ABSTRACT: Canola oil is not presently permitted in infant formulations in the United States because of lack of information concerning the effects of feeding canola oil to the newborn. We have previously reported a transient decrease in platelet counts and an increase in platelet size in newborn piglets fed canola oil for 4 wk, and have confirmed this in the present study. In canola oil-fed piglets, changes in platelet size and number were overcome by adding either long-chain saturated fatty acids from cocoa butter (16:0 and 18:0), or shorter-chain saturates from coconut oil (12:0 and 14:0). Feeding a high erucic acid rapeseed (HEAR) oil, with 20% 22:1n-9, led to an even greater platelet reduction and increased platelet size throughout the 4-wk trial. Bleeding times were longer in piglets fed canola oil or HEAR oil compared to sow-reared and soybean oil-fed piglets. There were no other diet-related changes. Diet-induced platelet changes were not related to platelet lipid class composition, but there were fatty acid changes. The incorporation of 22:1n-9 into platelet phospholipids of piglets fed canola oil was low (0.2–1.2%), and even for the HEAR oil group ranged from only 0.2% in phosphatidylinositol to 2.4% in phosphatidylserine. A much greater change was observed in the concentration of 24:1n-9 and in the 24:1n-9/24:0 ratio in platelet sphingomyelin (SM). The 24:1n-9 increased to 49% in the HEAR oil group compared to about 12% in animals fed the control diets (sow-reared piglets and soybean oil-fed group), while the 24:1n-9/24:0 ratio increased from about 1 to 12. Even feeding canola oil, prepared to contain 2% 22:1n-9, led to a marked increase in 24:1n-9 to 29% and had a 24:1n-9/24:0 ratio of 5. The canola oil/cocoa butter group, which also contained 2% 22:1n-9, showed a lower level of 24:1n-9 (20%) and the 24:1n-9/24:0 ratio (3) compared to the canola oil group. The results suggest that the diet-related platelet changes in newborn piglets may be related to an increase in 24:1n-9 in platelet SM, resulting from chain elongation of 22:1n-9. The inclusion of canola oil as the sole source of fat in the milk-replacer diets of newborn piglets resulted in significant platelet and lipid changes.

Lipids 33, 1–10 (1998).

The present U.S. Food and Drug Administration regulations do not permit the inclusion of canola oil in infant formulations (1) because of lack of experimental evidence concerning the effects of feeding canola oil, and specifically erucic acid (22:1n-9), to the newborn. We have recently shown that piglets fed milk-replacer diets containing canola oil showed a transient delay in the rise of platelet numbers and an associated increase in platelet volume (2). In addition, some vegetable oils high in oleic acid (18:1n-9), such as high-oleic acid sunflower oil (HOAS), a mixture of oils that mimicked canola oil, and olive oil, also showed these platelet changes. These platelet changes were overcome by the third week on continuous feeding of these diets, or immediately by adding coconut oil to canola oil (2). There was no evidence that the lower platelet counts were associated with increased bleeding times in piglets fed these diets compared to sow-reared piglets. However, the question remained as to whether 22:1n-9 could further decrease platelet counts in the newborn piglet, and possibly affect bleeding times. The inclusion of these oils into infant formulations with resultant low platelet count and a prolonged bleeding time may have serious implications for the infant, since thrombocytopenia is known to occur in premature and term infants (3,4).

Previous studies with human test subjects showed that normal young men given diets containing high-erucic acid rapeseed (HEAR) oil (39% 22:1n-9) for 22 d had a pronounced drop in platelet count with a return to normal after discontinuation of the diet for 1 wk (5). A similar decrease in platelet counts was observed in patients suffering from X-linked adrenoleukodystrophy (ALD) who had received a dietary mixture of triolein and trierucin (4:1) in order to reduce their level of plasma very long chain saturated fatty acids, particularly 26:0 (6–8). These patients showed minor bruising, but no clinical symptoms of bleeding (6), and their platelet counts returned to normal after discontinuation of the diet (6,7). It is of interest to note that lower platelet counts are not limited to

Abbreviations: ALD, adrenoleukodystrophy; CE, cholesterol esters; FFA, free fatty acids; Hb, hemoglobin; HEAR, high erucic acid rapeseed; HOAS, high oleic acid sunflower; PE, phosphatidylethanolamine; PC, phosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; SM, sphingomyelin.

22:1n-9 consumption. Eating fish and/or fish oil diets that contain high levels of cetoleic acid (22:1n-11), a positional isomer of erucic acid (22:1n-9), also caused a decrease in platelet counts and an increase in bleeding times (9–12).

The present study was undertaken to further evaluate the platelet changes associated with the feeding of milk-replacer diets containing canola oil. Newborn piglets were either left with the sow or fed milk-replacer diets containing soybean oil, canola oil, a canola oil/cocoa butter mixture, or a HEAR oil for 4 wk. The HEAR oil diet was included to determine the effect of high levels (20%) of 22:1n-9 on platelets and bleeding times in newborn piglets. The canola oil/cocoa butter mixture was included to determine if the long-chain saturated fatty acids caused the same ameliorating effect on platelets as the short-chain fatty acids derived from coconut oil (2).

MATERIALS AND METHODS

Animals and diets. Newborn Yorkshire male and female piglets were left with the sow for 1 d prior to allocating them to one of five dietary groups, balanced for litter and sex. Four groups of six piglets/diet were fed milk-replacer diets in specially designed cages (13), and one group of five piglets was left cross-fostered with one sow. Body weights were measured at 1 d of age and every 3 d thereafter, and the feed (dry matter) was adjusted to 7% of body weight/day.

The following dietary oils and oil mixtures were fed: soybean oil obtained from CanAmera Foods Inc. (Toronto, Ontario, Canada); a mixture (92:2) of canola oil (0.8% 22:1n-9) and HEAR oil (42.9% 22:1n-9) (both oils obtained from CanAmera Foods Inc., Altona, Manitoba, Canada) to increase the level of 22:1n-9 to 2%, the maximum permissible level of 22:1n-9 in canola oil in the United States (1); a mixture of canola oil, cocoa butter (26% 16:0, 29% 18:0, 38.5% 18:1n-9; Hershey Canada Inc., Smith Falls, Ontario, Canada), HEAR oil, and linseed oil in the ratio of 52:40:4:4, which contained about 2% 22:1n-9 and 8% linolenic acid (18:3n-3), similar to canola oil; and a mixture of HEAR oil and canola oil (46:54), prepared with a final content of about 20% 22:1n-9. The fatty acid compositions of the dietary oils are shown in Table 1.

The milk-replacer diets were prepared as described previously (14) with 25% dietary oil, and all vitamins were added after the spray-drying process. The vitamin E content was 150 IU/kg diet to avoid vitamin E deficiency in the canola oil-fed group (15). The dry-milk powders were stored at –20°C until used. The milk replacers were prepared daily to include 21% solids and 16% γ-globulin (2). The digestible energy content of the final milk replacer was 953 kcal/L (16).

Pathology. After 4 wk of experiment, each piglet was anesthetized within 2 h of removal from the diet with a 5:1 mixture of ketamine hydrochloride (Rogarsetic-Rogar/STB, Montréal, Québec) and acepromazine maleate (Atravet-Ayerst Lab., Montreal, Québec) and killed by exsanguination. A complete gross pathology was performed on each piglet, and 20 different tissues were sampled for histological analysis. All tissues were fixed in formalin.

TABLE 1
Fatty Acid Composition of the Dietary Oils

Fatty acids	Sow milk	Soybean oil	Canola oil[a]	Canola/cocoa[b]	HEAR oil[c]

[a]Mixture of canola oil (0.8% 22:1n-9) and high-erucic acid rapeseed (HEAR) oil (42.9% 22:1n-9) in a ratio of 98:2 to give a final oil with 2% 22:1n-9.
[b]Mixture of canola oil, HEAR oil, linseed oil (49% 18:3n-3), and cocoa butter in a ratio of 52:4:4:40.
[c]Mixture of canola oil and HEAR oil in a ratio of 54:46 to give a final oil with 20% 22:1n-9.
[d]n-6 PUFA, polyunsaturated fatty acids, includes 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6.
[e]n-3 PUFA, includes 20:5n-3, 22:5n-3, and 22:6n-3.

Blood measurements. Blood (0.5 mL) for hematological measurements was taken from the piglets by orbital sinus puncture (17) in tubes containing EDTA as anticoagulant. The blood was throughly mixed with the anticoagulant, transported at room temperature, and analyzed within 1–2 h for complete blood count using a Technicon H-2 analyzer (Technicon Instrument Corp., Tarrytown, NY). Bleeding time measurements were taken using a Simplate II device as described previously (2).

Platelet isolation. At time of kill, 15 mL of blood was taken from each piglet in vacutainer tubes containing EDTA. The whole blood was centrifuged at 150 × *g* at room temperature for 15 min. The plasma was adjusted to pH 6.5 with 1 M citric acid, and 2 drops of EDTA were added. Traces of red and white cells were removed by centrifuging the plasma again at 150 × *g* at room temperature, followed by 2500 × *g* at 4°C for 15 min to remove the platelets. The platelets were suspended in 1 mL of buffer (20 mM Na_2HPO_4, 130 mM NaCl, and 2 mM EDTA at pH 6.5) containing inhibitors (10 μL 4 mM iodoacetamide, 20 μL 4 mM *N*-ethylmaleimide in 50% ethanol, and 10 μL aprotinin containing 10,000 units/mL) and centrifuged at 2500 × *g* at 4°C for 15 min. The platelets were then stored at –70°C until analyzed.

Lipid analysis. Total platelet lipids were extracted using the Bligh and Dyer mixture (18). The total platelet lipids from each individual piglet were not sufficient to perform a complete lipid class analysis, and therefore, the lipids from two piglets on the same diet were pooled. All the lipid classes

were separated by three-directional thin-layer chromatography (TLC) using silica gel H plates (19). The spots were visualized with ultraviolet light after spraying the plates with 2′,7′-dichlorofluorescein. The spots were scraped off, methyl heptadecanoate was added as internal standard, and the lipids were methylated in the presence of the silica gel using anhydrous HCl/methanol (5% by wt) at 80°C for 1 h. The resulting methyl esters and dimethyl acetals were analyzed by gas–liquid chromatography using a 30-m Supelcowax-10 capillary column (Supelco Inc., Bellefonte, PA) (20).

Statistics. The blood data were analyzed using the general linear models procedure of SAS (21), with terms for litter and diet as major effects, while the fatty acid data were analyzed with diet as the major effect.

RESULTS

Growth and health. The piglets fed the milk-replacer diets gained significantly ($P < 0.05$) more weight over the 4-wk period (from 5.0–6.8 kg) than piglets left with the sow (4.0 ± 0.4 kg). There were some differences in weight gain among the four milk-replacer diets. After 9 and 12 d on diet, the HEAR oil group showed the best (1.3 ± 0.08 and 1.9 ± 0.1 kg) and canola oil the lowest weight gain (0.9 ± 0.08 and 1.3 ± 0.1 kg), but after 4 wk on diet, the soybean oil group showed best (6.8 ± 0.5 kg) and HEAR oil the lowest weight gain (5.0 ± 0.4 kg). No diet-related gross or histological abnormalities were observed among the piglets. One animal fed the canola/cocoa butter mixture was euthanized at 12 d of age because of congenital rectal stricture, and three animals died of unrelated causes: two fed soybean oil, on days 24 and 27, and one fed HEAR oil, on day 28.

Platelets. One-day-old piglets had a relatively low platelet count ranging from 167 to 372 × 10^9/L with an overall mean of 285 ± 21 × 10^9/L ($n = 29$). The platelet counts in the sow-reared piglets doubled after 1 wk, and remained high thereafter (Table 2). The platelet counts agreed with published data for normal newborn (337 ± 79 × 10^9/L) and adult (578 ± 128 × 10^9/L) pigs (22,23). The lifetime of pig platelets was reported to be 9–11 d (22). Piglets fed soybean oil showed a somewhat slower rise in platelet counts after the first 2 wk, which was, however, not significantly different compared to sow-reared piglets (Table 2).

Piglets fed canola oil with 2% 22:1n-9 showed an increase in platelet counts after the first week, but thereafter the counts were significantly lower throughout the 4-wk trial compared to the sow-reared control group (Table 2). The addition of cocoa butter to canola oil enriched the long-chain saturated fatty acids 16:0 and 18:0 in the dietary oil mixture, resulting in a significantly higher platelet count than seen with canola oil alone (Table 2).

The HEAR oil-fed group with 20% 22:1n-9 showed markedly lower platelet counts throughout the 4-wk trial (Table 2). Generally, the platelet counts for this group did not increase above the levels observed at 1 d of age.

Mean platelet volume. The platelet volume decreased in the sow-reared piglets from 14 to 10 fL per platelet (Table 2). The decease was slower in the soybean oil and the canola oil/cocoa butter groups, but at 4 wk on diet, the values were similar to the sow-reared controls. The platelet volume remained elevated for the canola oil group throughout the 4-wk trial, and increased significantly in piglets fed the HEAR oil diet. The platelet volume for the HEAR oil-fed group after 4 wk on diet was greater than 22 fL, the upper limit of discrimination of the H-2 analyzer. There was a significant negative correlation of platelet size to platelet counts (–0.64; $n = 135$).

Other hematological parameters. The packed cell volume, hemoglobin (Hb), and red blood cell counts were significantly higher in the sow-reared piglets compared to piglets fed the milk-replacer diets (Table 2). There were no significant differences among the piglets fed the milk-replacer diets, except for piglets fed the HEAR oil diet. The HEAR oil group showed lower values for all these three parameters, and which were significant for packed cell volume and Hb. There were generally no significant diet differences in mean corpuscular volume, mean corpuscular Hb, mean corpuscular Hb concentration, prothrombin time, and activated thromboplastin time (Table 2).

Bleeding times. The bleeding time increased in all piglets with age (Table 3). The increase was most rapid in the HEAR oil group. After 4 wk on diet, only the HEAR oil and canola oil groups gave significantly higher bleeding times compared to the other groups.

Platelet lipids. The platelet lipids were not significantly different between the dietary groups, and for that reason the mean for all diets for each of the platelet lipid classes is shown in Table 4. The major phospholipids were phosphatidylcholine (PC) and phosphatidylethanolamine (PE), with intermediate levels of sphingomyelin (SM) and phosphatidylserine (PS), a smaller amount of phophatidylinositol (PI), and trace amounts of diphosphatidylglycerol. In addition, the neutral lipids cholesterol, cholesterol esters (CE), and free fatty acids (FFA) were present. The results were expressed as percentage of total lipids and compared to results from human and dog platelets (Table 4).

Platelet phospholipid fatty acids. Each of the four phospholipids showed characteristic fatty acid profiles (Table 5). Alk-1-enyl ethers were present mainly in PE. All the phospholipids contained about 50% saturated fatty acids, except PE which had about 30%. PC had the highest concentration of 16:0, while 18:0 predominated in the other phospholipid classes. The highest levels of arachidonic acid (20:4n-6) were present in PE and PI, and the highest levels of C_{22} polyunsaturated fatty acids (PUFA) (22:4n-6, 22:5n-3, and 22:6n-3) were found in PE and PS.

Sow's milk consisted mainly of 16:0, oleic acid (18:1n-9), and linoleic acid (18:2n-6), with small amounts of preformed long-chain n-6 (1.6%) and n-3 (0.7%) PUFA (Table 1), which were reflected in the fatty acid profile of the phospholipids (Table 5). Piglets fed soybean oil in their milk-replacer diets generally showed increased levels of 18:0 and 18:2n-6 compared to sow-reared piglets, at the expense of 16:0 and 18:1n-9. Despite the fact that soybean oil was rich in 18:2n-6

and 18:3n-3, the concentration of PUFA derived from these precursors (i.e., 20:4n-6, 22:4n-6, and 20:5n-3, 22:5n-3, and 22:6n-3, respectively) was generally similar to, or lower than, that found in sow-reared piglets.

Both canola oil and HEAR oil were high in 18:1n-9 (36 and 51%, respectively), and contained similar levels of 18:2n-6 (~20%) and 18:3n-3 (~9%), but these two groups had marked differences in their concentration of long-chain monounsaturated fatty acids of the oleic acid family (n-9) (Table 1). The feeding of canola oil and HEAR oil generally resulted in similar changes in platelet phospholipids, except for the significantly higher levels of 20:1n-9, 22:1n-9, and

24:1n-9 in piglets fed HEAR oil (Table 5). The highest accumulation of 22:1n-9 in the platelet phospholipids of the HEAR oil group was found in PS (2.4%), intermediate in PC and PE (~1%), and lowest in PI (0.2%). With few exceptions, these two rapeseed oils resulted in increased levels of 18:1n-9, total monounsaturated fatty acids, 18:2n-6 and 18:3n-3 in all platelet phospholipid classes compared to sow-reared piglets, and decreased levels of 16:0 and total saturated fatty acids only in PC and PI. Furthermore, long-chain PUFA derived from 18:2n-6 (18:3n-6, 20:3n-6, 20:4n-6, and 22:4n-6) were lower in PE and PS, while long-chain PUFA derived from 18:3n-3 (20:5n-3, 22:5n-3, and 22:6n-3) were higher in all phospholipid classes.

The canola oil/cocoa butter mixture had similar dietary levels of 22:1n-9 and 18:3n-3 as canola oil, except for the much higher levels of long-chain saturated fatty acids, 16:0 and 18:0 (Table 1). Feeding this oil to piglets resulted in increased saturated fatty acids in platelet PC and PI, and lower levels of long-chain n-9 monounsaturated fatty acids in all phospholipid classes (Table 5). However, the n-6 and n-3 PUFA profile was similar to canola oil, but there was no reduction in the levels of 20:4n-6 in platelet PE as observed with the feeding of canola oil.

The ratio of n-6 to n-3 PUFA metabolites (from 18:2n-6 and 18:3n-3), in all phospholipids, was highest in sow-reared piglets, intermediate in piglets fed soybean oil, and lowest in piglets fed the three rapeseed oil type diets (Table 5). The rapeseed diets included canola oil, the canola oil/cocoa butter mixture, and HEAR oil. There were no significant differences in the n-6 to n-3 ratios between the three rapeseed oil-containing groups (Table 5).

Platelet SM fatty acids. Platelet SM consisted mainly of long-chain saturated fatty acids from 16:0 to 24:0, and n-9 monounsaturated fatty acids, of which nervonic acid (24:1n-9) was the major fatty acid (Table 6). The total saturated fatty acid content in platelet SM was about 66% in sow-reared and soybean oil-fed piglets, and decreased progressively with the feeding of canola oil (52%) and HEAR oil (38%), but remained unaffected with the feeding of the canola oil/cocoa butter mixture (66%). The decrease in total saturated fatty acids in the canola oil and HEAR oil group was in response to the marked increase in 24:1n-9 (Table 5). Compared to sow-reared piglets, the relative concentration of 24:1n-9, the elongation product of 22:1n-9, increased by 16 and 35%, respectively, for the canola oil and HEAR oil group. The ratio of 24:1n-9 to 24:0 increased from about 1 in the sow and soybean oil group to 3 in the canola/cocoa butter group, to 5 in the canola group, and to 11 in the HEAR oil group.

Platelet CE and FFA. These two minor neutral lipid classes closely reflected the dietary fatty acid composition, and contained only small amounts of C_{20} and C_{22} PUFA (data not included). The accumulation of 22:1n-9 in these two lipid classes was 5.8 and 10.0% in the HEAR oil group, 1.0 and 1.4% in the canola oil group, and 1.0 and 1.2% in the canola/cocoa butter group, respectively. In addition, the HEAR oil group showed significant amounts of 24:1n-9 in both CE (3.9%) and FFA (2.2%).

[d]No values reported.

DISCUSSION

This report is a continuation of studies to evaluate canola oil in milk-replacer diets of newborn test animals to determine if this oil is safe for inclusion into infant formulations. We previously reported that newborn piglets fed milk-replacer diets containing canola oil as the only source of fat in the diet showed a transient delay of 3 wk in the rise of platelet counts, increased platelet volume, but no increased bleeding times (2). The results of the present study indicated that newborn piglets fed canola oil had lower platelet counts and increased platelet size (Table 2) which were negatively correlated, increased bleeding times (Table 3), and these changes persisted to 4 wk of age. These platelet changes need clarification and further testing to determine if the presence of canola oil in milk replacers constitutes a potential risk for infants. Throm-

[a]A mixture of canola oil and cocoa butter; see Table 1.
[b]HEAR, high-erucic acid rapeseed.
[c]SEM, pooled standard error of the mean.
[d]Values are means of two pools of two animals each.

bocytopenia is know to occur in premature and term infants (3,4).

The results of our previous study appeared to indicate that the platelet changes in canola oil-fed piglets were related to the high content of 18:1n-9, since similar results were obtained with other oils high in 18:1n-9, such as HOAS oil (76.1% 18:1n-9), a mixture of nonrapeseed oils which mimicked the fatty acid profile of canola oil (54.1% 18:1n-9), and occasionally olive oil (75.5% 18:1n-9) (2). On the other hand, the addition of cocoa butter to canola oil raised the level of long-chain saturated fatty acids (16:0 and 18:0), and retained a high level of 18:1n-9 (43%) (Table 1), while normalizing the platelet count and size (Table 2). We previously observed that the addition of coconut oil (rich in 12:0 and 14:0) to canola oil was effective in restoring normal platelet parameters in piglets, despite the high 18:1n-9 content of 54% (2). These results suggest that factors other than 18:1n-9 were involved in platelet changes. There appeared to be a lack of dietary saturated fatty acids when canola oil was fed, since the platelet changes were corrected by addition of saturates. The correction also occurred naturally, at 3–4 wk of age, when piglets were able to synthesize fatty acids *de novo* (14). In our previous study we were unable to determine the contribution of 22:1n-9 (present at about 2% in the canola oil and oil mixture) to the observed platelet changes, and for this reason we now included an experimental diet containing an HEAR oil with 20% 22:1n-9 to test the effect of 22:1n-9.

The HEAR oil group showed marked reduction in platelet counts, increased platelet size, increased bleeding times, and decreased hemoglobin throughout the 4-wk trial (Tables 2 and 3). These newborn piglets fed HEAR oil consumed about 3 g of 22:1n-9/kg body weight/day (16). Similar results were obtained when healthy young men consumed a HEAR oil that contained 39% 22:1n-9 as the only source of fat in the diet (5). In these experiments, a pronounced drop in platelet number was observed with the consumption of about 1.4 g 22:1n-9/kg body weight/day. After 22 d, the diet was discontinued for health concerns, because the platelets dropped below 120×10^9/L. In that same report, low-erucic acid rapeseed oil with less than 2% 22:1n-9 did not cause a reduction in platelet numbers (5). Platelet size was not reported. A similar thrombocytopenia was also observed in patients suffering from ALD, a sex-linked disorder in which very long-chain saturated fatty acids accumulate in all tissues, after treatment with "Lorenzo Oil," a 4:1 mixture of glycerol triolein and glycerol trierucin (6–8). The consumption of 22:1n-9 in these children was up to 18 g glycerol trierucin/d (7) or about 0.5 g 22:1n-9/kg body weight/day based on a body weight of 35 kg. Decreased platelet counts and increased size were directly attributed to dietary 22:1n-9, since its removal from the diet restored platelet numbers and size to normal (7). The authors performed confirmatory studies to show that these platelet changes were not spuriously related to EDTA (8). ALD patients given a high triolein diet did not show symptoms of thrombocytopenia (7,8). There was no evidence of increased bleeding times in these patients, but a few patients showed a tendency to bruise easily (6). Furthermore, platelet reduction and increased platelet size were not restricted to long-chain monounsaturated fatty acids of the n-9 family such as erucic acid (22:1n-9). Consumption of fish, high in oil content and cetoleic acid (22:1n-11), a positional isomer of 22:1n-9, gave similar results. Dyerberg and Bang (9) also observed lower platelet counts, higher platelet volume, and increased bleeding times in adult Eskimos compared to control subjects from Denmark. Subsequent studies have shown that a high consumption of fish, rich in oil and 22:1n-11, produced similar platelet changes in healthy human subjects (10–12).

The evidence indicates that 22:1n-9 is involved in platelet changes; however, the etiology is not known. Bone marrow appeared to be normal on histological examination. This is in agreement with our previous piglet study (2) and in ALD patients (7,8). In addition, Zierz *et al*. (7) reported that the bone marrow of ALD patients revealed no evidence of megakaryocyte reduction.

Diets were prepared to include 150 IU of vitamin E per kg diet to ensure that the canola oil- and HEAR oil-fed piglets had sufficient vitamin E, since we previously observed that milk-replacer diets containing canola oil required additional vitamin E (15). The vitamin E levels in liver and heart were found to be lower in the canola oil and the canola oil/cocoa butter mixture compared to soybean oil, but the differences

were generally not significant (results published elsewhere, 24). On the other hand, the HEAR oil group showed significantly lower tissue vitamin E levels compared to the soybean oil group. However, the high dietary vitamin E level included in the diets of this study ensured adequate tissue vitamin E levels even in the HEAR oil group when compared to the sow-reared controls (24). These results support the conclusion of the previous study (15) that rapeseed oils (HEAR more than canola) appear to contain substances that induce oxidative stress in the piglets. This oxidative stress may have damaged platelets and reduced the Hb content, which would account for their lower levels in rapeseed oil-fed piglets. Further studies will be required to determine the mechanism of platelet changes in the newborn piglet using specific indicators (4).

The platelet lipids were investigated in this study to see if the platelet changes could be related to specific lipid or fatty acid changes. The relative proportions of the platelet lipid classes were not significantly affected, and the composition was similar to that found in adult humans (25) and dogs (26) (Table 4). Blomstrand *et al.* (27) also reported no differences in platelet lipid class composition between rats fed trierucin (22% 22:1n-9) or herring oil (12% 22:1n-11) diets for 10 wk, although they did not present any values.

The accumulation of 22:1n-9 into the structural platelet lipids was found to be relatively minor even when piglets were fed the HEAR oil diet which contained 20% 22:1n-9 (Tables 5 and 6). It ranged from 0.2 (PI) to 2.4% (PS). The minor lipids CE and FFA were an exception. They accumulated larger amounts of 22:1n-9, but these lipids are not considered to be structural platelet components. In addition, the accumulation of 22:1n-9 into platelet lipids was negligible in groups fed oils containing about 2% 22:1n-9, and absent when oils were devoid of 22:1n-9. Therefore, the level of 22:1n-9 in the platelet lipids does not appear to explain the observed thrombocytopenia in newborn piglets.

The greatest change in the fatty acid composition of structural platelet lipids was observed in the 24:1n-9 content of platelet SM. The 24:1n-9 is derived by chain elongation of 18:1n-9 (28,29), or from dietary 22:1n-9 (30–33), when present. The accumulation of 24:1n-9 reached 49% of the total platelet SM fatty acids in the HEAR oil-fed piglets, compared to 14% in sow-reared and 11% in soybean oil-fed piglets (Table 6). Canola oil-fed piglets also showed a marked increase of 24:1n-9 to 29%, while the canola oil/cocoa butter group showed an intermediate increase to only 20%. Our data suggest that dietary 22:1n-9 (and 20:1n-9) was effectively incorporated into the 24:1n-9 of the SM fraction (30-33) after an apparent control step, possibly the first step in the chain elongation of 18:1n-9 to 20:1n-9. This could explain why canola oil showed very high levels of 24:1n-9 despite only 2% 22:1n-9 in the diet. An increase in dietary saturates (canola oil/cocoa butter group) showed a moderation in the elongation of 22:1n-9 to 24:1n-9.

To test this hypothesis, one should evaluate the platelet SM composition of piglets fed an oil that gave similar platelet changes as canola oil but was devoid of 22:1n-9, such as HOAS oil in our previous study (2). We had only reported the total, not the platelet SM composition in our previous paper (2), now selectively presented in Table 7. The canola oil-fed group showed an increase in 24:1n-9 and the 24:1n-9/24:0 ratio in both platelet SM and red blood cell membranes SM, while the HOAS oil-fed group showed a similar response only in the red blood cell membranes SM. It should be noted that the HOAS platelet SM (Table 7) may not be entirely reliable because of the limited sample size. The sample size of red blood cell membrane SM was much larger, and it showed the increase in 24:1n-9 and the 24:1n-9/24:0 ratio (Table 7),

[a]All values (a–d) are means of [a]two pools of two animals each, [b]four animals/diet, [c]one pool of three animals, and [d]three animals/diet.
[b]HEAR, high-erucic acid rapeseed.
[c]This experiment was published previously (Ref. 2), but neither the platelet or red blood cell SM results were presented.
[d]HOAS, high-oleic acid sunflower.

which suggests that one can use these fatty acid changes as a predictor of platelet changes in newborn piglets.

It was not possible to evaluate the changes in platelet SM due to dietary 22:1n-9 or 22:1n-11 in the other studies, since the fatty acid composition of platelet SM was either not reported in piglets (34), rats (27) or humans (5–8,10–12,35,36), or the total platelet fatty acid composition did not include either 24:0 or 24:1n-9 (8,12,27,34–36). Dyerberg and Bang (9) were the only ones who reported 24:0 and 24:1 in total platelet lipids, and they confirmed the higher values of 24:1 (4.4 vs. 1.1%) and the 24:1/24:0 ratio (14.7 vs. 1.6) in adult Eskimos compared to Danish control subjects. A recent study by Jensen *et al*. (36) in which term infants were fed formulas containing up to 40% canola oil for 120 d was of interest. They reported the fatty acid composition of plasma and erythrocyte phospholipid, but not that of platelets, and did not include 24:0 and 24:1 in their analysis.

The platelet lipids of ALD patients fed the glycerol triolein/trierucin mixture were reported to have a negative correlation of platelet count to total platelet 18:1n-9 (–0.49; P = 0.01), 22:1n-9 (–0.56; P = 0.003) and 24:1n-9 (–0.65; P = 0.0003) (8). Based on these results, the authors concluded that 22:1n-9, but not 18:1n-9, affected the platelet biology, since a diet high in glycerol triolein did not show changes in platelet number. The 24:1n-9 was not considered, despite the evidence which showed that both the concentrations and correlations of 24:1n-9 were greater than for 22:1n-9 (Table 1, Ref. 8). It would be expected that the changes would have been much greater if platelet SM from ALD patients, instead of total platelet lipids, had been investigated. It was of interest to note that the plasma SM of the ALD patients showed a marked increase in 24:1 (from 16.0 to 46.8%), and in the 24:1/24:0 ratio (from 0.6 to 6.1) after consumption of glycerol trierucin, which was much greater than the incorporation of 22:1 (from 1.38 to 6.21%) into plasma SM (37). This would support the hypothesis that thrombocytopenia appears to be related to 24:1n-9, the elongation product of 22:1n-9. Furthermore, one cannot rule out an additive effect of 24:1n-9 in animals fed a diet low in 18:2n-6 to 18:3n-3 (canola 2.3). Jensen *et al.* (38) recently showed that infants fed a formula with an 18:2n-6 to 18:3n-3 ratio of 4.8 had reduced weights, and their plasma levels had lower 20:4n-6 and higher 22:6n-3 levels at 120 d of age compared to a formulation having an 18:2n-6 to 18:3n-3 ratio of 44.

In conclusion, a reduction in platelet number and an increase in platelet size and bleeding time were evident in newborn piglets fed milk-replacer diets containing canola oil as the only source of fat in the diet. The platelet changes with canola oil were overcome by the addition of long-chain saturated fatty acids to the diet, which were just as effective as the shorter-chain fatty acids from coconut oil. HEAR oils showed marked and consistent platelet and hemoglobin reduction, and increased platelet size and bleeding times. The greatest lipid changes were observed in platelet SM fatty acid composition, which showed a significant increase in 24:1n-9 and in the 24:1n-9/24:0 ratio both for canola oil and HEAR oil. The addition of cocoa butter to canola oil moderated these fatty acid changes in platelet SM. The results show significant platelet and lipid changes in newborn piglets fed milk-replacer diets containing canola oil as the sole source of fat in the diet, which was corrected by mixing canola oil with saturated fats in a 3:2 ratio. Canola oil should be evaluated as part of infant formula preparations which mimic mother's milk that contains about 45% saturates (39), similar to that undertaken by Jensen *et al.* (38) to test if these adverse effects are removed.

ACKNOWLEDGMENTS

The authors are grateful for the technical assistance of Robert C. Fouchard and the staff at the swine barn at Agriculture Canada, Mary Calvert and her staff at the Ottawa Civic Hospital, and the staff at the Ontario Veterinary Laboratory Services. The study was partially supported by a grant from the Canola Council of Canada. Contribution number 2437 from the Center of Food and Animal Research.

Effect of Modified Dairy Fat on Postprandial and Fasting Plasma Lipids and Lipoproteins in Healthy Young Men

Tine Tholstrup[a,*], Brittmarie Sandström[a], John E. Hermansen[b], and Gunhild Hølmer[c]

[a]Research Department of Human Nutrition, and Centre for Advanced Food Studies, The Royal Veterinary and Agricultural University, Frederiksberg, Denmark, [b]Department of Product Quality, Danish Institute of Animal Science, Foulum, Denmark, and [c]Department of Biochemistry and Nutrition, Technical University of Denmark, Lyngby

ABSTRACT: Fatty acid profile of milk fat can be modified by cow feeding strategies. Our aim was postprandially and after 4 wk to compare the effect of a modified milk fat (M diet) [with 16% of the cholesterolemic saturated fatty acid (C12–16) replaced by mainly oleic and stearic acids] with the effect of D diet, including a conventional Danish milk fat on plasma lipids and lipoproteins. A side effect of the cow feeding regime was a 5% (w/w) increase in *trans* fatty acid in M diet. Eighteen subjects were fed for two periods of 4 wk strictly controlled isoenergetic test diets with 40% of energy from total fat and the same content of dietary cholesterol in a randomized study with cross-over design. Contrary to expectations, fasting low density lipoprotein (LDL) cholesterol concentration did not differ after the experimental periods. However, M diet resulted in a higher fasting total triacylglycerol concentration compared to D diet ($P = 0.009$). Postprandial samples were taken at two different occasions (i) at day 21, after breakfast and lunch and (ii) on the last day of the study 2, 4, 6, and 8 h after a fat load. Postprandial plasma triacylglycerol and chylomicron triacylglycerol showed higher peak values after D diet than M diet (interaction effect, diet × times $P < 0.05$). In conclusion, M diet did not lower LDL cholesterol compared to D diet. Thus any cholesterol-lowering effect of oleic and stearic acids may have been obscured by the high content of cholesterol-raising saturated fatty acids in milk fat. A higher content of the *trans* fatty acids in M diet might have counteracted the cholesterol neutral/decreasing effect and increased plasma triacylglycerol.
Lipids 33, 11–21 (1998).

Dairy products are important nutrient sources contributing protein of high quality, vitamins, calcium, and zinc. However, a high intake of milk fat is considered cholesterol-raising as it contains a large proportion of saturated fatty acids (SFA). Fats high in SFA raise the plasma cholesterol concentration, although the individual SFA do not contribute equally to this effect. Fatty acids with a chain length of 4 to 10 carbon atoms and stearic acid (18:0) previously have not been considered to affect cholesterol concentrations (1–5). Recent research has demonstrated a cholesterol-raising effect of 8:0 and 10:0 (6,7). SFA with 20 or more carbon atoms are poorly absorbed (6). In contrast, palmitic acid (16:0), myristic acid (14:0), and lauric acid (12:0) are considered cholesterol-raising (2–5, 8–10). Oleic acid is demonstrated to be either neutral or cholesterol-lowering (9,11,12).

Numerous studies have investigated the effect of extreme changes of fatty acid composition of the diet, whereas only a few studies have included realistic changes in fatty acid composition of the conventional diet. The purpose of the study was to monitor the effect on lipoproteins, fasting and postprandially in healthy young men, of a modified milk fat compared to a conventional milk fat.

It is well known that the fatty acid composition of milk fat can be markedly influenced by the diet, especially by the amount and fatty acids profile of the fat in the cow's diet (13,14). The milk fatty acid profile generally reflects a balance between fatty acids synthesized *de novo* in the mammary gland on the basis of acetic acid originating from ruminal fermentation and fatty acids fed in the diet for the cows and perhaps modified in the rumen by biohydrogenation. Despite this complexity, it recently has been shown that the fatty acid profile of milk fat with regard to the major fatty acids can be forecast with good precision on the basis of fatty acids in the cow's diet (15). In this study the modification of the milk fat was a partial substitution of palmitic acid (and to a smaller extent myristic acid) with oleic acid (and to a smaller extent stearic acid) by means of a realistic, cost neutral modification of the feed of the cows.

SUBJECTS AND METHODS

Eighteen young men were recruited for the study. Their ages ranged from 21 to 28 yr (mean 25 yr), body weights from 63 to 104 kg (mean 80 kg), and body mass index from 19 to 27

Abbreviations: apo, apoprotein; CE, cholesterol esters; CLA, conjugated linoleic acid; D diet, Danish milk fat; 20:3n-6, dihomo-γ-linolenic acid; 22:6n-3, docosahexaenoic acid; 22:5n-3, docosapentaenoic acid; E%, energy percentage; HDL, high density lipoprotein; 12:0, lauric acid; LDL, low density lipoprotein; M diet, modified milk fat; MUFA, monounsaturated fatty acids; 14:0, myristic acid; 16:0, palmitic acid; PL, phospholipid; PUFA, polyunsaturated fatty acids; SFA, saturated fatty acid; 18:0, stearic acid; TAG, triacylglycerol; 18:1n-7, vaccenic acid; VLDL, very low density lipoprotein.

kg m^{-2} (mean 24 kg m^{-2}). The subjects had no history of atherosclerotic disease, and all were apparently healthy as assessed by a medical questionnaire. They were all nonsmokers. None took medicine. Most subjects had a moderate physical activity level (training max. 1–2 h twice a week and/or daily biking to work). They continued with the same physical activity throughout the trial. The participant's habitual diet was assessed from a 7-d weighed food record. We calculated energy intake and dietary composition using a national database (National Food Agency, Dankost, Denmark). Habitual energy intake ranged from 9 to 19 MJ (mean 14 MJ) with 26–42% of energy (E) from fat (mean 32 E%), the ratio of polyunsaturated fatty acid (PUFA) to SFA was 0.2–0.8 (mean 0.4); intake of cholesterol was 175–665 mg/10 MJ (mean 371 mg/10 MJ), and dietary fiber intake ranged from 1.4 to 3.2 g/MJ (mean 2.4 g/MJ). Two different diets were served in randomized order for 4 wk each. The two intervention periods were separated by a 2-mon period on habitual diet.

Diets. We served a diet high in conventional Danish butter (D), which was high in palmitic and low in oleic acid, and a modified butter (M), which was low in palmitic and high in oleic acid (for details of the fatty acid composition of the test butters, see Table 1). The butter was manufactured using two different bulks of milk produced at the Danish Institute of Animal Science (Foulum, Denmark). Forty cows were given a basal diet *ad libitum* (mixture of beet roots, grass silage, crushed barley, and straw) and supplemented with two different concentrate mixtures. By use of prediction formulas of Hermansen (15), the two concentrate mixtures were composed in such a way that they were expected to result in either a normal milk fat composition or in a milk fat high in oleic acid. The normal concentrate mixtures consisted of 94% soybean meal and 6% saturated fats and were given in an amount of 4.7 kg/cow/day. The experimental concentrates consisted of 50% soybean meal and 50% crushed double-low rape seeds (low in glucosinates and erucic acid) given in an amount of 3.2 kg/cow/day. After 3 wk of normal concentrates feeding, the milk was collected for butter production for the D diet high in palmitic acid. Subsequently, the cows were given the experimental concentrate for a period of 7 wk, in which the milk was collected for butter production of the M diet high in oleic acid.

The fatty acid composition of each test fat was determined by gas–liquid chromatography (Table 1). The experimental diets contained 40 E% of fat (30 E% derived from butter and 6.5% from grapeseed oil. The remaining fat content of 3.5% was contributed by other food items, which were constant and identical in the two test diets. The analyzed dietary cholesterol and macronutrient content of the diet high in palmitic acid (D diet) and the diet high in oleic acid (M diet) are shown in Table 2.

The experimental meals consisted of natural and common food items that were prepared and cooked in customary ways. The two kinds of test butter were served as spread and incorporated in bread, rolls, and cakes. On day 21 of the dietary periods, the effect of two consecutive realistic meals, breakfast and lunch with mean 25 g milk fat in each meal, including ingredients as just described, was investigated in the 18 subjects.

TABLE 1
Fatty Acid Composition of the Two Test Milk Fats

	% Fatty acid of total fatty acids	
Fatty acids	Modified milk fat (M)	Danish milk fat (D)
4:0	3.46	3.83
6:0	1.88	2.34
8:0	1.08	1.40
10:0	2.30	3.14
10:1	0.22	0.37
12:0	2.86	4.09
14:0	10.67	12.07
14:1	1.83	1.81
15:0[a]	1.01	1.45
16:0[a]	21.13	36.82

17:0[a]	0.89	1.17
17:1	0.24	0.31
18:0	10.88	7.23
18:1 *trans*	6.4	1.1
18:1n-9	24.95	15.33
18:1n-7	1.40	0.55
18:2n-6	1.93	1.61
20:0	0.22	0.14
18:3n-3	0.50	0.42
Conj. 18:2[b]	1.57	0.52

[a]16:0, 15:0, and 17:0 also include the branched isoforms typical for milk fat.
[b]Conjugated 18:2 also included 0.20–0.25% 20:0.

Dinner dishes, in which grapeseed oil was included, consisted of cooked vegetables and lean meat with pasta, rice, or mashed potatoes. Rolls, marmalade, orange juice, and tea or coffee were served for breakfast. Lunch was a cold meal consisting of lean roast beef or fish paté, salad dressing without fat. Fruit juice, fresh fruit, cakes, and candy were served as snacks.

Meal tests. On day 21 of the dietary periods the effect of two consecutive meals of the test diet, breakfast and lunch with mean 25 g milk fat in each meal, was investigated in the 18 subjects.

On the last day of the dietary periods, effect of a single high-fat meal, the butter load, was investigated in eight subjects. The meal consisted of butter, rolls, and cake with butter incorporated, orange juice, and marmalade. The fat intake of each test meal was fixed to 1.2 g milk fat/kg body weight, 55% of the energy contribution was derived from fat, 41% from carbohydrates, and 4% from protein. The energy content of the test meal ranged from 5.7 to 8.7 MJ (mean 6.7 MJ), and the content of fat in each test meal ranged from 83 to 126 g (mean 98 g).

Energy intake was individualized according to the food records of the subjects. To avoid bias from underreporting, the calculated energy intake from the records was compared with the estimated energy requirements for the subjects' basal metabolic rate according to body weight, sex, age, and level of physical activity (16). The experimental diet was com-

[a]Analyzed values are means of two duplicate portions. Diet D, high in palmitic acid; Diet M, high in oleic acid collected in two different periods. Variations between periods were negligible. There was good agreement between analyzed and calculated values (data not shown). See Table 1 for abbreviations.

posed to reflect the higher of the two energy-intake scores whenever the two were not identical.

Duplicate portions of each test diet were collected during 1 wk in each period of the study. For each test diet, portions were pooled per diet and analyzed by the National Food Agency of Denmark (Table 2). Analyzed energy content and nutritional composition of the diets were in good agreement with calculated values (data not shown). The analyses showed a general tendency to a lower fatty acid content in the experimental diets than calculated from the fatty acid composition in the test butters. Lower values in fatty acid content in mixed diets are a common finding of The National Food Agency of Denmark. This is probably due to a lower fatty acid content in some fats [like phospholipids (PL)] than in triacylglycerol (TAG), degradation of fat, and loss during handling and storage (T. Leth, The National Food Agency of Denmark, personal oral communication). This is obviously due to degradation and loss during handling and storage. All foods were prepared and weighed in individual servings in the experimental kitchen of the Department of Human Nutrition of the Royal Veterinary and Agricultural University (Frederiksberg, Denmark). Lunch was served on weekdays at the Department. All other dishes were provided daily as a package with instructions for its preparation. Meals for the weekend were provided on Fridays. Body weight without heavy clothing was recorded before lunch three times a week. Physical activity was restricted, and daily records of tea and coffee intake, physical activity, illness, and deviation from the protocol were monitored as described earlier (5,15). The subjects were highly motivated.

Blood analysis. Fasting samples: Morning blood samples were taken before each of the two study periods (two samples before the first and one sample before the second dietary period) and on day 21, 26, and 28 of each dietary period. Sampling was performed after at least 12 h of fasting and after 15 min of supine rest. Postprandial samples were taken on two different occasions in the study periods: (i) on day 21, at 3 h after breakfast and 3 h after lunch; (ii) on the last day of the dietary period (day 28) 2, 4, 6, and 8 h after a high butter load (1.2 g milk fat/kg body weight) of the test fats. The subjects refrained from heavy physical activity or alcohol intake for at least 24 h before the sampling. The plasma concentration of C-reactive protein was assessed to rule out infectious diseases of the subjects at the time of blood collection. Values were in the normal range (<5 mg/L) except for one subject. Data from this occasion were excluded from analysis of plasma lipids and lipoproteins. Blood for lipid and lipoprotein analysis was collected in tubes containing EDTA, which were immediately placed on ice and centrifuged at $3000 \times g$ for 15 min at 4°C. Plasma for apolipoprotein and fatty acid analysis was stored at −80°C. Plasma for lipoprotein analysis was stored at 4°C and analyzed within 48 h. Chylomicrons, very low density lipoprotein (VLDL) + chylomicron remnants, and low density lipoprotein (LDL) + high density lipoprotein (HDL) fractions were separated by ultracentrifugation. Chylomicrons were isolated by carefully overlayering 3 mL of plasma with 2.5 mL of salt solution of density 1.006 kg/L. The ultracentrifuge tubes (13 × 64 mm; Polyallomer Bell-Top Quick-Seal Centrifuge Tubes; Beckman Instruments, Palo Alto, CA) were centrifuged for 23 min at 20°C at $100,000 \times g$ in an ultracentrifuge (L7-55; Beckman Instruments) using a fixed-angle rotor (r = 96.1 mm) (50.4 Ti; Beckman Instruments). The tubes were sliced 45 mm from the bottom, and the top fraction ($S_f > 400$) was transferred and adjusted to a total volume of 5 mL with saline (17). The bottom fraction $S_f < 400$ was transferred to another UC tube, adjusted to 5.5 mL with saline of density 1.006 kg/L, and centrifuged for 16 h at 4°C at $105,000 \times g$. After tube slicing 30 mm from the bottom, the top fraction containing VLDL and chylomicron remnants and the bottom fraction containing LDL + HDL were transferred to separate tubes and adjusted to a final volume of 5 mL.

Cholesterol and TAG concentrations were assessed by enzymatic procedures (Boehringer Mannheim GmbH, Mannheim, Germany) on a Cobas Mira analyzer (Roche, Basel,

Switzerland). Total HDL and HDL_3 cholesterol concentrations were measured enzymatically after precipitation with polyethylene glycol (Quantolip; Immuno AG, Vienna, Austria) (16). HDL_2 was calculated by subtracting HDL_3 cholesterol from the total HDL cholesterol. LDL cholesterol was calculated from the difference of cholesterol in the infranatant and HDL cholesterol. The concentrations of plasma apolipoproteins (apo) B and A-1 were determined by immunoturbidimetry in a Monarch apparatus (Instrumentation Laboratories, Lexington, MA) using monospecific polyclonal antibodies against apo B and A-1 (kits from Orion Diagnostica, Espoo, Finland). Precision was determined by the analysis of internal plasma pool which gave run-to-run coefficient of variation percentages: TAG 1.75%, total cholesterol 1.6%, HDL cholesterol 3.61%, HDL_3 cholesterol 6.83%, apo A-1 1.46%, and apo B 3.11%. Accuracy was checked using a control serum of certified value (Quantolip control serum) (Immuno AG, Vienna, Austria) (18).

Fatty acid pattern in cholesterol esters (CE) and PL was determined at the end of each period. The plasma lipids were extracted into chloroform/methanol (1:1, vol/vol), and the PL and CE were separated by thin-layer chromatography on precoated silica gel 60 plates (Merck, Darmstadt, Germany) with hexane, diethyl ether, and acetic acid (80:20:1, by vol) as the mobile phase. Methyl esters were prepared by transmethylation catalyzed by BF_3 (19). The fatty acid composition was determined by GC using an HP5880A instrument (Hewlett-Packard, Palo Alto, CA) with split injection and a 30 m × 0.32 mm fused silica column with a 0.2 µm film of SP2380 (Supelco Inc., Bellefonte, PA). The oven was programmed to increase the temperature at a rate of 2°C/min from 140 to 160°C and after 2 min to 200°C at 3°C/min. The fatty acids were identified by comparing retention times with standards of fatty methyl esters.

Ethics. The protocol and the aim of the study were fully explained to the subjects, who gave their written consent. The research protocol was approved by the Scientific Ethics Committee of the municipalities of Copenhagen and Frederiksberg (01-487/93).

Statistical analysis. Because there were no significant differences in blood lipids and lipoproteins between the three samplings (day 21, 26, and 28) from each experimental period, a mean value was calculated and used in the statistical analysis. A paired *t*-test was used for fasting blood lipid values to compare the effect of the two diets. Owing to differences in VLDL cholesterol in habitual values before the two study periods, a paired *t*-test comparing differences between habitual and experimental values was done. To analyze postprandial data, repeated measures of analysis of variance (SPSS Inc., Chicago, IL) with Huynh-Feldt adjustment of degrees of freedom were used to assess effect of time, difference in effect of the experimental fats, and interaction between effects of time and type of fat during the 0 to 8 h period of the day. If a significant interaction between effects of time and type of fat is found, it means that the mean difference between the two fats varies with time. The graphs of the time course will illustrate how the means differ. In the case of a significant interaction, the tests for type of fat and time effects are not meaningful, and therefore not reported. If, however, there is no significant interaction, it means that the two time courses can be regarded as parallel, and the effects of time and type of fat can be tested separately.

RESULTS

Effect of experimental diet after 4 wk (fasting samples) follows: The body weights of the volunteers did not differ significantly at the end of the two experimental periods; the body weight was 79.5 ± 2.5 kg (mean ± SEM) on the D diet, 79.4 ± 2.5 kg on the M diet. The fasting mean plasma concentrations of total cholesterol, LDL cholesterol, HDL cholesterol, HDL_2-, HDL_3- cholesterol, VLDL cholesterol, ratio LDL/HDL cholesterol, TAG, and the plasma concentrations of apo A-1, and apo B, and ratio apo A-1 to HDL cholesterol and ratio apo B to LDL cholesterol for the two diets are given in Table 3.

Diet M compared with diet D resulted in 14% (0.14 mmol/L) higher plasma TAG ($P < 0.008$). No significant difference was observed between diet D and M for plasma total cholesterol, LDL, HDL, HDL_2, HDL_3, LDL/HDL cholesterol ratio, VLDL cholesterol, and apo A-1, apo B concentrations. There was no significant difference between the ratios apo A-1 to HDL cholesterol or ratio apo B to LDL cholesterol after the test diets, indicating that the size of the HDL and LDL particles did not differ after the two milk test fats.

[a]M = diet with milk fat high in oleic acid.; D = diet with milk fat high in palmitic acid; apo, apoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein; VLDL, very low density lipoprotein.
[b]Mean of three samplings, two before the first period and one before the second period.
[c]Mean of three samplings (except for one case, samples on one occasion, from one person were excluded).
[d]Mean of three samplings.
[e]Plasma lipids and lipoproteins are mmol/L.
[f]x ± SEM, significantly different from habitual diet $P < 0.05$.
[g]x ± SEM, significantly different from D diet $P < 0.05$.

Diet M compared with habitual diet resulted in 5% (0.23 mmol/L) higher total cholesterol ($P = 0.006$) and a 17% higher VLDL cholesterol concentration ($P = 0.014$). No other significant differences were observed.

Diet D compared with habitual diet (mean of three determinations) resulted in 7% (0.30 mmol/L) higher total cholesterol ($P = 0.009$) and 8% higher LDL cholesterol concentration ($P < 0.035$); a corresponding lower ratio apo A-1 to HDL cholesterol ($P < 0.029$) and a lower ratio apo B to LDL cholesterol ($P < 0.002$) were observed after D diet, indicating a larger size of the HDL and LDL particles. No other significant differences were observed.

The blood lipid levels on habitual diet before the two dietary periods (means of one and two samplings, irrespectively) did not differ with exception of VLDL cholesterol ($P = 0.007$), which was 36% (0.09 mmol/L) lower. However, no carry-over effect was observed on habitual samples collected prior to the second period.

The fatty acid composition of plasma CE and PL in the end of the test periods is presented in Table 4. In CE diet M resulted in a 59% higher content of 18:1,*trans* ($P = 0.039$) and a tendency to a higher content of 18:1n-7 ($P = 0.05$) than diet D. In CE there were no significant differences in 16:0, 18:0, 18:2, or the major fatty acid 18:1n-9 comprising about 56% after both diets. Conjugated 18:2n-6 was not incorporated in CE and PL. In PL an 11% lower concentration of the minor SFA with 15 carbon atoms and a higher 22:6n-3 after the M diet compared with D diet ($P < 0.05$) were found. The major fatty acids were 16:0 (about 25%) and 18:2 (about 20%) and there were moderate amounts of 18:0 (15–19%), 18:1, and 20:4 (9–10%). In contrast to the CE, other PUFA, dihomo-γ-linolenic acid (20:3n-6), docosapentaenoic acid (22:5n-3), and docosahexaenoic acid (22:6n-3) were also present in the PL fraction. The PUFA comprised totally about 50%, corresponding to the occupancy of the *sn*-2 position in the PL molecule.

Postprandial lipemia 3 h after breakfast and 3 h after lunch. Intake of breakfast and lunch with realistic amounts of butter (mean 25 g milk fat in each meal) resulted in an increase in total plasma TAG and chylomicron-TAG after 6 h (Fig. 1A,B) after both D or M diets. From 0 to 6 h there was an increase in VLDL–TAG ($P < 0.001$) and in LDL–TAG ($P < 0.005$), and a slight decrease in LDL cholesterol and HDL_3 cholesterol ($P = 0.03$) (Fig. 1C–F). According to the repeated-measures analysis of variance, there was a difference in effect of the test butters over time on plasma total TAG concentration and chylomicron TAG (interaction effect) ($P < 0.05$). From Figure 1A and B it appears that M diet caused a higher plasma total TAG and chylomicron TAG concentration than the D diet in the mean level.

Postprandial lipemia after fat load. The butter load either from D or M diet gave a rise in total plasma TAG and chylomicron and VLDL, LDL, HDL TAG, with the highest measured value 4 h after the load except for LDL TAG, which showed a somewhat different pattern (Fig. 2A–E). VLDL cholesterol increased up to 4 h and fell to lower concentra-

[a]M = diet with milk fat high in oleic acid; D = diet with milk fat high in palmitic acid. [a]Significantly different from D diet $P < 0.05$.

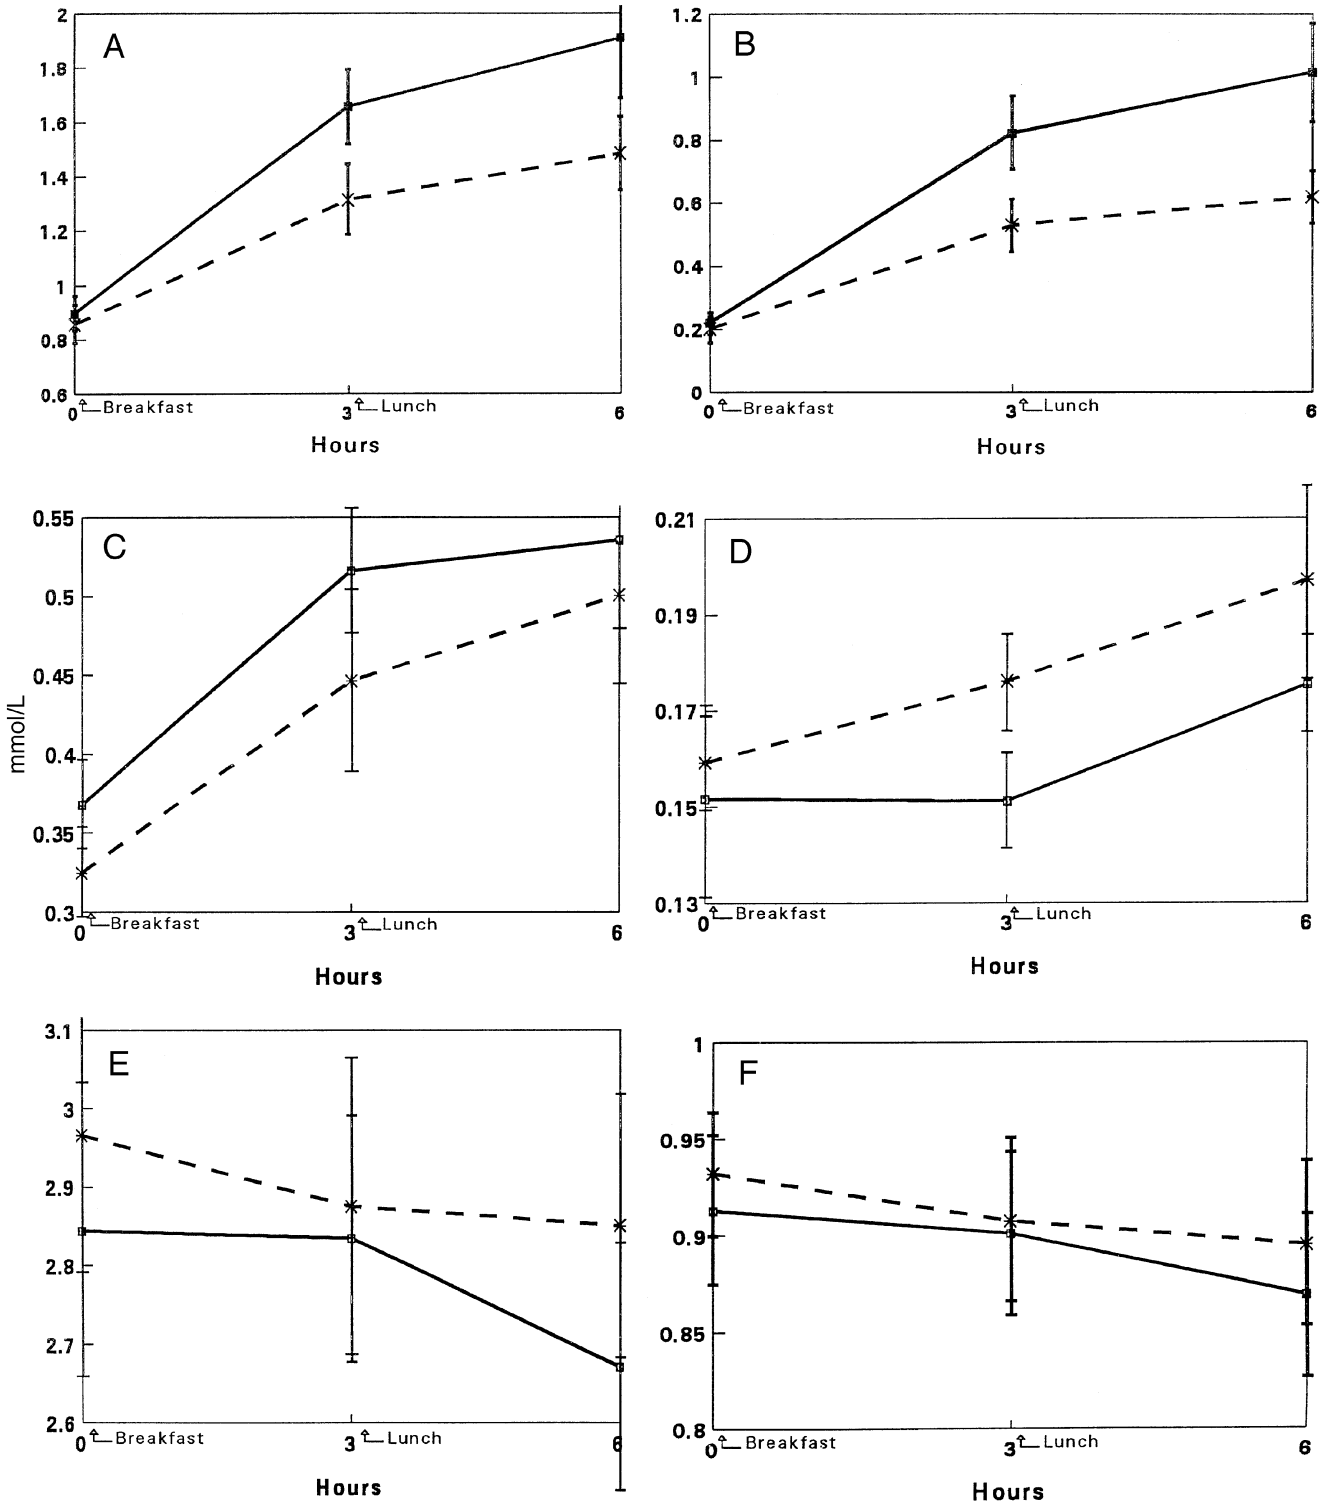

FIG. 1. Entry values before and changes after intake of breakfast and lunch, both meals each containing realistic amounts of milk fat (mean 25 g milk fat) in each meal. M diet contained modified milk fat (solid lines and squares) and D diet (dashed lines and crosses) contained Danish milk fat. Samplings at hours 0 are fasting values; other values are postprandial. Values are means ± SEM and $n = 18$. For details of fatty acid composition of the test fats, see Table 1. A, total (TAG); B, chylomicron TAG; C, very low density lipoprotein (VLDL)–TAG; D, low density lipoprotein (LDL)–TAG; E, LDL cholesterol; F, high density lipoprotein (HDL_2) cholesterol.

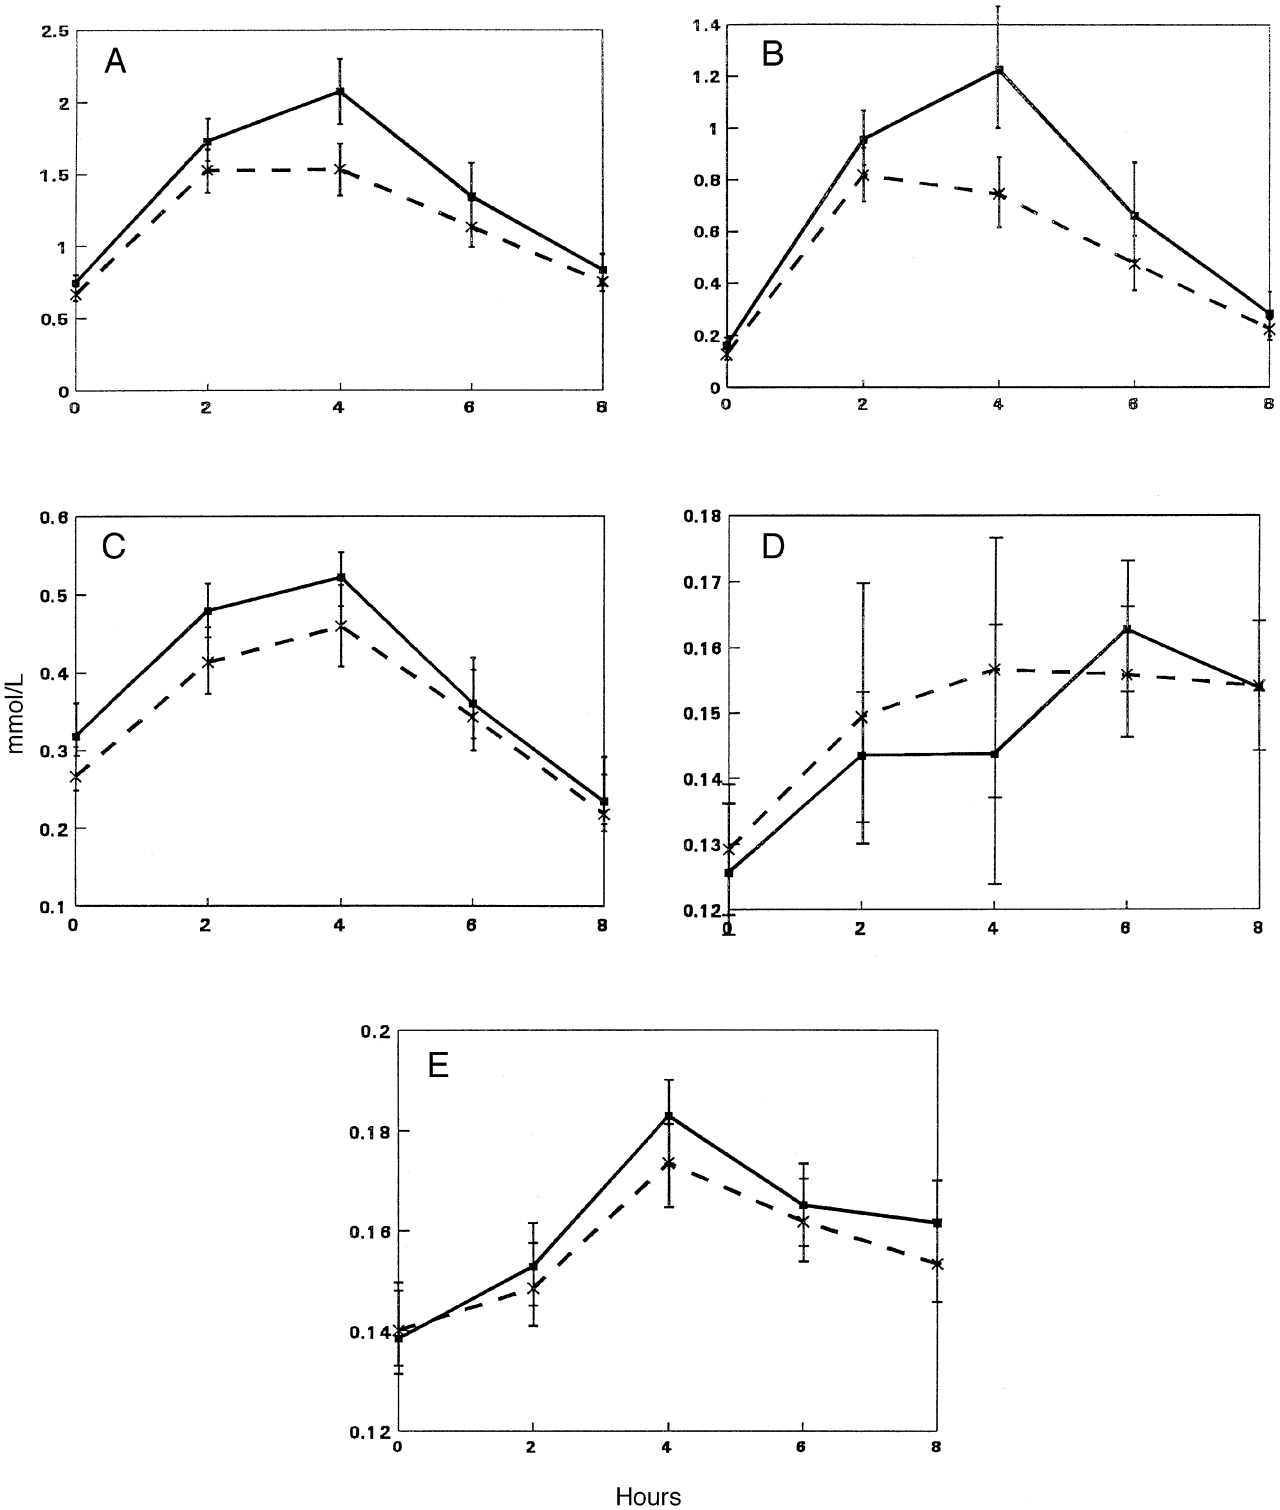

FIG. 2. Entry values before a high fat load (1.2 g/milk fat/kg body weight) and changes after intake of M diet (solid lines and squares) and D diet (dashed lines and crosses). Samplings at hours 0 are fasting values; other values are postprandial. Values are means ± SEM and $n = 8$. For details of fatty acid composition of the test butters, see Table 1. See Figure 1 for abbreviations. A, total TAG; B, chylomicron TAG; C, VLDL–TAG; D, LDL–TAG; E, HDL–TAG.

tions than fasting values in 8 h ($P < 0.001$) (Fig. 3A). LDL, HDL, and HDL_3 cholesterol concentrations decreased with the lowest value measured at 4 h and increased thereafter (Fig. 3B–D). According to the repeated measures analysis of variance, there was a difference in effect of the test butters over time on plasma total TAG concentration and chylomicron TAG (interaction effect) ($P < 0.005$). From Figure 2A and B it appears that M diet resulted in higher values of

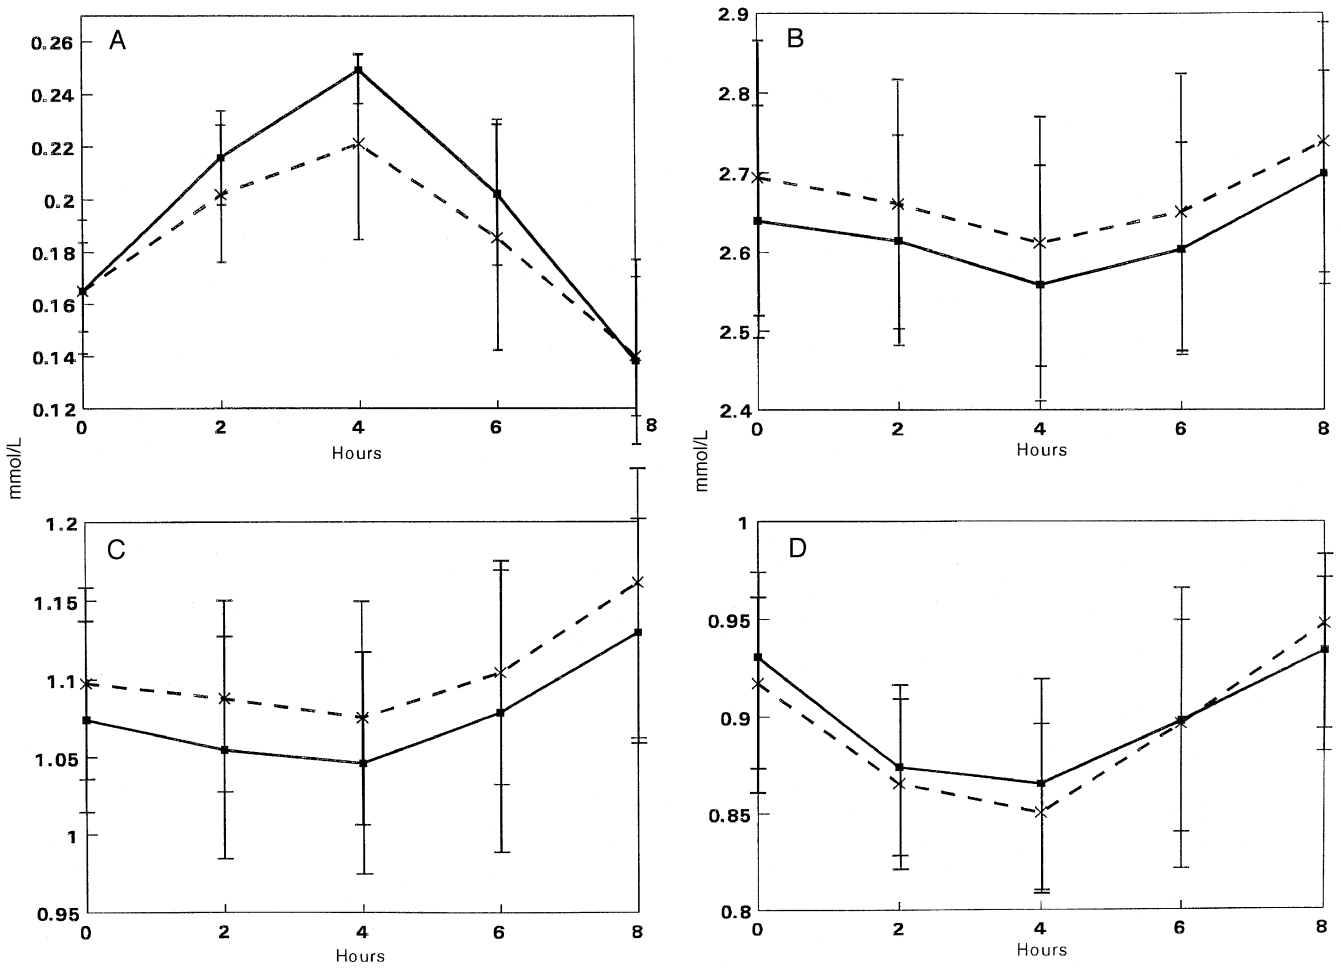

FIG. 3. Entry values before a high fat load (1.2 g/milk fat/kg body weight) and changes after intake of M diet (solid lines and squares) and D diet (dashed lines and crosses). Samplings at hours 0 are fasting values; other values are postprandial. Values are means ± SEM and $n = 8$. For details of fatty acid composition of the test butters, see Table 1. See Figure 1 for abbreviations. A, VLDL cholesterol; B, LDL cholesterol; C, HDL cholesterol; D, HDL_3 cholesterol.

plasma total TAG concentration and chylomicron TAG than D diet after 4 h.

A comparison of the plasma TAG elevating effect after 6 h after the butter load (1.2 g milk fat/kg body weight) with the effect of two meals with normal amounts of butter did not show any significant differences.

There was a positive significant relation between initial TAG levels and postprandial response after 6 h at the two meals' monitoring and after 4 h after the fat load indicated by positive regression coefficient [$\beta = 1.6$ ($P < 0.007$) and $\beta = 4.3$ ($P < 0.02$), respectively].

DISCUSSION

This study was designed specifically to compare the effect of a milk fat with a modified fatty acid composition (higher content of oleic and stearic acids and lower content of the cholesterol-raising SFA, especially palmitic acid) with conventional Danish milk fat on postprandial and fasting plasma lipids and lipoproteins in young healthy men. The change in fatty acid composition in the modified milk fat was obtained by natural feeding procedures, and the conventional Danish milk fat had a fatty acid composition typical for the winter period.

Contrary to our expectations, the results indicate that M diet high in oleic acid, enriched in stearic acid, and low in palmitic acid, and D diet high in palmitic and low in oleic acid had a similar effect on total cholesterol, LDL cholesterol, and apo B concentrations.

Nutritionally a decrease in the cholesterolemic SFA (C12–C16) and an increase in monounsaturated oleic acid and eventually stearic acid are assumed desirable (4,5,20). In our study the fatty acid composition in M butter had a 1.5-fold lower content of C12–C16 (from 53 to 35 wt%), a 5% higher 18:1n-7*trans,* and a 1.6-fold higher content of C18 + C18:1n-9 (from 23 to 36 wt%) compared to normal Danish butter (D butter). According to Keys' equation (21), the expected change in total plasma cholesterol when changing from diet D to diet M was −0.35 mmol/L (the energy from *trans* fatty acid was not included in equation owing to lack of

knowledge on effect of vaccenic acid, the *trans* fatty acid formed in the rumen). However, a relevant statement reported by Kris-Etherton's group is that when C_{12}-C_{16} SFA are high, the cholesterol-lowering effect of monounsaturated fatty acid (MUFA) is obscured (12). In this way there may be a threshold value for the ratio between cholesterolemic and beneficial fatty acid which has to be passed to obtain reduction in plasma total cholesterol. This might have been the case in other studies in which a substitution of cholesterolemic SFA with oleic acid did not result in a decrease in LDL cholesterol (22,23). In addition, a dietary fatty acid threshold has been suggested by K.C. Hayes *et al.* (24), who stated that sensitivity of plasma cholesterol to palmitic acid is based on the dietary C18:2, or C14, i.e., the 18:2/14:0 ratio.

Interestingly, a lowering of plasma lipids by modified milk fats (protected unsaturated fatty acids were fed to the cows) was demonstrated by an Australian group (25). Although the relative percentage modification was rather similar in the Australian study compared to our study, the absolute oleic acid and linoleic acid were higher and palmitic acid lower in the Australian study than in our study (25). In this way the relative lower SFA may be one of the reasons why the effect of oleic acid was successfully "expressed" in the above-mentioned study.

An additional explanation of the finding that M diet did not decrease LDL cholesterol compared with D diet may be the increased content of *trans* fatty acids, mainly vaccenic acid (18:1n-7) in M diet. This increase was a side effect of the cow-feed manipulation. It has been reported that elaidic acid, (18:1 *trans* n-9), a *trans* fatty acid formed mainly in partial hydrogenation of vegetable oils, is cholesterolemic (26–28). However, the effect of the *trans* fatty acids formed in rumen, mainly vaccenic acid (18:1 *trans* n-7) on lipoproteins, is to our knowledge not examined in experimental studies.

A side effect of the cow-feed manipulation was an increased content of conjugated linoleic acid (CLA). The effects of CLA on blood lipids have not been studied specifically. CLA possess apparent anticarcinogenic and antioxidant properties (29). Although M diet resulted in significantly higher CLA postprandially in total TAG than D diet (data not shown), the CLA were not found in the CE and PL fraction. This is unexpected as CLA are reported to be readily incorporated in PL (29).

The M diet resulted in higher, fasting total TAG concentration compared with D diet. A TAG-raising effect of beef tallow compared to olive oil on fasting plasma TAG has been demonstrated in men (30). Beef tallow has a similar content of oleic and *trans* fatty acids as M butter in this study. Oleic acid, however, has not been shown to increase fasting plasma TAG. The content of *trans* FA was 5.3% higher in the milk fat in M compared to D. For this reason it may be suggested that the increase in *trans* fatty acids may have resulted in the higher plasma TAG after M diet which agrees with observations by others (27,28,31,32). Although the increase in plasma TAG does not exceed the range for normal concentration in plasma, a TAG-increasing effect of dietary fat might be critical in risk groups in regard to coronary heart disease (33,34).

A higher postprandial response in total and chylomicron TAG was observed after M than D diet. It has been suggested that unsaturated fatty acids generally appear to produce a greater postprandial TAG response than do saturated fats (35). This observation agrees with unpublished results by us and others. However, reports on postprandial lipemea are not consistent (36–38). Dietary intake prior to the postprandial monitoring (37,39), amount (40), absorption time (41), and physical properties of test fat may play a role (36). Finally interaction processes may take place. Although a higher postprandial TAG response associated with reduced clearance is found in coronary heart disease patients compared to healthy people, a relatively high response may not be considered unbeneficial *per se*.

Comparing the two different postprandial experiments, the massive butter load and the two consecutive meals with butter in more realistic amounts, there was overall the same tendency in the effect on blood lipid parameters. The fat load but not the two meal events increased total HDL TAG and decreased total HDL cholesterol (HDL_3 significantly, and HDL_2 borderline significantly). We speculate if this may be due to a higher cholesteryl ester transfer protein activity during high butter load in comparison to intake of normal amounts of butter.

Postprandial fatty acid composition of plasma TAG after a butter load resembled as expected the fatty acid composition of test fats (data not shown). Except for a higher increase in 18:1 *trans* after the M diet, fatty acid composition of plasma CE did not reflect the difference in fatty acid composition of the test diets. We suggest that the equal proportion of palmitic acid in CE in spite of the different proportion in the test butters may be due to a higher rate of endogenous synthesis of palmitic as suggested previously by us (42) and by others (43). The rather equal proportion of oleic acid in CE may be due to elongation and desaturation of palmitic acid to oleic acid. Although there was a high content of 18:2n-6 in CE after both diets, conjugated 18:2n-6 was not found in CE or PL fraction. The somewhat higher content of C_{15} in D diet was reflected in the PL.

In regard to feeding strategy the increased content of *trans* fatty acids in the modified milk, a side effect of the cow-feed manipulation, could have counteracted the cholesterol-decreasing effect of MUFA. Thus to optimize milk fat in a nutritional way, a different feeding regime has to be used. In this experiment we fed the cows rapeseed oil rich in unsaturated fatty acids for the production of modified butter. Obviously the ability of the cow to completely hydrogenate these fatty acids in the rumen was exceeded. We hypothesize that a reduction of SFA without an increase in *trans* fatty acids could have been obtained if we had fed the cows stearic acid instead of rapeseed oil or rapeseed oil in the form of calcium soaps. These possibilities should be examined further.

In conclusion, a diet containing milk fat in which part of the cholesterol-raising SFA was substituted by MUFA and stearic acid did not lower total plasma cholesterol and LDL

cholesterol compared to typical Danish milk fat. The modified milk fat had an increasing effect on mean postprandial and fasting plasma TAG concentration. One possible reason that modified milk fat did not lower cholesterol compared to Danish milk fat may be that the decreasing effect of MUFA was obscured by the relatively high content of SFA in milk fat. The increase in fasting plasma TAG after modified milk fat might well be explained by the increase of *trans* fatty acids. Additional studies will be necessary to clarify effects of *trans* fatty acids, especially vaccenic acid, on lipemia and lipoproteins.

ACKNOWLEDGMENTS

We thank Aarhus Oliefabrik A/S, Oils and Fats Division, R&D, Denmark, for assistance with advice, analysis, and delivery of test fats. We are also very grateful to our dietitian Hanne Jensen and to Ingerlise Grönfeldt and the other staff of the metabolic kitchen. We thank Pia Lund, M.Sc. for the GC analysis and our technicians, and especially Kirsten Ebbesen and Klara Jörgensen for their conscientious and excellent work. Supported by grant JD-93 S 2464 Å9300085, The Danish Dairy Research Foundation and the Danish Research Development Program for Food Technology (FØTEK).

Regulation of Very Low Density Lipoprotein Apo B Metabolism by Dietary Fat Saturation and Chain Length in the Guinea Pig

Ghada Abdel-Fattah[1], Maria Luz Fernandez*, and Donald J. McNamara[2]

Department of Nutritional Sciences and Interdisciplinary Nutritional Sciences Program, University of Arizona, Tucson, Arizona 85721

ABSTRACT: Studies investigated the effects of dietary fatty acid composition and saturation on the regulation of very low density lipoprotein (VLDL) apo B flux, clearance, and conversion to low density lipoprotein (LDL) in guinea pigs fed semipurified diets containing 15% (w/w) corn oil (CO), lard (LA), or palm kernel oil (PK). Plasma cholesterol levels were highest with dietary PK (3.1 ± 1.0 mmol/L) followed by LA (2.4 ± 0.4 mmol/L) and CO (1.6 ± 0.4 mmol/L) intake. VLDL particles were larger ($P < 0.05$) in the LA (78 ± 7 nm) and PK (69 ± 10 nm) groups compared to animals fed CO (49 ± 5 nm). VLDL-apo B fractional catabolic rates (FCR) were highest in guinea pigs fed the LA diet ($P < 0.05$) and VLDL apo B flux, estimated from VLDL ^{125}I-apo B turnover kinetics, were higher in LA compared to PK or CO fed guinea pigs. In the case of PK consumption, the kinetic estimates of VLDL apo B flux significantly underestimated rates compared to direct VLDL apo B secretion measurements and LDL turnover analyses. These data demonstrate that differences in the composition and amount of saturated fatty acids have differential effects on VLDL apo B flux, catabolism, and conversion to LDL which, together with changes in LDL receptor-mediated catabolism, determine plasma LDL cholesterol levels in guinea pigs. The data also indicate that kinetic analysis of VLDL metabolism in PK fed animals is inaccurate possibly due to the presence of a small, nonequilibrating pool of newly synthesized VLDL which is rapidly converted to LDL.

Lipids 33, 23–31 (1998)

Very low density lipoprotein (VLDL) particles are secreted by the liver and function primarily in the transport of endogenous triacylglycerol (TAG). Elevated VLDL concentrations lead to hypertriglyceridemia and, in addition, VLDL is the precursor of low density lipoprotein (LDL), which is the major carrier of plasma cholesterol. Both hypertriglyceridemia and hypercholesterolemia are major risk factors for cardiovascular disease (1,2).

Numerous epidemiological studies suggest that dietary fat saturation modulates hepatic cholesterol metabolism and plasma lipoprotein concentrations, which in turn modify an individual's cardiovascular disease risk profile. There is a well-documented association between the intake of saturated fat (SFA) in the diet, elevated plasma LDL cholesterol levels, and increased risk of cardiovascular disease (3,4).

Metabolic studies have shown that the type of dietary fat has significant effects on LDL synthesis and intravascular remodeling as well as apo B/E (LDL) receptor-mediated catabolism (3). Decreased hepatic apo B/E receptor activity with intake of SFA, as compared to polyunsaturated fatty acids (PUFA), has been reported in guinea pigs (5–7), as well as other animal models (8,9). Furthermore, intake of diets containing palm kernel oil (PK) as the source of fat leads to increased LDL flux compared to intake of PUFA corn oil (CO) (5,6). This increased LDL flux mediated by SFA could be due to increased VLDL production, increased rates of VLDL conversion to LDL, or both. The only reported human study ($n = 4$) suggests that dietary SFA increases VLDL apo B flux as well as LDL production, but has a minimal effect on VLDL and LDL catabolism (10). In contrast, animal studies have shown that in gerbils (11) and in squirrel and cebus monkeys (12) SFA decreases VLDL–TAG secretion compared to intake of PUFA, and Groot *et al.* (13) reported no significant differences in VLDL–TAG secretion in rats fed palm oil vs. sunflower oil.

In a study using rhesus monkeys, an attempt was made to better define the specific effects of different polyunsaturated/saturated (P/S) ratios on lipoprotein metabolism (14). The authors found that monkeys fed the diet with the lower P/S ratio exhibited a significant increase in the VLDL-independent transport of LDL apo B compared to those fed the higher P/S ratio indicating the complexity of fatty acid composition in regulating LDL apo B transport (14).

Studies in guinea pigs demonstrated that the composition and amount of SFA alter the rates of hepatic VLDL–TAG and apo B secretion in the guinea pig by different mechanisms (15).

Abbreviations: CO, corn oil; FCR, fractional catabolic rate; LA, lard; LDL, low density lipoprotein; PK, palm kernel oil; P/S, polyunsaturated/saturated; PUFA, polyunsaturated fatty acids; RID, radial immunodiffusion; SFA, saturated fat; TAG, triacylglycerol; VLDL, very low density lipoprotein.

Intake of lard (LA) (rich in long-chain SFA) increased hepatic VLDL–TAG secretion rates, whereas PK in the diet (rich in short-chain SFA and higher concentrations of SFA) increased nascent VLDL apo B production, suggesting increased number of VLDL particles being secreted by the liver (15).

Since the majority of LDL apo B in normal humans is derived from VLDL (16), it is expected that SFA will affect VLDL metabolism. It has been shown that the mass of VLDL converted to LDL vs. the amount of VLDL cleared directly from the plasma compartment varies among normal and hypertriglyceridemic individuals (17). It also has been shown that the presence of apo E in the VLDL affects the rate of VLDL removal in rabbits (18). Based on these reports on the factors that influence VLDL channeling (14–18), the present studies were undertaken to further define the role of dietary SFA on the synthesis, intravascular remodeling, and catabolism of VLDL by using an animal model, the guinea pig, that, similar to humans, transports the majority of cholesterol in LDL (5,6).

The objectives were to determine whether the observed changes in plasma LDL cholesterol concentrations and flux (5,6) with intake of SFA are due to increased VLDL production and increased fractional conversion of VLDL to LDL, and to investigate how changes in VLDL metabolic channeling determine plasma LDL cholesterol concentrations.

MATERIALS AND METHODS

Materials. Agarose was from Gibco-BLR (Grand Island, NY). Agarose immunodiffusion tablets were purchased from Sigma Chemical (St. Louis, MO). LDL–Direct column chromatography was obtained from Isolab (Akron, OH). Radial immunodiffusion kit was from Bio-Rad (Richmond, CA). Rapid Silver Staining electrophoresis kit and cyanogen bromide activated sepharose were purchased from Sigma Chemical.

Diets. Diets were prepared and pelleted by Research Diets, Inc. (New Brunswick, NJ). All diets were isocaloric (15.9 Kj/g) and contained identical compositions except for the fat type. Fat content was 15% (w/w) as either CO, LA, or PK. The fatty acid compositions of the experimental diets were determined by gas chromatography (Table 1). The diets were formulated to meet Nutrition Research Center-specified nutritional requirements of guinea pigs (5). Plant sterols (0.9 mg sitosterol/g diet) and cholesterol (0.1 mg/g diet) content were normalized for all diets (5,6).

Animals. Male Hartley guinea pigs from Sasco Sprague-Dawley (Omaha, NE) weighing between 450–500 g were randomly assigned to one of the three diet groups for 4 wk prior to *in vivo* VLDL kinetic studies or isolation of plasma for electron microscopic studies. Previous studies have shown that this time period is sufficient to attain constant plasma cholesterol levels and a metabolic steady state. All animals consumed equal amounts of the diets, and there were no differences between growth rates or final body weights (Table 2). All animal procedures were conducted in accordance with U.S. Public Health Service and U.S. Department of Agriculture guidelines, and experimental protocols were approved by the University of Arizona Institutional Animal Care and Use Committee.

Electron microscopy. Four animals per dietary group were fasted overnight and used to isolate plasma VLDL for measurements of VLDL particle size. Plasma VLDL was isolated by ultracentrifugation at a density of 1.006 g/mL, and washed once at that density. Centrifugation was performed in a Ti-50.2 rotor (Beckman Instruments, Palo Alto, CA) for 24 h at 40,000 × *g* at 15°C. Freshly prepared VLDL was used 1–2 d after preparation to avoid deterioration of the intact particles and aggregate formation. Prior to microscopic examination, samples were dialyzed against a volatile buffer (0.125 M ammonium acetate, 2.6 mM ammonium carbonates, and 0.26 mM EDTA, pH 7.4) (19). VLDL particles were observed by negative stain electron microscopy with 2% sodium phosphotungstate, filtered through 0.45-mm filter, and adjusted to pH 7.0–7.5. Transmission electron microscope was used (Jeol 100-CX TEM, Tokyo, Japan) with a condenser aperture of 200 mm and accelerating voltage of 80 kV. Negative staining of the lipoprotein was done on formol-coated copper mesh grids (200 mesh). Images were taken at 20,000 × (20), and random photographs within the same grid squares and random grid squares were taken. At least one hundred particle diameters were examined from the negatives of the photographs, and the size of the VLDL particles was measured by a ruler under magnifying lens and normalized to the magnification factor of the electron microscope. The distribution of VLDL particle sizes, as well as the mean diameters, were calculated for all three dietary fat groups.

Preparation and purification of polyclonal antibodies against apo B-100. Guinea pig LDL was isolated by sequen-

Characteristics of Guinea Pigs Fed Test diets[a]

Diet (*n*)	Body weight (g)	Growth (g/d)	Plasma lipids (mmol/L)	
			Triacylglycerol	Cholesterol
CO (12)	741 ± 159	9 ± 2	1.12 ± 0.37	1.62 ± 0.44[a]
LA (12)	754 ± 169	9 ± 2	1.29 ± 0.49	2.41 ± 0.64[b]
PK (14)	733 ± 220	10 ± 2	1.12 ± 0.54	3.12 ± 1.0[c]

[a]Data are presented as the mean ± SD for *n* (number in parentheses) animals fed CO, LA, or PK. See Table 1 for abbreviations. [b]Values in the same column with different superscripts are significantly different ($P < 0.01$) as determined by analysis of variance and the Student-Newman-Keuls Multiple comparisons tests.

tial ultracentrifugation within a 1.023–1.075 g/mL density range. LDL was collected following tube slicing, washed once at d = 1.075 g/mL, dialyzed against 0.9% NaCl- 0.01% EDTA buffer, and purified by agarose-heparin column chromatography. The purity of LDL was checked by denaturing polyacrylamide gel electrophoresis (21). Purified LDL (antigen) was concentrated to 1 mg/mL apo B-100 protein. The recipient sheep was immunized subcutaneously with the antigen (300 mg in complete Freund's adjuvant) in one dose, followed by two booster doses (200 mg in incomplete Freund's adjuvant) every 10 d. After each injection blood samples were taken to check production of apo B antibodies using radial immunodiffusion kits (RID; Biorad). Four weeks after the initial injection, the animal was bled to collect 1 L of blood. The blood was allowed to clot at room temperature and the serum kept frozen at −20°C.

To prepare sheep antiguinea pig apo B-100 antibody, serum from immunized sheep was passed through a guinea pig LDL-sepharose column. The anti-apo B 100 antibodies, which were bound to the matrix after washing with 0.1 M phosphate buffered saline, pH 7.4 were eluted by lowering the pH to 3 using elution buffer (0.2 M glycine/HCL, pH 3) (22).

Apo B quantification by radial immunodiffusion (RID). Lipoprotein apo B mass values were determined by RID. Affinity purified sheep antiguinea pig antibody was incorporated in 1% Agarose at 50°C and cast as an open gel on an Agarose (0.2%) precoated glass plate (100 × 100 mm). Each gel contained approximately 250 mg of affinity column purified antibody for the RID assay. The polymerized gels were cured on ice, and 50 µL sample wells were created with a 4-mm gel punch. Calibrator apo were purified by affinity chromatography from ultracentifugally isolated guinea pig LDL, and the apo concentrations were determined by a modified Lowry procedure (23). The apoprotein calibrators and samples were diluted with phosphate buffered saline, loaded into the wells, and incubated in a humidified 37°C chamber for 24–72 h, depending on the sample concentrations and the lipoprotein fraction. Nonspecific proteins were removed by overlaying the gel with 1-cm stack of filter paper and a glass plate and applying pressure for 1 h. Gels were washed overnight with buffer using gentle agitation at room temperature, pressed, and rewashed with 5% glycerol, rinsed, and dried under a forced beam of warm air and stained with either Coommassie blue or silver nitrate (silver-enhanced RID) (24). Diameters of the immunoprecipitate rings were measured using an RID reader (Bio-Rad). Linear regression equations were generated for the standard calibrator curve with X as the concentration of standards (µg/mL) and Y the diameter squared of the precipitation rings (mm^2). Linear regression correlations were used to calculate apo B concentrations (µg/mL).

In vivo *VLDL kinetics.* Guinea pig plasma VLDL was isolated from animals fasted for 12 h by ultracentrifugation at density 1.006 g/mL, dialyzed against 0.9% NaCl-0.01% EDTA for 24 h, and concentrated to 0.5 mg/mL protein. VLDL iodination was carried out according to the methods of Goldstein *et al.* (25). ^{125}I-VLDL was used within 2 d after iodination of lipoproteins to minimize possible radiation oxidation (26). Guinea pigs were fasting 12 h before surgery and during the first 10 h of the study to avoid interference of intestinal chylomicrons with isolated VLDL. Measurements of VLDL-associated radioactivity indicated that only 3–5% of the radioactivity was accounted for by free iodine, while 95–97% was bound to the VLDL particle as determined by trichloroacetic acid precipitation. The percentage of labeled TAG and phospholipids ranged between 15–24% among the VLDL particles isolated from guinea pigs fed the autologous diet. Approximately 30–33% of the ^{125}I radioactivity was associated with apo B-100, and 45–55% of the radioactivity was associated with non-apo B-100 apo consistent with other reports (27). Animals were injected with labeled VLDL (35 µg) through an indwelling catheter inserted in the internal carotid artery, and blood samples were collected for the analysis of plasma VLDL and LDL specific radioactivities. Approximately 1 mL of blood was collected at 3 (zero time), 10, 20, and 40 min and at 1, 3, 6, 10, 22, and 27 h. Plasma was separated by low-speed centrifugation, VLDL and LDL isolated by ultracentrifugation, and an aliquot of isolated VLDL and LDL used to measure apo B mass by RID and radioactivity following isopropanol precipitation (28). Aliquots (170 µL) of VLDL or LDL and unlabeled LDL carrier (30 µL) were precipitated with an equal volume of 100% isopropanol (200 µL) and were incubated overnight at 4°C. Samples were centrifuged for 30 min at 1000 × g, and radioactivity in the apo B pellet was measured in a gamma counter. Apo B mass of VLDL and LDL was measured by RID as described above.

Model selection and kinetic analysis. The selected model for plasma VLDL turnover was the two pool model as described by Matthews (29). We used this model because the two-pool model is routinely used for analysis of plasma lipoprotein turnover studies in small laboratory animals (5,30,31).

VLDL apo B specific radioactivity was determined as cpm per µg apo B protein, and plasma VLDL apo B specific activity decay curves were resolved into two exponential functions. VLDL apo B fractional catabolic rate (FCR) values were measured using a curve-fitting program (JANA, SCI Software, Lexington, KY), which indicated that the data were best fit with a two-pool model. Apo B VLDL pool size was determined by multiplying VLDL apo B (mg/mL), calculated by RID, × plasma volume per unit of weight (mL/kg). Plasma volume is equivalent to 4% total body weight in guinea pigs (32).

The area under the plasma VLDL apo B specific radioactivity vs. time curve was calculated using the linear trapezoidal rule method (33). When the time interval between 2 points was long (e.g., from 10 to 22 h), the logarithmic trapezoidal rule was used (33). Total apo B specific radioactivity was calculated by the summation of all the measured individual areas under the specific radioactivity curves.

VLDL apo B production rates were calculated by two different methods. In one method, the production rate (µg/kg·h) was calculated as a function of VLDL apoB FCR (h^{-1}) × VLDL apo B pool size (µg/kg), and the second method VLDL apo B production rates were calculated by dividing the

total dose of injected radioactivity (cpm) by the area under the plasma VLDL apo B specific activity time curve (cpm/μg per h) and adjusting the value per kg body weight (34).

Statistics. Data are presented as mean ± SD. One-way analysis of variance was used to assess differences in plasma cholesterol, TAG, and apo B concentrations among diet groups; and between VLDL apo B FCR and production rates. Differences among mean values were evaluated by student-Newman-Keuls Multiple Comparison Tests and were considered significant at $P < 0.05$. Statistical analysis of the kinetic model was best fitted using a two-pool model (JANA). Linear regression analysis was used to determine correlation coefficients between variables.

RESULTS

Dietary fat effects on plasma lipids and growth rates. There were no significant differences in the final body weights of guinea pigs fed the experimental diets (Table 2). Guinea pigs fed the three test diets had similar growth rates, indicating equal dietary intakes among groups. There were significant differences in plasma cholesterol levels with animals fed the PK diet having the highest levels followed by animals fed the LA diet, and the lowest plasma total cholesterol concentrations occurred in animals fed the CO-based diet (Table 2). No differences were observed for plasma TAG concentrations among dietary treatments.

VLDL particle size. The size distribution of VLDL particles (Fig. 1) differed for VLDL isolated from the guinea pigs fed the three types of dietary fat. VLDL particles isolated from animals fed the CO diet had a smaller average diameter (49 ± 5 nm) compared to VLDL from LA (78 ± 7 nm) or PK fed guinea pigs (69 ± 10 nm) (Fig. 1) ($P < 0.05$). In addition, the frequency distribution of particles from CO-fed animals was shifted toward a smaller size and skewed to the left. In contrast, VLDL isolated from animals fed the PK- and LA-based diets were more heterogeneous.

In vivo *VLDL apo B-100 kinetics.* Analysis of VLDL apo B decay curves (Fig. 2) indicates that the turnover kinetics could be resolved into biexponential curves. Plasma ^{125}I-VLDL exhibited a significantly faster turnover rate with LA intake, followed by the PK and CO diet groups (Fig. 2). The metabolic parameters for guinea pig VLDL kinetics are summarized in Table 3**.** LA intake resulted in a faster VLDL apo B FCR compared to animals fed CO- and PK-based diets. VLDL apo B pool sizes and flux calculated by multiplying FCR × pool size were not statistically different among groups (Table 3).

A positive correlation was found between the mean VLDL apo B FCR and the mean VLDL particle size for the three diet groups ($r = 0.99$, $P < 0.05$) (Fig. 3), suggesting that the larger VLDL particles are more rapidly removed from the plasma VLDL lipoprotein density range compared to smaller particles.

There was a positive correlation ($r = 0.73$, $P < 0.002$) between VLDL apo B flux and VLDL apo B pool size (Fig. 4) for animals from all dietary fat groups. Comparable values were obtained for VLDL apo B flux determined by multiplying FCR × pool size (Table 3), and VLDL flux determined by dividing the total injected VLDL apo B radioactivity by the area under the curve (±10%). Values were 1.03 ± 0.40, 2.28 ± 0.93, and 0.88 ± 0.41 mg/kg–h for animals fed CO, LA, and PK, respectively.

VLDL–LDL precursor–product relationships. In addition to analysis of plasma VLDL turnover using a two-pool model, the turnover curves were analyzed to determine VLDL–LDL precursor–product relationships by analysis of the areas under the respective specific activity decay curves. Examination of the precursor–product relationship between plasma VLDL

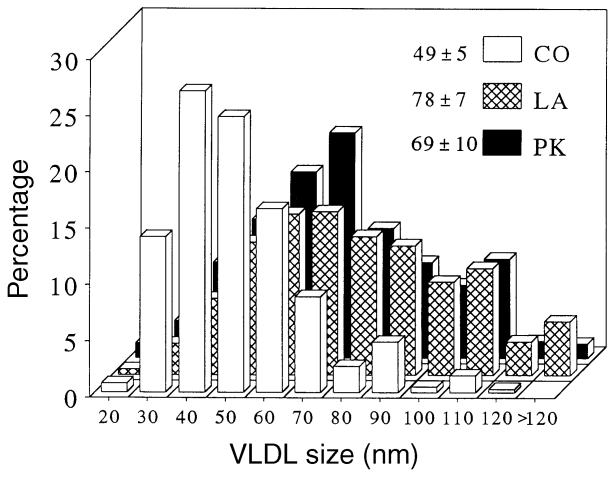

FIG. 1. Very low density lipoprotein (VLDL) particle size distribution of guinea pigs fed semipurified diets containing 15% (w/w) corn oil (CO: 49 ± 5 nm), lard (LA: 78 ± 7 nm), or palm kernel oil (PK: 69 ± 10 nm). Values represent percentage distribution of at least 100 particles counted directly from the negative of electron microscopic images of isolated mature VLDL particles (CO < LA = PK, $P < 0.05$).

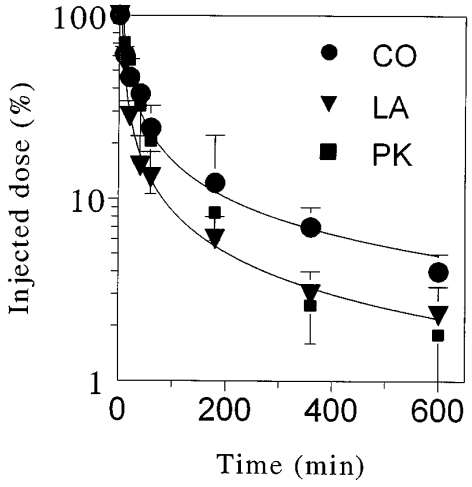

FIG. 2. Plasma disappearance curves of homologous VLDL isolated from guinea pigs fed semipurified diets containing 15% (w/w) CO, LA, or PK injected into animals fed the same diets. The values represent the mean of VLDL apoprotein (apo) B specific activity presented as percentage of injected dose for $n = 5$ determinations for animals fed CO and PK and $n = 4$ for LA fed guinea pigs. See Figure 1 for abbreviations.

TABLE 3
Metabolic Parameters of ^{125}I-VLDL Turnover Kinetics (two-pool analysis) in Guinea Pigs Fed Diets Containing 15% CO, LA, or PK Diets (for 4 wk)[a]

	VLDL kinetic parameters		
Diet (*n*)	FCR (pools/h)	Pool size (mg/kg)	Flux (mg/kg-h)[b]
CO (5)	0.65 ± 0.08[a]	2.11 ± 0.86	1.39 ± 0.67
LA (4)	1.22 ± 0.37[a]	1.91 ± 0.98	2.26 ± 1.33
PK (5)	0.98 ± 0.02[b]	1.09 ± 0.39	1.11 ± 0.50

[a]Data are presented as the mean ± SD for (*n*) animals. Values in the same column with different superscripts are significantly different ($P < 0.01$) as determined by analysis of variance and the Student-Newman-Keuls Multiple comparisons test

[b]Very low density lipoprotein (VLDL) apoprotein (apo) B flux calculated as VLDL apo B fractional catabolic rate (FCR) × VLDL apo B pool size. See Table 1 for other abbreviations.

and LDL–apo B specific radioactivity (Fig. 5) indicated that plasma LDL apo B specific activity reached its peak value at the intersect with the VLDL specific activity curve, consistent with LDL apo B being derived from VLDL apo B (35).

VLDL apo B secretion rates calculated from studies using guinea pigs fed the same diets and treated with Triton WR 1339 (18) were compared to VLDL apo B flux determined by ^{125}I-apo B turnover to determine whether there were significant differences between methods (Table 4). Animals from the CO and LA groups had similar values for apo B VLDL flux calculated from either method while the values for animals from the PK group were significantly lower when flux was calculated from the VLDL apo B turnover data (Table 4). These results suggest that apo B flux calculated from turnover studies is underestimated in animals fed PK diet, and this underestimation could be due to the presence of a rapid turnover pool of VLDL, which cannot be detected by use of isotopes as discussed below.

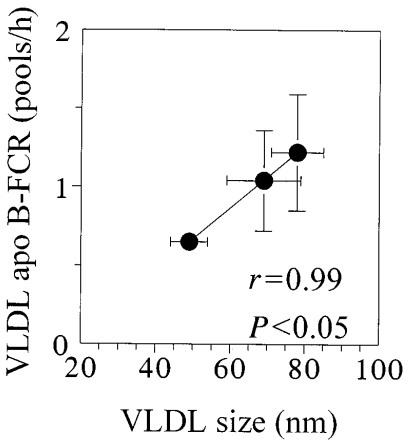

FIG. 3. Correlation between mean VLDL particles size and mean VLDL apo B fractional catabolic rate (FCR) values for guinea pigs fed semipurified diets containing 15% (w/w) CO, LA, or PK ($r = 0.99$, $P < 0.05$). See Figure 1 for other abbreviations.

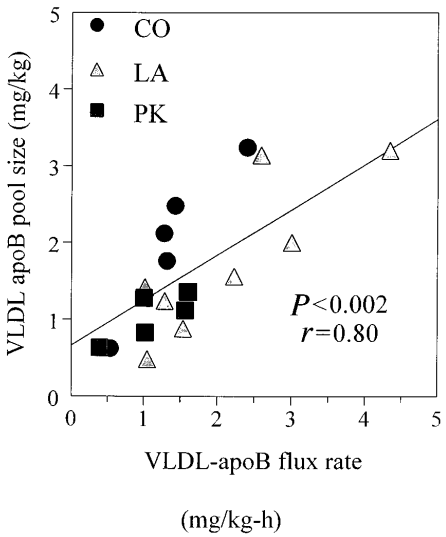

FIG. 4. Correlation between VLDL apo B flux rates (mg/kg·h) and VLDL apo B pool size (mg/kg) for guinea pigs fed semipurified diets containing 15% (w/w) CO (●), LA (▲), or PK (■) ($r = 0.80$, $P < 0.002$). See Figure 1 for abbreviations. See Figure 1 for abbreviations.

DISCUSSION

The present study tested two SFA with different SFA concentration and different proportions of fatty acid chain length: LA, rich in palmitic and stearic acids; and PK, rich in lauric and myristic acids, and compared their effects on VLDL metabolism to intake of polyunsaturated CO, rich in linoleic acid. The objective of this study was to determine the effects of fats varying in fatty acid composition and SFA amount on VLDL synthesis, intravascular remodeling, and catabolism.

Dietary fat saturation effects on plasma lipids and VLDL size. The results indicate that intake of PK and LA diets resulted in significantly higher plasma cholesterol levels compared to a CO-based diet. Plasma cholesterol levels decreased as the proportion of short-chain fatty acids decreased and the proportion of PUFA increased, similar to reports in humans (4) and in guinea pigs (5,6). In the guinea pig these effects are specific to plasma LDL with no significant effects on plasma HDL cholesterol concentrations (7).

Previous studies have shown that intake of SFA alters LDL composition and peak density resulting in larger particles compared to LDL isolated from animals fed CO (5,7). These changes in LDL composition with changes in dietary fat saturation are similar to the dietary fat-induced changes in VLDL, the precursor of LDL, observed in this study. Electron microscopic measurements demonstrated that intake of SFA resulted in larger VLDL particles. In addition, the particles were more heterogeneous as indicated by the frequency distribution. It has been reported that larger (65 ± 20 nm) VLDL particles are generated with a lipid-rich diet (15% CO, 1.6% cholesterol) in guinea pigs (36). VLDL can exist as a multidisperse population with particles size ranging between 30 and 80 nm (37), and heterogeneity of VLDL metabolism is thought to be affected by differences in VLDL particle size. These reports are consistent with the present observation of

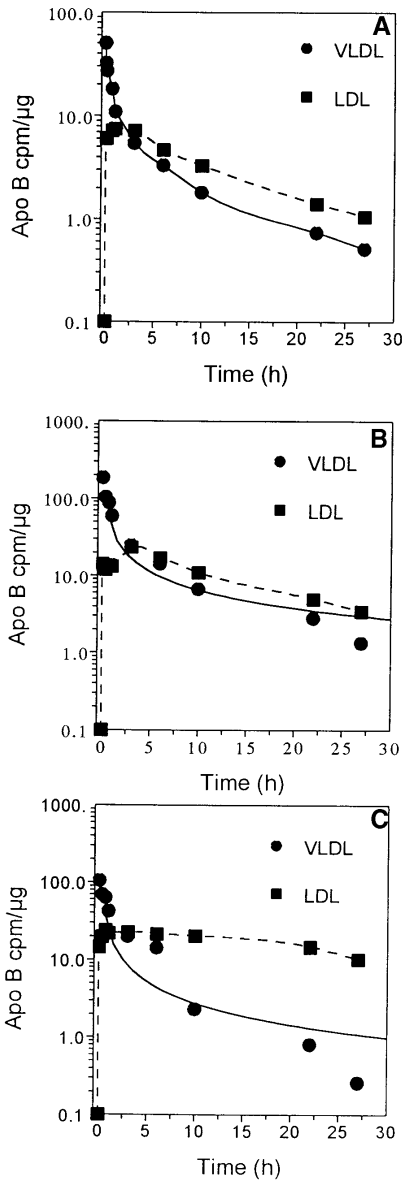

FIG. 5. A representative curve for the precursor–product relationships between VLDL and LDL as determined from VLDL apo and LDL apo B specific activity time course for animals fed CO (A), LA (B), or PK (C). See Figures 1 and 2 for abbreviations.

variability in VLDL particle size and indicate that variations in fat quantity as well as dietary fatty acid composition lead to significant changes in the size distribution of VLDL particles. These findings suggest that changes in fatty acid composition related to chain length and unsaturation can significantly affect the interactions of VLDL with the various enzymes involved in the delipidation of VLDL and on the intrinsic metabolic properties of these particles.

In addition, VLDL particle size has a significant effect on the metabolic fate of VLDL (35). Shames and Havel (38) employed the concept of kinetic heterogeneity to account for the fact that in some *in vivo* kinetic measurements of exogenously labeled VLDL kinetics the data are interpreted as indicating direct hepatic LDL secretion which can be due to rapidly metabolized nonequilibrated pools of VLDL subpopulations. As discussed below, data from the present study suggest that such heterogeneity due to differential effects of saturated fatty acids affects these kinetic determinants.

TABLE 4
Comparison of VLDL Flux Determined from VLDL Apo B secretion Measurements and from ^{125}I-VLDL Turnover Kinetics of Guinea Pigs Fed Diets Containing CO, LA, or PK Diets[a]

Diet	VLDL apo B secretion (mg/kg·h)[b]	VLDL ^{125}I-apo B flux (mg/kg·h)[c]
CO	1.14 ± 0.63[b] (15)	1.21 ± 0.54 (5)
LA	1.53 ± 0.83[b] (12)	2.27 ± 1.13 (4)
PK	3.11 ± 1.84[a] (12)	0.99 ± 0.46 (5)

[a]Data presented as mean ± SD for (*n*) animals per diet group. Values in the same column with different superscripts are significantly different as determined by analysis of variance and the Newman Keules *post hoc* test ($P < 0.01$).
[b]Data for VLDL apo B secretion rates in Triton WR 1339 treated guinea pigs fed the test diets have been previously reported (Ref. 15) and are presented here for comparative purposes only.
[c]Values for VLDL apo B flux are the average flux values calculated from the two-pool analyses and from the area under the specific activity curve analyses presented in Table 3. See Figures 1 and 3 for abbreviations.

Dietary fat saturation effects on in vivo *VLDL kinetics.* SFA of different chain length have differential effects on LDL metabolism (5–7), as well as on VLDL apo B synthesis and catabolism (9). The present study measured rates of VLDL production, catabolism, and intravascular conversion to LDL to determine effects of dietary fat chain length and saturation on plasma VLDL metabolism and intravascular remodeling. From our studies we concluded that, compared to the CO diet, intake of the LA diet increases VLDL apo B FCR. Increased direct hepatic removal of VLDL with intake of diets rich in 16:0 has been reported in rhesus monkeys (14). In our study, VLDL particle size was significantly correlated to VLDL apo B FCR, suggesting that the larger the VLDL particle, the shorter residence of the apo B in the VLDL density range: an observation previously noted for VLDL metabolism in guinea pigs treated with lovastatin (35).

Several investigators have suggested that dietary SFA have differential effects on VLDL–TAG secretion compared to VLDL apo B production, and we have previously shown that feeding LA increased VLDL–TAG secretion whereas intake of PK increased VLDL apo B secretion compared to CO intake (15). Grundy and Denke (3) suggested that the higher LDL apo B flux with intake of SFA could be due to increased VLDL apo B production, decreased VLDL catabolism, or increased conversion of VLDL to LDL due to decreased apo B/E receptor activity. Data from human studies suggest that SFA intake increases VLDL synthesis with little effect on VLDL apo B catabolism (10).

Human and animal studies have consistently demonstrated that dietary PUFA compared to SFA intake results in higher plasma LDL turnover (59,39); however, some discrepancies exist regarding the effects on LDL apo B flux (40). These studies suggest that intake of SFA decreases LDL catabolism but does not consistently increase LDL flux.

Studies in guinea pigs have shown that dietary SFA have

significant effects on LDL flux, composition, and catabolism (5,6). These data are consistent with the findings of the present study in that the calculated effects of PK intake on VLDL production were different from LA. PK intake did not increase the calculated VLDL production; however, the higher plasma LDL cholesterol levels suggest that there is an increased conversion to LDL in agreement with our previous data on the effects of PK on LDL flux (5,6). In contrast, LA intake led to a higher VLDL apo B flux and an apparently higher proportion of direct VLDL catabolism without conversion to LDL which explains the lower plasma LDL cholesterol concentrations in animals fed LA vs. PK diets.

LA feeding resulted in VLDL particles with faster FCR values than those VLDL isolated from CO- or PK-fed guinea pigs. It is possible that VLDL particles from LA-fed guinea pigs are enriched with apo E which has a greater affinity for cellular receptors (41), and thus the percentage of VLDL directly removed from the circulation is greater than the percentage converted to LDL. Apo E is necessary for TAG-rich lipoprotein receptor-mediated uptake and the LDL-receptor related protein binds apo E-enriched β-VLDL (42). These observations suggest that VLDL can be catabolized directly from the circulation through alternative routes, and are in agreement with the results from the present study in which a large proportion of VLDL secreted in response to LA feeding apparently was not converted to LDL but was rather removed from the circulation although LA intake reduces hepatic LDL receptors (5,7).

De novo *LDL production.* Analysis of VLDL conversion to LDL indicates that VLDL apo B flux in the PK group was less than LDL apo B flux, suggesting input of LDL apo B from a source not in equilibrium with the ^{125}I-VLDL apo B pool. There are two potential explanations to account for this observation. The first hypothesis is that there is direct *de novo* LDL secretion by the liver as proposed from some studies in animal models (14,43) as well as from lipoprotein kinetics studies in humans with familial hypertriglyceridemia (16). However, we have previously shown that there is no direct LDL secretion in guinea pigs fed the test diets used in this study (15). Interestingly, Goldberg *et al.* (44) reported that there was no direct LDL secretion in cynomolgus monkeys when the conversion of VLDL to LDL was blocked using lipoprotein lipase antibodies, even though these authors had previously suggested the existence of *de novo* LDL production in the same animal model based on *in vivo* VLDL turnover studies (45). In liver perfusion studies of cholesterol-fed guinea pigs, Guo and colleagues (46) found no evidence of direct LDL secretion, consistent with the results of our previous *in vivo* VLDL secretion studies (15). Shames and Havel (38) have suggested that the apparent dilution of plasma LDL apo B specific activity relative to VLDL apo B specific activity could be attributed to kinetic heterogeneity of VLDL apo B without the requirement of *de novo* LDL production. Based on the available evidence (15,38,46), there is no indication of direct LDL secretion by the liver in the guinea pigs.

The most likely explanation for the observation that LDL apo B flux is greater than VLDL apo B flux in guinea pigs fed the PK diet is the presence of a small pool of VLDL particles with a very rapid FCR that is not detected using the conventional isotope tracers, and consequently the production rate of VLDL apo B is underestimated (38). In normal and hyperlipidemic rabbits, Yamada *et al.* (18) reported that a large portion of VLDL particles were metabolized very rapidly and did not contribute to the measured VLDL mass which leads to underestimation of VLDL apo B flux. In agreement with this thesis, studies in humans have suggested that a portion of LDL is produced from a pool of VLDL which is very rapidly converted to LDL (47,48). These findings in part account for the fact that nascent VLDL apo B secretion was increased with PK feeding in the guinea pig (15), whereas in the present studies increased nascent VLDL apo B flux with intake of the PK diet was not detected with exogenously labeled VLDL. PK feeding may also be associated with the synthesis of TAG-poor VLDL particles which are preferentially converted to LDL and not directly removed from the liver. Oschry *et al.* (49) reported that large TAG-rich VLDL particles are removed by direct hepatic uptake, while smaller TAG-poor particles are converted to LDL. We have previously shown that hepatic nascent VLDL from animals fed PK diet had less TAG and more protein compared to nascent VLDL from the CO group (15), resulting in the formation of cholesterol-enriched mature VLDL particles which possibly are preferentially converted to LDL, leading to increased LDL production compared to animals fed CO- or LA- based diets. Interestingly, the relationship between VLDL apo B secretion rates, measured using Triton WR 1339 blockage, and VLDL apo B flux, measured using ^{125}I-VLDL, are comparable for CO- and LA-fed animals.

These and previously reported data demonstrate that intake of SFA increases VLDL flux relative to intake of PUFA; and that varying the amount and composition of SFA has differential effects on VLDL apo B and VLDL–TAG secretion. A higher amount of SFA with higher proportion of short-chain fatty acids (PK diet) increases hepatic VLDL apo B secretion and increases conversion of VLDL to LDL, resulting in elevated plasma LDL cholesterol concentrations. Compared to CO, intake of a higher proportion of long-chain SFA as in the case of LA was associated with an increase in VLDL flux and possibly an increase in VLDL direct removal with less transport to LDL; therefore, LA invoked a less-significant cholesterolemic effect compared to PK feeding. In either case, it is evident that effects of the amount of SFA and differences in the composition of fatty acids on plasma LDL cholesterol levels are in part due to effects on VLDL production, catabolism, and conversion to LDL. These modifications in VLDL metabolism together with changes in LDL receptor-mediated FCR (5–7) are major determinants of dietary fatty acid-mediated changes in plasma cholesterol levels in the guinea pigs.

ACKNOWLEDGMENTS

The authors would like to thank Stephanie Cameron for performing the animals' surgeries, Dr. Mark Wise and Anita Dunn for providing the sheep serum, and David Bentley for his assistance in the electron micro-

scopic facilities, Dr. Michael Mayerson for his helpful discussions and suggestions, and Henrik Steinberg for his excellent technical assistance.

Enhancement of Low Density Lipoprotein Binding to Both Low Density Lipoprotein Receptor-Positive and -Negative Cells by Tetracycline Antibiotics

Shinji Miura, Keiji Hasumi, Ritsuko Takayasu, Maki Sugimoto, and Akira Endo*

Department of Applied Biological Science, Tokyo Noko University, Tokyo 183, Japan

ABSTRACT: Some tetracycline (TC) antibiotics, including TC and anhydrotetracycline, have been found to enhance specific binding of low density lipoprotein (LDL) to both LDL receptor-positive and -negative cells at relatively higher concentrations. When incubated at 37°C, the ability of LDL receptor-negative human fibroblasts to bind ^{125}I-LDL was increased from <2 to 45 ng/mg by 170 μM TC. In normal human fibroblasts and Hep G2 cells, ^{125}I-LDL binding was elevated 1.4- to 2-fold by 113 μM TC. The ^{125}I-LDL binding in the presence of TC was diminished by both heparin and EDTA. The enhancement by TC was not observed when ^{125}I-LDL binding was assayed at 4°C. TC enhanced LDL binding to paraformaldehyde-fixed Hep G2 cells, excluding LDL receptor induction in the mechanism. These results demonstrated that TC enhanced cellular LDL binding through a process not involving functional LDL receptors.
Lipids 33, 33–38 (1998).

Extensive epidemiologic studies have shown that increased levels of plasma cholesterol are associated with an increased risk of cardiovascular diseases, especially coronary artery diseases (1,2). Most of the plasma cholesterol exists as lipoproteins, of which low density lipoprotein (LDL) predominates in humans. LDL supplies peripheral cells, as well as the liver, with cholesterol through its binding to specific receptors (LDL receptors) and subsequent internalization and lysosomal degradation (3,4). In experimental animals, approximately 70% of the total-body uptake of radiolabeled LDL takes place in the liver by the LDL receptor-dependent pathway (5,6). Pharmacologically, 3-hydroxy-3-methylglutaryl CoA reductase inhibitors raise the number of hepatic LDL receptors and lower plasma cholesterol levels (4,7–9).

The present study has been undertaken to find an agent that can enhance cellular LDL binding capacity. The searching from microbial culture extracts has led to the identification of some tetracycline (TC) antibiotics as active compounds. In this paper, we describe the effects of several TC antibiotics on the binding of LDL to cultured cells, including normal and LDL receptor-negative human skin fibroblasts.

Abbreviations: HDL, high density lipoprotein; KOK, receptor-negative form of familial hypercholesterolemia; LDL, low density lipoprotein; LPDS, lipoprotein-deficient serum; MN, internalization-defective form of familial hypercholesterolemia; TC, tetracycline.

MATERIALS AND METHODS

Materials. TC antibiotics except anhydrotetracycline and isotetracycline, which were chemically synthesized from TC, were obtained from Sigma (St. Louis, MO). Dimethylsulfoxide or methanol solutions of these agents were used for assays with solvent concentration of <1% (vol/vol). Human skin fibroblasts from a normal subject and from two patients with homozygous familial hypercholesterolemia (strains MN and KIK) were generous gifts from Drs. Akira Yamamoto and Yasuko Miyake, the National Cardiovascular Center, Japan. The strain MN is defective in the internalization of the surface-bound LDL (internalization-defective) (10–12), and the strain KIK produces neither functional nor immuno-detectable LDL receptors (LDL receptor-negative) (12). Hep G2 cells were obtained from the Riken Cell Bank, Tsukuba Science City, Japan. Macrophage J774 cells were provided by the Japanese Cancer Resources Bank (Tokyo, Japan). Human LDL and bovine lipoprotein-deficient serum (LPDS) were prepared by ultracentrifugation as described by Goldstein *et al.* (13). LDL was radioiodinated by the iodine monochloride method (13) to a specific activity of 200–500 cpm/ng protein. Oxidized LDL was prepared by incubating LDL with 5 μM $CuSO_4$ as described previously (14). The concentration of the lipoproteins is expressed in terms of protein.

Cell culture. Human fibroblasts were maintained in a humidified 5% CO_2 incubator at 37°C in dishes (90 mm) containing 6 mL medium A [Eagle's minimum essential medium containing 100 units/mL penicillin G, 100 μg/mL streptomycin, 1% (vol/vol) nonessential amino acids (Irvine Scientific, Santa Ana, CA)] supplemented with 10% (vol/vol) fetal bovine serum. Both Hep G2 cells and J774 macrophages were grown in medium B (Dulbecco's modified Eagle's medium containing 100 units/mL penicillin G and 100 μg/mL streptomycin) supplemented with 10% fetal bovine serum. For assays, human fibroblasts were seeded into six-well tissue culture plates at a density of 2×10^4 cells/well in 1.5 mL of antibiotic-free medium A (day 0). On days 3 and 5, medium was replaced with 1.5 mL of fresh medium A containing 10% fetal

bovine serum. On day 7, each monolayer was used for assay. Hep G2 cells were seeded into 24-well plates at a density of 3 $\times 10^5$ cells/well in 0.3 mL of antibiotic-free medium B supplemented with 10% fetal bovine serum. After growth for 24 h, the cells were used for assays. The macrophage J774 cells were seeded into 24-well plates at a density of 1.5×10^5 cells/well in 0.4 mL of medium B. The next day, medium was replaced with 0.3 mL of medium B containing 10% LPDS. After incubation for an additional 24 h, the cells were used for assays.

Surface binding, internalization, and degradation of ^{125}I-LDL at 37°C. Each monolayer of fibroblasts was rinsed with buffer A (137 mM NaCl, 2.7 mM KCl, and 7.9 mM sodium phosphate, pH 7.4), and then received 1 mL of medium A containing 10% LPDS and 10 μg/mL ^{125}I-LDL. After incubation at 37°C for 3 h, a portion of the medium was removed to determine trichloroacetic acid-soluble noniodide radioactivity (degraded ^{125}I-LDL). The remaining monolayer was sequentially washed as described by Goldstein *et al.* (13). Surface binding of ^{125}I-LDL was determined by incubating washed cells with 1 mL of 10 mg/mL heparin in 10 mM HEPES, pH 7.4, and 50 mM NaCl at 4°C for 60 min, followed by removing an aliquot of the buffer for counting. The remaining cells were dissolved in 1 mL of 0.2 M NaOH to determine internalized ^{125}I-LDL. In some experiments, washed cells were directly dissolved in 1 mL of 0.2 M NaOH for determination of cell-associated ^{125}I-LDL. To determine nonspecific binding, internalization, cell association and degradation, cells were incubated with ^{125}I-LDL in the presence of 400 μg/mL of unlabeled LDL. The specific values were calculated by subtracting the radioactivity obtained in the presence of excess unlabeled LDL from that obtained in its absence. Nonspecific values were usually <10% of total values. For determination using monolayers of Hep G2 cells which had been grown in 24-well plates, cells were incubated with 0.2 mL of medium B containing 10% LPDS and 10 μg/mL ^{125}I-LDL, and the volume of buffers used was reduced to 1/5.

Binding of ^{125}I-LDL to paraformaldehyde-fixed Hep G2 cells at 37°C. Each monolayer of Hep G2 cells grown in 24-well dishes was treated with 0.2 mL of 1.6% (wt/vol) paraformaldehyde in buffer A at 4°C for 45 min. This treatment renders cells unable to internalize surface-bound LDL at 37°C (15). After washing four times with 0.3 mL of 50 mM Tris-HCl, pH 7.4 containing 150 mM NaCl and 2 mg/mL bovine serum albumin, the fixed cells received 0.2 mL of medium B containing 10% LPDS and 10 μg/mL of ^{125}I-LDL. Cells were incubated at 37°C for 2 h, washed as described above, and then dissolved in 0.2 mL of 0.2 M NaOH. Nonspecific binding was determined in the presence of an excess of unlabeled LDL as described above.

Other methods. The incorporation of [^{14}C]oleate into cholesteryl esters and the binding of ^{125}I-LDL at 4°C were determined as described (13). Cell association and degradation of oxidized ^{125}I-LDL in macrophage J774 cells were determined as described previously (14). Protein was determined by the method of Lowry *et al.* (16) with bovine serum albumin as a standard. Antibacterial activity was determined turbidimetrically using *Staphylococcus aureus* IFO 12732 (17).

RESULTS

When normal human fibroblasts that had been grown in a medium containing fetal calf serum were incubated with ^{125}I-LDL at 37°C for 3 h, the cells specifically bound, internalized, and degraded 15, 130, and 164 ng of ^{125}I-LDL per mg cell protein, respectively. TC enhanced this activity 1.6- to 2.5-fold at a concentration of 113 μM (Fig. 1). Under these conditions, cholesteryl ester formation, as determined by

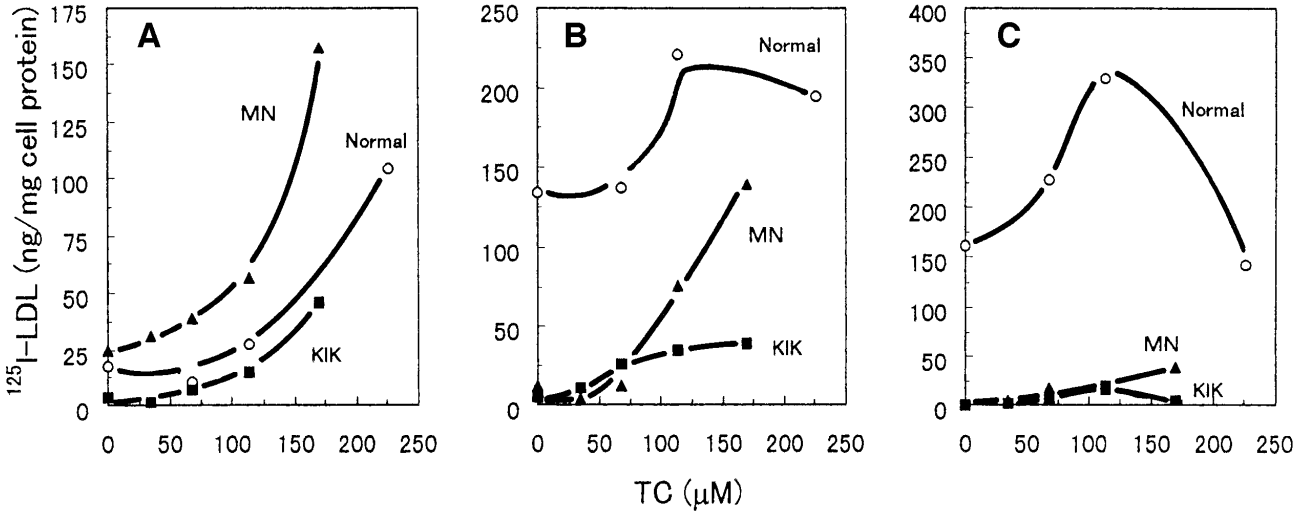

FIG. 1. Effects of tetracycline (TC) on the surface binding (A), intracellular accumulation (B), and degradation (C) of ^{125}I-low density lipoprotein (LDL) in three strains of human fibroblasts. Each monolayer of fibroblasts received ^{125}I-LDL (10 μg/mL) and the indicated concentrations of TC. After incubation at 37°C for 3 h, the amounts of ^{125}I-LDL specifically bound (A), internalized (B), and degraded (C) were determined. Fibroblasts used were from: ○, a normal subject; ▲, a patient with the internalization-defective form of familial hypercholesterolemia (MN); ■, a patient with the receptor-negative form of familial hypercholesterolemia (KIK). Each value represents the average of duplicate determinations.

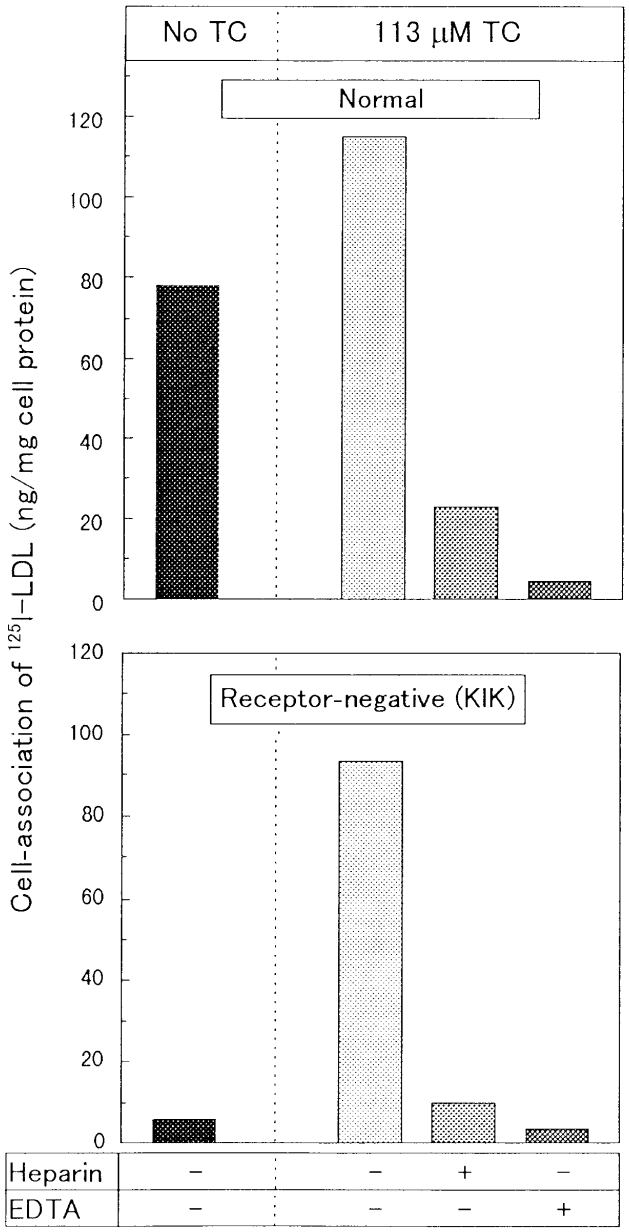

FIG. 2. Effects of heparin and EDTA on the cell association of ^{125}I-LDL in the presence of TC in normal and LDL receptor-negative fibroblasts. Each monolayer of fibroblasts received ^{125}I-LDL (10 μg/mL) and indicated concentrations of TC. After incubation at 37°C for 3 h in the absence or presence of heparin (10 mg/mL) or EDTA (5 mM), the amounts of ^{125}I-LDL specifically associated to the cells were determined. Each value represents the average of duplicate determinations. See Figure 1 for abbreviations.

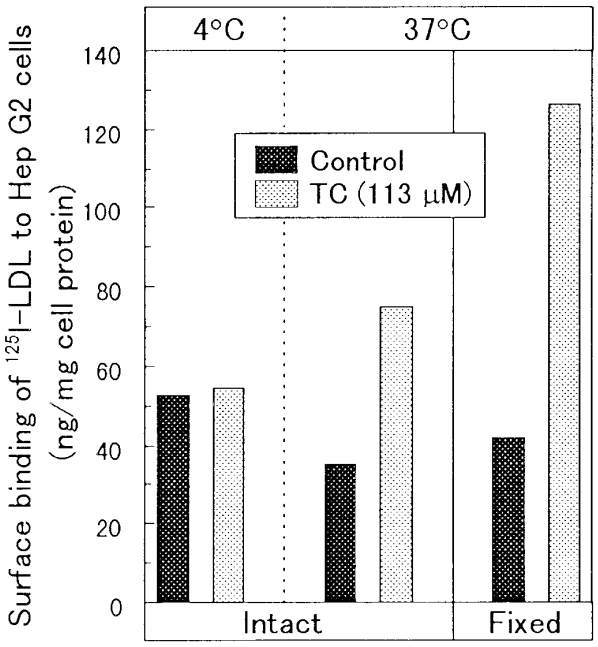

FIG 3. Effects of TC on the binding of ^{125}I-LDL to intact and paraformaldehyde-fixed Hep G2 cells at 4 and 37°C. Each monolayer of Hep G2 cells, either intact or fixed with paraformaldehyde, received ^{125}I-LDL (10 μg/mL) and the indicated concentrations of TC. After incubation at either 4 or 37°C for 2 h, the amounts of ^{125}I-LDL specifically bound were determined. Each value represents the average of duplicate determinations. See Figure 1 for abbreviations.

[^{14}C]oleate incorporation, was elevated 1.4-fold, from 0.261 to 0.369 nmol/3 h/mg cell protein. Similar elevation of ^{125}I-LDL binding was observed with Hep G2 cells (data not shown). TC also enhanced ^{125}I-LDL binding to two strains of mutant fibroblasts: one (MN) with a defect in the internalization of receptor-bound LDL and the other (KIK) producing neither functional nor immunodetectable LDL receptors (Fig. 1). ^{125}I-LDL binding to KIK fibroblasts was increased from <2 to 45 ng/mg cell protein by TC at a concentration of 170 μM. In both MN and KIK cells, the level internalization of ^{125}I-LDL was as low as the limit of detection, while in the presence of 113 μM TC the amounts of the internalized ^{125}I-LDL were increased to 75 and 37 ng/mg cell protein, respectively. The degradation of ^{125}I-LDL was enhanced by TC in MN fibroblasts but was not prominent in KIK cells (Fig. 1).

EDTA and heparin inhibited cell association (surface binding plus internalization) of ^{125}I-LDL in both normal and KIK fibroblasts incubated with TC (Fig. 2). The binding of ^{125}I-LDL to Hep G2 cells was unaffected by TC at 4°C. This is a striking contrast to the incubation at 37°C (Fig. 3). When Hep G2 cells were treated with paraformaldehyde and then subjected to ^{125}I-LDL binding at 37°C, TC enhanced the binding of ^{125}I-LDL to the fixed cells as well as to intact cells (Fig. 3), suggesting that the TC effect does not involve LDL receptor induction. In addition, the effect of TC to enhance LDL binding was reversible. Thus, when paraformaldehyde-treated Hep G2 cells were pretreated with 113 μM TC for 2 h at 37°C and then washed with buffer to remove TC, ^{125}I-LDL binding was 15.8 ng/mg cell protein, a value comparable to that of the fixed cells undergoing no pretreatment (15.0 ng/mg cell protein). When ^{125}I-LDL (50 μg/mL) was pretreated with 113 μM TC at 37°C for 2 h followed by being subjected to gel filtration on a Sephadex G-25 column (Pharmacia, Uppsala, Sweden) to remove TC, the binding of the pretreated ^{125}I-LDL to Hep G2 cells was 18.5 ng/mg cell protein, which

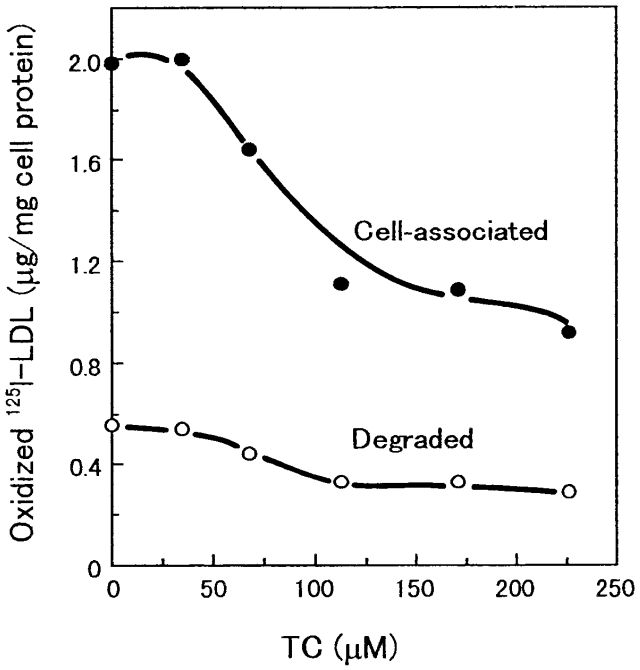

FIG. 4. Effects of TC on the cell association and degradation of oxidized ^{125}I-LDL in J774 macrophages. Each monolayer of J774 macrophages received oxidized ^{125}I-LDL (10 μg/mL) and the indicated concentrations of TC. After incubation at 37°C for 3 h, the amounts of oxidized ^{125}I-LDL specifically associated to the cells (●) and degraded (○) were determined. Each value represents the average of duplicate determinations. See Figure 1 for abbreviations.

was comparable to the value for the binding of untreated ^{125}I-LDL (17.0 ng/mg cell protein).

Unlike native LDL, oxidized LDL binds predominantly to scavenger receptors which recognize a wide variety of negatively charged molecules (18). When the macrophage-like J774 cell line, which expresses scavenger receptors, was incubated with 113 μM TC, the amounts of cell-associated and degraded oxidized ^{125}I-LDL were reduced by 40% (Fig. 4), excluding the possibility that TC enhances the scavenger receptor pathway.

Several TC analogs were tested for their ability to enhance ^{125}I-LDL binding to paraformaldehyde-fixed Hep G2 cells. The results indicated that compounds with R_4-hydrogen, TC, minocycline, chlortetracycline and anhydrotetracycline, were effective in enhancing the binding (Fig. 5A). On the other hand, R_4-hydroxy compounds, doxycycline, methacycline and oxytetracycline, failed to increase the binding. Isotetracycline, which has R_4-hydrogen but lacks the complete ring structure, was less active than TC. Anhydrotetracycline, which is 17 times less active than TC in antibacterial activity, was slightly more potent than TC in enhancing LDL binding (Fig. 5B).

DISCUSSION

In the present study, we have shown that some TC antibodies enhance the binding of LDL to both LDL receptor-positive and -negative cells. This effect was observed even with the paraformaldehyde-treated cells, but it required incubation of the cells in the presence of TC and LDL at the same time at 37°C but not at 4°C. Neither preincubating cells with TC nor preincubating LDL with TC enhanced the binding. The activity of TC analogs was dependent on the substituent of C-5 (see below). These results suggest that the LDL binding activation by TC is mediated by a specific, temperature-dependent process. One of possible mechanisms would be that a reversible modification of LDL (or a cell surface molecule) by TC leads the LDL (or the molecule) to bind cells (or LDL). These features are quite different from the effects of 3-hydroxy-3-methylglutaryl CoA reductase inhibitors, which induce LDL receptor expression at a transcriptional level (4,9).

The present experiments suggested that the TC enhancement of LDL binding involved a receptor other than the LDL receptor. There are two classes of multiligand lipoprotein receptors, the scavenger receptors and LDL receptor-related protein (19). These receptors bind nonlipoprotein ligands as well as lipoproteins and appear to participate in a wide variety of biological processes. Recently, Acton *et al.* (20,21) have identified the class B scavenger receptor (SR-BI), which can bind unmodified, native LDL and high density lipoprotein (HDL) as well as oxidized LDL and acetylated LDL. Like TC-induced LDL binding, the HDL binding to SR-BI does not accompany degradation of the protein moiety, whereas cholesteryl esters of the bound HDL is efficiently transferred to the cells (21). In addition, some proteoglycans bind lipoproteins including apoE-enriched lipoproteins, which are then internalized by the LDL receptor-related protein (19). While there would be the possibility that one (or some) of these molecules is involved in the TC-promoted LDL binding, additional studies are required to explore the detailed mechanism.

The antibacterial activity of TC antibiotics relates to oxygen-bearing groups: ketone or hydroxy at C-1, C-3, C-10, C-11, and C-12 is essential for antibacterial activity (22). The carbamoyl group at C-2 and the configuration at C-4, C-5a, and C-6 positions are also required for the activity. The present experiments demonstrated that the C-5 substituents played a crucial role in enhancing LDL binding. Thus, the analogs having hydrogen at C-5 were active, while the hydroxy-substituted compounds having substantial antibacterial activity were inactive. These findings demonstrated that the elevation of LDL binding by TC analogs was not related to their antibacterial activity. This conclusion was also supported by the fact that anhydrotetracycline, which was far less active than TC in antibacterial activity, showed LDL binding-promoting activity comparable to that of TC.

In preliminary experiments with normal dogs, oral administration of TC and anhydrotetracycline (3–10 mg/kg, twice daily) for 2–4 wk caused 10–25% reduction in plasma cholesterol levels. It is likely that cholesterol-lowering effects of these agents could be explained by the elevation of LDL binding. The relation between these two events is to be studied further in detail.

Stereochemistry-Dependent Inhibition of RAS Farnesylation by Farnesyl Phosphonic Acids

Raymond J. Hohl[a,*], Kriste A. Lewis, Diana M. Cermak[b], and David F. Wiemer[b]

Departments of [a]Internal Medicine, [a]Pharmacology, and [b]Chemistry, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: This investigation compares the effects of three farnesyl pyrophosphate analogs on selected aspects of isoprenoid metabolism. *E,E*-α-Hydroxyfarnesylphosphonate was prepared by an improved variation on a literature synthesis, which also gave access to the new *Z,E*-α-hydroxyfarnesyl- and α-hydroxygeranylphosphonates. A striking find is that only *E,E*-α-hydroxyfarnesylphosphonate induces alteration of RAS processing in intact human-derived leukemia cells and inhibits farnesyl protein transferase in enzyme assays, while the *Z,E*-α-farnesyl- and geranylphosphonates are inactive. The inhibitory activity of *E,E*-α-hydroxyfarnesylphosphonate is greater in enzyme than intact cell assays. This active compound does not significantly inhibit geranylgeranyl protein transferase I or squalene synthase, nor does it diminish cholesterol synthesis. These results indicate that the length of the terpenoid chain and olefin stereochemistry allow selective inhibition of critical enzymes of terpenoid metabolism. Discrimination was observed between inhibition of farnesyl protein transferase and squalene synthase by *E,E*-α-hydroxyfarnesylphosphonate, even though both enzymes utilize farnesyl pyrophosphate as their natural substrate.

Lipids 33, 39–46 (1998).

Mutated *RAS* genes that encode for activated and therefore transforming RAS proteins are present in a significant percentage of human tumors (1). Farnesyl protein transferase (FPTase) catalyzes the posttranslational farnesylation of both wild-type and mutated RAS as well as RAS-related proteins (2–4). RAS isoprenylation is important because this modification promotes RAS localization to the cell membrane, which is essential for RAS's biological activity (5–7). Cytoplasmic RAS proteins are devoid of signal transduction activity: transformed cells in which activated RAS is subsequently localized to the cytoplasm revert to the nontransformed phenotype. Thus impairment of RAS farnesylation is one strategy to block the transforming activity of mutated *RAS* genes and activated RAS proteins.

FTPase inhibitors are being developed by a number of laboratories (8–14). Development of these agents has been facilitated by the understanding that RAS and RAS-related proteins contain a consensus carboxy terminus that binds to the active site of FPTase (15,16). Tetrapeptides homologous to the carboxy terminus of the RAS proteins are extremely potent competitive inhibitors of FPTase and of RAS farnesylation in *in vitro* biochemical assays (8–13,17). However, without modification such oligopeptides are ineffective when added to intact cells because they are taken up inefficiently and/or because they are rapidly degraded (8–13). Development of FPTase inhibitors also has focused on natural products, such as chaetomellic acid and zaragozic acids, which have been shown to inhibit FPTase and RAS processing *in vitro* but not in intact cells (9).

An alternative approach to inhibit FPTase utilizes nonhydrolyzable analogs of farnesyl pyrophosphate that cannot participate in the transferase reaction. This strategy has resulted in the synthesis of α-hydroxyfarnesylphosphonic acid, a compound that inhibits FPTase and has been utilized to determine the *in vitro* kinetics of the farnesylation process (18). Expanding upon these such studies (9,18), we have synthesized two stereoisomeric α-hydroxyfarnesylphosphonic acids and the corresponding methyl esters and have examined the stereochemical requirements for these compounds to inhibit RAS processing in intact cells. Specifically, we have assessed the role of two isomeric farnesyl phosphonates and a geranyl phosphonate on RAS processing in human-derived leukemia cell lines. We observed discrimination between inhibition of FPTase and squalene synthase, which both utilize farnesyl pyrophosphate as their natural substrate. We have shown that the most active compound can selectively impair RAS farnesylation without greatly interfering with other aspects of isoprene metabolism, such as geranylgeranyl protein transferase I (GGPTase I) or cholesterol synthesis.

EXPERIMENTAL PROCEDURES

Chemical syntheses. Tetrahydrofuran (THF) was distilled from sodium/benzophenone while dichloromethane was distilled from calcium hydride, immediately prior to use. All reactions in these solvents were conducted under a positive pressure of an inert gas. Flash column chromatography was done on Merck (Rahway, NJ) grade 62 silica gel (230–400 mesh). Nuclear magnetic resonance (NMR) spectra (^{1}H at 300 MHz and ^{13}C at 75 MHz) were recorded with $CDCl_3$ as

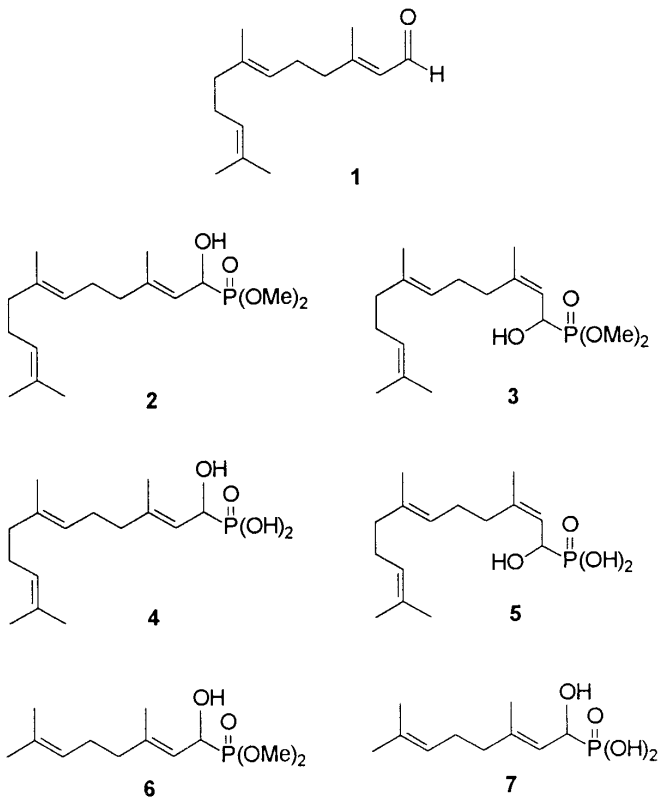
Abbreviations: FPP, farnesyl pyrophosphate; FPTase, farnesyl protein transferase; GGPTase I, geranylgeranyl protein transferase I; IC_{50}, 50% inhibitory concentration; NMR, nuclear magnetic resonance; THF, tetrahydrofuran.

solvent and $(CH_3)_4Si$ (^1H) or $CDCl_3$(^{13}C, 77.0 ppm) as internal standard. ^{31}P NMR shifts are reported in ppm relative to 85% H_3PO_4 (external standard). High-resolution and fast atom bombardment (FAB) mass spectra were obtained on a ZAB-HF reversed geometry mass spectrometer at the University of Iowa Mass Spectrometry facility. Elemental analyses were performed by Supersun Technology (Stony Brook, NY).

Chemical syntheses of the isoprenoid phosphonates. Scheme 1 shows the structures of the (α-hydroxyfarnesyl) phosphonate esters (**2**,**3**) and phosphonic acids (**4**,**5**), along with the geranyl analogs (**6**,**7**).



SCHEME 1

(E,E)-*3,7,11-Trimethyl-2,6,10-dodecatrienal (**1**).* Farnesol (2.18 g, 9.80 mmol) was added dropwise over 10 min to a stirred solution of pyridinium dichromate (19) (5.36 g, 14.3 mmol) and molecular sieve powder (20) (5.36 g) in dichloromethane (38 mL) under nitrogen at room temperature. After the resulting brown solution was stirred at room temperature for 2 h, the reaction mixture was diluted with ether (20 mL) and filtered through a pad of Celite. The orange filtrate, combined with repeated ether washings of the pad, was concentrated *in vacuo* to a volume of 100 mL. The solution was passed through silica gel under vacuum filtration, the silica was rinsed repeatedly with ether, and the filtrate was concentrated *in vacuo* to give compound **1** (1.86 g, 86%) as a yellow oil. This oil was a 10:1 mixture of the 2*E*,6*E* and 2*Z*,6*E* isomers, respectively. For the major isomer: ^1H NMR δ 10.00 (*d*, 1H, *J* = 8.0 Hz), 5.89 (*dd*, 1H, *J* = 8.0, 1.2 Hz), 5.05–5.15 (*m*, 2H), 2.20–2.28 (*m*, 4H), 2.17 (*d*, 3H, *J* = 1.2 Hz), 1.95–2.10 (*m*, 4H), 1.68 (*s*, 3H), 1.61 (*s*, 3H), 1.60 (*s*, 3H). Most resonances for the minor isomer overlap with those of the major isomer, but the ratio could be established by integration of the aldehyde resonances at δ 10.00 and δ 9.92 (*d*, 1H, *J* = 8.2 Hz).

(R,S)-*Dimethyl [1-hydroxy-3,7,11-trimethyl-2*E*,6*E*,10-dodecatrienyl] phosphonate (**2**) and (*R,S*)-dimethyl [1-hydroxy-3,7,11-trimethyl-2*Z*,6*E*,10-dodecatrienyl]phosphonate (**3**).* To a stirred solution of dimethyl phosphite (2.4 mL, 26 mmol) in THF (25 mL) was added lithium hexamethyldisilazane (26 mL, 1 M in THF) at −78°C. After the resulting mixture was stirred for 1 h, compound 1 (5.29 g, 24 mmol) in THF (105 mL) was added *via* cannula, and the mixture was stirred at −78°C for 2 h. The reaction was quenched by addition of 1 M acetic acid in ether (150 mL) and filtered through a pad of Celite. The filtrate, combined with repeated ether washings of the pad, was concentrated *in vacuo* to give an orange oil. Purification by flash column chromatography on silica gel (9:1, ethyl acetate/hexanes) provided a mixture of the isomeric phosphonates (6.38 g, 80%), and repeated chromatography gave pure *E,E*-phosphonate **2** and *Z,E*-phosphonate **3**, each as a yellow oil.

E,E-phosphonate **2**: (18) ^1H NMR ($CDCl_3$) δ 5.34 (*m*, 1H), 5.05–5.15 (*m*, 2H), 4.69 (*ddd*, 1H, *J* = 8.7, 8.7, 5.5 Hz), 3.82 (*d*, 3H, *J* = 10.4 Hz), 3.80 (*d*, 3H, *J* = 10.4 Hz), 2.88 (*dd*, 1H, *J* = 7.4, 5.5 Hz), 1.90–2.20 (*m*, 8H), 1.73 (*dd*, 3H, *J* = 3.1, 1.3 Hz), 1.68 (*s*, 3H), 1.60 (*s*, 6H); ^{13}C NMR δ 143.5 (*d*, J_{CP} = 13.8 Hz), 135.6, 131.4, 124.3, 123.5, 119.0 (*d*, J_{CP} = 3.1 Hz), 65.7 (*d*, J_{CP} = 164.2 Hz), 53.6 (*d*, J_{CP} = 5.8 Hz), 53.5 (*d*, J_{CP} = 5.5 Hz), 39.7, 39.7, 26.7, 26.2, 25.7, 17.7, 17.1, 16.0; ^{31}P NMR 26.35.

Z,E-phosphonate **3**: ^1H NMR ($CDCl_3$) δ 5.37 (*m*, 1H), 5.05–5.15 (*m*, 2H), 4.68 (*ddd*, 1H, *J* = 9.1, 8.7, 5.2 Hz), 3.82 (*d*, 3H, *J* = 10.4 Hz), 3.80 (*d*, 3H, *J* = 10.4 Hz), 2.65 (*dd*, 1H, *J* = 6.9, 5.3 Hz), 1.95–2.20 (*m*, 8H), 1.81 (*dd*, 3H, *J* = 3.8, 1.3 Hz), 1.68 (*s*, 3H), 1.60 (*s*, 6H); ^{13}C NMR δ 144.2 (*d*, J_{CP} = 14.4 Hz), 136.1, 131.5, 124.2, 123.4, 119.5 (*d*, J_{CP} = 2.8 Hz), 65.2 (*d*, J_{CP} = 165.7 Hz), 53.6, 53.5, 39.7, 32.6, 26.7, 26.4, 25.7, 23.5, 17.7, 16.0; ^{31}P NMR 26.43; high-resolution mass spectrum calculated for $C_{17}H_{31}O_4PNa$ 353.1858 $(M + Na)^+$, found 353.1845.

(R,S)-*[1-Hydroxy-3,7,11-trimethyl-2*E*,6*E*,10-dodecatrienyl]phosphonic acid (**4**).* According to the published procedure (18), phosphonate **2** (110 mg, 0.33 mmol) was treated with trimethylsilyl bromide (0.195 mL, 1.48 mmol) and 2,4,6-collidine (0.195 mL, 1.48 mmol) in dichloromethane (5 mL) to obtain the corresponding phosphonic acid **4** (54 mg, 54%): ^1H NMR [dimethyl sulfoxide (DMSO)] δ 5.00–5.25 (*m*, 3H), 4.23 (*t*, 1H, *J* = 9.5 Hz), 1.80–2.20 (*m*, 8H), 1.62 (*d*, 3H, *J* = 0.4 Hz), 1.60 (*d*, 3H, *J* = 0.6 Hz), 1.56 (*s*, 3H), 1.55 (*s*, 3H); ^{31}P NMR 25.10.

(R,S)-*[1-Hydroxy-3,7,11-trimethyl-2*Z*,6*E*,10-dodecatrienyl]phosphonic acid (**5**).* Through extension of the procedure described for the *E,E* isomer (18), phosphonate **3** (67 mg, 0.20 mmol) was treated with trimethylsilyl bromide (0.107 mL, 0.81 mmol) and 2,4,6-collidine (0.107 mL, 0.81

mmol) in dichloromethane (3 mL) to give phosphonic acid **5** (45 mg, 74%) as an orange oil: ^{1}H NMR ($CDCl_3$) δ 7.20 (*br*, 3H), 5.27 (*m*, 1H), 5.00–5.15 (*m*, 2H), 4.59 (*m*, 1H), 1.80–2.20 (*m*, 8H), 1.73 (*s*, 3H), 1.64 (*s*, 3H), 1.56 (*s*, 6H); ^{31}P NMR 23.51; high-resolution mass spectrum calculated for $C_{15}H_{26}O_4P$ 301.1569 $(M - H)^-$, found 301.1565.

(R,S)-*Dimethyl [1-hydroxy-3,7-dimethyl-2*E*,6-octadienyl]phosphonate (**6**).* In a manner similar to that described for preparation of phosphonate **2**, lithium hexamethyldisilazane (3.70 mL, 1 M in THF) was added to a solution of dimethyl phosphite (0.340 ml, 3.70 mmol) in THF (3.5 mL) at −78°C. After the resulting solution was stirred for 1 h, geranial (500 mg, 3.28 mmol) in THF (15 mL) was added *via* cannula and the mixture was stirred at −78°C for 2.75 h. Standard workup, as described above, and purification by flash column chromatography on silica gel (97:3 ethyl acetate/methanol) provided phosphonate **6** (751 mg, 87%) as a white crystalline solid: ^{1}H NMR ($CDCl_3$) δ 5.33 (*m*, 1H), 5.05–5.13 (*m*, 1H), 4.69 (*ddd*, 1H, *J* = 9.1, 4.6, 4.4 Hz), 3.83 (*d*, 3H, *J* = 6.7 Hz), 3.79 (*d*, 3H, *J* = 6.7 Hz), 2.74 (*dd*, 1H, *J* = 6.1, 0.4 Hz), 2.05–2.18 (*m*, 4H), 1.73 (*dd*, 3H, *J* = 3.2, 1.3 Hz), 1.68 (*s*, 3H), 1.61 (*s*, 3H); ^{31}P NMR 26.50; high-resolution mass spectrum calculated for $C_{12}H_{24}O_4P$ 263.1421 $(M + H)^+$, found 263.1420.

(R,S)-*[1-Hydroxy-3,7-dimethyl-2*E*,6-octadienyl]phosphonic acid (**7**).* Phosphonate **6** (71 mg, 0.27 mmol) was treated with trimethylsilyl bromide (0.160 mL, 1.21 mmol) and 2,4,6-collidine (0.160 mL, 1.21 mmol) in dichloromethane (3.2 mL) at 0°C for 30 min and then the reaction was allowed to warm to room temperature. After 17 h, toluene (5 mL) was added and all volatiles were removed *in vacuo* to give a white oily solid. Water (10 mL) and 1 M HCl was added until pH 2 was obtained. The mixture was extracted with ethyl acetate (3 × 20 mL), the combined organic extracts were dried over $MgSO_4$, and then concentrated in vacuo to afford compound **7** (57 mg, 88%) as a white solid: ^{1}H NMR (dimethylsulfoxide) δ 9.0–11.5 (*br*, 1H), 5.05–5.23 (*m*, 2H), 4.24 (*dd*, *J* = 10.1 Hz, 1H), 3.0–3.8 (*br*, 2H), 1.91–2.10 (*m*, 4H), 1.64 (*s*, 3H), 1.60 (*d*, *J* = 2.1 Hz, 3H), 1.57 (*s*, 3H); ^{31}P NMR 21.54. Analysis calculated for $C_{10}H_{19}O_4P$: C, 51.26; H, 8.18. Found: C, 51.13; H, 8.30.

Cell culture. RPMI-8402 cells were grown in RPMI-1640 media supplemented with 10% heat-inactivated fetal calf serum. Cells were maintained in TI-75 culture flasks at 37°C in humidified 5% CO_2 atmosphere. Trypan blue exclusion was measured by incubating cells for 5 min with a 1:1 0.4 mg/dL trypan blue solution and counting clear viable and blue nonviable cells with a hemacytometer. All studies with the phosphonic acids and esters contained a final dimethylsulfoxide concentration of 0.4% which does not alter the parameters measured in these studies (data not shown).

Measurement of total RAS. Cells (1×10^7 cells at 1×10^6 cells/mL) in logarithmic phase growth were incubated in RPMI-1640 media with 10% fetal calf serum supplemented with the test compounds for 24 to 72 h. Cells were pelleted by centrifugation at 800 × *g* for 10 min and washed twice with cold phosphate buffered saline (140 mM NaCl, 2.7 mM KCl, 8.0 mM Na_2HPO_4, and 1.5 mM KH_2PO_4). Cells were resuspended in 0.1 mL lysing buffer (20 mM Tris pH = 7.5, 0.1 M NaCl, 1.0% Nonidet, 0.05 g/dL Na deoxycholate) and vortexed intermittently for 30 min. The cell pellets were dounced 10 times and centrifuged at 10,000 × g for 30 min. Protein content of the supernatant was assayed according to the method of Lowry *et al.* (21). Cell lysate containing 100 µg protein was subjected to electrophoretic fractionation on denaturing 15% polyacrylamide gels (SDS-PAGE). An H-ras standard was loaded to one lane on each gel. The gel slab was transblotted to Immobilon-Polyvinylidene fluoride (Millipore, Bedford, MA) prior to blocking for 2 h with blocking buffer [5 mg/dL skim milk, 1 mg/dL bovine serum albumin, 0.01% antifoam A in phosphate buffered saline]. The membrane was then sequentially incubated with NCC-004 anti-RAS antibody (22,23) in hybridoma supernatant for 2 h, biotinylated rabbit antimouse IgG for 2 h, and avidin-linked horseradish peroxidase (Vectastain ABC, Vector Labs, Burlingame, CA) for 30 min. The membrane was washed five times with 0.1% Tween 20 in phosphate buffered saline between each incubation. The RAS bands were visualized by incubation of the membrane with 0.7 mM 3,3-diaminobenzidine and 0.006% H_2O_2 in 10 mM Tris (pH = 7.5).

Measurement of newly synthesized RAS. Cells were washed and incubated at 3×10^6 cells/mL in methionine RPMI-1640 media for 1.5 h with or without test compounds. [^{35}S]Methionine/cysteine (1180 Ci/mM) was added to a final concentration of 0.045 mCi/mL. After incubation for 4 h, the cells were harvested and lysed as described above in the measurement of total RAS section with the exception that 1 g/dL bovine serum albumin was added to the lysing buffer. Radiolabeled cell lysate containing 200 µg of protein was precleared, immunoprecipitated with Y13-259 rat anti-RAS IgG, and electrophoretically fractionated as described previously (23). After fixation the gels were dried and exposed to Eastman Kodak (Rochester, NY) XAR5 (X-OMAT) film for 48 h. With development, the density of the bands corresponded to the amount of radiolabeled RAS proteins.

FPTase and GGPTase I assay. Partially purified FPTase and GGPTase were isolated from bovine brain white matter by homogenization at 4°C in lysis buffer (50 mM Tris-HCl (pH = 8.0), 1 mM EGTA, 1 mM $MgCl_2$, 5 mM dithiothreitol, 10 µg/mL aprotinin, 0.5 mM phenylmethylsulfonyl fluoride, and 2 µg/mL leupeptin) (16). The homogenates were centrifuged at 10,000 × *g* for 20 min at 4°C. The supernatant was removed and centrifuged at 100,000 × *g* for 60 min at 4°C. The cytosolic protein fraction was removed and stored at −80°C (24).

Inhibition of FPTase and GGPTase was determined using the method of Harwood (25) with some modifications. Reaction mixtures, 15.3 µL containing 0.5 µM ^{3}H[FPP] or ^{3}H[GGPP] (12770 dpm/pmole), 5 mM $MgCl_2$, 20 mM Tris-HCl (pH = 7.5), 2 mM dithiothreitol, 8 µM $ZnCl_2$, 4 µM of H-ras/wild type (FPTase assay) or 8 µM of H-ras/CVLL (GGPTase I assay), without or with selected farnesyl phosphonates are set up in a 96-well plate. Reactions are started with

the addition of 9.7 μL of the bovine brain cytosol containing either 3.0 mg/mL (FPP) or 18.8 mg/mL (GGPP) of protein and incubated at 37°C for 60 min. Reactions are terminated with the addition of 200 μL of 10% HCl in EtOH. Samples are incubated for an additional 15 min at 37°C to ensure protein precipitation and enzyme hydrolysis. Samples are filtered through P-81 filters (Whatman, Maidstone, England) using a Brandel harvester (Biomedical Research and Development Laboratories Inc., Gaithersburg, MD). Filters are washed with EtOH and dried. Scintillation counting enabled determination of ^{3}H-FPP or ^{3}H-GGPP incorporation into RAS using 3A70 (Research Products International Corp., Mt. Prospect, IL) cocktail.

Cholesterol synthesis. Radiolabeled acetate incorporation into cholesterol was measured according to our previously described methods (26,27). In brief, RPMI-8402 cells were cultured in 20% lipoprotein-depleted serum. The cells were incubated for 18 h without or with the desired farnesyl phosphonate before the addition of ^{14}C-acetate. Four hours later the amount of radiolabeled cholesterol in the cultures was determined by thin-layer chromatography fractionation of cell lysates. The amounts of acetate metabolized to cholesterol were calculated for each cell culture and expressed as percentage observed in control cultures. Lovastatin, an inhibitor of hydroxymethylglutaryl CoA reductase and therefore cellular cholesterol synthesis, was used as a positive control.

Squalene synthase. Inhibition of squalene synthase activity was determined using the method of Ciosek *et al.* (28) with some modification. Microsomes were isolated from Sprague-Dawley rats (Harland, Indianapolis, IN) that had been fed a diet containing 10% cholestyramine for 1 wk. Microsomes were diluted to 2 mg/mL protein in 275 mM KH_2PO_4/K_2HPO_4 (pH = 7.4). Each reaction contained 0.16 mg microsomal protein in a final volume of 0.5 mL buffer (50 mM KH_2PO_4/K_2HPO_4 (pH = 7.4), 10 mM KF, 1.62 mM NADPH, and 5 mM $MgCl_2$) containing a final concentration of 22 μM farnesyl pyrophosphate (FPP) that includes 1.0 μCi of [1-^{3}H]FPP (15–30 Ci/mM) without and with selected farnesyl phosphonates. Reactions are started with the addition of [1-^{3}H]FPP and incubated at 30°C for 60 min under nitrogen. Reactions are terminated with the sequential addition of 0.5 mL 40% KOH and 0.5 mL ethanol containing internal standard ^{14}C-squalene (1000 dpm) with carrier squalene (15 μg) and lanosterol (25 μg). The samples were saponified by heating to a boil followed by gradual cooling. The mixtures were extracted twice with 2 mL hexane and the hexane evaporated to dryness. The residue was dissolved in 30 μL chloroform and subjected to thin-layer chromatographic separation on LK5D (Whatman) silica plates with hexane/chloroform/methanol (30:10:1). Lipids were visualized with iodine vapor. Squalene and lanosterol bands were scraped and counted in Budget Solve (Research Products International Corp.) cocktail. Dual label scintillation counting enabled determination of [1-^{3}H]squalene and lanosterol synthesis adjusted for extraction efficiency. (*E,E*)-(4,8,12-Trimethyl-3,7,11-tridecatrienylidene)bisphosphonic acid, a known inhibitor of mammalian squalene synthase (IC_{50} 32 nM), was employed as a positive control (28).

Materials. Farnesol (>99% pure) and geraniol (98% pure) were obtained from Aldrich (Milwaukee, WI). RPMI-1640 media and fetal calf serum were obtained from the Hybridoma Facility at the University of Iowa. Lovastatin was kindly provided by Alfred Alberts of Merck, Sharp & Dohme (Darmstadt, Germany) and was converted to the open acid prior to use. NCC-004 anti-RAS IgG was kindly provided by Dr. Setsuo Hirohashi (National Cancer Center, Tokyo), H-ras standard was kindly provided by Dr. Robert Deschenes (University of Iowa), Y13-259 anti-RAS IgG was from Oncogene Science (Uniondale, NY), and rabbit antimouse IgG, goat antirabbit IgG, and Vectastain ABC kits were from Vector Labs.

RESULTS

Effects of the isoprenoid phosphonates on RAS processing in intact cells. To determine the effects of the isoprenoid phosphonates on RAS processing, RPMI-8402 cells were incubated with 0, 100, and 200 μM of the phosphonates (Fig. 1) for 24 h prior to harvesting and lysing. Control cultures contained 0 or 100 μM lovastatin without and with 10 mM mevalonic acid. Figure 1 is a Western blot of cell lysate demonstrating that in control cells without lovastatin there is a couplet of RAS bands that corresponds to farnesylated RAS proteins. This couplet is a consequence of RAS phosphorylation and has been described (9). After incubation with 100 or 50 μM lovastatin for 24 h prior to harvesting, there is accumulation of increasing amounts of unmodified RAS protein that migrates with an apparent higher molecular weight than does the farnesylated RAS proteins. The effects observed with lovastatin are reversed with the addition of 5 mM mevalonic acid. Incubation of cells with the *E,E*- (**4**) and *Z,E*-α-hydroxy-

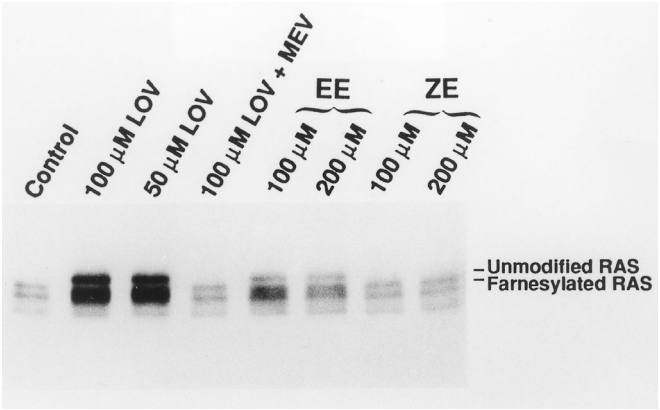


FIG. 1. Effects of *E,E*- and *Z,E*-α-hydroxyfarnesylphosphonates on RAS levels in RPMI-8402 cells. This Western blot was developed as described in the Experimental Procedures section. Above each lane is listed the chemical added to the incubation mixture. Cells were incubated without additive chemicals (Control), with lovastatin (LOV) without and with 10 mmolar mevalonic acid (MEV), and the *E,E*- and *Z,E*-isomers of α-hydroxyfarnesylphosphonate. Each lane contains 100 μg of protein from cell lysate.

farnesylphosphonate (**5**) isomers for 24 h reveals that the *E,E*-isomer **4**, but not the *Z,E*-isomer **5**, results in the accumulation of unmodified RAS protein. Mevalonic acid reverses the effect of *E,E*-α-hydroxyfarnesylphosphonate in a concentration-dependent fashion (data not shown).

Incubation of cells with up to 20 μM of either dimethyl *E,E*- or dimethyl *Z,E*-α-hydroxyfarnesylphosphonate (**2** and **3**) does not result in the accumulation of unmodified RAS protein (data not shown). Cells maintain viability, assessed as trypan blue exclusion, to above 90% when incubated with up to 200 μM of the *E,E*- (**4**) and *Z,E*-α-hydroxyfarnesylphosphonates (**5**). In contrast, above 20 μM concentrations, dimethyl *E,E*- or dimethyl *Z,E*-α-hydroxyfarnesylphosphonate (**2** and **3**) are nonspecifically toxic to these cells.

Neither α-hydroxygeranylphosphonate (**7**) nor its dimethyl ester (**6**) displays inhibitory activity for RAS farnesylation in intact RPMI-8402 cells (data not shown). Both compounds were tested at up to 200 μM concentrations because toxicity, assessed by trypan blue exclusion, does not occur.

Effects of isoprenoid phosphonates on newly synthesized RAS. Cells were incubated with 0.2 to 20 μM *E,E*-α-hydroxyfarnesylphosphonate (**4**) or 25 μM lovastatin prior to and during pulsing with radiolabeled methionine. Figure 2 demonstrates that radiolabeled RAS is detected as both unmodified and farnesylated forms after coincubation of cells with [^{35}S] methionine for 4 h without other added chemicals (control). Cells treated with 25 μM lovastatin contain only unmodified RAS protein because of the induced depletion of FPP that impairs RAS posttranslational processing. Cells treated with 0.2 μM α-hydroxyfarnesylphosphonate (**EE**) contain similar amounts of unmodified and farnesylated RAS as do untreated cells. In contrast, cells treated with either 2.0 or 20 μM α-hydroxyfarnesylphosphonate (**EE**) contain only unmodified RAS as do lovastatin-treated cells. This autoradiograph indicates that treatment of cells with between 0.2 and 2.0 μM α-hydroxyfarnesylphosphonate (**EE**) would decrease farnesylation of newly synthesized RAS by 50%.

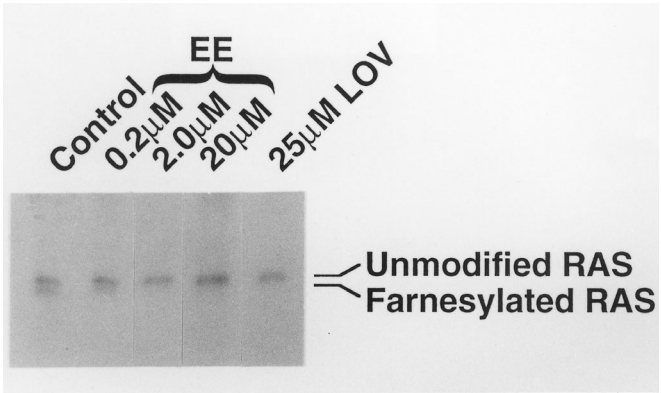

FIG. 2. Effects of *E,E*-α-hydroxyfarnesylphosphonate on newly synthesized RAS levels. RPMI-8402 cells were radiolabeled and 200 μg of protein from cell lysate immunoprecipitated as described in the Experimental Procedures section. For this autoradiogram, each lane is labeled as either Control or with the concentrations of *E,E*-α-hydroxyfarnesylphosphonate (EE) or lovastatin (LOV) used in the incubations.

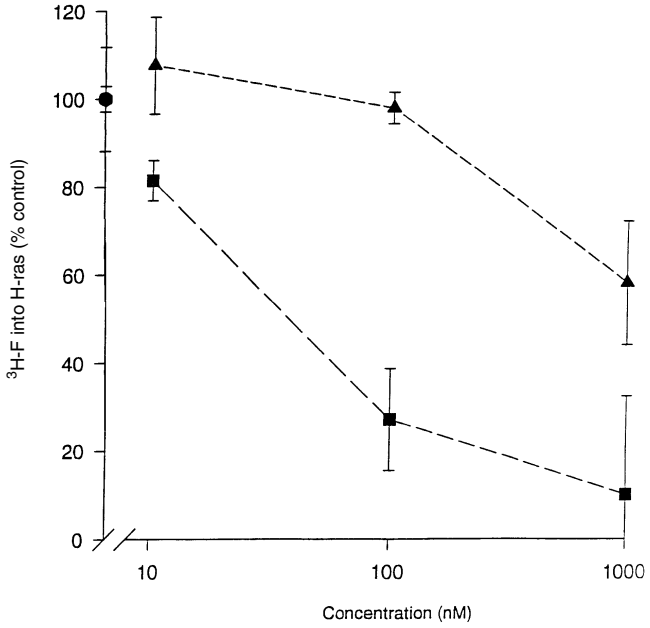

FIG. 3. Effects of (■), *E,E*- and (▲), *Z,E*-α-hydroxyfarnesylphosphonates on FPTase activity. This assay was performed as described in the Experimental Procedures section. The points are the mean of three experiments and the error bars indicate ±1 standard deviation.

Effects of the isoprenoid phosphonates on FTPase. Figure 3 displays the effects of increasing concentrations of compounds **4** (■) and 5 (▲) on *in vitro* FTPase activity. The abscissa indicates the concentration of the phosphonates in the FTPase reaction, and the ordinate indicates dpm of radiolabeled farnesyl from FPP incorporated into precipitable H-ras protein as percentage control. Compound **4** inhibits FTPase with IC_{50} of approximately 65 nM, whereas compound **5** displays no FTPase inhibitory activity up to 100 nM concentrations. Compounds **2**, **3**, **6**, and **7** do not inhibit FPTase, at least up to as high as 500 nM concentrations.

Effects of the isoprenoid phosphonates on GGPTase I. Figure 4 displays the effects of increasing concentrations of compound **4** on *in vitro* GGPTase I activity. The abscissa indicates the concentration of the phosphonate in the GGPTase I reaction, and the ordinate indicates dpm of radiolabeled geranylgeranyl from geranylgeranyl pyrophosphate incorporated into precipitable mutant H-ras/CVLL protein as percentage control. Compound **4** slightly inhibits GGPTase I although an IC_{50} is not reached even at 50 μM concentrations.

Effects of the isoprenoid phosphonates on cholesterol synthesis and squalene synthase. Table 1 displays the effects of *E,E*- (**4**) and *Z,E*-α-hydroxyfarnesylphosphonate (**5**) on cholesterol synthesis in intact cells and squalene synthase in enzymatic assay. Neither compound greatly decreased cholesterol synthesis nor squalene synthase activity in comparison to control experiments. Lovastatin was used as a positive control for the cholesterol inhibition assay and (*E,E*)-(4,8,12-trimethyl-3,7,11-tridecatrienylidene)-bisphosphonic acid was used as a positive control for the squalene synthesis assay.

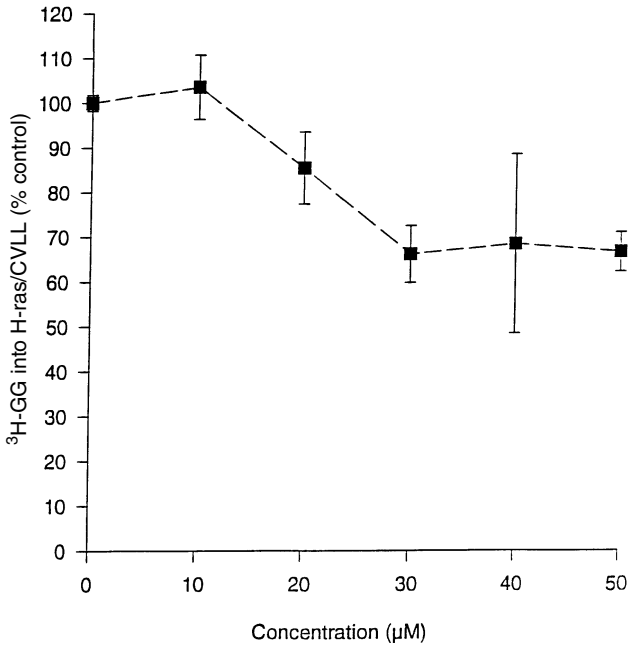

FIG. 4. Effects of *E,E*-α-hydroxyfarnesylphosphonate on geranylgeranyl protein transferase I activity. This assay was performed as described in the Experimental Procedures section. The points are the mean of three experiments and the error bars indicate ±1 standard deviation.

DISCUSSION

This preparation of the α-hydroxyfarnesylphosphonic acids employed a sample of farnesal (**1**) that was known to consist of a 10:1 mixture of the *E,E*- and *Z,E*-isomers. Condensation of this mixture with the anion of dimethyl phosphite according to an improved variation (29) of the procedure reported by Pompliano *et al.* (18) (80 vs. 38% yield), gave the expected mixture of the dimethyl *E,E*- and dimethyl *Z,E*-α-hydroxyfarnesylphosphonates (**2** and **3**). Because these olefin isomers could then be separated by column chromatography, it was possible to obtain both of the desired olefin stereoisomers of the farnesyl chain length. Each was then independently hydrolyzed to the corresponding phosphonic acid (**4** and **5**). Preparation of the geranyl derivatives was accomplished by a parallel set of reactions, giving the dimethyl α-hydroxygeranylphosphonate (**6**) and α-hydroxygeranylphosphonic acid (**7**) in very good yields. For the dimethyl esters, purity was established most readily by analysis of the ^{1}H NMR spectra and the purity of the phosphonic acids was verified by analysis of the ^{31}P NMR spectra.

TABLE 1
Effects of Isoprenoid Phosphonates on Cholesterol Synthesis and Squalene Synthase[a]

	Cholesterol Synthesis (% control)	Squalene Synthase (% control)
Control	100	100
Compound **4**	114	94
Compound **5**	113	80
Lovastatin	32	
Squalene synthase Inhibitor		9.3

[a]Cholesterol synthesis: Compound **4** and Compound **5** were tested at 200 μM. Lovastatin was tested at 1 μM. Squalene synthase: Compound **4** and Compound **5** were tested at 1 μM. Squalene synthase inhibitor refers to (*E,E*)-(4,8,12-trimethyl-3,7,11-tridecatrienylidene)bisphosphonic acid that was tested at 100 nM. Compound **4** is (*R,S*)-[1-hydroxy-3,7,11-trimethyl-2*E*,6*E*,10-dodecatrienyl]phosphonic acid. Compound **5** is (*R,S*)-[1-hydroxy-3,7,11-trimethyl-2*Z*,6*E*,10-dodecatrienyl]phosphonic acid.

The biological assay results for these compounds demonstrate that in intact cells, only the *E,E*- (**4**) but not the *Z,E*-α-hydroxyfarnesylphosphonate (**5**) impairs RAS processing. Inhibition of FPTase by compound **4** is consistent with that reported by Pompliano *et al.* (18), but a more dramatic effect is observed when [^{35}S]methionine incorporation into RAS in intact cells is measured. The *E,E*-isomer is a potent inhibitor of the farnesylation of newly synthesized RAS. Furthermore, the IC_{50} for the *E,E*-isomer (**4**) to inhibit RAS processing in intact cells is between 0.2 and 2.0 μM (Fig. 3), whereas IC_{50} for the *E,E*-isomer to inhibit bovine FPTase in enzyme assay is approximately 65 nM (Fig. 4), suggesting that cells may either impede intracellular localization, metabolically inactivate, or actively extrude compound **4**. Alternatively, the mechanisms that regulate RAS expression in intact cells (30) may compensate for compound **4** FPTase inhibitory activity. Our further expansion of the original data (18) with our demonstration that the *Z,E*-isomer **5** is less active in both intact cell and enzyme assays also indicates that competitive interaction with the site of the FPP binding to FPTase is dependent upon the olefin stereochemistry.

To assess the effect of alkyl chain length on inhibition of RAS processing in intact cells and in direct FPTase assays, a C-10 analog (**7**) of the active *E,E*-isomer **4** was tested for activity. If recognition of the α-hydroxyfarnesyl phosphonate is dominated by interactions with the phosphoryl group, one might expect smaller α-hydroxyalkylphosphonates to serve as competitive inhibitors as well. However, α-hydroxygeranylphosphonate (**7**) did not alter RAS expression in intact cells nor inhibit FPTase in enzyme assay. Thus competitive interaction of inhibitors with the site of FPP binding to FPTase is dependent upon alkyl chain length. A parallel impact of chain length is found with the enzyme GGPTase I, where the *E,E*-(α-hydroxyfarnesyl)phosphonate is not an inhibitor.

The dimethyl esters of active FTPase inhibitors should have increased cell permeability relative to the phosphonic acids because the esters remain neutral while the acids would be ionized under assay conditions. If hydrolysis to the parent acid were to occur within the cells, the dimethyl esters could interfere with RAS processing to a greater degree than the parent phosphonic acids. However, in our assays, the dimethyl ester **2** did not impair RAS processing in intact cells nor did it inhibit FPTase in enzyme assay despite the marked toxicity of this compound with respect to severely decreasing cell viability. The dimethyl ester **3** was similarly toxic to cells, raising the possibility that such toxicity is a consequence of the esterification. At the same time, the C-10 dimethyl ester **6** was nontoxic to cells. These results do not exclude the possibility that toxicity might be a consequence of detergent activity, as has been described for other similar compounds, (9) and that the longer alkyl chain is required for a detergent effect.

Ultimately, any clinical application of FPP analogs as FPTase inhibitors will depend on their selectivity for inhibition of FPTase as compared to the other enzymes in the isoprenoid/cholesterol metabolic pathway (9). The greatest concern is that isoprenoid phosphonates will inhibit other enzymes that utilize FPP as a substrate, such as squalene synthase. Our experiments clearly show that the active inhibitor **4** is specific for FPTase over squalene synthase and displays only minimal inhibition of GGPTase I. The limited inhibition of GGPTase I is particularly important because GGPTase I and FPTase share α-subunits (31), and one might speculate that there would be cross-inhibition of these two enzymes. To ensure valid assays of squalene synthase inhibition, (*E,E*)-(4,8,12-trimethyl-3,7,11-tridecatrienylidene)bisphosphonic acid was employed as a positive control. Our finding that the *E,E*-isomer **4** does not inhibit squalene synthase is contrary to the unpublished observation by others (9) that this compound inhibits squalene synthase with an IC_{50} of 0.63 μM.

Of these findings, the most significant result is that the *E,E*-phosphonate **4** completely blocks RAS farnesylation *via* inhibition of FPTase, while not reducing overall cholesterol synthesis in intact cells and not inhibiting squalene synthase in enzyme assay. Because both FPTase and squalene synthase utilize FPP as their natural substrate, it may have been reasonable to assume that both enzymes would be affected by this compound in a parallel fashion. Because this is not the case, phosphonate analogs of FPP are valuable as selective inhibitors of the various enzymes of isoprenoid metabolism.

ACKNOWLEDGMENTS

This work was supported by grants from the Roy J. Carver Charitable Trust, Leukemia Society of America, and University of Iowa Cancer Center. R. Hohl is a recipient of an American Society of Clinical Oncology Young Investigator Award and a Pharmaceutical Research and Manufacturers of America Foundation Faculty Development Award in Clinical Pharmacology. We thank Sarah Holstein, Department of Chemistry at the University of Iowa, for preparation of (*E*,*E*)-(4,8,12-trimethyl-3,7,11-tridecatrienylidene)bisphosphonic acid. The RPMI-8402 cells were provided by M. Diaz, Loyola University.

Stereospecific Metabolism of Isomeric Epoxyoctadecanoic Acids in the Lactone-Producing Yeast *Sporidiobolus salmonicolor*

Thomas Haffner and Roland Tressl*

Technische Universität Berlin, Institut für Biotechnologie, Fachgebiet Chemisch-technische Analyse, D-13353 Berlin, Germany

ABSTRACT: The metabolic course of four isomeric epoxyfatty acids derived from oleic-, elaidic-, (*Z*)-, and (*E*)-vaccenic acids in the lactone-producing yeast, *Sporidiobolus salmonicolor,* was studied by using the deuterium-labeled precursors. Dihydroxy-, hydroxyoxo-, and hydroxy fatty acids as well as γ-lactones were identified as metabolic intermediates. Quantitative analysis of the label content and estimation of the enantiomeric composition of the lactones established that, in the first step, the racemic epoxyfatty acids were enantiospecifically hydrolyzed by an epoxide hydrolase. During the subsequent metabolism, the stereochemical orientation of the hydroxy groups of the dihydroxyfatty acids were modified by an oxidation/reduction step.
Lipids 33, 47–58 (1998).

Epoxyfatty acids can be found in many plants as constituents of the cutine polymers in green leaves where they are involved in the defense mechanisms of green plants (1–4). Epoxyfatty acids are derived from unsaturated fatty acids by double-bond epoxidation, catalyzed either as a main or a side reaction by a variety of metallo-enzymes, mostly of the cytochrome P-450 type. Enzymes which utilize hydroperoxides as oxygen source are summarized under the terms "epoxygenases" or "peroxygenase" in the literature. Their activity was first discovered in spinach (5), but have been found in a variety of edible plants (6–8). Some authors also have confirmed the ubiquitous appearance of this kind of enzymatic activity indirectly while identifying epoxyfatty acids as products of bacteria, fungi, and mammals (9–13).

Epoxyfatty acids are chiral compounds. Stereochemical investigations of their formation, performed with microsomes or purified epoxygenases from Jerusalem artichokes, soybeans and broad beans, revealed that enzymatic epoxidation reactions are enantioselective (14–16). However, the subsequent metabolism of epoxyfatty acids is initiated in general by the hydrolytic cleavage of the oxirane ring, catalyzed by epoxide hydrolases. These enzymes, active on carboxylic epoxyfatty acids, were first discovered in a cell-free extract of the flax rust uredospores (*Melampsora lini*) (17). The stereospecificity of this enantioselective reaction toward both configural isomers of 9,10-epoxystearic acids was first established with an enzyme preparation from a *Pseudomonas* strain (18,19). The most detailed studies concerning the regio- and enantiospecificities of epoxyfatty acid hydrolases were performed by Blée and Schuber (20–23), using purified soybean enzyme.

Recently, Schöttler and Boland (24,25) have investigated the importance of a saturated epoxyfatty acid acting as a precursor in the biosynthesis of γ-dodecanolactone, an important flavor compound in many fruits. They proved the crucial role of the enantioselectivity of epoxyfatty acid hydrolases for the enantiomeric distribution of this γ-lactone in strawberries, peaches, and nectarines.

In this paper, we report the stereochemical aspects of the metabolism of epoxyfatty acids in the lactone-producing yeast *Sporidiobolus salmonicolor*. *Sporidiobolus salmonicolor* was chosen for the following reasons: The yeast shows a diverse fatty acid metabolism including a variety of interesting enzymes and is easy to cultivate. Therefore, the yeast has been used as an appropriate model for metabolic studies in the field of fatty acids for many years (26–31). The organism accumulates chiral lactones during its cultivation, which are in general biosynthesized from unsaturated fatty acids. These compounds are easy to obtain and to analyze. By using suitably labeled precursors, here double-bond labeled racemic epoxy fatty acids, these lactones will conserve stereochemical information by its configuration and labeling patterns about those enzymes which are involved in the metabolic pathways of the organism. Starting from deuterium-labeled racemic epoxides of (*Z*)- and (*E*)-oleates and vaccenates (9,10- and 11,12-epoxystearic acid esters), we are able to give a detailed insight into the β-oxidative course of these compounds with respect to the biosynthesis of the important aroma compounds, γ-decalactone and γ-

dodecalactone. The few examples given above show the widespread natural occurrence of γ-lactones in popular fruits. They may demonstrate the important contribution of C_{10}–C_{12} γ-lactones to the flavor of many foodstuffs. For this reason they are produced in ton-scale as flavor enhancers (fruity notes, such as coconut, apricot, peach, etc.) for use in flavor industry (for a recent review, see Ref. 32).

EXPERIMENTAL PROCEDURES

Syntheses. All four deuterium-labeled epoxyfatty acid isomers were synthesized by chemical epoxidation (*m*-chloroperbenzoic acid in CH_2Cl_2 for 18 h at room temperature) from the corresponding double-bond labeled monounsaturated fatty acids or their esters, respectively. The (*Z*)- and (*E*)-monoenoic acids were obtained by reductive deuteration of the 9-, 11-octadecenoic acids or the 9-, 11-octadecen-1-ols, respectively, which were synthesized by a C–C-bond formation between OH-protected ω-alkyn-1-ols and alkylbromides, followed by deprotection and/or oxidation to the corresponding acids.

The preparation of the [$^2H_2$]-(*Z*)-epoxyoctadecanoic acids was described elsewhere (26). The synthesis of the (*E*)-isomers was performed as follows:

To 0.625 g (14.88 mmol) of $LiAlD_4$ (99% isotopic purity), dissolved in 25 mL of anhydrous diethylenglycoldimethylether (diglyme) at 0°C, 1.0 g (3.71 mmol) of the octadecen-1-ol was added, and the reaction mixture was refluxed for 72 h. After cooling to 0°C, the reaction was hydrolyzed with 5 mL of D_2O (99% isotopic purity), acidified with 2 M HCl, and extracted three times using, in total, 100 mL of diethylether. The combined organic phases were washed with brine, dried over Na_2SO_4, and the solvent was evaporated in vacuum. The product was purified on silica gel to obtain 0.883 g (3.15 mmol) of the pure [$^2H_2$]-(*E*)-octadecen-1-ol. The alcohol was oxidized to the acid in a two-step procedure, using pyridinumchlorochromate followed by $HClO_2$ as oxidants. The overall yield was regularly higher than 70% for all isomeric fatty acids.

Analytical data. [9,10-$^2H_2$]-Methyl-(*Z*)-9,10-epoxyoctadecanoate: Proton nuclear magnetic resonance (^{1}H NMR) ($CDCl_3$): δ = 0.86 (*t, J* = 7 Hz, 3 H, CH_3CH_2), 1.17–1.48 (*m,* 22 H, CH_2), 1.57 (quint, *J* = 7 Hz, 2 H, $CH_2CH_2COOCH_3$), 2.28 (*t, J* = 7 Hz, 4 H, $CH_2CD(O)CDCH_2$), 3.63 (*s*, 3 H, CH_2COOCH_3). Mass spectrum (70 eV), *m/z* (%): 314 (<1) [M^+], 283 (2) [$M^+ - CH_3O$], 265 (1), 247 (<1), 215 (7), 186 (11), 169 (7), 157 (26), 156 (59), 140 (23), 125 (17), 110 (33), 101 (58), 96 (35), 88 (100), 69 (71), 55 (99), 43 (70), 41 (74); d-content at C(9)/C(10): averaged 93.1%.

[9,10-$^2H_2$]-Ethyl-(*E*)-9,10-epoxyoctadecanoate: ^{1}H NMR ($CDCl_3$): δ = 0.85 (*t, J* = 7 Hz, 3 H, CH_3CH_2), 1.20–1.54 (*m,* 22 H, CH_2), 1.23 (*t, J* = 7 Hz, 3 H, CH_3CH_2O), 1,58 (quint, *J* = 7 Hz, 2 H, $CH_2CH_2COOCH_2CH_3$), 2.25 (*t, J* = 7 Hz, 4 H, $CH_2CD(O)CDCH_2$) 4.09 (*q, J* = 7 Hz, 2 H, $CH_2COOCH_2CH_3$). Mass spectrum (70 eV), *m/z* (%): 329 (<1), 328 (<1) [M^+], 311 (<1) [$M^+ - H_2O$], 300 (<1), 283 (4) [$M^+ - C_2H_5O$], 265 (2), 247 (2), 223 (1), 215 (16), 186 (19), 157 (37), 156 (100), 153 (32), 140 (32), 125 (18), 110 (40), 101 (49), 96 (37), 88 (92), 83 (41), 69 (56), 55 (70), 41 (48); d-content at C(9)/C(10): averaged 93.9%.

[11,12-$^2H_2$]-Ethyl-(*Z*)-11,12-epoxyoctadecanoate: ^{1}H NMR ($CDCl_3$): δ = 0.87 (*t, J* = 7 Hz, 3 H, CH_3CH_2), 1.18–1.49 (*m,* 22 H, CH_2), 1.21 (*t, J* = 7 Hz, 3 H, CH_3CH_2O), 1.58 (quint, *J* = 7 Hz, 2 H, $CH_2CH_2COOCH_2CH_3$), 2.22 (*t, J* = 7 Hz, 4 H, $CH_2CD(O)CDCH_2$) 4.06 (*q, J* = 7 Hz, 2 H, $CH_2COOCH_2CH_3$). Mass spectrum (70 eV), *m/z* (%): 328 (<1), 283 (2) [$M^+ - 45$], 265 (2), 243 (8), 225 (2), 214 (11), 197 (4), 184 (28), 150 (13), 129 (26), 101 (82), 98 (40), 88 (100), 82 (41), 69 (66), 55 (99), 41 (71); d-content at C(11)/C(12): averaged 94.5%.

Synthesis of [11,12-$^2H_2$]-Ethyl-(*E*)-11,12-epoxyoctadecanoate: ^{1}H NMR ($CDCl_3$): δ = 0.85 (*t, J* = 7 Hz, 3 H, CH_3CH_2), 1.22–1.56 (*m,* 22 H, CH_2), 1.23 (*t, J* = 7 Hz, 3 H, CH_3CH_2O), 1.60 (quint, *J* = 7 Hz, 2 H, CH_2CH_2-$COOCH_2CH_3$), 2.24 (*t, J* = 7 Hz, 4 H, $CH_2CD(O)CDCH_2$) 4.10 (*q, J* = 7 Hz, 2 H, $CH_2COOCH_2CH_3$). Mass spectrum (70 eV), *m/z* (%): 328 (<1) [M^+], 310 (<1) [$M^+ - H_2O$], 283 (3) [$M^+ - C_2H_5O$], 265 (2), 243 (7), 225 (2), 214 (9), 197 (4), 184 (28), 165 (10), 150 (11), 129 (27), 101 (80), 98 (40), 88 (100), 69 (68), 55 (99), 41 (63); d-content at C(11)/C(12): averaged 94.1%. The enantiomeric excesses (ee) were calculated as in Equation 1:

$$ee = \frac{E_1(\%) - E_2(\%)}{E_1(\%) + E_2(\%)} \quad [1]$$

(concentration of enantiomer E_1 > enantiomer E_2).

The microorganism *S. salmonicolor,* a carotinoid pigment-producing yeast, was obtained from the Deutsche Stammsammlung (Braunschweig, Germany). It is identical to the yeast ATCC 24259 of the American strain collection. The organism was cultured and stored (4°C) on wort agar-agar-slants. For metabolic experiments, the cells of the agar slants were transferred to a 1-L Erlenmeyer flask under sterile conditions, containing 200 mL of the following medium: 45 g/L sucrose, 5 g/L lactose, 3.0 g/L $MgSO_4 \cdot 7\,H_2O$, 2.5 g/L L-alanine, 2.5 g/L K_2HPO_4, 2.5 g/L $(NH_4)_2SO_4$, 0.1 g/L $CaCl_2 \cdot 2\,H_2O$ in deionized water. The cultures were incubated at 22–24°C on a horizontal shaker (100 rpm). After 96–120 h incubation (stationary growth phase of the organism tested by estimating the dry weight of the organisms), 250 mg (0.79 mmol) of racemic 9,10-d_2-methyl-(*Z*)-9,10-epoxyoctadecanoate and 250 mg (0.76 mmol) 9,10-d_2-ethyl-(*E*)-9,10-epoxyoctadecanoate were administered to different flasks of cultured *S. salmonicolor* during the stationary growth phase of the organisms. At certain times 10-mL aliquots of the culture broths were taken and extracted. The formation of degradation products was monitored by gas chromatography–mass spectrometry (GC–MS) analysis after methylation and silylation of the etheral extracts. Additional information to the feeding experiments, the sample work-up as well as the

NMR, achiral and chiral GC–MS studies were previously described (26,27).

RESULTS

Experiments with [9,10-$^2H_2$]-(Z)- and [9,10-$^2H_2$]-(E)-9,10-epoxyoctadecanoates. During the course of the fermentation, both substrates were metabolized to several deuterated dihydroxy-, hydroxyoxo-, hydroxyfatty acids and labeled γ-dodecalactone. These compounds were identified by their prominent fragment ions of their MS-spectra [α-cleavage before and after trimethylsilyl (TMS)-group rearrangement] and compared with available reference data (Table 1) (33). Except for the precursor, no epoxyfatty acids were detected.

The quantitative course of the metabolite formation is summarized in Figures 1 and 2. Both substrates were completely metabolized by 168 h. As main metabolic products, C_{14} and C_{12} dihydroxyfatty acids temporarily accumulated in the culture broths in concentrations of up to 52 mg/L. There were apparent differences between the product spectra obtained from both isomeric substrates. After adding the (*Z*)-isomeric precursor, significant amounts of labeled 5,6-, and 3,4-hydroxy-oxo fatty acids were formed by the yeast (up to 20 mg/L), carrying the oxo-functionality always in the latter position of the vicinal hydroxy/oxo group in the alkyl chain of the acids. After the addition of the (*E*)-isomer, these acids could only be detected as trace components (<100 μg/L). However, only in the experiment starting with the (*E*)-precursor, up to 30 mg/L of 9,10-dihydroxyoctadecanoate could be found in the fermentation broth of the organism, representing the product of the first metabolic step, the hydrolysis of the oxirane ring of the 9,10-epoxyoctadecanoate.

Labeled γ-dodecalactone was formed from both isomers of 9,10-epoxyoctadenoate by the yeast. This chiral compound was suitable to study stereochemical aspects of the present metabolic pathway(s) in more detail. The deuterated part of the lactone conserves stereochemical information in its labeling patterns and its enantiomeric composition and was accordingly analyzed by both achiral and chiral GC–MS (26,27).

As shown in Figures 1B and 2B as well as in Table 2, compared to the (*Z*)-configured isomer, the (*E*)-configured substrate was the better precursor of γ-dodecalactone [yield: (*Z*) = 0.2 mol% vs. (*E*) = 1.26 mol% after 168 h]. The relative amounts of one- and twofold deuterated γ-dodecalactone, which were significantly different from both experiments, appear to be even more interesting. The formation of high quantities of monodeuterated γ-lactone [about 40–50% of the labeled part after addition of (*Z*)-, and 20–25% after administration of (*E*)-epoxyoctadecanoate] reflects the partial loss of one deuterium during the biotransformation process of the epoxy acids to the lactone. The reason for this deuterium re-

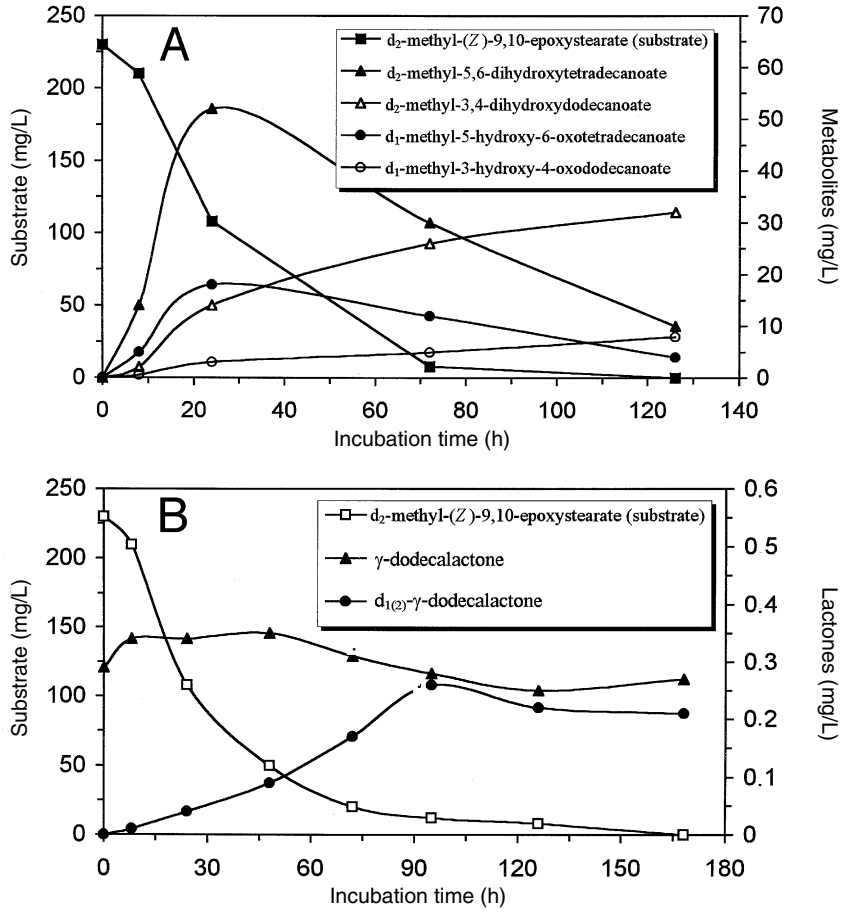

FIG. 1. Time-dependent course of the product formation after addition of 50 mg (250 mg/L) [9,10-$^2H_2$]-methyl-(*Z*)-9,10-epoxyoctadecanoate to 250-mL shaking-flask cultures of *Sporidiobolus salmonicolor* (stationary growth phase). (A) Substrate and hydroxyfatty acids as products; (B) substrate and lactonic products.

moval could be an oxidation/reduction step at the chirality center C-4 of the resulting lactone, comparable to the biosynthesis of δ-decalactone in *S. salmonicolor* (28). This hypothesis was confirmed by the finding that only this regioisomeric hydroxyoxofatty acid was formed by the yeast which carried the oxo-group at the latter C-atom of the vicinally arranged functional group in the carbon chain (Table 1).

More detailed information about the stereochemical course of this metabolic pathway to the γ-dodecalactone was obtained by the chiral GC–MS analysis of the isotopomeric lactones (Table 3). The enantiomeric distribution of the d_2-labeled lactone represents the initial stereochemical orientation of the latter hydroxy group (at C-10) after the ring-opening of the epoxide hydrolase and the subsequent β-oxidative degradation. Coming from the (*Z*)-configured substrate, the d_2-lactone was biosynthesized in 77.4% ee (*S*). When derived from the (*E*)-9,10-epoxystearate, the lactone occurred in the opposite configuration [86% ee (*R*)].

The only reasonable explanation of the loss of the label at the chirality center at C-4 of the lactone is the abstraction of a deuterium by a dehydrogenase or oxidase which formed the oxofatty acid. After another reduction step at this carbon, finally leading to the d_1-4-hydroxydodecanoic acid, the excreted d_1-labeled lactone product conserved the stereochemical specificity of this reductive enzymatic activity [The required cofactor(s) must have been protonated and not deuterated since the medium was based on H_2O. Consequently, one can discriminate between the stereospecificity of the two different pathways to d_2- and d_1-lactone]. Hence, the (*Z*)-precursor was metabolized to the (*R*)-configured d_1-γ-dodecalactone (47.2% ee) opposite to its d_2-isotopomer which occurred in the (*S*)-configuration. The d_1-labeled γ-dodecalactone from the (*E*)-configured substrate, on the other hand, was estimated to possess nearly the identical enantiomeric composition as its d_2-isomer [90.6% ee (*R*)], isolated from the same culture at the same time.

*Experiments with deuterated [11,12-$^2H_2$]-(*Z*)- and [11,12-$^2H_2$]-(*E*)-11,12-epoxyoctadecanoates*. The experiments with the racemic d_2-(*Z*)- and d_2-(*E*)-vaccenoates were performed in the same manner as described above. Again dihydroxy-, hydroxyoxo-, and hydroxyfatty acids as well as γ-decalactone as the corresponding lactone were identified as labeled metabolites from both incubation experiments (Table 4). The courses of the product formation are presented in Figures 3

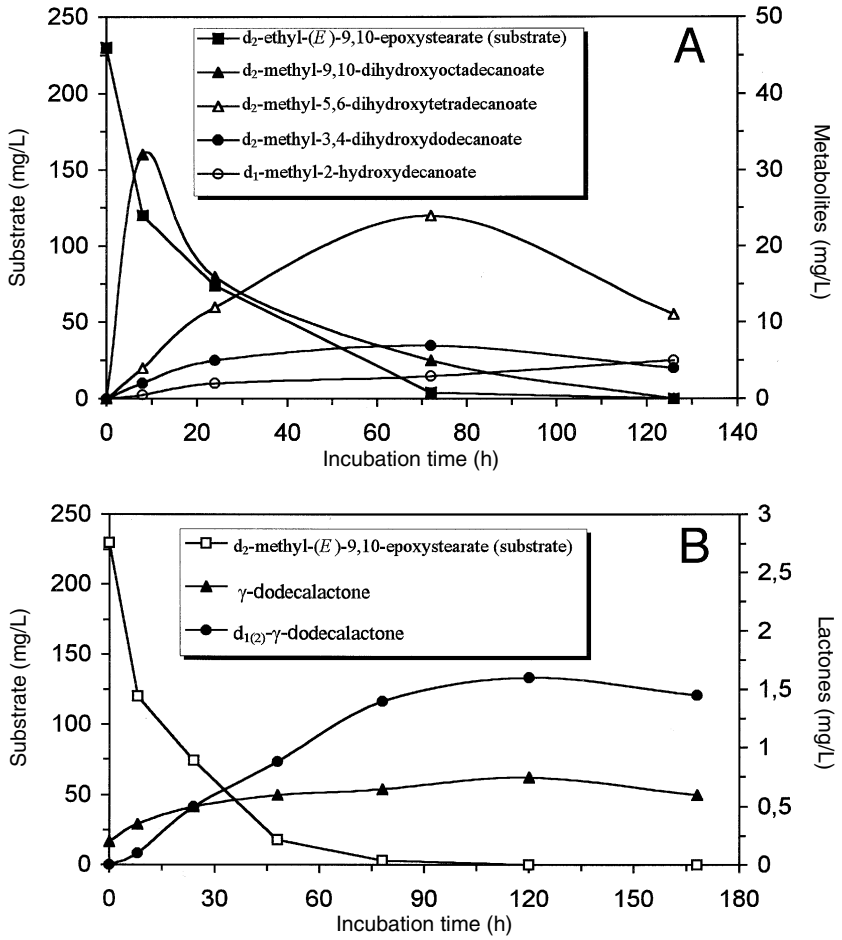

FIG. 2. Time-dependent course of the product formation after addition of 50 mg (250 mg/L) [9,10-$^2H_2$]-ethyl-(*E*)-9,10-epoxyoctadecanoate to 250-mL shaking-flask cultures of *Sporidiobolus salmonicolor* (stationary growth phase). For (A) and (B) see Figure 1.

and 4. The results are roughly comparable to those obtained from the epoxidized oleic and elaidic acid experiments. Once more the 5,6-dihydroxyfatty acids were detected in the highest concentration of all metabolic products excreted by the yeast (up to 64 mg/L); even hydroxy-oxo compounds could be identified in the cultures. As a consequence of the position of the epoxy group (C11/12) of the utilized precursors, this time labeled γ-decalactone was produced by *S. salmonicolor* as the lactonic compound. Comparable to the above-presented experiments, the (*E*)-configured epoxy acid was again the far better substrate for the production of γ-decalactone [yield: (*Z*) 0.46 mol%; (*E*) = 2.92 mol%) (Table 2)]. Accurate analytical estimation of the isotopomeric composition revealed that from both precursors mainly the double-labeled γ-decalactone was produced by the yeast. Nevertheless, the part of d_1-labeled γ-decalactone was obvious. The results of the chiral GC–MS analysis of the isotopomeric γ-decalactones are shown in Table 3. In contrast to the unlabeled γ-decalactone which was biosynthesized enantiomerically pure in its (*R*)-configuration, the deuterated isomers only occurred with moderate optical purity, each with an excess of the (*R*)-enantiomer.

DISCUSSION

The presented results allow us to gain a detailed insight into the metabolism of isomeric epoxyfatty acids in a yeast for the first time. Both enantiomers of all four isomeric substrates were metabolized, and their pathways could be successfully traced. Some common aspects of their degradation are obvious: (i) No chain-shortened epoxyfatty acids could be detected. Therefore, the first metabolic step of the pathway is the hydrolytic opening of the oxirane ring (accompanied by the hydrolysis of the ester group of the precursors), resulting in the formation of dihydroxyfatty acids. Consequently, this indirectly proves the existence of at least one epoxyhydrolase in *S. salmonicolor* which accepts epoxyoctadecanoates as substrates. (ii) Once included in the β-oxidation cascade, the C_{18}-dihydroxyfatty acids were successfully degraded by the separation of two, respectively three acetyl-CoA molecules and then released into the medium again (5,6- and 3,4-dihydroxyfatty acids accumulated in the highest concentration of all metabolites). For this reason, β-oxidation of these compounds appears to be the "bottleneck" of the metabolism in total. In contrast to the degradation of 4,5-dihydroxyalkanoic

[a]GC–MS, gas chromatography–mass spectrometry.

acids, which strictly accumulate in the culture broth as their 5-hydroxy-γ-lactones (no further metabolization) (30), obviously the 5,6- and the 3,4-dihydroxy compounds were introduced again in the β-oxidation cycle and were completely metabolized by *S. salmonicolor* at last. (iii) All of the four substrates served as precursors in the biosynthesis of deuterated γ-decalactone or γ-dodecalactone, respectively. The corresponding γ-lactones were excreted in relatively low amounts by *S. salmonicolor* (yields between 0.2–2.9 mol%). Apparently, the (*E*)-configured substrates were always the better precursors with respect to the lactone formation. (iv) No intermediates of the pathway from the 3,4-dihydroxy acids, the potential metabolic precursors of the γ-lactones, to the corresponding lactones could be detected [this is in contrast to the results of Albrecht and Tressl (29), who identified γ-dec-2-enolactone as an intermediate in the γ-decalactone formation from ethyl-3,4-epoxydecanoate in *S. salmonicolor*]. Here, we are not able to provide more information about the involved enzymatic steps from the 3,4-dihydroxy acids to the saturated γ-lactones.

Some additional remarks need to be made about points (iii) and (iv). The formation of the direct γ-lactone precursor 4-hydroxyfatty acid from the 3,4-dihydroxyfatty acid strongly depends on the metabolic sequence and the substrate affinity of the involved enzymes. A dehydration step of the 3-hydroxy group, leading to (*E*)-4-hydroxy-dec-2-enoic acid is known as a standard reaction step of the fatty acid biosynthesis. For that, the 3,4-dihydroxy compound must be transferred to an acyl carrier protein of the fatty acid biosynthesis cycle. After one enzymatic step (dehydration), it must be released again. Apart from this, the reduction of the Δ^2-double bond is not a very common reaction in yeasts. Consequently, it seems more likely that the cyclization of the 3,4-dihydroxy compounds, leading to the 3-hydroxy-γ-lactone, competes directly with the further β-oxidation of these compounds which will yield α-hydroxy acids.

The possibility of the enzyme-catalyzed dehydration of 3-hydroxy-γ-lactones to (*Z*)-γ-alk-2-enolactones and the further reduction to the saturated γ-lactone was established for yeasts by Fronza *et al.* (34) and Gatfield *et al.* (35). Therefore, it seems likely that *S. salmonicolor* uses the same biosynthetic pathway. One cycle of β-oxidation of the 3,4-dihydroxyfatty acid leads to 2-hydroxyacids (they could be detected in the broth of *S. salmonicolor* after adding the epoxyfatty acids). These compounds are not substrates for further β-oxidation. Fulco (36) could establish a decarboxylation (α-oxidation) of long-chain 2-hydroxyfatty acids in a *Saccharomyces* strain. Hence, α-oxidation in *S. salmonicolor* seems possible even

though there is no knowledge of α-oxidation occurring in microorganisms. Further examination is therefore still needed to explain the metabolic pathway of unusual oxygenated fatty acids.

However, besides the aspects of lactone biosynthesis, the presented results give access to a better understanding of the stereospecificity of the enzymes which are involved in the degradation of epoxyfatty acids. The stereochemical analysis of accumulated chiral lactones served as an advantageous approach for this purpose and is well established using chiral GC capillary columns with chemically modified cyclodextrin phases (37,38). The interpretation of the analytical data revealed the enantioselectivity of the epoxide hydrolase and the subsequent β-oxidation to the epoxyfatty acids. Therefore, it is worthwhile to discuss the results in detail here.

The d_1- and d_2-labeled parts of both γ-lactones were optically active, and each part was obtained having a different enantiomeric excess. These results prove the existence of at least one enantiodiscriminating step in the metabolic pathways of the racemic epoxides. Interestingly, the d_2-γ-dodecalactone synthesized from d_2-(*Z*)-9,10-epoxystearic acid had the opposite configuration [77.4% ee (*S*)] to the d_2-γ-dodecalactone isolated after adding d_2-(*E*)-9,10-epoxystearic acid [86.0% ee (*R*)]. This finding indicates that the enantioselectivity of this metabolic pathway depends on the stereochemical specificity of the epoxyhydrolase (provided that the β-oxidation enzymes involved react in the same stereochemical manner for both substrates). It seems that this enzyme depends strongly on the initial configuration (*E*- or *Z*-) of the

[2-$^2H_1$]-2-Hydroxyoctanoic acid[a]	232(14),188(48),104(16),98(15),89(50),73(100)

[a]Occurred accompanied with its unlabeled isotopomer; TMS, trimethylsilyl. See Table 1 for other abbreviation.

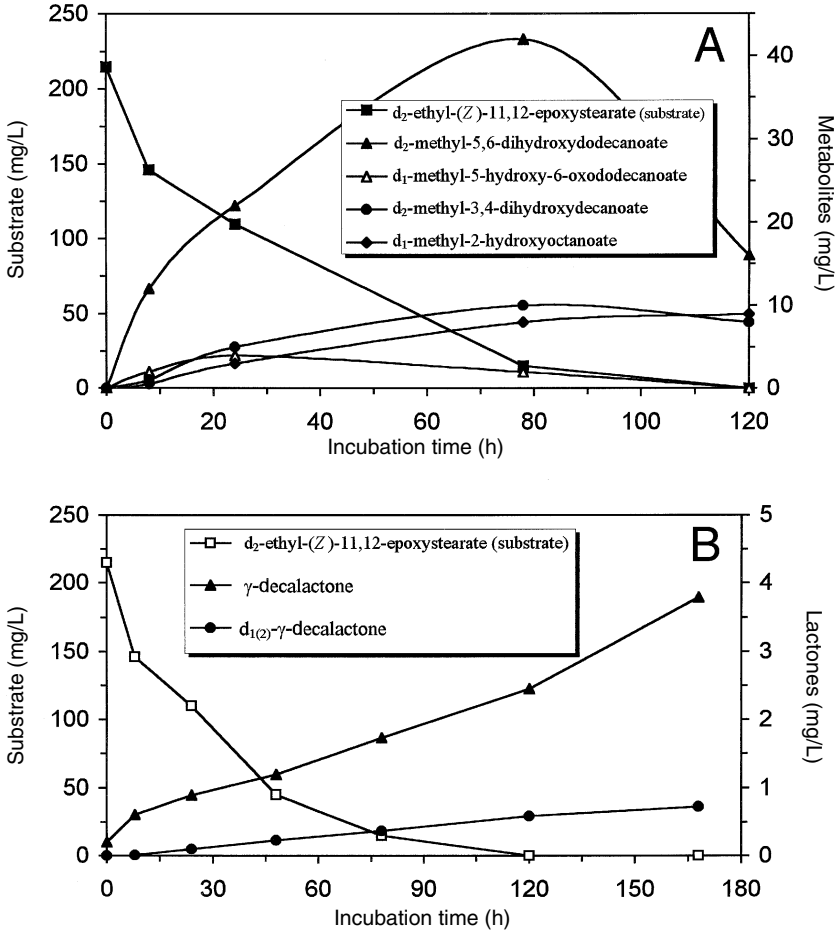

FIG. 3. Time-dependent course of the product formation after addition of 50 mg (250 mg/L) [11,12-$^2H_2$]-ethyl-(*Z*)-11,12-epoxyoctadecanoate to 250-mL shaking-flask cultures of *Sporidiobolus salmonicolor.* For (A) and (B) see Figure 1.

epoxy group in the substrates. Therefore, the epoxy groups of both enantiomers of the (*Z*)-substrate (*R*,*S*- or *S*,*R*-, respectively) were hydrolytically cleaved by a highly stereoselective attack of water at the (*R*)-9- or (*R*)-10-carbons to yield the (*S*,*S*)-9,10-dihydroxystearic acid enantiomer as intermediate. In the (*E*)-configured substrate, on the other hand, the water mainly either attacked the (*S*)-10- or the (*R*)-9-chirality center to produce the (*R*,*S*)-9,10-dihydroxystearic acid. This clearly demonstrates that in the case of the 9,10-epoxyfatty acids only one of the two stereocenters of each enantiomeric epoxy acid was attacked by a water molecule to cleave the oxirane ring (Fig. 5). Interestingly, these results are comparable with those of Schöttler and Boland (25) and Blée and Schuber (22) who found that the epoxide hydrolases of strawberries and soybeans introduce the water molecule (*S*)-specifically to racemic (*Z*)-9,10-epoxystearates. Therefore, epoxide hydrolases of different organisms seem to share common stereochemical features.

Discussing the results of the experiments with the epoxidized (*Z*)-, and (*E*)-vaccenic acids, one can say that these precursors follow the same metabolic sequence as the derivatives of oleic and elaidic acids. The 11,12-epoxystearates are also precursors for an important lactonic flavor compound in *S. salmonicolor*, the γ-decalactone. However, the analysis of the enantiomeric composition of the lactone revealed that these epoxyfatty acids are not the natural endogenous precursors of γ-decalactone. Unsupplemented cultures of *S. salmonicolor* and cultures fed with oleic acid produce exclusively the (*R*)-configured lactone [*via* an (*R*)-12-hydroxylation of oleic acid, followed by β-oxidation of the intermediate ricinoleic acid] (26). Therefore, the degradation of added epoxidized vaccenoates should be regarded as an "exogenously induced" pathway to both enantiomers of γ-decalactone in this yeast. Both biochemical pathways (*via* hydroxylation and epoxidation) to lactones should be discussed for future investigations, especially concerning the γ-decalactone biosynthesis in fruits and other microorganisms.

Nevertheless, these results obtained from the 11,12-epoxy isomers do not allow such an unambiguous interpretation of the stereochemical orientation of the metabolic pathway as for the 9,10-epoxy stearates. The d_2-γ-decalactone derived from (*Z*)-11,12-epoxystearic acid was analyzed to be nearly racemic [0.6% ee (*R*)], whereas the d_2-γ-decalactone isolated from cultured *S. salmonicolor,* fed with the (*E*)-isomer,

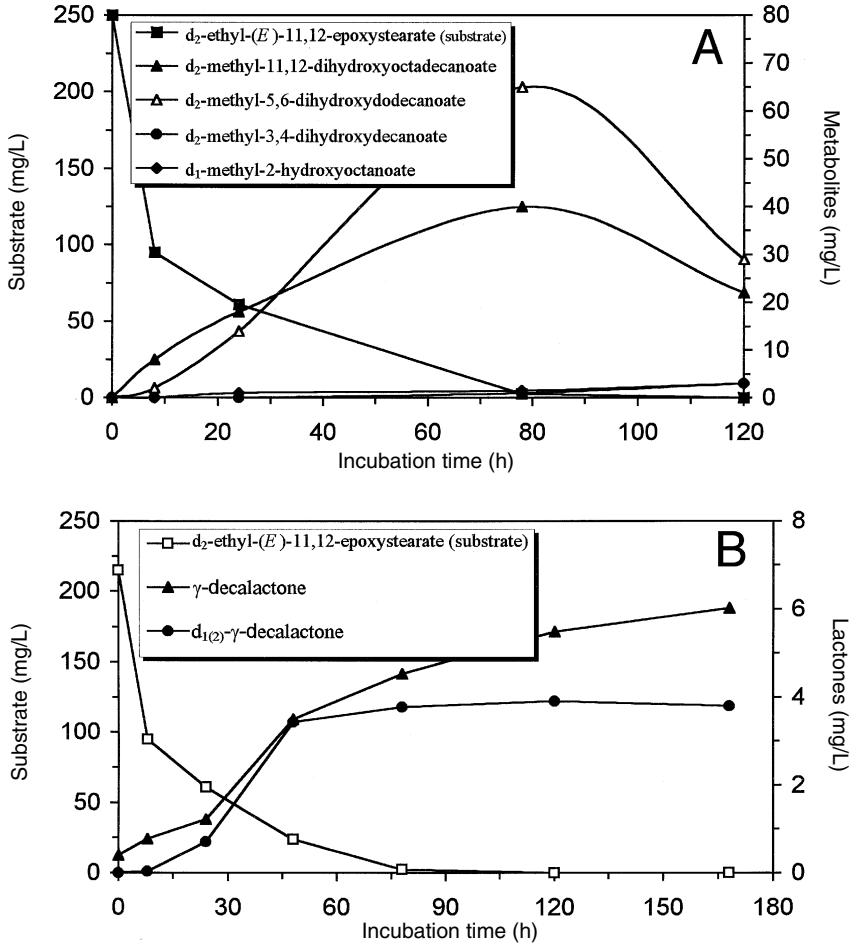

FIG. 4. Time-dependent course of the product formation after addition of 50 mg (250 mg/L) [11,12-$^2H_2$]-ethyl-(*E*)-11,12-epoxyoctadecanoate to 250-mL shaking-flask cultures of *Sporidiobolus salmonicolor*. For (A) and (B) see Figure 1.

showed only moderate optical purity [42.4% ee (*R*)]. Additional to the findings for the 9,10-epoxides, these results also clearly mark the dependency of the enantioselectivity of the epoxide hydrolase on the position of the epoxy group in the fatty acid chain.

The metabolism of the isomeric 9,10- and 11,12-epoxyoctadecanoic acids in the yeast *S. salmonicolor* is summarized in Scheme 1.

ACKNOWLEDGMENTS

The work was supported by AIF (Arbeitsgemeinschaft Industrieller Forschung), Köln, Germany. We thank Hans Köppler for his exceptional work in doing mass spectrometric analysis. We are also very grateful to Dr. R. Schäfer and Prof. Dr. D. Rewicki (Institut für Organische Chemie, Freie Universität Berlin) for their support in NMR spectroscopic analysis.

ABSTRACT: We have examined the biosynthetic pathway of triacylglycerols containing ricinoleate to determine the steps in the pathway that lead to the high levels of ricinoleate incorporation in castor oil. The biosynthetic pathway was studied by analysis of products resulting from castor microsomal incubation of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine, the substrate of oleoyl-12-hydroxylase, using high-performance liquid chromatography, gas chromatography, mass spectrometry, and/or thin-layer chromatography. In addition to formation of the immediate and major metabolite, 1-palmitoyl-2-[^{14}C]ricinoleoyl-*sn*-glycero-3-phosphocholine, ^{14}C-labeled 2-linoleoyl-phosphatidylcholine (PC), and ^{14}C-labeled phosphatidylethanolamine were also identified as the metabolites. In addition, the four triacylglycerols that constitute castor oil, triricinolein, 1,2-diricinoleoyl-3-oleoyl-*sn*-glycerol, 1,2-diricinoleoyl-3-linoleoyl-*sn*-glycerol, 1,2-diricinoleoyl-3-linolenoyl-*sn*-glycerol, were also identified as labeled metabolites in the incubation along with labeled fatty acids: ricinoleate, oleate, and linoleate. The conversion of PC to free fatty acids by phospholipase A_2 strongly favored ricinoleate among the fatty acids on the *sn*-2 position of PC. A major metabolite, 1-palmitoyl-2-oleoyl-*sn*-glycerol, was identified as the phospholipase C hydrolyte of the substrate; however, its conversion to triacylglycerols was blocked. In the separate incubations of 2-[^{14}C]ricinoleoyl-PC and [^{14}C]ricinoleate plus CoA, the metabolites were free ricinoleate and the same triacylglycerols that result from incubation with 2-oleoyl-PC. Our results demonstrate the proposed pathway: 2-oleoyl-PC → 2-ricinoleoyl-PC → ricinoleate → triacylglycerols. The first two steps as well as the step of diacylglycerol acyltransferase show preference for producing ricinoleate and incorporating it in triacylglycerols over oleate and linoleate. Thus, the productions of these triacylglycerols in this relatively short incubation (30 min), as well as the availability of 2-oleoyl-PC *in vivo*, reflect the *in vivo* drive to produce triricinolein in castor bean.

Lipids 33, 59–69 (1998).

Ricinoleate has many industrial uses; however, the only commercial source of ricinoleate, castor (*Ricinus communis* L.) bean, contains the toxin ricin and potent allergens that pose serious health hazards to growers and processors. Because of the potential danger of these components in harvest and processing, it is desirable to produce ricinoleate in an oilseed of a transgenic plant lacking these components. The cDNA for oleoyl-12-hydroxylase, the key enzyme in the biosynthesis of ricinoleate, has recently been cloned (1). Expression of this enzyme in transgenic plants resulted in low levels of hydroxy fatty acids (2) compared to castor oil (20% vs. 90% ricinoleate in castor). It is therefore important to maximize expression of the hydroxylase and optimize incorporation of ricinoleate into triacylglycerols to develop transgenic plants that produce higher levels of ricinoleate. To accomplish this, it is essential to determine which enzymatic steps drive ricinoleate into triacylglycerols. It is also crucial to determine how the oleate supply is maintained for oleoyl-12-hydroxylase, since the final oil contains 5% or less of oleate.

In order to optimize incorporation of ricinoleate into triacylglycerols in a transgenic plant, the biosynthetic pathway of triricinolein must be known. Bafor *et al.* (3) proposed the biosynthetic pathway of triricinolein from microsomal incubations of oleoyl-CoA which is rapidly incorporated into 2-oleoyl-phosphatidylcholine (PC), the proposed substrate of oleoyl-12-hydroxylase (4). We report here the identifications of some intact metabolites of 2-oleoyl-PC, including the immediate metabolite of oleoyl-12-hydroxylase, 2-ricinoleoyl-PC, free ricinoleate and triacylglycerols containing rici-

noleate, using high-performance liquid chromatography (HPLC) of intact lipids, demonstrating the major biosynthetic pathway to triricinolein. We also report the identification of enzymatic steps which drive ricinoleate into triacylglycerols. The key enzyme in the pathway, oleoyl-12-hydroxylase, has been characterized recently using both 2-oleoyl-PC (5) as immediate substrate and oleoyl-CoA (6) which is the acyl donor for biosynthesis of the substrate, 2-oleoyl-PC (3,4).

EXPERIMENTAL PROCEDURES

Microsomal incubation. Microsomes from castor bean were prepared as described previously (5). In order to keep the enzymes active after the microsomes were thawed for use in incubations, antipain-dihydrochloride (5 μg/mL; Boehringer Mannheim Corp., Indianapolis, IN) was added to the extraction buffer and microsome suspension buffer during microsomal preparation. The microsomal incubation mixture included in a total volume of 1 mL was: sodium phosphate (0.1 M, pH 6.3), NADH (0.5 mol), ATP (0.5 μmol), $MgCl_2$ (0.5 μmol), catalase (1000 units), and microsomal fraction of endosperm from immature castor bean (15 μL, 138 μg of protein). The radioactive substrate, 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (0.125 μCi, 2.16 nmol, 58.0 Ci/mol; DuPont NEN, Boston, MA) in 20 μL of ethanol was added last into a screw- capped tube followed by immediate mixing. The mixture was then incubated in a shaking water bath for 30 min at 22°C. The incubation was stopped by addition of 3.75 mL of chloroform/methanol (1:2, vol/vol). The mixture was again mixed with 0.63 mL of chloroform and 0.63 mL of water. The lower chloroform layer containing the lipid extract was dried and fractionated on a silica HPLC system for the separation of lipid classes described here. The radioactive 2-ricinoleoyl-PC was prepared by a microsomal incubation of 2-[1-^{14}C]oleoyl-PC up to 48 times the incubation mixture given above (48 × volume). Then the PC fraction obtained was purified by the C_8 HPLC system described here to obtain radioactive 2-ricinoleoyl-PC. In the study of metabolism of free ricinoleate, radioactive ricinoleate was added to the incubation (1 h) in place of radioactive 2-oleoyl-PC as described here, and CoA (0.5 μmol) also was added to the incubation. Radioactive ricinoleate was prepared by the castor microsomal incubation of radioactive oleoyl-CoA (6), hydrolysis by sodium hydroxide, and purification by C_{18} HPLC system of free fatty acids (FFA) (7). For the purpose of identifying the fatty acid constituents of intact lipids, lipid extracts were hydrolyzed and methylated in 5% HCl/methanol (1 mL) at 80°C for 1 h. The fatty acid methyl esters (FAME) formed were extracted with 2 × 1 mL of hexane.

HPLC. Different HPLC systems were carried out as described previously (5). Radioactive lipids were separated by HPLC and identified by cochromatography with lipid standards. The flow rates of eluents of different HPLC systems were 1 mL/min. Different HPLC systems provided separations for various products as follows:

(i) Separation of lipid classes: Lipid classes were separated according to Singleton and Stikeleather (8) by a silica column (25 × 0.46 cm, 5 μm, Spherisorb S5W; Phase Separations, Norwalk, CT) with a linear gradient starting at isopropanol/hexane (4:3, vol/vol) to isopropanol/hexane/water (4:3:0.75, by vol) in 20 min, then isocratically for 15 min. A Pre-Sat silica saturation column (25 × 0.46 cm; Alltech Associates Inc., Deerfield, IL) was installed between the pump and injector to saturate the mobile phase with silica before it reached the analytical column. Free phosphatidylglycerol (PG), cardiolipin, phosphatidylinositol (PI), and phosphatidic acid standards were obtained by acidification of their salts (Sigma Chemical Co., St. Louis, MO) with HCl.

(ii) Separation of PC molecular species: PC molecular species were separated by a C_8 column (25 × 0.46 cm, 5 μm, Ultrasphere C8; Beckman Instruments Inc., Fullerton, CA) with a linear gradient of 90–100% methanol (containing 0.1% of conc. NH_4OH) in 40 min. A Pre-Sat silica saturation column was installed between the pump and injector to prevent the rapid deterioration of the C_8 column by the pH 9.5 mobile phase.

(iii) Separation of FAME: FAME were separated in the same manner as we previously described (5) using a short C_{18} column (5 × 0.46 cm, 3 μm, Microsorb MV; Rainin Instrument Co. Inc., Woburn, MA) to save time. A linear gradient of 90–100% methanol in 15 min was used for 10 min. For the purpose of identifying the FAME, a regular C_{18} column (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman) was used (7) with a linear gradient of 90–100% methanol in 40 min.

(iv) Separation of FFA: FFA were separated as we reported previously (7) using a C_{18} column (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman) with a linear gradient of 85–100% methanol (containing 0.05% HAc as ion suppressor) in 40 min.

(v) Separation of acylglycerol molecular species: Acylglycerol molecular species (triacylglycerols and diacylglycerols) were separated by the use of a C_{18} column (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman) with a linear gradient starting at 100% methanol to 100% isopropanol in 40 min as we have reported (9). Another linear gradient (9) starting at 100% methanol to methanol/isopropanol (50:50) in 40 min was used for the identification of 1,2-dioleoyl-*sn*-glycerol.

Mass spectrometry (MS) by fast atom bombardment (FAB). Lipids were applied to the probe of a Jeol HX-110 double-focusing instrument (Tokyo, Japan). Glycerol was added to the sample to create optimal conditions for FAB ionization. FAB ionization was performed using xenon gas at 6 keV. Ions were accelerated out of the ion source at 10 kV. Both positive and negative ion acquisitions were obtained with the exception of only negative-ion acquisitions obtained for PI since this compound gave no signal in the positive mode. Mass ranges scanned were 400–1300 daltons for positive-ion and 200–1300 daltons in the negative-ion mode. Scan speed was 5 s per decade. Ion source temperature was maintained at 37°C.

Identification of FAME by gas chromatography (GC) and GC–MS. All FAME were tentatively identified and quantitated with an HP6890 gas chromatograph (Hewlett-Packard Co., San Fernando, CA) and identities were confirmed by GC–MS using an HP5970A quadrupole-based mass selective detector as previously described (10). Data were analyzed

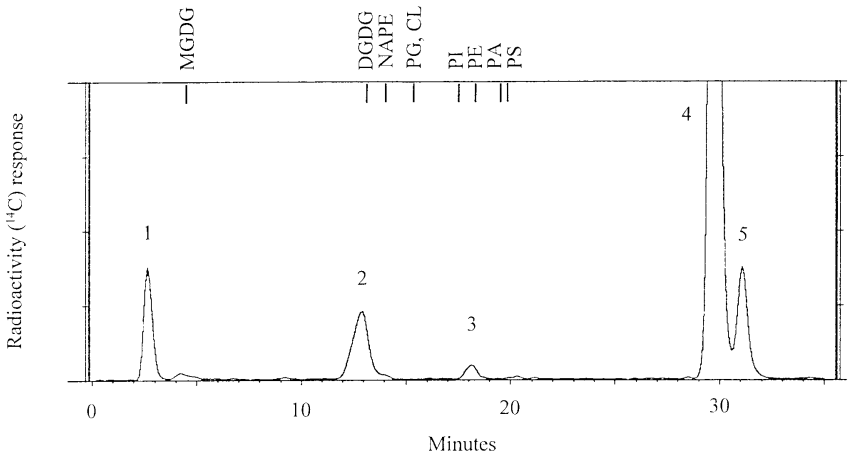

FIG. 1. Separation of lipid classes of total lipid extract from the castor microsomal incubation with 2-[^{14}C]oleoyl-phosphatidylcholine (PC) using a silica high-performance liquid chromatography (HPLC) system (see the Experimental Procedures section, HPLC, i). The radioactive peaks were: (1) acylglycerols and free fatty acids (FFA), retention time 2.7 min; (2) unknown, 13.0 min; (3) phosphatidylethanolamine (PE), 18.2 min; (4) PC, 29.8 min; (5) 2-ricinoleoyl-PC, 31.1 min. Retention times of other lipid classes in this HPLC system are also shown in the figure. MGDG, monogalactosyl diacylglycerol; DGDG, digalactosyl diacylglycerol; NAPE, *N*-acyl-phosphatidylethanolamine; PG, phosphatidylglycerol; CL, cardiolipin; PI, phosphatidylinositol; PA, phosphatidic acid; PS, phosphatidylserine.

using Hewlett-Packard MS ChemStation (DOS series) software (HP G1034C).

Thin-layer chromatography (TLC) of phospholipids and glycolipids. Phospholipids were separated by TLC on silica gel plates which were first immersed in 100 mM ammonium sulfate and dried for 1.5 h at 120°C. Samples were applied to the plates in a spotting chamber. Separation was with the solvent system 1-propanol/chloroform/propanoic acid/0.1%(wt/vol) KCl (3:2:2:1, by vol). Glycolipids were separated on a silica gel plate in the solvent system chloroform/methanol/conc. ammonia (13:5:1, by vol). Bands containing lipids to be analyzed were routinely localized by iodine staining. Lipids were identified by co-migration with standards and by specific spray reagents (11). The radioactivity was localized by autoradiography with Kodak X-Omat AR film (Eastman Kodak Co., Rochester, NY).

RESULTS AND DISCUSSION

It is generally accepted that oleoyl-12-hydroxylase catalyzes the reaction from 2-oleoyl-PC to 2-ricinoleoyl-PC in castor bean. We have previously (5) used the putative substrate, 2-oleoyl-PC, to characterize oleoyl-12-hydroxylase in microsomes from the endosperm of immature castor bean. In the previous study (5), the enzyme activity of oleoyl-12-hydroxylase was determined by the radioactivity of total ricinoleate after methanolysis of total lipid in the incubation. In this report, the intact lipid metabolites of 2-[^{14}C]oleoyl-PC have been identified, and the incorporation of radiolabel in each metabolite has been quantified in order to follow the label through the biosynthetic pathway of triacylglycerols containing ricinoleate.

The castor microsomal incubation of 2-[^{14}C]oleoyl-PC was performed as previously described (5). Figure 1 shows the radiochromatogram of the separated lipid classes from the total lipid extract of the incubation. By using standards, the radioactive peaks in Figure 1 were identified as follows: peak 1: acylglycerols (neutral lipids) and FFA, 2.7 min (retention time), 6% of total radioactivity; peak 2: unknown, 13.0 min, 7%; peak 3: phosphatidylethanolamine (PE), 18.2 min, 1%; peak 4: PC, 29.8 min, 78%; peak 5: 2-ricinoleoyl-PC, 31.1 min, 8%. Many standards of lipid classes were used for identifications as shown in Figure 1. Radioactive peak 2 in Figure 1 corresponded to digalactosyl diacylglycerol (DGDG) or *N*-acyl-PE (NAPE) on this HPLC system; however, it did not correspond to DGDG or NAPE on TLC. DGDG is synthesized from diacylglycerols by galactosylacyltransferases located in the plastid envelope (12), and NAPE is synthesized from PE and FFA by microsomal NAPE synthase (13). We have not yet identified the radioactive peak 2 in Figure 1.

Radioactive peak 3 in Figure 1 was identified as PE (tentatively) by HPLC retention time and TLC. However, the MS of this fraction [17.0–19.0 min in Fig. 1 which included PE and phosphatidylinositol (PI)] indicated the presence of PI. The FAB(–) showed the molecular ions, M – H (834 – 1 and 836 – 1), with their relative abundances at *m/z* 833 (52%) and 835 (27%) which correspond to 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoinositol and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoinositol, respectively. Other ions shown were *m/z* 671 (11%, M – 163 inositol), 571 (18%, M – 263 linoleoyl), 299 (40%, M – palmitoyl – linoleoyl), 281 (35%, oleoyl), 279 (60%, linoleoyl), 255 (100%, palmitoyl). The MS of peak 3 did not indicate the presence of PE. PE and PI were well separated by TLC as ammonium salts [with their

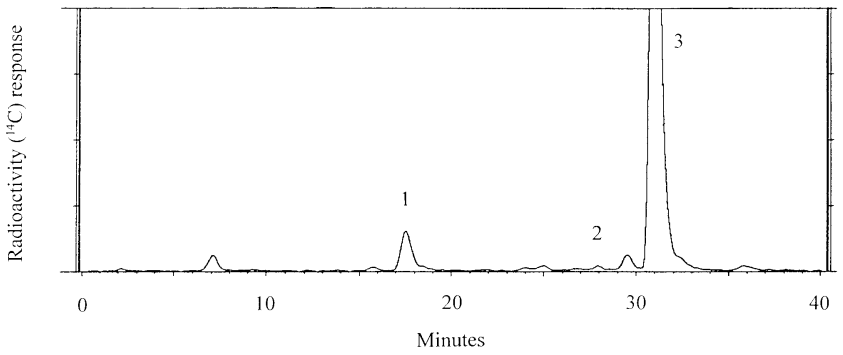

FIG. 2. Purification of 2-[^{14}C]ricinoleoyl-PC (peak 1), using a C_8 HPLC system (see the Experimental Procedures section, HPLC, ii). Radioactive peaks were: (1) 1-palmitoyl-2-ricinoleoyl-PC, 17.6 min; (2) 1-palmitoyl-2-linoleoyl-PC, 28.0 min; (3) 1-palmitoyl-2-oleoyl-PC, 31.0 min. See Figure 1 for abbreviations.

retention factor (R_f) values of 0.47 and 0.23, respectively] while HPLC did not resolve the free acids well. PE was radioactive on TLC, and its amount was not high enough to be detected by MS, while PI was not radioactive on TLC, and could be detected by MS. The radioactive peak 3 in Figure 1 thus contained radioactive PE together with unlabeled PI. Thus, the labeled 2-oleoyl-PC was metabolized in part to PE, but not to PI. The labeled PE could be derived from labeled diacylglycerols which were abundant in this incubation (as shown in Scheme 1) by CDP-ethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase in castor microsomes (14). The labeled PE also could be synthesized in castor microsomes by a base group exchange reaction (15). The biosynthesis of radioactive PI in this incubation was unlikely (16).

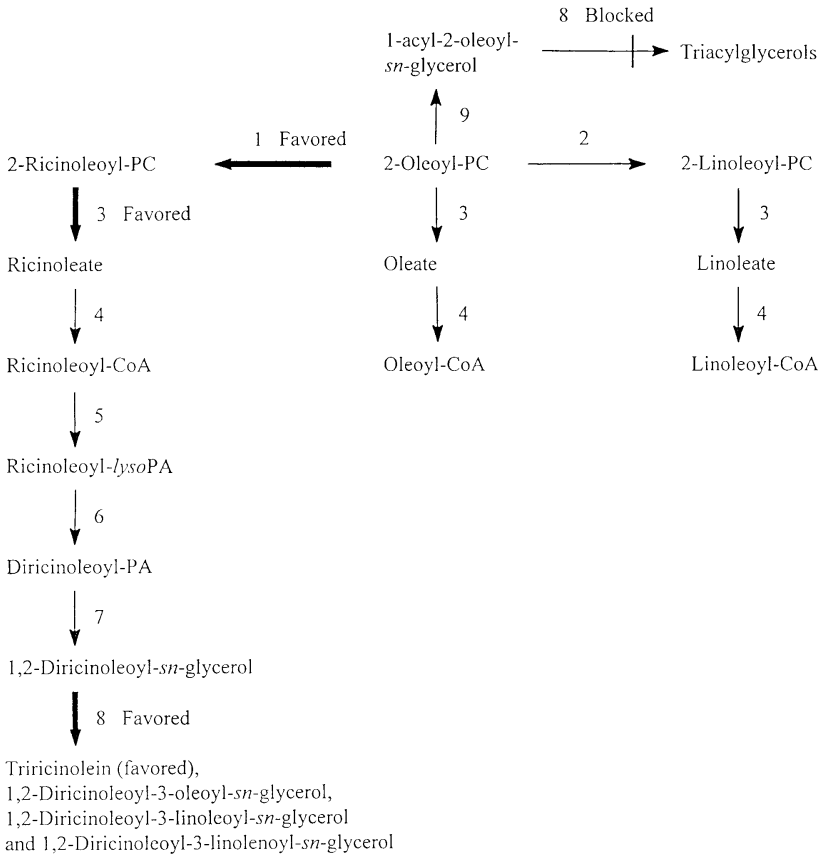
Since there was no 2-ricinoleoyl-PC standard available to us, peak 5 in Figure 1 was identified as follows. Half-minute fractions of radioactive peaks 4 and 5 in Figure 1 were collected and then hydrolyzed and methylated. HPLC of the radioactive FAME obtained showed that the radioactive peaks 4 and 5 on Figure 1 corresponded to 2-oleoyl-PC and 2-ricinoleoyl-PC, respectively. About 1% of peak 4 corresponded to radioactive 2-linoleoyl-PC. The radioactive peak 5, 2-ricinoleoyl-PC, was further purified by C_8 HPLC as shown in Figure 2. The radioactive peak 1 (19.8 min) in Figure 2 appeared to be 1-palmitoyl-2-ricinoleoyl-*sn*-glycero-3-phosphocholine by MS. A molecular weight of 776 was shown in MS of FAB(+). The MS of FAB(−) showed the characteristic negative ion of PC, 761 ($M - CH_3^-$). The hydrolysis of peak 1 in Figure 2 by phospholipase A_2 (from *Naja mocambique mocambique,* Sigma P-4034) showed the presence of free [^{14}C]ricinoleate by HPLC in the incubation product. We have thus identified 1-palmitoyl-2-[^{14}C]ricinoleoyl-*sn*-glycero-3-phosphocholine as the metabolite of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine by oleoyl-12-hydroxylase in castor microsomes. Since we have previously used 2-oleoyl-PC as the substrate of oleoyl-12-hydroxylase in the castor microsomal incubation (5) and we now identify its immediate metabolite, we have thus proved that 1-acyl-2-oleoyl-*sn*-glycero-3-phosphocholine is the substrate of oleoyl-12-hydroxylase in castor bean. Ricinoleate was mainly or completely made at the *sn*-2 position (3).

The only metabolites (fatty acids) of oleate from the *sn*-2 position of 2-oleoyl-PC were identified previously as ricinoleate and linoleate (5). Radioactive lipid classes shown in Figure 1 were hydrolyzed and methylated, and the FAME formed were separated by HPLC on a 5-cm, C_{18} column which resolves the three labeled FAME (5). All lipid classes contained radioactive ricinoleate, linoleate, and oleate. The distribution of labeled fatty acids in each lipid class is shown in Table 1. The PC fraction shown in Table 1 was the combination of radioactive peaks 4 and 5 in Figure 1 which included 2-oleoyl-PC (the substrate), 2-ricinoleoyl-PC, and 2-linoleoyl-PC. 2-Ricinoleoyl-PC was the major immediate metabolite of 2-oleoyl-PC. In the microsomal incubation, the conversion of PC to acylglycerols (neutral lipids) and FFA strongly favored ricinoleate among the three fatty acids on the *sn*-2 position of PC as shown by others (17). The incorporation of radioactivity into PE also showed preference for ricinoleate. Thus, the biosynthesis of PE likely occurred from the radioactive 1,2-diacyl-*sn*-glycerols shown in Scheme 1 by CDP-ethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase (14). Since 1,2-diacyl-*sn*-glycerols were enriched

TABLE 1
Radioactive Fatty Acid Composition of Lipid Classes and Acylglycerols from the Castor Microsomal Incubation of 2-[^{14}C]Oleoyl-PC[a]

Lipid classes and acylglycerols	Ricinoleate	Linoleate	Oleate
PC	6	3	91
PE	52	4	44
Unknown	6	4	90
Acylglycerols and FFA	63	7	30
FFA	73	5	22
Triricinolein	100	0	0
Diricinoleoyl-linolenoyl-glycerol	100	0	0
Diricinoleoyl-linoleoyl-glycerol	96	4	0
Diricinoleoyl-oleoyl-glycerol	93	0	7
1-Palmitoyl-2-oleoyl-*sn*-glycerol	0	0	100

[a]PC, phosphatidylcholine; PE, phosphatidylethanolamine; FFA, free fatty acid.



SCHEME 1

in ricinoleate, they were mostly formed after the enzymatic action of oleoyl-12-hydroxylase and phospholipase A_2 which provide ricinoleate for 1,2-diacyl-*sn*-glycerol. 1,2-Diacyl-*sn*-glycerols can also be formed by phospholipase C hydrolysis of the three labeled PC shown in Scheme 1, but this reaction is unlikely since 1-palmitoyl-2-oleoyl-*sn*-glycerol was identified as the major labeled metabolite (Fig. 5) while 1-palmitoyl-2-ricinoleoyl-*sn*-glycerol and 1-palmitoyl-2-linoleoyl-*sn*-glycerol were not identified. The biosynthesis of PE was unlikely from the base exchange reaction (15), incorporating free ethanolamine into PE, because the base exchange reaction would likely reflect the fatty acid composition of PC and thus not favor ricinoleate. The incorporation of label in the unknown peak 2 (Fig. 1) showed no fatty acid preference. The unknown peak 2 (Fig. 1) contained the unchanged diacylglycerol portion of PC which might be derived from PC by phospholipase C or D (18).

Radioactive FFA in the fraction of acylglycerols and FFA in Figure 1 (peak 1, 2–5 min) were identified by the C_{18} HPLC system for the separation of FFA as shown in Figure 3. Free ricinoleate, linoleate, and oleate were identified by HPLC cochromatography with the standards. The FFA represented about 23% of the radioactivity in this fraction, and the percentage radioactivity of each FFA shows that phospholipase A_2 favored release of ricinoleate (Table 1). Although the release of oleate was not favored in this study, it was much higher than that of previous studies (3,17) which showed that ricinoleate was specifically released from PC in castor microsomes.

The fraction of acylglycerols and FFA in Figure 1 (peak 1, 2–5 min) was cochromatographed with castor oil by the C_{18} HPLC system to separate molecular species of acylglycerols as shown in Figure 4. The radioactive triacylglycerols (peaks 1–4 in Fig. 4C) identified were the four major triacylglycerols in castor oil shown in Figure 4A, triricinolein (peak 1, the main triacylglycerols in castor oil, 8.5% of the total radioactivity in the fraction of acylglycerols and FFA), diricinoleoyl-linolenoyl-glycerol (peak 2, 0.8%), diricinoleoyl-linoleoyl-glycerol (peak 3, 4.0%), and diricinoleoyl-oleoyl-glycerol (peak 4, 11.9%). The four major triacylglycerols in castor oil (peaks 1–4, Fig. 4A) were identified by GC and GC–MS of the FAME after methanolysis of these peaks. The radioactive peak 5 in Figure 4C at the retention time of 2.9 min corresponded to free ricinoleate and was about 16% of the total radioactivity in the fraction of acylglycerols and FFA. The radioactive peaks of free linoleate (3.5 min) and oleate (4.5 min) were not detectable in Figure 4C, and were masked by other radioactive peaks as shown in Figure 4C.

Radioactive peak 6 in Figure 4C with retention time 17.3 min, the largest radioactive peak representing 23% of the total radioactivity in the fraction of acylglycerols and FFA (peak 1, Fig. 1), did not correspond to any acylglycerols and FFA detectable in castor oil (Fig. 4A) and castor microsomes (Fig.

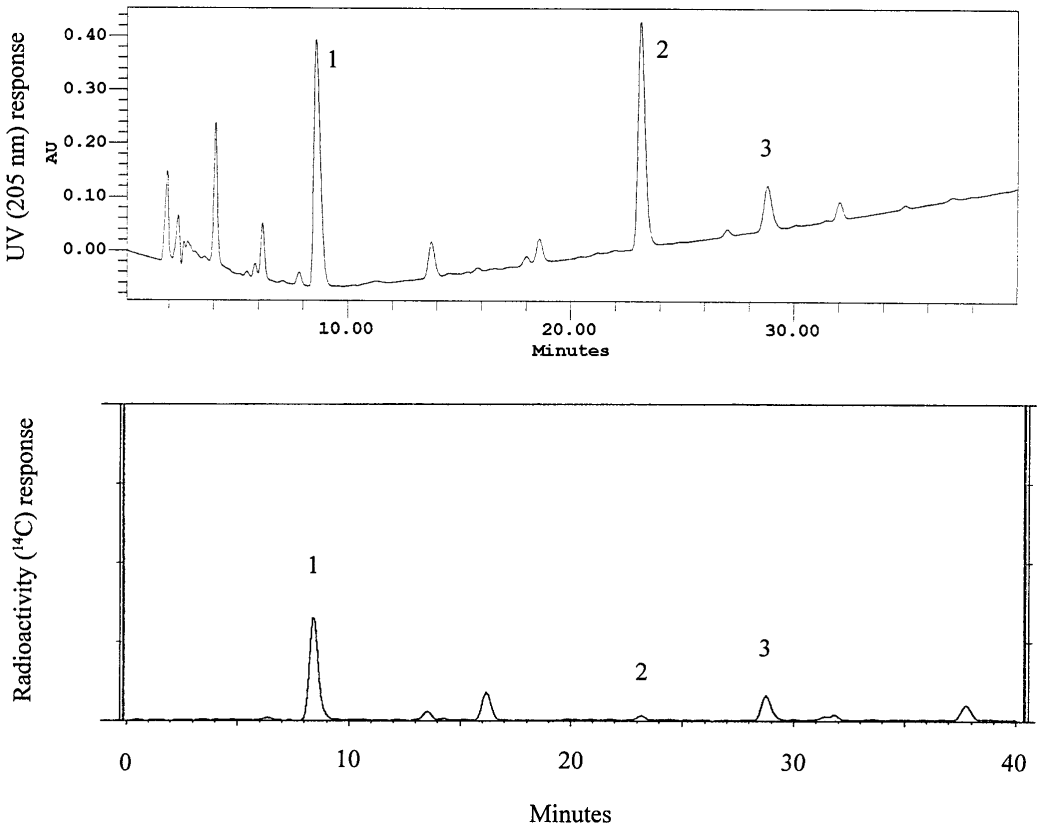


FIG. 3. HPLC identification of radioactive FFA in the fraction of acylglycerols and FFA (peak 1, Fig. 1) from the castor microsomal incubation of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine, using a C_{18} HPLC system (see the Experimental Procedures section, HPLC, iv). The sample was cochromatographed with free ricinoleate (10 μg), linoleate (10 μg), and oleate (5 μg). The radioactive peaks were: (1) ricinoleate, 8.57 min ; (2) linoleate, 23.12 min; (3) oleate, 28.82 min. UV, ultraviolet. See Figure 1 for other abbreviations.

4B). The HPLC of the FAME of peak 6 in Figure 4C after methanolysis showed that the only radioactive fatty acid was oleate. However, the GC showed equal amounts of palmitate and oleate only. The radioactive peak 6 in Figure 4C was coeluted with 1,2-dioleoyl-*sn*-glycerol as shown in Figure 5 using the linear gradient of 100% methanol to methanol/isopropanol (50:50) in 40 min. We have recently reported the HPLC of 45 synthetic diacylglycerols and triacylglycerols (9). The relative retention times of 1,3-dioleoyl-glycerol and 1,2-dioleoyl-*sn*-glycerol were 18.67 and 18.95 min, respectively, and they can be resolved by this HPLC system. The relative retention time of 1,2-dipalmitoyl-*sn*-glycerol was 18.97 min and was almost exactly the same as that of 1,2-dioleoyl-*sn*-glycerol. Even though we do not have the standard of 1-palmitoyl-2-oleoyl-*sn*-glycerol, it should be coeluted with 1,2-dioleoyl-*sn*-glycerol; and the radioactive peak 6 of Figure 4 was identified as 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycerol, the product of substrate hydrolysis by phospholipase C in castor microsomes. This labeled product also coeluted with 1,2-dioleoyl-*sn*-glycerol in the HPLC system of Figure 5. We can thus infer that phospholipase C activity toward PC is present in castor bean. The neutral metabolites (triacylglycerol) of 1-palmitoyl-2-oleoyl-*sn*-glycerol which eluted after 1-palmitoyl-2-oleoyl-*sn*-glycerol were minor, if any, as shown in Figure 4C. The minor radioactive peaks in Figure 4C were not identified. The unidentified radioactive peaks in Figure 4C might be triacylglycerols and diacylglycerols containing labeled ricinoleate, oleate, and/or linoleate.

Increasingly longer microsomal incubations with 2-[1-^{14}C]oleoyl-PC, up to 2 h, showed as in Figure 6 continuous increases in the labeling of acylglycerols and FFA (peak 1 of Fig. 1, including triricinolein), of the unknown (peak 2 of Fig. 1), and of PE (peak 3 of Fig. 1). However, radioactive 2-ricinoleoyl-PC (peak 5 of Fig. 1) was maximal at 30 min. Clearly, 2-ricinoleoyl-PC is an intermediate in the metabolic pathway. To further corroborate this, microsomal incubation of the radioactive 2-ricinoleoyl-PC showed the labeled metabolites, free ricinoleate, triricinolein, 1,2-diricinoleoyl-3-linoleoyl-*sn*-glycerol, and 1,2-diricinoleoyl-3-oleoyl-*sn*-glycerol as shown in Figure 7. Radioactive peak 6 in Figure 7 corresponded to 1-palmitoyl-2-oleoyl-*sn*-glycerol which was the same as peak 6 in Figure 4. Its origin needs to be investigated. 1-Palmitoyl-2-oleoyl-*sn*-glycerol was the hydrolyte of 2-oleoyl-PC by phospholipase C in the incubation.

Incubation with radioactive free ricinoleate also showed the incorporation of ricinoleate into triacylglycerols. The HPLC

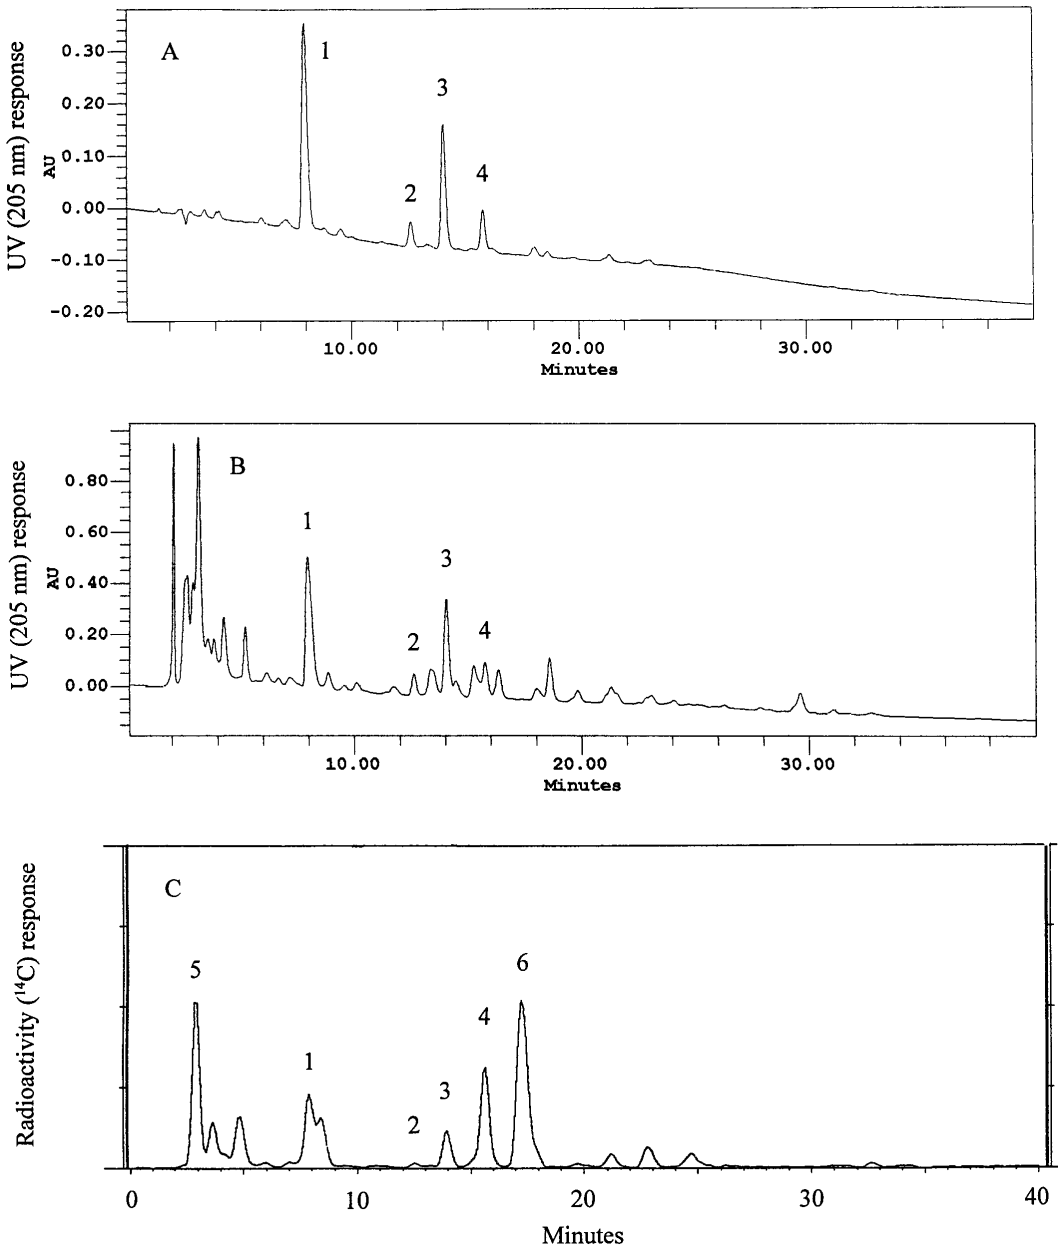

FIG. 4. HPLC identification of radioactive triacylglycerols in the fraction of acylglycerols and FFA (peak 1, Fig. 1) from the castor microsomal incubation of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine, using a C_{18} HPLC system (see the Experimental Procedures section, HPLC, v). A linear gradient from 100% methanol to 100% isopropanol in 40 min was used. Peak 1, triricinolein; peak 2, diricinoleoyl-linolenoyl-glycerol; peak 3, diricinoleoyl-linoleoyl-glycerol; peak 4, diricinoleoyl-oleoyl-glycerol. Figure 4A was the HPLC profile of castor oil (80 µg) which shows the retention times of triacylglycerols as: (peak 1) 7.94 min, (2) 12.62 min, (3) 14.05 min, (4) 15.79 min. Figure 4B was the HPLC profile of the fraction of acylglycerols and FFA of the lipid extract from the incubation (peak 1, Fig. 1) which was cochromatographed with castor oil (80 µg). The retention times were: (peak 1) 7.95 min, (2) 12.61 min, (3) 14.04 min, (4) 15.75 min. Figure 4C was the radiochromatogram of the same HPLC run as Figure 4B. The retention times obtained from the radioactive flow detector were: (peak 1) 7.9 min, (2) 12.6 min, (3) 14.0 min, (4) 15.7 min. Peak 5, free ricinoleate (2.9 min); peak 6, 1-palmitoyl-2-oleoyl-sn-glycerol (17.3 min). See Figures 1 and 3 for abbreviations.

of the fraction of acylglycerols and FFA cochromatographed with castor oil (Fig. 8) showed the identifications of radioactive triricinolein, 1,2-diricinoleoyl-3-linolenoyl-*sn*-glycerol, 1,2-diricinoleoyl-3-linoleoyl-*sn*-glycerol, and 1,2-diricinoleoyl-3-oleoyl-*sn*-glycerol. However, radioactive peak 6 of Figure 4C (1-palmitoyl-2-oleoyl-*sn*-glycerol, hydrolyte of the substrate 2-oleoyl-PC by phospholipase C) was not present in Figure 8 as expected. No incorporation of free ricinoleate into triacylglycerols was observed in the incubation without the addition of CoA. It is interesting that the incorporation of exoge-

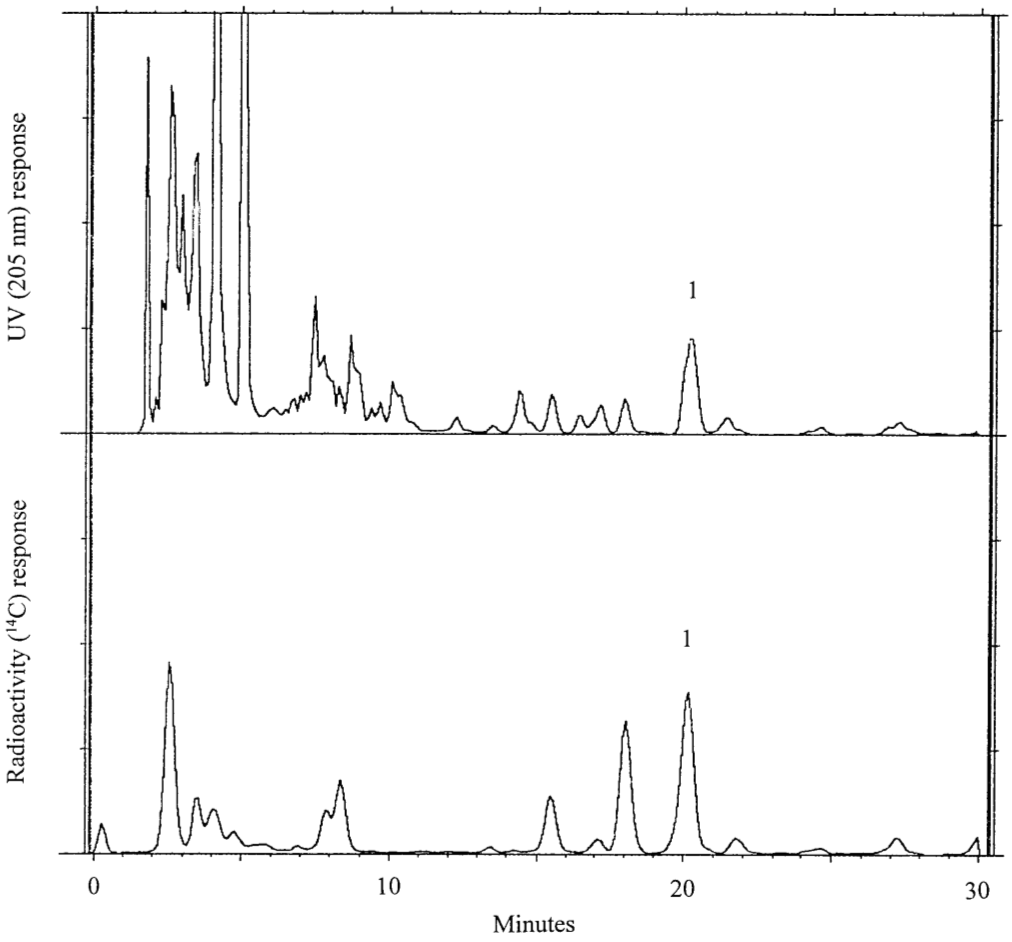

FIG. 5. HPLC identification of radioactive 1-palmitoyl-2-oleoyl-*sn*-glycerol in the fraction of acylglycerols and FFA (peak 1, Fig. 1) from the castor microsomal incubation of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine, using a C_{18} HPLC system (see the Experimental Procedures section, HPLC, v). The linear gradient was 100% methanol to methanol/isopropanol (50:50) in 40 min. The sample was cochromatographed with 1,2-dioleoyl-*sn*-glycerol (50 μg), and its retention time (20.2 min, peak 1 of UV chromatogram) was the same (20.2 min) as that of peak 1 of the radiochromatogram. Both the UV chromatogram and radiochromatogram were from the printer of radioactivity flow detector. See Figures 1 and 3 for abbreviations.

nous free ricinoleate into triacylglycerols in the incubation required CoA while the incorporation of ricinoleate from 2-ricinoleoyl-PC or 2-oleoyl-PC into triacylglycerols does not. It is possible that lipids derived from these substrates participate in acyl exchange reactions as recently described (19). Endogenous CoA was available for the activation of ricinoleate formed from 2-ricinoleoyl-PC (Scheme 1) while it was not available for exogenous ricinoleate. We have previously added CoA to the incubation (5), and it has not made a difference in the total ricinoleate-containing lipids produced. The radioactivity ratio of peaks 2, 3, and 4 in Figure 8 was similar to the ratio of peaks 2, 3, and 4 of castor oil of Figure 4A. The ratio probably reflected the substrate (acyl CoA) specificity of the diacylglycerol acyltransferase (step 8, Scheme 1) and/or the availabilities of acyl CoA in castor endosperm *in vivo*. The radioactivity of triricinolein (peak 1, Fig. 8) was lower than those of peaks 3 and 4 in Figure 8 and was probably due to the depletion of ricinoleoyl CoA used in the biosynthesis of 1,2-diricinoleoyl-*sn*-glycerol in the incubation. The radioactive peak 6 in Figure 8 has not been identified yet and might be 1,2-diricinoleoyl-*sn*-glycerol, the intermediate in the pathway (Scheme 1), according to the elution characteristic of acylglycerols (9). The possible labeled 2-ricinoleoyl-PC (identical relative retention time) was also shown in the total lipid extract in the radiochromatogram (not shown) using the HPLC system of Figure 1. The incorporation of [^{14}C]ricinoleoyl-CoA into triacylglycerols in castor microsomes previously has been reported (3,20). The incorporation of the ammonium salt of [^{14}C]ricinoleate into triricinolein, diricinoleoyl-acyl-glycerols, ricinoleoyl-diacyl-glycerols, and ricinoleoyl-acyl-glycerols has also been recently reported in castor endosperm *in vivo* (20). We have shown the phospholipase A_2 hydrolysis of 2-ricinoleoyl-PC and the incorporation of ricinoleate from 2-ricinoleoyl-PC into triacylglycerols in castor microsomes, thus demonstrating the pathway *in vitro:* 2-oleoyl-PC → 2-ricinoleoyl-PC → ricinoleate → triricinolein.

The major biosynthetic pathway from 2-oleoyl-PC to triacylglycerols containing ricinoleate is shown in Scheme 1.

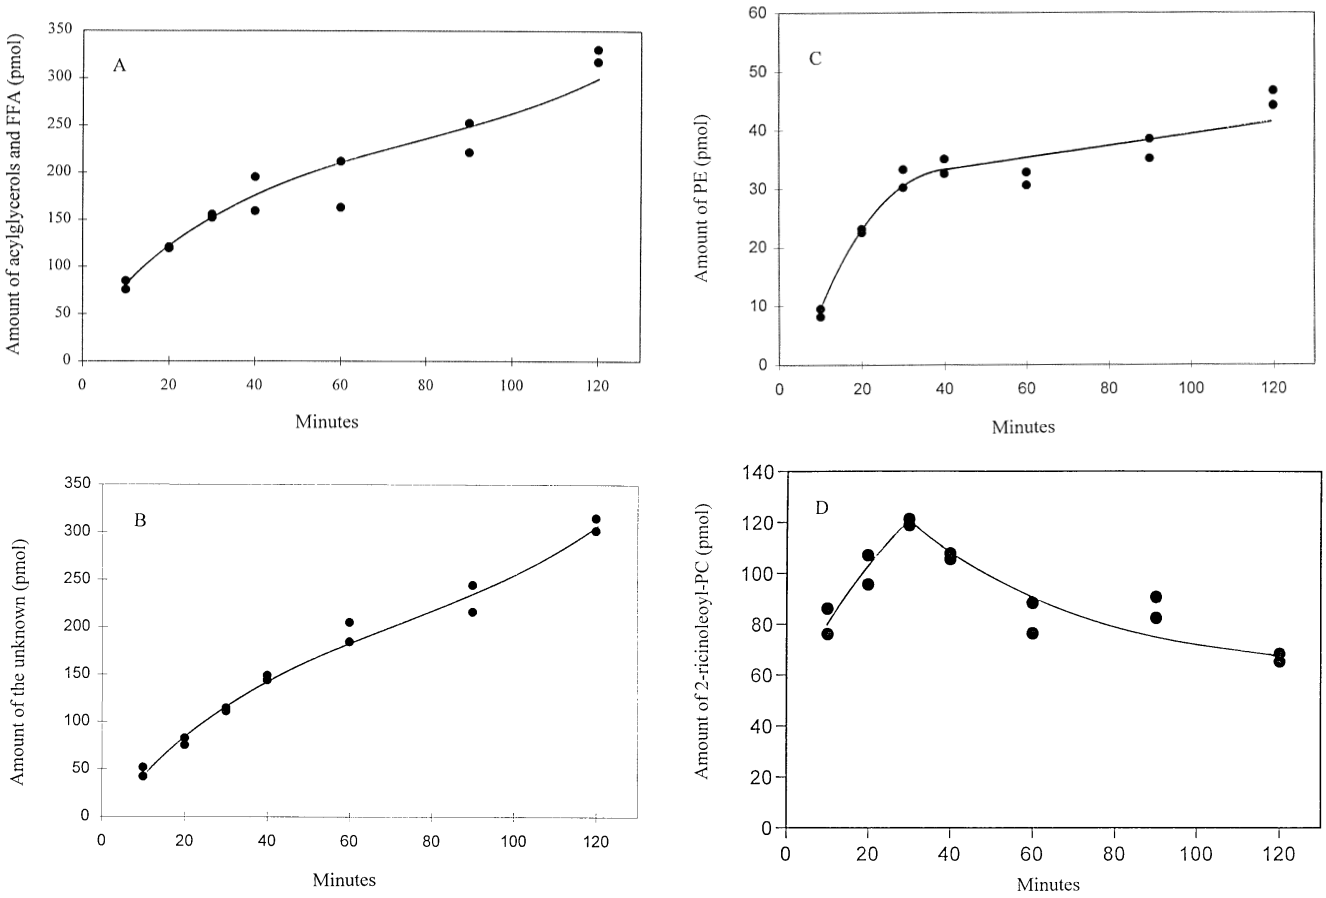

FIG. 6. Amounts of lipid classes shown in Figure 1 formed at various times of castor microsomal incubations with 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycero-3-phosphocholine. Units for y-axes are the pmol of labeled fatty acids in each lipid class derived from [^{14}C]oleate of the substrate. Figure 6A, acylglycerols and FFA (including triricinolein); Figure 6B, the unknown; Figure 6C, PE; Figure 6D, 2-ricinoleoyl-PC. See Figure 1 for abbreviations.

Step 1: oleoyl-12-hydroxylase, by cytochrome b_5, NADH, O_2, ATP (21). This step is favored between steps 1 and 2. Step 2: oleoyl-12-desaturase, by cytochrome b_5, NADH, O_2, ATP (21). Step 3: phospholipase A_2. Step 4: acyl-CoA synthetase, by ATP, CoA. Step 5: glycerol-3-phosphate acyltransferase, by acyl-CoA. Step 6: lyso-phosphatidic acid acyltransferase. Step 7: phosphatidic acid phosphatase. Step 8: diacylglycerol acyltransferase, by acyl CoA, blocked (completely or partially) when the substrate contains no ricinoleate, in favor of the formation of triricinolein. Because of the block, 1-acyl-2-oleoyl-*sn*-glycerol was accumulated. The conversion of 1,2-diricinoleoyl-*sn*-glycerol to PC by CDP-choline:diacylglycerol cholinephosphotransferase was blocked owing to the presence of membrane-incompatible fatty acid (22). Step 9: phospholipase C. The hydrolysis of PC at the *sn*-2 position by phospholipase A_2 favors ricinoleate as shown in Table 1. Removal of ricinoleate from PC has been explained in part by the action of phospholipid acyl hydrolases in castor microsomes that display strong preference for releasing ricinoleate from the *sn*-1 and *sn*-2 positions of PC (17). The accumulation of 1,2- diricinoleoyl-*sn*-glycerol was not significant as shown in Figure 4C, because it would elute before triricinolein (radioactive peak 1 in Fig. 4C, 7.9 min) and after ricinoleate (peak 5, 2.9 min), and the radioactive peaks at retention times of 3.7 and 4.9 min contained mostly radioactive oleate after the hydrolysis of these two peaks. The conversion from 1-palmitoyl-2-oleoyl-*sn*-glycerol to 1-palmitoyl-2-oleoyl-3-acyl-*sn*-glycerols was blocked (completely or partially) and the enzyme, diacylglycerol acyltransferase, favored the conversion of 1,2-diricinoleoyl-*sn*-glycerol to 1,2-diricinoleoyl-3-acyl-*sn*-glycerols. The diacylglycerol acyltransferase favored the formation of triricinolein and 1,2-diricinoleoyl-3-oleoyl-*sn*-glycerol as shown in Figure 4C. The castor endosperm diacylglycerol acyltransferase displays a 3- to 4-fold preference for acylating 1,2-diricinoleoyl-*sn*-glycerol over 1,2-dioleoyl-*sn*-glycerol and exhibits low activity toward diacylglycerols with only one ricinoleate residue (23). In a separate study, the diacylglycerol acyltransferase showed selectivities for substrates containing ricinoleate on both 1,2-diricinoleoyl-*sn*-glycerol and ricinoleoyl-CoA (24). The accumulation of a large quantity of radioactive 1,2-diricinoleoyl-3-oleoyl-*sn*-glycerol in this incubation (Fig. 4C), in contrast to castor oil constituents (Fig. 4A), might be due to the presence of a large quantity of oleoyl-CoA in the incubation which came from the large quantity of 2-oleoyl-PC as the substrate. In this study, we have produced metabolic evidence that three enzymatic steps, oleoyl-12-hydroxylase, phospholipase A_2 and diacylglycerol acyltransferase, drive ricinoleate into triricinolein. The prolonged and

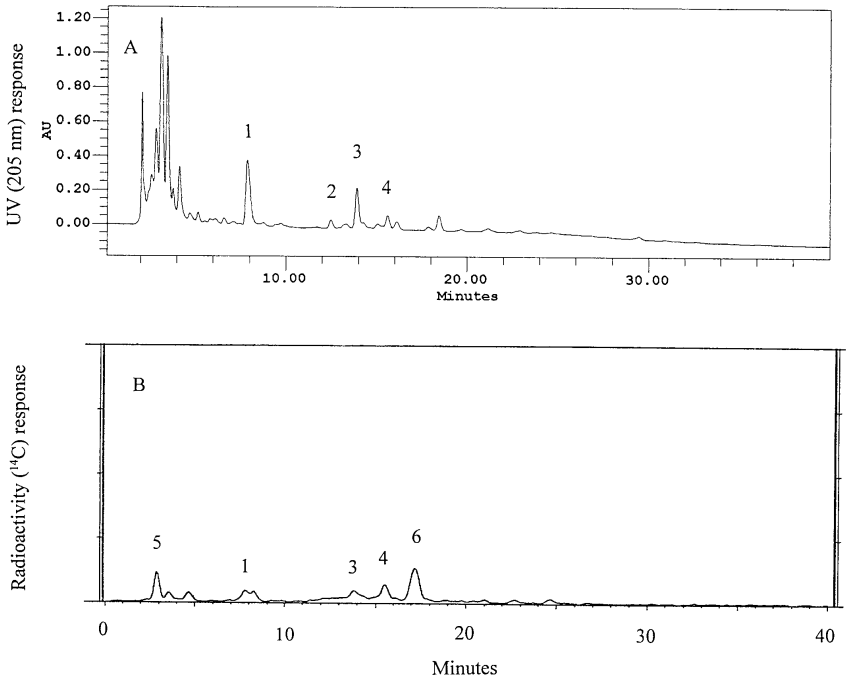

FIG. 7. HPLC identification of acylglycerols in the total lipid extract from the castor microsomal incubation of 1-palmitoyl-2-[^{14}C]ricinoleoyl-*sn*-glycero-3-phosphocholine, using a C_{18} HPLC system (see the Experimental Procedures section, HPLC, v). A linear gradient from 100% methanol to 100% isopropanol in 40 min was used. The sample was cochromatographed with castor oil (80 μg). Peak 1, triricinolein (7.8 min); peak 2, diricinoleoyl-linolenoyl-glycerol (12.4 min); peak 3, diricinoleoyl-linoleoyl-glycerol (13.8 min); peak 4, diricinoleoyl-oleoyl-glycerol (15.6 min); peak 5, ricinoleate (2.9 min); peak 6, 1-palmitoyl-2-oleoyl-*sn*-glycerol (17.2 min). See Figures 1 and 3 for abbreviations.

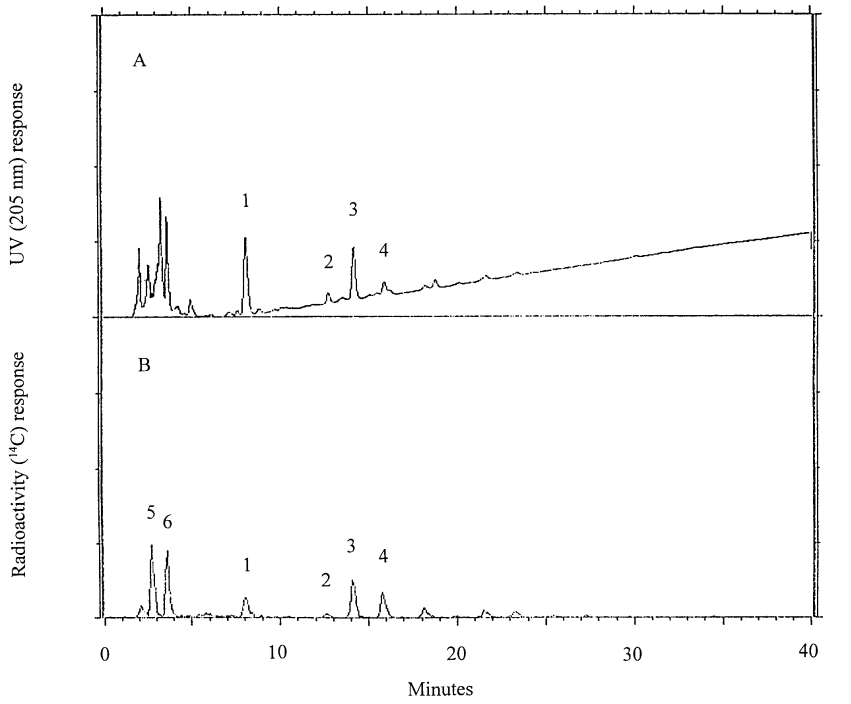

FIG. 8. HPLC identification of acylglycerols in the fraction of acylglycerols and FFA from the castor microsomal incubation of free [^{14}C]ricinoleate using a C_{18} HPLC system (see the Experimental Procedures section, HPLC, v). A linear gradient from 100% methanol to 100% isopropanol in 40 min was used. The sample was cochromatographed with castor oil (80 μg). Peak 1, triricinolein (8.1 min); peak 2, diricinoleoyl-linolenoyl-glycerol (12.6 min); peak 3, diricinoleoyl-linoleoyl-glycerol (14.1 min); peak 4, diricinoleoyl-oleoyl-glycerol (15.8 min); peak 5, ricinoleate (2.7 min); peak 6, may be 1,2-diricinoleoyl-*sn*-glycerol (3.6 min). See Figures 1 and 3 for abbreviations.

increasing activity of oleoyl-12-hydroxylase and diminishing activity of oleoyl-12-desaturase throughout development (5) are also important factors in the production of triacylglycerols containing ricinoleate.

Studies of Lipase-Catalyzed Esterification Reactions of Some Acetylenic Fatty Acids

Marcel S.F. Lie Ken Jie* and Fu Xun

Department of Chemistry, The University of Hong Kong, Hong Kong

ABSTRACT: Esterification of five positional isomers of acetylenic fatty acids [*viz.* 9:1(2a), 11:1(10a), 18:1(6a), 18:1(9a) and 22:1(13a)] of different chain lengths with *n*-butanol in *n*-hexane in the presence of eight different lipases [Lipozyme IM 20 (*Rhizomucor miehei*), Lipolase 100T (*R. miehei*), Novozyme 435 (*Candida antarctica*), PPL (porcine pancreatic lipase), CCL (*C. cylindracea*), PS-D (*Pseudomonas cepacia*), Lipase A-12 (*Aspergillus niger*) and Lipase AY-30 (*C. rugosa*)] was studied. 2-Nonynoic acid was not esterified except when catalyzed by the lipase from *C. antarctica* (Novozyme 435) to give 42% butyl ester after 48 h. The lipases from *A. niger* (Lipase A-12) and *C. rugosa* (Lipase AY-30) showed poor biocatalytic behavior in the esterification of the acetylenic fatty acids studied. 10-Undecynoic acid gave the highest conversion rate of esterification with each kind of lipase used. 6-Octadecynoic acid showed a marked degree of resistance to esterification carried out in the presence of *C. cylindracea* (CCL), *P. cepacia* (PS-D), or porcine pancreatic (PPL) lipase but not significantly in the presence of the lipases of *R. miehei* (Lipozyme IM 20), *R. miehei* (Lipolase 100T), or Novozyme 435. 9-Octadecynoic acid and 13-docosynoic acid were not discriminated and were readily esterified by the remaining six lipases, but when compared to oleic acid the acetylenic fatty acids were comparatively much slower in conversion to the esters.

Lipids 33, 71–75 (1998).

Lipase-catalyzed esterification of long-chain fatty acids has become common practice in laboratories for its prominent advantage over chemical methods owing to the mild conditions used and the high specificity in product formation. Numerous reports on this topic describe a large variety of enzymes, substrates and conditions employed (1–6). Knowledge of the specificity of lipases toward different types of fatty acids is essential, especially in the metabolic studies carried out *in vivo* or *in vitro*. For example, triglycerides containing short-chain fatty acids are more readily hydrolyzed by lipases than triglycerides composed of long-chain fatty acid moieties (7–9). In the hydrolysis of positional isomers of unsaturated fatty esters, substrates containing the double bond nearer to the carboxylate function (between Δ^2 and Δ^7) were found resistant to hydrolysis in the presence of porcine pancreatic lipase (PPL) with the highest discrimination found for the isomer with the double bond in the Δ^5 position of the alkyl chain (10). More recent results showed that lipases from papaya (*Carica papaya*) latex discriminate fatty esters containing a *cis*-double bond at Δ^4, Δ^6 and Δ^8, but not fatty esters with a Δ^9 double bond (11). However, the lipase from *Chromobacterium viscosum* showed preference for the Δ^6 olefinic isomer (12).

Fatty acid or ester substrates containing a Δ^9 olefin are most easily hydrolyzed or esterified by a variety of lipases (13–16). However, polyunsaturated long-chain fatty acids are often discriminated depending on their chain length and positions of the double bonds. This specificity allows particular fatty acids to be enriched using specific lipases for such processes (17–19). Most lipase studies have concentrated on saturated and olefinic fatty acids or esters. There is yet another family of unsaturated fatty acids, namely the acetylenic fatty acids, which exist in various plants, such as tariric acid (6-octadecynoic acid) (20) and stearolic acid (9-octadecynoic acid) (21), which deserve attention. The presence of stearolic acid in seed oils prompted Bu'lock and Smith (22) to postulate that C_{18} polyacetylenic fatty acids might be formed by successive dehydrogenation reactions of the fatty acid precursors (22). Acetylenic fatty acids were found to inactivate lipoxygenase (23) and stearolic acid was observed to act as a strong DNA-binding agent (24).

In view of the importance of acetylenic fatty acids in plants, this paper presents the results of enzymatic esterification reactions of some acetylenic fatty acid isomers and homologues with *n*-butanol in the presence of different lipases.

MATERIALS AND METHODS

Immobilized lipases from *Rhizomucor miehei* (Lipozyme IM 20 and Lipolase 100T) and *Candida antarctica* (Novozyme 435) were gifts from Novo Nordisk A/S (Hong Kong). Lipases from *C. cylindracea* (CCL, type VII, 905 U/mg) and PPL (type II, 179 U/mg) were purchased from Sigma Chemical Co. (St. Louis, MO). Lipases from *Pseudomonas cepacia* (PS-D, type I), *Aspergillus niger* (Lipase A-12), and *C. ru-*

Abbreviations: CCL, *Candida cylindracea* lipase; NMR, nuclear magnetic resonance; PPL, porcine pancreatic lipase; PS-D, *Pseudomonas cepacia* lipase; TMS, tetramethylsilane.

gosa (Lipase AY-30) were gifts from Amano Pharmaceutical Co. Ltd. (Nagoya, Japan). Methyl 2-nonynoate, oleic acid, and 10-undecenoic acid were purchased from Aldrich Chemical Co. (Milwaukee, WI). Carrot seeds and high erucic acid rape seed oil were obtained from local sources.

Gas–liquid chromatographic analyses were performed on a Hewlett-Packard (Hewlett-Packard Inc., Palo Alto, CA) model 5890 instrument equipped with a flame-ionization detector and fitted with a fused-silica capillary column coated with Nukol™ (15 m, 0.53-mm diameter, 0.50-μm film thickness) or with Omegawax™ (30 m, 0.32-mm diameter, 0.25-μm film thickness) as stationary phase at a column temperature of 200°C. Silica gel (type 60, 70–230 mesh, Merck, Darmstadt, Germany) was used for column chromatography. ^{13}C-nuclear magnetic resonance (NMR) spectra were obtained using a Brucker Avance DPX_{300} NMR spectrometer (Brucker, Fallanden, Switzerland) with the sample dissolved in deuteriochloroform and with tetramethylsilane as internal reference standard.

Preparation of acetylenic fatty acids. 2-Nonynoic acid was obtained by alkali hydrolysis of methyl 2-nonynoate. 10-Undecynoic acid was prepared from 10-undecenoic acid by the method described by Khan (25). 6-Octadecynoic acid, 9-octadecynoic acid, and 13-docosynoic acid were obtained by similar bromination and dehydrobromination reactions involving 6-octadecenoic acid from carrot seed oil and oleic acid and 13-docosenoic acid from high erucic acid rape seed oil, respectively, as described elsewhere (26).

General method for the enzymatic esterification of acetylenic acid as exemplified by the reaction of 9-octadecynoic acid with n-*butanol in the presence of* C. cylindracea *lipase.* A mixture of 9-octadecynoic acid (25 mg), *n*-butanol (0.10 mL), *n*-hexane (1.2 mL) and *C. cylindracea* lipase (25 mg) was stirred (800 rpm) at 40°C for definite periods in a glass culture tube. The reaction mixture was centrifuged, and the *n*-hexane solution was loaded on a silica gel (5.0 g) column (12-mm internal diameter). The mixture was eluted with a mixture of *n*-hexane/diethyl ether (95:5, vol/vol, 40 mL) to remove the butyl ester. The remaining fraction on the column was eluted with a mixture of *n*-hexane/diethyl ether (2:3, vol/vol, 120 mL) to isolate the unreacted acetylenic fatty acid. The solvent of each fraction was evaporated under reduced pressure and the weights of the butyl ester and free acetylenic acid were determined. The results (Fig. 1–6) represent the average of at least two determinations.

Competitive enzymatic esterification reaction of a mixture of acetylenic acids as exemplified by the reaction with a mixture of 10-undecynoic acid and 9-octadecynoic acid. A mixture of 10-undecynoic acid (30 mg) and 9-octadecynoic acid (30 mg), *n*-butanol (0.12 mL), *n*-hexane (1.6 mL) and PS-D lipase (18 mg) was stirred at 40°C for 6 or 12 h. The *n*-butyl esters and free acetylenic acids were isolated by column chromatography as described above. Yields were calculated from the weight of the butyl esters and the results of the gas–liquid chromatographic analysis of each isolated fraction. In the case where the mixture of acetylenic acids is composed of 6-octadecynoic acid and 9-octadecynoic acid, the relative amount

two positional isomers contained in the isolated butyl ester mixture.

RESULTS AND DISCUSSION

A total of eight lipases [Lipozyme IM 20 (*R. miehei*), Lipolase 100T (*R. miehei*), Novozyme 435 (*C. antarctica*), CCL (*C. cylindracea*), PPL, PS-D (*P. cepacia*), Lipase A-12 (*A. niger*), Lipase AY-30 (*C. rugosa*)] were used as biocatalysts to study the rate of esterification between *n*-butanol and five acetylenic fatty acids [*viz.* 9:1(2a), 11:1(10a), 18:1(6a), 18:1(9a), and 22:1(13a)]. (The first number denotes the chain length of the fatty acid. The number after the colon denotes the number of unsaturation, the number within the brackets indicates the position of the unsaturation, and the letter "a" stands for acetylene.)

When 2-nonynoic acid [9:1(2a)] was used as the substrate, none of the lipases used as biocatalysts furnished any butyl ester even after 48 h of contact time, except with the lipase of *C. antarctica* (Novozyme 435), which gave a 42% yield of the corresponding butyl ester. The poor performance or inactivity of this type of positional isomer with unsaturation at the Δ^2 position was similar to that previously observed in the case of the Δ^2 olefinic fatty acids (10), and also for that of 2-thia fatty acids (27). A plausible reason for such poor conversion rates was suggested to be the conjugative effect of the unsaturation center adjacent to the carboxylic acid group or, in the case of the 2-thia fatty acids, the electronic effect of the lone pair of electrons of the sulfur atom (27).

The results of enzymatic esterification of 11:1(10a), 18:1(6a), 18:1(9a), and 22:1(13a) with six different lipases for different reaction periods are graphically presented in Figures 1–6. In all six cases studied, 10-undecynoic acid [11:1(10a)] was most readily esterified. The lipases used appeared not to discriminate or have any adverse effect on the terminal acetylenic bond. It seemed that the position of the acetylenic bond from the carboxylic acid group was of greater importance than the nature of this unsaturated system in affecting the efficiency of the lipase in these reactions. 9-Octadecynoic acid [18:1(9a)] and 6-octadecynoic acid [18:1(6a)] were readily discriminated by CCL (Fig. 1), PPL (Fig. 2) and PS-D (Fig. 3), which showed that only about 40% of the 18:1(6a) was esterified after 48 h. By using Lipolase, Lipozyme or Novozyme, all four acetylenic substrates showed relatively efficient esterification rates irrespective of the position of acetylenic bond in the alkyl chain or difference in chain lengths (Fig. 4–6). Lipozyme and Novozyme were considered the most efficient enzymes for esterification where all substrates were converted to the corresponding butyl ester (>80%) within a period of 12 h. It must also be stressed that in the case of the reactions involving Lipozyme and Novozyme, the amount of catalyst used was only about 15% of the weight of the substrate, while in the other reactions the amount of lipase used was in a 1:1 ratio by weight of catalyst to substrate. The chain length of 13-docosynoic acid [22:1(13a)] did not cause much discrimination when compared to 18:1(9a), as the acetylenic bond is remotely positioned from the carboxylic function.

To compare the relative rates of esterification between oleic acid [18:1(9c)] and its acetylenic analogue [18:1(9a)], four experiments were conducted using the following lipases:

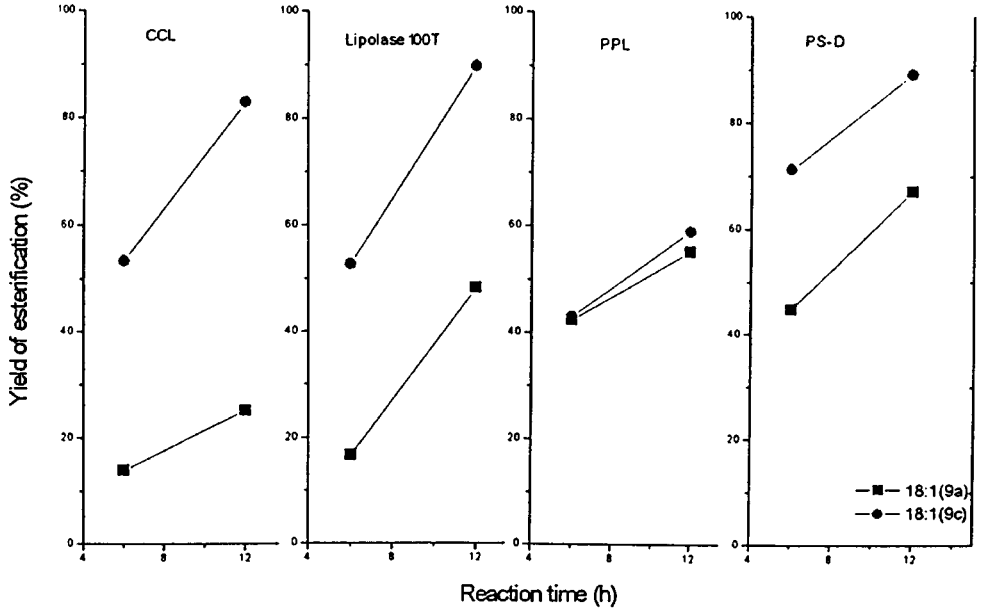

FIG. 7. Comparison of the yield of esterification of 9-octadecenoic acid and 9-octadecynoic acid catalyzed by lipases [*Candida cylindracea* (CCL), *Rhizomucor miehei* (Lipolase 100T), porcine pancreatic lipase (PPL), and *Pseudomonas cepacia* (PS-D)] at 40°C.

CCL, Lipolase 100T, PPL, and PS-D. The results are shown in Figure 7. In all instances, except for PPL, the rate of esterification of oleic acid was much faster than for the corresponding acetylenic analogue. When PPL was used, the rates of esterification for these substrates appeared to be very similar.

In view of the strong discriminating effects exhibited by PS-D, three mixtures of fatty acids (mixtures A–C) were used to test the case. Mixture A consisted of 30 mg each of 11:1(10a) and 18:1(6a). After 6 h of reaction time, the amounts of butyl esters of 11:1(10a) and 18:1(6a) were 94.4 and 11.7%; and after 12 h of reaction the yields of the butyl esters were 96.6 and 18.6%, respectively. Mixture B consisted of 30 mg each of 11:1(10a) and 18:1(9a). After 6 h of reaction time, the amounts of butyl esters of 11:1(10a) and 18:1(9a) were 97.6 and 62.3%; and after 12 h of reaction the yields of the butyl esters were 99.3 and 78.9%, respectively. These results were in good agreement with results described above for the individual isomer. Mixture C consisted of 30 mg each of 18:1(6a) and 18:1(9a). After 6 h of reaction time, the amounts of butyl ester of 18:1(6a) to that of 18:1(9a) as deduced from the relative intensities of signals from the ^{13}C NMR spectrum were in a ratio of 1:6 after 6 h and 1:4 after 12 h of reaction time. This experiment clearly showed that the PS-D was able to discriminate the fatty acid with the acetylenic bond at different positions albeit of the same chain length.

Lipase A-12 and Lipase AY-30 performed very poorly as biocatalysts. Lipase A-12 could esterify 11:1(10a), 18:1(9a) and 22:1(13a) in yields of only 5, 5, and 24%, respectively, after 48 h. Lipase AY-30 esterified the same set of fatty acids in yields of 33, 5, and 20%, respectively, after 48 h. Neither of these two lipases could esterify 9:1(2a) and 18:1(6a).

It can be concluded from these results that fatty acids containing an acetylenic bond at the Δ^2 position of the alkyl chain are very resistant to esterification by most lipases. Lipases of *A. niger* (Lipase A-12) and *C. rugosa* (Lipase AY-30) are also poor biocatalysts for esterification. Lipozyme (*R. miehei*) and Novozyme (*C. antarctica*) appeared to be the most efficient enzymes for esterification, while CCL, PPL, and especially PS-D showed a significant degree of discrimination toward positional isomers, such as 18:1(6a) and 18:1(9a).

Reaction of α-Tocopherol in Heated Bulk Phase in the Presence of Methyl Linoleate (13*S*)-Hydroperoxide or Methyl Linoleate

Ryo Yamauchi*, Kumiko Goto, and Koji Kato

Department of Food Science, Faculty of Agriculture, Gifu University, Gifu 501-1193, Japan

ABSTRACT: α-Tocopherol and methyl (9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoate (13-MeLOOH) were allowed to stand at 100°C in bulk phase. The products were isolated and identified as methyl 13-hydroxyoctadecadienoate (**1**), stereoisomers of methyl 9,11,13-octadecatrienoate (**2**), methyl 13-oxo-9,11-octadecadienoate (**3**), epoxy dimers of methyl linoleate with an ether bond (**4**), a mixture of methyl (*E*)-12,13-epoxy-9-(α-tocopheroxy)-10-octadecenoates and methyl (*E*)-12,13-epoxy-11-(α-tocopheroxy)-9-octadecenoates (**5**), a mixture of methyl 9-(α-tocopheroxy)-10,12-octadecadienoates and methyl 13-(α-tocopheroxy)-9,11-octadecadienoates (**6**), α-tocopherol spirodiene dimer (**7**), and α-tocopherol trimer (**8**). α-Tocopherol and 13-MeLOOH were dissolved in methyl myristate, and the thermal decomposition rate and the distributions of reaction products formed from α-tocopherol and 13-MeLOOH were analyzed. α-Tocopherol disappeared during the first 20 min, and the main products of α-tocopherol were **5** and **6** with the accumulation of **1–4** which were the products of 13-MeLOOH. The results indicate that the alkyl and alkoxyl radicals from the thermal decomposition of 13-MeLOOH could be trapped by α-tocopherol to produce **5** and **6**. The reaction products of α-tocopherol during the thermal oxidation of methyl linoleate were compounds **6** and **7**. Since the radical flux during the autoxidation might be low, the excess α-tocopheroxyl radical reacted with each other to form **7**.

Lipids 33, 77–85 (1998).

The primary products of lipid peroxidation are hydroperoxides, which can dissociate into free radicals. Lipid hydroperoxides are fairly stable at physiological temperatures, but they become susceptible to chemical change by transition metals, heat, and light (1). α-Tocopherol, an antioxidant in foods and living cells, can suppress further reactions of lipid hydroperoxides by donating hydrogen atoms to free radicals (2,3). Free radical reactions of α-tocopherol take place *via* the α-tocopheroxyl radical as intermediate (4,5). If a suitable free radical is present, a nonradical product may be formed from the coupling of the free radical with α-tocopheroxyl radical. The reaction products of α-tocopherol with lipid-peroxyl radicals have been reported to be 8a-(lipid-dioxy)-α-tocopherones (6–10). α-Tocopherol also traps alkyl and alkoxyl radicals to give alkylated products (11–16). In our previous study (16), we characterized 8a-alkyldioxy-α-tocopherones, 8a-epoxyalkyldioxy-α-tocopherones, 6-*O*-alkyl-α-tocopherols, and 6-*O*-epoxyalkyl-α-tocopherols as the reaction products of α-tocopherol during iron-catalyzed decomposition of methyl (9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoate (13-MeLOOH) under aerobic and anaerobic conditions. The thermal decomposition of hydroperoxides is believed to occur *via* homolytic cleavage of the oxygen-oxygen bond to yield a hydroxyl radical and an alkoxyl radical (1). Thus, α-tocopherol can react with these radicals to stop the thermal decomposition of lipid hydroperoxides. It has been reported that α-tocopherol can suppress the thermal decomposition of methyl linoleate hydroperoxides (MeLOOH) and inhibited the formation of volatile and nonvolatile decomposition products (2,3). However, the reaction mechanisms of α-tocopherol on thermal decomposition of hydroperoxide are still unclear.

In this study, we have characterized the reaction products of α-tocopherol during the decomposition of 13-MeLOOH at 100°C under air. A reaction mechanism of α-tocopherol during the decomposition of 13-MeLOOH and the autoxidation of methyl linoleate is discussed based on the reaction products observed in bulk phase of methyl myristate.

MATERIALS AND METHODS

Materials. (2*R*,4′*R*,8′*R*)-α-Tocopherol (Type V) was purchased from Sigma Chemical Co. (St. Louis, MO) and purified by reversed-phase high-performance liquid chromatography (HPLC) before use (16). γ-Tocopheryl acetate, used as an internal standard, was prepared by the acetylation of γ-tocopherol with acetic anhydride in pyridine. Authentic samples of the oxidation products of α-tocopherol were prepared as described previously (16–18). The spirodiene dimer of α-tocopherol was synthesized following the procedure of Nelan and Robe-

son (19). (9*Z*,11*E*)-(*S*)-13-Hydroperoxy-9,11-octadecdienoate (13-LOOH) was prepared by oxidation of linoleic acid (99% purity; Wako Pure Chemical Industries, Osaka, Japan) with soybean lipoxygenase-1 (Sigma) (20). The 13-LOOH was converted to its methyl ester with diazomethane in diethyl ether and purified by silica gel column chromatography using a mixture of hexane/diethyl ether. The purity of 13-MeLOOH was checked by normal-phase HPLC after reduction (21). The purity of 13-MeLOOH was about 90% of the total MeLOOH, the remainder being the (*E,E*)-13- and 9-isomers. Methyl myristate was purchased from Tokyo Chemical Industry Co. (Tokyo, Japan) and used as received. Methyl linoleate (Tokyo Chemical Industry Co.) was purified and made peroxide-free by silica gel column chromatography just before use (18).

Apparatus. HPLC was performed with a Jasco Trirotar pump (Japan Spectroscopic Co., Tokyo, Japan) equipped with a Model GP-A40 gradient programmer. A Jasco Model 875 ultraviolet (UV) detector or a Model 820-FP spectrofluorometer was used as the detector. ^{1}H (200 MHz) nuclear magnetic resonance (NMR) spectra were recorded on a Gemini 2000 FT NMR spectrometer (Varian Japan Ltd., Tokyo, Japan) using $CDCl_3$ as the solvent and tetramethylsilane as the internal standard. Mass spectra (MS) were obtained on a QP-1000 instrument (Shimadzu Co., Kyoto, Japan) operated in the electron impact (EI) mode with a 70-eV electron beam or in the chemical ionization (CI) mode with isobutane as the reagent gas. UV spectra were measured with a Jasco Ubest-30 spectrophotometer. Infrared (IR) spectra of samples in liquid film were measured on a Perkin-Elmer 2000 Fourier transform infrared spectrometer (Yokohama, Japan).

Reaction of α-tocopherol with 13-MeLOOH. A mixture of α-tocopherol (0.10 g, 0.23 mmol) and 13-MeLOOH (0.40 g, 1.2 mmol) in a test tube (1.6 cm in diameter) was incubated at 100°C for 20 min under air. The products were analyzed by normal-phase and reverse-phase HPLC. Normal-phase HPLC was done with a μBondasphere 5 μ Si-100 Å column (3.9 × 150 mm; Nihon Waters, Ltd., Tokyo, Japan) developed with hexane/diethyl ether (85:15, vol/vol) at a flow rate of 1.0 mL/min. Compounds were detected by an absorbance at 235 or 268 nm. Reversed-phase HPLC was done with a μBondasphere 5 μ C_{18} 100 Å column (3.9 × 150 mm) and a 15-min linear gradient of acetonitrile/methanol/water (10:88:2, by vol) to acetonitrile/2-propanol/hexane (30:40:30, by vol) at a flow rate of 1.0 mL/min. The eluent was monitored by an absorbance at 240 nm. The several reaction products detected by HPLC were isolated by preparative HPLC using an Inertsil Prep ODS column (10 × 250 mm; GL Sciences Inc., Tokyo, Japan) developed with methanol or methanol/ethanol (1:1, vol/vol) at 5.0 mL/min.

Time-course experiment. α-Tocopherol (2 or 10 mM) and 13-MeLOOH (40 mM) in methyl myristate solution (2 mL) were placed in a test tube (1.4 cm in diameter) and incubated at 100°C. Periodically, aliquots of the sample were withdrawn, dissolved in hexane or ethanol, and injected into HPLC. The amount of MeLOOH and its reaction products were determined by normal-phase HPLC with UV detection (3). α-Tocopherol was determined by reversed-phase HPLC with fluorescence detection (13). The reaction products of α-tocopherol were determined by reversed-phase HPLC with UV detection (18). γ-Tocopheryl acetate was used as the internal standard. Methyl linoleate (40 mM) with or without α-tocopherol in methyl myristate was also incubated in the same condition as described above.

RESULTS

Reaction products of α-tocopherol and 13-MeLOOH. A mixture of α-tocopherol and 13-MeLOOH was reacted at 100°C for 20 min, and the reaction mixture was analyzed by normal-phase and reversed-phase HPLC (Fig. 1). In normal-phase HPLC, the eluent was monitored at 235 or 268 nm. Peaks corresponding to 13-MeLOOH and its isomers, **a**–**c**, and a prod-

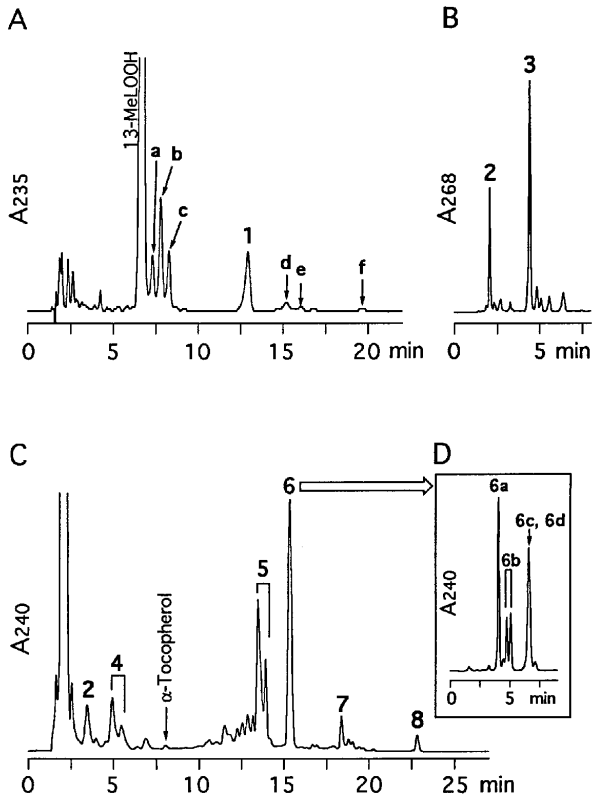

FIG. 1. High-performance liquid chromatography (HPLC) of the reaction products of α-tocopherol with methyl (9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoate (13-MeLOOH) at 100°C for 20 min. Normal-phase HPLC was done with a μBondasphere 5 μ Si-100 column (3.9 × 150 mm) developed with hexane/diethyl ether (85:15, vol/vol) at a flow rate of 1.0 mL/min. The eluent was monitored at 235 (A) and 268 nm (B). Reversed-phase HPLC was done with a μBondasphere 5 μ C_{18} column (3.9 × 150 mm) which was developed with a 15-min linear gradient of acetonitrile/methanol/water (10:88:2, by vol) to acetonitrile/2-propanol/hexane (30:40:30, by vol) at 1.0 mL/min (C). The eluent was monitored at 240 nm. Peak **6** was collected and analyzed by normal-phase HPLC, which was developed with hexane/2-propanol (1000:1, vol/vol) at 1.0 mL/min (D).

uct peak **1** appeared at 235 nm (Fig. 1A); and two product peaks, **2** and **3**, appeared at 268 nm (Fig. 1B). Peaks **a**–**c** were assigned to the MeLOOH isomers by comparison of the HPLC behavior with that of the authentic samples (3,21); **a**, the (*E,E*)-13-isomer; **b**, the (*Z,E*)-9-isomer; and **c**, the (*E,E*)-9-isomer. Peak **1** was identified as methyl (9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoate (13-MeLOH) based on the reference sample prepared by reducing 13-MeLOOH with $NaBH_4$ (3). In addition, other hydroxy isomers were also detected as peaks **d**, the (*E,E*)-13-isomer; **e**, the (*Z,E*)-9-isomer; and **f**, the (*E,E*)-9-isomer.

Peaks **2** and **3** were isolated by preparative reversed-phase HPLC using methanol as the solvent. Compound **2** showed absorption maxima at 258, 267, and 279 nm in ethanol, indicating the presence of conjugated triene in the molecule. The structure of compound **2** was identified as a mixture of methyl (9*Z*,11*E*,13*E*)-octadecatrienoate (**2a**) and methyl (9*E*,11*E*,13*E*)-octadecatrienoate (**2b**) from the spectral data (Table 1). Compound **3** was identified as methyl (9*Z*,11*E*)-13-oxo-9,11-octadecadienoate (3,22,23) (Table 1).

The reversed-phase HPLC gave peaks corresponding to the new reaction products, **4**–**8**, and some unknown peaks in addition to a peak corresponding to compound **2** (Fig. 1C). Peaks **4**, **5** and **6** were isolated by preparative HPLC using methanol/ethanol (1:1, vol/vol) as the solvent. Compound **4** showed absorption maximum at 234 nm in ethanol. The ^1H NMR spectrum has signals at δ 2.86 and 3.10 due to methin protons on an epoxy ring and at δ 4.35–4.43 due to two methin protons on an ether bond (Table 1). Thus, the structure of **4** was assumed to be epoxy dimers of methyl linoleate with an ether bond. Compound **4** might be produced from the reaction between the 12,13-epoxyalkyl radicals of methyl linoleate and the 13-alkoxyl radical. However, the isomeric structures of this compound were not further investigated.

Compound **5** contained two enantiomers of methyl (*E*)-(12*S*,13*S*)-9-(α-tocopheroxy)-12,13-epoxy-10-octadecenoate (**5a**) and two enantiomers of methyl (*E*)-(12*S*,13*S*)-11-(α-tocopheroxy)-12,13-epoxy-9-octadecadienoate (**5b**) by UV, IR, MS, and ^1H NMR data and coelution with the authentic samples (16). Compound **6** was identified as a mixture of methyl 9-(α-tocopheroxy)-10,12-octadecadienoate and methyl 13-(α-tocopheroxy)-9,11-octadecadienoate by UV, IR, MS, and ^1H NMR data (13,18). Compound **6** gave four peaks by normal-phase HPLC using hexane/2-propanol (1000:1, vol/vol)

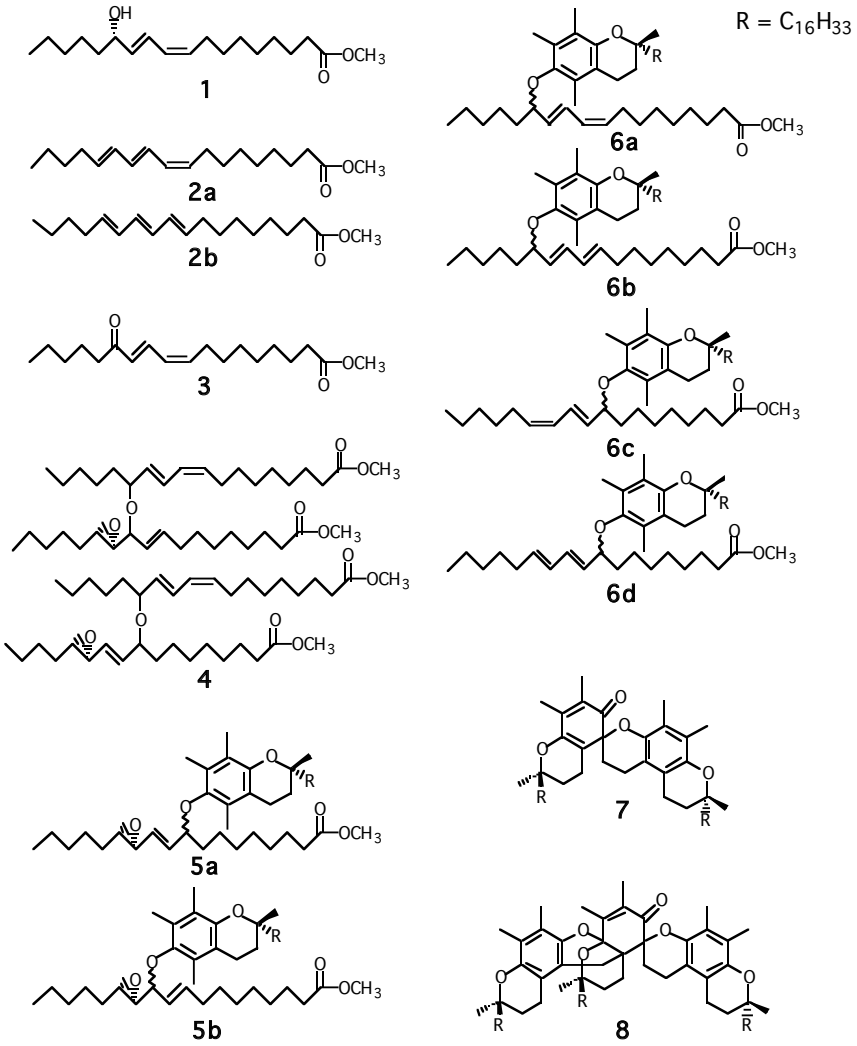
as the mobile phase (Fig. 1D), corresponding to an enantiomeric mixture of the (*Z,E*)-13-isomer (**6a**), the (*R,E,E*)- and (*S,E,E*)-13-isomers (**6b**), and a mixture of the (*E,Z*)- (**6c**) and (*E,E*)-9-isomers (**6d**) (18). Compound **7** was identified as α-tocopherol spirodiene dimer, and **8** was α-tocopherol trimer by comparison of the HPLC behavior with those of the authentic samples (17,19). Scheme 1 shows the structures of compounds **1**–**8**.

Stability of α-tocopherol. α-Tocopherol (10 mM) was dissolved in methyl myristate without or with 13-MeLOOH (40 mM) or methyl linoleate (40 mM), and incubated at 100°C (Fig. 2). Most of the α-tocopherol disappeared during the first 10-min incubation in the presence of 13-MeLOOH, and during the 6-h incubation in the presence of methyl linoleate, respectively. On the other hand, 80% of the α-tocopherol remained during the 6-h incubation without 13-MeLOOH or methyl linoleate. Thus, the free radical reaction of α-tocopherol occurred in the reaction mixture containing 13-MeLOOH or methyl linoleate.

Reaction of α-tocopherol during the decomposition of 13-MeLOOH. 13-MeLOOH (40 mM) in methyl myristate was heated at 100°C in the absence or presence of two different concentrations of α-tocopherol (2 and 10 mM). Figure 3 shows the results of the fate of α-tocopherol and 13-MeLOOH and the formation of their reaction products. α-Tocopherol at 2 mM inhibited the decomposition of 13-MeLOOH, but α-tocopherol at 10 mM accelerated the decomposition. The α-tocopherol at two concentrations disappeared during the first 20 min. The main product of α-tocopherol at 2 mM was **6**, and those at 10 mM were **5** and **6**, respectively. In addition to these products, compounds **1**–**4** accumulated in the 2 mM α-tocopherol and compounds **1**–**3** in the 10 mM α-tocopherol, respectively. Table 2 compares the relative product yields of compounds **1**–**6** from 13-MeLOOH. The reaction products from 13-MeLOOH in the 10-min reaction mixture containing 10 mM α-tocopherol could account for 96% of the consumed 13-MeLOOH.

Reaction of α-tocopherol during the autoxidation of methyl linoleate. Methyl linoleate (40 mM) in methyl myristate was incubated at 100°C in the absence or presence of α-tocopherol (2 and 10 mM). Figure 4 shows the fate of α-tocopherol and



SCHEME 1

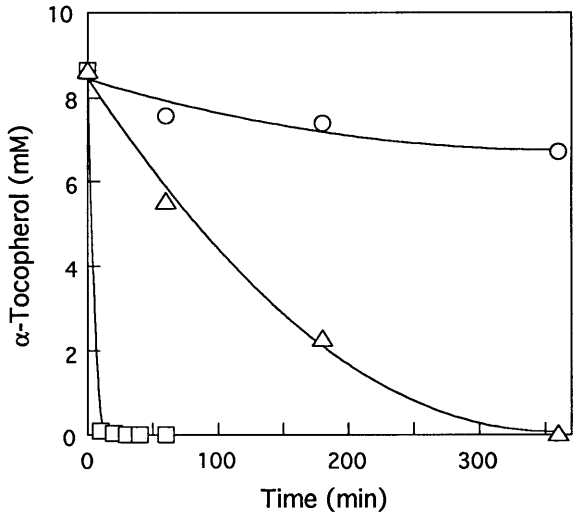


FIG. 2. Decomposition of α-tocopherol in bulk phase of methyl myristate. α-Tocopherol (10 mM) in methyl myristate without (○) or with 40 mM methyl linoleate (△) or 40 mM methyl (9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoate (□) was incubated at 100°C under air.

the formation of the reaction products: MeLOOH, MeLOH including **1**, conjugated triene compounds including **2**, ketodiene compounds including **3**, epoxy dimers of methyl linoleate with an ether bond including **4**, 6-*O*-alkyl-α-tocopherol (**6**), and spirodiene dimer of α-tocopherol (**7**), during the autoxidation of methyl linoleate. α-Tocopherol suppressed the formation of MeLOOH until it was consumed. The reaction products of α-tocopherol were compounds **6** and **7**. Compound **7** was the major product in the reaction mixture containing 10 mM α-tocopherol, and the ketodiene compounds also accumulated. The thermal oxidation of unsaturated lipids could result in carbon-carbon linked dimers (13,24–26) and epoxy dimers (18). However, we did not analyze the dimeric products of methyl linoleate other than the epoxy dimers of methyl linoleate.

Table 3 compares the relative product yields of α-tocopherol during the decomposition of 13-MeLOOH and the autoxidation of methyl linoleate. The reaction products from the 10 mM α-tocopherol during the decomposition of 13-MeLOOH accounted for 48% of the consumed α-tocopherol, but the reaction products during the autoxidation of methyl linoleate accounted only for 5–16% of the consumed α-tocopherol.

DISCUSSION

α-Tocopherol reacts with a variety of free radicals and stops free-radical chain reactions to form various reaction products. In the present study, the reaction products of α-tocopherol during the thermal decomposition of 13-MeLOOH were al-

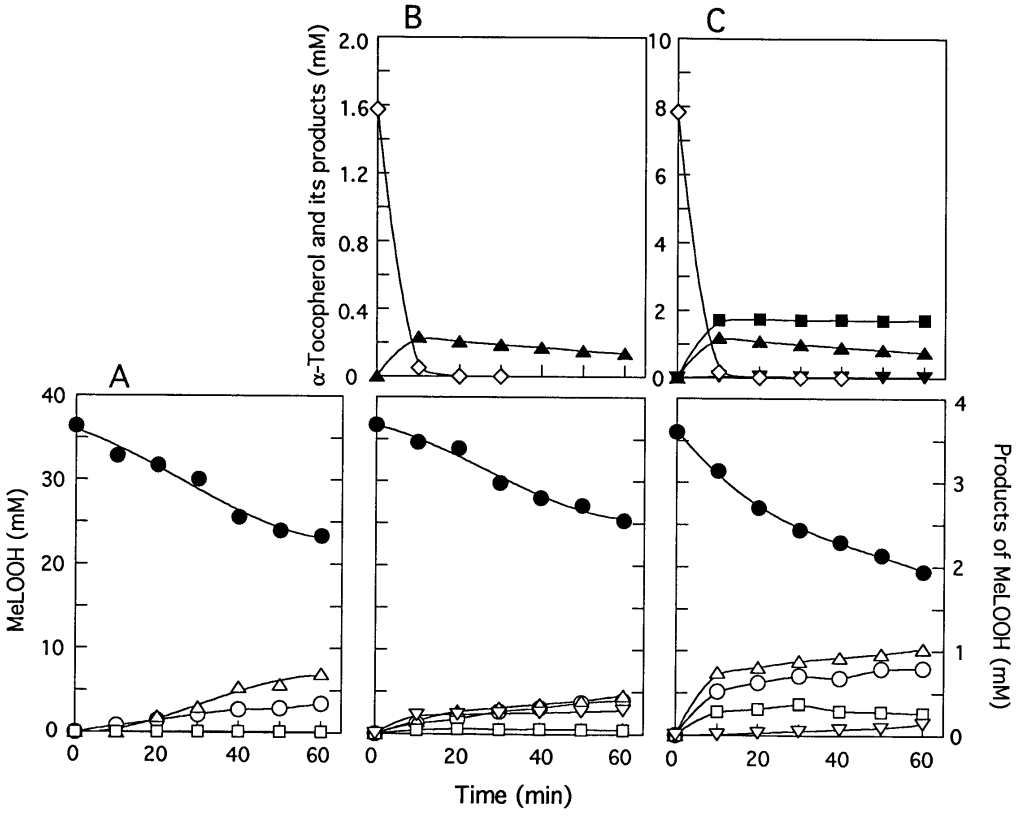

FIG. 3. Reaction of α-tocopherol during the decomposition of methyl (9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoate (13-MeLOOH) in methyl myristate. Methyl myristate containing 40 mM 13-MeLOOH was incubated at 100°C in the absence (A) or presence of 2 mM (B) or 10 mM (C) α-tocopherol. Residual amounts of 13-MeLOOH (●) and α-tocopherol (◇), and the reaction products, compound **1** (○), compound **2** (□), compound **3** (△), compound **4** (▽), compound **5** (■), compound **6** (▲), and compound **7** (▼), in the reaction mixture are shown. Compounds **1–7** are identified in Scheme 1.

most the same as those of α-tocopherol during the iron-catalyzed reactions between α-tocopherol and MeLOOH reported by Gardner *et al.* (14), Kaneko and Matsuo (15), and ourselves (16). The main products of α-tocopherol were 6-*O*-epoxyalkyl-α-tocopherols (**5**) and 6-*O*-alkyl-α-tocopherols (**6**) with small amounts of the dimer (**7**) and the trimer (**8**). Besides these products, we found 13-MeLOH (**1**), conjugated triene compounds (**2**), a ketodiene compound (**3**), and epoxy dimers of methyl linoleate with an ether bond (**4**) as the reaction products of 13-MeLOOH (Fig. 1 and Scheme 1).

Decomposition pathways of lipid hydroperoxides depend markedly on the reaction conditions, and several mechanisms for lipid hydroperoxide decomposition have been suggested (1,27,28). According to the bond dissociation energies, the thermal decomposition of MeLOOH may occur mainly through the alkoxyl radical (44 kcal/mol) rather than through the peroxyl radical (90 kcal/mol). Therefore, decomposition through the alkoxyl radical is considered to be an important pathway (1). Hopia *et al.* (3) have shown that the phenolic antioxidants, α-tocopherol and Trolox, at high concentrations efficiently inhibit the decomposition of MeLOOH at 60°C. They suggested that the phenolic antioxidants might markedly affect the reaction pathway involving the alkoxyl radical; they inhibit β-scission of the alkoxyl radical by hydrogen donation, and the hydrogen donation of antioxidants to the alkoxyl radical would lead to the formation of MeLOH. On the con-

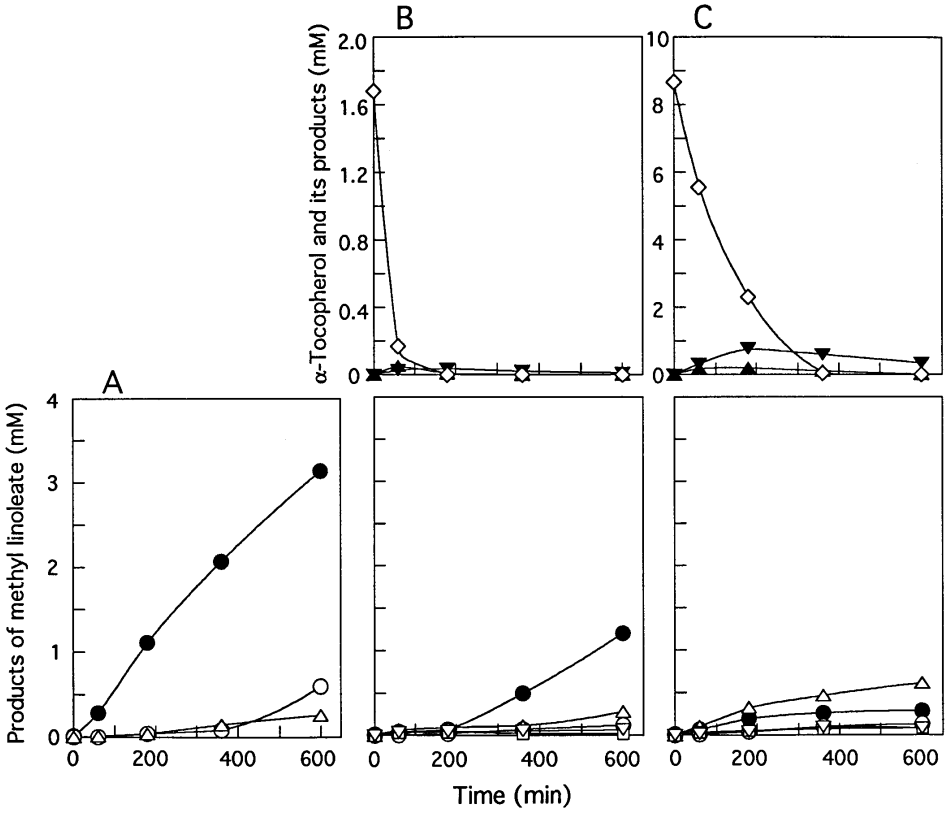

FIG. 4. Reaction of α-tocopherol during the autoxidation of methyl linoleate in methyl myristate. Methyl myristate containing 40 mM methyl linoleate was incubated at 100°C in the absence (A) or presence of 2 mM (B) or 10 mM (C) α-tocopherol. α-Tocopherol (◇), methyl linoleate hydroperoxides (●), methyl linoleate hydroxy compounds including **1** (○), conjugated triene compounds including **2** (□), ketodiene compounds including **3** (▲), methyl linoleate dimers containing two extra oxygen atoms including **4** (▽), compound **6** (▲), and compound **7** (▼) in the reaction mixture are shown. Compounds **1–7** are identified in Scheme 1.

TABLE 3
Product Distributions from the Reaction of α-Tocopherol[a]

Sample	Incubation time (min)	Yield (%)[b] α-Tocopherol	**5**	**6**	**7**
In 13-MeLOOH (40 mM)					
+ 2 mM α-tocopherol	10	3.2	n.d.[c]	14.8	n.d.
+ 10 mM α-tocopherol	10	20.9	21.9	15.3	0.6
In methyl linoleate (40 mM)					
+ 2 mM α-tocopherol	60	10.1	n.d.	3.1	1.7
+ 10 mM α-tocopherol	60	64.0	n.d.	2.1	3.7
	180	26.6	n.d.	2.3	9.0

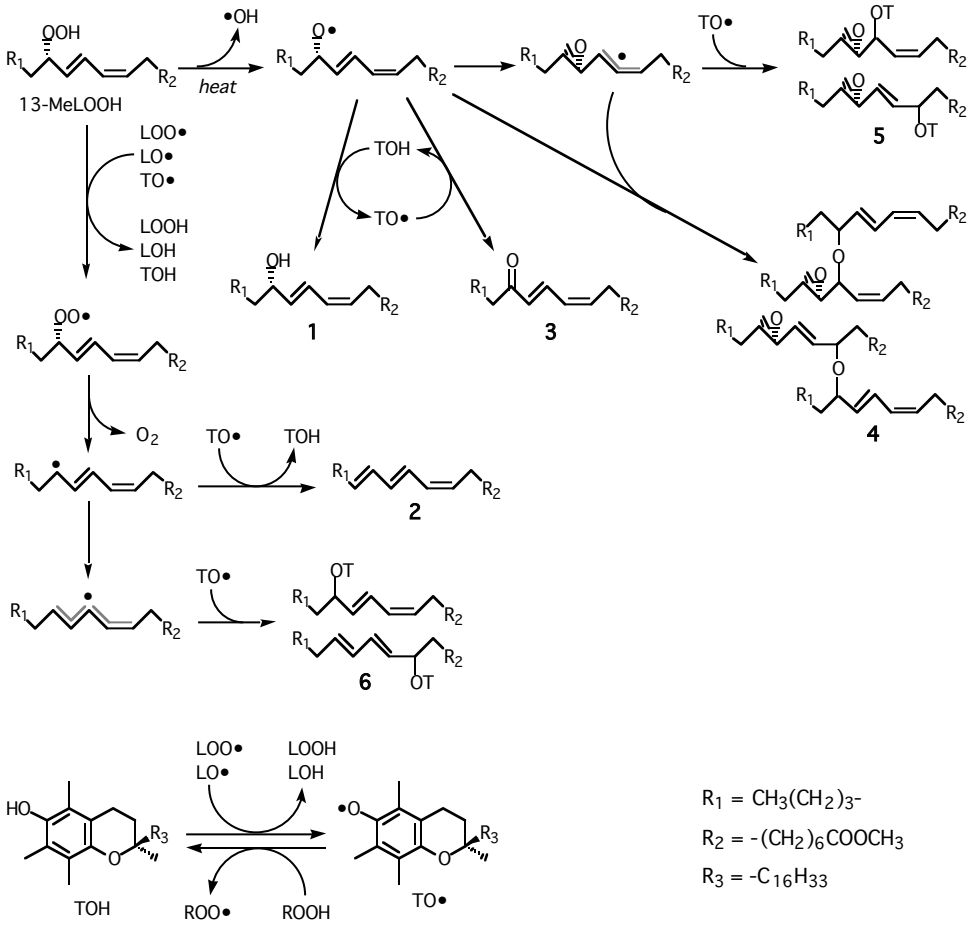
trary, the 10 mM α-tocopherol in our study accelerated the decomposition of 13-MeLOOH and produced reaction products, **1**–**6** (Fig. 3 and Table 2). Therefore, incubations at higher temperature result in the immediate loss of α-tocopherol, and the resulting α-tocopheroxyl radical may accelerate the decomposition of 13-MeLOOH.

The thermal decomposition of 13-MeLOOH and the reaction with α-tocopherol in methyl myristate are illustrated in Scheme 2 [proposed mechanism of the thermal decomposition of methyl (9*Z*,11*E*)-(*S*)-13-hydroperoxy-9,11-octadecadienoate (13-MeLOOH) and the reaction with α-tocopherol (TOH). LOOH, hydroperoxide; LOO·, peroxyl radical; LOH, hydroxy compound; LO·, alkoxyl radical; and TO·, the 8a-carbon radical of TOH]. The first reaction would be the formation of alkoxyl and peroxyl radicals of MeLOOH (1,23,27). The alkoxyl radicals generally are known for their



SCHEME 2

ability to abstract hydrogens. α-Tocopherol in the reaction mixture trapped the alkoxyl radicals by hydrogen-atom transfer, giving the α-tocopheroxyl radical and MeLOH (**1**). Because of the presence of unsaturation in the hydroperoxides, other reactions are evidently more competitive than hydrogen abstraction (1). Alkoxyl radicals of methyl linoleate tend to rearrange into epoxyallylic radicals, even in the presence of compounds with a readily abstractable hydrogen, like α-tocopherol (14–16). In the absence of oxygen, the resulting epoxyallylic radical is susceptible to a variety of radical combination reactions. In the present study, the epoxyallylic radicals reacted with the α-tocopheroxyl radical to form 6-*O*-epoxyalkyl-α-tocopherols (**5**). If the production of the tocopheroxyl radical is insufficient, the epoxyallylic radicals can react with the alkoxyl radical of 13-MeLOOH to form dimeric products. The epoxy dimers of methyl linoleate with an ether bond (**4**) appeared in the reaction mixture containing 2 mM α-tocopherol instead of the formation of 6-*O*-epoxyalkyl-α-tocopherols (Fig. 3 and Table 2). The results indicate that the alkoxyl radical rearrangement to epoxide is an important pathway in the homolysis of 13-MeLOOH by heat. The conversion of lipid hydroperoxides to the corresponding lipid ketones usually accounts for a relatively large portion of end products and they can be derived from hydroperoxides *via* alkoxyl radicals (22,23). From 13-MeLOOH, the corresponding oxodiene, methyl 13-oxo-9,11-octadecadienoate (**3**), was obtained, and high concentrations of α-tocopherol accelerated the formation of **1** and **3** (Fig. 3). Therefore, we assumed that the catalytic reactions of α-tocopherol to the alkoxyl radical might produce MeLOH and ketodiene compounds.

The formation of the peroxyl radical is the other important pathway of the decomposition of lipid hydroperoxides. Oxidation by higher oxidation states of transition metal ions is a pathway to form peroxyl radicals (27), but no metal catalyst is added in this study. The most likely process is that the peroxyl radicals might be produced from hydroperoxides by hydrogen abstraction; the free radicals, such as peroxyl, alkoxyl, and α-tocopheroxyl radicals could abstract the hydrogen atom from hydroperoxides (1). The peroxyl radicals thus formed should be trapped by the α-tocopheroxyl radical to form 8a-substituted α-tocopherones and epoxy-α-tocopherones (9,10,18). However, we could not detect such products in the present system. Since the 8a-alkyldioxy-α-tocopherones have been reported to be thermolabile (18), the produced tocopherones might immediately be decomposed at 100°C. The decomposition of these products to unidentified secondary products could account for the low recovery of α-tocopherol in terms of the products identified (Table 3). Alternatively, radical elimination of the peroxyl radicals results in the release of O_2 as a leaving group to form carbon-centered radicals (29). The formation of the carbon-centered radicals is substantiated by the finding that the isomerization of MeLOOH is accompanied by the exchange of the oxygen atoms of the hydroperoxy group with atmospheric oxygen (30). The alkyl radicals produced then react with the α-tocopheroxyl radical to form 6-*O*-alkyl-α-tocopherols (**6**) (18). In another pathway, the hydrogen atom of alkyl radical might be abstracted by the α-tocopheroxyl radical to produce the conjugated triene compounds (**2**). These results suggest that the elimination reaction of peroxyl radicals might occur during the thermal decomposition of 13-MeLOOH.

α-Tocopherol inhibited the autoxidation of methyl linoleate at 37 and 60°C and produced some reaction products including adducts of the α-tocopheroxyl radical with methyl linoleate-peroxyl radicals and methyl linoleate-alkyl radicals (18). When the autoxidation was performed at 60°C under air-insufficient conditions, the adducts of the α-tocopheroxyl radical with alkyl radicals accumulated, owing to the radical elimination of the peroxyl radicals followed by the addition of the α-tocopheroxyl radical. In the present study, α-tocopherol inhibited the formation of MeLOOH. α-Tocopherol traps the peroxyl radicals to produce hydroperoxide and α-tocopheroxyl radical (4,5). The resulting hydroperoxide is decomposed to alkoxyl radical at 100°C, and reacts with α-tocopheroxyl radical to form the ketodiene. Thus the ketodiene products accumulated in the reaction mixture at 10 mM α-tocopherol (Fig. 4). The adducts of α-tocopherol with methyl linoleate-alkyl radicals and spirodiene dimer of α-tocopherol were the other reaction products (Fig. 4 and Table 3). Because the radical flux of the autoxidation of methyl linoleate might be very low compared with that of the thermal decomposition of 13-MeLOOH, the produced α-tocopheroxyl radical reacted with each other to form the dimer as the main product.

In the present study, the main products of α-tocopherol with 13-MeLOOH were 6-*0*-epoxyalkyl-α-tocopherol (**5**) and 6-*O*-alkyl-α-tocopherol (**6**), whereas the product at 2 mM of α-tocopherol was only **6** and the epoxyalkyl radical reacted with the alkoxyl radical of 13-MeLOOH to form dimeric products (**4**). Therefore, the α-tocopheroxyl radical might prefer to react with alkyl radicals rather than epoxyalkyl radicals of polyunsaturated lipids.

Penetration and Distribution of α-Tocopherol, α- or γ-Tocotrienols Applied Individually onto Murine Skin

Maret G. Traber*, Michalis Rallis[1], Maurizio Podda[2], Christine Weber[3], Howard I. Maibach[4], and Lester Packer

Department of Molecular and Cell Biology, University of California, Berkeley, California 94720-3200

ABSTRACT: To evaluate skin penetration of various vitamin E homologs, a 5% solution of either α-tocopherol, α-tocotrienol, or γ-tocotrienol in polyethylene glycol was topically applied to SKH-1 hairless mice. After 0.5, 1, 2, or 4 h (*n* = four per time point and four per vitamin E homolog), the skin was washed, the animals killed, the skin rapidly removed, frozen on dry ice, and a biopsy taken and sectioned: stratum corneum (two uppermost, 5- μm sections—SC1 and SC2), epidermis (next two 10-μm sections—E1 and E2), papillary dermis (next 100 μm, PD), dermis (next 400 μm, D), and subcutaneous fat (next 100 μm, SF). SC1 contained the highest vitamin E concentrations per μ thickness. To compare the distribution of the various vitamin E forms into the skin layers, the percentage of each form was expressed per its respective total. Most surprising was that the largest fraction of skin vitamin E following topical application was found in the deeper subcutaneous layers—the lowest layers, PD (40 ± 15%) and D (36 ± 15%), contained the major portion of the applied vitamin E forms. Although PD only represents about 16% of the total skin thickness, it contains sebaceous glands—lipid secretory organs, and, thus, may account for the vitamin E affinity for this layer. Hence, applied vitamin E penetrates rapidly through the skin, but the highest concentrations are found in the uppermost 5 microns.

Lipids 33, 87–91 (1998).

Skin is protected from oxidative stress by a variety of enzymatic and nonenzymatic antioxidants (1–5). Among these, vitamin E is generally regarded as the most important lipid-soluble antioxidant and an obvious choice for enhancement of the antioxidant protection by topical application.

Vitamin E is a generic description for all tocol and tocotrienol derivatives that qualitatively exhibit the biological activity of α-tocopherol, and is the collective name for the eight major, naturally occurring molecules, four tocopherols and four tocotrienols. Tocotrienols differ from tocopherols in that they have an isoprenoid, instead of a phytyl side chain; the four forms of tocopherols and tocotrienols differ in the number of methyl groups on the chromanol nucleus (α- has three, β- and γ- have two, while δ- has one).

α-Tocopherol is generally regarded as the most important lipid-soluble antioxidant in plasma, circulating lipoproteins, and tissues (6–10), while γ-tocopherol and the tocotrienols are present in most tissues at much lower concentrations than α-tocopherol (11–14). Remarkably, however, we found that tocotrienols represent about 15% of the vitamin E in murine skin from hairless mice fed a chow diet (15). Earlier reports suggested that *in vitro* α-tocotrienol has higher antioxidant activity than α-tocopherol against Fe^{2+}/ascorbate and Fe^{2+}/NADPH induced lipid peroxidation in rat liver microsomes (16). Therefore, we hypothesized that tocotrienols might be more effective than tocopherols against oxidative damage to skin. Our studies demonstrated that a 5% solution containing TRF (tocotrienol-rich fraction) to the skin of hairless mice protected skin from oxidative stress produced by ultraviolet light (17) or ozone (18).

Our studies using ozone suggested that the surface of skin is particularly susceptible to oxidation. When hairless mice were exposed to 10 ppm ozone for 2 h, it increased skin malondialdehyde (MDA), depleted topically applied vitamin E, but not the vitamin E inherent in the skin (18). Next we localized the ozone-caused damage to the various murine skin layers. Ozone (10 ppm for 2 h) damaged the upper epidermis, decreasing both vitamins C and E and increasing MDA concentrations (19). Notably, antioxidants in the lower layers of skin were unaffected. Therefore, we undertook assessment of the antioxidant content of the uppermost skin layer, the stratum corneum (20). Sequential tape strippings of mouse stratum corneum demonstrated that ozone exposures as low as 1 ppm for 2 h on six consecutive days depleted vitamin E, and 5 ppm increased MDA formation in stratum corneum.

Our studies suggest that skin is quite susceptible to oxidative stress and that the stratum corneum serves as a barrier to oxidative insults. Since applied vitamin E was readily de-

pleted by ozone exposure, it was of interest to evaluate how well various vitamin E homologs penetrate skin. Knowledge about the topical bioavailabilities and the kinetics of absorption of a substance is essential for determination of its pharmacologic potency. The purpose of the present study was to measure the bioavailability of topically applied α-tocopherol in comparison with α-tocotrienol and γ-tocotrienol by determining the localization of each in murine skin at various time points after topical application.

MATERIALS AND METHODS

Chemicals. All chemicals used were of the highest grade available. Tocopherol standards were provided by Henkel Corporation (LaGrange, IL). Dr. Asaf A. Qureshi, University of Wisconsin (Madison, WI), purified the tocotrienols from TRF that was kindly provided by PORIM (Palm Oil Research Institute of Malaysia, Kuala Lumpur, Malaysia).

Animals. The animal care, handling, and experimental procedures were carried out as described in the animal use protocol approved by Animal Care and Use Committee of the University of California, Berkeley. SKH-1 hairless mice (females, between 8 and 10 wk old; Charles River Laboratories, Wilmington, MA were kept under standard light and temperature conditions. Food (Harlan Teklad Rodent Diet #1846, Madison, WI) and water were provided *ad libitum*. Mice were anesthetized by an intraperitoneal injection of sodium pentobarbital (50 mg/kg body weight, Nembutal^{R}; Abbott Laboratories, North Chicago, IL) and remained anesthetized during the entire experimental period.

Vitamin E application. A 5% wt/vol solution of each of the vitamin E homologs was prepared in polyethylene glycol-400 (PEG; Sigma, St. Louis, MO). Mice were anesthetized, then a polypropylene plastic ring (2 cm^2) was glued onto the animals' backs, and the vitamin E solution (40 µL) was applied (n = four per time point and four per vitamin E form). After 0.5, 1, 2 or 4 h, the treated area was washed as described (21). Briefly, the skin was rinsed three times rapidly with 300 µL ethanol/water (95:05) using a pipettor to flush the solution in and out of the ring surrounding the application site. Based on our previous experience with solvent extraction of skin (22), it is unlikely that the ethanol washes changed the barrier permeability characteristics. Then, the site was rinsed twice in a similar manner with water alone and dried with a cotton-tipped swab. Subsequently, the location of the application site was marked and the plastic ring removed. The animal was killed, the skin removed, immediately flattened on dry ice, and a 6-mm punch biopsy was taken. The frozen biopsy was sliced parallel to the skin surface with a cryomicrotome (Kryostat 1720; Ernst Leitz Wetzlar GmbH, Wetzlar, Germany) as described (23). Previously, cryosections of skin were hematoxylin/eosin stained, following tape stripping, and examined by microscopy to identify cell morphology of the individual sections. On the basis of this examination, the epidermis was localized to the first four slices of 5-µm thickness, and the subsequent 10 sections (10 µm) corresponded to papillary dermis (PD) (24). In the present study, two 5-µm sections are labeled stratum corneum (SC1 and SC2), the next two 10-µm sections are labeled epidermis (E1 and E2), the next 100 µm are labeled PD, the next 400 µm are labeled dermis (D), the remainder (approximately 100 µm) is labeled subcutaneous fat (SF).

Skin extraction and antioxidant analysis. Tocopherols and tocotrienols were extracted from skin, as described (25,26). Briefly, the skin sections were transferred to a tube containing 2 mL buffer (10 mM phosphate, 130 mM NaCl, 1 mM EDTA, pH 7.0) and 50 µL butylated hydroxytoluene (1 mg/mL) followed by mixing and the addition of 1 mL of 0.1 M sodium dodecylsulfate, 2 mL ethanol and extraction with 2 mL hexane. An appropriate aliquot was used for high-performance liquid chromatography (HPLC) analysis, as described (15). The electrochemical detector was operated with 0.5 V potential, full recorder scale at 50 nA for quantitation of α-tocopherol, α-, and γ-tocotrienols. The amounts of applied vitamin E (even the tocotrienols in lower layers) far exceeded the amounts present in controls tissues (data not shown). Thus, these inherent vitamin E concentrations were not subtracted from the data presented here.

Statistical analyses. All statistical analyses were carried out using SuperAnova (Abacus Concepts, Inc., Berkeley, CA) for the Macintosh. Analyses included three-factor analysis of variance with least square means comparisons. A P-value <0.05 was considered statistically significant. Values are given as means ± standard deviation of the concentrations in layers of skin (pmol/cm^2/µ) or as the percentage found in a given layer of total vitamin E recovered (pmol/cm^2).

RESULTS

The concentrations (pmol/cm^2/µ) of γ-tocotrienol, α-tocotrienol, or α-tocopherol after topical application of a 5% solution for 0.5, 1, 2, or 4 h were measured in murine skin layers SC, E, PD, D, and SF. Although there was a significant increase in the concentrations in the layers with time (main effect, $P < 0.001$), the relationship between the various vitamin E forms did not change differently with time, nor did the vitamin E contents of the layers change differently with time (no significant interactions). Therefore, for simplicity, the concentrations of each of the vitamin E forms in each of the layers were averaged over all time points as shown in Figure 1; the effects of time are shown in Figure 2. The uppermost layer of the skin (5 µm, SC1) contained the highest γ-tocotrienol, α-tocotrienol, and α-tocopherol concentrations of any of the layers ($P < 0.0001$ for each of the vitamin E forms). Furthermore, SC1 α-tocopherol concentrations were significantly greater than those of either SC1 γ-tocotrienol ($P < 0.0001$) or SC1 α-tocotrienol ($P < 0.0001$). None of the vitamin E concentrations in the other layers per µ were significantly greater than any other layers, possibly because of the large standard deviations observed.

The lengths of time that the vitamin E homologs penetrated the skin in relationship to the cutaneous layer vitamin

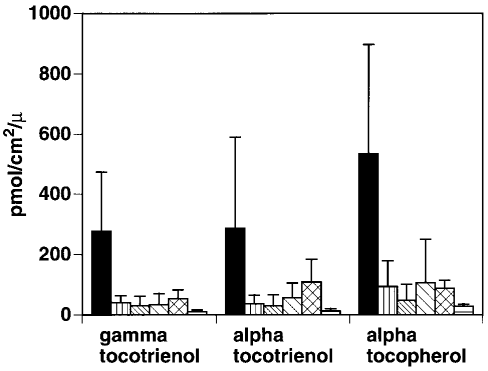

FIG. 1. Vitamin E content of murine skin after topical application of either γ-tocotrienol, α-tocotrienol, or α-tocopherol. The concentrations (pmol/cm^2/μ, mean ± SD, n = 16) of γ-tocotrienol, α-tocotrienol, or α-tocopherol after topical application of a 5% solution for 0.5, 1, 2, or 4 h were measured in skin layers (α-tocopherol, n = 16 for each layer): stratum corneum [SC1 (solid bar) γ-tocotrienol, n = 14; α-tocotrienol, n = 14], SC2 (vertical striped bar) γ-tocotrienol, n = 14; α-tocotrienol, n = 15], epidermis [E1(narrow, slanted, striped bar) γ-tocotrienol, n = 15; α-tocotrienol, n = 14], E2 (wide, slanted) (γ-tocotrienol, n = 16; α-tocotrienol, n =14) papillary dermis [PD cross-hatched bar (γ-tocotrienol, n = 15; α-tocotrienol, n = 16)], dermis [D (horizontal line bar) (γ-tocotrienol, n =15; α-tocotrienol, n = 13)]. Although subcutaneous fat vitamin E was measured, the thickness varied, so is not reported per μ. The average concentrations for all time points are shown. By least square means comparisons: γ-tocotrienol, α-tocotrienol, α-tocopherol in SC1 were significantly greater than their respective concentrations in any other layer ($P < 0.0001$); SC1 α-tocopherol concentrations were significantly greater ($P < 0.0001$) than those of either γ-tocotrienol or α-tocotrienol. There were no other significant differences between layers or between vitamin E forms.

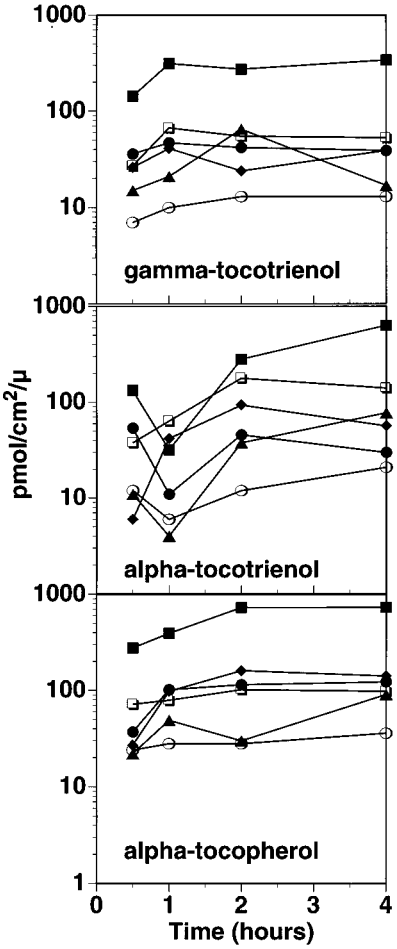

FIG. 2. Vitamin E content of murine skin at various times after topical application. The vitamin E concentrations from the same samples described in Figure 1 are shown for each of the time points (0.5, 1, 2, 4 h). By three-factor analysis of variance, there was a significant interaction between time and layer ($P < 0.0001$), but not with vitamin E form. The SC 1 vitamin E at 0.5 h was significantly less than for 2 h ($P < 0.0001$) or 4 h ($P < 0.0001$). In none of the other layers did the vitamin E concentrations significantly increase with time, although for each of the layers there was a trend toward increasing concentrations with time. See Figure 1 for abbreviations. SC1, ■; SC2, ●; ▲, E1; ◆, E2; □, PD; ○,D.

E are shown in Figure 2. It is clear that at all time points, SC1 contained the highest vitamin E concentrations, except for the comparison between SC1 at 0.5 and 1 h for α-tocotrienol.

SC1 contained the highest vitamin E concentrations when it was expressed per μ. If the thickness of the various skin layers is taken into account, it is apparent that the lower skin layers contain appreciable amounts of vitamin E. In order to compare the distribution of the various vitamin E forms into the skin layers, the total amount of each form in each of the layers was summed, then the percentage of each form was expressed per its respective total. When expressed as a percentage, the lowest layers (PD and D) contained the major portion of the applied vitamin E forms (Fig. 3). Although the percentage γ-tocotrienol in SC1 (10 ± 5%) was significantly greater ($P < 0.01$) than in SC2 (2 ± 1%), E1 (2 ± 2%), or E2 (2 ± 2%), it was significantly less than in PD (40 ± 15%) or D (36 ± 15%) ($P < 0.0001$). The SC1 percentage α-tocotrienol or percentage α-tocopherol was also significantly less than in PD or D ($P < 0.0001$).

The distribution into the PD was different for α-tocopherol compared with the tocotrienols. The percentage PD γ-tocotrienol (40 ± 15%) was similar to the fraction found in D (35 ± 15%); the percentage PD α-tocotrienol (53 ± 19%) was greater than that found in D (29 ± 16%) ($P < 0.0001$), while the percentage PD α-tocopherol (31 ± 6%) was less than that found in the D (41 ± 8%) ($P < 0.0005$). In all cases the percentage PD vitamin E homolog was greater than that found in the subcutaneous fat ($P < 0.0001$), which contained from 11 to 14% of the applied vitamin E. Thus, the penetration of the various vitamin E forms was rapid through the entire skin.

DISCUSSION

This study demonstrates that vitamin E applied to the skin is found in the highest concentrations in the uppermost layers of skin, if the data is expressed per μ of skin thickness (Fig. 1). It is not unsurprising that this is true whether measured at 0.5 h or up to 4 h (Fig. 2). What is surprising is that the largest fraction of skin vitamin E following topical application is not

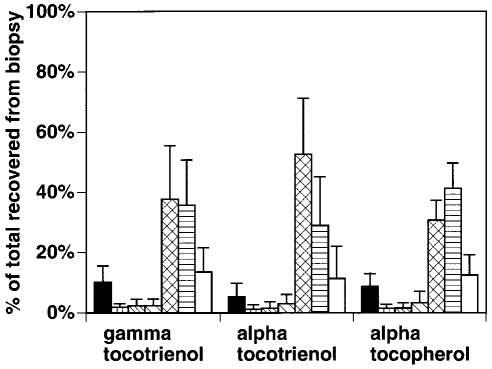

FIG. 3. Skin Vitamin E distribution following topical application. The percentage of each of the vitamin E forms found in each of the biopsies from γ-, α-, or α-tocopherol from the skin treated as described above is shown. The percentage γ-tocotrienol in SC1 was significantly greater ($P < 0.01$) than in SC2, E1, or E2, and significantly less than in PD or D ($P < 0.0001$). SC1 percentage α-tocotrienol or percentage α-tocopherol were also significantly less than their respective percentage in PD or D ($P < 0.0001$). The percentage α-tocotrienol was greater in PD than in D ($P < 0.0001$), while percentage α-tocopherol was less in PD than in D ($P < 0.0005$). In all cases the percentage PD vitamin E homolog was greater than its respective percentage in subcutaneous fat (SF) ($P < 0.0001$). SF (shaded bar). See Figure 1 for other abbreviations and symbols' explanations.

at the surface, but is found in the deeper subcutaneous layers (Fig. 3).

It should be noted that topical vitamin E application markedly increased skin vitamin E content. For example, α-tocopherol contents of untreated mice ($n = 8$) were: SC1 0.25 ± 0.09 pmol/cm^2/μ (Traber, M.G., Rallis, M., and Packer, L., unpublished observations) compared with 534 ± 363 pmol/cm^2/μ reported here; PD were 0.089 ± 0.037 pmol/cm^2/μ compared with 88 ± 27 pmol/cm^2/μ reported here, and D were 0.159 ± 0.059 pmol/cm^2/μ compared with 29 ± 7 pmol/cm^2/μ reported here. Thus, the application of a 5% α-tocopherol solution resulted in a 200- to 2000-fold increase in the skin α-tocopherol content. Trivedi *et al.* (27) proposed that topically applied vitamin E function as a penetration enhancer. Based on the large increases of vitamin E content, its rapid penetration and its well-known properties of increasing fluidity (28), it is not surprising that vitamin E has this effect.

We have calculated, based the thickness of each layer, that SC1 or SC2 each represents 0.8% of the skin thickness, E1 and E2 represent 1.6%, PD represents 16%, D represents 64%, and subcutaneous fat 15%. Comparing these percentages with those of the distribution of vitamin E homologs, about 10% of the skin vitamin E was found in SC1, far exceeding the percentage expected based on its thickness, while SC2, E1, or E2 contained a fraction of total equivalent to that expected from its fraction of the total. Most remarkably, PD represents about 16% of the total skin thickness but contained 40 to 50% of the various vitamin E homologs. This layer contains the sebaceous glands, which are lipid secretory organs, and, thus, may account for the affinity of this layer for vitamin E. The D represents about 64% of the thickness of the skin, but was comparatively unenriched in vitamin E (30–40% of total). The subcutaneous fat contained about 11–14% of the skin vitamin E and represents about 15% of the skin thickness. Remarkably, at the earliest time point 0.5 h, significant increases in vitamin E were found in the subcutaneous fat (data not shown), suggesting rapid penetration of the applied vitamin E through the skin.

In part, this study was carried out to evaluate whether tocotrienols, which have a higher fluidity (29,30), might more readily penetrate murine skin. In fact, we found that the distribution of tocotrienols was somewhat different than that of α-tocopherol. α-Tocotrienol appeared to accumulate more in the PD, while a greater fraction of α-tocopherol was present in the D. It is unknown what regulates tissue concentrations and whether this represents a real preference of the PD for tocotrienols and the D for α-tocopherol.

The high concentration of the applied vitamin E forms in SC1 is consistent with our observations of the high susceptibility of applied TRF to ozone exposure (18). These data also emphasize that topically applied vitamin E largely protects the first few microns of skin. Since oxidative stress depletes skin oxidants, it is now important to determine whether damage caused by oxidation by ozone at the surface, or ultraviolet light in deeper layers can be prevented by applied vitamin E and whether it protects other skin antioxidants and proteins, lipids, and DNA.

In conclusion, application of either γ-tocotrienol, α-tocotrienol, or α-tocopherol to murine skin results in extraordinary increases in stratum corneum vitamin E. If oxidative stress is applied to the surface of the skin, this level of vitamin E is sufficient to provide protection, as we have described in our studies with ozone exposure (18). Vitamin E homologs penetrated through the entire skin to the subcutaneous fat layer within the first 0.5 h. It is unclear whether this rapid penetration is into skin cells (keratinocytes or fibroblasts), around the cells in the skin lipids, or perhaps down the hair follicles into the deepest layers. It is clear from these studies that PD, the location of sebaceous glands, has a special affinity for vitamin E; the mechanism for this affinity remains to be determined.

ACKNOWLEDGMENTS

Beth Koh provided excellent technical assistance. We gratefully acknowledge the efforts of Dr. Asaf A. Qureshi, University of Wisconsin (Madison, WI), who isolated tocotrienols for use as standards for this study. This study was supported in part by the Palm Oil Research Institute of Malaysia.

ABSTRACT: The bile acid concentrations in the serum, liver, bile, intestines, and feces of 3- and 19-mon-old male and female Nagase analbuminemic (NA) rats were compared with those in Sprague-Dawley (SD) rats. There was no significant difference in the bile acid levels between NA and SD rats. However, increased biosynthesis and pool size of cholic acid (CD) derivatives and decreased levels of chenodeoxycholic acid (CDCA) derivatives (increased CA/CDCA ratio) were detected in male NA rats as compared to SD rats. The CA/CDCA ratio in female NA rats was not different from that in their SD counterparts. There were no significant differences between NA and SD rats in the biliary bile flow, bile acid levels in the small and large intestines, fecal bile acid excretion, bile acid concentration in the portal and systemic circulation, and in the pool size of bile acids. The blood lipid concentrations were significantly higher in the NA rats than in the SD rats. The hepatic levels of lipids were not significantly different between the two rat strains. In conclusion, this study showed that metabolism of bile acids in NA rats is not significantly affected, and that the hypercholesterolemia observed in these strains is not related to abnormalities of bile acid metabolism.

Lipids 33, 93–99 (1998)

Analbuminemic rats established from the normal Sprague-Dawley (SD) rats (Nihon Clea, Tokyo, Japan) by Nagase *et al.* (1,2) (Nagase albuminemic [NA] rats) exhibit several features resembling human analbuminemia. Analbuminemia of NA rats is inherited as an autosomal recessive trait. Deficiency or defect in the albumin mRNA has been reported in hepatocytes of NA rats (3). This mutant strain is characterized by a marked hypoalbuminemia, hypercholesterolemia, mild anemia, hypocalcemia, and hyperfibrinogenemia.

Albumin plays a crucial role in the blood transport of bile acids (BA). Hypoalbuminemic states are frequently associated with increased plasma level of cholesterol, which is converted to BA in the liver. In the present study, to investigate the alterations of the BA metabolism during hypercholesterolemia associated with analbuminemic states, we determined the BA concentrations in the serum, bile, intestines, and feces in NA and SD rats.

MATERIALS AND METHODS

Animals. Three-month-old and 19-mon-old male and female SD and NA rats (Sasaki Kenkyusho, Tokyo, Japan) were used in the experiments. The animals were raised in cages at room temperature (25 ± 1°C), with a humidity of 50–60% and illumination 12 h/day (from 7:00 to 19:00). The rats were kept in separate cages 2 wk before collection of feces. Food (CE-2; Nihon Clea) and tap water were given *ad libitum.*

Sample collections. Rats were laparotomized under pentobarbital anesthesia (50 mg/kg, i.p.); a polyethylene tube (PE-10; Clay Adams, Parsipanny, NJ) was inserted into the bile duct, and bile was collected for 30 min. Blood samples were then drawn from the portal vein and descending aorta, and serum was separated by centrifugation at 1,800 × *g* for 15 min. Thereafter, resection of the liver, small and large intestines was performed. Feces were collected continuously during the last 2 d before sacrificing the animals.

Sample preparations. After adding 25 μg of 7-α, 12-α-dihydroxy-5β-cholan-24-oic acid to 500 μL of bile samples, lipid extraction was performed using 40 vol of 99.5% ethanol for 10 min. The extract was pooled, adjusted to an appropriate volume, and filtered. The filtrates were used to measure the concentrations of BA, cholesterol, and phospholipids (PL).

For the determination of sterol and BA concentrations in feces, samples were lyophilized and pulverized using a commercial coffee mill. Absolute ethanol was then added to 500 mg of pulverized feces, and the filtrates were pooled and evaporated to dryness. Small and large intestines were separately homogenized with distilled water, and a fixed amount of each intestinal homogenate (1/30 of the total volume of the small intestine and 1/5 of the large intestine) was collected and lyophilized. The small and large intestine extracts were then

Abbreviations: BA, bile acids; C/P ratio, cholesterol/phospholipid ratio; CA, cholic acid; CDCA, chenodeoxycholic acid; EC, esterified cholesterol; FC, free cholesterol; MCA, muricholic acid; NA, Nagase analbuminemic; PL, phospholipids; SD, Sprague-Dawley; TC, total cholesterol; TG, triglyceride.

prepared as described above for fecal samples. Lyophilized samples were then dissolved in 70% ethanol, and triglycerides (TG) were partition-extracted with *n*-hexane. After removing the solvent by evaporation, the residue was used for assaying BA (4).

Serum samples were also added to 25 μg of 7-α, 12-α-dihydroxy-5β-cholan-24-oic acid, and extracts were prepared using 10–20 vol of 99.5% ethanol for 1 h. The extracts were then cooled, filtered, and used for assaying BA. The liver was resected, weighed, and 1 g of the left lateral lobe was homogenized. One-tenth volume of the homogenate was lyophilized, and extraction of hepatic lipids was performed using 95.5% ethanol. The extract of the remaining homogenate was cooled, filtered, and used for the assay of lipids.

Assays of BA, sterols, PL, and TG. BA were determined following methods previously described (4,5,8).

Conjugated BA were hydrolyzed enzymatically and then analyzed by gas chromatography. Sterols in bile and feces were assayed by gas chromatography (column DB-17; J&W Scientific, Folsom, CA; temperature 240°C) after dissolving the samples in methyl-ethyl ketone/carbon disulfide (1:1, vol/vol). Measurements of total cholesterol (TC), free cholesterol (FC), TG, and PL were carried out as previously described (6,7,9).

Statistical analysis. Data are expressed as the mean ± standard error. The difference between the means of variables was calculated by the Student's *t*-test. A $P < 0.05$ was considered as statistically significant.

RESULTS

Body and liver weights and the blood and hepatic concentrations of lipids (*Table 1*). The body weight of NA rats was 30–35% lower than that of SD rats of the same age. Little difference was found in the liver weight between the two strains, but the liver weight per unit of body weight (g/100 g body weight) was significantly higher in NA rats than in SD rats. Serum cholesterol levels were significantly increased in both female and male NA rats as compared to their SD counterparts. The degree of hypercholesterolemia was particularly high in the 19-mon-old female NA rats. The serum concentrations of FC and esterified cholesterol (EC) were significantly higher in NA rats than in the SD strains. On the other hand, the percentage of EC included in the TC was decreased in NA rats as compared to that observed in SD strains. No consistent difference in the serum levels of TG was observed between the two animal strains, except for increased serum TG levels in the 19-mon-old female NA rats as compared to their SD counterparts. NA rats presented higher serum PL levels than SD rats. The increase rate in cholesterol levels was proportionally greater than that of PL, resulting in a high cholesterol/phospholipid ratio (C/P ratio).

The lipid concentration in liver homogenates was not significantly different between the two strains in most experimental animal groups, except for higher levels of EC in the 19-mon-old male SD rats than in NA rats of the same age and gender. The hepatic level of EC was significantly lower in female than in male rats of both strains. This increased proportionally with age in female rats of both strains. The hepatic concentration of PL was not correlated with the strain, sex, or age of rats.

Bile flow and biliary lipid concentration (Table 2). Bile flow was decreased in 3-mon-old male NA rats as compared to their SD counterparts. However, it did not change markedly in all other groups when expressed per unit weight of the liver. There was no difference between SD and NA rats in the secretory levels of biliary cholesterol, PL, or BA, except for a

[a]Mean ± SE. *$P < 0.05$, compared to corresponding SD rats. **$P < 0.01$, compared to corresponding SD rats. BA, bile acids; CA, cholic acid; CDCA, chenodeoxycholic acid α or β indicates presence and position of OH residue. Superscripted numbers: 1, DCA; 2, α-muricholic acid (MCA); 3, β-MCA; 4, ω-MCA; 5, hyodeoxycholic acid. See Table 1 for other abbreviations.

significant decrease in the secretion of biliary cholesterol and PL in the 3-mon-old male NA rats and of biliary PL in 19-mon-old male NA rats as compared to those in the corresponding SD rats. Although the secretory level of each biliary lipid per animal was significantly lower in female than in male rats, it was nearly equal in both groups when the secretory activity was expressed per unit weight of the liver. With regard to the BA composition, CA was the most abundant component, followed by β-muricholic acid (β-MCA) in males and CDCA and α- and β-MCA in females. The BA composition was not significantly different between NA and SD rats, but the ratio of total CA and CDCA derivatives (CA/CDCA ratio) was significantly higher in male NA rats than in SD counterparts.

Fecal concentrations of cholesterol and BA (*Table 3*). The dietary intake and fecal excretion of cholesterol were lower in both male and female NA rats than in the corresponding SD rat groups at the age of 3 mon. However, little difference was observed between the same groups in 19-mon-old rats. The cholesterol/coprosterol ratio was almost the same in both animal strains.

No difference was observed in the rate of fecal BA excretion between SD and NA rats. However, the fecal BA excretion per gram liver weight was reduced in 19-mon-old male rats of both strains. This age-associated decrease in the fecal excretion per gram liver weight was not significant in female rats.

Deoxycholic acid, ω-MCA, and hyodeoxycholic acid were the major fecal BA components. The BA composition was not different between NA and SD rats. The difference in the CA/CDCA ratio between female and male rats was significant in the NA (higher in males) but not in the SD strain. This CA/CDCA ratio was higher in the aged rat groups than in their young counterparts.

Blood concentration of BA (Table 4). Decreased portal BA concentration and increased portal and systemic CA/CDCA ratios were observed in 3-mon-old male NA rats as compared to male SD rats of the same age. No difference was detected in other groups. The BA concentration in the systemic circulation was lower (male rats, 7%; female rats, 5%) than in the portal circulation in both NA and SD rats.

Size and composition of BA pool (Table 5). The BA pool size was calculated as the sum of the total amount of BA in bile collected during a 30-min period and the total amount of BA detected in the small and large intestines. The BA pool size was smaller in female than in male rats, but it was not significantly different between NA and SD rats. The CA/CDCA ratio was higher in male NA rats than in SD counterparts. No other substantial differences were observed.

The distribution of BA in the body was as follows: about

[a]Mean ± SE. *$P < 0.05$, compared to corresponding SD rats. See Tables 1 and 2 for abbreviations and Table 2, for further footnotes/explanations.

10% was present in bile, about 80% in the small intestine, and about 10% in the large intestine. Interestingly, the CA/CDCA ratio was significantly lower in large intestine and feces than in bile and small intestine. These findings suggest that absorption of CA group in the small intestine is predominant in relation to that of CDCA group. No difference was observed in the distribution of BA between NA and SD rats.

DISCUSSION

BA are bound primarily to albumin in biological fluids (10–12) and are eluted from rat liver only when the liver is perfused with a buffer containing albumin (13). Thus, we hypothesized that the metabolism of BA would be affected in NA rats. To demonstrate this, in the present study, we compared the BA metabolism between NA and SD rats (the parental strain of NA rats).

The results of our present study showed that there are insignificant differences between the two rat strains in the rate of biliary BA secretion, BA concentration in the small and large intestines, fecal BA excretion, BA concentrations in the portal and systemic circulations, BA pool size, and in the BA composition. Increases in the synthesis and in the pool size of BA of the CA group and decreases in the synthesis and pool size of BA of the CDCA group (increased CA/CDCA ratio) were the only abnormalities observed in male NA rats. Thyroid hormones previously have been reported to enhance the synthesis of BA of the CDCA group, and this hormonal activity may explain the reduced CDCA levels observed in hypothyroid states (14,15). The blood levels of thyroid hormones were reported to be significantly lower in male NA rats than in male SD strains (16), and low levels of thyroid hormones may explain the increased CA/CDCA ratio observed in male NA rats.

There were no statistically significant differences between NA and SD rats in the rate of BA secretion and in the blood BA levels. The fecal BA excretion indicates the daily amount of BA synthesis in the liver (4,5). Although we found no difference in the BA excretion between SD and NA rats, a previous study suggested that it is high in NA rats (17). The mechanism of this discrepancy remains to be clarified. On the other hand, little difference was observed between NA and

SD rats in the BA concentration and composition in the portal blood, suggesting that BA are probably bound to other proteins such as lipoproteins in the plasma of NA rats (18).

The hypercholesterolemia found in NA rats is consistent with the results reported in previous studies. The age-associated increase in the serum levels of cholesterol, which were particularly of esterified form, was observed in both male and female SD rats, but not in male NA rats (7,19). The serum PL level was also particularly high in NA rats. This was associated with an increase in the C/P ratio due to a more significant increase in the serum level of cholesterol than that of PL. Serum concentrations of TG were significantly higher in female NA rats than in the SD counterparts. Serum TG also tended to be higher in male NA rats, but their increase was not significant.

The mechanism of hypercholesterolemia associated with analbuminemia is not clear, but experimental and clinical studies carried out in the nephrotic syndrome, a kidney disease that is also associated with decreased plasma levels of proteins and hypercholesterolemia, suggested that it occurs due to increased synthesis and/or reduced catabolism of lipoproteins (20–22). The increased level of cholesterol is downregulated by its conversion to BA in the liver through the neutral and acid pathways. The ratio of the two major BA, CA and CDCA, produced in the liver varies according to the activity of either of these two pathways. In the present study, neither the production of the major BA nor their ratio (CA/CDCA ratio) was changed in NA rats, suggesting that analbuminemia induces no major changes in BA metabolism. In addition, previous studies have shown that the activities of the hepatic enzymes (i.e., HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis; cholesterol 7 α-hydroxylase, the rate-limiting enzyme in BA synthesis), responsible for increasing BA production in the liver, are not altered in the hypoalbuminemic states associated with the puromycin-induced nephrotic syndrome (23,24). Overall, the results of our present study and those reported in previous investigations suggest that the increased levels of cholesterol observed in analbuminemic conditions do not affect the metabolism of BA.

In contrast to the marked increase in the serum levels of lipids, little changes were observed in the hepatic lipid concentrations of NA rats. This finding differs from that observed during increased dietary cholesterol intake. In this situation, the lipid levels in the liver increase significantly as compared to the blood lipid concentrations (4,25).

In conclusion, this study showed that the metabolism of BA is not affected in NA rats. This result suggests that the hypercholesterolemia observed in these mutant strains is not related to abnormalities of the BA metabolism.

ABSTRACT: The structure–retention correlation of various C_{24} bile acid isomers was studied by the addition of methyl β-cyclodextrin (Me-β-CD) to mobile phases in reversed-phase high-performance liquid chromatography (HPLC). The compounds examined include a series of monosubstituted bile acids related to cholanoic acids differing from one another in the position and configuration of an oxygen-containing function (hydroxyl or oxo group) at the position C-3, C-6, C-7, or C-12 and the stereochemistry of the A/B-ring fusion (*trans* 5α-H and *cis* 5β-H) in the steroid nucleus. The inclusion HPLC with Me-β-CD was also applied to biologically important 4β- and 6-hydroxylated bile acids substituted by three to four hydroxyl groups in the 5β-steroid nucleus. These bile acid samples were converted into their fluorescence prelabeled 24-pyrenacyl ester derivatives and chromatographed on a Capcell Pak C_{18} column eluted with methanol–water mixtures in the presence or absence of 5 mM Me-β-CD. The effects of Me-β-CD on the retentions of each compound were correlated quantitatively to the decreasing rate of capacity factors and the relative strength of host–guest interactions. On the basis of the retention data, specific and nonspecific hydrogen-bonding interactions between the bile acids and the Me-β-CD were discussed.
Lipids 33, 101–108 (1998).

Cyclodextrins (CD) are toroidal-shaped cyclic oligosaccharides consisting of six to eight D(+)-glucopyranose units connected by α-(1,4) bonds and are able to include specific guest molecules into their hydrophobic cavity to form inclusion complexes (1). The stability of the inclusion complexes, i.e., strength of host–guest interaction, is influenced by the hydrophobic and/or hydrogen-bonding interactions between the cavity of CD and the guest molecules, including the shape and the size of the guests (2–5). By utilizing the properties of inclusion complex formation of CD, Armstrong *et al.* (1,3–5) have successfully separated many recalcitrant pairs of the positional, geometrical, and optical isomers of bioactive compounds using chromatographic techniques as they fit differently into the cavity of CD (1).

In reversed-phase high-performance liquid chromatography (HPLC), CD have been used in two different manners, either by adding a CD to the mobile phase (6) or by covalently bonding a CD to a silica gel (4). Of the two methods proposed in inclusion HPLC, Shimada *et al.* (6) have reported apparent superiorities of CD, particularly for β-CD or its methylated derivative (Me-β-CD), as a mobile phase additive in steroid analysis. By using the method, they have selectively resolved many difficult-to-separate pairs of cardiac steroids related to cardenolides (7,8) and bufadienolides (8,9), estrogens (6,10), and bile acids (11–14), which overlap one another in conventional HPLC without CD in the mobile phases.

The above findings in inclusion HPLC prompted us to explore in more detail the relationship between the retentions and the structures of various bile acid isomers and to compare the results with that observed in conventional HPLC. In addition, the retention data are expected to estimate what factors are responsible for the host–guest interactions of the bile acids with Me-β-CD and to elucidate the role of oxygen-containing functions in the complex formation. In this study, inclusion HPLC behavior induced by adding Me-β-CD in the mobile phases was examined for a series of monosubstituted bile acids related to 5α- and 5β-cholanoic acids having an oxygen-containing function (hydroxyl or oxo group) at the position C-3, C-6, C-7, or C-12 as their fluorescence-labeled 24-pyrenacyl ester derivatives (Scheme 1).

Abbreviations: CD, cyclodextrin; HPLC, high-performance liquid chromatography; Me-β-CD, methyl β-cyclodextrin; *rk′*, relative capacity factor; *rΔk′*, the ratio of the difference in the capacity factors between the k'_1 and k'_2 values of the same compound to that of a reference compound.

The inclusion HPLC of biologically important 4β- and 6-hydroxylated bile acids substituted by three to four hydroxyl groups in the 5β-steroid nucleus was also studied.

EXPERIMENTAL PROCEDURES

Materials and reagents. Almost all of the C_{24} bile acids related to 5α- and 5β-cholanoic acids having one to four oxygen-containing functions at the positions C-3, C-4, C-6, C-7, and/or C-12 in the steroid nucleus were taken from our laboratory collection. The fluorescence prelabeling reagent, 1-bromoacetylpyrene, was obtained from Wako Pure Industries Ltd. (Tokyo, Japan). Me-β-CD (heptakis-(2,6-di-D-methyl)-β-cyclodextrin; mean degree of substitution, 10.5–14.7) and dicyclohexyl 18-crown-6 ether were available from Sigma Chemical Co. (St. Louis, MO) and Nakarai Tesque (Kyoto, Japan), respectively. Prepacked silica cartridges, Sep-Pak Light (sorbent weight, 120 mg), for solid-phase extraction were purchased from Waters Associates (Milford, MA).

HPLC. The apparatus used for this work was Hitachi (Tokyo, Japan) L-6200 and L-6000 pumps equipped with an L-7610 degasser and an L-1050 fluorescence spectrophotometer. A Capcell Pak C_{18} UG120 column (250 mm × 4.6 mm i.d; particle size, 5 μm; Shiseido; Tokyo, Japan) was used at ambient temperature.

Methanol–water mixtures, ratios from 92:8 to 80:20 (vol/vol), were used as mobile phases at a flow rate of 1.0 mL/min under an isocratic condition. The effluents from the column were monitored with the fluorophotometer by using an excitation wavelength of 370 nm and an emission wavelength of 440 nm.

Sample preparation. Each of the C_{24} free bile acids (*ca.* 200 μg) was converted into the 24-pyrenacyl ester derivative by a procedure reported by Kamada *et al.* (15), using 1-bromoacetylpyrene as a prelabeling reagent and dicyclohexyl 18-crown-6 ether as a catalyst. After the reaction, sample solution was diluted with benzene (5 mL), applied to a preconditioned Sep-Pak silica cartridge, and washed successively with benzene (5 mL) and benzene/EtOAc (4:1, vol/vol; 5 mL). The desired pyrenacyl ester derivative of a bile acid was then eluted with methanol/CH_3CN (1:9, vol/vol; 10 mL), and an aliquot of the solution was injected into the HPLC system with an internal reference standard. The esters of 3α-hydroxy-5β-cholanoic acid and 3α, 6α, 7α-trihydroxy-5β-cholanoic acid were chosen as internal reference standards for the analysis of monosubstituted and polyhydroxylated bile acids, respectively.

RESULTS AND DISCUSSION

Preliminary study. Previously, optimal conditions for inclusion HPLC using CD as mobile phase additives have been studied by Shimada *et al.* (11–14) for the unconjugates of five common bile acids (i.e., lithocholic, chenodeoxycholic, ursodeoxycholic, deoxycholic, and cholic acids) and their glycine- and taurine-amidated, sulfated, and glucuronidated conjugates. On the basis of these studies, methanol and Me-β-CD were employed in this study as an organic mobile phase modifier and as a mobile phase additive, respectively. In addition, the carboxyl groups of free bile acid samples were converted into their 24-pyrenacyl ester derivatives using dicyclohexyl 18-crown-6 ether and 1-bromoacetylpyrene as precolumn labeling reagents, because of the high-sensitivity with fluorescence detector and of the excellent chromatographic properties in both conventional and inclusion HPLC (13–15).

When the eluent is low in water percentage (*ca.* 10%), excess fluorescence prelabeling reagent and reaction by-products in the 24-pyrenacyl esterification of monosubstituted bile acids with 1-bromoacetylpyrene do not generally interfere with the desired bile acid ester peaks of interest, so a preliminary purification step is avoided. However, with the esters of more polar polyhydroxylated bile acids, which require a higher percentage of water in the eluent for good resolution, the contaminating peaks can often interfere with early-emerging ester peaks. For this reason, a crude esterification product was purified by a preconditioned Sep-Pak silica cartridge for solid-phase extraction prior to HPLC analysis. After washing the product successively with benzene and benzene–ethyl acetate, the desired bile acid ester was recovered with eluting methanol/CH_3CN (1:9, vol/vol).

The pyrenacyl ester derivatives of bile acids were first chromatographed on a Capcell Pak C_{18} column eluting with methanol/water mixtures (92:8–80:20, vol/vol) and subsequently measured with the same eluent system containing 5 mM Me-β-CD. As expected, the presence of 5 mM Me-β-CD in the eluents did not affect the peak shape and symmetry. Under the HPLC conditions used, the retentions (i.e., capacity factors) observed for each compound in the absence and presence of Me-β-CD were expressed as k_1' and k_2' values, respectively. In order to facilitate a comparison of the effects of Me-β-CD on the k_1' and k_2' values of each substituent and to estimate the relative strength of host–guest interactions from bile acids and Me-β-CD, rk' and $r\Delta k'$ values were proposed in this study.

Thus, the rk' value is the relative capacity factor (k_2'/k_1') for the same compound, representing the decreasing rate of retentions induced by adding Me-β-CD (14); the effect of Me-β-CD on the retention is larger for compounds with a small rk' value than for compounds with a large one. On the other hand, the $r\Delta k'$ value is defined as the ratio of the difference in the capacity factors between the k_1' and k_2' values of the same compound to that of a reference compound, which reflects a relative time to pass through the Me-β-CD cavity; alternatively, compounds with a large $r\Delta k'$ value are more tightly complexed with Me-β-CD than compounds with a small one, indicating the relative strength of the host–guest interactions. Since the rk' and $r\Delta k'$ values are specific ones for individual compounds and are not being related to each other, the combined use of the two relative values would be useful for characterizing the structures of unknown bile acids (see below).

Chromatographic behavior of monosubstituted bile acids. At first, chromatographic behavior of the pyrenacyl ester derivatives of 24 monosubstituted bile acids was examined.

TABLE 1
Effect of Me-β-CD on the Retention of Monosubstituted Bile Acids[a]

[a]Column, Capcell Pak C_{18} (Shiseido, Tokyo, Japan), mobile phase, methanol/water (92:8, vol/vol); detection, fluorescence (excitation wavelength, 370 nm; emission wavelength, 440 nm); the designations 5β- and 5α-series refer to 5β- and 5α-cholanoates, respectively; measured as the 24-pyrenacyl ester derivatives.
[b]Capacity factor obtained without methyl-β-cyclodextrin (Me-β-CD) in the mobile phase.
[c]Capacity factor obtained with 5 mM Me-β-CD in the mobile phase.
[d]Relative capacity factor; the k'_1 value for the same compound was taken as 1.0.
[e]Relative $\Delta k'$ value; the $\Delta k'$ value of 3α-hydroxy-5β-cholanoic acid was taken as 1.0 for the calculation of the $r\Delta k'$ values.
[f]Difference in the k'_1 and k'_2 values for the same compound.

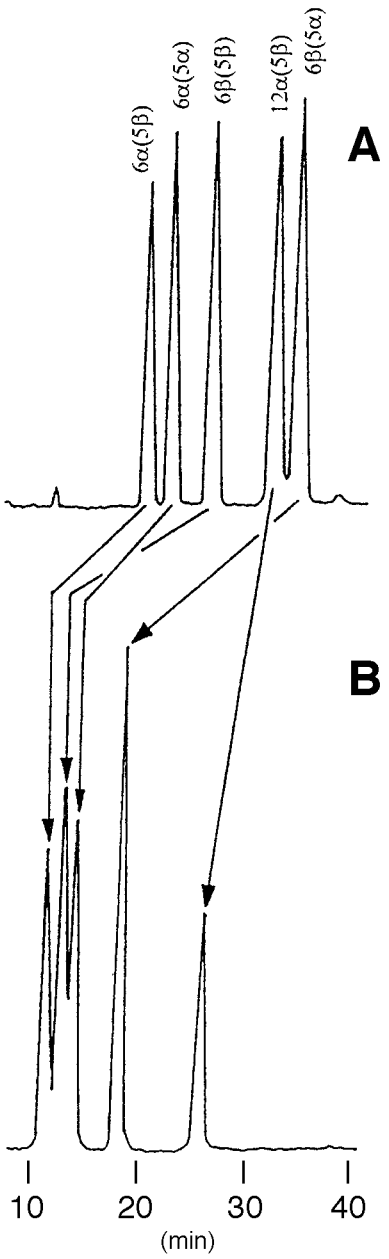

FIG. 1. High-performance liquid chromatography (HPLC) chromatograms of a mixture of the 24-pyrenacyl ester derivatives of monohydroxylated bile acid isomers eluted by methanol/water (92:8, vol/vol) (A) without or (B) with 5 mM methyl-β-cyclodextrin (Me-β-CD) in the mobile phase.

These compounds differ from one another in the position and configuration of an oxygen-containing function (hydroxyl or oxo group) at the position C-3, C-6, C-7, or C-12 and the stereochemistry of the A/B-ring fusion (5β-H normal and 5α-H "*allo*" series) in the steroid nucleus. A methanol/water mixture of 92:8 (vol/vol) was employed as the eluent without or with 5 mM Me-β-CD. The compounds examined and their retention data are compiled in Table 1. It is noticed here that since the capacity factors are dependent on both the Me-β-CD concentration (14) and mobile phase composition (unpublished results; Momose, T., and Iida, T.), the data are essential for the HPLC conditions used. Typical chromatograms are also shown in Figure 1.

In conventional HPLC without Me-β-CD in the mobile phase, the elution orders of the pyrenacyl esters of each group of monohydroxy and monooxo compounds in the 5α- and 5β-series on a Capcell Pak C_{18} column were essentially identical with those observed previously for the corresponding 4-nitrophthalimide methyl esters on a Nova-Pak C_{18} column (16). However, slight differences observed in the separation efficiency and the elution order of some of the isomeric pairs are probably attributable to the differences in the nature of the C_{18} reversed-phase columns used and of the ester derivatives at C-24.

By adding 5 mM Me-β-CD to the eluent, the retention of these compounds responded dramatically to the minor structural differences in the steroid nucleus, and the observed k_2' values were decreased to a large extent, compared to the corresponding k_1' values. The decrease in the retentions observed for the same compound indicates the formation of host–guest interactions between the Me-β-CD and the bile acid. Two different mechanisms have accounted for the host–guest interac-

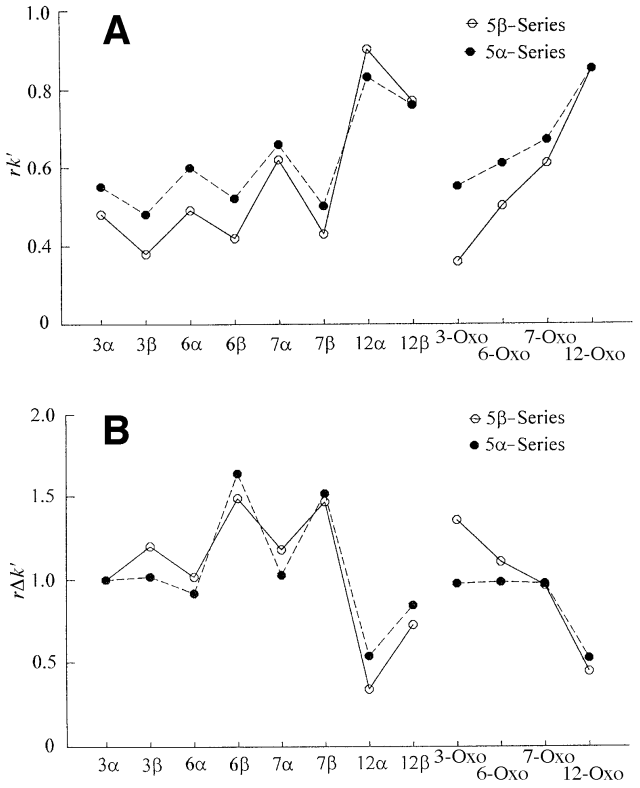

FIG. 2. Relationship of the (A) relative capacity factor (*rk′*) values and (B) the ratio of the difference in the capacity factors between the k'_1 and k'_2 values of the same compound to that of a reference compound (*rΔk′*) for monosubstituted bile acids.

tions (17): a hydrophobic interaction between the inside of the hydrophobic cavity of a host CD and the hydrophobic face of a guest molecule, and a hydrogen-bonding interaction between hydroxyl groups around the rims of the CD and polar functional groups of the guest molecule. Of the two interactions, the hydrogen-bonding interaction seems to be essential for the observed changes in the retention of the bile acids, because the polar and hydrophilic functional groups in the nucleus and the carbonyl group in the side-chain of the solutes accelerate the formation of strong hydrogen bonds with Me-β-CD (12,17).

As shown in Figure 2, the following general trends were observed for the *rk′* values in the monosubstituted bile acids. The effects of Me-β-CD on the *rk′* values of analogous compounds are usually similar in both the 5β- and 5α-series, and the following order of the increasing *rk′* values was observed for each series: 12α- >> 12β- > 7α- > 3α-, 6α- > 6β-, 7β- > 3β-ols; 12- > 7- > 6- > 3-ketones. Retentions of compounds having a β-oriented hydroxyl group are much more strongly influenced by Me-β-CD than those of the corresponding α-epimers. The largest decrease (*ca.* 50–60%) in the retentions was observed for 3β-hydroxy compounds (*rk′*, 0.38 and 0.48), whereas 12α-hydroxy and 12-oxo compounds (*rk′*, 0.83–0.90) were slightly affected by Me-β-CD (*ca.* 10–15%). In addition, the decrease in retentions was found to be more prominent in the 5β-series of compounds than in the corresponding 5α-analogs, except for 12α- and 12β-hydroxy compounds. These results imply that in bile acids, β-configuration of hydroxyl groups and shape of the *cis*-A/B (5β-H) ring fusion of the steroid nucleus, as well as the position of an oxygen-containing function, are preferentially oriented to fit well into the Me-β-CD cavity.

On the other hand, inspection of the *rΔk′* values revealed that the relative strength of the host–guest interactions of Me-β-CD with monohydroxylated bile acids in each of the 5β- and 5α-series increases in the following order: 12α- << 12β- < 3α-, 6α- < 3β-, 7α- < 6β-, 7β-ols (Fig. 2). This order of the *rΔk′* values is inconsistent with that observed for the *rk′* values, suggesting that the decreasing rate of retentions is not necessarily proportional to the relative strength of host–guest interactions. For example, both 6α-hydroxy-5β-cholanoate and 7β-hydroxy-5α-cholanoate exhibited very similar *rk′* values of 0.49 and 0.50, respectively, but their *rΔk′* values differed greatly from each other and showed 1.02 and 1.48, respectively. The combined use of the *rk′* and *rΔk′* values is therefore useful for characterizing the structures of the types of bile acids. In each of the 5β- and 5α-series, compounds having a β-hydroxyl group form more stable inclusion complexes than the corresponding α-isomers, in accord with their decreasing rate of the retentions as mentioned above. In particular, 6β- and 7β-hydroxy compounds (*rΔk′*, 1.47–1.61) exhibit the strongest affinity with Me-β-CD, whereas 12α-hydroxy compounds (*rΔk′*, 0.34–0.53) show the weakest affinity to give the least-stable complexes. In the case of oxo-bile acids, the complex stability increased in the order of 12- << 7- < 6- < 3-ketones in the 5β-series and 12- << 3-, 6- and 7-ketones in the 5α-series. Again, the order of the *rΔk′* values in the 5α-series also differed from that of the *rk′* values.

The above finding that compounds having a hydroxyl group at the A- or B-ring of the steroid nucleus form much more stable inclusion complexes with Me-β-CD than compounds having an oxygen-containing function at C-12 in the C-ring can be reasonably explained by suitable spatial distances between hydroxyl groups and carbonyl groups of the former, which allow for specific hydrogen bondings with the Me-β-CD. As illustrated in Figure 3A, assuming that if a bile acid pyrenacyl ester enters from the less bulky side of the A/B-ring of the solute into the wider rim of Me-β-CD, hydrogen bonds may occur at the two sites: firstly, a hydrogen bond between a hydroxyl of the steroid nucleus in the solute and one or two of seven primary hydroxyls ($-CH_2OH$) at the 6′-position of each glucopyranose moiety, which are situated in the narrower rim of the Me-β-CD cone; secondly, a hydrogen bond between a carbonyl group in the side-chain in the solute and one of secondary hydroxyls (>CHOH) at the 2′- or 3′-position of each glucopyranose unit, which is located at the wider rim of the Me-β-CD cone.

Examination of a molecular model revealed that hydroxyl groups at the position C-3, C-6, or C-7 in the steroid nucleus and a carbonyl group in the side-chain of bile acid pyrenacyl esters are situated in preferred positions, which form easily the specific hydrogen bonds with a primary 6′-hydroxyl group

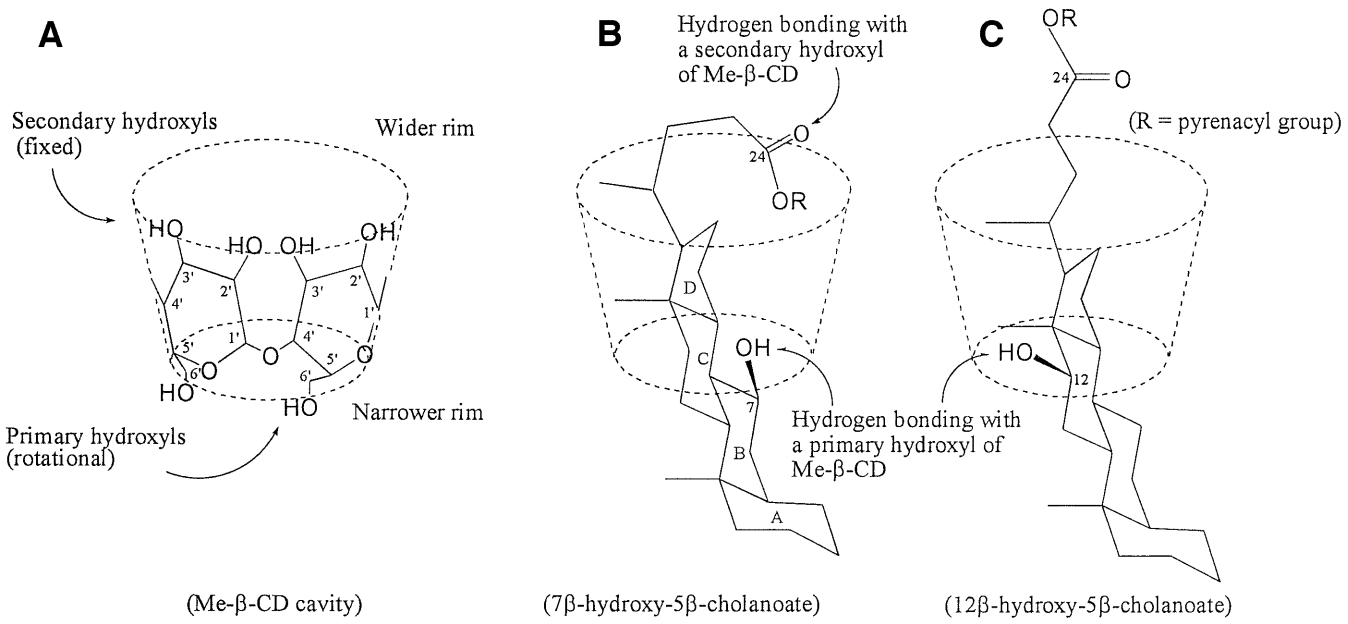

FIG. 3. Conceptual illustration of inclusion complexes between Me-β-CD and monohydroxylated bile acids. See Scheme 1 for abbreviation.

(free rotational) at the narrower rim and a secondary 2′- or 3′-hydroxyl group (fixed) at the wider rim of the Me-β-CD cone, respectively (Fig. 3B). These compounds would therefore be held by the two specific hydrogen bonds at both rims of the Me-β-CD, forming stable complexes. The validity of the above assumptions is supported by the previous observations in similar inclusion HPLC studies of polyhydroxylated sterols having an alkyl side-chain (17) and C_{24} unconjugated bile acids and their glycine- and taurine-amidated conjugates (12,14).

In a similar manner, the HPLC behavior of 12-oxygenated compounds which show the least-stable hydrogen bonds with Me-β-CD can be interpreted as follows. Concerning the anomaly of analogous 12α-hydroxy bile acids such as deoxycholic and cholic acid derivatives, previous workers have reported that a steric interaction between the 12α-hydroxyl group and the carbonyl group of the solutes interferes with the hydrogen bonding between the carbonyl group of the solutes and hydroxyl groups of Me-β-CD (12). However, the restriction of the free rotation of the side-chain by a steric hindrance between the functional group at C-12 and the side-chain appears to be more well-explained than the anomalous behavior of these compounds. According to our previous study of bile acids by nuclear magnetic resonance spectroscopy (18), they should have a preferential conformation about the 17(20) bond such that C-21 and C-22 lie pseudo-equatorially to the rear of the 17(20) bond with the third substituent (H) on C-20 pseudo-axially to the front, opposing C-18 (C-22, *trans*-oriented to C-13). If the presence of a 12-substituent in the bile acids restricts the free rotation of the side-chain, the most preferred conformer at the 17(20) bond is fixed as mentioned above. Such conformation of the side-chain may interfere with the two hydrogen bonds of the solutes with Me-β-CD. In fact, a molecular model exhibited that a hydrogen bonding of the solutes with Me-β-CD is possible at the one site, either at the wider or narrower rim of the Me-β-CD cone (Fig. 3C). These compounds would therefore be held only by one hydrogen bond with Me-β-CD, forming less-stable complexes. It is, however, noticed here that further study is necessary to obtain more precise information on the hydrogen-bonding mechanism.

Chromatographic behavior of polyhydroxylated bile acids. In recent years, considerable attention has been focused on the metabolism of unusual bile acids such as 4β- and 6-hydroxylated bile acids (19). These unusual bile acids, most of which possess a vicinal 3,4- or 6,7-glycol structure, are present in significant amounts in biological materials excreted by patients with hepatobiliary diseases and by newborn infants and in the fetus. The concurrent occurrence of 4β- and 6-hydroxylated bile acids is of keen current interest in biological and metabolic studies in connection with liver diseases. Although conventional HPLC of the bile acids on a reversed-phase column has been reported by Batta *et al.* (20) and by us, Iida *et al.* (21), their inclusion HPLC behavior has not yet been studied. We performed here additional experiments using various unusual C_{24} bile acids substituted by three to four hydroxyls in the 5β-steroid nucleus, in order to elucidate further what factors are responsible for changing the retentions of the compounds.

Analogous with the monosubstituted bile acids mentioned above, the polyhydroxylated bile acids were measured as the 24-pyrenacyl ester derivatives on a Capcell Pak C_{18} column, eluting with a methanol–water mixture (80:20, vol/vol) in the presence or absence of 5 mM Me-β-CD as a mobile-phase additive. The retention data for the compounds examined and typical chromatograms obtained are shown in Table 2 and Figure 4, respectively.

TABLE 2
Effect of Me-β-CD on the Retention of Polyhydroxylated Bile Acids[a]

Position and configuration of hydroxyls

α	β			α	6.92	5.39	0.78	0.42	(1.53)

[a]All the compounds examined are of 5β-series; measured as the 24-pyrenacyl ester derivatives; column, Capcell Pak C_{18}; mobile phase, methanol/water (80:20 vol/vol); detection, fluorescence (excitation wavelength 370 nm; emission wavelength 440 nm); the $\Delta k'$ value of 3α,6α,7α-trihydroxy-5β-cholanoic acid was taken as 1.0 for the calculation of the $r\Delta k'$ values; see footnotes to Table 1 for other explanations, abbreviations, and company source.

In the absence of Me-β-CD in the mobile phase, four stereoisomeric 3α,6,7-trihydroxy acids afforded well-resolved peaks, emerging from the column in the elution order of 3α 6α 7β < 3α 6β 7α < 3α 6β 7β << 3α 6α 7α. Analogously, 3α,6,7,12α-tetrahydroxy stereoisomers follow the same elution order with that observed for the 3α,6,7-triols, while 3β,6,7-trihydroxy stereoisomers were eluted in the order of 3β6β7α < 3β6α7β < 3β6β7β < 3β6α7α. Four stereoisomeric 3,6,12α-trihydroxy acids were less strongly adsorbed on the column than any other 3,6,7-triols, and the following elution order was observed: 3β6β12α < 3α6β12α < 3β6α12α < 3α6α12α. These elution orders observed on a Capcell Pak C_{18} column are at slight variances with those reported previously by Batta *et al.* (20) and by us, Iida *et al.* (21), in which we used different columns, mobile phases, and/or C-24 ester derivatives. In each of the stereoisomeric groups, compounds having all α-oriented hydroxyls had definitely the lowest mobility, because they do not have a β-substituent which reduces the hydrophobic β-surface area of steroid molecules and increases the polarity of the molecules, resulting in a decrease in the retentions (22).

Addition of Me-β-CD to the mobile phase resulted in a considerable reduction of the retentions of 3,4β,7- and 3,6,7-trihydroxy compounds and caused a significant change in the elution order of several isomeric pairs due to a combined effect of Me-β-CD on the retentions of each hydroxyl. However, the retention data for the polyhydroxylated compounds did not demonstrate an additive property of each hydroxyl contribution. Hence, the result probably suggests that nonspecific hydrogen bondings occur between the solutes and the Me-β-CD (17).

In the inclusion HPLC, the retention (k_2') of the 3,6,7-trihydroxy acids was shortened greatly by *ca.* 50–70%, compared with those (k_1') observed in the conventional HPLC, and the observed rk' and $r\Delta k'$ values for these compounds were 0.26–0.47 and 0.70–1.38, respectively. A comparison of the rk' values between two epimeric pairs at the 3-, 6-, or 7-position in the eight stereoisomeric 3,6,7-triols (12 epimeric combinations are possible) showed that the β-hydroxy isomers in each combination always have smaller rk' values than the corresponding α-epimers and that the difference in the rk' values between the two epimers is usually larger for the 3β- and 7β-hydroxy isomers than for the 6β-epimers: e.g., 3α6α7β vs. 3β6α7β, 0.08; 3α6α7β vs. 3α6β7β, 0.01; 3α6α7α vs. 3α6α7β, 0.11. A similar comparison of the difference in the $r\Delta k'$ values between the two epimeric pairs also provided additional information for characterizing each of the eight stereoisomers: e.g., 3α6α7α vs. 3β6α7α, 0.06; 3α6α7α vs. 3α6β7α, –0.30; 3α6α7α vs. 3α6α7β, 0.28.

Particular interest should be paid for the inclusion HPLC behavior of 3,4,12α- and 3,6,12α-trihydroxy and 3,4,7α,12α- and 3α,6,7,12α-tetrahydroxy acids, all of which possess a 12α-hydroxyl group. The retention of all the compounds was

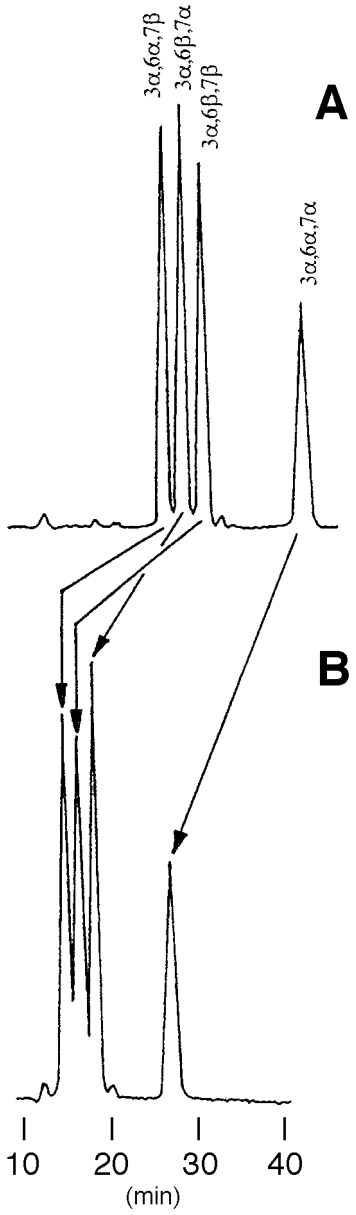

FIG. 4. HPLC chromatograms of a mixture of the 24-pyrenacyl ester derivatives of stereoisomeric 3α,6,7-trihydroxylated bile acids eluted by methanol/water (80:20, vol/vol) (A) without or (B) with 5 mM Me-β-CD in the mobile phase. See Scheme 1 for abbreviations.

decreased to a certain extent by Me-β-CD, but the elution order of each stereoisomeric group was unchanged. Such anomaly of the 12α-hydroxylated bile acids in the inclusion HPLC is compatible with those observed for 12-monosubstituted compounds mentioned above and for deoxycholic and cholic acid derivatives reported previously (12). Furthermore, all the 12α-hydroxylated compounds had a nearly constant rk' value of 0.76 (n = 13; standard deviation, 0.02; coefficient of variation, 2.69%), irrespective of the other structural features. On the contrary, the $r\Delta k'$ values of the 12α-hydroxylated compounds were somewhat influenced by the presence or absence and the configuration of additional hydroxyls at the positions C-6 and/or C-7 in the 5β-nucleus and classified roughly into the three classes of compounds. Those are compounds ($r\Delta k'$, 0.09–0.11) having a β-hydroxyl either at the 6- or 7-position, compounds ($r\Delta k'$, 0.18–0.25) having an α-hydroxyl either at the 6- or 7-position, and compounds ($r\Delta k'$, 0.36–0.42) without both the hydroxyls. The order of the $r\Delta k'$ values for the compounds reflects their structural features and nearly corresponds to that of the k_1' values. The above results may suggest that essentially there is either no or little effect of the addition of Me-β-CD on the retention of the 12α-hydroxylated compounds.

The reason why the retention of all the 12α-hydroxylated compounds is decreased by *ca.* 24% by adding 5 mM Me-β-CD in the mobile phase (methanol/water, 80:20, vol/vol) may be attributed to reduction of the retention ability (i.e., partition coefficient) of the C_{18}-bonded stationary phase in a Capcell Pak column employed. It is known that in inclusion HPLC, an organic mobile phase modifier such as methanol forms a weak inclusion complex with a CD (14,23). Analogously, if the stationary phase causes hydrophobic interactions not only with bile acid molecules but also with Me-β-CD, the solubility of the bile acids into the stationary phase is reduced. The decrease (*ca.* 24%) of the capacity factors of the bile acids in the mobile phase containing 5 mM Me-β-CD would therefore correspond to that of the retention ability of the column. Although the usefulness of the inclusion HPLC in the analysis of naturally occurring bile acids has been reported previously (14), a more detailed study is now being conducted in these laboratories.

In conclusion, the relationship between retentions and structures of a variety of monosubstituted and polyhydroxylated bile acid isomers was examined as their 24-pyrenacyl ester derivatives on a C_{18} reversed-phase column, eluting with methanol–water mixtures in the presence or absence of Me-β-CD. Retentions of all the compounds were decreased by the addition of Me-β-CD, and the magnitude of the decreases depended significantly on the position and configuration of oxygen-containing functions and the stereochemistry of the A/B-ring fusion in the solutes. The observed changes in the retentions were found to be essentially ascribed to hydrogen- bonding interactions between the functional groups of both the nucleus and the side-chain in the solutes and hydroxyl groups of both the narrower and wider rims in the Me-β-CD. The retention characteristics reported here provide much useful information in the understanding of the analysis of bile acid molecules.

COMMUNICATION

Seasonal Changes in Leaf Lipid and Fatty Acid Composition of Nine Plants Consumed by Two African Herbivores

Bruce C. Davidson*

Medical Biochemistry, University of the Witwatersrand Medical School, Parktown, 2193, South Africa

ABSTRACT: In the wild, nutrients from plants provide for the requirements of all herbivores and ultimately all animals, yet little work has been published on how such nutrients change with environmental conditions. Plant lipids are nutritionally important for browsing mammals, initially with respect to taste and palatability, but ultimately how they fulfill a variety of functions. This study reports on seasonal changes in fatty acid (FA) profiles of nine plants commonly consumed by two herbivore species (kudu and impala) in South Africa. The FA composition of the plants varied with both season and plant species but not with geographic location. The overall profile of FA provided a maximum of n-3-essential FA during the transition and wet seasons, but there was no parallel increase in n-6-essential FA.
Lipids 33, 109–113 (1998).

Browsing mammals in the wild systematically vary the selection of their food sources with season (1,2), yet little work has been published on variations in plant nutrient profiles. Seasonal, geographic, or inter/intraspecific variation of plant composition, in particular those components of nutritional significance to mammals, has received minimal attention. An exception to this is that seasonal differences in the mineral composition of plants have been shown to be significant in determining the spatial distribution (3) and migratory patterns (4) of East African herbivores.

Plants react to mammalian predation by production of a variety of unpalatable compounds (5) and fatty acid (FA)-derived intra-individual plant pheromones (6–10). Similarly, plants exhibit varying tolerance to insect-induced damage (11). Lipids contribute greatly to the flavor of a food, thus the FA composition of leaf lipids may be significant in the consumption patterns adopted by herbivorous mammals. General mammalian nutritional requirements also vary seasonally (12–13), with more of the FA and their derivative postdesaturation FA needed during growth, reproduction, and lactation (14–18). In southern Africa, these periods are usually coincident with the wet season, which is also the period of most active plant growth.

Abbreviation: FA, fatty acid.

Variation with time of food-plant selection has been noted for many herbivores but only quantitated for two of the more common South African browsing herbivore species, the kudu (*Tragelaphus strepsiceros*) and the impala (*Aepyceros melampus*) (1,2). Nine plant species constitute >95% of their food intake, but the amount of each plant species consumed varies with both season and mammal species (1,2). The present work was carried out in a small but geologically diverse reserve (Nylsvley, Fig. 1) situated in the subtropical region of the South African Northern Province highveld at an elevation of about l000 m.

An initial survey at Nylsvley of the FA profiles of these plant species showed minimal variation in FA between soil types, but significant differences dependent on both season and plant species (19,20). However, the distance between individual sampling sites was small (<5 km) and this may have limited any variation reflecting site or soil type.

The purpose of the study reported here was to extend observations obtained at Nylsvley to a wider geographical area. Samples were collected from the nine plant species every year for a 4-yr period, during the same months, but from eight geologically different regions of the Kruger National Park (Fig. 1, left insert) covering about 250 km^2. The Kruger Park itself spans the subtropical and tropical areas of Mpumalanga Province lowveld. The average elevation of the park is about 200 m, and it covers an area of more than 300,000 km^2.

MATERIALS AND METHODS

The eight sampling sites within the Kruger National Park were situated within the following geographical/geological areas, as categorized by the National Parks Board: Mopane Shrub Veld, Mixed Red Bushwillow–Mopane Veld, Lebombo Mountain, Knobthorn–Maroela Veld on Basalt and Dolomite, Mixed Combretum Veld, Mixed Combretum-Acacia Veld, Silver Clusterleaf-Sicklebush Veld, and Delagoa Thron Veld.

Roughly 50-g samples of leaves were collected at between l and 2 m above ground level, which approximated the average browsing heights of the impala and kudu. Samples were weighed, chopped, and extracted with a mixture of chloroform/methanol (2:1,vol/vol) (21). The lipid extracts were stored at −20°C under nitrogen, and the residual leaf material

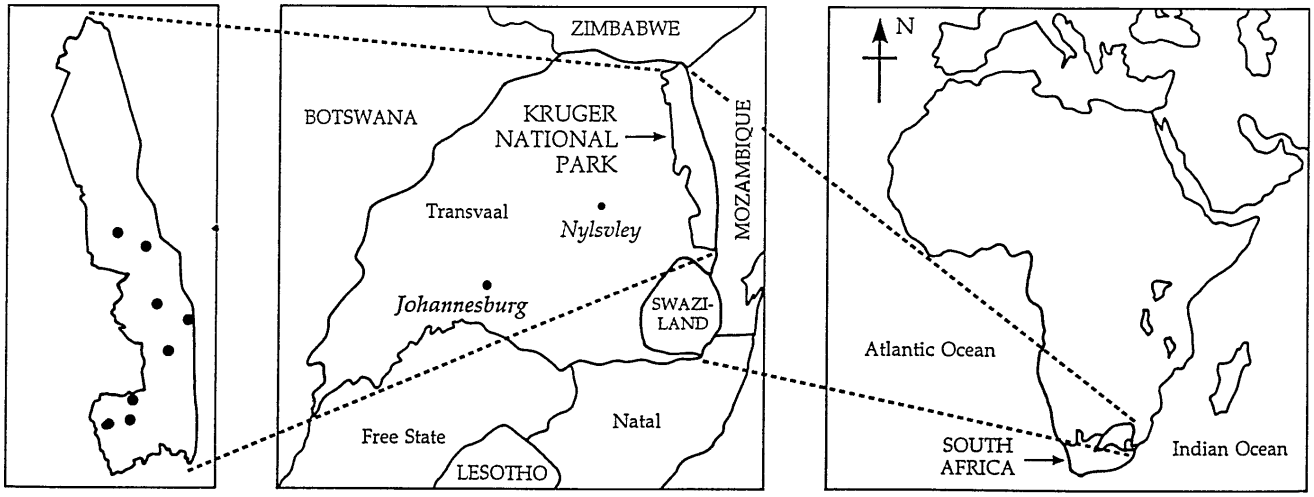

FIG. 1. Location of Nylsvley Reserve and Kruger National Park within South Africa.

was dried and reweighed. Aliquots of the extracts were used for lipid weight determination. FA methyl esters were prepared from 20 mg of each lipid sample using BF_3 in methanol (22). Analyses were performed using a Varian 3400 gas chromatograph (Varian-Aerograph, Walnut Creek, CA) with 4270 integrator and a 30-m SP2330 capillary column (SMM Instruments, Johannesburg, South Africa) run isothermally at 210°C.

In the Kruger National Park, materials were collected from the same individual specimens of each tree species at each sampling time in the different seasons. Wet season was defined as the period from November to April, dry season from May to August, and transition season from September to November, inclusive. The exact months of sampling were the same as those used for the Nylsvley study (19,20), i.e., January, June, and September. The nine plant species were also the same: *Acacia karroo*, *A. nilotica*, *A. tortilis*, *Dichrostachys cinerea*, *Burkea africana*, *Rhus leptodictya*, *Grewia flavescens*, *Euclea natalensis*, and *Terminalia sericea*. Individual trees were selected by arbitrary choice of compass direction from each start point and fell within approximately 5 m either side of a straight line from that point. Where more than one individual fell within the collection area, the first specimen was marked and used. Each species was sampled once only per site per season per year. No sampling trees were lost to fire, animal damage or other causes during the years of the study.

Statistical comparisons were carried out using the Student's *t*-test, as recommended by the Statistical/Research Advisory Service of the South African Medical Research Council.

RESULTS

Table 1 presents *A. karroo* dry-season data as a typical example of all the species, and shows the variation between the individual sampling sites on a yearly basis. There were no significant differences at $P > 0.25$ for all species.

Table 2 compares the FA profiles for *A. karroo* at the different sampling sites within the Kruger Park. There were no significant differences between the sampling sites, as in all cases $P > 0.25$. For the sake of brevity, only data for *A. karroo* in the dry seasons are shown; however, the same held true for all the species analyzed irrespective of season or FA class.

TABLE 1
Effect of Site and Year on the Percentage of Saturated Fatty Acids in *Acacia karroo* Across Four Years

Site	Year 1[a]	Year 2[a]	Year 3[a]	Year 4[a]	Mean
1	37.2	39.7	39.8	36.1	38.2 ± 1.6
2	37.9	34.1	37.4	34.3	35.9 ± 1.7

[a]Each data point based on $n = 4$. Means shown ±SEM. The *P* values in all cases were at least >0.25. The mean data for *A. karroo* for the four dry seasons are shown as an example. The data for Kruger National Park (NP) showed no significant differences from those of Nyslvley (Refs. 19,20), $P > 0.25$ in all cases.

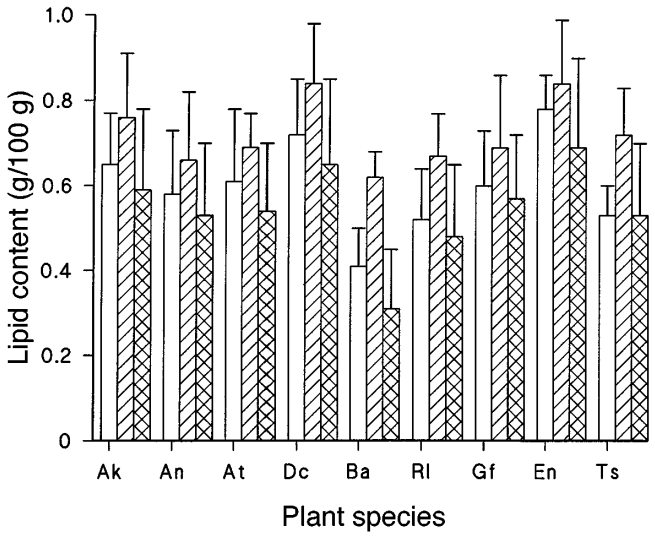

FIG. 2. Seasonal variation in lipid content (g/100 g) among the following nine plant species: *Acacia karroo* (Ak), *A. nilotica* (An), *A. tortilis* (At), *Dichrostachys cinerea* (Dc), *Burkea africana* (Ba), *Rhus leptodictya* (Rl), *Grewia flavescens* (Gf), *Euclea natalensis* (En), and *Terminalia sericea* (Ts). Data are shown as mean ± SEM, $n = 32$ (eight sampling sites over four years). Open bars are wet season, diagonal lines are dry season, and crosshatch are transition season.

Figure 2 shows the lipid content (g/100 g leaf matter). There were changes in total lipid between wet and dry season, with the amounts increasing across all the species, but only the changes for *B. africana* and *T. sericea* were significant at $P < 0.10$. Generally, the transition-season samples showed levels of total lipid slightly and nonsignificantly decreased compared to wet season.

Figure 3 shows the profiles of the FA for each species across the three seasons. In general, the saturated fatty acids (Fig. 3A) increased during dry season (only *Acacia karroo* and *B. africana* decreased) but showed a slight drop during transition season. The greatest increase between wet and dry season was shown by *T. sericea* (29.8 to 56.2 g FA/100 g dry matter), while the greatest decrease was that of *B. africana* (52.4 to 28.1 g FA/100 g dry matter). All differences were significant ($P < 0.05$ at least) except for *R. leptodictya,* where there was no significant change. There were fewer significant differences between wet and transition seasons with *A. nilotica* and *tortilis*, *D. cinerea*, *G. flavescens* and *T. sericea* showing no significant change, and the other species showing signficant decreases.

The monoenoic FA (Fig. 3B) also showed increases between wet and dry seasons, with the greatest increase occurring for *A. tortilis* (6.4 to 23.8 g FA/100 g). The only species not showing an increase was *R. leptodictya*; however, the decrease was not significant. In comparing wet and transition seasons, four species (*A. tortilis*, *D. cinerea*, *E. natalensis,* and *T. sericea*) showed no significant changes, whereas *A. karroo*, *A. nilotica,* and *B. africana* showed increases significant at $P < 0.10$. *Rhus leptodictya* monoenoic FA increased, but P was only <0.10, whereas *G. flavescens* showed an increase with $P < 0.05$.

Apart from *A. nilotica*, *A. tortilis*, and *T. sericea*, 18:2n-6 increased markedly in the dry season compared to the wet season (Fig. 3C). Both *A. nilotica* (15.7 to 11.3 g FA/100 g) and *T. sericea* (16.2 to 13.3 g FA/100 g) showed decreases significant at $P < 0.10$, whereas the differences for *A. tortilis* and *D. cinerea* were not significant. The other four species showed highly significant increases with $P < 0.05$, and the greatest change was shown by *A. karroo* (7.5 to 15.0) g FA/100 g. When wet and transition seasons were compared, all the species demonstrated increased levels of 18:2n-6 during transition. Only that of *A. nilotica* was not significant. In contrast *A. karroo, G. flavescens,* and *E. natalensis* showed changes significant at the $P < 0.05$ level.

The species showing the greatest decrease in 18:3n-3 in comparing wet and dry seasons were *G. flavescens* (44.3 to 11.6 g FA/100 g) and *T. sericea* (43.6 to 17.0 g FA/100 g), and these were significant at $P < 0.01$. Only *B. africana* showed no significant change, whereas the other species exhibited decreases significant at either $P < 0.10$ or $P < 0.05$ (Fig. 3D). When comparing wet and transition seasons, there were few significant differences. Only *A. karroo* and *E. natalensis* showed increased 18:3n-3 levels, increased with $P < 0.05$, while *G. flavescens* showed a decrease significant only at $P < 0.10$.

DISCUSSION

The site variation at Nylsvley reflected differences between soil types, mainly sandy vs. clay, while the variation at Kruger Park reflected much greater geological and botanical differences (Fig. 1). Figure 2 shows the variation between seasons in total lipid across the nine plant species. The dry-season samples showed higher levels of total lipid, but this may reflect the reduced availability of water, for the samples appeared less turgid than those from other seasons. There were no significant differences at $P < 0.05$ between the seasons; however *B. africana* and *T. sericea* showed differences between wet and dry seasons, but only at $P < 0.10$.

The FA profiles of the nine plant species showed no significant variation within a species or within a season when site, soil type, or location were compared (Tables 1 and 2). The profiles were thus independent of these parameters even between reserves over 300 km apart and at markedly different altitudes. There were, however, very significant differences both between plant species and between seasons (Fig. 3). The wet season is the period when metabolic activity is high but stable, whereas during dry season metabolic activity is relatively low. The transition period is the period of greatest change in metabolic activity. The adaptation of the species to the change from dry to transition appears to have been very fast, as the data for 18:3n-3 during the transition were very close to that for the wet season. However, *A. karroo* and *E. natalensis* both showed levels higher than wet season, whereas *G. flavescens* had lower levels of 18:3n-3 during transition.

The most significant FA was *cis*-C18:3n3 (α-linolenic acid), the polyunsaturate (polyenoic) precursor of the n-3 series. This FA is the major FA found ln photosynthetic plant

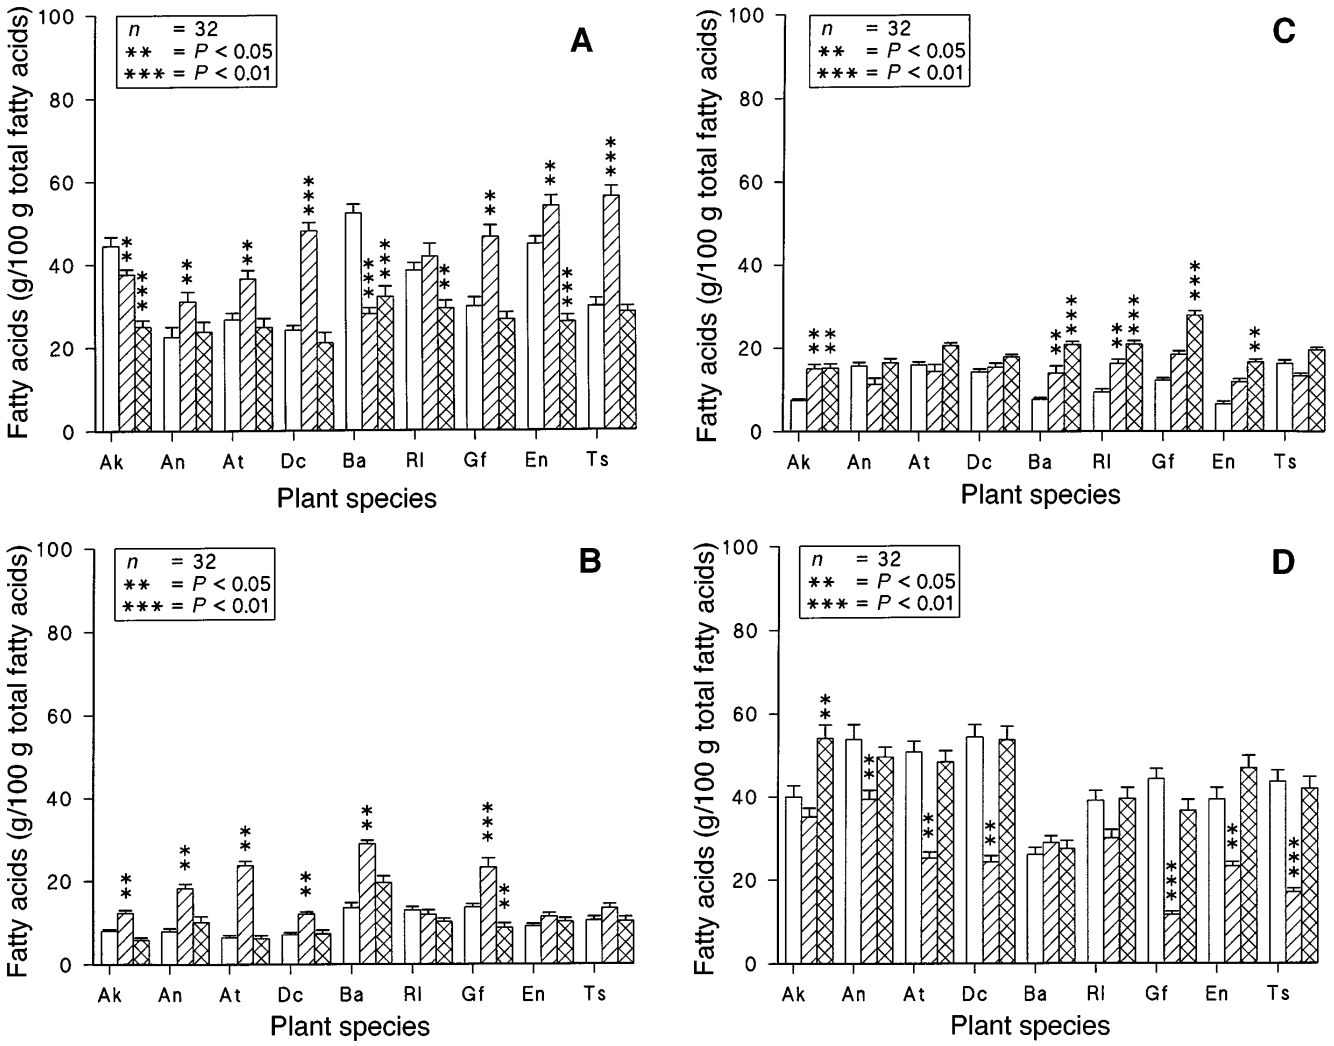

FIG. 3. Seasonal variations in fatty acid profiles among the nine plant species. Open bars are wet season, diagonal lines are dry season, and cross-hatch are transition season. Species identification is the same as used in Figure 2. Data are shown as mean ± SEM. The *P* values are relative to wet season data in all cases. (A) Total saturated fatty acids; (B) total monoenoic fatty acids; (C) *cis*-C18:2n-6 (linoleic acid); (D) *cis*-C18:3n-3 (α-linolenic acid).

matter (23), and it is interesting that it was this FA that most rapidly returned to wet-season levels during transition. This may correlate with a need to produce active photosynthetic organelles early to maximize energy production capability.

Conversely, the levels of *cis*-C18:2n-6 (linoleic acid), the n-6 series precursor, increased during dry season and remained elevated during transition. This may reflect that during dry season there may be a relatively greater removal of 18:3n-3 with the decrease in photosynthetic potential, thus leaving an apparently higher level of 18:2n-6 which is fulfilling a structural role. The continued higher levels of 18:2n-6 during transition may also reflect the need for more structural lipid during rapid leaf growth.

The pattern of species/seasonal differences did not vary greatly from year to year and appeared to be independent of variations in actual annual rainfall, at least within the time scale of these studies. During the period of this study, the actual rainfall did vary quite considerably, from a low of 13 mm to a high of 99 mm in January, 2 to 38 mm in June and 0 to 81 mm in September (wet, dry, and transition season collection months, respectively).

The intraspecies and seasonal differences among the three *Acacia* species emphasize that even relatively closely related species such as the acacias may show distinctly different patterns of FA content and FA change.

Both the kudu and the impala are diurnal browsing feeders and consume the same nine plant species, but the time spent browsing varied considerably with season and herbivore species (1,2). Quantitatively, *G. flavescens* and *D. cinerea* contributed the most to the intakes of these two herbivores; however, the plants contributing less may be providing nutrients not present in adequate levels in these two main species.

No quantitative data were available as to the contribution that the seeds of these plant species made to the herbivores' diets, except that it was sporadic and highly seasonal, being largely confined to the months from March to May. Given that the levels of linoleic acid (*cis*-18:2n-6) are commonly high in seeds (24), it is possible that they may have provided a source of this FA, but not on a regular year-round basis.

ACKNOWLEDGMENTS

The author thanks the Foundation for Research Development of South Africa and the National Parks Board of South Africa for their wholehearted cooperation during the Nylsvley and Kruger National Park phases of this project, respectively. They also thank Efamed (Pty.) Ltd., South Africa; Scotia Pharmaceuticals, United Kingdom; Medical Research Council, South Africa; and the University of the Witwatersrand, South Africa, for their financial and logistical support during this study. The editorial comments of Dr. Andrew Sinclair were invaluable in finalizing this manuscript.

ARTICLE

Arachidonic Acid Supplementation Enhances Synthesis of Eicosanoids Without Suppressing Immune Functions in Young Healthy Men

Darshan S. Kelley[a,*], Peter C. Taylor[a], Gary J. Nelson[a], and Bruce E. Mackey[b]

United States Department of Agriculture, Agricultural Research Service, [a]Western Human Nutrition Research Center, Presidio of San Francisco, California, and [b]Western Regional Research Center, Albany, California

ABSTRACT: This study was conducted to determine the effects of arachidonic acid (AA) supplementation on human immune response (IR) and on the secretion of prostaglandin E2 (PGE2) and leukotriene B4 (LTB4). Ten healthy men (20–38 yr) participated in the study and lived at the Metabolic Suite of the Western Human Nutrition Research Center. They were fed a basal diet (57, 27, and 16 energy percentage from carbohydrate, fat, and protein, respectively, and AA 200 mg/d) for the first 15 d of the study. Additional AA (1.5 g/d) was added to the diet of six men from day 16 to 65, while the remaining four subjects remained on the basal diet. The diets of the two groups were crossed-over from day 66 to 115. *In vitro* indices of IR were examined using blood drawn on days 15, 58, 65, 108, and 115. Influenza antibody titers were determined in the sera prepared from blood drawn on days 92 and 115 (23 d postimmunization). AA supplementation caused significant increases in the *in vitro* secretion of LTB4, and PGE2, but it did not alter the *in vitro* secretion of tumor necrosis factor α; interleukins 1β, 2, 6; and the receptor for interleukin 2. Nor did it change the number of circulating lymphocytes bearing markers for specific subsets (B, T, helper, suppressor, natural killer) and the serum antibody titers against influenza vaccine. The opposing effects of PGE2 and LTB4 may have led to the lack of change in immune functions tested.
Lipids 33, 125–130 (1998).

Studies conducted in cultured cells and animal models show that n-6 polyunsaturated fatty acids (PUFA) inhibit immune cell functions (1–10). The results from studies in humans are mixed. A moderate increase in dietary linoleic acid (18:2n-6, LA) did not affect human immune response (IR) when dietary fat was held constant (11–13). But a negative association between plasma LA concentration and the number of circulating natural killer (NK) cells has been reported in a group of elderly individuals (14).

LA is the most abundant dietary n-6 PUFA for humans. It can be converted to arachidonic acid (20:4n-6, AA) by humans and several other animal species. AA is the major n-6 fatty acid of the membranes and it is a precursor of the eicosanoids. It is metabolized by two distinct oxygenase pathways. The cyclooxygenase pathway converts AA to prostaglandins, thromboxanes, and prostacyclins; the lipoygenase pathway converts it to leukotrienes.

In vitro studies show that AA and its metabolic products can alter a number of lymphocyte and monocyte functions, including the maturation of immature T cells into helper and suppressor cells, lymphocyte proliferation, cytokine and antibody secretion (15–21). Prostaglandin E2 (PGE2) inhibited a number of lymphocyte functions in a dose-dependent manner, whereas the leukotriene B4 (LTB4) was stimulatory at low concentrations and inhibitory at higher concentrations (22). When eicosanoid synthesis was blocked with inhibitors of cyclooxygenase and lipooxygenase pathways, addition of AA still inhibited immune cell functions *in vitro* (23–27). Thus, it is not clear if n-6 PUFA inhibit immune cell functions through eicosanoids or through other mechanisms.

The effects of AA supplementation on both immune cell functions and eicosanoid synthesis have not been examined previously in humans, because of concerns regarding its safety and the nonavailability of natural triglycerides of AA. An algal source of natural AA triglycerides recently became available, making human studies of AA supplementation feasible. Use of natural triglycerides of AA permits one to study its effects on human IR while the total amounts of other dietary fatty acids are held constant.

The purpose of this study therefore was to measure eicosanoid secretion and immune functions in humans given a supplement of AA while consuming a constant diet. We examined *in vivo* antibody production in response to influenza vaccine, lymphocyte subsets, and *in vitro* secretion of PGE2, LTB4, interleukin (IL) 1β, IL 2, IL 2R, IL 6, and tumor necrosis factor α using peripheral blood mononuclear cells (PBMNC).

SUBJECTS AND METHODS

Subjects, protocol, and diets. Ten healthy men (20–38 yr) were selected to participate in the study. All subjects were nonsmokers, had no history of alcohol or drug abuse, had moderate exercise levels, had body weights within −10 to

Abbreviations: AA, arachidonic acid; IL, interleukin; IR, immune response; LA, linoleic acid; LPS, lipopolysaccharide; LTB4, leukotriene B4; NK, natural killer; PBMNC, peripheral blood mononuclear cells; PGE, prostaglandin E; PHA, phytohemagglutinin; PUFA, polyunsaturated fatty acids.

+20% of ideal body weight, and had chemical and hematological measurements within normal ranges. The participants lived and ate all meals at the Metabolic Unit of the Western Human Nutrition Research Center for 130 d (August 14–December 22, 1994). A crossover design was used. All subjects consumed the basal, low-AA, diet during the first 15 d. For the next 50 d six subjects (group 1) consumed the diet supplemented with AA (1.5 g/d) and the other four (group 2) continued to consume the basal diet. Diets of the two groups were switched on day 66, and the new diets were fed for 50 d (days 66–115). Both groups were fed the basal diet for the last 15 d (days 116–130). Body weights of the subjects were maintained constant throughout the study by adjusting the energy intake and by maintaining a constant physical activity schedule. All subjects walked two miles twice every day. Blood samples were collected on days 16, 58, 65, 108, and 115.

Basal diet consisted of natural foods and was adequate in all nutrients. A 5-d rotating menu with three meals and two snacks every day was used. The proportion of energy from carbohydrate, fat, and protein was 57, 27, and 16%, respectively (28). The energy was equally distributed among the saturated, monounsaturated, and n-6 PUFA. The basal diet provided 200 mg AA and 250 mg cholesterol per day. The calculated amount of vitamin E in the basal diet was two times the Recommended Daily Allowance. Three grams ARASCO® oil (a gift from Martek Biosciences Corporation, Columbia, MD) was added to the diet to provide 1.5 g AA/d. The total fat content of the two diets was held constant by replacing an equivalent amount of monounsaturated fat with AA.

Laboratory procedures. Blood was collected by antecubital venipuncture into evacuated tubes containing heparin for cell culture experiments, or EDTA for lymphocyte phenotypic analysis, or without anticoagulants for preparation of sera. Blood samples for all subjects were collected after an overnight fast, between 0700 and 0800 h.

Secretion of cytokines and eicosanoids. PBMNC were isolated using Histopaque-1077 as previously reported (29). The culture medium used was RPMI-1640 (Gibco, Grand Island, NY) containing 10% autologous serum and L-glutamine (2 mmoI/L), penicillin (100 KU/L), streptomycin (100 mg/L), and gentamicin (20 mg/L). Five hundred μL of the culture medium containing 5×10^5 PBMNC was inoculated in each well of a 24-well flat-bottom culture plate. An additional 500 μL of the culture medium with or without the mitogens was added to each well.

The production of IL 1β, IL 6, tumor necrosis factor, PGE2, and LTB4 was stimulated by the addition of lipopolysaccharide (LPS, 0.5 mg/L), and that of IL 2 and IL 2R was stimulated by adding phytohemagglutinin (PHA, 10 mg/L). Tissue culture media were collected by centrifugation 24 h after stimulation with LPS, and 48 h after PHA. The media were stored frozen at −70°C until the cytokine and eicosanoid concentrations were determined.

ELISA kits for cytokine assays were purchased from T Cell Diagnostics, Inc. (Cambridge, MA), and those for eicosanoids from Cayman Chemical Company (Ann Arbor, MI).

Influenza vaccination and serum antibody titers. All subjects were immunized on study day 92 with the trivalent influenza virus vaccine (Fluzone, 1993–1994 Formula) purchased from Connaught Laboratories Inc. (Swiftwater, PA). Preimmunization sera were prepared from the blood drawn on day 92, and the postimmunization sera from the blood drawn on day 115. The antibody titers were determined at the Centers for Disease Control using the hemagglutination inhibition assay (30) and the viral strains A/TEXAS/36/91, A/BEIJING/32/92, and B/PANAMA/45/90ET. Results for antibody titers are expressed as the geometric means of the antibody titer, the geometric mean transformations, and the percentage of subjects with an antibody titer ≥40 or 160.

Lymphocyte phenotypic analysis. Lymphocyte subsets, including B ($CD19^+$), T ($CD3^+$), helper ($CD3^+$, $CD4^+$), suppressor ($CD3^+$, $CD8^+$), and NK ($CD3^-$, $CD16^+$, $CD56^+$) cells, in peripheral blood were determined using the Becton-Dickinson Flowcytometer as previously reported (29).

Data analysis. The data were analyzed by an analysis of variance model using SAS/STAT PROC GLM (31). The cross-over design model included effects of order, subject (order), period, and diet, using subject (order) as an error term for order. The significance of the difference between with and without AA supplementation was assessed from the *P* values for the diet main effects. The data from the two groups were analyzed separately using a paired *t*-test when the treatment was given only during one period, such as immunization with influenza vaccine. Changes in the variables examined are considered significant for $P < 0.05$ or otherwise stated.

RESULTS

The mean ± SEM for age (yr), weight (kg), height (cm), and body mass index (kg/m^2) for subjects in groups 1 ($n = 6$) and 2 ($n = 4$) were 31.2 ± 3.2 and 32.2 ± 2.9, 73.8 ± 2.4 and 71.0 ± 5.4, 177.4 ± 3.6 and 175.5 ± 1.8, 23.8 ± 1.8 and 23.0 ± 1.3, respectively. The composition of the diets and the average daily intake of nutrients have been previously reported (28). None of these parameters was different between the two groups.

Eicosanoid secretion. PGE2 and LTB4 secretion into the tissue culture medium within 24 h of PBMNC stimulation with LPS is shown in Table 1. AA supplementation significantly ($P < 0.05$) increased the secretion of both of these eicosanoids, compared to the values at the end of stabilization period (day 16). The percentage stimulation of LTB4 secretion with AA supplementation was greater (200–400%) than that of PGE2 secretion (50–100%). In the group receiving AA supplementation first (days 16–65), eicosanoid secretions remained elevated 50 d after the discontinuation of the AA supplementation. The amount of PGE2 secreted into the medium in the absence of LPS (unstimulated cultures) was about 25% of that secreted in the presence of LPS and was not altered by AA supplementation (not shown). The amount of LTB4 secreted in unstimulated cultures was about 50% of the amount secreted in the presence of LPS, and it increased significantly ($P < 0.05$) with AA supplementation (not shown).

TABLE 1
Dietary Arachidonic Acid Increases *in vitro* Secretion of Eicosanoids by PBMNC Stimulated with LPS[a]

	Group 1 (n = 6)			Group 2 (n = 4)		
Eicosanoid	Day 15	Day 65	Day 115	Day 15	Day 65	Day 115
PGE2 (ng/mL)	0.81 ± 0.06[a]	1.25 ± 0.12[b]	1.11 ± 0.10[b]	0.53 ± 0.05[c]	0.47 ± 0.01[c]	0.87 ± 0.06[d]
LTB4 (ng/mL)	0.20 ± 0.02[a]	0.43 ± 0.04[b]	0.39 ± 0.04[b]	0.14 ± 0.01[c]	0.19 ± 0.02[c]	0.85 ± 0.14[d]

[a]Data shown are the mean ± SEM for the number of subjects shown. Diet of subjects in Group 1 was supplemented with arachidonic acid from days 16 to 65, and that of Group 2 from days 66 to 115. For each eicosanoid, comparisons were made within each group using a paired *t*-test, and the numbers bearing different superscripts within each group are significantly different ($P < 0.05$). PBMNC, peripheral blood mononuclear cells; LPS, lipopolysaccharide; PGE2, prostaglandin E2; LTB4, leukotriene B4.

Cytokine secretion. The effects of AA supplementation on cytokine secretion are presented in Table 2. The concentrations of IL 1β, IL 6, and tumor necrosis factor α secreted into the tissue culture media by the PBMNC are in response to stimulation with LPS, and that of IL 2 and IL 2R are in response to stimulation with PHA. Mitogens caused a several-fold increase in the release of all cytokines tested, compared to the corresponding cytokine concentrations in the media from unstimulated cultures, which were below the detection limits of the assay systems (not shown). AA supplementation did not alter the secretion of all the cytokines at any time in the study.

Influenza antibody titers. The pre- and postimmunization antibody titers for the A/Texas, A/Beijing, and B/Panama strains of influenza are shown in Table 3. Immunization caused an approximately 10-fold increase in the serum titer for B/Panama and 30-fold increase in A/Texas in both the AA-supplemented and -nonsupplemented groups. The amount of AA in the diet did not influence the antibody titer for these two strains. Immunization caused a 19-fold increase in the antibody titer for A/Beijing in Group 1 (fed low-AA diet at the time of immunization) and a 9-fold increase in Group 2 (fed high-AA diet). The apparent difference in the antibody titers between the two groups for this viral strain was also evident if the results for antibody titers were expressed as percentage of subjects with titers ≥40 or 160. These results suggest an inhibition of A/Bejing antibody production by AA supplementation, however, the differences between the two groups did not attain statistical significance.

Lymphocyte subsets. The percentage and the absolute numbers for the B, T, helper, suppressor, and NK cells at study days 16, 65, and 115 are shown in Table 4. AA supplementation did not alter the absolute numbers or the percentage of these lymphocytes in circulation. Nor was there an effect of AA supplementation on the ratio between the helper and suppressor T lymphocytes.

DISCUSSION

AA feeding caused significant increase in the *in vitro* secretion of both PGE2 and LTB4, without any change in a number of indices of IR tested. These results suggest that either AA has no effect on IR or it may alter immune functions independently of the changes in eicosanoid production. The second interpretation is consistent with the results from previous studies with inhibitors of lipoxygenase and cyclooxygenase (23–27), in which AA inhibited cytokine production *in vitro*, even when there was no change in eicosanoid synthesis. This inhibition could be due to changes in membrane fluidity or receptor expression. The lack of inhibition of cytokine secretion by AA in our study may be a function of AA concentration, or some other differences in experimental conditions.

Results obtained from *in vitro* studies have demonstrated that PGE2 inhibited (17,20,25) and LTB4 stimulated cytokine production. These opposing effects of PGE2 and LTB4 on cytokine production can also explain our results regarding immune functions. Our study design cannot distinguish between this and the possibility discussed above. We are not aware of any studies where the effects on immune cell functions of adding PGE2 and LTB4 concurrently have been tested. Evaluation of such interaction between these two cytokines is important and needs to be monitored in future studies.

Our results showing increases in eicosanoid production *in vitro* are consistent with the results from *in vivo* studies show-

TABLE 2
Dietary Arachidonic Acid Does Not Alter *in vitro* Secretion of Cytokines by PBMNC[a]

	Group 1 (n = 6)			Group 2 (n = 4)		
Cytokine	Day 15	Day 65	Day 115	Day 15	Day 65	Day 115

	% ≥160	17	83	0	25

[a]Data shown are mean ± SEM for the number of subjects shown for each group. Abbreviations: GM, geometric mean; GMT, geometric mean transformation. Immunization significantly increased the antibody titers for all three viral strains in both groups. There was no effect of arachidonic acid supplementation on the antibody titers for all three strains.

ing an increase in AA metabolites in the urine of subjects supplementing their diets with n-6 PUFA (32–35). Results regarding immune functions are also consistent with our previous report from the same study in which we found no changes in lymphocyte proliferation in response to PHA and Concanavalin A, NK cell activity, and delayed hypersensitivity skin response (28). These results, however, differ from those of several *in vitro* studies, which showed inhibition of cytokine production with PGE2 (20,25) and stimulation with LTB4 (18). As stated earlier, the opposing effects of the two eicosanoids may have canceled each other.

The lack of an AA effect on cytokine secretion in our study could also result from the failure of the mitogens to increase the synthesis of the receptors for the cytokines. This is unlikely, because the mitogens and the experimental conditions used in this study have previously been shown (18,20,29) to increase the secretion of the cytokines examined in this report. Even in the present study the cytokine secretion was severalfold higher in the cultures treated with mitogens, compared to the parallel cultures without mitogens. Together these data indicate that cytokine secretion was increased by the mitogens, but it was not altered by AA feeding.

AA feeding did not alter the concentration of serum antibody production against the A/Texas and B/Panama strains. There was a trend toward reduction in antibody produced in response to A/Beijing strain by AA feeding, but it did not attain significance. This is perhaps due to the small number of subjects (six in Group 1, and four in Group 2), or the crossover study design. We believe a 50-d wash-out period should have removed most of the AA in Group 1; however, the amount of eicosanoids produced in this group at day 115 suggests that the wash-out was not complete. Our study design cannot distinguish whether the residual AA leads to the lack of difference in antibody production between the two groups, or AA has no effect on antibody production. There was no carryover effect for other immune functions tested in the six subjects in Group 1. Thus, it is safe to assume that AA feeding did not alter cytokine production and the number of phenotypically distinct lymphocytes in circulation.

Our data indicate that the amount, form, and duration of AA fed had no adverse health effects, as long as the total fat and vitamin E intakes were maintained constant. Further-

more, the concurrent increase in PGE2, and LTB4 secretion had no effect on immune cell functions. These results are consistent with the results from our LA studies, in which several indices of IR were not inhibited by increase in LA intake as long as the total fat intake was maintained constant (8,9). Together these studies show that moderate intake of n-6 PUFA do not inhibit human IR if the diet is adequate in antioxidant nutrients and the total dietary fat is held constant.

ACKNOWLEDGMENTS

Authors thank the volunteers for their participation in the study, the nursing and dietary staff of the Metabolic Unit, and the staff of the Bioanalytical Laboratory at the Western Human Nutrition Research Center for their help in conducting the study. We also thank Dr. Helen Regenary of the Centers for Disease Control for analysis of serum antibody titers, and Dr. Janet King of our Center for a critical review of the manuscript.

[a]Department of Medicine, Institute of Clinical Medicine, [b]Institute of Community Medicine, University of Tromsø, and [c]Department of Clinical Nutrition, Tromsø University Hospital, Tromsø, Norway

ABSTRACT: Fourteen healthy volunteers were randomly allocated to receive 4 g highly purified ethyl esters of eicosapentaenoic acid (EPA) (95% pure, $n = 7$) or docosahexaenoic acid (DHA) (90% pure, $n = 7$) daily for 5 wk in supplement to their ordinary diet. The n-3 fatty acids were given with a standard high- fat meal at the beginning and the end of the supplementation period. EPA and DHA induced a similar incorporation into chylomicrons which peaked 6 h after the meal. The relative uptake of EPA and DHA from the meal was >90% compared with the uptake of oleic acid. During absorption, there was no significant elongation or retroconversion of EPA or DHA in total chylomicron fatty acids. The concentration of EPA decreased by 13% and DHA by 62% ($P < 0.001$) between 6 and 8 h after the meal. During the 5-wk supplementation period, EPA showed a more rapid and comprehensive increase in serum phospholipids than did DHA. DHA was retroconverted to EPA, whereas EPA was elongated to docosapentaenoic acid (DPA). The postprandial triglyceridemia was suppressed by 19 and 49% after prolonged intake of EPA and DHA, respectively, indicating that prolonged intake of DHA is equivalent to or even more efficient than that of EPA in lowering postprandial triglyceridemia. This study indicates that there are metabolic differences between EPA and DHA which may have implications for the use of n-3 fatty acids in preventive and clinical medicine.
Lipids 33, 131–138 (1998).

n-3 Polyunsaturated fatty acids (FA), especially long-chain eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), have antithrombotic, antiinflammatory and hypolipemic properties (1,2), suggesting that they may be useful in the prevention and treatment of atherothrombotic diseases. Postprandial triglyceridemia is thought to play an important role in atherogenesis (3). Male survivors of myocardial infarction have higher postprandial lipid levels following fat tolerance tests than control subjects (4–6). Moreover, patients with angiographically verified coronary artery disease displayed larger triglyceride increase and magnitude of postprandial lipemia as compared to control subjects (6). Thus, any therapy that lowers postprandial lipemia may be expected to be antiatherogenic (3,6).

Daily ingestion of moderate (7) and large amounts (8) of fish oil for some weeks reduces postprandial lipemia significantly, independent of the type of fat present in the test meal (8). Similar results were obtained after long-term fish oil feeding when a 24-h oral fat-load was administered to mimic normal eating patterns (9). These studies used mixtures of EPA and DHA and can therefore not discriminate between possible separate actions of these FA.

There is growing evidence that EPA and DHA may have specific, and partly different, effects on lipid metabolism. In rats, EPA have been shown to decrease serum triglycerides, probably by induction of mitochondrial oxidation of FA, whereas DHA did not influence the triglyceride level (10). Recently, Grimsgaard *et al.* (11) reported that DHA had a more pronounced triglyceride-lowering effect than EPA. Concentrations of EPA and DHA in serum phospholipids have also been shown to be divergently associated with high density lipoproteins (HDL) in humans (12).

EPA and DHA have been given as triglycerides, free fatty acids, or esters of methanol and ethanol. Ethyl esters (EE) and triglycerides have been preferred in clinical studies. The absorption of a mixture of EPA and DHA as EE has been reported to be attenuated and delayed compared to triglyceride-formulas or free fatty acids (13,14). However, other studies indicate that mixed EE of both EPA and DHA are apparently well absorbed and incorporated into blood lipids (15–17). The purpose of the present study was to investigate the absorption, FA incorporation, and effect on postprandial triglyceridemia of highly purified EPA or DHA supplemented as EE in the diet of healthy males.

Abbreviations: CM, chylomicrons; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EE, ethyl esters; EPA, eicosapentaenoic acid; FA, fatty acid; HDL, high density lipoproteins; LA, linoleic acid.

METHODS

Participants. Fourteen healthy normolipemic male employees at the University of Tromsø (mean age 36.2, range 28–49) on a traditional Western diet were recruited into the present study. They were healthy as determined by medical history, physical examination, and measurements of blood pressure, hematological variables, blood glucose, serum lipids, and routine biochemistry. One individual smoked cigarettes. The exclusion criteria were: regular use of drugs, history of peptic ulcers, gastrointestinal disturbances likely to influence absorption, alcoholism, drug abuse, and mental illness. The subjects were asked to maintain their regular physical activity and dietary habits throughout the trial. Informed written consent was obtained from each participant. The study was approved by the regional board of research ethics.

Experimental design. The study was carried out as a randomized double-blind, parallel trial. After a 2-wk run-in phase with weekly physical examinations and blood collections, the participants were randomly allocated at visit 3 to receive either 4 g/day of EPA (95% pure) or 4 g/day DHA (90% pure), as EE (Pronova Biocare AS, Oslo, Norway) for 5 wk. The EPA and DHA were given in soft gelatin capsules with a reddish-brown capsule shell, each containing 1.0 g of FA. The content of tocopherol was 4–6 IU/capsule, the peroxide value <0.020 meq/g and *p*-anisidine value <35.

Physical examination and blood collection were conducted weekly during the dietary intervention. Height was measured at baseline, and body weight was recorded at baseline and after 5 wk of supplementation using a digital weight with the subjects wearing light inner clothing. Compliance was assessed by capsule counts and by measurements of serum phospholipid FA.

Blood sampling. After 12 h of overnight fasting, blood was drawn at 8 a.m. from an antecubital vein by using a 19-gauge needle in a vacutainer system with minimal stasis. Serum was prepared by clotting whole blood in a glass tube at room temperature for 1 h and then centrifuged at 2000 × *g* for 15 min. Aliquots of 1 mL were transferred into sterile cryovials (Greiner Laboratechnik, Germany), flushed with nitrogen, and frozen at −70°C until further analysis. Blood for plasma preparation was collected into vacutainers (Becton Dickinson, Meylan Cedex, France) containing disodium EDTA as anticoagulant (EDTA k_3 0.12 mL, 0.34 M per tube). Plasma was prepared by centrifugation at 2000 × *g* for 15 min at 22°C, transferred into sterile cryovials in aliquots of 1 mL, flushed with nitrogen, and stored at −70°C until further analysis.

Fat-tolerance test. A fat-tolerance test was conducted before (visit 3) and at the end of the dietary supplementation period (visit 8). A standard 2.64 MJ (631 kcal) test meal was prepared as a 375-mL liquid formula containing 28.6 g carbohydrate, 22.6 g protein, and 47.0 g fat. The fat was mainly from cream and milk and comprised 65.4% saturated, 30.9% monounsaturated, and 3.8% polyunsaturated FA. The test meals were freshly prepared each morning, served at 8:15 a.m. and consumed over a 10-min period. Individuals allocated to the EPA and DHA groups received four capsules of EPA and DHA, respectively, with the test meal. The subjects were given 100 mL of orange juice with the meal, and were allowed to drink 350 mL calorie-free beverages and eat an apple during the following 8 h. Blood samples for chylomicron isolation and plasma preparation were collected before the meal and every second hour during the next 8 h.

Chylomicron (CM) isolation. CM were isolated by overlayering 8 mL plasma with 4 mL of buffer (150 mmol/L NaCl and 1 mmol/L EDTA) in a cellulose nitrate tube (18) and centrifuging in a Beckman SW40 Ti swinging bucket rotor at 20.000 rpm for 1 h at 4°C. The CM were carefully removed by aspiration, divided into three aliquots in cryovials, flushed with nitrogen, and frozen at −70°C until further analysis.

FA analysis. Total lipids were extracted from 500 µL serum according to Folch *et al.* (19) with phosphatidylcholine deheptadecanoyl added as internal standard (P-5014 Sigma Chemical Company, St. Louis, MO), chloroform/methanol (2:1, vol/vol) as the solvent, and butylated hydroxytoluene (75 mg/L) as the antioxidant. Total phospholipids were separated by solid-phase extraction using NH_2 columns (size 3 cc, Analytichem Bond Elut LRC; Varian, Harbor City, CA) (20), followed by transmethylation using boron trifluoride, extracted into hexane and evaporated to dryness. The fatty acid methyl esters were dissolved in hexane and analyzed by gas–liquid chromatography (Shimadzu GC-14 A; Shimadzu Corporation, Kyoto, Japan), fitted with a capillary column (CP-Sil 88, length 50 m, i.d. 0.25 mm) obtained from Chrompack Inc. (Raritan, NJ). Retention times and response factors for each FA were determined using standards obtained from Nu-Chek-Prep (Elysian, MN). The results were integrated on a Shimadzu C-R4A integrator, and the FA concentrations were reported as µmol/L serum. The intraprocedural coefficients of variation (n = 10) for 16:0, 18:2n-6, 20:4n-6, 20:5n-3, and 22:6n-3 were 1.4, 1.7, 2.3, 2.3, and 4.3%, respectively. The unsaturation index was calculated as the sum (in µmol/L) of all unsaturated FA within serum phospholipids, multiplied by the number of double bonds in each FA divided by 1000. Total FA were extracted from 500 µL CM with heptadecaenoic acid (17:0) as internal standard according to the above-mentioned procedure. The concentrations of FA in CM were reported as µmol/L plasma.

Serum lipids. Serum lipids were analyzed on a Hitachi 737 Automatic Analyzer (Boehringer Mannheim, Germany) with reagents from the manufacturer. Total cholesterol was measured with an enzymatic colorimetric method (CHOD-PAP) and HDL cholesterol was assayed by the same procedure after precipitation of lower density lipoproteins with heparin and manganese chloride. Triglyceride concentration was determined with an enzymatic colorimetric test (GPO-PAP). Apolipoprotein A-1 and apolipoprotein B were measured immunochemically by rate nephelometry, using the Array Protein System from Beckman Instruments Inc. (Brea, CA).

Statistics. Change was calculated as the value obtained after minus the normally distributed value obtained before in-

tervention. Paired *t*-test was applied for changes in normally distributed variables within a treatment group, whereas unpaired *t*-test was used for comparison of changes between treatment groups. Repeated measures analysis of variance was performed to assess changes in plasma phospholipid and postprandial CM FA over time. The postprandial increase in plasma triglycerides and CM triglycerides were assessed in two ways. First, we calculated the area under the curve for the triglyceride concentrations after intake of a standardized fat meal as the deviation from the basal value integrated over the sampling time (8 h). Next, the triglyceride response was calculated as the average of the two highest postprandial triglyceride concentrations minus the baseline value. Two-sided *P*-values <0.05 were regarded as significant. The SAS statistical software package was used (21).

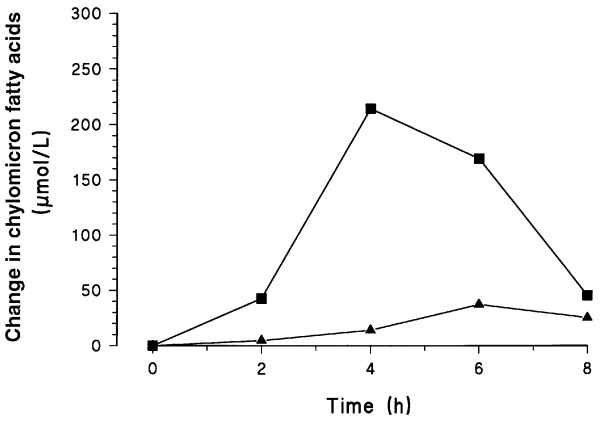

FIG. 1. Change in total saturated fatty acids (FA) (■) and total n-3 FA (▲) in chylomicrons after ingestion of a standardized high-fat meal with the addition of highly purified n-3 FA either as eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA). Values are means of pooled data from the EPA and DHA groups ($n = 14$).

RESULTS

None of the participants experienced discomfort, nausea, or diarrhea after ingestion of the liquid test meal with addition of highly purified n-3 FA. The participants did not experience significant side effects while taking EPA or DHA. All participants completed the study per protocol. The percentage of capsules taken was 98 (range 96–100%) in the EPA group and 91 (69–100%) in the DHA group.

The EPA and DHA groups were well balanced with regard to age, body mass index, and blood lipids (Table 1). During 5 wk of supplementation with EPA or DHA, serum triglycerides decreased by 13.4 ± 17.6% ($P = 0.09$) and 15.8 ± 19.4% ($P = 0.11$), respectively. Only minor changes were observed for other lipids and apolipoproteins.

Absorption of EPA and DHA before prolonged dietary intervention. Figure 1 shows absorption curves for saturated FA and total n-3 FA in total lipids extracted from CM after a standard test meal supplemented with 4 g n-3 FA, either as EPA ($n = 7$) or DHA ($n = 7$) (pooled data $n = 14$ at baseline). While saturated FA peaked 4 h after the meal, the peak concentrations of polyunsaturated n-3 FA were observed 6 h after the meal. The increase in EPA and DHA after a standard high fat meal with the addition of EPA (A) or DHA (B) at baseline are shown in Figure 2. Ingestion of both EPA and DHA induced a similar maximal increase in CM FA (8.4-fold and 8.5-fold increase, respectively) which peaked 6 h after the meal. The relative uptake of EPA and DHA compared to oleic acid calculated from peak concentrations was 94 and 100% respectively, whereas calculations based on the area under the concentration curve resulted in an estimated relative uptake of 91 for EPA and 93% for DHA. In the EPA group, the CM concentration of DHA did not change after the meal, and there was no change in the EPA concentration in the DHA group (Fig. 2). The clearance pattern for EPA and DHA differed, since the concentration of EPA decreased by 13.0% ($P = 0.57$) from 6 to 8 h after the meal, whereas the corresponding decrease in DHA was 61.9% ($P < 0.001$). The ratio between EPA and triglycerides in CM in the EPA group increased from 0.12 6 h after the meal to 0.25 8 h after the meal, mainly due to decreased levels of CM triglycerides. The corresponding ratios between DHA and CM triglycerides in the DHA group were 0.19 and 0.11, respectively, indicating a selective decrease of DHA from CM particles.

FA in serum phospholipids after prolonged intervention. Table 2 shows the concentration of FA in serum phospholipids at baseline and changes from baseline after intervention. EPA supplementation caused an increase in n-3 FA at

TABLE 1
Age, Body Mass Index, and Serum Lipids at Baseline and Changes from Baseline After Dietary Intake (4 g/d for 5 wk) of Either EPA or DHA

	EPA ($n = 7$)		DHA ($n = 7$)		EPA vs. DHA
	Baseline	Change	Baseline	Change	
Age (yr)	32.4 (5.0)		40.0 (8.4)		
Body mass index (kg/m^2)	25.2 (1.8)	0.13 (0.41)	24.5 (2.7)	0.26 (0.38)	NS
Total cholesterol (mmol/L)	5.80 (1.16)	0.00 (0.47)	5.34 (0.53)	0.09 (0.34)	NS
HDL cholesterol (mmol/L)	1.28 (0.12)	0.05 (0.11)	1.38 (0.26)	0.05 (0.19)	NS
Triglycerides (mmol/L)	1.19 (0.53)	–0.22 (0.36)	1.04 (0.41)	–0.21 (0.31)	NS
Apo-A1 (g/L)	1.30 (0.16)	–0.02 (0.13)	1.33 (0.11)	–0.04 (0.07)	NS
Apo-B (g/L)	0.99 (0.21)	0.01 (0.18)	0.89 (0.18)	0.02 (0.07)	NS

[a]Values are means (SD). HDL, high density lipoproteins. Apo-A1, Apolipoprotein-A1. Apo-B, Apolipoprotein B. NS, no significant difference between groups. EPA, eicosapentaenoic acid. DHA, docosahexaenoic acid.

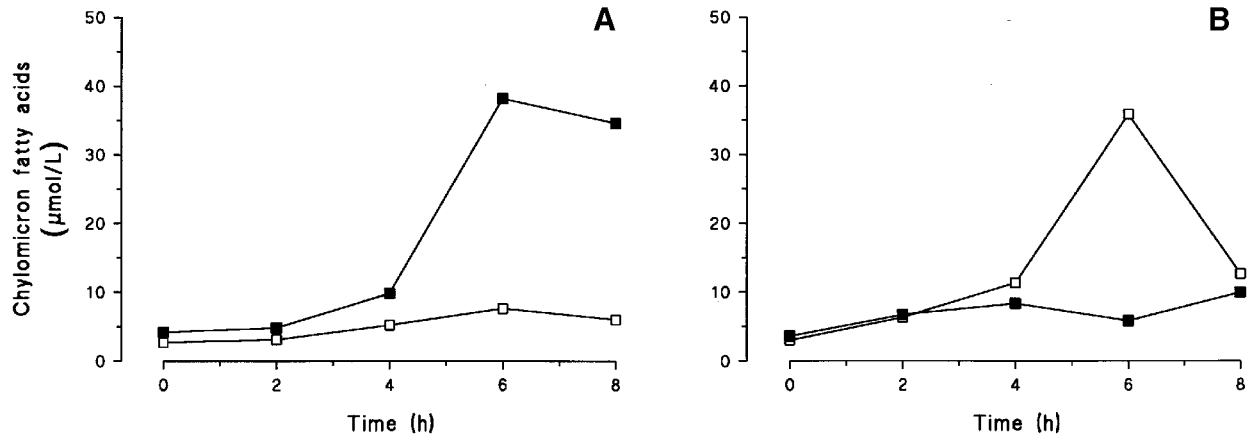

FIG. 2. Concentration of EPA (■) and DHA (□) in plasma chylomicrons after a standard high fat meal with the addition of 4 g of either EPA (A) or DHA (B). The values are means from seven subjects in each group. See Figure 1 for abbreviations.

the expense of n-6 FA. The decrease in linoleic acid (LA; 18:2n-6) was significantly greater after EPA than after DHA supplementation. The increase in n-3 FA after EPA was due to a 5.2-fold increase in EPA, and a 2.1-fold increase in docosapentaenoic acid (DPA), whereas the DHA concentration did not change. DHA supplementation caused a smaller increase in the total concentration of n-3 FA than did EPA (0.7- and 1.2-fold, respectively), but the difference between the two groups was not statistically significant. The increase in n-3 FA after DHA was due to 0.9-fold increase in DHA and 0.7-fold increase in EPA, whereas the DPA concentration did not change. A modest increase in the unsaturation index was seen both after EPA and DHA supplementation (0.36 ± 0.47 vs. 0.34 ± 0.53, $P = 0.94$). The incorporation of DHA in serum phospholipids after DHA supplementation was delayed compared to the incorporation of EPA after EPA supplementation (Fig. 3).

Influence of EPA and DHA on postprandial triglyceridemia. A standard test meal (2.64 MJ) with 4 g n-3 FA was given at the beginning and at the end of the 5-wk intervention period. Addition of EPA or DHA with the standard meal at baseline did not influence postprandial triglycerides or CM triglycerides differently as determined by the area under the curve or the peak response for the triglyceride curves (Table 3). Daily supplementation with EPA and DHA for 5 wk was associated with a 20 ($P = 0.11$) and 15% ($P = 0.13$) decrease in plasma triglycerides, respectively. After the intervention period, the peak response for plasma triglycerides decreased by 26 ($P = 0.04$) and 41% ($P = 0.02$) in the EPA and DHA groups, respectively, whereas the area under the curve decreased by 19 ($P = 0.20$) and 49% ($P = 0.05$),

[c]$P < 0.05$; P-value for changes within a group.

respectively. The differences between groups were not statistically significant. A similar pattern was seen for CM triglyceride concentrations (Fig. 4).

DISCUSSION

The present investigation examined the incorporation of EPA and DHA into CM after ingestion of purified EPA and DHA separately as EE together with a standard meal. Our data suggest that the enterocytic processing of the ingested fat and generation of CM do not involve significant elongation or retroconversion of EPA and DHA. This implies that ingested EPA and DHA are presented to their target organ(s) or cell(s) in their original form. Furthermore, DHA is apparently cleared from CM more efficiently than is EPA.

The relative uptakes from the standard meal of EPA and

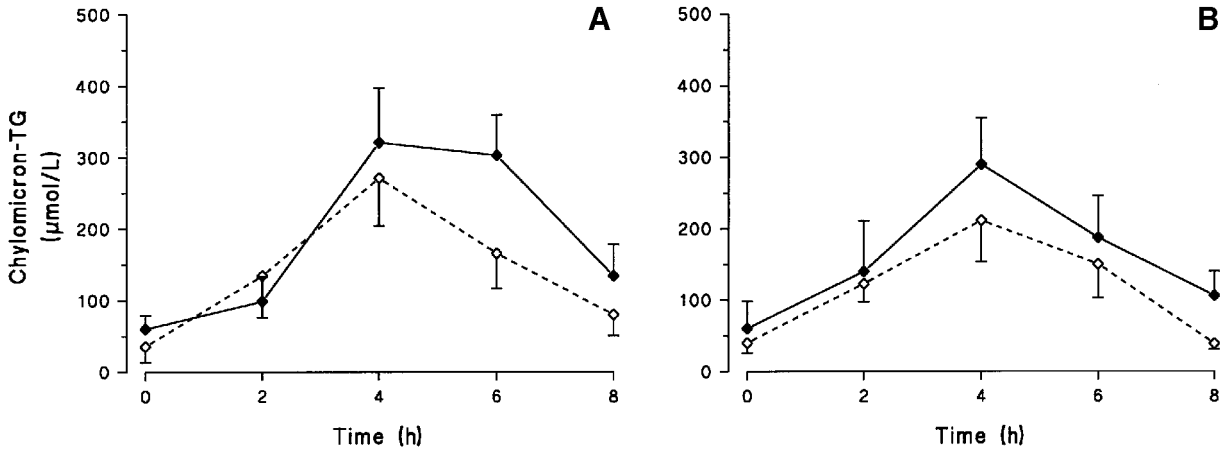

FIG. 4. Chylomicron triglyceride (TG) concentrations after a standard high-fat meal before (—) and after (– – –) a daily intake of 4 g EPA (A) or DHA (B) for 5 wk. Symbols are means ± SD.

DHA into CM were similar to that of oleic acid. Although the absorption of EPA and DHA was delayed compared with saturated FA, our data indicate that moderate and therapeutic amounts given as EE were well absorbed. These observations contrast with studies where equivalents of only 1.0 g EPA were given (13,14), and incomplete absorption of EE compared to triglycerides was observed. In a later study, Nordøy *et al.* (15) demonstrated that n-3 FA were equally well absorbed as EE or triglycerides when given in amounts of 28–40 g with the meal. Apart from differences in the amount of n-3 FA, the latter study measured absorption directly by analyzing CM triglycerides, rather than serum triglycerides, which is more precise. Equal absorption was further documented in a study showing similar incorporation of EPA and DHA into blood lipids after daily intake of 3.5 g EPA and DHA for 7 wk given either in a triglyceride or an EE formula (16).

It has been suggested, based on results obtained from *in vitro* studies, that the EE of n-3 FA are poor substrates for pancreatic lipase (4,7), and that this lipase has a reduced hydrolyzing activity toward trioctadecanoates containing double bonds in the third to sixth positions from the carboxyl end (22). The first double bonds of DHA and EPA are in positions 4 and 5, respectively. However, coingestion of EPA-EE with a meal normal for the American diet has been found to improve the uptake threefold (14). This may partly explain the substantial absorption of EPA and DHA in our study. A more recent study found that rates of release of oleic acid and DHA by lipase *in vitro* differ only by a factor of six (23). It was suggested that with the very high pancreatic lipase activity in the intestinal lumen, there should be little differences between the composition of FA ingested and that of FA released. Perhaps the delay in the maximal incorporation of EPA and DHA into CM compared to saturated FA reflected this difference.

Time-course incorporation of EPA and DHA into serum phospholipids had a different pattern after dietary supplementation with EPA and DHA. Daily ingestion of EPA caused a prominent and steep increase of EPA in serum phospholipids which reached a plateau after 1 wk. In contrast, ingestion of DHA caused a more gradual increase during the intervention period. In addition to different incorporation into and clearance from CM, this indicates different metabolism of EPA and DHA. The incorporation pattern for EPA indicates priority of the circulatory pool which seemed to be in equilibrium with other compartments after 1 wk.

Compared to EPA, more of the ingested DHA seemed to be channeled into extracirculatory compartments, since we observed a more rapid clearance from the circulation and a decreased incorporation of DHA into serum phospholipids. The mechanism(s) involved is unknown, but the selective decrease in DHA may suggest a more efficient cleavage of DHA than EPA by lipoprotein lipase. DHA is selectively enriched in the central nervous system (24) and is mandatory for normal central nervous system function. Recently, Anderson *et al.* (25) demonstrated incorporation of CM FA, and especially DHA, into the developing rat brain. They suggested that the brain derives a significant fraction of essential FA from CM. Whether this is a specific mechanism for the developing brain only is not known.

In agreement with previous studies (26,27), dietary EPA was not metabolized to DHA but caused a prominent increase in DPA (22:5n-3). The biological significance of the accumulated DPA after dietary EPA remains unknown. DHA supplementation caused a significant increase in EPA, confirming the retroconversion previously demonstrated both in rats (28) and humans (27). Thus, DHA may serve as a reservoir for EPA *via* partial β-oxidation (29) and saturation of the resulting *trans*-double bond (28).

Long-term intake of fish oil, rich in long-chain FA of the n-3 family (EPA and DHA) is reported to lower postprandial triglycerides by 30–55% in normolipemic subjects (7–9). The decrease in postprandial triglycerides by prolonged feeding of n-3 FA was seen regardless of whether saturated fat or fish oil was given with the meal (8). Harris and Muzio (9) also reported a similar decrease in postprandial triglycerides after a 24-h oral fat-load test, designed to mimic a normal eating pattern. Prolonged supplementation of n-3 FA may decrease postprandial triglyceridemia by diminished absorption, reduced synthesis, and release into the circulation by enterocytes, or by a more rapid removal of CM from the circulation. There is no evidence of diminished absorption (30) or enhanced removal of CM assessed by clearance rates of intravenous administered fat emulsions (9). However, fish oils have been reported to reduce triglyceride synthesis in and secretion from CaCO-2 cells, a human intestinal cell line (31). A similar inhibitory effect on the triglyceride synthesis pathway of n-3 fatty acids has also been observed in hepatocytes (32,33).

The present study indicates that prolonged intake of DHA is equivalent to or even more efficient than EPA in reducing postprandial triglyceridemia and fasting serum triglycerides. The postprandial triglyceridemia (area under the curve) was suppressed by 19 and 49% after ingestion of 3.8 g EPA or 3.6 g DHA daily for 5 wk. However, the present study was underpowered to detect statistically significant differences between groups. A recent study among 234 healthy subjects found that DHA tended to decrease serum triglycerides more efficiently than EPA (11). Experimental studies in perfused rat livers (34), $HepG_2$ cells (35), and hepatocytes (32,36) support our observation that both EPA and DHA inhibit triglyceride synthesis and secretion.

Patients with coronary artery disease have been found to have high plasma increased plasma concentrations of CM remnants (37) and postprandial lipemia (6). Fish oils containing a mixture of EPA and DHA lower postprandial triglyceridemia and thereby CM remnants. To our knowledge, the present study is the first to examine the separate actions of EPA and DHA on postprandial triglyceridemia. Our observations indicate that DHA may be more efficient than EPA in reducing postprandial CM remnants, but further studies are needed to establish the possible separate effects on lipid metabolism of the two major n-3 FA.

ACKNOWLEDGMENTS

This study was supported in part by grants from Pronova Biocare a.s. (Oslo, Norway), the Norwegian Council on Cardiovascular Dis-

eases, and the Norwegian Research Council. The skillful technical assistance of Vegard Lyngmo and Birgit Svensson at the Department of Medicine, Institute of Clinical Medicine, University of Tromsø is appreciated.

Effect of Apolipoprotein E Polymorphism on Serum Lipoprotein Response to Saturated Fatty Acids

Tim K. Tso, Sunmin Park, Yu-Hwai Tsai, Glenn Williams, and Jean T. Snook*

Department of Human Nutrition and Food Management, The Ohio State University, Columbus, Ohio 43210

ABSTRACT: This report summarizes two studies which investigated the effects of apolipoprotein E (apoE) polymorphism on the serum total cholesterol (TC) and lipoprotein cholesterol responses to 8:0 + 10:0 and 12:0 diets (Study I) and 14:0, 16:0, and 18:0 diets (Study II). Eighteen healthy premenopausal women (3 apoE 3/2, 12 apoE 3/3, 3 apoE 4/3) in study I and another 18 healthy premenopausal women (4 apoE 3/2, 10 apoE 3/3, 3 apoE 4/3, 1 apoE 4/2) in study II consumed a baseline diet providing 40 en% total fat, 11 en% 18:2, 15 en% 18:1, 11.5 en% saturated fat for the first week of each 5-wk period. The experimental diets for both studies provided 40 en% total fat, 13–14 en% as one of five test saturated fatty acids (SFA), 14–16 en% 18:1, and 3–4 en% 18:2. Analysis by apoE phenotypes showed that both the 8:0 + 10:0 diet and the 12:0 diet in Study I induced significant increases in serum TC in subjects with different apoE phenotypes with the exception of apoE 3/2 in the medium-chain triglyceride group. In contrast, in Study II, individuals with apoE 4/3 consuming the 14:0 diet showed significant increases in serum TC, high density lipoprotein-cholesterol (HDL-C), and HDL2-C, but the same subjects consuming the 16:0 diet showed significant increases in serum TC and low density lipoprotein-cholesterol. The findings from both studies indicated serum lipoprotein responses to SFA were different and the variation of responsiveness may be regulated, at least in part, by apoE polymorphism, especially when 14:0, 16:0, or 18:0 was consumed.

Lipids 33, 139–148 (1998).

Apolipoprotein E (ApoE) is a major protein constituent of chylomicrons, very low density lipoprotein (VLDL) and their remnants and, to a lesser extent, of high density lipoprotein (HDL) (1). It is also found to function as a ligand for the binding of lipoproteins to the LDL receptor and apoE receptor (1). There are three homozygous phenotypes (E 4/4, E 3/3, and E 2/2) and three heterozygous phenotypes (E 4/3, E 3/2, and E 4/2) (2). The different apoE forms have different affinities for lipoproteins. For example, apoE 2 compared to apoE 3 is associated less with VLDL, intermediate density lipoprotein (IDL), and low density lipoprotein (LDL) and more with HDL, while apoE 4 compared to apoE 3 is associated more with VLDL, IDL, and LDL and less with HDL (2). In addition, apoE phenotype is associated with changes in plasma total cholesterol (TC) and LDL-cholesterol (LDL-C). Among apoE 2, apoE 3, and apoE 4 phenotypes, individuals with apoE 2 phenotype tend to have the lowest plasma cholesterol concentrations while individuals with apoE 4 phenotype have the highest plasma levels of TC, LDL-C and apoB (3). With respect to the effect of dietary saturated fatty acids (SFA) on plasma cholesterol levels, SFA may act differently (4–8). For example, stearic acid (18:0) seems to be neutral compared to myristic acid (14:0) and palmitic acid (16:0) because of its partial conversion to oleic acid (18:1) or poor digestibility (6). In the general population, apoE polymorphism may account for some degree of the interindividual variation in plasma TC and LDL-C (2). In some studies individuals with apoE 4 phenotype have a greater LDL-C response to dietary changes in fat and/or cholesterol intakes than individuals with other apoE phenotypes (9–14). However, there are few reports elucidating the effect of varied apoE phenotypes on the response to dietary SFA changes. The purpose of the present study was to investigate the effect of apoE polymorphism on the serum TC and lipoprotein cholesterol responses to different SFA ranging in chain length from 8 to 18 carbons.

MATERIALS AND METHODS

Subjects. The apoE phenotype was determined in a total of 18 healthy premenopausal women recruited from among The Ohio State University female students in a two-period crossover study (Study I) and in a total of another 18 healthy premenopausal women in a three period-crossover study (Study II), the minimal number needed to detect a 10% mean difference in serum lipoprotein concentrations between treatments with a standard deviation of 8% by a statistical power of 0.9. Before starting the study, all subjects in both Study I and Study II signed a consent form approved by The Ohio State University Biomedical Human Studies Committee. All subjects were screened on the basis of information from a health questionnaire and a physical examination. The subjects' characteristics including age, weight, ethnic back-

TABLE 1
Characteristics of Subjects in Study I and Study II[a]

Variables	Study I (n = 18)	Study II (n = 18)
Age (year)	24 ± 4 (19–33)	28 ± 2 (19–43)
Weight (kg)	62.2 ± 11.7 (40.5–91.8)	61.3 ± 7.4 (50–77)
Serum cholesterol level at screening (mg/dL)	167 ± 22 (143–237)	178 ± 9 (122–252)
Ethnic background	Caucasian (n = 10) Asian (n = 7) African-American (n = 1)	Caucasian (n = 12) Asian (n = 4) African-American (n = 2)
Experimental diet	MCT diet Lauric acid diet	Myristic acid diet Palmitic acid diet Stearic acid diet
ApoE phenotype	E3/2 (n = 3) E3/3 (n = 12) E4/3 (n = 3)	E3/2 (n = 4 E4/2 (n = 1) E3/3 (n = 10) E4/3 (n = 3)

[a]MCT, medium-chain triglyceride; ApoE, apolipoprotein E.

ground, apoE phenotype, and serum TC concentration at screening are shown in Table 1.

Diets. The diets in both Study I and Study II were prepared in a metabolic kitchen in the Department of Human Nutrition and Food Management at The Ohio State University. Subjects ate breakfast and dinner in the metabolic dining room and took out a sack lunch. Weekend meals were also taken out except for Saturday night dinner. The baseline diet for both studies provided 40 en% total fat, 11 en% 18:2, 15 en% 18:1, 11.5 en% saturated fat, and about 323 mg cholesterol. The experimental diets for both studies were formulated to provide 40 en% total fat, 13–14 en% as one of five test SFA (8:0 + 10:0, 12:0, 14:0, 16:0, 18:0), 14–16 en% 18:1, 3–4 en% 18:2, and about 308–328 mg cholesterol. A basal menu providing 8.3 MJ (about 2000 Kcal) was given initially. Subjects requiring more food energy to maintain a stable weight were given extra cookies and cakes made up of fat blends with the same proportion of fatty acids as the overall diet. Dietary records of the subjects' food intake were kept and analyzed using Food Processor II software (ESHA Research, Salem, OR) with added data on fatty acid composition of the foods in the menu. Composites of the rotating 4-d menus were made and analyzed for specific fatty acid composition by gas–liquid chromatography (Table 2).

Research design. The protocols for both Study I and Study II were similar with the exception of participating subjects and experimental diets. All subjects were randomized into different groups using either a two-period (Study I) or three-period (Study II) crossover design. The baseline diet was fed for 1 wk and then each dietary treatment lasted 4 wk with a 7-wk washout period between experimental periods. Blood samples were obtained by venipuncture after an overnight fast twice during the last 3 d of the baseline period and two times during the last 3 d of each feeding period. Depending on the requirements of the procedure, either analyses commenced immediately or serum (or plasma), obtained by centrifugation at 2500 rpm for 20 min at 4°C, was frozen at −80°C for later analysis.

EXPERIMENTAL PROCEDURES

Plasma lipids. The concentrations of TC and triglyceride (TG) were measured by an enzymatic assay using a commercial kit (Sigma Chemical Company, St. Louis, MO; procedure#352-50 and #339, respectively) (15). HDL-C including HDL2-C and HDL3-C were measured by the same enzymatic procedure as TC. This involved precipitation of and removal by centrifugation of VLDL- and LDL-C by a precipitation reagent composed of 10 g/L of dextran sulfate and 0.5 M of Mg^{2+} with buffer (Sigma Chemical Company; procedure#352-2) (16). LDL-C was calculated by the Friedewald equation (17).

ApoE phenotyping. ApoE phenotype was determined by isoelectric focusing (IEF) according to a modification of the method of Kamboh *et al.* (18) and Kataoka *et al.* (19). Plasma

[c]As determined by gas–liquid chromatography. MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids. See Table 1 for other abbreviation.

samples were delipidated with 100 µL of dithiothreitol solution containing 0.771% of dithiothreitol and 250 µl of Tween 20 at 4°C for overnight. The IEF was carried out by 7.5% polyacrylamide gel electrophoresis (PAGE)-3 M urea gel. The gel was freshly prepared as follows: 7.2 g urea was dissolved in 10 mL polyacrylamide solution containing 30 g of monomer acrylamide and 0.8 g of bis acrylamide per 100 mL and the final volume was adjusted to 40 mL with deionized water. The pH gradient was created by adding 0.6 mL Ampholine pH 4–6 (Amersham Pharmacia Biotech, Piscataway, NJ) and 1.2 mL Pharmalyte pH 5–8 (Amersham Pharmacia Biotech). Before casting, 25 µL of *N*,*N*,*N*′,*N*′-tetramethylenediamine and 500 µL of 10% ammonium persulfate solution were added to the gel solution. After polymerization, the gel was placed on an IEF machine (Bio-Phoresis Horizontal Electrophoresis Cell; Bio-Rad Laboratories, Hercules, CA) connected with a Lauda RM6 cooling unit (Brinkmann Instruments, Inc., Westbury, NY) operating at 6°C and thus prefocused for 15 min at voltage of 1500 V, 60 mA, 15 W. The cathode strip and anode strip were saturated with cathode solution (1 M NaOH) and anode solution (1 M H_3PO_4), respectively, and strips were laid across the length of the gel as close to the edge of the gel as possible. After prefocusing, the sample wicks saturated with a 30 µL sample were located on the gel near the cathode strip. Then the gel was focused at the voltage of 1500 V, 60 mA, 15 W for 30 min. After that, the sample wicks were removed and the IEF was continued for an additional 1.5 h. Then, immunoblotting was conducted according to a modification of the method of Kamboh *et al.* (18).

LDL receptor activity. Degradation and binding of ^{125}I-LDL by mononuclear cell (MNC) were determined by a modification of methods of Ho *et al.* (20) as described previously by Park and Snook (21). An aliquot of freshly isolated MNC in Hank's buffer (21) was incubated with ^{125}I-LDL (20 µg/mL) in the presence and absence of a 20-fold excess of unlabeled LDL at 37°C for 5 h. Degradation values were expressed as specific degradation which was the difference in degradation in the presence and absence of a 20-fold excess unlabeled LDL. Expression of specific degradation was as nanograms of ^{125}I-LDL protein degraded/10^6 cells/h. Specific and nonspecific binding activity of LDL receptors was determined by incubation of MNC at 4°C with ^{125}I-LDL in the presence and absence of excess unlabeled LDL for 1 h. Bound counts were expressed as micrograms of LDL protein bound per 10^6 cells.

CETP and LCAT activity. The rates of cholesterol ester transfer (cholesterol ester transfer protein, CETP) and endogenous cholesterol esterification (lecithin-cholesterol acyl transferase, LCAT) were assessed by the isotopic method of Channon *et al.* (22). Briefly, for determination of esterification rate, fresh serum was preincubated at 4°C for 1 h with ^{3}H-cholesterol-albumin emulsion; after equilibration of the added cholesterol and endogenous cholesterol, the mixture was incubated at 37°C for 3 h. Lipids were extracted, separated by thin-layer chromatography, and radioactivity of cholesterol ester and free cholesterol spots was counted by liquid scintillation. For cholesterol transfer activity, transfer of radiolabeled cholesterol ester into VLDL and LDL was measured first by precipitating the two apoB-containing lipoproteins from the incubate with dextran sulfate. Then, total radioactivity in the incubate, in the HDL-containing supernatant, and in the apoB-containing lipids was measured by liquid scintillation counting. These data were used to calculate the rate of transfer of the cholesterol ester.

Statistical analysis. MINITAB statistical software (Minitab Inc., State College, PA) and the Statistical Analysis System (SAS; SAS Institute, Cary, NC) were used in the present study for analysis of serum lipid and lipoprotein responses to dietary manipulation. The significance of the differences between the beginning and the end of each period (mean ± SEM) was calculated using the paired *t*-test in the Minitab statistical software. Least squares means, adjusted for unequal subclasses, of changes in serum TC, TG, and lipoprotein cholesterol levels from baseline analyzed by apoE phenotypes and experimental diets were analyzed using the general linear models procedure of SAS. Two-way analysis of variance (ANOVA) was used to determine interactions between experimental diets and apoE phenotypes, as well as their independent effects. In addition, stepwise regression analysis was conducted to quantify the contribution of race, diet, and apoE isoforms to the variation in serum lipid and lipoprotein responses to experimental diets. The probability of significant difference was defined as $P < 0.05$ for all statistical analysis in both Study I and Study II.

RESULTS

Daily energy and nutrient intake on the baseline diet and five saturated fat diets is shown in Table 2. The experimental diets provided similar amounts of poly- and monounsaturated fat as well as dietary cholesterol, and the baseline diet provided three times as much 18:2 as the experimental diets and only half as much saturated fat (Table 2). However, there was no effect of apoE phenotype on any of the variables when subjects consumed the baseline diet (Table 3). Changes from

[a]Mean ± SEM = mean ± standard error of mean. Significant difference between baseline diet and experimental diet (*P* value) according to paired *t*-test. TC, total cholesterol; TG, triglycerides; LDL-C, low density lipoprotein-cholesterol; HDL-C, high density lipoprotein-cholesterol. See Table 1 for other abbreviation.

baseline in lipid and lipoprotein concentrations, variables associated with reverse cholesterol transport, and LDL receptor activity in MNC in subjects with different apoE phenotypes consuming both Study I diets (including 12:0 diet and 8:0 + 10:0 diet) and Study II diets (including 14:0, 16:0, and 18:0 diets) are shown in Table 4 and Table 5, respectively.

Serum changes in lipid and lipoprotein concentrations. In Study I (Table 4), both the 12:0 diet and 8:0 + 10:0 diet induced significant increases in serum TC in subjects with different apoE phenotypes (with the exception of apoE 3/2 on 8:0 + 10:0 diet). Specifically, the 12:0 diet significantly elevated serum TC, LDL-C, HDL-C, HDL_2-C, and HDL_3-C in subjects with apoE 3/3, while the same subjects consuming the 8:0 + 10:0 diet showed significant increases only in serum TC and HDL_3-C. Serum LDL-C increased and TG decreased when individuals with apoE 3/2 consumed the 12:0 diet. There was a trend toward elevated and reduced serum HDL_2-C on the 12:0 diet and 8:0 + 10:0 diet, respectively, in all subjects with different apoE phenotypes. In Study II (Table 4), individuals with apoE 4/3 consuming the 14:0 diet showed significant increases in serum TC, HDL-C and HDL_2-C, but the same subjects consuming the 16:0 diet showed significant increases in serum TC and LDL-C. There were no significant changes from baseline in lipid and lipoprotein levels when subjects with different apoE phenotypes consumed the 18:0 diet (with the exception of apoE 3/3).

Changes in variables associated with reverse cholesterol transport. In comparison to values measured on the baseline diet, the rate of CETP from HDL to VLDL + LDL tended to increase on all of the Study II diets (14:0, 16:0, 18:0), but only the mean increase from baseline in subjects with apoE 3/2 consuming the 14:0 diet was statistically significant (Table 5). The 12:0 diet raised the rate of cholesterol ester transfer whereas the 8:0 + 10:0 diet tended to decrease the rate of cholesterol ester transfer in all subjects among all apoE phenotypes, but none of the changes was significant (with the exception of apoE 3/3 consuming the 12:0 diet). The rate of cholesterol esterification (LCAT) increased in subjects with apoE 3/3 and 3/2 consuming the 12:0 diet but tended to decline nonsignificantly on the 18:0 diet for all apoE phenotypes (Table 5).

Changes in LDL receptor activity in MNC. In Study I (Table 5), in subjects with apoE 3/3, the rate of receptor-mediated ^{125}I-LDL degradation significantly declined on 12:0 diet and increased on 8:0 + 10:0 diet. On the other hand, data shown in Table 5 illustrate that the 12:0 diet tended to reduce LDL binding while the 8:0 + 10:0 diet enhanced LDL binding significantly in subjects with apoE 3/3. In Study II (Table 5), only subjects with apoE 3/3, the most common apoE phenotype, consuming the 16:0 diet showed a significant decrease in the rate of receptor-mediated ^{125}I-LDL degradation.

Effect of interactions between experimental diets and apoE phenotypes. In both Study I and Study II, two-way ANOVA was used to determine interactions between experimental diets and apoE phenotypes, as well as their independent effects (Table 6 and Table 7). There were no statistically ($P < 0.05$) significant interactions between experimental diets and apoE phenotypes for variables analyzed in both studies although the effect of interactions on LDL-C ($P = 0.0669$) approached significance in Study II. However, an analysis of the independent effects of experimental diets and apoE pheno-

types showed that the 8:0 + 10:0 and 12:0 diets in Study I had significant influences on HDL-C, HDL_2-C, CETP, receptor-mediated ^{125}I-LDL degradation and binding, while the 14:0, 16:0, and 18:0 diets in Study II showed significant effects on TC, LDL-C, and receptor-mediated ^{125}I-LDL degradation. With respect to the independent effect of apoE phenotype, the serum TC and LDL-C responses to the 14:0, 16:0, and 18:0 diets in Study II were regulated by apoE phenotypes.

Stepwise regression analysis. Race (Asian, African-American, and Caucasian), diet (8:0 + 10:0, 12:0, 14:0, 16:0, and 18:0), and apoE phenotype (E2, E3, and E4) were used in a stepwise regression analysis as dummy variables. Diet and apoE phenotype entered the regression model as significant factors explaining the variation in serum TC, LDL-C, and ^{125}I-LDL degradation responses to experimental diets. The regression equations were described as follows: (i) change of TC = 8.65 − 23.28 (18:0) + 23.98 (E4), the partial R^2 = 0.2579, 0.1420, and the model R^2 = 0.3999; (ii) change of LDL-C = 3.36 − 16.05 (18:0) + 22.85 (E4), the partial R^2 = 0.1826, 0.1663, and the model R^2 = 0.3489; (iii) change of ^{125}I-LDL degradation = −1.60 − 6.73 (16:0) + 7.05 (E2), the partial R^2 = 0.1639, 0.1666, and the model R^2 = 0.3305.

DISCUSSION

This was a controlled dietary intervention study in which the effects of apoE phenotypes on serum lipid and lipoprotein responses to five different SFA diets were investigated. The five SFA diets were medium-chain triglycerides (MCT) (8:0 + 10:0), lauric acid (12:0), myristic acid (14:0), palmitic acid (16:0), and stearic acid (18:0). In order to maximize their individual effects, these SFA were administered in amounts 2 to 10 times higher than those typically selected in an American diet.

Recently, considerable evidence has accumulated that suggests that apoE polymorphism may affect the serum lipid and lipoprotein responses to dietary intervention (5,9–14,23–33). A summary of a variety of studies of dietary-induced changes in serum lipids and lipoproteins in relation to apoE phenotype is shown in Table 8. Some studies demonstrated greater serum lipid and lipoprotein responses in individuals carrying the apoE 4 allele (apoE 4/3 or apoE 4/4) (9–14) while others failed to have the same conclusion (5,23–33). These various findings can be attributed, at least in part, to differences between these studies in the subjects' age and gender, composition of the baseline diet and experimental diet, content of fat and/or cholesterol, and the length of the period of dietary intervention. In addition, such characteristics as individual apoE phenotypes, subject's individual variation, and/or other genetic factors may also play a role in the serum lipid and lipoprotein responses to dietary manipulation. Among those studies (Table 8), most either modified the amounts of dietary fat and cholesterol or adjusted the ratio of polyunsaturated fat to saturated fat. There have been few studies (5) elucidating the effect of varied apoE phenotypes on the response to manipulation of dietary SFA. Like most studies (Table 8), however, the present report also found that subjects with apoE 4/3 showed the greatest lipid and lipoprotein responsiveness to dietary manipulation but only to certain SFA diets. This re-

sult may be due to the characteristics of the individual SFA, since SFA may not have the same influence on lipoprotein metabolism. Interestingly, in this report, there were no effects of apoE phenotype on any of the variables measured in both Study I and Study II when subjects consumed a baseline diet providing higher polyunsaturated fat (Table 2 and Table 3). It may be possible to hypothesize that the high polyunsaturated fat diet has its own hypocholesterolemic effect regardless of apoE phenotypes. In addition, Cobb and Risch (30, Table 8) reported that the degree of change in dietary saturated fat content was one of the most significant predictors of responses of plasma LDL-C to dietary intervention. According to results from stepwise regression analyses, 14% of the variance in change of serum TC and 16% of the variance in change of serum LDL-C were explained by apoE 4/3 phenotype. Although there were Asians and African-Americans in both Study I and Study II, ethnic difference did not contribute to serum lipid and lipoprotein (except for TG in Study II) responses to experimental diets. Therefore, the present study was a well-controlled feeding study designed to investigate whether the effects of different SFA on serum TC and lipoprotein cholesterol depend on the apoE phenotype in healthy premenopausal women.

Does apoE polymorphism influence SFA-induced serum lipoprotein responses? It is known that SFA have different cholesterolemic effects on the serum lipids and lipoproteins (4–8). The MCT (8:0 + 10:0) are thought not to raise cholesterol concentrations (4), while myristic acid (14:0) and palmitic acid (16:0) raise both serum total and LDL-C (4,5). Stearic acid (18:0) is considered neutral owing to its failure to increase either serum TC or LDL-C levels because of poor absorption and possible conversion to oleic acid (18:1) (6,34). With respect to effects of the apoE phenotypes on lipoprotein metabolism, it has been known that chylomicron remnants with apoE 2 on the surface are poorly recognized by receptors which results in accumulation of these particles in plasma (3), while clearance of chylomicron remnants is more rapid and cholesterol absorption is more enhanced in individuals with the apoE 4 phenotype (35,36). Therefore, when taking apoE polymorphism into account, the magnitude of cholesterolemic effects described above may not stay the same. In the present report, changes from baseline showed that both the 12:0 diet and 8:0 + 10:0 diet induced significant increases in serum TC in subjects with different apoE phenotypes (with the exception of apoE 3/2 in the 8:0 + 10:0 group) in contrast to previous reports suggesting 8:0 + 10:0 was neutral (4). The 16:0 diet significantly raised both serum TC and LDL-C in subjects with apoE 4/3. It is not clear that the cause of increased atherogenic factors in subjects with apoE 4/3 consuming the 16:0 diet is due to the hypercholesterolemic prop-

erty of the palmitic acid (4,5) or the greater responsiveness of apoE 4 (9–14) or interaction of both. The 18:0 diet tended to decrease LDL-C concentrations. Taken together, all variations regarding the cholesterolemic responses to dietary intervention providing enhanced individual SFA may be associated with the different metabolism of lipoproteins regulated by the apoE polymorphism. For example, Kesaniemi *et al.* (36) reported that subjects with apoE 2 showed lower intestinal cholesterol absorption efficiency than those with the apoE 4. Miettinen *et al.* (28) also showed that subjects with apoE 2 have more effective bile acid and cholesterol syntheses, fecal elimination of cholesterol, removal of LDL apoB, and low cholesterol absorption. In the present study, results from statistical analysis by two-way ANOVA showed that there were no significant interactions between experimental diets and apoE phenotypes although the interaction between the saturated fats in Study II and apoE phenotypes for LDL-C responsiveness ($P = 0.0669$) was close to a significant level (Table 6 and Table 7). However, with respect to the independent effects of experimental diets and apoE phenotypes, we found that serum TC and LDL-C level were independently regulated by apoE polymorphism: apoE 4/3 increased levels of TC and LDL-C the most, when subjects consumed the experimental diets in Study II (14:0, 16:0, and 18:0 diets).

Does apoE phenotype influence parameters related to reverse cholesterol transport? In a previous report (37), in which apoE polymorphism was not taken into account, we demonstrated that SFA had different effects on HDL-C in healthy women. For example, the 12:0 diet significantly raised HDL-C fractions (HDL_2-C and HDL_3-C), and the concentration of HDL_2-C declined and HDL_3-C increased in serum when subjects consumed 8:0 + 10:0, while 14:0 and 16:0 diets had no significant effect on the HDL-C fractions compared to the baseline diet (37). With respect to the influences of apoE phenotype on this aspect, Martin *et al.* (31) found that there was a significant effect of apoE phenotype on both the HDL-C and CETP responses to a high cholesterol diet. In their study, subjects with apoE 4/3 had a small increase in CETP and a large increase in plasma HDL-C whereas the apoE 3/2 subjects showed the opposite association (31). In the present study, the 12:0 diet significantly raised both HDL-C-including HDL fractions and CETP in the apoE 3/3 group, the most common apoE phenotype. In addition, no consistencies existed in the experimental diet-induced changes of the rate of LCAT among apoE phenotypes. Overall, statistical analysis of the independent effects of experimental diets and apoE phenotypes showed that apoE polymorphism had no significant influence on parameters re-

[a]ApoE phenotype showing the significantly greatest response. NS = no significant effect of apoE phenotype on the response to dietary manipulation. NA = not applicable. See Table 4 for other abbreviations. P/S = polyunsaturated/saturated; S/M/P = saturated/monounsaturated/polyunsaturated.

lated to reverse cholesterol transport regardless of experimental diets, whereas the experimental diets in Study I had significant effects on HDL-C and HDL_2-C, the 12:0 diet increased their serum levels, and the 8:0 + 10:0 diet lowered them. We may hypothesize that variations in reverse cholesterol transport system induced by the dietary manipulation are regulated not by apoE polymorphism but by certain SFA.

Is experimental diet-induced LDL-receptor mediated LDL metabolism regulated by apoE polymorphism? Since the steady-state concentrations of LDL-C in blood are predominantly a function of the rate of LDL-C production and the activity of the LDL-receptor, the SFA fed in cholesterol-containing diets have been found to enhance LDL-C production and reduce LDL-receptor activity (34). In addition, LDL-receptor activity in MNC has been shown to reflect the LDL-receptor activity in liver (38). In both Study I and Study II, MNC were isolated from fresh fasting blood to detect the LDL-receptor activity. In Study I, all apoE phenotypes consuming the 12:0 diet tended to decrease the receptor-mediated degradation of ^{125}I-LDL in MNC. This reduction may help explain why the 12:0 diet significantly raised both serum TC and LDL-C among all apoE phenotypes in the present study. Surprisingly, the 8:0 + 10:0 diet significantly induced the elevation of both receptor-mediated degradation and binding of ^{125}I-LDL in subjects with apoE 3/3 phenotypes. It has been known that apoE 4 may increase the intrahepatic pool of cholesterol, downregulate hepatic cholesterol synthesis and LDL receptor activity, and eventually elevate serum LDL-C levels, while the reduced binding affinity seen in subjects with apoE 2 may upregulate LDL receptor activity and increase LDL-C clearance (3,39). In the present study, however, the independent effect of apoE polymorphism on receptor-mediated degradation of ^{125}I-LDL in MNC was significant (P = 0.0093) only when subjects consumed the experimental diets in Study II (14:0, 16:0, and 18:0 diets) (Table 7). Compared to experimental diets in Study II, the 8:0 + 10:0 and 12:0 diets in Study I seemed to be more responsible for variation of LDL receptor-mediated degradation (P = 0.0025) and binding (P = 0.046) of ^{125}I-LDL in MNC (Table 7). It seems that the effect of apoE polymorphism on the response of receptor-mediated mechanisms to experimental diets may depend on the characteristics of individual saturated fats.

In summary, serum TC and LDL-C responses to the 14:0, 16:0, and 18:0 diets were regulated, in part, by apoE polymorphism, because subjects with apoE 4/3 responded well to the dietary manipulation providing certain SFA enhanced at levels above usual intake (Table 6). According to findings of the present report, it is possible to hypothesize that variations in the serum lipid and lipoprotein responses to dietary intervention providing enhanced individual SFA may be associated with differences in lipoprotein metabolism regulated in part by apoE polymorphism. However, since there were only three or four subjects in either the apoE 3/2 or apoE 4/3 groups participating in the present dietary intervention studies (both Study I and Study II), more controlled studies with larger subject sample sizes are needed. It is also important to study the less common phenotypes such as apoE 2/2, apoE 4/4, and apoE 4/2.

Low-Fat, Monounsaturate-Rich Diets Reduce Susceptibility of Low Density Lipoproteins to Peroxidation *ex vivo*[1]

Dawn J. O'Byrne, Sean F. O'Keefe, and Rachel B. Shireman*

Department of Food Science and Human Nutrition at the University of Florida, Gainesville, Florida 32611

ABSTRACT: Oxidative modification of low density lipoprotein (LDL) plays an important role in the process of atherosclerosis. The susceptibility of LDL to oxidation and the amount of peroxidation products formed are influenced by the lipoprotein content of 18:1n-9, 18:2n-6, and the 18:2n-6/18:1n-9 ratio, which is dependent in part on dietary fatty acids. The purpose of this study was to determine if changing from a typical American diet to a low-fat, monounsaturate-rich diet (LFMR) would result in favorable alterations in the fatty acid composition and oxidative profile of LDL in hypercholesterolemic individuals. Free-living postmenopausal hypercholesterolemic women who routinely consumed a diet moderately high in total fat and total saturates (34 and 11%, respectively) followed an LFMR diet (26% fat, 6% saturated fat, and 14% monounsaturated fat) for 6 mon. Sixteen postmenopausal hypercholesterolemic women already following standard low-fat (LF) diets acted as a control for seasonal variations in serum lipids. LDL from randomly selected subjects (LF $n = 6$, LFMR $n = 5$) was evaluated. LFMR diets resulted in LDL with increased concentrations and percentages of 18:1n-9, reduced 18:2n-6/18:1n-9 ratio, and lower percentages of 18:2n-6. No significant changes in LDL fatty acids occurred in the LF group. Conjugated diene lag time increased in both groups during copper-induced *in vitro* oxidation. Only the LFMR group experienced an increase in lipid peroxide lag time and a decrease in lipid peroxide formation. The LFMR diet was well tolerated and may be of therapeutic value in the treatment of hypercholesterolemia.

Lipids 33, 149–157 (1998).

Oxidative modification of low density lipoprotein (LDL) is thought to play an important initiating role in the process of atherosclerosis (1–6). Diets high in monounsaturated fatty acids (MUFA) have been shown to enrich LDL with oleic acid and result in lipoprotein particles that are more resistant to oxidation and produce less conjugated dienes (CD), lipid peroxides (LP), or malondialdehyde (MDA), relative to LDL rich in polyunsaturated fatty acids (PUFA) (7–12). The rate and extent of LDL oxidation during *in vitro* studies have been shown to be influenced by the fatty acid content of the lipoprotein. The amount of LDL oxidative products generated, and to a lesser extent the oxidative rate, have been positively associated with the ratio of 18:2n-6 to 18:1n-9, %18:2n-6, and %PUFA, and inversely correlated with %18:1n-9 and %MUFA (7,9,11,12). The influence of LDL fatty acid composition on lag time has been less clear (7,11,13–15).

To date, experimental diets used to alter the fatty acid composition and oxidative profile of human LDL have been relatively high in fat (34–45% energy) and consumed for only a few weeks. High MUFA diets often have been compared to high PUFA diets to determine efficacy, so it is not certain if high MUFA diets actually improve baseline oxidative resistance of LDL. In general, most of the experimental diets employed in previous studies do not reflect standard therapeutic practices for treating hypercholesterolemia. Current dietary guidelines for the prevention of coronary heart disease recommend that individuals consume <30% energy from fat and <10% from saturated fat (SFA), with MUFA making up the majority of dietary fat. The impact of such dietary modifications on the lipid composition and oxidative susceptibility of LDL has not been studied. It was the purpose of this investigation to determine if the fatty acid profile and oxidative potential of LDL can be altered when hypercholesterolemic individuals change from typical American diets to low-fat, high-MUFA diets.

SUBJECTS AND METHODS

Study design. This study was approved by the Institutional Review Board of the University of Florida. Thirty-six free-living healthy postmenopausal hypercholesterolemic women participated in this study. Twenty subjects habitually consuming a typical American diet (34% fat, 11% saturated fat) were placed on an experimental low-fat monounsaturate-rich diet (LFMR) for 6 mon. Sixteen subjects already following a low-

Abbreviations: BHT, butylated hydroxytoluene; BSA, bovine serum albumin; CD, conjugated diene; LDL, low density lipoprotein; LF, low-fat diet; LFMR, low-fat monounsaturate-rich; LP, lipid peroxide; MDA, malondialdehyde; MUFA, monounsaturated fatty acid; NCEP, National Cholesterol Education Program; PBS, phosphate buffered solution; PUFA, polyunsaturated fatty acid; SFA, saturated fatty acid; WHHL, Watanabe heritable hyperlipidemic.

fat diet (LF) similar to the National Cholesterol Education Program (NCEP) Step 1 guidelines were asked to continue following their typical diets. LF subjects were used as cohorts to monitor seasonal variation in lipids which might confound the results of the study. LDL was isolated before and after the experimental diet period from randomly selected subjects in both groups (LFMR $n = 8$, LF $n = 6$). LDL fatty acid composition and *in vitro* formation of CD, LP, and MDA were determined.

Subjects. Subjects were unpaid volunteers who gave informed consent to participate in the study. These women ranged in age from 50 to 65 yr, had fasting serum cholesterol levels between 220 and 300 mg/dL (5.68–7.76 mmol/L), did not smoke, were free of endocrine disorders, were not on hormone replacement therapy, were not taking medications that alter blood lipids, and discontinued all vitamin/mineral supplements 3 mon prior to initiation of the study.

The data from 12 of the participants were not used because the women were unable to successfully complete the study due to injury, illness, schedule conflicts, or noncompliance with the study protocol. Three of these subjects were part of the randomly selected LFMR subgroup used for the LDL studies. Therefore, only the results of the subjects who successfully completed the study are reported here (LFMR $n = 5$, LF $n = 6$).

Diet. The participants were taught how to weigh, measure, and record all foods and beverages consumed. Subjects completed 7-d diet records prior to the initiation of the study and on a monthly basis during the 6-mon experimental diet phase. The nutrient composition of the initial and 6-mon diet records were analyzed by computer (Professional Dietitian, Wellsource, Clackamas, OR). The database of the nutritional analysis program was expanded to include specific processed foods and information on the dietary fiber and vitamin E content of foods frequently eaten (16–27).

A registered dietitian instructed the free-living participants on their diet protocol, designed individualized daily eating plans, and provided monthly nutrition classes and counseling throughout the study. The LF and LFMR daily eating plans were based on the NCEP Step 1 guidelines as outlined by the American Heart Association (28). The energy distributions of the LF and LFMR diets were <30% fat, 50–60% carbohydrate, and 15–20% protein. Dietary SFA was limited to <10% energy, and dietary cholesterol was restricted to <300 mg/d. Monounsaturated fat comprised 50–60% of the fat in the LFMR diet. For convenience and to enhance compliance, a majority of the monounsaturated fat in the LFMR diet was supplied by a high-oleic acid peanut cultivar developed at the University of Florida (Gainesville, FL) (29). This peanut contains approximately 76–80% of the lipid as MUFA. Prepackaged daily rations of the dry roasted high-oleic peanuts were given to the participants. Depending upon energy requirements, subjects consumed 35–68 g of peanuts per day. Small amounts of olive oil and canola oil were allowed for cooking purposes.

Subjects were asked to maintain weight and activity level throughout the study. Dietary compliance was determined through monthly telephone conversations and evaluation of subject's body weight and diet records.

Isolation of LDL. Approximately 60 mL blood was drawn from randomly selected subjects after a 12-h fast. Subjects refrained from vigorous exercise and alcohol consumption for 24 h prior to donating blood. Serum was isolated, and 1 mL proteolysis inhibitor (10 mg EDTA, 10 mg merthiolate, and 20 mg sodium azide per 100 mL) was added per 100 mL serum. A Sorvall OTD-2 ultracentrifuge equipped with a T865 rotor (Sorvall, Newton, CT) was used to isolate LDL by sequential density gradient ultracentrifugation of serum (30) at 4°C under N_2. The KBr buffers used during ultracentrifugation contained 0.01% EDTA to prevent oxidation during the procedure (31). Isolated samples of LDL were dialyzed at 4°C with five changes of N_2-flushed phosphate buffered saline (PBS, pH 7.2) containing 0.01% EDTA.

LDL protein concentration. The protein concentration of freshly dialyzed LDL was determined in triplicate by the method of Lowry *et al*. (32) using bovine serum albumin (BSA, Sigma Chemical Co., St. Louis, MO) for the standard curve.

LDL fatty acid profile. The lipid from freshly dialyzed LDL was extracted by a modified method of Bligh and Dyer (33). During each step of the extraction and methylation process, samples were flushed with N_2 to prevent oxidation of the lipids. The extract residue was dissolved in chloroform with 0.05% butylated hydroxytoluene (BHT) and transferred to 2 mL Pyrex® sample containers with Teflon-lined screw caps. Samples were flushed with N_2 and stored at −70°C until the fatty acid analysis was performed at the end of the study. The initial and final LDL samples were methylated (34) and analyzed at the same time to minimize procedure variability. Fatty acid methyl esters were analyzed using a Shimadzu GC-14A gas chromatograph equipped with a flame ionization detector and C-R5A Chromatopac integrator (Shimadzu, Kyoto, Japan). A DB-225 capillary column, 30 m × 0.25 mm internal diameter (Alltech Associates, Deerfield, IL), was used at a constant temperature of 200°C. Duplicate injections were made for each LDL sample. Fatty acid methyl esters were identified by comparison of peak retention times with a standard containing a mixture of fatty acid methyl esters (GLC-68A; Nu-Chek-Prep, Inc., Elysian, MN). The fatty acid profile was calculated by dividing the area of each peak by the total area of the fatty acid peaks. The concentrations of individual fatty acids were calculated by comparing the mean area of each peak to the mean peak area of the 17:0 internal standard (Nu-Chek-Prep). The results were expressed as μg fatty acid/mg protein.

LDL oxidation studies. An aliquot of each freshly isolated LDL sample was dispensed into 2 mL polystyrene cryovials containing sufficient sucrose and EDTA for a final concentration of 20 and 0.01%, respectively. The samples were flushed with N_2 and stored at −20°C for oxidation experiments to be conducted at the end of the study. Prior to the oxidation experiments, each subject's initial and final LDL samples were

thawed and dialyzed together at 4°C in five changes of N_2-saturated PBS (pH 7.2) without EDTA.

Each LDL sample was diluted with PBS to a concentration of 50 µg protein/mL. *In vitro* oxidation of LDL was induced by adding 5 µM $CuSO_4$ to each sample and incubating at 37°C for 4 h (35). Initial and final LDL samples were analyzed at the same time. The production of CD was continuously monitored at 234 nm for 4 h in a DU-7 spectrophotometer (Beckman, Palo Alto, CA), and measurements were recorded every 5 min. CD concentration was calculated using the extinction coefficient 29,500 L mole^{-1} cm^{-1} (7). Lipid peroxides were measured every 30 min by an iodometric method (36). Absorbance was measured at 365 nm using a Beckman DU-40 spectrophotometer and the LP concentration was calculated from the extinction coefficient 24,600 L mole^{-1} cm^{-1}. MDA was determined every 30 min by a modification of the method of Tatum *et al*. (37). Thiobarbituric acid-MDA adduct was measured using a Perkin Elmer 204-A fluorimeter (Norwalk, CT) set at an excitation wavelength of 515 nm and an emission wavelength of 553 nm.

Statistical analysis. Statistical analyses were performed on data from the subgroups (LFMR $n = 5$, LF $n = 6$). Results are expressed as the mean ± standard deviation. The initial and final group mean values were compared by paired *t*-test. Because the LF group was already following a low-fat diet and served the purpose as a cohort for determining potential seasonal lipid variations, comparisons between the two groups were not made. Correlations were performed between variables selected "a priori" to assess the impact of specific variables on LDL fatty acid composition and oxidation. Statistical analyses were performed using the Microsoft Excel™ 4.0 (Microsoft Corporation, Redmond, WA) statistical program.

RESULTS

Diet. The LFMR diet was well-tolerated by the subjects. Table 1 summarizes the nutrient composition of the diets consumed by the subjects. Both LF and LFMR subjects reduced their reported energy intake during the study. The LF group continued to follow the NCEP guidelines for a low fat diet. LFMR subjects successfully modified their eating habits to meet the dietary guidelines by significantly reducing the amount of fat, saturated fat, and polyunsaturated fat consumed, and maintaining dietary cholesterol intake at <300 mg/d.

Overall, both diets provided at least 75% of the RDA for major vitamins and minerals (data not shown). Dietary fiber increased in the LFMR group, and Vitamin A and β-carotene increased in the LF group. The standard deviation was high for vitamin A, vitamin C, and β-carotene in both groups, which probably reflects the varying consumption of foods rich in these nutrients in this free-living population. High-oleic peanuts contain approximately the same amount of vitamin E as regular peanuts (7.8 mg α-tocopherol per 100 g edible portion) (23), and may have contributed to the slight increase in vitamin E in the LFMR diet ($P = 0.07$).

The fatty acid composition of the diet consumed by the LFMR group was significantly altered (Table 2). The ratios of SFA/UFA, PUFA/MUFA, SFA/fat, and PUFA/fat decreased and the ratio of MUFA/fat increased. A significant reduction in PUFA/fat was observed only in the LF group.

LDL fatty acid analysis. The fatty acid composition of LDL was significantly altered in the LFMR group, but did not change in the LF group (Table 3). The %18:0, %18:2n-6, and %total PUFA decreased while %18:1n-9 and %total MUFA increased in the LFMR LDL. The change in the proportion of LDL MUFA was due to an increase in the concentration of

16:1n-7 and 18:1n-9, rather than a decrease in 18:2n-6 or total PUFA (Table 4). As a consequence of the oleic-enrichment of LFMR LDL, the ratio of 18:2n-6/18:1n-9 was significantly lower. A nonsignificant trend toward increased fatty acid content was also observed in the LDL of LFMR subjects.

LDL oxidative profile. After subjects followed the LF and LFMR diets for 6 mon, several significant changes in the oxidative profile of LDL were noted. Lag time before the onset of CD formation increased by approximately 10–16 min for both groups (Table 5). The LFMR group also had a significant increase in LP lag time. Figure 1 illustrates the time course of LDL oxidation and depicts the mean change in absorbance at 234 nm during CD formation. No change in oxidative rate was seen in either group (Table 6). A decrease in LP production occurred after oleic enrichment of the LFMR LDL (Table 7). The LFMR diet was also associated with a trend ($P = 0.12$) toward lower CD production when the amount of oxidative product was expressed per mg LDL fatty acid. No changes in the concentration of oxidation products were seen in the LDL samples from the LF group.

DISCUSSION

The LFMR diet effectively increased the percentage and concentration of 18:1n-9 in LDL and lowered the proportion of 18:2n-6 and the 18:2n-6/18:1n-9 ratio. The change in the 18:2n-6/18:1n-9 ratio was primarily due to the enrichment of LDL with oleic acid. Although the LFMR diet did not result in the high proportions of LDL oleic acid associated with diets containing 30–34% MUFA (9,11,12), the %18:1n-9 was similar to that elicited by diets supplemented with olive oil or low-erucic acid rapeseed oil (13,38). The percentage decrease in the proportion of LDL linoleic acid and the resulting 18:2n-6/18:1n-9 ratio was also in line with that reported for diets high in fat and MUFA. Our study shows that significant modifications in the proportion of oleic and

[a]Concentration expressed as μg fatty acid/mg protein. Values represent the mean ± standard deviation. LF $n = 6$, LFMR $n = 5$. *$P \leq 0.05$, **$P \leq 0.01$; significantly different from the initial group mean. See Tables 1–3 for abbreviations.

linoleic acid in LDL can be elicited by an LFMR diet. Strong correlations were observed between LDL %18:1n-9 and the following: dietary %PUFA ($r = -0.825$, $P \leq 0.01$), dietary PUFA/MUFA ($r = -0.899$, $P \leq 0.001$), and MUFA/fat ($r = 0.943$, $P \leq 0.001$). Similarly, LDL %18:2n-6 was associated with the ratio of dietary PUFA and MUFA. Thus, the proportion of dietary PUFA and MUFA may be important factors influencing the 18:1n-9 and 18:2n-6 content of LDL, independent of the actual quantity of dietary fat.

An unexpected result of the LFMR diet was a trend ($P = 0.09$) toward lipid enrichment of LDL. The LDL particles tended to increase in total fatty acid content despite the fact that LFMR subjects were consuming less dietary fat compared to baseline. Similarly, the LDL-cholesterol/apolipoprotein B ratio increased slightly in the LFMR subgroup (1.63 ± 0.14 vs. 1.75 ± 0.46). Although serum LDL-cholesterol decreased significantly after subjects followed the LFMR diet, apolipoprotein B concentrations also tended to decrease (39). The resulting increase in the ratio of LDL-cholesterol/apolipoprotein B indicates that the diet resulted in slightly fewer circulating LDL particles, but the lipoprotein tended to contain more cholesterol. It is thought that LDL which is more lipid-rich and buoyant is less atherogenic while small dense LDL have been associated with increased oxidative susceptibility (40,41) and atherosclerosis (42,43). Increased oxidative susceptibility of small dense LDL may be due to the greater content of linoleic acid, cholesterol ester, and PUFA/vitamin E in this subfraction (41,44). In other studies, supplementation with dietary MUFA has resulted in LDL with greater 18:1n-9 concentration and a tendency toward increased fatty acid content (13). Oleate-enriched diets have also increased the 18:1n-9 content of small dense LDL, rendering them more resistant to oxidation (45). In contrast, low-fat diets have reduced the lipid content of LDL (46,47) and promoted the conversion of LDL from pattern A to the more dense pattern B phenotype in some individuals (46). Because LDL was not subfractionated in this study and the major lipid classes were not analyzed, it is unclear exactly how the LFMR diet may

TABLE 5
Lag Time Before Formation of Conjugated Diene (CD), Lipid Peroxide (LP), and Malondialdehyde (MDA) in LDL from Postmenopausal Hypercholesterolemic Women Following LF and LFMR Diets[a]

Lag time	LF baseline value	LF 6-mon value	LFMR baseline value	LFMR 6-mon value
CD (min)	39.6 ± 8.3	50.0 ± 10.8*	36.9 ± 8.8	52.7 ± 16.4*
LP (min)	45.9 ± 33.2	62.5 ± 36.7	48.7 ± 26.6	64.3 ± 30.6*
MDA (min)	44.4 ± 39.6	61.1 ± 45.9	63.7 ± 63.7	73.1 ± 60.5

[a]Values represent the mean ± standard deviation, LF $n = 6$, LFMR $n = 5$. LDL samples isolated prior to initiation of the diet phase and after 6 mon of the diet were diluted to a concentration of 50 μg protein/mL and incubated with 5 μM $CuSO_4$ at 37°C. Measurements were taken every 5 min for CD and every 30 min for LP and MDA during the 4-h incubation period. *$P \leq 0.05$, **$P \leq 0.01$; significantly different from the initial group mean. See Tables 1 and 3 for other abbreviations.

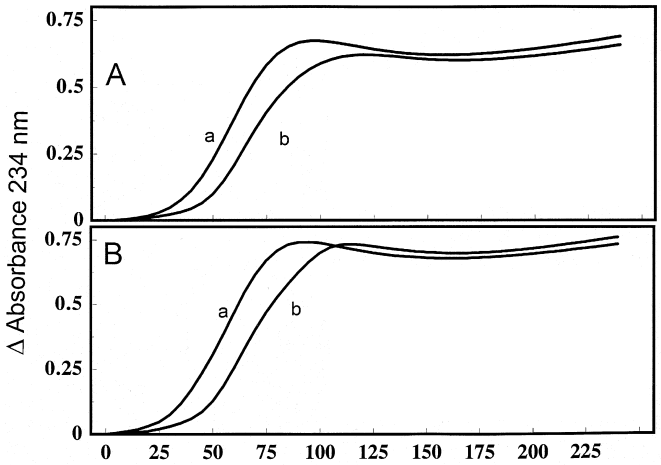

FIG. 1. Formation of conjugated dienes (CD) in LDL from postmenopausal hypercholesterolemic women before and after 6 month diet period. LDL samples were diluted to 50 μg protein/mL and incubated with 5 μM $CuSO_4$ at 37°C. The absorbance at 234 nm was measured every 5 min during a 4 h incubation period, and the results are expressed as the mean change in absorbance relative to baseline. (A) Oxidative profile of LDL from LF subjects (n = 6) before (a) and after (b) the diet period. (B) Oxidative profile of LDL from LFMR subjects (n = 5) before (a) and after (b) the diet period.

have affected the compositional pattern of LDL. However, it is possible that the relatively high MUFA composition and moderate dietary fat restriction of the LFMR diet may have prevented a potentially detrimental shift in LDL lipid composition from pattern A to pattern B. Additionally, already existing small dense LDL may have become enriched with oleic acid, potentially protecting against lipid peroxidation.

Changes in the fatty acid composition of LDL after the LFMR diet were accompanied by improved oxidative resistance as evidenced by increased CD and LP lag time. Two studies have also shown that, compared to baseline, lag time increased after humans (13) or Watanabe heritable hyperlipidemic rabbits (WHHL) (48) consumed high-MUFA diets. It has been proposed that lag time is affected by the ratio of LDL oleic acid and linoleic acid (15). The reduction in LDL 18:2n-6/18:1n-9 and %18:2n-6 may account for the prolonged lag time in the LFMR group, but does not fully explain the increased lag time in the LF group. Even though subjects in the LF group were instructed to maintain a constant diet throughout the study, subjects did reduce dietary PUFA and PUFA/fat, and tended to decrease the ratio of PUFA/MUFA in their diet. As a consequence LDL %18:2n-6, %PUFA, and 18:2n-6/18:1n-9 exhibited a downward trend in the LF group. Pooled data from both groups showed significant correlations between lag time and dietary MUFA/fat (r = 0.489) and PUFA/MUFA (r = –0.454). This correlation may represent the influence of the more oxidatively stable dietary MUFA or the potential impact of phytochemicals and antioxidants associated with sources of dietary MUFA (38,49). Surprisingly, no significant correlations were found between LDL fatty acid composition and lag time, although there was a slight inverse relationship between LDL %PUFA and CD lag time (r = –0.341). No single fatty acid appeared to have a significant relationship with lag time, which may indicate that lag time is a product of the overall LDL fatty acid and lipid composition, and endogenous and dietary antioxidants.

Antioxidant vitamins are known to influence oxidative resistance. The LFMR group had nonsignificant increases in vitamin E intake, both groups tended to consume more vitamin C, and the LF group had significant increases in dietary vitamin A and β-carotene. Vitamin E has been shown to inhibit LDL oxidation when given in relatively high doses (50–53), but most researchers have found little relationship between lag time and the content of endogenous vitamin E (14,15,54–56). Vitamin C is thought to enhance the antioxidant action of α-tocopherol (57), but it is doubtful that the small dietary increase in this study would have afforded protection when similar dietary levels have failed to prolong lag time (58). Abbey *et al.* (58) demonstrated a reduction in oxidative products when subjects were given diets containing approximately 19 mg of β-carotene, but lag time was not changed. Since the dietary antioxidant levels in the LF and LFMR diets were less than in supplementation studies, and no significant correlations were found between dietary antiox-

TABLE 6
Rate of Formation of CD, LP, and MDA in LDL from Postmenopausal Hypercholesterolemic Women on LF and LFMR Diets[a]

Oxidative rate	LF baseline value	LF 6-mon value	LFMR baseline value	LFMR 6-mon value

MDA/fatty acid[b]	45 ± 19	43 ± 17	53 ± 19	46 ± 32

[a]Values represent the mean ± standard deviation, LF $n = 6$, LFMR $n = 5$. LDL samples isolated prior to initiation of the diet phase and after 6 mon of the diet were diluted to a concentration of 50 μg protein/mL and incubated with 5 μM $CuSO_4$ at 37°C. Measurements were taken every 5 min for CD and every 30 min for LP and MDA during the 4-h incubation period. Maximal oxidative product is expressed as: [a]nmol oxidative product/mg LDL protein, [b]nmol oxidative product/mg LDL total fatty acid, [c]nmol oxidative product/mg LDL PUFA. *$P \leq 0.05$; **$P \leq 0.01$; significantly different from the initial group mean. See Tables 1–3 and 5 for abbreviations.

idants and lag time, it is doubtful that vitamins A, C, E, or β-carotene were the primary cause of increased lag time. However, because subjects in both groups consumed more plant-based foods in accordance with the NCEP Step 1 guidelines, it is possible that an increased consumption of various dietary antioxidants in combination with alterations in LDL fatty acid composition may have had a synergistic effect on oxidative resistance. Abbey *et al.* (7) observed a significant variation in lag time after subjects consumed fixed and free diets and hypothesized that this difference may be due to dietary antioxidants. An alternate explanation for the increased lag time in both groups may be that the endogenous content of LDL antioxidants decreased during storage, even though LDL samples were stored under N_2 at –20°C with 0.01% EDTA.

It has been suggested that a change in LDL fatty acid composition may influence oxidative rate, but this was not confirmed by this study. Kleinveld *et al*. (48) reported a significant reduction in the rate of oxidation when lipoprotein fatty acid composition was altered by a high MUFA diet. These investigators dramatically lowered the proportion of LDL 18:2n-6 and increased 18:1n-9 in WHHL rabbits fed high amounts of MUFA. The LFMR diet did not alter LDL fatty acid composition to a similar degree. Even very high MUFA diets have failed to alter the fatty acid composition of human LDL to the same extent as seen in WHHL rabbits (9,12,38), and LDL oxidation rates have not changed (9). Therefore, it is doubtful that changing from a typical American diet to one high in MUFA would have sufficient impact on the lipid composition of LDL to reduce the rate of lipoprotein oxidation.

The LFMR diet did result in LDL particles which produced less LP during *in vitro* oxidation. Significant correlations were found between LP/protein and the following: LDL %18:1n-9 ($r = –0.815$, $P \leq 0.01$), LDL %MUFA ($r = –0.832$, $P \leq 0.01$), and LDL %PUFA ($r = 0.877$, $P \leq 0.001$). These correlations are in line with the results of other studies (7,9,11,12). However, MDA and CD production were not significantly altered by the LFMR diet. CD formation is a good marker for the oxidation of PUFA, and is generally a function of the linoleic and arachidonic acid content of LDL (7,35). The LFMR diet lowered the proportion of LDL fatty acid as 18:2n-6, but the actual concentration of linoleic acid, arachidonic acid, and total PUFA did not change. This may explain the lack of significant reduction in the amount of CD or MDA formed during oxidation.

In conclusion, this study demonstrated that changing from a typical American diet to a low-fat diet rich in MUFA (26% fat, 14% MUFA) led to reductions in the 18:2n-6/18:1n-9 ratio of LDL and improvements in the LDL oxidative potential of hypercholesterolemic postmenopausal women. Alterations in LDL fatty acid composition were correlated with reduced LP production during Cu^{2+}-induced oxidation of LDL, but not to changes in oxidative rate. The LFMR diet was also associated with prolonged CD and LP lag time, but it was unclear if the change in LDL fatty acid composition was solely responsible for increased oxidative resistance. It is important to note that these free-living hypercholesterolemic women did not have to consume excessive amounts of MUFA in order to change LDL fatty acid composition or improve the oxidative profile of LDL. Switching from a typical American diet to the LFMR diet required only a reduction in the intake of SFA and PUFA and a modest increase in MUFA consumption. These dietary changes were easily incorporated into each individual's eating habits, were well tolerated, and provided a degree of protection against oxidative modification of LDL.

ACKNOWLEDGMENTS

We gratefully acknowledge the volunteers who participated in the study. The high-oleic peanuts were generously supplied by the Department of Agronomy, University of Florida (Gainesville, FL). The study was supported in part by a grant from the American Dietetic Association's Sports, Cardiovascular, and Wellness Nutritionists Practice Group and by special funding from the Institute of Food and Agricultural Sciences, University of Florida. A Comparison of Lycopene and Canthaxanthin Absorption: Using the Rat to Study the Absorption of Non-Provitamin A Carotenoids

Richard M. Clark*, Lili Yao, Li She, and Harold C. Furr

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269-4017

ABSTRACT: The purpose of this study was to validate the use of the mesenteric lymph duct cannulated rat to study the absorption of carotenoids which do not have provitamin A activity. The absorption of two carotenoids, a hydrocarbon carotenoid (lycopene) and a xanthophyll carotenoid (canthaxanthin), were investigated. In the first experiment, lipid emulsions containing lycopene (LYC) or canthaxanthin (CTX) were continuously infused into the duodenum, and lymph was collected for analysis at 2-h intervals. The time course for absorption of carotenoids and triacylglycerol (TAG) was similar. Carotenoids and TAG reached steady-state concentrations in the lymph by 6 h. There was no evidence for a delayed release of either carotenoid from the intestine relative to TAG. During a second experiment, emulsions containing increasing concentrations of LYC or CTX (5, 10, 15, 20 μmol/L) were infused. The LYC and CTX in the lymph increased in a dose-dependent manner. The average efficiency of CTX absorption was 16% while the efficiency of LYC absorption averaged only 6%. Efficiency of carotenoid absorption was not related to concentration infused. Finally, to test whether LYC and CTX interact during absorption both were added to a lipid emulsion at equal concentrations (20 μmol/L) and infused. The carotenoids did not significantly affect each other's absorption. These results demonstrate the usefulness of the rat as an animal model to study the absorption of non-provitamin A carotenoids.

Lipids 33, 159–163 (1998).

Recently much attention has been given to the possible role of carotenoids in the prevention and treatment of a wide variety of illnesses such as heart disease, cancer, and those of aging such as macular degeneration and cataract formation (1–3). Because there are differences in the metabolism, transport, and tissue distribution of individual carotenoids, specific carotenoids may be associated with different diseases. For example, lutein and zeaxanthin are found in the macula of the eye and may be important in prevention of age-related macular degeneration, while lycopene accumulates in the prostate and has been associated with reduced risk of prostate cancer (1). Because of the potential health effects of specific carotenoids, many without provitamin A activity, we were interested in the use of the mesenteric lymph duct cannulated rat as an animal model to study the absorption of non-provitamin A carotenoids. The lymph duct cannulated rat has been a useful animal model for studies of lipid absorption and in the past has been used in studies of β-carotene absorption and carotenoid conversion to vitamin A (4,5). Because the rat more efficiently cleaves β-carotene during absorption than does the human, it may not be an appropriate animal model for studies of carotenoids with provitamin A activity; however, it should be a useful model to study carotenoids that are absorbed intact.

The present work contains three experiments utilizing lycopene (LYC) and canthaxanthin (CTX), two carotenoids without provitamin A activity. The objective of the first experiment was to establish the time course for absorption of carotenoids to determine if the release of carotenoid and triacylglycerol (TAG) from the enterocyte is similar. In studies with humans, the time to maximum plasma concentration of carotenoid is slower than for TAG when both are consumed together, suggesting possible discrimination during absorption (6–8).

The objective of the second experiment was to compare the efficiency of absorption of a hydrocarbon carotenoid (LYC) and a xanthophyll (CTX). Chemically, the carotenoids can be classified as carotenes (containing carbon and hydrogen only) or xanthophylls (containing oxygen in addition to carbon and hydrogen). From limited data, it appears that the more polar xanthophylls may be handled differently during absorption than the hydrocarbon carotenoids (9,10).

The objective of the final experiment was to determine if LYC and CTX affect each other's absorption. Because both carotenoids are lipid-soluble, the potential to interact in the lumen of the digestive tract or during absorption is great. There are reports that suggest carotenoids interact during absorption (11–14).

MATERIALS AND METHODS

Animals and surgical procedure. Male Holtzman albino rats obtained from Harlan Sprague Dawley (Indianapolis, IN)

Abbreviations: CTX, canthaxanthin; HPLC, high-pressure liquid chromatography; LYC, lycopene; TAG; triacylglycerol.

were used in this study. At the time of surgery the rats weighed 350–400 g and were consuming a standard laboratory diet: Purina Rodent Chow 5001 (Purina Mills, St. Louis, MO) and water *ad libitum*. The animal protocol was approved by The University of Connecticut Institutional Animal Care and Use Committee.

A feeding tube was placed into the duodenum, and the major mesenteric lymph duct was cannulated as previously described (15). Immediately following surgery, the rats were placed in a warm dark environment and allowed to recover approximately 36 h. The rats had access to water and received a glucose/electrolyte solution (Pedialyte, Ross Laboratories, Columbus, OH) at 2.5 mL/h during the recovery period *via* the duodenal feeding tube.

Preparation of carotenoid stock solutions. LYC was purified from tomato paste on a 5% water-weakened alumina column eluted with hexane/ethyl acetate (95:5, vol/vol). Solvent was removed under reduced pressure and a stock solution prepared in dichloromethane. A CTX stock solution (Sigma Chemical, St. Louis, MO) also was prepared with dichloromethane. The concentration of carotenoid in each stock solution was determined by absorption spectroscopy. CTX concentration was estimated using the extinction coefficient E at 466 nm ($E^{1\%}_{1\ cm}$ = 2200), and LYC concentration was estimated at 472 nm ($E^{1\%}_{1\ cm}$ = 3450) (16). Purity of CTX and LYC was verified by spectral characteristics and high-pressure liquid chromatography (HPLC).

Treatment emulsions. The basic emulsion consisted of a buffer solution (115 mmol/L NaCl, 5.0 mmol/L KCl, 6.8 mmol/L Na_2HPO_4, and 16.5 mmol/L NaH_2PO_4), 10 mmol/L sodium taurocholate (Sigma Chemical), and 1.5% (wt/vol) olive oil with different concentrations of CTX or LYC.

To prepare treatment emulsions, olive oil was placed in a round-bottomed flask, and an appropriate amount of carotenoid stock solution was added to the oil. The carotenoid, either CTX or LYC, and olive oil were mixed and the solvent removed with a stream of nitrogen. Sodium taurocholate and buffer were added to the lipid–carotenoid mixture. The contents of the flask then were emulsified using a probe sonicator producing approximately 40 watts output for 15 s, repeated four or five times until no lipid droplets were observed (Branson Sonifier, Model 185; Branson Sonic Power, Danbury, CT). An aliquot of the emulsion was extracted three times with hexane and the final concentration of carotenoid in the emulsion determined by HPLC as described below for lymph analysis.

Experiment 1. The time course for absorption of each carotenoid was determined using three rats per carotenoid. After a recovery period of 36 h, rats were infused through the feeding tube (2.5 mL/h) with an emulsion containing 20 μmol/L of either CTX or LYC. Lymph samples were collected at 2, 4, 6, 8, 10, and 12 h after the start of the infusion.

Experiment 2. To compare the absorption of a hydrocarbon carotenoid and a xanthophyll, emulsions with four differing concentrations of LYC or CTX (5, 10, 15, 20 μmol/L) were prepared. A total of 24 animals, three rats per treatment, were intraduodenally infused at 2.5 mL/h for 12 h. Based on the results of Experiment 1, a sample of lymph collected from 6 to 12 h of infusion was used for analysis. The carotenoid in these samples therefore represents absorption under steady-state conditions.

The results of Experiment 2 were statistically analyzed as a 2×4 factorial experiment, the first factor being carotenoid type and the second factor being carotenoid concentration. Because the four concentrations of carotenoid infused were equally spaced, the linear, quadratic, and cubic relationships between amount of carotenoid infused and absorption into the lymph were statistically tested (see Reference 17 for description).

The efficiency of absorption for each carotenoid was calculated by dividing the concentration of carotenoid recovered in the lymph per hour by the concentration of carotenoid infused into the duodenum per hour.

Experiment 3. To investigate the possible interaction of LYC and CTX during absorption, the recovery of carotenoid in the lymph from three treatment emulsions was compared. Data from LYC (20 μmol/L) and CTX (20 μmol/L) treatments collected in Experiment 2 plus one additional animal per treatment were used as a measure of absorption of each carotenoid by itself. Four additional animals were infused with an emulsion containing both LYC (20 μmol/L) and CTX (20 μmol/L). The infusion of treatment emulsions and collection of lymph were the same as described for Experiment 2. The results for each carotenoid when infused alone were compared to those when they were infused together. Differences were tested for significance using the Student's *t*-test.

Carotenoid and TAG analysis of lymph. After collection, lymph was stored at −70°C until analyzed. On the day of analysis, lymph samples were thawed to room temperature and total lipid was extracted from the lymph by the method of Folch *et al.* (18). To correct for recoveries of carotenoids during extraction, ethyl β-apo-8′-carotenoate (Fluka, Ronkonkoma, NY) was added to the lymph as an internal standard. Carotenoids were analyzed by HPLC using a Waters C18 Resolve column (15 cm × 3.9 mm; Millipore, Milford, MA) protected with an Upchurch C18 guard column (Upchurch Scientific, Oak Harbor, WA) and an isocratic mobile phase consisting of acetonitrile/dichloromethane/methanol/*n*-butanol/ammonium acetate (90:15:10:0.1:0.1, by vol) (19). Carotenoids and ethyl β-apo-8′-carotenate were identified and quantified at a wavelength of 450 nm.

Lymph samples were diluted 1:10 with deionized water and TAG determined by an enzymatic assay (Sigma Chemical Co.).

RESULTS AND DISCUSSION

Carotenoid absorption involves a series of interdependent steps that include release of carotenoid from the food matrix, solubilization into mixed bile salt micelles, transfer into the intestinal mucosal cell, and incorporation into lymphatic lipoproteins (20–23). While *in vitro* methods may be used to

study individual steps in this process, investigation of the overall process of carotenoid absorption requires the use of a whole animal system. Unfortunately, animal models that perfectly mimic human carotenoid metabolism are not available. Nevertheless, animal models must be used because only a few carotenoids have been approved for formulation into products for ingestion by humans, and methods for direct measurement of carotenoid absorption in humans are not available. Data presented here utilize the mesenteric lymph duct cannulated rat, an animal model used extensively to study the digestion and absorption of lipids and a potential animal model for investigation of factors that influence carotenoid absorption.

In the current study, we chose to investigate LYC and CTX absorption because previous work has shown these carotenoids to be absorbed intact and stored in various tissues by the rat (24). The dose of carotenoid provided to the rats in the present study was approximately 0.2–1 mg/kg body weight. This is in the same range as human intervention studies with β-carotene which provided doses of 0.2–4.3 mg/kg body weight (25).

The results of Experiment 1 are shown in Figure 1. The appearance of LYC and CTX in the lymph coincided with that of TAG. The concentrations of carotenoids and TAG reached a plateau or steady-state transport in the lymph by 6 h of continuous intraduodenal infusion of the carotenoid emulsions.

The time course for appearance of carotenoids in the lymph does not support the notion that there is a delayed release of carotenoids from the intestine relative to other dietary lipids. In human studies a delayed release of carotenoid by the enterocyte has been suggested because the time to maximum plasma concentration after an oral dose of a carotenoid is slower than the time needed to reach maximum plasma concentration of TAG or retinyl esters (6,7). This effect in humans can be explained by clearance of chylomicra by the liver and reintroduction of carotenoids into very low density lipoproteins during normal lipoprotein metabolism and is not the result of discrimination between carotenoids and other dietary lipids during absorption. This conclusion is supported by time-course studies in which individual lipoprotein classes have been separated. In these studies, carotenoid in the chylomicron fraction was reported to reach a maximum concentration about the same time, by 6 h, as maximum concentration of chylomicron TAG, while carotenoids associated with low density lipoproteins and high density lipoproteins reach a maximum later at 16 to 24 h (8,26).

In the second experiment, the recoveries of CTX and LYC in the lymph were compared (Fig. 2). CTX was significantly ($P < 0.01$) better absorbed than LYC. Both carotenoids were absorbed in a concentration-dependent manner. There was a significant ($P < 0.05$) linear relationship, for both carotenoids, between the amount of carotenoid infused and the amount recovered in the lymph. The LYC response, as seen in Figure 2, appears to have some curvature, but this was not statistically significant and was probably due to normal variation.

The average efficiency of absorption for CTX was approximately 16% with a range from individual samples of 10 to 20%. The recovery of CTX in the lymph for the lower concentration intraduodenally infused averaged 18.5% and for the highest concentration was 14.4%; however, these values were not statistically different.

The efficiency of CTX absorption in the current study is approximately the same as reported for β-carotene absorption

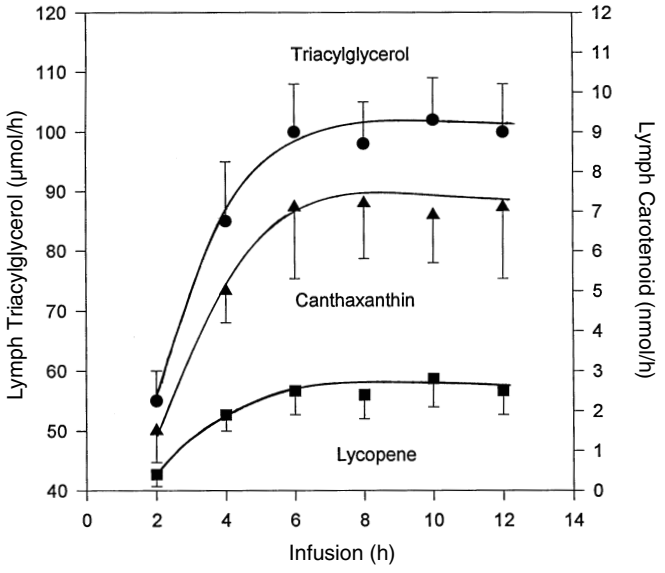

FIG. 1. Time course for absorption of canthaxanthin, lycopene, and triacylglycerol in the mesenteric lymph. Lipid emulsions containing 20 μmol/L of carotenoid were continuously infused (2.5 mL/h) into the duodenum. Shown are the mean ± SD of data collected from three rats per carotenoid.

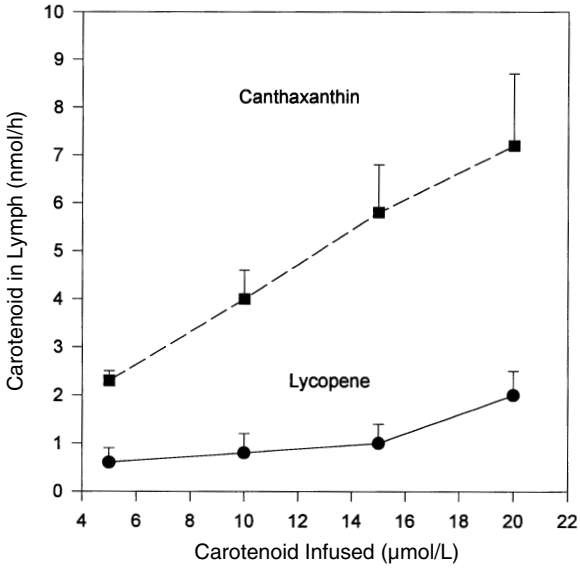

FIG. 2. Relationship between concentration of carotenoid continuously intraduodenally infused at the rate of 2.5 mL/h and concentration of carotenoid recovered per hour in the mesenteric lymph. The lymph samples were collected from 6 to 12 h after the initiation of infusion. These samples represent absorption under steady-state conditions. Each point is the mean ± SD from three individual rats. For both carotenoids, there was a significant ($P < 0.05$) linear relationship between the amount of carotenoid infused and the amount absorbed.

in the human. Using hospitalized patients with cannulated thoracic ducts, Goodman *et al.* (27) presented data suggesting that 10% of an oral dose of radioactive β-carotene was absorbed into lymph, while Blomstrand and Werner (28) presented data from a similar study suggesting that 23% of a similar dose was absorbed into lymph. Recently using stable isotope β-carotene-d_8, Novotny *et al.* (29) suggest that 22% of an oral dose of β-carotene in olive oil was absorbed in humans.

Under the conditions of the current study, LYC was absorbed poorly compared to CTX. The efficiency of LYC absorption ranged from 2 to 8% with an average recovery of LYC in the lymph of only 6%. The efficiency of absorption was not significantly affected by concentrations of LYC infused. A study comparing absorption of five carotenoids in preruminant calves noted poor LYC absorption compared to other carotenoids (30). Supplementation studies with humans would also suggest LYC is not efficiently absorbed (31,32).

In the final study, equal amounts of CTX and LYC were infused into the duodenum to determine if LYC and CTX affect each other's absorption. Based on indirect measures of absorption, there are several studies that suggest carotenoids interact during absorption. Almost 50 yr ago, by using liver vitamin A stores as a measure of β-carotene absorption, a xanthophyll (lutein) was reported to interfere with the absorption of β-carotene (33). In a more recent study with domestic ferrets, a negative interactive effect of β-carotene and either CTX or LYC on serum and tissue accumulation of β-carotene was observed (11). On the basis of kinetic analysis of serum carotenoids, two human studies also provide data that suggest carotenoids interact during absorption (12,13). White *et al.* (12) report that β-carotene appeared to inhibit intestinal absorption of CTX. In a similar human study, when a combined oral dose of β-carotene and lutein was administered, β-carotene reduced plasma lutein response by 40% (13).

As seen in Figure 3, LYC and CTX did not significantly affect each other's absorption. Lycopene in the lymph when infused alone was 2.0 ± 0.5 nmol/h compared to 1.6 ± 0.6 nmol/h when infused in equal molar amounts with CTX. When CTX was provided by itself, lymphatic CTX was 7.4 ± 1.6 nmol/h compared to 8.8 ± 1.9 nmol/h when infused simultaneously with LYC. The lack of significant interaction during absorption between these carotenoids may be a result of our choice of carotenoids. Because LYC was so poorly absorbed, its potential interaction with CTX may be limited. Also the relative concentrations of CTX and LYC used in the current study may not have been optimal for interactions. Using liver vitamin A stores as an index of β-carotene absorption, High and Day (34) reported that large amounts of lutein decrease β-carotene absorption, but small amounts had the opposite effect. Further studies are needed to investigate potential interactions during absorption using a wider range of concentrations and variety of carotenoids.

In conclusion, LYC and CTX were absorbed intact by the rat and appear in the lymph following a similar time course as other dietary lipids. Both carotenoids were absorbed in a dose-dependent manner with the xanthophyll (CTX) more efficiently absorbed than the nonpolar hydrocarbon carotenoid (LYC). When both carotenoids were infused together, LYC and CTX did not significantly affect each other's absorption. The results of this study demonstrate the usefulness of the rat as an animal model to study the absorption of non-provitamin A carotenoids. To our knowledge this is the first report using the mesenteric lymph duct cannulated rat to study the absorption of carotenoids other than β-carotene.

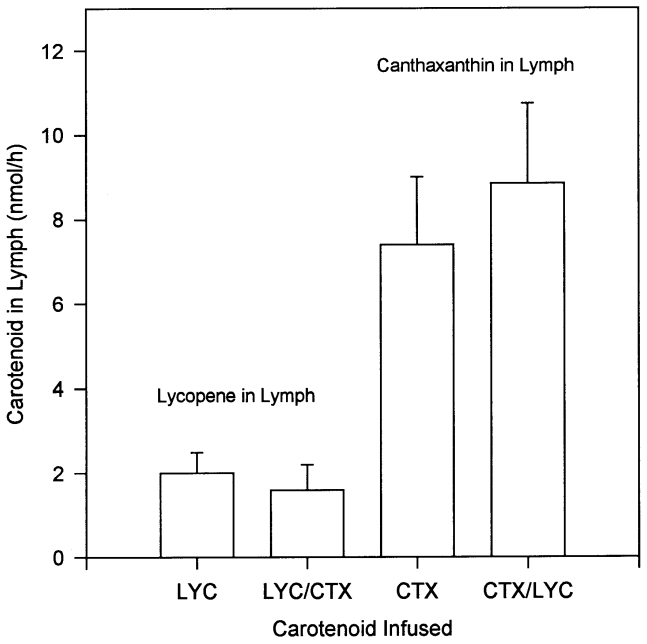

FIG. 3. A comparison of lymphatic lycopene (LYC) and canthaxanthin (CTX) when intraduodenally infused (2.5 mL/h) individually or together. LYC treatment contained 20 μmol/L lycopene; CTX treatment contained 20 μmol/L canthaxanthin; LYC/CTX and CTC/LYC treatments contained 20 μmol/L lycopene plus 20 μmol/L canthaxanthin. Shown are the mean ± SD (n = 4). CTX and LYC did not significantly affect each other's absorption.

ABSTRACT: Hypercholesterolemia is a consistent feature of the nephrotic syndrome. However, the mechanisms underlying this perturbation are unclear. In the present work, we have investigated different factors that influence hepatic cholesterol metabolism using the nephrotic rat as a model. The induction of nephrosis resulted in a severe and sustained hypercholesterolemia. However, no effect on the rate-limiting enzyme in cholesterol synthesis, 3-hydroxy-3-methylglutaryl CoA reductase, could be detected. Further, plasma lathosterol/cholesterol ratio, a measure of cholesterol synthesis, was not altered. Also, plasma levels of mevalonate, both a substrate for cholesterogenesis beyond the rate-limiting step and a marker for cholesterol synthesis, did not differ between control rats and those with established hypercholesterolemia. There was no detectable change in the expression of low density lipoprotein (LDL) receptor between the two experimental groups. We conclude that the early increase in cholesterol synthesis reported after the induction of nephrosis is not necessary for the maintenance of hypercholesterolemia. Established hypercholesterolemia of the nephrotic syndrome seems to represent a steady state in which neither enhanced hepatic cholesterol synthesis nor retarded LDL cholesterol clearance is of major importance.
Lipids 33, 165–169 (1998).

Hypercholesterolemia with increased plasma and LDL cholesterol levels is a major lipid abnormality in the nephrotic syndrome (1–3). As a consequence, this condition carries a risk for accelerated atherosclerosis and thereby coronary heart disease and progressive renal damage (4–7). The mechanisms underlying hypercholesterolemia of the nephrotic syndrome are complex, which explains the large and partially conflicting body of data reported. While early studies demonstrated a decrease in the incorporation of ^{14}C-labeled acetate into hepatic cholesterol in nephrotic rats suggesting a curtailment of cholesterogenesis (8), cholesterol synthesis as determined by the incorporation of ^3H_2O into cholesterol was later found to be increased in liver slices from nephrotic rats compared to controls (9). Also, *in vivo* studies in nephrotic rats have shown an increased incorporation of ^3H_2O into hepatic lipids (10). The increase in cholesterol biosynthesis in the nephrotic state has been ascribed to an increase in the activity of the rate-limiting enzyme in this pathway, namely 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase, and also to a disturbed mevalonate metabolism leading to increased substrate availability for cholesterol synthesis (11,12). However, in a study by Thabet and co-workers (13), neither HMG-CoA reductase activity nor the activity of the rate-limiting enzyme in cholesterol degradation, cholesterol 7α-hydroxylase, was altered in nephrotic rats. These findings argued against a marked alteration of hepatic cholesterol synthesis or degradation as a cause of hypercholesterolemia of the nephrotic syndrome. Alternatively, decreased removal of plasma cholesterol was suggested (13). However, apo-B kinetic measurements in puromycin aminonucleoside (PAN)-treated rats demonstrated a higher low density lipoprotein (LDL) synthetic rate in nephrotic rats relative to controls, while the fractional catabolic rate was only marginally affected (14).

In view of these conflicting data, we have in the present study examined different markers of cholesterol synthesis and catabolism in PAN-induced nephrotic syndrome, including the activity of HMG-CoA reductase; plasma levels of lathosterol, an indicator of cholesterol synthesis (15); plasma levels of mevalonate, which is both an indicator of (16) and a substrate for cholesterogenesis; and the expression of hepatic LDL receptor, which is responsible for the catabolism of cholesterol-rich plasma lipoproteins (17).

EXPERIMENTAL PROCEDURES

Animals. Male Sprague-Dawley rats weighing 200–250 g were housed in metal cages and maintained on a 12-h light–dark cycle. The animals were allowed to move freely in the cages and had free access to standard chow and water throughout the study.

Nephrosis was induced by a single intraperitoneal injection of PAN (Sigma Chemical Co., St. Louis, MO) in a dose of 100 mg/kg body weight. One week after the injection, rats

Abbreviations: GFR, glomerular filtration rate; HMG-CoA, 3-hydroxy-3-methylglutaryl CoA; LDL, low density lipoprotein; PAN, puromycin aminonucleoside.

were transferred to individual metabolic cages, and urine was collected for 24 h. Plasma and urine albumin concentrations were measured by an immunonephelometric method using rat albumin antibodies (Nordic Immunology, Tilburg, The Netherlands). Nephrosis was confirmed by the presence of hyperlipidemia, low plasma albumin, and urine albumin loss exceeding 250 mg albumin/24 h. The rats were killed 11–12 d after PAN injection. On the day of sacrifice, blood sampling was performed by open heart puncture under neuroleptic anesthesia (Hypnorm®; Janssen Pharmaceutica, Beerse, Belgium) aided by a muscle relaxant (Stesolid®; Dumex Ltd., Copenhagen, Denmark).

Analytical procedures. Cholesterol levels were determined in plasma and liver using a commercially available enzymatic kit (Boehringer Mannheim, Mannheim, Germany). Liver samples were homogenized with 4 vol of 10 mmol/L Tris/HCl, pH 7.4 containing 0.25 mol/L sucrose, 1 mmol/L EDTA and 0.2 mmol/L dithiothreitol (Buffer A). The homogenate was then treated with 20 vol of chloroform/methanol (2:1, vol/vol) and cholesterol measured in the resulting lipid extract.

Lathosterol was measured by isotope dilution–mass spectrometry. Plasma samples were treated with chloroform/methanol (2:1) and the extract was subjected to C_{18} column chromatography (Isolute MF C_{18}; International Sorbent Technology, United Kingdom). Unesterified lathosterol was eluted with methanol, derivatized into trimethylsilyl ether and analyzed by gas chromatography/mass spectrometry using $^2H_3$ lathosterol as internal standard (18).

Mevalonate levels were determined in plasma and urine by isotope dilution–mass spectrometry, essentially as described (19). In brief, samples were acidified to pH 3.5 using phosphoric acid, proteins were precipitated with acetone, and lipids removed by an extraction with cyclohexane. Mevalonolactone was extracted into ethylacetate/acetone (2:1, vol/vol) using a salt-out effect by saturing the aqueous phase with NaCl. Mevalonolactone was converted to mevalonic acid by adding 0.5 mol/L NaOH. After derivatization with methyl-tertiary-butyl-dimethylsilyl-trifluoracetamide, the derivative was extracted into *n*-decane and measured by gas–liquid chromatography/mass spectrometry using $^2H_3$-MVA as internal standard.

For the assay of the HMG-CoA reductase activity, liver homogenates were centrifuged at 20,000 × *g* for 15 min and supernatants recentrifuged at 100,000 × *g* for 60 min. Prior to use, the microsomal pellets obtained were suspended in Buffer A to a protein concentration of about 40 mg/mL and stored at −70°C. Microsomal fractions were thawed and diluted in 20 mmol/L imidazol/HCl (pH 7.4) containing 10 mmol/L DTT, and HMG-CoA reductase activity was measured as the conversion of [3-^{14}C] labeled HMG-CoA (NEN DuPont, Boston, MA) to mevalonate, essentially as described by Brown *et al.* (20). Tritium-labeled mevalonate was used as internal standard. The reaction product was purified by thin-layer chromatography and analyzed for radioactivity.

LDL receptor expression was measured by a ligand blot assay. Hepatic membranes were prepared as described in detail elsewhere (21). In brief, frozen liver samples were homogenized with a polytron in a buffer (50 mmol/L Tris-HCl, pH 7.5, 2 mmol/L $CaCl_2$, 0.5% Triton x-100 supplemented with 1 mmol/L leupeptin, 1 mmol/L phenanthroline, and 1 mmol/L phenylmethyl sulfonyl fluoride). After quick sonication, the homogenates were ultracentrifuged for 10 min and the supernatants collected and frozen in multiple aliquots at −70°C. Membrane proteins and molecular weight standards were separated by SDS polyacrylamide gels (6%) and electrotransferred to nitrocellulose filters. Filters were incubated with ^{125}I-labeled rabbit β-very low density lipoprotein (VLDL) and subjected to autoradiography on x-ray film for 3 h at −70°C after aligning molecular weight standard lanes which had been cut out and visualized by protein staining. The 120 kD bands corresponding to the receptor protein were quantified in arbitrary units after background subtraction using a Bio-imaging analyzer (Fujix BAS 2000; Fuji Photo Film Co., Tokyo, Japan).

Glomerular filtration rate (GFR) was determined as the endogenous creatinine clearance (mL/min) using the formula: $GFR = C_u \times V_u/C_p$ where C_u is urine creatinine concentration, C_p is plasma creatinine concentration, and V_u is urine flow (mL/min) (22).

Statistical analysis. Data were evaluated by Student's *t*-test with the level of statistical significance set at $P < 0.05$.

RESULTS

Treatment of rats with PAN resulted in albuminuria (>250 mg/24 h), hypoalbuminemia, and a mixed hyperlipidemia with elevations of plasma levels of cholesterol (6-fold) and triglycerides (20-fold) (Table 1).

Nephrotic rats displayed a 5-fold increase in plasma levels of lathosterol, a steroid precursor to cholesterol that has been suggested to reflect the rate of hepatic cholesterol synthesis (15,23,24). However, when expressed relative to plasma cholesterol levels, no difference between normal and nephrotic rats could be disclosed (Table 2). Further, no difference in the activity of the rate-limiting enzyme in cholesterol biosynthesis (HMG-CoA reductase) could be detected between nephrotic animals and normal controls (Table 2).

As shown in Table 3, neither plasma nor urine levels of mevalonate were altered in nephrotic rats. Also, the induction

TABLE 1
The Effect of Nephrosis on Plasma Levels of Albumin, Cholesterol and Triglycerides as Well as on Urinary Albumin Excretion[a]

	Control rats	Nephrotic rats	*P*-value
Plasma albumin (g/L)	21.3 ± 0.3[a]	4.7 ± 0.5[b]	<0.001

TABLE 2
The Effect of Nephrosis on Metabolic Markers of Cholesterol Metabolism[a]

	Control rats	Nephrotic rats	*P*-value
HMG-CoA reductase activity (pmol/min·mg protein)	414 ± 49[a]	329 ± 45[b]	N.S
Plasma lathosterol (μmol/L)	1.93 ± 0.33[c]	10.18 ± 0.95[d]	<0.0001
Plasma lathosterol: cholesterol ratio (μmol/mmol)	0.81 ± 0.11[c]	0.84 ± 0.23[d]	N.S
Liver cholesterol (μmol/g liver)	7.9 ± 0.3[e]	8.6 ± 0.3[f]	N.S

[a]Values are means ± SEM . N.S, not significant, $P > 0.05$. [a]($n = 12$), [b]($n = 14$), [c]($n = 11$), [d]($n = 13$), [e]($n = 16$), [f]($n = 20$). Samples were collected on day 11–12 after puromycin aminonucleoside injection.

of nephrosis did not affect the GFR, as reflected by essentially unchanged plasma creatinine levels (Table 3).

In order to examine whether retarded plasma cholesterol clearance might contribute to the hypercholesterolemia of nephrotic syndrome, a major determinant of plasma cholesterol clearance, namely the LDL receptor expression, was measured. As shown in Figure 1, no significant difference between nephrotics and normals was observed. This is in accordance with the finding that hepatic cholesterol levels were similar in the two experimental groups (Table 2).

DISCUSSION

In the present study, a number of key metabolic markers for hepatic cholesterol metabolism were examined and found to be unaltered in rats with PAN-induced nephrotic syndrome, despite a pronounced hypercholesterolemia. Hypercholesterolemia can arise from increased hepatic production and secretion of cholesterol-rich lipoproteins, decreased removal of cholesterol from the circulation, or a combination of both factors. An overproduction of lipoproteins has been demonstrated in perfused livers from nephrotic rats (25). Furthermore, these lipoproteins had a higher content of cholesterol (26), implying enhanced cholesterol synthesis. These findings are in accord with earlier *in vivo* and *in vitro* studies that showed an increased incorporation of ^3H_2O into hepatic cholesterol (9,10). However, the mechanisms underlying this effect have been a matter of debate.

It is well-established that the HMG-CoA reductase is rate-limiting in cholesterol biosynthesis under most experimental conditions (20). The activity of this enzyme has therefore been considered a good index of the absolute rate of hepatic cholesterol synthesis (27). As shown in Table 2, HMG-CoA reductase activity was not significantly different between nephrotic rats and normal controls, well in line with the results of Thabet *et al*. (13). The plasma concentration of the steroid cholesterol precursor lathosterol has been reported to be a good indicator of cholesterol synthesis (15,23,24). As shown in Table 2, plasma lathosterol levels were 5-fold higher in nephrotic rats compared to controls. However, since lathosterol is carried with plasma lipoproteins, changes in the absolute concentrations of lathosterol might merely reflect changes in the number of lipoprotein particles. In order to cor-

The 120 kD bands corresponding to the receptor protein were quantified in arbitrary units after background subtraction using a bio-imaging analyzer.

TABLE 3
The Effect of Nephrosis on Plasma Mevalonate Levels, Urinary Mevalonate Excretion and Glomerular Filtration[a]

	Control rats $n = 6$	Nephrotic rats $n = 6$
Plasma mevalonate levels (ng/mL)	11.9 ± 1.7	12.2 ± 1.1
Urinary mevalonate excretion (μg/24 h)	16.5 ± 3.0	16.8 ± 3.4
Glomerular filtration rate (mL/min)	1.1 ± 0.1	0.9 ± 0.1
Plasma creatinine (μmol/L)	48 ± 1	55 ± 2

[a]Values are means ± SEM. None of the parameters given was significantly different between the two experimental groups, $P > 0.05$.

rect for this, plasma lathosterol levels were expressed relative to cholesterol. Indeed, the lathosterol/cholesterol ratio has been shown to correlate better with the overall rate of cholesterol biosynthesis than the absolute levels of lathosterol in plasma (15,24). This ratio was not significantly different between normal and nephrotic rats (Table 2). Interestingly, similar results were obtained in patients with glomerular proteinuria (28).

Of interest is the report that hepatic HMG-CoA reductase mRNA and HMG-CoA reductase activity showed a transient increase after the induction of nephrosis in rats by PAN (29). However, both subsequently reverted to normal despite a persistent hypercholesterolemia. These data suggest that an effect on the reductase might play a role in initiating, though not in maintaining, a hypercholesterolemic state.

It has been demonstrated that oxidation, excretion, and removal of mevalonate are decreased in isolated perfused kidneys from nephrotic rats compared to controls (12). Also, livers from nephrotic rats have been shown to synthesize increased amounts of cholesterol from exogenous ^{14}C-labeled mevalonate (11). These data suggested that an impaired mevalonate metabolism in nephrosis would increase the delivery of this substrate to the liver and thereby stimulate cholesterogenesis (11). However, as shown in Table 3, plasma mevalonate levels were unaltered in nephrotic rats. Further, the renal excretion of mevalonate was not different between the two experimental groups. These data do not support the hypothesis that the availability of mevalonate for cholesterol synthesis in the liver is increased in the nephrotic state. The increase of cholesterol synthesis from exogenous mevalonate (11) might reflect a general increase in the liver capacity for lipid synthesis (30). Our findings on mevalonate in nephrotic rats are in contrast with those in mice with chronic renal failure where hypercholesterolemia was associated with reduced urinary excretion of mevalonate and elevated plasma levels of this precursor (31). It is noteworthy that in our study the nephrotic rats had normal GFR measured as creatinine clearance (Table 3). The absence of renal failure in these animals may explain why mevalonate retention did not occur. Altogether, our findings on plasma lathosterol/cholesterol ratio along with those on mevalonate do not indicate enhanced cholesterol biosynthesis in established nephrotic hypercholesterolemia.

As shown in Figure 1, the expression of LDL receptor binding activity was largely unaffected in nephrotic rats compared to controls. Further, the activity of HMG-CoA reductase was not affected by the nephrotic state (Table 2). It has been shown that hepatic mRNA levels for LDL receptor and HMG-CoA reductase seem to be coordinately regulated (32). Thus, the findings on HMG-CoA reductase activity and LDL receptor expression were in accord. Further, the lack of effect of nephrosis on the LDL receptor binding activity is well in line with the observations of Joven *et al*. (14), who found no significant effect of nephrosis on the fractional catabolic rate of LDL in PAN-treated rats. In a recent study, LDL receptor expression was found to be decreased in nephrotic rats 30 d after the induction of nephrosis (33). However, no significant changes in the receptor expression were seen at earlier time points despite a pronounced hypercholesterolemia. These findings, together with our results, suggest that down-regulation of the LDL receptor does not occur early after the induction of nephrosis but may be a secondary phenomenon in the course of PAN-induced nephrotic syndrome.

The data obtained in our study, together with those reported earlier, suggest that the mechanisms that mediate the initiation of hyperlipidemia of the nephrotic syndrome are different from those operative when the hyperlipidemia becomes established and reaches a steady state. It is plausible that the hypoalbuminemia characteristic of the nephrotic syndrome or some other related factor initially increases the availability of apolipoproteins with concomitant increases in hepatic synthesis of cholesterol and triglycerides leading to hyperlipoproteinemia (25,26,34,35). When a new steady state is reached, there will be an increased influx of cholesterol into the liver, largely determined by a concentration-dependent uptake that does not necessarily involve the LDL receptor. An increased uptake would down-regulate hepatic cholesterol synthesis (17) whereby the synthetic rate would revert to normal. However, since the lipoprotein output is increased (25,26), the flux of cholesterol from the liver is maintained at a high level. This would explain the findings on hepatic cholesterol levels, and hepatic cholesterol synthesis, as well as hepatic LDL receptor expression (Table 2, Fig. 1).

To summarize, using several independent metabolic parameters, we found no evidence for increased hepatic cholesterol synthesis in established nephrotic hypercholesterolemia. Further, a major determinant of LDL cholesterol clearance, namely the LDL receptor expression, did not appear to be altered in this condition. Taking into account previously published data that support enhanced cholesterol synthesis early in the course of the disease, our results suggest that a sustained increase in cholesterogenesis is not a prerequisite for hypercholesterolemia which is maintained by other mechanisms. Rather, it appears that the mechanisms that mediate the initiation of hypercholesterolemia are not necessary for the maintenance of this condition. Altogether, the results obtained suggest that established hyperlipidemia of the nephrotic syndrome constitutes a steady state in which neither enhanced hepatic cholesterol synthesis nor retarded LDL cholesterol clearance is of major importance.

ABSTRACT: Weanling rats were fed on high-fat (178 g/kg) diets which contained 4.4 g α-linolenic (ALA), γ-linolenic, arachidonic (ARA), eicosapentaenoic (EPA), or docosahexaenoic acid (DHA)/100 g total fatty acids. The proportions of all other fatty acids, apart from linoleic acid, and the proportion of total polyunsaturated fatty acids (PUFA) (approximately 35 g/100 g total fatty acids) were constant, and the n-6 to n-3 PUFA ratio was maintained as close to 7 as possible. The fatty acid compositions of the serum and of spleen leukocytes were markedly influenced by that of the diet. Prostaglandin E_2 production was enhanced from leukocytes from rats fed the ARA-rich diet and was decreased from leukocytes from the EPA- or DHA-fed rats. Replacing dietary ALA with EPA resulted in diminished *ex vivo* lymphocyte proliferation and natural killer (NK) cell activity and a reduced cell-mediated immune response *in vivo*. In contrast, replacing ALA with DHA reduced *ex vivo* lymphocyte proliferation but did not affect *ex vivo* NK cell activity or the cell-mediated immune response *in vivo*. Replacement of a proportion of linoleic acid with either γ-linolenic acid or ARA did not affect lymphocyte proliferation, NK cell activity, or the cell-mediated immune response. Thus, this study shows that different n-3 PUFA exert different immunomodulatory actions, that EPA exerts more widespread and/or stronger immunomodulatory effects than DHA, that a low level of EPA is sufficient to influence the immune response, and that the immunomodulatory effects of fish oil may be mainly due to EPA.

Lipids 33, 171–180 (1998).

In recent years there has been great interest in the effects of different types of dietary fatty acids upon the immune system. Much of this interest has focused on polyunsaturated fatty acids (PUFA), partly because the n-6 PUFA arachidonic acid (ARA; 20:4n-6) is the precursor of prostaglandins and leukotrienes which have potent pro-inflammatory and immunoregulatory properties (see Refs. 1–3 for reviews). ARA is formed from linoleic acid (18:2n-6), a major component of vegetable oils such as corn, sunflower, soybean, and safflower oils; an intermediate in the synthesis of ARA is γ-linolenic acid (GLA; 18:3n-6). The second reason for the interest in the immunomodulatory effects of fatty acids is that epidemiological studies have found that populations such as Greenland Eskimos, who consume large quantities of fish oil, which is rich in the n-3 PUFA eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), have a very low incidence of inflammatory and autoimmune disorders (4). Furthermore, a number of clinical studies have reported that fish oil supplementation of the human diet has some beneficial effects in acute and chronic inflammatory conditions (e.g., 5–11) and prolongs the survival of grafts (12). The precursor of EPA and DHA is α-linolenic acid (ALA; 18:3n-3), a major component of green plant tissues and of linseed oil. Interest in the potential clinical effects of oils rich in n-6 or n-3 PUFA has given rise to a number of investigations of the effects of fatty acids and dietary oils upon immune cell functions (see 13–19 for reviews).

Feeding laboratory animals (rats, mice, rabbits, chickens) diets rich in n-3 PUFA (canola, linseed, fish oils) results in suppressed *ex vivo* lymphocyte proliferation (20–27), cytotoxic T lymphocyte activity (28–32), and natural killer (NK) cell activity (26,27,30,33–35). Investigations which have directly compared the effects of these oils indicate that fish oil is more suppressive than linseed oil which is, in turn, more suppressive than canola oil (see 14–18 for references). Diets rich in n-6 PUFA appear to be either less suppressive than those containing n-3 PUFA or without effect (see 14–18 for references). Taken together, these *ex vivo* observations indicate that consumption of diets containing n-3 PUFA, particularly diets rich in fish oil, may result in immunosuppression *in vivo*. Indeed, three studies have reported that feeding laboratory rodents fish oil results in diminished *in vivo* graft vs. host and/or host vs. graft responses (36–38); feeding diets rich in n-6 PUFA [safflower oil (SO) or evening primrose oil] did

Abbreviations: ALA, α-linolenic acid; ARA, arachidonic acid; Con A, concanavalin A; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; NK, natural killer; PBS, phosphate-buffered saline; PG, prostaglandin; PLN, popliteal lymph node; PUFA, polyunsaturated fatty acid; SO, safflower oil.

not suppress these responses (38). In addition, one study has reported that, compared with sunflower oil feeding, linseed oil reduces the graft vs. host response (27).

Thus, the consumption of diets which contain large amounts of n-3 PUFA clearly causes immunosuppression whereas those rich in n-6 PUFA are less suppressive. However, the oils used in such experiments (e.g., sunflower, safflower, linseed, and fish oils) differ greatly in background fatty acid composition, in total PUFA content, and in n-6/n-3 PUFA ratio. Because both the level of PUFA and the n-6/n-3 PUFA ratio of the diet have significant effects on immune cell function (39), the influences of these two characteristics of the diet on immune cell functions have been difficult to distinguish in previous studies. Furthermore, most previous studies did not strictly control the proportions of dietary fatty acids other than those under study. Palmitic and oleic acids are now known to influence immune cell function (23,35, 40–42), and the proportions of these fatty acids differ greatly among diets previously used [e.g., fish oil contains twice as much palmitic acid as SO (23)]. By using single oils or mixtures of two oils, most previous studies investigated the effects of large amounts of n-3 or n-6 PUFA; the amounts used often could not be achieved in the human diet. As a result, there is little information about how much n-3 PUFA needs to be present to bring about the effects of fish oil. Finally, whether the immunomodulatory effects of fish oil are due to EPA or DHA or to both of these fatty acids is not yet clear. The current study was designed to investigate the immunomodulatory effects of specific PUFA (GLA, ARA, EPA, DHA) fed at the level of 4.4 g/100 g total fatty acids and as components of diets with very similar background fatty acid composition and with a near-constant n-6/n-3 PUFA ratio. A control diet containing approximately 31 g linoleic acid and 4.4 g ALA/100 g total fatty acids was used; the effects of GLA and ARA were examined by replacing a portion of the linoleic acid, whereas the effects of EPA and DHA were examined by replacing ALA. In this way the total PUFA content and the n-6/n-3 PUFA ratio of the diets were kept as constant as possible.

TABLE 1
Proportions of Different Oils Used

	Diet[a]				
Oil	Control	GLA	ARA	EPA	DHA
Canola	28.7	31.0	31.5		
High-oleic acid sunflower seed				12.3	16.3
Sunflower seed	16.2		9.8	43.4	43.8
Soybean	23.4	19.9	19.7		
Fractionated palm	31.8	29.8	28.0	31.1	29.2

MATERIALS AND METHODS

Animals and diets. Weanling male Lewis or DA/Lewis rats (aged 4 wk, weighing between 65 and 80 g) were obtained from Harlan-Olac, Bicester, Oxfordshire, United Kingdom. The rats were housed in the Department of Biochemistry, University of Oxford for a period of 5 (DA/Lewis) or 6 (Lewis) wk prior to sacrifice, during which time they were given free access to water and to one of five experimental diets provided by Unilever Research Colworth Laboratory, Sharnbrook, Bedfordshire, United Kingdom. Each diet contained 178 g/kg lipid. The diets differed according to the proportions of different n-6 and n-3 PUFA they contained; these proportions were varied by using mixtures of oils containing triacylglycerols rich in different PUFA (see Table 1). All diets contained 182 g/kg high-nitrogen casein, 520 g/kg corn starch, 60 g/kg fiber (Solkafloc), 42 g/kg AIN-76 mineral mix, 12 g/kg AIN-76 vitamin mix, 4 g/kg DL-methionine, 2 g/kg choline bitartrate, and 170 mg/kg α-tocopherol; the α-tocopherol content of the oil blends was measured and normalized by the addition of commercial α-tocopherol (Sigma Type V; Sigma Chemical Co., Poole, Dorset, United Kingdom) to give an α-tocopherol content equivalent to 80 mg/kg of the final diet (the diets also contained 90 mg/kg α-tocopherol as a component of the AIN-76 vitamin mix). The fatty acid composition of each diet is shown in Table 2. The diets contained very similar levels of palmitic (approx. 20 g/100 g total fatty acids), stearic (approx. 4.0 g/100 g fatty acids), total saturated (approx. 27 g/100 g fatty acids), oleic (approx. 36 g/100 g fatty acids), and total PUFA (approx. 35 g/100 g fatty acids). Furthermore, the ratio of n-6/n-3 PUFA was kept fairly constant (Table 2); thus, in the diets containing GLA or ARA, these fatty acids partly replaced linoleic acid, whereas in the

[a]g/100 g total fatty acids; n.d. indicates not detected; PUFA, polyunsaturated fatty acids. For other abbreviations see Table 1.

diets containing EPA or DHA, these fatty acids replaced ALA (Table 2). Diets were stored at 4°C and were provided fresh to the rats every 2 d. Rats were killed in the fed state by an overdose of CO_2. Blood was collected by cardiac puncture and allowed to clot at room temperature for 1 h; serum was then collected by centrifugation at $1000 \times g$. Serum was stored at −20°C until analysis. Spleen leukocytes were prepared as described elsewhere (23). All procedures involving animals were approved under the Animals (Scientific Procedures) Act 1986 by the Home Office.

Chemicals. Chemicals and cell culture media and supplements were obtained from the sources described elsewhere (23,27,35,38). Prostaglandin (PG) E_2 concentrations were determined using ELISA kits purchased from Cayman Chemical Co. (Ann Arbor, MI).

Lipid extraction and fatty acid composition analysis. Lipid extraction and fatty acid composition analysis were performed as described elsewhere (27), except that fatty acid methyl esters were prepared by incubation with 14% boron trifluoride at 80°C for 15 min.

Analysis of lymphocyte subpopulations. Flow cytometry was used to measure the presence of various markers on the surface of freshly-prepared spleen leukocytes. The cells were stained with monoclonal antibodies to the T-cell receptor (a T lymphocyte marker), κ-light chain of immunoglobulins (a B lymphocyte marker), or CD11b/c (a macrophage marker) and analyzed as described elsewhere (23,27).

Lymphocyte proliferation and NK cell activity. Spleen lymphocyte proliferation in response to 5 μg/mL concanavalin A (Con A) was determined as described elsewhere (23–27); cultures contained 2.5% (vol/vol) autologous serum, and data are expressed as stimulation index (see 23–27). Spleen leukocyte NK cell activity toward YAC-1 cells was determined as described elsewhere (27).

Measurement of PGE_2 concentrations. Spleen leukocytes were cultured at 37°C in an air/CO_2 (19:1) atmosphere in 24-well culture plates at a density of 5×10^6 cells/well and a total culture volume of 2 mL in HEPES-buffered Roswell Park Memorial Institute medium supplemented with 2 mM glutamine, 2.5% (vol/vol) autologous serum, antibiotics (streptomycin and penicillin), and 5 μg/mL Con A. After 48 h of culture, the medium was collected and PGE_2 concentrations were determined by ELISA, performed according the instructions of the manufacturers of the kits; samples were diluted by 1 in 4 before analysis. This assay can measure a minimum of 29 pg/mL PGE_2, and the level of serum present in samples from cell culture does not interfere with the assay.

Popliteal lymph node (PLN) assay. This *in vivo* measure of cell-mediated immunity was performed as described elsewhere (27,38). Briefly, a graft vs. host response was elicited by injecting 6×10^6 lymph node lymphocytes (prepared from adult male Lewis rats maintained on standard laboratory chow) subcutaneously into the footpad of one leg of weanling male DA/Lewis rats which had been fed for 4 wk on the diets described above. The total injection volume was 0.1 mL and the cells were resuspended in phosphate-buffered saline (PBS); the footpad of the control leg was injected with 0.1 mL PBS. The animals were sacrificed 7 d after injection; during this time they were fed the same diet that they had been previously fed. The PLN were dissected out and weighed. Preliminary experiments indicated that injection of 6×10^6 cells and sacrifice 7 d postinjection resulted in maximal PLN size (38). Injection of PBS or of 6×10^6 DA/Lewis lymph node lymphocytes did not cause any increase in PLN weight (38).

Data presentation and statistical analysis. Data are means ± SEM of five rats fed each diet. Statistical comparions between groups were made using one-way analysis of variance and a *post hoc* least significant difference test. Spearman linear rank correlation coefficients, one-way analysis of variance and *post hoc* least significant difference tests were determined using SPSS Version 6.0 (SPSS Inc., Chicago, IL); in all cases a value for P of less than 0.05 was taken to indicate statistical significance.

RESULTS

Rat growth. The diets used in this study were isocaloric, and there was no difference in food intake among rats fed the different diets (data not shown). Final body weights, and therefore the total growth, were not different among rats fed the different diets (data not shown). Liver and spleen weight and weights of the epididymal and dorsal wall of abdomen adipose depots did not differ among animals fed the different diets (data not shown).

Serum fatty acid composition. The fatty acid composition of the serum was markedly influenced by that of the diet (Table 3). There were significant positive linear relationships between the proportions of each of the major fatty acids in the diet, except palmitic acid, and the proportions of those fatty acids in the serum (Table 4). The proportion of linoleic acid in the serum of rats fed diets containing n-3 PUFA was significantly higher than in the serum of rats fed the GLA- or ARA-rich diets (Table 3); there was a significant ($r = 0.651$; $P < 0.001$) linear relationship between the proportion of DHA in the diet and the proportion of linoleic acid in the serum. This is in agreement with previous observations that feeding rats diets containing fish oil leads to increased linoleic acid levels in plasma and liver lipids (43). These observations suggest that n-3 PUFA might inhibit the further metabolism of dietary linoleic acid and/or that n-3 PUFA might increase the intestinal absorption of linoleic acid. There is some evidence in support of both these suggestions. For example, DHA is known to inhibit Δ-6 desaturase, the enzyme responsible for further metabolism of linoleic acid (44). On the other hand, feeding rats a fish oil-rich diet has been shown to result in enhanced absorption of linoleic acid, at least from some dietary oils (45). Only the serum of GLA-fed rats contained appreciable proportions of GLA (Table 3); serum from these animals contained more dihomo-γ-linolenic acid than that from animals fed the control or ARA diets (Table 3). The proportion of ARA was high in the serum of ARA-fed rats and low in the serum of rats fed the EPA or DHA diets (Table 3). This

[b]g/100 g total fatty acids; for abbreviations see Tables 1 and 2.

is in accordance with observations made following the feeding of an ARA-rich diet to hamsters where ARA levels in liver, heart, lung, kidney, testes, and platelets were significantly elevated compared with feeding a control diet or a diet enriched in EPA (46). Thus, when a significant level of ARA is available from the diet, blood and tissue ARA levels exceed those observed in the absence of significant levels of ARA in the diet; in the latter situation dietary linoleic acid is used as a substrate for the synthesis of blood and tissue ARA. The reduced proportion of linoleic acid in the plasma of ARA-fed rats (Table 3) is in accordance with the reduced proportion of linoleic acid observed in the tissues of ARA-fed hamsters (46). The serum of EPA-fed rats contained a high proportion of EPA and DHA, whereas the serum of DHA-fed rats contained a high proportion of DHA (Table 3).

Spleen leukocyte fatty acid composition. The fatty acid composition of spleen leukocytes was markedly influenced by that of the diet (Table 5). There were significant positive linear relationships between the proportions of each of the PUFA in the diet, except ALA, and the proportions of those fatty acids in spleen leukocytes (Table 4). The proportion of linoleic acid in the leukocytes of rats fed diets containing EPA or DHA was significantly higher than in the leukocytes of rats fed the GLA- or ARA-rich diets (Table 5); there was a significant ($r = 0.639$; $P < 0.001$) linear relationship between the proportion of DHA in the diet and the proportion of linoleic acid in leukocytes. Only leukocytes from GLA-fed rats contained appreciable proportions of GLA (Table 5). These cells also contained a significantly greater proportion of dihomo-γ-linolenic acid than cells from rats fed each of the other diets (Table 5). This observation reflects the availability of GLA, which is rapidly metabolized to dihomo-γ-linolenic acid. The proportion of ARA was high in the leukocytes of ARA-fed rats and low in the leukocytes of rats fed the EPA or DHA diets (Table 5). This agrees with the study of Whelan *et al.* (46) in which feeding an ARA-rich diet to hamsters increased spleen lipid ARA levels (and reduced spleen lipid linoleic acid levels, as found in the current study). Leukocytes from EPA-fed rats contained a relatively high proportion of EPA, whereas those from DHA-fed rats contained a high proportion of DHA (Table 5).

TABLE 4
Spearman Linear Rank Correlation Coefficients for the Relationships Between the Proportions of Particular Fatty Acids in the Diet and the Proportions of Those Fatty Acids in the Serum or Spleen Leukocytes[a]

	Proportion of fatty acid in serum		Proportion of fatty acid in leukocytes

[a]Data are for 25 animals.
[b]NS, not significant; ALA, α-linolenic acid. For other abbreviations see Tables 1 and 2.

Analysis of spleen leukocyte subpopulations. Diet did not affect the proportions of T lymphocytes (approximately 60%), B lymphocytes (approximately 20%), or macrophages (approximately 20%) in spleen leukocyte preparations (data not shown).

Proliferation of spleen lymphocytes. The proliferation of spleen lymphocytes from rats fed the EPA- and DHA-rich diets was significantly lower than that of lymphocytes from rats fed the control diet (Fig. 1). Maximal proliferation of lymphocytes from rats fed the DHA-rich diet was 65% that of lymphocytes from rats fed the control diet (Fig. 1).

Spleen NK cell activity. The NK cell activity of spleen lymphocytes from rats fed the EPA-rich diet was significantly lower than that of lymphocytes from rats fed the control or the ARA- or DHA-rich diets (Fig. 2).

PGE_2 production by cultured leukocytes. It is likely that the bulk of the PGE_2 produced in spleen leukocyte cultures is of macrophage origin (47). The highest level of PGE_2 production was from spleen leukocytes from rats fed the diet rich in ARA; this was greater than production by cells from rats fed the n-3 PUFA-containing diets (Fig. 3). PGE_2 production was lowest in leukocytes from rats fed the EPA- or DHA-rich diets; this was lower than production by cells from rats fed each of the other three diets (Fig. 3). There was a significant correlation between spleen leukocyte ARA levels and *ex vivo* PGE_2 production ($r = 0.738$; $P < 0.001$). This suggests that the main cause of the differences in PGE_2 production among leukocytes from rats fed different diets is the availability of substrate.

Graft vs. host response. The PLN assay was used as an *in vivo* measure of cell-mediated immunity. PLN weights were lowest in rats fed the EPA-rich diet (Fig. 4); these were significantly lower than those in rats fed the control diet.

DISCUSSION

In this study we have compared the effects of feeding rats high-fat (178 g/kg) diets with a near-constant PUFA content (35 g/100 g fatty acids) and a near-constant ratio of n-6/n-3 PUFA (approximately 7), but with different long-chain n-6 or n-3 PUFA. The characteristics of the diets used were selected so that this study would be of relevance to humans. For example, the level of fat in the diet was selected so that fat would provide approximately 35% of dietary energy, the current recommended level for the United Kingdom population (48). The levels of total saturated fatty acids, monounsaturated fatty acids, and total PUFA were selected so that they

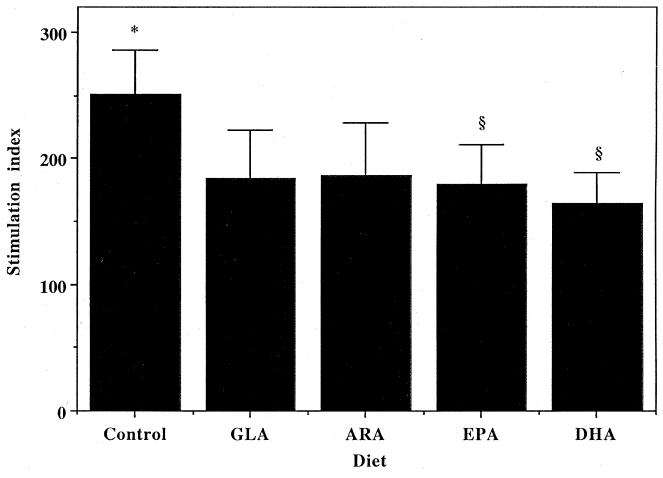

FIG. 1. Effect of feeding diets containing different polyunsaturated fatty acids (PUFA) upon the proliferation of rat spleen lymphocytes. Values are mean ± SEM of five animals fed each diet. Values indicated by different symbols are significantly different from one another. GLA, γ-linolenic acid; ARA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

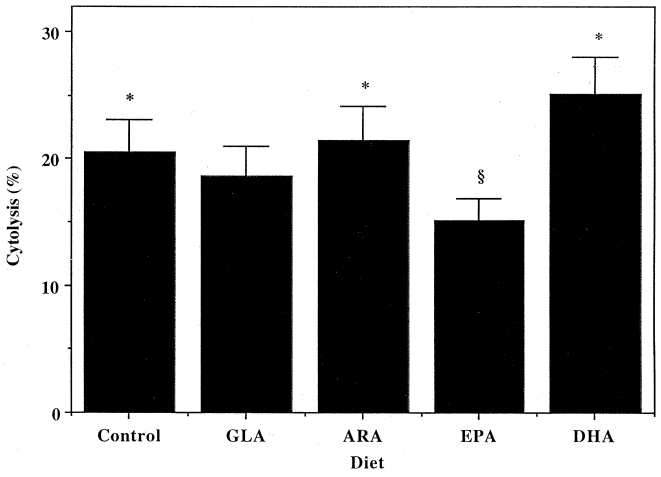

FIG. 2. Effect of feeding diets containing different PUFA upon the natural killer cell activity of rat spleen lymphocytes. Values are mean ± SEM of five animals fed each diet. Values indicated by different symbols are significantly different from one another. For abbreviations see Figure 1.

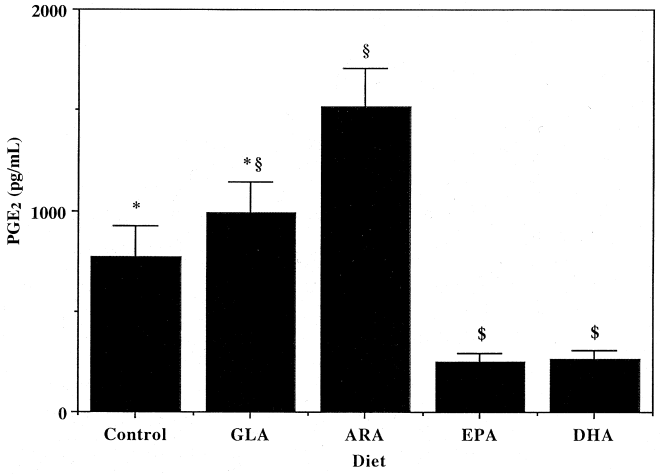

FIG. 3. Effect of feeding diets containing different PUFA upon *ex vivo* prostaglandin E_2 (PGE_2) production by rat spleen leukocytes. Values are mean ± SEM of five animals fed each diet. Values not sharing a common symbol are significantly different from one another. For abbreviations see Figure 1.

approximated those currently recommended for the United Kingdom diet (11, 14, and 7% of dietary energy, respectively; 48); however, the level of total PUFA actually used was higher than this. The n-6/n-3 PUFA ratio of 7 was selected so that it approximated that of the current United Kingdom diet (approximately 6.5; 49). The control diet contained 31 g linoleic acid and 4.4 g ALA/100 g total fatty acids. In all diets the content of long-chain PUFA was maintained at approximately 4.4 g/100 g fatty acids; therefore, in the experimental diets GLA and ARA partially replaced linoleic acid, and EPA and DHA replaced ALA. Importantly, the levels of all fatty acids other than PUFA were almost identical in all diets. Therefore, these diets investigate the effect of replacing a portion of dietary linoleic acid with a relatively low level of another n-6 PUFA (either GLA or ARA) without introducing any other changes in dietary fatty acid composition, total PUFA content, or n-6/n-3 PUFA ratio. Similarly, these diets investigate the effect of replacing dietary ALA with another n-3 PUFA (either EPA or DHA) without introducing any other changes in dietary fatty acid composition, total PUFA content, or n-6/n-3 PUFA ratio. Thus, feeding these diets represents a more strictly controlled situation than does feeding diets rich in particular oils (e.g., sunflower, safflower, evening primrose, linseed, fish), since these differ significantly in the proportions of fatty acids other than those being compared (e.g., palmitic and oleic acids). In addition, the characteristics of such oils differ widely. For example, linseed oil contains 50 g ALA/100 g total fatty acids, fish oil contains 25 g EPA plus DHA/100 g total fatty acids, and n-6 PUFA-rich oils such as sunflower or SO contain 60 to 85 g linoleic acid/100 g total fatty acids. Thus, experiments which compare the effects of feeding these oils are comparing diets with widely differing n-6/n-3 PUFA ratios and levels of PUFA. For instance, the n-6/n-3 PUFA ratio in sunflower and SO is greater than 100, whereas this ratio in linseed and fish oils is approximately 0.3.

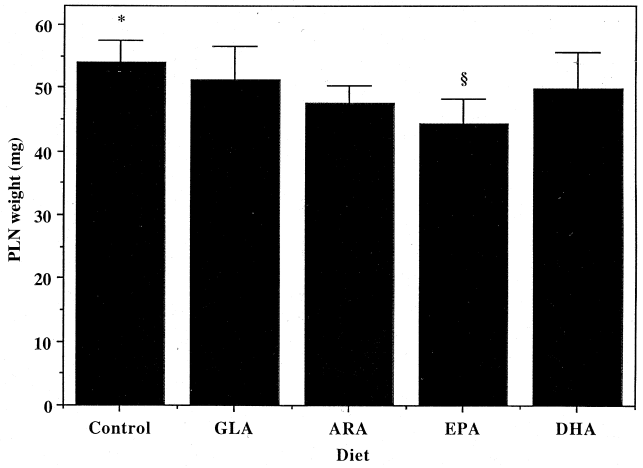

FIG. 4. Effect of feeding diets containing different PUFA upon the graft vs. host response in rats. Values are mean ± SEM of five animals fed each diet. Values indicated by different symbols are significantly different from one another. PLN, popliteal lymph node. For other abbreviations see Figure 1.

Feeding rats a diet containing 200 g/kg fish oil results in suppressed *ex vivo* lymphocyte proliferation (23,26) and NK cell activity (26,35), and diminishes the graft vs. host response *in vivo* (38). Similar effects of fish oil feeding have been reported in other species, including mice (25,30,33, 34,37), rabbits (21), chickens (22), and humans (50–52). Feeding linseed oil to laboratory animals also suppresses *ex vivo* lymphocyte proliferation (20–22,27) and NK cell activity (27) and diminishes the *in vivo* graft vs. host response (27). However, as described above, diets containing fish or linseed oils as the sole source of fat include very high levels of n-3 PUFA; the current study investigates the effects of lower levels of these PUFA. Differential effects of dietary n-3 PUFA were observed. Replacing dietary ALA with either EPA or DHA decreased lymphocyte proliferation. In contrast, replacing dietary ALA with EPA, but not with DHA, reduced NK cell activity and the graft vs. host reponse. These observations suggest that the suppressive effect of dietary fish oil upon lymphocyte proliferation might be due to the presence of both EPA and DHA, whereas the inhibitory effect of fish oil upon NK cell activity might be due to EPA alone. This study does not rule out the possibility that higher levels of DHA in the diet might exert effects upon NK cell activity. Furthermore, we have not investigated the effect of altering the ratio of EPA to DHA in the diet; this might be important in determining the precise effect of long-chain n-3 PUFA and of different fish oils upon lymphocyte function and cell-mediated immunity.

It is unlikely that the differences in lymphocyte function relate to differences in the populations of cells cultured: diet did not affect the proportions of T lymphocytes, B lymphocytes, or macrophages present in the spleen. This is in accordance with the lack of effect of diets rich in fish oil, evening primrose oil, or linseed oil upon spleen leukocyte subpopulations (23,27).

This study also reveals that replacing a proportion of dietary linoleic acid with another n-6 PUFA, either GLA or ARA, does not influence spleen lymphocyte proliferation or NK cell activity and does not affect the graft vs. host response.

The observations made in the current study can be compared with those of some other recent studies (53,54). Jolly *et al.* (53) fed mice for 10 d on diets containing 30 g SO/kg, 20 g SO plus 10 g ARA-rich triacylglycerol/kg, 20 g SO plus 10 g EPA-ethyl ester/kg or 20 g SO plus 10 g DHA-ethyl ester/kg. They found that compared with the SO diet, the ARA-rich diet did not affect spleen lymphocyte proliferation in response to Con A. In contrast, both EPA- and DHA-rich diets suppressed lymphocyte proliferation (by 80%); the two n-3 PUFA were equipotent. Qualitatively this agrees with the current study which found no effect of ARA on lymphocyte proliferation, but a suppressive effect of diets containing either EPA or DHA, which were equipotent in their effects (Fig. 1). However, lymphocyte proliferation was suppressed by about 30 to 35% in the current study (compared with the control diet). This quantitative difference in the effects of EPA and DHA between the two studies could be due to at least five key differences between the studies. First, the studies used different levels of n-3 PUFA in the diets; in the current study, EPA or DHA constituted approximately 4.4% of total fatty acids and approximately 1.5% of dietary energy, whereas in the study of Jolly *et al*. (53) EPA or DHA made up approximately 30% of total fatty acids and approximately 2.3% of dietary energy. Second, the total level of fat in the diets used was different; in the current study the diets contained 178 g fat/kg diet, whereas in Jolly *et al*. (53) the diets contained 30 g fat/kg diet. The level of dietary fat has been shown to influence lymphocyte proliferation (18), and this makes direct quantitative comparison between the two studies difficult. Third, the diets used in the two studies differed greatly in their PUFA content; in the current study PUFA constituted approximately 35% of total fatty acids whereas in the the study of Jolly *et al*. (53) PUFA made up 90% of total fatty acids. Lymphocyte proliferation has been shown to be markedly influenced by the level of PUFA in the diet (39); furthermore, the total PUFA content of the diet influences the effect of ALA (39), and perhaps other n-3 PUFA, on lymphocyte proliferation. Fourth, the diets used in the two studies differ greatly in the ratio of n-6/n-3 PUFA; in the current study the n-6/n-3 PUFA ratio was kept as constant as possible at approximately 7, whereas in the study of Jolly *et al*. (53) the n-6/n-3 PUFA ratio varied greatly between diets. Although the exact fatty acid compositions of the diets used were not given by Jolly *et al*. (53), sufficient information is available to indicate that the n-6:n-3 PUFA ratio of the control SO diet was at least 100, and perhaps as much as 800, while the n-6/n-3 PUFA ratios of the EPA and DHA diets were approximately 1.7. It is known that lymphocyte proliferation is markedly influenced by the n-6/n-3 PUFA ratio of the diet (27,39). Fifth, the exact comparisons being made are different between the two studies: in the current study the effect of replacing an exact amount of one n-3 PUFA (ALA) with the same amount of another n-3 PUFA (EPA or DHA) without altering any other dietary variable was examined, whereas in Jolly *et al*. (53) the effect of replacing a significant amount (30%) of linoleic acid in a diet almost devoid of n-3 PUFA with EPA or DHA was examined. Thus, the control diets are different between the two studies; in the current study the control diet contained 30 g linoleic acid, 4.4 g ALA, and 35 g PUFA/100 g total fatty acids and had an n-6/n-3 PUFA ratio of 7, whereas in the study of Jolly *et al.* (53) the control diet contained at least 84 g linoleic acid and PUFA/100 g total fatty acids and a negligible amount of ALA and had an n-6/n-3 PUFA ratio of at least 100. These profound differences most likely explain the quantitative differences in the effects of EPA and DHA upon lymphocyte proliferation between the two studies. It seems logical that, since adding ALA to an n-6 PUFA-rich diet reduces lymphocyte proliferation (27,39), adding EPA or DHA to an n-6 PUFA-rich diet (53) will have a greater effect upon lymphocyte proliferation than replacing ALA with either EPA or DHA (this study).

The lack of an immunological effect of feeding laboratory rodents diets enriched in ARA (this study; 53) agrees with a recent study in man, the first study in animals or man to have examined the effects of dietary ARA on components of the immune response, which showed no effect of 1.5 g ARA/day for 50 d on the proliferative response of peripheral blood mononuclear cells to Con A, phytohemagglutinin, or pokeweed mitogen (54). Human peripheral blood NK cell activity was unaffected by the consumption of ARA (54); again this observation is in agreement with that of the current study (Fig. 2). The current study observed a lack of effect of ARA upon the graft vs. host response, an *in vivo* measure of cell-mediated immunity (Fig. 4). This also agrees with the human study (54) which found no effect of the ARA diet on the delayed-type hypersensitivity response to seven recall antigens applied intradermally.

An n-3 PUFA-induced reduction in lymphocyte reactivity and cell-mediated immunity, although potentially useful in chronic inflammatory diseases (5–11) and following transplantation (12), could make individuals increasingly susceptible to bacterial and viral infections and to the development of cancers. Certainly inclusion of high levels of fish oil in the diet of experimental animals results in increased mortality following a challenge with *Salmonella typhimurium* (55), *Staphylococcus aureus* (56), or *Listeria monocytogenes* (57). However, the current study indicates that n-3 PUFA at the level of 4.4 g/100 g total dietary fatty acids cause rather minimal immunosuppressive effects. To achieve this level of n-3 PUFA intake, individuals would need to consume between 3.5 and 6 g long-chain n-3 PUFA per day. Since the current average United Kingdom intake of long-chain n-3 PUFA is less than 0.2 g/day (49), this would represent a vast increase in intake, achievable only by supplementation with encapsulated n-3 PUFA. We have not identified the lowest level of EPA or DHA required to suppress lymphocyte proliferation, but DHA at the level of 4.4 g/10 g total fatty acids did not af-

fect NK cell activity or a measure of the *in vivo* cell-mediated immune response. The data suggest that a modest increase in dietary long-chain n-3 PUFA or supplementation of the diet with relatively low levels of encapsulated fish oil will not compromise immunity. In agreement with this conclusion, Meydani *et al*. (51) reported that supplementation of the diet of women aged 23 to 33 yr with 2.4 g EPA plus DHA per day for up to 3 mon did not affect the response of peripheral blood lymphocytes to Con A or phytohemagglutinin. Similarly, supplementation of the diet with 6 g long-chain n-3 PUFA in the form of ethyl esters per day for 4 mon did not affect the response of peripheral blood lymophocytes to phytohemagglutinin (58). Interestingly, these levels of supplementation with n-3 PUFA significantly reduce the *ex vivo* production of proinflammatory cytokines (50–52; see 19 for a review), suggesting that proinflammatory cytokine production is more sensitive than lymphocyte function to n-3 PUFA intervention.

In the past it has been speculated that effects of dietary n-3 PUFA on immune cell function relate to changes in production of eicosanoids, particularly PGE_2. PGE_2 levels were elevated in the medium of leukocytes from rats fed the ARA-rich diet and were reduced in that of leukocytes from rats fed the EPA- or DHA-rich diets (Fig. 3). Thus, differences in PGE_2 production cannot be responsible for the differences in lymphocyte proliferation observed. This agrees with the outcomes of a number of *in vitro* studies which have concluded that the inhibitory effects of EPA and DHA upon lymphocyte proliferation are independent of their effects upon PGE_2 production (59–62). There is also agreement with studies in humans in which supplementation of the diet with fish oil has been shown to reduce both lymphocyte proliferation and PGE_2 production (50,51); these studies concluded that the effect of n-3 fatty acid supplementation on lymphocyte proliferation seems independent of, and is unlikely due to, decreases in PGE_2 production (50,51). The recent study of Wu *et al*. (63) in part also supports this conclusion: these workers found that feeding monkeys diets containing increased amounts of ALA resulted in significantly reduced PGE_2 production but did not affect lymphocyte proliferation. Where the study of Wu *et al*. (63) differs from this study and from that of Jolly *et al.* (53), as well as from earlier studies in rats (23,26), mice (25,30,33,34,37), rabbits (21), chickens (22), and humans (50–52), is in the effect of enrichment of the diet in EPA plus DHA upon lymphocyte proliferation. Adding EPA plus DHA to the diet of monkeys significantly reduced PGE_2 production but increased the response of lymphocytes to mitogens (63). The authors' explanation for the latter observation was that the monkeys had also been fed variable levels of α-tocopherol and so were better able to maintain antioxidant defenses in the face of differing dietary PUFA levels. In the current study, as well as that of Jolly *et al*. (53), the levels of antioxidants were constant in all diets.

If long-chain n-3 PUFA do not inhibit lymphocyte proliferation *via* changes in eicosanoid production, other mechanisms must be identified. The current study did not examine the possible mechanisms beyond measuring PGE_2 concentrations. However, the study by Jolly *et al*. (53) provides some insight into how EPA and DHA might act to suppress lymphocyte proliferation. These workers observed a marked reduction in generation of the intracellular second messengers diacylglycerol and ceramide in Con A-stimulated cells from EPA- or DHA-fed mice. Both diacylglycerol and ceramide are key second messengers in lymphocytes, ultimately giving rise to transcription factor activation and so regulating gene expression. The data are suggestive of effects of fish oil-derived n-3 PUFA on intracellular signaling pathways which control the functional activities of the cells. In agreement with Jolly *et al.* (53), we have observed diminished generation of inositol-1,4,5-trisphosphate in stimulated lymphocytes taken from rats fed fish oil; this appeared to be due to reduced activity of phospholipase C-γ (Sanderson, P., and Calder, P.C., unpublished observations). The mechanism(s) of action of EPA and DHA warrant further examination; in light of the current study it would seem important to identify the reasons why these fatty acids exert similar effects upon lymphocyte proliferation but different effects upon NK cell activity.

ABSTRACT: We have developed cultures of smooth muscle cells (SMC) isolated from arterial hypercholesterolemic chicks (cholesterol-SMC). These cultures are suitable for the study at the molecular level of the changes in arterial SMC induced by a cholesterol diet. By using a strong dose of cholesterol (5%) for 10 d, we obtained very proliferative SMC which became foam cells after 30 d in culture. On the other hand, SMC cultures isolated from control-fed chicks had a lower growth rate than the SMC ones under the same culture conditions. DNA synthesis was fourfold greater in cholesterol-SMC than in control-SMC cultures. Intracellular cholesterol concentrations were the same in both cholesterol and control SMC during the first 14 d of culture but afterward increased in differing ways: after 20 d of culture the cholesterol-SMC increased their cholesterol content to double the control. We give here the results obtained from transmission electron microscopy, lipid analysis, proliferation studies, DNA, RNA and protein synthesis, and then discuss their implications.

Lipids 33, 181–190 (1997).

Hypercholesterolemia is a known risk factor in arteriosclerosis, a complex disease involving prolonged processes in its evolution (1–4). The contractile-state smooth muscle cell (SMC) is the only cell type in the arterial media (5,6) and undergoes migration into the intima, proliferation, and abundant extracellular matrix production during the early stages of atherosclerosis (7,8).

In cell culture and in atherogenic processes, SMC changes from a contractile to a synthetic state (9–14). This modulation has been associated with phenotypic changes (15) characterized through cytoskeletal and cytoenzymatic studies (16,17) and makes the SMC responsive to chemotactic or mitogenic stimuli (2,18,19).

SMC is thought to be crucial in the development of arteriosclerotic plaques (20,21). In a rat aortal SMC culture model—including contractile, synthetic, and transformed cells—it has been shown that an increase in cholesterol biosynthesis associated with phenotypic changes (22) plus dedifferentiation in arterial SMC *in vitro* are associated with a decrease in intracellular cholesterol efflux and also a decrease in high-affinity binding sites for native high density lipoprotein (HDL) (23). Other cell-culture models use different additional elements in the culture to obtain foam cells *in vitro,* such as an elastin substrate (24) or lipid droplets isolated from cultured macrophages (25). Nevertheless, the molecular event that triggers the transformation of SMC in dedifferentiated and proliferative cells by cholestrol feeding is not yet completely understood.

Avian models were used in trials of atherosclerosis, and, in fact, cholesterol feeding has been described elsewhere as producing atherosclerotic lesions in fowl species (26–29). We have also used chicks previously to study lipid metabolism after cholesterol administration (30–33). The aim of this study was to develop a cell-culture avian model to look into the effect of a cholesterol diet on the transformation of SMC *in vivo*. We show a comparative study between cultures of SMC isolated from two chick groups: control- and high-cholesterol-feeding chicks. We have examined the morphological, molecular, and proliferative changes in arterial SMC in culture under conditions mimicking such a cholesterol diet and the reproducibility of our methods.

MATERIALS AND METHODS

Animals. Newborn white leghorn male chicks *(Gallus domesticus)* were bought from a commercial hatchery and fed *ad libitum* in a chamber with a daily light cycle from 0900 to 2100 and a controlled temperature of 29–31°C.

Diet and treatment. Different groups of newborn white leghorn male chicks were used. The control groups were 10-day-old chicks (C_{10}) and 20-day-old chicks (C_{20}) kept on a standard diet (Sanders A-00). The treated groups were 10-day-old chicks fed on the same diet supplemented with 2% w/w powdered cholesterol mixed homogeneously (Panreac reagent Barcelona, pure grade; Montplet & Esteban SA, Barcelona, Spain) (T_{10}-2%) or 5% w/w (T_{10}-5%). This treatment was also assayed with 20-day-old chicks (T_{20}-2% and

Abbreviations: DMEM, Dulbecco's modification of Eagle's medium; FCS, fetal calf serum; HDL, high density lipoprotein; LDL, low density lipoprotein; PBS, phosphate-buffered saline; SMC, smooth muscle cell.

T_{20}-5%). The diets were started at hatching and kept on until the chicks were killed. Water was available at all times. None of the chicks died a natural death during the treatment nor developed any illness.

Lipids analysis. Lipids were extracted by the Bligh–Dyer method (34). Serum total cholesterol content and intracellular cholesterol were determined by enzymatic colorimetry method CHOD-PAD, Cat. No. 290319 ("Test–Combination cholesterol," Boehringer Mannheim Chemicals GmbH, Mannheim, Germany).

Serum triglyceride and intracellular triglyceride contents were determined by enzymatic colorimetry Test Peridochrom ("Triglycerides GPO-PAP," Cat. No. 701904, Boehringer Mannheim GmbH).

Isolation and culturing of cells. Unless otherwise specified, at 10 d of age both the control and cholesterol-fed animals were decapitated and the aortic arch was removed. SMC explants from the medial layer of the arterial wall were prepared as described before (35,36) with slight modifications as described below.

Under meticulously sterile conditions, the arteries were placed in phosphate-buffered saline (PBS) (Flow) pH 7.4 at 37°C containing an antibiotic cocktail composed of penicillin (100 units/mL), streptomycin (100 µg/mL), and amphotricin (0.25 µg/mL) (Sigma-Aldrich, Madrid, Spain). The blood vessels were cleaned of all adipose and connective tissues and were then cut open longitudinally and incubated in PBS containing type II (1 mg/mL) collagenase and type IIA (0.5 mg/mL) elastase (Sigma) at 37°C for 30 min. The adventitious veins were cleanly stripped and discarded. The endothelium was removed using a paint brush. The artery was then washed extensively in PBS.

The aortas (100 mg) were cut into uniform-sized pieces of 1 mm^2 and then put into 75-cm^3 flasks with a small amount (1 mL) of normal culture medium, consisting of Dulbecco's modification of Eagle's medium (DMEM) supplemented with D-glucose (4.5 g/L), L-glutamate (0.584 g/L) (Flow), antibiotic cocktail, and 20% (vol/vol) fetal calf serum (FCS). The flasks were allowed to stand with the cap end up, to drain most of the medium in order to promote tissue adherence. The explants were maintained in a humidified incubator (5% CO_2) at 37ºC for 24 h. More medium (2 mL) was then added to cover the explants, and these were checked every day under an inverted light microscope. Half of the medium was replaced every 2–3 d. The cells that grew out from the explants were detached with 0.05%/0.02% Trypsin/EDTA solution (Flow), centrifuged at 200 × *g* for 10 min, resuspended in complete medium, counted, and seeded into new flasks (first passage). While in first passage, the cells were fed every day and maintained prior to subsequent trypsinization and repassage. The medium used for feeding after the first passage was DMEM with 10% FCS.

Unless otherwise specified, all the experiments were conducted using third- or fourth-passage cells plated at a density of 2.5×10^6 cells/P-75 tissue culture dish. Cells were determined to be vascular smooth muscle by their hill-and-valley configuration at confluence (36) and positive fluorescence staining for smooth muscle actin and myosin (10).

Examination of cell viability. Trypan blue (Sigma) was added to the cells with the help of a hemocytometer, and the flasks were examined with an inverted light microscope (Olympus Opticals Co. Ltd., Tokyo, Japan) to count live and dead cells. Cell viability in our cultures was 90%.

Electron microscopy. After the chicks were killed, their aortic arches were immediately removed and samples were taken for electron microscope examination. A small segment was taken from the aortic arch and fixed in 2.5% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4), postfixed in 1.5% osmium tetroxide in the same buffer, and embedded in epoxy resin. Ultrathin sections were cut and double-stained with uranyl acetate and lead citrate and observed under a Zeiss 902 transmission electron microscope (Carl Zeiss, Obercochen, Germany.

SMC cultures were also prepared for electron microscope examination. Aortic SMC growing in plastic dishes were fixed in cacodylate-buffered 2.5% glutaraldehyde (pH 7.2), postfixed in 1.5% osmium tetroxide, dehydrated in ethanol, and embedded in Epon 812 (Electron Microscopy Sciences, Fort Washington, PA). Ultrathin sections were viewed in a Zeiss 902 Microscope.

Cell proliferation studies. For cell proliferation studies confluent cultures were trypsinized, and the cells were seeded into 24-well plates (cel-Cult, Sterilin; Biby Sterilin, Staffordshire Stone, England) at a density of 1×10^5 cells/cm^3 with no precoating of the dishes with adhesion factors. The medium was changed every 24 h after seeding. For all cell proliferation studies, DMEM with glucose, glutamine, and antibiotic cocktail (Flow) supplemented with 10% FCS was used. At different times during the 10-d culture, the cells of three wells were washed with PBS and trypsinized to yield single cells. The cells were then pooled and transferred to a cell counter (Neubauer chamber; Rudolph Brand GmbH Co., Wertheim, Germany) for counting. Cell viability was checked by using Trypan blue.

Cell cycle arrest. To arrest cells in G_1, we deprived them of serum for 12 to 48 h. Serum deprivation was carried out by incubation in DMEM with 0.2% FCS added 12, 24, or 48 h after the cells were seeded (37).

Measurement of the rates of cell DNA, RNA, and protein synthesis. To measure the rate of cell DNA synthesis, we incubated the cells (5×10^5 per 25-cm^2 flask) for 24 h after inoculation to permit their recovery and then synchronized (0.2% FCS for 48 h) and pulse-labeled for 15 min at various times with 1 µCi/mL of [^{3}H]-*d*-thymidine (Amersham International, Little Chalfont, Buckinghamshire, England). The plates were washed five times with ice-cold PBS, and then the cells were harvested by scraping them with a cell-lifter (Costar; Corning Coster Corporation, Cambridge, MA) into 3 mL of ice-cold PBS and were centrifuged for 5 min at 220 × *g*; the pellet was resuspended in 0.5 mL of ice-cold PBS, sonicated, and mixed with a final volume of 10% ice-cold CCl_3COOH. Insoluble material was collected on a Whatman

GF/C filter (Maidstone, England) and washed extensively with cold 5% CCl_3COOH. The filter was then dried under a heat lamp, and the radioactivity incorporated was quantitated in Ready-Safe by liquid scintillation counting (Beckman LS 6000; Beckman Instruments, Inc., Fullerton, CA). The protein was determined according to Lowry *et al.* (38).

To measure the rate of RNA synthesis, the cells were pulsed as described above with 1 μCi/mL of [^{3}H]uridine (Amersham International) in DMEM medium. The CCl_3COOH-insoluble material was then determined as described for DNA.

To measure the rate of cellular protein synthesis [4,5-^{3}H]L-leucine (1 μCi/mL) incorporation into CCl_3COOH-insoluble material was performed as described for DNA synthesis except that a 30-min rather than a 15-min pulse was used.

Statistical analyses. The significance of differences between the SMC from cholsterol-fed and control chicks was computed using the unpaired Student's *t*-test. Results are presented as means ± SEM.

RESULTS

Outgrowth of the explants. As previously described in the Materials and Methods section, a simple, fast, and reproducible routine must be established between the removal of the artery and the outgrowth of the explants.

Smaller explants showed a reduced lag phase prior to outgrowth. When the tissues were cut into uniform 1-mm^2 pieces with a scalpel blade, 80–90% of the explants showed outgrowth after 10 d. Various concentrations of FCS were tested (5, 10, 20%); 20% FCS gave the best outgrowth from explants and was used routinely. The outgrowth from explants was better in 10- than in 20-day-old chick tissue.

Explants prepared using hypercholesterolemic chick arteries gave the shortest lag phase. The migration of SMC from explants of atherosclerotic tissues occurred 6–7 d after planting. The lag phase from control explants was 10 d or less. The migration out of the cells from the explants was much faster for cholesterol-fed chicks than for control chicks.

Maintenance of the SMC cultures' life. At the beginning of the study, tissue samples for preparing the explants were collected from different vessels (aortic arch and aorto-iliac bifurcation) to find the best arterial specimen to culture the SMC. This study was made by comparing the number of days that the different cultures remained viable. Aorto-iliac bifurcation and aortic arch SMC from different groups of control and treated animals were used. It can be seen in Table 1 that the SMC cultures from the aortic arches of younger chicks were kept in culture for longer times than the older ones. Moreover, Table 1 shows the effect of the proportion of cholesterol fed on the SMC culture life, which was longer with SMC from 5 than from 2% cholesterol-fed chicks. Results using SMC cultures from aorto-iliac bifurcation gave the same results (results not shown).

Transmission electron microscope analysis. Transmission electron microscope analysis of the aortas was made to choose the period of diet treatment because our first aim was to isolate the SMC prior to intimal thickening, considering that the effect of a high-cholesterol diet on SMC was a very early atherogenic process.

TABLE 1
Effect of Cholesterol Feeding on the Life of Smooth Muscle Cell (SMC) Cultures[a]

Chicks age (d)	Days that SMC cultures were maintained		
	C	T-2%	T-5%

[a]SMC obtained from control chicks group (C). SMC obtained from chicks fed on the same diet with 2 (T-2%) and 5% (T-5%) cholesterol. Results are expressed as the means of five experiments. Variations did not exceed 10%.

The effect of short-term (10 d) and long-term (20 d) cholesterol feeding on the morphological aspects in aorta tissues of chicks has been studied. No histological alterations were observed in aortas after 10 or 20 d of 2% cholesterol feeding (T_{10}-2% and T_{20}-2%) compared to the control chicks of the same age (C_{10} and C_{20}) (results not shown). Nevertheless, the histology of aortas from chicks fed long term (T_{20}-5%) on 5% cholesterol was different (Fig. 1A), with a considerable number of lipid droplets and a focal aggregation of foam cells, resulting in intimal thickening. When 5% cholesterol treatment was short-term (T_{10}-5%), no lipid droplets accumulated within 10 d in the aortas (Fig. 1B), similar to what happened in controls (Fig. 1C). However, we observed two morphological changes in T_{10}-5% cells compared to control: first, the relaxed aspect of the nuclear membrane (Fig. 1B) comparative to that of the control (Fig. 1C), and second, the increase of collagen fiber in the intracellular space (Fig. 1B). All of this suggests a preliminary indication of a change to a synthetic state from a contractile state and therefore to a more dedifferentiated SMC. Further studies using differentiation markers will be necessary in order to prove this.

On the basis of no short-term accumulation of lipid droplets in the aorta, the short-term treatment chicks (T_{10}-5%) were chosen for isolating and culturing SMC. Electron microscopy of the cultured cells was made to compare possible ultrastructural alterations. After 3- or 4-d culture the cells did not show any appreciable difference (result not shown), but after 30 d, whereas the control cells remained normal (Fig. 2A), the cells from treated chicks (T_{10}-5%) became more rounded and contained numerous lipid inclusions, like foam cells (Fig. 2B). Most of the lipid inclusions in the lipid-loaded SMC were membrane-delimited, and nonmembrane-bound intracellular lipid inclusions were also present. No plasma membrane-associated lipid was observed; extracellular matrix of collagen fibrils and extracellular lipid droplets were present (Fig. 2B).

Serum lipid analysis. The high-cholesterol diet caused a significant increase in circulating total cholesterol and triglycerides. Figure 3 shows the profile of serum cholesterol concentration of the chicks used in the experiments. As can be seen, the levels were more than twice as high in chicks after

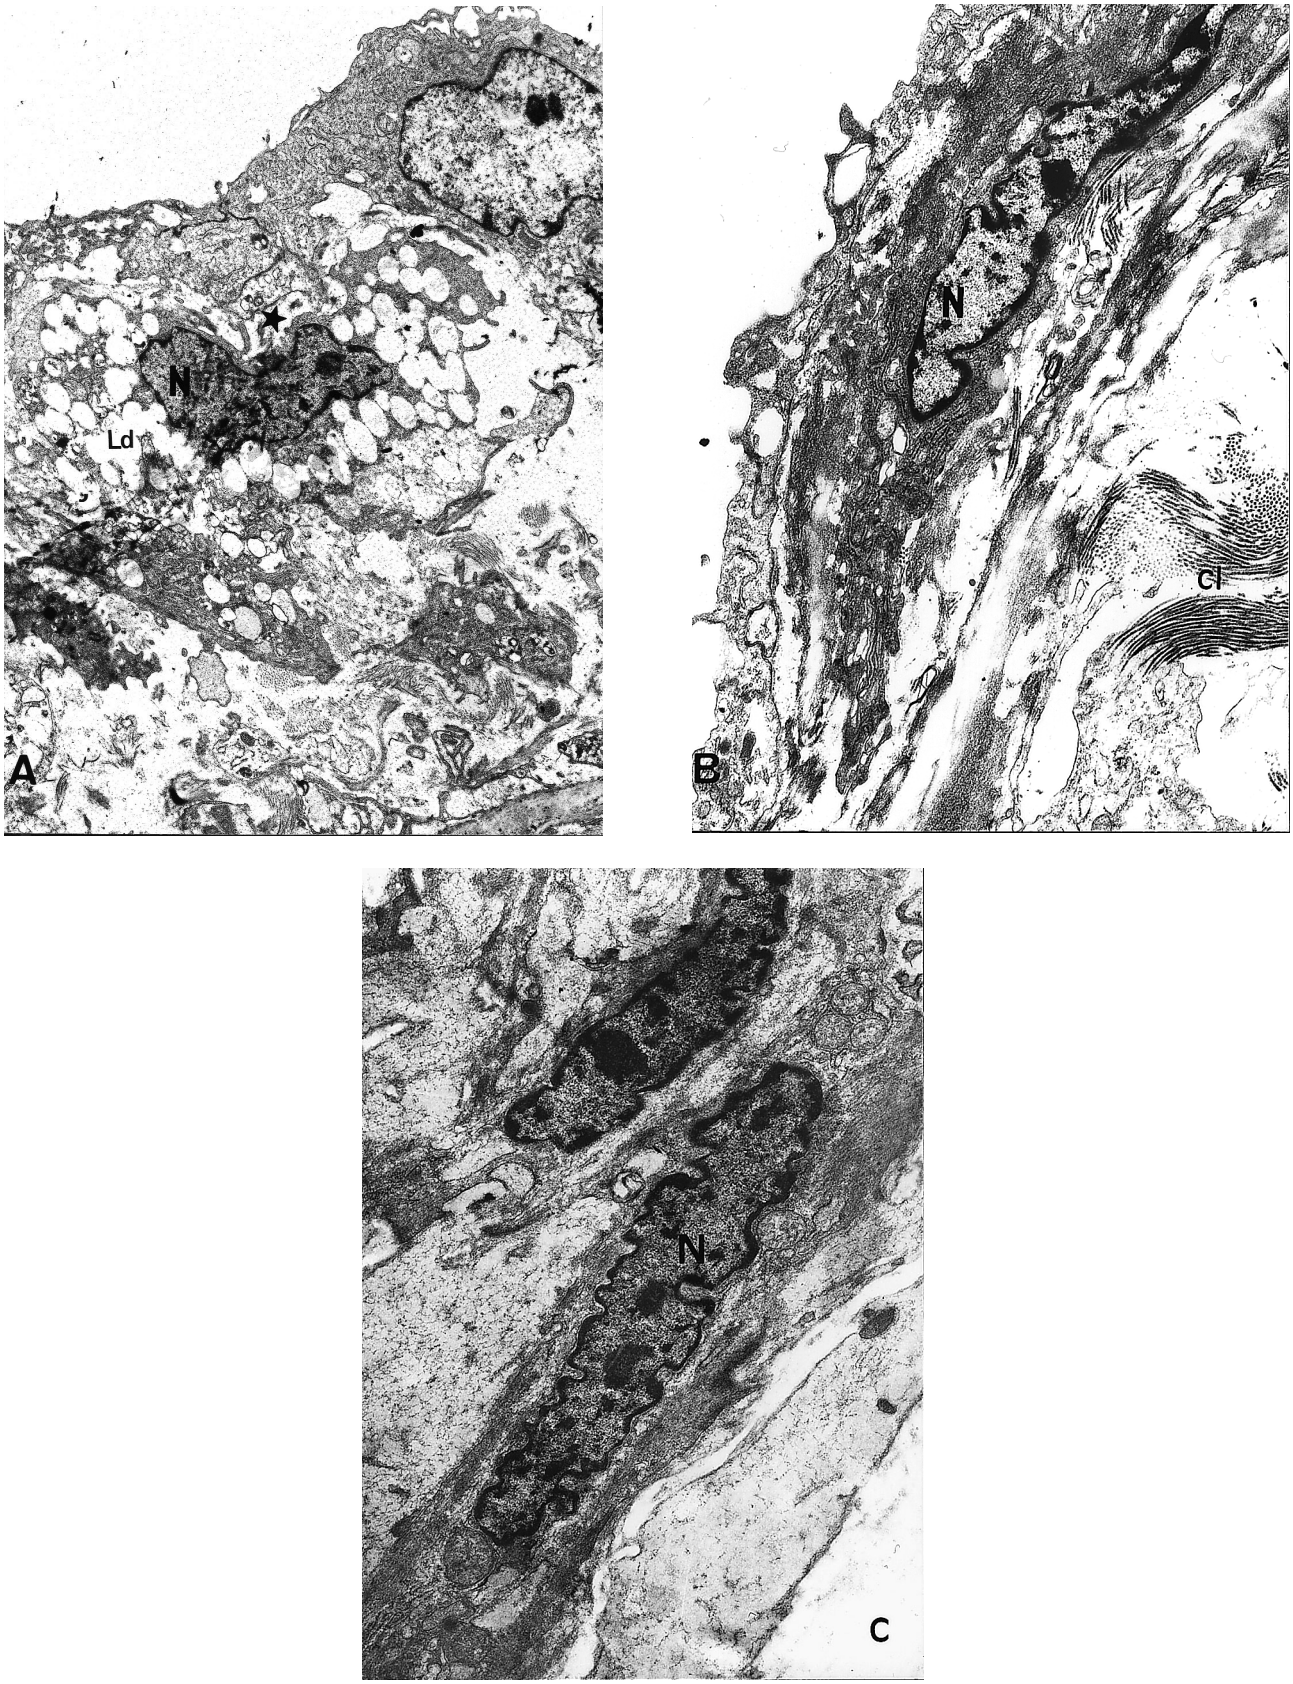

FIG. 1. Electron micrographs of aorta. (A) from T_{20}-5% chicks. Note the presence of smooth muscle cell (SMC)-like foam cells and focal aggregation in the intima (★), Ld = lipid droplets; (B) from T_{10}-5% chicks, cl = collagen fibers; N = nucleus. Original magnification, ×5.625, scale bar represents 183 nm; (C) from control chicks; N = nucleus. Original magnification, ×10.500, scale bar represents 350 nm.

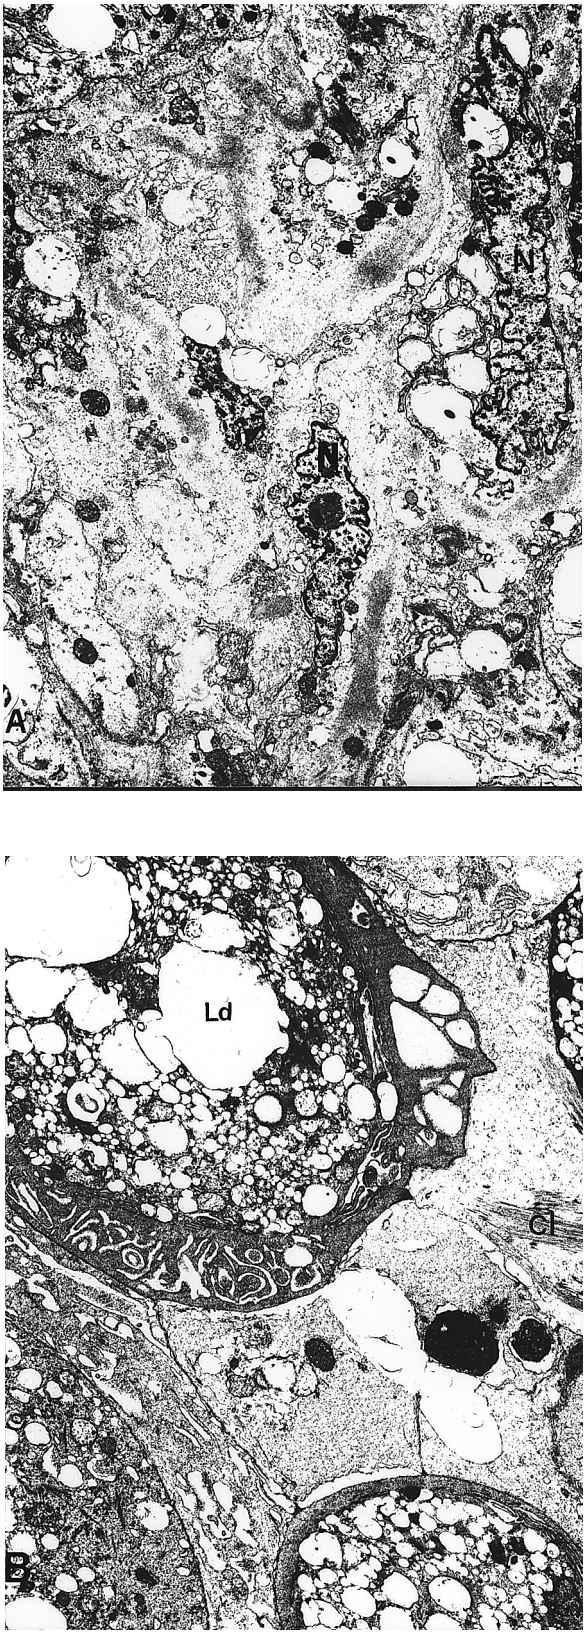

FIG. 2. Electron micrographs of SMC after 30 d in culture. (A) SMC isolated from control chicks. (B) SMC isolated from T_{10}-5% chicks. Ultrastructural morphology of SMC-like foam cells. FIG. 3. Profiles of concentrations of serum triglycerides (A) and cholesterol (B) during the postnatal developments of two chick groups: control (●) and 5% cholesterol feeding (▲). Results are expressed as means ± SEM of five chicks. $*P < 0.001$, $**P < 0.0001$.

10 d of 5% cholesterol feeding compared with those on control diets. They decreased slightly 5 d afterward but increased significantly again (fivefold) until day 25 of cholesterol feeding. Figure 3 shows the evolution of triglyceride serum levels in the controls and those of 5% cholesterol feeding during 25 d after hatching. The levels in cholesterol-fed chickens were higher than the controls throughout the whole experimental period.

Intracellular lipid contents in SMC in culture. SMC were isolated and cultured from C_{10} and T_{10}-5% chick groups to obtain two lines of cultures, control-SMC, and cholesterol-SMC. The maintenance of the two lines of SMC cultures was identical, as described in the Materials and Methods section. DMEM and 10% FCS were used. The changes caused in the SMC triglyceride contents are shown in Figure 4. In the cholesterol-SMC cultures, there was an increase in triglycerides compared to the control-SMC. The triglyceride concentration of both the control-SMC and the cholesterol-SMC cultures increased during the first 18 d but decreased slightly afterward.

Although the SMC cholesterol content (Fig. 4) was the same and constant in both lines of cultures during the first

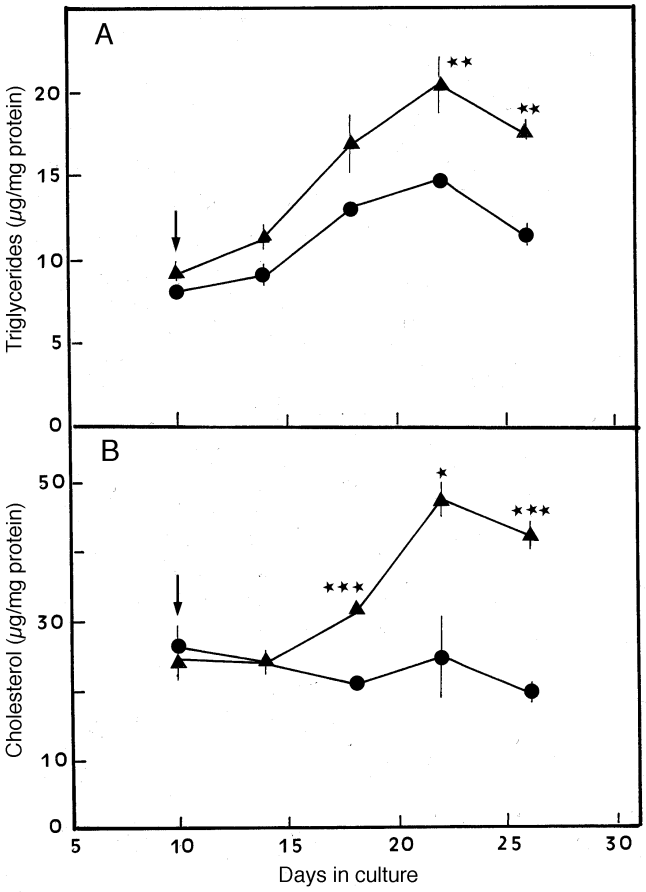

FIG. 4. Evolution of intracellular concentration of triglycerides (A) and cholesterol (B) during the period of culture. Control-SMC (●) and cholesterol-SMC (▲). After 10 d of explants, culture cells were seeded out in 150-cm^2 cell culture flasks (approximately 2.5×10^6 cells/flask), in 10 mL of Dulbecco's modification of Eagle's medium and 10% fetal calf serum (FCS). The arrows indicate the 0 d of culture of SMC (first passage). Results are expressed as means ± SEM of three determinations. $^*P < 0.05$, $^{**}P < 0.001$, $^{***}P < 0.0001$. For abbreviation see Figure 1.

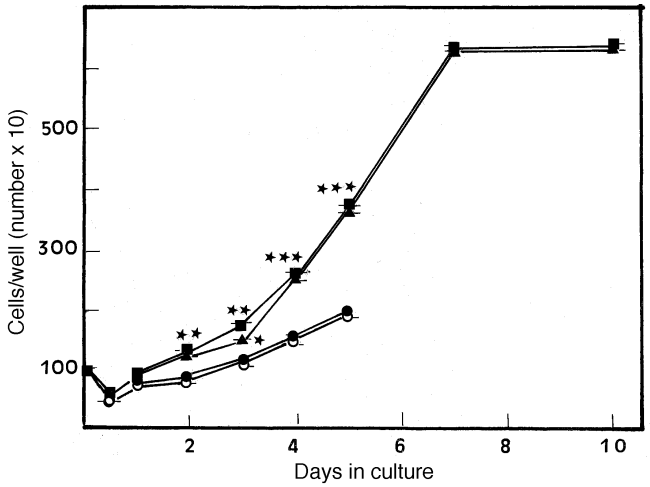

FIG. 5. Growth curves of SMC cultures derived from arteries: aortic arch from C_{10} (●); aortic arch from T_{10}-5% (▲); aorto-iliac bifurcation from C_{10} (○); aorto-iliac bifurcation from T_{10}-5% (■). Results are expressed as means ± SEM of three determinations. $^*P < 0.05$, $^{**}P < 0.001$, $^{***}P < 0.0001$. For abbreviation see Figure 1.

14 d, the cholesterol-SMC increased afterward, rising to more than double the control-SMC after 22 d of culture.

Cell number and proliferation. We tested growth curves of four different SMC cultures obtained from the aortic arch and aorto-iliac bifurcation of control chicks and cholesterol-fed chicks. The growth curves were made by counting the number of cells. Analysis of growth curves (Fig. 5) showed that after a lag phase of 12 h the number of cells began to increase in the same way in the four SMC cultures. Both cholesterol-SMC from the aortic arches and those from the aorto-iliac bifurcation arteries began to increase at approximately double the rate of the control-SMC cultures.

Macromolecule synthesis in SMC cultures. Macromolecule synthesis in synchronized SMC cultures is shown in Figure 6, where the differences in DNA (A), RNA (B), and protein (C) synthesis can be seen between control-SMC and cholesterol-SMC cultures. As the maintenance of the two lines of cultures was the same, the differences in macromolecule synthesis must be due to the transformation of the SMC *in vivo* caused by cholesterol feeding. There was a minor effect on RNA synthesis compared to both DNA and protein synthesis, both of which increased substantially in the cholesterol-SMC cultures.

The DNA and protein biosynthesis peak occurred 8 h after the supplementation with 10% serum, the synthesis of DNA in cholesterol-SMC becoming fourfold more than that in the control-SMC cultures.

DISCUSSION

Arterial SMC proliferation is an important early event in atherosclerosis (2). Hypercholesterolemia develops atherosclerotic plaques in roosters fed upon a high-cholesterol diet (26–29). Thus, in this report we have focused our attention on developing a model of avian SMC cultures, isolated from control and cholesterol-fed chicks. These two lines of SMC were kept in culture under identical conditions to compare the molecular changes in SMC in the arterial wall *in vivo* induced by cholesterol. We have concluded that cholesterol feeding triggers proliferation of SMC. High-cholesterol blood concentration is a known cardiovascular risk factor, and for this reason a study of the effects of hypercholesterolemia on the behavior of vascular SMC in culture has been the main aim of our study.

The aortic arches of male chicks were chosen for this study for two reasons: first, for the ability of chicks to absorb high amounts of dietary cholesterol (39,40); and second, because intimal thickening in the aortas from these hypercholesterolemic chicks can be detected after only 20 d (41,42). This short diet period is very convenient and contrasts with those reported for other experimental animal models, mainly non-human primates (43) and rabbits (21), which must be fed a cholesterol-containing diet for between 1 and 18 mon to ob-

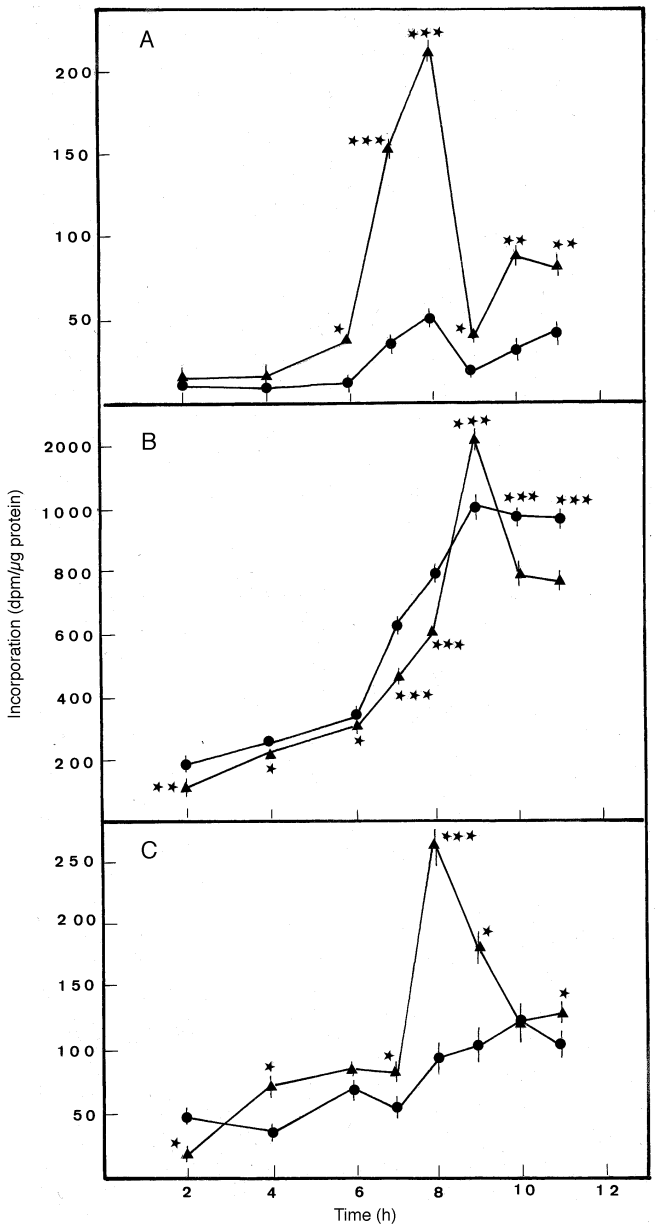

FIG. 6. SMC macromolecule synthesis. SMC were seeded out in 25-cm^2 cell culture flasks (approximately 0.5×10^6 cells/flask). Cells were grown in Dulbecco's modification of Eagle's medium supplemented with 10% (vol/vol) FCS. In log. linear (50% confluence) cultured cells were synchronized by serum deprivation (0.2% FCS during 48 h). For details see the Materials and Methods section. After the FCS stimulation, the cells were collected every hour and the [^{3}H]-*d*-thymidine incorporation into DNA for 15 min (A); [^{3}H]uridine incorporation into RNA for 15 min (B); and [4,5-^{3}H]leucine incorporation into proteins for 30 min (C) were determined in control-SMC (●) and cholesterol-SMC (▲). Results are expressed as means ± SEM of three experiments. $^*P < 0.05$, $^{**}P < 0.001$, $^{***}P < 0.0001$. For abbreviations see Figures 1 and 4.

tain an atherosclerotic lesion. The short time of the chicken model is comparable with that necessary to induce mitotic activity in aortas of white carneau pigeons or swine (44,45). The high serum cholesterol levels observed in 10-day-old control chicks is normal because newly hatched chickens reabsorb the yolk during the first week of life (46), thus developing hypercholesterolemia, which becomes almost three times higher in cholesterol-fed chicks. The significantly elevated cholesterol and triglyceride plasma levels are in accordance with previously reported plasma lipids levels (39,47).

Our research has shown that medial SMC from chick aorta undergoes changes in primary culture when it is obtained from 10-day-old chicks fed on a 5% cholesterol diet compared to SMC cultures from control chicks. Although morphological and ultrastructural studies of the aortas before the explants for the cultures were performed did not show any apparent differences, the behavior of the cells in the cultures was very different. The migration of the cells from the explants was much faster in the cholesterol-SMC than in the control-SMC cultures. In addition, after 4 d in culture, the proliferation rate of the cholesterol-SMC in culture was twofold compared to the control-SMC, as measured by the number of cells. This difference in the proliferation is comparable with that described elsewhere between human SMC from nonatherosclerotic arteries and atheromatous plaques (48).

Furthermore, DNA synthesis was four times greater in the cholesterol-SMC than in the control-SMC in the S phase at 8 h of culture. The change in the DNA synthesis profile observed between the two lines of SMC cultures agrees with the differences presented in the growth rates of the cultures expressed by the growth curves and population doubling per day. These observations are in close accord with the data from SMC cultures obtained directly from human atheromatous plaque (49) and with another arteriosclerosis experimental model made by cultures of SMC derived from atherosclerosis-susceptible pigeons (50). Synchronization procedures frequently introduce abnormalities into the cell cycle, particularly with chemical agents such as thymidine and hydroxyurea (37), and so we used serum deprivation to arrest the cells at the start of DNA replication (S phase). Only deprivation for 48 h resulted in satisfactorily synchronized cell cultures. Serum deprivation for 12 or 24 h resulted in randomly growing cells (nonsynchronized).

The proliferation and DNA synthesis profiles of cholesterol-SMC are comparable with the tumorogenic properties found in transformed phenotype SMC of rats in long-term cultures (51,52) and the involvement of mutagen/carcinogen exposure in atherogenesis (53); to establish the effect of cholesterol feeding we have shown the differences vs. control-SMC.

Progressive thickening of the intima and development of atherosclerotic changes can be observed by electron microscopy after 20 d of 5% cholesterol-feeding chicks (T_{20}-5%), similar to that which has been found in a previous accelerated arteriosclerosis study (54), which showed a proliferation of spindle-shaped cells and an increase in the amount of fibrous connective tissue and lipid vacuoles in the cells. Nevertheless, electron microscopy of the arteries after 10 d of 5% cholesterol feeding (T_{10}-5%) did not yet show any lipid droplet accumulation. Thus, we report cholesterol treatment of a period as short as 10 d in the belief that this chick SMC cultures model is suitable for study at a molecular level for a very early atherogenesis process.

While we did not find any differences in the concentration of intracellular cholesterol between control-SMC and cholesterol-SMC during the first 14 d of culture, we have found clear differences after 15 d, this amount was doubled in cholesterol-SMC after 20 d. These results are consistent with our aim of isolating SMC from the arteries prior to the transformation into foam cells, and they agree well with the electron microscopy analysis, which showed a very similar morphology between arterial control and cholesterol-fed chicks after 10 d of treatment (Fig. 1B,C). Nevertheless, cholesterol-SMC developed the characteristics of macrophage-like foam cells after 30 d in culture under the same culture conditions as the control-SMC (Fig. 2). All of these results demonstrate a higher interiorization of cholesterol in the cholesterol-SMC than in the control-SMC cultures. Further studies on cholesterol metabolism will be necessary to look into this. SMC *in vivo* were shown to increase cholesterol biosynthesis significantly and decrease the intracellular cholesterol efflux associated with phenotype changes in SMC in culture (22,23). In this work, however, we are making a comparison with a control-SMC which underwent the same phenotype modulation in culture as the cholesterol-SMC. Thus, the changes found between the two lines of cultures must be due to cholesterol feeding of the chicks, and this suggests that the high-cholesterol diet might induce changes in the expression of the genes related to lipid metabolism, or greater expression of the low density lipoprotein-receptor gene, or perhaps the expression of a scavenger receptor similar to the ones that convert macrophages into foam cells (55). In addition, the great amount of collagen secreted into the cholesterol-SMC cultures (Fig. 1B) may also explain the formation of SMC foam cells. Collagen binds many molecules (56,57), including oxidized low density lipoprotein (58), which is deposited in collagen-rich tissues such as atherosclerotic plaques. The scavenger receptor might compete with collagen for binding oxidized low density lipoprotein (59). In fact, the formation of characteristic foam cells in arterial smooth muscle cells growing in cultures was very difficult to achieve except in cells growing on elastin membranes (24).

Despite all these molecular changes, it is possible that in feeding the animals with a cholesterol-rich diet we are selecting one of two different phenotypes that exist in the normal chicken aorta (26). This possibility could agree with the monoclonal hypothesis as to the origin of atherosclerotic plaques (60). In any case, SMC cultures from cholesterol-fed chicks show a "transformed" SMC and are a good model to study this and other questions concerning the alterations of the differentiated state of SMC caused by a cholesterol-rich diet in vascular disease. Further studies will be necessary to characterize these SMC cultures and to determine how the cholesterol-rich diet might cause molecular and genetic changes that trigger the transformation of the SMC in the atherogenic process induced by cholesterol.

ACKNOWLEDGMENTS

This work was supported partly by a grant from DGICYT (PB93-1160) and also from the Research grant from the Junta de Andalucía (Group code 3229). Electron microscopy was done at the Centro de Instrumentación Científica at the University of Granada. We thank our colleague Dr. J. Trout for revising the English text.

Catalytic Properties of Allene Oxide Synthase from Flaxseed (*Linum usitatissimum* L.)

Claus Schneider and Peter Schreier*

Lehrstuhl für Lebensmittelchemie, Universität Würzburg, D-97074 Würzburg, Germany

ABSTRACT: We investigated the catalytic and kinetic properties of allene oxide synthase (AOS; E.C. 4.2.1.92) from flaxseed (*Linum usitatissimum* L.). Both Michaelis constant and maximal initial velocity for the conversion of 9(*S*)- and 13(*S*)-hydroperoxides of linoleic and linolenic acid were determined by a photometric assay. 13(*S*)-Hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD] as the most effective substrate was converted at 116.9 ± 5.8 nkat/mg protein by the flax enzyme extract. The enzyme was also incubated with a series of variable conjugated hydroperoxy dienyladipates. Substrates with a shape similar to the natural hydroperoxides showed the best reactivity. Monoenoic substrates as oleic acid hydroperoxides were not converted by the enzyme. In contrast, 12-hydroperoxy-9(*Z*),13(*E*)-octadecadienoic acid was a strong competitive inhibitor for AOS catalyzed degradation of 13(*S*)-HPOD. The inhibitor constant was determined to be 0.09 μM. Based on these results, we concluded that allene oxide synthase requires conjugated diene hydroperoxides for successful catalysis. Studying the enantiomeric preference of the enzyme, we found that AOS was also able to metabolize (*R*)-configurated fatty acid hydroperoxides. Conversion of these substrates into labile allene oxides was confirmed by steric analysis of the stable α-ketol hydrolysis products.

Lipids 33, 191–196 (1998).

Allene oxide synthase (AOS; hydroperoxide dehydratase, E.C. 4.2.1.92) is one of the key enzymes involved in the plant lipoxygenase pathway. This fatty acid metabolic pathway is assumed to be present in all plants (1). Formerly, allene oxide synthase was named "hydroperoxide dehydrase" (2) and, even before, "hydroperoxide isomerase" when it was first discovered in 1966 (3). Indeed, all three names offer aspects of the enzyme's catalytic properties. In plants, AOS is the second enzyme in the biosynthetic route leading to the plant hormone jasmonic acid. The starting substrate, linolenic acid, is oxygenated by lipoxygenase (LOX; E.C. 1.13.11.12) using molecular oxygen to yield 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid [13(*S*)-HPOT] (4). The resulting fatty acid hydroperoxide is dehydrated by AOS to form an intermediate, extremely labile allene oxide [12,13(*S*)-epoxy-9(*Z*),11,15(*Z*)-octadecatrienoic acid] (2,5). This intermediate compound, in turn, is cyclized enantioselectively into 9(*S*),13(*S*)-12-oxo-phytodienoic acid by allene oxide cyclase (6). Consecutive reduction and threefold β-oxidation yield the plant hormone jasmonic acid (4). Due to its instability, the allene oxide is also hydrolyzed by nucleophils such as water or methanol (7). The resulting products exhibit mainly an α-ketol structure [12-oxo-13-hydroxy-9(*Z*),15(*Z*)-octadecadienoic acid], which initially was thought to result from direct enzymatic isomerization of the hydroperoxide (8). To a lesser extent, and depending on pH (9), there occurs also a γ-ketol structure [9-hydroxy-12-oxo-10(*E*),15(*Z*)-octadecadienoic acid] during hydrolysis of the allene oxide.

The first AOS described was the enzyme from flaxseed (*Linum usitatissimum* L.) (3). The purified enzyme was proved to be a specialized type of cytochrome P450 (*CYP74A*) by ultraviolet (UV) spectroscopy (10) and its amino acid sequence (11). Veldink and coworkers (12) have described flaxseed AOS to be specific for the 13-regioisomers of linoleic and linolenic acid hydroperoxides, whereas Feng and Zimmerman (13) have reported also the conversion of the 9-regioisomers, certainly by about 36-fold decreased maximal velocity. Baertschi *et al.* (14) reported that flaxseed AOS preferentially converted the (*S*)-enantiomer of a racemic mixture of 13-linolenic acid hydroperoxides. Based on these findings, we attempted to reinvestigate some catalytic properties of AOS from flaxseed using a broad series of different hydroperoxide substrates. In addition, we checked the enantiomeric preference of the enzyme against racemic mixtures of linoleic and linolenic acid hydroperoxides.

MATERIALS AND METHODS

Chemicals. Linoleic acid (99% pure) and (−)-menthoxychloroformate were purchased from Fluka (Neu-Ulm, Germany). Linolenic acid (99% pure) and soybean lipoxygenase (type I-

S, L-8383) were from Sigma (Steinheim, Germany). High-performance liquid chromatography (HPLC) grade solvents, hexane, methanol, ethanol, *iso*-propanol, tetrahydrofuran (THF), and water were obtained from Merck (Darmstadt, Germany), and acetic acid from Baker Chemicals (Deventer, The Netherlands). All other chemicals were of analytical grade quality; solvents were redistilled before use.

Enzyme preparations. For preparation of AOS flaxseed (*L. usitatissimum* L.) (obtained from local market) was homogenized and the fine powder defatted with cold hexane. After evaporating the solvent *in vacuo*, the powder (80 g) was extracted with 800 mL of 0.1 M phosphate buffer (pH 7.0) at 0°C for 1 h. After centrifugation (15000 × *g*, 20 min), the supernatant was saturated up to 50% with solid ammonium sulfate and stirred for 1 h at 0°C. The precipitate was collected by centrifugation, dissolved in 50 mL of 0.1 M phosphate buffer (pH 7.0), and dialyzed overnight against the same buffer. As shown by gas chromatography–mass spectrometry (GC–MS) analysis of products formed upon incubation, the hydroperoxide degradation activity was caused by AOS in the enzyme preparation. We did not detect the aldehydes as formed by the hydroperoxide lyase-catalyzed cleavage of substrates.

LOX isoenzymes L-2 and L-3b were purified from soybean seeds (*Glycine max* L. cv. Mapple Arrow) as described before (15) and freeze-dried after addition of 0.1 M sodium chloride for storage. Tomato (*Lycopersicon esculentum* Mill.) LOX was prepared according to the procedure described (16).

Protein was measured by the bicinchoninic acid method (17), using bovine serum albumin as standard protein.

Enzyme assay. AOS activity was monitored in a double-beam recording UV spectrophotometer (DMR21; Carl Zeiss, Oberkochen, Germany) at 234 nm (18). The assays were conducted at constant ambient temperature (22°C) in 2 mL of 0.1 M Tris-HCl buffer pH 7.4 in a 1-cm path-length quartz cuvette. Substrates were taken from 15-mM stock solutions in ethanol. Additional ethanol was added up to a constant concentration of 20 μL per cuvette. Absorbance was recorded for 2 min after addition of 20 μL [for 13(*S*)-hydroperoxides] or 50 μL [for 9(*S*)-hydroperoxides], respectively, of the dialyzed and diluted (1:80) enzyme solution. AOS activity was quantified as the initial rate of decrease in 234 nm absorbance. One unit (kat) is defined as conversion of 1 nmol of hydroperoxide substrate per second as measured in the photometric assay using the molar extinction coefficient of 25,000 $M^{-1}cm^{-1}$ for all conjugated hydroperoxides. Kinetic data were obtained from assays that used 0–80 μM substrate concentrations.

For inhibitor assays, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD] (0–60 μM) and 12-HPOD (0, 0.13, and 0.26 μM; taken from 0.13 mM stock solution in ethanol) were given individually into the cuvette. Again, the ethanol concentration was kept constant at 20 μL in the cuvette by adding additional ethanol when appropriate. Reaction was started by adding 40 μL of 1:80 diluted enzyme solution and was measured photometrically.

Preparation of hydroperoxide substrates. Linoleic {9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HPOD] and 13(*S*)-HPOD} and linolenic {9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid [9(*S*)-HPOT] and 13(*S*)-HPOT} acid hydroperoxides were prepared as described previously using tomato and soybean LOX (16).

Enantiomeric 9- and 13-HPOD and -HPOT were obtained by enzymatic oxygenation of the fatty acids with soybean LOX isoenzymes L-2 and L-3b, respectively. One hundred mg of fatty acid was dissolved in 5 mL of ethanol and poured into 300 mL of 0.1 M phosphate buffer (pH 6.5). After the solution was saturated with oxygen, 10 mg of freeze-dried LOX (L-2 and L-3b, respectively) was added. The oxygenation was allowed to proceed for 2 h and was then terminated by lowering the pH to 3. After saturation with sodium chloride, the products were extracted with three portions of diethyl ether. Products were purified by column chromatography on silica gel (1 × 20 cm) using hexane/EtOAc/HOAc (85:15:1, by vol) as eluent. Regioisomers were separated by normal-phase HPLC on a preparative column (Lichrospher Si 60, 250 × 16 mm, 5 μm; Knauer, Berlin, Germany) with hexane/EtOH/HOAc (100:2:0.5, by vol) at a flow rate of 7.5 mL/min. Chromatography was monitored at 234 nm.

12-Hydroperoxy-9(*Z*),13(*E*)-octadecadienoic acid (12-HPOD) was prepared by singlet oxidation of linoleic acid (19). A 50 mL solution of 50 mg linoleic acid and 20 mg methylene blue in methanol was placed in a Pyrex photolysis well equipped with a side arm that allowed bubbling of oxygen gas through the solution during photolysis (300 W). The reaction mixture was cooled at −10°C. After photolysis was completed (24 h), the solvent was removed *in vacuo*, the residue was diluted in diethyl ether and purified by column chromatography on silica gel (1 × 20 cm) using hexane/EtOAc/HOAc (85:15:1, by vol) as eluent. The pooled hydroperoxide fraction was further purified by analytical scale normal-phase HPLC. Separation was performed on a 250 × 4 mm Eurospher Si 100 column (5 μm, Knauer, Berlin, Germany) with hexane/*iso*-PrOH/HOAc (100:1:0.1, by vol) as mobile phase at 1 mL/min flow rate. The UV detector was set at 205 nm.

For the synthesis of 9-hydroperoxy-10(*E*)-octadecenoic acid (9-HPOE) and 10-hydroperoxy-8(*E*)-octadecenoic acid (10-HPOE), oleic acid (50 mg) was diluted in 100 mL dichloromethane and poured into the photolysis well. After the addition of 2 mg of tetraphenylporphin, the solution was cooled to −10°C and bubbled through with oxygen. After 24 h of photolysis (300 W), the solvent was removed *in vacuo*; product work-up was carried out as described above.

The variable conjugated 3′(*Z*),5′(*E*)-7′-hydroperoxides **1b**–**5b** were obtained by soybean LOX-1 oxygenation of the corresponding 3′(*Z*),6′(*Z*)-pentadienes **1a**–**5a** (20). Work-up procedure of the products was performed as described above. The substrates for kinetic analyses (0–60 μM in 2 mL of 0.1 M Tris-HCl pH 7.4) were taken from 10 mM ethanolic stock solutions without further separation of regioisomers (or enantiomers). In the photometric assays, 50 μL of a 1:10 dilution of the dialyzed flax extract was used.

Chiral-phase HPLC of fatty acid hydroperoxides was carried out after reduction ($NaBH_4$) and methylation (etheral diazomethane) of the purified positional isomers. Enantiomers were separated by chiral-phase HPLC using a slightly modified procedure (21) for separation of methylated hydroxy-octadecadienoates. We used a Chiralcel OB-H column (250 × 4 mm, 5 µm; Daicel, Baker Chemicals) eluted with hexane/*iso*-PrOH 100+7 (by vol) at 0.5 mL/min flow rate.

Conversion of fatty acid hydroperoxides with AOS. Hydroperoxide samples in 5 mg amounts were incubated at ambient temperature with 7 mL of dialyzed flax extract in 100 mL of 0.1 M Tris-HCl buffer pH 7.4 constantly flushed with nitrogen. The following hydroperoxides were incubated individually: 13(*S*)- and 9(*S*)-HPOD, 13(*S*)- and 9(*S*)-HPOT, and enantiomeric 9- and 13-HPOD and -HPOT from L-2 and L-3b oxygenation of linoleic and linolenic acids, respectively. All products were extracted with diethyl ether after a reaction time of 15 min and termination with HCl up to pH 3.

For reversed-phase HPLC analysis of substrates and products a Spherisorb ODS2 column (250 × 4 mm, 5 µm; Knauer) was eluted with THF/methanol/water/HOAc (18:48:33.9:0.1, by vol) at 0.8 mL/min flow rate. Chromatography was monitored at UV 205 nm.

Steric analysis of ketol products. Steric analysis of the ketol products was carried out according to the procedure described by Hamberg (2). Briefly, 500 µg of the reaction products was taken up in 100 µL dry toluene, 20 µL dry pyridine and 100 µL (−)-menthoxychloroformate (1 µmol/µL in dry toluene), and incubated for 3 h at 60°C. The solvents were removed under a stream of nitrogen, and the material was dissolved in 300 µL acetic acid and treated with 15 mg $KMnO_4$ at 37°C for 1 h. The solution was diluted with brine and extracted with diethyl ether; the residue obtained after drying and evaporation was treated with etheral diazomethane. Authentic (*S*)-standards of methyl-2-hydroxy-heptanoate and dimethyl-2-hydroxy-sebacate were prepared by incubation of linoleic acid with soybean (Sigma) or tomato LOX, respectively. Resulting 13(*S*)- and 9(*S*)-HPOD were reduced with sodium borohydride, derivatized with (−)-menthoxychloroformate, cleaved by oxidative ozonolysis and finally methylated. Racemic and (*S*)-malic acid were also derivatized with (−)-menthoxychloroformate and methylated. GC analysis was performed on a Hewlett Packard 5890 series II gas chromatograph equipped with a J&W DB-Wax column (15 m × 0.25 mm) (Folsom, CA) programmed from 50°C (3 min) to 240°C (15 min) at 4°C/min. GC–MS (EI, 70 eV) was performed on a Finnigan MAT44S (San Jose, CA) directly connected to a Varian (Palo Alto, CA) Aerograph 1440 gas chromatograph using identical GC conditions.

RESULTS

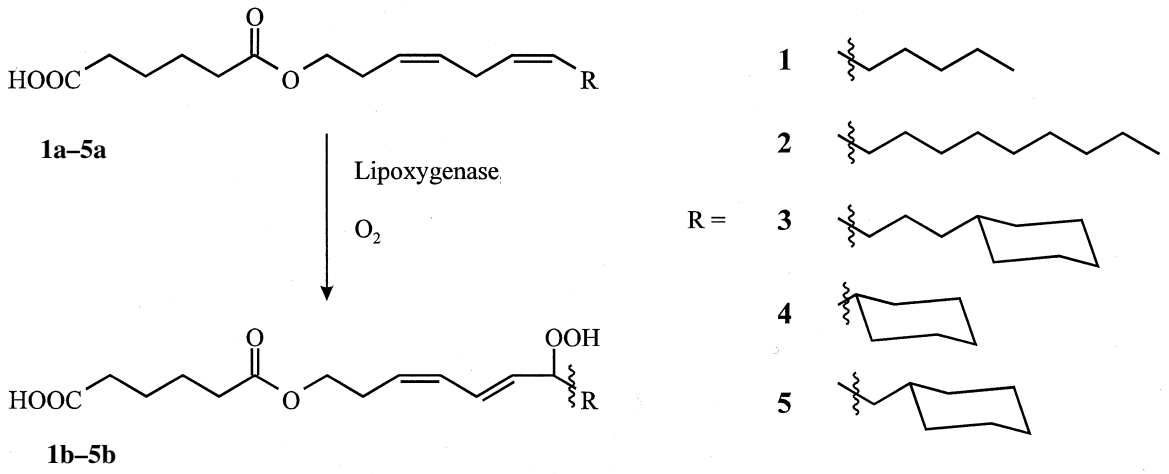
AOS kinetics. The spectrophotometric assay as described by Brash and Song (18) was used. The kinetic data for enzymatic dehydration of the four fatty acid hydroperoxides under study are summarized in Table 1. With a maximal initial velocity V_{max} of 116.9 ± 5.8 nkat/mg protein and a Michaelis constant K_m of 8.4 ± 1.2 µM, 13(*S*)-HPOD was the most effective substrate for flaxseed AOS. The 9-isomeric hydroperoxides reacted at comparable K_m but reduced V_{max}. We did not observe first-order kinetics for the substrate 13(*S*)-HPOT, but rather a sharp maximum of activity around 5 µM substrate that declined rapidly at concentrations higher than 10 µM, suggesting a mixture of overlapping enzymatic activities. This was probably caused by allene oxide cyclase which is also present in the flaxseed enzyme preparation (6). Allene oxide cyclase from corn (*Zea mays* L.) kernels was most effective at concentrations of 3–10 µM 13(*S*)-HPOT (6) and therefore would contribute noticeably—in addition to allene oxide hydrolysis—to the decline in absorbance at 234 nm. The enzymatic product, 9(*S*),13(*S*)-12-oxo-phytodienoic acid, contributes absorbance at 234 nm at a lesser extent than 13(*S*)-HPOT.

TABLE 1
Maximal Initial Velocity (V_{max}) and Michaelis Constant (K_m) for the Allene Oxide Synthase Catalyzed Dehydration of Fatty Acid Hydroperoxides[a,b]

Substrate	Maximal initial velocity (nkat/mg protein)	Michaelis constant (µM)
13(*S*)-HPOD	116.9 ± 5.8	8.4 ± 1.2
13(*S*)-HPOT	n.d.	n.d.
9(*S*)-HPOD	3.3 ± 0.05	3.4 ± 0.4
9(*S*)-HPOT	3.3 ± 0.17	8.6 ± 1.4

[a]The kinetic data were obtained by the photometric assay as described in detail in the Materials and Methods section. Substrates were used in 0–60 µM concentration in 2 mL 0.1 M Tris-HCl pH 7.4; the dialyzed flaxseed extract (2 mg/mL protein) was diluted 1:80 and 20 µL (for 13-isomers) or 50 µL (for 9-isomers) was used. All values are averages of a triplicate.
[b]Abbreviations: 9(*S*)-HPOD, 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid; 13(*S*)-HPOD, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid; 9(*S*)-HPOT, 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid; 13(*S*)-HPOT, 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid; n.d., could not be determined.

Enzymatic conversion of variable conjugated 3′(Z),5′(E)-7′-hydroperoxides. Conjugated hydroperoxydienes **1b**–**5b** were obtained by enzymatic oxidation of the corresponding 3′(*Z*),6′(*Z*)-dienes **1a**–**5a** with soybean LOX-1 (Scheme 1) (20). Steric analysis of the hydroperoxy products (see Ref. 20) revealed a 4:1 ratio of 7′- to 3′-hydroperoxides for all substrates. The ratio of (*S*)- to (*R*)-enantiomer was about 80:20. The hydroperoxides were used in the photometric assay without further purification. The kinetic data of AOS catalyzed dehydration are summarized in Table 2. In this series, hydroperoxide **1b** is an analogon to 13(*S*)-HPOD, having a similar distal and proximal carbon chain length. Also, it was the substrate out of this series with lowest K_m (6.8 ± 1.0 µM) which was comparable to 13(*S*)-HPOD and highest V_{max} (26.7 ± 2.2 nkat/mg protein). Elongation of the distal carbon chain length (**2b**) led to depletion of the enzymatic reaction. When a bulky residue (substrates **4b** and **5b**) was connected directly to the conjugated hydroperoxy diene, there was no conversion of the substrates at all. Only when the cyclohexyl ring was moved in the distal direction (**3b**) was the enzymatic activity restored.



SCHEME 1

Inhibition of AOS activity. Photosensitized oxygenation of linoleic acid yielded a mixture of racemic 9-, 10-, 12-, and 13-hydroperoxy-octadecadienoic acids. Attempts to convert this crude substrate mixture with the flaxseed extract failed due to complete inhibition of enzymatic activity. We supposed one of the positional isomers to be responsible for the inhibition. Consequently, the substrate mixture was separated by normal-phase HPLC into the four hydroperoxy isomers by multiple injection. Purified 12-hydroperoxy-9(*Z*),13(*E*)-octadecadienoic acid was tested for its ability to inhibit AOS. K_m and V_{max} for the dehydration of 13(*S*)-HPOD were determined at different fixed initial concentrations (0, 0.13, and 0.26 mM) of 12-HPOD in the photometric assay. As outlined in Table 3, increasing amounts of 12-HPOD led to increased values for K_m', whereas V_{max} was not or was only slightly affected. K_m' is indicated as apparent K_m in the presence of an initial concentration [I] of the inhibitor 12-HPOD. A Lineweaver-Burk plot of the obtained data (Fig. 1) showed typical criteria of a competitive inhibition: point of intersection of all three straight lines (0, 0.13, and 0.26 mM 12-HPOD) at $1/V_{max}$ with the y-axis and intersection at different $-1/K_m'$ with the abscissa. The inhibitor constant K_i was determined by a graphical method using secondary plots. Both types of secondary plots revealed a K_i of 0.09 μM 12-HPOD for the inhibition of AOS activity against 13(*S*)-HPOD.

Conversion of enantiomeric fatty acid hydroperoxides. Enantiomeric preference of AOS was studied using racemic fatty acid hydroperoxides derived from linoleic and linolenic acid. Enzymatic synthesis with LOX isoenzymes from soybean resulted in different enantiomeric compositions of the hydroperoxide products (Table 4). Only L-3b oxygenation yielded a genuine racemate for both 9- and 13-hydroperoxides, while L-2 produced predominantly 13(*S*)-hydroperoxides. Nevertheless, all synthesized substrates were used for conversion with the flax enzyme extract. The applied enantiomers [9(*R*,*S*)- and 13(*R*,*S*)-HPOD and -HPOT] were completely converted by the enzyme within 15 min. Enzymatic utilization of the substrates was proved by reversed-phase HPLC and thin-layer chromatography (TLC) analysis after extraction of the reaction mixture.

In order to prove dehydration of the (*R*)-hydroperoxides into the corresponding allene oxides, we studied the stereochemistry of the resulting α-ketol hydrolysis products. It is known from literature (2) that pure (*S*)-hydroperoxides are

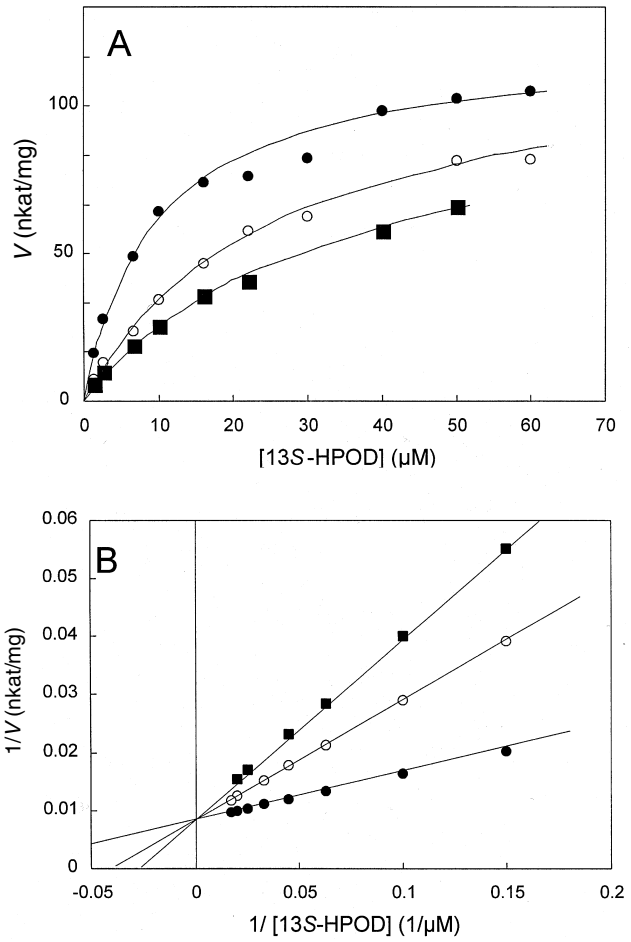

FIG. 1. Inhibition of allene oxide synthase catalyzed dehydration of 13(*S*)-HPOD by 12-HPOD. (A) Michaelis-Menten graph of *V* against [13(*S*)-HPOD] and (B) detail of the Lineweaver-Burk plot 1/*V* against 1/[13(*S*)-HPOD] at fixed concentrations of 12-HPOD (●, 0 μM, ○, 0.13 μM, and ■, 0.26 μM 12-HPOD). Abbreviations: 13(*S*)-HPOD, 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid; 12-HPOD, 12-hydroperoxy-9(*Z*),13(*E*)-octadecadienoic acid; V, reaction velocity; kat, one unit, defined as conversion of 1 nmol hydroperoxide molar extinction coefficient of 25,000 $M^{-1}cm^{-1}$ for all conjugated hydroperoxides.

converted *via* nonenzymatic allene oxide hydrolysis into α-ketols exhibiting 70:30 (*R*) to (*S*) configuration. Based on this knowledge, one may expect a 1:1 ratio for α-ketols when applying racemic substrates. The results from these studies are summarized in Table 4. As demonstrated for 13-HPOD, the pure (*S*)-enantiomer was dehydrated and hydrolyzed into an α-ketol exhibiting 72:28 (*R*) to (*S*) configuration. Increasing the amount of (*R*)-hydroperoxides in the substrate mixture up to 50% of total hydroperoxides increased, in parallel, the amount of (*S*)-ketol products from 28 to 51%. A similar tendency was observed with the 13-HPOT substrates (see Table 4).

When oleic acid hydroperoxides (9- and 10-HPOE) were incubated with the flaxseed extract, no conversion of the substrates was observed. This was proved by TLC and reversed-phase HPLC after various incubation procedures (results not illustrated).

[a]Five mg of each hydroperoxide was incubated with 14 mg of a dialyzed flaxseed protein extract in 100 mL of 0.1 M Tris-HCl pH 7.4 for 15 min. 13(*S*)-HPOD and -HPOT substrates contained about 5% of 9-hydroperoxides as estimated by analytical normal-phase high-performance liquid chromatography (HPLC). All (*R,S*)-hydroperoxides had been purified by preparative scale normal-phase HPLC and contained no 9-hydroperoxides.

[d]Enantiomeric composition determined by the gas chromatographic method as described in the Materials and Methods section.
[e]Obtained by L-2 oxygenation of fatty acid.
[f]Obtained by L-3b oxygenation of fatty acid.

DISCUSSION

We started our substrate studies by reexamining earlier work by Feng and Zimmerman (13) as well as by Veldink and coworkers (12). These authors have reported different results about the efficiency of 9-positional linoleic and linolenic acid hydroperoxides as substrates for flaxseed AOS. Our data confirm utilization of both 9- and 13-isomers by the enzyme, with the 9-isomer, however, being converted much more slowly. In fact, AOS reacted about 35 times faster with 13(*S*)-HPOD than with 9(*S*)-HPOD. The affinity of the substrates to the enzyme as shown by K_m was in the same range for the 13(*S*)- and 9(*S*)-hydroperoxides. The photometric assay we used was not suitable to determine the kinetic data of 13(*S*)-HPOT dehydration. We suppose this phenomenon to be caused by interference with allene oxide cyclase activity, which was also present in the enzyme preparation (22).

We extended the substrate investigations to a series of variable conjugated 3′(*Z*),5′(*E*)-7′-hydroperoxides. The chosen substrate feature allowed variations in the distal residue of the conjugated hydroperoxy diene moiety. Only those substrates with a shape similar to linoleic acid were converted at considerable rates by flax AOS.

The two oleic acid hydroperoxides, 9- and 10-HPOE, which show a monoene hydroperoxy moiety, were not converted into ketol fatty acids by the enzyme extract at all. This fact demonstrated the requirement of a 2,4-diene system conjugated to the hydroperoxy moiety for successful catalysis. Monoenoic fatty acid hydroperoxides do not serve as substrates for flaxseed AOS.

Interestingly, 12-HPOD was also no substrate for flax AOS. In fact, there is only one report in the literature about

the enzymatic conversion of 12-regioisomeric fatty acid hydroperoxides. Gardner and coworkers (23) have reported the cleavage of 12-HPOT by another fatty acid hydroperoxide degrading enzyme, hydroperoxide lyase, although the products of this reaction were not specifically defined. This substrate, however, also contains a conjugated hydroperoxy-diene moiety. When we incubated substrate mixtures containing 12-HPOD, we found no utilization of the substrates by the enzyme, but rather complete depletion of activity. Kinetic analyses revealed 12-HPOD as a strong competitive inhibitor of AOS. Like the oleic acid hydroperoxides, 12-HPOD does not exhibit a conjugated diene moiety. This also indicates the necessity of a conjugated hydroperoxy diene system for successful enzymatic conversion.

In order to prove dehydration of (*R*)-configurated hydroperoxides, mixtures of racemic regioisomeric HPOD and HPOT were incubated with AOS. By stereochemical analysis of the ketol hydrolysis products, we demonstrated the formation of (*R*)-configurated allene oxides by AOS. Using an excess of enzyme activity led to complete utilization of the substrates. This observation is in agreement with previous findings (14) in which enantiomeric selectivity for the (*S*)-enantiomers with sufficiently small amounts of enzyme has been described. Interestingly, a similar selectivity was reported recently for an enzyme named divinyl ether synthase from garlic bulbs (24). This activity dehydrated fatty acid hydroperoxides into a divinyl ether moiety. The enzyme reacted much more quickly with 13(*S*)-HPOD than with 13(*R*)-HPOD.

Positional Analysis of Triacylglycerols from Bovine Adipose Tissue Lipids Varying in Degree of Unsaturation

Stephen B. Smith*, Aijun Yang, Tom W. Larsen, and Ron K. Tume

CSIRO, Division of Food Science and Technology, Brisbane Laboratory, Tingalpa, Queensland, Australia 4173

ABSTRACT: The objective of this study was to demonstrate that changing the fatty acid composition of bovine adipose tissue concurrently changed (i) proportions of triacylglycerol species, (ii) fatty acid composition of triacylglycerol species, and (iii) positional distribution of the component fatty acids of the triacylglycerol species. To achieve this, we took advantage of adipose tissue lipids, from cattle fed in Australia and Japan, that varied widely in fatty acid composition and melting points. Treatment groups produced in Australia were cattle fed: a corn-based diet (MUFA1); a grain-based diet containing whole cottonseed (SFA); a grain-based diet containing protected cottonseed oil (PUFA); and a grain-based diet that resulted in high contents of *trans* fatty acids (TFA). Treatment groups produced in Japan (MUFA2 and MUFA3) were diets of unknown composition fed for over 300 d. The MUFA1, MUFA2, and MUFA3 samples all were rich in monounsaturated fatty acids, varying only in the proportions of the individual monounsaturates. The SFA, PUFA, and TFA samples had relatively high concentrations of stearic acid (18:0), PUFA, and TFA, respectively. Slip points (indicative of melting points) were 45.1, 41.5, 38.5, 30.7, 28.4, and 22.8°C, for the SFA, TFA, PUFA, MUFA1, MUFA2, and MUFA3 groups, respectively ($P < 0.05$). Triacylglycerols were separated by high-performance liquid chromatography on a silver nitrate-impregnated column into *sn*-1,2,3-saturated fatty acid triacylglycerol (SSS); [triacylglycerols containing two saturated acids and one *trans*-monounsaturated fatty acid (SSM*t* *sn*-positions unknown)]; *sn*-1-saturated, 2-monounsaturated, 3-saturated triacylglycerol (SMS); *sn*-1-saturated, 2-monounsaturated, 3-*trans*-monounsaturated triacylglycerol (SMM*t*); *sn*-1-saturated, 2,3-monounsaturated fatty acid triacylglycerol (SMM); *sn*-1-saturated, 2-polyunsaturated, 3-*trans*-monounsaturated triacylglycerol; *sn*-1,2,3-monounsaturated fatty acid triacylglycerol (MMM); and *sn*-1-saturated, 2-polyunsaturated, 3-monounsaturated triacylglycerol. Fatty acid methyl esters of each triacylglycerol species also were determined, and further analysis indicated *sn*-2, and *sn*-1/3 positions. As the percentage oleic acid increased in the total lipid extract, the proportions of SMM and MMM increased (e.g., from 31.4 and 2.4% in the SFA group to 55.4 and 17.8% in the MUFA3 group). The elevated 18:0 in the SFA group (26%) was reflected in increased percentages of SSS and SSM, and caused an increase in the proportion of 18:0 in all triacylglycerol species relative to the other treatment groups. The percentage of 18:0 in the *sn*-1/3 positions was elevated markedly in the SMS fraction of the SFA group (to 44%); this would account for the high melting point of the fat of these animals. We conclude that long-term feeding of cattle is sufficient to produce significant alterations in fatty acid composition in bovine adipose tissue. Alterations in the fatty acid composition of bovine adipose tissue changed both the distribution and the composition of the triacylglycerol species, which, in turn, accounted for marked differences in melting points among treatment groups.

Lipids 33, 197–207 (1998).

There is a renewed interest in the positional distribution of fatty acids within the triacylglycerol structure, as this appears to influence the metabolic effects of dietary fatty acids. For example, stearic acid (18:0) located in the *sn*-1/3 positions of triacylglycerols is absorbed poorly (1), which may explain its hypocholesterolemic nature. Also, there is a greater proportion of palmitic acid (16:0) in the *sn*-2 position of postprandial plasma, liver, and adipose tissue triacylglycerols in young piglets fed sow's milk (enriched with *sn*-2 16:0) than in piglets fed formula with 16:0 in the *sn*-1,3 position (2). Finally, the absorption of long-chain, polyenoic fatty acids apparently is not affected by positional distribution in triacylglycerols (3). Rather, the positional distribution of long-chain polyenoic fatty acids influences the rate of chylomicron clearance (4). These results suggest that positional distribution of fatty acids, in combination with their degree of saturation, could have a significant impact on the cholesterolemic nature of dietary fatty acids.

Cattle raised in Australia for the Japanese market are fed for long periods of time, and exhibit a high incidence of carcasses that are unacceptable for hand boning owing to excessively hard fat (5). Certainly, an increase in the adipose tissue concentration of 18:0 contributes to this problem (5,6). Re-

Abbreviations: HPLC, high-performance liquid chromatography; MMM, *sn*-1,2,3-monounsaturated fatty acid triacylglycerol; MUFA1, MUFA2, and MUFA3, samples containing elevated monounsaturated fatty acids; PUFA, samples containing elevated polyunsaturated fatty acids; SFA, samples containing elevated saturated fatty acids; SMM; *sn*-1-saturated, 2,3-monounsaturated fatty acid triacylglycerol; SMM*t*, *sn*-1-saturated, 2-monounsaturated, 3-*trans*-monounsaturated triacylglycerol; SMS, *sn*-1-saturated, 2-monounsaturated, 3-saturated triacylglycerol; SPM, *sn*-1-saturated, 2-polyunsaturated, 3-monounsaturated triacylglycerol; SPMt, *sn*-1-saturated, 2-polyunsaturated, 3-*trans*-monounsaturated triacylglycerol; SSM*t*, triacylglycerols containing 2 saturated and 1 *trans*-monounsaturated fatty acid (*sn*-positions unknown); SSS, *sn*-1,2,3-saturated fatty acid triacylglycerol; TFA, samples containing elevated *trans* fatty acids.

cently, it has become apparent that positional distribution of saturated fatty acids (SFA) also may be important in determining fat hardness. Placement of 18:0 in the outer position of triacylglycerols can increase the melting point by as much as 10°C relative to triacylglycerols with 18:0 solely in the *sn*-2 position (7). This may exacerbate the fat hardness problem in Australian beef production. To address this, lipid samples, obtained from cattle raised in Australia and Japan under widely varying production conditions (and differing by more than 20°C in melting point), were analyzed for proportions of individual triacylglycerol species and the fatty acid positional distribution of each of these species.

MATERIALS AND METHODS

Animals. Treatment groups were classified as: three groups whose fat contained relatively high levels of monounsaturated fatty acids, MUFA1 ($n = 4$), MUFA2 ($n = 6$), and MUFA3 ($n = 6$); a group whose fat contained relatively high levels of 18:0 (SFA, $n = 6$); a group whose fat contained relatively high levels of linoleic acid (18:2n-6) [polyunsaturated fatty acid (PUFA), $n = 4$]; and a group whose fat contained relatively high levels of 18:1*t*11 [*trans* fatty acid (TFA), $n = 4$]. The cattle were fed in either Australia (MUFA1, SFA, TFA, and PUFA) or Japan (MUFA2 and MUFA3). The MUFA1 cattle were fed a corn-based diet in southern Australia for approximately 300 d, whereas the SFA group was fed a grain-based diet containing approximately 10% whole cottonseed for >400 d. The PUFA group was fed casein-formaldehyde-protected cottonseed oil for 100 d, and the TFA cattle were fed a grain-based diet for 150 d. The diets of the cattle fed in Japan are unknown, but the cattle were fed these diets for as long as 2 yr postweaning. A typical finishing diet in Japan contains flaked corn, barley, wheat and/or rice bran, and soybean meal (8). The MUFA2 cattle were Murray Grey, whereas the MUFA3 cattle were purebred Japanese Black steers produced in the Osaka region. The MUFA1, SFA, TFA, and PUFA animals were typical crossbred Murray Grey, Angus, and Grey Brahman steers.

Assignment to treatment groups was based on previous measurements of total fatty acids on stored adipose tissue samples (Tume, R.K., unpublished observations). Sample groups were chosen to give as wide a range of fatty acid compositions as possible, although the MUFA groups also were separated based upon differences in breed type and production location. Each group represented a distinct location in Japan and/or a distinct production diet.

Slip points. Subcutaneous adipose tissue was collected from the loin region of carcasses after overnight chilling. Lipids were extracted into chloroform/methanol (9). Slip points were measured to verify that lipid extracts from each treatment group differed in hardness. Solvents were removed exhaustively by heating the lipid samples to 60°C under a nitrogen jet. The lipids were drawn 1 cm into capillary tubes while still warm. Triplicate capillary tubes were collected for each sample. The samples in the capillary tubes were stored overnight at 4°C, and then placed vertically in a chilled water bath. The temperature was increased gradually in the water bath (1–2°C/min), and the temperature at which the lipid began to move up the capillary tube (slip point) was recorded. Within-sample variation was less than 1%.

Separation of triacylglycerol species. Triacylglycerols were separated from the total lipid extracts into molecular species by silver ion high-performance liquid chromatography (HPLC) using the method of Christie (10). Triacylglycerol species were separated on a Nucleosil SA 5-micron silica column (Waters Corp., Milford, MA) (4.6 × 250 mm) impregnated with 5% silver nitrate using a Waters HPLC gradient system (Waters Corp.) coupled to an evaporative light-scattering detector (Varex Mark III; Alltech, Deerfield, IL). Approximately 30% of the column eluant passed through the detector, the remainder being split off for collection of individual fractions. The proportions of each triacylglycerol species were quantified using Waters Millennium software, and the mass of each fraction collected was calculated. Owing to the hardness of the SFA samples, the carousel chamber of the sample injector (Waters 717 Sampler Injector) was warmed to the keep the samples in solution prior to injection. For each animal, the triacylglycerol fractions were collected from 3–5 separate runs to provide enough lipid in each fraction (approximately 20 µg) to allow for analysis of fatty acid positional distribution.

Lipase digestion. Lipase digestions were as described (11,12) with modifications. Whereas Williams *et al.* (12) digested approximately 2 mg (2 µmol) lipid with 100–120 units lipase from *Rhizopus arrhizus* (Boehringer Mannheim, Indianapolis, IN), we digested at most 20 µg lipid with 200–250 units of lipase. The triacylglycerol fractions were dried and emulsified in 1 mL of buffer containing 1 mg/mL Triton X-100, 0.04 M Tris (pH 7.2). Borate (0.05 M) was included to reduce positional migration (12). The fractions were sonicated for 1–2 min to ensure complete emulsification. One-half of each fraction was transferred to a separate tube, to which was added approximately 200 units of lipase from *R. arrhizus*, which removes only the fatty acids in the *sn*-1/3 positions (11,12). The fractions were digested with lipase for 60 min at 37°C (increased from 30 min at 22°C; 12). That portion of the sample which did not receive lipase was incubated under the same conditions. Reactions were terminated by the addition of 0.5 mL 1 N acetic acid and 3 mL chloroform/methanol (2:1, vol/vol). The lipids were extracted three times with chloroform/methanol. Reaction conditions were tested with 5 to 200 µg total lipid; reducing the amount of lipid or digesting for longer periods of time did not increase enrichment at the *sn*-2 position.

Trans-*methylation.* The solvent portion, containing the lipids, was dried exhaustively under a nitrogen gas jet at 60°C to eliminate all traces of solvent and acetic acid, and the remaining glycerides were *trans*-methylated by incubating for 30 min at 65°C in 1 mL 0.1 N NaOH in methanol. Lipids were extracted with 3 × 3-mL vol of hexane. The hexane was evaporated, and the samples were redissolved in 200 µL

hexane. A total of 6 to 8 μL of each sample was used for gas–liquid chromatography for the analysis of fatty acid methyl esters. Fatty acid methyl esters were separated by gas chromatography [Shimadzu GC17 (Kyoto, Japan) with AOC17 autoinjector] using a 50 m × 0.25 mm glass capillary column (CP-Sil-88, ChromPak, Middleburg, The Netherlands) with nitrogen as carrier gas. The initial temperature was set at 150°C, incrementing at 5°C/min to 235°C and held at that temperature for 8 min. Fatty acids were identified by comparison of retention times with standards (Alltech).

The NaOH/methanol methylation procedure does not methylate nonesterified fatty acids. Therefore, the fatty acid composition of the lipase-digested and undigested (total) fractions was used to calculate the average composition of fatty acids in the *sn*-1/3 positions (12):

$$\text{average } sn\text{-}1/3\ \% = (3 \times \%\ \text{fatty acid in total lipids}) - (2 \times \%\ \text{fatty acid in } sn\text{-}2\ \text{position}) \quad [1]$$

Statistics. Data were analyzed by single-factor analysis of variance by the Super Anova program (Abacus Concepts, Inc., Berkeley, CA), with treatment group as the main effect. Means were separated by the Fisher's Protected LSD method contained in the same software program. Differences between means were considered significant at $P < 0.05$.

RESULTS

Total fatty acid compositions. The SFA group exhibited an unusually high percentage of 18:0 (26%), whereas the TFA group had a high concentration of 18:1*t*11 (11%; Table 1). Lipids from the MUFA1, MUFA2, and MUFA3 groups contained 49 to 53% oleic acid (18:1), and those of the MUFA1 and MUFA3 groups were especially high in palmitoleic acid (16:1; >5%). The PUFA group was remarkable for its high concentration of 18:2 (over 4%), which is unusual for bovine adipose tissue (13–15).

In general, lipase digestion resulted in an enrichment of 18:1 and 18:2 at the *sn*-2 position (Table 1). Conversely, 16:0 was enriched primarily at the *sn*-1/3 positions. As the percentage of 18:0 was increased by dietary regimen, the proportion of 18:0 observed in the *sn*-1/3 positions increased. The MUFA2 group was unique in that the *sn*-2 position was more enriched in 18:0 than the *sn*-1/3 positions.

Slip points. As anticipated, slip point temperatures were highest for the SFA and TFA groups (45.1 and 41.5°C, respectively; Table 1). The PUFA group displayed a relatively

[a]Means within a column for each fraction without a common superscript are different. Data are means for four (MUFA1, TFA, and PUFA) or six (MUFA2, MUFA3, and SFA) animals per treatment group. Some negative values occurred for the average *sn*-1/3 means when there was a low abundance of a particular fatty acid.
[b]MUFA1, MUFA2, MUFA3, samples containing elevated monounsaturated fatty acids; SFA, samples containing elevated saturated fatty acids; PUFA, samples containing elevated polyunsaturated fatty acids; TFA, samples containing elevated *trans* fatty acids; SD, standard deviation.

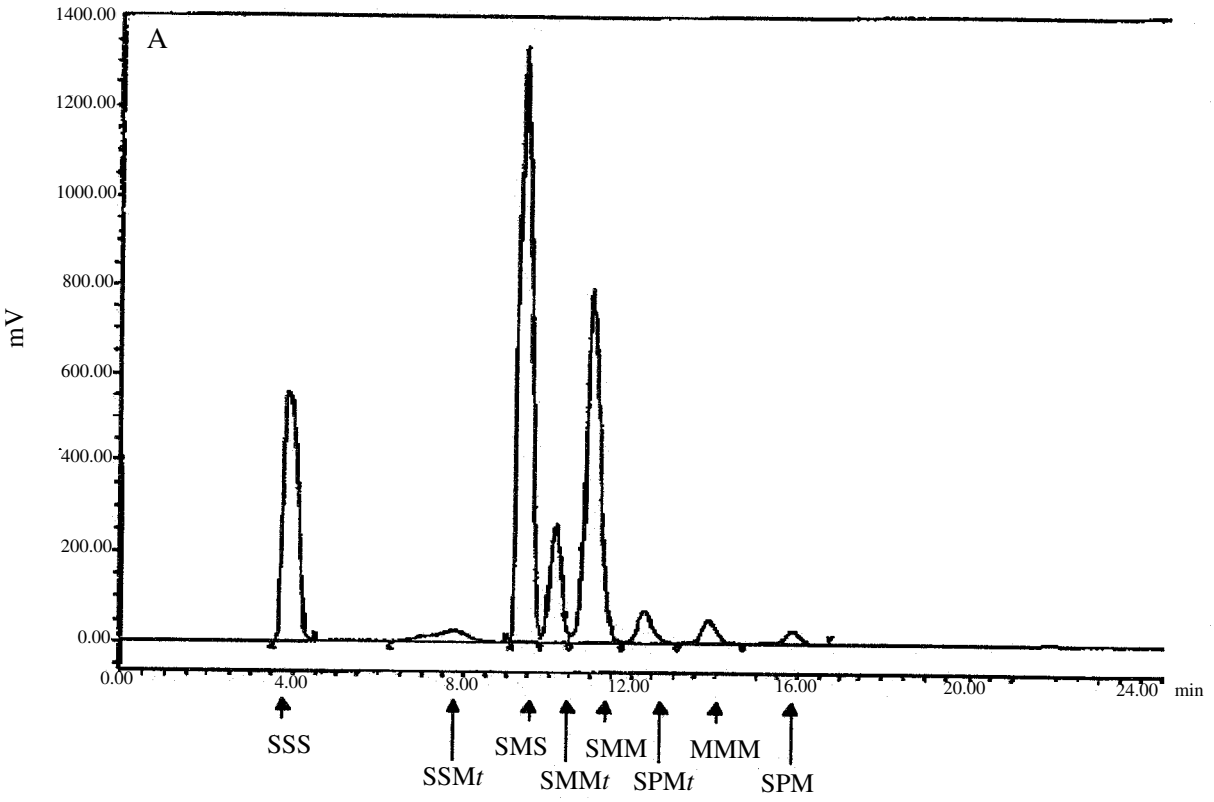

FIG. 1. Chromatograms from high-performance liquid chromatographic separation of triacylglycerol species from lipids extracted from SFA (A) and MUFA3 (B) adipose tissue tissue samples. Triacylglycerol species were separated on a Nucleosil SA 5-micron silica column (4.6 × 250 mm) impregnated with 5% silver nitrate. Abbreviations: SFA, samples containing elevated saturated fatty acids from long-fed Australian cattle; MUFA3, samples containing elevated monounsaturated fatty acids from long-fed Japanese Black cattle. Major positional species identified: SSS, *sn*-1,2,3-saturated fatty acid triacylglycerol; SSM*t*, triacylglycerols containing two saturated and one *trans*-monounsaturated fatty acid; SMS, *sn*-1-saturated, 2-monounsaturated, 3-saturated triacylglycerol; SMM*t*, *sn*-1-saturated, 2-monounsaturated, 3-*trans*-monounsaturated triacylglycerol; SMM, *sn*-1-saturated, 2,3-monounsaturated fatty acid triacylglycerol; SPM*t*, *sn*-1-saturated, 2-polyunsaturated, 3-*trans*-monounsaturated triacylglycerol; MMM, *sn*-1,2,3-monounsaturated fatty acid triacylglycerol; SPM, *sn*-1-saturated, 2-polyunsaturated, 3-monounsaturated triacylglycerol. The identities of the peaks are indicated below each chromatogram. The SSM*t* peak was undetectable in this MUFA3 sample. The MUFA3 sample was eluted several days after the SFA sample, and elution times had changed somewhat.

high slip point (38.5°C). The lowest slip point was exhibited by the MUFA3 group (22.8°C). The MUFA1 and MUFA2 samples were nearly identical in slip point temperatures.

Proportions of triacylglycerol species. The order of elution of triacylglycerols from the HPLC column was those containing: three saturated fatty acids (SSS); two saturated plus a *trans*-monounsaturated fatty acid, 18:1*t*11 (SSM*t*); two saturated plus a *cis*-monounsaturated fatty acid (SMS); one saturated plus a *cis*-monounsaturated fatty acid plus a *trans*-monounsaturated fatty acid (SMM*t*) (composition somewhat variable); one saturated plus two *cis*-monounsaturated fatty acids (SMM); one saturated plus a combination of polyunsaturated and *trans*- and *cis*-monounsaturated fatty acids (SPM*t*); three *cis*-monounsaturated fatty acids (MMM); and one saturated, one polyunsaturated, and one *cis*-monounsaturated fatty acid (SPM) (Fig. 1).

The SMM fraction constituted 47 to 48% of the triacylglycerols for the MUFA1 and MUFA2 groups, and was greatest ($P < 0.05$) for the MUFA3 group (55%) (Fig. 2). The MUFA3 group had the greatest percentage MMM triacylglycerols (nearly 18%). The PUFA group exhibited the highest proportions of SPM and SPM*t*. The SFA and TFA groups had the greatest proportion of SSS triacylglycerols, and the TFA was especially high in SSM*t* and SMM*t* (Fig. 2). The SSM*t* fraction eluted prior to the SMS fraction at variable retention times and was not analyzed other than for total fatty acid composition.

Fatty acid composition of triacylglycerol species. The MUFA3 and PUFA groups contained a small percentage of 18:1*c*9 and vaccenic acid (18:1*c*11) in their SSS fraction (Table 2), which should not have been observed and represents possible contamination within the column. The predominant fatty acid in the SSS fraction was 18:0 for the MUFA3, SFA, and TFA groups, but was 16:0 for the MUFA1, MUFA2, and PUFA groups. The PUFA group had a relatively small percentage of 18:0 in the *sn*-1/3 positions (15%), but a high percentage of 16:0 (68%). The SMS triacylglycerol fraction represented the predominant triacylglycerol species for the SFA and TFA groups (Fig. 2). This fraction contained the greatest percentages of 18:0 for the SFA and TFA treatment

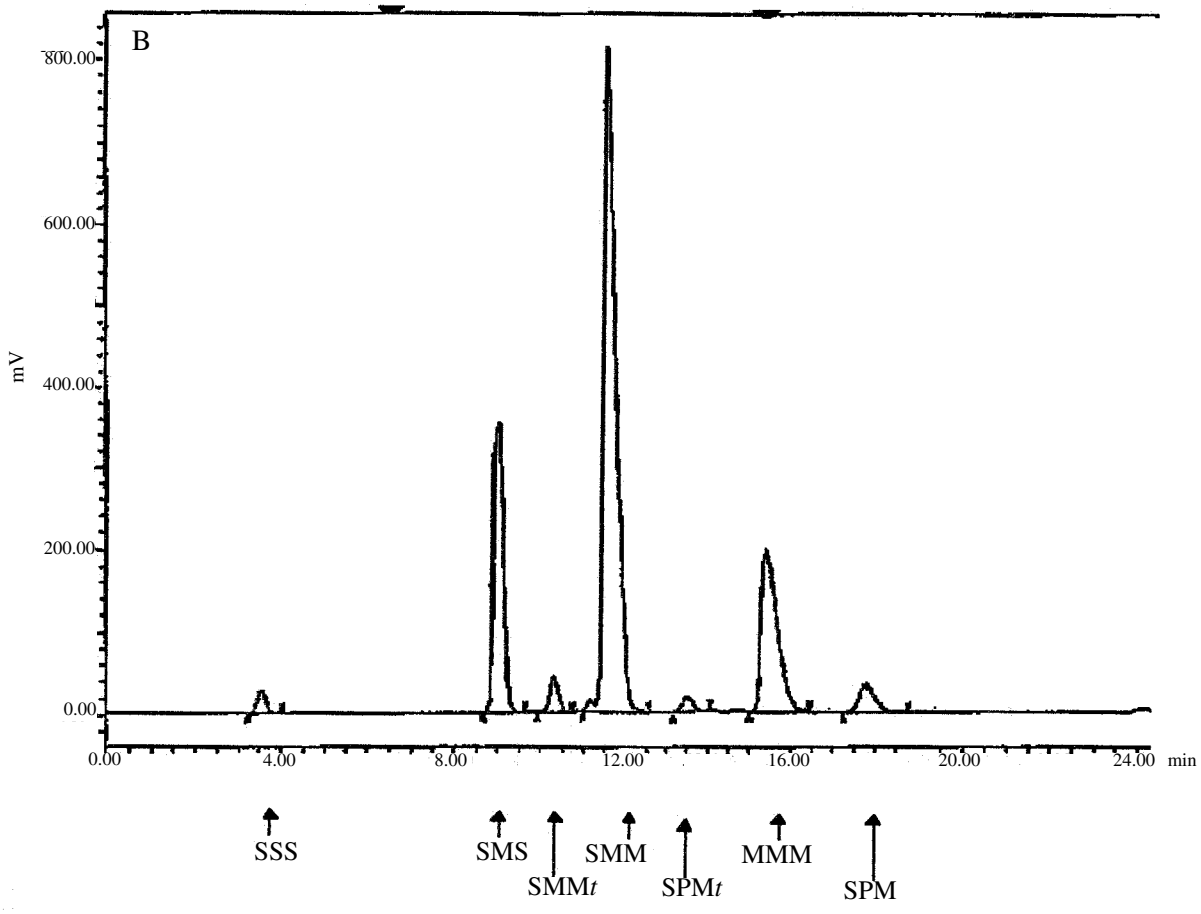

FIG. 1. (continued)

groups (Table 3). There was no difference ($P > 0.05$) in the percentage 18:0 in the *sn*-2 position of SMS triacylglycerols across treatment groups.

The composition of the SMM*t* fraction of the six sample types was rather variable in that the 18:1*t*11 content ranged from 10 to 23% (Table 4). This HPLC fraction may comprise a mixture of triacylglycerols; however, they always eluted in a sharp, discrete peak having a constant retention time. The MUFA3 group had the lowest percentage TFA in the SMM*t* fraction in addition to the lowest abundance of SMMt triacylglycerols (Fig. 2). There was no enrichment of 18:0 in the *sn*-1/3 positions in the SMM*t* fraction. The MUFA3 had an unusually high percentage myristic acid (14:0; over 9%) in the SMM*t* triacylglycerol fraction.

The SMM triacylglycerols were relatively enriched with myristoleic acid (14:1), 16:1, and 18:1 (Table 5). There was an enrichment of 18:1*c*9 in particular in the *sn*-2 position, whereas 16:0 was enriched at the *sn*-1/3 positions. The SPM*t* triacylglycerols (Table 6) were similar in composition to the SMM*t* triacylglycerols (Table 4) except for a relatively high abundance of 18:2 (up to 20%). For most treatment groups, the 18:2 was located primarily at the *sn*-2 position. However, in the PUFA group, there was a uniform distribution of 18:2 between the *sn*-2 and the *sn*-1/3 positions.

Monounsaturated *cis* fatty acids generally were abundant in the MMM triacylglycerols (Table 7) with the exception of the TFA group. Although the TFA MMM triacylglycerol peak eluted with the same retention time as for the other treatment groups, it contained only 47% 18:1, 1.5% 16:1, and no detectable 14:1. The MMM triacylglycerols from both the PUFA and TFA groups had relatively high concentrations of 18:1*t*11 and 18:2.

The composition of the SPM triacylglycerols was analyzed only for the MUFA1, SFA, and PUFA groups (Table 8). The SPM triacylglycerols contained approximately one-third SFA (primarily 16:0), one-third MUFA (18:1*c*9), and one-third 18:2. The 16:0 was concentrated primarily at the *sn*-1/3 positions, whereas the 18:0 was located primarily in the *sn*-2 position. There was a uniform distribution of 18:1*c*9 in the SFA and PUFA groups, but the *sn*-1/3 positions were enriched with 18:1*c*9 in the MUFA1 group. The 18:1*c*11 was located primarily in the outer *sn*-positions. The *sn*-2 position of the SPM triacylglycerols was particularly enriched with 18:2; and for the PUFA group, the *sn*-1/3 positions also contained a high percentage of 18:2. There was no detectable α-linolenic acid (18:3) in the SPM fraction. Rather, 18:3 was distributed thoughout the SMS, SMM*t*, SMM, and SPM*t* fractions, where it was concentrated in the *sn*-1/3 positions.

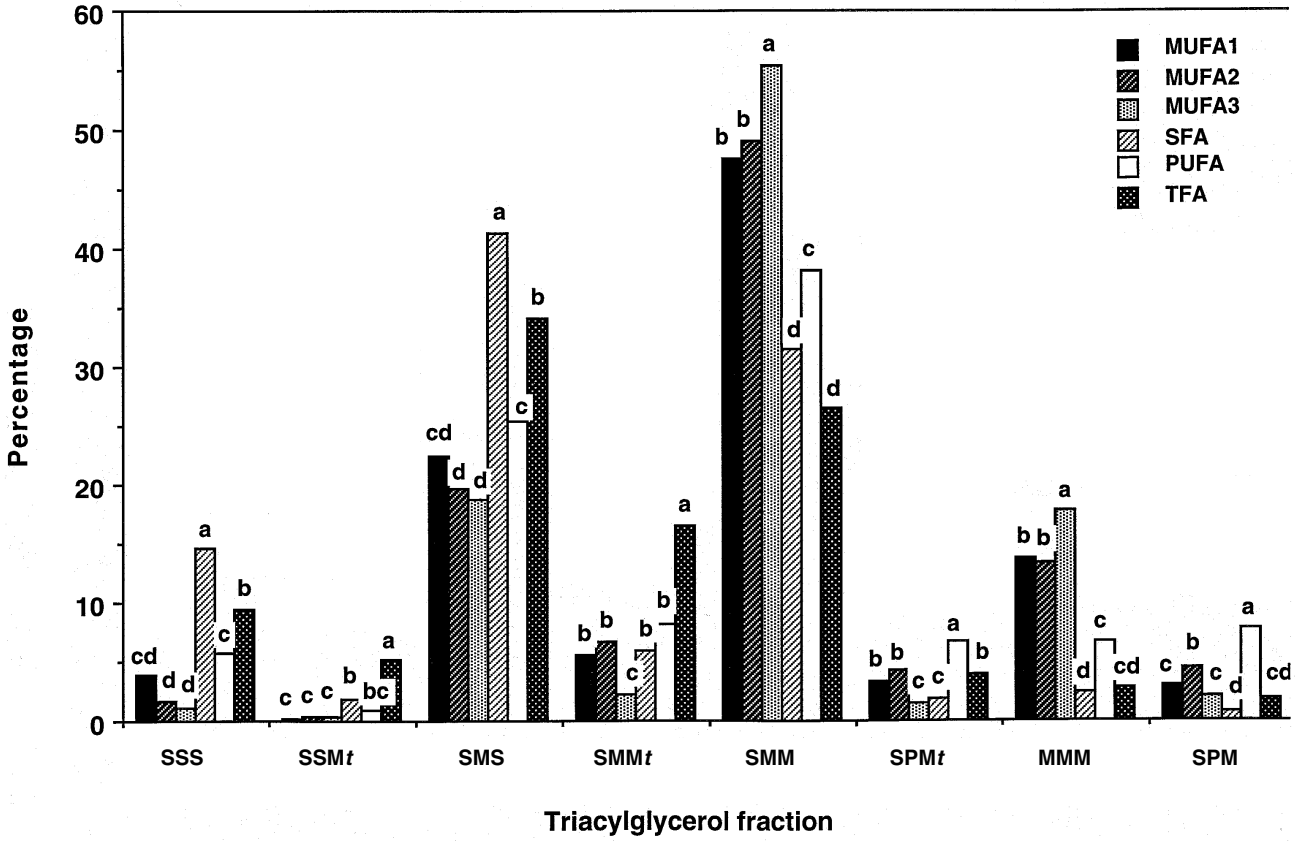

FIG. 2. Distribution of triacylglycerol molecular species in bovine subcutaneous adipose tissue lipids from cattle raised under widely varying conditions. Abbreviations: MUFA1, MUFA2, and MUFA3, samples containing elevated monounsaturated fatty acids; PUFA, samples containing elevated polyunsaturated fatty acids; TFA, samples containing elevated *trans* fatty acids. For other abbreviations see Figure 1. Means within a triacylglycerol fraction with different superscripts (a,b,c,d) are different ($P < 0.05$). Pooled standard deviations for the SSS, SSM*t*, SMS, SMM*t*, SMM, SPM*t*, MMM, and SPM fractions are 5.4, 1.8, 9.3, 4.5, 11.4, 2.0, 6.7, and 2.4, respectively.

Recovery of individual fatty acids after HPLC separation and subsequent methylation and extraction was estimated by summing the product of the proportions of each triacylglycerol fraction times the percentages of the individual fatty acids in all fractions. By this calculation, the sum of the 16:0 in the triacylglycerol fractions consistently was approximately 2 percentage units less than the percentage 16:0 observed in the lipid extracts that had not undergone HPLC separation (Table 1), and 18:0 was proportionately greater. The sums of the 18:1*c*9 proportions in the triacylglycerol fractions were nearly identical to the percentages listed in Table 1. This same pattern was observed in the total, *sn*-2, and *sn*-1/3 positions. None of these discrepancies alters the general finding that 18:0 was enriched in the *sn*-1/3 positions as its percentage increased in the total lipid extract.

DISCUSSION

The mechanism by which changes in fatty acid positional distribution are accomplished is unknown. Our results indicate that 16:0 and 18:0 composed up to 20 and 15%, respectively, of the fatty acids in the *sn*-2 position, and 18:1*c*9 constituted as much as 35% of the *sn*-1/3 positions. In these samples, 18:2 was preferentially incorporated into the *sn*-2 position, but became progressively enriched in the *sn*-1/3 positions as the total concentration of 18:2 increased. Thus, the acyltransferases responsible for triacylglycerol biosynthesis in bovine adipose tissue exhibit only partial specificity.

In those samples in which 18:0 accumulated, the proportion of 18:0 at the *sn*-2 and *sn*-1/3 positions increased perhaps merely owing to its greater concentration within the cell. When the concentration of total 18:0 approached 20%, glycerolphosphate acyltransferase and diacylglycerol acyltransferase placed more 18:0 in the outer positions. Because the concentration of 16:0 in the *sn*-1/3 positions generally was unaffected by the concentration of 18:0 in the samples, and because 16:0 generally is esterified to the *sn*-1 position prior to esterification of fatty acids in the other positions, we can conclude that enrichment of 18:0 occurred primarily at the *sn*-3 location. Jurriens (16) described the triacylglycerol composition of beef tallow as having a large percentage of triacylglycerols containing one *cis* double bond (35%, analogous to the SMS triacylglycerols in this study). Triacylglycerols with 18:0 in the *sn*-1/3 positions constituted over 40% of their "SMS" triacylglycerols, and nearly 30% of this fraction contained 18:0 solely in the *sn*-3 position (16). The samples de-

[a]Means within a column for each fraction without a common superscript are different. Data are means for four (MUFA1, TFA, and PUFA) or six (MUFA2, MUFA3, and SFA) animals per treatment group. Some negative values occurred for the average *sn*-1/3 means when there was a low abundance of a fatty acid. There was no detectable 18:3 in the SPM fraction. SPM, *sn*-1-saturated, 2- polyunsaturated, 3-monounsaturated triacylglycerol. For other abbreviations see Table 1.

scribed by Jurriens (16) most closely resemble the SFA samples in their large proportions of triacylglycerols containing zero or one *cis* double bond. The data from the current study provide the first detailed description of bovine lipid samples with substantially more MUFA and consequently lower melting points, and substantiate an earlier, preliminary report from this laboratory (17).

The samples obtained from these cattle provided an unusual opportunity to investigate fatty acid positional distribution in bovine lipids. Under typical production conditions in the United States, cattle are slaughtered at 18 to 20 mon of age, and dietary treatments are restricted to less than 180 d. Feeding whole, high-oleic acid, canola rapeseed to cattle for 100 d did not increase the percentage of 18:1 in subcutaneous adipose tissue, although the MUFA/SFA ratio was increased significantly (from 0.85 to 0.93; 13). Even after feeding cattle high-oleic acid sunflower seed for 180 d, the percentage of 18:1 subcutaneous adipose tissue increased only marginally (from 44.7% in controls to 46.7%) (calculated from 18).

The cattle produced in Australia in the current study either were fed for very long times (300 d, MUFA1, and >400 d, SFA) or were fed casein-formaldehyde-protected lipids (PUFA). The latter have been shown to alter bovine adipose tissue fatty acid composition markedly (19–21), as the casein-formaldehyde protection prevents ruminal hydrogenation of ingested fatty acids. Compared to cattle of similar genotype raised in the United States and fed corn-based diets for 100 d (13), the MUFA1 group was enriched with 18:1 (49 vs. 40%) and 16:1 (5 vs. 3%), and was notably lower in 18:0 (10 vs. 15%). The cattle fed for 180 d in the study of Chang *et al.* (18) were intermediate in fatty acid composition; apparently, long-term feeding of cattle is sufficient to produce significant alterations in subcutaneous adipose tissue fatty acid composition. The TFA group was unusual in that substantial changes in adipose tissue fatty acid composition were achieved (especially for 18:0 and 18:1*t*11) after a relatively short feeding period (150 d).

The fatty acid composition of the SFA, PUFA, and TFA groups suggested that their dietary treatments inhibited the activity of adipose tissue stearoyl-CoA desaturase. Samples from these groups were especially low in 14:1, 16:1, 18:1*c*9 and 18:1*c*11, all products of the desaturase. The diet of the SFA group included approximately 10% whole cottonseed, which contains the cyclopropene fatty acid, sterculic acid. Sterculic acid inhibits stearoyl-CoA desaturase activity *in vitro* by irreversibly binding sulfhydryl groups (22,23). It has not been possible to demonstrate an effect of dietary whole cottonseed on adipose tissue fatty acid composition or desaturase activity in cattle fed whole cottonseed for only 54 (14) or 150 d (24), as compared to >400 d for the SFA group. Although hydrogenation of sterculic acid by rumen microflora should have inactivated the inhibitor (25), sufficient sterculic acid may have been absorbed postruminally to reduce desaturase activity in the SFA group. In support of this, we have demonstrated a marked reduction in microsomal stearoyl-CoA desaturase activity from adipose tissues of cattle fed casein-formaldehyde-protected cottonseed oil (similar to that fed the PUFA group; Tume, R.K., and Yang, A., unpublished observations).

The high concentration of MUFA in the MUFA3 group suggests elevated stearoyl-CoA desaturase activity in adipose tissue of those animals. We previously sampled animals from

the same geographical region in Japan (26) and noted extraordinarily elevated levels of 14:1 (2.5%), 16:1 (11%), and 18:1 (55%). Other studies of American Wagyu (27) and Japanese Black cattle raised in Japan (28) have supported a genetic basis for the elevated MUFA in this breed type.

In summary, these groups of cattle provided a unique opportunity to investigate fatty acid positional distribution in ruminant adipose tissue displaying a wide range of fatty acid compositions. Enrichment with 18:0, particularly in the *sn*-1/3 positions, contributed to the high melting points of the SFA, TFA, and PUFA samples. This may play an important role in the production of meat products. In Australia, where beef carcasses are hand-boned, excessively hard fat, particularly in grain-fed cattle at chiller temperatures, can lead to a larger percentage of carcasses that are unacceptable for boning (5). Thus, the high melting point of lipids containing 18:0 in the *sn*-1/3 can have very practical implications.

METHOD

Stereospecific Analysis of Soybean Triacylglycerols

Teresa K. Harp and Earl G. Hammond*

Department of Food Science and Human Nutrition and Center for Crops Utilization Research, Iowa State University, Ames, Iowa

ABSTRACT: Thirty soybean germplasm lines representing a wide distribution of fatty acid compositions were analyzed stereospecifically by using a chiral column to resolve the *sn*-1 and *sn*-3 positions of glycerol. The amounts of each acyl group on each of the *sn* positions were plotted vs. the amount of that acyl group in the triacylglycerols (TAG), and the plots were fitted by linear regression. The deviation of individual data points from the linear regressions was much greater than observed in previous studies. This could be attributed to the inclusion of a number of germplasm lines with elevated or reduced percentages of saturates. The stereospecific distributions could not be fit with previously suggested mathematical models because the plots had intercepts that were not allowed by the models. Statistical tests of the analytical procedure indicated that slight oxidation of or bias against the polyunsaturates had occurred and that the Grignard deacylation method gave slightly less representative analyses of the *sn*-2 position than pancreatic lipase deacylation on these TAG.
Lipids 33, 209–216 (1998).

Natural vegetable oils have nonrandom distributions of acyl groups on the *sn*-1, -2, and -3 positions of triacylglycerols (TAG) that can affect their physical properties and oxidative stability (1). Stereospecific plots of plant lines that differ in acyl group composition show linear relationships between the percentages of an acyl group on the *sn*-1, -2, and -3 positions and the percentage of that acyl group in the total TAG. This relation has been shown for several species (2–6). Fatemi and Hammond (4) suggested that these plots would be helpful in identifying TAG distribution mutants since such mutants would yield data points that departed from the linear plots typical of the species. Lee *et al.* (7) proposed two mathematical models to account for the stereospecific distribution of TAG produced in the oleaginous yeast *Apiotrichum curvatum* fed various fatty acid mixtures.

Previous studies of the stereospecific distribution of acyl groups in oilseed varieties have used the analytical method developed by Brockerhoff (8) and modified by Christie and Moore (9). More recently, methods based on separations on chiral columns (10–14) or by using chiral reagents (15) have been developed. The mutation breeding program at Iowa State University (Ames, IA) has generated soybean germplasm lines with a wider range of acyl compositions than those examined earlier (4,6), especially with respect to the concentrations of the saturated acyl groups. This study examined these mutants by using the chiral column method of Takagi and Ando (11).

MATERIALS AND METHODS

The solvents and reagents were A.C.S. certified grade. Diethyl ether was distilled for daily use in the presence of lithium aluminum hydride.

Soybean [*Glycine max* (L.) Merr.] seed from germplasm lines representing a wide range of fatty acid compositions was obtained from the Agronomy Department of Iowa State University and Pioneer Hi-Bred International (Johnston, IA). Fifty to 100 seeds from each germplasm line were split into two equal parts with a razor blade, and one-half of each seed was analyzed for fatty acid composition. The half seeds were crushed with a hydraulic press and extracted with hexane as described by Hammond (16) and analyzed by gas chromatography (GC). Ten to 16 seeds/line were selected for homogeneity of their fatty acid compositions.

The selected half seeds were ground in a Wiley mill (A.H. Thomas Co., Philadelphia, PA), and 500 mg of the meal was extracted with 4–6 mL of hexane overnight at ambient temperature. The hexane was adjusted by evaporation under nitrogen to 0.9 mL and applied to a 900-mg Maxi-Clean silica cartridge (Alltech Associates, Deerfield, IL) that had been preconditioned with 5 mL of hexane. The cartridge was treated with 4 mL of 7% diethyl ether in hexane to elute the TAG, and the solvent was evaporated under nitrogen. A sample of the TAG was analyzed for fatty acid composition.

The chiral analysis was based on the method of Takagi and Ando (11): 50 mg of the remaining TAG was dissolved in 3 mL of diethyl ether and treated with 0.15 mL of 3 M ethylmagnesium bromide in diethyl ether. After 1 min, 0.05 mL of acetic acid in 3.35 mL of 0.4 M boric acid was added, the reaction mixture was centrifuged, and the reaction products were extracted with several portions of diethyl ether. The extract was washed with 3 mL of 2% aqueous sodium bicarbonate solution followed by 3 mL of water, dried with sodium

sulfate, and evaporated under nitrogen. The residue was dissolved in 0.5 mL of toluene and 0.05 mL of pyridine and reacted with 40 mg of 3,5-dinitrophenylisocyanate (Fluka Chemical Corp., Ronkonkoma, NY) overnight at ambient temperature to form dinitrophenylurethane derivatives (DNPU). The solvents were evaporated; the residue was then dissolved in 0.22 mL of chloroform and streaked on a 0.5-mm Adsorbisil®-Plus 1 silica thin-layer chromatographic (TLC) plate (Alltech). The plate was developed twice with chloroform/acetone (96:4, vol/vol), and the bands were visualized by spraying with 0.01% Rhodamine 6G in ethanol. The bands representing the *sn*-1, *sn*-3-diDNPU enantiomers and the *sn*-2-diDNPU were scraped from the plates separately and eluted from the silica with diethyl ether. Because the TLC separation was not as complete as desired, the two bands were rechromatographed on separate TLC plates as before. The band representing *sn*-2-diDNPU was converted to methyl esters and analyzed by GC. The *sn*-1, *sn*-3-diDNPU enantiomers were prepared for chiral high-performance liquid chromatography (HPLC) by dissolving them in 180 μL of HPLC-grade chloroform and filtering through 0.2-μm filters (Gelman Acrodisc, Ann Arbor, MI). HPLC separation of the *sn*-1 and *sn*-3-diDNPU enantiomers was accomplished on a 25-cm × 4-mm i.d. Sumichiral OA-4100 column (Sumika Ltd., Osaka, Japan) in a Shimadzu instrument (Shimadzu, Kyoto, Japan). The developing solvent was hexane/1,2-dichloroethane/ethanol (73:22:5, by vol) at 1 mL/min. Peaks were monitored at 254 nm. The two fractions were freed of solvent under nitrogen, dissolved in hexane, and prepared for GC analysis.

Acyl groups of the DNPU derivatives were converted to methyl esters by reaction with 1 M sodium methoxide in methanol for 50–60 min while shaking at 45°C. Methyl esters from other lipids were prepared by reaction at room temperature. GC analyses were performed on a Hewlett-Packard 5890A (Avondale, PA) on a J&W (Deerfield, IL) DB-23 column (15 m × 0.25-mm i.d.). Oven temperature was 180°C, inlet and detector 250°C. The peak areas were corrected by factors calculated according to Ackman and Sipos (17), and the weight percentages were converted to mole percentages.

Pancreatic lipase hydrolysis of the TAG by the procedure of Luddy *et al.* (18) was applied to 15 of the samples.

All analyses were duplicated, and Microsoft Excel was used to obtain least squares linear regression, *t*-test, Z-test, and analysis of variance.

RESULTS AND DISCUSSION

Plots showing the percentage of a given acyl group on each of the three glycerol positions vs. the percentage of that acyl group in the total TAG are shown in Figures 1–5. The data points in these plots were obtained from the separated DNPU derivatives. The data were fitted by least-squares linear regression, and the results are given in Table 1. Using a statistical Z-test on the linear regression residuals and normalizing them so that the residual mean is zero can identify outliers from the regression lines. Outliers were defined as falling more than 1.96 standard deviations from the normalized mean. By chance, about 5% of the data points should be defined as outliers by this procedure, and for our sample size of

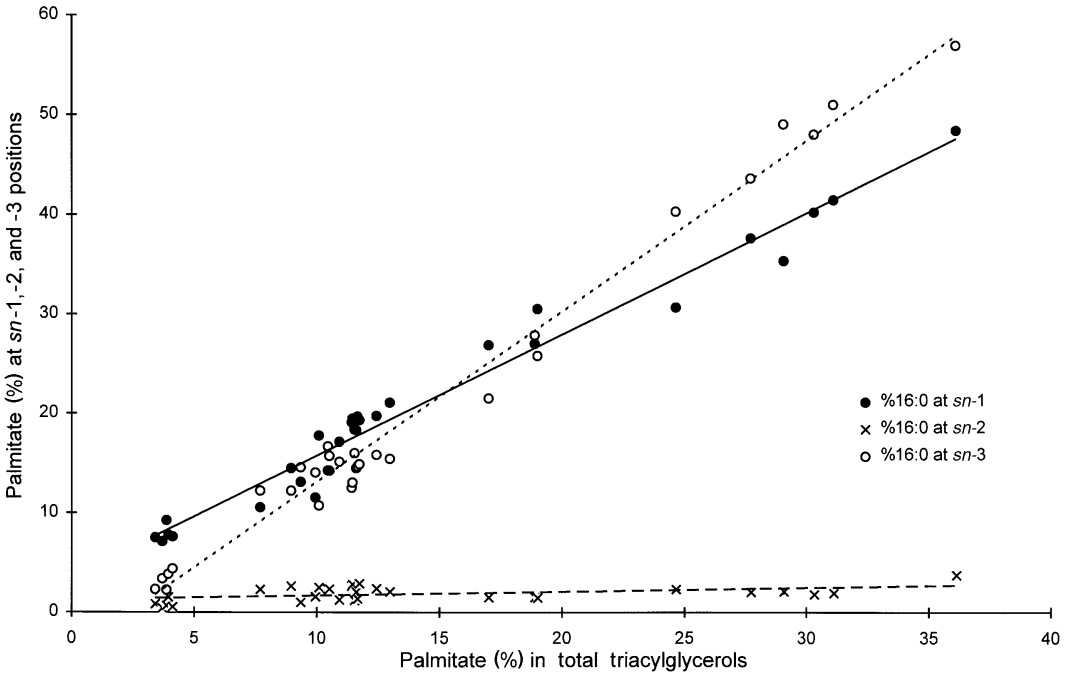

FIG. 1. The percentage of palmitate on the *sn*-1, *sn*-2, and *sn*-3 positions of glycerol vs. the percentage of palmitate in the whole triacylglycerol for *Glycine max* germplasm lines.

30, one or two data points per regression would be expected to fall outside this limit. Thus, the number of outliers for the regressions in Table 1 is not greater than the number expected by chance.

The palmitate and stearate data in Figures 1 and 2 were fit well by the linear regression. In agreement with previous studies (4,6), there was very little saturated acyl group on the *sn*-2 positions. The slope of the regression line for palmitate on the *sn*-2 position was significantly different from zero, but this may be because palmitate migrated from the *sn*-1 and *sn*-3 positions in proportion to the amounts present in the TAG. In contrast to earlier studies, which had a much more limited

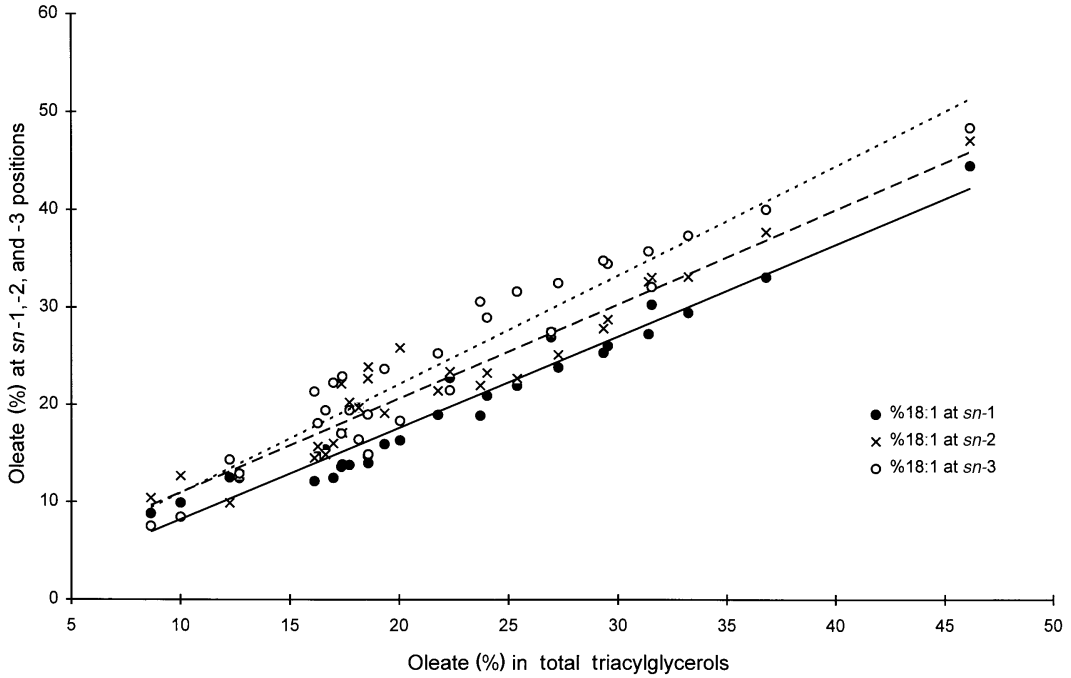

FIG. 3. The percentage of oleate on the *sn*-1, *sn*-2, and *sn*-3 positions of glycerol vs. the percentage of oleate in the whole triacylglycerol for *Glycine max* germplasm lines.

range for saturated acyl groups than the present study, the regression lines for the *sn*-1 and *sn*-3 positions crossed at about 15% for palmitate in the TAG and 8% for stearate. In both instances the percentages for *sn*-1 were greater than those for *sn*-3 at TAG percentages below the crossover points, and the reverse was true above the crossover points.

Figures 3, 4, and 5 show the distribution of oleate, linoleate, and linolenate on the three *sn*-positions of glycerol. The data for oleate and the *sn*-1 and *sn*-3 positions of linoleate were fit reasonably well by the linear regressions, but the data for the *sn*-2 position of linoleate and all the positions for linolenate showed considerable scatter not seen in previous

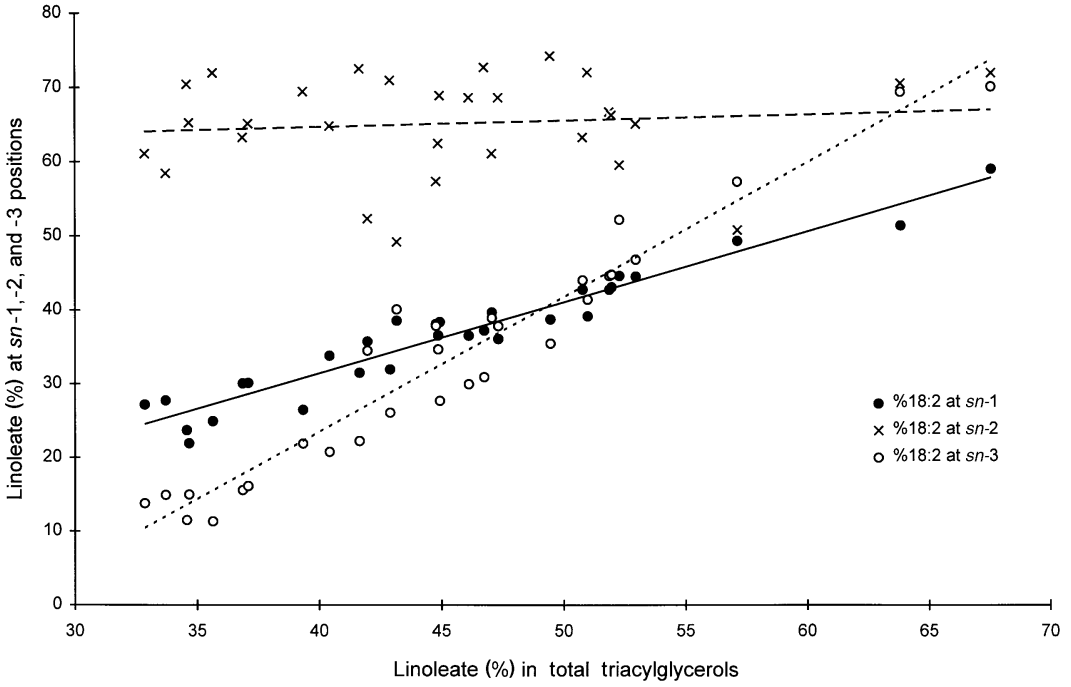

FIG. 4. The percentage of linoleate on the *sn*-1, *sn*-2, and *sn*-3 positions of glycerol vs. the percentage of linoleate in the whole triacylglycerol for *Glycine max* germplasm lines.

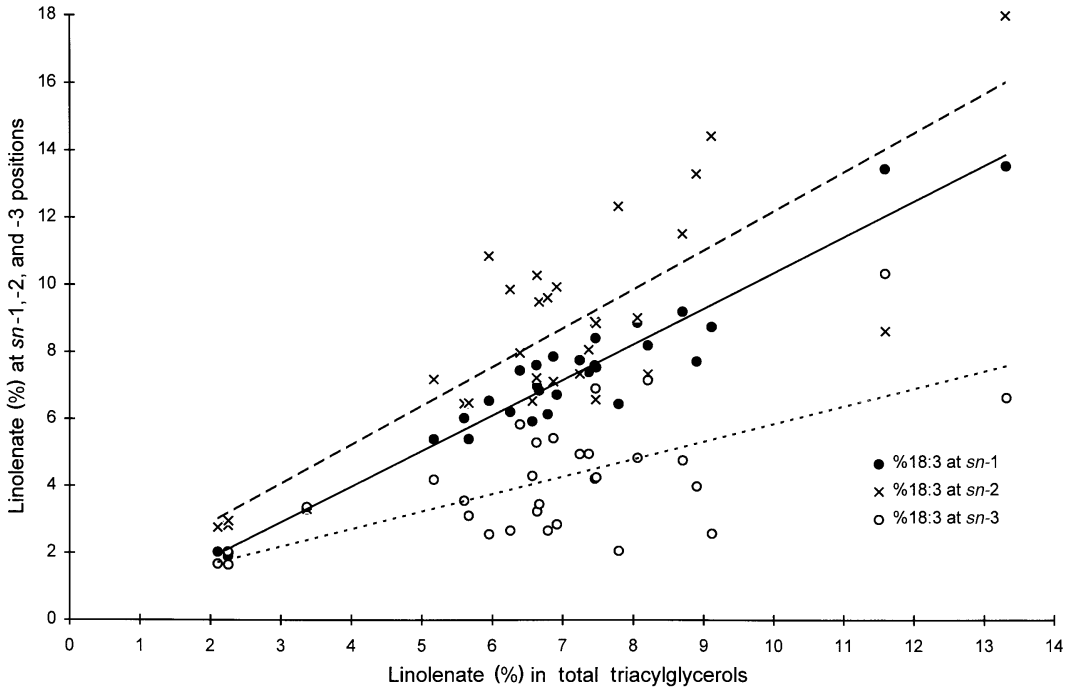

FIG. 5. The percentage of linolenate on the *sn*-1, *sn*-2, and *sn*-3 positions of glycerol vs. the percentage of linolenate in the whole triacylglycerol for *Glycine max* germplasm lines.

studies. Much of the scatter in this study could be attributed to the presence of a number of samples with either elevated or reduced saturate concentrations. For example, samples with typical saturate concentrations (~10% palmitate and ~4% stearate) had an enrichment of oleate on the *sn*-3 position (data not shown), as reported in previous studies. But in germplasm lines with elevated stearate, the oleate often was more enriched on the *sn*-2 position. In germplasm lines elevated in both palmitate and stearate, the oleate distribution favored *sn*-2 > *sn*-1 > *sn*-3. In germplasm lines with reduced saturates, the oleate was distributed more or less equally among the three *sn*-positions.

For linoleate, placement on the *sn*-2 position was generally favored, but as reported previously by Pan and Hammond (6), the regression line for the *sn*-3 position had a greater slope, and the linoleate on the *sn*-3 position equaled that of the *sn*-2 position at high levels of TAG linoleate. Like the *sn*-1 and *sn*-3 regression lines for stearate and palmitate, those for linoleate crossed, in this instance, at about 49% linoleate in TAG.

Figure 6 shows the distribution of linoleate on the *sn*-2 position for samples having normal, elevated, and reduced levels of the saturated acyl groups. The samples with typical saturate levels were fairly well fit by a straight line, but the samples with elevated saturates deviated to greater ordinate values, and those with reduced saturates deviated to lower values. The extent of these deviations was correlated with the TAG saturate content and the saturate content on the *sn*-1 position.

Previous studies showed that linolenate placement was favored at the *sn*-1 over the *sn*-2 or *sn*-3 positions, but in this study this was true only for germplasm lines with low or normal saturate levels (data not shown). Figures 7 and 8 show how saturate content affected the distribution of linolenate on the *sn*-2 and *sn*-3 positions. In soybean germplasm lines with elevated saturate contents, the linolenate deviated to lower ordinate values on the *sn*-3 plot and to higher values on the *sn*-2 plot. In low and normal saturate samples, the linolenate deviated in the opposite directions from samples with elevated saturates. The *sn*-1 plot for linolenate showed deviations related to saturates that were similar to those of the *sn*-3 plot (data not shown), but as Figure 5 shows, the scatter for the *sn*-1 line was much less than those for *sn*-2 and *sn*-3. This may be because the elevated saturates tended to accumulate on the *sn*-3 position preferentially.

Possibly, these deviations from the stereospecific distributions previously reported resulted from glyceride structure mutations as predicted by Fatemi and Hammond (4), and germplasm lines that contained elevated saturates were accompanied by mutations in glyceride assembly. But the number of outliers for each of the regressions shown in Table 1 was not greater than the number expected by chance.

A more likely explanation of the deviations from the linear regressions was that the inclusion of germplasm lines with unusual amounts of saturates revealed normal effects of saturates on glyceride assembly that were not obvious previously. Linoleate and linolenate are formed on the *sn*-2 position of phosphatidylcholine (19). Possibly, linoleate and linolenate move from the *sn*-2 to the *sn*-1 and *sn*-3 positions by a coupled exchange with oleate on the *sn*-1 and *sn*-3 position. If the saturates are elevated on the *sn*-1 and *sn*-3 positions, there would be less oleate to effect the exchange. A lack of oleate with which to exchange would increase the linoleate and linolenate on the *sn*-2 position and decrease linoleate and linolenate on

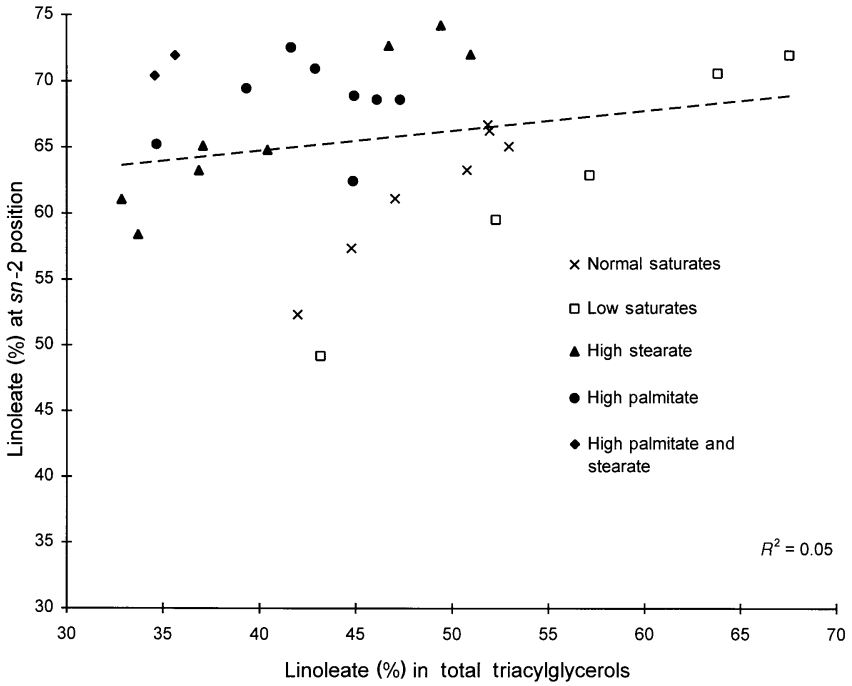

FIG. 6. The effect of germplasm lines with various saturate percentages on the percentage of linoleate on the *sn*-2 positions of glycerol vs. the percentage of linoleate in the whole triacylglycerol for *Glycine max* germplasm lines.

sn-3. Reduced saturate levels would have the opposite effect. Such mechanisms would explain the observed effects.

Samples rich in palmitate contained significant amounts (up to 2.4%) palmitoleate (16:1). Palmitoleate concentrations were approximately equal on the *sn*-1 and *sn*-3 positions, but the *sn*-2 position contained twice as much palmitoleate as *sn*-1 and *sn*-3.

Samples rich in stearate also contained significant amounts (up to 2%) arachidate (20:0). Arachidate was almost exclu-

sively at the *sn*-3 position. A similar distribution of acyl groups longer than stearate has been reported for peanut (20).

Theoretically, if there were 0 or 100% of an acyl group present in a particular TAG sample then the amount of that acyl group on three *sn* positions would have to be either 0 or 100%. Thus, each of the stereospecific plots must go through 0,0 and 100,100. For a linear plot, only a line with a slope of 1 will pass through both of these points, so the seemingly linear stereospecific plots observed in some of the figures cannot be linear over their entire range. Lee *et al.* (7) proposed two mathematical models to account for the stereospecific distribution of acyl groups in TAG. Model 1 assumes that some fraction of the glycerol molecules contains fixed proportions of specific acyl groups. The acyl group distribution at the *sn*-1, -2, and -3 positions of this fraction of the glycerol is controlled by specific enzymes that place the acyl groups independently of the total amount available for esterification. The remainder of the glycerol molecules, not affected by this mechanism, is acylated according to the proportion of acyl groups available. This model gives linear plots over the span in which it can operate. The second model was based on chemical kinetics and assumed that the three glycerol positions were filled in proportion to substrate concentrations and the affinities of the enzymes filling the three *sn* positions. This model is approximately linear over much of its range but bends to go through 0,0 and 100,100. Neither of these models fits the present data, primarily because the data for the *sn*-3 plots of palmitate, stearate, and linoleate show intercepts on the abscissa that are not possible with these models.

Previous studies showed that for stereospecific plots the slopes summed to 3 and the intercepts to 0 (4,6). The models of Lee *et al.* (7) give a mathematical basis for these observations. Table 1 shows that although the slopes sum to approximately 3, the intercepts are considerably greater than zero except for oleate. This reflects the greater scatter of these data compared with previous studies and results from the inclusion of many samples with altered saturate content.

To check the reliability of the analyses, the average fatty acid composition of the TAG being analyzed and the average found for the three *sn* positions were calculated, and the results are shown in Table 2. If there were no analytical errors, these values should agree, but the differences were all statistically significant. The sample means for the saturates and oleate were greater for the stereospecific analyses than from the whole TAG, whereas the opposite was true for linoleate and linolenate. Takagi and Ando (12) reported a bias against the recovery of polyenoates during the formation of DNPU

TABLE 2
Sample Means of the Percentage of Fatty Acid Composition for the Original TAG Compared with the Average Found on the Three *sn* Positions

derivatives and their conversion to methyl esters. Our results show considerably better recovery than they reported, and the small losses of polyenoates that we observed may be caused by oxidation during TLC and handling.

An analysis of variance for each of the acyl groups in the 30 duplicate samples showed that the standard errors of the means for each acyl group percentage on each *sn*-position and for the whole TAG were small. In general, the hydrolysis and separation steps did not increase the standard errors over those for TAG.

The compositions of the *sn*-2 positions for 15 germplasm lines were determined by pancreatic lipase hydrolysis as well as by the analysis of the DNPU derivatives representing the *sn*-2 position, and the results are compared in Table 3. A paired *t*-test of the means for the two methods showed that the Grignard deacylation method gave more saturate and less unsaturate on the *sn*-2 positions than did the lipase method, and the differences were significant for palmitate, stearate and linoleate ($P < 0.01$). This suggests that slightly more acyl migration occurred with the Grignard method than with lipase.

ABSTRACT: This is the first report of the application of silver-ion impregnated high-performance liquid chromatography (Ag^+-HPLC) to the separation of complex mixtures of conjugated linolenic acid (CLA) isomers present in commercial CLA sources and foods and in biological specimens. This method showed a clear separation of CLA isomers into three groups related to their *trans,trans, cis,trans* or *trans,cis,* and *cis,cis* configuration of the conjugated double-bond system. In addition, this method separated individual positional isomers of the conjugated diene system within each geometrical isomeric group. Following Ag^+-HPLC isolation, gas chromatography (GC)–electron impact mass spectrometry, and GC–direct deposition-Fourier transformed infrared spectroscopy were used to confirm the identity of two major positional isomers in the *cis/trans* region, i.e., Δ8,10- and Δ11,13-octadecadienoic acids, which had not been chromatographically resolved previously. Furthermore, the potential of this method was demonstrated by showing different Ag^+-HPLC profiles exhibiting patterns of isomeric distributions for biological specimens from animals fed a diet containing a commercial CLA preparation, as well as for a commercial cheese product.

Lipids 33, 217–221 (1998).

"Conjugated linoleic acid (CLA)" is an imprecisely defined term describing a mixture of octadecadienoic acids (18:2) that contain a conjugated double-bond system. Interest in CLA has increased in the last decade with reports that dietary CLA reduced carcinogenesis (1–4), atherosclerosis (5), and body fat (6) and provided several other beneficial effects (7–9) in laboratory animals. However, commercial CLA products fed to experimental animals are complex mixtures of CLA isomers, many of which have not been identified. To date, there is no direct evidence as to which isomer or isomers within the complex CLA mixture are the potentially active components, other than an assumption that it may be the major isomer, *cis,trans*-octadeca-9,11-dienoic acid (*c,t*-9,11-18:2), found in milk and dairy products (10).

Techniques used previously to measure CLA have included high-performance liquid chromatography (HPLC) and gas chromatography (GC). HPLC procedures using C_{18} (10–13) or silica columns (14) produced inadequate separation of CLA isomeric mixtures, analyzed as either free fatty acids (10–12,14) or fatty acid methyl esters (FAME) (13). The CLA isomers were detected by ultraviolet (UV), which takes advantage of the conjugated diene chromophore that absorbs at 234 nm. In GC separations, long capillary columns with polar liquid phases (e.g., SP 2560, CP-Sil 88, or Supelcowax-10) were used (11,15–17). Although several peaks in the CLA isomeric region were resolved by GC depending on the column and conditions used, the separation was not complete as evidenced by GC–mass spectrometry (MS) of the 2-alkenyl-4,4-dimethyloxazoline (DMOX) derivatives (11,16). In GC separations, CLA positional and geometrical isomers extensively overlap making their identification difficult, particularly of the minor components. Neither HPLC nor GC provided sufficient resolution for all the isomers in complex CLA mixtures.

We describe here an application of silver-ion HPLC (Ag^+-HPLC) that resolved CLA isomers on the basis of chain length, double-bond configuration, and position of the conjugated diene functional group in the fatty acid chain. For each CLA positional isomer, the corresponding *cis/trans* or *trans/cis* pair of geometric isomers were not separated by Ag^+-HPLC. The chromatographic resolution of complex mixtures of CLA isomers obtained by Ag^+-HPLC was substantially better than those reported previously by GC on polar phases, or by HPLC on C_{18} or silica columns.

MATERIALS AND METHODS

A mixture of CLA FAME was purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Several isomers or isomeric mixtures of CLA were obtained as free fatty acids from Matreya Inc. (Pleasant Gap, PA) and from Dr. Michael W. Pariza of the University of Wisconsin (Madison, WI). Acetonitrile and

Abbreviations: *cis/trans,* refers to the same positional isomers that have either a *cis,trans* or a *trans,cis* configuration; CLA, conjugated linoleic acid; DMOX, 2-alkenyl-4,4-dimethyloxazoline; FAME, fatty acid methyl esters; GC–DD–FTIR, gas chromatography–direct deposition–Fourier transform infrared; GC–EIMS, gas chromatography–electron impact mass spectrometry; HPLC, high-performance liquid chromatography; UV, ultraviolet.

hexane were UV grade. Other solvents were distilled-in-glass quality. 2-Amino-2-methyl-1-propanol, 95%, was purchased from Aldrich Chemical Company, Inc. (Milwaukee, WI). A 10% solution of trimethylsilyldiazomethane in hexane was obtained from TCI America (Portland, OR).

HPLC. HPLC analysis was performed with a Waters 510 solvent delivery system (Waters Associates, Milford, MA), a Waters 717 plus Autosampler with a 2-mL and 200-µL injection loop, a Waters 486 tunable absorbance UV detector (233 nm), a Waters fraction collector, and a Waters software program (Millennium™ version 2.15.01). A ChromSpher 5 Lipids semipreparative (10 mm i,d. × 250 mm stainless steel; 5 µm particle size) and an analytical (4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size) silver-impregnated column were used (Chrompack, Bridgewater, NJ). The solvent flows were 4.0 and 1.0 mL/min, for the preparative and analytical columns, respectively. Best resolutions were obtained with a mobile phase of 0.1% acetonitrile in hexane and isocratic operation. The mobile phase mixture was prepared fresh each day because the retention volumes of the CLA isomers changed with time with little loss of resolution. The flow was commenced for 0.5 h prior to sample injection. Typical injection volumes were 150–200 µL for the semipreparative column and 5–15 µL for the analytical column.

Preparation of FAME. The free acids (CLA) were dissolved in a screw-cap test tube with 1 mL of 20% methanol/benzene and reacted with trimethylsilyldiazomethane as described (18). Unreacted trimethylsilyldiazomethane was removed by adding *ca.* five drops of acetic acid with gentle swirling until the yellow color disappeared. Then 5 mL H_2O and 1 mL isooctane were added, and the tube was capped and shaken for 10 s. The solution was dried over Na_2SO_4 and stored for future injection. Test portions of purchased FAME mixtures were dissolved in hexane prior to Ag^+-HPLC analysis.

DMOX derivatives. To a reaction tube, 10–20 mg of methyl heptadecanoate (17:0) and *ca.* 1–2 mg of CLA FAME (collected from semipreparative HPLC column) were added, and the mixture was hydrolyzed with 1 N KOH/95% ethanol (19), in order to obtain free fatty acid. The free fatty acids were added to a screw-cap reaction tube, and a threefold excess (w/w) of 2-amino-2-methyl-1-propanol was added. The tube was purged with argon, capped, and heated at 170°C for 0.5 h in an oven. DMOX derivatives were partitioned into petroleum ether as described previously (11).

GC–electron impact mass spectrometry (GC–EIMS). The GC–EIMS was performed by using a gas chromatograph (Hewlett-Packard 5890, series II, Palo Alto, CA) coupled to a mass spectrometer (Autospec Q mass spectrometer) and data system (OPUS 4000) (Micromass, Manchester, United Kingdom). The GC–MS system utilized version 2.1 BX software. This system was used with a 100-m CP-Sil 88 capillary column (Chrompack) described previously (9). The GC–MS conditions were: splitless injection with helium sweep restored 1 min after injection; injector and transfer lines' temperature 220°C; oven temperature 75°C for 1 min after injection, then ramped 20°C/min to 185°C, and held at 185°C for 15 min, 4°C/min to 220°C, and held there for 45 min.

GC–direct deposition Fourier transform infrared (GC–DD–FTIR) spectroscopy. A Bio-Rad (Cambridge, MA) Tracer™ GC–FTIR 60A spectrometer system was used. This system, which was used with a 50 m CP-Sil-88 capillary column, has been described earlier (20).

Quantitation. The response factors were calculated as follows. Each response was first determined by GC–DD–FTIR to have either a *cis,cis*, a *trans,trans*, or a *cis/trans* configuration (21). Quantitation of each *cis,cis* isomer was calculated by taking the percentage of that response $[R(c,c)_i]$ relative to the total of all *cis,cis* responses obtained by Ag^+–HPLC $\left[\sum_1^n R(c,c)_i\right]$, and then multiplying this fraction $\left[R(c,c)_i/\sum_1^n R(c,c)_i\right]$ by the total amount of *cis,cis* isomers measured by GC. Response factors were also determined in this manner for the *trans,trans* and the *cis/trans* isomers.

RESULTS AND DISCUSSION

Figure 1 shows a typical Ag^+-HPLC chromatographic separation obtained from a commercial CLA mixture. The resolution depended on the concentration of acetonitrile in hexane

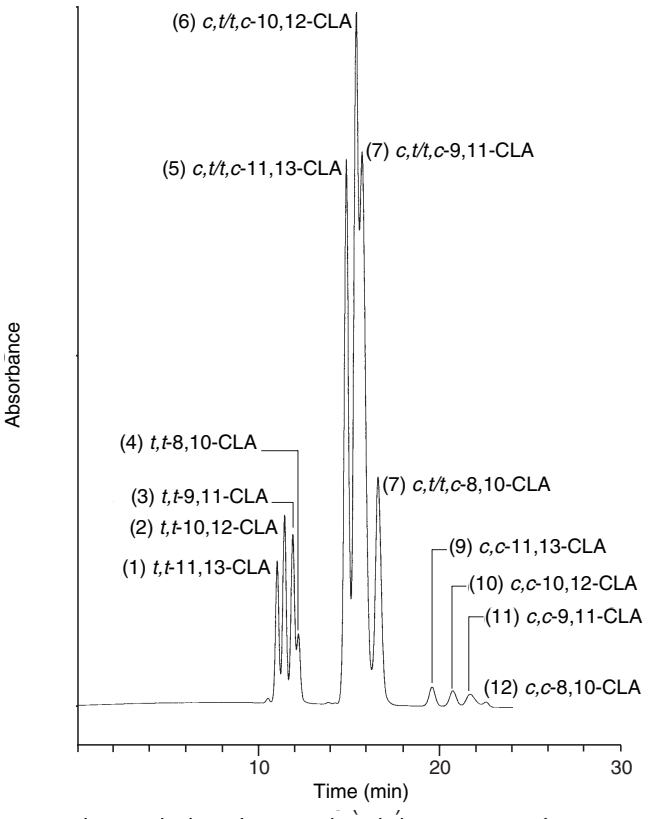

FIG. 1. Silver-ion high-performance liquid chromatogram of a commercial conjugated linoleic acid (CLA) standard (Nu-Chek-Prep, Elysian, MN), using a ChromSpher 5 Lipids analytical column (4.6 mm i.d. × 250 mm), and 0.1% acetonitrile in hexane as the mobile phase, at a flow rate of 1 mL/min. The slash between geometric isomers (i.e., *c,t/t,c*) means that either or both of the two isomers could be present.

of the mobile phase, first used by Adlof *et al*. (22) to separate isomeric *cis* and *trans* 18:1 FAME. At 1% acetonitrile, all the CLA isomers eluted as a single peak within 1 min. The resolution shown in Figure 1 was obtained with a concentration of 0.1% acetonitrile in hexane. Twelve peaks eluted, generally in three groups of four peaks each. The first group was shown to be *trans,trans* CLA isomers, while the second and third groups were *cis/trans* and *cis,cis* isomers, respectively. At 0.2 and 0.3% acetonitrile in hexane, all the peaks emerged earlier, and there was less resolution between the sets of geometric isomers. Evidence for the identification of the individual CLA isomers within each group was obtained by comparison with standard CLA isomers, from direct measurements of the isolated peaks by HPLC using both GC–DD–FTIR and GC–EIMS spectral techniques, and by simple comparison of the relative amounts of each isomer within each group.

Identification of the individual CLA isomers. Peaks 3, 7, and 11 had the same retention volumes as those of the standards, methyl *trans,trans*-octadeca-9,11-dienoate (*t,t*-9,11-18:2), *c,t*-9,11-18:2, and *c,c*-9,11-18:2, respectively. These standards were obtained from Matreya Inc. as the free fatty acids which we converted to their FAME. We confirmed the conjugated double-bond geometry and position, and purity of these three standards by GC–DD–FTIR and GC–EIMS (21).

The CLA mixture provided by Dr. Pariza was also methylated and analyzed by Ag^+-HPLC. This mixture showed peaks at retention volumes corresponding to peaks 2, 3, 6, 7, 10, and 11 (Fig. 1). Independent GC–EIMS analysis in our laboratory of Pariza's CLA mixture showed that this mixture contained CLA isomers with double bonds only at the Δ9,11 and Δ10,12 positions. These data, in conjunction with GC–DD–FTIR spectroscopy, GC–EIMS and the relative retention volumes on Ag^+-HPLC, indicated that peaks 2, 6, and 10 were due to *t,t*-10,12-18:2, *t/c*-10,12-18:2, and *c,c*-10,12-18:2, respectively.

Peaks 5 and 8 (Fig. 1) were collected after repeated injections using a semipreparative Ag^+-HPLC column. The DMOX derivatives of the isolated peaks 5 and 8 were shown by GC–EIMS to have a conjugated double-bond system at positions Δ11,13 (peak 5) and Δ8,10 (peak 8). The EIMS evidence for the double-bond position of these two conjugated octadecadienes with their characteristic fragmentation patterns is shown in Figure 2. The GC–DD–FTIR data were consistent with peaks 5 and 8 both containing isomers with a

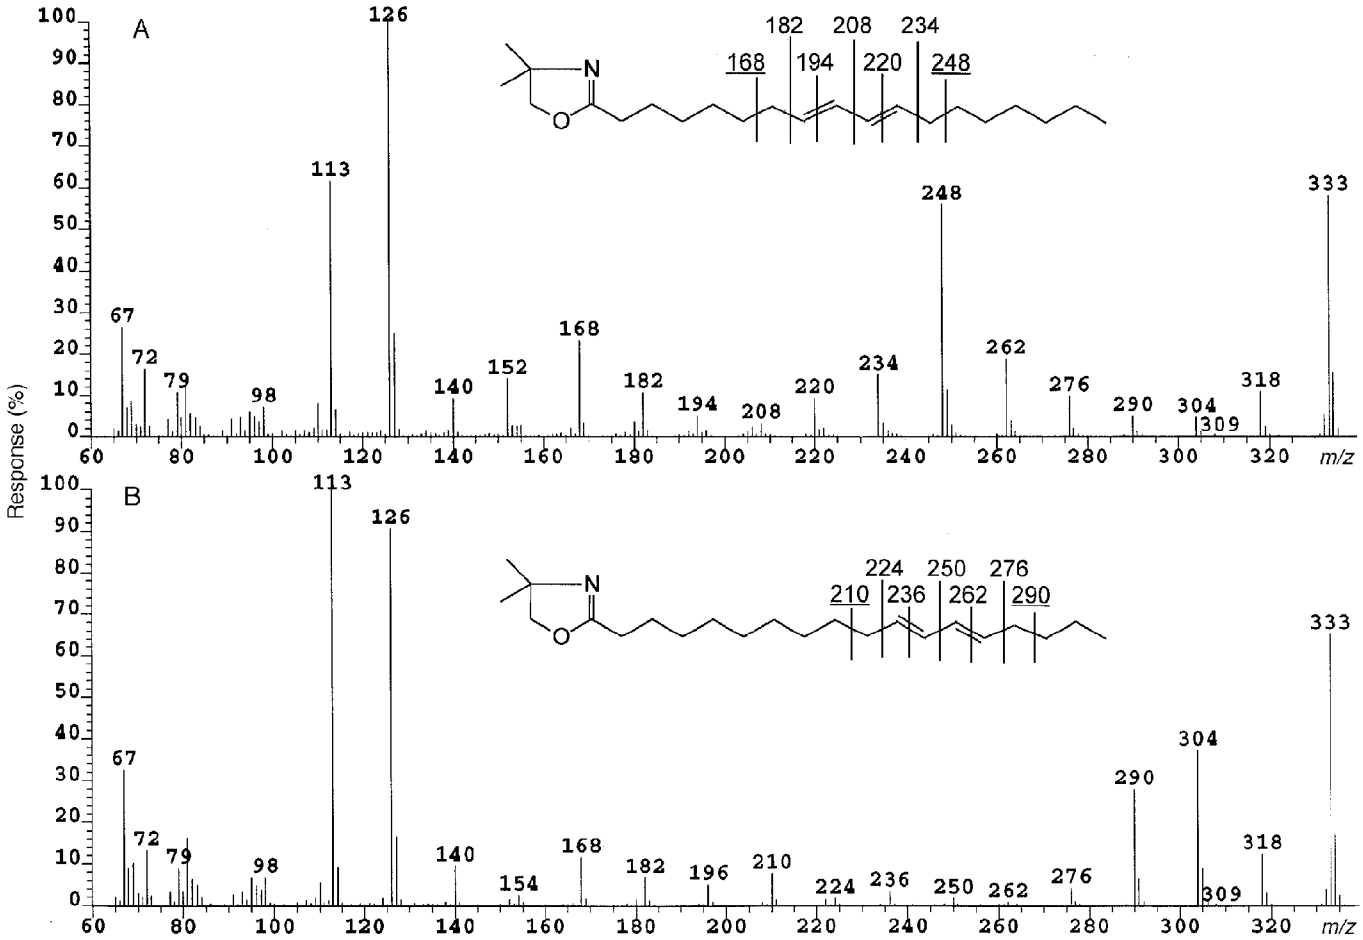

FIG. 2. Gas chromatography–electron impact mass spectrometry spectra of the 2-alkenyl-4,4-dimethyloxazoline derivatives of two CLA isomers isolated from a commercial CLA mixture which were identified as (A) *c,t/t,c*-8,10-18:2 and (B) *c,t/t,c*-11,13-18:2. The *trans,trans* structures shown in the figure are only meant to illustrate the *m/z* assignments. For abbreviations see Figure 1.

[a]Commercial CLA mixture was obtained from Nu-Chek-Prep, Inc. (Elysian, MN) (Ref. 24).
[b]For quantitative calculations see the Materials and Methods section.
[c]The composition was obtained from Nu-Chek-Prep, Inc. and reported previously (Ref. 24). It also included 0.7% 18:2n-6.
[d]—, Not reported.
[e]Represents content of both *t,t*-10,12-18:2 and *t,t*-9,11-18:2 (Ref. 24).
[f]The slash between geometric isomers (i.e., *c,t/t,c*) means that either or both of the two isomers could be present.

cis/trans and/or *trans/cis* double-bond configuration. This assignment was based on characteristic FTIR bands including those observed at 988 and 949 cm^{-1} (21,23). A tentative assignment of the minor peaks 1, 4, 9, and 12 (Fig. 1) was made based on a comparison of the retention volume order among the *cis/trans* group of isomers, and by the relative abundance of the CLA FAME present in the *cis/trans* region.

Application of the Ag^+-HPLC method for the quantitation of a commercial CLA standard. The Ag^+-HPLC method was used in conjunction with GC–EIMS and GC–DD–FTIR to analyze and quantitate the composition of the commercial standard obtained from Nu-Chek-Prep, Inc. (Fig. 1). The procedure is described in the Materials and Methods section. The revised composition of the Nu-Chek-Prep standard is shown in Table 1 and compared to the reported composition (24) of this material. The results from Table 1 showed that two major isomers of CLA [Δ8,10 (12.3%) and Δ11,13(21.7%)] were completely missed, and there was an incomplete analysis of the *trans,trans* (four isomers totaling 3.6%) and *cis,cis* isomers (four isomers totaling 2.9%). Erroneous analyses of commercial CLA mixtures used in feeding trials will result in misleading interpretations of observed biological response(s) in animals.

The revised assay (Table 1) reported for the CLA isomers was consistent with the finding of four similar sets of oxidation products, including four furan fatty acids from the Nu-Chek-Prep Inc. CLA mixture (9,24). This demonstrated that these four sets of oxidation products originated from four CLA positional isomers. It was just reported (25) that four positional isomers were found in a commercial CLA mixture using selected ion scanning of the 4-methyl-2,3,4-triazoline-3,5-dione derivative, but the CLA isomers were not separated chromatographically.

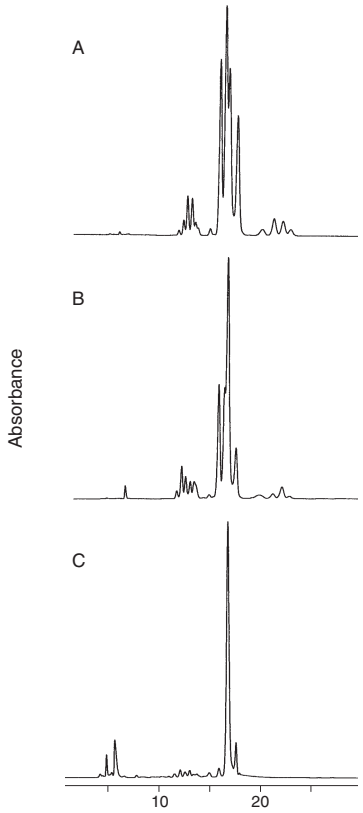

FIG. 3. Typical silver-ion high-performance liquid chromatographic separations. (A) A commercial CLA mixture used in a pig feeding study (Ref. 26); (B) the CLA composition of the total liver lipids of pigs fed this CLA mixture (Ref. 26); and (C) the CLA composition of a commercial cheese product. For abbreviation see Figure 1.

Application of the Ag^+-HPLC separation of CLA isomers in food and biological specimens. The potential of the Ag^+-HPLC method is illustrated with three examples. Figure 3 shows three additional Ag^+-HPLC separations of mixtures containing CLA isomers. Figure 3A represents the CLA composition of a commercial CLA mixture obtained from Natural Lipids Ltd. (Hovdebygda, Norway) fed to pigs in an experiment reported elsewhere (26), whereas Figure 3B shows the distribution of CLA isomers present in the total liver lipids of the pigs fed the above diet; pigs fed the control diet showed no observable CLA peaks. It is evident from Figures 3A and 3B that the commercial diet and biological matrix contained many geometric and positional isomers of CLA, some of which still remain to be identified. Some bioconcentration of the *c,t*-9,11-18:2 was evident compared to the dietary distribution of CLA isomers. A complete composition of CLA isomers in tissue lipids will be presented elsewhere. In addition, Figure 3C presents a typical CLA distribution found in a commercial cheese product. The only major CLA isomer in cheese is the *c,t*-9,11-18:2. Detailed analyses of food products are in progress.

In conclusion, Ag^+-HPLC proved to be an excellent method for the analysis and isolation of most geometric and positional isomers of CLA. Furthermore, this method allowed

the identification of CLA isomers not separable by other complementary techniques, such as GC. In combination with GC–DD–FTIR and GC–EIMS, a more accurate confirmation of the identity of CLA isomers in commercial and biological specimens is now possible.

Phospholipase D Hydrolyzes Short-Chain Analogs of Phosphatidylcholine in the Absence of Detergent

Leslee L. Davis, Jeffrey J. Maglio, and Joel Horwitz*

MCP ◆ Hahnemann School of Medicine, Allegheny University of the Health Sciences, Philadelphia, Pennsylvania 19129

ABSTRACT: Phospholipase D is an important enzyme in signal transduction in neuronal tissue. A variety of assays have been used to measure phospholipase D activity *in vitro*. The most typical measure of phospholipase D activity is the production of phosphatidylethanol in the presence of ethanol. Phosphatidylethanol is a product of transphosphatidylation activity that is considered a unique property of phospholipase D. To support transphosphatidylation activity, high concentrations of ethanol may be required. Furthermore, most assays in the literature utilize a detergent. These extreme conditions, detergent and ethanol, may alter phospholipase D and hinder the study of its regulation. In this manuscript we describe an assay that eliminates these potentially confounding conditions. It utilizes high specific activity [^{3}H]butanol as a nucleophilic receptor. This eliminates the need for high concentrations of alcohol. The substrate is an analog of phosphatidylcholine that contains short-chain fatty acids, 1,2-dioctanoyl-*sn*-glycero-3-phosphocholine. Phospholipase D readily hydrolyzes this substrate in the absence of detergent. This novel assay should be useful in the further characterization of phospholipase D.

Lipids 33, 223–227 (1998).

Phospholipase D is an important enzyme in neuronal signal transduction (1–3). It is activated by many neurotransmitters and hormones. In neuronal tissue, phospholipase D activity specifically hydrolyzes phosphatidylcholine (4–8). This hydrolysis leads to the production of phosphatidic acid and choline. Phosphatidic acid could act as a second messenger or be hydrolyzed by phosphatases to form diacylglycerol. Diacylglycerol activates protein kinase C, which can phosphorylate and activate other enzymes. Choline in cells that contain choline acetyltransferase can serve as a precursor to acetylcholine.

The most typical measure of phospholipase D activity is transphosphatidylation (6). Usually, this requires a high concentration of ethanol, ~400 mM. Furthermore, most *in vitro* assays for phospholipase D utilize a detergent, e.g., sodium oleate or Triton X-100 (5,6,9) . It is not clear whether the detergent is necessary to activate the enzyme or to make the substrate more accessible (10). These extreme conditions, detergent and ethanol, may alter phospholipase D and hinder the ability to study its regulation. In this paper we describe a novel assay for phospholipase D that attempts to eliminate these potentially confounding conditions. It utilizes high specific activity [^{3}H]butanol as a nucleophilic receptor. This eliminates the need for high concentrations of alcohol. The substrate is an analog of phosphatidylcholine that contains short-chain fatty acids, 1,2-dioctanoyl-*sn*-glycero-3-phosphocholine (PC8). Phospholipase D readily hydrolyzes this substrate in the absence of detergent or other cofactors such as phosphatidylinositol-4,5-bisphosphate and GTPγS.

MATERIALS AND METHODS

Isolation of microsomal membranes. Crude microsomal membranes were isolated from whole rat brain. Brains were homogenized in 10 vol of cold 0.32 M sucrose containing 1 mM EGTA. The crude homogenate was centrifuged for 10 min at 1,000 *g*. The supernatant was then centrifuged for 30 min at 20,000 *g*. Finally, the microsomal membranes were pelleted by centrifugation at 100,000 *g* for 60 min. The pellet was then washed with 0.32 M sucrose. The membranes were resuspended at a concentration of 2 mg protein/mL and stored at −80°C until use.

Phospholipase D activity. PC8, stored in chloroform, was dried under a stream of nitrogen, resuspended in ether, and then dried again. The lipid was resuspended in 5 mM HEPES, pH 6.6 and allowed to sit at room temperature for 1 h. At the the end of this time, the lipids were sonicated for 30 s with a probe sonicator, at low power, using a 50% duty cycle (Branson Sonifier 250; Danbury, CT). The reaction was initiated by adding 20 μL of this lipid suspension. Unless otherwise indicated, the assay conditions were: 3.5 mM phospholipid; 50 mM HEPES, pH 6.6; 5 μCi [^{3}H]butanol (15 Ci/mmol; American Radiolabeled Chemical, St. Louis, MO) and 100 μg of crude membrane protein in a final volume of 120 μL. The activity of the enzyme with PC8 as a substrate is linear from 10 to 100 μg of protein. In some experiments the buffer was β-dimethylglutaric acid or Tris maleate, and in other experiments 10 mM EDTA or a divalent cation was added to the incubation. These different conditions did not affect the activity of the enzyme. Blanks contained 0.32 M sucrose rather than membranes. Incubations were carried out for 10 min at

Abbreviations: CMC, critical micellar concentration; K_M, Michaelis constant; PC8, 1,2-dioctanoyl-*sn*-glycero-3-phosphocholine.

30°C unless otherwise stated. The reactions were stopped by adding 3 mL of ice-cold chloroform/methanol (1:2) and 0.7 mL of 1% perchloric acid. The mixture was vortexed for 1 min. The phases were separated by the addition of 1 mL of 1% perchloric acid and 1 mL of chloroform. After vortexing, the tubes were centrifuged and the upper phase was aspirated. The lower phase was then washed twice with 2 mL of 1% perchloric acid. An aliquot of 500 µL was removed and dried for thin-layer chromatography. When phosphatidylcholine from egg yolk was used as substrate, it was dried under a stream of nitrogen and then resuspended in 36 mM sodium oleate in 5 mM β-dimethylglutaric acid, pH 6.5. This suspension was allowed to sit for 60 min at room temperature. Vesicle formation was induced by sonicating in a small bath sonicator (Branson 1200) at 20-s intervals for 10 min. During the intervening 20-s interval, the tube was put on ice. In one experiment the substrate was L-α-dipalmitoyl-[2-palmitoyl-9,10-^{3}H(N)]phosphatidylcholine (specific activity 2 mCi/mmol). It was prepared as above except that it was mixed with egg yolk phosphatidylcholine.

Thin-layer chromatography was routinely done according to Liscovitch (11). Whatman LK6 plates (Clifton, NJ) were dipped in 1.3% potassium oxalate made up in methanol/H_2O (2:3) and allowed to dry at room temperature. Just before use, the plates were activated by heating at 115°C for 1 h. The mobile phase was the upper layer of a mixture of: ethyl acetate/isooctane/acetic acid/H_2O (13:2:3:10). The thin-layer chromatography scrapings were counted by scintillation spectrometry. Dioctanoyl-phosphatidylbutanol from cold butanol had the same R_f as dioctanoyl-phosphatidyl[^{3}H]butanol generated from [^{3}H]butanol (see Fig. 2).

Materials. Male Sprague Dawley rats were obtained from ACE Animals (Boyertown, PA) at 150–200 g. [^{3}H]Butanol (15 Ci/mmol) was obtained from American Radiolabeled Chemicals; and [^{3}H]dipalmitoyl-glycero-3-phosphocholine was from New England Nuclear (Boston, MA), sold as L-α-dipalmitoyl-[2-palmitoyl-9,10-^{3}H(N)] phosphatidylcholine. Phospholipids, sodium oleate, and dimethylglutaric acid were obtained from Sigma (St. Louis, MO). Phosphatidylethanol was obtained from Avanti Polar Lipids (Birmingham, AL).

RESULTS AND DISCUSSION

PC8 is a good substrate for phospholipase D. The production of phosphatidylalcohol is considered a reliable index of phospholipase D activity. The availability of high specific activity radiolabeled alcohol allows the use of novel unlabeled substrates that are not available in radiolabeled form. We have already used this approach to study the substrate specificity of neuronal phospholipase D (5). In this manuscript we further exploit this advantage to examine the use of short-chain analogs of phosphatidylcholine as substrates for phospholipase D. In the experiment shown in Figure 1, microsomal membranes prepared from whole rat brain were incubated with two different substrates: PC8 (3.5 mM) and phosphatidylcholine isolated from egg yolk (2 mM). The acceptor, [^{3}H]butanol, was added at a final concentration of 3 µM. We and many other investigators have shown that optimal activity of phospholipase D requires the presence of a detergent such as sodium oleate (6). Consistent with this finding, when egg yolk phosphatidylcholine was used as a substrate, detergent was absolutely required for activity. From the data in Figure 1 it is apparent that PC8 is a better substrate for phospholipase D even in the absence of detergent.

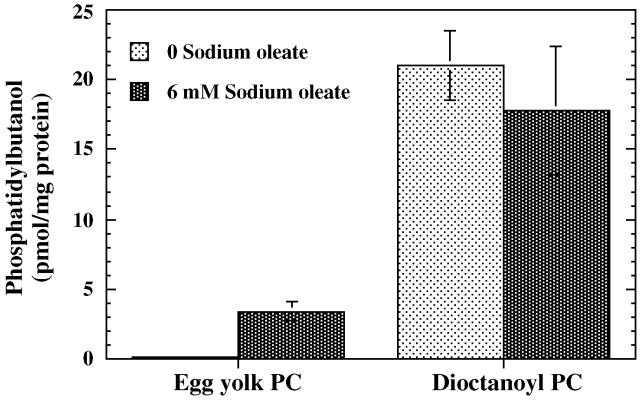

FIG. 1. The effect of sodium oleate on phospholipase D activity. Each reaction mixture contained 50 mM dimethylglutaric acid (pH 6.5), 10 mM EDTA, 5 µCi [^{3}H]butanol (15 Ci/mmol), and 100 µg of microsomal membrane protein. The final concentration of phosphatidylcholine (PC) from egg yolk was 2 mM, and the final concentration of dioctanoyl-PC was 3.5 mM. The substrate was prepared by sonicating the phospholipids in the presence and absence of 36 mM sodium oleate (final concentration = 6 mM) or buffer. Incubation time was 60 min. Data represent the mean ± SEM of three determinations.

PC8 is hydrolyzed to phosphatidic acid. The action of phospholipase D would be expected to lead to the production of phosphatidic acid. Figure 2 shows that there was an increase in phosphatidic acid in control incubations. This 1,2-dioctanoyl-*sn*-glycero-3-phosphate had the same R_f as a standard obtained from Avanti Polar Lipids (Birmingham, AL). Consistent with earlier findings, the greater the production of phosphatidylalcohol, the lower the production of phosphatidic acid (12). This was most apparent in the incubation with 100 mM butanol. Ethanol was added at a concentration of 400 mM because it is a less efficient acceptor than butanol (5). Phosphatidylethanol generated from the hydrolysis of PC8 has a lower R_f than phosphatidylethanol produced from egg yolk.

Phosphatidylbutanol is not produced via *a base exchange enzyme.* Phosphatidylbutanol could be formed by the action of a base exchange enzyme (13). This enzyme normally exchanges headgroups such as choline or serine. It is active at high pH and is stimulated by Ca^{2+}. If the base exchange enzyme is active, choline would be expected to compete with [^{3}H]butanol for this enzyme. However, choline at a concentration of 1 mM and in the presence of Ca^{2+} did not inhibit the production of phosphatidyl[^{3}H]butanol at pH 6 through 7.2 (data not shown). At pH 8.4 it caused a 34% inhibition of phosphatidyl[^{3}H]butanol production. Furthermore, when [^{3}H]choline was added to the incubation medium, there was only minimal incorporation into PC8. These data suggest that the production of phos-

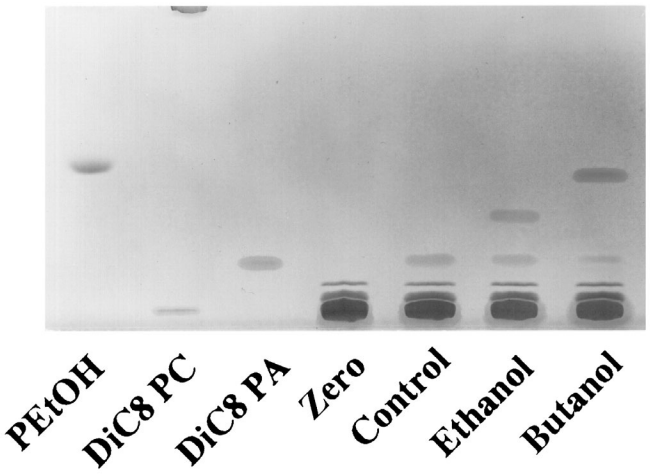

FIG. 2. Mass amount of phosphatidic acid and phosphatidylalcohol production. The first three lanes contain 4 mg of standards in the following order: egg yolk phosphatidylethanol (PEtOH), dioctanoyl-phosphatidylcholine (DiC8PC), and dioctanoyl-phosphatidic acid (DiC8PA). The last four lanes contain samples from standard reaction conditions without labeled [^{3}H]butanol but with unlabeled alcohol. Each reaction mixture contained 50 mM HEPES (pH 6.6), 1 mM $MgCl_2$, 25 mM NaF, and 100 µg of microsomal membrane protein. The final concentration of DiC8PC was 7 mM. The incubation time was 20 min. The lane labeled Zero contained sample that was not incubated. The lane labeled Control contained sample that was incubated without alcohol. The concentration of ethanol was 400 µM and the concentration of butanol was 100 µM. The phospholipids were visualized with molybdate phosphate spray and then photographed.

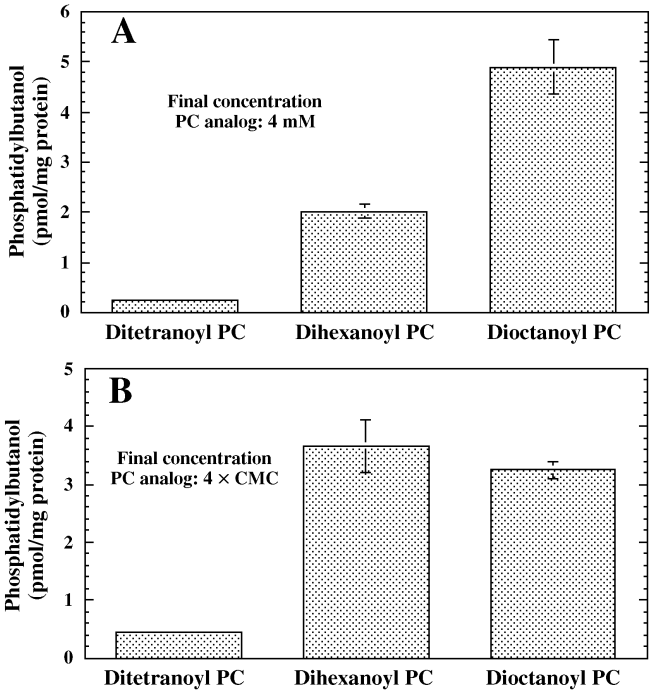

FIG. 3. Short-chain analogs of PC as substrates for phospholipase D. (A) Each reaction mixture contained 25 mM Tris maleate (pH 6.8), 1.25 mM EGTA, 6 mM $MgCl_2$, 5 µCi [^{3}H]butanol (15 Ci/mmol), and 90 µg of microsomal membrane protein. The final concentration of PC analog was 4 mM. Incubation time was 10 min. The substrate was prepared by sonicating the phospholipids for 30 s in water using a bath sonicator. (B) Each reaction mixture contained: 50 mM HEPES (pH 6.6), 5 µCi [^{3}H]butanol (15 Ci/mmol), and 70 µg of microsomal membrane protein. The final concentration of PC analog was 3.75 times the critical micellar concentration (CMC) for each phospholipid. 1,2-Ditetranoyl-*sn*-glycero-3-phosphocholine, 300 mM; 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine, 56 mM; 1,2-dioctanoyl-*sn*-glycero-3-phosphocholine, 1 mM. Incubation time was 20 min. The substrate was prepared by sonicating and vortexing in 5 mM HEPES, pH 6.6. Data represent the mean ± SEM of three or four determinations. For other abbreviation see Figure 1.

phatidylbutanol is not due to the base exchange enzyme.

Phospholipase D is affected by the chain length of the phosphatidylcholine analog. The activity of a phospholipase D is strongly influenced by the physical form of the substrate. The phospholipid may be present as a monomer, micelle, or bilayer. To address this issue, we measured the activity of phospholipase D against substrates containing fatty acids of different chain lengths. The data are shown in Figure 3A. All substrates were prepared such that the final concentration was 4 mM. 1,2-Ditetranoyl-*sn*-glycero-3-phosphocholine has a high critical micellar concentration (CMC). It does not form micelles up to 80 mM (14). Thus, at this concentration the 1,2-ditetranoyl-*sn*-glycero-3-phosphocholine would be present in the monomeric form. There is essentially no phospholipase D activity when this short-chain phosphatidylcholine is used as substrate. 1,2-Dihexanoyl-*sn*-glycero-3-phosphocholine has a CMC of 14 mM but does aggregate to form small micelles at lower concentrations (15). There is a small but significant amount of activity when this analog is used as substrate. The CMC for 1,2-dioctanoyl-*sn*-glycero-phosphocholine is approximately 0.25 mM (16). Thus, this substrate is probably present entirely in the micellar form. The activity is highest when PC8 is the substrate.

The foregoing data suggest that micellar structure is important for the activity of phospholipase D. To investigate this possibility, we measured phosphospholipase D at a substrate concentration four times the CMC (Fig. 3B). Under these conditions a phospholipase D hydrolyzes 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine just as well as PC8. However, the activity against 1,2-ditetranoyl-*sn*-glycerophosphocholine is relatively low despite the fact that it is at the CMC. Thus, micellar structure is important; however, chain length of the fatty acid also influences the ability of the phospholipid to interact with phospholipase D. The longer-chain analogs may have the additional ability to act as emulsifiers to enhance activity (10). Since the activity was highest with PC8 at the lowest concentration, additional experiments to characterize phospholipase D activity were done with this substrate.

Kinetics of phospholipase D activity. At a substrate concentration of 8 mM, the production of phosphatidylbutanol is linear for at least 40 min (Fig. 4A). The production of phosphatidylbutanol began without any apparent lag after the addition of liposomes. Figure 4B shows production of phosphatidylbutanol as a function of substrate concentration using an incubation time of 10 min. Under these conditions the apparent K_m for the PC8 is 1 mM. Maximal activity was obtained at a PC8 concentration of 3.5 mM. The enzyme activ-

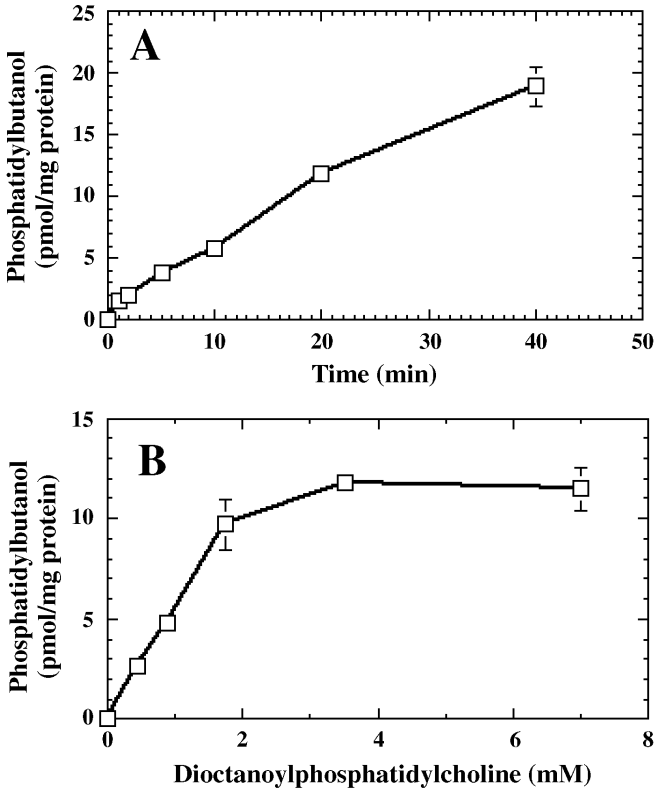

FIG. 4. Time course (A) and concentration dependence (B) of phospholipase D activity with dioctanoylphosphatidylcholine as substrate. Each reaction mixture contained 50 mM HEPES (pH 6.6), 1 mM $MgCl_2$, 5 μCi [^{3}H]butanol (15 Ci/mmol), and 100 μg of microsomal membrane protein. The incubation time for the determination of concentration dependence was 10 min. The substrate concentration in the time-course experiment was 8 mM. Data represent the mean ± SEM of four determinations.

ity appears to follow classic Michaelis-Menten kinetics.

The estimated specific activity of the radiolabeled alcohols obtained from American Radiolabeled Chemicals was 15 Ci/mmol. Each assay contained 5 μCi/120 μL. The actual concentration of cold alcohol therefore was approximately 3 μM. These data suggest that significant amounts of phosphatidylalcohol can be formed even at very low concentrations of alcohol. It is possible that the concentration of alcohol is too low to drive the reaction at an optimal rate. To investigate this issue, microsomal membranes were incubated with increasing concentrations of butanol while maintaining a constant specific activity (2 Ci/mmol). There was linear relationship between phosphatidylbutanol production and butanol concentration but only at concentrations higher than 10 μM (Fig. 5). Thus, at 5 μM the amount of phosphatidylbutanol formed in this particular experiment was 3.5 pmol/mg protein; at 10 μM the amount of production was 18 pmol/mg protein. Therefore, these data indicate that there is significant production of phosphatidylalcohol even at low concentrations; higher concentrations lead to a higher rate of reaction, proportional to the concentration of butanol.

Ionic and pH dependence of phospholipase D. Phospholipase D has been reported to have a pH optimum of 6.5 or 7.2.

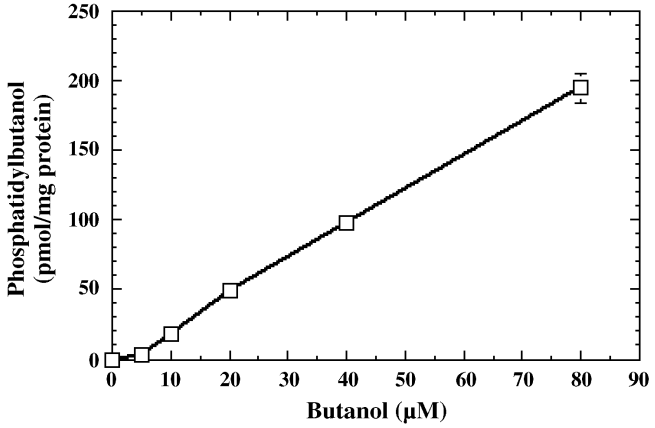

FIG. 5. Dependence of phospholipase D activity on butanol concentration. Each reaction mixture contained 50 mM HEPES (pH 6.6) and 100 μg of microsomal membrane protein. High specific activity [^{3}H]butanol was diluted with unlabeled butanol to make [^{3}H]butanol with a specific activity of 2 Ci/mmol. This labeled [^{3}H]butanol was added to the reaction mix to produce different concentrations of butanol. The final concentration of dioctanoylphosphatidylcholine was 8 mM. The incubation time was 10 min. Data represent the mean ± SEM. of three determinations.

Using the buffer dimethylglutaric acid and the detergent sodium oleate, Kobayashi and Kanfer (6) reported a pH optimum of 6.5 for microsomal membrane phospholipase D. In contrast, Chalifa *et al.* (17) using the same detergent but another buffer, HEPES, found that the pH optimum for phospholipase D in synaptic plasma membranes was 7.2. Figure 6 shows the pH dependence of this enzyme using PC8 as a substrate without any detergent and with HEPES as the buffer. There was activity in the entire pH range from 6 to 8.4 with a broad pH optimum between 7.2 and 7.8. Differences in reported pH optima may be due to different detergents used in the assay (9,18); alternatively these data may suggest the

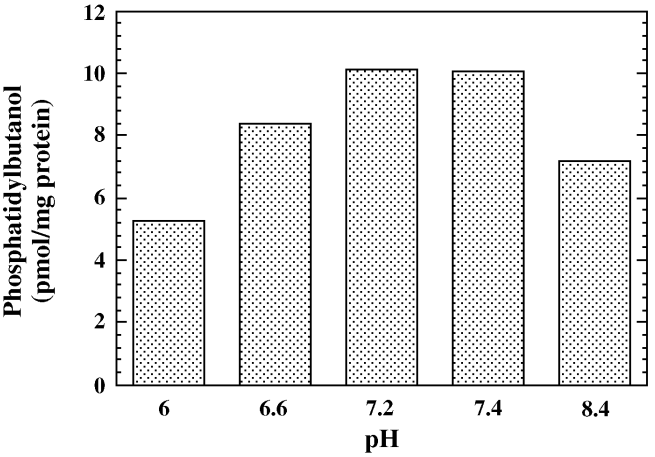

FIG. 6. The pH dependence of phospholipase D activity. Each reaction mixture contained 50 mM HEPES (pH 6.6 to 8.4), 1 mM $MgCl_2$, 5 μCi [^{3}H]butanol (15 Ci/mmol), and 100 μg of microsomal membrane protein. The final concentration of dioctanoylphosphatidylcholine was 7 mM. The substrate was prepared by sonicating the phospholipids in H_2O. Data represent the mean of two determinations.

presence of multiple isozymes of phospholipase D.

An investigation of the ionic dependence of phospholipase D was done. Mg^{2+} has been reported to stabilize the enzyme (17). Ca^{2+} has been reported to be both stimulatory and inhibitory (19–21). By using this assay, there was a high level of activity in the absence of any ions. Addition of Ca^{2+} and Mg^{2+} in concentrations ranging from 0.1 μM to 2 mM had only a mild stimulatory effect that was not significant and not reproducible (data not shown). Thus, there is no apparent ionic dependence under these conditions.

The novelty of this assay is that phospholipase D is active in the absence of phosphatidyinositol-4,5-bisphosphate. Liscovitch *et al.* (22) and Waksman *et al.* (23) have reported that phospholipase D hydrolyzes phosphatidylcholine analogs containing short-chain fatty acids in the 2-position in the absence of detergent. However, in the former case (22) this hydrolytic activity was dependent upon the presence of phosphatidylinositol-4,5-bisphosphate. In contrast, Vinggaard *et al.* (24) reported that phospholipase D hydrolyzes 1,2-didecanoyl-*sn*-glycero-3-phosphocholine in the absence of phosphatidylinositol-4,5-bisphosphate. Furthermore, the hydrolytic activity of phospholipase D against PC8 is not dependent on GTPγS or ADP ribosylation factor (data not shown). These studies represent a logical extension of the work of Vinggard *et al.* (24) and suggest that phospholipase D can hydrolyze short-chain analogs of phosphatidylcholine in the absence phosphatidylinositol-4,5-bisphosphate or other cofactors.

In conclusion, the use of [^{3}H]butanol in combination with the short-chain analog, PC8, represents a novel and potentially very useful method for assaying phospholipase D activity. PC8 is a very efficient substrate; therefore the assay is sensitive. The use of [^{3}H]butanol eliminates the need for high concentrations of alcohol which could affect enzymatic activity. Thus, this assay could be used to characterize phospholipase D under conditions that more closely reflect the situation *in vivo.*

Atherogenic Potential of Peanut Oil-Based Monounsaturated Fatty Acids Diets

Dear Editor,

In the dietary management of coronary heart disease (CHD), there is increasing recognition (1,2) that the traditionally recommended high carbohydrate, low-fat diet for hypercholesterolemia (3) may elicit undesirable blood lipid changes, including reductions in high-density lipoproteins and apolipoprotein A-1, while concurrently elevating triglycerides (TG) and very low density lipoproteins (4–6). Because of these untoward blood lipid changes induced by high-carbohydrate, low-fat diets, substitution of monounsaturated fatty acids (MUFA) for saturated fats may be a more effective strategy than substitution of carbohydrate for saturated fats in order to lower total and low density lipoprotein (LDL) serum cholesterol levels without adversely influencing high density lipoprotein, very low density lipoprotein, TG, and apolipoprotein A-1 (7–9). Most experimental diets have employed olive oil or canola oil as the MUFA source; however other MUFA-rich foods such as nuts (10) and avocados (11) have also been demonstrated to improve blood lipid profiles. In a recent report to *Lipids,* O'Byrne *et al.* (12) have shown that a low-fat, high-MUFA (14% energy) diet based upon high-MUFA (76–80%) peanuts improved total and LDL serum cholesterol levels in 12 postmenopausal women. Although diets based upon MUFA-rich peanuts (*Arachis hypogea*) should, in theory, be nonatherogenic because they reduce total and LDL cholesterol, there is substantial evidence to indicate that peanut oil, despite its hypolipidemic effects, is highly atherogenic to animals and possibly to humans as well.

Although the total MUFA content of peanut oil is high and can range from 36 to 59%, dependent upon the specific cultivar (13), it has been shown to be unexpectedly atherogenic when fed to laboratory animals (monkeys, rabbits, and rats) as part of a cholesterol-rich or a cholesterol-free diet (13–16). Because peanut oil can so rapidly produce atherosclerotic lesions which have similar biochemical and pathological characteristics to those in human atherosclerosis, it is routinely used in rabbit models to induce atherosclerosis (17,18). The reason for the high atherogenicity of peanut oil is unclear; however, it has been suggested that it may be due to residual lectins (glycoproteins with high affinity binding to cellular carbohydrate residues) found in the oil, since peanut oil induces fibromuscular arterial lesions in contrast to other vegetable oils which induce fatty lesions (19). Alternatively, the specific TG structure may also be responsible for its atherogenicity (20). In native peanut oil, all of the long-chain polyunsaturated fatty acids are found in the *sn*-3 position of glycerol; however, by utilizing a process to randomize the fatty acids within the TG, the atherogenicity of peanut oil has been shown to be reduced (21). It should be pointed out that the randomization process in some cases may also reduce peanut oil's lectin content (20,21).

When contrasting olive to peanut oil, rabbits which were fed peanut oil showed a higher frequency of arterial lesions, more intimal proliferation, and thicker intimas than did rabbits fed olive oil (15). Peanut oil-containing, atherogenic diets induce a preferential increase in intimal collagen and result in a characteristic fibromuscular lesion in intimal plaques that is attributable to the addition of peanut oil to the atherogenic diet (22,23). It has been suggested that residual peanut lectin (PNA) found in peanut oil, because of its specificity for D-galactose residues, may bind arterial smooth muscle cells expressing these sugar residues and thereby induce its characteristic fibromuscular lesions (19). In support of this concept are data which have shown that PNA stimulates *in vitro* vascular smooth muscle cell proliferation and that added lactose could inhibit the PNA-induced stimulation (24). A similar *in vivo* experiment would be able to distinguish if peanut oil's atherogenicity is more attributable to its PNA content or to its specific TG structure.

Although there are no direct epidemiological studies evaluating the atherogenic potential of peanut oil, there is suggestive information from India that implicates peanut oil with higher mortality rates from CHD. In India, wherein vegetable oils constitute 80% of the per capita fat consumption, there are regional preferences in the choice of oils, and peanut oil is preferred in southern states, whereas northern states use mustard oil (25). In southern India, the mortality rate from CHD 30 yr ago was reported to be seven times higher than that in northern India and similar to that in the United States and England (26,27). A more recent report showed the prevalence of CHD to be 61.6% higher in southern Indians compared to their more northerly counterparts (28). It is possible that one of the factors underlying these regional differences may be different levels of peanut oil consumption. In contrast to peanut oil, which is a fairly recent addition to the human diet, olive oil has been part of the traditional Mediterranean diet for thousands of years (29) and has been shown both epidemiologically (30) and clinically (31) to reduce the risk for

*E-mail: cordain@cahs.colostate.edu.

CHD in subjects living in industrialized countries. These studies suggest that olive oil may be superior to peanut oil in terms of its cardiovascular health benefits in such populations. Until further trials are conducted, it would seem premature to recommend peanut oil as part of high-MUFA diets for the management of CHD in Western populations.

ARTICLE

Dietary Methionine Level Affects Linoleic Acid Metabolism Through Phosphatidylethanolamine *N*-Methylation in Rats

Kimio Sugiyama[a,*], Akemi Kumazawa[a], Hong Zhou[a], and Shigeru Saeki[b]

[a]Department of Applied Biological Chemistry, Faculty of Agriculture, Shizuoka University, Shizuoka 422, Japan, and [b]Department of Food and Nutrition, Faculty of Human Life Science, Osaka City University, Osaka 558, Japan

ABSTRACT: The effects of dietary methionine level on the profiles of fatty acids and phospholipids and on the plasma cholesterol concentration were investigated to confirm whether the methionine content of dietary proteins is one of the major factors that cause differential effects on lipid metabolism. The effect of dietary supplementation with eritadenine, which is shown to be a potent inhibitor of phosphatidylethanolamine (PE) *N*-methylation, was also investigated. Rats were fed six diets containing casein (100 g/kg) and amino acid mixture (86.4 g/kg) differing in methionine content (2.5, 4.5, and 7.5 g/kg) and without or with eritadenine supplementation (30 mg/kg) for 14 d. The ratio of arachidonic to linoleic acid of liver microsomal and plasma phosphatidylcholine (PC) was significantly increased as the methionine level of diet was elevated, indicating that dietary methionine stimulates the metabolism of linoleic acid. The PC/PE ratio of liver microsomes and the plasma cholesterol concentration were also increased by dietary methionine. These effects of methionine were completely abolished by eritadenine supplementation The *S*-adenosylmethionine concentration in the liver reflected the methionine level of diet. These results support the idea that the differential effects of dietary proteins on lipid metabolism might be ascribed, at least in part, to their different methionine contents, and that methionine might exert its effects through alteration of PE *N*-methylation.
Lipids 33, 235–242 (1998).

It is confirmed that lipid metabolism can be modified by the type of dietary proteins. For instance, plant proteins compared with animal proteins generally lead to lower plasma cholesterol concentrations (1–4). The metabolism of fatty acids, especially linoleic acid, also has been shown to be affected by dietary protein types (5,6). Additionally, the profile of liver microsomal phospholipid classes, as represented by the ratio of phosphatidylcholine (PC) to phosphatidylethanolamine (PE), could be altered by the type of dietary proteins (7). A number of studies so far reported have suggested that both the difference in the physicochemical properties and the difference in the amino acid composition of dietary proteins participate in the differential effects on the plasma cholesterol concentration. In contrast, the mechanism underlying the differential effects of dietary proteins on the metabolism of fatty acids appears to be less understood. Recently we demonstrated that methionine supplementation of a low-methionine diet containing soybean protein brought about a significant increase in the ratio of arachidonic to linoleic acid of liver microsomes and plasma in rats, suggesting that dietary methionine stimulates the metabolic conversion of linoleic acid into arachidonic acid (8). The PC/PE ratio of liver microsomes and the plasma cholesterol concentration also were increased by methionine supplementation (8). These results suggest that the methionine content of dietary proteins may have a wide range of effects on lipid metabolism, and that metabolism of linoleic acid, phospholipids, and cholesterol may not be independent of each other. Furthermore, previous studies have suggested that dietary methionine level may affect the PC/PE ratio of liver microsomes through alteration of PE *N*-methylation (7,8). If this is true, the effect of dietary methionine on lipid metabolism would be abolished or suppressed by the inhibitor of PE *N*-methylation.

In this study, the effects of dietary methionine level on the composition of fatty acids and molecular species of PC on the microsomal PC/PE ratio and on the plasma cholesterol concentration were investigated to confirm whether the methionine content of dietary proteins is one of the major factors that cause differential effects on lipid metabolism. The effect of supplementation with eritadenine, which strongly depresses PE *N*-methylation (9), also was investigated to see whether the effect of methionine can be abolished by eritadenine.

MATERIALS AND METHODS

Animals. Thirty-six male 5-wk-old rats of the Wistar strain were received at 90–100 g body weight from Japan SLC (Hamamatu, Japan). The rats were individually housed in hanging stainless-steel wire cages kept in an isolated room at

Abbreviations: GLC, gas–liquid chromatography; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; LDL, low density lipoprotein; PC, phosphatidylcholine; PE, phosphatidylethanolamine; SAH, *S*-adenosylhomocysteine; SAM, *S*-adenosylmethionine; TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

a controlled temperature (23–25°C) and humidity (40–60%). Lights were maintained on a 12-h cycle (lights on from 0600 to 1800 h). For 5 or 6 d, rats were fed the powdered laboratory stock diet as described previously (10). Then, they were divided into six groups of six rats each with similar mean weights (~121 g) and allowed free access to the experimental diets and water for 14 d. The experimental plan was approved by the Laboratory Animal Care Committee of the Faculty of Agriculture, Shizuoka University.

Diets. Six diets differing in methionine content (2.5, 4.5, and 7.5 g/kg diet) and without or with eritadenine were utilized in this study. Table 1 shows the composition of experimental diets without eritadenine. Casein (100 g/kg) and casein-simulating amino acid mixture (86.4 g/kg) were used as protein sources. Therefore, the diets were comparable to 20% casein diet in the amino acid composition except for sulfur amino acids. The amount of total sulfur amino acids (methionine and cystine) in the diet was maintained to a constant level on a molar basis, which was equivalent to the amount of methionine of 8 g/kg diet. Eritadenine was added to the diet at a level of 30 mg/kg diet at the expense of lactose; this dose level was shown to be sufficient to elicit maximal effect (10). The eritadenine was isolated from dried *Lentinus edodes* mushroom as reported previously (10). The fatty acid composition of corn oil used was as follows (wt%): 16:0, 12.2; 18:0, 1.8; 18:1, 32.8; 18:2n-6, 51.4; and 18:3n-3, 1.6.

Tissue collection and fractionation. At the end of the feeding period, non-fasted rats were killed by decapitation under light anesthesia with diethyl ether between 1200 and 1300 h. Plasma was separated from heparinized whole blood by centrifugation at 2000 × *g* for 20 min at 4°C. An aliquot of the plasma was stored at 4°C until subsequent analyses for plasma lipid concentrations, and the residual plasma was stored at −80°C until analyses for phospholipids. After collection of blood, the whole liver was quickly removed, rinsed in ice-cold saline, blotted on filter paper, and weighed. The liver was homogenized in 4 vol (vol/wt) of an ice-cold 10 mM Tris-HCl buffer (pH 7.4) containing 0.15 M KCl, a modified solution of Nguyen *et al*. (11). An aliquot (2 mL) of the homogenate was stored at −30°C until subsequent analyses for liver lipid concentrations. Another aliquot (12 mL) of the homogenate was centrifuged at 10,000 × *g* for 12 min at 4°C, and the resultant supernatants were further centrifuged at 105,000 × *g* for 60 min at 4°C to obtain the microsomal fraction as a precipitate. The microsomes obtained were resuspended in the homogenizing buffer and stored at −80°C until analyses for phospholipids.

Lipid analysis. The plasma concentrations of total cholesterol, high density lipoprotein (HDL) cholesterol, free cholesterol, triglycerides, and phospholipids were measured enzymatically with kits (Cholesterol C-Test, HDL Cholesterol-Test, Free Cholesterol C-Test, Triglyceride G-Test, and Phospholipid B-Test, respectively; Wako Pure Chemical, Osaka, Japan). The difference between total cholesterol and HDL cholesterol or free cholesterol was assumed to be very low density lipoprotein (VLDL) + low density lipoprotein (LDL) cholesterol or esterified cholesterol, respectively. The total lipids of liver homogenate, liver microsomes, and plasma were extracted by the method of Folch *et al*. (12). The cholesterol, triglycerides, and phospholipids in the extract of liver homogenate were measured according to Zak (13), Fletcher (14), and Bartlett (15), respectively. For the determination of phospholipid class composition, the phospholipids in the extract of liver microsomes were separated into each class by thin-layer chromatography (TLC) on silica gel 60 (E. Merck, Darmstadt, Germany) using chloroform/methanol/water (65:25:4, by vol) as a developing solvent. The bands of each phospholipid class were visualized in iodine vapor, scraped off the plate, and analyzed directly for inorganic phosphorus (15). For the determinations of fatty acid and molecular species composition, PC was likewise separated by TLC from liver microsomes and plasma, visualized with dichlorofluorescein, scraped off the plate, and extracted with chloroform/methanol (1:2, vol/vol). An aliquot of PC was treated with 14% (w/w) BF_3/methanol reagent (Wako Pure Chemical), and fatty acid methyl esters formed were analyzed by gas–liquid chromatography (GLC) on a Model GC-17A (Shimadzu, Kyoto, Japan), equipped with a TC-FFAP capillary column (0.25 mm × 30 m; GL Sciences, Tokyo, Japan). Another aliquot of PC was converted to diacylglycerol benzoates according to the method of Blank *et al*. (16). The diacylglycerol benzoates were analyzed by high-performance liquid chromatography (HPLC) on a Model LC-6A system (Shimadzu), equipped with an ODS column (4.6 × 250 mm, Lichrosorb RP-18; E. Merck), essentially according to the method of Blank *et al*. (16). Since some peaks consisted of two molecular species, the ratio of two molecular species was determined by the analysis of fatty acids by GLC. A representative chromatogram of PC molecular species by HPLC was shown previously (17).

[a]Values are mean ± SEM for six rats. Values in a row with different superscripts are significantly different at $P < 0.05$.

Assay of methionine metabolites and protein. The concentrations of *S*-adenosylmethionine (SAM) and *S*-adenosylhomocysteine (SAH) in the liver were measured with HPLC according to Cook *et al*. (18) with some modifications. Frozen livers were thawed and homogenized in 4 vol (vol/wt) of ice-cold 0.5 M perchloric acid, and the homogenates were centrifuged at 10,000 × *g* for 10 min at 4°C. The resultant supernatants were filtered through a 0.45-μm Millipore filter (Nihon Millipore, Tokyo, Japan) and applied to an HPLC column (Shim-pak CLC-ODS, 6 × 150 mm; Shimadzu) . The mobile phase was a 100 mM KH_2PO_4 solution containing 10 mM sodium heptane sulfonate and 3% (vol/vol) methanol. The flow rate was 1.5 mL/min, and the elution was monitored at 254 nm. Liver microsomal protein was measured according to Lowry *et al*. (19).

Statistical analysis. Data were analyzed by one-way analysis of variance, and the differences between means were tested using Duncan's multiple range test (20) when the *F* value was significant. Simple correlation between variables was calculated by linear regression analysis using mean values. A *P* value of 0.05 or less was considered significant.

RESULTS

Growth, food intake, liver weight, and liver lipid concentrations. There was no significant difference in the body weight gain, food intake, and relative liver weights of animals among the six groups (Table 2). Dietary methionine level had little effect on liver lipid concentrations. Eritadenine supplementation tended to decrease the triglyceride concentration and inversely to increase the phospholipid concentration in the liver.

Plasma lipid concentrations. The plasma total cholesterol concentration was significantly increased by elevating dietary methionine level (Fig. 1). In the same manner, plasma concentrations of VLDL + LDL cholesterol, HDL cholesterol, and cholesteryl esters were significantly affected by dietary methionine level. The plasma concentrations of triglycerides and phospholipids were not affected by dietary methionine level. Eritadenine supplementation brought about marked decreases in the plasma concentrations of cholesterol and phospholipids, but not triglycerides. In those rats fed eritadenine-supplemented diets, the hypercholesterolemic effect of dietary methionine disappeared completely.

Methionine metabolites and microsomal phospholipids. The concentration of SAM in the liver was significantly increased by elevating dietary methionine level, whereas the concentration of SAH was unchanged (Fig. 2). Consequently, the SAM/SAH ratio was significantly increased by dietary methionine. Eritadenine supplementation significantly decreased the SAM/SAH ratio, which was mainly due to the increase in SAH concentration. The concentration of PC in liver microsomes was unaffected by dietary methionine level, whereas the concentration of PE was significantly decreased by elevating dietary methionine level. Eritadenine supplementation significantly increased the PE concentration and

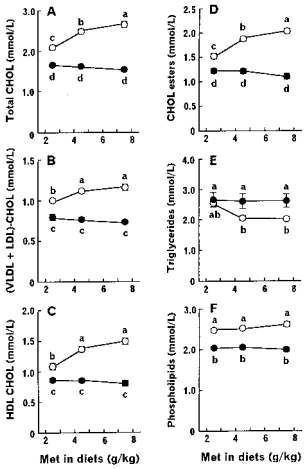

FIG. 1. Effects of dietary methionine (Met) level and eritadenine (Er) supplementation on plasma lipid concentrations in rats. The circle and its bar represent mean and SEM, respectively, for six rats. Values with different letters are significantly different at $P < 0.05$. CHOL, cholesterol; HDL, high density lipoprotein; VLDL, very low density lipoprotein; LDL, low density lipoprotein. ○, –Er; ●, + Er.

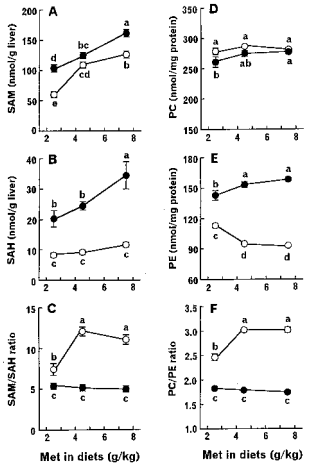

FIG. 2. Effects of dietary Met level and Er supplementation on the concentration of Met metabolites (A–C) and microsomal phospholipids (D–F) in the liver of rats. The circle and its bar represent mean and SEM, respectively, for six rats. Values with different letters are significantly different at $P < 0.05$. Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; SAH, *S*-adenosylhomocysteine; SAM, *S*-adenosylmethionine. See Figure 1 for other abbreviations and symbol legend.

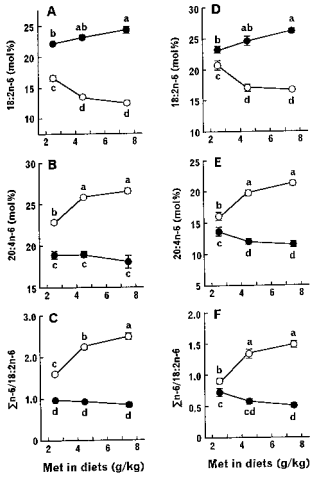

FIG. 3. Effects of dietary Met level and Er supplementation on the proportion of linoleic and arachidonic acids in liver microsomal (A–C) and plasma (D–F) PC in rats. The circle and its bar represent mean and SEM, respectively, for six rats. Values with different letters are significantly different at $P < 0.05$. Abbreviations: Σn-6, metabolites of 18:2n-6. See Figures 1 and 2 for other abbreviations. See Figure 1 for symbol legend.

consequently significantly decreased the PC/PE ratio. Eritadenine abolished the effect of dietary methionine on the PC/PE ratio.

Fatty acid and molecular species composition of PC. The proportion of linoleic acid in liver microsomal PC was significantly decreased, and conversely the proportion of arachidonic acid was significantly increased by elevating dietary methionine level (Fig. 3). Consequently, the ratio of linoleic acid metabolites to linoleic acid was significantly increased by dietary methionine. In the same manner, the proportion of linoleic and arachidonic acids in plasma PC was influenced by dietary methionine level. Table 3 shows the fatty acid composition of liver microsomal and plasma PC in rats fed diets without eritadenine. The diets higher in methionine brought about a decrease in the proportion of palmitic acid and increases in the proportion of 22:5n-6 and 22:6n-3, in addition to the suppression of linoleic acid metabolism. Table 4 shows the molecular species composition of plasma PC in rats fed diets without eritadenine. The diets higher in methionine caused a significant decrease in the proportion of 16:0-18:2 PC and a significant increase in the proportion of 18:0-20:4 PC. The effects of dietary methionine level on the other PC molecular species were relatively small. Figure 4 shows the effects of dietary methionine level and eritadenine supplementation on the proportion of plasma 16:0-18:2 and 18:0-20:4 PC molecular species. Eritadenine supplementation significantly increased the proportion of 16:0-18:2 PC and conversely significantly decreased the proportion of 18:0-20:4 PC. In the presence of dietary eritadenine, higher levels of dietary methionine potentiated the effect of eritadenine on plasma PC molecular species. There was a significantly negative or positive correlation between the concentration of plasma total cholesterol and the proportion of plasma 16:0-18:2 or 18:0-20:4 PC, respectively (Fig. 5).

DISCUSSION

Effects on fatty acid and phospholipid profiles. The conversion of linoleic acid into arachidonic acid is one of the most important metabolisms of fatty acids quantitatively and qualitatively in higher animals, since arachidonic acid exists in membrane phospholipids at relatively high levels, and since arachidonic acid is the predominant precursor for various types of eicosanoids. In rats, the metabolism of linoleic acid can be modified by dietary proteins types (5,6), in addition to the other dietary constituents, such as n-3 fatty acids (21) and cholesterol

(22). It has been shown that dietary soybean protein as compared with casein suppresses the metabolism of linoleic acid and consequently decreases the ratio of arachidonic to linoleic acid of phospholipids (6). However, by what factor of dietary proteins linoleic acid metabolism is differentially affected has not yet been fully elucidated. The present study clearly demonstrated that linoleic acid metabolism is significantly affected by the dietary level of methionine; low methionine diet led to suppressed metabolism of linoleic acid and conversely high methionine diet stimulated the metabolic conversion of linoleic acid into arachidonic acid. It is well recognized that the methionine content of soybean protein is considerably lower than that of casein. Our previous study showed that methionine supplementation of a soybean protein diet caused a significant increase in the arachidonic/linoleic acid ratio of liver microsomal and plasma PC in rats (8). Thus, the results obtained here, together with previous results, strongly suggest the idea that the differential effect of different types of dietary proteins on linoleic acid metabolism might be attributable to the difference in their methionine contents.

The conversion of linoleic acid into arachidonic acid is thought to be regulated by the activity of Δ6-desaturase, the rate-limiting enzyme of linoleic acid metabolism. Actually, it was shown that the Δ6-desaturase activity was significantly lower in rats fed a soybean protein diet than in rats fed a casein diet (22). Although Δ6-desaturase activity was not measured in the present study, fatty acid profiles, as represented by the arachidonic/linoleic acid ratio, suggest that dietary methionine level might affect the enzyme activity. This may be further supported by the fact that 22:5n-6 and 22:6n-3 were increased by elevating dietary methionine level, despite 22:4n-6 and 22:5n-3 being unchanged. The enzyme Δ6-desaturase is also thought to participate in the formation of 22:5n-6 and 22:6n-3 from 22:4n-6 and 22:5n-3, respectively (23). It is interesting to know by what mechanism dietary methionine level affects the metabolism of linoleic acid. With regard to this, there are several reports to provide available information. For instance, Leikin and Brenner (24–26) have reported that the activity of Δ5 or Δ6 desaturase might be regulated by the PC/PE or cholesterol/PC ratio of liver microsomal membranes. Consistent with this, She *et al.* (27) have

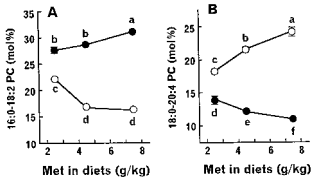

FIG. 4. Effects of dietary Met and Er supplementation on the proportion of 16:0-18:2 (A) and 18:0-20:4 (B) molecular species of plasma PC in rats. The circle and its bar represent mean and SEM, respectively, for six rats. Values with different letters are significantly different at $P < 0.05$. See Figures 1 and 2 for abbreviations. See Figure 1 for symbol legend.

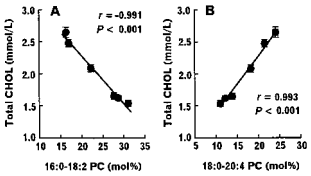

FIG. 5. Relationship between the plasma total CHOL concentration and the proportion of 16:0-18:2 (A) or 18:0-20:4 (B) molecular species of plasma PC in rats fed six experimental diets. The circle and its bar represent mean and SEM, respectively, for six rats. See Figures 1 and 2 for abbreviations.

shown that feeding a vitamin B_6-deficient diet caused decreases in both the PC/PE ratio and Δ6-desaturase activity of rat liver microsomes. Sugiyama *et al*. (10) also showed that there was a significantly positive correlation between the PC/PE ratio and the activity of Δ6 desaturase in rats fed graded levels of eritadenine. Furthermore, dietary supplementation with PE or ethanolamine (28,29) and diabetes caused by streptozotocin (30) have been shown to decrease both the PC/PE ratio and linoleic acid metabolism in rats. These results suggest that the activity of Δ6 desaturase can be affected by various types of dietary treatment through alteration of liver microsomal phospholipid profile, as represented by the PC/PE ratio. Previously we demonstrated that in rats fed different types of dietary proteins, the liver microsomal PC/PE ratio was significantly correlated with the methionine content of dietary proteins (7). In support of this, the present study showed that the PC/PE ratio of liver microsomes could be influenced by the level of dietary methionine. Taken together, it seems reasonable to consider that dietary methionine level might affect the metabolism of linoleic acid through alteration of the PC/PE ratio of liver microsomes in rats.

In the liver of rats, PC is synthesized either by the CDP-choline pathway or the PE *N*-methylation pathway, although the former is thought to be the main pathway (31). On the other hand, it appears that the PC/PE ratio of liver microsomes is regulated mainly by the extent of PE *N*-methylation (8). The decreased PC/PE ratio evoked by vitamin B_6-deficiency (27) or eritadenine supplementation (9) could be attributable to the increase in hepatic SAH concentration, since SAH is known to be a potent inhibitor of various types of methyltransferases, including PE *N*-methyltransferase. In contrast, the decreased PC/PE ratio caused by a low methionine diet cannot be ascribed to the change in SAH concentration (Fig. 2). It is confirmed that PE *N*-methylation is also influenced by the hepatic concentration of SAM, the substrate of the reaction. The K_m values for SAM of PE *N*-methyltransferase in rat liver microsomes for sequential methylation of PE were estimated to be 51, 58, and 79 μM, respectively (32). On the other hand, concentrations of SAM in the liver of rats fed the low- and high-methionine diets were found to be 60 and 126 μmol/g liver, respectively (Fig. 2). Taking these K_m values and hepatic SAM concentrations into consideration, it is reasonable to consider that the low-methionine diet might decrease the extent of PE *N*-methylation by decreasing hepatic SAM concentration, thereby leading to an increase in microsomal PE concentration and a resultant decrease in the PC/PE ratio. One of the most important findings of this study is that all of the effects tested of dietary methionine level on lipid metabolism disappeared completely under the condition of eritadenine supplementation. Since eritadenine strongly depresses the PE *N*-methylation (9), these results are taken to support the idea that dietary methionine level affects the metabolism of a variety of lipids (e.g., phospholipids, fatty acids, and cholesterol) through the depression of PE *N*-methylation.

Effect on plasma cholesterol concentration. Several reports have shown that methionine supplementation of a low-methionine diet, e.g., soybean protein diet, increases the plasma cholesterol concentration in rats (8,33–35). These results suggest that methionine has a hypercholesterolemic action at least under the experimental conditions used, although methionine also has been shown to have a hypocholesterolemic action under different dietary conditions. For instance, it was shown that methionine supplementation of a cholesterol-enriched low-protein diet, unlike standard or high-protein diet, resulted in a significant decrease in the plasma cholesterol concentration in rats (36). The hypercholesterolemic effect of methionine in rats fed a cholesterol-free diet was confirmed by the present study. However, the mechanism by which dietary methionine exerts its hypercholesterolemic action is not yet fully elucidated. The present study clearly demonstrated that the plasma cholesterol-elevating effect of methionine could be abolished by eritadenine supplementation, suggesting that the stimulation of PE *N*-methylation and a resultant increase in the PC/PE ratio of liver microsomes might participate in the enhancement of plasma cholesterol by methionine. In support of this, there was a significantly positive correlation between the PC/PE ratio and the plasma total cholesterol concentration in rats fed different

types of dietary proteins (7). However, it is possible that the stimulation of linoleic acid metabolism and a resultant decrease in the proportion of linoleic acid in phospholipids are more directly associated with the hypercholesterolemic action of methionine than the increase in the PC/PE ratio, since dietary linoleic acid is known to have a hypocholesterolemic action. In the present study, the depression of linoleic acid metabolism by the low-methionine diet was found to reflect mainly in the increase in the proportion of 16:0-18:2 molecular species of plasma PC (Table 4). This was also the case for the eritadenine-induced alteration of PC molecular species, although the extent of the effect of eritadenine was greater than that of dietary methionine. It was shown that the uptake rate of reconstituted HDL cholesterol by perfused rat livers was most stimulated by 16:0-18:2 PC of five PC molecular species used (16:0-18:2, 16:1-16:1, 18:0-18:2, 18:1-16:0, or 20:1-20:1) for the reconstitution of HDL (37). This PC molecular species-dependent differential uptake of lipoprotein cholesterol is thought to be mediated by hepatic lipase, since the hydrolysis of HDL phospholipids by the phospholipase A_1 activity of hepatic lipase is shown to be necessary for the subsequent uptake of HDL constituents (38), and since the 16:0-18:2 PC is the most preferred substrate for hepatic lipase (37). The uptake of the other lipoproteins, such as remnants of chylomicron (39) and VLDL (40), is also supposed to be mediated by hepatic lipase. Therefore, it is expected that the treatment to increase the proportion of 16:0-18:2 molecular species of plasma lipoprotein PC should enhance the cholesterol uptake of certain types of lipoproteins by the liver. Along this line, it seems reasonable to consider that dietary methionine level affects the phospholipid molecular species composition of plasma lipoproteins, thereby altering the uptake rate of lipoprotein cholesterol by the liver. This is also the case for the hypocholesterolemic action of eritadenine. In support of this, a significantly negative correlation was observed between the proportion of plasma 16:0-18:2 PC and the plasma total cholesterol concentration in rats fed six diets differing in methionine level and with or without eritadenine supplementation (Fig. 5).

Although 18:0-20:4 PC also had a significantly positive correlation with the plasma cholesterol concentration, it is currently unclear whether 18:0-20:4 PC exerts as a hypercholesterolemic factor. On the other hand, it has been shown that soybean protein increased the activity of lipoprotein receptor for β-VLDL in liver cells of rats fed a cholesterol-enriched diet (41). Hence, another mechanism is that a low-methionine diet may enhance the activity of lipoprotein receptors, thereby accelerating the uptake of plasma lipoprotein cholesterol by the liver. With regard to this, it is interesting that increased fluidity of LDL receptor membranes has been postulated to participate in the increase in LDL receptor activity in cynomolgus monkeys fed a diet rich in linoleic acid (42). Therefore, the possibility that dietary methionine level may affect the proportion of linoleic acid in lipoprotein receptor membrane phospholipids, in addition to plasma lipoprotein phospholipids, thereby possibly affecting lipoprotein receptor activities, cannot be ruled out. The effect of dietary methionine level on the activity of lipoprotein receptors in liver cell membranes remains to be further investigated.

Interaction of n-3 Long-Chain Polyunsaturated Fatty Acids with n-6 Fatty Acids in Suckled Rat Pups

Frances G. Boyle, Rebecca J. Yuhas, Kenneth Goldberg, and Eric L. Lien*

Wyeth Nutritionals International, Philadelphia, Pennsylvania 19101

ABSTRACT: The addition of long-chain polyunsaturated fatty acids (LCP: C20, and C22) to infant formula may permit fatty acid accretion rates similar to breast-fed infants, and may have long-term outcome benefits, such as improved visual acuity and cognitive development. Although fish oil may provide a source of n-3 LCP, sources of n-6 LCP have been more difficult to identify. The present study evaluates the effects of n-3 and n-6 LCP derived from single-cell oils on liver, plasma, and brain fatty acid levels in a neonatal animal model. Newborn rat pups were suckled for 14 d by dams receiving diets containing n-3 LCP alone or combinations of n-3 LCP and increasing doses of linoleic acid (18:2n-6) or arachidonic acid (20:4n-6). Dietary groups received 2% n-3 LCP and 1, 2, or 5% of either 18:2n-6 or 20:4n-6. The 20:4n-6 source also contained modest levels of 18:2n-6. At the termination of the study, liver, plasma, and brain were obtained from the rat pups and the phospholipid fatty acid profiles determined. The results indicate complex interactions of n-3 and n-6 fatty acids. Groups receiving dietary 20:4n-6 incorporated higher levels of n-6 LCP into tissues than did the groups receiving 18:2n-6. The brain was relatively resistant to changes in fatty acid composition compared with the liver and plasma. As expected, tissue n-3 LCP levels were reciprocally related to n-6 levels. The present results document that single-cell LCP oils are bioavailable in a neonatal animal model. The use of 20:4n-6 is a more effective means of supporting n-6 status than the use of 18:2n-6. These results may have implications for the addition of LCP to infant formula.

Lipids 33, 243–250 (1998).

The ability of preterm and term infants to elongate and desaturate C18 essential fatty acids to long-chain polyunsaturated fatty acids (LCP) may not be optimal. Plasma and red blood cell levels of n-3 and n-6 LCP fall following birth in formula-fed infants, whereas the circulating LCP levels in human milk-fed infants remain relatively constant or fall to a lesser extent (1–4). To ensure an adequate supply of LCP, several published guidelines have indicated that preterm and/or term infant formula should contain both n-3 and n-6 LCP (5–7).

Abbreviations: AA, arachidonic acid (20:4n-6); LA, linoleic acid (18:2n-6); LCP, long-chain polyunsaturated fatty acid(s); PC, phosphatidylcholine; PE, phosphatidylethanolamine.

The incorporation of n-3 LCP into infant formula may be achieved by the addition of marine oil. However, this is an unbalanced addition, since most marine oils contain relatively high levels of n-3 LCP and much lower levels of n-6 LCP (8). *In vitro,* the presence of n-3 LCP down-regulates the chain elongation/desaturation of 18:2n-6 to n-6 LCP, primarily owing to inhibition of the Δ6 desaturase, resulting in reduced production of n-6 LCP (9). Therefore, addition of n-3 LCP, with the only source of n-6 fatty acids being 18:2n-6, may produce an undesirable reduction in tissue n-6 LCP and a concomitant elevation of n-3 LCP. Carlson *et al*. (10) observed a reduction in plasma and red blood cell arachidonic acid (AA: 20:4n-6) status in preterm infants receiving a marine oil containing infant formula compared with a nonsupplemented formula. Since 20:4n-6 status may exert a positive effect on growth in young infants (11), the optimal addition of LCP to infant formulas would provide a docosahexaenoic acid (22:6n-3)-rich source of n-3 LCP (to mimic the n-3 profile of human milk), as well as a source of 20:4n-6.

The present study examines the interaction of n-3 and n-6 fatty acids in suckling pups whose dams received dietary n-3 LCP (2% of total fat) and various levels of either 18:2n-6 or 20:4n-6 (1, 2, or 5%). The ratio of dietary 22:6n-3/20:5n-3 (eicosapentaenoic acid) was 2.3:1.0, similar to the ratio found in human milk (12). The source of 20:4n-6 and most of the 22:6n-3 was from single-cell oils. Lactating rats received diets for 14 d, and the suckled pup phospholipid fatty acid profiles of plasma, liver, and brain were determined [similar to a model described by Yeh *et al.* (13)].

MATERIALS AND METHODS

Animals and diets. Sprague-Dawley rats (Harlan, Indianapolis, IN) were housed in a room controlled for temperature (21 ± 1°C), humidity (40–50%), and light (lights on 0600–1800 h). The rats were housed in suspended wire mesh cages before and during the mating period. They were fed a nonpurified diet (Purina Rat Chow #5001; Ralston Purina, St. Louis, MO) *ad libitum*; females continued the same diet during gestation and until postpartum day 2. The rats were mated (monogamous mating, one male/one female) for a 1-wk period. After the mating period, the pregnant females were divided into seven groups (six dams/group). The pregnant rats

were individually housed in plastic shoe box cages with ALPHA-dri™ bedding (Shepherd Specialty Papers, Inc., Kalamazoo, MI) and given free access to food and water. Body weights were recorded twice weekly.

Newborn pups were delivered naturally and weighed within 24 h of birth. Purified diets (stored at −70°C under argon and changed daily) were introduced to the dams on postpartum day 2. All diets contained 22% casein, 1% cellulose, 4% mineral mix (Bernhart-Tomarelli Salt Mixture), 1% AIN-76 vitamin mix (both mineral mix and vitamin mix from United States Biochemical Corp., Cleveland, OH), 0.1% choline chloride, 56.9% dextrose, and 15% fat. Seven fat blends were prepared to contain 2% of fat as n-3 LCP in all blends (22:6n-3/20:5n-3 = 2.3:1.0). This ratio was achieved by mixing a single-cell oil (Martek Biosciences Corp., Columbia, MD), rich in 22:6n-3, with menhaden oil. The blends contained n-3 LCP alone or n-3 LCP plus 1, 2, or 5% 18:2n-6 [linoleic acid (LA)] or 1, 2, or 5% 20:4n-6 (referred to as n-3 LCP, LA1, LA2, LA5, AA1, AA2, and AA5, respectively). The n-6 fatty acid sources for the diets were peanut oil (18:2n-6 source) and a 20:4n-6-rich single-cell oil (Martek Biosciences Corp.). The 20:4n-6 source contained modest levels of 18:2n-6; therefore, diets AA1, AA2, and AA5 also contained 18:2n-6. The remainder of the fat was hydrogenated coconut oil. Table 1 provides the fatty acid profiles of the diets. On postpartum day 0, the litter size (number live/number dead) was determined, and on day 7 the pups of each litter were weighed, sexed, and culled to four males and four females. On day 15 the pups were weighed, anesthetized with an intraperitoneal injection of Nembutal™ (Abbott Laboratories, North Chicago, IL) (5 mg/100 g body weight), and blood obtained by cardiac puncture with a 1-mL syringe containing sodium EDTA. Approximately 1.0 mL of blood was routinely obtained per pup; plasma was collected and pooled from each litter, and 20 μL of *d*-α-tocopherol (1.6 mg/mL EtOH) was added to each tube. The brain, liver, and stomach contents were obtained from one male pup per litter. The tissues were quickly removed and immediately rinsed in ice-cold saline. All samples were stored under argon at −70°C until lipid analysis.

Lipid extraction and analyses. Lipids were extracted from tissues according to the procedure of Folch *et al.* (14). The tissues were weighed, distilled water was added (10 mL for every gram of tissue), and tube contents were homogenized. For analyses of phospholipid fatty acids, an aliquot of the homogenate (1 mL) was added to 20 mL of a chloroform/methanol (2:1, vol/vol) mixture for lipid extraction. Phospholipid classes were separated from the lipid extracts by thin-layer chromatography using LK6 silica plates (Whatman Inc., Clifton, NJ) and a solvent system consisting of chloroform/methanol/petroleum ether/acetic acid/boric acid (40:20:30:10:1.8, vol/vol/vol/vol/wt) (15). Santoquin™ (Monsanto Co., St. Louis, MO) was added to the methanol to act as an antioxidant.

Lipids were methylated and extracted using the method of Morrison and Smith (16). Fatty acid methyl esters were analyzed by gas chromatography (Hewlett-Packard Model 5890 gas chromatograph interfaced with an HP 3365 Chemstation; Palo Alto, CA) using a capillary column (Omegawax, 30 m, 0.32 mm i.d.; Supelco, Bellefonte, PA) and flame-ionization detection. The following operating parameters were used: column temperature, 200°C; detector, 250°C; split ratio, 65:1; carrier gas, helium. Appropriate standards were analyzed to deter-

[a]LCP, long-chain polyunsaturated fatty acids; n-3 LCP plus 1, 2, or 5% linoleic acid (referred to as LA1, LA2, and LA5); n-3 LCP plus 1, 2, or 5% arachidonic acid (referred to as AA1, AA2, and AA5); values reported are weight percentage.

[b]—, Below detection limit.

mine retention times and response factors (Nu-Chek-Prep, Inc., Elysian, MN). Fatty acid composition was expressed as the weight percentage of the total fatty acids.

Statistics. The means of the seven diet groups were compared by the Student-Newman-Keuls test at the 1% level following a one-way analysis of variance (17). Multiple correlation coefficients (R^2) were calculated based on the most parsimonious multiple nonlinear regression model determined by stepwise regression. A single nonlinear coefficient, lambda, was fitted for the prediction model. A concentration additive model was employed to predict a fatty acid percentage in one tissue given the fatty acid composition of plasma. In this model a linear combination of all the independent variables was raised to lambda (18). The regression analysis and fatty acid Student-Newman-Keuls analyses used square root percentage as the response variable to induce normality and homogeneity of variance. The reported means and standard errors have been retransformed back to percentages.

RESULTS

Growth. All pups grew at similar rates with the exception of the high 18:2n-6 group (LA5). This group had a trend toward higher body weights at day 7, which reached statistical significance at day 15 vs. the other LA groups and the n-3 LCP group (Table 2). No differences in appearance or activity were noted in any group.

Stomach content (milk). Pup stomach contents at day 15 of life contained no particulates indicative of chow consumption, and therefore reflected the composition of their dams' milk. Stomach contents were generally related to the dams' diets (Table 3). The LA1, LA2, and LA5 diets of the dams contained no other n-6 fatty acids, although low levels of n-6 LCP were found in stomach contents. The diets containing n-6 LCP also contained modest amounts of 18:2n-6; as a result, the total n-6 level in diets AA1, AA2, and AA5 were higher than the corresponding LA diets. These differences were minimized in the pup stomach contents. The total n-6 levels in the stomach contents of the LA groups were 1.66, 2.32, and 5.93% vs. 2.06, 3.30, and 6.50% in the AA groups.

Liver phospholipids. The 18:2n-6 levels in both liver phosphatidylethanolamine (PE) and phosphatidylcholine (PC) increased progressively from the basal group through the groups receiving increasing dietary levels of 18:2n-6 (Table 4). Interestingly, 18:2n-6 levels in AA1–AA5 groups were lower (significant at $P < 0.05$, but not at $P < 0.01$) than the basal group, even though milk levels of 18:2n-6 were higher in the AA1–AA5 groups than in the basal group. Hepatic PE and PC 20:4n-6 levels increased progressively from the basal group to groups receiving high n-6 fatty acid levels in a dose-related manner as maternal diet and milk levels of 18:2n-6 and 20:4n-6 increased. Groups whose dams received dietary 20:4n-6 had higher levels of tissue 20:4n-6 than the groups receiving 18:2n-6. Liver phospholipid levels of 22:6n-3 were

[a]Values reported are weight percentage and are means ± SEM (n = 6, that is, one representative animal from each of six litters). Values not bearing the same superscript letters are different at $P < 0.01$. For abbreviations see Table 1.
[b]—, Below detection limit.

also influenced by diet. High levels of dietary 18:2n-6 resulted in modest reductions in liver PE and PC 22:6n-3 levels. Groups receiving dietary 20:4n-6 demonstrated more pronounced effects on hepatic PE tissue 22:6n-3 levels.

Plasma phospholipids. Plasma PC levels of 18:2n-6 increased in a dose-related manner as milk 18:2n-6 increased in LA1–LA5, whereas PE 18:2n-6 did not respond significantly to varying dietary levels of 18:2n-6 (Table 5). As in liver, the inclusion of dietary 20:4n-6 resulted in a reduction of plasma PE and PC 18:2n-6. Plasma phospholipid 20:4n-6 levels increased dramatically with increasing dietary 20:4n-6 levels. Plasma PC 20:4n-6 responded with a more pronounced increase to dietary 20:4n-6 than did plasma PE. Plasma 20:4n-6 may be derived from dietary 20:4n-6 or 18:2n-6 (following desaturation and chain elongation). The relationship of dietary 18:2n-6 and 20:4n-6 to plasma 20:4n-6 was assessed to determine the relative potency of the dams' dietary 18:2n-6 and 20:4n-6 in supplying pup plasma 20:4n-6. The relative potency of dietary 20:4n-6 to 18:2n-6 for supplying plasma 20:4n-6 was 5.1:1.0 (95% confidence limits = 3.7–9.2) for plasma PE and 56.2:1.0 (95% confidence limits = 14.5–356.3) for plasma PC. Decreases in the plasma PC 22:6n-3 levels occurred as 18:2n-6 and 20:4n-6 were added to the maternal diet and were related to the n-6 pup stomach contents. Decreases in 22:6n-3 also occurred in the plasma PE fraction, but were not related to the dietary level of n-6 fatty acids.

Brain phospholipids. Dietary manipulation did not alter brain levels of 20:4n-6 and 22:6n-3 at a significance level of $P < 0.01$, although marginal statistical significance was observed in a number of groups (for example the PE 20:4n-6 levels of AA1, AA2, and AA5 were all greater than n-3 LCP at $P < 0.05$, whereas the PE 22:6n-3 level of group AA5 was lower than the n-3 LCP group also at $P < 0.05$). Elevated dietary 20:4n-6 consumption resulted in significant alterations at $P < 0.01$ in several LCP fractions: PE and PC 22:4n-6 increased while PE 22:5n-3 decreased (Table 6). The ratio of major brain PE n-6 to n-3 LCP [(20:4n-6 + 22:4n-6)/22:6n-3] provided additional evidence of dietary control on the relative proportions of these fatty acids (Fig. 1). Increased levels of n-6 LCP (both in the dams' diets and in pup stomachs) resulted in a highly significant increase in this ratio. A similar effect was noted in brain PC (data not shown). Diet-related increases in this ratio for liver and plasma (Fig. 1) were proportionally greater than the increase in brain ratio. For example, the ratio increased 173% in plasma PE when the n-3 LCP group was compared to the AA5 group, while only a 57% increase was observed in the same groups in brain.

Correlation analysis. The relationship between plasma n-6 fatty acids and both liver and brain 20:4n-6 was evaluated. Plasma PE n-6 fatty acids (18:2n-6, 20:3n-6, and 20:4n-6) were not significantly predictive of 20:4n-6 levels in either liver or brain PE or PC. In contrast, plasma PC n-6 fatty acids (18:2n-6 and 20:4n-6) were highly predictive of liver PE and PC 20:4n-6, significantly so even after adjusting for plasma PE n-6 fatty acids (Table 7). Plasma 20:3n-6 was not required for an optimal correlation. Plasma PC 20:4n-6 was also pre-

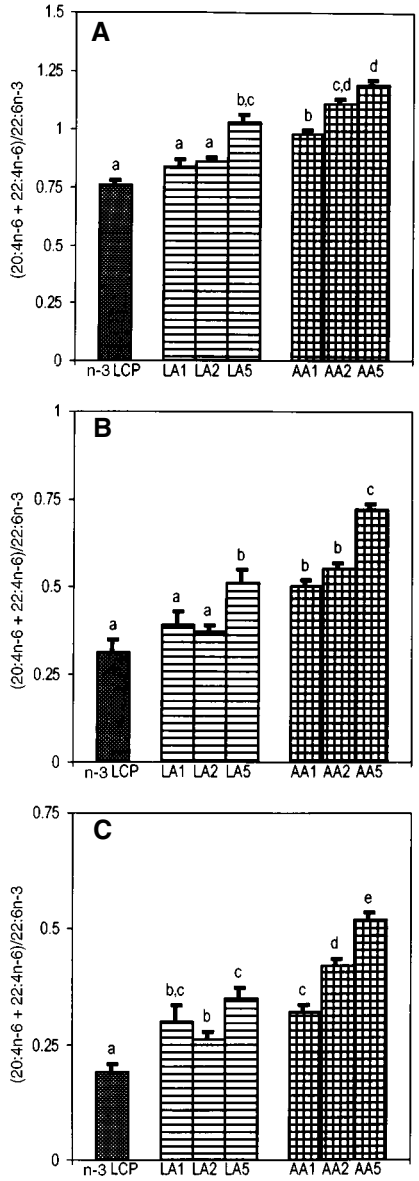

FIG. 1. Mean and SEM of the ratio of (20:4n-6 + 22:4n-6)/22:6n-3 in (A) brain, (B) liver, and (C) plasma phosphatidylethanolamine (PE); for brain and liver, *n* = one representative animal from each of six litters; for plasma, *n* = pooled samples from each of six litters. Bars not bearing the same letters are different at $P < 0.01$. Abbreviations: LCP, long-chain polyunsaturated fatty acids; n-3 LCP plus 1, 2, or 5% linoleic acid (referred to as LA1, LA2, and LA5); n-3 LCP plus 1, 2, or 5% arachidonic acid (referred to as AA1, AA2, and AA5).

dictive of brain PE and PC 20:4n-6. Because plasma PE n-6 fatty acids were highly correlated with plasma PC n-6 fatty acids, their effects were confounded and sometimes difficult to distinguish. Nevertheless, in all four cases, plasma PC n-6 fatty acids were more predictive than plasma PE n-6 fatty acids of liver and brain PC and PE n-6 fatty acids.

DISCUSSION

This study evaluated the complex interactions of n-6 and n-3 fatty acids in rat pups whose dams received diets containing a constant level of n-3 LCP and increasing levels of n-6 fatty acids. We chose rats pups as a model of the human preterm infant owing to the relative immaturity of the rat pup brain. The rat pup is born prior to its period of rapid brain growth (19); the relatively immature brain of the neonatal rat and subsequent rapid postpartum development may be analogous to the preterm human infant. The brain maturity of the 14-day-old pup is, in fact, similar to the term infant (20). The results of this experiment clearly demonstrate that the source of 20:4n-6 evaluated was bioavailable, being efficiently absorbed and incorporated into biological membranes. As reported previously (21), changes in maternal dietary fatty acid composition resulted in more significant fatty acid alterations of maternal milk, pup plasma, and pup liver than that of pup brain. The ability of dietary 18:2n-6 (as reflected in pup stomach fatty acid profiles) to influence pup n-6 LCP profiles was much less pronounced than the ability of 20:4n-6.

TABLE 7
Predictability of Liver and Brain 20:4n-6 from Plasma PC n-6 Fatty Acids[a]

Plasma n-6 species[b] (significant independent variables)	Tissue fraction (dependent variable)	R^{2c}	*P*
18:2n-6, 20:4n-6	Liver PE	0.87	0.0001
18:2n-6, 20:4n-6	Liver PC	0.96	0.0001
20:4n-6	Brain PE	0.41	0.0002
20:4n-6	Brain PC	0.36	0.0007

[a]Plasma phosphatidylethanolamine (PE) n-6 fatty acids were not predictive of liver or brain PE or phosphatidylcholine (PC).
[b]Fatty acids required for optimal correlation.
[c]All correlations are positive.

n-6 Accretion. The source of dietary 20:4n-6 employed in the current study contained modest levels of 18:2n-6. The levels of 20:4n-6 added to the maternal diets were designed to match the added level of 18:2n-6 (1, 2, or 5% of the fat blend). Owing to the presence of 18:2n-6 and other n-6 fatty acids in the single-cell oil employed in this study, the total level of dietary n-6 was higher for the dams receiving the 20:4n-6 oils than the groups receiving 18:2n-6 alone. However, when the stomach contents (milk) of the pups were examined, the total n-6 fatty acid levels were more closely matched. The striking differences in fatty acid profiles in some of the tissues examined (see below) clearly demonstrate that the observed effects were due to the presence of dietary 20:4n-6 aggressively inserted into biological membranes (22), and not to the relatively modest differences in stomach contents of total n-6 fatty acids.

Liver and plasma phospholipid 20:4n-6 levels were substantially higher when pups received preformed n-6 LCP (AA1–AA5) than when pups received 18:2n-6 as the predominant source of n-6 fatty acid (LA1–LA5). Plasma PC n-6 fatty acids were highly correlated with both liver PE and liver PC 20:4n-6 levels, suggesting a rapid exchange of fatty acids between these pools (a modest correlation was also observed between plasma 20:4n-6 and brain 20:4n-6 levels). In groups

with dams receiving 18:2n-6 as the only source of n-6 fatty acids, both pup hepatic and plasma 18:2n-6 levels tended to increase in a dose-related manner, while 20:4n-6 levels were significantly elevated only in groups receiving high 18:2n-6 levels. As a result of the presence of milk n-3 and n-6 LCP in LA1–LA5, the chain elongation and desaturation of 18:2n-6 to n-6 LCP by the pups may have been inhibited, since both n-3 and n-6 LCP can down-regulate elongation and desaturation of 18:2n-6 (9). Even in experimental systems which are not exposed to feedback inhibition, the accretion of hepatic 20:4n-6 from dietary 18:2n-6 is substantially less potent than if preformed 20:4n-6 is provided, as demonstrated by Mohrhauer and Holman (23) and Whelan *et al.* (24). Although the n-3 LCP, LA1, and LA2 groups received relatively low 18:2n-6 levels, no signs of essential fatty acid deficiency (elevated 20:3n-9) were observed. Milk in these groups contained sufficient 20:4n-6 to ensure adequate essential fatty acid status (approximately 0.25 energy percentage, see Ref. 23).

The present study also documents modest alterations in the n-6 fatty acid contents of brain phospholipids, with changes being observed in both PE and PC. Brain 20:4n-6 levels tended to be elevated in AA1–AA5 compared with the other groups, although statistical significance was observed only at a marginal level. Employing a similar model, Jumpsen *et al.* (25) evaluated the effects of dietary n-3 and n-6 LCP alone or in combination; milk LCP levels were within the range of the present study (25). Neuronal cell PE levels of LCP were not altered by dietary LCP at a pup age of 2 wk (the same as the current study), although differences were noted at 1, 3, and 6 wk of age. In addition, no significant differences were found at any time in neuronal PC 20:4n-6 levels. Mohrhauer and Holman (26) also studied the effect of increasing doses of 20:4n-6 in rats, but under different experimental conditions (weanling rat pups receiving various doses of 20:4n-6 ethyl ester for 100 d by oral gavage). They found no dose-related plateau of total brain 20:4n-6 levels over a wide range of 20:4n-6 levels (0.007–3.75 energy percentage) that bracketed the 20:4n-6 levels employed in the current study.

n-3 LCP accretion and interaction with n-6 fatty acids. Dramatic suppression of hepatic and brain 20:4n-6 levels occurs in weaned rats fed diets high in n-3 LCP and with 18:2n-6 as the only source of n-6 fatty acids, demonstrating the plasticity of tissue LCP content of these animals (27,28). The suppression of n-6 LCP tissue levels may be due to: (i) reduced chain elongation/desaturation rates resulting from n-3 LCP inhibition of the Δ6 desaturase, or (ii) competition of n-3 LCP for membrane insertion. Similarly, substantial reductions in hepatic, circulating, and brain n-6 LCP levels occur in rodent pups whose dams received diets containing n-3 LCP (fish oil) during pregnancy and nursing, although the levels of n-3 LCP administered in these studies were also relatively high (29–31). As expected, the n-3 LCP accretion in all tissues studied was significantly higher in LCP-treated groups than in control groups.

The present experiment provided dietary intervention with relatively low LCP levels only during the time of suckling, thus avoiding the prenatal complications of placental transfer of LCP to the fetus. The results of this experiment clearly demonstrate the sensitive reciprocal relationship of n-6 and n-3 fatty acids in liver, plasma, and brain. Although C18 precursors (in this case, 18:2n-6) may reduce n-3 LCP concentration, the present data clearly indicate that the provision of dietary n-6 LCP (to the pups) results in more pronounced alterations of n-3 LCP than does 18:2n-6. The ratio of major brain n-6 to n-3 LCP reflected this interaction, although relative responses were more pronounced in plasma and liver (Fig. 1).

Requirements for LCP. Human neonates may not possess adequate chain elongation/desaturation capacity to support maximal LCP levels, since both preterm and term formula-fed infants have lower plasma and red blood cell LCP levels than breast-fed infants (1–4). Carlson *et al.* (10) compared LCP status in preterm infants receiving either a marine oil-containing formula (20:5n-3 and 22:6n-3) or control formula for the first year of life. In this study, plasma and red blood cell 20:4n-6 levels were lower in the marine oil group compared to control, suggesting that n-3 LCP may inhibit 18:2n-6 chain elongation and desaturation to 20:4n-6 or may compete with n-6 LCP for insertion into phospholipids in human neonates. Growth parameters were correlated with 20:4n-6 status (11). Several other studies have also demonstrated an n-3 LCP mediated reduction in 20:4n-6 fatty acid levels in preterm and term infants, even when the n-3 LCP source high in 22:6n-3 and low in 20:5n-3 was employed (32,33). Thus, a more appropriate means of achieving optimal LCP levels may be to provide both n-3 and n-6 families of fatty acids as LCP.

In conclusion, we have explored the complex interactions of n-3 LCP with either 18:2n-6 or 20:4n-6 in rapidly growing neonatal rat pups employing single-cell oils as the primary source of LCP. Dietary 18:2n-6 was a less effective means of supplying n-6 LCP for tissue accretion than was preformed n-6 LCP. These observations were apparent not only in liver and plasma but, also to a modest extent, in brain.

Diabetes-Induced and Age-Related Changes in Fatty Acid Proportions of Plasma Lipids in Rats

Shigeru Nishida*, Tatsuhiko Kanno, and Shigeki Nakagawa

Department of Biochemistry, Nihon University School of Medicine, Tokyo 173, Japan

ABSTRACT: Diabetes-induced and age-related proportional changes in plasma fatty acids of triglycerides (TG), phospholipids (PL), and cholesteryl esters (CE) were investigated using streptozotocin-induced diabetic and control rats. Among n-6 fatty acids from diabetic rat plasma, increased proportions of 18:2n-6 and 20:3n-6 in all three lipid classes and of 18:3n-6 in PL at 1–3 months old and in TG at 3–5 months old were observed. The proportions of 20:4n-6 decreased in both PL and CE, but were unchanged in diabetic TG. Among the n-3 fatty acids, in the early stage, diabetes caused increases in the proportions of 18:3n-3 in PL and CE and of 20:5n-3 and 22:6n-3 in TG, while 22:5n-3 was decreased later in the disease course. These results suggest reduced Δ5-desaturase activities on 20:3n-6 but not on 20:4n-3, while Δ6-desaturase activity on 18:2n-6 was essentially unaffected. Furthermore, the reduction in Δ9-desaturase activity in diabetic rats may well explain the decreases in the proportions of 16:1n-7 and 18:1n-7. However, the proportion of 18:1n-9, another product of Δ9-desaturase, was significantly increased in CE and PL as compared to the controls. Thus, there was a discrepancy between our results and those of earlier studies with respect to the n-9, n-6, and n-3 fatty acid proportions of plasma lipids in diabetic rats. We also investigated age-related changes in the proportions of plasma fatty acids. Although rather small, age-related changes were evident in both diabetic and control rats.

Lipids 33, 251–259 (1998).

Several studies have shown that changes in the fatty acid compositions of phospholipid (PL) are observed in both humans (1–4) and animals (5–18) with diabetes. These alterations in PL have been reported in a variety of tissues including the liver, heart, kidney, aorta, and plasma. Decreases in palmitoleate (16:1n-7) and arachidonate (20:4n-6) and increases in linoleate (18:2n-6) and eicosatrienoate (20:3n-6) are common in these tissues, due mainly to suppressed Δ9, -6, and -5-desaturase activities in diabetes. Δ6-Desaturase (E.C. 1.14.99.5), the enzyme considered to be responsible for the first and rate-limiting step in arachidonic acid synthesis, catalyzes the conversion of 18:2n-6 to 18:3n-6. Its activity has been found to decrease rapidly in relation to aging in the rat testes (6) and more slowly in the liver (19–21). The activities of Δ9, -6, and -5-desaturases have been shown to be depressed in hepatic microsomes of rats with experimentally induced diabetes (10,11,16–18). These previous findings were obtained mainly from PL of humans and rats with diabetes mellitus, and the present results indicate that these enzyme activities are not suppressed in all tissues. Furthermore, some desaturase activities are undetectable in tissues such as platelets, endothelial cells, and skin (22–24). Dang *et al*. (25) showed an alternative mechanism by which the fatty acids in erythrocyte membrane PL were changed *via* decreased incorporation of long fatty acids. On the other hand, the proportions of fatty acids in PL were directly affected by the activities of PL synthetic and degradative enzymes (26,27). Iritani *et al*. (28) reported that acyl-CoA synthetase in rat liver exhibited high selectivity for both n-3 and n-6 polyunsaturated fatty acids and that acyl-CoA:1-acylglycerol 3-phosphocholine acyltransferase showed acyl-donor selectivity in the order of 20:4n-6-CoA > 20:5n-3-CoA ≥ 22:6n-3-CoA. Acyl-CoA:1-acylglycerol 3-phosphate acyltransferase and/or 1-acylglycerol 3-phosphocholine acyltransferase activities were reported to be increased in the livers of rats with experimentally induced diabetes, while mitochondrial phospholipase A_2 and lysophospholipase activities were decreased in diabetic rats (29). Changes in the activities of these enzymes on PL also may contribute to the altered fatty acid composition of PL from diabetic animals.

Furthermore, in rats with experimental diabetes, elongation of fatty acid chains may be affected along with changes in desaturase activities, possibly accounting, in part, for the altered fatty acid composition. Triglycerides (TG) and cholesteryl esters (CE), as well as PL, are the major components of plasma lipoproteins. TG in chylomicrons and very low density lipoproteins are hydrolyzed to fatty acids and glycerol by lipoprotein lipase, an insulin-sensitive enzyme activated by the apoC-I protein on the lipoprotein surface. The deacylation and acylation cycles of TG are therefore one factor potentially affecting the fatty acid composition of plasma lipids. To date, little attention has been paid to the effects of the stage of diabetes or aging on changes in the proportions of fatty acids associated with diabetes.

This report describes diabetes-induced and age-related

changes in the fatty acid compositions of three lipid fractions, TG, PL and CE, in plasma of diabetic and control rats.

MATERIALS AND METHODS

Animals. Diabetes was induced in male Wistar rats (5-wk old, initial weight ~124 g; Sankyo Laboservice, Tokyo, Japan) by administering streptozotocin (STZ; Sigma, St. Louis, MO) into the tail vein at a dose of 45 mg/kg body weight (30). Control rats were injected with 50 mM citrate buffer vehicle (pH 4.5). After STZ-administration, the diabetic rats were allowed access to 5% (wt/vol) sucrose solution for the next 20 h. The diabetic and age-matched rats were divided into three groups each, which were then maintained for 1, 3, and 5 mon and were given *ad libitum* access to normal laboratory chow and water until sacrifice.

Plasma glucose level. The plasma glucose levels of the nonfasted rats were measured by the electrode method using Antsense (Miles-Sankyo, Tokyo, Japan). Only rats with nonfasted blood glucose levels of at least 20 mM for the duration of the experimental period were considered diabetic.

Lipid extraction and separation. After 1, 3, or 5 mon, rats were anesthetized, and blood was collected by cardiac puncture. Plasma was obtained by centrifugation at 1,000 × *g* for 10 min at 4°C. Lipids were extracted from the plasma (100 μL) by the method of Folch *et al*. (31), and redissolved in 100 μL of chloroform/methanol (2:1) containing 0.02% (wt/vol) butylhydroxytoluene. An aliquot (40 μL) of the lipid solution was applied on a silica gel G thin-layer chromatography (TLC) plate (Merck, Darmstadt, Germany) using petroleum ether/diethylether/acetic acid (82:28:1, by vol) as the solvent. Three fractions, CE, TG and PL, were separated and identified on the TLC plates using authentic standards, and were employed for the fatty acid analyses.

Fatty acid analysis. The silica gel containing the lipid on the TLC plates was scraped off and inserted into a screw-capped test tube for methylation. Direct methylation of the fatty acids was carried out in 5% HCl–methanol (Wako, Osaka, Japan) or 14% boron trifluoride–methanol (Tokyo Kasei, Tokyo, Japan) at 90°C for 1 h with 29.3 nmol of 23:0 as the internal standard. Benzene (1 mL) was added to the CE samples owing to the poor solubility of CE in methanol during methylation. The methyl esters thus formed were extracted with hexane, dried under a N_2 stream, and identified and quantified using a gas–liquid chromatograph (Shimadzu GC-15A; Kyoto, Japan) with an Omegawax™ 320 capillary column (0.32 mm × 30 m, Supelco; Bellefonte, PA). The column was isothermally programmed at a temperature of 60°C for the initial 3 min, followed by a subsequent increase of 7°C/min from 60 to 180°C, then 3°C/min to 220°C, and finally 1°C/min to 255°C. Helium gas was used as the carrier gas at an approximate flow rate of 40 mL/min at a split ratio of 1:50 at 3 min after the injection. The injector and detector temperatures were 240 and 250°C, respectively. The sample volume applied to the column was 2 μL. The peaks were identified by comparison of the retention times with the standards of the Supelco 37 component FAME Mix™ or by gas chromatography–mass spectrometry analysis (JMS-DX 300 mass spectrometer; Jeol, Tokyo, Japan). At least 26 fatty acid methyl esters from 12:0 to 22:6n-3 could be identified and quantified by comparison with the internal standard (see Tables 2, 3, and 4). One batch of the experimental chow contained 5% (w/w) total lipids with the following molar percentages of fatty acids: 12:0, 0.01%; 14:0, 0.47%; 16:0, 15.7%; 16:1n-7, 0.86%; 18:0, 3.03%; 18:1n-9, 22.8%; 18:2n-6, 50.3%; 18:3n-3, 3.3%; 20:0, 0.30%; 20:1n-9, 1.33%; 20:2n-6, 0.06%; 20:4n-6, 0.05%; 20:5n-3, 0.75%; 22:0, 0.27%; 22:1n-9, 0.07%; 22:2n-6, 0.02%; 24:0, 0.06%; and 22:6n-3, 0.47%.

Blood analysis. Washed red blood cells (80 μL) from the rats were lysed by the addition of 0.1 mL of 0.1%(wt/vol) octylphenoxypolyethoxyethanol. The relative amounts of glycated hemoglobin (HbA_1) were determined in duplicate or triplicate by the affinity chromatography method with an *m*-aminophenylboronic acid–agarose column (Pierce, Rockford, IL). Total cholesterol, TG, and PL in the plasma were quantified enzymatically using commercial kits (Wako, Osaka, Japan). Each sample was tested in duplicate.

Statistical analysis. Data are presented as means ± SE. Data from the diabetic and control groups were compared by analysis of variance, and $P < 0.05$ was considered statistically significant.

RESULTS

The STZ-administered rats showed severe hyperglycemia and significant increases in HbA_1 levels at 1, 3, and 5 mon (Table 1). TG, PL, and total cholesterol levels were significantly elevated in diabetic plasma compared to controls.

To analyze the fatty acid alterations in lipid fractions, the proportions of fatty acids in diabetic plasma were compared with those obtained from nondiabetic plasma (Tables 2, 3, and 4). Diabetes caused significant increases in the proportions of TG fatty acids, 18:2n-6 (5.7–14.7%) and 20:3n-6 (0.3–0.5%) at 1–5 mon, 22:6n-3 (~1.2%) at 1–3 mon, 18:3n-6 (~0.2%) at 3–5 mon, and 20:5n-3 (0.34%) at 3 mon. As some of these changes were high in percentage but small in magnitude, the absolute changes are indicated in parentheses. Decreased proportions of fatty acids as compared to controls were found in diabetic rats as follows: 16:1n-7 [–(1.3–3.2%)], 18:1n-7 [–(0.5–1.8%)], 22:3n-6 [–(0.13–0.16%)], and 22:4n-6 [–(0.04–0.05%)] at 1–5 mon; 12:0 [–(0.4–0.5%)], 14:0 [–(0.8–1.2%)], 16:0 [–(2.6–3.4%)], 16:1n-9 [–(0.3–0.5%)], and 18:1n-9 [–(2.9–3.5%)] at 1–3 mon; 22:5n-3 [–(0.4–0.6%)] at 3–5 mon; 10:0 (–0.3%), 20:2n-6 (–1.9%), and 24:0 (–0.3%) at 1 mon (Table 2). In diabetic PL, the proportions of 18:2n-6 (7–8%) and 20:3n-6 (0.4–0.7%) at 1–5 mon; 18:3n-6 (~0.08%, 1–3 mon), 18:3n-3 (0.06%, 1 mon), 22:4n-6 (0.13%, 3 mon), and 18:1n-9 (0.6%, 5 mon) were significantly increased (Table 3). The following fatty acids were significantly decreased as compared to the controls: 16:1n-7 [–(0.4–0.6%)] and 20:4n-6 [–(3.2–5.5%)] at 1–5 mon; 14:0 (–0.4%) and 20:2n-6 [–(0.8–1.2%)] at 1–3

TABLE 1
Comparison of the Levels of Blood Glucose, HbA_1 and Plasma Lipid Concentrations in STZ-Induced Diabetic and Control Rats[a]

		1 Mon		3 Mon		5 Mon

[a]Rats (124 ± 1 g initial weight) were injected (i.v.) with streptozotocin (STZ) at a dose of 45 mg/kg body weight. Values are expressed as means ± SE. Measurement of hemoglobin A_1 (HbA_1) and blood chemistry analyses were performed in duplicate on number of rats, as indicated in parentheses. #, $P < 0.001$; $, $P < 0.005$; *, $P < 0.01$; +, $P < 0.05$ vs. control.

mon; 18:1n-7 [–(1.5–1.8%), 3–5 mon]; 16:1n-9 (–0.2%) and 22:3n-6 (–0.13%) at 1 mon; 20:1n-9 (–0.14%) at 3 mon; 22:1n-9 (–0.18%), 22:4n-6 (–0.13%), 22:5n-3 (–0.1%), and 24:0 (–0.13%) at 5 mon. In diabetic CE, the most striking increases in the proportions of fatty acids were as follows: 18:2n-6 (12–16%), 20:1n-9 (0.04–0.11%), and 20:3n-6 (0.17–0.31%) at 1–5 mon; 18:1n-9 (4.3–4.6%) and 18:3n-3 (0.33–0.44%) at 1–3 mo; 18:0 (4.4%) and 20:0 (0.3%) at 1 mon, while fatty acids 16:1n-7 [–(1.2–2.2%)] and 20:4n-6 [–(12–17%)] at 1–5 mon; 12:0 [–(0.8–0.9%)] at 1–3 mon; 10:0 [–(0.3–0.5%)], 14:0 [–(0.4–0.6%)], 18:1n-7 [–(0.4–0.6%)], and 22:5n-3 [–(0.03–0.08%)] at 3–5 mon; 18:3n-6 (–0.2%), 22:0 (–0.1%), and 24:0 (–0.2%) at 1 mon; 20:2n-6 (–1.2%) at 3 mon were decreased (Table 4).

Figure 1 shows changes in the fatty acid profiles of the three lipid fractions from diabetic vs. control rats. Among the n-6 fatty acids (Fig. 1A–C), significant increases in the proportions of 18:2n-6 and 20:3n-6 were observed in all lipid fractions from the diabetic animals at all time points. The proportions of 18:3n-6, the product of Δ6-desaturase from 18:2n-6, showed complex changes in the diabetic rats: significant increases in PL at 1–3 mon and TG at 3–5 mon and a decrease in CE at 1 mon. In PL and CE, 20:4n-6 was significantly reduced over the entire study period, suggesting Δ5-desaturase activity to be reduced in diabetic rats. However, 20:4n-6 was unchanged in TG. The proportion of fatty acid 22:4n-6 in diabetic TG was clearly decreased at all time points compared to that in control rats, while that in PL was increased at 3 mon and then decreased at 5 mon. Thus, profiles of the n-6 fatty acids in PL and CE were similar except for 18:3n-6 at 1 mon.

Among the n-3 fatty acids (Fig. 1D–F), the proportion of initial precursor, 18:3n-3, was significantly higher in diabetic CE (1–3 mon) and PL (1 mon) than in controls, while there was no significant change in TG. The fatty acids 18:4n-3 and 20:4n-3 were not detected in any lipid fractions examined. The acid 20:5n-3, the product of Δ5-desaturase, was slightly but significantly increased in diabetic TG at 3 mon, but no significant changes were observed at other time points in TG or the other lipids as compared to the controls. The proportions of 22:5n-3 were decreased in the late stage of diabetes in all three lipids. The acid 22:6n-3 was significantly increased in TG (1–3 mon), while there were no significant changes in PL and CE as compared to controls.

Among the n-7 fatty acids, 16:1n-7 was significantly reduced in all fractions (Fig. 1G–I), suggesting reduced Δ9-desaturase activity in diabetic rats. The elongation product of 16:1n-7, 18:1n-7 was decreased in all three lipid classes at 3–5 mon.

Among the n-9 metabolites, a large increase in 18:0 was observed only in the diabetic CE at 1 mon. Owing to the high percentage of 18:1n-9 (23%) in the diet, the proportions of 18:1n-9 in TG from both groups were higher (15–20%) than those in other lipids. However, 18:1n-9 was decreased in TG from diabetic rats (1–3 mon), despite polyphagia, as compared to controls. On the contrary, significant increases in the proportions of 18:1n-9 in CE (1–3 mon) and PL (5 mon) were observed. The proportion of 20:1n-9, the elongation product of 18:1n-9, was significantly increased in CE but reduced in PL of diabetic rats at 3 mon (Table 4). The acid 16:1n-9 was significantly decreased in diabetic TG (1–3 mon) and PL (1 mon) as compared to controls, whereas CE showed no significant change. The longer-chain fatty acid 22:1n-9 did not differ markedly between the two groups (TG and CE).

Significant age-related decreases in the proportions of the following fatty acids were seen in control TG: 10:0, 12:0, 14:0, 16:0, 16:1n-9, 18:0, and 24:0, while there were significant increases in 18:2n-6, 18:3n-3, 22:1n-9, 22:5n-3, and 22:6n-3 (Table 2). In diabetic TG, significant age-related increases were observed in n-3 and particularly n-9 fatty acids, specifically, 18:1n-9, 18:3n-3, and 22:1n-9. The proportions of n-3 fatty acids were not increased in control TG, while those of 18:0, 20:4n-6, 22:5n-3, and 22:6n-3 were significantly decreased. The control PL showed significant age-related reductions in 16:0, 16:1n-9, 18:0, 20:2n-6, and 22:3n-6 and significant increases in 18:1n-7, 18:2n-6, 18:3n-6, 20:1n-9, 20:4n-6, 20:5n-3, and 22:1n-9 (Table 3). In diabetic PL, significant age-related reductions were seen in 18:0, 20:0, and 22:5n-3, significant increases in 18:1n-9, 18:2n-6, 20:1n-9, 20:5n-3, and 22:4n-6. The diabetic CE showed age-

[a]Data are expressed as molar percentages of each fatty acid over total fatty acids identified. Values are means ± SE. The numbers of rats are shown in parentheses. Fatty acids from plasma triglycerides obtained by thin-layer chromatography (TLC) were methylated with 1 mL of HCl–methanol as described in the Materials and Methods section. Individual fatty acids were identified and quantified by gas chromatography. Fatty acid concentrations were calculated by the addition of molar amounts of individual fatty acids. #, $P < 0.001$; $, $P < 0.005$; *, $P < 0.01$; +, $P < 0.05$, significantly different from corresponding control rats. a, $P < 0.001$; b, $P < 0.005$; c, $P < 0.01$; d, $P < 0.05$, significantly different from corresponding 1-mon-diabetic rats. e, $P < 0.001$; f, $P < 0.005$; g, $P < 0.01$; h, $P < 0.05$, significantly different from corresponding 3-mon-diabetic rats.

See Table 2 for abbreviations.

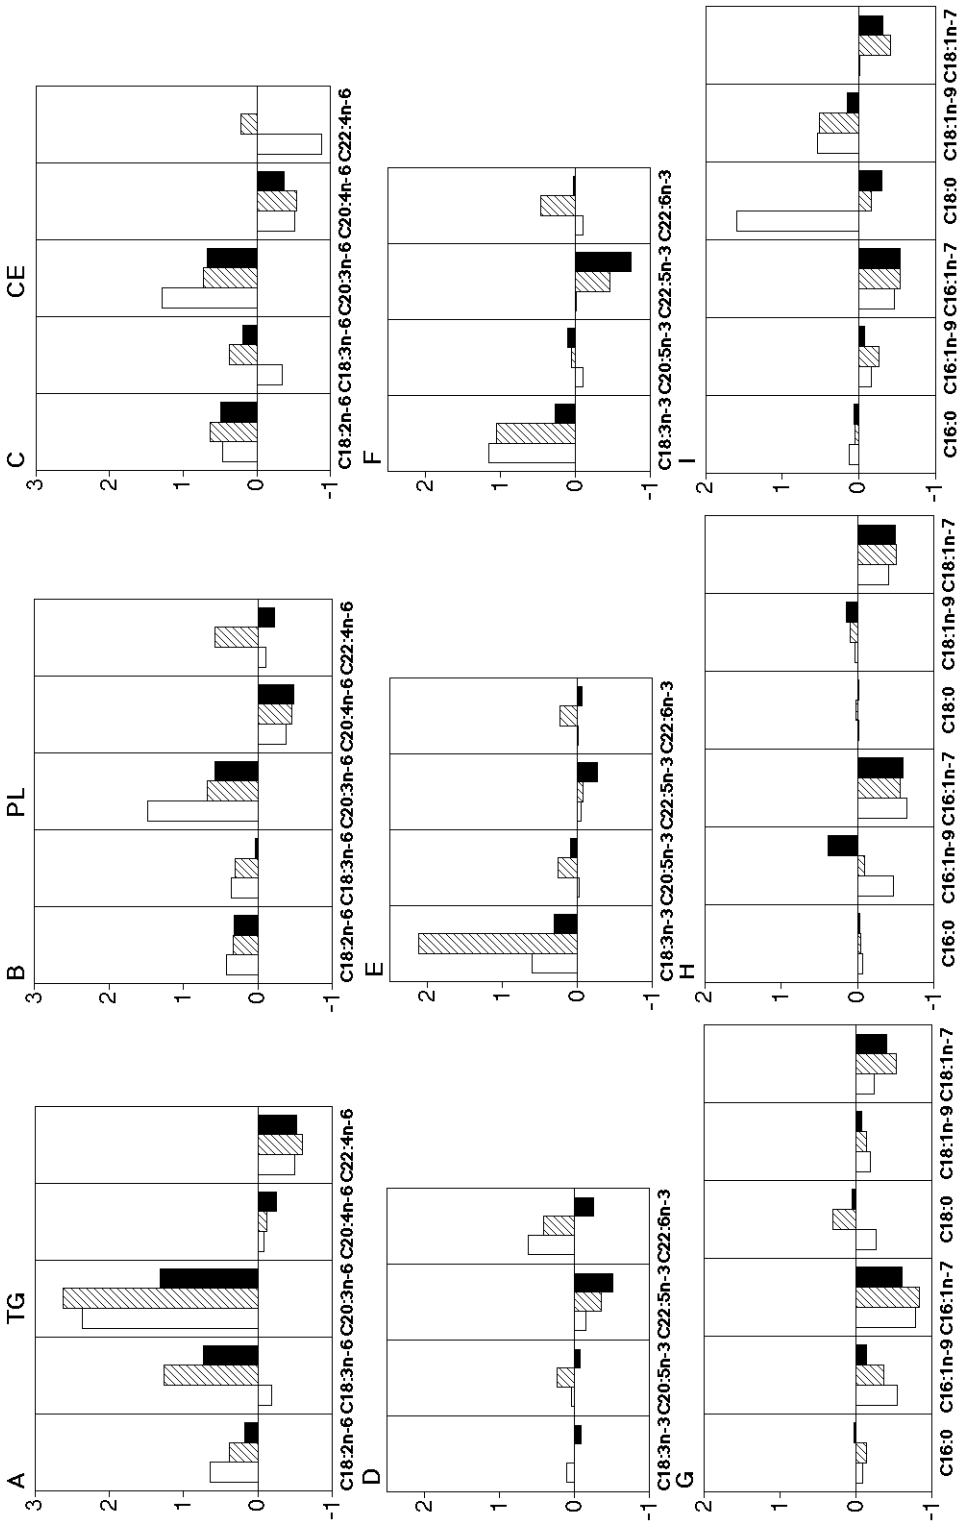

FIG. 1. Polyunsaturated fatty acid profiles of plasma triglycerides (TG) (A, D, and G), phospholipids (PL) (B, E, and H), and cholesteryl esters (CE) (C, F, and I) of diabetic rats compared to those of nondiabetic controls. Data are represented as ratios of the proportions of fatty acids in plasma lipid fractions from diabetic and control rats. Open, hatched, and solid bars refer to the ratios of fatty acid proportions at 1, 3, and 5 mon, respectively.

related reductions in 18:0, 20:0, 20:1n-9, and 22:6n-3, while 18:3n-6 and 20:4n-6 were increased. In control CE, 12:0, 22:0, and 22:6n-3 increased, while 18:1n-7 and 22:5n-3 decreased with aging (Table 4). In the late stage of diabetes, the fatty acid proportions in CE exhibited complex changes not seen in controls; saturated fatty acids were increased at 1 mon and then decreased, while unsaturated fatty acids showed the opposite changes. Monounsaturated acids were elevated at 1 and 3 mon in diabetic rats.

DISCUSSION

We found that rats with STZ-induced diabetes showed characteristic alterations in the proportions of plasma lipid fatty acids comparable to those in the diabetic rat liver. The proportions of 18:2n-6 and 20:3n-6 in diabetic plasma were increased over the entire experimental period in all three lipids, while 16:1n-7 and 20:4n-6 were reduced as compared to the control rats. The levels of 18:3n-6 formed by the action of Δ6-desaturase on 18:2n-6 decreased significantly in essentially the same manner as in diabetic PL and CE, showing Δ6-desaturase activity to be decreased in diabetic rats. Alterations in the fatty acid proportions of microsomal PL in rats with STZ-induced diabetes have been thoroughly investigated and well described. Direct evidence of fatty acid changes was obtained from *in vitro* experiments in which rat hepatic microsomal Δ9-, Δ6-, and probably Δ5-desaturase activities were decreased (10,11,16–18). These decreases in enzyme activities led to increases in 18:2n-6, 18:3n-6, and 20:3n-6 and decreases in 16:1n-9 and 20:4n-6 in diabetic human and rat hepatic PL (1–15). However, the results of the present study apparently contradict these earlier observations. We found that while one of the Δ9-desaturase products, 16:1n-7, was significantly decreased in all three lipids in diabetic plasma (1–5 mon), another Δ9-desaturase product, 18:1n-9, in CE in the early stage (1–3 mon) and in PL in the late stage of diabetes (5 mon), was unexpectedly increased. These findings indicate a discrepancy between diminished Δ9-desaturase activity and an increased proportion of one of its products. Because the chow given to the experimental rats contained a rather small amount of 16:1n-7 and an abundance of 18:1n-9, despite the higher chow intake of 18:1n-9 in the diabetic rats, the 18:1n-9 change was found to be smaller in diabetic TG. Furthermore, 18:3n-6, a product of Δ6-desaturase, was decreased as expected in CE only at 1 mon while being unexpectedly increased in PL in the early stage and TG in the late stage of diabetes, as compared to controls. Dang *et al*. (9) observed that the proportions of fatty acids in lipids isolated from plasma and red cells of rats (more than 2 mon old) with diabetes (for 2–3 wk) were significantly altered, while those in platelets and apparently the aorta were unchanged until a later stage (6 wk). These authors reported a significant 20:4n-6 increase in TG and significant 20:4n-6 decreases in PL and CE in 2–3-wk diabetic rats. Thus, the proportion of 20:4n-6 in diabetic plasma TG is not apparently reduced compared to that of controls. However, the mechanism underlying the stability of these fatty acid levels in plasma TG is unclear.

Voss *et al*. (32) have proposed a novel pathway in rat hepatocytes for the synthesis of 22:6n-3, a route independent of Δ4-desaturase, which involves elongation of 22:5n-3 and Δ6-desaturation of its product followed by chain shortening *via* β-oxidation. Δ6-Desaturase is the rate-limiting enzyme for the synthesis of 20:4n-6 from 18:2n-6. It is noteworthy that, despite the significant decrease in the proportion of 22:5n-3 in all three lipid fractions during the late stage of diabetes, the proportion of 22:6n-3 was significantly increased in TG at 1–3 mon while being unchanged in CE and PL. Furthermore, neither the proposed Δ6-desaturase product, 24:6n-3, nor 24:5n-3 was detected in our study. Δ5-Desaturase activities on the n-6 fatty acid 20:3n-6, but not the n-3 fatty acid 20:4n-3, were reduced. One possible explanation is that Δ5-desaturase exists as two distinct enzymes, as is the case with Δ9- and possibly Δ6-desaturase (33–35).

Elongation of 16:1n-7 to 18:1n-7 was significantly increased in CE and PL of diabetic animals. However, elongation of 18:1n-9 to 20:1n-9 was decreased in all three lipid fractions.

In diabetic rats, there was an overall decrease in the proportions of short-chain saturated fatty acids (10:0–16:0) as compared to controls. In TG, the proportions of 10:0, 12:0, 14:0, and 16:0 were reduced only in the early stage, whereas in CE, the proportions of 10:0 and 14:0 decreased in the late stage. Besides the saturated fatty acids discussed above, in control TG, the proportions of monounsaturated 16:1n-9 were age-dependently decreased, whereas the proportions of 18:2n-6 and 22:1n-9, and the n-3 fatty acids 18:3, 22:5 and 22:6, were increased. In diabetic TG, only the proportions of 18:0 and 20:4 showed age-related decreases, while 16:1n-9 and 18:1n-9 were increased, as were the fatty acids of which the proportions were increased in controls. In control PL, there were age-related decreases in the proportions of 16:0, 16:1n-9, 18:0, 20:2n-6, and 22:3n-6, the former three also being seen in control TG, and age-related increases in the proportions of 18:2n-6, 20:1n-9, and 20:5n-3 in both diabetic and control PL. In CE, only a few fatty acids showed age-related proportional changes.

Effect of Continuous Enteral Medium-Chain Fatty Acid Infusion on Lipid Metabolism in Rats

Yi Qian You, Pei Ra Ling, Zhensheng Qu, and Bruce R. Bistrian*

Laboratory of Nutrition/Infection, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

ABSTRACT: This study compared (i) the relative effects of long-chain triglycerides (LCT) and medium-chain triglycerides (MCT), (ii) the influence of amount of MCT, and (iii) the impact of medium-chain fatty acid position, on plasma and lymphatic triglycerides and portal vein free fatty acids. The animals were fed approximately at 250 kcal/kg · day for 20 h. The lymph from lymphatic duct and blood from portal vein and systemic circulation were collected. The results showed that feeding 100% MCT for 20 h was sufficiently long to reduce significantly the level of linoleic acid in portal vein fatty acids and plasma and lymph triglycerides. However, this alteration induced by MCT feeding was partially prevented by adding LCT to the diet. The level of arachidonic acid was significantly reduced in plasma triglycerides by any of the diets containing medium-chain fatty acids compared to 100% LCT. When feeding MCT only, palmitoleic acid, presumably reflecting *de novo* lipogenesis, was increased in lymphatic triglycerides and portal vein fatty acids. Total saturated fatty acids as a total percentage of total fatty acids were also significantly increased in plasma and lymphatic triglycerides and portal vein fatty acids. Thus, when linoleic acid is limiting, the conversion of MCT into long-chain fatty acids by *de novo* lipogenesis is likely to be an important metabolic route. Providing LCT with MCT or 2-monodecanoin appears to limit this pathway.

Lipids 33, 261–266 (1998).

It has long been known that the chain length and position of dietary fatty acids in the triglyceride structure are two important factors that influence lipid metabolism. For instance, medium-chain triglycerides (MCT) when consumed enterally are quickly hydrolyzed and rapidly absorbed into the intestinal cells, whereas long-chain triglycerides (LCT) are absorbed as free fatty acids and 2-monoglycerides after micellar formation (1–3). Moreover, after intestinal absorption, medium-chain fatty acids travel principally *via* the portal vein esterified to albumin, while LCT are largely reesterified in the intestinal cell into triglycerides by linking free fatty acids to the 2-monoglyceride and are incorporated into chylomicra to travel *via* the lymphatics into the circulation. MCT are also cleared more rapidly from the circulation compared to LCT. Given these metabolic differences, MCT can have a number of benefits in certain clinical situations.

For instance, a 50:50 physical mixture of LCT and MCT was found to be superior to 100% LCT emulsion owing to more rapid metabolic utilization and reduced deposition as fat in our previous animal study (4). Moreover, when subjects consumed a transesterified mixture of 50% MCT and 50% LCT as safflower oil, the mean serum cholesterol concentrations fell as compared to LCT alone (5). It appears that MCT or medium-chain fatty acids in the 2-position are favorable for displacing cholesterol-raising fatty acids, because it has been demonstrated that during reesterification the saturated long-chain fatty acids esterified to the 2-position raise cholesterol concentrations more than when esterified to the 1- or 3-position (5). Recent studies also demonstrate that MCT increase hepatic lipogenic enzyme activity in the liver (6) with the synthesis of saturated long-chain fatty acids when very large amounts of MCT are provided with very limited amounts of LCT or no LCT (7). Therefore, the various potential metabolic pathways of MCT are not completely known and could be influenced particularly by the amount of MCT feeding, the position of medium-chain fatty acids on the glycerol molecule, as well as the presence or absence of LCT.

The present study was designed to compare after enteral feeding: (i) the different effects of LCT and MCT when given alone; (ii) the influence of amount of isomolar mixture of MCT and LCT; and (iii) the impact of medium-chain fatty acid position on portal vein fatty acid and plasma and lymphatic triglyceride fatty acid composition in rats. L-Emental (Nutrition Medical, Buffalo, MN), a complete enteral nutrition formula, was used as the base feeding solution, because calories provided by fat are low (only 2.5%) in this diet. All the fat sources were added into the base feeding solution in isomolar amounts to reach total calories of approximately 250 kcal/kg · day with 25% of nonprotein from fat. Completely isocaloric comparison was not possible owing to the lower caloric content of medium-chain fatty acids and the presence of only one medium-chain fatty acid in 2-monodecanoin (2-mono). Animals were constantly fed for 20 h before blood samples were taken. The free fatty acids and triglyceride fatty acids were determined in the portal vein, lymphatic fluid, and plasma, respectively, to help define the effects of absorption pathway. The results suggest that by feeding MCT only, with

linoleic acid limiting, the conversion of MCT into long-chain fatty acids by *de novo* lipogenesis is likely to be an important metabolic route. Providing LCT with MCT or 2-mono appears to limit this pathway. This could be due either to greater amounts of linoleic acid or lesser amounts of medium-chain fatty acid or to the combination.

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats (Taconic Farms, Germantown, NY), weight 280–300 g, were housed in stainless-steel wire-bottom cages and exposed to a 12-h light–dark cycle at ambient temperature for 5 d before experimentation. Animals were provided with standard laboratory chow and water *ad libitum* during this period. The experiment was approved by the Animal Care Committee of the Beth Israel Deaconess Medical Center, which follows guidelines prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animal Resources of the National Research Council.

Under ether anesthesia, a silicone catheter (0.025 mm i.d. × 0.047 mm o.d.; Silastic™, Dow-Corning Laboratories, Corning, NY) was inserted into the antrum of the stomach and advanced ~1 cm beyond the pylorus for enteral feeding. The catheters were tunneled subcutaneously and exteriorized at the midscapular region and connected to a flow-through swivel (Instech Laboratories, Philadelphia, PA) that allowed for uninterrupted infusion and free movement by the rats. Rats were housed individually in wire-bottomed cages during recovery and had free access to rat chow diet and tap water. Normal saline was infused at 2 mL/h through the catheter to maintain patency of the catheter.

After 24 h of recovery from surgery, the rats were randomly assigned to four different feeding groups. The L-Emental enteral nutrition (Nutrition Medical) was used as a base formula. The different fats were added to meet conditions of 25% nonprotein calories provided by fat source at approximate total of 250 kcal/kg · day. Four different lipids were included: a commercial sunflower oil (LCT group) (distributed by Sunfresh Inc., West Seneca, NY), a standard MCT mixture (Mead Johnson, Evansville, IN) (MCT group), an isomolar mixture of 50% LCT and 50% MCT (LCT/MCT group) and an isomolar mixture of 50% LCT and 50% 2-monodecanoic acid (Stepan Company, Maywood, NJ) (LCT/2-mono group). All the fat sources were in isomolar amounts based on the calculation from LCT. The fat was provided at approximately 0.29 g/h in LCT group, 0.30 g/h in MCT group, and 0.30 g/h in LCT/MCT and LCT/2-mono groups. Although the different fat sources were controlled at isomolar amounts, the caloric content per gram of fat in each diet was slightly different. All the animals were constantly fed with these diets for 20 h at 2.2 mL/h to reach a steady-fed state. At the end of feeding, under ether anesthesia all the animals had a lymph sample collected over one-half hour through silicone tubing inserted into the lymphatic duct while feeding was continued and a blood sample (1–1.5 mL) taken from the portal vein by direct venipuncture. During anesthesia, breathing and muscle tension were monitored. Finally, a systemic blood sample was collected at sacrifice. All the samples were stored under nitrogen at −20°C until assay to avoid oxidation of lipids.

Analysis. The components of plasma triglycerides or free fatty acids were extracted according to the method reported by Folch *et al.* (8) with modification. Systemic plasma (1 mL), portal plasma (0.5 mL), or lymph fluid (0.2 mL) was mixed with chloroform/methanol (2:1, vol/vol) solution and water (8 and 1 mL, respectively). Tritridecanoic acid or tridecanoic acid ($C_{13:0}$) (Sigma Chemical Co., St. Louis, MO) was added to each sample before lipid extraction. Triglyceride and free fatty acids were separated on thin-layer plates using a mobile phase of petroleum ether/diethyl ether/glacial acetic acid (80:20:1, by vol), and identified relative to the migration of standards using dichlorofluorescein spray. The triglyceride and free fatty acid bands were isolated, hydrolyzed, and methylated under nitrogen with 14% BF_3 in methanol for 45 min in a steam bath in a closed system. The fatty acid methyl esters were separated using a Hewlett-Packard 5890 series II gas chromatograph (Palo Alto, CA) after some evaporation of solvent to reduce the sample size. The column used was a 50-m fused-silica capillary column containing SP-2330 as the stationary phase with a 0.20-μm film thickness (Supelco, Bellefonte, PA). The relative mole percentage of individual fatty acids was identified and quantified using Chem Station software (Hewlett-Packard) based on the relative responses of an external standard of pure tridecanoic acid methyl esters (Nu-Chek-Prep, Elysian, MN). The recovery rate of known amounts (from approximately 0.005–0.04 μmol/mL) of 10:0 and 18:0 under our assay conditions was 86.5 ± 4.5% and 102.9 ± 4.8% (mean ± SEM), respectively.

Statistics. The data were presented as mean ± SEM. The significant comparison among four different groups was determined using one-way analysis of variance with LSD as the *post hoc* test. Significance was set at $P < 0.05$.

RESULTS

The free fatty acid profiles in portal vein plasma are listed in Table 1. No medium-chain free fatty acids were detected in the portal vein when feeding MCT-containing diets, including 100% MCT, 50% MCT, and 50% of 2-mono for 20 h, presumably owing to the continuous nature of the feeding. However, feeding with these three medium-chain fatty acid-containing diets significantly increased the amount of palmitoleic acid (16:1n-7) as compared to the LCT diet ($P < 0.01$). The greatest effect was observed in the MCT group, followed by LCT/2-mono and LCT/MCT groups. These changes in palmitoleic acid in the MCT group were associated with the greatest decreases in linoleic acid (18:2n-6) and arachidonic acid (20:4n-6). The total free fatty acids in the portal vein were higher but not significantly so in the MCT group compared to other groups.

Table 2 lists the changes in triglyceride fatty acids in the

lymph. Decanoic acid (10:0) was detected in all groups. Although substantially more 10:0 was found in medium-chain fatty acid-containing groups, there were statistically no significant differences among all groups owing to the great variability of the data. MCT feeding significantly increased the palmitoleic acid and oleic acid (18:1n-9) content compared to other groups ($P < 0.05$). In contrast, MCT feeding significantly decreased the content of linoleic acid. There were no differences in arachidonic acid, docosahexaenoic acid (22:6n-3) and total fat content among groups.

The changes in fatty acids in plasma triglycerides are listed in Table 3. No MCT was detected in the systemic circulation in any group. MCT feeding led to slight but not significant increases in palmitic acid (16:0), palmitoleic acid, and oleic acid (18:1n-9) as compared to other groups. The arachidonic acid content of triglycerides was significantly higher in the LCT group as compared to the three MCT groups, whereas linoleic acid was significantly different only from 100% MCT. The lowest linoleic acid content was in the MCT group, which was significantly lower than LCT/2-mono and marginally significant when compared to LCT/MCT. The total fatty acids were not significantly different among groups.

Figure 1 presents the percentage total saturated fatty acids of the total fatty acids in portal vein and lymph and plasma triglycerides. The saturated fatty acids (i.e., 12:0, 14:0, 16:0, and 18:0) in portal vein triglyceride were significantly higher in the MCT group compared to LCT and LCT/MCT groups. The total saturated fatty acids as a percentage of total fatty acids in the lymph triglyceride were significantly higher in the MCT group as compared to other groups. The total percentage of saturated fatty acid in plasma triglycerides was also significantly higher in the MCT group compared to other groups.

DISCUSSION

In the present study, feeding 100% MCT as the principal lipid source in the diet for 20 h significantly reduced the level of linoleic acid in plasma triglycerides in the systemic circulation

to a level one-third that observed in LCT. Moreover, the period of feeding (20 h) was also sufficient to significantly reduce the level of arachidonic acid, a principal end-product of linoleic acid. However, these alterations in linoleic acid induced by MCT feeding were partially prevented by adding LCT to the diet. In the current study, when half of MCT was replaced by LCT, the relative amount of linoleic acid was doubled in plasma in LCT/MCT as compared to MCT alone, although the content of linoleic acid was still lower in the LCT/MCT and LCT/2-mono group compared to the LCT group.

Our results also showed that the constant feeding with 100% MCT did not lead to the appearance of medium-chain fatty acids in portal vein fatty acids. The three medium-chain fatty acid-containing diets also did not lead to the appearance of medium-chain fatty acids in plasma triglycerides. These results are not consistent with previous findings. It was reported that decanoic acid (10:0) infused alone was essentially transported through the portal system (9). Bougneres *et al.* (10) found very high plasma concentrations of octanoic (8:0) plus decanoic acid (10:0) in full-term and preterm infants 1 h after a single intragastric dose of 2.8 mL MCT/kg body weight. In healthy adults, MCT also modestly elevated plasma concentrations of medium-chain fatty acids in triglycerides after oral administration of MCT oil (11,12). The following possibilities may contribute to the discrepancy. Most important, feeding parameters were different in each study. In the present study, the dietary MCT was given continuously as an emulsion, providing a relatively lower dose of MCT per unit time, and MCT was mixed with other nutrients. In the previous studies, MCT was given as either bolus injection or a higher dose of infusion alone. Therefore, the levels of MCT transported *via* the portal system would be expected to be lower in the present study, and even below the detectable range, when compared to those in earlier studies. It is also possible that metabolic transformation of medium-chain fatty acids by *de novo* lipogenesis and lymphatic transport as a long-chain triglyceride may become an important pathway under these conditions rather than portal transportation as medium-chain fatty acids. Certainly, further studies are needed to identify directly the different metabolic pathways between the steady-state feeding and the bolus feeding conditions.

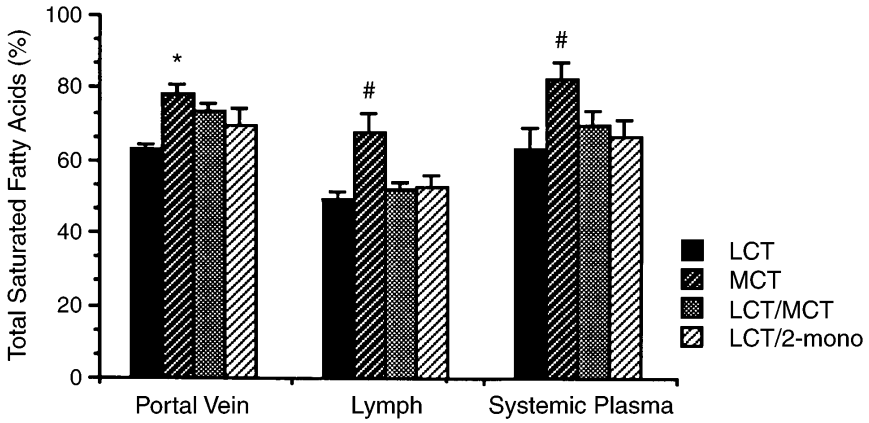

FIG. 1. Total saturated fatty acids as a percentage of total fatty acids in portal vein fatty acids, lymphatic, and plasma triglycerides. *$P < 0.05$ vs. long-chain triglycerides (LCT) and LCT/2-monodecanoic acid (2-mono); # $P < 0.05$ vs. all by one-way analysis of variance with least significant difference test. MCT, medium-chain triglycerides.

MCT feeding significantly increased the percentage of total saturated fatty acids in the portal vein fatty acids and palmitoleic and oleic acids in lymph triglyceride. It is well recognized that palmitoleic and oleic acids can derive from both dietary and endogenous origin. However, in the present study, MCT feeding did not provide these specific long-chain fatty acids. Although a possible source, it is unlikely that these two fatty acids were released from adipose tissues, given that the study was conducted in the fed-state at hypercaloric levels and feeding was continuous. Therefore, the higher levels of these fatty acids in the portal circulation and lymph are likely to be the results of *de novo* lipogenesis. Although *de novo* lipogenesis from MCT has been reported in premature infants with MCT feeding (13), the synthesis of fatty acids by this route is costly in terms of energy and is associated with a thermogenic cost of from 30 to as much as 100% of the MCT content of the diet (14,15). Thus, the present data provide further information that the conversion of MCT into long-chain fatty acids is likely to be an important route after its ingestion when linoleic acid intake is severely limited, especially in a well-fed state. However, that the contents of C_{16} and C_{18} saturated and monounsaturated fatty acids in portal vein fatty acids and lymph triglycerides in LCT/MCT and LCT/2-mono groups were not significantly different from the LCT group suggested the processes of *de novo* lipogenesis from medium-chain fatty acids are modulated by the long-chain fatty acid content of the diets (16–19).

It is also interesting to note that the changes in fatty acid appearance of palmitoleic acid induced by MCT feeding were most prominent in the portal vein, followed by the lymph triglyceride and least apparent in the systemic circulation. Presumably this endogenous fatty acid is largely synthesized in the intestine and then transported to some extent as a fatty acid by the portal vein, and in the lymph as a triglyceride, finally reaching the systemic circulation where fatty acid composition is influenced by the contributions from hepatic triglyceride production. Indeed, the incorporation of octanoic acid into fatty acids with chain length greater than 12 carbon atoms has been observed in intestinal slices (20,21). However, the relative contribution of liver and intestine to this *de novo* lipogenesis was not measured, and certainly the liver also contributes (6).

The percentage of total saturated fatty acids in lymphatic and systemic triglycerides was significantly higher in the MCT group when compared to each of the LCT-containing groups. However, there were no substantial differences found between LCT/MCT and LCT/2-mono except for the percentage of palmitoleic acid in the portal vein. LCT/2-mono increased the proportion of palmitoleic acid compared to LCT/MCT, although the difference was marginal ($P = 0.07$). The LCT/2-mono diet contains similar amounts of 10:0 but more 10:0 in the 2-position than the LCT/MCT diet. This is because one-third of the fatty acids in MCT are 10:0, but they are randomly distributed. The MCT diet would have six times as many medium-chain fatty acids as the LCT/2-mono diet but only twice as many 10:0, with two-thirds as many in the 2-position. One might anticipate that 10:0 fatty acids in the 2-position would be more likely to traverse the lymphatic route and might be metabolically more active in *de novo* lipogenesis. Although it is possible these differences contributed to the changes seen in palmitoleic acid in the portal vein, this is very speculative. Certainly, more study is needed to explore these possibilities.

In summary, the present study confirms previous findings that MCT feeding without linoleic acid appears to rapidly foster *de novo* lipogenesis, which might be considered early evidence of essential fatty acid deficiency. Providing LCT with either MCT or 2-mono effectively limits the former pathway. Our results thus suggest that continuous feeding is likely to produce markedly different pathways of medium-chain fatty acid utilization under conditions of energy surfeit than has been found with bolus or meal feeding.

ABSTRACT: Contribution of different gut segments to plant sterol absorption, adaptation of plant sterol absorption after partial small bowel resection, and effects of gut transplantation (necessitates extrinsic autonomic denervation and lymphatic disruption) on plant sterol biodynamics are unclear. We studied the consequences of massive proximal small bowel resection and autotransplantation of the remaining ileum on the adaptive absorption and biodynamics of plant sterols. Dietary, fecal, biliary, hepatic and plasma plant sterols, fecal elimination and absorption of cholesterol, small bowel morphology, and intestinal transit were determined before (n = 5) and at 4, 8, and 14 wk after resection of the proximal 75% of the jejunoileum (n = 15) and autotransplantation of the remaining ileum (n = 15) or transection (n = 5). Proximal gut resection significantly reduced cholesterol absorption efficiency; percentage absorption and biliary secretion of plant sterols; plasma, biliary and hepatic campesterol-to-cholesterol proportions; and sitosterol proportions in plasma and bile. Autotransplantation of the remaining ileum further significantly decreased cholesterol absorption efficiency; percentage absorption and biliary secretion of campesterol; campesterol proportions in plasma, bile and liver; and plasma proportions of sitosterol while increasing fecal excretion of neutral and acidic steroids. Plasma proportions of the two plant sterols, but absorption of just campesterol, were gradually improved with increasing cholesterol absorption and villus height after proximal gut resection; the same result was observed to a lesser degree after ileal autotransplantation. In addition, significant positive correlations were found between percentage cholesterol and campesterol absorption and the plasma plant sterol proportions in both proximal resection groups, between campesterol absorption and ileal villus height in the resection group, and between campesterol absorption and intestinal transit time in the autotransplantation group. In conclusion, plasma campesterol and sitosterol closely reflect absorption of cholesterol and plant sterols from intact and autotransplanted ileum during adaptation to proximal gut resection. A loss of proximal gut absorptive surface impairs cholesterol and campesterol absorption more than sitosterol absorption, the latter being apparently less dependent on available jejunal villus surface area.

Lipids 33, 267–276 (1998).

The major plant sterols normally found in small amounts in mammalian serum and tissues are campesterol and sitosterol. Except for differences in the side chain, these plant sterols are structurally similar to cholesterol with an identical sterol nucleus. Despite the structural similarities, plant sterols are absorbed to a much lesser extent than cholesterol, campesterol being absorbed more readily than sitosterol (1,2). The basis of the discrimination between cholesterol and plant sterol absorption is unclear, but the process may be mediated by differential uptake at the brush border membrane and a greater rate of cholesterol delivery from mixed micelle to the absorption site (3). Plant sterols are poorly absorbed from the intestine, are not synthesized endogenously, are poorly esterified in the liver, and are readily secreted into bile (4,5). They are detected in plasma only in low concentrations which are proportional to cholesterol absorption efficiency (6). As in healthy humans, serum plant sterol levels change in parallel with fractional cholesterol absorption in a variety of pathological conditions, including patients with untreated celiac disease or gut resections (6–9). Interestingly, at low cholesterol absorption rates in patients with celiac disease-induced villous atrophy of the proximal small bowel, the serum campesterol level is depressed relatively more than that of sitosterol (8), suggesting that the jejunum has a less central role in sitosterol absorption than in the absorption of cholesterol and campesterol.

Under physiological conditions absorption of cholesterol and plant sterols is believed to occur predominantly in the proximal small bowel through apical villus cells (10,11). Thus, removal of the proximal gut offers a useful model to examine the contribution of different small bowel segments to sterol absorption in general. On the other hand, after proximal small bowel resection, gut absorptive surface is reduced and sterol absorption occurs, abnormally, in the remaining ileum. The latter undergoes structural and functional adaptation to proximal small bowel resection, leading to increased absorption per unit gut length (12). As far as we know, adaptation of plant sterol absorption after partial small bowel resection has not been previously studied. Extrinsic denervation, lymphatic disruption, and ischemia, all necessitated by small bowel transplantation, may interfere with these compensatory changes

and further decrease overall intestinal absorption following resection (13,14). This is highly relevant, because intestinal transplantation has recently been applied to clinical use among patients with short bowel syndrome or end-stage intestinal failure. In our previous studies, 50% proximal resection of porcine small bowel, and especially autotransplantation of the remaining ileum, decreased plasma plant sterol-to-cholesterol proportions, a finding consistent with a loss of the major site for effective sterol absorption (15). The plasma plant sterol-to-cholesterol proportions improved gradually after the operations, campesterol more readily than sitosterol, indicating that ileal adaptation to plant sterol absorption occurred even after autotransplantation of the remaining ileum, and differently for campesterol and sitosterol.

We hypothesized that proximal small bowel resection and particularly autotransplantation of the remaining ileum would decrease absorption of campesterol more than of sitosterol. To this end and to further elucidate factors regulating absorption and plasma levels of plant sterols, to compare intestinal absorption of cholesterol, campesterol and sitosterol during postresectional adaptation of intact and autotransplanted ileum, and to ascertain whether plasma plant sterols reflect sterol absorption also under these conditions, plasma, biliary and hepatic contents, fecal excretion, absorption, and biliary secretion of plant sterols were determined before and after resection of the proximal 75% of the jejunoileum and autotransplantation of the remaining ileum or transection. Finally, the results were related to different variables of cholesterol biodynamics, small bowel morphology, and intestinal transit.

The results of the present study suggest first that a loss of proximal gut absorptive surface impairs cholesterol and campesterol absorption more than sitosterol absorption. Second, ileal autotransplantation in pigs with proximal gut resection further decreases cholesterol and campesterol absorption. Third, campesterol absorption in the ileum gradually increases, similarly to that of cholesterol, following massive proximal gut resection; and plasma campesterol and sitosterol closely reflect absorption of cholesterol and plant sterols from intact and autotransplanted ileum during adaptation to proximal gut resection.

MATERIALS AND METHODS

Experimental animals. Thirty-five growing female pigs purchased from a commercial supplier were housed individually in a light- and temperature-controlled environment, fed twice a day at standardized times, and offered water *ad libitum*. Standard pig chow (Suomen Rehu OY, Turku, Finland) containing 61.7% (w/w) carbohydrate, 17.0% protein, 3.5% fat, 4.7% crude fiber, and 12.0% aqueous substance was freely available for 1 h twice a day. Gas–liquid chromatographic (GLC) measurements of sterols in nonsaponifiable dietary material using a 50-m-long SE-30 capillary column (Hewlett-Packard, Palo Alto, CA) revealed that the diet contained 76.7 μg cholesterol, 133.7 μg campesterol, and 341.3 μg β-sitosterol per gram of chow. The animals used in this study received humane care in compliance with the principles of Laboratory Animal Care and the Guide for the Care and Use of Laboratory Animals prepared by the Institute of Laboratory Animal Resources and published by the National Institutes of Health (NIH publication no. 86-23, revised 1985). An authorization (No. 154613) to perform these experiments was given by the Provincial Government of Uusimaa in accordance with Finnish legislation.

Surgical procedures. Animals randomly assigned into transection (n = 5), resection (n = 15), and autotransplantation (n = 15) groups underwent surgery after an overnight fast under general anesthesia with endotracheal intubation. A single dose of 500 mg ceftriaxone and 100 mg phenylbutazon were given intramuscularly for antibiotic prophylaxis and postoperative analgesia, respectively. Animals were kept on a liquid diet for the first postoperative day, after which the standard chow was introduced.

In the transection group, the small intestine (1286 ± 60 cm) was transected 10 cm distal to the ligament of Treitz, in the middle of the ileum and 5 cm proximal to the ileocecal junction (Fig. 1). In the resection group, the proximal 75% of the small intestine was resected 10 cm distal to the ligament of Treitz after transection of the ileum 5 cm proximal to the ileocecal junction, leaving the distal 25%, or 320 ± 10 cm, of small bowel functioning. Intestinal continuity was restored by end-to-end anastomoses. As described in detail previously (16), orthotopic autotransplantation of the ileum with proximal small bowel resection was carried out with some modifications. Briefly, the distal 25%, or 343 ± 7 cm, of the small bowel was isolated on a vascular pedicle composed of the branches of the superior mesenteric artery and vein. After the mesentery to the ileum was freed, the superior mesenteric vessels were divided, and the graft was perfused *via* the artery with cold (4°C) heparinized Ringer's solution (5000 IU/1000 mL) until the venous effluent was clear. The harvested small bowel was kept in cold isotonic saline solution, and a proximal 75% small bowel resection was performed as described above. Following systemic heparinization, the superior mesenteric vessels were anastomosed to the aorta and the inferior vena cava below the renal vessels. Total ischemic time averaged 60.7 ± 2.5 min with no significant differences among the three subgroups.

Study design. Preoperatively, and at 4, 8, and 14 wk after resection or transplantation and 14 wk after transection, intestinal transit time was measured with carmine red powder before a 3-d stool collection was performed at the end of an 8-d marker feeding period. Then, after an overnight fast, blood, gallbladder bile, liver, and small intestinal samples were obtained under aseptic conditions, and the animals, excluding those studied preoperatively, were killed with a lethal injection of thiopental. Five pigs subjected to small bowel resection were studied twice: preoperatively and 4 wk after resection. Thus, five animals were studied preoperatively; five resected and five transplanted animals were studied 4 and 8 wk after the operation; and five transected, five resected, and five autotransplanted animals 14 wk postoperatively. All ani-

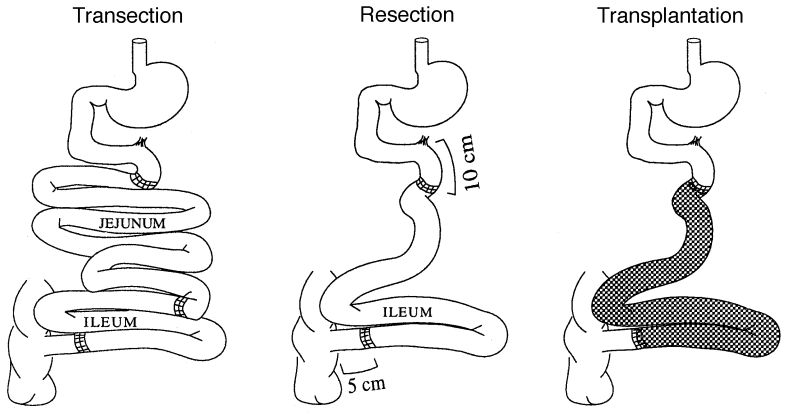

FIG. 1. Surgical procedures. In the transection group, the small bowel was transected and reanastomosed 10 cm distal to the ligament of Treitz, in the middle of the ileum and 5 cm proximal to the ileocecal valve. In the resection group, the proximal 75% of the small bowel, including the jejunum and proximal ileum, was resected after transection of the ileum 5 cm proximal to the ileocecal junction leaving the distal 25% of the small bowel functioning. In the autotransplantation group, the remaining distal ileum (shaded) underwent an additional autotransplantation. The graft mesenteric vessels were anastomosed to the aorta and the inferior vena cava below the renal vessels.

mals were weighed weekly and checked daily for chow intake.

Analytical methods. Fractional cholesterol absorption was measured using the double-isotope feeding method (17). For this and for determining fecal steroids of cholesterol origin, the pigs were fed capsules containing 0.09 μCi [^{14}C]cholesterol, 0.25 μCi [^{3}H]sitostanol (Radiochemical Centre, Amersham, United Kingdom), and 200 mg chromic oxide (Orion, Espoo, Finland) twice a day with each meal for 8 d under strict supervision. To measure intestinal transit time, the animals ingested 1 to 2 g of carmine red powder with the first capsules, and the appearance of the dye in feces was recorded.

Fecal neutral steroids of cholesterol origin, plant sterols, and bile acids were quantified with GLC on the 50-m-long SE-30 capillary column (Hewlett-Packard) (18–20). Fecal chromic oxide, used to correct the fecal flow, was determined from the 3-d fecal samples according to Bolin *et al.* (21).

Total (including free and esterified sterols) cholesterol, campesterol, and sitosterol concentrations in the diet, plasma, bile, and liver were determined by GLC on the 50-m cross-linked methyl silicone SE-30 capillary column (Hewlett-Packard) directly from nonsaponifiable material of respective lipid extracts (20,22–24). The bile and liver specimens were flash-frozen in liquid nitrogen and stored at −20°C along with plasma samples separated by centrifugation until analyzed. A weighed and homogenized sample of liver (200 mg) or chow (2000 mg), or an aliquot of plasma or bile (250 μL), was saponified by a mixture of 10 N KOH in 99.5% ethanol (1:9) after addition of internal standard 5α-cholestane (Sigma Chemical Co., St. Louis, MO). After a 2-h saponification, the mixtures were diluted to a 50% ethanolic solution and extracted at least twice with hexane, washed with 50% ethanol to remove adherents, dissolved with hexane/methanol, and evaporated to dryness. Finally, the sterol contents of the hexane extracts were quantified as trimethyl silyl ether derivatives. To eliminate the effects of varying cholesterol concentrations, plant sterols in plasma, bile, and liver are expressed in terms of μg/mg of cholesterol. The latter values are called proportions in the following text.

The small intestinal length was measured along the antimesenterial border, and small intestinal tissue samples were obtained from the proximal jejunum, mid-ileum, and distal ileum (Fig. 1). Samples were freed from mesentery, cut open along the mesenteric border, and measured for circumference. Separate full-thickness biopsies were fixed in formalin and embedded in paraffin. A pathologist determined villus height in a single-blind measurement from the villus–crypt junction to the tip of the villus using periodic acid–Schiff-stained slides. In every specimen an average of four well-oriented randomly chosen villi were measured and averaged to give single values representing mean villus height in the remaining small bowel.

Calculations and data analysis. Fractional cholesterol absorption was calculated from the difference between fecal and dietary ratios of [^{14}C]cholesterol and [^{3}H]sitostanol (17). Total intestinal cholesterol influx was calculated using an indirect method as follows (25): intestinal cholesterol influx = fecal neutral steroids/(1 − fractional cholesterol absorption). The difference between the intestinal cholesterol influx and dietary cholesterol equaled the biliary cholesterol secretion. The intestinal cholesterol influx multiplied by the fractional cholesterol absorption equaled the absorbed amount of total cholesterol. Biliary secretion of campesterol and sitosterol was calculated from their respective ratios to cholesterol, expressed as μg/mg of cholesterol in fasting pig gallbladder bile, by multiplying the ratios by the biliary cholesterol secretion (9,25). Fractional plant sterol absorption was calculated from the biliary plant sterol secretion divided by the

fecal excretion of campesterol and sitosterol, which represents the minimal absorption of plant sterols, because a small fraction of absorbed plant sterols may be eliminated as acidic steroids (26). The small bowel serosal surface area was obtained by multiplying the mean small intestinal circumference by its length.

Analysis of variance and the unpaired Student's *t*-test were used for comparisons between the groups. Fisher's protected least significant difference test was performed for multiple pairwise comparisons. Correlations were tested by linear regression analysis. The minimal level of statistical significance was defined as $P < 0.05$. All values are expressed as mean ± SEM.

RESULTS

Preoperative body weights (18.6 ± 0.6 kg) and small bowel lengths (1319 ± 23 cm) were similar in the three operated groups (data not shown). During the follow-up of 14 wk, weight gain was 65.0 ± 1.3 kg after transection, 38.6 ± 0.9 kg after resection, and only 4.8 ± 1.6 kg after transplantation. In Tables 1 and 2 data are given for all three experimental goups at 14 wk, and in Figures 2–5 preoperatively, 4, 8, and 14 wk, respectively, after resection and transplantation.

Small intestinal adaptation. Small intestinal serosal surface area, decreased by proximal small bowel resection, remained virtually unchanged during the follow-up in both proximal resection groups (Fig. 2). The values were over twofold higher in the resection than in the transplantation group, but remained about 50% lower than in the transected animals at 14 wk (Table 1). Villus height of the remaining small bowel increased markedly between 8 and 14 wk after resection and was significantly higher than in the transected or transplanted animals at the end of the study (Fig. 2 and Table 1). Intestinal transit time was similar in both proximal resection groups but considerably shorter when compared to the transected controls at the end of the follow-up (Table 1).

Cholesterol biodynamics. Table 1 displays the characteristics of cholesterol biodynamics 14 wk after the operations. Plasma and hepatic cholesterol contents were highest in the transected controls and lowest after ileal autotransplantation. Biliary cholesterol concentration was highest in the transplantation group and lowest in the transected controls. Fractional and total cholesterol absorption decreased markedly after resection and further after autotransplantation of the remaining ileum. Elimination of neutral and acidic steroids into feces was significantly increased after resection and even more so after autotransplantation of the remaining ileum.

Plant sterol biodynamics. Characteristics of plant sterol biodynamics 14 wk after the operations are shown in Table 2. In the transected controls, the plasma, biliary, and hepatic campesterol proportions were 2.2–3.3 times higher than the respective sitosterol proportions. Percentage absorption and biliary secretion of campesterol were, respectively, 5.6 and 2.2 times greater than those of sitosterol. When compared to the transection group at 14 wk, resection had greatly diminished campesterol proportions in plasma, bile and liver, sitosterol proportions in plasma and bile, and biliary secretion and percentage absorption of both plant sterols. In general, similar but even more pronounced changes were observed after transplantation. In both study groups, the decreases were markedly greater for campesterol than for sitosterol. Thus, the

[a]Determined 14 wk postoperatively.
[b]Superscript roman letters as follows: [a]$P < 0.05$ from transection in the same row; [b]$P < 0.05$ from resection in the same row.

plasma proportions and percentage absorption of campesterol in the resected animals exceeded those of sitosterol at the end of the follow-up.

The plasma, biliary, and hepatic proportions and biliary secretion of campesterol, dramatically decreased by proximal small bowel resection, gradually increased between 4 and 14 postoperative weeks in the resection group and, to a lesser degree, in the transplantation group (Fig. 3). Similar changes occurred in plasma sitosterol proportions (Fig. 4). In contrast, the biliary proportions and secretion of sitosterol tended to be lower in the resection than in the transplantation group. Unexpectedly, hepatic sitosterol proportions were not significantly decreased in either of the study groups and showed a significant temporal increase after resection. The campesterol/sitosterol proportion ratios in plasma, bile, and liver underwent temporal increases in both proximal resection groups (Fig. 5). The values were significantly greater after resection than after transplantation.

Adaptation of sterol absorption. When compared to the preoperative values, the resection and transplantation groups showed substantial mean decreases in the percentage absorption of cholesterol and campesterol, about 10- and 14-fold, respectively (Fig. 2). The respective decrease was considerably smaller, about twofold, for sitosterol. Percentage absorption of cholesterol and campesterol, but not of sitosterol, increased gradually after resection and, albeit less so, after transplantation.

Correlations. Fractional absorption of campesterol was positively related to villus height and intestinal transit time in the unresected controls, to villus height in the resection group, and to intestinal transit time in the transplantation group (Table 3). Although insignificant and weaker, similar associations existed for sitosterol. In all the groups studied, plasma campesterol and sitosterol-to-cholesterol proportions displayed significant positive correlations with cholesterol absorption efficiency, and plasma campesterol proportions with campesterol absorption efficiency. However, the plasma sitosterol proportion was significantly related to fractional sitosterol absorption only in the unresected control animals. Plasma plant sterol proportions were interrelated with biliary and hepatic plant sterol proportions, with the exception of biliary sitosterol proportions in the transplantation group. In the transplanted animals with bile acid malabsorption, the higher the biliary sitosterol secretion, the higher was fecal excretion of bile acids (Fig. 6). No such association was found between fecal bile acids and biliary secretion of campesterol (r = 0.166, P = 0.55). However, biliary secretion of sitosterol showed only weak and insignificant correlation with biliary bile acid secretion (r = 0.301, P = 0.28).

DISCUSSION

In principle, the intact upper small intestine appears to be the major site for effective sterol absorption (10,11). The different absorption rates for the individual sterols were actually high in the control pigs of the present series, which absorbed

cholesterol, campesterol, and sitosterol with respective percentages of 80–51, 45–19, and 8–4% at different ages. In general, these findings are in accord with previous studies in normal humans and rats, where higher intestinal absorption rates are reported for cholesterol (~40%) than for campesterol (~10%) or sitosterol (~5%) (1,2,4,27,28). As far as we know,

campesterol or sitosterol absorption rates have not previously been presented for pigs. However, the experiments performed here were primarily aimed at defining whether adaptation of plant sterol absorption occurs, analogously to that of cholesterol, after proximal gut resection and autotransplantation of the remaining ileum, whether this adaptation is different for the individual plant sterols, and whether plasma plant sterol proportions reflect their absorption efficiencies during ileal adaptation. In fact, close associations were demonstrated between cholesterol absorption efficiency and plasma proportions and absorption of plant sterols after massive proximal gut resection, with or without autotransplantation of the remaining distal small bowel.

The similarity in structure and physiology of the gastrointestinal tract of the pig to that of humans makes the pig an excellent animal model because of the important role of the gut in lipid metabolism (29). Lipoprotein distribution and composition are similar to that of humans, and low density lipoprotein is the major cholesterol-transporting lipoprotein in both species (30,31). The physical characteristics and

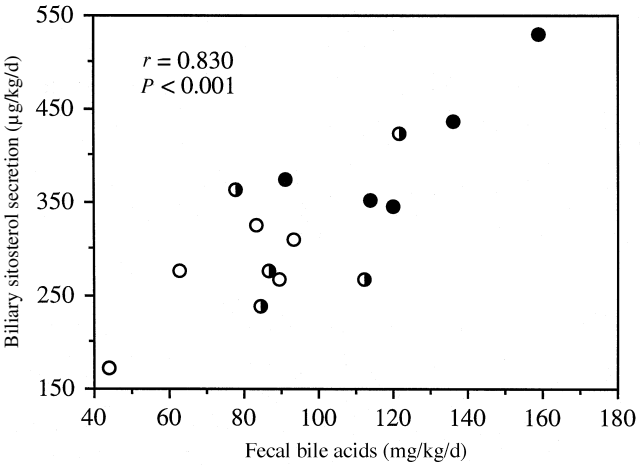

FIG. 6. Correlation of fecal bile acid excretion with biliary sitosterol secretion after proximal 75% small bowel resection with autotransplantation of the remaining ileum. ○, Week 4; ●, week 8; ◑, week 14.

turnover of pig low density lipoprotein resemble those of humans (30,32). Furthermore, interruption of the enterohepatic circulation of bile acids with cholestyramine and inhibition of hepatic cholesterol synthesis with mevinolin result in a decrease of plasma cholesterol, whereas enhanced intestinal absorption of cholesterol increases plasma cholesterol concentration as it does in humans (31,32).

Massive (75%) proximal resection of porcine small bowel dramatically decreased percentage absorption and biliary secretion of plant sterols, campesterol being affected much more severely than sitosterol. Because of the marked compensatory increase in cholesterol synthesis, the decrease in plasma cholesterol was only up to 46%, compared with 95% for campesterol and 81% for sitosterol concentrations by the respective absorption reductions of 88, 95, and 71% (Tables 1 and 2). At the end of the study, plasma proportions of campesterol and sitosterol in the two groups with proximal gut resection averaged about 13- and 4-fold lower than the corresponding values in the transection group. The approximately 15- and 3-fold higher average intestinal absorption of campesterol and sitosterol in the transection group could well explain these differences. Previous studies suggest that mucosal sitosterol uptake is well preserved throughout the length of the entire small intestine, whereas mucosal uptake of cholesterol and campesterol displays a precipitous proximodistal gradient in the intact small bowel, being most effective in the proximal jejunum (2,10,11). In agreement with this, the percentage absorption of both cholesterol and campesterol decreased about 10-fold or more after massive proximal gut resection, whereas the calculated fractional absorption of sitosterol was reduced relatively little, only about twofold (Fig. 2). In keeping with our findings, in untreated celiac disease with villous atrophy of the upper small intestine and low cholesterol absorption efficiency, serum concentration of campesterol is reduced more than that of sitosterol, and improved absorption during a gluten-free diet increases plasma campesterol more than sitosterol (8). Autotransplantation of the remaining ileum in pigs with proximal gut resection further decreased the various tissue proportions and absorption of campesterol (Fig. 3). In contrast, only the plasma proportions of sitosterol were decreased (Fig. 4). As shown in Table 3,

one of the main factors determining plasma levels of plant sterols, especially that of campesterol, was their absorption efficiency. The percentage absorption and plasma proportions of campesterol were reduced more than those of sitosterol; consequently, the campesterol-to-sitosterol proportion ratios decreased (Fig. 5). Thus, a loss of proximal gut absorptive surface, due either to villous atrophy or to small bowel resection, apparently impairs campesterol absorption more than sitosterol absorption. Absorption of the latter appears less dependent on available villus surface area and occurs with comparable efficiencies in all parts of the small intestine (2). In fact, the percentage campesterol absorption showed close positive correlations with villus height in the control and resection groups, whereas no such association was found for sitosterol in any of the groups studied (Table 3).

In the current study, campesterol absorption gradually increased, similarly to cholesterol, following massive proximal small bowel resection with or without autotransplantation of the remaining ileum. However, ileal autotransplantation disturbed plant sterol absorption in pigs with proximal gut resection. The high positive correlation between intestinal villus height and percentage campesterol absorption in the control and resected animals indicates that campesterol absorption, analogously to that of cholesterol (33), changed in parallel to available absorptive (villus) surface area in these growing pigs. The relatively small but significant increase in campesterol absorption after ileal autotransplantation may reflect improved individual ileocyte absorptive capacity (34), because villus height was not increased in the autotransplanted ileum. Moreover, in the absence of villus, enlargement intestinal transit time appeared as a major factor determining plant sterol absorption efficiency from the autotransplanted ileum (Table 3). In the present study, the adaptive increase in ileal sterol absorption was blunted by addition of the ethyl group of sitosterol instead of the methyl group of campesterol at position 24 in the side chain. Normally, incorporation of the ethyl group into the side chain of sterols decreases jejunal sterol absorption more than incorporation of the methyl group (1). Thus, the mechanisms responsible for the different jejunal absorption rates of individual sterols appear to regulate sterol absorption also in the ileum during adaptation to proximal gut resection. These findings accord well with our previous studies, where 50% proximal resection of porcine small bowel, and especially autotransplantation of the remaining ileum, decreased plasma plant sterol-to-cholesterol proportions, and the plasma plant sterol-to-cholesterol proportions improved gradually after the operations, campesterol more readily than sitosterol (15).

Importantly, different solubilization properties in the gut lumen may greatly and unevenly affect intestinal absorption of cholesterol and plant sterols (3,35). In the present study, the intraluminal solubilities of different sterols were not tested, leaving a possibility that the observed changes in absorption of cholesterol, campesterol, and sitosterol were also affected by changes in solubilization rather than being solely due to physical alterations in the gut anatomy. The former hardly explains the several-fold increase in cholesterol and campesterol absorption in the resection group (Fig. 2), because biliary bile acid secretion and composition remain constant in these animals (36), whereas villus height showed nearly 70% increase (Fig. 2). However, increased deconjugation and altered composition of intestinal bile acids secondary to increased bacterial activity could certainly impair overall sterol absorption especially after transplantation (36).

In man, low cholesterol absorption is associated with increased synthesis and biliary secretion of cholesterol, which may, in turn, enhance cholesterol-dependent biliary secretion of plant sterols (37). In the present study in pigs with proximal gut resection with or without autotransplantation of the remaining ileum, these associations were not apparent, presumably owing to the extent of cholesterol malabsorption (Table 1). The high positive correlation between biliary sitosterol secretion and fecal excretion of bile acids in pigs with ileal autotransplantation-induced bile acid malabsorption is of particular interest (Fig. 6). A similar association has previously been reported in patients with gut resection-induced bile acid malabsorption (9), suggesting that increased hepatic bile acid synthesis may promote biliary secretion of sitosterol by reducing hepatic conversion of sitosterol into bile acids (4). However, in humans this pathway may be nonsignificant, whereas in some other mammalian species it may be active (26,38). Interestingly, the hepatic sitosterol proportion was negatively related to fecal excretion of bile acids ($r = -0.514$, $P = 0.05$) in the pigs with ileal autotransplantation, lending further support to the conclusion that increased bile acid synthesis may also contribute to increased biliary secretion of sitosterol. In fact, it is apparent from Figure 6 that the highest level of fecal bile acid excretion occurred 8 wk after ileal autotransplantation, which could certainly explain the relatively high biliary proportion and secretion of sitosterol measured at the same time (Fig. 4).

The Effect of Dietary Vitamin E Supply and a Moderately Oxidized Oil on Activities of Hepatic Lipogenic Enzymes in Rats

Klaus Eder* and Manfred Kirchgessner

Institut für Ernährungsphysiologie der Technischen Universität München-Weihenstephan, 85350 Freising, Germany

ABSTRACT: Diets rich in polyunsaturated fatty acids (PUFA) are well known to suppress hepatic lipogenic enzymes compared to fat-free diets or diets rich in saturated fatty acids. However, the mechanism underlying suppression of lipogenic enzymes is not quite clear. The present study was undertaken to investigate whether lipid peroxidation products are involved in suppression of lipogenic enzymes. Therefore, an experiment with growing male rats assigned to six groups over a period of 40 d was carried out. Rats received semisynthetic diets containing 9.5% coconut oil and 0.5% fresh soybean oil (coconut oil diet, peroxide value 5.1 meq O_2/kg oil), 10% fresh soybean oil (fresh soybean oil diet, peroxide value 9.5 meq O_2/kg oil), or 10% thermally treated soybean oil (oxidized soybean oil diet, peroxide value 74 meq O_2/kg oil). To modify the antioxidant state of the rats, we varied the vitamin E supply (11 and 511 mg α-tocopherol equivalents per kg of diet) according to a bi-factorial design. Food intake and body weight gain were not influenced by dietary fat and vitamin E supply. Activities of hepatic lipogenic enzymes were markedly influenced by the dietary fat. Feeding either fresh or oxidized soybean oil diets markedly reduced activities of fatty acid synthase, (FAS), acetyl CoA-carboxylase, (AcCX), glucose-6-phosphate dehydrogenase, (G6PDH), 6-phosphogluconate dehydrogenase, and ATP citrate lyase (ACL) relative to feeding the coconut oil diet. Moreover, feeding oxidized soybean oil slightly, but significantly, lowered activities of FAS, AcCX, and ACL compared to feeding fresh soybean oil. Activities of hepatic lipogenic enzymes were reflected by concentrations of triglycerides in liver and plasma. Rats fed the coconut oil diet had markedly higher triglyceride concentrations in liver and plasma than rats consuming fresh or oxidized soybean oil diets, and rats fed oxidized soybean oil had lower concentrations than rats fed fresh soybean oil. The vitamin E supply of the rats markedly influenced concentrations of thiobarbituric acid-reactive substances in liver, but it did not influence activities of hepatic lipogenic enzymes. Because the vitamin E supply had no effect, and ingestion of an oxidized oil had only a minor effect, on activities of hepatic lipogenic enzymes, it is strongly suggested that neither exogenous nor endogenous lipid peroxidation products play a significant role in the suppression of hepatic lipogenic enzymes by diets rich in PUFA. Therefore, we assumed that dietary PUFA themselves are involved in regulation of hepatic lipogenic enzymes. Nevertheless, the study shows that ingestion of oxidized oils, regardless of the vitamin E supply, also affects hepatic lipogenesis, and hence influences triglyceride levels in liver and plasma.
Lipids 33, 277–283 (1998).

Several studies demonstrated that dietary polyunsaturated fatty acids (PUFA) suppress hepatic lipogenic enzymes by inhibiting enzyme protein synthesis (1,2). However, the mechanisms by which PUFA suppress hepatic lipogenic enzymes are not completely understood. Some experimental evidence suggests that the nutritionally important C18 PUFA, linoleic acid and α-linolenic acid, require Δ6 and Δ5 desaturation to C20 PUFA to exert their suppressive effect (3,4). According to a hypothesis of Clarke and Jump (5), those fatty acids interact directly at the genomic level to govern gene transcription. On the other hand, a recent study using primary hepatic monolayer culture indicated that PUFA require oxidative modification to exert their suppressive effect (6). If primary or secondary lipid peroxidation products are involved in lipogenic enzyme suppression, it might be expected that the effect of dietary PUFA on enzyme suppression would be modified by the antioxidant state of the animal. In this respect, feeding diets enriched with antioxidants could reduce, and feeding diets with low levels of antioxidants enhance the capability of dietary PUFA for lipogenic enzyme suppression. To test this hypothesis, we investigated the effect of PUFA from soybean oil accompanied by an insufficient and an excessive vitamin E supply in rats. Additionally, rats which were fed diets with thermally oxidized soybean oil were studied to ascertain the results from consumption of increased concentrations of lipid peroxidation products. According to the above hypothesis oxidized soybean oil should be a more potent inhibitor of lipogenic enzymes than fresh soybean oil.

MATERIALS AND METHODS

Animals and diets. Sixty male Sprague-Dawley rats weighing 51 (± 4, SD) g were assigned to six groups of 10 rats each.

Abbreviations: PUFA, polyunsaturated fatty acids; TBARS, thiobarbituric acid-reactive substances.

All the rats received a semisynthetic diet consisting of (in g/kg) casein (200), cornstarch (320), sugar (288), fat (100), fiber (30), minerals (40), vitamins (20), and DL-methionine (2). Minerals and vitamins with the exception of vitamin E were added in sufficient amounts as recommended by the American Institute of Nutrition (7). The dietary fat and the vitamin E supply were varied according to a bi-factorial experimental design. Dietary fats used were (I) a mixture of coconut oil and soybean oil (19:1, w/w; coconut oil diet), (II) fresh soybean oil (fresh soybean oil diet), (III) thermally treated soybean oil (oxidized soybean oil diet). Peroxide value (measured iodometrically) of the coconut oil/soybean oil mixture before inclusion into the diet was 0.8 meq O_2/kg, and that of fresh soybean oil was 3.7 meq O_2/kg. Oxidized soybean oil was prepared by bubbling air through fresh soybean oil at 130°C for 22 h. This treatment elevated the peroxide value to 23 meq O_2/kg and caused a loss of 83% of α-tocopherol, 93% of γ-tocopherol, and 38% of γ-tocopherol; percentages of PUFA were insignificantly reduced by heat treatment. Prior to inclusion in the diet, the fats were standardized to an identical vitamin E activity of 113 mg α-tocopherol equivalents per kg by supplementation with all-*rac*-α-tocopherol acetate. The fats were included into the diet either in this form or after supplementation with 7,450 mg all-*rac*-α-tocopherol acetate per kg. The calculated vitamin E concentrations of the diets were either 11 (low-vitamin E diet) or 511 mg (high vitamin E diet) α-tocopherol equivalents per kg. For preparing the diet, dietary components were mixed with water, homogenized, and dried at a temperature of 50°C for 4 d. During drying, the peroxide values of dietary oils increased. For assessing the peroxide value, aliquots of the diets were analyzed at different times within the experimental period. Average peroxide values of dietary fats over the whole experimental period are shown in Table 1. The fatty acid composition of dietary total lipids and analyzed concentrations of tocopherols are also given in Table 1. Both the fatty acid composition and tocopherol concentrations were not altered by storage at a temperature of 4°C during the experimental period. The experiment lasted 40 d. In order to stimulate activities of lipogenic enzymes, rats were given free access to food throughout until killing. Killing was carried out by decapitation after a slight anesthesia.

Analyses. After decapitation, the liver was excised and an aliquot was homogenized in a buffer containing 0.25 M sucrose and 0.1 M phosphate (pH 7.4) using a Potter-Elvehjem homogenizer. Homogenates were centrifuged (105,000 × *g* for 1 h at 4°C) and the supernatants were used for enzyme assays (8). All the enzymes were assayed by spectrophotometric methods. Glucose-6-phosphate dehydrogenase (E.C. 1.1.1.49) (9) and 6-phosphogluconate dehydrogenase (E.C. 1.1.1.44) (10) were determined by the rate of NADP reduction. In the assay of glucose-6-phosphate dehydrogenase, activity of 6-phosphogluconate dehydrogenase was inhibited by maleimide (9). Fatty acid synthase was determined from the rate of malonyl-CoA-dependent NADPH oxidation after the liver homogenate has been preincubated in a phosphate-buffered solution containing dithiothreitol to achieve maximal enzymatic activity (11). The activity of acetyl-CoA carboxylase (E.C. 6.4.1.2) was determined from NADH oxidation in an assay coupled with pyruvate kinase and lactate dehydrogenase (12). ATP citrate lyase (E.C. 4.1.3.8) was determined from NADH oxidation in an assay coupled with malate dehydrogenase (13).

For determination of triglycerides, cholesterol, and total

fatty acids in liver tissue, lipids were extracted with a hexane/isopropanol mixture (3:2, vol/vol, containing butylated hydroxy toluene) (14). For determination of liver total cholesterol and triglycerides, an aliquot of the extract was dissolved in Triton X-100 (15). Total cholesterol and triglycerides then were determined using enzymatic reagent kits obtained from Boehringer Mannheim (Mannheim, Germany). Fatty acids of liver total lipids were converted into methyl esters by transesterification with boron fluoride/methanol reagent (16). Fatty acid methyl esters were separated by gas chromatography using a Hewlett-Packard HP 5890A gas chromatographic system (Taufkirchen, Germany) fitted with an automatic on-column injector, a flame-ionization detector, and a CP-Sil 88 capillary column (50 m × 0.25 mm internal diameter, film thickness 0.2 μm; Chrompack, Middleburg, The Netherlands). Fatty acid methyl esters were identified by comparing their retention times with those of individually purified standards and quantified with heptadecanoic acid methyl ester as internal standard (17). Concentrations of tocopherols in liver, oils, and diets were determined by high-performance liquid chromatography (18). Samples were mixed with 1 mL 1% pyrogallol solution (in ethanol, absolute) and 150 μL saturated sodium hydroxide solution. This mixture was heated for 30 min at 70°C, and tocopherols were extracted three times with *n*-hexane. Individual tocopherols were separated using a mixture of *n*-hexane and 1,4-dioxane (94:6, vol/vol) as mobile phase and a LiChrosorb Si 60 column (5 μm particle size, 250 mm length, 4 mm internal diameter; Merck, Darmstadt, Germany) and detected by fluorescence (excitation wavelength: 295 nm, emission wavelength: 320 nm).

Thiobarbituric acid-reactive substances (TBARS) in liver were determined by high-performance liquid chromatography (19). Liver homogenates were mixed with 1 mL TBA reagent (10 mM TBA in 0.1 M phosphate buffer, pH 1) and 50 μL of a 0.5% solution of butylated hydroxytoluene (in ethanol, absolute). This mixture was heated for 45 min at 100°C. TBARS were extracted with *n*-butanol. The butanol phase was injected; the column used was a LiChrosorb RP-18 Cartridge (5 μm particle size, 250 mm length, 4 mm internal diameter; Merck). A water/acetonitrile mixture (80:20, vol/vol) was used for elution of TBARS; the fluorescence was measured at an excitation wavelength of 515 nm and an emission wavelength of 553 nm. 1,1,3,3-Tetramethoxypropane was used as standard. Plasma lipoproteins were separated by stepwise ultracentrifugation (230,000 × *g*, 20 h, 8°C). Plasma densities (δ) were adjusted by addition of potassium bromide. The lipoprotein classes (VLDL, $\delta < 1.019$ kg/L; LDL, $1.019 < \delta < 1.063$ kg/L; HDL, $1.063 < \delta < 1.21$ kg/L, where VLDL = very low density lipoprotein, LDL = low density lipoprotein; HDL = high density lipoprotein) were removed from each tube by suction with a pipette. The concentrations of triglycerides were measured enzymatically using an autoanalyzer (model 704; Hitachi, Tokyo, Japan) and a commercially available reagent kit (Boehringer Mannheim).

Statistics. Data were treated by analysis of variance. Classification factors were dietary fat, vitamin E supply and the interaction of those factors. For statistically significantly F-values ($P < 0.05$), means were compared by Fisher's multiple range test.

RESULTS

Daily food intake and body weight gains as well as concentrations of tocopherols and TBARS are shown in Table 2. Mean daily food intake and body weight gains were not influenced by either dietary fat or vitamin E supply and hence were similar within all the groups. Hepatic tocopherol concentrations were determined to assess the vitamin E status of the rats. As expected, hepatic tocopherol concentrations were markedly influenced by the dietary vitamin E supply. Rats fed the high-vitamin E diets on average had 13-fold higher tocopherol concentrations in liver than rats fed the low-vitamin E diets. The dietary fat also influenced the vitamin E status of the rats. Feeding the oxidized soybean oil reduced the tocopherol status relative to the other fat sources, regardless of the dietary vitamin E supply. Among groups receiving the high vitamin E supplement, rats fed the coconut oil diet had the

[a]Values represent means ± SD with $n = 10$ for each group. Means with different superscript letters (c,d,e,f,g) within one row differ significantly by Fisher's multiple range test ($P < 0.05$).

[b]Significance of factors: [h]Fat: $P < 0.05$; [i]vitamin E: $P < 0.05$; [j]fat × vitamin E: $P < 0.05$. [k]Values were transferred into their logarithms prior to analyses of variance. TBARS, thiobarbituric acid-reactive substances. For other abbreviations see Table 1.

highest hepatic vitamin E content. In contrast, among groups receiving the low vitamin E diets, rats fed fresh soybean oil and those fed the coconut oil diet were similar on the basis of absolute tocopherol concentrations; on the basis of tocopherol concentrations expressed per mg of lipid, rats fed fresh soybean oil even exhibited a slightly higher vitamin E status than rats fed the coconut oil diet.

Concentrations of hepatic TBARS as an estimate of *in vivo* lipid peroxidation were also markedly influenced by vitamin E supply. Rats fed the low-vitamin E diets had on average 2.3-fold higher TBARS concentrations than rats fed the high-vitamin E diets. The effect of the dietary fat on TBARS concentrations was less pronounced. Rats fed the coconut oil diets had lower concentrations of TBARS than rats fed the soybean oil diets. The difference was more pronounced on the basis of concentrations related to hepatic lipids (30%) than in their absolute concentrations (20%). Between rats fed fresh soybean oil and rats fed oxidized soybean oil, hepatic TBARS concentrations did not differ.

Activities of hepatic lipogenic enzymes are shown in Figure 1. In general, activities of all the lipogenic enzymes were influenced by the type of fat, whereas the vitamin E supply did not affect those enzymes. A noticeable difference existed between rats fed the coconut oil diet and rats fed the soybean oil diets. Feeding fresh or oxidized soybean oil reduced activities of all the lipogenic enzymes by 30 to 50%. Besides this main effect, there existed significant differences in the activities of fatty acid synthase, acetyl-CoA carboxylase, and ATP citrate lyase between rats fed oxidized soybean oil and those fed fresh soybean oil. Oxidized soybean oil reduced activities of those enzymes by 20 to 30% relative to fresh soybean oil. In contrast, activities of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase were not different between rats fed fresh and those fed oxidized soybean oil.

There was a marked effect of the dietary fat on hepatic triglyceride concentrations, which reflected activities of lipogenic enzymes (Table 3). Rats fed the coconut oil diets had markedly higher triglyceride concentrations than rats fed the soybean oil diets. Moreover, the rats fed fresh soybean oil had slightly, but significantly, higher concentrations of triglycerides than rats fed oxidized soybean oil. In parallel with increased triglyceride concentrations, rats fed the coconut oil diets also had the highest concentrations of total lipids and fatty acids, and those fed oxidized soybean oil had the lowest concentrations. The dietary fat also influenced the fatty acid composition of hepatic total lipids. In rats fed coconut oil, saturated and monounsaturated fatty acids were predominant whereas rats fed fresh and oxidized soybean oil had high levels of n-6 PUFA. Moreover, rats fed oxidized soybean oil had lower concentrations of all types of fatty acids in liver than rats fed fresh soybean oil. The concentration of total cholesterol was not influenced by the dietary fat and by the vitamin E supply.

Triglyceride concentrations in plasma and lipoproteins also reflected activities of hepatic lipogenic enzymes (Table 4). Rats fed coconut oil had markedly higher concentrations of triglycerides in plasma, VLDL, and LDL than rats fed soybean oil, and rats fed fresh soybean oil had higher concentrations than rats fed oxidized soybean oil. According to the

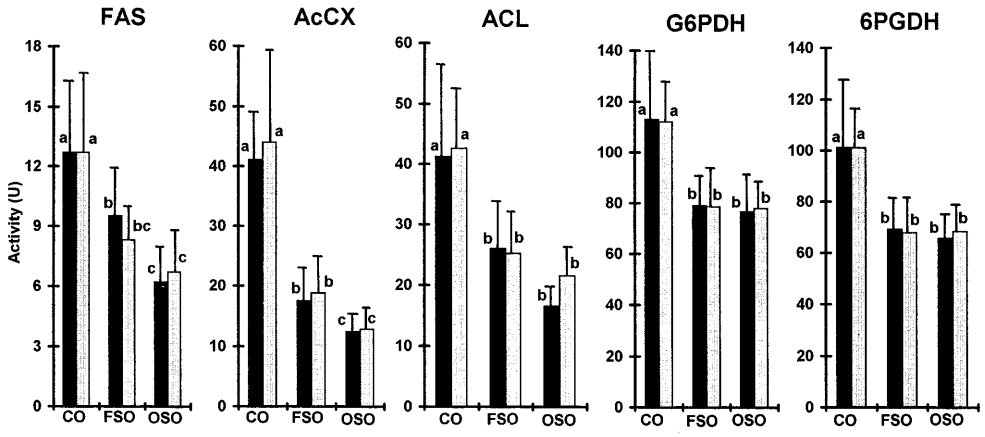

FIG. 1. The effect of dietary fat and vitamin E supply on activities of hepatic lipogenic enzymes (FAS = fatty acid synthase; AcCX = acetyl-CoA carboxylase; ACL = ATP citrate lyase; G6PDH = glucose-6-phosphate dehydrogenase; 6PGDH = 6-phosphogluconate dehydrogenase). Rats were fed diets containing predominantly coconut oil (CO), fresh soybean oil (FSO), or oxidized soybean oil (OSO). Vitamin E concentrations of the diets were: 11 mg α-tocopherol equivalents per kg (low-vitamin E diets, solid bars) and 511 mg α-tocopherol equivalents per kg (high-vitamin E diets, shaded bars). Results are means ± SD with $n = 10$ for each group. Units of activity are defined as: nmoles of NADH or NADPH oxidized per mg protein per minute at 37°C for AcCX and FAS, respectively; nmoles of NADP reduced per mg protein per minute at 37°C for G6PDH and 6PGDH; nmoles of NADH oxidized per mg protein per minute at 37°C for ACL. Significantly different means between the individual groups are marked by different letters (a,b,c). Statistical effects of factors: Dietary fat, $P < 0.05$ for all enzymes; vitamin E and vitamin E × dietary fat, nonsignificant for all enzymes.

analysis of variance, the vitamin E supply had no significant effect on concentrations of triglycerides in plasma and lipoproteins, although in the groups fed fresh and oxidized soybean oil diets, the group receiving a high vitamin E supplement had slightly higher concentrations in all the lipoproteins than those fed diets low in vitamin E.

DISCUSSION

The present study was carried out to investigate whether lipid peroxidation products are involved in the suppression of lipogenic enzyme activity by diets rich in PUFA. The effect of *in vivo* lipid peroxidation products was investigated by modifying the vitamin E status of the rats. The effect of exogenous lipid peroxidation products was investigated by feeding a thermally treated soybean oil. According to the peroxide values, the thermally treated soybean oil can be regarded as moderately oxidized. The relatively low level of oxidation of the oil used had two advantages: First, food intake was not suppressed by intake of lipid peroxidation products. This is an important demand in studying lipogenic enzymes because the food intake significantly influences the activities of lipogenic enzymes (20). In addition, the fatty acid composition of the oxidized oil was only negligibly different from that of the fresh soybean oil. Hence, the effect of oxidation products on lipogenic enzymes could be investigated without being confounded by a different fatty acid composition of dietary lipids. Most of the other studies dealing with dietary lipid peroxidation products used diets containing highly oxidized oils (21–24). Feeding such diets usually leads to lower consumption of diets containing highly oxidized oils by the animals than that of nonoxidized control diets, and rats fed highly oxidized oils also experience lower digestibility of fatty acids and lower dietary efficiency (22,23,25–27). Finally, highly oxidized oils contain less PUFA than the equivalent fresh oils (21–23,27,28). Therefore, dietary studies on the effects of

lipid peroxidation products are usually confounded by differences in nutritional status, growth rates, and fatty acid composition of dietary lipids, between the study groups.

Highly oxidized dietary oils have been reported to enhance *in vivo* lipid peroxidation as assessed by elevated levels of lipid peroxidation products in tissues (22–24). Ingestion of the moderately oxidized soybean oil in this study did not increase the generation of the malondialdehyde-TBAR adduct during the TBARS test from liver lipids, suggesting that there was not a marked increase of lipid peroxidation *in vivo*, regardless of the dietary vitamin E supply. It seems likely that an enhanced lipid peroxidation would be reduced by an elevated destruction of tocopherols. Destruction of tocopherols by peroxides could explain the lower vitamin E status of the rats fed oxidized soybean oil. Reduced tocopherol levels in animals fed oxidized oils, as observed in this study, have also been reported by other investigators (26,28–30). The effects of dietary fatty acids and vitamin E supply on lipid peroxidation products in liver were not unexpected. Other studies have also demonstrated reduced *in vivo* lipid peroxidation by feeding diets rich in saturated and monunsaturated fatty acids compared to diets rich in PUFA and by supplementing diets with high levels of vitamin E (31–33).

The present study strongly suggests that neither endogenous nor exogenous lipid peroxidation products play a significant role in the suppression of lipogenic enzymes by dietary oils rich in PUFA. This can be concluded from the observation that the suppression of lipogenic enzymes was completely independent of the vitamin E supply of the rats, and it was only slightly different between rats fed fresh and rats fed oxidized soybean oil. If lipid peroxidation products played an important role in suppression of lipogenic enzymes, it would be expected that both low vitamin E supply and ingestion of an oxidized oil would lead to suppression of lipogenic enzymes. Hence, it seems likely that PUFA *per se* exert a suppressive effect on hepatic lipogenic enzymes. This result agrees with a study by Iritani *et al.* (24) that also failed to demonstrate that autoxidation products of PUFA play a role in the suppression of lipogenic enzymes. An hypothesis on how PUFA *per se* could act on hepatic lipogenic enzymes recently has been given by Clarke and Jump (2,5). Triglyceride concentrations in liver and plasma reflected activities of hepatic lipogenic enzymes. Hence, the present study suggests that the effect of PUFA on triglycerides in liver and plasma is at least partially due to reduced hepatic lipogenesis. In the study of Iritani *et al.* (24), reducing activities of lipogenic enzymes by increasing dietary PUFA levels was also associated with lower concentrations of hepatic triglycerides.

Although the study suggests that lipid peroxidation products do not play a major role in regulation of lipogenic enzymes, such products potentially could affect hepatic lipogenesis. Rats fed oxidized soybean oil had lower activities of some key enzymes involved in lipogenesis than rats fed fresh soybean oil. As a consequence of reduced lipogenesis, rats fed the oxidized soybean oil exhibited reduced triglyceride concentrations in liver and plasma compared to rats fed the fresh soybean oil. This effect was independent of the vitamin E supply and TBARS generated from liver lipids, and hence probably is independent of *in vivo* lipid peroxidation processes, e.g., peroxidative damages to unsaturated fatty acids of membranes. From the results of the present study, the mechanism underlying reduced activities of lipogenic enzymes in rats fed oxidized oil cannot be determined. This phenomenon, however, may be due to general disturbances of energy production in rats fed oxidized oils. Ingestion of autoxidized oils has been shown to cause profound alterations in membrane composition and fluidity associated with alterations of some membrane-bound enzymes involved in energy metabolism (23,31). The study of Iritani *et al.* (24) did not observe differences in hepatic lipogenic enzymes and triglycerides between rats fed fresh and rats fed oxidized corn oil. This suggests that experimental factors other than different concentrations of primary and secondary lipid peroxidation products in the oxidized and control diets also may play a role in this regulatory process.

ABSTRACT: We examined effects of polyunsaturated fatty acids (PUFA), their corresponding hydroperoxy fatty acids (hp-PUFA), as well as various pro- and antioxidants on the growth of tumor cells in culture. When cultured in RPMI 1640 medium, A-427 and WEHI clone 13 cells were both highly sensitive to hydroperoxy docosahexaenoic acid (hp-DHA), but they were far less sensitive in minimum essential medium (MEM). In contrast, A-427 cells were also sensitive to DHA in both culture media, while WEHI clone 13 cells, as well as other cell lines, tested in their respective media, were resistant. The lower sensitivity of the cell lines to hp-DHA in MEM-medium was apparently due to a more rapid reduction of hp-DHA to the corresponding hydroxy-DHA in MEM-medium. Addition of glutathione (GSH) to the culture medium abolished the effects of hp-DHA, but not the effects of DHA, while depletion of intracellular GSH levels by L-buthionine-*S,R*-sulfoximine strongly enhanced the cytotoxic effect of hp-DHA, but not the cytotoxic effect of DHA. α-Tocopherol protected A-427 cells against the toxic effect of DHA and abolished the induced lipid peroxidation, while it did not protect against the toxic effects of hp-DHA in A-427 or WEHI clone 13 cells. Ascorbic acid reduced the cytotoxic effect of DHA, but potentiated the toxic effect of hp-DHA while selenite essentially abolished the toxicity of both DHA and hp-DHA. These results indicate that sensitivity of tumor cell lines to PUFA and their oxidation products depends on their antioxidant defense mechanisms, as well as culture conditions, and establishes hp-DHA as a major, but probably not the sole, metabolite responsible for cytotoxicity of DHA.
Lipids 33, 285–293 (1998).

Diets enriched in n-3 fatty acids have been shown to delay the development and growth of experimentally induced tumors (1,2) and to reduce their invasiveness and metastatic potential (3). Growth inhibition of several tumor cell lines in culture has also been reported, indicating a direct cytotoxic effect of n-3 fatty acids (4–6). Several processes important for growth control, such as signal transduction (7), gene expression (8) and eicosanoid metabolism (9–12), may be affected by n-3 fatty acids, but the major mechanisms responsible for inhibition of tumor cell growth remain uncertain. However, it has become increasingly clear that oxidation products of polyunsaturated fatty acids (PUFA) contribute to their cytotoxicity (13–16), and recently deficiencies in cellular antioxidant defense mechanisms were shown to strongly enhance the sensitivity of tumor cells to n-3 fatty acids (17–19). Lipid peroxidation is a radical chain reaction, and the primary products of lipid peroxidation of PUFA are lipid hydroperoxides (20). Therefore, accumulation of hydroperoxides may amplify lipid peroxidation resulting in a range of products that may be deleterious to cells (20). Consistent with this, lipid hydroperoxides added to growth media inhibit cell growth and/or induce cell death in several different cell lines (21–27).

In the present study we have compared the effect of several PUFA and their hydroperoxy derivatives on the growth of different tumor cell lines. Among the cell lines tested, only one is significantly growth-inhibited by PUFA, docosahexaenoic acid (DHA) being one of the most potent. This sensitive cell line is also growth-inhibited by the primary lipid peroxidation product of DHA, hydroperoxy-DHA (hp-DHA), indicating that cytotoxicity of n-3 fatty acids may be mediated through the formation of this primary product. This is further supported by the fact that agents inhibiting lipid peroxidation or inactivating hydroperoxides also reduce cytotoxicity. We also find that cytotoxic effects of PUFA and their hydroperoxy derivatives may be modulated by factors in growth media and sera, underlining the importance of standardization of culture conditions when comparing effects of fatty acids on cultured cells.

MATERIALS AND METHODS

Materials. Minimum essential medium with Earle's salts without L-glutamine (MEM), Dulbecco's modified Eagle's

medium (DMEM), sodium pyruvate, nonessential amino acids, Nutritient Mixture F-12 (HAM), L-glutamine, and trypsin were obtained from Gibco BRL, Life Technologies (Inchinnan, Scotland). RPMI-1640 medium was from Gibco BRL and from B.I. Bio Whittaker (Brussels, Belgium). Fetal bovine serum (FBS) was purchased from Hyclone (Cramlington, England), fetal calf serum (FCS) from Gibco BRL and Biological Industries (Kibbutz Beit Haemek, Israel). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), 2-thiobarbituric acid (TBA), 1,1,3,3,-tetramethoxypropane, glutathione (GSH), α-tocopherol, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), superoxide dismutase, sodium selenite, L-buthionine-*S,R*-sulfoximine (BSO), soybean lipoxidase type I-B, linoleic acid (LA), α-linolenic acid (α-LNA), γ-linolenic acid (γ-LNA), eicosapentaenoic acid (EPA), and DHA were obtained from Sigma (St. Louis, MO). Gentamicin sulfate was from Sigma and Schering Corp. (Kenilworth, NJ). Diethyl maleate (DEM) was purchased from Aldrich (Steinheim, Germany). Ascorbic acid was from E. Merck (Darmstadt, Germany). Hydroperoxy fatty acids were prepared by incubating the fatty acids with soybean lipoxygenase as previously described (27). They were purified by reversed-phase high-performance liquid chromatography (HPLC), and concentrations calculated as previously described (27).

Cell cultures. A-427, SK-LU-1, A-172, and A549 were purchased from American Type Culture Collection (Rockville, MD). WEHI clone 13 fibrosarcoma cell line (WEHI clone 13) was isolated as described previously (28). A-427 and SK-LU-1 were cultured in MEM supplemented with 10% (vol/vol) FCS, gentamicin (45 mg/L), L-glutamine (80 mg/L), sodium pyruvate (1 mM), and nonessential amino acids (100×, 10 mL/L). A549 was cultured in Nutritient Mixture F-12 (HAM) with L-glutamine (80 mg/L) supplemented with 10% (vol/vol) FCS and gentamicin (50 mg/L). A-172 was cultured in DMEM with 4.5 g/L glucose without L-glutamine, supplemented with 10% (vol/vol) FCS, gentamicin (50 mg/L), L-glutamine (80 mg/L), and sodium pyruvate (1 mM). WEHI clone 13 was cultured in RPMI-1640 medium containing 10% (vol/vol) FCS or FBS, 2 mM L-glutamine and 40 μg/mL gentamicin. All cell cultures were maintained in 5% CO_2 at 37°C.

Cell survival assay. Cell survival was measured in 96-well microplates (Costar 3598) seeding 3000 cells/well except for Figure 7 where 1500 cells/well were used. Cells were allowed to adhere for 4 h before additions were made. Stock solutions of parent fatty acids, hp-fatty acids, α-tocopherol, BHA, BHT, and DEM were prepared in ethanol, and the final ethanol concentration never exceeded 0.38% (vol/vol), which had no effect on cell survival alone. Stock solutions of GSH, ascorbic acid, sodium selenite, and BSO were prepared in purified, sterile water, and the final added water concentration never exceeded 2.0% (vol/vol), which had no effect on cell survival alone. Cell survival was measured at the times indicated, using MTT-assay, as previously described (29), measuring absorbance at 588 or 595 nm. Results are from one of at least two similar experiments with four parallels, and are given as mean with SD indicated as bars.

Reduction of hp-fatty acid in growth media alone. Hp-EPA was incubated with the growth media used for culturing A-427 cells and WEHI clone 13 cells (complete MEM and RPMI-medium, respectively) in 5% CO_2 at 37°C for the indicated time intervals. After incubation, lipids were extracted essentially according to the method described by Bligh and Dyer (30). Hp-EPA and hydroxy-EPA were then separated using reversed-phase HPLC as described in Reference 27. The peak area of hydroxy-EPA as percentage of the total peak area of hp-EPA and hydroxy-EPA combined was calculated. Results are given as mean of three experiments with SD indicated as bars.

Lipid peroxidation assay. The TBA test was used to measure the end products of lipid-peroxidation (31), mainly malondialdehyde (MDA). Cells were seeded at a concentration of 30,000 cells/mL (WEHI clone 13 cells) or 75,000 cells/mL (A-427 cells) in flasks (25 cm^2) with 4 mL medium. After 4 h, the medium was changed, and the cells were preincubated for 24 h with control medium or medium supplemented with antioxidant. The medium was then removed and control medium or medium supplemented with fatty acid added. After further 44 h, cells were killed by adding 2 mL 20% trichloroacetic acid to the flasks. Then 4 mL of 0.67% TBA was added, and the TBA test performed as previously described (32). Absorbance was converted to nmol MDA from a standard curve generated with 1,1,3,3,-tetramethoxypropane.

GSH assay. Cells were seeded at a concentration of 1.4×10^6 cells (A-427 cells) or 0.5×10^6 cells (WEHI clone 13 cells) in flasks (75 cm^2). After 4 h, medium was replaced with control medium or medium enriched with BSO (10 μM) or DEM (60 μM). After an additional 24 h of incubation, GSH analysis was performed as described below in one of the parallel flasks. In the remaining flasks, medium was changed to control medium or medium enriched with DHA (35 μM) or hp-DHA (35 μM). After a further 48 h of incubation, the cell layer was rinsed twice with cold phosphate buffered saline and harvested by scraping and then sonicated. The resulting homogenate was used as GSH source. Total GSH content was assayed using a GSH reductase assay (33). GSH content was quantitated by comparison with a standard curve generated with known amounts of GSH (reduced form), and expressed as nanomoles per milligram of protein.

Protein content was determined by the BioRad-assay (Bio-Rad Laboratories, Hercules, CA) using serum albumin as the standard.

Statistical analysis. If not otherwise stated, statistical analysis was carried out using one-way analysis of variance (ANOVA) with Student-Newman-Keuls method for multiple comparison or Kruskal-Wallis one-way ANOVA on ranks (when equal variance test failed), with a 0.05 level of significance. The analysis was performed using SigmaStat for Windows version 1.0 (Jandel Scientific Software, Jandel Corporation, Erkrath, Germany).

RESULTS

Effects of PUFA on growth of different malignant cell lines. The effects of the n-3 fatty acid DHA on growth of the murine fibrosarcoma cell line WEHI clone 13, the three human lung carcinoma cell lines A-427, A549 and SK-LU-1, and the human glioblastoma cell line A-172 are demonstrated in Figure 1. As previously shown (19), growth of the A-427 cell line was significantly inhibited in a time- and concentration-dependent manner by DHA, while DHA had little or no effect on growth of the other cell lines. Also γ-linolenic acid (γ-LNA) and arachidonic acid (AA) inhibited the growth of A-427 cells to approximately the same extent as DHA, while α-linolenic acid (α-LNA) and EPA had less effect (Fig. 2). The growth of the WEHI clone 13, SK-LU-1, A549, and A-172 cell lines were not affected by any of these fatty acids (results not shown).

Effects of the corresponding n-6-hydroperoxy fatty acids on growth of the malignant cell lines and the significance of growth media and sera. We have previously shown that lipid peroxidation is involved in the toxicity of DHA to A-427 cells (19). To investigate whether the toxicity of DHA could be explained by the primary lipid peroxidation product n-6 hp-DHA, we examined the effect of this product on different cell lines. Like the parent fatty acids, hp-DHA had no significant effect on growth of the SK-LU-1, A549 and A-172 cell lines (Fig. 3). The same was also the case for hp-γ-LNA, hp-AA, hp-α-LNA, and hp-EPA (results not shown). As previously shown (27), all the hp-fatty acids tested inhibited growth of WEHI clone 13 cells in a time- and concentration-dependent manner (Fig. 3, results shown for hp-DHA only).

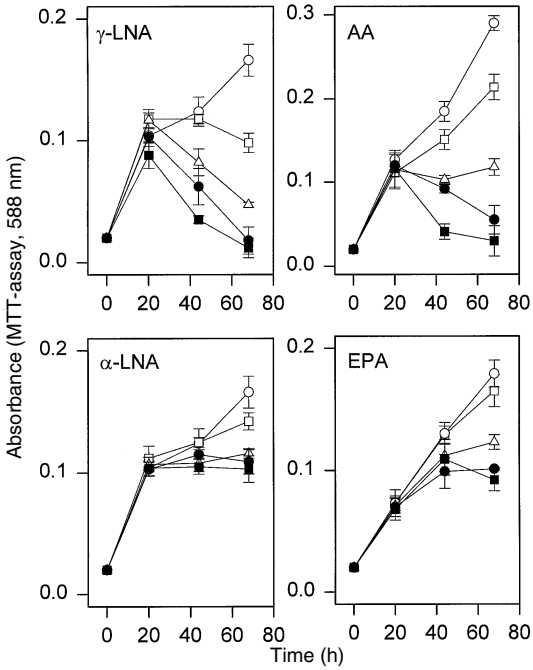

FIG. 2. Growth curves for the human lung carcinoma cell line A-427 cultured in the presence of different concentrations of γ-linolenic acid (γ–LNA), arachidonic acid (AA), α-LNA, or eicosapentaenoic acid (EPA). See Figure 1 for other abbreviations and symbol legend.

Somewhat surprisingly, A-427 cells seemed less sensitive to hp-DHA than to DHA (Figs. 1 and 3). Like hp-DHA, the other hydroperoxy fatty acids inhibited growth of A-427 cells only slightly, and significantly less than the corresponding parental fatty acid (results not shown). An exception was

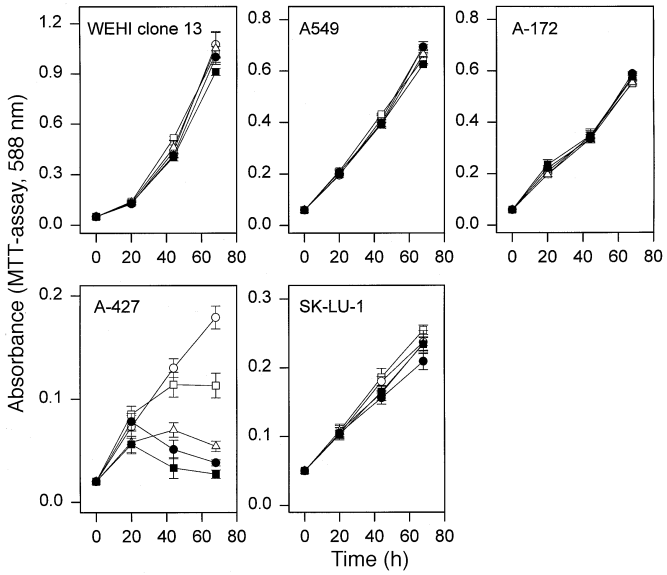

FIG. 1. Growth curves for the murine fibrosarcoma cell line WEHI clone 13, the three human lung carcinoma cell lines A-427, A549 and SK-LU-1, and the human glioblastoma cell line A-172 cultured in the presence of different concentrations of docosahexaenoic acid (DHA). MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide. ○, Control; □, 5 μM; △, 20 μM; ●, 35 μM; ■, 50 μM.

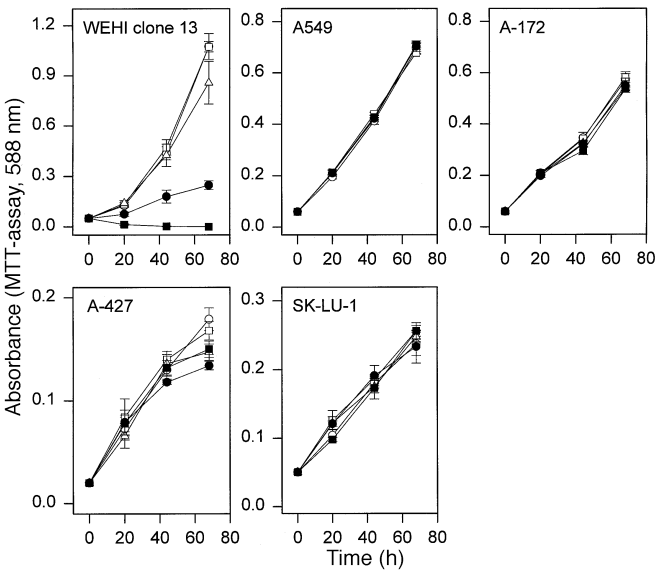

FIG. 3. Growth curves for the murine fibrosarcoma cell line WEHI clone 13, the three human lung carcinoma cell lines A-427, A549 and SK-LU-1, and the human glioblastoma cell line A-172 cultured in the presence of different concentrations of hydroperoxy (hp)-DHA. See Figure 1 for other abbreviations and symbol legend.

hp-α-LNA which inhibited growth of A-427 cells significantly more than the parental α-LNA in two out of four experiments (results not shown).

Also the degree of growth inhibition induced by parent fatty acid in A-427 cells showed some variation between experiments. We discovered that different batches of sera could explain much, if not all, of the variation in sensitivity between experiments due to a varying amount of selenium and/or α-tocopherol between batches (S. Schønberg, unpublished results). We also found that the synthetic part of the culture media was of importance for the growth inhibition observed. To investigate this in more detail, we compared the effect of DHA and hp-DHA on the growth of A-427 (DHA-sensitive) and WEHI clone 13 (hp-DHA sensitive) in complete MEM as well as complete RPMI medium using different batches of sera. The two batches of sera used in these experiments did not have any influence on the results (data not shown). Both the MEM and RPMI-medium used supported growth of the two cell lines to the same extent. We found that DHA and hp-DHA were considerably more toxic to A-427 cells when grown in RPMI medium than its recommended MEM, the effect of hp-DHA differing more than the effect of DHA (Fig. 4, results shown for hp-DHA only). Accordingly, hp-DHA was slightly more toxic to A-427 cells than DHA in RPMI medium (results not shown). Furthermore, hp-DHA was less toxic to WEHI clone 13 cells when grown in MEM instead of its standard RPMI medium (Fig. 4). Thus, when grown in the same medium, the effects of hp-DHA on the two cell lines were almost identical (Fig. 4). The hp-fatty acid was reduced to hydroxy fatty acid in a time-dependent way in both media (Fig. 5). However, the reduction was clearly faster in MEM compared to RPMI medium. Incubating hp-fatty acid in sterile water for 120 min only gave about 9% reduction (results not shown). In conclusion, A-427 cells and the WEHI-clone 13 cells are both highly sensitive to hp-DHA when cultured in RPMI- but not when cultured in MEM.

Effects of different antioxidants and GSH-modulating agents on DHA and hp-DHA-induced growth inhibition. To try to identify factors that may influence the toxicity of the parent fatty acids as well as the hp-fatty acids, we tested the effects of several antioxidants and GSH-modulating agents on the hp-DHA-induced growth inhibition in WEHI clone 13 cells and the DHA-induced growth inhibition in A-427 cells in their respective standard media. As shown in Figure 6, simultaneous addition of the GSH completely abolished the effect of hp-DHA, while GSH had little effect on DHA-induced growth inhibition. In contrast, the lipid-soluble, chain-breaking antioxidant α-tocopherol had no effect on hp-DHA-induced growth inhibition, but abolished the growth inhibitory effect of DHA almost completely (Fig. 6). The water-soluble antioxidant ascorbic acid also counteracted the DHA effect, while it potentiated the effect of hp-DHA (Fig. 6).

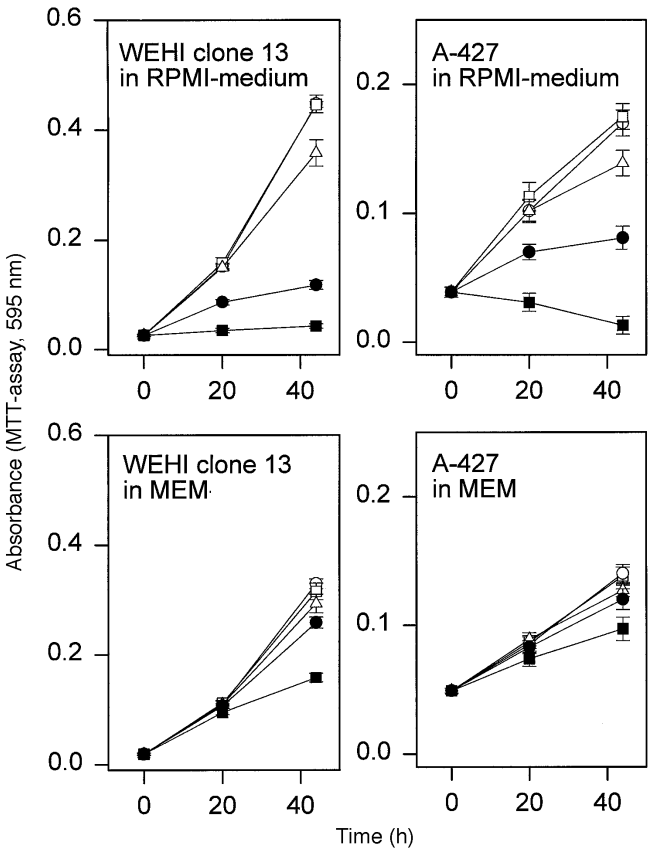

FIG. 4. Effect of different concentrations of hp-DHA on WEHI clone 13 cells and A-427 cells grown in both RPMI-based growth medium (used for the continuous culture of WEHI clone 13 cells) and minimum essential medium (MEM)-based growth medium (used for the continuous culture of A-427 and SK-LU-1 cells). See Figures 1 and 3 for other abbreviations. See Figure 1 for symbol legend.

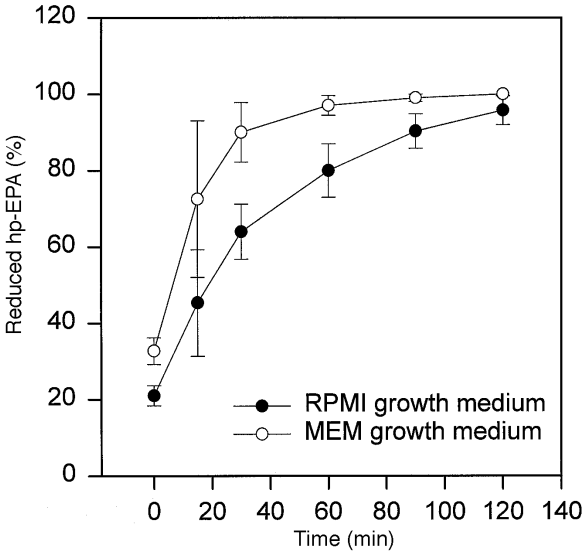

FIG. 5. Reduction of hp-EPA by growth media in the absence of cells. The hp-EPA was incubated with RPMI-based growth medium (used for the continuous culture of WEHI clone 13 cells) and MEM-based growth medium (used for the continuous culture of A-427 and SK-LU-1 cells) for the indicated time intervals. Lipids were then extracted, and amounts of hp-EPA and hydroxy-EPA were determined using reversed-phase high-performance liquid chromatography (HPLC). See Figures 2–4 for other abbreviations.

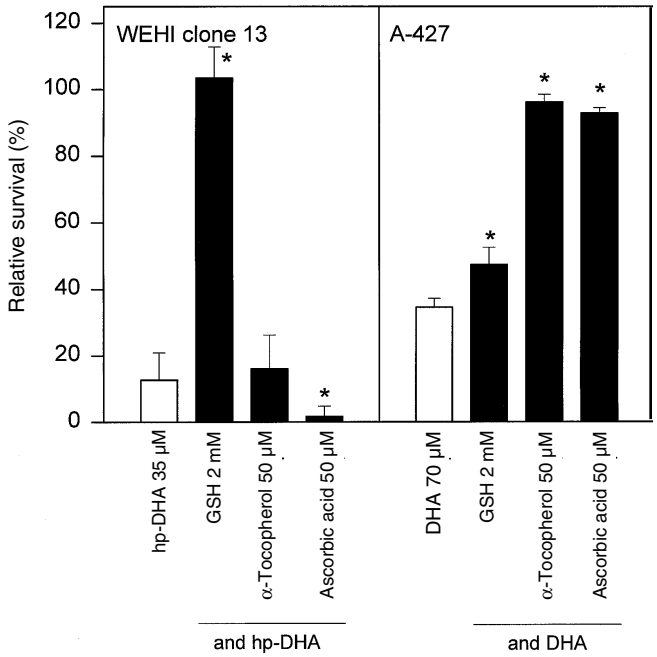

FIG. 6. Effect of various antioxidants on hp-DHA-induced (the WEHI clone 13 cell line) and DHA-induced (the A-427 cell line) growth inhibition. Fatty acid and antioxidant were added simultaneously, and cell survival was measured after 44 h using MTT assay. Relative survival was calculated as optical density (o.d.) (o.d. measured/o.d. control) × 100. *Significantly different from effects when cells are incubated with fatty acid alone. See Figures 1 and 3 for other abbreviations.

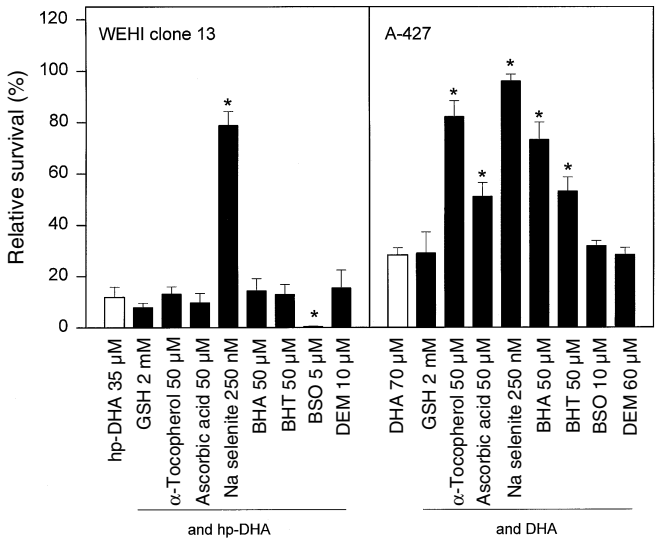

FIG. 7. Effect of preincubation with various antioxidants and GSH-modulating agents on hp-DHA-induced (the WEHI clone 13 cell line) and DHA-induced (the A-427 cell line) growth inhibition. Cells were preincubated for 24 h with the indicated additions before changing to medium containing hp-DHA (WEHI Clone 13) or DHA (A-427). Cell survival was measured after further 44 h using MTT assay. Relative survival was calculated as (o.d. measured/o.d. control) × 100. * Significantly different from effects when cells are incubated with fatty acid alone. See Figures 1, 3, and 6 for other abbreviations.

To further investigate the effects of antioxidant defense mechanisms, we preincubated the cells with antioxidants or GSH-modulating agents for 24 h before changing medium and challenging cells with DHA or hp-DHA for 44 h (Fig. 7). Preincubation with GSH had no effect on DHA or hp-DHA-induced toxicity, suggesting that the observed effect of GSH on hp-DHA-induced toxicity (Fig. 6) may be due to its ability to reduce the hp-fatty acid into the corresponding hydroxy fatty acid in the medium (27). We also investigated the importance of the intracellular GSH level and the GSH redox cycle on the growth inhibitory effect of DHA and hp-DHA by preincubating cells with BSO, a GSH synthesis inhibitor, and DEM, a GSH-depleting agent, as well as sodium selenite which has been shown to increase the activity of the selenium-dependent GSH peroxidase in A-427 cells (19). Figure 7 shows that preincubation with sodium selenite restored cell growth almost completely in A-427 cells, somewhat less in WEHI clone 13. BSO potentiated the effect of hp-DHA while the effect of DHA was unaffected.

Preincubation with α-tocopherol protected almost completely against DHA-induced toxicity in A-427 cells, while the cytotoxic effect of hp-DHA on WEHI clone 13 was unaffected. The same was true for the other lipid-soluble chain-breaking antioxidants that were included in this set of experiments, BHA and BHT, but to a lesser degree. In contrast, these lipid-soluble radical scavengers had no effect on hp-DHA-induced toxicity. Though to a lesser extent, preincubation with ascorbic acid still protected cells against DHA-induced toxicity, while the hp-DHA-induced toxicity was unaffected (Fig. 7).

Since we have shown that the effect of DHA, and in particular hp-DHA, depends on the synthetic part of the media, we also tested whether the media had any influence on the abolishing or potentiating effects of the antioxidants. This was done by incubating fatty acid in the presence of GSH, α-tocopherol, or ascorbic acid with A-427 cells for 44 h. To test the effect of antioxidants on hp-DHA-induced growth inhibition in MEM, we increased the hp-DHA concentration to 70 µM to obtain an effect. The effects of GSH and α-tocopherol on DHA-induced and hp-DHA-induced growth inhibition were the same in MEM and RPMI-medium. However, the effect of ascorbic acid varied depending on the growth medium, ascorbic acid being more protective in MEM than in RPMI medium (results not shown).

Effect of BSO and DEM on GSH level in A-427 and WEHI clone 13 cells. To further investigate the role of the intracellular GSH level for the cytotoxic effect of DHA and hp-DHA, we measured the GSH level after preincubation with BSO and DEM both before (Table 1) and after (Table 2) challenging cells with DHA or hp-DHA in their respective media. As shown in Table 1, after 24-h incubation, BSO reduced the GSH level in both A-427 and WEHI clone 13 cells. DEM also reduced the GSH level in WEHI clone 13 cells, but to a lesser extent than BSO. This difference may explain why preincubation with BSO, but not DEM, potentiated the hp-DHA effect in WEHI clone 13 cells. In contrast, DEM increased the GSH level in A-427 cells. An elevation in GSH level induced by DEM after an initial decrease has also been observed by

TABLE 1
Effect of 24-h Incubation with BSO and DEM on GSH Level in A-427 and WEHI Clone 13 Cells[a]

Cell line	Control	BSO (10 μM)	DEM (60 μM)
A-427	30.2 ± 2.2	9.2 ± 0.4*	40.4 ± 3.2*
WEHI clone 13	24.8 ± 3.7	9.2 ± 1.6*	15.5 ± 5.6*

[a]The values represent the mean ± SD of two separate experiments with each determination performed in at least triplicate, and are given as nmol GSH/mg protein. *Significantly different from control. BSO, L-buthionine-*S,R*-sulfoximine; DEM, diethyl maleate; GSH, glutathione.

others (34). Table 2 shows that when incubating with control medium for 24 h and then 48 h with the respective growth-inhibiting fatty acids, GSH levels in surviving cells of the two cell lines are not significantly different from the controls. When preincubating WEHI clone 13 cells with BSO, the GSH level in the surviving cells is still slightly reduced after 48-h incubation with hp-DHA (Table 2). When preincubating with DEM, the surviving WEHI clone 13 cells have regained normal GSH level after incubation with hp-DHA (Table 2). The GSH level in surviving A-427 cells when preincubating with DEM is not significantly different from the control, while GSH level when preincubating with BSO is still suppressed after 48-h incubation with DHA (Table 2). However, as shown in Figure 7, preincubating with BSO had no influence on DHA-induced toxicity, suggesting that the intracellular GSH level is of less importance for DHA-induced toxicity than hp-DHA-induced toxicity.

Effect of antioxidants on lipid peroxidation. To test whether the growth inhibitory effect of DHA and hp-DHA was correlated with an increase in lipid peroxidation products, we measured TBARS in A-427 and WEHI clone 13 cells incubated with DHA or hp-DHA in their respective media. When incubating cells with control medium only, TBARS were not detectable (Table 3). When incubating cells for 24 h with control medium and then 44 h with DHA or hp-DHA, the amount of TBARS increased, but was not significantly different either between cell type (using *T*-test) or between hp- and parent-fatty acid (using ANOVA, Table 3). This indicates that the amount of TBARS produced is not correlated to growth inhibition. We also tested whether the protective effects of some of the antioxidants were correlated to a reduction in lipid peroxidation products (Table 3). Preincubating with α-tocopherol protected A-427 cells against DHA-induced growth inhibition (Fig. 7), and also reduced the amount of TBARS after DHA exposure in these cells (Table 3). Preincubating WEHI clone 13 cells with α-tocopherol did not protect against hp-DHA-induced growth inhibition (Fig. 7) and had no effect on the TBARS level after hp-DHA exposure (Table 3). However, preincubating cells with sodium selenite, which protected both cell lines against growth inhibition (Fig. 7), had no effect on TBARS production in either of the cell lines after exposure to DHA or hp-DHA, again indicating that the amount of TBARS produced is not correlated to growth inhibition.

DISCUSSION

In an effort to elucidate mechanisms of toxicity of PUFA, we have studied the effects of n-3 and n-6 fatty acids and their hp derivatives on tumor cell lines. Our results indicate that only some tumor cell lines are appreciably sensitive to growth inhibition by PUFA. Further, the sensitivities vary not only depending on the properties of the cell line, but also depending upon medium composition. These results underline the importance of standardization of culture conditions when comparing sensitivities of different cell lines. However, the variation in sensitivities of cell lines in culture is not merely an *in vitro* culture phenomenon, since a correlation between *in vitro* and *in vivo* sensitivities has been documented (35).

Although it has become increasingly clear that lipid peroxidation induced by PUFA is involved in the cytotoxicity of such compounds to tumor cells (13–16), the molecular mechanisms have remained unclear. In agreement with reports from other laboratories (6,36), as well as recent work in our own laboratory (19), we have found that α-tocopherol essentially abolishes lipid peroxidation as well as the inhibitory effect of DHA on cell growth of A-427 cells. In addition, we found that ascorbic acid strongly reduces the toxicity of DHA to A-427 cells, possibly owing to recycling of α-tocopherol radicals to active α-tocopherol (37). The radical chain-breaking property of α-tocopherol prevents further formation of hp-PUFA (37). Consistent with this, ascorbic acid did not prevent the cytotoxic effect of hp-DHA, in fact, cytotoxicity was enhanced, the reason for which remains unclear. It is well known, however, that ascorbic acid may act both as a pro- and antioxidant depending on the given conditions. In the pres-

TABLE 2
Effect of 24-h Preincubation with BSO and DEM and Then 48-h Incubation with DHA or hp-DHA on GSH Level in A-427 and WEHI Clone 13 Cells, Respectively[a]

	Preincubation/incubation			
Cell line	Control/control	Control/fatty acid[b]	BSO 10 μM/fatty acid[b]	DEM 60 μM/fatty acid[b]
A-427	17.9 ± 1.7	16.4 ± 1.1	5.2 ± 0.5*	18.5 ± 2.9
WEHI clone 13	31.6 ± 4.6	38.2 ± 6.9	25.4 ± 5.2*	34.8 ± 2.0

[a]The values represent the mean ± SD of two separate experiments with each determination performed in at least triplicate, and are given as nmol GSH/mg protein.
[b]Docosahexaenoic acid (DHA) for A-427 and hydroperoxy (hp)-DHA for WEHI clone 13. *Significantly different from control/fatty acid. See Table 1 for other abbreviations.

TABLE 3
Lipid Peroxidation in Cells Supplemented with Antioxidant and/or Fatty Acid[a]

Agents added: preincubation/incubation	MDA (nmol/cell culture)	
	A-427	WEHI clone 13
Control/control	ND[b]	ND
Control/DHA	0.8 ± 0.2	1.0 ± 0.5
Control/hp-DHA	1.1 ± 0.3	1.2 ± 0.5
Sodium selenite/control	ND	ND
Sodium selenite/DHA	0.8 ± 0.2	—[c]
Sodium selenite/hp-DHA	—	1.0 ± 0.4
α-tocopherol/control	ND	ND
α-tocopherol/DHA	ND	—
α-tocopherol/hp-DHA	—	1.4 ± 0.1

[a]Cells were preincubated for 24 h with control medium or antioxidant before changing medium to medium with 35 μM DHA, 35 μM hp-DHA, or control medium as indicated. After a further 44 h, the TBA test was used to measure the end products of lipid peroxidation. The values represent the mean ± SD of two to four separate experiments each performed in duplicate or triplicate.
[b]ND, not detectable, which means <0.25 nmol.
[c]— Not performed. MDA, malondialdehyde. See Table 2 for other abbreviations.

ence of iron and hydroperoxide, it may function as a prooxidant by reducing ferric iron to ferrous iron which decompose hydroperoxide to alkoxyl radicals (37).

We have recently presented evidence that low levels of cellular Se-GSH peroxidase levels may explain the sensitivity to DHA of at least some tumor cell lines (19). Since hp-PUFA are known substrates for Se-GSH peroxidase (38), these results suggested that hp-DHA might be a major cytotoxic metabolite of DHA. Consistent with this, we have found that hp-DHA is highly toxic to both A-427 cells and WEHI clone 13 cells. Previously, an HIV-associated GSH peroxidase deficiency in transformed cultured cells was demonstrated to be associated with increased sensitivity and apoptotic cell death after exposure to 15-HPETE, probably as a result of reduced detoxification of 15-HPETE to 15-HETE (22). Together, these results indicate that Se-GSH peroxidase deficiency might be a common mechanism of cytotoxicity by PUFA. This is of considerable interest since tumor cells are frequently deficient in antioxidant defense systems (39,40). Although normal cells are generally insensitive to the cytotoxic effect of PUFA, the effects of hp-PUFA may not be restricted to transformed cells, since also normal endothelial cells in culture are injured by 15-HPETE (23). When cellular GSH levels are reduced by BSO, the susceptibility of these cells to 15-HPETE-induced injury is enhanced (41). These results are also consistent with our present observation that reduction of cellular GSH in tumor cells by BSO increases their sensitivity to hp-DHA. However, GSH depletion did not enhance the sensitivity of A-427 cells to DHA. This may indicate that the GSH level is less critical than the Se-GSH peroxidase activity, alternatively a part of the toxicity of DHA may be due to metabolites other than hp-DHA. Interestingly, WEHI clone 13 cells are essentially insensitive to DHA and other PUFA, but highly sensitive to hp-PUFA. This is somewhat intriguing since lipid peroxidation, measured as end point formation of TBARS, is essentially equal in WEHI clone 13 cells and the A-427 cells and since hp-PUFA are considered to be major intermediates in the lipid peroxidation process (20). We do not presently have a good explanation for this observation. It is possible, however, that this finding may be explained by kinetic differences in the lipid peroxidation process in the two cell lines leading to higher levels of certain transient intermediates, such as hp-DHA, in A-427 cells than in WEHI clone 13 cells.

Differences in the synthetic part of the media were apparently the reason for the lower sensitivity of cells to hp-fatty acids in MEM compared to RPMI medium, since in all experiments testing the growth inhibitory effect of fatty acids and their derivatives (Figs. 1–3), the different growth media were supplied with serum from the same batch. However, sera deficient in important antioxidants like vitamin E and selenium have been demonstrated to render cultured cells even more susceptible to oxidative damage (42). We also found that different batches of sera influenced the degree of cytotoxicity induced by different PUFA and hp-PUFA (R. Nøding, unpublished results). This emphasizes further the importance of a standardization of culture conditions when comparing effects of fatty acids on cultured cells. We found that preincubation with selenium almost totally restored growth in A-427 cells treated with DHA, and the toxicity of hp-DHA on WEHI clone 13 cells was also reduced, although to a lesser extent. The availability of selenium is known to regulate the activity of Se-GSH peroxidase (43). Consistent with this, we have previously reported that selenite added to the medium enhances Se-GSH peroxidase activity in A-427 cells (19) and this most likely explains the observed increase in resistance to both DHA and hp-DHA after addition of selenite to the culture medium.

The recovery of hp-fatty acid and hydroxy fatty acid was reduced with time up to about 60 min when incubated with the RPMI medium, while it remained at approximately the same level throughout the 120-min incubation period in the presence of MEM (results not shown). This may suggest that some of the increased effect of hp-DHA in RPMI medium is due to metabolites of hp-DHA that are too hydrophilic to be extracted with the lipids, or that have lost the conjugated double bond that gives the absorbance at 235 nm used to detect the hp- and hydroxy fatty acids.

In conclusion, our results demonstrate that tumor cell lines vary widely in their sensitivity to growth inhibition and cytotoxic effects of PUFA. This variation is apparently an intrinsic property of the cells and reflects their ability to withstand oxidative stress. Although lipid peroxidation products are clearly responsible for the cytotoxicity, variation in cytotoxicity of PUFA among cells in culture is not correlated to the degree of overall lipid peroxidation measured as the end point TBARS. Rather, the sensitivity is related to the ability of cells to detoxify specific peroxidation products, among which hp-PUFA are the most likely candidates. Furthermore, cytotoxicity of lipid peroxidation products depends upon culture conditions, underlining the importance of standardization of cul-

ture conditions when comparing the cytotoxicity of PUFA to different cell lines.

Gonzales *et al.* (13) showed that feeding fish oil to mice suppressed the growth of implanted breast carcinoma cells. They concluded that the growth suppression at least in part was a function of the accumulation of lipid peroxidation products. However, no clear association has been found between dietary intake of n-3 fatty acids and the incidence and staging of breast carcinoma in man (44–46). Differences between species could explain such discrepancies. However, the data presented here suggest that differences in the content of hydroperoxides and/or secondary peroxidation products could also explain some of the differences. Our data also suggest that when examining the effects of fats on carcinogenesis and cancer growth in experimental animal models, the content of hydroperoxides and secondary peroxidation products in the animal chow and oil supplements should be stated in addition to the fatty acid and total lipid content.

ACKNOWLEDGMENTS

The excellent technical assistance of Sylvia Nome Kvam and Merete Mack is gratefully acknowledged. We also thank Terje Espevik, Institute of Cancer Research and Molecular Biology, Norwegian University of Science and Technology, Trondheim, for kindly providing the WEHI clone 13 cells. This work was supported by grants from The Norwegian Cancer Society, The Cancer Research Foundation at the University Hospital of Trondheim, The Novo Nordisk Foundation, and The Research Council of Norway.

Cytotoxicity of Tocopherols and Their Quinones in Drug-Sensitive and Multidrug-Resistant Leukemia Cells

David G. Cornwell[a,*], Kenneth H. Jones[b], Zongcheng Jiang[c], Laura E. Lantry[d], Peter Southwell-Keely[e], Indrajati Kohar[f], and Donald E. Thornton[d]

Departments of [a]Medical Biochemistry, [b]Cell Biology/Neurobiology/Anatomy, [c]Radiology, and [d]Internal Medicine, The Ohio State University, Columbus, Ohio 43210; [e]Department of Organic Chemistry, The University of New South Wales, Sydney, Australia; and [f]Faculty of Pharmacy, University of Surabaya, Jawa Timor, Indonesia

ABSTRACT: Cytotoxicities of tocopherols (α-T, γ-T, δ-T), their para (α-TQ, γ-TQ, δ-TQ)- and ortho (Tocored)-quinone oxidation products, the synthetic quinone analog of γ-TQ containing a methyl group substituted for the phytyl side-chain (TMCQ) and the synthetic quinone analog of Tocored containing a methyl group substituted for the phytyl side-chain (PR) were measured in acute lymphoblastic leukemia cell lines that are drug-sensitive (CEM) and multidrug-resistant (CEM/VLB_{100}). Among tocopherols, only δ-T exhibited cytotoxicity. Among para quinones, α-TQ showed no cytotoxicity, while γ-TQ and δ-TQ were highly cytotoxic in both CEM and CEM/VLB_{100} cell lines (LD_{50} < 10 μM). δ-TQ and γ-TQ were more cytotoxic than the widely studied chemotherapeutic agent doxorubicin, which also showed selective cytotoxicity to CEM cells. The orthoquinone Tocored was less cytotoxic than doxorubicin in drug-sensitive cells but more cytotoxic than doxorubicin in multidrug-resistant cells. Cytotoxicity was not a function of the phytyl side-chain since both TMCQ and PR were cytotoxic in leukemia cells. Cytotoxic para and ortho quinones were electrophiles that formed adducts with nucleophilic thiol groups in glutathione and 2-mercaptoethanol. Cytotoxicity was enhanced when the glutathione pool was depleted by preincubation with buthionine-[*S,R*]-sulfoximine , but cytotoxicity was diminished by the addition of *N*-acetylcysteine to cultures. α-T also diminished the cytotoxicity of para- and orthoquinones. Buthionine-[*S,R*]-sulfoximine did not block the inhibitory effect of either *N*-acetylcysteine or α-T, showing that these agents did not act solely by maintaining the glutathione pool as an essential antioxidant system. In conclusion, tocopherylquinones represent a new class of alkylating electrophilic quinones that function as highly cytotoxic agents and escape multidrug resistance in acute lymphoblastic leukemia cell lines. *Lipids 33,* 295–301 (1998).

Tocopherols and tocotrienols have been studied extensively for their anticarcinogenic potential. Tocotrienols, unlike α-tocopherol (α-T), inhibit the proliferation of human breast cancer cells (1), and it was recently reported that only γ-tocotrienol and δ-tocotrienol exhibit this effect (2). We found in 1985 that γ-tocopheryl quinone (γ-TQ), a para quinone metabolite of γ-tocopherol (γ-T) (Fig. 1), was highly cytotoxic in smooth muscle cells, whereas α-T, γ-T and α-TQ did not exhibit this effect (3). We recently proposed that several quinone metabolites of the essential nutrient tocopherol family might have anticarcinogenic potential and, as naturally occurring compounds, these quinones might escape the immune surveillance imposed on xenobiotic quinones such as the chemotherapeutic agents doxorubicin and vinblastine by P-glycoprotein expression in multidrug-resistant tumors (4). This hypothesis was tested with γ-TQ, doxorubicin, and vinblastine in drug-sensitive acute lymphoblastic leukemia cell lines (CEM) and multidrug-resistant lymphoblastic leukemia cell lines (CEM/VLB_{100}), and we found that γ-TQ was highly cytotoxic in both CEM and CEM/VLB_{100} cells (4). We have now expanded these studies to compare parent tocopherols (α-T, γ-T, δ-T), para tocopheryl quinones (α-TQ, γ-TQ, δ-TQ), an ortho quinone 2,7,8-trimethyl-2-(4,8,12-trimethyltridecyl)-chroman-5,6-dione (Tocored), and the methyl side-chain analogs 2-(3-hydroxy-3-methylbutyl)-5,6-dimethyl-1,4-benzoquinone (TMCQ) and 2,2,7,8-tetramethylchroman-5,6-dione (PR) (Fig. 1).

Quinone cytotoxicity is explained either by the formation of reactive oxidant species through quinone redox cycling or by the formation of adducts between electrophilic quinones that act as alkylating agents (Fig. 1) and nucleophilic groups on proteins and DNA (4–8). In the present investigation, we examine the ability of para- and ortho tocopheryl quinones to form nucleophilic adducts with glutathione and 2-mercaptoethanol.

Quinone cytotoxicity is modified by intracellular glutathione, which functions both as a component of an essential antioxidant system and as a detoxifying nucleophile that blocks the formation of cytotoxic quinone adducts with nucleophilic groups on proteins and DNA (4–10). We have therefore examined the potential of a synergistic effect on quinone cytotoxicity with buthionine-[*S,R*]-sulfoximine (BSO), which depletes the intracellular glutathione pool by inhibiting γ-glutamyl-cysteine synthetase, the enzyme that catalyzes the rate-

limiting step in glutathione synthesis (11). We have also examined the potential of an antagonistic effect on quinone cytotoxicity with *N*-acetylcysteine (NAC), which may maintain the glutathione pool or function directly as a detoxifying nucleophile. Finally, we have examined the effect of the antioxidant α-T on the cytotoxicity of γ-TQ, δ-TQ, and PR.

MATERIALS AND METHODS

Materials. Chemicals were obtained from the following sources: vinblastine from Lilly (Indianapolis, IN); doxorubicin from Cetus (Emeryville, CA); glutathione from Aldrich (Milwaukee, WI); (*d*)-δ-T (91.2%, isolated from soybean oil and containing a minor component, 5.6%, tentatively identified as γ-T), NAC, BSO, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) from Sigma (St. Louis, MO); (*d*)-α-T (99.6%) from Mann Research (New York, NY); (*d*)-γ-T (92.6%) from Tama (Tokyo, Japan).

Synthesis of tocopheryl quinones. α-TQ and γ-TQ were synthesized by oxidation with $FeCl_3$ or $AuCl_3$ from parent tocopherols as previously described (4). δ-TQ was synthesized by a modification of the general $AgNO_3$ oxidation procedure for tocopherols (12). δ-T, 130 mg, and 920 mg of $AgNO_3$ were dissolved in 6 mL of ethanol/water (85:15, vol/vol), heated at 60–70°C for 30 min, and the products extracted with diethyl ether. Yields were low in the absence of water, and overoxidation to red compounds, presumably ortho quinones, occurred when the water content was increased. δ-TQ was purified (yield 30%) on a silica gel 60 column using petroleum ether (bp 35–60°C)/diethyl ether (1:1, vol/vol). Fractions were monitored on a silica gel 60 thin-layer chromatography (TLC) plate (R_f α-TQ, 0.460; γ-TQ, 0.408; δ-TQ, 0.330). δ-TQ was identified by an ^1H nuclear magnetic resonance spectrum ($CDCl_3$, 250 MHz) characteristic of a paratocopheryl quinone (4) containing two aromatic protons at 6.35 ppm. Fast atom bombardment mass spectrometry (FAB MS) *m/z* [relative intensity] showed 418 $[M]^+$ [5], 402 [100], 401 [24] and no higher mass fragments. Tocored, PR and TMCQ were prepared as previously described (13,14).

Synthesis of thiol adducts. A modification of the procedure used previously with γ-TQ and glutathione (4) was adapted for sequential Michael addition and oxidation using δ-TQ and glutathione (15). δ-TQ, 0.4 mmol, was dissolved in methanol, cooled to 0°C, and 0.6 mmol glutathione in 1.2 mL water added dropwise with stirring. A yellow-brown precipitate formed initially and then changed to a white precipitate which dissolved in 1 mL water. Additional δ-TQ, 0.4 mmol dissolved in 2.5 mL methanol, was added dropwise with stirring.

Methanol was removed, the precipitate dissolved in water, reprecipitated overnight with acetone, then redissolved in water. The products were separated by preparative high-performance liquid chromatography (HPLC) on a Vydac C_4 column as described previously for the glutathione adduct of γ-TQ (4), and individual fractions identified by FAB MS.

A procedure described for the synthesis of a benzo[α]pyrene-7,8-quinone thiol adduct (16) was adapted for the synthesis of a PR/2-mercaptoethanol adduct. 2-Mercaptoethanol, 20 μL, was added to a 10-mL solution of 1.6 mg PR dissolved in 50 mM phosphate buffer (pH 7) containing 8% dimethyl sulfoxide. The reaction mixture was analyzed by TLC on silica gel 60 using diethyl ether/petroleum ether (3:1, vol/vol) and by FAB MS.

Cells. Cell lines were purchased from CENTOCOR (Malvern, PA). The multidrug-resistant cell line, CEM/VLB_{100}, is derived from the drug-sensitive CEM line and has the classic multidrug-resistant phenotype of overexpression of the *mdrl* gene and its product P-glycoprotein (4). Cells were grown from frozen stocks (−140°C) in suspension cultures or spinner flasks with medium containing RPMI 1640, 10% fetal bovine serum (heat-inactivated), 200 mM L-glutamine, and 0.5 μg/mL penicillin–streptomycin, at 37°C and 5% CO_2. The viability of cells at the start of the experiment was greater than 95% by Trypan blue exclusion.

Cytotoxicity studies were carried out in 96-well microtiter plates with 1×10^5 cells/culture well in 200 μL of complete medium. Tocopherols and quinones were dissolved in ethanol, diluted 1:6 with medium, and 12 μL added to each well. Other vehicles for addition such as incorporation into lipoproteins or liposomes were not explored. Control cultures received diluted ethanol alone with no effect on viability. Doxorubicin was dissolved in 0.9% saline, NAC was dissolved in medium (pH adjusted to 7.4), and BSO was dissolved in phosphate-buffered saline. Cultures were incubated for 24 h. Some cultures were preincubated with BSO for 18 h.

Viability assays. Cell viability was measured by the absorbance of blue Formazan produced in viable cells from the reduction of MTT by mitochondrial dehydrogenases (4,17,18), and cytotoxicity was estimated as diminished viability (decreased Formazan absorbance). MTT is used routinely in studies on the effects of BSO and NAC on quinone cytotoxicity (9). Cells grown in spinner flasks grew vigorously and generated almost twice as much Formazan in the MTT assay as cells grown in suspension cultures. However, the same patterns of relative toxicity were obtained with both cell preparations. Each data point represents the absorbance from a single culture well; 6–12 replicate cultures per dose were used in each experiment. MTT was dissolved in phosphate-buffered saline (5 mg/mL), added to cell suspensions (100 μg/well), and incubated for 4 h. The supernatant was removed, Formazan precipitate dissolved in dimethyl sulfoxide, and absorbance measured by dual filter at either 490 or 570 nm, reference filter 630 nm, using a microplate reader (Dynatech MR 7000, Chantilly, VA). Tocopherols, quinones, and other agents did not reduce MTT to Formazan in the absence of viable CEM and CEM/VLB_{100} cells.

The validity of the MTT assay for viability in cultures treated with TQ was established in a previous study by a comparison with the Neutral Red assay (4), and confirmed in the present study by cell counts (hemocytometer) of viable cells (Trypan blue exclusion). Data (mean ± SD as percentage of control) for cell count and Formazan absorbance, respectively, were: 10 μM α-T, 100 ± 12 and 100 ± 4; 50 μM α-TQ, 84 ± 15 and 83 ± 6; 1 μM γ-TQ, 93 ± 7 and 90 ± 14; 5 μM γ-TQ, 46 ± 12 and 27 ± 18; 10 μM γ-TQ, 8 ± 5 and 9 ± 5.

Statistics. Data from 3 to 10 experiments per treatment protocol were analyzed. Main effects for cell line, agent, and concentration and their interactions were calculated by two- and three-way analyses of variance (ANOVA). *Post-hoc* comparisons where appropriate used the highly conservative Scheffe test.

RESULTS

Cytotoxicity of tocopherols and of tocopheryl quinones compared to doxorubicin. The cytotoxicity of tocopherols was compared in drug-sensitive CEM and multidrug-resistant CEM/VLB_{100} leukemia cell lines using the MTT assay. Among parent tocopherols, only δ-T showed dose-dependent cytotoxicity and was cytotoxic in both cell lines (Table 1).

The cytotoxicity of TQ was then compared to that of doxorubicin in the drug-sensitive CEM and multidrug-resistant CEM/VLB_{100} leukemia cell lines. As expected, doxorubicin was more cytotoxic in CEM than CEM/VLB_{100} cells (Table 2). In contrast to doxorubicin, however, γ-TQ, δ-TQ, Tocored, and PR were equally cytotoxic in both the drug-sensitive and multidrug-resistant CEM cell lines in a dose-dependent manner. Unlike doxorubicin or the other TQ, α-TQ was not cytotoxic in either cell line. Analysis of the dose–response data showed that γ-TQ and δ-TQ were highly cytotoxic (LD_{50} between 1 and 10 μM) and that 1 μM δ-TQ was more cytotoxic than 1 μM γ-TQ.

The ortho quinone Tocored and its methyl side-chain analog PR were cytotoxic in both cell lines (Table 2). Tocored was less cytotoxic than either γ-TQ or δ-TQ. The difference in cytotoxicity between Tocored and PR compared to α-TQ was particularly striking in that neither ortho quinones nor α-TQ forms classic Michael adducts with nucleophiles. However, ortho quinones will form tautomeric quinone methides, and these reactive compounds may form adducts with nucleophiles; structural formulas for these quinones and tautomeric quinone methides showing (arrows) positions available for nucleophile addition are shown in Figure 1. PR (methyl side-chain) was more cytotoxic than Tocored (phytyl side-chain) (Table 2). The reason for this difference was not apparent since we found in another experiment (data not shown) that TMCQ, the methyl side-chain analog of γ-TQ (Fig. 1) was somewhat less cytotoxic than γ-TQ (F 15.01, P 0.0002) with a structure/concentration interaction (F 11.00, $P < 0.0001$) only at the 10 μM concentration.

Synthesis of nucleophile adducts of para- and ortho-quinones. We have synthesized monoglutathion-*S*-yl adducts of menadione (5) and γ-TQ (4) and shown that these adducts

TABLE 1
Effects of Tocopherols on Viability[a] in CEM and CEM/VLB$_{100}$ Leukemia Cells

[a]Viability estimated as relative Formazan absorbance (mean ± S.D. in percentage). Cytotoxicity is reciprocal of viability.
[b]Three-way analysis of variance (ANOVA) (213 points) showed: cytotoxicity dose-dependent (F 6.00, P 0.0001); cytotoxicity structure-dependent (F 21.55, $P < 0.0001$) with δ-T cytotoxicity greater than either α-T or γ-T ($P < 0.001$), which did not differ from each other. Abbreviations: CEM, drug-sensitive lymphoblastic leukemia cells; CEM/VLB$_{100}$, multidrug-resistant lymphoblastic leukemia cells; α-T, γ-T, and δ-T, α-, γ-, and δ-tocopherol.

are, like other fully substituted glutathion-*S*-yl quinones (15), not cytotoxic agents. Studies with quinone adducts (6–8,15,19) predict that δ-TQ, with one less methyl group substitution than γ-TQ, will react even more rapidly than γ-TQ with thiols. The reactivity of δ-TQ was similar to 1,4-benzoquinone (15), with δ-TQ in excess glutathione depleting δ-TQ and rapidly forming a derivative with the appropriate molecular weight (FAB MS) for the monosodium salt of the monoglutathion-*S*-yl hydroquinone, *m/z* 748 $[M + H]^+$. The monoglutathion-*S*-yl hydroquinone was reoxidized by slowly adding excess δ-TQ, and a single product separated by HPLC. The product had the appropriate molecular weight (FAB MS) for the diglutathion-*S*-yl hydroquinone, *m/z* 1031 $[M + H]^+$. Purified hydroquinones did not reoxidize on standing.

Ortho quinones are in equilibrium with their tautomeric quinone methides (Fig. 1), which may both dimerize and form adducts with nucleophiles (7,8,16). Tocored is a reactive quinone that decomposed in alcohol solution to several compounds visualized on TLC (R_f 0.69, 0.53). PR dimers had been described previously (13). A new product (R_f 0.27) was formed when PR (R_f 0.52) reacted with 2-mercaptoethanol. FAB MS identified the hydroquinone adduct of PR and 2-mercaptoethanol, *m/z* 299 $[M + H]^+$. These studies showed that cytotoxic para- and ortho tocopheryl quinones shared a common property in their ability to react with thiol nucleophiles.

Thiol status and cytotoxicity. BSO alone had no effect on the viability of CEM cells. Data (mean ± SD as percentage of control) for Formazan absorbance were: media alone, 100 ± 5.7; 50 μM BSO, 102 ± 6.6. BSO increased the cytotoxicity of several TQ in CEM cell cultures (Table 3). Increasing concentrations of BSO enhanced the cytotoxicity of both γ-TQ and δ-TQ in the middle range of the quinone doses tested. δ-TQ was more cytotoxic than γ-TQ (Table 2), and the maximum BSO effect was found with 10 μM γ-TQ and 5 μm δ-TQ. Similarly, PR was less cytotoxic than para quinones (Table 2), and the maximal effect with BSO was found with 50 μM PR. As expected, BSO had no effect when the quinone concentrations were lower than their cytotoxic levels, nor did BSO add to the

50.0		96 ± 14	106 ± 4	8 ± 2	6 ± 1

[a]See Table 1 for this footnote.
[b]Two-way ANOVA (198 points) showed: cytotoxicity not affected by BSO (F 1.02, P 0.3862) and no α-TQ/BSO interaction (F 0.51, P 0.9066).
[c]Two-way ANOVA (370 points) showed: cytotoxicity enhanced by BSO (F 8.28, P <0.0001); a γ-TQ/BSO interaction (F 7.46, P < 0.0001) with 5 and 50 μM BSO affecting 10 μM γ-TQ.
[d]Two-way ANOVA (715 points) showed: cytotoxicity enhanced by BSO (F 6.07, P 0.0004); a δ-TQ/BSO interaction (F 16.66, P < 0.0001) with 0.5, 5, and 50 μM BSO affecting 5 μM δ-TQ.
[e]Two-way ANOVA (205 points) showed: cytotoxicity enhanced by BSO (F 26.60, P < 0.0001); a PR/BSO interaction (F 21.74, P < 0.0001) with 0.5, 5, and 50 μM BSO affecting 50 μM PR. For abbreviations see Tables 1 and 2.

cytotoxicity of the quinone when very high cytotoxic concentrations of quinone were tested. Unlike γ-TQ and δ-TQ, α-TQ was not cytotoxic (Table 2) and 50 μM BSO had no effect on cell viability with α-TQ even at a 100-μM α-TQ concentration.

NAC alone had no effect on the viability of CEM cells. Data (mean ± SD as percentage of control) for Formazan absorbance were: media alone, 100 ± 8.4; 0.5 mM NAC, 103 ± 6.2; 1 mM NAC, 103 ± 8.1. NAC had an effect on the cytotoxicity of γ-TQ and δ-TQ in CEM cell cultures (Table 4). Increasing concentrations of NAC diminished the cytotoxicity of 5 μM γ-TQ and 2.5 μM δ-TQ. NAC had no effect on higher concentrations of these quinones, which were very cytotoxic. Another study (data not shown) found that 1 mM NAC decreased the cytotoxicity of 2.5 and 5 μM δ-TQ in CEM cell cultures pretreated with 50 μM BSO (F 80.89, $P > 0.0001$). NAC/BSO data are consistent with a mechanism involving the detoxification of alkylating quinones through the formation of quinone NAC adducts rather than simply maintaining the glutathione pool as an essential antioxidant system.

α-T status and cytotoxicity. α-T alone had no effect on viability (Table 1), but α-T had a profound effect on the cytotoxicity of TQ in CEM cultures. Increasing concentrations of

TABLE 4
***N*-Acetylcysteine (NAC) Enhances Viability[a] in CEM Cells Treated with TQ**

	Quinone (μM)

[a]See Table 1 for this footnote.
[b]Two-way ANOVA (634 points) showed: cytotoxicity diminished by α-T (F 271.97, $P < 0.0001$); a γ-TQ/α-T interaction (F 39.08, $P < 0.0001$) with 50 μM α-T affecting 5 μM γ-TQ and 100 μM α-T affecting 5 and 10 μM γ-TQ.
[c]Two-way ANOVA (1068 points) showed: cytotoxicity diminished by α-T (F 263.26, $P < 0.0001$); a δ-TQ/α-T interaction (F 23.54, $P < 0.0001$) with 50 μM α-T affecting 2.5 and 5 μM δ-TQ and 100 μM α-T affecting 2.5, 5, and 10 μM δ-TQ.
[d]Cells preincubated with 50 or 100 μM BSO. Three-way ANOVA (889 points) showed: cytotoxicity enhanced by increasing concentration of BSO (F 72.83, $P < 0.0001$); cytotoxicity diminished by α-T (F 193.44, $P < 0.0001$); a δ-TQ/α-T interaction (F 159.38, $P < 0.0001$) with 100 μM α-T diminishing the cytotoxicity of 2.5 and 5 μM δ-TQ. For abbreviations see Tables 1–3.

no effect on δ-TQ (F 0.70, P 0.4966). α-T/BSO data show that α-T does not exert its effect simply by maintaining the glutathione pool as an essential antioxidant system.

DISCUSSION

Physiologic concentrations (<1 μM) of α-TQ have been found in serum (20). High or pharmacologic concentrations (>1 μM) of several TQ metabolites are cytotoxic in acute lymphoblastic leukemia cell lines, with cytotoxicity decreasing in the order δ-TQ > γ-TQ > Tocored. Furthermore, δ-TQ and γ-TQ are more cytotoxic in acute lymphoblastic leukemia cells than the widely studied chemotherapeutic agent doxorubicin. The comparison between TQ and doxorubicin is striking, with doxorubicin being much less cytotoxic in multidrug-resistant CEM/VLB_{100} cells. Our results with TQ identify a new class of cytotoxic quinones that escape multidrug resistance without the necessity of other agents and strategies to overcome the multidrug-resistance effect.

Trace amounts of a number of TQ and quinone oxides have been found in cells, tissues, and tissue cultures (20–25). Several early studies showed that both α-T and γ-T were metabolized to their para quinones after ingestion or intraperitoneal injection in rats (21–24). After 27 h, liver contained 4% of labeled α-T as α-TQ and 1% of labeled γ-T as γ-TQ. α-T is also metabolized to Tocored in cell cultures that generate nitric oxides (26,27). Studies on the chemotherapeutic potential of pharmacologic concentrations of many metabolites of tocopherol oxidation are indeed warranted.

The cytotoxic TQ are electrophilic alkylating agents that form Michael adducts and quinone methide adducts with nucleophilic thiol groups. We propose that alkylation reactions with electrophilic TQ contribute to their cytotoxicity. α-TQ is not an alkylating agent, nor is it cytotoxic in our cell lines. Reactive oxidant species may contribute to TQ cytotoxicity, but the large step-function between α-TQ and γ-TQ cytotoxicity and the small difference between γ-TQ and δ-TQ cytotoxicity are not predicted from the effect of reduction potentials alone on the generation of reactive oxidant species. TQ are a new and interesting series of compounds to be included in the continuing discussion of mechanisms for the cytotoxicity of antitumor quinones (4,6–8).

Data that show BSO enhances and that NAC inhibits TQ cytotoxicity are consistent with many studies on the detoxification of quinones through the formation of fully substituted adducts with the nucleophiles glutathione and NAC (4–10,15). Detoxification by cellular thiols would help to explain why physiologic concentrations of γ-TQ, δ-TQ and Tocored are not *in vivo* cytotoxic agents.

Data showing that α-T inhibits γ-TQ and δ-TQ cytotoxicity could be interpreted as evidence for reactive oxidant species cytotoxicity. However, TQ are reduced by NADH + H^+ and $FADH_2$ (14) and by DT-diaphorase [NAD(P)H: quinone-acceptor oxidoreductase; E.C. 1.6.99.2] (28), an enzyme induced by phenolic antioxidants (29). The induction of DT-diaphorase by α-T should be explored. Hydroquinones are not alkylating electrophiles, and α-T may induce the reduction of alkylating TQ or prevent the autoxidation of hydroquinones to alkylating quinones. The body retains α-T selectively (30). For example, the α-T/γ-T ratio ranges from 6.5 in human serum (31) to 70 in mouse liver (32), and the protective effect of α-T in tissue cultures is found at α-T/γ-T ratios in the 10 to 20 range (Table 5). High α-T/γ-T ratios may help to explain why physiologic concentrations of γ-TQ are not cytotoxic *in vivo*.

Our data show that δ-T is the only parent tocopherol that is cytotoxic in leukemia cells. δ-T is oxidized to the most cytotoxic alkylating quinone, δ-TQ, suggesting that δ-T cytotoxicity is the result of oxidation. Recent studies show that γ- and δ-tocotrienols, unlike α-tocotrienol, are cytotoxic in several tumor cell lines (1,2). These data could be explained by the oxidation of γ- and δ-tocotrienols to alkylating quinones. The biological properties of these quinones should be explored.

Conversion of Palmitate to Unsaturated Fatty Acids Differs in a *Neurospora crassa* Mutant with Impaired Fatty Acid Synthase Activity

Allan E. Stafford, Thomas A. McKeon*, and Marta Goodrich-Tanrikulu

USDA, ARS, Western Regional Research Center, Albany, California 94710

ABSTRACT: The *Neurospora crassa cel* (fatty acid *c*hain *el*ongation) mutant has impaired fatty acid synthase activity. The *cel* mutant requires exogenous 16:0 for growth and converts 16:0 to other fatty acids. In contrast to wild-type *N. crassa*, which converted only 42% of the exogenous [7,7,8,8-$^2H_4$]16:0 that was incorporated into cell lipids to unsaturated fatty acids, *cel* converted 72%. In addition, *cel* contains higher levels of 18:3$^{\Delta 9,12,15}$ than wild-type, and synthesizes two fatty acids, 20:2$^{\Delta 11,14}$ and 20:3$^{\Delta 11,14,17}$, found at only trace levels in wild-type. Thus, the Δ15-desaturase activity and elongation activity on 18-carbon polyunsaturated fatty acids are higher for *cel* than wild-type. This altered metabolism of exogenous 16:0 may be directly due to impaired flux through the endogenous fatty acid biosynthetic pathway, or may result from altered regulation of the synthesis of unsaturated fatty acids in the mutant.
Lipids 33, 303–306 (1998).

The filamentous fungus *Neurospora crassa* is a model system for the study of fatty acid metabolism. Several mutants in the fatty acid biosynthetic pathway exist; one such mutant is *cel* (fatty acid *c*hain *el*ongation). The *N. crassa cel* mutant has a defective cytosolic fatty acid synthase complex, with the complex containing only 2% of the wild-type content of 4′-phosphopantetheine prosthetic groups (1). The *cel* mutant synthesizes only minor amounts of fatty acid *de novo*, and requires exogenous fatty acids for normal growth. The optimal supplement is 16:0, an end-product of the fatty acid synthase, which allows near wild-type growth rates (2). In a key study using *cel*, fatty acid biosynthesis was first demonstrated to also occur in mitochondria by a prokaryotic-type fatty acid biosynthetic complex utilizing acyl carrier protein (3), a finding later confirmed (4).

In wild-type *N. crassa*, exogenous 16:0 is utilized only to a limited extent for the synthesis of unsaturated fatty acids (5). Previous studies of *cel* have given conflicting reports on the proportion of unsaturates in the mutant (2,6). If the fatty acid composition of *cel* is similar to wild-type *N. crassa*, it is likely to differ from wild-type in metabolism of exogenous 16:0 to unsaturated fatty acids. This study was undertaken to compare *cel* to wild-type in fatty acid composition and exogenous 16:0 metabolism.

EXPERIMENTAL PROCEDURES

Neurospora crassa strains were obtained from the Fungal Genetics Stock Center (Kansas City, KS). Conidia (1×10^5) of wild-type strain 74-OR8-1 *a* or the mutant strain *cel a* (FGSC #819) were inoculated into liquid Vogel's medium N containing 30 μM [7,7,8,8-$^2H_4$]16:0 (98%; Cambridge Isotope Laboratories, Andover, MA). Cultures were incubated for 48 h at 34°C, with a single change of medium 24 h after inoculation, as described (5).

Cultures were harvested by filtration, lipids extracted, and fatty acids analyzed as previously described (7). Gas chromatography–mass spectrometry was used to identify fatty acid derivatives (20:2$^{\Delta 11,14}$ and 20:3$^{\Delta 11,14,17}$) and to determine the metabolic fate of the [7,7,8,8-$^2H_4$]16:0 (5). The percentage of each fatty acid which was deuterated was obtained from selective ion monitoring mass spectrometry data and, with the relative mass of each fatty acid, was used to calculate the percentage of total fatty acid which was derived *de novo* and from the supplement.

RESULTS AND DISCUSSION

The major fatty acids synthesized by vegetative cultures of wild-type *N. crassa* are 16:0, 18:0, 18:1$^{\Delta 9}$, 18:2$^{\Delta 9,12}$, and 18:3$^{\Delta 9,12,15}$. *Neurospora crassa* grown with supplemental [$^2H_4$]16:0 for 2 d had a typical fatty acid composition profile (composite of Fig. 1A and B, described below). Fatty acid profiles of *cel* grown with [$^2H_4$]16:0 differed from wild-type; *cel* had higher levels of 18:3 (26% of total fatty acids, compared to 6% in wild-type) and of total polyunsaturates (70%, compared to 57%). In addition, 20:2$^{\Delta 11,14}$ and 20:3$^{\Delta 11,14,17}$ made up 5% of the total fatty acid mass in *cel*, but these were detectable at only trace levels in wild-type.

By incubating the cultures with [$^2H_4$]16:0 throughout the culturing period, we were able to determine the fraction of fatty acids synthesized both *de novo* and from the deuterated

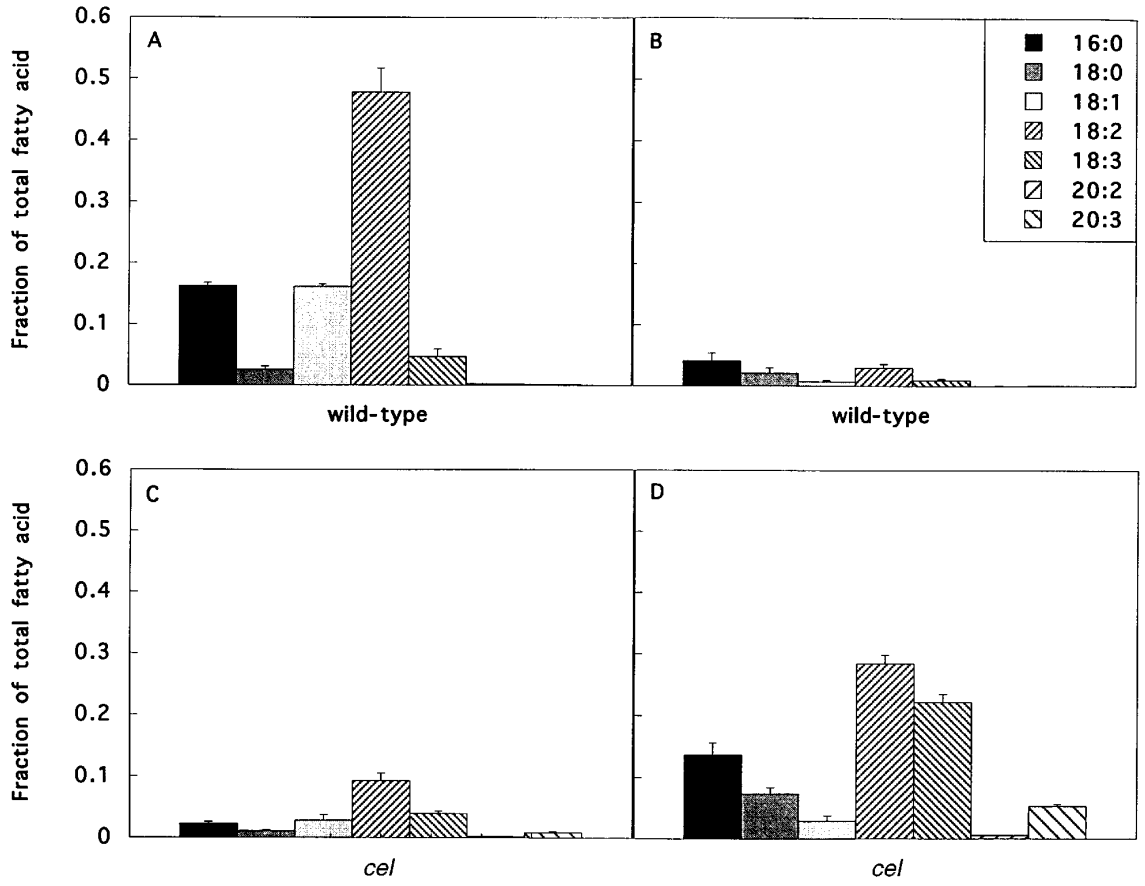

FIG. 1. Fatty acids synthesized by *Neurospora crassa de novo* and from supplemental [7,7,8,8-$^2H_4$]16:0. (A) Fatty acids synthesized *de novo* and (B) from exogenous [$^2H_4$]16:0 by wild-type; (C) fatty acids synthesized *de novo,* and (D) from [$^2H_4$]16:0 by *cel.* Cultures were grown for 2 d in presence of supplement, with the medium replenished after 1 d. ^2H incorporation into individual fatty acids was determined by gas chromatography–mass spectrometry (GC–MS) (selective ion monitoring), and used to calculate the fraction of total fatty acids derived from supplement. The fraction synthesized *de novo* was calculated by difference from the total. Data are presented as the fraction (out of 1.0) of the total fatty acid mass present in lipid extracts of the cultures. Values shown are averages ± SE for three wild-type cultures and six *cel* cultures. Average total fatty acid in wild-type cultures, 1440 ± 290 μg, and in *cel,* 264 ± 21 μg.

supplement. We compared fatty acids synthesized *de novo* and from exogenous [$^2H_4$]16:0 in wild-type and *cel* (Fig. 1). Wild-type synthesized the majority of its fatty acid *de novo* (Fig. 1A), with smaller amounts obtained from the supplement (Fig. 1B). Wild-type converted 42% of the exogenous [$^2H_4$]16:0 to unsaturates, comparable to the amount we observed earlier (37%) for a shorter uptake period (5). As expected, *cel*, because of its impairment in fatty acid biosynthesis, synthesized considerably less fatty acid *de novo* (Fig. 1C) than did wild-type (Fig. 1A). The majority of cel's fatty acids were obtained from the exogenous [$^2H_4$]16:0 (Fig. 1D). The *cel* mutant converted 72% of the [$^2H_4$]16:0 to unsaturates. It also utilized more of the [$^2H_4$]16:0 added to the medium in its lipids; *cel* incorporated 22% of the exogenous fatty acid into lipids, whereas wild-type incorporated only 14%, suggesting that less of the supplement enters the β-oxidation pathway in *cel*. Wild-type utilizes exogenous 16:0 preferentially for incorporation into triacylglycerols, and for elongation to longer-chain saturates (5). The *cel* mutant contained less triacylglycerol than wild-type (7% of total fatty acid *vs.* 18% for wild-type), but *cel* did not preferentially incorporate supplemental 16:0 into triacylglycerols (7% of fatty acid derived from the supplement, *vs.* 33% for wild-type). In addition, a greater proportion of the supplemental 16:0 incorporated into triacylglycerols had been converted to unsaturated fatty acids than in wild-type (Fig. 2).

The profiles of the fatty acids made by *cel* both *de novo* and from the supplement were similar (compare Figs. 1C, D), suggesting that, unlike wild-type (Figs. 1A, B), *cel* utilizes fatty acids obtained from the supplement similarly to fatty acids synthesized *de novo*. The single exception is the lower proportion of $18{:}1^{\Delta 9}$ relative to the other fatty acids derived from the supplement, compared to fatty acids synthesized by *cel de novo*. This effect is similar to that noted for wild-type (compare Fig. 1A, B, and Ref. 5). The *cel* mutant also produced a higher proportion of $18{:}3^{\Delta 9,12,15}$, $20{:}2^{\Delta 11,14}$ and $20{:}3^{\Delta 11,14,17}$, whether synthesized *de novo* or from the supplement, than did wild-type. The higher proportion of $18{:}3^{\Delta 9,12,15}$ indicates efficient desaturation of the $18{:}2^{\Delta 9,12}$ once formed.

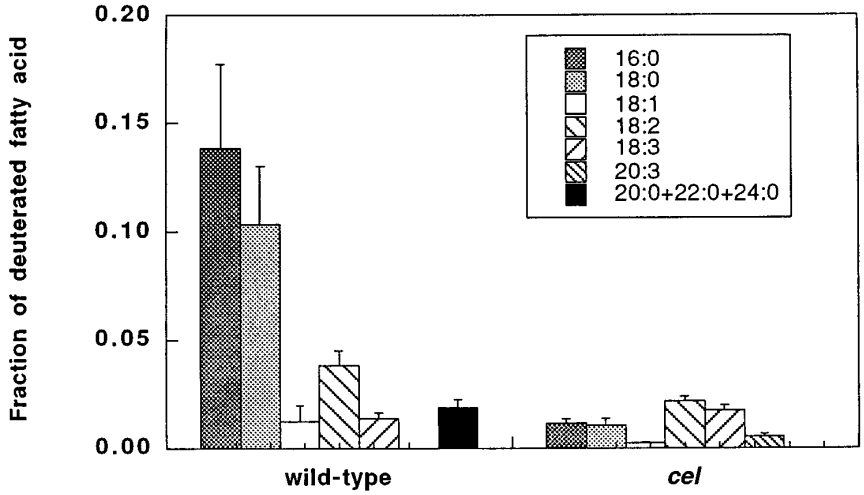

FIG. 2. Fraction of deuterated fatty acids incorporated into triacylglycerols by wild-type and *cel.* Triacylglycerols were separated from total lipids by thin-layer chromatography, and their fatty acid methyl esters analyzed by GC–MS as in Figure 1. Data are the fraction (out of 1.0) of the total deuterated fatty acids in each strain. Values are averages ± SE for three wild-type and two *cel* cultures. See Figure 1 for abbreviation.

Our earlier observation that exogenous 16:0 is poorly utilized for desaturation by wild-type, which has been confirmed here, suggested the presence of two pools of 16:0 in *N. crassa* (5): one that is used for synthesis of saturated fatty acids and one that leads into the unsaturated fatty acid pathway. Since the [$^2H_4$]16:0 is elongated to [9,9,10,10-$^2H_4$]18:0, an isotope effect on desaturation (18:0 to 18:1$^{\Delta 9}$) was considered as part of the reason for limited desaturation. However, lower levels of desaturation were also observed with 16:0 labeled in other positions. Although the isotope effect may have affected the fatty acid composition in wild-type cultures fed [$^2H_4$]16:0, exogenous 16:0, regardless of label position, was used preferentially for synthesis of saturated fatty acids while endogenously produced 16:0 was used for saturated and unsaturated fatty acids. On the other hand, because *cel* growth is dependent on supplemental fatty acid, *cel* must use exogenous 16:0 to produce saturated and unsaturated fatty acids in order to grow. We have found (Goodrich-Tanrikulu, M., Stafford, A.E., and McKeon, T.A., unpublished results), after feeding 16:0 labeled with deuterium in either the 2- or 16-position, that the isotope effect alters fatty acid composition in *cel*.

The production of the longer-chain polyunsaturated fatty acids 20:2$^{\Delta 11,14}$ and 20:3$^{\Delta 11,14,17}$ in *Neurospora* has not previously been reported (although they have been observed to be produced by *cel*; S. Brody, personal communication). The proportions of these fatty acids are also at least in part subject to culturing conditions, contributing as much as 20% of the total fatty acid in *cel* (not shown). The production of the longer-chain polyunsaturates presumably occurs by elongation of 18:2$^{\Delta 9,12}$ and 18:3$^{\Delta 9,12,15}$. In the yeast *Saccharomyces cerevisiae,* elongases are located in microsomes and mitochondria (8,9); various elongase systems optimally utilize fatty acid substrates ranging from 12 to 18 carbons (10). The formation of these fatty acids may be an indirect consequence of increased elongation activity of *cel*. We suspect that increased elongase activity is a mechanism for increasing the fatty acid biosynthetic capabilities of *cel*, assuming the elongases have some activity on short-chain fatty acids. Although *cel* derives the majority of its fatty acid from supplemental 16:0, the remaining fatty acid synthesized *de novo* is presumably derived from a combination of residual activity of the impaired cytosolic fatty acid synthase, mitochondrial fatty acid synthesis, and elongase activity. Elovson (1) assayed *cel* fatty acid synthase activity *in vitro* and found activity higher than expected based upon the content of 4′-phosphopantetheine in the impaired fatty acid synthase; however, the assay (based on oxidation of NADPH) would not have distinguished among these activities. Assays designed to distinguish among these activities will allow an estimate of the relative contributions of each to total fatty acid biosynthetic capability in *cel.*

ACKNOWLEDGMENTS

We thank Stuart Brody, for encouraging us to examine the metabolism of palmitate in the *cel* mutant and for helpful discussions and criticism throughout this study, and Charles Martin, for critical reading of the manuscript.

ABSTRACT: Cellular lipids were extracted from three species of Oomycete plant pathogens (*Pythium ultimum, Phytophthora infestans,* and *Ph. capsici*) and analyzed *via* normal-phase high-performance liquid chromatography with flame-ionization detection. The most abundant polar lipids in each of the three species were the polar membrane lipids, phosphatidylethanolamine (PE), phosphatidylcholine, and a phosphosphingolipid that eluted soon after PE. Structural analysis *via* mass spectrometry and nuclear magnetic resonance spectrometry revealed that the phosphosphingolipid was ceramide phosphorylethanolamine (Cer-PE). The most abundant molecular species of Cer-PE in *P. ultimum* had a molecular weight of 670.5, contained an unusual 19-carbon branched triunsaturated sphingoid (C19-Δ4, 8, 10, 9-methyl long-chain base) and palmitic acid as the amide-linked fatty acid. The most abundant molecular species of Cer-PE in *Ph. infestans* had a molecular weight of 714.5, contained a common 16-carbon 1,3 di-OH sphingoid, and erucic (*cis* 13-docosenoic, C22-Δ13) acid as the amide-linked fatty acid. The Cer-PE in *Ph. capsici* comprised a mixture of each of the two molecular species found in *P. ultimum* and *Ph. infestans.*
Lipids 33, 307–317 (1998).

Formerly classified as fungi, the Oomycetes have so many physiological and biochemical peculiarities that they have recently been placed in a separate kindom, the Stramenopila (1). Unlike most fungi, the cell walls of Oomycetes contain no chitin, and instead contain structural carbohydrate polymers composed of glucans (2). Pythiaceous members of the Oomycetes (including the *Phytophthora* and *Pythium* species of this study) are unable to synthesize sterols and do not require them for growth, but must obtain sterols in their host or environment because sterols are necessary for their sexual reproduction (3,4). For this reason, fungicides that inhibit ergosterol biosynthesis are not effective against Oomycetes. There are several reports that certain Oomycetes contain high levels of an unusual sphingophospholipid, ceramide aminoethylphosphonate. This unusual sphingophospholipid was reported to occur in *P. prolatum* (5), *Ph. parasitica* (5), and *Ph. infestans* (6,7).

Our laboratory has recently developed sensitive high-performance liquid chromatography (HPLC) methodologies to quantitatively analyze phospholipids and other lipids in microorganisms (8,9)**.** This study was undertaken to employ the tools of modern HPLC methodology to rigorously reinvestigate the occurrence and structure of phosphosphingolipids in three plant pathogenic species of Oomycetes**,** *P. ultimum, Ph. infestans,* and *Ph. capsici.* These species infect many agricultural commodities and cause considerable economic losses.

EXPERIMENTAL PROCEDURES

Growth of Oomycetes. *Pythium ultimum* (ATCC 26083) from the American Type Culture Collection (Rockville, MD) was maintained on potato dextrose agar at 25°C. Mycelium for lipid isolation was prepared by inoculating 20-mL aliquots of a liquid asparagine–sucrose medium (10) in petri dishes (9 cm in diameter, 2 cm in depth) with a mycelial plug, 7 mm in diameter, taken from the growing edge of a culture. The dishes were incubated for 48 h at 25°C with shaking on a gyratory shaker at 60 rpm. Mycelium was harvested by filtration on glass fiber filters, washed with water, and freeze-dried.

Phytophthora infestans (A1 strain) was obtained from Dr. W. Fry (Cornell University, Ithaca, NY) and was maintained on pea juice agar, prepared by autoclaving 283 g of frozen peas in 1 L of distilled water and filtering through cheesecloth. Agar (20 g) was added to the filtrate, which was autoclaved again before pouring culture plates. Mycelium for lipid isolation was prepared as described above for *P. ultimum* except that cultures were grown for 20 d before harvesting the mycelium.

Phytophthora capsici (ATCC 15399) from the American Type Culture Collection was maintained on V-8 juice agar,

Abbreviations: CAD, collisionally activated dissociation; CAEP, ceramide aminoethylphosphonate; Cer-PE, ceramide phosphorylethanolamine; Cer-PI, ceramide phosphorylinositol; 2D, two-dimensional; FAB, fast atom bombardment; FID, flame-ionization detector; GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography; LC/MS, liquid chromatography/MS; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; PE, phosphatidylethanolamine.

pH 7.0, containing 200 mL V-8 juice, 4 g $CaCO_3$, and 20 g agar per liter. Mycelium for lipid isolation was prepared as described above for *P. ultimum* except that cultures were grown for 96 h before harvesting the mycelium.

Lipid extraction and mild alkaline hydrolysis. Lyophilized hyphae (200 mg) were homogenized in chloroform/methanol/water (8 mL/16 mL/4.8 mL) with a Polytron Homogenizer (Brinkmann, Westbury, NY), and lipids were extracted with chloroform/methanol (11). Some lipid samples were subjected to mild alkaline hydrolysis by evaporating the solvent under N_2, adding about 5 mL of 1.5 M methanolic KOH/10 mg lipid, heating the mixture to 70°C for 30 min, acidification to pH 2, and reextraction of the hydrolysate with chloroform/methanol.

Analytical normal-phase HPLC. The lipids were separated and quantified using a method similar to one we have used for hopanoid analyses in other species (9). The column was a LiChrosorb 5 Si 60 (3 × 100 mm) from Chrompack, Inc. (Raritan, NJ), with a flow rate of 0.5 mL/min. The solvents were: A, hexane; B, isopropanol; and C, 0.04% triethylamine in water (C was prepared fresh daily). The linear gradient timetable was: at 0 min, 100/0/0; at 5 min, 95/5/0; at 10 min, 85/15/0; at 15 min, 40/60/0; at 53 min, 40/51/9; at 68 min, 40/51/9; at 73 min, 40/60/0; at 78 min, 100/0/0; at 100 min, 100/0/0; (%A/%B/%C, respectively). The HPLC system consisted of an Isco (Lincoln, NE) Model 2350 pump, an Isco Model 2360 gradient programmer, and a Tremetrics (Austin, TX) Model 945 flame-ionization detector (FID).

Semipreparative normal-phase HPLC. For purification of milligram quantities of ceramides, 10–20 mg of total lipid extract was injected in a volume of 1 mL on a column (10 × 250 mm, LiChrosorb 10 micron Silica 60A, packed by Phenomenex, Torrance, CA). The flow rate was 5.0 mL/min, and the ternary gradient was identical to that described above. The HPLC pumping system and detectors were also identical to those described above, except that the column effluent was split, using a Valco T (VICI Valco, Houston, TX), so that 10% of the flow entered the detector and 90% was collected.

Reverse-phase HPLC. Ceramide phosphorylethanolamine (Cer-PE) was purified by semipreparative normal-phase HPLC and analyzed by reverse-phase HPLC using a LiChrosorb 7 RP18 column (3 × 100 mm, Chrompack) and a mobile phase consisting of methanol/acetonitrile/water, 88:6:6, by vol, at a flow rate of 0.5 mL/min. The HPLC pumping system and detectors were as described above.

Mass spectrometry (MS). Liquid chromatography (LC)/MS measurements were performed on a Fisons Quattro SQ mass spectrometer (Beverly, MA) coupled to a Hewlett-Packard 1090 HPLC (Palo Alto, CA). The HPLC was operated with the same conditions as the reverse-phase HPLC method just described. The flow rate was 0.5 mL/min with approximately 12 μL/min of the eluant split post-column and directly introduced into the mass spectrometer. The analyte was ionized by electrospray ionization with detection of negative ions. The ion source was at 100°C, and the instrument scanned from 50–1000 *m/z* at 2.0 s/scan.

A Jeol HX-110 mass spectrometer (Peabody, MA) was employed for all other mass spectrometric measurements. The instrument was operated with 10 kV acceleration and detection of positive or negative ions. Mass resolution was 1000 (10% valley) except for high mass accuracy measurements where the resolution was 10,000 (10% valley). Analyte was ionized by fast atom bombardment (FAB) with a Xe beam and 3-nitrobenzyl alcohol matrix. For collisionally activated dissociation (CAD) measurements, helium was used as the target at a sufficient pressure to attenuate the primary beam to 30% of its original intensity. Linked scanning at constant B/E (magnetic field/electric field) provided spectra of the product ions. For high mass accuracy measurements, manual peak-matching was performed using a suitable calibrant with a mass similar to that of the unknown.

The sphingolipids were hydrolyzed by dissolution of a small amount in 3 N methanolic HCl and heating at 70°C for 4 h. FAB of the entire solution was performed for determination of the sphingoid and ceramide moieties. The fatty acid methyl esters were extracted with methylene chloride and analyzed by gas chromatography (GC)/MS to determine the fatty acid components, using a Hewlett-Packard 5970 for those of *P. ultimum* and a Hewlett-Packard 5890 GC connected to a Finnigan SSQ7000 (Sunnyvale, CA) for those of *Ph. infestans* and *Ph. capsici*. The analyses employed a J&W DB-5 column (30 m, 0.25 mm i.d., 0.025 mm film thickness; Folsom, CA), which was heated from 50 to 285°C at 8°C/min while the mass spectrometer scanned from 50 to 800 *m/z*.

Nuclear magnetic resonance (NMR) spectrometry. The NMR analyses were performed on a Bruker AMX500 spectrometer (Billerica, MA) at 25°C. The two-dimensional (2D) spectrum correlation spectroscopy experiment was acquired with 2K by 512 points which were zero-filled to make up a 2K × 2K set of data points. The projections along the two axes were from one-dimensional ^{1}H NMR data collected separately.

All experiments were repeated at least two times, and the data presented are the mean of duplicate samples from one experiment.

RESULTS

The yield of total lipid extract was 12–16 mg lipid per 200 mg dry weight of mycelia of *P. ultimum,* 17–20 mg lipid per 200 mg dry weight of mycelia of *Ph. infestans,* and 7–8 mg lipid per 200 mg dry weight of mycelia of *Ph. capsici*.

The total lipid extracts from each of the three organisms were analyzed with an analytical normal-phase HPLC–FID system (Fig. 1). The major phospholipids were phosphatidylethanolamine (PE) and phosphatidylcholine (PC). The chromatogram of *Ph. infestans* lipids contained an unidentified peak at a retention time of 47.3 min; because this peak was resistant to mild alkaline hydrolysis, it was postulated to be a sphingolipid (probably a ceramide) and was labeled Cer 1. The chromatogram of *P. ultimum* lipids contained PE, PC, and an unidentified peak at a retention time of 48.3 min

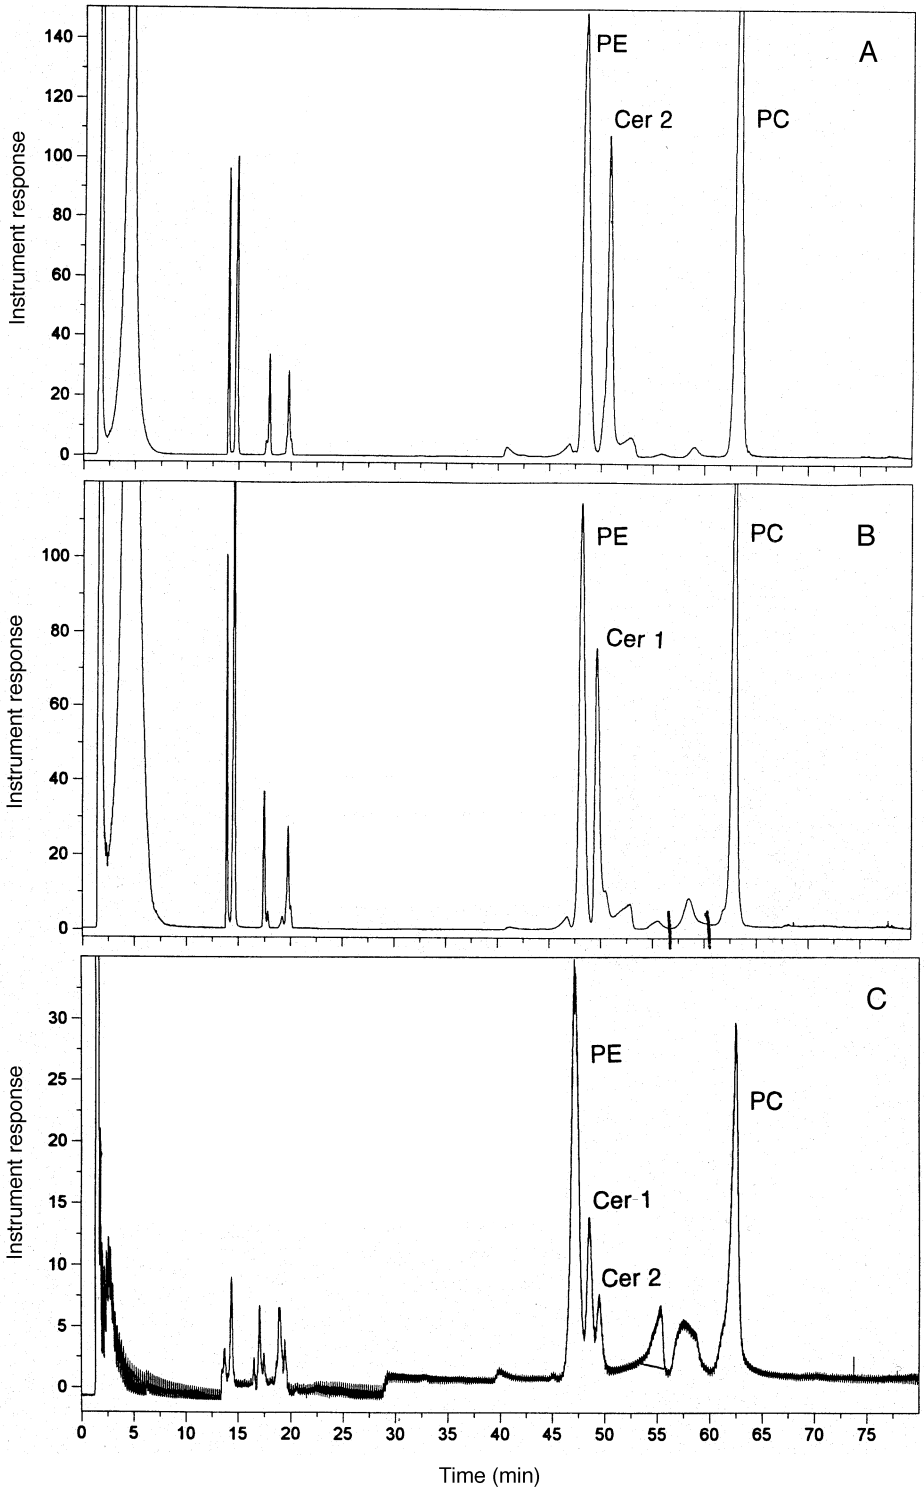

FIG. 1. Analytical normal-phase high-performance liquid chromatography–flame-ionization detector (HPLC–FID) chromatograms of the lipid classes in mycelial lipid extracts of (A) *Pythium ultimum,* (B) *Phytophthora infestans,* and (C) *Ph. capsici.* Abbreviations: PE, phosphatidylethanolamine; PC, phosphatidylcholine; Cer 1 and Cer 2, ceramide-1 and -2.

that was also resistant to mild alkaline hydrolysis. Thus it was also postulated to be a sphingolipid and was labeled Cer 2. The chromatogram of *Ph. capsici* lipids contained PE, PC, and unidentified peaks at the retention times of 47.3 and 48.3 min that were tentatively labeled Cer 1 and Cer 2.

To purify milligram quantities of Cer 1 and Cer 2 for structural analysis, we scaled up the above analytical normal-phase HPLC system to the semipreparative level, injecting larger samples (10–20 mg, in 1 mL) of total lipid extracts from each of the three species (Fig. 2). The semipreparative

chromatograms (Fig. 2) were very similar to those obtained with corresponding samples at the analytical level (Fig. 1). By using this system, several milligrams each of PE, PC, and Cer 1 from *Ph. infestans* and *Ph. capsici* and of Cer 2 from *P. ultimum* and *Ph. capsici* were purified.

Most phospholipid and sphingolipid classes that have been purified by normal-phase HPLC can be separated into their individual molecular species by reinjecting them in an appropriate reverse-phase HPLC system (12). When samples of purified PE and PC were injected in this reverse-phase system, multiple peaks of individual molecular species were observed with each (data not shown). To attempt to separate the molecular species of Cer 1 and Cer 2, we injected the four purified samples from the semipreparative normal-phase HPLC into an analytical reverse-phase HPLC system (Fig. 3). In this chromatographic system, injection of purified Cer 1 from both *Ph. infestans* and *Ph. capsici* yielded a major peak with a retention time of 27.8 min. Injection of purified Cer 2 from *P. ultimum* and *Ph. capsici* yielded a major peak with a retention time of 13.8 min. Because the chromatograms of the two

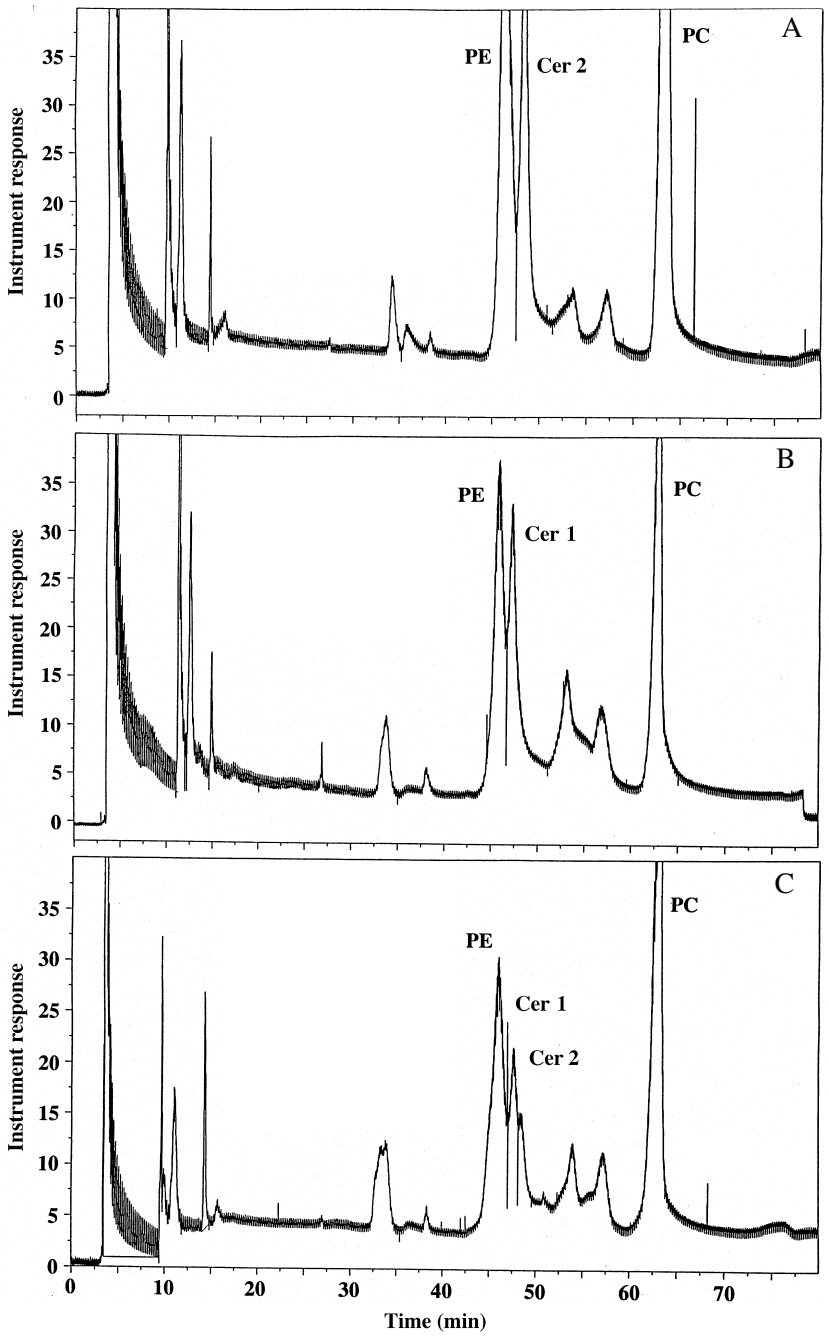

FIG. 2. Semipreparative normal-phase HPLC–FID chromatograms of the lipid classes in mycelial lipid extracts of (A) *Pythium ultimum,* (B) *Phytophthora infestans,* and (C) *Ph. capsici.* Abbreviations are defined in Figure 1.

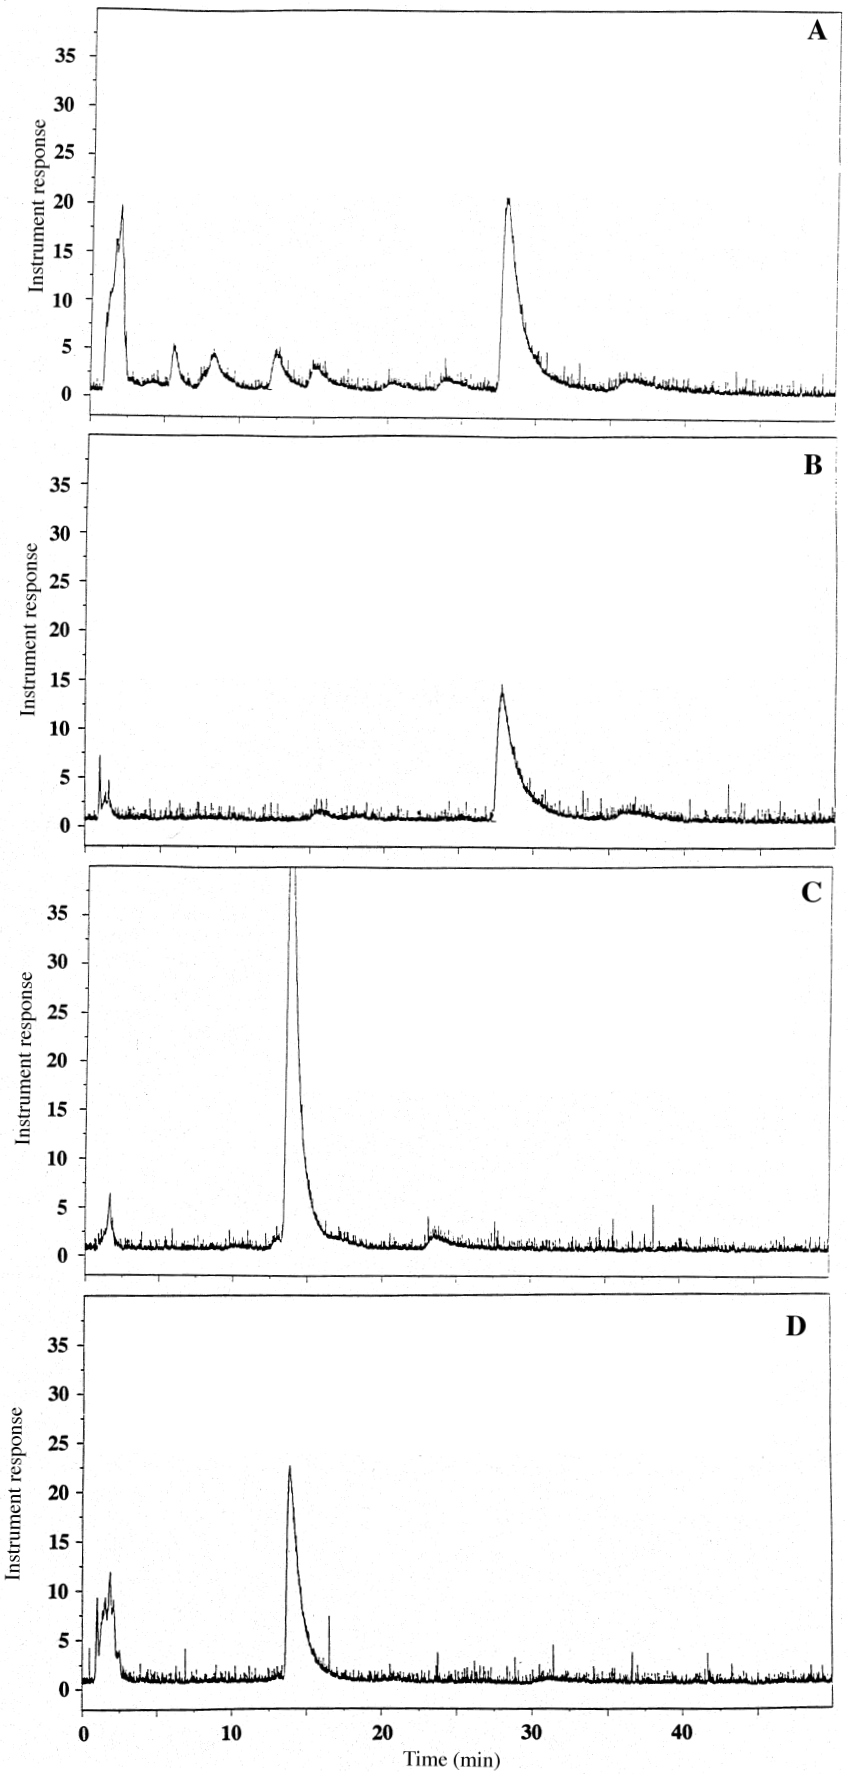

FIG. 3. Analytical reverse-phase HPLC–FID chromatograms of the molecular species of ceramides in the three species: (A) Cer 1 peak from *Phytophthora infestans*, (B) Cer 1 peak from *Ph. capsici*, (C) Cer 2 peak from *Pythium ultimum*, and (D) Cer 2 peak from *Ph. capsici*.

Cer 1 samples each show only one major peak and because the retention times are identical, it is likely that the samples contain the same major component. Similarly, because the two Cer 2 samples each only have one major peak, they apparently only contain one major molecular species; and because the retention times for these are identical, it is likely that their chemical structures are identical.

The Cer 1 and Cer 2 samples isolated by semipreparative normal-phase HPLC were then analyzed by electrospray LC/MS, using the above reverse-phase HPLC system, to determine the molecular weight of the major sphingolipid molecular species in the lipid fractions. The LC/MS chromatograms were similar to those from the reverse-phase HPLC–FID analyses shown in Figure 3. The mass spectra of the major components which corresponded to the intense peaks in Figure 3 are shown in Figure 4. The molecular weights of these components are readily determined as the negative ion electrospray produces the deprotonated molecular ions. In summary, the molecular weight of the major component in *P. ultimum* is 670.4 Da; in *Ph. infestans*, it is 714.5 Da; and in *Ph. capsici,* the major components are 670.4 and 714.5 Da. This supports the proposition that the sphingolipids in *Ph. capsici* are identical to those found in *P. ultimum* and *Ph. infestans*.

The FAB mass spectra, Figure 5, of the sphingolipid fractions, isolated by semipreparative normal-phase HPLC, confirmed the molecular weights of the major components. The mass spectrum for the *P. ultimum* sphingolipid shows the protonated molecular ion at *m/z* 671.4 while the *Ph. infestans* sphingolipid has *m/z* 715.5 as the protonated molecular ion. Additionally, the peaks at *m/z* 141 lower are seen in each of these spectra at *m/z* 530.4 and 574.5, respectively. This is indicative of loss of phosphorylethanolamine from the molecular ion (13). In the case of *Ph. capsici,* both the *m/z* 671.4 and 715.5 peaks and the *m/z* 530.4 and 574.5 peaks are observed.

Additional structural information was obtained from the FAB mass spectra of the total hydrolysate solution and is summarized in Schemes 1 and 2 (spectra not presented). The *P. ultimum* sphingolipid hydrolysate showed a major peak at *m/z* 433.3 which would correspond to the hydrolytic loss of a 16:0 fatty acid chain from the sphingolipid. An additional peak at *m/z* 310.3 shows further loss of phosphorylethanol-

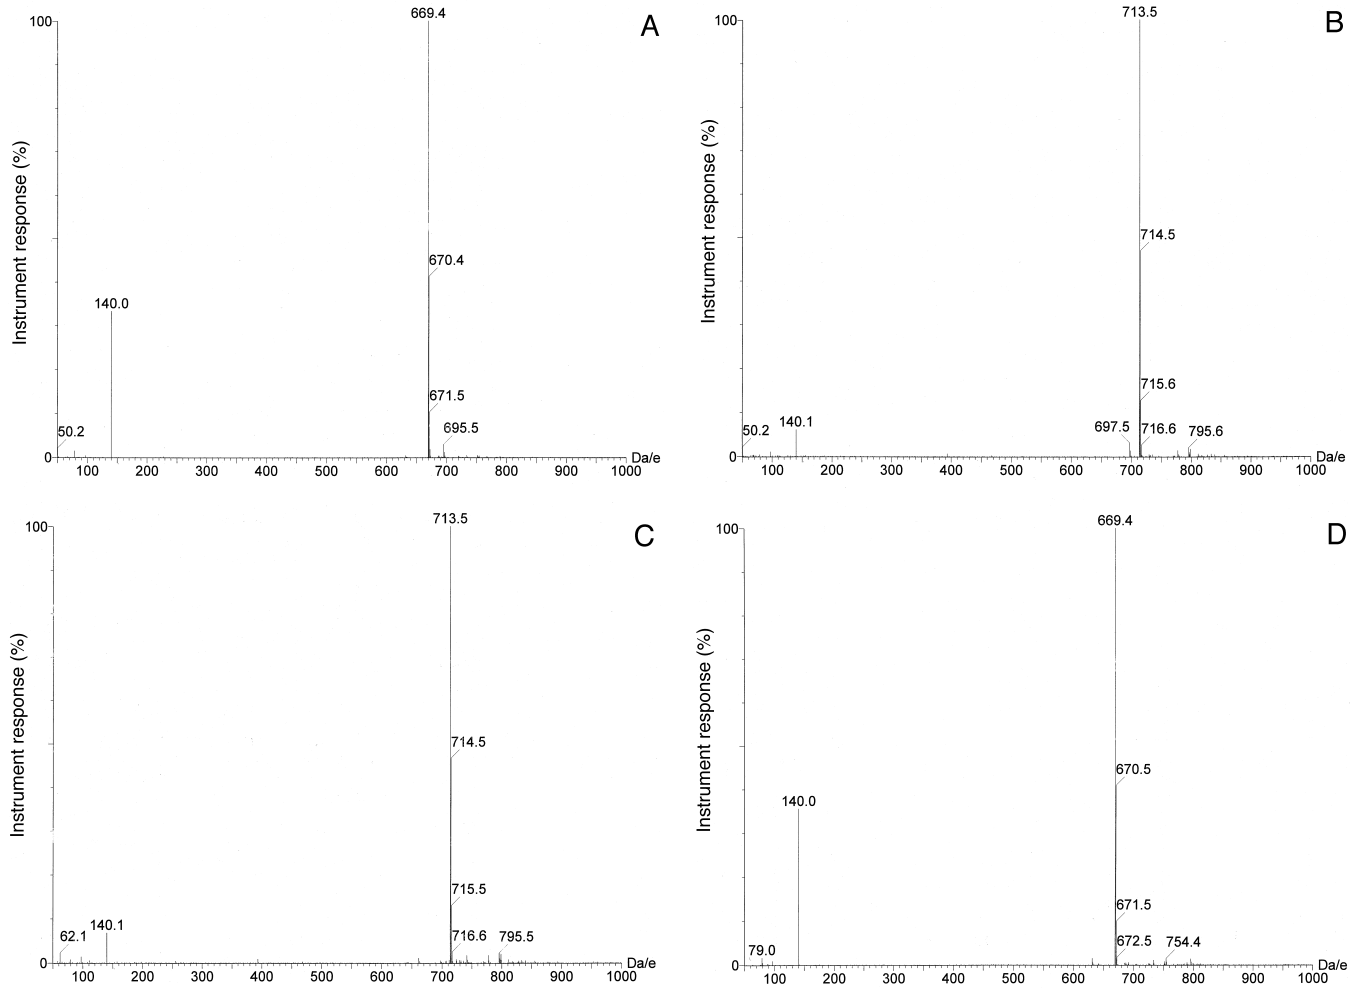

FIG. 4. Liquid chromatography–mass spectrometry electrospray analysis of (A) *Pythium ultimum,* (B) *Phytophthora infestans,* (C) *Ph. capsici* Cer 1, and (D) *Ph. capsici* Cer 2. The mass spectra of the major components were obtained using a micromass quadrupole mass spectrometer operating in the negative ion mode. For abbreviations see Figure 1.

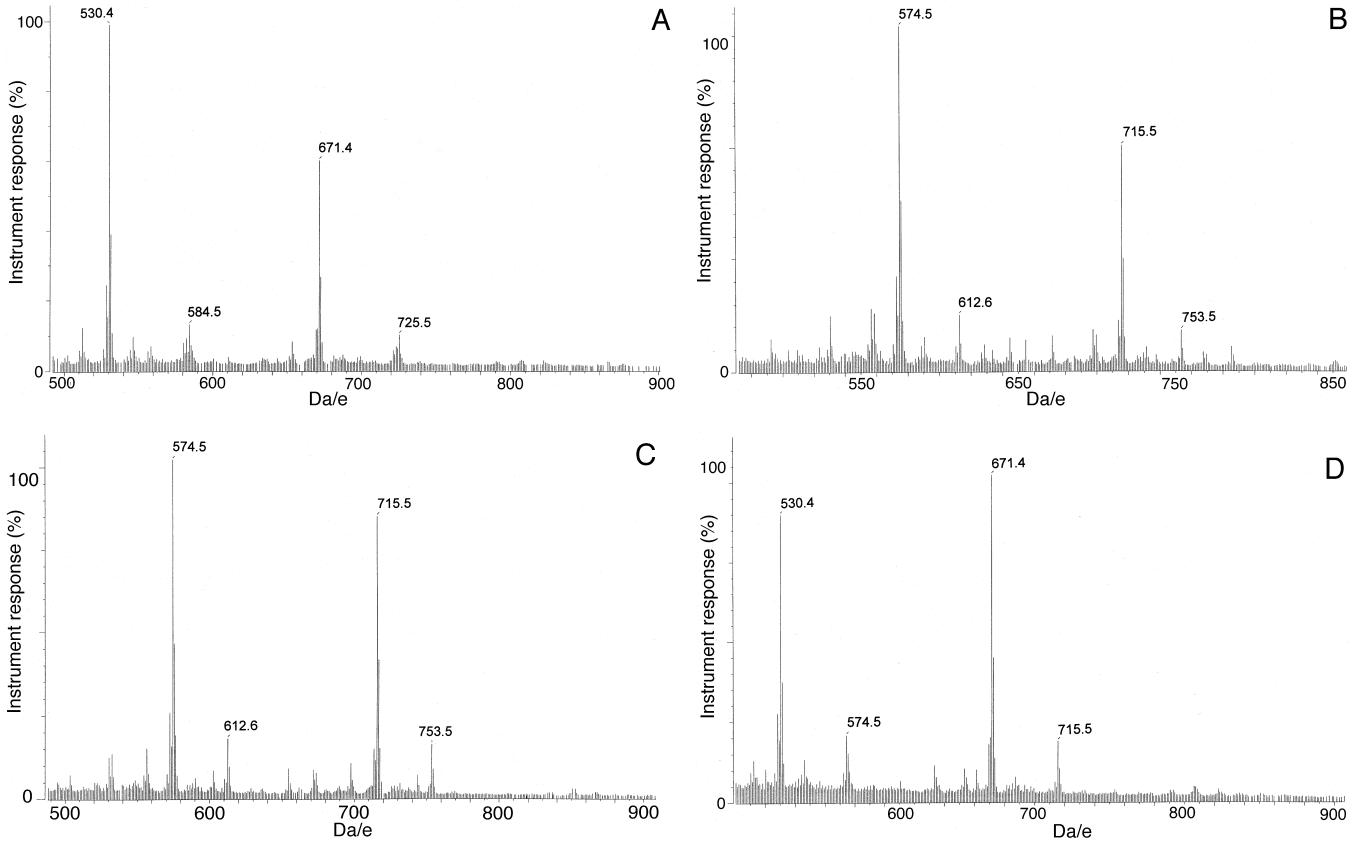

FIG. 5. The fast atom bombardment mass spectra of the sphingolipid fractions of (A) *Pythium ultimum,* (B) *Phytophthora infestans,* (C) *Ph. capsici* Cer 1, and (D) *Ph. capsici* Cer 2. The mass spectra were obtained using a Jeol HX-110 double focusing mass spectrometer (Peabody, MA) operating in the positive ion mode. Fractions were prepared in a 3-nitrobenzyl alcohol matrix. For abbreviations see Figure 1.

amine leaving *m/z* 310.3 as the protonated molecular ion of the sphingoid. The FAB mass spectrum of the *Ph. infestans* hydrolysate solution showed a major peak at *m/z* 395.3. This corresponds to the hydrolytic loss of a 22:1 fatty acid from the sphingolipid. The other significant hydrolysis product *m/z* 272 reflects further loss of phosphorylethanolamine. The *Ph. capsici* hydrolysate showed both pairs of hydrolysis products, further reinforcing the supposition

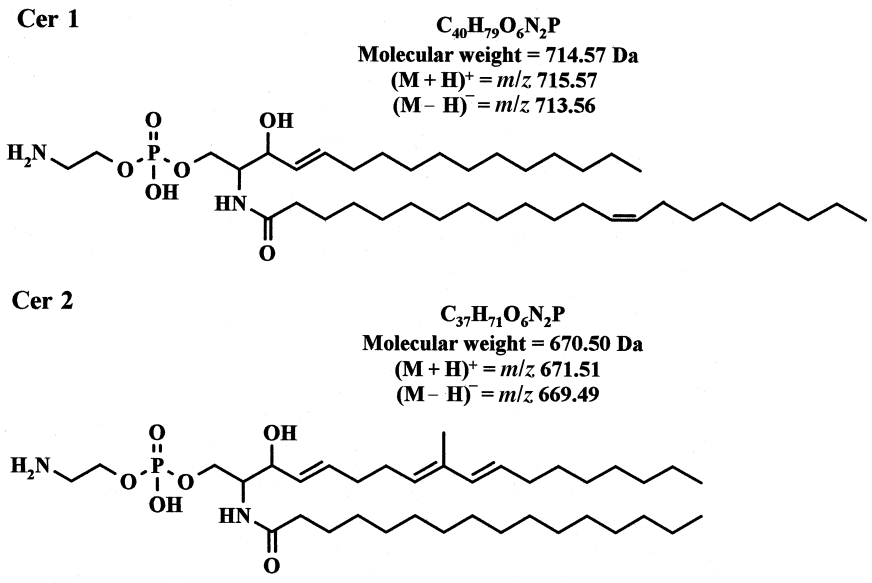
[a]PE, phosphatidylethanolamine.

that the sphingolipids in *P. ultimum* and *Ph. infestans* are both present in *Ph. capsici*.

The GC/MS analysis of the hydrolysate extract gave qualitative information on the fatty acid components of the sphingolipids. For *P. ultimum* the methyl esters of 14:0, 16:0, 18:0, 18:1, 20:0, and 20:1 were detected. For *Ph. infestans* the methyl esters of 16:0, 18:0, 22:0, and 22:1 fatty acids were found.

Strong structural evidence is provided by the accurate mass measurements of the sphingolipids and their hydrolysates. Table 1 summarizes the data showing the measured mass, the proposed formula, and the difference between the expected and measured mass. Mass errors of less than 0.001% are generally considered a good match. The difference in composition between the protonated molecular ion of the *P. ultimum* sphingolipid and the peak corresponding to the loss of *m/z* 141 almost exactly accounts for loss of phosphorylethanolamine. This strong indication of loss of phosphorylethanolamine is also shown for the *Ph. infestans* sphingolipid fragments. Similarly, the assignments of the hydrolysate products are very near the measured values. All of the assignments in Table 1 are within 0.00055% of the proposed masses, giving strong support for the proposed structures (Scheme 3).

The connectivity in these sphingolipids is further elucidated by the CAD spectra of the various molecular ions. These CAD spectra provide a fingerprint of the molecule and are a sensitive indicator of molecular structure. The major ions resulting from the fragmentation of the molecular ions are shown in Table 2. The notation is similar to that used in Pivot *et al.* (14). These data provide clear evidence of the connectivity of the various moieties mentioned in the above re-



SCHEME 3

TABLE 2
The Collisionally Activated Dissociation Spectra of Cer 1 and Cer 2

	Ion mode	$(M + H)^+$	$(M - H)^-$	Y	U	Y – B	Y – F – H_2O	XPO_4H_3	XPO_4
Cer 1	Positive	715.5		573		362	236	142	
	Negative		713.5		501				140
Cer 2	Positive	671.5		530		280	274	142	
	Negative		669.4		419				140

sults. Based on these CAD spectra and the above data, the structures of the Cer 1 and Cer 2 can be assigned with certainty and are shown in Scheme 3. Additionally the CAD spectra of Cer 1 and Cer 2 from *Ph. capsici* are essentially the same as these shown here, proving that the sphingolipids in *Ph. capsici* have the same structure as those in *Ph. infestans* and *P. ultimum* (Scheme 3).

The only ambiguities which are unresolved by the above MS analyses are in the position of the three double bonds and branching in the *P. ultimum* sphingoid moiety. Proton NMR was used to address this point and provide further evidence for the proposed structures.

The positions of the olefinic groups along the sphingoid (or sphingatriene) chain were determined in a 2D NMR spectrum correlation spectroscopy experiment (15) that was carried out on a 500 MHz NMR spectrometer. In this experiment, signals arising from protons three bonds apart are correlated in the 2D map as shown in Figure 6. There are two sets of signals in the 2D plot. The diagonal peaks running from the top right corner of the figure to the bottom left end are essentially the same as the normal one-dimensional proton NMR signals that are also shown on the top as well as left side of the 2D plot. The off-diagonal peaks indicate the connectivities among neighboring proton species. Horizontal and vertical dashed lines are drawn on the 2D spectrum to assist with these correlations. For example, the long vertical line at 5.34 ppm at the olefinic methine proton (**8** on the structure) shows two correlations to 1.69 and 2.16 ppm as highlighted by the two horizontal dashed lines. As indicated on the left side of the figure, these correspond to the methylene **7** and methyl group at **19**. The rest of the correlations are assigned in a similar fashion, as indicated with several dashed lines on the spectrum, and identify the *P. ultimum* sphingoid as a C19-Δ 4,8,10, nine-methyl-long chain base. A summary of the proton chemical shift assignment for the sphingoid (or sphingatriene) side chain is given in Table 3. The *J* coupling between the protons across the double bond for pairs 4–5 and 10–11 is 15.3 Hz—indicative of *trans* configuration of the two olefins. We could not accurately measure the *J* coupling between 8–9 (CH_3) owing to severe overlap and weak coupling. Thus, we could not determine its configuration.

Based on the above structural information, Cer 1 and Cer 2 appear to be molecular species of Cer-PE, with proposed structures shown in Scheme 3. The analytical HPLC data presented in Figure 1 were used for the quantitative analysis of each of the lipid classes in the lipid extracts of the three species (Table 4). To accomplish this quantification, several samples of each of the major peaks purified by semipreparative HPLC (Fig. 2) were injected, and the FID was calibrated to convert peak area to mass in the range of 1–50 µg for each of the major lipid classes. The levels of total lipids and nonpolar lipids varied significantly among the three species. Although no attempt was made to quantify the individual nonpolar lipid classes, they appeared to be mostly triacylglycerol, with some free fatty acids, and several other minor unidentified peaks. For *P. ultimum* and *Ph. infestans* the most abundant polar lipid class was PC, followed by PE, and then Cer-PE. For *Ph. capsici*, the most abundant polar lipid class was PE, followed by PC, and then Cer-PE.

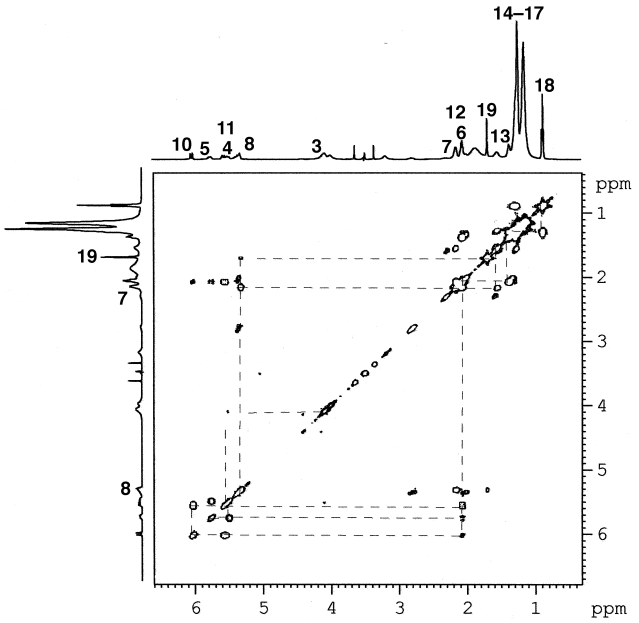


FIG. 6. The two-dimensional nuclear magnetic resonance spectrum correlation spectroscopy of *Pythium ultimum* ceramide phosphorylethanolamine.

DISCUSSION

This study is the first report of the occurrence of Cer-PE in a eukaryotic microorganism. It is also the first report of a 19-carbon-9-methyl-triunsaturated (Δ4, 8, 10) long chain base in a microbial sphingolipid. Several reports of the lipid composition of *P. ultimum* (16–18) failed to identify any sphingolipids. One of these reports noted the presence of a double peak of PE and several other unidentified phospholipid peaks, any of which could have been Cer-PE (16).

The current study now brings into question earlier reports of the occurrence of ceramide aminoethylphosphonate (CAEP) in *P. prolatum* (5), *Ph. palmitovora* (5), and *Ph. infestans* (6,7). In the cases of *P. prolatum* and *Ph. palmitovora*, it is not possible to comment on whether these species contain CAEP or Cer-PE, since these species were not examined in our current study. However, for *Ph. infestans*, all of the rigorous battery of mass spectral and NMR data that was employed in this study point to the occurrence of only Cer-PE (and no CAEP was detected). The two previous reports of CAEP in *Ph. infestans* (6,7) did not employ MS or NMR, and instead, the structural identification was based mainly on cochromatography of the hydrolyzed polar head group with commercial standards of aminoethylphosphonate. In one of the previous reports of CAEP in *Ph. infestans* (6) the major fatty acid moiety of CAEP was reported to be arachidonic acid. However, in the current study we found that erucic acid (*cis*-13-docosenoic, C22-Δ13) was the most abundant fatty acid in the Cer-PE of *Ph. infestans*. The identification of arachidonic acid in CAEP in the previous study (6) was performed by gas–liquid chromatography with packed columns. It is not known whether the arachidonic acid identified in the previous study could be adequately separated from erucic acid with the technique used. However, because the identification of erucic acid in Cer-PE in the current study is based on capillary gas–liquid chromatography with mass spectral analysis, we feel quite confident that this is the major fatty acid in the Cer-PE of *Ph. infestans*.

Ceramide phosphorylinositol (Cer-PI) was recently reported to be the major sphingolipid in *Ph. capsici* (14,19,20) and *Ph. parasitica* (21). Inositol sphingolipids such as these have been reported to occur in yeast and fungi (22,23). In our current study we did not see any evidence for the occurrence of Cer-PI or other inositol sphingolipids as major membrane lipids in *P. ultimum, Ph. infestans,* or *Ph. capsici*. While it is possible that Cer-PI is present in *Ph. parasitica* but absent from *Ph. infestans* and *P. ultimum*, we have no explanation for the failure to detect Cer-PI in *Ph. capsici* in our study except for the possibility of (i) differences in lipid composition between individual isolates, (ii) differences in the growth conditions, or (iii) differences in extraction procedures used in our study as compared to others (14,19,20).

Although this study is the first report of the occurrence of Cer-PE in a eukaryotic microorganism, Cer-PE has been reported to occur in *Sinotaia histrica*, a freshwater snail (24) and three genera of anaerobic Bacteroides (25).

The unusual 19-carbon-9-methyl-triunsaturated (Δ4, 8, 10) long chain base (sphingoid) that was found in the Cer-PE in *P. ultimum* (Scheme 3) has also been reported to occur in the glucosylceramides of *Asterias amurensis*, a starfish (26), and *Ophidiaster ophidiamus*, a sea star (27). Two fungal species, *Lentinus edodes* and *Schizophyllum commune*, have been reported to contain a somewhat similar 19-carbon-9-methyl, diunsaturated (Δ4, 8) long chain base in their glucosylceramides (28,29).

The subcellular localization and physiological significance of Cer-PE in Oomycetes are not known. However, because most of the sphingolipids in other species [including inositol sphingolipids in yeast (30), glucocerebrosides in plants (31), and sphingomyelin in animal cells (32)] are all localized in the plasma membrane, it is reasonable to expect that most of the Cer-PE in Oomycetes is localized in the plasma membrane. Cer-PE would be expected to be resistant to phospho-

TABLE 4
Quantitative Analysis (mg/g dry wt) of Ceramides and Other Lipid Classes in *Pythium ultimum, Phytophthora infestans,* and *Ph. capsici*[a]

CL	trace	trace	trace
PE	9.44	5.29	3.66
Cer-PE 1	n.d.	3.03	1.39
Cer-PE 2	4.72	trace	0.84
PI	trace	trace	trace
PC	12.6	6.71	2.93
Total lipids	65.1	102.0	37.5

[a]Quantification is based on the normal-phase high-performance liquid chromatograms reported in Figure 1. Standard curves of each lipid class, injected as several concentrations, were used to calculate the mass of each lipid class.
[b]Abbreviations: n.d., not detected; CL, cardiolipin; Cer-PE 1 and 2, ceramide phosphorylethanolamine 1 and 2, with structures shown in Scheme 3; PI, phosphatidylinositol; PC, phosphatidylcholine. For other abbreviation see Table 1.

lipases A1, A2, and B, since these enzymes hydrolyze the fatty acid–oxygen ester bonds and there are no such bonds in Cer-PE. Since many plants (including potatoes and tomatoes, major hosts of *Ph. infestans*) contain high levels of phospholipase B [also called lipolytic acyl hydrolase (7)], the localization of Cer-PE in the plasma membrane could help protect the membrane from hydrolysis by plant phospholipase B. However, certain hydrolytic enzymes that are also common in certain plant tissues, phospholipase C and D, would presumably be capable of hydrolyzing Cer-PE.

The pathway leading to Cer-PE remains to be elucidated. Nevertheless, the discovery of Cer-PE as a novel class of sphingolipid found in *Phytophthora* and *Pythium* species but not in plants or mammals prompts the speculation that enzymes involved in biosynthesis of these lipids may represent potential biochemical targets for the discovery of new agricultural fungicides (Stramenopilocides).

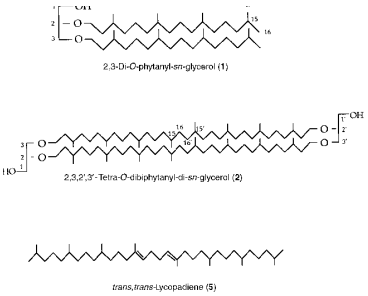
ABSTRACT: The membrane lipids of a deep-sea hydrothermal vent archaea, *Thermococcus hydrothermalis*, were isolated, purified, and structurally characterized. On the basis of acid methanolysis and spectroscopic studies, the polar lipids, amounting to 4.5% (w/w) of the dry cells, comprised diphytanyl glycerol diethers and dibiphytanyldiglycerol tetraethers, in a 45:55 ratio. No cyclopentane ring was present in the tetraethers. From the neutral lipids, accounting for 0.4% (w/w) of the dry cells, besides low amounts of di- and tetraethers occurring in a free form, four acyclic tetraterpenoid hydrocarbons, di- and triunsaturated were identified. All were structurally related to lycopane. The presence of these hydrocarbons provides some evidence that lycopane, widely distributed in oceans, could be derived, at least partially, from the hydrocarbons synthesized by some thermophilic Archaea. Finally, analysis of the uninoculated culture medium indicates that fatty acid derivatives and some steroid and triterpenoid compounds identified in the lipidic extract of the archaea originated from the culture medium. *Lipids 33*, 319–326 (1998).



SCHEME 1

All Archaea, including the halotolerant species, are characterized by the presence of isopranyl glycerol ether lipids in their membranes (1–6). Two types of complex ether lipids occur generally in Archaea: the diphytanyl glycerol diether, i.e., 2,3-di-*O*-phytanyl-*sn*-glycerol **1** and the dibiphytanyl diglycerol tetraether, i.e., 2,3,2′,3′-tetra-*O*-dibiphytanyl-di-*sn*-glycerol **2** (Scheme 1). In these latter, the C_{40} isoprenoid chains derive from ω,ω′ linkages of two *O*-phytanyl residues.

In the Archaea of the thermoacidophilic group, a typical feature is the presence of cyclopentane rings in the C_{40} chains (1). It has been suggested that the macrocycle and the cyclopentane rings occurring in tetraethers enhance the rigidity of the membranes of the microorganisms that are able to grow at elevated temperatures (7,8). However this assumption was reconsidered when new archaea, including some *Thermococcales* isolated from marine hydrothermal vent environments, were shown to contain very low amounts of dibiphytanyl diglycerol tetraethers with cyclopentane rings (2,9,10). In these cases, it has been proposed that the polar groups of the ether lipids, extensively enriched in carbohydrates, would ensure the rigidity of the membranes and reduce their permeability (11).

Within the *Thermococcales*, the genus *Thermococcus* is represented by eight species and some new isolates recognized from their morphological, physiological, and molecular features (12–20). The type species, *T. celer*, exhibits a rather simple lipid composition with phosphatidylmyoinositol ester of phytanyl diether being the most abundant lipid (2) but, in sharp contrast, *T. chitonophagus* is characterized by a more complex composition in core lipids with the presence of diphytanyl glycerol diether and acyclic and monocyclic dibiphytanyl diglycerol tetraether derivatives (16). Recently, we examined *T. hydrothermalis*, a new hyperthermophilic heterotrophic archaeal species isolated from a deep-sea hydrothermal vent on the East Pacific Rise, for its neutral lipid and ether lipid composition.

MATERIALS AND METHODS

Materials. Silica gels for column chromatography (CC) (silica gel 60, 70–230 mesh) and thin-layer chromatography (TLC) (silica gel PF) were from Merck (Darmstadt, Germany). In-

frared (IR) spectra were recorded from carbon tetrachloride solutions in NaCl cells (0.1 mm), using a Perkin-Elmer 1420 (Norwalk, CT) spectrometer. ^{13}C nuclear magnetic resonance (NMR) spectra were obtained from deuterochloroform solutions, with tetramethylsilane as internal reference, on a Bruker 250 spectrometer (Wissenbourg, France). Standard *trans,trans*-lycopadiene was isolated from the green microalga *Botryococcus braunii* as previously described (21), and lycopane standard was prepared by catalytic reduction of *trans,trans*-lycopadiene (21). 6,10,14-Trimethyl pentadecan-2-one was prepared *via* ozonolysis of phytol (21). Standards of isopropyl esters were synthesized by refluxing (1 h) myristic, palmitic, and oleic acids in propan-2-ol, added with a few drops of acetyl chloride to generate hydrochloric acid. Concentration of the reaction mixtures under reduced pressure afforded the pure isopropyl esters. Standards of fatty acid methyl esters were prepared by refluxing separately (1 h) corresponding fatty acids in methanol, added with a few drops of acetyl chloride to generate HCl. Concentration of the reaction mixtures under reduced pressure afforded the pure methyl esters. Standards of ether lipids were obtained from *Caldariella*.

*Microorganism origin and culture conditions***.** The strain AL662^T was isolated from an active chimney and was recovered from a hydrothermal site on the East Pacific Rise. On the basis of phenotypic and phylogenetic analyses and DNA/DNA relatedness, this strain was recognized as a new species of the genus *Thermococcus* and the name *T. hydrothermalis* was adopted (19). Growth medium contained the following nutrients per liter of sea water: tryptone (1 g) (from Biokar Diagnostics, Beauvais, France), yeast extract (4 g) (from Bio-Springer, Maisons-Alfort, France), cystine (5 g) (from Merck), and sea salt (30 g) (from Europrix, Lens, France). The archaea was grown at 79°C for 23 h at pH 6.8 under N_2. The cells were harvested by centrifugation. The yield was approximately 1.7 g lyophilized cells/I.

Lipid extraction and fractionation. A first extraction of the lipids was performed on the lyophilized archaeal biomass (10 g), using dichloromethane/methanol (2:1, vol/vol; 450 mL) with stirring at room temperature, 2 × 18 h. The combined extracts were fractionated, after concentration under reduced pressure, by CC on silica gel in the proportion of 15 g silica for 180 mg lipids. Neutral lipids were first eluted by 305 mL chloroform. Polar lipids were recovered by elution with 1220 mL of acetone and then with 305 mL methanol. Neutral lipids were separated into five fractions (frs. I–V) by CC on silica gel (12 g), using heptane (45 mL; fr. I), heptane/diethyl ether (19:1, vol/vol; 60 mL; fr. II), heptane/diethyl ether (23:2, vol/vol; 75 mL; fr. III), heptane/diethyl ether (17:3, vol/vol; 115 mL; fr. IV), and diethyl ether (45 mL; fr. V). The residual biomass from the first extraction was further extracted with 380 mL of chloroform/methanol/water (1:2:0.8, by vol), buffered with sodium acetate, according to the Bligh and Dyer procedure (22), 2 × 3 h. To the combined supernatants, 60 mL of chloroform and 48 mL of water were added to generate a biphasic system; the chloroform phase was concentrated under reduced pressure.

The presence of lipids in the starting culture medium was also examined by extraction of 40 g lyophilized fresh medium with 500 mL dichloromethane/methanol (2:1, vol/vol), 2 × 18 h. The combined crude extracts were separated on silica gel CC by elution with chloroform, acetone, and methanol, and the culture medium neutral lipids were further separated into five fractions by silica gel as above.

Methanolysis of polar lipid fractions. Acetone and methanol eluates and Bligh and Dyer extract were separately subjected to acid methanolysis (20 mL of dry methanol/HCl, 1 N), at 100°C for 18 h in closed tubes. The reaction mixture was extracted with dichloromethane and then diethyl ether, and the organic phases were washed with water until neutrality. Fractionation of the concentrated extracts by preparative silica gel TLC using heptane/diethyl ether/methanol (4:1:1, by vol) as eluent afforded fatty acid methyl esters (R_f = 0.66), glycerol diether (R_f = 0.34), and diglycerol tetraether (R_f = 0.19). Diphytanyl glycerol diether **1** and dibiphytanyl diglycerol tetraether **2** were analyzed by fast atom bombardment–mass spectrometry (FAB–MS) (Micromasse ZAB-SEQ; Manchester, England) in positive mode *via* inclusion of the products in a nitrobenzyl alcohol matrix and addition of lithium chloride to provide ionized $[M + Li]^+$ species. Diphytanyl glycerol diether, **1**: FAB–MS (low resolution): $[C_{43}H_{88}O_3 + Li]^+$, observed *m/z* 659.7, calculated *m/z* 660.1. Dibiphytanyl diglycerol tetraether, **2**: FAB–MS (high resolution): $[C_{86}H_{172}O_6 + Li]^+$, observed *m/z* 1308.3344, calculated *m/z* 1308.3313.

Fatty acid methyl esters. These were identified by gas chromatography–mass spectrometry (GC–MS) analysis with an HP 5890 chromatograph coupled with an HP 5989 mass spectrometer (Hewlett-Packard, Evry, France) and coinjection with standards. The chromatograph was equipped with a CPSil-5CB fused-silica capillary column (25 m × 0.25 mm) coated with polydimethylsiloxane (Chrompack, Middleburg, The Netherlands). The temperature program was from 150 to 300°C (4°C/min).

Neutral lipid analyses. Neutral lipid fractions, fractions I–V, were analyzed by GC–MS (same spectrometer and CPSil-5CB column). The temperature programs were as follows: fraction I from 140 to 300°C (4°C/min); fractions II–V, from 100 to 300°C (4°C/min).

Diphytanyl glycerol diether **1** and dibiphytanyl diglycerol tetraether **2** were identified as free compounds in fraction IV by silica gel TLC, using heptane/diethyl ether/methanol (4:1:1, by vol) as eluent, and by comparison of their solvent front solvent ratio values (R_f = 0.34 and R_f = 0.19, respectively) with those of standards.

Ratios and amounts of the compounds were evaluated by weighing (ether lipids) and/or GC analyses with an internal standard (lycopane and lycopadiene, fatty acid methyl esters).

Catalytic reduction of C_{40} hydrocarbons. Hydrocarbons (2 mg) dissolved in 5 mL heptane were reduced with H_2 (25 atm), in the presence of catalytic amounts of rhodium (5%) on charcoal, at 40°C for 24 h. Then the catalyst was removed by filtration and the products analyzed by GC–MS (same conditions as for fr. I). Lycopane was identified by coinjection

and comparison of its mass spectrum with that of an authentic standard.

Ozonolysis. Fraction I (2 mg), dissolved in 2 mL dichloromethane was treated by ozone at −78°C until the characteristic blue color of ozone persisted. The excess ozone was then removed by bubbling nitrogen into the cold solution and thereafter the ozonides formed were reduced with triphenylphosphine (3 mg). The resulting solution was allowed to warm to room temperature and, after concentration under reduced pressure, directly analyzed by GC–MS (CPSil-5CB column; temperature programmed from 80 to 300°C, 4°C/min).

Dimethyl disulfide (DMDS) adduction. DMDS adducts were prepared as previously described (23). A portion of fraction I (2 mg) was treated in 100 mL of *n*-heptane by addition of 100 mL of DMDS and 1.2 mg of iodine in 20 mL of diethyl ether. The reaction was carried out in a 10-mL closed tube and kept for over 48 h at 50°C. Thereafter, 200 mL *n*-heptane was added to the reaction mixture, and the excess of iodine was reduced by treatment with 200 mL of an aqueous solution of 5% Na_2SO_3. After recovery of the organic phase, the aqueous phase was extracted for a second time with 200 mL *n*-heptane. The combined extracts were concentrated under a stream of nitrogen and immediately analyzed by GC–MS; the temperature was programmed from 240 to 300°C at 4°C/min.

RESULTS

Lipids extracted from the dry archaeal biomass with dichloromethane/methanol accounted for 4% of the dry weight. Silica gel CC allowed us to fractionate this extract into neutral lipids by elution with chloroform (accounting for 10% of the total extract) and polar lipids by elution with acetone (7.5%) and methanol (70%). Additional lipids were obtained from the extracted biomass by the procedure of Bligh and Dyer (22). They accounted for 0.9% of the dry weight. Acid methanolysis of the residual biomass did not furnish any other lipidic material.

Polar lipids. The polar lipid eluates and the Bligh and Dyer extract were submitted to acid methanolysis in order to release ether lipids in a free form. From the methanol-eluted fraction and the Bligh and Dyer extract, three bands were detected by silica gel TLC (R_f values: 0.66, 0.34, and 0.19) and separated by preparative TLC. FAB–MS analyses (at low and high resolutions), IR and ^{13}C NMR spectroscopies, and comparison with literature data (24) allowed us to establish that compounds exhibiting R_f values of 0.34 and 0.19 on TLC plates were diphytanyl glycerol diether **1** and dibiphytanyl diglycerol tetraether **2**, respectively. Moreover, a comparison of the ^{13}C NMR spectrum of the compound exhibiting the lowest R_f with literature data relative to ^{13}C NMR of cyclopentane-containing tetraethers (24,25) established clearly that no cyclopentane ring occurs in the tetraethers of *T. hydrothermalis.* Dibiphytanyl diglycerol tetraether **2** accounted for *ca.* 43 and 63 wt% of the ether lipids of the methanol-eluted fraction and the Bligh and Dyer extract, respectively.

The farther eluted compounds (R_f = 0.66) consisted in low amounts of fatty acid methyl esters. Through GC–MS analysis, palmitate (16:0, 42.5%), oleate (18:1 *cis* Δ9, 17.5%), stearate (18:0, 15%), laurate (12:0, 7.5%), palmitoleate (16:1 *cis* Δ9, 5%), and myristate (14:0, 5%) were the main fatty acid components identified.

No ether lipid could be detected from the hydrolysis of the acetone-eluted fraction. In this case, only fatty acid methyl esters were isolated. They exhibited a composition similar to that found for the methanol-eluted fraction and the Bligh and Dyer extract. All these methyl esters were also obtained from the acid methanolysis of the polar lipidic fractions of the culture medium extract. This indicates that they are not biosynthesized by the archaea.

On a whole, the ether lipids recovered from methanolyses and purified by TLC accounted for 0.32% of the dry biomass, dibiphytanyl diglycerol tetraether **2** showing a slight predominance (55%).

Neutral lipids. Table 1 shows results concerning the fractionation of the neutral lipids by silica gel CC and the composition of the different fractions.

Fraction I exclusively contained hydrocarbons. GC–MS analysis showed the presence of a range of normal chain hydrocarbons (unsaturated C_{16} and C_{18}, saturated C_{16} to C_{36}) and four C_{40} isoprenoid compounds. Formation of DMDS adducts of the C_{16} and C_{18} alkenes, followed by GC–MS analysis of these products, allowed us to identify four *n*-hexadecenes (Δ2, Δ3, Δ4, and Δ5) and five *n*-octadecenes (Δ2, Δ3, Δ4, Δ5, and Δ6). The analysis of the neutral lipids isolated from the fresh culture medium showed, however, the presence of all these normal hydrocarbons. Thus, only the C_{40} isoprenoid compounds can be considered as metabolites of the *Thermococcus* strain.

Two $C_{40}H_{78}$ and two $C_{40}H_{76}$ hydrocarbons, with two and three degrees of unsaturation, respectively, were identified (Fig. 1). Catalytic reduction of fraction I led to a single $C_{40}H_{82}$ compound other than the nonarchaeal normal alkanes; this hydrocarbon was found to coelute on GC analysis with lycopane (2,6,10,14,19,23,27,31-octamethyldotriacontane), an acyclic tetraterpane. The formation of lycopane through hydrogenation was confirmed by the similarity of its mass spectrum with the one of an authentic standard. The C_{40} hydrocarbons in fraction I thus correspond to two tetradehydrolycopanes (lycopadienes; 35 and 27% of the C_{40} mixture) and two hexadehydrolycopanes (lycopatrienes; 24 and 14% of the C_{40} mixture).

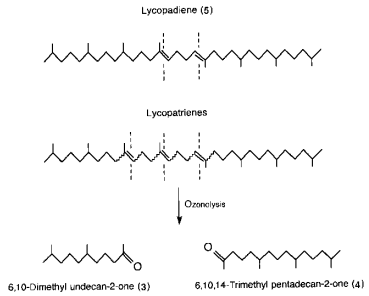
DMDS adducts of the unsaturated C_{40} afforded a very complex mixture of derivatives which did not allow us to determine the position of the unsaturations; instead, this was achieved by means of ozonolysis of the C_{40} dienoic and C_{40} trienoic mixture. GC–MS analysis of the compounds obtained from the reductive degradation of the ozonides indicated the formation of the 6,10-dimethyl undecan-2-one **3** and 6,10,14-trimethyl pentadecan-2-one **4** in a 4:1 ratio (Scheme 2). The nature of these ketones and the relative percentages of the dienic and trienic hydrocarbons strongly suggested that unsaturations occur at positions 14 and 18 in the lycopadienes and at positions 10, 14, and 18 in the lycopatrienes. (Nevertheless, ozonolysis does not allow for the identification of double-bond stereochemistry.)

TABLE 1
Composition of Neutral Lipids Extracted from the Archaeal Biomass[a]

Column chromatography fraction	Percentage of neutral lipids	Percentage of dry weight	Composition[b]
I	20.0	0.08	Normal hydrocarbons: (unsaturated C_{16}*–C_{18}*, saturated C_{16}*–C_{36}*), C_{40} isoprenoid hydrocarbons
II	22.5	0.09	Fatty acid isopropyl esters*, squalene*
III	10.0	0.04	Phytol*, DGD **1**
IV	8.7	0.03	DDT **2**, steroids*, triterpenoids*
V	11.3	0.05	Steroids*, triterpenoids*

[a]In addition to archaeal compounds (ether lipids, lycopadienes, and lycopatrienes), these fractions contain large amounts of nonarchaeal lipids (indicated by * in the Table) originating from the culture medium. Regarding nonarchaeal hydrocarbons, note that the growth medium contained a high amount of yeast extract; and normal hydrocarbons from C_{10} to C_{39} are known to occur commonly in yeasts (26). Moreover, the growth medium is composed of 40 g of nutrients per liter. Accordingly, even if the nutrients contain very low levels of lipidic contaminants, the latter should be present in substantial amounts when compared to the lipids of the archaea (*ca* 1.7 g of dry biomass containing less than 1 mg of free ether lipids and *ca*. 0.7 mg of lycopadienes and lycopatrienes from 1 L of culture). Moreover, to avoid cell lysis, the archaeal biomass was not washed after centrifugation, so nonarchaeal lipids may have been adsorbed on the cells. Additionally, lipids from the culture medium may have been incorporated by *Thermococcus hydrothermalis* as xenobiotic compounds.
[b]DGD **1** = diphytanyl glycerol diether, DDT **2** = dibiphytanyl diglycerol tetraether.

Furthermore, the major lycopadiene was found to coelute on GC analysis with the *trans*,*trans*-lycopadiene **5**, unsaturated at position C-14 and C-18 and previously isolated from a freshwater green microalga, *Botryococcus braunii* (21). Moreover, both compounds exhibited the same mass spectrum, thus demonstrating similar structures; the mass spectra of the derived lycopane, archaeal *trans*, *trans*-lycopadiene, and one lycopatriene are shown in Figure 2. Based on ozonolysis and on the identification of this C_{40} diene, the second diene should correspond to the *trans, cis*- or *cis, cis*-lycopadiene. The stereochemistry of the C_{40} trienes has not been determined. On the whole, the hydrocarbons structurally related to lycopane accounted for 54% of fraction I and *ca.* 0.04% of the dry archaeal biomass.



SCHEME 2

Based on IR and GC–MS analyses, fraction II was shown to comprise mainly a series of saturated and monounsaturated *n*-C_{14}, *n*-C_{16}, and *n*-C_{18} fatty acid isopropyl esters and low amounts of squalene. All these compounds were identified in the neutral lipids isolated from the culture medium extract, thus precluding an archaeal origin. Similarly, phytol, cholesterol, 4-cholesten-3-one, sitosterol and α-amyrin, all found in trace amounts in the more polar CC fractions, were shown to originate from the culture medium.

Finally, TLC of fractions III and IV revealed the presence of free diphytanyl glycerol diether **1** and dibiphytanyl diglycerol tetraether **2** in very low amounts.

DISCUSSION

The ether lipids of *T. hydrothermalis* are characterized by a slight dominance of dibiphytanyl diglycerol tetraethers over diphytanyl glycerol diethers. Similar ether lipid profiles have been reported to occur in several Archaea of the order of *Thermococcales*, including some *Thermococcus* species (6,27,28). It was considered that the tetraether/diether ratio tends to increase with the temperature of growth and could be

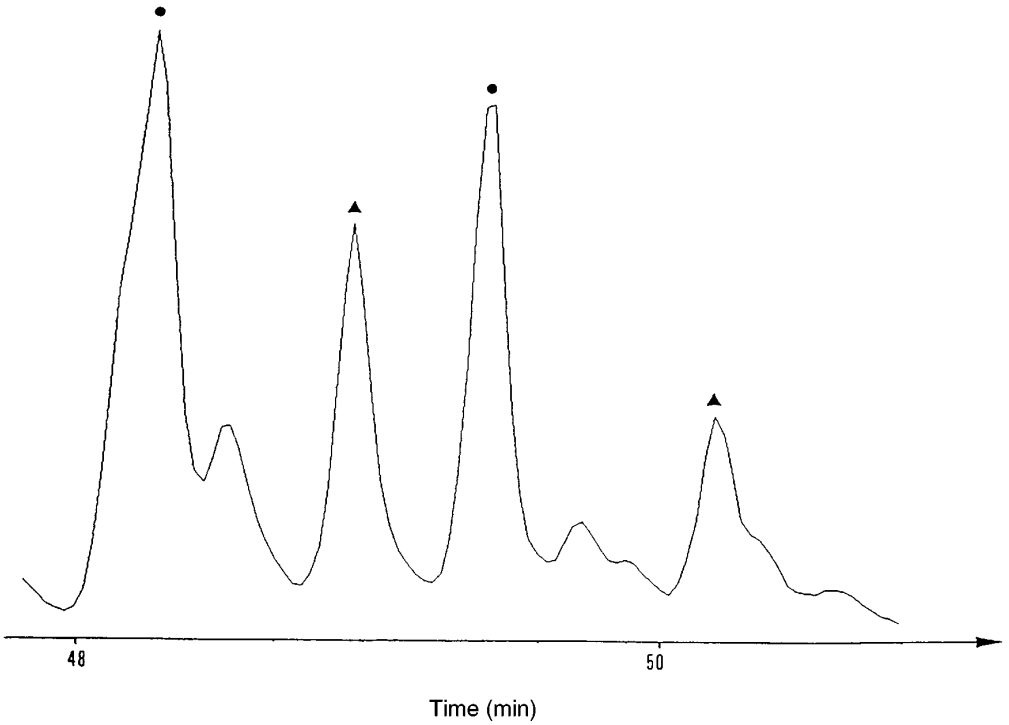


FIG. 1. Gas chromatographic trace of the C_{40} isoprenoid compounds. ●, $C_{40:2}$ isoprenoid; ▲, $C_{40:3}$ isoprenoid.

qualified as a temperature-related adaptative feature. However, as suggested by some authors (6), the exclusive presence of diethers in some other species of this genus precludes the use of the tetraether/diether ratio as a criterion for classification of this hyperthermophilic Archaea. Furthermore, no cyclopentane ring occurs in the tetraethers. Accordingly, as previously suggested for other Archaea isolated from deep-sea hydrothermal vent environments (11), it is very likely that the polar head groups of the ether lipids reinforce the membrane rigidity of these microorganisms growing at elevated temperatures in such environment.

Trace amounts of free diphytanyl glycerol diether and dibiphytanyl diglycerol tetraether were detected in the neutral lipids of *T. hydrothermalis*. This occurrence has previously been noticed for some other Archaea (29–32). However, the most important feature observed from neutral lipid analysis in this species is the identification of hydrocarbons structurally related to lycopane. To date, some hydocarbons have been clearly identified only in two groups of Archaea. Thus, in halophilic archaea, squalene and hydrosqualenes have been identified, and C_{15}, C_{20}, C_{25} and C_{30} isoprenoids in methanogens (8,31,33–35). The presence of compounds exhibiting a low polarity, which may thus correspond to hydrocarbons but for which the structure was not examined, has been previously reported in a very limited number of cases in the lipids of thermoacidophilic Archaea (29,36,37). The tetraterpenoid hydrocarbons, lycopadienes, and lycopatrienes identified in *T. hydrothermalis* arise, based on the structure of the central part of these molecules, from the tail-to-tail condensation of two diterpene derivatives. In sharp contrast, the C_{40} chains of the tetraethers are formed *via* a head-to-head linkage of two phytanyl residues. Two different biosynthetic pathways for the production of C_{40} isoprenoid chains seem therefore to coexist in *T. hydrothermalis*. The taxonomic value of these C_{40} hydrocarbons with a lycopane-type skeleton in Archaea, especially in the order of *Thermococcales*, remains to be established. To date, the dominant hydrocarbon of *T. hydrothermalis* had been identified only in a freshwater green microalga, *Botryococcus braunii* (21).

Unsaturated hydrocarbons show a well-known and general trend to be reduced into alkanes during the first step of fossilization in surface sediments. Accordingly, the occurrence of lycopane-related hydrocarbons in an Archaea is important from a geochemical point of view. Indeed, it is well documented that lycopane is widely distributed in oceans—concentrations up to 1.5 ng/L of seawater have been measured (38)—and its presence in some marine sediments has been noted (39–42); its origin, however, remains unknown.

The identification of potential geochemical precursors of lycopane in *T. hydrothermalis* gives some support to a previous assumption for an archaeal origin of this biomarker (39). In this respect, it is important to note that lycopane and archaeal ether lipids have been found together in a same sediment (43). The present finding does not rule out, however, a photoautotrophic source for lycopane (38), especially in oxic marine waters.

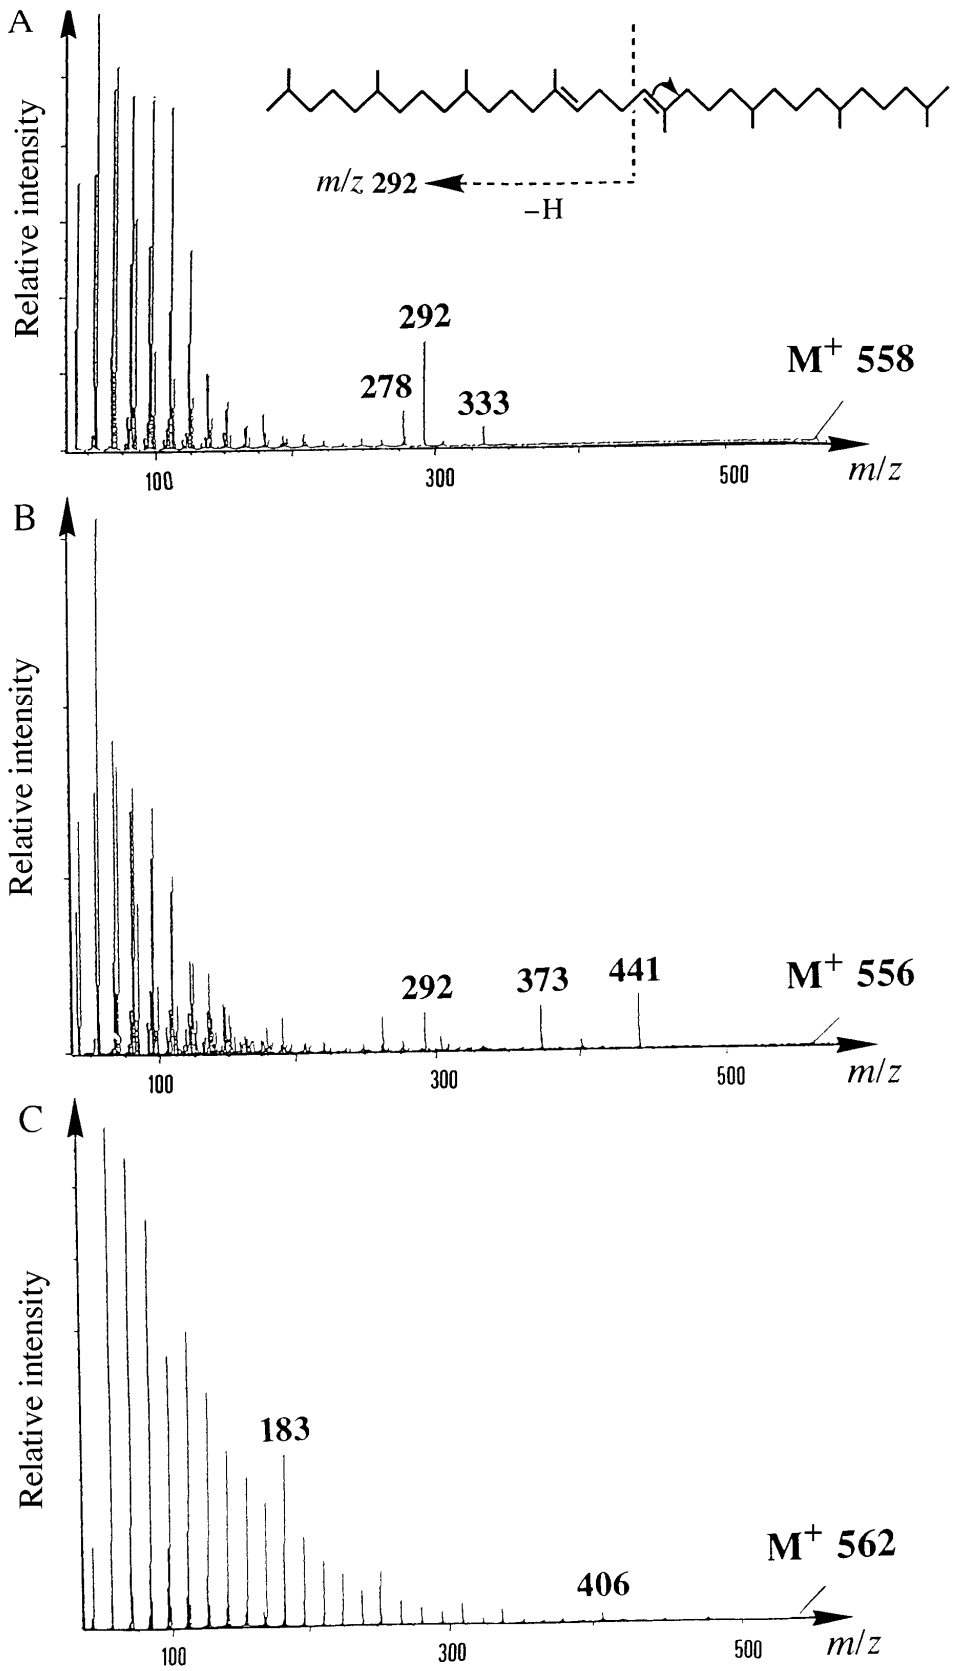

FIG. 2. Mass spectra of *trans,trans*-lycopadiene (A), first eluted lycopatriene (see Fig. 1) (B), and lycopane (C).

Fatty Acid Composition of the Cellular Slime Mold *Polysphondylium pallidum*

Tamao Saito* and Hiroshi Ochiai

Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo, 060-0810 Japan

ABSTRACT: The cellular slime mold *Polysphondylium pallidum* was grown upon *Escherichia coli* B/r, and the fatty acid compositions of total lipids obtained from vegetative amebae and aggregation-competent cells were compared. Fatty acids isolated from vegetative cells included C-17 and C-19 cyclopropane fatty acids and also straight-chain, saturated fatty acids. The cyclopropane fatty acids were derived from the ingested bacteria. Development of amebae to aggregation-competent cells was accompanied by a substantial decrease in saturated cyclopropane fatty acids and a concomitant increase in unsaturated fatty acids and unsaturated cyclopropane fatty acids, mostly as 18:3 (5,9,12). We report here the fatty acid composition and identify the occurrence of Δ5 desaturation of cyclopropane fatty acids, namely, 9,10-methylene 5-hexadecenoic acid and 11,12-methylene 5-octadecenoic acid. These fatty acids have not been reported previously in the related species *Dictyostelium discoideum,* which also feeds on *E. coli* B/r and has Δ5-desaturation activity.

Lipids 33, 327–332 (1998).

A wild-type strain (WS320) of the cellular slime mold *Polysphondylium pallidum* grows upon *Escherichia coli* B/r as a food source; lack of food (starvation) triggers a well-characterized pattern of development which begins with the aggregation of individual amoebae and culminates in a multicellular fruiting body. *Polysphondylium pallidum* is an excellent model system for study of cell–cell interactions. Knowing the fatty acid composition is the first step in obtaining information with regard to membrane fluidity in relation to the cell–cell interaction. Many unusual fatty acids have been found in cellular slime molds, and the unsaturation patterns of fatty acids in *Dictyostelium discoideum* have been reported (1–3), but only a few chemical studies have been published on the fatty acids of a related species *P. pallidum* (4).

Cyclopropane fatty acids have been mainly noted in *E. coli* (5), and are formed by a postsynthetic modification of the unsaturated fatty acids of membrane phospholipids (6). The reaction involves the addition of a CH_2 group from *S*-adenosylmethionine to the double bond of a fatty acid to form the cyclopropane ring. To determine the membrane components of the cells involved in cell–cell interactions, we have now analyzed the fatty acids of *P. pallidum*. In this study, we determined the fatty acid composition and identified Δ5 desaturation in C-17 and C-19 cyclopropane fatty acids that also have a cyclopropane ring at Δ9 and Δ11 positions, respectively. These fatty acids have not been reported in *D. discoideum,* which also feeds on bacteria and has Δ5 desaturation.

EXPERIMENTAL PROCEDURES

Cell culture. Cells of *P. pallidum* strain WS320 were cultured with or without *E. coli* B/r as described previously (7,8) to the density of 2–5 × 10^6 cells/mL. At this stage, cells were harvested as vegetative cells (t_0). To obtain aggregation-competent cells ($t_{6.5}$), vegetative cells were washed with 17 mM phosphate buffer (pH 6.2) and resuspended at a density of 1 × 10^7 cells/mL and incubated for 6.5 h. The food source bacterium, *E. coli* B/r, was cultured in Luria-Bertani medium at 37°C, 150 rpm for at least 20 h to be a stationary phase.

Chemical materials. Silica gel plates for thin-layer chromatography (TLC) were purchased from E. Merck (Darmstadt, Germany). Hydrazine hydrate was from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Dimethyl disulfide and pyrrolidine were supplied from Nacalai Tesque (Kyoto, Japan). All other chemicals were of the highest grade available.

Preparation of lipids and fatty acids. Total lipids were extracted by the method of Bligh and Dyer (9) from the vegetative-growth phase and 6.5-h starved wet cells as described above. Alkaline methanolysis of the total lipids released ester-linked fatty acids as methyl esters. The total fatty acid methyl esters (FAME) were separated according to the degree of unsaturation by argentation TLC (AgTLC) on a silica gel plate with a solvent system of chloroform/ethanol (99:1, vol/vol). After the plate had been developed, it was dried and sprayed with acetone/water (4:1, vol/vol) containing 0.01% primuline. The spots were detected under ultraviolet light. Each FAME was extracted with a mixture of hexane, methanol, and 500 mM NaCl in water (2:1:1, by vol) from the silica gel that had been scraped from the plate, dried, and then redissolved in hexane.

Derivatization and mass spectrometry. FAME were then

Abbreviations: AgTLC, argentation TLC; DMDS, dimethyl disulfide; FAME, fatty acid methyl ester; GC, gas chromatography; GC–MS, gas chromatography–mass spectrometry; TLC, thin-layer chromatography.

analyzed by gas chromatography (GC) (model 263-30; Hitachi, Tokyo, Japan) using a flame-ionization detector and capillary column (CPS-1; 50 m × 0.25 mm, i.d.; Quadrex, New Haven, CT). The separated FAME were identified by comparing their retention times with those of authentic standards and by GC–MS, and were quantitated with a data analyzer (Chromato-Integrator D-2500; Hitachi) as previously described (10). Hydrogenation was carried out in glacial acetic acid with PtO_2 as a catalyst at room temperature for 6 h (11). The position of the double bond in the FAME was determined by the pyrrolidine method (12), and by an I_2-catalyzed reaction for the formation of the adducts with dimethyl disulfide (DMDS) according to a minor modification (13) of the procedure of Shibahara *et al.* (14). Pyrrolidine adducts and DMDS adducts were analyzed on a slightly polar HP-5 column (30 m × 0.32 mm, i.d.; Hewlett-Packard, Palo Alto, CA) in a Hewlett-Packard HP-5890 gas chromatograph coupled to a JMS-AX500 mass spectrometer (Jeol, Tokyo, Japan). The column temperature was increased from 260 to 300°C and from 230 to 330°C at a rate of 2°C/min for the pyrrolidine adducts and DMDS adducts, respectively. Hydrazine-reduced and hydrogenated fatty acids were analyzed by GC and GC–MS as described above.

RESULTS AND DISCUSSION

The lipid compositions from the cellular slime mold *P. pallidum* were examined at the different stages of development by two-dimensional TLC to see the changes in the composition of membrane lipids occurring during cell aggregation. We obtained 21–31 mg of total lipids from 1×10^9 cells by the method of Bligh and Dyer (9). The major phospholipid classes were shown to be phosphatidylethanolamine, phosphatidylcholine, phosphatidylinositol, and phosphatidic acid. These results are essentially the same with those of *D. discoideum* (15). For further analysis, total lipids were extracted from cells at both the growth and aggregation-competent phases, and subjected to alkaline methanolysis. In mixed cell suspensions, *D. discoideum* and *P. pallidum* form common aggregates, but the two cell types are sorted out within the aggregate during the aggregation-competent stage (16). This suggests that some membrane components may be involved in cell recognition during the aggregation-competent stage.

The resultant FAME were fractionated by AgTLC which separates the subcomponents according to the degree of unsaturation, and we were able to detect saturated, monoenoic, dienoic, and trienoic fractions in the cellular slime mold *P. pallidum*.

We analyzed the monoenoic fraction by a capillary GC (Fig. 1A) and by the pyrrolidine method (12) to determine the positions of double bonds. The mass spectra of the pyrrolidide derivatives of these acids disclosed the unexpected presence of two dienoic-like fatty acids in a monoenoic fraction (Fig. 1 A, peaks 1 and 2), which had co-migrated with *cis*-monoenoic fatty acids on an above-mentioned AgTLC plate. The pyrrolidine method enabled us to estimate peaks 1 and 2 as 17:2(5,9) and 19:2(5,11), respectively (data not shown). To confirm the position of the double bond, we subjected the monoenoic fraction to an I_2-catalyzed reaction for the formation of the adducts with DMDS (13,14). Figure 2 shows the mass spectra of the DMDS adducts of peak 1 and 2 methyl esters, respectively. The mass spectra indicated only Δ5 desaturation in peaks 1 and 2. If the reaction had been incomplete, other typical fragment ions that implicate the desaturation must have appeared at other positions (i.e., Δ9 or Δ11); actually, no other typical fragmentation was detected. To clar-

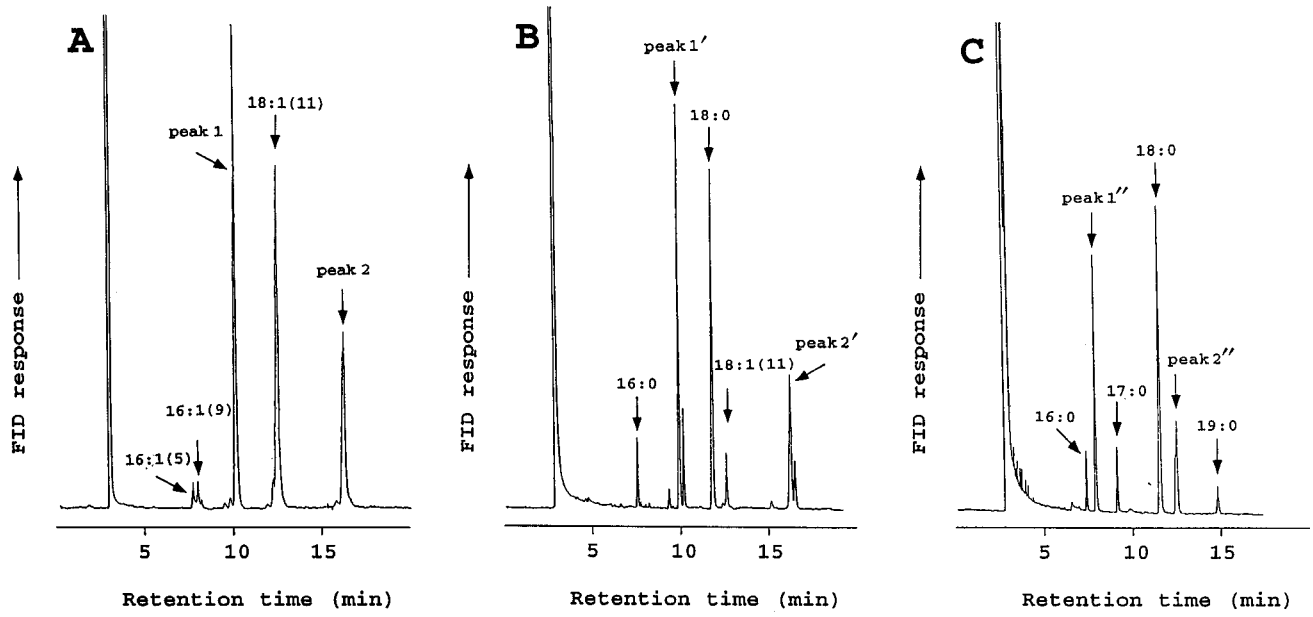

FIG. 1. Gas chromatograms of methyl esters of a monoenoic fraction. (A) Before hydrazine reduction, (B) after hydrazine reduction, and (C) after hydrogenation in glacial acetic acid of a hydrazine-reduced monoenoic fraction.

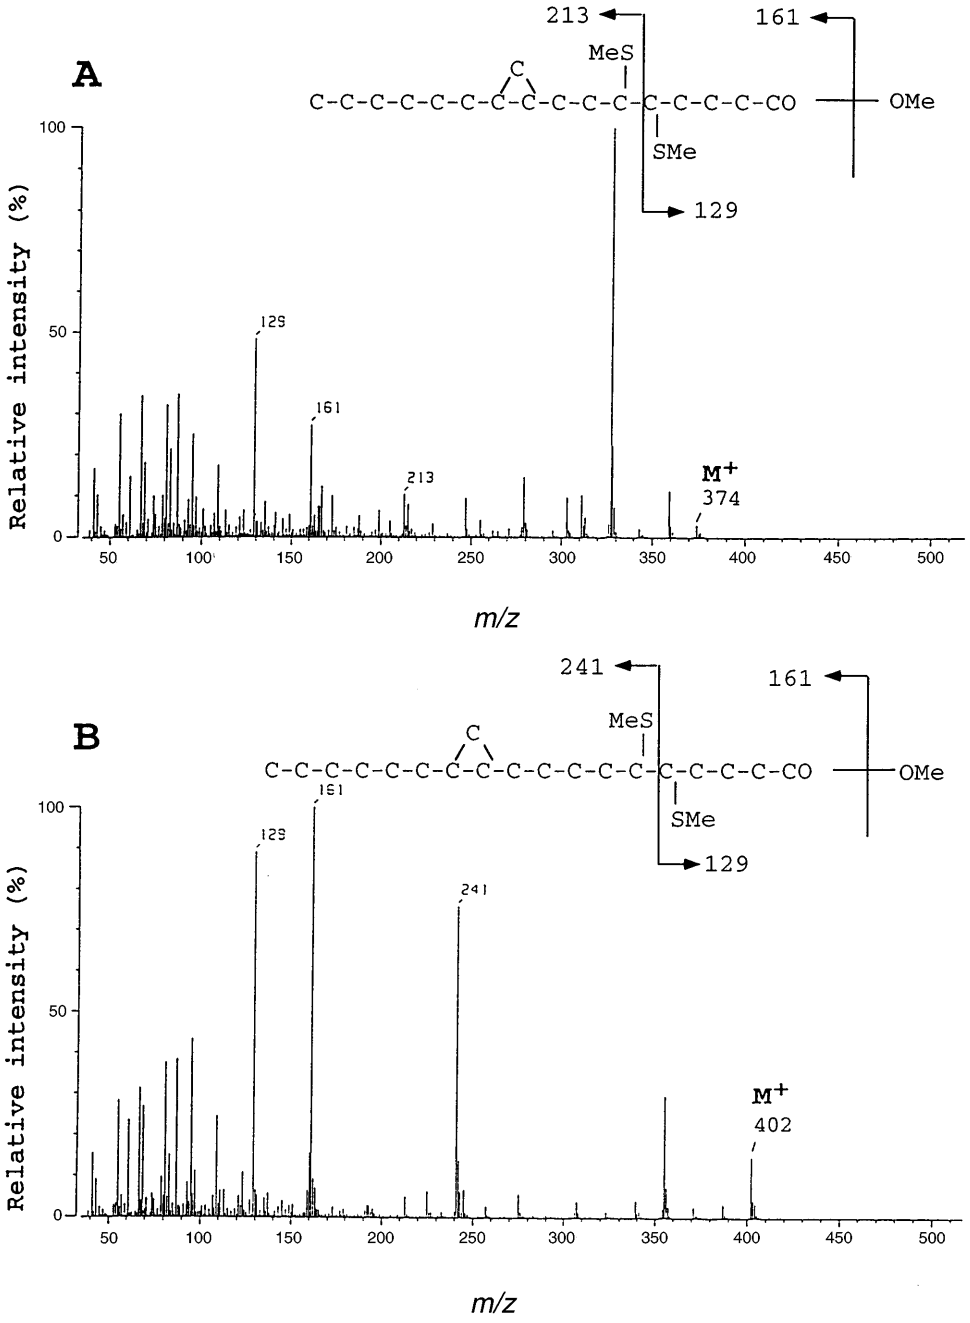

FIG. 2. Mass spectra of dimethyldisulfide (DMDS) adducts of peaks 1 (A) and 2 (B) acid methyl esters. Fragmentation scheme of DMDS adducts of these fatty acids is also indicated.

ify the inconsistency between these results, the monoenoic fraction was subjected to a hydrazine reduction, which reduces double bonds without geometrical or positional isomerization (14), to test whether a standard material (9,12-octadecadienoic fatty acid) can be reduced. It could. It was almost completely reduced to the saturated octadecanoic acid. The hydrazine-reduced monoenoic fraction was then subjected to capillary GC (Fig. 1). Peaks 1 and 2 shifted to the positions of cyclopropane or monoenoic acids, but not the saturated acids (Fig. 1B, peaks 1′ and 2′).

To clarify the issue further, we measured the mass spectra of peaks 1′ and 2′ reduced with hydrazine (data not shown). The results were similar to those recorded for *cis*-cyclopropane fatty acids described previously (17), and we therefore speculated that peaks 1 and 2 were cyclopropane monoenoic fatty acids. A method used to confirm the identity of this estimated structure was a combined procedure: a monoenoic fraction was reduced with hydrazine (14), and then subjected to hydrogenation in glacial acetic acid (11). Any cyclopropane fatty acid esters before the hydrogenation

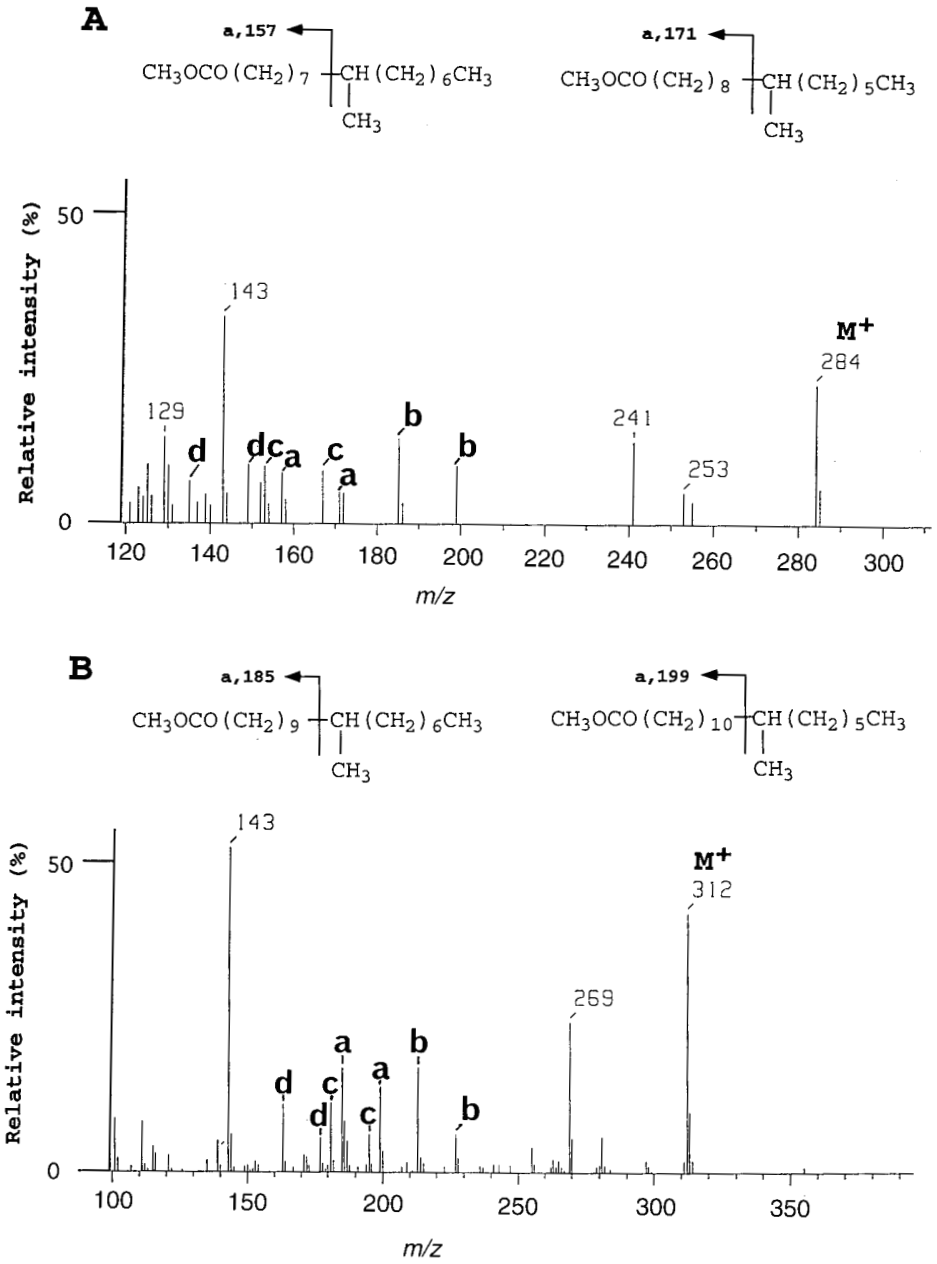

FIG. 3. Partial mass spectra of peaks 1″ and 2″ after hydrogenation in glacial acetic acid. Origins of the most common peaks in these spectra are summarized in Table 1. (A) The branched-acid esters derived from 9,10-methylene hexadecanoic acid. (B) The branched-acid esters derived from 11,12-methylene octadecanoic acid.

would now be a mixture of branched-chain and straight-chain fatty acid esters (11). Mass-spectral analysis of the mixture of branched-chain acid esters permits assignment of the position of the methyl groups: the position, that is, of the cyclopropane ring in the parent acids (11). Figure 1C shows a capillary GC trace of FAME from a hydrazine-reduced, hydrogenated monoenoic fraction. Peaks 1′ and 2′ shifted, respectively, to peaks 1″ and 2″, the positions of the branched-chain fatty acids, although about 15% of peaks 1′ and 2′ shifted to the saturated fatty acids. The partial mass spectra of peaks 1″ and 2″ are shown in Figure 3. The origins of the most common peaks in these spectra are summarized in Table 1. The location of the cyclopropane ring *via* the branch location is indicated by ions a, a+1 which were formed by α cleavage to the points of branching and abstraction of one hydrogen. The resulting characteristic sets of two adjacent peaks 14 mass units apart are easily recognized and used to establish the points of branching as shown by Figure 3 and Table 1. These results (Fig. 3 and Table 1) enabled us to identify peaks 1′ and 2′ *cis*-9,10-methylene hexadecanoic acid and *cis*-11,12-methylene octadecanoic acid. Finally, we conclude that peaks 1 and 2 in Figure 1 are all *cis*-9,10-methylene hexadeca-5-enoic acid

TABLE 1
The Origins of the Most Common Peaks

Designation in figures	Origin	*m/z*
a	$CH_3OCO(CH_2)n+$[a]	157, 171 185, 199
a + 1	Rearrangement of one and two hydrogens from the remainder of the molecule to a	158, 172 186, 200
b	$CH_3OCO(CH_2)nCH^+$ $\vert$ CH_3	185, 199 213, 227
c	Formed predominantly by elimination of CH_3OH from b	153, 167 181, 195
d	Due to elimination of H_2O from c	135, 149 163, 177

[a]*n,* Indicates the position of branching.

[a]The above data were indicated by relative % (w/w) to the total lipid extracted from swollen cells. Vegetative stage cells (t_0) and aggregation competent cells ($t_{6.5}$) were analyzed according to the Experimental Procedures section.
[b]Indicates several unidentified minor components.

and all *cis*-11,12-methylene octadeca-5-enoic acid, and the scheme is shown in Figure 2. The percentage of these fatty acids in total fatty acids increased in the cells that had been starved for 6.5 h in shaken suspension without bacteria (Table 2), but not in just-harvested cells of bacterially grown, vegetative growth-phase cells, indicating that all *cis*-9,10-methylene hexadeca-5-enoic acid and all *cis*-11,12-methylene octadeca-5-enoic acid are actual metabolites of this organism.

To clarify the origin of these cyclopropane fatty acids, we also analyzed the fatty acids of axenically grown cells. Under these conditions, *Polysphondylium* cells grow normally and make aggregates. We could not, however, detect any cyclopropane fatty acids in the axenically grown cells (Fig. 4). The most reasonable explanation is that *P. pallidum* took saturated cyclopropane fatty acids from bacteria and converted them into unsaturated cyclopropane fatty acids using an endogenous Δ5 desaturase. This idea is supported by C-17 and C-19 cyclopropane fatty acids being the major lipid components of *E. coli*. We analyzed the fatty acid compositions of *E. coli* B/r and obtained results that were similar to previous reports (5).

On the other hand, it is known that *D. discoideum* wild-type strain, which contains Δ5-desaturated fatty acids, is also able to grow upon bacteria, and contains only saturated cyclopropane fatty acids but not desaturated ones (1), although we could not explain from where the difference between *D. discoideum* and *P. pallidum* was derived. In contrast, there are reports describing the inhibition of fatty acid Δ5- and Δ6-desaturation in liver microsomes of rats which were fed with baobab seed oil containing cyclopropane fatty acids but not heated oil practically devoid of cyclopropane fatty acids (18). Figure 1 shows that *Polysphondylium* contains an equal amount of 16:1 (5) and 16:1 (9). Taken together, it is speculated that *P. pallidum* cells have Δ5 desaturase whose specificity was not reported before. Cyclopropane fatty acids are one of the major types of fatty acids found in *E. coli* and other bacteria. These acids are formed by a postsynthetic modification of the unsaturated fatty acids of membrane phospholipids. Many functions have been proposed for cyclopropane fatty acids. However, *E. coli* Cfa-mutants completely defective with a cyclopropane synthetase grew and survived under various environmental stresses similar to strains which are able to synthesize cyclopropane fatty acids originally (19). It is not known, at present, whether the desaturation of cyclopropane fatty acids during aggregation is necessary or not.

Finally, it may be meaningful to address an evolutionary significance: when an organism feeds on some other organism as a new food source, the organism may be not able to employ a previously unencountered metabolite (in this case, cyclopropane), but during a long time the organism might acquire an ability (by addition of a new gene to the genome) to employ an ingested metabolite useful for the cells. The above result may be a mechanism promoting evolution. Although the obtained characteristics may have only a subtle effect on the survival of the cells, the mechanism may promote addition of a particular gene to a given species.

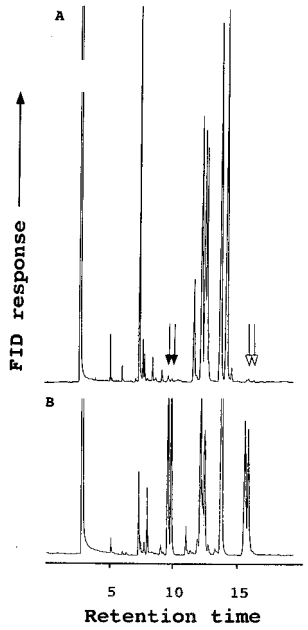

FIG. 4. Mass spectra of total fatty acid methyl esters of axenically grown cells (A) and bacterially grown cells (B). Arrows indicate the positions of the C17 cyclopropane fatty acid, 9,10-methylene hexadeca-5-enoic acid (closed) and C19 cyclopropane fatty acid, 11,12-methylene octadeca-5-enoic acid (open), respectively. In axenically grown cells, we could not detect any cyclopropane fatty acids, although we can see small peaks at the positions of closed arrow. The positions of C17 cyclopropane fatty acid and 9,10-methylene hexadeca-5-enoic acid are identical with those of 17:1 and 17:2.

ABSTRACT: In recent years, defects of bile acid synthesis caused by disorders of peroxisome biogenesis have led to increased interest in C_{27} bile acids. In humans, while the majority of bile acids are C_{24} carboxylic acids, the presence of increased concentrations of C_{27} bile acids and their metabolites in hereditary diseases associated with peroxisomal dysfunction can serve as a useful marker for the intensity of the metabolic disorder. Our present studies describe an efficient method for the rapid hydrolysis of C_{27} and C_{24} bile acid conjugates using a commercial microwave oven. The advantages of this method include freedom from racemization, minimal activation, mild reaction conditions, and the highly stereocontrolled nature of the reaction, thus allowing for free bile acid recovery in high yield. For example, when (25*R*) 3α,7α,12α-trihydroxy-5β-cholestan-26-oyl taurine, a major compound present in the bile of *Alligator mississippiensis*, was deconjugated with 4% NaOH/diethylene glycol or 1 M LiOH/propylene glycol in the microwave oven for 4–6 min, 3α,7α,12α-trihydroxy-5β-cholestan-26-oic acid (THCA) was obtained in 81% yield with retention of configuration at C-25. It is suggested that present studies will be helpful in delineating the absolute stereochemistry of 3α,7α,12α-trihydroxy-5β-cholestanoyl-CoA oxidase, the peroxisomal enzyme that catalyzes the first step in the oxidation of THCA.
Lipids 33, 333–338 (1998).

Several genetic diseases, including disorders of peroxisome biogenesis such as Zellweger syndrome, have been described (1–3) in which abnormal bile acid metabolism is characteristic of the primary defect (4,5). The presence of abnormally high plasma levels of 3α,7α,12α-trihydroxy-5β-cholestan-26-oic acid (THCA) and of 3α,7α-dihydroxy-5β-cholestan-26-oic acid in Zellweger syndrome has resulted in increased interest in these C_{27} bile acid intermediates and their intact conjugates which are usually absent or present in very low concentrations in normal humans (4,5).

In mammals, the naturally occurring bile acids are C_{24} carboxylic acids which are formed from cholesterol in the liver. After their biosynthesis, their sidechain is amidated with glycine or taurine to form *N*-acyl conjugates which are secreted into the bile and stored in the gallbladder (6–8). However, in order to analyze them by gas–liquid chromatography (GLC), it is necessary to carry out the hydrolysis of the C_{24} and C_{27} amide bonds to give C_{24} and C_{27} free carboxylic acids. Hydrolysis of bile acid amides has traditionally been carried out by vigorous saponification in [15% NaOH/50% aqueous ethanol at 115–120°C,10 h in a Parr bomb, Compound **I**, Scheme 1, and Compound **I**, Scheme 2 (9)]. These drastic reaction conditions are unsuitable because many broken-down products are produced leading to decreased yield. Also, such reaction conditions frequently lead to isomerization of the stereogenic center at C_{25} in the taurine or glycine conjugates of THCA (Compound **III**, Scheme 2) (9,10). The commercially available bacterial enzyme, bile salt hydrolase or cholylglycine hydrolase (CGH), has been utilized in hydrolyzing an unactivated and sterically unhindered amide bond of tauro- and glyco-conjugates of the normally occurring C_{24} bile acids (Compound **I**, Scheme 1) (11). A careful and systematic study on the relationship of chemical structure (nuclear or sterically hindered side chain) to the enzymatic hydrolysis of conjugated bile salts recently has been reported by Huijghebaert and Hofmann (12). These results as well as the report of Batta *et al.* (13) suggest that a sterically hindered amide bond or alteration of the length of the side chain in bile acid conjugates causes significant resistance to hydrolysis by CGH (12–15). For example, this enzyme has been found to be ineffective in cleaving the taurine and glycine conjugates of THCA (Compound **III**, Scheme 2) (16), a major C_{27} bile acid found in patients with Zellweger syndrome (4,5) as well as a normal component in the bile of *Alligator mississippiensis* (17,18). ney and Vessey (19) and Kimura *et al.* (20) have demonstrated that C_{23} nor-cholyltaurine and ursodeoxycholylsarcosine are resistant to hydrolysis by CGH.

Our interest in the hydrolysis of bile acid amides stems from ongoing research on the microwave-induced organic reactions of bile acids and bile alcohols (18,21–24). This paper describes an efficient method for the rapid hydrolysis of C_{24} and C_{27} amidated bile acids using a commercial microwave oven (MW). This methodology, which recently has been used for saponification, acetylation, amidation of free bile acids, and rapid hydrogenation of unsaturated sterols and bile alcohols (18,21–25), will be shown to hydrolyze the amidated C_{24} and C_{27} bile acids with high yield and with a high degree of purity. For example, the taurine conjugate of 25*R* diastereomer of THCA (C_{27} amidated bile acid) when subjected to microwave heating conditions yielded a single diastereoisomer of the C_{27} bile acid with retention of original configuration (Compound **II**, Scheme 2).

EXPERIMENTAL PROCEDURES

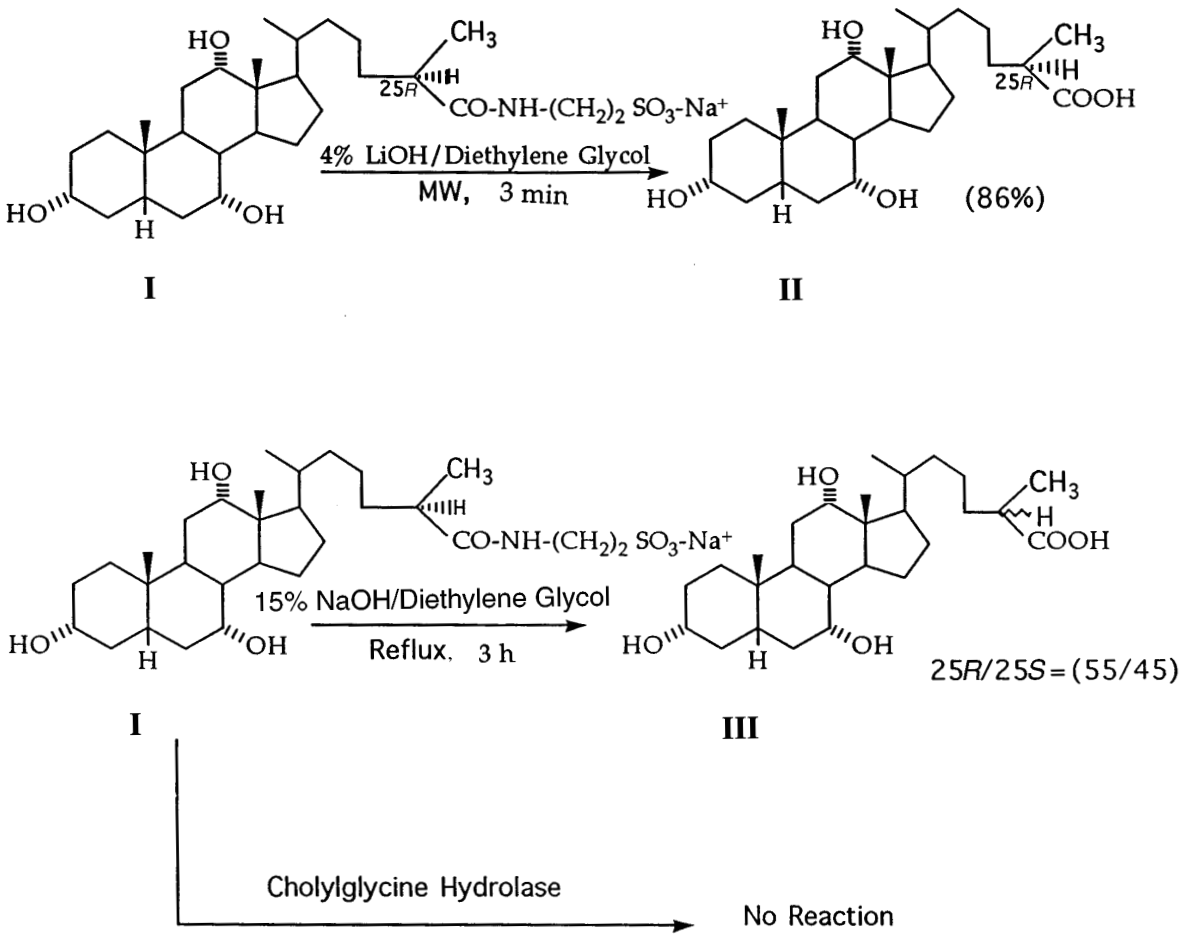
Melting points. These were determined on a Thermolyne apparatus (model MP-12600; Dubuque, IA) and are uncorrected.

Thin-layer chromatography (TLC) was performed in silica gel G plates (0.25 mm thickness, Brinkmann). The spots were detected with phosphomolybdic acid (3.5% in isopropanol) and sulfuric acid (10%).

Fourier transform infrared spectra were determined in $CHCl_3$ on a Perkin-Elmer model 421.

Optical measurements. The circular dichroism measurements were carried out on a Jasco-500A (Manchester, England) spectropolarimeter at 24°C, under a stream of high-purity, dry N_2. The coefficient of dichroic absorption, $\Delta\varepsilon$, was calculated from the molar ellipticity $[\Theta]$ by the following equation: $\Theta = 3300\ \Delta\varepsilon$. Both the Θ and $\Delta\varepsilon$ are expressed in degree $\times$ cm^2 $\times$ dmol^{-1} (26).

Positive ion fast atom bombardment mass–spectrometry (FAB–MS). Direct probe mass spectrum analysis of the con-



SCHEME 2

jugated bile acids was performed by FAB mass spectrometer using a ZAB-1F instrument (VG, Manchester, England) equipped with a standard FAB-source as described previously (26,27). In the FAB mode (positive ions), the sample was dissolved in thioglycerol, and a small aliquot (1 to 2 µL) was placed on the mass spectrometer direct probe. After insertion into the mass spectrometer, the sample was bombarded with a neutral atom beam of xenon with approximately 6 kV of translational energy.

GLC. Capillary GLC analysis of bile acid methyl esters (as the trimethyl silyl derivatives) was performed on Hewlett-Packard model No. 4890 (Palo Alto, CA) (equipped with a flame-ionization detector) and a split column injector using a CPsil 5 (CB) WCOT capillary column (25 m × 0.22 mm with 0.13-mm film thickness) as described previously (18–22,26,27). Helium was used as a carrier gas at a flow rate of 20.2 mL/min (135 kPa).

The MW used in these experiments was a domestic Whirlpool Commercial Microwave (model number 3600XS; Whirlpool Corporation, Benton Harbor, MI) operating at 2450 MHz (maximum power: 650 watts). The reactions described in this study were carried out in Erlenmeyer flasks or scintillation vials covered with a funnel or watch glass at ambient pressure in the MW as described previously (18–25). Taurocholic acid (3α,7α,12α-trihydroxy-5β-cholan-24-oyl taurine), taurochenodeoxycholic acid, glycoursodeoxycholic acid, glycocholic acid, and CGH (E.C. 3.5.1.24) were purchased from Sigma Chemical Company (St. Louis, MO) (Product No. C-4018). Taurine conjugates of THCA (Compound **I**, Scheme 2) were isolated from the bile of *A. mississippiensis* (17,18).

Isolation and characterization of 3α,7α,12α-trihydroxy-5β-cholestan-26-oyltaurine. Gallbladder bile of *A. mississippiensis* (5 mL) was deproteinized (17,18) with 12 mL of methanol, the supernatant decanted and evaporated, and the greenish-yellow residue thus obtained was dissolved in 0.5 mL of methanol and applied on a 20 × 20 cm preparative TLC silica gel G plate and developed twice with $CHCl_3/CH_3OH/CH_3COOH/H_2O$ (26:8:4:2, by vol) showing two major components with R_f values of 0.45 and 0.39. The less polar component had mobility as the taurine conjugate of the 25*R* diastereoisomer of 3α,7α-di-

hydroxy-5β-cholestan-26-oic acid and the more polar component had mobility as the taurine conjugate of the 25*R* diastereoisomer of THCA (Compound **I**, Scheme 2). The infrared spectrum in chloroform (Scheme 2, Compound **I**, R_f 0.39) gave a broad band at 3420 cm^{-1}, indicative of OH and NH groups and a strong peak of the amide bond at 1650 cm^{-1}. The FAB mass spectrum of the nonderivatized native molecule of the taurine conjugate of THCA gave only one significant peak at *m/z* (602, 100%) which is $[M + Na]^+$ for the structure shown in Scheme 2, Compound **I**. The protonated and deprotonated molecules of this amide were also observed at *m/z* (580, 10%) and (578, 8%), respectively. The chirality at C-25 was assigned as *R* on the basis of circular dichroism spectra ($\Delta\varepsilon_{195} = -0.58$ degree $\times$ $cm^2 \times dmol^{-1}$) as described by Dayal *et al.* (26).

Representative procedure for the hydrolysis of bile acid conjugates by MW. The procedure described below was applied to all of the following conjugated bile acids: taurocholic acid, taurochenodeoxycholic acid, glycocholic acid, glycochenodeoxycholic acid, glyco- and tauroursodeoxycholic acids and taurine conjugate of THCA (Compound **I**, Scheme 2). Approximately the same substrate–reagent and substrate–solvent ratios were used in each case. The deconjugations of taurocholic acid and taurine conjugate of THCA (Schemes 1,2) are described below.

(i) 3α,7α,12α-Trihydroxy-5β-cholan-24-oic acid (from Compound **I**, Scheme 1): Cleavage of the amide bond in 3α,7α,12α-trihydroxy-5β-cholan-24-oyltaurine (Compound **I**, Scheme 1) involved heating a solution of the bile salt (50 mg dissolved in 2 mL of 4% NaOH/diethylene glycol (or 1 M LiOH solution (eight equivalents) in propylene glycol in an Erlenmeyer flask covered with an inverted funnel (or sealed Teflon vessel) in a commercial MW for 3–4 min. Completion of the reaction was monitored by TLC and GLC. Workup of the reaction mixture involved acidifying to pH 2 with 10% HCl and extracting with 20 mL of ether twice. The ether layer was then dried over anhydrous $MgSO_4$ and filtered and, following solvent removal, yielded 43 mg of solid residue (86%). The authenticity of cholic acid was proven by comparison of its physical characteristics, TLC, infrared, and GLC–MS with those of an authentic reference standard (18,21–23).

In certain cases a saturated solution of $Ba(OH)_2$ also was used for 4–7 min for hydrolysis, but the reactions were not cleaner as compared to using a saturated solution of LiOH for the same reaction.

(ii) (25*R*) THCA (from Compound **I**, Scheme 2): 3α,7α,12α-trihydroxy-5β-cholestan-26-oyltaurine (15 mg) was deconjugated with 5% NaOH/diethylene glycol (0.5 mL) in the MW for 4–5 min according to the general protocol detailed above to afford THCA (Compound **III**, Scheme 2), in 86% yield. After crystallization with ethyl acetate/acetone (95:5, vol/vol) at 0°C this material provided colorless prisms (mp 181–183°C, lit. mp 180–182°C) (17,18,28). This crystalline material was found by TLC analysis using silica gel G plates and a solvent system of chloroform/acetone/methanol 70:50:10, by vol; developed twice), to have one component only with R_f= 0.41. This compound had identical TLC, GLC, infrared spectra, and showed identical mass spectral fragmentation patterns which agreed with that obtained from *A. mississippiensis* (17). ^{1}H Nuclear magnetic resonance ($CDCl_3$ + CD_3OD) 400 MHz *d*: 0.68 (*s*, 3H, Me − 18), 0.89 (*s*, 3H, Me − 19), 0.97 (*d,J* = 6.5 Hz, 3H, Me − 21), 1.15 (*d,J* = 6.5 Hz, 3H, Me − 27), 3.40 (*m*, 1H, H − 3), 3.85 (*br s*, 1H, H − 7), 3.95 (*br s*, 1H, H − 12), 3.45 (*m*, 1H, 25 − H). The chirality at C-25 was assigned as *R* on the basis of the circular dichroism spectra ($\Delta\varepsilon_{212} = -0.174$ degree $\times$ $cm^2 \times dmol^{-1}$) and was found to be in agreement with the x-ray diffraction studies described previously (18,28).

Some of the reactions also were carried out in sealed 5-mL capacity Teflon vessels. In such experiments, the reagents were thoroughly mixed in the Teflon vessel, the lid screwed on tightly, and the mixture heated in the oven for 90–120 s. After the heating was complete, the vessel was left to stand in the oven for 5 min to reduce the pressure in the vessel. Then the vessel was removed from the oven and cooled to room temperature, unscrewed, and worked up as described in the Experimental Procedures section.

We must emphasize that great care is to be exercised when adopting the microwave technique to new reactions in sealed or open vessels. Longer reaction times and chemical reactions using larger volumes of reactants must be avoided because these conditions generate very high pressures in the Teflon vessels and may result in an explosive reaction.

DISCUSSION

Recently, several laboratories, including our own, have reported the use of MW for rapid organic synthesis (18,21–25,29–36). We have reported rapid and efficient saponification, deacetylation, hydrogenation, and esterification reactions of bile acids and sterols (21–25). More recently Bose and his coworkers (29,30) have utilized microwave technology for the hydrolysis of peptides using dihydrogen phosphate (pH < 2.8). Microwave-induced vapor phase hydrolysis of proteins and a rapid hydrolysis of phosphoanhydride bonds in nucleotide triphosphates also have been reported recently (37,38). In this report we have further expanded the usefulness of the MW technique for the rapid hydrolysis of C_{24} and C_{27} bile acid conjugates (Schemes 1,2). This method provides rapid, convenient, and inexpensive access to very high temperatures and pressures, leading to a dramatic decrease in reaction times and increased yields. As shown in Schemes 1 and 2, the bile acid conjugates were hydrolyzed in 4–6 min, and the free bile acids were isolated in almost quantitative yields (see Experimental Procedures section).

CGH isolated from *Clostridium perfringens* is routinely used by many laboratories to deconjugate bile salts prior to GLC (11–14,39). This enzyme has been found to be ineffective in the hydrolysis of the taurine conjugate of the 25*R* and 25*S* diastereomer of THCA (12,13). Furthermore, drastic alkaline hydrolytic conditions yield a mixture of diastereomers (Compound **III**, 25*R*/25*S* = 55/45, Scheme 2) that are diffi-

cult to separate on a preparative scale (9,10,16,28). In contrast, complete hydrolysis of the taurine conjugate of THCA, (25*R*) 3α,7α,12α-trihydroxy-5β-cholestan-26-oyltaurine, was achieved in 3–4 min in the MW (Compound **I**, Scheme 2) with the retention of configuration. Of particular importance was the fact that only the original diastereomer of THCA was isolated from the reaction mixture, indicating that heating the substrate in the MW effectively split the amide linkage of the taurine conjugate of THCA without isomerizing the stereogenic center at C-25 (Compound **II**, Scheme 2).

THCA (Compound **I**, Scheme 2), the major component of the bile of *A. mississippiensis* (17), is a key intermediate in the biosynthesis of cholic acid from cholesterol (8–10,40). In human bile, the natural isomer is (25*R*)-THCA, while both conjugates of (25*R*)- and (25*S*)-THCA have been found to be excreted in urine in patients with Zellweger syndrome (5,40). Furthermore, the enzyme 5β-cholestane-3α,7α,12α-triol-27-hydroxylase, responsible for the formation of THCA, has been found to have *R* absolute stereochemistry (40). Therefore, the retention of absolute configuration at C-25 *via* the rapid hydrolysis of the 27-amide bond may be helpful in delineating the absolute stereochemistry of the peroxisomal enzyme, 3α,7α,12α-trihydroxy-5β-cholestanoyl-CoA oxidase (THCA-CoA oxidase) that catalyzes the first step in the oxidation of THCA.

In summary, our present studies illustrate the great usefulness of microwave technology in providing rapid and high-yielding hydrolysis of bile acid amides. Recent studies by Setchell *et al.* (41) have elucidated a new and unique inborn error in bile acid conjugation involving a deficiency in amidation. The present methodology may further help in the rapid identification and diagnosis of this and other inborn errors of bile acid metabolism. Our laboratory is currently investigating such hydrolytic reactions utilizing microwaves.

ACKNOWLEDGMENTS

We are indebted to Santy Mathew, undergraduate student from Stevens Institute of Technology, for her skillful technical assistance. This work was supported in part by a grant from the New Foundation for Diabetes and a grant US-PHS, HL-17818. We also wish to thank Kenneth Mizrach, Director, V.A. New Jersey Health Care System, for his encouragement and continuing support. This paper is dedicated to Prof. Ajay K. Bose (Stevens Institute of Technology) on the occasion of his 70th birthday.

REVIEW

Gas Chromatography–Mass Spectrometry Methods for Structural Analysis of Fatty Acids

William W. Christie*

Scottish Crop Research Institute, Invergowrie, Dundee (DD2 5DA), Scotland

ABSTRACT: Procedures for structural analysis of fatty acids are reviewed. The emphasis is on methods that involve gas chromatography–mass spectrometry and, in particular, the use of picolinyl ester and dimethyloxazoline derivatives. These should be considered as complementing each other, not simply as alternatives. However, additional derivatization procedures can be of value, including hydrogenation and deuteration, and preparation of dimethyl disulfide and 4-methyl-1,2,4-triazoline-3,5-dione adducts. Sometimes complex mixtures must be separated into simpler fractions prior to analysis by gas chromatography–mass spectrometry. Silver ion and reversed-phase high-performance liquid chromatography are then of special value. In particular, a novel application of the latter technique, involving a base-deactivated stationary phase and acetonitrile as mobile phase, is described that is suited to the separation of fatty acids in the form of picolinyl ester and dimethyloxazoline derivatives, as well as methyl esters.
Lipids 33, 343–353 (1998).

The common fatty acids of animal and plant origin have even-numbered chains of 16 to 22 carbon atoms, with zero to six double bonds of the *cis* configuration; methylene-interrupted double-bond systems predominate. Nature provides countless exceptions, however, and odd- and even-numbered fatty acids with up to nearly 100 carbon atoms exist. In addition, double bonds can be of the *trans* configuration, acetylenic and allenic bonds occur, and there can be innumerable other structural features, including branch points, rings, oxygenated functions, and many more (1,2). More than a thousand different fatty acids of natural origin must exist, as well as others produced as artifacts when fats are used in commerce and in cooking, for example.

It is essential to have simple, rapid methods for determination of fatty acid structures. In particular, new methods involving gas chromatography–mass spectrometry (GC–MS), GC linked to Fourier-transform infrared spectroscopy (FTIR), and silver ion and reversed-phase high-performance liquid chromatography (HPLC) are available, among others. I described the current state of the methodology in a recent review (3). This paper is much less comprehensive in its coverage of the literature, and it lays particular emphasis on those GC–MS methods that the author has found especially useful. All of the derivatization procedures described utilize readily available reagents and have simple glassware requirements, so they should be accessible to most laboratories.

Abbreviations: DMOX, dimethyloxazoline; FTIR, Fourier-transform infrared spectroscopy; GC–MS, gas chromatography–mass spectrometry; HPLC, high-performance liquid chromatography.

MASS SPECTROMETRY OF PICOLINYL ESTER AND DIMETHYLOXAZOLINE DERIVATIVES

General comments. Fatty acids are usually analyzed by GC as methyl ester derivatives, but their mass spectra rarely contain ions indicative of structural features; the positions of double bonds in the aliphatic chain, for example, cannot be determined. Instead, the carboxyl group must be derivatized with a reagent containing a nitrogen atom. When the molecule is ionized in the mass spectrometer, the nitrogen atom, not the alkyl chain, carries the charge, and double-bond ionization and migration are minimized. Radical-induced cleavage occurs evenly along the chain and gives a series of relatively abundant ions of high mass from the cleavage of each C-C bond. When a double bond or other functional group is reached, diagnostic ions tend to occur. The first useful nitrogen-containing derivatives, i.e., pyrrolidides, were described more than 20 yr ago, and their mass spectral properties were reviewed by Andersson (4). Although they give useful spectra and should not be discounted, most analysts now prefer either picolinyl (3-hydroxymethylpyridinyl) ester or 4,4-dimethyloxazoline (DMOX) derivatives. A definitive review of mass spectral fragmentation properties of such compounds has been published by Harvey (5), and other reviews have appeared (6,7). Here, I will concentrate on practical applications of the derivatives to structure determination of natural fatty acid mixtures as opposed to mechanistic concepts.

Both picolinyl ester and DMOX derivatives have their merits in MS terms, and neither should be neglected. Each has advantages for particular types of fatty acid, and they are best considered as complementary.

In choosing a derivative for MS, good chromatographic properties are also important. One advantage of DMOX derivatives is that they are only slightly less volatile than methyl esters; they can be subjected to GC analysis on polar stationary phases under comparable conditions and give equivalent

resolution (8). Picolinyl esters, on the other hand, require column temperatures about 50°C higher than methyl esters (9), meaning initially that they had to be separated on nonpolar phases, which gave relatively poor resolution. With the introduction of new polar phases that are stable to high column temperatures and have low-bleed characteristics for MS analysis, such as BPX-70™ (SGE Europe Ltd. Milton Keynes, United Kingdom) (10,11) or even some of those of the Carbowax type, such as Supelcowax 10™ (Supelco UK, Poole, United Kingdom) (12), the problem of GC resolution of picolinyl esters is greatly lessened and only very long chain fatty acids (>C_{20}) tend to cause problems.

Picolinyl esters must be prepared from free fatty acids, and intact lipid or methyl ester samples must first be hydrolyzed. The author (unpublished) then prepares the acid chloride by reaction with oxalyl chloride overnight and reacts this with 3-hydroxymethylpyridine in dichloromethane to form the picolinyl ester. Alternatively, a mild quantitative method developed for derivatizing sensitive polyunsaturated fatty acids containing epoxy groups may be preferred, involving an imidazolide intermediate (13). Dry solvents and fresh reagents are required because the reactions are sensitive to moisture.

DMOX derivatives are prepared in a simple one-pot reaction. Lipids are reacted with 2-amino-2-methyl-1-propanol in a nitrogen atmosphere at 180°C [2 h for free acids (14), or 18 h for methyl esters (15,16) and intact lipids (17)]. Unfortunately, we have often observed incomplete reaction and appearance of an intermediate that elutes later from GC columns (and gives a mass spectrum almost identical to that of the required derivative). The prolonged high temperature required for the preparation of DMOX derivatives gives cause for concern, and there must be some risk to polyunsaturated fatty acids or any other compound with a labile functional group. However, the only important problem reported to date was with *trans*-3-hexadecenoic acid, common in plant photosynthetic tissue, which was found to have isomerized largely to *cis*-2-hexadecenoic acid during the reaction (18). Although an alternative two-step reaction has been described, it uses a strong acid as catalyst and may not be safer (14).

Saturated and branched-chain fatty acids. The mass spectrum of the picolinyl ester derivative of 14-methylhexadecanoic acid is illustrated in Figure 1. It is typical in that it has prominent ions at *m/z* = 92, 108, 151 (the McLafferty ion), and 164, which are all fragments about the pyridine ring. The molecular ion (*m/z* = 361) is easily distinguished and is always odd-numbered, because of the presence of the nitrogen atom, but most other ions are even-numbered. In interpreting such spectra, the simplest approach is to start with the molecular ion and progress downward, as if one were unzipping the molecule one methylene group at a time. Thus, there is loss

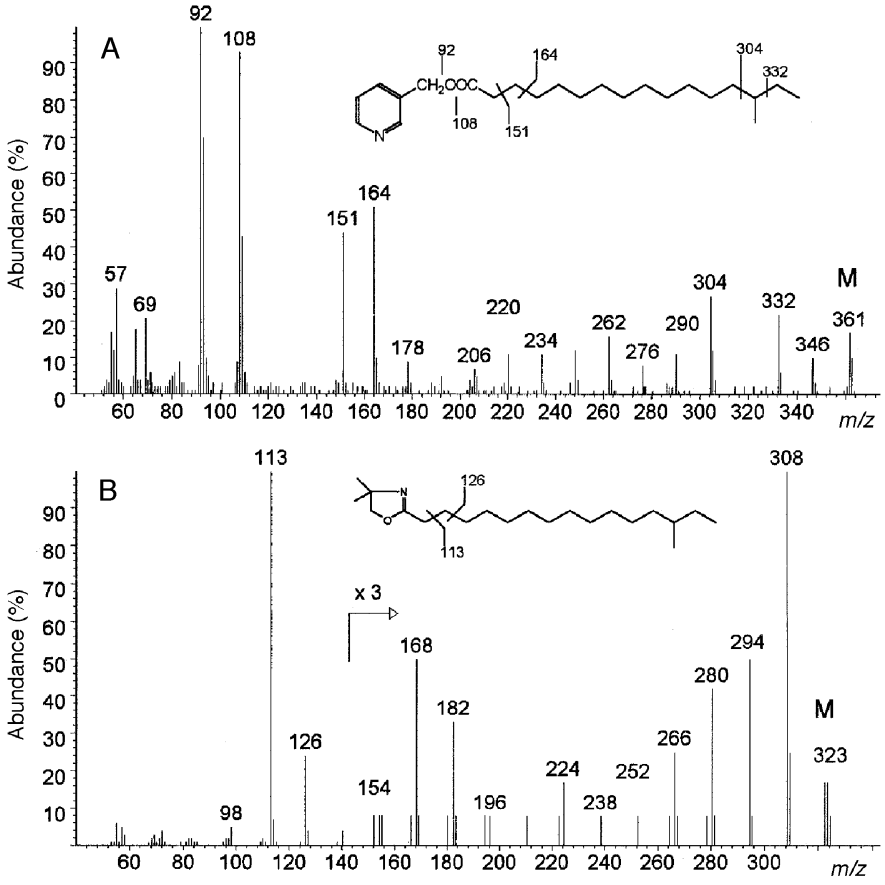

FIG. 1. Mass spectrum of 14-methylhexadecanoic acid as the picolinyl ester (A) and dimethyloxazoline derivative (B).

of a methyl group to *m/z* = 346, and a further methylene to *m/z* = 332. Then there is a gap of 28 amu to *m/z* = 304, representing loss of the carbon 14 with the associated methyl group, affording definitive identification. Finally a series of ions is observed 14 amu apart for loss of successive methylene groups. There is little sign of the complex rearrangement ions that can be found with such fatty acid derivatives as methyl esters, in which minor changes in ion intensities must be used in an attempt to identify branch points, so interpretation of spectra can be very difficult.

The mass spectrum of the DMOX derivative of this acid is also illustrated in Figure 1. Prominent ions at *m/z* = 113 and 126 are invariably seen, the former representing cleavage between carbons 2 and 3 (the McLafferty ion). With DMOX derivatives of saturated fatty acids, the fragments of higher molecular weight are often in relatively low abundance and have been magnified here. The molecular ion (*m/z* = 323) is easily recognized, as is the loss of the terminal methyl group (*m/z* = 308). Then there is a series of ions 14 amu apart for loss of successive methylene groups, but nothing that defines the loss of the methyl group on carbon 14. This is one of a few instances where picolinyl esters are demonstrably greatly superior to DMOX derivatives. However, when methyl groups are further from the terminal end of the molecule, some small differences in intensity are seen that it is claimed may be used for diagnostic purposes (14). The author is not convinced that such small differences will have practical value with unknown compounds.

Unsaturated fatty acids. As an example, the mass spectrum of the picolinyl ester of 11-octadecenoic acid is illustrated in Figure 2. There is a large molecular ion (*m/z* = 373), and then an ion at *m/z* = 358 representing loss of the terminal methyl group, followed by a series of ions 14 amu apart for cleavage at successive methylene groups. When a double bond is reached, there is a gap of 26 amu (between *m/z* = 262 and 288). This gap can sometimes be difficult to locate precisely, but a further distinctive feature of clear diagnostic value is two abundant ions 14 amu apart, representing cleavage on the distal side of the double bond at *m/z* = 302 and 316 in this instance (5,19,20). In practice, these two ions can be picked out for identification purposes even when isomeric fatty acid derivatives are imperfectly resolved by GC. Formation of the ions has been rationalized in mechanistic terms as an initial abstraction of allylic hydrogens on each side of the double bond with the production of conjugated diene systems, which form relatively stable ions (5,19). Similar series of ions are seen in most monoenes, but it is advantageous to have access to spectra of authentic standards when the double bond

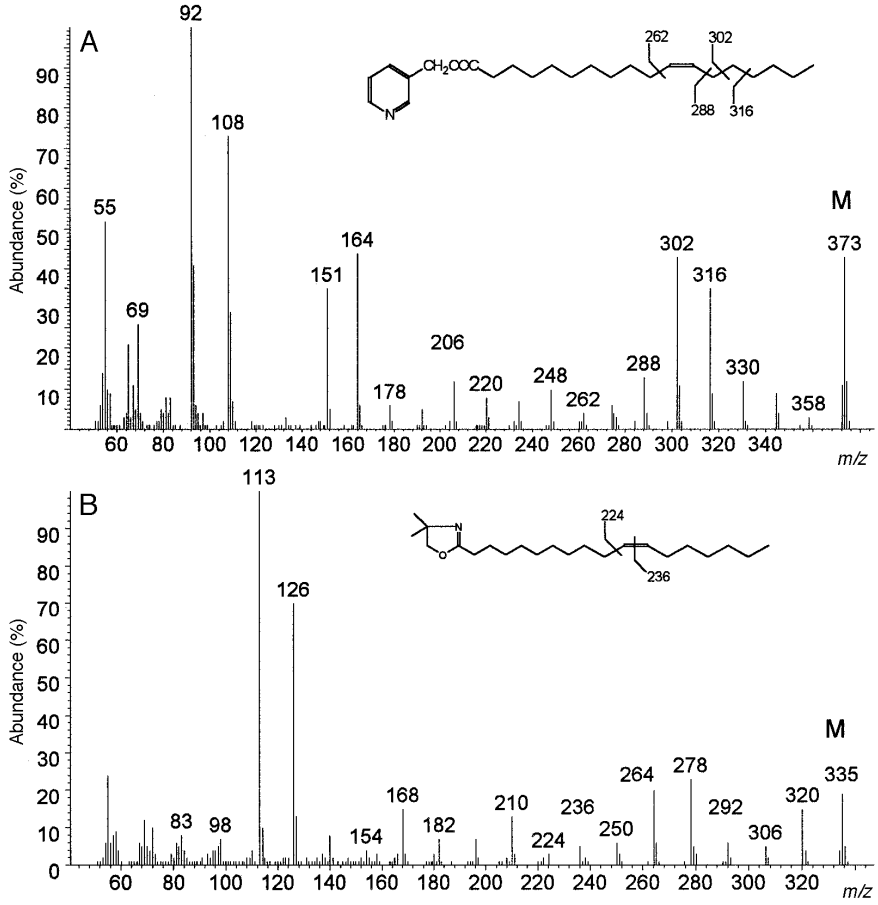

FIG. 2. Mass spectrum of 11-octadecenoic acid as the picolinyl ester (A) and dimethyloxazoline derivative (B).

is close to either end of the molecule to avoid any confusion (20). For example, when the double bond is closer to the carboxyl group, the second ion of the two is relatively more abundant.

In the case of the DMOX derivative of vaccenic acid, illustrated also in Figure 2B, the molecular ion is at *m/z* = 335, and there are characteristic ions at *m/z* = 320, 306, 292, 278, and so forth for the loss of each successive methylene group. A gap of 12 amu, instead of the usual 14, between *m/z* = 224 (C-10) and 236 (C-11) is indicative of a double bond between carbons 11 and 12. Although interpretation of the spectrum differs in principle from that with picolinyl esters, the result is equally clear. The author (unpublished) has mass spectra for DMOX derivatives of the complete series of octadecenoic acid isomers, and again it is apparent that anomalies can arise when the double bond is close to either end of the molecule. Indeed, it has been demonstrated that odd-numbered ions may be found in spectra of polyunsaturated fatty acids with double bonds in positions 4 to 6 (21).

Similar principles apply to interpretation of spectra from polyunsaturated fatty acids. As an example, the mass spectrum of the picolinyl ester of 5,9,12-octadecatrienoic acid, a common constituent of the seed oils of conifers, is illustrated in Figure 3. The molecular ion is at *m/z* = 369, and again there is a regular series of ions 14 amu apart until the double bond in position 12 is reached, recognized by the gap of 26 amu between *m/z* = 272 and 298. As a practical point with polyenes, a double bond on carbon atom *n* is sometimes more easily distinguished from a gap of 40 amu between carbons *n* − 1 and *n* + 1, in this instance from *m/z* = 258 to 298. The double bonds in positions 9 and 5 are recognized by gaps of 26 amu between *m/z* = 232 and 258 and between *m/z* = 178 and 204, respectively. However, an even more characteristic feature for a bis-methylene-interrupted diene is an ion at *m/z* = 219 (actually 218 + 1, which unusually is odd-numbered). This has been found in a number of fatty acids with 5,9-double bonds (22–26), including those in sponges, and analogous ions are found with other *bis*-methylene interrupted dienes (27).

The mass spectrum of the DMOX derivative of 5,9,12-octadecatrienoic acid is also illustrated in Figure 3B. In this instance, the double bonds in positions 9 and 12 are recognized by gaps of 12 amu between *m/z* = 194 and 206 and *m/z* = 234 and 246, respectively. The base peak is at *m/z* = 180 and represents a cleavage between carbons 7 and 8, i.e., at the center of the bis-methylene-interrupted system, and is a key diagnostic ion for this feature (15,17,28). Analogous ions are present for DMOX derivatives of other fatty acids containing bis-methylene-interrupted systems (author,

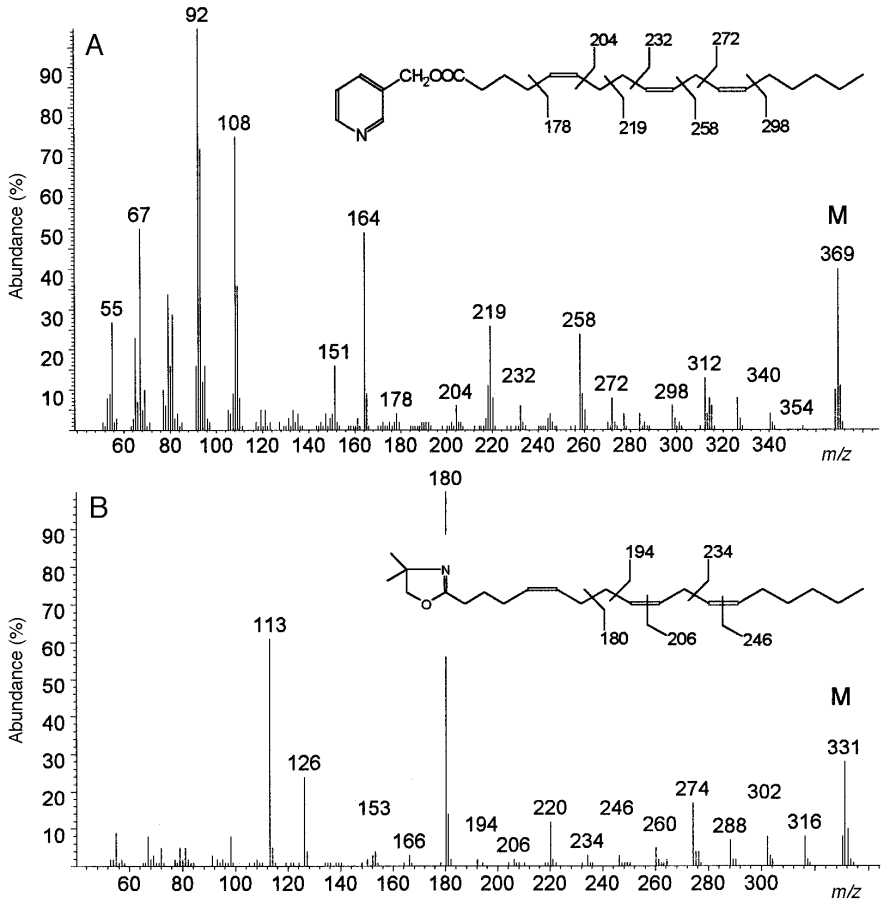

FIG. 3. Mass spectrum of 5,9,12-octadecatrienoic acid as the picolinyl ester (A) and dimethyloxazoline derivative (B).

unpublished). DMOX derivatives also give excellent spectra when conjugated double-bond systems are present (15,29).

From the practical standpoint of identification of unknown unsaturated fatty acids, the author has observed that DMOX derivatives tend to give spectra which are easier to interpret, provided the GC peak contains a single fatty acid. With poorly resolved peaks, picolinyl esters are often best, provided there is access to standard spectra. Again, this illustrates that the two types of derivatives complement each other.

Cyclic fatty acids. The picolinyl esters of cyclopropanoid fatty acids gave distinctive spectra with a diagnostic ion that included the first carbon of the ring, and unusually were odd-numbered (30). In contrast, the mass spectra of the DMOX derivatives of cyclopropyl fatty acids appear to be much less distinctive. They lack a diagnostic odd mass ion, corresponding to that of the picolinyl esters, and essentially resemble the spectra of monoenes (as is the case for methyl esters), the only differences being the relative intensities of certain ions (7,31). Although it has been argued that these minor differences can be used diagnostically, there is evidence to contradict this (6). In contrast, both types of derivative gave definitive spectra for cyclopropenoid fatty acids. For example, the picolinyl ester derivatives gave mass spectra with diagnostic ions representing cleavage beta to the ring on each side (32). Similarly, characteristic ions were obtained with DMOX derivatives (33). With the DMOX derivative of sterculic acid, a gap of 10 amu between ions at *m/z* = 196 and 206 (carbons 8 and 9) located the cyclopropene ring between carbons 9 and 10 (33).

Both picolinyl ester (34) and DMOX derivatives (35) gave excellent spectra with natural cyclopentenoid fatty acids, enabling identification of a number of novel components in certain seed oils. When a double bond occurred also in the aliphatic chain, the expected mass spectral features were present and located its position, but there were no ions to indicate the position of a double bond in the ring and this remains an unsolved problem in MS. Similarly, the complex range of cyclic fatty acids, with internal 5- and 6-membered rings and double bonds in many different positions, which are formed by free-radical mechanisms when vegetable oils are heated to high temperatures as during frying of food or the commercial physical refining process, has been characterized both as DMOX and picolinyl ester derivatives (36–42). Here DMOX derivatives may be marginally better.

SOME ANCILLARY MASS SPECTROMETRIC TECHNIQUES

Hydrogenation. Catalytic hydrogenation is a simple procedure that provides invaluable structural information regarding fatty acid identity, when combined with GC or GC–MS analysis. Some needlessly complex procedures are sometimes described, but details of a convenient practical procedure are available (43). At its simplest, hydrogenation is used merely to determine the chain length of components. By eliminating all unsaturated centers in fatty acid methyl esters from most samples of natural origin, a simple set of peaks is obtained for the saturated even-numbered homologous series and can be compared with authentic standards. However, the presence of anomalous peaks may be an indication of novel structures. In samples of animal origin, small amounts of odd-chain fatty acids may be detected in the GC trace, together with methyl-branched fatty acids, usually *iso*- closely followed by *anteiso*-isomers, which can be identified as described above. Similarly, this technique was of great value in characterizing the cyclic fatty acids in the papers cited above. It is best carried out with methyl esters prior to conversion to picolinyl ester or DMOX derivatives.

Deuteration. Deuteration has been used since the early days of MS of lipids as a means of locating double bonds, but the value of the procedure for structure determinations was limited with methyl ester derivatives, as the wide range of rearrangement ions formed led to some scrambling of the deuterium atoms in the alkyl chain. However, by using nitrogen-containing derivatives, which give clean radical-induced fragmentations with minimal rearrangement, most problems have been eliminated.

Deuteration with deuterium gas and Wilkinson's catalyst [tris(triphenylphosphine)rhodium(I) chloride] is usually employed for the purpose, including in the author's laboratory, and can be recommended. Gaseous deuterium is available commercially in small cylinders, or it can be generated *in situ* by reaction of deuterium chloride with sodium borodeuteride (44). It is essential to have a good excess of deuterium so that the reaction goes rapidly to completion, otherwise some isomerization of the double bonds and scrambling of the hydrogen atoms is possible (author, unpublished). Again, the reaction is best carried out with methyl esters prior to conversion to picolinyl ester or DMOX derivatives.

The technique was first used in conjunction with pyrrolidide derivatives and has also been used with DMOX derivatives, but picolinyl esters appear best for the purpose, as they give cleaner radical-induced fragmentations with fewer rearrangement ions. Also, they give more abundant ions of high molecular weight with saturated fatty acids. Lie Ken Jie and Choi (45) were first to demonstrate this with mono- to hexaenoic fatty acids and for some acetylenic fatty acids (46). On mass spectral analysis, clear diagnostic ion fragments were obtained that permitted the determination of the positions of the original double bonds in the alkyl chain.

As an example, the mass spectrum of the picolinyl ester of 12-oxo-octadec-9-enoic acid is shown in Figure 4 (11). In addition to the ions characteristic of picolinyl esters, there was a small molecular ion (*m/z* = 387). The gap of 26 amu between *m/z* = 234 and 260 was diagnostic for the double bond, the gap of 28 amu between the base ion at *m/z* = 274 and the prominent ion at *m/z* = 302 represented fragmentation involving loss of the 12-oxo group. However, it was noted that in this instance cleavage occurred alpha (as opposed to beta as is more normal) to the oxo group, presumably because of the directing

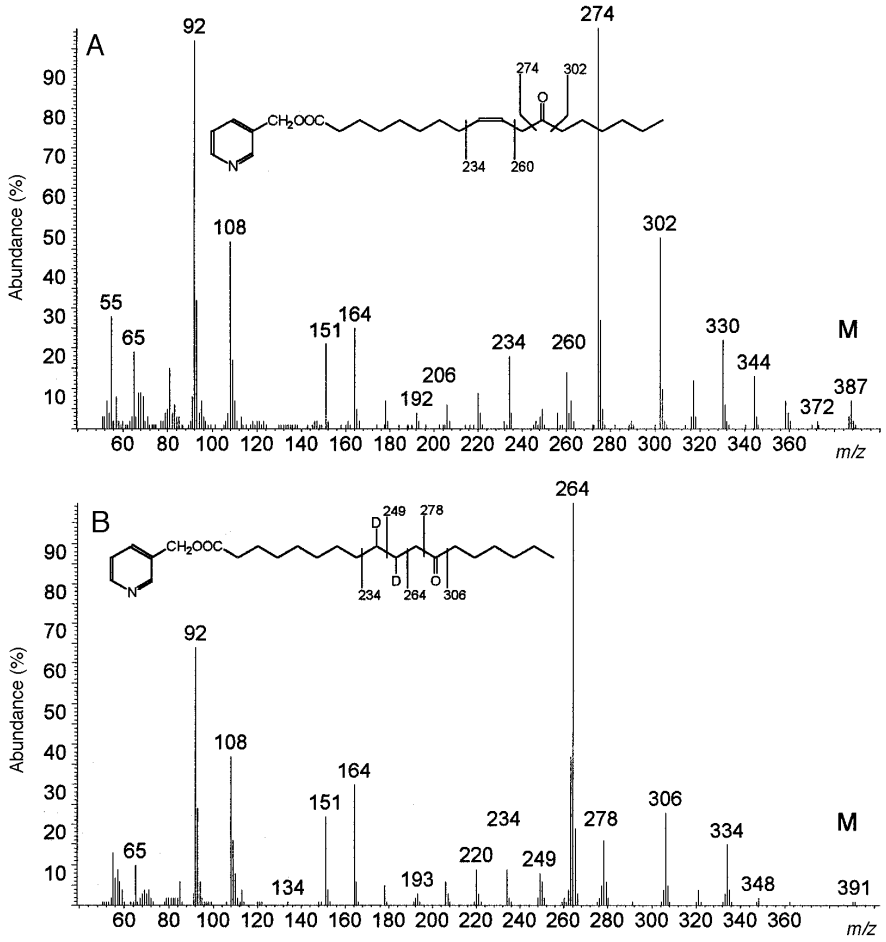

FIG. 4. Mass spectra of picolinyl 12-oxo-octadec-9-enoate (A) and 9,10-d_2,12-oxo-octadecanoate (B) (redrawn from Ref. 11).

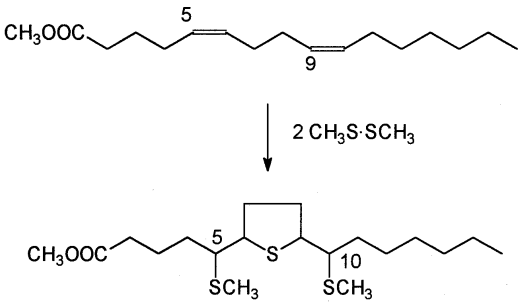
influence of the double bond in position 9. This could greatly hinder interpretation of the spectra of unknowns, so deuteration was performed. The mass spectrum of picolinyl 9,10-d_2,12-oxo-octadecanoate is also illustrated in Figure 4. Now, the base peak at *m/z* = 264 represents cleavage beta to the oxo group, with a gap of 28 amu between ions at *m/z* = 278 and 306 for the loss of the oxo group. Gaps of 15 (rather than 14) from *m/z* = 234 to 249 and from 249 to 264 confirm the presence of deuterium atoms on carbons 9 and 10.

Such methodology enabled identification of 15 novel fatty acids of this type in milk fat and cheese (11). It was also invaluable for characterizing the cyclic fatty acids produced in heated vegetable oils, enabling location of double bonds both in the aliphatic chain and in the ring structures, both with picolinyl ester and DMOX derivatives (36,37), and for fatty acids with two bis-methylene-interrupted double-bond systems from a sponge (26).

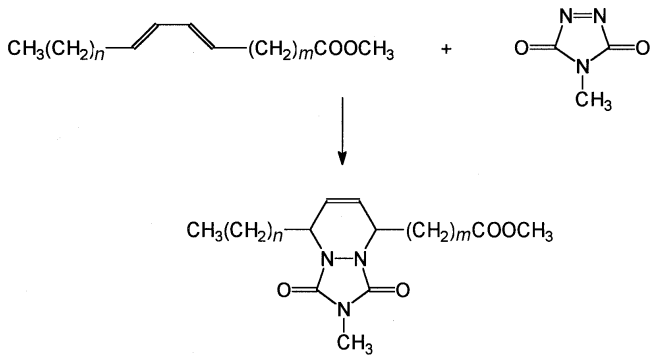
Dimethyl disulfide adducts. A large number of further reagents that involve addition to a double bond have been described, but the only one to have stood the test of time involves preparation of dimethyl disulfide adducts. A single reagent and a one-step reaction are required for the preparation, which is carried out simply by dissolving the methyl ester of the fatty acid in dimethyl disulfide with a trace of iodine (47). Adduct formation is entirely stereospecific, presumably by *trans* addition, so that *threo*- and *erythro*-derivatives are formed from *cis*- and *trans*-isomers, respectively. Although the different geometrical isomers have indistinguishable spectra, they are eluted separately from GC columns containing either polar or nonpolar phases, that derived from the *cis*-isomer eluting first (48).

The reaction has proved especially useful for monoenes (see Ref. 3 for a full list of references). Dienoic fatty acids present more of a problem for the technique, partly because comparatively high temperatures are required for GC analysis, but mainly from complications in the reaction with dimethyl disulfide. There is no problem when double bonds are separated by more than four carbon atoms, but methylene-interrupted double bonds give products with thietane, tetrahydrothiophene, and tetrahydrothiopyran structures (4-, 5-, and 6-membered rings) (49,50). However, such compounds can give characteristic and diagnostic spectra, so that the technique continues to have some practical value. Only conjugated fatty acids cannot be analyzed usefully by this means (50).

Fatty acids with a bis-methylene-interrupted double-bond system, as in a 5,9-diene systems, are common constituents



SCHEME 1



SCHEME 2

of marine sponges and of seed oils in many species of Gymnosperms. Reaction of these with dimethyl disulfide under appropriate conditions gives a 5-membered cyclic thioether with methylthio groups on the carbons immediately adjacent to the ring as illustrated in Scheme 1 (50). These compounds give characteristic spectra permitting location of the double bonds, and many different demospongic acids of this type have been identified in this way, including some containing bromine atoms and methyl branches in addition to the 5,9-double-bond system (51,52).

Diels-Alder adducts for conjugated double bonds. As shown in Scheme 2, a useful derivative specific for determination of double-bond positions in conjugated dienes is to form the Diels-Alder adduct of the fatty acid methyl ester by reaction with the reagent 4-methyl-1,2,4-triazoline-3,5-dione (53). Such derivatives have excellent mass spectrometric properties, enabling determination of structures in such samples as commercial conjugated linoleic acid (CLA) (53,54) and metabolites formed from this in animal tissues (55). It was also used to establish the absence of conjugated double-bond systems in cyclic dienes produced in heated vegetable oils (37).

SIMPLIFICATION OF COMPLEX MIXTURES PRIOR TO ANALYSIS BY GC–MS

Reversed-phase HPLC. When samples are subjected to GC–MS in the form of picolinyl esters or DMOX derivatives, there may be loss of resolution, and minor components may not give definitive spectra. Sometimes, natural mixtures are so complex that it is unreasonable to expect adequate resolution. In such circumstances, some subdivision into simpler fractions by chromatographic means is desirable. Also, if a technique such as deuteration is to be used, it must be applied to relatively pure compounds.

Reversed-phase HPLC [reviewed by Nikolova-Damyanova (56)] is a mild method in that it is carried out at ambient temperature and involves only liquid–liquid interactions. The principle is well known in that separation is based both on the chain length and degree of unsaturation of components, each double bond reducing the retention time by the equivalent of about two methylene groups. It was one of the first techniques to be used for micropreparative separation of picolinyl esters *per se* in 1987 (57). In this instance, a stationary phase of the octadecylsilyl type was employed with a gradient of water/pyridine/acetic acid into methanol and evaporative light-scattering detection. The polar mobile phase was necessary to overcome the attraction between residual silanol groups on the stationary phase and the nitrogen moiety of the derivative.

New deactivated stationary phases of the octadecylsilyl type are now available that permit elution of basic compounds as sharp peaks without addition of ionic species to the mobile phase. Figure 5 illustrates a separation of picolinyl ester derivatives, prepared from borage oil, on a column of Hichrom RPB™ (Hichrom Ltd., Reading, United Kingdom) using acetonitrile only as the mobile phase with a flow gradient of 0.5 to 1.5 mL/min (author, unpublished). If the column temperature is kept constant, the elution times are highly reproducible, facilitating automated fraction collection. In this instance, evaporative light-scattering detection was used for convenience, but ultraviolet detection should also be possible by using the specific absorbance of the pyridine ring. By avoiding water as a component of the mobile phase, it is easy to recover fatty acid derivatives from fractions that are collected. It is noteworthy that the 18:1 derivative eluted before rather than after 16:0, as is more usual in reversed-phase HPLC.

Methyl esters and DMOX derivatives can be chromatographed under comparable conditions, except that corresponding components elute a little earlier than for picolinyl esters. Again, ultraviolet detection should be possible, but at 206 nm.

Silver ion HPLC. Silver ion chromatography has been widely used for separation of fatty acid derivatives, and the technique has been reviewed comprehensively (58,59). Only a few papers relating to the main theme of this review will be cited here. The principle is well known, and involves transient formation of polar charge-transfer complexes so that components are separated by degree of unsaturation. In addition, it can be used to separate fatty acids with *cis*- from *trans*-double bond, at the same time providing confirmatory evidence as to geometry, and to separate positional isomers.

Until recently the most useful manifestation was silver ion thin-layer chromatography, but silver ion HPLC affords more efficient separations and cleaner fractions in micropreparative applications. The author's approach was to convert a

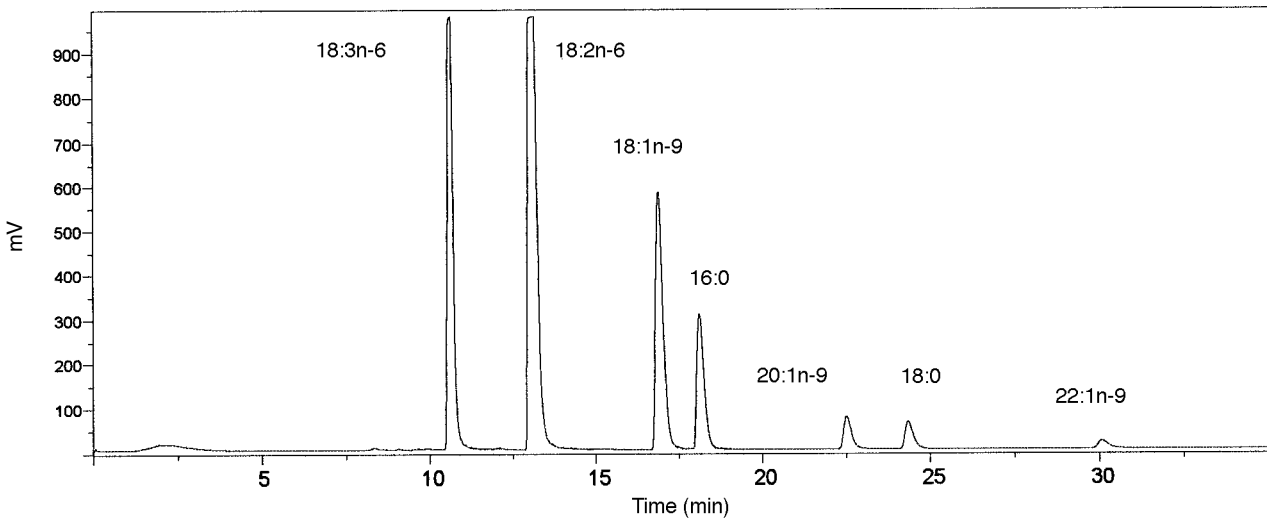


FIG. 5. Separation of picolinyl esters prepared from borage oil by reversed-phase high-performance liquid chromatography (HPLC). A column of Hichrom RPB™ (250 × 4.6 mm; Hichrom Ltd., Reading, United Kingdom) was employed with acetonitrile as mobile phase, with the flow rate programmed from 0.5 to 1.5 mL/min over 30 min, and held at this for a further 5 min. The temperature of the column was maintained at 20°C. The sample (5 μL) was injected in a solution of acetone/acetonitrile (1:9, vol/vol). An evaporative light-scattering detector was used.

commercial ion-exchange column (Nucleosil 5SA™; Hichrom Ltd., Reading, United Kingdom) to the silver ion form by the simple process of pumping water through the column into which silver nitrate was introduced *via* the rheodyne valve, before the water was replaced by organic solvents of decreasing polarity (60). Pre-silvered columns are now available commercially (Chromspher Lipids™ from Chrompack BV, Netherlands).

It should be noted that methyl and other simple esters of fatty acids must be used for this technique, and not DMOX derivatives or picolinyl esters. Apparently, the nitrogen-containing moieties are held so strongly that they cannot be recovered from the column (3).

For group separations of components differing in degree of unsaturation, satisfactory resolution of fatty acid derivatives into fractions with zero to six *cis* double bonds was achieved on silver-loaded Nucleosil™ 5SA columns by using binary gradient elution schemes. For example, good resolution was obtained with a gradient of dichloromethane/1,2-dichloroethane (1:1, vol/vol) to dichloromethane/1,2-dichloroethane/methanol/acetonitrile (47:47:3:3, by vol), as illustrated in Figure 6 (23,24,26). An evaporative light-scattering detector was employed with a stream-splitter inserted to enable collection of samples. In this example, seven fractions were collected, some differing according to geometry and others according to position, as well as to the number of double bonds. This procedure has been applied to many complex natural mixtures as fatty acid methyl esters, as a means of simplification before proceeding to structural analysis by GC–MS. For example, in studies of sponges (23,24, 26), up to 10 fractions were collected, and subsequent analysis by GC–MS revealed as many as a hundred fatty acids including cyclic and mono- and multimethyl-branched isomers, as well as methylene- and multimethylene-interrupted unsaturated components of several different biosynthetic families. Many of these were minor components that would have been hidden by more abundant fatty acids if this simplification step were not undertaken. My recent review (3) should be consulted for a full list of applications.

If the HPLC separation is carefully optimized and the type of fatty acid derivative is chosen correctly, much better resolution is possible, and individual positional, as well as configurational, isomers can be separated. Phenacyl derivatives of fatty acids were used in early work on separation of positional isomers, the choice being determined by a requirement for ultraviolet detection. However, it has become evident that these are especially useful in that formation of a chelate complex between a silver ion, a double bond, and the additional carbonyl moiety of the phenacyl moiety facilitated separation of positional isomers; indeed, *p*-methoxyphenacyl esters may prove to be even better (61). Among many applications that could be cited is the work on structure determination of cyclic fatty acids formed in heated vegetable oils (36,37).

In conclusion, this has been a selective review of the present methodology for structural analysis of fatty acids, but it is my experience that those procedures discussed are adequate for most purposes. Some important techniques have been neglected here. For example, GC coupled to FTIR is an enormously powerful technique that has been well utilized in some laboratories. Similarly, nuclear magnetic resonance spectroscopy can give valuable structural information, but at present it requires relatively large amounts of fatty acids in a pure state. The GC–MS methods described above can give satisfactory results with submilligram amounts of lipid.

ACKNOWLEDGMENT

This paper is published as part of a program funded by the Scottish Office Agriculture, Environment and Fisheries Dept.

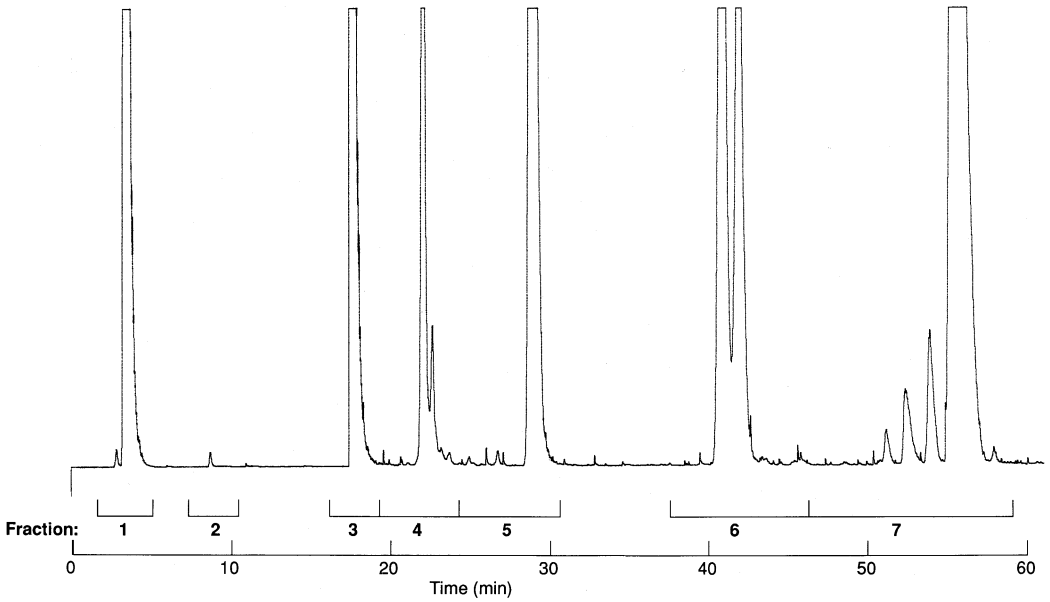

FIG. 6. Silver ion HPLC of methyl esters from the sponge *Hymeniacidon sanguinea*. A column (4.6 × 250 mm) of Nucleosil™ 5SA was utilized in the silver ion form, and a gradient of dichloromethane/dichloroethane (1:1, vol/vol) to dichloromethane/dichloroethane/acetonitrile/methanol (47:47:3:3, by vol) was utilized with evaporative light-scattering detection. Fraction 1 = saturated; 2 = *trans*-monoenes; 3 = *cis*-monoenes; 4 = dienes; 5 = 5,9-dienes; 6 = trienes and tetraenes; 7 = pentaenes and hexaene. Isolation and Structure of a New Galactolipid from Oat Seeds

Mats Hamberg[a,*], Edvards Liepinsh[b], Gottfried Otting[b], and William Griffiths[c]

Department of Medical Biochemistry and Biophysics, [a]Division of Physiological Chemistry II, [b]Division of Molecular Biophysics, and [c]Division of Physiological Chemistry I, Karolinska Institutet, S-171 77 Stockholm, Sweden

ABSTRACT: Seeds of oat (*Avena sativa* L.) were recently shown to contain significant quantities of a new hydroxy acid, (15*R*)-hydroxy-(9*Z*),(12*Z*)-octadecadienoic acid (trivial name, avenoleic acid). In the present work, avenoleate was found to be mainly (63%) localized in the glycolipid fraction of oat seed lipids. Fractionation of the glycolipids by thin-layer chromatography and reversed-phase high-performance liquid chromatography revealed the presence of a main molecular species which accounted for 20% of the total avenoleate content of oat seeds. Structural studies by chemical methods and mass spectrometry demonstrated that the avenoleate-containing glycolipid was a galactolipid assembled of one molecule of avenoleic acid, two molecules of linoleic acid, two molecules of D-galactose, and one molecule of glycerol. Degradation of the new galactolipid by chemical and enzymatic methods demonstrated the localization of acyl chains, i.e., linoleate at *sn*-1 and linoleoyl-avenoleate at *sn*-2. Nuclear magnetic resonance spectroscopy gave independent support for this structure and also demonstrated that the two galactoses formed an α-D-galactopyranosyl-1-6-β-D-galactopyranosyl moiety which was bound to the *sn*-3 position. Based on these experiments, the new galactolipid could be formulated as 1-[(9′*Z*),(12′*Z*)-octadecadienoyl]-2-[(15″*R*)-{(9‴*Z*),(12‴*Z*)-octadecadienoyloxy}-(9″*Z*),(12″*Z*)-octadecadienoyl]-3-(α-D-galactopyranosyl-1-6-β-D-galactopyranosyl)-glycerol. Quantitatively, the amount of the avenoleate-containing galactolipid was of the same order of magnitude as those of individual molecular species of digalactosyldiacylglycerol containing nonoxygenated acyl chains. The content of the new galactolipid in oat seeds was 0.5–0.6 mg per g of seed.

Lipids 33, 355–363 (1998).

A new oxylipin, i.e., 15(*R*)-hydroxy-(9*Z*),(12*Z*)-octadecadienoic acid, was recently isolated from seeds of oat (*Avena sativa* L.) (1). The trivial name "avenoleic acid" was given to the new hydroxy acid. Quantitative determination of avenoleic acid in oats showed a content of 0.6–0.7 mg per g of dry seed (1). Avenoleic acid was also present in seeds of wild oats (*A. fatua*) (Hamberg, M., and Hamberg, G., unpublished observations); however, it was not detectable in seeds of barley, rye, or wheat (1). Avenoleic acid is chemically related to ricinoleic acid. Both compounds possess a homoallylic alcohol group, and in both compounds the alcohol group is located at a position that in the corresponding nonhydroxylated compound can undergo desaturation. Thus, oleate, precursor of ricinoleate [(12*R*)-hydroxyoleate], can be transformed into linoleate by desaturation at C-12/C-13 whereas linoleate, the putative precursor of avenoleate [(15*R*)-hydroxylinoleate], can be transformed into α-linolenate by desaturation at C-15/C-16. Interestingly, two enzymes catalyzing hydroxylation and desaturation of oleate, i.e., oleoyl 12-hydroxylase from *Ricinus communis* and n-6-oleoyl desaturase from *Arabidopsis*, have been shown to be homologous (2). It seems possible that the putative linoleoyl 15-hydroxylase responsible for biosynthesis of avenoleate from linoleate is related to n-3-linoleoyl desaturase involved in the formation of α-linolenic acid from linoleic acid.

The present paper is concerned with the localization of avenoleic acid in lipids of oat seeds and with the isolation of an unusual galactolipid which serves as a quantitatively important storage form of avenoleic acid in oat seeds. The structure of the new galactolipid was determined by chemical, physical, and enzymatic methods.

EXPERIMENTAL PROCEDURES

Plant material. Seeds of oat (*A. sativa* L., cv. Vital) were obtained from Svalöf Weibull, Svalöv, Sweden.

Chemicals. Lipase from *Rhizopus arrhizus* was purchased from Boehringer Mannheim (Mannheim, Germany). D-Glucose, D-galactose, L-galactose, methyl α-D-galactopyranoside, and methyl β-D-galactopyranoside were obtained from Sigma Chemical Co. (St. Louis, MO). *S*-(+)-2-Butanol was purchased from Aldrich Chemical Co. (Gillingham, United Kingdom). A mixture of methyl α- and β-D-glucopyranosides was prepared by refluxing D-glucose in methanol/concentrated hydrochloric acid (2.6:0.4, vol/vol) for 1 h. Digalactosyldiacylglycerol from wheat flour was purchased from Sigma Chemical Co. This material was subjected to preparative reversed-phase high-performance liquid chromatography

Abbreviations: Avenoleic acid, (15*R*)-hydroxy-(9*Z*),(12*Z*)-octadecadienoic acid; ES, electrospray; FT-IR, Fourier-transform infrared; GC–MS, gas–liquid chromatography–mass spectrometry; GLC, gas–liquid chromatography; HMBC, heteronuclear multiple bond correlation spectroscopy; HPLC, high-performance liquid chromatography; Me_3Si, trimethylsilyl; NMR, nuclear magnetic resonance; RP, reversed-phase; TLC, thin-layer chromatography; TOCSY, total correlation spectroscopy.

(RP-HPLC) [solvent: methanol/water (95:5, vol/vol)] to provide a major molecular species having an effluent volume of 89.4–98.4 mL. Alkaline hydrolysis of this material afforded linoleic acid as the sole fatty acid, demonstrating that the parent galactolipid was identical to 1,2-dilinoleoyl-3-(α-galactopyranosyl-1-6-β-galactopyranosyl)-glycerol.

Methyl 3-(8′-carbomethoxyoctanoyloxy)-hexanoate. To a solution of methyl 3-hydroxyhexanoate (2 mmol) and pyridine (0.5 mL) in toluene (5 mL) was added 8-carbomethoxyoctanoyl chloride (2.2 mmol). The mixture was stirred at 23°C for 18 h and subsequently extracted with hexane. The hexane layer was washed with dilute NaOH and taken to dryness. Purification by SiO_2 chromatography and preparative thin-layer chromatography (TLC) (solvent system A) afforded methyl 3-(8′-carbomethoxyoctanoyloxy)-hexanoate which was pure as judged by gas–liquid chromatography (GLC) analysis. The Fourier-transform infrared (FT-IR) spectrum (film) showed bands at *inter alia* 2936, 2860, and 1739 cm^{-1} (ester carbonyls). Mass spectrometric analysis showed prominent ions at *m/z* 299 (2%; M − 31; loss of $\cdot OCH_3$), 257 (5; M − 73; loss of $\cdot CH_2–COOCH_3$), 185 [100; $CH_3OOC–(CH_2)_7–C{\equiv}O^+$], 145 [37; M − 185; loss of $CH_3OOC–(CH_2)_7–(CO)\cdot$], and 128 [48; M − 202; elimination of $CH_3OOC(CH_2)_7–COOH$]. As expected, alkaline hydrolysis of an aliquot of the diester resulted in the formation of 3-hydroxyhexanoic acid and azelaic acid as determined by gas chromatography–mass spectrometry (GC–MS).

Chemical methods. Acetylation was carried out by treating samples with acetic anhydride/pyridine (1:1, vol/vol) at 23°C for 15 h. Alkaline hydrolysis was performed by treatment with 0.2 M NaOH in 80% aqueous ethanol under an atmosphere of argon at 23°C for 18 h. Oxidative ozonolysis (3) was performed as described.

Method for identification of carbohydrate. For identification of carbohydrate, the galactolipid sample (1.8 mg) was dissolved in methanol (2.6 mL), and concentrated hydrochloric acid (0.4 mL; final concentration of HCl, *ca.* 5%) was added. The mixture was refluxed for 2 h. One-tenth of the residue obtained after evaporation was trimethylsilylated and analyzed by GLC and GC–MS. The remaining material was dissolved in water (2.6 mL), and concentrated hydrochloric acid (0.4 mL; final concentration of HCl, *ca.* 5%) was added. The mixture was refluxed for 2 h, taken to dryness, trimethylsilylated, and analyzed by GLC and GC–MS.

Steric analysis of galactose. Configurational assignment of galactose was performed by modification of the method described by Gerwig *et al.* (4). Thus, samples of galactolipid or D- or L-galactose (10 μmol) were heated at 85°C under argon for 1 h with *S*-(+)-2-butanol (450 μL) and concentrated hydrochloric acid (50 μL). The mixtures were taken to dryness under a stream of argon and trimethylsilylated. Separation of the trimethylsilyl (Me_3Si) derivatives of the diastereomeric *S*-(+)-2-butyl-galactopyranosides was carried out by GLC using a methyl silicone capillary column operated at 190°C. The retention times of the derivatives of the two anomers of D-galactose were 8.57 and 10.50 min whereas the retention times recorded for the derivatives of the anomers of L-galactose were 8.98 and 9.90 min. The α- and β-configurations of the anomers were not determined (4).

Enzymatic hydrolysis. Galactolipid (1.3 mg) was dissolved in 0.2 mL of chloroform/methanol (2:1, vol/vol) containing 3 mg of Triton X-100. The solvent was removed under a stream of argon, and 1 mL of 0.04 M Tris buffer pH 7.7 was added to the residue. After careful vortex mixing, a clear solution was obtained. Lipase from *R. arrhizus* (2500 units) was added and the mixture was stirred at 23°C for 1 h. The mixture was acidified to pH 3 and extracted with 6 mL of chloroform/methanol (2:1, vol/vol). An aliquot of the extracted material was esterified, trimethylsilylated, and analyzed by GLC and GC–MS. The lysolipid was isolated by TLC using solvent system D.

Extraction of lipids from oat seeds. Batches of oat seeds were ground in an electric rotating knife coffee mill and the powder (10 g) was homogenized with an Ultra-Turrax (Janke & Kunkel, Staufen, Germany) in chloroform/methanol (2:1, vol/vol; 100 mL) containing 2,6-di-*tert*-butyl-4-methylphenol (1 mg). The mixture was filtered through cheesecloth and centrifuged at $1200 \times g$ for 10 min. The supernatant was taken to dryness *in vacuo* and the residue subjected to open column SiO_2 chromatography.

Preparation of galactolipid B_1. For large-scale preparations of galactolipid B_1, the major avenoleate-containing galactolipid in oat seeds, batches of oat seed powder (100 g) were homogenized in acetone (1 L) containing 2,6-di-*tert*-butyl-4-methylphenol (10 mg). The mixture was centrifuged and the supernatant taken to dryness. The residue (weight, 3.0–3.2 g) was subjected to SiO_2 chromatography (column, 25 g of SiO_2; elution with 300 mL of chloroform followed by 400 mL of acetone). The residue obtained after evaporation of the fraction eluted with acetone (280–330 mg) was dissolved in methanol (5 mL) and subjected to preparative RP-HPLC. Effluent containing galactolipid B_1 (75–83 mL) was collected and taken to dryness. The specimen of galactolipid B_1 thus obtained (25–39 mg) contained contaminants and was further purified by preparative TLC (solvent system B) followed by a second step of RP-HPLC. In this way galactolipid B_1 was obtained as a semitransparent solid (10–14 mg). The preparation was homogenous upon TLC analysis (solvent system B; $R_f = 0.34$; reference, 1,2-dilinoleoyl-3-(α-galactopyranosyl-1-6-β-galactopyranosyl)-glycerol, $R_f = 0.28$).

Preparation of the acetate of galactolipid B_1. Galactolipid B_1 (20 mg) was treated with acetic anhydride (1 mL) and pyridine (1 mL) at 23°C for 18 h. The residue obtained following evaporation (24 mg) was subjected to preparative straight-phase HPLC to provide the pure acetate of galactolipid B_1 as a colorless oil (19.5 mg; 10.8–12.5 mL effluent).

Quantitative determination of avenoleic acid in lipid fractions of oat seeds. Methyl 17-hydroxystearate (124.7 μg) was added to the lipid fraction to be analyzed and the mixture was subjected to alkaline hydrolysis. Material obtained after extraction was methyl-esterified and trimethylsilylated and analyzed by GLC (temperature, 230°C). The amount of avenoleic acid was calculated from the areas of the peaks correspond-

ing to the Me_3Si derivatives of methyl avenoleate (retention time, 8.2 min) and 17-hydroxystearate (retention time, 10.5 min) and from the amount of the 17-hydroxystearate internal standard added.

Chromatographic and instrumental methods. TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, Germany). The following solvent systems were used: A, ethyl acetate/hexane (7:93, vol/vol); B, chloroform/methanol/water (50:10:1, by vol); C, chloroform/methanol/water/acetic acid (50:10:1:1, by vol); D, chloroform/methanol/water (50:20:2, by vol). Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under ultraviolet light. RP-HPLC was performed with a column of Nucleosil C_{18} 100-7 (250 × 10 mm) purchased from Macherey-Nagel (Düren, Germany). If not otherwise indicated, methanol at a flow rate of 4 mL/min was used as the mobile phase. The detector was set at 210 nm. Straight-phase HPLC was carried out with a column of Nucleosil 50-5 (200 × 4.6 mm; Macherey-Nagel). The solvent system used was 2-propanol/hexane (5:95, vol/vol) and the flow rate was 1.5 mL/min. GLC was performed with a Hewlett-Packard model 5890 gas chromatograph (Avondale, PA) equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm). Helium at a flow rate of 25 cm/s was used as the carrier gas. GC–MS was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. Infrared spectroscopy was carried out with a Perkin-Elmer model 1650 FT-IR spectrophotometer (Norwalk, CT).

Electrospray (ES) MS. Positive- and negative-ion ES mass spectra were recorded on an AutoSpec OATOFFPD mass spectrometer (5) (Micromass, Manchester, United Kingdom) equipped with a conventional ES interface. Samples were introduced in a methanol solution at a flow rate of 2 μL/min, and the interface was tuned on the $(M + Na)^+$ or $(M - H)^-$ ion. Low resolution (2000 Resolution, 10% valley definiton) mass spectra were recorded over a *m/z* range of 2000–100 at a rate of 15 s/decade. Accurate mass measurements were made at moderately high resolution (5000 Resolution, 10% valley definition) by voltage scanning at a rate of 15 s/scan; the mass range scanned was just sufficient to include two calibrant ion peaks on either side of the ion of interest.

Nuclear magnetic resonance (NMR) spectroscopy. A Bruker DMX-600 instrument (Karlsruhe, Germany) was used for the NMR analyses. Deuteriobenzene was used as the solvent. Proton NMR spectra were recorded at 600 MHz and ^{13}C spectra at 150 MHz. Analyses included double-quantum filtered two-dimensional correlaton spectroscopy (DQF-COSY), total correlation spectroscopy (TOCSY), ^{13}C-heteronuclear single-quantum correlation spectroscopy, and ^{13}C-heteronuclear multiple bond correlation spectroscopy (HMBC), all recorded with 512 × 8192 data points, t_{1max} = 70–85 ms, t_{2max} = 560 ms. The TOCSY spectrum was recorded with an unusually long mixing time, i.e., 2 s. The ^{13}C-HMBC spectrum was recorded with a ^1H-^{13}C *J*-evolution delay of 80 ms. Scalar coupling constants were measured from the 1D ^1H NMR spectrum and the DQF-COSY spectrum. Chemical shifts are referred to tetramethylsilane.

RESULTS

Detection and isolation of galactolipid B_1. Total lipids obtained from 10 g of oat seeds were subjected to open column chromatography using SiO_2 (20 g) as the adsorbent. Elution was accomplished with chloroform (300 mL), acetone (400 mL), and methanol (400 mL). An aliquot (10 mL) of each fraction was removed for quantitative determination of avenoleate. As seen in Table 1, the main part (62–63%) of the total amount of avenoleic acid was present in the glycolipid fraction eluted with acetone. Of total acyl chains in this fraction, 16.6–18.5% were identical to avenoleate.

An aliquot of the material present in the glycolipid fraction (Table 1) was subjected to TLC using solvent system C. As reference, 1,2-dilinoleoyl-3-(α-galactopyranosyl-1-6-β-galactopyranosyl)-glycerol was used. Several bands, labeled A–H, were visualized by spraying with dichlorofluorescein (Table 2). The materials forming these bands were eluted with chloroform, subjected to alkaline hydrolysis, and analyzed by GLC following methyl-esterification and trimethylsilylation. Material in band A, which cochromatographed with the reference and was essentially devoid of avenoleate, was provisionally identified as digalactosyldiacylglycerol containing only nonhydroxylated acyl chains. Hydrolysis of material in band B liberated a fatty acid mixture containing 33.1% avenoleate, suggesting the identity of this material with glycolipid containing one avenoleate and two nonhydroxylated fatty acid residues. Hydrolysis of material forming the less intense bands C and D afforded a fatty acid mixture comprising a higher proportion (41.2–47.8%) of avenoleate.

In another experiment, an aliquot of the glycolipid fraction was subjected to TLC, and the amounts of avenoleate present in band B and in the remaining zones of the plate were separately determined. It was found that the amount of avenoleate associated with band B accounted for 46% of the total amount of avenoleate present in the glycolipid fraction.

Analysis of material forming band B by RP-HPLC showed two components, i.e., galactolipid B_1 (68%; effluent volume, 72.0–77.0 mL) and galactolipid B_2 (32%; effluent volume,

TABLE 1
Separation of Lipids from 10 g of Oat Seeds by SiO_2 Chromatography

Experiment	Eluent	Weight (mg)	Avenoleic acid[a] (mg)	Avenoleic acid[b] / total fatty acids
1	Chloroform	231	1.48 (29%)	0.009
	Acetone	74	3.24 (63%)	0.185
	Methanol	142	0.41 (8%)	0.031
2	Chloroform	250	1.52 (29%)	0.008
	Acetone	64	3.19 (62%)	0.166
	Methanol	148	0.46 (9%)	0.030

[a]Determined by gas–liquid chromatography (GLC) using methyl 17-hydroxystearate as internal standard.
[b]Ratio between avenoleic acid and total fatty acids as determined by GLC.

TABLE 2
Separation of Glycolipid Fraction from SiO_2 Chromatography by Thin-Layer Chromatography[a]

	Band							
	A	B	C	D	E	F	G	H
Intensity	Strong	Strong	Medium	Medium	Medium	Weak	Weak	Weak
R_f value	0.30	0.40	0.46	0.57	0.66	0.80	0.87	0.96
Avenoleic acid[b]	<0.8	33.1	47.8	41.2	7.2	9.2	3.9	3.8

[a]Solvent system C (described in the Experimental Procedures section); reference, 1,2-dilinoleoyl-3-(α-galactopyranosyl-1-6-β-galactopyranosyl)-glycerol, R_f = 0.30.
[b](Avenoleic acid/total fatty acids) × 100 as determined by GLC. For abbreviation see Table 1.

86.5–94.6 mL). Alkaline hydrolysis performed on galactolipid B_1 produced avenoleic acid (33.7%) and linoleic acid (66.3%), suggesting that galactolipid B_1 contained one ester-bound avenoleate and two ester-bound linoleates. Hydrolysis of galactolipid B_2 produced avenoleic acid (34.2%), palmitic acid (13.5%), linoleic acid (31.8%), and oleic acid (20.5%). Obviously, galactolipid B_2 was due to more than one molecular species, probably a mixture of two compounds containing: 1 avenoleate + 1 linoleate + 1 oleate, and 1 avenoleate + 1 linoleate + 1 palmitate. This material was not further characterized.

IR and mass spectrometric analysis of galactolipid B_1. The FT-IR spectrum of galactolipid B_1 showed absorption bands at *inter alia* 3408 (OH), 2927 (CH_2), 1733 (ester carbonyl), 1653 (C=C), 1071 (C–O), and 916 cm^{-1} (type 1 band of sugars: ring vibration). Acetylation of galactolipid B_1 by treatment with acetic anhydride/pyridine abolished the hydroxyl absorption band and produced a strong absorption band at 1752 cm^{-1} (ester carbonyl). In addition, the FT-IR spectrum of the acetate of galactolipid B_1 showed prominent bands at 2929 (CH_2), 1653 (C=C), 1371 (CH_3), 1223 (asymmetric stretching of C–O–C of acetate), 1069 (symmetric stretching of C–O–C of acetate), and 911 cm^{-1} (type 1 band of sugars: ring vibration).

The negative-ion ES mass spectrum of galactolipid B_1 revealed an intense ion at *m/z* 1217.8 corresponding to the $(M - H)^-$ ion. Accurate mass measurements gave an *m/z* value of 1217.835 compatible with the chemical formula $C_{69}H_{117}O_{17}$. The positive-ion ES mass spectrum of galactolipid B_1 showed an intense ion at *m/z* 1241.8 corresponding to the $(M + Na)^+$ ion. Accurate mass measurement gave an *m/z* value of 1241.828 compatible to within 1 ppm of the chemical formula $C_{69}H_{118}O_{17}Na$. The data mentioned thus strongly indicated that the empirical formula of galactolipid B_1 was $C_{69}H_{118}O_{17}$, i.e., identical to the formula calculated for a molecule assembled of one avenoleate, two linoleates, one glycerol, and two galactose residues.

Identification of the carbohydrate moiety of galactolipid B_1. Galactolipid B_1 was subjected to acid methanolysis as well as acid hydrolysis, and the trimethylsilylated products were analyzed by GLC and GC–MS. GLC analysis (column temperature, 200°C) of the acid methanolysis product of galactolipid B_1 showed peaks due to methyl linoleate (retention time, 10.08 min) and to the Me_3Si derivative of methyl avenoleate (22.99 min). In addition, four peaks due to the carbohydrate moiety of galactolipid B_1 were observed with retention times of 4.46 (63%), 5.05 (27%), 5.36 (4%), and 6.35 min (6%). As references, the Me_3Si derivatives of the following carbohydrates were used: anomers of D-glucopyranose (retention times, 6.06 and 8.33 min), anomers of D-galactopyranose (5.36 and 6.35 min), anomers of methyl D-glucopyranoside (5.43 and 5.85 min), methyl α-D-galactopyranoside (4.46 min), and methyl β-D-galactopyranoside (5.05 min). The mass spectrum recorded on the peak eluting at 4.46 min in the analysis of the acid methanolysis product of galactolipid B_1 was identical to that of the Me_3Si derivative of methyl α-D-galactopyranoside and showed a prominent ion at *m/z* 361 [3%; M − (31 + 90); loss of $\cdot OCH_3 + Me_3SiOH$], 217 (26; $Me_3SiO^+{=}CH{-}CH{=}CH{-}OSiMe_3$), 204 [100; $(Me_3SiO{-}CH{=}CH{-}OSiMe_3)^+$ or its equivalent], 147 (18; $Me_3SiO^+{=}SiMe_2$), and 133 ($CH_3O{-}CH{=}O^+SiMe_3$). Weak ions indicating the molecular weight were observed at *m/z* 482 (0.04; M^+) and 435 (0.1; $M^+ - (15 + 32)$; loss of $\cdot CH_3 + CH_3OH$). In the same way, the mass spectrum recorded on the material eluting at 5.05 min in the analysis of the acid methanolysis product of galactolipid B_1 was identical to that of the Me_3Si derivative of authentic methyl β-D-galactopyranoside.

GLC analysis of the material obtained following acid hydrolysis of galactolipid B_1 showed peaks at 5.36 (37%) and 6.35 min (63%), cochromatographing with the Me_3Si derivatives of the anomers of D-galactopyranose. The mass spectra recorded on the materials produced from galactolipid B_1 were identical to those recorded on the corresponding peaks of the Me_3Si derivatives of the two anomers of D-galactopyranose.

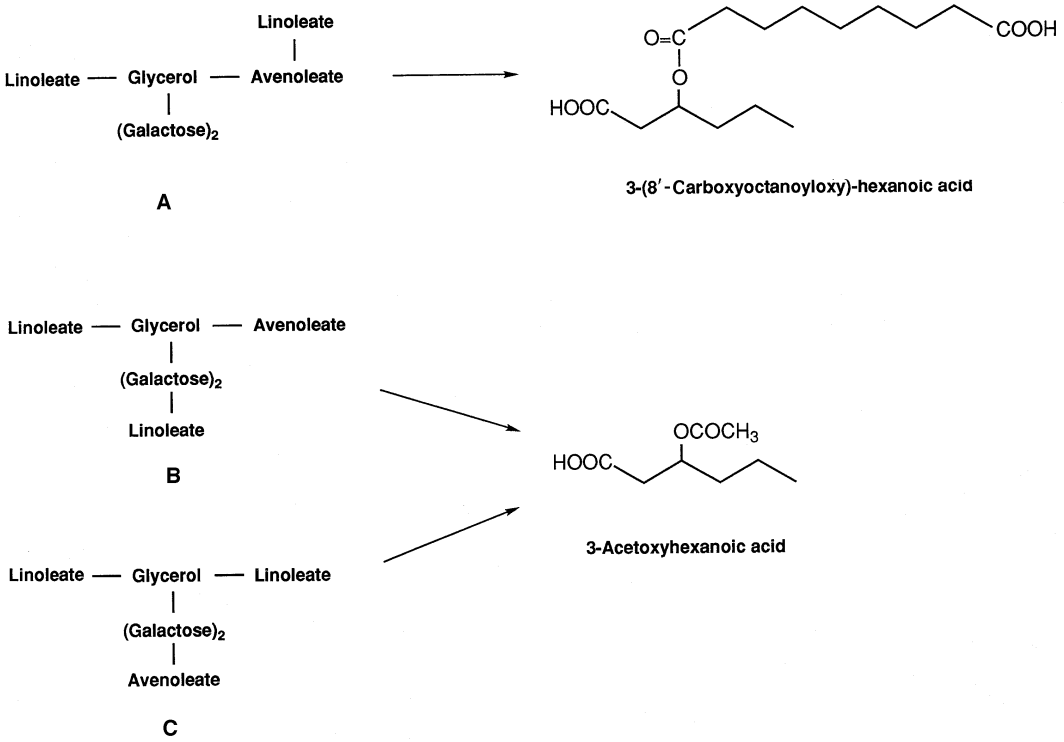
Configurational assignment of the galactopyranose moieties of galactolipid B_1 was accomplished by GLC analysis of the trimethylsilylated *S*-(+)-2-butyl galactopyranoside obtained by treatment of galactolipid B_1 (10 μmol) with *S*-(+)-2-butanol/concentrated hydrochloric acid (9:1, vol/vol). GLC performed using a column temperature of 190°C demonstrated two major peaks coinciding with the peaks of trimethylsilylated *S*-(+)-2-butyl D-galactopyranoside (8.57 and 10.50 min) but separated from the peaks of the corresponding derivative of L-galactopyranoside (8.98 min and 9.90 min). The identity of the derivatives was confirmed by MS. Thus, the mass spectra of the earlier-eluting derivative obtained from galactolipid B_1 and D-galactose were identical

and showed prominent ions at *m/z* 451 [0.2%; $M^+ - 73$; loss of $CH_3–CH_2–CH(O\cdot)–CH_3$], 419 (1; $M^+ - (15 + 90)$; loss of $\cdot CH_3 + Me_3SiOH$), 361 [6; $M^+ - (73 + 90)$], 305 (4), 217 (19; $Me_3SiO^+=CH–CH=CH–OSiMe_3$), 204 [100; $(Me_3SiO–CH=CH–OSiMe_3)^+$ or its equivalent], 175 [$CH_3–CH_2–CH(CH_3)–O–CH=O^+SiMe_3$], 147 (18; $Me_3SiO^+=SiMe_2$), 129 (6; $CH_2=CH–CH=O^+SiMe_3$), and 73 (41; Me_3Si^+).

From these data, combined with the results of the mass-spectrometric analysis of galactolipid B_1, it was concluded that galactolipid B_1 contained two D-galactopyranose residues.

Identification of the acyl chains of galactolipid B_1. As already mentioned, alkaline hydrolysis performed on galactolipid B_1 liberated avenoleic acid (33.7%) and linoleic acid (66.3%), suggesting the presence in galactolipid B_1 of one avenoleate and two linoleates. Assuming that two of the fatty acid residues were esterified to the *sn*-1 and *sn*-2 positions of the glycerol backbone, it was conceivable that the third acyl chain was esterified either to the alcohol group of the avenoleate residue (structure **A** in Scheme 1) or to one of the alcohol groups of the galactose residues (structures **B** and **C**). To distinguish between these possibilities, a sample (1 mg) of galactolipid B_1 was treated with acetic anhydride/pyridine and subjected to oxidative ozonolysis. Analysis of the esterified product by GLC showed the presence of one major oxidation product which was identified as methyl 3-(8′-carbomethoxyoctanoyloxy)-hexanoate by its retention time and its mass spectrum using the authentic compound as reference. Methyl 3-acetoxyhexanoate was undetectable in spite of scrupulous search using temperature programming from 100°C with the authentic compound as reference. On the basis of these results, it was concluded that galactolipid B_1 contained one linoleate residue and one linoleoyl-avenoleate residue esterified to glycerol (structure **A**, Scheme 1).

Localization of acyl chains in galactolipid B_1. Lipase from *R. arrhizus* catalyzes selective hydrolysis of the ester bond at *sn*-1 of galactolipids (6). To identify the acyl chain which was esterified at *sn*-1 of galactolipid B_1, a sample of the galactolipid was treated with lipase from *R. arrhizus*. An aliquot of the hydrolysis product was esterified, trimethylsilylated, and subjected to GLC (230°C). A major peak (96%; 4.1 min) coeluting with methyl linoleate, and a minor peak (4%; 8.2 min) coeluting with the Me_3Si derivative of methyl avenoleate were observed. Analysis by GC–MS confirmed the identities of these compounds. The remaining part of the product obtained following the lipase treatment was subjected to TLC using solvent system D. This analysis showed that galactolipid B_1 ($R_f = 0.68$) had been completely hydrolyzed and converted to a major ($R_f = 0.44$) and a minor ($R_f = 0.29$) lysolipid. The proportion of the less abundant material was reduced when smaller amounts of enzyme were used or when Triton X-100 was excluded from the reaction mixture. The nature of this material was not further investigated. Part of the major lysolipid was subjected to alkaline hydrolysis to afford a 1:1 mixture of avenoleic acid and linoleic acid. In another experiment, the major lysolipid was acetylated and subjected to oxidative ozonolysis. Analysis of the esterified product by GLC demonstrated the presence of methyl 3-(8′-carbomethoxyoctanoyloxy)-hexanoate and the absence of



SCHEME 1

methyl 3-acetoxyhexanoate. This result demonstrated that the lysolipid retained the linoleoyl-avenoleate residue. On the basis of these findings, it was concluded that galactolipid B_1 contained a linoleate residue esterified at the *sn*-1 position and a linoleoyl-avenoleate residue esterified at the *sn*-2 position (Scheme 2). In Scheme 2, letters A, B, and C indicate acyl chains, i.e., linoleate esterified to *sn*-1 of glycerol, avenoleate esterified to *sn*-2 of glycerol, and linoleate esterified to the C-15 alcohol group of avenoleate, respectively; Gal = galactose.

Analysis of galactolipid B_1 by NMR. NMR spectroscopy was used in order to verify the structure of galactolipid B_1 established by chemical and enzymatic methods and MS (Scheme 2). A challenging problem in the NMR analysis was posed by the question, whether the linoleate (A) and linoleoyl-avenoleate (C-B) residues of Scheme 2 were connected to *sn*-1 and *sn*-2, respectively, or *vice versa*, since the acyl chains A and B differ chemically only at a position remote from the glycerol moiety. The ^{1}H NMR resonances of the methylene protons at position 2 of acyl chains A, B, and C were assigned by a ^{13}C-HMBC spectrum, correlating the ^{13}C NMR signals of the C-1 carbons with the protons on both sides of the ester bonds. The spectral region with the cross peaks C-1 to H_2-2 for all three acyl chains is shown in the lower panel of Figure 1. The figure shows that the ^{13}C chemical shifts of the carboxy groups are well resolved, but for the three C-2 methylene groups only the ^{1}H chemical shift of acyl chain A was clearly different from those of the acyl chains B and C. Furthermore, the ^{1}H chemical shifts of the protons within each methylene group are indistinguishable. The multiplet fine structure of the H_2-2 (C) resonance is much better resolved than for the H_2-2 (A) and H_2-2 (B) resonances. Quite generally, narrower lineshapes were observed for the linoleoyl residue C than for the other acyl chains, and broader signals were observed for the carbohydrate and glycerol moieties. This effect may be explained by reduced mobility caused by intermolecular hydrogen bonds transiently formed between the hydroxyl groups of different molecules in the apolar solvent used. The ^{1}H and ^{13}C NMR signals from the 4, 5, 6, and 7 positions of acyl chains A, B, and C were indistinguishable (Table 3). For the protons at positions 13 to 17, the ^{1}H NMR signals of the avenoleoyl chain (B) could be resolved from the corresponding signals from the linoleoyl chains (A and C). To determine whether the H_2-2 (A) or the H_2-2 (B) resonance belongs to the avenoleoyl chain requires the correlation of the H_2-2 signals with the H-13 signals. This correlation was obtained by a TOCSY experiment recorded with a very long mixing time (2 s), using the scalar proton–proton couplings for magnetization transfer within each acyl chain. The cross peak between the resolved H-13 resonance of the avenoleoyl chain and the H_2-2 resonance of the same acyl chain is identified by a horizontal rectangle in the upper panel of Figure 1. The locations of the corresponding cross peaks of the acyl chains A and C are identified by an oval and a vertical rectangle, respectively. The ^{1}H chemical shift of the H_2-2 signal of the avenoleate residue revealed in this experiment matched the ^{1}H chemical shift observed with the ^{13}C-HMBC cross peak at 173.8 ppm, but not the ^{1}H chemical shift of the cross peak at 173.6 ppm (Fig. 1). The match is complicated by the different cross peak multiplicities and lineshapes of the TOCSY and ^{13}C-heteronuclear single-quantum correlation spectroscopy cross peaks. Thus, the H_2-2 resonance of

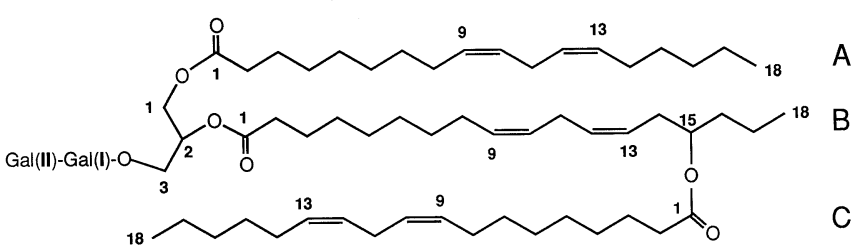
[c]Roman numerals **I** and **II** refer to galactose residues as indicated in Scheme 2.



SCHEME 2

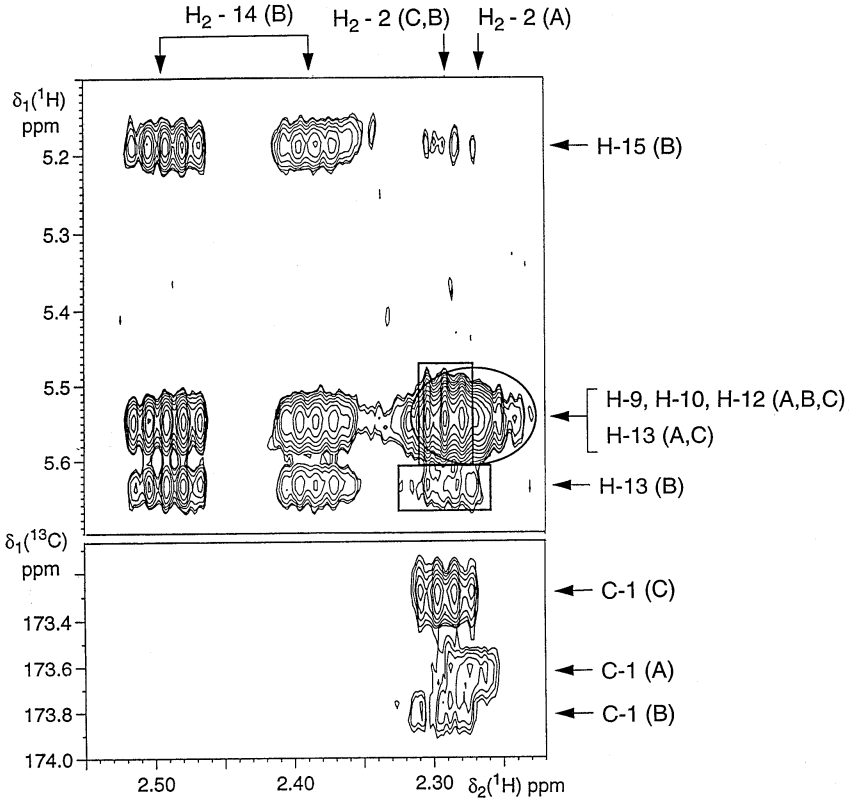


FIG. 1. Assignment of the acyl chains by nuclear magnetic resonance (NMR). Top panel: spectral region from the total correlation spectroscopy (TOCSY) experiment showing the ^{1}H-^{1}H cross peaks between H-13 in the δ_1 dimension and H_2-2 in the δ_2 dimension for the acyl chains A–C of Scheme 2. The chemical shifts of all protons involved in the cross peaks are indicated in the margins. The oval, the horizontal box, and the vertical box identify the location of the H-13–H_2-2 cross peak for the acyl chain A, B, and C, respectively. Bottom panel: spectral region from the ^{13}C heteronuclear multiple bond correlation spectroscopy (HMBC) spectrum showing the ^{13}C-^{1}H cross peaks between C-1 in the δ_1 dimension and H_2-2 in the δ_2 dimension for the acyl chains A–C. Note that the multiplet fine structures of the H_2-2 resonances in the δ_2 dimension are different in the TOCSY and ^{13}C-HMBC spectrum because of additional ^{1}H-^{13}C couplings in the ^{1}H NMR multiplets of the ^{13}C-HMBC spectrum and different, mixed lineshapes in both experiments.

acyl chain C appears as a quartet in the ^{13}C-HMBC spectrum but as a triplet in the TOCSY spectrum. Furthermore, the H-13 (B)–H_2-2 (B) cross peak in the TOCSY spectrum appears asymmetric with higher intensity toward the low ppm end of the cross peak and a larger total width than the C-1 (B)–H_2-2 (B) cross peak in the ^{13}C-HMBC spectrum. However, there is clearly no cross peak intensity at 2.26 ppm, which would be expected if the match were with the H_2-2 (A) resonance. The H_2-2 resonance of acyl chain A appears at a lower ppm value in the TOCSY spectrum, as illustrated by the cross peak between the degenerate protons 9, 10, 12, 13 and the H_2-2 resonance (identified by an oval in Fig. 1). The successful correlation of the H-13 (B) with the H_2-2 (B) resonance, which was nontrivial because of the long distance between the protons, completes the assignment of the avenoleoyl acyl chain to the position 2 of the glycerol moiety.

The ^{13}C-HMBC experiment further confirmed that the disaccharide residue was bound at the terminal position of the glycerol moiety. Analysis of vicinal ^{1}H-^{1}H coupling constants recorded on acetylated galactolipid B_1 showed that the galactose ring proximal to the glycerol moiety is a β-anomer and that the terminal galactose ring is an α-anomer (Table 4).

Quantity of galactolipid B_1 in oat seeds. On the basis of the facts that 63% of the total amount of avenoleic acid of oat seeds was present in the glycolipid fraction obtained by SiO_2

5-6	5.4, 7.5	6.2, 6.9
6-6	10.2	11.2

[a]Roman numerals **I** and **II** indicate galactose residues which are proximal and distal, respectively, to the glycerol moiety.

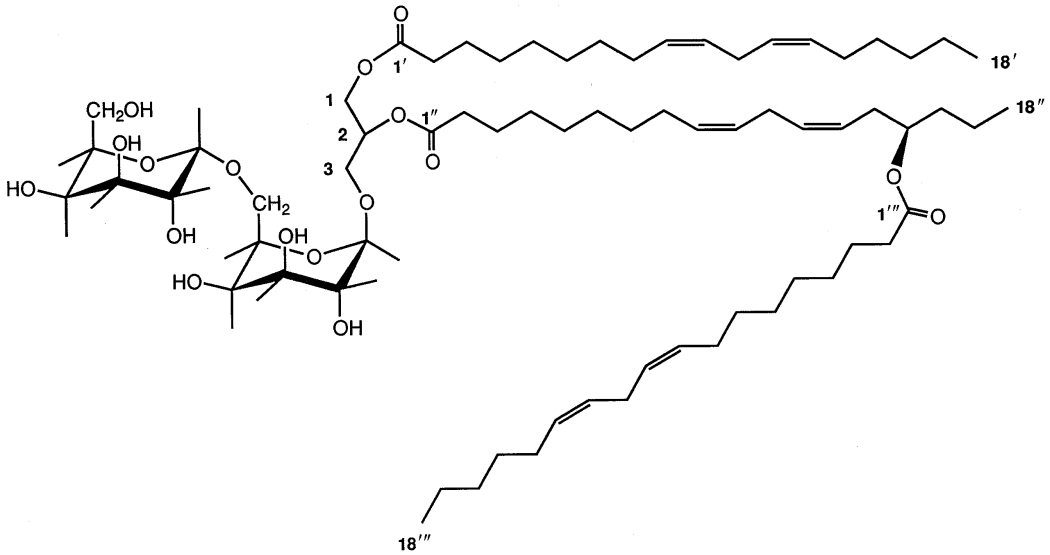
chromatography, that 46% of avenoleic acid of the glycolipid fraction was associated with band B found upon TLC, and that 68% of avenoleic acid of band B was associated with galactolipid B_1 isolated by RP-HPLC, it was concluded that 20% of the total amount of avenoleate of oat seeds was associated with galactolipid B_1. On the basis of the previously determined content of avenoleic acid in oat seeds, i.e., 593–725 μg/g (1), and the molecular weights of avenoleic acid (296) and galactolipid B_1 (1218), it was further calculated that the amount of galactolipid B_1 in oat seeds was 0.5–0.6 mg/g.

The quantitative relationship between galactolipid B_1 and digalactosyldiacylglycerol, the major galactolipid of oat seeds (7,8), was determined in the following way. An aliquot of the material present in the glycolipid fraction isolated by SiO_2 chromatography (10 mg; see Table 1) was subjected to TLC using solvent system C. The zones corresponding to digalactosyldiacylglycerol (R_f = 0.30) and galactolipids $B_1 + B_2$ (R_f = 0.40) were recovered, and methyl 17-hydroxystearate (124.7 μg) was added as an internal standard. The two samples were subjected to alkaline hydrolysis and the methyl-esterified and trimethylsilylated products analyzed by GLC. From the relative amounts of fatty acids in the two fractions, making correction for the presence of three acyl chains per molecule of galactolipid in the galactolipid B sample, it was found that the amount of galactolipids $B_1 + B_2$ was 26% of the amount of digalactosyldiacylglycerol. Because galactolipid B_1 constituted 68% of galactolipids $B_1 + B_2$, it was calculated that the percentage of galactolipid B_1 relative to digalactosyldiacylglycerol was 18%. Digalactosyldiacylglycerol in oat seeds exists as a mixture of molecular species, the major ones being molecules containing two linoleates (37%) and one linoleate plus one palmitate (31%) (9). From these percentages it was apparent that the amount of galactolipid B_1 in oat seeds was of the same order of magnitude as those of previously recognized molecular species of digalactosyldiacylglycerol. Oat seed lipids have been thoroughly studied (7–10), and it was surprising that galactolipid B_1 and related avenoleate-containing galactolipids had not been previously observed.

DISCUSSION

Avenoleic acid, a new oxylipin present in oat seeds (1), was found to be largely localized in the galactolipid fraction of oat seed total lipids. Fractionation of the galactolipids by TLC and HPLC afforded a major molecular species (galactolipid B_1) which accounted for 20% of the avenoleate content of oat seeds. Chemical methods and MS revealed that galactolipid B_1 was assembled of linoleoyl-avenoleate, linoleate, galactose, and glycerol. An enzymatic method demonstrated that the linoleoyl-avenoleate residue was positioned at *sn*-2 and the linoleate residue at *sn*-1. NMR spectroscopy confirmed these results and also showed that the proximal and distal galactopyranosyl residues had the β and α configurations, respectively. Steric analysis of diastereomeric S-(+)-2-butyl galactopyranoside derivatives by GLC demonstrated that the galactopyranosyl residues of galactolipid B_1 had the D absolute configurations. From these data, the new galactolipid was assigned the structure 1-[(9′*Z*),(12′*Z*)-octadecadienoyl]-2-[(15″*R*)-{(9‴*Z*),(12‴*Z*)-octadecadienoyloxy}-(9″*Z*),(12″*Z*)-octadecadienoyl]-3-(α-D-galactopyranosyl-1-6-β-D-galactopyranosyl)-glycerol (Scheme 3).

Galactolipids containing oxygenated fatty acids are rare. To the best of our knowledge, the only previous examples are galactolipids containing 12(*R*),13(*S*)-dihydroxy-5(*Z*),8(*Z*),-10(*E*),14(*Z*),17(*Z*)-eicosapentaenoic acid (11) and 5-hydroxy-12-oxo-6(*E*),8(*E*),10(*E*)-dodecatrienoic acid (12) isolated from the red alga *Gracilariopsis lemaneiformis*. Another unusual feature of the oat seed galactolipid was its content of an estolide, i.e., an acylated, not free, hydroxy acid residue. Ricinoleic acid [12(*R*)-hydroxy-9(*Z*)-octadecenoic acid], to which avenoleic acid is structurally related, is present in its



SCHEME 3

nonacylated form in the triacylglycerol fraction of castor oil; however, the occurrence of acylated ricinoleate residues (mono-, di-, and triestolides) in lipids from ergot oil has been described (13).

Galactolipid-bound linoleate undergoes desaturation into α-linolenate in the presence of linoleate n-3 desaturase (14). In our ongoing studies of the biosynthesis of avenoleate in preparations of oat seeds, attention is being paid to the possibility that galactolipid-bound linoleate may serve as the substrate for the putative linoleate 15-hydroxylase.

Stoichiometric and Kinetic Studies on *Ginkgo biloba* Extract and Related Antioxidants

Honglian Shi and Etsuo Niki*

Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro, Tokyo 153, Japan

ABSTRACT: Owing to increasing evidence showing the importance of lipid peroxidation in oxidative stress *in vivo*, the role and evaluation of antioxidants have received much attention. *Ginkgo biloba* extract (GBE), well-known as an efficient drug against diseases induced by free radicals, has been suggested to exert its effect by antioxidant action. A method was established to determine the activity of GBE as a hydrogen donor by stoichiometric and kinetic studies, and GBE was compared with several other antioxidants such as α-tocopherol, propyl gallate, and two kinds of flavonoids which are found in GBE, quercetin, and kaempferol. It was found that there were 6.62×10^{19} active hydrogens in 1 g of GBE. Stoichiometric studies showed that one molecule of α-tocopherol reacted with one molecule of galvinoxyl radical. For quercetin, kaempferol and propyl gallate, the experimental stoichiometric numbers were 4.0, 1.9, and 3.1, respectively. The rates of reaction of antioxidants with galvinoxyl in ethanol were determined spectrophotometrically, using a stopped-flow technique. The second-order rate constant, k_2, obtained at 25°C was 0.13 $(g/L)^{-1}s^{-1}$ for GBE and 5.9×10^3, 2.1×10^3, 1.2×10^4, and 2.4×10^3 $M^{-1}s^{-1}$ for quercetin, kaempferol, propyl gallate, and α-tocopherol, respectively. The second-order rate constant, k_2', on the molar basis of active hydroxyl groups in the tested substances obtained at 25°C decreased in the order of propyl gallate > α-tocopherol > quercetin > GBE ≈ kaempferol. This is the first study on GBE as an antioxidant which reports both stoichiometric and kinetic results.

Lipids 33, 365–370 (1998).

Extracts from the leaves of *Ginkgo biloba* trees have been used therapeutically in China from ancient times and in Western countries such as France and Germany from the 1960s for the treatment of atherosclerotic diseases of peripheral vascular and cerebrovascular insufficiency (1). The well-defined but complex product consists of two major groups of substances, flavonoid glycosides and terpenoids (2,3). The flavonoid fraction is composed of three flavonols, quercetin, kaempferol and isorhamnetin, which are linked to a sugar (2,4,5). The terpenoid fraction is composed of ginkgolides and bilobalides (6). The antioxidant action has been claimed to be one of the molecular mechanisms underlying the beneficial effects of *Ginkgo biloba* extract (GBE). GBE has been reported to scavenge superoxide (7) and hydroxyl radicals (8,9), to quench peroxyl radical (10,11), and to interact with nitric oxide (12) produced from cell or biochemical reaction systems. GBE attenuates oxidative stress in macrophages, endothelial cells, and cardiomyocytes (13–15). It was also reported that hydroxyl radical-induced apoptosis and death in rat cerebellar neuronal cells could be prevented by GBE (16,17). The antioxidant activity of GBE has been attributed to the free radical-scavenging activity of the flavonoid fraction in GBE, and confirmed experimentally (18).

However, because GBE is a mixture, it is difficult to evaluate the antioxidant effectiveness of GBE and to compare the scavenging and inhibiting effects of GBE on free radicals and lipid peroxidation with those of other antioxidants. It is important to understand the behavior of GBE as an antioxidant and to find a way to measure the rates at which it reacts with radicals. The lack of published studies on the efficiency and kinetics of GBE prompted us to carry out the present work.

For comparison, we studied several other well-known antioxidants that are pure chemicals and whose antioxidant activity is ascribed to the phenolic hydroxyl groups. Two of them are quercetin and kaempferol, the two main flavonoids in GBE and the most important flavonoids studied as antioxidants. A third is propyl gallate, a polyphenol used as a food additive. Another is α-tocopherol, an important chain-breaking antioxidant that has been extensively studied *in vitro* and *in vivo.* In the present work, we have established a method to determine the stoichiometric number of active phenolic hydroxyl groups. Furthermore, we used a stopped-flow technique to measure the reaction rate constants for related antioxidants with galvinoxyl.

MATERIALS AND METHODS

Reagents. Galvinoxyl, quercetin, and *n*-propyl gallate were obtained from Wako Pure Chemical Co. Ltd. (Osaka, Japan). Kaempferol was purchased from Aldrich Chemical Co. Ltd. (Milwaukee, WI) GBE was provided by Takehaya Co., Ltd. (Tokyo, Japan). α-Tocopherol was kindly supplied by Eisai Company Ltd. (Tokyo, Japan). All of the substances were dissolved in ethanol and used as received. Ethanol was of analytical reagent grade. Experiments were always performed on freshly made up solutions. The structures of tested substances

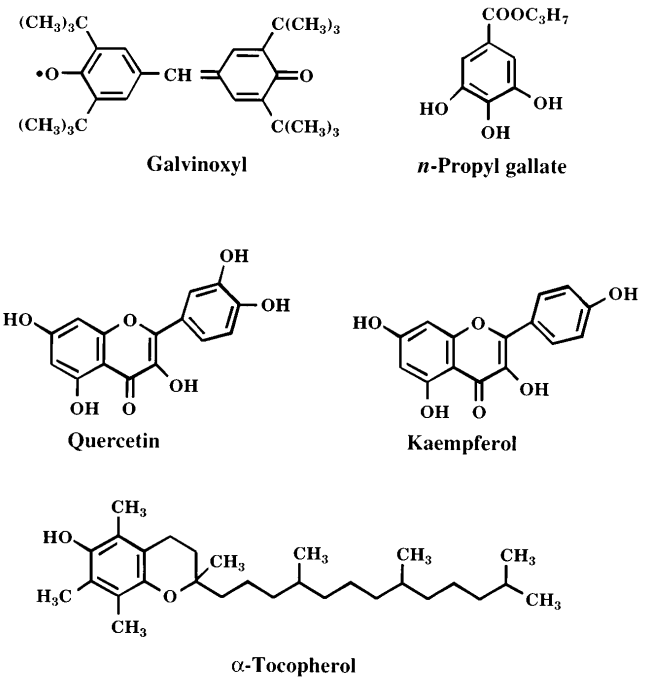

SCHEME 1

are shown in Scheme 1.

Stoichiometric study. Galvinoxyl, a stable phenoxyl radical, has a strong absorption peak at 428 nm in ethanol. It can be reduced by hydrogen-donating free-radical scavengers and has been used to assess the antioxidative activity of various compounds (19,20). The reaction of galvinoxyl with a hydrogen-donating antioxidant is represented by Equation 1:

$$G\cdot + XOH \rightarrow GH + XO\cdot \quad [1]$$

where G· is the galvinoxyl radical, XOH, the hydrogen-donating free-radical scavenger, GH, the reduced galvinoxyl, and XO·, the corresponding radical derived from XOH.

On the basis that one galvinoxyl molecule reacts with one active hydroxyl group, we can determine the quantity of active phenolic hydrogens in the reaction with galvinoxyl by the absorbance decrease of galvinoxyl in the reaction solution under the condition of [G·] > [XOH], which allows all of the XOH to take part in the reaction with galvinoxyl. The stoichiometric factor may be calculated as follows from the decrease in absorbance of galvinoxyl and the concentration of XOH.

From the definition of molar absorption of a substance (Equation 2), Equation 3 can be obtained for the reaction in Equation 1:

$$A = \varepsilon C l \quad [2]$$

(A: absorbance; ε: molar extinction coefficient; C: concentration, l: cell length);

$$\Delta N = V \Delta A/(\varepsilon l) \quad [3]$$

where, ΔN is the molar quantity of galvinoxyl reduced in the reaction solution, ΔA is the absorbance difference of galvinoxyl at 428 nm between the initial and the end reaction, and V is the reaction volume.

Here we assume that one mole of XOH reacts with n moles of galvinoxyl. In Equation 1, where XOH is consumed completely Equation 4 can be obtained:

$$\Delta N = n V C_x \quad [4]$$

where C_x is the concentration of XOH (for pure substances, c is expressed as mol/L; for GBE, c is in g/L).

From Equations 3 and 4, the stoichiometric number of radicals trapped by each antioxidant, n, is given by Equation 5.

$$n = \Delta A/(\varepsilon l C_x) \quad [5]$$

In our experiments, the concentration of galvinoxyl was set at 10 μmol/L (final concentration). For pure compounds, the concentrations were set between 0.1–2 μmol/L (final concentration). The concentration of GBE was selected as 0–0.02 g/L so that considerable galvinoxyl would remain at the end of reaction. The reaction was started by mixing the galvinoxyl ethanol solution with the hydrogen-donating compound ethanol solution. The decrease in absorbance of galvinoxyl at 428 nm was traced for 20 min after mixing by using a spectrophotometer (DU 640; Beckman, Fullerton, CA) at 25°C.

Kinetic study. A stopped-flow spectrophotometer (RA-2000; Photal Otsuka Electronics, Osaka, Japan) equipped with an advanced data acquisition and processing system was used for the fast reaction kinetics. Kinetic runs were carried out under pseudo-first-order conditions, [XOH] » [G·]. The reaction was monitored at 428 nm, the absorption maximum for galvinoxyl in ethanol. Appropriate volumes of the reactants were taken in two cells: cell A containing galvinoxyl in ethanol, and cell B containing test substance in ethanol. All kinetic runs were performed with a sweep-time longer than 10 half-lives of the corresponding reaction. The data acquisition system acquired absorbance vs. time data and computed the rate constants from log $(A_t - A_\infty)$ vs. time plots, where A_t and A_∞ correspond to the absorbances at time t and infinite time (after completion of the reaction), respectively. Each kinetic run was performed five times, and the average first-order rate constants, k_1, were evaluated. The measurements were performed at 25°C.

RESULTS

Molar extinction coefficient of galvinoxyl. Galvinoxyl was stable in ethanol. Its molar extinction coefficient was determined as 1.50×10^5 M^{-1} cm^{-1} at 428 nm in ethanol.

Stoichiometric studies of tested substances in the reaction with galvinoxyl. In Figure 1 we see that the fall in absorbance attributable to galvinoxyl (10 μmol/L) at 428 nm was proportional to the concentrations of the antioxidant (inset is an example of time course in the reaction between quercetin and galvinoxyl). Excellent linear correlation was obtained in plots for all the antioxidants studied. By using Equation 5, n values could be determined. The value used for ε for galvinoxyl at

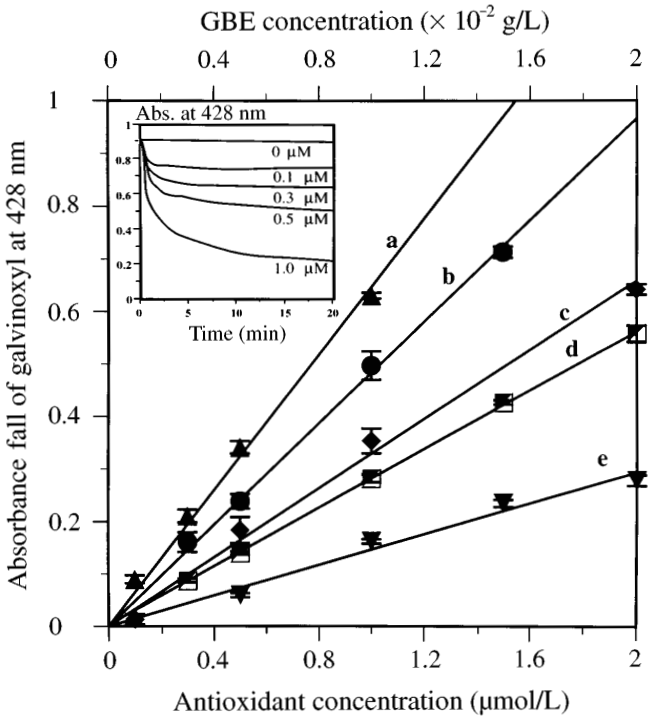

FIG. 1. Plots of absorbance falls of galvinoxyl at 428 nm against concentrations of hydrogen-donating antioxidants. Upper abscissa represents the concentration of *Gingko biloba* extract (GBE) whereas lower abscissa represents concentrations of pure compounds tested. Line a: quercetin; b: propyl gallate; c: GBE; d: kaempferol; and e: α-tocopherol. Data points represent means ± SD of five individual experiments.

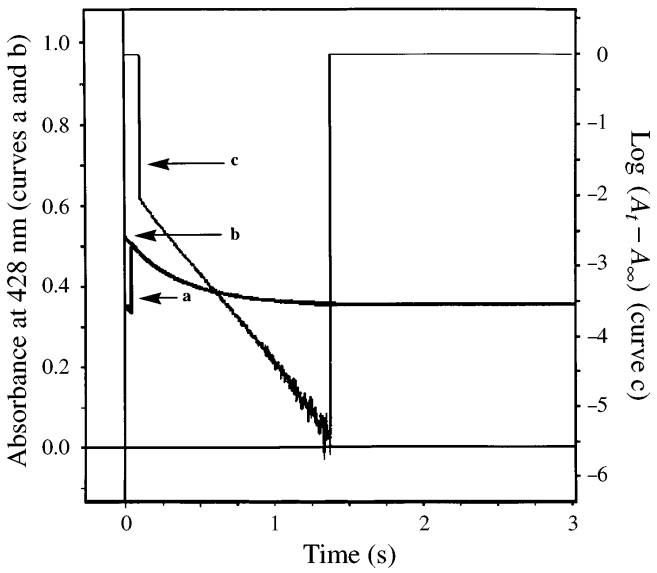

FIG. 2. Representative experiment of the pseudo-first-order study. Galvinoxyl (20 μmol/L ethanol) was mixed with propyl gallate (0.4 mmol/L ethanol) (curve a). Curve b is a theoretical fit to curve a. A typical log plot vs. time is also shown (curve c) which gives a pseudo-first-order rate constant of 2.4 s^{-1}. See the Methods section for the definition of log ($A_t - A_\infty$).

428 nm in Equation 5 was 1.50×10^5 M^{-1} cm^{-1}, and the cell length, *l*, was 1 cm. The slopes of the lines in Figure 1 correspond to $n/\varepsilon l$, from which *n* was calculated (Table 1). The *n* value for GBE was determined as 1.1×10^{-4} mol/g, meaning 1 g GBE could react with 1.1×10^{-4} mol galvinoxyl. In other words, there are 1.1×10^{-4} mol (6.62×10^{19} molecules) of active phenolic hydroxyl groups (OH) in 1 g GBE on the basis that one molecule of galvinoxyl reacts with one active OH. Similarly, the results show that quercetin, kaempferol, propyl gallate, and α-tocopherol contain 4.0, 1.9, 3.1, and 1.0 mole active hydrogens per mole, respectively, to reduce galvinoxyl.

Kinetic study of tested substances in the reaction with galvinoxyl by stopped-flow spectrophotometer. The kinetics of the oxidation of tested substances by galvinoxyl was carried out by following the decrease in absorbance of galvinoxyl at 428 nm. The concentration of galvinoxyl radical was always more than five times lower than those of tested substances (in the case of GBE, the number of active OH groups was taken into account) to obtain the pseudo-first-order rate constant, k_1. The second-order rate constant, k_2, may be calculated from the k_1 values by using Equation 6:

$$-d\,[G\cdot]/dt = k_1\,[G\cdot] = k_2\,[XOH]\,[G\cdot] \qquad [6]$$

Figure 2 is a typical time course of the decrease in absorbance at 428 nm when an ethanol solution of galvinoxyl is mixed with that of an antioxidant. The theoretical curve b fits very well with an experimentally obtained curve a which increased rapidly and then decreased. A typical plot of log ($A_t - A_\infty$) vs. time (curve c) gives a pseudo-first-order rate constant. The first-order rate constants observed at 428 nm were linearly dependent on the concentrations of the substances tested (Fig. 3). The plots of k_1 against the concentrations of tested substances yielded the second-order rate constants k_2 (Eq. 6) for quercetin, kaempferol, propyl gallate, and α-tocopherol in the reaction with galvinoxyl. These data are also summarized in

TABLE 1
Stoichiometric Numbers and the Second-Order Rate Constants for the Reactions Between Galvinoxyl and Antioxidants

	GBE	Quercetin	Kaempferol	Propyl gallate	α-tocopherol
n	1.1×10^{-4} [a]	4.0	1.9	3.1	1.0
k_2 [b]	0.13 [c]	5.9×10^3	2.1×10^3	1.2×10^4	2.4×10^3
k_2' [b]	1.2×10^3	1.5×10^3	1.1×10^3	3.9×10^3	2.4×10^3

[a]Mol active hydroxyl groups/g.
[b]Second-order rate constant for molecule (k_2) and per active hydrogen (k_2') in M^{-1} s^{-1}.
[c]$(g/L)^{-1}$ s^{-1}. GBE, *Gingko biloba* extract.

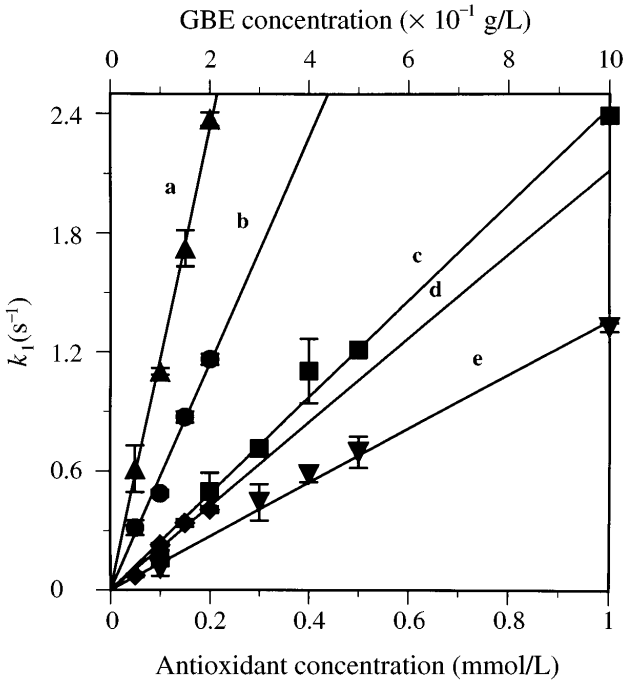

FIG. 3. Linear plots of first-order rate constants (k_1) as a function of concentrations of the antioxidant tested. Upper abscissa represents the concentration of GBE whereas lower abscissa represents concentrations of pure compounds tested. Line a: propyl gallate; b: quercetin; c: α-tocopherol; d: kaempferol; and e: GBE. The data points represent means ± SD of five individual experiments. The measurements were carried out at 25°C. See Figure 1 for abbreviations.

Table 1. The k_2 value obtained for GBE was 0.13 (g/L)$^{-1}$ s^{-1}. For the pure substances, the values decreased in the order of propyl gallate > quercetin > α-tocopherol > kaempferol.

We may rewrite Equation 1 in the following form by taking the stoichiometric factor into consideration:

$$G\cdot + (1/n)\ XOH \rightarrow GH + (1/n)\ XO\cdot \quad [7]$$

and rewrite Equation 6 as Equation 8:

$$-d\ [G\cdot]/dt = k_1\ [G\cdot] = (1/n)\ k_2\ [XOH]\ [G\cdot] = k_2'[XOH]\ [G\cdot] \quad [8]$$

where $k_2' = k_2/n$. The term k_2' may be defined as the rate constant of a single active hydroxyl group in the hydrogen-donating compound.

The rate constants k_2 and k_2' may be considered as the total reactive potential and the average reactive potential of a single active hydroxyl group, respectively, for these reactions. From k_2', we may compare the relative reactivities of active hydroxyl groups in different substances or mixtures of several substances like GBE. The results in Table 1 reflect that the active phenolic hydrogen of GBE has a similar reactivity to that of quercetin and kaempferol and a slightly smaller reactivity than that of α-tocopherol and propyl gallate.

DISCUSSION

The previous suggestion (20) that galvinoxyl reacts with phenolic antioxidant by a hydrogen atom abstraction was confirmed by our result that one molecule of galvinoxyl reacted with one molecule of α-tocopherol. The potency of antioxidant will be discussed below in terms of both stoichiometric and kinetic factors.

As expected from Equation 5, the decline in absorbance attributable to galvinoxyl by every antioxidant was directly proportional to the concentration of the antioxidant over the concentration range selected. If a higher concentration of an antioxidant than that of galvinoxyl was selected, the reduction of galvinoxyl was saturated (data not shown). A preliminary experiment was carried out to determine the range of GBE concentration in which the plot was linear. The stoichiometric study gave the number of active hydroxyl groups in 1 g of GBE as 1.1×10^{-4} mol. The stoichiometric numbers (n) of the tested pure substances in the reaction with galvinoxyl were determined experimentally as 4.0, 1.9, 3.1, and 1.0 for quercetin, kaempferol, propyl gallate, and α-tocopherol, respectively. We may consider the numbers strictly or theoretically as 4, 2, 3, and 1 for these compounds reacting with galvinoxyl. These values indicate that in the reaction with galvinoxyl in ethanol, quercetin provides four of its five hydroxyl groups, kaempferol two of its four hydroxyl groups, and that all of the three hydroxyl groups of propyl gallate take part in the reaction. The stoichiometric number of α-tocopherol for the reaction with peroxyl radicals is two (21,22), rather than one observed for galvinoxyl. This difference may be ascribed to the fact that α-tocopherol reacts with the first peroxyl radical to donate its hydrogen, and the resulting α-tocopheroxyl radical reacts with the second peroxyl radical to give an adduct (23), whereas α-tocopheroxyl radical does not react with galvinoxyl.

For measuring antioxidant potentials, the total antioxidant activity (TAA) or the Trolox-equivalent antioxidant activity (TEAC) has been reported by Rice-Evans *et al.* (24–28) as measuring the concentration of Trolox solution with an equivalent antioxidant potential to a standard concentration of the compound or the mixture under investigation. The TEAC or TAA reported for quercetin, kaempferol, gallic acid, and α-tocopherol were 4.7, 1.3, 3.0, and 1.0 (24–28), respectively, which gave the order of antioxidant potential as quercetin > gallic acid > kaempferol > α-tocopherol. Our stoichiometric studies gave the order quercetin (4) > propyl gallate (3.1) > kaempferol (1.9) > α-tocopherol (1.0). The orders obtained by using different methods are in accord. However, the TAA method was designed to compare the ability of a hydrogen-donating antioxidant to scavenge $ABTS^{\cdot+}$ radical, which is generated from the reaction of 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) with ferrylmyoglobin radical species (29), with that of Trolox. The value of TAA or TEAC may be considered as the same as the stoichiometric factor defined in the text because TAA or TEAC for Trolox is set at 1.0. In fact, our result showed that the TAA or TEAC values of gallic acid and α-tocopherol are equal to their stoichiometric numbers. The TAA or TEAC values of quercetin and kaempferol are not strictly the same as the stoichiometric

numbers we determined, but they are similar. Here we may say that the antioxidant activity defined by Rice-Evans is actually the number of active OH groups of substances.

Whether a certain substance acts as a radical scavenger may be revealed by determining the rate constant for reaction with a specific radical. Although stoichiometric number determines the duration of the inhibition period or lag time, the rate constant can indicate the extent of oxidation inhibition, that is, how much the antioxidant reduces the rate of oxidation. The results obtained from our kinetic studies and summarized in Table 1 show that the total reactive potentials of pure substances decrease in the order propyl gallate > quercetin > α-tocopherol > kaempferol, but we could not compare GBE with the pure chemicals. Based on the average reactive potential, however, the reactivity of GBE could be compared with those of the pure compounds, and the results in Table 1 show that the reactivity of phenolic hydroxy groups decreases in the order of propyl gallate > α-tocopherol > quercetin > GBE ≈ kaempferol.

Structure–activity relationships have been used to explain the role and potency of flavonoids as antioxidants (25,30,31). On the basis of spectral and kinetic evidence for the formation and decay of flavonoid aroxyl radicals, there are three mainly chemical criteria for flavonoids as effective antioxidants: (i) the *o*-dihydroxy structure in the B ring confers higher stability to the radical formed and participates in electron delocalization; (ii) a 2,3-double bond in conjugation with the 4-oxo function in the C ring contributes through participation in electron delocalization from the B ring; and (iii) the 3- and 5-OH groups with 4-oxo function in A and C rings provide maximal radical scavenging potential. Quercetin, satisfying all three criteria, shows higher reactivity than kaempferol with a lone B-ring hydroxyl group in the 4′ position. A catechol moiety in ring B, required for good scavenging activity, has also been confirmed by van Acker *et al.* (32) from quantum chemical explanation and electron spin resonance data on spin densities. They also showed the importance of intramolecular hydrogen bonding (32). Propyl gallate was found to possess the highest reaction potential with galvinoxyl among the substances studied. This activity could also be ascribed to the catechol moiety. The phenoxyl radical derived from polyphenol in the reaction with galvinoxyl could be stabilized by hydrogen bonding with an adjacent phenolic hydroxyl as well as by the aromatic ring (32,33); this stabilization promotes polyphenols to react with more galvinoxyl radicals, giving a stoichiometry greater than 1.

The order in relative activities of quercetin and α-tocopherol is reversed in the total reactive potential and the average reactive potential. This reversal indicates that the total activity of scavenging galvinoxyl of α-tocopherol is lower than that of quercetin, whereas the activity of the phenolic hydroxyl group of α-tocopherol is higher than that of the active hydroxyl groups of quercetin. The hydroxyl group activity of GBE is equal to that of kaempferol and lower than those of propyl gallate, α-tocopherol, and quercetin. [The two reactive potential orders of pure compounds (k_2 and k_2' in Table 1) are different from their TAA order (25) or our stoichiometric order.]

The antioxidative potentials compared here are the reactivities of substances toward galvinoxyl radical. To understand the whole activity of GBE as an antioxidant will be very complex because GBE may act not only by scavenging radicals but also (i) by chelating metal ions *via* the phenolic *o*-dihydroxy structure of the flavonoids, although it has been recognized that the antioxidative and lipid peroxidation-inhibiting potential of flavonoid predominantly resides in the radical-scavenging capacity rather than the chelation of metals (34,35) or (ii) by regenerating α-tocopherol through reduction of the α-tocopheroxyl radical. To act as a hydrogen-donating antioxidant is one of the mechanisms not only for GBE but also for flavonoids such as quercetin and kaempferol. Furthermore, the total antioxidant efficiency of radical-scavenging antioxidants is determined not only by their reactivities toward radicals but also by other factors such as fate of antioxidant-derived radicals, interactions with other antioxidants, and physical factors such as location and mobility at the microenvironment (36).

In conclusion, we have reported the quantity of active hydroxyl groups in GBE and in other pure substances which are contained in GBE or well-known antioxidants in the reaction with galvinoxyl. Taking the stoichiometric number into consideration, we have compared the second-order rate constant of GBE with other pure substances on the molar basis of active hydroxyl groups. We propose that the method devised in this study will be a useful one to evaluate and understand stoichiometrically and kinetically the antioxidative activity of hydrogen-donating compounds, pure substances, or mixtures.

ACKNOWLEDGMENTS

We are very grateful for the many valuable comments from the reviewers. We thank Dr. Mareyuki Takahashi and Dr. Noriko Noguchi for providing kind help. This study was supported in part by Grant-in Aid for Scientific Research and COE Research from the Ministry of Education, Science, Sports and Culture, Japan.

Lipid Molecular Order in Liver Mitochondrial Outer Membranes, and Sensitivity of Carnitine Palmitoyltransferase I to Malonyl-CoA

Victor A. Zammit*, Clark G. Corstorphine, Marys P. Kolodziej, and Fiona Fraser

Hannah Research Institute, Ayr, Scotland, United Kingdom, KA6 5HL

A**BSTRACT:** Mitochondrial outer membranes were prepared from livers of rats that were in the normal fed state, starved for 48 h, or made diabetic by injection of streptozotocin. Membranes were also prepared from starved late-pregnant rats. The latter three conditions have previously been shown to induce varying degrees of desensitization of mitochondrial overt carnitine palmitoyltransferase (CPT I) to malonyl-CoA inhibition. We measured the fluorescence polarization anisotropy of two probes, 1,6-diphenyl-1,3,5-hexatriene (DPH) and 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene-*p*-toluenesulfonate (TMA-DPH) which, when incorporated into membranes, report on the hydrophobic core and on the peripheral regions of the bilayer, respectively. The corresponding polarization indices ($\mathbf{r}_{DPH}$ and $\mathbf{r}_{TMA\text{-}DPH}$) were calculated. In membranes of all three conditions characterized by CPT I desensitization to malonyl-CoA, $\mathbf{r}_{DPH}$ was decreased, whereas there was no change in $\mathbf{r}_{TMA\text{-}DPH}$, indicating that CPT I is sensitive to changes in membrane core, rather than peripheral, lipid order. The major lipid components of the membranes were analyzed. Although significant changes with physiological state were observed, there was no consistent pattern of changes in gross lipid composition accompanying the changes to membrane fluidity and CPT I sensitivity to malonyl-CoA. We conclude that CPT I kinetic characteristics are sensitive to changes in lipid composition that are localized to specific membrane microdomains.
Lipids 33, 371–376 (1998).

Under most physiological conditions, carnitine palmitoyltransferase of the mitochondrial outer membrane (CPT I) catalyzes the reaction at which most of the control over β-oxidation of fatty acids is exerted (1–3). In the liver, this is particularly pertinent under basal conditions and during the onset of ketogenic states, whereas control over the pathway shifts to step(s) proximal to CPT I during the early phase of the reversal of these conditions. The property of CPT I that makes it possible for the reaction it catalyzes to exert such a level of control is its inhibition by malonyl-CoA (4). This inhibition diminishes its activity sufficiently *in vivo* so that, coupled with the efficient removal of the product (acylcarnitine) by its transport into the mitochondria (or the lumina of other membrane systems), it makes the reaction virtually unidirectional. Although this role of malonyl-CoA is central to the regulation of the rate of fatty acid oxidation in the liver (4–6), the decrease in the hepatic concentration of malonyl-CoA observed in ketogenic states, e.g., starvation, diabetes (7–11), does not appear to be sufficient by itself to ensure that the rate of acylcarnitine formation is increased to the extent required during the establishment of maximal rates of ketogenesis, even when the availability of fatty acid substrate has been maximally achieved (11). The additional feature of malonyl-CoA inhibition that enables full activation of ketogenesis to occur is the severalfold desensitization of CPT I to malonyl-CoA inhibition that occurs during the development of ketogenic conditions (12–15). This has been demonstrated through the monitoring of changes of different parameters *in vivo* during the onset of the pharmacological effects of streptozotocin-induced diabetes (16) and starvation (11). Conversely, studies in which the fate of fatty acids specifically directed to the liver *in vivo* (17) were monitored during the refeeding of starved rats (18) or insulin treatment of diabetic rats (19) have shown that only when the sensitivity of CPT I to malonyl-CoA is reestablished is the control of CPT I over the rate of acylcarnitine formation recovered.

In all instances, the changes in CPT I sensitivity to malonyl-CoA occur over a relatively slow time scale, requiring several hours for completion. This has been confirmed most recently through studies *in vivo* (11,18,20) and on cultured rat liver cells treated with insulin (21). This time scale has prompted us previously to suggest (5,6,22) that it is changes in the properties of the membrane (e.g., in the order of the membrane lipids) and the consequent alterations in the interactions between protein and membrane that mediate the changes in CPT I kinetic characteristics. This suggestion was made in light of previous data which showed that the changes in CPT I sensitivity observed in mitochondria isolated from rats in different physiological states can be mimicked *in vitro* by temperature- or chemically induced modulation of outer membrane lipid bilayer fluidity (23–25). In general, conditions that increase membrane fluidity *in vitro* result in decreased malonyl-CoA sensitivity of CPT I. A plausible basis for this strong effect of outer membrane fluidity on CPT I has recently been obtained through the elucidation of the topol-

ogy of the protein within the membrane (26,27). However, direct demonstration that changes in membrane fluidity actually occur *in vivo* in parallel with changes in the sensitivity of CPT I to malonyl-CoA has not hitherto been available.

MATERIALS AND METHODS

Animals. Wistar rats (A. Tuck & Sons, Battlesbridge, Kent, United Kingdom) were either fed *ad libitum* on a standard laboratory chow diet (see Ref. 11 for details) or starved for 48 h. Diabetes was induced by intraperitoneal injection of streptozotocin (60 mg/kg body weight); the animals were used 4 d later when their blood glucose was >20 mM. Rats used in the pregnant state were mated when they weighed about 180–200 g, and their pregnancy was allowed to proceed to day 19, when they were starved for 24 h before being used.

Preparation of mitochondrial outer membranes. These were prepared as described previously (28). Briefly, a crude preparation of mitochondria was obtained by differential centrifugation of liver homogenates prepared in a medium containing 300 mM sucrose, 5 mM Tris, 1 mM EGTA (pH 7.4 at 0°C). The mitochondria were further purified on self-forming Percoll gradients as described (28). After washing, the mitochondria were swollen in hypotonic medium and homogenized lightly to release outer membrane vesicles which were further purified by incubation with cytochrome C-Sepharose to minimize inner membrane contamination. Although, as expected, this resulted in the loss of some outer membrane material, routinely it increased the enrichment of monoamine oxidase (outer membrane marker) over that of cytochrome oxidase (inner membrane) by >50-fold compared to that in intact mitochondria. After high-speed sedimentation at 100,000 × *g* for 45 min, membranes were finally resuspended in a buffer containing 150 mM KCl, 5 mM Tris, and 1 mM EGTA (pH 7.4 at 0°C) and frozen at –80°C until used.

Measurement of fluorescence anisotropy. The probes 1,6-diphenyl-1,3,5-hexatriene (DPH) and 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene-*p*-toluene sulfonate (TMA-DPH) were used. They were dissolved in tetrahydrofuran to a concentration of 2 mM and then dispersed in degassed phosphate-buffered saline (pH 7.1) to give a final concentration of 2 μM. The solutions were purged for 20 min with nitrogen gas to remove the tetrahydrofuran and mixed with equal volumes of membrane suspensions prepared in the same medium. The final protein concentration was 0.7 mg protein/mL. The mixture was kept at 37°C, and fluorescence (excitation at 360 nm, emission at 430 nm) was measured at 30-min intervals over the following 2 h, to ensure attainment of stable readings. A Perkin-Elmer fluorimeter (EL-5), equipped with a 400-mm filter, temperature-controlled cell holder and polarizer, was used. Fluorescence was measured with the emission polarizer in the vertical ($I_{//}$) and horizontal ($I_{\perp}$) positions. The intensities of the fluorescence by membranes incubated without either of the probes were subtracted from the corresponding experimental values before calculation of the fluorescence polarization index, **r**, as defined by Equation 1 (29):

$$\mathbf{r} = (I_{//} - GI_{\perp}) / (I_{//} + 2GI_{\perp}) \quad [1]$$

where *G* (the correction factor for instrument polarization) is the ratio of the vertical and horizontal polarized emission components with the excitation polarizer in the horizontal position. Routinely, the value of *G* was always very close to unity.

Lipid analyses. These were performed as described by Christie (30). Aliquots of membrane suspensions containing 0.4–1.0 mg protein were homogenized by hand, using a 10-mL glass–glass homogenizer, in 5 mL chloroform/methanol (3:2, vol/vol) to which had been added 100 μL of D,L-α-phosphatidyl-*N*,*N*-dimethylethanolamine, dipalmitoyl as standard. After the addition of a further 4 mL of chloroform, the samples were rehomogenized to ensure full extraction of total lipids. The extract was washed with 2.25 mL of 0.88% KCl and left on ice for 30 min. The organic phase was collected, dried under nitrogen at 40°C, solubilized in 0.5 mL methanol, and taken to dryness under nitrogen. The lipids were finally stored in 1 mL of chloroform under nitrogen at –20°C. Samples were filtered (polytetrafluoroethylene, 0.45 μm) and dried to <100 μL for injection onto a high-performance liquid chromatography column (10 cm × 5 mm) packed with Spherisorb™ 3-μ silica (Hichrom Ltd., Reading, Berkshire, United Kingdom). The solvent systems used and the mass detection of the eluted lipids were as described previously (30). Calibration curves for the major lipid classes were constructed using purified lipids and were used to quantitate individual lipids in the samples after correction for losses calculated from the recovery of phosphatidyl-*N*,*N*-diethanolamine, dipalmitoyl. The fractions containing the main lipid classes were collected and their constituent fatty acids quantified by gas chromatography after formation of their methyl esters using standard methods (30).

Enzyme assays. The activity of CPT I in purified mitochondrial outer membrane preparations was measured exactly as described (28). The concentration of malonyl-CoA required to achieve 50% inhibition of CPT I activity was calculated from a series of activity measurements conducted in the presence of increasing concentrations (1–200 μM) of malonyl-CoA. Marker enzyme activities were also measured as described (28).

Materials. DPH and TMA-DPH were obtained from Molecular Probes Inc. (Cambridge Bioscience, Cambridge, United Kingdom). Solvents (high-performance liquid chromatography grade) were obtained from Fisher Scientific UK (Loughborough, Leicestershire, United Kingdom). Percoll, cytochrome C, cholesterol and phospholipid standards, and phosphatidyl-*N*,*N*-dimethylethanol-amine, dipalmitoyl were obtained from Sigma (Poole, Dorset, United Kingdom).

RESULTS AND DISCUSSION

Many instances are documented in the literature of the desensitization of hepatic CPT I to malonyl-CoA in starvation and diabetes. To test the hypothesis that a link exists *in vivo* between mitochondrial outer membrane lipid order and CPT I sensitivity to malonyl-CoA, we prepared purified outer membranes of mitochondria isolated from normal-fed, 48 h-starved, and 4-d

streptozotocin diabetic rats. In addition, we studied membranes isolated from 24-h starved 20-d pregnant rats, as in (31) and found that CPT I in mitochondria isolated from the livers of these animals (in which the metabolic demands placed by the fetuses result in pronounced starvation effects) is extremely insensitive to malonyl-CoA. The relative sensitivities of CPT I to malonyl-CoA inhibition in membranes prepared from rats in these four conditions were expressed as IC_{50} values (concentration of inhibitor required to achieve 50% inhibition of CPT I activity; see the Materials and Methods section) in Table 1.

The fluidity of the acyl chain core of the membranes and of the outer regions of the leaflets of the bilayer was assessed, respectively, by the measurement of the fluorescence polarization of two probes: (i) DPH, a rodshaped probe which partitions between the two acyl chain layers of the membrane core, and (ii) a charged derivative of DPH, namely, TMA-DPH which, by virtue of its positively charged tertiary ammonium group, partitions with this group alongside the phospholipid headgroups in the membrane, with its aliphatic chain alongside the outer regions of the acyl chains of the bilayer (32). Consequently, TMA-DPH monitors the fluidity of the outer regions of the membrane leaflets (33).

The polarization indices (**r** values) for the two probes (calculated as described in the Materials and Methods section) in the four types of membrane studied are also given in Table 1. The value of $\mathbf{r}_{DPH}$ is decreased in membranes from rats in all the ketogenic states studied, compared to that for membranes from normal-fed rats. Preliminary experiments established that the value of $\mathbf{r}_{DPH}$ for mitochondrial outer membranes was decreased by approximately 0.01 of a unit when membranes were fluidized by incubation with 20 mM-benzyl alcohol (not shown)—a treatment which mimics the magnitude of the effects of starvation with respect to the desensitization of CPT I to malonyl-CoA (23). Conversely, when the order of the mitochondrial outer membrane lipids was increased by lowering the incubation temperature from 37 to 30°C, $\mathbf{r}_{DPH}$ increased by about the same amount [c.f. (34,35) for plasma membrane]. The data in Table 1 indicate that decreases in the sensitivity of CPT I to malonyl-CoA are accompanied by increases in fluidity of the membrane core lipids (decreased $\mathbf{r}_{DPH}$ value) induced by the same physiological condition. By contrast, $\mathbf{r}_{TMA\text{-}DPH}$ was invariant for membranes from different physiological states, suggesting that differences in the restriction of the movement of this probe in the more peripheral regions of the bilayer are not significant in membranes prepared from the range of physiological conditions studied. Consequently, CPT I kinetic characteristics appear to respond primarily to changes in membrane core lipid order, as would be expected from the existence of its two highly hydrophobic transmembrane segments (26).

TABLE 1
Values of Fluorescence Polarization Indices *r* for DPH and TMA-DPH Incorporated into Mitochondrial Outer Membranes Prepared from Livers of Rats in Different Physiological Conditions[a]

Animals	$\mathbf{r}_{DPH}$	$\mathbf{r}_{TMA\text{-}DPH}$	IC_{50} for malonyl-CoA (μM)
Fed (n = 4)	0.079 ± 0.005	0.121 ± 0.007	14 ± 2
48-h-starved (n = 4)	0.071 ± 0.008	0.131 ± 0.006	39 ± 3*
Streptozotocin-diabetic (n = 4)	0.069 ± 0.002*	0.121 ± 0.001	42 ± 5*
20-d pregnant , 24-h starved (n = 5)	0.057 ± 0.006*	0.122 ± 0.007	71 ± 12*

[a]The IC_{50} values for CPT I inhibition by malonyl-CoA are also given. Values are means (± SEM) for the number of determinations on separate membrane preparations indicated in parentheses. Values significantly different from those for fed, normal animals ($P < 0.05$) are indicated by asterisks. Abbreviations: DPH, 1,6-diphenyl-1,3,5-hexatriene; TMA-DPH, 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene-*p*-sulfonate.

Membrane lipid composition changes associated with changes in fluidity. The motion of the DPH molecule within membranes can be described as wobbling within a double cone about axes which lie in the plane of the membrane. This motion is influenced mainly by the hindrance offered to free molecular wobbling and, to a lesser extent, by dynamic considerations, with lipid order being the most important influence (36). Since membrane proteins have to undergo conformational changes in order to achieve optimal catalytic activity and regulatory function, the rate of shift between conformations and the probability of the attainment of these conformations would be expected to be affected by the hindrance offered by membrane lipids (i.e., their fluidity). This is particularly applicable to CPT I which appears to undergo large conformational changes upon interaction with malonyl-CoA, as evidenced by its hysteretic behavior (23,24,37,38) and the ability of malonyl-CoA and other enzyme ligands to render it very resistant to proteolysis (39,40). We have recently shown that CPT I is likely to adopt a highly folded and compact conformation, as evidenced by its remarkable resistance to proteolysis in intact mitochondria (26). Moreover, loss of the extreme N-terminus of the protein is sufficient to disrupt both catalytic activity and malonyl-CoA sensitivity of the enzyme (26). Therefore, it would be anticipated that restriction of the motion of the enzyme molecule would favor malonyl-CoA sensitivity (27).

Three aspects of membrane lipid composition are particularly important in determining the molecular order of the acyl chains that make up the hydrophobic core of membranes: (i) the cholesterol/phospholipid ratio; (ii) the phospholipid head group composition, and (iii) the degree of saturation of the acyl chains (41). All these parameters potentially affect the ordered packing of the hydrocarbon (acyl) chains. Thus, cholesterol rigidifies membrane lipids above their transition temperature as it intercalates perpendicularly to the plane of the membrane, whereas phospholipids differ in their ability to achieve tight packing by virtue of the respective properties of their different headgroups. Of the three main phospholipids, phosphatidylethanolamine (PE) is capable of the closest packing of its acyl chains because of its small neutral headgroup. By contrast, the negatively charged headgroup of phosphatidylinositol (PI) packs much less readily, whereas the packing ability of phosphatidylcholine (PC) is intermediate. The more tightly

the headgroups of the constituent phospholipids (and hence the attached acyl chains) are packed, the higher the molecular order (rigidity) of the membrane lipids. The relative packing ability of the three phospholipid classes is illustrated by the large differences in capacity of artificial membranes made from the respective lipids to swell to accommodate water molecules (PI>PC>PE, 4:2:1) (41). Consequently, low PE/PC and high PI/PC ratios both result in looser packing of the acyl chains (i.e., fluidization of the core of the membrane). Finally, increased unsaturation of the acyl chains (decreased saturation index, see legend to Table 3) would also be expected to fluidize membranes, as *cis*-double bonds antagonize ordered packing, although previous observations have suggested that there is little correlation between the saturation index of the component fatty acyl chains of phospholipids and the fluidity of naturally occurring membranes (see below).

The lipid composition of the purified outer membrane vesicles prepared from rats in the four conditions studied is given in Tables 2 and 3. The data indicate that the decreases in $\mathbf{r}_{DPH}$ (increased fluidity) observed for membranes in which CPT I is less sensitive to malonyl-CoA are not accompanied by marked or consistent changes in the gross lipid composition of the membranes.

Diabetic rats and rats starved for 48 h. The only significant change observed for membranes prepared from these two groups of rats was a 50% decrease in their cholesterol content compared to membranes from normal, fed rats. Neither the relative contents of the different classes of phospholipids nor the overall saturation indices of the component acyl chains were altered by starvation or streptozotocin-induced diabetes. However, as expected from the well-established effects of insulin deficiency to decrease Δ6 desaturase activity (42–45), the 20:4/18:2 ratio was markedly decreased (Table 3). Moreover, even if the decrease in the already low cholesterol content of these membranes had any fluidizing effect in membranes from diabetic rats, it would be expected to be antagonized by the decrease in PI content of these membranes. The latter was expected from the fact that short-term streptozotocin treatment is known to result in decreased myoinositol content in the liver and other tissues (46,47).

Starved pregnant rats. Membranes prepared from these animals showed the largest decrease in $\mathbf{r}_{DPH}$ and, correspondingly, the largest increase in the IC_{50} value for malonyl-CoA (Table 1). However, this increased fluidity appeared not to be related to changes in either overall cholesterol content of the membrane or the saturation index of the component acyl chains of the phosphoplipids. However, there was an increase in the PI/PE ratio from a value of 0.34 in membranes of control animals to 0.74 in membranes obtained from starved pregnant rats. As already mentioned, such a change in the head group composition of phospholipids would be expected to result in increased fluidity of the membrane. However, only starved pregnant rats showed this change. Indeed, in diabetic rats the PI content decreased (see preceding paragraph). Late

TABLE 2
Lipid Composition of Mitochondrial Outer Membranes Prepared from Livers of Rats in Different Physiological States[a]

	Animals			
Lipid	Fed (n = 3)	Starved (n = 5)	Diabetic (n = 3)	Pregnant starved (n = 3)
Cholesterol	4.3 ± 1.0	2.2 ± 0.5*	2.3 ± 0.7*	4.0 ± 0.1
PC	60.5 ± 4.5	58.3 ± 2.5	64.9 ± 1.5	61.7 ± 2.8
PE	25.7 ± 1.7	29.0 ± 0.3	29.2 ± 0.9	19.7 ± 1.4*
PI	9.5 ± 2.5	8.8 ± 1.8	3.5 ± 0.3*	14.5 ± 3.3*
PS	1.0 ± 0.4	0.5 ± 0.4	0.5 ± 0.5	0.5 ± 0.3
CL	0.5 ± 0.1	0.9 ± 0.4	0.5 ± 0.4	0.5 ± 0.4
SM	1.8 ± 0.5	1.2 ± 0.6	0.5 ± 0.4	0.7 ± 0.4

[a]Values are expressed as means of the percentage composition (± SEM) for the number of separate outer membrane preparations analyzed. Those that are significantly different from "fed" values ($P < 0.05$) are indicated by asterisks. Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; CL, cardiolipin; SM, sphingomyelin.

[a]Only the major fatty acyl species are listed. Values are means (± SEM). Statistically significantly different values (compared to controls, $P < 0.05$) are indicated by asterisks. The saturation (Sat.) index is defined as the number of saturated acyl chains divided by the sum of each unsaturated chain multiplied by its number of double bonds. For abbreviations see Table 2.

pregnancy is characterized by hyperinsulinemia and insulin-resistance (48,49), as well as by other specific hormonal changes (e.g., high levels of progesterone and placental lactogen) which, in addition to inducing changes in insulin signaling (50,51) may exert their own effects on fatty acid and phospholipid metabolism. This may explain the very marked changes in mitochondrial outer membrane lipid composition observed in the liver of pregnant animals.

In all the membrane preparations studied, sphingomyelin (which occurs in association with cholesterol) and cardiolipin (a mainly inner membrane lipid) were present only in trace concentrations (0.5–1.0%). In particular, we could not confirm the changes in sphingomyelin content of membranes described (52) for 48-h-starved and streptozotocin-diabetic rat liver mitochondrial outer membranes. However, it is to be noted that the preparations used in Reference 52 appear to have contained inordinately high amounts of cholesterol and sphingomyelin for the mitochondrial outer membrane (see, e.g., Ref. 53), suggesting that the apparent increase in sphingomyelin content may have resulted from the use of less pure preparations of mitochondrial outer membranes.

The results of this study have shown that the relationship between mitochondrial outer membrane fluidity and desensitization of CPT I to malonyl-CoA, previously deduced from *in vitro* studies (23), also occurs *in vivo*. Membranes isolated from liver mitochondria of animals displaying a wide range of CPT I sensitivity to malonyl-CoA display an equally wide (inverse) range of fluidity of the core of the membrane (accessed by DPH). However, these parallel changes in the two parameters are not accompanied by a consistent pattern of changes in gross lipid composition of the membranes. It is noteworthy that a lack of correlation of saturation index of the acyl chain components of phospholipids and of the lipid molecular order has been observed previously for several other types of cell membrane (see, e.g., Ref. 54). Changes in the fluidity of the core of the lipid bilayer sensed by the transmembrane segments of CPT I may be associated with changes in composition that are more subtle than can be discerned by gross analysis of membrane lipids, possibly because of the specialized distribution of the enzyme within the mitochondrial contact sites (55). Transmembrane segments of integral membrane proteins are known to favour helix–helix packing in preference to interaction with the hydrophobic core of the membrane (56). CPT I has two closely located transmembrane segments (26), the packing of which may be affected specifically by the microdomain in which the enzyme resides (55). It would appear from our data that changes in the composition of these lipids may occur in parallel to those that occur in the bulk of the membrane lipids and which are reflected in changes in DPH fluorescence. However, any specific changes that occur in the vicinity of CPT I do not appear to be reflected in the gross lipid composition of the isolated mitochondrial outer membranes.

Biochemical and Structural Characterization of Triacylglycerol Lipase from *Penicillium cyclopium*

Aida Ibrik[a], Henri Chahinian[a], Nathalie Rugani[b], Louis Sarda[c,*], and Louis-Claude Comeau[a]

[a]Laboratoire de Chimie Biologique Appliquée and [b]Laboratoire de Microbiologie, Faculté des Sciences et Techniques de St-Jérôme, 13397 Marseille Cedex 20, France, and [c]Laboratoire de Biochimie, Faculté des Sciences Saint-Charles, Université de Provence, Cedex 3, France

ABSTRACT: An extracellular lipase, active on water-insoluble triacylglycerols, has been isolated from *Penicillium cyclopium*. The purified enzyme has a molecular mass of 29 kDa by gel filtration and SDS-polyacrylamide gel electrophoresis. It hydrolyzes emulsions of tributyrin, trioctanoin, and olive oil at the same rate as pancreatic lipase and shows very low activity against partial acylglycerols (monooctanoin and dioctanoin) and methyl esters. It is stable at 35°C for 60 min and has maximal activity in a pH range of 8–10. Hydrolysis of triacylglycerols by *P. cyclopium* lipase is inhibited by detergents such as Triton X-100. Comparison of the sequence of the 20 first amino acid residues of *P. cyclopium* triacylglycerol lipase with other *Penicillium* lipases indicates a high homology with previously characterized lipases produced by *P. expansum* and *P. solitum* which are enzymes of comparable size and substrate specificity. Conversely, homology between *P. cyclopium* lipase and *P. simplicissimum* lipase, a nonspecific lipolytic enzyme, is low. *Penicillium cyclopium* triacylglycerol lipase shows no homology with *P. camembertii* lipase which is specific to monoacylglycerol and diacylglycerol.
Lipids 33, 377–384 (1998).

Lipases (triacylglycerol hydrolases, E.C. 3.1.1.3) are found in all organisms (1). Early studies with pancreatic lipase have shown that enzyme activity is related to the physical state of the substrate (2,3). Pancreatic lipase binds to the lipid–water interface and hydrolyzes water-insoluble tributyrin and triolein or water-soluble triacetin and tripropionin at concentration beyond the solubility limit. This particular mode of action was originally proposed to distinguish between lipases and nonspecific carboxylesterases which show maximal activity on aqueous dispersion of water-soluble short-chain triacylglycerols. These observations have led to the speculative proposal that lipase activity could result from conformational changes of the enzyme protein upon binding at interface, a phenomenon known as interfacial activation (4–6). In recent years, the elucidation of the three-dimensional structure of mammalian pancreatic lipase as well as lipases from microorganisms such as *Mucor miehei*, *Geotrichum candidum* and, more recently, from *Pseudomonas cepacia* have confirmed that these lipases are serine enzymes in which access of triacylglycerol to the catalytic site is impaired by an amphiphilic α-helical peptide segment (lid) that lies over the catalytic site (7–12). Further studies have provided evidence that lipases crystallized in the presence of substrate analog or covalently bound to a serine-specific inhibitor show conformational rearrangements which include movement of the lid giving free access to the catalytic site (13–17). However, structural and catalytic studies with cutinase from *Fusarium solani* (18) and with lipase from guinea pig pancreas which contain a mini-lid structure have challenged the classical distinction between lipases and nonspecific esterases and called for a reassessment of the structure–function relationships of triacylglycerol-hydrolyzing enzymes with respect to interfacial activation, substrate specificity, and conformational changes (19–22).

Lipases also have received a great deal of interest because of the potential applications of these enzymes in many industrial domains. The molecular and biochemical properties of lipases isolated from a large variety of microorganisms, including fungi of the *Penicillium* species such as *P. expansum* (23), *P. solitum* (P. sp. UZLMA-4) (24,25), *P. simplicissimum* (26), *P. camembertii* (27), *P. citrinum* (28,29), and *P. crustosum* (30) have been reported. The primary structure of *P. camembertii* lipase has been established (31). In the case of *P. cyclopium*, several reports indicate that this fungus produces various types of lipolytic enzymes with preference for triacylglycerol or partial acylglycerol, respectively (32–35).

In this report, we describe the biochemical characterization of an extracellular lipase produced by *P. cyclopium* which specifically hydrolyzes triacylglycerol in the alkaline pH range. A comparison between *P. cyclopium* triacylglycerol lipase and other *Penicillium* lipases based on molecular mass, substrate specificity, and sequence of the first 20 amino acid residues is presented in this communication.

MATERIALS AND METHODS

Microorganism and cultivation. The *Penicillium* strain was isolated from walnut in our laboratory and identified as *P. cy-*

clopium. The strain was maintained in Sabouraud medium (Merck, Nogent-sur-Marne, France) and produced extracellular lipolytic activity. Lipase production was estimated with the tributyrin assay each day during cultivation. The medium used for highest lipase production consisted of 2% corn steep (Roquette, Lille, France) with 1% commercial olive oil. This medium was adjusted to pH 6 with NaOH and sterilized at 120°C for 20 min. Cultivation was carried out at the constant temperature of 25°C, without shaking, in 1-L Erlenmeyer flasks containing 100 mL of medium to which was added 1 mL of spore suspension containing around 10^2 spores. After 5 d, lipase activity sharply increased fourfold and, 2 d later, the mycelia were separated by filtration. The culture filtrate was used as enzyme source for lipase purification.

Assay of lipase activity. Lipase activity was determined titrimetrically with the pH-stat method by using an emulsion of tributyrin (tributanoylglycerol), trioctanoin (trioctanoylglycerol) purchased from Fluka (Saint-Quentin-Fallavier, France), or commercial olive oil. All triacylglycerols were previously chromatographed on a silica gel column (2 × 30 cm) developed in hexane/diethyl ether (95:5, vol/vol). Monooctanoin and dioctanoin were separated chromatographically from a mixture of acylglycerols obtained by incomplete hydrolysis of trioctanoin by *Candida cylindracea* lipase (Meite Sangyo, Nagoya, Japan) as follows: 10 g of trioctanoin was mixed with 400 mg of crude enzyme suspended in 60 mL of 2.5 mM phosphate buffer pH 7 and incubated at 30°C. After 2 h, the pH was raised to 10 with NaOH, and the reaction mixture was extracted twice with 60 mL of diethyl ether. The extract was evaporated and analyzed by thin-layer chromatography (TLC) and reversed-phase liquid chromatography (RP-HPLC). TLC was performed on silica gel plates (20 × 10 cm). The hexane/diethyl ether/acetic acid mixture (80:20:1, by vol) was used for plate development. Acylglycerols were visualized by spraying with 9 M H_2SO_4 followed by heating at 120°C. Analytical RP-HPLC of the acylglycerol mixture was performed on a Shimadzu Liquid Chromatography System (Shimadzu, Kyoto, Japan) equipped with a C18 Beckman column (0.4 cm internal diameter × 25 cm). The solvent used for elution of the column was the acetone/acetonitrile mixture (60:40, vol/vol). Under the conditions used for triacylglycerol hydrolysis, the relative proportions of monooctanoin, dioctanoin, and trioctanoin in the acylglycerol mixture were 12:38:50, respectively. Acylglycerols were separated by chromatography on a silica gel column (2 × 30 cm). Trioctanoin and dioctanoin were recovered from the column with 500 mL of the hexane/diethyl ether mixture (95:5 and 50:50, vol/vol, respectively). Monooctanoin was eluted by washing the column with 500 mL of diethyl ether. Purity of each acylglycerol fraction was checked by TLC and HPLC. Other substrates, namely, methyl butyrate and methyl propionate, were purchased from Fluka and used without further purification.

Lipase activity against tributyrin was determined at 30°C and pH 8 as follows: 0.2 mL of tributyrin was suspended under stirring in 20 mL of 2.5 mM Tris buffer pH 8 with 100 mM NaCl. Kinetics of hydrolysis were zero-order within the first 5 min of the reaction. The rate of the reaction was measured at constant pH by adding 20 mM NaOH. Activity against long-chain triacylglycerol (olive oil) was determined at pH 9 with 20 mL of substrate emulsion prepared in a blender (Sofraca Turmix, Vitrolles, France) by mixing 40 mL of olive oil with 400 mL of a 10% solution of gum acacia in distilled water. No bile salt was added. Finally, activity against monooctanoin, dioctanoin, or trioctanoin was determined under the same conditions as above but with 25, 50, and 200 µL of substrate, respectively. Assays were performed in duplicate and averaged. In all cases, results of duplicate assays differed by less than 5%. Activity was expressed as lipase units. One lipase unit corresponds to the release of one microequivalent of fatty acid per minute under standard assay conditions.

Determination of protein concentration. Protein concentration in culture filtrate and lipase samples was estimated with the colorimetric method of Lowry *et al.* (36) using serum albumin as standard protein. In chromatography experiments, the protein content of fractions was routinely estimated by measuring absorbance at 280 nm.

Purification. After 1 wk cultivation of *P. cyclopium*, the culture broth from eight flasks was separated from the mycelia by filtration. The average lipolytic activity of the filtrate (650 mL), determined with the standard tributyrin assay, was 210 units per mL. No lipase was released by washing mycelia with distilled water after filtration. Detergent that might interfere in the following purification steps was not used during extraction. Proteins of the ice-cold filtrate were precipitated with solid ammonium sulfate at 80% saturation. Insoluble proteins were collected by centrifugation and resuspended in a minimal volume of 25 mM Tris buffer pH 7.5. The protein solution (30 mL) was placed on a G 75 Sephadex column (Pharmacia Biotech, Saint-Quentin-Fallavier, France) (2.5 × 100 cm) in the same Tris

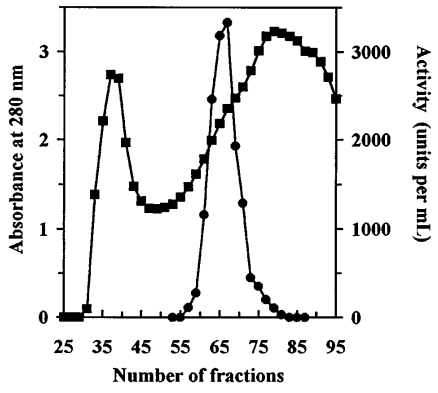

FIG. 1. Gel filtration of a crude sample of *Penicillium cyclopium* lipase. Proteins of the culture broth were separated by precipitation with ammonium sulfate and filtered through a Sephadex G 75 column (2.5 × 100 cm) in 25 mM Tris buffer pH 7.5 at 4°C . Flow rate: 15 mL per hour. Fraction volume: 3 mL. Void volume (V_o) of the column: 93 mL. Lipase-containing fractions (59 to 74) were pooled for further separation by ion-exchange chromatography. ■: Absorbance at 280 nm; ●: lipase activity against tributyrin (units per mL).

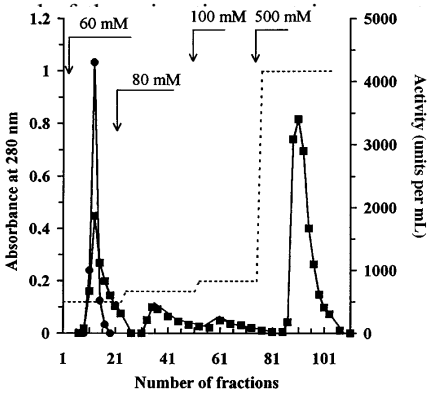

FIG. 2. Ion-exchange chromatography of *P. cyclopium* lipase. Lipase fractions from the Sephadex G 75 column were pooled and placed on a DEAE-Sephadex column (2 × 10 cm) equilibrated at 4°C in 25 mM Tris buffer at pH 7.5. The column was washed with 100 mL of buffer to separate nonadsorbed proteins. Stepwise elution was carried out by successive passage of 100 mL of NaCl solution in buffer at the concentration of 60, 80, 100 and 500 mM, respectively. Flow rate: 60 mL per hour. Fraction volume: 5 mL. Dotted line: stepwise NaCl gradient. See Figure 1 for abbreviation and symbols.

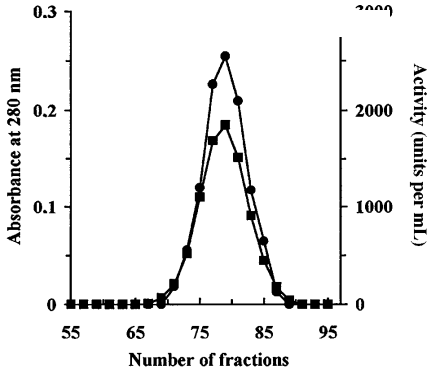

FIG. 3. Gel filtration of partially purified *P. cyclopium* lipase. The enzyme sample was a pool of lipase fractions collected from the DEAE-Sephadex column and concentrated by ultrafiltration. Chromatography was performed on a column (2.5 × 100 cm) of Sephadex G 75 in 25 mM Tris buffer at pH 7.5 with 100 mM NaCl. Flow rate: 15 mL per hour. Fraction volume: 2.3 mL. Fractions 75 to 85 were pooled, concentrated to a final volume of 5 mL by ultrafiltration, and stored at –20°C. See Figure 1 for abbreviation and symbols.

mined on 10 µL aliquots after 15 and 60 min incubation. The of *P. cyclopium* lipase by RP-HPLC (Fig. 5) shows one major buffer at 4°C. From the elution diagram (Fig. 1), it appears that all lipase activity against tributyrin emerged in one peak eluted with 1.9 void volume. Lipase-containing fractions were pooled and submitted to ion-exchange chromatography on a DEAE-Sephadex column (Pharmacia Biotech) (2 × 10 cm) at 4°C in the same Tris buffer. The column was washed with 100 mL of buffer, and adsorbed proteins were eluted by stepwise increase of NaCl concentration in Tris buffer. All lipase recovered from the column was eluted with 60 mM NaCl (Fig. 2). Lipase fractions were pooled, concentrated to 5 mL by ultrafiltration (Amicon membrane PM_{10}; Millipore S.A., Saint-Quentin-en Yvelines, France), and filtered through a Sephadex G 75 column (2.5 × 100 cm) at 4°C in 25 mM Tris buffer with 100 mM NaCl (Fig. 3). Specific activity of lipase and enzyme recovery at each step of purification are shown in Table 1. Purified lipase was concentrated to 3 mL by ultrafiltration and kept at –20°C for months without loss of activity.

protein eluted with acetonitrile/water (55:45, vol/vol) to-

Gel electrophoresis and isoelectric focusing (IEF). Homogeneity of the purified enzyme was checked using 12% polyacrylamide gel electrophoresis with 1% SDS (SDS-PAGE). IEF was performed in the pH range 3–10. In both cases, proteins were detected with the silver staining method. The SDS-PAGE gel was also stained with Coomassie Blue. The molecular mass of *P. cylopium* lipase was estimated by SDS-PAGE and by gel filtration on a G 75 Sephadex column (2.5 × 100 cm) carried out in 25 mM Tris buffer pH 7.5 with 100 mL NaCl.

Analytical RP-HPLC. The purified lipase preparation was analyzed under conditions previously described (37). Elution was achieved with a linear gradient (total volume: 70 mL) from 2 to 72% acetonitrile in 0.1% trifluoroacetic acid in water at a flow rate of 1 mL per min. Proteins were detected at 230 nm.

Carbohydrate detection, amino acid composition, and amino terminal sequence determination. The method of Zacharius *et al.* (38) was used to detect carbohydrate in the purified enzyme. A sample of lipase for amino acid analysis was prepared as follows: *P. cyclopium* lipase (15 µg) was submitted to SDS-PAGE electrophoresis as described above. At

[a]Activity determined against tributyrin.

gether with minor contaminants absorbing at 230 nm. The acetonitrile concentration required for lipase elution is indicative of the strong affinity of *P. cyclopium* lipase for the hydrophobic phase. Actually, under the same chromatographic conditions, *M. miehei* lipase is eluted with 40% acetonitrile.

The molecular mass of *P. cyclopium* lipase was estimated to be around 28 kDa by SDS-PAGE (Fig. 4, diagrams 1 and 2) and 29 kDa by gel filtration (not shown). No carbohydrate was detected in the protein. The amino acid composition of *P. cyclopium* lipase is reported in Table 2 together with other *Penicillium* lipases for the sake of comparison. Values in Table 2 show large similarities in amino acid composition of *P. cyclopium* and *P. expansum* lipases, in particular with respect to the content of hydrophobic residues. As shown by the curves of Figure 6, purified *P. cyclopium* lipase is stable at 30°C and pH 8 and loses about 10% activity after 1 h incubation at 35°C at the same pH. The stability of the enzyme decreases markedly at 40°C. Activity is fully lost after 10-min incubation at 45°C.

The pH activity dependence curve (Fig. 7) indicates that the activity of the enzyme sharply increases from pH 5 to pH 8 and remains constant from pH 8 to pH 10.

The activity of *P. cyclopium* lipase against tributyrin (Fig. 8A) and olive oil (Fig. 8B) was determined in the presence of increasing concentrations of sodium taurodeoxycholate, sodium taurocholate, or SDS. It appears from the curves that lipase activity is not affected by sodium taurodeoxycholate at concentrations below 8 mM and that the inhibitory effect of sodium taurocholate or SDS is dependent on the triacylglycerol used as substrate, as observed earlier in the case of pancreatic lipase (39,40). Moreover, hydrolysis of emulsified tributyrin or olive oil was fully inhibited by Triton X-100 (Fig. 9) and by other detergents such as Brij 35, Tween 20, or Tween 80 (not shown).

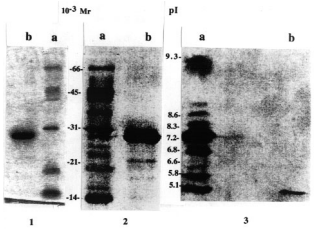

FIG. 4. Analytical gel electrophoresis and isoelectric focusing of *P. cyclopium* lipase. (1) and (2): SDS-polyacrylamide gel electrophoresis. Purified lipase (a) and reference proteins (b) were detected with Coomassie Blue (1) or with the silver staining method (2). Both analyses were performed with 5 µg of protein. (3): Isoelectric focusing. Proteins were detected as in (2). See Figure 1 for abbreviation.

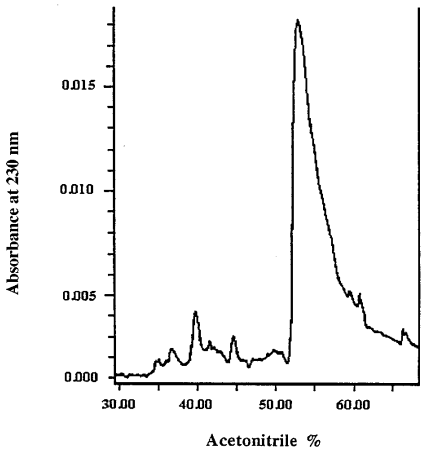

FIG. 5. Analytical reversed-phase liquid chromatography of purified *P. cyclopium* lipase. A sample of purified lipase (30 µg in 50 µL) was chromatographed at room temperature. Elution was achieved with a linear gradient from 2 to 72% acetonitrile in 0.1% trifluoroacetic acid in water (total volume: 70 mL) at a flow rate of 1 mL per min. No protein was eluted at concentration of acetonitrile below 30%. Ordinates: absorbance at 230 nm. Abscissae: percentage of acetonitrile.

Substrate specificity. Rates of hydrolysis of tributyrin, trioctanoin, olive oil, monooctanoin, dioctanoin, methyl propionate, and methyl butyrate by purified *P. cyclopium* lipase are listed in Table 3. It can be observed that the enzyme is highly active against all triacylglycerols and shows very low activity against partial acylglycerols or monoesters. Further, the specific activity of *P. cyclopium* lipase, measured against tributyrin (8000 units per mg) and medium- or long-chain triacylglycerols, is in the same range as that of mammalian pancreatic lipases.

Several groups (32–35) reported that three extracellular lipolytic enzymes are produced by *P. cyclopium*. Amounts of each of the enzymes depend upon cultivation conditions of the mold. So far, these lipases have been identified and characterized only by their specific activity against various ester substrates. Lipase I and Lipase II are proteins with molecular mass around 30 kDa and act specifically on triacylglycerols and partial acylglycerols, respectively. Lipase III hydrolyzes *p*-nitrophenyl laurate and rapidly releases glycerol from triacylglycerols in serum in the presence of Triton X-100. Lipase III is a dimer of molecular mass of 108 kDa. Our results show that lipase isolated from the cuture medium is identical with Lipase I.

For the first time, we have determined the amino terminal sequence of *P. cyclopium* lipase over 20 amino acid residues. This sequence is presented in Table 4 together with the corresponding sequence of other *Penicillium* lipases and lipases from *M. miehei* (41) and *Rhizopus delemar* (42). This offers

the opportunity to compare the triacylglycerol-hydrolyzing lipase produced by *P. cyclopium* with lipases previously isolated from other *Penicillium* species, on a structural basis. From the alignment of the sequences, *P. cyclopium* lipase is homologous to lipases from *P. expansum* and *P. solitum* (Table 4), with 15 out of the 20 residues at the *N*-terminus conserved in the three proteins. Conversely, it may be noticed that only three residues of alanine of the amino terminal region of these three enzymes are conserved in *P. simplicissimum* lipase, at positions 1, 3, and 14. On the other hand, only two residues of the amino terminal sequence of *P. camembertii* lipase, namely, valine at position 2 and serine at position 5, are common with *P. expansum* lipase. *Penicillium camembertii* lipase shows no homology with lipases from *P. cyclopium* or *P. solitum*. Moreover, lipases from *P. cyclopium*, *P. expansum,* and *P. solitum* have a molecular mass in the 25–35 kDa range and comparable substrate specificity, with preference for tributyrin and olive oil, with a tributyrin/olive oil rate ratio of 2. Instead, lipase from *P. simplicissimum* has been characterized as nonspecific with the capacity to hydrolyze each of the three ester bonds of triolein (26), and lipase from *P. camembertii* is specific for monoacylglycerols and diacylglycerols and has no activity on triacylglycerols (27). Then, from the comparison of the molecular and biochemical properties and amino-terminal amino

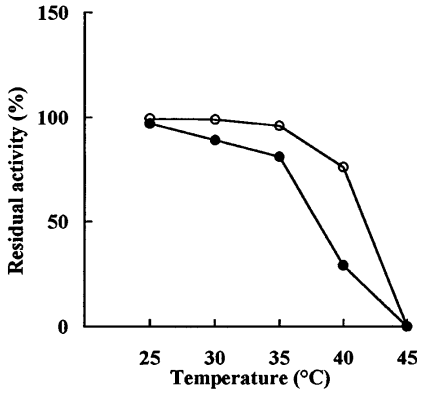

FIG. 6. Thermal stability of *P. cyclopium* lipase. The purified enzyme (0.1 mg per mL in 2.5 mM Tris buffer pH 8 with 100 mM NaCl) was incubated at 25, 30, 35, 40 and 45°C, and residual activity was measured on 10 µL after 15 and 60 min with the standard tributyrin assay. ○: Residual activity after 15 min incubation; ●: residual activity after 60-min incubation. Residual activity is expressed as percentage of initial activity. See Figure 1 for abbreviation.

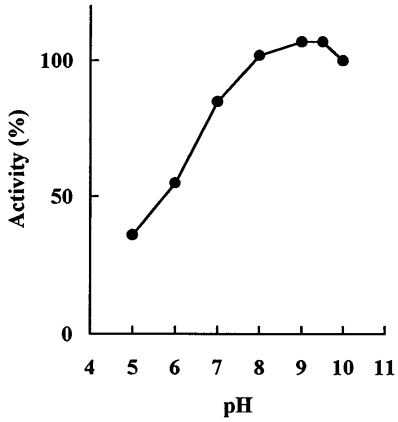

FIG. 7. Effect of pH on *P. cyclopium* lipase activity. Hydrolysis of triacylglycerol substrate (emulsified tributyrin) was measured potentiometrically under standard conditions, at constant pH ranging from pH 5 to pH 10. Correction was made for butanoic acid ionization at pH below 6 and for nonenzymatic hydrolysis of tributyrin at pH above 8. Activity is expressed as percentage of hydrolysis at pH 8 (100%). See Figure 1 for abbreviation.

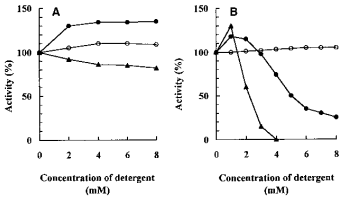

FIG. 8. Effect of increasing concentration of bile salt and SDS on *P. cyclopium* lipase activity against triacylglycerol. Residual activity is expressed as percentage of the initial rate of hydrolysis (100%) of tributyrin (curves A) and olive oil (curves B) determined at pH 8 and 9, respectively, in absence of detergent. ●: Sodium taurocholate; ○: sodium taurodeoxycholate; ▲: SDS. See Figure 1 for abbreviation.

acid sequence, it appears that triacylglycerol lipases (Lipase I) from *P. cyclopium*, *P. solitum*, and *P. expansum* belong to the same lipase gene family. Since no structural data are presently available for *P. cyclopium* lipase II, a comparison between Lipase I and Lipase II is not yet possible. From previous reports (32–35) and from our experience (data not shown), it appears that the relative amounts of lipases of types I and II produced by *P. cyclopium* are dependent upon the cultivation conditions. In this respect, notice can be made that the production by *P. camembertii* of an extracellular triacylglycerol-hydrolyzing enzyme has never been reported. More work then remains to be done to know if all fungi of the *Penicillium* species can produce both types of lipases and how production of these enzymes is regulated at the gene level.

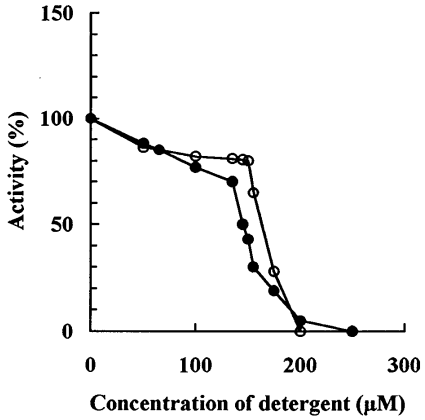

FIG. 9. Effect of increasing concentration of Triton × 100 on the activity of *P. cyclopium* lipase against emulsified triacylglycerol. Residual activity against tributyrin (●) and olive oil (○) is expressed as in Figure 8. See Figure 1 for abbreviation.

TABLE 3
Substrate Specificity of *Penicillium cyclopium* Triacylglycerol Lipase[a]

Tributyrin	100	Dioctanoin	6.5	Methyl propionate	0
Trioctanoin	53	Monooctanoin	1	Methyl butyrate	1
Olive oil	46				

[a]Activities are expressed as per cent of activity determined against tributyrin (100%) under standard assay conditions. All assays are performed at 30°C and pH 8 except for hydrolysis of olive oil performed at pH 9.

Enhanced Macrophage Uptake of Lipoprotein(a) After Ca^{2+}-Induced Aggregate-Formation

Seiya Tanaka, Akira Yashiro*, Hiromi Tasaki, and Yasuhide Nakashima

Second Department of Internal Medicine, University of Occupational and Environmental Health, Japan, School of Medicine, Kitakyushu 807, Japan

ABSTRACT: We tested the hypothesis that aggregated lipoprotein(a) [Lp(a)] is avidly taken up by macrophages. Lp(a) was isolated by sequential centrifugations and gel chromatography from a patient with high plasma levels of Lp(a) who was being treated with low density lipoprotein (LDL)-apheresis. Aggregated Lp(a) was prepared by mixing native Lp(a) with 2.5 mmol/L $CaCl_2$, and 54% of the ^{125}I-Lp(a) aggregated after interacting with $CaCl_2$. The binding and degradation of aggregated Lp(a) in macrophages were 4.6- and 4.7-fold higher than those of native Lp(a), respectively. An excess amount of LDL did not inhibit either increase. Cholesterol esterification in macrophages was markedly stimulated by aggregated Lp(a), and macrophages were transformed into foam cells. Cytochalasin B, a phagocytosis inhibitor, strongly inhibited the degradation and cholesterol esterification (78 and 83%, respectively). These findings suggested that aggregation may be partially involved in Lp(a) accumulation, thereby contributing to the acceleration of atherosclerosis.

Lipids 33, 385–392 (1998).

Lipoprotein(a) [Lp(a)] is now recognized as a strong independent risk factor for coronary artery disease (CAD). This unique lipoprotein consists of low density lipoprotein (LDL)-like particles containing apolipoprotein B-100 and highly negatively charged apolipoprotein(a) [apo(a)] (1). The apo(a) moiety is formed by three different structural domains having high homology with kringle 4, 5, and the protease domain of plasminogen (2). The kringle 4 domain in apo(a) is present in a sequence consisting of various numbers of multiple copies, thereby giving rise to different sizes of apo(a) isoform and consequently of Lp(a) (3,4). In subjects with high plasma levels of Lp(a), apo(a) isoforms of smaller size or smaller number of kringle 4 domains is commonly observed (5–7).

Histochemical studies suggest that Lp(a) contributes to the occurrence of CAD by accelerating atherosclerotic lesions through accumulation in the arterial wall (8–10). The observation of colocalization of Lp(a) with cholesteryl ester-rich cells (foam cells) in atherosclerotic lesions strongly supports this notion. Despite these data, previous *in vitro* studies were unable to demonstrate significant internalization and degradation of native Lp(a) by cultured macrophages (11–13). Unlike other lipoproteins, Lp(a) possesses a unique property of self-aggregation under *in vitro* condition. In addition, Hoff *et al*. (14) showed that in human atherosclerotic lesions apo(a) is present in some possibly aggregated forms. These findings suggest a possibility that aggregation of Lp(a) is related to the mechanism of foam cell formation.

In the present study, to address this issue, we tested macrophage uptake of Ca^{2+}-induced Lp(a) aggregates, a model of self-aggregation of Lp(a) (15).

MATERIALS AND METHODS

Materials. Dulbecco's modified Eagle's medium (DMEM) without $CaCl_2$ was obtained from Gibco Laboratories (Grand Island, NY). Bovine serum albumin (BSA) was purchased from Intergen Company (Purchase, NY). Fetal bovine serum (FBS) was obtained from Cansera International Inc. (Rexdale, Ontario, Canada). Sephacryl 400 HR, premade 4–15% gradient polyacrylamide Phast Gel for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), and a silver stain kit for PAGE were obtained from Pharmacia LKB Biotechnology Inc. (Uppsala, Sweden). Na^{125}I (100 mCi/mL of iodide) and [9,10(n)-^{3}H]oleic acid (370 GBq/mmol) were purchased from Amersham International plc. (Bucks, United Kingdom). Silica gel on aluminum sheets for thin-layer chromatography was obtained from Merck (Darmstadt, Germany). An apo(a) phenotype analyzing kit was purchased from Sanwa Chem. Co. (Tokyo, Japan).

Isolation of mouse peritoneal macrophages. Macrophages were elicited by intraperitoneal injection of 2 mL of thioglycolate medium 4 d before harvesting. The macrophages were plated in 12-well tissue culture plates (area/well = 4.5 cm^2) at a density of 1.0×10^6 cells in 1 mL of DMEM containing FBS (20%), streptomycin (0.1 mg/mL), and penicillin (100 U/mL). Plated macrophages were then incubated for 2–3 h at 37°C in a humidified-air incubator (95% air, 5% CO_2). After incuba-

Abbreviations: apo(a), apolipoprotein(a); BSA, bovine serum albumin; CAD, coronary artery disease; DMEM, Dulbecco's modified Eagle's medium; FBS, fetal bovine serum; LDL, low density lipoprotein; Lp(a), lipoprotein(a); PBS, phosphate buffered saline; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; TEM, transmission electron microscopy.

tion, they were washed twice with serum-free DMEM to remove any contaminating lymphocytes and platelets. Before the cellular assay, the macrophages were incubated for 24 h at 37°C in 1 mL of DMEM containing lipoprotein-deficient serum (5 mg/mL), streptomycin (0.1 mg/mL), and penicillin (100 U/mL) (medium A).

Preparation and iodination of lipoproteins. LDL (d = 1.020 to 1.050) was isolated by preparative ultracentrifugations from fresh plasma of a healthy young male (16). These were dialyzed against 0.15 mol/L NaCl (pH 7.4) containing Na_2EDTA (0.3 mmol/L) followed by sterilization using a 0.45 μm-filter and stored at 4°C. Lp(a) was isolated from a patient who was being treated with LDL-apheresis. The Lp(a) which adsorbed to the apheresis column was eluted with NaCl solution (0.5 mol/L) and collected in the presence of Na_2EDTA (1 mg/mL) and aprotinin (100 kallikrein-inactivating units/mL) immediately after LDL-apheresis. The solution containing Lp(a) was subjected to sequential ultracentrifugations to isolate the density fraction of $1.050 < d < 1.120$ g/mL. To separate Lp(a) from high density lipoprotein and LDL, this density fraction was filtered on Sephacryl 400 HR (2.5 × 90 cm) at a flow rate of 120 mL/h with 1 mol/L NaCl and 5 mmol/L Tris-HCl (pH 7.4) containing Na_2EDTA (1 mg/mL) and NaN_3 (0.01%) (buffer A). For the present study, only Lp(a) from a 63-year-old female patient with high levels of plasma Lp(a) (127 mg/dL) was used unless mentioned otherwise. The purity of Lp(a) was monitored by SDS-PAGE under a nonreduced condition. Isolated Lp(a) was stored at 4°C in buffer A and was extensively dialyzed against 0.15 mol/L NaCl and 5 mmol/L Tris-HCl (pH 7.4) containing 0.3 mmol/L Na_2EDTA before iodination. One day before the experiments were performed, isolated Lp(a) was labeled with $Na^{125}I$ using the iodine monochloride procedure of MacFarlane (17) as modified by Bilheimer *et al*. (18). Free iodine was removed by subsequent dialysis against 200-fold volumes of calcium-free DMEM three times. The specific activities of labeled Lp(a) were 400 to 700 cpm/ng of protein.

Preparation of aggregated Lp(a). Aggregated Lp(a) was made by mixing 1 mL of native Lp(a) with 2.5 mmol/L $CaCl_2$ in calcium-free DMEM according to the method of Yashiro *et al*. (15). To determine the extent of Lp(a) aggregation, ^{125}I-Lp(a) mixed with 2.5 mmol/L $CaCl_2$ in calcium-free DMEM was pipetted into 1.5 mL microtubes and centrifuged immediately at 10,000 rpm for 10 min. The percentage of ^{125}I-Lp(a) which precipitated was determined by counting the radioactivity in the supernatant before and after mixing with $CaCl_2$. Fifty-four percent of the ^{125}I-Lp(a) aggregated under this condition. In our experiments a mixture of aggregates and remaining soluble material was provided for cells, because the precipitated Lp(a) aggregates were difficult to resuspend in DMEM.

Evaluation of aggregated Lp(a) morphology. The size and degree of aggregated Lp(a) after mixing native Lp(a) with 2.5 mmol/L $CaCl_2$ in calcium-free DMEM were examined using transmission electron microscopy (TEM) after negative staining with 2% Na-phosphotungstate (19). The area and diameter profile of aggregates were quantified using NIH Image Version 1.52 (Wayne Rasband, National Institutes of Health, Research Service Branch, NIMH, Washington, D.C.). These results were expressed as the mean ± SD.

Binding of ^{125}I-Lp(a). The binding assays of lipoproteins with macrophages were carried out at 4°C essentially as described by Innerarity *et al.* (20). Macrophage monolayers were washed once with serum-free DMEM, then twice with calcium-free DMEM containing BSA (0.2%), streptomycin (0.1 mg/mL), and penicillin (100 U/mL) (medium B), and cooled to 4°C with medium B. The medium was then removed, and 1 mL of medium B containing indicated concentrations of native or aggregated ^{125}I-Lp(a) with or without a 20-fold excess of corresponding unlabeled Lp(a) was added. After incubation at 4°C for 4 h, the cells were washed four times with 1 mL/well of ice-cold phosphate-buffered saline (PBS) containing 0.2% BSA and once with 1 mL/well of ice-cold PBS; the first wash was allowed to sit 10 min before proceeding with the remaining three washes in rapid succession as described by Haberland *et al*. (21). Then, after washing them, each cell sheet was lysed with 0.5 mL of 0.1 N NaOH, and the radioactivity was measured. An aliquot of the lysate was removed to determine cellular protein by the method of Lowry *et al*. (22).

Degradation of ^{125}I-Lp(a). The degradation experiments were performed essentially as described by Goldstein *et al.* (23). Macrophage monolayers were washed once with serum-free DMEM then twice with medium B. Medium B containing indicated concentrations of native or aggregated ^{125}I-Lp(a) with or without a 20-fold excess of the corresponding unlabeled Lp(a) was added to the cells. Cells were then returned to the 37°C incubator for 5 h. Proteolytic degradation of ^{125}I-Lp(a) was measured by assaying the amount of ^{125}I-labeled trichloroacetic acid-soluble (noniodide) material formed by the cells and excreted into the medium. Each cell sheet was lysed after washing, and protein content was measured as described for the binding assays.

Incorporation of [^{3}H]oleate into cholesteryl esters. To assay cholesterol esterification in macrophages, the incorporation of [^{3}H]oleate into cellular cholesteryl [^{3}H]oleate was determined as described by Miyazaki *et al*. (24). The [^{3}H]oleate was conjugated with BSA as described by Brown *et al*. (25). Macrophage monolayers were washed once with serum-free DMEM then twice with medium B. Each well was incubated with 0.1 mmol/L of [^{3}H]oleate (10,000 dpm/nmol) in the presence of indicated concentrations of aggregated Lp(a) in 1.0 mL of medium B. After a 5-h incubation, cells were washed five times with 1.0 mL of ice-cold PBS and extracted twice with 0.5 mL of hexane/isopropanol (3:2, vol/vol). The extract was evaporated to dryness, resuspended with 200 μL of isopropanol, spotted on a silica gel thin-layer plate, and developed in hexane/diethyl ether/methanol/acetic acid (85:20:1:1, by vol). A band corresponding to cholesteryl oleate was cut out, and the radioactivities were measured. Each cell sheet was lysed after washing, and protein was mea-

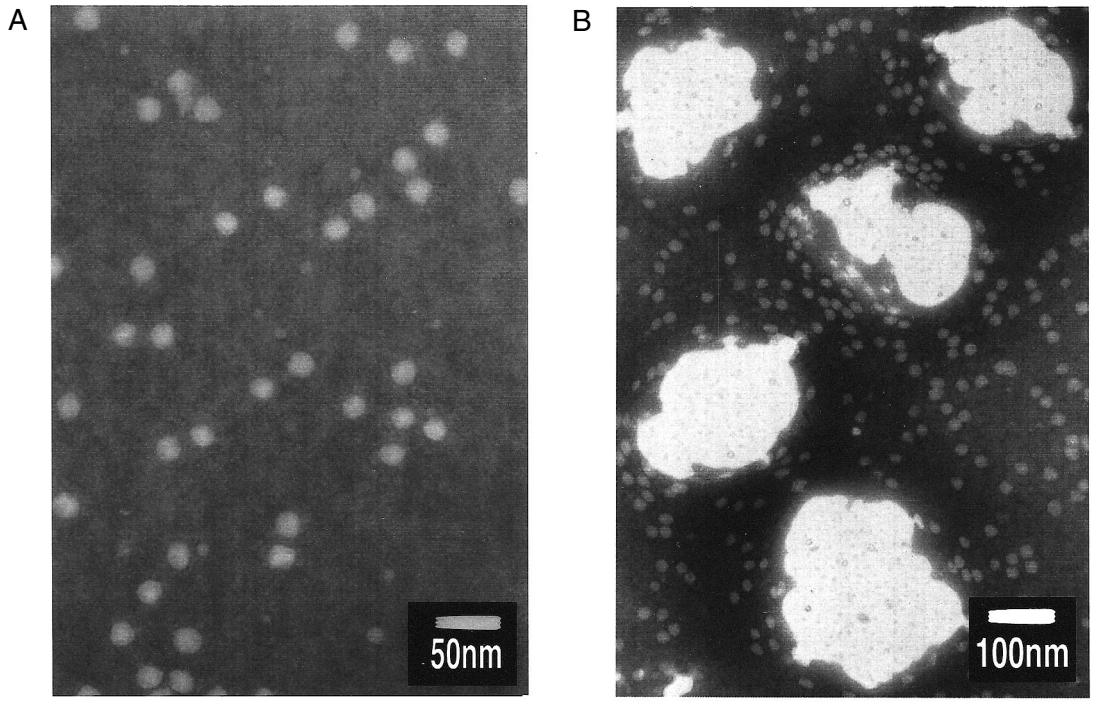

FIG. 1. Morphology of native and aggregated lipoprotein(a) [Lp(a)]. Aggregated Lp(a) was made by mixing native Lp(a) with 2.5 mmol/L $CaCl_2$ in calcium-free Dulbecco's modified Eagle's medium. Samples of native Lp(a) (A) and aggregated Lp(a) (B) were examined by transmission electron microscopy after negative staining with 2% Na-phosphotungstate.

sured as described for the binding assays. All assays were performed in triplicate.

Oil Red O staining. Macrophages (5×10^5 cells) were plated on 11-mm circular coverslips within a 12-well tissue culture plate. Each coverslip received 1.0 mL of medium A and was incubated at 37°C for 24 h. Then 1.0 mL of medium B containing 100 µg protein/mL of native or aggregated Lp(a) was added to the cells. After incubation at 37°C for 15 h, the cells were stained with Oil Red O, followed by counter-staining with Mayer's hematoxylin, as described by Brown *et al.* (25). The coverslips were mounted face-down on glass microscope slides using pre-warmed, liquefied 20% glycerol. The stained cells were photographed with a Nikon photomicroscope (Nippon Kogaku K.K., Tokyo, Japan) at 250× magnification.

Apo(a) isoform phenotype determinations. Apo(a) isoform phenotyping was performed with SDS-PAGE of plasma from peripheral venous blood under reducing conditions followed by immunoblotting using a commercially available apo(a) isoform analyzing kit (Sanwa Chem. Co.). This analysis basically follows the method of Abe and Noma (26). Using the terminology proposed by Utermann *et al.* (5), the various isoforms of apo(a) have been designated according to the electrophoretic mobility relative to that of apolipoprotein B-100.

Lipid analysis. Plasma Lp(a) was quantified using the latex-enhanced turbidimetric immunoassay by the method described by Abe *et al.* (27). Total cholesterol, free cholesterol, phospholipids, and triglycerides were determined using standard enzymatic kits (28). Protein was measured by the method of Lowry *et al.* (22).

RESULTS

Morphology of aggregated Lp(a). To assess the morphology of aggregated Lp(a), we subjected native Lp(a) and these aggregates to TEM after negative staining. As shown in Figure 1, native Lp(a) particles after isolation are monomeric and did not coalesce. In contrast, aggregated Lp(a) consisted of numerous monomeric particles. The mean profile area and diameter of Lp(a) aggregates were $3.7 \pm 1.2 \times 10^4$ nm^2 and 255.0 ± 9.4 nm, respectively.

Concentration dependency of binding and degradation of Lp(a). Figures 2A and 2B illustrate the binding of native and aggregated ^{125}I-Lp(a) to macrophages held at 4°C. Specific binding for native ^{125}I-Lp(a) reached saturation, and 0.49 µg protein of ^{125}I-Lp(a) was bound per mg cell protein when 200 µg/mL lipoprotein was added. In contrast, for aggregated ^{125}I-Lp(a), specific binding was markedly enhanced compared with that for native ^{125}I-Lp(a), and there was a greater than 4.6-fold increase in binding when 200 µg/mL lipoprotein was added [2.27 µg protein/mg cell protein for aggregated Lp(a)].

Figures 2C and 2D illustrate the degradation of native and aggregated ^{125}I-Lp(a) in macrophages at 37°C. Reflecting enhanced binding, specific degradation for aggregated

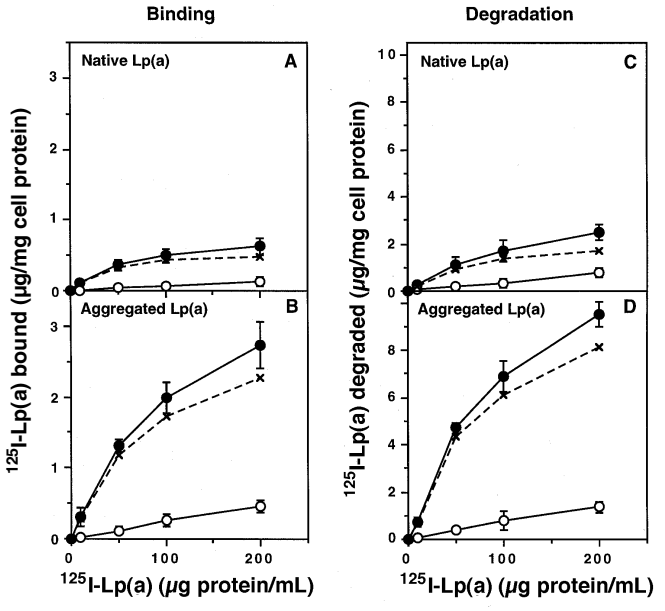

FIG. 2. Concentration dependency of the binding and degradation of native or aggregated Lp(a). Macrophage monolayers were incubated with the indicated concentrations of native or aggregated ^{125}I-Lp(a) with or without a 20-fold molar excess of the corresponding unlabeled Lp(a), respectively. Cellular binding or degradation was analyzed after incubation at 4°C for 4 h or at 37°C for 5 h, respectively. Specific binding or degradation (x) of native or aggregated ^{125}I-Lp(a) was defined as total binding or degradation (●) minus nonspecific binding or degradation (○) seen in the presence of the corresponding unlabeled Lp(a). Each data point represents the mean value of three experiments with the indicated SD. See Figure 1 for abbreviation.

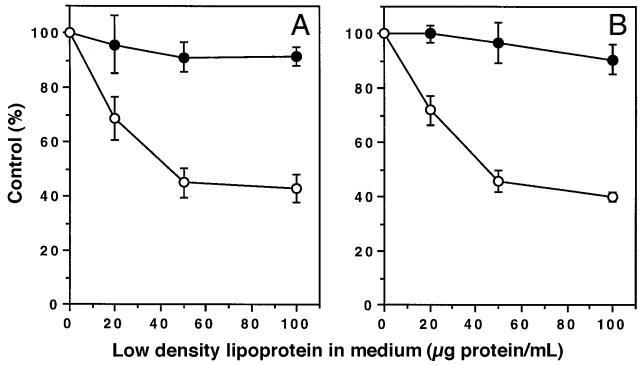

FIG. 3. Ability of unlabeled native low density lipoprotein (LDL) to compete for the binding or the degradation of native or aggregated ^{125}I-Lp(a). Macrophage monolayers were incubated with 5 μg protein/mL of native or aggregated ^{125}I-Lp(a) and the indicated concentrations of native LDL. Cellular binding or degradation was analyzed after incubation at 4°C for 4 h or at 37°C for 5 h, respectively. The results were expressed as percentages of the (A) binding or (B) degradation of native or aggregated ^{125}I-Lp(a) in the absence of native LDL. In the binding study, the 100% values for native and aggregated ^{125}I-Lp(a) were 0.10 and 0.32 μg protein/mg cell protein, respectively. In the degradation study, the 100% values for native and aggregated ^{125}I-Lp(a) were 0.18 and 0.47 μg protein/mg cell protein, respectively; ○, represent the total binding and degradation of native ^{125}I-Lp(a); ●, represent the total binding and degradation of aggregated ^{125}I-Lp(a). Each data point represents the mean value of three experiments with the indicated SD. See Figure 1 for other abbreviation.

^{125}I-Lp(a) was markedly elevated, and the extent of degradation was 4.7-fold higher than that of native ^{125}I-Lp(a) when 200 μg/mL lipoprotein was added [8.13 μg protein/mg cell protein for aggregated Lp(a) and 1.70 μg protein/mg cell protein for native Lp(a)].

To test whether the LDL receptor is involved in the uptake of native or aggregated Lp(a), we examined the extent to which unlabeled native LDL competed for the binding and degradation of native or aggregated ^{125}I-Lp(a). As shown in Figure 3, native LDL inhibited, although incompletely, the binding and degradation of native ^{125}I-Lp(a) (57 and 60%, respectively) at a 20-fold excess concentration. On the other hand, very little competition was observed with native LDL at a concentration 20-fold in excess of that of aggregated ^{125}I-Lp(a) both in the binding and degradation (9 and 10%, respectively).

Stimulation of cholesteryl ester synthesis by aggregated Lp(a). Consistent with the results of degradation, cholesteryl ester synthesis in macrophages was markedly enhanced by aggregated Lp(a), and 16.4 ± 1.2 nmol of [^{3}H]oleate was incorporated into cholesteryl ester per milligram of cell protein (Fig. 4). On the other hand, native Lp(a) showed almost no stimulation of cholesteryl ester synthesis. This considerable difference in intracellular cholesterol accumulation also was confirmed by Oil Red O staining. As shown in Figure 5, in the presence of aggregated Lp(a), massive lipid droplets were observed in the cytoplasm indicating the transformation of macrophages into foam cells. In contrast, there was very little lipid deposition in the presence of native Lp(a). These findings strongly indicated that aggregated Lp(a) could lead macrophages to change into foam cells and that the process of aggregation may play an important role in the mechanism of Lp(a) deposition in macrophages.

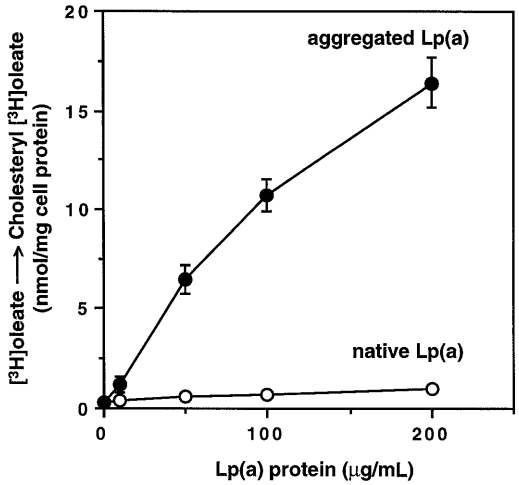

FIG. 4. Concentration dependency of cholesterol esterification induced by aggregated Lp(a). Macrophage monolayers were incubated with 0.1 mmol/L [^{3}H]oleate and increasing concentrations of native (○) or aggregated ^{125}I-Lp(a) (●). After incubation at 37°C for 5 h, the cellular content of cholesteryl [^{3}H]oleate was determined. Each data point represents the mean value of three experiments with the indicated SD. See Figure 1 for abbreviation.

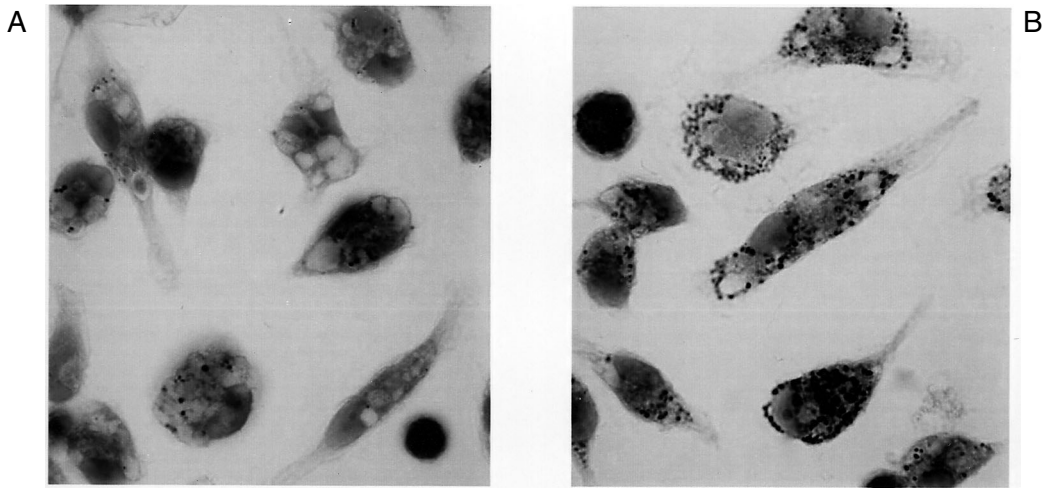

FIG. 5. Appearance of Oil Red O-stained macrophages observed under light microscope; 5×10^5 cells plated on 11-mm circular coverslips incubated with 100 µg protein/mL of native (A) or aggregated Lp(a) (B) at 37°C for 15 h. The cells on the coverslips were then washed with phosphate buffered saline and stained with Oil Red O as described in the Materials and Methods section.

Effects of cytochalasin B on degradation and cholesterol esterification induced by aggregated Lp(a) in macrophages. There have been several reports showing that aggregated lipoproteins can be avidly uptaken by macrophages by phagocytosis. To determine the involvement of this process in the enhanced uptake of aggregated Lp(a) observed, phagocytic inhibitor cytochalasin B was employed. As shown in Figures 6A and 6B, in case of aggregated ^{125}I-Lp(a), cytochalasin B dramatically inhibited degradation and cholesterol esterification by 78 and 83%, respectively, but no significant inhibition was observed in that of native ^{125}I-Lp(a), suggesting that the phagocytosis is involved in the internalization of aggregated Lp(a) by macrophages.

Cholesterol esterification induced by aggregation of Lp(a) of two phenotypes. We compared the rate of cholesterol esterification obtained with two Lp(a) of different phenotypes to observe if there is a significant difference between them. Lp(a) were isolated from two patients treated with LDL-apheresis. The patient with the S_3/B isoform is the same from whom all data presented above were obtained. The patient with the S_3/S_2 isoform was a 75-year-old female with high levels of plasma Lp(a) (47 mg/dL). The extent of Lp(a) aggregation of the two phenotypes was almost equivalent (54 vs. 49%). As shown in Table 1, aggregates of S_3/B-Lp(a) were 2.6-fold larger in profile area than those of S_3/S_2-Lp(a) ($n = 20$, $P < 0.012$, S_3/B vs. S_3/S_2, analysis of variance). In addition the former induced 2.4 times more cholesterol esterification than the latter.

DISCUSSION

This is the first study showing that Ca^{2+}-induced Lp(a) aggregates, a model of self-aggregation of Lp(a), were avidly uptaken by macrophages, possibly by phagocytosis, leading to the transformation of macrophages into cholesteryl ester-rich foam cells.

Documented *in vitro* modifications of Lp(a) that may lead to the formation of macrophage-derived foam cells are malondialdehydration (29), oxidation (30), and association with

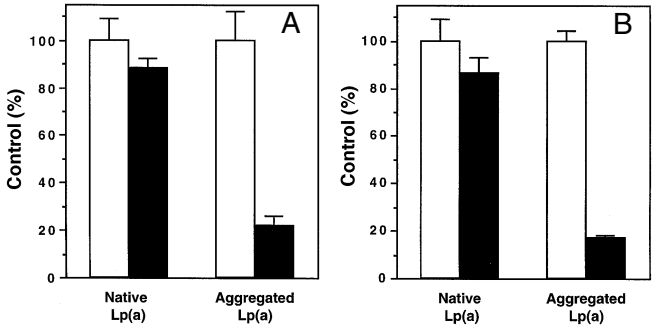

FIG. 6. Effects of cytochalasin B on (A) degradation and (B) cholesterol esterification induced by aggregated Lp(a) in macrophages. (A) Macrophage monolayers were incubated with 50 µg protein/mL of native or aggregated ^{125}I-Lp(a) with or without 10 µg/mL of cytochalasin B at 37°C for 5 h. After incubation, the amount of ^{125}I-labeled trichloroacetic acid-soluble material in the medium was determined. The 100% values for native and aggregated ^{125}I-Lp(a) were 1.12 and 3.80 µg protein/mg cell protein/5 h, respectively. (B) Macrophage monolayers were incubated with 0.1 mmol/L [^{3}H]oleate and 50 µg protein/mL of native or aggregated Lp(a) in the presence or absence of 10 µg/mL of cytochalasin B at 37°C for 5 h. After incubation, the cellular content of cholesteryl [^{3}H]oleate was determined. The 100% values for native and aggregated Lp(a) were 0.63 and 6.35 nmol of cholesteryl oleate/mg cell protein/5 h, respectively. The results were expressed relative to the amount of ^{125}I-Lp(a) degraded or cholesteryl oleate formed in the presence of cytochalasin B. □, 10 µL DMSO/mL medium. ■, 10 µg of cytochalasin B in 10 µL DMSO/mL medium. Each bar represents the mean value ± SD of three experiments. See Figure 1 for abbreviation.

TABLE 1
Comparison Between Two Lp(a)[a] and Their Aggregates

Lp(a) phenotype	Composition (wt%)					Profile area of aggregates[b] ($\times 10^4$ nm^2)	Incorporation of [^{3}H]oleate into CE induced by aggregates[c] (nmol/mg cell protein)
	Pro	PhL	Cho	TG	CE		
S_3/B	26.3	20.2	11.4	5.2	36.9	3.7 ± 1.2	1.68 ± 0.09
S_3/S_2	30.7	19.8	9.8	4.1	35.6	1.4 ± 0.4	0.69 ± 0.02

[a]Lp(a), lipoprotein(a); Pro, protein; PhL, phospholipids; Cho, free cholesterol; TG, triglycerides; CE, cholesteryl esters.
[b]The profile areas of aggregates were quantified after mixing native Lp(a) with 2.5 mmol/L $CaCl_2$ in calcium-free Dulbecco's modified Eagle's medium under transmission electron microscopy.
[c]Macrophage monolayers were incubated with 20 μg cholesterol/mL of aggregated Lp(a) in the presence of 0.1 mmol/L [^{3}H]oleate at 37°C for 5 h. After incubation, the [^{3}H]oleate incorporation into cholesteryl esters was determined as described in the Materials and Methods section. Each value represents the mean value ± SD of three sets of experiment from the same donor, except composition of Lp(a).

extracellular matrix (31). Lp(a) modified in such ways has been shown to be internalized through a scavenger pathway. However, all these studies were conducted with the focus on proposed mechanisms of LDL-induced lipid deposition, and did not focus on the unique property of Lp(a), i.e., self-aggregation. Although aggregated Lp(a) might not precipitate in circulation *in vivo*, one cannot rule out the possibility that it might undergo aggregation in an atherosclerotic milieu. In fact, Hoff *et al.* (14) characterized tissue Lp(a) extracted from human atherosclerotic lesions and found that some of the tissue Lp(a) formed aggregates. Similar to our results, Tertov *et al.* (32) demonstrated, using Lp(a) isolated from a patient with CAD, that aggregates formed after 6-h incubation under cell culture conditions induced massive lipid deposition in macrophages, indicating a significant role of self-aggregation in cellular uptake of Lp(a). Taking these findings and our data into consideration, it can be said that aggregation may be related to the mechanisms of Lp(a) accumulation in the artery wall, or may even be a crucial step for accelerating the development of atherosclerotic lesions.

At the present time, the metabolism of native Lp(a) is still unclear. Studies with cultured cells (33), partially purified receptors (34), and transgenic mice overexpressing the LDL receptor (35) provided evidence of a specific binding of Lp(a) to the LDL receptor. Our findings that LDL in excess concentration inhibited the binding and degradation of native Lp(a) in macrophages are consistent with the findings of previous studies and support the significant role of the LDL receptor in native Lp(a) metabolism. On the other hand, the failure of LDL to inhibit the binding and degradation of aggregated Lp(a) indicated that the LDL receptor was not involved in the metabolism of aggregated Lp(a). This is possibly because conformational changes of apo(a) and/or Lp(a) induced by aggregation sterically hinder the receptor binding domain of apolipoprotein B-100 in Lp(a) from interacting with the LDL receptor of macrophages. Earlier, Yashiro *et al.* (15) reported that monomeric LDL can bind to Ca^{2+}-induced aggregated Lp(a) under *in vitro* conditions. This evidence raises the possibility that aggregated Lp(a) internalization was not inhibited because of LDL sequestration by aggregated Lp(a). However, this is unlikely because monomeric LDL showed little binding to aggregated Lp(a) in the culture medium used in these experiments (data not shown). Although the precise reason for this is not known, a higher ionic strength of the medium compared with that of previously reported interacting solutions (15) may inhibit the ionic binding between LDL and aggregated Lp(a).

As shown in the results, the inhibition of aggregated Lp(a) uptake by cytochalasin B suggested that a phagocytic pathway was possibly involved in its metabolism. Several reports have suggested that Fc receptor, one of the phagocytosis-promoting receptors, is related to enhanced uptake of modified LDL such as immune complexes of aggregated LDL or oxidized LDL (36,37). Therefore, we tested the contribution of the Fc receptor to the uptake of aggregated Lp(a) using heat-aggregated gamma globulin as a competitor. Although the results were not shown in the results section, the Fc receptor was only slightly involved in the uptake of aggregated Lp(a). Cholesterol esterification in macrophages was reduced by 15% in the presence of heat-aggregated gamma globulin. This is consistent with the previous report by Khoo *et al.* (36) using vortex-induced aggregated LDL, and suggested that aggregated Lp(a) may be taken up *via* non-Fc receptor-mediated phagocytosis.

Recently, a novel endocytic pathway such as sequestration or macropinocytosis has been proposed for the mechanism of macrophage uptake (38,39). These pathways are actin-dependent and inhibited by cytochalasin as phagocytosis is. Therefore, we cannot rule out the possibility that such pathways are associated with the aggregated Lp(a) metabolism observed in this study. To better understand the precise mechanism by which aggregated Lp(a) is taken up by macrophages, further studies will be needed.

It has been already reported for LDL that self-aggregation is one of the important steps leading to foam cell formation of macrophages (40). Therefore, a comparison of cholesterol esterification between aggregated LDL and Lp(a) may be valuable. However, a direct comparison cannot be made because, unlike Lp(a), LDL does not undergo self-aggregation by calcium as reported by Yashiro *et al.* (15). Although many

different aggregation models have been proposed for LDL (32,40–44), it is meaningless to compare these models with ours because results obtained using different aggregation models may be biased by different properties of aggregates derived from the method used.

In this study, the ability of Lp(a) of two different phenotypes to stimulate cholesterol esterification in macrophages was also examined, and we found a significant difference between them. This difference might be a clue for explaining differences in atherogenicity between Lp(a) phenotypes as previously suggested (45–47); however, our data are too preliminary to justify a conclusion. To clarify this issue, further studies using a greater number of donors and Lp(a) phenotypes must be performed.

The present study proposed one potential mechanism by which Lp(a) accumulates in the artery wall, and thereby supports the significant role of Lp(a) in atherosclerotic diseases.

Effect of Selenium and Vitamin E Supplements on Tissue Lipids, Peroxides, and Fatty Acid Distribution in Experimental Diabetes

C. Douillet[a], M. Bost[b], M. Accominotti[c], F. Borson-Chazot[d], and M. Ciavatti[a,*]

[a]National Institute of Health and Medical Research Unit 331, 69375 Bron, [b]Trace Element Institute for UNESCO, 69007 Lyon, [c]Department of Pharmacological Biochemistry, Edouard Herriot Hospital, 69008 Lyon, and [d]Department of Endocrinology Antiquaille, Claude Bernard University, 69008 Lyon , France

ABSTRACT: The protective role of selenium (Se), given as a Se-rich yeast, selenomethionine or selenomethionine + vitamin E supplement, toward changes in lipid, peroxide, and fatty acid distribution in tissues of streptozotocin-induced diabetic rats, was investigated, after 24 wk of disease. Diabetes increased liver thiobarbituric acid-reactive substances and conjugated dienes; Se supplement completely corrected these changes. In kidney, as in heart, the peroxide levels were not significantly changed by diabetes. In diabetic rat liver, a significant drop in triglycerides and phospholipids ($P < 0.05$) was observed; this was modulated by Se + vitamin E supplementation. Se + vitamin E supplementation also inhibited the decrease in 18:2n-6 and the increase in 22:6n-3 observed in liver of diabetic rats, changes which reflect altered glycemic control. In kidney, heart, and aorta, diabetes produced some changes in lipid content and fatty acid distribution, especially an increase in heart triglycerides which was also corrected by the Se supplement. Se supplementation to diabetic rats also increased 18:0 ether-linked alcohol, 20:4 n-6, and 22:5 n-3 in cardiac lipids. In aorta, Se + vitamin E significantly increased 20:5 n-3. These polyunsaturated fatty acids are precursors, *in situ*, of prostaglandin I_2 (PGI_2) and PGI_3 which may protect against cardiovascular dysfunction. In kidney, conversely, Se decreased 20:4 n-6, the precursor of thromboxane A_2 implicated in diabetic glomerular injury. Thus Se, and more efficiently Se + Vitamin E supplementation, in experimental diabetes could play a role in controlling oxidative status and altered lipid metabolism in liver, thereby maintaining favorable fatty acid distribution in the major tissues affected by diabetic complications.
Lipids 33, 393–399 (1998).

Diabetes mellitus is associated with characteristic vascular complications. The capillaries, arterioles and large arteries can be affected, leading to clinical manifestations of micro- or macroangiopathy (1). Lipid abnormalities such as hypertriglyceridemia (2) and fatty acid distribution changes (3) could participate in the development of vascular lesions in diabetes. However, hyperglycemia alone has been reported to have a causal link with diabetic microangiopathy complications (4). The toxicity of glucose has been confirmed by studies on nonenzymatic glycosylation of proteins, on the polyol pathway, and on autooxidation of sugars and sugar-adduct proteins. These products and oxidized unsaturated lipids generate free radicals and may induce an oxidative stress *in vivo* possibly indicating a common pathway linking diverse mechanisms for the pathogenesis of vascular diabetic complications (5). However, to confirm the importance of oxidative stress in this pathology, it is important to show that its inhibition prevents or delays abnormalities in diabetic tissues.

In previous studies, we have shown that antioxidant supplementation could modulate platelet hyperactivity and fatty acid changes and also delay cataract development in diabetic rats (6). More recently, we have shown that a pharmacologic dose of vitamin E could decrease cholesterol in the aorta of diabetic rats (7) and that a selenium (and more efficiently a selenium + vitamin E) supplement delayed renal lesions in streptozotocin-induced diabetic rats (8). This study was undertaken to show whether selenium, a constituent of glutathione peroxidase and selenoproteins with antioxidant properties (9), along with vitamin E could modulate peroxide and lipid levels in different diabetic rat tissues.

MATERIALS AND METHODS

Animals and treatments. Seventy-six male Sprague-Dawley rats (Charles River, Saint Aubin les Elbeuf, France) with initial body weight of 525 ± 80 g were used for the study. Sixty-four rats were injected iv with 30 mg/kg streptozotocin dissolved in a buffer (7). All rats with glycemia >2.5 g/L were considered diabetic. Six rats died 48 h after streptozotocin injection. Twelve rats were used as a control group and injected with buffer alone (Group C). Before experimentation, all rats were fed with a standard laboratory chow (A04 from UAR, Villemoison sur Orge, France) containing selenium (Se) at 200 µg/kg of diet, and had a normal blood selenium of 524 ± 14.5 µg/L. A week after streptozotocin injection, all rats received a diet according to the current recommendations for

Abbreviations: DMA, dimethyl acetal; GSH, glutathione; MDA, malondialdehyde; TBARS, thiobarbituric-acid reactive substances.

diabetes (6). Briefly, the diet contained 15% protein, 52% carbohydrate, and 33% lipid in percentages of total calories. The lipids were a mixture of butter and hydrogenated coconut, canola, and sunflower oils (4, 1.7, 7, and 4.5 g/100 g of diet, respectively). The ratio of polyunsaturated/saturated fatty acids was 1. Purified diet without supplementation contained 20 µg of Se and 9.6 mg of vitamin E per 100 g of diet [vitamin E consisted of 5 mg of α-tocopherol acetate from a vitamin mixture added to basal diet (ICN, Aurora, OH), and 4.6 mg of natural tocopherols (α, β, γ) from the vegetable oils]. Diabetic rats were separated into four groups. Group D (14 rats) received the purified diet without supplementation as given to the control group. The other groups received the same diet supplemented either with Se-rich yeast (i.e., Selenion; Cellife Intern No. 4537; Montrouge, France) (63.2 mg/100 g of diet for 14 rats, group: DSel), with selenomethionine (194.5 µg/100 g, for 14 rats, group: DSm), or with a double supplementation, i.e. selenomethionine + α-tocopherol acetate (Sigma, Isle d'Abeau, France) (194.5 µg/100 g and 62.5 mg/100 g, respectively, for 16 rats, group: DSmE). The elemental Se in the three groups was 78.2 µg/100 g of diet. Diabetic rats were injected subcutaneously four times per week with 3.2 IU ultra-slow insulin (Novo, Boulogne, France). After 24 wk of diet, following a fast of 7 h and 24 h of insulin deprivation, blood was removed from the jugular vein of each rat and the animals were sacrificied by iv pentobarbital injection. The different organs (liver, heart, aorta, and kidney) were quickly collected, surrounding adipose tisssue was carefully removed, and the tissues were lyophilized.

Biochemical determinations. Tissue lipids were extracted by the technique of Folch *et al.* (10), and total cholesterol levels were evaluated in accurately measured aliquots of lyophilized lipid tissue extract according to the technique of Omodeo Sale *et al.* (11). Phospholipids and triglycerides were determined by enzymatic kits: Biomérieux (Marcy l'Etoile, France), and Merck (Darmstadt, Germany). Aorta vitamin E was measured in lipid extracts by high-performance liquid chromatography (7). Kidney, heart, and liver vitamin E levels were determined using the same technique preceded by a saponification step according to the technique reported by Rittenmaier and Schuep (12) with some modifications (7). Tissue Se was determined by atomic electrothermal absorption spectroscopy with a Varian model Spectra AA 300 (Tokyo, Japan) (8). Thiobarbituric acid-reactive substances (TBARS) and conjugated dienes were measured in aliquots of lipid extract (8).

Fatty acid distribution in lipid extracts was studied. Fatty acids were transesterified using BF_3-methanol by the technique of Morrison and Smith (13) and purified by thin-layer chromatography on silica gel G with a solvent composed of petroleum ether and diethyl ether (90:30, vol/vol.). The spots of methylated fatty acids were revealed by a spray of dichlorofluorescein dissolved in ethanol/acetone (1:1, vol/vol). Fatty acid methyl ester distribution was studied by gas–liquid chromatography. Liver and heart fatty acid methyl esters were separated on an Intersmat instrument IGC 120 DFL (Courtry, France) using a flame-ionization detector on a semi-capillary column Restek CRTX 2330 (30 m × 0.52 mm) (Restek Corporation, Bellefonte PA). The oven temperature was 85°C at injection and was maintained for 10 min, then raised by 4°C/min to 235°C. Injector and detector temperatures were 260 and 230°C, respectively. Helium was used as carrier gas under a pressure of 0.6 bars. Kidney and aorta methylated fatty acids were obtained as described before and gas–liquid chromatographic analysis was performed on a Carlo Erba HRCG 5160 instrument (Milan, Italy) and a capillary column SP 2340 (30 m × 0.32 mm) (Supelco Company, Bellefonte, PA). The oven temperature was 90°C for 1 min at injection and raised by 6°C/min to 145°C, 2°C/min to 200°C , then 3°C/min to 220°C and isothermal maintained for 17 min.

Statistical analysis. Unpaired Student's *t*-test preceded by analysis of variance was used to evaluate the significance of differences.

RESULTS

Tissue lipids levels are reported in Table 1. Liver phospholipids and triglycerides significantly decreased in group D, diabetic rats without supplements compared to group C, controls ($P < 0.05$). This decrease of phospholipids was prevented only in group DSmE, diabetic rats supplemented with selenomethionine and α-tocopherol acetate. Triglyceride levels were more than three times less in group D than in group C. A double supplementation with Se + vitamin E restored the liver triglyceride level in group DSmE nearly to that in group C, the control. The different lipids in heart and kidney were not significantly changed in diabetic animals supplemented or not with Se; only a significant increase in heart triglycerides for diabetic rats without supplements (group D) compared to controls was noted ($P < 0.05$). Results for tissue peroxides, evaluated by measurement of TBARS and conjugated dienes, are given in Figure 1. A significant increase in TBARS was noted in the hepatic tissue of group D, diabetic rats without supplements compared to controls ($P < 0.05$); antioxidant supplementation decreased this effect. Heart and kidney tissues presented higher TBARS levels than liver, but these were not significantly changed in diabetic groups compared to group C (controls). For conjugated dienes, we observed the same effects in liver tissue as for TBARS: a significant increase in diabetic rats without supplements compared to controls ($P < 0.05$), corrected by Se supplementation. These compounds were also higher in heart and kidney than in liver but were not significantly changed by the disease.

Tissue antioxidant concentrations are given in Figure 2. Liver vitamin E level was very significantly decreased in (group D) compared to controls (group C) ($P < 0.0005$); this was completely corrected in the group DSmE. Vitamin E concentrations in group DSmE were very significantly increased compared to group D ($P < 0.0005$). Liver Se level in group D was only slightly decreased compared to group C. In Se-supplemented diabetic groups, liver Se increased significantly compared to groups C (control) and D (diabetic rats without supplements). In heart, vitamin E and Se levels were lower

Aorta					
Triglycerides					
Liver	280 ± 37[b]	83 ± 20[c]	125 ± 23[c]	141 ± 18[b]	207 ± 64[b]
Heart	4 ± 0.5[b]	4.8 ± 0.8[c]	3.4 ± 0.6[b]	2.7 ± 0.4[b]	3.5 ± 0.6[b]
Kidney	3.6 ± 0.4[b]	3 ± 0.4[b]	3.2 ± 0.7[b]	2.6 ± 0.3[b]	2.3 ± 0.2[b]

[a]Values are means ± SD of 7–11 rats in each group. [b,c]Values not bearing the same superscript letters in the same row are significantly different from each other at $P < 0.05$. Abbreviations: C, control; D, diabetic rat with no supplements; DSel, diabetic rat supplemented with Se-rich yeast; DSm, diabetic rats supplemented with selenomethionine; DSmE, diabetic rat supplemented with selenomethionine + vitamin E.

than those observed in liver in all groups. Heart vitamin E level was significantly increased in group DSmE (diabetic rats supplemented with selenomethionine + α-tocopherol acetate) compared to groups C (control), D (diabetic rats without supplements), DSel (diabetic rats with Se-rich yeast) ($P < 0.005$, $P < 0.0005$, $P < 0.0005$, respectively). Concerning heart Se concentration, a significant increase was observed, as for liver, in all diabetic Se-supplemented groups. Kidney tissue had a lower vitamin E level compared with the other tissues studied; this was not changed by disease, nor supplementation. On the contrary, kidney had a higher Se content than did other tissues. Diabetes did not modify kidney Se level, but the Se supplementation very significantly increased kidney Se content in diabetic groups ($P < 0.0005$).

Changes in liver fatty acid distribution are given in Table 2. A significant decrease in linoleic acid (18:2 n-6) was observed

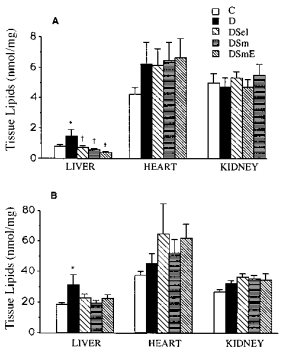

FIG. 1. (A) Tissue thiobarbituric acid-reactive substances (TBARS) and (B) conjugated diene levels in control rats (C) and diabetic rats without supplements (D); and diabetic rats supplemented with a Se-rich yeast (DSel), selenomethionine (DSm), or selenomethionine + vitamin E (DSmE). Values are means ± SD for 7 to 11 animals in each group. Symbols denote statistically significant differences vs. C, control group * = $P < 0.05$; vs. unsupplemented diabetic rats, group D † = $P < 0.05$.

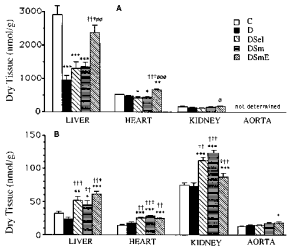

FIG. 2. Tissue vitamin E (A) and Se (B) levels in control and diabetic rats (C, D) and diabetic rats supplemented with a Se-rich yeast (DSel), selenomethionine (DSm), or selenomethionine + vitamin E (DSmE). Values are means ± SD for 7 to 11 animals in each group. The symbols denote statistically significant differences vs. control group C, * = $P < 0.05$, ** = $P < 0.01$, *** = $P < 0.0005$; vs. unsupplemented diabetic rats, group D †, ††, †††; and vs. DSel, ø, øø, øøø idem. Vitamin E and Se levels in kidney are reprinted by permission of Blackwell Science Inc. from Douillet, C. *et al.* A selenium supplement associated or not with vitamin E delays early renal lesions in experimental diabetes, *Proc. Soc. Exp. Biol. Med. 21,* 323–331.

20:3n-6	0.6 ± 0.04[b]	1.1 ± 0.0[c]	0.9 ± 0.05[c]	1.0 ± 0.08[c]	0.9 ± 0.08[c]
20:4n-6	11.2 ± 0.99[b]	13.8 ± 0.7[b]	12.9 ± 0.73[b]	12.9 ± 0.82[b]	12.4 ± 0.95[b]
22:4n-6	0.40 ± 0.02[b]	0.4 ± 0.04[b]	0.3 ± 0.02[b]	0.4 ± 0.07[b]	0.3 ± 0.03[b]
18:3n-3	1.1 ± 0.07[b]	0.6 ± 0.05[c]	0.6 ± 0.06[c]	0.7 ± 0.09[c]	0.8 ± 0.08[c]
20:5n-3	0.2 ± 0.02[b]	0.2 ± 0.06[b]	0.2 ± 0.01[b]	0.2 ± 0.02[b]	0.2 ± 0.02[b]
22:5n-3	0.6 ± 0.07[b]	0.4 ± 0.04[c]	0.4 ± 0.03[c]	0.5 ± 0.08[b]	0.4 ± 0.03[c]
22:6n-3	2.5 ± 0.22[b]	3.4 ± 0.26[c]	3.3 ± 0.12[c]	3.2 ± 0.25[c]	2.8 ± 0.24[b]

[a]Values reported are weight percentage and are means ± SD (n = 7–13 rats in each group). [b,c]Values not bearing the same superscript letters in the same row are significantly different from each other at $P < 0.05$. DMA: dimethyl acetal. For other abbreviations see Table 1.

in groups D, DSel, and DSm (diabetic rats supplemented with selenomethionine) compared to group C ($P < 0.05$); this decrease was corrected in group DSmE. A significant increase in dihomo-γ-linoleic acid (20:3n-6) was noted in all diabetic groups compared to control group C. A decrease in linolenic acid (18:3n-3) ($P < 0.05$) and docosapentaenoic acid (22:5n-3) associated with an increase in docosahexaenoic acid (22:6n-3) ($P < 0.05$) were observed in diabetic groups compared to group C except for group DSmE, which was supplemented with both selenomethionine and α-tocopherol acetate.

Changes in cardiac fatty acids are shown in Table 3. In rat heart tissue, diabetes induced a significant decrease in arachidonic acid (20:4n-6) and docosapentaenoic acid (22:5n-3) ($P < 0.05$) compared to control. These changes in diabetic rats were prevented by Se supplementation. Moreover, an increase in ether-linked 18:0 alcohol was observed in all diabetic Se-supplemented rat groups compared to control group C, but this was only significant in groups DSm and DSmE ($P < 0.05$).

Changes in kidney fatty acids are indicated in Table 4. Conversely, in kidney, a significant increase in 20:4n-6 was noted in Group D (diabetic rats with no supplementation) compared to C, which was corrected in groups DSm and DSmE. We also observed in this tissue a significant decrease in monounsaturated fatty acids (18:1n-9 + 18:1n-7) and a significant increase in 22:6n-3 in all diabetic groups compared to control group C.

Fatty acid changes in aorta are noted in Table 5. An increase in ether-linked 18:0 alcohol was observed in diabetic Se-supplemented groups compared to control group C but, as in heart, this was only significant in groups DSm (supplemented with selenomethionine) and DSmE (supplemented with selenomethionine and α-tocopherol acetate). A significant increase in 20:3n-6 was noted in all diabetic groups compared to control group C. In group DSmE, 20:5n-3 also was significantly increased ($P < 0.05$) compared to groups D (unsupplemented) and C (control). Moreover, 22:5n-3 and 22:6n-3 were increased in the diabetic groups compared to C, but this was significant only for groups DSel and DSmE ($P < 0.05$).

[a]Values reported are weight percentage and are means ± SD (n = 7–13 rats in each group). [b–d]Values not bearing the same superscript letters in the same row are significantly different from each other at $P < 0.05$. For other abbreviations see Tables 1 and 2.

DISCUSSION

Two forms of Se supplementation were utilized in the present work: a selenium-rich yeast representing a natural organic-bound form, and selenomethionine. Previous studies showed that the Se-rich yeast steadily increased plasma selenium (14) and prevented secondary myocardial infarction (15). Supplementation with selenomethionine was studied, as the major Se constituent of yeast, to determine whether it had biological activity.

Se supplementation in streptozotocin-diabetic rats provoked a significant increase of this element in liver, heart, and kidney, but this increase only occurred in aorta when Se was given in association with vitamin E. Se-cysteine is an active site of glutathione (GSH) peroxidase. GSH peroxidase has antioxidant activity since it catalyzes the conversion of hydroperoxides to stable nonradical products (9). One could hypothesize that a Se increase in tissue could prevent oxidative damage. In diabetic rats, serum oxidative markers are raised (16). Hence, it seemed interesting to observe changes in lipids, polyunsaturated fatty acids (targets for peroxidation), and peroxide levels in different tissues, after Se supplementation.

In the present study, a significant decrease in liver lipid levels, especially triglycerides, was observed in diabetic rats without supplements compared to controls. In contrast, hepatic triglycerides have been reported to accumulate after only a few hours in experimental diabetes; this correlated with ketosis and was partially reversed by insulin treatment (17). In our study, diabetic rats were treated with insulin for a long period (24 wk), to avoid ketoacidosis or hyperosmolarity, and fed with a lipid-rich diet. Decrease in liver triglycerides, observed in this study, could be a result of these hormonal and dietary changes. It has been reported that chronic deficiency of insulin provokes a lowering of triglyceride synthesis (18). Both selenium and vitamin E have been associated with insulin-like properties (19,20). In the present study, Se supplementation tended to normalize liver triglyceride levels. Moreover, in group DSmE, triglyceride levels were close

to control. The large increase in liver TBARS observed in diabetic rats could promote DNA and protein alterations (21), inducing changes in the enzyme activities implicated in lipid metabolism. In Se- supplemented diabetic rats, these alterations could be partly diminished. This point would be worthy of further study.

Liver phospholipid levels also decreased in all diabetic rats, supplemented whether with selenium or not. As seen with triglycerides, this decrease could be a result of altered liver phospholipid synthesis, or perhaps due to liver peroxide levels. It has been reported that lipid peroxidation stimulates expression of phospholipase A_2 in liver which preferentially hydrolyzes peroxidized phospholipids (22). In group DSmE (supplemented with selenomethionine and α-tocopherol acetate) only, liver phospholipid loss was weakly prevented, perhaps because membrane phospholipid unsaturated fatty acids are highly susceptible to oxygen free-radical attack (23).

An increase in triglycerides and cholesterol in rat myocardium was reported after streptozotocin injection but was completely corrected by insulin after 8 wk of diabetes (24). Under our experimental conditions, after 24 wk of diabetes, an increase in heart triglycerides persisted in group D. Accumulation of cholesterol and triglycerides in the left ventricle and septum in diabetic patients has been associated with cardiomyopathy (25). Thus, decrease in heart triglyceride observed in diabetic Se-supplemented rats after 24 wk could represent a protective effect of selenium on cardiac function.

Concerning liver antioxidant and peroxide levels, diabetes induced a large decrease in vitamin E which tended to be prevented with Se supplementation and was completely corrected in group DSmE. In contrast, liver Se decreased slightly in group D (diabetic rats with no supplementation) compared to control group C but was significantly increased in all Se supplemented groups; this increase was amplified by concomitant vitamin E administration as observed previously in plasma and platelets (26). In liver, TBARS and conjugated dienes were increased in group D compared to group C. Se or Se + vitamin E supplementation in diabetic rats significantly decreased liver TBARS. The same effect of selenium and vitamin E was also observed in liver of rats submitted to a diet inducing oxidative stress (27). Liver conjugated dienes were also reduced by antioxidant supplements. TBARS partly reflect generation of malondialdehyde (MDA), a cytotoxic aldehyde, formed in the peroxidative degradation of membrane lipids. The excretion of urinary MDA-conjugated metabolites (28) was reported as being increased in diabetic rats (29). Accelerated detoxification of MDA by liver in Se- and vitamin E-supplemented rats may play a role in the preservation of oxidative status and polyunsaturated content of other tissues.

Diabetes under our conditions of diet and insulin treatment did not change Se or vitamin E levels in heart and kidney, nor consequently peroxide levels measured as TBARS and conjugated dienes. However, basal peroxide levels are more elevated in these tissues than in liver. This could reflect a decreased capacity to destroy these compounds, perhaps in relation to a relatively weak vitamin E content and lower activity of antioxidant enzymes than in liver.

For tissue fatty acid distributions in diabetic rats (groups D, DSel, DSm), the main changes were observed in liver: a decrease in 18:2n-6 associated with an increase in 20:3n-6 which could suggest an upregulation of Δ-6 desaturase by insulin as described (3). The decrease in 18:2n-6 was prevented by Se + vitamin E supplementation. In the liver of diabetic rats, a decrease in fatty acids of the n-3 series was observed: 18:3n-3, 22:5n-3, whereas, paradoxically, the 22:6n-3 was increased compared to control, except for group DSmE. Increase in 22:6n-3 has been associated with insufficient metabolic control (30).

In heart, an increase in ether-linked 18:0 alcohol in groups DSm and DSmE compared to C and D could indicate an improved possibility for long-term preservation of cardiac function. There has been a proposed link between lethal ischemic damage to myocardial tissue and plasmalogen degradation (31). Plasmalogen ethanolamine has also been described as the storage form of myocardial arachidonic acid (32). Increased plasmalogen through Se supplementation could help to maintain the myocardium. In the same way, a significant decrease in 20:4n-6 in group D (unsupplemented), compared to C, was also noted which disappeared in groups DSel, DSm, and DSmE. Prostacyclin is the major prostaglandin formed from arachidonic acid in the heart of most animals (33). Prostacyclin increases coronary flow, and protects myocardium *in vivo* from ischemic damage (34). Se treatment tended also to increase polyunsaturated fatty acids of the n-3 series in heart and aorta, 22:5n-3 and 20:5n-3, respectively. The latter of these may serve as the precursor of PGI_3, a vasodilator and a platelet antiaggregant (35).

In the kidney, diabetes mainly induced a significant increase in 20:4n-6. This increase was partially reduced by Se supplementation. This observation could partly explain the delay in development of renal lesions in diabetic streptozotocin-induced rats treated with vitamine E (8). Elevation of 20:4n-6 could play a role in the formation of thromboxane A_2, implicated in diabetic glomerulopathy (36).

In conclusion, in streptozotocin-induced diabetic rats, Se or Se+ vitamin E supplementation for 24 wk normalized lipid metabolism in liver and enhanced its capacity to destroy peroxidant compounds as observed before *in vitro* in liver slices (37). The effects of this supplementation were to modulate fatty acid composition in heart, kidney, and aorta and thus to help maintain normal tissue functions *in situ*. The treatment of diabetic patients with free radical scavengers such as Se and vitamin E with the aim of reducing oxidative stress is a question for further study.

Chronic Dietary n-3 Polyunsaturated Fatty Acids Deficiency Affects the Fatty Acid Composition of Plasmenylethanolamine and Phosphatidylethanolamine Differently in Rat Frontal Cortex, Striatum, and Cerebellum

ABSTRACT: As chronic consumption of a diet devoid of n-3 fatty acid induced modification of neurotransmission pathways in the frontal cortex of rats, plasmalogen alteration could occur in this area. Because of the propensity to facilitate membrane fusion, plasmenylethanolamine (PmE), a major plasmalogen of brain, may be involved in synaptic transmission. Female rats were fed diet containing peanut oil [(n-3)-deficient diet] through two generations. Two weeks before mating, half of the female rats of the second generation received a diet containing peanut oil and rapeseed oil (control group). The distribution and acyl composition of major phospholipids, phosphatidylethanolamine and PmE, were measured in the frontal cortex, striatum, and cerebellum of the male progeny of the two groups at 60 d of age. The n-3 polyunsaturated fatty acid (PUFA) deficiency had no effect on the distribution of phospholipids in all brain regions but affected their acyl composition differently. The level of 22:6n-3 was significantly lower and compensated for by higher levels of n-6 fatty acids in all regions and phospholipids studied. However, docosahexaenoic acid, being more concentrated in the PmE of frontal cortex, is also more decreased in the n-3-deficient rats compared to the striatum. By contrast, striatum PmE has retained more 22:6n-3 than PmE of the other regions. In addition, the increase of n-6 PUFA was significantly lower in frontal cortex PmE compared to the striatum and cerebellum PmE. In association with altered neurotransmission observed in frontal cortex of n-3-deficient rats, our results suggest that frontal cortex PmE might be more affected in chronically α-linolenic-deficient rats. However, by retaining 22:6n-3, striatum PmE could be most resilient.

Lipids 33, 401–407 (1998).

Polyunsaturated fatty acids (PUFA) derived from the n-6 or n-3 series of fatty acids (FA) are fundamental components of the structural membrane lipids of the brain. They are derived from the essential FA precursors, linoleic (18:2n-6) and α-linolenic acids (18:3n-3), which must be obtained from an exogenous source, i.e., the diet. It has been previously shown that a chronic dietary n-3 PUFA deficiency dramatically alters the FA composition of brain membranes, decreasing brain levels of n-3 PUFA which are compensated for by increased amounts of n-6 PUFA. This diet also altered learning ability in rats (1–7). Moreover, it has been shown that a lesion of dopaminergic neurons disturbed brain integrative functions, i.e., learning and memory, cognitive functions, and reinforcement processes (8–10). On the assumption that impairment of this neuronal system can occur as a result of this specific diet deficiency, Delion *et al.* (11) evaluated the influence of a diet deficient in α-linolenic acid on neurotransmission in the different regions under serotoninergic and dopaminergic regulation: frontal cortex and striatum. Chronic dietary α-linolenic acid deficiency led to a reduced docosahexaenoic acid (DHA), or 22:6n-3, level in these two cerebral regions (11), as already described by Bourre *et al.* (3) in the whole brain. However, a modification of several specific factors of the dopaminergic and the serotoninergic neurotransmission was observed only in the frontal cortex, a region which may be more specifically affected by the FA composition of the diet. The level of DHA in control rats was found to be slightly higher in the frontal cortex than in the striatum (11), which could make the frontal cortex more sensitive to a n-3 PUFA deficiency. PUFA, specifically DHA, are fundamental components of ethanolamine glycerophospholipids (EGP). Plasmalogens, as a subclass of EGP, are often not distinguished from diacyl components, even though they constitute 50% of EGP total levels and about 17% of total phospholipids in brain. These ether-lipids exhibit a different molecular structure as compared to diacylphospholipid. They are characterized by the presence of 1-*O*-alk-1′-enyl ether (vinyl ether)

Abbreviations: ANOVA, analysis of variance; 20:4n-6, arachidonic acid; DHA, docosahexaenoic acid; 22:6n-3, docosahexaenoic acid; EGP, ethanolamine glycerophospholipids; FA, fatty acid; 18:3n-3, α-linolenic acid; 18:1n-9, oleic acid; PE, phosphatidylethanolamine; PmE, plasmenylethanolamine; PUFA, polyunsaturated fatty acid; Pi, total phosphorus; TLC, thin-layer chromatography.

linkage at the *sn*-1 position as compared to the 1-*O*-acyl ester linkage present in diacylphospholipids. Furthermore, the *sn*-2 hydroxyl group is usually esterified to highly unsaturated FA such as 20:4n-6 and 22:6n-3. Cellular functions of plasmalogens are poorly understood. However, several hypotheses have been proposed. Because of reactivity of the alkenyl ether bond of plasmalogens with singlet oxygen and other reactive oxygen species, plasmalogens may function as effective antioxidants (12,13). They may be a reservoir of PUFA that serve as precursors or modulators in eicosanoid production (14–16). In addition, the high vinyl ether content of membrane phospholipids seems to be a ubiquitous characteristic of electrically active tissues such as heart and brain (17). Their presence in significant amounts in these tissues suggests that they may be involved in the regulation of transmembrane ion movements. Indeed, specific interactions of plasmalogens with membrane proteins have been observed, i.e., rabbit skeletal muscle calcium ATPase (18) and Na^+/K^+ ATPase (19). Moreover, plasmenylethanolamine (PmE), the major brain plasmalogen, is abundant in several subcellular membranes which undergo rapid membrane fusion, e.g., synaptic vesicles and plasma membranes (20). Because of the greater propensity of this phospholipid to adopt a hexagonal phase, vesicles containing PmE undergo fusion six times more rapidly than those containing phosphatidylethanolamine (PE). This suggests that PmE may be involved in membrane fusion, a process occurring during synaptic transmission (21). On the basis of these previous experiments, we hypothesized that plasmalogens play a role in neurotransmission processes. Thus, the aim of this study was to evaluate the influence of chronic dietary n-3 PUFA deficiency on plasmalogens in different brain regions under monoaminergic regulation by determining whether modifications could be obtained in their composition in parallel with changes in neurotransmission observed in the frontal cortex of rats deficient in n-3 PUFA. Accordingly, we measured the distribution and FA composition of major phospholipids of the brain, i.e., PE and PmE in rats chronically fed a diet deficient in n-3 PUFA. These components were studied in frontal cortex, striatum, and cerebellum. This last region was chosen as a reference area since it is poor in monoaminergic innervation (22).

MATERIALS AND METHODS

Animals and diets. The experimental protocol was in accordance with the procedure previously described by Delion *et al.* (11) and was detailed as follows: two generations of female Wistar rats (Laboratoire de Nutrition et Sécurité Alimentaire, Jouy-en-josas, France) were fed all their life a diet containing 6% fat as African peanut oil specifically deficient in α-linolenic acid. This deficient diet provided around 1200 mg of linoleic acid but less than 6 mg of linolenic acid per 100 g of diet. Two weeks before mating, at 8 wk of age, female rats originating from the second generation of the α-linolenic acid-deficient rats were divided into two equal groups. The first group continued to receive the deficient diet, and the second a diet in which peanut oil was replaced by a 60/40% mixture of peanut oil and rapeseed oil. The latter (control) diet provided the same amount of linoleic acid as the deficient diet and also around 200 mg of α-linolenic acid per 100 g of diet [(n-6)/(n-3) = 6]. Diets were consumed *ad libitum* by both groups. At weaning, the male progeny (third generation) of these groups of female rats received the same diet as their respective dams until sacrifice. Each measurement was realized on 6 male rats per group. Animals were killed at 60 d of age. The composition of diets and the composition in FA are reported in Tables 1 and 2. This protocol was in compliance with applicable guidelines from "Ministère de l'Agriculture, France."

Isolation of different brain regions. The animals were anesthetized with diethyl ether and infused with 0.9% saline sodium. The brain regions from each rat were rapidly removed and dissected, and the frontal cortex, striatum, and cerebellum were weighed and frozen at −80°C until use. Each tissue from each rat was homogenized in 10 vol of Tris-HCl buffer, pH 7.4.

Lipid analyses. Total lipids were extracted according to the method of Bligh and Dyer (23). A part of total lipid extract was used for total phosphorus (Pi) determination and another part for separation of the phospholipid classes by thin-layer chromatography (TLC) on precoated silica gel 60 plates (E. Merck, Darmstadt, Germany), as described by Owens (24). The method is based on the lability of plasmalogens toward mercuric chloride. Lipid samples containing around 250 nmoles of lipid phosphorus were fractionated by TLC. The plates were then developed in freshly prepared chloroform/methanol/water/acetic acid (65:43:3:1, by vol). In order to separate PmE and PE, the left lipid track of the chromatogram was sprayed with 5 mM mercuric chloride in 10 mM

acetic acid, while the remainder of the chromatogram was screened. After being evaporated to dryness under a stream of nitrogen for 1 h, the plates were developed in the second dimension with chloroform/methanol/water (60:35:8, by vol). The chromatogram was allowed to dry and then sprayed with diphenylhexatriene (Sigma Chemical, St. Louis, MO) to locate phospholipid spots under ultraviolet light. Appropriate blank areas also were marked. Each spot was scraped off into tubes containing appropriate chloroform/methanol (2:1, vol/vol) solvents. Phospholipid fractions were extracted with chloroform/methanol (2:1) and then quantified for phosphorus content using the procedure of Bartlett (25) modified by Böttcher (26). Results are expressed in nmoles/100 nmoles of Pi. To determine the FA composition of the phospholipids studied, around 600 nmoles of Pi were used to separate the different phospholipids by the procedure described above. FA were saponified and then methylated with 6% methanolic sulfuric acid. Separation of fatty acid methyl esters was done by capillary gas chromatography on a Hewlett-Packard model N 5890 gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector and a capillary column (length, 50 m; diameter, 0.25 mm; CP-Sil 88; Chrompack, Les Ulis, France). The oven temperature was programmed to rise from 170 to 230°C at a rate of 2°C/min. The injector temperature was 230°C and the detector temperature 270°C. Peaks were integrated by a programmable integrator-calculator (D 2500A chromato-integrator; Merck, Nogent sur Marne, France). The relative concentration of each FA was expressed as percentage of identified FA equal or greater than 16 carbon atoms for tissue samples. For statistical analyses, a one-way analysis of variance (ANOVA) was performed, and comparisons of means were determined using the Student's *t*-test. Values between control and deficient rats were considered significantly different when $P < 0.05$.

RESULTS

Weights of body and brain regions. The difference in mean body weight of the deficient (248 ± 8 g) and control (246 ± 8 g) groups was not significant ($P > 0.05$, ANOVA) at the time of the study. The dietary α-linolenic acid deficiency had no effect on the brain region weight of the animals. The weights in control vs. deficient rats were 272 ± 45 vs. 239 ± 26 mg, 50 ± 9 vs. 53 ± 8 mg, and 275 ± 25 vs. 288 ± 7 mg in frontal cortex, striatum, and cerebellum, respectively. The difference was not significant ($P > 0.05$, ANOVA).

Proportions of phospholipids classes (Table 3). Analysis of phospholipid composition in all three areas studied concerned only PE and PmE. The EGP levels, i.e., sum of PE and PmE levels, were similar for the three brain regions in the control group but the proportions of PE and PmE in this phospholipid class varied according to the region. In frontal cortex and striatum, PE levels were slightly higher than PmE levels and represented 55 and 52% of EGP levels, respectively. In contrast, cerebellum contained higher amounts of PmE than PE, since data showed PE levels about 47% of EGP total levels. In all brain regions studied, the proportions of PE and PmE were not modified by the n-3-deficient diet.

Fatty acid composition of PE (Table 4). In control rats, total PUFA levels were rather similar between the three re-

[a]Values represent means ± SD for six animals/group. See Tables 2 and 3 for abbreviations. ∑ (n-6) PUFA: sum of linoleic series. ∑ (n-3) PUFA: sum of linolenic series. (n-6) + (n-3): sum of linoleic and linolenic series. Minor fatty acids of the sum as 16:1n-9, 16:1n-7, 17:0, 18:3n-3, 20:0, 20:1n-9, 20:1n-7, 20:3n-9, 20:3n-6, 20:5n-3, 22:0, 22:1n-9, 24:0, and 22:5n-3 have been excluded from the table. [a]Significant difference from the control group at the level of $P < 0.05$. [b]Significant difference from the control group at the level of $P < 0.01$. [c]Significant difference from the control group at the level of $P < 0.001$.

gions, i.e., 31% in the frontal cortex and striatum and 36% in the cerebellum. However, the relative distribution of n-3 and n-6 PUFA varied from one brain area to another. The PUFA composition of frontal cortex and striatum PE did not differ significantly, but great differences were observed between cerebellum and the other two regions. The cerebellum was significantly enriched in 22:6n-3 compared to the other regions, by 46% ($P < 0.05$) and by 76% ($P < 0.01$) compared to frontal cortex and striatum, respectively, and the proportions of n-6 PUFA were less than the striatum, by 22% ($P < 0.05$).

Differences in FA composition of PE between the two dietary groups involved principally the PUFA. DHA levels were significantly decreased in all three regions compared to controls ($P < 0.001$). The decrease was significantly higher in cerebellum than in the striatum and in the frontal cortex, i.e., 78% in the cerebellum, 71% ($P < 0.01$) in the striatum, and 73% in the frontal cortex ($P < 0.05$). In the deficient group, the reduction in DHA was compensated for by the increase in level of n-6 PUFA including 22:5n-6, 22:4n-6, and 20:4n-6. The largest change occurred for 22:5n-6 for all brain regions studied. The overall results were that the total (n-6 + n-3) PUFA level in the deficient group was equivalent to that of the control group only in the striatum and the cerebellum. Total PUFA levels in the frontal cortex were significantly increased in the deficient group compared to the control group ($P < 0.01$), by 37%. Highest 22:5n-6/22:6n-3 ratio was observed in the frontal cortex compared to striatum and cerebellum in the deficient group. Although increased, 20:4n-6/22:6n-3 and 22:5n-6/22:6n-3 ratios were lower in the cerebellum of deficient rats than in the other two regions.

Fatty acid composition of PmE (Table 5). In the control group, PUFA proportions were dramatically different for each region. The level was significantly higher in the frontal cortex than in the striatum and the cerebellum ($P < 0.01$). DHA was the major fatty acid in frontal cortex PmE, since levels were significantly higher than in the striatum and the cerebellum by 31% ($P < 0.05$) and 33% ($P < 0.01$), respectively. Oleic acid (18:1n-9) was the predominant FA in striatum and cerebellum, and the level was 44% ($P < 0.001$) higher in the cerebellum than in the frontal cortex. So, in contrast with PE, significant differences were observed between frontal cortex and striatum in FA composition of PmE in control group. They involved 22:6n-3 and 18:1n-9.

n-3 PUFA deficiency induced profound modifications in PUFA proportions. As expected, DHA levels were significantly lower in the PmE of all regions for the deficient group, but the decrease was significantly greater in the frontal cortex and cerebellum PmE, i.e., 81 and 79%, respectively, than in the striatum (74%) ($P < 0.01$). Moreover, the increase of n-6 PUFA, which compensated for the low levels of n-3 PUFA, was significantly lower in the frontal cortex ($P < 0.05$) compared to the other two regions, i.e., 66, 82, and 85% increases were measured in the frontal cortex, striatum, and cerebellum, respectively. Total (n-6 + n-3) PUFA levels did not vary significantly in frontal cortex and cerebellum PmE, whereas this value increased significantly in striatum ($P < 0.01$).

In frontal cortex, as in cerebellum, the increase of n-6 PUFA was significantly higher in PE than in PmE in the deficient group ($P < 0.001$), whereas in the striatum, n-6 PUFA levels were increased in the same proportions in PE and PmE.

DISCUSSION

It appeared from the study that a chronic n-3 PUFA-deficient diet altered the PUFA composition of PmE and PE differently in the three brain regions.

Delion *et al.* (11) have reported that the proportions of different phospholipid classes in frontal cortex, striatum, and cerebellum were not modified by α-linolenic acid deficiency. However, these authors did not analyze the composition of plasmalogen phospholipids, important constituents in cerebral membranes. The role of these ether-lipids has not been well established, but their high concentrations in the brain tissue suggest an involvement in cerebral function. We analyzed plasmalogen content in the same regions and with the same animal model as Delion *et al.* (11), i.e., frontal cortex, striatum, and cerebellum in rats fed control diet and rats fed n-3 PUFA-deficient diet. Plasmalogen composition already has been analyzed in the whole rat brain (17), in the grey matter, white matter, and myelin in human brain (27), but no information is available on the distribution and acyl composition of plasmalogen of different brain regions. It appeared from this study that the proportions of EGP were similar in the three brain regions and were in accordance with proportions already observed in the whole rat brain (17). However, we showed that PmE and PE levels varied from one region to another, essentially from cerebellum to the other two regions. It has been previously shown that PmE are particularly enriched in the white matter and myelin (28,29). It can be speculated that PmE levels obtained in various regions of the central nervous system depend on the degree of myelination and proportion of white matter of the region. This explains the relatively high values of PmE for cerebellum, which contained larger amounts of white matter compared to striatum and frontal cortex. It is already interesting to note that the FA composition of cerebellum EGP differs from the FA composition of EGP observed in striatum and frontal cortex in control group. The great differences concerned PmE which contained larger amounts of monounsaturated fatty acids and low levels of n-6 PUFA compared to the other two regions. Almost 40% of cerebellum PmE contained oleic acid (18:1n-9) esterified in position *sn*-2. It is believed that plasmalogen species with 18:1 acyl chains participate exclusively in the activity of oligodendrial cells and myelin sheets (30).

PUFA composition of PE did not differ between the two regions under monoaminergic regulation, i.e., frontal cortex and striatum in the control groups, but marked differences were observed in PUFA composition of PmE: a greater proportion of DHA was found in the frontal cortex than in the striatum. Delion *et al.* (11) have demonstrated the greater richness of DHA in this region, and our study indicates the more specific implication of plasmalogen content. The present study also showed that the different cerebral regions studied seemed to have a specific need for n-6 and n-3 PUFA. It is interesting to note that striatum EGP are rich in n-6 PUFA and poor in n-3 PUFA compared to those present in the frontal cortex and cerebellum. By contrast, cerebellum EGP contained higher proportions of n-3 PUFA than n-6 PUFA. The proportions of n-6 PUFA were lowest in the cerebellum EGP. In the frontal cortex, n-6 PUFA and n-3 PUFA were equally distributed in the PE and in the PmE, but PUFA were present in larger amounts than in the other two regions. This area contained a higher concentration of 22:6n-3 compared to the

striatum, and highest levels of DHA were observed particularly in PmE.

Dietary n-3 PUFA deficiency did not modify plasmalogen proportions in the three brain regions. This diet seemed to have no influence on the synthesis of these phospholipids. However, this deficiency induced marked changes in FA content of PmE and PE. In all areas and phospholipids studied, our results showed a reduced 22:6n-3 level and compensatory higher levels of n-6 FA, essentially 22:5n-6 and 22:4n-6, in the deficient group. These results have been previously observed in the whole brain (12) and in total phospholipids of the same cerebral regions (11). In a recent study, this has been confirmed in the brain phosphatidylcholine, -ethanolamine and -serine of n-3-deficient rats. The proportion of 22:6n-3 was partially compensated for by an increase in the 22:5n-6 level (31). However, no studies have been performed on the effect of this diet in the FA composition of PmE and PE separately in brain. Our study showed that the total (n-6 + n-3) PUFA level could be increased or maintained according to the phospholipid and to the cerebral region. This specific phenomenon has not been observed in total phospholipids (11). Moreover, frontal cortex and striatum underwent different changes not only in PmE but also in PE. The decrease in DHA was significantly greater ($P < 0.05$) in frontal cortex PmE (81%) than in the striatum PmE (74%). This decrease level was similar in PE of these two regions. The increase of n-6 PUFA which compensated for the loss of n-3 PUFA was significantly lower ($P < 0.01$) in frontal cortex PmE (66%) than in PE of this region (140%), whereas in the striatum, n-6 levels were increased in the same proportions in PE and PmE, i.e., 94% in PE and 92% in PmE. In addition, this increase was significantly lower in the frontal cortex PmE than in the striatum PmE ($P < 0.05$) and in the cerebellum PmE ($P < 0.01$). On the basis of these observations, we could hypothesize that frontal cortex might be more specifically affected by n-3 PUFA deficiency than striatum. The frontal cortex contained a higher concentration of 22:6n-3 compared to the striatum, particularly in PmE. In deficient group, n-6 PUFA were incorporated preferentially in PE of the frontal cortex in comparison with PmE of this same region and with PmE of the other regions. This could correspond to the greater need for n-3 PUFA in frontal cortex PmE. The n-3 diet-induced deficiency in DHA may have modified the physicochemical properties of plasmalogen in the frontal cortex. By contrast, striatum could be most resilient to a n-3 deficiency by retaining more 22:6n-3 in PmE than frontal cortex. The decrease in DHA was significantly lower than that in frontal cortex ($P < 0.01$) and cerebellum ($P < 0.05$). So, striatum could be least affected by the n-3 PUFA deficiency.

A link has already been established between DHA and plasmalogen in human brain. DHA deficiency has been a constant finding in early-onset peroxisomal disorders in brain (32). These diseases are characterized by severe deterioration of the central nervous system. In addition, patients with impaired peroxisomal biogenesis have a deficient plasmalogen synthesis. Treatment with pure DHA ethyl ester of two patients with peroxisomal disease has increased the erythrocyte levels of 18:0 plasmalogen in both patients (33). This observation suggests a cause–effect relationship between the DHA deficiency and the defective plasmalogen synthesis in peroxisomal disorder. DHA is, in fact, an important factor in cerebral development, and it appears that this specific role could be linked to its presence in plasmalogen. Moreover, the ethanolamine plasmalogens are decreased in plasma membrane phospholipid in affected regions in Alzheimer's disease (34). The characteristic symptoms of this disease are progressive loss of memory and cognitive function. Behavior studies have shown that cognitive processes are altered in a dietary α-linolenic acid deficiency rat model. Enrichment of frontal cortex with plasmalogen species with 22:6n-3 acyl chains could be in accordance with a specific implication for this phospholipid in learning and cognitive functions.

In conclusion, in association with neurotransmission changes occurring only in the frontal cortex and not in the striatum, we show different modifications of the acyl composition of PmE and PE of the frontal cortex and the striatum. Different changes in plasmalogen composition of cerebral membranes in frontal cortex compared to striatum could contribute to alterations in synaptic transmission. In frontal cortex, PmE might be more affected by the n-3 deficient-diet. The striatum seems to be most resilient to the deficiency by retaining more 22:6n-3 than the two other areas in PmE.

We did not observe any modification of the proportions of PmE in the frontal cortex of deficient rats. However, PmE is concentrated in synaptic membranes. Studies focused on these membranes should provide more precise analysis, and we expect that changes in phospholipid composition will be observed specifically in these membranes.

DHA is preponderant in synaptic membranes (35) which are particularly rich in plasmalogens. DHA could have an influence on the mechanisms of neurotransmission through plasmalogen mediation. Studies focused on these synaptosomal membranes should determine whether the changes observed in frontal cortex plasmalogen relate specifically to these synaptic membranes.

Inhibitory Effect of Linoleic Acid on Chain Elongation and Desaturation of 18:2 *c,t* Isomers in Lactating and Neonatal Rats

Kwok Yiu Kwan, Li-Ya Wang, Kwok Pan Chan, and Zhen Yu Chen*

Department of Biochemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

ABSTRACT: The previous studies showed that dietary 18:2 *c,t* isomers could be chain-elongated and desaturated to produce unusual 20:4 isomers. The present study was undertaken to determine the minimal amount of 18:2n-6 required to suppress the chain elongation and desaturation of 18:2 *c,t* isomers in the lactating and neonatal rats when animals were fed 15% partially hydrogenated canola oil diet containing 1.72% energy as 18:2 *c,t* isomers and varying amounts of free 18:2n-6. These diets induced marginal essential fatty acid (EFA) deficiency states (0.56% energy 18:2n-6) to EFA adequacy (2.56% energy 18:2n-6). After feeding for 50 d, the female animals were mated with males by overnight pairing. After conception, the lactating rats were killed, together with one pup from each dam, at term and day 26 of lactation. Two unusual 20:4 isomers in both maternal and neonatal liver phospholipids were identified as 20:4Δ5*c*,8*c*,11*c*,14*t* and 20:4Δ5*c*,8*c*,11*c*,15*t*, which were derived from 18:2Δ9*c*,12*t* and 18:2Δ9*c*,13*t*, respectively. The results showed that 18:2n-6 at about 2.0% of total energy in maternal diet was required to block the production of 20:4Δ5*c*,8*c*,11*c*,14*t* and 20:4Δ5*c*,8*c*,11*c*,15*t* in the maternal liver, whereas 18:2n-6 at about 2.5% of total energy in maternal diet was required to suppress production of these unusual 20:4 isomers in the neonatal liver.

Lipids 33, 409–416 (1998).

The health effects of dietary *trans* fatty acids in humans are controversial. Dietary *trans* isomers of oleic acid (18:1n-9) have been shown to raise serum low density lipoprotein cholesterol and lower high density lipoprotein cholesterol (1–3). Some epidemiological studies have suggested that high intake of *trans* fatty acids may be a significant risk factor in development of cardiovascular disease (4–7). However, other studies have not proved a health risk associated with their intake (8–11).

Several isomers of linoleic acid (18:2n-6) present in the Western diet are formed during refining or partial hydrogenation of vegetable oils. These isomers in the partially hydrogenated vegetable oil mainly include 18:2Δ9*c*,13*t*, 18:2Δ9*c*,12*t*, and 18:2Δ9*t*,12*c*, with the former being most abundant (12,13). We have previously found that human adipose tissue contains these 18:2 isomers and has a similar isomeric distribution as that in partially hydrogenated vegetable oils (14). We also have demonstrated that 10% of the breast milk samples of 198 Canadian lactating women have as much as 1.7% of total milk fat as these 18:2 isomers (15). Interest in these 18:2 *c,t* isomers is related to their possible inhibition of synthesis of arachidonic acid (20:4n-6) and formation of unusual 20:4 isomers *via* chain elongation and desaturation pathway (16,17). Subsequently, the unusual isomers of 20:4n-6 may, *via* lipoxygenase and cycloxygenase pathways, serve as precursors of uncommon eicosanoids with unknown structures and functions (18). In fact, dietary 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t*, *via* processes similar to the conversion of 18:2n-6 to 20:4n-6, have been shown to be desaturated and elongated to form 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* in the rat liver, respectively (19).

Trans fatty acids may interfere with biosynthesis of long-chain polyunsaturated fatty acids (20). One study showed that human infant birth weight was inversely correlated to *trans* fatty acids in cord blood (21). Both 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t* seem to be ideal substrates for Δ6 desaturase and compete for this desaturation and elongation pathway with 18:2n-6 since their first double bond is at Δ9 position and is in *cis* configuration. Thus, high dietary intake of these isomers may increase the requirement of 18:2n-6, especially during early life when adequate synthesis of very long chain polyunsaturated fatty acids such as 20:4n-6 and docosahexaenoic acid (22:6n-3) is essential for normal brain development. On the other hand, dietary 18:2n-6 should exhibit an inhibitory effect on the production of unusual 20:4 isomers. The present study was therefore undertaken to determine the minimal amount of dietary 18:2n-6 required to suppress the chain elongation and desaturation of these unusual 20:4 isomers in the neonatal and lactating rats fed partially hydrogenated canola oil (PHCO).

MATERIALS AND METHODS

Diet. The animals were fed one of six diets containing either 15% canola oil (Diet F) or PHCO (Diet A) with supplementa-

Abbreviations: DMOX, 2-alkenyl-4,4-dimethyloxazoline; EFA, essential fatty acid; FAME, fatty acid methyl ester; GLC, gas–liquid chromatography; PHCO, partially hydrogenated canola oil; PL, phospholipid; TLC, thin-layer chromatography.

tion of free 18:2n-6 at 0.25% energy (Diet B), 0.50% energy (Diet C), 1.25% energy (Diet D), and 2.00% energy (Diet E). The other ingredients in the diets were, in g/kg, cornstarch, 288; sucrose, 243; casein, 235; cellulose, 32; AIN-76 mineral mix, 35; AIN-76A vitamin mix, 10; choline bitartrate, 4; and DL-methionine, 3. The diets were prepared biweekly and stored at –4°C. The fatty acid composition of each diet was determined using gas–liquid chromatography (GLC, Table 1)

Animals. Female Wistar rats (200 g) were randomly divided into six groups and housed individually in an animal house maintained at 23°C with 12-h light and dark cycles. Diets and water were provided *ad libitum*. The females were mated with male rats by overnight pairing. The animals were fed one of six diets prior to pregnancy (50 d) and through gestation (21 d) and lactation (26 d). The litter size varied from 8–13 pups. The lactating rats were killed at day 26 of lactation under carbon dioxide anesthesia. One neonate from each dam was killed at term and day 26 of lactation. The maternal and neonatal livers were removed, washed with saline, and immediately frozen in liquid nitrogen and stored at –80°C.

Lipid separation. Total lipids of maternal and neonatal liver were extracted using chloroform/methanol (2:1, vol/vol) containing 0.02% butylated hydroxytoluene (Sigma Chemical, St. Louis, MO) as an antioxidant. L-Phosphatidylcholine (diheptadecanoyl) was added as an internal standard to an aliquot of the total lipid extract to quantify total phospholipids (PL). Lipid classes were separated by neutral lipid thin-layer chromatography (TLC; 20 × 20 cm plate precoated with 250 µm silica gel 60A; Macherey-Nagel, Duren, Germany) using a developing solvent system of hexane/diethyl ether/acetic acid (80:20:1, by vol). PL band was recovered from the TLC plate, and its fatty acids were converted to the corresponding fatty acid methyl esters (FAME) using 14% boron trifluoride in methanol (Sigma Chemical) under nitrogen gas.

Fatty acid analysis. FAME were analyzed by GLC using a SP-2560 flexible fused silica capillary column (100 m × 0.25 mm i.d., 20 µm film thickness; Supelco, Inc., Bellefonte, PA) in a Hewlett-Packard 5890 Series II gas chromatograph (Palo Alto, CA). The column temperature was programmed from 180 to 220°C at a rate of 1°C/min and then held for 20 min. Injector and detector temperatures were set at 250°C. Hydrogen gas was used as the carrier gas at a column head pressure of 15 psi.

Determination of 18:1 trans, *18:2* trans*, and 20:4* trans *isomers.* The total 18:1 *trans* fatty acids were determined using $AgNO_3$-TLC in conjunction with capillary GLC as described previously (15,22). The geometric and positional isomers of 18:2 *trans* were identified and determined as described by Ratnayake and Pelletier (12). Determination and identification of 20:4 isomers were made as we previously described (19). In brief, the total FAME from the liver PL were saponified and acidified to the free fatty acids and then converted to 2-alkenyl-4,4-dimethyloxazoline (DMOX) derivatives (23). The double-bond positions were confirmed by GLC/mass spectrometry analysis of DMOX derivative. GLC separation of the DMOX derivatives was performed in the same SP-2560 capillary column, and helium was the carrier gas. Mass spectra of the DMOX derivatives were obtained on a VG Analytical MS system (Model 7070 EQ; VG Analytical, Manchester, England) equipped with an 11/250 data system interfaced to a Varian GC (Model Vista 6000; Varian Associates, Palo Alto, CA) operated at an ionization energy of 70 eV. Mass DMOX spectra of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* have been reported in detail elsewhere (19).

[a]Diet A, 15% partially hydrogenated canola oil (PHCO; 0.56% energy 18:2n-6); Diet B, 15% PHCO + 0.25% energy 18:2n-6; Diet C, 15% PHCO + 0.50% energy 18:2n-6; Diet D, 15% PHCO + 1.25% energy 18:2n-6; Diet E, 15% PHCO + 2.00% energy 18:2n-6; and Diet F, 15% canola oil (reference diet).

RESULTS

Fatty acid composition of dietary fats. The fatty acid composition (g/kg diet) of the six diets is summarized in Table 1. Diets A–E had similar fatty acid composition except for 18:2n-6, which was increased from 2.6 to 14.1 g/kg diet. Dietary 18:2n-6 as percentage of total energy was 0.56% in Diet A, 0.81% in Diet B, 1.06% in Diet C, 1.81% in Diet D, and 2.56% in Diet E. The 18:1 *t* isomer in Diets A–E was 33.3 g/kg diet (7.17% energy), whereas 18:1n-9 was 73.1 g/kg diet (15.74% energy). The total 18:2 *c,t* isomers accounted for 8.0 g/kg diet (1.72% energy), with 18:2Δ9*c*,13*t* being a major isomer followed by 18:2Δ9*t*,12*c* and 18:2Δ9*c*,12*t*.

Food consumption, body and organ weights. Maternal rats fed different diets with varying levels of 18:2n-6 supplementation consumed similar amounts of food (18.1–20.8 g dry weight/rat/d). However, maternal rats in Group A fed PHCO diet appeared to gain less body weight than the rest of the

groups although a significant difference was not found statistically (Table 2).

Fatty acid composition of maternal liver and brain PL. The fatty acid composition of maternal liver at day 26 of lactation is shown in Table 3. In contrast to that observed with feeding the canola oil diet (Diet F), the feeding PHCO diet (Diet A) led to the incorporation of 18:1 *trans* and 18:2 *trans* fatty acids in maternal liver PL (Table 3).

[a]Data are mean ± SD/n = 6.
[b]Diet A, 15% PHCO (0.56% energy 18:2n-6); Diet B, 15% PHCO + 0.25% energy 18:2n-6; Diet C, 15% PHCO + 0.50% energy 18:2n-6; Diet D, 15% PHCO + 1.25% energy 18:2n-6; Diet E, 15% PHCO + 2.00% energy 18:2n-6; Diet F, 15% canola oil. Means in the same row with different superscript letters (a–d) differ significantly at $P < 0.05$. See Table 1 for abbreviations.

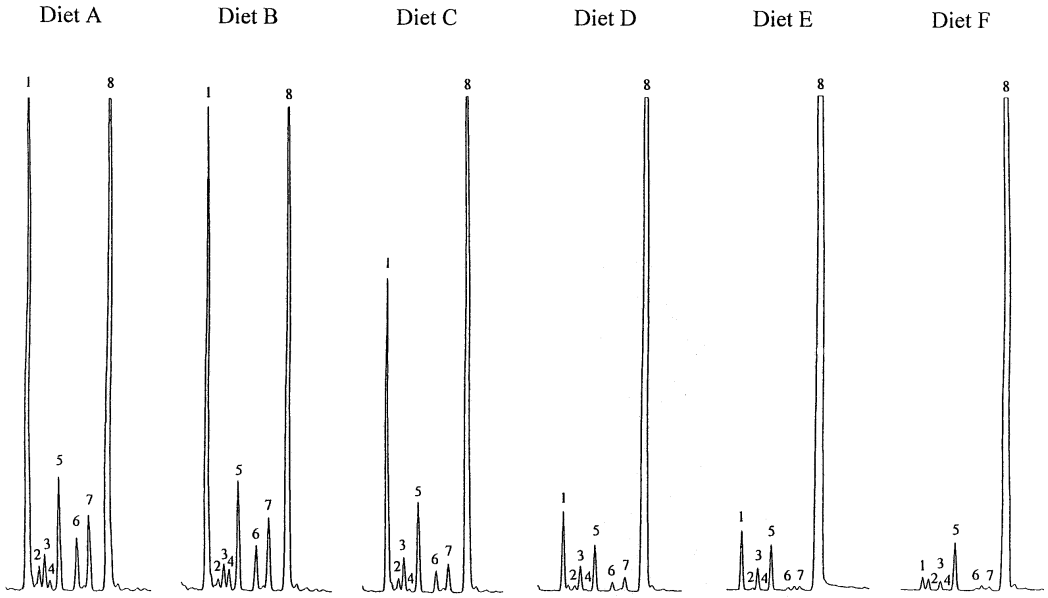

FIG. 1. The C20 region of gas chromatograms of the fatty acid methyl esters from the liver phospholipids of rats fed partially hydrogenated canola oil (PHCO). Peak identification: 1, 20:3n-9; 2, 20:3Δ5*c*,8*c*,14*c*; 3, 20:3Δ5*c*,11*c*,14*c*; 4, unknown; 5, 20:3n-6; 6, 20:4Δ5*c*,8*c*,11*c*,15*t*; 7, 20:4Δ5*c*,8*c*,11*c*,14*t*; 8, 20:4n-6. Diet A, 15% (PHCO; 0.56% energy 18:2n-6); Diet B, 15% PHCO + 0.25% energy 18:2n-6; Diet C, 15% PHCO + 0.50% energy 18:2n-6; Diet D, 15% PHCO + 1.25% energy 18:2n-6; Diet E, 15% PHCO + 2.00% energy 18:2n-6; and Diet F, 15% canola oil.

Among 18:2 unusual isomers, the relative proportions of 18:2Δ(9*c*,13t/8*t*,12*c*), 18:2Δ9*c*,12*t*, 18:2Δ9*t*,12*c*, and 18:2Δ9*t*,12*t* were lower in the maternal liver PL than in the dietary PHCO. On the other hand, the proportion of these 18:2 *trans* isomers incorporated into the liver PL was different from that in the diet, with 18:2Δ9*t*,12*c* being highest followed by 18:2Δ(9*c*,13*t*/8*t*,12*c*). The feeding of PHCO diet (Diet A) also led to the formation of two unusual 20:4 isomers, namely, 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t*, which collectively accounted for 0.85% of total liver PL. These isomers were not observed in Diet F, the reference diet. Supplementation with unesterified 18:2n-6 suppressed the formation of these two unusual 20:4 isomers in the maternal liver PL (Figs. 1 and 2; Table 3). The ratio of 20:3n-9 to 20:4n-6 in the liver PL of Group A maternal rats was 0.28, indicating borderline essential fatty acid (EFA) deficiency (24).

In addition, supplementation of dietary free 18:2n-6 (Diets B–E) did not result in an increase in the content of 18:2n-6 and 20:3n-6 in the maternal liver PL. However, it increased the metabolites of 18:2n-6 with four or more double bonds, including 20:4n-6, 22:4n-6, and 22:5n-6 (Table 3). In contrast, supplementation with dietary 18:2n-6 generally decreased the content of n-3 metabolites, mainly 20:5n-3, 22:5n-3, and 22:6n-3 in the maternal liver PL. Similarly, the content of monounsaturated fatty acids including 18:1n-9, 16:1n-9, and 16:1n-7 was decreased with supplementation of dietary 18:2n-6.

Feeding Diet A (PHCO) did not lead to the formation of the two unusual 20:4 isomers, 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t*, in the brain PL of maternal rats. However, feeding PHCO (Diet A) increased the amount of 20:3n-9 in the brain PL. Supplementation with increasing amounts of dietary 18:2n-6 gradually decreased 20:3n-9 formation while increasing 20:4n-6, 22:4n-6, and 22:5n-6 in the maternal brain PL, but the levels of docosahexaenoic acid (22:6n-3) were unaffected (data not shown).

Fatty acid composition of neonatal liver and brain PL at day 26 of lactation. After feeding Diet A (PHCO) to the maternal rats, a higher incorporation of 18:1 *trans* and 18:2 *trans* fatty acids was observed in the neonatal liver PL at day 26 of lactation than that found in the maternal PL (Tables 3 and 4).

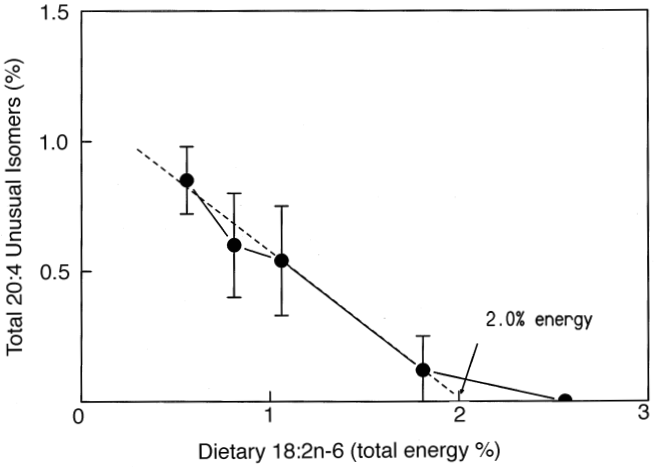

FIG. 2. Effect of dietary 18:2n-6 on biosynthesis of unusual 20:4 isomers (sum of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t*) in the maternal liver. Data are expressed as mean ± SD/*n* = 6. Diet A, 0.56% energy 18:n-6; Diet B, 0.81% energy 18:2n-6; Diet C, 1.06% energy 18:2n-6; Diet D, 1.81% energy 18:2n-6; Diet E, 2.56% energy 18:2n-6.

[a]Data are mean ± SD/*n* = 6.
[b]Diet A, 15% PHCO (0.56% energy 18:2n-6); Diet B, 15% PHCO + 0.25% energy 18:2n-6; Diet C, 15% PHCO + 0.50% energy 18:2n-6; Diet D, 15% PHCO + 1.25% energy 18:2n-6; Diet E, 15% PHCO + 2.00% energy 18:2n-6; Diet F, 15% canola oil. Means in the same row with different superscript letters (a–f) differ significantly at $P < 0.05$. See Table 1 for abbreviation.

Dietary supplementation with unesterified 18:2n-6 in the maternal diet increased most of the longer-chain n-6 metabolites in the neonatal liver PL (20:4n-6, 22:4n-6, and 22:5n-6) except for 20:3n-6, which decreased. In contrast to the maternal liver, supplementation with dietary 18:2n-6 did not decrease the longer-chain n-3 metabolites. Instead, 22:6n-3 was increased in the liver PL of pups from the dams fed Diet E. Similar to that found in the maternal liver PL, supplementation of the maternal diet with 18:2n-6 decreased the incorporation of 18:2Δ(9*c*,13*t*/8*t*,12*c*), 18:2Δ9*c*,12*t*, 18:2Δ9*t*,12*c*, and 18:2Δ9*t*,12*t* in the neonatal liver PL. Among these unusual 18:2 isomers, 18:2Δ9*t*,12*c* exhibited the highest incorporation followed by 18:2Δ(9*c*,13*t*/8*t*,12*c*) and 18:2Δ9*c*,12*t* (Table 4). Compared with the maternal PL, feeding Diet A (PHCO) to the lactating rats produced a greater amount of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* in the neonatal liver PL (Table 4). In addition, supplementation of the maternal diet with 18:2n-6 gradually decreased the biosynthesis of these two 20:4 isomers in the neonatal rats (Fig. 3). The ratio of 20:3n-9 to 20:4n-6 in the liver PL of neonatal rats whose

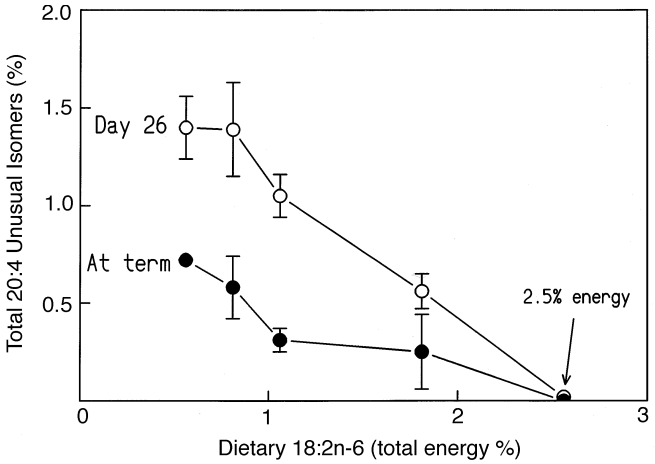

FIG. 3. Effect of dietary 18:2n-6 on biosynthesis of unusual 20:4 isomers (sum of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t*) in the neonatal liver at term and day 26 of lactation. Data are expressed as mean ± SD/*n* = 6. Diet A, 0.56% energy 18:n-6; Diet B, 0.81% energy 18:2n-6; Diet C, 1.06% energy 18:2n-6; Diet D, 1.81% energy 18:2n-6; Diet E, 2.56% energy 18:2n-6.

[a]Data are mean ± SD/n = 6.
[b]Diet A, 15% PHCO (0.56% energy 18:2n-6); Diet B, 15% PHCO + 0.25% energy 18:2n-6; Diet C, 15% PHCO + 0.50% energy 18:2n-6; Diet D, 15% PHCO + 1.25% energy 18:2n-6; Diet E, 15% PHCO + 2.00% energy 18:2n-6; Diet F, 15% canola oil. Means in the same row with different superscript letters (a–f) differ significantly at $P < 0.05$. See Table 1 for abbreviation.

mothers had been fed Diets A and B was 0.82 and 0.73, respectively, suggesting induction of EFA deficiency. Further increases in the proportion of dietary 18:2n-6 in the maternal diet (C–E) gradually decreased the ratio to less than 0.4 (24).

As observed in the maternal rats, 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* were not detected in the brain PL of neonatal rats at day 26 of lactation. Supplementation of dietary 18:2n-6 increased 22:4n-6 and 22:5n-6 without affecting the level of 20:4n-6. In contrast, the inclusion of unesterified 18:2n-6 in the diets decreased both 20:3n-9 and 22:6n-3 in the brain PL of neonatal rats (data not shown).

Fatty acid composition of neonatal liver and brain PL at term. Feeding Diet A (PHCO) to the maternal rats also resulted in an incorporation of 18:1 *trans* and 18:2 *trans* fatty acids in the neonatal liver at term. However, the degree of incorporation of these isomers in the neonatal liver PL at term was less than that at day 26 of lactation but more than that in the maternal liver PL (Table 5). Similarly, the longer-chain n-6 metabolites in the neonatal liver PL at term increased with supplementation of dietary 18:2n-6 in the maternal diet except for 20:3n-6 (Table 5). Compared with that in the maternal liver PL, a similar amount of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* also was found in the neonatal liver PL at term. Supplementation with 18:2n-6 at the level of 2.0% energy in the maternal diet completely blocked the production of these two unusual isomers (Fig. 3; Table 5).

The change caused by supplementation of varying levels of 18:2n-6 in the brain PL of neonatal rat at term was similar to that observed at day 26 of lactation. The ratio of 20:3n-9 to 20:4n-6 in the liver PL of Group A, B, and C neonatal rats at term was more than 0.4, and supplementation of dietary 18:2n-6 in the maternal diet gradually decreased the ratio to the level less than 0.1 (24).

DISCUSSION

Many geometric and positional isomers of 18:2n-6 are formed during partial hydrogenation of vegetable oils (12,13) or during the deodorization of oils (25,26); 18:2Δ9*c*,13*t*, 18:2Δ9*c*,12*t*, and 18:2Δ9*t*,12*c* are the major *trans* isomers of 18:2n-6. A significant amount of these isomers is present in margarine and other dietary fats (12). The present results support the previous observation that some of these 18:2 isomers can be chain-elongated and desaturated to form unusual 20:4 isomers in the rats fed PHCO. This occurred not only in male rats (19) but also in neonatal and pregnant/lactating rats fed PHCO diet. Two unusual 20:4 isomers, 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t,* have been previously identified and are most likely derived from two corresponding precursors, 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t, via* alternating sequence of desaturation, chain elongation, and desaturation (19).

It is known that dietary 18:2n-6 exhibits an inhibitory effect on production of unusual 20:4 isomers in the liver because 18:2 *c,t* isomers and 18:2n-6 compete for the same desaturase and elongase pathways (27). In a study by Holman *et al.* (17), the formation of these unusual 20:4 isomers was extensive and was even more than 20:4n-6 in the liver PL of rats fed partially hydrogenated soybean oil. However, the partially hydrogenated soybean oil used in their study contained very low 18:2n-6 (<0.08% of total fatty acids) and should be regarded as an EFA-deficient diet (28). In another study (19), it was found that 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t* were metabolized to 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t*, respectively, even under sufficient intake of 18:2n-6 (1.46% energy). This led us to determine the minimal amount of dietary 18:2n-6 required to completely suppress chain-elongation and desaturation of 18:2 *c,t* isomers. As shown in Figure 1, it is clear that formation of unusual 20:4 isomers in the rats fed PHCO is inversely associated with dietary supplementation of 18:2n-6. The present results suggest that 18:2n-6 at about 2.0% of total energy is required to block completely the production of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* in the maternal liver PL (Fig. 2), whereas 18:2n-6 intake at about 2.5% of total energy in the maternal diet is minimal to suppress synthesis of these unusual 20:4 isomers in the neonatal rats (Fig. 3).

In parallel with formation of 20:4Δ5*c*,8*c*,11*c*,15*t* and 20:4Δ5*c*,8*c*,11*c*,14*t* in both neonatal and maternal rats of Group A (0.56% energy 18:2n-6) fed PHCO diet, the ratio of 20:3n-9 to 20:4n-9 was relatively higher (maternal rats: 0.28; neonatal rats: 0.82), indicating a marginal EFA deficiency in maternal rats and EFA deficiency in neonatal rats (24). When 18:2n-6 in maternal diet was increased to 1.06% total energy (Diet C), the ratio was correspondingly reduced to 0.10 in maternal rats while in the neonatal rats it was only reduced to 0.35, indicating the level of 18:2n-6 in diet C was not adequate for neonatal rats but it was adequate for maternal rats fed PHCO diet with supplementation of 0.50% energy 18:2n-6. The present data demonstrated clearly not only that 20:4 *trans* isomers were formed but also that the requirement for dietary 18:2n-6 was increased in rats fed PHCO diet, particularly the neonatal rats.

The present study, together with previous work (19), has demonstrated clearly that formation of unusual 20:4 isomers is possible in the rats fed PHCO when dietary 18:2 is well above 0.6% energy recommended by the National Research Council for EFA adequacy (29). However, it still remains unclear whether these unusual 20:4 isomers can be precursors of uncommon eicosanoids and exert physiological effect despite being quantitatively minor (18). However, a *trans* isomer of 22:6n-3 derived from a mono *trans* isomer of linolenic acid (18:3n-3) *via* desaturation and elongation system has been found to incorporate into the retina of rats (30) and consequently alter the electroretinography (31).

The examination of incorporation pattern of all 18:2 *c,t* isomers into the liver PL indicates a preferential accumulation of 18:2Δ9*t*,12*c* to 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t*. This observation was in agreement with many previous studies (27,32,33). In a study using deuterium labeling, 18:2Δ9*t*,12*c* was found to incorporate into the mouse liver several times faster than 18:2Δ9*c*,12*t* (27). However, the mechanism involved remains poorly understood. Perhaps a lower accumulation of 18:2Δ9*c*,13*t* and 18:2Δ9*c*,12*t* than 18:2Δ9*t*,12*c* is due to their faster catabolic rate. In fact, only the former two isomers but not the latter can be desaturated and elongated to form corresponding longer-chain metabolites. This is most likely because the Δ6 desaturase recognizes an 18:2 isomer with the first double bond at Δ9 position with a *cis* configuration better than the other isomers (34).

In conclusion, the present study was the first to determine the minimal amount of dietary 18:2n-6 required for complete suppression of chain-elongation and desaturation of the geometric and positional isomers of 18:2n-6 in the neonatal and lactating rats fed a PHCO diet. The present results indicate that dietary 18:2n-6 intake at the recommended 0.6% energy for EFA adequacy is insufficient to inhibit biosynthesis of unusual 20:4 isomers derived from 18:2 *c,t* isomers. In view of the higher requirement for longer-chain polyunsaturated fatty acids during fetal/neonatal development, the overconsumption of partially hydrogenated vegetable oils containing a significant amount of 18:2 *c,t* isomers should be questioned although the physiological effect of these unusual 20:4 isomers remains undetermined at the present time.

Conjugated Linoleic Acids Alter Bone Fatty Acid Composition and Reduce *ex vivo* Prostaglandin E_2 Biosynthesis in Rats Fed n-6 or n-3 Fatty Acids

Yong Li and Bruce A. Watkins*

Department of Food Science, Lipid Chemistry and Metabolism Laboratory, Purdue University, West Lafayette, Indiana 47907

ABSTRACT: This study evaluated the effects of conjugated linoleic acids (CLA) on tissue fatty acid composition and *ex vivo* prostaglandin E_2 (PGE_2) production in rats given diets varying in n-6 and n-3 fatty acids. Four groups of rats were given a basal semipurified diet (AIN-93G) containing 70 g/kg of added fat for 42 d. The fat treatments were formulated to contain CLA (0 vs. 10 g/kg of diet) and n-6 (soybean oil having an n-6/n-3 ratio of 7.3) and n-3 fatty acids (menhaden oil + safflower oil having an n-6/n-3 ratio of 1.8) in different ratios in a 2×2 factorial design. Fatty acids in liver, serum, muscle, heart, brain, spleen, and bone (cortical, marrow, and periosteum) were analyzed by capillary gas–liquid chromatography. The various dietary lipid treatments did not affect growth; however, CLA improved feed efficiency. The CLA isomers were found in all rat tissues analyzed although their concentrations varied. Dietary CLA decreased the concentrations of 16:1n-7, 18:1, total monounsaturates and n-6 fatty acids, but increased the concentrations of n-3 fatty acids (22:5n-3 and 22:6n-3), and saturates in the tissues analyzed. *Ex vivo* PGE_2 production in bone organ culture was decreased by n-3 fatty acids and CLA. We speculate that CLA reduced the concentration of 18:1 fatty acids by inhibiting liver Δ9-desaturase activity. The fact that CLA lowered *ex vivo* PGE_2 production in bone organ culture suggests that these conjugated fatty acids have the potential to influence bone formation and resorption.

Lipids 33, 417–425 (1998).

Conjugated linoleic acids (CLA) are positional and geometric isomers of linoleic acid that occur naturally in several foods but are highest in dairy products and beef (1). The CLA isomers have been suggested to possess potent beneficial health and biological effects (2–6). CLA isolated from extracts of grilled ground beef were found to exhibit anticarcinogenic activity against chemically induced skin cancer in mice (7). Recent experiments on prostate cancer cell lines demonstrated that CLA isomers are incorporated into cell lipids and that CLA compared to linoleic acid decreased cell proliferation (8). Further, CLA were reported to reduce prostaglandin E_2 (PGE_2) concentration in rat serum and spleen (9).

CLA isomers become enriched in tissue and cell lipids when administered in a diet or supplemented in a cell culture medium (8–10). As CLA incorporates into membrane phospholipids, it may compete in elongation and desaturation steps with other unsaturated fatty acids that are precursors of arachidonic acid (the precursor of PGE_2), and such competition in arachidonate synthesis may alter eicosanoid biosynthesis (11,12). The *cis*-9, *trans*-11 isomer of CLA was preferentially incorporated into the membrane phospholipids of mice (13) and rats (14), suggesting that *cis*-9, *trans*-11 is the biologically active isomer. Therefore, CLA may exert physiological effects by altering the formation of phospholipid-derived hormones, e.g., eicosanoids, or by modifying the signal transduction system (15).

This laboratory recently reported that milk fat stimulated bone formation rate in growing chicks possibly by modulating *ex vivo* PGE_2 production in bone (16). Having a concentration up to 30 mg CLA/g fat (17), milk fat is a primary dietary source of CLA. With regard to bone metabolism, PGE_2 is recognized as a mediator of bone formation and bone resorption *in vivo* (18). Although CLA recently has been shown to affect PGE_2 production (9) and to modulate cytokine production (19), the purpose of the present investigation was twofold: first, to quantify the effects of CLA on the fatty acid composition of tissue lipids in the presence of relatively high dietary n-6 or n-3 fatty acids; second, to document that CLA could alter PGE_2 production in mammalian bone in the presence of dietary lipids varying in an n-6/n-3 fatty acid ratio.

MATERIALS AND METHODS

Animals and diets. Forty male weanling rats (21-d-old, mean body weight 46 ± 2.0 g; Harlan Sprague-Dawley, Indianapolis, IN) were housed in individual cages under a 12-h light-dark cycle. Animal care was in compliance with applicable guidelines from the Purdue University (West Lafayette, IN) policy on animal care and use. The rats were randomly assigned to four groups and fed *ad libitum* the basal diet (AIN-93G without fat; Dyets, Inc., Bethlehem, PA) with one of the following fat treatments at 70 g/kg (Table 1): soybean oil (SBO, diet rich in n-6 fatty acids); soybean oil + CLA

[a]The semipurified basal diet contained the following (g/kg): casein, 200; corn starch, 397.486; DYETROSE, 132; sucrose, 100; cellulose, 50; L-lysine, 3; choline bitartrate, 2.5; salt mix, 35; vitamin mix, 10.
[b]Salt mix provided (mg/kg diet): $CaCO_3$, 12495; K_2HPO_4, 6860; $C_6H_5O_7K_3 \cdot H_2O$, 2477; NaCl, 2590; K_2SO_4, 1631; MgO, 840; $C_6H_5O_7Fe$, U.S.P., 212.1; $ZnCO_3$, 57.75; $MnCO_3$, 22.05; $CuCO_3$, 10.5; KIO_3, 0.35; Na_2SeO_4, 0.359; $(NH_4)_2MoO_4 \cdot H_2O$, 0.278; $Na_2O_3Si \cdot 9H_2O$, 50.75; $CrK(SO_4)_2 \cdot 12H_2O$, 9.625; LiCl, 0.609; H_3BO_3, 2.853; NaF, 2.223; $NiCO_3$, 1.113; NH_4VO_3, 0.231.
[c]Vitamin mix provided (mg/kg diet): thiamine HCl, 6; riboflavin, 6; pyridoxine HCl, 7; niacin, 30; calcium pantothenate, 16; folic acid, 2; biotin, 0.2; cyanocobalamin (B-12) (0.1%), 25; vitamin A palmitate (500,000 IU/g), 4000; vitamin E acetate (500 IU/g), 75; vitamin D_3, 1000; vitamin K_1, 0.75.
[d]Dietary treatments included soybean oil (SBO), or menhaden oil + safflower oil (MSO) and with (+) or without (–) conjugated linoleic acids [CLA; 41.9% 18:2(*c*-9,*t*-11/*t*-9,*c*-11), 44.3% 18:2(*t*-10,*c*-12), 13.6% 18:2(*t*-9,*t*-11/*t*-10,*t*-12), and <1% 18:2(*c*-9,*c*-11/*c*-10,*c*-12)]. Total fat content in each diet was 70 g/kg of diet and CLA was added (10 g/kg of diet) at the expense of SBO or MSO.
[e]n.d., not detected (peak detection at 10 ng).
[f]SAT, total saturated fatty acids.
[g]MONO, total monounsaturated fatty acids.

(SBOC); menhaden oil + safflower oil mixture (MSO, menhaden/safflower = 56:44 weight basis, diet rich in n-3 fatty acids); MSO + CLA (MSOC). The CLA was added at 10 g/kg at the expense of the SBO or MSO. All dietary lipids were stored at –80°C before use. Four 49-d-old rats were used in a preliminary study to evaluate the acute enrichment of tissues with CLA. Two rats were fed SBO and the other two SBOC, and the rats on the SBOC diet also were administered CLA intragastrically twice (0.5 g CLA mixed with 0.5 g SBO, at day six and eight) before being killed after 9 d of feeding. Fresh diets were mixed every 14 d, and all the diets were kept at –20°C until fed. Food cups were refilled three times weekly and feed consumption measured at the same time. Body weights were recorded weekly and feed efficiency (total gram weight gain/total gram feed consumed) calculated for each treatment group.

Sample collections. After 42 d of feeding (9 d of feeding for the four rats in the preliminary study), the rats were killed and tissue samples (liver, heart, thigh muscle, spleen, femur, blood, and brain) collected for lipid analysis. Blood was collected by bleeding from axillary vessels. All samples were kept on ice at the time of collection and then frozen at –20°C. Serum was separated by centrifuging the clotted (room temperature) blood at $1200 \times g$ for 20 min (Beckman GS-6; Palo Alto, CA) and stored at –20°C until analyzed.

Analysis of fatty acids. Lipids in the diet and tissue samples were extracted with chloroform/methanol (2:1, vol/vol). Fatty acid methyl esters (FAME) were prepared from dietary lipids by transesterification using boron trifluoride (BF_3) in methanol (14%, w/w; Supelco Inc., Bellefonte, PA). Cortical bone, freed of periosteum and marrow, was cooled with liquid nitrogen and pulverized to a fine powder with a mortar and pestle, placed in 7 mL methanol, and sonicated for 10 min to extract lipids (16). Lipids extracted from rat tissue samples were methylated (sodium methoxide) as follows: sample was dissolved in dry toluene (1 mL) in a test tube with a Teflon-lined screw cap, 0.5 M sodium methoxide in anhydrous methanol (2 mL) added, the solution maintained at 50°C for 10 min, and glacial acetic acid (0.1 mL) added followed by deionized water (5 mL). The FAME were extracted into hexane (2×3 mL), dried over anhydrous sodium sulfate, and filtered. For comparison, lipids from several replicate samples were methylated using BF_3-methanol. All FAME were analyzed using a gas chromatograph (HP 5890 series II, autosampler 7673, HP 3365 ChemStation; Hewlett-Packard Co., Avondale, PA) equipped with a DB 225 or DB 23 column (30 m, 0.53 mm i.d., 0.5 μm film thickness; J&W Scientific Co., Folsom, CA) and operated at 140°C for 2 min, temperature programmed 1.5°C/min to 198°C and held for 7 min. The injector and flame-ionization detector temperatures were 225 and 250°C, respectively. FAME were identified by comparison of their retention times with authentic standards [GLC-422, CLA (UC-59-A and UC-59-M); Nu-Chek-Prep, Elysian, MN; CLA (Cat# 1245, *c*-9,*t*-11 and Cat# 1181, *t*-9,*t*-11); Matreya Inc., Pleasant Gap, PA] and FAME prepared from menhaden oil (Matreya Inc.).

Ex vivo *PGE_2 production.* PGE_2 production by bone organ cultures was performed as previously described (16,20). Shafts from the right tibia and femur bones were removed and carefully flushed with 0.9% NaCl to remove marrow cells. A section of bone shaft was immersed in 20 mL of Hank's balanced salt solution (Sigma Chemical Co., St. Louis, MO) and incubated with shaking for 2 h at 37°C. After incubation, the bone culture medium was collected and stored at –80°C until analyzed for PGE_2 by radioimmunoassay. Values for PGE_2 were expressed per unit of bone wet or dry weight.

Statistical analysis. Data were statistically analyzed by a one-way or two-way analysis of variance, and where significant differences were found, a Tukey's range test was performed at a probability of $P < 0.05$ (SAS software package for UNIX; SAS Institute Inc., Cary, NC). Variation between treatment groups was expressed as the pooled standard error of the mean (SEM).

RESULTS

Body weights between the four treatment groups were not significantly different throughout the feeding period. Final mean body weights at 42 d ranged from 305–313 g (average weight gain in grams: 260 ± 8 SBO, 264 ± 4 SBOC, 267 ± 9 MSO, 263 ± 5 MSOC). Feed efficiency (total grams weight gain/total grams feed consumed), however, was significantly improved ($P < 0.01$) in rats fed CLA compared with those not given CLA (0.42 vs. 0.39). Dietary levels of n-6 and n-3 fatty acids did not influence mean body weights nor feed efficiencies.

Upon analysis of FAME by gas chromatography, the sodium methoxide method gave superior results for CLA isomer distribution compared with those obtained by the BF_3 method. The latter tended to overestimate the concentrations of 18:2(*c,c*) and 18:2(*t,t*) but underestimate those for 18:2(*c*-9,*t*-11/*t*-9,*c*-11) and 18:2(*t*-10,*c*-12). Therefore, all rat tissue fatty acid values reported herein were obtained by the sodium methoxide method.

The short-term feeding and gavage of rats with CLA enriched cortical bone (femur and tibia) with 18:2(*c*-9,*t*-11/*t*-9,*c*-11) and 18:2(*t*-10,*c*-12). The CLA content reached 2.57% of the total fatty acids in 9 d of treatment (data not shown). The enrichment of CLA in bone was accompanied by an increase in n-3 fatty acids, primarily 18:3n-3, and a decrease in 16:0.

After 42 d of feeding, CLA isomers were detected in femur (cortical bone, marrow, and periosteum), brain, heart, liver, muscle, serum, and spleen in rats given CLA (Table 2). The concentration of CLA isomers varied across the rat tissues analyzed with bone containing the greatest amounts. For bone, CLA were highest in bone periosteum (5.46% of total fatty acids), while only trace amounts were detected in brain. The 18:2(*c*-9,*t*-11/*t*-9,*c*-11) and 18:2(*t*-10,*c*-12) isomers were incorporated into all tissues of rats given CLA independent of the n-6 and n-3 fatty acid content of the diet. In contrast, the 18:2(*t*-9,*t*-11) isomer was only observed in bone marrow and periosteum. Liver, serum, bone, marrow, and periosteum had more 18:2(*c*-9,*t*-11/*t*-9,*c*-11) than 18:2(*t*-10,*c*-12), while spleen, muscle, and heart had more 18:2(*t*-10,*c*-12).

Significant differences in tissue fatty acid composition were observed between the dietary treatment groups. For example, rats given CLA had lower concentrations of 16:1n-7, 18:1, 18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6, and total monounsaturates in liver regardless of the level of n-6 and n-3 fatty acids in the diet (Table 3). Total liver n-6 fatty acid concentration was lower in the MSOC group compared to that in the MSO group, but it was not different between the SBO and SBOC groups. The concentrations of 22:5n-3, 22:6n-3, and total saturates were increased by CLA in liver of rats independent of the n-6 and n-3 fatty acid treatments. However, CLA increased the concentration of 18:0 in liver of rats given the n-6 but not n-3 fatty acid diet. CLA had a similar effect on serum and spleen fatty acid composition (data not shown) compared with liver except that the concentrations of 18:2n-6, 18:3n-6, 20:2n-6, and 18:0 were not affected.

When given CLA, the fatty acid composition of rat skeletal muscle (Table 4) and heart (data not shown) showed similar changes, that is, decreased 16:1n-7, 18:1, and total monounsaturates. Both tissues had increased 22:5n-3, but heart contained reduced concentrations of 18:0 and 22:6n-3. The biceps femoris of rats given diets rich in n-3 fatty acids (MSO and MSOC) had increased 20:5n-3 and 22:6n-3, but lower 20:4n-6 and total n-6 fatty acid concentrations.

Rat brain fatty acid composition was least affected by 42 d of CLA feeding. CLA decreased 16:1n-7 and 20:2n-6, but increased 22:5n-3, 22:5n-6 in rats given the n-6 fatty acid treatment (data not shown). The total n-3 fatty acid concentration was greatest in brain of rats on the MSO and MSOC treatments. Total monounsaturates, saturates, and polyunsaturated fatty acids (PUFA) were not affected by either CLA or n-6

TABLE 2

[a]Mean values for liver fatty acid composition ($n = 6$) within a row having different superscripts (m,n for PUFA effect; x, y for CLA effect; A, B, C for interaction effect) are significantly different by two-way ANOVA and Tukey's studentized range test ($P < 0.05$). The factorial design of dietary treatments allowed for an $n = 12$ in the statistical analysis of main effects.
[b]Dietary treatments included SBO, or MSO and with (+) or without (–) CLA. Total fat content in each diet was 70 g/kg of diet, and CLA was added (10 g/kg of diet) at the expense of SBO or MSO.
[c]NS, not significant. See Table 1 for other abbreviations.

and n-3 fatty acids. Generally, rats fed high n-3 fatty acids (MSO and MSOC) had more 16:1n-7, 20:3n-6, 20:5n-3, 22:5n-3, and 22:6n-3. In contrast, rats fed high n-6 fatty acids (SBO and SBOC) had higher 20:2n-6, 20:4n-6, and 22:4n-6. The 18:2n-6 concentration in brain was not affected by the fatty acid treatments.

Consumption of CLA lowered the concentrations of 20:3n-6, 22:6n-3, and total n-6 in cortical bone (Table 5). The rats given n-3 fatty acids (MSO and MSOC) had higher concentrations of 16:0, 20:5n-3, 22:5n-3, 22:6n-3, total n-3, and saturates but lower 18:1, 18:3n-3, 22:4n-6, total n-6, and monounsaturates compared to those given n-6 fatty acids (SBO and SBOC). In bone marrow of rats supplemented with CLA, the concentrations of 12:0, 14:0, 16:0, and total saturates were higher while those for 16:1n-7, 18:1, 18:2n-6, 20:2n-6, 20:3n-6, 22:5n-6, total monounsaturates, PUFA, and n-6, were lower (Table 6). The n-3 fatty acid diets (MSO and MSOC) resulted in higher 12:0, 14:0, 15:0, 16:0, 16:1n-7, 17:0, 20:3n-6, 20:5n-3, 22:5n-3, 22:6n-3, total saturates, and n-3, but lower 18:1, 18:2n-6, 20:2n-6, 20:4n-6, 22:4n-6, total monounsaturates, PUFA, and n-6 concentrations in marrow. A CLA–PUFA interaction influenced the 18:3n-6, 18:3n-3, 20:1n-9, and 22:6n-3 concentrations in bone marrow. The periosteum of rats given CLA had higher 12:0, 14:0, 16:0, and total saturates but lower 18:1, 18:2n-6, total monounsaturates, PUFA, and n-6 (Table 7). Rats given n-3 fatty acids compared with those on the n-6 fatty acid diets (SBO and SBOC) had higher 14:0, 15:0, 16:0, 16:1n-7, 20:1n-9, 20:3n-6, 20:5n-3, 22:5n-3, 22:6n-3, total saturates, and n-3 although lower 12:0, 18:1, 18:2n-6, 18:3n-3, 20:2n-6, 20:4n-6, 22:4n-6, 22:5n-6, total monounsaturates, PUFA, and n-6 concentrations in periosteum.

In rats, CLA and n-3 fatty acids both reduced *ex vivo* PGE_2 production (Table 8). The *ex vivo* PGE_2 production by bone organ cultures from rats given n-3 fatty acids (MSO and MSOC) was lower than the values from those given n-6 fatty acids (SBO and SBOC). Interestingly, CLA consumption by rats further reduced *ex vivo* PGE_2 production in bone (femur and tibia) independent of n-6 and n-3 fatty acid intake.

DISCUSSION

The results from the feeding experiment showed that neither CLA nor n-6 and n-3 fatty acids (SBO high in n-6 and MSO high in n-3 fatty acids) influenced final body weight or weight gain of the rats. However, feed efficiency was significantly

[a]Mean values for muscle fatty acid composition ($n = 6$) within a row having different superscripts (m,n for PUFA effect; x, y for CLA effect; A, B, C for interaction effect) are significantly different by two-way ANOVA and Tukey's studentized range test ($P < 0.05$). The factorial design of dietary treatments allowed for an $n = 12$ in the statistical analysis of main effects.
[b]Dietary treatments included SBO, or MSO and with (+) or without (–) CLA. Total fat content in each diet was 70 g/kg of diet, and CLA was added (10 g/kg of diet) at the expense of SBO or MSO. See Tables 1 and 3 for other abbreviations.

improved for rats given CLA independent of the dietary n-6 and n-3 fatty acid treatments. Our results corroborate those of Chin *et al.* (21) who observed that CLA given to rats improved feed efficiency. Sugano *et al.* (9) also found that CLA feeding to rats did not influence growth, but an experiment in mice revealed that CLA reduced body weights without influencing feed disappearance (22). Unfortunately, the authors of study in mice did not measure feed wastage (22) which could have explained the discrepancy in food disappearance and the 50% depression in growth.

CLA was reported to reduce the catabolic response from immune stimulation in animals without adversely affecting immune function (23,24). Cytokines and PGE_2 (21) are believed to mediate this catabolic response, and recently, CLA was found to lower *in vivo* and *ex vivo* production of cytokines in rats (9,19). The present investigation with rats is consistent with other findings that dietary CLA did not affect body weight but decreased feed consumption to improve feed efficiency. Further research is needed to characterize the biochemical and physiological actions of CLA on energy metabolism.

The pattern of CLA enrichment in rats showed certain tissue selectivity for the various isomers. For example, liver, serum, bone, marrow, and periosteum contained more 18:2(*c*-9, *t*-11/*t*-9,*c*-11) than 18:2(*t*-10,*c*-12), the two predominant isomers. Spleen, muscle, and heart, however, contained more 18:2(*t*-10,*c*-12) than the 9,11 isomer. Furthermore, only trace amounts of 18:2(*c*-9,*t*-11/*t*-9,*c*-11) and 18:2(*t*-10,*c*-12) were detected in brain. To our knowledge this is the first report demonstrating that CLA are found in bone tissue. Surprisingly, concentrations of CLA in bone tissues (cortical, marrow, and periosteum) were the highest of all tissues analyzed. Moreover, the various isomers of CLA incorporated into bone tissue lipids equally well for diets high in n-6 or n-3 fatty acids.

The fatty acid composition of rat tissues was significantly modified by the dietary lipids. The effects of dietary n-6 and n-3 enrichment (SBO and MSO, respectively) on fatty acid composition of bone in rats were similar to the results in chicks we have reported previously (20). Linoleate (18:2n-6) and its chain elongation and desaturation products (20:4n-6, 22:4n-6, and 22:5n-6) were higher in liver, spleen, serum, muscle, heart, bone (marrow and periosteum), and brain in rats given SBO. CLA consumption decreased the concentrations of 16:1n-7, 18:1, total monounsaturates, and n-6, but increased those for 22:5n-3, 22:6n-3, total n-3, and saturates in most tissues analyzed. CLA decreased the concentration of 18:2n-6 in bone marrow and periosteum, 18:3n-6, 20:2n-6, 20:3n-6, 22:5n-6 in marrow, and 20:3n-6 in cortical bone. Further, CLA decreased the ratio of n-6/n-3 in liver, brain,

[a]Mean values for femur cortical bone fatty acid composition ($n = 5$) within a row having different superscripts (m, n for PUFA effect; x, y for CLA effect; A, B, C for interaction effect) are significantly different by two-way ANOVA and Tukey's studentized range test ($P < 0.05$). The factorial design of dietary treatments allowed for an $n = 10$ in the statistical analysis of main effects.
[b]Dietary treatments included SBO, or MSO and with (+) or without (–) CLA. Total fat content in each diet was 70 g/kg of diet, and CLA was added (10 g/kg of diet) at the expense of SBO or MSO. See Table 1 for other abbreviations.

spleen, and serum of rats given MSO. The relative sparing of n-3 fatty acids in rats given CLA might be explained as either an increase in the utilization of n-6 or a conservation of n-3 fatty acids. The increase of total saturates in liver, marrow, periosteum, spleen, muscle, and serum of rats consuming CLA could indicate a depression of desaturase activity. Since liver is a major organ for fatty acid synthesis in mammals, and we observed a decrease of 18:1n-9 in rat tissues (liver, marrow, and periosteum), one would speculate that CLA affects the saturates/monounsaturates ratio by inhibiting liver Δ9-desaturase activity as proposed by Lee *et al.* (10).

The n-3 fatty acid treatment (MSO) significantly reduced *ex vivo* PGE_2 production in bone organ culture (tibia and femur) compared to the n-6 dietary treatment (SBO). In bone, dietary CLA lowered *ex vivo* PGE_2 production beyond that of n-3 fatty acid feeding. Sugano *et al.* (9) also reported that the concentration of PGE_2 in spleen tended to be reduced by CLA. Dietary supplementation with CLA may impact bone modeling in the young since PGE_2 mediates bone formation and bone resorption (18). Recent work from our laboratory demonstrated that modulation of *ex vivo* PGE_2 production in bone with dietary lipids was associated with changes in bone formation rate (16,20). PGE_2 is a potent agent regulating both bone modeling and remodeling, but its effect in bone may be concentration-dependent. For example, Raisz and Koolemans-Beynen (25) showed that PGE_2 inhibits matrix formation at high concentrations in bone organ culture. However, at lower doses, PGE_2 can stimulate bone formation *in vitro* and *in vivo* (26–29). Therefore, excessive production of PGE_2 may adversely affect bone modeling, and a lower level of PGE_2 is believed to stimulate bone formation in animals fed diets containing moderate levels of n-6 fatty acids. Chicks fed a diet containing a lower n-6/n-3 fatty acid ratio demonstrated reduced PGE_2 production in bone that was accompanied by an increased bone formation rate when compared with those given a higher n-6/n-3 ratio (20). Although different mechanisms may be operative for CLA and n-3 fatty acids to reduce *ex vivo* PGE_2 production, the fact that both fatty acids lowered PGE_2 by cultured bone may be significant in understanding their potential effects on bone health.

In summary, supplementing the diets of rats with CLA led to differences in CLA enrichment in various tissues, with

[a]Mean values for femur bone marrow fatty acid composition ($n = 6$) within a row having different superscripts (m, n for PUFA effect; x, y for CLA effect; A, B, C for interaction effect) are significantly different by two-way ANOVA and Tukey's studentized range test ($P < 0.05$). The factorial design of dietary treatments allowed for an $n = 12$ in the statistical analysis of main effects.
[b]Dietary treatments included SBO, or MSO and with (+) or without (–) CLA. Total fat content in each diet was 70 g/kg of diet, and CLA was added (10 g/kg of diet) at the expense of SBO or MSO. See Tables 1 and 3 for other abbreviations.

brain having the lowest concentrations of isomers but bone tissue containing the highest. Furthermore, CLA influenced the fatty acid composition of rat tissues leading to reduced 18:1 in liver, muscle, heart, and bone (marrow and periosteum). The data on tissue fatty acid composition presented here suggest that CLA may affect the formation of 18:1n-9 and metabolism of n-6 and n-3 fatty acids. Consistent with the hypothesis that CLA modifies arachidonate-derived eicosanoid production, we observed that CLA depressed *ex vivo* PGE_2 production in bone organ cultures. The reduction in PGE_2 by CLA might be explained as a competitive inhibition of n-6 fatty acid formation (30) that would lower substrate availability for cyclooxygenase. Since PGE_2 is a potent agent that stimulates both bone formation and resorption, research on CLA will be relevant to understanding the potential role of essential fatty acids in bone biology.

ABSTRACT: The influence of various dietary marine oils and olive oil on fatty acid composition of serum and platelets and effects on platelets and serum lipids were investigated as part of an extensive study of the effects of these oils on parameters associated with cardiovascular/thrombotic diseases. Healthy volunteers (266) consumed 15 mL/d of cod liver oil (CLO); whale blubber oil (refined or unrefined); mixtures of seal blubber oil and CLO; or olive oil/CLO for 12 wk. In the CLO, seal oil/CLO, and whale oil groups, serum levels of eicosapentaenoic acid (EPA) were increased. In platelets, EPA was increased in the CLO, seal/CLO, and olive oil/CLO groups. The localization of n-3 polyunsaturated fatty acids in the triacylglycerols did not seem to influence their absorption. Intake of oleic acid is poorly reflected in serum and platelets. No significant differences in triacylglycerols (TG), total cholesterol, or high density lipoprotein cholesterol were observed, even though TG were reduced in the CLO, CLO/seal oil, and whale oil groups. Mean platelet volume increased significantly in both whale oil groups and the CLO/olive oil group. Platelet count was significantly reduced in the refined whale oil group only. Lipopolysaccharide-stimulated blood tended to generate less thromboxane B_2 in CLO, CLO/seal, and CLO/olive groups. The whale oils tended to reduce *in vivo* release of β-thromboglobulin. In conclusion, intake of various marine oils causes changes in platelet membranes that are favorably antithrombotic. The combination of CLO and olive oil may produce better effects than these oils given separately. The changes in platelet function are directly associated with alterations of fatty acid composition in platelet membranes.

Lipids 33, 427–436 (1998).

In the 1970s, Bang, Dyerberg, and coworkers (1–3) suggested that the low incidence of death attributable to coronary heart disease among Greenland Eskimos was due to their high intake of n-3 polyunsaturated fatty acids (PUFA) derived from fish and other seafoods. These studies created the basis for the great increase in the interest in cardiovascular benefits of fish oils, and the effects of the consumption of fish and fish oils have been examined in various important biological systems.

Dietary supplementation with fish and fish oils is reported to modify platelet and leukocyte function in several ways. Suggested modes of action are through their modulation of eicosanoid synthesis (4–6) and reduction in plasma triacylglycerol (TG) concentration (for review see Ref. 7). n-3 Fatty acids as a dietary supplement decrease platelet aggregation and release thromboxane A_2 (TxA_2). Another mechanism for the effect of n-3 PUFA has been suggested to be associated with the change in fluidity by incorporation of PUFA in the cell membranes and an influence on the activities of membrane-associated enzymes or receptors (8). Because of variable results, additional human clinical studies are still needed.

Attention has been directed on n-3 PUFA, although it was evident from Bang and Dyerberg's studies that the traditional Eskimo diet consists of substantial quantities of meat and blubber from seals and whales (1). The fat composition of seal, and of whale in particular, differs significantly from that of fish (9). In marine mammals eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) are found mainly in the *sn*-1 and *sn*-3 positions of the TG, whereas in fish these fatty acids are positioned in *sn*-2 (10,11). However, the diet of Greenland Eskimos also differs from the Western diet in other respects, especially in the intake of saturated fatty acids (2). The favorable disease pattern in Eskimos may be caused by the combination of a diet low in saturated fat together with high n-3 PUFA intake, but the beneficial effects of this diet also may be due to components other than the fatty acids. A previous study in our laboratory indicated that oils from the blubber of seal and whale have beneficial effects on some selected parameters thought to play a role in cardiovascular disease, and it was hypothesized that the effect of whale oil is not mediated by n-3 fatty acids alone (12).

Abbreviations: AA, arachidonic acid; CLO, cod liver oil; CV, coefficient of variation; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FAME, fatty acid methyl ester; HDL, high density lipoprotein; LPS, lipopolysaccharide; MPV, mean platelet volume; PGA_1, $-A_2$, $-D_2$, $-E_2$, $-F_{1\alpha}$, $-F_{2\alpha}$, prostaglandin A_1, $-A_2$, $-D_2$, $-E_2$, $-F_{1\alpha}$, $-F_{2\alpha}$; PUFA, polyunsaturated fatty acid; r_s, steady-state fluorescence anisotropy; TG, triacylglycerol; β-TG, β-thromboglobulin; TMA-DPH, 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene, *p*-toluenesulfonate; TxA_2, $-B_2$, thromboxane A_2, B_2.

The so-called Mediterranean diet is characterized, among other things, by a moderately low intake of PUFA and by a high intake of monounsaturated fatty acids from olive oil. Since Mediterranean populations have shown a low mortality from cardiovascular diseases, which is negatively correlated to the percentage of dietary energy supplied by monounsaturated fatty acids (13,14) in addition to findings of favorable effects of n-3 fatty acid supplementation to a diet rich in olive oil (15), it was of major interest to include olive oil in this dietary study.

With the traditional diets of Mediterranean populations and Greenland Eskimos in mind, we have focused on the effects of marine oils and olive oil on important parameters concerning the physical and functional properties of blood platelets. Platelets play an essential role in arterial thrombosis and atherosclerosis, but the mechanisms for the effects of dietary oils on platelet function are not well understood. In this controlled study we investigated whether any of the dietary oils contributed to changes in structural order (membrane fluidity) of the platelets and related membrane fluidity to platelet function by measuring eicosanoid production thromboxane [(TXB_2 and prostaglandin E_2) (PGE_2)] and release of the α-granule protein β-thromboglobulin (β-TG) from platelets. In addition, we have related these results to plasma lipids and to the corresponding fatty acid composition in serum and platelets and compared the changes in fatty acid patterns of serum and platelet membranes to the composition of the dietary oils. The results are also discussed in relation to the intramolecular TG structures of the oils.

MATERIALS AND METHODS

Subjects and dietary protocol. Healthy volunteers (266) living in Tromsø, Norway (124 women and 149 men), aged 16–69 yr (median 36), were randomly selected to consume 15 mL/d of cod (*Gadus morhua*) liver oil (CLO), olive (*Olea europea*) oil (extra virgin), refined (steam refined by heating to 170°C with N_2) and unrefined oil from the blubber of minke whale (*Balaenoptera acutorostrata*), mixtures of CLO and harp seal (*Phoca groenlandica*) blubber oil (1:1, vol/vol) and CLO and olive oil (1:1, vol/vol), and no oil (control group). Table 1 shows the number of subjects in each group and some characteristics of the groups regarding distribution of gender, age, and smoking habits. The oils were a supplement to their normal dietary habits, and the subjects were counseled to continue eating their regular diet. The study was double-blinded for the groups given various dietary oils. No placebo oil was given in the control group, and the study of this group could thus not be blinded to volunteers or investigators. The seven groups were run in parallel for a period of 12 wk. The procedures followed were in accordance with the Helsinki declaration of 1964 as revised in 1989.

The fatty acid composition of the dietary oils, determined by gas–liquid chromatography as described shortly, is given in Table 2. There were no changes detected during storage over the period of 12 wk. The vitamin E concentrations of the oils were analyzed according to Lie *et al.* (16) and were as follows: CLO: 1.52 mg/g; olive oil: 0.23 mg/g; refined whale oil: 0.17 mg/g; whale oil: 0.25 mg/g; seal oil/CLO: 1.38 mg/g; and olive oil/CLO: 0.85 mg/g.

Blood sampling. Blood samples were taken before the start of the study, after 8 wk, and after 12 wk of supplementation. The data after 12 wk of supplementation are presented in this work. The participants were informed not to drink alcohol or perform any strenuous exercise for 48 h prior to each blood sampling. They fasted overnight, and all the blood samples were taken between 8:00 and 10.00 A.M. Venous blood (25 mL) was drawn into a plastic syringe with a 19-gauge needle and immediately distributed into serum tubes or tubes containing anticoagulants as specified for each procedure described.

Mean platelet volume (MPV) and platelet counts. MPV and platelet counts were measured in whole blood anticoagulated with Na_2-EDTA (final concentration 0.2%) with a Coulter Counter (STRK, Luton, England).

Platelet preparation. Platelet-rich plasma was obtained by centrifugation of citrated blood (5 mL, final concentration of Na_3-citrate: 0.38%) at $180 \times g$ for 15 min at room temperature with the brake off. For fatty acid analysis, the platelets were washed once in 0.15 mol/L NaCl, centrifuged at $1500 \times g$ for 10 min and resuspended in 0.15 mol/L NaCl. The platelet preparations were kept at −70°C until extraction of the fatty acids was performed for the gas chromatographic analysis. For membrane fluidity studies, the platelet pellets were washed twice with 0.15 mol/L NaCl, centrifuged at $1500 \times g$ for 10 min and resuspended in potassium phosphate buffer (0.01 mol/L, pH 7.4). The platelet suspensions were

[a]MUFA = monounsaturated fatty acids; PUFA = polyunsaturated fatty acids. For other abbreviation, see Table 1.

frozen at −70°C until anisotropy measurements were performed (17). Before labeling with the fluorescent probe, the suspensions were sonicated in an MSE sonicator (Sussex, United Kingdom) (high power, setting 4, 10 s × 2 with 10-s interval, on ice). The platelet preparations were adjusted to a final optical density of 0.03 at 600 nm to minimize the effect of light scattering on the anisotropy measurements (18). Platelet counts were performed both in whole blood and in platelet-rich plasma.

Fatty acid analysis. The fatty acids were extracted from serum and platelet membrane preparations using chloroform/methanol (1:1 vol/vol; Merck, Darmstadt, Germany) by a modified method of Folch and coworkers (19), esterified with 2 mL boron trifluoride in methanol (Supelco, Bellefonte, PA) at 100°C for 90 min (20). Fatty acid methyl esters (FAME) were analyzed by capillary gas–liquid chromatography using a Fisons Carlo Erba 8340 gas chromatograph (Carlo Erba, Rodano, Italy). FAME were separated on a 50-m × 0.25-mm CP-Sil 88 (FAME) capillary column with 0.2 μm film thickness (Chrompack, Middelburg, Holland) after splitless injection of a 1-μL sample at a column temperature of 80°C. The operating conditions were as follows: The initial temperature was maintained for 1 min and then raised by 20°C/min to 160°C, followed by a gradient of 2°C/min to 177°C and 20°C/min to 230°C, and it was kept there for 15 min. The injector and the flame-ionization detector temperatures were 250 and 270°C, respectively. The carrier gas was hydrogen, with an inlet pressure of 110 kPa. The fatty acid composition is expressed as percentage FAME with respect to the total peak surface (area/area).

Analysis of the stereochemistry of TG in the marine oils. The positional distribution of EPA (20:5n-3) and DHA (22:6 n-3) in CLO, seal blubber, and whale blubber oils was analyzed by high-resolution ^{13}C nuclear magnetic resonance spectroscopy as previously described (21).

Measurements of platelet membrane fluidity. The membrane fluidity was assessed by measurements of steady-state fluorescence anisotropy (r_S) of 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene, *p*-toluenesulfonate (TMA-DPH; Molecular Probes. Inc., Eugene, OR) (22–24). A stock solution of TMA-DPH in *N*,*N*-dimethylformamide (Uvasol®; spectroscopy grade, Merck) was prepared at a con-

centration of 10 mmol/L, stored at –20°C and diluted before use. The diluted platelet preparation (2 mL) was incubated for 10 min at 37°C in the dark with TMA-DPH at a final concentration of 1.0 μmol/L. The r_s measurements were carried out with a Perkin-Elmer LS 50 Luminescence Spectrometer (Buckinghamshire, United Kingdom) equipped with polarizers. The measurements were made at excitation and emission wavelengths of 360 and 430 nm, respectively, with slit widths of 5 nm in both excitation and emission. The r_S-value for each sample is an average of five readings (integration time, 10 s), measured at a constant temperature of 37.0 ± 0.1°C, controlled with a digital thermometer. The r_S is automatically calculated from the following equation:

$$r_S = \frac{IV_V - GIv_H}{IV_V + 2GIV_H} \text{ with a correcting factor } G = \frac{IH_V}{IH_H} \quad [1]$$

where r_S is the corrected anisotropy, and IV_V and IH_V are the emission intensities of vertically polarized light parallel and perpendicular to the plane of excitation, respectively. Likewise, IV_H and IH_H are the emission intensities of horizontally polarized light perpendicular and parallel to the plane of excitation. Fluorescence anisotropy values are inversely related to the rotational rate of the probe in the membrane, thus low anisotropy values indicate high fluidity of the membrane.

Lipids in serum. Serum samples were analyzed for TG, cholesterol, and high density lipoprotein (HDL) cholesterol using commercially available enzyme kits from Boehringer (Mannheim, Germany) in combination with an RA-1000 automatic analyzer (Technion RA-100; Bayer Norway, Hagan, Norway).

Quantitation of β-TG. β-TG was measured in heparinized plasma with a β-TG radioimmunoassay kit according to the manufacturer's instructions (Kodak Clinical Diagnostics Ltd., Amersham, United Kingdom). At 45 ng/mL the within-assay coefficient of variation (CV) was 7.5%, and the between-assay CV was 9.9–15.3% in the range 19.6–108 ng/mL.

Stimulation of whole blood in vitro. Lipopolysaccharide (LPS; *Escherichia coli* 026:B6; Difco, Detroit, MI) was added to heparinized blood (1.0 mL) to a final concentration of 5 ng/mL, followed by incubation at 37°C in an incubator shaker (180 rpm) for 2 h. The stimulation was stopped by adding 0.1 mL 2% Na_2-EDTA/mL blood, and the blood was immediately centrifuged at 1400 × *g* for 10 min. The plasma was pipetted off and frozen at −70°C until quantitation of TxB_2 and PGE_2 was performed.

Quantitation of TxB_2. TxB_2, the stable metabolite of TxA_2, was measured in plasma of LPS-stimulated blood with a TxB_2 enzyme immunoassay system (Biotrak, Amersham, United Kingdom), as described by the manufacturer. The cross reactivities to related compounds were: 2,3-dinor-TxB_2: 60.50%; 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$: <0.40%; 6,15-diketo-13,14-dihydro-$PGF_{1\alpha}$; <0.01%; 11-dehydro-TxB_2, 0.10%; 6-keto-PGE_2, <0.01%; PGD_2, 0.18%; PGE_2, <0.01%; $PGF_{1\alpha}$, 1.6%; $PGF_{2\alpha}$, 0.06%; and arachidonic acid (AA), <0.01%. The sensitivity of this assay was 3.6 pg/mL, and the within and between assay CV were 2.5–9.2% (range 21.4–254 pg/mL) and 9.9–13.9% (range 46.2–222 pg/mL), respectively.

Quantitation of PGE_2. PGE_2 was measured in plasma of LPS-stimulated blood in a PGE_2 [^{125}I] RIA (radioimmunoassay) Kit (Du Pont, NEN Research Products, Boston, MA). The following compounds have been tested for cross reactivity: PGE_1, 30%; 13,14-dihydro-15-keto-PGE_2, 0.02%; PGA_2, 0.8%; $PGF_{1\alpha}$, 0.7%; TxB_2, 0.01%; $PGF_{2\alpha}$, 0.9%; AA, 0.01%; 13,14-dihydro-15-keto-$PG_{2\alpha}$, 0.005%; PGA_1; 0.08%; PGB_2, 0.07%; 6-keto-$PGF_{1\alpha}$, 1%; linoleic acid, 0.002%; and PGD_2, 0.3%. The sensitivity of the system was 4.4 pg/mL.

Measurements of antioxidant capacity. Antioxidant capacity was measured in citrated plasma by enhanced chemiluminescent assay as described elsewhere (25). The enhanced chemiluminescent immunoassay signal reagent and horseradish peroxidase conjugate were obtained from Amersham International (Amersham, United Kingdom). The signal reagent consisted of assay buffer and tablets A and B containing luminol, enhancer, and oxidant. The tocopherol analog standard, Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid), was obtained from Aldrich (Gillingham, United Kingdom). Chemiluminescence was measured in a Biocounter (Schaesberg, The Netherlands) (Lumac/3M, M2010, Switzerland).

Statistical analysis. The data are presented as mean ± standard error of mean (SEM). Differences between gender groups in baseline values of various parameters were determined by Student's unpaired *t*- or Mann-Whitney *U*-test. For each parameter tested, the differences between the values before and after intake of dietary oils were calculated within the groups. One-way analysis of variance followed by Dunnett's *t*-test was used for simultaneous, multiple comparisons of the test groups with the control group. When data are presented as percentages, statistical analysis was performed on absolute values, unless otherwise stated. Correlations were calculated by means of the Spearman's rank correlation coefficient (*r*). *P*-values <0.05 were considered as statistically significant. All analyses were performed on an Apple Macintosh using StatView™ SE+ Graphics version 1.04 statistical software (Abacus Concepts Inc., Berkeley, CA).

RESULTS

Baseline characteristics. Statistical analysis (one-way analysis of variance and Dunnett's *t*-test) of baseline characteristics in the different groups of oils showed that TG in the whale oil group were significantly higher than the values observed in the control group ($P < 0.05$). For the other clinical and biochemical variables, there were no significant differences between the groups of oils.

Comparisons of differences in clinical and biochemical characteristics between the gender groups showed that men had higher mean values for age (37.9 and 34.3 yr for men and women, respectively), TG (1.5 ± 0.1 and 1.1 ± 0.1 mmol/L), and cholesterol (6.3 ± 0.1 and 5.7 ± 0.1 mmol/L). Women had

significantly higher HDL cholesterol (1.6 ± 0.03 and 1.2 ± 0.03 mmol/L) and TxB_2 values (12.5 ± 0.6 and 10.5 ± 0.5 ng/mL) than men.

Fatty acid composition in serum. The composition of total fatty acids in serum before and after 12 wk of supplementation with different dietary oils is given in Table 3. After 12 wk of daily intake, CLO and the mixture of CLO and seal oil both produced highly significant rises ($P < 0.01$) in serum EPA (20:5n-3), by 188 and 115%, respectively, and DHA (22:6n-3), by 56 and 50%. The same groups experienced a significant reduction (50–60%) of dihomo-γ-linolenic acid (20:3n-6) compared with the control group. The changes in EPA (110% increase, $P < 0.01$) and dihomo-γ-linolenic acid (43% decrease, $P < 0.05$) levels were also seen in the whale oil group. In addition, we observed an increase in the serum concentration of oleic acid (18:1n-9) in the group given olive oil (from 18.8 to 20.8%), but this change was not statistically significant.

There was a dose–response relationship between the relative contents of n-3 fatty acids in the various dietary oils and the change in total n-3 fatty acids in serum.

Fatty acid composition in platelets. When comparing the baseline fatty acid composition of serum (Table 3) and platelets (Table 4), we found that the relative composition of fatty acids did not differ much for all except three fatty acids: There were striking differences between stearic acid (18:0), linoleic acid (18:2n-6), and AA (20:4n-6) in serum and platelets. The relative contents of these fatty acids were as follows: 7.5 and 20.4% (18:0), 31.6 and 6.1% (18:2n-6), and 4.9 and 18.1% (20:4n-6) for serum and platelets, respectively. The strongest positive correlation between fatty acids in serum and platelets was found for 20:5n-3 ($r = 0.84$, $P < 0.0001$).

Table 4 shows that in all three groups given CLO (CLO alone or in mixtures with seal oil or olive oil) the concentration of EPA in platelet membrane preparations was significantly raised (by 118, 92, and 64%, respectively). In addition, in the CLO group, there were increases in 22:5n-3 and 22:6n-3 and a reduction in the relative content of AA (20:4n-6) by 21%.

Intramolecular fatty acid distributions in the marine oils. Distribution of the main n-3 PUFA in the TG molecule in the oils of marine origin was dependent on their source. Nuclear magnetic resonance data showed that 81% of EPA and 93.7% of DHA were localized in *sn*-1/3 positions of the TG in minke whale oil. Corresponding values for harp seal oil were 97.7 and 98.1%, and for CLO 58.2 and 22.3% for EPA and DHA, respectively.

Serum lipids. Neither the TG, total cholesterol, nor the HDL-cholesterol concentrations in any of the groups were significantly altered after 12 wk of supplementation with dietary oils, even though the TG were reduced by 10–12% in the CLO, CLO/seal, and whale oil groups (data not shown). Although men and women differed in baseline values of the serum lipids, no difference was observed between the two groups concerning effects of the oils when tested separately. Still, there was a strong trend to reduction of TG in the CLO and seal/CLO groups in women.

Platelet membrane fluidity. The r_S of the platelet membrane preparations labeled with TMA-DPH was unchanged after intake of marine oils and olive oil (data not shown).

MPV and platelet counts. MPV increased in both whale oil groups as well as in the CLO/olive oil group after 12 wk of dietary supplementation (Fig. 1), with the most pronounced effect in the refined whale oil group with a rise from 8.7 to 9.4 μm^3 (8%, $P < 0.01$). Baseline values of MPV correlated negatively with platelet counts ($r = -0.41$, $P < 0.0001$). The platelet count was significantly reduced only in the refined whale oil group (7%, $P < 0.01$).

Platelet products. TxA_2 is generated mainly from platelets in LPS-stimulated blood, and the measurement of its stable metabolite TxB_2 showed no significant changes after intake of dietary oils, both when the results were analyzed for the two genders together and separately. However, there was a tendency to reduction in all groups given CLO: TxB_2 was reduced by 39, 34, and 28% in the CLO, seal/CLO, and olive/CLO groups, respectively.

There were significant changes in the concentration of PGE_2 ($P < 0.01$) in all the groups given CLO [CLO only (28%) or CLO in mixture with seal oil (22%) or olive oil (32%)] when compared with the control group. However, the rise in PGE_2 was most pronounced in the control group (81%), so that the significant changes in PGE_2 in those three groups mean less rise in the concentrations of PGE_2 when compared with the control group.

The release of β-TG from platelets was not affected by any of the dietary oils (data not shown), even though the whale oils tended to reduce the concentrations of β-TG from 7.59 ± 0.41 to 6.43 ± 0.43 ng/mL (15%) in the unrefined whale oil group and from 7.63 ± 0.49 to 5.84 ± 0.34 ng/mL (23%) in the group receiving refined whale oil.

Antioxidant capacity. Analyses of antioxidant capacity in citrated plasma were preliminary studies and only performed on a limited number of samples in some of the test groups. There were no significant changes in the antioxidant capacity following supplementation with CLO, whale oil, or olive oil. In the control group ($n = 15$), the antioxidant capacities were 564 ± 34 (before) and 550 ± 35 μmol/L (after 12 wk). The baseline values were significantly ($P < 0.0001$) higher in men (628 ± 24 μmol/L, $n = 30$) than in women (464 ± l5 μmol/L, $n = 30$), as revealed by Student's unpaired *t*-test.

DISCUSSION

The main interest in the present work was to investigate the effects on physical and functional properties of platelets and possibly find any associations between the parameters measured and the fatty acid composition in serum and platelets. Changes in the distribution of total serum fatty acids partly reflected the fatty acid composition of the ingested dietary oils as seen in Tables 3 and 4. Serum ordinarily contains low levels of EPA (20:5n-3) and DHA (22:6n-3), but after admin-

[a]Mean values ± SEM. The differences between values before and after dietary supplementation were tested by one-factor analysis of variance and Dunnett's *t*-test for multiple comparisons of the test groups with the control group. [b]$P < 0.05$ [c]$P < 0.01$.

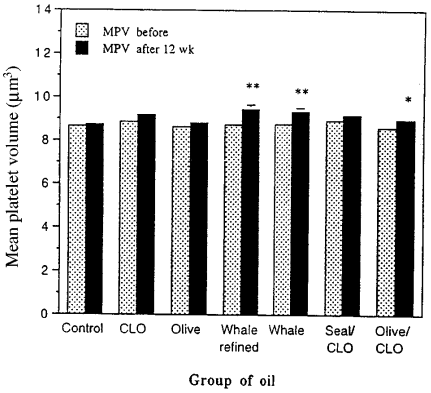

FIG. 1. Mean platelet volume (MPV) before and after 12 wk of supplementation with dietary oils. Values are means ± SEM. MPV was measured with a Coulter Counter in whole blood anticoagulated with Na_2-EDTA. MPV was significantly raised in both whale oil groups (**$P < 0.01$) and the group given a mixture of olive oil and cod liver oil (CLO) (*$P < 0.05$), tested by one-way analysis of variance and Dunnett's *t*-test for comparisons of the test groups with the control group.

istration of oils rich in these fatty acids, the levels were increased by more than 100%. Previous results showed an even stronger effect of similar oils on the levels of EPA and DHA, and in addition, whale oil induced a significant increase in these fatty acids (12). Compared to the high concentrations of n-3 PUFA in CLO and seal oil, the high content of monounsaturated fatty acids in the whale oils did not seem to influence the distribution of fatty acids in serum to the same extent. This may be due to the relatively high concentration of oleic acid (18:1n-9) already present in our regular diet.

It has been suggested that the stereochemistry of TG molecules may influence the digestion and absorption of fatty acids (26). The n-3 PUFA are located mainly in the outer positions *sn*-1 and *sn*-3 of the TG in seal and whale oil, whereas in TG from CLO the *sn*-2 position is enriched in n-3 PUFA. The present long-term study does not indicate differences in absorption of n-3 PUFA from oil of marine mammals or fish oil. Christensen *et al.* (27) demonstrated that the digestibility and lymphatic absorption in rats of n-3 PUFA from native marine oils were not significantly influenced by the localization of the n-3 PUFA within the TG. These findings, however, do not exclude possible differences in digestibility and absorption rates of n-3 PUFA from different sources. In a study in humans it was suggested that finwhale oil (with EPA mainly in positions *sn*-1/3) may provide a moderately more available source of dietary EPA than herring oil (EPA mainly in *sn*-2), as there was observed a higher average accumulation of EPA in platelet phospholipids after whale oil consumption (28). However, retroconversion from DHA (higher level in the whale oil) to EPA may have contributed to these effects (28). In addition, the short duration (10 d) of the study and the low number of subjects ($n = 3$) must be taken into account. The changes in DHA levels in serum and platelets following intake of DHA-containing oils were considerably lower than corresponding values for EPA, supporting differences in digestion and incorporation of these fatty acids, as shown by others (29).

The highly significant, positive correlation between EPA in serum and platelets indicates that the relative content of EPA in platelets is strongly dependent on the availability and the fact that EPA appears to be easily incorporated into phospholipids. Even though the serum concentration of AA (20:4n-6) was not altered significantly after intake of CLO, the increase in n-3 PUFA in platelets seemed to occur at the expense of AA. However, the fatty acid composition of phospholipids in platelets reflects the fatty acid composition of total fatty acids in serum only to some extent.

One objective of this work was to study whether the various dietary oils have any effect on platelet membrane fluidity. The oils had no observed influence on the physical properties of the platelet membrane, and thus membrane fluidity was not associated with alterations in platelet membrane fatty acid composition. This is supported by other studies on human platelets (30, 31), whereas rat platelets have shown increased membrane fluidity under the influence of a marine oil diet (32). Possibly, the modifications of the fatty acid pattern in our study were not extensive enough to alter the membrane fluidity, but this could also be due to mechanisms which are able to buffer changes in fatty acid composition and maintain the physical properties in the hydrocarbon region measured by the fluorescent probe. These findings may also be a consequence of the low sensitivity of the TMA-DPH fluorescence anisotropy technique.

In human intervention studies, the most consistent effect of n-3 PUFA on the plasma lipid profile is that they lower the level of TG in both normolipidemic and hyperlipidemic subjects (7), apparently by reducing hepatic TG synthesis and secretion of very low density lipoprotein TG (33–35). Even though our results did not show significant reductions in any of the groups, the oils with the highest relative contents of n-3 PUFA had the most pronounced reducing effects on the TG concentrations.

The overall results from several fish oil studies (7) showed that normolipidemic subjects responded to n-3 fatty acids with essentially no change in total or low density lipoprotein cholesterol and a slight rise in HDL cholesterol, which is consistent with the findings of our study. Women have a more favorable lipid pattern than men, including higher HDL cholesterol levels (36), but despite gender differences in baseline values in the present study there were no sex-related differences in serum lipids in response to the dietary oils. Lipid data from numerous fish oil studies reviewed by Harris (7) show a mean value of total cholesterol in control groups at about 4.8 mmol/L (range of means 3.4–6.2 mmol/L), and one might ask if the high level of total cholesterol (6 mmol/L) found in our

study reflects high cardiovascular risk in the population of northern Norway (37). More likely, the high cholesterol concentrations reveal the tendency of people with known moderately high cholesterol levels and a familial history of coronary heart disease to volunteer in such studies.

TxB_2 is the main oxygenated end product of the cyclooxygenase pathway in platelets and can be regarded as a parameter of platelet functionality. A nonlinear relationship has been demonstrated between the reduction of Tx production and reduction of platelet aggregation (38). It has been shown that more than 90% inhibition of Tx is necessary to obtain some inhibition of platelet aggregation (38). For practical reasons no aggregation measurements were done in the present study, but the reduced (not significantly) TxB_2 production (30–40%) observed in the CLO groups may indicate no severe impairment of the platelet aggregation caused by TxB_2. Previous studies have shown 30–65% reductions (17,39) in TxB_2 production in response to dietary marine oils, but in the study of Østerud *et al.* (17) only whale oil reduced the TxB_2 significantly. In several other *in vivo* and *in vitro* assays, dietary n-3 PUFA reduced eicosanoid synthesis significantly (40). We have used weak LPS stimulation of whole blood as a model for the reactivity of blood platelets, and we believe that this *ex vivo* system may reflect the weak stimuli for aggregation found in most *in vivo* conditions more than does measurement of maximally stimulated TxB_2 formed in serum. Thus the Tx production probably reflects the platelets' ability to be activated in this model system.

PGE_2, the other cyclooxygenase product measured, was clearly increased in all groups, including the control group during the period of 12 wk. Plasma was analyzed in bulk after each blood sampling, within 1 wk after the start of the dietary supplementation and within 3 wk after the end of the study. This difference in storage time may be the cause of the change observed. Nevertheless, when the results are adjusted for changes in the control group, the pattern is similar to the changes seen in TxB_2, with significant reductions in all CLO groups. As for TxB_2, although not significant, this may be connected to the observed reduction of 20:4n-6 in platelets in the CLO group.

For both TxB_2 and PGE_2, the measured values of the 2-series of these eicosanids may be overestimated owing to cross reactivity in the assay with the corresponding 3-series compounds. This could also possibly explain the failure to see any differences in TxB_2 and PGE_2 after intake of dietary oils.

Platelet factor 4 and β-TG are both released from the α-granules of platelets upon activation and correlate closely with the platelet aggregation score (41). In our study the β-TG concentration in plasma from LPS-stimulated whole blood was reduced in both whale oil groups (15–23%), but the changes were not statistically significant.

A reduction in platelet number associated with increased platelet volume has been observed in subjects given about 10 g of n-3 fatty acids as salmon oil per day (42). In our study the whale oils had the most pronounced effect on these platelet parameters. Large platelets are reported to be more reactive than small platelets (43) and are believed to be an independent risk factor for myocardial infarction (44). However, the reduced platelet number and slightly increased platelet size induced by fish oil supplements have been associated with reduced responsiveness to some aggregating agonists (45). It has repeatedly been observed in one individual that intake of marine oils over several months is associated with an increase in MPV and a decrease in platelet count. This is followed by a transient increase in platelet count and decrease in MPV after end of marine oil intake (Østerud, B., unpublished data); and interestingly, 4–6 wk after end of marine oil intake, there is a rise in MPV and a decrease in platelet count which resembles the platelets before intake of marine oils. Since the platelets from this person in their normal condition are large (MPV 11.0–11.5) and highly reactive, we believe that it is unlikely that the rise in MPV induced by marine oils is related to higher reactivity of platelets but may rather reflect alteration of the platelet membrane by unknown mechanisms.

Preliminary measurements do not indicate any differences between the oil groups regarding effect on the antioxidant capacity in plasma measured by enhanced chemiluminescent assay. Thus, the low levels of antioxidants present in the various oils did not seem to influence the antioxidant capacity. The supplement of PUFA may lead to enhanced oxidation of the fatty acids in plasma and possibly reduce the antioxidants buffering these reactions. However, this needs to be further investigated before any conclusions can be drawn.

In summary, EPA and DHA, both from marine fish and mammals, induced increases in the serum concentrations of the corresponding fatty acids as well as their relative contents in platelets. The absorption and incorporation of EPA were dependent on its availability. The present study indicates that none of the dietary oils induced changes in the plasma lipids, although oils containing CLO tended to induce reductions in the TG concentration. CLO, seal/CLO and olive/CLO also produced significant reductions in PGE_2 and a strong tendency toward reduction of TxB_2 generation in plasma of LPS-stimulated whole blood. β-TG, however, was not affected by any of the oils. In spite of alterations in fatty acid composition in the platelets in some of the groups, we observed no changes in platelet membrane fluidity. MPV was significantly increased and platelet counts reduced by dietary supplementation with refined and unrefined whale oils. Olive oil alone as a dietary supplement did not have significant effects on any of the parameters measured in this study. The doses of the dietary oils in this study (corresponding to 1.5 g EPA and 2.1 g DHA per day in the CLO group) were rather low compared both to other studies and to the complete diet of Greenland Inuits and Mediterranean populations. Based on the *in vivo* parameters measured (β-thromboglobulin, MPV, and platelet count), the whale oils and to some degree the combination of olive oil and CLO may have the best anticoagulant effect. These oils are also found to have antiinflammatory effects (Østerud, B., unpublished data).

The intake of fatty acids through the ordinary diet is not

adjusted for in this study. Possible relationships between the complete diet of the subjects and the parameters measured in the present study may give further explanation to some of the observations, and investigations are in progress in our group.

COMMUNICATION

Contribution of Meat Fat to Dietary Arachidonic Acid

Duo Li, Alice Ng, Neil J. Mann, and Andrew J. Sinclair*

Department of Food Science, RMIT University, Melbourne 3001, Australia

ABSTRACT: Arachidonic acid (AA) in the diet can be efficiently absorbed and incorporated into tissue membranes, resulting in an increased production of thromboxane A_2 by platelets and increased *ex vivo* platelet aggregability. Results from previous studies have shown that AA is concentrated in the membrane phospholipids of lean meats. However, the concentration of AA in the visible fat portion of meats also may be significant despite being ignored in most studies. The aim of this study was to accurately quantitate the AA content of visible fat and the lean portion of beef, lamb, pork, chicken, duck, and turkey. The visible fat of meat contained a significant quantity of AA, ranging from 20 to 180 mg/100 g fat, whereas the AA content of the lean portion of meat was lower, ranging from 30 to 99 mg/100 g lean meat. Beef and lamb meats contained lower levels of AA in both the visible fat and lean portion than that from the other species. The highest level of AA in lean meat was in duck (99 mg/100 g), whereas pork fat had the highest concentration for the visible fats (180 mg/100 g). The lean portions of beef and lamb contained the higher levels of n-3 polyunsaturated fatty acids (PUFA) compared with white meats which were high in AA and low in n-3 PUFA. The present data indicate that the visible meat fat can make a contribution to dietary intake of AA, particularly for consumers with high intakes of fat from pork or poultry meat.

Lipids 33, 437–440 (1998).

The major cause of premature death in Western society is occlusive vascular disease, and the high dietary fat intake of modern societies has been implicated as one of the major dietary causes. In particular, saturated fats raise blood cholesterol levels, whereas polyunsaturated fatty acids (PUFA) lower blood cholesterol (1–3). Although, the PUFA are seen to be beneficial in this respect, there is concern that the Western diet may have an excessively high ratio of n-6/n-3 PUFA (4). This dietary imbalance is believed to cause an imbalance in the ratio of n-6/n-3 PUFA in the tissue membranes. Arachidonic acid (AA) is an essential n-6 PUFA which can be derived either from linoleic acid (18:2n-6) or directly from the diet, and it is the precursor of a multitude of vasoactive eicosanoids. It has been proposed that elevated tissue AA leads to increased production of thromboxane and leukotrienes, associated with thrombotic disease, arthritis, asthma, and psoriasis (5). Ferretti *et al.* (6) confirmed that 1.5 g/d of AA fed to 10 healthy male volunteers for 50 d led to a significant increase in metabolites of thromboxane A_2 and prostacyclin; however, these changes were not associated with increased platelet aggregation (7). Consumption of either red or white meat leads to increased levels of AA in plasma lipids (8).

We have previously calculated the AA content of the Australian diet based on the premise that all the AA in meat was found in the lean portion of the meat rather than the fat (9). In the past, most analytical studies have ignored the concentration of AA in visible fat of meat, perhaps because the level was too small to be significant when compared with the higher proportion of AA found in the lean portion of meat. The aim of this study was to examine the concentration of AA in both the visible fat and lean portion of meats commonly consumed in Australia. To achieve this, we have determined AA and other fatty acid concentrations in both visible fat and lean portions of beef, lamb, pork, chicken, duck, and turkey.

MATERIALS AND METHODS

Samples. All samples were purchased fresh from the local market and kept at −20°C for 4 d. The retail cut of meats included lamb chop, pork chop, T-bone steak, and turkey, chicken and duck drumsticks. Each type of meat was obtained from three different shops. The lean portion used was obtained from the flesh where all visible fat was trimmed off. Likewise, all the lean portion was trimmed from the fat portion, in order to avoid cross contamination. The fat of the poultry samples was obtained from underneath the skin whereas the fat from the beef and lamb was solid white visible fat. Before lipid extraction, all samples were chopped manually into fine pieces to increase the surface area of the samples exposed to solvent during lipid extraction.

Lipid analysis. The analytical procedures followed were those used previously to determine the lipid and fatty acid content of lean meat (10,11), with the following exceptions: 5-g samples of lean meat were analyzed here compared with 10-g previously, and tricosanoic acid (23:0) was used as an internal standard here compared with heptadecanoic acid previously (10). The chopped samples, approximately 1 g of visible fat and 5 g of lean portion of the meat from the six different species, were extracted with chloroform/methanol (2:1, vol/vol) containing 10 mg/L of butylated hydroxytoluene.

Abbreviations: AA, arachidonic acid; PUFA, polyunsaturated fatty acids.

After storage of the samples overnight at 4°C, each sample was filtered, rinsed with an additional volume of extracting solvent, and partitioned against 0.2 vol of 0.9% NaCl solution until the lower phase was clear. This was evaporated under vacuum and the lipids transferred to a volumetric flask. The total lipid content was determined gravimetrically on an aliquot of this extract (10). The methyl esters of fatty acids of the total lipid extract were prepared by saponification of an exact amount of lipid (about 10 mg lipid for lean portion and 16 mg lipid for the fat portion lipid) together with 0.25 mg for the lean sample and 0.1 mg for the fat sample of tricosanoic acid (23:0) using KOH (0.68 mol/L in methanol) followed by transesterification with BF_3 in methanol (10). The 23:0 internal standard was used in preference to 17:0 because it is not present in meat samples, whereas 17:0 is a component of meat fat, particularly from ruminants (12). The AA content was determined by comparison of peak areas with that of the 23:0 internal standard. The fatty acid methyl esters were separated by capillary gas–liquid chromatography using a 50 m × 0.32 mm (i.d.) fused silica column bonded phase column (BPX70; SGE, Melbourne, Australia) with helium as carrier gas at a flow rate of 43 cm/s. The column oven was maintained at 125°C for 3 min and increased at a rate of 8°C/min to 220°C, and this temperature was maintained for the duration of the run. Fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters, and the results were calculated using response factors derived from chromatographing standards of known composition (Nu-Chek-Prep, Elysian, MN).

Statistics. Results are shown as mean ± SD. The differences in AA content between the lean and fat portion were tested by *t*-test, with $P < 0.05$ being considered significant.

RESULTS AND DISCUSSION

The percentage of total lipids in the visible fat portion of the meat cuts ranged from 54 to 84 g/100 g, with turkey containing the least and beef containing the most lipid among the six species. The lipid content of lean meats ranged from 1 g/100 g in turkey to 4.2 g/100 g in lamb meat (Tables 1 and 2).

Visible fat of ruminants had a lower n-6 proportion (<3%) compared with nonruminants (>11%). The lean portion of ruminant meats was lower in total PUFA (<17%) and in the proportion of n-6 PUFA (<11%) than the other meats. Lean portions from duck and turkey were particularly high in PUFA (>34%) and the n-6 fraction (>30%). In both the lean tissue and visible fat of all meats, there was a higher proportion of n-6 than n-3 PUFA. However, beef and lamb had a notably higher n-3 level in the lean tissue than the poultry and pork and a much lower n-6/n-3 ratio in lean and fat tissue than did the subcutaneous fat of poultry and pork (<2 compared with >9). These differences in n-3 PUFA levels in red and white meat are reflected in the serum phospholipid fatty acid of subjects consuming red and white meats (8). No long-chain n-3 PUFA were detected in the visible fat samples (<0.01% total fatty acids) and only trace amounts of long-chain n-6 PUFA. AA was present at levels from 0.03 to 0.3% in the fat tissue from the samples. Lean beef contained the highest proportion of n-3 PUFA (6.4%) followed by 3.7% in lean lamb and 1.4 to 3.0% in the white meats (Tables 1 and 2).

The principal fatty acid of interest in this study is the n-6 PUFA, AA. Figure 1 shows the concentration of AA in both visible fat and lean portions of the meats, which ranged from 21 to 180 mg/100 g for the visible fats and from 27 to 99 mg/100 g for the lean meats. This showed that AA was sig-

[d]mg/100 g.

nificantly ($P < 0.05$) more concentrated in visible fat than in lipids of the lean portion of the meats for pork, chicken and duck, although as a percentage the AA was only a minor constituent in the visible fat (<0.3%) compared with 1.2–9.0% in the lean meat (Tables 1 and 2). The total AA concentrations in both the fat and lean portions of lamb and beef were lower than in the pork and poultry samples. The richest fat source of AA was the pork fat (180 ± 8 mg/100 g). The AA concentration of lean duck varied from 62 to 137 mg/100 g (mean ± SD; 99 ± 38), and there was also generally more variation in the fatty acid composition of lean duck meat than for the other lean meats. While we don't have an explanation for this result, it is possible that there are differences in fatty acid composition between muscle types in ducks (that is, the site on each drumstick) or that the duck samples analyzed were from animals fed diets with different proportions of n-6 PUFA. The AA concentrations from lean meat obtained in this study were in agreement with the values reported by Mann *et al.* (9).

In the present study, we found that AA concentration in the visible fat of meat cuts was greater than in the lean portion in four of six species examined. The likely reason that AA was not reported in visible fats of meat previously is because the proportion of AA (percentage of total fatty acid) is very low in visible fat of meat (0.03 to 0.3% of total fatty acids) and therefore difficult to accurately measure even using capillary gas–liquid chromatography. In a separate study, we found that more than 80% of the AA was in the triacylglycerols from similar meat fats (D. Li and A. Sinclair *et al.*, unpublished data).

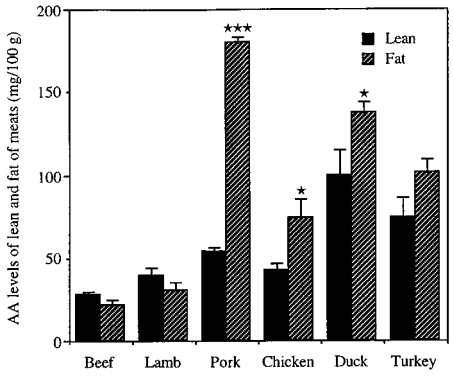

FIG. 1. Arachidonic acid (AA) levels of lean and visible fat of common Australian meats (mg/100 g). Results are shown as the mean ± SD; *$P < 0.05$, ***$P < 0.001$ (*t*-test).

Previous data from our group reported that the dietary AA intake of Australians was between 100–200 mg/d (9). This estimate was based on the AA values from raw meat and calculated assuming that AA was only found in lean meat. The present data, which indicate that visible fat contains AA, could alter the dietary intake data depending on which meat a consumer favored. In the case of beef and lamb consumers, there would be little difference between dietary AA intakes with and without fat-trimming of the meat since the AA levels are about the same in the fat and the lean. On the other hand, the dietary AA intake would be expected to be higher than previously reported for consumers who primarily ate pork, chicken, duck, and turkey. For example, a person who consumed 100 g beef which included 10% visible fat would have an AA intake of 28 mg compared with an intake of 29 mg from 100 g lean beef (without visible fat), while a person who consumed 100 g pork with 10% visible fat would have an AA intake of 67 mg compared with an intake of only 55 mg from 100 g lean pork (without visible fat). These figures are only approximate since they do not take into account the possible losses of PUFA which can occur following cooking (13) or losses due to fat dripping from meat following cooking.

In conclusion, this study shows that meat fats do contain a significant proportion of AA compared with the lean meat. Therefore, calculation of dietary intakes of AA need to take account of the AA content of both the visible and lean portion of meat.

ACKNOWLEDGMENT

This study was supported by a grant from the Meat Research Corporation of Australia.

Cycloserine-Induced Decrease of Cerebroside in Myelin

Sheldon L. Miller[a,b,*] and Lyudmila Denisova[b]

[a]Division of Neurology Research, Children's Hospital of Philadelphia and [b]Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104

ABSTRACT: L-Cycloserine has been shown specifically to lower brain cerebroside levels *in vivo,* but the extent to which the decrease in whole brain cerebroside content reflects lower myelin cerebroside levels is not known since a substantial portion of cerebroside is found in nonmyelin membranes. The present report demonstrates that chronically administered cycloserine lowers the proportion of cerebroside in rat brain myelin. Cycloserine-induced decrease of myelin cerebroside should provide a useful tool in investigating the role of cerebroside in maintaining myelin stability.
Lipids 33, 441–443 (1998).

Galactosylceramide (GalCer; cerebroside) is highly enriched in brain membranes as compared with other tissue membranes and constitutes a significant portion of the lipid in myelin (1). Although the specific role of GalCer in myelin has not been firmly established, the high levels suggest that GalCer significantly contributes to the organization of myelin, presumably through its interaction with other lipids and/or proteins in myelin.

Mouse mutants unable to synthesize GalCer have proven useful in answering some questions regarding the role of galactosphingolipid in myelination and myelin structure (2,3). However, these mouse models have several disadvantages as a tool to investigate the interaction of cerebroside with other myelin components; the foremost disadvantage is that sulfatide, synthesized from GalCer and a myelin component at levels ~25% of GalCer levels, is also absent in the GalCer-deficient mice, which precludes distinguishing the specific effects that the absence of GalCer has on myelin structure. An alternative experimental paradigm could be useful in overcoming disadvantages of these mouse models.

L-Cycloserine is an inhibitor of serine palmitoyltransferase (3-ketodihydrosphingosine synthase) (E.C. 2.3.1.50) (4), the first step in the synthesis of sphingolipids. Chronic, subcutaneous cycloserine injections in 16-d-old mice significantly lowered levels of whole-brain GalCer as compared to controls, although the level of other brain sphingolipids was not significantly altered (5). Because a substantial portion of the brain GalCer is present in nonmyelin membranes (1,6), the cycloserine-induced decrease in brain GalCer could reflect lower levels of GalCer in nonmyelin membranes or in myelin or in both groups of membranes. If this cycloserine treatment decreased myelin GalCer levels as observed with the level of whole brain GalCer, the experimental protocol could be used to investigate the role of myelin GalCer in myelin structure. In the present study, we asked whether chronic treatment of rats with L-cycloserine specifically decreases the concentration of myelin GalCer in a manner analogous to the cycloserine-induced decrease of whole-brain GalCer.

MATERIALS AND METHODS

Female Wistar rats, 16 d old (Charles River Laboratories, Wilmington, MA) received a daily subcutaneous injection (100 mg/kg of body weight) of L-cycloserine (Sigma Chemical Co., St. Louis, MO) in phosphate-buffered saline, pH 7. Control rats received a daily injection of phosphate-buffered saline. After 7 d, rats were killed; the brain was removed; medulla oblongata, pons and cerebellum were discarded; and the remaining portion of the brain was weighed and frozen.

Myelin was isolated (7,8), and aliquots were lyophilized and used to determine total weight of myelin isolated and total myelin protein (9,10). Lipids were extracted (11) from the remaining myelin, and an aliquot of the lipid fraction was used to quantitate lipid phosphorus (12) which included glycerophospholipids and sphingomyelin. To quantitate GalCer and sulfatide, the remaining lipid fraction was subjected to alkaline methanolysis (8), and lipids in the $CHCl_3$ fraction were chromatographed on an activated silica gel thin-layer plate (Fisher Scientific, Philadelphia, PA) using $CHCl_3/CH_3OH/H_2O$ (55:27:4, by vol). GalCer and sulfatide were subsequently visualized with I_2, and silica gel areas binding these lipids were scraped from the plate. Lipids, without extraction from the silica gel, were reacted with fluorescamine (Sigma Chemical Co.) and quantitated using spectrofluorometry (13).

Data for the control and cycloserine-treated rats were obtained from six individual rats in each group and are expressed as means ± SEM. Statistical difference between cycloserine-treated and corresponding control data was determined using an unpaired Student's *t*-test.

Abbreviation: GalCer, galactosylceramide (trivial name: cerebroside).

RESULTS AND DISCUSSION

With the notable exceptions of the medulla oblongata and pons, relatively little myelin deposition had taken place in rat brain when cycloserine treatment was initiated at 16 d of age. Since a significant amount of myelin deposition in medulla oblongata and pons would have resulted in an apparent higher level of myelin cerebroside in cycloserine-treated rats (assuming the level of cerebroside in preformed myelin is not affected by cycloserine treatment), these regions were excluded in this study. The cerebellum was not used to expedite the handling of the tissue.

Table 1 lists the effects of cycloserine treatment in 16-d-old rats injected subcutaneously with L-cycloserine for seven consecutive days. Body and brain weight were slightly, but significantly, lower (14 and 7%, respectively; $P < 0.001$) as compared to control rats. In contrast, the amount of brain myelin recovered from cycloserine-treated rats was dramatically reduced (51%; $P < 0.001$) compared to controls. A lower rate of increase in body and brain weight during the critical period of developmental myelination has been correlated with a decrease in the accumulation of brain myelin, as in the case of undernutrition; however, based on the small differences in brain and body weight between cycloserine-treated and control rats, the accumulation of brain myelin in cycloserine-treated rats, when compared to the accumulation of brain myelin in control rats, was dramatically lower than expected (14).

Compared with myelin from control rats, the total myelin lipid phosphate, i.e., phospholipid component of the myelin lipid, and the total myelin protein from cycloserine-treated rats were diminished in brain myelin. However, compared with myelin from control rats, the quantity of myelin isolated from cycloserine-treated rats was also diminished and to the same extent as the relative decrease in cycloserine-treated rats of myelin phospholipid and protein. The fact that the relative decreases of myelin phospholipid and protein parallel the relative decrease in the quantity of myelin isolated from cycloserine-treated rats suggests that the lower amount of myelin phospholipids and protein reflect the diminished myelin accumulation in cycloserine-treated rats. Nevertheless, the apparently unchanged level of total phospholipids in myelin in cycloserine-treated rats does not preclude the possibility that the levels of individual phospholipid classes are altered as a result of the altered GalCer level in myelin. Similarly, the absence of any significant change in total protein levels in brain myelin of cycloserine-treated rats compared to controls does not rule out changes in individual myelin protein levels. Myelin sulfatide levels in cycloserine-treated rats were decreased slightly but not significantly as compared to levels in control rats.

The GalCer level in brain myelin from cycloserine-treated rats was decreased significantly compared to levels in control rats, analogous to the whole-brain GalCer levels in cycloserine-treated mice (4). The partial inhibition of cerebroside synthesis could have resulted in the unexpected dramatic decrease of brain myelin deposition in cycloserine-treated rats. Baumann (15) proposed that a minimal level of specific myelin components, including GalCer, might be required for the deposition of stable myelin. Thus, it is possible that the cycloserine treatment diminished the synthesis of GalCer to a level which was insufficient for the amount of myelin deposition observed in control rats. The fact that the relative level of sulfatide in myelin was not significantly affected by cycloserine treatment, even though GalCer is the precursor to sulfatide, suggests that the regulation of myelin sulfatide levels is not necessarily linked to myelin GalCer levels.

These data demonstrate that the chronic, subcutaneous injection of 16-d-old rats with L-cycloserine, analogous to the mouse (5), results in a significant decrease in the proportion of GalCer in brain myelin. Thus, this report extends earlier observations by demonstrating that myelin GalCer is specifically reduced by cycloserine treatment. An experimental paradigm utilizing cycloserine could prove useful in delineating the role of GalCer in maintaining myelin structure through its interaction with myelin components.

TABLE 1
Effects of Cycloserine Administration on Body and Brain Weight and the Deposition and Composition of Myelin[a]

	Control	Cycloserine-treated	Decrease (%)
Body weight (g)	56.0 ± 2.2	48.2 ± 0.8[a]	14
Brain weight (g)	1.18 ± 0.02	1.10 ± 0.02[a]	7
Myelin isolated (mg/brain)	15.3 ± 0.4	7.8 ± 0.6[a]	51
Myelin lipid P (μg)	1202 ± 108	594 ± 65[b]	51
Myelin protein (μg)	2852 ± 219	1492 ± 141[b]	48
Myelin lipid P (μg)/myelin protein (μg)	0.42	0.40[c]	5
Myelin GalCer (μg)/100 μg myelin lipid P	9.39 ± 0.38	6.20 ± 0.70[a]	34
Myelin sulfatide (μg)/100 μg myelin lipid P	3.09 ± 0.22	2.91 ± 0.29[c]	6

[a]Experimental rats received a daily injection of L-cycloserine in buffer. Control rats were injected with buffer. After 7 d, rats were killed; the brain was removed; myelin was isolated; and aliquots were used to quantitate myelin weight, lipid phosphorus (glycerophospholipids and sphingomyelin), and protein. GalCer and sulfatide were isolated and quantitated from the remaining myelin. Data from control and cycloserine-treated rats (6 rats/group) are expressed as means ± SEM. Statistical difference between cycloserine-treated and corresponding control data was determined using an unpaired Student's *t*-test. [a]$P < 0.001$; [b]$P < 0.01$; [c]Not significant.

Departments of [a]Biophysics and [b]Medicine, Boston University School of Medicine, Boston, Massachusetts 02118

ABSTRACT: To understand the role of free fatty acid (FFA) incorporation in the accumulation of lipids in the adipocyte and ultimately in the development of obesity, ^{13}C nuclear magnetic resonance was used to study lipid metabolism in differentiating preadipocytes. The incorporation of ^{13}C=O-labeled FFA into cellular lipids in primary cultured rat preadipocytes and 3T3L1 preadipocytes at different stages of differentiation was monitored by the ^{13}C carbonyl chemical shift. Significant incorporation of palmitic acid into phosphatidylcholine in both the α and β acyl chain positions was found in cells at early stages of differentiation. At later differentiation stages or after extended incubation periods, most of the ^{13}C=O signals were found in the triacylglycerol (TG) molecules. Unsaturated ^{13}C=O-labeled acyl chains were detected in the TG molecules when cells were incubated with saturated ^{13}C=O-labeled FFA, indicating that intracellular dehydrogenation had occurred in the ^{13}C=O-labeled palmitoyl chain. By using ^{13}C-labeled methyl myristate as an internal intensity reference, incorporation of ^{13}C FFA into each acyl chain position of the major intracellular lipids was determined quantitatively.

Lipids 33, 449–454 (1998).

Circulating fatty acids can exist in esterified [e.g., triacylglycerols (TG) in lipoprotein particles] or unesterified forms [free fatty acids (FFA) bound to serum albumin]. In addition to acting as signal transducers and regulators of gene expression (1), FFA serve as an important energy source either for direct oxidation or for lipid synthesis and storage. Adipocytes are the major reservoir of FFA storage and release (2,3).

The applicability of ^{13}C nuclear magnetic resonance (NMR) spectroscopy for investigating adipose tissue metabolism, both *in vitro* and *in vivo*, has been demonstrated (4–7). More recently, ^{13}C NMR analysis of perfused cultured 3T3L1 adipocytes (2) documented the utility of ^{13}C=O-labeled FFA as substrates for monitoring lipid metabolism. These studies were all performed on adipose tissue or fully differentiated adipocytes, and the observed ^{13}C signals were exclusively from TG molecules.

In vivo ^{13}C NMR studies have limitations in spectral resolution and, in some cases, sensitivity. The alternative procedure of studying cell extracts by ^{13}C NMR permits optimal resolution and sensitivity for a given mass of lipid, as samples can be signal-averaged for long time periods in stable organic solutions. The latter approach is advantageous especially when the cell numbers per experiment are limited (as is often the case in studies of primary cultured cells) or when the incubation time with FFA is short (see below).

We examined incorporation of ^{13}C -labeled FFA into the lipids of differentiating preadipocytes by obtaining ^{13}C NMR spectra of cellular lipid extracts. With the high spectral resolution obtained, the incorporation of exogenous FFA into both phospholipids and TG was detected, and the specificity of the esterification reaction with respect to acyl chain position was studied. *De novo* acyl chain dehydrogenation of the TG-incorporated ^{13}C-labeled FFA both at the α and β positions was also detected. Such dehydrogenation occurred in both rat and 3T3L1 preadipocytes, but was more significant in the latter.

EXPERIMENTAL PROCEDURES

Cell preparation and differentiation. Male 3-mon-old Fischer 344 rats (Harlan Sprague-Dawley) were acclimatized for 1 wk and then were decapitated under CO_2 analgesia. The caudal portion of perirenal fat depots, which contains little brown fat (8), was removed and digested in collagenase as described previously (9). Stromal-vascular cells were isolated by centrifugation at $800 \times g$ for 10 min and were plated in basal medium with α minimum essential Eagle's medium supplemented with 10% fetal bovine serum, penicillin (100 units/mL) and streptomycin (100 μg/mL). After 12 h, a period during which no cell replication occurs (10), the attached cells were trypsinized and replated in basal medium at a density of 4×10^4 cells/cm^2 in 25 cm^2 flasks. Replating permits separation of preadipocytes in the stromal-vascular fraction from other cell types. We have shown that 95% of cells isolated by this procedure are preadipocytes (9,11). After 1 d, the basal medium was changed, and then for another 2 d, cells were cultured in basal

Abbreviations: DMEM, Dulbecco's Modified Eagle Medium; FFA, free fatty acid; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; TG, triacylglycerol.

medium by which time they were confluent. After this, cells were cultured in an enriched differentiation medium containing 10 μg/mL insulin, 10 μM glucose, 5 μL/mL Intralipid 10% (Miles Laboratory, North Chicago, IL), and 20% Nuserum (Collaborative Research, Bedford, MA), which promotes preadipocyte differentiation (9). In most experiments, cells were exposed to this medium for 2 d to achieve partial differentiation; in some experiments, cells were exposed for longer periods to increase the percentage of cells with extensive lipid accumulation before incubation with FFA.

NIH 3T3L1 cells were cultured as described previously (12). Briefly, DMEM supplemented with 10% calf serum and antibiotics was used to culture cells until confluence. The cells were then treated with DMEM containing methylisobutylxanthine (120 μg/mL), dexamethasone (0.39 μg/mL), and insulin (10 μg/mL) to induce differentiation. Two days later, methylisobutylxanthine was removed, and cells were maintained in DMEM + 10% fetal calf serum containing insulin (2.5 μg/mL) for 6 d.

Sample preparation. When cells were ready for the FFA incubation experiments, a solution containing ^{13}C=O-labeled FFA (10 mM, mole FFA/mole bovine serum albumin = 5) was added to the culture medium (final concentration of FFA = 1 mM) during a regular medium change. Cell cultures were harvested by removing the medium, washing three times with phosphate-buffered saline buffer, and scraping off the cells in methanol. After the cells were extracted by the Folch method, the organic phase containing the lipids was dried under N_2, redissolved in deuterated chloroform ($CDCl_3$), and covered with dry N_2 in the NMR tube to prevent oxidation during NMR experiments. Vacuum drying was not used to prevent the loss of low boiling-point lipids.

Chemicals. ^{13}C=O-labeled FFA (palmitic acid and myristic acid) and $CDCl_3$ were purchased from Cambridge Isotope Laboratory (Cambridge, MA). Tripalmitin was purchased from Nu-Chek-Prep (Elysian, MN). Mixed acyl chain TG (1,2-dipalmitoyl-3-oleoyl-*rac*-glycerol and 1,3-dipalmitoyl-2-oleoyl-*rac*-glycerol, ~99%) were purchased from Sigma (St. Louis, MO). The BF_3-methanol kit (5 mL/ampule) was purchased from Supelco (Bellefonte, PA). All other organic solvents (methanol, hexane, benzene, and chloroform) were high-performance liquid chromatographic grade and purchased from Aldrich (Milwaukee, WI). ^{13}C=O-labeled methyl myristate was synthesized as follows: 5 mg of ^{13}C=O-labeled myristic acid was dissolved in 5 mL of benzene in a 25-mL test tube; 5 mL of dry methanol was added, followed by 5 mL of BF_3 in methanol (Supelco). The tube was covered with Teflon tape and a screw cap, then heated for 30 min at 100°C in an aluminum heating block. After cooling, 5 mL of deionized water was added and the methyl myristate, a long-chain methyl ester, extracted with hexane. The solvent was evaporated under a N_2 stream. The reaction yield was usually near 95%, and thin-layer chromatography (hexane/ethyl ether/acetic acid = 80:20:1) was used to check purity. There was no detectable FFA on the thin-layer chromatography plate. The methyl myristate was recrystallized in hexane at 4°C.

NMR methods. ^{13}C NMR spectra were obtained at 125 MHz on a Bruker DMX-500 spectrometer (Billerica, MA). A 5-mm triple resonance probe was used to minimize the sample volume (~0.5 mL). A 90° pulse width (12 μs), ^{1}H decoupling with the inverse-gated Waltz-16 sequence, and a pulse interval of 7.0 s were used for all spectra. All NMR experiments were performed at 12°C to minimize solvent evaporation during the data acquisition period. The center peak of solvent ($CDCl_3$) in the ^{13}C NMR spectrum was used as an internal chemical shift reference (77.0 ppm). All spectra were acquired with 8000 scans (rat cells), 4000 scans (3T3L1 cells), or 1000 scans (pure TG). Spectra were processed without linebroadening to optimize resolution. The integrated intensities had an experimental uncertainty of <5%.

To study FFA incorporation quantitatively, an internal intensity reference is needed. Ideally, this molecule would have a carbonyl signal with a resonance frequency close to, but not overlapping, the carbonyls of phosphatidylcholine (PC), TG, and other acylated common lipids or the carbonyls of FFA. For this purpose, we chose methyl myristate which has a chemical shift at 174.5 ppm in $CDCl_3$ at 12°C. However, the spin-lattice relaxation time (T_1) of the ^{13}C=O in this molecule (8.5 s) is longer than the values usually found in TG and PL (1–2 s). To achieve quantitative measurements with minimal experimental times, we first acquired a spectrum of a lipid extract with the internal integral reference using a 50-s pulse interval to achieve equilibrium intensities for every resonance; in this experiment, the integrated intensity is in direct proportion to the concentration of the nucleus. Then, we repeated the experiment with the same sample at a 7-s pulse interval. It was found that the lipid signal (per internal reference intensity) was 4.2 times higher in spectra with a 50-s pulse interval than that with a 7-s pulse interval because of attenuation of the reference signal with the longer T_1. Thus, 4.2 was used as a calibration factor to calculate the lipid quantities obtained from the integrated intensities from the ^{13}C spectrum obtained with a 7-s pulse interval.

RESULTS AND DISCUSSION

Effects of stage of differentiation on FFA incorporation. Differentiating preadipocytes take up and metabolize FFA rapidly, and the amount of lipid accumulated depends on the extent of differentiation. Cultures usually contain a mixture of cells at various stages of differentiation. Because the general features of the ^{13}C NMR spectra of lipid extracts are likely to depend on the extent of cell differentiation, cells used in this study were first examined under phase contrast microscopy and categorized into four different stages according to the extent of lipid accumulation (see Table 1). Cells at a specific stage of differentiation were then studied by ^{13}C NMR as a function of incubation time.

The ^{13}C NMR spectra of lipid extracts from rat perirenal cells at various stages of differentiation [Table 1 (rows A–C)] incubated with ^{13}C=O-labeled palmitic acid for 5 h are shown in Figure 1. Signals from naturally abundant lipids in these

TABLE 1
The Stages of Differentiation[a] of Cells as Observed by Phase Contrast Microscopy at the Time When FFA/BSA Incubation Was Initiated[b]

Sample	S1	S2	S3	S4

C	15	70	15	0
D	30	65	4.5	0.5
E	2	72	25	1

[a]Cell morphology changes with the amount of lipid accumulated. We arbitrarily divided differentiation into four stages: S1, rounded cells with faint dark stripling; S2, a dozen clear droplets seen inside cells under high-power magnification; S3, larger doubly refractive droplets, more than six droplets in each cell; S4, one to six lipid droplets visible under low power magnification.
[b]Because incubation with free fatty acid/bovine serum albumin (FFA/BSA) affects the intracellular lipid accumulation process, and hence possibly the stages of differentiation, therefore, the state of cell differentiation was determined only at the beginning of the incubation (error ±15%).

cell extracts were too weak to be detected in our spectra, and only the spectral region containing the signals from ^{13}C=O-labeled lipids is presented. [The lack of signals from ^{13}C-enriched carbons in other spectral regions also implies that there was not significant acyl chain elongation of the ^{13}C=O FFA during the incubation period (within 24 h) as discussed in a previous study (2).] Each carbonyl signal in the ^{13}C NMR spectra represents a specific carbonyl group with ^{13}C=O enrichment. By comparison with chemical shifts of known individual lipids (TG, PC, and FFA) under the same experimental conditions (not shown), the lipid mixture in the cell extract was identified as PC and TG as designated in Figure 1a. The FFA signal in $CDCl_3$, which resonates ~2–5 ppm downfield from the carbonyl signals of PC and TG, was not detected in these experiments. This finding is in agreement with previous reports that the intracellular concentrations of FFA are very low in living cells (13–15). [The chemical shift of pure FFA in dry $CDCl_3$ has been reported to be about 180 ppm (17). However, lipid extracts from tissue contain trace amounts of water and inorganic salts that are very difficult to remove. Because the chemical shifts of C=O in FFA are very sensitive to ionization conditions, these minor components might shift the C=O resonance.] The different acyl chains are designated PC(1) (α chain esterified at the *sn*-1 position), PC(2) (β chain at the *sn*-2 position), TG(1,3) (α chains at the *sn*-1 and *sn*-3 positions), and TG(2) (β chain at the *sn*-2 position). The α chains esterified at the *sn*-1 and *sn*-3 ^{13}C=O of TG with the same FFA cannot be discriminated by this technique.

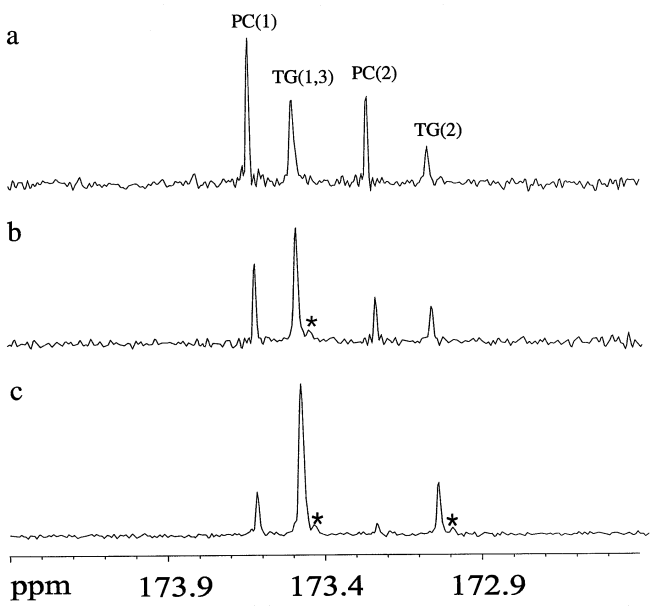

FIG. 1. ^{13}C nuclear magnetic resonance (NMR) spectra of the carbonyl region showing the distribution of ^{13}C-enriched carbonyl groups detected in extracts of differentiating rat perirenal cells after incubation with ^{13}C=O-labeled palmitic acid/bovine serum albumin for 5 h. Spectra a, b, and c correspond to different stages of differentiation as shown in Table 1, and are representative of observations from three to six repeated experiments. Peaks are designated as PC(1)/PC(2) for phosphatidylcholine at the *sn*-1/*sn*-2 (α,β) position, and TG(1,3)/TG(2) for triacylglycerol at the *sn*-1,3/*sn*-2 (α,β) positions. Peaks marked with (*) near the main peak of TG(1,2) and TG(2) are from dehydrogenated acyl chains (see Results and Discussion section).

The intensities of carbonyl signals in Figure 1 indicate that the ^{13}C=O incorporation among different lipids was not uniform, even among different acyl chain positions in the same lipid class. In most cases, when cells were incubated with ^{13}C-labeled palmitic acid, the signal intensity ratio of TG(1,3)/TG(2) was close to 2.0, demonstrating nearly equal incorporation of label among the three acyl chains in the TG molecule. On the other hand, the PC(1)/PC(2) intensity ratio was significantly higher than 1.0, demonstrating a preferential incorporation of palmitic acyl chains into the *sn*-1 carbon. Figure 1 also shows that with 5 h of incubation, cells at earlier stages of differentiation incorporated more ^{13}C=O-labeled FFA into PC than those at later stages, in which most of the ^{13}C=O carbonyl signals were detected in the TG fraction. NMR spectra were also obtained after various incubation times using cells having an initially similar stage of differentiation (Table 1, row D). Spectra of lipid extracts of cells (pooled from six animals) harvested at different time points after the FFA/bovine serum albumin incubation showed differences in incorporation of ^{13}C=O groups (Fig. 2). After incubation for 1 h, the ^{13}C=O carbonyl signals were detected in both PC and TG, with slightly more incorporation into TG (Fig. 2a). Note that this spectrum is similar to that in Figure 1b. As incubation time increased, there was a gradual increase in the TG signal intensity and a corresponding decrease in PC intensity. At 24 h, intense TG signals were seen, whereas the PC signals were nearly undetectable (Fig. 2e). These results show that the exogenous FFA is stored mainly in the TG pool, provided the incubation time is long enough, in agreement with previous results (3). The spectrum at 24 h also showed a broad, low-intensity signal slightly downfield from PC(1) peak in this spectrum (Fig. 2e). This signal may represent phospholipids other than PC, as shorter incubation times favor the incorporation of exogenous FFA into PC which turn over more rapidly than other phospholipids, but later transacylation processes may convert them to other species such as phosphatidylethanol-

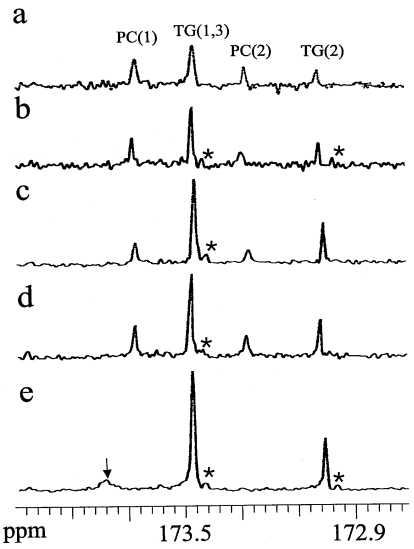

FIG. 2. The ^{13}C NMR spectra of lipid extracts of rat perirenal cells at various incubation times. The cells were at an early stage of differentiation corresponding to the data shown in Table 1 (row D). The spectra shown (traces a–e) are representative of cells incubated with ^{13}C=O-labeled palmitic acid/bovine serum albumin for (a) 1 h; (b) 3 h; (c) 7 h; (d) 11 h; and (e) 24 h, respectively. Peaks are designated as in Figure 1. See Figure 1 also for abbreviations.

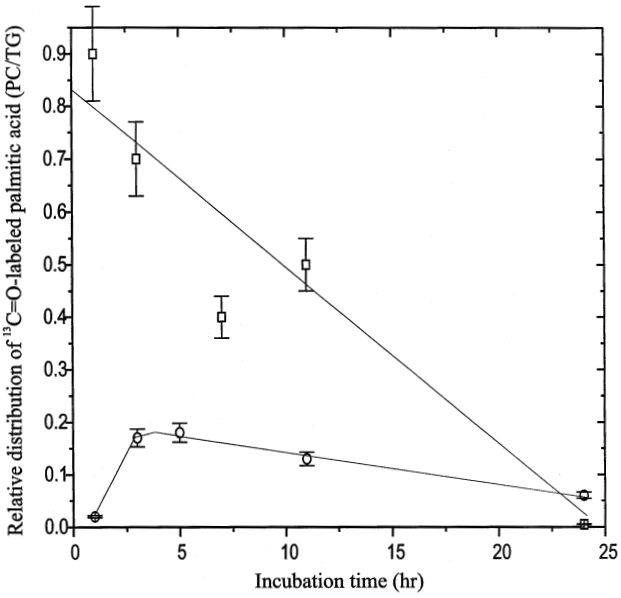

FIG. 3. The distribution of incorporated ^{13}C-enriched carbonyl in the PC fraction vs. TG fraction estimated by the integral intensity of [PC(1) + PC(2)]/[TG(1,3) + TG(2)] from NMR signals. The symbols represent results for cells in early stages of differentiation [(□), Table 1 (row D)] and a later stage of differentiation [○, Table 1 (row E), see below]. The solid lines represent the schematic trends of PC/TG distributions as the incubation time increased. See Figure 1 for abbreviations.

amine with slower turnover rates (16). Further work is required to clarify this.

The distribution of the incorporated ^{13}C=O groups between PC and TG was obtained by comparing the integral intensities of total PC signals ($\alpha + \beta$) vs. that of TG ($\alpha + \beta$) as a function of incubation time. The linear decrease of the PC/TG intensity ratio (Fig. 3, upper trace) showed that cells at early stages of differentiation tended to incorporate a higher proportion of exogenous FFA into the PC fraction (relative to TG) at early time points. Such incorporation decreased at later time points. This could indicate that the incorporated ^{13}C=O-labeled palmitoyl chain in PC tends to be replaced with unlabeled (also presumably mainly unsaturated) FFA during the deacylation/reacylation process.

In the spectra of the more differentiated cells (Fig. 1b and c) or of cells incubated for longer intervals with FFA (Fig. 2c–e), there were small signals (designated *) near the main TG(1,3) and TG(2) peaks. The intensities of these minor signals varied with the lipid composition in the medium and the extent of differentiation. The minor peaks were usually more intense in differentiating 3T3L1 cells and cannot be interpreted as naturally abundant background signals (Fig. 4a). To identify the molecules giving rise to these signals, we obtained ^{13}C NMR spectra of TG with mixed saturated and unsaturated acyl chains (Fig. 4b–d). [Although palmitoleic acid is mostly likely the product of desaturation, TG with mixed chains of palmitic and palmitoleic acids were not commercially available. Since TG containing olefinic chains at Δ9 positions have similar ^{13}C=O resonances when the acyl chains are varied from 16 to 18 (18), we used the oleoyl chain as a model for the palmitoleoyl chain.] With an oleoyl chain at the *sn*-2 position, a small upfield shift in the TG(2) was detected compared to that of tripalmitin. With oleoyl esterified at the *sn*-3 position, the TG(1,3) peak was split into two peaks of identical intensity with a lower chemical shift for the unsaturated chain (17,18). The signals representing the unsaturated acyl chains in the model systems corresponded well to the lower-frequency peaks in the cell extract (designated *). This implies that there is intracellular conversion of the saturated acyl chain of ^{13}C=O-labeled palmitoyl chains to unsaturated acyl chains. Such detection of intracellular acyl chain dehydrogenation by NMR has never been reported, probably because of limitations in signal resolution.

The more extensive dehydrogenation in 3T3L1 cells compared to primary rat preadipocytes seems to be related to substrate availability in the cell culture medium and also to how the cells obtain FFA for lipid storage. 3T3L1 cells have a high capacity for *de novo* synthesis FFA from glucose and contain 16-carbon FFA (16:0 and 16:1), whereas rat cells use predominantly exogenous FFA and contain 18-carbon (18:0 and 18:1) as the major FFA components in their TG fractions. In addition, in our experiments, 3T3L1 cells were cultured in a high-glucose medium without lipid supplementation, whereas rat preadipocytes were cultured in medium supplemented with a lipid emulsion (mostly polyunsaturated TG). Therefore, 3T3L1 cells probably have a higher tendency than rat preadipocytes to convert the TG-incorporated ^{13}C=O-labeled 16:0 to 16:1, because of the need to have unsaturated chains.

Quantitation of FFA incorporation into intracellular lipid pools by NMR. To date, quantitation of incorporation of FFA

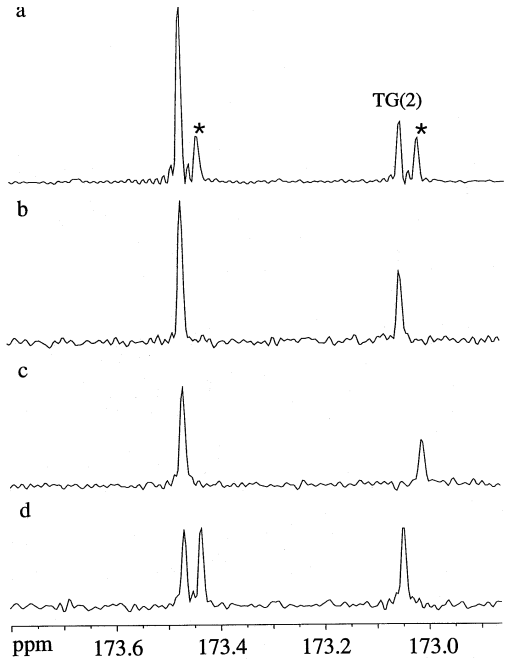

FIG. 4. The spectra of pure TG with different acyl chains compared with lipid extracts from differentiating 3T3L1 cells; (a) lipid extract from differentiating 3T3L1 cells (dominated by cells at stage 4, incubated with ^{13}C=O-labeled palmitic acid); (b) pure tripalmitin; (c) pure 1,3-*rac*-dipalmitoyl-2-oleoylglycerol; (d) pure 1,2-*rac*-dipalmitoyl-3-oleoylglycerol. Peak designation is the same as in Figure 1. Spectrum in (a) is representative of six parallel cell cultures. See Figure 1 for abbreviation.

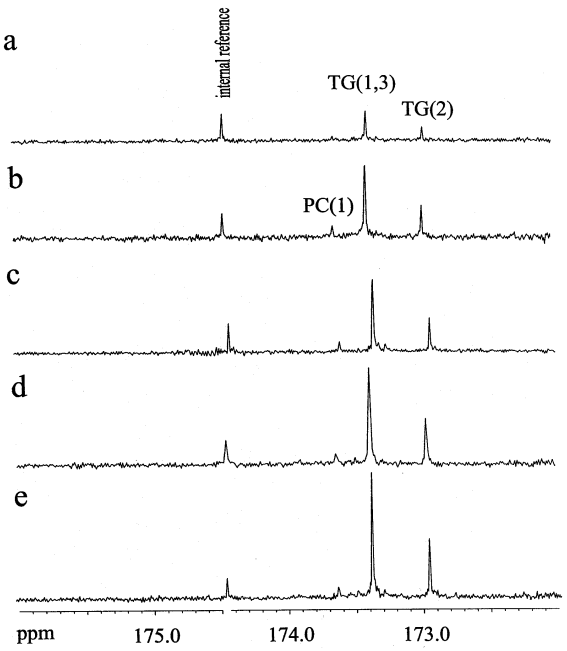

FIG. 5. ^{13}C NMR spectra of lipid extracts from differentiating rat perirenal cells at various incubation times with a ^{13}C=O-labeled methyl myristate internal reference standard. The spectra shown are representative of cells incubated for (a) 1 h; (b) 3 h; (c) 7 h; (d) 11 h; and (e) 24 h, respectively. The same amount of internal reference was added to each culture flask. To optimize signal/noise ratio, the number of culture flasks (25 cm^2) used for each spectrum was: (a, b) 3; (c) 2; (d, e) 1. Peaks are designated as in Figure 1. See Figure 1 for abbreviations.

into intracellular lipid pools has been achieved only with ^{14}C isotopically labeled molecules (3). To determine the site of labeling of a specific FFA, each presumed lipid component has to be separated by a chromatographic method before counting. ^{13}C NMR represents a method for obtaining this information without assumptions concerning the identity of the lipids involved or purification of each lipid.

Each signal in the NMR spectrum can be quantified in an absolute sense by comparison of its integrated peak intensity with that of a suitable standard, as discussed in the NMR methods section. In our experiments, 50 μg of ^{13}C=O-labeled methyl myristate (50 μL ethanol solution; 1 mg/mL) was added during the Folch extraction of highly differentiated cultures (Table 1, row E). These cells showed ^{13}C=O signals mainly in the TG(1,3) and TG(2) carbonyls. Unlike the results for the less differentiated cells which showed high PC incorporation at early incubation time points (Fig. 2), the net incorporation of ^{13}C=O FFA in the PC fraction within the 1-h incubation period was very low. Within 24 h, only a weak PC(1) signal [but not PC(2)] was detected (Fig. 5). The distribution of ^{13}C=O FFA incorporation between PC and TG was obtained by comparing the integrated intensities of the total PC signals vs. that of TG. Data are shown in Figure 3 (lower trace). There was a slight increase in the PC/TG ratio as the incubation time increased from 1 to 5 h, followed by a gradual decrease to a lower level. These results show that the incorporation of exogenous FFA into the PC and TG fractions is controlled by different kinetic mechanisms, depending on the stage of differentiation. Further investigations are needed to understand the enzymatic pathways responsible for this.

By comparing the integrated peak intensities of the lipids with that of the internal reference peak, the amount of ^{13}C=O-labeled palmitic acid in the TG ($\alpha + \beta$) was found to increase rapidly and linearly with incubation time. Within the same time period, incorporation into the PC(1) only increased slightly, and the PC(2) carbonyl was below the limit of detection (Fig. 6). At the end of the 24-h incubation, the peak intensities corresponded to ~1 μmole of ^{13}C=O-labeled palmitoyl in the lipids [TG(1,3) + TG(2) + PC(1)], which represents ~20% of the total ^{13}C=O-labeled exogenous FFA added.

Although high-resolution ^{13}C NMR spectroscopy has been applied to the study of adipose tissue previously, to our knowledge this work presents the first NMR study of differentiating preadipocytes. With the capability to probe cellular FFA metabolism at the molecular level, this NMR protocol provides a tool for evaluating the influence of environmental variables on the rate and magnitude of fat storage.

ABSTRACT: In this study, the effects of caffeine on lipoprotein lipase (LPL) gene expression were investigated in the 3T3-F442A preadipocyte cell line during the adipocyte differentiation process by determining LPL enzymatic activity and its messenger RNA (mRNA) level. The results demonstrate that caffeine acts on the gene expression of LPL, an early marker of adipocyte differentiation. It has a biphasic action: it increases gene expression in terms of mRNA when it is added to preadipocytes during the early stage of differentiation, but this is accompanied by a reduction of enzymatic activity. On the other hand, when caffeine is added for long periods during differentiation and/or when it is added to mature adipocytes, it induces marked inhibition of mRNA levels, correlated with a marked reduction of secreted enzymatic activity. The inhibitory effect of caffeine on LPL mRNA level can be reproduced by theophylline, a phosphodiesterase inhibitor, and by dibutyryl cyclic AMP, a nonmetabolizable analog of cyclic AMP. However, the effect of caffeine and theophylline lasts longer than that of cyclic AMP, suggesting that a mechanism other than inhibition of cyclic AMP hydrolysis may be involved in the action of caffeine.
Lipids 33, 455–460 (1998).

Lipoprotein lipase (LPL) is an enzyme, mainly synthesized by adipose tissue and muscle, which plays a central role in the metabolism of triglyceride-rich plasma lipoproteins (1). It hydrolyzes exogenous (chylomicrons) and endogenous triglycerides (very low density lipoproteins) by generating free fatty acids and monoglycerides, using apolipoprotein CII as cofactor. A dysfunction of LPL could also be involved in the development of obesity, since this enzyme directs the distribution of dietary lipids toward adipose tissue for their subsequent storage or toward muscle where they are used as energy substrates.

The synthesis, maturation, and secretion of LPL are regulated transcriptionally or post-transcriptionally in a tissue-specific manner *via* complex mechanisms during development and in response to nutritional and hormonal variations (2,3).

Previous studies have emphasized that insulin is the hormone which predominantly regulates the activity of adipocytic LPL. Under certain physiological or pathophysiological conditions associated with an increase in the insulin level (postprandial period, obesity), an increase in LPL activity is observed in adipose tissue (4), whereas defects in insulin secretion, both in nontreated insulin-dependent diabetes and in postabsorptive and postprandial states, are correlated with a low LPL protein level (5). Many possible mechanisms of LPL regulation at posttranscriptional and posttranslational levels have been reported (6).

Adipose tissue from rats fasted overnight exhibits a decreased LPL catalytic activity (7), suggesting that this enzyme is also regulated by intracellular cyclic AMP (cAMP) content. The accumulation of cAMP has been shown to inhibit lipogenic enzymes such as glycerol phosphate dehydrogenase (8) in mouse adipocytes. Agonists known to increase cellular cAMP, such as isoproterenol (9) or epinephrine (10), induced a marked decrease of LPL enzyme activity in rat adipocytes in primary culture. However, the actual target of this regulation remains unclear, since in some cases the level of LPL mRNA has been found to be decreased (9), increased (7), or unaffected (10) depending on the model used and on the experimental conditions. Inhibition of the translation process of LPL mRNA by epinephrine has been related to the first 50 (1601–1650) nucleotides in the 3′ untranslated region of the messenger (11).

The cAMP signaling pathway can be regulated in several ways. For example, the antilipolytic action of insulin on adipocytes has been suggested to act either by stimulation of cGMP-inhibited cAMP phosphodiesterase activity (12) or by down-regulation of the β_3 adrenergic receptor (13). This might in part explain some of the action of insulin on LPL gene expression.

Under appropriate culture conditions, the 3T3-F442A preadipocyte cell line differentiates into adipocytes according to a process similar to that which occurs during the development of adipose tissue (14). Lipoprotein lipase is considered to be a specific marker of the differentiation of the 3T3-F442 preadipocyte cell line (15). This cell line is therefore an excellent model to study the action and mechanisms of effectors on LPL gene expression either during differentiation or on fully differentiated adipocytes which possess the features of highly specialized cells.

In the present study, we used caffeine, which is known to inhibit phosphodiesterase activity (16), to define the actual

Abbreviations: CBP, CREB-binding protein; CRE, cyclic AMP (cAMP) response element; CREB, CRE-binding protein; LPL, lipoprotein lipase, PKA, protein kinase A.

role of intracellular cAMP on LPL gene expression. We showed that chronic treatment of 3T3-F442A cells by caffeine induced a marked decrease in heparin-releasable LPL activity in preadipocytes, as well as in fully differentiated adipocytes. In contrast, caffeine increased the level of LPL mRNA at an early stage of differentiation, but decreased the LPL mRNA level in mature adipocytes, suggesting that multiple targets are involved in mediating the cAMP effect.

EXPERIMENTAL PROCEDURES

Cell culture. 3T3-F442A cells were obtained through the courtesy of Dr. Howard Green (Harvard Medical School, Boston, MA) (14). Cells were seeded on tissue culture dishes (Falcon, Polylabo, Strasbourg, France) at a density of 10^3 cells/cm^2 in Dulbecco-Vogt modified Eagle's medium containing 25 mM glucose supplemented with 5% calf serum (from Gibco, Life Technologies, Cergy Pontoise, France), 5% fetal calf serum (from Dutscher, Dominique Dutscher, Brumath, France), a 0.7% penicillin/streptomycin mixture, 25 mM $NaHCO_3$ and 40 μM d-biotin from Sigma (Sigma Aldrich, Saint Quentin Fallavier, France). The medium was changed every 2 d. One day before confluence, cell cultures were washed and then cultured in Dulbecco-Vogt modified Eagle's medium containing 10% fetal calf serum and 20 nM insulin for the time indicated in the legends of the figures. Adipocyte conversion was achieved 10 to 12 d following confluence and checked by inverse phase microscopy (Nikon, Nikon France s.a., Champigny sur Marne, France). To release membrane-bound lipoprotein lipase, 100 μg/mL heparin was added to each flask, and the cells were incubated at 37°C for 40 min. The remaining cells were washed with phosphate-buffered saline at 4°C and treated with guanidium thiocyanate for RNA isolation.

RNA analysis. Total RNA was extracted using the method of Chomczynski and Sacchi (17) and total RNA (10 μg) analyzed by Northern blot as previously described (18). The blots were hybridized with a murine LPL cDNA probe labeled with [α-^{32}P]-dCTP by random priming (Amersham kit; Amersham Life Science, Les Ulis, France). In order to standardize the amount of mRNA in each line, blots were hybridized again with a 28S RNA probe labeled with [γ^{32}P]-ATP by T4 polynucleotide kinase. The intensities of the bands corresponding to LPL mRNA and the internal control, 28S rRNA, were measured by scanning densitometry of the autoradiograms. The relative amounts of LPL transcripts were quantified by calculating the ratio of the LPL-band integrated densities to those of 28S rRNA.

Lipoprotein lipase activity. The enzymatic activity was assayed by a modification of the technique of Nilson-Ehle and Ekman (19). Briefly, labeled and unlabeled trioleine (triacylglycerol emulsion), stored in benzene and chloroform, respectively, were mixed to obtain 7 mg (7.92 μmoles) of triacylglycerol with a specific activity around 10×10^6 cpm per μmole. Lysolecithin [0.3 mg (0.6 μmoles)] was then added. Solvents were removed under a nitrogen stream, followed by evaporation under reduced pressure. The emulsion was performed after adding 2.4 mL of 0.2 M Tris-HCl buffer pH 8.0 and 1.2 mL of 1% (w/v) bovine serum albumin on icebath by a Sonicator 100W model n°M72405 (Bioblock Scientific, Illkirch, France) at a setting of 3.5, which corresponds to a gram force of at least 1.5 g. Intervals of 40 s for a total of 3 min were applied. After sonication, 0.3 mL of heat-inactivated human serum and 0.3 mL of 4% bovine serum albumin in 0.2 M Tris-HCl pH 8.0 were added, and the substrate was shaken in a vortex mixer for 15 s. LPL assays were carried out in borosilicate glass tubes by mixing 100 μL of the trioleine substrate and 100 μL of the sample. The mixture was vortexed again for 15 s and agitated at 37°C for 60 min. The reaction was stopped by submerging the glass tubes into an ice bath, and the fatty acids released were isolated by a partition system of 3 mL of methanol/chloroform/heptane (1.41:1.25:1, by vol) and 1 mL of 0.1 M tetraborate buffer pH 10.5. After vigorous shaking for 15 s on a vortex mixer, the mixture was centrifuged for 15 min at $3{,}000 \times g$, and a 1-mL aliquot of the methanol/water phase was counted. Blank incubations, corrections, and calculations were performed as described by Nilson-Ehle and Ekman (19). LPL activity is expressed as milli-units (mU/mg of cellular protein), which represent the release of 1 nmol of fatty acid per min and per mg of cellular protein.

The protein content was assayed according to the method of Lowry *et al.* (20), and the triacylglycerol level was determined on lipid extracts by an enzymatic technique (Boehringer Mannheim Automated analysis kit; Boehringer Mannheim, Meylan, France). All statistical comparisons were performed using Student's test.

RESULTS

When 3T3-F442A cells were cultured in fetal calf serum in the presence of insulin, they started a process of adipocytic differentiation which included progressive accumulation of lipid droplets rich in triacylglycerol (Fig. 1). This process was slow at the beginning of differentiation from day 4 to day 7 and jumped abruptly after day 11, when the triacylglycerol level was increased sixfold. Treatment of the cells by caffeine affected neither the pattern of triacylglycerol content during the differentiation process (Fig. 1) nor the morphological changes (not shown).

The LPL gene is expressed early in the process of adipocyte differentiation. Its expression is obvious after 4 d of treatment by insulin, and secreted LPL activity was maximal after 7 d, plateaued for 11 d, and slightly decreased at 14 d (Fig. 2A). The steady-state level of LPL mRNA progressively increased from day 4 to day 11, then remained unchanged until 14 d (Fig. 2B), suggesting a progressive loss of translational efficiency of the mRNA throughout the differentiation process. When the cells were induced to differentiate in the presence of caffeine, secreted LPL activity was greatly reduced (Fig. 2A). In contrast, its mRNA increased to a greater extent in the presence of caffeine than in control cells from day 4 to day 9 and then fell abruptly at day 11 and
