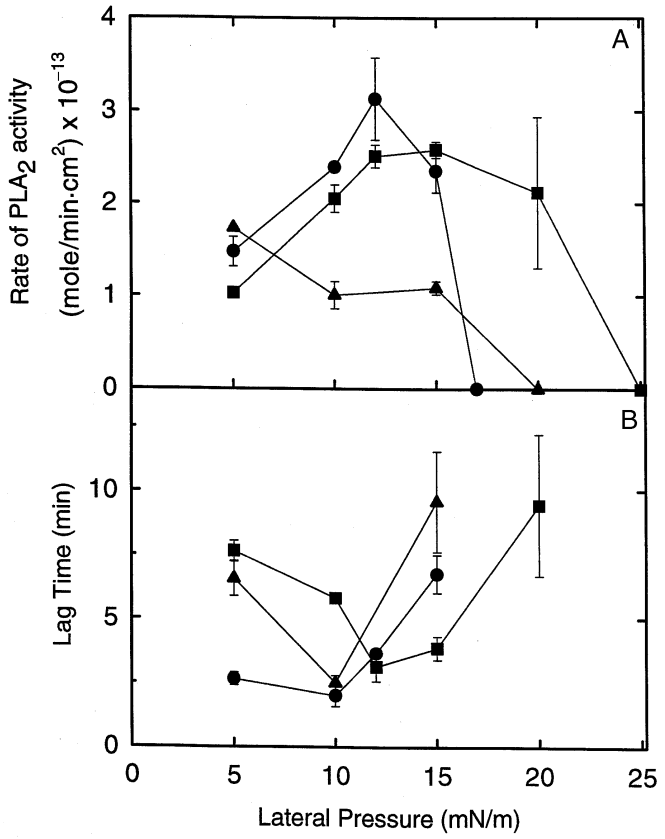

FIG. 5. Surface pressure dependence of PLA_2 activity against monolayers containing the substrate and product of Sphmase. The rates of PLA_2 activity (A) and lag time (B) against monolayers of pure dlPC (●), dlPC/Cer (9:1) (■), and dlPC/Cer*P*Cho (9:1) (▲) are shown at different constant surface pressures. The results are average values ± SEM; where no error bars can be seen these are within the size of the point. See Figures 1 and 4 for abbreviations.

lar organization in real time, the generic physicochemical factors that may modulate the surface activity of two enzymes catalyzing different phosphohydrolytic pathways as mediated by their noncommon lipid substrates and products. Two well-characterized enzymes were used, namely porcine pancreatic PLA_2 and *B. cereus* Sphmase. The reason for this choice, apart from the fact that both enzymes are readily available, was that published information already exists on several aspects of the interfacial regulation by different lipids of porcine pancreatic PLA_2 (1–3,6,7,22–24,32–34) and Sphmase (10,11,27,28). This is an invaluable advantage for further exploring the new aspects described in this work on the complex factors regulating phosphohydrolytic surface catalysis. Moreover, all phosphohydrolytic enzymes studied so far in model systems have revealed very similar generic interfacial factors for their surface regulation (1–9,12–15). Obviously, the specific critical values of the regulatory surface parameters (i.e., cut-off and optimal surface pressure points, composition-dependent lateral microheterogeneity, electrostatic surface potential) may certainly be expected to vary for different enzymes, including the physiologically relevant mammalian enzymes such as Group II or V secretory PLA_s, the various forms of membrane or cytosolic PLA_2 (35) that might work in conjunction with membrane Sphmase. Except for both brain phosphatidylinositol phosphodiesterase (8) and more recently for phosphoinositide-specific phospholipase C (12,13) and phospholipase Cβ (14) for which surface pressure-dependent activity was shown, biophysical studies have not yet been performed with most membrane phospholipases.

Our results show that the generic interfacial molecular factors regulating the cross-modulation of Sphmase and PLA_2 by their respective substrates and products are complex and appear to act at several independent levels. The effects of the different lipids are all exerted at the interface itself and are not the consequence of a direct action on the enzymes in the bulk subphase. As described before (10), the enzymatic activities against monolayers of the corresponding pure substrates are unaltered if the enzymes are injected into the subphase after preincubation for 10 min with the lipids studied in molar ratio 10:1 with respect to the enzyme (but still keeping a subphase lipid concentration below their respective critical micellar concentration values in order to prevent increases of surface pressure due to lipid adsorption).

The activity of one enzyme is affected by the presence of its own reaction products and by the substrate or products of the other enzyme; all this depends differently on the lateral surface pressure. The effects on the enzymatic rates of activity and on the lag times are not directly correlated to alterations of mean molecular area and average surface potential/molecule induced on each substrate by specific interactions with the lipids belonging to either hydrolytic pathways (Table 1). Sphmase from *S. aureus* degrades unsaturated (liquid-expanded) Cer*P*Cho substrates with a higher rate of activity than saturated (liquid-condensed) Cer*P*Cho (11). Our results on the surface pressure dependence of the activity of *B. cereus* Sphmase are in general agreement with these observations and also indicate that the rate of activity against monolayers of pure Cer*P*Cho decreases dramatically at 18 mN/m and above, with a marked increase of the lag time. This surface pressure approximately coincides with the surface pressure at which Cer*P*Cho monolayers undergo a liquid-expanded to a liquid-condensed two-dimensional phase transition. The lipids belonging to the hydrolytic pathway catalyzed by PLA_2, at 10 mol% in mixed films with Cer*P*Cho, induce very little alteration of the mean molecular area of Cer*P*Cho (deviations from the ideal mixing behavior, see Table 1). Furthermore, the isotherms of the mixtures are only slightly displaced along the axis of area/molecule, but their compressibility, and thus the surface-phase state, is not altered (not shown). However, the presence of these lipids can markedly activate or inhibit Sphmase (depending on surface pressure) as well as modify the lag time of the reaction. This indicates that an increase of Sphmase activity or a shortening of the reaction lag time is not occurring merely as a consequence of the lipid interface simply acquiring a more liquid-expanded character. The modulation appears to act at least at two different levels affecting independently the rate of catalysis and

the lag time of the reaction [which involves enzyme adsorption and precatalytic steps (2,23,24)]. This suggests that the lipids studied in this work influence the phosphohydrolytic reactions at the level of interfacial enzyme activation and/or the catalytic reaction itself, either specifically or simultaneously, rather than at the level of intermolecular packing or dipolar properties of the substrates (at least in mixed films with the proportions of lipids used). Film-transfer experiments with PLA_2 (2,10,23,25) and with Sphmase (10; Fanani, M.L., and Maggio, B., unpublished data) showed that phospholipid degradation starts immediately (without lag time) in films that were transferred at constant surface pressure over an enzyme-free subphase, indicating that the precatalytic steps of adsorption and interfacial activation of Sphmase and PLA_2 (2,10,23–25) proceed separately from those required for effective catalysis.

The expected correlation between lower rate of activity and increased lag time or vice versa (2,7,32,33) observed for both enzymes acting against monolayers of their pure substrates is lacking in the mixed films studied. This is similar to what we found previously for the modulation by gangliosides of PLA_2 and *B. cereus* phospholipase C activities (7). For Sphmase, Cer inhibits the rate of activity but exhibits shorter lag times and abolishes the increase of lag time at high surface pressures (Fig. 2) that is observed against monolayers of pure Cer*P*Cho, without extending the cut-off pressure point for activity. Analysis of the precise step at which nonsubstrate lipids affect interfacial catalysis is of paramount importance but very complex due to the multiple molecular and supramolecular levels of regulation of membrane-associated enzymes (1–9,36,37). In work related to phosphohydrolytic inhibition by nonsubstrate lipids, it has recently been proposed that the observed Cer*P*Cho inhibition of phospholipase Cδ1 activity may be due to a tightening and dehydration of the lipid interface region resulting in poor penetration of the enzyme (38). However, Cer (having the same hydrogen-bonding donor–acceptor interfacial amide group as Cer*P*Cho) induces intermolecular expansion rather than condensation (Table 1) which should have facilitated enzyme activity in mixed films, contrary to the effects observed. Experiments undertaken in our laboratory using labeled ^{125}I-Sphmase are showing that films containing Cer induce the adsorption of 3.8 ± 0.1 ng protein/cm^2 instead of the 2.1 ± 0.2 ng protein/cm^2 adsorbed to a pure film of Cer*P*Cho. The dual and apparently opposite effects of Cer on the rate of catalytic activity and on the lag time are probably due to a facilitation by Cer of enzyme adsorption to the interface, together with the induction of decreased specific enzymatic activity at all surface pressures studied. This and the marked decrease of the lag time in mixed films with Cer (Fig. 2) indicate that this lipid favors, as yet in unknown molecular terms, the precatalytic steps of the Sphmase reaction but subsequently inhibits the effective rate of hydrolysis. No significant effect on Sphmase activity and on the lag time was induced by dlPC or dpPC. On the other hand, contrary to Cer, lpPC and palmitic acid activate the enzyme at high surface pressures and, similar to Cer, abolish the increase of lag time above 18 mN/m (Fig. 3). This suggests that the products of dpPC hydrolysis by PLA_2, lpPC, and palmitic acid favor both the precatalytic steps and the rate of hydrolysis of Cer*P*Cho by Sphmase at high pressure by mechanisms independent of the changes of intermolecular packing or the mean surface potential per molecule in mixed monolayers (Table 1).

The products of the PLA_2 reaction have only a moderate effect on PLA_2 activity except for films containing palmitic acid in which a slight displacement to high surface pressures of the cut-off point for activity is found (Fig. 4). It has been known for a long time that a small amount of fatty acid products enhances the activity of PLA_2 (33,34). The presence of Cer*P*Cho in the film with dlPC generally inhibits (except at 5 mN/m) the activity of PLA_2 (Fig. 5), but the lag times at the surface pressure where the largest inhibition is observed are not altered, indirectly suggesting little alteration (or complex compensation) of overall precatalytic steps. On the other hand, compared to films of pure dpPC, the presence of Cer increases the PLA_2 activity above 15 mN/m but the corresponding lag times are longer, even compared to those found in films containing Cer below 15 mN/m and vice versa. Thus, also in the case of the effects on PLA_2, Cer exhibits a dual effect and appears to act on precatalytic steps in a way that is not simply correlated to its subsequent effect on the rate of enzymatic activity.

Direct biological correlations of our results are not yet possible, but they open possibilities for generic implications of some of the biophysical factors required for the kinetic regulation and interfacial cross-modulation of phosphohydrolytic pathways by nonsubstrate and nonproduct lipid intermediates. Figure 6 summarizes in a simplified sketch the general combined effects observed in monolayers (as controlled by low or high surface pressures) illustrating the possible mutual "communication" of both pathways if they were evolving si-

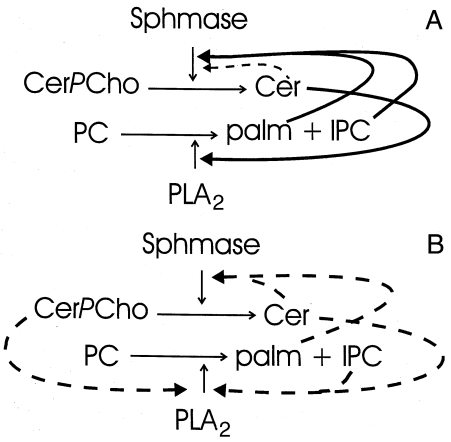

FIG. 6. Simplified scheme summarizing the interfacial cross-talk between Sphmase and PLA_2 activities at representative high and low surface pressures. The influences of substrates and products of both phosphohydrolytic pathways on the Sphmase and PLA_2 activities are illustrated at 20 (A) and 10 (B) mN/m. Solid lines represent activation, and dashed lines correspond to inhibition. PC, phosphatidylcholine. See Figures 1 and 3 for other abbreviations.

multaneously within the limits of a same surface microregion [i.e., over an interfacial two-dimensional space region covering the size of physically correlated microheterogeneous lipid domains (36,39)]. At 20 mN/m, no degradation of phosphatidylcholine by PLA_2 occurs since this pressure is above the cut-off point for activity against the pure substrate (Fig. 4). On the other hand, Sphmase exhibits a low activity against pure Cer*P*Cho monolayers (Fig. 2) and, according to the rate observed against a film of pure Cer*P*Cho, a film composition containing 10 mol% of Cer can be reached in about 30 min (in the conditions of trough surface area used in our experiments, local domain concentrations could be reached much faster). The presence of Cer inhibits the Sphmase activity while, at the same time, decreasing the lag time, allowing a slow continuous activity and, in conditions in which the amount of Cer*P*Cho does not become rate-limiting, Cer can be slowly produced. The presence of 10 mol% Cer should induce a shift to high pressure of the cut-off point for PLA_2 activity (Fig. 5), and this enzyme could become active after the reaction catalyzed by Sphmase started. Our results on the rate of activity of PLA_2 against films containing Cer show that about 10 mol% of fatty acid and lysoderivative can be produced in about 14 min. The accumulation of either product of PLA_2 markedly activates Sphmase at 20 mN/m, accelerating by about five times the production of Cer (Fig. 3). Increased production of Cer can again activate PLA_2 to produce more products which should further activate Sphmase and so on, in an amplified effect of mutual activation between both phosphohydrolytic pathways.

The kinetic pattern and its implications change dramatically at 10 mN/m. At this surface pressure, both enzymes can degrade their own substrates, with the PLA_2 reaction being slightly more active than that mediated by Sphmase. At 10 mN/m, either Cer*P*Cho or Cer can inhibit the rate of activity of PLA_2 (Fig. 5). Also, the products of this enzyme formed at a slow rate have a further inhibitory effect on PLA_2 (Fig. 4) so that this enzyme would become inhibited at 10 mN/m. Sphmase is likewise inhibited by Cer and palmitic acid (Figs. 2 and 3) which would lead to a decreased production of Cer and a relative accumulation of Cer*P*Cho. This latter lipid, in turn, further inhibits PLA_2 and so on. Thus, at 10 mN/m, the simultaneous influence of both phosphohydrolytic pathways should lead to a synergic and large decrease of the activity of both enzymes, causing a mutual dampening and cooperative shutdown of their reaction pathways, compared to when either enzyme is acting in the absence of the lipid intermediates produced by the other.

Several thermodynamic, mechano-elastic, partitioning, and enzymatic studies are consistent in defining the range of 30–35 mN/m as a reasonable figure for the average half-bilayer-equivalent surface pressure (40). However, clearly, the average value can fluctuate by more than ±15 mN/m depending on the compressibility of the lipid–protein interface at each temperature (41); in addition, the fluctuations are enhanced in mixtures exhibiting lateral phase separation and domain microheterogeneity (40). Considering these facts, fluctuations of surface pressure between 10–40 mN/m are likely in bilayer and cell membranes (40,41). Taken together, our observations suggest that a cross-modulation by the substrates and products of the activities of Sphmase and PLA_2 may be regulated by lipid composition and overall lateral surface pressure altering the catalytic properties of the enzymes associated with the interface through lipid–enzyme interactions in the film while local changes of lipid packing or dipolar properties caused by specific lipid–lipid interactions are less likely. Probable levels at which the regulation may occur involve precatalytic adsorption and activation steps, conformational changes of the enzyme associated to the interface, or alterations involved directly in the effective catalytic rate (i.e., enzyme–substrate recognition, enzyme accessibility to the substrate cleavage sites, and/or rate of product release) that are currently under investigation.

GD_3 and GM_2 Synthase Activities in Rat Testes During the Period of Sexual Development

Juana L.G.T. Gamallo, Vera M.T. Trindade, and Elena A. Bernard*

Departamento de Bioquímica, Instituto de Ciências Básicas da Saúde, Universidade Federal do Rio Grande do Sul, CEP 90.035-003, Porto Alegre, RS, Brazil

ABSTRACT: Activities of two key enzymes of gangliosides biosynthesis were determined in rat testes during development. GD_3 synthase activity was low and showed small variations with age. GM_2 synthase activity increased 10-fold in testes from 10- to 30-d-old animals, showing a maximum activity at 30 d, followed by a small decrease until 45 d and then a constant activity up to adulthood. These developmental changes in the activity of both glycosyltransferases were related to the increasing complexity in the ganglioside pattern observed in rats testes during the period of sexual development.

Lipids 33, 1089–1092 (1998).

Gangliosides are synthesized in a stepwise manner by transfer of carbohydrates from sugar nucleotide donors to glycolipid acceptors by specific glycosyltransferases. This process occurs in the endoplasmic reticulum and Golgi apparatus (1). The mechanisms of intracellular traffic of gangliosides have been elucidated, particularly in the nervous system (2–4). Modifications in the ganglioside pattern during development may be associated with correspoding changes in the activities of specific glycosyltransferases. In the chick embryo retina system and the mammalian brain developmental changes in ganglioside composition correlate with variations in the activities of the key ganglioside glycosyltransferases: GD_3 and GM_2 synthases (5–8).

Gamallo and Bernard (9) demonstrated that rat testes gangliosides show a pattern of increasing complexity with aging. GM_3 is the major ganglioside present in rat testes of 10-d-old animals. With sexual development, the content of GM_3 decreases and the complexity of gangliosides increases, with the appearance of longer-chain gangliosides as GM_1, GD_{1a} (series "a"), and GT_{1b} (series "b") (9).

The aim of this study was to investigate a possible correlation between the developmental changes in ganglioside composition observed in rat testes and the variations in the activity of the two key ganglioside glycosyltransferases: GD_3 (E.C. 2.4.99.8) and GM_2 (E.C. 2.4.1.92) synthases.

MATERIALS AND METHODS

Chemicals. UDP-*N*-acetylgalactosamine (UDP-GalNAc), CMP-*N*-acetylneuraminic (CMP-NeuAc), Triton CF54, sodium cacodylate, CDP-choline, octylglucoside, bovine serum albumin, mercaptoethanol, Sephadex A-25, and gangliosides GD_3, GM_2 and GM_3 were from Sigma Chemical Co. (St. Louis, MO). CMP-[4,5,6,7,8,9-^{14}C]*N*-acetylneuraminic acid (CMP-[^{14}C]NeuNAc), 256 mCi/mmol, was from Amersham International plc (Amersham, United Kingdom). UDP-*N*-acetyl-D-[6-^{3}H]galactosamine (UDP-[^{3}H]GalNAc), 10 Ci/mmol, was from American Radiolabeled Chemicals Inc. (St. Louis, MO). Ultima Gold was from Packard B.V. Chemical Operators (Groningen, The Netherlands). All other chemicals and solvents used were of analytical grade.

Animals. Male Wistar rats from our breeding stock, aged between 10 and 90 d, were used. The size of the litters was adjusted to eight pups per mother on the first day after birth. The animals were weaned at 21 d of age and kept in an animal room under controlled conditions of temperature, with alternating periods of light (12 h) and dark (12 h). Standard dry pellets and water were available *ad libitum.*

Sertoli cell-enriched testes (SCE). SCE were obtained by *in utero* irradiation with 100 rad of ^{60}Co at day 20 of pregnancy (11).

Enzyme preparation. The total particulate fraction, used as the enzyme source, was prepared as described by Bushway *et al*. (12). Pools of testes from unequal numbers of animals (according with their ages) were homogenized in 3 vol of cold 320 mM sucrose/14 mM 2-mercaptoethanol. Homogenates were centrifuged at $1,000 \times g$ (Sorvall centrifuge, RC-2B, SS-34 rotor; Du Pont Instruments, Newton, CT) for 10 min to remove debris. The resulting supernatant was centrifuged at $176,000 \times g$ (Model L5-75B, SW 50.1 rotor, Beckman Instruments, Palo Alto, CA) for 1 h. The resulting pellet, designated total particulate fraction, was resuspended in cold 0.32 M sucrose/14 mM 2-mercaptoethanol and was used as the enzyme source.

The terminology used for gangliosides in this paper is that recommended by Svennerholm (Ref. 10): GD_{1a}, *N*-acetylneuraminylgalactosyl-*N*-acetylgalactosaminyl-(*N*-acetylneuraminyl)-galactosylglucosyl ceramide; GD_3, (*N*-acetylneuraminyl)$_2$-galactosylglucosyl ceramide; GM_1, galactosyl-*N*-acetylgalactosaminyl-(*N*-acetylneuraminyl)-galactosylglucosyl ceramide; GM_2, acetylgalactosaminyl-(*N*-acetylneuraminyl)-galactosylglucosyl ceramide; GM_3, *N*-acetylneuraminylgalactosylglucosyl ceramide; GT_{1b}, *N*-acetylneuraminylgalactosyl-*N*-acetylgalactosaminyl-(*N*-acetylneuraminyl)$_2$-galactosylglucosyl ceramide. Abbreviation: SCE, Sertoli cell-enriched.

GM_3 isolation. The lipid acceptor GM_3 was extracted from dog spleen and purified as described by Nores and Caputto (13). Identity and purity of GM_3 were monitored by thin-layer chromatography (9) with an authentic GM_3 standard.

Enzyme activity determination. The compositions of the incubation systems were those described by Klein *et al*. (14) with minor modifications according to the method of Bushway *et al*. (12) and Senn *et al*. (15) for GD_3 synthase and GM_2 synthase activities, respectively.

GD_3 synthase activity was determined in an incubation system containing 500 µM glycolipid acceptor GM_3, 500 µM CMP-[^{14}C]-NeuAc (25,000 cpm), 150 mM cacodylate/HCl buffer (pH 6.35), 10 mM $MgCl_2$, 120 µg Triton CF54, and 150 µg total particulate protein as enzyme source, in a final volume of 20 µL.

GM_2 synthase activity was assayed in a similar incubation mixture containing 500 µM glycolipid acceptor GM_3, 100 µM UDP-[^{3}H]-GalNAc (400,000 cpm), 160 µg octylglucoside, 150 mM cacodylate/HCl (pH 7.3), 5 mM CDP-choline, 20 mM $MnCl_2$, and 120 µg total particulate protein in a final volume of 20 µL.

The systems were incubated at 34°C for 150 min for GD_3 synthase and 60 min for GM_2 synthase. In both cases an assay was run in the absence of exogenous glycolipid acceptor, in order to discount the incorporation into endogenous acceptors. Reactions were begun by the addition of particulate protein fraction and were stopped by addition of 0.5 mL 5% (wt/vol) trichloroacetic acid/0.5% phosphotungstic acid. The products of the two enzymatic activities were extracted as described by Maccioni *et al*. (6). Radioactivity was measured with an LKB Scintillation Spectrometer 1215 Rack Beta using Ultima Gold.

Enzyme specific activities were expressed as pmol of NeuAc or GalNAc transferred/mg protein/h for GD_3 or GM_2 synthase activities, respectively, and were calculated from the difference in the average radioactivity of the exogenous acceptor assay minus the radioactivity of the corresponding one without acceptor.

The identification of the reaction products was performed in a system with twice the volume of the standard assay, which was interrupted by adding chloroform/methanol (2:1, vol/vol), purified as described by Wells and Dittner (16), and analyzed chromatographically on high-performance thin-layer chromatographic plates and developed in chloroform/methanol/0.25% aqueous $CaCl_2$ (60:35:8, by vol) (9). Labeled reaction products with the same R_f as the ganglioside standards were determined as reaction products.

Protein determination. Protein contents were estimated by the method of Lowry *et al.* (17). Bovine serum albumin (Sigma Chemical) was used as the standard.

RESULTS AND DISCUSSION

Gangliosides are sialic acid-containing glycosphingolipids that have a function as structural membrane components *per se* and that, possibly, play an important role in receptor-mediated signal transduction (18) as well as direct cell/cell and cell/extracellular matrix interactions (19).

The present work studied the activities of two key enzymes of the biosynthesis of gangliosides: GD_3 and GM_2 synthases. These enzymes, acting in the commom precursor GM_3, are responsible for the biosynthesis of the gangliosides of the series "b" and "a," respectively, and are considered regulatory enzymes (20).

GD_3 synthase activity was low and showed small variations with age. It diminished about 30% from 10- to 30-d-old rats (Fig. 1). This result agrees with that of Bushway *et al*. (12) in adult bovine testis, where various sialyltransferase activities have been measured, and GD_3 synthase likewise showed low activity. SCE animals (deprived of germ cells) also showed this result (Table 1).

GM_2 synthase activity increased 10-fold from 10- to 30-d-old rats, showing a maximum enzymatic activity at 30 d of age, followed by a small decrease until 45 d of age, at which time activity remained the same until adulthood (Fig. 1).

As mentioned previously (9), adult rat testes contain a complex pattern of gangliosides that is different from the one frequently observed in most extraneural tissues where gangliosides of the hematoside series (GM_3 and GD_3) predominate (21–23). Short-chain gangliosides are present in testes of 10-d-old animals (GM_3 and GD_3) (9). From this age on, other longer-chain gangliosides appear (GM_1, GD_{1a}, GT_{1b}). This increase in complexity is already evident in 20-d-old animals, when more than one trisialoganglioside is present (9). This pattern correlates with the increasing activity of GM_2 synthase, which is coincident with the appearance of more complex gangliosides. Fishman (21) previously referred to participation of this enzyme in ganglioside chain complexity.

In testes of SCE rats (deprived of germ cells), the activity of GM_2 synthase in adult animals (90 d old) was similar to that of 20-d-old normal animals (compare Table 1 to Fig. 1). By 20 d of age, as we reported (9), complex gangliosides were already present in rat testes, as well as in rat testes of SCE animals. These observations allowed us to state that the activity of GM_2 synthase observed in SCE animals is enough for the appearance of complex gangliosides in rat testes. Therefore, it seems that the variations in testicular gangliosides during sexual maturation cannot be correlated with the appearance of advanced germinal cells (12).

Developmental changes in ganglioside glycosyltransferases have been extensively demonstrated in central nervous system (6–8,24). In embryonic rat brain, major GD_3 synthase activity has been observed during early embryonic stages, while an increase in GM_2 synthase activity has been shown to occur during later embryogenesis and adulthood (6,7). Similar results have been observed in embryonic chick retina and embryonic human brain (5,8).

As far as we know, there are no published data about GM_2 synthase activity variations in extraneural tissues during development. In bovine thyroid of adult animals GM_2 synthase activity is considered high when compared to other glycosyltransferases measured in this tissue (22). This activ-

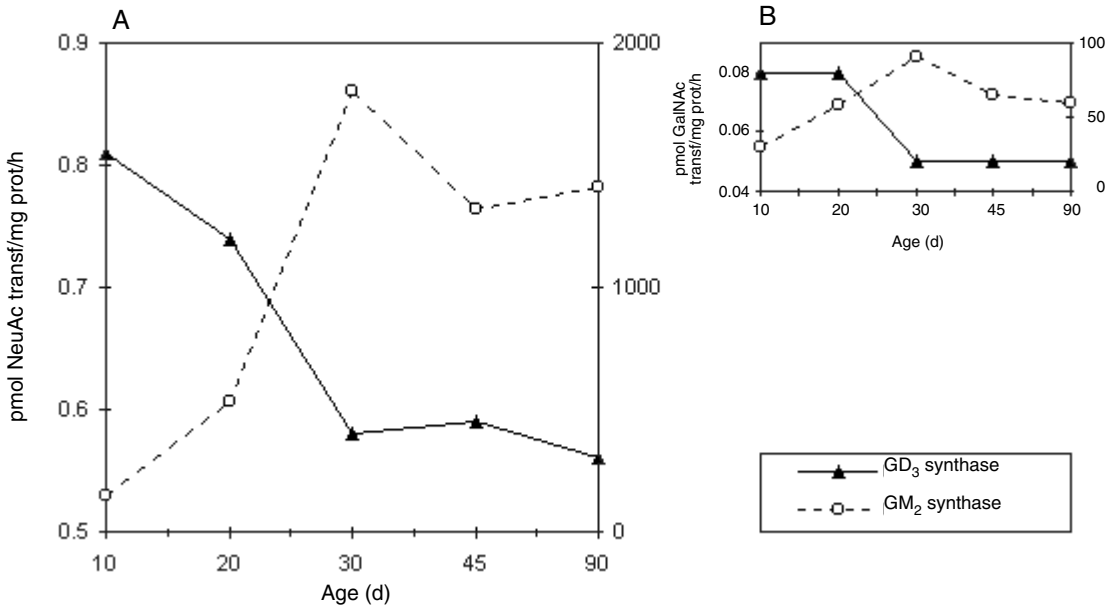

FIG. 1. GD_3 (▲) and GM_2 (□) synthase activities in rat testes during the period of sexual development. (A) Representative experiment of three determinations with different enzymatic preparations, in which each point corresponds to an assay carried out in triplicate; (B) enzymatic activities obtained without exogenous acceptor addition.

ity is correlated with the high abundance of GD_{1a} in this organ.

The present study described, for the first time, the variations of GD_3 and GM_2 synthase activities in rat testes during development. According to the literature relating to the central nervous system (6–8,24), developmental changes observed in rat testicular gangliosides (9) may be related to variations of the activities of these key ganglioside glycosyltransferases during the period of sexual development. We suggest, in agreement with Maccioni *et al*. (6), Yu *et al*. (7), and Percy *et al*. (8) for the central nervous system, that the simple ganglioside predominance and major GD_3 synthase activity in testes of 10-d-old animals might be correlated with the proliferation phase of Sertoli cells (25). The later decrease of GD_3 synthase activity and simultaneous increase of GM_2 synthase activity with consequent complex ganglioside synthesis may be correlated with the maturation of the Sertoli cells.

Recent experiments with knockout mice of β-1,4-GalNac transferase (GD_2/GM_2 synthase) showed that complex gangliosides are not essential in the morphogenesis and organogenesis of the brain, but they are required in neural functions (26). Perhaps these observations cannot be applied to testis development since spermatogenesis is arrested in knockout mice (27). This blockade may be due to an alteration in spermatogeneis regulation as modulated by the hypothalamic-hypophyseal unit (28) or by Sertoli cells (29).

TABLE 1
GD_3 and GM_2 Synthase Activities of Normal and of SCE Rat Testes of Adult Animals (90 d old)

	GD_3 synthase[a]	GM_2 synthase[b]
Normal testes	0.6 ± 0.15	1406 ± 140
SCE testes	1.28 ± 0.04	666 ± 10

[a]Results are expressed as pmol NeuAc transferred/mg prot/h ± standard error of the mean.
[b]Results are expressed as pmols GalNAc transferred/mg prot/h ± standard error of the mean. The data of the normal and of the SCE rat testes represent the mean of three and two determinations, respectively, with different enzymatic preparations, each one carried out in triplicate. SCE, Sertoli cell-enriched.

ACKNOWLEDGMENTS

This research was supported by Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPQ), Fundação de Amparo à Pesquisa do Estado do Rio Grande do Sul (FAPERGS), and Financiadora de Estudos e Projetos (FINEP). We are grateful to Dr. Guilhermo F. Wassermann for irradiation of the pregnant females and to Dra. F.T.R. Guma for helpful discussions.

ABSTRACT: Alterations in the lipid and fatty acid composition of brush border membrane (BBM) of small intestine were studied in well-fed, starved, and refed rats. The ratios of cholesterol/phospholipid (mol/mol), sphingomyelin/phosphatidylcholine (mol/mol), protein/lipid (w/w), and free fatty acids (w/w) decreased whereas the total phospholipid (w/w) ratio and the double-bond index increased in BBM of the intestine of the starved rat compared to that of the well-fed rat. Analyses of fatty acids showed higher percentage of stearic and arachidonic acids whereas oleic and linoleic acids decreased under starvation. The acyl chain of starved rat BBM was less ordered compared with that of well-fed rat BBM. On refeeding, these changes were restored to well-fed levels. The change in membrane state under starvation is associated with alterations in the lipid and fatty acid composition of BBM and may be responsible for functional changes that occur under nutritional stress.
Lipids 33, 1093–1097 (1998).

The structure and function of the brush border membrane (BBM) of enterocytes are sufficiently differentiated to absorb a wide variety of luminal nutrients (1,2). Several physiological and/or pathological conditions such as dietary composition, postnatal maturation, diabetes and intestinal resection are associated with selective alterations in the percentage composition of lipids in BBM (3–6), with alterations in the biophysical characteristics of the BBM, and with transport of the nutrients and activity of certain enzymes in the membrane (4,5,7,8). Starvation is one of the physiological stresses that an animal often undergoes in its lifetime; however, not much is known about the structural and compositional changes of BBM under this stress.

Studies from our laboratory showed that starvation increases transport of glucose and amino acids such as lysine, proline, glycine, and glutamic acid across the membrane of intestinal epithelial cells (IEC) of the rat (9–11). The increase in the transport of these substances may be due to the increase in surface area of microvilli and fluidity of BBM of IEC (9–11). However, changes in the lipid composition of BBM that may be associated with changes in membrane state have not been investigated in detail. In this communication, we report the effect of starvation on the composition and acyl chain order of rat intestinal BBM, which in turn might affect its function.

MATERIALS AND METHODS

Materials. Fatty acids, methyl esters, lipid standards, and 1,6-diphenyl-1,3,5-hexatriene (DPH) were obtained from Sigma Chemical Company (St. Louis, MO). The gas–liquid chromatographic column was purchased from Shimadzu (Tokyo, Japan). High-performance thin-layer chromatographic plates were from Merck (Darmstadt, Germany). All other chemicals were of analytical grade and purchased locally.

Preparation of animals. Adult male (90 ± 5 d) Wistar rats weighing 300 ± 20 g each were used for the present study. The well-fed, starved and refed rats were prepared as described earlier (9,11). The protocol of animal preparations for the present experiment was approved by the Ethics Committee of our institute (Centre for Cellular and Molecular Biology). A standard rat diet containing 5% fat (Hundusthan Liver Limited, Mumbai, India) was provided to the rats. The rats belonging to well-fed, starved and refed groups were killed by cervical dislocation. After dissecting away 10 cm from the pyloric end of the stomach, about 15 cm of the anterior portion of the small intestine from each animal was used for the present study.

Preparation of BBM. The proximal region of each intestine was washed throughly with ice-cold 0.15 M NaCl, the enterocytes were collected by scraping the everted intestine with a glass slide into buffer I (50 mM mannitol, 2 mM Tris/HCl, pH 7.1), and BBM was prepared according to the method of Kessler *et al.* (12). Briefly, epithelial cells were homogenized in a polytran homogenizer (Kinematica, Lucern, Switzerland) for 1 min at maximum speed. $CaCl_2$ was added to a final concentration of 10 mM, and after 15 min the homogenate was centrifuged at $3000 \times g$ for 15 min. The supernatant was then spun down at $27{,}000 \times g$ for 30 min. The pellet was resuspended in buffer II (50 mM mannitol, 10 mM Tris/HCl, pH 7.1) and centrifuged once more at $27{,}000 \times g$ for 30 min. Purity and comparability of the BBM were assessed using various criteria as described earlier (9–11).

BBM composition. Total lipids were extracted from BBM

by the method of Folch *et al*. (13). Cholesterol and phospholipids were estimated by the methods of Zak *et al*. (14) and Meclare (15), respectively. Total lipid containing 1 µg of cholesterol was applied to 10 cm × 10 cm high-performance thin-layer chromatography plates. The plates were developed first with chloroform/methanol/ammonia (65:25:6, by vol) to 4 cm and then with hexane/ether/acetic acid (70:30:1.5, by vol) to full length. The plates were immersed in phosphoric acid/33% acetic acid/sulfuric acid/0.5% copper sulfate (5:5:0.5:90, by vol) for 40 s and then heated at 130°C for 12 min (16). The chromatogram was scanned by photodensitometer (Molecular Dynamics) at 650 nm. Percentage composition of the total lipid was determined based on integration of the peaks for the lipid fractions.

To determine the acyl chain composition, fatty acids of the total lipid extract were derivatized as described by Gartner and Vahouny (17), and the fatty acid methyl esters were quantified on a Shimadzu-17A gas chromatograph (DB-Wax capillary column) equipped with a flame-ionization detector and interfaced with an integretor. Authentic fatty acid methyl esters were used to identify retention times. Proteins were estimated by the method of Waheed and Gupta (18) using bovine serum albumin as the standard.

Fluorescence polarization. Steady-state fluorescence polarization experiments were performed using the lipid-soluble fluorophore DPH in a Hitachi F-4000 spectrophotometer. A stock solution of 2 mM DPH in tetrahydrofuran was added directly to the membrane preparations such that the final concentration of the probe was 1 µM; the resultant solution was mixed thoroughly and then incubated at 25°C for 30 min. Measurements were made by using the ratio of the intensity of excitation (355 nm) to the intensity of emission (430 nm) (19). Correction for light scattering was routinely made. Fluorescence polarization was expressed as the fluorescence anisotropy, *r*. The results were obtained according to the modified Perrin relationship (20): $r = r_\alpha + (r_o - r_\alpha)\,[T_c/(T_c + T_f)]$, where *r* is the fluorescence anisotropy; r_o is the maximal limiting anisotropy, taken as 0.365 for DPH; r_α is the limiting hindered anisotropy, T_c is the correlation time; and T_f is the mean lifetime of the excited state. Values for r_α for DPH were calculated from steady-state fluorescence anisotropy, r_s values ($r_\alpha = 4/3r_s - 0.10$) as described by van Blitterswijk *et al*. (21). Values of r_s were calculated from fluorescence emission intensities recorded parallel and perpendicular to the excitation plane of the probe as described (21). The static component of membrane fluidity was assessed by an order parameter, *S*, which was obtained from the equation $S = (r_\alpha/r_o)^{1/2}$ (21).

Statistical analyses. Statistical analyses were carried out by one-way analysis of variance with linear contrasts for comparison of the subgroups. Results are expressed as means ± S.E. $P < 0.05$ was considered significant.

RESULTS

Composition of lipids in BBM. Lipids extracted from starved-rat BBM showed higher amounts of phosphatidylcholine, phosphatidylethanolamine, and lysophosphatidylcholine compared with that of well-fed rats (Table 1). As a result, the total phospholipid content was higher in starved-rat BBM. Sphingomyelin was the only phospholipid which did not change

[a]Values are means ± SEM for seven determinations from four rats per group. Values of composition are given as percentage (w/w) of total fatty acids.
[b]Saturation index was calculated by dividing the number of saturated acyl chains by the sum of each unsaturated chain multiplied by number of double bonds.
[c]Double-bond index is the sum of each unsaturated fatty acid chain multiplied by number of double bonds/100.
[d–f]A significant difference from the values of well-fed group at $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively.
[g–i]Values statistically differ from 6-d starved group, $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively.

significantly during starvation. In contrast to phospholipids, neutral lipids decreased during starvation, with the decrease in fatty acid and cholesterol esters being highly significant compared with cholesterol. The ratios of protein/lipid (w/w), cholesterol/phospholipid (mol/mol), and sphingomyelin/phosphatidylcholine (mol/mol) decreased in starved-rat BBM. The decrease in the molar ratio of cholesterol/phospholipid and sphingomyelin/phosphatidylcholine was not due to a decrease in the contents of cholesterol or sphingomyelin but to an increase in the quantities of phosphatidylcholine and phosphatidylethanolamine.

Compositional analyses of fatty acids showed greater variation under starvation (Table 2). There was an increase in the content of stearic acid (18:0) and arachidonic acid (20:4) to 138 and 200%, respectively, in starved-rat BBM compared with that of well-fed rats. Decreases of about 50% in oleic acid (18:1) and linoleic acid (18:2) were observed in starved-rat BBM. No significant changes in the composition of lauric (12:0), myristic (14:0), palmitic (16:0), and arachidic (20:0) acids were observed. The double-bond index was higher in starved-rat BBM whereas the change observed in saturation index was not significant. The changes in lipid and fatty acid composition were reversable since the levels in the refed group were comparable to those of the well-fed group (Tables 1 and 2).

Fluorescence polarization. Steady-state fluorescence polarization studies using DPH showed that fluorescent anisotropy, *r*, of DPH decreased in starved rats' BBM, indicating decreased acyl chain order of these membranes (Table 3). The decrease in *r* values was 4% for rats starved for 2 d, 6.6% for 4 d, and 11.3% for 6 d compared with that of well-fed rats. The static component of membrane order as assessed by r_α and *S* values of DPH was found to be less in membranes prepared from the starved rat, suggesting that the lipid order parameter decreased during starvation. The decrease in order parameter was progressive with days of starvation, i.e., 2.2% in rats starved for 2 d, 3.8% for 4 d, and 7.0% for 6 d compared with the well-fed group. In refed rats, the fluorescent anisotropy *r*, limiting hindered anisotropy r_α, and order parameter *S* were restored to levels found in well-fed animals.

DISCUSSION

The present data demonstrate that during starvation the acyl chains of BBM become less ordered, and also that significant alterations occur in the lipid and fatty acid composition of the membrane. The quantitative changes in cholesterol and proteins have profound effects on packing of phospholipids in the membrane (6). In starved-rat BBM the molar ratios of

TABLE 3
Fluorescence Polarization Studies of DPH in BBM of Rat Small Intestine from Well-fed, Starved and Refed Rats[a]

Experimental condition	Fluorescent anisotropy (*r*) of DPH	Limiting hindered anisotropy (r_α)	Order parameter (*S*)
Well-fed	0.256 ± 0.001	0.245 ± 0.001	0.819 ± 0.002
2-d Starved	0.246 ± 0.001[b]	0.235 ± 0.001[b]	0.801 ± 0.002[b]
4-d Starved	0.239 ± 0.001[b,c]	0.226 ± 0.001[b,c]	0.788 ± 0.002[b,c]
6-d Starved	0.227 ± 0.004[b,d]	0.212 ± 0.004[b,d]	0.762 ± 0.007[b,d]
Refed	0.251 ± 0.001[e]	0.239 ± 0.001[e]	0.809 ± 0.002[e]

[a]Values are means ± SEM for seven determinations from four rats per group. A significant difference [b]from well-fed ($P < 0.001$), [c]from 2-d or 6-d starved ($P < 0.01$), [d]from 2-d starved ($P < 0.001$), and [e]from 6-d starved ($P < 0.001$).
DPH, 1,6-diphenyl-1,3,5-hexatriene

cholesterol/phospholipid and protein/lipid decrease; this may be one of the factors for the less-ordered acyl chains of these membranes. The decrease in sphingomyelin/phosphatidylcholine ratio also accounts for the decreased lipid order of BBM as suggested by Dudeja *et al*. (20). Our earlier studies on freeze-fracture replica of BBM showed that the levels of intramembranous particles and filipin-sterol complexes which represent protein and cholesterol, respectively, decreased during starvation (22). The ratio of phosphatidylethanolamine/phosphatidylcholine does not change because the levels of both these phospholipids increase. This increase is likely to counterbalance the distribution of these phospholipids in inner and outer leaflets of the lipid bilayer. The present data indicate that, under starvation, the content of free fatty acids decreases, which may be utilized in synthesis of phospholipids; therefore, there is a net increase in the content of total phospholipids in starved-rat BBM.

Brasitus *et al*. (19) reported that the lipid fluidity of intestinal microvillus membranes is associated with an increase in double-bond index. During starvation there is a decrease in the levels of oleic and linoleic acids; however, because of an increase in the levels of arachidonic acid there is a net increase in the double-bond index by about 25% in starved-rat BBM. This is in agreement with observations of Garg *et al*. (23), who showed that after 24 h of fasting the arachidonic acid content of the microsomal membrane of IEC increased with a concomitant decrease in linoleic acid. A decrease in linoleic acid accounts for increased amounts of arachidonic acid, as linoleate is the sole precursor for arachidonate (23). In model bilayer membrane *cis* unsaturation of phospholipid acyl chains increases the molecular packing area; as a result, the membrane acyl chain becomes less ordered (24). The percentage composition of saturated fatty acids does not change significantly during starvation. The unaltered saturation index and increased double-bond index in BBM of rats fed a diet containing unsaturated fats (corn oil) may be responsible for enhanced fluidity of these membranes compared to rats fed a saturated fat diet (butter fat) (24). Others have reported that the increased fluidity of cell membranes of the large intestine of small bowel-resected rats is due to an increased double-bond index (6). The changes observed in lipid and fatty acid composition are rapid by 2 d of starvation and do not change much on further starvation. Refeeding experiments in which the lipid order, composition of lipids, and fatty acids revert back to well-fed levels suggest that the structural and compositional changes in starved-rat BBM are likely to be physiological and not pathological.

Transport through BBM is correlated to its membrane state in various physiological and pathological conditions (1,2,5, 7,9,11,25). Under starvation there is an increase in surface area of microvilli (9–11), which is likely due to loose packing of phospholipids; however, the levels of glucose transporter proteins decrease and cannot account for the increased transport of glucose (unpublished data from this laboratory). Hence, it is likely that the increase in transport is due to greater transporter activity, which is facilitated in more fluid membrane (1,2,7,25). In the present study we have shown that the change in membrane state of starved-rat intestinal BBM is associated with alterations in lipid and fatty acid compositions.

ABSTRACT: Short-term (i.e., 3 d) continuous enteral feeding of diets containing eicosapentaenoic (EPA) and γ-linolenic (GLA) polyunsaturated fatty acids (PUFA) to endotoxemic rats reduces the levels of arachidonic acid (AA) and linoleic acid (LA) in alveolar macrophage (AM) and liver Kupffer and endothelial (K&E) cell phospholipids with attendant decreases in prostaglandin formation by these cells *in vitro*. Diets that contain α-linolenic acid (LNA) as a substrate for endogenous formation of EPA may not be as effective in facilitating these immune cell modifications given the limited activity of Δ6 desaturase. In the present study we compared the effectiveness of an LNA-enriched diet vs. an (EPA + GLA)-enriched diet to displace phospholipid AA from AM and liver K&E cells *in vivo* in endotoxemic rats fed enterally for 3 or 6 d. We determined the fatty acid composition of AM and K&E cell phospholipids by gas chromatography. We found that AM and K&E cells from rats that had received the EPA + GLA diet for 3 d had significantly ($P < 0.001$) higher mole percentage of EPA and the GLA metabolite, dihomoGLA, than corresponding cells from rats given the LNA diet or a control diet enriched with LA. Rats given the LNA diet had relatively low levels of stearidonic acid, EPA and other n-3 PUFA, while rats given the LA diet had low levels of GLA and dihomoGLA. We conclude that diets enriched with LNA or LA may not be as effective as those enriched with EPA + GLA for purposes of fostering incorporation of EPA or dihomoGLA into and displacement of AA from macrophage phospholipids under pathophysiologic conditions commonly found in acutely septic patients.

Lipids 33, 1099–1105 (1998).

Alveolar macrophages (AM) and liver sinusoidal Kupffer and endothelial cells (K&E) play a prominent role in the host immune response to infection. When activated during sepsis or trauma, these immune cells are capable of altering the intermediary metabolism and physiologic function of proximal parenchymal cells within their respective organs by releasing vasoactive eicosanoids derived from arachidonic acid (AA, 20:4n-6) and cytokines that promote neutrophil chemotaxis, platelet aggregation, and inflammation (1–3). Overexpression of these and other mediators fosters a persistent systemic inflammatory response, increasing the likelihood of organ dysfunction in the critically ill patient (4–6). For this reason, newer therapeutic modalities are being directed toward the modulation of immune cell AA metabolism to attenuate disregulated inflammatory processes.

Experimental and clinical studies showed that the fatty acid composition and inflammatory responses of host immune cells can be modulated by providing diets enriched with eicosapentaenoic acid (EPA, 20:5n-3) from marine oil either alone (7–11) or in combination with γ-linolenic acid (GLA, 18:3n-6) from borage oil (12–15). We demonstrated that EPA and the GLA metabolite, dihomoGLA (DHGLA, 20:3n-6), is rapidly incorporated into immune cell membranes *in vivo* after short-term enteral feeding with EPA- and GLA-enriched diets (16) irrespective of concurrent endotoxemia (17). EPA and DHGLA displace both AA and linoleic acid (LA, 18:2n-6), respectively, from macrophage phospholipids and effectively compete with AA for cyclooxygenase and lipoxygenase binding sites to foster formation of eicosanoids with relatively lower inflammatory properties (18), e.g., thromboxane A_3, leukotriene B_5 and prostaglandin E_1 (PGE_1), than those generated from AA (e.g., thromboxane A_2 and leukotriene B_4)(Figs. 1 and 2). In our recent study, rats that had been given an (EPA + GLA)-enriched diet had lower ratios of thromboxane A_2/A_3 and leukotriene B_4/B_5 measured in the supernatants of AM exposed to endotoxin *in vitro* than corresponding levels measured from rats given a standard diet enriched with LA (19). The AM from the rats given the (EPA + GLA)-supplemented diet also released greater quantities of PGE_1 than AM from the rats receiving the LA-supplemented diet. PGE_1 is a metabolite of DHGLA that exhibits vasodilatory and antiaggregatory properties in the lung, effects that appear to be beneficial to patients with the acute respiratory distress syndrome (20,21).

One concern in the design of enteral formulations enriched with n-3 polyunsaturated fatty acids (PUFA) is whether α-linolenic acid (LNA, 18:3n-3) present in canola oil could

Abbreviations: AA, arachidonic acid; AM, alveolar macrophage; DHA, docosahexaenoic acid; DHGLA, dihomo-γ-linolenic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; K&E, Kupffer and endothelial; LA, linoleic acid; LNA, α-linolenic acid; PBS, phosphate buffered saline; PGE_1, prostaglandin E_1, PUFA, polyunsaturated fatty acids.

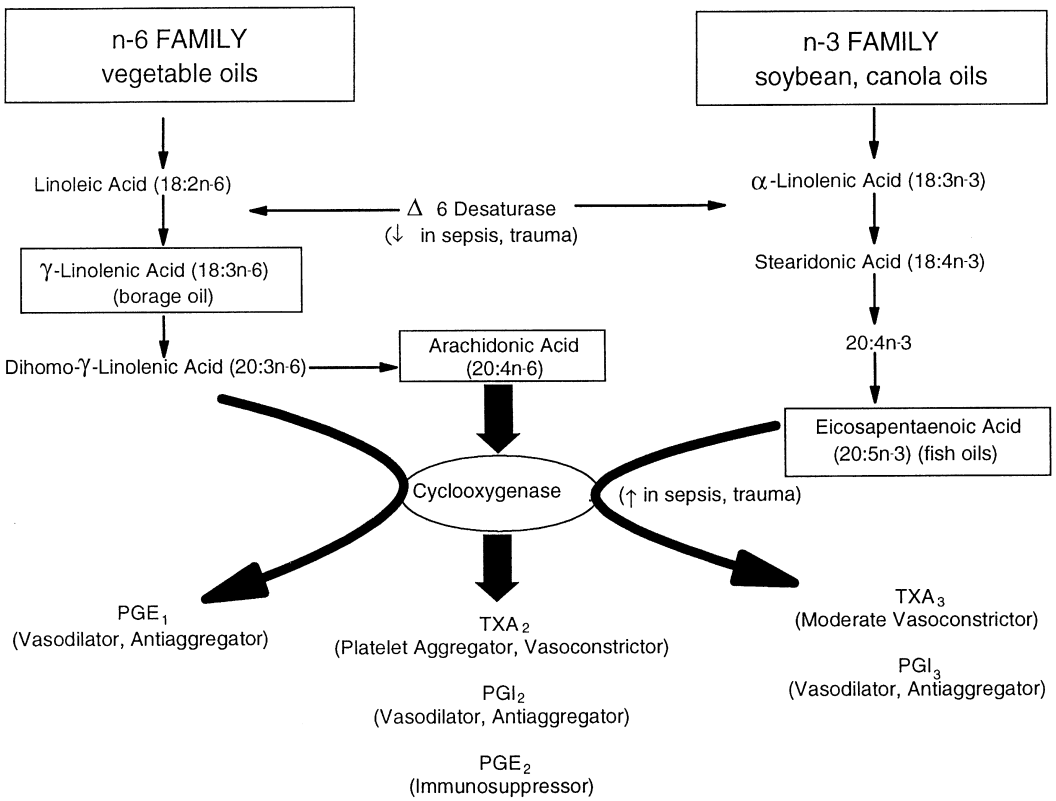

FIG. 1. Metabolic pathways for conversion of dietary polyunsaturated fatty acids to prostaglandins and thromboxanes. PGE_1, PGE_2, PGI_2, and PGI_3 are prostaglandins E_1, E_2, I_2 and I_3, respectively. TXA_2 and TXA_3 are thromboxanes A_2 and A_3, respectively.

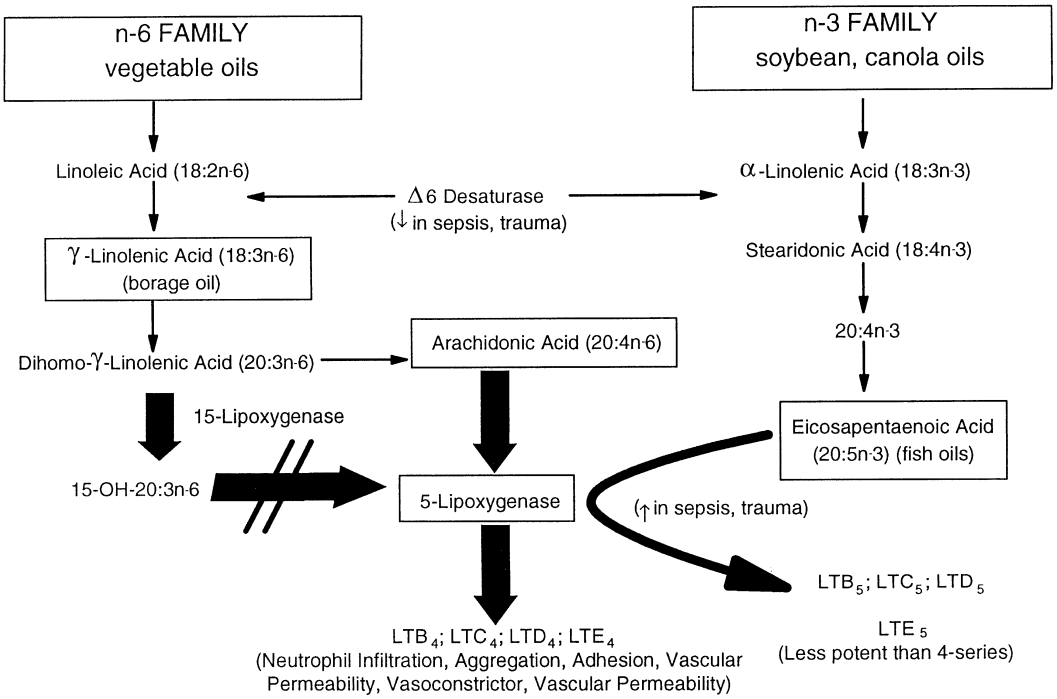

FIG. 2. Metabolic pathways for conversion of dietary polyunsaturated fatty acids to leukotrienes. LTB_4, LTC_4, LTD_4, LTE_4, LTB_5, LTC_5, LTD_5, and LTE_5 are the leukotrienes B_4, C_4, D_4, E_4, B_5, C_5, D_5, and E_5, respectively.

serve as a metabolic precursor of EPA and its longer-chain derivatives, docosapentaenoic (DPA, 22:5n-3) and docosahexaenoic (DHA, 22:6n-3) acids (Fig. 1). It is not known whether dietary LNA can be rapidly elongated and desaturated within mammalian immune cells to form EPA, DPA, and DHA within a clinically relevant time frame, i.e., 3 to 6 d. Experimental studies in rodents orally fed LNA-enriched diets over a 3- (22) or 12-wk period (23) showed that both the amount of EPA present in and the amount of AA displaced from plasma or cell phospholipids were lower than those measured in animals supplemented with dietary EPA. Recent clinical studies in healthy subjects consuming diets enriched in LNA and low levels of LA demonstrated that the percentage of EPA appearing in plasma (24) and mononuclear cell (25) phospholipids had increased slowly over an 8-wk period, with little change occurring in AA levels. This in part may have been due to the postabsorptive release of LA from adipose stores, fostering restoration of AA displaced by LNA or newly formed EPA (16,26). Moreover, formation of EPA from LNA is subject to the activity of Δ6 desaturase, a rate-limiting enzyme that catalyzes the initial desaturation of LNA to stearidonic acid (18:4n-3) (27,28). Compounding this quandary are reports that the stress hormones, i.e., epinephrine (29,30), ACTH (30) or glucocorticoids (31), have an inhibitory effect on both the Δ6 and Δ5 desaturases involved in LNA desaturation to EPA. Reduced activity of Δ6 desaturase may also limit GLA formation from dietary LA, potentially retarding formation of DHGLA and its metabolite, PGE_1. Thus, stressed or septic patients may not be able to effectively convert dietary LNA to EPA and other long-chain n-3 PUFA in sufficient quantities to promote displacement of endogenous AA from immune cell membrane phospholipids (32,33). For this reason, provision of diets containing long-chain PUFA, such as EPA and GLA, that are metabolized regardless of existing alterations in Δ6-desaturase activity, may prove beneficial to critically ill patients with ongoing inflammatory processes.

Our objective in the present study was to assess whether short-term continuous enteral feeding with an LNA-enriched formulation could effectively displace AA and its precursor LA from rat hepatic and lung immune cell phospholipids under septic conditions *in vivo* to the same extent as that achieved with an (EPA + GLA)-enriched formulation. Comparisons were made with immune cells procured from rats given either a standard control diet enriched with LA or a diet enriched with EPA and GLA. We also assessed whether cell phospholipid DHGLA increased in rats given the high-LA diet relative to that in rats given the EPA + GLA formulation.

MATERIALS AND METHODS

The study design was approved by the Institutional Animal Care and Use Committee. The care of the animals was in accordance with the guidelines set forth by the National Institutes of Health's *Guide for the Care and Use of Laboratory Animals*. The surgical catheterization, treatments, and analytic methods were similar to those described recently (11,17).

Pathogen-free male (225–275 g) Sprague-Dawley rats (Harlan, Altamont, NY) were allowed free access to a low-fat nonpurified diet devoid of fish meal (Teklad 7001; Harlan) for 5 d prior to study entry. All rats were randomized to a dietary treatment prior to study entry. After food was withheld overnight, each rat was anesthetized at 0900 h of day −1 with diethyl ether. A 1.0-mm i.d. Tygon® (Norton Plastics, Wayne, NJ) feeding catheter was inserted aseptically though a fundal gastrostomy, advanced 2.5 cm into the duodenum, and anchored to the stomach wall with a purse-string suture. A 0.64-mm i.d. silastic catheter was inserted in the left jugular vein for intravenous infusion of endotoxin. The proximal ends of the catheters were tunneled subcutaneously, exteriorized at the midscapular region, and attached to a dual channel flow-through swivel to permit freedom of movement during infusion. All incisions were closed with surgical-grade silk sutures. The rats were allowed to recover and were housed in individual wire-bottomed cages for the study duration. The rats were allowed free access to water.

All rats were infused enterally with a low-fat basal diet (Vital HN; Ross Laboratories, Columbus, OH) from 1500 h of day −1 until 0900 h of day 0 to facilitate rehydration and adaptation to enteral feeding as described (17). At 0900 h of day 0, subsets (n = 6–8/group) of rats were infused in continuous fashion with one of three diets (Table 1) @ 250 kcal/kg/d until 0900 h of either day 3 or day 6 using a programmable syringe pump (Model 42; Harvard Apparatus, Natick, MA). Under these conditions, we have found that the body weights and health of rats receiving similar test diets remain stable for at least 1 wk (17). All rats received fresh daily portions of their assigned diet to minimize the potential for bacterial growth during infusion.

Enteral diets. The rats were randomized to receive one of three high-fat, low-carbohydrate diets which have been utilized in the clinical setting (Table 1): an LA-enriched diet (59% of total fatty acids as LA) served as a standard control diet derived principally from corn oil; an LNA-enriched diet

[a]LA, linoleic acid; LNA, α-linolenic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid.

(5.3% LNA) represented an enteral diet containing canola oil, medium-chain triglycerides, and high-oleic safflower oil to reduce the dietary level of LA; the third diet also contained medium-chain triglycerides but was enriched with EPA (5.3%), LNA (3.9%), and GLA (4.6%) from sardine oil, canola oil, and borage oil, respectively. The fatty acid compositions of these diets were determined by gas chromatography. Each of these diets provided 16.7% of total energy as protein, 28.1% as carbohydrate, and 55.2% as lipid, and all were fortified with minerals and antioxidant vitamins (C, E, and β-carotene). Each diet was manufactured (Ross Products Division, Abbott Laboratories, Columbus, OH) in 237-mL portions and sealed under nitrogen.

Endotoxin infusion. We utilized a nonlethal model of endotoxicosis (17) which consistently produced the following clinical signs: piloerection, conjunctival hemorrhage, ear flattening, and general lethargy. The intravenous infusion of endotoxin lipopolysaccharide B (*Escherichia coli* 026:B6; Difco, Detroit, MI) in 1 g albumin/L of saline was started at 1500 h on day −1. The endotoxin solution was delivered continuously by syringe pump at 0.4 mg/kg for as long as the rats were undergoing enteral feeding.

Isolation of sinusoidal K&E cells. The method for collection and isolation of AM and sinusoidal K&E cells has been described (17). Briefly, each rat was anesthetized with 50 mg/kg pentobarbital administered by intraperitoneal injection at 0900 h of either day 0 (Baseline), day 3 (Day 3) or day 6 (Day 6), depending on the randomization schedule. After laparotomy, 0.5 mL heparin was injected into the vena cava and allowed to circulate. A 16-gauge angiocatheter was inserted in the exposed hepatic veins, and the liver lobes were flushed with HEPES buffer (5 mmol/L, pH = 7.2) in retrograde fashion. The liver was then flushed *in situ* with collagenase (2.5 g/L type II and 2.5 g/L type IV; Sigma, St. Louis, MO) in HEPES (pH = 7.6). The liver was then excised and incubated at 37°C for 15 min before separation of the cells from the supporting connective tissue. The sinusoidal cells were separated from the hepatocytes and other contaminating cells by differential centrifugation (2 min at $50 \times g$, three times) followed by isolation on a 17.5% metrizamide discontinuous gradient. The K&E cells removed from the gradient interface were resuspended in Grey's balanced salt solution prior to assessment of cell number and viability (>90%) by trypan blue exclusion under light microscopy. The K&E cells were then pelleted by centrifugation ($500 \times g$, 10 min) and stored at a density of 2×10^7 cells/mL at −20°C under nitrogen.

AM collection and isolation. A 16-gauge angiocatheter was inserted through a laparotomy into the superior vena cava, and the lung vasculature was flushed with Ca^{2+}- and Mg^{2+}-free phosphate buffered saline (PBS) to remove blood components. The vena cava was severed and the rats expired by exsanguination. A 14-gauge angiocatheter was inserted through a tracheostomy, and the lungs were lavaged eight times with 5 mL cold PBS containing 0.6 mmol/L EDTA; gentle chest massage facilitated fluid recovery (>90%). The cumulative lavage fluid was kept on ice during this procedure. The lavage fluid was spun at $400 \times g$ for 10 min at 4ºC, and the cell pellet was then resuspended in PBS and centrifuged at $110 \times g$ for 10 min at 4ºC. The cell pellet was resuspended in PBS, layered on Ficoll Paque (Pharmacia, Piscataway, NJ), and centrifuged at $500 \times g$ at 22°C for 35 min to isolate the AM. Purity and viability by trypan blue exclusion were >95%. The AM were stored at a density of 5×10^6 cells/mL PBS under nitrogen in PBS at −20ºC for analysis of the fatty acid composition of the total phospholipid fraction.

Analysis of macrophage phospholipid fatty acids. Quantitation of 16 identifiable fatty acids (12–24 carbons in length) in the phospholipid fraction of AM and K&E cells was carried out (17). The lipid component of the cells was extracted in chloroform/methanol (2:1, vol/vol), and the phospholipid fraction was isolated on silica gel H (Analtech, Newark, DE) thin-layer plates using a mobile phase of petroleum ether/diethyl ether/glacial acetic acid (80:20:1, by vol), and identified relative to the migration of standards using dichlorofluorescein spray. The phospholipid band was isolated, hydrolyzed, and methylated with 140 g/L boron trifluoride in methanol. The fatty acid methyl esters were separated on a 50-m fused-silica capillary column containing SP-2330 (Supelco, Bellefonte, PA), using a Hewlett-Packard 5890 Series II gas chomatograph (Hewlett-Packard, Palo Alto, CA) equipped with a 7673 Autosampler. The relative mol% of individual fatty acids was identified and quantified using Chem Station software (Hewlett-Packard) based upon the relative responses of an external standard of pure fatty acid methyl esters (Nu-Chek-Prep, Elysian, MN).

Statistical analyses. Descriptive and inferential statistics were generated using computer-based programs. Generalized linear models for two-way analysis of variance were employed to examine the effects of diet and time for each cell type and fatty acid. Contrasts were included in the models to compare levels of each effect while holding levels of other effects fixed. Sensitivity analyses of model assumptions were robust under most data conditions, e.g., normality assumption. Statistical significance was set at $P < 0.05$.

RESULTS

The control (i.e., LA-enriched) and experimental [LNA- or (EPA + GLA)-enriched] diets were well tolerated during enteral infusion for the 3- and 6-d periods. All rats showed persistent signs of endotoxicosis, as described above, during endotoxin infusion. No significant differences occurred in initial or final body weights or changes in body weight among the dietary groups for a given time period.

Overall, the majority of dietary effects on the composition of phospholipid fatty acids of the alveolar (Table 2) and hepatic (Table 3) immune cells occurred rapidly within the first 3 d of enteral feeding. These changes generally reflected the differences in the composition of fatty acids present within each diet, with notable exceptions as discussed below. For example, after 3 d of continuous enteral feeding, the AM and K&E cells from the rats fed the LA diet had significantly

[a]See Table 2 for footnote information.

higher mole percentage of LA and total n-6 PUFA than corresponding cells from the LNA or (EPA + GLA)-supplemented rats. However, AA levels in these immune cells were relatively similar across the LA and LNA diet groups after 6 d. AM and K&E cells from rats given the LNA diet which contained high-oleic safflower oil had higher levels of 18:1n-9 and total monounsaturates than cells from rats infused with the LA or EPA + GLA diet after 3 or 6 d of feeding. Levels of LNA, stearidonic acid, and GLA were either negligible or not detectable in most cell phospholipids (data not shown). As observed in previous studies (16,17), the mole percentage of DHGLA was significantly higher in both the AM (Table 2) and K&E cell (Table 3) phospholipids from rats that had received the EPA + GLA diet relative to rats given either the LA or LNA diet after either 3 or 6 d.

With regard to the long-chain n-3 PUFA (i.e., EPA, DPA, or DHA), the immune cells from rats that received the EPA + GLA for 3 d had significantly higher ($P < 0.001$) enrichment of each of these n-3 PUFA than that observed in corresponding cells from either the LA or LNA rats. Moreover, the percentage of EPA present in the AM after 6 d of feeding the EPA + GLA diet was higher (3.7 vs. 2.5%, $P < 0.05$) than that observed after 3 d (Table 2), whereas K&E cell EPA remained unchanged after an additional 3 d of feeding (Table 3). Given that the levels of EPA, DHA, and total n-3 PUFA present in either the AM or K&E cells from the rats given the LNA-supplemented diet for 3 or 6 d were similar to those measured in the corresponding cells from rats given the LA diet, these data indicate that dietary LNA was not effectively elongated and desaturated to the longer-chain n-3 PUFA under existing endotoxemic conditions. Interestingly, a small but significantly higher mole percentage of DPA was measured in the K&E cells (Table 3) on both day 3 and day 6, but only on day 6 in the AM (Table 2) from rats given the LNA diet vs. the LA diet.

DISCUSSION

The data from this study indicated that provision of a diet enriched with LNA to endotoxemic rats by continuous enteral infusion for either 3 or 6 d did not promote EPA or DHA formation or displacement of AA from AM or K&E phospholipids *in vivo*. In addition, rats which had received the LA-enriched diet for 6 d did not have increased levels of DHGLA or AA in the AM or K&E cell phospholipids relative to the rats given the LNA-enriched diet. As discussed above, these outcomes may be attributable to several compounding factors. While Δ6 desaturation of both LNA to stearidonic acid (18:4n-3) and LA to GLA is a rate-limiting step under normal conditions, evidence exists to suggest that Δ6-desaturase activity is further reduced under conditions that foster release of epinephrine and other stress-associated hormones (29–31). This hormonal milieu can be found in traumatized or acutely septic patients. The finding that the mole percentage of DPA was increased in immune cells from rats consuming the LNA diet (Tables 2 and 3) attests to the probability that Δ6-desaturase activity was a primary factor influencing fatty acid metabolism and incorporation into these immune cells. In this regard, other investigators have proposed that the conversion of DPA to DHA occurs independently of Δ4 desaturase, i.e., DPA is instead initially elongated to 24:5n-3 prior to Δ6 desaturation to form 24:6n-3, which in turn undergoes β-oxidation to form 22:6n-3 (34). Thus, inhibition of Δ6-desaturase activity would foster a buildup of both DPA and 24:5n-3, with preferential β-oxidation of 24:5n-3 back to DPA under these conditions (34).

The limitations imposed by Δ6 desaturase on the metabolism of LNA or LA under endotoxemic conditions can be circumvented by providing dietary fatty acids that bypass the Δ6 desaturation step (Figs. 1 and 2). As shown in the present study, dietary EPA was readily incorporated into the AM and K&E cell membrane phospholipids irrespective of concurrent endotoxemia (Tables 2 and 3). Similarly, the significant increase in immune cell DHGLA content in rats given the EPA + GLA diet demonstrated that GLA metabolism was not inhibited during endotoxicosis. In this regard, EPA enhances accumulation of DHGLA by decreasing Δ5-desaturation activity and conversion of DHGLA to AA (35). As observed previously (16,17), the incorporation of EPA and DHGLA promoted the rapid displacement of AA and its precursor, LA, from AM and K&E cell phospholipids. As we and others have shown, this exchange of PUFA favors the formation of eicosanoids derived from EPA and DHGLA, which have reduced inflammatory properties, as opposed to eicosanoids derived from AA which are more vasoactive and proinflammatory (8,13,14,19).

It is not known whether the observed modulation of immune cell phospholipid fatty acids is due primarily to exchange with plasma lipoprotein fatty acids or to elongation/desaturation processes within the macrophages (36). Our previous studies in endotoxemic rats enterally fed with either an EPA (11) or EPA + GLA diet (17) revealed that plasma phospholipids are enriched with EPA or EPA and DHGLA, respectively. We did observe in the present study that the mole percentage of EPA in AM increased significantly between day 3 and day 6 (Table 2). Given the relative isolation of these cells from the liver and intestine as well as the circulating plasma within the lung capillaries, the latter finding suggests that exchange mechanisms could play an important role for incorporation of EPA into AM phospholipids over time. However, the concurrent findings that the mole percentage of the GLA and EPA metabolites, i.e., DHGLA, and DPA and DHA, respectively, did not increase further after day 3 (Table 2) and that GLA was not detected in these cells would suggest that elongation and desaturation processes also may have facilitated fatty acid modification (36). With regard to the K&E cells, we did not observe any significant modifications in fatty acid composition between day 3 and day 6 (Table 3). The proximity of the K&E cells to hepatocytes as well as to dietary fatty acids present in the portal circulation (37) would favor exchange processes as a mechanism for rapidly modulating the composition of the phospholipid fatty acids within these immune cells.

In summary, short-term enteral feeding of a diet enriched with LNA and a reduced level of LA under endotoxemic conditions did not promote AA displacement or formation of EPA in lung and liver immune cell phospholipids *in vivo*. The results of this study did demonstrate that provision of dietary EPA and GLA to circumvent the rate-limiting step of Δ6 desaturation, while also reducing dietary LA, rapidly decreased the mole percentage of AA and LA present in lung and liver immune cell phospholipids within a clinically relevant time frame irrespective of concurrent endotoxemia. In addition, displacement of AA and LA occurred in conjunction with the incorporation of EPA and DHGLA into the cell phospholipids. The exchange of AA and LA with EPA and DHGLA can foster generation of eicosanoids with reduced inflammatory properties, which should prove beneficial to critically ill patients with excessive systemic inflammation due in part to persistent generation of vasoactive eicosanoids derived from AA.

ABSTRACT: 6,9,12,15,18,21-Tetracosahexaenoic acid (24:6n-3) was isolated from a brittle star, *Ophiura sarsi* Lütken, at >95% purity to evaluate its physiological functions. The effects of 24:6n-3 on the production of leukotriene (LT)-related compounds such as LTB_4, LTC_4 and 5-hydroxyeicosatetraenoic acid, and the accumulation and release of histamine in an MC/9 mouse mast cell line were studied. We found that 24:6n-3 could inhibit the antigen-stimulated production of LT-related compounds as well as other n-3 polyunsaturated fatty acids (PUFA) such as eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), which are major n-3 PUFA in fish oils; 24:6n-3 was also shown to reduce the histamine content in MC/9 cells at 25 μM (27% reduction from the control), and the effect was diminished with increase of the fatty acid concentration (up to 100 μM). These two n-3 PUFA, 20:5n-3 and 22:6n-3, also reduced the histamine content (16 and 20% reduction at 25 μM, respectively), whereas arachidonic acid (20:4n-6) increased it (18% increase at 25 μM). Spontaneous- and antigen-induced release of histamine was not influenced with these PUFA (at 25 μM). Ionophore-stimulated release of histamine was suppressed by the PUFA (13, 9, 15, and 11% reduction with 20:4n-6, 20:5n-3, 22:6n-3, and 24:6n-3, respectively). The patterns of the effects of 24:6n-3 on the synthesis of eicosanoids and histamine content were more similar to those of 22:6n-3 than 20:5n-3. From these results, 24:6n-3 can be expected to have anti-inflammatory activity and antiallergic activities similar to those of 22:6n-3.
Lipids 33, 1107–1114 (1998)

Since the discovery by Dyerberg *et al.* (1–3) of a low incidence of heart disease in Eskimos, the nutritional, physiological, and pharmacological effects of fish oil on humans have been recognized, and several studies on the beneficial effects of fish oil have been carried out. As a result of these studies, eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), which are major n-3 polyunsaturated fatty acids (PUFA) rich in fish oil, were demonstrated to have beneficial effects on pathophysiological states like coronary heart disease, hyperlipidemia, and inflammation (4).

Fish oil contains various n-3 PUFA besides 20:5n-3 and 22:6n-3. 6,9,12,15,18,21-Tetracosahexaenoic acid (24:6n-3) is one of the n-3 PUFA and is a very long chain fatty acid (5). Distribution of 24:6n-3 in marine organisms was investigated by several researchers. Takagi *et al.* (6) reported relatively high contents of 24:6n-3 in sea lilies and brittle stars (4–10% of total fatty acids). High 24:6n-3 content was also found in marine coelenterates (7). In some edible fishes, 24:6n-3 was detected at significant levels (0–10% of total fatty acids) (8,9).

The existence of 24:6n-3 in mammalian tissues was reported with other very long chain fatty acids in the spermatozoa (10), the retina (11), and the brain (12). Voss *et al.* (13) reported that 24:6n-3 is formed as an intermediate in the metabolic pathway from 20:5n-3 to 22:6n-3 in rat liver.

Even though 24:6n-3 is a PUFA existing in fish and mammalian species, physiological functions of 24:6n-3 have not been studied. As functions to be studied, anti-inflammatory and antiallergic effects of 24:6n-3 are noteworthy because these events are known to be closely related to the unsaturated fatty acid metabolism such as in the arachidonic acid cascade, and 20:5n-3 and 22:6n-3 were reported to suppress inflammatory actions by influencing arachidonic acid metabolism (4,14–16).

In this paper, we isolated 24:6n-3 from brittle stars, *Ophiura sarsi* Lütken, and examined the effects on the production of eicosanoids and the accumulation and release of histamine, using an MC/9 mouse mast cell line (17). Histamine and eicosanoids are produced and released by mast cells and act as chemical mediators in allergic reactions (18). MC/9 cells accumulate histamine and synthesize lipoxygenase pathway metabolites such as leukotriene (LT) B_4, LTC_4, and 5-hydroxyeicosatetraenoic acid (5-HETE) from arachidonic acid (20:4n-6)(19,20).

EXPERIMENTAL PROCEDURES

Materials. Linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) were purchased from Wako Pure Chemical Indus-

Abbreviations: DNP-KLH, dinitrophenylated keyhole limpet hemocyanine; FAME, fatty acid methyl ester; FFA, free fatty acid; GC, gas chromatography; HETE, hydroxyeicosatetraenoic acid; HPLC, high-performance liquid chromatograph; IgE, immunoglobulin E; LT, leukotriene; PUFA, polyunsaturated fatty acid.

try (Osaka, Japan), and 20:4n-6 and 22:6n-3 from Sigma Chemical Company (St. Louis, MO); all of these fatty acids were obtained as methyl esters. The 20:5n-3 ethyl ester was a kind gift from Nissui Pharmaceuticals (Tokyo, Japan). Prostaglandin B_2, LTB_4, LTC_4, LTD_4, LTE_4, 5-HETE, 12-HETE, and 15-HETE were obtained from Cascade Biochem Ltd. (Reading, United Kingdom). RPMI-1640 medium, a culture medium for MC/9, was purchased from Nissui Pharmaceuticals; fetal calf serum, from Biological Industry Inc. (Kibbutz, Israel); dinitrophenylated keyhole limpet hemocyanine (DNP-KLH), from LSL (Tokyo, Japan); and murine anti-DNP-KLH immunoglobulin E (IgE) and calcium ionophore A23187, from Sigma. All other chemicals used in this report were of analytical grade or higher.

The MC/9 mouse mast cell line was purchased from American Type Culture Collection (Rockville, MD) and maintained in RPMI-1640 medium supplemented with 10 μM β-mercaptoethanol (Wako), 10% fetal calf serum, and 20% conditioned medium of WEHI-3 cell (Riken Gene Bank, Saitama, Japan), which is a murine monocyte-like cell and produces growth factor(s) to support the growth of MC/9. WEHI-3-conditioned medium was prepared as described by Razin *et al.* (21)

Preparation and purification of 24:6n-3 from brittle star. Brittle stars, *O. sarsi* Lütken, were caught at Wakasa Bay, Fukui Prefecture, Japan. Total lipid of the brittle stars was extracted by Bligh and Dyer's method (22). Fatty acid methyl esters (FAME) were prepared by refluxing total lipid in 3% HCl-methanol for 3 h. The methyl esters were fractionated by silver-nitrate impregnated thin-layer chromatography in toluene/acetic acid (19:4, vol/vol). The chromatogram was visualized under ultraviolet light (360 nm) following spraying with 0.005% primuline in acetone/water (1:1, vol/vol). FAME retarded at the origin (including 20:5n-3, docosahexaenoic acid and 24:6n-3 as major components) were scraped from the thin-layer chromatography plate and extracted by the method of Folch *et al.* (23). The extracted FAME were saponified in a mixture of 10 N NaOH and methanol (1:9, vol/vol) for 3 h at 4°C on a magnetic stirrer. Free fatty acids (FFA) were then extracted with hexane after acidification with 6 N HCl. FFA were dissolved in 90% methanol and applied to the high-performance liquid chromatograph (HPLC) (Waters 600 system) using a μ-Bondapak ODS column (Waters; 20 × 150 mm) and methanol/water (9:1, vol/vol) as the mobile phase (5 mL/min). Elution of FFA was monitored with a Waters Multiwavelength ultraviolet/visible detector Model 490 at 217 nm. A peak of 24:6n-3 was collected and was dried with a rotary evaporator. The residue was dissolved in argon-bubbled ethanol at a concentration of 50 mM and stored at −80°C. Small portions of it were applied for gas chromatography (GC) and GC–mass spectrometry analyses after derivatization (methyl esterification and pyrrolidination, respectively) (24). A GC analysis of FAME was carried out at 205°C with a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) equipped with a flame-ionization detector and Omegawax 320 capillary column (0.32 mm × 30 m; Supelco Inc., Bellefonte, PA). The GC–mass spectrometric analysis was performed using JEOL JMS-DX303 (column: Omegawax 320, 260°C, EI 70eV; JEOL, Tokyo, Japan). Other fatty acids used in this report were saponified and purified by HPLC in the same manner as the case for 24:6n-3.

Stimulation of MC/9 cells. MC/9 cells grown as described in the preceding section were collected and washed with Ca^{2+}-, Mg^{2+}-free phosphate buffered saline twice and suspended in Tyrode solution (10^7 cells/mL). Cell suspension was dispensed into 1.5 mL micro test tubes (0.25 mL for histamine assay, 0.5 mL for eicosanoid assay). For stimulation with ionophore A23187, cell suspensions were added with A23187 in ethanol (final conc. 5 μM) and incubated for 10 min. For stimulation with antigen-IgE complex, cells were sensitized by incubating with murine monoclonal anti-DNP-KLH IgE (100 ng/10^6 cells) for 1 h. The cells were pelleted by centrifugation. The supernatant was discarded and the cells were resuspended in Tyrode. The sensitized cells were stimulated by the addition of the antigen, DNP-KLH (100 ng/10^6 cells), and incubated for 10 min. In case of eicosanoid production assay, the cell suspensions contained 30 μM arachidonic acid as a substrate for lipoxygenase pathway unless otherwise indicated in figure legends.

Assay of the production of eicosanoids. To stop the LT production of stimulated cells, 1 mL of acetonitrile containing 1 nmol of prostaglandin B_2 (internal standard) was added to the cell suspension. The mixture was stored at −20°C overnight and centrifuged at 10,000 × *g* to precipitate proteins. The supernatant was treated as described by Eskra *et al.* (25) on a Sep-Pak C18 cartridge (Waters) to extract the LT and HETE. The samples were dried with a centrifuge evaporator (Iwaki Glass Co., Tokyo, Japan) and dissolved in 200 μL of 66% methanol/ water. Of the sample, 100 μL was injected onto an HPLC with a Novapak ODS column (4 × 150 mm; Waters), equipped with a Waters 717 plus autosampler connected to a Waters model 600 pump system. Elution was carried out using a nonlinear gradient program as follows: 0–18 min, methanol/water/trifluoroacetic acid/triethylamine (65:35:0.09:0.05, by vol), 18–36 min; methanol/water/trifluoroacetic acid/triethylamine (75:25:0.09:0.05, by vol), 36–40 min; 100% acetonitrile (solvent flow: 1 mL/min). Elution was monitored with a photodiode array detector (Model 996; Waters). LT and HETE were quantified at 280 and 235 nm, respectively, with Waters Millennium software. With this procedure, LT (LTB_4, LTC_4, LTD_4, LTE_4) and HETE (5-HETE, 12-HETE, 15-HETE) were completely separated.

Assay of histamine accumulation and release. MC/9 cells were incubated in the medium containing various amounts of FFA (0–100 μM) for 24 h at a density of 2×10^6 cells/mL. The cells were collected by centrifugation at 100 × *g* for 5 min, washed with phosphate buffered saline twice, and suspended in Tyrode solution (10^7 cells/mL). For measurement of total histamine content, the cell suspension was added with 2.5% perchloric acid to achieve the final concentration at 1%. For histamine release assay, the cell suspension was stimu-

lated with ionophore or antigen as described above. Histamine release was stopped by the addition of 125 μL of ice-cold 4 mM EDTA in Ca^{2+}-, Mg^{2+}-free Tyrode. The cells were pelleted by centrifugation at 100 × *g* for 10 min at 4°C. An aliquot of the supernatant (200 μl) was mixed with 133 μL of 2.5% perchloric acid. The cell pellet was washed once with ice-cold 4 mM EDTA/Tyrode, resuspended in 200 μL of the same solution, and mixed with 133 μL of 2.5% perchloric acid. Each mixture was incubated in boiling water for 5 min to extract histamine and centrifuged at 10,000 × *g* for 5 min. The supernatants were used to measure the histamine concentration by the on-column HPLC method described by Saito *et al.* (26) with a Waters 600 pump connected with Waters 717 plus autosampler and model 474 fluorescence detector. Histamine release was expressed as a percentage of the histamine of the supernatant in the sum of the histamine of the supernatant and the cell suspension.

Statistical analysis. Data obtained in this report were analyzed by one-way analysis of variance. If significant, data were further analyzed by Duncan's multiple range test (27).

RESULTS

Isolation of 24:6n-3 from brittle stars. The purity of the fatty acid isolated from the brittle stars was >95% estimated by using GC analysis (data not shown). From the mass spectrum of the pyrrolidine derivatives of the fatty acid, double-bond locations were confirmed at the 6-, 9-, 12-, 15-, 18-, and 21-positions from the fragmentation pattern showing a molecular ion at *m/z* 409 and fragments at 394, 380, 366, 354, 340, 326, 314, 300, 286, 274, 260, 246, 234, 220, 206, 194, 180, and 168 *m/z*. Thus, the fatty acid purified from the brittle stars was identified as 24:6n-3. Identification of 24:6n-3 was confirmed by comparison of the equivalent chain length value on a Silar 5CP column (Supelco) with the value reported (9).

Effect of substrate concentration on eicosanoid production in MC/9 cells. In the absence of exogenously added 20:4n-6 as a substrate for eicosanoid production, neither LT nor HETE was observed in both ionophore- and antigen-stimulated MC/9 cells (Fig. 1). The production of LTB_4, LTC_4, and 5-HETE increased with increasing concentration of 20:4n-6. The synthesis of LTB_4 and LTC_4 reached almost a plateau

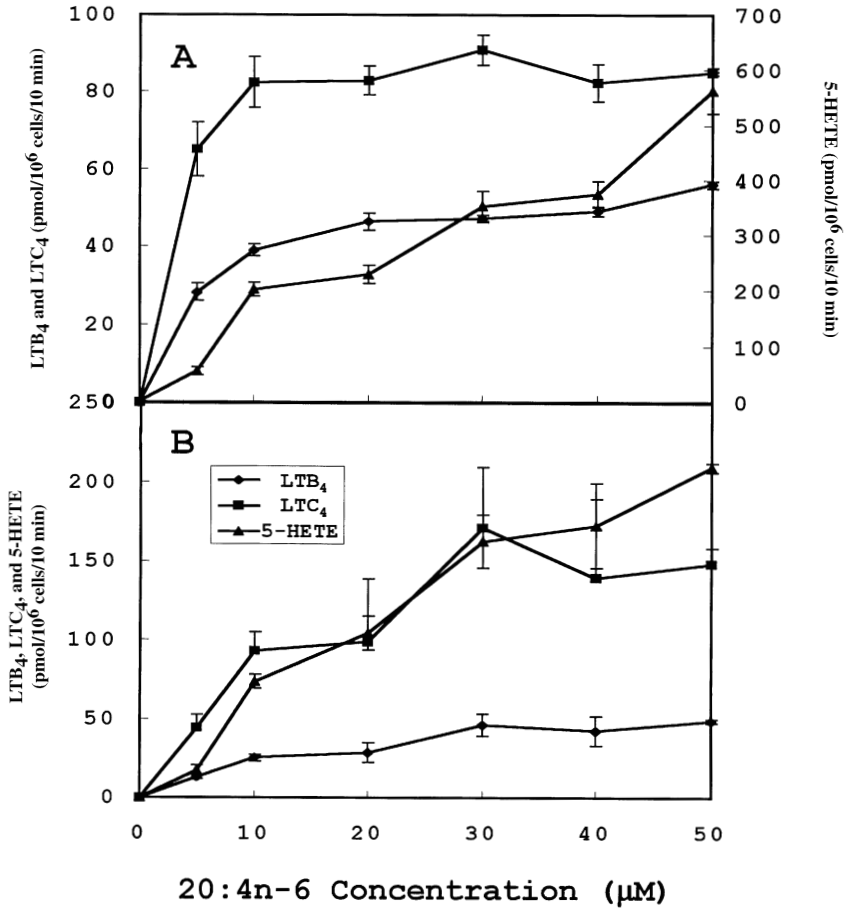

FIG. 1. Dose dependence of 20:4n-6 on the production of eicosanoids in: (A) ionophore- and (B) antigen-stimulated MC/9 cells. MC/9 cells were stimulated with (A) ionophore and (B) antigen in the presence of various concentrations of 20:4n-6 (0–50 μM). Leukotriene B_4 (LTB_4), LTC_4, and 5-hydroxyeicosatetraenoic acid (5-HETE) were analyzed as described in the Experimental Procedures section. Values are the mean of 3–4 samples. Vertical bars indicate the standard error of the mean.

from a concentration of 30 μM of 20:4n-6 although 5-HETE production increased with increasing concentrations of the substrate (Fig. 1A and B). Thus, we determined the concentration of 20:4n-6 as a substrate for the following assay of eicosanoid production in MC/9 at 30 μM.

Inhibition of eicosanoid production by 24:6n-3 in comparison with other n-3 PUFA. In the ionophore-stimulated production of eicosanoids, LTB_4 production tended to be suppressed by 20:5n-3, 22:6n-3, and 24:6n-3 (Fig. 2). However a significant difference was observed only in the presence of 20:5n-3 (30, 45 μM). Concerning the production of LTC_4 and 5-HETE, no significant inhibition by PUFA was observed in the ionophore-activated cells, although n-3 PUFA tended to suppress weakly the production of the two eicosanoids (Fig. 2B and C). In antigen-stimulated cells, inhibition of eicosanoid production by n-3 PUFA appeared more clearly (Fig. 3). LTB_4 production was inhibited strongly by 20:5n-3 and less strongly by 22:6n-3 (Fig. 3A); 24:6n-3 only exhibited a slight inhibitory effect on LTB_4 production. As for LTC_4 synthesis, the inhibitory effect of n-3 PUFA was more evident (Fig. 3B). All of n-3 PUFA significantly suppressed LTC_4 production. The inhibitory activity of 24:6n-3 was weaker than that of the other two PUFA (20:5n-3 and 22:6n-3), as a significant inhibition by 24:6n-3 was not found at the lowest concentration (15 μM). The production of 5-HETE was also significantly suppressed by all PUFA (Fig. 3C).

Concentration dependence of the inhibition of eicosanoid production by 24:6n-3. Antigen-stimulated eicosanoid production was inhibited by 24:6n-3, the inhibitory effect increasing with 24:6n-3 concentration (Fig. 4B). In the ionophore-activated MC/9 cells, LTB_4 synthesis tended to be suppressed with increase in the concentration of 24:6n-3 (Fig.

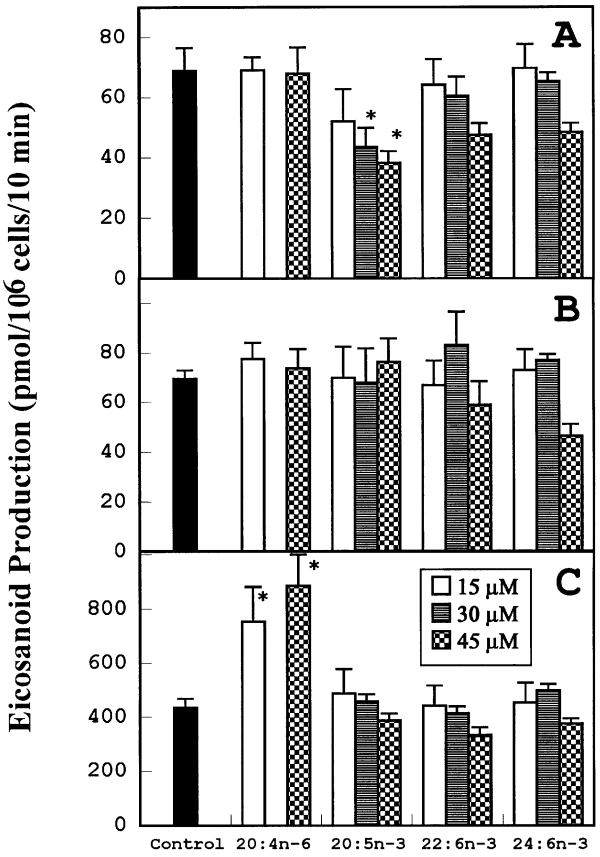

FIG. 2. Effect of 24:6n-3 on the production of lipoxygenase pathway metabolites in ionophore-stimulated MC/9 cells. MC/9 cells were stimulated by the addition of calcium ionophore A23187 and 20:4n-6 (30 μM as a substrate). The fatty acids were added simultaneously with the stimulants at 15, 30, and 45 μM (20:4n-6 was added additionally to the substrate 20:4n-6). (A) LTB_4, (B) LTC_4, and (C) 5-HETE were analyzed as described in the Experimental Procedures section. Values are the means of 3–4 samples. Vertical bars indicate the standard error of the mean. *Significantly different from the control at $P < 0.05$. See Figure 1 for abbreviations.

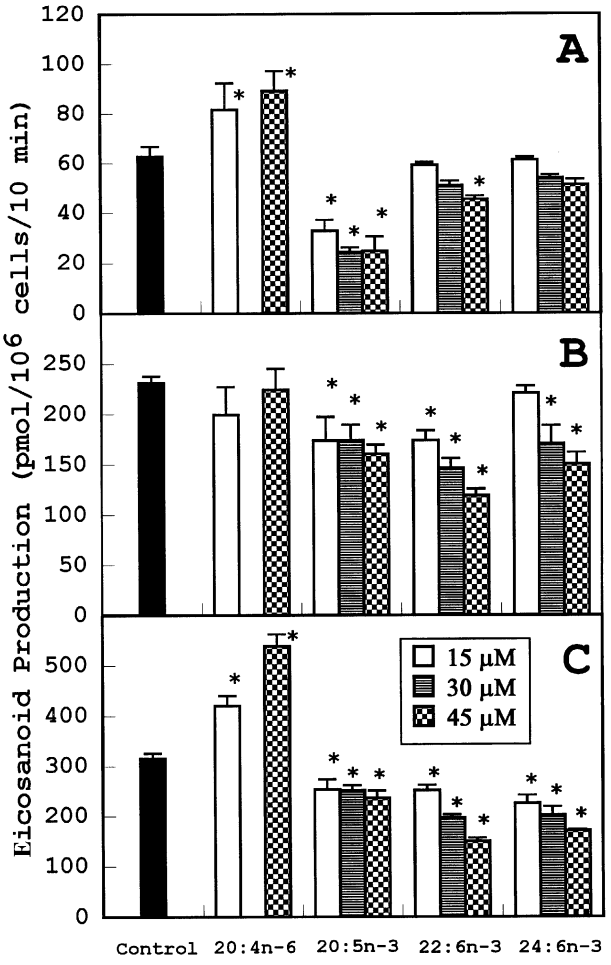

FIG. 3. Effect of 24:6n-3 on the production of eicosanoids in antigen-stimulated MC/9 cells. Immunoglobulin E-sensitized MC/9 cells were stimulated by the addition of antigen, dinitrophenylated keyhole limpet hemocyanine, and 20:4n-6 (30 μM as a substrate). The fatty acids were added simultaneously with the stimulants at 15, 30, and 45 μM (20:4n-6 was added additionally to the substrate 20:4n-6). (A) LTB_4, (B) LTC_4, and (C) 5-HETE were analyzed as described in the Experimental Procedures section. Values are the means of 3–4 samples. Vertical bars indicate the standard error of the mean. *Significantly different from the control at $P < 0.05$. See Figure 1 for abbreviations.

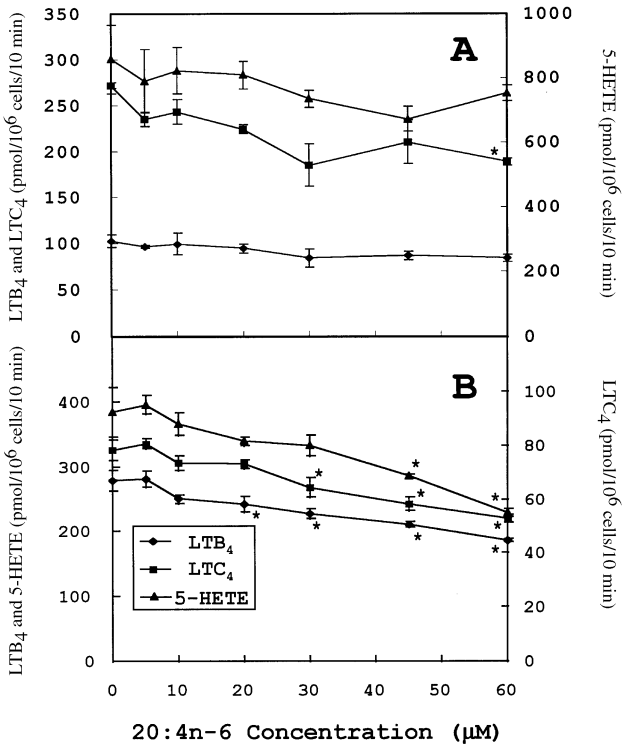

FIG. 4. Effect of the concentration of 24:6n-3 on the production of eicosanoids in (A) ionophore- and (B) antigen-stimulated MC/9 cells. MC/9 cells were stimulated with (A) ionophore and (B) antigen in the presence of various concentrations of 24:6n-3 (0–60 μM). All samples contained 30 μM of 20:4n-6 as a substrate. LTB_4, LTC_4, and 5-HETE were analyzed as described in the Experimental Procedures section. Values are the mean of 3–4 samples. Vertical bars indicate the standard error of the mean. *Significantly different from the control at $P < 0.05$. See Figure 1 for abbreviations.

4A). Significant suppression of LTC_4 production was observed at 60 μM of 24:6n-3 (Fig. 4A); however, significant inhibition of 5-HETE production was not observed. In the antigen-stimulated production of eicosanoids, a significant inhibition appeared at 20 μM and higher concentrations of 24:6n-3 for LTB_4 synthesis, 30 μM and higher for LTC_4 production, and 45 μM and higher concentrations for 5-HETE production, respectively (Fig. 4B).

Histamine content in MC/9 cells incubated with PUFA. MC/9 cells were incubated with PUFA (20:4n-6, 20:5n-3, 22:6n-3, and 24:6n-3) at various concentrations (0–100 μM) for 24 h, and the histamine content of the cells was measured (Fig. 5). A dose-dependent relationship was observed in MC/9 cells treated with 20:4n-6. On the other hand, with 20:5n-3, histamine levels decreased with increase of substrate concentration. Cellular histamine content did not decrease with increase in the concentrations of 22:6n-3 and 24:6n-3. At lower concentrations of 22:6n-3 and 24:6n-3, the histamine content was lower than the control. But at higher concentrations (100 μm) of these two PUFA, histamine content was not significantly different from the control.

Effect of PUFA on spontaneous, ionophore-induced, and antigen-stimulated release of histamine. Spontaneous, ionophore-induced, and antigen-stimulated release of histamine was observed in MC/9 cells incubated with 25 μM of various PUFA for 24 h (Fig. 6). All PUFA used did not influence the spontaneous and antigen-induced release of histamine in MC/9 cells (Fig. 6A and C). In the ionophore-stimulated cells, PUFA except for 18:3n-3 exerted a suppressive effect on the histamine release (Fig. 6B).

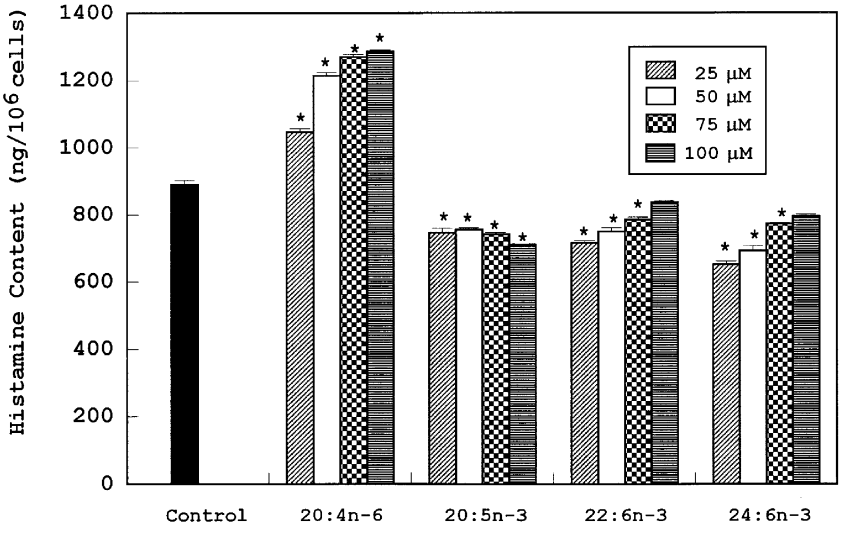

FIG. 5. Effect of 24:6n-3 on the accumulation of histamine in MC/9 cells. MC/9 cells were incubated with polyunsaturated fatty acids at various concentrations (0–100 μM) for 24 h. Cellular histamine content was measured as described in the Experimental Procedures section. Values are the mean of four samples. Vertical bars indicate the standard error of the mean. *Significantly different from the control at $P < 0.05$.

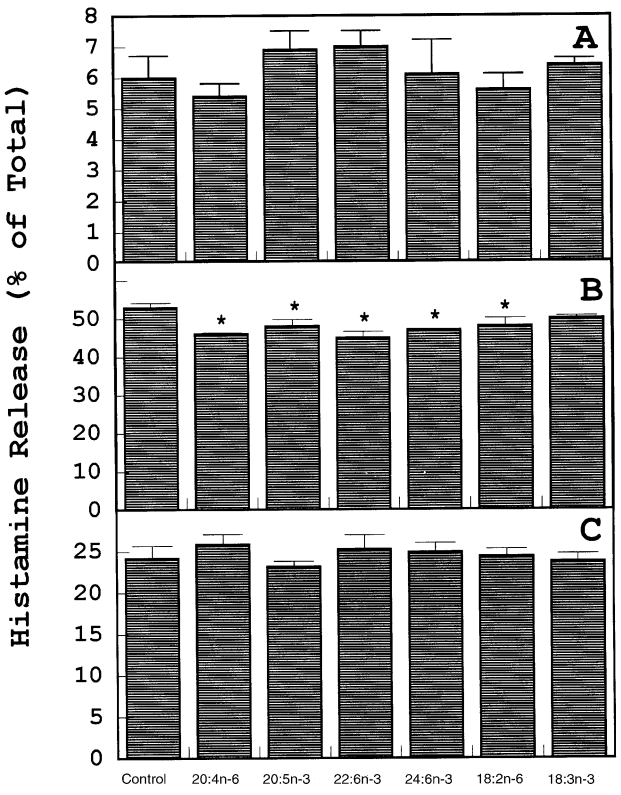

FIG. 6. Effect of 24:6n-3 on histamine mobilization in MC/9 cells. MC/9 cells were incubated with 25 μM of polyunsaturated fatty acids for 24 h. (A) Spontaneous, (B) ionophore-stimulated, and (C) antigen-activated releases of histamine were measured as described in the Experimental Procedures section. Values are the mean of four samples. Vertical bars indicate the standard error of the mean. *Significantly different from the control at $P < 0.05$.

DISCUSSION

In the present study, we isolated 24:6n-3 from brittle stars, *O. sarsi* Lütken, and investigated the effects of 24:6n-3 on the production of eicosanoids in the lipoxygenase pathway and the accumulation and release of histamine in MC/9 mouse mast cells in comparison with the effects of other PUFA including 20:5n-3 and 22:6n-3. The MC/9 mouse mast cell clone was isolated from mouse fetal liver and resembles mucosal mast cells (17,20), which accumulate histamine and release it in response to stimulation of the IgE-antigen complex or calcium ionophore (19,20). MC/9 cells also produce eicosanoids such as PGD_2, thromboxane B_2, LTB_4, LTC_4, and 5-HETE from exogenous and endogenous 20:4n-6 (19,20). Histamine- and lipoxygenase-pathway metabolites are known to be produced by mast cells and are involved in inflammatory and allergic reactions as chemical mediators (18). Therefore, in using MC/9 cells the effect of 24:6n-3 on the accumulation and release of histamine and eicosanoid production must be assessed.

In the absence of exogenously added 20:4n-6, no eicosanoid was detected in our experiment (Fig. 1). Thus, in our experimental system, we assessed the synthesis of eicosanoids from exogenously added 20:4n-6. LT (LTB_4 and LTC_4) synthesis reached a plateau at 30 μM of 20:4n-6 in both ionophore- and antigen-stimulated MC/9 cells (Fig. 1). Thus, we set the concentration of 20:4n-6 at 30 μM as a substrate for the assay of the inhibitory activity of 24:6n-3 on eicosanoid production. Reportedly, the plasma FFA level is about 0.3 mM (20). Thus, the concentration of 20:4n-6 seemed to be adequate for physiological concentration of individual fatty acids. For the same reason, the concentration of PUFA (25 μM) that we used for observations on their effect on histamine release also seemed to be physiological (Fig. 6).

The suppressive effect of 20:5n-3 and 22:6n-3 on the synthesis of lipoxygenase pathway metabolites *in vitro* has previously been described (14,16,29–34). Most of the reports studied the effects of PUFA on LT and HETE production from endogenous 20:4n-6 (16,29–32), although this study examined LT and HETE formation from exogenous 20:4n-6. As for LTB_4 formation, the suppression by 20:5n-3 has been demonstrated (16,29–32,34). The fatty acid 22:6n-3 was reported to have both no suppressive activity on LTB_4 generation (14,16) and a stronger inhibitory activity of 22:6n-3 than 20:5n-3 (31). In our present results, the effects of PUFA on LT and HETE synthesis in ionophore-activated cells (Fig. 2) roughly agreed with previous findings (suppression of LTB_4 synthesis by 20:5n-3 and little or no effect by 22:6n-3). The inhibition pattern of PUFA on antigen-stimulated production of LT and HETE was significantly different from the above-mentioned reports and the present result in the ionophore-stimulated cells (Fig. 3). In antigen-stimulated cells, LTB_4 production was inhibited most strongly by 20:5n-3 (Fig. 3A). LTC_4 and 5-HETE generation was suppressed more strongly by 22:6n-3 than by 20:5n-3 (Fig. 3B, C). Differences in the suppression pattern by PUFA in antigen-stimulated cells from ionophore-stimulated cells suggest that the processes of antigen-induced release of LT and HETE contain step(s) that could be inhibited by n-3 PUFA other than processes in ionophore-induced LT and HETE production.

In the dose-dependence study of 24:6n-3 on the synthesis of LT and HETE, 24:6n-3 showed minimal inhibition of the production of LT and HETE in ionophore-stimulated cells (Fig. 4A). In antigen-activated cells, the production of LT and HETE was inhibited dose dependently by 24:6n-3 (Fig. 4B).

Histamine content of MC/9 cells was increased by incubating with 20:4n-6, whereas incubation with n-3 PUFA decreased the histamine content (Fig. 5). Yamada *et al.* (31) examined the effects of fatty acids on histamine accumulation in RBL-2H3 rat basophilic leukemia cells and found the enhancing effect of 18:3n-3, 20:4n-6, 20:5n-3, and 22:6n-3 on histamine accumulation in the cells. In the report of Kawasaki *et al.* (35), histamine content of RBL-2H3 cells was decreased by the addition of 18:3n-3. Engels *et al.* (36) demonstrated by an *in vivo* study that dietary modulation of fatty acid composition of mast cells did not affect histamine content and release. The reasons for the inconsistency of the results of these reports are not clear. Our present results show that the effects of PUFA on histamine accumulation are complex (Fig. 5).

Thus, it seems that further detailed investigations on the effect of fatty acids on histamine accumulation in mast cells are necessary to resolve this quandary.

The effects of PUFA on histamine release in intact, ionophore-stimulated, and antigen-activated cells were observed (Fig. 6). Since spontaneous release of histamine was not altered (Fig. 6A), it was unlikely that reduced histamine content in the cells incubated with n-3 PUFA was due to increased leakage of histamine from the cells. Ionophore-induced release of histamine was suppressed by PUFA, excluding 18:3n-3 (Fig. 6B). Antigen-induced histamine release was not influenced (Fig. 6C). A contradiction exists in the effect of PUFA on the release of histamine. Data indicate an augmentative (31), suppressive (Ref. 35 and Fig. 6B), and noneffective (Ref. 36 and Fig. 6C) effect of PUFA on histamine release. Clarification of the net effects of PUFA on histamine release examination under well-defined conditions is necessary.

In the present study, we showed that 24:6n-3 has an inhibitory effect on the antigen-stimulated production of lipoxygenase pathway metabolites in MC/9 mouse mast cells. Also 24:6n-3 reduced the content of histamine in the cells. These effects of 24:6n-3 closely resemble those of 22:6n-3, a fatty acid prominent in fish oils and well stated to have an anti-inflammatory effect *via* the modulation of arachidonate metabolism (14,15), than of 20:5n-3 (Figs. 2, 3, 5). Therefore, 24:6n-3 has an anti-inflammatory activity similar to 22:6n-3. Further studies about the incorporation, metabolism, and action of 24:6n-3 are necessary to evaluate its nutritional and physiological functions.

ACKNOWLEDGMENTS

We thank Yumiko Miyauchi for her excellent technical assistance and Nissui Pharmaceuticals (Tokyo, Japan) for the gift of 20:5n-3 ethyl ester. This work was granted in part by The Agriculture, Forestry and Fisheries Research Council, Ministry of Agriculture, Forestry and Fisheries, Japan.

ABSTRACT: Oxidatively modified low density lipoprotein (LDL) has many biological activities which could contribute to the pathology of the atherosclerotic lesion. Because atherosclerosis has an inflammatory component, there has been much interest in the extent to which LDL could be oxidatively modified *in vivo* by inflammation. The present study examined LDL present in an accessible inflammatory site, the inflamed synovial joint, for evidence of compositional change and oxidative modification. LDL was isolated from knee joint synovial fluid (SF) from subjects with inflammatory arthropathies and also from matched plasma samples. SF and plasma LDL had similar free cholesterol and α-tocopherol content, but SF LDL had a lower content of esterified cholesterol. On electrophoresis, SF LDL was slightly more electronegative than LDL from matched plasma samples, but the changes were much less than those resulting from Cu^{2+}-treatment of LDL. Oxidized cholesterol was not detected in any samples, but cholesterol ester hydroperoxide levels were greater in SF than in plasma LDL. When samples from three subjects were incubated with macrophages, the SF LDL did not cause significant loading of the cells with cholesterol or cholesterol esters, in contrast to the situation with acetylated LDL. Overall, the SF LDL displayed evidence of slightly increased oxidation by comparison with matched plasma samples. Despite their isolation from an environment with active inflammation, changes were modest compared with those resulting from Cu^{2+} treatment. Thus, extensive LDL oxidation is not a necessary correlate of location in a chronic inflammatory site, even though it is characteristic of atherosclerotic lesions.

Lipids 33, 1115–1121 (1998).

Oxidized low density lipoproteins (LDL) have multiple biological effects which are potentially pro-atherogenic. These include stimulation of monocyte recruitment *via* enhanced chemokine production (1), unregulated uptake by macrophages resulting in foam cell formation (2), cytotoxicity (3), and T lymphocyte activation (4).

Oxidized LDL can be generated *in vitro* by incubation of native LDL with transition metal ions. In this form, it is recognized by a range of receptors, including the scavenger receptor, and the membrane glycoprotein CD36. CD36 is a highly conserved protein which is expressed by human and murine monocytes/macrophages (5) and also by synovial microvascular endothelium in rats (Zhang, X., Cleland, L.G., and Mayrhofer, G., unpublished). Oxidized LDL undergoes accelerated and unregulated uptake by macrophages, and there is decreased intracellular degradation of its apoprotein B-100 (2,6). Both of these processes could contribute to formation of the lipid-laden "foam cells" characteristic of early and advanced atherosclerotic lesions.

Furthermore, metal-oxidized LDL injected intravenously in hamsters promoted generalized leukocyte adhesion to endothelium (7), and *in vitro* it caused induction of heat-shock protein in monocytic cells (8), increased expression of MHC Class II molecules on human mononuclear cells (9), and activation of T-lymphocytes manifest as upregulation of IL-2 receptors (4). All these events are important features of early stages of atherogenesis. LDL can be oxidatively modified to high-uptake forms also by incubation with neutrophils and macrophages in the presence of transition metal ions (10,11).

In mildly oxidized forms, LDL is not specifically recognized by cellular receptors with the possible exception of CD36, nor usually subject to accelerated endocytosis, but it has other activities which may be directly relevant to the generation of foam cells in the vessel wall. For example, minimally modified LDL can stimulate formation of monocyte chemotactic protein-1 and monocyte transmigration into the subendothelium (1).

Whereas most of the information on oxidatively modified LDL and foam cell formation derives from investigations into the cellular pathology of atheroscelerosis, foam cells have been observed also in the synovial membranes of subjects with rheumatoid arthritis (RA) (12). In addition, the lesions in both RA and atherosclerosis have in common monocyte and lymphocyte infiltrates, cellular hyperplasia, and fibrosis. Lipids from human atherosclerotic plaques are heavily oxidized, in spite of the maintenance of at least normal levels of several antioxidants including both vitamin E and ascorbate

(13). In addition, oxidized proteins and lipids are present in lipid–protein fractions isolated from such plaques at the density of LDL (and containing its characteristic apoprotein) (14; Dean, R.T., and Fu, S., unpublished). The commonality between inflammatory and atherosclerotic sites suggests that it is important to establish whether LDL present at nonatherosclerotic inflammatory sites is also oxidized, as might be the case if its oxidation were dependent on the inflammatory events *per se*. Conversely, it would be of interest if LDL oxidation were not characteristic of inflammatory sites in general, but rather, selective for atherosclerotic lesions.

Inflammatory sites contain appropriate cells and mechanisms for the induction of oxidative stress. In inflammatory joint disease, the synovium and joint space contain leukocytes that are capable of producing reactive oxygen species, and there are also suggestions of the production of reactive oxygen species in inflamed joints with effusions as a consequence of cycles of ischemia and reperfusion (15,16). Accordingly, it has been claimed that oxidized lipids and proteins are present in synovial fluid (SF) from subjects with RA (15,16). However, these studies (15,16) used assays of limited discrimination [thiobarbituric acid reactive substances (TBARS), IgG protein fluorescence]. In the more detailed of these studies (16), there were changes in SF TBARS during or independent of exercise, but no changes in overall conjugated dienes; although second-derivative spectra were used to gain further information about the conjugated dienes, no quantitative data were presented on the comparison between the exercised and nonexercised groups. The interpretation of these data, and particularly of whether lipid and protein oxidation products are accumulated more in rheumatoid SF, remains difficult.

Thus, it is of great interest to use SF LDL from inflamed joints to assess the extent of oxidative LDL modification *in vivo* in an inflammatory, oxidative environment. In the present study, we have examined human SF LDL for alterations in composition and for markers of oxidative modification. The results indicate that modest oxidative changes occurred, but they are minor by comparison with those present in LDL oxidized *in vitro* by exposure to Cu^{2+} ions. Also, the changes are not sufficient to promote accelerated LDL uptake by macrophages leading to foam cell formation.

METHODS

Plasma and SF. All SF samples were aspirated from knee effusions from patients with inflammatory arthropathies. In some instances where bilateral effusions were present, both knees were aspirated and the samples were examined individually as indicated. The clinical diagnoses are listed in Table 1. A peripheral venous blood sample was collected at the same time as joint aspiration and both SF and blood samples were collected into EDTA-containing tubes (final concentration 1 mg/mL). Aprotinin and soybean trypsin inhibitor (Sigma Chemical Co., St. Louis, MO) (10 μg/mL) were added to all of the samples and bovine testicular hyaluronidase (Sigma Chemical Co.) (10 μg/mL) was added also to the SF samples.

[a]RA, rheumatoid arthritis.

Blood and SF were centrifuged ($350 \times g$, 10 min) at room temperature, after which the supernatants were stored at 4°C.

Isolation of lipoproteins. KBr was used for density adjustments of SF and plasma which were subjected to ultracentrifugation at 4°C in a Beckman TL-100 Tabletop ultracentrifuge as follows. LDL were isolated in the density range $1.019 < d < 1.055$ g/mL with a single 18 h spin at the lower densities followed by two 18 h spins at the higher densities. The lipoprotein preparations were dialyzed against 3×1 L Tris-buffered saline (0.01 M, pH 7.4) containing NaCl (0.15 M), Na_2-EDTA (0.005% wt/vol), and NaN_3 (0.006% wt/vol).

Lipid analyses. LDL (approximately 20 μg protein) was added to 1 mL phosphate-buffered saline and extracted with 2 mL methanol (containing 0.02% acetic acid) and 10 mL water-washed hexane. All samples and reagents were kept on ice. Samples were centrifuged, and the hexane phases were stored at −80°C. High-performance liquid chromatography (HPLC) separation with ultraviolet (UV) detection at 210/234 nm was used for estimation of cholesterol, cholesteryl esters, and 7-keto cholesterol (17); electrochemical detection was used for estimation of α-tocopherol (18). Cholesteryl ester hydroperoxides were estimated by HPLC with postcolumn luminol/microperoxidase chemiluminescence detection (18).

Protein oxidation products. Evidence for protein oxidation in intact LDL was sought by measurement of valine hydroxides and hydroperoxides (19), protein-bound 3,4-dihydroxyphenylalanine (DOPA) (20), and hypochlorite modification of apo B protein (21).

Macrophage uptake of LDL. Murine peritoneal macrophages were harvested from QS mice by lavage (6), resuspended in culture medium (Dulbecco's modified Eagle's medium, DMEM) and plated at a density of 2×10^6 cells per 22-mm diameter well. After 2 h, nonadherent cells were removed. The remaining macrophages (>95% pure) were incubated with DMEM containing lipoprotein-deficient human serum (10% vol/vol) and 25 μg/mL of the indicated lipopro-

teins, dialyzed against phosphate-buffered saline before use. After 24 h at 37°C, cells were washed, lysed in NaOH (0.2 M), and lipids were extracted in hexane/methanol as described above. Cholesterol and cholesteryl esters were determined by HPLC as described above.

Statistical analysis. Except where specified, the Wilcoxon signed rank test was used to examine differences between values for the SF and matched plasma samples (22).

RESULTS

SF LDL lipids. The free cholesterol content in LDL isolated from SF was similar to that in LDL isolated from matched plasma samples (Table 2) [mean ± SD; plasma, 1163 ± 296; SF, 1026 ± 195 nmol/mg LDL protein; difference not significant (n.s.)]. However, the cholesterol ester content of SF LDL was significantly less than that of plasma LDL (Table 2) (plasma, 2765 ± 689; SF, 2077 ± 331 nmol/mg LDL protein; $P < 0.01$, *t*-test). A parallel difference was also observed for the individual cholesteryl esters linoleate, arachidonate, oleate, and palmitate (results not shown). There was no difference in the α-tocopherol content of SF and plasma LDL (Table 2) (plasma, 18.8 ± 3.7; SF, 18.6 ± 5.2 nmol/mg LDL protein; n.s.).

Lipid oxidation products in SF LDL. In samples where cholesterol ester hydroperoxides were detected in SF LDL, there were consistently higher levels compared with those in matched plasma LDL samples (Table 3). On average, plasma LDL contained 0.42 ± 0.27 (mean ± SD), whereas SF LDL contained 1.65 ± 1.11 nmol cholesteryl linoleate hydroperoxide/mg protein. These amounts were significantly different ($P < 0.01$). 7-Keto-cholesterol was not detectable in any of the plasma or SF LDL samples. Overall, these levels of oxidized lipids were considerably less than those generated in Cu^{2+}-treated plasma LDL, which after 24 h of oxidation with Cu:LDL particle ratios of 10:1 typically contain 150 nmol 7-keto cholesterol/mg protein (23). Furthermore, our reported values for atherosclerotic plaque homogenate are also substantially higher than those we observed for SF LDL (13).

Protein oxidation products in SF LDL. Three markers of protein oxidation were measured in LDL samples from patient nos. 9 and 14. SF LDL levels of valine hydroxides and protein-bound DOPA were within the normal range we determine for plasma LDL (approximately 10 pmol valine hydroxide/mg LDL protein and a DOPA/tyrosine ratio of approximately 50×10^{-5}). Also, there was no evidence of hypochlorite epitopes of apoB in these samples.

Charge alterations in SF LDL. When subjected to agarose gel electrophoresis, SF LDL was slightly more electronegative than matched plasma LDL samples (Table 4, Fig. 1). Relative to plasma samples, SF LDL had a mean (± SD) relative mobility of 1.13 ± 0.14 ($n = 13$). This value is statistically significantly different from 1.0 (*t*-test, $P < 0.05$), indicating that SF LDL was slightly more electronegative by comparison with matched plasma LDL. A comparable modest enhanced electronegativity has been observed for human aortic intimal LDL in comparison with matched plasmas (24), although comparison of LDL isolated from normal intima vs. atheromatous lesions indicated that both were comparably affected (25). However, these alterations are much less than those generated by Cu^{2+} treatment of plasma LDL samples (Table 4 and Ref. 23).

Macrophage uptake of SF LDL. Samples from three patients (3 plasma, 5 SF) were examined for uptake by murine peritoneal macrophages. There was no evidence for altered cholesterol levels or of cholesteryl ester accumulation in cells incubated with SF LDL (Fig. 2). By contrast, lipids from acetylated LDL caused greatly increased accumulation in

macrophages, indicating that functional endocytic receptor pathways were present (Fig. 2).

DISCUSSION

In subjects with inflammatory joint disease, the synovium and joint space become a potentially pro-oxidative environment.

[a]Mobilities are expressed as migration of synovial fluid LDL samples relative to the migration of matched plasma LDL samples.
[b]Selected plasma LDL samples were treated with $CuSO_4$ (10 μM) for 12 h at 37°C. The protein concentrations of the LDL used were 0.9 mg/mL (patient 3) and 1.7 mg/mL (patient 4).
[c]Mean ± SD for all synovial fluid samples, i.e., $n = 13$.
[d]Statistically significantly different from 1.0 (*t*-test, $P < 0.05$).

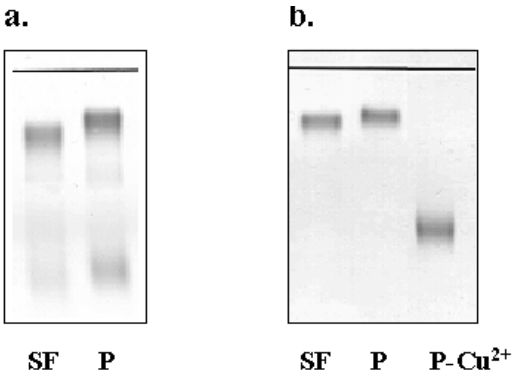

FIG. 1. Agarose gel electrophoresis of LDL. The horizontal line represents the origin and migration is toward the anode. (a) Patient #1; (b) patient #3. SF, synovial fluid sample; P, plasma sample; P-Cu^{2+}, Cu^{2+}-oxidized plasma sample (see Table 4 for details).

The leucocyte infiltrates comprise cells capable of producing reactive oxygen species when stimulated and there is evidence that, in joints with effusions, exercise causes cycles of synovial ischemia and reperfusion which result in production of reactive oxygen species (15,16). The evidence for production of reactive oxygen species is based on claims of detection of oxidized lipid and protein in SF of subjects with RA (15,16), and caveats about these data have been outlined above. In addition, there are suggestions of the presence of oxidatively modified LDL in rheumatoid joints. Thus, by

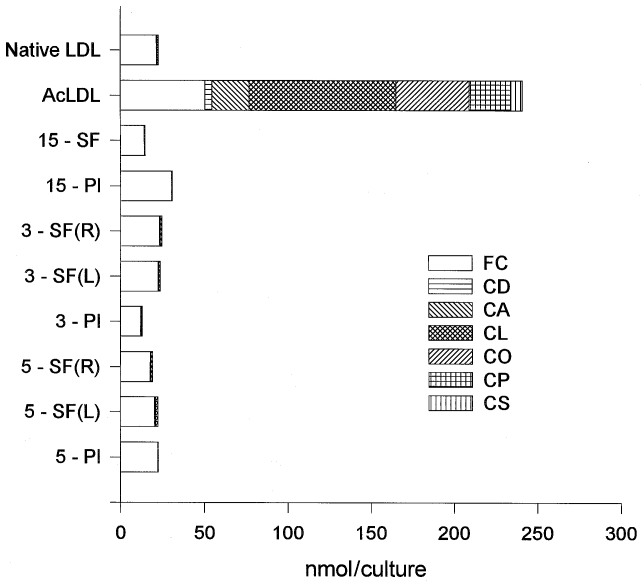

FIG. 2. Macrophage content of free and esterified cholesterol. Murine macrophages (2×10^6/culture) were incubated for 24 h with 25 μg/mL of the indicated low density lipoprotein (LDL) samples, as described in the text. Lipids were extracted and determined by reversed-phase high-performance liquid chromatography. Numbers refer to specific patients whose diagnoses are given in Table 1. Key: AcLDL, acetylated LDL; SF, synovial fluid LDL; Pl, plasma LDL. Letters in parentheses specify the right (R) or left (L) knee synovial fluid from which LDL was isolated. FC, free cholesterol; CD, cholesteryl docosahexaenoate; CA, cholesteryl arachidonate; CL, cholesteryl linoleate; CO, cholesteryl oleate; CP, cholesteryl palmitate; CS, cholesteryl stearate.

using antisera raised against Cu^{2+}-oxidized LDL, positive staining of perivascular macrophages was observed in some rheumatoid synovial samples (12). However, it has become increasingly apparent that such antibodies recognize a range of epitopes present on proteins other than apo B, and so the interpretation of such observations is very difficult (26).

In the present study, we have demonstrated the presence of mildly oxidized LDL in inflammatory synovial fluid. Mobility on agarose gel was slightly increased compared with matched plasma samples, suggesting modification of apo B lysines which is usually a consequence of derivatization by aldehydic products of lipid peroxidation (27). However, the mobility shift was considerably less than that observed in atherosclerotic plaque LDL. There was also evidence of increased fatty acid hydroperoxides, a marker of limited LDL oxidation, but no evidence of cholesterol oxidation, a later process (17,28). The mobility of LDL is also changed only late during oxidation (17,23), largely consequent on reactions of lipid peroxidation end-products with apo B lysines; again there were only slight changes in LDL mobility in the synovial samples, further suggesting that oxidation had proceeded only to a very limited degree. In agreement, there was no evidence of protein oxidation, including hypochlorite modification, and the SF LDL was not capable of loading macrophages with lipid. Thus, the SF LDL analyzed in the present study is not sufficiently modified to support foam cell formation.

The lack of oxysterols and oxidized protein in the synovial LDL samples suggests that the oxidation in the RA synovium is limited in extent. This may be due to limited oxidant generation, effective inhibition, and perhaps a contribution from removal of oxidation products. For example, LDL oxidation *in vitro* is inhibited by the presence of serum (29) and, in particular, by HDL (30). Several of the components in serum which suppress LDL oxidation are present in inflammatory SF. We observed that high density lipoprotein (HDL) (apo A-I) is present in inflammatory SF at approximately 50% of the concentration in plasma (James, M.J., Rye, K.A., Cleland, L.G., and Barter, P.J., unpublished observations). We observed also that inflammatory SF contains cholesterol ester transfer protein (CETP) activity at approximately 40% of the concentration in plasma (James, M.J., Rye, K.A., Cleland, L.G., and Barter, P.J., unpublished observations). This could be significant in explaining the low levels of cholesterol ester hydroperoxides in SF LDL because CETP can transfer cholesterol ester hydroperoxides from LDL to HDL where they are converted to hydroxides (31). Nevertheless, the same inhibitory factors are present in atherosclerotic plaque where oxidized lipids and proteins are present (13).

An additional contribution to the low levels of oxidation products in synovial LDL may be the residence time of the particles at this site, and this needs to be considered. Although residence time of LDL has not been measured, estimates can be made. The SF/plasma ratios of macromolecules which are plasma-derived reflect the net interactions of synovial vascular permeability, synovial blood flow, and the extent of lymphatic removal from the synovial space (proteins are removed *via* the lymphatics rather than the microcirculation (32,33). In the present study the synovial fluid/plasma ratios of LDL protein averaged 0.57 (data not shown). This value is similar to those reported for other plasma proteins such as albumin, ceruloplasmin and α_2-macroglobulin (33), suggesting that the rates of delivery and removal of lipoproteins are similar to those of the plasma-derived proteins. The rate of clearance of albumin from rheumatoid synovial effusions is about 30-fold less than the rate of clearance of small molecules such as NaI (34). Thus, the transit time of LDL in the synovial space is expected to be substantial. Although measurements of the transit time of lipoproteins have not been made, estimates can be made based on reported clearance rates of similar-sized proteins. α_2-Macroglobulin has a radius of 9.1 nm, similar to that of HDL but smaller than that of LDL, and was reported to be cleared from rheumatoid synovial effusions at the rate of 0.09 $mg \cdot min^{-1}$ (33). An effusion of 50 mL would have approximately 50 mg HDL and 120 mg LDL protein, and, if cleared with rates similar to that of α_2-macroglobulin, the fractional clearance would be 0.0018 and 0.00075 min^{-1}, respectively. Whereas this estimated clearance rate for LDL indicates a substantial transit time, it may not be sufficient to permit the extensive oxidation required to promote macrophage uptake.

Myeloperoxidase, a product of neutrophils which can catalyze the production of hypochlorite, has been detected in human atherosclerotic lesions (35) and in inflammatory SF (36). Hypochlorite can modify the apo B protein component of LDL to produce a high-uptake form of LDL (37). The lack of evidence for hypochlorite modification of LDL protein in the present study may result from the presence of an inhibitor of myeloperoxidase which has been detected in SF and in serum (38).

A role for localized inflammation in atheroma formation has been postulated because the atherosclerotic lesion has many elements commonly associated with chronic inflammation such as a macrophage and lymphocyte infiltrate, smooth muscle cell hyperplasia, and fibrosis (39–43). Thus, many cell types present in an atherosclerotic lesion, including endothelial cells and the leukocytes, can potentially oxidatively modify LDL. These elements and conditions are also present in the synovium and joint space of patients with inflammatory joint disease. However, the lack of substantial oxidative modification of LDL in inflammatory SF indicates either that appropriate oxidants do not reach the LDL particles there or that some of the many antioxidant defenses present even in an inflammatory focus are successful in limiting oxidation. As we have shown, however (13), a barrage of antioxidant molecules are present in advanced atherosclerotic lesions even though highly oxidized lipid–protein particles are present. A deficiency of co-antioxidation may account for the oxidation in plaque. However, an alternative explanation is that after oxidation occurs, antioxidants are repleted in plaque.

The observations here suggest that, although lipoprotein oxidation is pronounced in atherosclerotic lesions, extensive lipoprotein oxidation is not general in inflammatory sites. Since pro-inflammatory factors are present in both cases, it is

possible that other factors are critical in the causation of lipoprotein oxidation in plaque. An important implication of these findings is that markers of lipoprotein oxidation may be markers of atherosclerosis, and not simply of inflammation.

Department of Medicine, [a]Institute of Clinical Medicine and [c]Institute of Community Medicine, University of Tromsø, Tromsø, Norway; and [b]Laboratory of Clinical Biochemistry, University of Bergen, Bergen, Norway

ABSTRACT: Fourteen healthy male volunteers were given two separate high-saturated-fat meals with and without the addition of 4 g highly purified ethyl esters of either eicosapentaenoic acid (EPA) (95% pure, $n = 7$) or docosahexaenoic acid (DHA) (90% pure, $n = 7$) supplied as 1-g capsules each containing 3.4 mg vitamin E. The chylomicrons were isolated 6 h after the meals, at peak concentrations of n-3 fatty acids (FA). Addition of n-3 FA with the meal caused a 10.4-fold increase in the concentration of n-3 FA in chylomicrons compared to the saturated fat meal without addition of n-3 FA. After the saturated-fat meal, the concentration of thiobarbituric acid-reactive substances (TBARS) was 327.6 ± 34.6 nmol/mmol triacylglycerol (TAG), which increased to 1015.8 ± 212.0 nmol/mmol TAG ($P < 0.0001$, $n = 14$) after EPA and DHA were added to the meal. There was no significant correlation between the concentrations of TBARS and vitamin E in the chylomicrons collected 6 h after the test meal. The present findings demonstrate an immediate increase in chylomicron peroxidation *ex vivo* provided by intake of highly purified n-3 FA. The capsular content of vitamin E was absorbed into chylomicrons, but the amount of vitamin E was apparently not sufficient to protect chylomicrons against lipid peroxidation *ex vivo*. Daily intake of 4 g n-3 FA either as EPA or DHA for 5 wk did not change the plasma concentration of TBARS. Although not significantly different between groups, DHA supplementation decreased total glutathione in plasma ($P < 0.05$) and EPA supplementation increased plasma concentration of vitamin E ($P < 0.05$). The other lipid-soluble and polar antioxidants in plasma remained unchanged during 5 wk of intervention with highly purified n-3 FA.

Lipids 33, 1123–1129 (1998).

Fish oils, rich in n-3 polyunsaturated eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have antithrombotic, antiinflammatory, and hypolipemic properties (1,2), indicating that these fatty acids (FA) may be used in the prevention and treatment of atherothrombotic diseases.

Abbreviations: AUC, area under the curve; CM, chylomicrons; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acid(s); HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; TAG, triacylglycerol; TBA, thiobarbituric acid; TBARS, TBA-reactive substance.

Lipid peroxidation, especially of low density lipoproteins (LDL), may be important in the pathogenesis of atherosclerosis (3). Oxidatively modified LDL promotes atherosclerosis *in vitro* by increasing the expression of adhesion molecules at the endothelial surface (4,5), by inhibiting repair of wounded endothelial monolayers (6), by inducing foam cell formation through uptake of oxidized LDL *via* the scavenger receptor, which is resistant to intracellular proteolysis (7,8), and by inducing release of cytokine and eicosanoids with chemotactic and proliferative properties (9,10). In general, autooxidation of polyunsaturated FA increases with the extent of unsaturation. Thus, dietary intervention with highly polyunsaturated n-3 FA may render blood lipids and cells more susceptible to oxidation and thereby be potentially harmful (7). However, inconsistent data have been reported regarding the impact of n-3 polyunsaturated FA on the susceptibility of LDL to lipid peroxidation in humans (11–13).

Postprandial triglyceridemia may have an important role in atherogenesis (14). Patients with coronary artery disease (CAD) have increased plasma concentrations of chylomicron (CM) remnants and higher postprandial lipemia (15,16). Dietary oxidized lipids are absorbed and incorporated into CM and may thereby contribute to the oxidative stress of the vascular system (17). Long-term intake of n-3 FA reduces postprandial triglyceridemia (18,19), but it is unknown whether incorporation of n-3 FA into the CM particle affects its susceptibility to peroxidation. The purpose of the present study was to investigate the susceptibility of CM to peroxidation after intake of a standard high-saturated-fat meal with and without supplement of n-3 FA. Furthermore, we assessed the effect of daily intake of highly purified EPA and DHA for 5 wk on pro- and antioxidative systems in plasma.

MATERIALS AND METHODS

Participants. Fourteen healthy normolipemic male employees at the University of Tromsø (mean age 36.2 yr, range 28–49), who were consuming a traditional Western diet, were recruited into the study. The subjects were evaluated by medical history, physical examination, and measurements of blood pressure, hematological variables, blood glucose,

serum lipids, and routine biochemistry. One participant smoked cigarettes. The exclusion criteria were regular use of drugs, history of peptic ulcer, gastrointestinal disturbances likely to influence absorption, alcohol or drug abuse, and mental illness. The subjects were asked to maintain their regular physical activity and dietary habits throughout the study. None of the participants was taking supplements containing antioxidants (i.e., vitamin E and vitamin C) before and during the study. The study was approved by the regional board of research ethics, and informed, written consent was obtained.

Experimental design. The study was carried out as a randomized double-blind, parallel trial. After a 2-wk run-in phase with weekly physical examinations and blood collections (visits 1 and 2), the participants were randomly selected at visit 3 to receive 4 g/d of EPA (95% pure) or 4 g/d of DHA (90% pure), both prepared as ethyl esters (Pronova Biocare AS, Oslo, Norway), for 5 wk. The n-3 FA were given in soft gelatin capsules each containing 1.0 g of FA. The content of vitamin E (α-tocopherol) was 3.4 mg per capsule, the peroxide value was <0.020 meq/g, and *p*-anisidine value was <35.

Blood was collected weekly during the 5-wk intervention period (visits 4–8). A final examination and blood sampling were performed 15 wk after the intervention period (visit 9). Height was measured at visit 1, and body weight was recorded at visits 1, 3 and 8 using a digital scales with the subjects wearing light indoor clothing. Compliance was assessed by capsule counts and by measurements of serum phospholipid FA.

Blood sampling. Blood was drawn at 8 A.M. from an antecubital vein on the right arm after 12 h of overnight fasting by using a 19-gauge needle in a vacutainer system with minimal stasis. Serum was prepared by clotting whole blood in a glass tube at room temperature for 1 h and then centrifuging at 2000 × *g* for 15 min. Aliquots of 1 mL were transferred into sterile cryovials (Greiner Laboratechnik, Frickenhausen, Germany), flushed with nitrogen, and frozen at −70°C until further analysis. Blood for plasma preparation was collected into vacutainers (Becton Dickinson, Meylan Cedex, France) containing disodium EDTA as anticoagulant (EDTA K_3 0.12 mL, 0.34 M per tube). Plasma was prepared by centrifugation at 2000 × *g* for 15 min at 22°C, transfer into sterile cryovials in aliquots of 1 mL, flushing with nitrogen, and storage at −70°C until further analysis.

Fat-tolerance test. A fat-tolerance test was performed before intervention (visit 3) and under basal conditions 15 wk after completion of the dietary intervention period (visit 9). A standard 2.64 MJ (631 kcal) test meal was prepared as a 375-mL liquid formula containing 28.6 g carbohydrates, 22.6 g protein, and 47.0 g fat. The fat was mainly obtained from cream and milk and comprised 65.4% saturated, 30.9% monounsaturated, and 3.8% polyunsaturated FA. The test meals were freshly prepared each morning, served at 8.15 A.M. and consumed over a 10-min period. The subjects were given 100 mL orange juice with the test meal. At visit 3 the EPA and DHA groups received 4 capsules (1 g each) of EPA and DHA, respectively, with the test meal. At visit 9 the EPA and DHA capsules were replaced by similar amounts of fat from cream. The participants were allowed to drink 350 mL calorie-free beverages and eat a 200-g apple during the following 8 h. Taken together, the test meal, apple, and the orange juice contained 2.2 mg vitamin E (α-tocopherol) as calculated from standard food tables using a specially designed computer program (20). Blood samples for CM isolation and plasma preparation were collected prior to the meal and every second hour during the next 8 h.

CM isolation. CM were isolated by overlayering 8 mL plasma with 4 mL of buffer (150 mmol/L NaCl and 1 mmol/L EDTA) in a cellulose nitrate tube and centrifuged in a Beckman SW40 Ti swinging bucket rotor at 20,000 rpm for 1 h at 4°C (21). The CM were carefully removed by aspiration, divided into three aliquots in cryovials, flushed with nitrogen, and frozen at −70°C until further analysis.

Fatty acid and lipid analysis. Total fatty acids were extracted from 500 μL CM according to Folch *et al.* (22) with heptadecaenoic acid (17:0) as internal standard according to previously described procedures (23). The concentration of FA in CM were reported as μmol/L plasma. Serum lipids were analyzed on a Hitachi 737 Automatic Analyzer (Boehringer Mannheim, Mannheim, Germany) with reagents from the manufacturer. Total cholesterol was measured with an enzymatic colorimetric method (CHOD-PAP) and high density lipoprotein cholesterol was assayed by the same procedure after precipitation of LDL with heparin and manganese chloride. Triacylglycerol (TAG) concentration was determined with an enzymatic colorimetric test (GPO-PAP).

Prooxidants and antioxidants. Plasma and CM were analyzed for lipid peroxidation by the high-performance liquid chromatography (HPLC)-based thiobarbituric acid (TBA) method (24–26). Plasma and CM samples were processed for colorimetric reaction of TBA as described by Yagi (24) and Ohkawa *et al.* (25), respectively. Ten microliters of the samples was then injected onto a Spectral Physics SP 8800 HPLC system with a 5 μ Supelcosil LC18 column (25 cm × 4.6 mm). Malondialdehyde-TBA adducts were quantified by a Shimadzu RF 535 Spectrofluorimeter (excitation wave length 515 nm, emission wavelength 553 nm). Peak analysis was performed using a Spectral Physics Chromjet SP 4400 integrator. The mobile phase was initially 25 mM potassium phosphate buffer, pH 7.0/methanol, 65:35, vol/vol, at a flow rate of 1.0 mL/min. The methanol content was increased to 80% from 4.6–10 min. The typical retention time of the adduct was 4.6–4.8 min.

Plasma samples were analyzed for vitamin E (α-tocopherol), vitamin A (retinol), and β-carotene levels by HPLC as previously described (27–29). In brief, 200 μL plasma was mixed with an equal volume of 300 μM standard in ethanol. To these solutions 500 μL hexane was added, shaken vigorously for 2 min, centrifuged, and partly evaporated (250 μL under a stream of N_2; 125 μL ethanol was added, and then the sample was analyzed by HPLC. The analysis was performed with Supelcosil LC-8 column (25 cm × 4.6 mm i.d.) with LC-8 guard column packed with PERISORB RP-8 (2 cm × 2 mm i.d.). Methanol/H_2O (95:5, vol/vol and 100% methanol

were used as mobile phases. The flow was set to 1.0 mL/min, and the injection volume was 40 µL. Detection was achieved at 292 nm using a Shimadzu RF-535 detector with multiplicator (Hamamatsu R928-08).

The total and reduced forms of glutathione, cysteine, and cysteinylglycine were quantified after derivatization with the fluorescent agent monobromobimane by reversed-phase HPLC as previously described in detail (26,30).

Statistics. Changes in variables were calculated as the value obtained after minus the value obtained before intervention. Examination of data frequencies revealed normal distribution of the data. A paired *t*-test was applied for changes in variables within a treatment group, whereas an unpaired *t*-test was used for comparison of changes between treatment groups. Repeated measures analysis of variance was performed to assess changes in thiobarbituric acid-reactive substances (TBARS) and antioxidants over time. The postprandial increase in CM TAG concentrations was assessed in two ways. First, we calculated the areas under the curve (AUC) for the CM TAG concentration after intake of a standardized fat meal as the deviation from the basal value integrated over the sampling time (8 h). Second, the CM response was defined as the average of the two highest postprandial CM TAG concentrations minus the baseline value. Values are means ± SD if not otherwise stated. Two-sided *P*-values < 0.05 were regarded as significant. The SAS statistical software package was used (31).

RESULTS

There were no statistically significant differences between the EPA and DHA groups with regard to age, body weight, blood lipid concentrations, and n-3 FA levels in serum phospholipids (Table 1). None of the participants experienced discomfort, nausea, or diarrhea after ingestion of the liquid test meal with or without the addition of the highly purified n-3 FA. The participants did not experience significant side effects while taking EPA and DHA. The body weights remained stable during the intervention in both groups. All participants completed the study per protocol. The percentage of capsules taken was 98 (range 96–100%) in the EPA group and 91 (69–100%) in the DHA group.

Fat tolerance tests and CM peroxidation. The increase in plasma CM TAG induced by the liquid fat meals are shown in Figure 1A. After intake of the standard fat meal with addition of cream, the CM concentrations increased 7.6-fold, peaked after 4 h, then declined but still remained higher than baseline values 8 h after the meal. The CM response was 255.0 ± 125.4 µmol/L, and the AUC was 615.7 ± 253.3 µmol/L. A similar response was observed when 4 g of fat from cream was replaced by n-3 FA (either EPA or DHA); the CM response and the AUC were 224.3 ± 81.1 µmol/L and 520.0 ± 201.2 µmol/L, respectively. The concentration of n-3 FA in total lipids extracted from CM is shown in Figure 1B. Ingestion of EPA or DHA with the meal induced a similar maximal increase in CM n-3 FA (data not shown) which peaked 6 h after the meal (10.4-fold increase) (Fig. 1B). The

TABLE 1
Age, Body Weight, Serum Lipids, and Concentrations of the Main n-3 Polyunsaturated Fatty Acids in Serum Phospholipids at Baseline of Subjects Randomized to Receive Either 3.8 g EPA or 3.6 g DHA Daily for 5 wk[a]

	EPA (n = 7)	DHA (n = 7)
Age (yr)	32.4 (5.0)	40.0 (8.4)
Body weight (kg)	82.4 (5.0)	79.8 (7.5)
Total cholesterol (mmol/L)	5.80 (1.16)	5.34 (0.53)
HDL cholesterol (mmol/L)	1.28 (0.12)	1.38 (0.26)

DHA (µmol/L)	125.2 (42.8)	133.1 (28.8)

[a]Values are means (SD). Abbreviations: HDL, high density lipoproteins; EPA, eicosapentaenoic acid; TAG, triacylglycerol; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid.

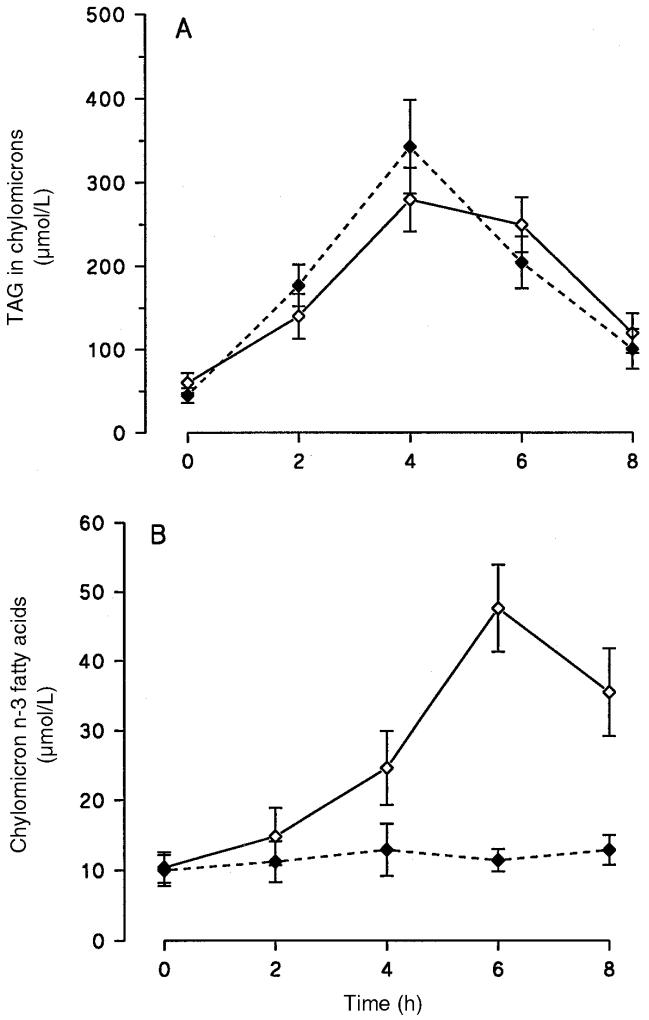

FIG. 1. Concentration of (A) triacylglycerols (TAG) and (B) total n-3 fatty acids in chylomicrons isolated from plasma after ingestion of a standard high-fat meal (solid symbol, n = 14) or a standard high-fat meal with 4 g n-3 fatty acids (open symbols, n = 14). Values are means ± SD.

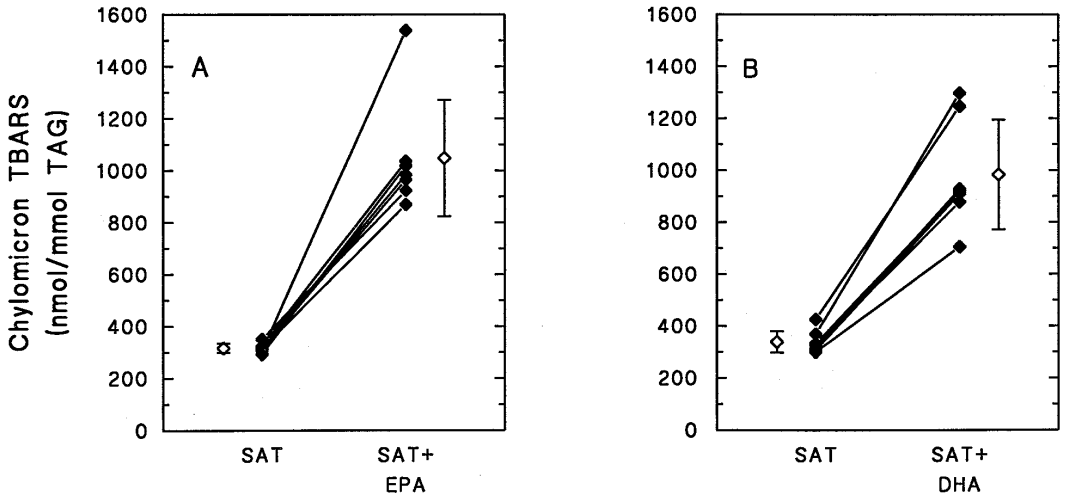

FIG. 2. Graphs showing individual values and means ± 1 SD of thiobarbituric acid-reactive substances (TBARS) in chylomicrons 6 h after a standard high-fat meal (SAT) or a standard high-fat meal with the addition of either 4 g (A) eicosapentaenoic acid (EPA; $n = 7$) or (B) docosahexaenoic acid (DHA; $n = 7$).

absorption of n-3 FA was delayed and prolonged compared to the CM curve. The concentration of n-3 FA in CM lipids did not change after the saturated-fat meal (Fig. 1B).

The CM fractions were isolated 6 h after the meal, at peak concentrations of n-3 FA, and TBARS were measured after both fat tolerance tests. After the saturated-fat meal the TBARS concentration was 327.6 ± 34.6 nmol/mmol TAG, which increased to 1015.8 ± 212.0 nmol/mmol TAG ($P < 0.0001$) when n-3 FA were added to the meal. The increase in TBARS was similar whether EPA or DHA was given as supplement to the meals (1048.1 ± 223.8 nmol/mmol TAG vs. 983.4 ± 211.8 nmol/mmol TAG, respectively, $P = 0.59$) (Fig. 2). The mean concentration of vitamin E in CM was 3.03 ± 1.18 µmol/L 6 h after meal containing 4 g highly purified n-3 Fa had been consumed. There was no significant correlation between the concentrations of TBARS and vitamin E in the CM ($r = 0.04$, $P = 0.87$).

Oxidative status after intake of EPA or DHA for 5 wk. Intake of highly purified EPA or DHA for 5 wk did not alter plasma levels of TBARS significantly (Fig. 3A). The antioxidant status in plasma at baseline and change after the intervention are shown in Table 2. The plasma concentration of vitamin E increased significantly ($P < 0.05$) within the EPA group, but the increase did not differ from that seen in the DHA group (Table 2 and Fig. 3B). The concentration of total glutathione was modestly decreased (−12%, $P < 0.05$) in the DHA group, whereas the reduced form was unchanged, indicating an actual decrease in its oxidized and/or protein-bound form. However, no statistical difference from the EPA group was observed. There was no significant change in the other antioxidants during dietary intervention with purified n-3 FA.

DISCUSSION

We observed a substantial increase in the amount of TBARS in plasma CM when highly purified EPA and DHA were supplied with a high-fat meal. Despite recommended amounts of vitamin E added to the capsules containing highly purified n-3 FA, the amount of vitamin E was apparently insufficient to

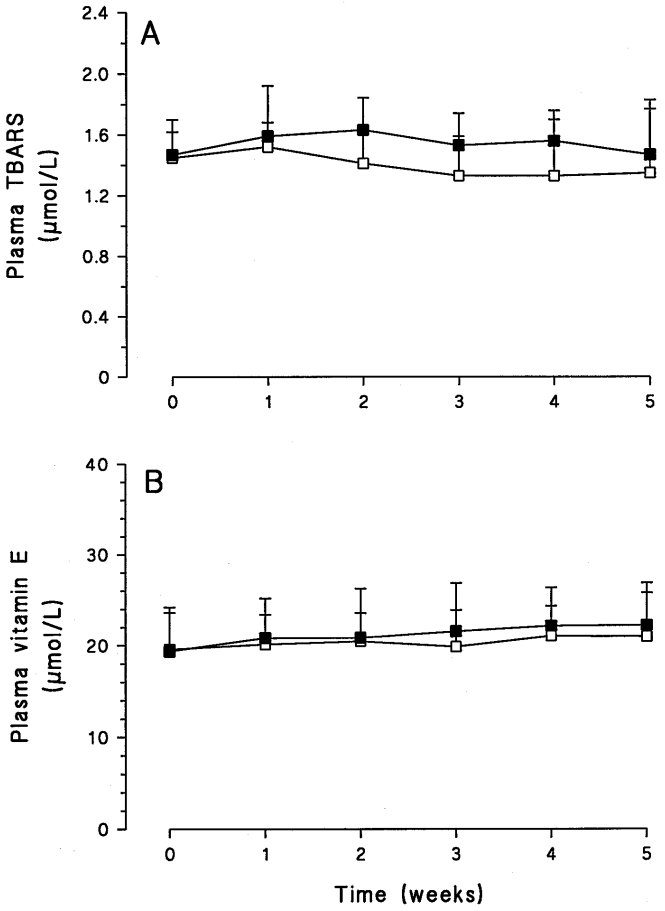

FIG. 3. Graphs showing plasma levels of (A) TBARS and (B) vitamin E during dietary intake of 4 g/d for 5 wk of EPA (■) or DHA (□). Values are means ± SD. For abbreviations see Figure 2.

TABLE 2
Antioxidants (μmol/L) in Plasma at Baseline and Changes from Baseline After Intake of 4 g/d for 5 wk of EPA or DHA[a]

	EPA (n = 7)		DHA (n = 7)		EPA vs. DHA
	Baseline	Change	Baseline	Change	Change during intervention
Cysteine					
Total	1.85 (0.41)	0.05 (0.61)	2.34 (1.05)	0.22 (0.79)	NS
Reduced	0.67 (0.42)	–0.10 (0.49)	1.05 (0.55)	–0.19 (0.66)	
Cysteinylglycine					
Total	0.78 (0.27)	–0.03 (0.05)	0.96 (0.23)	–0.12 (0.28)	NS
Reduced	0.23 (0.19)	0.01 (0.14)	0.17 (0.22)	–0.02 (0.18)	NS

[a]Values are mean (SD). Superscript letter a indicates statistical significant changes ($P < 0.05$) within each group by paired t-test. NS, no significant difference in change during intervention between groups (unpaired t-test). See Table 1 for abbreviations.

protect the CM particle against lipid peroxidation *ex vivo*. However, the oxidative status in plasma remained unchanged during 5 wk of daily supplementation with 4 g EPA or DHA, even though DHA tended to stress both lipid-soluble and polar antioxidants.

Postprandial triglyceridemia is thought to play an import role in atherogenesis (14). Oxidized lipids consumed in the diet are absorbed and incorporated into CM where they can contribute to the total body pool of oxidized lipids (17). Oxidized lipids may be involved in injury of the arterial wall and thereby provide a link between postprandial lipemia and atherothrombotic disease. Long-term supplementation with highly purified n-3 FA is believed to be antiatherogenic owing to its pronounced lowering effect on postprandial triglyceridemia (18,19). Recently, Mabile *et al*. (32) demonstrated that CM isolated after a meal rich in n-6 polyunsaturated FA exhibited a high oxidizability compared to CM enriched with monounsaturated and saturated FA. In our study, human CM enriched with n-3 polyunsaturated FA were more susceptible to lipid peroxidation than CM enriched with saturated fat. The TBARS values measured in isolated CM may be augmented, in part, as a result of removal of antioxidants present in plasma, thereby rendering the isolated CM more susceptible to oxidation. The observed difference in TBARS of CM isolated after the two meals, however, could not be explained by the methodological conditions since equal isolation procedures was performed.

In humans, vitamin E is an important lipid-soluble antioxidant, which is absorbed *via* the lymphatic pathway and transported in association with CM (33). Kontush *et al*. (34) recently reported that vitamin E could play a triggering role in lipoprotein oxidation by metal ions. The highly purified n-3 FA capsules administered in the present study contained 3.4 mg vitamin E each to avoid lipid oxidation. If vitamin E served as an efficient antioxidant in CM, one might have expected an inverse association between lipid peroxidation and vitamin E concentration in CM particles. However, no such association was observed in our study. This may indicate that vitamin E was inefficient as an antioxidant, that the amount of vitamin E in the capsules was insufficient to protect the CM particles against lipid peroxidation, or that peroxidation occurred in the gastrointestinal tract prior to CM assembly.

The investigation of the pathophysiological role of lipid peroxides in atherogenesis has mainly been concerned with oxidized LDL (3). However, oxidized CM exerts cytotoxic effects on endothelial cells (32) and promotes leukocyte adhesion through mechanisms involving the superoxide anion, platelet-activating factor (PAF), and adhesion molecules on leukocytes and endothelial cells (35). Thus, oxidized CM may be involved in the injury of the artery wall and provide a link between postprandial lipemia and atherogenesis (32).

Long-term supplementation with DHA was accompanied by a decrease in the total plasma glutathione content, but no such changes were observed after supplementation with EPA. In the DHA group, the level of the reduced/total ratio for the precursor aminothiol in glutathione synthesis, cysteine, tended to be lower, while the breakdown product of glutathione remained unchanged. These findings may indicate that the redox status of the aminothiols is essentially maintained during EPA supplementation, whereas aminothiols may undergo redox cycling and thiol–disulfide exchange in the DHA group. Likewise, the EPA and DHA capsules were equally enriched with vitamin E (3.4 mg/capsule), but the plasma concentration of vitamin E increased significantly only after long-term EPA supplementation. This may further indicate that DHA ingestion accompanied by consumption of supplied vitamin E implied more oxidative stress to blood lipids. As there were no changes in the aminothiols in the EPA group, this indicates that supplied lipid-soluble vitamin E renders the system efficient to manage free-radical attack, as increased lipid peroxidation was not observed.

Harmful lipid peroxidation is, however, dependent on the balance between cellular prooxidative processes and the level of antioxidants. For both the EPA and DHA groups, lipid per-

oxidation remained unchanged even though DHA supplementation tended to stress both lipid-soluble and polar antioxidants. In principal, these observations are in agreement with observations in rats (26) and mice (36). Surprisingly, EPA has been reported to attenuate lipid peroxidation both in animals (26,36) and under *in vitro* conditions (37).

In conclusion, enrichment of CM with polyunsaturated n-3 FA during a high-fat meal was accompanied by an immediate increase in lipid peroxides of isolated CM, whereas the oxidative status in plasma remained unchanged during 5 wk of supplementation with highly purified EPA and DHA.

ACKNOWLEDGMENT

This study was supported in part by grants from Pronova Biocare a.s., Oslo, Norway, the Norwegian Council on Cardiovascular Diseases, and the Norwegian Research Council.

Low Doses of Eicosapentaenoic Acid, Docosahexaenoic Acid, and Hypolipidemic Eicosapentaenoic Acid Derivatives Have No Effect on Lipid Peroxidation in Plasma

Hege Vaagenes*, Ziad A. Muna, Lise Madsen, and Rolf K. Berge

Department of Clinical Biochemistry, University of Bergen, N-5021 Haukeland Hospital, Bergen, Norway

ABSTRACT: It was of interest to investigate the influence of both high doses of eicosapentaenoic acid (EPA) and low doses of 2- or 3-methylated EPA on the antioxidant status, as they all cause hypolipidemia, but the dose required is quite different. We fed low doses (250 mg/d/kg body wt) of different EPA derivatives or high doses (1500 mg/d/kg body wt) of EPA and DHA to rats for 5 and 7 d, respectively. The most potent hypolipidemic EPA derivative, 2,2-dimethyl-EPA, did not change the malondialdehyde content in liver or plasma. Plasma vitamin E decreased only after supplementation of those EPA derivatives that caused the greatest increase in the fatty acyl-CoA oxidase activity. Fatty acyl-CoA oxidase activity increased after administration of both EPA and DHA at high doses. High doses of EPA and DHA decreased plasma vitamin E content, whereas only DHA elevated lipid peroxidation. In liver, however, both EPA and DHA increased lipid peroxidation, but the hepatic level of vitamin E was unchanged. The glutathione-requiring enzymes and the glutathione level were unaffected, and no significant changes in the activities of xanthine oxidase and superoxide dismutase were observed in either low- or high-dose experiments. In conclusion, increased peroxisomal β-oxidation in combination with high amounts of polyunsaturated fatty acids caused elevated lipid peroxidation. At low doses of polyunsaturated fatty acids, lipid peroxidation was unchanged, in spite of increased peroxisomal β-oxidation, indicating that polyunsaturation is the most important factor for lipid peroxidation.

Lipids 33, 1131–1137 (1998).

Administration of peroxisome-proliferating hypolipidemic compounds produces marked increases in the enzyme activities of the peroxisomal fatty acid β-oxidation cycle, including the hydrogen peroxide-generating enzyme fatty acyl-CoA oxidase (FAO, E.C. 1.3.3.6) (1). In contrast, hydrogen peroxide-degrading enzymes such as catalase (E.C. 1.11.1.6) are not proportionally induced by peroxisome proliferators (1). This imbalance between hydrogen peroxide-generating and -degrading enzymes is an undesirable effect of the peroxisome-proliferating compounds as it may create cellular oxidative stress.

Membrane fatty acid composition can be rapidly modified by changing the source of dietary lipids (2). When polyunsaturated oils are increased in the diet, tissues become enriched with polyunsaturated fatty acids (PUFA) such as eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). Membranes containing increased levels of these fatty acids are more easily oxidized (3), and the susceptibility of liver lipids to peroxidation is increased after ingestion of diets high in fish oil (4). Increasing polyunsaturation has been reported to be antagonistic to vitamin E status (5). A fish oil-containing diet may thus have an unfavorable effect on the antioxidant/prooxidant balance. In contrast, we showed that hypolipidemic doses of EPA enhance the hepatic antioxidant defense (6). PUFA have a hypolipidemic effect when administered to rats. However, high doses of EPA are necessary to cause hypolipidemia, whereas high doses of DHA have no lipid-lowering effect (7). The hypolipidemic effect of EPA was potentiated by branching, and the resulting 2- and 3-methylated EPA molecules caused hypolipidemic effects at low doses (Vaagenes, H., Madsen, L., Dyrøy, E., Elholm, M., Stray-Pedersen, A., Frøyland, L., Lie, Ø., and Berge, R.K., submitted for publication). It was of interest to investigate the influence of the above-mentioned fatty acids on the antioxidant status in rats, as they all cause hypolipidemic effect, but the doses of PUFA required to achieve this effect are different. For this purpose we measured the content of vitamins E, A and C, thiols, and lipid peroxidation, in addition to the enzyme activities of several enzymes participating in the antioxidant defense system.

MATERIALS AND METHODS

Chemicals. Ethyl esters of EPA (97.0% pure), DHA (91.2% pure), and the ethyl esters of the EPA derivatives 2-methyl-EPA (93.8% pure), 2-ethyl-EPA (96.1% pure), 2,2-dimethyl-EPA (95.3% pure), and 3-methyl-EPA (>90% pure) were obtained from Norsk Hydro AS, Research Centre (Porsgrunn, Norway). [α-^{32}P]deoxycytidine triphosphate (3000 Ci/mmol) was from Amersham (Buckinghamshire, England). Restriction enzymes were from Promega (Madison, WI). Nylon membranes (NY 13N) were from Schleicher & Schuell (Das-

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FAO, fatty acyl-CoA oxidase; HPLC, high-performance liquid chromatography; MDA, malondialdehyde; PUFA, polyunsaturated fatty acid; SOD, superoxide dismutase; XDH, xanthine dehydrogenase; XOX, xanthine oxidase.

sel, Germany). All other chemicals were obtained from common commercial sources and were of reagent grade.

Animals and treatments. Male Wistar rats from Möllegaard breeding Laboratory (Ejby, Denmark), weighing 160–180 g, were housed as pairs in plastic cages in a room maintained at 12 h light-dark cycles and a constant temperature of 20 ± 3°C. The animals were acclimatized for at least 1 wk under these conditions before the start of the experiment. The different fatty acids (all as ethyl esters) were suspended in 0.1% carboxymethylcellulose, and 0.5% (wt/vol) α-tocopherol acetate was added to the PUFA to prevent autooxidation. In the low-dose experiment EPA, DHA, and the EPA derivatives were administered at a dose of 250 mg/d/kg body wt for 5 d by gastric intubation in a final volume of 0.5 mL once a day. In the high-dose experiment, EPA, DHA, and oleic acid were administered at a dose of 1500 mg/d/kg body wt for 7 d by gastric intubation in a final volume of 1.0 mL once a day. In both experiments the control animals received only sodium carboxymethylcellulose. All animals had free access to water and food (rat and mouse standard diet, from B&K Universal, Sollentuna, Sweden). The food contained 61.0 mg/kg DL-α-tocopherol acetate and 7.0 mg/kg retinol. At the end of the feeding period, after overnight fasting, the animals were anesthetized by Hypnorm (Janssen Pharmaceutical Ltd., Oxford, England) Dormicum® (F. Hoffmann-La Roche AG, Basel, Switzerland) (Fentanyl/fluanisone-Midazolam), 0.2 mL/100 g body wt. Cardiac puncture was performed to obtain blood samples, and the liver was removed. Parts of the liver were immediately frozen in liquid nitrogen, and the rest of the liver was chilled on ice for homogenization.

Preparation of subcellular fractions. The livers were homogenized in ice-cold sucrose solution (0.25 M sucrose in 10 mM HEPES buffer pH 7.4 and 1 mM EDTA) using a Potter-Elvehjem homogenizer. The subcellular fractions were isolated as previously described (8). Briefly, the homogenate was centrifuged at 1,000 × *g* for 10 min to separate the postnuclear from the nuclear fraction. A mitochondrial-enriched fraction was prepared from the postnuclear fraction at 10,000 × *g* for 10 min. A peroxisome-enriched fraction was prepared by centrifugation of the postmitochondrial fraction at 23,500 × *g* for 30 min. A microsomal-enriched fraction was isolated from the postperoxisomal fraction at 100,000 × *g* for 1 h 15 min. The remaining supernatant was collected as the cytosolic fraction. The procedure was performed at 0–4°C, and the fractions were stored at −80°C. Protein was assayed using the BioRad protein assay kit (BioRad, Richmond, CA) using bovine serum albumin as a standard.

*Vitamins E and A***.** Both liver and plasma were analyzed for vitamin E (α-tocopherol) and vitamin A (retinol) by high-performance liquid chromatography (HPLC). Plasma (200 μL) was mixed with an equal volume of 300 μM standard (α-tocopherol acetate) in ethanol, or 200 μL 10% (wt/vol) liver homogenate with 300 μM standard was added to an equal volume of water. To these solutions 500 μL hexane was added. The resultant mixture was shaken vigorously for 2 min, centrifuged, and partly evaporated (250 μL) under a stream of N_2. Then 125 μL ethanol was added, and the mixture was analyzed by HPLC. The analysis was performed with Supelcosil LC-8 column (25 cm × 4.6 mm i.d.) with LC-8 guard column packed with Perisorb RP-8 (2 cm × 2 mm i.d.). Methanol/H_2O, 95:5, and methanol were used as mobile phases. The flow was set to 1.0 mL/min and the injection volume was 40 μL. Detection was achieved at 292 nm using a Shimadzu RF-535 detector with multiplicator (Hamamatsu R928-08).

Vitamin C. Vitamin C (ascorbic acid) was measured in liver by HPLC. Two hundred microliters 10% (wt/vol) liver homogenate in 50 mM perchloric acid was added to 400 μL deproteinization solution [7% (vol/vol) perchloric acid, 1% (vol/vol) metaphosphoric acid], shaken vigorously for 20 s, frozen at −80°C, and centrifuged at 12,000 × *g* for 5 min. Supernatant was added 1:1 to the mobile phase [20 mM $NH_4H_2PO_4$, 0.015% (vol/vol) metaphosphoric acid, pH 3.0], and 20 μL was injected onto a Supelcosil LC-8 column (25 cm × 4.6 mm i.d.) with LC-8 guard column packed with Perisorb RP-8 (2 cm × 2 mm i.d.). Detection was achieved at 245 nm using a Spectra FOCUS detector.

Malondialdehyde (MDA). MDA was measured in plasma and liver by HPLC. As stated by Halliwell and Chirico (9), the HPLC-based MDA test can be used as a preliminary general measurement of lipid peroxidation. Briefly, 250 μL 20% (wt/vol) acetic acid and 250 μL 0.8% (wt/vol) 2-thiobarbituric acid in 0.1 N NaOH was added to 100 μL liver homogenate [10% (wt/vol) in sucrose solution (0.25 M sucrose in 10 mM HEPES buffer pH 7.4 and 1 mM EDTA)] or plasma. The sample was then heated at 95°C for 1 h and then chilled, an equal volume of 1-butanol was added, and the resultant mixture was shaken vigorously for 2 min. After centrifugation at 1,700 × *g* for 5 min, the supernatant was analyzed by HPLC. The analysis was performed with Supelcosil LC-18 column (5 μm, 25 cm × 4.6 mm i.d.). KH_2PO_4 (25 mM, pH 7)/methanol, 65:35, was used as mobile phase. The flow was set to 1.0 mL/min, and the injection volume was 20 μL. Detection was achieved using a Shimadzu RF-535 detector with multiplicator (Hamamatsu R928-08), with excitation at 532 and emission at 553 nm.

Enzyme activities. Superoxide dismutase (SOD, E.C. 1.15.1.1) activity was measured spectrophotometrically by monitoring the decay of superoxide ($O_2^{\bullet -}$) (10). FAO activity was determined in the peroxisome-enriched fraction of rat livers by the coupled assay (11). The production of hydrogen peroxide was measured by monitoring the increase in dichlorofluorescein absorbance in the presence of palmitoyl-CoA.

Preparation of hybridization probes. DNA fragments were labeled by random priming using the oligolabeling technique of Feinberg and Vogelstein (12). The DNA probes were purified fragments of cloned rat genes. Copper zinc (CuZn)-SOD: 600 bp *Eco*RI fragment of pCuSOD (13), and manganese (Mn)-SOD: 1400 bp *Eco*RI fragment of pMnSOD (13). As control we used rat P0 rRNA: 1046 bp *Bam*HI/*Xho*I fragment in pBluescript II SK (z29530, provided by A. Molven, University of Bergen, Norway) or human 28S rRNA: 1400 bp *Bam*HI fragment of pA (Gonzalez, I.L., personal communication).

RNA purification and analysis. Total cellular RNA was isolated by the guanidinium-thiocyanate method described by

Chomczynski and Sacchi (14). The RNA concentrations were determined spectrophotometrically. RNA was blotted onto nylon (15). Hybridization to immobilized RNA was performed in the presence of 50% formamide, 5 × saline-sodium citrate, 200 μg/mL heat-denatured herring sperm DNA, 0.1% (wt/vol) sodium dodecyl sulfate, 25 mM sodium phosphate pH 6.5, 8.25% dextran sulfate at 42°C for 24 to 48 h (16). Filters were washed to high stringency [0.2 × saline-sodium citrate, 0.1% (wt/vol) sodium pyrophosphate, 0.1% (wt/vol) sodium dodecyl sulfate at 65°C] and Kodak XAR-5 X-ray films were exposed in the presence of intensifying screens at −80°C. Densitometric scanning of autoradiograms was performed using the LKB Ultrogel laser–densitometer (Bromma, Sweden). When the filters were to be rehybridized, the bound probe was first stripped off in 0.1% (wt/vol) sodium dodecyl sulfate at 90–100°C for 7 min. The hybridization results were normalized to the signal of a cDNA probe for a ribosomal protein used as control or 28S rRNA hybridization in the individual samples. Relative mRNA inductions of the different genes were then calculated.

Thiols. Glutathione, cysteine, cysteinylglycine, and homocysteine were quantified in plasma and liver after derivatization with the fluorescent agent monobromobimane by reversed-phase HPLC (17).

Presentation of results. The results are reported as means ± SD from 3 to 8 animals. Statistical analysis was by one-way analysis of variance.

RESULTS

Effects on vitamins. Table 1 shows the changes in vitamin E, vitamin A and vitamin C in the different dietary groups. At low doses the plasma vitamin E content decreased 35 and 22%, respectively, in rats fed 2,2-dimethyl- and 3-methyl-EPA compared to EPA, while the plasma level of vitamin A was unchanged. In liver, the vitamin E content was unchanged, while vitamin A increased in rats fed EPA. At high doses, plasma vitamin E decreased 43% in rats fed EPA and DHA, but the hepatic content of vitamin E was unchanged. Plasma vitamin A, hepatic vitamin A and hepatic vitamin C were unaffected by the different feeding groups of the high-dose experiment (Table 1).

Effect on MDA. MDA, a product of lipid peroxidation, was unchanged in plasma and liver of rats fed a low dose of EPA derivatives, EPA, or DHA, compared to controls (Table 2). In the high-dose experiment, DHA feeding caused a 1.5- and 1.6-fold elevation of plasma and hepatic MDA, respectively. EPA-feeding at high doses did not affect the plasma MDA, but the hepatic MDA increased 1.4-fold (Table 2).

Effect on plasma and hepatic thiols. When measuring the plasma levels of total homocysteine, cysteine (the rate-limiting precursor amino acid in glutathione synthesis), glutathione, and cysteinylglycine (the breakdown product of glutathione), we found that low doses of 3-methyl-EPA caused a small increase in homocysteine, while glutathione, cysteine and cysteinylglycine were unchanged (Table 3). In liver, the cysteine and glutathione levels were unchanged (Table 3). In the high-dose experiment, we found no significant changes of the hepatic thiols after treatment with EPA, DHA, or oleic acid compared to control (data not shown).

Effect on enzyme activities and mRNA levels. In the low-dose experiment 2,2-dimethyl-EPA tended to increase total SOD activity in the peroxisome-enriched fraction, although not significantly (Table 4). This was accompanied by a 1.9-fold elevated mRNA level of Mn-SOD compared to the control or EPA, and a small (1.3-fold) elevation of CuZn-SOD mRNA compared to EPA. At high doses, the enzyme activity

[c]Significantly difference from EPA ($P < 0.05$). MDA, malondialdehyde; for other abbreviations see Table 1.

of total SOD was unchanged in rats fed EPA and DHA. However, the SOD activity tended to decrease in rats fed oleic acid and there was a reduced expression of CuZn-SOD and Mn-SOD mRNA by oleic acid (Table 4). The SOD activity was unchanged in the mitochondrial-enriched and the cytosolic fractions in both the high- and low-dose experiments (data not shown). Low doses of 2,2-dimethyl- and 3-methyl-EPA or high doses of EPA and DHA did not affect the enzyme activities of xanthine oxidase (XOX, E.C. 1.1.3.22) and xanthine dehydrogenase (XDH, E.C. 1.1.1.204) compared to the control in the postnuclear or the cytosolic fractions (data not shown). Also, the activities of glutathione reductase (E.C. 1.6.4.2), glutathione peroxidase (E.C. 1.11.1.9), and glutathione-*S*-transferase (E.C. 2.5.1.18) were unchanged in the postnuclear, cytosolic or peroxisomal fractions (data not shown), as was the mRNA level of glutathione peroxidase (data not shown) in both experiments.

The enzyme activity of FAO was measured both in the low-dose (Fig. 1A) and the high-dose (Fig. 1B) experiments. Low doses of 2,2-dimethyl- and 3-methyl-EPA increased the FAO activity 2.7- and 2.2-fold, respectively, whereas 2-ethyl-EPA increased the FAO activity 1.7-fold compared to control.

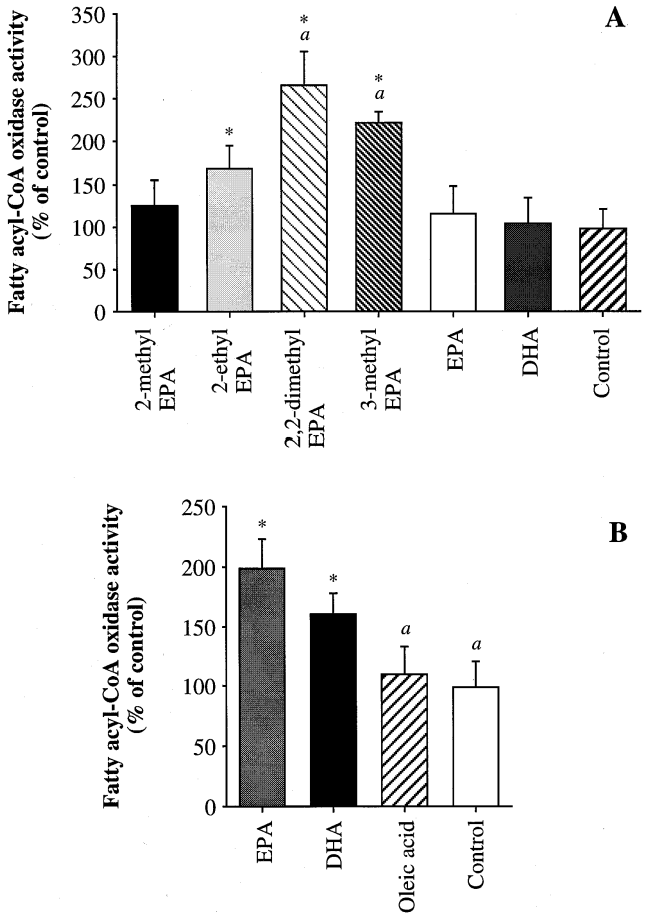

FIG. 1. Enzyme activity of fatty acyl-CoA oxidase in rats fed (A) low doses (250 mg/d/kg body wt) of the EPA derivatives, EPA or DHA, and (B) high doses (1500 mg/d/kg body wt) of EPA, DHA, or oleic acid. CMC-fed animals were used as control. Fatty acyl-CoA oxidase activity was measured in the peroxisome-enriched fraction. Data are relative percentage change from the means of the control values of 20.05 ± 4.08 and 16.41 ± 3.46 nmol/min/mg protein for (A) and (B), respectively. Data are given as means ± SD for 4–5 rats. *Significantly different from control. [a]Significantly different from EPA ($P < 0.05$). Abbreviations: EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; CMC, sodium carboxymethylcellulose.

In the high-dose experiment EPA and DHA increased the FAO activity 2.0- and 1.6-fold, respectively.

Control	460.3 ± 62.3	1.0 ± 0.3	1.0 ± 0.2

[a]The enzyme activity of SOD was measured in the peroxisomal-enriched fraction. RNA purification and hybridization experiments were performed as described in the Materials and Methods section, and the mean for the control from the mRNA data is set to 1. The values are means ± SD for 4–6 animals.
[b]Significantly different from control.
[c]Significantly different from EPA ($P < 0.05$). For other abbreviations see Table 1.

DISCUSSION

In the present experiments, the effects of hypolipidemic doses of different PUFA on the antioxidant status were investigated. Rats were fed EPA, DHA, and different EPA derivatives, that is, EPA methylated or ethylated at the 2- or 3-position, at doses known to cause hypolipidemia. Earlier our group found that high doses of EPA (1000 mg/d/kg body wt) were necessary to obtain hypolipidemic effects and elevate fatty acid oxidation in rats (7,18). The EPA derivatives used in this study have proved to reduce plasma lipids and increase the mitochondrial and peroxisomal β-oxidation in rats at low doses (Vaagenes, H., Madsen, L., Dyrøy, E., Elholm, M., Stray-Pedersen, A., Frøyland, L., Lie, Ø., and Berge, R.K., unpublished data). Low doses (250 mg/d/kg body wt) of the EPA derivatives also increased the activity of FAO. These EPA derivatives differed in their ability to increase the FAO activity, and the most potent derivatives were 2,2-dimethyl-EPA and 3-methyl-EPA (Fig. 1A). In this low-dose experiment, where rats were fed EPA derivatives, EPA or DHA, the plasma vitamin E content (Table 1) decreased only in the groups that caused the greatest induction of FAO activity, that is, 2,2-dimethyl-EPA and 3-methyl-EPA. At high doses (1500 mg/d/kg body wt) of EPA and DHA, the plasma vitamin E content decreased concomitantly with increased peroxisomal β-oxidation, measured as enzyme activity of FAO (Table 1, Fig. 1). Furthermore, plasma vitamin A was not changed by PUFA feeding in the two experiments. As both high doses of EPA and low doses of EPA derivatives are hypolipidemic (7; and Vaagenes, H., Madsen, L., Dyrøy, E., Elholm, M., Stray-Pedersen, A., Frøyland, L., Lie, Ø., and Berge, R.K., unpublished data) and the vitamin A content is unchanged, we can conclude that the plasma contents of the lipid-soluble vitamins are not a consequence of plasma lipid concentration. In the low-dose experiment, it is therefore reasonable to believe that the primary cause of decreased vitamin E content in plasma is upregulated peroxisomal β-oxidation, not polyunsaturation or reduced plasma lipids. In relation to this, it has recently been found that administration of low doses (360 mg/d/kg body wt) of EPA or DHA, which are known not to upregulate the peroxisomal fatty acid oxidation, to rats did not change the hepatic or plasma vitamin E level (19). Although the plasma vitamin E content decreased in the low-dose experiment, we observed no increase in lipid peroxidation, measured as MDA (Table 2). However, increasing the dose of PUFA administered to rats would increase the vulnerability of the cell to the hydrogen peroxide produced during elevated peroxisomal β-oxidation. Therefore, administration of DHA at high doses, which increases the peroxisomal β-oxidation, reduces plasma vitamin E content and consequently elevates lipid peroxidation. Increased vitamin E requirement with increasing polyunsaturation (5) may explain the difference between high doses of EPA and DHA on plasma lipid peroxidation. The difference in plasma MDA in rats fed equal doses of EPA and DHA could also be due to difference in the metabolism of these two n-3 fatty acids. It has recently been shown that EPA is mainly oxidized in the mitochondria, whereas DHA is most likely oxidized by the peroxisomes (20). Furthermore, DHA is a stronger peroxisome proliferator than EPA, whereas EPA causes mitochondrial proliferation. Unlike the mitochondria, the first enzyme in peroxisomal β-oxidation, FAO, produces hydrogen peroxide (1). Moreover, as EPA seems more easily oxidized than DHA (21), we expect to find a higher concentration of DHA than of EPA in plasma. Taken together, the higher amount of peroxisome-derived radicals and the higher concentration of DHA in plasma, as well as the fact that DHA contains one additional double bond, would increase the susceptibility of DHA to lipid peroxidation compared to EPA.

That the hepatic levels of vitamin E and A were unchanged in both the low- and the high-dose experiments shows that, although the plasma vitamin E level decreased, the rat was not depleted of vitamins. This observation fits with the assumption that parenchymal cells in the liver have the ability to conserve their content of vitamin E (22). Over a 3-mon period, however, administration of EPA or DHA to rats reduces the hepatic vitamin E content (6). In the low-dose experiment, there was no change in hepatic lipid peroxidation, measured as MDA. In the high-dose experiment, however, both EPA and DHA caused elevated lipid peroxidation in liver, but the hepatic content of vitamins E, A, and C were unaffected (Tables 2 and 1, respectively). Seemingly, these vitamins were not sufficient to prevent lipid peroxidation in the liver, and this might explain why EPA, with fewer double bonds than DHA, also increased hepatic lipid peroxidation. A small increase in the hepatic vitamin A content was observed in the low-dose experiment, which was not present in the high-dose experiment. The reason for this cannot be explained.

The total SOD activity tended to increase in the hepatic peroxisomal fraction of rats fed low doses of the EPA derivative

2,2-dimethyl-EPA. Significantly induced gene expression of Mn-SOD was observed (Table 3). These effects could be a kind of cellular adaptation, i.e., a secondary effect, to oxidative stress induced by 2,2-dimethyl-EPA. At high doses of EPA or DHA the activity and gene expression of SOD remained unchanged. Oleic acid, however, tended to decrease the SOD activity in the peroxisomal fraction concomitant with decreased gene expression of both Mn-SOD and CuZn-SOD. Reaven (23) has proposed that oleic acid has antioxidant properties, and these could possibly reduce the necessity of SOD activity in rats fed oleic acid, thereby downregulating this activity. Why low doses of 2,2-dimethyl-EPA, but not high doses of EPA and DHA, seemed to affect the activity of SOD remains unclear. Perhaps this effect is due to the production of hydrogen peroxide, as 2,2-dimethyl-EPA induces the FAO-activity 2.7-fold, whereas high doses of DHA or EPA only increase the FAO-activity by 1.7- and 2.0-fold, respectively. The enzyme activities of XOX and of XDH did not change in the low- or the high-dose experiments (data not shown). As the rate of conversion of XDH to XOX seemed to be unchanged compared to the control, it is likely that the amount of superoxide produced from XOX is constant. The superoxide produced from XOX would therefore not affect the SOD activity.

The enzyme activities of glutathione peroxidase, glutathione-*S*-transferase, and glutathione reductase did not change in the low- or the high-dose experiments (data not shown). The levels of glutathione and the glutathione metabolites were not affected in plasma or liver by any of the fatty acid administrations (Tables 4; additional data not shown). This indicates that the low- and high-dose experiments did not affect the glutathione metabolism to any great extent. Thus, EPA, DHA and the EPA derivatives did not seem to weaken the capacity of glutathione as an antioxidant.

The presence of homocysteine is an independent risk factor for cardiovascular diseases (24). The mechanism does not seem to involve lipid peroxidation (25,26). Our results in the low-dose experiment confirm this, since elevated plasma homocysteine in rats fed 3-methyl-EPA (Table 4) did not cause increased lipid peroxidation (Table 2).

To conclude, increased peroxisomal β-oxidation primarily seems to cause oxidative stress in rats fed PUFA. However, the amount of accumulated PUFA in the cell membranes is the critical parameter. Therefore, low doses of lipid-lowering EPA derivatives do not affect lipid peroxidation. High doses of EPA and DHA, however, overwhelm the antioxidant defense mechanisms, resulting in elevated levels of MDA in plasma and liver, even though the activity of the hydrogen peroxide-producing FAO was higher in rats fed low doses of lipid lowering EPA derivatives than high doses of EPA and DHA. The antioxidant enzymes were not affected to any great extent in these experiments.

ACKNOWLEDGMENTS

This work was supported by The Norwegian Council on Cardiovascular Disease and Norsk Hydro. The authors are grateful to Svein Krüger, Kari Williams, Bjørn Netteland, Liv-Kristine Øyseid, Randi Sandvik, and Kari Helland for excellent technical assistance. We thank the Medical Research Centre, University of Bergen, for providing equipment used in this study. We appreciate Drs. A. Molven, I.L. Gonzalez, C.-C. Lai, and J.L. Tilly for sharing probes with us.

Quantitative Determination of Butylated Hydroxyanisole, Butylated Hydroxytoluene, and *tert*-Butyl Hydroquinone in Oils, Foods, and Biological Fluids by High-Performance Liquid Chromatography with Fluorometric Detection

Vivienne V. Yankah, Hideki Ushio*, Toshiaki Ohshima, and Chiaki Koizumi

Department of Food Science and Technology, Tokyo University of Fisheries, Tokyo 108, Japan

ABSTRACT: Concentrations of synthetic antioxidants butylated hydroxyanisole, butylated hydroxytoluene, and *tert*-butyl hydroquinone were quantified using a high-performance liquid chromatograph with spectrofluorometric detector. The antioxidants were separated and eluted on a reversed-phase column by gradient of a mixture of H_2O/acetonitrile/acetic acid (66.5:28.5:5, by vol) and a mixture of acetonitrile/acetic acid (95:5, vol/vol). The eluants were monitored at emission and excitation wavelengths of 310 and 280 nm, respectively. Calibration curves obtained using peak areas against concentration showed high coefficients of multiple determination ($R^2 > 0.99$) for all antioxidants. Known concentrations of added antioxidant standards were recoverable within 98–99% from oils and over 93% from mouse blood. This method requires minimum sample extraction and purification before analysis and provides a relatively high percentage recovery. The method has been applied successfully for the measurement of antioxidant concentrations in oils, dried foods, and biological fluids.

Lipids 33, 1139–1145 (1998).

Synthetic antioxidants are defined by the U.S. Food and Drug Administration (FDA) as food preservatives that specifically retard deterioration, rancidity, or discoloration due to lipid oxidation (1). When added beyond certain limits, however, antioxidants tend to be pro-oxidant (2,3), and rat experiments have revealed that a high dosage in the body causes various tumors and cancers (4). Thus, information on the amounts of antioxidants incorporated into foods is important for agencies controlling foods, for food processors, and for consumers. Many methods including colorimetry (5), spectrophotometry (6), fluorimetry (7,8), voltammetry (9), chromatography [paper (10), thin-layer chromatography (11,12), gas–liquid chromatography (13–16), or high-performance liquid chromatography (17–25)] have been used for qualitative and quantitative determination of antioxidants including butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and *tert*-butyl hydroquinone (TBHQ) added to fats, oils, and foods. Almost every procedure requires considerable sample preparation such as saponification, extraction, and liquid–liquid separation prior to estimation of individual antioxidants (2,26). Recently, reversed-phase HPLC with direct injection and ultraviolet (UV) detection have been applied to phenolic antioxidants, tocopherols, and triglycerides in oils (25). However, possible interferences from other antioxidants and/or naturally occurring phenolic compounds were reported with the use of some UV procedures, such as spectrophotometry in antioxidant detection (26). Direct injection and fluorimetric detection improved the analysis of TBHQ in oils (19). Simultaneous detection with fluorescence, UV, and electrochemical detectors were applied for determination of phenolic antioxidants (21). However, these methods have not been applied to foods with possible interferences.

In this study, an HPLC method with fluorometric detector and simple extraction was applied to the determination of antioxidants including BHA, BHT, and TBHQ in oils and foods.

EXPERIMENTAL PROCEDURES

HPLC conditions. A gradient liquid chromatography system equipped with two Shimadzu LC 10 AS pumps, a Shimadzu C-R6A chromatographic integrator, and a 10 μL sample loop auto-injector was used for analysis. Eluants were detected with a Shimadzu RF-10 A spectrofluorometric detector with slit widths of 15 nm for excitation and emission and with a 12 μL flow cell. A reversed-phase column, Lichrosorb RP-18 (5 μm, 4 mm i.d. × 250 mm; Merck, Darmstadt, Germany), was used for separation of antioxidants.

Mobile phases and a solvent gradient program were used for elution of antioxidants according to the method of Page (18) with slight modifications. A mobile phase A, comprising water/acetonitrile/acetic acid (66.5:28.5:5, by vol), and mobile phase B, made up of acetonitrile/acetic acid (95:5, vol/vol) were used as eluants. The flow rate was 1 mL/min. The solvent gradient for elution was programmed as listed in Table 1.

The emission and excitation spectra of BHA, BHT, and

45	0	100
45.1	75	25

[a]Solvent A: water/acetonitrile/acetic acid (66.5:28.5:5, by vol); solvent B: acetonitrile/acetic acid (95:5, vol/vol).

TBHQ were obtained with a Shimadzu RF 1500 spectrofluorimeter equipped with stirring apparatus at slitwidths of 10 nm for excitation and emission. Solvent compositions were = 33:62:5 in water/acetonitrile/acetic acid by volume for BHA, 13:82:5 for BHT, and 50:45:5 for TBHQ, respectively. Stopped-flow analyses in the above HPLC system gave almost similar values for maximum excitation and emission wavelengths as listed in Table 2. The wavelengths of 280 and 310 nm were adopted as excitation and emission, respectively.

Calibration curves. Acetonitrile solutions of antioxidants within the concentration range of 0.01–50 μg/mL for BHA and TBHQ and of 0.1–200 μg/mL for BHT were prepared, filtered with a Millipore filter [polyvinylidene difluoride, 0.5 μm pore size, Millipore] and subjected to HPLC with an injection volume of 10 μL. Calibration curves of peak area against concentration were obtained. The limit of detection was calculated from the following equation:

$$L_d = a + 3\left\{\frac{\sum_i (y_i - \hat{y}_i)^2}{n - 2}\right\}^{1/2} \quad [1]$$

where L_d is the limit of detection, a is the y-axis intercept deduced from line of regression of area on concentration, y_i are the experimental values of area, $\hat{y}_i$ are the individual values of area in line of regression for area on concentration, and n is the number of samples.

Recovery. The percentage recovery of antioxidant was determined for the acetonitrile extraction for lipids, foods, and mouse blood, and also when antioxidants were extracted by the Bligh and Dyer procedure (27) prior to quantification. The following procedures were carried out at an ambient temperature of 25–29°C.

(i) Acetonitrile extraction from lipids. A known amount of antioxidant was added to soybean oil or total lipid extracted from horse mackerel (*Trachurus japonicus*) white muscle. An aliquot of 5 mL of acetonitrile was added to 2 g of lipids in a screw-capped vial. After a brief purge with a N_2 stream, the vial was tightly capped and shaken vigorously for 2 min to extract the added antioxidant. The resulting extract was then filtered with a Millipore filter (PVDF, 0.5 μm pore size) and loaded into the HPLC system. Antioxidant concentrations were determined by measurement of the peak areas and interpolation from calibration curves.

(ii) Acetonitrile extraction of smoke-flavored sausage. Smoke-flavored sausage without preservatives (sausage A) was obtained from a local supplier. A known amount of antioxidant in ethanol was added to 50 g minced sausage and mixed vigorously. A 5-g minced sample was homogenized in 5 mL acetonitrile and filtered through No. 5C filter paper (Advantec TOYO, Tokyo, Japan). The extraction and filtration procedure for the residue plus filter paper was repeated two times. The resulting filtrates were combined and made up to volume in a 25-mL volumetric flask. All extraction procedures were carried out within 30 min from addition of antioxidants. An aliquot of the solution was filtered through a Millipore filter (polyvinylidene difluoride, 0.5 μm pore size) and loaded into the HPLC system.

(iii) Acetonitrile extraction from biological fluid. A 10-μL ethanol solution containing 10 μg BHA, 10 μg TBHQ, and 100 μg BHT was added to 2 mL whole blood freshly obtained from mice. One milliliter of acetonitrile was added to 250 μL of the resulting blood, shaken vigorously for 2 min, and centrifuged for 10 min at 3,000 × *g*. The supernatant was collected and the same extraction procedure was repeated. The combined supernatant was made up to 5 mL with acetonitrile, then applied to an HPLC analysis as above.

(iv) Recovery after chloroform/methanol/water extraction. A known amount of antioxidant in chloroform solution was extracted using the Bligh and Dyer procedure for simulation of total lipids extraction. The concentration of extracted antioxidant was determined to estimate the losses that occurred during extraction and liquid–liquid separation.

Application to foods. The method was further applied to the determination of antioxidant concentrations in boiled and dried anchovy product and smoke-flavored sausage (sausage B) obtained from local suppliers. The sample was minced and crushed with a food cutter. Extraction from the samples and

TABLE 2
Maximum Excitation and Emission Wavelength (nm) of Antioxidants

Antioxidant[a]	Spectrophotometer Excitation	Emission	Stopped-flow analysis Excitation	Emission
BHA	290	320	285	320
BHT	276	304	280	310
TBHQ	293	322	295	328

[a]BHA, butylated hydroxyanisole; BHT, butylated hydroxytoluene; TBHQ, *tert*-butyl hydroquinone.

the following procedures were carried out as described above. The concentration of antioxidants in the samples was estimated from the calibration curve.

Peak assignnment by gas chromatography–mass spectrometry (GC–MS). Peaks obtained in the above HPLC system were assigned by fragmentation patterns in GC–MS.

Samples were prepared for injection into the HPLC system as described above. The eluants from the HPLC column were fractionated and evaporated by flushing them to dryness with a N_2 stream; then they were immediately dissolved in *n*-hexane and subjected to GC–MS analysis as below. The trimethylsilyl (TMS) ether derivatives were also prepared and analyzed. TMS ether derivatives were prepared by addition of 0.5 mL distilled pyridine, 1 mL 1,1,1,3,3,3-hexamethyldisilazane, and 0.5 mL trimethylchlorosilane. After 1 h all solution was evaporated by flushing under a N_2 stream. The contents of the flask were dissolved in *n*-hexane and filtered with a Millipore filter (polyvinylidene difluoride, 0.5 µm pore size). Samples were analyzed by GC–MS using a Shimadzu QP 1000 or QP 5000 mass spectrometer fitted with an electron impact ionization source to which a Quadrex 65HT column (0.25 mm i.d. × 15 m) was directly connected.

RESULTS

Operating wavelengths and separation. The emission and excitation spectra for 0.01 µg/mL of BHA, BHT, and TBHQ are shown in Figure 1. The order of increasing sensitivity was BHT < TBHQ < BHA. The maximum excitation and emission wavelengths were similar for BHA and TBHQ—290 and 320 nm, respectively, for BHA, and 293 and 322 nm, respectively, for TBHQ—but different for BHT at excitation and emission of 276 and 304 nm, respectively, as listed in Table 2. These wavelengths were fairly consistent with the values obtained through stopped-flow analyses, where the wavelengths for maximum emission and excitation were 285 and 320 nm, respectively, for BHA, 280 and 310 nm, respectively, for BHT, and 295 and 328 nm, respectively, for TBHQ. The operating wavelengths favored the detection of BHT rather than BHA and TBHQ, because fluorescence intensity of BHT was much lower compared to those of the others mentioned below. Thus, antioxidants were analyzed at an excitation wavelength of 280 nm and an emission wavelength of 310 nm. The wavelengths caused reduction of fluorescence intensity for BHA, about 60% of its maximal intensity, and TBHQ, about 40% of its maximal intensity. However, such intensities were satisfactory for detection of the two antioxidants, which exhibited very high emission yields.

Calibration and recovery. Peak area and concentration of BHA, BHT, and TBHQ correlated well (Fig. 2). Coefficients of determination were over 0.99 for all antioxidants, and the limits of detection were 93 ng for BHA, 810 ng for BHT, and 57 ng for TBHQ. Percentages recoverable from fish oil containing 0.5 µg/g BHA, 5 µg/g BHT, and 0.5 µg/g TBHQ by the acetonitrile extraction were as follows: 98.0% for BHA, 99.2% for BHT, and 98.2% for TBHQ (Table 3). These percentages were consistent with those of fish oil containing 20 µg/g BHA, 20 µg/g TBHQ, and 200 µg/g BHT, and with those in soybean oil. Recoveries of acetonitrile extraction from sausage A to which were added 0.5 µg/g BHA, 5 µg/g BHT, and 0.5 µg/g TBHQ were 87.7% for BHA, 85.9% for BHT, and 50.3% for TBHQ, whereas those for addition of 20 µg/g BHA, 200 µg/g BHT, and 20 µg/g TBHQ were 92.5, 89.9, and 62.3%, respectively. Recoveries from mouse blood were higher than those from sausage A; 97.5% for BHA, 93.6% for BHT, and 93.2% for TBHQ. With the Bligh and Dyer procedure, more losses were observed in the recoverable concentrations of TBHQ, but not in BHA and BHT; 86.6% for BHA, 99.5% for BHT, and 43.9% for TBHQ.

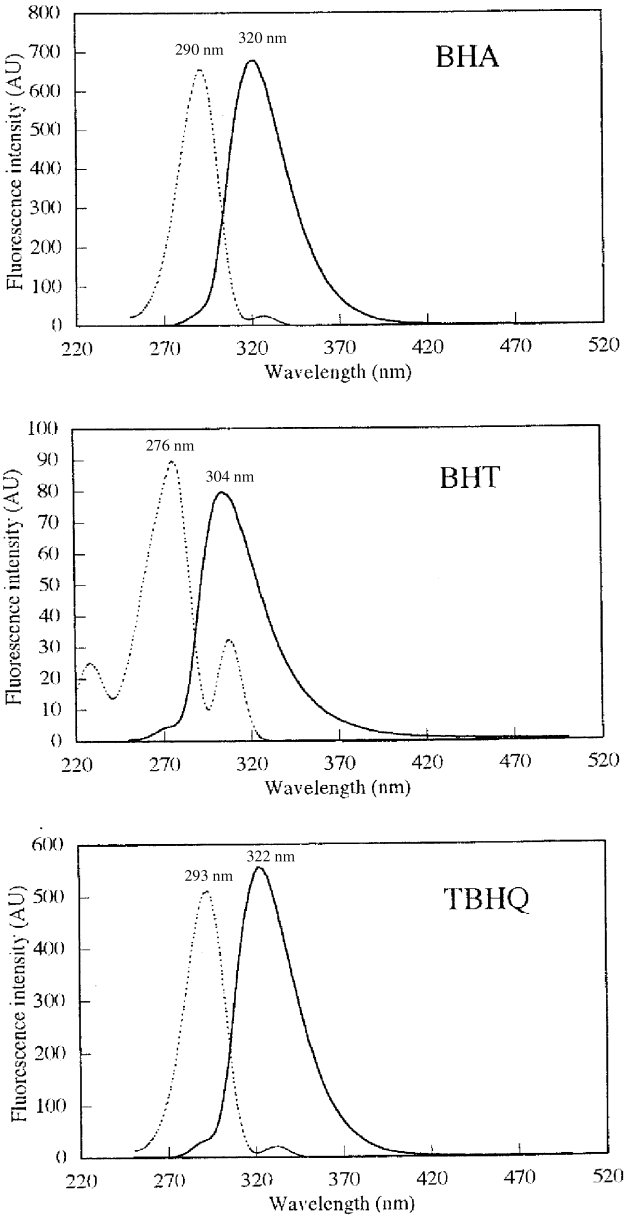

FIG. 1. Excitation (....) and emission (—) spectra of butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and *tert*-butyl hydroquinone (TBHQ).

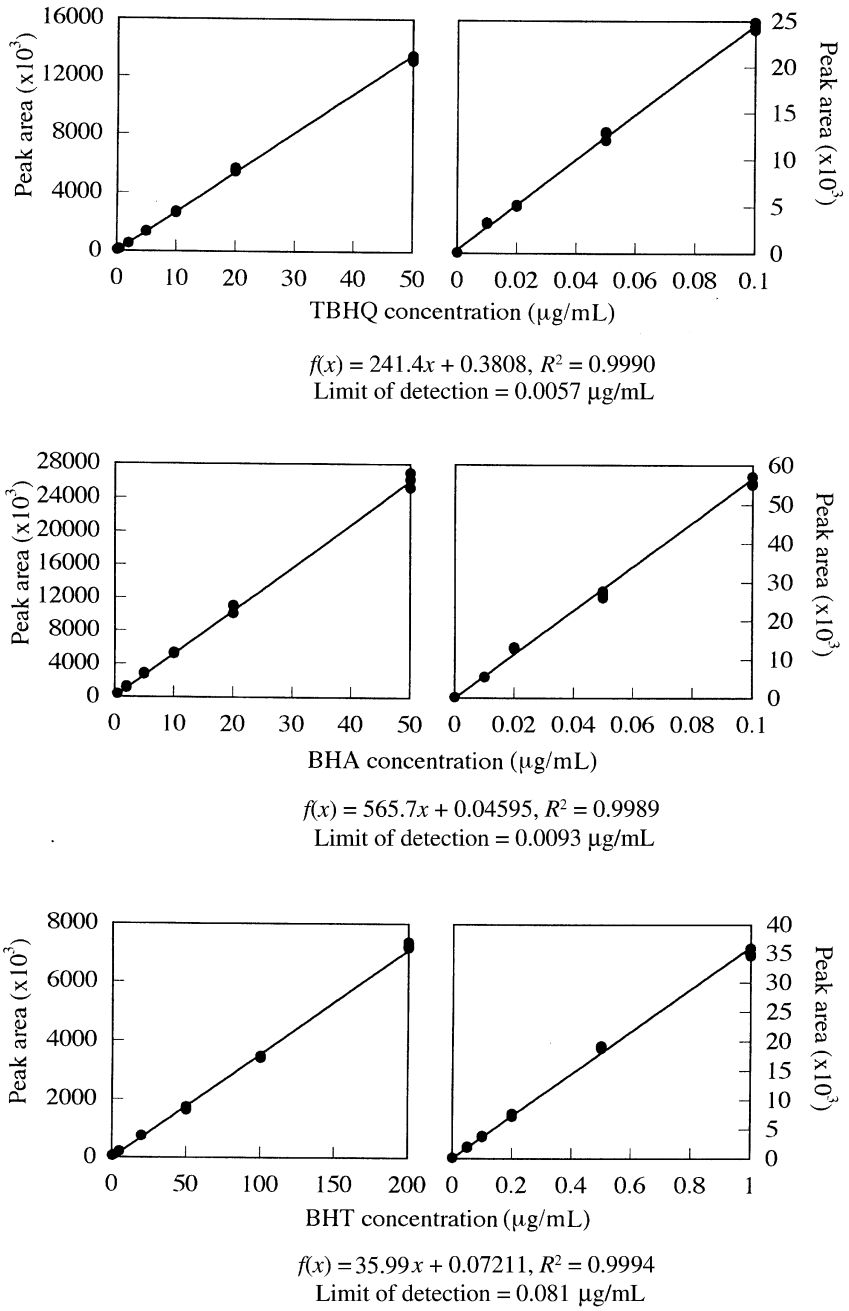

FIG. 2. Calibration curves of TBHQ, BHA, and BHT. The right-hand sides of each panel are calibration curves for the smaller range of the left-hand sides. For abbreviations see Figure 1.

Typical HPLC elution patterns of standards, foods, and blood extract are shown in Figure 3. Antioxidant peaks were well-isolated from interfering peaks in each sample, except for TBHQ with a small shoulder peak in sausage A plus standards.

Determination of antioxidant in foods. Peaks A and B collected from sausage B and anchovy eluants (Fig. 4) were subjected to GC–MS analysis. Because fragmentation patterns of both peaks were consistent with that of BHA, the corresponding peak was assigned to BHA. Neither BHT nor TBHQ was detected in both cases. BHA content of sausage B was calculated as 22.4 ± 1.8 mg/kg wet basis (n = 3). BHA concentration determined in commercial boiled and dried anchovy was 32.9 ± 1.9 mg/kg wet basis for BHA (n = 3).

DISCUSSION

The present study demonstrated that the reversed-phase HPLC with fluorescence detection enables one to detect BHA, BHT, and TBHQ at sufficiently low limits. It also prevents some interferences in oils, foods, and a biological fluid without the necessity of complicated pretreatments, such as

TABLE 3
Percentage Recovery of Antioxidants BHA, BHT, and TBHQ

Antioxidants	Amount	Fish oil	Soybean oil	Sausage A	Mouse blood	CH_3Cl/MeOH
BHA	0.5 μg/g[a]	97.8 ± 0.3[d]	98.0 ± 0.5	87.7 ± 2.1	—	—
	20 μg/g	98.1 ± 0.6	97.6 ± 0.7	92.5 ± 1.7	—	—

liquid–liquid separation. Although a much lower limit of detection for BHT, around 0.5 ng, was achieved by Mizutani *et al.* (22), the method needs the derivatization procedure of BHT.

One cause that elevated the limit of detection for BHT was a low yield in emission as reported by Latz and Hurtubise (7). They also reported maximal wavelengths for excitation and emission in ethanol as follows: 293 and 342 nm, respectively, for BHA, and 287 and 350 nm, respectively, for BHT. These values were inconsistent with the present results in water/acetonitrile/acetic acid, probably due to different solvents. However, we could not confirm their results, obtained in ethanol solutions, with our experimental instruments.

The recoveries of BHA, BHT, and TBHQ from oils, mouse blood, and sausages achieved practical determination levels for the most part, except for TBHQ from sausage. Remark-

able losses of TBHQ during extraction and analysis procedures were reported by other investigators (17–19,25,28). Stijve and Diserens (28) carried out direct extraction from milk fat with acetonitrile to improve recovery of the antioxidant. However, a rapid extraction procedure with acetonitrile and cooling could not curtail the recovery loss for sausage. The latter is thought due to loss in extraction and breakdown in the procedure.

Initially extracting the total lipid fraction from the food sample before analysis, using the chloroform/methanol/water method, achieved high recoveries for BHA and BHT and resulted in high losses for TBHQ. Causes of that loss are not clearly known but may be due to degradation of TBHQ, and also to losses to the more polar methanol/water layer during extraction procedures as discussed above.

With the AOCS recommended method for antioxidant analysis (24), a problem especially with the analysis of TBHQ was the loss of antioxidant during sample extraction and preparation, and also the incomplete separation of hexane and acetonitrile solution due to formation of emulsion. Andrikopoulos *et al.* (25) improved on the AOCS method and the direct oil injection method of Anderson and Van Niekerk (23) using UV detection. The application of this extraction method described in this paper is convenient for extraction of the antioxidants before detection, to eliminate interferences from other naturally occurring phenolic compounds in the sample.

The BHA concentration in a boiled and dried anchovy sample obtained commercially did not exceed the permitted level of BHA in Japanese fish products, which is restricted to 200 mg/kg wet basis (29). Although the use of antioxidant is not allowed in meat products, sausage B contained a detectable amount of BHA. This observation is supposedly due to the facts that the sausage was imported and/or that the antioxidant may migrate from wrapping materials into the sausage (11,26).

In conclusion, antioxidants BHA, BHT, and TBHQ in foods can be extracted with acetonitrile and measured using HPLC with a spectrofluorometric detector. Sample extraction is simple and reproducible with minimal losses.

ARTICLE

Assessment of the Arachidonic Acid Content in Foods Commonly Consumed in the American Diet

Laura Taber, Chun-Hung Chiu, and Jay Whelan*

Department of Nutrition, University of Tennessee, Knoxville, Tennessee 37996-1900

ABSTRACT: Arachidonic acid (AA) is an extremely important fatty acid involved in cell regulation. When provided in the diet, it is cogently incorporated in membrane phospholipids and enhances eicosanoid biosynthesis *in vivo* and *in vitro*; however, controversy exists as to the levels of AA in food and in the diet. This study determined the amount of AA in cooked and raw portions of beef (rib eye), chicken (breast and thigh), eggs, pork (loin), turkey (breast), and tuna; it compared these results to values published in Agriculture Handbook No. 8 (HB-8). The cooked portions were prepared as described in HB-8. With the exception of chicken thigh and tuna, the levels of AA (w/w) in the selected foods analyzed were significantly higher, in general, than those values published in HB-8. The greatest differences were observed in beef (raw and cooked), turkey breast (raw and cooked), and pork (cooked) where AA levels were twice that of the values in HB-8. In contrast, the AA and n-3 fatty acid contents in tuna were almost half the HB-8 values. The present data indicate that HB-8 tends to underreport the amounts of AA in a number of foods commonly consumed in the American diet, and new initiatives should be considered to validate and update the current database for fatty acid composition of foods.
Lipids 33, 1151–1157 (1998).

Arachidonic acid (AA) is among the most important fatty acids associated with membrane phospholipids, and its diverse biological functions are unraveling with increased scrutiny (1). Intracellular AA can modulate cell differentiation (2–4), cell proliferation (5–7), gene expression (8–12), and signal transduction (13–17). The best-described functions of AA are mediated through eicosanoids. Increasingly, AA and its metabolites are being linked to chronic diseases, such as cancer; and antagonism of AA and its metabolism, i.e., eicosanoid formation, reduce risk (18,19).

AA is derived metabolically from linoleic acid (LA: 9,12 octadecadienoic acid, 18:2n-6), the major polyunsaturated fatty acid (PUFA) in the diet. Although dietary LA is the major source of tissue AA, this metabolic pathway is regulated such that variations in the LA content of the Western diet do not significantly alter AA content of tissue phospholipids (20). In addition to LA, dietary AA also can contribute to tissue AA levels. Even though dietary LA is the primary metabolic source of AA in tissues, AA from food can significantly impact tissue levels. Both animal (21–23) and human (24,25) studies demonstrated that consuming AA increases plasma and tissue levels of AA and significantly augments eicosanoid biosynthesis *in vivo* and *in vitro*.

Compared to the daily intake of LA (10–20 g/day), the estimated intake of AA (100–500 mg/day) is a minor contributor to the total daily dietary intake of PUFA (22,26–29). But even at these levels, AA is able to alter tissue AA content. Phinney *et al.* (29) reported that AA content in plasma lipids was significantly higher in subjects whose diets contained meat and eggs as compared to vegetarians. Sinclair *et al.* (30) reported that increasing dietary AA intakes from 70 to 490 mg/d significantly enriched plasma phospholipids and cholesteryl esters with AA. Diets high in lean beef (500 g lean beef/d; ~230 mg AA/d) significantly increased the concentration of AA in plasma phospholipids compared to diets containing 30–100 g of lean beef per day (31). Increasing dietary intakes of AA to 1.7 g/d in 50 volunteers, from a baseline intake of 200 mg/d, increased the levels of urinary metabolites of thromboxane A_2 (TXA_2) and prostaglandin I_2 (PGI_2) (25) and resulted in an enrichment of AA in platelet phospholipids (32). However, increasing AA consumption from 76–78 to 137–140 mg/d in Australian subjects in the form of various meats did not alter platelet AA content, *ex vivo* platelet TXB_2 production, nor levels of the urinary metabolites of TXA_2 and PGI_2 (33).

These data suggest that the impact of dietary AA on tissue AA content is dose-dependent and that these doses are within reasonable dietary ranges. However, conflicting information exists as to how much AA is actually consumed and how much is in the foods we eat (22,26–29,31,34). A series of comprehensive studies on the Australian diet suggest the amount of AA in their foods and in their diet may be lower than anticipated, but these numbers are influenced by the lean and visible fat portions of the food samples (26,34). A reanalysis of meats from the U.S. diet has yet to be done.

Agriculture Handbook No. 8 (HB-8), as published by the United States Department of Agriculture (USDA), is a comprehensive compilation of the nutrient composition of virtu-

Abbreviations: AA, arachidonic acid; BRE, beef rib eye; CB, chicken breast; CT, chicken thigh; HB-8, Agricultural Handbook No. 8; LA, linoleic acid; MUFA, monounsaturated fatty acids; PL, pork loin; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acids; TB, turkey breast; TX, thromboxane; USDA, United States Department of Agriculture; WE, whole egg.

ally all foods consumed in the American diet (35). Many software programs assessing human nutrient intakes rely on this database. Understandably, it is difficult for this database to remain current by keeping pace with technological advances in analytical procedures and changes associated with animal feeding and breeding practices. Therefore, despite volumes of nutrient composition tables, direct empirical data of the fatty acid composition, of many foods, in particular AA, is lacking. Preliminary data from our laboratory suggested that HB-8 was underreporting the amount of AA in a number of U.S. food products (36). Therefore, the purposes of this study were to determine the amount of AA in foods known to be relatively high in AA and commonly consumed in the American diet and to compare these results to those published in HB-8.

MATERIALS AND METHODS

Samples. The selection criteria for samples were based on foods known to be relatively rich in AA that are commonly consumed in the American diet, including beef, chicken, eggs, pork, and turkey. White tuna canned in water was included as a food known to be rich in n-3 fatty acids.

With the exception of the tuna and crackers, all samples were obtained fresh from local outlets of a large supermarket chain. They were refrigerated at 4°C after purchase and processed on the same day, usually within 1 h of purchase. Beef rib eye (BRE, $n = 4$), chicken breast (CB, $n = 5$), chicken thigh (CT, $n = 5$), pork loin (PL, $n = 4$), and turkey breast (TB, $n = 4$) samples were trimmed of excess fat, cut in half, and weighed. Poultry samples were skinned. One-half of each BRE sample was broiled, and one-half of each sample of CB, CT, PL, and TB was roasted according to protocol established in HB-8 (37–39). All meat samples were cooled for 1 h after cooking prior to further processing and analysis. Approximately 77-g samples of commercially canned and processed (in water) tuna were analyzed. The fatty acid composition of single raw whole eggs (WE) weighing approximately 50 g was determined. In addition, four eggs were hard-boiled for 10 min, cooled for 20 min, shelled, weighed, and analyzed.

All samples were finely chopped in a Cuisinart food processor (Model DLC-10E; Greenwich, CT) for 2 min in 0.9% NaCl at a concentration of 380 g sample/L buffer. The average weight of the samples prior to processing was approximately 70 g (before or after cooking). Of the internal standard nonadecanoic acid methyl ester (19:0) 50 mg was added to each sample prior to processing. The chopped samples then were finely pureed in a Waring blender (New Hartford, CT) for 3 min at a final concentration of 210 g sample/L buffer. The pureed homogenates were filtered through cheesecloth (crude mesh) to remove connective tissue, and under constant stirring three aliquots were removed for fatty acid analysis. Four to five individual food samples were prepared and analyzed as indicated above. [Note: Follow-up experiments indicate if food samples are homogenized in a 20% saline solution of methanol/chloroform (2:1, vol/vol), the recovery of the internal standard is improved by approximately 5%.]

Lipid extraction and fatty acid analysis. Lipids were extracted by a modified method of Bligh and Dyer (40). Briefly, one part sample was suspended in three parts methanol/chloroform (2:1, vol/vol), and lipids were extracted following the addition of chloroform and 200 μL saturated NaCl solution. The chloroform extraction was repeated (× 2). Following complete evaporation of the pooled chloroform fractions under a stream of nitrogen, the lipids were solubilized with toluene and saponified with KOH (0.5 N) in methanol for 8 min at 86°C. The samples were cooled and acidified with HCl (0.7 N) in methanol, extracted with 2 vol of hexane (× 2), evaporated under an atmosphere of nitrogen, and methylated with ethereal diazomethane. The fatty acid methyl esters were resuspended in hexane and separated by gas chromatography [Hewlett-Packard 5890 Series II gas chromatograph (Palo Alto, CA) equipped with a flame-ionization detector] using a DB-23 capillary column (J&W Chromatography, Folsom, CA) with hydrogen as the carrier gas. The fatty acid methyl esters were identified by comparison of retention times with those of known standards (Nu-Chek-Prep, Elysian, MN) and quantitated based on the internal standard. As previously established, each sample did not contain an appreciable amount of the internal standard.

Statistical analysis. The Statistical Analysis System (SAS Institute, Inc., Cary, NC) was used to analyze the data. Data were expressed as means ± SEM of 4–5 samples, each of which was expressed as the means of three aliquots. Differences between experimental values and those published in HB-8 were analyzed using the one-sample *t*-test. Data were considered significant at $P < 0.05$.

RESULTS

PUFA composition of raw samples. Levels of AA varied in raw samples from a low of 46 mg/100 g in raw BRE to a high of 156 mg/100 g in raw WE, significantly different from those values reported in HB-8 (Table 1). AA content was significantly higher in BRE (46 vs. 20 mg/100 g), CB (64 vs. 40 mg/100 g), and TB (59 vs. 30 mg/100 g) compared with the HB-8 values. Overall, AA content was significantly higher in half of the raw foods analyzed (Fig. 1). LA content was significantly lower in PL (262 vs. 440 mg/100 g) and higher in WE (1272 vs. 1148 mg/100 g) compared to HB-8 (Table 1). Similar inconsistencies among the experimental and HB-8 values were observed with the n-3 PUFA. HB-8 reports significantly higher levels of 22:6n-3 in CB and CT, and significantly lower levels in TB. They failed to report the presence of a number of n-3 and n-6 PUFA that we observed, including 20:3n-6, 22:4n-6, 22:5n-6, 20:5n-3, 22:5n-3, and 22:6n-3, in many of the food items.

PUFA composition of cooked samples. Values of AA in cooked samples varied from 33 mg/100 g in white tuna packed in water to 239 mg/100 g in WE hard-boiled (in the shell) (Table 2). In general, AA content (per 100 g cooked sample) was found to be significantly higher in the experimental samples compared to the HB-8 values, i.e., BRE (77 vs. 30 mg), CB (83 vs. 60 mg), WE (239 vs. 149 mg), PL (74

[a]United States Department of Agriculture (USDA) Nutrient Data Bank (NDB) numbers: beef: #13097; chicken breast: #05062; chicken thigh: #05096; whole egg: #01123; pork loin: #10040; turkey breast: #05219.
[b]Values are means ±SEM of 4–5 independent samples, each analyzed in triplicate.
[c]$P < 0.05$ significantly different compared with USDA value.

vs. 30 mg), and TB (72 vs. 40 mg); and significantly lower in white tuna packed in water (33 vs. 51 mg). No detectable levels of AA are present in saltine crackers. Overall, AA content was significantly different in six out of the seven foods analyzed as compared to those values published in HB-8 (Fig. 1).

Significant differences also were observed in the 18:2n-6 content of seven of the eight experimental foods as compared to HB-8. For example, HB-8 reports more than twice the levels of 18:2n-6 in CT, but one-third the levels in TB. In addition, HB-8 reports that 18:2n-6 content increases threefold in CT following cooking (Tables 1 and 2). Similar discrepancies were observed with the n-3 PUFA. For example, in tuna, the experimental value (per 100 g sample) for 20:5n-3 was significantly lower compared to HB-8 (94 vs. 233 mg). In addi-

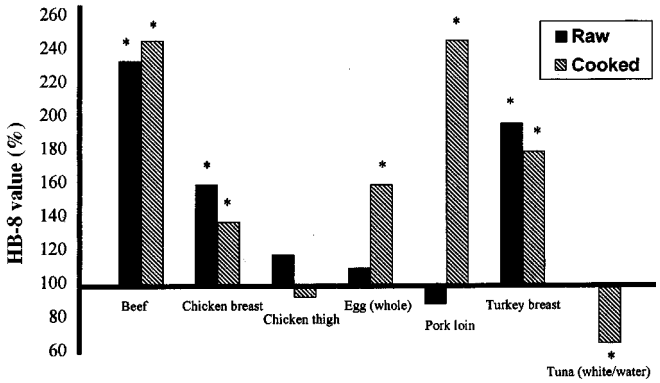

FIG. 1. Relative amounts of AA (based on g/100 g sample) in selected foods as compared to values published in Agricultural Handbook No. 8 by the United States Department of Agriculture (USDA). Asterisks denote values that were significantly different from the USDA values at $P < 0.05$.

tion, HB-8 failed to report the presence of a number of n-3 and n-6 PUFA, including 20:3n-6, 22:4n-6, 22:5n-6, 20:5n-3, 22:5n-3 and 22:6n-3, in many of the food items. Some of the data were missing as indicated by blanks in the data for some select fatty acids.

Saturated fatty acid (SFA) composition of raw samples. Of the major SFA, 16:0 was significantly lower in BRE and WE, and 16:0 and 18:0 were significantly lower (per 100 g of sample) in PL compared to HB-8 (Table 1). In many of the food items, HB-8 failed to report the presence of a number of SFA, i.e., 10:0, 12:0, 15:0, and 17:0.

SFA composition of cooked samples. The 12:0, 14:0, 16:0, and 18:0 content of CB, CT, and PL, and 14:0 and 16:0 of white tuna were significantly lower in the experimental foods compared to HB-8, while the 16:0 and 18:0 content of TB were significantly higher (Table 2).

Monounsaturated fatty acid (MUFA) composition of raw samples. MUFA values for 16:1 and 18:1n-9 were significantly lower in BRE, WE and PL, and 16:1 was higher in CT compared to HB-8 (Table 1).

MUFA composition of cooked samples. MUFA values for 16:1 and 18:1n-9 were significantly lower in CB, CT, PL, and tuna compared to HB-8. The 18:1n-9 levels in TB were significantly higher than the HB-8 values (Table 2).

Total fatty acid composition of raw and cooked samples. For the most part, total fatty acid, SFA, MUFA, and PUFA content in the raw samples reported in HB-8 were similar in the experimental foods with the exception of BRE and PL (Table 1).

Total fatty acid, SFA, MUFA, and PUFA content were significantly lower in the cooked samples of CB, CT, PL, and tuna compared to HB-8 (Table 1). In contrast, overall fatty acid content was higher in WE (hard-boiled) and TB compared to HB-8. Saltine crackers, the only nonanimal product included in the analyses, contained significantly lower amounts of PUFA, in the form of 18:2n-6, compared to the value reported in HB-8.

DISCUSSION

Fatty acid analysis of eggs and a variety of meats revealed that the values reported in HB-8 for AA content were significantly different ($P < 0.05$), in general, from those observed in our experimental foods (Fig. 1). AA content in land-based meats tended to be underreported in HB-8, while AA content in the marine source meat (tuna) was significantly lower than the HB-8 value. In a number of instances, the HB-8 fatty acid values for raw and cooked portions of the same food were inconsistent. For example, the HB-8 reports that the total PUFA content (w/w) of pork loin increased 31% following cooking, but the AA content decreased by 50%. We did not observe a decrease in AA content in any of the samples tested following cooking. In general, we and others (41,42) observed consistent increases in fatty acid content (w/w), including AA, in cooked portions compared to raw samples. Consistent with HB-8 values, we did not observe reductions in the PUFA content following cooking. Sinclair *et al*. (31) report that cooking lean beef results in significant reductions in PUFA content, in particular the 20-carbon PUFA. Possibly the incongruity of these data may be related to different methods of cooking (i.e., roasting vs. grilling and frying) and how the cooked data were reported (i.e., mg/100 g cooked sample vs. mg/100 g original raw sample weight). Loss of moisture due to cooking resulted in a higher fatty acid content on a w/w basis, and as such, the relative abundance of AA to the total fatty acid content remained fairly similar (43). Cooking can result in 30% moisture loss and can enrich the amount (w/w) of extractable lipids in the muscle component (44,45). However, Chang and Watts (46) report that they did not consistently observe an enrichment of fatty acids in meats following cooking, including AA, suggesting nonuniform distribution of triglycerides rather than the destruction of unsaturated fatty acids (46) contributed to these results. More recently, though, Li *et al.* (34) report that the amount of AA (w/w) in the visible fat of animal meats (beef, lamb, turkey, pork, chicken, and duck) is equal to or greater than that of comparable lean portions even though the relative amounts of AA (wt% of total fatty acids) were 10–100 times higher in the lean portions. These data indicate that the triglyceride portion of meat can have a significant impact on AA content, and care must be taken when selecting and comparing meat portions for fatty acid analysis.

Several explanations are possible for the discrepancies between the HB-8 values and the experimental values of this study. Studies conducted for the USDA report the relative contributions of AA to the total fatty acid profile of the triglyceride portion (separable fat) of meats (i.e., beef) were considered quantitatively insignificant (42), while more recent data indicate this is not the case (34).

Many of the values in HB-8 are estimates. When analytical data were not available, calculation or imputing of nutrient values (35) was sometimes necessary. The USDA routinely generated fatty acid data by using mathematical formulas based on the weight percentage of the total lipid in a food,

[c]$P < 0.05$ significantly different compared with USDA value. See Table 1 for abbreviations.

multiplied by a set of conversion factors (42,47–49). The conversion factors varying among different foods, raw and cooked samples (47), were primarily based on the relative abundance of triglycerides and phospholipids and their fatty acid contents (42). For a given sample, the fatty acid composition (w/w) was determined by first determining the amount of total lipid gravimetrically and by multiplying this value by its conversion factor and the weight percentage (sometimes assumed) of the individual fatty acid methyl esters. Based on preliminary experiments, fatty acid profiles for related anatomical portions of meat from a beef carcass, for example, were assumed to be similar (47). When necessary, the

fatty acid data were adjusted so that the amount of fatty acid was consistent with the total amount of extracted lipid.

Scientific advances in breeding, feeding practices, and analytical techniques may influence fatty acid composition data. Over the last 30 yr, feeding practices for beef cattle have increasingly shifted from forage-fed to grain-fed animals resulting in significantly higher levels of AA in the muscle of grain-fed animals (50). Also, it is assumed that cuts of meat presented in HB-8 reflect retail cuts of meat. But, retail beef is leaner than the values published in HB-8 (possibly reflecting the health-conscious trend of the public), and retail cuts may have multiple muscle groups associated with them (51).

The breed and age of an animal and an interaction of these two variables (52) also may affect fatty acid composition. For example, PUFA content of muscle phospholipids increase and SFA and MUFA decrease with age in Jersey and Limousin cows, and the level of AA in muscle phospholipids in mature Limousin cows is 28% higher compared to Jersey cows. In addition, the AA content in muscle phospholipids in heifers is almost 2.5 times higher than that of steers (52).

Most of the food analyses for HB-8 were performed in the 1970s and 1980s (35). For example, the HB-8 Series for poultry, pork, and beef products were issued in 1979, 1992, and 1990, respectively, but some of the data, such as poultry, originated from the mid 1960s and 1970s and have not been updated. The food analysis data published in HB-8 are derived from multiple sources including contracts with universities and commercial laboratories, contacts with the food industry, trade groups, academia, and other government agencies (35). Previously, fatty acid data were generated using packed-column gas chromatography, gas–liquid chromatography (43–45), and spectrophotometric methods (46); this may explain many of the missing values for the PUFA (see Tables 1 and 2). Recent advances in analytical techniques using internal standards and capillary gas chromatography improved the separation, identification, and measurement of fatty acids, in particular, longer-chain unsaturated fatty acids.

Finally, the inconsistency between our results and those in HB-8 could be related to the sample size used in this study, source of the samples, and the limited variation in the analyzed samples. We selected samples, as the public would, from a regional supermarket chain and analyzed 4–5 samples in each of the food categories. The sample size and the limited variation in the samples could account for the observed differences. The breeding and feeding practices of the animals from which the samples came are unknown. Similarly, this information is unavailable from the USDA, but the data published in HB-8 is based on a compilation of data from a variety of sources, seasons, and geographic locations as indicated previously.

In summary, our results suggest wide differences exist in the fatty acid content of individual foods when compared with the HB-8 values; these differences may be related to scientific advances in breeding, feeding practices, and analytical techniques. The content of AA in foods analyzed in this study was, for the most part, significantly higher than that reported in HB-8. Because of the importance of HB-8 as a reliable source of nutrient content in foods and for determining average daily intakes, a reevaluation of the fatty acid data may be warranted.

Involvement of Phospholipids in Apolipoprotein B Modification During Low Density Lipoprotein Oxidation

Angeliki I. Karakatsani[a], Theodoros A. Liapikos[a], Anastasios N. Troganis[b], and Demokritos C. Tsoukatos[a,*]

[a]Laboratory of Biochemistry, and [b]NMR Centre, Department of Chemistry, University of Ioannina, 45110 Ioannina, Greece

ABSTRACT: An increased amount of phospholipids remained attached on delipidated apolipoprotein B originated from oxidized low density lipoprotein (LDL). ^{31}P nuclear magnetic resonance analysis of such apolipoprotein showed an organic phosphorus peak at –0.55 ppm, which suggests the formation of adducts (most probably Schiff bases) of oxidized phospholipids with apolipoprotein B. The above reaction occurs in parallel with the hydrolysis of oxidized phospholipids, catalyzed by the LDL-attached platelet-activating factor acetylhydrolase, and may contribute to the proatherogenic effect of oxidatively modified low density lipoprotein.
Lipids 33, 1159–1162 (1998).

Recent studies have shown that oxidative modification of low density lipoprotein (LDL) plays an important role in the initiation and progression of atherosclerosis (1). Oxidation of LDL is a free radical, autocatalytic process. The polyunsaturated fatty acids (PUFA), which are bound in the different lipid classes of the LDL molecule, are the major targets of the active forms of oxygen. The initial products of phospholipid (PL) oxidation are their hydroperoxy derivatives which, after chain fragmentation, give rise to a variety of aldehydic lipid peroxidation products (2–4). This fragmentation also leads to polar PL, containing short-chain acyl groups at the *sn*-2 position (5). The oxidized PL (oxPL) serve as substrates for platelet-activating factor-acetylhydrolase (PAF-AH), which hydrolyzes them toward lysophospholipids (lyso-PL) (6). PAF-AH is an enzyme that is associated, in plasma, with LDL and high density lipoproteins (7,8), and that plays a major role in the regulation of the pathophysiologic effects of PAF (9).

The aldehydic peroxidation products react with ε-amino groups of lysine residues in apolipoprotein B (apoB), forming Schiff bases and thus contributing to the modification of apoB (3). Oxidized LDL (oxLDL) do not bind to LDL receptors, but instead are recognized by other types of receptors, namely, the acetylated LDL (10) or scavenger receptors (11,12), leading to foam cell formation, an early step of atherosclerosis (1). After delipidation of oxLDL, solubilized fractions of apoB are responsible for the recognition of oxLDL by the scavenger receptor (13). The aim of the present study was to investigate the possible involvement of the oxPL, generated during the oxidation of LDL, in the modification of apoB.

Abbreviations: ApoB, apolipoprotein B; LDL, low density lipoprotein; lyso-PC, lysophosphatidylcholine; nLDL, native LDL; NMR, nuclear magnetic resonance; oxLDL, oxidized LDL; oxLDLi, oxidized LDL treated with pefabloc; oxPL, oxidized phospholipids; PAF-AH, platelet activating factor-acetylhydrolase; PC, phosphatidylcholine; pefabloc, 4-[2-aminoethyl]benzenesulfonyl fluoride; PL, phospholipids; PLA_2, phospholipase A_2; PL-apoB, phospholipids bound to apoB; SDS, sodium dodecyl sulfate.

EXPERIMENTAL PROCEDURES

LDL preparation. LDL (d = 1.019–1.063) was prepared from freshly isolated, pooled, normolipidemic, human plasma containing 0.01% EDTA (wt/vol) and 5 μg/mL gentamicin sulfate (Garamycin, Schering-Plough, produced by Famar, Athens, Greece) by sequential ultracentrifugation (14) in a Beckman L7-65 ultracentrifuge (Fullerton, CA) at 40,000 rpm, 14°C for 10 h with a Type NVT65 rotor. The LDL preparation was dialyzed against 10 mM Tris buffer containing 0.9% NaCl (wt/vol) (pH = 7.4) for 24 h at 4°C. Then it was filter-sterilized (0.22 mM, Millipore, Bedford, MA) and stored in the dark at 4°C under nitrogen for up to 2 wk. LDL protein was determined using the Bicinchoninic Acid assay (BCA Protein Assay Reagent Kit; Pierce, Rockford, IL).

LDL oxidation. OxLDL was prepared by incubating LDL (1 mg of protein/mL) with 50 μM $CuSO_4$ in Tris buffer (pH = 7.4) at 37°C for 6 h. Oxidation was terminated by the addition of 0.01% EDTA and subsequent refrigeration. In some experiments 4-[2-aminoethyl]benzenesulfonyl fluoride (pefabloc) (Pefabloc SC, Pierce) (1 mM), an irreversible inhibitor of PAF-degrading AH, was added to the LDL preparation (oxLDLi) (15). The LDL oxidation was followed by the thiobarbituric acid-reactive substances assay and the relative electrophoretic mobility value on agarose gel electrophoresis.

Measurements. Total lipids of native LDL (nLDL) or oxLDL (treated or not with serine esterase inhibitor), corresponding to 0.5 mg of protein, were extracted according to Bligh and Dyer (16) and subjected to thin-layer chromatography on silica gel G plates using chloroform/methanol/water (65:35:6, by vol) as solvent system. Lipids were identified after brief exposure to iodine vapors, and the bands corresponding to the R_f of standard sphingomyelin, phosphatidylcholine (PC), lysophosphatidylcholine (lyso-PC), and phos-

phatidylethanolamine were scraped off the plate and submitted to phosphorus assay according to Bartlett (17) as modified by Marinetti (18). (Standard lipids were purchased from Sigma (St. Louis, MO) and solvents, analytical grade, from LAB-SCAN, Dublin, Ireland). The phosphorus assay was not affected by 100 mM sodium dodecyl sulfate (SDS) or by lipid peroxidation products formed during PL oxidation.

ApoB preparation. Delipidated, water-soluble apoB was prepared according to Cardin *et al.* (14). Briefly, LDL (nLDL, oxLDL, and oxLDLi) (4.5 mg/mL) was dialyzed for 24 h against 1 mM EDTA, pH = 8. The LDL was then lyophilized and subjected to four extractions with 12 mL of ether/ethanol (3:1, vol/vol). At each step of the extraction, the protein–solvent mixture was incubated at −20°C for 1 h and pelleted by low-speed centrifugation at −20°C; the solvent was then removed by aspiration. After the final extraction, the protein was washed once with anhydrous ether and pelleted, and the solvent was removed by aspiration while the protein was dried under nitrogen. The delipidated apoB was suspended in 2 mL of 10 mM Tris-HCl and 1 mM EDTA buffer (pH = 8.5) containing 100 mM SDS. Complete solubilization of apoB was achieved by gentle vortexing, followed by stirring at room temperature. ApoB was then dialyzed at 4°C against 10 mM Tris-HCl and 1 mM EDTA buffer (pH = 8.5) to remove the excess SDS. The apoB modification was tested by SDS-polyacrylamide gel electrophoresis (5–19% gradient) (20). Since the amount of phosphorus remaining attached to the delipidated apoB is a measure of PL bound to the apolipoprotein (PL-apoB), the apoB preparations were submitted to phosphorus assay.

^{31}P nuclear magnetic resonance (NMR) analysis. The ^{31}P NMR spectra were obtained at 161.9 MHz with a Bruker AMX-400 instrument (Rheinstetten-Forchheim, Germany). The chemical shifts were determined relative to the resonance position of 1% H_3PO_4 as an external standard. The resolution of spectra was enhanced by multiplication of the free-induction decay with a Gaussian exponential function (21).

RESULTS AND DISCUSSION

Table 1 shows the composition of plasma LDL PL which were separated by silica gel thin-layer chromatography, before and after oxidation of LDL, treated or not with the serine esterase inhibitor. In accordance with results reported previously by our laboratory (22) and other investigators (23), there was a marked loss of the PC content and an increase in the amount of lyso-PC after oxidation. No significant change was observed in the amount of the other PL, suggesting that PC and its oxidation and hydrolysis products may be involved in LDL modification. The increase in lyso-PC was higher when the LDL was oxidized in the absence of pefabloc, supporting the assumption (22) that PAF-AH is mainly responsible for the formation of lyso-PC on LDL, after PC oxidation.

Note that (Table 1) the sum of the amount PC + lyso-PC was significantly higher on nLDL than on oxLDL and oxLDLi. This finding suggests that PAF-AH hydrolyzes only a part of the oxidized PC products. As shown in Table 1, in accordance with Tertov *et al*. (24), an increased amount of phospholipids (PL), remained attached on oxidized apoB after delipidation (PL-apoB), suggesting that a part of oxidized PC might have formed adducts with apoB. The adducts of oxidized PL with apoB render the PL more hydrophilic, and thus they cannot be extracted in the chloroform phase of the Bligh and Dyer extraction mixture. The above can explain the decrease in the total amount of LDL PL after oxidation (Table 1), which was also reported by other investigators, working with oxidized human plasma (25).

To investigate the above suggestion further, we submitted delipidated apoB (1.5 mg/mL) before and after oxidation, with or without treatment with pefabloc, to ^{31}P NMR analysis. In some experiments apoB, from oxLDL, were treated with phospholipase A_2 (PLA_2) before the NMR analysis. The apoB preparation was incubated with 100 μg of PLA_2 (porcine pancreatic PLA_2; Boehringer, Mannheim, Germany) in the presence of 2 mM Ca^{2+} for 30 min, at room temperature.

TABLE 1
Composition of LDL Phospholipids Which Were Separated by Silica Gel Thin-Layer Chromatography, Before and After Oxidation of LDL[a]

PL	nLDL	oxLDL	oxLDLi	nLDL vs. oxLDL	nLDL vs. oxLDLi	oxLDL vs. oxLDLi
	(nmol PL/mg of protein)					
lyso-PC	24.3 ± 14.8	91.7 ± 24.7	46.5 ± 12.5	$P < 0.002$	$P < 0.02$	$P < 0.003$
Sph	272.8 ± 91.0	241.6 ± 105.0	271.5 ± 112.9	N.S.	N.S.	N.S.
PC	707.4 ± 163.1	403.1 ± 146.3	439.3 ± 202.1	$P < 0.02$	$P < 0.05$	N.S.
PE	32.3 ± 13.2	23.9 ± 12.9	28.2 ± 11.9	N.S.	N.S.	N.S.
Total PL	1034.7 ± 179.0	760.3 ± 196.8	785.5 ± 268.2	$P < 0.03$	N.S.	N.S.
lyso-PC + PC	731.7 ± 146.5	494.8 ± 117.5	485.8 ± 173.9	$P < 0.02$	$P < 0.03$	N.S.
PL-apoB	25.3 ± 9.6	68.0 ± 20.0	71.8 ± 18.4	$P < 0.01$	$P < 0.005$	N.S.

[a]Data represent mean ± SD from six independent LDL preparations and were compared by *t*-test for independent samples. $P < 0.05$ is considered significant. Abbreviations: LDL, low density lipoprotein; PL, phospholipid; nLDL, native LDL; oxLDL, oxidized LDL; oxLDLi, oxidized LDL treated with 4-[2-aminoethyl]benzenesulfonyl fluoride; lyso-PC, lysophosphatidylcholine; Sph, sphingomyelin; PE, phosphatidylethanolamine; PL-apoB, phospholipids bound to apolipoprotein B. N.S., not significant.

As shown in Figure 1A the ^{31}P NMR spectrum of delipidated apoB from nLDL shows one peak at –0.37 ppm corresponding to the PL remaining hydrophobically bound to the protein even after the delipidation process. This peak is observed in all the other preparations (Fig. 1B,C) and disappears after PLA_2 treatment, giving rise to two new peaks at –0.06 and –0.21 ppm, possibly corresponding to lyso PL (Fig. 1D). The ^{31}P NMR spectrum of PC in $CHCl_3$/MeOH/H_2O (50:50:15, by vol), showed two peaks at –0.40 and –0.37 ppm, whereas the spectrum of lyso-PC, in the same solvent mixture, showed one peak at –0.13 ppm (data not shown). In the apoB preparations originated from oxLDL (Fig. 1B,C) treated or not with pefabloc, a second peak of organic phosphorus at –0.55 ppm was observed, which could explain the higher amount of PL (Table 1) attached on apoB after oxidation. Moreover, the ratios of the integrals of the two peaks, 1:2 and 1:2.5, for apoB from oxLDL and oxLDLi are in agreement with the results from the PL attached on delipidated apoB observed in Table 1. The amount of PL that remained hydrophobically bound to apoB even after the delipidation procedure, calculated by the integrals of the two peaks of the ^{31}P NMR spectrum (Fig. 1B,C) and the total amount of PL bound to delipidated apoB (Table 1), did not exceed the 22–25 nmol per mg apoB. It corresponded to the amount of PL-apoB measured by the phosphorus assay on apoB derived from nLDL (Table 1). The second peak of organic phosphorus at –0.55 ppm was only slightly affected by the PLA_2 treatment(Fig. 1D). The observed magnetic shielding of phosphorus and the failure of PLA_2 to recognize and hydrolyze the *sn*-2 ester bond, presented in Figure 1B,C,D, support the suggestion that adducts of oxidized forms of PC with apoB are formed during LDL oxidation. The possibility that lyso-PC also accounts for the above adducts could not be excluded. However, in this case the second phosphorus peak in Figure 1B would be expected to be higher than that of Figure 1C, since lyso-PC formation on oxLDL without PAF-AH inhibition is twofold higher than that on oxLDLi (Table 1).

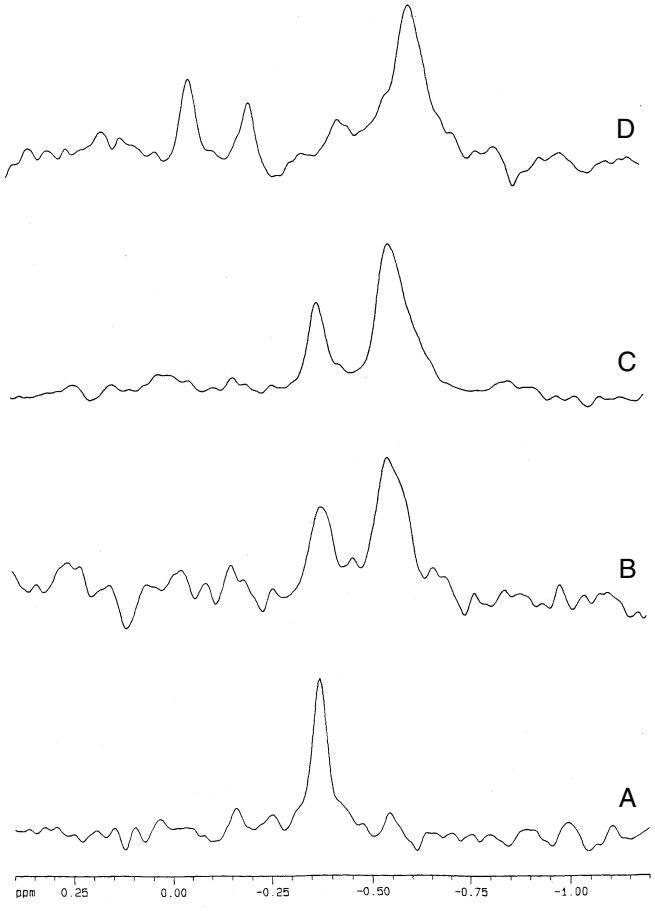

FIG. 1. Conventional ^{31}P nuclear magnetic resonance spectrum of apolipoprotein B. (A) From native low density lipoprotein (LDL), (B) from oxidized LDL, (C) from oxidized LDL treated with 4-[2-aminoethyl]benzenesulfonylfluoride (pefabloc), and (D) from oxidized LDL treated with pefabloc and phospholipase A_2. Solvent, temperature and acquisition parameters for A–D are as follows: 10 mM Tris-HCl and 1 mM EDTA, at 300 K, 5 mm sample tube, on a Bruker AMX-400 instrument (Rheinstetten-Forchheim, Germany). Spectral acquisition parameters: 0.74 s acquisition time, 4 hHz spectral width, 2 s relaxation delay time, 36000 scans.

The present work does not elucidate the chemical character of the adducts mentioned above. OxPL with semialdehydic oxidized short-chain fatty acid in the *sn*-2 position are formed during oxidation (26), and the aldehydic group esterified on the PL backbone may react with the proteins to form Schiff base adducts (27). The above evidence, together with our results, strongly suggests that Schiff base adducts of PL could be formed with the lysine residues of apoB. This reaction occurs in parallel with the hydrolysis of oxPL to lyso-PL, a reaction catalyzed by the LDL attached PAF-AH, and may have an important role in apoB modification during oxidation and the pathophysiological effects of oxLDL.

Fish Oil Supplementation With and Without Added Vitamin E Differentially Modulates Plasma Antioxidant Concentrations in Healthy Women

E. Turley, J.M.W. Wallace, W.S. Gilmore, and J.J. Strain*

The Northern Ireland Centre for Diet and Health (NICHE), University of Ulster, Coleraine, Northern Ireland, BT52 1SA, United Kingdom

ABSTRACT: The purpose of this study was to assess the effect of fish oil with or without vitamin E on plasma vitamin antioxidants. Thirty-three apparently healthy women aged 18–28 yr were recruited from the university environs, and 30 completed the double-blinded, parallel design supplementation trial. Blood samples were collected at baseline (week 0) and following 28 d of supplementation with three capsules/d (0.8 g × 3) of either fish oil (FO) or FO with vitamin E (3 IU/g) (FOE). An additional blood sample was taken at day 91 (washout). Plasma antioxidant vitamins, fatty acid composition, and lipid peroxides were measured. Plasma α-tocopherol concentrations were increased significantly in both groups postsupplementation FO ($P = 0.018$) and FOE ($P = 0.003$) compared with baseline and washout values. Plasma retinol concentration was significantly increased ($P = 0.034$) compared with baseline and washout values following supplementation with FOE but not FO, while plasma β-carotene was significantly increased ($P = 0.036$), compared with baseline and washout values, following supplementation with FO but not FOE. There was a trend ($P = 0.059$) toward decreased plasma ascorbic acid following FO supplementation compared with baseline and washout. Plasma lipid peroxides did not change following either supplementation. Results suggest that low-dose FO feeding with and without vitamin E differentially modulates plasma antioxidant vitamins but has no significant effect on lipid peroxidation.

Lipids 33, 1163–1167 (1998).

Epidemiological studies linking fatty fish consumption with a low incidence of coronary heart disease have led to numerous clinical trials. Evidence that fish oils (FO) do not act on a single aspect, but rather modulate the entire cascade of factors involved in atherogenesis—curbing the excesses and correcting the deficiencies—continues to accumulate from these clinical trials.

Concurrent with the proposed beneficial effects, workers caution that potential side effects of fish oil supplementation are increased vitamin E requirements and increased oxidative stress *in vivo* (1). Vitamin E deficiency is induced with pharmacological doses of FO over prolonged periods of time in animal studies (2). Likewise in human trials, administration of 30 mL/d of FO results in decreased serum vitamin E (3). The importance of vitamin E in maintaining the biological integrity of cells and lipoproteins is well established (4). Epidemiological studies usually link high plasma α-tocopherol with low incidence of coronary heart disease (5), whereas decreased plasma α-tocopherol is associated with increased susceptibility to lipid peroxidation (6). In many animal and human studies, the decreases in plasma vitamin E are only a reflection of decreases in circulating lipoproteins following FO supplementation (7,8).

More subtle and perhaps more physiologically relevant effects of FO on vitamin E status have not been reported in detail, as most supplementation studies use FO with added vitamin E FOE and often use pharmacological doses of FO. The lack of a sensitive and accurate marker for *in vivo* lipid peroxidation and the presence of vitamin E in all commercial FO preparations have hampered progress toward resolving the effects of n-3 polyunsaturated fatty acids on antioxidant status *in vivo*.

Reported effects of high-dose FO supplementation decreasing plasma α-tocopherol and increasing lipid peroxidation, coupled with high-dose FO feeding being used to induce vitamin E deficiency in animals, have lead to a generalized acceptance that FO supplementation is liable to result in oxidant stress *in vivo*. This study, using 2.4 g of FO/d [equivalent to approximately 0.72 g of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)], comparable to that used in the Diet and Reinfarction Trial (DART) which proved to be cardioprotective (9), focused on the effects of FO prepared without any vitamin E (FO) on plasma antioxidant vitamin status and lipid peroxide levels in healthy female volunteers, using FOE as a positive control.

MATERIALS AND METHODS

Subjects and protocol. A total of 33 healthy women volunteers (mean age 22; range 18–28 yr) were recruited from university staff and students. Informed consent was obtained and the study protocol was approved by the University of Ulster Research Ethical Committee. Eligibility for enrollment re-

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FO, fish oil; FOE, fish oil with vitamin E; MDA, malondialdehyde.

quired that subjects be healthy women; aged 18–30 yr; not pregnant; and not currently using aspirin, anti-inflammatory agents, vitamin, mineral or other nutritional supplements.

The study was conducted on a double-blind, parallel design with washout. FO supplementation studies are notoriously difficult to blind or to provide an appropriate placebo; therefore, FOE was used as a positive control. Subjects were randomly assigned to one of two groups and were required to take three capsules (0.8 g × 3) daily of either FO or FOE (3 mg/g) for 28 d and give three blood samples. The FO (a gift from Seven Seas Ltd., Hull England) provided approximately 18% EPA and 12% DHA. Sodium dodecyl gallate was present (100 ppm) as an antioxidant in both preparations. Compliance was assessed through close personal communication with the subjects, and changes in plasma total fatty acid were analyzed. Blood samples (25 mL) were taken, by venipuncture, at day 0 (baseline), day 28 (postsupplementation), and day 91 (washout). Subjects were requested to maintain their usual dietary habits and activity levels throughout the study.

Venous blood (25 mL) was drawn, carefully avoiding stasis into tubes containing lithium heparin. Samples were centrifuged at 2000 rpm for 15 min. The plasma was removed, aliquoted for each assay, and stored at −70°C. Plasma for ascorbate analysis was stabilized immediately with 50 g/L metaphosphoric acid before storage. Following the collection of the final washout blood samples, samples were batch-analyzed.

Ascorbate in plasma. Plasma ascorbate was measured by electrochemical detection following reverse-phase chromatography through a 10 cm Spherisorb-C18 3 μm ODS2 column and a 201-PSC guard column (5 × 0.4 cm) (Technicol Ltd., Manchester, United Kingdom). Homocysteine (100 mg/L) was added to the mobile phase to stabilize the ascorbate during chromatography. The mobile phase (pH 5.5) was run at a flow rate of 1 mL/min and contained 0.1 M sodium acetate (pH 5.0), 1 mM octylamine, and 200 mg/L Na_2EDTA (10).

Fat-soluble vitamins in plasma. Fat-soluble vitamins in plasma were assessed using reverse-phase high-performance liquid chromatography by the method of Thurnham *et al*. (11). The mobile phase was methanol/dichloromethane/acetonitrile (500:128:500, by vol, with 10 mg butylated hydroxytoluene), and samples were run on a Spherisorb 53-micron (ODS2) 10-cm column. In this method the samples were extracted with *n*-hexane, evaporated to dryness under nitrogen gas, and reconstituted in the mobile phase. Plasma lipid levels were measured on the Cobas Fara Automatic Analyser. Total cholesterol was assessed using a kit (Roche Diagnostic Systems, Basel, Switzerland).

Plasma EPA and DHA. Total lipids were extracted with chloroform/methanol (2:1, vol/vol) containing butylated hydroxytoluene as an antioxidant and dried under nitrogen gas. Fatty acids were transmethylated with sulfuric acid and methanol. Fatty acid methyl esters were separated on a fused-silica capillary column (SGE; Foss Scientific, Belfast, United Kingdom) in a gas–liquid chromatograph equipped with a flame-ionization detector.

Lipid peroxide analysis. Lipid peroxides were measured using commercial kits (LPO-586 Biotech). A patented chromogenic agent reacts with malondialdehyde (MDA) and 4 hydroxynonenal at 45°C to give a stable chromophore with maximal absorbance at 586 nm. The detection threshold of the assay is quoted by the manufacturers as 0.5 μM; reproducibility determined over 10 d gave SEM values lower than 5%.

Assessment of food intake. Subjects' habitual food intake was assessed by diet history interview. The method established meal patterns in both working and weekend days and obtained details of meals and snacks in terms of a description of the food and an outline of portion sizes. Food portions were quantified using standard food portion sizes (12) and analyzed for composition using the computerized dietary analysis program, Food Base (The Institute of Brain Chemistry and Human Nutrition, version 1.2, 1992).

Statistical analysis. Differences between values at the baseline, postsupplementation, and washout were tested using multivariate analysis of variance for repeated measures with the least significant difference *post-hoc* test. All data are expressed as mean ± standard error (SE) with each subject acting as her own control.

RESULTS

Of the 33 subjects enrolled, 30 completed the study; the three withdrawals were for personal reasons unrelated to supplementation. Oral communication, between investigator and subjects, and the change in plasma total fatty acid profile (Fig. 1) suggested good compliance with the supplementation regime. EPA and DHA were undetectable in the plasma of this healthy population at baseline. EPA and DHA were still detectable following 63 d of washout. The supplements were generally well tolerated, although subjects did complain of experiencing a "fishy" aftertaste. Dietary intakes of the antioxidant vitamins E and C were within the normal range for this population group (Table 1). Group intakes were not significantly different.

Following FO supplementation (Table 2), plasma ascorbate was decreased ($P = 0.059$) when compared with baseline and washout. Plasma α-tocopherol increased ($P = 0.018$) postsupplementation. This effect, however, was nonsignificant when α-tocopherol was corrected for cholesterol concentration. Plasma β-carotene increased ($P = 0.036$) postsupplementation with FO when compared to baseline and washout.

The FOE supplementation (Table 2) resulted in a significant increase in plasma α-tocopherol ($P = 0.003$) and in α-tocopherol corrected for cholesterol ($P < 0.000$) postsupplementation compared with baseline and washout. Likewise, plasma retinol increased ($P = 0.034$) postsupplementation.

Neither supplementation regime showed any effects on plasma lycopene, lutein, α-carotene, and γ-tocopherol (data not shown) or on lipid peroxidation as assessed by plasma MDA and 4-hydroxynonenal levels. In the FO group ($n = 14$) the mean ± SE values for MDA and 4-hydroxynonenal (μmol/L) for baseline, postsupplementation, and washout were 10.0 ± 1.0, 10.6 ± 1.5, and 11.5 ± 1.0, respectively. For the FOE group ($n = 16$), the corresponding values were 10.6 ± 1.2, 10.6 ± 1.0, and 12.3 ± 1.0.

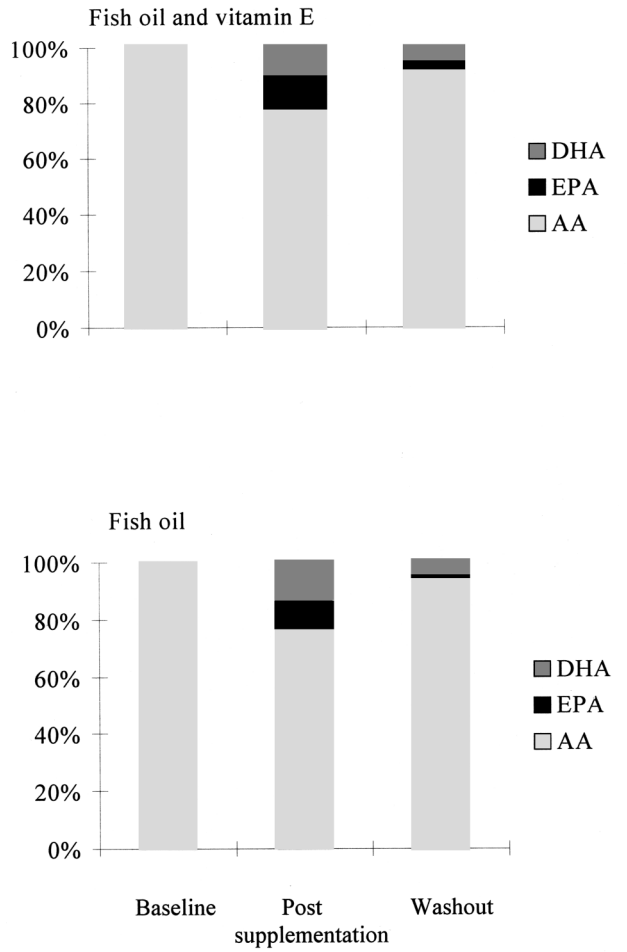

FIG. 1. Changes in percentage distribution of plasma long-chain C_{20} and C_{22} fatty acids following fish oil supplementation of healthy female volunteers. Only the long-chain polyunsaturated fatty acids were assessed. Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; AA, arachidonic acid.

When comparing the effect of the oils on plasma antioxidant status, the notable difference was the effect on plasma ascorbate, with FO producing a nonsignificant decrease and FOE a nonsignificant increase in plasma ascorbate concentration.

TABLE 1
Daily Intakes of Energy, Vitamin E, and Vitamin C by the Healthy Female Volunteers[a]

	Fish oil and vitamin E (FOE) (n = 16)	Fish oil (FO) (n = 14)
Energy (kJ)	8761 ± 367	9299 ± 433
Fat (% energy)	37%	35%
Protein (% energy)	15%	14%
Carbohydrate (% energy)	48%	51%
Vitamin E (mg)	9.8 ± 0.93	11.4 ± 1.30
Vitamin C (mg)	90.0 ± 11.3	83.2 ± 9.3

[a]Values reported as mean ± SE.

DISCUSSION

The essential paradox of FO supplementation is that, while many workers highlight that it is accompanied by an increased requirement for vitamin E, the purported health benefits accruing from FO are generally antioxidant in nature and show functional similarities with vitamin E *in vivo* (13).

This study was conducted to compare the effects of low doses of FO, with or without added vitamin E, on plasma antioxidant vitamins in healthy female volunteers. This low dose was found to modulate leukocyte function and cytokine production in these subjects (14).

The increases in plasma α-tocopherol and tocopherol/lipid ratio following both supplementation regimes are notable. The level of vitamin E in the FOE oil is relatively low (7.2 IU/d), supplementation with vitamin E usually is in the range of 50–1000 IU/d. It appears that low-dose FO, the only natural polyunsaturated fatty acid rich oil not loaded with vitamin E, has the capacity to mobilize α-tocopherol in plasma. Shapiro *et al.* (15) found that using MaxEPA, a commercial FO rich in EPA (18 g/d, approximately 5 g n-3 fatty acids), for 6 wk increased plasma α-tocopherol. Luostarinen *et al.*

TABLE 2
Effect of Supplementation on Plasma Antioxidant Vitamins in Healthy Female Volunteers

Variable	Baseline (mean ± SE)	Postsupplementation (mean ± SE)	Washout (mean ± SE)	Significance level[a]

Retinol (μmol/L)	1.69 ± 0.09	1.92[a] ± 0.12	1.78 ± 0.08	.034*

[a]Differences at each of the sample times were tested using multivariate analysis of variance for repeated measures with least significant differences. *$P \leq 0.05$; **$P \leq 0.01$; ***$P \leq 0.001$; [a]denotes significantly different from baseline and washout. For abbreviations see Table 1.

(16), however, showed that supplementing with 30 mL/d FO (8.6 g n-3 fatty acids) produced no change in plasma α-tocopherol. Older populations are more susceptible to oxidative stress, and FO supplementation has been shown to decrease plasma α-tocopherol in these subjects (17). Moreover FO supplementation resulted in a significant decrease in plasma α-tocopherol in non-insulin-dependent diabetics (18).

FO may modulate vitamin E absorption, transport, storage and utilization. Absorption of vitamin E is dependent upon digestion and absorption of fat. Free tocopherols are absorbed by a nonsaturable passive process into the lymphatic circulation (19). The effects of differing fatty acids, ethyl esters, and triacylglycerols on this process are unclear. There have been relatively few investigations of how vitamin E can exchange between lipoproteins and red blood cells, and between plasma and red blood cells. Vitamin E is known to exchange more slowly than cholesterol but more rapidly than triacylglycerols. Although a transfer protein is not required for exchange to occur, transfer will be affected by low density lipoprotein receptor and lipoprotein lipase function (20,21).

Total plasma vitamin E concentration, however, is not considered a suitable predictor of cell vitamin E status (22). It has been shown that FO (15 g/d) given for 10 wk can lower plasma, red blood cell, and platelet α-tocopherol (23). Animal experiments have shown that immune cell vitamin E status seems particularly resistant to any decrease following FO supplementation despite significantly decreased plasma and liver α-tocopherol concentrations (24).

In the present study FO supplementation resulted in a significant increase in β-carotene. Mean plasma concentration of β-carotene shows seasonal variation with a twofold increase from July to September (25). It has been calculated that the critical difference for two serial results to be significantly different ($P < 0.05$) is such that, at a level of 0.5 μmol/L, an increase of 0.8 μmol (160%) is required (25). Therefore, the difference observed here of only 12.5% may reflect natural variation in plasma levels over the study period. FOE supplementation had no significant effect on plasma β-carotene but did significantly increase plasma retinol compared with baseline. This is in agreement with other studies (26,27) and may reflect the retinal esters content of commercial FO products (26) although FO did not show a similar effect. Others have suggested that FO modulates the conversion of β-carotene to retinol (23).

While the change in plasma ascorbate following either oil was insignificant, the contrasting effect of FO, which decreased plasma ascorbate, and FOE, which increased plasma ascorbate, is notable. Relatively little has been published concerning the effect of FO supplementation on plasma ascorbate. Weber *et al*. (27) reported FO supplementation had no effect on plasma ascorbate.

FO or FOE supplementation had no effect on plasma lipid peroxidation as indicated by the lack of change in hydroxyalkanes and MDA concentration. Higher doses of FO have been shown to increase MDA production, because MDA is a marker of peroxidation only of fatty acids with three or more double bonds. Increases, however, have been reported as transitory, with values returning to normal within the first 4 wk of supplementation (28).

In conclusion, this study showed that FO and FOE have modulatory effects on plasma α-tocopherol, retinol, and β-carotene concentrations and differential effects on plasma ascorbate. Plasma antioxidant status appeared to remain adequate among these healthy young women as there was no change in lipid peroxide concentrations in either group. Further work is required to examine the potential role of FO in modulating plasma and cellular antioxidant status.

ABSTRACT: The effects of vitamin E on cholesteryl ester (CE) metabolism in J774 cells were examined. Pretreatment of J774 cells with vitamin E at concentrations above 50 μM significantly decreased acetylated low density lipoprotein (LDL)-induced incorporation of [^{14}C]oleate into CE in cells in a dose-dependent manner. This was partly due to vitamin E also significantly inhibiting the uptake of [^{3}H]CE-labeled acetylated LDL by J774 cells. A trend existed toward suppression of acyl-CoA:cholesterol acyltransferase (ACAT) activity in the cell lysate at high vitamin E concentration, but there was no effect on hydrolysis of CE. These data indicate that vitamin E reduces the uptake of modified LDL and suppresses ACAT activity, resulting in less cholesterol esterification in macrophages: a novel mechanism underlying the antiatherogenic properties of vitamin E.
Lipids 33, 1169–1175 (1998).

Epidemiological studies demonstrated that antioxidant consumption, especially of vitamin E, is inversely correlated with the incidence of coronary heart disease (CHD) (1–6). Previous studies reported that vitamin E is one of the most effective antioxidants present in low density lipoprotein (LDL), and that its supplementation protects LDL from oxidative stress *in vitro* (7–9). Moreover, vitamin E is believed to exert additional effects that could result in antiatherogenic activities (10–15).

Formation of foam cells in arterial walls is an important event in the early stage of atherogenesis. Foam cells in atheromatous plaques are thought to be derived predominantly from monocyte-derived macrophages (16). The macrophages take up oxidized LDL through scavenger receptors, accumulate cholesteryl ester (CE), and are transformed into foam cells (17,18). CE accumulation in cells is mediated by the intracellular esterification of cholesterol by acyl-CoA:cholesterol acyltransferase (ACAT). Several studies addressed the effects of vitamin E on the formation of foam cells (19–21). Van der Schroeff *et al.* (19) reported that low doses of vitamin E failed to suppress the accumulation of CE in J774 cells that was induced by acetylated LDL. Suzukawa *et al.* (20) reported that enrichment of J774 cells with vitamin E inhibited macrophage-mediated oxidation of LDL and inhibited CE formation in J774 cells. In that study, however, no information was provided on whether these effects of vitamin E on foam cell formation were due to a decreased capacity of macrophages to oxidize LDL or to effects on cholesterol metabolism. Asmis *et al.* (21) reported that the enrichment of P388D macrophages with vitamin E reduced the cellular ratio of CE/free cholesterol after incubation with fetal bovine serum (FBS), but without significantly changing CE accumulation induced by modified LDL. Thus, the effects of vitamin E on CE accumulation induced by atherogenic lipoproteins in macrophages remain unclear.

In the present study, we examined the effects of cellular (J774 cells) enrichment with vitamin E on whole-cell cholesterol esterification, ACAT activity, lipoprotein uptake, and cellular CE hydrolysis.

METHODS

Materials. DL-α-Tocopherol and L-ascorbic acid were obtained from Wako Pure Chemicals (Osaka, Japan). Dulbecco's modified Eagle's medium (DMEM) was obtained from Flow Laboratories (ICN Biochemical, Auroa, OH). Oleic acid, oleoyl CoA, phenylmethylsulfonyl fluoride (PMSF), and bovine serum albumin were obtained from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]Oleic acid and [1-^{14}C]oleoyl CoA were obtained from New England Nuclear (Boston, MA). [1a,2a(*n*) ^{3}H]Cholesteryl oleate and [1a,2a(*n*) ^{3}H]cholesteryl linoleate were obtained from Amersham (Arlington Heights, IL).

Cell culture. J774 macrophages (RIKEN Cell Bank, Tsukuba, Japan) were grown in DMEM containing 10% (vol/vol) FBS. For each experiment, the cells were cultured in 12-well Multiwell (Falcon, Franklin Lakes, NJ) cultured plates at 37°C in 5% CO_2 and 95% air.

Isolation, modification, and labeling of LDL. Blood was collected in vacutainer tubes containing 1 mg/mL of EDTA

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; ANOVA, analysis of variance; CE, cholesteryl ester; CHD, coronary heart disease; DMEM, Dulbecco's modified Eagle's medium; FBS, fetal bovine serum; LDL, low density lipoprotein; LPDS, lipoprotein-deficient serum; PBS, phosphate buffer saline; PKC, protein kinase C; PMSF, phenylmethylsulfonyl fluoride; TLC, thin-layer chromatography.

from healthy male volunteers fasted overnight. LDL ($1.019 < d < 1.063$ g/mL) was isolated by sequential ultracentrifugation (22). LDL was acetylated by the method of Basu *et al*. (23). CE in LDL was labeled by exchange with a microemulsion containing [^{3}H]cholesteryl linoleate by the method of Zhang *et al*. (24). [^{3}H]CE-labeled LDL was acetylated by the method of Basu *et al*. (23). Specific activity of [^{3}H]CE-labeled LDL and acetylated LDL was 1027 ± 16 and 1235 ± 15 dpm/μg protein, respectively. LDL, acetylated LDL, [^{3}H]CE-labeled LDL, and [^{3}H]CE-labeled acetylated LDL were extensively dialyzed at 4°C against 0.15 M NaCl, 0.24 mM EDTA, pH 7.4. Each lipoprotein was sterilized by filtration (0.22 μm). Lipoprotein-deficient serum (LPDS) was prepared by the method of Goldstein *et al*. (25). The contents of protein in each lipoprotein and LPDS were determined by the method of Lowry *et al.* (26).

Enrichment of J774 macrophages with vitamin E. Monolayers of cells were incubated in DMEM with 10% FBS and with 10–200 μM of vitamin E. Cultured medium was supplemented with vitamin E dissolved in ethanol (10 μL ethanol/1 mL DMEM) and then incubated at 37°C for 24 h. The same amount of ethanol without vitamin E was added to control dishes.

Whole-cell cholesterol esterification assay in J774 cells. Whole-cell cholesterol esterification in J774 cells was assayed by the method of Goldstein *et al*. (25). Monolayers of J774 cells were incubated in DMEM containing 10% LPDS and 0.2 mM of [1-^{14}C]oleate-albumin (5,500 dpm/nmol) in the presence or absence of acetylated LDL for 6 h. After incubation, cellular lipids were extracted by hexane/isopropanol (3:2, vol/vol). [1,2-^{3}H]Cholesteryl oleate was added to the solvent as an internal standard. CE was isolated by thin-layer chromatography (TLC) developed in heptane/ethyl ether/acetic acid (90:30:1, by vol), and radioactivity assayed. After the lipids were extracted, the cells were dissolved, and cellular protein was determinated by the Lowry *et al.* procedure.

Uptake of [^{3}H]CE-labeled lipoprotein in J774 cells. Monolayers of J774 cells were incubated in DMEM containing 10% LPDS with 5 μg/mL [^{3}H]CE-labeled lipoproteins for 24 h. After incubation, cell monolayers were washed by phosphate buffer saline (PBS), and total lipids were extracted as described above. The organic solvent was collected and measured by scintillation counting. After the lipids were extracted, cellular protein was determined as described above.

Cell-free extract ACAT activity assay. ACAT activity was assayed in cell-free extracts by a modification of the method of Nagayoshi *et al*. (27). Cell-free extracts were prepared by suspending pellets of J774 macrophages from 60-mm dishes in 1 mL of sucrose buffer (10 mM Tris-HCl buffer, pH 7.5, containing 250 mM sucrose, 0.1 mM PMSF, and 0.1 mM EDTA), and then sonicated. The sonicated cells were then centrifuged for 15 min at $10{,}000 \times g$ at 4°C, and clear supernatants were assayed both for ACAT activity and for protein content using the Lowry *et al.* procedure. Twenty-five μL of extract was incubated in 225 μL of 0.1 M potassium phosphate buffer, pH 7.4, containing 0.02 mM bovine serum albumin for 5 min, then 5 nmol [1-^{14}C]oleoyl CoA was added to each extract. After incubation for 5 min, the reaction was terminated, and [^{3}H]cholesteryl oleate was added as an internal standard. The cholesteryl [^{14}C]oleate in the chloroform/methanol extracts was isolated by TLC as described above.

Hydrolysis of cholesteryl [1-^{14}C]oleate in J774 cells. Hydrolysis of cholesteryl [^{14}C]oleate was assayed by the method of Tomita *et al*. (28). [^{14}C]Oleic acid was incorporated into CE in cells by incubating for 24 h with 0.2 mM [^{14}C]oleic acid–albumin complex and acetylated LDL. Cell monolayers were extensively washed with PBS and were further incubated for indicated times in fresh medium with 10% LPDS in the presence or absence of vitamin E. The radioactivity of remaining cholesteryl [^{14}C]oleate was extracted and counted as described above. The hydrolyzed amount of cholesteryl [^{14}C]oleate was calculated by subtracting the remaining cholesteryl [^{14}C]oleate radioactivity from that at time 0.

Vitamin E measurement. The vitamin E content of J774 cells was measured by the method of Bieri *et al*. (29).

Statistical analysis. Data are presented as means ± SE. Groups were compared by one-way analysis of variance (ANOVA). Bonferroni test was performed with $P < 0.005$ level of significance to adjust for multiple testing, when there were indications of significance by one-way ANOVA.

RESULTS

To investigate the effect of vitamin E on whole-cell cholesterol esterification, J774 cells were loaded with 10–200 μM vitamin E. Cytotoxicity, as assessed by trypan blue procedures and lactic dehydrogenase assay in the medium, was not apparent in cells incubated in DMEM containing 10% FBS and indicated concentrations of vitamin E. In the absence of vitamin E in the medium, cellular vitamin E could not be detected in J774 cells. After incubation of J774 cells with medium containing 10–200 μM vitamin E for 24 h, the vitamin E content of J774 cells increased up to 6.8 ± 1.1 nmol/mg protein in a dose-dependent manner.

Pretreatment of J774 cells with vitamin E at doses up to 200 μM inhibited whole-cell cholesterol esterification inducible with acetylated LDL (Fig. 1A). The content of cholesteryl [^{14}C]oleate in nonstimulated cells (no addition of acetylated LDL) was 1.25 nmol/mg/6 h cell protein. In the presence of 50 μg/mL of acetylated LDL, the content of cholesteryl [^{14}C]oleate in cells was 9.2-fold that without acetylated LDL (11.45 vs. 1.25 nmol/mg cell protein/6 h). Vitamin E significantly inhibited whole-cell cholesterol esterification in a dose-dependent manner ($P < 0.0001$, one-way factorial ANOVA). In the cells pretreated with 50 μM of vitamin E [which is found in plasma with moderate vitamin E supplementation (30)], whole-cell cholesterol esterification was 14% lower than that in cells without vitamin E (9.9 vs. 11.45 nmol/mg protein/6 h, $P < 0.0001$). In the cells pretreated with 200 μM of vitamin E, it was 55% lower than that in the absence of vitamin E (5.2 vs. 11.45 nmol/mg protein/6 h, $P < 0.0001$). Pretreatment of J774 cells with vitamin C over a

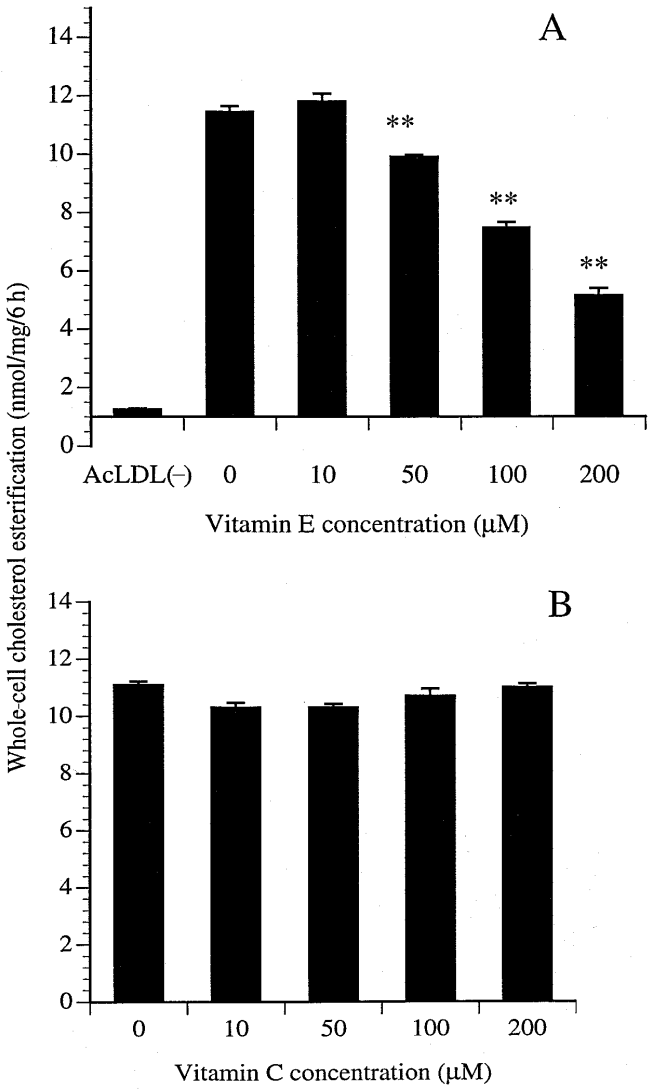

FIG. 1. Effects of vitamin E and vitamin C on whole-cell cholesterol esterification in J774 cells incubated with acetylated low density lipoprotein (AcLDL). J774 cell monolayers were incubated in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS) and indicated concentrations of vitamin E (A) or vitamin C (B) for 24 h. Thereafter cells were thoroughly washed with phosphate buffered saline (PBS) and further incubated in DMEM containing 10% lipoprotein-deficient serum (LPDS), 50 μg/mL AcLDL, and 0.2 mM [^{14}C]oleate-albumin for 6 h. After incubation, cells were washed thoroughly by PBS, and cellular lipids were extracted with 2 mL of hexane/isopropanol (3:2, vol/vol), and developed by thin-layer chromatography (TLC) with developing solvent [heptane/ethyl ether/acetic acid (90:30:1, by vol)]. Cholesteryl [^{14}C]oleate was quantified by liquid scintillation counting. Data represent means ± SE of 12 dishes. $^{**}P < 0.0001$ compared to control (without vitamin E).

range of concentrations failed to inhibit acetylated LDL-induced whole-cell cholesterol esterification (Fig. 1B).

The inhibition of acetylated LDL-inducible whole-cell cholesterol esterification by vitamin E could occur at several steps. First, we investigated whether this represented reduced substrate availability, thus measuring the effects of vitamin E on the lipoprotein uptake by J774 cells. After incubation of J774 cells with vitamin E for 24 h, cells were further incubated in DMEM containing 10% LPDS with 5 μg protein/mL of [^{3}H]CE-labeled acetylated LDL or [^{3}H]CE-labeled native LDL for 24 h. Supplementation of J774 cells with vitamin E significantly decreased the uptake of [^{3}H]CE-labeled acetylated LDL in a dose-dependent manner ($P < 0.001$, one-way ANOVA) (Fig. 2A). The uptake of acetylated LDL was 9% lower in cells pretreated with 50 μM of vitamin E than in the absence of vitamin E (5.9 vs. 6.5 μg protein/mg cell protein, $P < 0.005$), and was 17% lower in the cells pretreated with 200 μM of vitamin E compared with those without vitamin E (5.4 vs. 6.5 μg protein/mg cell protein, $P < 0.001$). On the other hand, vitamin E had no effect on the uptake of native LDL (Fig. 2B). These data indicate that enrichment of cells with vitamin E selectively inhibits the uptake of acetylated

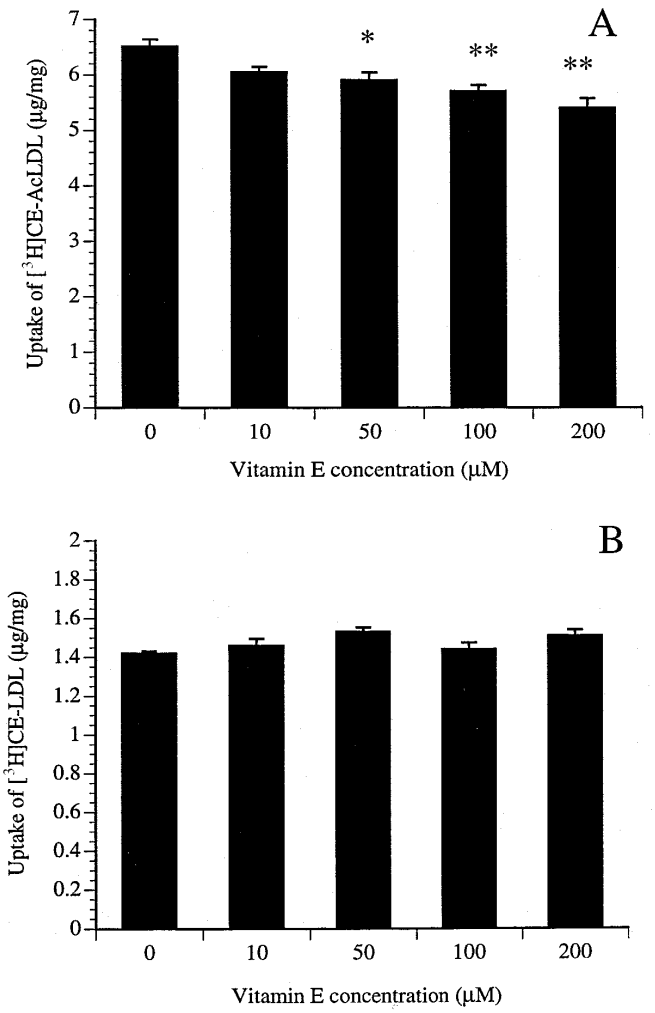

FIG. 2. Effects of vitamin E on the uptake of [^{3}H]cholesteryl ester (CE)-labeled AcLDL and [^{3}H]CE-labeled native LDL by J774 cells. J774 cells were incubated in DMEM containing 10% FBS and indicated concentrations of vitamin E for 24 h. Thereafter cells were washed with PBS and further incubated in DMEM containing 10% LPDS and 5 μg/mL of [^{3}H]CE-labeled AcLDL (A) or [^{3}H]CE-labeled native LDL (B) for 24 h. After incubation, cells were thoroughly washed with PBS, cellular lipids were extracted, and [^{3}H]CE was counted by scintillation counting. Data represents means ± SE of 12 dishes. $^{*}P < 0.005$, $^{**}P < 0.001$, compared to control (without vitamin E). See Figure 1 for other abbreviations.

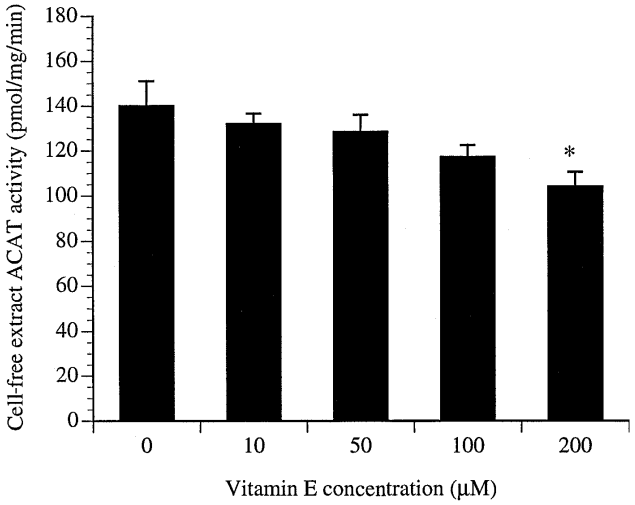

FIG. 3. Effects of vitamin E on cell-free extract acyl CoA:cholesterol acyltransferase (ACAT) activity in J774 cells. J774 cells were incubated in DMEM containing 10% FBS and indicated concentrations of vitamin E for 24 h. Thereafter cells were thoroughly washed with PBS and harvested. Cell-free extracts were assayed for ACAT activities. Data represent means ± SE of 16 dishes. *$P < 0.005$ compared to control (without vitamin E). See Figure 1 for other abbreviations.

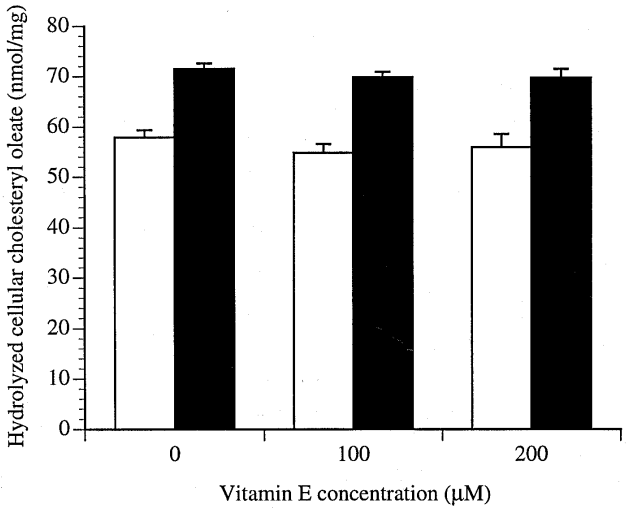

FIG. 4. Effects of vitamin E on hydrolysis of esterified cholesterol in J774 cells. J774 cells were loaded with cholesteryl [^{14}C]oleate as described in the Methods section and were then incubated in fresh DMEM containing 10% LPDS and indicated concentrations of vitamin E for 24 or 48 h. Thereafter cells were washed with PBS, cellular lipids were extracted, and cholesteryl [^{14}C]oleate was quantified as described in the legend to Figure 1. The cellular content of cholesteryl [^{14}C]oleate at time 0 was 95.45 ± 3.45 (mean ± SE of 12 dishes). Data represent means ± SE of six dishes. □, 24 h; ■, 48 h. See Figure 1 for abbreviations.

LDL, but not of native LDL. These data suggested that decreased uptake of acetylated LDL in vitamin E-treated cells may have at least partly accounted for decreased whole-cell cholesterol esterification.

Calculations based on data in Figures 1 and 2 showed that 50 μg/mL of acetylated LDL (3.0 nM total cholesterol/μg protein) delivered 49 nmol of cholesterol/mg protein/6 h, which was associated with an increment in whole-cell cholesterol esterification of 10.2 nmol cholesterol/mg protein/6 h. Therefore, at most, about 21% of cholesterol delivered within acetylated LDL was esterified into CE, assuming for the purpose of argument that all newly synthesized CE was derived from acetylated LDL cholesterol. Pretreatment with vitamin E at concentrations of 50, 100, and 200 μM decreased the acetylated LDL-delivered cholesterol to 44.8, 41.4, and 39.4 nmol/mg protein/6 h, and also reduced whole-cell cholesterol esterification by 1.5, 4.0, and 6.3 nmol cholesterol/mg protein/6 h, respectively. By assuming a constant proportion of delivered cholesterol becomes esterified, one would expect decrements of delivered cholesterol of 4.2, 7.6, and 9.6 nmol to decrease whole-cell cholesterol esterification by 0.9, 1.6, and 2.0 nmol, respectively. However, inhibition of whole-cell cholesterol esterification by vitamin E was substantially greater, with only 19, 15, and 10% of cholesterol delivered through acetylated LDL uptake esterified in cells treated with 50, 100, and 200 μM vitamin E, respectively. These calculations showed that the reduced acetylated LDL uptake was most unlikely to fully explain the reduction in whole-cell cholesterol esterification by vitamin E.

We next investigated the effects of vitamin E on ACAT activity in a cell-free extract. After preincubation of J774 cells with increasing amounts of vitamin E for 24 h, cells were harvested, and ACAT activity of the cell-free extract was assayed. A trend existed for reducing ACAT activity by pretreating cells with vitamin E ($P < 0.05$, one-way ANOVA) (Fig. 3). However, inhibition of ACAT activity in cells reached statistical significance only with 200 μM vitamin E, by 26% (104.5 vs. 140.0 pmol/mg/min, $P < 0.005$).

The effect of vitamin E on the hydrolysis of cellular CE was also examined since changes in hydrolysis would also affect substrate availability. Cells loaded with cholesteryl [^{14}C]oleate were incubated with fresh DMEM containing 10% LPDS in the presence or absence of vitamin E, and the remaining cellular cholesteryl [^{14}C]oleate in the extracted lipids was quantified by TLC. The content of cholesteryl [^{14}C]oleate was approximately 100 nmol/mg protein at the start of incubation and decreased with incubation time. Approximately 50% of cholesteryl [^{14}C]oleate was hydrolyzed after 24 h incubation in control cells. Hydrolysis of cholesteryl [^{14}C]oleate was not significantly altered by the presence of vitamin E (Fig. 4).

DISCUSSION

Accumulation of CE in macrophages in the subendothelial space plays a critical role in the initiation and progression of atherogenesis (31). Modified LDL is reportedly recognized and internalized by macrophages through scavenger receptors that stimulate CE accumulation which in turn transform macrophages into foam cells (17,32). Thus, reducing CE accumulation in macrophages would diminish the initiation and progression of atherogenesis. Both macrophages and endothelial cells can oxidize LDL that is transported into the artery through several pathways (33). Protecting LDL against

oxidation by antioxidants, such as vitamin E, would be expected to reduce CE accumulation in macrophages. In addition to the antioxidant protection of LDL, vitamin E has other beneficial effects on endothelial cells, platelets, and smooth muscle cells (10–15). Few studies exist of the effects of vitamin E on cholesterol metabolism in macrophages, and the effects on CE accumulation induced by an atherogenic lipoprotein are unclear. In this study, enrichment of J774 cells with vitamin E inhibited acetylated LDL-inducible whole-cell cholesterol esterification in a dose-dependent manner. Whole-cell cholesterol esterification after acetylated LDL uptake was significantly reduced by pretreating with 50 μM vitamin E, a concentration reported in human plasma after moderate vitamin E supplementation (30). This would be a novel mechanism whereby vitamin E might contribute to the prevention of atherogenesis.

Monocyte-derived macrophages take up and degrade lipoproteins by receptor-mediated endocytosis. Lysosomal acidic CE hydrolase releases free cholesterol from CE, and thereafter the free cholesterol is reesterified in the cytoplasm by ACAT. Accumulated CE is not inert, but undergoes hydrolysis by neutral CE hydrolase (32). The relative activities of ACAT and of two CE hydrolases are believed to be responsible for the regulation of cellular CE content (34). Therefore, the accumulation of CE in foam cells will depend on the uptake of atherogenic lipoprotein and the relative activities of ACAT and CE hydrolase. In the present study, enrichment of macrophages with vitamin E significantly inhibited also the uptake of acetylated LDL in addition to the reduction in whole-cell cholesterol esterification. In contrast, cellular hydrolysis of CE was not affected by vitamin E. These data indicate that vitamin E inhibits whole-cell cholesteryl esterification, which is mediated in part by interfering with the uptake of acetylated LDL and partly by suppressing ACAT activity. The lesser inhibition by vitamin E of ACAT activity in cell-free extracts is probably not contradictory as will be discussed later.

In this study, pretreatment of J774 cells with 50 μM or higher concentrations of vitamin E significantly decreased the uptake of acetylated LDL. We did not explore further mechanisms whereby this might have occurred. Acetylated LDL is taken up by macrophages through scavenger receptors (32). Previous studies reported that induction of scavenger receptors in macrophages or smooth muscle cells is regulated by protein kinase C (PKC) (35–37). For example, platelet-derived growth factor-mediated induction of the scavenger receptor in J774 cells is regulated by PKC, and this induction is inhibited by a PKC inhibitor (35). Many earlier studies reported that vitamin E suppressed PKC activity in various cells, including macrophages (10,13–15,38,39). In the present study, we cultured J774 cells in DMEM containing 10% heat-inactivated FBS and did not stimulate these cells further. Possibly vitamin E might limit the induction of scavenger receptors in J774 cells stimulated by some growth factors remaining in FBS.

As discussed previously, calculation of the data for whole-cell cholesterol esterification and acetylated LDL uptake showed that the diminished uptake of acetylated LDL could not fully explain the reduction in whole-cell cholesterol esterification by vitamin E. Changes in cellular hydrolysis of CE were excluded. Further, ACAT activity in cell-free extract was also reduced but only at the highest concentration of vitamin E. Since the aqueous cell-free extract of macrophages (used to measure ACAT activity) was likely to contain a much lower concentration of the lipid-soluble vitamin E than present in intact cells, the cell-free extract assay was probably not as sensitive a method to estimate the effect of vitamin E.

Another possibility is an alteration of cholesterol trafficking by vitamin E. Previous studies reported that whole-cell cholesterol esterification in J774 cells after uptake of acetylated LDL is regulated by the amount of cholesterol that comes into contact with ACAT, and not through the induction of ACAT itself (40–42).

Whole-cell cholesterol esterification is an index that could represent CE accumulation in cells (32). However, notably, others found no significant effect of vitamin E on CE mass accumulation in macrophages following incubation with modified lipoproteins (19,21). In one of the earlier studies, the final concentration of vitamin E was only 10 μM (19) which was ineffective also in our study. In the other study, P388D macrophages were used (21), and the difference in cell species might underlie the discrepancy.

In summary, enrichment of J774 macrophages with vitamin E significantly inhibited acetylated LDL-inducible whole-cell cholesterol esterification in J774 macrophages. Although this was associated with reduced acetylated LDL uptake, the latter could not fully account for diminished whole-cell cholesterol esterification. This effect would be a novel mechanism underlying the antiatherogenic properties of vitamin E.

ABSTRACT: We investigated the possibility that dietary cholesterol downregulates the expression of low density lipoprotein (LDL) receptor and 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase genes of circulating mononuclear cells *in vivo* in healthy humans. We also studied the variations of the LDL receptor-related protein (LRP) gene in the same conditions. Dieters ($n = 5$) were submitted to a 4-d fat restriction (mean cholesterol intake: 6 ± 4 mg/d), followed by a 7-d cholesterol (a mean of 791 ± 150 mg/d) supplementation. Controls ($n = 3$) did not change their diet. During fat restriction, serum total and LDL cholesterol decreased significantly ($P < 0.05$), and LDL receptor and HMG-CoA reductase mRNA copy numbers in mononuclear cells increased by 57 and 147%, respectively ($P < 0.05$). After reintroducing cholesterol, serum cholesterol was stable whereas LDL receptor and HMG-CoA reductase mRNA decreased by 46 and 72% ($P < 0.05$) and LRP mRNA increased by 59% ($P < 0.005$). The changes in LDL receptor and HMG-CoA reductase mRNA abundance were correlated ($r = +0.79$, $P = 0.02$) during cholesterol reintroduction as were LDL receptor and LRP mRNA levels, but negatively ($r = -0.70$, $P = 0.05$). Also, 70% of the variability in LRP mRNA ($P < 0.005$) was explained by dietary cholesterol. Thus, the basic mechanisms regulating cellular cholesterol content, the coordinate feedback repression of genes governing the synthesis and uptake of cholesterol, are operating *in vivo* in humans. However, serum cholesterol did not increase in response to dietary cholesterol, suggesting that these mechanisms may not play as predominant a role as previously believed in the short-term control of serum cholesterol *in vivo* in humans. A new finding is that LRP gene is also sensitive to dietary cholesterol, suggesting that it may participate in the control of serum cholesterol. Further *in vivo* studies in humans are warranted to explore the molecular mechanisms of the physiological response to dietary cholesterol in humans.

Lipids 33, 1177–1186 (1998).

Abbreviations: CHD, coronary heart disease; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; HMG-CoA, 3-hydroxy-3-methylglutaryl CoA; LDL, low density lipoprotein; LRP, LDL-receptor-related protein; RT-PCR, reverse transcriptase-polymerase chain reaction; VLDL, very low density lipoprotein.

The exact molecular mechanisms by which dietary lipids (1,2) are risk factors for coronary heart disease (CHD) are unknown. Epidemiological studies show that dietary cholesterol is an independent predictor of CHD, apart from its effect on blood cholesterol (3,4), but how this deleterious effect is mediated was not determined. Another unresolved major question is why healthy humans show no or only a mild increase in their blood cholesterol in response to high cholesterol intake (5,6). Answers to these questions may have major clinical implications.

In humans, cholesterol metabolism is thought to be integrated and coordinated in the liver (7). Much of our knowledge about how the hepatocytes achieve this regulation comes from experiments conducted on cultured cells or animal models, with results varying considerably among species relative to sensitivity to dietary cholesterol. Cultured cells respond to the presence or absence of cholesterol in the medium by regulating the activity of 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase, the rate-limiting enzyme of cholesterol synthesis, and the abundance of the low density lipoprotein (LDL) receptors. These processes act coordinately to maintain intracellular cholesterol levels within narrow limits (7,8). One commonly proposed mechanism for increases (in sensitive animals) in blood LDL cholesterol in response to increased dietary cholesterol is the suppression of LDL receptor-mediated uptake secondary to increased cholesterol content of hepatocytes (7–9). Promoters of the HMG-CoA reductase and LDL receptor genes contain 10 bp sterol regulatory elements (10,11) that are believed to be responsible for the coordinate nature of these regulatory processes. Thus, the primary regulatory mechanism to prevent the intracellular accumulation of cholesterol and the increase of blood cholesterol is thought to be the repression of the transcription of these two genes (7–9).

No studies however have examined these regulatory hypotheses in humans, and very little is known about the transcriptional regulation of cholesterol metabolism in healthy humans *in vivo,* in particular in response to dietary changes. Re-

cently, using deuterium incorporation and urinary mevalonic acid levels, Jones *et al.* (12) reported only modest suppression of cholesterol synthesis in humans in response to dietary cholesterol *in vivo,* suggesting a possible failure of the feedback repression of the genes regulating endogenous cholesterol synthesis. Also, it should be noted that other cholesterol-rich lipoprotein receptors, for instance the the LDL receptor-related proteins (LRP) (13–15) or the very low density lipoprotein receptor (16), may be implicated in humans in cholesterol homeostasis although few data are presently available.

In humans, the *in vivo* approach is especially difficult because of the lack of appropriate tissues from which repetitive samples may be made and also the lack of accurate methodologies for quantitative measurements of low abundant materials. Thus, detailed kinetic studies of *in vivo* cholesterol regulatory mechanisms within individuals were not conducted. Recent studies however have begun to focus on the *in vivo* regulation of the major genes involved in cholesterol homeostasis, primarily because in humans, basic regulatory mechanisms in hepatocytes and blood mononuclear cells are similar (17,18), allowing repetitive samplings and time-course evaluation. Also, competitive reverse transcriptase-polymerase chain reaction (RT-PCR) provides a new powerful tool for quantifying very low abundant species of mRNA (19–21).

The primary aim of the present study in humans therefore examines whether dietary cholesterol actually and significantly downregulates the expression of HMG-CoA reductase and LDL receptor genes *in vivo*. A two-step dietary protocol was specifically designed to control for dietary confoundings (fatty acids) when studying the specific effects of dietary cholesterol and to sensitize the responses of the genes. A secondary aim was to investigate the response of the LRP gene because this cholesterol-rich lipoprotein receptor was proposed for use in the regulation of blood lipoprotein levels (13–15), but no data are available presently in humans.

MATERIALS AND METHODS

Eight healthy men ages 24 to 45 years volunteered for this study. They were of average fitness levels and none was taking medication. No attempt was made to alter their usual lifestyle pattern.

The protocol was approved by the Ethics Committee of the Hospices Civils de Lyon, and informed consent was obtained from each subject. The protocol was designed to study the effects of dietary cholesterol on gene expression, independent of other dietary fats known to have a major impact on cholesterol metabolism (e.g., saturated fatty acids). The confounding effects of other fats were controlled by eliminating all fats from the diet during a first period followed by the reintroduction of cholesterol, and only cholesterol, in the diet. Statistically, the main endpoint of the study was to compare, between dieters and control subjects, the changes in mRNA levels between the period without fat and the period with cholesterol only. Practically, after a 6-d observation allowing baseline diet recording, the dieters modified their diet in two steps according to individual instructions of a dietitian. In a first step (a total fat restriction period of 4 d), they were instructed to eliminate from their diet all the foodstuffs containing fat. Then, during a second step of 7 d, a cholesterol reintroduction period, two eggs per day for 3 d (day 4 to day 6) and four eggs per day for 4 d (day 7 to day 10) were added to the previous fat-restricted diet. The two time intervals were chosen for practical purposes: not to disturb the daily life of the subjects (who were hospital workers) and to be ethically acceptable and nutritionally efficient. Therefore, the protocol started on Monday morning, lasted less than 2 wk, and ended on the Friday morning of the second week. Obviously, a third week of fat restriction would have been too difficult for the dieters along with the concern that prolonging such a diet might disturb nutrient balances (essential fatty acids, indispensable amino acids, liposoluble vitamins).

Control subjects maintained their usual dietary habits. Adherence to the experimental diet and evaluation of the diet of the controls were monitored daily by the dietitian and by measuring plasma fatty acids as biomarkers of the dietary modifications. The subjects weighed their foods, and information was translated into nutrients using nutrition software (2).

Isolation of blood mononuclear cells. Venous blood was collected for the isolation of mononuclear cells (15 mL) and the determination of serum lipids and lipoproteins (5 mL) at 8 A.M. after a 12-h overnight fast. Mononuclear cells were immediately isolated by centrifugation of whole blood on a Ficoll gradient at 4°C as described (22) and stored at −70°C. Cell population consisted of 85–95% lymphocytes.

Total RNA preparation. Total RNA was prepared from frozen samples by the RNAzol method (Bioprobe Systems), a variant of the guanidinium/chloroform procedure described by Chomczynski and Sacchi (23). To remove any contaminating DNA, total RNA was incubated with 20 units of DNase RNase-free for 1 h at 37°C. Then total RNA was again extracted and resuspended in water. Total RNA was quantified spectrophotometrically at 260 nm and by electrophoresis on agarose gel of serial dilutions compared with known amounts of standard RNA (Boehringer Mannheim, Indianapolis, IN). Gel electrophoresis showed clear undegraded 18S and 28S bands. Fifty nanograms of total RNA was used for each PCR.

Measurement of LDL receptor and HMG-CoA reductase mRNA levels. LDL receptor and HMG-CoA reductase mRNA copy numbers were determined by competitive RT-PCR according to methods described by Powell and Kroon (17) and Gebhard *et al*. (19), using a commercial kit (Perkin Elmer Cetus Instruments, Norwalk, CT). The unique advantage of including a synthetic RNA as an internal standard in the RT-PCR is that one can know the exact copy number per reaction. Total cellular RNA was thus reverse-transcribed into cDNA in the presence of dilution series of AW 109 cRNA (internal standard) which derives from the plasmid pAW 109 and contains primer sites for the LDL receptor and HMG-CoA reductase. Reactions were performed in a final volume of 100 µL containing 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl,

2.5 mmol/L $MgCl_2$, 150 µmol/L of each of the four deoxyribonucleoside triphosphates (Pharmacia LKB Biotechnology Inc., Uppsala, Sweden), and 0.65 µmol/L of LDL receptor or HMG-CoA reductase downstream primers. Primer sequences were identical to those described by Powell and Kroon (21). After initial denaturation, 10 units of reverse transcriptase were added to the reaction mixture, incubated at 42°C for 40 min and at 94°C for 2 min. PCR was performed by adding 5 units of Taq DNA polymerase (Perkin Elmer Cetus) and 0.65 µmol/L of LDL receptor or HMG-CoA reductase upstream primers to the entire cDNA product from the RT reaction. Thus, the competitor product was that from the AW 109 cRNA. All PCR included a negative control for each RNA, and each experiment was performed omitting reverse transcriptase in one control tube. The number of PCR cycles was 35 as amplification was shown to be exponential up to 37 cycles. Reaction products corresponding to the mRNA tests and the internal controls were analyzed on agarose gel stained with ethidium bromide and documented on Polaroid nº667 film. For quantitation, we used densitometric scanning of photographic images of the gels. The ratio of amplified RNA test to amplified competitor was determined for each sample, and the logarithm of the band density ratio was plotted against the logarithm of the initial amount of the competitor, giving linear titration curves. The initial amounts of each RNA test and competitor were assumed to be equal when the ratio competitor/RNA test was equal to one. The results were expressed as copy number per µg of total cellular RNA.

Measurement of LRP mRNA levels. LRP mRNA levels were evaluated according to a semiquantitative RT-PCR adapted from Dante *et al*. (24). Briefly, aliquots (50 ng) of total cellular RNA were reverse-transcribed into cDNA. The cDNA encoding for LRP and the ubiquitous glycolytic enzyme, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), were simultaneously amplified in each assay tube. Reactions were performed following the methods described for the LDL receptor and HMG-CoA reductase mRNA. LRP primer sequences were 5′-CTCAGGTACGTGGCCAAGAT-3′, located at position 1311–1330 and 5′-CGAGTTGGTGGACTAGAGAT-3′, located at position 1730–1750 according to the LRP gene sequence published by Herz *et al*. (25). GAPDH primers are those used by Dante *et al*. (24). PCR products were analyzed on agarose gel stained with ethidium bromide. For quantitation of relative band intensities, densitometric scanning of photographic images was performed, and the ratio of LRP to GAPDH was determined for each sample. Regarding the specificity of the RT-PCR assay for the LRP mRNA, the expected PCR product of 440 bp should contain Hinc II, Alu I, and Ava II restriction sites at positions 242, 236, 146, and 278, respectively. The restriction map of the RT-PCR products indicated that the fragments of predicted size were obtained using these enzymes and confirmed the authenticity of the PCR products. RT-PCR was also performed using a serial dilution of total RNA in sterile water which indicated that the ratio of LRP to GAPDH was not dependent on the total RNA concentration for amounts ranging from 10 to 200 ng. All PCR included a negative control, and the absence of genomic DNA contamination in the RNA samples was confirmed by the use of RT-negative RNA samples. The number of PCR cycles was also 35.

Plasma lipids and lipoprotein measurements. Cholesterol and triglyceride concentrations in plasma and in lipoprotein fractions were assayed by enzymatic procedure using commercial kits (Boehringer Mannheim). LDL-cholesterol was determined using the Friedewald formula (26). Apo B_{100} and A_1 were measured with a Beckman nephelometer (Fullerton, CA) (27).

Plasma fatty acid analysis. Plasma lipids were extracted by the method of Folch *et al.* (28) and methylated by boron fluoride fatty acids methanol reagent according to Morrison and Smith (29). Fatty acids were analyzed by gas–liquid chromatography with a Hewlett-Packard 6890 series gas chromatograph (Palo Alto, CA), a BPX 70 (SGE) capillary column, and nitrogen as the carrier gas as described (2).

Statistical methods. Statistical significance of the differences between dieters and controls in the changes in each mRNA, between day 0 and day 4 and between day 4 and day 11, respectively, was determined by two-tailed unpaired Student's *t*-test. The relationships between the changes in mRNA levels (between day O and day 4 and between day 4 and day 11, respectively) and between the changes in each mRNA and the changes in dietary cholesterol (between day 0 and day 4 and between day 4 and day 11) were evaluated by linear regressions performed by the least-squares method. A $P < 0.05$ was considered significant.

RESULTS

Dietary and plasma lipid results. Daily nutrient intakes of the dieters (mean ages 31.5 ± 4.7 yr, mean body mass index 23.2 ± 1.0 kg/m^2), and controls (30.5 ± 3.5 yr and 22.7 ± 0.6 kg/m^2) are shown in Table 1. The control subjects did not change their dietary habits. In particular, the slight increases in total lipid and cholesterol intake during the second period were not significant. In dieters at the end of the fat restriction period (day 4), total energy, proteins, total lipids, and cholesterol significantly ($P < 0.05$) decreased whereas carbohydrates increased ($P < 0.05$) compared to baseline (day 0). Lipid intake decreased from 36.9 to 2.6% of energy and cholesterol from 438 to 6 mg/day. During the cholesterol reintroduction period (from day 4 to day 11), energy intake did not change (8494 ± 565 and 8498 ± 1050 Joules), whereas the consumption of eggs provided a mean intake of 791 ± 150 mg cholesterol per day.

Analyses of plasma fatty acids (Table 2) indicated in dieters a significant decrease in the concentration of the major essential fatty acid, linoleic acid, observed already at day 4 (22.8 ± 6.4% of total fatty acids against 31.0 ± 4.6 at day 0, $P < 0.05$) and persisting at day 11 (22.6 ± 3.8), confirming (as the other changes between day 4 and day 11 were not significant) that dieters actually did not eat fat other than eggs during the study.

TABLE 1
Summary of Daily Nutrient Intake in Dieters and Controls[a]

	Baseline	Fat restriction	Cholesterol reintroduction
Dieters (n = 5)			
Total energy (Joules)	11556 ± 2556	8494 ± 565	8498 ± 1050
Proteins (% energy)	14.6 ± 2.0	10.8 ± 1.1	12.2 ± 1.1
Carbohydrates (% energy)	44.5 ± 7.0	85.1 ± 1.1	74.2 ± 3.8
Total fat (% energy)	36.9 ± 3.5	2.6 ± 0.4	10.8 ± 1.2
Cholesterol (mg/day)	438 ± 206	6 ± 4	791 ± 150
Controls (n = 3)			
Total energy (Joules)	11242 ± 3682	9858 ± 2695	10682 ± 1937
Proteins (% energy)	14.7 ± 3.0	15.2 ± 1.1	13.7 ± 2.2
Carbohydrates (% energy)	47.1 ± 4.6	46.4 ± 2.7	45.6 ± 2.3
Total fat (% energy)	37.0 ± 3.6	37.7 ± 1.9	39.3 ± 1.0
Cholesterol (mg/day)	374 ± 156	389 ± 193	507 ± 187

[a]Results are given as means ± SD. Baseline data correspond to the mean daily intake recorded during the 6 d prior to day 0; fat restriction data to the mean daily intake between day 0 and day 4 and cholesterol reintroduction data to the mean daily intake between day 5 and 10.

[a]Results are given as means ± SD. *P < 0.005; **P < 0.001vs. baseline. In parentheses are indicated the days when blood samples were collected.

Total cholesterol, high-density lipoprotein-cholesterol, LDL-cholesterol, and apo A_I in the dieter group decreased significantly ($P < 0.05$) by day 4 as compared with controls (Table 3). During the cholesterol reintroduction period, the changes in blood lipoproteins and lipids were not significant.

LDL receptor and HMG-CoA reductase mRNA measurements. Figure 1 shows the results of LDL receptor (A) and HMG-CoA reductase (B) mRNA measurements. During the 4-d dietary fat restriction period, mean LDL receptor and HMG-CoA reductase mRNA copy numbers increased respectively from $41.2 \pm 5.4 \times 10^4$ and $996 \pm 244 \times 10^4$ per µg of total RNA at day 0 to 64.8 ± 9.1 and 2462 ± 645 at day 4 (both $P < 0.05$ when compared with the changes in the control group). These changes corresponded to 57 and 147% increase for each gene, respectively. After cholesterol reintroduction, the mRNA levels of both genes decreased to 34.8 ± 3.3 and 678 ± 129 copy numbers ($P < 0.05$) corresponding to 46 and 72% decrease. When analyzing individual data, the responses of the two genes (amplitude and kinetics) to the fat restriction were not homogeneous as shown by the large standard deviations of the means at days 0, 2, and 4. Certain subjects responded immediately (+244% for HMG-CoA reductase in dieter 2 after 2 d), whereas others had a delayed response (+3% after 2 d but +72% after 4 d for the LDL receptor in dieter 4) or had an early paradoxical response with −12% after 2 d for the LDL receptor in dieter 1 followed by +37% after 4 d. In contrast, cholesterol reintroduction was associated with a more homogeneous response for both LDL receptor (reduction range, 28 to 60%) and HMG-CoA reductase (52 to 84%) at day 11, and standard deviations were small at days 9 and 11 (Fig. 1).

TABLE 2
Plasma Fatty Acids (in % of total fatty acids)[a]

	Baseline (day 0)	Fat restriction (day 4)	Cholesterol reintroduction (day 11)
Dieters (n = 5)			
Sum of saturated FA	29.8 ± 1.1	32.0 ± 4.5	33.4 ± 3.6

α-Linolenic acid 18:3n-3	0.35 ± 0.1	0.45 ± 0.2	0.36 ± 0.1
Sum of n-6 FA	41.7 ± 4.6	40.9 ± 1.2	40.4 ± 1.8
Sum of n-3 FA	4.9 ± 0.3	5.4 ± 1.1	6.3 ± 1.7

[a]Results are given as means ± SD. In parentheses are indicated the days when blood samples were collected. FA, fatty acids; *P < 0.05 vs. baseline.

LRP mRNA measurements. The results are expressed as LRP to GAPDH ratio with day 0 taken as 100%. A significant decrease (from 100% to 76 ± 4%) of the LRP mRNA level was observed between day 0 and day 4 ($P < 0.05$, Fig. 2). After day 4, as cholesterol was reintroduced, LRP mRNA levels increased progressively, reaching about 100% at day 9 and 121 ± 10% at day 11 ($P < 0.05$), corresponding to a mean increase of 59% (range 13 to 80%). The influence of dietary lipids on LRP mRNA levels in a representative subject (dieter 4) is shown in Figure 3.

Relationship analyses. We principally addressed the question of whether the expression of the LDL receptor, HMG-CoA reductase, and LRP genes are coordinated in response to dietary cholesterol, when cholesterol was reintroduced (from day 4 to day 11). As a matter of fact, during fat restriction (between day 0 and day 4), the relationship between the changes in LDL receptor mRNA levels and either the changes in HMG-CoA reductase or LRP mRNA levels were not significant (r^2 = 0.25 and 0.20), whereas the relationship between the changes in HMG-CoA reductase and LRP mRNA levels

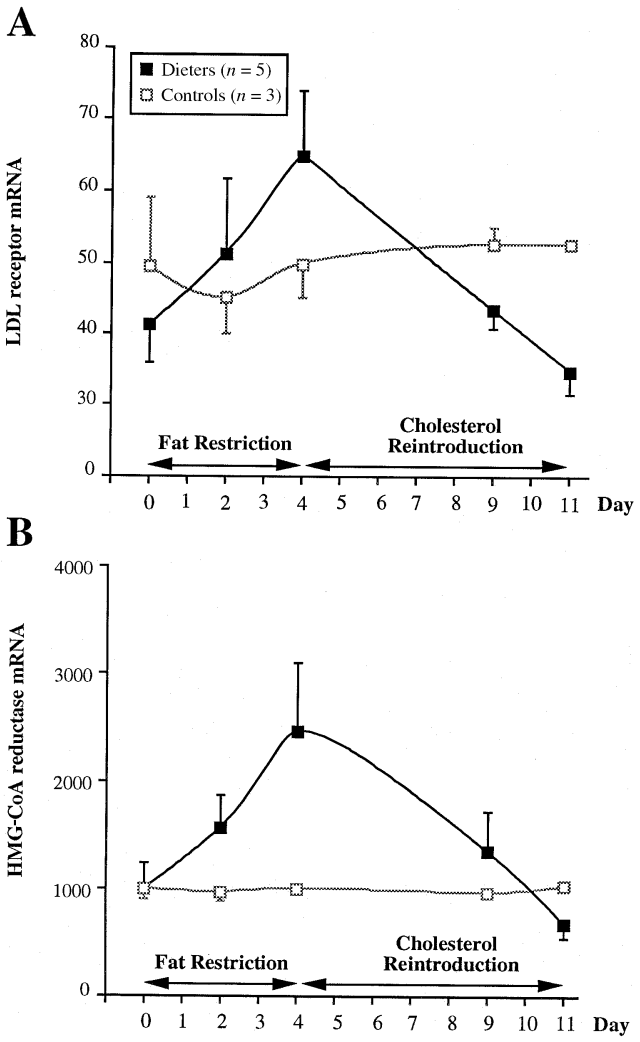

FIG. 1. Low density lipoprotein (LDL) receptor (A) and 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase (B) mRNA measurements (means ± SD) at baseline (day 0) and during fat restriction (from day 0 to day 4 in the morning) and after reintroducing cholesterol (from day 4 at lunch to day 11 in the morning) in five dieters compared with three controls who did not change their diet during the same periods. The between-group differences in the changes (from day 0 to day 4 and from day 4 to day 11) were statistically significant ($P < 0.05$) for both genes.

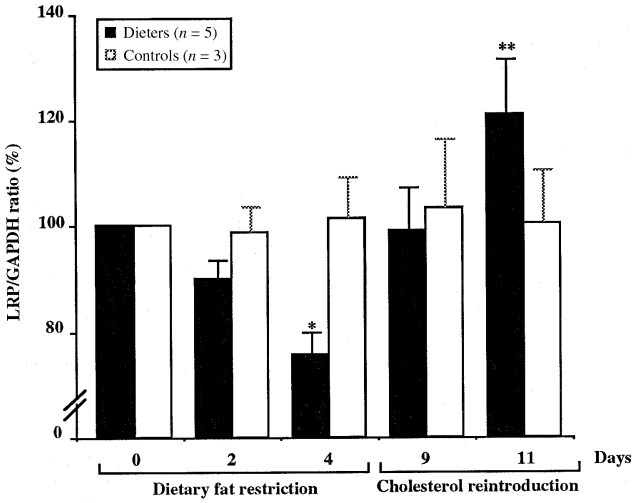

FIG. 2. Effect of the two-step dietary modifications on LDL-receptor-related protein (LRP) mRNA levels in mononuclear cells of five dieters and three control subjects. Evaluations were performed during a 4-d dietary fat restriction (from day 0 to day 4 in the morning with blood samplings at day 2 and day 4 in the morning) and during the cholesterol reintroduction period (from day 4 at lunch, after the day 4 blood sampling, to day 11 with blood samplings at day 9 and day 11). The levels of LRP mRNA at day 2, 4, 9, and 11 are expressed in percentage of the day 0 levels which are taken as 100%. Results are given as means ± SD. $^*P < 0.05$ vs. day 0 and $^{**}P < 0.005$ vs. day 4. GAPDH, glyceraldehyde-3-phosphate dehydrogenase. See Figure 1 for other abbreviation.

was significant ($r = 0.69$, $r^2 = 0.48$, $P = 0.05$).

Figure 4 shows the relationship between the changes in LDL receptor and HMG-CoA reductase mRNA levels during cholesterol reintroduction (between days 4 and 11). These data are consistent with a coordinate regulation of LDL receptor and HMG-CoA reductase genes ($r = 0.79$, $r^2 = 0.62$, $P = 0.02$). The relationship between LDL receptor and LRP genes ($r = 0.70$, $r^2 = 0.49$, $P = 0.05$) is less significant, whereas it is not significant at all between HMG-CoA reductase and LRP ($r^2 = 0.17$, $P = 0.30$).

We also analyzed the relationship between blood lipids and mRNA level changes. We found no statistically significant correlation.

We finally examined the relationship between the changes in dietary cholesterol and the changes in mRNA. The strongest correlations (Fig. 5) were found between dietary cholesterol and LRP during both cholesterol reintroduction ($r = 0.81$, $r^2 = 0.65$, $P < 0.01$) and total fat deprivation ($r = 0.86$, $r^2 = 0.74$, $P < 0.005$), indicating that about 70% of the changes in LRP mRNA may be explained by the variations in dietary cholesterol. Regarding the relationship between dietary cholesterol changes and changes in LDL receptor and

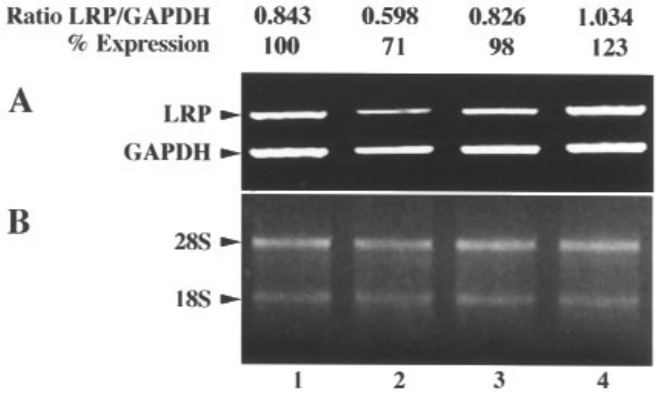

FIG. 3. Detection of LRP transcripts by reverse transcriptase-polymerase chain reaction (RT-PCR) in a representative subject dieter. A, RT-PCR was performed from 50 ng of total RNA, using GAPDH as an internal control. An aliquot of 15 µL of the reaction was analyzed on 2% agarose gel with: day 0 in lane 1, day 4 in lane 2, day 9 in lane 3, and day 11 in lane 4. B, 50 ng of total RNA extract was electrophoresed in 1% agarose gel at day 0 in lane 1, day 4 in lane 2, day 9 in lane 3, and day 11 in lane 4. Ethidium bromide staining was performed to confirm clear undegraded 18S and 28S bands and that the same amount of RNA was applied to each lane. See Figure 2 for other abbreviations.

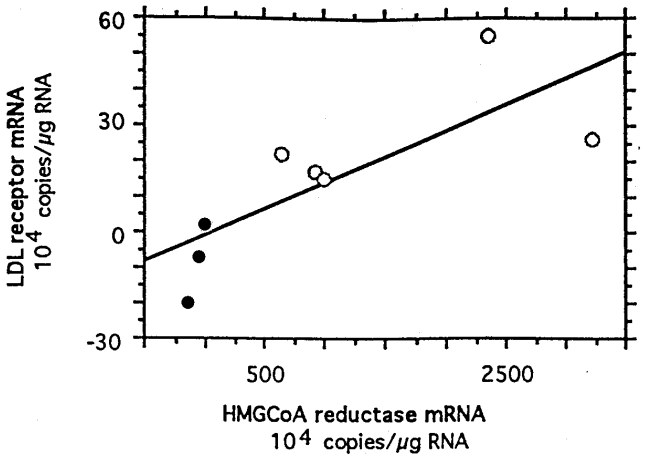

FIG. 4. Relationships between the changes (the differences between the values measured at day 4 and day 11) in LDL receptor and HMGCoA reductase mRNA levels ($r^2 = 0.62$, $P = 0.02$) during cholesterol supplementation, dieters (○), controls (●). See Figure 1 for abbreviations.

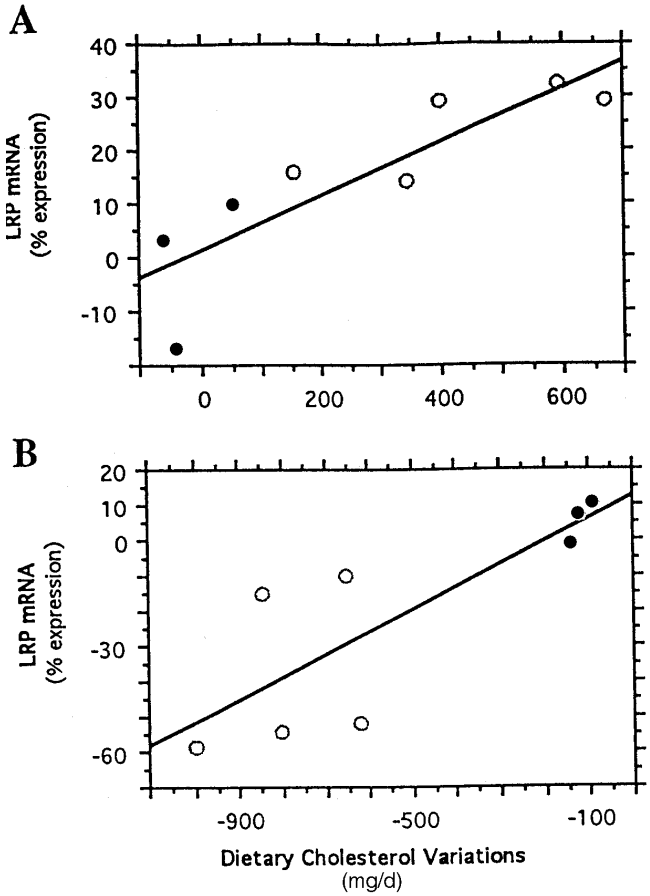

FIG. 5. Relationships between dietary cholesterol variations (the differences between the values measured at two different days) and changes in LRP mRNA levels during fat restriction, from day 0 to day 4 (A, $r^2 = 0.74$, $P < 0.005$), and during cholesterol supplementation, from day 4 to day 11 (B, $r^2 = 0.65$, $P < 0.01$). Dieters (○), controls (●). See Figure 2 for abbreviation.

HMG-CoA reductase mRNA levels, nonsignificant trends were observed during either fat restriction or cholesterol reintroduction.

DISCUSSION

Under physiological conditions, dietary lipids are incorporated into chylomicrons in the intestinal mucosa during their digestive absorption and are then processed by lipoprotein lipase in the peripheral organs. The resulting chylomicron remnants, enriched in dietary cholesterol, are rapidly cleared from the plasma, being taken up by the liver and other tissues (7). The LDL receptor is involved in the metabolism of cholesterol and the control of blood cholesterol not only by mediating the uptake of LDL from plasma into cells (8) but also by participating in the clearance of chylomicron remnants from the circulation (30–32). Another major and distinct receptor that binds apoprotein E, the LRP, is also involved in the clearance of chylomicron remnants and perhaps of LDL (13–15), whereas little is known about the factors which regulate its synthesis.

Although blood cholesterol is influenced by the amount and type of dietary fats, the response to dietary cholesterol varies widely among species and among individuals of the same species (5,6). For instance, 0.5% cholesterol feeding in the rabbit or the hamster results in a considerable increase in blood cholesterol (9,33), whereas in most healthy humans comparable high cholesterol intake in the absence of saturated fats has little effect and sometimes no effect at all (5,6). Low cholesterol absorption, high conversion to, and excretion of, bile acid (5), feedback inhibition of endogenous cholesterol synthesis, and reduced rate of the production of LDL (8,9) may explain the human resistance to dietary cholesterol. Another unexamined possibility is that the sterol-mediated feedback repression of LDL receptor gene transcription, the main mechanism regulating cellular cholesterol homeostasis and thought to aid in the control of blood cholesterol (7,8), is not operating *in vivo* in humans, possibly because of a lack of significant absorption of cholesterol. To investigate that point, we characterized, at the mRNA level, the response of circulating mononuclear cells known to reflect liver lipid metabolism in humans (17,18). For that purpose, we designed a dietary protocol in which the first period served to place the subjects in a "fat-deprived state" and the second period served to actually test the effect of reintroducing cholesterol (and only cholesterol) in the diet on the expression of the genes.

Summary of the results and interpretation. After 4 d of fat deprivation, blood cholesterol decreased significantly in association with an augmented expression of the LDL receptor gene. In contrast, after reintroducing cholesterol, serum total and LDL cholesterol did not change, whereas LDL receptor and HMG-CoA reductase mRNA levels decreased significantly, consistent with the current theory that in response to increased cholesterol availability, cells coordinately suppress endogenous cholesterol synthesis and repress the synthesis of LDL receptors. In other words, what is true for the isolated cultured cell is also true for circulating cells known to reflect

liver lipid metabolism in humans. On the other hand, these data cannot explain why the dieters were resistant to high cholesterol intake. The fact that the two genes were repressed indicates that a sufficient amount of dietary cholesterol was actually absorbed. Thus, low absorption of cholesterol cannot explain the resistance to dietary cholesterol in this study (5,6). While comparing the degree of gene repression in this study with those reported in animal species either resistant (rat, mouse) or sensitive (rabbit, hamster) to dietary cholesterol, we observed similar trends. For instance, in the mouse, Rudling (34) reported 43 and 66% reduction for hepatic LDL receptor and HMG-CoA reductase mRNA, whereas in the hamster Horton *et al.* (35) showed 33 and 55% reduction of hepatic LDL receptor mRNA in response to 0.06 and 0.12% cholesterol diets. Finally, in the cebus monkey, which is also very sensitive, Hennessy *et al.* (36) reported variations of less than 30% of hepatic LDL receptor mRNA.

Thus, despite major differences among species in the blood cholesterol responses to dietary cholesterol, roughly parallel gene suppressions were observed in both sensitive and nonsensitive species. This strongly suggests that neither low cholesterol absorption nor LDL receptor and HMG-CoA reductase gene repression can explain the human (or mouse) resistance to dietary cholesterol *in vivo*.

Which alternative explanations could be proposed? First, it is possible that increased cholesterol intake may induce increased conversion of cholesterol to bile acids through increased expression of the hepatic cholesterol 7-α-hydroxylase. Certain cholesterol-resistant animal species actually differ from the sensitive ones with respect to their ability to upregulate expression of hepatic 7-α-hydroxylase at both mRNA and protein levels in response to increasing levels of the substrate (34,37). In the hamster, transient overexpression of the enzyme was reported to reduce blood cholesterol levels (38). In the present study, however, we did not observe (in the few measurements we performed) significant changes in blood concentrations of total bile acids (data not shown), suggesting that recirculation of bile acids, and probably excretion, were not greatly modified. This is actually not surprising as the increase in 7-α-hydroxylase expression was shown to be accompanied by a parallel increase in HMG-CoA reductase gene expression (38). It was not the case in the present study where HMG-CoA reductase gene expression was actually reduced after cholesterol reintroduction. However, we cannot exclude the possibility that the excretion of bile acids was not augmented in these subjects, and further studies (requiring repetitive biliary catheterism) are warranted to clarify that point.

Another possibility is that, in parallel with a reduced uptake of LDL by hepatic LDL receptors, LDL production rate was reduced in our subjects, resulting in an absence of significant effect on blood LDL levels. This is, however, quite unlikely as in most studies in which LDL production rate and uptake were studied, the two parameters were shown to change in a reciprocal manner. For instance, when LDL receptor activity is reduced (by either genetic or environmental factors), LDL production invariably increases (39–41). One major reason for this reciprocal relationship is the specificity of the clearance process of LDL in the liver (42). When LDL receptor activity is high, a large proportion of VLDL remnants is taken up by the receptors and not converted to LDL, whereas when LDL receptor activity is low, VLDL remnants are metabolized to LDL and, consequently, LDL production rate increases (42).

Another type of regulation is thus probably operating to explain the human resistance to dietary cholesterol, possibly involving another form of LDL clearance that does not depend upon the LDL receptor. This LDL receptor-independent component of LDL clearance was identified in every species that was examined and may account for almost 50% of LDL clearance in humans (43). Whether this process involves LRP is currently unknown but may represent a realistic hypothesis given our present data on LRP regulation discussed below.

Methodological issues. Once the experimental use of pure cholesterol is excluded [as its effects were shown to be different from those observed when cholesterol is associated with substantial amounts of oil or fat as in natural foods (44)], an additional difficulty lies in the control for the possible dietary confoundings, chiefly fatty acids, that may influence cholesterol metabolism (45,46). Supplementation by egg yolk was used in many studies because the amount of fatty acids present in that aliment is considered negligible. Nonetheless, for a given amount of dietary cholesterol, other dietary modifications (consumption of meat, fish, butter, edible oils, etc.) induced by egg consumption may result in different, and maybe opposing, effects on blood cholesterol in different subjects. For instance, in one of the few studies investigating the effect of dietary cholesterol on LDL receptor and HMG-CoA reductase activities in blood mononuclear cells in man, Mistry *et al*. (47) reported a wide range of responses after daily addition of 1500 mg of cholesterol (which is quite considerable) in the diet in the form of eggs. Unfortunately, the authors did not control for the other lipid components of the diet, preventing a clear interpretation of the data.

To control for such confoundings in the present study, subjects were submitted to a period of total fat restriction prior to the period of cholesterol supplementation and, in the second period, only the effect of dietary cholesterol was tested. In fact, upon reintroducing egg yolk, a small amount of fatty acids is also reintroduced, as our evaluation indicated a mean intake of total fats of 2.6% of total energy during fat restriction and 10.8% when consuming eggs. This difference was however small and did not result in significant changes in plasma fatty acids after reintroducing cholesterol (Table 2).

It should be pointed out that the primary aim of this study was to investigate in humans the possibility that mechanisms of transcription regulation considered as basic for the survival of cells were also operating *in vivo*. We did not intend to study general metabolic regulations. Thus, post-transcriptional regulation and protein measurements were not within the scope of the present study. Nevertheless, notably, the pathways under study are essentially (but not exclusively) regulated at the transcriptional level (7,8,10,11,17,18,34–36,48–50) and,

in most studies, changes in LDL receptor mRNA correlate well with the changes in the corresponding protein mass or activity and also the relative rate of transcription (35,49,50), indicating that mRNA changes usually reflect fairly well metabolic regulations.

When comparing the copy numbers of LDL receptor and HMG-CoA reductase measured in this study with those reported by Powell and Kroon (17), who used very similar methodologies and the same synthetic internal standard in the RT-PCR, surprisingly, the data differ dramatically. The most plausible explanation is that the two populations under study are very different. Our subjects were young (mean age 35 yr), healthy males. Powell's subjects were quite old (mean age 53 yr), sick (all underwent major surgery for liver disease), and 70% were female. Despite the high percentage of women, their mean weight was 76 kg (against 69 kg in our study), and blood lipids (for instance, mean cholesterol was >6 mmol/L) were very different than those of our subjects (mean cholesterol <5 mmol/L). Thus, lipid metabolism in the two populations was very different, and not surprisingly to see differences existed in the expression of genes implicated in cholesterol homeostasis.

Coordinate gene regulation and the response of the LRP gene. The basic mechanisms regulating cellular cholesterol content, the feedback repression of genes governing the synthesis and uptake of cholesterol, are thus operating *in vivo* in humans. However, as expected from many previous data (summarized in Ref. 51), blood lipids were not modified by increasing cholesterol intake, suggesting that this regulation by itself does not play a predominant role in the control of blood lipids in healthy humans. These results are consistent with those reported in animal species known to be resistant to high cholesterol intake (34).

This study also documents that, in response to a dietary cholesterol challenge, the HMG-CoA reductase and LDL receptor genes are coordinated. This is in agreement with previous animal or human nonnutritional studies (17,34), whereas, to our knowledge, this is the first report showing in humans such a coordinated gene response to a dietary manipulation. We observed that after cholesterol reintroduction, the two genes were similarly downregulated, up to 62% of the variability of one gene being related to the variability of the other. Given the *in vivo* situation, the shortness of the study and the small sample size, this correlation is actually strong.

Yet, we found significant inverse correlations between the variations of LDL receptor and LRP mRNA levels and also between dietary cholesterol and LRP mRNA, demonstrating that LRP mRNA changes likely resulted from the dietary changes.

A 59% increase in LRP mRNA levels was observed after reintroducing cholesterol in the diet, demonstrating that the LRP gene is actually sensitive to dietary cholesterol. Although specific mechanisms of LRP gene regulation were not addressed in this study, these data raise questions as to whether LRP may be responsible, at least partly, for the lack of increase of serum cholesterol levels in response to high dietary cholesterol in humans.

LRP is a multifunctional and multiligand receptor expressed in a large variety of cells and tissues (52–54). In addition to its role in the cellular uptake of the remnant lipoproteins, LRP mediates the cellular internalization and catabolism of a number of molecules and molecular complexes potentially involved in inflammation (55), thrombogenesis (56,57) thrombolysis (58,59), and lipid metabolism (60,61). Therefore it may contribute to the formation of the atherosclerotic fatty streak lesion (54,62–64).

Recently it was established in the rat that LRP and the mannose receptor are the sole major receptors responsible for the clearance of tissue plasminogen activator, a serine protease that plays a central role in the fibrinolytic system (65). Speculatively, given its several possible interactions in the development of CHD, LRP may constitute a link between dietary cholesterol and CHD independent of blood cholesterol level, one mystery in the epidemiology of CHD (3,4).

Regarding the mechanism(s) by which dietary cholesterol increases LRP mRNA levels, notably the promoter of the LRP gene was reported either to contain (66) or not contain (52) a sterol regulatory element. The present data indicate an upregulation of LRP in response to cholesterol, which is in agreement with a previous study showing that cholesterol feeding enhances the expression of the LRP gene in the aorta of the rabbit (63). Also, Willnow *et al.* (14) showed in mice submitted to transient inactivation of LRP *in vivo* that not only chylomicron remnants but also LDL (although to a lesser degree) accumulated in the plasma, suggesting that LRP participates in the clearance of LDL and may contribute to the control of blood LDL level. Thus, theoretically, increased synthesis of LRP during high cholesterol intake is an adequate physiological response to ensure efficient clearance of chylomicron and VLDL remnants and also of LDL. Although these mechanisms are quite speculative, upregulation of LRP gene expression in response to high dietary cholesterol may be interpreted as either a protection against blood cholesterol increase or as a contribution to the accumulation of lipids within cells, in particular, vascular cells. Also, LRP may influence the occurrence of acute thrombotic complications by altering the anticoagulant properties of the vessel wall as this receptor mediates degradation of molecular complexes involved in thrombogenesis and fibrinolysis (56–59,65). Further basic and clinical studies are urgently warranted to examine whether LRP may be, in terms of CHD, a friend or a foe.

ABSTRACT: Dogs were born to mothers fed commercial diets low or enriched in n-3 fatty acids and raised on those diets until they were about 50 d old. Retinas were removed, lipids were extracted, and total phospholipids were analyzed for fatty acid and molecular species composition. Animals from the low n-3 group had significantly lower retinal levels of 22:6n-3 and higher levels of n-6 fatty acids, especially 20:4n-6 and 22:5n-6. There was no difference in the retinal levels of 18:2n-6, and only small differences were found in saturated and monounsaturated fatty acids. The most dramatic differences in molecular species occurred in 22:6n-3–22:6n-3 (4.7 vs. 0.8%) and 18:0-22:6n-3 (27.6 vs. 14.4%); total molecular species containing 22:6n-3 were significantly lower in the low n-3 group (45.5 vs. 24.0%). Molecular species containing 20:4n-6 and 22:5n-6 were greater in the low n-3 animals (13.0 vs. 25.7%), as were molecular species containing only saturated and monounsaturated fatty acids (40.8 vs. 35.4%). These results show that modest differences in the amount of n-3 fatty acids in the diets of dogs can have profound effects on the fatty acid and molecular species composition of their retinas.
Lipids 33, 1187–1193 (1998).

Neural tissues, including the retina, can take up small amounts of n-3 fatty acids present in the circulation and conserve them during n-3 deficiency (1–4). In the retina, 22:6n-3, the most abundant n-3 fatty acid in neural tissues (5), is conserved by recycling from the retinal pigment epithelium (6–9). This pathway, called the "short loop" by Bazan *et al.* (10), is very effective in maintaining high retinal levels of n-3 fatty acids for glycerolipid synthesis. In the vertebrate retina, the distal 10% of rod outer segment (ROS) discs is shed daily and phagocytized by the retinal pigment epithelium (11). Without an efficient "short loop," the retina could easily become depleted of n-3 fatty acids during dietary n-3 deficiency.

Prolonged deprivation of n-3 fatty acids in adult or weanling rats leads to a reduction in retinal n-3 fatty acids, but the changes are relatively small and occur over a long period of time (1–4). However, if the dietary restrictions are begun during pregnancy and continued through the nursing period and thereafter, greater changes can be effected, as observed in rats (12) and monkeys (13). In the retina (1–4, 12,13) and brain (14–16), changes in n-3 fatty acids, primarily in 22:6n-3, are balanced by an increase in 22:5n-6. This occurs even in animals denied both n-3 and n-6 fatty acids, probably owing to the larger stores of 18:2n-6 than of 18:3n-3 in adipose tissue (3).

Our laboratories have studied inherited retinal degenerations in miniature poodles for a number of years and have reported that animals with progressive rod-cone degeneration (*prcd*), which is genetically inherited, have lower plasma (17) and ROS (18) levels of 22:6n-3 than unaffected dogs. In these studies, dog food was routinely analyzed to determine dietary levels of both n-3 and n-6 fatty acids. Recent analyses have revealed that the levels of polyunsaturated fatty acids (PUFA), particularly the n-3 family, are now higher in commercial dog food compared to feed analyzed several years ago. To determine if this increase in dietary n-3 fatty acids has any effect on plasma and retinal levels of PUFA we analyzed the plasma and retinal fatty acid and molecular species compositions of total phospholipids from unaffected dogs that had been born and raised in our dog colony and fed dog food low or enriched in n-3 fatty acids.

MATERIALS AND METHODS

Animals and diets. The unaffected dogs used in this study were made available as part of an National Eye Institute–National Institutes of Health-sponsored project (EY06855, "Canine Models for Hereditary Retinal Degenerations"). The low n-3 group had 5 females and 1 male, and the high n-3 had 6 males; there was no difference between lipid analyses in male and female animals. The study was done in accordance with the guidelines of the Association for Research in Vision and Ophthalmology and followed protocols approved by the animal protocol review committee of Cornell University and the University of Oklahoma Health Sciences Center. All dogs

[a]From Aguirre *et al.* (18). n.d. = not detectable. Only identified fatty acids are listed in the table.

were maintained in the same animal care facilities (Retinal Disease Studies Facility, Kennet Square, PA), in indoor runs with controlled cyclic illumination (12 h on–12 h off). In the low n-3 groups, adult dogs were fed Purina Lab chow (Ralston Purina, St. Louis, MO) and pups were fed Purina Puppy chow plus canned dog food (Hi Tor beef, Triumph Pet Industries, Warnick, NY). Adult dogs receiving the diets enriched in n-3 fatty acids were fed Eukanuba Premium Performance Adult Formula (IAMS Company, Dayton, OH) and pups received IAMS Puppy chow plus canned dog food (Beef Formula for Dogs, IAMS). The mothers of dogs were fed dry food *ad libitum*. One week prior to whelping, and continuing until pups were weaned, they received canned food to supplement dry food. For this period, in terms of weight ratio, canned food constituted about 25% of the diet. Mothers were always on the respective diets. The weaning age for the pups was 6–7 wk postnatal. The fatty acid compositions of the low n-3 diets, published previously (18), are presented in Table 1, along with the compositions of diets enriched in n-3 fatty acids. Dogs were killed between 47–66 d of age, and retinas were taken and kept frozen at –80°C.

Lipid extraction. The retinas were homogenized in 1 mL Tris-HCl 150 mM (pH 7.4) and centrifuged at 1000 × *g* for 15 min at 4°C. The supernatant was analyzed for protein (BCA reagents; Pierce, Rockford, IL), and aliquots containing 1 mg protein were taken in duplicate for lipid analysis. Retina and plasma samples were extracted with chloroform/methanol by the procedure of Bligh and Dyer (19) and separated by thin-layer chromatography (TLC) using the solvent system hexane/diethyl ether/acetic acid (70:30:1, by vol). Phospholipids were extracted from the silica gel according the procedure of Arvidson (20) and used for methyl ester or molecular species analysis. Diets were extracted by the method of Bligh and Dyer (19), and an aliquot was taken for total lipid analysis.

Fatty acid analysis. Total phospholipids and lipids were treated with 14% boron trifluoride-methanol (21), and the resulting fatty acid methyl esters were analyzed by gas–liquid chromatography using a DB-225 capillary column with helium as a carrier gas (22), and identified by comparison with appropriate standards.

Molecular species analysis. Total phospholipids were converted to their respective diradylglycerols with phospholipase C (23). Diradylglycerols were derivatized with benzoic anhydride (24) and resolved into diacylglycerobenzoates (DGBZ) and ether-linked glycerobenzoates by TLC on silica gel using a solvent system of toluene/hexane/diethyl ether (50:45:5, by vol). The DGBZ were visualized by spraying with 0.05% 2′,7′-dichlorofluorescein in 75% aqueous methanol, and the silica gel was scraped into 2 mL of ethanol and mixed vigorously. Two milliliters of water was added, and the suspension was extracted three times with 2 mL of hexane. The pooled hexane extracts were dried under nitrogen and redissolved in acetonitrile/isopropanol (80:20, vol/vol). The DGBZ were fractionated into molecular species by high-performance liquid chromatography (HPLC) on a Supelcosil LC-18 column (5 μm, 25 cm × 4.6 mm i.d.; Supelco, Bellefonte, PA) using acetonitrile/isopropanol (80:20, vol/vol) at a flow rate of 1.0 mL/min. Lipids were detected at 230 nm and identified by comparison with standard (25). The identities of the peaks of interest were confirmed by gas–liquid chromatography analysis of the fatty acid methyl esters.

[a]Values are mean mol% ± SD of n retinas analyzed in duplicate; plasma values are from single analyses. The percentage distribution was calculated on the sum of identified fatty acids listed on the tables. n.d., not detected. Significant differences between the diets: [a]$P < 0.05$, [b]$P < 0.01$, [c]$P < 0.001$.

RESULTS

Fatty acid composition of dog food. The fatty acid compositions of several types of commercial dog food fed over the past 8 yr at the Retinal Disease Studies Facility are given in Table 1. Since 1995, there has been an increase in the level of n-3 fatty acids in the food, due to the inclusion of fish products**.** This is especially evidenced by higher contents of 18:3n-3 and 22:6n-3 in the high n-3 lab chow diet, the average of total n-3 fatty acids (from lab chow, puppy plus canned food) being twice more in the high n-3 than in the low n-3 diets.

Effect of diet on the fatty acid composition of plasma phospholipids. Table 2 contains the fatty acid composition of total phospholipids from plasma of dogs fed commercial diets low and high in n-3 fatty acids. Several interesting differences are noteworthy. The total n-3 and 22:6n-3 levels are higher in the high n-3 group, as expected. However, the 22:5n-3 level was higher in the low n-3 group (but the difference is not significant by *t*-test). The total n-6 fatty acid levels were the same, although the low n-3 group had higher 18:2n-6 and 22:5n-6, and lower 20:4n-6 than the high n-3 group.

Effect of diet on the fatty acid composition of retinal phospholipids. Fatty acid compositions of total phospholipids from retina of each diet group are presented in Table 2. The major PUFA in both groups is 22:6n-3, which is significantly lower in the low n-3 group; the level of 22:5n-3 is also lower in this group. These lower levels of n-3 fatty acids are balanced by significantly higher proportions of 22:5n-6, 20:4n-6, and 22:4n-6. Overall, when dogs were fed the low n-3 diet, there was a reciprocal replacement of n-3 by n-6 fatty acids in the retina, especially evidenced in 22-carbon fatty acids. Interestingly, the percentage of 22-carbon PUFA remained remarkably similar in the two groups (25.5% in low n-3, and 27.0% in high n-3). However, the n-3/n-6 ratio was threefold higher in the high n-3 group. Apart from the differences in PUFA levels, only minor differences were noted between groups in the levels of saturated and monoenoic fatty acids.

Effect of diet on the molecular species composition of retinal phospholipids. The molecular species of retinal phospholipids from the two groups are shown in the representative high-performance liquid chromatographic tracings illustrated in Figure 1. The unidentified peaks between 22:6n-3–22:6n-3 and 18:1–22:6n-3 contain co-eluting molecular species composed of one 22:6n-3 and one 20-, 22-, or 24-carbon fatty acids having four, five, or six double bonds (23). The relative mole percentage of the identified molecular species are given in Table 3. Those molecular species not cleanly resolved are combined as "others." The data show that the fatty acid compositional changes are reflected in the molecular species compositions. The proportions of 22:6n-3-containing species are lower in the low n-3 group, and are compensated for by higher levels of 22:5n-6-containing species. The greatest effect is seen in 22:6n-3–22:6n-3, where the level is sixfold higher in the high n-3 group. The levels of the other 22:6n-3–containing

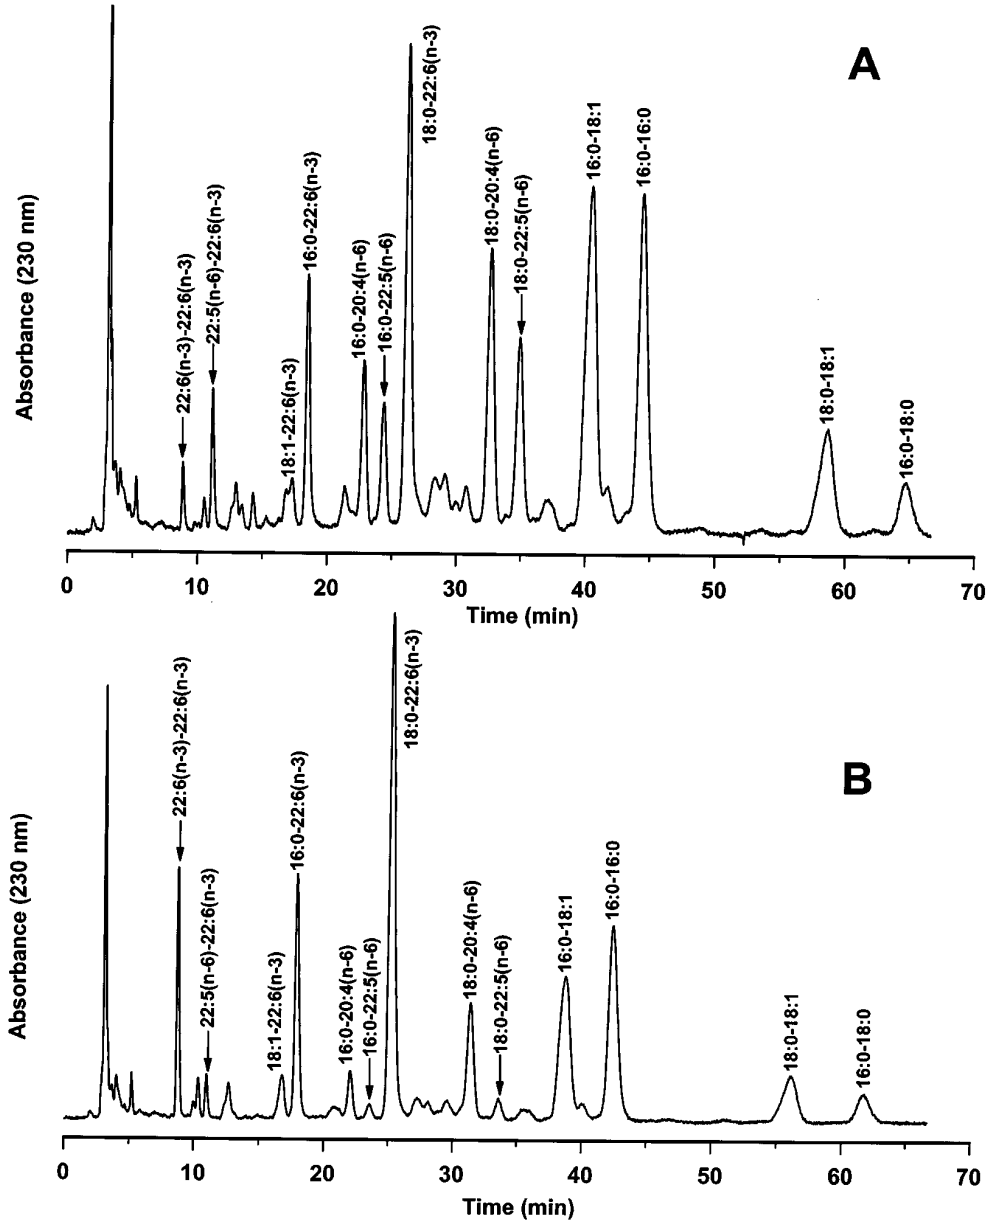

FIG. 1. Representative high-performance liquid chromatographic elution profiles of the molecular species of diacylglycerobenzoates derived from retinal phospholipids of dogs fed (A) low n-3 diet or (B) high n-3 diet. The separations were achieved on a C-18-phase column with acetonitrile/isopropanol (80:20, vol/vol) as solvent, and diacylglycerobenzoates were detected at 230 nm.

species are about two fold higher. The two major 22:5n-6-containing species, 16:0–22:5n-6 and 18:0–22:5n-6, are fourfold higher in the low n-3 group. The proportions of 20:4n-6-containing molecular species are also higher in the low n-3, although to a lesser extent. Only minor changes are seen in 18:1-containing species, while disaturated species are not affected by the diet.

DISCUSSION

PUFA of the n-3 family have been shown to be important in retinal function of experimental animals and human infants. Rats (26–29), guinea pigs (30,31), and monkeys (13,32) fed n-3 deficient diets undergo characteristic electroretinographic changes associated with decreased retinal ability to absorb light and generate a visual signal. Human infants, especially those born prematurely, show a slower development of their visual system if they do not receive n-3 fatty acids, especially 22:6n-3 (reviewed in Ref. 33). Therefore, maintenance of optimal visual function depends on a dietary source of n-3 fatty acids.

Dogs (17), cats (34), and humans (35–38) with inherited retinal degenerations have been shown to have lower plasma and red blood cell levels of PUFA, especially 22:6n-3, than

TABLE 3
Effect of Diet on the Molecular Species Composition of Phospholipids in Normal Dog Retina

Molecular species	Low n-3[a] (n = 6)	High n-3[a] (n = 9)

22:5n-6-containing species	11.76 ± 1.42	4.01 ± 0.88

[a]Values are mean mol% ± SD of n retinas analyzed in duplicate. Others: sum of unidentified molecular species. Differences between diets are all significant ($P < 0.001$) except where *ns* (not significant) is indicated.

appropriate controls. Retinal photoreceptor membrane levels of 22:6n-3 are also reduced in affected dogs (18). We originally thought that the lower 22:6n-3 in the retina reflected a reduced synthetic capability (17); however, we subsequently demonstrated that the retina and retinal pigment epithelium from affected dogs could convert 22:5n-3 to 22:6n-3 as efficiently as tissues from normal animals (39). Since 22:6n-3 is the most abundant fatty acid in the retina, it has been suggested that the retinal degeneration may be causally related to the low 22:6n-3 levels (17,39,40). To address this question, we administered fish oil to affected and normal dogs for 5 mon and then measured retinal function and structure (18). Fish oil supplementation did not preserve either, but the retinal levels of 22:6n-3 were less in supplemented affected dogs compared to controls. Currently, we are considering two possibilities to explain the 22:6n-3 findings in affected dogs: (i) there is a defect in transport of 22:6n-3 from liver to target organ, and (ii) the mutation produces a metabolic stress on the animals that results in increased catabolism of 22:6n-3.

The results of the present study show that it is possible to alter the retinal fatty acid composition of dogs by feeding them diets with different levels of n-3 fatty acids. Surprisingly, profound effects were observed, especially a marked increase of 22:6n-3 content, with only small additional amounts of n-3 fatty acids to the diets. The magnitude of the changes was indeed higher that we had predicted from the diet composition. It thus appears imperative, in any dietary study where animals are fed commercial diets, that all diets be analyzed prior to use. To observe these changes in neural tissues at such a relatively young age was unexpected, and undoubtedly reflects the n-3 state of the mother. In studies with rats fed fat-free or n-3 deficient diets from weaning age (3 wk), only small changes in retinal membrane fatty acid compositions could be achieved (1–3). Similarly, only a small decrease of 22:6n-3 in retinal lipids was observed for neonatal piglets fed formula low in n-3 fatty acids (low 18:3n-3 and no 20C or 22C n-3) for 15 d after birth (41). However, if the dietary restrictions were started during pregnancy and continued through the nursing period, then much more profound changes in retinal fatty acids occurred (12). In the present study, the female dogs were fed diets containing the two levels of n-3 fatty acids prior to conception, and their blood levels of 22:6n-3, which were not determined, presumably were quite different. Therefore, the pups had access to different levels of 22:6n-3 *in utero* and during nursing, both periods of time when the most profound effect of dietary changes on retinal fatty acid composition can be achieved (12). Feeding neonatal piglets a formula enriched with only small amounts of 22:6n-3 for 25 d after birth resulted in an increase of 22:6n-3 in retinal lipids (42). Interestingly, the phosphatidylcholine fraction was more responsive to dietary supplementation than the phosphatidylethanolamine fraction (42). In another study comparing high α-linolenate formula or low α-linolenate plus fish oil formula to a low α-linolenate formula, and where retinal phosphatidylethanolamine was analyzed, only a minor increase of 22:6n-3 was observed (41).

The higher levels of n-3 fatty acids in the retina of animals fed the high n-3 diet are compensated for by lower levels of n-6 fatty acids. Such a compensatory effect between these two fatty acid series has been described in the retina of rats and monkeys fed diets specifically formulated to be low (1–4,12,13) or high (43) in n-3 fatty acids. However, this phenomenon has not been previously observed in dogs fed commercially available diets. As reported for the rat photoreceptor membranes (12), the variations in the fatty acid composition of dog retina were reflected in the molecular species. Indeed, the greatest differences were found for molecular species containing 22:6n-3 or 22:5n-6. Based upon the magnitude of the change of di-22:6n-3 species compared to 22:6n-3 levels, analyses of molecular species appear to be especially appropriate to detect some variations in fatty acid metabolism. Interestingly, the 22:6n-3–22:6n-3 species was the most increased, by sixfold, compared to a twofold increase (on a relative basis) of species containing 22:6n-3 and monounsaturated or saturated fatty acid. However, the increase of 18:0–22:6n-3 is also of interest as it has the most significant amplitude, resulting in a predominant proportion (about 30%) of 18:0–22:6n-3 over the other molecular species. This large increase may represent a large incorporation of 22:6n-3 in phosphatidylcholine as reported in the study by Craig-Schmidt *et al.* (42). The functional significance of the di-22:6n-3 molecular species is unknown, but it is noteworthy that, to our knowledge, it has only been described in the retina (44), and more recently in fish sperm phospholipids (45), another 22:6n-3 enriched tissue. Metabolic studies have shown that, in bovine ROS, the di-22:6n-3 molecular species selectively incorporates 22:6n-3 compared to other 22:6n-3-containing molecular species (46). In frog ROS, the same investigators have reported that the different 22:6n-3-containing molecular species show distinctive rates of biosynthesis and

turnover (25). In addition, these parameters vary for the same molecular species depending on the glycerophospholipid. These metabolic studies support a role for 22:6n-3-containing molecular species in visual function. Interestingly, in rat ROS, 22:6n-3-containing molecular species are selectively decreased during oxidative stress related to light (12).

In conclusion, we report here that the fatty acid and molecular species compositions of dog retina are very sensitive to the diet received by the mother during gestation and nursing, and then by the dog during the first months after birth. Whether such changes have any effect on retinal function of normal dogs or contribute to the progression of retinal degeneration in *prcd*-affected dogs remains to be determined.

Regiospecific Analysis of Fractions of Bovine Milk Fat Triacylglycerols with the Same Partition Number

Paul Angers, Édith Tousignant, Armand Boudreau, and Joseph Arul*

Dairy Research Center (STELA), and Department of Food Science and Nutrition, Université Laval, Sainte-Foy, Québec, G1K 7P4, Canada

ABSTRACT: Bovine milk fat was fractionated using preparative reversed-phase high-performance liquid chromatography. The conditions consisted of two successive linear gradients of acetonitrile and *tert*-butylmethylether, followed by a final isocratic mixture of the two eluants, leading to triacylglycerols grouped by their partition number (PN). Fractions corresponding to partition numbers 32 to 50 were isolated and analyzed for fatty acid distribution between *sn*-1,3 and *sn*-2 positions by Grignard degradation. Results showed that the fatty acid distribution in milk fat triacylglycerols is nonrandom. The distribution of short-chain fatty acids, stearic (predominantly at *sn*-1,3 position) and palmitic (predominantly *sn*-2 position), did not change with triacylglycerol size. Medium-chain fatty acids were predominantly located at *sn*-2 position, but their proportion at this position decreased with triacylglycerol size. Oleic acid distribution was also size-dependent in that it was located in high proportions at *sn*-2 position in smaller triacylglycerols and vice versa. Results also showed that the *sn*-2 position was more unsaturated than *sn*-1,3 position in the PN range from 32 to 40, but it was more saturated in triacylglycerols with higher PN.
Lipids 33, 1195–1201 (1998).

Stereospecific analyses have shown that the distribution of fatty acids in bovine milk fat triacylglycerols is nonrandom. In overall fatty acid composition, short-chain fatty acids are largely found in the *sn*-3 position, and unsaturated fatty acids tend to be in higher concentration in the *sn*-1 and *sn*-3 positions. Although many studies have been carried out to determine the positional distribution of fatty acids in milk fat, few studies have addressed the relationship between stereo- or regiospecific distribution of fatty acids and size or acyl carbon number (ACN) of triacylglycerols. The importance of this knowledge lies in its implication in both functional and nutritional properties of milk fat and its fractions. Kuksis and coworkers overcame the difficulties in the stereospecific analysis of milk fat, using pancreatic lipase because of its preference for short-chain triacylglycerols (1), by analyzing milk fat fractions which had been enriched in either short-chain triacylglycerols (ACN34 to 42) or long-chain triacylglycerols (ACN36 to 54) (2–5). Their results suggested that positional distribution of some fatty acids in bovine milk fat could vary with size or ACN of triacylglycerols.

In the present study, reversed-phase high-performance liquid chromatography (HPLC), which constitutes the most widely used method for triacylglycerol analysis, including identification (6–9), has been used to fractionate milk fat by partition number (PN = ACN – 2 × DB, where DB is the number of double bonds). A method for structural analysis of milk fat triacylglycerols was adapted from literature methods for vegetable oils and used a Grignard reagent to degrade triacylglycerols (10–12). Since milk fat triacylglycerols are composed of short-, medium-, and long-chain fatty acids, analysis presents certain difficulties at both the stages of hydrolysis and of separation of the degradation products (mono-, di-, and triacylglycerols). Milk fat fractions corresponding to PN 32 to 50 were obtained and analyzed for the regiospecific distribution of fatty acids between *sn*-1,3 and *sn*-2 positions.

MATERIALS AND METHODS

Bovine milk fat. The winter butterfat was a sample from Ault Food (Mitchell, Ontario, Canada). A 25-kg block was tempered and then divided into samples of 100 g, which were rapidly melted and washed with deionized water in an oven (60°C), dried over anhydrous sodium sulfate, filtered, and kept under nitrogen in closed vials, at –30°C, until utilization.

Fractionation of milk fat by HPLC. Fractionation of bovine milk fat was carried out by micro-scale preparative reversed-phase HPLC to yield enough material, in a limited number of runs, to proceed with regiospecific analysis of most fractions. Standard triacylglycerols covering an extensive range of ACN (i.e., ACN12 to 54) and degrees of unsaturation were eluted for determination of the temporal limits on PN, in order to fractionate milk fat triacylglycerols according to this parameter. HPLC conditions consisted of an elution in three steps—two linear gradients of a mixture of acetonitrile and methyl-*tert*-butyl ether (MTBE) followed by an isocratic period—that allowed an even separation of triacylglycerols grouped by PN (Angers, P., F. Cho, R. Lencki, A. Bondreau, and J. Arul., 1998, submitted for publication). This technique was used to fractionate milk fat triacylglycerols by PN, and

Abbreviations: ACN, acyl carbon number; AN, acetonitrile; HPLC, high-performance liquid chromatography; MTBE, methyl-*tert*-butyl ether; PN, partition number; TLC, thin-layer chromatography; UV, ultraviolet.

was carried out on a Hewlett-Packard liquid chromatograph (Model HP-1050; Palo Alto, CA), equipped with an ultraviolet (UV) detector (220 nm) and a 60 mm × 10 mm Spherisorb 5 ODS 2 precolumn (Phenomenex, Torrance, CA) connected to a 250 mm × 10 mm Spherisorb 5 ODS 2 column, both maintained at 30°C. Data were acquired with a Hewlett-Packard ChemStation. Milk fat triacylglycerols were resolved with two consecutive linear gradient programs, followed by isocratic conditions, at a flow rate of 5 mL min^{-1}, using HPLC-grade solvents: (i) acetonitrile (AN)/MTBE from 90:10 to 80:20 (vol/vol) over a 42-min period; (ii) AN/MTBE from 80:20 to 70:30 (vol/vol), over the next 18 min; and (iii) AN/MTBE at 70:30 (vol/vol) for the remainder of the run. Samples (100 mg) were dissolved in chloroform (1.0 mL) and filtered. Aliquots of these solutions (100 µL) were injected, and the retention time of chloroform was taken as hold-up time (t_0). Fractions were collected using a Pharmacia fraction collector (Model 18-1010-19; Uppsala, Sweden), and the corresponding fractions from different runs were combined, dried over anhydrous sodium sulfate, filtered, concentrated at room temperature under a stream of dry nitrogen, and kept at −30°C until analysis. Collection times of the different fractions were based on retention times of a series of standards that were eluted under the same conditions, and were adjusted to collect triacylglycerols by PN. Mass of the recovered fractions allowed a precise determination of their relative proportions. Thus, calibration of the UV detector was not necessary.

Reference compounds. The following mono- and diacid triacylglycerols (99%, unless otherwise stated) were obtained from Sigma Chemical (St. Louis, MO) and used as standards: tributyrin, tricaprin, tricaproin, tricaprylin, trielaidin, trilaurin, trilinolein, trilinolenin, trimyristin, trimyristolein (98%), triolein, tripalmitelaidin, tripalmitin, tripalmitolein, tristearin, 1,2-dioleoyl-3-stearoyl-*rac*-glycerol, 1,2-distearoyl-3-myristoyl-*rac*-glycerol, 1,2-distearoyl-3-oleoyl-*rac*-glycerol, 1,3-distearoyl-2-oleoylglycerol, and 1,2-distearoyl-3-palmitoyl-*rac*-glycerol. Additional racemic diacid triacylglycerols were prepared for identification purposes, by chemical interesterification (13) of the following pairs of monoacid triacylglycerols, in ratios of 3 to 2: tributyrin and tricaprin; tributyrin and trimyristin; tributyrin and tripalmitin; tricaproin and tripalmitin; tricaprylin and tricaprin; tricaprylin and tripalmitin; tricaprylin and trilinolein; tricaprylin and trilinolenin; tricaprin and trimyristin; tricaprin and tripalmitin; tricaprin and triolein; trilaurin and trimyristin; trilaurin and tripalmitin; trilaurin and trilinolein; trimyristin and tripalmitin; trimyristin and triolein; tripalmitin and triolein; tripalmitin and trilinolein; triolein and trilinolein.

Degradation of milk fat triacylglycerols and thin-layer chromatography (TLC) separation. Grignard degradation was adapted from literature procedures (10–12) based on the use of a Grignard reagent. It was carried out on fractions that amounted to at least 4 mg (fractions 5 to 14), with ethylmagnesium bromide in slight excess (125%) of the required amount, to optimize the ratio of monoacylglycerols in the products, compared to large excesses usually utilized (11,12, 14,15). *sn*-2-Monoacylglycerols were isolated, and values for *sn*-1,3 positions were estimated from analysis of triacylglycerols and *sn*-2-monoacylglycerols (12). The procedure employed was as follows: to a solution of milk fat triacylglycerols (10 mg) in anhydrous diethyl ether (0.5 mL), contained in a flame-dried flask under an inert atmosphere, a solution of ethylmagnesium bromide in the same solvent (3.0 M; 42 µL, 5 eq) was added. After stirring 30 s at room temperature, glacial acetic acid (10 µL) was added slowly, followed by 300 µL of a 10% boric acid solution. The mixture was extracted with diethyl ether saturated with boric acid (4 × 2 mL), and the organic extracts were combined, washed sequentially with sodium bicarbonate (2%), water, and brine (saturated aqueous solution of sodium chloride), dried over anhydrous sodium sulfate, filtered, and concentrated under a stream of dry nitrogen. The residue was dissolved in a 1:1 mixture of chloroform/methanol (50 µL), and the solution was applied on a plate of silica gel (20 cm × 20 cm, 0.2 mm thickness). Standards of mono-, di-, and triacylglycerols were also applied as references. Migration was carried out with a mixture of chloroform/methanol (98:2 vol/vol), and the references were sprayed with dichlorofluorescin (0.1% in ethanol) and visualized under UV light. The band corresponding to monoacylglycerols was scraped off and extracted with diethyl ether (4 × 2 mL) aided by sonication. The solvent was evaporated and the residue was solubilized as before and applied on a homemade plate of silica gel containing 10% (w/w) boric acid (20 cm × 20 cm, 0.5 mm thickness). Migration was achieved with a mixture of chloroform/methanol (96:4 vol/vol). Usual treatment was carried out for isolation of *sn*-2 monoacylglycerols. Fractions 1 to 4 and 15, which were isolated in very small amounts (≤2.0 mg), were not analyzed for regiospecific distribution of fatty acids.

Gas chromatography of fatty acids. Methylation of fatty acids was carried out in a sealed tube with 0.4 N sodium methoxide in methanol (16). Analyses of the methyl esters were performed with a gas chromatograph (Model 5890 Series II; Hewlett-Packard) equipped with a flame-ionization detector and connected to a computer with a Hewlett-Packard ChemStation. Sample volumes (1.0 µL) in hexane were injected on a DB-225 capillary column (J&W, Folsom, CA; 30 m × 0.25 mm i.d., 0.25 µm film thickness), with a split ratio of 50:1. Hydrogen was the carrier gas, with a linear velocity of 35.5 cm s^{-1} at 50°C. The injector and detector temperatures were maintained, respectively, at 215 and 230°C, while the oven temperature was programmed from 35 to 180°C at 20°C min^{-1}, then up to 200°C at 3°C min^{-1}, and held for 13 min at this temperature, for a total time of 30 min. Fatty acid methyl ester standards (GLC Reference Standards, Catalogue No. GLC-60 and GLC-76; Nu-Chek-Prep, Elysian, MN) were used for identification and calibration of the detector response. The standard mixture was composed of saturated fatty acid esters C_4–C_{20}, including odd carbon number fatty acid esters C_{13}, C_{15}, and C_{17}; and unsaturated fatty acid esters, $C_{14:1}$, $C_{16:1}$, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$.

RESULTS AND DISCUSSION

Fractionation of milk fat by HPLC. Reversed-phase HPLC fractionation of bovine milk fat was based on the utilization of standard triacylglycerols for collection times of the fractions. Although triglycerides were not as well resolved in preparative conditions as they were in analytical conditions (17–20), a total of 67 peaks, exclusive of shoulders, was divided into 15 differentiated peak groups (Fig. 1). As a result, starting with fraction 2, the HPLC fractions corresponded to PN of triacylglycerols (Table 1). Values reported in Table 1 show that fractions 7, 8, 12, and 13 constituted the major fractions, since they accounted for 54.0% of milk fat, which displayed a bimodal distribution for triacylglycerols.

Grignard degradation and TLC separation. Partial deacylation of triacylglycerols was carried out with ethylmagnesium bromide. To ensure there was no isomerization of the monoacylglycerols during degradation, workup, and TLC separation, the method was performed with synthetic *sn*-1,3-dipalmitoyl-2-oleoylglycerol. Fatty acid analysis of the *sn*-1,3 and *sn*-2 monoacylglycerols showed very little or no detectable isomerization with the procedure used. A two-step

[b]Value does not total 100.0 because of rounding of figures.

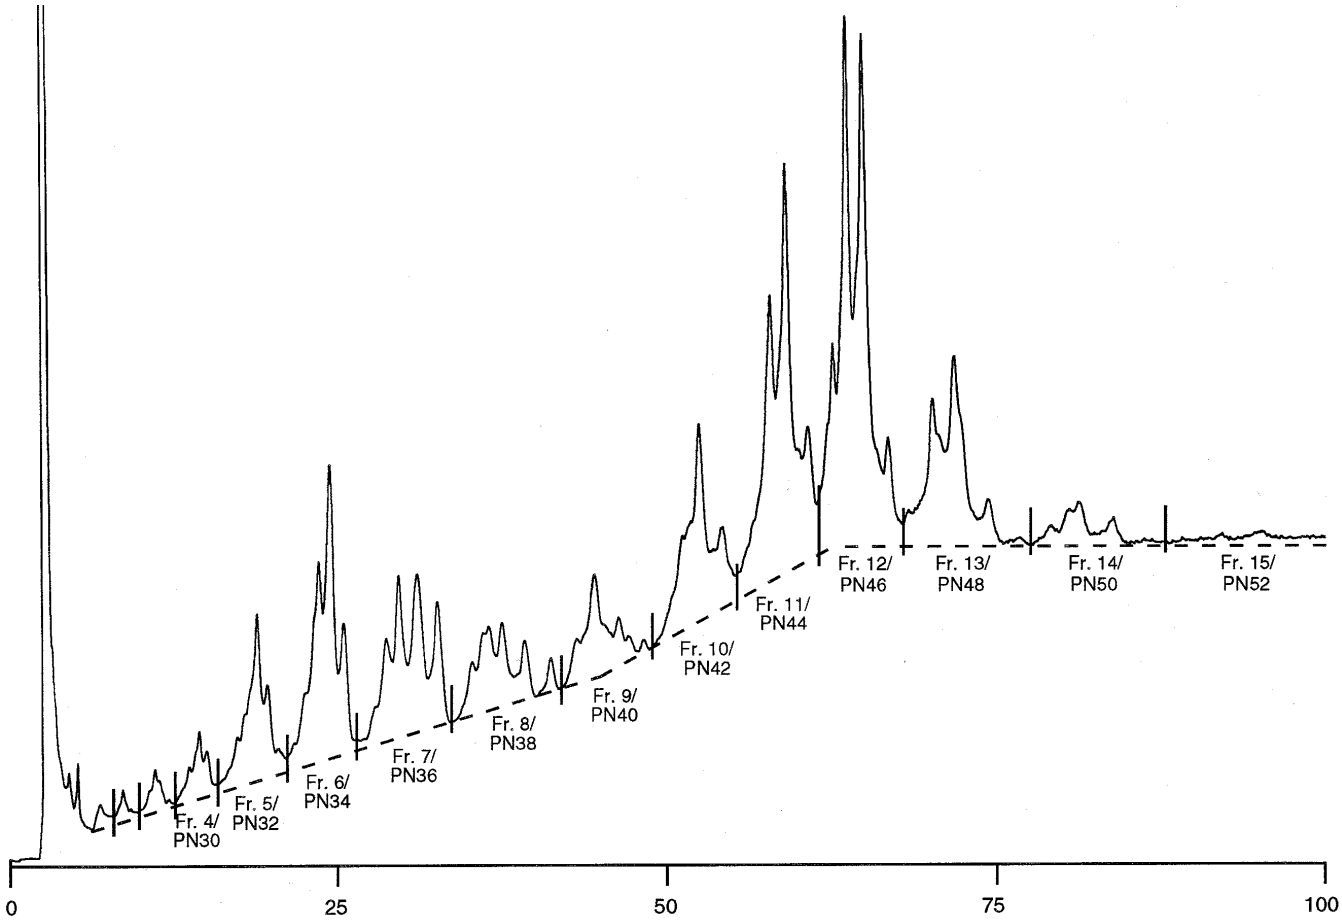

FIG. 1. High-performance liquid chromatogram of bovine milk fat, on a C-18 semipreparative column, using eluent mixtures of acetonitrile (AN)/methyl-*tert*-butyl ether (MTBE) from 90:10 to 80:20 (vol/vol) over a period of 42 min, followed by a second gradient of AN/MTBE from 80:20 to 70:30 (vol/vol), over the next 18 min, and an isocratic mixture of AN/MTBE 70:30 for the remainder of the run. The ultraviolet detector was set at 220 nm. The vertical lines indicate the border of the fractions (Fr.) corresponding to partition number (PN).

TLC separation was selected because it allowed a cleaner separation of the bands corresponding to *sn*-1,3 and *sn*-2 monoacylglycerols, compared to only one TLC migration (21), for which separation between *sn*-1,3 and *sn*-2 monoacylglycerols was never very clear with milk fat samples, unlike simple standards.

Fatty acid analysis. Fatty acid analyses of triacylglycerols and of monoacylglycerols resulting from their Grignard degradation were carried out for fractions 5 to 14 (Table 2). Fatty acids were analyzed as methyl esters, and only the 17 most common were quantified. The saturated fatty acids analyzed included arachidic, butyric, capric, caproic, caprylic, lauric, margaric, myristic, palmitic, pentadecanoic, stearic and tridecanoic, whereas unsaturated fatty acids were entirely of *cis*-configuration and of methylene-interrupted unsaturation (linoleic, linolenic, myristoleic, oleic, and palmitoleic acids). Neither branched-chain fatty acids, acids with conjugated unsaturation, nor unsaturated acids of *trans*-configuration were identified in the analysis.

Saturated fatty acids. C_4 to C_8 fatty acids were present only in the fractions corresponding to triacylglycerols with PN of 32 to 42 (Table 1). As expected, butyric acid was found exclusively in *sn*-1,3 position, with values of around 40% in triacylglycerols with PN32 and 34, in agreement with previous results by pancreatic lipase deacylation (2), by ^1H and ^{13}C nuclear magnetic resonance (22,23), and by direct measure-

[a]Values are means of duplicate analyses.
[b]Values in parentheses represent the percentage of fatty acids located between the *sn*-1,3 and *sn*-2 positions in any given fraction.
[c]Fatty acid not detected or value was less than 0.1%. PN, partition number, defined as acyl carbon number – 2 × DB, where DB is the number of double bonds.

ment by gas chromatography (24), which assigned this acid almost exclusively at either *sn*-3 or *sn*-1,3 position. Since butyric acid is found only in the *sn*-3 position of milk fat triacylglycerols (2), its level at this position of the glycerol is 80% in these two fractions. Caproic acid was found only in fractions containing triacylglycerols with PN32 to 42, and mostly in *sn*-1,3 positions, with the highest ratio in the fractions with PN36 to 40, which compares to the reported values (2,24). As only one butyric or caproic acid may be present in triacylglycerols with PN of 32 and 34, data in Table 1 suggest that more than 90% of those triacylglycerols contain either butyric or caproic acid. The distribution of caprylic acid was also nonrandom and was preferentially located at *sn*-1,3-positions with increasing frequency from PN32 to PN40. Above PN40, the proportion of C_8 in the *sn*-1,3 positions decreased. The distribution of capric acid (C_{10}) also varied with the triacylglycerol PN. It was preferentially located at the *sn*-2 position of triacylglycerols with PN32 and 34 and nearly random in triacylglycerols with PN of 36 and 38, but above PN40, it was predominantly located at *sn*-1,3 positions.

Generally, C_{12}–C_{15} fatty acids were preferentially located in the *sn*-2 position, but their frequency at the *sn*-2 position varied with the PN of triacylglycerol. The frequency of lauric acid (C_{12}) at the *sn*-2 position decreased gradually with increase in the PN of triacylglycerols until PN of 44 where its distribution was nearly random, but above PN44, its frequency at the *sn*-2 position increased again. The distribution pattern for myristic acid (C_{14}) was quite similar to lauric acid except that a nearly random distribution occurred at PN46.

Of the C_{16} to C_{20} saturated fatty acids, which included palmitic, margaric, stearic and arachidic acids, palmitic and stearic acids were the most abundant. The distribution of the latter two acids between *sn*-1,3 and *sn*-2 positions was essentially opposite and was greatly affected by PN, but with some exceptions. Palmitic acid (C_{16}) was nearly random in triacylglycerols with PN42 and was distributed predominantly at the *sn*-2 position in triacylglycerols with PN36, 38, 48, and 50. The distribution of stearic acid (C_{18}) was predominantly at the *sn*-1,3 position with two exceptions in triacylglycerols with PN of 34 and 46, where the distribution was nearly random. Concentration of palmitic acid at the *sn*-2 position was the highest of all the fatty acids in most of the HPLC fractions (fractions 7 to 14 or PN36 to PN50), with values ranging from 18.9% in fraction 5 (PN32) up to 54.6% in fraction 13 (PN48). Distributions of myristic and palmitic acids are in good agreement with reported values for distributions of fatty acids in triacylglycerols with PN of 48 (ACN50:1 and 52:2) (25).

Unsaturated fatty acids. Among the unsaturated fatty acids analyzed, oleic acid was by far the most abundant. The distribution pattern of oleic acid ($C_{18:1}$) was different from other major fatty acids. It was nearly random in triacylglycerols with PN32 and 34. Above PN34, it was predominantly located at the *sn*-2 position until PN40, where 65% of the oleic acid was at the *sn*-2 position. Above PN40, oleic acid was predominantly located at the *sn*-1,3 positions, somewhat similar to the stearic acid distribution in the PN range of 42 to 50. This distribution pattern was also true for myristoleic and palmitoleic acids. Myristoleic acid was the second-most abundant unsaturated fatty acid (5.0%) at the *sn*-2 position in fraction 5 (PN32), second only to oleic acid (8.4%). Linoleic and linolenic acids were mostly found in the *sn*-1,3 position, but their levels were low. Moreover, linolenic acid was found only in a limited number of fractions and was highest in fraction 5 (PN32).

The fatty acid distribution in bovine milk fat between *sn*-1,3 and *sn*-2 positions followed the general trends observed by Kuksis and co-workers for fractions enriched either in short- or long-chain triacylglycerols (2–4), but we report fatty acid distribution of milk fat on a number of fractions enriched in triacylglycerols varying in size. Our results also show the changes in the distribution of various fatty acids between the *sn*-2 and *sn*-1,3 positions with size of triacylglycerol. Fatty acids C_4, C_6, and C_8 are predominantly located at the *sn*-1,3 positions irrespective of the triacylglycerol size. The distribution pattern of the fatty acid C_{10} was mixed. It was predominantly located at the *sn*-2 position only in the short-chain triacylglycerols (PN32 and 34); above PN36, it was preferentially distributed at the *sn*-1,3 positions like the short-chain fatty acids and its frequency at the *sn*-2 position decreased with triacylglycerol size, similar to fatty acids C_{12} and C_{14}. Fatty acids C_{12} and C_{14} present a different pattern in that they are preferentially located at the *sn*-2 position, but their frequency at this position decreases with triacylglycerol size. Although the distributions of C_{16} and C_{18} are not greatly affected by size, the distribution of palmitic acid is predominantly at the *sn*-2 position and that of stearic acid in the *sn*-1,3 positions. However, the distribution of oleic acid presents a different pattern. It is distributed predominantly at the *sn*-2 position, somewhat like palmitic acid below PN40; but in longer-chain triacylglycerols it is predominantly located at the *sn*-1,3 positions, somewhat similar to stearic acid. Considering only the distribution of saturated vs. unsaturated fatty acids (Table 3), we observed that in fractions 5 to 9 (PN32–40), the *sn*-1,3 positions were more saturated than the *sn*-2 position. This trend was the opposite in fractions 10 to 14 (PN42 to 50). For all fractions except 12 and 13 (PN46 and 48), the difference between values for saturated and unsaturated fatty acids was not very high (3 to 10%). But for fractions 12 and 13, the difference was 16 to 24%. In addition, the *sn*-1,3 positions were about twice more unsaturated than the *sn*-2 position in these two fractions (Table 3).

Fractions of milk fat triacylglycerols corresponding to PN 32 to 50 were isolated and analyzed for their fatty acid distribution between the *sn*-1,3 and *sn*-2 positions. First, our results confirm that fatty acid distribution is nonrandom in milk fat triacylglycerols. Second, our results show that the distribution pattern of various fatty acids between the *sn*-2 and *sn*-1,3 positions varies with triacylglycerol size. Short-chain fatty acids (C_4–C_8) and stearic acid are located at the *sn*-1,3 position at high proportions irrespective of size. The frequency of the medium-chain fatty acid, C_{10}, at the *sn*-2 posi-

TABLE 3

	2	16.5	77.6	22.4

[a]Fractions were obtained by reversed-phase high-performance liquid chromatography of milk fat, and fractions 5 to 14 accounted for 93.3% of milk fat.
[b]Carbon number (CN) was calculated from the fatty acid composition.

tion decreased with triacylglycerol size and it was preferentially located only in short-chain triacylglycerols. Other medium-chain fatty acids C_{12} and C_{14} are located at the *sn*-2 position in high proportions, but their proportion at the *sn*-2 position decreases with triacylglycerol size. Palmitic acid is predominantly located at the *sn*-2 position irrespective of the size of triacylglycerol. Interestingly, oleic acid distribution is unique in that it is located in high proportions at the *sn*-2 position in triacylglycerols of lower size, but at *sn*-1,3 positions in longer triacylglycerols. Our results also showed the *sn*-2 position was more unsaturated than the *sn*-1,3 position in the PN range of 32–40, but it was more saturated in triacylglycerols of higher PN owing to the distribution pattern of oleic acid.

Calcium-Independent Phospholipase A_2 in Isolated Rabbit Ventricular Myocytes

Jane McHowat* and Michael H. Creer

Department of Pathology, St. Louis University School of Medicine, St. Louis, Missouri 63104

ABSTRACT: We characterized phospholipase A_2 (PLA_2) activity in isolated rabbit ventricular myocytes with respect to subcellular distribution, substrate specificity, and Ca^{2+} dependency. Membrane-associated PLA_2 was found to be an order of magnitude greater than cytosolic PLA_2. Ventricular myocyte PLA_2 activity was enhanced following protease-activated receptor stimulation with thrombin and was found to be largely Ca^{2+}-independent and selective for phospholipid substrates containing arachidonic acid at the *sn*-2 position. Immunoblot analysis using an antibody to cytosolic Ca^{2+}-independent PLA_2 from Chinese hamster ovary cells recognized a membrane-associated protein with a molecular mass of approximately 80 kDa; however, differences in pH optima, response to inhibitors, and substrate selectivity of membrane-associated and cytosolic PLA_2 activity suggest the presence of multiple Ca^{2+}-independent PLA_2. Pretreatment with bromoenol lactone, a specific inhibitor of Ca^{2+}-independent PLA_2, significantly attenuated membrane-associated and cytosolic PLA_2 in unstimulated and thrombin-stimulated myocytes. Pretreatment with methyl arachidonyl fluorophosphonate, mepacrine, or dibucaine had no significant effect on PLA_2 activity under all conditions tested. Ventricular myocyte PLA_2 activity was significantly inhibited by ATP, GTP, and their nonhydrolyzable analogs and was regulated by protein kinase C activity. These studies demonstrate the presence of one or more unique membrane-associated Ca^{2+}-independent PLA_2 in isolated ventricular myocytes that exhibit a preference for phospholipids with arachidonate at the *sn*-2 position and that are activated by thrombin stimulation.

Lipids 33, 1203–1212 (1998).

The present study was undertaken to characterize phospholipase A_2 (PLA_2) activity in isolated rabbit ventricular myocytes. Although detailed characterization of PLA_2 was described in whole myocardium from several species (1–4) and in vascular smooth muscle cells from the dog (5), little is known regarding detailed characterization of PLA_2 isoforms in ventricular myocytes. It is important to provide a detailed characterization of PLA_2 in different myocardial cell populations because of cell-specific differences in phospholipid composition and in the mechanisms of enzyme activation. For example, we showed that increased production of lysophospholipids and free fatty acids resulting from PLA_2 activation during ischemia or following thrombin stimulation in the heart plays an important role in the subsequent development of electrophysiologic alterations (6,7). Because there are likely to be significant differences in the nature of the electrophysiologic alterations produced by monoacyl lysophospholipids (derived from PLA_2-catalyzed hydrolysis of diacyl phospholipids in endothelial cells and smooth muscle cells) as opposed to lysoplasmalogens (derived from PLA_2-catalyzed hydrolysis of plasmalogens in ventricular myocytes), it is important to determine the substrate selectivity of the PLA_2 activity present in isolated cardiac myocytes and to distinguish this activity from that present in other nonmyocytic myocardial cell populations.

Previous studies of PLA_2 in whole myocardium demonstrate that Ca^{2+} is not required for PLA_2 activity (i.e., myocardial PLA_2 is Ca^{2+}-independent) and that PLA_2 is selective for arachidonylated ether-linked phospholipid substrates. Studies of purified cytosolic myocardial PLA_2 activity demonstrated that this isoform is tightly associated with phosphofructokinase (PFK) (8), is stimulated by ATP (9), and specifically binds to calmodulin in a Ca^{2+}-dependent fashion (10).

The goal of the present study was to characterize the subcellular distribution, Ca^{2+}-dependency, and substrate selectivity of PLA_2 activity in isolated ventricular myocytes. Since the phospholipid composition of isolated ventricular myocytes is unique because of the predominance of phospholipids containing an unsaturated ether covalent linkage at the *sn*-1 position (i.e., plasmalogen phospholipids) (11), our characterization of PLA_2 activity in isolated ventricular myocytes was performed in the absence (<1 nM) and presence (10 mM) of Ca^{2+} using phospholipid substrates containing *O*-acyl ester, saturated ether, or unsaturated (vinyl) ether-linked aliphatic groups at the *sn*-1 position and oleate or arachidonate at the *sn*-2 position. Alterations in ventricular myocyte PLA_2 activity in the presence of high-energy phosphates, thrombin, and modulated protein kinase C (PKC) activity are also described.

Abbreviations: BEL, (*E*)-6-(bromomethylene) tetrahydro-3-(1-naphthalenyl)-2H-pyran-2-one or bromoenol lactone; $cPLA_2$, cytosolic PLA_2; CHO, Chinese hamster ovary; DAG, diacylglycerol; DTT, dithiothreitol; $iPLA_2$, calcium-independent PLA_2; LPC, lysophosphatidylcholine (this term is also used to refer collectively to 1-*O*-alkyl, 1-*O*-alk-1′enyl, and 1-*O*-acyl forms of monoradyl choline glycerophospholipids); MAFP, methyl arachidonyl fluorophosphonate; PAP, phosphatidic acid phosphohydrolase; PFK, phosphofructokinase; PKC, protein kinase C; PLA_1, phospholipase A_1; PLA_2, phospholipase A_2; PLC, phospholipase C; PLD, phospholipase D; PMA, phorbol 12-myristate 13-acetate.

MATERIALS AND METHODS

Isolation of ventricular myocytes. Adult female rabbits weighing 2–3 kg were anesthetized with intravenous pentobarbitone sodium (50 mg/kg), and the heart was rapidly removed. The heart was mounted on a Langendorff perfusion apparatus and perfused for 5 min with a Tyrode solution containing (in mmol/L) NaCl 118, KCl 4.8, $CaCl_2$ 1.2, $MgCl_2$ 1.2, $NaHCO_3$ 24, KH_2PO_4 1.2, and glucose 11 (all from Sigma Chemical Co., St. Louis, MO); the Tyrode solution was saturated with 95%O_2:5%CO_2 to yield a pH of 7.4. This was followed by a 4-min perfusion with a Ca^{2+}-free Tyrode solution containing EGTA (100 μM) and a final perfusion for 20 min with the Tyrode solution containing 100 μM Ca^{2+} and 0.033% collagenase (type II; Worthington Biochemical, Lakewood, NJ). The left and right ventricles were cut into small pieces which were then shaken in fresh enzyme solution. The first harvest of myocytes was discarded. Cells from the next three harvests were combined and washed with a HEPES buffer containing (in mmol/L): NaCl 133.5, KCl 4.8, $MgCl_2$ 1.2, KH_2PO_4 1.2, HEPES 10, and glucose 10, plus 300 M $CaCl_2$, pH adjusted to 7.4 with 10 N NaOH. Extracellular Ca^{2+} concentration was increased to 1.2 mM in three stages at intervals of 20 min. Elongated myocytes were separated from rounded nonviable cells by repeated differential sedimentation.

PLA_2 assays. Myocytes were suspended in 1 mL of buffer containing (mmol/L): sucrose 250, KCl 10, imidazole 10, EDTA 5, dithiothreitol (DTT) 2 with 10% glycerol, pH = 7.8 with 10 N KOH (all from Sigma Chemical Co.). The suspension was sonicated on ice three times for 10 s, and the sonicate was centrifuged at 14,000 × *g* for 10 min. The supernatant was then centrifuged at 100,000 × *g* for 60 min to separate the membrane fraction (pellet) from the cytosolic fraction (supernatant). PLA_2 activity in subcellular fractions was assessed by incubating enzyme (typically 8 μg membrane protein or 200 μg cytosolic protein) with 100 μM *sn*-2 radiolabeled plasmenylcholine, alkylacyl glycerophosphocholine, or phosphatidylcholine in assay buffer containing 10 mM Tris, 10% glycerol, pH = 7.0 with either 4 mM EGTA or 10 mM Ca^{2+} at 37°C for 5 min in a total volume of 200 μL. Synthesis of radiolabeled phospholipid substrates was described previously (3,6,8). The reaction was initiated by adding the substrate as a concentrated stock solution in ethanol (5 μL total volume) which was injected into a total volume of 200 μL of aqueous buffer to achieve a final substrate concentration of 100 μM. Reactions were terminated by the addition of 100 μL of butanol, and released radiolabeled fatty acid was isolated by application of 25 μL of the butanol phase to channeled Silica Gel G plates, development in petroleum ether/diethyl ether/acetic acid (70:30:1, by vol) and subsequent quantification by liquid scintillation spectrometry. The reaction conditions we selected resulted in linear reaction velocities with respect to both time and enzyme concentration for each substrate examined. Protein content of each sample was determined by the Lowry method utilizing freeze-dried bovine serum albumin (Bio-Rad Laboratories, Richmond, CA) as the protein standard as described previously (12).

Immunoblot analysis of PLA_2. Myocytes were suspended in lysis buffer containing (in mmol/L) HEPES 20 (pH 7.6), sucrose 250, DTT 2, EDTA 2, EGTA 2, β-glycerophosphate 10, sodium orthovanadate 1, phenylmethylsulfonyl fluoride 2, leupeptin 20 μg/mL, aprotinin 10 μg/mL, and pepstatin A 5 μg/mL. Cells were sonicated on ice for three bursts of 10 s and centrifuged at 14,000 × *g* at 4°C for 10 min to remove cellular debris and nuclei. Cytosolic and membrane fractions were separated by centrifuging the supernatant at 100,000 × *g* for 60 min. The pellet was resuspended in lysis buffer, and the suspension was centrifuged at 100,000 × *g* for 60 min twice to minimize contamination of the membrane fraction with cytosolic protein. The final pellet was resuspended in lysis buffer containing 0.1% Triton X-100. Protein (total protein, cytosol, or membrane) was mixed with an equal volume of SDS sample buffer and heated at 95°C for 5 min prior to loading onto a 12% polyacrylamide gel. Protein was separated by SDS/polyacrylamide gel electrophoresis at 200 V for 35 min and electrophoretically transferred to polyvinylidene difluoride (PVDF) membranes (Bio-Rad) at 100 V for 1 h. Nonspecific sites were blocked by incubating the membranes with Tris-Buffered saline containing 0.05% (vol/vol) Tween-20 (TBST) and 5% (wt/vol) nonfat milk for 1 h at room temperature. The blocked polyvinylidene difluoride membrane was incubated with antibodies to cytosolic PLA_2 ($cPLA_2$; Santa Cruz) or Ca^{2+}-independent PLA_2 (iPLA, 1:2000 dilution; Cayman Chemical, Ann Arbor, MI) for 1 h at room temperature. Unbound antibodies were removed with three washes with TBST solution, and membranes were incubated with horseradish peroxidase-conjugated secondary antibodies (1:5000 dilution). Following six washes with TBST, regions of antibody binding were detected using enhanced chemiluminescence (Amersham, Arlington Heights, IL) and exposure to film (Hyperfilm; Amersham).

RESULTS

In initial studies, examination of the metabolic pathways potentially responsible for the production of fatty acid from diradyl choline glycerophospholipid substrates and the stability of PLA_2 activity in sonicated cell preparations derived from freshly isolated cells was examined. These initial studies of ventricular myocyte PLA_2 used 1-*O*-hexadec-1′-enyl-2-[^{3}H]oleoyl-*sn*-glycero-3-phosphocholine (16:0, [^{3}H]18:1 plasmenylcholine) as substrate and unfractionated sonicates of isolated myocytes as the enzyme source in the absence (<1 nM) and presence (10 mM) of added Ca^{2+}. Following incubation of the substrate with sonicated cell preparations, the reaction products were subjected to thin-layer chromatographic analysis using both one- and two-dimensional thin-layer chromatographic techniques which permitted the separation of fatty acids from other neutral lipids and which clearly resolved choline lysophospholipids from the diradyl

TABLE 1
Quantitation of Radiolabeled Products Generated Following Incubation of 100 μM (16:0,[^{3}H]18:1) Plasmenylcholine (PlasCho) or Phosphatidylcholine (PC) Substrate with 8 μg Membrane Protein (for 5 min at 37°C)[a]

Substrate	Product	dpm	Substrate	Product	dpm
(16:0,[^{3}H]18:1)	Oleic acid	20934 ± 306	(16:0,[^{3}H]18:1)	Oleic acid	14952 ± 227
Plasmenylcholine	LPlasC	216 ± 17	Phosphatidylcholine	LPC	176 ± 27
	AAG	220 ± 23		DAG	132 ± 16
	PA	145 ± 21		PA	128 ± 21

[a]The individual radiolabeled products were isolated by thin-layer chromatography and the radioactivity determined by liquid scintillation counting. The majority of radioactivity released from the phospholipid substrate was observed in the free fatty acid fraction, with minimal production of lysoplasmenylcholine (LPlasC), lysophosphatidylcholine (LPC) (indicating plasmalogenase or phospholipase A_1 activity), alkylenyl acyl glycerol (AAG) or diacylglaycerol (DAG) (indicating phospholipase C activity), or the phosphatidic acid (PA) (indicating phospholipase D activity). Results are mean ± SEM for three separate determinations.

choline glycerophospholipid substrate. These studies demonstrated that radiolabeled free fatty acid production accounted for >94% of the total reduction in diradyl choline glycerophospholipid radioactivity under all reaction conditions tested. There was no evidence for significant production of radioactive diradylglycerol, phosphatidic acid, or lysophospholipid (Table 1). Thus, we could not find evidence for measurable phospholipase C (PLC), phospholipase D (PLD), plasmalogenase, or phospholipase A_1 (PLA_1) activity under these assay conditions during the short incubation period used. To rule out the possibility that radioactive free fatty acid production was the result of sequential PLA_1 (or plasmalogenase)-lysophospholipase activity, PLC-diglyceride lipase activity or PLD-phosphatidate phosphohydrolase-diglyceride lipase activity, unlabeled lysophosphatidylcholine (LPC) or diacylglycerol (DAG) was added to the incubation mixture. The presence of these unlabeled lipids would result in an apparent decrease in the rate of radiolabeled fatty acid production and cause the accumulation of radioactively labeled LPC or DAG as a result of an isotope dilution effect if there was substantial flux of radiolabeled substrate through the sequential enzymatic pathways described above. Following addition of unlabeled LPC or DAG, we did not detect any significant reduction in radiolabeled fatty acid production or accumulation of radiolabeled LPC or DAG. Accordingly, based on these results and the stoichiometric relationship between production of radioactive fatty acid and decrease in radioactivity of diradyl choline phospholipid substrate, we are confident that under the incubation conditions employed in our study, the rate of production of radiolabeled fatty acid represents the rate of regiospecific hydrolysis of the *sn*-2 fatty acyl moiety from the diradyl choline glycerophospholipid substrate molecule catalyzed by PLA_2.

The addition of protease inhibitors including leupeptin, pepstatin, and aprotinin had no significant effect on enzyme stability during the course of cell sonication and preparation of cytosol and membrane fractions. The addition of glycerol and DTT was essential to maintain enzyme activity in sonicated cell suspensions, suggesting the requirement for reduced sulfhydryl groups for expression of intracellular PLA_2 activity.

PLA_2 activity in cytosol and membrane fractions isolated from ventricular myocytes was examined for thermal stability. When membrane fractions were incubated at 37°C, an apparent half-life of 1 h for PLA_2 activity was observed. The loss of PLA_2 activity was greatly attenuated following storage at lower temperatures, with less than 10% activity lost after 4 h when membranes were stored on ice. Isolated membrane fractions frozen for up to 24 h maintained PLA_2 activity levels comparable to initial values.

Following isolation of ventricular myocytes, less than 10% loss of PLA_2 activity occurred over 4 h when cells were placed on ice in the presence of 2 mM DTT and 10% glycerol. For our studies, considerable effort was expended to ensure that the time which elapsed between removal of the heart, isolation of the cells, and assay of enzyme activity was consistent between cell preparations.

In cytosol and membrane fractions isolated from ventricular myocytes, we found linear reaction velocities with respect to protein concentration for 2–20 g membrane protein and 100–500 μg cytosolic protein. Using 8 μg membrane protein and 200 μg cytosolic protein, the rate of liberation of radiolabeled free fatty acid from 100 M (16:0[^{3}H]18:1) plasmenylcholine or (16:0[^{3}H]18:1) phosphatidylcholine was found to be linear up to 10 min of incubation. We decided to use an incubation time of 5 min for determination of PLA_2 activity to ensure that linear reaction rates were obtained. Longer incubation times were associated with a loss in linearity, and shorter incubation times were associated with less reproducibility of activity measurements. Maximal reaction velocities were consistently achieved with substrate concentrations >50 μM. We used 100 μM as the substrate concentration for our assays to ensure that maximal rate measurements were being made and to minimize any effects of isotope dilution by unlabeled endogenous substrates (in all assays, we calculated that exogenous radiolabeled substrate was present in >5–10-fold molar excess over all potential endogenous substrates in both cytosolic and membrane fractions).

The cytosolic and membrane subcellular distribution, Ca^{2+} requirements, and substrate selectivity of PLA_2 activity in isolated rabbit ventricular myocytes are presented in Figure 1. Basal ventricular myocyte PLA_2 activity exhibited the following characteristics: (i) The highest specific PLA_2 activity is in a membrane-associated form (Fig. 1A). After adjustment for the total protein content of each fraction and normalizing

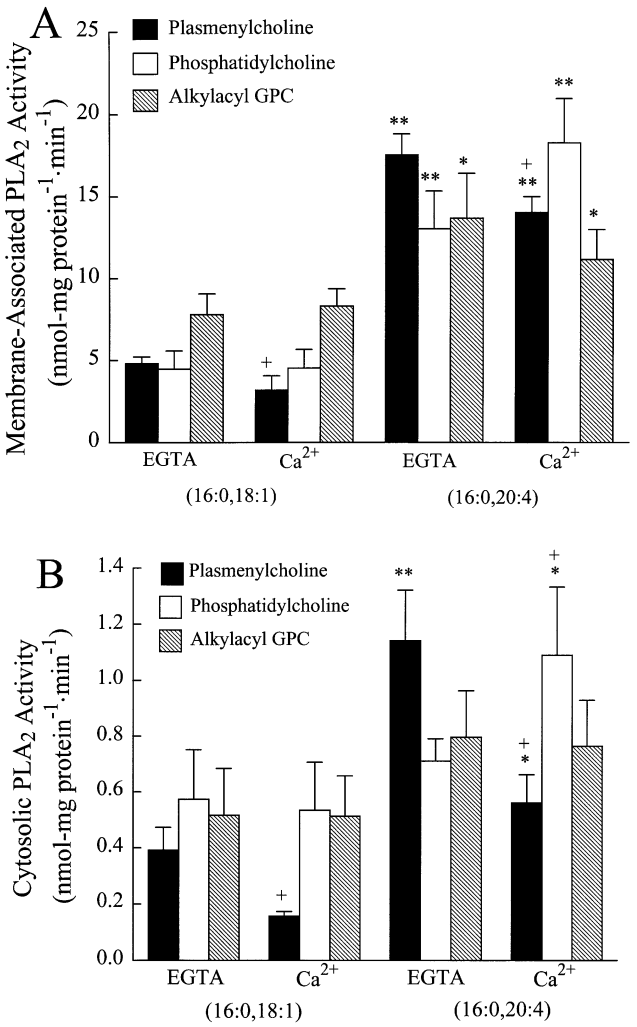

FIG. 1. Phospholipase A_2 (PLA_2) activity measured in the membrane (A) or cytosolic (B) fractions isolated from cardiac myocytes using plasmenylcholine, phosphatidylcholine, or alkylacyl glycerophosphocholine (GPC) substrates radiolabeled at the *sn*-2 position with oleic (16:0,[^{3}H]18:1) or arachidonic (16:0,[^{3}H]20:4) acid. Activity measurements were made in the absence (4 mM EGTA) or presence of (10 mM) Ca^{2+}. Values shown represent the mean ± SEM of independent results derived from four separate animals. $^*P < 0.05$, $^{**}P < 0.01$ for comparisons between (16:0,[^{3}H]18:1) and (16:0,[^{3}H]20:4) substrates; $^+P < 0.05$ for comparisons between the absence and presence of Ca^{2+} using the same substrate.

to 1×10^6 myocytes, total membrane-associated PLA_2 activity was 10- to 20-fold greater than total soluble (cytosolic) PLA_2 with all substrates tested. The PLA_2 activity in the membrane fraction could not be recovered in soluble form following repeated sonication, exposure to high- or low-ionic strength solutions, or exposure to EGTA and thus, on this basis, appears to represent a membrane-anchored or integral membrane protein. (ii) PLA_2 activity is influenced by the nature of the covalent linkage of the *sn*-1 aliphatic group and the composition of the *sn*-2 aliphatic group of the substrate molecule (Fig. 1). (iii) The majority of ventricular myocyte PLA_2 does not demonstrate a catalytic requirement for Ca^{2+} (i.e., ventricular myocyte PLA_2 is Ca^{2+}-independent).

Increasing the Ca^{2+} concentration from $<10^{-9}$ M (estimated concentration of Ca^{2+} in nominally Ca^{2+}-free solutions in the presence of 4 mM EGTA assay buffer) to concentrations greater than 10^{-6} M significantly decreased both membrane-associated and cytosolic PLA_2 activity using (16:0,[^{3}H]18:1) plasmenylcholine substrate. In contrast, increasing the Ca^{2+} concentration had no significant effect on cytosolic or membrane-associated PLA_2 activity measured using (16:0,[^{3}H]18:1) phosphatidylcholine substrate.

Comparisons of the pH profiles of PLA_2 in cytosolic and membrane fractions from isolated myocytes demonstrate a difference in pH for optimal activity in each fraction, further supporting the hypothesis of the presence of different PLA_2 isoforms in these subcellular fractions (Fig. 2). Membrane-associated PLA_2 activity measured using (16:0,[^{3}H]18:1) plasmenylcholine or (16:0, [^{3}H]18:1) phosphatidylcholine exhibited a pH optimum of 8.5 (Fig. 2A), whereas cytosolic PLA_2 activity was maximal at pH 7.0 using (16:0, [^{3}H]18:1) plasmenylcholine or (16:0, [^{3}H]18:1) phosphatidylcholine (Fig. 2B).

The marked differences in substrate selectivity, differential responses of PLA_2 activity to alterations in Ca^{2+} concentration, and differences in optimal pH for activity in cytosolic and membrane-associated PLA_2 activity suggest the presence of multiple PLA_2 isoforms in isolated ventricular myocytes. However, we cannot rule out the possibility that these observations are the result of Ca^{2+}-mediated alterations in the interaction of a single enzyme species with different aggregated phospholipid substrates.

By using our protocol for the preparation of cytosol and membrane fractions, unbroken myocytes, nuclei, and mitochondria are collectively sedimented following centrifugation at $14{,}000 \times g$ for 10 min. The total activity recovered in this fraction represents approximately 25% of the total enzyme activity recovered from the isolated cells. This enzyme activity was not further characterized. The $14{,}000 \times g$ supernatant contained both cytosolic and membrane-associated enzyme activities which were further fractionated by centrifugation at $100{,}000 \times g$ for 60 min to prepare cytosol (supernatant) and membrane (pellet) functions. Previous studies of cytosolic (e.g., Creatine Kinase, lactate dehydrogenase) and membrane (e.g., Na,K-ATPase, Ca-ATPase) marker enzyme activities showed that the cytosolic fraction from this final step contains no detectable membrane marker enzyme activity (13). The membrane fraction is composed predominantly of microsomes, including vesicles of sarcolemma and sarcoplasmic reticulum with >70% recovery of sarcolemma and sarcoplasmic reticulum marker enzyme activities in this fraction and minimal contamination by cytosolic proteins.

To determine whether previously characterized, intracellular PLA_2 isoforms could be identified in subcellular fractions isolated from ventricular myocytes, we used antibodies to known cytosolic, $cPLA_2$, and $iPLA_2$ enzymes for immunoblot

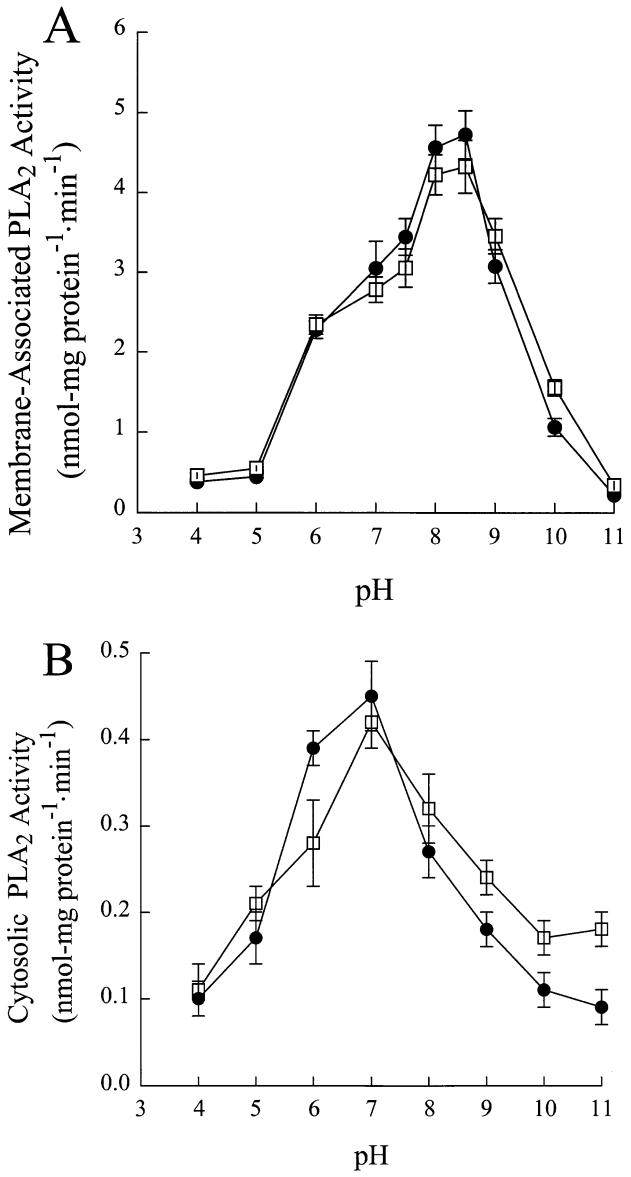

FIG. 2. The pH profile for PLA$_2$ activity at increasing pH values in membrane (A) and cytosolic (B) fractions from isolated cardiac myocytes using (16:0,[^{3}H]18:1) plasmenylcholine (●) and (16:0,[^{3}H]18:1) phosphatidylcholine (□). Values shown represent the mean ± SEM of independent results derived from three separate animals. See Figure 1 for abbreviation.

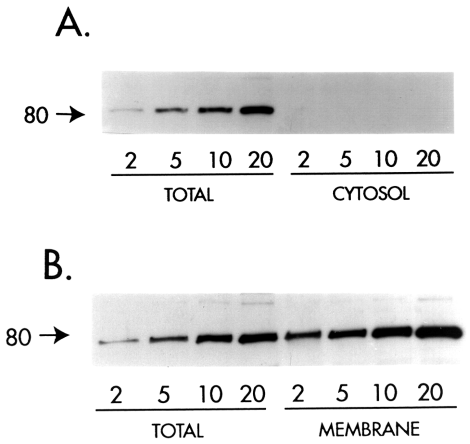

FIG. 3. Immunoblot analysis of calcium-independent PLA$_2$ (iPLA$_2$) in adult rabbit ventricular myocytes. Total (cytosol + membrane) and cytosolic protein (2–20 μg, A) and total and membrane protein (B) were separated by SDS-polyacrylamide gel electrophoresis and transferred to polyvinylidene difluoride membranes. Membranes were probed with iPLA$_2$ antibody (1 in 2,000 dilution; Cayman Chemical, Ann Arbor, MI) for 60 min and incubated with horseradish peroxidase-linked secondary antibody (antirabbit, 1 in 5,000 dilution; Amersham, Arlington Heights, IL) for 45 min. Immunoblots were detected with enhanced chemiluminescence and exposure to film for 5 min. Specific iPLA$_2$ protein in the total and membrane protein migrated at approximately 80 kDa compared with molecular weight markers. No iPLA$_2$ was detectable in the cytosolic protein at comparable amounts of protein. For abbreviation see Figure 1.

analysis. By using a specific antibody to iPLA$_2$, a distinct band at approximately 80 kDa was observed in the total cellular protein and membrane protein samples. The intensity of the iPLA$_2$ band detected by immunoblot analysis was concentration-dependent over 2–20 μg protein (Fig. 3B). No band was observed in the cytosolic fraction (Fig. 3A). Thus, iPLA$_2$ appears to be selectively enriched in the membrane fraction of rabbit ventricular myocytes. Immunoblots probed with anti-cPLA$_2$ antibody did not reveal detectable cPLA$_2$ in either the cytosolic or membrane fractions from ventricular myocytes.

Ventricular myocyte membrane-associated PLA$_2$ activity was increased following stimulation of surface membrane protease-activated receptors with thrombin. Thrombin increased membrane-associated PLA$_2$ activity measured using (16:0,[^{3}H]18:1) plasmenylcholine (4.47 ± 0.87 to 9.65 ± 1.12 nmol-mg protein^{-1}·min^{-1}) phosphatidylcholine (4.37 ± 0.92 to 8.77 ± 1.37 nmol-mg protein^{-1}·min^{-1}) and alkylacyl GPC (7.04 ± 1.10 to 11.12 ± 1.63 nmol-mg protein^{-1}·min^{-1}) substrates in the absence of Ca^{2+}. To confirm that the majority of basal and thrombin-stimulated PLA$_2$ was Ca^{2+}-independent, myocytes were incubated with bromoenol lactone (BEL), a potent, mechanism-based inhibitor specific for myocardial iPLA$_2$ (14), and PLA$_2$ activity was measured in thrombin-stimulated and unstimulated cytosolic and membrane fractions using all phospholipid substrates in the absence of Ca^{2+}. Incubation of rabbit ventricular myocytes with BEL concentrations greater than 2 μM for 30 min resulted in a significant decrease in basal membrane-associated PLA$_2$ activity measured using all phospholipid substrates (Fig. 4A). Thrombin-stimulated PLA$_2$ activity was significantly inhibited at BEL concentrations greater than 5 μM and blocked completely by BEL concentrations greater than 10 μM (Fig. 4A). Cytosolic activity was also decreased significantly in BEL-pretreated myocytes (data not shown). Pretreatment with methyl arachidonyl fluorophosphonate, an irreversible inhibitor of both cPLA$_2$ and iPLA$_2$ (15) had no significant effect on basal or thrombin-stimulated PLA$_2$ activity in either the membrane fraction (Fig. 4B) or the cytosol (data not shown) at concentrations up to 20 μM. Pretreatment of isolated myocytes with the cPLA$_2$ inhibitors, 10 μM mepacrine, or 50 μM dibucaine

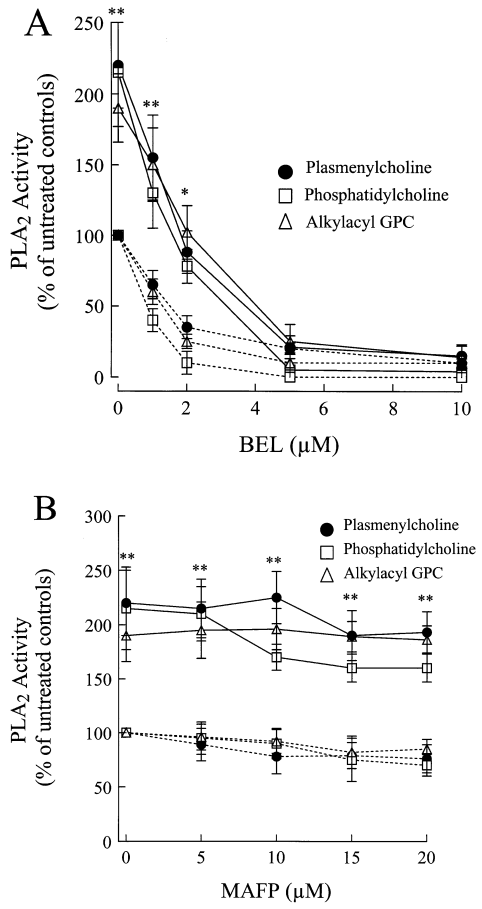

FIG. 4. Influence of preincubation of isolated ventricular myocytes with bromoenol lactone (BEL; 1 to 10 μM, 30 min, panel A), or methyl arachidonyl fluorophosphonate (MAFP; 5 to 20 μM, 15 min, B) on membrane-associated PLA_2 activity under control (dotted lines) or thrombin-stimulated (0.05 U/mL, 1 min, solid lines) conditions. Measurement of PLA_2 activity used (16:0,[^{3}H]18:1) plasmenylcholine, (16:0,[^{3}H]18:1) phosphatidylcholine, and (16:0,[^{3}H]18:1) alkylacyl GPC substrates in the absence of Ca^{2+}. Values are means ± SEM of independent results derived from six separate animals. $^*P < 0.05$, $^{**}P < 0.01$ compared to unstimulated values in the presence of the same concentration of inhibitor. Significant decreases in basal PLA_2 activity were observed in unstimulated cells at concentrations of BEL greater than 1 μM. See Figure 1 for other abbreviations.

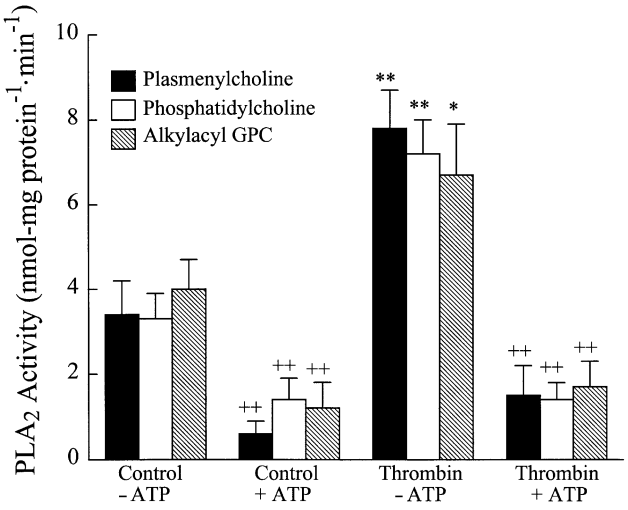

FIG. 5. Effect of including 10 mM ATP in the assay buffer on membrane-associated PLA_2 activity in cardiac myocytes under control and thrombin-stimulated (0.05 U/mL, 1 min) conditions. PLA_2 activity was measured using (16:0,[^{3}H]18:1) plasmenylcholine (filled bars), (16:0,[^{3}H]18:1) phosphatidylcholine (open bars), and alkylacyl GPC (hatched bars) substrates in the absence of Ca^{2+}. Values are means ± SEM of independent results derived from four separate animals. $^*P < 0.05$ compared to control values. $^{**}P < 0.01$ compared to control values; $^{++}P < 0.01$ compared to activity in the absence of ATP between unstimulated and thrombin-stimulated groups. See Figure 1 for abbreviations.

for 30 min had no significant effect on cytosolic or membrane-associated PLA_2 activity measured using all substrates under basal or thrombin-stimulated conditions (data not shown). These results further support our hypothesis that thrombin-stimulated, membrane-associated ventricular myocytes PLA_2 is an $iPLA_2$ isoform that is selectively inhibited by BEL.

Since previous studies of cytosolic $iPLA_2$ purified from whole myocardium indicate that the presence of ATP enhances activity, we measured ventricular myocyte PLA_2 activity in the presence and absence of 10 mM ATP. In contrast to previous findings (9), we found that the presence of ATP inhibits PLA_2 activity in both the membrane (Fig. 5) and cytosolic (data not shown) fractions isolated from rabbit myocytes that were either unstimulated or thrombin-stimulated. For example, by using (16:0,[^{3}H]18:1) plasmenylcholine, the presence of ATP reduced membrane-associated PLA_2 activity in unstimulated and thrombin-stimulated cells by 80% (Fig. 5; solid bars). To eliminate the possibility of ATP hydrolysis occurring during the PLA_2 assay procedure, we used nonhydrolyzable analogs of ATP in the assay buffer. The ATP-induced decrease in membrane-associated PLA_2 activity using (16:0,[^{3}H]18:1) plasmenylcholine in the absence of Ca^{2+} was also observed with the nonhydrolyzable analogs adenosine 5′-*O*-(3-thiotriphosphate) and adenosine 5′-(β,γ-methylene)triphosphate (Fig. 6). The addition of the nonhydrolyzable analogs of GTP, guanosine 5′-*O*-(3-thiotriphosphate) and guanyl-5′yl-imidodiphosphate, also reduced PLA_2 activity, but not as much as with the ATP analogs (Fig. 6).

Since stimulation of protease-activated receptors by thrombin is accompanied by activation of PKC, additional experiments were performed to determine whether ventricular myocyte PLA_2 activity is regulated by PKC. For these experiments, we treated cells with 100 nM phorbol 12-myristate 13-acetate (PMA) for 5 min (to activate PKC) or 24 h (to downregulate PKC). Incubation of myocytes with PMA for 5 min resulted in an approximate twofold increase in membrane-associated PLA_2 activity using all phospholipid substrates (Fig. 7). In contrast, 24-h incubation with PMA almost completely abolished PLA_2 activity (Fig. 7). Thrombin stimulation of ventricular myocytes following PMA pretreatment for 5 min or 24 h did not significantly alter PLA_2 activity from that following PMA pretreatment alone (data not shown).

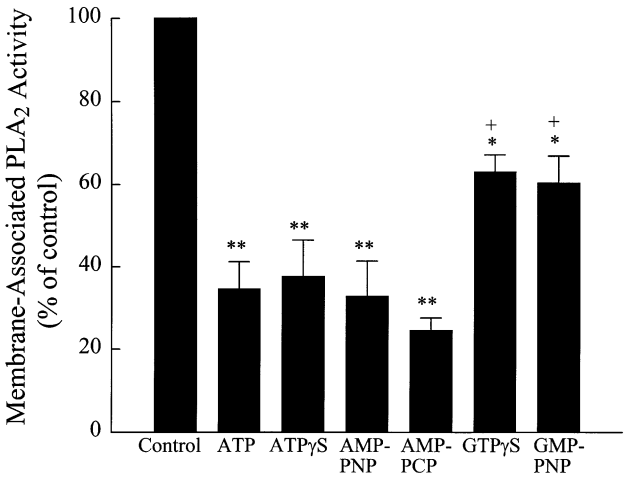

FIG. 6. Effect of ATP, adenosine 5′-*O*-(3-thiotriphosphate) (ATPγS), adenyl-5′-yl-imidodiphosphate (AMP-PNP), adenosine 5′-(β,γ-methylene) triphosphate (AMP-PCP), guanosine 5′-*O*-(3-thiotriphosphate) (GTPγS), and guanyl-5′-yl-imidodiphosphate (GMP-PNP) inclusion in the assay buffer on PLA$_2$ activity in the membrane fraction isolated from cardiac myocytes. PLA$_2$ activity was measured using (16:0,[^{3}H]18:1) plasmenylcholine in the absence of Ca^{2+}. Values are means ± SEM of independent results derived from three separate animals. $^*P < 0.05$, $^{**}P < 0.01$ compared to activity in the absence of any analog. $^+P < 0.05$ for comparisons between corresponding ATP and GTP analogs. See Figure 1 for other abbreviation.

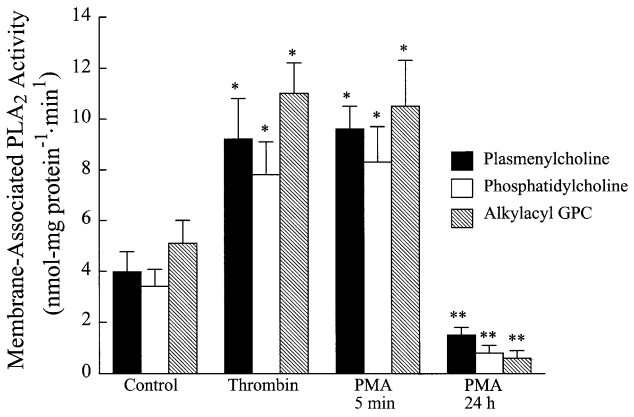

FIG. 7. Influence of incubation of isolated ventricular myocytes with phorbol 12-myristate 13-acetate (PMA) (100 nM) for 5 min or 24 h and thrombin (0.05 U/mL, 1 min) on membrane-associated PLA$_2$ activity. Measurement of PLA$_2$ activity used (16:0,[^{3}H]18:1) plasmenylcholine (filled bars), (16:0,[^{3}H]18:1) phosphatidylcholine (open bars), and (16:0,[^{3}H]18:1) alkylacyl GPC (hatched bars) substrates in the absence of Ca^{2+}. Values are means ± SEM of independent results derived from six separate animals. $^*P < 0.05$, $^{**}P < 0.01$ compared to control unstimulated values. See Figure 1 for other abbreviations.

Thus, PLA$_2$ activation in ventricular myocytes in response to thrombin stimulation is regulated by PKC activity. PKC activity also appears to play a role in the regulation of basal membrane-associated ventricular myocyte iPLA$_2$ since down-regulation of PKC activity significantly reduced basal iPLA$_2$ activity (Fig. 7).

DISCUSSION

This study demonstrates that ventricular myocyte PLA$_2$ displays a preference for phospholipid substrates with arachidonate esterified at the *sn*-2 position and does not exhibit a catalytic requirement for Ca^{2+}. The enzyme is thermolabile and requires reduced sulfhydryl groups for activity. These characteristics of PLA$_2$ in isolated ventricular myocytes clearly distinguish this enzyme activity from that catalyzed by the low-molecular weight secretory group I, II, and III PLA$_2$ since the low-molecular weight PLA$_2$ require mM concentrations of Ca^{2+} ion for maximal activity, are heat-stable, do not exhibit a distinct preference for highly unsaturated fatty acyl residues at the *sn*-2 position of phospholipid substrate molecules, and are inactivated following exposure to reduced sulfhydryl reagents (16–18).

The recently cloned 85 kDa cPLA$_2$ effectively utilizes ether-linked phospholipid substrates and displays a distinct preference for those phospholipid substrate molecular species containing esterified arachidonate (19,20). These features of substrate selectivity are virtually identical to that exhibited by ventricular myocyte PLA$_2$. Ventricular myocyte PLA$_2$ and the cloned 85 kDa cPLA$_2$ also do not require Ca^{2+} ion at the active site in order to catalyze phospholipid hydrolysis; however, cPLA$_2$ contains an amino terminal Ca^{2+}-dependent lipid binding domain that functions to mediate attachment of the enzyme to aggregated phospholipid substrate interfaces (19,20). This process greatly increases the dwell time for the enzyme at the interface, resulting in markedly enhanced rates of phospholipid hydrolysis in response to alterations in ionized Ca^{2+} concentration in the physiologic (0.1–10 M) range. Thus, the proposed mechanism for activation of cPLA$_2$ is Ca^{2+}-dependent translocation of the enzyme from the cytosolic fraction to the membrane interface mediated by the Ca^{2+}-dependent lipid binding domain. Cytosolic PLA$_2$ activity is also inhibited by methyl arachidonyl fluorophosphonate (MAFP) (16). In contrast, ventricular myocyte PLA$_2$ is maximally active at Ca^{2+} concentrations below 1 nM (i.e., nominally Ca^{2+}-free media at 4 mM EGTA concentration) and is not inhibited by MAFP; activity measured with ether-linked phospholipid substrates is significantly attenuated when the Ca^{2+} concentration is greater than 10^{-6} M. The differential responses to Ca^{2+} and MAFP and the membrane localization of ventricular myocyte PLA$_2$ illustrate substantial differences between ventricular myocyte PLA$_2$ and the 85 kDa cPLA$_2$. The membrane localization and differential Ca^{2+} responses of the ventricular myocyte PLA$_2$ also distinguish this enzyme activity from the cloned 30 kDa dimeric cytosolic PLA$_2$ isolated from platelets which exhibits considerable sequence similarity to the 14-3-3 family of signal transduction proteins (21).

A cytostolic iPLA$_2$ isoform was purified or cloned from Chinese hamster ovary (CHO) cells and P388D$_1$ macrophages. This iPLA$_2$ protein has a molecular weight of 80–85

kDa. Immunoblot analysis using antiserum against this $iPLA_2$ protein demonstrated that $iPLA_2$ immunoreactivity could be detected in the membrane fraction of rabbit ventricular myocytes but was not detected in the cytosol. The membrane-associated form of $iPLA_2$ in ventricular myocytes has a molecular mass of approximately 80 kDa, similar to that reported in $P388D_1$ macrophages and CHO cells. Thus, membrane-associated $iPLA_2$ in isolated rabbit ventricular myocytes has sufficient homology with the previously cloned $iPLA_2$ from CHO cells for the antibody to recognize it. However, the $iPLA_2$ present in isolated ventricular myocytes possesses several characteristics that distinguish it from $iPLA_2$ in CHO or $P388D_1$ cells. Previously described isoforms of $iPLA_2$ were demonstrated to be cytosolic enzymes (22,23), whereas the overwhelming amount of $iPLA_2$ in ventricular myocytes assessed by immunoblot or activity measurements is membrane-associated and not removed from the membrane by sonication, removal of Ca^{2+}, or variations in salt concentration. In addition, we demonstrated that $iPLA_2$ in ventricular myocytes is the major isoform responsible for arachidonic acid release and lysophospholipid production in response to stimulation, whereas studies in $P388D_1$ cells indicate that $iPLA_2$ plays a minor role in signal transduction (24). Further studies are necessary to determine whether ventricular myocyte and $P388D_1$ macrophage $iPLA_2$ represent alternative splicing products or post-translational modifications of the same gene product with different localization and intracellular function in different cell types.

Previous studies of PLA_2 activity prepared by homogenization of whole myocardium demonstrated the presence of both cytosolic and membrane-associated enzymes which also exhibit maximal activities in the absence of Ca^{2+} (i.e., nominally Ca^{2+}-free with mM concentrations of EGTA or EDTA) and demonstrate a preference for arachidonylated ether-linked phospholipid substrates, particularly plasmalogens (1–4). Cytosolic $iPLA_2$ and plasmalogen-selective PLA_2 were isolated from homogenates of dog, rabbit, and human myocardium (1–4). These enzymes exhibit catalytic features that are virtually identical to those described for ventricular myocyte PLA_2, but differ from the latter by the fact that these enzymes are present in soluble form, whereas the majority of ventricular myocyte PLA_2 appears to be firmly anchored to the membrane. In homogenates of whole myocardium, it was demonstrated that ischemia results in the selective activation of membrane-associated $iPLA_2$ (1,4). The increase in $iPLA_2$ activity during ischemia appears to be the result of the activation of a latent, membrane-associated enzyme and not the result of translocation of $cPLA_2$ to the membrane as described previously for $cPLA_2$ (21,25,26). Thus, it is reasonable to conclude that separate and distinct cytosolic and membrane-associated forms of $iPLA_2$ exist.

Since during the course of isolation, ventricular myocytes may undergo some degree of metabolic compromise, it is possible that the predominance of membrane-associated $iPLA_2$ activity we describe in isolated ventricular myocytes may reflect, in part, the increase in membrane-associated $iPLA_2$ activity described previously during myocardial ischemia (1,4). However, ischemia-induced increases in myocardial membrane-associated $iPLA_2$ are reversible upon reperfusion (1), and our isolated myocytes are maintained in oxygenated buffer and do not exhibit creatine kinase or lactate dehydrogenase release, electrophysiologic abnormalities, or morphologic changes suggestive of ischemic cell injury.

Several recent studies provided insight into the regulation of purified cytosolic PLA_2 from whole myocardium, suggesting that multiple mechanisms may regulate PLA_2 activity in the myocardium. Coordination of anaerobic glycolysis and phospholipolysis in myocardial ischemia appears to be regulated by the highly specific association of a PFK isoform with cytosolic $iPLA_2$ (8). This association between PFK and $iPLA_2$ allows increased production of glycolytically derived ATP during ischemia to result in allosteric alterations in the conformation of PFK which lead to an increase in cytosolic $iPLA_2$ activity, and increased phospholipolysis perhaps even under conditions of global ATP depletion. In addition, there is evidence that depletion of Ca^{2+} from intracellular stores, such as could occur during myocardial ischemia, may also activate cytosolic $iPLA_2$ by interactions between $iPLA_2$, calmodulin, and Ca^{2+} (10). Our studies demonstrating that ATP and its nonhydrolyzable analogs inhibit membrane-associated $iPLA_2$ in both basal and thrombin-stimulated conditions suggest that activation of membrane-associated ventricular myocyte PLA_2 could result from a decrease in global ATP concentration during myocardial ischemia. This effect could be additive and independent of the activation of cytosolic $iPLA_2$. In any case, our data demonstrating a distinct difference in pH optima for cytosolic and membrane-associated $iPLA_2$ and the differential ATP response of isolated ventricular myocyte membrane-associated $iPLA_2$ and purified cytosolic $iPLA_2$ from whole myocardium suggest that these enzyme activities may be mediated by distinct catalytic entities.

Previous studies suggested that PLA_2 activity is regulated by PKC (27–29), however, this was not demonstrated previously in isolated cardiac myocytes. We demonstrated that activation of PKC by brief exposure to PMA results in increased ventricular myocyte PLA_2 activity, whereas downregulation of PKC by prolonged PMA exposure almost completely abolishes PLA_2 . Recently, it was suggested that BEL may decrease arachidonic acid release by inhibiting phosphatidic acid phosphohydrolase (PAP) which would inhibit the production of DAG from phosphatidic acid (30). Since DAG activates PKC, and since we have demonstrated that PLA_2 activity is regulated by PKC, it is possible that attenuation of PLA_2 activity by BEL may be mediated through this alternative pathway. However, we were able to demonstrate inhibition of PLA_2 activity in ventricular myocytes with BEL concentrations as low as 2 μM. Complete inhibition of PAP with BEL was not observed with concentrations as high as 50 μM; thus, we believe that the dramatic inhibition of PLA_2 activity observed using BEL in this study is a result of direct inhibition of PLA_2, although we cannot rule out the possibility of the involvement of an alternative inhibitory pathway operating through inhibition of PAP by BEL.

In conclusion, we demonstrated the presence of PLA_2 activity in isolated mammalian ventricular myocytes, the majority of which is membrane-associated, Ca^{2+}- independent with maximal activity measured with phospholipid substrates with an ether linkage at the *sn*-1 position and arachidonic acid at the *sn*-2 position. Important differences between this enzyme(s) and PLA_2 enzymes reported previously suggest that this is a novel PLA_2 enzyme that has not been characterized to date.

ABSTRACT: Fatty acid α-hydroxylase, a cytochrome P450 enzyme, from *Sphingomonas paucimobilis,* utilizes various straight-chain fatty acids as substrates. We investigated whether a recombinant fatty acid α-hydroxylase is able to metabolize phytanic acid, a methyl-branched fatty acid. When phytanic acid was incubated with the recombinant enzyme in the presence of H_2O_2, a reaction product was detected by gas chromatography, whereas a reaction product was not detected in the absence of H_2O_2. When a heat-inactivated enzyme was used, a reaction product was not detected with any concentration of H_2O_2. Analysis of the methylated product by gas chromatography–mass spectrometry revealed a fragmentation pattern of 2-hydroxyphytanic acid methyl ester. By single-ion monitoring, the mass ion and the characteristic fragmentation ions of 2-hydroxyphytanic acid methyl ester were detected at the retention time corresponding to the time of the product observed on the gas chromatogram. The K_m value for phytanic acid was approximately 50 μM, which was similar to that for myristic acid, although the calculated V_{max} for phytanic acid was about 15-fold lower than that for myristic acid. These results indicate that a bacterial cytochrome P450 is able to oxidize phytanic acid to form 2-hydroxyphytanic acid.

Lipids 33, 1213–1216 (1998).

Fatty acid α-hydroxylase (FAAH) activity has been found in various organisms, but this enzyme has not been fully characterized. We have studied FAAH isolated from *Sphingomonas paucimobilis* since this organism contains a large amount of 2-hydroxymyristic acid, a product of α-hydroxylation (1). FAAH purified from *S. paucimobilis* oxidized straight-chain saturated and unsaturated fatty acids in the presence of H_2O_2, with the oxygen atom from H_2O_2 being incorporated into the fatty acid to form the corresponding 2-hydroxy fatty acid (2,3). Recently, we have cloned the FAAH gene (4). Sequence analysis of the FAAH gene and spectral analysis of recombinant FAAH revealed that FAAH from *S. paucimobilis* is a novel member of the cytochrome P450 (P450) superfamily. This recombinant form of FAAH avidly α-hydroxylated myristic acid. Bacterial FAAH, a P450 enzyme, is a soluble enzyme similar to other bacterial P450s, but belongs to the E-class (5) like $P450_{BM-3}$. FAAH is saturated with very small amounts of H_2O_2 (approximately 60 μM), but not other hydroperoxides, to catalyze α-hydroxylation of fatty acids. In this regard, bacterial FAAH is a unique P450 enzyme.

In general, P450s catalyze hydroxylation of a variety of endogenous substances (e.g., fatty acids and steroids) and xenobiotics (e.g., drugs and environmental pollutants). Among bacterial P450s, $P450_{BM-3}$, isolated from *Bacillus megaterium,* is also involved in the metabolism of nonesterified fatty acids (6). Unlike FAAH, $P450_{BM-3}$ catalyzes ω-*n* (*n* = 1–3) hydroxylation of saturated and monounsaturated fatty acids. Recently, English *et al.* (7) demonstrated that phytanic acid (3,7,11,15-tetramethyl-hexadecanoic acid) derived from the phytyl chain of chlorophyll was a good substrate for $P450_{BM-3}$, as were straight-chain fatty acids.

On the other hand, in mammals, phytanic acid initially undergoes α-oxidation, by which the carboxyl carbon is removed, and then is degraded *via* β-oxidation (8). Refsum disease in humans is caused by a deficiency in phytanic acid α-hydroxylation, the rate-limiting step in the α-oxidation pathway (9).

These observations led us to investigate whether bacterial FAAH can utilize phytanic acid as a substrate. We wished to clarify the involvement of FAAH in phytanic acid α-oxidation of this bacterium and to compare bacterial FAAH to mammalian FAAH. The present study was undertaken to define the metabolism of phytanic acid by the use of the bacterial recombinant FAAH.

MATERIALS AND METHODS

Materials. Phytanic acid was purchased from Sigma Chemical Co. (St. Louis, MO). Hydrogen peroxide was purchased from Wako Pure Chemicals (Osaka, Japan). The expression plasmid pGEX-4T-3 was purchased from Amersham Pharmacia Biotech (Tokyo, Japan). Diazomethane was synthesized from *N*-nitroso-*N*-methylurea (Sigma Chemical Co., St. Louis, MO). Other reagents were purchased from Wako Pure Chemicals (Osaka, Japan).

Preparation of recombinant FAAH and assay of FAAH activity. AgeI and EcoR52I sites were found 7 bp upstream from the translation initiation codon and 294 bp downstream of the termination codon of the FAAH gene, respectively. A blunt-ended AgeI-EcoR52I fragment including the FAAH gene was

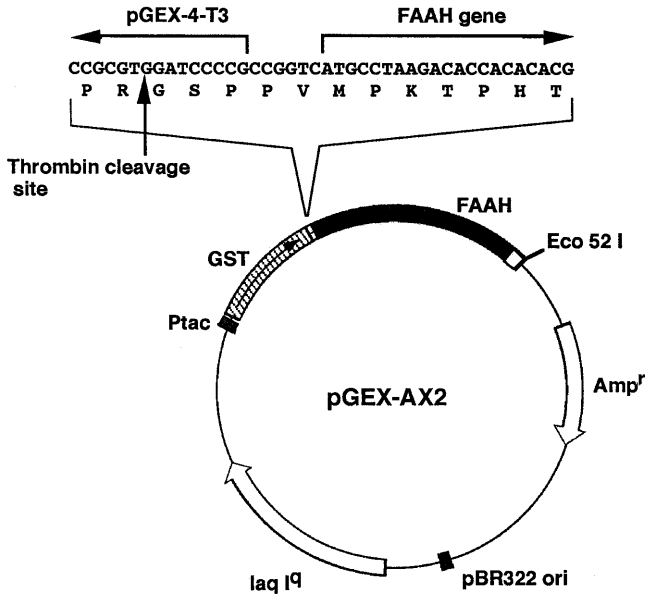

FIG. 1. Schematic representation of the expression plasmid including the full-length fatty acid α-hydroxylase (FAAH) gene.

ligated into blunt-ended EcoRI-NcoI-cleaved pGEX-4T-3 (Fig. 1). Expression and purification of the recombinant FAAH were performed as previously described (4). FAAH was purified to homogeneity on sodium dodecylsulfate-polyacrylamide gel. Specific content of the purified FAAH was 10.2 nmol/mg protein. In this procedure, the purified enzyme protein contained the entire FAAH enzyme with an additional five amino acids at its N-terminus. The standard reaction mixture contained 0.1 M Tris-HCl (pH 8.0), 0.2 mM H_2O_2, 20 nmol of phytanic acid dissolved in 1 μL of ethanol, and 0.2 μg of the purified recombinant FAAH in a total volume of 0.2 mL. The reaction was performed at 37°C and terminated by the addition of 20 μL of 2 N HCl. Phytanic acid and the reaction product were extracted with ethyl acetate, and the ethyl acetate layer was collected. After washing with distilled water, the ethyl acetate layer was evaporated under vacuum. The resultant residue was then treated with diazomethane. Quantitation of phytanic acid and the reaction product was determined by gas chromatography (GC).

Identification of the reaction product by gas chromatography–mass spectrometry (GC–MS). GC–MS was performed on the 5971A mass spectrometer (Hewlett-Packard, Palo Alto, CA) with a 5890 series II gas chromatograph (Hewlett-Packard) using a DB-5MS capillary column (30 m × 0.25 mm, film thickness 0.1 mm, J&W Scientific, Folsom, CA). For GC, samples (1 μL) were introduced onto the column. Injector temperature was 280°C. A GC oven temperature program was then applied: an initial temperature of 80°C was held for 1 min, and then the temperature was raised to 280°C in 8°C/min increments and held at 280°C for 4 min. Helium was used as the carrier gas at a flow rate of 1 mL/min. The GC–MS interface temperature was 280°C. Electron-impact MS was performed with an ion source temperature of 280°C, emission current of 0.3 mA, and electron energy of 70 eV.

RESULTS AND DISCUSSION

When phytanic acid was incubated as a substrate with recombinant FAAH in the presence of H_2O_2, a reaction product was detected by GC at a retention time of 19.7 min (Fig. 2). To determine whether this reaction product was formed enzymatically, we investigated the effects of incubation period, the amount of H_2O_2 added to the reaction mixture, and the effects of heat treatment of FAAH on the amount of product formed. In the presence of H_2O_2, the amount of product increased in a time-dependent manner and reached a plateau at 20 min, whereas in the absence of H_2O_2, a product was not detected with any incubation time (Fig. 3A). When the FAAH enzyme was incubated with the substrate, the amount of product increased as the concentration of H_2O_2 in the reaction mixture increased and approached a plateau at a concentration of 0.2 mM (Fig. 3B). Conversely, when heat-treated enzyme was used, no product was formed with any concentration of H_2O_2. These results indicated that formation of the product was due to an enzymatic reaction of the recombinant FAAH.

To identify the reaction product, analysis by GC–MS was performed. The mass spectrum of the methylated product displayed a pattern identical to that of 2-hydroxyphytanic acid methyl ester (Fig. 4), which has been previously reported (10). The molecular ion is *m/z* 342. The characteristic fragment ion of 2-hydroxy fatty acid, *m/z* 283, has lost the car-

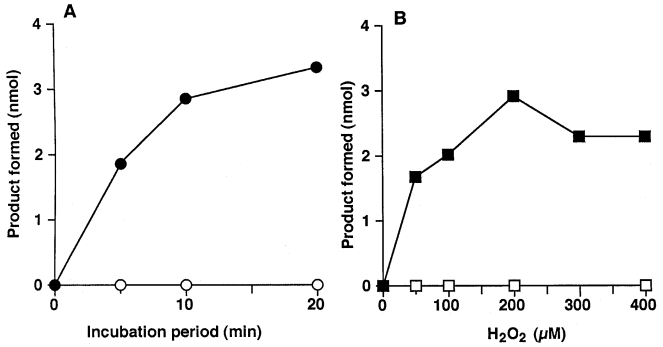

FIG. 3. Changes in the amount of product formed as a result of (A) varying the incubation period in the presence (●) and absence (○) of H_2O_2 and (B) varying the amount of H_2O_2 used with heat-treated (□) and non-treated enzyme (■). Heat treatment 100°C for 10 min.

boxylmethyl group of *m/z* 342. Cleavage of the C_2-C_3 bond and the McLafferty rearrangement yield *m/z* 90. The fragments *m/z* 117 and 159 are formed by cleavages between C_3 and C_4 and between C_6 and C_7, respectively. These ions (*m/z* 342, 283, 159, 117, 90) were observed at a retention time of 19.7 min (Fig. 5). Only negligible amounts of these ions were detected at other retention times. Therefore, we concluded that the reaction product was 2-hydroxyphytanic acid.

We compared K_m and V_{max} for phytanic acid to those for myristic acid. As shown in Figure 6, the K_m value for phytanic acid (50 μM) was similar to that for myristic acid (43 μM). However, the calculated V_{max} for myristic acid (44 μmol/min/mg protein) was about 15-fold higher than that for phytanic acid (2.9 μmol/min/mg protein).

In *S. paucimobilis*, 2-hydroxymyristic acid, a product of α-hydroxylation of myristic acid, was found as a component of sphingoglycolipids which are characteristic of this bacterium (1). The majority of the fatty acid of sphingolipid in this bacterium is 2-hydroxymyristic acid. Therefore, FAAH was speculated to be normally involved in sphingolipid metabolism where myristic acid is α-hydroxylated and incorporated into ceramide. Interestingly, phytanic acid was also α-hydroxylated by this bacterial FAAH. The bacterial FAAH metabolized phytanic acid at a slower rate than myristic acid, although the metabolic rate of phytanic acid by FAAH was still comparable to those of straight-chain fatty acids by mammalian ω-hydroxylase of CYP4A subfamily (11). However, judging from K_m values for these fatty acids, the affinity of

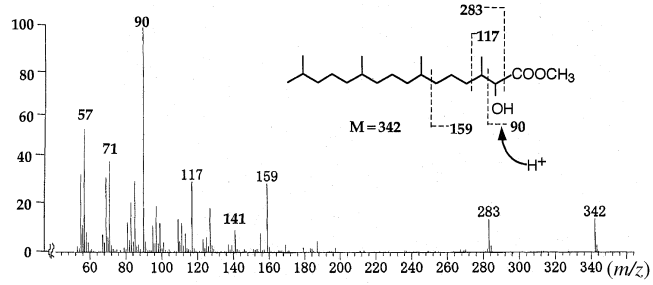

FIG. 4. Mass spectrum of the methylated product, having *m/z* of 342 for the mass ion (M).

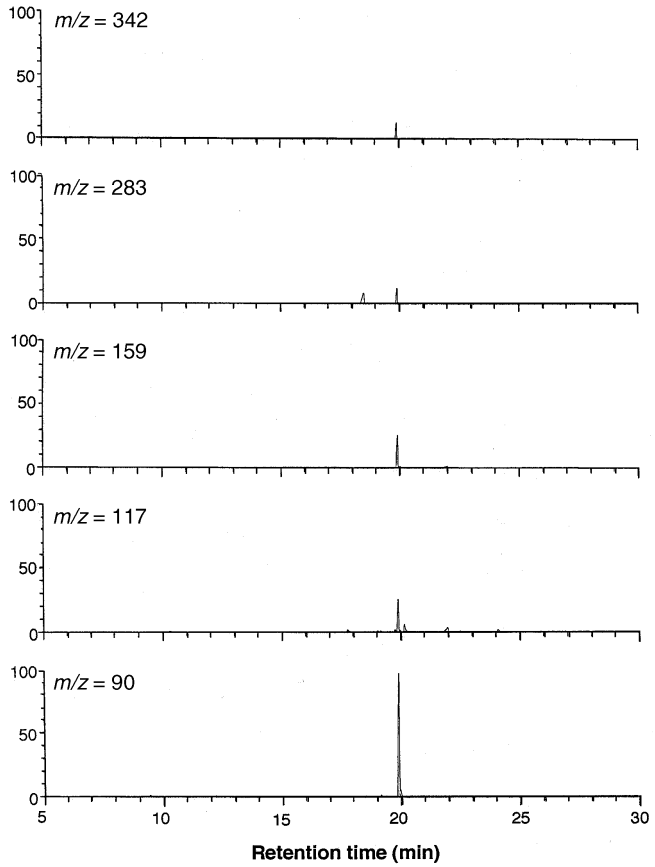

FIG. 5. Single-ion monitoring of mass ion (*m/z* 342) and fragmentation ions (*m/z* 283, 159, 117, and 90) of the methylated product.

phytanic acid for FAAH is almost the same as that of myristic acid, suggesting significant involvement of FAAH in catabolism of phytanic acid in this bacterium. Furthermore, *S. paucimobilis* is a soil bacterium, and thus it is possible that it will

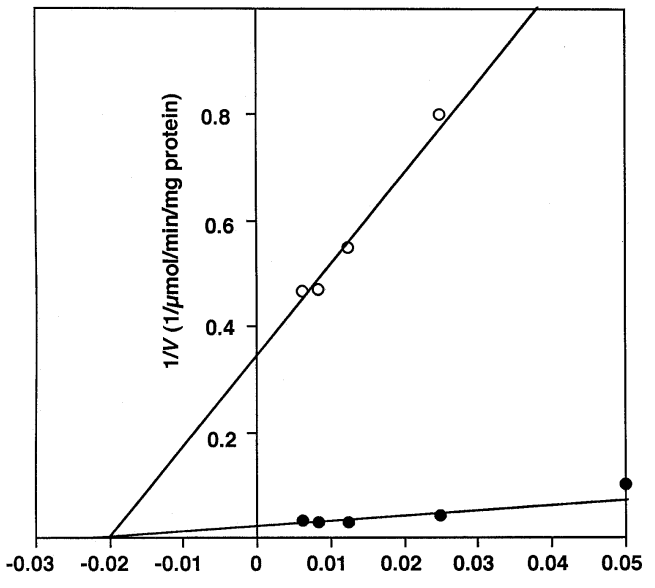

FIG. 6. Lineweaver-Burk plot of FAAH with phytanic acid (○) and myristic acid (●) as substrates. Incubation period was 5 min. For abbreviation see Figure 1.

be exposed to phytanic acid as a breakdown product of plant matter. Therefore, a metabolic pathway for phytanic acid would be useful for this bacterium. However, the exact significance of phytanic acid oxidation to 2-hydroxyphytanic acid by bacterial FAAH remains to be elucidated.

English *et al.* (7) demonstrated that phytanic acid is hydroxylated by $P450_{BM-3}$ to form (ω-1)-hydroxyphytanic acid. They also reported that phytanic acid and (ω-1)-hydroxyphytanic acid as xenobiotic compounds regulated transcription of the $P450_{BM-3}$ gene. We have not yet investigated the occurrence of regulation of FAAH gene expression by such fatty acids. FAAH significantly metabolized phytanic acid as a substrate. Thus, we are now interested in studying the regulation of the FAAH gene by phytanic acid.

In mammals, the α-oxidation pathway is indispensable in catabolizing 3-methyl-branched fatty acids, including phytanic acid, because the 3-methyl branch of phytanic acid prevents its degradation *via* the β-oxidation pathway. Refsum disease is an inherited human disorder caused by a deficiency of phytanic acid α-hydroxylation (9). Recently, Mihalik *et al.* (12) and Jansen *et al.* (13) identified the gene responsible for Refsum disease. They reported that this gene encoded phytanoyl-CoA α-hydroxylase, which is a 2-oxoglutarate-dependent dioxygenase. Bacterial FAAH does not metabolize acyl-CoA (2). Therefore, bacterial FAAH can apparently be distinguished from mammalian phytanoyl-CoA α-hydroxylase, due to differing properties of these enzymes such as substrate specificity. Thus, in bacteria, other catabolic pathways of phytanic acid may also exist to metabolize this exogenous fatty acid.

In Vivo Studies of the Biosynthesis of Vernolic Acid in the Seed of *Vernonia galamensis*

Linsen Liu[a,1], Earl G. Hammond[a,b,*], and Basil J. Nikolau[a,b]

Departments of [a]Food Science and Human Nutrition and [b]Biochemistry and Biophysics, Iowa State University, Ames, Iowa 50011

ABSTRACT: *In vivo* radiotracer experiments using [1-^{14}C]acetate as the precursor were conducted to investigate the biosynthesis of vernolic acid (12, 13-epoxy-*cis*-9-octadecenoic acid) in the seeds of *Vernonia galamensis*. The acetate precursor radioactively labeled vernolate in phosphatidylcholine (PC), diacylglycerol, and triacylglycerol. Time-course kinetics of the incorporation of the radioactive tracer indicated that vernolate is synthesized while the acyl moiety is esterified to PC. Pulse-chase experiments provided additional supporting evidence that vernolate is synthesized while esterified to PC. These results are consistent with the hypothesis that linoleoyl PC is the precursor of vernoleoyl-PC. Subsequently, vernolate is quickly moved from the PC pool to the triacylglycerol pool, where it accumulates.

Lipids 33, 1217–1221 (1998).

Epoxidized oils such as epoxidized soybean and palm oils are widely used as plasticizers and stabilizers for plastics (1,2). The epoxy fatty acids can increase the flexibility and stability of plastics, particularly polyvinyl chloride. Currently, epoxidized oils are produced by the treatment of unsaturated oils with peracetic acid to introduce epoxy rings into the unsaturated positions of the fatty acids. Epoxidation of vegetable or animal oils and fats is a relatively expensive chemical process. Plant seed oils that contain vernolic (12,13-epoxy-*cis*-9-octadecenoic) acid, a natural epoxy fatty acid, could be substituted for chemically epoxidized oils. Only a few plants contain large percentages of vernolate in their seed triacylglycerol (TAG), and none of them are cultivated presently in the United States (1–4). *Vernonia galamensis*, whose seed contains 40% lipid of which 80% is vernolate, was successfully cultivated in Africa (3,5), but little has been done to improve the plant's agronomic properties.

Research on the epoxidation of fatty acids is receiving increasing attention (6–9). Bafor *et al*. (7) studied the formation of vernolate in the microsomes of *Euphorbia lagasca,* and they postulated that linoleoyl PC was the substrate for epoxidation, and the resulting vernoleoyl PC was hydrolyzed to give free vernolic acid, which was incorporated into TAG after activation as a CoA ester. More recently, the enzyme catalyzing the epoxidation of linoleate was identified from *Crepis palaestina* (9). We describe herein *in vivo* radiotracer studies of the biosynthesis of vernolic acid in the developing seeds of *V. galamensis*, using [1-^{14}C]acetate as the precursor.

MATERIALS AND METHODS

Materials. *Vernonia galamensis* was grown from seeds in a greenhouse under 14-h artificially supplemented illumination, at a temperature ranging between 22 and 25°C. To promote flowering, 90-d-old plants were grown for a period of 30 d in the same conditions, except illumination was 10 h per day. Under these conditions, seeds matured in about 35 d after flowering (DAF). Developing seeds rapidly accumulate lipids between 21 and 28 DAF and then start to desiccate. In our studies, seeds were collected between 21 and 28 DAF and expelled from their seedcoats. The decoated seeds were kept in ice-cold phosphate buffer (0.1 M, pH 7.2) and used immediately. Sodium [1-^{14}C]acetate (55 Ci/mol) solution was purchased from ICN (Irvine, CA). Chemicals and biochemicals were obtained from Sigma (St. Louis, MO) and Fisher Chemicals (Pittsburgh, PA).

In vivo *radioisotopic labeling*. In time-course experiments, approximately 6 g of decoated seeds were placed in 2 mL of 0.1 M phosphate buffer, pH 7.2, containing 10 μCi of sodium [1-^{14}C]acetate (55 Ci/mol) and incubated at room temperature (about 25°C) while shaking at 100 rpm. At various times after the start of the incubation, 15 seeds (about 1 g) were removed and washed three times with 1 mL of ice-cold water. The seeds were placed in 1 mL of water, heated for 15 min in a boiling-water bath to inactivate phospholipases, and stored at –30°C until the lipid was extracted.

For the pulse-chase experiments, about 7 g of decoated seeds were incubated as above in the presence of 20 μCi of [1-^{14}C]acetate (55 Ci/mol) for 1 h. After this pulse of label, the buffer containing the radioisotope was removed, and 15 seeds (about 1 g) were washed and heated in water as previously described. The remaining seeds were washed three times with 5 mL of phosphate buffer containing nonradioac-

Abbreviations: DAF, days after flowering; DAG, diacylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; TAG, triacylglycerol; TLC, thin-layer chromatography.

tive 10 mM sodium acetate. Incubation was continued as before in fresh phosphate buffer in the absence of the radioisotope. At various times after the start of the chase incubation, samples of 15 seeds were removed, processed, and stored as previously described.

All *in vivo* radioactive labeling experiments were conducted three times, and very similar results were obtained each time. In each type of experiment, the data from one typical experiment were presented.

Lipid extraction. The seeds were homogenized with 1 mL of methanol in a 7-mL Broeck Tissue Grinder (Fisher Chemicals). The homogenates were centrifuged, the supernatant was removed and retained, and the residual solids were extracted twice with 2 mL of chloroform/methanol (2:1, vol/vol) and once with 2 mL of chloroform. All four extracts were combined, 0.9 mL of water was added, and the chloroform layer containing the lipids was recovered and concentrated by evaporation under reduced pressure at ambient temperature. The recovered lipids were dissolved in 1 mL of chloroform/methanol (2:1) and stored under nitrogen at –30°C.

Lipid separations and analyses. Lipid classes were fractionated by thin-layer chromatography (TLC) on silica gel H plates (200 × 200 × 0.5 mm) impregnated with 0.8 mM sodium carbonate (10). All lipids were identified by comparing their migration to authentic lipid standards. Polar lipids were fractionated with the solvent chloroform/methanol/acetic acid-water (25:15:8:4, by vol). Neutral lipids were fractionated with hexane/diethyl ether/acetic acid (60:40:1, by vol). These fractionations were undertaken either on separate plates or by double development. In the latter, the polar lipids were first fractionated by developing the plate half way to the top; the solvent was evaporated under a stream of nitrogen or carbon dioxide, and the neutral lipids, which were in the solvent front, were separated by developing the plate all the way to the top with the second solvent. After chromatography, the developing solvents were removed under a stream of nitrogen or carbon dioxide, and the neutral lipid bands were located by exposing the vertical edges of the plates to iodine vapor.

For fatty acid analysis, the portion of the silica gel containing each lipid that had not been exposed to iodine was scraped from the TLC plates, and the fatty acids were directly converted to methyl esters without removal of the lipids from the silica gel (11). To accomplish this, the silica was treated with 0.5 mL of 1 M sodium methoxide in methanol and 1 mL of diethyl ether and incubated with shaking at 30–40°C for 1 h. Next, 20 µL of glacial acetic acid and 1 mL of water were added, and the fatty acyl methyl esters were recovered by extraction with diethyl ether. The ether was evaporated under a stream of nitrogen or carbon dioxide and the residue was dissolved in 0.1–0.3 mL of methanol. The methyl esters were analyzed immediately after derivatization on a Beckman System Gold HPLC fitted with a 4 mm × 25 cm Supelco C-18 column (State College, PA), using 5% water in methanol as the mobile phase. The eluate of fatty acyl methyl esters was detected by their absorbance at 202 nm with an in-line ultraviolet detector (Beckman Model 166). Radioactivity was detected with an in-line radioactivity detector (Beckman Model 171) equipped with a 1-mL cell, using Ready Flow III (Beckman) as the scintillation cocktail. The methyl ester peaks were identified by comparing their retention times with those of standards.

The fatty acid compositions of lipids from developing and mature seeds were analyzed as methyl esters by GC (Model 5890; Hewlett-Packard, Wilmington, DE) fitted with a flame-ionization detector and a 15-m × 0.244 mm DB-23 capillary column (J&W, Deerfield, IL) operated at 200°C with a helium flow of 1 mL/min. Peaks were identified by comparing retention times with those of standards.

Determination of radioactivity. An aliquot of lipid sample was mixed with 4 mL of ScintiVerse BD (Fisher Scientific) in 4-mL polypropylene vials, and radioactivity was detected on a scintillation analyzer (Model 2200CA; Packard Instruments, Downers Grove, IL). Lipid bands on TLC plates were revealed with iodine vapor, the lipid-containing silica was scraped into vials, and radioactivity was determined as described.

RESULTS AND DISCUSSION

Lipid accumulation during seed development. In the greenhouse conditions used in these experiments, *V. galamensis* seeds matured by 35 DAF. During this period, the lipid content of the seeds increased gradually to reach 5% by 21 DAF, and then more rapidly to reach 28% at 28 DAF. The seeds subsequently desiccated and had a lipid content of 34% at 35 DAF (Fig. 1). Thus, in the experiments described below, seeds between 21 and 28 DAF were used because this is the period when lipids rapidly accumulate.

Vernolic acid was found mainly in the neutral lipids, TAG and diacylglycerol (DAG), where it accounts for 61.9 and 54.6% of the total fatty acids, respectively (Table 1). Linoleate was the second most prevalent acyl component in TAG and DAG. In polar lipids, linoleate was the major fatty acid (data not shown). Of the three phospholipids examined,

phosphatidylethanolamine (PE), phosphatidylinositol (PI) and phosphatidylcholine (PC), only the latter contained detectable amounts of vernolic acid (5.3%).

In vivo *labeling of seed lipids with [1-^{14}C]acetate*. As shown in Figure 2A, [1-^{14}C]acetate was rapidly incorporated into lipids in the first 4 h of incubation, but in the subsequent 4 h little increase of radioactivity occurred either in total or individual lipids. PC was the most heavily radioactively labeled lipid throughout the incubation time. Initially DAG was more heavily radioactively labeled than TAG; however, after 2 h the radioactivity in DAG reached a plateau and by 4 h the radioactivity in TAG exceeded that in DAG. The only other lipids that incorporated radioactivity to any significant extent were PE and PI, which accounted for only 3 to 6% of the total radioactivity each and are not shown in the figures. No vernolate was detected in these lipids.

The distribution of radioactivity in each acyl group of the various lipids was determined by transesterification of each isolated lipid to form the methyl acyl esters, which were analyzed by radio-high-performance liquid chromatography. In the three lipids that were examined in detail (PC, DAG, and TAG), the oleoyl moieties were the most heavily labeled fatty acid in the initial stages of the incubation (Fig. 2B–D). With increasing time, the proportion of label in the oleoyl moieties declined as the proportion of label increased in the linoleoyl and vernoleoyl moieties of the three lipids. Vernolate first became radioactively labeled on PC (Fig. 2B and E). With increasing incubation time, radioactive label was incorporated into the vernoleoyl moieties of DAG and TAG. In all these lipids, saturated fatty acids (16:0 and 18:0, not shown in the figure) were the least labeled (~1%), and the percentage of label did not change with the incubation time.

The results of these experiments are consistent with the hypothesis that vernolate is initially synthesized while it is esterified to PC. Subsequently, the acyl moiety rapidly associated with the neutral lipids, DAG and TAG, TAG being the preferred lipid. It was not possible from these experiments to directly ascertain the immediate acyl precursor of vernolate.

In vivo *pulse-chase labeling of seed lipids with [1-^{14}C]acetate.* To further investigate the biosynthesis of vernolic acid, decoated developing *V. galamensis* seeds were exposed to [1-^{14}C]acetate, and after 1 h, the radioactive acetate was replaced with nonradioactive acetate, and the incubation was continued for an additional 8 h. Figure 3A shows the total incorporation of radioactivity into the lipids of the seeds at various times after the label was removed. The total amount of

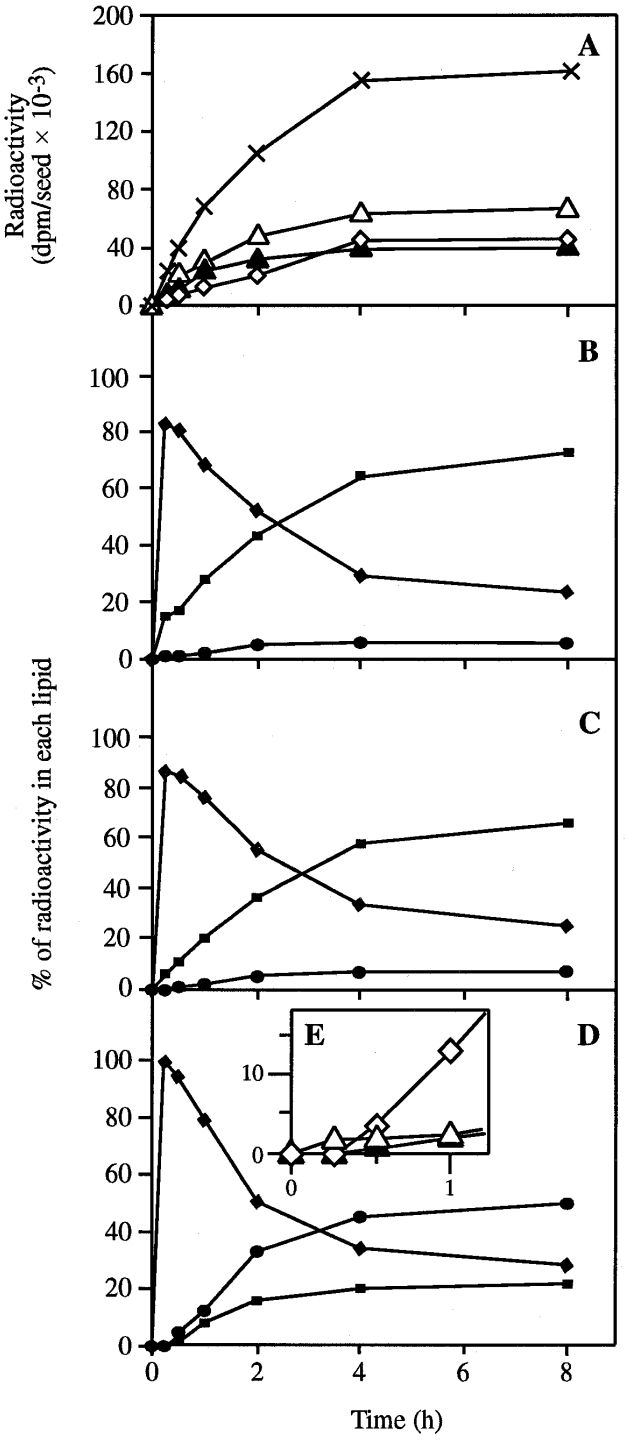

FIG. 2. Incorporation of radioactivity from [1-^{14}C]acetate into lipids and fatty acids of developing *Vernonia galamensis* seeds. Developing seeds were incubated in the presence of [1-^{14}C]acetate. (A) At the indicated times, the amount of radioactivity incorporated into total lipids (x), phosphatidylcholine (PC) (△), diacylglycerol (DAG) (▲), and triacylglycerol (TAG) (◇) was determined. The proportion of radioactivity in the oleoyl (◆), linoleoyl (■), and vernoleoyl (●) moieties of PC (B), DAG (C), and TAG (D) were determined. (E) Magnified view of the data in panels B, C, D to illustrate the proportion of radioactivity associated with the vernolate moiety of PC (△), DAG (▲), and TAG (◇). Vernolate is initially labeled on PC. Each data point is an average of two determinations.

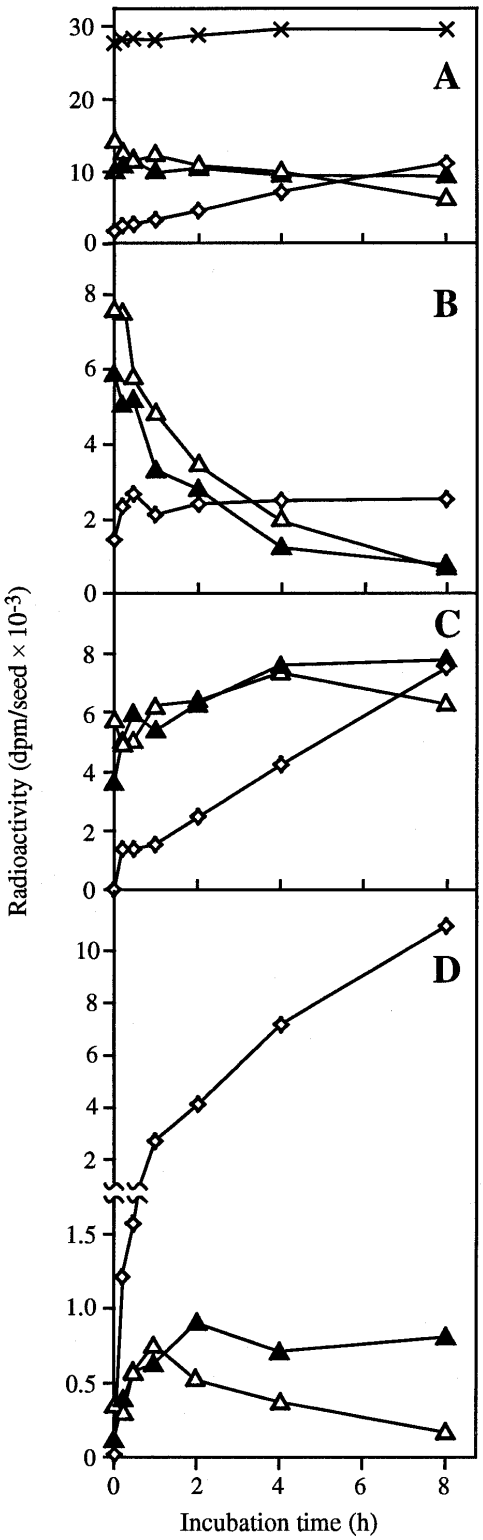

FIG. 3. Pulse-chase analysis of the incorporation of radioactivity from [1-^{14}C]-acetate into lipids and fatty acids of developing *Vernonia galamensis* seeds. Developing seeds were incubated in the presence of [1-^{14}C]-acetate for 1 h, after which, seeds were incubated for the indicated times in the presence of nonradioactive acetate. (A) The amount of radioactivity incorporated into total lipids (x), PC (△), DAG (▲), and TAG (◇). The amount of radioactivity in the oleoyl (B), linoleoyl (C), and vernoleoyl (D) moieties of PC (△), DAG (▲), and TAG (◇). Each data point is an average of two determinations. See Figure 2 for abbreviations.

radioactivity recovered in lipids was relatively constant during the chase phase of the experiment. PC was the most heavily labeled lipid at the end of the pulse phase and subsequently declined steadily during the chase phase of the experiment. Concomitant with the disappearance of radioactivity from PC, radioactivity associated with TAG increased, but radioactivity associated with DAG remained relatively stable. By the end of the chase, TAG was the most heavily labeled lipid. PE and PI contained a constant, low level (less than 5%) of radioactivity over the chase phase of the experiment (data not shown), and these lipids were not characterized further.

Figure 3B–D illustrates the distribution of radioactivity in oleate, linoleate, and vernolate, respectively, associated with PC, DAG, and TAG during the chase phase of the experiment. Palmitate was the only other acyl group labeled, but it contained only a small amount of radioactivity (data not shown). As expected from the experiment described in Figure 2, at the end of the pulse phase of the experiment, oleate esterified on PC and DAG was the most heavily labeled acyl moiety (Fig. 3B). During the chase, radioactivity in the oleoyl moiety of PC and DAG declined (Fig. 3B and C). This decline was associated with an increase in radioactivity in linoleate and vernolate (Fig. 3B and C). The most dramatic increases in radioactivity associated with these acyl moieties occurred in the TAG fraction. At the start of the chase phase of the experiment, the greatest amount of radioactivity associated with vernolate was associated with that esterified to PC (Fig. 3D). As the chase progressed, radioactivity in the vernoleoyl moiety of PC transiently increased, reached a peak at 1 h into the chase, and subsequently declined. This contrasts with the radioactivity associated with vernoleoyl-DAG, which although also at a low level reached a plateau at about 2 h into the chase. As with the previous experiments, these results indicate that vernolate is first synthesized while it is esterified to PC, and subsequently it rapidly becomes associated with the neutral lipids, particularly TAG.

In conclusion, epoxy fatty acids are found in a number of plant families (1–4,12,13), but only in Compositae and Eurphorbiaceae are high concentrations found. The reactive epoxide ring of these acids makes them ideal for use as stabilizers in vinyl plastics. Seeds of *V. galamensis* accumulate a large quantity of vernolic acid, most of which is esterified to TAG. Developing *V. galamensis* seeds accumulate seed lipids at maximal rates between 20 and 28 DAF. Such seeds proved highly amenable to radiotracer studies designed to elucidate the biosynthesis of this unusual fatty acid. The decoated seeds readily took up exogenously provided [1-^{14}C]acetate and incorporated into lipids, including vernolate.

The data gathered from *in vivo* radiotracer incubations and pulse-chase experiments are consistent with the hypothesis that vernolate is synthesized while it is esterified to PC. This conclusion is based on the observation that in developing *V. galamensis* seeds radioactivity from ^{14}C-acetate is first incorporated into vernolate while this acyl moiety is esterified to PC. In the pulse-chase experiments, the appearance of radioactive vernoleoyl-PC preceded the appearance of radioac-

tive vernoleoyl-TAG. However, these *in vivo* experiments did not clearly identify the acyl precursor of vernolate. Nevertheless our results are consistent with previous *in vitro* experiments with isolated microsomes from developing seeds of *Euphorbia lagascae*, which indicate that vernolate is synthesized by the epoxidation of linoleate while it is esterified to PC (6,7).

Inhibition of Lipoxygenase 1 by Phosphatidylcholine Micelles-Bound Curcumin

G. Began, E. Sudharshan, and A.G. Appu Rao*

Department of Protein Chemistry and Technology, Central Food Technological Research Institute, Mysore - 570 013, India

ABSTRACT: Curcumin (diferuloyl methane) from rhizomes of *Curcuma longa* L. binds to phosphatidylcholine (PC) micelles. The binding of curcumin with PC micelles was followed by fluorescence measurements. Curcumin emits at 490 nm with an excitation wavelength of 451 nm after binding to PC-mixed micelles stabilized with deoxycholate. Curcumin in aqueous solution does not inhibit dioxygenation of fatty acids by Lipoxygenase 1 (LOX1). But, when bound to PC micelles, it inhibits the oxidation of fatty acids. The present study has shown that 8.6 μM of curcumin bound to the PC micelles is required for 50% inhibition of linoleic acid peroxidation. Lineweaver-Burk plot analysis has indicated that curcumin is a competitive inhibitor of LOX1 with K_i of 1.7 μM for linoleic and 4.3 μM for arachidonic acids, respectively. Based on spectroscopic measurements, we conclude that the inhibition of LOX1 activity by curcumin can be due to binding to active center iron and curcumin after binding to the PC micelles acts as an inhibitor of LOX1.
Lipids 33, 1223–1228 (1998).

Some natural phenolic antioxidants have potential preventive activity in the initial stages of antioxidant-related diseases (1). Recently, curcumin, the major constituent of the spice turmeric, has received much attention because of both its antioxidant and antiinflammatory activities (2–4). It has been shown to be highly effective in inhibiting the stimulation of HIV type 1 virus (5). It inhibits neutrophil activation, mixed lymphocyte reaction, and proliferation of smooth muscle cells, and suppresses nitrogen-induced proliferation of blood mononuclear cells (6). Further, it is a potent scavenger of reactive oxygen species (7), protects hemoglobin from nitrate-induced oxidation, and inhibits lipid peroxidation (8,9). Huang *et al.* (10) reported that the antitumor-promotion activity of curcumin in mouse epidermis is linked with the suppression of arachidonic acid metabolism. This metabolic pathway is one of the lipid peroxidation events in living organisms catalyzed by lipoxygenases.

Arachidonic acid lipoxygenases are involved in the biosynthesis of various bioregulators that are closely related to the pathogenesis of some diseases, such as allergy, atherosclerosis, and cancer (11). Lipoxygenase catalyzes the initial step in the production of leukotrienes and lipoxins, which mediate allergic and inflammatory responses (12). Since the discovery of the role of lipoxgenases in the biosynthesis of effectors critical in animal and plant physiology, extensive research has been carried out to study their effective inhibitory activities. Most studies have used soybean lipoxygenase (LOX1), whose three-dimensional structure and catalytic mechanism have been characterized in detail (13,14). Earlier reports showed that curcumin is a potent inhibitor for nonenzymatic lipid peroxidation (15,16).

The results presented in this paper suggest that curcumin inhibits LOX1-catalyzed oxidation of linoleic and arachidonic acids and demonstrate that this natural antioxidant inhibits the enzyme by binding to the active center iron. The inhibitory activity of curcumin is potentiated in the presence of hydrophobic environment, which can be provided by phosphatidylcholine (PC) micelles.

MATERIALS AND METHODS

Materials. Soybean LOX1 was isolated according to the method of Axelrod *et al.* (17) with some modifications as described earlier (18). The specific activity was 200–240 μmoles/min/mg of protein. Linoleic and arachidonic acids were from Nu-Chek-Prep (Elysian, MN). Egg PC, curcumin, and sodium deoxycholate (DOC) were purchased from Sigma (St. Louis, MO). Stock solutions of fatty acids were prepared with a concentration of 10 mM in 10% ethyl alcohol containing 50 mM borate buffer pH 9.0

Preparation of the mixed micelles. Mixed micelles were prepared using the mixture of PC and DOC. After solubilizing the PC and DOC in chloroform/methanol (2:1) mixture, the solvent was evaporated by flash evaporator and dried in the presence of nitrogen gas. The resulting thin film was solubilized in 50 mM Tris HCl, pH 7.4, and then sonicated for 5 min using a bath-type sonicator.

Fluorescence microscopy. PC micelles (10 mM), after mixing with curcumin (60 mM) solubilized in ethyl alcohol (the final concentration of alcohol did not exceed 2 mM), were immediately examined under Leitz Diaplan (Wetzlar, Germany) Fluorescence microscope fitted with exciter filter BP 450-490 nm and suppression filter block of 520 nm.

Assay of lipoxygenase and inhibition by curcumin. The concentration of LOX1 was calculated from A_{280} by using the value E_{280} = 14.0 (18). Activities were determined by spec-

Abbreviations: DOC, deoxycholic acid; LOX1, lipoxygenase 1; PC, phosphatidylcholine.

trophotometry. The formation of hydroperoxide was followed at 234 nm (ε = 25,000 $M^{-1}cm$) in a solution of 50 mM Tris HCl (pH 7.4) containing 100 μM PC micelles and 100 μM of fatty acid solubilized in ethyl alcohol (the final concentration of alcohol did not exceed 1 mM). In the inhibition experiments, curcumin was added to the assay mixture as an ethanolic solution (the final concentration of alcohol was 2 mM). The residual activity was independent of the sequence of reagents addition, when related to the activity in the absence of the inhibitor. Reversibility of inhibition was assessed by assaying residual activity after dilution of the enzyme/inhibitor complexes with 50 mM Tris HCl, pH 7.4 at 4°C.

Curcumin fluorescence studies. Fluorescence measurements were performed with a Shimadzu (Kyoto, Japan) spectrofluorophotometer RF 5000. Temperature was maintained at 25°C by circulating the water through the thermostated cuvette holder. Fluorescence titrations of curcumin and PC micelles were made according to the method of Azzi (19). Samples were excited at 451 nm, and emission was recorded at 490 nm. The dissociation constant (K_{cur}) and the number of binding sites on PC micelles were determined using the Scatchard plot method. The interaction of LOX1 and metal ion, Fe^{3+} ($FeCl_3$), was made by following the fluorescence quenching. The PC micelles were saturated with curcumin as reflected in maximum relative fluorescence intensity, F_{max}, at 490 nm. To this PC–curcumin complex, LOX1 or $FeCl_3$ was added gradually and the decrease in fluorescence intensity, F, was recorded. The dissociation constant (K_D) for the fluorescence quenching ligand (L) was determined using equation $F_{max}/F = (1 + K_{cur}/[cur])(1 + [L]/K_D)$ (20), where K_{cur} is the dissociation constant for PC–curcumin determined by Scatchard plot, [cur] is the concentration of curcumin, and [L] is the concentration of LOX1 or $FeCl_3$ added during the titration. The reciprocal of the dissociation constant was used as the equilibrium constant (K_{eq}).

The affinity of curcumin for PC micelles in the presence of fatty acid was calculated using the fluorometric titration of curcumin with PC micelles and fatty acid, and K_{cur} was calculated using the Scatchard plot method. The concentration of bound curcumin used in the inhibition studies was determined using the fluorometric titration of curcumin against 100 μM of PC micelles and 100 μM fatty acid (the concentration similar to activity measurements); the following equation was used to calculate the bound curcumin concentration: $C_B = C_T - (K_D/n)$ (RFI/RFI_{max} – RFI), (21) where C_T was the concentration of curcumin used for the inhibition, K_D was the dissociation constant of LOX1 or Fe^{3+} with PC micelles in the presence of fatty acid, RFI_{max} was maximum fluorescence intensity which was the intercept of the reciprocal plot of curcumin against PC micelles in the presence of fatty acid, and RFI was obtained from the reciprocal plot for the corresponding C_T of curcumin.

RESULTS

Figure 1 shows that curcumin in the presence of PC micelles has a characteristic fluorescence emission maximum of 490 nm at an excitation wavelength of 451 nm. This result indicates that the binding of curcumin with PC micelles could be due to the interaction between the hydrophobic group of curcumin and the hydrophobic regions of PC micelles. This observation was confirmed by fluorescence microscopy measurements which clearly show the binding of curcumin to the PC micelles and the influence of curcumin fluorescence in visualizing the size and shape of PC-micelles (Fig. 2). The luminous disks had diameters of 0.1 to 0.3 μm. Curcumin in aqueous solution and in a solution containing only DOC has a weak fluorescence, but its fluorescence intensity is very high in organic solvents, and the quantum yield increases with increase in the hydrophobicity of the solvent (22). It has been

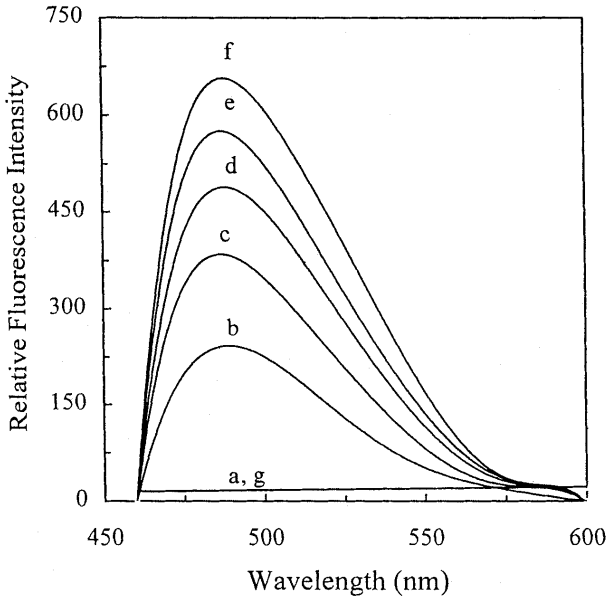

FIG. 1. Fluorescence emission spectra of curcumin with phosphatidylcholine (PC) micelles. To 50 μM PC micelles, various concentrations of curcumin were added in 50 mM Tris HCl buffer, pH 7.4 (a, 0; b, 1; c, 2; d, 3; e, 4; and f, 5 μM of curcumin; g, 5 μM curcumin in 100 μM dioxycholic acid).

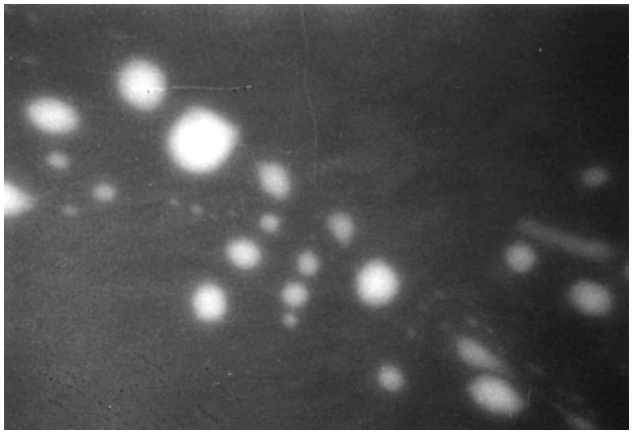

FIG. 2. Fluorescence photomicrograph of PC micelles–curcumin complex in 50 mm Tris HCl buffer, pH 7.4 (PC to curcumin molar ratio was 6.0). Magnification factor 40×. For abbreviation see Figure 1.

reported that curcumin in aqueous solvent is not stable in the alkaline pH and undergoes degradation at high alkaline pH. Therefore, all measurements were made at pH 7.4 in the present study.

LOX1 utilizes linoleic acid bound to the PC micelles as substrate, with a pH optimum of 7.4 (23). The LOX1-catalyzed rate of oxidation of linoleic and arachidonic acids inserted into PC micelles at pH 7.4 is given in Figure 3A. Only the fatty acids bound to the PC micelles are the substrates for LOX1, and the LOX 1 activity is maximum with equal concentrations of fatty acid and PC micelles. This method is very useful for LOX activity determination in the presence of curcumin, because measurements can be made at neutral pH. Although activity of LOX1 with linoleic and arachidonic acids solubilized in equal amounts of Tween 20 had a pH optimum around 9.0, the enzyme had around 50% of its activity at pH 7.4. The effect of different concentrations of curcumin in aqueous system on the LOX1 activity for the Tween 20-solubilized fatty acid substrate suggested that curcumin did not inhibit LOX1 activity (Fig. 3B). However, the inhibitory effect of curcumin on LOX1 activity was observed only with PC-bound fatty acid as substrate. These results clearly show that curcumin inhibits LOX1 in the presence of PC micelles, presumably by binding to the PC micelles, but not in aqueous solution.

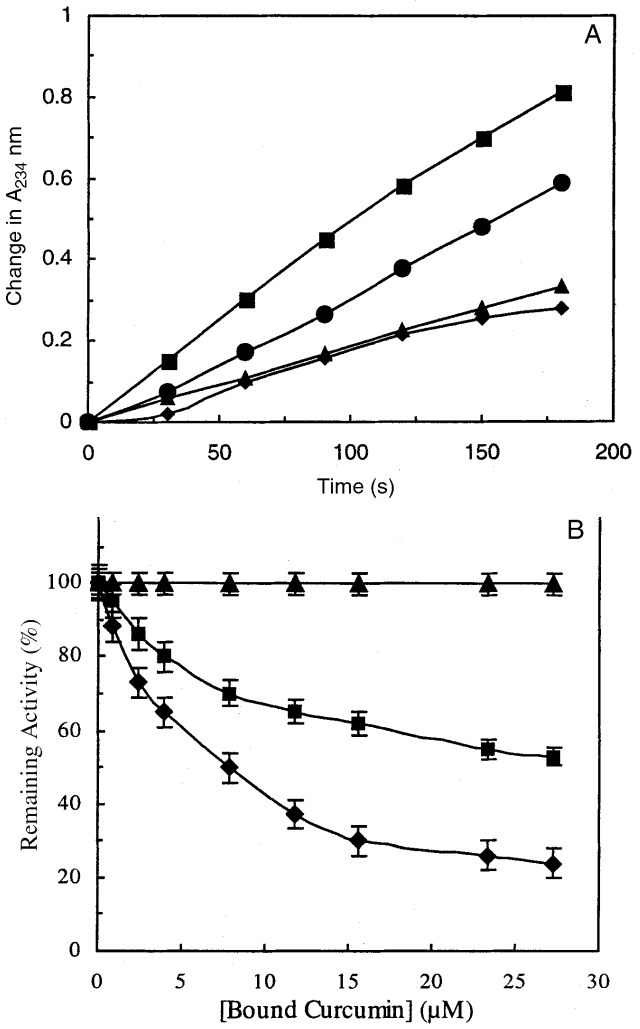

FIG. 3. (A) Soybean lipoxygenase 1 (LOX1)-catalyzed oxidation of fatty acids. Rates were measured in the presence of (i) 100 μM of fatty acid with 100 μM of micellar PC (arachidonic acid, ■; linoleic acid, ●) and (ii) 100 μM of fatty acid dispersed in Tween 20 (arachidonic acid, ▲; linoleic acid, ◆) at pH 7.4 (50 mM Tris HCl). (B) The concentration-dependence inhibition of curcumin on LOX1-dependent dioxygenation. The reaction mixture consisted of 100 μM fatty acid with (i) 100 μM PC micelles (linoleic acid, ◆; arachidonic acid, ■) and (ii) Tween 20 (arachidonic and linoleic acids, ▲) in 50 mM Tris HCl, pH 7.4, and various concentrations of ethanolic solution of curcumin. The reaction was initiated by adding LOX1. For other abbreviation see Figure 1. In Part B the error bars signify the percentage error in measurements.

LOX1 has optimal activity at 100 μM of fatty acid and 100 μM of micellar PC. Since only bound fatty acid is the substrate and the inhibitory effect by curcumin is also due to binding to PC micelles, the concentration of PC micelles is the limiting factor in the LOX1 activity and its inhibition by curcumin. As shown in Figure 3B, the incorporation of increasing amounts of curcumin into the PC micelles led to a successive inhibition of oxidation of fatty acid bound to the PC micelles. Curcumin inhibited dioxygenation of linoleic acid more effectively than arachidonic acid. The 50% inhibitory activity toward linoleic acid oxidation was observed with 11 μM curcumin, which corresponded to 8.6 μM bound curcumin.

When the effects of linoleic and arachidonic acids on lipoxygenase inhibition by curcumin were examined, the rate of oxidation became greater, as the concentration of substrate increased. The Lineweaver-Burk plots at a fixed curcumin concentration showed that K_m increased without changing the V_{max} of the reaction (Fig. 4), suggesting that curcumin is a competitive inhibitor of LOX1, K_i values being 1.7 μM and 4.3 μM for linoleic and arachidonic acid oxidation, respectively (Fig. 5).

Earlier reports on the antioxidant activity of curcumin suggested that curcumin can chelate the metal ion (24,25). Further, LOX1 contains iron as the cofactor. Therefore, studies were made to check whether the competitive inhibition of curcumin is due to binding to the active site iron. Fluorimetric titrations of curcumin with PC micelles with increasing concentrations of LOX1 and $FeCl_3$ suggest that curcumin inhibits LOX1 activity competitively by binding to the active site iron, as the LOX1 quenches the curcumin fluorescence in PC micelles. The equilibrium constant of curcumin bound to the PC micelles with LOX1 is 0.33×10^6 M^{-1}; this value is comparable with the affinity of curcumin with PC micelles, which is 0.37×10^6 M^{-1}. These data further confirm that curcumin can elicit its inhibitory activity only after binding to the PC micelles. The reversible inhibition of LOX1 by curcumin bound to the PC micelles was further confirmed by complete recovery of catalytic activity after dilution of enzyme/inhibitor complex with the buffer. Fe^{3+} also quenched curcumin fluorescence, which was used for determining the affinity of curcumin (PC bound) with Fe^{3+}. This had equilibrium constant of 0.23×10^6 M^{-1}. However, Fe^{2+} was more ef-

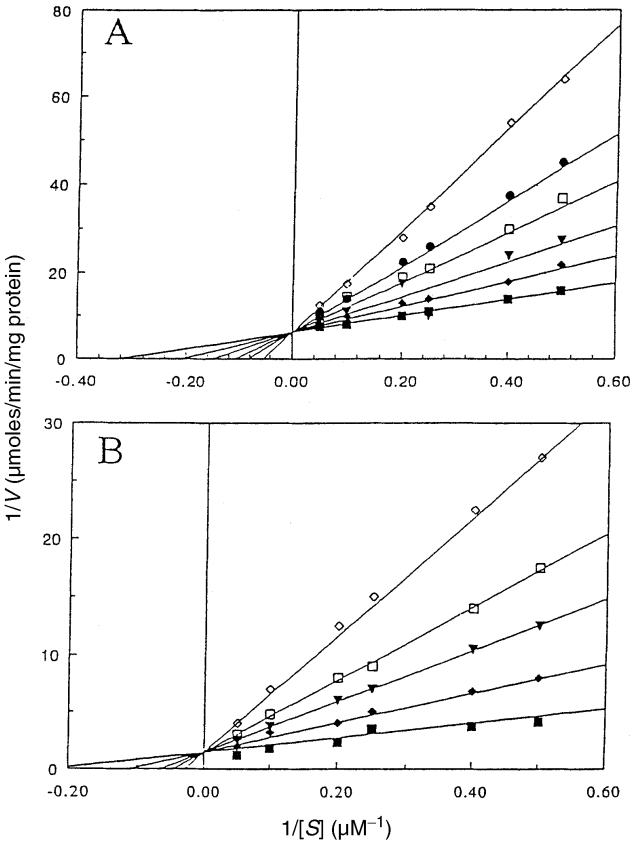

FIG. 4. Lineweaver-Burk plot analysis of the inhibitor of LOX1 by curcumin for the dioxygenation of (A) arachidonic acid and (B) linoleic acid. The concentrations of bound curcumin for arachidonic acid were 0 (■), 3.9 (◆), 7.8 (▼), 11.73 (□), 15.6 (●), and 24 μM (◇); and for linoleic acid 0 (■), 3.13 (◆), 6.25 (▼), 9.4 (□), and 15.6 μM (◇). The micellar PC concentration was 100 μM, and the fatty acid concentration was 100 μM. For abbreviations see Figures 1 and 3.

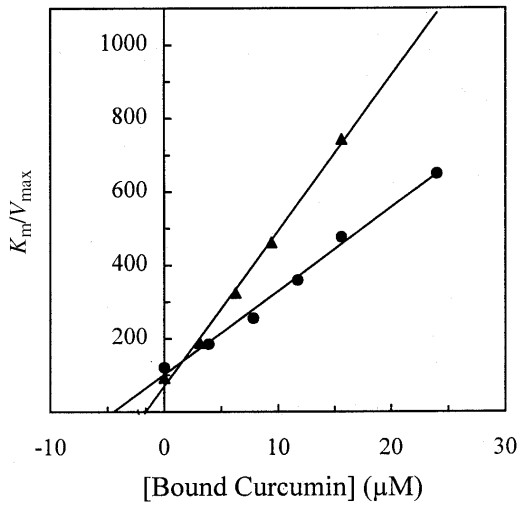

FIG. 5. The slope (K_m/V_{max}) of the lines described from the double reciprocal plot are plotted against the curcumin concentration (bound to PC micelles) in order to derive the K_i value for curcumin (linoleic acid, ◆; arachidonic acid, ●). For abbreviation see Figure 1.

Our earlier study demonstrated that LOX1 can oxidize fatty acids bound to the PC micelles at neutral pH (23). Therefore, this reaction system to monitor the LOX1 activity was used in the present study. Curcumin binds to PC micelles with a high affinity, exhibiting a characteristic fluorescence spectrum that could be attributed to the amphilic nature of curcumin. The binding of curcumin with PC micelles enhances its hydrophobicity. Further, from the equilibrium constants for curcumin–PC micelles and the LOX1–curcumin (bound to PC micelles), it can be inferred that enhancing the hydrophobicity of the curcumin makes it more effective in reaching the active site iron of LOX1. Similar observations

fective in quenching the curcumin fluorescence (data not shown). Comparison of equilibrium constant of PC micelles-bound curcumin with LOX1 (0.33×10^6 M^{-1}) and Fe^{3+} (0.23×10^6 M^{-1}) suggests that curcumin incorporated in PC micelles inhibits LOX 1 activity by binding to the active site iron (Fig. 6).

DISCUSSION

Several studies on the inhibition of LOX1 have shown that inhibitors can act through a number of mechanisms, for example, by reducing the catalytically active ferric enzyme to its inactive ferrous form through the formation of free-radical metabolites (26), or by preventing the formation of the activated Fe(III) form of LOX (27), or by binding to sites other than the active site of the enzyme molecule (28). In general, the inhibition of lipoxygenase reaction seems to be derived from inactivation of the active site of the enzyme or scavenging of free radical at the active site. Therefore, most antioxidants are inhibitors of LOX1. The results of the present study suggest that curcumin inhibits LOX1 by binding with the active site iron.

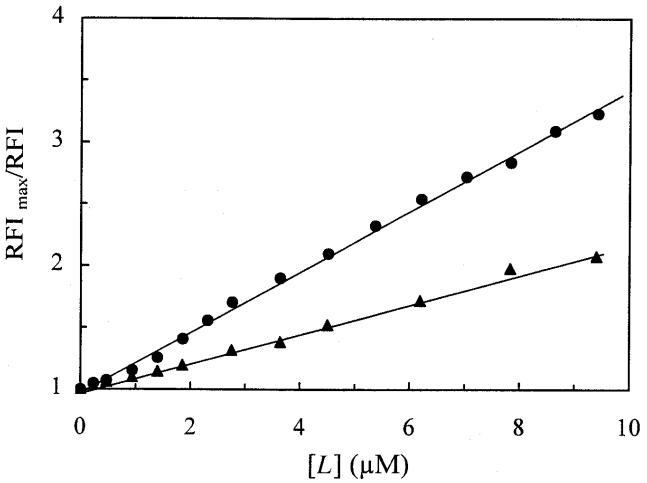

FIG. 6. Fluorescence titration of LOX1 (●) and $FeCl_3$ (▲) against curcumin bound to PC micelles. To 100 μM PC micelles, 100 μM fatty acid and 5 μM curcumin in 50 mM Tris HCl, pH 7.4, various concentrations of LOX1/$FeCl_3$ were added, and the fluorescence quenching was recorded. The plot was made as described in the Materials and Methods section. RFI_{max}, maximum fluorescence intensity, defined as the intercept of the reciprocal plot of curcumin against PC micelles in the presence of fatty acid. For other abbreviations see Figures 1 and 3.

have been made in the earlier study on the competitive inhibition of LOX1 by *n*-alcohols, where longer alkyl chains were shown to increase the affinity of these compounds for the enzyme (29). Similarly, 6-palmitoyl ascorbic acid inhibits more effectively than ascorbic acid (30). It has also been shown that some of the membrane-bound enzymes like protein kinase C and pp $60^{c\text{-}src}$, tyrosine kinase are inhibited by curcumin (31). Hence, it is conceivable that the inhibitory effect of curcumin could be potentiated after binding to the membranes.

The results of the present studies demonstrate that curcumin after binding to the PC micelles acts as competitive and reversible inhibitor of LOX1. Unlike other antioxidant inhibitors of LOX1, curcumin does not require radical formation during LOX inhibition. The dissociation constant of curcumin (bound to PC micelles) with LOX (3.03 μM) determined by fluorometric titrations is comparable with the K_i (1.72 μM) value of LOX inhibition by curcumin for linoleic acid oxidation, indicating clearly that curcumin inhibits LOX1 by binding to the active site iron, the binding is reversible, and the inhibition can be overcome by excess of fatty acid. On the other hand, the K_{eq} ($0.33 \times 10^6 M^{-1}$) for Fe^{3+} binding with PC-bound curcumin is comparable with the K_{eq} (0.23×10^6 M^{-1}) constant of LOX1 interaction with PC micelles-bound curcumin, suggesting that curcumin can bind the active Fe^{3+} form of LOX1. The present observations that PC micelle-bound curcumin binds to the Fe^{3+} can be explained using earlier reports, which suggested that the β-diketone moiety of curcumin could chelate the metal ion, and chelation affinity increased with the increase in hydrophobicity of the curcumin molecule. Hence, curcumin became more potent for inhibiting the LOX1 after its association with PC micelles.

The low K_i value of curcumin for linoleic acid oxidation (K_i = 1.72 μM) compared to arachidonic acid (K_i = 4.3 μM) implies that curcumin is more specific for inhibiting the LOX1 for linoleic acid peroxidation, although LOX 1 shows almost similar values of K_{cat} (4.53×10^7 $M^{-1}s^{-1}$) and K_m (9 μM) for arachidonic acid oxidation compared to linoleic acid oxidation ($K_{cat} = 3.6 \times 10^7$ $M^{-1}s^{-1}$ and K_m = 10 μM). However, some of the reported anti-inflammatory effects of curcumin could be due to inhibition of arachidonic acid peroxidation (10). It is also known that curcumin inhibits mammalian 5-lipoxygenase and cyclooxygenase (32).

These studies imply that curcumin, after binding to PC micelles, acts as a potent inhibitor of LOX1-dependent fatty acid peroxidation, although the micellar system in these experiments may not reflect directly the event of lipid peroxidation occurring *in vivo*. However, observations made in this study may have physiological significance, involving lipoxygenase in biomembrane alteration, both in animals and plants.

ACKNOWLEDGMENTS

We thank Dr. V. Prakash, Director CFTRI, for his keen interest; Dr. K. Udaya Sankar, for constant encouragement; and Dr. Umesh Kumar, for his help in fluorescence microscopy measurements. Senior Research Fellowships to G.B and E.S from CSIR, New Delhi, India, are greatfully acknowledged.

Lysophosphatidylcholine Acyltransferase Activity in *Saccharomyces cerevisiae*: Regulation by a High-Affinity Zn^{2+} Binding Site

Martin G. Richard and Christopher R. McMaster*

Atlantic Research Centre, Departments of Pediatrics and Biochemistry, Dalhousie University, Halifax, Nova Scotia, B3H 4H7 Canada

ABSTRACT: *Saccharomyces cerevisiae* cells were demonstrated to contain lysophosphatidylcholine (lysoPtdCho) acyltransferase (E.C. 2.3.1.23) activity. The enzyme displayed $K_{m(app)}$ of 69 μM for lysoPtdCho and 152 μM for oleoyl CoA. Enzyme activity was not affected by the addition of 1 mM Mg^{2+}, Mn^{2+}, Ca^{2+}, or 200 mM EDTA. However, Zn^{2+} inhibited lysoPtdCho acyltransferase activity to 33% control values at 0.1 mM and to 7% at 1.0 mM Zn^{2+}. To further explore the possibility that lysoPtdCho acyltransferase may contain a high-affinity Zn^{2+} binding site, we tested the strong Zn^{2+} chelator *o*-phenanthroline for its ability to inhibit enzyme activity. LysoPtdCho acyltransferase activity was inhibited to 18 and 27%, respectively, those of control values in the presence of 2 and 1 mM *o*-phenanthroline, implying that a high-affinity Zn^{2+} binding site exists in lysoPtdCho acyltransferase or in an accessory protein that is essential for protein stability and/or activity. *Saccharomyces cerevisiae* lysoPtdCho acyltransferase activity displayed a broad lysoPtdCho fatty acyl chain substrate specificity utilizing lysoPtdCho molecules ranging in length from C_{10}–C_{20} (the entire range tested). In addition, the enzyme was capable of using the ether-linked analog of lysoPtdCho, 1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine, as a substrate. The ability of *S. cerevisiae* to incorporate radiolabeled 1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine into phosphatidylcholine *in vitro* was exploited to demonstrate a direct precursor–product relationship between lysoPtdCho molecules and their incorporation into phosphatidylcholine *in vivo*. Identical labeling results were obtained in *S. cerevisiae* cells disrupted for their major transacylase activity, *PLB1,* demonstrating that the incorporation of lysolipid was *via* acyltransferase, and not transacylase, activity.

Lipids 33, 1229–1234

Phosphatidylcholine (PtdCho) is a major constituent of eukaryotic membranes constituting approximately half of cellular phospholipid mass (1). In eukaryotic cells, PtdCho is synthesized *de novo via* the Kennedy (CDP-choline) pathway in all cell types except yeast and mammalian liver cells, which are also capable of synthesizing PtdCho through the methylation of phosphatidylethanolamine (2,3). The final step within the Kennedy pathway is catalyzed by cholinephosphotransferase *via* transfer of phosphocholine from CDP-choline to diacylglycerol to form PtdCho and CMP (4). The molecular species of diacylglycerol utilized by cholinephosphotransferase determines the fatty acyl composition of *de novo* synthesized PtdCho. *De novo* synthesized PtdCho undergoes fatty acyl chain remodeling through a phospholipase A_2-mediated deacylation followed by reacylation *via* lysophosphatidylcholine (lysoPtdCho) acyltransferase (5,6). This deacylation–reacylation mechanism is believed to be responsible for maintaining polyunsaturated fatty acid pools (e.g., arachidonic acid) at the *sn*-2 position of PtdCho (7,8). PtdCho-derived polyunsaturated fatty acid stores are released from PtdCho in an agonist-dependent manner during most inflammatory responses for subsequent conversion to prostaglandins, leukotrienes, and other inflammation-mediating lipid molecules (9). However, the deacylation–reacylation of PtdCho occurs in many cell types that do not mediate immune responses (10), implying a biological role beyond storage of fatty acyl pools for agonist-stimulated release.

A lysoPtdCho acyltransferase cDNA or gene has not been cloned from any source, and the technical difficulties associated with purifying intrinsic membrane proteins have prevented the purification of the enzyme to homogeneity (10). In this study we report the biochemical and enzymatic characterization of a microsomal lysoPtdCho acyltransferase activity in the yeast *Saccharomyces cerevisiae*. This activity displayed properties consistent with regulation *via* a high-affinity Zn^{2+} binding site either within the enzyme or an accessory protein. The ability to use the observed characteristics to isolate an *S. cerevisia*e gene coding for lysoPtdCho acyltransferase is also discussed.

MATERIALS AND METHODS

Materials. The *S. cerevisiae* strain w303a (*MAT* **a** *ade2-1 his3-11 leu2-3,112 trp1-1 ura3-1 can1-100*) (the kind gift of Robert M. Bell, Glaxo Wellcome, Inc.) was used for all experiments

Abbreviations: GTE, buffer made from 20% glycerol, 50 mM Tris-HCl pH 7.4, 1 mM EDTA; lysoPAF, 1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine; lysoPtdCho, lysophosphatidylcholine; PtdCho, phosphatidylcholine; YPD, growth medium containing 1% Bacto-Yeast Extract, 2% Bacto-Peptone, and 2% glucose.

except the *PLB1* experiment in which DL882 MATa/MATα 1788 *plb1Δ*:::URA3/*plb1Δ*:::URA3, and its parental strain DL1788 MATa/MATα *leu2-3, 112 ura3-52, trp1-1, his4 can1*^{r} (the kind gifts of Susan A. Henry, Carnegie Mellon University), were used. Lipids were supplied by Avanti Polar Lipids (Alabaster, AL). Oleoyl CoA was supplied by Sigma Chemical Co. (St. Louis, MO), and [oleoyl-1-^{14}C]oleoyl CoA was supplied by Amersham Life Sciences (Arlington Heights, IL). Fatty acyl CoA stocks were stored in aliquots at −20°C. [Alkyl-1,2-^{3}H]1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine was obtained from Du Pont NEN (Boston, MA). Media components were obtained from Difco (Detroit, MI), and all other chemicals were obtained from Sigma.

Enzyme assay. Saccharomyces cerevisiae w303a cells were grown to mid-log phase in YPD medium (1% Bacto-Yeast Extract, 2% Bacto-Peptone, 2% glucose), pelletized by centrifugation at 3,000 rpm for 5 min, washed once with ice-cold GTE buffer (20% glycerol, 50 mM Tris-HCl pH 7.4, 1 mM EDTA), and resuspended in 0.7 mL GTE buffer. Cells were disrupted by vortexing in the presence of 0.5-mm glass beads for five bursts of 30 s separated by 30-s incubations on ice. The supernatant was transferred to a new tube, and the beads were rinsed twice with 0.5 mL GTE. The pooled sample was centrifuged at 16,000 × *g* for 15 min at 4°C, and the resulting supernatant was centrifuged at 450,000 × *g* for 15 min. The pellet was resuspended in 250 µL GTE by Dounce homogenization (11). Membranes were stored at −70°C. LysoPtdCho acyltransferase activity was stable for at least 2 mon at −70°C. Yeast lysoPtdCho acyltransferase assays were adapted from previously published assays for the mammalian enzyme (12,13). For a standard assay, 18:1 lysoPtdCho was dried under N_2 gas, resuspended in 5 µL H_2O by water-bath sonication for 5 min with occasional vortexing, and added to a freshly prepared reaction mixture containing 100 mM Tris-HCl (pH 7.4) and 20 µg microsomal protein. The reaction mixture was preincubated at 25°C for 5 min, and catalysis was initiated by the addition of [^{14}C]oleoyl CoA (2500 dpm/nmol). Final substrate concentrations were 150 µM for oleoyl CoA and 125 µM for lysoPtdCho, unless otherwise indicated, in a reaction volume of 100 µL. The reaction was allowed to proceed for 20 min at 25°C. Catalysis was terminated by the addition of 3 mL $CHCl_3/CH_3OH$ (2:1, vol/vol) and 1.4 mL 0.9% KCl. The mixture was centrifuged for 10 min at 1,400 × *g* to facilitate phase separation. An aliquot of the organic phase was dried under N_2, resuspended in 40 µL chloroform spiked with PtdCho, and applied to Whatman (Haverhill, MA) silica gel 60A thin-layer chromatography plates alongside a PtdCho standard. Lipids were separated in a solvent system containing $CHCl_3/CH_3OH/NH_4OH/H_2O$ (70:30:4:2, by vol) and analyzed for radiolabel with a BIOSCAN imaging scanner. PtdCho was identified by iodine staining, and the appropriate region of the silica gel plate was scraped into a scintillation vial for radioactivity determination.

*[^{3}H]1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine ([^{3}H]lysoPAF) metabolism.* [^{3}H]lysoPAF (1.0 µCi, 36 mCi/µmol) was added to mid-log phase *S. cerevisiae* cells grown in YPD broth, and 1-mL aliquots were removed at the indicated times. Cells were washed twice with 1 mL H_2O and resuspended in 1 mL $CHCl_3/CH_3OH$ (1:1, vol/vol). A modified Folch *et al.* (14) extraction procedure was used to extract lipids as described (11). Organic and aqueous phases were assessed for the accumulation of radiolabel by scintillation counting. In addition, the organic phase was dried under N_2 gas for thin-layer chromatography analysis (as described above) and phospholipid phosphorus determination.

Standard assays. Lipid phosphorus was assessed using the method of Ames and Dubin (15). Protein was determined by the method of Lowry *et al.* (16).

RESULTS

LysoPtdCho acyltransferase activity in S. cerevisiae. LysoPtdCho acyltransferase activity was present in *S. cerevisiae* microsomal membranes. Enzyme activity was linear at 25°C for 30 min in the presence of up to 50 µg microsomal protein (data not shown). To ensure linearity with both time and protein, standard assay conditions allowed catalysis to proceed for 20 min using 20 µg of microsomal membrane protein as enzyme source.

The effect of oleoyl CoA concentration on lysoPtdCho acyltransferase activity was investigated in the presence of 125 µM lysoPtdCho (Fig. 1). LysoPtdCho acyltransferase activity increased linearly up to 100 µM oleoyl CoA whereupon enzyme activity plateaued; activity was inhibited by oleoyl CoA concentrations beyond 300 µM, most likely owing to the detergent properties of the fatty acyl CoA solubilizing the membrane. Lineweaver-Burk double-reciprocal plot analysis (17) yielded a $K_{m(app)}$ of 152 µM for oleoyl CoA and a $V_{max(app)}$ of 10.9 nmol min^{-1} mg protein^{-1}. Varying the concentration of the second substrate, lysoPtdCho, in the presence of 150 µM oleoyl CoA resulted in lysoPtdCho activity that was linear up to 60 µM (Fig. 2). Enzyme activity was inhibited by lysoPtdCho concentrations of 150 µM and beyond, again most likely owing to the detergent properties of this substrate solubilizing the membrane used as enzyme source. Lineweaver-Burk plot-derived values for lysoPtdCho were $K_{m(app)}$ of 69 µM and $V_{max(app)}$ of 9.1 nmol min^{-1} mg protein^{-1}.

The specificity of the *S. cerevisiae* microsomal lysoPtdCho acyltransferase activity for *sn*-1-lysoPtdCho containing different acyl chains was determined (Table 1). LysoPtdCho acyltransferase activity was detectable using substrates with acyl chains ranging in length from 10 to 20 carbons, and the highest activity was measured using 18:1 lysoPtdCho as substrate. With 14:0 lysoPtdCho as substrate, the activity observed was 64% of that using 18:1 lysoPtdCho, followed by 12:0 (56%), 18:0 (49%), 16:0 (44%), 10:0 (34%), and 20:0 (30%). *Saccharomyces cerevisiae* was also capable of catalyzing the lysoPtdCho acyltransferase reaction utilizing the ether-linked lysoPAF as substrate. This was unexpected as *S. cerevisiae* does not contain ether-linked phospholipids (18).

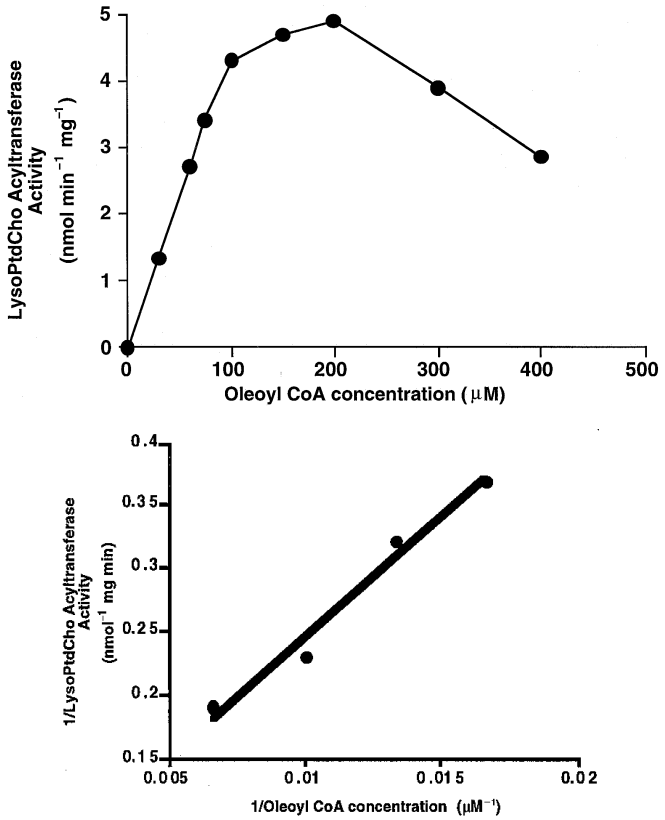

FIG. 1. Effect of oleoyl CoA concentration on *Saccharomyces cerevisiae* lysophosphatidylcholine (lysoPtdCho) acyltransferase activity. The activity of lysoPtdCho acyltransferase was determined in the presence of various concentrations of oleoyl CoA at a constant concentration of 125 μM lysoPtdCho. Each point represents the mean of four individual experiments performed in duplicate. All standard errors were less than 15% of the mean for all points.

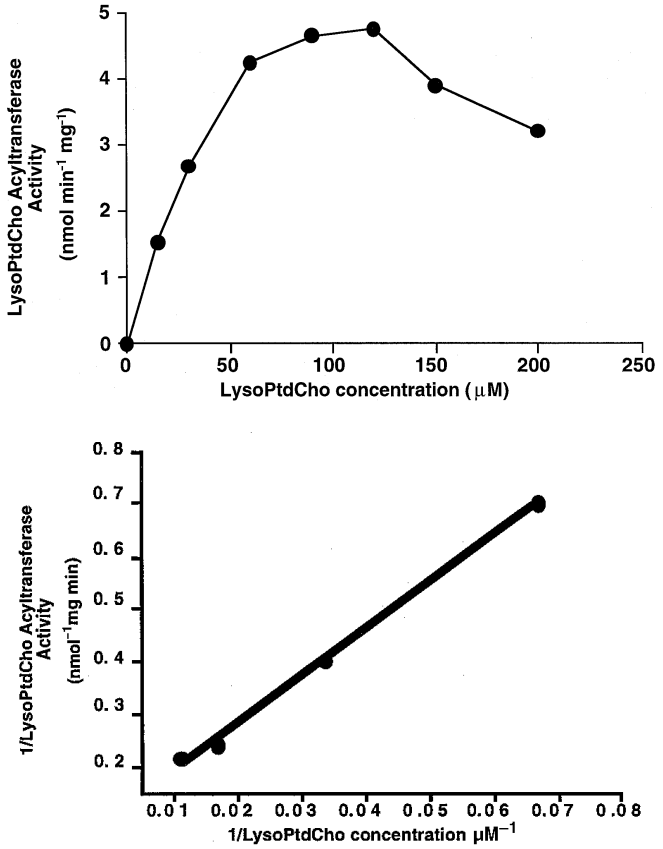

FIG. 2. Effect of lysoPtdCho concentration on *S. cerevisiae* lysoPtdCho acyltransferase activity. The activity of lysoPtdCho acyltransferase was determined in the presence of various concentrations of lysoPtdCho at a constant oleoyl CoA concentration of 150 μM. Each point represents the average of four individual experiments performed in duplicate. All standard errors were less than 15% of the mean for all points. For abbreviatins see Figure 1.

Effect of lipids and cations on lysoPtdCho acyltransferase activity. Many integral membrane-bound phospholipid-metabolizing enzyme activities are affected by their lipid environment, although the biological role of particular lipids affecting specific enzymes is just now being elucidated (19–21). The effect of lipids on lysoPtdCho acyltransferase activity was determined (Table 2). None of the lipids tested resulted in an inhibition of lysoPtdCho acyltransferase. However, several acidic phospholipids including phosphatidylinositol, phosphatidic acid, and cardiolipin increased lysoPtdCho activity to 212, 182, and 236% of control values, respectively.

TABLE 1
LysoPtdCho Fatty Acyl Specificity of LysoPtdCho Acyltransferase Activity[a]

LysoPtdCho fatty acyl chain species	Enzyme activity (nmol min^{-1} mg^{-1})
10.0	1.45 ± 0.21
12:0	2.41 ± 0.13
14:0	2.75 ± 0.38
16:0	1.92 ± 0.37
18:0	2.11 ± 0.32
18:1	4.32 ± 0.38
20:0	1.29 ± 0.17
LysoPAF	0.90 ± 0.13

[a]Results are expressed as mean ± standard error (n = 4). LysoPtdCho, lysophosphatidycholine; lysoPAF, 1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine.

LysoPtdCho acyltransferase activity was determined in the presence of divalent cations (Table 2). Neither Mg^{2+}, Mn^{2+}, Ca^{2+}, nor EDTA had an appreciable effect on lysoPtdCho acyltransferase activity. However, Zn^{2+} inhibited lysoPtdCho acyltransferase activity. Since many Zn^{2+} metalloenzymes are inhibited by Zn^{2+} *in vitro* (22–24), the effect of various concentrations of Zn^{2+} on lysoPtdCho acyltransferase activity was determined (Table 3). LysoPtdCho acyltransferase activity was reduced to 93% control values at 0.01 mM Zn^{2+}, 33% at 0.1 mM Zn^{2+}, and 7% at 1 mM Zn^{2+}. The strong Zn^{2+} chelator, *o*-phenanthroline, is capable of chelating (and thus removing) Zn^{2+} from high-affinity binding sites within proteins (EDTA does not chelate Zn^{2+} in a manner capable of physically removing Zn^{2+} from high-affinity sites). The addition of 1 or 2 mM *o*-phenanthroline to the assay mixture inhibited activity to 27 and 18% of control levels, respectively (Table 3). Since *o*-phenanthroline is delivered in an ethanol

TABLE 2
The Effect of Lipids and Cations on LysoPtdCho Acyltransferase Activity[a]

Treatment	Enzyme activity (% control)
None	100 ± 6
PtdCho	97 ± 7
PtdEtn	127 ± 13
PtdSer	91 ± 9
PtdIns	212 ± 22
PtdOH	182 ± 17
PtdGro	94 ± 14
CL	236 ± 28
Oleic acid	91 ± 5
DAT	135 ± 11
CDP-DAG	116 ± 18
SM	112 ± 15
200 mM EDTA	96 ± 9
1 mM $MgCl_2$	100 ± 9
1 mM $MnCl_2$	102 ± 12
1 mM $CaCl_2$	95 ± 8
1 mM $ZnCl_2$	7 ± 6

[a]The lipid mixture contained 10 mol% of the indicated mixture (relative to the lysoPtdCho concentration). Other assay conditions were as described in the Materials and Methods section. The control (100% activity) was 4.3 nmol min^{-1} mg^{-1}. Results are expressed as mean ± standard error (n = 4). Abbreviations: PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdSer, phosphatidylserine; PtdIns, phosphatidylinositol; PtdOH, phosphatidic acid; PtdGro, phosphatidylglycerol; CL, cardiolipin; DAG, diacylglycerol; CDP-DAG, cytidine diphosphate-diacylglycerol; SM, sphingomyelin. For other abbreviation See Table 1.

suspension, the effect of 1% ethanol on lysoPtdCho acyltransferase activity was also tested to ensure that this organic solvent was not inhibiting activity. Ethanol did not inhibit lysoPtdCho acyltransferase activity (Table 3). The concentrations of Zn^{2+} and *o*-phenanthroline required for inhibition of lysoPtdCho acyltransferase activity are in the range observed for inhibition of activity of known Zn^{2+} metalloenzymes that contain high-affinity Zn^{2+} binding sites (22,23). In an attempt to gain insight into whether the Zn^{2+} bound directly to the lysoPtdCho acyltransferase enzyme itself or to an essential activator protein, heat denaturation experiments were performed. However, a time course of heat denaturation of lysoPtdCho activity at 55°C in the absence or presence of Zn^{2+} did not reveal significant differences in enzyme activity stability, preventing any conclusions with respect to a more precise role for the Zn^{2+} requirement to be drawn.

TABLE 3
Effect of Zn^{2+} on LysoPtdCho Acyltransferase Activity[a]

Cation/chelator	Activity (% control)
None	100 ± 15
None (1% EtOH)	90 ± 15
$ZnCl_2$, 1 mM	7 ± 6
$ZnCl_2$, 0.1 mM	33 ± 19
$ZnCl_2$, 0.01 mM	93 ± 14
o-Phenanthroline, 2 mM	18 ± 15
o-Phenanthroline, 1 mM	27 ± 18

[a]The prereaction mixture contained either $ZnCl_2$ or *o*-phenanthroline at the indicated concentration. The prereaction mixture was incubated for 30 min at room temperature before the addition of radiolabeled oleoyl CoA (to allow for efficient chelation of Zn^{2+} by *o*-phenanthroline). The 30-min preincubation (in the absence of assay modifiers) did not significantly reduce enzyme activity. The control (100% activity) was 4.3 nmol min^{-1} mg^{-1}. Results are expressed as mean ± standard error (n = 6).

[^{3}H]lysoPAF metabolism in S. cerevisiae. To conclusively prove that the observed lysoPtdCho acyltransferase activity was due to direct acylation of lysoPtdCho by fatty acyl CoA and not *via* indirect mechanisms including lipid biosynthetic and/or transacylation pathways, the observed incorporation of lysoPAF into PtdCho *in vitro* (Table 1) was exploited. Ether bonds are poorly metabolized in all eukaryotic cells (25), and the absence of ether-linked glycerophospholipids in *S. cerevisiae* (17) implies that the ability of *S. cerevisiae* cells to hydrolyze this linkage is highly unlikely. The capacity of mid-log phase *S. cerevisiae* cells to metabolize [^{3}H]lysoPAF was examined temporally (Fig. 3). Radiolabel was recovered exclusively in the organic (lipid) fraction (data not shown), and thin-layer chromatographic analysis of the label within the organic phase resulted in its accumulation exclusively in PtdCho (Fig. 3). These results indicate that the ether linkage was not metabolized and also demonstrate a direct precursor–product relationship between lysoPAF and PtdCho formation. To ensure that the acylation of [^{3}H]lysoPAF was not due to transacylase activity, the labeling protocol was repeated in a yeast strain carrying a disruption of the *PLB1* gene (devoid of measurable transacylase activity) (26). The *PLB1*-disrupted yeast cells acylated lysoPAF *in vivo* in a manner indistinguishable from the wild-type parental strain. That is, strain DL882 (*plb1Δ*URA3/*plb1Δ*::URA3), incorporated 1207 ± 39 dpm/nmol lipid P_i [mean ± standard error (n = 8)] 45 min after the addition of [^{3}H]lysoPAF to mid-log phase organisms grown in YPD medium, whereas the wild-type parental strain DL1788 incorporated 1344 ± 33 dpm/nmol lipid P_i under the same experimental conditions.

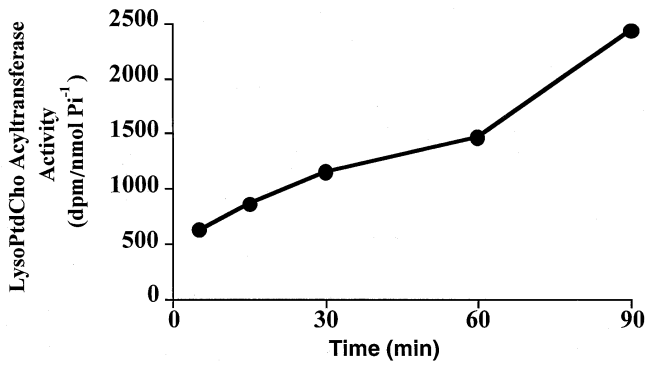

FIG. 3. Metabolism of [^{3}H]1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine by *S. cerevisiae*. [^{3}H]1-*O*-alkyl-2-hydroxy-*sn*-3-glycerophosphocholine was added to mid log-phase w303a yeast cells grown in YPD medium (1% Bacto-Yeast Extract, 2% Bacto-Peptone, 2% glucose). Aliquots were removed at the indicated times and analyzed as described in the Materials and Methods section. Each point represents the mean of two separate experiments performed in duplicate. Pi refers to inorganic phosphorus. See Figure 1 for abbreviations.

DISCUSSION

The distribution of fatty acyl species along the backbone of PtdCho molecules determines the availability of a particular PtdCho molecule for its use in many biological processes including the production of lung surfactant (27) and the release of arachidonic acid from PtdCho stores for conversion to leukotrienes and prostaglandins during agonist-induced inflammatory responses (7,9). Furthermore, unsaturated PtdCho fatty acyl species may undergo oxidative cleavage for the production of platelet-activating factor mimetic, and this process has been linked to the formation of atherosclerotic plaques (28,29).

The interrelationships between the activities and substrate specificities of cholinephosphotransferase and lysoPtdCho acyltransferase are the major dictators of the fatty acyl profile of PtdCho synthesized *de novo*, or *via* the Land's remodeling pathway, respectively. The isolation of lysoPtdCho acyltransferase protein or cDNA has met with limited success owing to the difficulties associated with purifying integral membrane proteins, as well as an absence of genetic tools.

Saccharomyces cerevisiae glycerophospholipids have limited diversity in acyl chain composition (18). Yeasts possess only Δ9 desaturase activity and hence do not contain polyunsaturated fatty acyl chains within their lipids, unless these are supplied from an exogenous source. Despite this limit in diversity, lysoPtdCho acyltransferase activity has been detected in yeast (30). Furthermore, phospholipid remodeling occurs in yeast (31), implying that fatty acyl chain remodeling plays a biological role other than the specific physiological roles listed above. Our study demonstrated that *S. cerevisiae* lysoPtdCho acyltransferase activity has many characteristics similar to those of lysoPtdCho acyltransferase activities present in other eukaryotic cell types. Most notable of these similarities was the inability of Mg^{2+}, Mn^{2+}, Ca^{2+}, and EDTA to affect activity (32). However, Zn^{2+} was found to inhibit lysoPtdCho acyltransferase activity dramatically in *S. cerevisiae* cell membranes. Many Zn^{2+} metalloenzymes are inhibited by high concentrations of Zn^{2+} (22–24). In addition, the strong Zn^{2+} chelator, *o*-phenanthroline, inhibited lysoPtdCho acyltransferase at concentrations similar to its inhibition of known Zn^{2+}-binding protein activities (22,23). Collectively, these results provide strong evidence that lysoPtdCho acyltransferase activity is dependent upon a high-affinity Zn^{2+} binding site on the enzyme itself or an essential accessory protein.

Our *in vitro* characterization of the lysoPtdCho fatty acyl species preferences of *S. cerevisiae* lysoPtdCho acyltransferase indicated that the enzyme was capable of utilizing a broad range of chain lengths, covering the entire range tested (C10–C20). Since each lysoPtdCho substrate was prepared as a micellar suspension, a direct comparison of the efficacy of substrate utilization is not practical because substrate presentation will vary from micelle to micelle. However, it was noted that lysoPAF was utilized as a substrate *in vitro*. LysoPAF is identical in structure to lysoPtdCho except that the fatty acyl group at the *sn*-1 position is linked through an ether bond as opposed to an ester bond. Ether-linked fatty acyl chains are metabolized at a much lower rate than ester-linked fatty acids in all eukaryotic cells (18,25). The addition of labeled lysoPAF to log-phase yeast cells resulted in its conversion to PtdCho in a time-dependent manner. PtdCho was the only radioactive metabolite detected, indicating that the ether bond was not metabolized and that PtdCho was formed directly from lysoPAF, and demonstrating that lysoPtdCho acyltransferase activity is operative *in vivo*.

Our characterization of *S. cerevisiae* lysoPtdCho acyltransferase activity has revealed several important characteristics: (i) the *S. cerevisiae* lysoPtdCho acyltransferase activity shares biochemical and enzymatic properties similar to those in other eukaryotic cell types (8,32); (ii) enzyme activity is inhibited by Zn^{2+} and the Zn^{2+} chelator, *o*-phenanthroline (22,23,33); this is the first demonstration of this effect on this enzyme activity from any source; and (iii) it can utilize a broad range of lysoPtdCho molecules as substrates. The ability of Zn^{2+} to inhibit lysoPtdCho acyltransferase activity coupled with the observation that a broad range of lysoPtdCho molecules (with varying degrees of organic and aqueous solubilities) can be utilized as substrates should aid in the isolation of a *S. cerevisia*e lysoPtdCho acyltransferase gene *via* the development of biochemical screens for mass colony-based assays (34,35).

[a]Department of Legal Medicine, Kobe University School of Medicine, Kobe, Japan, and [b]Kobe Pharmaceutical University, Kobe, Japan

ABSTRACT: A method for separating, detecting, and quantifying cholesterol hydroperoxide (Ch-OOH) based on extraction, purification by solid-phase extraction cartridge, high-performance liquid chromatography with chemiluminescent detection (HPLC-CL), and liquid chromatography–mass spectrometry has been developed for human erythrocyte membrane. We prepared standard compounds of the cholesterol 5α-, 7α-, and 7β-hydroperoxides (Ch 5α-OOH, Ch 7α-OOH, and Ch 7β-OOH). An octyl silica column with methanol/water/acetonitrile 89:9:2 (by vol) as eluent was used to determine Ch-OOH. HPLC-CL that incorporated cytochrome c and luminol as the post-column luminescent reagent was used. We also investigated the optimal assay conditions and how to prevent formation of artifact Ch-OOH. Analysis of erythrocyte membranes from seven healthy volunteers identified Ch 7α-OOH and Ch 7β-OOH, but not Ch 5α-OOH, as commonly occurring components. The respective mean concentrations of Ch 7α-OOH and Ch 7β-OOH were 2.5 ± 1.6 and 5.4 ± 3.5 pmol/mL blood.
Lipids 33, 1235–1240 (1998).

Lipid peroxidation has been linked to a number of pathological conditions and diseases, including ischemia–reperfusion injury, inflammation, and atherosclerosis. It has been monitored on the basis of the formation of thiobarbituric acid-reacting substances (1) and conjugated diene determination (2), but these lack specificity.

Highly sensitive, specific methods for direct measurement of lipid peroxides have now been developed. Phospholipid hydroperoxide levels have been determined in human blood plasma (3) and human red blood cells (4) by high-performance liquid chromatography with chemiluminescent detection (HPLC-CL). Cholesterol ester hydroperoxide in human blood plasma has been analyzed by HPLC-CL (5) and by HPLC with coulometric detection (6).

The possible production of cholesterol hydroperoxide from cholesterol is outlined in Scheme 1. Peroxidation of cholesterol can be induced by such active oxygen species as singlet oxygen, producing cholesterol 5α-hydroperoxide (Ch 5α-OOH) as the first step, then rearrangement of the hydroperoxide giving cholesterol 7α-hydroperoxide (Ch 7α-OOH), and finally epimerization of Ch 7α-OOH giving cholesterol 7β-hydroperoxide (Ch 7β-OOH) (7). In contrast, cholesterol may be autoxidized, producing cholesterol 7-hydroperoxide Ch 7-OOH (8). Ch 7α-OOH and Ch 7β-OOH were detected in the rat by HPLC-CL (9, 10), and in humans were found by HPLC combined with electrochemical detection from photooxidized erythrocyte ghosts (11), but not from the human erythrocyte ghost itself.

We report a sensitive, simple method for determining cholesterol hydroperoxides (Ch-OOH) in erythrocyte membranes

Abbreviations: 7α-OH, 7α-hydroxycholesterol; 7β-OH, 7β-hydroxycholesterol; BHT, 3, 5-di-*tert*-butyl-4-hydroxytoluene; Ch-OOH, cholesterol hydroperoxides; Ch 5α-OOH, cholesterol 5α-hydroperoxide; Ch 7α-OOH, cholesterol 7α-hydroperoxide; Ch 7β-OOH, cholesterol 7β-hydroperoxide; CL, chemiluminescent, chemiluminescence; DMF, dimethylfuran; HPLC-CL, high-performance liquid chromatography with chemiluminescent detection; IS, internal standard; LC–MS, liquid chromatography–mass spectrometry; NMR, nuclear magnetic resonance; PCOOH, phosphatidylcholine hydroperoxide; UV, ultraviolet.

of healthy volunteers using HPLC-CL and liquid chromatography–mass spectrometry (LC–MS) with an atmospheric pressure chemical ionization interface to identify Ch-OOH. Furthermore, to prevent formation of artifact Ch-OOH during extraction, we examined purification using a solid-phase cartridge, and the influences of light and antioxidants.

MATERIALS AND METHODS

Materials. Cholesterol was obtained from Sigma (St. Louis, MO). 3,5-Di-*tert*-butyl-4-hydroxytoluene (BHT), luminol (3-aminophthaloylhydrazine), and cytochrome c (from horse heart, type VI) were purchased from Wako Pure Chemical Co. (Osaka, Japan). Ch 5α-OOH, Ch 7α-OOH, and Ch 7β-OOH were synthesized as follows: A solution of cholesterol (960 mg) and rose bengal (10 mg) in pyridine (200 mL) was irradiated with a halogen lamp at 10°C with oxygen bubbling for 8 h. Subsequent evaporation of pyridine gave a crystalline residue, of which half was purified by medium-pressure column chromatography (silica gel) and recrystallized from benzene to give Ch 5α-OOH, m.p. 145–148°C. The product had an ^{1}H nuclear magnetic resonance (NMR) spectrum identical to that of an authentic sample (7). The remaining half of the crystals was dissolved in chloroform, and the resultant solution was stirred at room temperature for 3 d. Evaporation of the solvent gave a residue which was purified by medium-pressure column chromatography (silica gel), then recrystallized from ethyl acetate, affording Ch 7α-OOH, m.p. 144–147°C, and Ch 7β-OOH. Although Ch 7β-OOH was obtained as a 6:1 mixture with the 7α-isomer, both compounds had ^{1}H NMR spectra identical to those of authentic samples (12).

β-Sitosterol 5α-hydroperoxide was prepared by irradiating a solution of β-sitosterol (400 mg) and hematoporphyrin (7 mg) in pyridine (208 mL) with a high-pressure mercury lamp through a Pyrex filter at 10°C with oxygen bubbling for 9 h. The crude products were purified and recrystallized from ether to give β-sitosterol 5α-hydroperoxide. The product had a characteristic ^{1}H NMR spectrum as in the case of Ch 5α-OOH. β-Sitosterol 5α-hydroperoxide was the internal standard (IS).

HPLC-CL analysis. Ch-OOH were determined by reverse-phase HPLC with post-column chemiluminescent (CL) detection: HPLC was done in a column of TSK gel Octyl-80Ts (150 × 4.6 mm, i.d.) using an LC-10AD vp pump (Shimadzu, Kyoto, Japan). The column was kept at 40°C and flushed with methanol/water/acetonitrile (89:9:2), the mobile phase, at the flow rate of 0.7 mL/min. The premixed mobile phase was degassed by 5 min of sonication before use. A Rheodyne 7125 injector (100 μL, Cotati, CA) was used to inject the sample solution into the column. After passage through a SPD-6A spectrophotometric detector (Shimadzu) set at 210 nm, the eluate was mixed with a luminescent reagent in the post-column mixing joint, at the controlled temperature of 37°C, of a CLD-10A CL detector (Shimadzu). The luminescent reagent, prepared by dissolving cytochrome c and luminol in alkaline borate buffer (pH 10), was loaded with an LC-10AD vp pump at the flow rate of 0.5 mL/min. The CL generated by the reaction of the hydroperoxide with the luminescent reagent was measured with a CL detector.

The concentrations of cytochrome c and the luminol prepared, respectively, 10 and 2 μg/mL, were the same as those employed by Miyazawa *et al.* (13,14). The luminescent solution was 20 mM $H_3BO_3 \cdot Na_2CO_3$ buffer at pH 10. The effect of the flow rate of this reagent was examined between 0.2 and 0.8 mL/min. The injection volume and supply voltage also were examined in terms of the hydroperoxide-dependent CL intensities.

Standard curves were prepared by the analyses of 1, 2, 4, and 10 ng (2.39, 4.78, 9.58, and 23.9 pmol) of Ch 5α-OOH and of Ch 7β-OOH, and 0.5, 1, 2, and 5 ng (1.20, 2.39, 4.78, and 12 pmol) of Ch 7α-OOH with 2.5 ng of the IS. Individual peak areas were calculated with an integrator (Chromatopac C-R4A; Shimadzu). The ratios of the hydroperoxides to the IS also were calculated for the standard compounds and lipid extracts of the specimens. The recoveries from the sample extracts were determined by comparison of the peak areas obtained after injection of a sample extract spiked with a known concentration. The recoveries of Ch 7α-OOH and IS varied from 55 to 65%.

HPLC–MS analysis. An L-7000 series (Hitachi, Tokyo, Japan) liquid chromatography system fitted with spherisorb ODS-2-5 (250 × 4.6 mm, i.d.) and a model M-1200AP LC–MS system that incorporated an atmospheric chemical ionization system (Hitachi) were used. The mobile phase, methanol containing 0.1 M ammonium acetate or methanol alone, was delivered at the flow rate of 0.7 mL/min. By adding ammonium acetate to the methanol as the mobile phase, an ion appeared at *m/z* 401 so that Ch-OOH were distinguishable from the 7-hydroxycholesterols as shown in Figure 1, although most had similar retention times. Application parameters for the mass spectrometer were positive-ion measurement mode, a nebulizer temperature of 170°C, a desolvator temperature of 400°C, and a needle-electrode voltage of 3000 V.

Artifact formation. Two milligrams of cholesterol was extracted twice with 9 mL chloroform/methanol (2:1) containing 0.005% (50 ppm) BHT by the modified method of Folch *et al.* (15). The combined chloroform layer was concentrated in a rotary evaporator, then dried under a nitrogen stream. The residue was dissolved in 1 mL of methanol and a 10 μL portion injected into the HPLC column (Method A). A silica column (Bond Elut® Varian, Harbor City, CA) of 3-mL capacity, containing aminopropyl- derivatized silica (-NH_2) as packing material, was conditioned by washing it with 5 mL of acetone and 10 mL of *n*-hexane, after which 2 mg of cholesterol in a small amount of chloroform was passed through, followed by elution with a mixture of 2 mL chloroform and 1 mL isopropanol. The eluate was concentrated, and the residue subjected to HPLC (Method B), or after concentration it was passed through another Bond Elut® column with elution using 3 mL of 10% of ethyl acetate/*n*-hexane. The eluate was concentrated and the residue subjected to HPLC (Method C). When two cartridges of Bond Elut® were conditioned, 0.1%

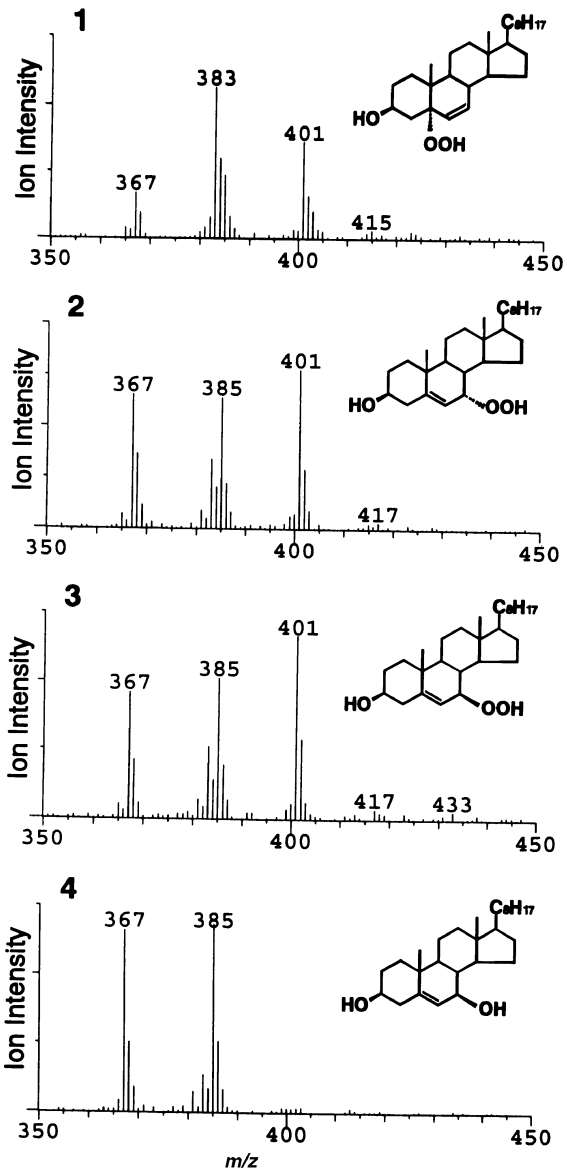

FIG. 1. Mass spectra of the cholesterol 5α-, 7α-, and 7β-hydroperoxides (M = 418) and 7β-hydroxycholesterol (M = 402) were detected by liquid chromatography–mass spectrometry with an atmospheric pressure chemical ionization interface. Methanol containing 0.1 M ammonium acetate was used as a mobile phase.

EDTA · 2Na was used before water and acetone (Method D). Dark test tubes were used during solid extraction with Bond Elut® (Method E). Two milligrams of cholesterol was extracted twice with 9 mL chloroform and methanol containing BHT and dimethylfuran (DMF) to give final concentrations of 10, 20, 50, 100, 400, and 1000 ppm BHT. The concentrations of DMF were 0, 15, 60, and 150 ppm. The chloroform layer was evaporated, and the residue was applied to a Sep-Pak® (Waters, Milford, MA) of 3-mL capacity containing aminopropyl-derivatized silica (-NH_2) packing material (Method F).

Extraction. Seven healthy male volunteers (39.3 ± 12.2 yr) participated in the study. After obtaining their informed consent, venous blood samples were drawn. Five milliliters of blood was collected in a glass test tube containing 0.5 mg EDTA · 2Na, then centrifuged at 4°C and 800 × *g* for 10 min; the erythrocytes were then fractionated. A method for erythrocyte ghost preparation was used (16). IS (200 pmol in 100 μL chloroform) was added to lipids from the white ghosts and extracted twice with 9 mL chloroform and methanol containing 0.005% BHT at room temperature, essentially by the method of Folch *et al.* (15). The combined chloroform layer was concentrated, and the residue applied to Sep-Pak®. Each column was conditioned by washing it with 5 mL of acetone and 10 mL of *n*-hexane. Before the column became completely desiccated, the crude membrane lipids dissolved in a small amount of chloroform were applied and drawn through, followed by elution with a mixture of 2 mL chloroform and 1 mL isopropanol. The eluate was concentrated. The residue was dissolved in 200 μL of methanol, and a 10-μL portion injected to an HPLC column.

Statistical analysis. Mann-Whitney's U-test was used to determine the statistical significance of the difference between group means. *P*-values of <.05 were considered statistically significant.

RESULTS

Figure 2 shows typical HPLC chromatograms obtained with a mixture of standard Ch-OOH and hydroxycholesterols. The 3 Ch-OOH (7β-, 7α, and 5α-OOH) separated when methanol/water/acetonitrile was the mobile phase, as shown by CL, and the two hydroxycholesterols also were separated as seen by ultraviolet (UV). The retention times were Ch 7β-OOH, 6.8 min; Ch 7α-OOH, 7.3 min; Ch 5α-OOH, 7.8 min; IS, 9.5 min; 7β-hydroxycholesterol (7β-OH), 6.6 min; and 7α-hydroxycholesterol (7α-OH), 7.1 min. Because CL detection is specific, the Ch-OOH were distinguishable from peaks 7α-OH and 7β-OH despite the similar retention times. Although Ch-OOH theoretically are detectable by CL and UV, no Ch-OOH peaks appeared on UV because of the small amount used. The CL detector response was about 300 times greater for Ch 7α-OOH than the UV detector response.

The injection volume of Ch 7α-OOH (20 pmol) vs. peak areas (CL intensity) was linear. We usually injected 10 μL of the sample to the HPLC. Standard curves (ratio of the IS vs. the amount of Ch-OOH injected) for Ch 5α-OOH, Ch 7α-OOH, and Ch 7β-OOH were linear. The detection limit for Ch 5α-OOH was 0.7 pmol, that for Ch 7α-OOH 0.3 pmol, and that for Ch 7β-OOH 0.3 pmol at the signal-to-noise ratio of six.

We investigated the effects of the supply of the chemiluminescent detection voltage (–0.7 to –0.9 kV) and the flow rate of the chemiluminescent reagent (0.2 to 0.8 mL/min) on the chemiluminescence response. At the supply voltage of –0.9 kV, Ch 7α-OOH (20 pmol) gave its maximum response. We used –0.7 kV as the supply voltage. At the flow rate of 0.5 mL/min, Ch 7α-OOH (20 pmol) gave its maximum CL response.

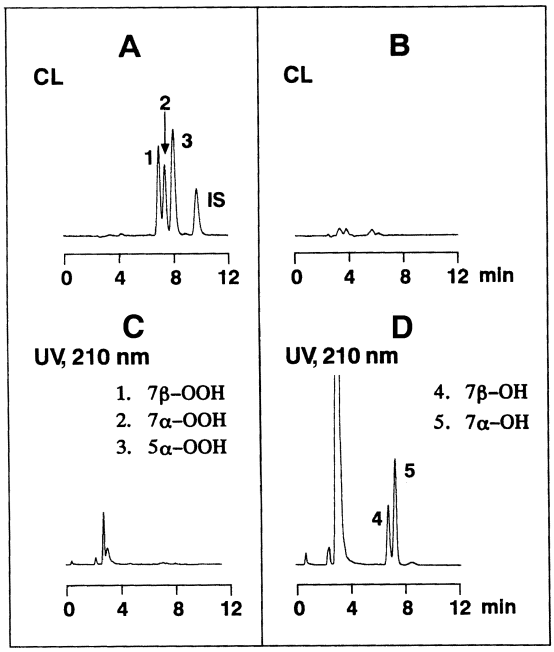

FIG. 2. Chromatographic separation of cholesterol hydroperoxides (Ch-OOH) and corresponding diols in standard mixtures. (A,C) A 10-μL sample containing known Ch-OOH in methanol [2 pmol cholesterol 7α-hydroperoxide (Ch 7α-OOH), 4 pmol cholesterol 5α-hydroperoxide (Ch 5α-OOH), and cholesterol 7β-hydroperoxide (Ch 7β-OOH)]. (B,D) A 10-μL sample containing known hydroxycholesterol in methanol [50 nmol 7α-hydroxycholesterol (7α-OH) and 25 nmol 7β-hydroxycholesterol (7β-OH)]. CL, chemiluminescent detection; UV, ultraviolet detection.

Table 1 compares artifact formation by Methods A to F. Method A, extraction of cholesterol itself by the method of Folch *et al.* (15), did not cause artifact formation, nor did passing cholesterol through one cartridge of Bond Elut® result in artifact formation (Methods B). Passing cholesterol through two cartridges (Method C), however, sometimes caused artifact formation, and formation was prevented neither by washing the cartridge with EDTA · 2Na (Method D) nor by shading it with a dark test tube (Method E). When we used DMF as well as BHT as the antioxidants in the extraction solvent (Method F), to prevent artifact formation 0.1% (1000 ppm) BHT and 0.015% (150 ppm) DMF were necessary. A large negative peak appeared, which disturbed the Ch-OOH peak. When BHT alone was the antioxidant in the extraction solvent (Method F), artifact formation did not occur at any concentration (10 to 100 ppm). We therefore did the extraction with chloroform and methanol containing 0.005% (50 ppm) BHT as the antioxidant, and followed it by purification with Sep-Pak® (Method F).

Figure 3 shows a typical HPLC chromatogram of artifact formation. Peak 1 seemed to be Ch 7β-OOH, peak 2 Ch 7α-OOH, and peak 3 Ch 5α-OOH because the retention times corresponded to these standard compounds. Peaks A, B, and C could not be determined.

Figure 4 shows chromatograms for the erythrocyte sample from a healthy volunteer, a mixture of standard Ch-OOH, and IS. Standard Ch 7β-OOH, Ch 7α-OOH, Ch 5α-OOH, and IS appeared, respectively, at 6.8, 7.3, 7.8, and 9.5 min. The extracts from human erythrocyte membranes contained Ch 7β-OOH and Ch 7α-OOH, but not Ch 5α-OOH. The addition of the standards Ch 7β-OOH and Ch 7α-OOH independently confirmed the peak identities.

The mean levels of Ch 7β-OOH and Ch 7α-OOH in erythrocyte membranes of seven healthy volunteers were 5.4 ± 3.5 (range 1.9–9.2) and 2.5 ± 1.6 (range 1.1–5.3) pmol/mL blood (means ± standard deviations). The concentration of Ch 7β-OOH was not significantly higher than that of Ch 7α-OOH.

DISCUSSION

There are many recent reports of analytical methods for determining phospholipid hydroperoxides and cholesteryl ester hydroperoxides in biological samples, but only a few researchers have given an analytical method for Ch-OOH and showed the presence of Ch-OOH. To develop an analytical

method for Ch-OOH, we first prepared the standard compounds Ch 5α-OOH, Ch 7α-OOH, and Ch 7β-OOH. The standard Ch-OOH were subjected to LC–MS using an atmospheric pressure chemical ionization interface. It is important to confirm the chemical structure of the Ch-OOH, and this has not been previously achieved.

We then investigated the optimal assay conditions for HPLC-CL. We separated Ch 5α-OOH, Ch 7α-OOH, and Ch 7β-OOH from one another in a C8 column with methanol/water/acetonitrile, under similar conditions to those of Korytowski *et al.* (11). They, however, used HPLC combined with electrochemical detection, establishing the detection limit for Ch-OOH as ~25 pmol, so that they could analyze the Ch-OOH generated by photodynamic action, not from erythrocyte ghosts. Because of the report of Zhang *et al.* (17) that the HPLC-CL system employed by Miyazawa *et al.* (13,18,19) and them (20) combined with a cytochrome c–luminol cocktail was 16- to 100-fold more sensitive to phosphatidylcholine hydroperoxide (PCOOH) than the microperoxidase–isoluminol cocktail

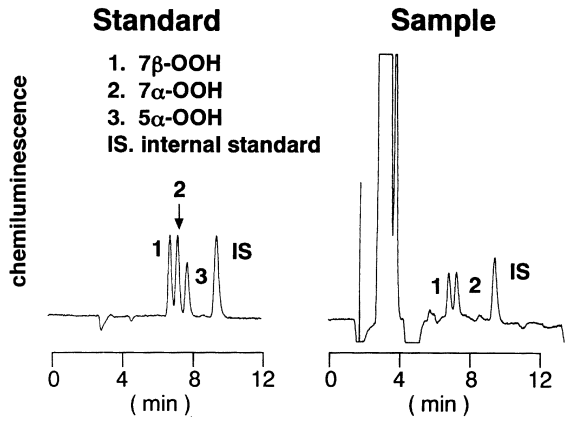

FIG. 4. Chromatograms from high-performance liquid chromatography with chemiluminesent detection for the erythrocyte sample from a healthy volunteer, a mixture of standard Ch-OOH, and the IS.

used by Yamamoto *et al.* (21), we used the cytochrome c–luminol cocktail. Brown *et al.* (22) reported a normal-phase HPLC method with UV detection that could resolve all the cholesterol products oxygenated at the 7-position: 7-ketocholesterol, Ch 7α-OOH, Ch 7β-OOH, 7α-OH, and 7β-OH, but they detected Ch-OOH from the lipid extract of atherosclerotic plaque only in trace amounts because of the low detection limit.

Lastly, we examined the extraction procedure and some antioxidants to avoid artifact formation. Cholesterol in low density lipoprotein was easily oxidized with the help of the metal ion Cu^{2+} (22,23) or a metal-independent peroxy-radical generated system (AAPH) (22) and yielded Ch 7α-OOH and Ch 7β-OOH. BHT (0.1%) and DMF (0.015%) are reported to be absolutely necessary as antioxidants to prevent artifact formation during the assay process (9,10), but both antioxidants at a high level produced a negative peak, thereby disturbing the Ch-OOH peak. In contrast, we found that the presence of BHT alone was sufficient to prevent artifact formation. Ozawa *et al.* (9,10) purified the lipid extract from rat skin using two Bond Elut® cartridges, but artifact formation might occur on passage through the two cartridges due to metal contaminants. Unknown peak A in the chromatograms of artifact formation (Fig. 3) was assumed to be cholesterol 6β-hydroperoxide based on a comparison with the chromatograms of Korytowski *et al.* (11).

In conclusion, for the first time we detected Ch 7α-OOH and Ch 7β-OOH in the erythrocyte membranes of healthy volunteers. The respective mean concentrations of Ch 7β-OOH and Ch 7α-OOH were 5.4 and 2.5 pmol/mL blood. Healthy human plasma is reported to contain 0.5 μM of PCOOH (18), 3 nM (5,24) and 4.2 nM (25) of cholesterol ester hydroperoxide, and less than 20 nM hydroperoxide of eicosatetraenoic acid (26). Plasma glutathione peroxidase was reactive with linoleic acid hydroperoxide but had a low reducing activity toward Ch 7α-OOH and no detectable activity with the Ch 5α-OOH (27); therefore, PCOOH might be absent but Ch-OOH might be present in human plasma. The concentration of total Ch 7-OOH in rat skin was 20–150 μmol/g skin (7), which was higher than the values we found, probably because lipid peroxides easily accumulate in the skin of the rat.
